* Highest concentration used for theoretical conductance analysis.

B values are summarized in Table VIII for each electrolyte at different temperatures. The results of computer analyses are summarized in Table IX. The conductance data were unweighted in the analyses. Solvent viscosities and dielectric constants at 25°, 35°, 45°, and 55°C used in the analyses have been given in Table I. Approximate ionic radii of 4.8Å (35), 5.0Å (36), 4.0Å (36), 4.0Å (36), 5.8Å (36), and 9.5Å (37) were initially assigned to $NaClO_4$, NaSCN, $NaCF_3SO_3$, $NaCH_3SO_3$, $NaB(Ph)_4$, and $(i\text{-amyl})_3BuNB(Ph)_4$ salts, respectively, in the analyses. Values of Λ_o for the initial evaluation of the coefficients *E* and *S* for the iteration procedure were obtained from Shedlovsky extrapolations (38) of the data. A value of zero was assigned to the association constant K_A in the initial analyses.

In Table IX, the limiting equivalent conductance Λ_o, the theoretical Onsager slope *S*, the ion size fitting parameter $\mathring{a}$ in Å, the association constant K_A, and the *J* parameter in the conductance equation are tabulated. Of the three parameters, Λ_o, $\mathring{a}$, and K_A, the value of the viscosity *B* coefficient used affects only the ion-size parameter $\mathring{a}$, and then only slightly. A 10% change in *B* changes $\mathring{a}$ by only 0.04.

* Weighting factor $C\gamma\pm$ was used for these two sets of data only.

Units for Λ_o, *S*, $\mathring{a}$, K_A, and *J* are given in List of Symbols.

$NaCH_3SO_3$-DMSO solutions have not been included in Table IX. The equivalent conductance of $NaCH_3SO_3$ salt solution decreased very rapidly *vs.* $C^{1/2}$, and the conductance data could not be unambiguously extrapolated to infinite dilution to obtain an initial Λ_o for analysis by the conductance equation. Even with a tentative extrapolated Λ_o for CH_3SO_3Na solution, the result of the computer analysis for the conductance data using the Fuoss-Onsager equation yielded a negative ion size, $\mathring{a}$. This conductance behavior of $NaCH_3SO_3$ solution is typical for a weak electrolyte.

Analysis of the conductance data for a weak electrolyte can be expected to follow the Ostwald dilution law and the law of mass action. An equation of the form similar to the Fuoss-Shedlovsky equation (39), except $S(z)$, can be conveniently applied. The $\gamma_\pm{}^2$ are here approximated by unity as a limiting case. The equation is of the form

$$1/\Lambda = 1/\Lambda_o + C\Lambda/K_d\Lambda_o{}^2 \qquad [3]$$

A plot of $1/\Lambda$ as a function of $C\Lambda$ for CH_3SO_3Na solution gave a straight line. Limiting equivalent conductance, Λ_o, and dissociation constant, K_d, for the solution were obtained, respectively, from the intercept and the slope. The values are summarized in Table X.

Equivalent conductances of the other electrolyte solutions in the dilute concentration range were plotted *vs.* $C^{1/2}$ at different temperatures. All electrolyte solutions approached a limiting Onsager slope at infinite dilution. $NaClO_4$, NaSCN, and $NaCF_3SO_3$ solutions showed that the conductance curves approached the Onsager slopes from above, while $(i\text{-amyl})_3BuNB(Ph)_4$ solution showed that the conductance curve approached the limiting slope from slightly below. $NaB(Ph)_4$ solution appeared to be in between the two cases. $NaClO_4$, NaSCN, $NaCF_3CO_3$ are therefore considered to be completely dissociated, while $NaB(Ph)_4$ and $(i\text{-amyl})_3BuNB(Ph)_4$ appeared to be slightly associated.

$(i\text{-amyl})_3BuN^+$ ion and $B(Ph)_4{}^-$ ion are two large nearly symmetrical ions which have been shown to possess equal limiting mobilities in methanol at 25°C (20). The assumption of equal mobilities of those two ions has been applied for different electrolyte solutions (40, 41) when transference numbers were not available. Assuming that equal limiting mobilities hold

SCN^-	29.80	35.58	41.61	47.66

for (i-amyl)$_3$BuN$^+$ ion and B(Ph)$_4^-$ ion in DMSO between 25° and 55°C, the individual ionic limiting mobilities were then obtained as shown in Table XI. The ionic limiting mobilities were obtained from the Λ_o values (tabulated in Table IX) and the application of Kohlrausch's law of independent mobility at infinite dilution. The ionic mobility increases in the order shown in the table. The mobilities of the ions have positive temperature coefficients. This appears to be due to decrease of the viscosity of DMSO with increasing temperature. The temperature coefficients of the mobilities are 0.595, 0.528, 0.462, 0.334, and 0.256 conductance unit/°C for SCN^-, ClO_4^-, $CF_3SO_3^-$, Na^+, and (i-amyl)$_3$BuN$^+$ ions, respectively, which is the reverse order of the ionic mobilities. B(Ph)$_4^-$ ion, of course, is assumed to have the same temperature coefficient as (i-amyl)$_3$BuN$^+$ ion.

Ionic Walden products, $\lambda_o\eta_o$, in cm² poise/ohm equivalent are given in Table XII as a function of temperature. Stokes' radii for these ions were calculated using the values in Table XII and the Stokes-Einstein equation (28), *i.e.*, $r_s(\text{Å}) = 0.820/\lambda^o_i\eta_o$. The calculated Stokes' radii are given in Table XIII. In the sixth column of Table XIII are given the crystallographic radii r_c which have been estimated from sources listed in the parentheses. Table XIII shows that the calculated Stokes' radius, except that of Na^+ ion, are all smaller than the corresponding crystallographic radius. Such unrealistic Stokes' radii were also observed for halide ions and ClO_4^- in sulfolane (tetrahydrothiophene-1-dioxide) (42).

An empirically modified Stokes' equation of the form

$$r_s(\text{corrected}) = \mathbf{Fe}(r_c/r_s)_{\text{corr.}}/6\pi\eta_o\lambda_o \qquad [4]$$

was proposed by Robinson and Stokes (28) to obtain more realistic hydrated ionic radii in water. Equation [4] contains a correction factor, $(r_c/r_s)_{\text{corr.}}$, which is usually obtained from the assumption that large symmetrical and low surface charge ions such as $(Et)_4N^+$, $(Pr)_4N^+$, are unsolvated. The procedure for using Eq. [4] is to first construct a calibration curve of

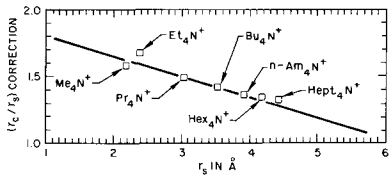

Fig. 1. Calibration curve for determining corrected Stokes' radii in DMSO at 25°C [data from Arrington and Griswold (14)].

$(r_c/r_s)_{\text{corr.}}$ *vs.* r_s based on the mobilities of $(Et)_4N^+$, $(Pr)_4N^+$, $(Bu)_4N^+$, and $(Am)_4N^+$ ions available in the particular solvent medium and subsequently using the calibration curve to obtain the corrected Stokes' radius, Eq. [4], for other ions.

In DMSO, the mobility data for a series of tetraalkylammonium ions at 25°C have been reported recently by Arrington and Griswold (14). Based on their data, a calibration curve was constructed as shown in Fig. 1. The calibration curve becomes the basis for obtaining corrected Stokes' radii for other ions in DMSO at 25°C.

For completeness, the ionic mobility data for other ions in DMSO at 25°C were collected and the Stokes' radii, r_s in Å, for these ions were calculated as given in the second column of Table XIV. In the third column $(r_c/r_s)_{\text{corr.}}$ is the correction factor obtained from Fig. 1 for the corresponding r_s. In the fourth column $r_{\text{corr.}}$ is the corrected Stokes' radius. The corrected Stokes' radii for the large ions are in good agreement with their crystallographic radii, r_c, which are given in the fifth column. Comparison of the $r_{\text{corr.}}$ and r_c for alkali and halide ions shows that alkali ions are heavily solvated while halide ions are slightly or not solvated in DMSO at 25°C.

The volume of solvation sheath surrounding an ion is approximately

$$V_{\text{solv.}} = 4\pi(r_{\text{corr.}}^3 - r_c^3)/3 \qquad [5]$$

The solvation volume for the alkali and halide ions are calculated using the values for $r_{\text{corr.}}$ and r_c given in Table XIV. The calculated solvation volume, $V_{\text{solv.}}$ in Å^3, is given in Table XV. The molecular volume of DMSO is approximately 118.4 Å^3 as obtained from the molecular weight and the density data of DMSO at 25°C. Assuming the volume contraction of the solvent molecules in the solvation sheath due to electrostriction is negligible, a solvation number for the alkali-halide ions in DMSO can be calculated. The calculated solvation number, *s*, is given in Table XV. Na^+ and K^+ ions are solvated to approximately the same extent and Li^+ ion is solvated with 4.8 molecules of DMSO. Halide ions are only slightly solvated and the order of solvation is $Cl^- > Br^- > I^-$.

Solvation volume or solvation number at 35°, 45°, and 55°C for the ions studied in the present work was not determined because of lack of a calibration curve

such as shown in Fig. 1 at these temperatures. However, it is clear from the temperature dependence of the limiting ionic Walden products, Table XII, that the temperature effect on solvation is practically negligible, if there is any, for the temperature range between 25° and 55°C.

Activation energies for ionic conductance, E_A in kcal/mole, were calculated as a function of concentration. The activation energies were obtained from the slopes of simple Arrhenius plots; *i.e.*, log Λ *vs.* $1/T$ at various concentrations. Linear plots were obtained for all electrolyte solutions within the temperature range studied. (i-amyl)$_3$BuNB(Ph)$_4$, NaB(Ph)$_4$, and NaSCN whose maximum solubilities are below 0.3 mole/liter have average activation energies of 3.49, 3.30, and 3.16 kcal/mole, respectively. $NaClO_4$ has an activation energy of 3.23 kcal/mole at a concentration of 0.01 mole/liter, and subsequently the activation energy increases to 4.44 kcal/mole at a concentration of 1.4 mole/liter. The average activation energy for CF_3SO_3Na below 0.3600 mole/liter is 3.23 kcal/mole. The activation energy increases for the electrolyte solutions in the order of NaSCN < $NaClO_4$ ≃ $NaCF_3SO_3$ < NaB(Ph)$_4$ < (i-amyl)$_3$BuNB(Ph)$_4$ for concentration below 0.25 mole/liter.

Discussion

Examination of the ion size fitting parameter $\mathring{a}$ in Table IX shows that a value of 4.75Å for $NaClO_4$ is reasonable and is in good agreement with a value of 4.8Å for $NaClO_4$ (35) which was found necessary to fit the data of Sears *et al.* (12). Prue and Sherrington (35) have analyzed the conductance data of $NaClO_4$ in other solvents, using the Fuoss-Onsager equation, at 25°C and the ion size fitting parameters $\mathring{a}$ found for $NaClO_4$ in dimethylacetamide, dimethylpropionamide, methanol, and water, respectively, 5.3, 5.0, 2.2, and 3.0Å. It is interesting to note that the ion size for $NaClO_4$ in the hydrogen donor solvents, *i.e.*, methanol and water, is smaller than those in dimethylacetamide, dimethylpropionamide, and DMSO.

In this present study NaB(Ph)$_4$ in DMSO has an ion size parameter $\mathring{a}$ of 4.07Å at 25°C using the Fuoss-Onsager equation; this value appears small compared to that for $NaClO_4$. This may be due to some association of NaB(Ph)$_4$ in DMSO. For example, Skinner and Fuoss (43) have studied the conductance of NaB(Ph)$_4$ in water and later Covington and Tait (22) have redetermined the conductance of NaB(Ph)$_4$ in CO_2 free water. The ion size parameter $\mathring{a}$ for NaB(Ph)$_4$ in water was determined to be 6.64 ± 0.06Å by Skinner and Fuoss (43) and 9.9 ± 0.9Å by Covington and Tait (22) for $K_A = 0$. Covington and Tait showed that the calculated ion size, $\mathring{a}$ = 6.64Å, for NaB(Ph)$_4$ as determined by Skinner and Fuoss for $K_A = 0$ can be increased to $\mathring{a}$ = 10Å if an association constant of 2.07 liters/mole was allowed using Skinner and Fuoss data. It is clear that the ion size parameter $\mathring{a}$ is not independent of the association constant in a sense that an identical set of conductance data can be fitted with a smaller $\mathring{a}$ if it is assumed there is no association. A larger $\mathring{a}$ is obtained if some association is assumed. Thus, for an electrolyte solution with a slight association such as NaB(Ph)$_4$ in DMSO, the determination of $\mathring{a}$ and K_A is not unambiguous.

(i-amyl)$_3$BuNB(Ph)$_4$ solutions at 25°C have been analyzed as an associated electrolyte. The ion size parameter $\mathring{a}$ is 6.24 with standard deviation 11.9, and K_A is 12.4 with standard deviation 28.6. The standard deviation in $\mathring{a}$ and K_A reflect partly the sensitivity of $\mathring{a}$ to experimental accuracy and again illustrate how $\mathring{a}$ can be adjusted by simply adjusting K_A. Recently Dyke *et al.* (44) obtained an ion size parameter $\mathring{a}$ = 5.3 ± 0.1Å for (i-amyl)$_3$BuNB(Ph)$_4$ salt in N-methyl-2-pyrrolidone (ϵ = 32.0) at 25°C assuming $K_A = 0$.

The ion size parameter $\mathring{a}$ for a salt varies with temperature as shown in Table IX and the variation has no systematic trend. The Fuoss-Onsager conductance equation assumes the solvent medium to be a continuum; therefore, any inadequacy of the theory due to the neglect of the solvent's role may be taken care of by the adjustable ion size parameter $\mathring{a}$. Substantially different values of $\mathring{a}$ obtained for an identical salt in different solvents (33) and the fact that $\mathring{a}$ varies with dielectric constant of the solvent (45, 46) illustrates the importance of the solvent's role. In this work $\mathring{a}$ is viewed as a fitting parameter. It remains to be seen whether greater experimental accuracy can achieve greater discrimination in K_A and $\mathring{a}$ which have been found to be mutually adjustable.

The corrected Stokes' radii for ions in DMSO at 25°C have been given in Table XIV. The values for the corrected Stokes' ionic radii are quite reasonable, although the major assumption that tetraalkylammonium ions are unsolvated in DMSO, *i.e.*, the basis for the calibration curve, has yet to be verified. Alkali ions, Li^+, Na^+, and K^+, are solvated with approximately five, three, and three DMSO molecules, respectively. The anions, Picrate$^-$, $CF_3SO_3^-$, ClO_4^-, SCN^-, and NO_3^-, are unsolvated while halide ions Cl^-, Br^-, and I^- are slightly solvated, if any. This conclusion is in general agreement with Parkers' (2) view that anions in dipolar aprotic solvents are much less solvated than in protic solvents. Maxey and Popov (47) studied the vibrational absorption bands of DMSO solutions of $LiClO_4$, NH_4SCN, NaSCN, and NaB(Ph)$_4$ and found that the absorption band is essentially independent of the nature and the mass of the anion. This again suggests that the interaction of the alkali cations with the solvent molecules exists, but for the anions the interaction is absent.

Solvation of alkali ions in DMSO is easily explained in terms of the ion-DMSO dipole interaction. The mutual electrostatic potential energy of the rigid DMSO dipole and the singly charged alkali ions is at least six times greater than the DMSO-DMSO bond strength (27) which is estimated to be 0.44 x 10^{-12} ergs, *i.e.*, one-half of the heat of vaporization of DMSO at 25°C (L_v = 12.64 kcal/mole) (48). The spherically symmetrical ions, (i-amyl)$_3$ BuN^+ and $(Bu)_4N^+$, both have unsolvated radii of approximately 5Å. The ion-dipole interaction energy for these ions is approximately equal to the DMSO-DMSO bond strength and solvation is not favored for these large ions.

Solvation of the anions by DMSO molecules is more complicated. Both the sulfur and oxygen atoms in a DMSO molecule have a lone pair of electrons available for bonding. Anions are solvated by ion-solvent dipole interactions, on which is superimposed an interaction due to the mutual polarizability of the anion and the

* λ_0^+ ((i-amyl)$_3$BuN$^+$) = λ_0 (B(Ph)$_4$) was assumed.

solvent molecule, which is greatest for large anions. The result obtained for the anions in DMSO is that the large anions, $B(Ph)_4^-$, and Picrate$^-$, and the unsymmetrical ions, $CF_3SO_3^-$, and SCN^-, are unsolvated while the halide ions, Cl^-, Br^-, and I^-, are only slightly solvated. This result appears to indicate that the mutual polarization and dipole-dipole interactions do not contribute significantly to the anion solvation in DMSO. Cl^-, Br^-, and I^- ions are slightly solvated and the solvation decreases slightly in the order $Cl^- \approx Br^- > I^-$ indicating that perhaps ion-dipole interactions play a role in anion solvation as was the case in cation solvation.

The temperature dependence of the ionic solvation in DMSO can be illustrated by referring to the limiting ionic Walden products as given in Table XII. It clearly shows that temperature affects ionic solvation very little in DMSO.

To illustrate further the effect of solvent properties on ionic transport, the limiting Walden product, $\Lambda_0\eta_0$, for (i-amyl)$_3$BuNB(Ph)$_4$, NaB(Ph)$_4$, $NaClO_4$, NaSCN, and CF_3SO_3Na in different solvents of varying dielectric constant are tabulated in Table XVI and are plotted as a function of dielectric constant as shown in Fig. 2.

It is observed from Fig. 2 that the effect of dielectric constant upon $\Lambda_0\eta_0$ of large ions such as (i-amyl)$_3$BuN$^+$, $B(Ph)_4^-$, and solvated Na^+ ions is small and Stokes' law is more nearly obeyed, while for smaller ions such as unsolvated ClO_4^-, SCN^-, and $CF_3SO_3^-$, the effect of dielectric constant upon $\Lambda_0\eta_0$ is greater and the limiting Walden product depends on dielectric properties of the solvent as well as other intrinsic solvent properties, *e.g.*, hydrogen bonding and perhaps acid and base properties.

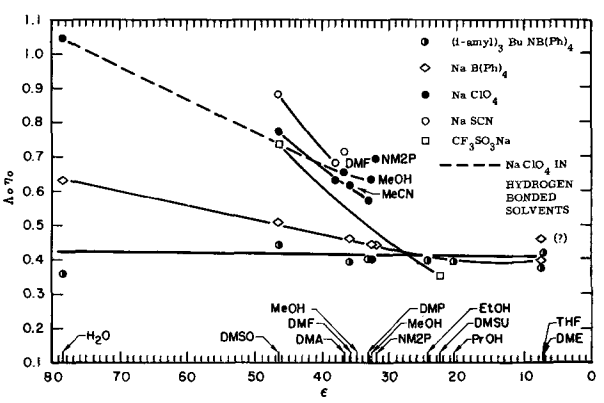

Fig. 2. Effect of solvent dielectric constant on the limiting Walden product for different salts.

Theoretical consideration of ionic mobility in a dielectric medium has been given by Boyd (16) and Zwanzig (17). The theoretical ionic mobility which accounts for the effect of dielectric relaxation is of the form

$$\lambda_i^o = Fe|z_i|/6\pi\eta_0(r_i + D/r_i^3) \qquad [6]$$

where

$$D = (2/3)z_i^2e^2\tau(\epsilon_s - \epsilon_\infty)/6\pi\eta_0\epsilon_s^2$$

Using Eq. [6], the theoretical limiting ionic mobility as a function of reciprocal of crystallographic size was calculated with the following parameter values for DMSO at 25°C: $\eta_0 = 1.998 \times 10^{-2}$ poise, $\epsilon_0 = 46.4$, $\epsilon_\infty \simeq n_0^2$ (index of refraction) (31, 49) = 2.18, and τ(DMSO) = η_0(DMSO)τ(acetone)/η_0(acetone) = 20.42×10^{-12} s where τ(acetone) is given by Boyd (16). The theoretical $\lambda_0\eta_0$ are shown in Fig. 3 by a dotted line. Experimental $\lambda_0\eta_0$ values for some ions in DMSO (open circle) at 25°C are also plotted in Fig. 3, and the values are summarized in Table XVII. Figure 3 shows that Stokes' law is at best an approximation for large ions and does not predict a maximum in $\lambda_0\eta_0$ as

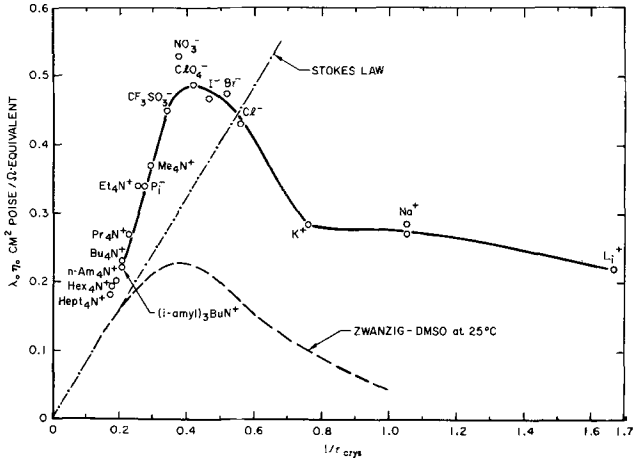

Fig. 3. Limiting ionic Walden product as a function of reciprocal of crystal radius, experimental results compared to Stokes' law and Zwanzig theory.

** Assuming 1 Bohr radius.

a function of the reciprocal of the ionic radii. On the other hand, comparison of the observed $\lambda_o\eta_o$ and Zwanzig theory in DMSO shows remarkable similarity in shape, but not in magnitude. The Zwanzig theory predicts the maximum $(\lambda_o\eta_o)_{max} = 0.231$ cm² poise/ohm equivalent at $(r_c)_{max} = 2.69$Å, *i.e.*, $(1/r_c)_{max} = 0.372$Å^{-1}, while the observed maximum in $\lambda_o\eta_o$ is about 0.49 cm² poise/ohm equivalent at 2.5Å. The observed $(\lambda_o\eta_o)_{max}$ is larger than the theoretical $(\lambda_o\eta_o)_{max}$ by a factor of about two. This is apparently due to the incompleteness of the Boyd-Zwanzig theory which considers the dielectric relaxation drag, but ignores the existence of streamlines in the medium. This in effect complements the simple Stokes law, which ignores everything but the streamlines. Recently, Atkinson and Mori (50) examined the Zwanzig theory applied to alkali ions in H_2O, D_2O, MeOH, EtOH, and MeCN solvents and to a number of ions in dioxane-water and glycerol-water mixtures. In all cases the theory gives a good qualitative description of ion mobility. A plot of $\mathbf{F}^2/N\eta_o\lambda_i^o$ as a function of $\tau(\epsilon_s - \epsilon_\infty)/\eta_o\epsilon_s^2$ for the ions as suggested by a rearranged Zwanzig's equation, Eq. [6]

$$\mathbf{F}^2/N\eta_o\lambda_i^o = 6\pi r_i + (2/3)e^2\tau(\epsilon_s - \epsilon_\infty)/r_i^3\eta_o\epsilon_s^2$$

gives a slope of $2e^2/3r_i^3$ and an intercept of $6\pi r_i$. The r_i obtained from the slope and the intercept from plots of experimental data not only disagree with each other, but are of questionable magnitude. Several possible modifications to the Boyd-Zwanzig theory have been discussed by Frank (51). These include consideration of molecular slip and microscopic local viscosity.

These possible modifications are certainly justifiable from physical intuition, but it appears that such adjustments push the theory too far. Since the theory attempts to describe the ionic motion on a molecular level, it appears that molecular jumps (52) as a mode of transport mechanism, specific solvent structure, and short range interactions will all enter in an ultimate refined form for describing ionic mobility in a dielectric medium.

Conclusions

1. $NaClO_4$, NaSCN, and CF_3SO_3Na salts are completely dissociated and $NaBPh_4$ is slightly associated. $(i\text{-amyl})_3BuNB(Ph)_4$ and CH_3SO_3Na are associated and have association constants of 12 and 100 liters/mole, respectively, at 25°C.

2. Corrected Stokes' radii for $(i\text{-amyl})_3BuN^+$, $B(Ph)_4^-$, Na^+, $CF_3SO_3^-$, ClO_4^-, and SCN^- ions are, respectively, 5.12, 5.12, 4.32, 3.03, 2.82, and 2.37Å at 25°C.

3. Alkali ions, Li^+, Na^+, and K^+, are solvated with 4.8, 2.8, and 2.8 molecules of DMSO while the halide ions Cl^-, Br^-, and I^- are only slightly solvated, if any, at 25°C.

4. Effective ionic radii are insensitive to temperature from 25° to 55°C.

5. Transport of ions in DMSO is limited principally by viscous drag.

6. The Zwanzig theory of dielectric relaxation as applied to ionic mobility in DMSO shows only qualitative agreement.

Solid Bielectrolyte Cells for Thermodynamic Measurements

David A. Shores[*,1] **and Robert A. Rapp**[*]

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Galvanic cells utilizing two mixed conducting solid electrolytes in intimate contact with each other, and in which transport occurs by a common ion, have been analyzed. The voltage of such cells depends on the nonmetal (or metal) chemical potential at the interface between the electrolytes. A method for calculating the chemical potential at the interface from steady-state transference conditions has been described and example calculations for a ThO_2 (Y_2O_3)-$ZrO_2(CaO)$ bielectrolyte cell have been presented. Voltages less than the thermodynamic value must be expected for bielectrolyte cells when one or both electrolytes exhibit $t_i < 1$ and their partial electronic conductivities are comparable. The bielectrolyte cell arrangement seems to offer no outstanding advantages for thermodynamic measurements over a single electrolyte cell with a properly chosen reference electrode.

Before the physicochemical details of mixed ionic and electronic conduction in solid ionic compounds were fully realized or established by experiment, Wagner (1) outlined the steady-state conditions which would exist for galvanic cells with two solid electrolytes exhibiting mixed conduction. To evaluate this theory, Wagner (1) interpreted the voltage of the galvanic cell

$$\text{Ag} \mid \text{AgI} \mid \text{Ag}_2\text{S} \mid \text{S, Pt} \qquad \text{(I)}$$

for which only average partial electrical conductivities were available for the AgI and Ag_2S "electrolytes."

More recently, zirconia- and thoria-base electrolytes have found wide application in high-temperature thermodynamic studies. Measurements of partial conductivities in these oxide electrolytes as a function of oxygen chemical potential have been reported and reviewed (2). Wagner (3) and Schmalzried (4, 5) have described and tested an analysis of the voltage of a solid electrolyte cell with a single mixed conducting electrolyte. As limiting applications of the Schmalzried theory, the "plateau" voltage of a cell may be interpreted to provide values for $P_\oplus$ or $P_\ominus$, which represent for a given electrolyte those values of P_{O_2} at which the positive hole or excess electron conductivity equals the ionic conductivity.

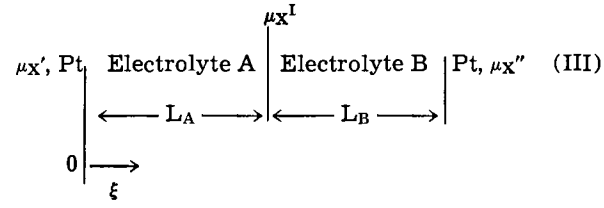
It was recently proposed (6) that a bielectrolyte cell involving thoria- and zirconia-base electrolytes could extend the P_{O_2} range of thermodynamic cell measurements compared to the range of either electrolyte used singly. In such a cell arrangement, the mobile oxygen ions as well as electronic carriers are common to both electrolytes, as in the cell

$$P_{O_2}', \text{Pt} \mid \text{ThO}_2(\text{Y}_2\text{O}_3) \mid \text{ZrO}_2(\text{CaO}) \mid \text{Pt}, P_{O_2}'' \qquad \text{(II)}$$

In what follows, a general analysis for the interpretation of voltages for solid galvanic cells with two mixed conducting electrolytes is presented. In particular, the voltage of cell II was selected for an evaluation of the theory. Finally, the usefulness of a bielectrolyte cell arrangement in competition with single electrolyte cells for thermodynamic measurements is discussed.

Theoretical Considerations

As a model for the calculations to follow, consider the following hypothetical cell



(III)

having a voltage, E, and comprised of electrolytes A and B having a common anion and thicknesses, L_A and L_B. Anions are presumed to be the predominantly mobile ionic species, and the electrodes establish chemical potentials of μ_X' and μ_X''. The electrolytes are characterized by their total electrical conductivities σ^A and σ^B, the value of n in the expressions for partial electronic conductivities $\sigma_\oplus \propto P_{X_2}^{1/n}$ and $\sigma_\ominus \propto P_{X_2}^{-1/n}$ and values of $P_\oplus^A$, $P_\oplus^B$, $P_\ominus^A$, and $P_\ominus^B$ denoting values of P_{X_2} at which the ionic transference number, t_i, equals 0.5 owing to the partial positive hole conduction at high μ_X (4, 5). The chemical potential of X at the electrolyte A/electrolyte B interface is denoted as μ_X^I. It is presumed that the two electrolytes are in intimate contact with each other, and that as a result, μ_X^I is established exclusively by electronic and ionic transport through the electrolytes and is not affected by interactions with a surrounding gas environment.

The cell voltage, E, is the sum of the voltage across each electrolyte, or for cell III (1, 3).

$$E = (1/\mathbf{F})\int_{\mu_X'}^{\mu_X^I} (t_i^A/|z_X|)\, d\mu_X + (1/\mathbf{F})\int_{\mu_X^I}^{\mu_X''} (t_i^B/|z_X|)\, d\mu_X \qquad [1]$$

where t_i^A and t_i^B are the ionic transference numbers in electrolytes A and B, respectively, and z_X is the valence of the anion X. If these ionic transference numbers are essentially unity over the individual ranges of μ_X, the integrals can be combined immediately and the resulting (thermodynamic) voltage, equal to $(\mu_X'' - \mu_X')/|z_X|\mathbf{F}$, is the same as if either electrolyte were used singly. Otherwise, a different (lower) voltage results which depends on μ_X^I and the transference numbers. One may attempt to measure μ_X^I, *e.g.* by inserting a fine Pt wire in the interface, or it may be calculated from steady-state transference conditions as described in the following.

We begin by calculating the rates of ionic and electronic transport through each electrolyte following the method of Wagner (1, 3). For two electrolytes having anions as the mobile ionic species, the steady-state rates of ionic transport and electronic transport in the

* Electrochemical Society Active Member.

Key words: solid electrolyte, galvanic cell, zirconia, thoria, silver iodide, Ag_3SI, bielectrolyte.

one electrolyte will be equivalent and equal to those in the other electrolyte if the interface is not a source or sink for ions or electrons. Thus, assuming linear cell geometry

$$-j_2^A = j_3^A = -j_2^B = j_3^B \quad [2]$$

where j_2 and j_3 are, respectively, the transport rates in equivalents per second for anions and electrons, and are given by the expression (1, 3)

$$j_{2 \text{ or } 3} = (300S\, t_2\, t_3\, \sigma / |z_X|\mathbf{F}) \mid d\mu_X/d\xi \mid \quad [3]$$

where S is the interfacial area and t_2 and t_3 are, respectively, transference numbers for anions and electrons. Substitution of Eq. [2] with integration across the thickness of the electrolytes gives

$$L_A^{-1} \int_{\mu_{X'}}^{\mu_X^I} t_2^A t_3^A \sigma^A d\mu_X = L_B^{-1} \int_{\mu_X^I}^{\mu_X''} t_2^B t_3^B \sigma^B d\mu_X \quad [4A]$$

Equivalent expressions for electrolytes exhibiting predominant cationic or mixed cationic plus anionic conduction, respectively, are

$$L_A^{-1} \int_{\mu_{Me'}}^{\mu_{Me}^I} t_1^A t_3^A \sigma^A d\mu_{Me} = L_B^{-1} \int_{\mu_{Me}^I}^{\mu_{Me}''} t_1^B t_3^B \sigma^B d\mu_{Me} \quad [4B]$$

and

$$L_A^{-1} \int_{\mu_{Me'}}^{\mu_{Me}^I} (t_1^A + t_2^A) t_3^A \sigma^A d\mu_{Me} = L_B^{-1} \int_{\mu_{Me}^I}^{\mu_{Me}''} (t_1^B + t_2^B) t_3^B \sigma^B d\mu_{Me} \quad [4C]$$

In principle, each of these equations involves only one unknown, *i.e.* the chemical potential at the interface, if the total conductivities and transference numbers of the electrolytes are known as functions of μ_X (or μ_{Me}). Then Eq. [1] could also be evaluated to obtain the voltage of the bielectrolyte cell.

Accordingly, we proceed by taking as a specific example $ThO_2(Y_2O_3)$ and $ZrO_2(CaO)$ solid electrolytes for A and B of cell III, respectively. Both electrolytes are known to be oxygen anion conductors with electronic conduction appearing at low P_{O_2} and positive hole conduction at high P_{O_2} (2). By applying the law of mass action, with the assumptions of (*a*) fully ionized defects, (*b*) concentration-independent mobilities, and (*c*) an infinitely dilute solution of electronic defects, it can be shown for such electrolytes that (4, 5)

$$\sigma_3^A = \sigma_2^A(\Delta_{A\oplus} + \Delta_{A\ominus}) \quad [5]$$

and

$$\sigma_3^B = \sigma_2^B(\Delta_{B\oplus} + \Delta_{B\ominus}) \quad [6]$$

where

$$\Delta_{A\oplus} = (P_{O_2}/P_\oplus^A)^{1/n} \quad [7A]$$

$$\Delta_{A\ominus} = (P_{O_2}/P_\ominus^A)^{-1/n} \quad [7B]$$

$$\Delta_{B\oplus} = (P_{O_2}/P_\oplus^B)^{1/n} \quad [8A]$$

$$\Delta_{B\ominus} = (P_{O_2}/P_\ominus^B)^{-1/n} \quad [8B]$$

By definition

$$t_2 = \sigma_2/(\sigma_2 + \sigma_3) \quad [9]$$

$$t_3 = \sigma_3/(\sigma_2 + \sigma_3) \quad [10]$$

Equations [5], [6], [9], and [10] may be substituted into Eq. [4A]. With the knowledge that σ_2^A and σ_2^B are independent of P_{O_2}, one obtains

$$\frac{\sigma_2^A}{L_A} \int_{P_{O_2'}}^{P_{O_2}^I} \frac{\Delta_{A\oplus} + \Delta_{A\ominus}}{1 + \Delta_{A\oplus} + \Delta_{A\ominus}} d \ln P_{O_2} = \frac{\sigma_2^B}{L_B} \int_{P_{O_2}^I}^{P_{O_2}''} \frac{\Delta_{B\oplus} + \Delta_{B\ominus}}{1 + \Delta_{B\oplus} + \Delta_{B\ominus}} d \ln P_{O_2} \quad [11]$$

With the assumption that $L_A = L_B$, upon integration the left-hand side of Eq. [11] becomes

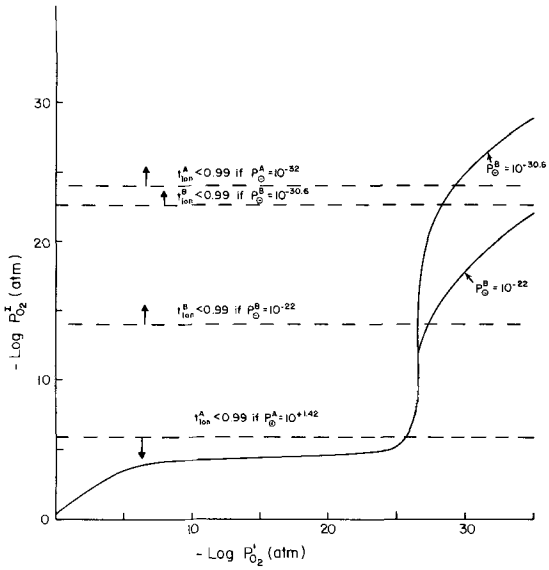

Fig. 1. Calculated values of log $P_{O_2}^I$ vs. log $P_{O_2'}$ with $P_{O_2}'' = 0.21$ atm for $P_\ominus^B = 10^{-30.6}$ and 10^{-22}, A ≡ $ThO_2(Y_2O_3)$ and B ≡ ZrO_2 (CaO).

$$\left\{ \sigma_2^A \ln P_{O_2} - n\sigma_2^A \left[w_A^{-1/2} \ln \frac{1 + 2\Delta_{A\oplus} - w^{1/2}}{1 + 2\Delta_{A\oplus} + w^{1/2}} \right] \right\} \Bigg|_{P_{O_2'}}^{P_{O_2}^I} \quad [12]$$

where $w_A = 1 - 4(P_\ominus^A/P_\oplus^A)^{1/n}$. An analogous result is obtained for the integration of the right-hand side of Eq. [11]. With the expansion of $w^{1/2}$ as a series, the dropping of higher terms, and the assumption that $P_\ominus^A$, $P_\oplus^B << P_\oplus^A$, $P_\oplus^B$, Eq. [12] may be simplified. Finally, with the substitution of the limits of integration and rearrangement, Eq. [11] becomes

$$(\sigma_2^A + \sigma_2^B) \ln P_{O_2}^I - n\sigma_2^A \ln (\lambda_1/\lambda_2) - n\sigma_2^B \ln (\lambda_3/\lambda_4) = \sigma_2^A \ln P_{O_2'} + \sigma_2^B \ln P_{O_2}'' - n\sigma_2^A \ln (\lambda_5/\lambda_6) - n\sigma_2^B \ln (\lambda_7/\lambda_8) \quad [13]$$

where the λ's are defined in the list of symbols appended to this paper.

Equation [13] can be evaluated graphically or by numerical methods to obtain $P_{O_2}^I$ for substitution into Eq. [1] and the further calculation of E for the bielectrolyte cell.

Discussion

As shown in the preceding sections, the steady-state chemical potential at the interface between the electrolytes of a bielectrolyte cell can be calculated from the ionic and electronic partial electrical conductivities of the individual electrolytes. For a cell involving $ThO_2(Y_2O_3)$ and $ZrO_2(CaO)$ electrolytes of equal thickness, *e.g.*

$$\text{Pt}, P_{O_2'} \mid ThO_2(Y_2O_3) \mid^{P_{O_2}^I} ZrO_2(CaO) \mid P_{O_2}'' = 0.21 \text{ atm (air)}, \text{Pt} \quad \text{(IV)}$$

values of $P_{O_2}^I$ have been computed for various values of $P_{O_2'}$ from Eq. [12] for $P_{O_2}'' = 0.21$ atm (air), and sets of values of the other parameters as listed in Table I. These results are shown in Fig. 1 as a plot of log $P_{O_2}^I$ *vs.* $P_{O_2'}$.

Table I. Values of $P_\ominus$, $P_\oplus$, and ionic conductivities at 1000°C for cell IV

	log $P_\ominus$	log $P_\oplus$	σ_2 (ohm-cm)$^{-1}$	Reference
Electrolyte A $Th_{0.84}Y_{0.16}O_{1.92}$	−32	+1.4	0.008	(6, 7)
Electrolyte B $Zr_{0.85}Ca_{0.15}O_{1.85}$	−30.6 or −22.0	+6.5	0.022	(8, 13)

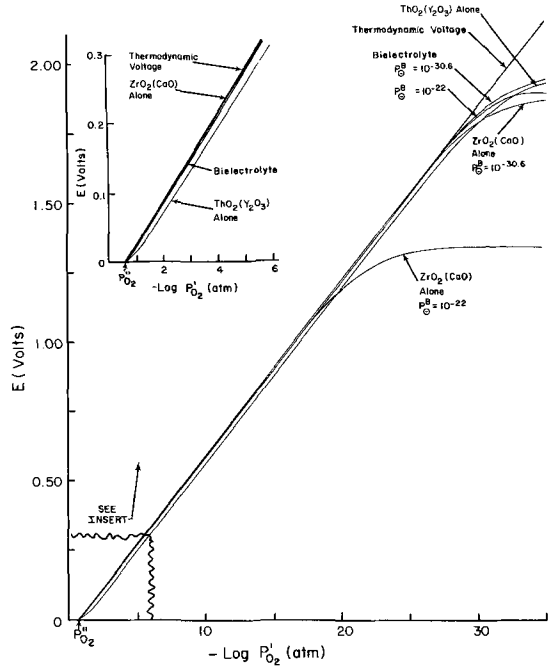

Fig. 2. Calculated values of E (volts) vs. log P_{O_2}' with $P_{O_2}'' = 0.21$ atm for single electrolytes and for the bielectrolyte arrangement of cell IV.

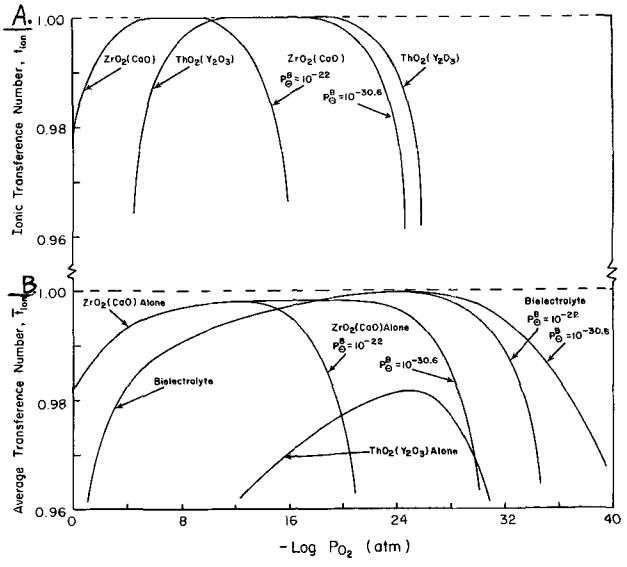

Fig. 3. A—Individual ionic transference numbers for single electrolytes; B—average ionic transference numbers for single- and bi-electrolytes in cell IV.

The values of the ionic conductivities (7-12) and $P_{\oplus}^{A \text{ or } B}$ (7, 8) and $P_{\ominus}^{A \text{ or } B}$ (6, 8, 13) chosen for Table I were taken from previously reported measurements. The most important parameter, $P_{\oplus}$ for $Th_{0.84}Y_{0.16}O_{1.92}$, was interpolated from the conductivity data of Lasker and Rapp (7). For $Zr_{0.85}Ca_{0.15}O_{1.85}$ at 1000°C, $P_{\ominus}$ has been reported as 10^{-22} (13), 10^{-23} (14), 10^{-24} (4), $<10^{-26}$ (15), 10^{-28} (16), and $10^{-30.6}$ atm (8). A recent determination of $P_{\ominus}$ for $Zr_{0.86}Y_{0.14}O_{1.93}$ by Swinkels (20) yielded an extrapolated value of $10^{-30.8}$ atm at 1000°C. The disagreement among the values of $P_{\ominus}$ is not unexpected, since the measurements are difficult experimentally and different techniques were used; further, small differences in the types and amounts of impurities may have a large effect on the electronic conductivity, and hence on $P_{\ominus}$. However, as seen in Fig. 1, values of $P_{O_2}{}^{I}$ calculated for cell IV are not sensitive to the choice of $P_{\ominus}$ for ZrO_2(CaO), until P_{O_2}' is reduced to values approaching $P_{\ominus}{}^{B}$. The two curves of Fig. 1 were calculated for the extremes in the reported values for $P_{\ominus}{}^{B}$: 10^{-22} and $10^{-30.6}$ atm.

When $P_{O_2}{}^{I}$ is known for a particular bielectrolyte cell, the expected voltage may be calculated from Eq. [1]. As an example, we may consider cell IV at 1000°C with $P_{O_2}' = 1$ atm. From Fig. 1, $P_{O_2}{}^{I} = 0.795$ atm; thus, the calculated cell voltage equals −0.0401V. This calculated value may be compared with an experimentally reported value (6) of −0.0427V. Because the $ThO_2(Y_2O_3)$ electrolyte is in a P_{O_2}-range of significant electronic conduction, the condition $P_{O_2}' = P_{O_2}{}^{I}$, *i.e.* with no chemical potential difference existing across the $ThO_2(Y_2O_3)$ electrolyte, would be required for the cell voltage to correspond exactly to the thermodynamic voltage (0.0427V), *i.e.* with an "apparent" $\bar{t}_i$ for the bielectrolyte cell equal to unity.

Voltages calculated from Eq. [1] using the data of Table I for cell IV at 1000°C are shown in Fig. 2 as a plot of E *vs.* log P_{O_2}'. For comparison, the cell voltages calculated for the single electrolytes have also been plotted. It is obvious (17) that the deviation from the thermodynamic voltage resulting from p-type conduction in the thoria electrolyte of cell IV will become a smaller fraction of the total voltage as P_{O_2}' is lowered. By calculation of this effect as illustrated in Fig. 3B, $\bar{t}_i$ for the bielectric cell becomes greater than 0.99 at about $P_{O_2}' < 10^{-6.8}$; however, for $P_{O_2} < 10^{-31.3}$, if $P_{\ominus}{}^{B} = 10^{-22}$ (or for $P_{O_2}' < 10^{-34.2}$ if $P_{\ominus}{}^{B} = 10^{-30.6}$), $\bar{t}_i$ will again decrease below 0.99 because of electronic conduction. Figure 3B is based on cell IV which specifies air ($P_{O_2}'' = 0.21$ atm) as the reference electrode in contact with the ZrO_2(CaO) electrolyte. In Fig. 3B, the bielectrolyte cell exhibits a broader range of P_{O_2} over which the average ionic transference number, $\bar{t}_i$, exceeds 0.99 than either of the two single electrolytes. However, this apparent advantage of the bielectrolyte cell must be evaluated in competition with the single electrolyte cells which may also be used to accomplish the equivalent measurement of some unknown P_{O_2}'.

Almost without exception, investigators have previously chosen to use a single electrolyte and a reference electrode well within the range of predominant ionic conduction. In Fig. 3A are plotted the ionic transference numbers of the two electrolytes described in Table I. The data of Patterson *et al.* (8) for $P_{\oplus}{}^{B}$ indicate that t_i is actually slightly less than 0.99 in air or pure oxygen. More recent and yet unpublished work by Heyne (21) and by Patterson (22) has yielded higher values for $P_{\oplus}{}^{B}$. The usual purpose of galvanic cell measurements is to determine an unknown (usually very low) P_{O_2}' as accurately as possible. For example, consider the use of a single $ThO_2(Y_2O_3)$ electrolyte cell with either a Fe-FeO or Cr-Cr_2O_3 reference electrode to measure, at 1000°C, the P_{O_2}' for the coexistence electrodes Nb-NbO or U-UO_2. It is assumed for the following calculations that any chemical attack or electrode polarization may be ignored and that the electrodes maintain their equilibrium oxygen activities (19), which are taken as: P_{O_2}(Fe,FeO) = $10^{-14.8}$, P_{O_2}(Cr,Cr_2O_3) = $10^{-21.8}$, P_{O_2}(Nb,NbO) = $10^{-25.1}$, P_{O_2}(U,UO_2) = $10^{-35.5}$ atm. This group of cells may be represented as

$$\begin{array}{c|c|c} \text{Nb, NbO} \\ \text{or} \\ \text{U, } UO_2 \end{array} \quad \begin{array}{c} \\ Th_{0.84}Y_{0.16}O_{1.96} \\ \\ \end{array} \quad \begin{array}{c|} \text{Fe, FeO} \\ \text{or} \\ \text{Cr, } Cr_2O_3 \end{array} \qquad \text{(V)}$$

In competition with cells V, we shall consider the bielectrolyte cell VI with the air reference electrode, which according to Fig. 3B might appear superior

$$\text{Nb, NbO or U, } UO_2 \mid ThO_2(+Y_2O_3) \mid P_{O_2}{}^{I} \; ZrO_2(+CaO) \mid \text{Pt, air } (P_{O_2}'' = 0.21) \qquad \text{(VI)}$$

The purpose of the comparison is, of course, to establish by calculation which cell should most accurately

Table II. Calculated values of cell voltage error and $\bar{t}_i$ for cells V and VI

Cell		E_c[a] (V)	E_t[b] (V)	Error (cal/mole)	$\bar{t}_i$[c]
Nb, NbO | $ThO_2(Y_2O_3)$ | Fe, FeO		0.6774	0.6797	106	0.997
Nb, NbO | $ThO_2(Y_2O_3)$ | Cr, Cr_2O_3		0.2159	0.2178	87	0.991
U, UO_2 | $ThO_2(Y_2O_3)$ | Fe, FeO		1.1204	1.3659	22,580	0.820
U, UO_2 | $ThO_2(Y_2O_3)$ | Cr, Cr_2O_3		0.6589	0.9040	22,540	0.729
Nb, NbO | $ThO_2(Y_2O_3)$ | $ZrO_2(CaO)$ | Pt, air ($P_{O_2} = 0.21$)	$P_\ominus^B = 10^{-22}$	1.6052	1.6116	294	0.996
	$P_\ominus^B = 10^{-30.6}$	1.6052	1.6116	294	0.996
U, UO_2 | $ThO_2(Y_2O_3)$ | $ZrO_2(CaO)$ | Pt, air ($P_{O_2} = 0.21$)	$P_\ominus^B = 10^{-22}$	1.9575	2.2978	31,300	0.852
	$P_\ominus^B = 10^{-30.6}$	2.0484	2.2978	22,940	0.891

[a] Cell voltage calculated with Schmalzried's equation for cells V, and Eq. [1] and [12] for cells VI.
[b] Thermodynamic cell voltage; *i.e.*, $E = -\Delta G^\circ/nF$.
[c] $\bar{t}_i = E_c/E_t$.

measure the low value of P_{O_2}', which in these cells is presumed to be known. The results of the calculations using Schmalzried's (4, 5) equation for cells V and our Eq. [12] and [1] for the bielectrolyte cell are listed in Table II. As seen in Table II, regardless of the higher values of $\bar{t}_i$ for the bielectrolyte cells, the more accurate measurement of P_{O_2}' is made by the single electrolyte cells. Thus, the use of $\bar{t}_i$ as a measure for the usefulness of a cell is misleading.

The calculations of Table II indicate that the least error from mixed conduction in a single electrolyte cell is realized by choosing a reference electrode whose P_{O_2} is as close as possible to that of the unknown electrode. Then, in principle, the Cr, Cr_2O_3 electrode is superior to other electrodes with higher P_{O_2}'' to measure very low values of P_{O_2}'. For a single electrolyte cell, the cell voltage may also be obtained from the graphical integration of Fig. 3A from the reference to the "unknown" electrode (7). While the area below the curve is proportional (a factor of $RT/4\mathbf{F}$) to the cell voltage, the area above the curve is proportional to the error in the measurement which results from mixed conduction. Obviously, this area and the error are minimized as the two electrodes approach each other. In the limit, an exact determination of an unknown P_{O_2}' can be made regardless of the value of t_i if a known P_{O_2}'' can be adjusted so that the cell voltage equals zero (19).

In the application of the Schmalzried (voltage plateau) technique to cell IV for the determination of an "apparent" $P_\ominus$ for the bielectrolyte, P_{O_2}' would be reduced to an extremely low value so that a limiting cell voltage is obtained. From Eq. [1], it follows that

$$E \text{ (plateau)} = E^A + E^B \qquad [14]$$

where E^A and E^B are, respectively, the voltages across electrolyte A [$ThO_2(Y_2O_3)$] and electrolyte B [$ZrO_2(CaO)$]. The interpretation of such a limiting (plateau) voltage in terms of the electronic conductivities of the individual thoria and zirconia electrolytes is as follows. If Schmalzried's equation (4, 5) for the voltage of a cell involving a mixed conducting electrolyte is applied to the thoria electrolyte of cell IV, with the condition that $P_{O_2}' \ll P_\ominus \ll P_{O_2}^I$, one obtains

$$\ln P_\ominus^A = \ln P_{O_2}^I - 4\mathbf{F}E^A/RT \qquad [15]$$

For $ZrO_2(CaO)$

$$E^B = RT/\mathbf{F} \ln (\lambda_4/\lambda_8) + RT/\mathbf{F} \ln (\lambda_7/\lambda_3) \qquad [16]$$

Substitution of Eq. [14] and [16] into Eq. [15] and neglecting the small contribution of the first term on the right side of Eq. [16] gives

$$\ln P_\ominus^A = \ln P_{O_2}^I - 4\mathbf{F}E(\text{plateau})/RT + 4 \ln (\lambda_7/\lambda_3) \qquad [17]$$

where $n = 4$.

Reported values of the plateau voltage (6)[2] for cell IV

$$E(\text{plateau}) = 2.87 - 7 \times 10^{-4}T(1000\text{-}1400\text{K}) \text{ (V)} \qquad [18]$$

may be substituted into Eq. [16] and values of $P_\ominus^A$ can be obtained if $P_{O_2}^I$ or P_{O_2}' is known. For example, at 1000°C with $P_\ominus^B = 10^{-22}$ atm, $P_\ominus^A$ is calculated to equal $10^{-32.9}$ atm if P_{O_2}' is assumed to be 10^{-34} atm and thereby $P_{O_2}^I = 10^{-21.3}$ atm (from Fig. 1), or to equal $10^{-33.6}$ atm if P_{O_2}' is assumed to be 10^{-36} atm and $P_{O_2}^I = 10^{-22.7}$ atm. Alternatively, for $P_\ominus^B = 10^{-30.6}$ atm again assuming $P_{O_2}' = 10^{-34}$ or 10^{-36} atm, $P_\ominus^A$ is calculated to equal $10^{-32.3}$ or $10^{-32.6}$ atm, respectively. These values of $P_\ominus^A$ do not differ substantially from those obtained by neglecting the contribution of $\sigma_\ominus^B$ in the bielectrolyte cell (6). It should be noted that the above calculated values of $P_\ominus^A$ depend on $P_{O_2}^I$, which is already a function of $P_\ominus^A$, and on an arbitrary choice of P_{O_2}' corresponding to the voltage plateau. An exact solution for $P_\ominus^A$ would require an iterative calculation procedure as well as a knowledge of P_{O_2}'. If values for $P_\ominus^A$ are obtained in this manner, or are otherwise available, the oxygen pressure range for which $t_i \geq 0.99$ for $ThO_2(Y_2O_3)$ alone (the usual criterion for thermodynamic measurements) may be calculated by combining Eq. [6] and [7], and setting $n = 4$, or

$$\log P_{O_2} (t_i = 0.99) \cong \log P_\ominus^A + 8 \qquad [19]$$

The foregoing general treatment of bielectrolyte cells can also be applied to cells with exchange electrodes which exhibit mixed conduction. As an example of a limiting case, the exchange electrode Ag_2S in cell I may be considered as a second electrolyte, indeed one with predominant electronic conduction. Wagner (1) has previously described this cell in which Ag is the transported species. At steady state in the absence of an external circuit, the countertransference of silver ions and electrons in AgI is extremely small because of the very low σ_e(AgI). On the other hand, because of the high $\sigma_e(Ag_2S)$, the steady-state ionic and electronic fluxes in Ag_2S are maintained with only a negligible voltage drop across Ag_2S. Thereby, the silver activity at the AgI/Ag_2S interface is virtually equal to that at the Ag_2S/S interface. Thus, the voltage across the Ag_2S "electrolyte" is zero, and the thermodynamic voltage is measured for the cell. However, as already discussed, deviations from the thermodynamic voltage must be expected for a bielectrolyte cell when one electrolyte exhibits $t_i < 1.0$ and the partial electronic conductivities of the single electrolytes are comparable.

When an electrode component reacts with the electrolyte, the cell voltage may decrease. If a compact product layer is formed, it may be considered as a second electrolyte, and information about the transport properties of the product layer may be deduced from changes in the cell voltage so long as the electrodes remain reversible. Such an interpretation of a changing cell voltage may be pertinent to the shelf life and voltage stability of a solid-state battery. Owens *et al.* (18) have questioned previous reports of the high stability of the cell

[2] These measurements may have been carried out with the oxygen activity at the thoria-zirconia interface established by coexisting Co-CoO, in which case the plateau voltage arises exclusively from electronic conduction in the thoria electrolyte.

$$Ag \mid Ag_3SI \mid I_2 \qquad (VII)$$

based on their experimental observation that Ag_3SI reacts with I_2 to form AgI and S. If AgI in the presence of I_2, or AgI doped with S, should exhibit $t_{ion} < 1$, then the mixed conducting AgI product layer would lead to a lower open-circuit voltage; if the AgI product layer is an exclusive ionic conductor, then the open-circuit cell voltage would be stable.

The Effect of Anions on the Thermodynamics of Silver-Sodium Exchange between Glass and Molten Salts

Kurt H. Stern*

Naval Research Laboratory, Electrochemistry Branch, Washington, D. C. 20390

ABSTRACT

$\Delta H°$ and $\Delta S°$ were determined for the ion exchange Na^+(glass) + Ag^+(salt) = Na^+(salt) + Ag^+(glass) in mixed chloride-sulfate melts in the range 500°-600°C. The small value of the equilibrium constant K in the pure chloride melt results primarily from a negative $\Delta S°$ which is accounted for by the lower mobility of Ag^+ in the glass relative to Na^+. In the mixed anion melts both $\Delta H°$ and $\Delta S°$ contribute to K.

In previous work (1) it was shown that the equilibrium constant K for the process

$$Na^+(g) + Ag^+(s) = Na^+(s) + Ag^+(g) \qquad [1]$$

where g represents the glass and s the salt phase, is highly dependent on the melt anion, although only the cations participate in the actual exchange. For example, in mixed chloride-sulfate melts K increased by three orders of magnitude as the melt composition was changed from pure chloride to 58 mole per cent (m/o) sulfate. These results were accounted for in terms of a model in which the anionic adsorption sites on the glass and the melt anions in the double layer near the glass-melt interface "compete" for the cations. When only oxyanions are present in the melt, values of $\Delta G°$ for the exchange calculated by assuming that all cation-anion interactions are coulombic were in good agreement with experiment. However, in bromide and chloride melts, experimental values of $\Delta G°$ were much

* Electrochemical Society Active Member.
Key words: membrane potentials, glass, molten salts.

more positive.[1] This result was explained in terms of the strong tendency of halide ions to complex Ag^+, resulting in a smaller value of K than expected from electrostatics alone.

The purpose of the present work is to explore the validity of the model further by obtaining the thermodynamic functions $\Delta H°$ and $\Delta S°$ for the exchange. A comparison of the contribution these functions make to $\Delta G°$ should give further insight into the mechanism of the exchange.

Since the various oxyanions investigated previously (1) all gave similar results, only chloride-sulfate melts were studied. Membrane potentials and glass conductances were determined in the range 500°-600°C.

Experimental

The general procedures for carrying out membrane potential measurements have been described previously (1, 2). For the present work the U-shaped cells, made of General Electric Type 204 fused silica, were modified by sealing a short piece of tubing directly over the membrane so that the Platinel II thermocouple could be inserted into it with its junction in contact with the membrane. The thermocouple was calibrated initially against a National Bureau of Standards calibrated Pt-13% Rh thermocouple and recalibrated occasionally against the melting point of AgCl. The same AgCl-Ag_2SO_4 mixture was added to each side of the cell and the silver electrodes, sheathed in 3 mm OD fused silica tubing, were inserted into the cell through the top of caps through which a stream of dry helium passed continuously to reduce access of moisture to the melt. After the EMF had stabilized, usually to within a few mV of zero, sodium was added incrementally as NaCl up to ~5 m/o. Since the additions were small the Cl^-/SO_4^{-2} ratio remained approximately constant during a run. The temperature dependence of the emf was measured for each Na^+ concentration in the range 500°-600°C after the emf had become constant at each temperature. All measurements were corrected for the initial asymmetry potential.

The conductance of the membrane was measured with a General Radio 544-B Megohm Bridge, accurate to ±3%. Although AgCl is a stable liquid in the range 500°-600°C, there seems to be no sodium salt for which this is true. Several experiments were made with a NaCl-NaI eutectic which is liquid above 573°C, but this solution evolved I_2 and appeared to change the glass irreversibly since the conductance ratio with Ag^+ and Na^+ in the glass changed with the sequence of filling the cell. The most reproducible results were obtained when the cell was filled with AgCl, electrolyzed at 100-200V between Pt electrodes until the resistance became constant. The resistance was then measured as a function of temperature. The AgCl was then replaced by undried NaBr which was allowed to sinter in the cell. The electrolysis and conductance measurements were then repeated.

Treatment of Experimental Data

Since the method of calculating ion exchange equilibrium constants has been discussed in detail elsewhere (3), it is only summarized here. The emf of the concentration cell

$$Ag|AgCl, Ag_2SO_4|glass|Ag^+, Na^+, Cl^-, SO_4^{-2}|Ag \quad [2]$$

is given by $E_{cell} = E_M + E_{electrode}$, where the membrane potential E_M is (4)

$$E_M = (nRT/F) \ln [(a^{1/n} + K'^{1/n} b^{1/n})/(K'^{1/n}] \quad [3]$$

where a and b are the activities of the exchanging ions and K' is the ion-exchange selectivity constant, n is a thermodynamic factor which for the present system is near unity (3).

Since the melts in this study did not contain more than a few mole per cent sodium, the activities were replaced by mole fractions on the assumption that the activity coefficients would not vary greatly over the concentration range. The ionic activities were identified with the mole fractions of the salt components

$$a = n_{NaCl}/(n_{NaCl} + n_{AgCl} + n_{Ag_2SO_4}) \quad [4a]$$

$$b = (n_{AgCl} + n_{Ag_2SO_4})/(n_{NaCl} + n_{AgCl} + n_{Ag_2SO_4}) \quad [4b]$$

The ion-exchange selectivity constant K' can be written as the product of the equilibrium constant for reaction [1] and the ionic mobility ratio

$$K' = K(U_{Ag}/U_{Na})^n \quad [5]$$

Since it was shown previously (3) that K' is virtually independent of n, it was calculated with $n = 1$. The value of K does depend on n since this parameter appears as exponent of the mobility ratio, but it was determined that the values of $\Delta H°$ and $\Delta S°$ which are of interest in this work are affected very little by small departures (±10%) of n from unity. The K values reported in this work are therefore those with $n = 1$.

Results and Discussion

Between 500° and 600°C the conductance ($1/R$) of the glass is linear in $1/T$ for both Na^+ and Ag^+, the corresponding Arrhenius activation energies being 83.3 and 109.2 kJ, respectively. As a consequence of these different activation energies, the mobility ratio is quite temperature dependent:

t (°C)	$(U_{Na}/U_{Ag}) \pm 5\%$
500	9.8
550	7.5_0
600	5.7_6

The ratio for 570°C, the temperature of the previous study (3) is 6.4, somewhat higher than the previously reported value of 5. Linear extrapolation of the ratio in $1/T$ to 337°C gives 21 compared to 13.7 reported by Doremus (5) for fused silica at this temperature. Linear extrapolation of the plot shows that the mobilities of Ag^+ and Na^+ are expected to become equal ($U_{Na}/U_{Ag} = 1$) at 760°C.

In Table I are listed values of K' and K for the four $Cl^- - SO_4^{-2}$ melts at three different temperatures. The first two lines compare the values obtained in pure chloride melts when activity corrections are taken into account (3). For the mixed anion melts activity corrections cannot be made since the activity coefficients are not known. However, as has been pointed out elsewhere (3, 6), AgCl-Ag_2SO_4 solutions are virtually

[1] The sign of $\Delta G°_{exp.}$ in Tables II and III of Ref. 1 was inadvertently reversed. It should be positive.

Table I. K' and K values for Ag^+-Na^+ exchange on fused silica

Table II. $\Delta H°$ and $\Delta S°$ for the exchange reaction $Na^+(g) + Ag^+(s) = Na^+(s) + Ag^+(g)$

$X_{Ag_2SO_4}$	$\Delta H°$ (kJ)	$\Delta S°$ (JK^{-1})
0.000*	−2.5	−65.7
0.000	+0.2	−65.7
0.286	−7.5	−41.0
0.500	−11.0	−33.0
0.575	−27.0	−49.0

* With activity correction.

ideal, and in the ternary melt the sodium concentration range used is sufficiently small to preclude large variations of activity coefficient with melt composition. Thus, although the neglect of activity corrections affects the actual value of K (see the first two lines of Table I for the effect of the known activities in the AgCl-NaCl system), it would hardly affect the temperature coefficient of K for a particular anion composition; as pointed out previously (3) the assumption of ideality can also not account for the thousand-fold change of K with anion composition.

Values of K' at 550°C are in fairly good agreement with those determined previously (1) near that temperature. In general, the new values are somewhat lower. The marked increase of K' and K with increased sulfate concentration is apparent. With the exception of K' at 600°C for $X_{Ag_2SO_4} = 0.575$ the trend is for K' to increase somewhat with temperature. Since (U_{Na}/U_{Ag}) decreases markedly with temperature, the equilibrium constant K shows a slightly reverse trend, particularly at the higher sulfate concentrations.

The values of K can be used to calculate the enthalpy and entropy values for the cation exchange by standard thermodynamic methods. These are shown in Table II.

A comparison of the first two lines shows that the effect of neglecting the nonideality of the melts on $\Delta H°$ and $\Delta S°$ is very minor, most probably because both of these functions depend only on the temperature coefficient of K which is less sensitive to activity corrections than the absolute value of K.

The most notable feature of Table II is the fact that, particularly in the chloride-rich melts, the small values of K are almost entirely accounted for by the negative $\Delta S°$ for the exchange reaction. As the sulfate concentration increases the situation becomes more complex with both $\Delta H°$ and $\Delta S°$ contributing to $\Delta G°$, but in opposite directions: $\Delta H°$ favors the exchange process [1] as written and $\Delta S°$ opposing it. This result is surprising in terms of the model which was used to account for the increase in K (decrease of $\Delta G°$) with increasing $X_{SO_4^{-2}}$. In terms of the electrostatic interactions of the cations with the melt anions and the $AlOSi^-$ exchange sites on the glass, values of K near unity were predicted. The small values of K in halide melts were accounted for by the nonelectrostatic bonding involved in the formation of silver halide complexes which increases the activity of silver in the melt relative to that in the glass, but this effect might have been expected to be reflected in enthalpy rather than entropy changes.

The problem can be examined in more detail by writing the exchange process as the difference of two terms

$$Ag^+(s) \rightarrow Ag^+(g) \qquad (a)$$

$$Na^+(s) \rightarrow Na^+(g) \qquad (b)$$

Then

$$\Delta S° = \Delta S_a - \Delta S_b$$

$$\Delta H° = \Delta H_a - \Delta H_b$$

It seems reasonable to suppose that the entropy of the cations is greater in the melt than in the glass since they must lose at least some of their translational entropy by becoming relatively immobile on or in the glass. Therefore, ΔS_a and ΔS_b are both negative. But the experimental negative $\Delta S°$ then requires that ΔS_a be more negative than ΔS_b. If we write

$$\Delta S_a = S_{Ag(g)} - S_{Ag(s)} < 0$$

$$\Delta S_b = S_{Na(g)} - S_{Na(s)} > 0$$

this means that either one or both conditions apply

$$S_{Na(s)} < S_{Ag(s)}$$

$$S_{Na(g)} > S_{Ag(g)}$$

where the entropies are not the third law values but include only contributions to the entropy from the position of the ions. If Ag^+ is complexed in the melt, its freedom of movement should be somewhat less than that of Na^+ and the first inequality should be reversed. The argument then requires that the negative $\Delta S°$ be accounted for entirely by the second inequality which must outweigh the effect of the first. It is known that the mobility of Na^+ in the glass is much greater than that of Ag^+ so that this inequality is reasonable, *i.e.* Na^+ is less tightly bound to the glass network than Ag^+ *is*.

With increasing sulfate concentration $\Delta S°$ becomes less negative. Since the cationic mobilities are not affected by anions in the melt, it follows that this effect must arise from the first inequality, *i.e.* the interactions between the cations and SO_4^{-2} are more nearly equal than with Cl^- and $S_{Ag(s)}$ increases relative to $S_{Na(s)}$. Hence ΔS_a becomes less negative.

We next consider possible interpretations of $\Delta H°$. In chloride melts $\Delta H° \simeq 0$ and therefore $\Delta H_a = \Delta H_b$. Then,

$$\Delta H_a = H_{Ag(g)} - H_{Ag(s)}$$

$$\Delta H_b = H_{Na(g)} - H_{Na(s)}$$

where the reference state ($H_i = 0$) is the bare ion in free space. Since electrostatic attraction operates between each cation and the anions in the melt and in the glass, all the ionic enthalpies are negative. If the enthalpy terms for all interactions except $Ag^+ - Cl^-$ are identified with coulombic energies [in contrast to the previous work (1) in which they were identified with Gibbs energies] then the condition $\Delta H° = 0$ permits the calculation of $H_{Ag(s)}$ in a pure chloride melt

$$H_{Ag(s)} = H_{Ag(g)} - H_{Na(g)} + H_{Na(s)}$$
$$= (-103) - (-113) + (119) = -109 \text{ kcal}$$

But this value of $H_{Ag(s)}$ is only slightly more negative than the purely electrostatic value of −107 kcal (1). This would indicate that nonelectrostatic $Ag^+ - Cl^-$ interactions are not very significant. The experimental value of $\Delta H°$ becomes increasingly negative as the sulfate concentration is increased. In terms of electrostatics alone this is not well accounted for since the predicted value is near zero for a pure sulfate melt (1).

As a result of the present work, the ion exchange model presented previously requires some revision. The small value of K in the pure chloride melt is seen to result primarily from a negative entropy change for the exchange process. This negative $\Delta S°$ is largely accounted for by the greater mobility of Na^+ in the glass rather than the nonelectrostatic complexing of Ag^+ by Cl^- in the melt. Only the increase of $\Delta S°$ with SO_4^{-2} concentration is accounted for by the decrease of this complexing in the mixed $Cl^- - SO_4^{-2}$ melts. The major unexplained feature is the decrease of $\Delta H°$ with increasing SO_4^{-2} concentration.

Manuscript submitted July 1, 1970; revised manuscript received *ca.* Jan. 4, 1971. This was Paper 40 presented at the Atlantic City Meeting of the Society, Oct. 4-9, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Hydrogen Embrittlement and Hydrogen Traps

J. O'M. Bockris* and P. K. Subramanyan[1]

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The permeation of H through iron and an iron-nickel alloy as a function of time is reported. Below a certain critical H overpotential η, the H permeation occurs as a function of time in a simple way; and can be repeated indefinitely on the same specimen. But, when $\eta > \eta_{crit}$, the permeation-time transient attains a new and characteristic shape. It is no longer repeatable on the same specimen. These characteristic differences of H permeation are seen during injection of H into the metal and after the cessation of H injection. The decay of H permeation follows simple laws before η_{crit}. At $\eta > \eta_{crit}$, the decay is complex and the permeation-time (P-t) relationship shows successive maxima. The critical overpotential is that at which microcracks begin to nucleate, spread, and provide traps for H_2. Calculated pressures, using the amount of lattice-dissolved H and adsorbed H at the cathodic surface at η_{crit}, are shown to be consistent with an H_2 pressure in voids which would cause the spreading of cracks. This leads to an electrochemical condition for the beginning of H damage: the observed critical overpotential gives reasonable values for the embrittling[2] critical pressure. Such an electrochemical condition for damage also applies during corrosion. The amount of trapped H is calculated from the permeation-time transients at overpotentials higher than η_{crit}. The H trapping constant is calculated. Distribution of hydrogen in the embrittled membrane is given. In the permeation decay transients, the first maximum represents the hydrogen in cavities and the second, H bound to chemical impurities.

Studies of embrittlement and damage to materials caused by the ingress of H are usually carried out in two ways: either by exposing the specimen to gaseous H_2, usually at relatively high temperature and pressure; and by the cathodic evolution of H_2 on the surface of the specimen, whereby H enters the metal as though its fugacity were very much above 1 atom (1). The electrochemical studies were shown to be much more convenient than the gas phase studies by Devanathan and Stachurski (2, 3). They evolved H on the cathodic side of a bi-electrode membrane and oxidized the permeating hydrogen anodically on the other side. By this simple and elegant method, the permeation, P, the diffusion coefficient, D, and the solubility corresponding to a certain fugacity (that of the overpotential, η) (1), can be quickly determined.

Permeation-time transients at constant overpotential (η) can be made repeatedly and reversibly on the same membrane (4) below a critical overpotential (η_{crit}). At higher overpotentials the shape of the permeation-time transient changes, in the sense that at constant η, the permeation of H is diminished. An attempt to repeat the permeation-time transient at lower η now shows that the metal has undergone some change of property, so that the steady-state permeation is attained at a much longer time than that which was necessary before exceeding the critical overpotential. Beck *et al.* (4) suggested that the critical overpotential corresponded to the commencement of embrittlement and produced indirect evidence that the η_{crit} was connected in some way with the dissolution of H in the metal.

In the present paper an electrochemical condition for the commencement of H damage in the metals is suggested and the anomalous behavior of the permeation at higher overpotentials is interpreted in terms of the nucleation of traps when the H fugacity reaches sufficient values to cause spreading of microcracks formed from dislocation pile-ups.

Information about the nature of the traps can be obtained from the damped oscillatory behavior of the permeation-time transient after the injection of cathodic H.

Experimental Technique

A very brief description of the experimental technique will be given here. It has been described in previous papers (2-5). A detailed description of the most recent version is given by Beck, Bockris, Genshaw, and Subramanyan (6).

Cell.—The two compartments of the cell were separated by the 0.002-0.1 cm thick metal membrane. The cathodic side of the membrane was galvanostatically controlled, while on the anodic side the H was potentiostatically ionized. The potentiostatic current (proportional to the rate of H permeation) was measured.

Membranes.—The iron specimens used were Armco Fe, (99.99%). In addition, membranes of 5% Ni, 95% Fe were used. Annealing was carried out at 600°C for 3 hr with cooling at <5°C min^{-1} in H_2.

A thin layer of Pd was electrodeposited on the anodic side of the membranes to protect them against anodic dissolution.

Solutions.—The solutions were 0.1N NaOH prepared from Baker analyzed NaOH pellets, pre-electrolyzed and deoxygenated using purified nitrogen gas. The purity of the electrolyte controls the sensitivity with which the ionization current can be determined.

Procedures.—The cathodic current used varied over a range from 5×10^{-5}-10^{-1} A cm^{-2}. During any permeation measurement a constant cathodic current was switched on and the quasi-constant cathodic overpotential observed. The permeation-time transients were

Key words: hydrogen embrittlement, trapping, electrochemical condition of embrittlement, iron-nickel alloys.

[2] In this article, we use the word embrittlement to mean the permanent damage like cracks produced by hydrogen in metals.

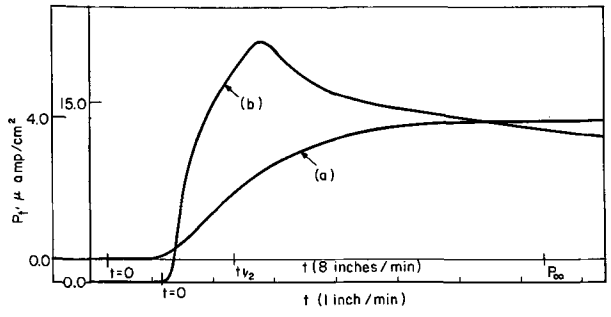

Fig. 1. Laboratory records of hydrogen permeation-time relations. (a) A typical permeation transient (for Armco iron, thickness $L = 0.106$ cm, at 60°C. Cathodic current density 10 mA/1.13 cm^2 and electrolyte 0.1M NaOH). The point $t = 0$ represents the time at which the cathodic current is switched on, $t_{1/2}$ the half-rise time of the transient, and P_∞ the steady-state permeation current. (b) An abnormal permeation transient showing the characteristic peak. (5% Ni + 95% Fe, $L = 0.09$ cm, $i_c = 108$ mA/cm^2, 50°C, and 0.1M NaOH solution.)

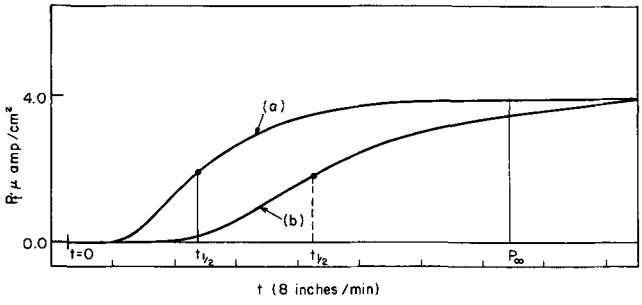

Fig. 2. Laboratory records of hydrogen permeation-time transients. (a) The typical transient shown in Fig. (1a). (b) The same transient repeated after recording a few transients at overpotentials beyond η_{crit} (cf., Fig. 1b).

followed for times up to about 30 min. Decay transients were observed over about the same period of time.

Results

The permeation-time transient at overpotentials $< \eta_{crit}$.—A typical result in shown in Fig. 1a. After switching off the injection current and waiting for the permeation decay to reach the background level, it was possible to repeat the permeation-time (P-t) transient (Fig. 1a) without noticeable difference. Repetition was possible for at least ten times and probably indefinitely.

Permeation-time transients at overpotential $> \eta_{crit}$.—It was found that there existed a threshold value of the hydrogen overpotential, η_{crit}, characterized by a cessation of the simple shape of the permeation-time transients, shown in Fig. 1b. Two differences now arise. (*i*) The P-t transient passes through a maximum. (*ii*) After the cathodic current has dropped to zero, and the permeation current on the anodic side of the bi-electrode dropped to the background level, the attempt to repeat a P-t transient at $\eta < \eta_{crit}$ failed; instead the permeation transient had a much greater rise time than that which was needed before the critical overpotential has been exceeded. These effects are shown in Fig. 2.

Decay of H *permeation.*—At situations for which $\eta < \eta_{crit}$, the decay transient is simple and is shown in Fig. 3a. However, for the decay at $\eta > \eta_{crit}$, the form of the P-t curve was radically changed and passed through one or two[3] maxima (Fig. 4).

Evaluation of P,D and C_o.—The calculation of these quantities has been described before (2, 3). The value of P is read directly from the recorded anodic current;

[3] The second maximum was seldom observed.

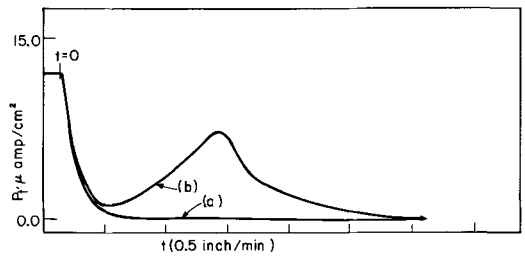

Fig. 3. Laboratory records of hydrogen permeation decay transients. (a) A typical permeation decay transient. At time $t = 0$, the hydrogen charging current is switched off. (b) An anomalous permeation decay transient with the characteristic hump. Hydrogen charging time 11 min. (5% Ni + 95% Fe, $L = 0.09$ cm, $i_c = 88$ mA/cm^2, 50°C, and 0.1M NaOH solution.)

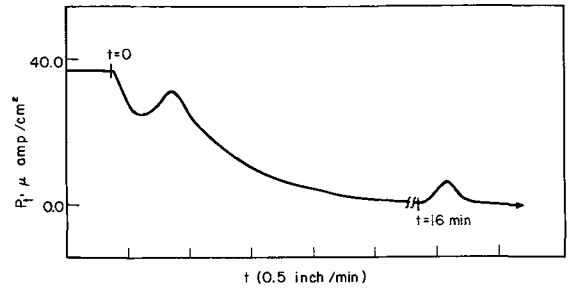

Fig. 4. A laboratory record of an anomalous permeation decay transient showing two humps. Hydrogen charging time 34 min. (5% Ni + 95% Fe, $L = 0.094$ cm, $i_c = 87$ mA/cm^2, 60°C, and 0.1M NaOH solution.)

that of D can be obtained from the half-rise time of the permeation transient; and $(C_o)_\eta$, the solubility of H at a fugacity corresponding to the η (1) can be obtained from the steady state P by means of the simple relation

$$P = (D\mathbf{F}/L)\ (C_o)_\eta \qquad [1]$$

where L is the thickness of the membrane and $\mathbf{F}$, the Faraday constant. Validity tests of these evaluations have been published elsewhere (2).

Discussion

What happens at η_{crit}?—Let it be supposed [Beck *et al.* (4)] that at η_{crit}, a critical concentration of H is dissolved and as this level is reached, some kind of change in metal lattice could occur. It is possible to assume that D remains unchanged until this internal change in the metal occurs appreciably. Therefore, just at the commencement of critical behavior

$$P_{crit} = (D\mathbf{F}/L)C_{crit} \qquad [2]$$

and hence C_{crit} can be calculated.

The minimum value of C_{crit} for Armco Fe is 1.5×10^{-7} g·atom cc^{-1}. The value is a minimum because the P-t relation should go higher (*i.e.*, higher C_{crit}) but is overtaken by the results of the change in internal properties of the metal, which decreases P.

For $C_{crit} = 1.5 \times 10^{-7}$ g·atom cc^{-1}, one obtains using a Sievert's law constant of 3.6×10^{-9} g·atom$^{-1/2}$, a value of 2×10^3 for the fugacity of H_2 which would be in equilibrium with C_{crit} and initiates the internal change.

If, now, we assume that this represents the critical pressure needed to expand a microcrack, it is easy to show that (4, 7)

$$P_{H_2,crit} = \sqrt{\frac{2Y\gamma}{\pi l(1-\nu^2)}} \qquad [3]$$

where Y is Young's modulus, γ the surface energy, $2l$ the length of the crack, and ν Poisson's ratio. With $\gamma = 1000$ ergs/cm^2, $Y = 2 \times 10^{12}$ dynes/cm^2, and $\nu =$

0.3, one obtains for a value of $l = 10^{-4}$ cm a critical pressure of 3.8×10^3 atm.

In this calculation we have not taken into account the work of plastic deformation which normally would be additive with surface energy in Eq. [3], for the following reasons:

(*i*) It is a general observation that the plastic deformation in presence of hydrogen in the metal is considerably decreased.

(*ii*) Equation [3] predicts that crack propagation can occur at such low values of pressure at which the metal cannot undergo plastic deformation. Correction for plastic work may become important in the region where $P_{H_2,crit} \gtrsim P_{P.Y}$ (stress or pressure corresponding to the yield point) but it is insignificant below $P_{Y.P}$, which for annealed iron is $\simeq 8 \times 10^3$ atm.

(*iii*) At the regions where cracks nucleate, there could be pre-existing internal stresses which modify the effective pressure to $(P_{H_2} + \sigma)$. Metals like iron start deforming when the deformation energy density exceeds 4×10^5 erg/cc and breaks when it attains approximately 4×10^6 ergs/cc. What portion of this energy is contributed as plastic work, in the process of creation of 1 cm^2 of new surface (over and above the surface energy) is not known with any degree of certainty. Some authors estimate the work of plastic deformation to be a few orders of magnitude higher than the surface energy (3000-4000 ergs/cm^2 for clean metal surfaces) (8). Tetelman has assumed the work of plastic deformation as three times the actual surface energy (9). However, for the reasons mentioned above, we think our calculation is quite meaningful. The length of the crack is assumed to be of the order of 10^{-4} cm for the reason that it represents the normal diameter of a grain.

It seems, therefore, reasonable to conclude that the process corresponding to the maximum of the *P-t* relationship is the spreading of microcracks. This is in agreement with the hypothesis of Beck *et al.* (4) and with their observation that the temperature coefficient of C_{crit} was related to the heat of solution H in Fe.

Electrochemical condition for the beginning of H-damage.—It has been shown elsewhere that the fugacity of H_2 in the metal can be related to the H_2 overpotential (1). The first critical transient was observed at $\eta \simeq -300$ mV. The evolution of H_2 on Fe occurs from alkaline solution by means of a coupled discharge-recombination mechanism. Accordingly (1), the fugacity of H_2 in cracks and internal voids are related to the overpotential by the equation

$$P_{H_2} = 10^{1.5} \exp(-\eta \mathbf{F}/2RT) \quad [4]$$

At an η_{crit} of -0.3V

$$P_{H_2} \simeq 10^{3.9} = 8 \times 10^3 \quad [5]$$

this is in reasonable accord with the pressure determined from a combination of Sievert's law and the critical concentration of the maximum in the first anomalous *P-t* graph.

We illustrate, thus, an electrochemical condition for the beginning of possible H damage. No H damage is possible until the potential of the surface of the metal is equivalent to an overpotential determined by the relation between overpotential and the fugacity of H_2 in internal cracks, with the latter exceeding the critical pressure (P_{crit}, the condition for the commencement of the spreading of cracks).

Thus, for iron, in alkaline solutions, the pressure necessary to cause damage is

$$P_{H_2} > \left(\frac{2Y\gamma}{\pi l(1-\nu^2)}\right)^{1/2} = 10^{1.5} \exp(-\eta_{crit}\mathbf{F}/2RT)^4 \quad [6]$$

The critical value for η can, hence, be found.

[4] The r.h.s. of this relationship is characteristic of the mechanism of hydrogen evolution reaction and will be different in the different cases (1).

This electrochemical limit for the possible commencement of H damage applies also to the situation in which there is no net current, *e.g.*, in corrosion. Thus, it is necessary only to know the corrosion potential. Then, one can calculate phenomenologically [knowing the solution pH and P_{H_2} (soln)] the overpotential for hydrogen evolution in the corrosion reaction, and thereby ascertain whether the situation will be embrittling or not.

Amount of trapped hydrogen.—Several investigators have observed the effect of hydrogen trapping on permeation (10-12). Some have considered the theory of hydrogen diffusion with simultaneous trapping, to various extents and in varying details (10, 11, 13, 14). Johnson and Hills (11) concluded that hydrogen trapping in cold-worked steel involved the formation of chemisorbed and molecular hydrogen at the internal crack surfaces. They assumed the existence of an equilibrium between the lattice dissolved and trapped hydrogen and obtained the lattice diffusivity from nonsteady-state measurements of hydrogen evolution from precharged specimens. Harhai *et al.* (12) observed that cold-worked steels absorbed hydrogen exothermically. From this observation, they reached the conclusion that hydrogen is trapped essentially as chemisorbed hydrogen at the internal surfaces of microcracks.

Darken and Smith (10) treated the diffusion of hydrogen with trapping in a way analogous to the problem of oxygen diffusion into copper containing small amounts of silicon (with which it could be "trapped" in the form of SiO_2). The treatment of McNabb and Foster (13) is very elaborate and involves less assumptions. However, their results are of limited use. Recently, Oriani (14) considered the theory of hydrogen diffusion with trapping with the assumption that an equilibrium exists between the lattice hydrogen and trapped hydrogen in the transient state, as assumed by Johnson and Hills. He applied this concept to obtain trap density in steels from hydrogen charging or permeation measurements. In the opinion of the present writers, the existence of an equilibrium between lattice hydrogen and trapped hydrogen especially in hydrogen charging cases in the transient state is a remote possibility.

In all these situations, the traps are uniformly distributed throughout the membrane, or the absorbing medium, before hydrogen charging. In the following we consider a unique situation in which traps do not exist (or only in insignificant numbers) until the lattice solubility C attains a value greater than a critical value C_{crit}. Before C reaches this limit, the diffusion process can be described by the familiar Fick's equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x} \quad [7]$$

where D is the diffusion coefficient of H and C its concentration. However, where C exceeds the critical solubility, C_{crit}, H begins to be trapped.

We propose the following model for a theoretical consideration of anomalous permeation. The traps are switched on only when C exceeds C_{crit}. We assume the nucleation of the traps to be a fast process. However, the filling up of the traps will be diffusion controlled. Let us consider trapping as a reaction like

$$H + \square \rightarrow \boxed{H} \quad [8]$$

When this reaction attains equilibrium

$$C_{H,tr} = K^1 C_{\square} C_{H,L} \quad [9]$$

where $C_{H,tr}$ is the concentration of H in the traps, $C_{H,L}$ the concentration of H in the lattice sites, $C_{\square}$ the concentration of unfilled traps, and K^1 the equilibrium constant. For a given concentration of lattice hydrogen, the number of filled traps at equilibrium will be

proportional to $C_{H,L}$. Hence

$$C_{H,tr} = KC_{H,L} \quad [10]$$

from which $K = K^1C_{\square}$.

However, during the transient state of diffusion, the type of relationship expressed by Eq. [10] is not true. We propose the following relationship for the transient situation

$$C_{H,tr} = \tau KC_{H,L} \quad [11]$$

where τ is a numerical constant which could have values from 0 to 1. When diffusion attains steady state or trapping is in equilibrium, $\tau = 1$ and Eq. [11] becomes identical with Eq. [10].

Let us now try to formulate a differential equation describing lattice diffusion with trapping. Consider a thin lamina of the metal membrane. It contains normal lattice sites as well as trapping sites. Diffusing hydrogen atoms enter through one side of the lamina and leave through the other. Hydrogen is supposed to enter or leave the lamina at the lattice sites. In other words, diffusion from one trapping site to another does not occur by direct jump without the intermediate stage of diffusion through the lattice sites. The rate of change of concentration in such a lamina will be the sum of the rate of change of concentration in the lattice sites and in the traps. Hence

$$\frac{\partial C_{H,L}}{\partial t} + \frac{\partial C_{H,tr}}{\partial t} = D\frac{\partial^2 C_{H,L}}{\partial X^2} \quad [12]$$

Introducing the relationship between $C_{H,L}$ and $C_{H,tr}$ from Eq. [11] into Eq. [12], we get

$$\frac{\partial C_{H,L}}{\partial t} + \tau K\frac{\partial C_{H,L}}{\partial t} = D\frac{\partial^2 C_{H,L}}{\partial X^2} \quad [13]$$

Now substituting

$$C = (1 + \tau K)C_{H,L} \quad [14]$$

we obtain

$$\frac{\partial C}{\partial t} = \frac{D}{(1 + \tau K)}\frac{\partial^2 C}{\partial X^2} \quad [15]$$

Equation [15] can be solved for the following boundary conditions

$$\text{At } X = 0, \text{ for } t > 0, C = (1 + K)C_o \quad [16]$$

because the entry of H into the lattice is a fast process (9), and the trapped H will always be in equilibrium with lattice dissolved hydrogen (C_o) and hence, $\tau = 1$.

$$\text{At } X = L, \text{ for } t > 0, C = 0 \quad [17]$$

The solution can be obtained as (15)

$$C(X,t) = (1 + K)C_o \left[\sum_{n=0}^{\infty} (-1)^n \operatorname{erfc} \frac{(X + 2nL)\sqrt{1 + \tau K}}{2\sqrt{Dt}} - \sum_{n=0}^{\infty} (-1)^n \operatorname{erfc} \frac{(-X + 2L + 2nL)\sqrt{1 + \tau K}}{2\sqrt{Dt}} \right] \quad [18]$$

and the permeability as

$$P_{t,tr} = \frac{DFC_o}{L}\frac{2}{\pi^{1/2}}\left(\frac{L^2}{Dt}\right)^{1/2} \exp\left(-\frac{L^2(1 + \tau K)}{4Dt}\right) \quad [19]$$

The additional subscript tr for P_t signifies trapping. Equation [19] shows that at relatively short times, *i.e.*, when $L^2/4Dt \cong 1$, $P_{t,tr}$ will be smaller than P_t in the absence of traps. In other words, the flux at times $t << \infty$ is reduced by the traps. As a result of this, the permeability, once the trapping is switched on, decreases from the normal permeability and gives rise to the prominent hump in the build-up permeation transients (Fig. 1b). At infinite time a steady-state

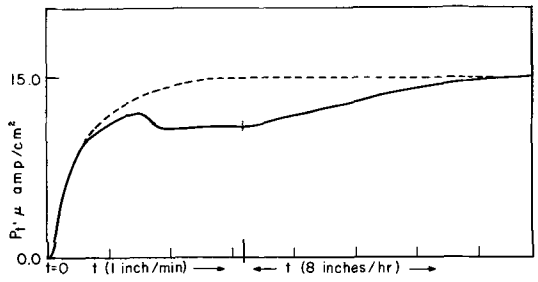

Fig. 5. A laboratory record of an anomalous permeation transient attaining a steady state. The broken line represents the expected normal course of the transient in the absence of hydrogen trapping. (5% Ni + 95% Fe, i_c = 105 mA/cm^2, L = 0.094 cm, 70°C, and 0.1M NaOH solution.)

concentration drop occurs between $X = 0$ and $X = X^1$, and another steady-state concentration drop between $X = X^1$ and $X = L$. This is in agreement with observed fact that the permeability rises again to the level $P_\infty = FDC_o/L$. The steady-state permeability, calculated from Eq. [18], would be

$$P = \frac{FD}{(1 + K)}\frac{(1 + K)C_o}{L} = \frac{FDC_o}{L} \quad [20]$$

which is the same as in the absence of traps. The permeability decreases initially when trapping begins, and then rises back to the original level. This has been found in cases where permeation with trapping was observed for sufficiently long times (*cf.* Fig. 5).

Determination of the trapping constant K.—When the trapping attains a steady state, the concentration profiles of hydrogen in the membrane are as shown in Fig. 6.[5] Corresponding to this situation we have the permeation-time relationship shown in Fig. 5. Here initially we have the permeation maximum followed by a slow increase of permeability to a final steady-state value. This steady-state value will be seen to be the same as that which the transient would have attained if it had gone the normal way. To obtain the total amount of trapped hydrogen, we extrapolate the initial part of the transient to the final steady-state value as shown in Fig. 5. The area between the extrapolated and the actual transients gives the amount of trapped hydrogen (Q_T). The amount of trapped hydrogen in the material corresponds to the triangle ABD in the concentration profile diagram (Fig. 6). We can write down a simple relation for the amount of hydrogen in the trapping region above the critical amount

$$\frac{[(1 + K)C_o - C_{crit}]}{2}AX^1 = Q_T + \frac{(C_o - C_{crit})}{2}AX^1 \quad [21]$$

where A is the permeation area. The values of C_o, C_{crit}, A, and Q_T are all known. The value of C_{crit} has to be determined from the transient which just ex-

[5] Darken and Smith (10) have reported that the distribution of hydrogen, when trapped in membranes with similar initial and boundary conditions as in the present work, is nonlinear [*cf.* Fig. 6 of ref. (10)] and is different from our results. They found that in charging a membrane by corrosion from one side and exposing the other to air (or rather a mixture of air and hydrogen), the hydrogen taken up by the membrane was 85% of the amount of the hydrogen when charged from both sides. One would expect the former to be 50% of the latter. However, there is a fundamental uncertainty involved in this study. They assumed that the concentration of H at the exit side is zero or negligibly small. In the opinion of the present writers, this boundary condition is not true. In fact, in their experimental situation there will be a good amount of H at the exit side as lattice dissolved and adsorbed H. This error invalidates their results. Second, in deriving an equation for permeability, these investigators assume that at the center of the permeation membrane, or slab, along the diffusion direction, the concentration of hydrogen is equal to the mean concentratin. This would only be true in the case of a linear distribution at steady state. They have used this derived relationship to construct the total solubility *vs.* permeability curve which they consider as the distribution of hydrogen as a function of distance. It does not uniquely follow that this curve [*cf.* Fig. 6, ref. (10)] represents the hydrogen distribution in the membrane.

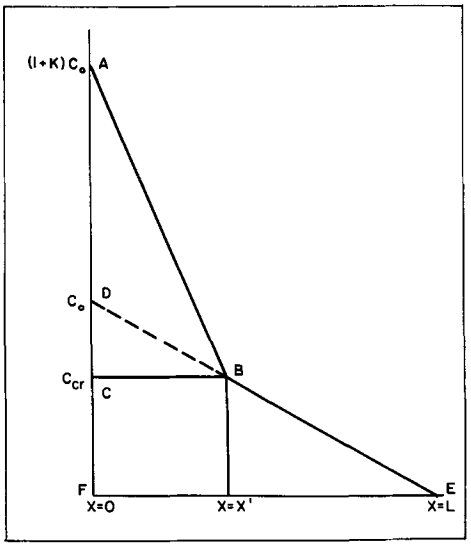

Fig. 6. Representation of the steady-state concentration profile as a function of the thickness of the membrane when hydrogen trapping is at steady state (cf., Fig. 5). Up to a thickness X^1, the concentration of hydrogen is above the C_{crit} level. K is the trapping constant.

hibits the development of the permeation maximum. However, X^1 is not yet known. This is obtained by using the properties of similar triangles (BCD and EFD)

$$(C_o - C_{crit})/X^1 = C_o/L \qquad [22]$$

For the transient in Fig. 5, we have $C_o = 2.2 \times 10^{-7}$ g-atom/cc, $C_{crit} = 1.3 \times 10^{-7}$ g-atom/cc, $A = 1.13$ cm^2, $Q_T/A = 3500$ μcoulombs ($=3.5 \times 10^{-8}$ g-atom), and $L = 0.094$ cm. From Eq. [22] we obtain $X^1 = 0.02$ cm and from Eq. [21], the value of K is found to be 16. K itself is not an equilibrium constant of trapping; it is the product of the true equilibrium constant of trapping and the concentration of the unfilled traps.

We try to obtain a reasonable value of K^1 in the following way. Let us assume that the density of microcracks or Stroh cracks formed from dislocations is 10^8/cm^2 (16). An average length of a dislocation line or of a microcrack can be taken as 10^{-4} cm. Hence, the density of the microcracks is 10^{12}/cc. The internal surface area, assuming the width to be equal to 20Å, is $2 \times 2 \times 10^{-11}$ cm^2. Therefore, the number of metal atoms at the internal surface of a microcrack is 4×10^4. Let us assume that on trapping H is adsorbed on the surface of the microcrack and that each surface atom is a potential trapping site for H. The coverage on trapping is assumed to be 99% (*i.e.*, $\theta_H = 0.99$). The trap density per cubic centimeter is then 4×10^{16}/cc or $\simeq 10^{-7}$ mole/cc. Therefore, $C_{\square} = 10^{-6}$ mole/liter. The value of K^1 which can be obtained from the relationship $K^1 C_{\square} = K = 16$ is 2×10^7. The standard free energy change of trapping, therefore, is $-RT \ln K^1 = -14$ kcal/g-atom which, in magnitude, is comparable with the standard free energy of dissolution of H_2 in iron (11.7 kcal/g-atom) at 27°C (17). The situation is that there are H_2 molecules in the microcracks, but the amount of hydrogen in the form of H_2 is much less than that of adsorbed atomic hydrogen because the volume of the microcrack is small compared to its surface area. Owing to the equilibrium between H_2 in the microcrack and the adsorbed atomic hydrogen on the surface of the microcrack, during the crack nucleation and spreading, the standard free energy change of adsorption is equal to—(the standard free, energy change of solution).[6] The experimentally evaluated (−11.7 kcal/g-atom) and the calculated (−14 kcal/g-atom) values are comparable. Hence, trapping is essentially the reverse of the dissolution of hydrogen in the metal.

The above considerations show that the model of H trapping at the internal surfaces of cracks is quite plausible. The creation of new internal surfaces ought to decrease the capability of the material to undergo plastic deformation and, therefore, it should be irreversibly embrittled.

Decay of the permeation transient; two kinds of trapped H.—Sometimes (Fig. 4) a second peak was observed (*cf.*, the decay transients). To understand the essential processes, we make the following simplifications. At regions close to cathodic surface (H input side) there are filled traps (for example, impurities) which bind hydrogen with different strengths. Monovacancies could also function as traps for atomic hydrogen. The binding energy of hydrogen will depend on the type of traps. Consider the situation represented by Fig. 5. When the steady state is attained, the concentration profile will be as shown in Fig. 7. For ease of quantitative consideration, we will assume that hydrogen in traps is uniformly distributed in the region $0X^1$. The steady-state permeation current when traps are filled can be considered as due to lattice diffusion with solubility equal to C_o. Hydrogen escaping from traps and hydrogen falling into traps occurs at the same rate at the steady state. Or

$$dn_{H,esc} = dn_{H,tr} \qquad [23]$$

when $i_c = 0$. During the transient, however, the lattice hydrogen tends to decay in the usual manner, and hence

$$dn_{H,esc} > dn_{H,tr} \qquad [24]$$

As a function of time, $(d^2n_{H,esc}/dt^2)$ goes through a maximum. Correspondingly, we have the concentration gradient of H in the lattice sites increasing to a maximum and then beginning to decrease. Here we will consider two different kinds of trapped hydrogen. An approximate relation for the flux at the anodic surface, *i.e.*, $X = L$ cm can be written as (15, 18)

$$\begin{aligned} P_t = \Bigg\{ & \left[P_o \left(1 - \frac{2}{\pi^{1/2}} \frac{Dt}{L^2} \exp - \frac{L^2}{4Dt} \right) \right] \\ & + \left[P_{\infty,P_1} \frac{2}{\pi^{1/2}} \left(\frac{D_1 t}{L^{*2}} \right)^{1/2} \exp - \frac{L^{*2}}{4D_1 t} \right]_{t=0}^{t=t_{P1}} \\ & + \left[P_{\infty,P_1} \left(1 - \frac{2}{\pi^{1/2}} \left(\frac{D_1 t}{L^{*2}} \right)^{1/2} \exp - \frac{L^{*2}}{4D_1 t} \right) \right]_{t=t_{P1}}^{t=\infty} \\ & + \left[P_{\infty,P_2} \frac{2}{\pi^{1/2}} \left(\frac{D_2 t}{L^{*2}} \right)^{1/2} \exp - \frac{L^{*2}}{4D_2 t} \right]_{t=0}^{t=t_{P2}} \\ & + \left[P_{\infty,P_2} \left(1 - \frac{2}{\pi^{1/2}} \left(\frac{D_2 t}{L^{*2}} \right)^{1/2} \exp - \frac{L^{*2}}{4D_2 t} \right) \right]_{t=t_{P2}}^{t=\infty} \Bigg\} \end{aligned} \qquad [25]$$

Here $D > D_1 > D_2$. D_1 and D_2 are the effective diffusion coefficients for H in traps of first and second kinds. P_o is the steady-state permeation current at $t \to 0$. P_{∞,P_1} and P_{∞,P_2} represent the peak permeation current of first and second humps and are approximately equal to the maximum permeation currents corresponding to the maximum concentration gradients built up by the hydrogen escaping from the different traps. L^* is the effective thickness of the membrane for the trapped H to diffuse out (*cf.*, Fig. 7), t_{P1} and t_{P2} are the times corresponding to the peak points of first and second decay humps. The following boundary conditions are assumed (*cf.*, Fig. 7). For decay

$$\text{At } X = 0,\ C = 0 \text{ for } t > 0 \qquad [26]$$

$$\text{At } X = L,\ C = 0 \text{ for } t \lessgtr 0 \qquad [27]$$

$$\text{At } X = 0,\ C = 0 \text{ for } t > t_p \qquad [28]$$

[6] This assumes that adsorption of H and formation of H_2 at the surface of the crack (which should be very clean) are always in equilibrium.

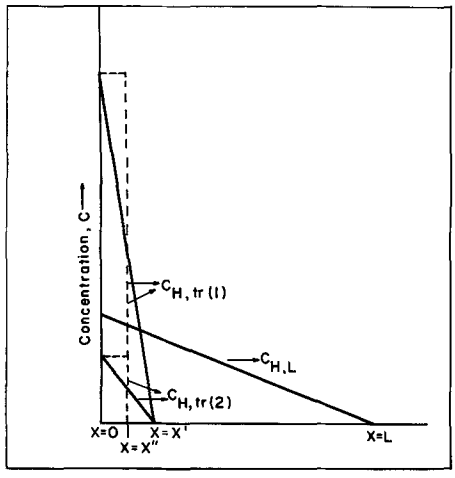

Fig. 7. Representation of the steady-state concentration profiles of hydrogen in two different kinds of traps (apart from the normal lattice hydrogen profile). The rectangles in broken lines represent the profiles assumed in the present approximate model. Beyond the range of 0 to X^{11}, there is no trapped hydrogen in the membrane. ($C_{H,L}$ means H in the usual lattice sites, $C_{H,tr(1)}$ hydrogen in traps of kind 1 and $C_{H,tr(2)}$ hydrogen in traps of kind 2.)

$$\text{At } X = L,\ C = 0 \text{ for } t \lessgtr 0 \qquad [29]$$

For the rising part of the decay transient

$$\text{At } X = X^{11},\ C = C_0 \text{ (constant) for } t \geqslant 0 \text{ up to } t = t_P \qquad [30]$$

$$\text{At } X = L,\ C = 0 \text{ for } t \lessgtr 0 \qquad [31]$$

Equation [25], if properly evaluated, will give rise to two humps in the decay transient. By incorporating appropriate number of terms in Eq. [25] the occurrence of any number of peaks in the decay transient could be understood as each being due to hydrogen in a different kind of trap.

Thermal Diffusion Studies with the Ag/AgCl/Cl⁻ Electrode[1]

L. F. Vekens,[2] J. F. Zeeland, and J. Lin

Boston College, Department of Chemistry, Chestnut Hill, Massachusetts 02167

ABSTRACT

The initial thermoelectric powers, ϵ_0, and steady-state thermoelectric powers, ϵ_∞, of the thermocell (T)Ag-AgCl/Solution (M)/AgCl-Ag$(T + \Delta T)$ were measured for 0.01M solutions of LiCl, NaCl, KCl, RbCl, CsCl NH_4Cl, TlCl, and $CdCl_2$; 0.05M solutions of KCl and $CdCl_2$; and 0.005M solutions of KCl and $CdCl_2$. From these measurements, the entropies of transport S^* for these 12 solutions and the transported entropy of the chloride ion $\bar{S}_{Cl^-}$ were calculated. The results are compared with available literature values and discussed in terms of ion-solvent interaction and solvent structure.

Thermoelectric studies of electrolytes may yield much interesting information concerning the structure of the solvent system and other phenomena such as the ion-solvent interaction (1, 2). Physical quantities of interest in such a discussion are molar entropies of transport S^*_{salt} (or the corresponding heats of transport Q^*_{salt}) and transported entropies of ions $\bar{S}_i$. The transported entropy of an ion is defined as $\bar{S}_i = S_i +$

[1] Supported partially by OSW, U.S. Department of the Interior.
[2] NIH Predoctorate Fellow 1969-1970; NDEA Trainee 1968-1969.
Key words: thermal diffusion of some chloride salts.

S_i^*, where S_i^* is the ionic entropy of transport and S_i is the ionic partial molal entropy. Although neither of its components S_i and S_i^* may be measured experimentally (on an absolute scale), $\bar{\bar{S}}_i$ is a single ionic property which may be measured by studying the thermal diffusion process in a thermocell potentiometrically (*i.e.*, from the measurements of the initial and final thermal emf's of a thermocell). Up to the present, however, only a few thermocells have been investigated potentiometrically from their homogeneous initial states to the final (Soret) steady states. Most of them are thermocells with an electrode system reversible to the cation (3).

The purpose of this paper is to report a potentiometric study of several chloride salt thermocells using Ag/AgCl/Cl^- electrodes at a mean temperature of 25°C. Although Ag/AgCl/Cl^- electrodes have been used extensively in isothermal studies, applications in nonisothermal measurements are relatively few. Most investigations refer to the initial state (4), in which the solution is of uniform composition. Use of Ag/AgCl/Cl^- electrodes in the study of the final steady state may be found in the works of Chanu (5), and Haase and Behrend (6). In Chanu's work, Ag/AgCl/Cl^- electrodes were used in combination with the optical method and the thermal emf's were not available for comparison with the present study. In Haase and Behrend's paper, measurements were listed only for two salts, LiCl and KCl.

The initial and steady-state thermoelectric powers were measured for the thermocell:

Terminal—Ag/AgCl/Solutions (M)/
T_0 m T AgCl/Ag—Terminal (A)
$T + dT$ m T_0

where T_0 is room temperature, $T = 20$°C, $dT = 10$°, and m was platinum for the initial readings and copper for the final readings. The electrode reaction for this thermocell is

$$AgCl - Ag - Cl^- + e(m) = 0$$

and the equation governing the initial thermoelectric powers ϵ_0 may be written as

$$\mathbf{F}\epsilon_0 = [z^+ (\bar{\bar{S}}_{Cl^-} - S_{AgCl} + S_{Ag} - \bar{\bar{S}}_{e(Pt)}) - S^*_{salt}t_+]/z^+ \quad [1]$$

where $\mathbf{F}$ is the Faraday constant, $\bar{\bar{S}}_{e(m)}$ is the transported entropy of the electron in the mettal m, t_+ is the cation transference number, and z^+ is the charge on the cation. The equation governing the final thermoelectric powers ϵ_∞ is given by

$$\mathbf{F}\epsilon_\infty = \bar{\bar{S}}_{Cl^-} + S_{Ag} - S_{AgCl} - \bar{\bar{S}}_{e(Cu)} \quad [2]$$

Combining Eq. [1] and [2] yields

$$S^*_{salt} = z^+\mathbf{F}(\epsilon_\infty - \epsilon_0)/t_+ + z^+(\bar{\bar{S}}_{e(Cu)} - \bar{\bar{S}}_{e(Pt)})/t_+ \quad [3]$$

Values of $\bar{\bar{S}}_{e(Cu)}$ and $\bar{\bar{S}}_{e(Pt)}$ are available (7) and, consequently, the entropy of transport of a given salt is easily determined from the initial and steady-state thermoelectric powers, provided that the cation transference number is known. For most of the chloride salt solutions investigated, the transference numbers were readily available in the literature. However, those for 0.01M RbCl, CsCl, and TlCl were calculated from the conductance data using an equation obtained from a simple Debye-Hückel consideration (1, 8). The transport numbers used are given in Table I.

The transported entropy of the chloride ion, $\bar{\bar{S}}_{Cl^-}$, can be calculated from Eq. [2]. Since S_{AgCl}, S_{Ag}, and $\bar{\bar{S}}_{e(Cu)}$ are all known, the experimental determination of steady-state thermoelectric powers is all that is necessary.

Experimental

All solutions used were prepared from analytical reagents and conductivity water. The concentration of each solution was checked by titrations with standard $AgNO_3$ solutions and density measurements.

For the purpose of measuring ϵ_0 and ϵ_∞ values during the same experiment, in the present study a mechanical stirrer was fitted into the sandwich type cell previously used by Lin (2). A similar type of cell has been used by Breck, Cadenhead, and Hammerli (9). However, the present design of the cell stirrer differs from that of Breck, Cadenhead, and Hammerli (10) in that our stirrer was driven by a variable speed motor rather than by forced air over a propeller shaft. This provision allows us to produce the initial homogeneous state for any given length of time by adjusting the speed of the motor. The stirrer consisted of a platinum axle on which a nylon mesh impeller was mounted. A variable speed d-c motor provided the stirring power. The shaft between the cell axle and motor was a flexible plastic material. One end of the plastic connector was fitted over the platinum axle, while a small circular magnet was cemented on the opposite end. This came in contact with another magnet cemented on the shaft of the motor. The flexible shaft absorbed any torque, thus preventing any leakage. To protect against any other unexpected leakage around the axle, a silicon grease reservoir in the form on a recess on the outside of the Plexiglas ring was provided along with a Teflon washer.

Many methods are available for the preparation of Ag/AgCl/Cl^- electrodes (10). In this work electrodes were prepared in two ways, one using the standard thermal method and the other by anodizing pure silver in 0.1*N* HCl. When the thermal method was used, a Ag and AgCl mixture was prepared on a thin platinum foil which was then assembled in between a Plexiglas ring and the gold disks. When the electrodes were prepared by anodizing pure silver, the following procedures were followed. Starting from metallic sheets 0.015 in. in thickness and at least 99.99% pure (supplied by A. D. Mackay, Incorporated), the electrodes were cut exactly to fit into the cells. They were then soaked several hours in concentrated NH_4OH, thoroughly rinsed with distilled water, and immersed briefly into approximately 3*N* HNO_3 until all surface contaminants were removed and a finely divided surface area formed. After again thoroughly rinsing the electrodes with conductivity water, they were anodized in 0.1*N* HCl saturated with purified argon and stirred magnetically. A current density of approximately 0.43 mA/cm^2 was maintained and approximately 2% of the silver by weight anodized. Two electrodes were always anodized simultaneously to assure as low a bias as possible. A piece of platinum wire served as the anode. The electrodes prepared in this way were reproducible to within 50 μV or better and were stable

over a period of weeks. $Ag/AgCl/Cl^-$ electrodes have never been prepared in exactly this manner, but the results were in excellent agreement with electrodes prepared from the thermal method.

The apparatus used for temperature control and thermal emf measurements have been described elsewhere (2). The reproducibility of ϵ_0 and ϵ_∞ values was generally within 10 μV/deg, although for $CdCl_2$ solutions it was about 15 μV/deg. The isothermal residual emf for both the sandwich cell and the N-shaped cell was small, being of the order of 50 μV and was corrected from thermal emf readings.

Results and Discussion

The measured initial thermoelectric powers are given in Table II. These have been compared with initial values determined previously. The steady-state thermoelectric powers are tabulated in Table III. The only other experimental values with which they may be compared are those for the 0.01M LiCl solution and the three KCl solutions obtained by Haase and Behrend (6). In all cases, the emf is positive when the terminal connected to the hotter electrode is positive.

The actual molar entropies of transport calculated from the experimental data using Eq. [3] are given in Table IV. The only comparisons possible are with the various conductometric and potentiometric determinations conducted at the appropriate concentrations and temperature.

Table V is a tabulation of the transported entropies calculated for the chlorides from Eq. [2]. The Third law values of 22.97 and 10.206 eu were used for S_{AgCl} and S_{Ag}, respectively.

As indicated in Eq. [2], the transported entropy of a given ion should theoretically be independent of the nature of the gegenion in dilute solutions. Applied to this particular study, this means that the value of $\bar{\bar{S}}_{Cl^-}$ should be the same for all the solutions tested in which the chloride ion concentration is 0.01M, *i.e.* in all the uni-univalent chloride salts and 0.005M $CdCl_2$. Inspection of Table V shows that this is true. On the basis of Eq. [2], this same consistency should also be displayed in the steady-state thermoelectric powers for these solutions, which it is.

Examination of Table IV shows that the agreement between the S^*_{salt} values determined in this study and in previous investigations is excellent for 0.01M LiCl, NaCl, KCl, RbCl, CsCl, and TlCl. The values attributed to Agar and Turner (11), Snowdon and Turner (12), and Price (13) were all obtained using the conductometric method. The entropies of transport for 0.01M LiCl and KCl attributed to Haase *et al.* were calculated from the ϵ_0 values reported by Haase and Schonert (4) and the ϵ_∞ values reported by Haase and Behrend (6).

The agreement of the entropy of transport for 0.01M NH_4Cl determined in this study with literature values is reasonably good. Sagert and Breck (14), like Price, used the conductometric method. Although neither of them obtained a value exceptionally close to zero entropy units, all of the early investigators of the Soret effect concluded that aqueous NH_4Cl was very similar in behavior to aqueous LiCl and that both salts were essentially concentration independent and had entropies of transport very close to zero. More recently, Ikeda and Kimura (15) obtained almost identical Soret coefficients for 0.01M NH_4Cl and LiCl solutions at 25°C. In each case, the value was very small and negative.

Actually, because of the hydrogen-bonding facility of the ammonium ion, this ion would be expected to be only weakly structure altering. Consequently, an entropy of transport close to zero entropy units is quite reasonable.

The $CdCl_2$ and KCl solutions were studied at three different concentrations. Examination of Table IV shows that the only $CdCl_2$ solution for which the entropy of transport agrees well with previously reported values is the 0.05M solution. However, this S^* value is of particular interest since the literature value with which it is compared was obtained potentiometrically (16) using cadmium amalgam electrodes. Despite this, our S^* values for 0.01 and 0.005M $CdCl_2$ differ considerably from those obtained conductometrically by Snowdon and Turner (17). Previous studies made of concentration effects on entropies of transport (5, 17). for both univalent and divalent halides, all show an increase in the entropy of transport with decreasing concentration in this low concentration range. We have observed the exact opposite, a decrease in entropy of transport with decreasing concentration.

Although our results for $CdCl_2$ are in poor agreement with those of Snowdon and Turner, it must be emphasized that for these particular solutions the potentiometric method has one significant advantage over the conductimetric method. With the former, entropies of transport are measured directly, while with the latter, entropies of transport are calculated from the measured Soret coefficients, o, using the equation (11)

$$S^* = \nu RT(1 + \partial \ln \gamma_{\pm}/\partial \ln M)o \qquad [4]$$

where ν is the number of ions produced by dissociation of one molecule and $\gamma_{\pm}$ is the mean activity coefficient. Consequently, for calculation of S^* from conductimetric data, reliable activity data are necessary; but, for polyvalent electrolytes such as $CdCl_2$, this information is rather insubstantial.

In addition, $CdCl_2$ forms complexes to an unusually pronounced degree even at these quite low concentrations. The existence of species such as $CdCl^+$, $CdCl_2$, and $CdCl_3^-$ could easily lead to anomalities in the behavior of $CdCl_2$ solutions.

In contrast, the entropies of transport observed for the KCl solutions at concentrations of 0.005, 0.01, and 0.05M are in excellent agreement with the values obtained conductimetrically by Snowdon and Turner, as shown in Table IV. In this case the expected trend, an increase in entropy of transport with decreasing concentration in this concentration range, was obtained.

Both the electrostatic and electrophoretic effects on entropy that will be produced by an ion in solution have been developed theoretically (3, 18). According to Helfand and Kirkwood (18) for an uni-univalent electrolyte denoted [1, 2]

$$Q^*_{12} = Q^{*,o}_{12} + [-(e^2/6D) + (r^s_1 - r^s_2)(B_1 - B_2)]\kappa \qquad [5]$$

where $Q^{*,o}_{12}$ is the molar heat of transport at infinite dilution, e is the electronic charge, D is the dielectric constant, r^s_i is the Stokes' law radius of ion i, and κ is the Debye-Hückel parameter. This equation offers the means for calculating the transported entropy of the chloride ion at infinite dilution, $\bar{\bar{S}}^o_{Cl^-}$, although $(B_1 - B_2)$ cannot be evaluated exactly for salts such as KCl $r^s_1 \simeq r^s_2$; and, thus, this entire nonideality term is expected to be small enough to be ignored. Utilizing the average $\bar{\bar{S}}_{Cl^-}$ value for the 0.01M solutions studied, which is 28.00 eu, this equation yields an $\bar{\bar{S}}^o_{Cl^-}$ value of 18.88 eu. That this value agrees quite well with those obtained by other investigators is shown in Table VI.

Utilizing the convention of setting the entropy of transport of the chloride ion at 0.01M and 25°C equal to zero, ionic entropies of transport may be determined. On this basis, all of the cations examined are structure makers with the exception of Li^+ and NH_4^+ which are structure breakers.

Increased order in the solvent, corrsponding to a positive entropy of transport, would be expected in the vicinity of small or highly charged ions. Thus, the negative entropy of transport of Li^+ appears anomalous. However, this same high charge density would also cause the lithium ion to be heavily hydrated with firmly bound water molecules and thus act as a large ion of low surface charge. Naturally, this effect decreases with size among the alkali metal cations and there is roughly a corresponding increase in the magnitude of the entropy of transport, with the exception of K^+.

Electrochemical Reduction of Potassium Chromate in the Presence of Zinc(II) and Cobalt(II) in Molten Lithium Chloride-Potassium Chloride Eutectic

K. W. Hanck[1] and H. A. Laitinen*

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The electrochemical reduction of K_2CrO_4 in molten LiCl-KCl eutectic is shifted to more positive potentials by the addition of $ZnCl_2$ or $CoCl_2$. In the case of added $ZnCl_2$ three electrons are consumed per mole of K_2CrO_4 and an insoluble reduction product having the empirical formula $LiZn_2CrO_4$ is obtained. In the presence of $CoCl_2$, the reaction product depends on the electrolytic conditions, especially the cathodic potential. The limiting processes appear to be a two-electron process, favored by low cathodic potential and high cobalt(II) concentration to yield Co_2CrO_4, and a three electron process, favored by high cathodic potential and low cobalt(II) concentration to yield $LiCo_2CrO_4$. A mechanism consistent with these observations is proposed.

Laitinen and Bankert (1) used chronopotentiometry to study the electrochemical reduction of K_2CrO_4 in molten LiCl-KCl and observed a single, irreversible, diffusion-controlled, three-electron reduction step. In the presence of Mg(II), the chromate reduction potential is shifted from −1.1V *vs.* a 1M Pt(II)/Pt reference to −0.2V and a highly insoluble, chemically resistant electrode deposit is obtained at the cathode. Propp and Laitinen (2) characterized the magnesium deposit and described it as a single unstoichiometric compound having the empirical formula $Li_xMg_yCrO_4$, where $x + 2y = 5$. The values of x and y were dependent on electrolysis conditions; typically $0.3 < x < 0.5$. Popov and Laitinen (3) have recently shown that a similar deposit is obtained by electrolysis of Ni(II)·Cr(VI) mixtures. The nickel deposit is slightly more stoichiometric than the corresponding magnesium one ($0.6 < x < 0.85$) but has nearly the same lattice structure and thermal stability as $Li_xMg_yCrO_4$.

The results of an extensive characterization of the electroreduction of K_2CrO_4 in the presence of Zn(II) and Co(II) are the subject of this paper. In addition, possible mechanisms for the electroreduction of chromate in the presence of divalent metal ions are discussed.

Experimental

Reagents.—Reagent grade anhydrous $ZnCl_2$ (J. T. Baker) was further purified by fusion under an HCl atmosphere followed by scrubbing the resulting melt with dry HCl for 1 hr. After filtration through a medium porosity, sintered glass frit and scrubbing with dry argon for 2 hr, the purified molten $ZnCl_2$ was allowed to solidify. The $ZnCl_2$ prepared by this method contained 99.95% of the theoretical amount of chloride.

Anhydrous $CoCl_2$ was prepared by dehydrating the hexahydrate (J. T. Baker) in a vacuum. The temperature was slowly increased from room temperature to 150°C where it was maintained for 6-8 hr. The $CoCl_2$ prepared by this method contained 99.94% of the theoretical amount of chloride.

Anhydrous K_2CrO_4 was prepared by drying reagent grade K_2CrO_4 (J. T. Baker) at 150°C under vacuum for 6-8 hr a few days before use.

Chemicals other than those mentioned were reagent grade and were used without prior purification other than drying where required.

Molten salt procedures.—The LiCl-KCl eutectic was obtained from Anderson Physics Laboratories, Inc., Champaign, Illinois, where it was prepared and purified by the method outlined by Laitinen, Tischer, and Roe (4).

The molten salt furnace and glassware associated with the molten salt apparatus have been previously described (5). The procedures employed for cleaning glassware and handling the molten eutectic have been described in detail (5).

Electrochemical measurements.—A Pt(II)/Pt reference electrode was utilized in this work; its construction and properties have been described (6). A carbon electrode was used whenever a counterelectrode was required. The electrodes were constructed and cleaned according to the procedure outlined by Propp (7).

Both the platinum flag electrodes used in the chronopotentiometric and chronoamperometric studies and the platinum gauze electrodes used in preparative work were detachable. The construction of both the platinum gauze electrodes and the electrode holders were described by Propp (7). The platinum flag electrodes were constructed by spot welding 1 in. of 26 gauge platinum wire to a platinum foil (0.001 in. thick) approximately 5 mm on a side. The area of each flag was determined prior to spot welding by measuring its length and width with a micrometer and calculating the area by assuming the flag to be rectangular. The platinum microelectrodes used for voltammetric work were constructed as described by Lucas (8) except that soft glass was used throughout.

Voltammetric measurements were made with a Heath EUA-19-2 Polarography Module which was plugged onto a tube-type, operational amplifier manifold which has been previously described (9).

The constant current source employed for chronopotentiometric studies has been described (7). A Tektronix 502A oscilloscope and Tektronix C-12 oscilloscope camera were used to record the chronopotentiometric potential-time curves.

A Model 61 RS Wenking potentiostat was employed in the chronoamperometric experiments. A Tektronix Type 161 pulse generator supplied the desired potential pulse to the potentiostat.

A Sargent Model IV Coulometric Current Source was used in preparation of deposits and for generation of the Pt(II)/Pt reference electrode.

Analytical procedures.—In the preparative portion of this work, a number of routine analyses were performed to establish the composition of the electrode deposit as a function of various experimental parameters. The deposits were dissolved in $HClO_4$ according to the procedure described by Propp (2, 7). Chromium

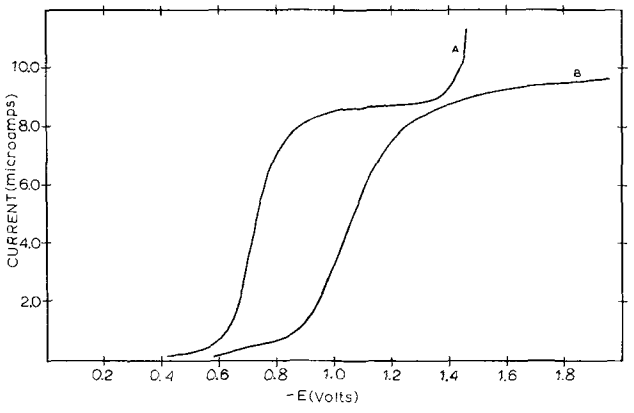

Fig. 1. Current-voltage curves for the reduction of K_2CrO_4 in the presence of $ZnCl_2$. Electrode area = 2.5 x 10^{-3} cm^2. Curve A, $[K_2CrO_4]$ = 4.51 mM, $[ZnCl_2]$ = 0.067M; Curve B, $[K_2CrO_4]$ = 4.51 mM, no $ZnCl_2$ added.

was determined by titration with coulometrically generated Cu(I); the procedure and equipment employed are described elsewhere (5). Lithium was determined by flame photometry; a detailed procedure is available (5). Zinc was determined by a spectrophotometric titration with EDTA using Eriochrome Black T as an indicator. Cobalt was also determined by spectrophotometric titration with EDTA; Xylenol Orange served as the indicator. The apparatus and procedure followed are described elsewhere (5).

Results and Discussion

Reduction of K_2CrO_4 *in the presence of* $ZnCl_2$.—As can be seen from Fig. 1, the half-wave potential for the voltammetric reduction of K_2CrO_4 is shifted in a positive direction by approximately 300 mV by the addition of anhydrous $ZnCl_2$. In the presence of $ZnCl_2$, a green, adherent film forms on electrodes polarized at potentials on the limiting plateau of the voltammetric wave. The film does not inhibit the electrode process but is extremely difficult to remove from the electrode mechanically.

Characterization of electrode deposit.—Samples of electrode deposit were prepared by constant current electrolysis using the method outlined by Propp (2, 7) and analyzed for Cr, Zn, and Li by employing the methods previously described. The average number of electrons consumed per mole of chromium was calculated to be 3.06 by comparing the micromoles of chromium found in a sample of deposit by chemical analysis to the microequivalents of current consumed in preparing the sample.

If the microequivalents of each metal are mathematically converted to an equivalent weight of metal oxide, the sample weight can be completely accounted for in terms of Li_2O, ZnO, and Cr_2O_3. Thus even though Zn(II) forms a strong chloro-complex, no chloride is found in the deposit. As with the previously reported magnesium and nickel deposits, no potassium is incorporated into the deposit.

Propp (2) and Popov (3) observed changes in the composition of the magnesium and nickel deposits as preparative parameters were changed. As can be seen from Tables I, II, and III, such was not the case for the zinc deposit. On the basis of analyses of 20 different preparations of the deposit under varying conditions an average molecular weight of 253.4 was found compared to 253.7 for $LiZn_2CrO_4$.

Table I. Composition of zinc deposit as a function of temperature

$[K_2CrO_4]$ = 0.112M Temperature (°C)	$[ZnCl_2]$ = 0.221M Empirical formula	I_o = 2 mA/cm^2 % Sample wt accounted for

X-ray powder diffraction studies have shown the crystal structure of $LiZn_2CrO_4$ to be disordered face centered cubic, the length of a unit cell edge being 4.205Å (5, 10). The stoichiometry of lithium zinc chromite suggests the existence of the CrO_4^{-5} anion, but it is clear from the lattice structure that such an anion does not exist as a separate entity in the solid state.

Chronopotentiometry.—Chronopotentiograms of K_2CrO_4 in molten LiCl-KCl containing $ZnCl_2$ were found to depend on the relative concentrations of $ZnCl_2$ and K_2CrO_4. Two transitions, one at −0.76V and the other at −1.18V, were observed for solutions in which $[CrO_4^{-2}] > [Zn(II)]$. As the Zn/Cr molar ratio is increased, the first transition lengthens at the expense of the second. When the Zn/Cr molar ratio is made greater than 2, the second transition is not observed. This effect is illustrated in Fig. 2.

With the Zn/Cr molar ratio maintained at a value greater than 2.25, duplicate chronopotentiograms were obtained at 5 current densities at 5 different chromate concentrations ranging from 6.12 to 29.01 x 10^{-3}M. The reduction was found to obey the Sand equation, the value of $I_o \tau^{1/2}/C$ being 755 ± 13 A-$sec^{1/2}$ cm/mole.

The quarter-wave potential for the reduction of chromate in the presence of excess $ZnCl_2$ was found

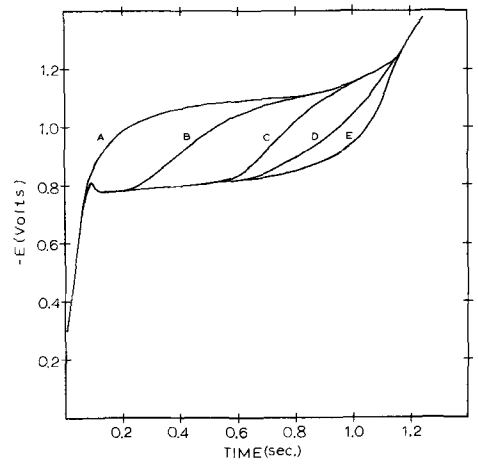

Fig. 2. Potential-time curves for the chronopotentiometric reduction of K_2CrO_4 in the presence of $ZnCl_2$. Current density = 8 mA/cm^2. Curve A, $[K_2CrO_4]$ = 11.43 mM, no $ZnCl_2$ added; curve B, $[K_2CrO_4]$ = 11.43 mM, $[ZnCl_2]$ = 7.18 mM; curve C, $[K_2CrO_4]$ = 11.43 mM, $[ZnCl_2]$ = 16.92 mM; curve D, $[K_2CrO_4]$ = 11.43 mM, $[ZnCl_2]$ = 21.60 mM; curve E, $[K_2CrO_4]$ = 11.43 mM, $[ZnCl_2]$ = 23.77 mM.

to be independent of applied current density over the range studied (4.95-34.48 mA/cm^2); the average value being -0.764V *vs.* a 1M Pt(II)/Pt reference electrode. A quarter-wave potential of -1.18V has been reported for the reduction of pure chromate (1).

Reverse current chronopotentiometry was employed to study the ease with which the insoluble film could be electrochemically oxidized. From Table IV it is seen that Q_r/Q_f (where Q_f and Q_r are the forward and reverse coulombs) approaches the limit of *ca.* 0.7 as Q_f is increased. Microscopic examination of electrodes subjected to both forward and reverse electrolysis revealed the presence of an unoxidized film. The number of molecular layers of deposit left on the electrode after electrochemical oxidation approaches a limit of 16. The inner layers of deposit are rendered nonoxidizable by strong interaction with the Pt cathode.

Chronoamperometry.—Chronoamperograms were obtained for the reduction of chromate both in the presence and absence of Zn(II). In the presence of Zn(II) the potential was stepped from the rest potential (usually about -0.4V) to -1.15V (see Fig. 1). For the reduction of pure chromate, the final potential was -1.65V. Plots of I_o against $t^{-1/2}$ were found to be linear for both systems as predicted by the Cottrell equation.

In the absence of $ZnCl_2$, the Cottrell slope of 0.723 $\pm$ 0.009 mA sec$^{1/2}$/cm^2 gives a diffusion coefficient of 0.96 x 10^{-5} cm^2/sec based on a three-electron reduction. When $ZnCl_2$ was added a slope of 0.709 $\pm$ 0.009 was observed indicating a diffusion coefficient of 0.92 x 10^{-5} cm^2/sec. The excellent linearity of the Zn plot indicates that film formation does not adversely effect the electrode process over the time interval studied.

The important conclusion to be drawn from the chronoamperometric results, however, is that the diffusion coefficient of the electroactive species is unchanged in the presence of zinc chloride. The chronoamperometric value of D for pure chromate disagrees with the value of 1.73 x 10^{-5} cm^2/sec previously reported by Laitinen and Bankert (1). Because of higher purity starting materials, the eutectic used in this work is of slightly better quality than the eutectic used by Laitinen and Bankert. The presence of reducible impurities in the solvent causes the potential-time curve to become drawn out, consequently Laitinen and Bankert may have systematically overestimated τ. The chronoamperometric method eliminates the ambiguity associated with measuring τ and allows for convenient compensation for the reduction of impurities; consequently we conclude that the diffusion coefficient is unchanged by the addition of $ZnCl_2$ to the solvent.

Reduction of K_2CrO_4 in the presence of $CoCl_2$.—A typical current voltage curve for the reduction of K_2CrO_4 in melt containing excess $CoCl_2$ is presented in Fig. 3. During electrolysis of K_2CrO_4 solutions containing $CoCl_2$ a black, insoluble film formed on the cathode. The film was usually obtained as clumps of crystals irregularly distributed across the electrode rather than as a uniform film. Under magnification the crystals appeared to have an octahedral shape; the crystal faces were smooth with sharp edges and a metallic luster.

Characterization of electrode deposit.—Samples of electrode deposit were prepared by constant current

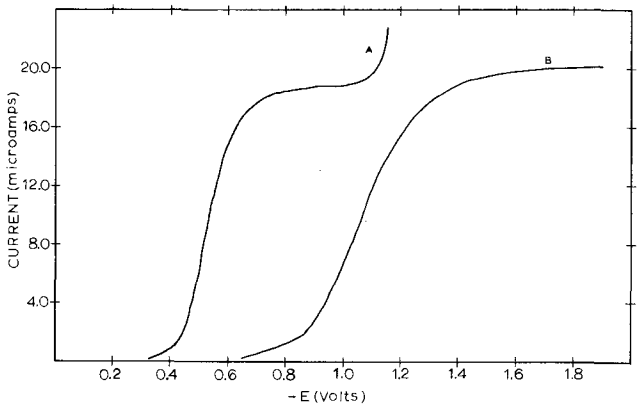

Fig. 3. Current-voltage curves for the reduction of K_2CrO_4 in the presence of $CoCl_2$. Electrode area = 4.9 x 10^{-3} cm^2. Curve A, $[K_2CrO_4]$ = 4.98 mM, $[CoCl_2]$ = 0.064M; curve B, $[K_2CrO_4]$ = 4.98 mM, no $CoCl_2$ added.

electrolysis using the method previously employed in preparing the Zn deposit; the electrode potential was not allowed to become more negative than -0.7V during preparation of the deposit. As may be seen from Table V, two electrons are consumed per mole of chromium. Deposits prepared at high Co/Cr molar ratios had n values which were consistently slightly greater than 2 but well below 3. Based on a two-electron reduction step, an oxidation number of +4 may be formally assigned to chromium.

The composition of three samples of deposit prepared under similar conditions is presented in Table VI. The sample weight can be completely accounted for in terms of the component oxides Li_2O, CoO, and CrO_2. The sample weight could equally well be accounted for if all or part of the moles of Cr were present as Cr(III) (*i.e.*, Cr_2O_3) providing an equal number of moles of Co(III) (*i.e.*, Co_2O_3) were present. Because of this interrelation of oxidation states, no oxidation states have been indicated in the empirical formulas of Table VI.

The composition of the Co deposit has been studied as a function of preparative conditions. As can be seen from Tables VII, VIII, and IX the lithium content of the deposit is very sensitive to changes in preparative parameters while the cobalt and chromium contents are not. It should be noted that except for the effect of added metal ion concentration, the compositional trends of the Co deposit are exactly the opposite of those of the previously reported Mg and Ni deposits.

Table V. Calculation of n for the case of added $CoCl_2$

μ equiv. of current passed	μmoles of Cr found	n
100.4	48.10	2.09
100.0	49.51	2.02
100.2	48.74	2.05
100.1	48.55	2.08
100.1	49.39	2.04
		$\bar{n}$ = 2.06

Table VI. Typical analyses of the cobalt deposit

B. Total mg found	Sample wt mg	% wt found	Empirical formula
11.732	11.799	99.4	$Li_{0.07}Co_{1.97}CrO_{4.00}$
11.714	11.830	99.0	$Li_{0.06}Co_{2.00}CrO_{4.03}$
11.723	11.686	100.3	$Li_{0.06}Co_{2.03}CrO_{4.05}$

Table VII. Composition of cobalt deposit as a function of temperature

$[K_2CrO_4]$ = 0.25M Temperature (°C)	$[CoCl_2]$ = 0.48M Empirical formula	I_o = 2 mA/cm² % Sample wt accounted for
400	$Li_{0.08}Co_{2.00}CrO_{4.04}$	99.3
450	$Li_{0.06}Co_{1.99}CrO_{4.02}$	98.7
500	$Li_{0.01}Co_{1.99}CrO_{3.96}$	100.3

Table VIII. Composition of cobalt deposit as a function of current density

$[K_2CrO_4]$ = 0.094M Current density (mA/cm²)	$[CoCl_2]$ = 0.18M Empirical formula	Temp = 450°C % Sample wt accounted for
2.16	$Co_{2.02}CrO_{4.02}$	100.5
4.32	$Li_{0.14}Co_{1.93}CrO_{4.02}$	99.9
8.58	$Li_{0.25}Co_{1.93}CrO_{4.05}$	99.6
21.55	$Li_{0.34}Co_{1.92}CrO_{4.09}$	99.0

Table IX. Composition of Co deposit as a function of $CoCl_2$ concentration

Temperature = 450°C $[K_2CrO_4]$	$[CoCl_2]$	Co/Cr molar ratio	I_o = 2 mA/cm² Empirical formula	% Sample wt accounted for
0.022M	0.193M	8.76	$Li_{0.50}Co_{1.97}CrO_{4.22}$	99.5
0.046M	0.189M	4.12	$Li_{0.20}Co_{1.91}CrO_{4.04}$	99.6
0.094M	0.184M	1.96	$Li_{0.14}Co_{1.93}CrO_{4.02}$	99.8
0.246M	0.481M	1.96	$Li_{0.06}Co_{1.99}CrO_{4.02}$	98.7

Samples of deposit with an empirical formula approaching Co_2CrO_4 can be prepared by using a low current density, high temperature, and high $CoCl_2$ concentration. X-ray powder diffraction studies of Co_2CrO_4 have shown it to have a diamond cubic lattice with a unit cell edge of 8.173Å (5, 10). A spinel-like structure in which the tetrahedral sites are occupied by Co(II) ions and the octahedral sites shared by Cr(III) and Co(III) ions has been proposed as the only structure consistent with both the observed x-ray data and previously established structures of multiple metal oxides of Co(II), Co(III), Cr(III), and Cr(IV) (5, 10).

Chronopotentiometry.—A typical chronopotentiogram of chromate in the presence of excess $CoCl_2$ is shown in Fig. 4. As with the case of added $ZnCl_2$ two transitions are observed at Co/Cr molar ratios below 2.09. Over the chromate concentration range studied (4.71 to 33.00 x 10^{-3}M) the reduction obeyed the Sand equation. At 450°C, $I_o \tau^{1/2}/C$ = 751 ± 7 A-sec$^{1/2}$ cm/mole, consequently $nD^{1/2}$ = 8.81 x 10^{-3} cm equiv./mole sec$^{1/2}$.

The quarter-wave potential was found to be independent of applied current density over the range 4.07-21.90 mA/cm², the average value being −0.558 ± 0.002V *vs.* a 1M Pt(II)/Pt reference. At current densities greater than 22 mA/cm² $E_{\tau/4}$ shifts in a cathodic direction as I_o is increased. Attempts to oxidize the Co deposit electrochemically were unsuccessful.

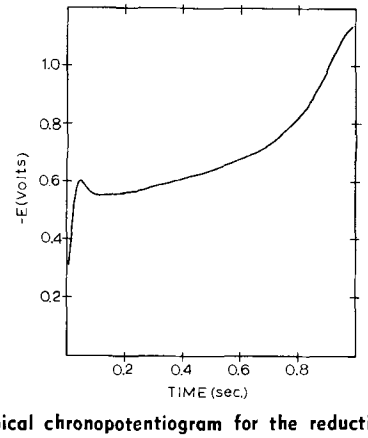

Fig. 4. Typical chronopotentiogram for the reduction of K_2CrO_4 in the presence of excess $CoCl_2$. Current density = 15.82 mA/cm². $[K_2CrO_4]$ = 17.41 mM. $[CoCl_2]$ = 0.132M.

Chronoamperometry.—Chronoamperograms were obtained for the reduction of chromate in the presence of cobalt chloride by stepping the potential of the test electrode to −0.90V (see Fig. 3) and measuring the current which flowed as a function time. Currents were measured over the time interval 20 msec to 1 sec. A plot of I_o *vs.* $t^{-1/2}$ was found to be linear as predicted by the Cottrell equation. A slope of 0.775 ± 0.13 mA sec$^{1/2}$/cm² was observed for a 4.98 x 10^{-3}M solution of K_2CrO_4 which was also 0.063M in $CoCl_2$. From the experimental slope $nD^{1/2}$ is found to be 9.06 x 10^{-3} cm equiv./mole sec$^{1/2}$.

Electroreduction mechanism.—The over-all electroreduction mechanism of chromate in the presence of a divalent metal chloride must contain a chemical reaction in order to account for the presence of the divalent metal in the reduction product. The reaction could occur before, after, or during the charge transfer process and still provide a means for incorporating divalent metal into the deposit.

If the reaction occurred prior to charge transfer, it must be analogous to the formation of a Cr(VI) complex containing the divalent metal which is more easily reduced than uncomplexed chromate. A M(II)·chromate complex would be expected to be larger in size than the uncomplexed chromate ion. Since the diffusion coefficient of chromate is unchanged by the addition of $ZnCl_2$, $NiCl_2$, or $MgCl_2$ to the melt, the size of the electroactive species in the presence of Zn(II), Ni(II), or Mg(II) must be approximately the same as in their absence and the existence of M(II)·chromate complexes may be ruled out for the cases where M = Zn, Ni, or Mg.

The initial reduction product of chromate is believed to be the oxy-anion $Cr(III)O_5^{-5}$. A chemical reaction between this anion and M(II) could also account for the presence of divalent metal in the deposit. A reaction of this type would account for the positive shift in potential as well, since the activity of the reduced form of the couple would decrease as a result of the reaction causing the equilibrium potential to become more positive.

Delahay *et al.* (11) have derived an equation relating the potential time curve of a reversible charge transfer followed by a chemical reaction to the chemical kinetic parameters. Since the electroreduction of chromate is, at best, quasireversible, Delahay's equation must be modified to take charge transfer kinetics into account. The nature of the modifications are discussed elsewhere (5). The equation is a complex one and must be solved by numerical methods

$$\frac{2k^\circ_{sh}}{D^{1/2}\pi^{1/2}}(\tau^{1/2} - t^{1/2})\theta^{-\alpha} - \frac{Kk^\circ_{sh}}{D^{1/2}(K+1)}\left\{\frac{2t^{1/2}}{\pi^{1/2}K} + \frac{\mathrm{erf}[\Delta^{1/2}t^{1/2}]}{\Delta^{1/2}}\right\}\theta^{1-\alpha} = 1 \quad [1]$$

where k°_{sh} is the standard heterogeneous charge transfer rate constant at $E = E^{\circ\prime}$, $\theta = \exp\{n\mathbf{F}/RT\ (E - E^{\circ\prime})\}$, K is the equilibrium constant of the chemical reaction, and $\Delta = (k_f + k_b)$ where k_f and k_b are the forward and reverse rate constants of the chemical reaction.

Using the data of Laitinen and Bankert (1) for the electroreduction of pure chromate, we estimate k°_{sh} to be 2 x 10^{-3} cm/sec and $E^{\circ\prime}$ to be −1.05V *vs.* a 1M Pt(II)/Pt reference electrode. Inserting these electrokinetic parameters into Eq. [1], we find that a following chemical reaction will shift the quarter-wave potential for the reduction of chromate a maximum of only 0.25 mV even if K and k_f are infinitely large. Since the ion $Cr(III)O_4^{-5}$ must have an average lifetime of at least 10^{-13} sec to be considered real (12),

the highest feasible value for k_f is 10^{13} sec^{-1}. Thus even if $k°_{sh}$ is increased by the presence of a divalent metal ion to 100 cm/sec, Eq. [1] predicts that $E_{\tau/4}$ will shift by only 202 mV. In the presence of added $ZnCl_2$, $E_{\tau/4}$ shifts by 400 mV; consequently we conclude that a simple charge transfer followed by a chemical reaction cannot be used to explain the shift in $E_{\tau/4}$ because such a mechanism requires the rate of the chemical step to be impossibly fast for reasonable values of $k°_{sh}$.

A mechanism involving an interaction between M(II) and an intermediate oxidation state of chromium remains as the only plausible way to account for the positive shift in quarter-wave potential and the incorporation of divalent metal into the reduction product.

Suppose that the reduction mechanism of pure chromate involves the following steps

$$Cr(VI) + 2e^- \overset{\text{rapid}}{\rightleftharpoons} Cr(IV) + 1e^- \overset{\text{slow}}{\rightleftharpoons} Cr(III)$$

The first step is more rapid than the second since no coordination change is involved, but the second step requires the oxygen coordination to change from tetrahedral to octahedral and is consequently slower than the first. The ion $Cr(IV)O_4^{-4}$ is a much better electron donor than $Cr(VI)O_4^{-2}$; the change in nucleophilicity of the chromium species could lead to a donor-acceptor interaction between $Cr(IV)O_4^{-4}$ and a soluble divalent metal species. The interaction would either reduce the energy required to change the oxygen coordination or change the coordination as a result of the interaction and thus allow the second charge transfer step to occur at a less negative potential than in the absence of the divalent metal. Following the second charge transfer, a second chemical step could occur to produce the solid deposit. For the case of added $ZnCl_2$

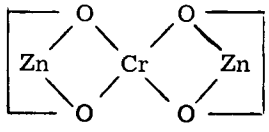
$$Cr(VI)O_4^{-2} + 2e^- \overset{\text{rapid}}{\rightleftharpoons} Cr(IV)O_4^{-4}$$

$$Cr(IV)O_4^{-4} + 2ZnCl_4^{-2} \overset{\text{rapid}}{\rightleftharpoons} Zn_2Cr(IV)O_4 + 8Cl^-$$

$$ZnCr(IV)O_4 + 1e^- \rightleftharpoons (Zn_2Cr(III)O_4)^-$$

$$(Zn_2Cr(III)O_4)^- + Li^+ \rightleftharpoons LiZn_2CrO_{4(solid)}$$

The structure of the zinc orthochromate(IV) complex has not been established, but in view of the chemistry of molten $ZnCl_2$ and ZnO it is likely to involve oxygen bridges



The mechanism for the electroreduction of chromate in the presence of $CoCl_2$ is similar to that proposed for the case of added $ZnCl_2$ but involves a chemical reduction path parallel to the second charge transfer step

$$Cr(VI)O_4^{-2} + 2e^- \overset{\text{rapid}}{\rightleftharpoons} Cr(IV)O_4^{-4}$$

$$Cr(IV)O_4^{-4} + 2CoCl_4^{-2} \overset{\text{rapid}}{\rightleftharpoons} Co(II)_2Cr(IV)O_4 + 8Cl^-$$

$$Co(II)_2Cr(IV)O_4 \overset{\text{path 1}}{\rightleftharpoons} Co(II)Co(III)Cr(III)O_{4(solid)}$$

$$Co(II)_2Cr(IV)O_4 + 1e^- \overset{\text{path 2}}{\rightleftharpoons} (Co(II)_2Cr(III)O_4)^{-1}$$

$$(Co(II)_2Cr(III)O_4)^{-1} + Li^+ \rightleftharpoons LiCo(II)_2Cr(III)O_{4(solid)}$$

In path 1, Cr(IV) is intramolecularly reduced to Cr(III). Based on the composition of the deposit and the fact that n is 2, path 1 is the preferred route. The second path is necessary to provide a means of incorporating Li(I) into the deposit. It, however, would predict an n value of 3.

Table X. Correlation of n with N_{Li}

Number of Li atoms per molecule (N_{Li})	Observed n	Calculated n
0.07	1.98	2.07
0.14	2.05	2.14
0.20	2.15	2.20
0.25	2.15	2.25
0.34	2.55	2.34
0.50	2.43	2.50

According to the parallel path mechanism, the value of n should equal $N_{Li} + 2$, where N_{Li} is the number of Li atoms per molecule of deposit. Several calculated and observed values of n are compared in Table X from which it may be seen that the correlation of n with the amount of lithium has some merit. When N_{Li} is small, n is nearly 2 as shown in Table X.

The changes in lithium content of the deposit may also be rationalized in terms of a parallel path mechanism. At high current density, path 1 may not be rapid enough to consume all of the $Cr(IV)O_4^{-4}$ produced by electrolysis. Consequently a significant fraction goes by path 2 and Li is found in the deposit. If the rate of the chemical path increases with temperature faster than that of the electrochemical path, very little Cr(IV) would be reduced electrochemically; hence the Li content of the deposit decreases with increasing temperature.

The rate of path 2 is potential dependent while that of path 1 is not; consequently path 2 should be favored at negative potentials. It has recently been shown by Lieto (13) that chromate is reduced via path 2 if a controlled potential electrolysis is performed at -1.07V. A deposit having a face centered cubic lattice ($a = 4.177$Å) and the empirical formula $Li_{1.11}Co_{2.22}CrO_{4.27}$ was obtained; Lieto's data were consistent with an n value of three. The increase in lithium content, the change in n from 2 to 3, and the change in lattice structure of the deposit are in excellent agreement with our mechanism.

In the case of added $CoCl_2$, the number of electrons exchanged per chromium is a function of potential. Consequently a true diffusion coefficient cannot be calculated from chronopotentiometric measurements. However, at potentials more negative than -0.90V, n is nearly equal to 3 (13) and D is calculated to be 0.91×10^{-5} cm^2/sec from our chronoamperometric results. The diffusion coefficient of the chromate ion is thus unchanged by the presence of all divalent metal ions studied.

Acknowledgment

One of the authors (K.W.H.) is indebted to the University of Illinois, Monsanto Chemical Company, and the American Chemical Society (Petroleum Research Fund) for their support in the form of fellowships. We are grateful to Dr. Louis Lieto for permission to use the results of his controlled potential electrolyses of the K_2CrO_4·$CoCl_2$ system. Financial support of this research was provided by the Army Research Office, Contract Numbers USDA-ARO-D-G586 and USDA-ARO-D-G968.

Manuscript submitted Sept. 23, 1970; revised manuscript received Jan. 16, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Technical Notes

EMF Measurements of Sodium Activity in Sodium Amalgam with Beta-Alumina

Limin Hsueh[1]* and Douglas N. Bennion*

Department of Energy and Kinetics, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

Beta-alumina,[2] nominal formula $Na_2O \cdot 11Al_2O_3$, has been used as a refractory material for decades (1, 2). Recently, Ford Motor Company has used it for developing a sodium-sulfur battery system (3, 4).

Emf measurements have been performed with beta-alumina to test for behavior as a solid electrolyte for measuring sodium activity in amalgams and to test the assumption that the conductivity of beta-alumina is ionic in nature. The latter is in contrast to potassium ferrite (5), an isomorphous compound of beta-alumina, for which the electrical conductivity is partially electronic and partially ionic. Emf measurements such as this can indicate if the electronic conductivity is high enough in a practical sense to cause interference with electrochemical measurements.

Emf measurements of activity of sodium in sodium amalgams have been carried out previously by a number of workers (6-8). The early work encountered the problem of finding a solvent which is not attacked by sodium and which dissolves a reasonable amount of sodium salt to form an ionically conducting solution. A stable emf measurement with beta-alumina would enable one to develop an electrode to measure sodium content in sodium amalgams or alloys.

Present sodium amalgam analysis methods are awkward to apply accurately under many practical situations. The most commonly used techniques are:

1. The gasometric method (9) based on the volume of hydrogen evolved when sodium amalgam reacts with hydrochloric acid.

2. The potentiometric method (10) based on the potential of the cell Na-Hg|NaOH(50%)|HgO,Hg.

Experiment

Sample beta-alumina disks were obtained from Ford Motor Company (Firing No. 347) and Alcoa Company (batch 21G-5410). Physically, the Ford disks have a smooth and shiny appearance. From their physical size and weight, the density of these disks was calculated as 3.25 g/cc. Details of some transport behavior have been reported by Yao and Kummer (11). The chemical composition and crystal structure of the polycrystalline disks have been reported by Bettman and Peters (12). The analysis of beta-alumina from Alcoa was given as Na_2O 7.3%, SiO_2 0.02%, Fe_2O_3 0.03%, water 0.90%. The Alcoa disks are less smooth and have a density of 3.06 g/cc. They were fabricated and described by Francis (13).

Amalgams were prepared with triple distilled mercury and reagent-grade sodium metal (J. T. Baker Chemical Company). Sodium oxide on the metallic sodium was removed by filtering molten sodium through fritted glass. The concentrations of amalgams were determined gravimetrically (Sartorius balance, Model 2402).

Before each experiment, beta-alumina disks were heated in an alumina crucible, filled with beta-alumina powder, under an argon atmosphere at 900°C for 1 hr. The surrounding powder is used for minimizing the loss of sodium content, if any, in the disks. The measurements were made in a split U tube cell with one side arm filled with sodium and the other side with sodium amalgam as shown in Fig. 1. Experiments were carried out in an argon atmosphere dry box (Vacuum Atmosphere Corporation, Model HE-243-2 DRI-LAB). The box is equipped with a VAC Model HE-493 gas purifier for removing water vapor and oxygen and a VAC Model HE-593 titanium furnace (operated at 1600°F) for removing nitrogen. The water and oxygen content inside the box is estimated at below 1 ppm. This estimate is based on the long life (over 1 day) of a 25W tungsten light bulb filament and rate of formation of an oxide film on molten sodium. The temperature of the argon atmosphere was controlled with a thermoregulator to within ±0.2°C.

The emf of a sodium |Na-β-alumina| sodium amalgam cell was measured with a Leeds and Northrup K-3 potentiometer (catalog No. 7553) and a Hewlett

Key words: electromotive force, sodium, aluminum sodium oxide (beta-alumina), sodium amalgam, ionic conduction, solid electrolyte, conduction in solid, sodium activity.
[2] The official nomenclature for $Na_2O \cdot 11Al_2O_3$ adopted by *Chemical Abstracts* are and have been: 1947-1956, β-alumina; 1957-1966, sodium-aluminate ($Al_{11}NaO_{17}$); 1966-present, aluminum sodium oxide ($Al_{11}NaO_{17}$).

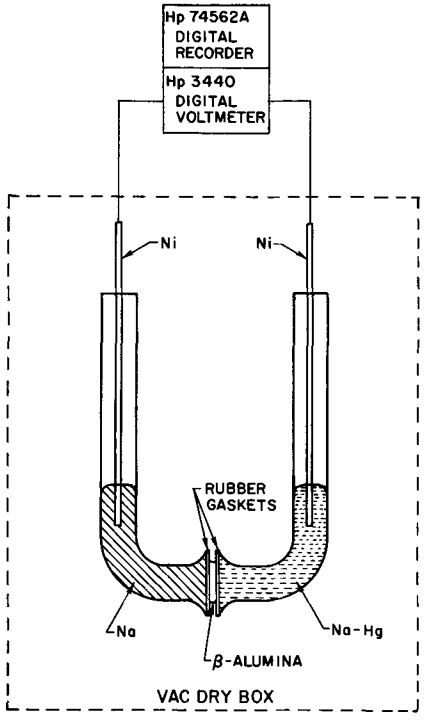

Fig. 1. Emf measurements of Na | Na-Hg cell with beta-alumina

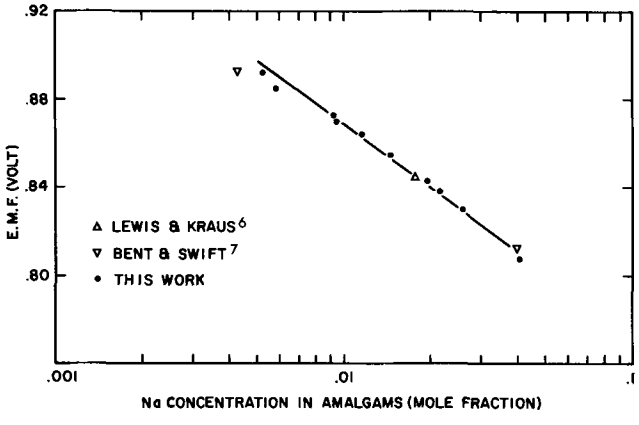

Fig. 2. Emf measurements of Na | beta-alumina | Na-Hg at 30°C

Packard Model 3440 digital voltmeter. The emf drift during a 1 hr period was less than 0.2 mV for most measurements. Both Ford disks and Alcoa disks were used for these measurements. The results for both agreed to within 0.2 mV. The measured results are tabulated in Table I.

The logarithm of activity of sodium, log a_{Na}, in amalgam is calculated from the measured emf by the relationship

$$nE\mathbf{F} = -2.303\,RT \log a_{Na} = -2.303\,RT \log \gamma x$$

where n is the number of electrons transferred, E is the measured emf, $\mathbf{F}$ is the Faraday constant, R is the universal gas constant, and T is absolute temperature. For this system, the pure sodium has been chosen as a reference state. The activity coefficients, γ, are calculated based on the mole fraction, x, of sodium in the amalgam solutions.

Table I. Observed values of emf of sodium | beta-alumina | sodium amalgam cell at 30°C

x (mole fraction of sodium)	Ford disk, volt	Alcoa disk, volt	log a_{Na}	log γ

7	0.0042270	−0.04921	−0.89418	−0.84597

* Solution No. 5 has mole fraction of sodium x = 0.0177086.

Discussion

The measured results of this work are compared with some early work in Fig. 2. Lewis and Kraus (6) reported an emf measurement for the cell

Sodium|Ethylamine + NaI|Sodium amalgam

For a sodium amalgam of 0.2062 w/o (weight per cent) (x = 0.01771), the emf was 0.8456V at 25°C. The temperature coefficient they report is dE/dt = −0.0000408 V/deg. This result agrees well with this work after correction to 30°C.

Bent and Swift (7) performed the same measurements with dimethylethylamine saturated with sodium iodide as the electrolyte solution. They measured the emf of two sodium amalgam solutions (solutions No. 3 and 7) *vs.* pure sodium. However, their results were not consistent with the same two solutions *vs.* another sodium amalgam (solution No. 5) (see Table II). The deviation is 8.7 mV. This raises the question as to which, if either, measurement is correct.

The emf measurements of Iverson and Recht (8) were carried out with borosilicate glass as a separator at high temperatures (350°-400°C). No comparison is made with this work.

The agreement between the beta-alumina measurements and the results using organic solvents indicates that the electronic conduction in beta-alumina is low enough not to interfere with electrochemical measurements of this type.

Acknowledgments

We wish to thank Thomas L. Francis of the Alcoa Company and Thomas J. Whalen of the Ford Motor Company for providing beta-alumina disks.

Reduction Mechanism of Thin-Film CuF_2 Electrodes in Propylene Carbonate Electrolyte

Brian Burrows*

School of Chemistry, Macquarie University, North Ryde, New South Wales, 2113, Australia

One of the principal factors limiting the utility of high energy density batteries based on organic electrolytes is the poor performance of the positive electrode. The specific causes of this poor behavior in the case of CuF_2 are not yet clear. Very little systematic work under closely controlled experimental conditions has been carried out; neither the mechanism nor the kinetics of the CuF_2 reduction process is known.

Most of the investigative work on CuF_2 has been done on electrodes of complex structure (1), *i.e.* made up from CuF_2 powder mixed with some finely divided conducting material such as graphite which acts as a current collector. An organic binder holds the structure together. The electrochemical behavior of this type of electrode, which is intended to have a large surface area, is not readily amenable to analysis. A simpler approach is to form CuF_2 on a Cu substrate in a controlled fashion and then to study the discharge of the thin film of CuF_2 in the organic electrolyte. Anhydrous HF, containing KF to improve the conductivity, was chosen as the reaction medium, and it was found to be possible to form CuF_2 of controlled thickness on a Cu substrate by electrochemical means (2).

This note presents the results of a study of the electrochemical behavior of thin-film CuF_2 electrodes in $PC/LiClO_4$ solutions under a variety of conditions.

Experimental

The CuF_2 electrodes consisted of thin porous films of CuF_2 formed on a copper wire substrate (2) by anodizing in HF/KF solution at 0.1 mA for 100 sec. The geometric electrode area was 0.33 cm^2; thus, the film thickness corresponded to 30 MHz cm^{-2}. This is equivalent to an average thickness of 24 molecular units of CuF_2. More complete details relating to the Cu/CuF_2 couple in HF-KF solutions are given in a previous paper (2).

After being formed, the CuF_2 electrodes were transferred immediately into a dry box. The CuF_2 electrodes were discharged in organic electrolyte under constant current conditions in a three-compartment cell. Unless otherwise stated, all electrodes were discharged within 5 min from time of immersion. The cell was contained inside a recirculating argon-atmosphere dry box (Vacuum Atmosphere Corporation) in which the temperature was maintained at 28° ± 0.2°C. Discharge curves (*i.e.*, potential-time curves) were recorded on a X-Y recorder (Houston Omnigraphic, Model HR-98T). A constant-current power source (Electronic Measurements, Model C623) supplied the current at voltages up to 400V. Emf's were measured with a potentiometer. A Li/Li^+ reference (3) was used in the discharge experiments.

The $PC/LiClO_4$ solutions were prepared and dried over Molecular Sieves (4A) as described elsewhere (4). The PC/Et_4NClO_4 and $THF/LiClO_4$ solutions were prepared and dried in an analogous manner. Stirring was achieved magnetically using a small Teflon-covered stirring bar in the bottom of the working-electrode compartment.

Results and Discussion

A typical discharge curve is shown in Fig. 1. The main feature is the long transition region terminating at about +2.0V. This was presumed to correspond to net CuF_2 reduction (see below). The charge recovered from the moment that constant current was applied through to the end of the major transition region was taken as a measure of the extent of net CuF_2 reduction. With increasing current density, the transition terminated at lower potentials and with less charge recovery.

As shown in the discharge curve of CuF_2, there was an initial potential drop of several hundred millivolts from the open-circuit potential of 3.4V. Fast pulse experiments were carried out to investigate whether this initial drop in potential was due to *IR* effects or to overvoltage effects. The application of a relatively high current density (3 mA/cm^2) and the simultaneous recording of the galvanostatic transient on the oscilloscope screen (1 msec/div) showed that the *IR* drop was only about 15 mV. This value is about the same as that calculated for the solution *IR* drop.

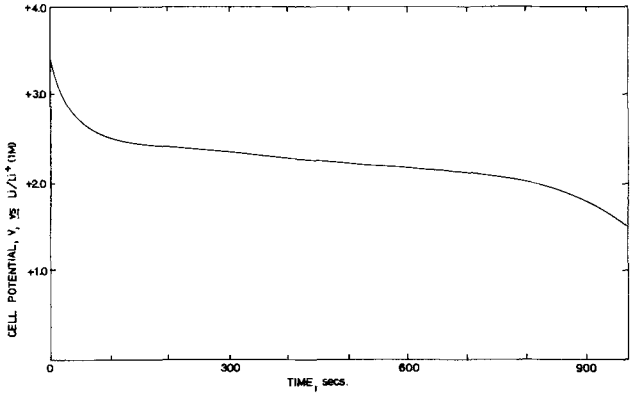

Fig. 1. Galvanostatic discharge curve for a CuF_2 electrode (30 MHz/cm^2) in $PC/LiClO_4$ (1M). Discharge efficiency was 83% to a 2V cutoff. Current density, 0.03 mA/cm^2.

Table I. Reduction of thin-film CuF_2 electrodes (30 MHz cm^{-2}) in PC/$LiClO_4$ (stirred solution)

	i, mA cm^{-2}	Q, MHz cm^{-2}
1.0M $LiClO_4$	0.03	13
	0.30	2
0.5M $LiClO_4$	0.03	10.5
	0.30	1.4
0.25M $LiClO_4$	0.03	12.2
	0.30	0.6

Table II. Reduction of thin-film CuF_2 electrodes (30 MHz cm^{-2}) in PC/$LiClO_4$ (quiescent solution)

	i, mA cm^{-2}	Q, MHz cm^{-2}
1.0M $LiClO_4$	0.03	26.3
	0.15	4.1
	0.30	3.9
0.5M $LiClO_4$	0.03	15.4
	0.15	3.8
	0.30	3.6
0.25M $LiClO_4$	0.03	11
	0.15	1.3
	0.30	1.2

Furthermore, a tenfold increase in current density caused but a fractional increase in the potential drop as observed on the X-Y recorder. This implies an overvoltage effect (kinetic and/or mass transport) as opposed to an ohmic drop, in agreement with the fast pulse measurements.

Effect of stirring.—To investigate mass transport control, discharge curves were recorded at various current densities and $LiClO_4$ concentrations in which stirring was effected by a magnetic stirrer in the bottom of the working electrode compartment. The results are listed in Table I. Comparing the results with those in Table II (static conditions), it can be seen that stirring caused a significant decrease in Q (*i.e.*, the total charge recovered) over the whole current density range and $LiClO_4$ concentration range. This is consistent with a dissolution mechanism for the reduction of CuF_2; *i.e.*, a soluble intermediate is the species which is reduced (see below). The effect of stirring would be to reduce the concentration of this species at the electrode surface, hence causing a reduction in charge recovered as compared to the case of a quiescent solution where the local concentration at the interface in viscous PC/$LiCl_4$ electrolyte would be relatively much larger.

Effect of current density and $LiClO_4$ concentration.—The results of CuF_2 reduction as a function of current density and $LiClO_4$ concentration are listed in Table II. The trend of the results is that Q decreases to a more or less constant value as current density increases. This is also consistent with a prior dissolution-reduction mechanism in that the constant Q at high i (see Table II) can be accounted for in terms of the reduction of the equilibrium amount of the intermediate present in the immediate vicinity of the electrode. At low i, Q is higher due to the ability of the dissolution process to keep supplying the electroactive intermediate at a rate sufficient to maintain reduction at about +2.5V *vs.* Li/Li^+.

The effect of decreasing $LiClO_4$ concentration is to cause a decrease in Q for a given i. This effect has also been observed by other workers using electrodes of more complex structure (1), and can be related to the proportionality between CuF_2 solubility and $LiClO_4$ concentration (5). This relationship is due to the metathetical reaction (6)

$$CuF_2\ (solid) + 2LiClO_4\ (solution) \rightarrow 2LiF\ (solid) + Cu(ClO_4)_2\ (solution) \quad [1]$$

No data are yet available on the time for this reaction to come to equilibrium.

Table III. Reduction of thin-film CuF_2 electrodes (30 MHz cm^{-2}) in PC/$LiClO_4$(1M) containing 500 ppm H_2O

i, mA cm^{-2}	Q, MHz cm^{-2}
0.03	35.0
0.15	9.8
0.30	6.3
Effect of stirring	
0.03	25
0.30	2.5

Effect of H_2O.—The solubility of CuF_2 in PC is about 10^{-4}M (5). In H_2O the solubility is of the order of 0.5M (7). Hence, the addition of H_2O to PC should increase the solubility of CuF_2 and presumably of the soluble intermediate. The discharge results obtained when 500 ppm of H_2O were added are shown in Table III. It can be seen that H_2O did indeed significantly increase Q over its corresponding value in the "dry" solution (*cf.* Table II) and stirring again caused a decrease in Q. A dry PC/$LiClO_4$ solution contains a small amount of H_2O, the last traces of which are difficult to remove (4). This trace of H_2O presumably assists the dissolution of CuF_2. On prolonged wet stand in such a "dry" solution, the CuF_2 discharge performance could be expected to worsen, as solubilized copper diffuses into the bulk of solution. The results of such an experiment showed a fourfold loss in capacity at 0.03 mA cm^{-2} over a 6 day wet stand and a 2.5-fold loss at 0.3 mA cm^{-2} over the same period. This loss in capacity has been commonly observed in experimental batteries (1).

Effect of supporting electrolyte and solvent.—Previous work indicates that LiF is a product of CuF_2 reduction (5). LiF is quite insoluble ($<10^{-5}$M) in PC (5) and its effect on the reduction of CuF_2 was investigated by replacing $LiClO_4$ with Et_4NClO_4 as supporting electrolyte. A solution of Et_4NClO_4 (at the saturation concentration of about 0.75M) in PC was prepared and dried over 4A Molecular Sieves. Discharge of CuF_2 showed no detectable transition region.

The effect of Et_4N^+ ions could be that they do not react metathetically with CuF_2 as do Li^+ ions and thus there is no mechanism for the formation of an appreciable Cu^{2+} ion concentration. The reduction of CuF_2 again became apparent after the addition of $LiClO_4$ to the Et_4NClO_4 solution.

In THF/$LiClO_4$ solution the results of the discharge of CuF_2 electrodes were not significantly different to those in PC/$LiClO_4$. It was observed, however, that well-dried THF/$LiClO_4$ solution reacted with the Li reference electrode producing a grey sponge-like film. This film was mildly explosive when impacted. When the solution contained more than about 10^{-3}M (~18 ppm) H_2O, the Li metal was stabilized, suggesting that a reaction between H_2O and Li resulted in the formation of a passive film. The presence of PC also stabilized the lithium.

Time dependence of CuF_2 dissolution.—The results thus far suggest that CuF_2 is reduced *via* a dissolution mechanism. An experiment which supported this conclusion was one in which thin-film CuF_2 electrodes (30 MHz/cm^2) were pulsed at 0.3 mA/cm^2 for 4 sec periods followed by rest periods until the end of the transition region was reached. The results are listed in Table IV in which it can be seen that, with increasing dura-

Table IV. Pulsed reduction of thin-film CuF_2 electrodes (30 MHz cm^{-2}) at 0.3 mA cm^{-2} in PC/$LiClO_4$(1M)

Rest period after each 4 sec discharge pulse (sec)	Total charge recovered to end of transition region (MHz cm^{-2})
0	5.1
10	6.9
20	9.0
30	10.8

tion of the rest period for a given electrode, there was an increasing amount of charge recovered. This is consistent with more soluble intermediate being formed as the rest period became longer, leading to an increased charge recovery.

Conclusions

This investigation of CuF_2 reduction has shown that: (*a*) the initial potential drop is not due to *IR*; (*b*) stirring causes a decrease in *Q*, the charge recovered from CuF_2 reduction; (c) a decrease in $LiClO_4$ concentration causes a decrease in *Q* in the same sense as the solubility of CuF_2 is decreased; and (*d*) an increase in H_2O concentration causes an increase in *Q* in the same sense as the solubility of CuF_2 is increased. These results point to the conclusion that CuF_2 is reduced *via* a soluble intermediate rather than through the solid state. The intermediate presumably is the cupric ion and the rate-limiting step could be either of (i) the kinetics of the Cu^{2+} ion reduction process, (ii) the rate of dissolution of CuF_2 to Cu^{2+} ions, or (iii) the mass transport of these ions to reduction sites. Until more detailed studies are carried out, it is not possible to be more specific as to the exact nature of the dissolution-reduction mechanism for CuF_2 in propylene carbonate $LiClO_4$ electrolyte.

Acknowledgments

The work reported herein was carried out at Tyco Laboratories Incorporated, Waltham, Massachusetts, and the author wishes to thank Dr. Raymond Jasinski of Tyco Laboratories for his helpful discussions and suggestions and Susan Kirkland for assisting with the experimental work. This work was carried out under Contract NOO19-67-C-0680 for the U. S. Navy Air Systems Command.

The Limiting Rate of Deposition by P-R Plating

H. Y. Cheh*,[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Plating by periodically reversing the polarity of the applied current (p-r plating) is a technique used by electroplaters to reduce nodular growth, edge buildup, and surface roughness (1, 2). The instantaneous limiting current density during the cathodic part of the cycle was also known to exceed that of direct-current (d-c) plating (2). However, no satisfactory theory exists to calculate the limiting rate of deposition. In this paper we show how the diffusion model developed for plating by pulsed current (p-c plating) (3) can be extended to calculate the limiting rate of deposition by p-r plating.

The diffusion model for p-r plating is complete analogy to that of p-c plating. The only difference appears in the boundary condition involving the form of the applied current density at the electrode surface. Similar to the nomenclature used in Ref. (3), the applied current density for p-r plating can be expressed as

$$i = i_f \text{ for } 0 < t \leqq t_1, t_2 < t \leqq t_3, \text{ etc.} \quad [1]$$

and

$$i = i_r = \frac{1}{r} i_f, \text{ for } t_1 < t \leqq t_2, t_3 < t \leqq t_4, \text{ etc.} \quad [2]$$

and the cyclic period is given by

$$\theta = \theta_1 + \theta_2 = t_2 = (t_4 - t_2) = (t_6 - t_4), \text{ etc.} \quad [3]$$

where i is the applied current density, i_f is the current density during the forward part of the cycle, θ_1, i_r is the current density during the reverse part of the cycle, θ_2, r is the ratio of i_f and i_r and is always negative for p-r plating, t is time and t_n is defined in Fig. 1. The mathematical problem was solved by Rosebrugh and Miller (4), and similar to p-c plating (3), the ratio of the instantaneous cathodic limiting current density for p-r plating to that of d-c plating can be expressed as

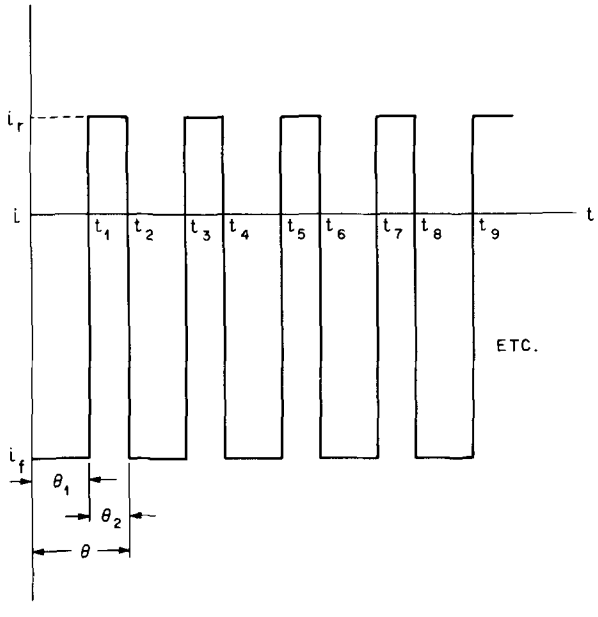

Fig. 1. Schematic diagram of applied current in p-r plating

$$\frac{(i_{p\text{-}r})_l}{(i_{d\text{-}c})_l} = \frac{1}{1 - \frac{8}{\pi^2}\left(\frac{r-1}{r}\right)\sum_{j=1}^{\infty} \frac{1}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2 a\theta_2] - 1)}{(\exp[(2j-1)^2 a\theta] - 1)}} \quad [4]$$

where $(i_{p\text{-}r})_l$ and $(i_{d\text{-}c})_l$ are limiting current densities for p-r and d-c plating, respectively. The asymptotic form for $a\theta << 1$ is, therefore

* Electrochemical Society Active Member.
[1] Present address: Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027.
Key words: *electroplating, gold.*

$$\left[\frac{(i_{p\text{-}r})_l}{(i_{d\text{-}c})_l}\right]_{a\theta<<1} = \frac{1}{1-\left(\frac{r-1}{r}\right)\frac{a\theta_2}{a\theta}} \qquad [5]$$

The over-all rate of plating which can be calculated by integrating over the entire cycle is

$$\frac{\text{Max over-all rate of p-r plating}}{\text{Max rate of d-c plating}} = \frac{(i_{p\text{-}r})_l\left(\theta_1+\frac{1}{r}\theta_2\right)}{(i_{d\text{-}c})_l\theta} = \frac{\left(\theta_1+\frac{1}{r}\theta_2\right)/\theta}{1-\frac{8}{\pi^2}\left(\frac{r-1}{r}\right)\sum_{j=1}^{\infty}\frac{1}{(2j-1)^2}\cdot\frac{(\exp[(2j-1)^2a\theta_2]-1)}{(\exp[(2j-1)^2a\theta]-1)}} \qquad [6]$$

Numerical results of Eq. [4] and Eq. [6] for various values of $a\theta$, θ_1/θ, and $1/r = -0.20$ are plotted in Fig. 2 and Fig. 3.

Experimental investigation of Eq. [6] was carried out using the same gold plating solutions under the same experimental conditions as reported in Ref. (3). The only difference appeared in the applied current densities. A calculation on the instantaneous cathodic limiting current density was first made for $(1/r) = -0.20$ by using Eq. [3]. To ensure the fact that the cathodic limiting current density was reached, an additional current of -3 mA (*i.e.*, -9.47 mA/cm^2) was added to the calculated $(i_{p\text{-}r})_l$ value and the total value was used as i_f. $(-0.20)\cdot(i_{p\text{-}r})_l$ was used as i_r. The results for phosphate, citrate, and cyanide (corrected for chemical dissolution of gold) gold solutions were given in Fig. 4-6.

Satisfactory agreement was observed between theory and experimental results for large values of θ_1/θ for all three solutions. However, for both phosphate and citrate gold solutions, the measured limiting rate of deposition was considerably higher than that from the theory for small values of θ_1/θ. A qualitative explanation for this disagreement can be obtained by considering the anodic dissolution of gold. Gold dissolves electrochemically according to the following two reactions

In alkaline medium

$$Au + 2CN^- \rightarrow Au(CN)_2^- + e^- \qquad [7]$$

In acid medium

$$Au + 2HCN \rightarrow Au(CN)_2^- + 2H^+ + e^- \qquad [8]$$

Since the dissociation constant of $Au(CN)_2^-$ is approximately[2] 3 x 10^{-35} at 60°C, the CN^- and HCN in phosphate and citrate gold solutions must essentially come from the cathodic part of the plating cycle. The small amount of these species may cause the anodic dissolution of gold to be inefficient and consequently

[2] Calculated from standard electrode potential data from W. M. Latimer, "Oxidation Potentials," 2nd Ed., Prentice-Hall, Englewood Cliffs, N. J. (1952).

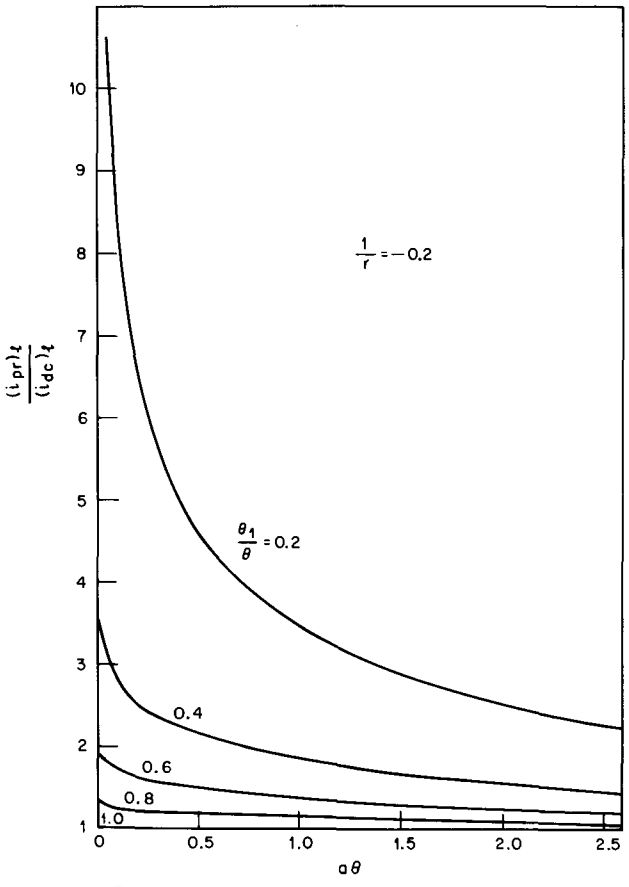

Fig. 2. Limiting current density for p-r plating

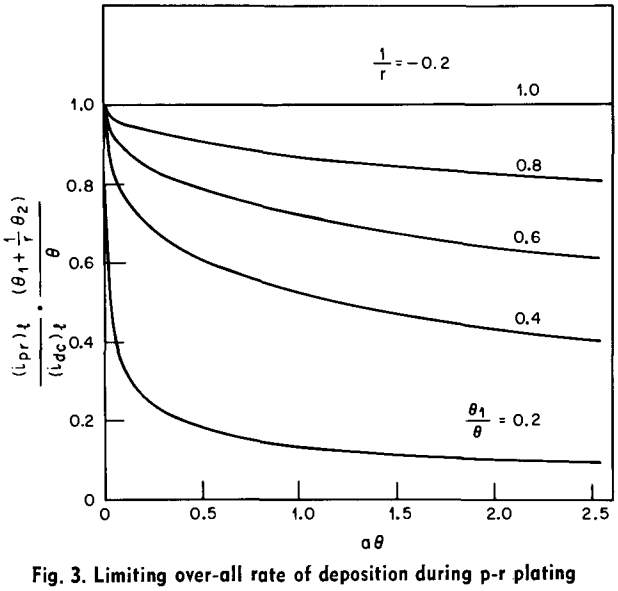

Fig. 3. Limiting over-all rate of deposition during p-r plating

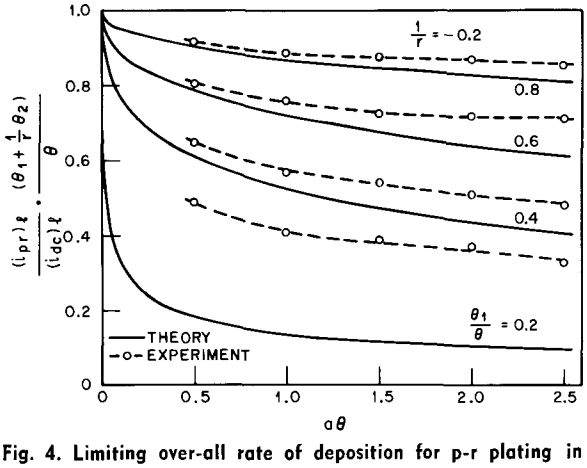

Fig. 4. Limiting over-all rate of deposition for p-r plating in a phosphate gold solution.

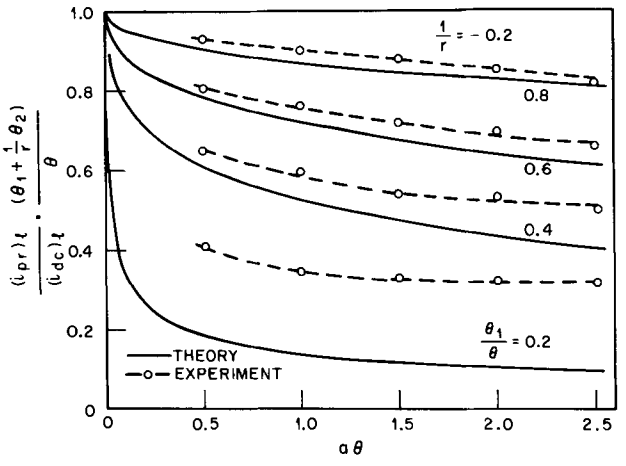

Fig. 5. Limiting over-all rate of deposition for p-r plating in a citrate gold solution.

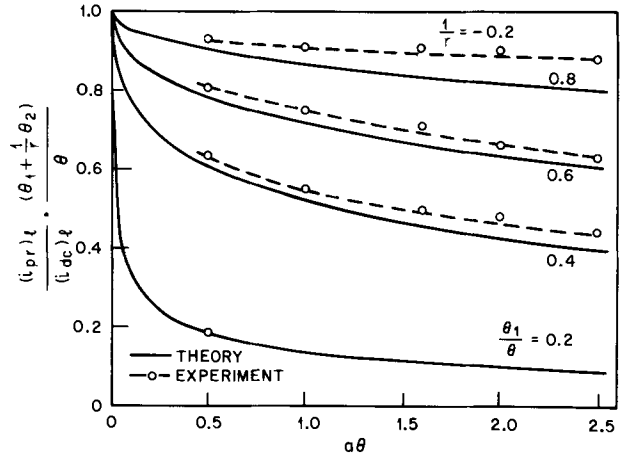

Fig. 6. Limiting over-all rate of deposition for p-r plating in a cyanide solution. Corrected for chemical dissolution of gold.

leads to a higher plating rate than that predicted from the theory. Other complexes involving citrate or phosphate with gold may also exist in the solution. However, their concentration is probably too low to cause a significant amount of dissolution of gold during the anodic part of the plating cycle. This is supported by the fact that no significant gold dissolution is found by applying an anodic current to a gold electrode in either the citrate or phosphate gold solutions.

In conclusion, the diffusion model adopted for p-r plating can be used to predict the limiting rate of deposition provided that anodic dissolution of the metal is at 100% current efficiency. A sample calculation on the application of this theory to a practical plating process is given here. Assuming the following data: $c_o = 0.1$ moles/liter, $D = 10^{-5}$ cm^2/sec, $\delta = 0.005$ cm (a typical thickness in a stirred solution), $n = 1$, $\theta = 50$ msec, $\theta_1/\theta = 0.6$, and $1/r = -0.20$, one can readily calculate $(i_{d\text{-}c})_l$, $(i_{p\text{-}r})_l$, and the limiting over-all rate of p-r plating.

$$(i_{d\text{-}c})_l = -nFD\frac{c_o}{\delta} = -19.3 \text{ mA/cm}^2$$

Since

$$a\theta = \frac{\pi^2 D}{4\delta^2}\theta = 0.0493,\ \theta_1/\theta = 0.6 \text{ and } 1/r = -0.20$$

from Fig. 2

$$\frac{(i_{p\text{-}r})_l}{(i_{d\text{-}c})_l} = 1.8$$

therefore

$$(i_{p\text{-}r})_l = -35 \text{ mA/cm}^2$$

From Fig. 3

$$\frac{\text{Limiting over-all rate of p-r plating}}{\text{Limiting rate of d-c plating}} = 0.92$$

therefore

$$\text{Limiting over-all rate of p-r plating} = -18 \text{ mA/cm}^2$$

Contacts for Resistivity Measurements of Beta-Alumina

R. D. Armstrong, T. Dickinson, and J. Turner

Electrochemistry Research Laboratories, Department of Physical Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, NE1 7RU, England

The determination of the conductivity of an ionic conductor is complicated by interfacial (electrode) effects. The cell impedance with two electrodes contacting the material under investigation can be represented to a good approximation (1) by the analog circuit of Fig. 1a, where the assumption is made that the interfacial regions are separated by a large number of Debye lengths.[1] In Fig. 1a, C_∞ represents the capacitance between the electrodes with the ionic conductor behaving as a dielectric material, while R_∞ is the bulk resistance. These quantities are virtually frequency independent, although C_∞ may show frequency-dependent effects due to dielectric relaxation. In solids, dipole relaxation can occur at comparatively low frequencies (kHz or less).

The interfacial impedance (Z_i) depends on the precise nature of the contacts. It can be represented as in Fig. 1b, where C_{dl}, R_{dl} represent the double layer (nonfaradaic path) and R_{ct} and W the faradaic path. It has recently been shown that these paths cannot be strictly separated since the one flux leads both to charge transfer and double-layer charging (2). The double layer is purely capacitative up to frequencies comparable with those at which the Debye-Falkenhagen relaxation occurs in the bulk material. For electrodes where charge transfer is not possible, $R_{ct} = \infty$. W is the Warburg impedance, which for β-alumina is negligible because of the high concentration of mobile species.

For $\omega \to \infty$, $Z_i \to 0$ so that for sufficiently high frequencies the cell impedance is R_∞ with C_∞ in parallel. Therefore, to determine the conductivity of the sample, it is sufficient to determine the cell impedance at such (high) frequencies that it can be represented by frequency-independent elements, R_p and C_p, which can then be identified with R_∞ and C_∞. Unfortunately, in a real cell, at high frequencies, the leads from the cell to the measuring equipment give rise to inductive effects and thus set an upper limit on the usable frequency.

In the present work, we have investigated the use of different electrodes for resistivity measurements on β-alumina. The electrodes which have been reported previously are summarized in Table I.

Key words: beta-alumina, conductivity, solid electrolyte.

[1] In β-alumina, the Debye length is ~0.1 nm.

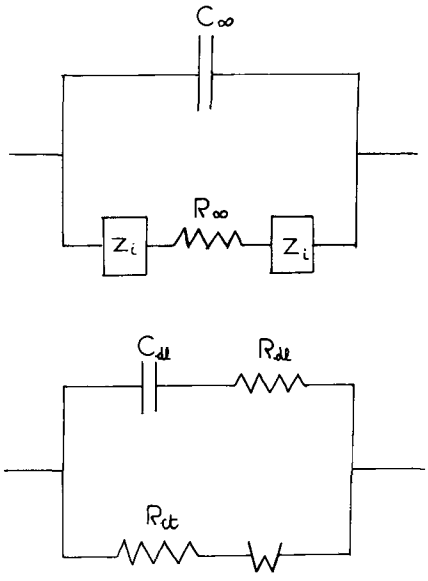

Fig. 1. Equivalent circuit for cell (a—top, b—bottom)

Experimental

Measurements were made on fully dense sintered β-alumina in the form of disks (thickness 1 mm, diameter 10 mm, English Electric) and on selected single crystals (cross section 3 mm x 0.5 mm, length 4 mm, Harbison Carborundum Company). The composition of these materials was near to $Na_2O \cdot 11\ Al_2O_3$.

Contact was made to the samples by means of

(i) molten $NaNO_3$ + Pt electrodes (320°-400°C)
(ii) molten $NaNO_3/NaNO_2$ + Pt electrodes (250°-350°C)
(iii) aqueous 5M $NaNO_3$ (30°-80°C)
(iv) evaporated gold electrodes (30°-300°C)
(v) sodium [5 w/o (weight per cent)]—mercury amalgam under an argon atmosphere (50°-300°C)

Table I. Resistivity measurements on β-alumina

Physical form	Contact	Frequency	Frequency dependence	Conductivity (ohm^{-1} cm^{-1})	Temp (°C)	Activation energy (kj mole^{-1})	Ref.
Single crystal	Indium	500 kHz	Const. from 0.5 to 1.5 MHz	$30 \pm 3 \times 10^{-3}$	25	11.1	(3, 4)
		500 kHz	—	285×10^{-3}	300		
	—	—	—	23×10^{-3}	25	14.0	This work
	—	—	—	355×10^{-3}	300		
Sintered disk (fully dense)	Na	1592 Hz	Frequency independent	36×10^{-3}	300	13.7	(5)
		1592 Hz	Frequency independent	20×10^{-3}	227	15.8	
	—	—	—	1.84×10^{-3}	25	14.0	This work
				28.5×10^{-3}	300		
Sintered disk (less than fully dense)	Ag/Ag_2O/5N NaOH	D.C.	—	$4\text{-}5 \times 10^{-3}$	25		(4)
	Na	D.C.	—	55×10^{-3}	300		
	Pt	800 kHz	—				

The sintered β-alumina was attached to within a Pyrex glass cell central glass tube with "Autostic" (Carlton Brown Limited, Elford, England), an alumina-based cement of negligible conductivity and apparently inert toward the molten salts and amalgam. The single crystals were also embedded in "Autostic," the ends of the crystal being polished flat after the cement had set. When aqueous contacts were used, the crystals were mounted in P.T.F.E. disks with "Araldite." When evaporated gold electrodes were used, spring-mounted platinum foil contacts were held against the gold; the results were not affected by increasing the pressure on these contacts. The glass cells were immersed in either an oil bath or a fluidized sand bath to control their temperature. System (iv) was held within a small temperature-controlled furnace.

Cell impedances were determined, over the frequency range 100 Hz-5 MHz, using transformer ratio-arm bridges, as equivalent R_p, C_p values (Wayne Kerr B221, B201). With systems (i)-(iii), the measured resistance was corrected for the cell resistance in the absence of β-alumina. These corrections generally amounted to less than 10%.

Results

The results obtained enable the contacts to be divided into three groups:

1. With the molten salt contacts, and the aqueous solution in contact with a single crystal, a satisfactory frequency range could be found where R_p was frequency independent ($f > 10$ kHz).
2. With Au and Na/Hg contacts at high temperatures and perhaps Au in contact with the single crystal at room temperature, R_p showed only a slight dependence on frequency at the highest usable frequencies (1 MHz).
3. With the amalgam contact, and the aqueous solution or gold in contact with the sinter, near room temperature, the highest frequency achievable (1 MHz) was obviously less than that necessary in order to identify R_p with R_∞.

We should therefore expect the conductivity measurements obtained with the systems in group 1 to be in accord with and not very different from those obtained with the members of group 2. The systems listed in group 3 should, however, show lower conductivities. This pattern of behavior is essentially confirmed by the results shown in Fig. 2 and 3. These graphs show the apparent conductivity of the single crystal (Fig. 2) and sinter (Fig. 3) as a function of temperature. The measurements were made at the highest usable frequency for each type of contact. With the single crystal, concordant results are obtained with the molten salt, aqueous, and high-temperature amalgam contacts. The results obtained with the Au contacts are in fairly satisfactory agreement with these, whereas a significantly lower conductivity was obtained with amalgam contacts at lower temperatures. With the sinter, the results obtained with the molten salt and high-temperature amalgam contacts are again

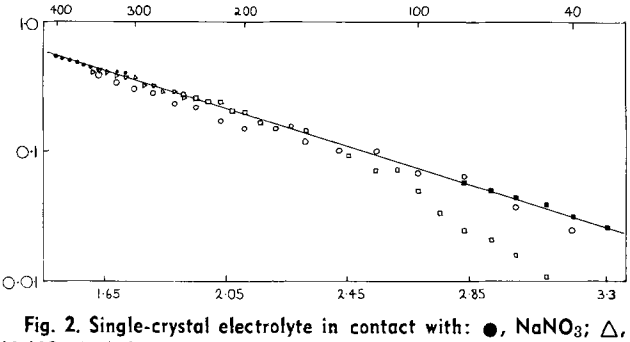

Fig. 2. Single-crystal electrolyte in contact with: ●, $NaNO_3$; △, $NaNO_3/NaNO_2$; ○, Au; □, Na/Hg; ■, aqueous $NaNO_3$. Ordinate, conductivity (ohm^{-1} cm^{-1}). Abscissa, $10^3/T$ (K^{-1}).

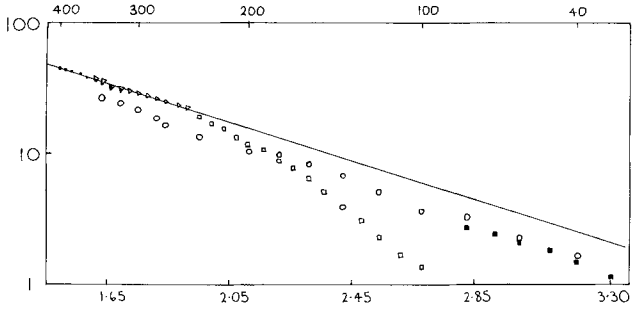

Fig. 3. Sintered electrolyte in contact with: ●, $NaNO_3$; △, $NaNO_3/NaNO_2$; ○, Au; □, Na/Hg; ■, aqueous $NaNO_3$. Ordinate, conductivity (ohm^{-1} cm^{-1}). Abscissa, $10^3/T$ (K^{-1}).

concordant. Somewhat lower conductivities are obtained with gold and aqueous contacts, assuming the graph should be linear. The amalgam contacts again gave significantly lower conductivities at lower temperatures. The lines on these graphs are believed to represent the true relation between conductivity and temperature.

Discussion

The reported results underline the need for study of the frequency dependence of the resistivity whenever conductivity measurements are being made. In the present work, the high interfacial impedance with amalgam contacts, particularly in the case of the ceramic at low temperature, gave rise to erroneously low conductivity values. This high interfacial impedance is probably due to nonwetting of the irregular surface of the ceramic by the amalgam.

The activation energies for ionic transport in the single crystal (14.0 kJ mole^{-1}) and sintered specimens (14.0 kJ mole^{-1}) are equal and in reasonable agreement with previously published values (Table I). The conductivity of the single crystal (0.355 ohm^{-1} cm^{-1} at 300°C) was considerably higher than that of the sinter (0.0285 ohm^{-1} cm^{-1}), presumably because of the lack of ordering of the crystallites in the latter. Differences of conductivity of similar magnitude have been observed previously. The conductivity values obtained for the two samples are in reasonable agreement with the published values (Table I).

Yao and Kummer (3) found an activation energy of 15.94 kJ mole^{-1} for diffusion in the single crystal, which compares well with the value of 15.86 kJ mole^{-1} for diffusion calculated from the conductivity data quoted by Weber and Kummer (4); whereas we obtain a value of 18.75 kJ mole^{-1} from our conductivity measurements.

The values of the diffusion coefficient at 300°C calculated from the Nernst-Einstein relationship on the basis of our results (3.3×10^{-5} cm^2 sec^{-1}) or those of Weber and Kummer (4) (2.66×10^{-5} cm^2 sec^{-1}) are not in accord with the value of 0.85×10^{-5} cm^2 sec^{-1} obtained by direct measurement (3). This discrepancy has been regarded as evidence supporting an interstitialcy mechanism for sodium ion migration.

Acknowledgments

We would like to thank British Rail for their support of this work, and Mr. J. L. Sudworth for helpful discussions.

Brief Communications

Mo-Permalloy Film Deposited on a Continuous Wire Substrate

William L. Wade, Jr., and Gordon Sands

United States Army Electronics Command, Electronic Components Laboratory, Fort Monmouth, New Jersey 07703

A nickel-iron permalloy composition containing molybdenum (79% Ni, 17% Fe, 4% Mo) has been successfully deposited on 0.005 in. diameter beryllium-copper wire. Previous attempts to electroplate (4-79) permalloy and other Mo substituted compositions have been disappointing (1). These newly developed films were deposited up to 4000Å thick using a modified continuous plating system. The development of these ternary compositions provides an additional family of plated wire materials for potential application in computer memories.

A continuous coating of magnetic molybdenum permalloy film was electroplated onto the wire in the presence of a circumferential magnetic field that established a magnetic anisotropy axis circumferentially around the wire (2, 3). Table I outlines a typical plating bath whose plating current was 22 mA. The current required to produce the preferred magnetization direction was 0.5A.

Both nondestructive readout (NDRO) and destructive readout (DRO) films were fabricated. The coercive force (H_c) ranged from 1.1 to 1.9 oersteds, and the anisotropy (H_k) ranged from 2.5 to 3.7 oersteds (4).

Key words: electrodeposition, cylindrical magnetic films, permalloy films, plated wire, magnetic film.

Qualitative determination of the presence of molybdenum was made using spectrographic instrumentation. Quantitative determination of the presence of molybdenum was made by analyzing nickel and iron spectrophotometrically, and taking molybdenum as the difference.

Manuscript received Mar. 11, 1971.

Oxygen Reduction on Tungsten Carbide

M. Voïnov,* D. Bühler, and H. Tannenberger

Institut Battelle, Carouge-Genève, Switzerland

Tungsten carbide WC has been found to be a good electrocatalyst for the oxidation of H_2, CO, N_2H_4, HCHO, and HCOOH (1, 2).

We wish to report that on this material the exchange current for oxygen reduction is of the same order of magnitude as on platinum in an acid medium ($HClO_4$ 1M).

Nonporous WC containing 0.1% Co (3) was heat-pressed in kel-F and mounted as a rotating electrode.

Water twice distilled in quartz was used with $HClO_4$ p.a. to make the electrolyte. Potentiostatted tensions are referred to a dynamic hydrogen electrode in the

* Electrochemical Society Active Member.

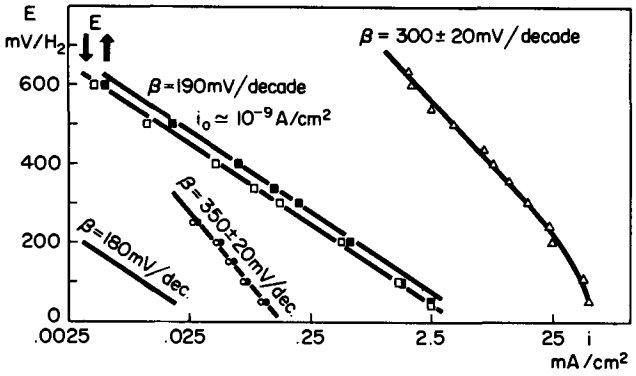

Fig. 1. Reduction of O_2 ($\simeq$ 1 atm) on WC, □ ■; Pyrocarbone, ——; and W, ○ ●. Reduction of H_2O_2 (0.04 M/liter, N_2) on WC: all measurements, $HClO_4$ 1M, 55°C, 1400 rpm.

same solution. Potential sweep (1 mV/sec) measurements were performed with nitrogen or oxygen bubbling in the thermostatted solution.

For unknown reasons, the electrode potential had to be swept at least 10 cycles between 0 and +700 mV/H_2 under nitrogen in order to obtain stable results.

The exchange current obtained by extrapolation to 1.23V of the E (log i) curve (Fig. 1) for O_2 reduction is 10^{-9} A/cm^2. The extrapolation to 1.23V is justified by the fact that H_2O_2 reduction does not appear to be rate determining in view of the relative Tafel slope for O_2 and H_2O_2 reduction on WC (Fig. 1).

The comparison between the electrocatalytic properties of WC and pure W and pyrocarbone (Fig. 1) for oxygen reduction illustrates the need for a solid-state physics approach to electrocatalysis.

Specific Adsorption of Sulfate Ions on Platinum

Sigmund Schuldiner* and Murray Rosen*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

Balashova and Kazarinov (1) in an analysis of their radioactive tracer work concluded that there was some specific adsorption of sulfate ions on Pt at the potential of zero charge (p.z.c.). They further concluded that, in the potential range positive to the p.z.c., the amount of sulfate ion which is superequivalent (surface excess) to the surface charge on Pt was very slight. In the presence of adsorbed oxygen, they postulated that the bond of sulfate ions adsorbed on Pt was of a chemisorptive nature.

Accurate determinations of the double-layer capacitance, C, (2, 3) and of the potential of zero charge (1, 3,4) now give a direct method of determining the dependence of surface charge, $q_M = -\int_{p.z.c.}^{E} CdE$, on Pt with potential, E. Hence, any superequivalency of sulfate ion adsorption should be directly apparent from a comparison of q_M positive to the p.z.c. with Balashova and Kazarinov's [(1), Fig. 10] and of Schuldiner, Rosen, and Flinn's (5, 6) data on sulfate ion adsorption, $q_{SO_4^=}$, with potential. Figure 1 shows such comparisons.

The q_M curve shown in Fig. 1 is for 1M H_2SO_4 and was determined by graphically integrating under the C *vs.* E curves given in Ref. (2, 3) from the p.z.c. (0.23V) to a given E. Determination of q_M for lower concentrations of sulfuric acid would give lower values of q_M. However, for the referenced data (2, 3), the q_M values will be lowered only by less than 3 μC/cm^2. The Balashova and Kazarinov $q_{SO_4^=}$ results (1) were for 0.05M H_2SO_4 in N_2-saturated solution. All of the Schuldiner, Rosen, and Flinn $q_{SO_4^=}$ values (5, 6) were for 1M H_2SO_4 in H_2-saturated solutions. In these H_2-saturated solutions, there is no interference due to oxygen adsorption at potentials below 1.0V (6).

A comparison of the Balashova and Kazarinov $q_{SO_4^=}$ in Fig. 1 with q_M shows a superequivalency of sulfate ions at all potentials from the p.z.c. (0.23V) to 0.8V. At potentials above 0.8V, oxygen adsorption interferes with anion adsorption in the N_2-saturated Balashova and Kazarinov solution. The Schuldiner, Rosen, and Flinn $q_{SO_4^=}$ values (5, 6) generally confirm the superequivalency of sulfate ion adsorption and hence show significant specific adsorption of these anions. Oxygen atoms did not interfere for this latter case at potentials below 1.0V.

The $q_{SO_4^=}$ values for the Schuldiner, Rosen, and Flinn data represent the decrease in Pt sites available for the adsorption of oxygen atoms generated during

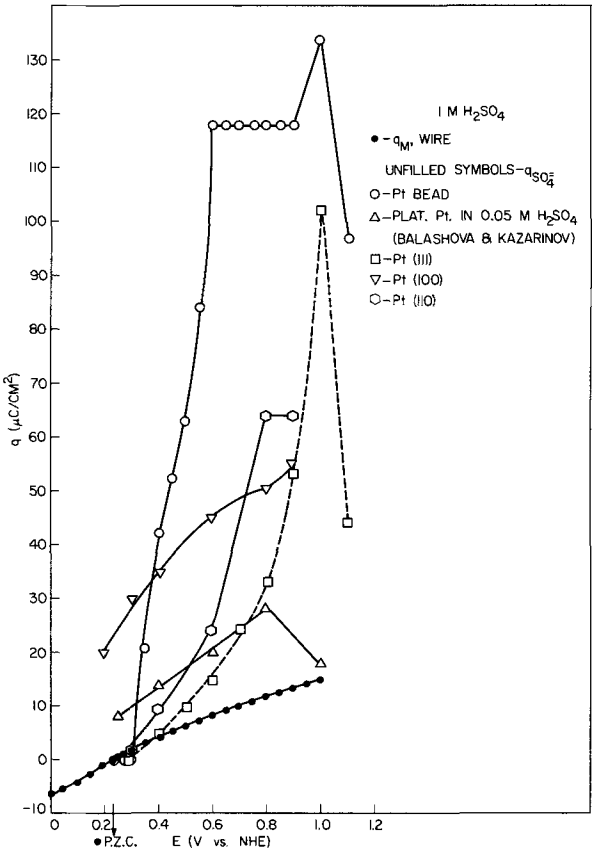

Fig. 1. Surface charge, q_M, compared to $q_{SO_4^=}$ for various Pt electrodes.

* Electrochemical Society Active Member.

Key words: anion adsorption, sulfate ion, platinum, double-layer capacitance, potential of zero charge, surface charge, surface excess.

rapid anodic charging; that is, based on the assumption that, for a bare Pt electrode, 420 $\mu C/cm^2$ of charge will be consumed to form one monolayer of oxygen atoms at 1.76V. When less charge is required, then that loss in charge is assumed to be due to the blocking of active Pt sites by $SO_4^=$ ions. The number of Pt sites which would be occupied by each sulfate ion is not known, and the assumed one-to-one correspondence may not hold, or indeed the ions may be bisulfate. If the sulfate ions are not specifically adsorbed, then the only important consideration is the net number of negative charges on the solution side of the double layer. It is difficult to see how sulfate ions which were not specifically adsorbed would block Pt sites. In any case, as high as ten times too many Pt sites are blocked as can be accounted for by q_M.

There are significant differences in the Balashova and Kazarinov data as compared to the Schuldiner, Rosen, and Flinn data. The latter not only show that the presence of H_2 increases the potential at which oxygen is first adsorbed, but also show that metallurgical factors are important. A twenty-time increase in the sulfuric acid concentration used by Balashova and Kazarinov may give a closer agreement with the 1M data shown in Fig. 1. However, there are significant variations that are due to the metallurgical differences between platinized Pt, bright polycrystalline Pt, and oriented faces of single Pt crystals. At the p.z.c. for the Pt wire, the platinized Pt shows a superequivalency of sulfate ions, as does the (100) oriented single Pt crystal. All of the other Pt electrodes show no significant excess of sulfate ions below 0.3V and, for the (111) orientation, no excess is found up to at least 0.4V. From these comparisons, it is apparent that the atom geometry, grain boundaries, dermasorbed and surface impurities associated with the metal, and stresses in the surface layers of Pt may affect both the p.z.c. and the *C vs. E* relation that thereby influences the specific adsorption of sulfate ions.

Electrolytic Behavior of Yttria[1]

Jon Schieltz,[2,*] John W. Patterson,[*] and D. R. Wilder

Institute for Atomic Research and Departments of Ceramic Engineering and Metallurgy, Iowa State University, Ames, Iowa 50010

ABSTRACT

The electrolytic behavior of Y_2O_3 was investigated. Within the temperature range 700°-1000°C, there is no electrolytic domain ($t_{ion} \geqq 0.99$), however, a small ionic domain ($t_{ion} \geqq 0.5$) does exist and is defined within the following boundaries

$$\log P_{\oplus} = \frac{11{,}030}{T(°K)} - 15.84$$

and

$$\log P_{\ominus} = \frac{-35{,}300}{T(°K)} + 15.59$$

Yttrium sesquioxide, Y_2O_3, is the only known solid oxide of yttrium. At room temperature and under one atmosphere pressure it possesses the cubic rare earth type C structure (Ia3) (1, 2) with 16 sesquioxide formula units per unit cell. The C-type rare earth structure is almost identical to the fluorite structure (3, 4) except that the lattice points are slightly displaced and ¼ of the anions are missing to balance the trivalent cation charge. These open sites are aligned to form relatively open pathways that could serve as high conductivity paths for oxide ions. Therefore the emf measurements described below were undertaken to determine the log P_{O_2} and $1/T$ ranges, if any, wherein Y_2O_3 exhibits predominantly ionic conductivity (5-8).

Noddack and co-workers (9-11) determined the electrical conductivity of yttria, many of the rare earth oxides, and several rare earth oxide binary solid solutions and zirconia-yttria solid solutions. Their results suggested that Y_2O_3 is a predominant electronic conductor over the temperature range from 600° to 1200°C.

More carefully controlled conductivity measurements on yttria have been made by Tallan and Vest (12). The electrical conductivity of reportedly very pure, polycrystalline Y_2O_3 in controlled P_{O_2} atmospheres and temperatures from 1200° to 1600°C was obtained from guarded (3-probe) measurements with an a-c bridge. The data indicated that yttria is an amphoteric semiconductor over the temperature range 1200°-1600°C and oxygen partial pressures from 10^{-1}-10^{-17} atm. Within this region the ratio of ionic to electronic conductivity was determined to be less than 1% by a blocking electrode polarization technique. In the region of predominant hole conduction, the conductivity in ohm^{-1} cm^{-1} was expressed by the relationship

$$\sigma_{ac} = \sigma_{\oplus} = 1.3 \times 10^3 P_{O_2}^{3/16} \exp(-1.94/kT) \quad [1]$$

where 3/16 power pressure dependence was attributed to fully ionized yttrium vacancies. Polarization effects detected at lower temperatures indicated that the ionic transference number at $P_{O_2} = 10^{-15}$ atm was about 0.15 at 800°C and about 0.3 at 700°C, indicating mixed conduction in yttria below 900°C.

While investigating the defect structure of ThO_2-Y_2O_3 solid solutions, Subbarao *et al.* (13) measured the electrical conductivity of undoped yttria in air between 800° and 1400°C. The activation energy for conduction agreed quite well with that reported by Tallan and Vest (12).

In contrast to the conductivity measurements, galvanic cell emf measurements indicate a much higher ionic transference number for yttria. Such measurements by Schmalzried (6) and Tare and Schmalzried (14) indicate that the ionic domain boundaries for Y_2O_3 at 825°C are

$$\log P_{\oplus}(Y_2O_3, 825°C) = -4.2 \quad [2]$$

$$\log P_{\ominus}(Y_2O_3, 825°C) = -21.5 \quad [3]$$

These values imply that t_{ion} of Y_2O_3 is about 0.975 at $T = 825$°C and $P_{O_2} = 10^{-15}$. Subsequently Schmalzried's closed-end tube cell design (5, 6) was used by McPheeters *et al.* (15) who employed a Y_2O_3 tube as a solid electrolyte electrochemical cell for measuring oxygen activities in liquid sodium. The calibration curve given in the patent implies that Y_2O_3 has an ionic transference number of unity at extremely low oxygen activities in the temperature range from 400°-500°C.

The previously reported results for Y_2O_3 are compared in Fig. 1 which also shows the log P_{O_2} *vs.* $1/T$ trajectories corresponding to Na,Na_2O coexistence and various concentration levels of oxygen dissolved in liquid Na.[3] The log $P_{\ominus}$, $1/T$ boundary (A) is estimated conservatively from the work of McPheeters

[3] To avoid unnecessary duplication later, Fig. 1 also shows the log $P_{\oplus}$, the p to n transition and the log $P_{\ominus}$ lines deduced in the present study and discussed below.

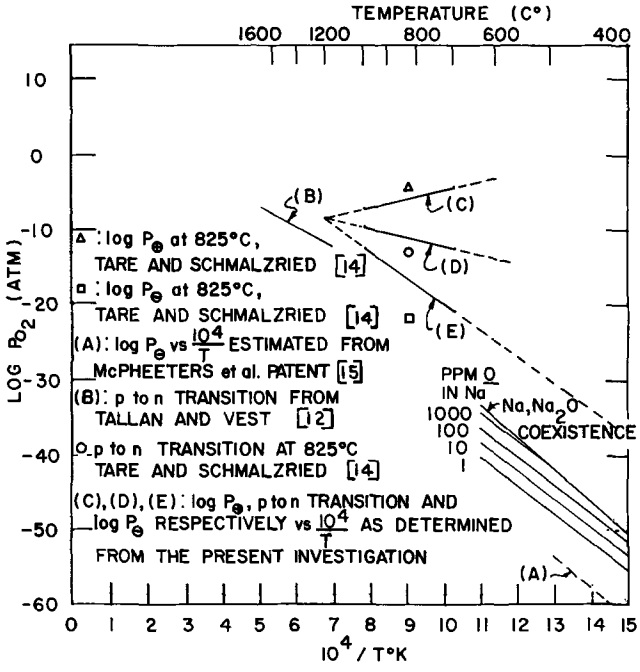

Fig. 1. Comparison of ionic domain boundary data for undoped Y_2O_3.

et al. (15) by placing (A) 7 log units below the 10 ppm trajectory. The data reported by Tallan and Vest (12) cannot be quantitatively converted into log $P_\oplus$ and log $P_\ominus$ domain boundaries without considerable additional assumptions regarding the temperature dependence of the ionic conductivity of Y_2O_3. However, the p-type to n-type conductivity transition line was deduced from their conductivity minima (12) and is shown on Fig. 1 as line (B).

Since no investigation was known to have established the ionic domain and electrolytic domain boundaries for Y_2O_3 over a range of temperatures, the present emf study was undertaken to determine the temperature dependence of the ionic domain boundaries log $P_\oplus$ and log $P_\ominus$ for Y_2O_3 over the temperature range from 700° to 1000°C.

Experimental Procedure

The yttrium sesquioxide used was supplied by the Ames Laboratory as an oxide calcination product of hydrated yttrium oxalate. A spectrographic analysis is given in Table I. The oxide was wet ground for 1 hr in a porcelain ball mill using distilled water as the liquid medium and dried to a powder. Spectrographic analysis failed to detect any contamination from the milling. Analysis showed the average agglomerate size to be 5-10μ with a crystallite size of 0.1-0.2μ. A theoretical density of 5.030 g/cm^3 was calculated from a lattice parameter of 10.6066Å which was determined from several x-ray patterns.

Table I. Spectrographic analysis of Y_2O_3

Element	Concentration (ppm)
Ca	20

Er	<100
Ho	<60
Dy	<100
Gd	<100
Tb	<200
Sm	<250
Total	1570

Sample batches were prepared by four different methods:

(*a*) Samples were prepressed at 1800 psi in a ¾ in. diam double action steel die lined with tungsten carbide. The prepressed disks were isostatically pressed to 50,000 psi and sintered in a covered yttria crucible at 1850°C for 1 hr in an oxidizing atmosphere. The final bulk densities ranged from 85 to 90% of theoretical density.

(*b*) Prepressed ¾ in. diameter specimens were sintered in argon for one hour at 2000°C. Bulk densities were 90-95% of theoretical with a significant amount of closed porosity.

(c) Samples were hot pressed in graphite dies to achieve densities approaching theoretical. Densification was done at 1600°C and a pressure of 3300 psi for 15 min. After the samples were annealed (oxidized) in air at 1200°C for one week, the densities were greater than 99% of theoretical.

(*d*) Slip casting was also used to fabricate several disks. The slip was cast and allowed to stand 1 min. The slip-cast disks were prefired in air at 1000°C, and finally sintered in argon for 1 hr at 1900°C. Densities were greater than 97% of theoretical. This method gave the most reproducible densities and the specimens appeared translucent.

After firing, all specimens were diamond ground to produce parallel faces. Figure 2 shows typical microstructures for methods (*a*), (c), and (*d*). Argon sintering at 2000°C yields microstructures highly similar to air sintering at 1850°C.

The cell assembly and furnace chamber are essentially those described by Hardaway *et al.* (16). Cell assemblies employing reversible metal-metal oxide electrodes were contained in an inert atmosphere of purified helium. The tank helium was passed through a Pyrex gas purification train with the following reaction chambers in series: activated BTS Catalyst at 160°C; a mixture of activated alumina, Drierite, and Anhydrone; Ascarite; and a liquid nitrogen cold trap. For controlled atmospheres of high oxygen pressures, dried tank oxygen, dried air, and He/O_2 ratios of 10

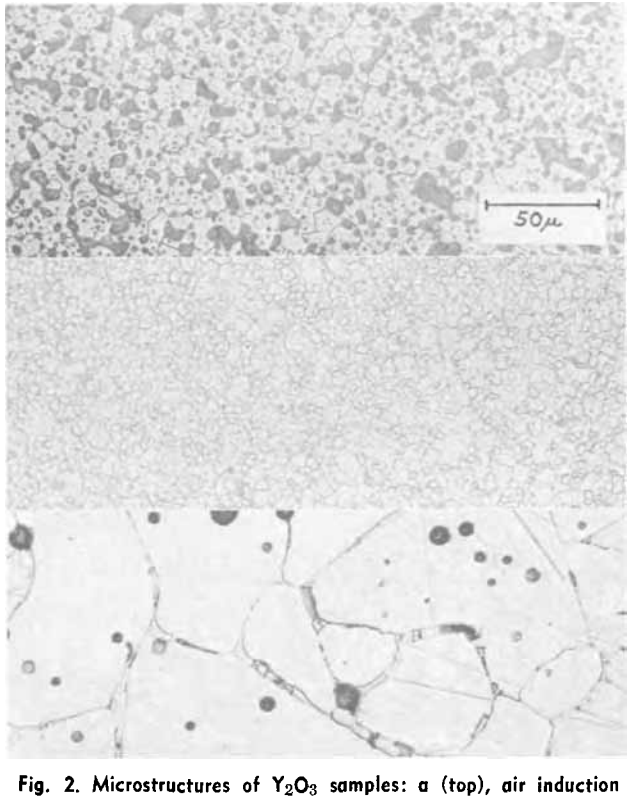

Fig. 2. Microstructures of Y_2O_3 samples: a (top), air induction fired, 280X; b (middle), hot pressed, 280X; c (bottom) slip cast, 280X.

Table II. Equilibrium oxygen activities for reversible electrodes

Electrode	Standard free energy change (cal/mole O_2)	$-\text{Log } P_{O_2}$(atm) at 1000°C	Reference
Cu-Cu_2O	$-79{,}850 + 34.2T$	6.24	17
Ni-NiO	$-111{,}930 + 40.6T$	10.34	18
Co-CoO	$-112{,}950 + 34.4T$	11.88	19
Y-Y_2O_3	$-279{,}500 + 48.1T$	37.46	20

and 100 were established with the help of a calibrated Matheson Gas Proportioner. Low oxygen partial pressures were established by CO_2-CO mixtures also controlled by the gas proportioner.

Open-circuit emf measurements were made using reversible metal-metal oxide electrodes with cells of the type

$$\text{Pt;M,MO/}Y_2O_3\text{/M',M'O;Pt} \qquad \text{(Cell I)}$$

where M,MO and M',M'O represent mixtures of dissimilar metals with their respective oxides.

The reversible electrode mixtures were prepared to give a 10:1 molar ratio of metal to metal oxide at equilibrium. Equilibrium oxygen activities for the reversible metal-metal oxide electrodes used in this investigation are listed in Table II.

Fe-FeO was eliminated as a possible electrode material since it was found to react with Y_2O_3 to form the compound $YFeO_3$ as pointed out by Worrell (21).

Results

Figure 3 shows the raw data obtained from the emf cell investigated. The distances between the dotted lines on Fig. 3 indicate the thermodynamic emf's for the corresponding reversible electrodes, *i.e.* the emf's that would result if the yttria specimen had t_{ion} unity. In all cases the measured emf's fell significantly short of the thermodynamic values.

The following cells were employed to study Y_2O_3 at low oxygen activities

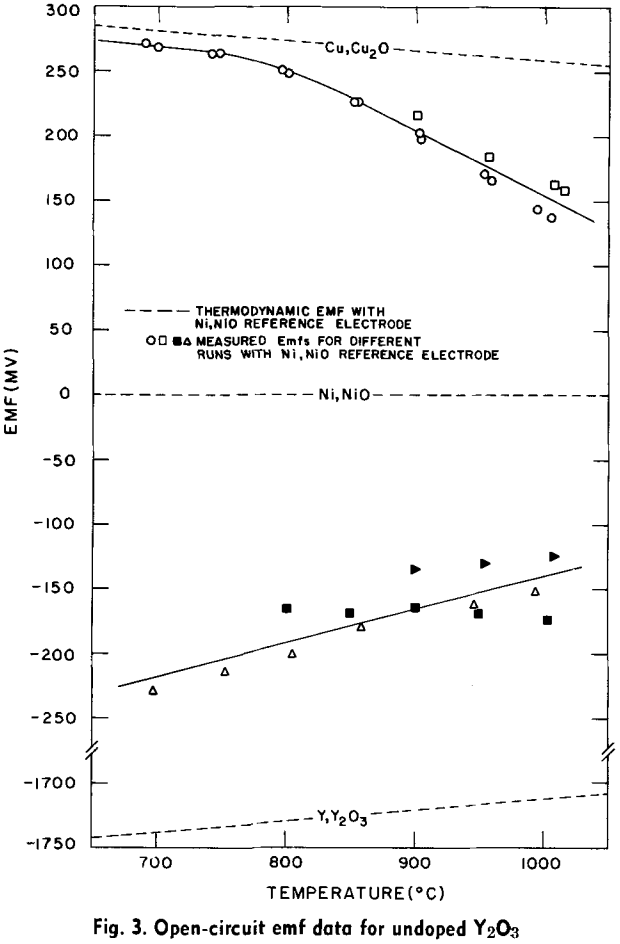

Fig. 3. Open-circuit emf data for undoped Y_2O_3

$$\text{Ni,NiO/}Y_2O_3\text{/Y,}Y_2O_3 \qquad \text{(Cell II)}$$

and

$$\text{Co,CoO/}Y_2O_3\text{/Y,}Y_2O_3; \qquad \text{(Cell III)}$$

however, reliable emf's were not obtained from Cell III. The emf data from Cell II are plotted as distances below the Ni,NiO dotted line. No data from Cell III are shown.

The cell

$$\text{Ni,NiO/}Y_2O_3\text{/Cu,}Cu_2O \qquad \text{(Cell IV)}$$

was used to study galvanic emf's from yttria under relatively oxidizing conditions. Emf's from this cell are plotted as distances above the Ni,NiO dotted line. Below 800°C the open circuit emf almost paralleled the thermodynamic emf based on Cu-Cu_2O equilibrium, whereas increasing the temperatures above 800°C caused the measured emf's to systematically decrease with respect to the thermodynamic values. Qualitatively, this behavior indicates that $P_\oplus$ is on the order of P_{O_2} for Cu,Cu_2O coexistence and, in fact, that $P_\oplus$ crosses the Cu,Cu_2O coexistence line.

To interpret the open circuit emf's quantitatively in terms of $P_\oplus$ and $P_\ominus$ values at various temperatures, an elaborate trial and error procedure was employed. The over-all procedure determines the linear function for log $P_\oplus$ and log $P_\ominus$ *vs.* $1/T$ which yields the closest fit of the observed emf data according to Schmalzried's equation (6)

$$E = \frac{RT}{\mathbf{F}w}\left\{ \ln \left| \frac{1 + w + 2\beta}{1 + w + 2\alpha} \right| + \ln \left| \frac{1 - w + 2\alpha}{1 - w + 2\beta} \right| \right\}_{P'_{O_2}}^{P''_{O_2}} \qquad [4]$$

where the reversible electrode P_{O_2} values P'_{O_2} and P''_{O_2} can be calculated from Table II and where

$$w = \{1 - 4[P_\ominus/P_\oplus]^{1/4}\}^{1/2} \qquad [5]$$

$$\alpha = [P'_{O_2}/P_\oplus]^{1/4} \qquad [6]$$

$$\beta = [P''_{O_2}/P_\oplus]^{1/4} \qquad [7]$$

A first approximation to log $P_\ominus$ was obtained from the following simplified form of Eq. [4]

$$E = \frac{RT}{4\mathbf{F}} \ln \frac{P''_{O_2}}{P_\ominus} \qquad [8]$$

where E is the emf measured from cell II, T is the temperature of the emf measurement and P''_{O_2} is the P_{O_2} for Ni,NiO coexistence. A least squares fit of these log $P_\ominus$ values to the formula

$$\log P_\ominus = A_\ominus + B_\ominus/T \qquad [9]$$

gives values for $A_\ominus$ and $B_\ominus$.

Next the measured emf's of cell IV are considered. Equation [9] was used to calculate the $P_\ominus$ value corresponding to each emf measurement from cell IV. This value of $P_\ominus$ was then inserted into Eq. [4] with P''_{O_2} and P'_{O_2} now set equal to the coexistence values for Cu,Cu_2O and Ni,NiO equilibrium respectively. The value of $P_\oplus$ was then adjusted until the calculated emf matched the value measured from cell IV at each experimental temperature. These $P_\oplus$ values were then fitted to the formula

$$\log P_\oplus = A_\oplus + B_\oplus/T \qquad [10]$$

to obtain best fit values for $A_\oplus$ and $B_\oplus$. Thus an approximate value of $P_\oplus$ could be calculated for each emf measurement made on cell II. This value of $P_\oplus$ was put into Eq. [4] with P'_{O_2} corresponding to Y,Y_2O_3 coexistence and P''_{O_2} corresponding to Ni,NiO coexistence. The value of $P_\ominus$ was then adjusted until the emf calculated from Eq. [4] matched the value measured from cell II at each temperature. This provides a new set of log $P_\ominus$ values to replace the first approximations and hence completes one full cycle of the iter-

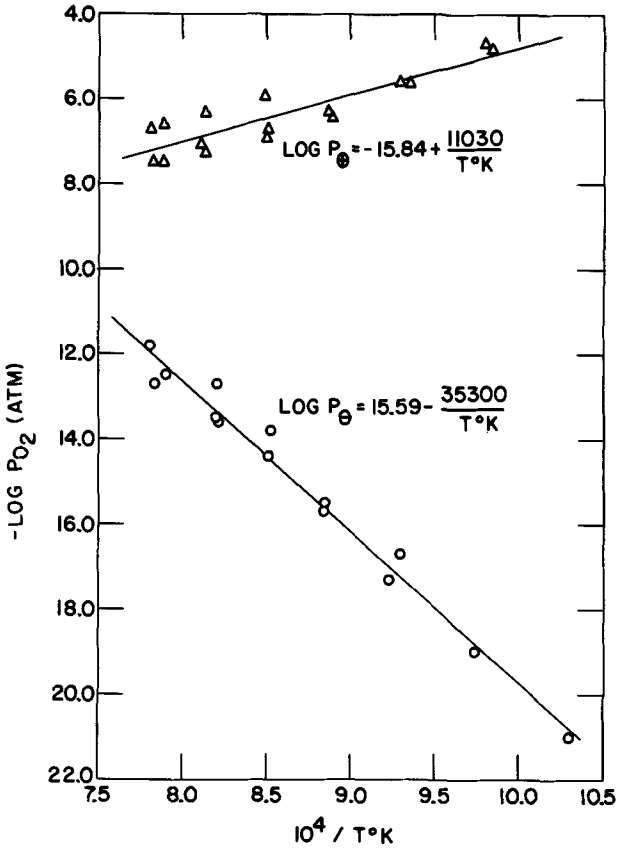

Fig. 4. Ionic domain boundaries for undoped Y_2O_3

ation scheme. This iteration cycle was repeated until the successive values of log $P_\oplus$ and log $P_\ominus$ changed by less than 0.1 at each experimental temperature. The resulting values are plotted in Fig. 4. The final least squares best fit values for the A and B parameters gave the following analytical expressions

$$\log P_\oplus = \frac{11{,}030}{T(°K)} - 15.84 \qquad [11]$$

$$\log P_\ominus = \frac{-35{,}300}{T(°K)} + 15.59 \qquad [12]$$

Values of t_{ion} of Y_2O_3 as a function of P''_{O_2} were calculated from Eq. [11], [12], and the formula

$$t_{ion} = [1 + [P''_{O_2}/P_\oplus]^{1/4} + [P''_{O_2}/P_\ominus]^{-1/4}]^{-1} \qquad [13]$$

for T = 1000°, 900°, 800°, 700°, and 400°C. The results are summarized in Fig. 5 which illustrates that t_{ion} is less than 0.99 at all P_{O_2} values between 700° and 1000°C.

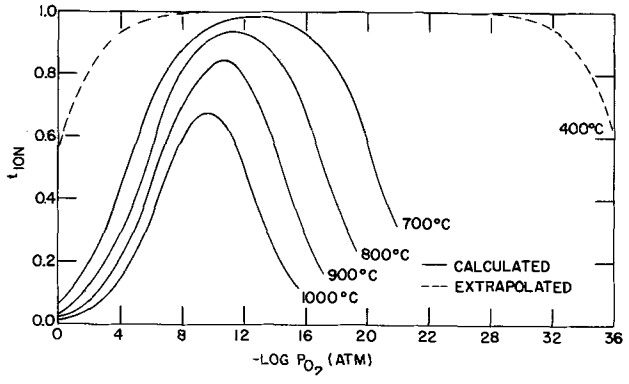

Fig. 5. Ionic transference number of undoped Y_2O_3 as a function of oxygen partial pressure determined from emf measurements.

Discussion

Figure 1 compares the ionic domain boundaries for Y_2O_3 determined by the present study with the previously reported results. The discrepancy between the present results and those reported by Tare and Schmalzried (14) is relatively minor but exceeds the scatter of points shown in Fig. 4. The p to n transition line deduced from Tallan and Vest conductivity minima (12) disagrees more significantly with the present study in which the p to n transition line is taken to be the locus of points equidistant between log $P_\oplus$ and log $P_\ominus$ at each temperature. Qualitatively the present study confirms the increase in t_{ion} with decreasing temperature that was suggested by Tallan and Vest (12). Since none of the yttria specimens used by Tare and Schmalzried, Tallan and Vest and none of those in the present study were intentionally doped, it is conceivable that the discrepancies are due to relatively minor differences in the concentrations of impurities.

The discrepancy between the present results and the results of McPheeters *et al.* (15) requires more discussion. Extrapolation of the present ionic domain boundary results to the 400°-500°C temperature range shows that the log P_{O_2} 1/T domain of liquid Na with dissolved oxygen is substantially below log $P_\ominus$. Because t_{ion} would be essentially zero, this means that no meaningful emf's should be observed from high purity Y_2O_3 electrolytes under the conditions reported by McPheeters *et al.* The following possible explanations of this discrepancy can be offered.

First of all the straight line extrapolation of log $P_\ominus$ is valid only as long as no transformations occur which can alter the conduction mechanisms for ionic and/or electronic transport. However a first order phase transformation would alter both types of conduction significantly, producing a discontinuity in the log $P_\ominus$ boundary and in its slope at the transformation temperature. Since no first order phase transformation for Y_2O_3 is known to occur in Y_2O_3 between 1000° and 500°C this possibility would seem to be ruled out at present.

However a significant change in slope of the log $P_\ominus$ line can occur if the iso-P_{O_2} activation energies of either the oxygen ion or the electronic conduction modes changes in an intermediate temperature range (8). Since this can occur without a first order phase transformation, such a possibility can not be ruled out until emf measurements of the type described above, are carried out over the intermediate temperature ranges.

Another explanation is the possibility that sodium ions from the liquid sodium electrodes dissolved as substitutional ions into the Y_2O_3 tube used in McPheeters' *et al.* study. The valence difference between Na and Y ions could greatly enhance the concentration of oxygen vacancies, much as substitutional Y ions do in the oxide solid electrolyte ZrO_2 + 7.5 m/o Y_2O_3. This would require substantial solubility and diffusivity for Na in Y_2O_3 at the low temperatures. The observed inertness of Y_2O_3 to liquid Na would seem to rule out this possibility; however a mixed conduction galvanic cell investigation of Y_2O_3-Na_2O solid solutions may be in order.

Conclusion

Undoped Y_2O_3 is a mixed conductor showing a narrow ionic conduction domain ($t_{ion} \geqq 0.5$) but no electrolytic domain ($t_{ion} \geqq 0.99$) within the temperature range (700°-1000°C) studied. The ionic domain boundaries for Y_2O_3 may be represented by

$$\log P_\oplus = \frac{11{,}030}{T(°K)} - 15.84$$

and

$$\log P_\ominus = \frac{-35{,}300}{T(°K)} + 15.59$$

High-Conductivity Solid Electrolytes: C_aH_bNI-AgI Double Salts

Boone B. Owens,* J. H. Christie,[1] and G. Trent Tiedeman[2]

Gould Ionics Inc., Canoga Park, California 91304

ABSTRACT

Substituted ammonium iodides combine with silver iodide to form solid electrolytes that exhibit high ionic conductivities at ambient temperature. The formation of conductive compounds is related to the size of the organic ammonium ion. Results are given for a large number of syntheses.

With the recent discoveries of high-conductivity solid electrolyte materials (1-5) there has been a renewed interest in the field of solid-state electrolytes and related electrochemical devices. Previously, high-conductivity solid materials were known only at elevated temperatures. The largest group of solid electrolytes that has been reported is the tetraalkylammonium iodide-silver iodide group (5). Ten compounds were reported that have ionic conductivities in the range of 8×10^{-4} to 6×10^{-2} (ohm cm)$^{-1}$ at 22°C and electronic conductivities of less than 10^{-10} (ohm cm)$^{-1}$. In order to extend the area of investigation of solid electrolytes, the present study of the electrical properties of the products formed between silver iodide and hydrocarbon substituted ammonium iodides, C_aH_bNI (a and b are integers), was undertaken.

Experimental

Mallinckrodt silver iodide (nominally 99% pure) was used without further purification. The substituted ammonium iodide salts QI were obtained commercially from either Eastman Organic Chemicals, Division of Eastman Kodak Company, or Aldrich Chemical Company, Inc., or else were prepared from reagents obtained from these suppliers. The reported purities of the organic materials were in the range of 95-99%; these materials were used without further purification.

Where it was necessary to synthesize the substituted ammonium iodides, they were made by combining the suitable amine with an alkyl iodide. The conducting electrolytes were prepared by combining AgI with QI, as previously described (5), in the molar ratio of n

$$QI + n\,AgI \rightarrow Q\,Ag_nI_{n+1}$$

The method for determining the conductivity has been previously described in some detail (5, 6). The resistance cells were ½ in. diameter pressed powder pellets containing the three layers, Ag, $RbAg_4I_5$/Sample/Ag,$RbAg_4I_5$. Sample weights were normally 2g which resulted in resistance values ranging from about 4 ohms for products with specific conductivities of 0.07 (ohm cm)$^{-1}$ up to $> 10^6$ ohms for nonconductive products. Contact resistance can contribute significantly to the total cell resistance; it was reported for $RbAg_4I_5$ that 0.3 ohm (or 30%) of the cell resistance was due to contact resistance (6). The reproducibilities of the resistance measurements on identical samples of the tetraalkylammonium iodide-silver iodide salts were observed to be about 10-25%. The results of the present study (in which the contact resistance was not measured) are estimated to be accurate to about ± 30%.

The phase diagrams for the 58 binary salt systems investigated here have not been reported; therefore the selection of compositions for resistance measurements is somewhat arbitrary. The five organic ammonium iodide-silver iodide systems for which the composition-conductivity function has been determined formed conductive phases at compositions of between 80 and 90 m/o (mole per cent) silver iodide

[2] Present address: Weyerhaeuser Research, 3400 13th Avenue, S.W., Seattle, Washington 98134.

Key words: conductivity, quaternary ammonium iodide, silver iodide, solid electrolyte, solid-state electrochemistry, substituted ammonium iodide, tetraalkylammonium iodide.

(5, 7, 8). It was assumed in the present investigation that if conductive phases are formed, they would contain this same amount of silver iodide. In general, then, the conductive products must be assumed to contain a resistive phase as well as the conductive phase. Further detailed investigation of each of the binary systems reported here is necessary to determine the precise stoichiometry of the conducting phases. (The only structure known is that of $[(CH_3)_4N]_2Ag_{13}I_{15}$ which was reported by Geller and Lind (7).) The purpose of the present investigation was to determine the extent of the formation of conductive compounds between silver iodide and hydrocarbon substituted ammonium iodide salts as a function of the substituted ammonium ion, and did not require preparation of single-phase products.

Densities were measured only for the most electrically conductive products. This was done as previously described (5). Where the densities were not measured, the reported specific conductivities were calculated from the sample resistance and an approximate density.

Results and Discussion

The set of hydrocarbon substituted ammonium iodide salts was divided into the following subsets for the present study:

Subset 1—Completely substituted acyclic alkyl ammonium iodide (*e.g.*, Me_4NI).
Subset 2—Partially substituted acyclic ammonium iodide (*e.g.*, MeH_3NI).
Subset 3—Saturated azacyclic substituted ammonium iodide (*e.g.*, pyrrolidinium iodide).
Subset 4—Unsaturated azacyclic substituted ammonium iodide (*e.g.*, pyridinium iodide).
Subset 5—Carbocyclic, aryl, benzyl or allyl substituted ammonium iodides.

This breakdown of hydrocarbon substituted ammonium iodide salts is based partially on structural groups and partially on the availability of materials for test. The selection of compounds was sufficient to permit the testing of the extent to which conductive electrolytes $C_aH_bNI \cdot nAgI$ are formed and to form some empirical rules governing the formation of conductors.

Subset 1, the acyclic tetraalkylammonium iodide-silver iodide electrolytes, has already been reported (5). The results for our investigation of subset 2 are given in Table I. Without exception, no conductive electrolytes were formed between AgI and the partially substituted acyclic alkyl ammonium iodides, in direct opposition to what we would have expected based on results obtained with both ammonium iodide (3, 4) and the acyclic tetraalkylammonium iodides (5). Apparently, in the acyclic alkyl ammonium ions, the presence of an N-H bond introduces enough asymmetry or polarity to prevent its stabilizing the iodide anion lattice into a structure permitting high Ag^+ ion mobility (7, 8).

Subset 3 is characterized by the presence of at least one saturated azacyclic group in the ammonium ion which may be completely or partially substituted. The results are given in Table II. All of these compounds formed conductive products, relative to the silver iodide conductivity (5) of 3×10^{-4} (ohm cm)$^{-1}$. The highest value of 0.06 (ohm cm)$^{-1}$ was found with the three completely substituted ammonium ions.

Subset 4, the unsaturated azacyclic substituted ammonium ions, includes the heterocyclic pyridinium and quinolinium ions with varying numbers of alkyl groups substituted onto the rings. Results are tabulated in Table III. As shown there, eight conductors had $\sigma > 10^{-2}$ (ohm cm)$^{-1}$, eight conductors had $10^{-2} > \sigma > 10^{-3}$ (ohm cm)$^{-1}$, and seven nonconductors had $\sigma < 10^{-4}$ (ohm cm)$^{-1}$.

Subset 5 contains all remaining compounds $C_aH_bNAg_nI_{n+1}$ that were investigated and includes several groups as previously indicated. Results are given in Table IV.

Composition dependence of conductivity.—The effect of composition on the conductivity was determined for the binary system dimethylpyrrolidinium iodide-silver iodide. This study followed the procedure for binary systems that was previously reported (5). The results are given in Table V; the maximum value of 0.065 (ohm cm)$^{-1}$ occurred at 88 m/o AgI, in agreement with prior studies wherein the cation substituted silver iodide solid electrolytes contained 80-90 m/o AgI (4-8).

Temperature dependence of conductivity.—The temperature dependence of the conductivity was determined for some of the more conductive members of this group. Results for 1,1-dimethylpyrrolidinium silver iodide and 3,5-dimethylpyridinium silver iodide (at the stoichiometry QAg_7I_8) are shown in Fig. 1, with previously reported results for other solid electrolytes (5). As seen, the conductivities of these compounds are very similar to those of the tetraalkylammonium silver iodide solid electrolytes, with activation energies of 3 to 4 kcal/mole. The results for 3,5-dimethylpyridinium silver iodide, exhibit an increasing activation energy at low temperatures, which suggests

that a phase transformation occurs near −50°C. However, the 1,1-dimethylpyrrolidinium iodide was still conductive at −50°C, with a value of 0.01 (ohm cm)$^{-1}$.

Size parameter.—The results that have been reported show that in this large set of AgI-QI compositions, where Q^+ is $C_aH_bN^+$, many highly conductive products are formed. It was of some interest to determine what structural parameters of the Q^+ ion determine the stability or existence of a conductive QAg_nI_{n+1} compound. The original postulate that was tested in the present study stated simply that high-conductivity solid electrolytes would be complex salts of the type $MX \cdot nAgI$ (5). Sufficient data on salts of empirical formula QAg_nI_{n+1} have now been obtained to permit a limited evaluation of the effect of Q^+ on electrical properties of the product salts.

In the group of solid electrolytes MAg_4I_5, the conductive structure was formed by $M^+ = K^+$, Rb^+, and NH_4^+ (4). Partial occupancy of the M^+ sites by Cs^+ was also permitted but no Na^+, Li^+, or $N(CH_3)_4^+$ occupancy was observed. The size of the monovalent alkali metal type cation appeared to be the parameter determining whether a stable MAg_4I_5 structure was formed. Therefore, in the present study one would logically consider the role of ionic size. However, since the Q^+ ions are complex and include species such as trimethylhexadecylammonium, pyridinium, and cyclohexyltrimethylammonium, there is considerable flexibility and ambiguity in assigning a radius to each of these ions. In the QAg_nI_{n+1} compounds formed by the homologous series of acyclic tetraalkylammonium ions there was a fairly straightforward separation of conductors from insulators. The conductivity dropped by a factor of 10^4 as the ion formula went from $C_9H_{22}N^+$ to $C_{10}H_{24}N^+$ (5). This result would indicate that there is a fairly critical volume effect in these compounds, since the ionic size would be expected to be a monotonically increasing function of molecular weight (M), with some corrections for isomer structural differences. A plot of the log of the conductivity *vs.* formula weight of QI for all of these materials investigated is shown in Fig. 2. A division between conductors and nonconductors occurs at a formula weight of about 290 g/mole for QI. As previously stated, partially substituted alkylammonium iodides formed no conductors whereas the completely substituted tetraalkylammonium iodides (up to $C_9H_{22}NI$) all form conductors. Some similarity to this apparent effect of an N-H bond is noted in subset 5 where the partially substituted cyclopentylammonium iodide and benzylam-

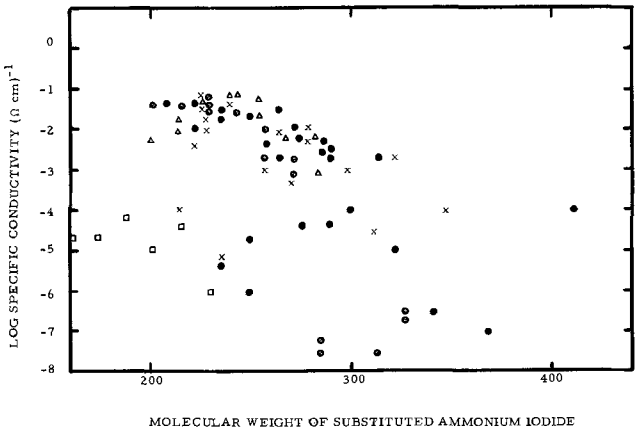

Fig. 2. Correlation between specific conductivity of QAg_nI_{n+1} and molecular weight of the QI. ⊙, Subset 1, completely substituted acyclic alkyl ammonium iodide; □, subset 2, partially substituted acyclic ammonium iodide; △, subset 3, saturated azacyclic substituted ammonium iodide; ●, subset 4, unsaturated azacyclic substituted ammonium iodide; x, subset 5, carbocyclic, aryl, benzyl, or allyl substituted ammonium iodides.

monium iodide form nonconductors whereas the completely substituted trimethyl analogs form conductors.

The four remaining nonconductive, low formula weight QI ($M < 285$ g/mole) shown in Fig. 2 are members of subset 4, the unsaturated azacyclic substituted ammonium silver iodide compounds. It was observed with several of the substituted pyridinium silver iodide electrolytes that the conductive products transformed to nonconductive structures during storage at 22°C, or on cooling to low temperatures. The compounds containing either 3-methylpyridinium, 3,5-dimethylpyridinium, or 1,2,6-trimethylpyridinium ions were conductive at ambient temperatures and became nonconductive at about −25°C. The transformations were not sharply defined but suggested a slow, solid-state reaction such as the disproportionation of KAg_4I_5 (3, 4). The 1,3-dimethylpyridinium silver iodide electrolyte increased in resistivity from 30 to 10^{+5} ohm cm during ambient storage; however, on heating the resistive product to 60°C, it transformed back into a conductive structure.

These results demonstrate that conductive solid electrolytes are formed by the combination of silver iodide with many substituted ammonium iodides. The determination of the crystal structures as well as the thermodynamic and transport properties of these compounds will be of considerable interest in the further understanding of cation substituted silver iodide solid electrolytes.

Acknowledgment

The authors wish to thank S. Geller for helpful discussions and to acknowledge the contribution of L. Hermo who performed many of the syntheses and physical measurements. The work was performed under the North American Rockwell Corporation Independent Research and Development Program.

The Effect of Sodium Oxide on the Thermal Oxidation of Silicon

Owen F. Devereux,* Rong Yau Wang, and Kuang-Ho Chien[1]

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Polycrystalline silicon wafers coated with Na_2CO_3 were oxidized in ambient air with $P_{H_2O} = 24$ mm in the temperature range 702°-1052°C. Initial oxidation followed cubic kinetics due to the linear change in composition of the oxide film with oxidation. At longer times, the oxidation became parabolic as the concentration of and, therefore, diffusivity of hydroxyl in the oxide became nonlinear with the sodium concentration in the film. This occurs at lower concentration of sodium, where the presence of sodium is manifested in the formation of hydroxyl by an autocatalytic reaction. Activation energies for both cubic and parabolic regions were 40.8 kcal/mole; the cubic pre-exponential constant was $5.1 \times 10^6 \mu^3$/hr, and the parabolic pre-exponential constant was $6.8 \times 10^4 \mu^2$/hr. Untreated specimens oxidized as controls during these experiments showed similar behavior due to vapor phase transport of Na_2O.

There has been an increasing awareness in recent years of the deleterious effect of impurity oxides in an otherwise protective film during thermal oxidation of metals. This is commercially important in the case of high-strength, nickel-base alloys in hot gaseous environments containing sodium and sulfur compounds. The present investigation of the role of sodium oxide on silicon oxidation was initiated in order to study these effects in a simpler, better-defined oxide than that extant on the nickel alloys.

Recent papers by Deal and Grove (1) and by Revesz and Evans (2) review in large part, together with their own contribution, the status of knowledge concerning the thermal oxidation of silicon. Deal and Grove find that existing knowledge on film growth can be described as surface reaction rate limited for short oxidation times and/or low temperatures, and diffusion rate limited at long times and/or high temperatures. Combining these terms, film thickness, X, after oxidation time, t, is given by

$$X^2 + AX = B(t + \tau) \qquad [1]$$

They find an activation energy for the parabolic constant, B, of 16.3 kcal/mole under wet oxidation conditions, and 28.5 kcal/mole under dry conditions. The linear constant, B/A, has an activation energy of 46 kcal/mole in either case. The time constant, τ, which corrects for an oxide layer extant prior to the start of the experiment or for early oxidation behavior not taken into account by the linear-parabolic equation [1], has a value of zero under wet conditions, and corresponds to an initial film thickness of 230Å under dry conditions. The activation energies of B are in accord with activation energies for the diffusion of the oxidizing species, hydroxyl and superoxide ion (O_2^-),

Key words: hot corrosion, alkali, impurity.

respectively, in fused silica, and the τ variance is explained by the variation in the thickness of the diffuse charge layer in the oxide film with the concentration of water. The parabolic constant, B, is found to vary directly with the partial pressure of the oxidant, while the value of A remains constant.

Revesz and Evans, while in agreement with the linear-parabolic rate behavior, find a considerable dependence of the reaction rates and of the activation energies on the sodium content of the oxide film. Thus their activation energies for the parabolic rate constant range from 12.45 kcal/mole for oxidation under very clean conditions in water vapor to 52.8 kcal/mole for oxidation in water vapor through a heavily sodium-contaminated oxide film. The activation energy for the linear constant varied from 44.0 kcal/mole in the clean experiment to 29.9 kcal/mole with sodium contamination. For both the linear and parabolic terms, considerable variation of the pre-exponential constants was also seen.

The present authors have conducted a further study of the oxidation of silicon with deliberate sodium contamination, using polycrystalline silicon, with moist air as oxidant. Inasmuch as the linear rate constant, but not the parabolic constant, depends on silicon orientation, some ambiguity was anticipated in the data for the linear parameters (3).

Experimental

Silicon wafers were prepared from a 1 in. diameter polycrystalline ingot of nine 9's purity. After slicing and lapping, the wafers were degreased in hot trichlorethylene followed by hot nitric acid, and rinsed in deionized water. The wafers were then chemically polished in a solution of 60 parts nitric acid, 20 parts acetic acid, and 8 parts hydrofluoric acid. After polishing, the wafers were rinsed in deionized water and stored under methanol. Final thickness was approximately 200μ.

The wafers were oxidized in a resistance-heated horizontal mullite tube furnace with an inside diameter of 1 and 11/16 in. The oxidant was ambient air saturated with water at room temperature. Flow rate was maintained at 150 cc/min, STP, with a small diaphragm pump. Saturation of the air was accomplished by bubbling it through a vessel containing water. This environment possessed a certain degree of ambiguity inasmuch as it contained both oxygen and water as oxidants; however, the oxidation rate in water vapor is sufficiently large compared to that in dry oxygen (1) that adequate control of the oxidation rate could be maintained by control of the water vapor pressure. Equilibrium water vapor pressure during the experiments was 24 $\pm$ 1 mm. The wafers were supported in a grooved ceramic combustion boat, with cylinder axis horizontal and normal to the direction of air flow. In the usual experiment two specimens were oxidized at once, a clean wafer placed upstream in the boat and a contaminated wafer placed downstream in the boat. Contamination by reagent-grade Na_2CO_3 was accomplished by dusting the surface of each specimen lightly prior to oxidation with the finely ground powder. Amounts of Na_2CO_3 applied to each contaminated specimen are given in Table I. It was anticipated that the silicon would undergo a rapid initial oxidation through partial reduction of the sodium oxide and that a uniform film across the surface would be formed quickly due to the high diffusivity of sodium ion in soda silicate glasses. This technique of applying the contaminant differed from that of Revesz and Evans, who preoxidized the silicon prior to exposing it to $NaNO_3$. However, both macroscopic and microscopic examination of the oxide films obtained during this work indicated uniformity of thickness, inferring that a homogeneous distribution of sodium in the film was obtained. Inasmuch as loss was anticipated both through the Na_2CO_3 reagent physically disengaging itself from the specimen surface and through volatility, the values recorded in Table I are not considered significant in a absolute sense, but do represent the relative amounts of sodium oxide contaminant present on each specimen during oxidation. Although the oxide films thus contained, in principle, two volatile compounds, CO_2 and Na_2O, these were not expected to evolve to any appreciable extent during the portion of the experiment subject to gravimetric analysis due to rapid dilution by SiO_2 during the early stages of oxidation. Temperature was measured at the boat and controlled to within 1°C.

Oxidation rate was determined by weight change; the wafers were removed periodically and weighed with a Cahn RG electrobalance. This technique was found to be more sensitive and reproducible than continuously recording the weight of a specimen suspended in the furnace. The use of a weighing technique as opposed to the direct observation of oxide thickness that has predominated the experimental work on silicon oxidation was dictated by the more complex nature of the soda silicate oxide film. That is, color changes were not consistent with those observed on clean silicon, and a definite crystallinity in the oxide film was observed as will be noted later in the paper. It was recognized that the periodic removal of the specimens and their reinsertion in the furnace could have a decided effect on the oxidation process through stressing and possible fracture or spalling of the oxide films. For this reason, companion studies were made of specimens which were not removed but merely weighed at the end of the oxidation process. Total weight gained for these specimens scattered statistically about that for specimens oxidized for the same time, but intermittently removed, with a typical deviation of several per cent. Estimated reproducibility of individual weight measurements is of the order of 1 μg. Removal of the specimens from the furnace and their reinsertion were made as rapidly as possible to minimize the loss of heat from the interior of the furnace. Recovery time for the specimen on reinsertion as estimated by visual observation was of the order of 1 min and was neglected in considering the time of oxidation.

Tapered sections with a 10:1 ratio were made of each specimen for optical microscopy, and an x-ray diffraction pattern was obtained for each of the contaminated samples and for a representative "clean" oxidized sample.

Results

Oxidation data for the alkali-treated specimens are shown in Fig. 1. Oxidation is initially cubic and, although it is not apparent in the log-log plot shown, becomes parabolic at longer oxidation times. Defining the kinetic rate constants by means of the equations

$$X^3 = Ct \quad [2]$$

$$X^2 = Bt + \text{Const} \quad [3]$$

the cubic and parabolic regimes in terms of weight increase due to oxidation per unit area, ΔW, are given by

$$\Delta W^3 = C\rho^3 t \quad [4]$$

$$\Delta W^2 = B\rho^2 t + \text{Const} \quad [5]$$

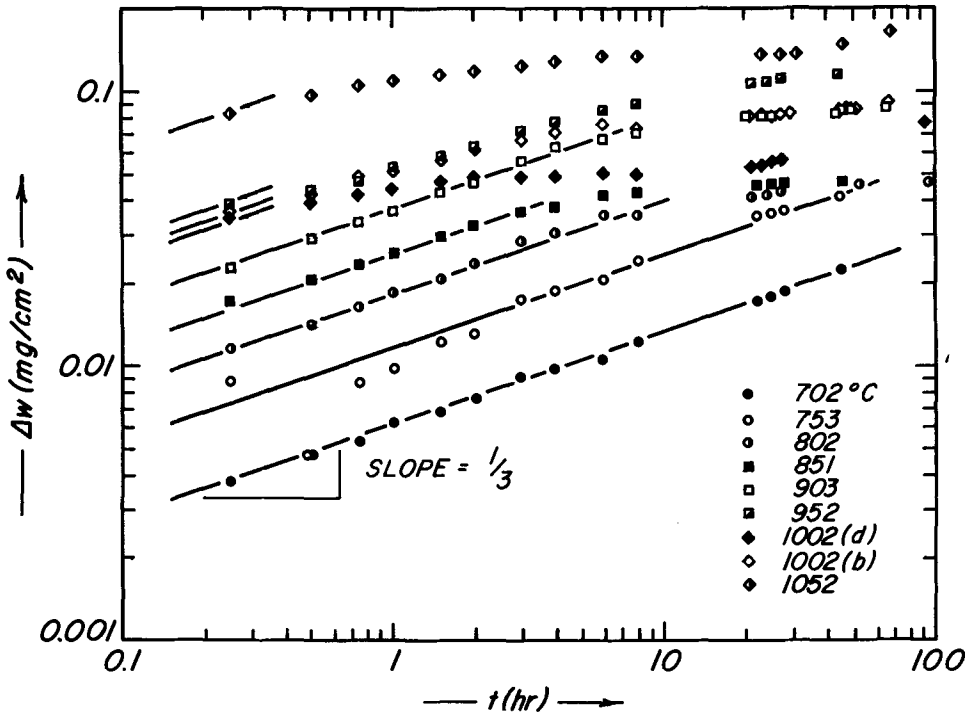

Fig. 1. Kinetic data—Na_2CO_3 treated specimens.

where ρ is the density of oxygen in the oxide film. High silica glasses have a density of the order of 2; this corresponds to an oxygen density of approximately 1 g/cm³, which has been used in this paper. Arrhenius plots of the cubic and parabolic constants are shown in Fig. 2; both are linear and exhibit the same slope, with an activation energy of 40.8 kcal/mole.

Oxidation of the untreated specimens showed similar behavior to that of the treated specimens; these data are shown in Fig. 3, with Arrhenius plots of the cubic and parabolic constants in Fig. 4. It was inferred that vapor phase transfer of a sodium oxide species had occurred and, therefore, that the untreated specimens were different from the treated specimens only in the quantities of alkali contaminant in the oxide film. Transition from cubic to parabolic oxidation occurred, in general, at thinner film thicknesses for the untreated specimens, and the cubic rate constants were considerably smaller. The rate constants plotted in Fig. 4 show more scatter than those for the treated specimens; this is especially true for the cubic constant. The line through the cubic constants is drawn with the same slope as that for the parabolic constants largely because of the apparent similarity to Fig. 2. The activation energy for these constants is 39.6 kcal/mole.

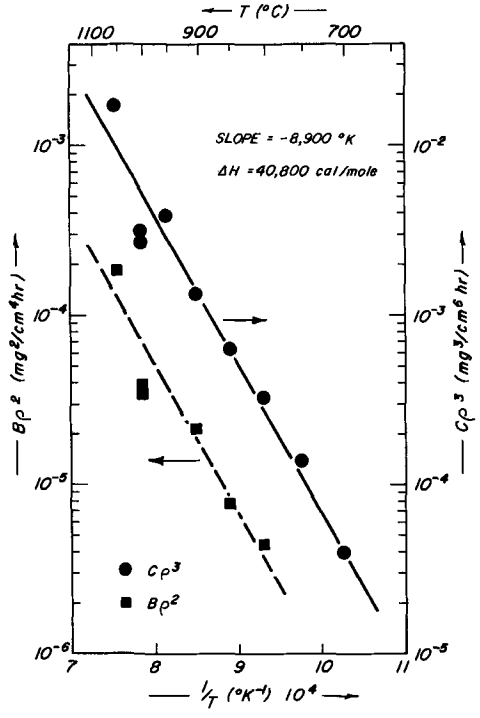

Fig. 2. Kinetic rate constants—Na_2CO_3 treated specimens

Defining the pre-exponential constants and activation energies by means of the equations

$$C = C_0 \exp(-\Delta H_C/RT) \quad [6]$$

$$B = B_0 \exp(-\Delta H_B/RT) \quad [7]$$

these parameters are shown in Table II along with values determined by Revesz and Evans. Two sets of values determined by Revesz and Evans are quoted; both were evaluated in helium with a water pressure of 24 mm. One set refers to sodium-free oxide films, and the other to films containing on the order of 10^{20} sodium atoms/cm³.

X-ray diffraction revealed only silicon peaks from the untreated, oxidized samples. Peaks other than those from silicon diffracted from the treated samples are shown in Table III. The diffraction angle, 2θ, of peaks attributed to the oxide film and the relative intensity of these peaks are reported. For each diffraction pattern, the nearest intense silicon peak was used as a 2θ standard. As seen in Table III, over the range of experimental conditions four distinct peaks were observed. These correspond to average d spacing values of 4.5135, 4.0812, 3.4717, and 3.4447Å. None of the observed combinations of these spacings corresponded to ASTM-listed values for the various polymorphs of silica or to the listed sodium silicates.

Macroscopic examination of the oxidized specimens revealed the uniform bright interference colors in-

dicative of an amorphous film on the untreated specimens, but a gray appearance suggestive of granularity on the treated specimens. Tapered sections through the unoxidized silicon surface showed an initial surface roughness caused by preferential dissolution near the grain boundaries during specimen preparation. This roughness was retained during oxidation at low temperatures in both treated and untreated specimens, suggesting surface control of the oxidation rate. At high temperatures, particularly in the alkali-treated specimens, the surface roughness was markedly decreased, in accord with a diffusion-controlled reaction. Also visible in tapered sections of the treated specimens was a fine granularity with an apparent dendritic character at the metal/oxide interface. This appeared to be the unidentified crystalline deposit evidenced by x-ray diffraction.

Discussion

The cubic phase of the oxidation observed in these experiments was not observed by Revesz and Evans in their study of sodium-affected oxidation. This may be attributed to the method of sodium doping. Revesz and Evans preoxidized their wafers, then placed them in contact with $NaNO_3$ to permit dissolution of Na_2O in the amorphous silica film. Thus, at the onset of oxidation they had a somewhat uniform film with a Na/Si ratio on the order of 0.02. In the present experiments, the initial film may be idealized as consisting solely of Na_2O; thus, initial oxidation occurred not only through a film of high alkali content but also of changing composition.

The rate of oxidation is initially surface reaction limited; Deal and Grove have proposed that this reaction is first order with respect to the oxidant. In the presence of a high concentration of sodium oxide, the oxidant will be oxide ion and the product of the reaction will be silicate ion, the formation of which will consume oxide ions. Thus, the surface reaction rate will decrease with time according to the changing concentration. The kinetic rate expression for this mechanism may be readily calculated and is a sum of both linear and logarithmic terms; however, a comparison of the available free oxide ion, as determined from Table I, with the kinetic data in Fig. 1, shows that the available oxide ion will have been consumed in the formation of silicate during the initial oxidation period of 15 min. Therefore, this mechanism describing the initial oxidation behavior was no longer valid over the range of data taken in these experiments.

In Table IV are shown the amount of applied alkali, calculated as Na_2O, compared with the amount of oxidation, as SiO_2, after the first 15 min of oxidation, *i.e.* at the onset of the observed cubic region. Due to possible loss of the volatile Na_2O, the resulting per-

centage of SiO_2 calculated in the film represents a minimum quantity. In comparing these values to the Na_2O-SiO_2 equilibrium diagram, Fig. 5, it is apparent that during observation of oxidation above 753°C the stable phases in the oxide film were a liquid and a crystalline silica, quartz at 802° and 851°C, and tridymite at higher temperatures. While there is no reason to propose that the film present during oxidation possesses an equilibrium phase structure, it is reasonable to assume that the oxidation occurs by means of transport of oxidant through a liquid phase, rather than through a solid, though amorphous, silica film. This is not the case in the experiments reported by Revesz and Evans. Their films contained only 1% Na_2O, and the appreciable effect on oxidation rate was explained by the autocatalytic reaction suggested by Charles (4), in which a relatively small quantity of Na^+ in the amorphous structure can cause a disproportionate increase in the OH^- concentration.

Due to incomplete knowledge concerning the state of the oxide layer during oxidation, it is not possible to propose a definitive mechanism. However, it is likely that the film either remains liquid throughout the cubic region, and therefore that precipitation of silica is repressed, or that the film possesses a near-equilibrium phase structure of liquid and crystalline silica. In the former case, the silica content of the liquid would increase during oxidation, and would be manifest in a corresponding increase in viscosity resulting in a decrease in diffusivity of hydroxyl as shown by the Einstein equation. Assumption of a linear change of viscosity with composition in this region leads to a cubic oxidation rate. In the latter case, a liquid phase of reasonably constant composition would persist throughout the oxidation; however, crystalline silica would precipitate in an amount proportional to the extent of oxidation. Inasmuch as the silica phase has a much lower diffusivity to hydroxyl than the liquid alkali silicate, in effect precipitation would decrease the area for diffusion in proportion to the extent of oxidation, again leading to cubic oxidation. In these proposed mechanisms, onset of the parabolic region of oxidation would, in the first case, correspond to an increase in silica content of the film to the extent that the mechanism of Charles became significant, *i.e.* formation of appreciable hydroxyl content without linear dependence on the sodium ion content. In the latter case, parabolic behavior would ensue when the liquid phase so decreased in proportion to the solid phase as to become discontinuous. Failure of x-ray diffraction to provide data to distinguish between these mechanisms may be a reflection of incomplete knowledge of the possible nonequilibrium phases in this system.

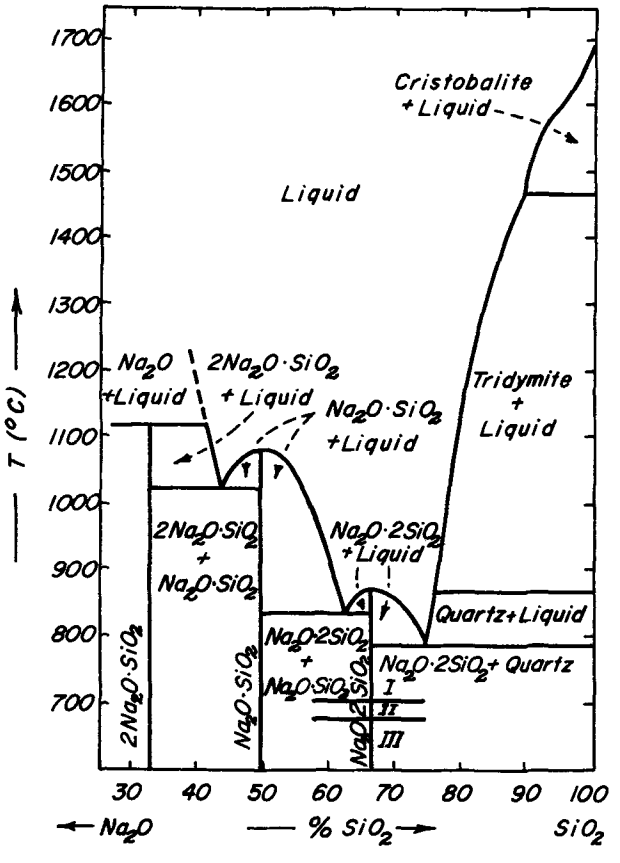

Fig. 5. Portion of the Na_2O-SiO_2 phase diagram [after Levin *et al.* (5)].

The kinetic constants of Table II are in accord with both hypotheses. The large increase in the pre-exponential constant of the treated specimens *vs.* that of the untreated is a reflection of the increased sodium content of the treated films and consequent increased diffusivity. However, in the parabolic region, the hydroxyl content and, therefore, diffusivity is determined by an autocatalytic reaction and is thus insensitive to composition. Hence the pre-exponential constants in the parabolic region are nearly the same. It is clear from the work of Revesz and Evans that a wide range of values of the kinetic constants is possible depending on experimental conditions. Thus, lack of exact agreement with their values is not surprising; however, both the activation energies and pre-exponential constants do fall with in the range reported by them.

Summary and Conclusions

Oxidation of polycrystalline silicon through a Na_2O surface film initially follows cubic kinetic behavior due to the changing composition of the film; the oxidation rate eventually becomes parabolic as transport processes in the film become insensitive to further composition changes. Activation energies for both cubic and parabolic regions are the same, approximately 40 kcal/mole. The cubic pre-exponential constant is dependent on sodium concentration in the film; however, the parabolic pre-exponential constant is relatively insensitive.

It is proposed that transport in the cubic region of oxidation is diminished by silica production due either to alteration of the viscosity of a single liquid phase, or to formation of a second phase of low diffusivity. Available data are consistent with either model. In the parabolic region of oxidation, the enhanced oxidation rate due to sodium is manifest in the production of hydroxyl ion by an autocatalytic reaction proposed by Charles (4), a process not proportional to the sodium concentration.

X-Ray Efficiency of Powder Phosphors

G. W. Ludwig†

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

Powder phosphors including CsI:Tl and (ZnCd)S:Ag were excited with x-rays, in the energy range 25-135 keV, obtained from radioisotope sources. The phosphor efficiency (light output per unit incident x-ray energy) was measured as a function of phosphor screen weight for each of five sources. The measured efficiencies are in reasonable agreement with theoretical curves having no adjustable parameters. The curves were calculated using tabulated x-ray energy-absorption coefficients and measured light transmission parameters, and assuming that the efficiency of conversion of absorbed x-ray energy to light energy is equal to the cathode-ray efficiency.

Powder phosphors such as (ZnCd)S:Ag and $CaWO_4$:Pb are of considerable importance for the detection of x-rays having photon energies in the region 25-135 keV. Crucial to this application is the efficiency with which incident x-ray energy is converted to useful light energy. This efficiency η may be expressed as

$$\eta = \eta_a \eta_c \eta_t \quad [1]$$

where η_a is the fraction of the incident x-ray energy which is absorbed, η_c describes the efficiency of conversion of absorbed x-ray energy to light energy, and η_t is the efficiency with which the light energy is transmitted through the powder to the detector. The detector may be a photoemissive surface, a photographic film, or the human eye.

In the work of Hamaker (1), Klasens (2), Klasens and de Groot (3), Coltman *et al.* (4), and Broser *et al.* (5), the x-ray efficiency of phosphors is discussed in the following manner. The x-ray absorption efficiency is either measured or is deduced from tabulated x-ray absorption coefficients of the elements knowing the phosphor screen weight and composition, and also the spectral distribution of the incident x-ray beam. The transmission efficiency is related to the scattering and absorption of the emitted photons by the phosphor particles within the screen, and the reflection coefficients at the screen surfaces. The measured x-ray efficiency of the phosphor screen can then be used to deduce a value for the conversion efficiency η_c. Coltman *et al.* (4) and Klasens (2) reported on $CaWO_4$ screens, while Broser *et al.* (5) presented information on some additional materials. All of these workers used for sources x-ray tubes which yielded a broad spectrum of x-ray energies, and presented no data on the possible dependence of the conversion efficiency on x-ray energy. Klasens and de Groot (3) discussed the processes involved in conversion of x-ray energy to light and concluded that the conversion efficiency should depend on x-ray energy.

Although there has been additional work,[1] remarkably little discussion of the response of powder phosphors to x-rays has appeared in the recent literature. On the other hand, there have been numerous studies of the x-ray response of scintillation crystals such as NaI:Tl, which are highly transparent to their own emitted light.

In this paper we report on the x-ray efficiency of powder phosphors such as (ZnCd)S:Ag, $CaWO_4$:Pb, and CsI:Tl. To excite the phosphors we employed a series of five radioisotopes, each of which emits x-rays at several well-defined and rather closely spaced energies in the range 25-135 keV. The phosphor response to such excitation can be conveniently analyzed, since the absorption of the beam at each x-ray energy follows an exponential law. Availability of data for a series of sources giving different x-ray energies clearly is of advantage for comparison with theory, and particularly for testing whether the conversion efficiency varies with x-ray energy.

The x-ray response was measured for a series of different phosphors, screen weights, and radioisotope sources, using a photomultiplier as the detector. The photomultiplier sensitivity to the spectrum emitted by each phosphor was calibrated by comparing the photomultiplier signal to that from a thermocouple with the phosphor excited by cathode rays. The light transmission of the screens was measured, as was the reflectivity of thick phosphor layers, in order to determine the parameters describing scattering and absorption of light within the screens.[2] The cathode-ray efficiency of the phosphors was measured. Finally, the x-ray mass absorption coefficient of each phopshor was calculated from tabulated values for the elements for each

Key words: luminescence, phosphors, x-rays, efficiency.

[1] See, for example, ref (6-9).

[2] The density of a powder phosphor screen is dependent on preparative techniques. For this reason we prefer discussing x-ray attenuation in terms of the phosphor mass traversed rather than the phosphor thickness traversed.

x-ray energy present in the radiation from the sources. It was then possible to compare phosphor efficiency with curves calculated from theory with no adjustable parameters.

Using the assumption that the efficiency of conversion of absorbed x-ray photon energy to emitted light is equal to cathode-ray efficiency, we find reasonable agreement between our data and a formula based on work of Hamaker (1). Thus, we find no substantiation for the assumption of Klasens and de Groot that the energy of the ions produced by x-ray absorption is less efficiently used in producing light than is that of the fast electrons. Rather it appears that Hamaker's formulas can be used together with phosphor parameters such as the cathode-ray efficiency to provide a guide to the x-ray efficiency to be expected under a wide range of experimental conditions.

Hamaker's analysis of the light output of powder phosphor screens under x-ray excitation is reviewed briefly in the following section. In subsequent sections the radioisotope sources are characterized, measurement of x-ray response and calculation of the mass absorption coefficient is described, the determination of other relevant phosphor parameters is discussed, and a comparison is made between the measured phosphor efficiency and predictions from theory. Results are also discussed.

Light Output of a Phosphor Screen

We now discuss the light output of a phosphor screen under x-ray excitation using an approach similar to that of Hamaker (1). Consider a screen which is sandwiched between media, labeled 1 and 2, which may affect its light output by reflecting or absorbing some of the emitted light (see Fig. 1). X-ray photons of energy E are incident from the left, the energy flux being N_0E. The x-ray absorption by the screen is governed by its mass absorption coefficient $\mu' = \mu/\rho$, where ρ is the phosphor density. Thus, after passing through a screen weight w the flux will be reduced to $N_0E \exp(-\mu' w)$. The flux absorbed in a weight increment dw at w is $-EdN = EN_0 [\exp(-\mu' w)]dw$ and the emitted light flux is $\mu_c EdN$, where μ_c is the efficiency for conversion of absorbed x-ray energy to light energy. We expect half of the light flux to be emitted toward the left and half toward the right.

Suppose that at w within the phosphor there is a light flux I traveling toward the right and a flux J traveling toward the left. In passing through the layer of weight dw these fluxes will be augmented by light generation (*via* x-ray absorption and phosphor fluorescence) while being attenuated by the self-absorption of the phosphor. In addition, the phosphor grains will scatter light from each flux into the other. Thus

$$dI/dw = -(a + s)I + sJ + \frac{1}{2}\eta_c EN_0 \exp(-\mu' w) \quad [2]$$

$$dJ/dw = +(a + s)J - sI - \frac{1}{2}\eta_c EN_0 \exp(-\mu' w) \quad [3]$$

Here a and s are coefficients describing the self-absorption and scattering, respectively, of the emitted light by the phosphor. Equations [2] and [3] are one-dimensional; they apply to regions sufficiently far from the screen periphery that lateral light losses and additions effectively cancel.

The solutions of Eq. [2] and [3] are of the form[3]

$$I = A(1 - \beta)e^{\sigma w} + B(1 + \beta)e^{-\sigma w} - \frac{1}{2}\eta_c EN_0 \frac{\beta\mu' + \sigma}{\beta(\mu'^2 - \sigma^2)} e^{-\mu' w} \quad [4]$$

$$J = A(1 + \beta)e^{\sigma w} + B(1 - \beta)e^{-\sigma w} + \frac{1}{2}\eta_c EN_0 \frac{\beta\mu' - \sigma}{\beta(\mu'^2 - \sigma^2)} e^{-\mu' w} \quad [5]$$

In [4] and [5] the coefficients a and s have been replaced by new parameters σ and β so defined that the expressions are simplified

$$\sigma = [a(a + 2s)]^{1/2} \quad [6]$$

$$\beta = [a/(a + 2s)]^{1/2} = \sigma/(a + 2s) \quad [7]$$

The quantities A and B in [4] and [5] are constants, the values of which are determined by imposing appropriate boundary conditions. Let r_i be the reflectivity and t_i be the transmissivity of the media 1 and 2. Then, as discussed by Hamaker (1), the light flux to the right per unit flux in the incident x-ray beam is given by [8] while that to the left is given by [9].

$$\eta_r = \frac{t_2 I(W)}{N_0 E} = t_2\eta_c\mu' \cdot \frac{(1 + \rho_2)}{2(\mu'^2 - \sigma^2)} \cdot e^{-\mu' W} \times \frac{(-\mu' + \sigma)(\rho_1 + \beta)e^{\sigma W} + (\mu' - \sigma)(\rho_1 - \beta)^{-\sigma W} + 2(\sigma\rho_1 + \mu'\beta)e^{\mu' W}}{(\rho_1 + \beta)(\rho_2 + \beta)e^{\sigma W} - (\rho_1 - \beta)(\rho_2 - \beta)e^{-\sigma W}} \quad [8]$$

$$\eta_l = \frac{t_1 J(0)}{N_0 E} = t_1\eta_c\mu' \cdot \frac{(1 + \rho_1)}{2(\mu'^2 - \sigma^2)} \times \frac{(\mu' - \sigma)(\rho_2 + \beta)e^{\sigma W} - (\mu' + \sigma)(\rho_2 - \beta)e^{-\sigma W} + 2(\sigma\rho_2 - \mu'\beta)e^{-\mu' W}}{(\rho_1 + \beta)(\rho_2 + \beta)e^{\sigma W} - (\rho_1 - \beta)(\rho_2 - \beta)e^{-\sigma W}} \quad [9]$$

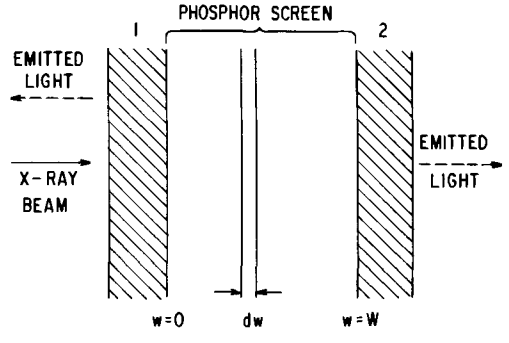

Fig. 1. X-ray excitation of a phosphor screen which is sandwiched between partially reflecting media 1 and 2.

Here W is the screen weight and the reflectivities r_i have been replaced by the related parameters $\rho_1 = (1 - r_i)/(1 + r_i)$, while η_r and η_l represent the efficiency of Eq. [1] for the detector to the right of the screen and to the left, respectively.

Equations [8] and [9] are easily generalized if the phosphor is simultaneously exposed to x-rays of several different fluxes, energies, and absorption coefficients. In particular, [8] generalizes to

$$\eta_r = (\Sigma_i N_{oi}E_i\eta_{ri})/\Sigma_i N_{oi}E_i \quad [10]$$

Simplifications of [8] and [9] which apply under special conditions have been discussed by Hamaker (1) and Klasens (2).

X-ray Generation by Radioisotopes

A number of radioisotopes which are available commercially are worth considering as sources of radiation in the x-ray region. Important characteristics, such as half-life and emitted radiations, of several isotopes which have come to our attention are listed in Table I (10). All but one of the isotopes in the table decay by capture of an electron from an inner shell to produce a daughter nucleus in an excited nuclear state. The daughter may return to its ground state with the emission of a gamma ray having an energy listed in

[3] Equation 92 of ref (1) contains a minor error.

Table I. Decay characteristics of potential x- or gamma-ray sources

Isotope	Decay mode*	Half life	Daughter	Gamma rays (keV)	X-rays (keV)
$_{26}Fe^{55}$	EC	2.6 years	$_{25}Mn^{55}$	—	~5.9
$_{50}Sn^{119m}$	IT	250 days	$_{50}Sn^{119}$	24, 65	~25
$_{53}I^{125}$	EC	60 days	$_{52}Te^{125}$	35.5	~28
$_{66}Dy^{159}$	EC	144 days	$_{65}Tb^{159}$	58	~46, ~6.7
$_{74}W^{181}$	EC	140 days	$_{73}Ta^{181}$	Weak	~58, ~11
$_{79}Au^{195}$	EC	183 days	$_{78}Pt^{195}$	31, 99, 129, 211	~68, ~10
$_{27}Co^{57}$	EC	270 days	$_{26}Fe^{57}$	14, 122, 136	6.5
$_{38}Sr^{85}$	EC	64 days	$_{37}Rb^{85}$	514	13
$_{48}Cd^{109}$	EC	453 days	$_{47}Ag^{109}$	88	22

* EC = electron capture, IT = internal conversion.

Table I. However, internal conversion of the gamma ray may also take place, whereby the photon is absorbed internal to the atom with accompanying expulsion of an electron, generally from the K- or L-shell.

Holes in the deep inner shells (K- and L-shells) of the daughter atoms are produced both by the initial electron capture and by subsequent internal conversion. Consequently, such radioisotope samples emit x-rays characteristic of the daughter element. Usually this x-ray emission is considerably more intense than the gamma-ray emission.

As an example, the decay scheme of $_{79}Au^{195}$ is depicted in Fig. 2 (11). The gold isotope decays *via* electron capture to any one of three excited nuclear states of $_{78}Pt^{195}$. Four gamma rays at 31, 99, 129, and 211 keV are reported as a result of transitions among these levels and to the ground state of Pt^{195}. However, the dominant emission in the energy region above 10 keV is the characteristic K x-ray emission of Pt at ~68 keV. This K-shell emission can be separated into four components, $K_{\alpha 1}$, $K_{\alpha 2}$, $K'_{\beta 1}$ and, $K'_{\beta 2}$ having intensity ratios 28:50:17:5 (10). The first two at 65.1 and 66.8 keV represent electronic transitions from the L-shell to the hole in the K-shell, while in the last two, at 75.7 and 77.8 keV, the electron originates in the M- or in the N-shell, respectively. There also are L-shell emissions at about 10 keV, but these low energy radiations can be effectively filtered out if desired.

Amounts ranging from 0.5 to 2 mc of the isotopes listed in Table I were obtained from commercial

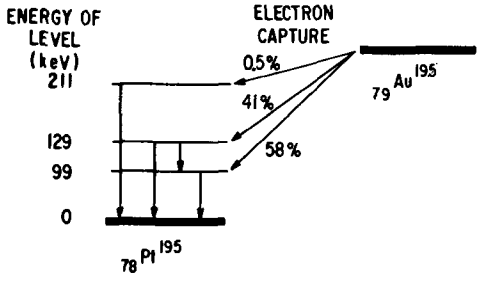

Fig. 2. Decay scheme of the radioisotope, $_{79}Au^{195}$, resulting in emission of 31, 99, 129, and 211 keV gamma rays as well as x-rays characteristic of the daughter, $_{78}Pt^{195}$ isotope [after ref. (10)].

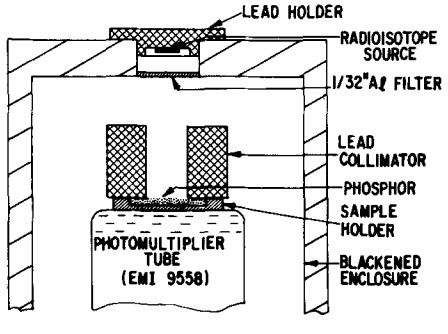

Fig. 3. Experimental arrangement used to measure x-ray response of phosphor screens.

sources.[4] The isotopes were supplied in aqueous solution. A portion of the solution was pipetted into a lead holder and evaporated to dryness. A cover was then glued over the holder to prevent escape of radioactive material while permitting passage of x-rays and gamma-rays. Beryllium foil (0.010 in. thick) was used for the low energy x-rays from the Fe^{55} sample, and 0.003 in. aluminum foil was used in the other cases.

The spectrum of the radiation from the mounted sources was examined using a Nuclear Chicago scintillation counter with a NaI crystal as the scintillator, and a pulse height analyzer. In this manner five sources were selected as yielding radiation in the range 25-135 keV of sufficient spectral purity to warrant further study. The selected sources were examined with a germanium detector and associated circuitry at substantially higher energy resolution. Taking the Au^{195} radioisotope source as an example, the $K_{\alpha 1}$, $K_{\alpha 2}$, $K'_{\beta 1}$, and $K'_{\beta 2}$ peaks of the Pt daughter were clearly resolved, as well as the weak γ-rays at 98.5 and 129.4 keV. Still weaker Pb x-rays, arriving from the irradiation of the lead holder, could also be discerned. The relative amplitudes of the K-shell components were found to be in reasonable agreement with the published values, and relative amplitudes for the γ-ray peaks could also be determined.

Characteristics of the five sources actually employed in our further experiments are summarized in Table II. In that table the $K_{\alpha 1}$ and $K_{\alpha 2}$ peaks and also the $K'_{\beta 1}$ and $K'_{\beta 2}$ peaks are lumped together and assigned an average energy and a total relative intensity.

The Nuclear Chicago scintillation counter was used to monitor the total x-ray flux from each of the mounted sources. The fluxes were measured several times during the course of the work and were found to decay in accordance with the known half-lives of the radioisotopes.

Measurement of X-ray Response

The experimental arrangement used for measurement of phosphor x-ray response is shown in Fig. 3. The radiation from the radioisotope source passed through a thin 0.031 in. Al filter and a lead collimator before reaching the powder phosphor sample. The sample was contained in a holder with a glass bottom positioned on the input window of an EMI 9558 photomultiplier tube. All parts of the enclosure about the

[4] Dy^{159}, Au^{195}, I^{125}, and Sn^{119m} were obtained from New England Nuclear Corporation, Boston, while Fe^{55}, Co^{57}, W^{181}, and Sr^{85} were obtained from International Chemical and Nuclear Corporation, Nuclear Science Division, Pittsburgh.

Table II. Characteristics of mounted x-ray sources

Isotope	Dominant emissions[a] (keV)
I^{125}	27.3(75), 31.3(17), 35.5(8)
Dy^{159}	44.1(78), 51.0(19), 58(3)
W^{181}	56.9(79), 66.1(21)
Au^{195}	66.0(71), 76.8(20), 99(9)
Co^{57}	122(90), 136,(10)

[a] The numbers in parentheses refer to the relative intensities of the emissions.

collimator, sample, and photomultiplier were blackened to minimize effects of reflected light.

Most of the phosphors investigated are available commercially. The samples were prepared by lightly pressing the powder into one of several holders which differed in depth. The screen weight was calculated from the diameter of the holder and the weight of the powder. The same screens were preserved for measurement of light transmission and of x-ray attenuation.

Originally it was thought that screens of more uniform screen weight could be prepared by settling. However, it was found that such screens tended to emit light preferentially toward the glass plate on which they were settled, presumably because of particle size separation occurring during the settling process. The use of settled screens was therefore abandoned.

The basic experimental data obtained for each phosphor were the photomultiplier currents for each source as a function of phosphor screen weight. A quantity of greater interest is the efficiency η_r as defined in Eq. [1] and given in Eq. [10], *i.e.*, the light energy emitted toward the photomultiplier per unit x-ray energy incident on the phosphor screen. The incident x-ray energy was calculated from the flux as measured with the scintillation counter taking into account the dominant emission energies from each source and their relative intensities (see Table II), and also the solid angles from the source subtended by the sample and by the counter. No corrections for attenuation by Al filter or by the Al can surrounding the scintillation crystal were required since the Al thicknesses were the same. (The Al filter served the additional useful purpose that it effectively removed low energy x-rays such as M-shell emissions at ~10 keV from the Au^{195} source.)

To convert the photomultiplier current readings to the desired values of light energy output, it was necessary to calibrate the sensitivity of the photomultiplier to the light emitted by each phosphor. This was accomplished by measuring the light output under cathode-ray excitation both with the photomultiplier and with a thermopile which gives a reading proportional to emitted light energy independent of wavelength. The photomultiplier readings had previously been calibrated in terms of emitted light energy (12). For determination of the photomultiplier sensitivity it was also necessary to compute the fraction of the emitted light gathered by the photomultiplier, taking Lambert's law into account.

A correction to the photomultiplier sensitivity was required because in the measurement of x-ray response the light is diffusely incident on the face plate, and may also undergo multiple reflections between the tube and the phosphor plaque. To estimate this basically geometrical correction readings were taken both with the arrangement of Fig. 3 and with the photomultiplier lowered to match the geometry used for cathode-ray excitation. The computed correction amounted to 20%.

Direct excitation of the photomultiplier by the sources proved to be negligible.

X-ray Cross Sections

A recent tabulation of x-ray cross sections of the elements is that of Storm and Israel (13). Of prime importance to x-ray efficiency is the total energy-absorption cross section. This cross section, labeled $(\mu/\rho)_{tot,en}$, was plotted as a function of energy for selected elements. Values at the dominant emission energies of each radioisotope source were estimated by interpolation and are given for several of these energies in Table III. Also listed in that table for convenient reference is the energy of the K-shell absorption edge (13). As the x-ray energy falls below the absorption edge for a shell, there is a sharp drop in the energy-absorption cross section, corresponding to the inability of lower energy photons to supply enough energy to ionize an electron from that shell.

Table III. Energy absorption coefficients and the K-shell absorption edge of selected elements

Atomic Number	Element	μ' in cm²/g 27.3 keV	44.1 keV	56.9 keV	66.0 keV	122 keV	K_{edge} (keV)

74	W	24.5	7.3	3.65	2.35	1.47	69.5

Table IV. Energy absorption coefficients μ', in units of cm²/g, at selected emission energies of the radioisotope sources

Phosphor \ Energy (keV)	27.3	44.1	56.9	66.0	122.0
$Zn_{0.68}Cd_{0.32}S$	11.47	3.2	2.13	1.48	0.29
$CaWO_4$	16.35	4.84	2.41	1.56	0.94
ZnO	10.48	2.82	1.35	0.91	0.16
Gd_2O_3	14.94	3.99	4.51	3.69	1.09
CsI	9.91	8.40	5.05	3.70	0.87

Energy-absorption cross sections of phosphors are readily calculated from the cross sections of their constituent elements. If μ'_i is the coefficient of an element having an atomic weight A_i, then the cross section μ'_c of a compound of molecular weight c is given by

$$\mu'_c = \sum_i \frac{A_i}{c} \mu'_i \qquad [11]$$

Energy-absorption cross sections of several phosphors, calculated from Table III and Eq. [11], are listed in Table IV.

With the apparatus available to us it was not convenient to attempt a direct measurement of the total energy-absorption cross section. However, measurements were made of the attenuation of the flux from the different sources produced by interposing phosphor screens between the source and the scintillation crystal. Values were thereby obtained for the narrow beam total cross section, labeled $(\mu/\rho)_{tot,t}$ by Storm and Israel. Each x-ray energy emitted by a source is characterized by its own cross section, and the measurement yields the average cross section provided the total attenuation is small.

The ratio between the measured and calculated average total cross section for different phosphors and sources is displayed in Fig. 4. The closeness of the

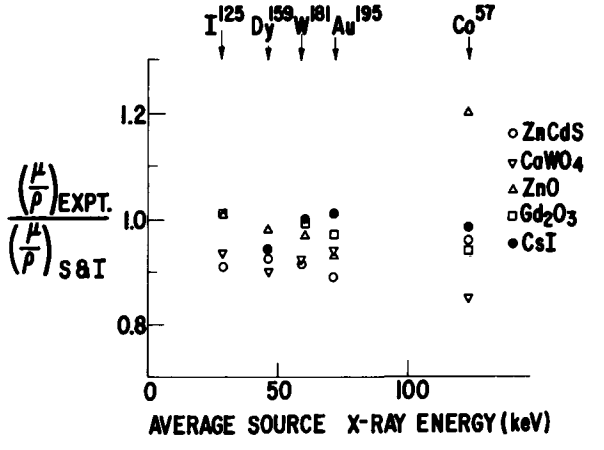

Fig. 4. Ratio of experimental and calculated values of the average total x-ray cross section of different phosphors. Calculated values were computed from the phosphor composition using $(\mu/\rho)_{tot,t}$ of ref. (13) taking into account the x-ray spectrum of the sources.

ratio to 1 tends to substantiate both our characterization of the radioisotope sources and the accuracy of the (μ/ρ) values computed for the different phosphors. The tendency for the ratio to fall below 1 may reflect insufficient collimation.

Conversion of X-ray Energy into Light Energy

A factor of prime importance to the x-ray efficiency of a phosphor is the efficiency with which it converts absorbed x-ray energy to light energy. In the region of present concern, 25-135 keV, the photoelectric process dominates x-ray energy absorption (13). In the photoelectric process the x-ray photon ionizes an electron from a deep inner shell, the excess of the photon energy over the ionization energy going to kinetic energy of an electron. We would therefore like to know the efficiency with which both the electron kinetic energy and the energy of the hole in the inner shell are converted to light energy.

In discussing the conversion of x-ray energy to light, Klasens and de Groot (3) made the assumption that only the electron kinetic energy is utilized. This assumption implies that the conversion efficiency in a compound such as NaI will have a striking dependence on x-ray photon energy. In particular, as the energy increases through the K-shell absorption edge of I at 33.2 keV, the conversion efficiency would be expected to drop by about a factor of two (the ratio of the energy absorption above the edge to that below the edge). Otherwise stated, the increase in energy absorption at the edge contributes nothing to the light output, since it represents the energy of holes in the K-shell.

Collinson and Hill (14) and more recently Aitken *et al.* (15) have studied the efficiency of NaI(Tl) and other scintillation crystals over a broad range of x-ray energies including the K-shell edge of I. They find fractional variations in efficiency of only a few per cent in the neighborhood of the K-shell edge. Collinson and Hill suggest that the energy of holes is either reradiated or is channeled via Auger transitions into electron kinetic energy. The observed efficiency variations are attributed to a dependence of efficiency on electron energy and on excitation density. Thus, they equate the efficiency under x-ray excitation to an efficiency for conversion of electron kinetic energy to light, which is the cathode-ray efficiency.

It appears reasonable to use the cathode-ray efficiency as an estimate to the efficiency with which a powder phosphor converts absorbed x-ray photons to light. Accordingly, we have measured the cathode-ray efficiency of phosphors of interest by a technique described previously (12). The values thereby obtained represent the intrinsic efficiency as diminished by light absorption within the settled plaque. The intrinsic efficiency, which is of present interest, was estimated by correcting the measured values by the factor $2/(1 + R_p)$, where R_p is the plaque reflectivity (16). Results are listed in Table V.

Table V. Cathode-ray efficiency and light transmission parameters of phosphors

Phosphor	Designation	η_{cr}	λ (Å)	β	σ (cm²/g)
(ZnCd)S:Ag	du Pont 1200	0.211	5400	0.04	5.6

[c] In the case of ZnO a 10% correction was applied to the efficiency as measured at 10 kV to take into account surface losses (ZnO has an unusually high dead voltage) (16).

Optical Properties of the Phosphor Screens

The parameters σ and β (or alternatively a and s) describing the absorption and scattering of light in a powder phosphor can be deduced from a study of screen reflection and transmission. Consider Eq. [4] and [5] with $N_0 = 0$ (no x-ray excitation) and with a light beam of intensity I_0 incident from the left of Fig. 1. Then the appropriate boundary conditions are

$$I(0) = t_1 I_0 + r_1 J(0) \quad [12]$$

$$J(W) = r_2 I(W) \quad [13]$$

and the fraction of the light transmitted is (1)

$$\frac{I_t}{I_0} = \frac{t_2 I(W)}{I_0} = \frac{\beta t_1 t_2 (1 + \rho_1)(1 + \rho_2)}{(\rho_1 + \beta)(\rho_2 + \beta)e^{\sigma W} - (\rho_1 - \beta)(\rho_2 - \beta)e^{-\sigma W}} \quad [14]$$

Similarly for $t_1 = 1$ the reflectivity R_∞ of a phosphor layer which is so thick that transmission through it is negligible is given by (1)

$$R_\infty = \frac{J(0)}{I_0} = \frac{1 - \beta}{1 + \beta} \quad [15]$$

Measurements of light transmission were made on the same samples that were examined under x-ray excitation. In one experimental arrangement light from a tungsten bulb was passed through color glass filters to select the wavelength region of interest. It was then focused through a window into an integrating sphere. The light intensity in the sphere was measured with the phosphor screen positioned in the window first so it did not and then so it did intercept the incident light beam. Data were thus acquired on I_t/I_0 as a function of W. To determine R_∞, the light was focused through a window in the sphere onto a window on the opposite end of a sphere diameter. Successive brightness meter readings were taken from the far window blocked with a thick phosphor screen and with a thick reference screen of $BaSO_4$. Grum and Luckey (17) have shown that the reflectivity of $BaSO_4$ is very close to unity in the visible. Thus, the ratio of the two readings was taken to be R_∞.

The parameter β was calculated from the relation $\beta = (1 - R_\infty)/(1 + R_\infty)$. The quantity σ was determined by matching the experimental transmissivity values to [14] using $t_1 = 0.92$, $\rho_1 = 0.85$, $t_2 = \rho_2 = 1$, and β as determined above. Values are summarized in Table V.

Using the integrating sphere the transmission of the glass holders in which the phosphors were pressed was measured to be 0.92. Thus we assume $t_2 = 0.92$ and $\rho_2 = 0.85$ in [8], while t_1 and ρ_1 were taken equal to one (the surroundings were blackened).

Comparison of X-ray Efficiency with Hamaker's Formula

We now are in a position to compare the x-ray efficiency of a series of phosphors with predictions based on other phosphor parameters. For example, the efficiency of a (ZnCd)S:Ag phosphor as a function of phosphor screen weight is summarized in Fig. 5 for each of the five radioisotope sources. The experimental points are the phosphor light output, as measured by the photomultiplier, divided by the photomultiplier sensitivity to the emitted spectrum and by the incident x-ray energy flux. The theoretical curves represent the efficiency η_r as given by Eq. [10] with appropriate values for the parameters N_{oi}, E_i, and $\mu'(E_i)$ (see, *e.g.*, Table II and IV), η_c, β, and σ (see Table V), and ρ_1, ρ_2, and t_2 (see Section on Optical Properties of the Phosphor Screens). For simplicity each curve is labeled with the average x-ray energy and average μ' for the source in question. The labels 29, 46, 59, 71, and 123 keV refer to the sources I^{125}, Dy^{159}, W^{181}, Au^{195}, and Co^{57}, respectively. The efficiency of other phosphors is summarized in Fig. 6-10.

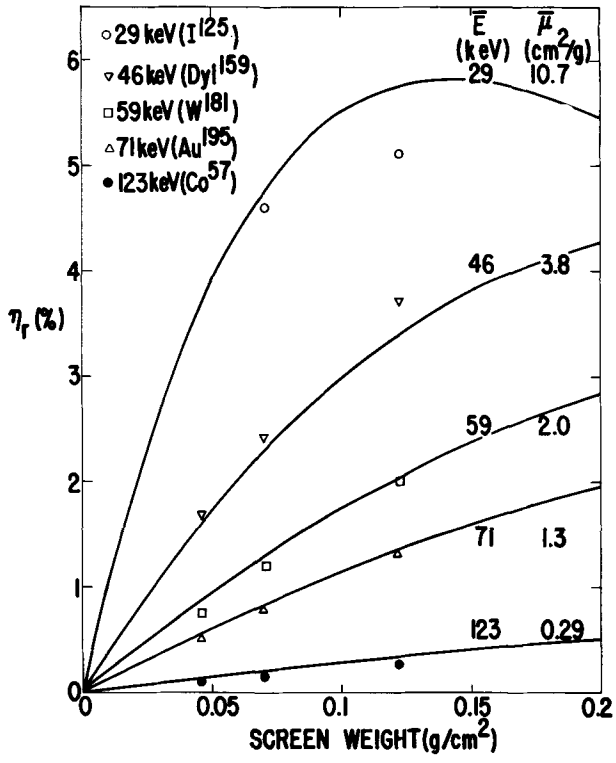

Fig. 5. X-ray efficiency of (ZnCd)S:Ag (du Pont 1200 phosphor) screens as a function of screen weight for different radioisotope sources. The experimental points represent photomultiplier readings normalized by dividing them by the product of the photomultiplier sensitivity and the incident x-ray energy. The solid lines are the theoretical efficiencies η_{lr} (see text and Eq. [8] and [10]) with η_{lc}, σ, and β as given for du Pont 1200 in Table V.

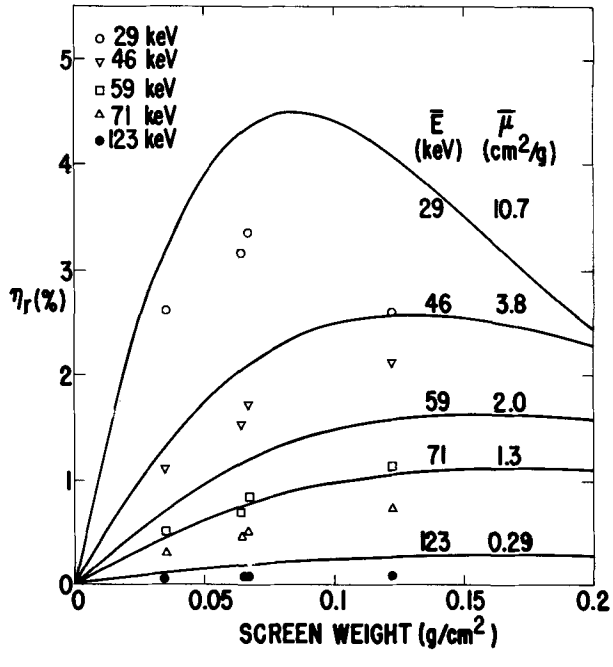

Fig. 6. X-ray efficiency of (ZnCd)S:Ag (TV green phosphor)

Discussion and Conclusions

The agreement between the experimentally determined phosphor efficiency and the theoretical curves is good for du Pont 1200 (ZnCd)S:Ag and Gd_2O_3:Eu (Fig. 5 and 9). It would be good for $CaWO_4$:Pb (Fig. 7) and much improved for the TV green (ZnCd)S:Ag (Fig. 6) if one assumed $\sigma = 30$ cm²/g in each case rather than the measured values of 20 cm²/g. Since the measured values of σ and β are quite sensitive to wavelength for $CaWO_4$:Pb and (ZnCd)S, a 50% error in σ is not unreasonable. For ZnO and CsI:Tl the experimental points tend to lie above the calculated curves.

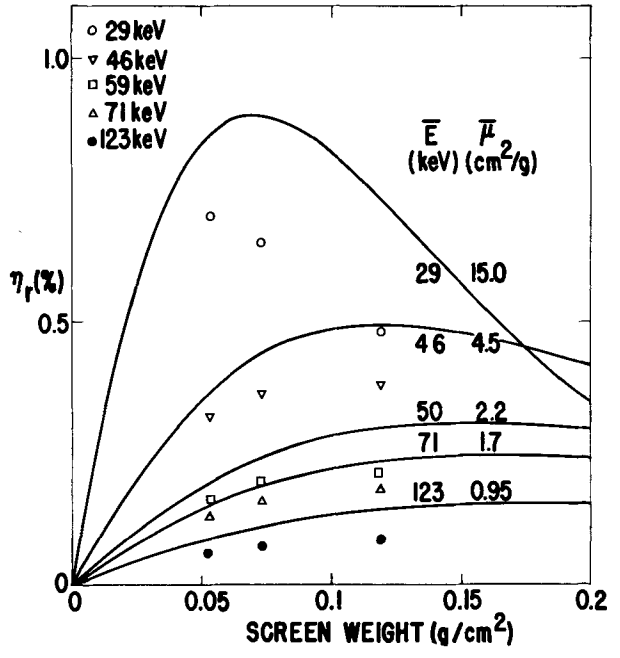

Fig. 7. X-ray efficiency of $CaWO_4$:Pb (National Bureau of Standards No. 1026 phosphor).

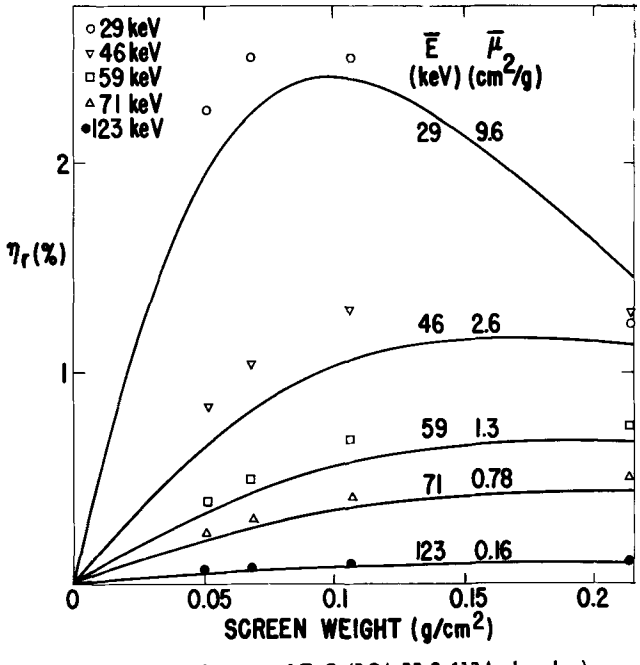

Fig. 8. X-ray efficiency of ZnO (RCA 33-2-613A phosphor)

To further explore the agreement between experiment and theory, apart from errors associated with transmission losses, the ratio $(\eta_r)_{expt}/(\eta_r)_{calc}$ was computed for the lowest screen weight of each phosphor studied. (Transmission losses are smallest at the lowest screen weight.) As shown in Fig. 11, this ratio departs from one by amounts as large as about ±30%. In most cases the ratio for a given phosphor shows a smaller scatter as the source is changed. The departure of the ratio from one would be reduced for $CaWO_4$ and the TV green phosphor if $\sigma = 30$ cm²/g had been used to compute $(\eta_r)_{calc}$.

Errors in the photomultiplier current readings, the photomultiplier sensitivity to the emitted radiation, the flux from the radioactive sources, the fraction of the flux incident on the sample, and the phosphor screen weight all affect $(\eta_r)_{meas}$. Similarly, errors in the energy-absorption cross sections, cathode-ray efficiency, and optical parameters affect $(\eta_r)_{calc}$. The scat-

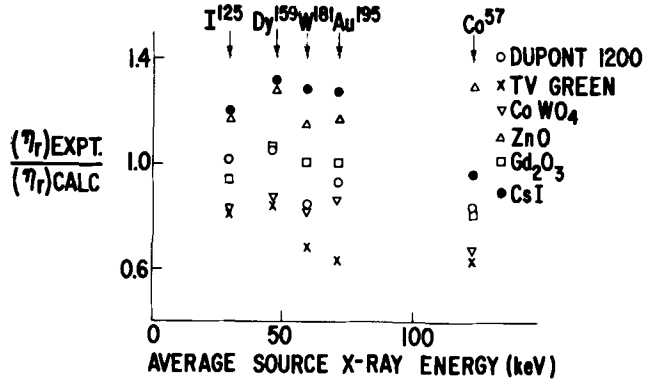

Fig. 11. Comparison of experimental and calculated values of η_r at low phosphor weight (see Fig. 5-10).

ter of ±30% may represent the composite of errors of 5-10% in half a dozen or so different measurements. Note that no adjustable parameters have been employed.

The generally good agreement between experiment and theory is evidence that the conversion efficiency for absorbed x-ray energy to light energy is at least approximately equal to the cathode-ray efficiency. Suppose, for example, only the energy of the fast electron treated on x-ray absorption were utilized [with the cathode-ray efficiency as assumed by Klasens and de Groot (3)]. Then there would be a sharp drop in conversion efficiency and in x-ray response as one increased the x-ray energy through the K-shell absorption edge of the heavy element responsible for the bulk of the x-ray absorption by the screen. For example, one would anticipate a sharp drop in the response of Gd_2O_3:Eu screens between 46 and 59 keV, associated with the K-shell edge of Gd at 50.2 eV. No such drop is observed.

The results of this paper lead us to believe that Hamaker's formulas [8] and [9] can be used together with phosphor parameters such as the cathode-ray efficiency to provide a guide to the x-ray response to be expected under a wide range of experimental conditions.

In selecting a powder phosphor for efficient x-ray detection, one obviously must optimize the three factors η_a, η_c, and η_t of Eq. [1]. Our study points to CsI:Tl and (ZnCd)S:Ag as outstanding candidates. CsI:Tl has high x-ray absorption and high cathode-ray efficiency together with good light transmission up to substantial screen weights. (ZnCd)S:Ag has a lower x-ray absorption but still higher cathode-ray efficiency. The fine-grained (ZnCd)S used as a TV green phosphor is inferior to the coarse-grained phosphor produced for x-ray detection in its transmission of the emitted light (*c.f.*, Fig. 5 and 6), particularly at the higher screen weights.

It is of interest to consider to what extent a different x-ray efficiency would be obtained for a given phosphor composition using a different phosphor lot or a different technique of screen preparation. Of the three factors in Eq. [1], the x-ray absorption would be affected the least, since it is determined solely by the phosphor composition and screen weight. The cathode-ray efficiency will vary somewhat with preparative techniques, but usually not by more than 20-30%. The transmission efficiency will depend on the grain size of the phosphor, on how tightly the grains are packed, and on the binder employed. The variation will be greater where the transmission is less, *viz.*, at the higher screen weights. Once again Fig. 5 and 6 demonstrate the kind of variation in x-ray efficiency which may be anticipated.

Acknowledgments

The author is indebted to S. J. Lubowski for carrying out many of the measurements. He wishes to thank R. A. Sieger, the Tube Department, General Electric Company, for suggesting the use of radioisotopes as x-ray sources. He is also indebted to J. D. Kingsley and J. S. Prener for valuable discussions.

Manuscript submitted May 11, 1970; revised manuscript received March 10, 1971. This was Paper 55 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Electronic States of Mn^{2+}-Activated Phosphors

II. Orange-to-Red Emitting Phosphors

ABSTRACT

The electronic states of Mn^{2+} are derived from excitation spectra for eight orange-to-red emitting phosphors: (*i*) ZnF_2:Mn, (*ii*) ZnS:Mn, (*iii*) $Zn_3(PO_4)_2$:Mn, (*iv*) $CaSiO_3$:Pb,Mn, (*v*) $CdSiO_3$:Mn, (*vi*) $Cd_{10}Cl_2(PO_4)_6$:Mn, (*vii*) $Ca_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:Sb,Mn, and (*viii*) $Sr_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:Sb,Mn. All eight phosphors show complete splitting of at least one electronic level. The observed splittings are compared to the expected splittings from crystal field theory. New assignments of the ZnS:Mn levels are given.

We gave in Part I (1) a description of the electronic energy levels of five green-emitting, Mn^{2+}-activated phosphors. Here we consider Mn^{2+}-activated phosphors with orange-to-red emission. We give below excitation and emission spectra for: (*i*) ZnF_2:Mn, (*ii*) ZnS:Mn, (*iii*) $Zn_3(PO_4)_2$:Mn, (*iv*) $CaSiO_3$:Pb,Mn, (*v*) $CdSiO_3$:Mn, (*vi*) $Cd_{10}Cl_2(PO_4)_6$:Mn, (*vii*) $Ca_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:Sb,Mn, and (*viii*) $Sr_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:Sb,Mn. Level assignments are made and compared with previously reported results where possible.

The Mn^{2+} levels in order of increasing energy in an octahedral crystal field are given by Orgel (2) as $^6A_{1g}(^6S)$, $^4T_{1g}(^4G)$, $^4T_{2g}(^4G)$, $^4A_{1g}$-$^4E_g(^4G)$, $^4T_{2g}(^4D)$, $^4E_g(^4D)$, $^4T_{1g}(^4P)$, etc., where A, E, and T refer to single, double, and triple orbital degeneracies; the free-ion-level origins are given in parentheses. In Table I, we list the crystal classes of the eight phosphors, the expected site symmetry for Mn^{2+}, and the maximum orbital degeneracy allowed in the given site symmetry. We cite, also, the appropriate references.

The energy level structure of ZnS:Mn is the subject of a number of works. Bube (11) gives excitation and absorption spectra for ZnS:0.01Mn. Ford *et al.* (15) give absorption spectra for ZnS:0.1Mn. Curie (16) comments on the reduction of the tetrahedral site symmetry of Mn^{2+} if Cl^- is introduced in the ZnS lattice, and in his text gives a summary of absorption measurements on this system. McClure (12), Ryskin *et al.* (13), and Langer and Ibuki (14) note fine structure in the absorption spectra of single crystals of ZnS:Mn; all three authors place the ^4A, $^4E(^4G)$ level at about 21,600 cm^{-1}. Mehra (38), in a recent note, also follows this assignment in his fit of McClure's observed levels.

Narita (33) calculated the energy levels of Mn^{2+} for the C_3 site in calcium fluorophosphate with change in lattice constant. Johnson (35) reports emission from both sites in the calcium halophosphates and notes that the distribution of Mn^{2+} between the two sites is a function of the halide ratio. Ryan *et al.* (39) give the optical properties of calcium fluorophosphate single crystals, giving spectra of Mn^{2+} in the C_3 and C_s sites. They also report emission from a "modified" C_s site. No detailed level assignments are given. Konstantinova-Schlezinger and Kabakova (34) gave excitation spectra for Mn^{2+} red emitters. For $Zn_3(PO_4)_2$:Mn they place the most intense band at 417 nm and show three additional excitation bands at longer wavelength.

Experimental Procedures

Procedures for measurement of excitation and emission spectra have been given in Part I (1). Samples were prepared by the usual solid-state phosphor synthesis. Preparative techniques are well-documented in the literature and are cited in Table I. All phosphors considered here are commercially available materials.

Experimental Results and Discussion

ZnF_2:0.03 Mn.—We use the ZnF_2:Mn excitation spectrum, given in Fig. 1, as a guide for the level assignments. The sharp triplet structure at about 395 nm is assigned as the ^4A, $^4E(^4G)$ level, the triplet indicative of complete orbital splitting of the level. Stout (36) places the $^4A(^4G)$ level of MnF_2 at 25,180 cm^{-1}; he assigns the incompletely resolved structure at 25,500 cm^{-1} to the $^4E(^4G)$ level. We assume here that the strongest excitation band in the ZnF_2, at 398.2 nm (25,113 cm^{-1}), is the ^4A (^4G) level. The triplet at about 350 nm is assigned as the split $^4T_2(^4D)$ level; the doublet at about 330 nm is assigned as the split $^4E(^4D)$ level. We would expect six excitation bands lying below the $^4A(^4G)$ level as a result of complete splitting of the $^4T_2(^4G)$ and $^4T_1(^4G)$ levels. Only three of these appear resolved, although the shapes of the bands at about 430 and 510 nm suggest the presence of additional overlapping bands.

From the barycenters of the $^4E(^4G)$ and the $^4E(^4D)$ levels, we computed values of the Racah parameters B and C, using the Tanabe and Sugano $^4\Gamma_3$ matrix, which is independent of the crystal field strength. The results are given in Fig. 2. A crystal field strength (10 Dq) of 9300 cm^{-1} gives a reasonable fit to the barycenters of the ZnF_2:Mn levels. Although in the calculations the assumption of an octahedral field is a poor approximation to the actual field (lower than octahedral), the calculated values for the barycenters of the ^4T levels are in reasonable agreement with the observations. Table II offers a comparison of our values with those reported in the literature.

$Cd_{10}Cl_2(PO_4)_6$:0.06 Mn.—Cadmium chlorophosphate exhibits more resolved structure in excitation than does the ZnF_2. Figure 3 gives the excitation spectrum. Again we attribute the sharp bands at about 405 nm to splitting of the ^4A, $^4E(^4G)$ level. While only three

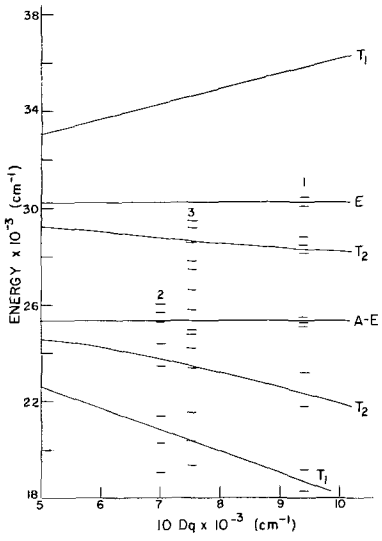

Fig. 2. Calculated energy level diagram based on position of the ^4E levels in ZnF_2:0.03Mn, for B = 698 cm^{-1} and C = 3678 cm^{-1}. Level positions shown for: 1, ZnF_2:Mn; 2, ZnS:Mn; 3, $Ca_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:Sb, Mn.

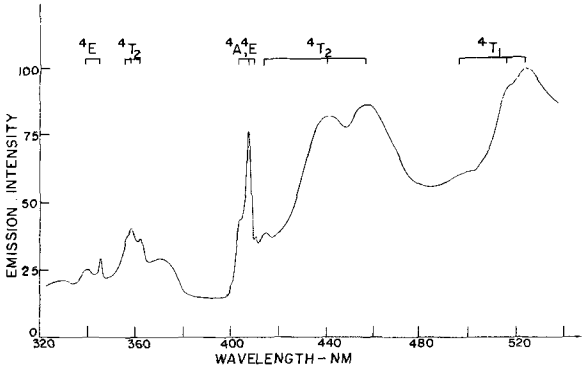

Fig. 3. Excitation spectrum of $Cd_{10}Cl_2(PO_4)_6$:0.06Mn, liquid-N_2 temperature.

bands are expected for complete orbital splitting, we observe four bands at 403.2, 405.4, 407.3, and 410.2 nm. There is also an indication of an unresolved band between the 405.4 and 407.3 nm bands. The six bands at longer wavelength are assigned to complete splitting of the $^4T_2(^4G)$ and $^4T_1(^4G)$ levels; the triplet at about 360 nm is assigned as the split $^4T_2(^4D)$ level; the doublet at about 340 nm is assigned as the split $^4E(^4D)$ level. The broad band at about 370 nm, as well as the additional levels observed in the ^4A, $^4E(^4G)$ level structure cannot be assigned unequivocally. Several possibilities exist: first, there are two possible sites for Mn^{2+} in the apatite lattice (with C_3 and C_s symmetry) and if fluorescence occurs from both sites, we could expect additional structure in the excitation spectrum; second, transitions from the $^2T_2(^2I)$ level can introduce additional structure; and third, spin-orbit coupling could produce additional splittings. Experimentally, no definitive procedure is available for differentiating among these possibilities. The structure observed, however, requires a Mn^{2+} site symmetry lower than C_3 if emission originates only from the C_3 site.

ZnS:Mn.—For ZnS:Mn we first note a previously unreported excitation band at about 410 nm. Figure 4 gives excitation spectra, measured at room temperature, for 1, 2, and 5% Mn concentrations. The intensity of the 410 nm band is seen to increase with increasing Mn concentration. The five bands shown we assign as components of the $^4T_2(^4G)$ and $^4T_1(^4G)$ levels. We would expect six bands here for complete

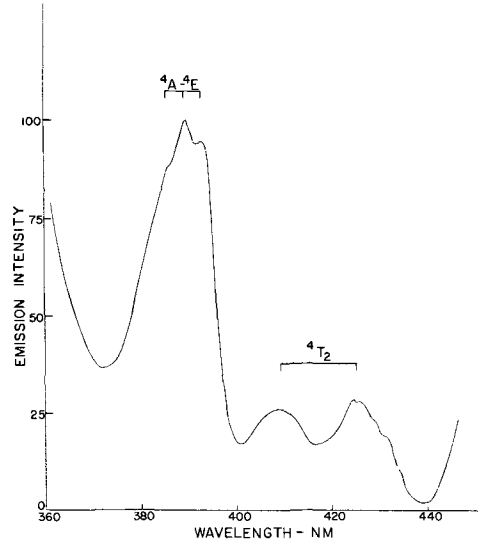

Fig. 5. Excitation spectrum for ZnS:0.008 Mn, liquid-He temperature.

splitting of the two T levels. We were unable to resolve the sixth band.

Figure 5 gives the excitation spectrum for ZnS:0.008 Mn, measured at liquid-He temperature, for the region from 360 to 450 nm. The triplet structure at about 390 nm we attribute to splitting of the ^4A, $^4E(^4G)$ level. This assignment differs with the assignments given by McClure (12), Langer and Ibuki (14), Ryskin *et al.* (13), and Mehra (38). These authors assume tetrahedral symmetry of Mn^{2+} obtains; no splitting of degenerate E and T levels is expected for this symmetry. However, the similarity of the ZnS:Mn spectrum to the ZnF_2:Mn and $Cd_{10}Cl_2(PO_4)_6$:Mn spectra, and in fact, as is developed below, the similarities in the spectra of all eight phosphors leaves little doubt that the ^4A, $^4E(^4G)$ level is found in the region from 390 to 410 nm. Curie (16) has suggested that substitution of Cl^- for S^{2-} would lower the Mn^{2+} site symmetry from T_d to C_3. We find, however, that similar splittings are observed in chloride-free samples. We conclude that substitution of Mn^{2+} for Zn^{2+} is sufficient to distort the normal T_d site symmetry.

The vibrational fine structure, reported by McClure (12), Langer and Ibuki (14), and Ryskin *et al.* (13), observed in the absorption mode is also observed in the excitation mode. We do not observe all the detailed structure reported by Langer and Ibuki (14); our results more nearly parallel those of McClure (12)

and Ryskin *et al.* (13), Table III lists the observed fine structure compared with McClure's and Ryskin's values.

$Ca_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:0.08Sb, 0.12Mn.—Johnson (35) has noted Mn^{2+} emission from both sites (C_3 and C_s) in the apatite lattice. Our measurements of excitation spectra, while indicating more structure than is expected from a site with C_3 symmetry, do not show all the structure consistent with emission from both sites. This presumes, of course, that there is no overlapping of band positions, *i.e.*, all bands can be resolved.

Figure 6 gives the excitation spectrum for the 400 to 540 nm region and Fig. 7 gives it for the 300 to 380 nm region. The bands at about 400 and 404 nm we assign to the ^4A, $^4E(^4G)$ level and the five bands at

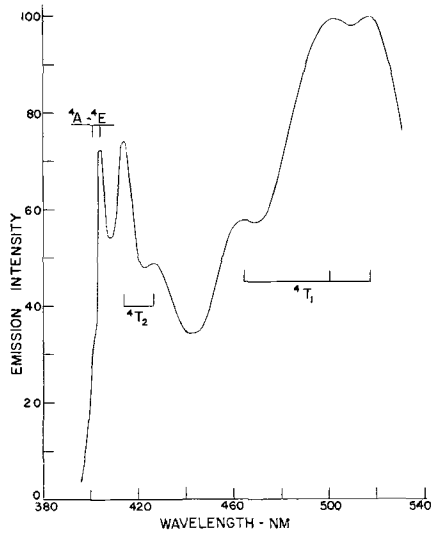

Fig. 6. Excitation spectrum for $Ca_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:0.08Sb, 0.12 Mn, liquid-N_2 temperature.

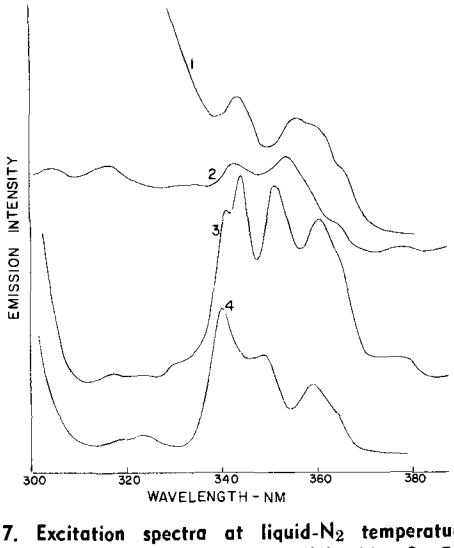

Fig. 7. Excitation spectra at liquid-N_2 temperature for: 1, $CdSiO_3$:0.03 Mn; 2, $CaSiO_3$:0.008 Pb, 0.07 Mn; 3, $Ca_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:0.08 Sb, 0.12 Mn; 4, $Sr_{10}F_{1.8}Cl_{0.2}(PO_4)_6$:0.08 Sb, 0.08 Mn.

longer wavelength to the split $^4T_2(^4G)$ and $^4T_1(^4G)$ levels. The bands at 375 and 387 nm we leave unassigned; these may originate from the $^2T_2$ (^2I) level. The bands at 349, 359, and 364 nm we assign as components of the $^4T_2(^4D)$ level. The weak structure observed in the region of 320 nm we assign as the $^4T_1(^4D)$ level.

Our choice of assignment of the band at 404 nm warrants some comment. It could be argued that the band is the third component of the split $^4T_2(^4G)$ level. Our method, following Orgel, is to assign the sharpest and strongest excitation band as the $^4A(^4G)$ level. There seems little question of the validity of the method for the assignments in ZnF_2, ZnS, $Cd_{10}Cl_2(PO_4)_6$, and in the phosphors cited in Part I (1). Whether the assignment is correct in all cases, however, is not resolvable in the light of existing data.

The recent work of Ryan *et al.* (39) with single crystals of calcium fluorophosphate is a case in point. Their absorption spectra for the C_3 site suggests a band at about 510 nm. They do not observe the band in the excitation mode. As noted above, we assign a level at 517 nm as the third component of the $^4T_1(^4G)$ level; our assignments of the remaining two components of this level correspond to the levels observed by Ryan *et al.* at 487 and 461 nm. Their observation of additional structure in the $^4T_2(^4G)$ and the ^4A, $^4E(^4G)$ levels suggests complete splitting of these levels, indicative of a site symmetry lower than C_3, if we attribute the observed bands to simple orbital splittings. We would assign their level at 403.7 nm as the $^4A(^4G)$ based on the narrow band width, in correspondence with our observed level at 403.8 nm.

For the C_s site symmetry, Ryan *et al.* observe a less-structured excitation spectrum than is observed for the C_3 site. In particular, a sharp band at 400.9 nm could be assigned as the ^4A, $^4E(^4G)$ level. If so, then the band we observe at 400.5 nm may arise from the C_s site. In all, although no completely definitive assignments can be made for all the observed levels, except possibly for the $^4T_2(^4G)$ level, present data are not inconsistent with emission from a site with lower than C_3 symmetry.

Our observed levels for the calcium halophosphate show little correspondence with the levels calculated by Narita (33) for the fluorophosphate. In his first paper (33), he places the lowest energy level at 24,200 cm^{-1}; our observed value is 19,300 cm^{-1}. His second paper (33) introduces a correction in the calculation based on the ionicity of the phosphate ion. An ionicity value between two and three could place the lowest level at the observed value. However, his calculated levels show smaller separations in energy than are actually observed.

$Sr_{10}F_{1.8}Cl_{0.2}(PO_4)_6$: 0.08Sb, 0.08Mn.—The excitation spectrum of the strontium halophosphate, given in Fig. 7 and 8, is similar to that of the calcium halophosphate with some exceptions. No splitting of the ^4A, $^4E(^4G)$ level is observed; only one component of the $^4E(^4D)$ level and two components of the $^4T_1(^4P)$ level are resolved. The unassigned levels observed in the calcium halophosphate (at 375 and 387 nm do not appear in the spectrum.

$CaSiO_3$: 0.008Pb, 0.07Mn and $CdSiO_3$: 0.03Mn.—The calcium and cadmium silicates show similar features in their excitation spectra, given in Fig. 7 and 9. Both show five broad bands in the region from 420 to 540 nm, a single band for the ^4A, $^4E(^4G)$ level, a triplet at about 360 nm assigned as the $^4T_2(^4D)$ level, and doublet at about 340 nm assigned as the $^4E(^4D)$ level. The calcium silicate shows additional structure at about 310 nm assigned as the $^4T_1(^4P)$ level. From site symmetry considerations, we expect complete lifting of the orbital degeneracies in both phosphors. Although several of the levels are not experimentally observed, the spectra are consistent with complete splitting of E and T levels.

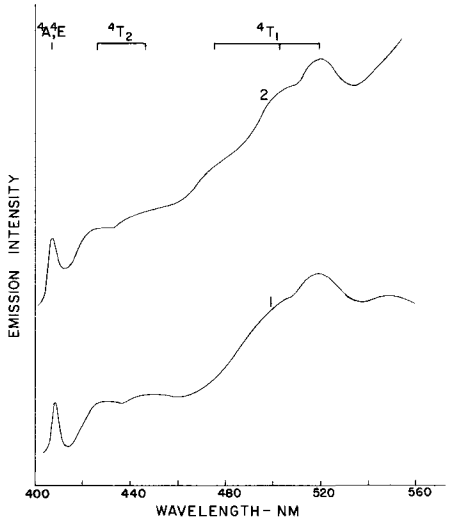

Fig. 9. Excitation spectra at liquid-N_2 temperature for: 1, $CdSiO_3$:0.03 Mn; and 2, $CaSiO_3$:0.008 Pb, 0.07 Mn.

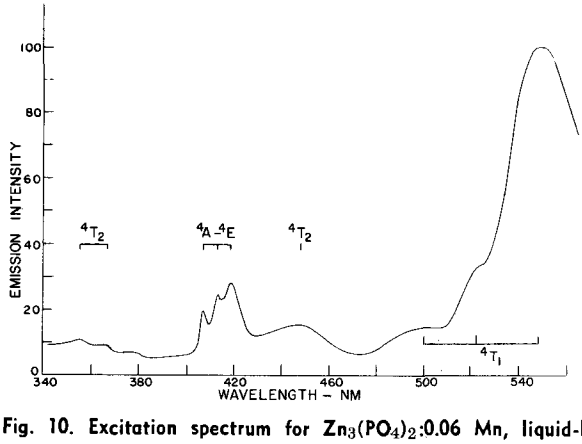

Fig. 10. Excitation spectrum for $Zn_3(PO_4)_2$:0.06 Mn, liquid-N_2 temperature.

$Zn_3(PO_4)_2$: 0.06 Mn.—The zinc phosphate shows three weak bands in the region from 350 to 380 nm. These are probably components of the $^4T_2(^4D)$ levels. The three sharp bands in the region from 400 to 420 nm we assign to the split ^4A, $^4E(^4G)$ level. Four broad bands are resolved in the region from 430 to 560 nm and are assigned as components of the $^4T_2(^4G)$ and the $^4T_1(^4G)$ levels. Konstantinova-Schlezinger and Kabakova (34)

* Unassigned levels.

show a single broad band for the ^4A, $^4E(^4G)$ triplet and three additional bands on the low energy side of the triplet. The observed complete splitting of the ^4A, $^4E(^4G)$ and the $^4T_1(^4G)$ levels indicates a distortion of the expected site symmetry for Mn^{2+} in $Zn_3(PO_4)_2$.

We have noted failure to resolve some of the expected levels in a spectrum, on the assumption that complete splitting of one level requires complete splitting of all levels. While this is true for transitions between levels of the same symmetry species, *e.g.*, $^4A_1 \rightarrow {}^4T_1(^4G)$ and $^4T_1(^4P)$, it is not necessarily true for transitions between levels of different symmetry species, *e.g.*, $^4A_1 \rightarrow {}^4T_1(^4G)$ and $^4T_2(^4G)$. Group theoretical arguments require that in order for electric dipole transitions to be observed the integrals, $\int \psi'_e(X, Y, \text{or } Z)\ \psi_e\, d\tau$ or $\int \psi'_v \psi'_e(X, Y, \text{or } Z)\psi_v\psi_e d\tau$, contain the totally symmetric representation, where the (ψ'_v, ψ_v) and $\psi'_e, \psi_e)$ are the vibrational and electronic wave functions, respectively, between the two states. Granted we are correct in our thesis that at least one electronic level in each of the phosphors considered above shows complete splitting, we require evaluation of the integrals for the point groups C_1, C_s, C_i, C_2, C_{2v}, C_{2h}, D_2, and D_{2h}, site symmetries consistent with complete splitting of electronic levels. Our evaluations show all the expected transitions are allowed in these symmetries. Cotton (40) gives an excellent treatment of the calculation.

We give in Table IV a summary of the wavelengths and wave numbers for the excitation bands observed for the eight phosphor systems classified according to the free-ion origin and appropriate crystal field assignment.

Emission Spectra

Only ZnS:Mn and $CaSiO_3$:Pb,Mn show structure in their emission spectra. Langer and Ibuki (14) have given the ZnS:Mn spectrum and attribute the sharp line structure to vibrational levels. Froelich (23) shows splitting of the $CaSiO_3$:Pb,Mn emission spectrum into two bands at liquid-N_2 temperature. Our results parallel these findings.

Summary

We have derived the electronic energy level structures of the two classes of Mn^{2+}-activated phosphors, *i.e.*, the green, and the orange-to-red emitters, from their excitation spectra. The position of the ^4A, $^4E(^4G)$ level is relatively constant in both classes and is found at about 23,500 cm^{-1} for the green emitters, and at about 24,800 cm^{-1} for the orange-to-red emitters. Distortion of the site symmetry is common; eight of the thirteen phosphors examined show splittings consistent with a site symmetry lower than is expected from crystallographic considerations.

On the Optimum Efficiency of Cathodoluminescence of Inorganic Phosphors

Willi Lehmann*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

The maximum possible efficiency of a phosphor excited by an electron beam depends primarily on the mean excitation energy required to create, by collision, a free electron-hole pair or a free carrier-ionized activator pair or an excited but nonionized activator. This energy is expressed as a multiple (factor α) of the band gap energy, E_g. Values of α measured for various phosphors scatter over a wide range depending on host material and activator and, in many cases, strongly deviating from $\alpha \approx 3$ observed in free-carrier-collection experiments in semiconductors.

The intensity of light emission of cathodoluminescence of a phosphor powder layer depends on the parameters of excitation in a fairly complex manner (1). Generally, the light intensity is not proportional to either the acceleration voltage or the current density of the exciting electron beam. The two main deviations from linearity, "dead voltage" and "current saturation," both reduce the efficiency, and it has been recognized for a long time that the highest possible efficiency of cathodoluminescence requires excitation conditions where these two deviations are minimized, *i.e.*, excitation by an electron beam of fairly high excitation voltage but of low current density. This optimum efficiency is relatively independent of voltage and current and is only a function of the particular phosphor. Some energy efficiencies of cathodoluminescence of various phosphors, believed to be measured under relatively optimized conditions by various workers, are compiled in Table I.

Experimental

We have made such measurements also on calcium sulfide and calcium oxide phosphors. The sulfides were prepared as described elsewhere (2). The oxides were made from calcium carbonate containing the desired impurities and about 1 molar-% of CaF_2 as flux by firing in O_2 at 1200°C. All phosphors were excited at room temperature, in a demountable tube, with electrons of 8 kV and a current density of approximately 10^{-6} A/cm^2 or somewhat lower. The luminescence was observed from the excited side and its intensity compared, by means of a selected silicon photodiode of very flat spectral quantum response, to several standard phosphors (P-1, P-22, $MgWO_4$) whose efficiencies were known from other sources. Division of the measured quantum intensities by the mean wavelength of the emission spectrum yields the energy efficiency in relative units. This technique delivers results reproducible to about ±5%. However, the method relies on the efficiencies of the standard phosphors and, therefore, the final results are reliable only to about ±10%. Some results so measured are given in Table II.

Discussion

Tables I and II reveal a very pronounced difference between sulfide phosphors on the one hand, and oxygen-dominated phosphors (including oxides, silicates, vanadates, etc.) on the other. The efficiencies of good sulfide phosphors may go to about 15-20% or even higher while those of oxygen-dominated phosphors rarely come to about 10%. The question naturally arises why the various phosphors display such widely different efficiencies and what is the ultimate maximum of efficiency of a particular phosphor material prepared and excited under all imaginable optimum conditions? This problem has been attacked in the literature (1, 3) with the help of semi-quantitative considerations originally developed to describe carrier multiplication effects in semiconductors (4-7). The following reasoning is developed along the same line but

Table II. Energy efficiencies of CaS and CaO phosphors

(Highest values, measured on best samples)

		%

CaS:Pb	Ultraviolet	17
CaO:Mn	Yellow	5
CaO:Pb	Ultraviolet	10

keeps open the possibility of excitations in phosphors which are not, or to a much lesser degree, possible in semiconductors.

A relatively small fraction of the primary high-energy electrons arriving from the electron gun at the phosphor surface is back scattered from the latter and does not contribute to luminescence. The amount of energy lost in this way has recently been determined by Meyer (8) to be close to 10% for typical phosphor powder layers somewhat dependent on the phosphor material and the surface texture of the layer. Hence, close to 90% of the incident energy is actually absorbed by the phosphor.

Primary electrons penetrating into the lattice of the phosphor create, by collision, avalanches of free carriers and localized excited states. One may simplify the task of a mathematical description of the complicated avalanche process and consider only the low-energy tail of it, *i.e.*, the creation of the final states of excitation which emit light quanta when they recombine afterward. Possible excitation states in a phosphor are schematically shown in Fig. 1. They include free electron-hole pairs (A), free carrier-ionized activator pairs (B), and excited but nonionized activators (C).

The mean energy required to create, by collision with hot free carriers, one of the final excitation states may be E_x. Each state delivers only the energy E_m (mean energy of the emission light) if the recombination is radiative, and nothing if it is nonradiative. Hence, the over-all energy efficiency can formally be written as

$$\eta = \eta_a \frac{CE_m}{E_x} \qquad [1]$$

where $C \leq 1$ is the probability of the recombination to be radiative and where η_a ($\approx$90% in typical phosphors) is the primary energy absorption coefficient. The mean excitation energy, E_x, may be expressed as multiple (factor α) of the band gap energy, E_g, of the material

$$\eta = \eta_a \frac{CE_m}{\alpha E_g} \qquad [2]$$

This equation has been published (in slightly different formulation) by Garlick (1) and by Ludwig and Kingsley (3).

The quantity E_g depends only on the phosphor material (*e.g.*, $E_g = 3.7$ eV for all ZnS phosphors) and E_m depends only on the emission spectrum of the luminescence (*e.g.*, $E_m = 2.75$ eV for blue ZnS:Ag). The recombination coefficient, C, may vary from sample to sample and may be responsible, to some degree at least, for the scatter in efficiency reported by different workers on different samples of the same phosphor type. The assumption is made here that C is between 80 and 100% in cases of the very best phosphor samples within each type, and this assumption is supported by measurements of the quantum efficiency of photoluminescence (3, 9-11).

The main unknown in Eq. [2] is the factor α of which no reliable measurements are available for most phosphor materials. The situation is simpler in semiconductors in which carrier multiplication by creation of free electron-hole pairs (A in Fig. 1) dominates. This

case is accessible to theory which leads to a minimum value of α close to 3 for semiconductors of equal masses of (hot) electrons and holes (6). Direct measurements of α in Ge,Si, SiC, InSb, GaAs, GaP, CdTe, CdS, PbS, and PbO all gave the uniform result of an α slightly above 3 (12) which may be understood on the basis that effective masses of very hot carriers (in contrast to carriers in thermal equilibrium with the lattice) are nearly equal because they do not correspond to single extrema in conduction band and valence band, respectively.[1]

The excitation process in many phosphors probably is more complicated than in simple semiconductors since excitations other than the creation of free carrier pairs (transition A in Fig. 1) are possible, and since effective masses even of very hot carriers are not necessarily equal in highly ionic wide-gap compounds. Because of these unknowns, we have tried to determine values of α of common phosphor materials with the help of Eq. [2], *i.e.*

$$\alpha = \frac{\eta_a C E_m}{\eta E_g} \qquad [3]$$

from measured values of η, E_m, and E_g with the assumptions of $\eta_a = 0.9$ and $C = 0.9 \pm 0.1$. The latter requires that only the best values of η for each phosphor material can be considered. Some results are shown in Table III. Here, E_m follows from the emission spectra and values of E_g were measured from optical reflection spectra on powders. The values of α so determined in Table III are reliable only to about $\pm$20%. However, there can be little doubt that they do not cluster about 3 but scatter over a fairly wide range including values much higher and much lower than 3. It is also apparent that α-values of sulfides are consistently lower than those of oxygen-dominated phosphors.

Conclusion

We are not able to understand this result in all details but suggest the following effects to be involved and to be worth a further consideration:

(*a*) Oxides are more ionic compounds than sulfides,[2] and it is conceivable that hot free carriers, although they appear to be nearly equal in sulfides, are very unequal in oxides. This should affect the mean excitation energy required at least of transition A (Fig. 1). If so, then sulfide phosphors permit, in principle, higher efficiencies of cathodoluminescence than oxides.

(*b*) The probability factor of radiative recombination, C may be near unity for low-energy excitation characteristic of photoluminescence but may be substantially lower than $C = 0.9 \pm 0.1$ (as assumed in Table III) for excitations involving hot carriers because of competition of a nonradiative way of recombination accessible by hot but not by thermal carriers. This case probably exists in red emitting CaS:Eu^{2+} phosphors (14). If it is possible also in other phosphors it could explain some very high α-values ob-

[1] Pointed out by one of the reviewers of this paper.
[2] Electronegativities are 2.5 eV for $S^=$ and 3.5 eV for $O^=$ (13).

tained with Eq. [3] which otherwise are hard to understand. An example is $CaWO_4$ ($\alpha = 13$) in Table III.

(c) Exciting transitions B and C (Fig. 1) may compete with transition A in many phosphors. For instance, creation of free electron-ionized activator pairs (transition B) by collision with hot carriers has long been considered to take place during electroluminescence of ZnS:Cu and there is no reason to deny the possibility of this transition during cathodoluminescence. The possibility of nonionizing excitation (corresponding to internal 4f → 5d transitions) is demonstrated by a strong optical absorption band at 2.73 eV in CaS:Ce^{3+} phosphors (14), and corresponding nonionizing internal transitions within Mn^{2+} ions are well known in many Mn-activated phosphors. In either case, transitions B and C require less energy than transition A and can easily account for the very low values of α in Table III measured on ZnS:Cu, CaS:Ce, and CaS:Mn.

These three effects *a*, *b* and *c* may be present in different phosphors to various degrees and, in view of this complication, it is hardly a surprise to observe α-values to scatter over a wide range. In fact, α varies even more from phosphor to phosphor than the band gap energy, E_g, and thus is mainly responsible for variations of the optimum efficiency of cathodoluminescence in different materials.

Manuscript submitted Sept. 23, 1970; revised manuscript received Jan. 13, 1971. This was Paper 56 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Manganese-Activated Luminescence in $SrAl_{12}O_{19}$ and $CaAl_{12}O_{19}$

Arnost Bergstein[1] and William B. White[2]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Manganese-activated $SrAl_{12}O_{19}$ and $CaAl_{12}O_{19}$ phosphors have been prepared under oxidizing and reducing conditions, and by direct cation exchange. The red emission of oxidized phosphor and green emission of reduced phosphor confirm previous assignments to octahedral Mn^{4+} and tetrahedral Mn^{2+}, respectively. New emission bands in the yellow and orange arise from centers which are related to cation exchange, presumably the Sr^{2+} or 5-coordinated Al^{3+} sites. The behavior of the various emission bands during further oxidation and reduction provides a guide to the sites on which the activator centers are located.

The compounds $SrAl_{12}O_{19}$ and $CaAl_{12}O_{19}$ with the magnetoplumbite structure are interesting phosphor hosts because of the variety of cation sites and the effect on the luminescence of a distribution of activators among them. Our interest here is to interpret the emission spectrum of Mn in terms of the various valence states and host lattice sites available to it. To achieve this objective, phosphors have been prepared under carefully controlled oxidizing and reducing conditions. By relating the emission to the chemistry of preparation we can achieve an improved understanding of the valence state and site distribution of the activator ion.

Phosphors based on the alkaline earth aluminates were described by Kröger (1) who prepared his materials under both oxidizing and reducing conditions and so was able to show that a characteristic green emission was due to Mn^{2+} and a characteristic red emission to Mn^{4+}. Sakamoto and Hitomi (2) have investigated Tl and Ce sensitizers in Ba and Ca aluminates but did not consider the valence and site distribution of the Mn^{2+} activator itself.

The magnetoplumbite structure is known in considerable detail (3) because of the interest in the magnetic ferrites (4, 5). The structure of $CaAl_{12}O_{19}$, isomorphous with $SrAl_{12}O_{19}$, has been recently refined by Kato and Saalfeld (6). The structure of those aluminates consists of spinel-like blocks with Al^{3+} in both tetrahedral and octahedral sites. The blocks are bound with layers in which Ca^{2+} (Sr^{2+}) in 12-fold coordination replaces an O^{2-} and Al^{3+} occupies sites with 5-fold coordination. The interatomic distances and the geometry of the various sites are summarized in Table I.

Experimental

$CaAl_{12}O_{19}$ and $SrAl_{12}O_{19}$ containing a small amount of Mn were prepared as a sintered, coarse-grained mass of oriented crystals by flame fusion. The valence

Table I. Coordination numbers and cation-anion distances in $CaAl_{12}O_{19}$ [from (6)]

Cation	Coord. number	Distance from O^{2-} anion				
		O(1)	O(2)	O(3)	O(4)	O(7)
Ca	12				2.694	2.848
Al(1)	6	1.995	1.818	1.970	1.860	
Al(2)	4	1.801			1.828	
Al(3)	6		1.865			1.896
Al(4)	6	1.883				
Al(5)	5				2.187	1.839

Lattice constants of hexagonal structure: $a = 5.564$, $c = 21.892$A.

state of the Mn was adjusted in the final crystals to obtain an oxidized material, a reduced material, and an exchanged material.

$CaCO_3$ or $SrCO_3$ and Al_2O_3 were mixed in the ratio of 1:6 or 1:(6-2x), x being the mole per cent of $MnCO_3$. The activator concentration ranged from 0.012 to 0.30 m/o (mole per cent). The mixtures were homogenized and heated in air at temperatures from 1250° to 1400°C in intervals of 50°C. After each heating the homogenization was repeated and an x-ray analysis performed to check the phase composition. The annealed powder was used as starting material for growing single crystals or conglomerates of oriented single crystals by the flame fusion method, using an A.D. Little Verneuil apparatus. The ratio of hydrogen to oxygen in the flame was varied from reducing to oxidizing. The growth rate diminished when the percentage of hydrogen increased. The exact composition of the gas was not determined.

The rods from the Verneuil growth were cut into sections parallel or perpendicular to the c-axis. These sections were treated in one of the following ways:

Oxidized: Heated in air at temperatures from 900° to 1400°C for 8-100 hr.

Reduced: Heated in a reducing atmosphere of H_2 or in a carbon furnace flushed with argon at temperatures from 900° to 1250°C for 4-24 hr. The oxygen fugacity under these conditions is in the range of 10^{-5}-10^{-20}.

Exchanged: Soaked in molten $MnCl_2$ at 750°-850°C in a streaming atmosphere of purified argon and carefully washed to remove soluble chlorides.

The structure of the samples was checked by x-ray after the heat treatment. All samples showed only diffraction lines of the magnetoplumbite structure. No α-Al_2O_3 could be detected, in spite of the incongruent melting point reported by Wisnyi (7).

The chemical composition of the starting materials was checked by emission spectroscopic analysis. They contained traces of Fe, Si, Mg, and Be, about 1% Ca and an amount of Mn by which the Mn concentration in the aluminate became 0.01-0.02 m/o. Rare earths, Cr, and Na were not found.

Emission spectra were recorded on a Cary Model 14 spectrophotometer using a luminescence attachment with excitation at 254 and 365 nm. Measurements at temperatures between −168°C and room temperature were performed using liquid nitrogen and an excitation frequency of 365 nm. Qualitative cathodoluminescence and polarization experiments were performed on a luminoscope ELM-2A from the Nuclide Corporation, using 20 and 50X magnifications, and cathode rays of 6-18 kV, and on an electron microprobe. Absorption spectra were obtained on a Beckman DK 2A spectrophotometer using a diffuse reflectance attachment and a MgO reference. Some emission spectra were also obtained using the 488 nm line of an ionized argon laser as an exciting source with a Spex Ramalog spectrophotometer. In general these spectra did not show any features in addition to those observed by more conventional excitation.

Results

Emission spectra.—Emission spectra of $SrAl_{12}O_{19}$ prepared in various ways are shown in Fig. 1 and 2. These spectra are direct tracings from the Cary charts. No correction for photomultiplier response has been made and for this reason no intensity scale is shown.

Rods of $SrAl_{12}O_{19}$:Mn prepared by the flame fusion method at a very high ratio of H_2 to O_2 in the flame were white and when excited by uv radiation of both 254 and 365 nm they showed the emission spectra reproduced in Fig. 1. Five emission bands appear with their peaks at 385, 515, 560, 593, and 640 nm, the band at 640 nm being very weak.

Rods of $CaAl_{12}O_{19}$:Mn and $SrAl_{12}O_{19}$:Mn prepared under more oxidizing ratios of H_2 to O_2 were pink in their outer region and white in the center. The relative extension of the pink region increased with increasing oxygen content in the flame. The spectra were similar to the "oxidized" material in Fig. 1. There is one band with its peak at 511 nm and another intense band between ~600 and 700 nm, with sharp peaks at 643 and 657 nm.

When further manganese was introduced into such a sample by ion exchange with molten $MnCl_2$ in an inert atmosphere at 680°-750°C, emission spectra shown in Fig. 2 resulted. In addition to the green and red bands a broad band between ~520 and 600 nm with peaks at 565 and 600 nm occurred in $SrAl_{12}O_{19}$ and peaks at 562 and 590 nm occurred in $CaAl_{12}O_{19}$.

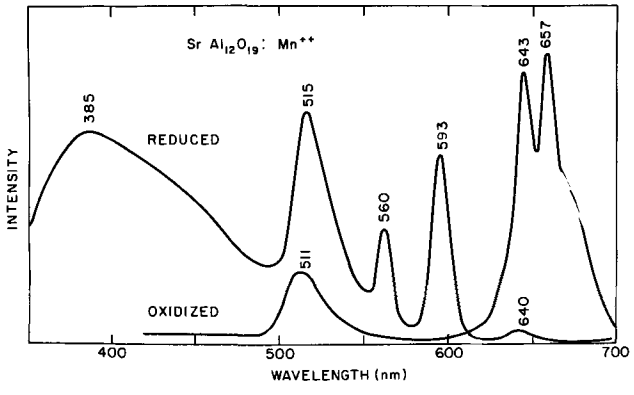

Fig. 1. Emission spectra of $SrAl_{12}O_{19}$ with 0.02 m/o Mn^{++}. "Reduced" was prepared by flame fusion with reducing (hydrogen-rich) flame. "Oxidized" was prepared by firing starting materials in air at 1400°C.

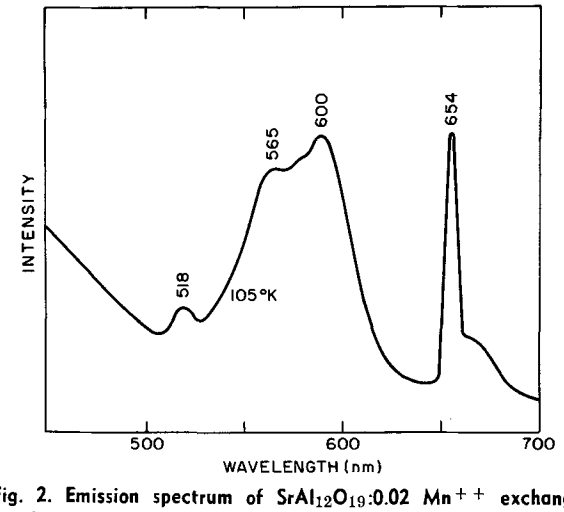

Fig. 2. Emission spectrum of $SrAl_{12}O_{19}$:0.02 Mn^{++} exchanged by soaking in $MnCl_2$ at 680°C. Excitation 365 nm. Temperature 105°K.

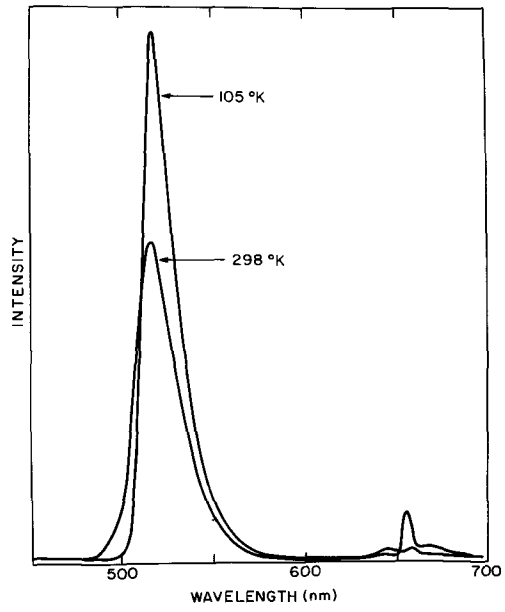

Fig. 3. Temperature dependence of the green band in totally reduced phosphor, $SrAl_{12}O_{19}$:0.2 Mn^{++} fired in hydrogen.

When $SrAl_{12}O_{19}$ is reduced by firing at 1400°C in hydrogen only the green band appears. The intermediate 560 and 590 nm bands vanish and the red band is very weak (Fig. 3).

Visual observations of cathode ray-excited samples in the electron microprobe and in the luminoscope ELM-2A showed sharp boundaries between red and green luminescent regions, corresponding to the pink and white colors without excitation. In the $MnCl_2$ exchanged samples veins of orange emission could be observed. The green and the orange emissions were polarized parallel to the c-axis; the red emission did not show evidence of polarization.

Oxidation of Verneuil-grown samples in air at 900°-1000°C for 4 hr caused a decrease of the intensity of the green emission band but no change of the intensity of the red band. Oxidation for a shorter time at 1300°-1400°C caused a decrease and eventually the disappearance of the green band and a considerable increase in the intensity of the red band. Analogously, reduction at temperatures 900°-1000°C in hydrogen or in a CO-containing argon atmosphere lead to a decrease of the intensity of the red band but to no change of the green band, whereas reduction at 1200°C made the red band decrease and disappear and the green band increase simultaneously within the same or a shorter time. The reduction of samples showing originally only the red and no green emission band at lower temperatures (900°-1000°C) produced nonluminescent samples.

Temperature dependence.—The green band present in almost completely reduced material increased in intensity with decreasing temperature (Fig. 3). However, when both the red and green centers were present, the intensity of the green band decreased with decreasing temperature (Fig. 4). The spectrum of the red center in this phosphor sharpens and the high-frequency component nearly disappears. When only the red center is present, the low-frequency component increases markedly at low temperatures while the high-frequency component becomes very weak. This effect is illustrated in Fig. 5 and the temperature dependence of the two bands is shown in Fig. 6.

Discussion

Valence state and site distribution of activator centers.—The green and the red emission bands of the alkaline earth aluminates were reported by Kröger (1) who ascribed them to Mn^{2+} activator centers and

to Mn with a higher valence than 2, from the dependence of their presence on the oxygen partial pressure of the atmosphere during preparation or heat treatment. The higher valence was shown to be Mn^{4+}, by chemical analysis and from the similarity of the emission spectrum to the spectra of phosphors activated with the isoelectronic Cr^{3+} ion. Since then the characteristic emission of Mn^{4+} has been identified in a large number of hosts and its identification does not seem to be in doubt (8-11).

The additional emission peaks at ~560-595 nm in the spectra in Fig. 1 and 2 must be ascribed to Mn^{2+} centers in lattice positions different from the centers causing the green emission at 500-520 nm. They appear only in reducing conditions in the hydrogen flame and in $MnCl_2$ exchanged material.

We examine first the green emission with its peak between 510-520 nm and have two experimental hints as to the location of the Mn^{2+} center to which it is linked. First, the green emission is not found in α-Al_2O_3, containing only Al^{3+} ions in octahedral coordination, but it is found in the spinel $MgAl_2O_4$ which contains both tetrahedrally and octahedrally coordinated sites but no 5-fold coordinated Al^{3+} sites nor 12-fold coordinated Sr^{2+} sites. The Mn^{2+} according to its relative site preference energy (−14.7 kcal/m) compared with Al^{3+} and Mg^{2+} (−2.5 and −5.0 kcal/m) (12) will occupy mostly tetrahedral sites. Second, the transformation of a green emitting $CaAl_{12}O_{19}$:Mn or $SrAl_{12}O_{19}$:Mn into a red emitting material requires a considerably higher temperature at equal annealing time than the mere oxidation of the Mn^{2+} centers, which means that the transformation is linked with cation diffusion and that the two kinds of centers occupy different lattice sites. All this suggests that the Mn^{2+} ions causing the green emission are situated in the tetrahedral Al(2) lattice site. The polarization of this emission may be due to deformations of the surroundings in consequence of the difference in size and charge between the Mn^{2+} ion and the Al^{3+} ion. The difference in charge should be compensated by Al^{3+} ions in interstitial positions or, less likely, by anion vacancies.

Addition of 0.02 m/o Fe as Fe_2O_3 to the starting material of the Verneuil grown samples resulted in quenching of the green emission band, whereas the red emission band was not affected contrary to the observation in Kröger (1).

It is interesting that no emission was observed that could be assigned to Mn^{2+} on the octahedral sites of the spinel block. Since the sites, Al(1), Al(3), and Al(4), are all small, the manganese emission should be pushed into the far red or near infrared. The emission is at 730 nm in MgO (13) and the AlO_6 octahedra are smaller than the MgO_6 octahedra. Either the tetrahedral site preference of Mn^{2+} has concentrated it on the tetrahedral site or the emission of octahedral Mn^{2+} lies in the near infrared beyond the range of our instrumentation.

The red bands arise from the ^2E, $^2T_1 \rightarrow {}^4A_2$ transition of Mn^{4+} · Mn^{4+} with an effective radius of 0.54Å will easily replace Al^{3+} (0.53Å) in octahedral coordination and is unlikely to substitute for the far too large Ca^{2+} or Sr^{2+} ions in any coordination. According to Table I, three kinds of oxygen octahedra around Al^{3+} ions with different anion-cation spacing and different degree of symmetry are present in the crystal lattice. From the lack of polarization of the emitted radiation the most symmetrical site, labeled Al(4) would represent the most likely location of the Mn^{4+} centers. If vicinity of the charge compensating Ca^{2+} or Sr^{2+} ions should be critical, the Al(3) sites would be preferred, which are situated on both sides of the mirror planes containing the alkaline earth ions.

The two emission peaks introduced into the Verneuil grown $CaAl_{12}O_{19}$:Mn and $SrAl_{12}O_{19}$:Mn by ion exchange with molten $MnCl_2$ in an inert atmosphere (Fig. 2) seem to be identical with peaks at 560 and 593 nm in the spectrum of a Verneuil grown sample prepared with a relatively high hydrogen ratio in the flame (Fig. 1). In both cases the Mn centers responsible for the peaks will contain Mn^{2+} in consequence of the neutral, and reducing atmosphere present during ion exchange and preparation, respectively. None of these emission peaks appeared when crystals containing only Mn^{4+} ions were reduced under any conditions of temperature or time. Thus we may assume that the Mn^{2+} centers and the Mn^{4+} centers are situated in different lattice sites. If our assignment of the tetrahedral sites to the green Mn^{2+} emission is correct and if we can eliminate the three kinds of octahedral sites in Table I on size and coordination considerations the only sites left for the yellow to orange emitting Mn^{2+} centers are the Al(5) five-fold coordinated site and twelve-fold coordinated Sr site.

There are other reasons for which Al(5) and Ca^{2+}(Sr^{2+}) lattice sites seem to be more likely than the octahedral Al^{3+} sites. Ion exchange proceeds more easily in the Sr^{2+}- and Al(5)-containing mirror planes than in the more compact Al^{3+} spinel blocks. The spacing is larger than in the Al^{3+} octahedra, the Ca(Sr)-O distance being 2.67(2.85) and 2.85(3.0)Å and the Al-O distances about 1.85 and 2.3A for the five-coordinated Al^{3+}. There are no clean-cut criteria by which to make specific assignments. Mn^{++} in either the 5-coordinated or the 12-coordinated site should emit in the green to orange range. It is interesting the $MnCl_2$-exchanged β-alumina also contains an orange band at 590 nm but no band at 560 nm (14). The structures of β-Al_2O_3 and $SrAl_{12}O_{19}$ are very similar except that the easily exchangeable Na^+ site in $NaAl_{12}O_{17}$ is 6-coordinated. The most reasonable conclusion seems to be that the orange emission at 590-600 nm arises from Mn^{2+} on the easily exchangeable large cation site (Sr^{2+}, Ca^{2+}, or Na^+) and that the yellow-emitting center is associated with the 5-coordinated Al(5) site.

It seems from our experiments that only Mn^{2+} and Mn^{3+} or Mn^{3+} and Mn^{4+} are simultaneously present in equilibrium in regions of the crystal which can be considered homogeneous thermodynamic systems, and not Mn^{2+} and Mn^{4+} or all three valences at once. This observation is in agreement with the predictions of Kröger (15). The appearance of the green and the red emission bands in one spectrum is often the result of inhomogeneous samples, containing oxidized and reduced regions, as shown by the optical microscopic observation of the cathodoluminescence.

This is of importance for the mechanism of the charge compensation assumed when tetravalent manganese is substituted for trivalent aluminum into aluminate lattices. It makes unlikely the formation of Mn^{4+} ions by disproportionation of two Mn^{3+} ions into Mn^{2+} and Mn^{4+}. As a consequence, other charge-compensating ions such as Mg^{2+} or Zn^{2+} had to be added to α-Al_2O_3 to produce the red Mn^{4+} emission (1). It is worth mentioning that no red luminescence could be obtained in $ZnAl_2O_4$, which is a normal spinel with the bivalent Zn^{2+} ions in tetrahedral lattice sites, even when treated under the same oxidizing conditions as the luminescent mixed spinel $MgAl_2O_4$, in which part of the Mg^{2+} ions are in octahedral surroundings. If, however, Zn^{2+} is dissolved in α-Al_2O_3, which contains only octahedral lattice positions, the Mn^{4+} spectrum characteristic for α-Al_2O_3 was obtained by Kröger in inhomogeneous samples containing both spinel and corundum phases. This indicates that in aluminates the valence of a cation alone is not decisive for its ability to compensate for the charge of the Mn^{4+} ions and that the coordination number might be an important factor as well. In magnetoplumbite alkaline earth aluminates, the bivalent alkaline earth ions in the mirror planes seem to provide the compensating effect, either indirectly by making possible the introduction of lattice defects like interstitial oxygen ions

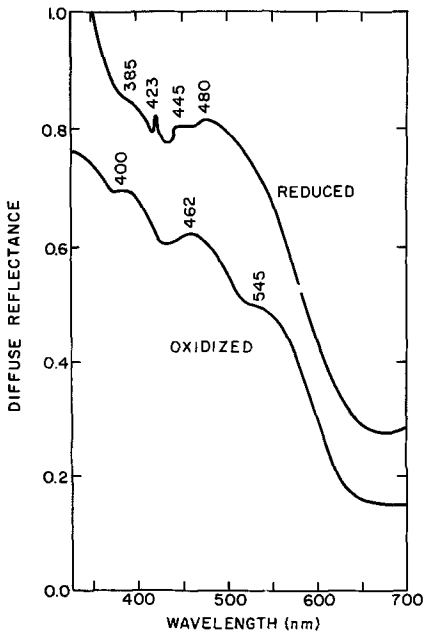

Fig. 7. Diffuse reflectance spectra of highly oxidized and highly reduced $SrAl_{12}O_{19}$:5.0 Mn^{++}.

or Al^{3+} vacancies or directly by being present in an amount exceeding stoichiometry. But here too the substitution of part of the twelve-coordinated Ca^{2+} ions by the smaller Mg^{2+} ions in six-fold (and four-fold) coordination, greatly increases the intensity of the Mn^{4+} emission.

Additional evidence for the valence state and site distribution of the manganese is provided by the reflectance spectrum in Fig. 7. The "reduced" material emits only in the green band. The absorption spectrum shows quite clearly the presence of Mn^{2+} by the characteristic sharp band at 423 nm due to the $^6A_1 \rightarrow {}^4A_1, {}^4E$ transition. Also much in evidence and obscuring the Mn^{2+} band is a broad absorption centered at 480 nm. This same band also appears in the spectrum of "oxidized" $SrAl_{12}O_{19}$ at 462 nm. The single band in this position is very characteristic of Mn^{3+}. The frequencies, 20,800 and 21,600 cm^{-1} respectively, yield a Dq value for the $^5E \rightarrow {}^5T_2$ transition of 2080 and 2160 cm^{-1} which may be compared with the value 1965 cm^{-1} measured in corundum by McClure (15). Geschwind *et al.* (11) reported a band at 21,300 cm^{-1} which they assigned to the $^4A_2 \rightarrow {}^4T_2$ transition of Mn^{4+}. However, there does not seem to be any final proof that they did not have in addition to Mn^{4+} also Mn^{3+} in their Al_2O_3 crystals. This band would place Mn^{3+}, present in both red-emitting and green-emitting materials, on an octahedral site.

New bands at 545 and 400 nm appear in the spectrum of "oxidized" phosphor. These should be the spin-allowed transitions $^4A_2 \rightarrow {}^4T_2$ and $^4A_2 \rightarrow {}^4T_1$ transitions of Mn^{4+}. The Dq value obtained from the 545 nm band is 1830 cm^{-1}, lower of course, than the value obtained by Geschwind *et al.* (11) because of the different assignment, but still a not-unreasonable value for Mn^{4+} on an octahedral site. By comparison Cr^{3+} in Al_2O_3 yields a Dq value of 1845 cm^{-1}. Dq for Mn^{4+} should have been somewhat larger because of the higher charge.

Unlike Fe^{2+} which has a similar but inverted energy level scheme, Mn^{3+} appears not to act as a killer center for luminescence. This is because the critical quintet $\rightarrow$ quintet transition lies above the emitting levels for both Mn^{2+} and Mn^{4+}, whereas in Fe^{2+} with a much smaller Dq (typically 1000 cm^{-1}) the quintet levels lie below the manganese emitting levels and so quench them.

Red-emitting bands and their temperature dependence.—The red-emitting center is generally agreed to arise from the ^2E and $^2T_1 \rightarrow {}^4A_2$ transition of Mn^{4+}. The usual Tanabe-Sugano diagram shows that these two levels are close together and essentially independent of the crystal field strength. The energies of the pair of levels are functions of the Racah B parameter, and thus of the degree of covalency of the Mn^{4+}-O bond. The emission from a wide variety of Mn^{4+}-activated phosphors including MgO (13), magnesium fluorogermanate (9), $MgSnO_3$, and magnesium arsenate (17) all fall in the range of 638-671 nm, indicating only small bond-type changes in this group of phosphors. The emission of $SrAl_{12}O_{19}$ falls directly into the range of previously known phosphors. Schläfer *et al.* (18) were able to move this emission over a range of 650-900 nm in a variety of Cr^{3+}-activated phosphors by varying the nature of the ligand and thus the degree of covalent bonding. A similar behavior would be expected for Mn^{4+}-activated phosphors.

Geschwind *et al.* (11, 19) explained the striking temperature dependence of the red emission from Mn^{4+}-activated Al_2O_3 as a thermal equilibrium between the populations of the ^2E and $^2T_1$ energy levels. A similar temperature dependence was observed in $SrAl_{12}O_{19}$ (Fig. 5). A plot of the ratio of the intensities (from Fig. 6) of the two red bands against reciprocal temperature yields a straight line spanning all points in Fig. 6 from which the energy separation was calculated as 323 cm^{-1}. Precise measurement of the red band positions at room temperature gives values of 15, 560, and 15,200 cm^{-1}. The difference, 360 cm^{-1}, is in good agreement with the thermal value. The larger energy difference compared with 82 cm^{-1} in Al_2O_3 is likely due to the increased distortion of the AlO_6 octahedra in the $SrAl_{12}O_{19}$ host.

Electron Microscope Characterization of Defects on Gaseous-Etched Silicon Surfaces

E. R. Levin, J. P. Dismukes,* and M. D. Coutts

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Gaseous etching of silicon with HI-HF mixtures can produce mirror-smooth surfaces at temperatures as low as 900°C. Steps result when etching is too rapid. Triangular pits with plane facets can be formed, showing that etching is by a layer mechanism. Mesa-like protrusions, continuous with the silicon matrix, appear on wafers etched in the presence of SiC. The protrusions are not related to precipitated impurities, second phase inclusions, or crystallographic imperfections present in the silicon prior to etching. Rather, they are generated during the etching process by passivation of the silicon surface.

An important step in the processing of silicon wafers is the gas-phase etching to remove the SiO_2 layer and the residual work damage prior to epitaxial growth. It is desirable that this process be carried out at a relatively low temperature to simplify equipment and to reduce harmful diffusion. Both HCl (1, 2) and H_2S (3, 4) attack silicon at a rapid rate and provide smooth surfaces at the relatively high temperature of 1250°C. However, below 1100°C these reagents give typically rough surfaces.

Recent work has been directed toward etching at lower temperatures (5-11). The most critical factor in etching at low temperatures is the much decreased volatility of the SiO_2 coating (11-13). This layer is easily removed at high temperatures by the forward reaction

$$SiO_2(s) + Si \rightleftarrows 2SiO(g)$$

but at lower temperatures, the reverse reaction causes SiO_2 deposition. At 900°C, for example, SiO_2 begins to form on a bare silicon surface when the O_2 concentration exceeds 0.1 ppm. In etching with HI-HF mixtures, the HF removes the oxide film from the surface and prevents its reformation; however, other process variables must be controlled to give surfaces that are smooth and free of defects.

This paper describes the morphology of defects observed under different etching conditions. These deviations from perfectly smooth surface conditions include stepped structures, pits, and raised defects which appear under certain conditions.

Experimental

Apparatus and procedure for etching.—The apparatus and conditions of etching have been given previously (11). Typical total etchant gas flow was 10 l/min, giving an average linear flow velocity of 50 cm/sec in the reaction chamber (1 cm x 4 cm cross section). Typical concentrations of HI were 0.5-2.5%, and those of HF were 0.001-0.1%. The susceptor was usually silicon carbide-coated graphite, with, in some cases, an additional coating of silicon. The susceptor was heated by a 5 kW, 450 kHz Lepel generator; the temperature of the silicon was monitored by an optical pyrometer.

The specimens were <111> wafers, 1 in. in diameter and 0.2 mm thick, with soft-polished faces (14, 15). Wafers of both n- and p-type silicon were studied, and both high- and low-resistivity variations of each type were included. Etch rates were determined from weight loss of the wafers with a Mettler balance sensitive to 0.01 mg, and are given in Fig. 1.

Examination of etched surfaces.—The general features of the etched surfaces, including such factors as the smoothness and uniformity of the etch and the presence of gross defects or irregularities, were easily established by visual examination and by low-power optical microscopy. Details of the surface morphology of the etched wafers were studied by scanning electron microscopy in the emissive mode (16) with a Cambridge "Stereoscan." Since the SEM image is pro-

Key words: semiconductor surfaces, surface etching, scanning electron microscopy, silicon.

duced by secondary electrons emitted from the surface under observation, no pretreatment of the silicon specimens was required.

The optical and scanning electron microscope observations were supplemented by electron microprobe analysis, x-ray topography and transmission electron microscopy and diffraction.

Results and Discussion

There was no appreciable difference in etch rate between n- and p-type wafers, nor between wafers of low and high resistivity. However, n-type wafers were generally found to etch very slightly smoother than p-type, and therefore the n-type wafers were selected for the bulk of the work.

Smooth vs. *stepped surfaces.*—An array of steps is one major cause of roughness on etched surfaces. Figure 1 shows the quadratic dependence of etch rate upon HI concentration at 900°C (11). At low concentrations of HI, smooth surfaces are obtained. As the HI concentration is increased, a transition from smooth to stepped etched surfaces is observed. At high etch rates, individual steps or arays of steps become evident, as in Fig. 2. It is significant that the stepped, rough surface in Fig. 2 does not contain pits of the kind usually encountered in preferential etching with liquid (17) or other gaseous (1) etchants.

It is useful to consider the formation of steps during etching in relation to conclusions of other studies. Joyce (18) has attributed step formation during growth to adsorbed impurities. However, in our case the steps observed after etching at high rates are apparently not related to impurities in the etchant gas, for the surface goes from very smooth to very rough over a small range of HI concentration (Fig. 1). On the other hand, since the etch rate increases with temperature, the steps could be formed by a process which is the inverse of the dendritic growth conditions described by Sirtl (9b).

Pits.—Pits are a common defect on rough or preferentially etched surfaces (1, 17). Figure 3 shows a surface etched at 900°C with 1% HI (without HF) in 95% He-5% H_2 carrier gas. The surface is made rough by a distribution of triangular etch pits and by a background array of very fine steps that are barely resolved. Somewhat similar surfaces, showing uniformly oriented triangular etch pits have been observed on (111) diamond surfaces etched with oxygen gas at reduced pressures (19). The appearance of steps and the fact that the pits have plane faces are evidence that etching proceeds by a layer mechanism, the close-packed planes being attacked relatively slowly. Thus, the etching process may be the inverse of the growth of single crystal silicon, which has been shown to take place by the propagation of submicroscopic steps (20). The pits could be "etch pits" formed in preferential attack at dislocations by oxygen or the HI reagent.

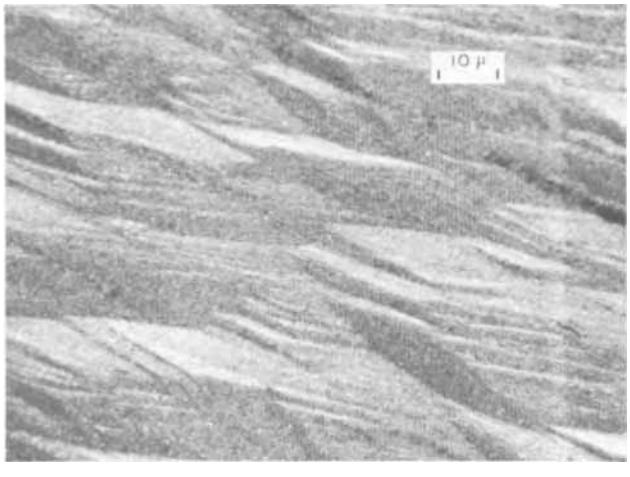

Fig. 2. Scanning electron micrograph showing surface roughness caused by large steps. The silicon wafer was etched at 900°C with 2.75% HI-10^{-3}% HF in 80% He-20% carrier (45° tilt).

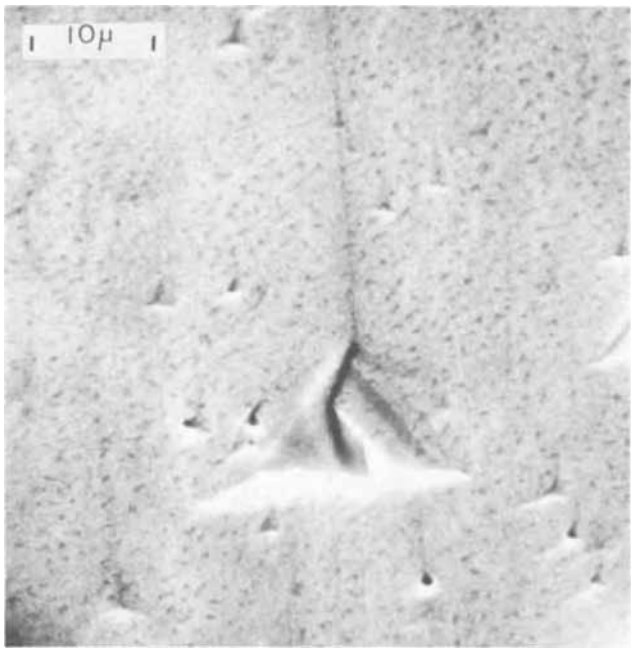

Fig. 3. Surface roughened by triangular etch pits and array of fine steps (45° tilt).

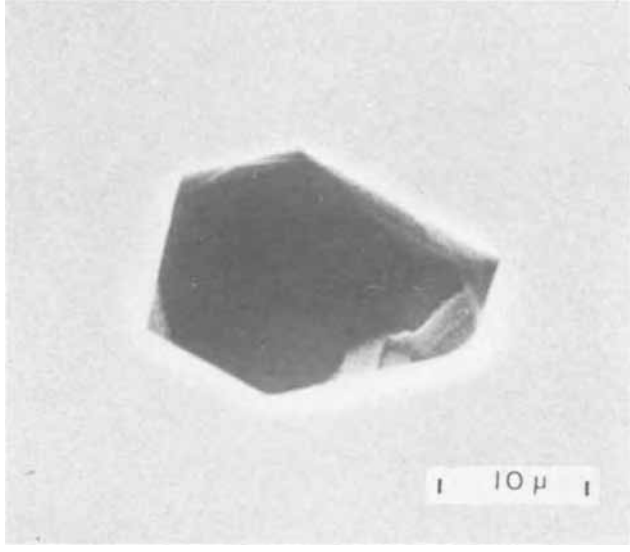

Fig. 4. Hexagonal "etch" pit with planar facets. Brightness around edge of pit suggests it is a low conductivity region (45° tilt).

Figure 4 shows a hexagonal pit in an otherwise smooth surface, etched with 0.5% HI (10^{-3}% HF) in 95% He-5% H_2 at 900°C. The area surrounding the pit is flat and featureless. Pits of this kind were relatively isolated; they occurred over only a portion of the wafer surface, with a maximum density of about 50/cm^2. The pit in Fig. 4, like those in Fig. 3, has straight edges and often planar facets which are parallel to the faces of other pits. This indicates that both the triangular and the hexagonal pits bear a crystallographic relation to the silicon matrix. It does not necessarily mean that the different pits are nucleated by the same mechanism.

The area of the surface immediately surrounding the hexagonal pit in Fig. 4 appears bright compared with the rest of the smoothly etched silicon surface. This is not the normal contrast related to enchanced production of secondaries at an edge, since this effect

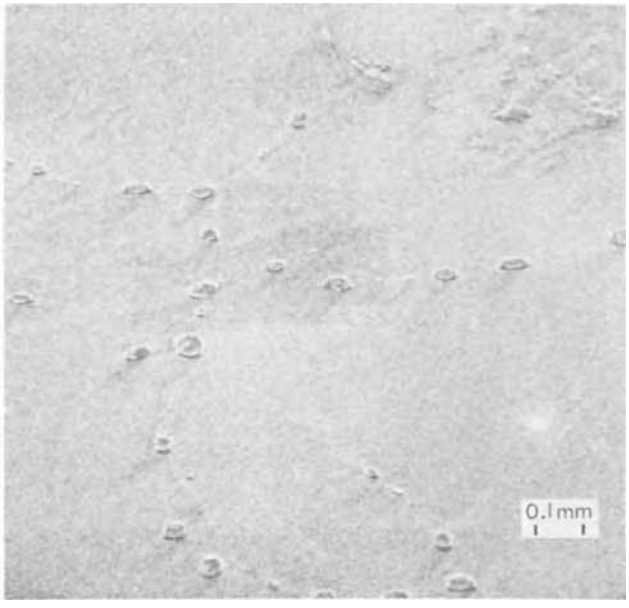

Fig. 5. Mesa-like defects on wafer etched on SiC-coated susceptor (45° tilt).

is not apparent near pits on other samples of Si and GaAs produced by growth or chemical etching. This bright contrast in the scanning electron micrograph indicates that the region may have lower conductivity or a slightly different surface composition than the surrounding matrix.

Raised defects.—Silicon wafers can be etched with HI-HF mixtures on SiC-coated graphite susceptors to produce surfaces which are smooth and free of steps and pits. However, wafers etched in this manner often exhibit defects which protrude outward from the etched surface. A low-magnification view of an etched wafer containing many such raised defects is shown in Fig. 5. This wafer was etched at 900°C with 1% HI (0.1% HF) in 80% He-20% H_2 carrier gas. These defects are present in area densities ranging from 1 to 100 per cm^2. However, they appear only when the wafer is etched on a SiC-coated susceptor: when the SiC susceptor is overlaid with a coating of silicon, the raised defects are not produced.

In Fig. 5, the defects have formed at almost regularly spaced intervals along lines which divide the surface into a cellular configuration. This arrangement suggests that the crystal may be a mosaic of slightly misoriented subgrains. Low-angle subgrain boundaries constitute very favorable sites for dislocation arrays, stacking faults, and precipitates. However, Lang x-ray topographs of this wafer showed it to be free of strain fields. No evidence was found for the existence of subgrain boundaries, dislocations, or stacking faults in the crystal. The mesa-like defects of Fig. 5 are therefore not related to strain in the crystal.

Defect features are shown in Fig. 6 at higher magnification. The defect joins the Si matrix smoothly, with no apparent boundary discontinuity. The sides are straight and prismatic, and the outer wall section is flat-topped, both of these features suggesting the structure is bounded by crystallographic facets. The central region of the mesa is flat but slightly lower than the outer wall on one side, while on the other side the plane surface is tilted downward and breaks through the outer wall. In many of the defects, the central region is completely flat and the encircling outer wall unbroken.

A similar raised defect from a different wafer is in Fig. 7. This micrograph was taken with the specimen tilted at 86° so that the wafer surface is seen at almost grazing incidence. The defect is regular in shape and extends about 1μ above the etched surface. The raised area behind the defect appears to be associated with

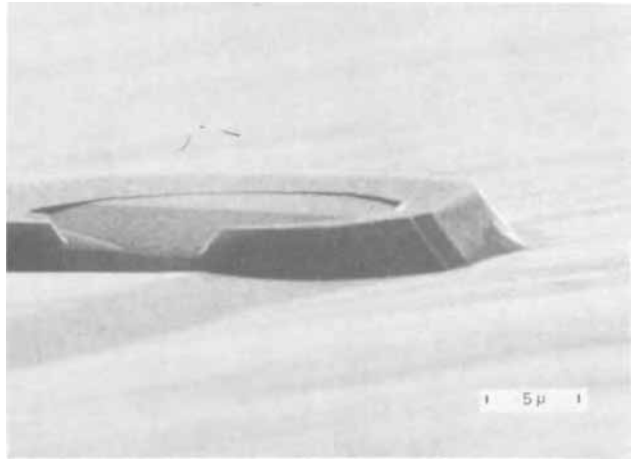

Fig. 6. Typical example of mesa defect on the surface of the wafer of Fig. 5 (80° tilt).

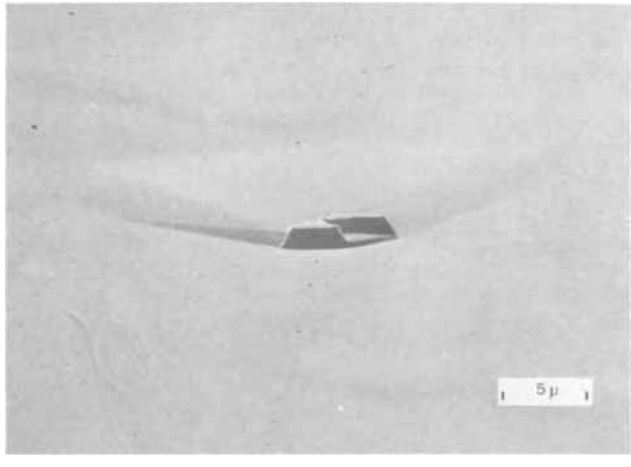

Fig. 7. A protruding defect on a different etched wafer, showing the similarity to the defects in Fig. 5-6. Note the slightly raised area spreading out behind the defect and similar smaller bumps in the foreground (86° tilt).

deflection of the etchant gas stream. The surface is otherwise featureless, except that several smaller bumps of the same general shape and orientation appear in the foreground, suggesting that smaller defects had been present but were etched away.

All of the defects in Fig. 5-7 are similar in appearance and in relation to the silicon matrix, and can evidently be attributed to the same cause. Their appearance suggests that they formed because the silicon has been etched rapidly around the periphery of the formation, while the flat central area has been etched at a slower rate. The etchant gas mixture did not attack the defect region as rapidly as the surrounding silicon, which is etched down around the defect. The slight ridging of the surfaces behind the defects in Fig. 7 may have resulted from disturbance of the gas flow pattern.

Raised defects on the surfaces of etched silicon crystals have been observed by a number of investigators (9*d*, 21-23). Although these protrusions have been attributed to precipitation of impurities with low solubility, such as carbon (β-SiC) or oxygen (SiO_2) (9*d*), no consensus has been reached on their exact nature.

It has long been recognized that oxygen in silicon can cause thermal conversion (24) of p-type silicon and precipitated SiO_2 (9c). For example, typical Czochralski-grown silicon contains up to 10^{17} oxygen atoms/cm^3 (9*e*). Similarly, typical high quality silicon can contain carbon in concentrations of 10^{18} atoms/cm^3

(25, 26), while the solubility limit for carbon in silicon is only of the order of 10^{16} atoms/cm^3 at 1000°C (25, 27). β-SiC has been identified as a second phase in Si crystals with high carbon content (27). Thus, precipitates of β-SiC or SiO_2 could be expected in even relatively high quality Si. However, electron microprobe analysis of the surface of Fig. 5 shows that the mesa-like defects are not precipitated SiO_2 or SiC. The microprobe observations indicate that there is no appreciable shift in the concentration of C or O (nor of B, N, or Sb) at or near the defects.

In further attemtps to identify and characterize the raised defects, conventional electron microscopy and diffraction were employed to study the wafer of Fig. 5. Reflection electron diffraction from the surface exhibiting the defects (Fig. 5) yielded only the well-defined single-crystal patterns to be expected from the silicon matrix. No broadening of the diffraction spots, suggestive of small misorientations, were detected. The reflection method is recognized to have limitations, in this case uncertainty in locating the exact site of electron beam interaction with the surface and in gauging the relative contributions of the matrix and defects in producing the observed patterns. However, the density of defects on the surface was great enough, and they protruded far enough out from the matrix surface to give confidence that they would make an appreciable contribution to the reflection diffraction patterns. In previous cases (31, 32) β-SiC was easily identified by transmission or reflection electron diffraction. In the present work the same techniques gave no evidence for β-SiC on the mesa-type defects.

Several pieces of the wafer containing the defects were thinned by chemical polishing and ion bombardment to allow transmission electron microscope investigations. One group of these specimens was prepared by thinning the crystal entirely from the back side, leaving the original defect surface unchanged. In these specimens, both the Si matrix and the defect areas, which were clearly defined and identifiable by the contrast alterations attendant to the thickness changes, yielded only good, sharp single-crystal silicon patterns. No shifts in orientation or quality of the patterns were detected in moving between the matrix and the defects. Very hard materials such as crystalline SiC or SiO_2 might be expected to introduce strain, which is not present in this case.

The remaining electron transmission specimens were prepared by thinning the crystal from both sides simultaneously, thereby completely effacing the original surfaces and leaving only a thin portion from the middle of the wafer. These specimens were studied by transmission microscopy and selected-area diffraction. The observations showed conclusively that no minute precipitates were present in the wafer. The specimens were also found to be completely free of dislocations and other crystallographic imperfections such as low angle boundaries and stacking faults. Only sharp, perfect single crystal diffraction patterns of Si were obtained.

These electron-optical results give further confirmation to the electron microprobe evidence and x-ray topography studies cited. Together, this body of evidence further substantiates that the mesa-like defects are not associated with precipitates or crystal imperfections present in the bulk silicon wafer before etching. Rather they must be hillocks of almost pure silicon remaining on the surface as the rest of the wafer etches down around them, perhaps with a very thin layer of possibly amorphous oxide or carbide protecting the surface.

Recently both D'Asaro *et al.* (9*f*) and Wagner (23) reported that numerous large "ridges" or "spikes" appear on single-crystal silicon surfaces after standard aqueous etching at room temperature. Using thermodynamic arguments, Wagner derived ternary phase diagrams for the Si-O-C system which are slightly revised from the earlier ones of Krivsky and Schuhmann (28), the relevant feature being inclusion of a separate "α" phase in the low carbon, low oxygen region.

There is no basis to associate the mesa-like defects observed in the present work with a second phase in the Si crystal. Rather, the evidence of the x-ray and electron-optical results demonstrates that no definite crystalline second phase is present in the HI-HF etched crystals.

Conclusions

Etching of single-crystal silicon wafers with HI-HF gas mixtures produces smooth featureless surfaces. Mesa-like defects are observed when the etching is done with a SiC-coated susceptor plate. If an additional layer of silicon is applied over the SiC plate, the raised defects do not appear during etching.

Heretofore, such defects on etched surfaces have been attributed to impurities precipitated in the silicon matrix. However, the results here are against an impurity or second-phase interpretation. The defects do not stem from the bulk silicon prior to etching. Instead, they are formed by an interaction at the surface during etching.

A plausible explanation is that the Si surface is partially passivated by trace impurities escaping from the heated SiC susceptor. The passivation might occur because of inhibition of the HI etchant by adsorbed impurity atoms or by formation of a partial and very thin overlayer on the silicon surface, probably containing oxygen or carbon. We have, for example, observed an apparent passivation of silicon during HI-HF etching where a small leak allowed a slight intrusion of oxygen. This effect also could be enhanced by attack of the SiC by the HI or HF reagents.

If it is assumed that the equations

$$2HI + SiC \rightarrow SiI_2 + C + H_2 \quad [1]$$

and

$$2HF + SiC \rightarrow SiF_2 + C + H_2 \quad [2]$$

represent the most probable reactions for attack of SiC by HI and HF, respectively, we may consider the thermodynamics of the situation as follows. The equilibrium constants estimated from thermodynamic data (29, 30) are about 5×10^{-4} for Reaction [1] and about 10 for Reaction [2]. On this basis, it appears that HI does not react with the SiC-coated susceptors, but HF does.

Thus, passivation of the Si surface by SiC-associated impurity is a reasonable mechanism for generation of the mesa-like defects. Similarly, an overlayer of silicon on the susceptor plate provides a barrier to attack by HF or a "sink" for the impurities, and thus prevents passivation of the wafer surface.

Thermodynamic Analysis of the III-V Alloy Semiconductor Phase Diagrams

I. InSb-GaSb, InAs-GaAs, and InP-GaP

L. M. Foster* and J. F. Woods

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A thermodynamic analysis was made of the pseudobinary phase diagrams of the III-V semiconductor alloys, InSb-GaSb, InAs-GaAs, and InP-GaP. The excess free energy of mixing is expressed as Bx_1x_2, where B is a parameter characteristic of each system and x_1 and x_2 are the mole fractions of the end components. This homologous series of alloys showed consistent behavior in that all of the B/RT *vs.* composition plots were linear for both the liquids and solids. The greater part of the excess free energy of mixing of the solids appears to be in the excess entropy rather than in the enthalpy, indicating that these materials freeze with local ordering or structure rather than as homogeneous random solids. The magnitude of the departure from ideality in the solids increases from the antimonide to the arsenide and to the phosphide, which is also the order of increasing lattice mismatch between the pairs of pure components. Implications of these results in the use of the alloys in semiconductor devices are discussed.

It has been recognized for many years that the III-V alloy semiconductors might be useful for fabrication of new electronic and optical devices because of the possibility of adjusting the width of the forbidden energy gap by varying the composition of the alloys (1-3). In principle, by selecting the proper combinations of III-V compounds and adjusting the composition of the mixtures, semiconductors with band gaps ranging more or less continuously from 0.18 eV (InSb) to about 2.4 eV (AlP) could be prepared.

Whether these mixtures will be useful semiconductors will depend not only on solving such obvious problems as the growth of suitably doped single crystals, but also on whether such alloys are indeed homogeneous mixtures with properties that are smooth blends of the properties of the individual components. Thermodynamic analysis of the phase diagrams of these pseudobinary systems can give an insight into the nature of the solid alloys. This information comes from the magnitude of the departure of the systems from ideal behavior and how this depends on temperature and composition.

* Electrochemical Society Active Member.
Key words: phase diagrams, compound semiconductors, solution theory.

There are several procedures for calculating the liquidus and solidus boundaries of binary systems which depend on different basic assumptions. No attempt is made here to evaluate the relative merits of the various procedures and reference is made to standard texts (4-6). Success has been claimed for each technique in treating individual cases, but possibly in some instances this is fortuitous because of the assumptions involved (4). The most common approach is the quasi-chemical method first proposed by Guggenheim (7). It was originally intended to treat liquid solutions only, because it is based on chemical interactions between different kinds of molecules and makes no provisions for strain energy or other effects resulting from mixing molecules of different sizes in a crystalline lattice. However, this quasi-chemical approach has been employed successfully in treating some solid solutions where there is no difference in atom sizes and, hence, no lattice distortion, *e.g.* the aluminum-rich portion of the Al-Zn system (8). In most of the III-V semiconductors there is considerable difference in atom sizes, so these systems presumably are not amenable to treatment by the quasi-chemical method.

The procedure employed in the present investigation assumes that the excess free energy of mixing in a phase can be expressed as Bx_1x_2, where x_1 and x_2 are the mole fractions of the components (6). B is a parameter that contains both enthalpy and entropy contributions to nonideality, as well as distortion energy in the case of solids. In the extensive literature on phase equilibria, B seems to show some regularity in behavior only in cases of homologous series of compounds (4). Homologous series are found in the liquid and solid alloys between the group III and group V semiconductor compounds, and regularity and trends should be evident in the parameter B in these cases. These materials are isoelectronic and have the same diamond cubic crystal structure in the solid, but offer a gradation in both anion and cation size as well as in melting point and heat of fusion of the separate compounds. Trends in B should be useful in indicating which properties are important in determining the degree of nonideality in these systems.

The nine combinations of the group III metals, Al, Ga, and In, with the group V nonmetals, P, As, and Sb, give 18 possible pseudobinary systems. About half of these have been studied in some manner, although in several instances only to the extent of demonstrating that miscibility exists over the complete composition range in the solid (9). For the present study, the systems InSb-GaSb, InAs-GaAs, and InP-GaP were selected since reliable experimental data were available for both their liquidus and solidus boundaries and the melting points of the separate pure components. This provided a homologous series of three alloys differing only in the group V substituent. Additional systems will be treated as the data become available, with the objective of trying to establish trends with atom size, bond strength, *etc.*, within the group of III-V alloys and to evolve a model to describe the solid solution phase of these technologically important systems.

Detailed mathematical analysis of phase diagrams can be extremely tedious and, as a consequence, the additional effort of correlating the calculations with error limits on experimental data has seldom been made. For the present investigation, computer programs were written which provided the flexibility necessary to undertake such a correlation.

Calculation Procedure

The free energy of mixing per mole of a two-component ideal liquid is

$$\Delta F^{M(l)} = RT(x_1 \ln x_1 + x_2 \ln x_2) \quad [1]$$

where x_1 and x_2 are the mole fractions of components 1 and 2, and $-R(x_1 \ln x_1 + x_2 \ln x_2)$ is the configurational entropy of mixing. The ideal heat of mixing is zero. From $F = \mu_1 x_1 + \mu_2 x_2$, the change in the chemical potentials becomes

$$\Delta\mu_1{}^l = RT \ln x_1 \quad [2a]$$

$$\Delta\mu_2{}^l = RT \ln x_2 \quad [2b]$$

For a real solution, the heat of mixing is usually not zero because of the reforming of chemical bonds and changes in van der Waal's forces between neighbors. These effects are grouped together in the interaction parameter, B^l. Thus, for a real liquid solution, Eq. [1] becomes

$$\Delta F^{M(l)} = RT(x_1 \ln x_1 + x_2 \ln x_2) + B^l x_1 x_2 \quad [3]$$

and the change in chemical potentials becomes

$$\Delta\mu_1{}^l = RT \ln x_1 + B^l x_2{}^2 \quad [4a]$$

$$\Delta\mu_2{}^l = RT \ln x_2 + B^l x_1{}^2 \quad [4b]$$

From $\mu = RT \ln a = RT \ln x + RT \ln \gamma$, where a is the activity, the activity coefficients, γ, are obtained from Eq. [4]

$$\ln \gamma_1{}^l = (B^l/RT) x_2{}^2 \quad [5]$$

$$\ln \gamma_2{}^l = (B^l/RT) x_1{}^2 \quad [6]$$

The free energy of mixing per mole of solid solution is

$$\Delta F^{M(s)} = RT(x_1 \ln x_1 + x_2 \ln x_2) + x_1 L_1 (T/T_1 - 1) + x_2 L_2 (T/T_2 - 1) + B^s x_1 x_2 \quad [7]$$

where $L_1(T/T_1 - 1)$ and $L_2(T/T_2 - 1)$ are the changes in the chemical potentials upon fusion of a mole of the pure components. No difference is expected between the specific heats of the solid and liquid pure components so the enthalpies of fusion, L_1 and L_2, are considered constant. The parameter B^s for the solid solution is expected to be different from and larger in magnitude than B^l because of additional effects that contribute to nonideality, such as lattice distortion, that are not present in the liquid. The activity coefficients in the solid become

$$\ln \gamma_1{}^s = (B^s/RT) x_2{}^2 \quad [8a]$$

$$\ln \gamma_2{}^s = (B^s/RT) x_1{}^2 \quad [8b]$$

In order to put the relations into a form amenable to computer calculation, particularly for an iteration procedure that is required later on, the derivatives of [3] and [7] are taken with respect to the component 2 composition to give the following two expressions for straight lines on a ΔF^M *vs.* x plot

$$\Delta F^M = RT \ln(1 - x^l) + B^l (x^l)^2 + \{RT \ln [x^l/(1 - x^l)] + B^l(1 - 2x^l)\} x \quad [9]$$

$$\Delta F^M = RT \ln(1 - x^s) + B^s (x^s)^2 + L_1(T - T_1)/T_1 + \{RT \ln [x^s/(1 - x^s)] + B^s (1 - 2x^s) - L_1 (T - T_1)/T_1 + L_2 (T - T_2)/T_2\} x \quad [10]$$

where $x = x_2 = (1 - x_1)$, the mole fraction of component 2. Equations [9] and [10] are tangents to the free energy curves, Eq. [3] and [7], for the liquid and solid, respectively. When they have equal intercepts and slopes, *i.e.* when they coincide with the common tangent to both curves, the points of tangency, x^l and x^s, are compositions in the liquid and solid where the chemical potentials are equal and, hence, correspond to intersections on the liquidus and solidus boundaries of the phase diagram at temperature T. The conditions for equilibrium, then, are given by

$$RT \ln(1 - x^l) + B^l (x^l)^2 = RT \ln(1 - x^s) + B^s (x^s)^2 + L_1(T - T_1)/T_1 \quad [11]$$

for the intercepts, and

$$RT \ln [x^l/(1 - x^l)] + B^l(1 - 2x^l) = RT \ln [x^s/(1 - x^s)] + B^s(1 - 2x^s) - L_1(T - T_1)/T_1 + L_2(T - T_2)/T_2 \quad [12]$$

for the slopes.

In the special case where both liquid and solid are ideal ($B^l = B^s = 0$), [11] and [12] may be solved for x^l and x^s, giving

$$x^l_{id} = \{1 - \exp [- L_1(T - T_1)/RTT_1]\}/\{\exp [- L_2 (T - T_2)/RTT_2] - \exp [- L_1(T - T_1)/RTT_1]\} \quad [13]$$

$$x^s_{id} = \{1 - \exp [L_1(T - T_1)/RTT_1]\}/\{\exp [L_2 (T - T_2)/RTT_2] - \exp [L_1(T - T_1)/RTT_1]\} \quad [14]$$

Thus, the ideal $T - x$ phase diagram can be calculated directly in closed form if L_1, L_2, T_1, and T_2 are known.

In nonideal systems, the most useful information about the departure from ideality is expressed by the parameters B^l and B^s. These can also be given in closed form. Thus, from [11] and [12]

$$B^l = \frac{RT\{(1 - x^s)^2 \ln [(1 - x^l)/(1 - x^s)] - (x^s)^2 \ln (x^l/x^s)\}}{(x^s)^2(1 - x^l)^2 - (x^l)^2(1 - x^s)^2} - \frac{(1 - x^s)^2 L_1(T - T_1)/T_1 - (x^s)^2 L_2(T - T_2)/T_2}{(x^s)^2(1 - x^l)^2 - (x^l)^2(1 - x^s)^2} \quad [15]$$

$$B^s = \frac{RT\{(1 - x^l)^2 \ln [(1 - x^s)/(1 - x^l)] - (x^l)^2 \ln (x^s/x^l)\}}{(x^l)^2(1 - x^s)^2 - (x^s)^2(1 - x^l)^2} + \frac{(1 - x^l)^2 L_1(T - T_1)/T_1 - (x^l)^2 L_2(T - T_2)/T_2}{(x^l)^2(1 - x^s)^2 - (x^s)^2(1 - x^l)^2} \quad [16]$$

Equations [15] and [16] give the values of B^l and B^s required to fit experimental liquidus and solidus curves at compositions x^l and x^s and temperature T.

A remaining calculation that is required is to determine the liquidus and solidus points, x^l and x^s, for a given set of values of B^l, B^s, L_1, L_2, T_1, and T_2. This calculation is especially important near the two composition extremes where the calculated parameters, B, can change drastically as a result of very small variations in the way the experimental curves are drawn through the data points. It permits B's that result from different possible extrapolations from a less sensitive region to be tested for reasonableness and consistency, all with limits imposed by allowable variations in the experimental curves. An iteration procedure is required. The one used here is illustrated in Fig. 1 for a hypothetical case. Curves of the free energy of mixing for the liquid and solid at a particular temperature are drawn from Eq. [3] and [7], with $x_2 = (1 - x_1) = x$, and a set of lines tangent to the former are computed from [9] for a set of trial values of x^l. For each tangent line the difference, $\Delta F^{M(s)}$ (Eq. [7]) $- \Delta F^M$ (Eq. [9]), is calculated over a range of values of x. For a certain set of tangents, corresponding to a set of values of x^l, and a certain set of values of x, this difference will be negative (shaded area, Fig. 1). By presenting the computer calculations as an x^l/x array, the column and row in which sign change occurs is readily seen, and successive iteration determines the point of tangency of relation [9] to the two free energy curves, [3] and [7], to any arbitrary degree of precision. These points of tangency are the values of x corresponding to the liquidus, x^l, and solidus, x^s, at temperature T for the combination of B^l, B^s, L_1, L_2 T_1, and T_2 that is being tested.

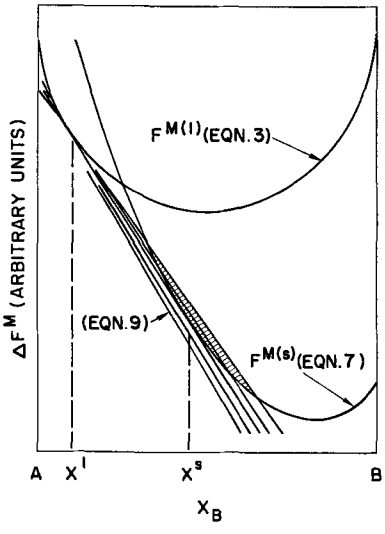

Fig. 1. Free energy of mixing of liquid and solid for hypothetical system to illustrate iteration procedure for determining liquidus and solidus points, x^l and x^s.

Procedure for Analysis of Experimental Data

Experimental data for both the liquid and solid are required. Large errors can result from assuming an ideal liquidus curve and basing calculations on an experimental solidus curve only, as has sometimes been done in literature. Recent values of L_f for the III-Sb compounds and InAs and GaAs by Lichter and Sommelet (10, 11) appear to be very reliable and are preferred to earlier literature values. Information on the enthalpies of fusion of the III-P compounds is very sparse, but values can be gotten from the entropies of fusion that can be estimated from the entropies of Si and Ge and the III-V compounds that have been measured. The assumption that L_f is constant over the temperature ranges encompassed by the phase diagrams is not on a very firm basis. Lichter and Sommelet have provided the only reliable heat content data, and only in the case of InSb and GaSb (10) are they carried sufficiently far into the liquid for an estimate of ΔC_p to be made. In those cases, the maximum change in L_f for either component is only about 4.5% over the entire temperature range of the InSb-GaSb diagram.

In making the calculations described above for an experimental phase diagram, it is generally not possible to use the actual data points since they seldom occur at the same temperature for both the liquid and solid. Therefore, a curve is drawn through the liquidus and solidus data points; values of x^l and x^s are taken from the curves at a series of temperatures; and the interaction parameters, B^l and B^s, are calculated from these values by means of [15] and [16]. The calculations of B^l and B^s are presented in two ways: as activity coefficients *vs.* composition (from Eq. [5], [6], and [8]) and as B/RT *vs.* composition.

In order to observe the effect of errors in the data on the behavior of B^l and B^s, a phase diagram was calculated for a hypothetical system by the iteration procedure described earlier, with nominal values for the parameters of $B^l = 0.5\ RT$, $B^s = 1.2\ RT$,[1] $S_1 = L_1/T_1$

[1] As will be seen when actual experimental phase diagrams are treated, the B/RT *vs.* x plots are straight lines with very small slopes, so the assumption of a constant B/RT is justified for the present purpose.

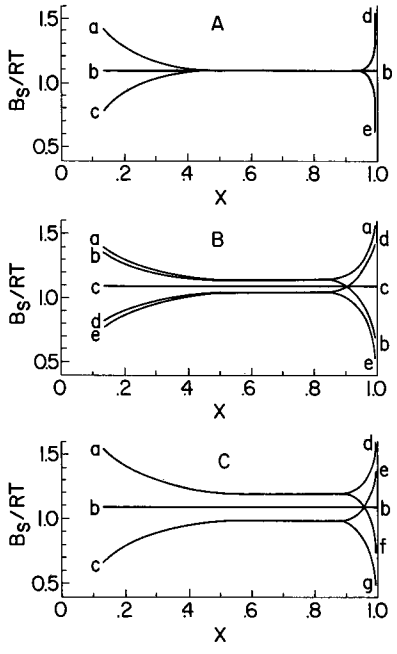

Fig. 2. Effect of errors in system parameters and data on B^s/RT for hypothetical system. A—Error in melting points of separate components: *a*, with error of +1° in component 1; *b-b*, with correct data (T_1 = 1273°K, T_2 = 1773°K); *c*, with error of −1° in component 1; *d*, with error of −1° in component 2; *e*, with error of +1° in component 2. B—Error in liquidus and solidus data: *a-a*, −5% in x^l, +5% in x^s; *b-b*, +5% in x^l, +5% in x^s; *c-c*, with correct data; *d-d*, −5% in x^l, −5% in x^s; *e-e*, +5% in x^l, −5% in x^s. C—Error in enthalpies of fusion: *a*, with error of −1 eu in L_1/T_1, and −1, 0, or +1 eu in L_2/T_2; *b*, correct data (L_1/T_1 = 14 eu, L_2/T_2 = 15 eu); *c*, with error of +1 eu in L_1/T_1, and −1, 0, or +1 eu in L_2/T_2; *d*, with error of −1 eu in L_1/T_1, and −1 eu in L_2/T_2; *e*, with error of +1 eu in L_1/T_1, and −1 eu in L_2/T_2; *f*, with error of −1 eu in L_1/T_1, and +1 eu in L_2/T_2; *g*, with error of +1 eu in L_1/T_1, and +1 eu in L_2/T_2.

= 14 eu, T_1 = 1273°K, $S_2 = L_2/T_2$ = 15 eu, T_2 = 1773°K. These parameters were then varied one at a time by small amounts to see what effect the change had on the behavior of the *B/RT vs. x* curves. This information is shown in Fig. 2 for an error in melting point of the pure components of ±1°C (Fig. 2A), an error in entropy of fusion of ±1 eu (Fig. 2B), and composition errors in the experimental curves of ±5%, where "error" in the last case is defined as 5% of x when $x \leq 0.5$, and 5% of $(1 - x)$ when $x \geq 0.5$. Figure 2 shows only the situation in the solid. Very similar results are found for the liquid with, however, a right for left reversal in the character of the curves.

The value of this information on errors is that it assists in recognizing and treating anomalous data. There is no physical model of solutions that would predict wide deviation of the *B/RT* plots at the composition extremes, and when this is encountered it must be due to errors in the system parameters or in the experimental data of the phase diagram. The sensitivity of the *B/RT* plots to error in x^l and x^s (Fig. 2B) is particularly significant. Whereas a 5% error in x near the middle of a phase diagram is probably outside the precision of a well-controlled experiment, the same error near the ends (as error is defined here; *e.g.*, ±0.0025 at x = 0.95) is quite possible. This situation is handled by extrapolating the *B/RT* plots from the less sensitive region (*i.e.*, between approximately x = 0.2 and x = 0.8) to the ends and, with these extrapolated values, recalculating the extremities of the liquidus and solidus curves by the iteration procedure described previously. It is a matter of judgment in any particular case whether the error limits on the experimental data for x^l and x^s permit redrawing of the liquidus and solidus curves acording to calculations based on extrapolated values of *B/RT*.

Considering the great sensitivity of the *B/RT* plots at the extreme ends to small errors in melting points and enthalpies of fusion, it is unlikely that a completely linear plot would be obtained the first time even if the rest of the data were precise. From the character of the anomalous curves in Fig. 2A and C, it is possible to obtain a clue as to which parameter is in error and to make a better choice. In all systems that were treated in this investigation, the final "best" parameters agreed with the most reliable literature values within the experimental precision stated by the authors.

Results

InSb-GaSb system.—Data for both the liquidus and solidus were obtained by Woolley and Lees (12). Melting points for InSb have been reported from 524° to 526°C (10, 12-16), and for GaSb from 703 to 712°C (10, 12, 13, 17, 18). Enthalpies of fusion ranging from 11.2 to 12.2 kcal/mole for InSb (10, 13, 19, 20) and from 12.0 to 16.3 kcal/mole for GaSb (10, 13, 20) were reported. Lichter and Sommelet's values (10) of 524° ± 1°C and 712° ± 1°C for the melting points and 11.414 ± 0.200 kcal/mole and 15.560 ± 0.200 kcal/mole for the enthalpies of fusion of InSb and GaSb, respectively, appear to be the most reliable.

The data of Woolley and Lees are shown as the points in Fig. 3. The solid curves were calculated by the iteration procedure, with T_1 = 523°C, T_2 = 712°C, L_1 = 11.41 kcal/mole, L_2 = 15.56 kcal/mole, and using linearity of the *B/RT* plot [shown in Fig. 4 (bottom)] as the criterion for an acceptable curve. The dashed curves are the ideal boundaries calculated from [13] and [14]. The activity coefficients of InSb and GaSb in the two phases, calculated from Eq. [5], [6], and [8], are given in Fig. 5.

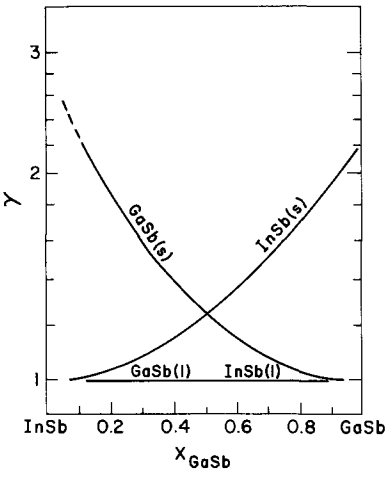

Fig. 5. Activity coefficients in the InSb-GaSb system

InAs-GaAs system.—The solidus boundary of this system was determined by Woolley and Smith (21). Three points on the liquidus boundary were determined by Van Hook and Lenken (22). Enthalpies of fusion of the pure compounds were reported at 17.58 (11), 18.2 (13), and 18.4 kcal/mole (23) for InAs, and at 25.18 (11) and 28.9 kcal/mole (13) for GaAs. The melting point of InAs has been reported at 937 (24, 11) and 942°C (13). There are many references to the melting point of GaAs, ranging from 1230° to 1255°C. Lichter and Sommelet's values (11) of 937° ± 1°C and 1240° ± 1°C for the melting points, and 17.58 ± 0.40 and 25.18 ± 0.60 kcal/mole for the enthalpies of fusion for InAs and GaAs, respectively, are taken to be the most reliable.

The experimental data points and the calculated liquidus and solidus (continuous lines) and ideal (dashed lines) curves are shown in Fig. 6. The B/RT *vs.* x plots corresponding to the continuous curves of Fig. 6 are shown in Fig. 4 (center). The activity coefficients are shown in Fig. 7. The system parameters that were used in the calculations were taken from Ref. (11).

InP-GaP system.—The solidus boundary was determined by Foster and Scardefield (25). The liquidus was determined by Panish (26) by extrapolation of isotherms from the metal-rich region of the Ga-In-P ternary to the InP-GaP pseudo-binary section. A new melting point for GaP of 1485°C was determined by Chicotka (27), which is considerably higher than that of Richman (28). The melting point of InP has been reported at 1070° (29) and 1068°C (30).

Following the same procedure as for the other two systems, the information for InP-GaP is shown in Fig. 8, 4 (top), and 9, where T_1 = 1068°C, T_2 = 1485°C, L_1 = 19.71 kcal/mole, and L_2 = 26.37 kcal/mole. The enthalpies of fusion of InP and GaP have not been

measured, and the values that were used were calculated from estimates of the entropies of fusion of 14.7 and 15 eu, respectively. The value for InP was assumed to be the same as that of AlSb, since they have approximately the same melting point and each contains an element for the third and fifth row. AlSb had been measured by Lichter and Sommelet (10). The entropy of fusion of GaP had been roughly estimated by Thurmond (31). Neither of these estimates is on a firm foundation. However, almost as satisfactory a fit to the experimental data and linear B/RT *vs.* x plots were

obtained with entropies ±0.5 eu different from those chosen.

Discussion

Thermodynamic treatment of the III-V pseudobinary phase diagrams provides information of several sorts. It makes it possible to distinguish between poor and acceptable data; it gives an insight into the nature of these semiconductor alloys, and provides a basis of comparison between members of the group. The B/RT *vs.* x plots provide the most visible indication of the quality of the data. The same information could be gotten from the activity coefficient plots, although anomalous behavior is less conspicuous in that case. The test for an "acceptable" phase diagram in the systems studied to date is taken to be linearity of the B/RT *vs.* x plot for both the liquidus and solidus. This criterion could not have been set down in advance for it was not possible to predict that these systems would exhibit such behavior. Darkin and Gurry (32) noted that many binary metal systems fall into one of three classes, where the B/RT (their α) *vs.* x plot is linear, where it shows pronounced curvature, or where it is linear with an abrupt change of slope. They pointed out that few systems seemed to exhibit intermediate or mixed behavior.

The homologous series of alloys, $Ga_xIn_{1-x}Sb$, $Ga_xIn_{1-x}As$, and $Ga_xIn_{1-x}P$, have strictly linear B/RT *vs.* x plots over the entire composition range for both liquid and solid and, hence, appear to fall into the first class described by Darkin and Gurry. On the other hand, the diagrams of several III-V systems that showed anomalous B/RT plots with wide excursions, especially near the ends, typical of those illustrated in Fig. 2, were found to be based on questionable data. Calculation of the InAs-InP system showed such anomalies when the data of Koster and Ulrich (29) were used, for example. However, recent work of Willardson *et al.* (33) suggests that the earlier data were seriously in error. The data of the InSb-InAs system, which also showed anomalous B/RT plots, are similarly suspect (34).

For the three systems treated here, the B/RT plots were almost flat (Fig. 4). If B is independent of composition, a perfectly flat plot (B/RT = constant) requires that B be directly proportional to T, or $B = AT$, where A is a constant containing R. Since $Bx_1x_2 = ATx_1x_2$ is the excess free energy of mixing, ΔF^M_{ex}, the excess entropy at constant pressure is $\Delta S^M_{ex} = -Ax_1x_2$ if there are no anomalies in the heat capacity. Then, the excess enthalpy $\Delta H^M_{ex} = \Delta F^M_{ex} - T\Delta S^M_{ex}$ is zero.

The assumption that B is independent of composition has considerable historical justification. It has as its basis the fact that this parameter can be accounted for by the difference in energy of vaporization between the two components, which should be insensitive to composition (36) or, in a parallel argument, that it involves the difference in binding energy between the possible combinations of nearest neighbors (quasi-chemical approach) (7). A considerable number of systems exhibit this "regular" behavior. It is pointed out, however, that the regular solution theory predicts that B should also be independent of temperature, which would make the excess free energy of mixing, Bx_1x_2, essentially an excess enthalpy with little or no contribution from excess entropy.

The extended quasi-chemical approach predicts a temperature dependence in B due to a loss of randomness in the distribution of unlike molecules, which involves an activation energy. However, it can be shown that according to the quasi-chemical theory the temperature-dependent part of the excess free energy, *i.e.* the entropy term, will always be substantially smaller than the enthalpy for the systems we are considering. For example, Guggenheim (7) and others have given the following approximate expressions for the excess functions

$$\Delta H^M_{ex} = x_1x_2\,\Omega(1 - x_1x_2\,2\Omega/ZRT) \qquad [17a]$$

$$\Delta S^M_{ex} = -x_1^2x_2^2\,\Omega^2/ZRT^2 \qquad [17b]$$

$$\Delta F^M_{ex} = x_1x_2\,\Omega(1 - x_1x_2\,\Omega/ZRT) \qquad [17c]$$

where Ω is the net energy change in breaking the bonds of the pure components and reforming nearest neighbor bonds, and Z is the coordination number, assumed to be 4 in the solid. (In the generalized approach used in the present investigation, Eq. [17c] is equivalent to our Bx_1x_2.) When there is a completely random distribution of molecules of the two kinds, the temperature-dependent terms are zero, and Eq. [17] reduces to the simple expressions for the excess quantities for a regular solution, $\Delta F^M_{ex} = \Delta H^M_{ex} = x_1x_2\Omega$, with no excess entropy. These relations show that, according to the quasi-chemical approach, the contribution of the entropy term to the excess free energy will always be less than half the enthalpy for all values of Ω less than $ZRT/4x_1x_2$ (approximately $4RT$).

It is apparent that there is a serious contradiction between the experimental results for the InGa-Sb, -As, and -P systems and the predictions of the regular or quasi-chemical solution theories, for it appears that the experimentally determined excess free energy is made up almost entirely of the $T\Delta S^M_{ex}$ term. This is probably not an accurate description of the make-up of ΔF^M_{ex} for it is unlikely that a real system could exhibit a substantial excess entropy of mixing and near zero excess enthalpy, since the nonrandom structure implied by the excess entropy should involve some rearrangement of chemical bonds or, at least, a change in van der Waal's forces, which should be accompanied by an enthalpy change. This change can be extremely small, however, and in some theoretical treatments (35) it is considered zero. The conclusion that the excess enthalpy of mixing is small or zero could be in error if the parameter B were not independent of composition. There is no supporting evidence for or against this contention at the present time.

The excess free energy for the three systems is plotted against composition in Fig. 10. The B parameters are shown in Fig. 11. It is seen that they are substantially larger for the solids than for the liquids, reflecting the greater departures from ideality in the former. The $Ga_xIn_{1-x}Sb$ liquid is perfectly ideal, and the $Ga_xIn_{1-x}As$ liquid is nearly so. B for the solid of $Ga_xIn_{1-x}Sb$ varies only about 6% across the entire diagram and, hence, nearly meets the criterion of a "regular" solution. However, this is because the magnitude of B^s is small in this system and trends are not conspicuous. Rather than $Ga_xIn_{1-x}Sb$ being an ex-

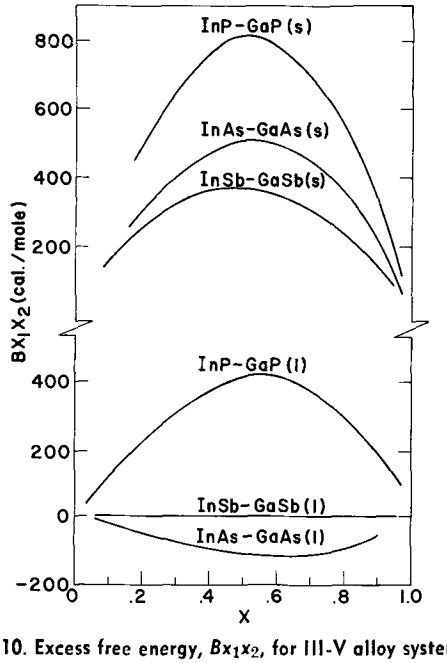

Fig. 10. Excess free energy, Bx_1x_2, for III-V alloy systems

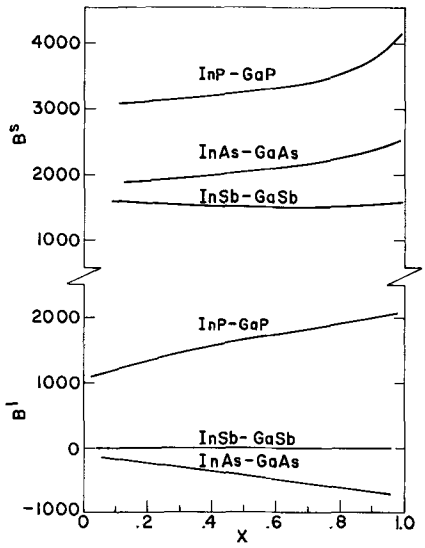

Fig. 11. The parameter, B, for the liquid and solid of III-V alloy systems.

ceptional case, it is clear from Fig. 11 that there is a gradual change in shape of the B^s *vs.* x curves, and a gradual trend in the magnitude of B^s in going from the antimonide to the arsenide and to the phosphide.

In an effort to identify the origin of the excess free energy, it is of interest to see if any parameters of these systems correlate with $\Delta F^{M(s)}{}_{ex}$. The two most obvious properties that change in going through the series InSb-GaSb, InAs-GaAs, and InP-GaP are the molecular size and the lattice binding energy, the latter being manifest in the increasing melting points, enthalpies of fusion, and shear moduli of the pure compounds. Table I lists the lattice parameters, the molar volumes, and the shear moduli for the three systems at room temperature.

The possibility that the large contribution of the excess entropy to $\Delta F^M{}_{ex}$ could result entirely from the volume change on mixing molecules of different sizes can be readily discounted. The molal excess entropy of mixing x_1 moles of molecules of one size with x_2 moles of another is given approximately by (35)

$$\Delta S^M{}_{ex} = x_1 R \ln (x_1/z_2) + x_2 R \ln (x_2/z_2) \quad [18]$$

where z_1 and z_2 are the two volume fractions. Making the calculations at $x_1 = x_2 = 0.5$ for the solid of the InP-GaP system, for which the difference in molal volumes is greatest, gives $\Delta S^M{}_{ex} = 0.012$ eu, and $T\Delta S^M{}_{ex} \approx 17$ cal/mole. This is only about 2% of the $\Delta F^M{}_{ex}$ for that system and, moreover, is of opposite sign.

Whereas a significant size-effect contribution to $\Delta F^M{}_{ex}$ appears to be excluded according to [18], that relation does not consider the concomitant strain energy that is produced in a solid lattice. Calculation of strain energy is only approximate, even in the most straightforward case of simple metals. However, a rough estimate of its expected contribution at room temperature in the present cases can be made by the procedure of Lawson (37). This yields the distortion energy, E^D, resulting from substitution of a molecule of the first kind for a molecule of the second kind in a lattice of the second kind, when the two molecules are of different size. The energy is given in terms of the shear moduli, G_1 and G_2, and the molar volumes, V_1 and V_2, as

$$E^D = 2/3[G_1/V_1(x_1) + G_2/V_2(x_2)](V_1 - V_2)^2 x_1 x_2 \quad [19]$$

where x_1 and x_2 are the mole fractions.[2] In addition to the assumptions in the original derivation, it is also assumed that there is minimal volume change on mixing, so $E^D \approx H^D$, and that the theory originally developed for metals applies to the covalently bonded mixed crystals as well.

Substitution of the appropriate quantities from Table I into [19] gives distortion energies at room temperature of 1900, 2625, and 3075 cal/mole for InSb-GaSb, InAs-GaAs, and InP-GaP, respectively, calculated at $x_1 = x_2 = 0.5$. If we identify these with the excess free energy, it is seen that they exceed $B^s x_1 x_2$ calculated from the phase diagrams (Fig. 10) by four- to five-fold. It is impossible to estimate the magnitude of the strain energies at high temperature. The shear moduli of the covalently bonded semiconductors are not greatly temperature sensitive within a few hundred degrees of room temperature where data are available, and values extrapolated to the temperatures of the solidus curves would still be of the order of 75% of the room temperature values (39). On the other hand, the moduli approach zero at the melting points and undoubtedly fall off very rapidly just short of that.

Thus, it is not possible to find a definite correlation between lattice strain and the excess free energy of mixing, even though the direction of change of the shear moduli with temperature points toward better agreement at the high temperatures than is found at room temperature.

It has been suggested (38) that an experimentally observed positive value of $B^s x_1 x_2$ might actually be the difference between a large negative $\Delta F^M{}_{ex}$, which would result when pairing or other chemical interactions between unlike atoms are favored (4), and a larger distortion energy which is always positive. That this is not the case in the systems studied here is demonstrated by the fact that the chemical effects should persist into the liquids where distortion energies are absent. This would result in large negative values for $\Delta F^{M(l)}{}_{ex}$; whereas it is seen from Fig. 11 that the liquid of the $Ga_xIn_{1-x}Sb$ system is perfectly ideal, and those of the other two systems show much smaller departures from ideality than do the solids. From the same argument, it would appear that the good agreement obtained by Stringfellow and Greene (40) between the experimental phase diagram and that calculated from a quasi-chemical approach for $Ga_xIn_{1-x}As$ might possibly be fortuitous [they used 14.7 eu for the entropy of fusion of GaAs instead of the more recent value of 16.5 (23)], since the quasi-chemical approach does not take into account the difference that would be expected between the liquid and solid as a consequence of lattice strain.

Even though the identification of $B^s x_1 x_2$ in terms of the excess thermodynamic functions is not clear, its magnitude is cause for concern in view of the rather

[2] The distortion energy calculated from [19] is ½ that given by Lawson's original relation which contained an arithmetic error (38).

Table I. Crystal properties of III-V alloys

System		Lattice parameter				Molar volume				Shear modulus* (cal. cm^{-3})	
a	b	a(Å)	b(Å)	diff. (Å)	diff. (%)	a(cm^3)	b(cm^3)	diff. (cm^3)	diff. (%)	a	b

stringent requirements on materials for semiconductor device applications. A serious consequence of significant departure from ideality in multicomponent systems is the possibility of phase separation in the solid. Miscibility gaps have not been reported for any of the diagrams of the III-V alloys. However, because of the great problem in attaining equilibrium below the solidus boundaries, they cannot be ruled out. Phase separation to produce a miscibility gap will occur at temperatures less than a critical temperature given by $T_c \approx B/2R$ (41). Referring to Fig. 10, T_c, calculated at the maximum in the $\Delta F^{M(s)}{}_{ex}$ curves, is 850°, 510°, and 380°K for $Ga_xIn_{1-x}P$, $Ga_xIn_{1-x}As$, and $Ga_xIn_{1-x}Sb$ solids, respectively. This calculation assumes that the observed variation of B^s with temperature describes only the condition during solidification, and that B^s remains constant below the solidus boundary, as would be expected if it were largely due to strain.

In the case of $Ga_xIn_{1-x}P$, at least, T_c is approaching the temperature at which this material might be grown by vapor or liquid phase epitaxy, or at which it might be subsequently processed. Moreover, as was demonstrated in some other systems that were studied extensively, the critical temperature need not actually be reached for local ordering to occur. In the Al-Zn (42), Al-Ag (43), and Cu-Au (43, 44) systems, for example, segregation in the form of clustering and superlattice formation could be observed at almost 100°C above the temperature of the miscibility gaps.

As in the metal systems cited above, it is suggested that the excess free energy in the three semiconductor systems investigated here results from strain-relief processes that occur during solidification to produce local order and a decrease in entropy. This entropy change is substantial. By making the approximation, as indicated by almost flat B/RT *vs.* x curves, that all of the excess free energy is in $T\Delta S^{M(s)}{}_{ex}$, $\Delta S^{M(s)}{}_{ex}$ amounts to −0.45, −0.42, and −0.59 eu, which are about 32, 30, and 42% of the ideal mixing entropies for $Ga_xIn_{1-x}Sb$, $Ga_xIn_{1-x}As$, and $Ga_xIn_{1-x}P$, respectively.

No details about the nature of the ordering can be presented in the absence of diffuse x-ray scattering data, but the formation of stacking faults, clusters, or vacancy-stabilized defects of various sorts is a possibility. Reports of inhomogeneities in InP-GaP alloys are beginning to appear. Evidence that phase separation might be occurring during low-temperature liquid phase epitaxial growth was seen (45), and Richman (46) observed diffuse structure in x-ray patterns of this material that was produced by vapor epitaxy.

It is too early to predict the effect of possible structural inhomogeneities on the semiconductor properties of semiconductor alloy systems. The electron mobility in InAs-InP vapor-deposited alloys was found to fall much below the expected value throughout the mid-range of compositions (47), and in the InAs-GaAs system there was actually a pronounced minimum in mobility at $x = 0.5$ (48). On the other hand, in the InSb-GaSb system the mobility was essentially an additive function of the mobilities of the pure end components (49). Electrical properties can be difficult to interpret and are influenced by many factors, such as the basic conduction process, degree of compensation, *etc.*, as well as by lattice strain and inhomogeneities, all of which can vary with composition of the alloy. In electroluminescence applications, where these alloys have particular interest, structural inhomogeneities might act as trapping centers to lower the efficiency of radiative processes.

Summary

A generalized thermodynamic treatment of the pseudobinary T-x diagrams of the homologous series of III-V compound alloys, InSb-GaSb, InAs-GaAs, and InP-GaP, was carried out. These materials are all in a class characterized by linear plots of B/RT *vs.* composition, where B is defined by Bx_1x_2, the excess free energy of mixing of the two end components. The liquid phase of InSb-GaSb is perfectly ideal ($B = 0$), and the liquids of the two other systems show only small departures from ideality. The solid phases show substantial nonideal behavior, increasing in magnitude in going from InSb-GaSb to InAs-GaAs to InP-GaP. This parallels the disparity in molecular size between the two components of each pair.

The flatness of the B/RT *vs.* x plots ($B/RT \approx$ constant) indicates that the partition of the excess free energy between the entropy and enthalpy greatly favors the former. Thus, the alloys are not regular solutions and, moreover, cannot be described by a quasi-chemical approach which allows only small dependence of B on temperature. It is suggested that some of these alloys might not freeze as homogeneous random mixed crystals, but might exhibit some degree of local order in the nature of clustering, layering, or perhaps a vacancy-stabilized defect structure. Such structures would be expected to have adverse effects on the performance of some semiconductor devices that are envisioned for these alloys. The magnitude of the excess free energy in the case of InP-GaP, at least, suggests that the tendency toward inhomogeneity may be so great as to bring about phase separation in the solid at some temperatures where this alloy might be grown or processed.

Substrate Surface Preparation and Its Effect on Epitaxial Silicon

P. Rai-Choudhury*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Silicon substrates prepared carefully by chemical-mechanical techniques, such as the silicon dioxide process, are comparable with those prepared by the chemical polishing technique, which in turn, are comparable with the bulk material. Defects are found to generate on substrates during oxidation even under idealized conditions probably by migration and collapse of vacancy clusters, and some of these defects (*i.e.* the extrinsic faults) are nucleation centers for intrinsic stacking faults in the epitaxial layers. In addition to removing shallow mechanical damage, HCl etching in an rf heated system usually generates many thermally induced dislocations, which, in turn, prevent formation of defects during oxidation. The probability of stacking fault formation is significantly reduced by using (100) wafers instead of (111) wafers.

Depending on the type of device to be fabricated, chemically or chemical-mechanically polished wafers may be used as the starting material for thermal oxidation or epitaxial growth. The surface of a chemically polished wafer, although free from mechanical damage, is not flat over large distances and not mirror-like. Surface flatness over large areas is becoming increasingly important in masking operation by photolithographic techniques for devices such as photodiode arrays and many integrated circuits. Fortunately, with the development of electron beam lithography (1) such stringent requirements for surface flatness are not necessary. Among the various methods of producing very flat surfaces over large areas are the cupric ion process and the silicon dioxide colloidal suspension process (2-4). The cupric ion process takes place in an acidic medium ($pH \leq 7$) may be represented by the following reaction

$$Si(s) + 2Cu(NO_3)_2\ (soln.) + 6NH_4F\ (soln.) = (NH_4)_2SiF_6\ (soln.) + 4NH_3(g) + 2Cu(s) + 4NHO_3\ (soln.)$$

The silicon dioxide process takes place in an alkaline medium ($pH \geq 9.8$) and may be approximated as

$$Si(s) + 4NaOH\ (soln.) = Na_4SiO_4\ (soln.) + 2H_2(g)$$

Both processes being of a chemical nature, and the very small solid particles involved being either softer (*i.e.* Cu) or of hardness comparable to that of silicon (*i.e.* SiO_2), no mechanical damage is introduced during polishing (2-4). However, the possibility of introducing mechanical damage through a fractured and freed silicon particle or not removing all the prior process-induced damage exists in all these various shaping processes. Consequently, the procedure followed from sawing to the final polishing step is of importance. If the mechanical damage is shallow and the associated microstrain small then *in situ* etching at high temperature might remove the damaged layer.

Unfortunately there are some disadvantages of having a perfectly damage-free surface. Nowadays most melt-grown ingots used to prepare substrates are either free of or very low in dislocation density. As a result these crystals are supersaturated with vacancies, which may lead to the formation of vacancy clusters (5, 6), because vacancy sinks are either absent or are too far apart. Such vacancy clusters, when decorated with metallic impurities are shown to produce diodes with high leakage current (6). Fortunately these decorated vacancy clusters can be effectively cleaned by gettering, for example, with phosphorus glass at 1050°C. If, however, the surface of a dislocation-free crystal is

Key words: stacking faults, mechanical damage, polishing, vacancies.

mechanically damaged during shaping operation a flowed lattice with minute surface crevices results. Dislocations develop from the damaged lattice during high-temperature annealing which then act as vacancy sinks. Lawrence (7) indicated that the fault nucleation appears to occur at pinning centers in the flowed lattice provided by crevices fixed by a thermally grown silicon dioxide film. Such pinning centers increase the probability of dislocations intersecting with one another. The intersection of two dislocations which satisfies the Lomar-Cottrell conditions will form a stacking fault. These stacking faults are extrinsic and grow by vacancy emission.

The surface layers of a polished wafer can, at best, be similar to the bulk of the material from the point of view of crystallographic perfection. The Czochralski grown ingots usually contain many microinhomogeneities, which of course, become part of the surface features of a polished wafer. In the absence of any fast diffusing impurities, the importance of the substrate (when it is not an active part of a device) exists only during the initial few seconds of nucleation and growth. If the substrate microinhomogeneities are of coherent or semicoherent type, they are not detrimental to the growth of a relatively thick epitaxial layer. However, when a thin layer of epitaxial material is grown on substrates containing coherent or semicoherent type of inhomogeneities, the quality of the layers may be profoundly influenced. If the microinhomogeneities are of the incoherent type, defects such as stacking faults might be nucleated. This is, of course, a distinctly different mechanism of fault formation from that in the substrate, where stacking faults are formed by the collapse of vacancy clusters during high temperature ($\geqq$1000°C) heat treatments.

The present investigation consists of examining the substrate surface after suitable polishing in terms of surface morphology and mechanical damage. These surfaces are then compared with the bulk material in terms of microinhomogeneities. The polished wafers are subjected to tests such as oxidation and epitaxial growth to assess the quality of the starting material as well as the grown epitaxial layers. The effectiveness of *in situ* etching in removing mechanical damage and other surface contaminants are also examined.

Experimental Procedure

The polished wafers examined were of two basic types, namely, those polished by the chemical-mechanical processes, such as the silicon dioxide process, and the cupric ion process, and those chemically polished by liquid etchants. Effects of abrading with diamond and garnet particles prior to silicon dioxide polishing were also examined. The chemical polishing of the lapped wafers were performed using $HF:HNO_3:HAc::3:15:5$ mixture. Immediately before use the polished wafers were cleaned thoroughly by a special process to remove any organic and metallic contaminants from the surface. They were then Sirtl etched (8) to reveal any scratches and other crystallographic defects. Some of the shallow and isolated damages and bulk-induced defects are not always visible after Sirtl etching. Therefore, another test was performed in which cleaned wafers were oxidized in wet oxygen at 1100°C for 3 hr to give about 10,000Å of SiO_2 film and then Sirtl etched after removing the SiO_2. This is a sensitive test for revealing any defects induced by the mechanical damage and the collapse of vacancy clusters. The surfaces were examined by optical microscopy and scanning electron microscopy. The surface layers and the bulk of a number of wafers were examined by transmission electron microscopy for comparison purposes. The wafers were etched using a 1% HCl gas in palladium purified H_2 at 1270°C (corrected pyrometer temperature) for 10 min to see how effectively any damaged material can be removed from the surface. The etching was carried out in a conventional horizontal epitaxial reactor having a SiC coated graphite susceptor, heated externally by rf coils. Epitaxial layers were grown from a $SiCl_4$-H_2 system at about 1100°C. These layers were examined by optical and electron microscopy for defects and inhomogeneities that might be induced by the substrates.

Results

Ideally the silicon substrates should be prepared in such a way that the surface layer shows only the bulk features in transmission electron microscopy. Thinned surface layers from several chemically polished substrates were examined in TEM, and found to be very similar to the bulk material (from the point of view of microinhomogeneities) regardless of the doping level except when solid solubility is reached. Therefore the objective one would like to achieve is to prepare a substrate surface that has the perfection of a chemically polished surface and the flatness of a mechanically polished surface. The objective has been largely achieved as demonstrated by the test results to be presented below. However, if proper process sequence is not followed, defects can be introduced even under idealized conditions during high-temperature device processing, especially thermal oxidation.

Figure 1 shows some of the surface features of wafers, polished by the silicon dioxide process, made visible by Sirtl etching. Figure 1(a) shows the surface of a wafer that was sawed, chemically etched and then polished using an SiO_2-$NaOH$-H_2O slurry of *p*H 9.8, wheel speed 500 rpm, and a pressure of 5.5 psi. The removal or polishing rate under these conditions was approximately 0.4 mil/hr. One line defect is shown on the photograph, although most of the wafer appears flawless. A chemically polished surface is at least as good as this surface as far as the defect density is concerned, but has a typical orange peel structure. If a lapping or mechanical polishing step is introduced prior to silicon dioxide polishing then deep damage may result which is difficult to remove by such slow polishing action. Figure 1(b) shows typical surface defects caused by 12.5 micron garnet particles, and Fig. 1(c) shows scratches (made visible by Sirtl etching) from diamond abrasive particles which were not removed by the silicon dioxide polishing. It is therefore advisable not to introduce any lapping steps in the preparation of silicon substrates by the silicon dioxide process. In this regard polishing by the cupric ion process that removes typically 4 to 5 mil/hr may be preferable. Of course, the possibility of copper contamination is also increased by this process and careful procedure must be followed to remove any residual copper.

As was mentioned before, most dislocation-free or low dislocation silicon crystals contain excess vacancies and vacancy clusters, formed during cooling of the crystals grown from the melt. On subsequent annealing these vacancies will diffuse towards the surface, especially along the dislocation lines, and at pinning centers such as the SiO_2-Si interface the vacancy clusters may collapse forming stacking faults. Therefore, a more sensitive test for revealing defects induced by mechanical damage is to oxidize the wafer, remove the oxide and then Sirtl etch for about a minute or two. Figure 2 shows some of the results from this test. The diamond polishing leaves the surface severely dislocated as revealed by the etch pits [Fig. 2(a)] and since these dislocations act as numerous sinks, vacancy clusters do not grow to form stacking faults. Figure 2(b) and (c) show the faults induced by 12.5μ garnet particles. The very interesting feature is the absence of any defects in a zone surrounding the clusters of "worm-like" faults [Fig. 2(b)] or line of "saucer-like" defects [Fig. 2(c)]. Quite often such "denuded" or precipitate-free zones (P.F.Z.) are formed in the vicinity of grain boundaries in age hardened alloys. Experimental evidence (9) has shown that apart from a very narrow region immediately next to the grain boundaries, the P.F.Z.'s are depleted of vacancies

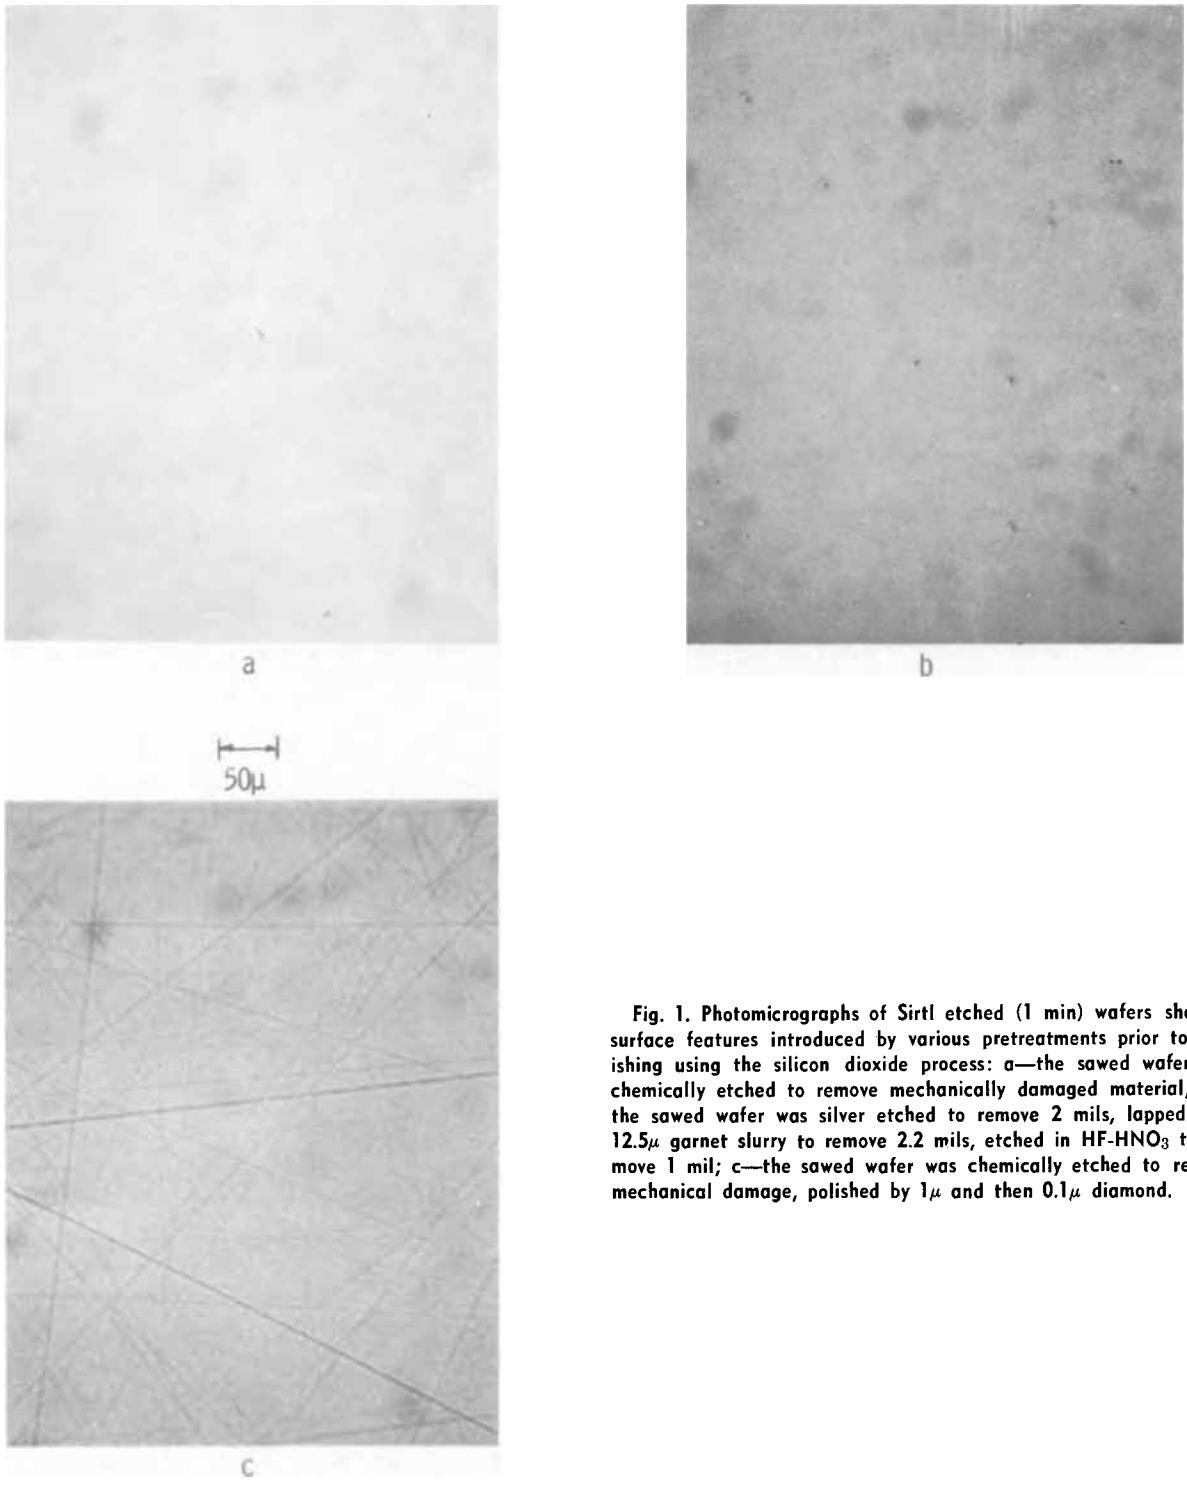

Fig. 1. Photomicrographs of Sirtl etched (1 min) wafers showing surface features introduced by various pretreatments prior to polishing using the silicon dioxide process: a—the sawed wafer was chemically etched to remove mechanically damaged material; b—the sawed wafer was silver etched to remove 2 mils, lapped with 12.5μ garnet slurry to remove 2.2 mils, etched in HF-HNO_3 to remove 1 mil; c—the sawed wafer was chemically etched to remove mechanical damage, polished by 1μ and then 0.1μ diamond.

rather than solutes. Consequently, the vacancy concentration and therefore the bulk diffusivity changes with distance from the boundary. The width of the P.F.Z. can be changed by altering the heat-treatment conditions; the zones are narrower for higher heat-treatment temperatures and faster quenching rates, both of which increase the excess vacancy content. From the above observations together with the fact that the wafer is cut from a float zone crystal, free from any precipitates and gross inhomogeneities (as examined by transmission electron microscopy), it is concluded that these faults grow by vacancy clustering and might be decorated by impurities. As will be shown later these "worm-like" and "saucer-like" defects are really dislocation etch pits and are therefore effective sinks for vacancy migration. Figure 2(d) shows some of the defects (which resemble stacking faults) induced by the sawing damage not completely removed by chemical etching and silicon dioxide polishing.

The defects shown in Fig. 2(b) and (c) could not be resolved adequately in the optical microscope. It was necessary to Sirtl etch these defects for about 3 min and any residual surface oxides removed (to prevent sample from charging) before these faults were resolved in the scanning electron microscope. Figure 3 shows the micrograph which clearly reveals these faults to be dislocation etch pits.

As mentioned before, the quality of a polished surface or the surface layer cannot be better than the bulk of the material. Therefore, several samples, polished by different techniques, were examined by transmission electron microscopy and compared with the bulk. Figure 4 shows the transmission electron micrographs of surface layers from a number of wafers. Figure 4(a) reveals some scratches not removed by

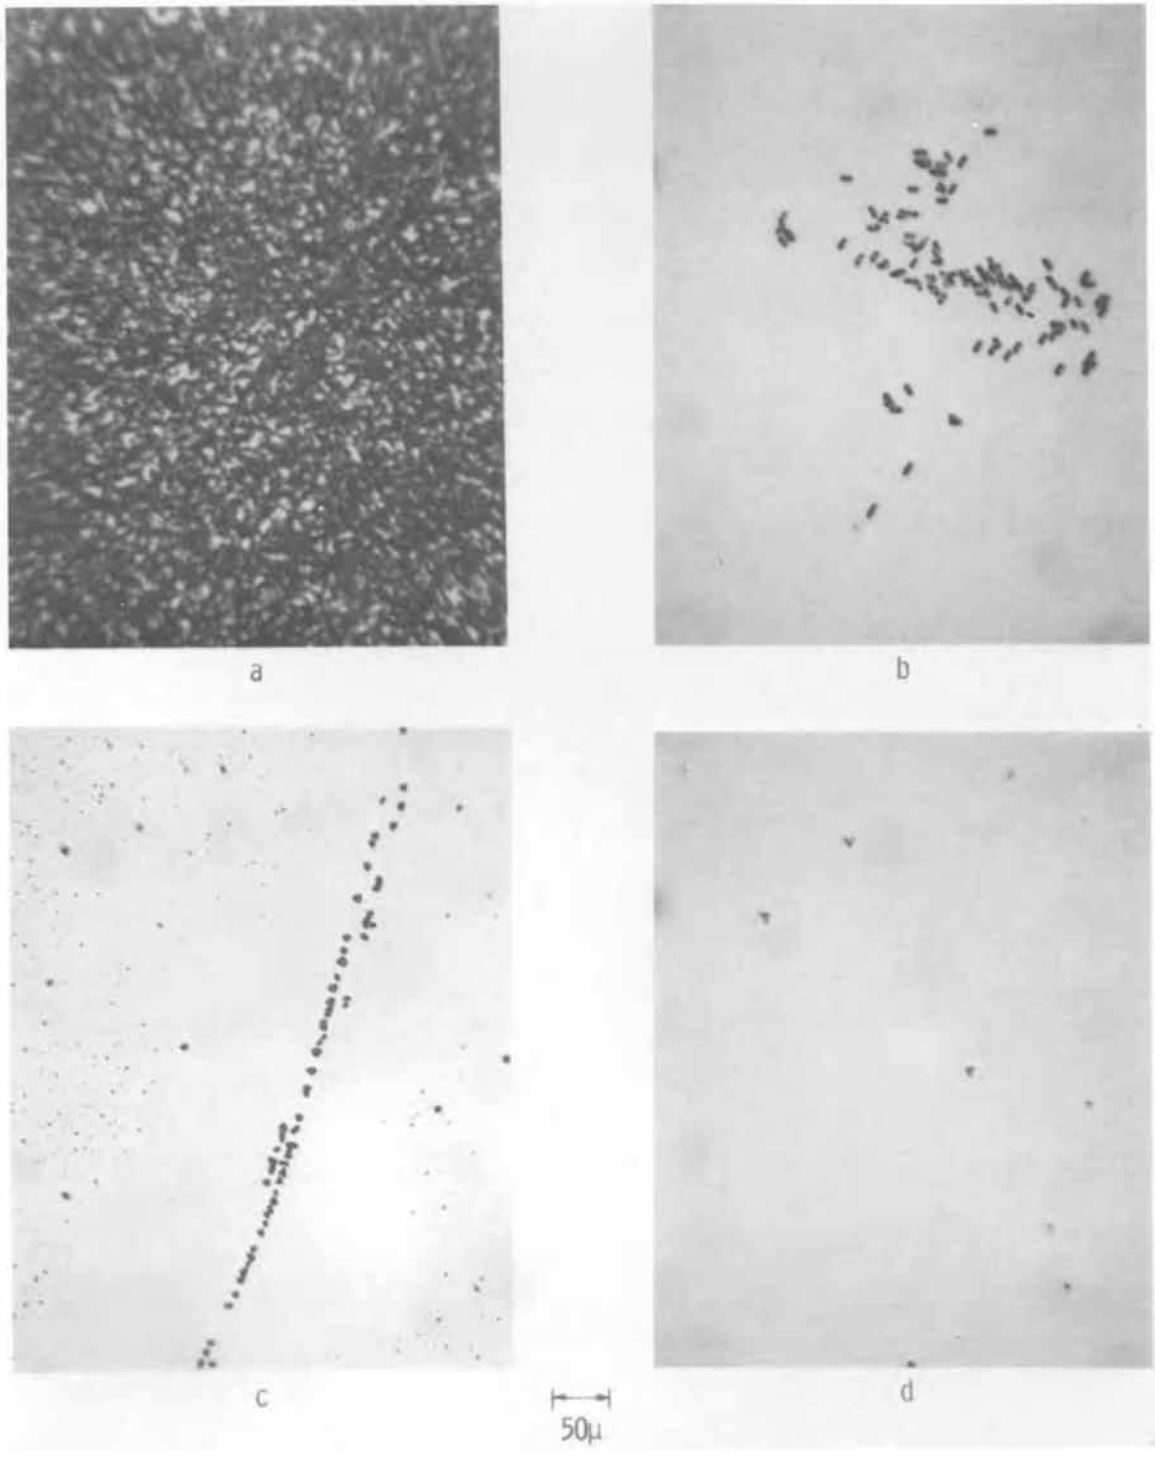

Fig. 2. Photomicrographs showing the effect of incomplete removal of the mechanical damage; the wafers were oxidized at 1100°C for 3 hr in wet oxygen followed by oxide stripping and 1 min Sirtl etching. a—Wafer showing damage from diamond abrasives (1 and 0.1μ size); b and c—wafer showing damage from 12.5μ garnet particles; d—wafer showing the effect of incomplete removal of sawing damage.

the silicon dioxide polishing. These scratches are, however, removable by HCl etching in the epitaxial reactor. Figures 4(b) and 4(c) show the surface layers of wafers polished by the silicon dioxide process and the chemical etchant, respectively. In both cases the inhomogeneities are comparable to the bulk of the respective wafers, and it is believed that these inhomogeneities are not of the type that propagate into the epitaxial layer. The characteristics and the causes of microinhomogeneities in the epitaxial layers are being investigated in detail. None of the inhomogeneities shown in the micrographs are of incoherent type, and therefore, do not contribute to the nucleation of any defects such as stacking faults. Neither are these inhomogeneities fast diffusing, because annealing in H_2 at 1220° for periods of up to 4 hr did not noticeably change their size or distribution. It can be concluded that a properly prepared wafer surface (*i.e.* avoiding any lapping steps) by the silicon dioxide process is comparable to a chemically polished surface, which, in turn, is comparable to the bulk material. A copper polished as well as an HCl etched wafer were similarly examined by TEM and the surfaces were found to be comparable to the bulk material.

If the depth of damage is shallow or the associated microstrain low, then *in situ* HCl etching might remove the damage effectively. In order to show the effectiveness in removing damaged material and surface contaminants, if any, epitaxial layers were grown on substrates with and without HCl etching. Figure 5

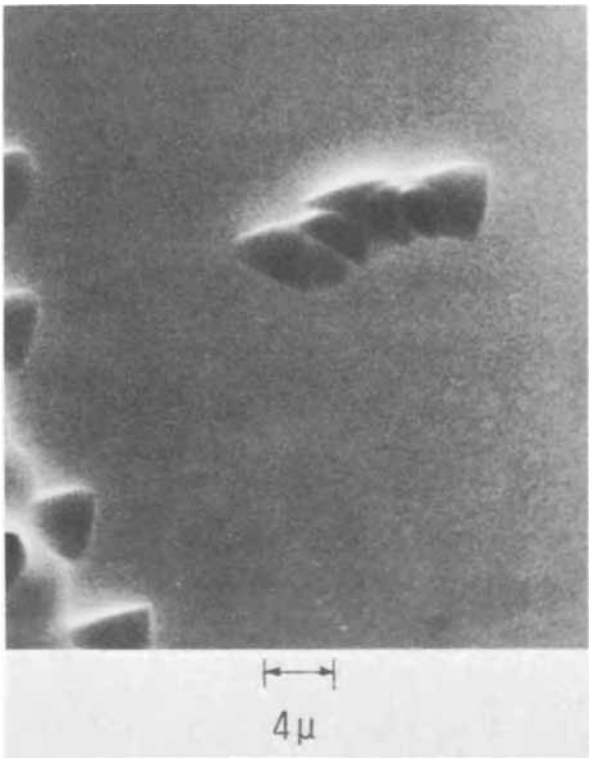

Fig. 3. Scanning electron micrograph at 45° incidence revealing dislocation etch pits; these are the same faults that appear in Fig. 2b and c.

shows that *in situ* etching does indeed remove most of the shallow damaged material. Figure 5(a) shows single stacking faults, groups of stacking faults at various stages of cancellation, line faults, and dislocation etch pits. No stacking fault interaction with incomplete cancellation is visible. All the epitaxial stacking faults are of intrinsic type, and Booker (10) has shown that they arise from small area of extrinsic fault on the (111) plane (or something equivalent). Although one fault is shown in Fig. 5(b) the entire wafer had only 4 stacking faults. Under identical growth conditions as those for Fig. 5, a 1.25 in. diam wafer, properly polished by the silicon dioxide process, gave about 115 stacking faults without HCl etching and 1 stacking fault with HCl etching. Thus *in situ* etching of the wafer before any processing reduces considerably the risk of process-induced defect formation.

As was mentioned before, all stacking faults in the substrate from vacancy collapse are of extrinsic type, and therefore are nucleation centers for the stacking faults in the epitaxial layers. The effect of the excess vacancies in causing stacking faults in the epitaxial layers was tested using (111) substrate silicon wafers that were chemically polished, dislocation free (as shown by x-ray topography) and a resistivity of 260 ohm-cm (p-type). The level of oxygen was below the detection limit of the *IR* absorption technique (<0.2 ppm), and the minority carrier lifetime was 700 μsec. All wafers were HCl etched prior to the growth of the epitaxial layers. Some of the wafers were oxidized and the oxide stripped before putting in the epitaxial reactor. The epitaxial layers were Sirtl etched to reveal the defects. The layer grown on unoxidized wafers had stacking fault density of less than 10 per wafer whereas about 400 stacking faults were found on the oxidized wafers. A possible explanation of the results is that enough dislocations are generated during the rf heating in the epitaxial reactor (11) so that the excess vacancies and vacancy clusters can be removed effectively. Absence of any effective pinning centers, such as those provided by a thermally grown SiO_2 layer makes fault nucleation difficult. Of course, in the presence of an oxide layer the vacancies will collapse to form stacking faults in the substrate (7) during oxidation, which will subsequently propagate into the grown layer. To further substantiate this point one batch of the 260 ohm-cm substrates were heat treated in H_2 to simulate the thermal cycling during HCl etching, and then oxidized along with another batch of wafers that were HCl etched. Sirtl etching of these wafers indicated practically complete absence of any oxidation-induced defects on the HCl etched wafers whereas a very few localized areas of oxidation induced defects were seen on the heat-treated wafers. Of course there was a general increase in the dislocation density of these wafers (11). Epitaxial layers were grown on some of these wafers (not Sirtl etched) after an *in situ* HCl etching. The stacking fault densities on the heat-treated wafers were ≤20 faults as compared to about 400 faults if the wafer was first oxidized. Further oxidation and examination of these epitaxial layers indicated no increase in the defect density. The results are summarized below with indicated defect densities (only to show the general trends).

Wafer treatment before oxidation	Wafer treatment after oxidation	Defects in epitaxial silicon	
		Stacking faults* No./cm²	Dislocations* No./cm²
None	HCl etch and epitaxial growth	70	300
Heat-treatment in epitaxial reactor simulating HCl etching	HCl etch and epitaxial growth	3	200
HCl etching in epitaxial reactor	HCl etch and epitaxial growth	<10	170
HCl etch and epitaxial growth	None	3	480

* Defect densities were obtained by counting all the faults in a wafer and indicate representative figures

Thus, in order to reduce the density of the stacking faults in the epitaxial layer it is not only necessary to remove any surface contaminants, but the presence or generation of a fair number of dislocations is also essential; HCl etching seems to fulfill both the requirements.

If the vacancies are present in the substrates in the form of clusters, such as, the vacancy spirals reported by deKock (6), then, these clusters cannot be removed by heat-treatment in the epitaxial reactor. When epitaxial layers were grown on such substrates the characteristic spiral pattern became visible, and consisted of numerous stacking faults (revealed by Sirtl etching) along the spiral. Thus vacancy clusters in the substrates are effective nucleation centers for stacking faults in the epitaxial layers.

Since stacking faults are nonequilibrium defects with stored energy (12) of the order of 50 ergs/cm², they can be annealed out under appropriate conditions, such as, heating in H_2 at about 1300°C for faults on (111) silicon. Hydrogen annealing causes disappearance of the characteristic fringe contrast and leave an impression of the fault on the wafer surface. However, such high-temperature annealing is not a practical solution. Segregation of impurities at the stacking faults has been observed directly by TEM. This can be interpreted as a result of the Suzuki interaction of impurity or dopant atoms with dislocations, resulting in a lowering of the stacking fault energy. Such stabilized stacking faults would be difficult to anneal, and if decorated with metallic impurities are detrimental to device performance (7, 13). Nucleation probability of stacking faults on the (111) plane is relatively high. The defects can start from an error in the stacking sequence of a single atomic plane and consist of three intrinsic faults on the inclined {111} planes. Since all the three faults are of intrinsic type there is no cancellation of (compressive and tensile) forces and the stored energy is relatively high. On the other hand the nucleation probability on the (100) plane is relatively low. In this case the formation of an (111) plane

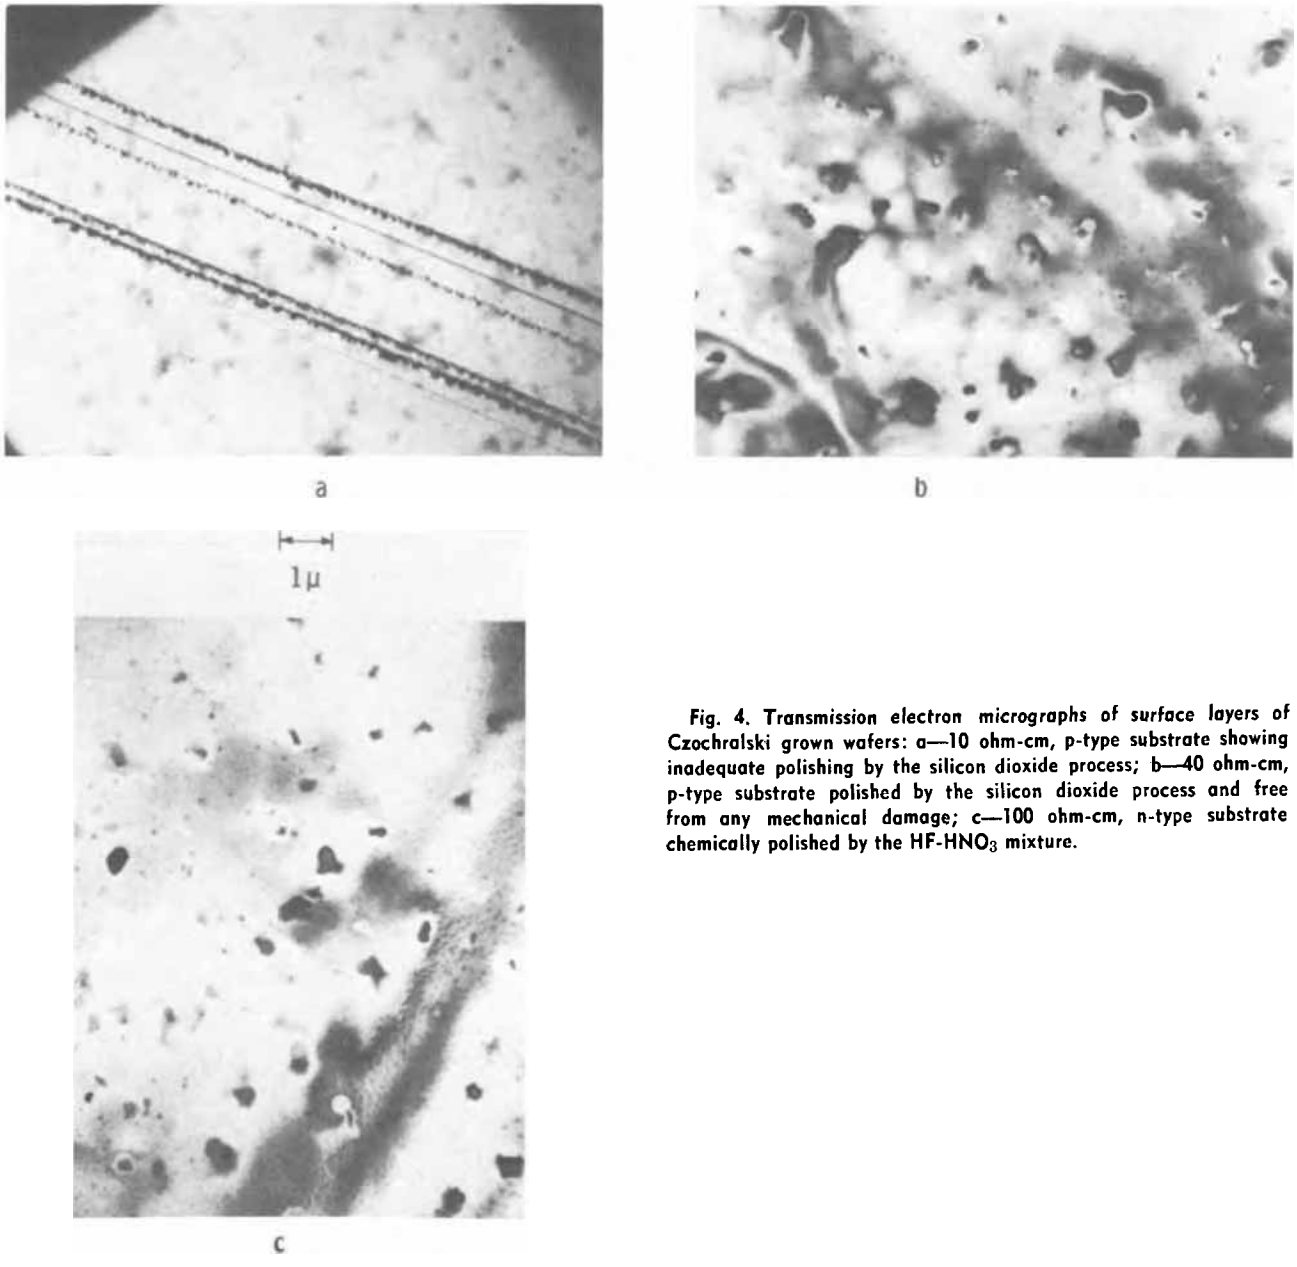

Fig. 4. Transmission electron micrographs of surface layers of Czochralski grown wafers: a—10 ohm-cm, p-type substrate showing inadequate polishing by the silicon dioxide process; b—40 ohm-cm, p-type substrate polished by the silicon dioxide process and free from any mechanical damage; c—100 ohm-cm, n-type substrate chemically polished by the $HF-HNO_3$ mixture.

must take place for which a larger error in the stacking sequence, such as, an oxide island is necessary. Also the square-type stacking faults in the epitaxial layer on (100) substrates consist of four faults as intrinsic/extrinsic/intrinsic/extrinsic on going around the defect. The total stored energy in this defect is expected to be lower than that in the (111) silicon due to some cancellation of forces, and therefore should not attract impurities as effectively as the faults on (111) silicon. Epitaxial layers were grown on chemically polished (111) as well as (100) wafers without *in situ* HCl etching. The resulting stacking fault density on the (111) wafer was about 100 faults/wafer whereas zero on the (100) wafer. It has also been observed by Thomas (14) that the stacking fault density in epitaxial silicon grown on (111) substrates was about 10^7 faults/cm^2, whereas, the density was essentially zero on the (100) silicon under identical conditions. These layers were grown at 600°C, a vacuum of 10^{-10} Torr, and at a rate of about 200 Å/min. Such large differences in the stacking fault densities between the two orientation substrates can be considered as evidence that nucleation probability of stacking faults on (100) substrates is considerably less and at sufficiently slow growth rate the mobility of the depositing atoms is high enough to prevent any errors in the stacking sequence. The preceding discussion indicates that the stacking faults are detrimental to good device performance, and in this regard (100) wafers provide a definite advantage over the (111) orientation. Therefore, (100) wafers should be preferred to (111) wafers for device fabrication.

Summary

Silicon substrates carefully polished by the chemical-mechanical processes, such as the SiO_2-NaOH-H_2O slurry possess the flatness of a mechanically polished surface and the structural perfection comparable to the bulk material. Shallow damaged material can be removed effectively from the wafer by HCl etching in the epitaxial reactor. However, if it is necessary to oxidize the wafer prior to epitaxial growth then the wafer must be free of damaged layer and should be HCl etched before oxidation. If the starting wafer is

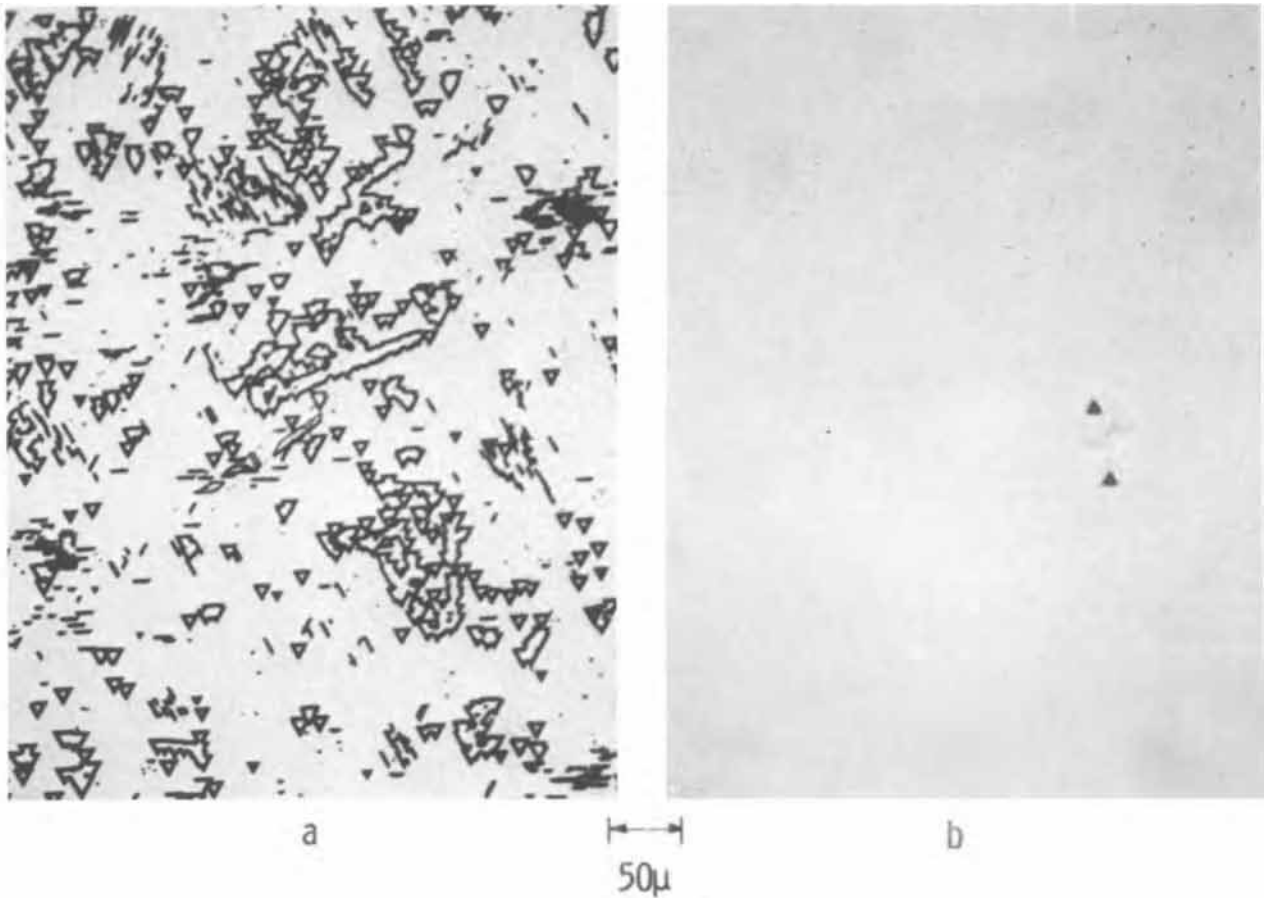

Fig. 5. Photomicrographs showing the effectiveness of HCl etching in removing mechanical damage and improving the quality of the epitaxial layers; all wafers Sirtl etched for 1 min. a—Epitaxial layer grown without *in-situ* HCl etching on the surface described in Fig. 1c; b—same as a, with HCl etching.

free from or very low in dislocation density then oxidation will generate many defects by a vacancy migration and collapse mechanism, which in turn will cause numerous stacking faults in a subsequently grown epitaxial layer. The probability and the energy of the stacking fault assembly is considerably reduced when (100) instead of (111) oriented wafers are used.

Etching Studies of Impurity Precipitates in Pulled GaP Crystals

T. Iizuka[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Light-emitting diodes prepared by p-tipping on n-type pulled GaP substrates are considerably less efficient than those diodes prepared by p-tipping on solution-grown substrates. The present study represents an attempt to use chemical etching and optical microscopy to determine the differences between n-type pulled GaP crystals and crystals obtained by solution- and vapor-growth techniques. Etch patterns believed to be associated with impurity precipitates were observed in large numbers in pulled crystals heavily doped (up to $N_D - N_A = 6 \times 10^{17}$ cm^{-3}) with sulfur or tellurium, and to a much lesser extent in lightly doped and undoped pulled crystals. Clusters of small etch pits attributed to isolated precipitates and short etch grooves attributed to decorated dislocations lying parallel to the surface were both observed. These etch patterns were not seen in solution-grown or vapor-grown crystals doped to approximately the same carrier concentrations.

Considerable work has been carried out on the growth and physical properties of GaP single crystals. These studies have been concerned mainly with crystals prepared by growth from gallium solution, vapor phase transport, or liquid phase epitaxial deposition. Recently, the liquid encapsulated Czochralski (LEC) technique (1-5) has become a major source of GaP crystals. However, relatively little work has been reported on defects in GaP crystals (6-11).

Crystals of n-type, doped with the elements sulfur, selenium, and tellurium, are widely used as substrates for light emitting diode fabrication. The solubility and electrical properties of these impurities in solution-grown, n-type GaP crystals have been reported by Trumbore *et al.* (12).

In this report, etching studies of impurity precipitation in n-type LEC GaP crystals are described. Etching can reveal the presence of precipitate-like defects, but there is a limitation in that it cannot directly identify the nature of the precipitate.

At present there are no standard etching solutions which reveal defects on all surfaces of GaP crystals. For example, no known etchant will reveal dislocations on {110} cleavage surfaces. However, this situation is rather useful for the study of impurity precipitation as is described later.

Experimental

Pulled GaP crystals were grown in vitreous silica crucibles with the growth axis in a <111> direction (5). Undoped, sulfur- and tellurium-doped crystals with carrier concentrations between 3×10^{15} cm^{-3} and 6×10^{17} cm^{-3} were studied. For comparison, solution-grown and vapor-grown crystals doped with sulfur and tellurium were examined.

Slices were cut parallel to the {111} plane, mechanically lapped, and then polished with Linde A. The slices were rinsed with acetone and methanol and dried. After these procedures, the slices were inspected with transmitted visible light. Then, the slices were pre-etched with chlorine-saturated methanol to remove surface damage on the P($\bar{1}\bar{1}\bar{1}$) surfaces. This pre-etching is effective for obtaining a scratch-free, smooth P($\bar{1}\bar{1}\bar{1}$) surface for detailed optical observation, but it is not effective on the Ga(111) surface. Thus, P($\bar{1}\bar{1}\bar{1}$) and cleaved {110} surfaces were mainly employed for observation. Then, a modified AB etchant [10 ml H_2O, 40 mg $AgNO_3$, 5g CrO_3, 8 ml HF for 50 min at 75°C (9, 13)] or RC etchant [8 ml H_2O, 10 mg $AgNO_3$, 6 ml HNO_3, 4 ml HF for 3 min at 60°C (14)] was used to reveal defects. The solution was occasionally stirred during etching, which was performed under ordinary room illumination. Defects on the etched surfaces were observed mainly with an interference contrast microscope (15).

Key words: Defects, compound semiconductor, optical microscopy.

Results

Undoped, S- and Te-doped pulled crystals.—Etching produced the following types of etch patterns on the surfaces of n-type LEC crystals.

Dislocation etch pits.—Deep, conical dislocation etch pits were revealed on the P($\bar{1}\bar{1}\bar{1}$) surface (Fig. 1, 2, and 3). The diameters of the pits were about 5-10μ and the density was generally of the order of 10^5 cm^{-2}. The shape and the appearance of the pits in the doped crystals were not as distinct as those in the undoped crystals (Fig. 2 and 3).

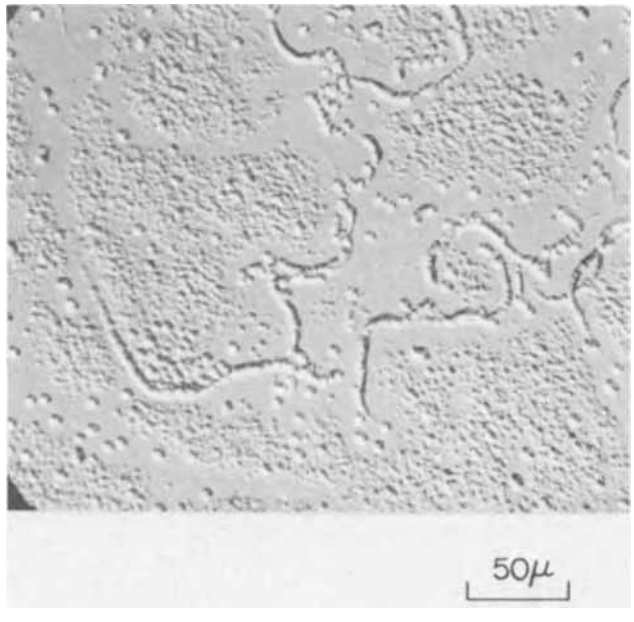

Fig. 1. Dislocation etch pits, etch grooves, and clusters of small etch pits on P($\bar{1}\bar{1}\bar{1}$) surface of S-doped crystal (N_D-$N_A \sim 6 \times 10^{17}$ cm^{-3}). Defect-free regions around the dislocation pits and grooves are seen. Etched with RC etchant.

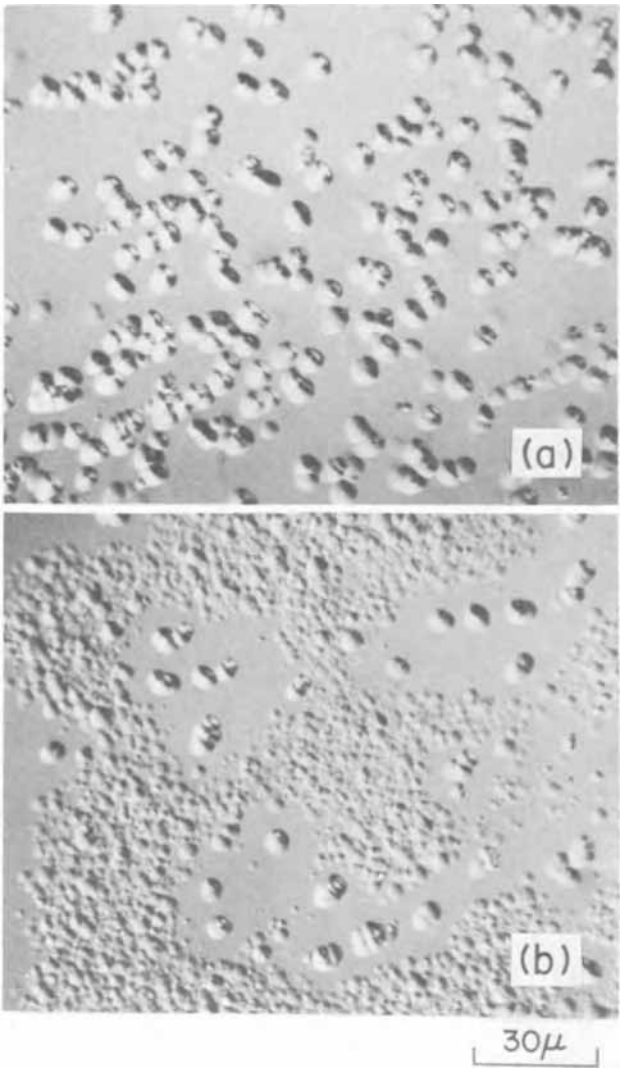

Fig. 2. Correlation between dislocation etch pit density and small-pit clusters on P($\bar{1}\bar{1}\bar{1}$) surface of S-doped crystal (N_D-N_A ~ 6x10^{17} cm^{-3}). Etched with RC etchant. (a) A peripheral region with high dislocation density (~ 8x10^5 cm^{-2}) and without small-pit clusters. (b) A central region with low dislocation density (~ 2x10^5 cm^{-2}) and with small-pit clusters, on the same slice as in (a).

Fig. 3 (a). Dislocation pits and etch grooves on P($\bar{1}\bar{1}\bar{1}$) surface of an undoped crystal. No small-pit clusters are seen. Etched with AB etchant.

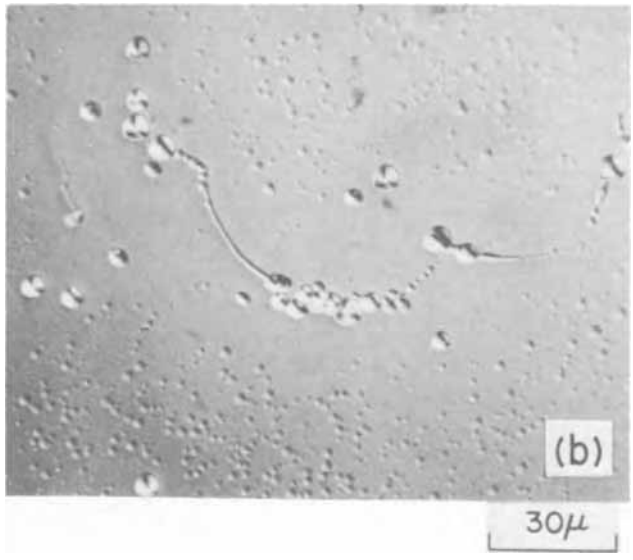

Fig. 3 (b). Another undoped crystal showing dislocation pits, etch grooves, and small-pit clusters on P($\bar{1}\bar{1}\bar{1}$) surface. Etched with AB etchant.

Clusters of small, shallow, flat-bottomed etch pits.— Clusters of small, shallow, flat-bottomed etch pits were also observed on the P($\bar{1}\bar{1}\bar{1}$) surface of one undoped crystal and all doped crystals as shown in Fig. 1, 2(b), and 3(b). However, another undoped crystal did not show these clusters on the P($\bar{1}\bar{1}\bar{1}$) surface [Fig. (3a)]. The individual pit diameter varied from approximately 0.5 to 5μ, and the density was less than 2-3 x 10^7 cm^{-2} at the clustering region on the P($\bar{1}\bar{1}\bar{1}$) surface.

These small pits were also revealed on {110} cleavage surfaces of relatively highly doped crystals ($N_D - N_A \geqq 3 \times 10^{17}$ cm^{-3}), but they were not as clearly shown as on the P($\bar{1}\bar{1}\bar{1}$) surface (Fig. 4 and 5). They were, however, readily observed by ordinary optical microscopy without an interference contrast attachment. There was always a good correspondence between the small-pit cluster distributions on the opposite {110} cleavage halves, indicating the spatial distribution of the defects responsible for the clusters in the bulk. However, even when interference contrast microscopy was employed, it was impossible to observe the small-pit clusters on the etched {110} cleavage surface of undoped ($N_D - N_A \sim 3 \times 10^{15}$ cm^{-3}) and some lightly Te-doped ($N_D - N_A \sim 1 \times 10^{17}$ cm^{-3}) LEC crystals. This result suggests that the etch patterns were related to the dopant impurity concentration.

Distribution of the small-pit clusters varied from crystal to crystal and location to location. Nonuniform distributions of the clusters were observed both in the growth direction and in the radial direction. Sometimes the distribution of the clusters was limited by growth striations on the "off-core" region of a longitudinal {110} surface including the growth axis [Fig. 5(a)]. Discontinuous distribution of the clusters was also seen on the "off-core" to "on-core" transition region as shown in Fig. 5(b). On the P($\bar{1}\bar{1}\bar{1}$) surface of the same sample cut perpendicular to the growth direction, the small-pit clusters were distributed in annular rings as shown in Fig. 6. These results suggest that the formation of the original defects responsible for the small-pit clusters is dominated by crystal growth conditions.

In general, small-pit clusters were not found at the periphery of the P($\bar{1}\bar{1}\bar{1}$) surfaces examined, but a high density of dislocation etch pits was observed [Fig. 2(a)]. In the inner region of the slice, how-

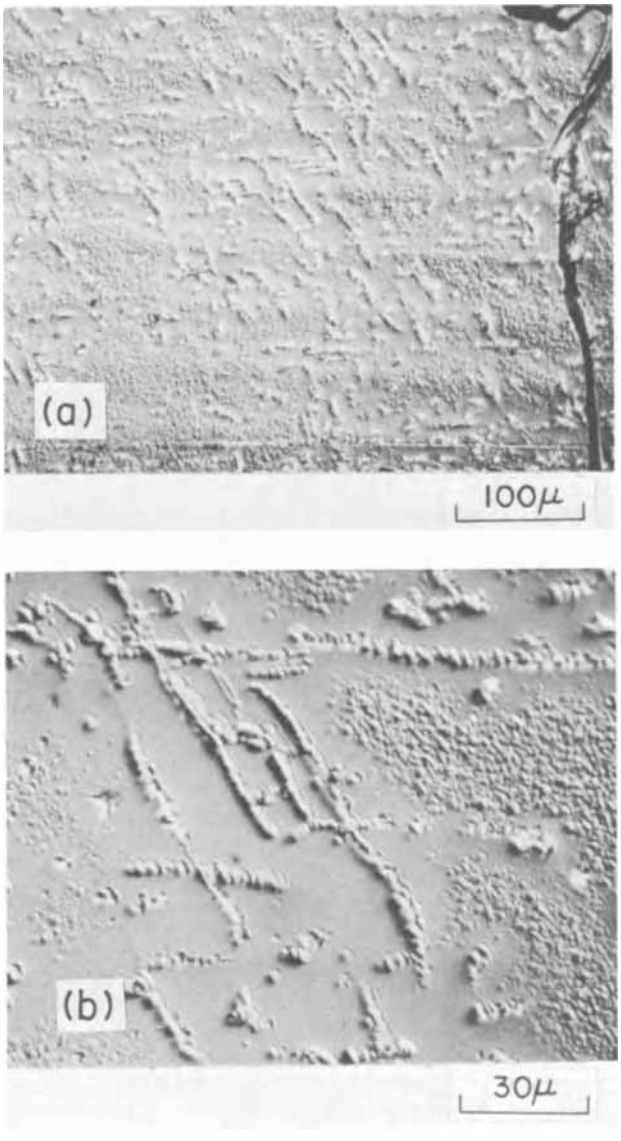

Fig. 4. Etch grooves and clusters of small etch pits on {110} cleavage surface of S-doped crystal (N_D-N_A ~ $6x10^{17}$ cm^{-3}). Defect-free smooth regions around the grooves are clearly seen. Most of the grooves are approximately parallel to either a <211> or <110> direction. Horizontal is a <211> direction. Etched with AB etchant. (a) Low magnification view. Weak striations are seen in this sample. (b) Detailed etch patterns.

ever, the dislocation pit density was lower and small-pit clusters were distributed between the dislocation etch pits [Fig. 2(b)].

Etch grooves.—Etch grooves were revealed on the P($\bar{1}1\bar{1}$) surfaces of all undoped and doped crystals (Fig. 1 and 3). While the grooves were easily revealed on the {110} cleavage surface of relatively highly doped crystals ($N_D - N_A \geq 3 \times 10^{17}$ cm^{-3}), as shown in Fig. 4 and 5, they were revealed with difficulty on the {110} cleavage surface of undoped ($N_D - N_A \sim 3 \times 10^{15}$ cm^{-3}) and lightly doped ($N_D - N_A \sim 1 \times 10^{17}$ cm^{-3}) crystals; their distribution also varied from one crystal to another. There was a correspondence between the densities of the etch grooves on the {110} cleavage surface and the dislocation etch pits on the corresponding P($\bar{1}1\bar{1}$) surface close to the cleaved edge. This correlation may indicate that the etch grooves on the {110} surface are attributed to dislocations lying on, or just under, the surface.

Smooth regions.—It is also noteworthy that there are smooth regions around both dislocation pits and etch grooves as shown in Fig. 1, 2(b), 3(b), 4, and 5.

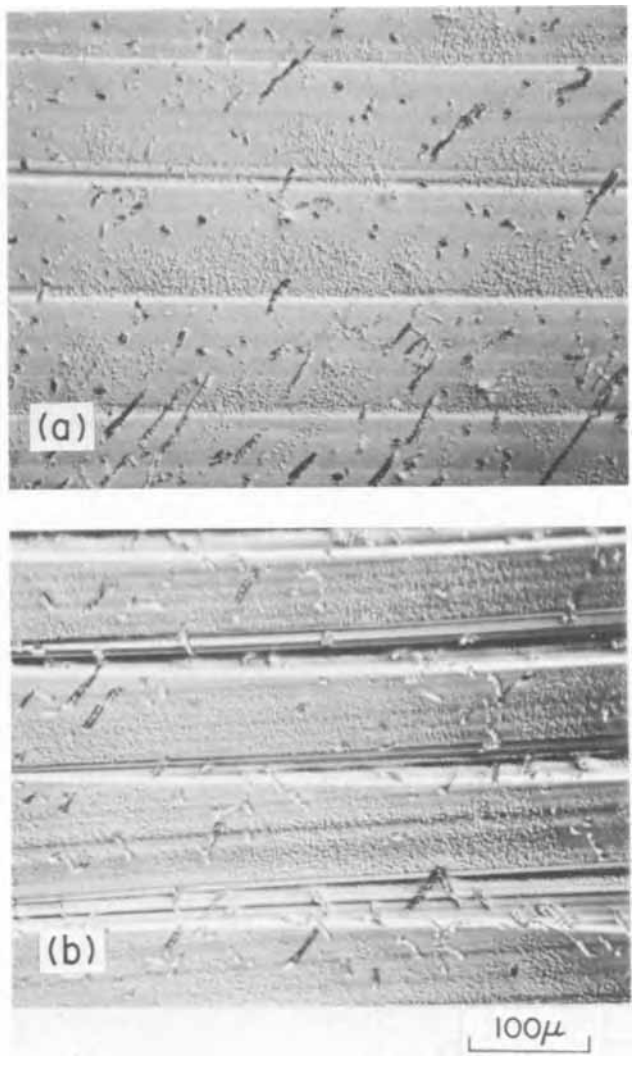

Fig. 5. Etch patterns on a {110} surface parallel to the growth axis. Striations, small-pit clusters, and etch grooves are seen. Te-doped crystal (N_D-N_A ~ $3x10^{17}$ cm^{-3}). Etched with AB etchant. (a) Off-core region. The distribution of the small-pit clusters is limited by growth striations (white lines). (b) Edge of core region (central core region is on the right-hand side of the picture). Discontinuous distribution of the clusters in the growth direction.

The width of such regions was between 10 and 30μ. The presence of similar regions has previously been observed on heavily Te- and Se-doped GaAs crystals (16-18). In Te-doped GaAs, the width of such regions was found to be 25-100μ by Casey (16), and 30-150μ (etching), and 50-200μ (x-ray topography) by the author (18). The formation mechanism of these regions is not well understood. However, it may be assumed that the mechanism is the same in both GaP and GaAs.

N-type solution-grown and vapor-grown crystals.—Neither small-pit clusters nor etch grooves were observed on any surfaces of solution-grown or vapor-grown crystals comparably doped with sulfur or tellurium.

Dislocation etch pits were observed on the {111} surfaces of these crystals. In the solution-grown crystals, they were mostly localized around impurity inclusions.

Discussion

Nature of the characteristic etch patterns of S- and Te-doped crystals.—In addition to the usual dislocation etch pits, clusters of small pits were observed on the surface of most of the donor-doped pulled crystals. The size of the individual pits is smaller than

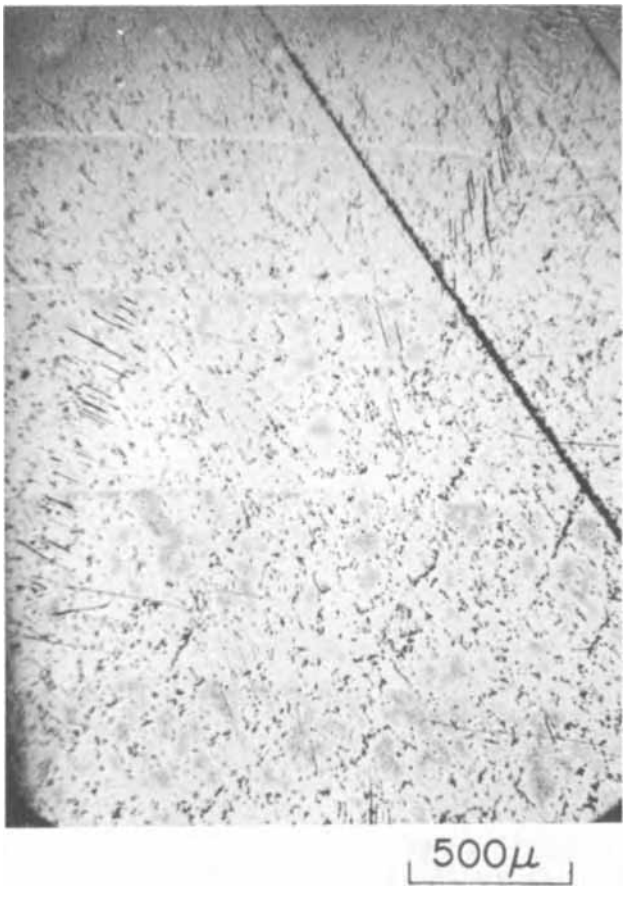

Fig. 6. Part of annular rings revealed on a P(111) surface cut perpendicular to the growth axis. The same crystal as in Fig. 5. Dark cloud-like patterns corresponding to the small-pit clusters are also limited by the annular rings. Etched with AB etchant.

that of the usual dislocation pits, and the density is larger than the usual dislocation density in pulled crystals. The small pits on P($\bar{1}\bar{1}\bar{1}$) surfaces are shallow and flat-bottomed and have no tails. These properties indicate that the small pits are not associated with the usual dislocations, but are due to defects such as impurity precipitates or vacancy aggregates, or small dislocation loops with a diameter of less than 1μ. Small etch pits not corresponding to dislocations were previously observed on Ge (19-26), Si (27, 28), and GaAs crystals (16-28, 29). They were attributed to silica (22-25), vacancies (19, 28), Te (or a Te-rich complex) (16-18), or oxygen (20, 29).

Etch pits corresponding to vacancy aggregates have been observed only in nearly dislocation-free crystals (19, 28). Thus vacancy pits were not observed in Ge crystals with dislocation densities greater than about 200 cm^{-2} (19). Therefore it is believed that dislocations serve as very effective sinks for excess vacancies. Since pulled GaP crystals have very high dislocation densities ($\sim 10^5$ cm^{-2}), it is quite improbable that the small pits observed in these crystals are due to vacancy aggregates.

The possibility that small dislocation loops are the source of the small pits is also rejected for the following reason. Dislocation can be revealed on the P($\bar{1}\bar{1}\bar{1}$) surface of GaP crystals as deep, conical etch pits, but cannot be revealed on the {110} cleavage surface. Therefore it might be thought that a small dislocation loop could be revealed on the P($\bar{1}\bar{1}\bar{1}$) surface as a small etch pit pair, but could not be revealed on the {110} cleavage surface at all. However, small-pit clusters were easily revealed on the {110} cleavage surface of highly doped n-type LEC GaP crystals. It is concluded that the small etch pits are not due to small dislocation loops.

Now we shall discuss the possibility that impurity precipitates are the origin of the small etch pits. These pits are absent from the smooth regions surrounding individual dislocation etch pits or etch grooves, and they are entirely absent from the highly dislocated areas at the periphery of the GaP slices. These observations indicate that the dislocations act as sinks for the defects responsible for the small etch pits, or in other words that the dislocations can be decorated by these defects. Decoration of the dislocations also accounts for the easy delineation of the etch grooves on P($\bar{1}\bar{1}\bar{1}$) surfaces and especially on {110} cleavage surfaces of the pulled crystals. In general, dislocations lying close and nearly parallel to the surface cannot be revealed by etching. In some cases, however, such dislocations have been revealed by etching as lines (30), channels (31, 32), trails (9, 13), or ridges (33). The delineation of these features is mainly attributed to decoration of the dislocations by impurity precipitates, which results in faster or slower etching. By analogy, formation of the etch grooves on doped GaP can be attributed to decoration by impurity precipitates. Since the defects responsible for the small etch pits can also decorate the dislocations, it seems probable that these defects are impurity precipitates, and that etching of isolated precipitates (not associated with a dislocation) leads to the formation of the characteristic flat-bottomed pits.

In pulled GaP crystals doped with S or Te, where the small-pit clusters and etch grooves are much more prominent than in undoped crystals, the impurity precipitates are formed primarily by the dopant element. Dislocation lines decorated with Se or Te have been observed with an infrared microscope as dark lines in heavily doped GaAs crystals ($n \sim 2 \times 10^{18}$ cm^{-3}) grown from the melt (17, 34). In LEC GaP crystals with carrier concentrations up to 6×10^{17} cm^{-3}, decorated lines have never been observed by transmitted visible light. Thus the dislocations are not sufficiently decorated with the dopant impurity to be detected in this manner, but are decorated enough to be revealed by preferential etching.

The appearance of the etch grooves in the doped GaP crystals varies from one groove to another and from one sample to another. Such variations are considered to be due both to different amounts of impurity precipitation and to the type of dislocation (*i.e.*, edge or screw). The difference in the appearance of the dislocation etch pits between doped and undoped crystals, as seen in Fig. 2 and 3, is attributed to a difference in the amount of impurity precipitation along the dislocations.

Etching behavior of undoped crystals.—Even in the case of undoped LEC crystals, etch grooves were revealed on the P($\bar{1}\bar{1}\bar{1}$) surface of two samples, and small-pit clusters were observed on this surface for one sample. These results also suggest the presence of isolated impurity precipitates and dislocations decorated with the same impurity. Both nondelineation of the clusters on the {110} cleavage surface and poor delineation of the grooves on this surface suggest that the degree of impurity precipitation in the undoped crystals is not as high as in the doped crystals.

The probable impurities in undoped LEC GaP crystals are considered to be boron, silicon, carbon, and oxygen (4, 5, 11) incorporated from the silica crucible, graphite susceptor, and/or boric oxide during crystal growth. Therefore it is likely that in these crystals the small pits and the etch grooves are associated with the precipitation of one or more of these impurities.

Precipitation mechanism.—Finally, some comment can be made on the mechanism of impurity precipitation in pulled GaP crystals, even though no detailed mechanism has been established. In general precipita-

tion occurs when the concentration of an impurity incorporated in the crystal lattice exceeds the solubility at a temperature where the kinetics are sufficiently rapid to permit precipitation. It would not be surprising for these conditions to be satisfied for pulled GaP crystals. First, since substitutional impurities such as sulfur and tellurium can be expected to exhibit retrograde solubility (35), the concentrations incorporated at the melting point, 1470°C, could exceed the solubilities at lower temperatures. Second, since the initial cooling rates after solidification are relatively low, the crystal spends an appreciable time at temperatures high enough for the precipitation rate to be rapid. In contrast, the vapor- and solution-grown crystals are prepared at much lower temperatures, approximately 900° and 1140°C, respectively, where the precipitation kinetics would be extremely slow.

Such a difference in precipitation behavior between LEC crystals and solution-grown or vapor-grown crystals leads to a difference between them in etching behavior.

Summary

1. Characteristic clusters of small etch pits, etch grooves, and cluster-free regions around dislocations were revealed on the surface of pulled GaP crystals by etching techniques.

2. There is a distinct difference in etching behavior between pulled crystals and solution-grown or vapor-grown crystals.

3. The delineation of these etch patterns is attributed to impurity precipitation followed by preferential etching.

4. The impurity which is mainly responsible for the formation of etch patterns in doped crystals is the dopant element (sulfur or tellurium).

5. In undoped crystals, the impurity responsible for precipitation is thought to be boron, silicon, carbon, or oxygen incorporated during crystal growth.

6. The easy formation of precipitates in the pulled crystals is attributed to retrograde solid solubility and crystal growth at a high temperature.

Thermogravimetric Study of the Oxidation of ZrB_2 in the Temperature Range of 800° to 1500°C

and H. C. Graham

Aerospace Research Laboratories, Wright Patterson Air Force Base, Dayton, Ohio 45433

ABSTRACT

A thermogravimetric system is described for the determination of the total oxygen consumption, sample weight-change, and vaporization rate during the oxidation of $ZrBr_2$. The results show an increasing deviation from parabolic kinetics with increasing temperature at 250 mm oxygen pressure. The following equation is used to describe the total oxygen consumption in the temperature range of 800°-1500°C

$$\frac{\Delta n_{O_2}}{A}\left(\frac{\text{moles } O_2}{\text{cm}^2}\right) = 5.41 \times 10^{-4} \exp\left(\frac{-25{,}000}{2RT}\right) t^{1/2} + 2.86 \exp\left(\frac{-47{,}000}{RT}\right) t$$

Because ZrB_2 is oxidized stoichiometrically, this result can be converted to the recession of ZrB_2 as follows

$$\delta\,(\text{cm}) = 4.06 \times 10^{-3} \exp\left(\frac{-25{,}000}{2RT}\right) t^{1/2} + 2.10 \times 10^{1} \exp\left(\frac{-47{,}000}{RT}\right) t$$

The total oxygen consumed in the oxidation of ZrB_2 has been investigated by Berkowitz (1) over the temperature range of 1150°-1550°C. Parabolic oxidation was reported in that study as well as in the study by Kuriakose and Margrave (2), who measured sample weight change over the temperature range of 950°-1250°C. In both of these studies, the effect of oxygen partial pressure on the oxidation behavior was investigated at 1056°C. Kuriakose and Margrave found the increase in the parabolic rate constant to be directly proportional to the oxygen pressure over the oxygen partial pressure range of 100-740 Torr. Berkowitz substantiated this finding but found no oxygen pressure dependence at 1287°C over the range of 8-40 Torr or at 1557°C over the range of 20-700 Torr. Clougherty *et al.* (3) have measured recession rates of ZrB_2 at temperatures up to 1900°C and reported their data on the basis of a parabolic time dependence.

In view of the current technological need for materials with good oxidation resistance at high temperatures, this study was undertaken to obtain additional quantitative data on the oxidation of ZrB_2 by independent determinations of sample weight-change, total vaporization, and total oxygen consumption. These measurements allow the evaluation of the amount of ZrO_2 and B_2O_3 formed.

Experiment

A common method of studying the kinetics of an oxidation process is by continuously recording weight-change at constant temperature. For many materials this method has proved to be very successful. However, in the study of the oxidation of some alloys and high-temperature refractory materials, care must be used in interpreting weight-change data because of the formation of volatile oxides. Weight-change measurements indicate only the amount of oxide products remaining on the sample.

If volatile oxides are formed, then other methods, such as the measurements of total oxygen consumed by means of pressure changes or volume changes, must be used to determine reaction rates. Thermal conductivity measurements of the gas stream before and after reaction have been used successfully (4). Some experimental difficulties are encountered in all of these methods, particularly at very high temperatures.

The techniques described here are designed for the thermogravimetric measurement of total oxygen consumption for materials that form a volatile oxide which is condensable at temperatures below the reaction temperature. Slight modifications of the system can be made to measure separately the vaporization rates and sample weight-change.

During this study of the oxidation of ZrB_2, three methods were used to separate into parts the oxidation processes which occur simultaneously. These methods were:

1. Sample weight-change—conventional weight-change measurements in which only the weight increase due to the oxidation products remaining on the sample are recorded.
2. Oxygen consumption—measurement of the weight increase of the sample plus the weight of any volatile oxides that are condensable within the temperature range of the system.
3. Vaporization—only the weight of the condensable oxides is measured.

Measurements of sample weight-change were made with an Ainsworth FV-AU-1 recording microbalance. The capacity of the balance is 10g and the sensitivity is ±3 μg. A total weight-change of 100 mg can be recorded. In the conventional weight-change measurements, the gaseous B_2O_3 collected on the cooler parts of the furnace and represented an unknown weight loss. Single-crystal sapphire rods were used to suspend the samples, and measurements were made only to 1500°C.

At 1500°C and above, it was not possible to complete a run because of a reaction which destroyed the sapphire rods. It was observed that the reaction product of ZrB_2, probably B_2O_3, reacts quite destructively with most materials at high temperatures. Rh, Pt, Ir, Al_2O_3, ThO_2, ZrO_2 were tried without success in attempts to

Key words: thermogravimetric, oxidation, oxygen consumption, vaporization, ZrB_2, B_2O_3, paralinear.

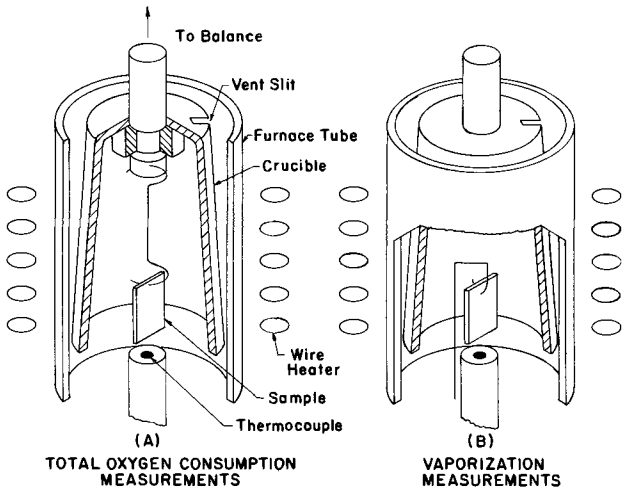

Fig. 1. Sample suspension for measuring total oxygen consumption and vaporization rates of a condensable oxide.

suspend a specimen in the temperature range of 1500°-2000°C (5).

The oxygen consumption and vaporization measurements were made with a Cahn RH Electrobalance which has a capacity of 100g and a sensitivity of ±10 μg. The total weight-change that can be recorded with this balance is variable but can be as much as 20g. Figure 1 is a diagram of the methods used to measure total oxygen consumption and vaporization. ZrB_2 oxidizes to form both ZrO_2 and B_2O_3. Since B_2O_3 is a liquid above 450°C and has an appreciable vapor pressure above 1000°C (6), some vaporization of this oxide is expected. In Fig. 1(a) is shown the method used for measuring total oxygen consumption. An inverted crucible 100 mm long is suspended from the balance with the specimen hanging inside. A modification of this, as shown in Fig. 1(b), is used to directly measure vaporization rates. Here the sample is not connected to the balance but is again inside the crucible. In this case, only the vapor condensed on the crucible is measured. In both arrangements, the top of the crucible is considerably cooler than the specimen so that any condensable products will collect there. The total load on the balance is about 50g in either case.

The furnace system used in this study has been described previously (7). Sample temperature was measured by a thermocouple placed just below the sample. The temperature profile of the furnace showed that the specimen should be within 10°C of the measured temperature. All the temperatures reported are thermocouple temperatures.

The ZrB_2 material was supplied by Manlabs Incorporated as a hot-pressed billet about 75 mm in diameter and 25 mm thick. The major impurity in this material is ZrO_2 and the B/Zr ratio is slightly less than two. Small rectangular coupons weighing about 1g and with an area of approximately 4 cm^2 were cut from the billet with a diamond saw. The specimens were ground smooth with a 150 grit diamond wheel and ultrasonically cleaned in alcohol.

The samples used to measure weight change were annealed in a vacuum of 10^{-5} Torr at 600°C for about 15 hr before the start of each run. In the oxygen consumption experiments, argon at a pressure of 20 Torr was used for the annealing environment. These different annealing methods did not appear to affect the kinetics in any way. After annealing, the sample was heated to the desired temperature and oxygen was introduced into the system as quickly as possible. During the time of heating to the temperature of the run, the weight was observed to be constant up to 1100°C. Small weight gains were observed above this temperature.

The dependence of the oxidation rates on gas flow was measured. In the temperature range covered and

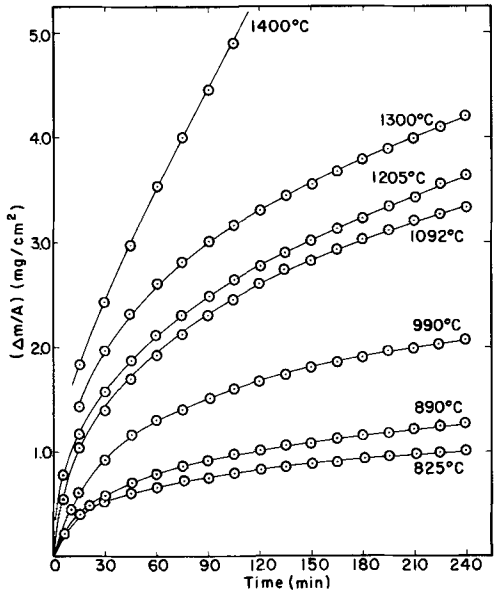

Fig. 2. Sample weight change, ZrB_2 at 250 Torr O_2

for the size of specimens that were used, a flow rate of 0.5 cm/sec was found to supply enough oxygen so that the reaction rate was not flow dependent. All the measurements reported here were made at a total pressure of 250 Torr in pure oxygen.

Results

The measurements of sample weight change are presented in Fig. 2. Since B_2O_3 has an appreciable vapor pressure above 1000°C, some vaporization of this oxide will occur. At the higher temperatures, the data, therefore, represent both a gain in weight from the addition of oxygen forming ZrO_2 and B_2O_3 and a loss in weight due to a loss of boron in the vaporization of B_2O_3.

The B_2O_3 left on the sample after an oxidation run at 250 Torr O_2 could be vaporized by heating at 1100°C in a vacuum of 10^{-5} Torr until a constant weight was recorded. With the assumption that all of the B_2O_3 had evaporated, the weight-change measured after this vacuum treatment represented the total oxygen consumed in the formation of ZrO_2 minus the boron lost in the vaporization of B_2O_3. From this weight-change, the total oxygen consumption can be calculated if it is assumed that ZrB_2 oxidized stoichiometrically.

The direct measurements of total oxygen consumption agreed quite well with these calculations particularly for temperatures of 1100°C and below. Specimens oxidized above this temperature were cooled to 1100°C before the furnace was evacuated. Consequently, some excess oxide was formed and the agreement between the calculations and experiments was not as good. However, because of the agreement between calculated values of total oxygen consumed and measured values, ZrB_2 must oxidize stoichiometrically within the conditions of these experiments.

Using the second method described, *i.e.*, the weighing of the sample plus the condensed vapor species, the data presented in Fig. 3 were obtained. Since any B_2O_3 that evaporates will condense at the cool end of the crucible, these data represent the total oxygen consumed during the oxidation process.

A measure of the rate of vaporization can be obtained from the difference between the total oxygen consumed (Fig. 3) and the specimen weight-change (Fig. 2). The vaporization rate was also measured directly by the third technique described. The results of all three measurement methods at 1200° and 1300°C are shown in Fig. 4 and 5, respectively.

The curves labeled "sample weight" are the net specimen weights observed in conventional weight-change measurements of oxidation kinetics. The "oxy-

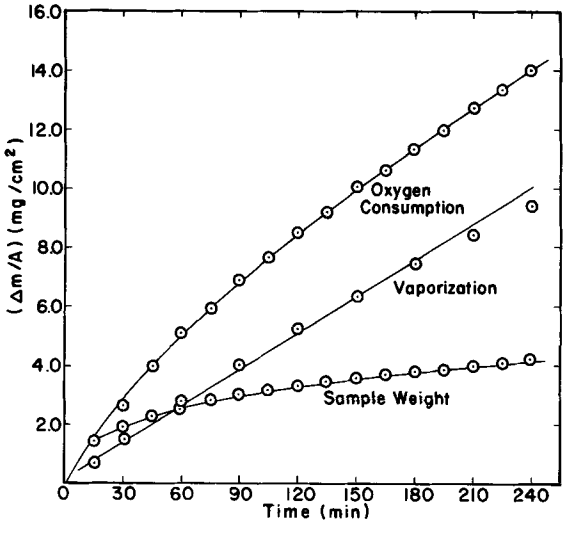

Fig. 5. Three types of measurements of the oxidation rate of ZrB_2, 1300°C, 250 Torr O_2.

gen consumption" curves describe the total oxygen consumed when all of the oxidation products are collected and weighed. Since this study indicates that ZrB_2 oxidizes stoichiometrically, the values of oxygen consumption can be converted directly into material consumed, or recession rates.

The third curve in the figures, vaporization, was determined by weighing only the condensable oxides formed, using the technique shown in Fig. 1(b). This curve can also be determined by simply subtracting the sample weight values from the total oxygen consumption values at any time. The agreement between all three measurement methods was found to be quite good at all temperatures.

Discussion

Previous investigators (1-3) have interpreted measurements of boride recession, oxygen consumption, and weight-change as being a parabolic process and therefore have suggested that the reaction is controlled by diffusion through a continuously growing oxide layer. Because of the evaporation of B_2O_3, weight-change measurements alone are of questionable value when used to determine a time dependence for the oxidation process. Measurements of the total amount of oxygen consumed will not be influenced by vaporization and are, therefore, more suitable for use in the determination of reaction kinetics. Since ZrB_2 oxides stoichiometrically, oxygen consumption measurements can be converted directly to boride recession.

Berkowitz (1) has presented evidence from microstructural examination of the oxide layer formed in the neighborhood of a crack that intersected the surface, that the oxide must grow by the inward diffusion of oxygen. The original surface of the crack was replaced by the oxide, and there was no indication of the crack closing due to an outward diffusion from the boride. There are no known ternary compounds formed in the Zr-B-O system and B_2O_3 is the predominant species detected during the vaporization of boron oxide (6). The condensed oxide layer formed on ZrB_2 will consist of a mixture of both $B_2O_3(l)$ and $ZrO_2(s)$. If the temperature is high enough or the reaction time long enough, $B_2O_3(l)$ can vaporize as quickly as it is formed and the oxide layer will contain only ZrO_2.

The measurement of a linear vaporization rate for times less than 4 hr at temperatures between 800° and 1400°C indicates that liquid B_2O_3 is present under these conditions. Figures 4 and 5 show the relationship between the amount of oxygen consumed and the amount of vaporization. Because the oxygen consumption data show a decreasing time dependence and the vaporization is linear, the amount of $B_2O_3(l)$ in the scale is decreasing with time. Since the scale consists of a mixture of B_2O_3 and ZrO_2, it would be expected that the inward diffusion of oxygen would occur at a much faster rate through $B_2O_3(l)$ than through $ZrO_2(s)$. The length of the diffusion path for the inward diffusion of oxygen is, therefore, decreasing with time as the thickness of $B_2O_3(l)$ is reduced through vaporization. The reduction in the diffusion barrier would certainly be expected to increase the rate of recession and, therefore, truly parabolic recession behavior would not be expected.

When the oxygen consumption data are plotted as weight-gain squared *vs.* time, an increasing deviation from parabolic behavior is observed as the temperature is increased. Figure 6 shows these data from 1095° to 1400°C. At 1095°C and for temperatures less than 1095°C, a straight line is observed, indicating that the reaction rate is parabolic and limited by diffusion through a barrier layer which does not suffer significant vaporization. The data below 1095°C are not shown because of the relatively small magnitude when plotted on the scale used in Fig. 6. Above 1095°C, a positive curvature is observed and the curvature in-

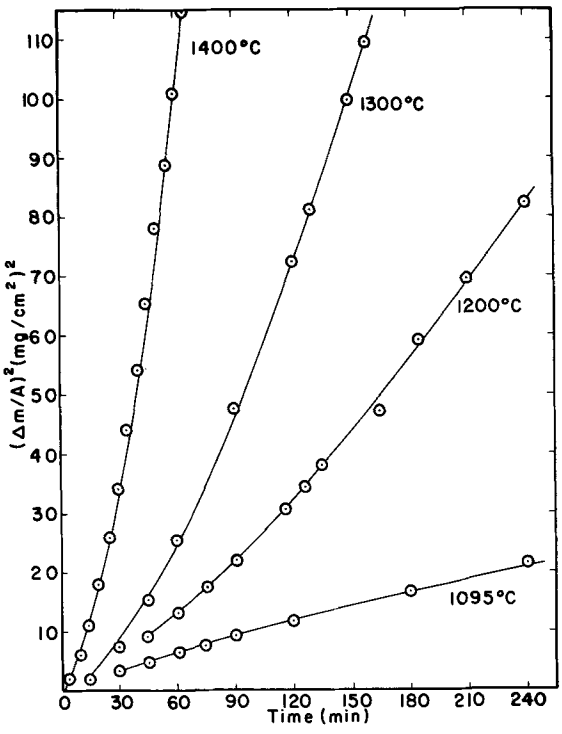

Fig. 6. Parabolic plot of the total oxygen consumption data, ZrB_2, 250 Torr O_2.

creases with increasing temperature. In this temperature range, the rate of oxygen consumption is faster than parabolic because of a decreasing thickness of the barrier layer caused by the evaporation of B_2O_3 (1).

The increase of the reaction rate with temperature can also be shown if it is assumed the oxygen consumption rate is dependent on time in the following manner

$$\left(\frac{\Delta n_{O_2}}{A}\right)^x = kt$$

Values of x are shown in Table I and clearly indicate that above 1100°C the scale is no longer an effective barrier for oxygen diffusion.

Previous investigators have interpreted their measurements of oxygen consumption and weight-change of ZrB_2 as a diffusion-controlled reaction obeying a parabolic rate equation. Although the measurements made in this study do not show a parabolic time dependence at temperatures above 1095°C, a comparison can be made between the results presented here and those of previous studies. An "apparent" parabolic rate constant was determined from a least-squares value of the slope when the oxygen consumption and weight-change data were plotted as in Fig. 6. These "forced" rate constants are shown on the Arrhenius plot in Fig. 7 together with the parabolic rates for oxygen consumption obtained by Berkowitz (1) and the parabolic rates for weight-change obtained by Kuriakose and Margrave (2). The close agreement of the data from the three separate studies indicates that equivalent measurements have been made on similar material. However, it must be emphasized that simple parabolic behavior is not the interpretation of the measurements presented here.

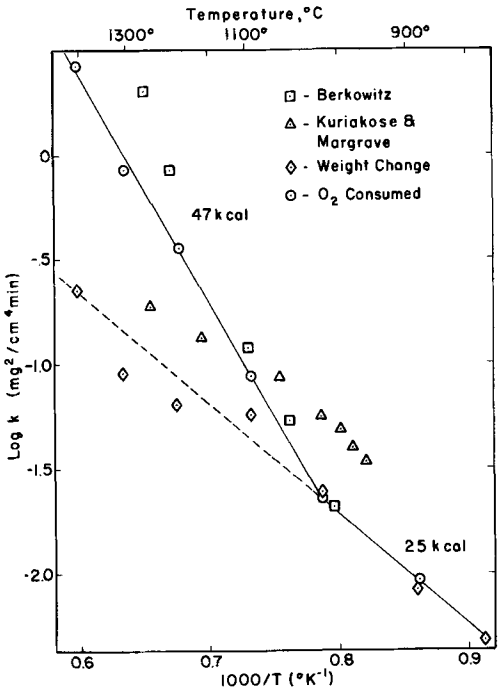

Fig. 7. Arrhenius plot of the parabolic rate constants, ZrB_2

The vaporization of B_2O_3 from the oxide layer influences the rate of oxygen consumption and is the reason for the deviation from parabolic kinetics. A paralinear-type equation having the form

$$\frac{\Delta n_{O_2}}{A} = at^{1/2} + bt \qquad [1]$$

is a better representation of the oxygen consumption data. If the linear rate constant for vaporization, b, is plotted as shown in Fig. 8, a slope can be calculated which will represent the temperature dependence of the vaporization. This can be combined with the temperature dependence of the weight-change, Fig. 7, and an equation can then be written to represent the total oxygen consumption. The following equation is found to represent the total oxygen consumption

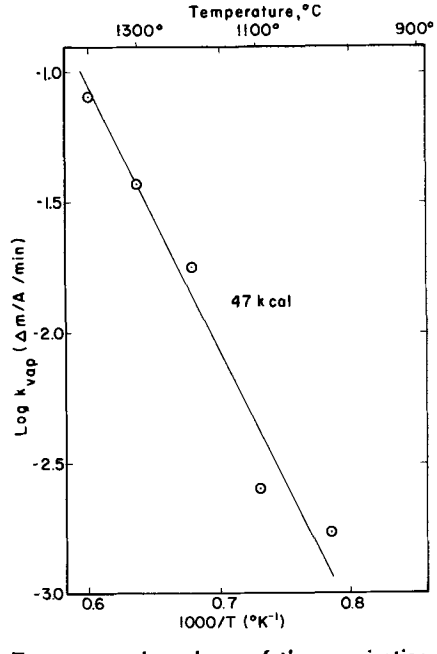

Fig. 8. Temperature dependence of the vaporization of B_2O_3 on oxidizing ZrB_2 at 250 Torr O_2.

$$\frac{\Delta m}{A}\left(\frac{\text{mg}}{\text{cm}^2}\right) = 17.65 \exp\left(\frac{-25{,}000}{2RT}\right) t^{1/2} + 9.15 \times 10^4 \exp\left(\frac{-47{,}000}{RT}\right)_t \quad [2]$$

or

$$\frac{\Delta n_{O_2}}{A}\left(\frac{\text{g moles } O_2}{\text{cm}^2}\right) = 5.41 \times 10^{-4} \exp\left(\frac{-25{,}000}{2RT}\right) t^{1/2} + 2.86 \exp\left(\frac{-47{,}000}{RT}\right) t \quad [3]$$

where T is the temperature in degrees Kelvin and t is the time (min). The first term on the right approximates the net sample weight-gain and is parabolic. The second term is derived from the vaporization data and is linear with time. Since stoichiometric oxidation occurs, recession rates can be calculated from this equation by assuming that 40% of the total oxygen consumed forms ZrO_2 and 60% forms B_2O_3. From these values, the amount of zirconium and boron consumed, and therefore the amount of ZrB_2, can be calculated

If 6 g/cm^3 is used for the density of ZrB_2, then the total oxygen consumed, as calculated from Eq. [2], can be multiplied by 2.3 x 10^{-4} to give the amount of boride recession

$$\delta(\text{cm}) = 4.06 \times 10^{-3} \exp\left(\frac{-25{,}000}{2RT}\right) t^{1/2} + 2.10 \times 10^1 \exp\left(\frac{-47{,}000}{RT}\right) t \quad [4]$$

It can also be seen from Eq. [3] that for sufficiently long times, the second term representing the constant vaporization rate will eventually exceed the rate of formation of $B_2O_3(l)$. Therefore, this equation can only be true over the temperature-time range where $B_2O_3(l)$ is present at the surface.

The heat of vaporization of B_2O_3 is about 90 kcal, whereas the vaporization energy measured in these oxidation experiments is only 47 kcal. Vaporization of liquid B_2O_3 would involve mass transport through a gas phase, thus there is no reason to expect the temperature dependence to be a measure of the heat of vaporization. However, a separate experiment was performed to measure the temperature dependence of the vaporization of B_2O_3 under these same experimental conditions. The energy measured was 50 ± 10 kcal, in very close agreement with the oxidation results.

Equation [2] for total oxygen consumption is plotted together with the experimental data in Fig. 9. The agreement can be seen to be quite reasonable. As can be noted, the data at 1100°C and below agree very closely. In this region, the parabolic term is the predominate term in the equation and the reaction rate is controlled by diffusion of oxygen through $B_2O_3(l)$. Excellent agreement is also observed at 1400°C where the linear term will predominate after short times. At this temperature, there will no longer be a protective barrier layer of $B_2O_3(l)$.

Summary

A system has been described that allows the thermogravimetric determination of total oxygen consumption, sample weight-change, and vaporization rate of a material that oxidizes with the formation of volatile products that are condensable at temperatures below the reaction temperatures.

This system has been used to study the oxidation of ZrB_2 at 250 Torr O_2 over the temperature range of 800°-1500°C. The volatile oxide formed is B_2O_3 which is a liquid above 450°C and vaporizes readily above 1100°C.

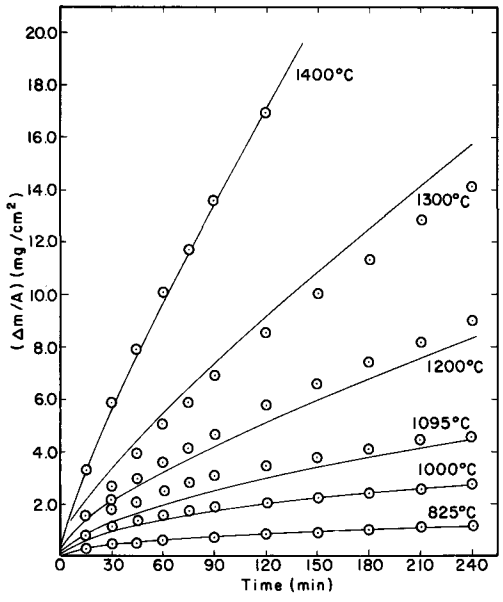

Fig. 9. Comparison between calculated and measured oxygen consumption values; solid line, calculated; circle, measured.

The vaporization of B_2O_3 influences the kinetics of the oxidation process. At temperatures below 1100°C measurements showed the vaporization to be negligible. The scale, composed of a mixture of $B_2O_3(l)$ and $ZrO_2(s)$, formed a barrier layer and the rate of oxygen consumption was controlled by diffusion through the $B_2O_3(l)$.

At higher temperatures the vaporization of $B_2O_3(l)$ became significant and the influence of this on the kinetics was clearly demonstrated by separate measurements of oxygen consumption, weight-change, and vaporization.

A paralinear equation was derived to describe the rate of oxygen consumption within the range of these measurements. Since ZrB_2 oxidizes stoichiometrically this equation can be converted into boride recession rates.

Acknowledgments

The authors wish to thank Mr. Joseph Henry for assistance with the thermogravimetric measurements; Professor Robert Rapp, Ohio State University, for his many helpful suggestions and discussions; and Mr. John Fenter, Air Force Materials Laboratory, for supplying the material. This work was performed at the Aerospace Research Laboratories under contract No. F33615-69-C-1017.

Gallium Nitride Films[1]

T. L. Chu*

Electronic Sciences Center, Southern Methodist University, Dallas, Texas 75222

ABSTRACT

The thermal decomposition of a gallium tribromide-ammonia complex in an ammonia, argon, or nitrogen atmosphere has been used for the deposition of gallium nitride films on silicon and hexagonal silicon carbide substrates in a gas flow system. The substrate temperature and the nature of the ambient are the most important parameters of the deposition process. Adherent and transparent films of gallium nitride have been deposited at substrate temperatures up to about 600°C in an ammonia atmosphere and up to about 750°C in a nitrogen or argon ambient. At higher temperatures, the deposit became contaminated with gallium. The gallium nitride films deposited on {111} oriented silicon substrates at 600°-700°C were found to show a (110) fiber orientation. Epitaxial, single crystalline gallium nitride films have been grown successfully on the basal plane of hexagonal silicon carbide substrates at 520°-600°C. These films are of high resistivity indicating that the thermal decomposition of gallium nitride is negligible. Thus, the thermal decomposition of the gallium tribromide-ammonia complex provides a new promising technique for the crystal growth of gallium nitride.

Gallium nitride, one of the less-known III-V compounds, has an energy gap of 3.2 eV at room temperature (1). Because of this relatively large energy gap, gallium nitride has potential applications for high-temperature devices and for visible-light opto-electronic devices.

Gallium nitride crystallizes in the wurzite structure with lattice parameters $a = 3.18$A and $c = 5.16$A (2). Polycrystalline gallium nitride has been reported to dissociate into its elements at temperatures above 600°C, and the rate of dissociation is decreased by the presence of nitrogen (3). This thermal instability suggests that lower temperatures are preferred for the preparation and crystal growth of gallium nitride. Gallium does not combine directly with nitrogen to yield gallium nitride. Various chemical techniques, such as the reaction of gallium oxide with ammonia (3) and the thermal decomposition of gallium trichloride-ammonia complex (4), have been used for the preparation of polycrystalline gallium nitride. Gallium nitride produced by the reaction of gallium oxide with ammonia in the temperature range 600°-1100°C varied from light yellow to gray in color, depending on temperature; the gray color produced at 1100°C was due to the formation of free gallium (3). Recently, the reaction between gallium monochloride and ammonia in a hydrogen atmosphere has been used for the epitaxial growth of gallium nitride on the basal plane of sapphire at 825°C (5). The room-temperature energy gap of the deposited material has been determined to be 3.39 eV from optical-absorption measurements. The undoped crystals, though colorless, have a very high inherent electron concentration, 1 to 5 x 10^{19} cm^{-3}, which was attributed to nitrogen vacancies due to the thermal dissociation of gallium nitride. Epitaxial gallium nitride films have also been deposited on the basal plane of sapphire and {111} faces of gallium arsenide at 550°C by the evaporation of gallium in a nitrogen discharge (6). Films prepared in this manner were low-resistivity n-type and had an absorption edge at about 3.4 eV.

In general, the group V nitrides can be prepared by the ammonolysis of their halides at high temperatures. Since the Ga-Br bond is of lower energy than the Ga-Cl bond, the formation of gallium nitride by the ammonolysis of gallium tribromide is expected to be more feasible than that of gallium trichloride. Due to the hygroscopic nature of gallium tribromide, it is more convenient to use a gallium tribromide-ammonia complex which is stable in the laboratory ambient. In this work, the thermal decomposition of a gallium tribromide-ammonia complex has been used for the deposition of gallium nitride on {111} oriented silicon and the basal plane of hexagonal silicon carbide substrates. This reaction can produce gallium nitride at temperatures considerably below those required for reactions used by previous authors (3-5) so that its thermal dissociation can be minimized. Hexagonal silicon carbide was chosen as a substrate because its basal-plane lattice parameter ($a = 3.08$A) is similar to that of gallium nitride. The deposition process and the properties of the deposited gallium nitride are discussed below.

Experimental

The decomposition of a gallium tribromide-ammonia complex in an ammonia, argon, or nitrogen atmosphere was used for the deposition of gallium nitride on {111} oriented silicon and the basal plane of hexagonal silicon carbide substrates. Gallium tribromide and anhydrous ammonia, each of better than 99.99% purity, were used for the preparation of the complex. Molten gallium tribromide was saturated with ammonia at about 150°C, and the resulting mass was distilled in an ammonia atmosphere to yield a white crystalline solid. Its composition, deduced from the analysis of its bromine and ammonia contents by conventional chemical analysis, corresponds to $GaBr_3:4NH_3$. The silicon substrates were in the form of slices with main faces of {111} orientation and were chemically polished with a nitric acid-hydrofluoric acid mixture before use. Hexagonal silicon carbide substrates were in the form of thin platelets, the main faces of which were parallel to the basal plane. They were heated in a sulfuric acid-nitric acid mixture followed by treating with hydrofluoric acid. To minimize contaminations, the rinsing and drying of the substrates were carried out in a laminar flow bench.

The apparatus used for the deposition of gallium nitride is shown schematically in Fig. 1. The reaction was carried out in a 25 mm ID fused silica tube. The gallium tribromide-ammonia complex was placed in a fused silica container in the reaction tube and was heated externally by a resistance heater. The substrates were supported on a gallium nitride-coated graphite susceptor in the reaction tube, and the susceptor was heated by an rf generator. Ammonia, nitrogen, argon, or hydrogen, at a flow rate of 2 liters/min, was used to carry the vapor of the gallium tribromide-ammonia complex to the substrate surface. The rate of vaporiza-

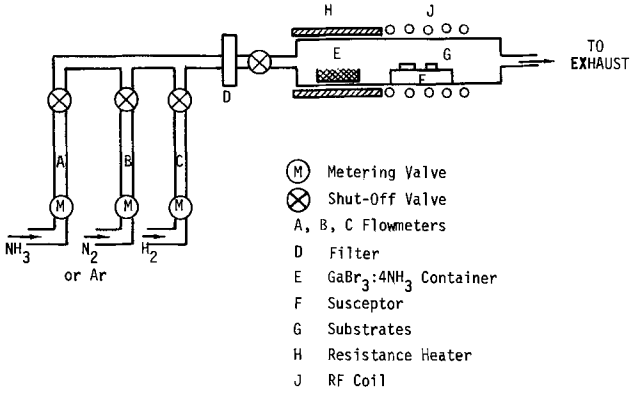

Fig. 1. Schematic diagram of the apparatus for the deposition of gallium nitride films by the pyrolysis of a gallium tribromide-ammonia complex.

tion of the complex was varied by adjusting its temperature, which was in the range of 200°-240°C.

The thickness of gallium nitride films deposited on silicon and silicon carbide substrates was measured directly on the angle-lapped surface with an optical microscope.

To measure the electrical properties of gallium nitride films, aluminum-gallium nitride-silicon structures were made from gallium nitride films deposited on 0.01 ohm-cm n-type silicon substrates by vacuum evaporation of aluminum through a metal mask. The aluminum electrode on the gallium nitride film was 1.3×10^{-2} cm^2 in area. The resulting structure was annealed in argon at about 400°C and mounted on a TO-5 header, and its d-c current voltage characteristics were measured from room temperature to about 500°C.

Results and Discussion

The deposition of gallium nitride by the decomposition of the gallium tribromide-ammonia complex was carried out in ammonia, argon, nitrogen, and hydrogen atmospheres at substrate temperatures in the range of 400°-900°C. Ammonia was used with the objective of preventing nitrogen deficiency in the deposit. Argon and nitrogen are chemically inert under the conditions used here and are expected to have similar effects on the deposition of gallium nitride. The nature of the carrier gas was found to have a pronounced effect on the deposition process. By using a carrier gas containing the gallium tribromide-ammonia complex at a flow rate of 2 liters/min, adherent and transparent films were deposited on silicon and silicon carbide substrates at 430°-600°C in an ammonia atmosphere and at 600°-750°C in a nitrogen or argon ambient. These deposits, after removing the silicon substrate with a hydrofluoric acid-nitric acid mixture, were identified as gallium nitride from their Debye-Scherrer patterns. As the substrate temperature was increased above the stated temperature limits, the deposit became gray and then black due to the formation of free gallium. Furthermore, no adherent deposits were obtained in a hydrogen atmosphere in the temperature range 400°-600°C. These results indicate the reactivity and instability of gallium nitride at high temperatures. The decomposition of gallium nitride in ammonia takes place at lower temperatures than that in argon. Since ammonia is thermodynamically unstable at temperatures above 500°K (7), it is likely that the hydrogen liberated from the thermal dissociation of ammonia has hindered the formation of gallium nitride. Similarly, gallium nitride cannot be formed in the presence of a large excess of hydrogen under the conditions used here. Thus, the thermal decomposition of the gallium tribromide-ammonia complex is quite different from the ammonolysis of gallium monochloride since clear gallium nitride has been deposited by the latter at temperatures as high as 825°C.

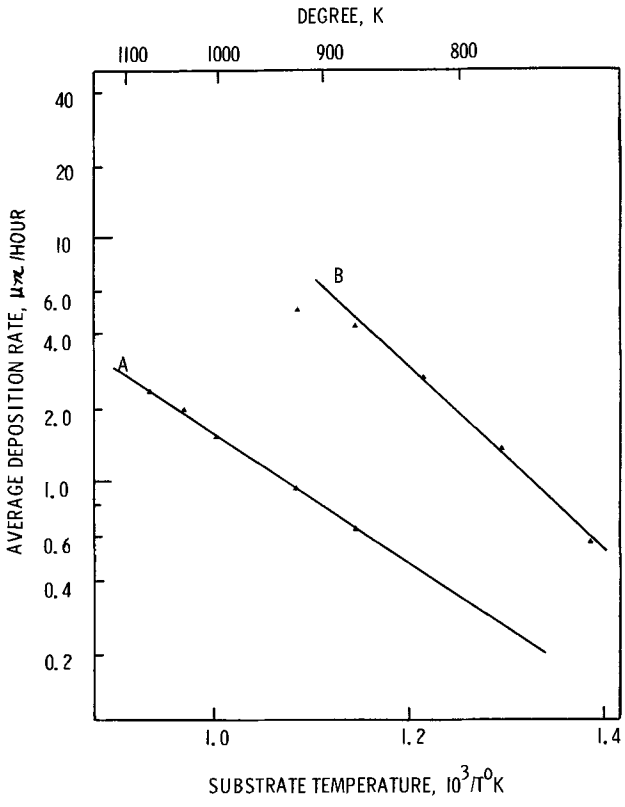

Fig. 2. Temperature dependence of deposition rate of gallium nitride on silicon substrates in argon (A) and ammonia (B) ambients.

This difference must be due to the widely different reaction kinetics.

The deposition of gallium nitride in ammonia and argon atmospheres was studied in more detail. Using the carrier gas at a flow rate of 2 liters/min, the temperature dependence of the deposition rate of gallium nitride on silicon substrates is shown in Fig. 2. It is noted that, at the same temperature, the deposition rate of gallium nitride in argon is considerably less than that in ammonia, as expected from the mass-action law. At 600°C, for example, the average deposition rates of gallium nitride in argon and ammonia are 0.65 and 4.3 μm/hr, respectively. The deposition rate in argon was negligible at temperatures below 500°C. Furthermore, the apparent activation energy of the deposition process is approximately 12.4 kcal/mole in the argon atmosphere in the temperature range 600°-800°C and is approximately 17.6 kcal/mole in the ammonia atmosphere in the temperature range 400°-600°C. This difference in activation energy is presumably related to the heat of adsorption of ammonia on the silicon surface.

Gallium nitride films deposited on silicon substrates in ammonia and argon atmospheres were highly adherent to the substrates; however, those deposited on silicon carbide substrates frequently cracked, particularly in films greater than 5 μm in thickness. This cracking is due to the large difference in thermal expansion coefficients of gallium nitride and silicon carbide. All gallium nitride deposits exhibited no structural features when examined with an optical microscope. They were examined by the reflection electron diffraction technique. Figure 3 shows the electron diffraction pattern of a gallium nitride film, approximately 2 μm thick, deposited on the basal plane of a hexagonal silicon carbide substrate at 530°C in an ammonia atmosphere. This pattern, obtained with the electron beam azimuth in a $<1\bar{1}0>$ direction, indicated that the grown film is single crystalline gallium nitride and is of parallel orientation with respect to the substrate, *i.e.* of {001} orientation. Figure 4 shows the elec-

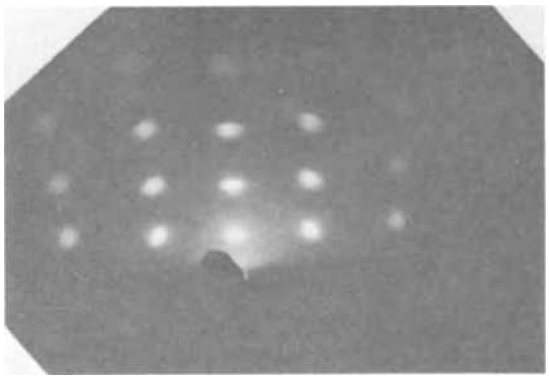

Fig. 3. Reflection electron diffraction pattern of a gallium nitride film deposited on a hexagonal silicon carbide substrate.

Fig. 4. Reflection electron diffraction pattern of a gallium nitride film deposited on a {111} oriented silicon substrate showing a (110) fiber orientation.

tron diffraction pattern of a gallium nitride film, approximately 5 μm thick, deposited on a {111} oriented silicon substrate at 700°C in a nitrogen atmosphere. This pattern indicated that the deposited gallium nitride showed a (110) fiber orientation. The lack of three dimensional epitaxial growth is apparently related to the large difference in lattice parameters of gallium nitride and silicon. The fiber structure was not observed when gallium nitride was deposited at lower temperatures.

The deposited gallium nitride films are relatively inert, insoluble in common acids at room temperature. For example, silicon substrates can be removed from gallium nitride-silicon structures by using a hydrofluoric acid-nitric acid mixture, leaving behind gallium nitride films. Gallium nitride dissolves slowly in aqueous solutions of sodium hydroxide. Figure 5 shows the dissolution rate of gallium nitride films, deposited in argon at 600° and 760°C and in ammonia at 450° and 550°C, in a 50% aqueous solution of sodium hydroxide in the temperature range 5°-90°C. The temperature of deposition has a very pronounced influence on the dissolution rate of gallium nitride films, as shown in Fig. 5. At a given temperature of the etchant, the dissolution rate increases rapidly with decreasing deposition temperature, due presumably to the higher density of the films deposited at higher temperatures. (The densities of gallium nitride deposited at 650° and 750°C are 5.7 and 6.1g cm^{-3}, respectively, as compared with a theoretical density of 6.1g cm^{-3}.) For a film deposited under a given set of conditions, the dissolution rate also increases with increasing dissolution temperature. The activation energy of this dissolution process is 18 $\pm$ 1 kcal/mole for all films studied.

The room-temperature, d-c current-voltage characteristics of an aluminum-gallium nitride-silicon structure, prepared from a gallium nitride film of 4 μm thickness deposited on a 0.01 ohm-cm n-type silicon substrate at 650°C in argon, are shown in Fig. 6. The

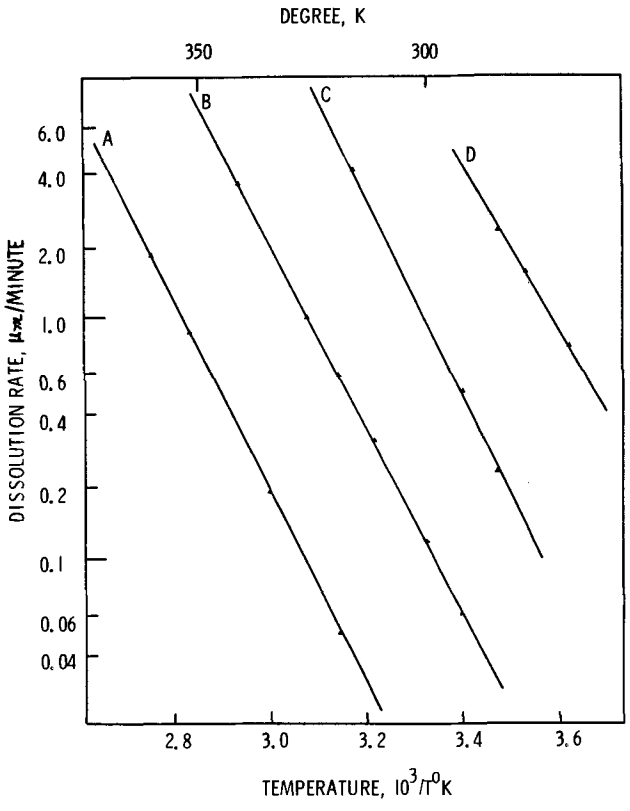

Fig. 5. Dissolution rate of gallium nitride films in a 50% aqueous solution of sodium hydroxide as a function of temperature. Gallium nitride was deposited in argon at 760°C (A) and 600°C (B) and in ammonia at 550°C (C) and 450°C (D).

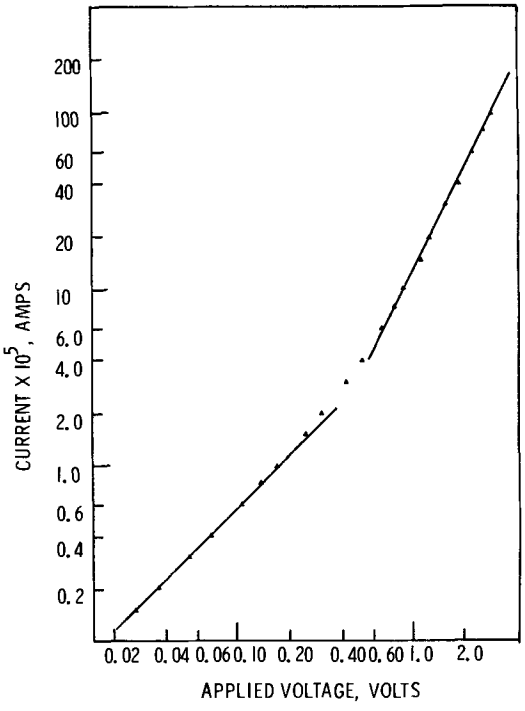

Fig. 6. Current-voltage characteristics of an aluminum-gallium nitride-silicon structure.

measured characteristics were essentially polarity independent, indicating the ohmic nature of the aluminum contacts. Two regions may be distinguished in the log I *vs.* log V plot. Ohmic behavior prevails at low bias levels, 500 V/cm or less, and the electrical resistivity of gallium nitride is approximately 10^6 ohm-cm. As the bias is increased, the slope of the log I *vs.* log V plot increases to two, indicating a space-charge-

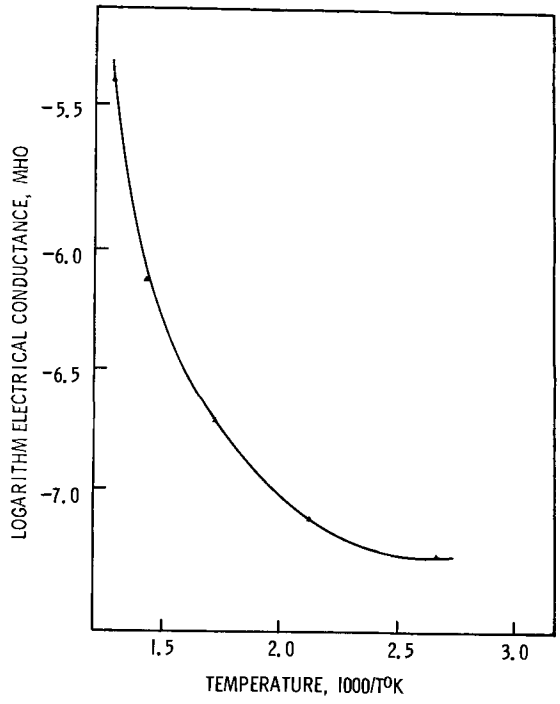

Fig. 7. Electrical conductance of an aluminum-gallium nitride-silicon structure as a function of temperature.

limited current situation. This is expected because of the high resistivity of gallium nitride. The current-voltage characteristics of the aluminum-gallium nitride-silicon structure were also measured in the temperature range 100°-500°C. The logarithm of the conductance is plotted *vs.* the reciprocal absolute temperature in Fig. 7, where a large variation of conductance with temperature is shown. The contact resistance is concluded to be insignificant as compared with the bulk resistance since the contact resistance is relatively insensitive to temperature. The activation energy deduced from the high-temperature region of Fig. 7 is approximately 1.1 eV, indicating the presence of a deep-lying impurity.

The gallium nitride films deposited on silicon carbide substrates were also of high resistivity at room temperature, similar to those deposited on the silicon substrates. Intrinsic gallium nitride is expected to be of high resistivity at room temperature because of its relatively large energy gap. On the other hand, the gallium nitride prepared by the ammonolysis of gallium monochloride at 825°C was n-type with a room-temperature resistivity of 0.001-0.005 ohm-cm (5). This low resistivity has been attributed to the nitrogen vacancies produced at the high temperature used in the deposition process. The low resistivity of the gallium nitride films deposited by the vacuum evaporation of gallium in a nitrogen discharge is presumably also associated with nitrogen vacancies. The high resistivity of gallium nitride achieved in this work indicates that the decomposition of the gallium nitride prepared from the gallum tribromide-ammonia complex is negligible compared with that prepared by other techniques. Thus, the thermal decomposition of the gallium tribromide-ammonia complex provides a new promising method for the crystal growth of gallium nitride.

Summary

The reaction between gallium tribromide and ammonia has been used for the preparation of a gallium tribromide-ammonia complex, $GaBr_3:4NH_3$. This complex is stable in laboratory ambient and decomposes at 450°C and above to yield gallium nitride. Gallium nitride films have been deposited on silicon and hexagonal silicon carbide substrates in this manner in an ammonia, argon, or nitrogen atmosphere. Adherent and transparent films have been deposited in ammonia atmospheres at temperatures up to 600°C and in argon or nitrogen atmospheres at temperatures up to 750°C. At higher substrate temperatures, the deposit became contaminated with gallium.

Gallium nitride is relatively inert at room temperature, insoluble in common acids, and dissolves slowly in aqueous alkalies. The gallium nitride films deposited on {111} oriented silicon substrates were found, by the electron diffraction technique, to have a (110) fiber orientation, and epitaxial, single crystalline gallium nitride films have been deposited on the basal plane of hexagonal silicon carbide substrates. Gallium nitride films were found to have high electrical resistivity at room temperature, indicating the negligible decomposition of the nitride. Thus, the thermal decomposition of the gallium tribromide-ammonia complex provides a new promising method for the crystal growth of gallium nitride.

Condensation Coefficients of Refractory Materials

I. AlN and BN

M. Hoch and D. Ramakrishnan

Department of Materials Science and Metallurgical Engineering, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

A method was developed for determining the condensation coefficient β of component B in reactions of the type

$$AnBm \rightarrow nA\,(g \text{ or } s) + \frac{m}{2} B_2(g)$$

β is measured by studying the rate of exchange of isotopically marked $B^*_2(g)$ on the surface of $AnBm$. For the method to be applicable, component B must be present as a dimer (or higher) in the gas. The condensation coefficients of AlN and BN were measured using this method, employing N^{15} nitrogen isotope. The condensation coefficients thus measured, $\beta = 5 \times 10^{-3}$ for AlN, and $\beta = 1 \times 10^{-2}$ for BN, compare favorably with values obtained by conventional methods where the kinetic pressure is compared with the equilibrium pressure.

The kinetics of vaporization of nitrides such as AlN and BN are of interest in the study of vaporization mechanisms. Metal nitrides decompose primarily to the elements. Current (1, 2) theories of the evaporation and condensation of solids postulate that evaporation and condensation are processes which involve several steps. The vaporization of metal nitrides include a slow step which results in a low vaporization coefficient α, the ratio of the rate of vaporization at the experimental conditions to the rate at the equilibrium conditions. α is generally determined by measuring the Langmuir pressure P_L, using the Langmuir free evaporation technique (3), and the equilibrium pressure P_{eq}, as obtained by the Knudsen effusion technique (4); α is then given by P_L/P_{eq}.

In the Knudsen effusion method under steady-state conditions, the rate of vaporization equals the rate of condensation plus the rate of effusion so that $\alpha C\, P_{eq} = \beta C\, P_{cell} + C\, P_{cell} \cdot h/S$ or

$$\alpha P_{eq} = P_{cell}\left(\beta + \frac{h}{S}\right) \qquad [1]$$

where β is the condensation coefficient, h/S is the ratio of the areas of the effusion hole and the vaporizing solid. In all work where only the weight loss is measured, it is usually assumed that $\alpha = \beta$. Thus

$$P_{eq} = P_{cell}\left(1 + \frac{h}{\alpha S}\right) \qquad [2]$$

It is possible in favorable cases to evaluate P_{eq} and β using Eq. [2] by measuring P_{cell} as a function of h/S. Hoch and White (5) as well as Hildenbrand and Hall (6) used Eq. [2] to evaluate α for AlN and BN by measuring P_{cell} as a function of h/S. However, it is feasible to measure β, the condensation coefficient, separately in a Knudsen experiment if, instead of the total effusion rate, the isotope exchange rate of the vaporizing species with the solid is measured. In the research reported here, an isotopic exchange technique has been developed to determine the condensation coefficients of AlN and BN.

Mathematical Treatment

The experimental set-up developed to study the isotopic exchange reactions between AlN^{14} and AlN^{15} is shown in Fig. 1. Pellets of AlN^{14} and AlN^{15} of equal size are placed in the Knudsen cell so that they do not make physical contact. On heating the cell to a high temperature, the two pellets vaporize independently:

Key words: aluminum nitride, boron nitride, condensation, isotope exchange, vaporization.

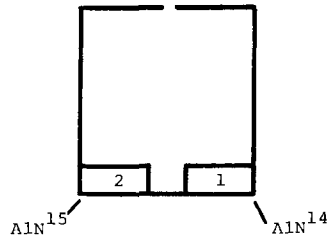

Fig. 1. Schematic arrangement of samples in Knudsen cell

pellet 1 reacts as $AlN^{14} \rightarrow Al(g) + \frac{1}{2} N_2^{14}(g)$, and pellet 2 as $AlN^{15} \rightarrow Al(g) + \frac{1}{2} N_2^{15}(g)$. Within a few microseconds, a steady-state pressure P_{cell} will build up in the cell. The gas in the cell will be composed of Al(g) and equal amounts of $N_2^{14}(g)$ and $N_2^{15}(g)$. The Al(g), however, does not enter into subsequent considerations so it will not be discussed further.

Inside the cell, exchange collisions of $N_2^{14}(g)$ with AlN^{15} pellet and $N_2^{15}(g)$ with AlN^{14} pellet will generate $N^{14}N^{15}(g)$ molecules. This will increase the $N^{14}N^{15}(g)$ concentration with time and decrease the $N_2^{14}(g)$ and $N_2^{15}(g)$ concentrations in the gas until a steady-state is reached, *i.e.*, the concentration of each species in the gas phase remains constant. A certain amount of gas will effuse from the hole of the Knudsen cell. $AlN^{14}(s)$ and $AlN^{15}(s)$ will vaporize to compensate the effusion loss. Exchange reactions between the gas molecules and the solid pellets will contaminate $AlN^{14}(s)$ by $AlN^{15}(s)$ and vice versa. This contamination will also increase with time. The increase in $N^{14}N^{15}(g)$ concentration in the gas will be followed by analyzing the effusion flow with a mass spectrometer. The contamination of the $AlN^{14}(s)$ by $AlN^{15}(s)$ will be determined by interrupting the exchange experiment, removing the $AlN^{15}(s)$ and vaporizing the original $AlN^{14}(s)$ pellet alone. The fraction of $AlN^{15}(s)$ in $AlN^{14}(s)$ can then be calculated from the composition of the gas.

It is assumed here that exchange between nitrogen molecules takes place only on the surface of the AlN pellets. This assumption is justified by work of Clusius (7) which showed that the exchange reaction

$$N_2^{14}(g) + N_2^{15}(g) \rightarrow 2N^{14}N^{15}(g) \qquad [3]$$

does not occur on platinum wires even at 1000°K. In fact, the reaction could be initiated only after the dissociation of nitrogen molecules to nitrogen atoms in discharge tubes. This suggests, though, that the exchange reaction could take place in the ion source of the mass spectrometer, but fragmentation of N_2 mole-

cules in the ion source is minimized by using a low ionizing electron energy.

At high temperatures where isotopic effects can be neglected and each atom or molecule has an equal probability to react, the equilibrium constant for Eq. [3] has a value of 4 (7, 8), that is

$$\frac{(N^{14}N^{15})}{(N_2{}^{14}\,N_2{}^{15})} = 4 \qquad [4]$$

Since only nitrogen molecules are present in the gas phase, the subscript (g) is omitted, and $N_2{}^{14}$ means $N_2{}^{14}(g)$. In the solid, only atoms are present, and hence, $N^{14}(s)$ means nitrogen bound in the solid AlN. Thus, if a vaporizing solid contains a fraction γ of N^{15}, and $(1-\gamma)$ of N^{14}, the concentration of the various species in the gas will be

$$(N^{14}N^{15}) = 2\alpha(1-\alpha);\ (N_2{}^{14}) = (1-\alpha)^2,$$

$$\text{and } (N_2{}^{15}) = \alpha^2$$

The reactions which contribute to the N^{15} enrichment of the AlN^{14} pellet (and vice versa) and to the build-up of $N^{14}N^{15}$ are as follows

$$N_2{}^{14} + N^{15}(s) \rightarrow N^{14}N^{15} + N^{14}(s) \qquad [5]$$

$$N_2{}^{15} + N^{14}(s) \rightarrow N^{14}N^{15} + N^{15}(s) \qquad [6]$$

$$N^{14}N^{15} + N^{14}(s) \nearrow N^{14}N^{15} + N^{14}(s) \qquad [7a]$$

$$\qquad\qquad\qquad\quad \searrow N_2{}^{14} + N^{15}(s) \qquad [7b]$$

$$N^{14}N^{15} + N^{15}(s) \nearrow N^{14}N^{15} + N^{15}(s) \qquad [8a]$$

$$\qquad\qquad\qquad\quad \searrow N_2{}^{15} + N^{14}(s) \qquad [8b]$$

Equations [7] and [8] have to be written in this split fashion: $N^{14}N^{15}$ has the same probability to react as $N_2{}^{14}$ but because it is asymmetric, it can react either way, each having the probability ½.

Enrichment of solid.—Let us consider the AlN^{14} pellet and assume that after a certain time, t, it contains a fraction γ of AlN^{15}. (Similar considerations apply to the AlN^{15} pellet.) The change of γ with time is then, from Eq. [5]-[8]

$$\frac{d\gamma}{dt} = k\,[(1-\gamma)(N_2{}^{15}) + \tfrac{1}{2}(1-\gamma)(N^{14}N^{15}) - (N_2{}^{14})\gamma - \tfrac{1}{2}\gamma(N^{14}N^{15})] \qquad [9]$$

In the gas phase

$$(N_2{}^{15}) + (N_2{}^{14}) + (N^{14}N^{15}) = 1 \qquad [10]$$

and

$$(N_2{}^{15}) = (N_2{}^{14}) \qquad [11]$$

thus

$$\frac{d\gamma}{dt} = k \cdot \left(\frac{1-2\gamma}{2}\right) \qquad [12]$$

This expression contains only the enrichment due to Eq. [5]-[8]. A certain amount of $N^{15}(s)$ is removed because the pellet is constantly vaporizing due to the gas effusing through the hole. Thus

$$\frac{d\gamma}{dt} = k \cdot \left(\frac{1-2\gamma}{2}\right) - k'\gamma \qquad [13]$$

where

$$k = \frac{F \cdot S/2 \cdot n_g}{n_o \cdot S/2 \cdot z}\beta \text{ and } k' = \frac{F \cdot S/2 \cdot n_g}{n_o \cdot S/2 \cdot y} \cdot \frac{h}{S} \qquad [13a]$$

$(F \cdot S/2 \cdot n_g)$ is the number of gas molecules hitting the surface per second. $(n_o \cdot S/2)$ is the total number of nitrogen atoms in a single layer.

The reaction between gas and solid will take place on a monolayer surface of the solid. Though diffusion of $N^{15}(s)$ from the monolayer is very slow, a certain amount will accumulate in the adjacent layers. This is taken into account by expanding the thickness of the reacting zone, z, expressed in atoms of nitrogen. Thus, $(n_o \cdot S/2 \cdot z)$ is the number of nitrogen atoms in the reaction layer. If diffusion is absent, the reacting zone is a monolayer and $z = 1$; if diffusion is extremely rapid and the composition of the whole solid uniform, z is large (but varies with time as the solid sample gets thinner due to vaporization). Similar considerations apply to the vaporization process. However, since all vaporization will take place from the surface (monolayer), $y \simeq 1$.

β is defined as the efficiency of a gas molecule collision with the surface and thus is identical to the condensation coefficient.

Equation [13] can be rewritten

$$\frac{d\gamma}{dt} = A \cdot \frac{\beta}{z}\left(\frac{1-2\gamma}{2}\right) - A \cdot \frac{h}{yS}\gamma \qquad [13b]$$

Both Eq. [13] and [13b] express the rate of N^{15} increase in the AlN^{14} pellet as a function of the condensation coefficient β. Assuming constant z and y, Eq. [13b] can be integrated, with the boundary conditions of $\gamma = 0$ at $t = 0$

$$\gamma = \frac{1}{2}\,\frac{1 - e^{-\left(\frac{\beta}{z} + \frac{h}{yS}\right)At}}{1 + \frac{z}{y} \cdot \frac{h}{\beta \cdot S}} \qquad [14]$$

Change of composition of gas.—Let us now calculate the change in $N^{14}N^{15}$ concentration of the gas. Consider the reaction on the AlN^{14} pellet which again contains γ AlN^{15} after at time t.

From Eq. [5]-[8]

$$\frac{d(N^{14}N^{15})}{dt} = k''\,[(N_2{}^{14})\gamma + (N_2{}^{15})(1-\gamma) - \tfrac{1}{2}(N^{14}N^{15})(1-\gamma) - \tfrac{1}{2}(N^{14}N^{15})\gamma] \qquad [15]$$

combining [15] with Eq. [10] and [11]

$$\frac{d(N^{14}N^{15})}{dt} = k''\left[\frac{1 - 2(N^{14}N^{15})}{2}\right] \qquad [16]$$

where $k'' = F \cdot (S/2)/V \cdot \beta$ and $F \cdot (S/2)/V$ is the number of times a molecule hits the surface per second.

An equation similar to [16] applies to the AlN^{15} pellet; thus the total will be

$$\frac{d(N^{14}N^{15})}{dt} = \frac{F \cdot S}{V}\beta\left[\frac{1 - 2(N^{14}N^{15})}{2}\right] \qquad [17]$$

Equation [17] takes into consideration only the change in concentration of $(N^{14}N^{15})$ due to reaction of the gas with the pellet. A certain amount of $(N^{14}N^{15})$ is lost by effusion through the hole, and a certain amount gained by vaporization of the pellet to replace the effused gas. Taking these facts into account, the final equation becomes

$$\frac{d(N^{14}N^{15})}{dt} = \frac{F \cdot S}{V}\beta\left[\frac{1 - 2(N^{14}N^{15})}{2}\right] - \frac{F \cdot h}{V}[(N^{14}N^{15}) - 2\gamma(1-\gamma)] \qquad [18]$$

with $F \cdot h/V$ $(N^{14}N^{15})$ the $(N^{14}N^{15})$ lost due to effusion, and $F \cdot h/V$ $2\gamma(1-\gamma)$ the amount gained by vaporization of the solid. γ can be obtained from Eq. [14].

1. At the beginning of an experiment when γ and the $N^{14}N^{15}$ concentration in the gas are small, $[(N^{14}N^{15}) - 2\gamma(1-\gamma)] \simeq 0$, and the integration of Eq. [18] results in

$$\ln[1 - 2(N^{14}N^{15})] = -\frac{F \cdot S}{V}\beta t \qquad [19]$$

Equation [19] thus expresses the initial increase of the $(N^{14}N^{15})$ content of the gas as a function of β.

2. After a period of time, the system reaches steady state both in the solid and gas phases, which means

$$\frac{d\gamma}{dt} = \frac{d(N^{14}N^{15})}{dt} = 0$$

Under those conditions, Eq. [13b] can be rearranged to give

$$\gamma = \frac{1}{\beta + \left(\frac{z}{y} \cdot \frac{h}{S}\right)} \cdot \frac{\beta}{2} \qquad [20]$$

Equation [18] under the same conditions becomes

$$\frac{d(N^{14}N^{15})}{dt} = \frac{F \cdot S}{V}\beta\left(\frac{1 - 2N^{14}N^{15}}{2}\right) - \frac{F \cdot h}{V}[(N^{14}N^{15}) - 2\gamma(1-\gamma)] = 0 \qquad [21]$$

Introducing Eq. [20] and rearranging we get

$$(N^{14}N^{15})\left[\frac{S\beta}{h} + 1\right] = \frac{S\beta}{2h} + \frac{\beta\left(\frac{\beta}{2} + \frac{zh}{yS}\right)}{\left(\beta + \frac{zh}{yS}\right)^2} \qquad [22]$$

Given the steady-state value of $(N^{14}N^{15})$, and the quantities S, h, and z/y (which are fixed), β can be evaluated numerically. Two limiting cases can be formulated more simply

1. If $z/y \cdot h/S >> \beta$, then

$$\beta = \frac{h}{S}\frac{(N^{14}N^{15})}{\left[\frac{1}{2} - (N^{14}N^{15}) + \frac{y}{z}\right]} \qquad [23]$$

The limits on y/z are $0 < y/z < 1$.

2. If $z/y \cdot h/S << \beta$, the solution gives $(N^{14}N^{15}) = \frac{1}{2}$. Thus if the condensation coefficient is high, equilibrium will be attained in the Knudsen cell.

Now Eq. [18] predicts that the mass spectrum as a function of time should appear schematically as in Fig. 2. In that figure, N_2 indicates the sum of the intensity of the 28, 29, and 30 peaks (corresponding to the total amount of N_2), Al corresponds to the peak of aluminum, and R corresponds to the concentration of the $N^{14}N^{15}$) molecule; thus, $R = I_{29}/N_2$. The Al and N_2 are given on the ordinate scale in arbitrary intensity units whereas R is given as a fraction. When starting with AlN^{15} and AlN^{14} at constant temperature, N_2 and Al do not change with time whereas R should increase from 0 to the steady-state value given by Eq. [18]. While R is small (near $t = 0$) Eq. [19] indicates that it increases linearly with t. When the steady-state value of R is reached, Eq. [22] and [23] specify its magnitude.

If, after a certain time, t, the sample is cooled to room temperature so that no vaporization takes place and the gas in the Knudsen cell is pumped out, then N_2 and Al will become zero. On retreating the system to the same temperature as before, N_2 and Al will again quickly reach constant value while R will rise from a value close to zero toward its steady-state value. The second starting point for R is not zero because the samples now are each somewhat contaminated. If a change in temperature occurs during the run, then N_2 and Al should increase or decrease together.

It should be clear that the equations derived above for AlN, must also apply to BN, NiO, and any other compound which decomposes according to the reaction

$$AnBm \rightarrow nA(g \text{ or } s) + \frac{m}{2}B_2(g)$$

Equation [19] then indicates that R will start as a small number and increase rapidly to its steady-state value. However, this predicted rapid rise was not observed experimentally for AlN and BN. All the exchange runs of AlN and BN made with fresh samples showed a gradual rise of R with time. On reheating the same set of pellets next day, though, R rose rapidly to the steady-state value.

The condensation coefficients of AlN and BN were calculated using Eq. [23] with z as a parameter. The reported values of β are those where z is large and $y/z \simeq 0$ in Eq. [23].

Materials

AlN.—Several methods (9-13) of preparation of AlN are known. AlN^{14} samples used in this work were prepared by reacting about 100-500 ml of high purity NH_3 gas with about 400 mg of aluminum metal at 1400°K. Aluminum wire of 99.99% purity was supplied by Alcoa (No. Cl-44311-C). AlN^{15} samples were prepared in the same way using $N^{15}H_3$ obtained from Bio-Rad Laboratories, Richmond, California. Two purity levels of N^{15} (97.8 and 99.3%) were used. The description of the apparatus and the details of the method of preparation is given elsewhere (14). The AlN^{14} and AlN^{15}

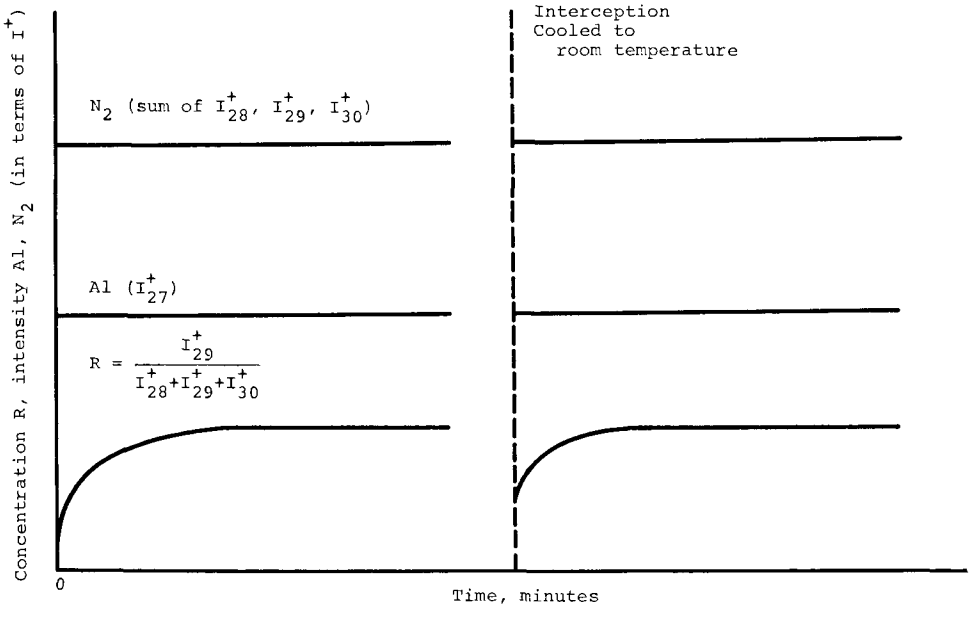

Fig. 2. Expected change $(N^{14}N^{15})$ concentration (R) with time.

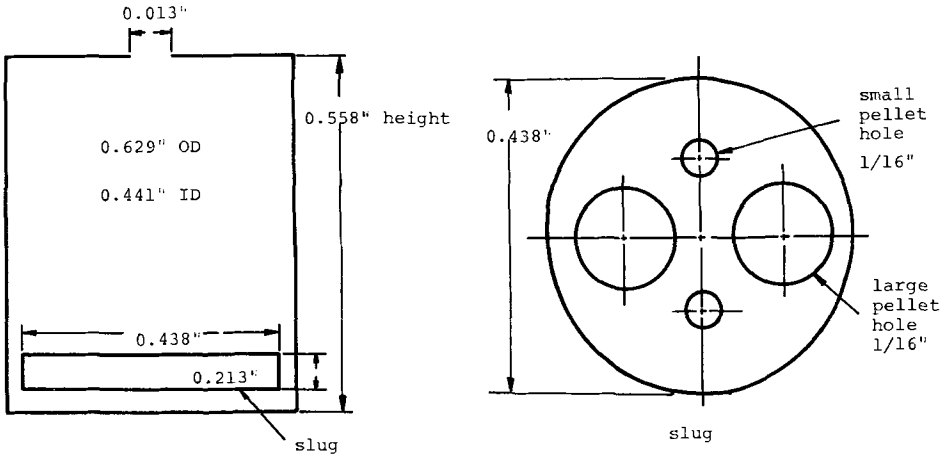

Fig. 3. Knudsen cell and tungsten slug assembly (schematic).

samples were purified by heating in chlorine atmosphere (15) at 1000°K for 90 min to remove any unreacted Al as $AlCl_3$. X-ray diffraction studies showed only the sharp lines of recrystallized AlN. The purified powder was pressed into 3/16 in. diameter pellets and degassed in vacuum at 1800°K for 60 min.

BN.—A general survey of the known methods of preparation of BN is given by Giardini (16). Attempts to react elemental boron with NH_3 or N_2 gave poor yields. BN^{14} and BN^{15} samples for this work were prepared by forming the addition product $BCl_3 \cdot NH_3$ using 99.9% pure BCl_3 and its subsequent decomposition to BN and other decomposition products. The details are given elsewhere (14). A fluffy white solid was obtained after decomposition. The white product was first heated to 1400°K in argon to remove the volatile impurities. The residue was then boiled in dilute HCl, washed with distilled water, and dried. To recrystallize the product, the powder was passed into 3/16 in. diameter pellets and heated in vacuum at 1900°K for 3 hr first and for 2 hr subsequently. The first heating resulted in 40% weight loss. The weight loss was about 2% after the second heating. An x-ray diffraction pattern showed the sharp lines of hexagonal BN.

Knudsen cells.—A tungsten Knudsen cell fitted with a tungsten slug was used to study the exchange reactions of AlN samples. The dimensions of the cell and the slug are shown in Fig. 3. The slug contained four holes, two of 3/16 in. diameter, and two of 1/16 in. diameter. The degassed AlN^{14} and AlN^{15} pellets were either introduced into the large holes or introduced into the small holes. In this manner, the surface area S of the evaporating surface could be varied, keeping the other properties of the cell constant. Some runs were made without using the slug. In that case, each pellet was cut into half and the two half pellets were placed in the bottom of the cell facing each other's cut edges. One drawback in this arrangement is that the area S is not well defined.

The exchange reactions between BN^{14} and BN^{15} were studied in a graphite cell fitted with a graphite slug. The dimensions of the cell and slug were essentially identical to the dimensions of the tungsten cell assembly except that the graphite cell had a 0.025 in. diameter hole in the lid.

Experimental Procedure and Results

AlN.—The exchange runs were made by heating the AlN^{14} and AlN^{15} placed in the tungsten Knudsen cell. The cell was heated by electron bombardment in the Bendix (Model 12) Time-of-Flight mass spectrometer. The temperature was measured by a L&N disappearing filament optical pyrometer sighted through a prism and a window on the black-body hole of the cell. The pyrometer readings were corrected for the window and prism absorptions. To reduce the background interference at mass 28 corresponding to the N_2^{14} ion, the mass spectrometer was baked for several days. The mass spectrometer was also fitted with an extended flight tube to improve its resolution. Fragmentation and recombination of nitrogen molecules in the ion source was minimized by operating the mass spectrometer with only 20V electron energy.

In a typical exchange run, the cell with the pellets was heated gradually in the mass spectrometer to the operating temperature. When a fresh sample was introduced into the Knudsen cell, it took approximately 3 hr to reach this temperature due to outgassing of the samples. After reaching the temperature of the run, the intensities of signals (I_{27}, I_{28}, I_{29}, and I_{30}) corresponding to Al, N_2^{14}, $N^{14}N^{15}$, and N_2^{15} ions were recorded at 15-min intervals. All runs made with a fresh pair of sample pellets are designated as "a." The subsequent runs made with the same pellets are designated as b, c, d, etc.

The data on run 17 shown in Fig. 4a and 4b are representative of the exchange runs made without using the tungsten slug. At the beginning of run 17a, the temperature was high (1840°K) and then dropped to the steady-state values (1818°K). This is shown by the parallel variation of Al and N_2 intensities. It can be seen that $R = \dfrac{I_{29}}{I_{28} + I_{29} + I_{30}}$ rises very slowly from 0.1 to the steady-state value of 0.4. This was characteristic of all "a" runs, suggesting some difficulty in the reactivity of the material.

The run was continued the next day (run 17b). The temperature was fairly constant at 1819°K in run 17b as indicated by the constant N_2 and Al intensities. R started at 0.25 and rose as expected to 0.4 again. In contrast to run 17a, only 15 min was required to reach the temperature in run 17b. After run 17b, the cell was opened. The contamination of the half-pellet of AlN^{15} by N^{14} was determined by vaporizing it separately at 1819°K in run 17c. The concentration of N^{14} in AlN^{15} pellet was calculated from the ratio (17) of intensities of mass 29 and mass 30 peaks. Similarly, the N^{15} concentration in AlN^{14} was calculated from the ratio of mass 29 and mass 28 peak intensities by vaporizing AlN^{14} half pellet in run 17d. These results are shown in Fig. 5. At the start, both half-pellets show a large amount of contamination, but it decreases with time as the top layers are eliminated by the vaporization of the sample pellets. Only after a substantial amount of time had elapsed were the contaminated layers completely removed, indicating that for this configuration $z = 1$.

Run 22, an extremely long run using the large holes of the slug, was made at 1808°K. The results show the same characteristics as run 17, *i.e.*, a fairly slow buildup of R at the beginning, culminating in a steady-state value of 0.33. Results of exchange run 29 made with samples in the small holes of the slug were unsatisfactory, because it was very difficult to obtain constant N_2 and Al intensities.

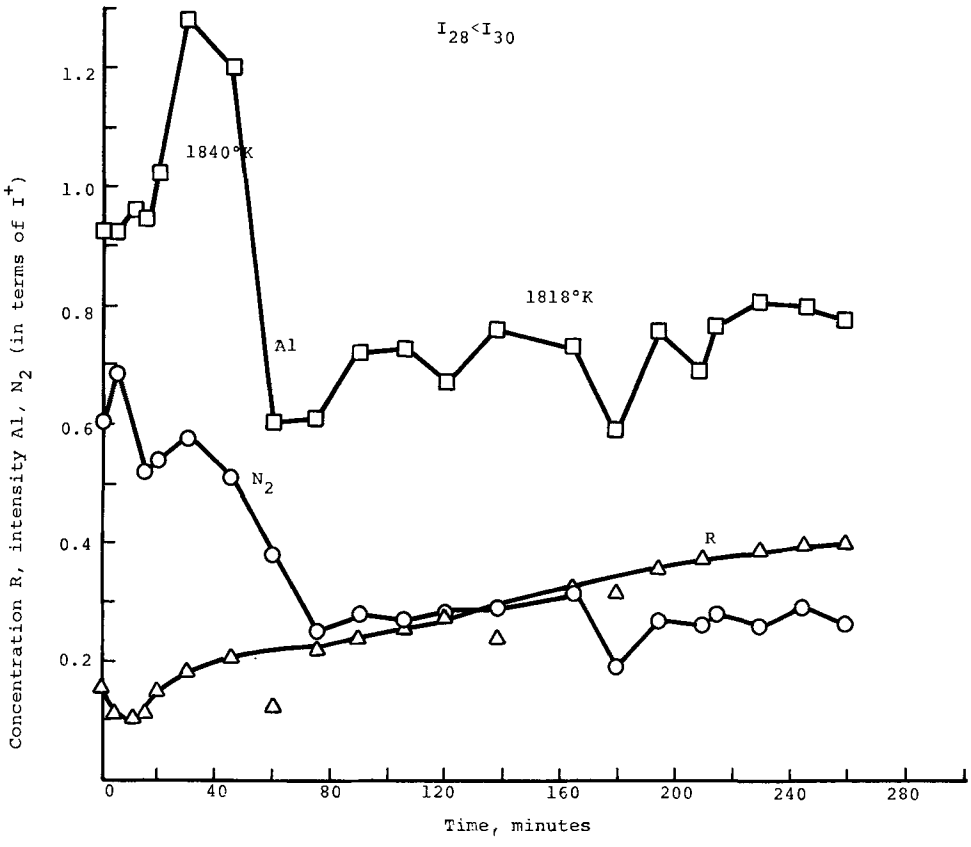

Fig. 4a. Run 17a. AlN^{14}, AlN^{15} half pellets, no tungsten slug.

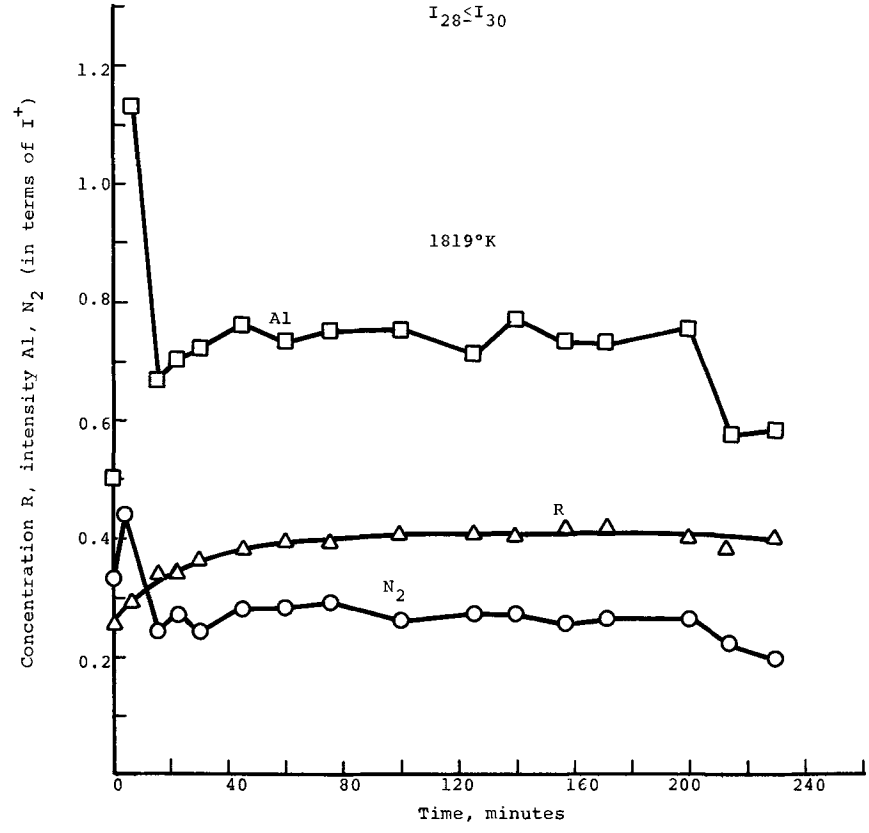

Fig. 4b. Run 17b. AlN^{14} half pellets, no tungsten slug.

In one of the runs made with sample pellets in large holes, the Knudsen cell was exposed to air (after interrupting the run) in order to study the effect of absorbed nitrogen on the exchange reaction. No great influence was observed. To study the effect of free aluminum at the beginning of the exchange reaction, a piece of aluminum was put into both holes at the end of an exchange run. When the cell was reheated, the aluminum vaporized but no effect on the steady-state value of R was detected.

The temperature variation of R was studied in run 35. The data is shown in Fig. 6, run 35e. As before, R increased from a small value to the steady-state value of 0.34. When the temperature was raised or lowered, Al and N_2 increased and decreased together while R remained practically constant.

Finally, an equimolar mixture of AlN^{14} and AlN^{15} was prepared. The powder containing AlN^{14} and AlN^{15} was pressed into two pellets. Exchange run 36 was made after placing the two pellets in the large holes of

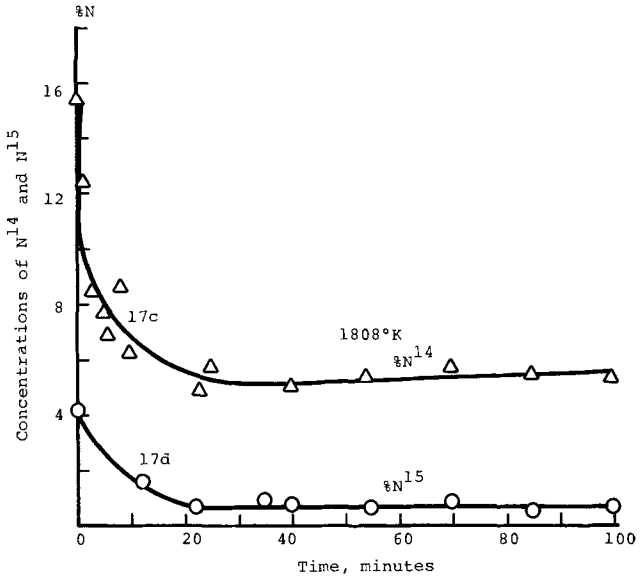

Fig. 5. Runs 17c and 17d. Separate pellets (AlN^{14} and AlN^{15}) to determine contamination.

the tungsten slug. At this moment, a "mixed crystal" is not present. A mixed crystal is defined as a material where within each grain N^{14} and N^{15} (present in equal amounts) are distributed at random. Vaporization of such a sample would yield a value of $R = 0.5$ irrespective of β value because both pellets are equal: no gas exchange between the two pellets is required to buildup ($N^{14}N^{15}$). In the present experiment, however, each pellet contained separate grains of AlN^{14} and AlN^{15}; therefore, at the start of the run, the system was not different from the one with separate pellets. During the experiment, however, diffusion between the two types of grains and sintering should take place in the pellets so that the material progressively approaches the status of a mixed crystal. Thus, experimentally, R should first reach a steady-state value and then increase slowly due to interdiffusion between the grains. Run 36a confirmed these expectations. R reached a steady-state value of 0.34, but on repeated heatings in runs 36b, 36c, and 36d, it increased linearly with time to a maximum value of 0.46.

Equation [23] could be used to calculate β, the condensation coefficient. In that calculation, it is assumed that $y = 1$ (only the top surface vaporizes), whereas z is assumed to vary with $S/2$. The rate of diffusion of nitrogen in the pellet is fixed; but the rate of surface recession of the pellet due to vaporization depends on its surface area. For a large surface area, the rate of vaporization per unit area will be small, the rate of recession of the surface will be small; thus a large amount of diffusion will take place resulting in large z. A small surface area, on the other hand, will recede faster. Hence, before a large amount of diffusion can take place, the material vaporizes. In this case, z will be small. In either case, y/z is the significant parameter in the calculation of β using Eq. [23].

Table I summarizes our results. For the "no slug" configuration and the runs where the sample was placed in the 3/16 in. holes, z is large, so $y/z \simeq 0$. For the small holes configuration, where $S/2$ is only 1/20 of its value when no slug is used, z will be nearly 1. Thus, $y/z \simeq 1$. Using these approximations, the calculations give an average value of $\beta = 5 \times 10^{-3}$ for the temperature range of 1800°-1900°K where the measurements were carried out.

BN.—Preheated BN^{14} and BN^{15} pellets were loaded into the large holes of the tungsten slug and the exchange run[51] was made at 1952°K using the tungsten Knudsen cell. In this run, R started from an unusually large value of 0.37, rose to 0.45 within 60 min and remained constant. At the end of the run, examination of the pellets and the cell revealed evidence of chemical reaction between the samples and tungsten metal. The pellet had shrunk in size and the tungsten slug was welded to the body of the cell. Therefore, subsequent exchange runs were made with a graphite Knudsen cell and a graphite slug containing two 3/16 in. diameter holes.

The empty graphite cell assembly was degassed in vacuum at 2100°K for several hours. Later, in order to

estimate the contribution of CO contamination to the mass 28 readings, the cell was heated in the mass spectrometer to 1963°K. The measured background at the intensity mass 28 peak, was as expected, much higher than with the tungsten cell.

With this in mind, exchange run 52a was carried out at 2112°K and run 52b at 2050°K. In each case, 4-5 hr of preheating was needed to reach the operating temperature. In run 52a, R rose rapidly from an initial value of 0.09 to a steady-state value of 0.23 which remained constant in the two subsequent runs. At the end of run 52c, the cell was opened and the contamination of BN^{14} and BN^{15} by the other isotope species was determined by heating each pellet separately in the mass spectrometer. The results, which resembled those obtained for the AlN pellets, are shown in Fig. 7.

In all the runs, however, the intensity of the peak at mass 28 was much larger than the peak intensity of mass 30. That deviation from predicted behavior seems to be due to the evolution of CO from the graphite cell. This was inferred from the fact that at 70V electron energy, two intense peaks at mass 14 and 15 were observed in the spectrum, with $I_{15} > I_{14}$. In contrast, if the intensity of the mass 28 peak in run 52 was entirely due to N_2^{14} ions, then $I_{15} < I_{14}$. Moreover, the calculated ionization efficiency curves for mass 28 and mass 30 peaks were not identical as they should be if only N^{14} and N^{15} ions were involved.

To minimize this background interference, the empty graphite cell assembly was reheated in vacuum to 2300°K for 4 hr. Runs 53a and 53b were then made with a fresh pair of BN^{14} and BN^{15} pellets. In run 53a (1963°K), R rose from 0.03 to 0.14. At the beginning, $I_{28} > I_{30}$; but after 135 min, I_{28} became nearly equal to I_{30}. In run 53b the temperature was raised to 2018°K; the value of R rose to 0.21 and remained constant, but I_{28} stayed larger than I_{30}.

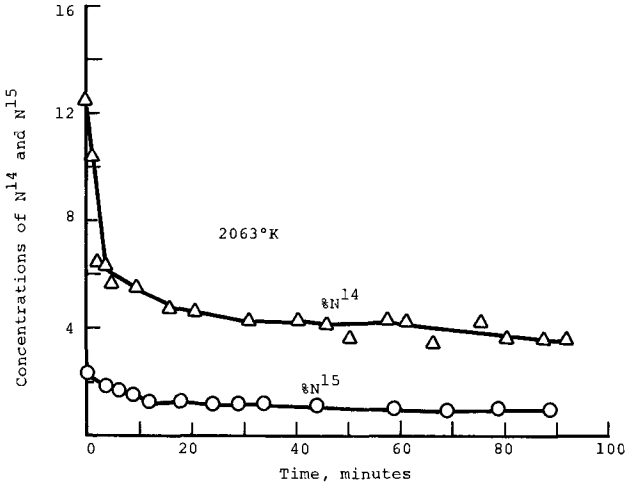

Fig. 7. Runs 52d and 52e. Separate pellets (BN^{14} and BN^{15}) to determine contamination.

To correct for the background contribution to the 28 peak, R was calculated assuming $I_{28} \simeq I_{30}$. Thus, $R = I_{29}/(I_{29} + 2I_{30})$. The steady-state value calculated on this assumption was 0.27. The condensation coefficient β of BN was calculated using Eq. [23], and the results are given in Table I.

Comparison of data from runs 52a, 52b, and 52c with that from runs 53a and 53b indicates that the steady state is reached much more rapidly when the run is made at a higher temperature. The steady-state value of R, however, is not influenced by temperature. At the end of run 53b, the temperature was decreased from 2018° to 1952°K; and though the intensity of N_2 peaks decreased correspondingly, R remained nearly constant.

Discussion

The condensation coefficient of $N_2(g)$ on AlN determined by this work ($\beta = 5 \times 10^{-3}$) is in good agreement with earlier work of Hoch and White (5), Hildenbrand and Hall (6), and Dreger *et al.* (18) which is summarized in Table II. The condensation coefficient of Al cannot be determined by the isotopic exchange technique because Al(g) exists as a monomer.

It is well established (5, 6) that AlN vaporizes congruently evolving Al(g) and $N_2(g)$ in stoichiometric ratio. One might expect, however, different values for the condensation coefficients of Al(g) and $N_2(g)$ on an AlN surface. On the other hand, Dreger, Dadape, and Margrave (18) found by x-ray studies that the lattice constant of AlN did not change during evaporation. Therefore, a large difference in the two condensation coefficients may not be present, and the value of β for $N_2(g)$ on AlN may be a good approximation for the β of Al(g) on AlN. The condensation coefficient of N_2 on BN determined by this work and the values of the vaporization coefficients determined by earlier workers are summarized in Table II.

In the BN vaporization-condensation equilibrium, a layer of amorphous boron forms on the BN surface. However, Knudsen effusion studies on BN by Hoch and White (5), as well as Hildenbrand and Hall (6), established that this boron layer did not block the subsequent escape of nitrogen molecules during vaporization of AN. Moreover, in the present work, the total intensity of all the nitrogen peaks in the exchange runs remained nearly constant with time even though the thickness of boron layer over BN was increasing with time. These observations are in contradiction with the work of Dreger *et al.* (18) who found that in Lang-

muir evaporation of BN, the rate of weight loss decreased as a function of time until it approached a constant rate determined by the vapor pressure of boron.

The formation of a boron layer on BN, thus raises the question of where the exchange reaction takes place. There are two possibilities: (*i*) on the boron layer, or (*ii*) on the BN. If the exchange reaction is taking place on the boron layer, then the value of R should increase continuously with time because the boron surface area increases as the BN sample is progressively decomposed. In these experiments, though, R was found to be constant with time after reaching a steady-state value. The contamination of the BN^{14} pellet by N^{15} and vice versa (shown in Fig. 7) also supports the conclusion that the exchange reaction takes place not on the boron surface layer, but on the boron nitride.

Condensation Coefficients of Refractory Materials

II. NiO

D. Ramakrishnan and M. Hoch

Department of Materials Science and Metallurgical Engineering, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

The condensation coefficient of oxygen in NiO was studied using the isotope exchange technique applied earlier for aluminum nitride and boron nitride. Experiments were carried out in a platinum Knudsen cell and in an aluminum oxide Knudsen cell. Using the aluminum oxide Knudsen cell, the condensation coefficient β for NiO was found to be 1.1×10^{-1} in the temperature range 1700°-1750°K. Using the platinum Knudsen cell, the exchange coefficient reached an equilibrium value of 0.5 because oxygen exchange also took place on the hot platinum surface. It was found also that NiO exchanges with oxygen in the air very slowly at room temperature.

The isotopic exchange technique in combination with the time-of-flight mass spectrometer has been used to determine the condensation coefficients of AlN and BN (1, 2). The purpose of these experiments was to determine whether the method of isotopic exchange devised for nitrides works with oxygen on NiO. The problem was to determine the condensation coefficient of oxygen on NiO. A large number of diffusion experiments are reported in the literature where the oxygen exchange is used to determine the diffusion coefficient of oxygen in metal oxides. The diffusion of oxygen in an oxide of a metal is expected to be a two-step process (3): (*i*) oxygen exchange on the surface, and (*ii*) migration of oxygen into the solid. Experimenters have assumed that the first step takes place faster than the second and that instantaneous equilibrium exists at the solid-gas interface (isotopic composition of oxygen in surface is equal to that in the gas). This assumption will be tested by applying the isotopic exchange technique to nickel oxide. The vaporization of nickel oxide has been the subject of several investigations (4-7). The most recent work is that of Grimley, Burns, and Inghram (8). They used a molybdenum Knudsen cell with an inner liner and lid made of recrystallized morganite alumina. The effusing beam was analyzed by a mass spectrometer. In the temperature range 1575°-1710°K, Ni^+ and O_2^+ were the predominant species in the vapor. They also reported the presence of free nickel on the lids of their Knudsen cells used for vaporization of NiO. Free nickel on the lids of the cell was also observed in this work. The authors concluded that NiO vaporizes primarily by dissociation to the elements.

Theory

The theory and the mathematical treatment of the experimental data of the isotopic exchange technique which is applicable to nitrides and oxides of metal was reported by Hoch and Ramakrishnan in the earlier report cited. The condensation coefficient, β, was obtained from an analysis of the steady-state conditions in the isotopic exchange reactions. First, expressions were derived which define the fractional changes in the solid and vapor compositions resulting from the exchange reactions. Second, a relationship was then established for the time rate of change of γ, the concentration of the contaminating isotope on the surface of the solid. Finally, a relationship was obtained between the concentration of the mixed isotope in the vapor and γ.

The isotopic exchange technique employs a Knudsen effusion cell which contains two samples of the solid which is to be vaporized, each containing a high concentration of a particular isotope. In this work, the solids are NiO^{16} and NiO^{18}. The samples are of equal size and are physically separated. When the cell is heated, the samples vaporize producing a gas with equal concentrations of O_2^{16} and O_2^{18}. The oxygen recondenses, with some of the O_2^{16} condensing on the NiO^{18} sample and becoming incorporated into the solid and vice versa. Since some of the vapor escapes through the orifice, equilibrium is not established and the solids continue to vaporize. Each sample contains some of the other isotope and subsequent vaporization produces gaseous $O^{16}O^{18}$ molecules. The concentration of $O^{16}O^{18}$ increases and the concentration of O_2^{16} and O_2^{18} decreases with time. If the temperature of the cell is held constant, a steady state is obtained. The condensation coefficient, β, can then be calculated from the steady-state values of vapor composition using the relationship

$$\beta = h/S \frac{(O^{16}O^{18})}{[\frac{1}{2} - (O^{16}O^{18}) + y/z]} \quad \text{if} \quad \frac{zh}{yS} >> \beta \qquad [1]$$

where: h = area of effusion hole (cm^2)
S = total exposed area of two pellets in Knudsen cell (cm^2)
$(O^{16}O^{18})$ = steady-state concentration of mixed isotopic molecule in vapor
y = thickness of layer of solid, in oxygen atoms, which takes part in vaporization reaction
z = thickness of layer of solid, in oxygen atoms, which takes part in condensation (exchange) reaction.

No attempt was made to convert to absolute pressures because the isotopic exchange technique does not depend on the knowledge of absolute pressure.

Preparation of Nickel Oxide

Use of the isotopic exchange technique for determining the condensation coefficient of nickel oxide requires a nickel oxide sample with a very high concentration of the atomic weight 18 isotope of oxygen. Commercially available NiO^{18} was obtained from Volk Radiochemicals Company, Burbank, California, and tested in the mass spectrometer. The sample was found to be unsuitable since it was essentially $NiCO_3$ which decomposed on heating to NiO and CO_2 gas. The mass spectrum was characterized by an intense peak at mass 44 which corresponds to CO_2^+. Therefore, it was necessary to prepare NiO^{18} in the laboratory.

Several preparation techniques for NiO are described in the literature (10). The most common method of preparation of NiO is the precipitation of $NiCO_3$ from a nickel salt solution and the thermal decomposition of nickel carbonate to nickel oxide. These wet methods were found unsuitable and the direct oxidation of nickel metal was selected as the most expedient prep-

Key words: nickel oxide, condensation, isotope exchange, vaporization.

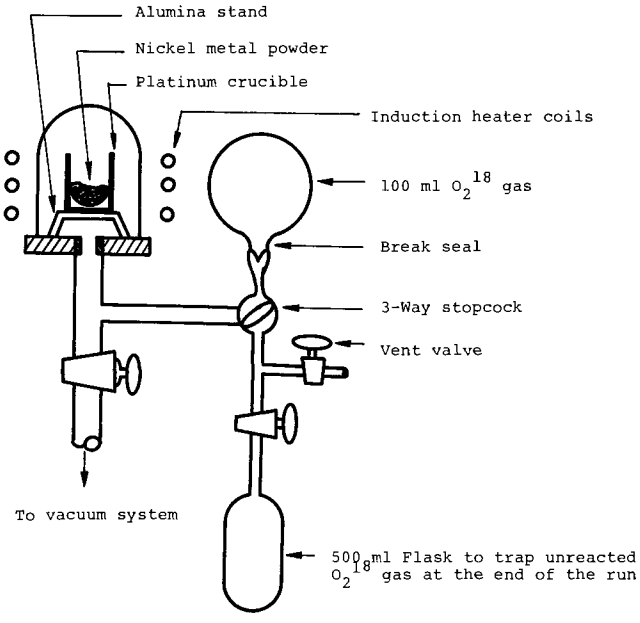

Fig. 1. Apparatus for the preparation of NiO^{18}

aration technique. Since O_2^{18} is available only in limited quantities, it was necessary to develop a preparation technique which would yield a maximum amount of NiO using 100 ml of O_2^{18} gas.

Initial studies indicated that the oxidation of compressed nickel metal powder in a limited volume of oxygen gas at 1 atm pressure is slow at 1300°K. Hence nickel powder was reacted with 100 ml of O_2 gas at NTP in an apparatus shown in Fig. 1 which was constructed to prepare NiO^{16} and NiO^{18}. The apparatus consists of a small quartz bell jar, a vacuum system, a gas inlet, a 500 ml flask to collect unreacted O_2 gas, and a sample heating system. The volume of the system was kept small to conserve oxygen. The nickel powder was placed in an open platinum crucible fabricated from platinum foil. The crucible was heated by an induction heater while sitting on an alumina stand. The alumina stand was coated with platinum paste to avoid any loss of O_2^{18} due to exchange with oxygen atoms in alumina.

Procedure.—Nickel oxide was prepared by introducing 400 mg of nickel metal powder into the platinum crucible, evacuating the whole system to below 5×10^{-5} Torr, degassing the powder under vacuum, admitting the oxygen gas after closing the stopcock connecting the 500 ml flask to the system, and heating the crucible. Within a few minutes of the start of the induction heating, the reaction set in as indicated by a glow inside the crucible. After 5 to 10 min, the glow disappeared and the surface temperature was slowly increased to 1300°K and held for about 2 hr. The surface temperature was corrected for surface emissivity and absorption of the quartz bell jar. The total correction is 108° at 1300°K. At the end of the run, any unreacted oxygen gas was collected in the evacuated flask.

X-ray diffraction powder patterns of the samples were made, which showed the sample was nickel oxide. No nickel lines were present in the powder pattern. Samples for the exchange runs were ground in an agate mortar and were pressed into pellets by using either a 3/16 or a 0.15 in. die. The pellets were degassed in vacuum at 1173°K for 105 min. Generally about 500 mg of the product nickel oxide was obtained starting with 400 mg of nickel metal and 100 ml O_2 gas at NTP. The yield was nearly 100%.

Bogatski (11) reports that NiO exists over the composition $Ni_{0.998}O$-$N_{0.758}O$. Our samples were green in color indicating lower oxygen content in our samples as compared to the oxygen-rich black oxide. Using the equation for vacancy concentration in NiO

$$\frac{Nv}{N} = 0.055\, P_{O2}^{1/6} \exp \frac{-17{,}800}{RT}$$

given by Mitoff (12) and $P_{O2} = 4.22 \times 10^{-6}$ atm (oxygen partial pressure over NiO at 1707°K measured by Grimley *et al.*), one has $x = 3.7 \times 10^{-5}$ in $Ni_{1-x}O$. Thus the deviation in stoichiometry in our samples is believed to be very small. Since R remained constant in the exchange runs, it is believed that the excess Ni(s) in the partially vaporized samples did not affect the results.

Knudsen Cells

Two different Knudsen cells were used to study the exchange reaction. A schematic sketch of the two cells and their inserts for holding the samples is shown in Fig. 2. One of the Knudsen cells was made of platinum. It was 11/16 in. tall and had an ID of ½ in. The thickness of the walls of the cell was 1/32 in. The lid of the cell was 1/16 in. thick and had a hole whose diameter was 0.025 in. The samples were placed in the two platinum inserts.

The other Knudsen cell had an outer cell of molybdenum and a molybdenum lid (1/16 in. thick) and an inner cell fabricated from 97% pure Al_2O_3. The alumina inner cell was ¾ in. tall and had an ID of 7/16 in. The diameter of the hole in the 1/16 in. thick alumina lid was 0.028 in. The samples were placed in an alumina insert.

Materials

Pure nickel metal powder (99.9%) was supplied by Gallard Schlesinger Chemical Manufacturing Corporation, Carle Place, New York.

The isotopic oxygen gas containing 99.6% O^{18} was obtained from Bio-Rad Laboratories, New York, New York.

The platinum Knudsen cell was fabricated by Engelhard Industries, Inc., Newark, New Jersey, and the

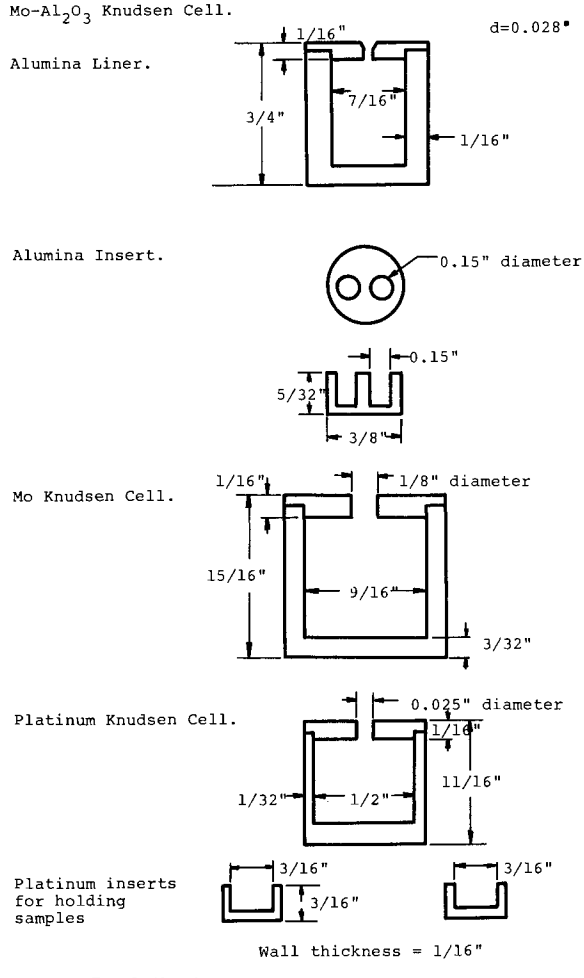

Fig. 2. Knudsen cells and inserts (schematic)

alumina Knudsen cell was supplied by McDanel Refractory Porcelain Company, Beaver Falls, Pennsylvania. The molybdenum Knudsen cell used with the alumina cell was machined in our machine shop.

To prepare NiO^{16} samples, commercial oxygen gas was used which was purified by passing through a liquid nitrogen trap.

Preliminary Experiments

Commercial nickel oxide was heated in the mass spectrometer using the platinum Knudsen cell to identify the vaporizing species. Above 1600°K, the only species detected was O_2^+ at mass number 32. Ni^+ peaks were absent in the mass spectrum. It was concluded that the nickel atoms in the vapor stuck to the walls and the lid of the platinum cell, and thus, they did not effuse through the hole in the lid. When NiO^{16} sample was heated in the molybdenum Knudsen cell with alumina liner, Ni peaks at mass numbers 58, 60, and 62 appeared in the spectrum along with O_2^+ peak at mass 32.

The intensity of O_2^+ (I_{32}) at mass 32 and the intensity of the peak at mass 16 (I_{16}) corresponding to O_2^{++} or O^+ were studied as a function of electron energy. Below 20 eV electron energy, the mass 16 peak disappeared completely. To minimize the dissociation of oxygen molecules to atoms and their recombination in the ion source, the exchange runs were made with 20 eV electron energy. The apparent temperature of the Knudsen cell was measured in degrees Fahrenheit by a disappearing filament type optical pyrometer sighted on the effusion hole through a glass prism and window. The correct temperature was obtained by converting the optical pyrometer readings in degrees Fahrenheit to degrees centigrade and adding the correction for the absorption due to the glass prism and the window. This correction was about 20°C at 1400°C. Sighting on the hole eliminated the need for an emissivity correction.

Experimental Results and Discussion

The first exchange run 1a was made using the platinum Knudsen cell (the detached mass spectrometric data can be obtained from the authors). The degassed NiO^{16} and NiO^{18} pellets were placed in tightly fitted holes drilled in an insert for the cell, and the cell was loaded in the mass spectrometer. The temperature was slowly raised to 1470°K and held there for about 20 min before increasing to 1703°K. The exchange reaction was studied to 1703°K and the intensities of mass peaks 32, 34, and 36 [I_{32}, I_{34}, and I_{36}] corresponding to O_2^{16}, $O^{16}O^{18}$, and O_2^{18} ions were recorded and the temperature measured at 15 min intervals. I_{34} was larger than I_{32} or I_{36} from the beginning of the run. The ratio $R = I_{34}/I_{32} + I_{34} + I_{36}$ was very close to 0.5 right from the beginning of the run and remained constant throughout the run which lasted 135 min. The run was continued (run 1b) the next day for 100 min and R was nearly 0.5 from the start to the end of the run. In both run 1a and run 1b, $I_{32} \approx I_{36}$, which suggests that the background interference at mass 32 was insignificant.

After run 1b, the cell was opened and the contamination of the half-pellets NiO^{16} and NiO^{18} by the other oxygen isotope were investigated. This was done by heating each half-pellet separately and observing the decrease in O^{16} concentration (or O^{18} concentration) with time. The concentration of O^{16} in NiO^{18} pellet was calculated from the ratio of the intensities of mass 34 and mass 36 peaks. Similarly, the O^{18} concentration in NiO^{16} pellet was calculated from the ratio of the mass 34 and 32 peak intensities. At the start, both half-pellets showed a large amount of contamination which decreases with time. For some reason the decrease in contamination in run 1c is not as fast as it is in run 1d.

The value of R was nearly 0.5 initially and it remained constant during the runs 1a and 1b. If every impact of the oxygen gas molecules with the solid nickel oxide results in exchange producing the mixed molecule $O^{16}O^{18}$, the R will be nearly 0.5 and remain constant. The second possibility is that the exchange reaction $O_2^{18}(g) + O_2^{16}(g) \rightarrow 2(O^{16}O^{18})(g)$ would take place on the hot platinum surface (13) of the cell. In either case, equilibrium will be achieved in the cell and R will be 0.5

To investigate the two possibilities, exchange runs 2a and 2b were made using the molybdenum Knudsen cell lined with alumina. In these runs, Ni^+ peaks at mass 58 and 60 were recorded along with mass 32, 34, and 36 peaks. In both the runs, $I_{32} \approx I_{36}$. R started with an initial value of 0.28 and reached a steady-state value of 0.43 after 30 min. The runs were made at an average temperature of 1697°K. During run 2b, the temperature was increased to 1753°K and held for 10 min. R remained constant at 0.43. The results are shown in Fig. 3. At the end of run 2b, the NiO^{16} pellet was removed. Run 2c was made to determine the amount of contamination of the NiO^{18} pellet by O^{16}. Similarly, run 2d was made to determine the amount of contamination of NiO^{16} pellet by O^{18} The results are given in Fig. 4. Both pellets showed a high degree of contamination in the beginning of the runs and then dropped to a nearly constant value. The cell was examined at the end of the run. The inner walls of the alumina cell and the lid developed a bluish coloration.

The Mo-Al_2O_3 cell was heated in the mass spectrometer (run 3) without any sample inside to find the reason for the bluish color of the liner. The mass spectrum consisted of mass 32, 34, and 36 peaks corresponding to the oxygen species and mass 58 and 60 peaks corresponding to the nickel species. Throughout run 3 the ratio R was nearly 0.5. It seems that the metal and the oxygen species adhered to the walls of the alumina liner and desorbed when heated. This desorption could have affected the results of the contamination runs 2c and 2d since oxygen may have desorbed from the walls of the cell while either of the nickel oxide pellets were being heated. If desorption takes place, it makes the data incorrect. Examination of the intensities of the oxygen peaks in runs 2c and 2d shows that desorption did not take place when the cell was heated with the specimen in it. When NiO^{18} pellet alone was heated, I_{36} was several times larger than I_{32} and the intensities of the oxygen peaks were consistent with the extent of contamination by O^{16} that was expected. If the walls of the alumina cell were contributing to the effusion flow, the amount of contamination

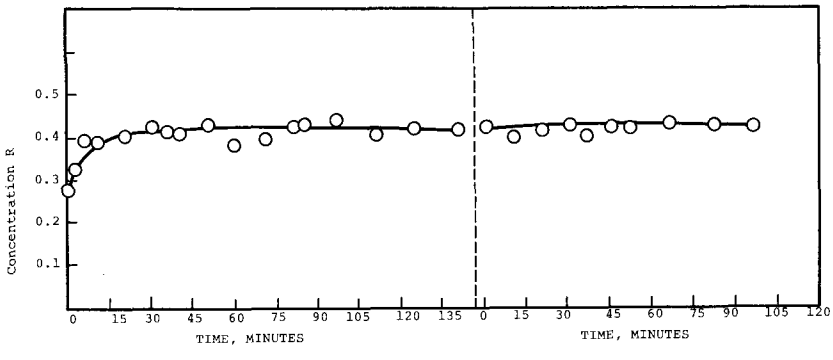

Fig. 3. Runs 2a and 2b. NiO^{16}, NiO^{18} pellets in alumina inserts (Mo-Al_2O_3 cell).

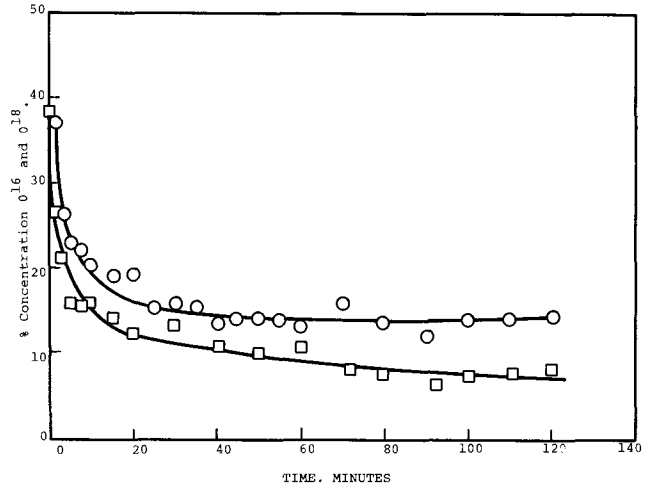

Fig. 4a. Runs 2c and 2d. Separate pellets (NiO^{16} and NiO^{18}) to determine contamination.

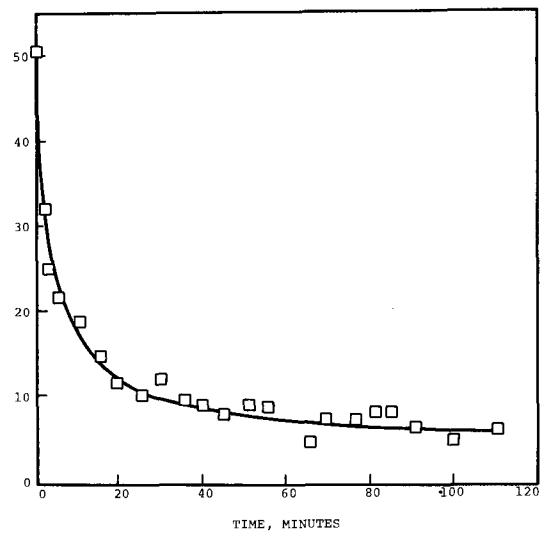

Fig. 4c. Run 1d. NiO^{16} pellet to determine contamination

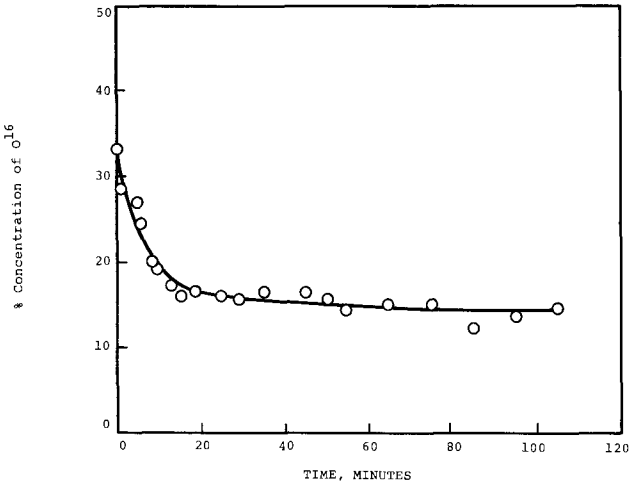

Fig. 4b. Run 1c. NiO^{18} pellet to determine contamination

would have been larger. The decrease in contamination as a function of time would have been less than that observed. Based on these observations, it is reasonable to conclude that any vapor species which stick to the alumina liner desorb only when the empty cell is heated. When the nickel oxide sample is heated in the cell, the sorbed species do not desorb and contribute to the effusion flow.

The O^{18} concentration in NiO^{16} sample was determined immediately after a pellet was made from NiO^{16} powder which was prepared sometime earlier. Run 4 was made by heating the NiO^{16} pellet in the mass spectrometer using the platinum Knudsen cell. This pellet was not used in any of the exchange runs and hence should contain only about 0.2% of O^{18} (natural abundance of O^{18} in oxygen). The O^{18} concentration was 2% at the start of the run and it decreased to less than 1% after 20 min. The same procedure was repeated in run 5 for an NiO^{18} sample (freshly made from NiO^{18} powder) using the platinum cell. The initial concentration of O^{16} in the NiO^{18} sample was 17% which decreased to 6% in the first 20 min of the run. The average concentration of O^{16} was 3-4% throughout the latter part of the run. The $O_2{}^{18}$ gas with which the NiO^{18} powder was prepared may have been contaminated with O^{16} isotope, or the NiO^{18} sample may have picked up some O^{16} during its preparation. In either case, the concentration of O^{16} in the NiO^{18} sample would have remained constant as a function of time in run 5. But the O^{16} concentration in the NiO^{18} sample was initially high and it decreased rapidly to a steady-state value. This decrease suggests that NiO^{18} exchanges slowly with atmospheric oxygen even at room temperature. The rapid decrease in the O^{16} content with time was due to the elimination of the surface layers contaminated with O^{16} isotope because of vaporization of the NiO^{18} sample.

Since the steady-state value of R in runs 2a and 2b made with the Mo-Al_2O_3 cell was 0.43 and not 0.5, it is improbable that each impact of the oxygen molecule with NiO solid results in the exchange. The reason for R being equal to 0.5 in runs 1a and 1b made with the platinum cell is that the exchange was taking place on the hot platinum surface.

The condensation coefficient of NiO was calculated taking the steady-state value of R as 0.43 and substituting the values of h (the area of the effusion hole) and S (the surface area of nickel oxide exposed to gas) in Eq. [1]. The results are given in Table I. The diffusion of oxygen in the solid NiO is fast; and hence, the depth of penetration z will be large, in which case $y/z \simeq 0$. The value of β (the condensation coefficient) is 1.1×10^{-1}.

Conclusions

1. The isotopic exchange technique is applicable to solids like oxides which have larger condensation coefficients than nitrides like AlN and BN.

2. A method has been developed to prepare required amounts of NiO^{18} by heating nickel metal powder in a limited volume of $O_2{}^{18}$ gas.

Table I. Calculation of the condensation coefficient of NiO from the steady-state $O^{16}O^{18}$ concentration

Sample	Cell	S, cm^2	h, cm_2	R,* steady-state	β $y/z = 0$	β $y/z = 0.5$
NiO^{16} and NiO^{18}	Mo-Al_2O_3	0.23	3.97×10^{-3}	0.43	1.07×10^{-1} 1.1×10^{-1}	2.31×10^{-2} 2.3×10^{-2}

* $R = \dfrac{I_{34}}{I_{32} + I_{34} + I_{36}}$.

3. The condensation coefficient of NiO is 1.1×10^{-1} in the temperature range 1697°-1753°K.

4. The exchange reaction $O_2^{18}(g) + O_2^{16}(g) \rightarrow 2(O^{16}O^{18})$ takes place on a hot platinum surface.

5. NiO^{18} when exposed to air at room temperature slowly exchanges oxygen and picks up O^{16}.

6. Under the conditions obtained in this investigation on the NiO system, the assumption that instantaneous equilibrium exists at the solid-gas interface (isotopic composition of oxygen in the surface is equal to that in the gas) is not valid.

Analysis of the Exchange Reaction Between Nitrogen and Aluminum Nitride

Emile Rutner and E. J. Rolinski

Materials Physics Division, Air Force Materials Laboratory Wright-Patterson Air Force Base, Ohio 45433

ABSTRACT

A model has been proposed to simulate the rate of isotopic exchange of a solid with a gas formed by its decomposition. The model considers the effect of the vaporization and condensation reactions, accompanied by effusion of the gas from a Knudsen cell, on the measured rate of exchange. The reaction rate constants for the vaporization of nitrogen from AlN and the condensation of N_2 and gaseous Al on solid AlN, at near equilibrium conditions, have been calculated. The condensation and the vaporization coefficients have been formulated in terms of the kinetic processes. The model has been applied to data of Hoch and Ramakrishnan (1) for the isotopic exchange reaction of nitrogen on aluminum nitride.

In the study of vaporization and condensation reactions it is desirable to determine the kinetics of such reactions at the equilibrium pressure since in many cases the reaction rates are dependent on the pressure of the gas in contact with the solid. One method for doing this is to study the isotopic exchange reaction between the gas and the solid. Such a reaction was carried out by Hoch and Ramakrishnan (1), who studied the time rate of isotopic exchange of N_2 gas with AlN and calculated an exchange coefficient from their data which they equated to a vaporization coefficient.

To fully utilize the data generated in (1) a kinetic model is proposed herein which takes into account the kinetics of the solid-gas reactions taking place. Since models for the vaporization and condensation of solids cannot be formulated in general terms, because the particular forms which the rate equations assume are determined by the kinetics of the reactions taking place, it is necessary in formulating a model to express the exchange reaction rates in terms of the kinetics of the processes involved. For the particular experimental arrangement utilized in (1), this required a model which described the processes involved in the vaporization of the solid, the condensation of the gas to form the solid, and the flow of the gas from the Knudsen cell.

Key words: Knudsen cell, vaporization, condensation, isotopic exchange, model.

Model for Isotopic Exchange of N_2 with AlN Accompanied by Flow from a Knudsen Cell

Utilizing an experimental arrangement as shown in Fig. 1, Hoch and Ramakrishnan (1) measured mass

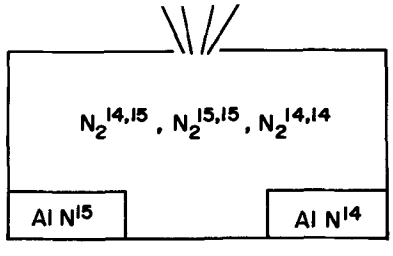

Fig. 1. Arrangement of aluminum nitride pellets in the Knudsen cell. AlN^{14} and AlN^{15} are pellets initially composed of the N^{14} isotope and N^{15} isotope, respectively.

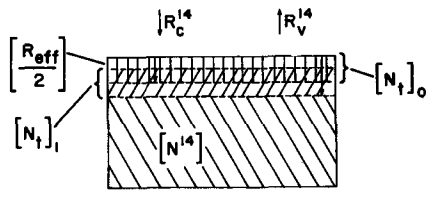

Fig. 2. Relation between the positions of reaction zone $[N_t]$ at time zero, $[N_t]_o$, and at some later time, $[N_t]_1$. Rate of mass motion of the zone is equal to one half of the rate of effusion of nitrogen plus aluminum.

spectrometrically, as a function of time, the fraction of N_2^{29} molecules, $[N_2^{29}]/[N_2^{28}] + [N_2^{29}] + [N_2^{30}]$, in the gas phase generated by the decomposition of two pellets of AlN in a Knudsen cell. Originally, one of the pellets was composed entirely of AlN^{14}(I) and the other pellet was composed of AlN^{15}(II). When the pellets were heated in a Knudsen cell a gas phase was generated which at zero time was composed of equal concentrations of N_2^{28} and N_2^{30}; and which during the course of time of the experiment became enriched with N_2^{29}, as a result of isotope exchange between the two pellets. The model proposed herein accounts for the time rate of change of the isotopic distribution of N atoms in the N_2 molecules.

Since the change in the isotopic composition of the gas is accompanied by a change in the isotopic composition of the solid any model proposed must account for the simultaneous changes in the composition of the gas and the solid. The change in the composition of the solid is actually limited to a region defined as a reaction zone as shown in Fig. 2. The reaction zone is assumed to be of constant volume. The zone recedes into the unreacted portion of the solid as the sample evaporates, and thus becomes enriched by N^{14} in the case of pellet I and N^{15} in the case of pellet II. The actual thickness of the zone is physically determined by the volume of the solid confined to the gas-solid interface. The gas-solid interface is determined by the control volume in which diffusion is fast enough so that there is thorough mixing between (*a*) the nitrogen that is in the zone, (*b*) the nitrogen that is added to it by the motion of the zone into the unreacted solid, and (*c*) the nitrogen that condenses from the gas phase into the zone. The total change in the composition of the zone can therefore be attributed to the following factors, assuming that the nitrogen gas is composed of N_2^{28}, N_2^{29}, and N_2^{30} molecules:

A. Vaporization of nitrogen from the zone.

B. Condensation of nitrogen from the gas phase onto the pellet.

C. Addition of nitrogen to the zone from unreacted solid.

On the other hand the change in gas phase composition is due to:

A'. Vaporization of nitrogen from each of the pellets into the gas phase.

B'. Condensation of nitrogen from the gas phase onto the pellets.

C'. Flow from the gas phase through the orifice of the Knudsen cell.

Change in Composition of the Solid

Reaction [1] represents the exchange of nitrogen isotope (j) with AlN^i, solid, where i and j represent the two different nitrogen isotopes

$$AlN^i + N_2^{jj} \rightarrow AlN^j + N_2^{ij} \quad [1]$$

To obtain a rate expression for the vaporization process [1] above, the over-all reaction must be represented by a mechanism. The mechanism is depicted by the following steps

$$[Al]_s \rightleftarrows [Al]_{ads} \quad [2]$$

$$[N^i]_s \rightleftarrows [N^i]_{ads} \quad [3]$$

$$[Al]_{ads} + [N^i]_{ads} + [N^j]_{ads} \rightleftarrows [AlN_2^{ij}Al]_{ads}^* \quad [4]$$

$$[AlN_2^{ij}Al]_{ads}^* \rightarrow [Al]_g + [N_2^{ij}]_g \quad [5]$$

Steps [2] and [3] represent the motion of (Al) and (N) atoms, respectively, from a lattice site in the solid (s) to an adsorbed site (ads) on the surface of the solid. Step [4], represents the formation of an activated complex involving N_2, which is required to satisfy the activated complex model for the reaction rate [2]. Step [5] represents the dissociation of this complex to form Al and N_2^{ij} in the gas phase. It should be noted that the nature of the complex requires that the adsorption site for $[N_2]$ on $[AlN]_s$ be Al atoms.

The steps in the condensation process (*B* and *B'* above) are given as follows

$$[Al]_g \rightleftarrows [Al]_{ads} \quad [6]$$

$$[Al]_{ads} + [N_2^{ij}]_g \leftrightharpoons [AlN_2^{ij}Al]_{ads}^* \quad [7]$$

$$[AlN_2^{ij}Al]_{ads}^* \rightarrow [Al]_s + [N^i]_s + [N^j]_s \quad [8]$$

Reactions [6] and [7] represent the adsorption of aluminum and nitrogen on the surface of aluminum nitride. Reaction [8] represents the over-all reaction leading to reverse of reactions [4], [3], and [2]. To utilize the data, the observed rates must be expressed as the rates of the reversible phenomenological reactions [9] for vaporization and condensation.

$$[Al]_s + [N^i]_s + [N^j]_s \underset{c}{\overset{v}{\rightleftarrows}} [Al]_g + [N_2^{ij}]_g \quad [9]$$

The rate of formation of $[N_2^{ij}]_{gv}$ by vaporization from a single pellet of solid AlN is given by Eq. [10].

$$\left(\frac{d[N_2^{ij}]}{dt}\right)_{gv} = \frac{1}{\sigma_{ij}} k_v[N^i]_s[N^j]_s[Al]_s^2 \frac{A_s}{V_c} \quad [10]$$

In Eq. [10], t is time, k_v is the rate constant for vaporization, σ_{ij} is the symmetry number of ij-th species; the bracketed quantities represent concentration, the subscript (s) refers to the solid phase, A_s represents the area of a single pellet, and V_c represents the gas volume of the Knudsen cell. All symbols are defined in Table I.

The condensation reaction can be expressed as Eq. [11] where the symbol (gc) represents change in gas phase concentration due to condensation, and k_c represents the reaction rate constant for condensation

$$-\left(\frac{d[N_2^{ij}]}{dt}\right)_{gc} = k_c[N_2^{ij}]_g[Al]_g^2 \frac{A_s}{V_c} \quad [11]$$

Defining $\gamma = [N^{14}]_s/([N^{14}]_s + [N^{15}]_s)$, the fraction of nitrogen atoms present in the solid reaction zone as N^{14} isotope, the time rate of change of γ is given by [12], letting $[N_t] = [N^{14}]_s + [N^{15}]_s$, the total number of atoms of nitrogen per square centimeter of reaction zone, and $\gamma_o = \gamma(t = 0)$.

$$[N_t]_s \frac{d\gamma}{dt} = -k_v[Al]_{ads}^2([N^{14}]_s^2 + [N^{14}]_s[N^{15}]_s) + k_c[Al]_{ads}^2([N_2^{14,15}]_g + 2[N^{14,14}]_g)K_a^2 + B\frac{W_h A_h \gamma_o}{A_s}([N_2^{14,15}]_g + 2[N_2^{14,14}]_g) \quad [12]$$

The last term in Eq. [12] represents the mass loss rate of nitrogen from the pellets due to effusion of nitrogen molecules from the Knudsen cell. In Eq. [12], K_a is the equilibrium constant for Eq. [6]; W_h is the Clausing factor for the Knudsen cell effusion [3], A_h is the area of the effusion hole, and $B = (2\pi M/RT)^{-1/2}$, M being the molecular weight of the effusing species, R the gas constant, and T the temperature, °K. Dividing by $[N_t]$, using the ratio $(\gamma/1-\gamma) = [N^{14}]_s/[N^{15}]_s$, and the stoichiometric relation for the concentration of N^{14} as atoms in the gas phase in terms of nitrogen molecules,

Table I. Symbols and values of experimental and calculated quantities

Symbol	Definition	Value
ads (subscript)	adsorbed	
[Al]	Aluminum atom concentration	
A_c	Cross-sectional area of Knudsen cell	0.986 cm^2 [a]
A_h	Area of Knudsen cell effusion hole	8.55×10^{-4} cm^2 [a]
A_s	Area of sample per pellet	0.180 cm^2 [a]
B	$RT(2\pi MRT)^{-1/2}$	2.85×10^4 cm × sec^{-1} at 1786°K [a]
e (subscript)	Denotes equilibrium conditions	
g (subscript)	Refers to gas phase	
h (subscript)	Related to effusion hole	
h	Planck's constant	6.63×10^{-27} ergs × sec [b]
I	Ratio $([N_2^{14,15}]/[N_2^{14,15}] + [N_2^{14,14}] + [N_2^{15,15}])_g$	
$I(\infty)$	I at $t = \infty$	0.4 [a]
k	Boltzmann constant	1.38×10^{-16} ergs × $(°K)^{-1}$ [b]
k_c	Reaction rate constant for condensation	2.08×10^{-27} $molecules^{-2}$ × cm^7 × sec^{-1} at 1786°K
k_v	Reaction rate constant for vaporization	2.84×10^{-43} $molecules^{-3}$ × cm^6 × sec^{-1} at 1786°K [c]
K_a	Equilibrium constant	$K_a = [Al]_{ads}/[Al]_g$
L	Lodschmidt's number	6.06×10^{23} molecules/mole [b]
M	Molecular weight	As given in text
N_1	Molecules in single layer	2.4×10^{15} atoms × cm^{-2} [e]
N_t	Total molecules in reaction zone	2.4×10^{20} [c]
$[N_2^{ij}]_g$	Concentration of nitrogen molecules of isotopic mixture of atomic weight i and j	
$[N^i]$	Refers to concentration of atoms of isotope of atomic weight i	
$[N_2]_g$	Concentration of N_2 molecules in the gas phase	2.58×10^{13} molecules × cm^{-3}
$[N_2]_{ge}$	Concentration of N_2 molecules in the gas phase at equilibrium	1.12×10^{14} molecules × cm^{-3} at 1786°K [ref. (6)]
$(P_e)_{1786}$	Equilibrium pressure at 1786°K	8.1×10^{-5} atm [ref. (6)]
$(P_c)_{1786}$	Pressure measured at 1786°K	1.9×10^{-5} atm [ref. (6)]

[e] Calculated from physical properties, ref. (13).

i.e., $[N^{14}]_g = \gamma_0([N_2^{29}]_g + 2[N_2^{28}]_g)$, Eq. [12] can be solved to give [13]. The concentration of $[N^{14}]_g$ is independent of time, if the temperature is a constant

$$\gamma = \frac{K_4}{K_1}\exp -(K_1 t) + \frac{K_3 + K_2}{K_1} \quad [13]$$

Where the constants are defined as

$$K_1 = k_v[N_t]_s[Al]_{ads}^2 \quad [14]$$

$$K_2 = \frac{BW_hA_h[N^{14}]_g}{[N_t]A_s} \quad [15]$$

$$K_3 = k_cK_a^2[Al]_{ads}^2[N^{14}]_g \quad [16]$$

$$K_4 = K_1\gamma_0 - K_2 - K_3 \quad [17]$$

Change of Gas Phase Composition

Relation [13] can now be used in the determination of the gas phase composition as a function of time. Referring to steps *A'*, *B'*, and *C'* above, the contributions of these processes must be added to determine the total rate of change in gas composition. If the fraction of N_2^{29}, nitrogen molecules in the gas phase is defined as $I = [N_2^{29}]_g/\Sigma[N_2^{ij}]_g$, where $\Sigma[N_2^{ij}]_g = [N_2^{28}]_g + [N_2^{29}]_g + [N_2^{30}]_g$, the change in I with time due to the effects of both pellets can be expressed as Eq. [18]

$$\frac{dI}{dt} = \frac{2k_v[Al]_{ads}^2[N_t]^2A_s}{V_c[\Sigma N_2^{ij}]_g}(\gamma - \gamma^2) - \frac{[N_2^{29}]_gA_s}{V_c[\Sigma N_2^{ij}]_g}\left[2k_c[Al]_g^2 + \frac{BW_hA_h}{A_s}\right] \quad [18]$$

A solution of this equation is obtained by substituting Eq. [13] for γ, and integrating to obtain Eq. [19]

$$I = \frac{1}{[\Sigma N_2^{ij}]_g}\left(\frac{K_5K_8}{2K_1 - K_9}\exp -(2K_1t) + \frac{K_8K_6}{K_1 - K_9}\exp -(K_1t) + K_{10}\exp -(K_9t) + \frac{K_8K_7}{K_9}\right) \quad [19]$$

where the constants are defined in terms of quantities used previously.

$$K_5 = \frac{K_4^2}{K_1^2} \quad [20]$$

$$K_6 = \frac{K_4}{K_1} - \frac{(K_3 + K_2)^2}{K_1^2} \quad [21]$$

$$K_7 = \frac{K_3 + K_2}{K_1}\left[1 - \frac{K_3 + K_2}{K_1}\right] \quad [22]$$

$$K_8 = \frac{2k_v[Al]_{ads}^2[N_t]^2A_s}{V_c} \quad [23]$$

$$K_9 = \frac{2k_c[Al]_{ads}^2K_a^2A_s}{V_c} + \frac{BW_hA_h}{V_c} \quad [24]$$

Utilizing the initial condition, *i.e.*, $I_0 = ([N_2^{29}]/[\Sigma N_2^{ij}])_g = 0$ at $t = 0$, an expression for K_{10} can be obtained. The measured value of I at $t = \infty$, *i.e.*, $I(\infty) = 0.4$, is the steady-state value which is less than the equilibrium value of I; *i.e.*, $I_e(\infty) = 0.5$.

Referring to Eq. [13], on substituting the equilibrium value of $\gamma = \gamma_e = 0.5$ obtained at $t = \infty$, a relation between the equilibrium gas concentration, $[\Sigma N_2^{ij}]_{ge}$, and the reaction rate constants can be obtained. The expression is

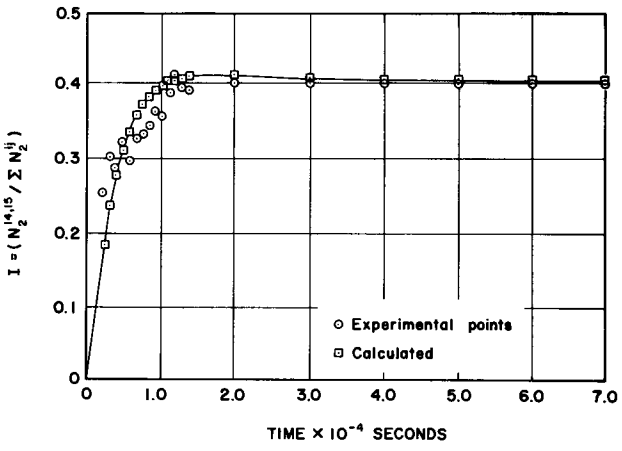

Fig. 3. Best fit to experimental data from ref. (1). Utilizing Eq. [19] or for $I(t)$, at a pressure equal to the equilibrium pressure of nitrogen, 8.1 x 10^{-5} atm at 1786°K, and k_c = 2.08 x 10^{-27}.

$$\frac{k_v}{k_c} = \frac{2[\Sigma N_2^{ij}]_{ge} K_a^2}{[N_t]^2} \qquad [25]$$

Utilizing Eq. [25], the number of unknown parameters in Eq. [19] is reduced to two; *i.e.* N_t and k_c.

Discussion

The best fit for the values of k_c and N_t utilized to reproduce the experimental results are given in Table I and Fig. 3. The value of $[N_t]$ indicated that the reaction zone is a region 10^5 atoms thick per square centimeter, or that a zone containing this number of atoms per square centimeter is required to give a rate of exchange with the gas phase nitrogen which is rapid enough to reproduce to experimental data. It should be noted that if the actual zone becomes too thick the rate of exchange approaches zero due to the slow mixing by diffusion of the atoms in the unreacted portion of the solid with the atoms already in the zone.

Estimation of the reaction rate constant for vaporization.—In order to determine the value of k_v it was necessary to estimate the concentration of $[Al]_{ads}$ on the surface on the AlN. This was done by utilizing the activated complex reaction rate theory (4) and applying it to adsorption of atoms on the surface.

$$\text{Velocity of desorption} = [Al]_{ads} \frac{kT}{h} \frac{F+}{F_a} \exp - E_2/RT \qquad [26]$$

where h is Planck's constant, $F+$ is the partition function for the activated complex, F_a is the partition function for the adsorbed species, and E_2 is the energy of activation for desorption. If it is assumed that $F_a = F+$ then the rate of desorption is equal to the rate of vaporization, and they may be estimated from the vapor pressure of [Al] over the [AlN]. If it is further assumed that the rate of vaporization is the equilibrium rate, and that a stoichiometric relation exists between the rate of desorption of N_2 and Al, the rate of vaporization per square centimeter of sample is given by

$$-\left(\frac{d[Al]}{dt}\right)_{ve} = 2k_c[N_2]_{ge}[Al]_{ge}^2/V_c \qquad [27]$$

$$= \frac{8k_c[N_2]_{ge}^3}{V_c} \qquad [28]$$

Utilizing the constants in Table I the rate of vaporization was found to be 2.8 x 10^{16} atoms x cm^{-2} x sec^{-1}.

The value of E_2 (50 kcal/mole) was estimated by taking one-half of the heat of atomization of Al from AlN. This value was obtained by considering that an adsorbed Al atom is bound by only three bonds as required by the form of the activated complex. The calculated concentration of adsorbed aluminum atoms was: $[Al]_{ads}$ = 1.03 x 10^9 atoms x cm^{-2}. Utilizing this value in Eq. [25] a value of k_v = 2.84 x 10^{-43} was obtained.

Values of the vaporization coefficient (α_c) and condensation coefficient (α_v) were found by using the following relations (5)

$$\alpha_v = \frac{\text{observed rate of vaporization}}{\text{maximum possible rate of vaporization}} \qquad [29a]$$

$$\alpha_c = \frac{\text{rate of condensation}}{\text{rate of molecular collision with the surface}} \qquad [29b]$$

The maximum rate of vaporization is the equilibrium rate which is equal to the condensation rate at equilibrium. The maximum possible condensation rate is the rate of collision with the surface.

Considering the vaporization and condensation of N_2 molecules the following expressions can be written for α_c and α_v

$$\alpha_v(N_2) = \frac{2k_v[Al]_{ads}^2\,[N_t]^2}{B[\Sigma N_2^{ij}]_{ge}} \qquad [30]$$

$$\alpha_c(N_2) = \frac{k_c[Al]_{ads}^2 K_a^2 [\Sigma N_2^{ij}]_g}{B[\Sigma N_2^{ij}]_g} \qquad [31]$$

The calculated value of α_v equals α_c = 2.7 x 10^{-3}. These compared with the values of α_c estimated in ref. (1) to be 5 x 10^{-3}, and in ref. (6) to be 2 x 10^{-3}. In general, equal values for α_c and α_v are obtained when the activated complex is the same for the vaporization reaction as for the condensation reaction. This is so, as noted in Eq. [4] and [8] for AlN.

Thermodynamics of reactions used.—An examination of the significance of the thermodynamic quantities involved in the reactions which were used to determine the equilibrium concentrations and to guide the formulations of the kinetics led to the following results. The value of the equilibrium constant for the gas phase isotopic equilibrium is derived in the manner described in Eq. [7]. The only difference in the partition functions of the molecules N_2^{ij} is that the rotational partition function differs by the value of the symmetry number; *i.e.*, σ_{ij} equals 1 for $i \neq j$ and equals 2 for $i = j$. This leads to a value of the equilibrium constant K_p = 4 for reaction [32].

$$N_2^{30} + N_2^{28} \rightleftharpoons 2N_2^{29} \qquad [32]$$

The equilibrium ratio then becomes I_e = 0.5. The measured value of $I(\infty)$ = 0.4, is less than I_e. This difference is due to flow from the Knudsen cell which maintains the steady-state pressure in the cell lower than the equilibrium pressure.

The binding energy of Al atoms to the surface of AlN was estimated as follows: To maintain congruency in the vaporization processes over a temperature range, the heat of vaporization per Al atom must be equal to one-half the heat of vaporization per nitrogen molecule. Therefore, the heat of reaction for [33] which equals to the heat of vaporization of Al atoms plus half of the heat of vaporization of nitrogen molecules must be equal to 1.5 times the heat of vaporization of Al from AlN. Reference (6) gives a value of 150.11 kcal for $\Delta H°$ for [33] at 1786°K, the temperature of the experiments.

$$[AlN]_s \rightarrow [Al]_g + \tfrac{1}{2}[N_2]_g \quad \Delta H°_{1786°} = 150.11 \text{ kcal} \qquad [33]$$

The heat of vaporization of $(N_2/2)$ from AlN must, therefore, be 50 kcal. Half of the heat of vaporization of Al from AlN is assumed to equal the binding energy of Al atoms on the surface of AlN and, therefore, is equal to 50 kcal. The fraction one-half is based on the

assumption that only one-half of the normal bonds in $[AlN]_s$ are binding the Al atom to the surface.

An examination of the results (Fig. 3) indicates that the mechanism proposed which involves the activated complex $[AlN_2Al]^*$ is consistent with the experimental results, and that the value of the vaporization and condensation coefficients obtained, $\alpha = 2.7 \times 10^{-3}$, is in agreement with that obtained in ref. (1); *i.e.*, $\alpha = 2 \times 10^{-3}$, and compares reasonably well with that found in ref. (6); *i.e.*, $\alpha = 5 \times 10^{-3}$. The model also predicts a variation in condensation rate of N_2 with the partial pressure of Al, and that the condensation and vaporization coefficients are a function of the pressures of Al and N_2. Although not shown in Fig. 3, the variation of the parameter $[N_t]$ indicated that the model may give results which are not physically possible for very large values of N_t.

Use of the Motzfeldt equation for Knudsen cell flow.— The calculation was extended to include the Motzfeldt formulation to describe the flow from a Knudsen cell (9). These equations take into account the effect of the Clausing factor of the cell on the pressure distribution inside the cell. By combining the Motzfeldt equations with the equations describing the kinetics of the reaction taking place as proposed by Rutner (10), the results obtained did not significantly differ from those shown in Fig. 3, and as noted in Table I. A complete solution of these equations is given in ref. (11).

Conclusions

A model which simulates the change in isotopic compositions of a gas in a Knudsen cell due to vaporization from and condensation on a solid, accompanied by effusion from the cell has been proposed and applied to the data in ref. (1) for the exchange of N_2 on AlN. This model was able to give reaction rate constants for the vaporization and condensation reactions, and vaporization (α_v) and condensation (α_c) coefficients. The value of the coefficients found $\alpha_c = \alpha_v = 2.7 \times 10^{-3}$ agree with previously reported values. It can, therefore, be concluded that the model describes the processes involved in the isotopic exchange reaction of N_2 on AlN.

Acknowledgment

The authors wish to thank Professor M. Hoch for discussions during the course of this research, and for providing the experimental data before publication; and to Mr. Thomas E. Duvall for programming the computations (12).

Manuscript submitted Jan. 12, 1970; revised manuscript received *ca.* Sept. 22, 1970. This was Paper 210 presented at the Detroit Meeting of the Society, Oct. 5-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

An Analysis for Si Contamination in GaP

L. C. Luther

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

and H. W. Verleur

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania 19604

ABSTRACT

Chemical transport of solid GaP using HCl as reactant often results in the formation of a voluminous residue conforming to the shape of the initial charge. Analysis by x-ray fluorescence showed such residues to consist primarily of silicon, probably as SiO_2. It was shown that the transport reaction did not introduce extraneous SiO_2 from vapor phase reactions with the quartz liner. In addition it was demonstrated that silicon dissolved in gallium could be almost completely recovered as a SiO_2 residue. Thermodynamic considerations are presented to show that unintentional or deliberate moisture contamination of the reactants is required to prevent SiO_2 losses. The method is proposed as a quantitative tool for determination of Si content in Ga, GaP, and GaAs with a sensitivity of $\geq 5 \times 10^{16}$ atoms/cc. It was applied to analyze polycrystalline GaP and single crystals of GaP grown from this material by the Liquid Encapsulated Czochralski (LEC) technique. The analysis confirmed that Si doping of the LEC crystals by the quartz crucibles does not occur and undoped LEC crystals normally contain less than 5×10^{16} Si atoms/cc. Moreover, most of the Si contained in Si-doped melts is "gettered" by the B_2O_3 encapsulant, probably through oxidation.

When GaP or GaAs is chemically transported by reaction with gaseous HCl a white or sometimes gray residue is formed at the site of the original material. Silicon-doped GaP or GaAs in the shape of a large compact ingot leaves a voluminous "ghost" residue reproducing the original shape (Fig. 1). Frosch (1) has made similar observations on evaporation of Si-doped GaP in a wet hydrogen transport system. Moest (2) observed residues after evaporating GaAs and obtained a mass spectrometric analysis indicating that the residue was mainly SiO_2.

Present analytical procedures for determining the total Si content in GaP are unsatisfactory. The sensitivity limit for wet chemical analysis is $2 \times 10^{18}/cm^2$ [Trumbore (3) and Kometani (4)]. Neutron activation analyses have been performed in GaAs but not in GaP because matrix phosphorus is converted to Si during the activation (5). Electrical measurements are not definitive because silicon is an amphoteric dopant in GaP. Although spark source mass spectrometric measurements have been shown to give accurate analytical results for Si at the 10^{21} atom/cm^3 level (6), it is not clear what accuracies may be expected on the parts per million level. Interference from hydrocarbon lines raise serious problems of interpretation.[1] Thus in view of the generally expected contamination of GaP by Si, a simple unambiguous analytical method is needed. The present study shows that impurity enrichment by matrix evaporation is a reliable quantitative tool for silicon and potentially applicable to other elements that form refractory oxides.

Material Preparation

The analytical method, to be described in more detail in the next section, was applied to study the Si content of both polycrystalline and single-crystal GaP. The polycrystalline GaP was prepared both at the Bell Lab-

[1] Survey analyses are routinely performed claiming a sensitivity limit of 1 ppm Si. In the absence of standards an uncertainty factor of 3 is attached to all analytical results (7).

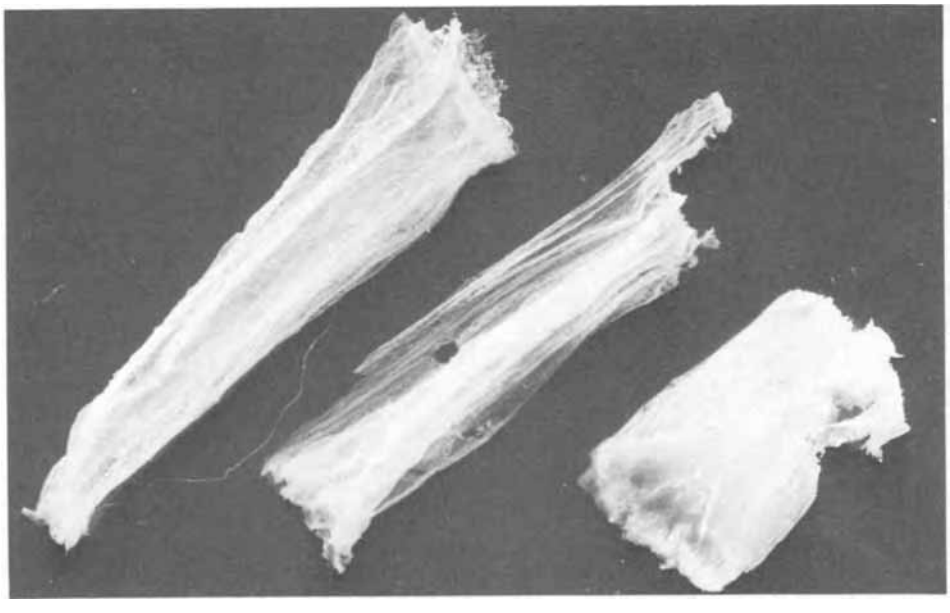

Fig. 1. Residues obtained by evaporating GaP single crystals.

oratories and by an outside supplier by dissolving phosphorus, obtained from the dissociation of PH_3, in Ga at temperatures near 1150°C. The details of this technique are described by Ringel (8). The material supplied from the outside was prepared in an all BN system, *i.e.*, pyrolytic BN liner tubes and boats. The material preparation at Bell Laboratories employed BN boats and quartz liners.

Both kinds of polycrystalline GaP were used as starting material in the Liquid Encapsulated Czochralski (LEC) growth of single crystals. In this method, which has been described elsewhere (9, 10), B_2O_3 was used as the liquid encapsulant and the melt was contained in quartz crucibles. The crystals analyzed were either undoped or doped with Ga_2O_3, C, Si, or B. All dopants were added in the crystal puller, while the polycrystalline starting material was undoped except for unintentional contamination from the boat or liner material.

The pulled crystals to be analyzed were etched for a few minutes in hot aqua regia, rinsed in deionized water and methanol, and weighed after drying.

Analytical Technique

The vapor transport apparatus used in these experiments was originally designed and used for the vapor growth of GaP single crystals and has been described elsewhere (11). The temperature of the Ga or GaP source material was 930°C. Pure hydrogen chloride used to transport the source material was derived from reaction of PCl_3 with carrier hydrogen. The hydrogen flow rate was kept at 60 ml/min, which in our apparatus corresponds to a flux of 10 ml/min-cm^2. a much lower value than was used during crystal growth runs, when the flow rates varied from 300 to 500 ml/min. The HCl partial pressure, however, was increased to 7.8 x 10^{-2} atm from a value of 5 x 10^{-2} atm existing during the crystal growth runs. The transport took place in vitreous SiO_2 furnace tubes except in certain control experiments when a pyrolytic BN liner was used. Pyrolytic BN boats were used to contain the source material to be analyzed except in those runs when the reaction between Ga and silica was studied. Under the above conditions 1 cm^3 of analytical sample can be evaporated in 1 hr.

During the early runs, the importance of complete evaporation of the Ga and GaP was realized. While in principle it would be possible to weigh the residue (ranging from several milligrams to a few micrograms), treat it with HF to dissolve the SiO_2 and subtract the weight of the remaining particles, in practice this can lead to considerable inaccuracies.

The SiO_2 residue from GaP crystals was judged to be amorphous SiO_2 on the basis of Laue back scattering experiments.

Qualitative analysis of the residues by x-ray fluorescence showed the major constituent to be Si. Other elements found by this analysis were Ga, Al, and Ca. While only trace quantities of Al and Ca were detected, Ga was found to be a major constituent only in the residue resulting from the transport of polycrystalline material. In all residues derived from pulled crystals only trace quantities of Ga were found. The presence of Ga in the polycrystalline GaP is to be expected. While the polycrystalline ingots are etched in hot HNO_3 or HCl after growth to remove excess gallium, some Ga inclusions can remain or be converted to α-Ga_2O_3, or $Ga(NO_2)_3$ unless the material is crushed prior to etching, which was not done for any of the material analyzed in these experiments. The β-form of Ga_2O_3 is formed from various compounds containing Ga and O on heating above 650°C (12). Thus, Ga $(NO_3)_3$, α-Ga_2O_3, etc., contained in aqua regia etched and poorly washed, porous GaP may be converted to β-Ga_2O_3 on heating to transport temperature (930°C). Once formed it may react relatively slowly with HCl compared to GaP. Elemental Ga, however, would not be oxidized in the reducing atmosphere of the transport system and hence not yield Ga-rich residues.

Reliability and Sensitivity of Analytical Technique

To determine whether SiO_2 is introduced in the residue from either the boats or the liner tubes, several control experiments were carried out. When gallium was placed in an SiO_2 boat and transported through reaction with HCl, films of SiO_2 were detected in the boat. No such residues were ever formed with BN boats. At temperatures near 1100°C, used for synthesis of GaP by saturation of gallium with gaseous phosphorus, it is well known that severe Si contamination occurs if SiO_2 liner tubes are used, even when Ga is contained in a BN boat. Under these conditions reactions between hydrogen and the silica furnace tubes produce gaseous Si species which are dissolved in the gallium (8).

To check that no such reactions occurred in our system at 930°C two samples from the same GaP ingot were evaporated separately in two runs. One evaporation was carried out as usual using a BN boat placed in a SiO_2 furnace tube. The other sample was evaporated from a BN boat placed in a BN tube. In both cases the amounts of residues were extremely small (a few micrograms) and yielded comparable Si levels.

These results indicate that the SiO_2 residues are indeed derived from the GaP and not from the container materials. As additional proof, we note that not all GaP material evaporated in SiO_2 tubes left residues. Polycrystalline material prepared in an all BN system as well as several pulled crystals yielded no detectable SiO_2 residues.

Several control experiments were performed to ascertain the reliability of the method as a quantitative analytical tool. Pure gallium[2] was doped with small quantities of elemental silicon and evaporated from BN boats in SiO_2 furnace tubes under the same conditions as the GaP. The weights of the SiO_2 residues recovered are listed in Table I. SiO_2 losses are calculated by subtracting the recovered amounts from the known contamination converted to SiO_2. The deviations from the known amount of Si always correspond to a loss of Si, again indicating that no extraneous Si is introduced in the process.

Silicon, in the material to be analyzed, can be lost by vapor transport in a reaction with HCl to form $SiCl_4$. The suppression of $SiCl_4$ depends on the amount of residual oxygen contained in the incoming hydrogen carrier gas in the form of both O_2 and H_2O. For the reaction

$$SiO_2 + 4HCl \rightarrow SiCl_4 + 2H_2O \qquad [1]$$

an equilibrium coefficient

$$K_1 = \frac{p_{SiCl_4} p_{H_2O}{}^2}{p_{HCl}{}^4}$$

was calculated for 1200°K from data given in the JANAF Tables (13). From K_1 one can make reasonable estimates of the theoretical Si losses through conversion to $SiCl_4$ during the transport reaction. K_1 at 1200°K is 4 x 10^{-11} atm^{-1}.

Thermodynamic considerations presented in ref. (11) indicate that the partial pressure of HCl in equilibrium with the GaP source is 7.8 x 10^{-2} atm. The partial pressure of H_2O derived from impurities in

[2] Which according to manufacturer's mass spectrometric analysis contained less than 0.04 ppm Si.

Table I. Recovery of silicon from gallium

Wt. of Ga, g	Wt. of Si dopant, μg	Wt. of SiO_2 residue, μg	Loss of SiO_2, μg	% Recovery
39.41	21,100	40,200	5000	89
4.87	92	135	62	69
3.53	421	834	69	92

the dry H_2 and the PCl_3 is not known. An analysis provided by the supplier of PCl_3 indicates a $POCl_3$ content of 0.2 m/o (mole per cent). From this number we can calculate an H_2O partial pressure of 8×10^{-5} atm. This pressure is expected to increase with increasing enrichment of the PCl_3 in the higher boiling $POCl_3$ as the reaction proceeds. Experiments with GaP and GaAs transport in the dry H_2 used as a carrier gas indicated a H_2O residual partial pressure of 2×10^{-5} atm.

A reasonable estimate of the total partial pressure of H_2O in the system is, therefore, 1×10^{-4} atm. Inserting this value together with $p_{HCl} = 7.8 \times 10^{-2}$ atm into the equation for K_1 (1200°K) we find a partial pressure of $SiCl_4$ equal to 1.5×10^{-8} atm.

From this estimate of the partial pressure of $SiCl_4$ one can calculate that during an experiment in which 1 cm^3 of GaP is evaporated over 1 hr into a carrier gas flow of 60 ml/min an amount of 0.1 μg of SiO_2 will be lost. This estimate is to be increased, however, because toward the end of the run almost all the GaP is consumed and the p_{HCl} rises to the value of the incoming HCl pressure. Since p_{SiCl_4} increases with the fourth power of p_{HCl}, SiO_2 consumption increases drastically and will after complete evaporation of the GaP sample rise to 1.3 μg/min. It is therefore useful to provide an auxiliary GaP source downstream from the analytical sample.

In the above it was assumed that the only source of SiO_2 in the system is the sample. Considering the finely divided state of the SiO_2 residues this is likely to be true. However, the reaction between HCl and the quartz furnace tube walls used in all our routine analytical runs may have served to reduce the Si_2O losses.

The actual SiO_2 losses observed in the control experiments using Si-doped Ga indicate SiO_2 losses ranging from 5000 to 60 μg, roughly proportional to the amount recovered. It is concluded that these losses represent both mechanical losses occurring during transfers and the expected theoretical losses. It is also possible that convection currents in the transport tube carry away small amounts of the extremely light SiO_2.

On the basis of these considerations it is suggested that the Si concentrations in GaP deduced by this method present a lower limit to the actual Si content. The method yields a total silicon content regardless of distribution. Due to the increased importance of mechanical losses when the residues are small, we would expect this method to yield values that are only about 50% of the actual concentrations. Since a convenient sample size in view of running time is about 5g, Si concentrations less than 5×10^{16} atoms/cc (1 ppm) yield residues less than 5 μg. Such small quantities become extremely hard to handle accurately. Consequently, the sensitivity limit of this method should be considered to be 5×10^{16} atoms/cc.

Discussion of Analytical Procedure and Results

The procedure as presented was derived from crystal growth experiments and relies on an unintentional moisture content of the reactants. The experimenter can control the moisture content of the reactant gas by saturating part of the incoming hydrogen with water vapor by passing it through a temperature controlled water bubbler as described by Kamath and Bowman (14).

The results of the analysis of the various GaP samples are listed in Table II. For a comparison we have included spark source mass spectrometric data on the same or similar material measured by Malm (7). In comparing the two methods it must be borne in mind that the sampling procedures for the two methods differ radically. The evaporation method measures the total silicon content of a large sample (~5g), regardless of distribution inhomogeneities. The spark source mass spectrometric analysis yields a value pertaining to a very small crystal volume. The discrepancy between the silicon content values given by the two methods can be quite large (*e.g.*, RD 111 and RD 117 in Table II).

With the limitations of both methods in mind, two significant conclusions may be drawn from Table II. First, the silicon content of LEC grown ingots which are not intentionally doped with silicon is less than or equal to 5×10^{16} atoms/cc or about 1 ppm (atomic).[3] This is comparable to the Si concentrations in the polycrystalline starting material. Hence, no significant contamination from the quartz crucibles occurs.

Second, in both cases where the polycrystalline material contained silicon, either by direct addition of elemental Si to the melt (RD 117) or because of its preparation in SiO_2 liners (RD 111), the Si concentration in the LEC grown ingot dropped by nearly two orders of magnitude. This confirms the gettering action of B_2O_3 with respect to silicon as already reported by Bass and Oliver (15, 16), who suggested

[3] One cubic centimeter of GaP weighs 4.13g and contains 4.9×10^{22} atoms. One part per million (atomic) corresponds to 4.9×10^{16} atoms/cc. One part per million (by weight) of Si would correspond to 8.8×10^{16} atoms/cc.

Table II. Si content in polycrystalline GaP and LEC grown single crystals of GaP

that B_2O_3 might be reduced by elemental Si. Malm's (7) mass spectrometric analysis of RD 117, a Si-doped crystal, shows a considerable amount of boron, *i.e.*, 20-30 ppm as compared to 1 ppm in undoped ingots. While this confirms that some of the Si is removed, through reduction of B_2O_3, Weiner has pointed out that the residual water content of the B_2O_3 is primarily responsible for oxidation of the elemental Si into SiO_2 which then dissolves in the B_2O_3 (17).

Acknowledgments

We gratefully acknowledge the mass spectrometric analysis work performed by D. L. Malm as well as the use of his unpublished data. We also thank C. M. Ringel for supplying some of the polycrystalline material, Mrs. M. Reed for the x-ray study of the SiO_2 residue, and Miss S. Vincent for x-ray fluorescence analysis. It is a pleasure to acknowledge valuable discussions with F. A. Trumbore.

Manuscript submitted July 10, 1970; revised manuscript received *ca.* Jan. 10, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Crystallization Studies of Nickel-Tellurium Oxide Films

M. L. Lieberman,[1] B. Boller, and R. C. Medrud

Research and Development Laboratories, Corning Glass Works, Corning, New York 14830

ABSTRACT

Crystallization of amorphous nickel-tellurium oxide films prepared by multicathodic reactive sputtering has been studied by x-ray diffraction. Devitrification resistance is maximized for films with an atomic ratio (Te/Ni) near 0.47. A new compound has been prepared which has a structure resembling that of rutile. It has been identified as $Ni^{+2}Te^{+6}O_4$. The identification of this compound, the preparation of similar known mixed-oxides by the same method, and other evidence indicates that amorphous tellurate films can be prepared by reactive sputtering.

Previous work in multicathodic reactive sputtering has shown that amorphous mixed-oxide films can be prepared over a wide composition range (1). Crystallization of amorphous bismuth-tellurium oxide films produced unidentified phases which are probably bismuth tellurates (compounds with Te^{+6}), but identification has not been possible because no structural data on bismuth-tellurium oxides have been reported.

To continue the work on multicathodic reactive sputtering and to obtain stronger evidence for tellurate formation, we have studied the nickel-tellurium-oxygen system in which at least one well-characterized compound, trinickel tellurate, Ni_3TeO_6, exists (2). This report deals primarily with the preparation and identification of phases in nickel-tellurium oxide films. Other similar systems have also been studied.

Experimental

Multicathodic reactive sputtering was used to deposit mixed-oxide films on rotating, liquid-nitrogen cooled glass substrates in a 1:1 Ar-O_2 gas mixture. Deposition parameters and film compositions are given in Table I. The apparatus has been described elsewhere (3). Film composition was varied in different deposition experiments by changing the cathode voltages. Seven different compositions were prepared over the atomic-ratio range 0.049_1-2.02 g-atom Te/g-atom Ni.

Films were deposited simultaneously on four substrates during each deposition experiment. Different films from each deposition experiment were used for phase identifications and for chemical analyses. Phase identifications were based on x-ray diffraction analyses, as in previous work (1, 3). A G.E. diffractometer was used with CuKα radiation. Chemical analyses were obtained by spectrophotometric methods. The uncertainties in the mass values are estimated as $\pm$ 3% for mass values greater than 1 mg; for smaller mass values, the uncertainties are larger.

Discussion and Results

Film crystallinity.—Under the experimental conditions outlined in the previous section, films with low

atomic ratios (Te/Ni) are black, as are nickel oxide films (3). With increasing atomic ratio (Te/Ni), the films progressively approach the virtually colorless character of as-deposited tellurium oxide films (3). After heat treatments at 350°C or higher, the black films turned olive green. Nachman, Cojocaru, and Ribco (4) have attributed the black color in NiO to the presence of Ni^{+3} ions. Such ions are present in NiO as charge compensation for nickel vacancies which occur with an excess of oxygen. Nearly stoichiometric NiO is pale green. Consequently, it seems likely that when the films are heated, the Ni^{+3} ions are reduced to Ni^{+2} ions, and the excess oxygen is eliminated.

Previous work (1) in multicathodic reactive sputtering has indicated that amorphous, mixed-oxide films of some systems can be prepared at all compositions if each of the metal oxides involved forms amorphous single-oxide films. Since nickel oxide films prepared in the present apparatus are crystalline and those of tellurium oxide are amorphous (3), it was anticipated that crystallinity in the nickel-tellurium oxide films would depend on composition. That this was the case is shown by the diffractometer traces of Fig. 1. All curves show the broad peak from the glass substrates at about 22° in 2θ. As the atomic ratio Te/Ni) increases, the three NiO peaks decrease in intensity. For films 178-181 with atomic ratios (Te/Ni) equal to or greater than 0.472, no crystalline NiO is observed. Instead, the films appear to be amorphous.

Diffractometer traces from films heated for 3 hr at different temperatures showed variations with both temperature and atomic ratio. The portions of the diffractometer traces which exhibited the most intense peaks are presented in Fig. 2. Films with atomic ratios (Te/Ni) of 0.736 and 1.32 crystallized with the formation of a new phase. The film with an atomic ratio (Te/Ni) of 2.02 crystallized with the formation of a mixture of the new phase and tetragonal TeO_2. The latter film became a white-tan, opaque film on crystallization and exhibited the "splatter" marks characteristic (1, 3) of TeO_2 formation from TeO_{2+x} ($0 < x \leq 1$). Crystallization of the films with an atomic ratio (Te/Ni) of 0.472 was not possible because the films peeled off the substrates when heated at 550°C. It is significant to note, however, that they were still amorphous after a 500°C heat treatment.

In all samples the only phases obtained on crystallization were tetragonal TeO_2, the new phase, and what appeared to be cubic NiO. The true symmetry of NiO is actually rhombohedral but the distortion of the structure from cubic is very slight and the breadth of the diffraction lines from these films was sufficient to make the symmetry appear to be cubic. In no case was trinickel tellurate, Ni_3TeO_6, obtained on crystallization. It was formed by reheating pieces of the crystallized films 177, 179, and 180 to 700°C in air. X-ray fluorescence analyses indicated that the quantity of tellurium in the films decreased after the 700°C heat

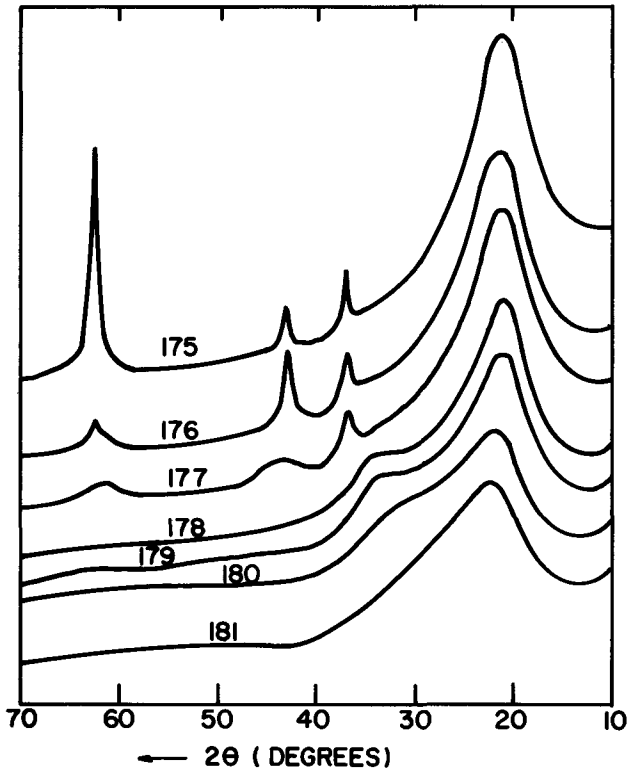

Fig. 1. Diffractometer traces of nickel-tellurium oxide films heated at 400°C for 3 hr. These traces are identical to those obtained from as-deposited films. Films are identified by deposition experiment number. The broad peak on the right is from the glass substrate.

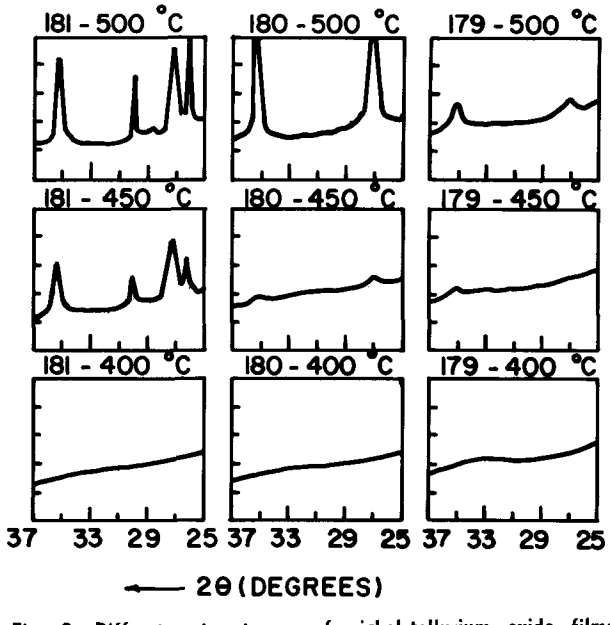

Fig. 2. Diffractometer traces of nickel-tellurium oxide films heated at various temperatures for 3 hr. Films are identified by deposition experiment numbers and temperatures of heat treatments.

treatment. This loss was undoubtedly due to vaporization of some tellurium species.

The x-ray diffraction data show that devitrification resistance of the nickel-tellurium oxide films depends highly on composition. The greatest devitrification resistance was exhibited by a film with an atomic ratio (Te/Ni) of 0.472. Films with either higher or lower atomic ratios (Te/Ni) exhibited less devitrification resistance. This suggests a region of glass formation in the nickel-tellurium-oxygen system, although no such bulk glasses have been reported.

Tellurate formation.—Whether tellurates are formed in the amorphous films must be considered further. No evidence of gas evolution or any other physical change was visible when the new phase formed upon crystallization of the amorphous films. This suggests that the oxidation state of tellurium in the new phase is the same as that in the amorphous films. Therefore, if this phase is shown to be a tellurate, it can be concluded that amorphous tellurate films have been prepared. This would also suggest that the amorphous TeO_{2+x} ($O < x \leq 1$) and bismuth-tellurium oxide films reported earlier (1, 3) represent amorphous TeO_3 and bismuth tellurate(s), respectively.

The new phase gives an x-ray diffraction pattern whose strong lines resemble those from compounds having the tetragonal rutile-type structure. Table II shows a comparison between the diffraction data from RuO_2, which is isostructural with rutile, and of the new phase which we believe to be $NiTeO_4$. The compound RuO_2 was chosen for comparison because of similarities to $NiTeO_4$ with respect to ionic radius and atomic number as well as atomic arrangement. The intensities for RuO_2 were calculated from the data of Cotton and Mague (5) using the computer program of D. K. Smith (6). The additional, weak lines in the $NiTeO_4$ data indicate that deviations from the atomic arrangement in the rutile-type structures exist which require a larger unit cell and/or lower symmetry in order to fully describe the structure.

Our first choice for comparison was the trirutile structure which Fe_2TeO_6 possesses (7, 8). The trirutile unit cell is obtained from the rutile unit cell by tripling the c axis, $c = 3c_R$, where the subscript R denotes the rutile unit cell dimensions. However, the only observed Fe_2TeO_6 diffraction lines that agree with our data in either position or intensity were those from the rutile-type subcell.

Tetragonal				Tetragonal		
$a = 2\sqrt{2}a_R = 13.1^4$ (.65) A				$a = 4.491$ A		
$c = 3c_R = 9.17$ (3.06)				$c = 3.107$		

The next possibility which we examined was that the structure of $NiTeO_4$ might be similar to that of NbO_2 (9). The NbO_2 unit cell is obtained by making $a = 2\sqrt{2}a_R$ and $c = 2c_R$. This model accounts for intensity and position of the rutile-type subcell lines and the position of some of the additional lines. We then succeeded in indexing all observable diffraction lines in the $NiTeO_4$ data by choosing $a = 2\sqrt{2}a_R$ and $c = 3c_R$. The agreement between observed and calculated line positions is shown in Table II and is within the precision of the data. However, the intensity agreement between the weak lines of $NiTeO_4$ and related lines of NbO_2 and Fe_2TeO_6 is not good, indicating that the atomic arrangement of $NiTeO_4$ is similar to either NbO_2 or Fe_2TeO_6 in gross features only. Since there are no other similar known structures to use as models, neither the quality nor the quantity of our experimental data permits more detailed analysis.

Bayer (10) has surveyed materials with the rutile-type structure and cites examples with the following general formulas: $A^{+4}O_2$, disordered $A^{+3}B^{+5}O_4$, and the two trirutile types, $A_2^{+3}B^{+6}O_6$ and $A^{+2}B_2^{+5}O_6$. Corresponding formulas in this system are then: $Ni^{+3}Te^{+5}O_4$, $Ni_2^{+3}Te^{+6}O_6$, and $Ni^{+2}Te_2^{+5}O_6$. It is probable that Te^{+5} would actually be a combination of Te^{+4} and Te^{+6}. This has been postulated but not substantiated for Te_2O_5 (11). There are apparently no reported $A^{+2}B^{+6}O_4$ compounds with the rutile-type structure, but we consider $Ni^{+2}Te^{+6}O_4$ to be the most likely formula for the new compound for the following reasons. The number of compounds in which nickel appears exclusively in the plus three state is very small and the majority of these compounds are coordination complexes, not simple salts (12). The presence of Te^{+6} in a compound with the rutile-type structure is much more likely than Te^{+4} or a combination of the two species. The ion Te^{+6} has thus far been found only in octahedral coordination (13-15), while Te^{+4} has been found only in three or fourfold coordination (16). As Zemann has pointed out in the paper just cited, oxides of Te^{+4}, which has fourfold coordination, tend to have relatively low densities when compared with oxides which have ions of similar size but with a coordination number of six. This difference also appears in unit cell size. Table III gives some data taken from Bayer (10) showing ionic radii and unit cell dimensions for several compounds which have the rutile-type structure and also for TeO_2. It is obvious that TeO_2 has a much larger c unit cell dimension. This causes a large volume difference which is primarily due to the differences in coordination, fourfold for Te^{+4} in TeO_2 and sixfold for both A and B ions in the compounds with the rutile-type structure. The close similarity between the data for $NiTeO_4$ and for the rutile-type compounds (such things as unit cell dimensions, x-ray intensities, and cation radii) lends further support to our conclusions. If either Te^{+4} or a combination of Te^{+4} and Te^{+6} were present, we would expect a larger unit cell, closer to that of TeO_2. The $NiTeO_4$ stoichiometry is also favored over the other possibilities because Film 180 with an atomic

ratio (Te/Ni) of 1.32 gives the most intense diffraction pattern, much stronger than would be expected just from thickness considerations (see Table I and Table II). Film 181 also gives a strong diffraction pattern but TeO_2 is present in an equivalent amount to $NiTeO_4$. Film 179 gives a diffraction pattern which contains only $NiTeO_4$ but it is considerably weaker than the previous two and the pattern from Film 178 is weaker still.

We obtained additional supporting evidence on the identity of the new phase by studying mixed-oxide films in systems in which similar bulk compounds have been reported. Films prepared by multicathodic reactive sputtering were thermally crystallized and examined by x-ray diffraction. Nickel-tantalum and nickel-antimony oxide films crystallized in the range 500°-700°C and yielded diffraction patterns of the known rutile-like $NiTa_2O_6$ and $NiSb_2O_6$ phases, respectively (10, 17). The crystallization of iron-tellurium oxide films at 500°-600°C produced the known (7, 8, 10) rutile-type tellurate, Fe_2TeO_6, without any visible change in the films. There is one difference between the diffraction patterns obtained from the films and those reported for the bulk compounds. The films appear to be in the disordered form because of the absence on the diffraction pattern of all super-lattice lines which distinguish the ordered trirutile form from the disordered form. A calculation of x-ray intensities for the bulk forms of these three compounds was made using the computer program of Jeitschko and Parthé (18). The results indicate that some of the super-lattice lines should be of sufficient intensity to appear in our data if the films were fully ordered. Partial ordering cannot be ruled out by our data, however. In the phases $NiTa_2O_6$, $NiSb_2O_6$, and Fe_2TeO_6, the nickel and tellurium atoms are in the +2 and +6 oxidation states, respectively. There is no reason to believe that the oxidation states differ in the nickel-tellurium oxide films. From the evidence just presented, we believe that the most likely formula for this new phase is $Ni^{+2}Te^{+6}O_4$.

Three attempts were made to prepare the new compound in bulk form. The first attempt used pressed pellets of NiO plus TeO_2 with atomic ratios (Te/Ni) of 2.0, 1.0, and 0.5. The pellets were heated in air at 500°C for 66 hr and 700°C for 24 hr. NiO and TeO_2 were seen in all samples and those heated at 700°C also contained large amounts of Ni_3TeO_6 and an unidentified phase not seen before. No evidence of $NiTeO_4$ was found. The second attempt used pellets of NiO plus a mixture of H_6TeO_6 and H_2TeO_4 with the same atomic ratios as above. These pellets were heated at 350°C for 120 hr to drive off water, repressed, and again heated to 350°C for 160 hr. The only crystalline phase seen in these mixtures was NiO, but there was also a substantial amorphous peak on the patterns. This indicates that the tellurium is in the amorphous phase which has been reported previously (11). We also attempted to grow crystals by evaporating a dilute nitric acid solution of NiO, H_2TeO_4, and H_6TeO_6. Again the product was only NiO.

Conclusions

Crystallization studies have been performed on nickel-tellurium oxide films prepared by multicathodic reactive sputtering. The devitrification resistance of the films is greatest at a composition intermediate to the two component oxides. Crystallization of the amorphous mixed-oxide films produced a new compound with a structure resembling that of rutile which has been identified as $Ni^{+2}Te^{+6}O_4$. We conclude that amorphous tellurate films have been prepared in this and in earlier (1, 3) work.

Acknowledgments

The authors wish to thank Dr. Y. S. Su for the chemical analyses and Mr. Oliver W. Kendall for technical assistance in preparing the films and bulk materials. Helpful discussions with Dr. Peter R. Segatto are gratefully acknowledged.

Technical Note

The Use of Plated Metal Films for Semiconductor Oxide Parameter Measurements

Don L. Cannon

Department of Electrical Engineering, University of Texas at Arlington, Arlington, Texas 76010

In order to measure oxide charge levels or oxide thickness by interferometer techniques, a metal film must be formed on the wafer. For many experiments, such as etch rate measurements, vacuum evaporation becomes unfeasible from the standpoint of turnaround time and the requirements for whole wafers. An alternative to such expensive and time-consuming processing is to chemical plate the metal films on the experimental wafers. While there are many electroless plating procedures, the examples described are the well-known silver plating mirror process and an electroless nickel plating procedure. In actual practice one may prefer a more immobile element nickel especially when MOS C-V measurements are to be made at high temperature. The actual plating procedures used in the experiment described are given in Ref. (1), (silver plating solution), and Ref. (2) (nickel plating). The plating procedures are summarized in the appendix for quick reference.

The technique has been verified by performing the following sequence of measurements. The oxide thickness and MOS flat-band voltages of several wafers were measured using evaporated aluminum films. The aluminum was then removed, and the silver films were chemically plated on the oxide. The oxide thickness was again measured, again using interferometry techniques. Areas of the silver located over the oxide were isolated by mechanically scraping the silver with a tungsten probe. Then the capacitance-voltage curves were traced, and the parameters shown in Fig. 1 were recorded. Then the procedure was repeated with new samples only with nickel used as the electrode instead of silver. The results of these measurements are shown in Table I. These results demonstrate that the plated films yield the same data as do the evaporated aluminum films when the measurements are conducted at room temperature. When temperature-bias measurements are required, the nickel or some other immobile (in oxide) metal element should be used.

Key words: oxide charge, interferometry.

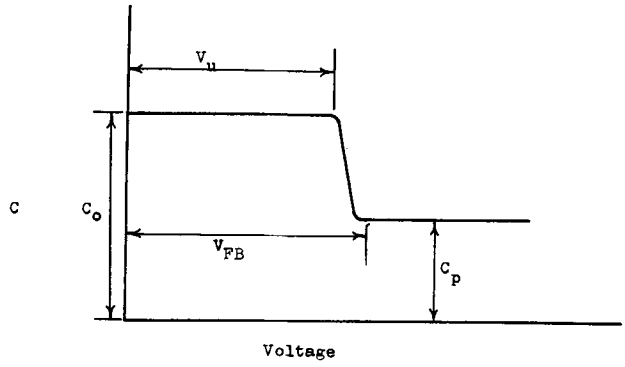

Fig. 1. Capacitance vs. voltage measurement parameters

In summary, in-process or experimental oxide parameter measurements that require the use of metal film deposits can be made accurately and simply by using a chemically plated metal film. Such metallization is then readily removed chemically, leaving the wafers ready for their next processing step. Since plating baths may be rich in alkali ions, care must be exercised in using such techniques on production wafers. In such cases, use of test wafers for the measurement of samples would be advisable.

Manuscript received Feb. 15, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Table I. Summary of results

A. Silver films

Film	Aluminum film				Plated silver film			
Parameter / Units	V_{FB} Volts	V_u Volts	C_o/C_p —	t_{ox} fringes[b]	V_{FB} Volts	V_u Volts	C_o/C_p —	t_{ox} fringes[a]
Wafer 3-1	7	25	1.25	2.1, 1.9	5, 6.5	20, 30	1.33	2.0
Wafer 3-2	15	35	1.20	2.0	13, 15	33, 35	1.33	2.0
Water 3-3	8	27	1.25	2.0	7	25	1.33	2.0

B. Nickel films

Film	Aluminum film			Plated nickel film		
Parameter / Units	ΔV_{FB}[c] Volts	C_o/C_p —	t_{ox} fringes[a]	ΔV_{FB} Volts	C_o/C_p —	t_{ox} fringes
Wafer 4-1	0	1.25	2.0	0	1.37	2.0
Wafer 4-2	1	1.20	2.0	0	1.31	2.0

[a] All measurements at room temperature.
[b] 1 fringe = 2.23μ.
[c] ΔV_{FB} is the change in the band voltage after applying +25V bias (+ on the aluminum) for 10 min.

APPENDIX A

Silver Plating Solutions

Sensitizer Solution

10 g/liter $SnCl_2 \cdot 2H_2O$
40 ml/liter HCl

Reducing Solution

90 g/liter granulated sugar
4 ml/liter HNO_3
Boil for 5 min

Solution A

50 g/liter $AgNO_3$
25 g/liter KOH

Solution B

65 g/liter $AgNO_3$

Plating Solution

Add enough NH_4OH to solution A to dissolve precipitate. Add enough solution B to this to slightly darken.

Plating Procedure

1. Clean wafers: (*a*) rinse in Acetone, (*b*) rinse in running DI water, (*c*) hot HNO_3, (*d*) rinse and store in DI water.
2. Place wafers to be plated in Sensitizer Solution for 1 min.
3. Place sensitized wafer in beaker and pour in 1 part reducing solution to 4 parts plating solution. Leave wafer in this solution for at least 1 min.
4. Rinse plated wafers with DI water and blow dry.

APPENDIX B

Nickel Plating Solution

Sensitizer Solution

Same as for Silver Plating.

Activator Solution

Palladous chloride solution 2 g/liter

Plating Solution

30 g/liter Nickel Chloride
10 g/liter Sodium Hypophosphite
10 g/liter Sodium Citrate

Plating Procedure

1. Clean wafers as in silver plating procedure.
2. Place wafers to be plated in sensitizer solution for 1 min.
3. Place sensitized wafers in activator solution for 1 min.
4. Place activated wafers in plating solution at 60°C and plate for 1 min (longer if a thicker film is desired).
5. Rinse wafers in 60°C DI water and blow dry.

Brief Communication

The Influence of Dopant Concentration on the Oxidation of N-Type GaAs in H_2O

B. Schwartz* and S. E. Haszko

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

and D. R. Wonsidler

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18100

In a recent communication (1), Schwartz described the results of exposing GaAs and GaP to various oxidizing media. He showed that when n-type, silicon-doped GaAs with an $N_D - N_A = 1.5 \times 10^{18}$ was exposed to warm (60°C) water for 6 days, a readily observable crust was formed that was identified by x-ray diffraction as $Ga_2O_3 \cdot H_2O$. Figure 1 shows the as-polished surface (bottom) and the oxidized surface (top) of that sample; this was a (100)-oriented slice cut from a <111>, Czochralski-grown ingot. The observation that the oxide was nonuniform in thickness and striated over the surface of the sample called for further investigation. The series of photographs in Fig. 2 shows the one-to-one correlation between the oxide striae and strain fields in the slice, determined by reflection x-ray topography[1]; this analysis was done on a portion of the oxidized region shown in Fig. 1.

Figure 3 shows the two halves of an identical slice of GaAs, one half of which had been boiled in water for 2 hr (top), while the other half was suspended over a beaker of boiling water in air for 2½ hr (bottom). One can see the randomly oriented scratch lines left

* Electrochemical Society Active Member.
Key words: gallium arsenide, oxidation, impurity striations.

[1] Note that the x-ray topographic technique results in a mirror image of the optical photomicrograph.

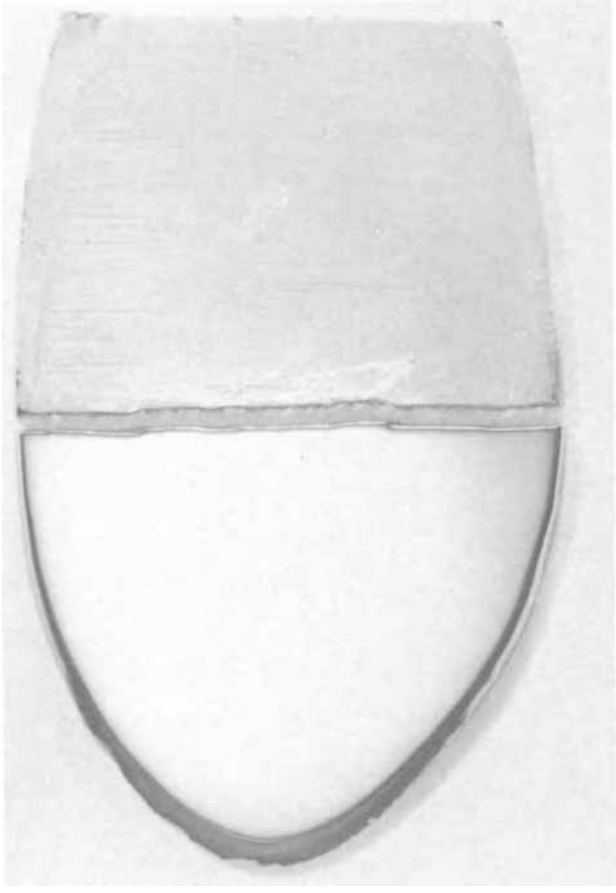

Fig. 1. Photomicrograph of (100)-oriented, Si-doped, $N_D - N_A = 1.5 \times 10^{18}$ slice of GaAs. Bottom, as-polished in Br_2-CH_3OH; top, after immersion in 60°C H_2O for 6 days (~7X magnification).

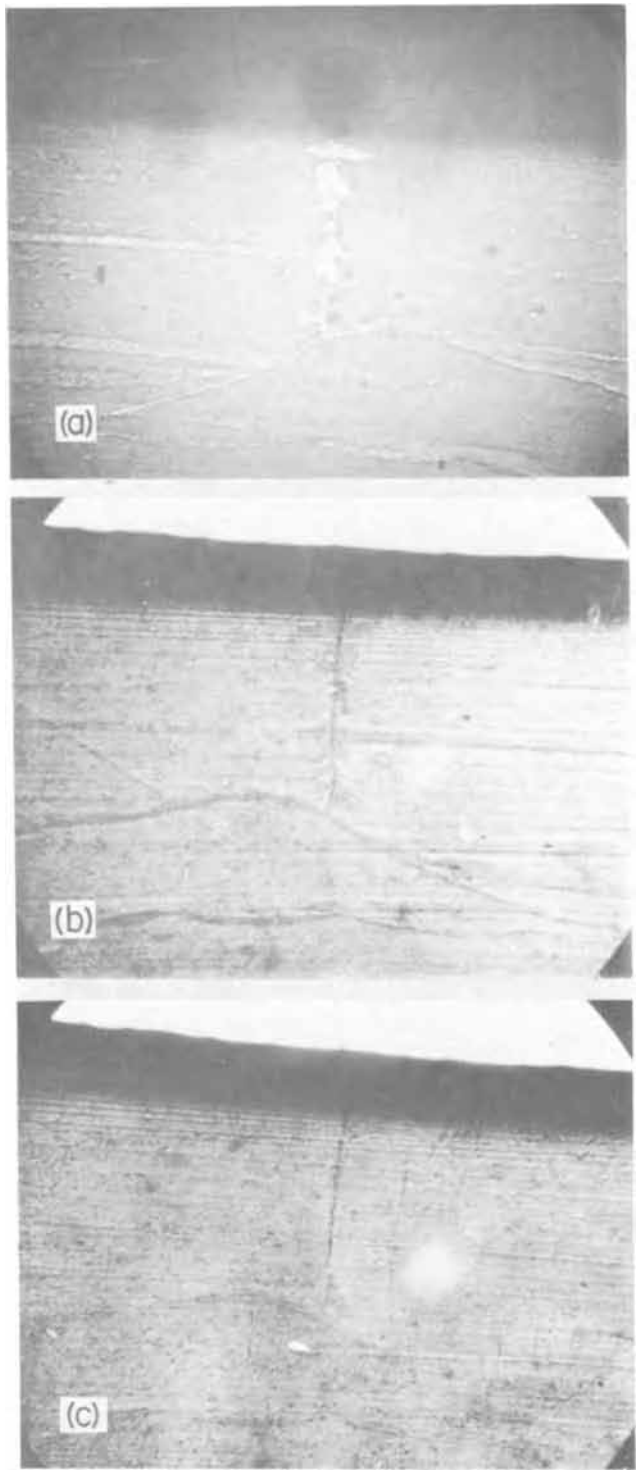

Fig. 2. Photomicrograph of portion of same sample as Fig. 1 top, showing correlation of strain fields and oxide striae: (a) optical photograph of as-deposited film (~30X magnification); (b) x-ray topograph of same area with oxide still in place; (c) x-ray topograph of same area after oxide film was removed.

in both samples from the polishing operation. Nonuniform oxidation has taken place on both pieces, and the immersed sample contains thicker oxide regions than does the sample exposed to water vapor. Note that the very clearly delineated striations are regions of lines which alternate in tilt from the horizontal. This is the two-dimensional representation one would expect to find on looking at a (100) plane cutting through an inhomogeneous medium, with the inhomogeneity being basically a helical plane, with the <111> as the major axis of the helix (2, 3). Obviously, the fact that the major striae are made up of groups of parallel striae indicates that there is also a radial inhomogeneity as well as the vertical helix to be considered.

An electron beam microprobe analysis of a portion of the oxidized sample shown in Fig. 3 (top) established: (a) that the Ga:O ratio is 1:2, a finding consistent with the formula $Ga_2O_3 \cdot H_2O$ found by x-ray analysis; and (b) that, where the oxide was thick, the integrated silicon concentration was high and, where it was thin, the integrated silicon concentration was low (see the schematic in Fig. 4). As Fig. 4 shows, at the surface of the GaAs, the silicon content was relatively uniform, while, only a short distance below the surface (about 7000Å), it was again high in the region of the thick oxide.

When these data are coupled with the fact that an attempted oxidation of GaAs doped at 2×10^{17} in boiling water for 5 hr produced an oxide only about 50-100Å thick, it becomes clear that free carrier concentration greatly influences the oxidation rate of GaAs in water. The strong striation effect seen in Fig. 3 merely reflects the free carrier inhomogeneity caused by the nonuniform distribution of the dopant, when Czochralski growth of GaAs is attempted at silicon concentrations above about 1×10^{18}.

Lest one conclude that this striation effect might be due strictly to the silicon in the samples, we can report that striated oxide growth has also been observed in the oxidation of boat-grown, n-type, Te-doped GaAs with an $N_D - N_A = 3 \times 10^{18}$, where the silicon concentration was known to be extremely low.

Manuscript received Apr. 12, 1971.

The Operation of an Ion-Membrane Fuel Cell with Microbially-Produced Hydrogen

G. C. Blanchard

Laboratory Service, Veterans Administration Hospital, Boston, Massachusetts 02100

and R. T. Foley*

Department of Chemistry, The American University, Washington, D. C. 20016

ABSTRACT

A consideration of various methods of converting the energy associated with biochemical or microbiological reactions to electrical energy indicates that the most practical approach is the indirect whereby products produced by enzymatic reactions are fed to an electrochemical converter. Hydrogen can be produced by the action of *Clostridium perfringens* on glucose and natural product substrates in technologically significant quantity and purity. The hydrogen produced by the action of *Clostridium perfringens* on glucose and bananas (as an example of natural products) has operated an ion-membrane H_2-O_2 fuel cell for periods of 24-48 hr with no evidence of detrimental reactions. Such systems operate at power densities order-of-magnitude greater than direct biochemical fuel cells wherein the enzymatic reaction takes place on the electrode. They would offer advantages for operation in remote areas.

In the last decade there has been a renewed interest in utilizing biochemical or microbiological reactions for energy conversion. Aside from scientific curiosity, the new emphasis has been derived from the desire to use cheap and readily available fuels for the production of electrical energy.

There are three general methods by which microorganisms or enzyme solutions can convert chemical energy into electrical energy: *1*) Synthesis of metabolic products which either increase or decrease the potential of the medium with respect to its original state (bioanodes); 2) Depolarization of cathodes, thus permitting spontaneous galvanic cells (*i.e.* Mg-Fe couple) to function at a reasonable rate (biocathodes); *3*) Synthesis of gaseous products (H_2, CH_4, NH_3) which can be subsequently fed to some electrochemical converter.

The purpose of this paper is to report on work employing the third conversion method, the utilization of microbially-produced hydrogen in a hydrogen-oxygen fuel cell.

Pioneering work on the utilization of microbiological reactions for energy conversion was done around 1910 by Potter (1). More precise work was done in 1931 by Cohen (2). Also, at this time Boyd and Reed (3), Clifton, Cleary, and Beard (4), and Johnstone (5) conducted experiments which were successful in clarifying the oxidation-reduction relationships developed in *E. coli* cultures. In the early 1960's the field dealing with the utilization of microorganisms to produce electrical power was revived. Sisler (6), Rohrback, Scott, and Canfield (7), and Wilson (8) described the operation of "biochemical fuel cells" based on the sulfate reduction capability of *Desulfovibrio desulfuricans,* the latter author clarifying the cathode depolarizing role of the bacteria. In this period, several attempts were made to use natural products, an objective related to the present investigation. Silverman (9) reported on a cell which involved the oxidation of formic acid produced from coconut milk, and Perry and Christopulos (10) a cell involving the oxidation of ethanol produced by the action of yeast on glucose.

From a survey of these and other reports (11) it may be concluded that no system possessing significant electrochemical capacity derived only from microbiological energy has been developed to the working state. The cells that have operated at practical power levels, derived their capacities from sacrificial anodes (*e.g.* Mg). The so called "direct" biochemical fuel cell which would have the enzyme-substrate electron transfer reaction occur on the metallic electrode has been limited by colloid chemistry considerations. Specifically, in bacterial systems the electron transfer process takes place within large molecules or within cell structures which are separated from the electrode by distances very large when compared with atomic (electron transfer) dimensions. This then suggests that the energy associated with the microbiological process might be best converted by the employment of the low molecular weight products formed during the growth of microbial cells. This has led to the investigation of the production of hydrogen by microorganisms and the utilization of microbiologically produced hydrogen in a hydrogen-oxygen fuel cell.

Blanchard *et al.* (12, 13), and May *et al.* (14) examined 18 different microbial species and showed that *Clostridium perfringens* (ATCC 10873) produced hy-

* Electrochemical Society Active Member.

Key words: fuel cell, biochemical fuel cell, microbial hydrogen, clostridium perfringens, energy conversion.

drogen at a greater rate and quantity than any of the other species. The present report deals with the utilization in an ion-membrane type fuel cell of hydrogen produced by *Clostridium perfringens* with glucose and natural product substrates.

Experimental Materials and Methods

The microorganism used in this study, *Clostridium perfringens* ATCC 10873 was obtained from the American-type culture collection, Rockville, Maryland. Stock cultures were maintained with 2% deep liver medium (15). Inocula for fermentors and Warburg flasks were prepared by growing the cells in 2% glucose deep liver medium for 18 hr at 37°C. Cells were harvested in a Sharples-type centrifuge, washed twice by centrifugation and suspended in 0.1M phosphate buffer at pH 6.5. The number of bacterial cells being studied was determined microscopically with a Petroff-Hausser counting chamber and by a standard plate count on Brewer Anaerobic Agar (BBL). The number of cells used for inoculation varied depending on the experiment being performed. In the fuel cell experiments a cell suspension sufficient to yield 5 x 10^9 cells/ml in the final fermentation broth was used.

The ability of *Cl. perfringens* to produce hydrogen from fruits and vegetables was evaluated by Warburg respirometry. The natural product resulting in the greatest rate and yield of hydrogen was then evaluated in a fermentation system. The fermentation studies were performed in tightly closed glass carboys especially adapted with sampling ports for the addition and removal of either gas or liquid samples during the fermentation. The medium (medium 1) for the glucose experiments contained 10 liters of Quinns (16) D-58 salts solution [10.9g $(NH_4)_2SO_4$, 21.8g $MgCl_2 \cdot 6H_2O$, 60.5g $K_2HPO_4 \cdot 3H_2O$, 12.0g KH_2PO_4, 1.3g $CaCl_2$ and 10 liters of tap water], 200g glucose, 100g tryptone, 100g yeast extract and 50 ml of salts B (17). Fermentors containing banana suspensions were prepared by homogenizing 2000g of bananas in 20 liters of D-58 salts solution (16) and salts B (17). The banana medium was sterilized in an autoclave deaerated with helium and inoculated by the same procedures as used for the glucose fermentors.

Gas evolution from the fermentors was recorded in a wet test meter (Precision Scientific Company). The composition of evolved gas was determined by gas chromatography using a cross-section ionization detector with 25 x ⅛ in. column of 100/120 mesh, 13 x molecular sieve and a 7 x ⅛ in. column of 200/230 mesh, silica gel as previously described (12, 13, 18). This system easily separated H_2, O_2, N_2, CH_4, CO_2, and CO and detection was in the parts per million range.

The hydrogen-oxygen ion-exchange membrane fuel cell was supplied by the Direct Energy Conversion Operation of the General Electric Company. This fuel cell which uses air as the oxygen source, and operates at one atmosphere of pressure was assembled with the instrumentation as shown in Fig. 1. The input gas line to the fuel cell was attached to a three-way valve which permitted operation of the system first on tank helium to flush the cell, then on tank hydrogen to calibrate, and then on hydrogen supplied by the microbial generator. The unit was cooled by flowing tap water. The cell was flushed with helium for 15 min before and after use, and stored under helium. The exposed membrane was kept moist during use by occasional wetting with distilled water. During storage the exposed membrane was moistened and sealed.

Results and Discussion

Hydrogen generation from glucose and natural products.—The objective of the microbiological studies was to develop a hydrogen generator which would produce hydrogen of sufficient quantity and purity to operate a hydrogen-oxygen fuel cell at a practical level. To accomplish this objective, studies were performed to determine the factors which limit the rate

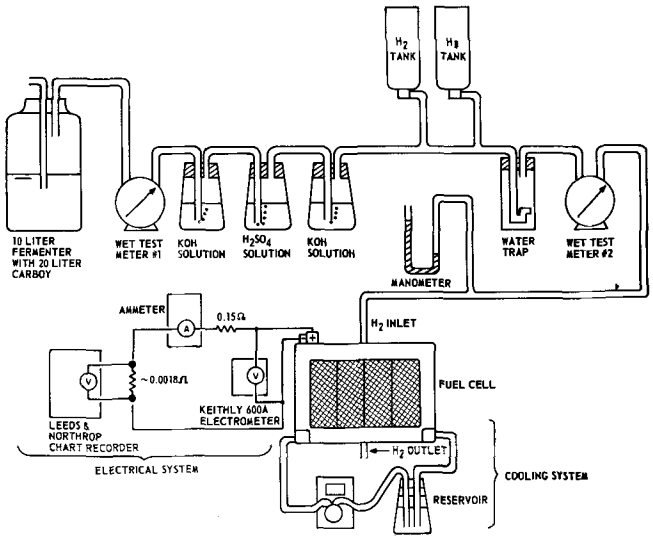

Fig. 1. Experimental arrangement with ion-membrane fuel cell utilizing microbially-produced hydrogen.

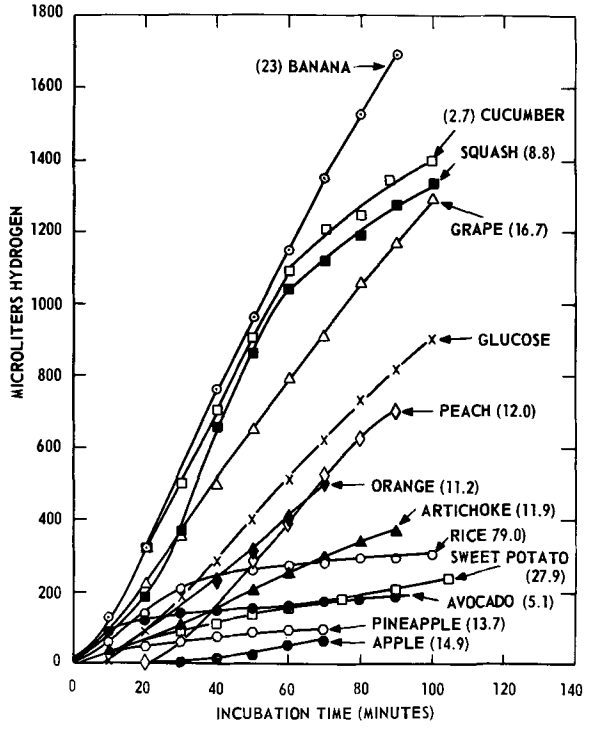
and total yield of hydrogen production as well as to establish the conditions required for maintaining continuous hydrogen evolution and power production by the microbial fermentor system. These studies will be reported in detail elsewhere (19) but certain observations can be made to summarize the pertinent findings as follows:

1. Hydrogen evolution was proportional to cell number between 3 x 10^8 and 3 x 10^9 cells. Beyond this number a lower hydrogen yield per cell was obtained.
2. Both the initial pH and the incubation temperature were important in the synthesis of the hydrogen evolving system. The greatest activity per (resting) cell was obtained at 30° to 35°C in a medium with an initial pH of 5.0-6.5. Essentially no hydrogen was formed by cells grown at 40°C at any pH.
3. For growing cells the optimum pH for growth was between pH 5.9 and 7.5, whereas the optimum pH for hydrogen generation was between pH 5.9 and 6.9.
4. Hydrogen production in the fermentors appeared to be directly related to the glucose concentration; the bacterium produced 34 liters or about 1.5 moles of hydrogen from 0.77 moles of glucose.
5. It appeared possible to obtain continuous gas production in the fermentors by using a large inoculum, a nonlimiting substrate concentration, and a pH between 5.5 and 7.0.
6. Using optimized conditions hydrogen could be produced at a constant rate of about 10 liters per hour.
7. The study of the ability of *Cl. perfringens* to metabolize fruit and vegetable homogenates, as tested in a Warburg respirometer, showed that the resting cells produced hydrogen without lag and that the rate of production and total yield was greater with banana, cucumber, squash, and grapes than with glucose or other natural products (Fig. 2).

Fuel cell studies with microbial hydrogen generators.—After demonstrating that hydrogen production by microbial generators could be maintained at a uniform rate the power output by the hydrogen-oxygen fuel cell was studied using microbially-produced hydrogen. The system used for fuel cell calibration and for determining power production by the microbial fermentors is shown in Fig. 1. For calibration, the fuel cell was first flushed with helium for 15 min and then flushed with tank hydrogen. Tank hydrogen was allowed to flow through the fuel cell at a rate in excess of the fuel cell consumption. The input hydrogen rate was measured but no attempt was made to measure the excess output hydrogen except by visually observing it bubble through approximately ½ in. of water. The helium flush was used to remove oxygen



NUMBERS IN PARENTHESIS REPRESENT APPROPRIATE CARBOHYDRATE COMPOSITIONS ON BASIS OF WET WEIGHT (WOOSTER AND BLANDS)

Fig. 2. Production of hydrogen from natural products

which might have entered the internal membrane surface during storage.

After demonstrating that the fuel cell was performing properly, a microbial generator containing 10^{14} cells in medium 1 was assembled as shown in Fig. 1. The microbial generator was permitted to incubate and thus flush with microbial hydrogen for 2 hr before connection to the fuel cell. During these 2 hr the fuel cell was flushed with helium for about 30 min, followed by hydrogen for 90 min. Hydrogen from the microbial generator was allowed to flow through the fuel cell at a flow rate of 7 liters/hr. In the initial experiments hydrogen generation decreased during the periods when glucose and NH_4OH were added to the fermentation mixture. However, these problems were overcome by the use of glucose solutions, previously deaerated by nitrogen flushing and by slow addition of the glucose and NH_4OH to the bottom of the fermentor. Although some fluctuations were observed in hydrogen production during the 22 hr experiment, power production was steady between the 3.1 and 3.3W (Fig. 3). Glucose and NH_4OH were added periodically to maintain a nonlimiting substrate concentration and a pH between 5.6 and 6.8. At the end of the experiment the fuel cell was tested with tank hydrogen to make certain that no loss in efficiency had occurred.

The microbial generator system used for demonstrating power production from bananas was identical to Fig. 1 except two 10 liter fermentors were used to make certain that hydrogen production would be in excess of the fuel cell requirement. Each of the two fermentors were prepared as described above and contained 2000g of homogenized bananas in D-58 salts solution and an inoculum of 10^{14} cells of *Cl. perfringens*. The microbial generator was flushed with its own gas for 3 hr while the fuel cell calibration was being performed. The hydrogen line from the microbial generator was clamped off for 10 min prior to connection to the fuel cell. This step partially eliminated the fluctuation in pressure which occurs when the microbial generator is connected to the fuel cell. The results in Fig. 4 show that the 2000g of bananas added initially contained sufficient quantities of fermentable carbohydrate to maintain the hydrogen evolution rate relatively constant for 24 hr. As a result of this, the power output was maintained between 3.1 and 3.5W for the 24 hr. It is believed that the fluctuations which did occur in the hydrogen evolution rate were due to changes in the pH of the medium and that an automatic pH controller would eliminate this variation.

These studies demonstrate the feasibility of using microorganisms to convert natural products into hydrogen for use in a hydrogen-oxygen fuel cell. No serious problem was found in coupling the biochemical hydrogen generator to a commercially available fuel cell. Although no problems were observed in 24 to 48 hr operation, studies of greater duration would be needed before conclusions could be drawn about long-term performance. However, the gas chromatographic analysis of the gas does not indicate the presence of compounds such as CO which are known to poison the catalytic electrodes of the fuel cell.

The ability to use hydrogen from fruits and vegetables suggests that this approach for utilizing microbiological energy offers potential for use in remote areas, because the unit can operate on natural products obtained on-site. This, of course, offers certain logistic advantages over most of the other presently available hydrogen generators.

A comparison of these results with those reported for the direct approach (methods 1 and 2 above) indicates that the indirect biochemical fuel cell approach for generating energy from biological materials is far more successful than the direct approach. A good direct

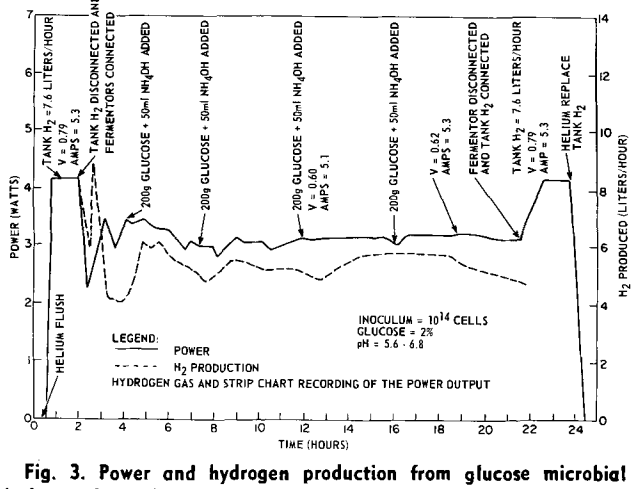


Fig. 3. Power and hydrogen production from glucose microbial hydrogen fuel cell system.

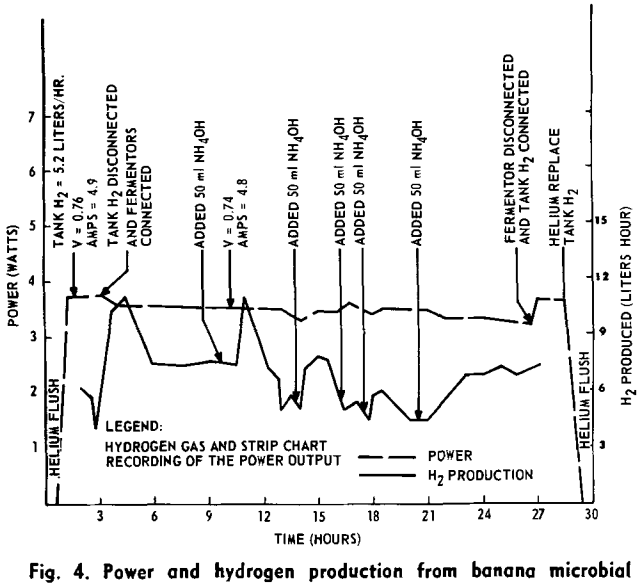

Fig. 4. Power and hydrogen production from banana microbial hydrogen fuel cell system.

biochemical fuel cell will produce about 10 mA at 0.3V with a 100 cm^2 electrode, or a current density of 0.1 mA/cm^2 at 0.3V. Microbially produced hydrogen in the H_2-O_2 fuel cell produced about 5A at 0.78V with an air electrode size of 272 cm^2. This is about 18 mA/cm^2 at 0.78V. Thus, the indirect approach has given 100 to 500 times greater current densities than the direct approach, and has bypassed all the nettling electrochemical difficulties which followed from the direct approach. In using the indirect method of utilizing microbiological processes the limitation in the electrochemical sense is imposed by the hydrogen-oxygen fuel cell rather than the microbiological process. Until the problems associated with electrode reaction in solution are solved, the direct approach will probably always give much lower current densities than the indirect approach. Because there are no obvious solutions to these problems, it would appear that future effort can be more profitably directed to the indirect approach.

Electroless Copper Plating as an Image Amplifier for Electrolytic Printing

Dennis R. Turner* and Catherine Wolowodiuk

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Electroless copper plating was found to be an effective image amplifier for silver electrolyzed into paper. An amplification factor of up to one million times was demonstrated. The small amount of silver required to produce an image makes high-speed electrolytic printing feasible. This was demonstrated with 1 μsec-20V pulses used to electrolyze silver into a moving paper, followed by electroless copper plating.

Electrolytic printing is an old art. The first record of its use or recording facsimile was in 1843. The technique was used for many years in telephone and radio facsimile recording where immediate visual observation of the result was more important than the print quality (1). Electrolytic printing has also been used for qualitative analysis of a metal by electrolytically dissolving the metal into paper containing a specific reagent capable of producing a colored reaction product with the metal ions (2).

To our knowledge, the only present-day commercial application of electrolytic printing for facsimile application is in the Stewart-Warner System known as Datafax. In Datafax printing, an electrolyte premoistened paper is slowly pushed between two electrodes. The cathode is mounted on a drum in a spiral fashion so that, as the drum rotates once, the cathode area which contacts the paper moves across the entire width of the paper. The anode is a strip of silver on the opposite side of the paper. Silver is electrolyzed into the paper from the anode bar where it is reduced to the metallic form by a chemical reducing agent contained in the paper. The entire image is composed of finely divided silver particles which appear black in the paper. The speed of printing is relatively slow since the rate of anodic silver dissolution is limiting. An 8½ by 11 in. page of print is reproduced in about 6 min. The silver anode bar must be replaced periodically as it is consumed. The Datafax technique cannot be speeded up to produce 1 page of printed copy in about 2 sec as is required for some applications. The cathode drum rotation speed becomes too high and it is not

Key words: silver electrolysis, pulse anode dissolution, paper-supported electrolyte, catalytic sensitivity, hard copy.

practical electrochemically to electrolyze enough silver into the paper in the time required.

This paper describes a new process in which relatively small amounts of silver are electrolyzed into the paper from stationary multiple electrodes. This silver serves as a catalyst to carry out electroless copper metal deposition which serves to amplify the latent silver image. Since very small amounts of silver are required, the process is sensitive and high writing speeds can be achieved. A prime advantage of electrolytic printing over electrostatic printing is that it can be carried out at relatively low voltages between 2 and 20V as compared to 300-600V for electrostatic methods. One important consequence of this is that cheaper solid-state electronic devices can be used for accessing individual electrodes of multiple arrays when low voltages are involved.

Over-all Description of Electrolytic Printing Technique

A schematic view of the electrolytic printing process is shown in Fig. 1. The paper is preimpregnated with electrolyte, rolled tightly, and kept in a confined compartment. This arrangement keeps the paper moist for long periods of time—months. As printing is required, the paper is passed over an electrode assembly. Good image resolution can be achieved with an electrode array 8 in. wide and segmented into about 1700 individual electrodes. These can be accessed by electronic means, so that pulsed printing signals are fed into individual electrodes as the paper moves by. Counter-electrodes can be placed on the opposite side of the paper but, for very rapid paper transport, it is more practical that both anode and cathode electrodes are on the same side as illustrated in the printing electrode detail shown in Fig. 1. Very small amounts of silver are electrolyzed into the paper with each pulse and this is amplified with an electroless plating solution. Finally, the paper is cut into suitable length to provide the hard copy required. A detail of the electrode assembly is shown in cross section indicating one silver anode electrode and one platinum cathode. Electronic techniques are available so that it is not necessary to provide a separate cathode electrode for each anode.

All the common metals available were tried as anode electrodes; however, silver proved to be most effective. Other materials were also tried in place of platinum; nickel was found to be suitable. Most of the exploratory work was done with pairs of electrodes—one silver and one platinum spaced 12 μm apart with Mylar film and potted in epoxy resin.

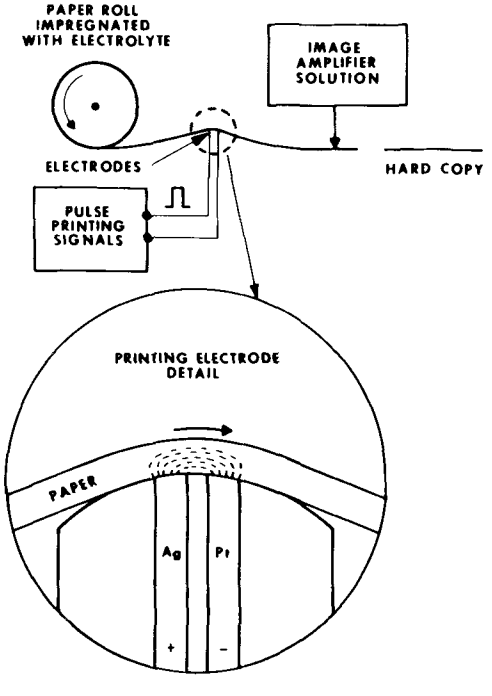

Fig. 1. Schematic of electrolytic printing process

The paper used for electrolytic printing must meet certain requirements: (*a*) high absorbency to electrolyte and development solutions, (*b*) good wet strength, (*c*) reasonably smooth surface, (*d*) long-term stability to solutions and residues, and (*e*) low cost. The paper industry has developed papers which meet these requirements. They are mainly cellulose-base papers containing an organic polymer (usually melamine-formaldehyde resins). Most of our work was done with paper developed for the Datafax printing process.

The paper was preimpregnated with either sodium or potassium nitrate solutions, 0.1-1 normal. Current flows between the silver and platinum electrodes through the paper as a voltage pulse is applied. Silver dissolution occurs at the anode and nitrate reduction takes place at the cathode. It is not clear at this point whether the silver enters the paper as silver ions or a silver oxide is formed which is wiped off by the moving paper. In either case, the silver is reduced to metallic silver in the presence of the reducing agent used in the electroless copper plating solution. The cathode reaction involves the reduction of nitrate ions. This is a low cathode polarization reaction with no gas evolution to complicate the printing process. One reason silver is such a good anode electrode material is that the kinetics of silver dissolution are extremely favorable as illustrated in Fig. 2. The Tafel relation was constructed from exchange current data reported by Price and Vermilyea (3), 7 A/cm^2 and a transfer coefficient of 0.32 as determined by Gerischer (4). Typical current densities using 20V pulses of 1 μsec duration are about 80 A/cm^2. Even at this high current density, as seen in Fig. 2, the polarization voltage is only slightly more than 0.3V. Therefore, silver dissolution does not appear to be a limiting process. Most of the applied potential appears as an *IR* drop in the paper between the electrodes.

An oscilloscope recording of the voltage pulse applied to the electrodes and the resulting current pulse are shown in Fig. 3. The top curve is the voltage pulse. The vertical axis is 2V per large division; thus, the applied pulse is 11.2V. The time axis is 1 μsec per large division so that the pulse is about 2 μsec long. The corresponding current pulse reaches a maximum of 30 mA and decreases slightly with time. This corresponds to a current density of about 55 mA/cm^2 at the silver anode. The electrolyte used in this experiment was 0.5*N* sodium nitrate solution.

Assuming a double-layer electrode capacitance of 20 μf/cm^2, the number of coulombs required to charge the double layer to the full voltage of 11.2V is about 1000 times less than the total coulombs in the current pulse. Thus, most of the current flowing during each pulse electrolyzes silver into paper.

Study of Electroless Plating Process

Preliminary results indicated that an electroless copper plating solution could be used as an image amplifier. However, it was necessary to optimize the process so that image amplification could be maximized. Previous work (5) indicated that there is a minimum amount of catalysis which will initiate plating for a given electroless metal plating solution and conditions.

A simple technique was developed to test the effect of modifying the electroless copper bath composition and temperature on the ability of the process to develop a latent silver image in paper. Strips of No. 1 Whatman filter paper about 1.4 cm wide and 7 cm long were ruled into five sections 1.4 cm long. A 0.05 drop of silver nitrate solution from a microsyringe was placed in the center of each section. By varying the silver nitrate concentration of the drop placed in each section, a range of silver concentrations was achieved in each paper strip. Silver ions probably were reduced to metallic silver by room light; however, the reducing agent in the electroless plating solution would convert

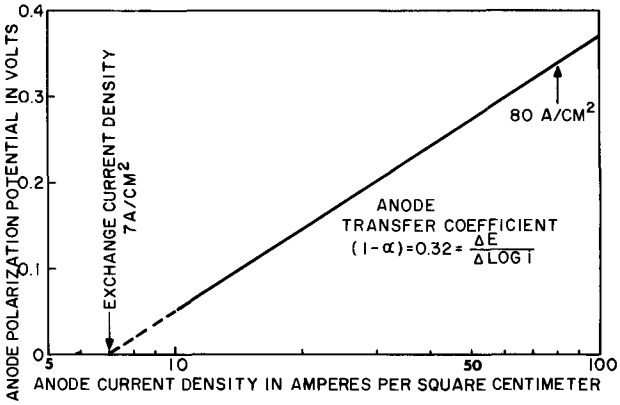

Fig. 2. Silver anode polarization relation from kinetic parameters: $i_o = 7$ A/cm² and $(1 - \alpha) = 0.32$.

any unreduced silver. The paper strips could be made up in quantity, dried, and stored for later use.

The effect of temperature on electroless copper plating sensitivity with various amounts of silver is illustrated in Fig. 4. The total amount of silver placed in each section ranged from 5×10^{-12} to 5×10^{-8}g. The area of the developed spot varied from about 0.16 to 0.33 cm². The images were black or dark brown and permanent-ideal for hard copy. Thus, the amount of silver per unit area ranged from about 3×10^{-11} g/cm² for the lowest to 1.5×10^{-7} g/cm² for the highest in Fig. 4. It is well known (6) that increasing bath temperature increases the electroless copper plating rate. The results of Fig. 4 show that increased temperature also increases copper plating sensitivity to small amounts of silver catalyst. The optimum bath (to be described later) was used in this experiment. A 10 deg increase in temperature (50°-60°C) results in a 100 times increase in sensitivity. The over-all image amplification capability of electroless copper plating at 60°C is about one million times. This was determined by increasing the silver concentration in each drop until a visible image in reduced silver was observed. This occurred at a silver concentration of 5×10^{-5} g/cm² on the paper.

At 60°C, an unstabilized electroless copper bath decomposes in a few minutes. However, the copper image on silver develops in a few seconds at 60°C so there is a margin of safety. Furthermore, a fast development time is desirable for a practical printing process and the hot solution facilitates drying.

The composition of the electroless copper bath was studied to optimize it for maximum sensitivity without premature bath decomposition. Copper ion concentration, complexing ion and its concentration, reducing

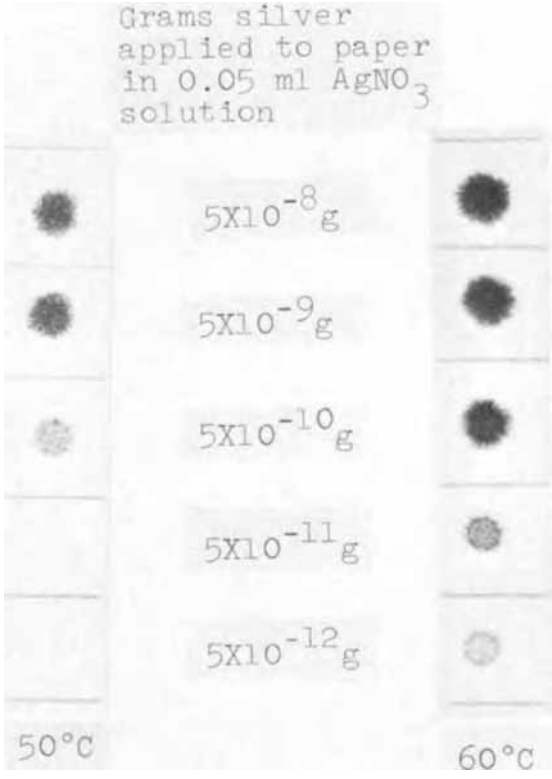

Fig. 4. Effect of electroless copper solution temperature and silver concentration in paper on image development sensitivity.

agent concentration, and *p*H were varied. The calibrated silver spots on paper strips[1] were used to observe the effects of bath composition changes. The effect of copper concentration is shown in Fig. 5—between 10 and 60 g/liter copper sulfate—$CuSO_4 \cdot 5H_2O$. In these experiments, Rochelle salt complexing agent concentration was 2½ times the copper concentration. KOH concentration was equal to the copper concentration and development time was 5 sec. The temperature was 60°C. At 10 g/liter, the image was just visible at 5×10^{-10}g of silver. Whereas, at 60 g/liter copper sulfate, a dark image is visible at 5×10^{-12}g silver but

[1] This idea of a catalyst-impregnated paper strip is considered to be a simple and convenient way of monitoring the condition of any electroless metal plating bath and particularly one that must initiate plating on surfaces containing a relatively small amount of catalyst. This work also suggests that, under certain conditions, two electroless baths may be desirable: one which initiates metal deposition with very small amounts of catalyst present but has a short life, and a second which deposits that bulk of the metal with good physical properties and has a long bath life.

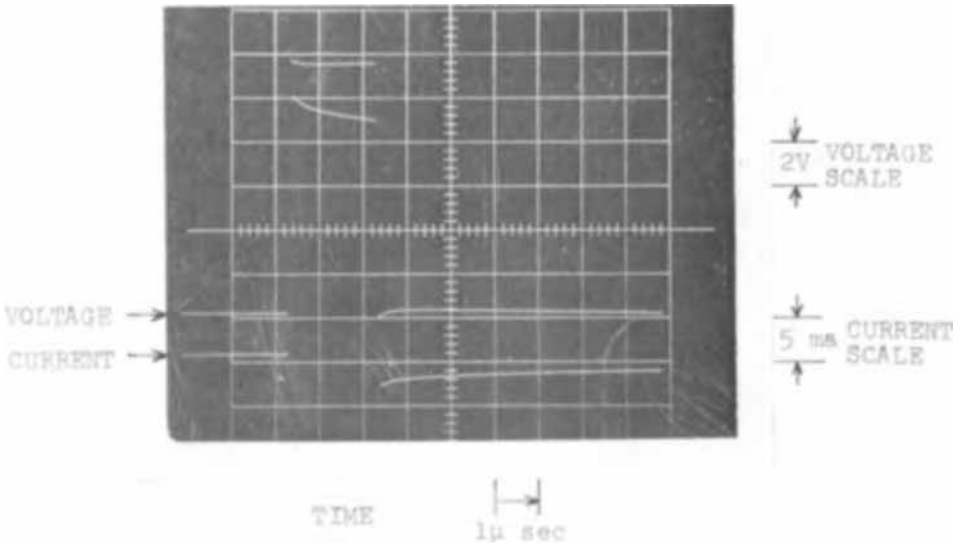

Fig. 3. Typical voltage pulse and corresponding current pulse. Silver anode and platinum cathode. Electrolyte 0.5*N* $NaNO_3$.

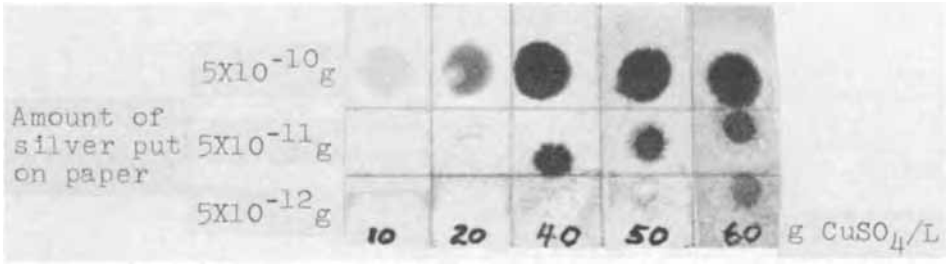

Fig. 5. Effect of copper sulfate concentration on sensitivity of the electroless copper amplification process.

the bath decomposes and darkens the paper. On the basis of this study, 20-40 g/liter copper sulfate were considered optimum.

Rochelle salt was found to be better than EDTA[2] as the copper complexing agent, and paraformaldehyde was better than formaldehyde as the reducing agent since it left less residual odor in paper. The optimum solution composition arrived at is as follows:

Electroless Copper Image Amplifier Solution

Part A	g/liter
Copper sulfate ($CuSO_4 \cdot 5H_2O$)	40
Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$)	100
Potassium hydroxide (KOH)	40
Part B	
Paraformaldehyde $(HCHO)_3$	130
Potassium hydroxide (KOH)	120

The bath is made up in two parts. As an image amplifier, an equal volume of each part is mixed together so that the final concentration of each constituent is one half that shown above (for example, 20 g/liter copper sulfate, *etc.*). It is estimated that, to develop an 8½ by 11 in. page of print, about 5 cc of electroless copper solution are required.

Over-all Feasibility Study

The initial phase of a feasibility study on the over-all technique was carried out using stationary electrodes consisting of one silver and one platinum electrode. Later, a multiple electrode array was used. The problem of moving paper past the electrodes at the required speed to simulate printing 1 page in 2 sec without resorting to a large expensive machine was resolved by adapting a record player capable of turntable rotation speed of 16 rpm. A strip of premoistened Datafax paper, 2 cm x 5 cm, attached to a 12 in. long-play record about 5 in. (12 cm) from the center moves at about the right speed at 16 rpm. The spacing between microgrooves on an LP record is 0.17 mm which is about the spacing desired between electrodes across a page, and between scan raster lines down the page. The electrode assembly was fastened to the record player needle transport head and, while the record needle tracked in the microgrooves, the electrode assembly moved over 0.17 mm each revolution. An E-H Research Laboratories, Incorporated, electronic pulser generated a 1 μsec 20V pulse with 1000 μsec between pulses. These pulse trains were interrupted with a mechanical switch made by attaching a gold foil to the edge of the record and masking off sections of gold with Scotch tape. A spring contact then was placed on the record at that point and, as each conducting strip moved past the contact, voltage pulses were applied to the printing electrodes.

After a latent image of silver is printed into the paper, the image is made visible with electroless copper plating as previously described. Success of the printing process with very short pulses down to 1 μsec and 1000 μsec between pulses is illustrated in Fig. 6.

[2] Ethylenediamine tetra acetic acid-sodium salt.

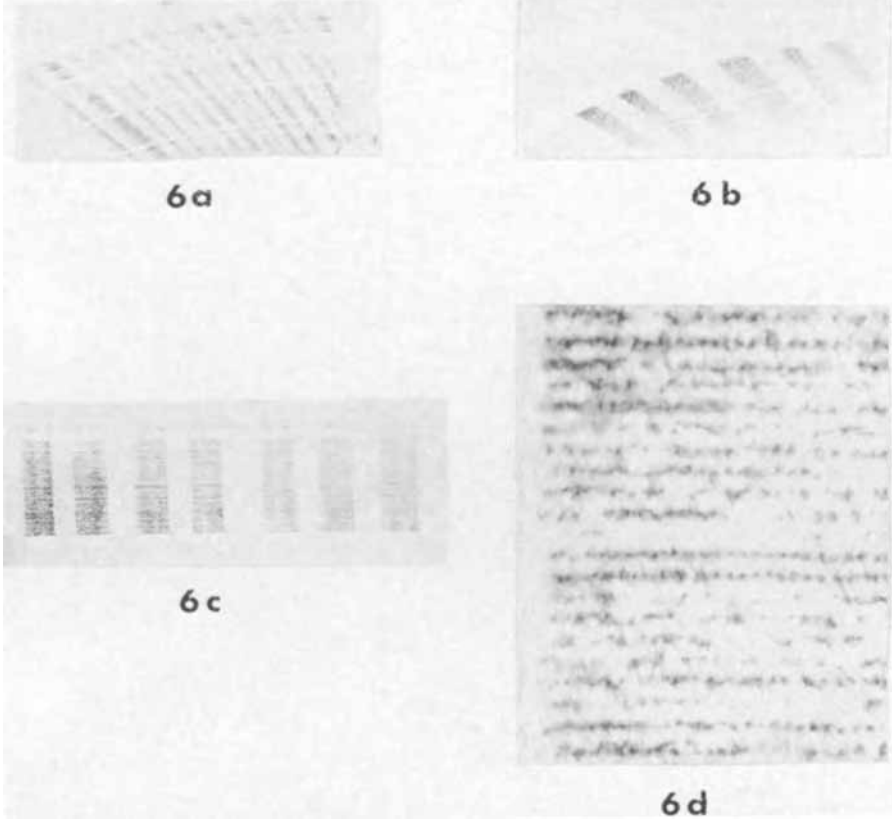

Fig. 6. Examples of high-speed electrolytic printing with electroless copper image amplification. a—Image with 1 μsec-20V pulses 1000 μsec apart; paper moistened with 0.1*N* HNO_3; paper speed ~ 14 cm/sec. b—Same as in a; paper allowed to dry while printing. c—Image with multiple electrode printing head; electrodes 0.1 mm wide and 0.1 mm between electrodes; 30 μsec-20V pulses 1000 μsec apart. d—Magnified view of c.

The total time required to record the entire image in Fig. 6a and 6b was about 15 min. In that time, the paper tended to dry out. Therefore, in Fig. 6a the paper was kept moist with 0.1*N* HNO_3 solution. In a real electrolytic printing system, the paper would move by the electrodes only once and drying would not be a problem. The dampness of the paper is an important variable in determining the current through the paper and the amount of silver electrolyzed into the paper when voltage pulses are used. Therefore, constant current pulses are more desirable to maintain a uniform image density. Figure 6b shows the effect of drying as the paper is rotated on the record player with constant voltage pulses. The image becomes lighter with each revolution since the electrolysis current is decreasing. The result does show that the technique has a gray scale potential. In practice, the image darkness could be varied by modulating the current level of printing pulses.

Experiments were also carried out with multiple silver electrodes. These were made using standard thin film device technology. The silver electrodes were 0.1 mm wide with 0.1 mm spacing between them. Typical images formed with these multiple electrode printing heads are shown in Fig. 6c. The 1.3 cm wide electrode array contained 65 individual electrodes. For these experiments they were connected together, but for printing useful information each electrode would need to be accessed electronically. In this arrangement, a common platinum cathode was placed on the opposite side of the paper. Premoistened paper was moved past the electrodes only once at the same speed as before, 1 page length in 2 sec. The image in Fig. 6c was printed with 30 μsec-20V pulses spaced 1000 μsec apart and intensified with electroless copper plating.

A magnified view of part of Fig. 6c is given in Fig. 6d. The image introduced with the 30 μsec pulse is evident as dark spots and the spacing between spots is 1000 μsec. The spacing between the center of each row of dots is 0.2 mm. Image quality at the magnification in Fig. 6d is poor, but it is comparable with many commercial copying processes. Image resolution could be improved if the paper were smoother without individual fibers protruding. Gelatin coated papers were tried and they did improve image resolution. However, gelatin absorbs copper solution during image intensification, causing the paper to darken.

Summary and Conclusions

Electrolytic hard copy printing with electroless copper plating image amplification is capable of high-speed printing. Extremely small amounts of silver introduced into paper by whatever means are capable of initiating electroless copper plating. Image intensification by the process can be as high as one million times.

Advantages of the process are: (*a*) it is capable of high-speed facsimile printing, (*b*) it operates with relatively low voltage pulses, (c) the image is dark and permanent, and (*d*) an inexpensive paper may be used.

The disadvantages include: (*a*) image development is a wet process, (*b*) paper contains residual salts, and (c) the silver printing electrodes erode and must be renewed periodically.

Finally, electrolytic printing with electroless copper amplification may have some application for printed circuit pattern generation. Computer generated pulse trains could print any desired metallic pattern. Techniques developed for computerized drafting should be useful here. The substrate must be somewhat porous to retain electrolyte and provide mechanical adhesion for the image and electroless metal deposit.

Electrochemically Thinned N/N$^+$ Epitaxial Silicon—Method and Applications

Ronald L. Meek*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The method of thinning n/n$^+$ epitaxial silicon wafers by selective anodic dissolution of the substrate in aqueous HF is described. Some of the properties of the system are discussed and applications are presented. It appears the technique is best suited for use where the material has not had extensive prior processing, especially n$^+$ diffusions, and/or where the epitaxial layer is of high resistivity. The most promising areas of application appear to be: (*a*) fabrication of thin films for experimental purposes, (*b*) thinning of simple diode arrays, and (c) solid dielectric isolated IC fabrication. Considerable impediments to use of the process are the necessity of having epitaxial layers of unusual perfection and the fact that local anodic etching occurs at sites of high carrier generation.

While thin silicon ($\sim 1\mu$) is of interest for some high-frequency, high-power device applications (1, 2), its primary impact is expected to be in the field of air or solid dielectric isolated integrated circuitry where thin slices lead to small junction-junction spacing and potential economic advantages. Selective etching techniques have seemed a natural method for thinning, as it has been known for some years that silicon may or may not be anodically dissolved depending on the type and resistivity of the silicon, its electrical potential, and the properties of the solution. In particular, it is well known that n$^+$ and p-type silicon readily dissolve when anodically biased in HF solution, whereas n-type does not (3). This knowledge has led to a method for removing the substrate of an n/n$^+$ epitaxial wafer leaving the thin n-epi layer (4, 5).

Method

The basic method of wafer thinning is, in principle, rather straightforward: an n/n$^+$ epitaxial wafer, which might have previously received some or all of the normal planar device processing, is mounted with acid-resistant wax on a sapphire plate with the n$^+$ side exposed. The silicon is then biased anodically relative to a platinum mesh cathode and the electrodes are lowered into a 5 w/o (weight per cent) aqueous HF solution; the n$^+$ substrate is selectively dissolved, leaving the thin n-type epitaxial layer.

There has apparently been some confusion as to an appropriate way to make electrical contact to the slice. Contact should not be made across the n-side of the wafer since, as will be seen shortly, it is unwise to maintain the n-material at a higher potential than necessary for an extended time period. Furthermore, if p-diffused regions are present in the n-layer and if electrical contact is made to them, which will be practically unavoidable, areas will be etched through on the slice since the forward-biased p-n junctions will inject holes into the n-layer allowing it to dissolve electrochemically.

If a wire is simply clipped to the n$^+$ side, an irreproducible and likely nonlinear contact resistance will result and the actual cell potential will be unknown. A simple method of circumventing this and maintaining a constant silicon potential regardless of current or contact resistance is illustrated in Fig. 1. Two platinum wires are clipped to one edge of the n$^+$ side of the wafer. An operational amplifier implemented as shown then maintains the cell voltage constant at the power supply setting, V_c. For applications where potential control is extremely critical, the potential sensing lead may instead be connected through a buffer amplifier to a reference electrode with the silicon grounded and amplifier output to the cathode, thereby achieving potentiostatic control. (In Fig. 1, the reference electrode serves only as a monitor, and may be omitted for routine work.)

The apparatus used for silicon thinning is schematically shown in Fig. 2. It consists essentially of a gear-driven raising and lowering mechanism. The apparatus is contained in a light-tight box (not shown)

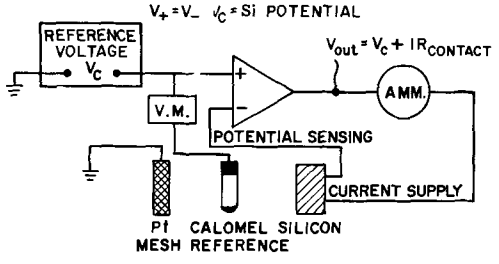

Fig. 1. Circuit to maintain constant cell potential

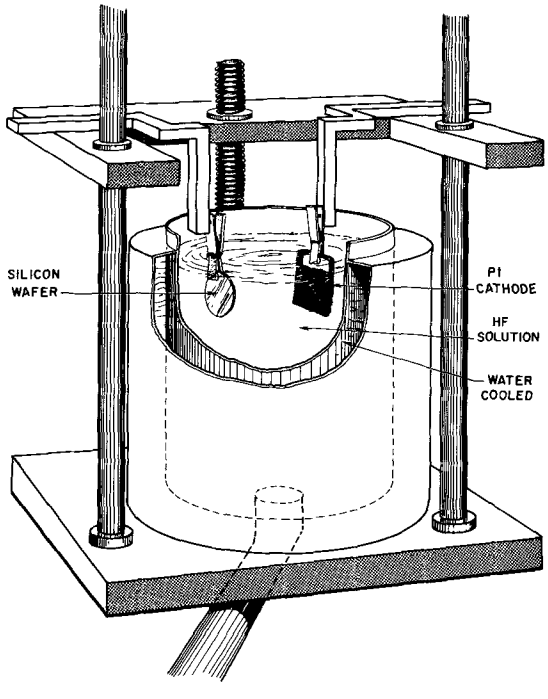

Fig. 2. Lowering apparatus for wafer thinning

* Electrochemical Society Active Member.

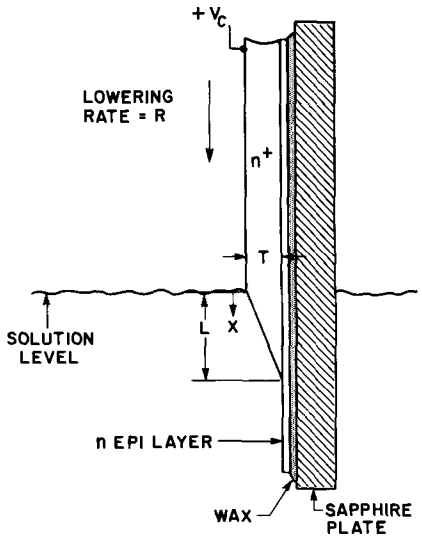

Fig. 3. Expanded view of silicon wafer being thinned

and the electrolyte container is water cooled. The platinum mesh cathode has a projected area of 25 cm² and is 1 cm from the silicon wafer.

Discussion of the lowering is facilitated by reference to Fig. 3. The wafer may not simply be completely immersed initially as the impedances involved are such that the current will flow from the silicon into the solution over an area close to the contact, or the solution-air interface as the case may be; and, consequently, only this area will be thinned. Rather, suppose the wafer is lowered into the solution producing the wedge-shaped remnant of n^+ material below the solution surface ($x = 0$) as illustrated in Fig. 3. Now, if the lowering rate is too large, the potential distribution will be such that sufficient current will not reach the bottom of the wedge ($x = L$) to electropolish it; consequently, in time, L will increase and the material will not be totally removed.

For steady state and $L >> T$, the lowering rate, R, is related to the etch rate, E, by

$$R = \frac{L}{T} E \qquad [1]$$

For n^+ material, the etch rate is approximately 0.02 cm/hr (6).

The determination of the maximum L which can be tolerated is not readily amenable to analysis but has been determined experimentally to be in the range 0.1-0.5 cm, depending on the substrate resistivity, the applied potential, and on the substrate thickness, T. The following table summarizes the experimentally determined R_{max} for various substrate thicknesses at $V_{cell} = 6V$ for $\rho = 0.001$ ohm-cm and <111> orientation.

T (mil)	R_{max} (cm/hr)
10	0.2
5	1.0
3	3.0

These values supply a sufficiently good design criterion for $\rho = 0.01$-0.001 ohm-cm, $V_{cell} = 5$-$10V$, and <111> or <100> orientation, as it has been found that R_{max} depends most strongly on the thickness, T.

Most satisfactory results have been obtained with substrate thicknesses in the range 3-7 mils and $R \simeq 0.7 R_{max}$. It is often desirable to mechanically thin (lap) or chemically etch thicker wafers to this range to minimize wax deterioration due to extended exposure to HF and also to reduce time-dependent attack on the n-layer (6).

To permit selection of an appropriate cell potential for a given substrate resistivity and orientation, the

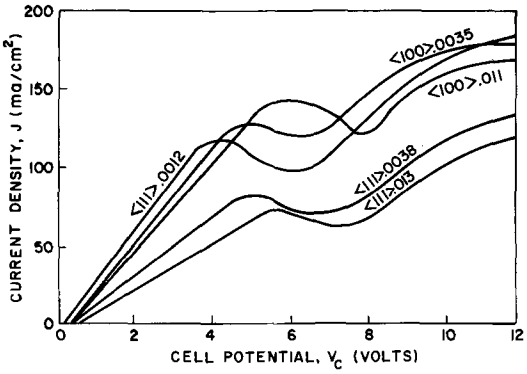

Fig. 4. Current density vs. cell potential for n^+ silicon

data of Fig. 2 of Ref. (6) are replotted *vs.* cell potential in Fig. 4. The optimum operating point is a potential just beyond the maximum in a J-V curve; that is, just into the electropolishing range. Smaller cell potentials require considerably reduced lowering rates because the current density *vs.* potential decreases so rapidly that values of L as discussed in the preceding paragraph cannot be maintained. Only slightly higher potentials actually result in a slower etching; and much larger potentials, while yielding a somewhat greater removal rate, result in an extensively degraded epi layer.

Results

Figure 5a shows a wafer which was partially masked during thinning so that a window was cut through the substrate to the epitaxial layer which is <111>, 2 ohm-cm, 6μ thick. The window size is 6 by 10 mm. The

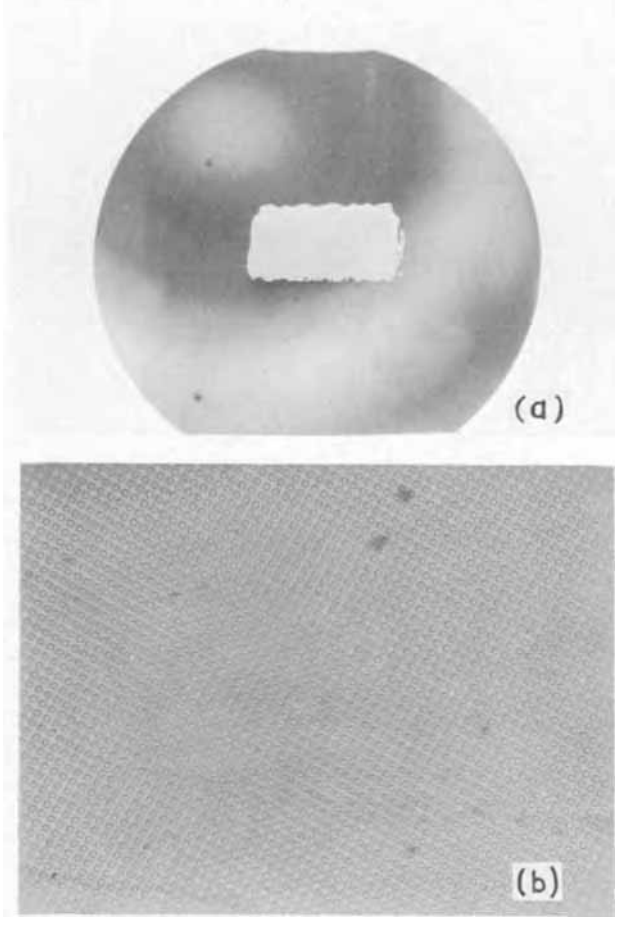

Fig. 5. Wafer with window etched to epi layer: (a) low magnification—window is 10 mm x 6 mm x 6μ; (b) high magnification—showing diffused diode array.

remaining thin silicon membrane is structurally sound, is not buckled or wrinkled, and contains no pinholes when examined at 400X. Thin membranes having thicknesses as small as 1μ have been prepared for use in channeling studies. The thin membranes may be further processed without adverse effect. For example, they have been steam oxidized (1μ oxide each side of 2μ silicon), the oxide stripped in buffered HF, and they have also been rf sputtered. Further evidence of the resultant film quality can be drawn from the aforementioned channeling experiments, the preliminary results of which indicate that the material is crystallographically sound (7).

The particular slice in Fig. 5a had a camera tube diode array diffused into it before thinning (steam oxide, 1050°C, 45 min; boron diffusion, 1140°C, 20 min) as is apparent at higher magnification in Fig. 5b. The dot size is 8μ diam on 15μ centers. In light of the comments of the previous paragraph, application to diode array thinning seems promising. Also, it appears possible to thin the wafer before the array is fabricated.

Early attempts to thin integrated circuits were unsuccessful because etch-through occurred around the periphery of each chip as illustrated in Fig. 6a and b which show a slice (epitaxial layer: <100>, 3 ohm-cm, 8μ thick) upon which phototransistor arrays had been fabricated. Both views are from the etched side; 6a is reflected, and 6b is transmitted, light. The reason for this etch-through behavior was determined to be the fact that in normal processing the base and emitter diffusion are applied also to the grid area around the chips. In fact, it has been found that if either an n^+ [Fig. 6c (8μ epi, <100>, 3 ohm-cm nominal)] or a p [Fig. 6d (8μ epi, <100>, 3 ohm-cm nominal)] grid is present, etch-through of the n-layer results.

The reason for etch-through at p-grids at first seems apparent as the p-regions would be able to inject holes, if they were forward biased, into the n, allowing its dissolution. However, a reverse-biased junction also seems to exist in the circuit as contact has been made to the n^+. It has been found that etch-through occurs below p-diffused areas only if the area diffused extends over the edge of the wafer. It is perfectly possible to retain 1 ohm-cm n-epi layers which have had an area 1 cm on a side p-diffused as long as the diffused area does not extend to the wafer edge. If the p-diffusion extends over and around the slice edge, no effective junction is formed and the p is at the cell potential. Of course, the p-material is, itself, not in contact with the electrolyte. (The junction which does exist is an n^+p^+ surface junction and is very leaky.) The n-material is then etched due to hole injection from the p-diffusions.

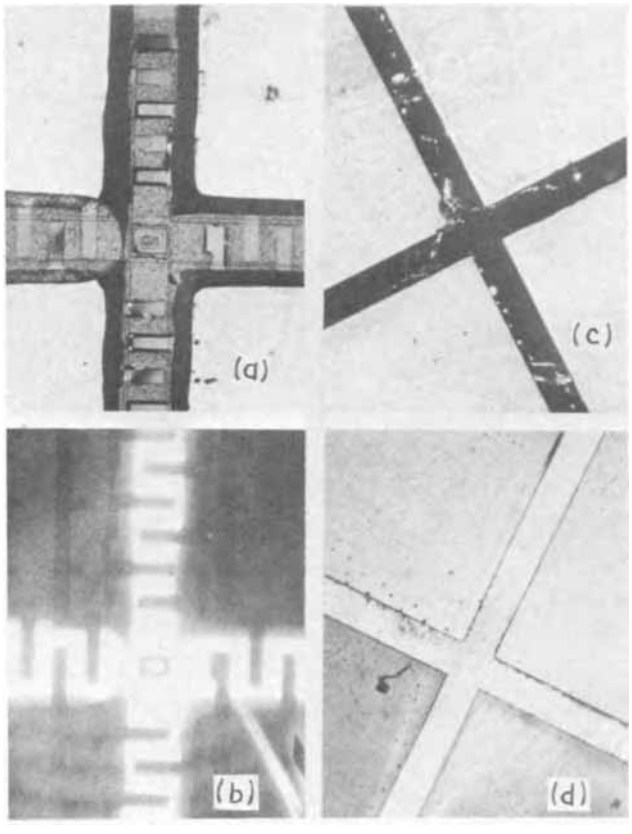

Fig. 6. Etch-through of layers with diffused grids: (a) phototransistor array—reflected illumination; (b) phototransistor array—transmitted illumination; (c) N^+ grid, 1 mil wide; (d) P^+ grid, 1 mil wide.

The mechanism of etch-through at n^+ is considerably more interesting. The effect can best be discussed by reference to a particular example (see Fig. 7). These micrographs are of a thinned slice containing diffused areas. The large squares contain p-diffusion (boron, 1140°C, 20 min), while the rectangular areas and the small squares in the upper-right corner of each large square are n^+ diffusions (phosphorus, 925°C, 36 min; 1000°C, 20 min). The photographs are of the etched side of the layer which is 3 ohm-cm, 8μ thick, and was thinned at 6V and a lowering rate of 0.7 cm/hr. In the first photograph, the slice is shown as it appears only 10 min after the n^+ substrate has been etched away. One of the lines of n^+ rectangles is just beginning to etch. (The residual n^+ substrate in each case is off the bottom of the pictures.) After 20 min considerable etching has taken place, and after 30 min the epi layer has been etched through. (In this particular case, the etching has produced a residual "brown film" but sometimes clean etch-out occurs; see, for example, Fig. 10 which also shows other features to be discussed later.)

The explanation for this must be carrier generation at or below the surface of the n^+ diffused areas, perhaps due to diffusion-induced defects or due to incorporation of large numbers of impurities which act as generation centers. The band diagram through the epi layer to the electrolyte interface appears qualitatively as in Fig. 8, demonstrating that any holes generated would be driven toward the electrolyte interface. The electrons are attracted along the slice to the contact. A local large number of generation centers would thus allow the n-material in the vicinity to etch.

We note that p-diffused areas do not in general etch, even though they surround n^+ diffusions, because the built-in biases retard any extra hole migration to the interface.

This etch-through is enhanced for large-area n^+ diffusions because the adjacent n is maintained at a higher potential for a long time. The current voltage data of Ref. (6) for n-silicon are presented with cell potential as abscissa in Fig. 9. As has been discussed (6), when the initial current density (which is the value plotted in Fig. 9) exceeds 0.05 mA/cm^2, an increase of current with time is observed and pitting of the surface occurs. Above 1 mA/cm^2, current fluctuations are so large that meaningful measurement cannot be made. When n-silicon is held at the potential necessary to electropolish the substrate (about 6V), after an initial induction period the current will increase and pitting will occur.

A number of other etching and staining phenomena are observed both before and after processing. A stain film is sometimes found on the surface but its thickness and the coverage of the surface is variable. The occurrence seems to depend in some undefined way on the material, being fairly consistent within a batch of epitaxial slices but varying widely from batch to batch. The fact that it is sometimes completely absent is attested to by the success of channeling experiments which would reveal the existence of a disordered surface layer. It is to be noted, however, that, if a wafer is partially thinned, removed from the etch and dried,

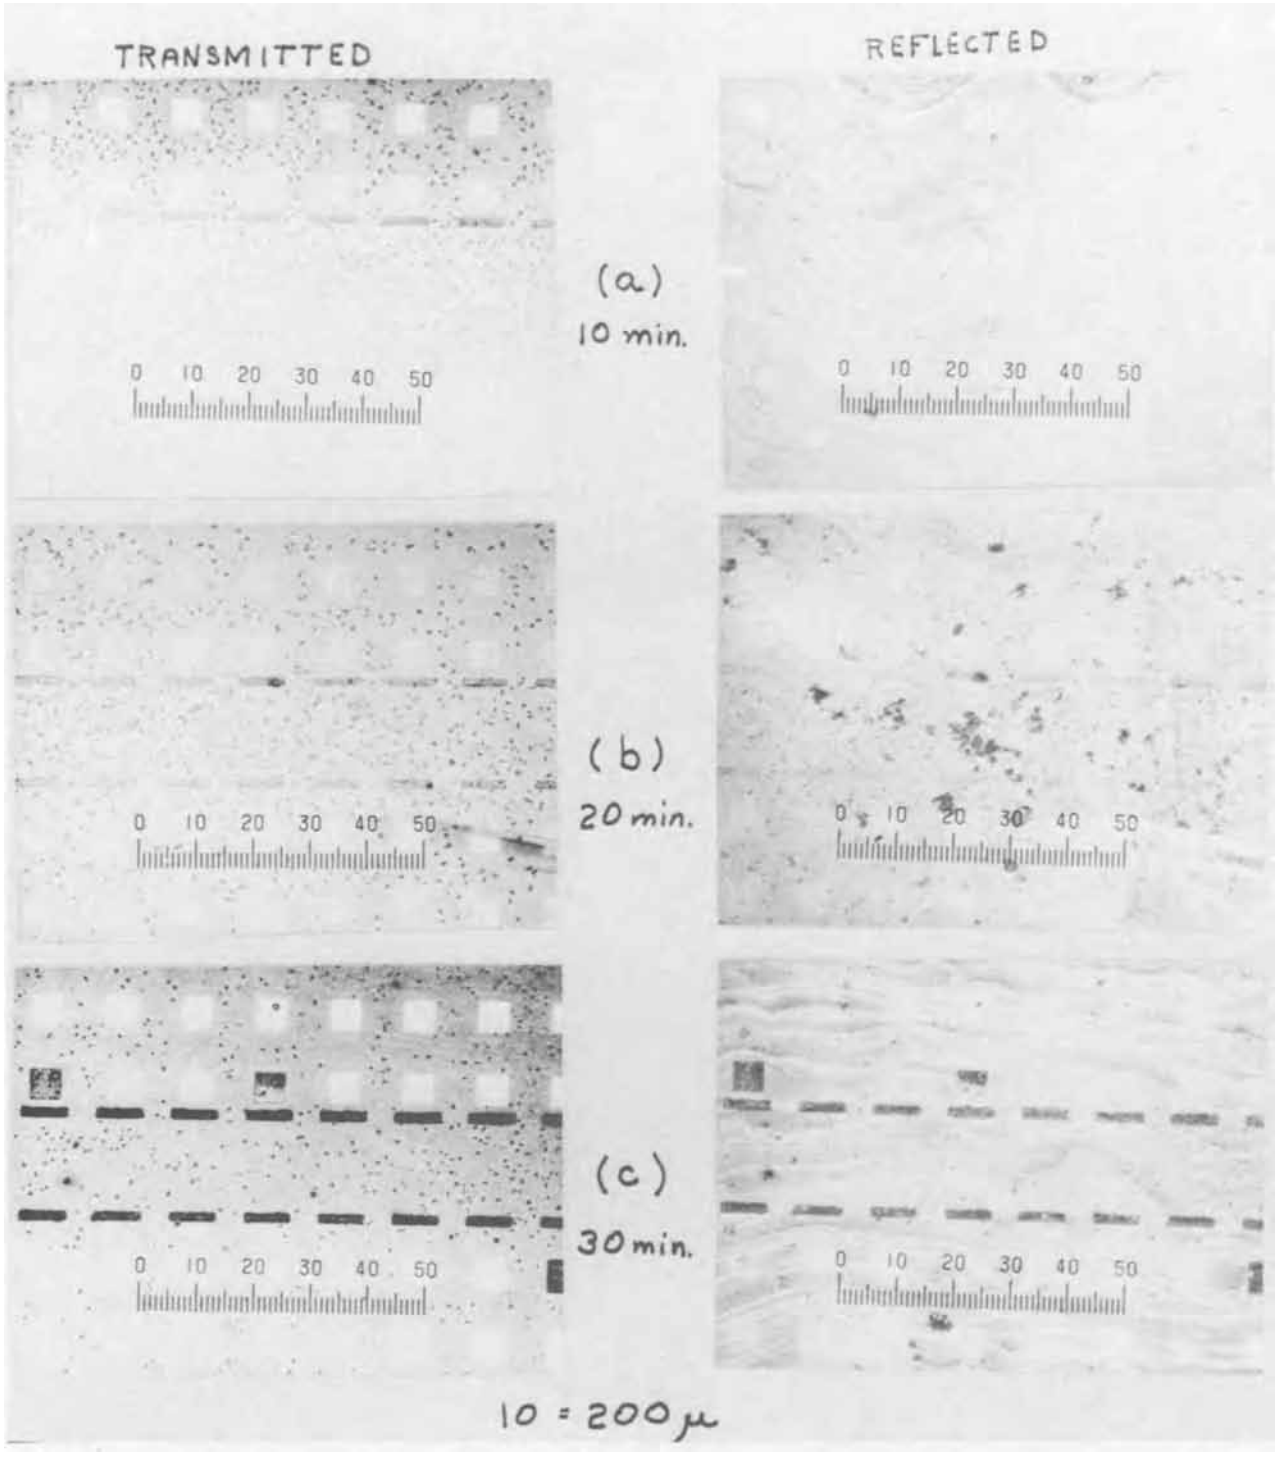

Fig. 7. Etch-through at isolated n^+ diffusions

and the rest of the substrate removed, a film will form on the previously thinned part of the wafer.

The wafer of Fig. 10, although it has received processing, illustrates features often found both before and after processing. The material is severely wrinkled along the right edge of the photograph and a curved line along which etching and staining have occurred also appears. In Fig. 11, we see that holes have etched through the epi layer and, furthermore, etching has been so accelerated that they extend even through the n^+ material where it has been thinned to 20-30μ. These are believed to be dislocations. Only about one batch of epitaxial material in ten has been found to be substantially free of all of these problems.

Two additional types of defects have been observed after "good" epitaxial layers are processed (oxidized and diffused). These are illustrated in Fig. 12. It is very interesting to note that they have not formed in areas which were p-diffused. (The same kinds of defects, but much less dense, have occasionally been observed before processing.) The identity of either defect is not known but those of Fig. 12a have the appropriate morphology to be stacking faults.

It is also noted, parenthetically, that the etch-through at diffused grids (Fig. 6) produces very precisely sized silicon elements. This may be of use as a separation technique where chips or arrays of precise size and/or spacing are desired, as the tolerance depends only on the masking tolerance; consequently, the element edge is in very precise registry with the device diffusions, as the grid and emitters and/or bases are diffused at the same time.

Another interesting etch-through problem may now also be interpreted sensibly. Suppose in Fig. 3 that

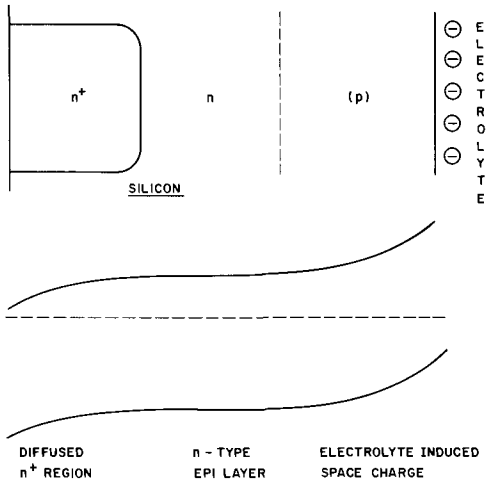

Fig. 8. Qualitative band diagram laterally across the positively biased epitaxial layer in the presence of an n^+ diffusion and the electrolyte.

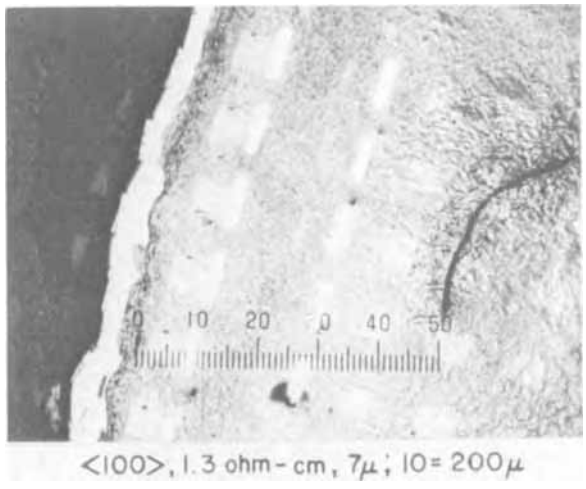

Fig. 10. Thinned layer showing complete etch-out of n^+ diffused areas, etch-through at a window edge, wrinkling, and a line defect.

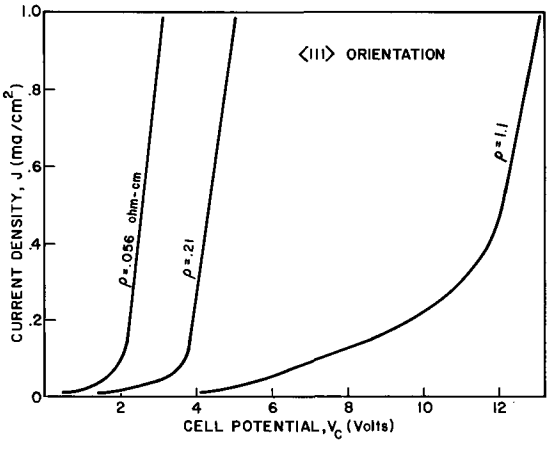

Fig. 9. Current density *vs.* cell potential for n-silicon

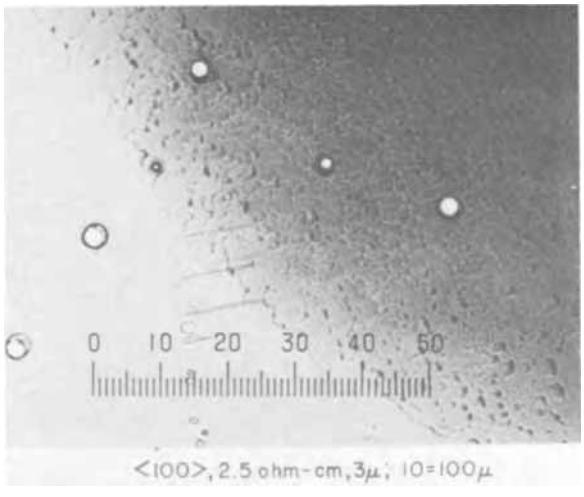

Fig. 11. Pinholes in the epitaxial layer after thinning

$L \rightarrow 0$. Now the n^+ is etching at a very slow rate; or, from a frame of reference attached to an exposed point on the n-material, the n^+ is receding very slowly. This is the case, for example, if $R = 0$ or when the window edges are approached for a structure such as that of Fig. 5. The experimental observation is that the n-material etches through on a stripe about 100μ wide adjacent to the stationary edge of the n^+ material in something like 10 min. (Figure 10 also serves to illustrate this, along the left side of the picture.) The obvious explanation is diffusion of holes into the n, allowing etching within about a diffusion length. The question is, of course, where do the holes come from? It appears from recent C(V) measurements (8) that they are generated at the n^+ surface.

Clearly, if one expects to retain windows as shown in Fig. 5, either great skill must be exercised in removing the wafer at the appropriate time or it must be mechanically preshaped so the n^+ is still receding at an appropriately large rate when etching is terminated.

Application to Integrated Circuits

Although certain performance advantages might be designed into specialized p-n junction isolated IC's, the main impact of thin silicon is on the junction spacing (and, consequently, the economics) of dielectric-iso-

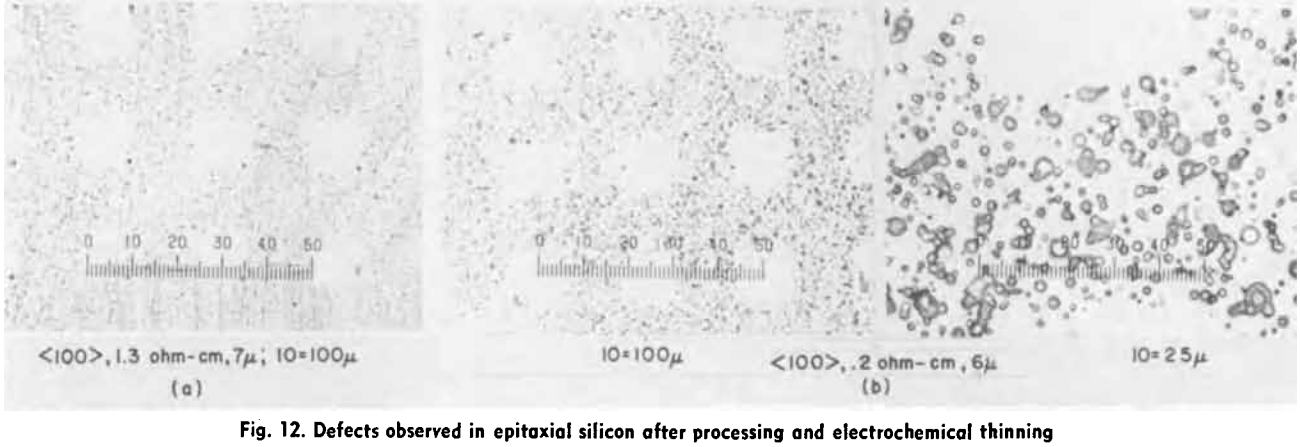

Fig. 12. Defects observed in epitaxial silicon after processing and electrochemical thinning

lated circuits. Consequently, only dielectric isolation is considered here, and an entirely arbitrary distinction is made between air (AIM) and solid dielectric isolation because of the importance of Beam Lead Technology (9) to the Bell System.

Dielectric isolation of integrated circuits has attracted increasing interest in past years for the following reasons: (a) very high breakdown voltages are possible, (b) parasitic capacitances are very much reduced compared to p-n junction isolation, (c) complementary transistors of comparable quality may be produced, and (d) circuits are resistant to nuclear (gamma radiation) effects.

The two principal difficulties with dielectric isolation have been that a difficult and expensive precision mechanical shaping step has been necessary, and that isolation etch channels are of such a depth (~ mils) that utilization of available wafer area is poor. Both these difficulties will be seen to be eliminated by use of the electrochemical thinning procedure.

Consideration of the economics (10) of integrated circuit processing, in conjunction with data on defect density, leads to the conclusion that the cost per unit useful area is a minimum if the chip is about 30 mils on a side. For a complex circuit, then, the area occupied by each element should be minimized.

At present, slices are back-etched (or ground or polished) down to 1 or 2 mils, masked, and finally an isolation etch is performed. To do this, a stripe of 2-4 mils, depending on slice thickness, around the active element must be allowed. This means the total chip area must be 2-4 times the active device area to allow for isolation. Clearly, then, if the wafer could be uniformly thinned to a few microns, instead of mils, the number of active elements per circuit chip could be doubled or even quadrupled.

Air-Isolated IC

When electrochemical etching is substituted for mechanical thin-down on a completed air-isolated structure, there arises, of course, the problem of etch-through at n^+ diffused areas. Three ways can be thought of to eliminate the n^+ etch-through:

1. Have no n^+ diffusions.
2. Ion-implant and thin before the impurities are activated.
3. Zone-etch so the n-layer is exposed to the electrolyte for only very short times after the n^+ substrate is etched away. (That is, confine the etchant to a zone slightly greater than L on the wafer.)

Number 1 requires no comment. The latter two methods have both been applied successfully.

AIM structures thinned by this method would suffer from a high series collector resistance, since it is not possible to retain an n^+ area on the back of the chips. This can, perhaps, be eliminated by metallization of the back of the slice. Such a procedure would have a number of additional advantages:

1. To supply structural integrity to very thin devices.
2. To allow possible electrical contact to back of chip.
3. To permit face-up handling and mounting of chips.

It appears that Turner's (11) method of nickel plating silicon could be incorporated, as it would simply entail addition of certain chemicals to the etching bath after the wafer is thinned and subsequent plating as the slice is withdrawn. Preliminary results of this procedure appear promising (12).

Dielectric Isolated IC

Numerous detailed process sequences have been proposed to produce material suitable for fabrication of dielectric isolated circuits. These may, however, be divided into two general categories (13): (a) those which involve two polycrystalline silicon, or other "handle" material, depositions but which utilize the original wafer surface for device fabrication, and (b) those which require only one polycrystalline silicon deposition and which therefore use the back-etched or polished surface for device diffusions.

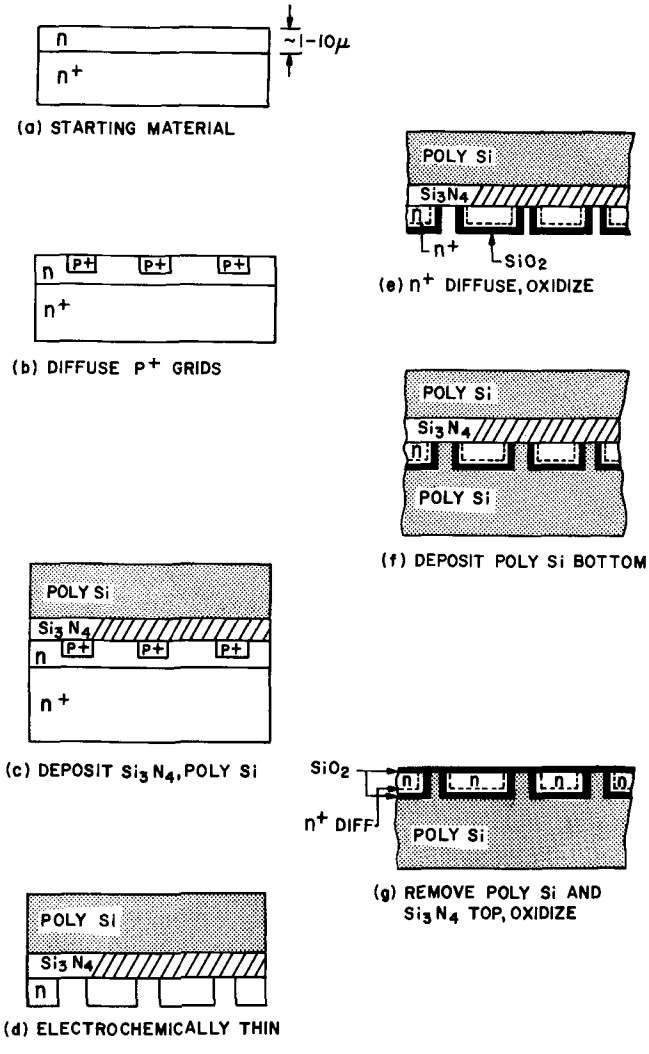

Fig. 13. Dielectric isolated IC fabrication—double poly process

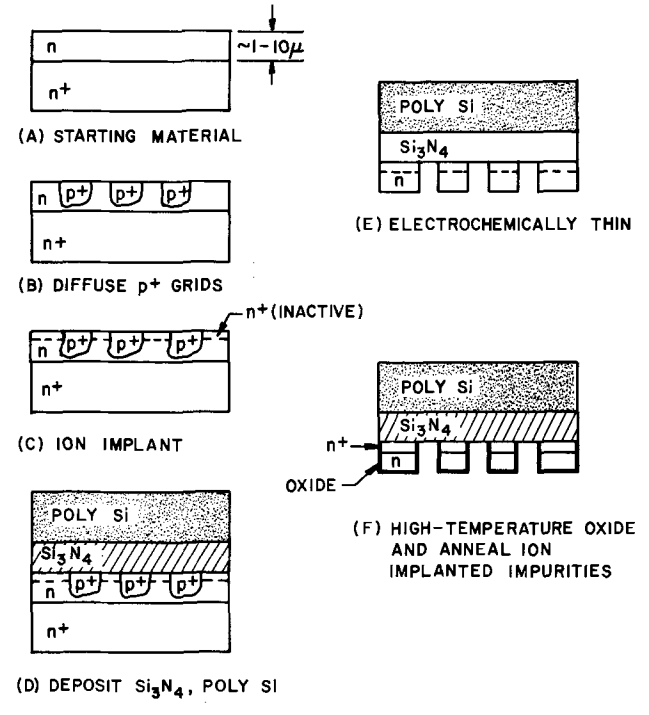

Fig. 14. Dielectric isolated IC fabrication—single poly process

Figure 8 illustrates a process sequence typical of the first category. A total of 10 steps is needed to prepare the starting material for device fabrication, but only one mask is used and the original slice surface is reclaimed. The phenomenon of grid etch-through is utilized to separate the islands as the wafer is thinned.

Figure 9 illustrates the second method. Again, grid etch-through is utilized as well as ion implantation to reduce series collector resistance. The ion-implanted impurities are not activated, annealed in, until after electrochemical thinning so that complete etch-through of the wafer does not occur. Here, the electrochemically etched substrate-epitaxial layer interface is to be the device surface. Six steps and again only one mask are needed.

It may also be noted that material of any orientation may be used since anisotropic etching is not utilized.

Summary

The process for electrochemically thinning n/n^+ epitaxial silicon wafers in HF solution yields satisfactory results when the n-layer is of high resistivity and defect free and where either no n^+ diffusions are present or they are otherwise prevented from causing accelerated etching. Most promising applications seem to be: (*a*) preparation of thin films for experimental study, (*b*) thinning of simple diode arrays, (c) solid dielectric isolated integrated circuit fabrication, and (*d*) perhaps specialized AIM circuits. Principal limitations on the method are availability of very perfect epitaxial layers to be thinned and the fact that etching takes place at local areas of carrier generation.

Electrochemical Fluorination

H. M. Fox,* F. N. Ruehlen, and W. V. Childs*

Research and Development Department, Phillips Petroleum Company, Bartlesville, Oklahoma 74003

ABSTRACT

A new process is described for continuous and efficient electrochemical fluorination. The description is supported by detailed data on the fluorination of ethane and qualitative information on some other paraffins and aliphatic chlorides. The preferred anode material is porous carbon, and the electrolyte is composed of approximately one mole of potassium fluoride and two moles of hydrogen fluoride. The cell is operated at about 100°C. An essential feature of the process is that the feed to be fluorinated is kept confined to the pores of the porous carbon and is not permitted to break out into the bulk electrolyte. This is achieved by control of the permeability and pore size distribution of the porous carbon. It is necessary that the electrolyte not wet the anode (contact angle greater than 90°) under electrolysis conditions. Aliphatic hydrocarbons, typified by results on ethane reported herein, fluorinate smoothly and give the hydrogen substituted derivatives predominantly. Over 95% of the ethane converted was recovered as fluoroethanes. This yield did not vary significantly when conversion of ethane was between 31 and 85% per pass or conversion of total hydrogens in the ethane feed was between 10 and 65% per pass. Other products were predominantly various fluorobutanes. The quantity of products obtained by carbon-carbon scission was negligible. Some aliphatic halides also were fluorinated. The chlorides gave even higher efficiencies to hydrogen-substituted derivatives than did the hydrocarbons. The chlorides were subject to scrambling of the halide atoms, the extent of which depended on the compound being fluorinated. Like the hydrocarbons the halides produced a negligible quantity of carbon-carbon scission products. The yield of dimers and other telomers was even smaller.

Shortcomings of conventional fluorination methods have led investigators to seek more effective approaches to electrochemical fluorination. Direct fluorination with elemental fluorine is both expensive and hazardous. Unless elaborate and costly measures are taken to moderate the reactions, poor yields are generally obtained. Fluorination by milder fluorinating agents such as metal fluorides requires elemental fluorine to regenerate the fluorinating agent, and this is expensive. Substitution of fluorine for another halo-

Key words: electrochemical fluorination, hydrocarbons, chlorohydrocarbons, fluorocarbons, porous carbon anode, hydrogen fluoride, potassium fluoride, molten salt, high efficiency, high current density, moderate temperature, wide application.

gen such as chlorine is unsatisfactory because of the limited range of materials which can be made, and the inefficiency resulting from weight loss of feedstocks. Thermodynamic considerations exclude oxidative processes analogous to oxychlorination.

The well-known Simons electrochemical fluorination process (1) is reported to be in commercial use by the 3M Company (2) to produce perfluoro compounds. While his process is primarily suitable for feeds that are soluble in the electrolyte, Simons also disclosed methods for fluorination of insoluble compounds, and other investigators have further refined the process. Radimer (3), and Ashley and Radimer (4) used porous anodes to sparge the feed to be fluorinated into the electrolyte in proximity to the suface of the electrode where fluorine is generated.

The present work is a new approach to electrochemical fluorination (5), distinguished by a novel method of feeding a reactant to a porous electrode. The reactant to be fluorinated, which is insoluble in the electrolyte, is fed continuously to the anode where it remains while it is fluorinated, and the fluorinated products and unreacted feed are recovered continuously from the anode. The process is characterized by its applicability to a wide range of feedstocks and by its high efficiency in producing fluorinated derivatives at conversion rates that approach 100% per pass. In most cases carbon-carbon bond scission does not take place.

Basic Concepts

An essential feature of the process is that the feed and fluorinated products while in the cell remain within the pores of the anode and do not break out into the bulk electrolyte. This occurs if the electrolyte does not wet the anode material and if the permeability of the anode is such that the pressure drop due to feed flow is less than the hydrostatic head of the electrolyte. Ideally, there should be no pores in the anode large enough to be flooded by the electrolyte. However, a substantial proportion of total porosity can be in pores which will flood without causing the feed to break out into the electrolyte. A practical limitation on permeability or porosity is reached when the carbon is too weak mechanically or has too high an electrical resistance to be used as an electrode.

It is known that the nonaqueous electrolyte used in commercial fluorine cells, composed of about 1 mole of potassium fluoride to 2 moles of hydrogen fluoride ($KF \cdot 2HF$), does not wet carbon during electrolysis. Rudge (6) reports that when carbon is made anodic in the $KF \cdot 2HF$ electrolyte, the contact angle increases from 0° to 140° and the anode is no longer wetted by the electrolyte.

Operation of the anode reactor is readily understood in terms of capillarity, as discussed recently by Schwartz (7). In a solid-liquid-vapor capillary system such as porous carbon in a nonwetting liquid, the capillary pressure, P_c, is derived from Young's equation

$$P_c = \frac{2\gamma \cos \theta}{R}$$

where γ is the surface tension of the liquid, θ is the contact angle between the solid and liquid surfaces at the point of contact (Fig. 1), and R is the radius of the capillary.

When a porous material is immersed in a liquid, the smallest pore will fill when P_c equals the negative of P_h (hydrostatic head of the liquid, defined as the product of height of the liquid, density of the liquid, and the gravitational constant)

$$\frac{2\gamma \cos \theta}{R} = -\rho g h$$

or

$$R = -\frac{2\gamma \cos \theta}{\rho g h}$$

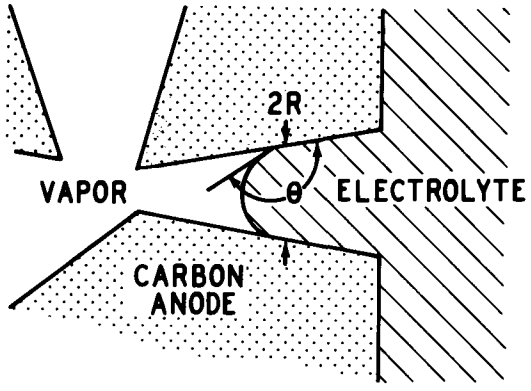

Fig. 1. Idealized pore

In the porous carbon-$KF \cdot 2HF$ system at about 100°C considered herein, γ is approximately 100 dyne cm^{-1}, $\rho = 1.91$ g cm^{-3}, and $g = 981$ cm sec^{-2}. Under electrolysis conditions, θ is reported by Rudge to be about 140°. Calculations of minimum pore size to flood with electrolyte at various depths of immersion can serve as a basis for selecting porous carbons that can be used at different depths of immersion. For example, at 10 cm immersion, the smallest pore that will fill with electrolyte has a radius of about 81 μm.

As mentioned previously a certain amount of filling of electrode pores with electrolyte can be tolerated if there is enough permeability in the unfilled porous structure for the feed flow rate desired. If these conditions are met, the porous carbon acts like a chimney. A gas will flow from one end to the other and will not break out into the electrolyte. Typically, an anode for this process is a cylindrical or rectangular piece of porous carbon immersed vertically with feed at the bottom; products are taken from the top. However, the direction of feed flow could be horizontal if the carbon is completely immersed and suitable inlet and outlet ports are provided.

Experimental

Cell.—Figure 2 is a schematic drawing of the experimental cell used in this study. The cell case, which was jacketed for heating and cooling purposes, and the cathode were of mild steel. The cell lid and anode support were cut from ½ in. and 1 in. Teflon sheeting. The electrolyte level was controlled by means of a level probe extending through the lid to the desired level. When contact between the probe and electrolyte was broken, HF was added automatically until contact was reestablished. The cell temperature was maintained near 100°C by adjusting the temperature of the coolant. This was done automatically by means of a temperature-sensing electronic controller which controlled the water rate to an in-line heat exchanger. The coolant was General Electric SF-96(20) silicone fluid which was circulated from a steam-heated reservoir through the heat exchanger and cell jacket. The steam-heated reservoir was necessary to maintain the cell temperature above the freezing point of the electrolyte during shutdowns. Electrolyte flow as indicated by the arrows on Fig. 2 was due to lift by hydrogen generated at the cathode.

Anode.—A schematic representation of the anode, the mounting assembly, and path of feed flow are given in Fig. 2. The porous carbon was 6 in. long and 1¾ in. in diameter. It was drilled and tapped (½-20) to a depth of 5½ in. to receive a copper stem which served as current collector and feed tube. The data reported were obtained where the electrolyte level was maintained at 5 in. immersion. The lateral surface area was 167 cm^2. The arrows in Fig. 2 illustrate the flow of feed down to the bottom of the electrode and up through the porous structure of the anode. Unreacted feed and fluorinated products left the anode at or slightly above the surface of the electrolyte. Products are mixed with

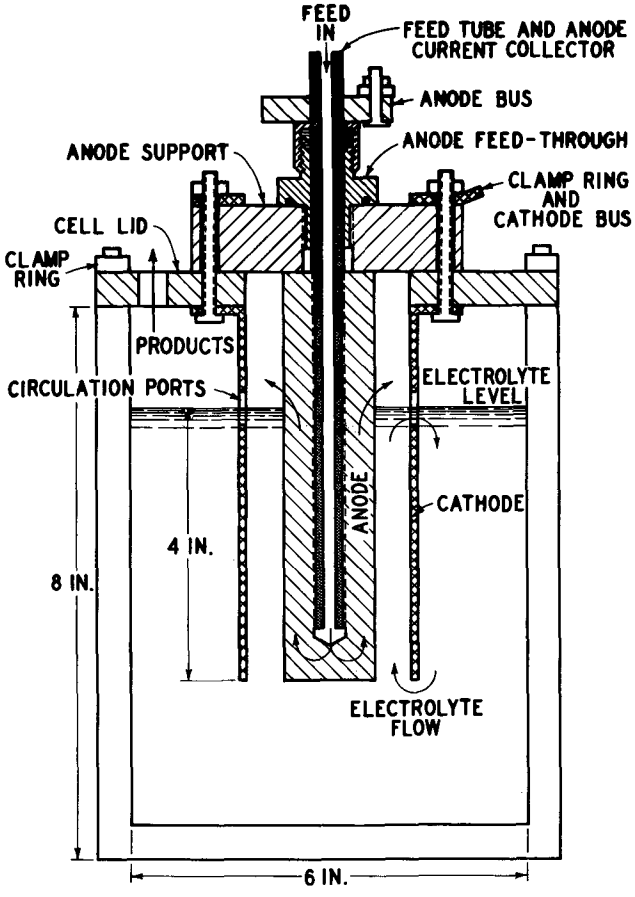

Fig. 2. Experimental fluorination cell

cathode hydrogen before leaving the cell. By a slight modification of the cell, products can be extracted from the anode before they are mixed with cathode hydrogen.

A variety of porous carbons have proven successful. Stackpole Carbon Company SD-139 exhibits little or no flooding of its largest pores at deep immersions. However, the permeability of this carbon is so low that at appropriate flow rates there is break-out of gas into the electrolyte at depths greater than 3 in. National Carbon Corporation PC-60 permits a greater depth of immersion to a limit of about 12 in. Great Lakes Carbon Corporation B-303 and National Carbon Corporation PC-45 give good feed distribution throughout the carbon structure to depths of at least 24 in. Carbon B-303 was used in the runs on ethane to be discussed. These carbons are readily available and have an acceptable combination of pore properties and mechanical properties.

Electrolyte.—Nominal composition of the electrolyte was KF · 2HF containing 0.05 weight per cent (w/o) LiF. Hydrofluoric acid content was maintained at 41-42 w/o. The electrolyte was described by Cady (8) and Schumb *et al.* (9). It was prepared by cautious addition of anhydrous HF to KF · HF rather than to KF, because the reaction is less violent. Hazards of preparation and handling the electrolyte are discussed in Saunders (10). Analysis was done by adding excess base and back-titrating with 1M HCl to a phenolphthalein end point.

Organic feedstocks.—Ethane used was Phillips Pure Grade Product (99.0+ % ethane). Other reactants were high grade products from various sources.

Power supply—Two Sorenson DCR40-125A power supplies were used They were set to operate at constant current with crossover to voltage control at 20V when an "anode effect" occurred (6). An anode effect was relieved by allowing the voltage to rise to 45-70V at constant current for 1-3 min. When the power supplies were turned off and restarted the cell resumed normal operation at about 8V.

Product analysis.—Total cell effluent except hydrogen was collected in one or more receivers cooled with liquid nitrogen. A weighed quantity of sodium fluoride (⅛ in. pellets) was placed in the receiver(s) to remove HF from the cell product. The product was flash-evaporated from the sodium fluoride pellets. Its weight was checked against feed flow and fluorine generated as calculated from the current passed. Mass balances determined in this way were usually within 1 or 2% of unity. The increase in weight of sodium fluoride was taken as the amount of HF removed and was usually in agreement with that calculated based on the vapor pressure of HF over the electrolyte.

Products were analyzed by gas chromatography. The peaks were identified by a GC-mass spectrograph combination and comparison with authentic samples where available. A Perkin-Elmer F11 machine was used with a hot wire detector. Flame ionzation detectors give widely varying responses and poor sensitivity with highly fluorinated materials. The column used was a 20 ft by ⅛ in. Porapak Q. He flow was 40 cc/min. The oven temperature was programmed as follows: temperature was held at 100°C for 8 min; then temperature was increased at 6°C/min to 220°C; then temperature was held at 220°C until heavies eluted.

Results and Discussions

Chemical efficiency.—Data are given in Table I for a series of runs of varying feed rate on ethane. The limiting rate at which the feed will not break out of the B-303 carbon into the electrolyte at 5 in. immersion is about 60 liters/hr; thus the maximum rate evaluated in this series of runs, 35 liters/hr, is considerably below the breakout point. The variations in flow rate were such as to give a range of Faradays of current passed per hydrogen equivalent fed between 0.21 and 1.30. At 2.00**F** per hydrogen equivalent, perfluoroethane would be the sole product if only hydrogen substitution occurred. Stated in another way, 10.5% of the hydrogens in the ethane feed would be converted at the highest flow rate, and 64.8% at the lowest feed rate, if hydrogen substitution accounted for all of the current used.

Product yield is the ratio of the moles of product or products specified to the total moles of ethane converted, multiplied by one hundred. Efficiency is the ratio of moles of fluorine-substituted ethanes to the total moles of ethane converted, multiplied by one hundred.

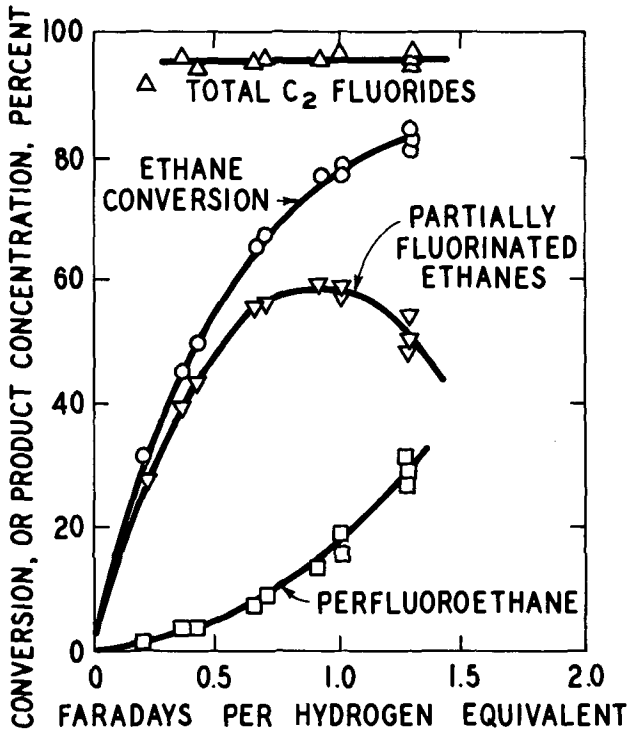

Fig. 3. Effect of Faradays per hydrogen equivalent (feed flow varied) on conversion or product concentration.

Figure 3 is a plot of the results as a function of Faradays per hydrogen equivalent. The proportion of total products represented by the higher fluorinated derivatives increases with increasing Faradays per hydrogen equivalent, while the proportion of ethane and less fluorinated derivatives decreases. The efficiency to C_2 fluorocarbons, or the efficiency to fluorine-substituted products of ethane, is insensitive to Faradays per hydrogen equivalent (thus hydrogen conversion) or to ethane conversion within the range investigated.

Major products obtained are those which can be formed by a radical process such as

$$CH_3\text{-}CH_3 + [F] \rightarrow CH_3\text{-}CH_2\cdot + HF \quad [1]$$

$$CH_3\text{-}CH_2\cdot + [F] \rightarrow CH_3\text{-}CFH_2 \quad [2]$$

The major by-products from ethane fluorination are fluorobutanes. Trace amounts of olefins, especially ethylene and vinyl fluoride, are observed. They are believed to be derived from radical disproportionation reactions, such as

$$2CH_3\text{-}CH_2\cdot \rightarrow CH_3\text{-}CH_3 + CH_2{=}CH_2 \quad [3]$$

Rather than a combination of two radicals, the butanes appear to come from the reaction of an olefin and a radical such as

$$CH_3\text{-}CH_2\cdot + CH_2{=}CH_2 \rightarrow CH_3\text{-}CH_2\text{-}CH_2\text{-}CH_2\cdot \quad [4]$$

At low conversions 1-fluorobutane is present in much higher concentration than any other, including butane itself.

Very small amounts of one-carbon compounds are produced.

Table II qualitatively summarizes data on some other compounds fluorinated by this process. A variety of low-boiling paraffins, up to and including isooctane, all fluorinated smoothly. Scission products in all cases were low. Dimerization of fluorides or chlorides was usually lower than that obtained on the corresponding hydrocarbon. For example, the fluorination efficiency (to the fluorine-substituted derivatives) of 1,1-difluoroethane was above 98%.

Disproportionation of chlorine was observed during the fluorination of the chlorine substituted paraffins.

Table II. Summary of results on various feedstocks

Feedstocks	Efficiency to expected substitution products (%)	Types of major by-products observed
Methane	90	Fluoroethanes
Ethane	95	Fluorobutanes
Propane	95	Heavies—probably fluorohexanes
1,1-Difluoroethane	98	Fluorobutanes
1,2-Dichloroethane	85	Fluoromonochloroethanes and fluorotrichloroethanes
1,1,2-Trichloroethane	75	Fluorodichloroethanes and fluorotetrachloroethanes
Chloroform	99	—
Methylene chloride	60	Fluoromonochloromethanes, fluorochloroform, and fluorochloroethanes

For example, ethylene dichloride produced some fluorinated monochloroethanes and trichloroethanes in addition to the main products, fluorinated 1,2-dichloroethanes. The products of disproportionation of halogen can occur by reactions such as the following

$$CClH_2\text{-}CClH_2 + [F] \rightarrow CClH_2\text{-}CClH\cdot + HF \quad [5]$$

$$2(CClH_2\text{-}CClH\cdot) \rightarrow CH_2{=}CClH + CClH_2\text{-}CCl_2H \quad [6]$$

$$CH_2{=}CClH + 2[F] \rightarrow CFH_2\text{-}CClFH \quad [7]$$

Products of these reactions and analogous reactions of the partially fluorinated derivatives were observed.

Monochlorides and trichlorides could disproportionate accordingly to give the tetrachlorides and compounds without any chlorine which were observed in trace quantities in some cases.

Chloroform is an example of a chloride which fluorinated almost quantitatively to the fluorine-substituted derivative, trichlorofluoromethane. Methylene chloride disproportionated chlorine to a considerable extent.

Electrical efficiency.—As mentioned previously, the electrical efficiency of this process approaches unity. The total current consumed was accounted for by fluorine in the product as determined by gas chromatographic analysis. This has been confirmed by analysis of product for total fluorine by the Wickboldt method. Careful measurement of the amount of hydrogen produced gave the predicted amount based on current passed indicating no internal shorting such as by oxidation of H_2 or reduction of F_2.

Analysis of Porous Electrodes with Sparingly Soluble Reactants

John S. Dunning,** Douglas N. Bennion,* and John Newman*

Department of Energy and Kinetics, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

A model is developed for the operation of a porous electrode in which slightly soluble reactants are present. Numerical techniques are used to predict current distribution and total electrode polarization for the case of a uniform porous structure. This technique is extended to the case where nonuniformities in reactant conversion are produced by a nonuniform current distribution within the electrode. In addition, a simulation of electrode behavior on repeated cycling is obtained. The implications of nonuniform reactant conversion and mass transfer limitations for real battery electrodes are discussed. The results of the numerical calculations indicate that diffusion-limited currents within the porous electrode are possible for certain input parameters. The high polarization at constant current corresponding to a limiting current may be obtained after some time of discharge, but before all of the theoretically available active material is used. In the cycling simulation, significant changes in the relative distribution of reactants and products were observed as a function of depth in the electrode. These changes caused differences in the total electrode polarization from cycle to cycle.

Various idealized mathematical models have been proposed to explain the operation of porous electrodes. The ultimate aim of such studies is the formulation of a model which predicts the performance of practical electrodes. With such a model the optimum design of new cells, particularly power cells of high energy density, may be achieved. Previous work in this field is extensive and has been reviewed elsewhere (1). In general, efforts have been made to determine the effects of ohmic, activation, and diffusion overpotentials (2-4). In addition, changes in porous structure as a result of the passage of current have been investigated for the case of a dissolving metal electrode (5).

In this study a new model is developed which considers transport of active species within the porous electrode itself. The transport of species to and from the bulk solution is not considered, so the model represents a rather special case. It is assumed that the active material is stored within the electrode in the form of small, dispersed crystallites of low solubility. The reactants and products of the electrochemical reaction tend to diffuse out of the porous structure at a very low rate. The model thus corresponds somewhat to the situation in a lead-lead sulfate negative or cadmium hydroxide negative electrode in an actual battery. During operation, the active material dissolves and is transported by diffusion to an electrochemically active site. After reaction, the products diffuse from a region of supersaturation to a saturated region where conditions are favorable for the precipitation of product crystallites

Description of the Model

The general model is formulated using a macroscopic approach. The electrode is assumed one dimensional as shown in Fig. 1. An electronically conducting matrix phase is interspersed with small pores which contain electrolyte solution. The current density in the matrix phase is given by Ohm's law

$$i_1 = -\sigma \frac{d\phi_1}{dx} \qquad [1]$$

The symbols are defined at the end of this paper. In the presence of supporting electrolyte, the current density in solution is given by

$$i_2 = -\kappa \frac{d\phi_2}{dx} \qquad [2]$$

An equation describing the kinetics of the electrochemical reaction which takes place at the solution-matrix interface is necessary. A fairly general equation describing an oxidation-reduction reaction which is first order with respect to both reactants and products is

$$\frac{di_1}{dx} = -ai_o \left\{ \frac{c_1}{c_1^o} \exp\left[\beta(\phi_1 - \phi_2)\right] - \frac{c_2}{c_2^o} \exp\left[-\beta(\phi_1 - \phi_2)\right] \right\} \qquad [3]$$

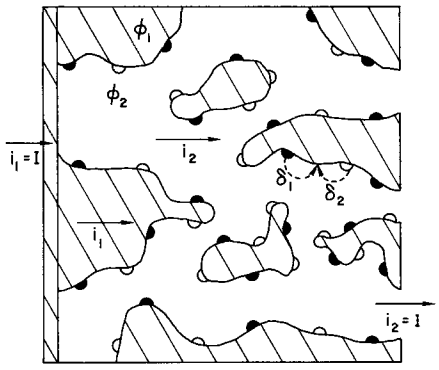

Fig. 2. Detailed structure of porous electrode showing small crystallites of active species: ● anodic reactant, ○ cathodic reactant.

The quantity di_1/dx is the cathodic reaction rate per unit volume of electrode at a point within the electrode. In general, the factor β appearing in the exponential terms can be different for the forward and backward reactions. However, using just one parameter simplifies the mathematics, and most features of the model will not be affected.

The model to this point is essentially the same as those of other workers, in particular that of Newman and Tobias (2). The new feature incorporated into this model is the consideration of diffusional transport of active species stored within the electrode. In Fig. 2 the detailed structure of the model is shown. The anodic reactant crystallites (species 1) are shown as solid dots on the matrix structure while the cathodic reactant crystallites (species 2) are represented as white dots. The active materials are nonconductors and react only when they diffuse to the surface of the conducting matrix. The saturation concentration of the reactant is so low that diffusion out of the porous matrix is slow. However, since the crystals may be small and highly dispersed, the diffusion paths within the electrode may be short and reasonable reaction rates may be possible. Similarly, the reaction products are assumed to be only slightly soluble and to be nonconductors. The reaction product concentration will build up at the reaction site until supersaturation occurs. Then the product will diffuse a short distance to small product crystallites or other preferred nucleation sites and precipitate. An effective diffusion path δ_i is assumed for each species. This represents a typical distance between a storage site and an active site at which the charge transfer reaction takes place. It is an averaged property which depends on the local geometry of the pores and crystallites within the electrode. In general it is expected that δ_i would be the order of one tenth of the average pore diameter. A typical pore diameter of 10μ would therefore indicate a value of δ_i the order of 10^{-4} cm.

A mass transfer coefficient k_{mi} is also defined for each species i. The flux of active material to the reaction site is assumed to be given by

$$N_i = k_{mi}\,(c_i^o - c_i) \qquad [4]$$

The mass transfer coefficient may be approximated by

$$k_{mi} \cong D_i/\delta_i \qquad [5]$$

If a diffusion coefficient of 10^{-5} cm^2/sec is taken as typical, a reasonable estimate of the mass transfer coefficient would be 0.1 cm/sec. The exact value of the average diffusion path is difficult to estimate. A precise estimate requires solution of the 3-dimensional species conservation equation for a given pore wall and crystallite geometry to establish the boundary conditions. An effective mass transfer coefficient could then be determined by averaging the flux and diffusion path over a given area of pore wall. Qualitatively, a high mass transfer coefficient is expected for small crystallites and a low mass transfer coefficient for larger crystallites. Thus, the mass transfer coefficient depends on crystallization dynamics and the crystallite and pore morphology. In this paper these subtleties are not explicitly considered, and an average value of k_{mi} is used as a variable parameter.

A general expression for an electrochemical reaction is

$$\sum_i s_i M_i^{z_i} \rightarrow ne^- \qquad [6]$$

where the s_i are stoichiometric coefficients and the z_i are ionic charges for each species taking part in the reaction. For simplicity, in this paper we will restrict ourselves to the case where s_1 is 1 and s_2 is -1. Using this notation the local reaction rate is related to the flux of active material toward the active site by

$$\frac{di_1}{dx} = \frac{-n\mathbf{F}aN_i}{s_i} \qquad [7]$$

for each species.

As current is passed, there is assumed to be a change in the sizes of reactant and product particles with time. Such changes cause variations in the diffusion path length and, correspondingly, in the mass transfer coefficient. In order to account for this phenomenon, it is necessary to assume a functional form for the dependence of the mass transfer coefficient on the amount of active material present in any part of the electrode. A function of the form

$$k_{mi} = k_{mi}^{max}\left(\frac{w_i}{\Sigma w_i}\right)^p \qquad [8]$$

satisfies the initial and long-time conditions. That is, as the amount of active material remaining, w_i, vanishes, the mass transfer coefficient and local reaction rate must fall to zero. Of course, this applies only to the species which is diffusing toward the electrode. The fact that only a small amount of product may be present cannot be allowed to hinder the reaction. For this reason a lower limit of 0.1 was placed on the ratio k_{mi}/k_{mi}^{max} for the product species in the actual calculations. The upper limit on the mass transfer coefficient, k_{mi}^{max}, is attained when all of the material present has been converted to the form of species i. It is to be noted that the value of Σw_i is a constant which corresponds to the capacity of the electrode in the fully charged state. The exponent p in Eq. [8] depends on the local geometry of the crystallites and is essentially an adjustable parameter. In this work p has been set equal to unity.

The amount of any species remaining at a point within the electrode depends on the history of that point. In terms of the reaction rate, the remaining amount of material is given by

$$w_i = w_i^o + s_i \int_o^t \frac{di_1}{dx}\,dt \qquad [9]$$

The condition of charge conservation requires that

$$i_1 + i_2 = I \qquad [10]$$

or

$$\frac{di_1}{dx} + \frac{di_2}{dx} = 0 \qquad [11]$$

where I is the total apparent current density in the electrode. In this paper all results are reported for galvanostatic polarization.

Equations [1], [2], [3], [4], [7], and [11] represent a set of coupled, nonlinear, first-order differential equations at a time t. The boundary conditions are

$$\begin{aligned} &\text{at } x = 0,\ i_1 = I \\ &\text{at } x = L,\ i_2 = I \text{ and } \phi_2 = 0 \end{aligned} \qquad [12]$$

The condition on ϕ_2 represents the choice of a zero point of potential. The total electrode overpotential, which is of primary importance to battery design, is

given by the quantity $\phi_1(0) - \phi_2(L)$. All results of this paper are presented in terms of the total electrode overpotential.

It is convenient to transform the set of differential equations into dimensionless form. The following set of definitions were used for this purpose

$$\begin{aligned} j &= i_1/I \\ y &= x/L \\ \xi_1 &= c_1/c_1^0 \\ \xi_2 &= c_2/c_2^0 \\ \psi &= \beta(\phi_1 - \phi_2) \end{aligned} \qquad [13]$$

The following dimensionless groups were defined

$$\begin{aligned} z_1 &\equiv nFaL\, c_1^0\, k_{m1}^{max}/s_1 I \\ z_3 &\equiv nFaL\, c_2^0\, k_{m2}^{max}/s_2 I \\ z_5 &\equiv LI\beta/\sigma \\ z_6 &\equiv LI\beta/\kappa \\ z_7 &\equiv La i_0/I \end{aligned} \qquad [14]$$

As a result of these transformations, Eq. [1], [2], and [10] become

$$\frac{d\psi}{dy} = z_6 - (z_5 + z_6)j \qquad [15]$$

Equation [3] becomes

$$\frac{dj}{dy} = -z_7\{\xi_1 e^{\psi} - \xi_2 e^{-\psi}\} \qquad [16]$$

Equations [4] and [7], when combined and written for the two species considered here, become

$$\frac{dj}{dy} = -z_1(1 - \xi_1) \qquad [17]$$

and

$$\frac{dj}{dy} = -z_3(1 - \xi_2) \qquad [18]$$

The boundary conditions on the above four equations are

$$\begin{aligned} &\text{at } y = 0,\ j = 1 \\ &\qquad y = 1,\ j = 0 \end{aligned} \qquad [19]$$

The above equations were solved numerically for the current in each phase, the local concentrations, and the local overpotential as functions of position in the electrode for the case of a constant imposed current density. The following computational procedure was used:

1. Equations [15], [16], [17], and [18] were solved for the initial conditions using the technique of Newman (6).
2. New values of the mass transfer coefficients were calculated after a short time interval, Δt, by assuming that the reaction rate at any point was constant during the time interval. Equations [8], [9], and [10] were used for this calculation.
3. The new values of the mass transfer coefficients were used to solve Eq. [15], [16], [17], and [18]. In this manner the transient behavior of the electrode could be followed.

Results

It was necessary to select numerical values for the constants appearing in the differential equations. In all cases presented here, a single electron transfer ($n = 1$) was assumed. In addition the value of β was taken to be 19.55 V^{-1}. The exchange current density, i_o, was assumed to be 10^{-5} A/cm^2 in all cases. The value of the matrix conductivity, σ, was assumed to be 10^3 mho/cm. The thickness of the electrode, L, was taken to be 1 mm. The values of w_1^0 and w_2^0 were both taken to be 720 coulomb/cm^3 in all cases. The other parameters of interest were chosen as reasonable guesses for organic electrolyte systems. For each set of results given, the values of the important parameters appear in the figure captions.

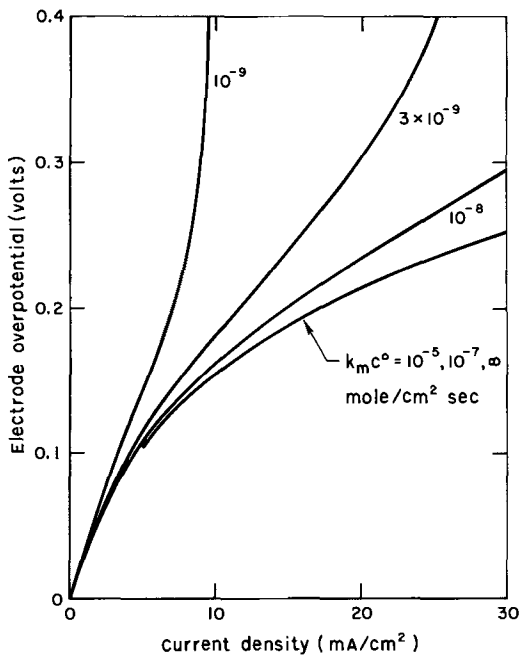

Fig. 3. Overpotential vs. current density for different values of $k_m c^0$. $a = 10^3$ cm^{-1}, $\kappa = 7\times10^{-3}$ mho/cm. Initial conditions.

Initial behavior.—The time-dependent behavior of the model proposed in this paper is conveniently introduced by an examination of the initial behavior of the model, *i.e.* for time equal to zero. A semianalytic solution for this case has been presented previously for relatively high local overpotentials where the back reaction can be neglected (7). The present numerical treatment allows for the inclusion of both forward and back reaction terms of Eq. [3] and thus represents a more complete description of the entire range of local overpotentials. Figure 3 shows the dependence of the calculated electrode overpotential, $\phi_1(0) - \phi_2(L)$, as a function of the applied current density for a specific set of electrode parameters. The various curves are for different values of the product of the mass transfer coefficients and the saturation concentrations of reactants and products. In this figure we have let $k_{m1} = k_{m2} = k_m$ and $c_1^0 = c_2^0 = c^0$ so that the parameter of interest is $k_m c^0$. At high current densities, activation control is represented by an infinite mass transfer coefficient. This corresponds to an analytic solution given by Newman and Tobias (2) for a constant concentration within the pores. As the quantity $k_m c^0$ decreases, the overpotential increases until a mass transfer limiting current is obtained. This is indicated by the rapid increase in electrode overpotential with current density near 9.5 mA/cm^2 for $k_m c^0$ equal to 10^{-9} mole/cm^{2}sec.

The approach to limiting current is accompanied by increasing uniformity of transfer current distribution within the electrode. In Fig. 4 the dimensionless volumetric reaction rate distribution, dj/dy, is shown as a function of position in the electrode for a given current density, 20 mA/cm^2. For large values of $k_m c^0$, the major portion of charge transfer takes place near the free solution edge of the electrode, $y = 1$. For this situation mass transport effects are not important compared with the interplay between activation control and ohmic drop in the solution. However, for lower values of $k_m c^0$ the reaction distribution becomes more uniform and approaches -1 throughout the electrode. This is a result of the surface concentration of reactant being driven to zero due to the difficulty of transporting active species from storage sites. This phenomenon is not explicitly dependent on the amount of charge stored in the electrode. A mass transfer

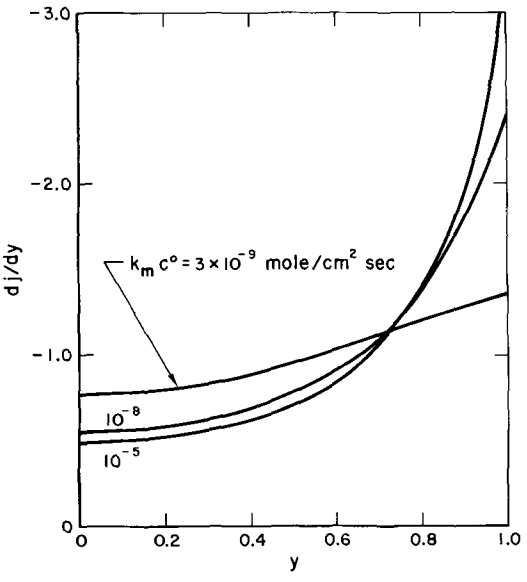

Fig. 4. Dimensionless volumetric reaction rate vs. dimensionless distance from backing plate for various values of $k_m c^o$. $I = 20$ mA/cm², $a = 10^3$ cm^{-1}, $\kappa = 7 \times 10^{-3}$ mho/cm.

limitation may occur even in fully charged electrodes so that high power densities may not be possible.

Transient behavior.—Let us now consider the time-varying behavior of the electrode overpotential under conditions of constant current. Equation [8] was used to give the form of the variation of mass transfer coefficient with the charge remaining at any point. Figure 5 shows the calculated overpotential as a function of discharge time for various saturation concentrations of active species. An initial capacity of 0.2 A-hr/cm³ was assumed present at zero time. That is, the equivalent of 0.2 A-hr/cm³ of the species to be oxidized was present, distributed uniformly throughout the electrode. In addition, another 0.2 A-hr/cm³ of species already oxidized was assumed to be present initially. If the oxidation were carried to completion, there would eventually be 0.4 A-hr/cm³ of oxidized species present, and none of the reduced species.

A number of phenomena are apparent from the different curves. Curve A, representing high saturation concentrations, has three distinct sections. For short times the overpotential is nearly constant. At some intermediate time the overpotential begins to rise almost linearly with time. At this point all of the reactant at the free solution-electrode interface has been converted to product. The reaction then begins to "eat" its way back into the electrode. At a later time the third section of the curve becomes apparent. This is when, as the reaction is driven further into the electrode, the local reaction rate becomes too large for the mass transfer mechanism to accommodate. The result is a rapid rise in overpotential indicating approach to limiting current conditions. The constant and linearly varying types of overpotential behavior have recently been reported in experimental cells using slightly soluble reactants (8). This type of polarization behavior was also obtained by Winsel (3) as a consequence of his assumption of a limited amount of reactant at each point. The difference between the results presented here and those of Winsel is the presence of diffusion-limiting current regimes in curves B, C, and D in Fig. 5. For comparatively low values of saturation concentrations, mass transfer effects become apparent at earlier times. Thus it is possible that, even if the initial polarization of a practical electrode is not prohibitively high, it may become so after a relatively short time, *i.e.* before a large fraction of the active material is consumed. The result is that the effective capacity (and true energy density) of the electrode must be sacrificed if a high current density drain is insisted upon. For example, curve A represents a discharge such that essentially all of the available reduced species is oxidized before the overpotential reaches 0.4V. Curve B shows 0.4V being reached before 93% of the active species is used. Curve D indicates that 0.4V overpotential is reached before only 68% of the active species present initially has been reacted.

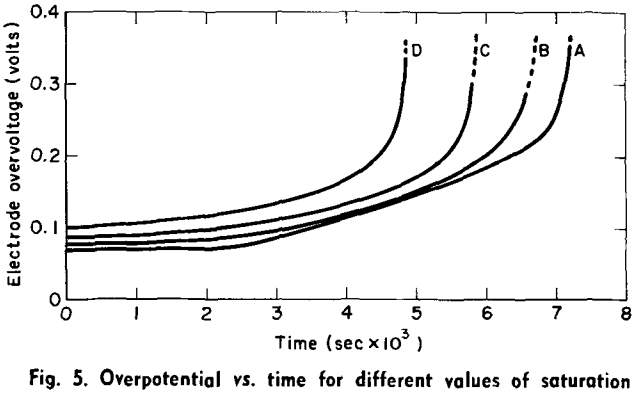

Fig. 5. Overpotential vs. time for different values of saturation concentration. $I = 10$ mA/cm², $a = 10^4$ cm^{-1}, $k_m^{max} = 0.2$ cm/sec, $\kappa = 10^{-3}$ mho/cm. Values of c^o are: (A) 5×10^{-8}, (B) 10^{-8}, (C) 5×10^{-9}, (D) 3×10^{-9} mole/cm³.

In Fig. 6 the reaction distribution is shown for the set of operating conditions represented by curve A in Fig. 5. The different curves represent the distribution at various stages of discharge. The percentage discharged is based on the theoretically available capacity of 0.2 A-hr/cm³. For the initial conditions (0% discharged), the curve shows a monotonically increasing nonuniform distribution similar to those in Fig. 4. However, as time progresses the initial nonuniform nature of the reaction distribution has the effect of reducing the mass transfer coefficient more near the free solution interface than in the interior of the electrode. This results in a maximum in the reaction distribution. After about 37% of discharge has been reached (curve not shown), the outer part of the electrode becomes converted entirely to product, and the reaction maximum slowly works its way into the electrode. When the maximum has moved beyond the backing plate, a limiting current condition is obtained.

Cycling behavior.—The nonuniform conversion of active species, resulting from the long time discharges

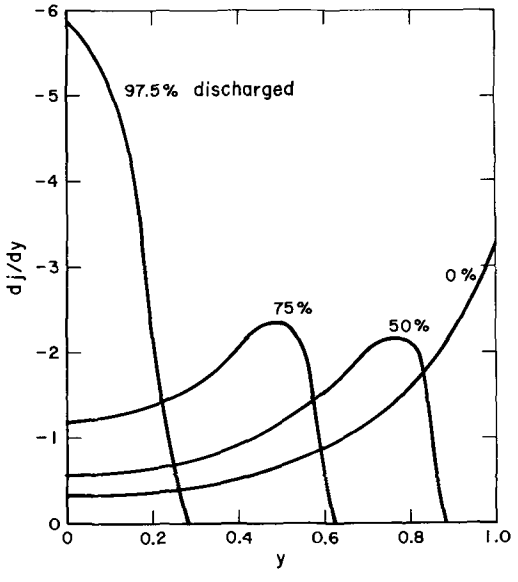

Fig. 6. Dimensionless volumetric reaction rate vs. dimensionless distance from the backing plate for different states of discharge. $I = 10$ mA/cm², $a = 10^4$ cm^{-1}, $k_m^{max} = 0.2$ cm/sec, $\kappa = 10^{-3}$ mho/cm, $c^o = 5 \times 10^{-8}$ mole/cm³. This sequence of curves corresponds to curve A in Fig. 5.

discussed above, suggests that significant redistribution of the proportion of oxidized and reduced species might occur on repeated cycling of the electrode with positive and negative currents. This was investigated by applying current densities of 10 mA/cm^2 alternately anodically and cathodically. The distribution of active material between the oxidized and reduced species at the end of one half-cycle was used as the initial distribution for the following half-cycle of opposite polarization. In order to prevent an unrealistic contribution to the overpotential due to a small amount of product present at the beginning of each half-cycle, the value of k_{mi}/k_{mi}^{max} for the product species was not allowed to fall below 0.1. Initially, the species were dispersed throughout the electrode as a uniform, equimolar mixture of reactant and product. In other words, the electrode was 50% charged, based on the total possible capacity, which was assumed to be 0.4 A-hr/cm^3. The duration of each half cycle was such that the state of charge varied between 50 and 75% of the total capacity. The computer program can be easily modified to accommodate any combination of initial conditions and duty cycles, but the above set was chosen for illustrative purposes.

Figure 7 shows the electrode overpotential as a function of time for the various cycles. The anodic cycles (positive overpotentials) show gradually increasing overpotential as a function of time during a half-cycle. Each successive anodic half-cycle shows a lower over-all overpotential at a given time. The cathodic half-cycles show very flat potential-time curves, with overpotentials increasing slightly in magnitude with cycle number.

Figure 8 shows the relative distribution of cathodic reactant at the end of each charge and discharge. It is to be recalled that the total amount of material at each point is constant. In addition the problem was formulated such that $w_1^o = w_2^o$. The above two facts imply that $w_1/w_1^o = 2 - w_2/w_2^o$, so that the amount of anodic reactant at any point can also be calculated from Fig. 8. Initially the distribution is uniform at 1, but after each whole cycle the conversion is such that

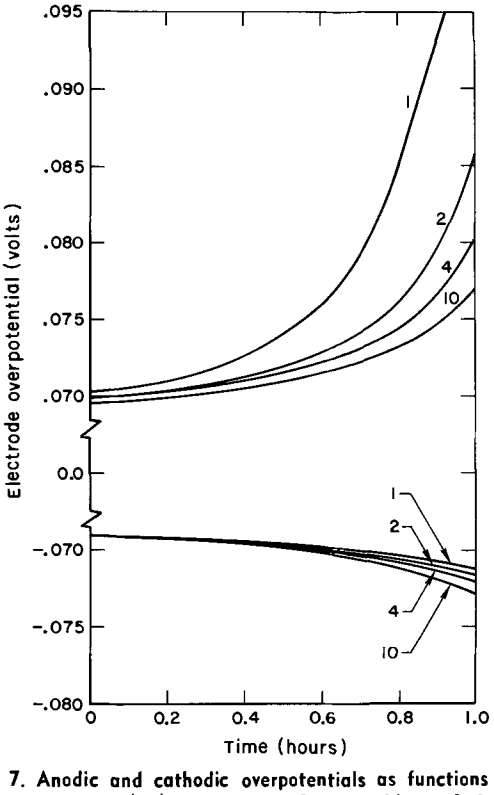

Fig. 7. Anodic and cathodic overpotentials as functions of time for different cycles. $|I| = 10$ mA/cm^2, $a = 10^4$ cm^{-1}, $k_m^{max} = 2.39 \times 10^{-2}$ cm/sec, $\kappa = 0.005$ mho/cm, $c^o = 10^{-7}$ mole/cm^3. Anodic part of cycle precedes cathodic part of cycle.

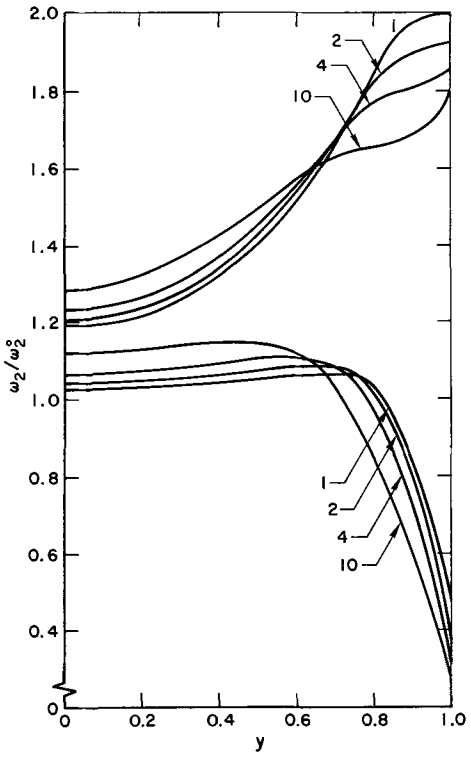

Fig. 8. Distribution of cathodic reactant at the end of each half-cycle. Parameters are the same as for Fig. 7.

there is relatively more of the oxidized species (w_2) near the backing plate and relatively less near the pore mouth. This, in effect, makes the free solution side of the electrode depleted in cathodic reactant and forces the discharge (cathodic) potential curves downward. The symmetry of the roles of reactants and products is such that another conclusion can be drawn from Fig. 8. If the electrode were cycled between 50 and 25% of total capacity (instead of 50 and 75%), the discharge curves would show lower overpotentials and the charge curves would show higher overpotentials with increasing charge number. It is important to note that these changes occur as results of nonuniform conversion of reactants as predicted by the combined kinetic and transport equations and are not due to side reactions, formation of soluble complexes, or other strictly chemical or mechanical problems.

Discussion and Conclusions

The model which has been described in this paper is necessarily idealized, but it could be applied to practical electrodes presently in use with suitable modifications. One possible improvement would be to consider explicity ionic transport in solution and to replace Eq. [2] with a more general expression. In this manner such phenomena as $SO_4^=$ transport in lead acid negatives and OH^- transport in cadmium negatives could be included. The present treatment does not consider actual changes in the total amount of active species present (*i.e.*, Σw_i is constant). However, for actual cells the movement of active species, induced by temperature differences resulting from nonuniform current distributions, should be considered.

In spite of these shortcomings, the model does point out a possible mode of failure caused by an internal mass transfer limitation of electrodes with sparingly soluble reactants. It also suggests an important criterion by which possible new electrode systems could be evaluated in terms of the solubility and diffusivity of the active species. These quantities must be small enough to ensure that the self-discharge of the cell is slow and they must be large enough so that mass transfer limitations do not cause unacceptably high overpotentials at reasonable discharge rates. For ex-

ample, from Fig. 5 one might decide that a solubility of 5×10^{-5} molar is the minimum acceptable for good battery performance for that particular system. Let us assume a minimum acceptable shelf life of two years and calculate a maximum acceptable solubility. If the capacity of the electrode is 0.2 A-hr/cm^3 and the electrode thickness is 1 mm (these are conditions assumed for Fig. 5), then the total capacity of the electrode is 2×10^{-2} A-hr/cm^2. We will also assume a 1 mm separation between plates. Based on these assumptions, a solubility of 11.4×10^{-5} molar will give a two-year shelf life. Thus, for this particular set of assumptions, the acceptable range of solubilities is rather narrow, *i.e.* between 5×10^{-5}M and 11.4×10^{-5}M. The lower limit of the range is quite sensitive to the choices of physical constants made for the model. This is especially true of the mass-transfer coefficient which is roughly estimated and may be good only to an order of magnitude. Nevertheless, it is interesting to note that the solubility of $PbSO_4$ in 10% sulfuric acid solutions is about 2.25×10^{-5}M (9) which is near the range predicted for a successful battery electrode involving a sparingly soluble reactant.

LIST OF SYMBOLS

- a Specific surface area of porous electrode, cm^2/cm^3
- c_1 Local concentration of oxidant, mole/cm^3
- c_1^o Saturation concentration of oxidant, mole/cm^3
- c_2 Local concentration of reductant, mole/cm^3
- c_2^o Saturation concentration of reductant, mole/cm^3
- D_i Effective diffusion coefficient of species i, cm^2/sec
- $\mathbf{F}$ Faraday's constant, 96,500 coul/equivalent
- i_1 Current density in matrix phase (based on over-all apparent porous electrode area), A/cm^2
- i_2 Current density in solution phase, A/cm^2
- I Total apparent current density applied to porous electrode, A/cm^2
- i_o Exchange current density, A/cm^2
- j Dimensionless current (i_1/I)
- k_{mi} Mass transfer coefficient of species i, cm/sec
- k_{mi}^{max} Maximum possible value of mass transfer coefficient of species i; occurs when all active species have been converted to species i, cm/sec
- L Thickness of porous electrode, cm
- M_i Symbol for chemical species i
- N_i Flux of active species i to local active site, moles/cm^2 sec
- n Number of electrons transferred in electrochemical reaction
- p Dimensionless parameter
- s_i Stoichiometric coefficient of species i
- t Time, sec
- w_i Amount of active material i stored at a point within the electrode, coulombs/ cm^3
- x Distance coordinate from backing plate of porous electrode, cm
- y Dimensionless distance (x/L)
- z_i Ionic charge on species i
- β A convenient reciprocal voltage ($n\mathbf{F}/2RT$), V^{-1}
- δ_i An effective diffusion path length from crystallite of active species i to electrochemically active site, cm
- κ Effective conductance of solution inside porous electrode, mho/cm
- ξ_i Dimensionless concentration (c_i/c_i^o)
- σ Effective electrical conductivity of matrix phase, mho/cm
- ϕ_1 Potential in the matrix, V
- ϕ_2 Potential in solution, V
- ψ Dimensionless overpotential [$\beta(\phi_1 - \phi_2)$]

Electrolytic Behavior of Yttria-Stabilized Hafnia[1]

Jon D. Schieltz,*,[2] John W. Patterson,* and D. R. Wilder

Institute for Atomic Research and Departments of Ceramic Engineering and Metallurgy, Iowa State University, Ames, Iowa 50010

ABSTRACT

X-ray analysis and electrical conductivity measurements (800°-1000°C) on yttria-hafnia solid solutions between 2 and 20 m/o (mole per cent) Y_2O_3 were made to locate the cubic phase and to select the composition best suited as a solid electrolyte. The phase boundary is located near 7 m/o Y_2O_3. Total conductivities obtained from the cubic phase solid solutions appear to be ionic. The 8 m/o Y_2O_3-HfO_2 composition showed the highest conductivity (log $\sigma_T = -1.57$ at 1000°C), and lowest activation energy (16.9 kcal/mole), and was selected as the optimum composition for a solid electrolyte. Open-circuit emf, electrical conductivity, and Wagner d-c polarization measurements between 800° and 1000°C were made to determine the electrolytic domain of the 8 m/o Y_2O_3 composition. The electrolytic domain width at 1000°C extends from log P_{O_2}(atm) $= -16.6$ to $+0.4$. The 8 m/o yttria-stabilized hafnia composition does appear suitable as a solid electrolyte. Its electrical properties are very similar to those of calcia-stabilized zirconia.

The investigation of solid electrolytes has been influenced by the proven behavior of the fluorite solid solutions of zirconia and thoria. Fluorite solid solutions of hafnia are obvious potential materials (1-3). The relationships between the cubic fluorite structure and the C-type rare-earth oxide structure suggest applications of C-type rare-earth oxides. The present study was undertaken to study the best Y_2O_3-HfO_2 solid electrolyte and to determine if its electrolytic domain (4) includes conditions not covered by other presently known oxide solid electrolytes.

Johansen and Cleary (3) measured the electrical conductivity of CaO-HfO_2 solid solutions from 800° to 2000°C. The conductivity was assumed to be ionic, based on previously reported investigations of CaO-ZrO_2 solid solutions. The oxygen potential was not reported but must have been limited to low or intermediate oxygen partial pressures, since a graphite resistance furnace with an argon atmosphere was used. The maximum conductivity was found to be at 12.5 m/o CaO or 6.25% anion vacancies.

Oxygen permeability studies by Smith (1) show a 1/4-power oxygen pressure dependence of the permeability of 13.5 m/o CaO-HfO_2 with an activation energy for hole conduction of 58.5 kcal/mole. The transport mechanism was attributed to the migration of oxygen vacancies and electron holes.

Most of the studies involving rare earth oxides (Re_2O_3) and hafnia deal with the structural determination of solid solutions, the existence of a pyrochlore compound $Re_2Hf_2O_7$, and the determination of phase diagrams (5, 6). Caillet *et al.* (7) have examined the HfO_2-Y_2O_3 system from 0 to 50 m/o Y_2O_3. From x-ray diffraction analyses, a two-phase region was reported between 0 and 8 m/o Y_2O_3, and only the cubic fluorite phase was present above 8 m/o Y_2O_3. The lattice parameter showed an anomaly at 33.3 m/o Y_2O_3. Along with the electrical conductivity studies by Besson *et al.* (2) which showed a minimum in conductivity and a maximum in activation energy at 1000°C for the 33.3 m/o Y_2O_3 composition, the existence of the pyrochlore compound $Y_2Hf_2O_7$ was predicted but never observed. An a-c two-probe method was used to measure the electrical conductivity of various yttria-hafnia solid solutions in a controlled atmosphere. The 8 m/o Y_2O_3 composition exhibited a maximum conductivity, which was pressure independent, and a minimum activation energy. Oxygen pressure dependence of the conductivity was observed with compositions containing less than 8 m/o Y_2O_3 and was interpreted as the electronic contribution from the monoclinic solid solution within the two-phase region. Open-circuit emf values across various cubic fluorite compositions between Ni-NiO and Fe-FeO electrodes agreed with thermodynamic values verifying that the electrical conductivity remains ionic down to oxygen pressures fixed by those electrodes.

Preparation of Samples

Spectrographic-grade hafnium oxychloride obtained from the Wah Chang Corporation (Lot SP10684B) and previously described yttria powder (8) were the starting materials. Spectrographic analysis supplied with the hafnium oxychloride is given in Table I.

The hafnium oxychloride was dissolved in distilled water and the hafnium oxide content determined analytically to establish a standardized concentration. Yttria was dissolved in hot concentrated HCl and the solution was standardized. These two solutions were mixed and slowly added to an equal stirred volume of 10*N* NH_4OH. The gelatinous coprecipitate was filtered, washed, dried, and calcined.

Calcination appeared to have an influence on the final sintered state. Dried precipitates were calcined at 600°, 800°, and 1000°C for various lengths of time. Those calcined at 1000°C possessed the highest sintered densities, while those calcined at 600°C possessed the

lowest sintered densities. Calcination times were not controlled sufficiently to produce an observable effect on the sintered samples. The calcination temperature used in the present investigation was 1000°C.

X-ray diffractometer traces of calcined compositions known to be within the single-phase region indicated that the calcined material was a one-phase fluorite solid solution.

The calcine was ground to −325 mesh in a mortar and pestle, prepressed to 1800 psi in a ¾ in. diam tungsten carbide lined steel die, isostatically pressed to 50,000 psi, and fired in a Centorr furnace for 1 hr at 2000°C and 30 min at 1500°C. The lower temperature was employed to stabilize the expected anion vacancies as demonstrated in the calcia-zirconia system (9). Disks of identical composition were placed in a covered yttria crucible, and rhenium metal was used to separate the individual disks within the crucible. The hafnia solid solutions investigated ranged from 2 to 20 m/o Y_2O_3 in 2 m/o intervals and were light brown in color after firing, indicating partial reduction. Annealing the disks for several hours in air at 1000°C produced a color change to white. The bulk density (total mass divided by total volume including open and closed pores) of the sintered yttria-hafnia samples varied from 80 to 94% of theoretical density as the calcination temperature was increased from 600° to 1000°C. Figure 1 shows the typical microstructure of an 8 m/o Y_2O_3 sample of 92% theoretical density.

Apparent densities (bulk densities corrected for open pore volume but not for closed pore volume) were used to determine the defect model for Y_2O_3-HfO_2 solid solutions as discussed below. The apparent densities were obtained by a water displacement-water saturation method for specimens of various Y_2O_3 concentrations but with approximately the same bulk density. Thus, systematic variations of closed porosity with Y_2O_3 content are not expected. Also, only the high total porosity (low bulk density) sintered disks were used for apparent density determinations because they contain almost no closed pores. Thus, the apparent density of the low bulk density disks is expected to be very close to, but slightly less than, the true density of the solid solution phase; the difference is due to closed pores in the sintered disk.

An x-ray analysis of the yttria-hafnia system was made to determine the lattice parameter as a function of composition. Diffraction patterns for the YSH (yttria stabilized hafnia) disks were recorded before and after each conductivity run. Lattice parameters were determined by Cohen's extrapolation method as modified by Vogel and Kempter (10). The monoclinic hafnia solid solution was identified by comparing the diffraction patterns with the monoclinic HfO_2 ASTM card. The fluorite structure of the YSH solid solutions was confirmed by comparing intensities and 2θ values to those obtained for erbia stabilized hafnia solid solutions which have been identified as possessing the calcium fluoride structure with anion vacancies.[3]

Results and Discussion

Structural system.—Sintered hafnia solid solutions with 2-20 m/o Y_2O_3 annealed at 1500° were subjected to x-ray analysis to determine the 1500°C solubility limit of HfO_2 in the cubic fluorite structure. The presence of both the monoclinic HfO_2 and the cubic fluorite peaks on the diffractometer traces indicated that the system is two phase between 2 and 6 m/o Y_2O_3. Between 8 and 20 m/o Y_2O_3, only the cubic fluorite phase appeared; consequently, the phase boundary lies between 6 and 8 m/o Y_2O_3 at 1500°C. The temperature dependence of the phase boundary was not investigated.

The variation in fluorite phase lattice parameter with composition is shown in Fig. 2. This can be accounted for by the size of the ions, since the ionic radius of Y^{+3} (1.02Å) (11) is larger than that of Hf^{+4} (0.83Å) (11). The lattice parameters are based on all the observed peaks for the two-phase compositions and only those peaks for which $2\theta > 60°$ for the single-phase compositions. The lattice parameters obtained are in good agreement with published values (7).

As Y_2O_3 is added to HfO_2, charge neutrality is maintained by one of two defect structures. Either the cation sublattice remains completely filled and the appropriate number of anion vacancies are created, or the anion sublattice remains filled and the excess cations occupy interstitial sites. The difference between the two models is the addition of extra cations or the absence of oxygen ions within a unit volume and should be reflected by a difference in densities. A comparison between the measured apparent densities and the theoretical densities for each model calculated from the lattice parameter data is shown in Fig. 3. On the basis of these data and the similarity between YSH and CSZ, it was concluded that the single-phase cubic solid solutions possess a fluorite-type structure with a filled cation sublattice and anion vacancies.

Electrical conductivity.—Electrical conductivity was measured as a function of composition and oxygen partial pressure. Figure 4 is a plot of $\log \sigma$ *vs.* $1/T$(°K) for compositions from 6 to 20 m/o Y_2O_3; apparent activation energies deduced from the slopes of these plots are given for each composition.[4] The a-c conductivities shown in Fig. 4 were measured at 1592 Hz in

[4] If $\log \sigma T$ *vs.* $1/T$ slopes are used instead, all the activation energies reported above are increased by the amount $-R[d\ln T/d(1/T)]$. In the temperature range 800°-1000°C, this averages out to an increase of +0.05 eV for each of the Q values.

dry air using a guard ring technique (12) with porous platinum electrodes.

At 1000°, the conductivities remained unchanged in pure oxygen, air, He/O_2 at ratios of 10 and 100, and purified helium in which log P_{O_2} was found to be < -10 as measured by an *in-situ* solid electrolyte oxygen gauge. This behavior indicates that all the compositions investigated were ionic conductors. In the low P_{O_2} range where He-O_2 and CO-CO_2 mixtures give overlapping P_{O_2} values, conductivities measured in CO-CO_2 mixtures were significantly lower than those measured in the above atmospheres. No explanation for this type of behavior is offered; however, other independent experiments supported the presence of a pressure-independent ionic conductivity.

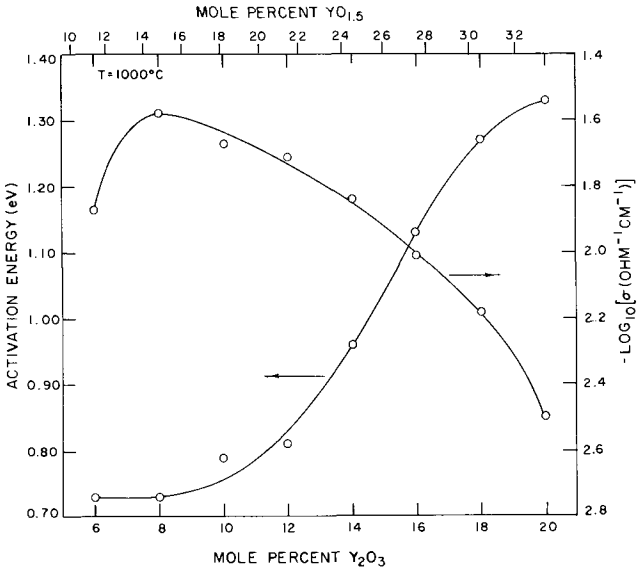

Fig. 5. Activation energy and 1000°C isothermal conductivity as a function of composition in the Y_2O_3-HfO_2 system.

The electrical conductivities agree well with values previously reported (2) at 900°-1000°C. However, the previously reported activation energies (2) are approximately 0.25 eV higher than those obtained from this work.

Because the 8 m/o Y_2O_3 composition possessed the highest conductivity and the lowest activation energy as shown in Fig. 5, it was chosen for further investigation as a possible electrolyte. The fact that the 6 m/o composition had the same activation energy as the 8 m/o composition, but a lower total conductivity, supports the x-ray studies in placing the phase boundary between these two limits. If there are two phases present at the 6 m/o composition, the monoclinic HfO_2 solid solution would be present as small islands in a continuous cubic fluorite host with a composition corresponding to the solubility limit of HfO_2 in the fluorite structure. Indications are that the conductivity is much lower in the monoclinic phase (2) than in the fluorite phase; consequently, the measured conductivity and activation energy would correspond to the continuous fluorite host with a reduced cross-sectional area. Thus, the effect of the nonconducting islands would be to decrease the total flux and thereby decrease the apparent total conductivity without altering the activation energy.

Figure 5 shows a trend of increasing activation energies and decreasing conductivities for increasing Y_2O_3 content above 8 m/o. This trend has been previously observed for the fluorite phase of the Y_2O_3-HfO_2 system (2, 13) and in similar systems (3, 14, 15). It has been suggested that this trend is due to ordering of anion vacancies (16).

Open-circuit emf measurements on 8 m/o Y_2O_3 hafnia.—Open-circuit emf measurements were made on the cells: Ni,NiO/YSH/Co,CoO and Cu,Cu_2O/YSH/Ni,NiO. The results of these measurements as a function of temperature are given in Fig. 6. The measured emf's are slightly lower than the calculated thermodynamic emf's. However, the pressure independence of the conductivity in the high oxygen pressure region and the magnitudes of $\sigma_\oplus$ and $\sigma_\ominus$ deduced from polarization experiments, described below, suggest that the low emf values are not the result of a perceptible electronic transference number. The emf discrepancies

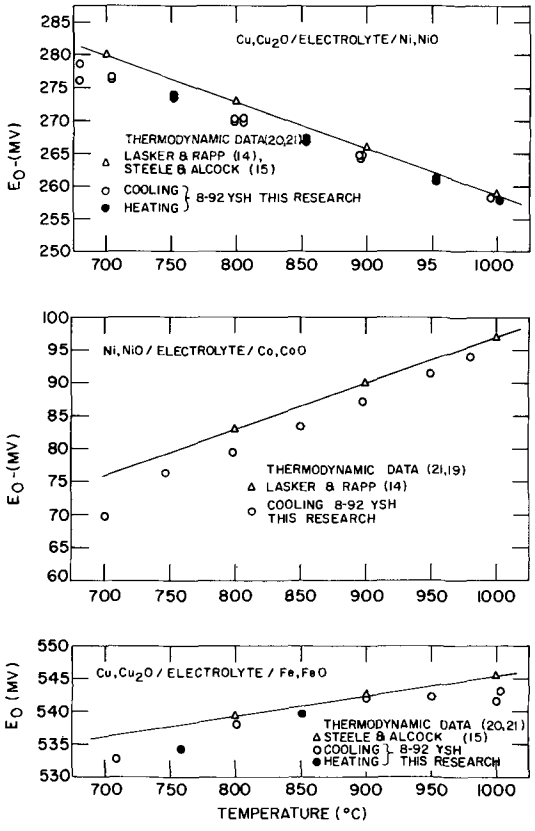

Fig. 6. Comparison of previously reported data with open-circuit emf's measured with 8 m/o Y_2O_3-HfO_2 solid electrolyte.

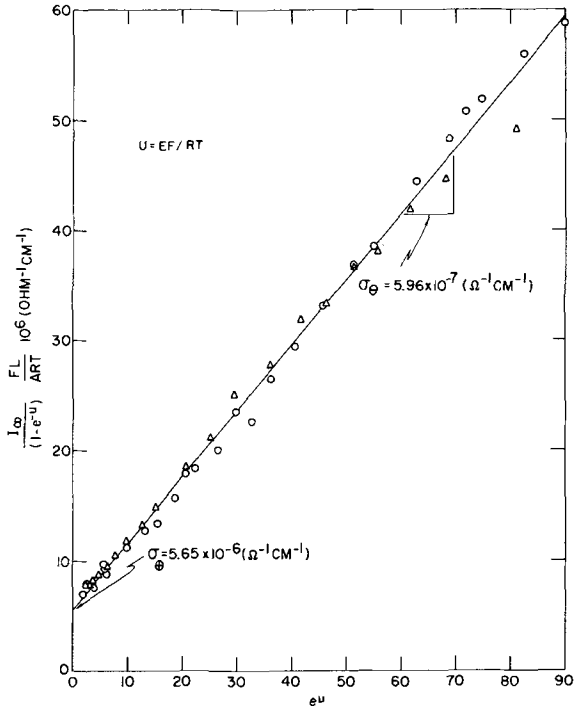

Fig. 7. Converted data plot according to Patterson (18) for d-c polarization measurements with the cell Cu, Cu_2O/8 m/o Y_2O_3-HfO_2/Au, Pt at 1000°C.

are presumed to be due to minor polarization effects associated with molecular or atomic transport through the electrolytes which were relatively porous.

In fact, emf cells such as Cu,Cu_2O/YSH/Fe,FeO and Fe,FeO/YSH/Hf,HfO_2, and Co,CoO/YSH/NbO,NbO_2, which involved large oxygen potential gradients, did not produce stable emf's. It was believed that the open porosity in the samples allowed molecular or atomic oxygen to be transferred through the electrolyte causing polarization and eventual failure of the electrodes to maintain a fixed oxygen potential. To combat this problem and rejuvenate the cell, an appropriate voltage was applied to the cell to titrate oxygen from the low to the high oxygen potential electrode. The titrations were deliberately designed to "overrestore" the apparently polarized electrodes. The titration current leads were then disengaged and the open-circuit emf was recorded as a function of time. The open-circuit emf's dropped almost instantaneously to a value which remained essentially constant for perceptible periods of time (on the order of minutes) before rapidly dropping once again. In all cases, these emf *vs.* time arrests fell very slightly below the thermodynamic emf's.

Representative samples taken after the sintering process, the conductivity, and the emf investigations were submitted for electron microprobe and wet chemical analyses to verify the composition of the solid solutions and to check for contamination resulting from the electrodes used in the emf studies. Results showed that the compositions remained unchanged and equaled the calculated compositions based on the standardized yttria and hafnia liquid solutions. As expected, the microprobe analysis indicated that the Fe-FeO electrode reacted slightly with the fluorite solid solutions, probably due to the presence of Y_2O_3. No reaction zones could be detected for the other electrodes used.

D-C polarization measurements.—An electrolyte of 8 m/o Y_2O_3 was subjected to Wagner d-c polarization measurements (17) at 1000°C to determine the magnitude of the electronic conductivity. A voltage was applied across the cell Cu,Cu_2O/YSH/Au,Pt forcing the oxygen ions to migrate to the reversible electrode. The steady-state current, assumed to be entirely electronic, was recorded as a function of the applied voltage. The data were analyzed by the method of Patterson *et al.* (18) and the results are shown in Fig. 7, where $\sigma_\oplus$ and $\sigma_\ominus$ represent the hole and excess electron conductivity, respectively, at the Cu-Cu_2O electrode.

The total conductivities of the 8 m/o Y_2O_3 were assumed to be ionic conductivities. The hole and excess electron conductivities were extrapolated based on a $+\frac{1}{4}$ and a $-\frac{1}{4}$ oxygen pressure dependence until they intersected the ionic conductivity. These intersections define the ionic domain (4) at 1000°C and are given by log $P_\oplus = +8.4$ and log $P_\ominus = -24.8$. Moreover, the lower domain limit of log $P_\ominus = -24.8$ is in excellent agreement with that of log $P_\ominus = -24.4$ obtained by open-circuit emf measurements.

Figure 8 compares this YSH electrolyte with other oxide solid electrolytes by showing the relative location of their respective ionic domain ($t_{ion} \geq 0.50$) boundaries. Because log $P_\oplus$ for YSH is higher (at 1000°C) than that for YDT (yttria-doped thoria), the ionic and hence the electrolytic domain for YSH is superior to that for YDT on the high P_{O_2} side. However, using Patterson's assessment (4) for CSZ (calcia-stabilized zirconia), YSH is found to be inferior to SCZ at high P_{O_2} values.

On the low P_{O_2} side, the ionic domain for YSH is about the same as that estimated by Patterson (4) for CSZ but is substantially inferior to (*i.e.*, has a much higher log $P_\ominus$ value than) YDT (8). Hence the ionic domain of YSH at 1000°C does not extend beyond conditions already covered by the previously known solid electrolytes CSZ and YDT. Using Patterson's analysis (4) and $+\frac{1}{4}$ and $-\frac{1}{4}$ oxygen pressure dependences for positive hole and excess electron conductivities implies that the electrolytic domain ($t_{ion} \geq 0.99$) for YSH extends from log $P_{O_2} = -16.8$ up to log $P_{O_2} = +0.4$ at 1000°C.

Conclusions

1. The cubic fluorite phase of yttria-stabilized hafnia is stable from about 7 m/o Y_2O_3 to compositions greater than 20 m/o Y_2O_3 at 1500°C.

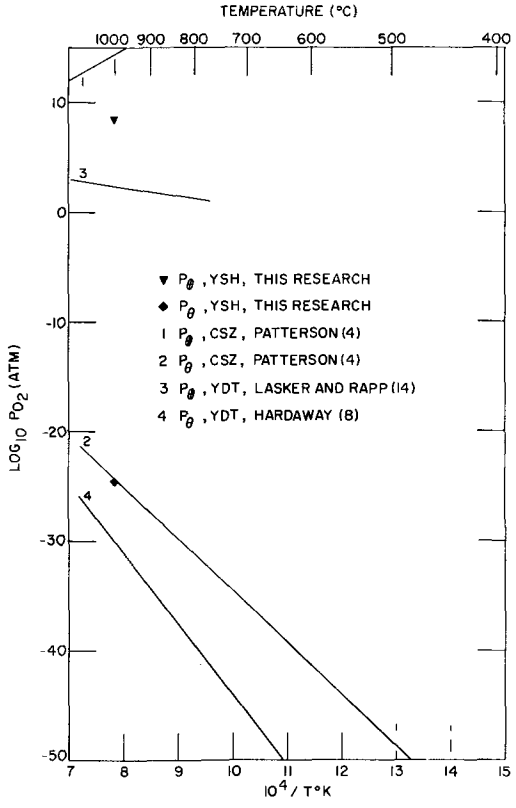

Fig. 8. Ionic domain boundaries for various oxide materials

2. The fluorite phase is an anion defective structure with substitutional replacement of hafnium with yttrium. Charge neutrality is maintained by fully ionized anion vacancies.

3. All yttria-hafnia solid solutions between 6 and 20 m/o Y_2O_3 exhibit a predominant ionic conductivity over the temperature range from 800° to 1000°C as evidenced by the oxygen pressure independence of the total conductivity.

4. Within the yttria-stabilized hafnia fluorite phase, activation energies increase and total conductivities decrease with increasing Y_2O_3 content. These trends suggest a tendency toward anion vacancy ordering.

5. The 8 m/o Y_2O_3-HfO_2 composition is a solid electrolyte over finite oxygen pressure and temperature ranges. The electrolytic domain width ($t_{ion} \geq 0.99$) for this composition at 1000°C is from log P_{O_2}(atm) = −16.6 to 0.4. It does not extend beyond conditions already covered by the previously known solid electrolytes CSZ and YDT at 1000°C.

Differential Capacitance and Linear Sweep Voltammetry Studies on Polycrystalline Lead and Electrodeposited Lead Dioxide

J. P. Carr and N. A. Hampson

Chemistry Department, Loughborough University of Technology, Loughborough, Leicestershire, England

ABSTRACT

Impedance and linear sweep voltammetry (LSV) studies are reported on polycrystalline Pb and electrodeposited PbO_2 (α and β) in aqueous NaOH. The impedance studies indicate a pzc of -0.62 ± 0.01V (NHE) for Pb and $+1.15 \pm 0.01$V (NHE) for β-PbO_2. The LSV studies indicate that the anodic oxidation of Pb and cathodic reductions of α-PbO_2 involve mass transport of OH^- ions by diffusion in solution. Reduction of β-PbO_2 is complicated by modification to α-PbO_2.

Studies of lead dioxide electrodes in acid media are numerous. PbO_2 exists as two polymorphs, the orthorhombic α-form and the tetragonal β-form (1-3). It has been established that in acid media β-PbO_2 is the more stable polymorph (4, 5), however, α-PbO_2 has been observed in positive plates of lead acid batteries (6) and other investigations (7-10) have shown that α-PbO_2 is the main constituent of the anodic corrosion product on Pb.

Thermodynamically α-PbO_2 is the more stable polymorph in alkaline solutions (11) and recent work (12) has established the production of basic conditions in the interior of positive plates in the lead acid battery during the initial stages of formation which would provide the conditions conducive to the formation of α-PbO_2.

In spite of this few electrochemical measurements have been made on polycrystalline lead and lead dioxide in alkaline media. In this work we present differential capacitance and fast linear sweep voltammetry (LSV) data on polycrystalline lead and electrodeposited PbO_2 (α and β) in aqueous NaOH.

Previous Work in Alkali

Venstrem and co-workers (13, 14) studied the variation of hardness, with potential, of lead electrodes in NaOH (1M) and report the potential of zero change (pzc) at -0.55V (NHE). This confirms differential capacitance determinations in other aqueous solutions (15-21).

Following earlier work by Jones, Thirsk, and Wynne-Jones (22), Elbs and Forssell (23), and Glasstone (24), Farr and Hampson (25) studied the anodic behavior of polycrystalline lead in aqueous KOH and showed that the anodic oxidation of lead is complicated by transitions between the processes

$$Pb + 2\,OH^- = PbO + H_2O + 2e \qquad [i]$$

$$PbO + 2\,OH^- = PbO_2 + H_2O + 2e \qquad [ii]$$

$$\text{discharge of } OH^- \text{ on the } PbO_2 \text{ layer} \qquad [iii]$$

It was concluded that during oxidation, part of the oxidized lead was incorporated into a film of tetragonal lead oxide while the remainder dissolved in the electrolyte until the electrolyte in the immediate vicinity of the electrode became saturated with the anodic product, and orthorhombic lead oxide was deposited on the electrode blocking reaction [*i*]. α-PbO_2 was formed by oxidation of the tetragonal lead oxide on the electrode surface.

In previous differential capacitance studies (26) on time stable lead dioxide electrodes in aqueous KNO_3, we reported the pzc as 1.06 ± 0.01V (NHE) (α-PbO_2) and 1.15 ± 0.01V (NHE) (β-PbO_2). Other workers (27-29) have reported the pzc at 1.5-1.85V (NHE), but in the latter cases the results were for short electrode/electrolyte contact times.

In an earlier galvanostatic study (30), it was established that in alkaline solutions containing Pb(II), α-PbO_2 is the stable polymorph. PbO is adsorbed at the α-PbO_2 electrode surface and, at potentials near the equilibrium, the charge transfer reaction involves a simultaneous two-electron transfer between adsorbed PbO and two OH^- ions in solution whereas at higher overpotentials the exchange involves two consecutive electron steps.

Chartier and co-workers (31, 32) have studied the cathodic reduction of α- and β-PbO_2 in alkali. For β-PbO_2 they suggest that the electrode reaction involves two mechanisms
(*a*) a solution reaction

$$\beta\text{-}PbO_2 + H_2O + 2e = HPbO_2^- + OH^- \qquad [iv]$$

and (*b*) a solid phase reaction

$$\beta\text{-}PbO_2 + H_2O + 2e = PbO + 2\,OH^- \qquad [v]$$

Experimental

Double layer capacitance measurements.—The experimental technique and electrolytic cell have been described previously (33, 34). Charcoal purification of electrolytes (AR NaOH and doubly distilled water from deionized stock) was used, each electrolyte solution being continuously circulated through the cleaned activated charcoal for at least 14 days before making measurements. Potential measurements were made against a saturated calomel electrode using an electrometer (Keithley Type 610B). The counterelectrode was platinum gauze of high surface area. PbO_2 test electrodes were of α- and β-PbO_2 deposited on platinum bases (35, 36). Comparative x-ray studies were made in order to establish the freedom of each deposit from the unrequired polymorph [Phillips Diffractometer Type P.W. 1015 (36)]. Pb test electrodes were prepared by drawing molten Pb (99.999% pure supplied by Johnson Matthey Company Ltd.) into a glass capillary while under an atmosphere of N_2. The end was cut square and polished on a diamond wheel. Before each set of readings on Pb the electrode was mechanically polished on roughened glass using conductivity water as a lubricant, electrochemically etched in perchloric acid (20%), and finally chemically etched in the perchloric acid for 30 min.

LSV experiments.—Potential sweep measurements were carried out at $23° \pm 0.5°$C using a fast response potentiostat in conjunction with a linear sweep generator (Chemical Electronics Ltd.). The current was recorded on an x/y plotter (Bryant Instruments Ltd.). No parasitic interaction between the potentiostat and recorder was observed.

The test electrodes were as above. The counter and test electrodes were always of identical material. The

reference electrode was a saturated calomel electrode. The electrolytic cell, Fig. 1, consisted of three compartments separated by glass frits. The reference electrode was joined to the test electrode compartment by a Luggin capillary and in all sweeps it was ensured that the test electrode was within 1 mm of the Luggin capillary tip, in order to minimize IR drop which was small in all the experiments. The Luggin capillary was finely drawn out at the tip to minimize shielding of the electrode.

Results and Discussion

Differential Capacitance Studies

Polycrystalline lead.—Figure 2 shows a characteristic faradaic current-bias potential curve for polycrystalline lead in NaOH electrolytes. The experimental polarizable region extends from ~ -0.25 to -1.0V,[1] the limits being governed by hydrogen evolution at the negative extremity and lattice dissolution at the positive extremity. Figure 2 indicates that for Pb the polarizable region is not ideal; however, the extent of the deviations from ideality is not very different from that observed for other metals (34).

Stable electrode impedances were obtained after 2 hr electrode/electrolyte contact. Readings taken at very short times showed a certain amount of drift but once stability had been achieved the system remained stable at potentials within the polarizable region for at least 24 hr without significant change. Replicate electrode impedances indicated an 8% variation about a mean.

Hysteresis was observed at both the negative and positive extremes of the polarizable region but for potential excursions within these limits no hysteresis

[1] All potentials are reported with respect to the normal hydrogen electrode.

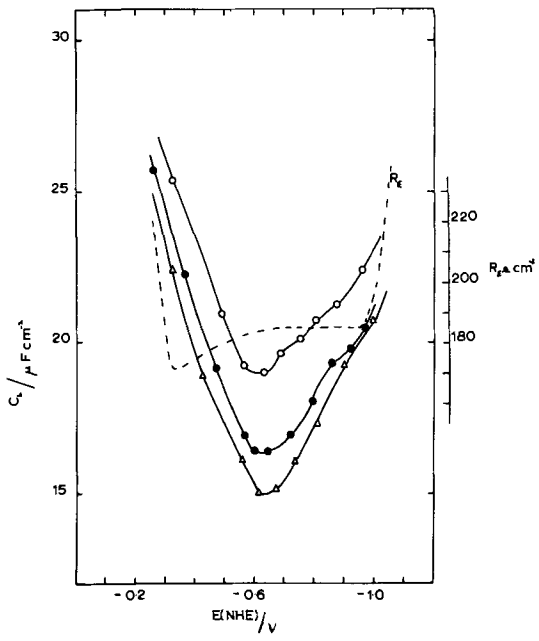

Fig. 3. Differential capacitance curves for polycrystalline lead in NaOH electrolyte, 23°C, 1000 Hz, (○) 0.401; (●) 0.091; (△) 0.0148M.

was observed. Electrodes forced to potentials outside the polarizable region and then returned to the polarizable region never reverted to their original electrode conditions indicating that irreversible electrode changes had occurred.

Figure 3 shows differential capacitance curves at 1 kHz for the range of concentrations investigated. (The separation of the anodic branch of the differential capacitance curves with $[OH^-]$ is a consequence of the equilibrium reaction

$$Pb(OH)_3^- + 2e \rightleftarrows Pb + 3\ OH^-$$

which predicts that E° shifts by ~ -90 mV for each decade in $[OH^-]$). On the same diagram is plotted the electrode resistance, R_E. A well-defined minimum in the differential capacitance curves, which increased with dilution, appears at -0.62V. This minimum is characteristic of the potential of zero charge, pzc, and compares with the work of Venstrem and co-workers (13, 14) who reported the pzc as -0.56V. R_E is potential dependent to some extent, a maximum occurring at ~ -0.41V, however, at potentials more negative R_E is reasonably constant indicating that at the pzc of Pb indicated (~ -0.6V) the true Pb/NaOH interphase is being observed.

Figure 4 shows a typical frequency dispersion of the differential capacitance. The extent of the dispersion amounted to less than 5% for a frequency change 1 kHz to 120 Hz. The dispersion observed is similar to that expected for solid metal electrodes and is most probably due to a certain amount of surface roughness as discussed by De Levie (37).

Electrodeposited PbO_2.—Figure 5 shows characteristic faradaic current-bias potential curves for α- and β-PbO_2 in NaOH electrolytes. The experimental polarizable region extends from $\sim$ 0.6 to 1.25V for α-PbO_2 and $\sim$ 0.6 to 1.20V for β-PbO_2, in each the limits are governed by oxygen evolution at the positive extremity and lattice dissolution at the negative extremity. A small change in the potential of zero current flow was observed for the two polymorphs, $\sim$ 0.65V for α-PbO_2 and $\sim$ 0.76V for β-PbO_2.

For α-PbO_2 electrodes stable electrode impedances were obtained within 1 hr of electrode/electrolyte contact, however, for β-PbO_2, 10-hr contact times were required. Impedance readings taken at short contact times showed a certain amount of drift. Once stability

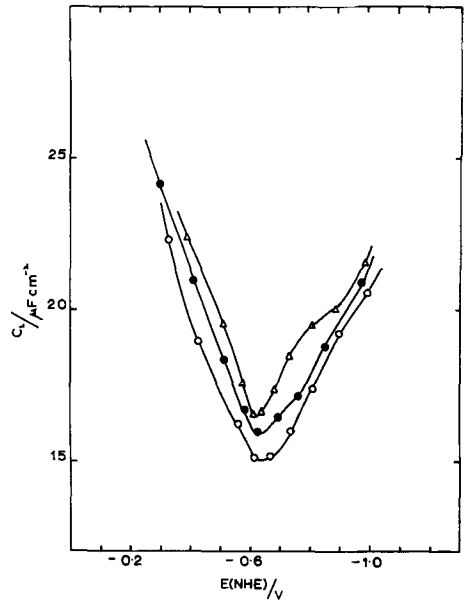

Fig. 4. Typical frequency dispersion of differential capacitance curves for polycrystalline lead in NaOH electrolyte (0.0149M), 23°C; △, 120 Hz; ●, 300 Hz; ○, 1000 Hz.

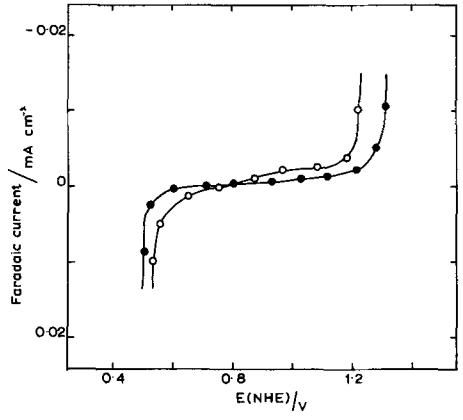

Fig. 5. Typical faradaic current-bias potential curves for electrodeposited lead dioxide in NaOH electrolyte (0.1M), 23°C; ●, α-PbO_2; ○, β-PbO_2.

had been achieved however the α-PbO_2 system remained stable at potentials within the polarizable region for at least 24 hr without significant change, the β-PbO_2 system was stable for only a relatively short time (1-2 hr). Replicate impedances indicated a 5% variation about a mean. No hysteresis was observed for potential excursions within the polarizable region, however, forcing the potentials outside this region caused serious irreversible changes at the electrode and it was found impossible to return to the original electrode condition.

Figures 6a and 6b show differential capacitance curves for α- and β-forms, respectively, at 1 kHz for the concentration of NaOH electrolytes investigated. On the same diagram is plotted the electrode resistance, R_E, which was satisfactorily constant in all electrolyte concentrations over the experimental polarizable region, for both polymorphs.

The differential capacitance curves shown for α-PbO_2 (Fig. 6a) were flatter than similar curves for β-PbO_2 (Fig. 6b) and the capacitance minimum was less well defined. For β-PbO_2 a minimum in the capacitance curves, taken to be the potential of zero charge, E_z, appears at 1.15V. Figures 7 and 8 show the typical frequency dispersion of capacitance which was observed in all experiments and appeared to be an inherent property of the electrode. The extent of the

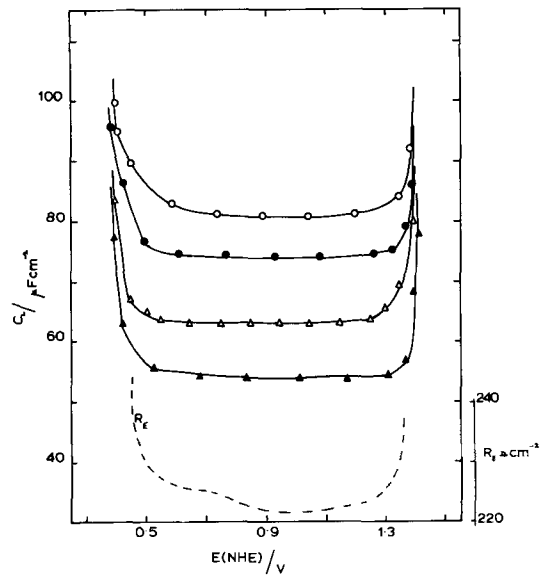

Fig. 6a. Differential capacitance curves for electrodeposited α-PbO in NaOH electrolytes, 23°C, 120 Hz; ○, 0.105; ●, 0.0405; △, 0.007; ▲, 0.0023M.

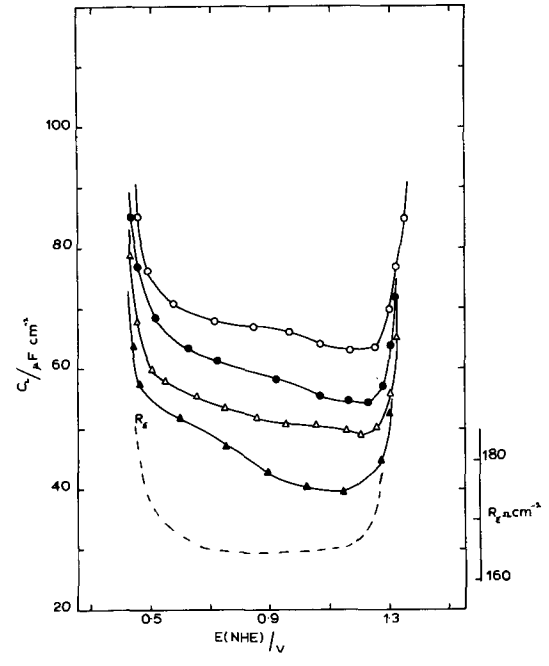

Fig. 6b. Differential capacitance curves for electrodeposited β-PbO_2 in NaOH electrolytes, 23°C, 120 Hz; ○, 0.105; ●, 0.0405. △, 0.007; ▲, 0.0023M.

dispersion, which was similar for both polymorphs, amounted to ~ 10% variation for a frequency change 1 kHz to 500 Hz.

Fast LSV Studies

LSV has been widely used for the examination of surface phenomena at electrodes (38-40). The general theory was developed by Randles (41) and Ševčik (42). In the case of the formation of a soluble substance at the electrode the current limitation is caused by a progressive removal of the reacting species in the immediate vicinity of the electrode. The magnitude of the maximum current (I_m) is proportional to the concentration of the rate-controlling species. Considering the general electrode equation

$$O + Ze = R \qquad [1]$$

and an ideal system in which the transport of reacting species at the electrode surface is by linear diffusion,

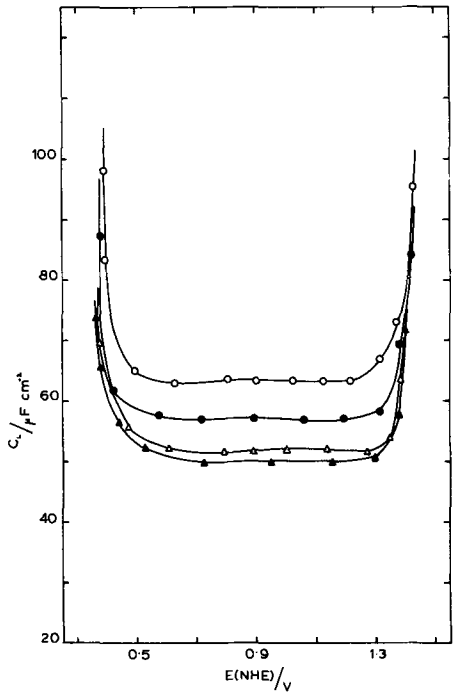

Fig. 7. Typical frequency dispersion of differential capacitance curves for electrodeposited α-PbO_2 in NaOH electrolyte (0.007M), 23°C; ○, 120 Hz; ●, 300 Hz; △, 500 Hz; ▲, 1000 Hz.

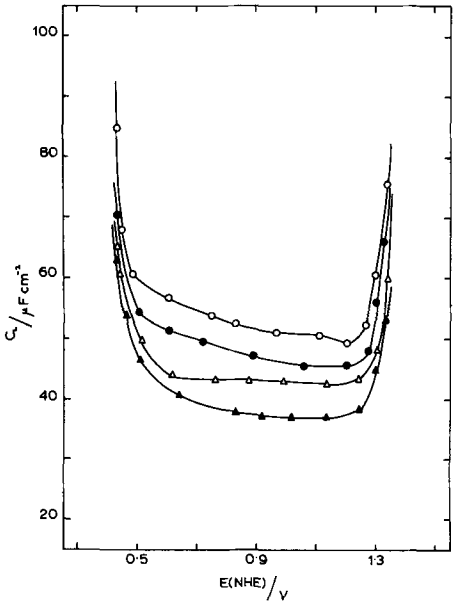

Fig. 8. Typical frequency dispersion of differential capacitance curves for electrodeposited β-PbO_2 in NaOH electrolyte (0.045M), 23°C; ○, 120 Hz; ●, 300 Hz; △, 500 Hz; ▲, 1000 Hz.

Delahay (43) has shown that at 25°C

$$I_m = 2.72 \times 10^5 \cdot Z^{3/2} \cdot A\, D^{1/2} \cdot C \cdot v^{1/2} \qquad [2]$$

where Z is the number of electrons involved in the reaction, A is the area of the electrode, D the diffusion coefficient, C the concentration of the rate-controlling electroactive species, and v the potential sweep rate.

Similarly for the reversible formation of an insoluble substance at the electrode and assuming linear diffusion Delahay (43) has shown that at 25°C

$$I_m = 3.67 \times 10^5 \cdot Z^{3/2} \cdot A\, D^{1/2} \cdot C\, v^{1/2} \qquad [3]$$

Experiments with solid metals are complicated by difficulties which prevent quantitative measurements being made, for example, doubt concerning the true

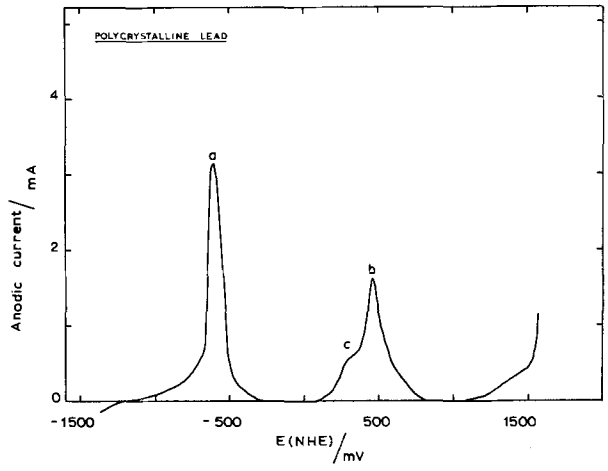

Fig. 9. Typical fast anodic potential sweep on polycrystalline lead in NaOH (3.45M), 23°C, 58.3 mV sec^{-1}.

surface area, true concentration of electroactive species, and the exact value of the diffusion coefficient. Also the problem arises of what proportion of the total current flowing is due to the capacitive component (I_c) where

$$I_c = X_c \left(\frac{d\eta}{dt}\right) \qquad [4]$$

where X_c is the double layer capacitance.

It is however, possible to obtain qualitative information concerning the controlling modes of diffusion occurring.

Polycrystalline lead.—Figure 9 shows the results of a typical fast anodic potential sweep. The experimental potential range (~ −1300 mV to ~ +1700 mV) was limited by hydrogen evolution at the negative extremity and oxygen evolution at the positive extremity. Between these potential limits two clearly defined, sharp current peaks (*a* and *b*) were observed and a minor peak *c* appeared as a shoulder on peak *b*. Peak *a* occurred at approximately the Pb/PbO redox potential (−585 mV NHE) and corresponded to the anodic oxidation of Pb to PbO as given by the general reaction

$$Pb + 2\,OH^- = PbO + H_2O + 2e \qquad [5]$$

Peaks *b* and *c* occurred at a potential approximately corresponding to the PbO/PbO_2 redox potential. Later experiments with the separate polymorphs of PbO_2 indicated that peak *b* was due to formation of α-PbO_2 and peak *c* due to formation of β-PbO_2.

Figure 10 shows the effect of sweep rate on the anodic peak height (peak *a*). A linear relationship between I_m and $\sqrt{v}$ was observed, the I_m-$\sqrt{v}$ line passing through the origin throughout the experimental concentration range. Figure 11 shows the effect of [OH^-] on I_m (peak *a*). I_m is directly proportional to [OH^-] in agreement with Eq. [2].

From Fig. 10 and 11 it is clear that the process which controls the flow of current is a diffusion process in solution and that the OH^- ion is the species which is involved in the diffusion process. Since I_m is directly proportional to [OH^-], Eq. [2] and [3] indicate that only one OH^- ion is involved in this process. It is suggested that a possible sequence of reactions at the electrode is as follows

$$Pb + 2\,OH^- = Pb(OH)_2 + 2e \qquad [6]$$

$$Pb(OH)_2 + OH^- = Pb(OH)_3^- \qquad [7]$$

$$Pb(OH)_3^- = PbO + OH^- + H_2O \qquad [8]$$

where [7] and [8] occur subsequently to produce a PbO phase at the electrode and, at the same time, [7] occurs in absence of [8] to form plumbite ions in

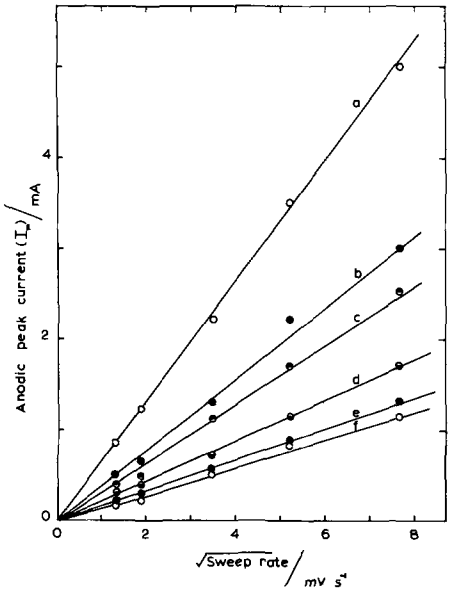

Fig. 10. Anodic peak current (I_m) vs. (sweep rate)$^{1/2}$ for formation of PbO on polycrystalline lead (peak *a* of Fig. 9) in NaOH, 23°C. (a) 4.7; (b) 3.45; (c) 2.53; (d) 1.79; (e) 1.39; (f) 1.02M. Electrode area 3.3 x 10^{-2} cm^2.

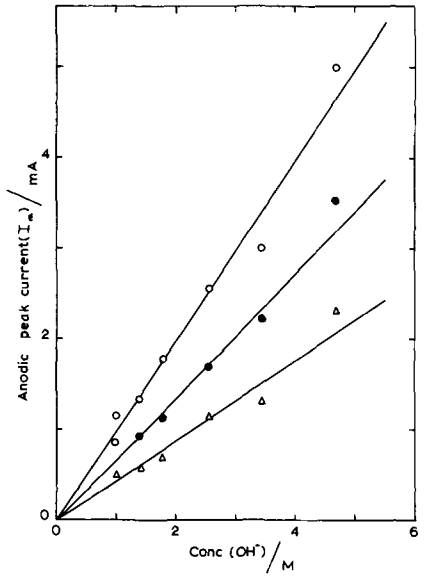

Fig. 11. Anodic peak current (I_m) vs. [OH^-] for formation of PbO (peak *a* of Fig. 9) on polycrystalline lead, 23°C. ○, 58.3 mV sec^{-1}; ●, 29 mV sec^{-1}; △, 12 mV sec^{-1}. Electrode area 3.3 x 10^{-2} cm^2.

solution. This mechanism is similar to that proposed by Farr and Hampson (25) on the basis of an electron microscopic study of the electrode surface coupled with a galvanostatic electrometric investigation.

The apparent diffusion coefficient of the OH^- ion calculated from the slopes of the I_m *vs.* $\sqrt{v}$ lines (Fig. 11) indicates a mean value of $\sim 10^{-7}$ cm^2 sec^{-1}. This value is considerably smaller than published data (46) for the diffusion coefficient of the OH^- ion in aqueous solution. A possible explanation of this is that diffusion of OH^- ions must occur through a layer of anodic products and the diffusion coefficient involved is that of the diffusing ion in the product phase. An alternate explanation is that the true surface area of the electrode available for diffusion is very much less than the apparent area due to the presence of a solid phase of PbO (25). It is difficult to decide which of these two explanations is formally correct but both indicate the well-established fact that in the region of the dissolution of a lead electrode in alkali a layer of solid products exists at the electrode surface (25). (It is not likely that a transpassive dissolution occurs at the electrode since the potential region at which peak *a* is observed is too low and in any case a transpassive dissolution would be expected to yield ions of a higher valence state.)

Linear relationships between I_m and $\sqrt{v}$ were not obtained within the experimental concentration range for peaks *b* and *c* indicating that the rate-controlling reaction mechanism is more complex than simple diffusion. The fact that I_m of peak *b*, which corresponded to the formation of α-PbO_2, was always greater than I_m of peak *c* (β-PbO_2), indicated that at high anodic potentials, although α-PbO_2 was the major product formed, traces of β-PbO_2 were always present. If the PbO_2 deposit was scraped from the electrode surface after a complete anodic potential sweep the presence of an orange brown colored deposit of PbO underneath the PbO_2 was observed. This would be in agreement with Farr and Hampson (25) that PbO_2 overlays a layer of PbO.

Nonreproducible relationships between I_m and sweep rate for peaks *b* and *c* indicate the possibility of formation of PbO_2 by more than one mechanism as observed previously by Rüetschi and Cahan (44) who suggest simultaneous oxidation of PbO and underlying Pb.

A slight negative shift of the potential of peak *b* and *c* occurred with increasing sweep rate indicating that the reaction occurring was significantly irreversible. For such a reaction Delahay (43) derived the relationship

$$E_p = E - \frac{RT}{a\,z\,\mathbf{F}}\left[0.77 - \ln k_f^{i}\,(\beta D\cdot)^{1/2} + \frac{1}{2}\ln\frac{a\,\mathbf{ZF}}{RT}\,v\right] \quad [9]$$

where E is the initial potential and E_p the potential at sweep rate v, α is the charge transfer coefficient for the electrode reaction, β is given by the expression

$$\beta = \frac{a\mathbf{ZF}}{RT}\,v$$

and k_f^{i} a reaction constant. Although theoretically α should be obtainable from $E_p - v$ data, in practice the uncertainties in the study of solid electrodes prevent this.

Electrodeposited α-PbO_2.—Figure 12 shows the results of a typical fast cathodic potential sweep. Between the two potential limits two clearly defined peaks (*d* and *e*) were observed. Peak *d* occurred at a potential representing reduction of the α—PbO_2 to PbO.

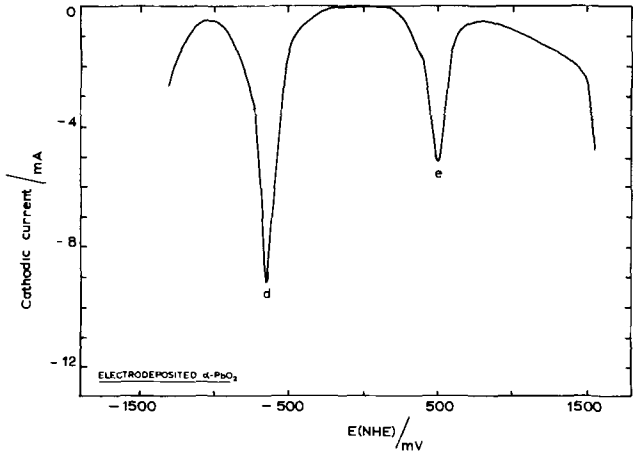

Fig. 12. Typical fast cathodic potential sweep on electrodeposited α-PbO_2 in NaOH (4.7M), 23°C, 58.3 mV sec^{-1}. Electrode area 4.9 x 10^{-2} cm.

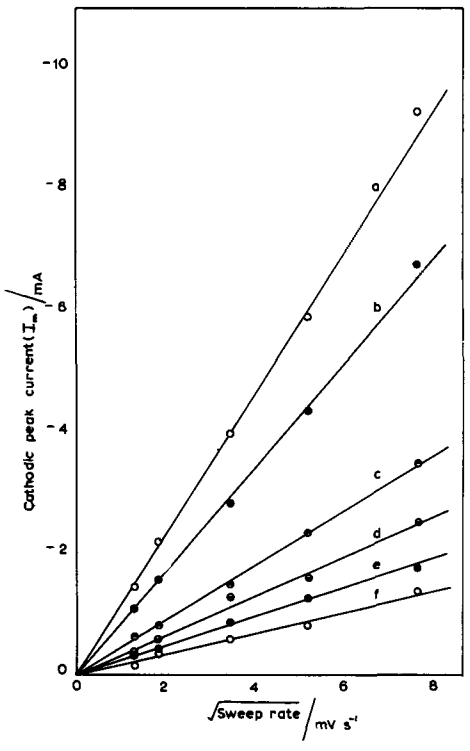

Fig. 13. Cathodic peak current, I_m, vs. $\sqrt{\text{sweep rate}}$ for formation of PbO (peak *d* of Fig. 12) on electrodeposited α-PbO_2 in NaOH, 23°C. (a) 4.7; (b) 3.45; (c) 2.53; (d) 1.79; (e) 1.39; (f) 1.02M. Electrode area 4.49 x 10^{-2} cm^2.

A shift of the potential of peak *d* to more negative values with increasing v indicated some irreversibility of this reaction. Peak *e* appeared at the Pb/PbO redox potential and represented reduction of PbO to Pb.

Figure 13 shows the effect of sweep rate on the cathodic peak height (peak *d*). A linear relationship between I_m and $\sqrt{v}$ was observed and within the experimental concentration range the I-$\sqrt{v}$ curves passed through the origin indicating that the current-limiting reaction is the diffusion of OH^- ions in solution.

Figure 14 shows the variation of I_m with concentration of OH^-; a linear relationship was not observed, the slope of $\log_{10} I_m$ *vs.* $\log_{10}$ [OH^-] having a value of ~1.4. The results confirm our previous work (30) indicating that adsorption of the electrode reaction products intrudes in the electrode reaction. The following sequence represents the electrode reaction

$$PbO_2 + H_2O + 2e = PbO_{ads} + 2\,OH^- \quad [10]$$

$$PbO_{ads} = PbO_{aq} \quad [11]$$

$$PbO_{aq} + OH^- + H_2O = Pb(OH)_3^- \quad [12]$$

Calculation of the diffusion coefficient using Eq. [2] and the initial part of the curves in Fig. 14 yields a value of ~10^{-7} which is far too small to be the true diffusion coefficient of the OH^- ion in aqueous solution. As previously suggested for the case of lead in alkali these data can be interpreted by either of the two explanations previously outlined, however, in this case it seems that the presence of an adsorbed layer through which the OH^- ion must diffuse is better supported by previous experimental work (30) than the postulation of an incomplete oxide film.

For peak *e*, a linear relationship of I_m *vs.* $\sqrt{v}$ was not observed indicating a duplex reaction system depending on prior reactions.

Electrodeposited β-PbO_2.—Figure 15 shows the results of a typical fast cathodic potential sweep. Between the potential limits three peaks were observed (*f*, *g*, and *h*). Peak *h* occurred at the Pb/PbO redox potential. Peak *g* occurred at the α-PbO_2/PbO redox

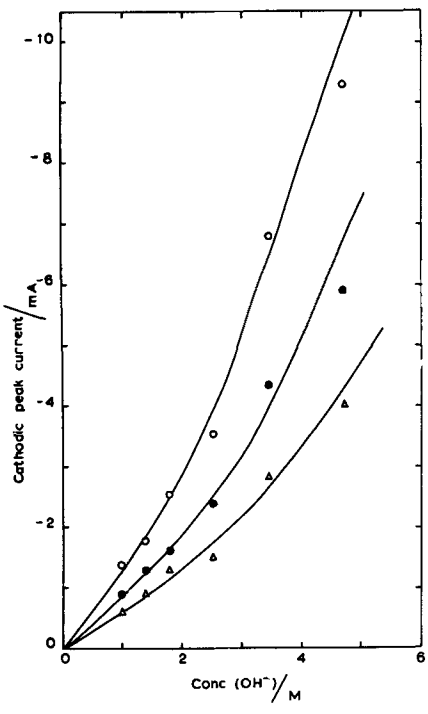

Fig. 14. Cathodic peak current (I_m) vs. [OH^-] for formation of PbO (peak *d* of Fig. 12) on electrodeposited α-PbO_2, 23°C; ○, 58.3 mV sec^{-1}; ●, 29 mV sec^{-1}; △, 12 mV sec^{-1}. Electrode area 4.49 x 10^{-2} cm^2.

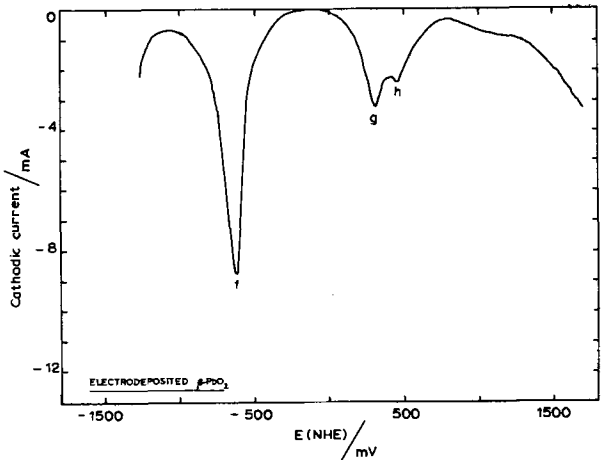

Fig. 15. Typical fast cathodic potential sweep on electrodeposited β-PbO_2 in NaOH (4.7M). 23°C, 58.3 mV sec^{-1}. Electrode area 4.9 x 10^{-2} cm^2.

potential indicating the presence of α-PbO_2 in the deposit. Peak *f* was observed only for β-PbO_2 and must be due to the β-PbO_2/PbO redox reduction. Continuous cathodic cycling showed a decrease in peak *f* but increase in peak *g* indicating a possible modification of the β-PbO_2 on the electrode surface to α-PbO_2 confirming earlier work (30) the reverse of which was observed in acid solutions (45), *i.e.*, modification of α-PbO_2 to β-PbO_2.

Conclusions

1. Differential capacitance studies
   (*a*) The pzc of Pb in aqueous NaOH is −0.62 ± 0.01V (NHE). The differential capacitance-bias potential curves show a distinct minimum.
   (*b*) The pzc of β-PbO_2 in aqueous NaOH is 1.15 ± 0.01V (NHE). The differential capacitance-bias potential curves show a broad minimum.
   (c) The pzc of α-PbO_2 could not be estimated.
2. Fast LSV studies

(a) The anodic oxidation of Pb to PbO in aqueous NaOH involves mass transport control by diffusion of OH^- ions in solution.
(b) The cathodic reduction of α-PbO_2 to PbO in aqueous NaOH involves mass transport control by diffusion of OH^- ions in solution but is complicated by adsorption of PbO at the electrode surface.
(c) The cathodic reduction of β-PbO_2 is complicated by a modification of surface β-PbO_2 to α-PbO_2.

Effects of Carbonate on the Anodic Dissolution and the Passivation of Zinc Electrode in Concentrated Solution of Potassium Hydroxide

Yuichi Sato, Hirokazu Niki, and Tsutomu Takamura

Toshiba Research and Development Center, Tokyo Shibaura Electric Company, Ltd., Kawasaki, 210, Japan

ABSTRACT

The effect of carbonate ions on the anodic behavior of a horizontal zinc anode in concentrated KOH solutions has been investigated by measuring the passivation time at constant current. Anodic dissolution of zinc was found to be associated with the diffusion-controlled zincate ion saturation near the electrode and the passivation time of the electrode, which is defined to be a period until the passivation occurs, was reduced with increasing concentration of carbonate ions at constant concentration of KOH. The phenomenon was explained from the linear relationship between t_p and $1/\eta$ as a result of the increase in viscosity η of the solution.

Although many authors have studied the anodic behavior of zinc electrodes in alkaline electrolyte (1, 2), few papers appear to have been published regarding the effect of carbonate ion on the zinc electrode reactions. Preliminary experiments showed that the presence of carbonate accelerates the passivation of the zinc electrode during the anodization in alkaline solution. Carbonate may be introduced in the solution when it is in contact with atmospheric air in the process of alkaline battery production. The knowledge of the effect of carbonate, therefore, appears valuable from the practical standpoint. The present study was initiated in order to determine the effect quantitatively and to establish a mechanism.

Of the many possible experimental approaches, measurements of the time for passivation at constant current with a horizontal plane electrode seem most suitable for obtaining a direct correlation between the battery performance and the carbonate concentration. In the present paper, passivation time of the zinc electrode was measured at constant anodic current and the relation between the passivation time and the carbonate concentration was investigated.

Experimental

The zinc electrode used was a disk of 20 mm diameter, that was cut from a rolled zinc sheet of 0.3 mm thickness and of about 99.99% purity. The electrode was cleaned by immersing in dilute HCl for about 5 min and rinsed in a stream of distilled water until the chloride ion was not detected by the $AgNO_3$ test. The sample treated by nitric acid (1) gave nearly the same results as that treated by hydrochloric acid. After being dried at room temperature, the electrode of lustrous surface was placed in an electrolysis cell. A H-type electrolysis cell of acrylic acid resin was used. The diameter of each compartment of the cell was about 30 mm. The solution volume of the sample compartment, 25 ml, was sufficient to prevent the concentration change during the anodic dissolution of zinc. The bottom of the sample compartment had a hole of 1.28 cm^2 and the zinc plate was sandwiched between the outer face of the bottom and a nickel plate which was covered by a thick plate of acrylic resin. The sandwich was tightened by screws to prevent any liquid leak. The actual working area of the zinc electrode was the same as that of the hole. The nickel plate was used as an electric contact. The potential of the zinc electrode at constant anodic current density was monitored through a Luggin capillary *vs.* a mercury-mercuric oxide electrode in pure KOH of the same concentration as that in the test cell. In another compartment of the cell, a nickel gauze of large area was placed and used as a counterelectrode. A constant anodic current of $\pm 0.3\%$ accuracy was supplied to the test electrode from a regulated power supply (Showa Electronics Model VSA 710S) until the onset of passivation on the surface. The passivation time, t_p, of the electrode was determined from the potential-time curves recorded on an electric polyrecorder (Toa Electronics Ltd. Model EPR-2TB) as illustrated in Fig. 1. The electrolysis was carried out in a thermostat kept at 25° ± 0.1°C, and oxygen dissolved in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution for about 15 min. Ten minutes of nitrogen bubbling was found satisfactory for the complete removal of dissolved oxygen, which was checked polarographically. During the electrolysis, nitrogen gas was passed over the solution. Electrolysis was started 15 min after the immersion of the specimen electrode into the solution.

The base electrolytic solution was prepared by dissolving a known amount of reagent grade KOH pellet into doubly distilled water, the concentration being determined by titration. A solution containing the required concentration of ZnO or K_2CO_3 was prepared by dissolving a known amount of ZnO or K_2CO_3 of reagent grade into the base solution. All the procedures were carried out in a glove box filled with flowing nitrogen gas.

Viscosity and density measurements at 25°C were made for the electrolytic solution by conventional methods in a constant temperature bath controlled to ± 0.05°C. The white precipitate formed on the test electrode during the anodization was determined by x-ray and IR analysis. Samples for the analysis were collected as white leaves from the passivated electrode surface which, in advance, was washed with distilled water and dried in air. IR reflection spectra measurements were also made for the surface of the anodized zinc electrode which was washed with water and dried.

Results

The anodization was carried out at various current densities. The passivation time, t_p, was found dependent on the electrolysis conditions as has been pointed out (1, 2), and, of course, it increased when the solution was agitated during the electrolysis. Therefore, all the values cited below were obtained by keeping the solution quiescent. The reproducibility of t_p was excellent with the experimental error of $\pm 5\%$.

A typical potential-time curve at constant current is reproduced in Fig. 1, from which the passivation time of the electrode is determined as indicated in the figure.

Key words: alkaline batteries, viscosity, constant current electrolysis, zinc oxide.

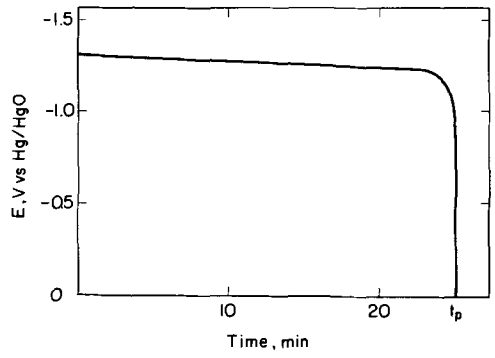

Fig. 1. Typical potential-time curve for horizontal zinc anode in a solution of 7.84M KOH containing 0.5M dissolved ZnO. Current density is 40 mA/cm^2.

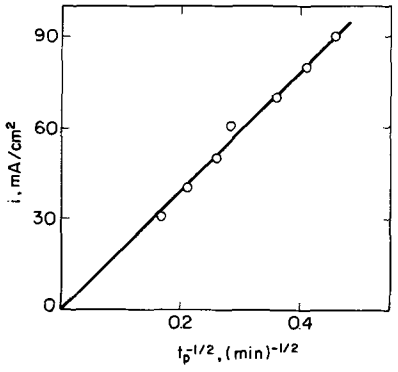

Fig. 2. Passivation time and current density relationship in a solution of 7.84M KOH containing 0.5M dissolved ZnO.

Figure 2 shows the relation between the anodic current density and the passivation time of the electrode for the solution of 7.84M KOH containing 0.5M dissolved ZnO at 25°C. As is seen in the figure, $t_p^{-1/2}$ increased linearly with the increase of applied anodic current.

When K_2CO_3 was added to KOH solution, t_p was found to be reduced in a linear manner and the slope was dependent on the concentration of dissolved ZnO. Figure 3 shows the variation of t_p in the solution of KOH against varied concentration of K_2CO_3 with and without 0.5M dissolved ZnO. The effect of ZnO can also be seen in the figure: at constant concentration of K_2CO_3, t_p was decreased by the addition of 0.5M ZnO, indicating the same tendency as with K_2CO_3. Addition of K_2CO_3 or ZnO may decrease the OH^- activity resulting in the decrease of t_p. In order to check whether there is a factor other than OH^- activity acting on t_p, t_p was measured in the system of KOH-NaOH where the OH^- concentration was kept constant. In Fig. 4, the relation between t_p and the gram equivalent fraction of KOH in the solution is given, where a marked reduction of t_p is shown to be caused by the increase of Na^+ concentration in spite of keeping the OH^- concentration constant.

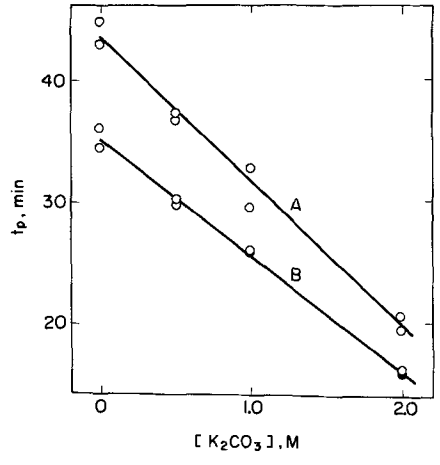

Fig. 3. Effects of carbonate ions on the passivation time in both 7.86M KOH (plot A) and 7.83M KOH + 0.5M dissolved ZnO (plot B). Concentration of K_2CO_3 was varied from zero to 2M and the current density was kept at 30 mA/cm^2.

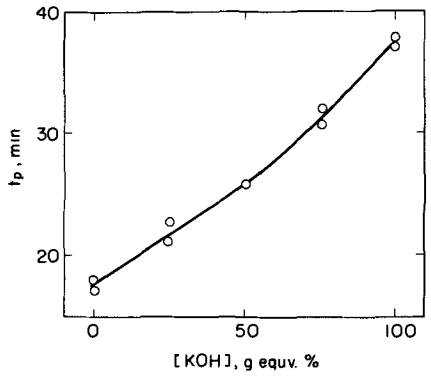

Fig. 4. Relation between the passivation time and gram equivalent fraction of KOH in the 8M alkaline solution whose total alkaline concentration was adjusted with NaOH and contained 0.5M ZnO. Current density is 30 mA/cm^2.

Density and viscosity data for the various solutions used in these experiments are tabulated in Tables I-III. The viscosity of the solution is increased with increasing the concentration of K_2CO_3 or the fraction of NaOH.

One may ascribe the decrease in t_p in the presence of CO_3^{2-} to the formation of $ZnCO_3$ film which retards further dissolution of zincate ion by covering the electrode surface. Low solubility of $ZnCO_3$ in water (3) appears to support this explanation. In order to detect the presence of $ZnCO_3$, the reaction product formed during the anodization was determined by x-ray and IR analyses. The x-ray analysis of the reaction products showed that the products consist of ZnO and do not contain $ZnCO_3$ and $Zn(OH)_2$. Neither IR spectra of the reaction products nor the reflection spectra of the surface of the zinc electrode after the electrolysis gave signals characteristic of $ZnCO_3$ (4).

Discussion

Since longer t_p favors the better discharge performance of the battery, solution contact with atmospheric air should be avoided during the production process of alkaline batteries. It is well known that the dissolution of carbon dioxide in caustic alkali causes a decrease in OH^- activity resulting in the decrease of t_p. An additional disadvantage due to the presence of CO_3^{2-}, however, has been shown to exist in the present study even if OH^- concentration is kept constant. Clear indication of lowering t_p due to increased concentration of CO_3^{2-} is seen in Fig. 3, where OH^- concentration is kept constant.

We wish to consider the mechanism of accelerated passivation due to CO_3^{2-}. For a situation in which ions generated at the anode diffuse away, time and current density are related by the following form of the diffusion equation (5, 6)

$$i = \frac{n\mathbf{F}\pi^{1/2}D^{1/2}\Delta C}{2t_p^{1/2}} \qquad [1]$$

where ΔC is the concentration difference of zincate ions between the electrode surface and the bulk solution, other symbols have the usual meaning. Figure 2 shows that the present experimental conditions satisfy the diffusion-controlled condition where anodic current is inversely proportional to the square root of the passivation time. Thus, the passivation is associated with a diffusion-controlled zincate ion saturation or supersaturation of the solution layer adjacent to the electrode resulting in the deposition of ZnO.

Of the oxide films formed by the anodic polarization in alkaline solution, existence of two different types has been reported by several authors (1, 2): the type 1 film is white, loose, and flocculent and the type 2 is a more adherent, compact, and protective film. According to Powers and Breiter (1), the former is formed at about −1.27V and influences the polarization, but it is not so strong as to cause the complete passivation, whereas the latter is of predominant importance in controlling the active to passive transition. The potential at which the type 2 film begins to form is uncertain but is considered to be more anodic than that of type 1. The potential-time curve in Fig. 1 begins to fall at about −1.25V, indicating the type 1 film forms initially, followed by the formation of the type 2 film, which passivates the zinc electrode. The passivation time, t_p, is shown to decrease linearly with the increase of CO_3^{2-} concentrations (Fig. 3). Two factors in Eq. [1] can contribute to the reduced t_p, *i.e.*, the decrease in ΔC or D.

First, we consider the reduction in ΔC. If the solubility of zincate ion which is formed as a result of the anodic dissolution is lowered by some reasons, ΔC should be decreased. If the solubility of $ZnCO_3$ is smaller than that of ZnO in alkaline solution, the passivation time would be shortened by the formation and the deposition of $ZnCO_3$ on the surface. This possibility, however, is denied by the analytical results of the passivation film, where $ZnCO_3$ could not be identified. This is in accordance with the solubility consideration in which the effect of OH^- activity is taken into account. The solubility product of $ZnCO_3$ in water is very small ($K = [Zn^{2+}][CO_3^{2-}] = 1.6 \times 10^{-11}$, at 25°C) (3), but the solubility in alkaline solution is shown to be very much increased as follows. The equilibrium constant of the equation (3) is a measure of the solubility of $ZnCO_3$ in alkaline solution

$$ZnCO_3 + 4\,OH^- \rightleftarrows [Zn(OH)_4]^{2-} + CO_3^{2-} \qquad [2]$$

$$K_1 = \frac{[Zn(OH)_4^{2-}][CO_3^{2-}]}{[ZnCO_3][OH^-]^4} \qquad [3]$$

Since the following equilibrium constants are known

$$Zn^{2+} + 4\,OH^- \rightleftarrows [Zn(OH)_4]^{2-} \qquad [4]$$

$$K_2 = \frac{[Zn(OH)_4^{2-}]}{[Zn^{2+}][OH^-]^4} = 1.4 \times 10^{15}\ (7) \qquad [5]$$

$$ZnCO_3 \rightleftarrows Zn^{2+} + CO_3^{2-} \qquad [6]$$

$$K_3 = [Zn^{2+}][CO_3^{2-}] = 1.6 \times 10^{-11} \qquad [7]$$

K_1 can be calculated by assuming the activity of $ZnCO_3$ as unity. The calculated value of K_1 is 2.2 x 10^4, showing that $ZnCO_3$ is very soluble in concentrated alkaline solution and would not deposit before the deposition of ZnO on the electrode.

Now we have to take into consideration the other factor, *i.e.*, the decrease in D which is reasonably expected to be caused by the increasing viscosity of the solution with increasing concentration of K_2CO_3. Because the anodic dissolution of zinc electrode is diffusion controlled as discussed above, the increase in viscosity would retard zincate ions to diffuse away from the electrode and facilitate the passivation of the electrode.

The relation between the passivation time and the viscosity of the solution will be derived for the purpose of explaining the present experimental data. According to Stokes' law, a particle of radius r moving through a homogeneous medium of viscosity η under the influence of a force f will maintain a velocity v, given by $v = f/6\pi\eta r$. When the definition of equivalent ionic conductance λ is introduced, the following relation holds

$$\lambda = \frac{|z|\mathbf{F}^2}{6\pi\eta r N} \qquad [8]$$

where N is Avogadro's number. The diffusion coefficient is given by Eq. [9]

$$D = \left(\frac{RT}{|z|\mathbf{F}^2}\right) \cdot \lambda \qquad [9]$$

By using these relations, Eq. [1] is rewritten as

$$t_p = \frac{n^2\mathbf{F}^2RT\Delta C^2}{24\,i^2N\pi} \cdot \frac{1}{\eta} \qquad [10]$$

Equation [10] shows that passivation time should be inversely proportional to the viscosity of the solution if the other factors are kept constant. Mean values of t_p at a given concentration of K_2CO_3 shown in Fig. 3 are plotted *vs.* the reciprocal of η cited in Tables I and II. As shown in Fig. 5, the experimental values fall on a straight line going through the original point, indicating the mechanism can be elucidated in terms of the viscosity increase. Equation [10] shows that ΔC can be calculated from the slope of the plot if the ionic radius is known. The values of ΔC for both cases of A and B, namely in the absence and the presence of 0.5M ZnO, can be calculated from the slopes of Fig. 5. Calculated values are 5.5M for the case of plot A, and

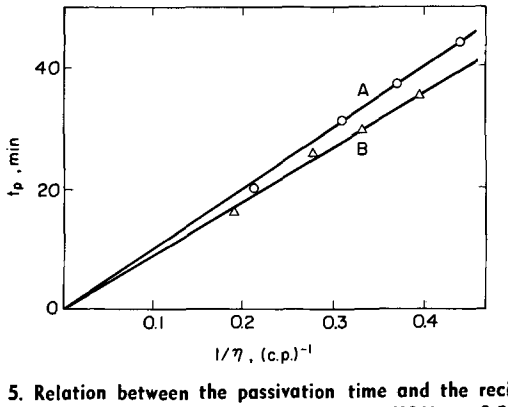

Fig. 5. Relation between the passivation time and the reciprocal viscosity in 7.86M KOH (plot A) and in 7.83M KOH + 0.5M dissolved ZnO (plot B). Viscosity was changed by adding K_2CO_3 (see Tables I and II).

5.1M for B, where the ionic radius of zincate ion is assumed to be the same as the literature value of 3.5A for Zn(II) aquo ion (8). The calculated concentration difference seems to be too large in comparison with the solubility of ZnO in concentrated KOH solution, which is about 0.9M in 8M KOH solution at 25°C (9). However, initial zincate ion concentrations have been found fairly higher than the equilibrium solubility when zincate ion is dissolved by anodization in caustic alkali, the tendency being explained by the feasibility of supersaturation (5, 10). This evidence justifies the higher values obtained here. It is obvious from Eq. [10] that the value of ΔC is dependent on r whose accuracy determines the validity of ΔC. The difference of ΔC obtained by the calculation for two sorts of solutions with and without ZnO is 0.4M which is nearly coincident with the experimental concentration difference of 0.5M. This would be an indication of the validity of the present treatment, which will provide one possible method for determining the concentration of dissolved material in the vicinity of the electrode.

Another factor influencing t_p is the activity of OH^-. The solubility of ZnO decreases with decreasing concentration of OH^- (9) and the OH^- activity may be lowered by the addition of K_2CO_3. But the slight lowering of the activity seems not enough to reduce to half the passivation time. The data given in Fig. 4 and 6 support the present argument. The solubility of ZnO in 8M KOH is 0.9M (9), and about 1.3M in 8M NaOH (11). If the passivation time is governed by the solubility of ZnO only, it must be longer in NaOH solution than in KOH, which contradicts the experimental results in Fig. 4. Figure 6 shows that t_p is mainly controlled by the viscosity of the solution. The slight downward departure from a straight line in Fig. 6 would be explained in terms of the solubility of ZnO. The solution of low viscosity was prepared by mixing a smaller amount of NaOH and a larger amount of KOH, where the solubility of ZnO is lower. In such a solution, the deposition of ZnO is facilitated resulting in the shorter t_p. A nondiffusional process like convection cannot explain the downward departure because t_p is expected to increase at the high $1/\eta$ value region, where the effect of convection seems to be more significant if convection occurred in the present case. Migration is not considered because of the high concentration of the electrolyte as compared to the electrolysis current.

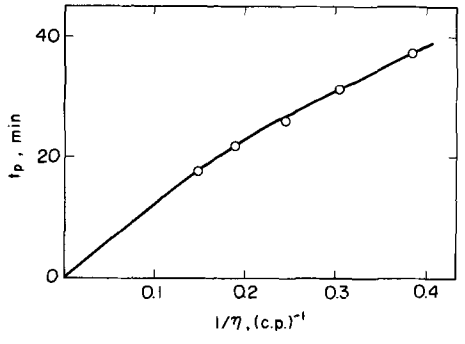

Fig. 6. Relation between the passivation time and the reciprocal viscosity in 8M (KOH + NaOH) solution containing 0.5M dissolved ZnO. Viscosity was changed by varying the ratio of KOH to NaOH as shown in Table III.

Electrode Behavior of Iron in 2M HCl Containing Oximes or Quinuclidine

Erwin Laengle[1] and Norman Hackerman*[,2]

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Galvanostatic anodic and cathodic potential measurements were carried out with pure iron in 2M hydrochloric acid plus aliphatic and aromatic oximes and quinuclidine at different concentrations. Inhibition of both the anodic iron dissolution and the cathodic H_2-evolution by oximes and quinuclidine was caused by adsorption of the organic molecules on the metal surface. The cathodic polarization curves were interpreted quantitatively by the assumption of two rate-determining charge transfer reactions in a combined Volmer-Heyrovský mechanism. Anodic polarization curves were S-shaped with small Tafel regions around the rest potential. A change to less polarizable behavior at large polarizations was explained as due to desorption of adsorbed Cl^- and inhibitor molecules. The anodic Tafel slopes changed continuously from 120 to 30 mV with increasing inhibitor concentration and were interpreted by proposing a reaction mechanism on the basis of the combination of two limiting cases, namely the iron dissolution in inhibitor-free and in concentrated inhibitor-HCl solution.

The efficiency of nitrogen-containing organic compounds (amines, amides, pyridines, quinolines, acridines, thiourea, etc.) as inhibitors of iron in acid solutions has been extensively studied (1-5). It was clearly established that inhibition in a system without oxygen and oxidizing agents must be caused by the adsorption of the organic molecule on the iron surface (6). Enhanced inhibition can be attributed to improved adsorption due to the functional group and the polarizability of the inhibitor molecule.

In this study some aliphatic and aromatic oximes were investigated. In addition quinuclidine was studied in order to provide a comparative substance which is expected to adsorb without complications, such as different possibilities of orientation on the iron surface, etc.

Anodic and cathodic galvanostatic polarization measurements of pure iron in 2M HCl solution at 25° ± 1°C were made with several concentrations of the inhibitors. Metal dissolution rates were determined colorimetrically for dissolved iron. Kinetic parameters of the iron dissolution and the hydrogen evolution with and without inhibitors were sought in order to propose a mechanism for the inhibition.

Experimental

Chemicals.—Triple-distilled water prepared by redistilling standard laboratory water through a two-stage still (Model E-1, Barnstead Still & Sterilizer Company) was used in the preparation of the test solutions. All chemicals used were analytical reagent grade. Test electrodes were machined from a stock of zone-refined iron supplied by Battelle Memorial Institute with the following impurities in ppm: total nonmetallic, 8; total metallic, 38.

Polarization measurements.—The test electrode was a cylindrical iron rod pressed into a cylindrical Teflon plug with one flat edge (0.125 cm^2) exposed to the solution. A brass center rod was screwed into both the Teflon plug and the glass support. After abrading with 0, 1, and 4/0 emery papers the electrode was electropolished immediately before use in a mixture of 70-72% perchloric acid and glacial acetic acid (4:1 by volume) for 3 min at 150 mA/cm^2 and finally cleaned with pure acetone and water.

A glass cell in which the anode and cathode compartments were separated by fritted glass was used for the polarization measurements. A platinum sheet served as auxiliary electrode and the reference electrode was a Ag/AgCl electrode fitted into a Haber-Luggin capillary filled with 2M HCl solution. The potential of the reference electrode was found to be +195 mV *vs.* SHE, checked periodically with a saturated calomel electrode. The polarization current was supplied by a 90V battery and a series of variable resistances. The potentials and applied currents were determined with two Model 610B Keithley electrometers.

The measurements were carried out with 150 ml of test solution. Purified helium gas was bubbled through the solution for at least 15 hr before each experiment was started. Readings were started 2 hr after immersion of the test electrode. Upon application of a constant current, the potential required between 4 and 10 min to reach a steady value.

Colorimetric measurements.—After immersing in 50 ml of deareated test solution in a glass cell, the test electrode, pretreated in the same way as described above, was prepolarized for 1 hr with a constant cathodic current of 0.2 mA/cm^2. This procedure was used to reach a stable rest potential without iron dissolution. The circuit was then opened and after 6 hr the electrode was removed from the solution. The colorimetric iron determinations were carried out with 1,10-phenanthroline (7) and a student-type Bausch & Lomb colorimeter.

Results

Anodic and cathodic polarization measurements were conducted separately. The polarization curves in 2M HCl solution without inhibitor were measured several times and showed well-defined Tafel regions extending over about a decade of the current axis. Reproducibility of the cathodic Tafel slopes was somewhat better than those of the anodic slopes (±5 mV/decade and ±10 mV/decade, respectively). For uninhibited 2M HCl, the corrosion current (Table I) and the rest potential were given by the intersection of extrapolated anodic and cathodic Tafel lines. (When an inhibitor was added, the rest and corrosion potentials were not necessarily the same.) The rest potential was found to be −240 ± 5 mV; the corrosion current density was reproducible to ±3%.

Cathodic galvanostatic polarization curves.—All experimental curves with inhibitor solution showed a

Table I. Corrosion rates and inhibitor effectivenesses ($E = (i_{\text{uninhibited}} - i_{\text{inhibited}})/i_{\text{uninhibited}}$) of iron in 2M HCl solutions with and without inhibitors extrapolated from anodic polarization curves (i_{corr} and E_1), and the inhibitor effectivenesses calculated from colorimetric iron determinations (E_2)

	i_{corr}, mA/cm²	E_1	E_2
2M HCl	4.5×10^{-2}	0	0
1×10^{-3}M acetone oxime	2.9×10^{-2}	0.36 ± 0.03	0.31 ± 0.04
1×10^{-3}M 2-butanone oxime	2.5×10^{-2}	0.44 ± 0.03	0.37 ± 0.04
1×10^{-3}M acetophenone oxime	2.2×10^{-2}	0.51 ± 0.03	0.51 ± 0.04
1×10^{-3}M benzaldoxime	1.9×10^{-2}	0.58 ± 0.03	0.59 ± 0.04
1×10^{-3}M benzophenone oxime	1.5×10^{-2}	0.67 ± 0.03	0.63 ± 0.04
1×10^{-3}M quinuclidine	3.0×10^{-2}	0.33 ± 0.03	0.31 ± 0.04

characteristic shape as given in Fig. 1. The same polarization curves were obtained whether the solution was stirred by bubbling helium during the measurements or not. The intersection of the linear portions of the cathodic curves with the potential axis at the rest potentials indicates that quinuclidine and all oximes act as accelerators. However, the intersection of the linear portions of the anodic curves with the potential axis at the rest potentials indicates that these compounds showed inhibition. Colorimetric determinations of the dissolved iron in solutions with and without inhibitors proved that the real corrosion currents were those derived from the anodic curves, as shown in Table I.

In the concentration range between 1×10^{-4}M and 1×10^{-1}M, no relation was found between the rest potentials and the corrosion rates for any inhibitor investigated here. The rest potentials were all between −223 and −261 mV with a maximum error of ±10 mV for each experiment.

The characteristic shape of the cathodic polarization curves can be explained by the assumption of the following two rate-determining charge transfer reactions in a combined Volmer-Heyrovský mechanism

$$H^+ + e^- \rightarrow H_{ad} \quad \text{Volmer}$$

$$H^+ + H_{ad} + e^- \rightarrow H_2 \quad \text{Heyrovský}$$

Vetter (8) derived a theoretical expression for the current-potential relation of the Volmer-Heyrovský mechanism.

$$i_{H_2} = 2i_{0,V} \exp\left[-\frac{(1-\alpha_1)\mathbf{F}}{RT}\eta_{H_2}\right] \frac{1 - \exp\left(\frac{2\mathbf{F}}{RT}\eta_{H_2}\right)}{1 + \frac{i_{0,V}}{i_{0,H}} \exp\left[\frac{(1+\alpha_1-\alpha_2)\mathbf{F}}{RT}\eta_{H_2}\right]} \quad [1]$$

where

i_{H_2} = total current density
η_{H_2} = overvoltage
$i_{0,V}$ = exchange current density of the Volmer reaction
$i_{0,H}$ = exchange current density of the Heyrovský reaction
α_1 = transfer coefficient of the Volmer reaction
α_2 = transfer coefficient of the Heyrovský reaction

Without the factor 2 and by using polarization π instead of η_{H_2} this formula can be used for the calculation of all cathodic polarization curves measured in this study.

$$i_{H_2} = i_{0,1} \exp\left[-\frac{(1-\alpha_1)\mathbf{F}}{RT}\pi\right] \frac{1 - \exp\left(\frac{2\mathbf{F}}{RT}\pi\right)}{1 + \frac{i_{0,1}}{i_{0,2}} \exp\left[\frac{(1+\alpha_1-\alpha_2)\mathbf{F}}{RT}\pi\right]} \quad [2]$$

$i_{0,1}$ and $i_{0,2}$ are now not exchange current densities at the equilibrium potential of the hydrogen electrode, but current densities at the rest potential. Kaesche (9) also explained his cathodic curves for iron in acid perchlorate solutions with phenylthiourea by the Volmer-Heyrovský mechanism. He used Eq. [2] in a simpler form by setting $[1 - \exp(2\mathbf{F}/RT\ \eta_{H_2})] = 1$. The experimental results described in the present study were found to fit the complete expression [2] better.

Representative examples of calculated polarization curves by using Eq. [2] are shown in Fig. 1-4. The values of the parameters $i_{0,1}$, $i_{0,2}$, and α_1 were graphically extrapolated from the experimental data by determining the cathodic and anodic Tafel lines. Values for α_2 were selected to give the best fit of the experi-

mental data to the curves which Eq. [2] provides theoretically.

Table II lists the concentration dependence of the α_1 and α_2 values obtained from cathodic polarization curves of all investigated inhibitors. All experimental curves with benzophenone oxime, acetophenone oxime, and benzaldoxime fit theoretical curves with constant values of the parameters α_1 and α_2. Benzophenone oxime could not be investigated at concentrations higher than 1×10^{-3}M because of the limited solubility. For acetone oxime and 2-butanone oxime within a concentration range of 1×10^{-3} to 1×10^{-1}M and also for quinuclidine between 5×10^{-4} and 1×10^{-2}M, the same α values were obtained. At very small concentrations, the aliphatic oximes and quinuclidine fit curves with smaller transfer coefficients. In uninhibited 2M HCl solution the cathodic curve can be calculated by using the following parameters: $\alpha_1 = 0.42$, $\alpha_2 = 0$ (*e.g.*, infinitely small) and $i_{0,1} = i_{0,2}$. This result can be interpreted by the assumption that transfer coefficients obtained from measurements at very low inhibitor concentrations are very similar to those determined in uninhibited solutions (Fig. 4).

The current densities $i_{0,1}$ and $i_{0,2}$ at the rest potential as functions of the inhibitor concentration are shown in Fig. 5 and 6, with $i_{0,2}$ corresponding to the measured corrosion rate at the rest potential. The inhibitors can be divided into two groups (one in Fig. 5 and the other in Fig. 6) according to their concentration dependence. The group in Fig. 5 exhibits linear relations of the log $c/i_{0,1}$ and log $c/i_{0,2}$ plots of the aliphatic oximes and quinuclidine. The corrosion rates ($i_{0,2}$) as well as the current densities of the Volmer reaction at the rest potential ($i_{0,1}$) became smaller with increasing inhibitor concentrations, as shown in Fig. 5 and 6. Acetone oxime and quinuclidine had the same corrosion rates. For the log $c/i_{0,2}$ plot of 2-butanone oxime the current densities decreased by 4×10^{-3} mA/cm² but this plot was still parallel to that of acetone oxime and quinuclidine. The slope of both lines is about -4×10^{-3} mA/cm²/decade on the concentration axis. Slopes of the $i_{0,1}$ plots increase in the series: acetone oxime, 2-butanone oxime, quinuclidine. The other group (Fig. 6) includes acetophenone oxime and benzophenone oxime for which concentration independent values of $i_{0,1}$ and $i_{0,2}$ were obtained at high concentrations. The concentration dependence of benzaldoxime is very close to that of the first group (Fig. 5). In relation to $i_{0,2}$ it shows the same behavior as the aliphatic oximes with the same linear slope of the log $c/i_{0,2}$ line.

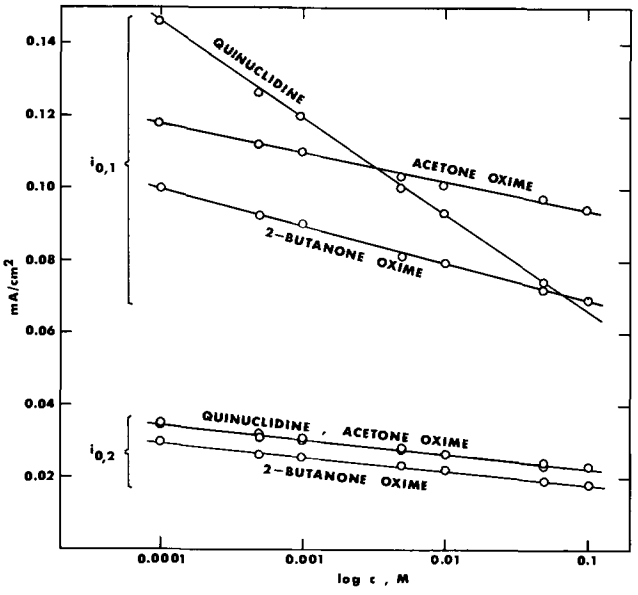

Fig. 5. Concentration dependence of the current densities $i_{0,1}$ and $i_{0,2}$ at the rest potential of iron measured in 2M HCl solutions containing acetone oxime, 2-butanone oxime and quinuclidine.

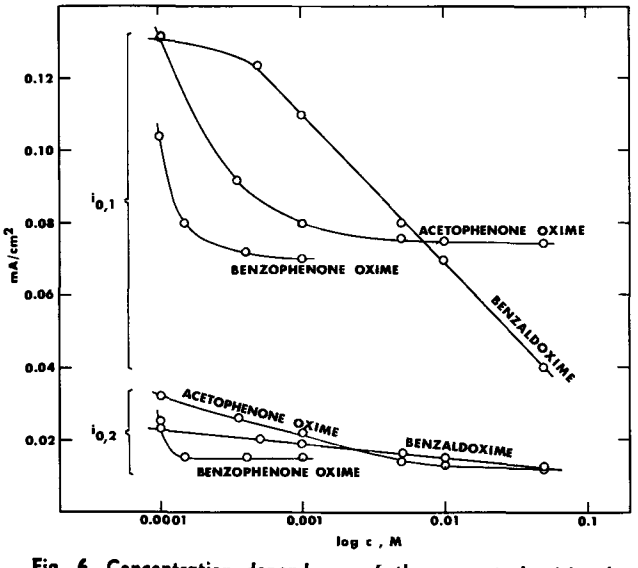

Fig. 6. Concentration dependence of the current densities $i_{0,1}$ and $i_{0,2}$ at the rest potential of iron measured in 2M HCl solutions containing acetophenone oxime, benzophenone oxime, and benzaldoxime.

Anodic galvanostatic polarization curves.—Anodic polarization measurements in 2M HCl solutions with and without inhibitors resulted in S-shaped polarization curves as shown in Fig. 7 and 8. Stern (10), and more particularly Schwabe and Voigt (11), found the same type of polarization curves for dissolution measurements of iron in acid solutions containing Cl^-; the less polarizable behavior of the anodic curves at high polarizations was probably due to Cl^- desorption.

While the anodic polarization curve of iron in 2M HCl solution shows a well-defined Tafel region extending to over 1 mA/cm² with a Tafel slope of 120 mV/decade, addition of inhibitor effected a drastic reduction of the Tafel region. In Fig. 7 and 8 the concentration dependence of the anodic polarization curves of two representative examples are shown. With increasing inhibitor concentration the Tafel regions decrease from about +0.4 mA/cm² at 1 x 10^{-4}M inhibitor to +0.15 mA/cm² at 1 x 10^{-2}M inhibitor. As can be seen

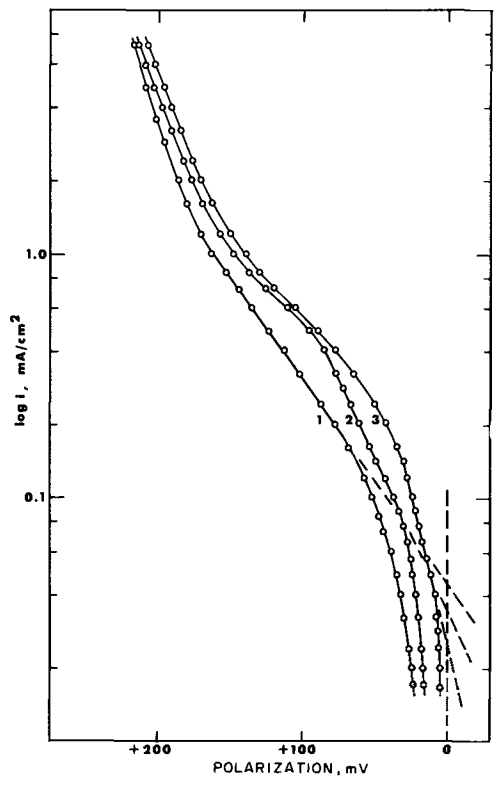

Fig. 7. Anodic polarization curves of iron in inhibitor-free 2M HCl solution, 1; in 2M HCl solution with 1x10^{-4}M quinuclidine, 2; and 1x10^{-2}M quinuclidine, 3.

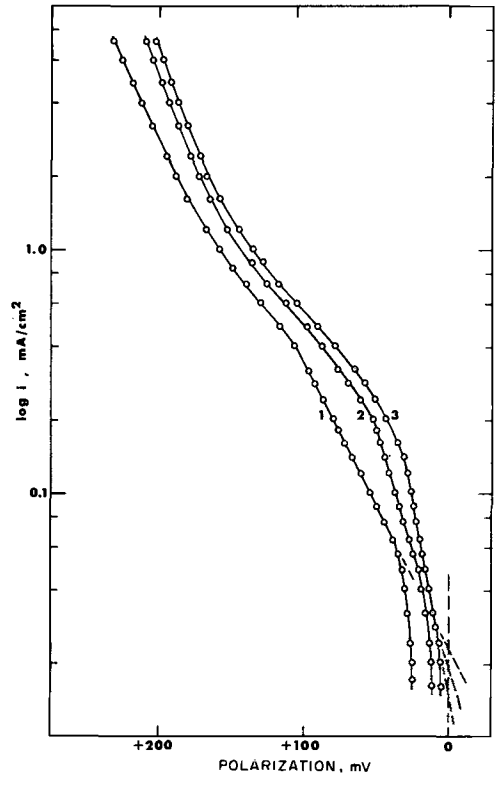

Fig. 8. Concentration dependence of anodic polarization curves of iron measured in 2M HCl solutions with benzaldoxime at 1x10^{-4}M, 1; 1x10^{-3}M, 2; and 1x10^{-2}M, 3.

in Table II the Tafel slopes, b_3, decreased with increasing inhibitor concentrations from 100 to 31 mV/decade.

It should be noted that the cathodic partial current density cannot be neglected when the linear portions of the anodic polarization curves extend to less than 20 mV from the rest potential. Therefore, the corrosion

effectivenesses, E_1, are not completely correct when they are derived only from the anodic curves. Nevertheless, the E_1 values are reasonable because the corresponding $i_{0,2}$ values can be used in Eq. [2] for the calculation of the cathodic polarization curves.

Discussion

The relative order of inhibitive effectiveness of the ketoximes at 1 x 10^{-3}M (Table I) is acetone oxime < 2-butanone oxime < acetophenone oxime < benzophenone oxime. Replacing methyl by ethyl or phenyl increases molecular polarizability and therefore increases the corrosion effectiveness of the ketoximes. Benzaldoxime does not fit this relation (it should be less effective than acetophenone oxime). This may be because only benzaldoxime exhibits both the syn- and anti-isomers in HCl solution (12), that is, *cis* and *trans* position of the OH group in relation to the planar carbon-nitrogen double bond. Quinuclidine and acetone oxime produce the same corrosion rate in 2M HCl solution. Alkyl groups increase the electron density on the nitrogen atom of amines and lead to better inhibition (13). Because the alkyl portion of the double ring compound quinuclidine consists of 7 CH_2-groups, compared with two methyl groups of acetone oxime, it can be assumed that oxime compounds have a relatively better inhibitive effect than corresponding amines. However, the relative area of metal surface which the two molecules would effectively cover in the adsorbed position has also to be considered. A comparison is not possible here because the position of adsorbed acetone oxime is uncertain.

No relationship was found between the rest potentials and the corrosion rates in inhibited solutions and all corrosion potentials were found to be within a range of 40 mV. Therefore it can be assumed that all inhibitors investigated exhibit anodic as well as cathodic inhibition effects.

Reaction mechanism of the cathodic H_2 evolution.— For large cathodic polarizations Eq. [2] is reduced to

$$i_{H_2} = i_{0,1} \exp\left[-\frac{(1-\alpha_1)\mathbf{F}}{RT}\pi\right] \qquad [3]$$

This is the equation for the cathodic polarization curve of the Volmer reaction, $H^+ + e^- \rightarrow H_{ad}$.

For very small cathodic polarizations, exp ($2\mathbf{F}/RT\,\pi$) in Eq. [2] is much smaller than 1 and can be neglected. Under the additional assumption $i_{0,1}/i_{0,2} >> 1$, Eq. [2] simplifies to the current-polarization relation of the Heyrovský reaction, $H^+ + H_{ad} + e^- \rightarrow H_2$ (9)

$$i_{H_2} = i_{0,2} \exp\left[-\frac{(2-\alpha_2)\mathbf{F}}{RT}\pi\right] \qquad [4]$$

Since the corrosion current density corresponds to $i_{0,2}$, the cathodic polarization behavior of iron in inhibited 2M HCl solution can be explained in the following manner. At the rest potential and at very small polarizations, the charge transfer of the Heyrovský reaction is rate-determining. With increasing cathodic polarization the Volmer reaction starts to control the reaction rate of H_2 evolution after a transition range with two consecutive electron transfer reactions. As shown in Fig. 1-4, for $\pi > 100$ mV the polarization curves fit the Tafel equation with slopes required by the Volmer reaction.[3]

Except for very low concentrations of acetone oxime, 2-butanone oxime plus possibly 5 x 10^{-2}M quinuclidine, constant values of the parameters α_1 and α_2 (therefore constant Tafel slopes) were found for all inhibitors at all concentrations. The inhibition effect for both the Heyrovský and Volmer reactions is attributed to adsorption of inhibitor molecules on the iron surface. Under the assumption that the concentration of adsorbed hydrogen on the metal surface is diminished by adsorbed inhibitor molecules, the inhibition of iron dissolution around the rest potential is understandable because the concentration of H_{ad} (and H^+) determines the reaction rate of the Heyrovský reaction.

The combined Volmer-Heyrovský mechanism also fits quinuclidine and the less effective aliphatic oximes, but smaller values for α_1 and α_2 were measured in less concentrated inhibitor solutions. With decreasing inhibitor concentration α_2 tends to 0 and α_1 to the value extrapolated from the Tafel slope measured in inhibitor-free 2M HCl solution (Table II). With respect to α_1 and α_2, the cathodic polarization behavior of iron at low inhibitor concentrations becomes more like the limiting case of inhibitor-free 2M HCl solution (Fig. 4). However, this should not be overrated because the polarization curve of the cathodic H_2 evolution of iron in HCl solution can also be interpreted on the basis of the Volmer reaction as the only rate-determining step instead of a combined Volmer-Heyrovský mechanism.

Reaction mechanism of the anodic iron dissolution.— S-shaped anodic polarization curves were measured in both inhibited and uninhibited 2M HCl solutions; this type of polarization behavior for iron in Cl^- containing acid solutions has been explained by the desorption of Cl^- at higher polarizations (10, 11). In inhibited solutions both Cl^- and organic inhibitor molecules are adsorbed on the iron surface, and both the organic species and Cl^- will desorb at large polarizations. As inhibitor concentrations increased, shorter linear regions and smaller Tafel slopes were measured, as shown in Fig. 7 and 8. The change of the Tafel slopes and the shorter linear portions of the polarization curves during anodic polarization indicate a possible acceleration of the metal dissolution by complex formation of iron with Cl^- and/or organic molecules. Table II shows that for all inhibitors investigated Tafel slopes decreased as inhibitor concentrations increased. Therefore it can be assumed that the iron dissolution, similar to the combined Volmer-Heyrovský reaction for H_2 evolution, apart from the desorption effect, is characterized by a change in the dissolution mechanism depending on the inhibitor concentration. On a qualitative basis, it is possible to propose a reaction mechanism composed of two limiting cases, (*i*) the dissolution of iron in 2M HCl solution and (*ii*) in high inhibitor-concentrated solution. However, a quantitative description is too difficult because the anodic polarization curves are not as reproducible as the cathodic curves.

In inhibitor-free 2M HCl solutions, anodic Tafel slopes of approximately 120 mV have been measured. Under the assumption of two one-electron charge transfer reactions followed by hydrolysis of the intermediate, the following reactions are possible

$$\mathrm{Fe} + \mathrm{Cl_{ad}^-} \rightleftarrows \mathrm{FeCl_{ad}} + e^- \qquad [a]$$

$$\mathrm{FeCl_{ad}} \rightarrow \mathrm{FeCl^+} + e^- \qquad [b]$$

$$\mathrm{FeCl^+} + \mathrm{H^+} \rightarrow \mathrm{Fe^{+2}aq} + \mathrm{H^+} + \mathrm{Cl^-} \qquad [c]$$

$$\mathrm{Fe} \rightarrow \mathrm{Fe^{+2}aq} + 2e$$

The corresponding current-potential expression for the rate-determining reaction (*a*) is

$$i_+{}^0 = \mathrm{K}\, q^0{}_{\mathrm{Cl-ad}} \exp\left(\frac{\alpha\mathbf{F}}{RT}\epsilon\right) \qquad [5]$$

(q = surface concentration) with a Tafel slope $b = d\epsilon/d(\log i) = 2.303\ RT/\alpha\mathbf{F} = 120$ mV for $\alpha = 0.5$.

Heusler (14) and Lorenz *et al.* (15) discussed the reaction mechanism of anodic iron dissolution in acid solutions and proposed a multistep reaction where hydroxyl anions react to give catalytic intermediates. In a similar partial reaction sequence, using Cl^- and adsorbed inhibitor molecules X instead of OH^-, the iron dissolution reaction mechanism at low polariza-

[3] No Tafel lines of the Heyrovský reaction could be measured because $i_{0,1}$ and $i_{0,2}$ were found to be in the same order of magnitude and therefore the assumption $i_{0,1}/i_{0,2} >> 1$ for getting Tafel lines at small polarizations was not valid.

tions (*e.g.*, where the Tafel behavior is valid) in more concentrated inhibitor solutions may be as follows.

Adsorbed Cl^- and X species react with the iron in two steps followed by a fast electron transfer reaction and decomposition of the intermediates in acid solution

$$Fe + Cl_{ad}^- \rightleftarrows FeCl_{ad} + e^- \quad [d]$$

$$Fe + X_{ad} + FeCl_{ad} \rightleftarrows FeX^+ + FeCl^+ + 2e^- \quad [e]$$

$$FeX^+ \rightarrow FeX^{+2} + e^- \quad [f]$$

$$FeX^{+2} + FeCl^+ + 2H^+ \rightarrow 2Fe^{+2}aq + 2H^+ + Cl^- + X \quad [g]$$

$$2Fe \rightarrow 2Fe^{+2}aq + 4e^-$$

For reaction (*e*) the current-potential relation is given by

$$i_+ = K_1 q_{X_{ad}} q_{FeCl_{ad}} \exp\left(\frac{2\alpha F}{RT}\epsilon\right) \quad [6]$$

Considering the potential dependence of Cl^-_{ad}, the Nernst relation for reaction (*d*) is

$$\epsilon = \epsilon^0 + \frac{RT}{F} \ln \frac{q_{FeCl_{ad}}}{q_{Cl^-_{ad}}} \quad [7]$$

$q_{FeCl_{ad}}$ can then be calculated as

$$q_{FeCl_{ad}} = K_2 q_{Cl^-_{ad}} \exp\left(\frac{F}{RT}\epsilon\right) \quad [8]$$

Elimination of $q_{FeCl_{ad}}$ from Eq. [6] and [8] gives the final expression for the two rate-determining steps (*d*) and (*e*)

$$i_+ = K_3 q_{X_{ad}} q_{Cl^-_{ad}} \exp\left[\frac{(1+2\alpha)F}{RT}\epsilon\right] \quad [9]$$

Comparison of the current densities in inhibited and uninhibited solution at the rest potential by using Eq. [5] and [9] gives

$$i_+ = K_4 i_+^0 \frac{q_{Cl^-_{ad}}}{q^0_{Cl^-_{ad}}} q_{X_{ad}} \quad [10]$$

Assuming Cl^- is partially replaced by X on the metallic surface ($q^0_{Cl^-_{ad}} = q_{X_{ad}} + q_{Cl^-_{ad}}$), Eq. [10] becomes

$$i_+ = K_4 i_+^0 \frac{q_{Cl^-_{ad}} \cdot q_{X_{ad}}}{q_{Cl^-_{ad}} + q_{X_{ad}}} \cong K_4 i_+^0 q_{Cl^-_{ad}} \quad [11]$$

The inhibitive effect of the organic molecules depends therefore on the surface concentration of Cl^- which decreases with increasing inhibitor concentration.

For $\alpha = 0.5$ the corresponding Tafel slope (Eq. [9]) is calculated to be 30 mV which is, within the error limit, in good agreement with the experimentally determined Tafel slopes for inhibitors at concentrations above 1×10^{-2}M.

Hydrogen Overpotential on Pure Metals in Alkaline Solution

T. S. Lee*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

Hydrogen overpotentials on pure Zn, Cd, Fe, and Pb were measured in 6*N* potassium hydroxide solution at 2°, 25°, and 50°C. Measurements were also made in 9*N* potassium hydroxide solution at room temperature. Exchange current densities, transfer coefficients, and heats of activation for the hydrogen solution process were obtained, and the mechanism for process in the solution is discussed. The transfer coefficients in the alkaline solutions are compared with these in acid solutions.

The hydrogen overpotential in alkaline solutions on mercury has been measured by Bockris and Watson (1), on nickel by Lukovzev, Levina, and Frumkin (2), Legran and Levina (3), and Bockris and Potter (4); and on copper by Bockris and Pentland (5). All of these workers have made the measurements in dilute alkaline solutions. Zholuder and Stender (6) have measured hydrogen overpotentials on a number of metals in 6*N* sodium hydroxide solution in an open

* Electrochemical Society Active Member.

Key words: hydrogen overpotential, hydrogen overvoltage, hydrogen evolution process in alkaline solution, electrode kinetics hydrogen evolution process.

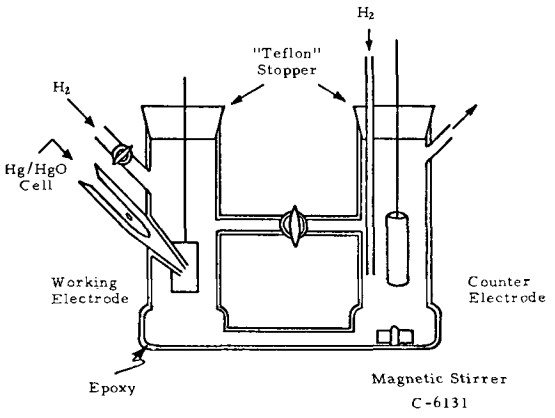

Fig. 1. Schematic drawing of the cell

vessel. Iofa, Komlev, and Bagotskii (7) have measured the same property at a zinc surface in different concentrations of potassium hydroxide solutions. The purpose of this paper is to report the measurement of hydrogen overpotentials on high purity metals in highly purified 6*N* and 9*N* KOH solutions. The results will be interpreted by a theoretical treatment of the hydrogen evolution process.

Experimental

The cell used for this study is shown schematically in Fig. 1. The cell is made from epoxy-lined Pyrex. The purpose of using the epoxy lining is to prevent the introduction of impurities into the solution through attack on the cell walls.

The epoxy used in this study is made from Union Carbide products ERL-2793 and ERL-2774. The procedure is as follows: 1 part (by volume) of ERL-2793 and 3 parts of ERL-2774 are slowly mixed together. In about 10 to 15 min, the mixture changes from a relatively thick mass to a less viscous liquid. At this time, the well-mixed liquid is poured into the Pyrex cell. By rotating the glass apparatus, the inside wall is coated with a layer of the liquid epoxy, which will solidify in another 15 to 20 min. The apparatus is kept at room temperature for a few hours. Finally, the apparatus is placed in an oven at 65°-75°C and baked for 4 hr. Before it can be used, the epoxy-lined apparatus is soaked in distilled water and 35% KOH solution for a few days. If the lining is not too thick, the wall is somewhat opaque, yet semitransparent. In a closed system, the semitransparent wall could enable the operator to see where the electrode and reference electrode are placed.

To make sure no epoxy had leached into the alkaline solution during a reasonable length of time, the following experiment was conducted. Epoxy-lined glass beakers were used to store 9*N* and 12*N* KOH solutions for 4 to 5 weeks. These KOH solutions were extracted with organic solvents. The extracts were then evaporated and their IR spectra were examined. Epoxy exhibits good IR spectra with powder as well as extracts. One IR spectrum for epoxy is shown in Fig. 2 and the spectrum for the extract from 12*N* KOH solution which was in contact with epoxy for 4 weeks, is shown in Fig. 3.

The typical IR adsorption peaks for epoxy are observed at 8 and 12μ. In Fig. 3 there is no evidence that even a trace of epoxy is present in the residue. However, there might be a very small amount of epoxy that could go into the solution which would not be detected by the IR technique, but still could affect the electrochemical measurement. Thus, the operation of soaking the cell in concentrated KOH solution for a few days is important. The feasibility of this system for high-purity electrochemical measurement is emphasized by the fact that the hydrogen overpotentials are highly reproducible (within a few millivolts) and quite linear over a five decade range of current densi-

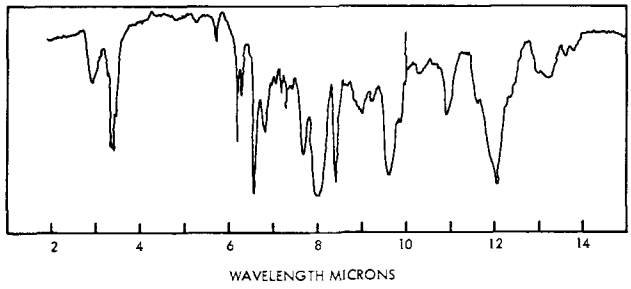

Fig. 2. IR spectra of chloroform extract of the epoxy

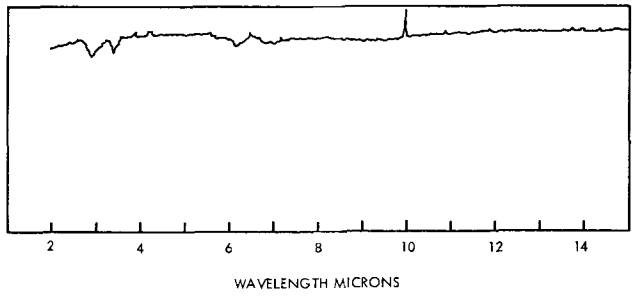

Fig. 3. IR spectra of chloroform extract from 12N KOH which has been contacted with epoxy for 4 weeks.

ties, regardless of whether the measurements are begun at high or low current densities.

The cell is a closed system with a slightly positive hydrogen pressure to prevent air entry. There is a separate compartment for both anode and cathode. A stream of high-purity hydrogen is passed through the anode compartment during the measurement to carry away the oxygen produced at the anode.

The reference electrode is a Hg/HgO electrode in the same solution in a separate tube. The Luggin capillary, which has an ID of about 0.1 mm, contacts the electrode being measured. In designing the cell, attention was given to the reference electrode compartment, such that the possibility of contamination from Hg/HgO to the solution in the measuring cell is kept to a minimum. The counterelectrode, which is made of pure nickel sheet, has an area of about eight to ten times that of the metal electrode. The purity of the Zn, Cd, and Pb electrodes is 99.999+% and the Fe electrode is spectroscopically pure.

The potassium hydroxide solution is made from AR grade chemical and conductance water. This solution is kept in KOH preleached high-density polyethylene bottles. Occasionally, the KOH solution is made in a Teflon bottle. The results do not show any difference. The solution is pre-electrolyzed in the cell each time for several days before the measurement is started.

The back and edges of the metal electrodes are covered with the same epoxy coating as the glass vessel and are subjected to the same treatment as the cell. The exposed area of the electrode is about 1 cm^2. The surface of the electrode (except lead) is prepared by successive abrasion with emery paper, ending with 000 paper. The lead electrode is prepared by light abrasion with 00 paper or by scratching with a stainless steel knife edge.

After a smooth surface is obtained, the electrode is washed well with a jet of distilled water to remove any particles which may have become attached during the process of abrasion. The electrode is then placed in a separate cell of the same type to be cathodized against the counterelectrode for at least 30 min at a current density of 30-50 mA/cm^2. The main purpose of this cathodization in a separate cell is to leave any impurities introduced during the preparation of the surface in the separate cell. Finally, only the working electrode is transferred to the measuring cell, which

Table I. Reversible potential for hydrogen evolution process

KOH	Temp, °C	E_{rev} (V) measured	E_{rev}, calculated
6N	2	−0.9376	−0.937
	25	−0.9306	−0.932
	50	−0.9245	−0.924
9N	25	−0.9396	−0.938

has been degassed with "Ultra Pure" hydrogen[1] for a couple of hours, and the same cathodization process is continued for another half hour with a different counterelectrode before measurement begins. Care is taken to avoid the possibility of dissolution of active metals into the KOH solution by connecting both working and counterelectrodes to the current source before the working electrode is introduced into the solution. The constant current is supplied by a Harrison Laboratories Model 855C power supply through a series of variable power resistors. The potentials are measured by a Keithley Model 630 potentiometric electrometer which has a minimum input resistance of 10^{13} ohms. The measurements are carried out from the high current density to the low current density region and back again; this process is then repeated. The steady potential is recorded at each current density. Variations of only a few millivolts are observed in the steady potential even though the potentials are occasionally observed as long as 30 min to 2 hr at certain current densities. There is no sign of hysteresis in any of the measurements.

The data reported here are the average values of four or more runs for each point. After each run, the electrode is washed, dried, and examined under a microscope. Except for lead, the surfaces are still shiny and appear unchanged. The lead surface appears darker after the measurement.

The temperature of the cell is kept constant by placing it in a water bath in which the temperature is controlled by a Lauda K-2/R constant temperature circulator. The accuracy of the temperature control is within 0.02°C.

In order to obtain the values of overpotential, the reversible potential for hydrogen evolution under the specific conditions is needed. This is obtained by measuring the potential of the platinized platinum hydrogen electrode against the Hg/HgO electrode in the solution. The values of the reversible hydrogen potential under various conditions are listed in Table I. In most cases, the measured potential is within 1 mV of the theoretically calculated value based on the best available activity data in the literature (8). At 25°C the reversible hydrogen potential is calculated from the equation

$$E = -0.920 + 0.0296 \log a_{H_2O}$$

where a_{H_2O} is the activity of water in the solution. At other temperatures, the reversible potential is calculated through temperature coefficients given by de Bethune (9).

Results and Discussion

The hydrogen overpotentials and the logarithm of current density plots for Zn, Cd, Fe, and Pb in 6N KOH at various temperatures are shown in Fig. 4-7. The plots for these metals in 9N KOH at 25°C are shown in Fig. 8. The transfer coefficients (α) and the exchange current densities (I_0) for the reaction are obtained from these plots. The standard activation energy (ΔH°) for the process is obtained through the rate of change of the overpotential with temperature at constant current. To obtain the numerical value, an equation derived by Bockris (10) assuming that the transfer coefficient is constant with temperature is used. That is

[1] Produced by Linde Division of Union Carbide, the purity is 99.999% and the oxygen content is less than 1 ppm.

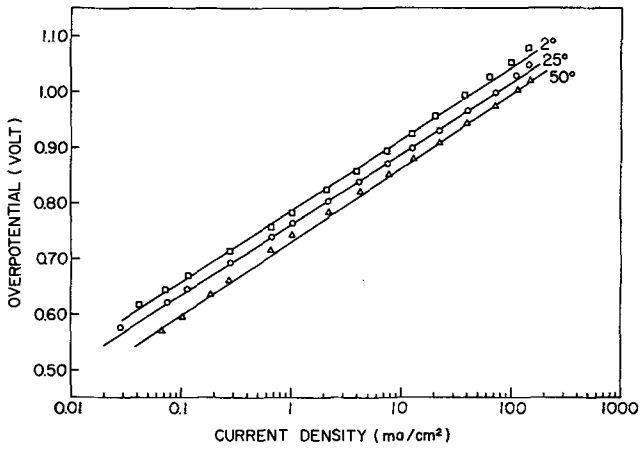

Fig. 4. Hydrogen overpotential on Zn in 6N KOH

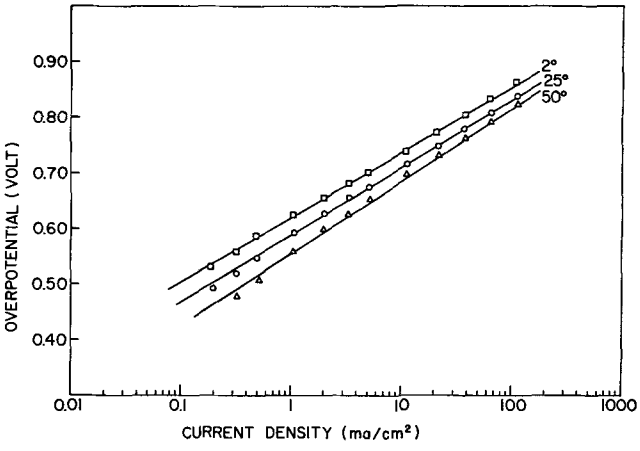

Fig. 5. Hydrogen overpotential on Cd in 6N KOH

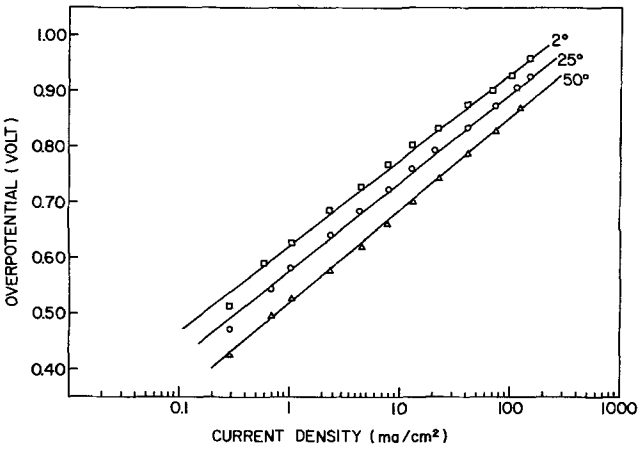

Fig. 6. Hydrogen overpotential on Fe in 6N KOH

$$\left(\frac{\partial \eta}{\partial T}\right) i_c = (\alpha \eta F + \Delta H^\circ + RT)/\alpha F T$$

The electrochemical parameters for those metals in 6N KOH are listed in Table II and those in the 9N KOH are listed in Table III. The Tafel slopes in Tables II and III are at 25°C. It is also interesting to note in Fig. 4-7 that the Tafel slopes for different metals at various temperatures in 6N KOH vary slightly with temperature.

It is known that the over-all reaction for the process in this medium is

$$2H_2O + 2e = H_2 + 2\,OH^- \qquad [1]$$

There are three possible rate determining steps

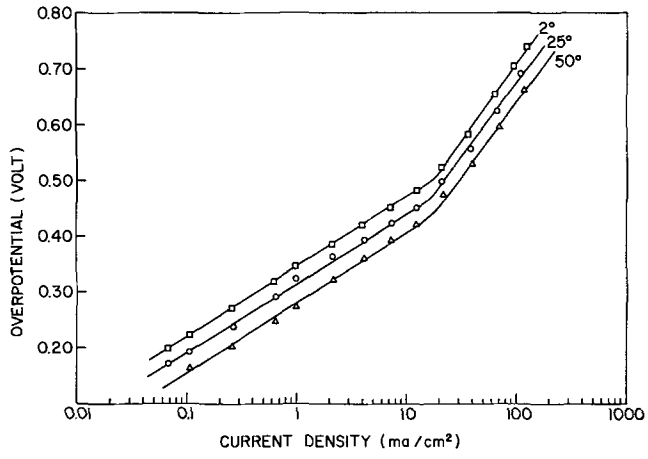

Fig. 7. Hydrogen overpotential on Pb in 6N KOH

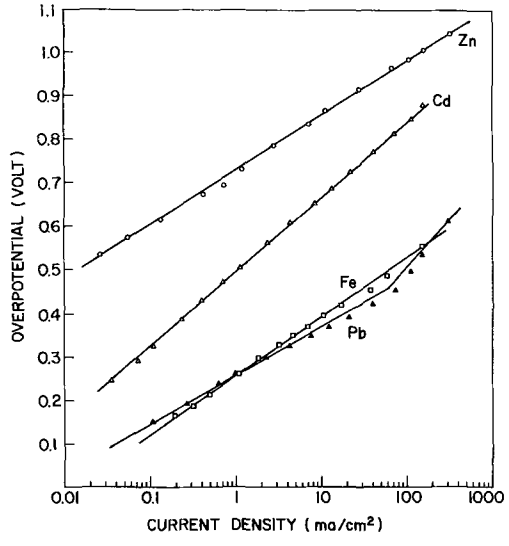

Fig. 8. Hydrogen overpotential on Zn, Cd, Fe, and Pb in 9N KOH at 25°C.

$$H_2O + e = H_{ad} + OH^- \text{ (Volmer)} \quad [2]$$

$$H_{ad} + H_2O + e = H_2 + OH^- \text{ (Heyrovsky)} \quad [3]$$

$$2H_{ad} = H_2 \text{ (Tafel)} \quad [4]$$

and each one of the three steps could lead to Eq. [1].

Pb*	0.120	0.49	1×10^{-7}

* For the low current density region.

Since all measurements are in concentrated solutions, no double layer correction[2] has been made. Referring to reaction [2], one can write the following rate equation by neglecting the back reaction

$$\text{rate} = K_f \exp(-n\alpha \mathbf{F}\phi/RT) \quad [5]$$

where ϕ is the potential between the metal electrode and the bulk of the solution and K_f is the rate constant for the forward reaction. The other symbols have the usual meanings. Omission of the back reaction is justified here, since all of the measurements are made at relatively high overpotentials. The current per unit area (I) of the reaction surface can be written as

$$I = n\mathbf{F}a_{H_2O} \text{ rate} \quad [6]$$

where a denotes activity. From [5] and [6]

$$\phi = K_f' + \frac{RT}{\alpha\mathbf{F}}(\ln a_{H_2O} - \ln I) \quad [7]$$

One can also write the Nernst equation for [1] at 1 atm of H_2

$$\phi_{eq} = E° + \frac{RT}{\mathbf{F}} \ln (a_{H_2O}/a_{OH^-}) \quad [8]$$

and the overpotential η is

$$\eta = \phi - \phi_{eq} \quad [9]$$

From [6], [7], [8], and [9] one obtains

$$\eta = \text{const.} + [(1-\alpha)/\alpha]\frac{RT}{\mathbf{F}} \ln a_{H_2O} + \frac{RT}{\mathbf{F}} \ln a_{OH^-} - \frac{RT}{\alpha\mathbf{F}} \ln I \quad [10]$$

if $\alpha = \frac{1}{2}$.

$$\eta = \text{const.} + \frac{RT}{\mathbf{F}} \ln a_{H_2O}\, a_{OH^-} - \frac{2RT}{\mathbf{F}} \ln I \quad [11]$$

The experimental data show that, for the same KOH concentration, the numerical values of the overpotential are higher (less negative) at a higher temperature. It also shows that, at the same temperature, the numerical values of the overpotential are higher (less negative) in a lower KOH concentration. In connection with this, Eq. [11] indicates that, in the concentration range of this study, the activity of H_2O and OH^- is smaller at a higher temperature in the same concentration of KOH. It also indicates that the activity of H_2O and OH^- is smaller in a lower KOH concentration solution at the same temperature. This is consistent with the experimental trend found by Akerlof and Bender (8).

At a definite KOH concentration and a definite temperature, the first two terms of Eq. [11] are constant, so that the equation then becomes the familiar Tafel equation. At 25°C, a plot of η against log I will have a slope of 120 mV per decade. By examining the experimental data, one can conclude that the one-electron transfer is the rate-determining step in the process.

The high slope for lead in the higher current density region might be due to other processes occurring simultaneously with the reduction of water. It is plausible that the formation of some kind of lead hydride occurs at the higher potential (12). Since no hysteresis loop is observed in moving up and down the curve, the formation of a hydride must be potential dependent and unstable.

The reason for the slightly higher slope on Cd in both 6N and 9N KOH is not completely clear yet. It may be due to the formation of a thin layer of hydrated oxide on the cadmium surface.

Finally, it is interesting to compare the transfer coefficients obtained in this study to those obtained in acid solution by others (13, 14). This comparison is

[2] Double layer correction sometimes called Frumkin correction, for example, see Delahay (11).

Table IV. Comparison of transfer coefficient of hydrogen evolution process in acid and alkaline solutions

Metal	α
Zn	0.5 (0.01-1*N* H_2SO_4) (14) 0.48 (6, 9*N* KOH)
Cd	0.3 (1*N* HCl, 2*N* H_2SO_4 (13) 0.38 (6*N* KOH), 0.35 (9*N* KOH)
Fe	0.4 (1*N* HCl), 0.5 (2*N* H_2SO_4) (13) 0.49 (6*N* KOH), 0.48 (9*N* KOH)
Pb	0.48 (0.01-8*N* HCl, 0.1*N* H_2SO_4) (13) 0.49 (6, 9*N* KOH)

shown in Table IV, where the value of α is followed in parenthesis by the solutions in which the hydrogen overpotentials are measured. One can see that there is not much difference in α in the hydrogen evolution process from dilute acid solutions to concentrated alkaline solution.

Corrosion Inhibition and Hydrogen Adsorption in the Case of Iron in a Sulfuric Aqueous Medium

I. Epelboin,* P. Morel, and H. Takenouti

Groupe de Recherche du C.N.R.S., Physique des Liquides et Electrochimie, Université de Paris VI, Paris 5e, France

ABSTRACT

The corrosion process for two iron samples of different purities in a molar solution of sulfuric acid has been studied by means of a rotating disk electrode. This study supports the previously formulated hypothesis which assigns the hysteresis, observed when corrosion is low, to the partial coverage (θ_H) of the electrode surface by adsorbed hydrogen $(FeH)_{ads}$. The decrease of the cathodic reaction rate is then accounted for by a slow diminution of the number of active sites due to this coverage. The hydrogen adsorption is favored by the presence of 2-butyne 1,4-diol. At potentials more anodic than the corrosion potential, the same coverage persists. The study of the θ_H variation with potential, in the presence of 2-butyne 1,4-diol, shows that θ_H, close to unity near the corrosion potential, diminishes when the anodic potential increases and tends toward zero for potentials above which hysteresis is no longer observed. All these results tend to confirm the role of $(FeH)_{ads}$ as a corrosion inhibitor.

In a previous work (1), it was reported that the current-potential characteristics obtained in sulfuric acid for certain samples of very pure iron, whose corrosion rates were low, showed hysteresis. This phenomenon occurred even with a pure industrial iron, characterized by a higher corrosion rate, provided that an acetylenic-type corrosion inhibitor, such as 2-butyne 1,4-diol, was added to the sulfuric medium. This hysteresis of the current-potential curve and the inhibiting action of acetylenic alcohols were then attributed to a partial coverage of the iron surface by adsorbed hydrogen. In this article, we intend to present new information on the relation between corrosion inhibition and hydrogen adsorption.

* Electrochemical Society Active Member.

Key words: 2-butyne 1,4-diol, dissolution mechanism, faradaic impedance, hydrogen evolution reaction, hysteresis, polarization curve.

Polarization curves (2) and faradaic impedance (3, 4) studies showed that two of the iron samples used in the above-mentioned investigation (1) followed the same anodic dissolution mechanism, *i.e.* one of the mechanisms proposed by Bockris, Drazič, and Despič (5). According to this mechanism, OH^- would be adsorbed in a first step, I

$$Fe + OH^- \rightleftharpoons (FeOH)_{ads} + e^- \qquad \text{I}$$

to give rise to $(FeOH)_{ads}$. In a second step, II

$$(FeOH)_{ads} \rightarrow FeOH^+ + e^- \qquad \text{II}$$

the iron would leave the metallic lattice as a $FeOH^+$ cation which would finally undergo the rapid chemical reaction III

$$FeOH^+ \rightleftharpoons Fe^{++} + OH^- \qquad \text{III}$$

This anodic mechanism is still valid when the sulfuric acid solution contains 2-butyne 1,4-diol (6).

In order to understand the corrosion inhibition and the hydrogen adsorption mechanisms, it is important also to study the cathodic reaction kinetics for these two iron samples in a sulfuric acid medium with and without addition of acetylenic alcohol.

Experimental

This investigation was carried out in an air-free medium for which it can be supposed that the cathodic process is limited to the mere hydrogen evolution. One of the two metal samples studied here is a spectroscopically pure iron provided by Johnson-Matthey (denoted in this paper as iron I); the second sample, Holzer iron provided by Compagnie des Ateliers et Forges de la Loire (iron II), has a corrosion rate 25 times as great as that of iron I when measured in a molar solution of sulfuric acid. The main impurities of the two irons are: Iron I—C, 0.03%; Si, 0.0004%; Mn, 0.0003%; Mg, 0.0002%; Iron II—Si, 0.33%; Mn, 0.06%; S, 0.018%; C, 0.003%. Iron I was cold worked, while iron II was wrought in a furnace under vacuum and subjected to a treatment of standardization at 900°C.

We used a molar solution of sulfuric acid prepared from concentrated acid (Merck) diluted in water of resistivity greater than 2 megohms/cm. The solution was maintained at 25° ± 0.1°C, and was deoxygenated by argon bubbling (Ultrapure Argon, provided by Air Liquide).

For the study of the two iron samples, we employed disk electrodes oriented downward. So as the gas bubbles resulting from the cathodic process did not remain on the electrode surface, the electrode was turned at a speed of at least 1000 rpm. Under our experimental conditions, the cathodic current does not depend on the disk rotation speed, which confirms the complete deoxygenation of the solution (7).

Except for the separation of cathodic current from the over-all current, the potential of the working electrode is controlled by a fast potentiostat built in our laboratory (8). The methods of impedance measurements have been described elsewhere (3).

Results and Discussion

Study of the cathodic process in a deoxygenated sulfuric acid medium.—Absence of a steady-state $I = f(V)$ polarization characteristic.—We have not been able to obtain any steady-state $I = f(V)$ polarization curve, since the successive potentiokinetic traces cannot be superposed. As a matter of fact, when the potential V is fixed at a certain value, a slow evolution of the cathodic current I is observed, whose rate and behavior depend on the iron nature.

As an illustration, Fig. 1 shows, as a function of time, a current variation which is characteristic of iron I, the apparent area of the electrode being 0.2 cm². Curves 1, 2, and 3, respectively, correspond to the polarization potentials of −0.5, −0.55, and −0.6 V/SCE. The current decreases very rapidly just after immersion of the electrode, then more and more slowly, and after some 3 hr reaches a stationary value. During this evolution, the metal, practically, does not dissolve, and the surface remains bright.

In the case of iron II, when the electrode is polarized at −0.5 V/SCE, the current decreases just after immersion of the electrode (Fig. 2), goes through a minimum after some 3 min, and then increases during more than 4 hr up to a relatively stationary value. The metal then appears to be strongly attacked, even to the naked eye. On the other hand, when the electrode is polarized at a higher potential, we can obtain one or the other of the types of evolution represented in Fig. 1 and 2, according as the electrode is polarized at potentials higher or lower than −0.55 V/SCE. In the first case, the surface remains unaltered; in the second, it is markedly attacked.

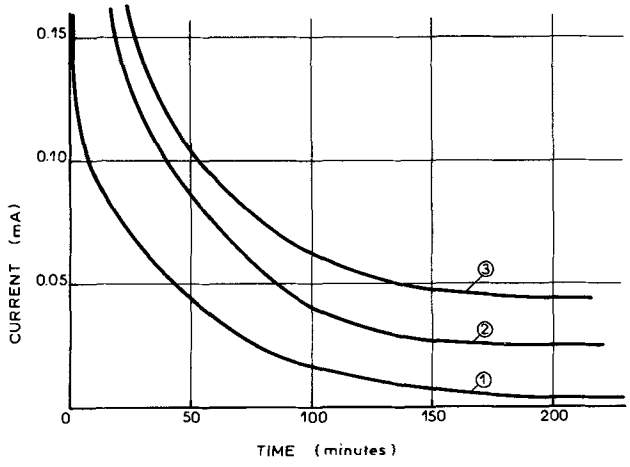

Fig. 1. Variation of the cathodic current with time: iron I, 1M H_2SO_4. Curve 1, $V = -0.50$ V/SCE; Curve 2, $V = -0.55$ V/SCE; curve 3, $V = -0.60$ V/SCE.

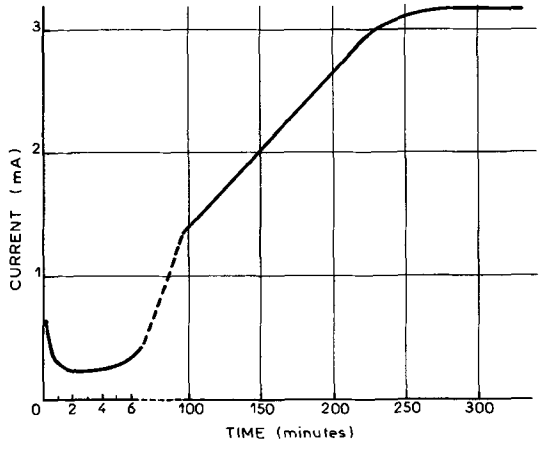

Fig. 2. Variation of the cathodic current with time: iron II, 1M H_2SO_4. $V = -0.50$ V/SCE.

It is well known that the hydrogen adsorbed at the iron surface penetrates into the metal. This absorbed hydrogen considerably modifies the state of the electrode surface, especially in the case of iron II, and plotting the steady-state $I = f(V)$ curve becomes impossible. It is therefore difficult to study the cathodic reaction kinetics at the corrosion potential by means of a $I = f(V)$ characteristic obtained point by point, at least for high cathodic polarizations. Now, acetylenic alcohols are known to inhibit hydrogen absorption into iron (9). We therefore studied for iron I and iron II the influence on the current variation, in the cathodic range, of 2-butyne 1,4-diol, one of the most representative inhibitors of the family of acetylenic alcohols.

Influence of 2-butyne 1,4-diol.—When 2-butyne 1,4-diol is added in the electrolyte, there is always a decrease of the above-defined stationary current (see first paragraph under Results and Discussion). This inhibiting effect increases with increasing acetylenic alcohol concentration up to 10^{-3}M, the concentration chosen for the experiments described here. Furthermore, whatever the moment the inhibitor is introduced into the sulfuric acid solution (before the metal sample —*i.e.*, "previous addition"—or after the polarization current has reached its stationary value—*i.e.*, "subsequent addition"), after the introduction the current evolves up to a stationary value very slowly.

In the case of iron I, whatever the method of the 2-butyne 1,4-diol addition, the stationary current decreases by only 30% and the inhibiting effect is not very obvious.

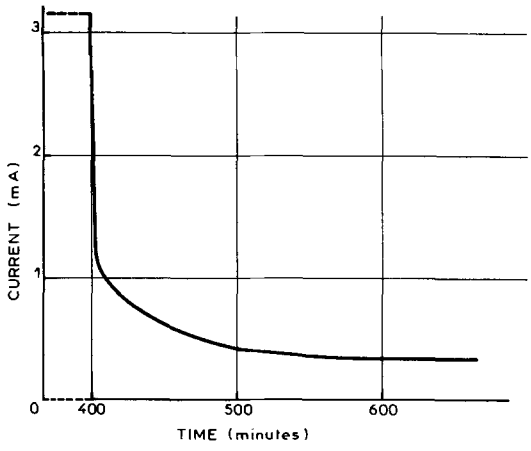

Fig. 3. Variation of the cathodic current with time after introduction of 10^{-3}M 2-butyne 1,4-diol. ("Subsequent addition": see *Influence of 2-butyne, 1-4 diol* under Results and Discussion). Iron II, 1M H_2SO_4. $V = -0.50$ V/SCE.

For iron II and a "previous addition," the current continually decreases even at −0.5 V/SCE, which is contrary to the case presented in Fig. 2. After about 5 hr, the current reaches a stationary value which is 50 times as low as that reached in the absence of an inhibitor. Visual examination of the electrode surface then reveals no trace of corrosion. In the case of a "subsequent addition" (and at the same polarization potential of −0.5 V/SCE) carried out after 400 min under the conditions of Fig. 2, the current rapidly diminishes as soon as the inhibitor is introduced. This decrease carries on more and more slowly for several hours until the current reaches a new stationary value, as shown in Fig. 3. This value is higher than that obtained in the case of a "previous addition." The observed difference can be explained by a change in the state of the surface during corrosion without an inhibitor.

The problem of the stationary current having been specified, we will now examine whether impedance measurements allow us to explain the influence of the nature of the iron sample on the cathodic reaction rate in a sulfuric acid medium with and without the acetylenic alcohol.

Measurements of the frequency dependence of the cathodic impedance.—Such measurements have been performed only when the direct current I could reach a stationary value. We have plotted the impedance diagrams in the complex plane $Z = R - jG$ in which frequency is the parameter. All these diagrams, obtained with and without inhibitor, for iron I as well as for iron II have the same shape, *i.e.* that of a capacitive arc.

As an example, in Fig. 4 is given a diagram obtained at −0.5 V/SCE with iron II in the absence of an inhibitor. From this diagram, a value of 2.3 ohms is found for the electrolyte resistance R_e which is the impedance limit at infinite frequency; this value is in good agreement with that determined by an interrupter method

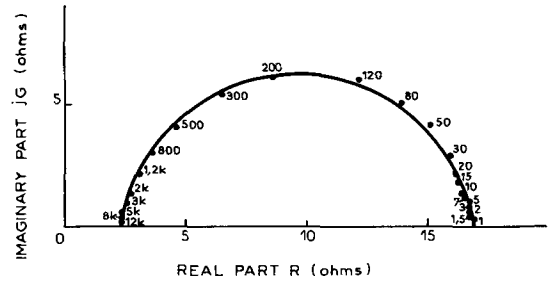

Fig. 4. Cathodic impedance diagram (parameter = frequency in Hz): iron II, 1M H_2SO_4. $V = -0.50$ V/SCE.

(2). It can also be seen that, at zero frequency, the impedance tends to become a resistance whose value is about 16.8 ohms.

Furthermore, a least-squares analysis of our impedance diagrams, carried out on an IBM 360/75 computer, reveals that the impedance Z variations with frequency can be represented by a capacitive time-constant τ which obeys a Cole-Cole-type distribution law (10) to the exclusion of any other time constant

$$Z = \frac{R_t}{1 + (j\omega\tau)^\gamma}$$

where R_t is the transfer resistance and γ, a dispersion parameter, is a nondimensional number between 0 and 1.

Now, in the case of a simple transfer reaction, the calculation of the impedance also involves only one time constant which is due to the transfer resistance R_t, the product R_tI being independent of the current. We therefore calculated the product of the current I and the limiting value of the impedance at zero frequency: we verified that it is the same for all the diagrams, its value being close to 52 mV, as can be seen in Table I which gathers together as an example the results from five diagrams. Note lastly that this product, in the case of a single electrochemical step obeying Tafel's law, allows an indirect measurement of the Tafel slope (which, in the case of our experiments, would be 120 mV/decade).

Discussion of results.—It is generally accepted that the hydrogen evolution occurs in two steps implying the intermediate species $(FeH)_{ads}$. The faradaic impedance calculation, in this case, predicts that the relaxation of the coverage θ_H by $(FeH)_{ads}$ introduces a further time constant which is expressed either by an inductive term or by a capacitive term (11). The fact that such a reactive term could not be detected during our measurements indicates that, under our experimental conditions, the potential variation causes no θ_H variation. This lack of variation can be accounted for by one of the following hypotheses: (*a*) the hydrogen adsorption step is rate determining ($\theta_H \simeq 0$), (*b*) the hydrogen desorption step is rate determining ($\theta_H \simeq 1$), and (*c*) the steps are both electrochemical and have the same Tafel slope ($0 < \theta_H < 1$). According to Gerischer and Mehl (11), in the case of iron and other transition

Table I. Results from cathodic impedance measurements

R_t = transfer resistance
γ = dispersion parameter
(The two methods of addition are defined in the paragraph "Influence of 2-butyne 1,4-diol" under Results and Discussion.)

Sample	Iron I	Iron I	Iron II	Iron II	Iron II
V(V/SCE)	−0.55	−0.55	−0.50	−0.50	−0.50
Concentration of 2-butyne 1,4-diol (M)	0	10^{-3}	0	10^{-3}	10^{-3}
Method of addition	—	Subsequent	—	Subsequent	Previous
Stationary current I(mA)	0.026 ± 0.001	0.017 ± 0.001	3.3 ± 0.2	0.31 ± 0.02	0.058 ± 0.002
R_t(ohms)	2120 ± 40	3280 ± 140	14.5 ± 0.2	172 ± 70	900 ± 10
IR_t(mV)	55 ± 3	56 ± 6	48 ± 4	53 ± 5	52 ± 2
γ	0.931 ± 0.005	0.921 ± 0.015	0.967 ± 0.015	0.908 ± 0.018	0.928 ± 0.017

metals, the second hypothesis in highly probable, due to the high strength of the bond between H_{ads} and the metal. This statement has been confirmed by the recent work of Bockris *et al.* (12): the electrochemical desorption step actually determines the hydrogen evolution rate for the transition metals, and in this case $\theta_H \simeq 1$. Furthermore, according to the recent work of Tomashov and Vershinina (13), in the case of iron the Tafel slopes corresponding to these two steps would be equal and θ_H would be close to unity.

The results from impedance measurements (Table I) seem to show that the reaction mechanism remains unchanged, although the cathodic reaction rate may depend on the electrode nature and on the presence or absence of 2-butyne 1,4-diol. As it is known on the other hand (3) that the product R_tI is independent of the reacting surface, the observed differences in rates must be attributed only to a variation of this surface.

The decrease of the reaction rate, revealed by the current-time curves (Fig. 1 and 3), would correspond to a slow diminution of the number of active sites caused by the adsorbed hydrogen. In the absence of 2-butyne 1,4-diol and at −0.5 V/SCE (Fig. 2), the passage into the solution of impurities contained in iron II [sulfur, in particular (14)] increases the number of active sites (15, 16) and thus gives rise to the marked corrosion mentioned above. This would also explain the observed increase of current with time at this potential.

These results strongly support the hypotheses that we put forward (1, 2) during the last several years in order to interpret the hysteresis phenomenon: they tend indeed to indicate that $(FeH)_{ads}$, resulting from the cathodic reaction and covering almost all the surface, has an inhibiting effect. We shall now show that in the anodic range near the corrosion potential the θ_H variation with the potential is responsible for the hysteresis phenomenon.

Mixed kinetics of the iron corrosion process.—Near the corrosion potential, two reactions occur simultaneously: cathodic hydrogen evolution and anodic iron dissolution. The former leads to coverage of a fraction θ_H of the electrode surface by $(FeH)_{ads}$, and the latter to coverage of a fraction θ_{OH} of the same electrode by $(FeOH)_{ads}$. Having no common intermediate, these two reactions compete and, hence, give rise to mixed kinetics.

In the literature, many authors (17-20) consider that at the corrosion potential almost the whole electrode surface is covered by $(FeH)_{ads}$. Now, the coverage fraction θ_H, close to 1 at cathodic potentials, must decrease when the anodic polarization is increased. Nevertheless, it does not seem that this θ_H variation has been systematically studied. In this paper, the analysis of the hysteresis phenomenon allows us to carry out such a study.

The hysteresis phenomenon.—In the anodic range near the corrosion potential and in a molar solution of sulfuric acid, the potentiokinetic traces carried out for iron II exhibited no hysteresis (1, 2). On the other hand, for iron I and under the same conditions, a narrow cycle is observed, much narrower than that observed with a single-crystal iron (2). However, in the presence of 2-butyne 1,4-diol and for both iron I and iron II, the hysteresis cycle becomes more obvious. This phenomenon has also been observed on iron samples of different natures (2). Moreover, even for the lowest sweep rates compatible with good reproducibility of the measurements (dissolution alters the state of the surface little by little), the curves recorded successively at increasing anodic potential (forward trace), then at decreasing potential (backward trace), remain distinct. We have shown elsewhere (6) that at frequencies close to 10^{-3} Hz the impedance tends, in this potential range, to become a pure resistance that must be considered as the slope of a steady-state polarization curve independent of the sweep conditions.

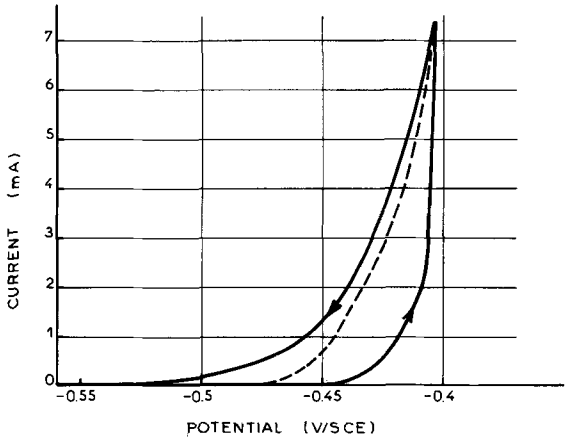

Fig. 5. Anodic polarization curves: iron I, 1M H_2SO_4 + 10^{-3}M 2-butyne 1,4-diol. Solid line: potentiokinetic trace; dV/dt = 0.2 V/min (the arrows show the sweep direction). Dotted line: steady-state trace.

In other words, there must exist only one $I = f(V)$ characteristic.

According to this result, the observed hysteresis would be caused by the fact that the surface coverage by $(FeH)_{ads}$ cannot reach a steady-state, even for the lowest sweep rates used here, because of the slowness of the hydrogen adsorption-desorption process.

Steady-state $I = f(V)$ polarization curve.—We obtained this curve by immersing the electrode, then by waiting at each point for the stabilization of the current. In order to check that there is only one $I = f(V)$ curve, we stopped the potential sweep during either the forward trace or the backward trace, and recorded the subsequent evolution of the current. We then confirmed that the value toward which the current tends depends only on the potential where the sweep was stopped, and that the curves obtained by these two methods are identical. As an illustration, we give in Fig. 5 the steady-state curve (dotted line) obtained point by point for iron I in a molar solution of sulfuric acid containing 10^{-3}M of 2-butyne 1,4-diol. In the same figure is shown the quasi-steady-state potentiokinetic curve (solid line) recorded at a speed of 0.2 V/min. The arrows indicate the sweep direction. The time needed to stabilize the current after the sweep is stopped is about 10-30 min, depending on the anodic potential; then we again obtained the $I = f(V)$ characteristic shown in dotted line. It can be seen that the steady-state curve is identical with the forward trace near the corrosion potential and with the backward trace at potentials above −0.4 V/SCE. As these curves here represent the over-all current I, *i.e.* the difference between the anodic current I_a and the cathodic current I_c, we wanted to separate its two components before attempting any interpretation.

Separation of the cathodic component I_c from the over-all current.—In an acidic medium, iron dissolves as a divalent ion. If iron is assumed to undergo no disaggregation, the measurement of weight loss allows the separation of I_a and I_c at a given current I. We have determined them in the case of the dissolution of iron I by means of Faraday's law in a molar solution of sulfuric acid containing 10^{-3}M of 2-butyne 1,4-diol. The constant current I is supplied by a wide-band galvanostat built in our laboratory by C. Gabrielli. The dissolution time is limited to 1 hr in order to avoid pitting. The dissolved iron is determined by colorimetry with o-phenanthroline as an indicator.

Table II summarizes, for each value of I, the values of I_a and I_c with their confidence interval calculated on the 10% level of significance from 8 experiments for I = 0.1 and 0.2 mA, and from 4 experiments for I greater than 0.2 mA. From this table, it can be noted

Table II. Results from the measurements of weight loss: iron I, 1M H_2SO_4 + 10^{-3}M 2-butyne 1,4-diol

R_t = Measured transfer resistance
R_{ta} = Anodic transfer resistance
θ_H^* = Surface coverage by $(FeH)_{ads}$
I = Over-all current
I_a = Anodic current
I_c = Cathodic current

I(mA)	$-I_c$(μA)	I_a(μA)	V(mV/SCE)	R_t(ohms)	$R_{ta}I_a$(mV)	θ_H^*
0.1	45 ± 6	145 ± 6	−470	221 ± 17.5	37 ± 3.8	0.78
0.2	47 ± 12	247 ± 12	−464	133 ± 5	38.4 ± 4.0	0.70
0.3	37 ± 10	337 ± 10	−460	101 ± 8	38.1 ± 4.0	0.62
0.5	54 ± 29	554 ± 29	−454	65.3 ± 1.6	38.7 ± 3.2	0.54
0.7	44 ± 28	744 ± 28	−450	50.2 ± 1.8	39.0 ± 1.6	0.45
1	42 ± 20	1042 ± 20	−445	36.7 ± 2.5	39.7 ± 2.2	0.40

that I_c is independent of I. Although the polarization potential varies only by 25 mV when I passes from 0.1 to 1 mA, a marked variation of the surface available for the cathodic reaction can be expected. Therefore, we may consider that the reaction responsible for the term I_c merely occurs on particular sites. Besides, this interpretation is corroborated by the microscopic observation, *in situ*, of the electrode through an objective immersed in the electrolyte: the gas bubbles always appear on well-determined sites whose positions depend on the structure of the surface.

The obtained I_a (V) values do not correspond to the anodic dissolution mechanism (5) which is applicable at higher currents (2). We shall now show that this deviation, which cannot be attributed to the cathodic current, may be explained by the coverage of the surface by $(FeH)_{ads}$.

Evaluation of the coverage fraction θ_H.—Column 5 of Table II shows the transfer resistance R_t, deduced from anodic impedance measurements (6) carried out during the dissolution experiments themselves. It hence can be seen that the product R_tI, which elsewhere (3) was shown to be constant for high currents ($\simeq$40 mV), diminishes for currents lower than 2 mA. If we take into account that R_t has an anodic component R_{ta} and a cathodic component R_{tc}, we can write that

$$\frac{1}{R_t} = \frac{1}{R_{ta}} + \frac{1}{R_{tc}}$$

The product R_{ta} I_a is constant (Table II, Col. 6) within the precision of measurements, even at the lowest polarization, and is equal to the value of R_tI found for currents higher than 2 mA. Consequently, it can be considered that the dissolution mechanism (5) remains valid even for very low anodic currents, although we have found an obvious difference between the variations of I_a and of its density J_a with the potential (6). Since R_{ta} I_a does not depend on the reaction surface, this difference can be attributed only to a variation of the area of cathodic coverage by the hydrogen (θ_H) and perhaps by the inhibitor (θ_{inh}). However, according to Mayer *et al.*, the inhibiting effect of 2-butyne 1,4-diol appears only when the electrode surface is covered by H_{ads} (21). In the same way, referring to the polarization curves obtained in the presence and absence of the inhibitor, it can be seen that 2-butyne 1,4-diol has the same effect as H_{ads} and that θ_H and θ_{inh} cannot be distinguished. Consequently, we may write

$$I_a = J_a\,(1 - \theta_H^*)$$

where θ_H^* is the cathodic coverage in the presence of 2-butyne 1,4-diol.

The last column of Table II presents the values of θ_H^* as a function of I. The values of J_a were obtained from the extrapolation of the anodic Tafel line corresponding to step I of the iron dissolution reaction (5). Figure 6 represents the variation of θ_H^* as a function of the potential V. From this figure it can be seen that θ_H^* tends toward 1 near the corrosion potential, which is in agreement with the results obtained at the

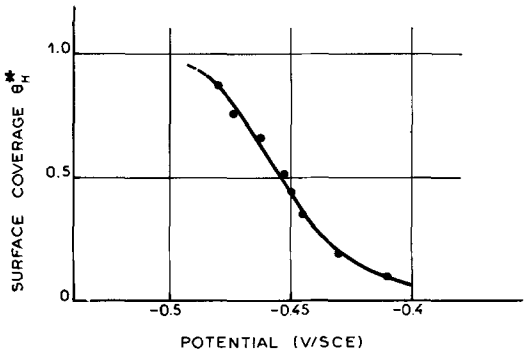

Fig. 6. Variation of the surface coverage θ_H^* with the anodic polarization potential: iron I, 1M H_2SO_4 + 10^{-3}M 2-butyne 1,4-diol.

cathodic range (see first section under Results and Discussion). On the other hand, θ_H^* tends toward zero for anodic potentials close to −0.4 V/SCE. These results explain the hysteresis of the potentiokinetic curve presented in Fig. 5. According to our interpretation (1, 2), the forward trace corresponds to an almost complete coverage by $(FeH)_{ads}$ and the backward trace to an almost uncovered surface. Moreover, it can be noted that the −0.4 V/SCE value is close to that above which hysteresis is no longer observed (2) with a single-crystal iron (−0.38 V/SCE).

Finally, it is to be noted that further support for this interpretation of the observed hysteresis is given by the impedance measurements within the anodic range (6). As a matter of fact, in the (R,jG) diagram, there appears a second inductive loop which is clearly distinguished from that caused by the relaxation of the coverage by $(FeOH)_{ads}$ and which can be assigned to the relaxation of the cathodic coverage (22). In this latter case, if there were two distinct coverages, θ_H and θ_{inh}, one might expect to observe two different time constants. We should observe, on the whole, three time constants, which is not the case here. We may therefore conclude that there is only one coverage, that of hydrogen, 2-butyne 1,4-diol having only the effect of reinforcing the bond between H_{ads} and the metal.

Conclusion

We have been able to elucidate the influence on the cathodic phenomenon of an acetylenic alcohol, namely 2-butyne 1,4-diol, during the corrosion of iron in a sulfuric acid medium. From our results, it appears, indeed, that 2-butyne 1,4-diol increases the surface coverage by $(FeH)_{ads}$ by reinforcing the Fe-H bond.

This coverage causes, in the cathodic range, a decrease with time of the reaction rate, probably by diminishing the number of active sites. In the anodic range, the persistence of the coverage by $(FeH)_{ads}$ at potentials much higher than the corrosion potential reduces the surface available for the dissolution reaction. Consequently, the variation of the hydrogen coverage θ_H with the potential is at the origin of the hysteresis phenomenon.

Lastly, for a highly pure iron, even in the absence of 2-butyne 1,4-diol the presence of $(FeH)_{ads}$, which leads to a very low corrosion rate, would explain the observed low inhibiting efficiency.

Manuscript submitted Dec. 1, 1970; revised manuscript received *ca.* Mar. 1, 1971. This paper was presented at the 3e Symposium Européen sur les Inhibiteurs de Corrosion, Ferrare, Italy, Sept. 1970 (and appeared in French in the Abstracts of the symposium proceedings).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Low Defect Density Electrodeposits on Copper Single Crystals[1]

U. Bertocci and C. Bertocci

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

The electrodeposition of layers of copper over 100 μm thick on copper single crystals has been carried out on highly perfect copper single crystal substrates, having {111} orientation. Conditions for the achievement of low defect density deposits have been investigated. The defects present in the deposit have been studied by Borrmann topography and other x-ray techniques as well as optical microscopy and dislocation etching. In the most perfect deposits produced, no mosaic structure has been found, and the concentration of defects visible by Borrmann topography did not increase substantially the absorption of the x-ray beam. Small loops or point defect clusters in concentrations of the order of $10^6/cm^2$ have been detected by etching. The orientation of the substrate has been found to affect the perfection of the deposits. It is concluded that random nucleation is likely to be the mechanism for step generation where the orientation is very close to {111}.

Epitaxial growth of copper single crystals by electrodeposition is very well documented, particularly from sulfate solutions (1-8). Not so well known, however, is the degree of perfection which can be attained by electrodeposition, as well as the characteristics of the defect structure.

Among the structural studies reported in the literature, many are concerned with the preferential orientation of polycrystalline deposits (9-13), since knowledge on this topic is of considerable practical interest. Epitaxial growth on single crystal substrates has been examined by x-rays (14), but most of the information is not topographic in nature (3, 5, 15) and gives only a general idea of the defects in the deposit. When sensitive techniques have been employed, the use of substrates having a substantial defect density tended to obscure the significance of the results (16).

A more detailed picture of the defects present in electrodeposits has been obtained employing transmission electron microscopy (10, 12, 13, 17). Although very valuable, this method is in general limited to examination of very thin deposits. The substrate, usually produced by evaporation, tends to contain a high number of defects. Electron microscopy has been mostly used to study the deposition of a metal on a substrate of different composition; this gives rise to defects peculiar to the difference in lattice parameters of substrate and deposit.

In recent years, because of the availability of metal crystals of high perfection and the improvement of x-ray techniques, Borrmann topography has been developed as a powerful tool for the examination of defects in crystals, and copper has been extensively studied (18-21). This technique is based on the phenomenon known as anomalous transmission. If a single crystal is so perfect that changes in orientation of the lattice are no more than a few seconds of arc, a monochromatic collimated x-ray beam will travel through it in certain directions with an absorption coefficient 10 to 20 times smaller than the ordinary value. For copper, specimens up to about 1 mm can be examined by transmission. If defects such as dislocations are present inside the crystal, images of them can be

[1] Research sponsored by the U.S. Atomic Energy Commission under contract with Union Carbide Corporation.
Key words: electrodeposition, x-rays, anomalous transmission Borrmann topography.

formed on the topographs, and by means of stereo pairs, the spatial arrangement of the defects inside the crystal can be determined. Intensity sufficient for obtaining a useful topograph can be transmitted only if no mosaic structure is present and the dislocation density is not more than about $10^4/cm^2$. As far as resolution is concerned, defects smaller than a few microns do not form an image, although contributing to the absorption.

Since specimens hundreds of microns thick are well suited as electrodes, Borrmann topographs can be used to gather information about the perfection of the deposits and about the relationships between defects in the substrate and in the deposit. The method allows examination of much thicker layers than possible by transmission electron microscopy, so that no doubt exists that the deposits were obtained in steady-state conditions.

The aim of the work described here has been to investigate the conditions for obtaining high perfection deposits and to contribute to the knowledge of the nature and spatial distribution of defects in the deposit, as well as the influence of perfection and orientation of the substrate on the deposit perfection. The experimental method employed has been the correlation of Borrmann topographs and other x-ray data with optical microscopy and dislocation etching.

Experimental Methods

The depositions were carried out on crystals of purity 99.999% approximately 10 x 10 mm, whose thickness ranged from 0.2 to 0.5 mm. The two main surfaces had {111} orientation. The crystals had been irradiated with 10^{17} fast neutrons/cm^3 in order to increase their hardness so as to withstand handling (20). The specimens were electropolished in a phosphate bath, rinsed in 10% H_3PO_4 for a minute and finally under flowing distilled water for several minutes. This preparation technique produces surfaces reasonably free of contamination. In particular, phosphorus is not present (22). The specimens were kept under water during the time (approximately 30 sec) necessary to transfer them into the cell.

The solution, whose composition was 0.5M $CuSO_4$, 0.2M H_2SO_4, was prepared by dissolving recrystallized reagent grade $CuSO_4$ and adding reagent grade H_2SO_4. The solution was filtered several times through fritted glass, and care was taken that particulate matter could not be detected by observing scattered light under a low power microscope.

The cell was all Pyrex glass, with Teflon stoppers and magnetic stirrer. The anodic and cathodic compartments were separated by fritted glass disks, and the solution was introduced into the cell from the anodic compartment so that a final filtration was achieved for the solution filling the cathodic compartment. The closed cell was swept with pure argon and kept permanently under an argon blanket at slight, positive pressure. Further purification was achieved by preelectrolysis on high purity copper cathodes, the current density being about five times larger than that used for the depositions. Stirring was employed only during pre-electrolysis.

All depositions were carried out at room temperature, about 23°C. The thickness of the deposits ranged from 30 to 120 μm.

Some depositions were made with periodic current reversal by means of a Hewlett-Packard 6823A Power Supply in the constant current configuration modulated by a signal generator. A cathode ray oscilloscope was used for measuring amplitude and duration of the pulses. The average c.d. calculated from pulse shape was checked against the weight gain of dummy specimens; the differences were of the order of 2 or 3%.

Borrmann topographs were taken using MoK_α radiation, the diffraction vector being either $\bar{1}\bar{1}\bar{1}$, $\bar{1}11$, or $1\bar{1}\bar{1}$, considering the crystal surface where the x-rays enter as (111). As a faster method for checking the perfection of the deposits, the measurement of the half-width of the 444 Bragg peak was chosen. Since the theoretical value for a perfect crystal, using MoK_α radiation, is 2″ of arc (23), small deviations from a perfect crystal, corresponding to a few seconds of arc, can be detected. The measurements were carried out by means of a double crystal spectrometer.

The deposits were also examined by optical microscopy, both as obtained after deposition and after electropolishing and etching with a dislocation etch (24). The orientation of the facets developed during deposition, particularly at the edges of the specimens, was determined by means of a two circle goniometer.

By sectioning some specimens and measuring the thickness of the deposits, it was deduced that the current density on high index planes was not more than three times that on close-packed ones. Since the flat crystals used as electrodes had their main faces oriented within a few degrees from {111} and at the edges—which accounted at most for 10% of the total surface area—slowly growing facets soon developed, it was concluded that the average current density did not differ from the actual current density on the {111} planes by more than 20%. Optical measurement of the thickness of the electrodes before and after deposition supported this conclusion.

Production of low defect density deposits.—By examining the deposits, standards for assessing their quality were developed. In the course of the work it became apparent that trace impurities affected both surface structure and perfection; repeated pre-electrolysis was generally beneficial. However, particulate matter suspended in solution was very detrimental, as was shown during preliminary work in cells without separation between cathodic and anodic compartment. During pre-electrolysis copper powder is generated at the anode by preferential attack at grain boundaries. If the powder reaches the cathode, abnormal growth protrusions are formed, often misoriented with respect to the substrate.

The features marking deposits whose perfection was considered unsatisfactory, because they were unsuitable for Borrmann topography, were a tendency for the surface steps to aggregate, forming steep ledges exhibiting crystallographic character (see Fig. 1). These ledges developed into {210} facets which broke up the {111} surface into areas often of different height. The same facets also bound hexagonal pits, which tended to cover large areas of the surface.

Visual examination was therefore sufficient for detecting unsatisfactory deposits. Their appearance correlated well with x-ray data; the half-width of the

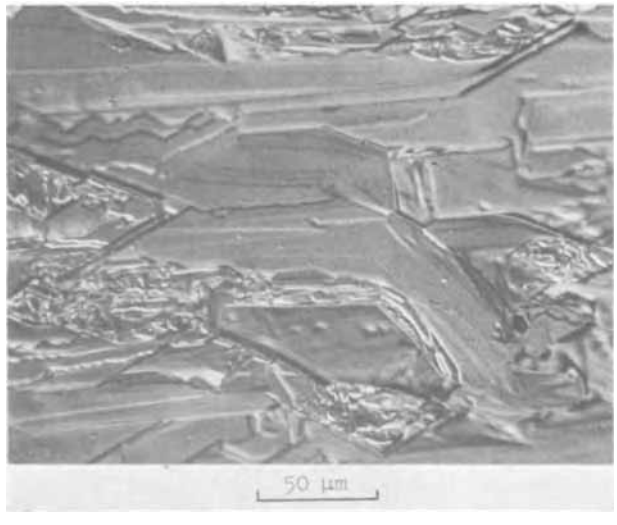

Fig. 1. Deposit of unsatisfactory perfection. (111) surface after deposition of 45 μm at 0.5 mA/cm^2. Nomarski interference contrast.

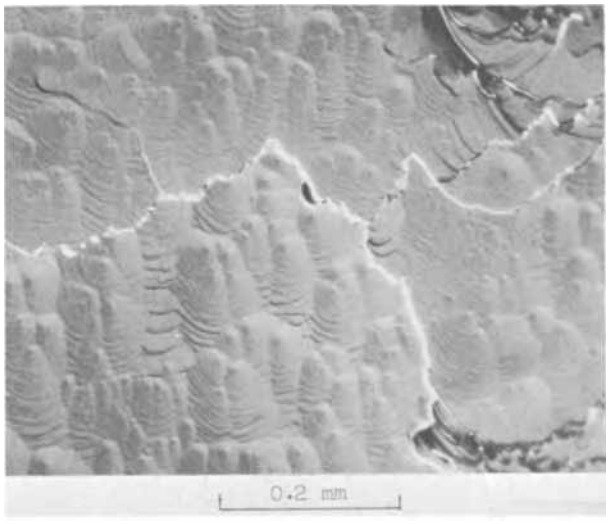

Fig. 2. Deposit of high perfection. (111) surface after deposition of 50 μm at 0.5 mA/cm^2. Nomarski interference contrast.

444 reflection on such surfaces varied from 10″ of arc up to 1′, indicating the angular range of the mosaic structure in the deposit. The transmitted x-ray intensity was so low that Borrmann topographs could not be taken.

More perfect deposits were characterized by regular arrays of macrosteps about 10-12 μm apart, if the surface was more than about 1°10′ to 1°30′ from {111}, and by randomly distributed hillocks as shown in Fig. 2 for smaller misorientations. The transition between the two surface structures is quite sharp. The slope of the hillocks, as measured by means of a modified Nomarski interference contrast microscope (25) is between 6′ and 10′ of arc. Steeper ledges such as those crossing Fig. 2 (see also Fig. 6) reach misorientations of 4° to 5°. The tendency to form pits bound by {210} facets was largely suppressed. The half-width of the 444 peak was from 4″ to 5″ of arc. Borrmann topographs could be taken and areas of higher or lower perfection could be observed and examined.

The experiments at constant current density showed that consistently good deposits could not be obtained at current densities higher than about 0.5 mA/cm^2. At 1 mA/cm^2, Borrmann topographs showed that most of the deposit had a high defect density, and the half-width of the 444 peak was of the order of 20″.

Some depositions were carried out with periodic current reversal using either sinusoidal or square wave signals. In the present experiments no improvement over constant current deposition was found, either in the perfection of the deposits or in the possibility of increasing the deposition rate without increasing the defect density.

In a series of tests a sinusoidal signal was superimposed on a direct c.d. of 0.5 mA/cm^2. The conditions were the following: 500 Hz, 1.8 mA/cm^2 rms; 2000 Hz, 2 and 5 mA/cm^2 rms. The appearance of the deposit was substantially different compared with d-c deposition, particularly at the lower frequency, showing formation of large triangular hillocks on the {111} faces. The perfection was low, half-width was 30″ to 1′, and the topographs were opaque, except in very few isolated patches. Subsequent electropolishing and etching showed a pit density greater than 10^6/cm^2.

Some experiments were carried out using rectangular current pulses. The current density, both anodic and cathodic, varied between 0.6 and 0.9 mA/cm^2, the duration of the anodic pulse being 20 msec and that of the cathodic pulse 180 msec. Longer pulse durations have also been tested. This work is still in progress, but preliminary observations have given little indication that higher deposition rates and/or highly perfect deposits can be achieved in this way. This method, however, seems to affect the growth habit so that facets different from those observed with d-c depositions are formed.

Experimental Results

The experimental evidence to be analyzed principally consists of photographs recording x-ray or visible light intensity patterns, and their analysis mainly consists in comparing topographs with different diffraction vectors, as is necessary in order to examine line defects, or in correlating spatially x-ray pictures with photomicrographs, both before and after etching. The experimental data, therefore, do not lend themselves to being presented in compact form as with numerical tables or graphs. An effort has been made to show some of the most significant examples, but it must be understood that only a small part of the evidence can be presented.

Figures 3 and 4 show stereo pairs of topographs of the same area of a specimen before and after deposition. The thickness of the deposit on each side is approximately 130 μm, and the total thickness is 430 $\pm$ 30 μm. The main faces of the crystal are misoriented about 5° from {111}. In the deposit very few defects can be seen except on the edges of the crystal (lower left corner), where they are associated with growth of facets other than {111}.

Some dislocations ending at the surface of the substrate can be recognized. For the comparison between the dislocation network in Fig. 3 and 4, it must be remembered that after taking Fig. 3, the specimen had to be electropolished immediately before the deposition, as described in a preceding section. Therefore some dislocation lines were shortened, particularly those intersecting the surface at a low angle.[2] In all cases, instead of a clear dislocation line continuing into the deposit, only a faint line starting from the end of the dislocation line in the substrate can be seen. Also, series of small spots roughly aligned so as to cross the deposit perpendicularly to the surface are visible.

Figure 5 shows a topograph of another specimen; the deposit obtained at 0.5 mA/cm^2 is approximately 50 μm thick. The orientation of the surface, very close to {111}, is shown in Fig. 6, a composite photomicrograph of the same area (Nomarski interference contrast and

[2] Defects close to the exit surface for the x-ray beam exhibit reverse contrast, producing a black and white double image, instead of a simple black image (on positive prints). The reader should notice that the dislocation lines showing reverse contrast in Fig. 3 have been in general removed by the electropolishing and no longer appear in Fig. 4.

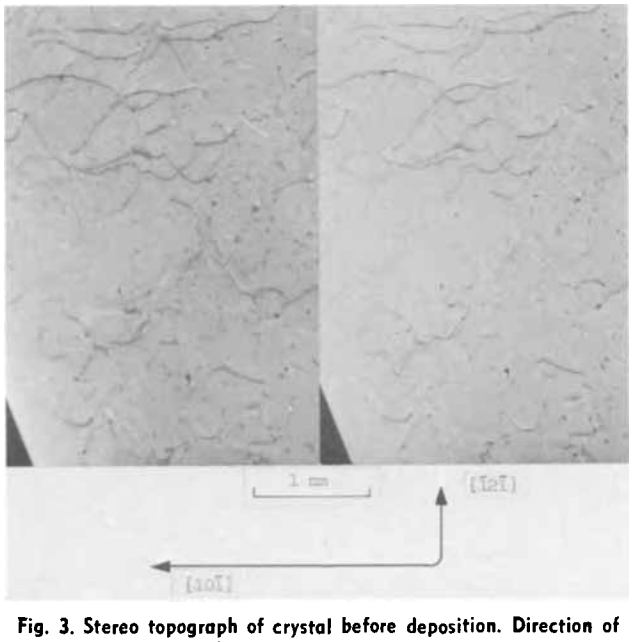

Fig. 3. Stereo topograph of crystal before deposition. Direction of diffraction vector = $\bar{1}\bar{1}\bar{1}$.

a low magnification objective were used so as to obtain high contrast; the surface is actually fairly smooth). In Fig. 5 a number of defects can be seen, but many cannot be resolved as either dislocation lines or point defect clusters. Areas of higher defect density, as revealed by the topograph, correspond on Fig. 6 to areas where closely spaced hillocks grew together or where surface ledges were pinned, bent sharply, or bunched. The correspondence between higher defect regions and recognizable surface features is, however, not complete: the defect regions appear to be at different levels inside the deposit; this can be seen by comparing Fig. 5 with Fig. 7, a topograph of the same region of the crystal taken after electropolishing the specimen so as to remove most of the deposit, and

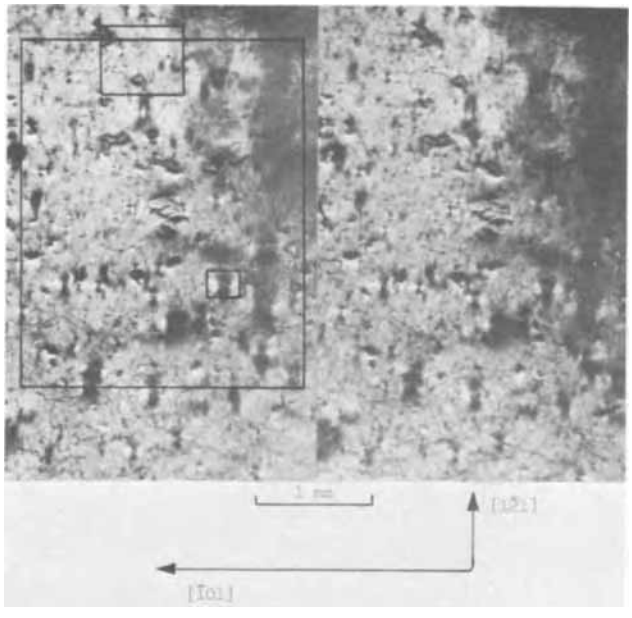

Fig. 5. Stereo topograph of crystal after deposition of 50 μm at 0.5 mA/cm^2. Direction of diffraction vector = $\bar{1}1\bar{1}$. Black lines show outlines of Fig. 6. (large rectangle), Fig. 8 (lower rectangle) and Fig. 9 (upper rectangle).

etching with a dislocation etch (23). A number of the high defect regions have completely disappeared but others are now at the surface, as can be inferred from the strong black-white contrast. Microscopic observation of the etch-pits shows that tight clusters of pits are found in positions corresponding to the black spots

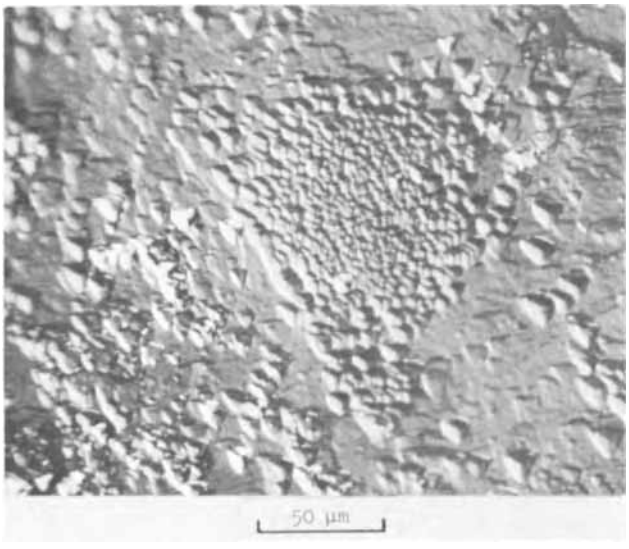

Fig. 8. Photomicrograph of part of crystal shown in Fig. 5 after electropolishing and etching. Nomarski interference contrast.

seen on the topograph (see Fig. 8). However, pit densities (of the order of $5 \cdot 10^5$ per cm^3) higher than in the substrate could be seen also where the x-ray topograph did not show a significant defect density. Figure 9 shows clearly the difference between substrate and deposit, which had been completely removed in some areas. It is noteworthy that the etch-pits produced have different sizes, a number of them being small and flat-bottomed. This feature is generally not associated with long dislocation lines, but rather with small dislocation loops (26).

In some instances, growth of isolated pyramids has been observed. The steps on the side of the pyramid, although bunching to form multi-atomic ledges clearly visible by optical microscopy, generated only relatively few defects detectable in the x-ray topographs. At the center of the pyramid a rather diffuse spot showing black-white contrast can be seen. The isolated pyramid, therefore, is not associated with a single dislocation line. Figures 10 and 11 show a stereo topograph and a micrograph of an area containing isolated growth pyramids. The slope of the steepest one (bottom left in Fig. 11) is about 2°. The others are less than 1°.

Some information about the nature and location of defects present in deposits considered of unsatisfactory perfection was obtained by electropolishing and etching. As is clearly visible in Fig. 12, etch-pits are often

clustered in lines. The lines follow approximately the contour of the steep ledges observed on the surface of the deposit. Furthermore, strain centers surrounded by etch-pits and seemingly having a hollow core are fairly numerous (see Fig. 13, where double rows of pits, revealing punched-out prismatic loops, are shown).

In the course of this work data about the growth habit of electrodeposited copper were gathered by measuring the orientation of the facets formed at the edge of the specimens. These data were supplemented by depositions carried out on hemispherical crystals (see Fig. 14). The results can be summarized as follows: The tendency to form flat and well-oriented facets (deviations being generally less than 1°) is exhibited only by {111} and {110}. The latter orientation, however, is not a preferred one, and only small facets are formed, generally at the intersection of two {210} facets (see Fig. 15). An orientation which develops preferentially is {210}. Large facets are formed by deposition on hemispherical crystals, as Fig. 14 shows. The facets are not very smooth; the reflections at the goniometer indicate that most of the surface is oriented about 4° from {210} toward the nearest {110}, but slightly off the <001> zone. The results of the goniometer readings agree with microscopic observations (see Fig. 16), where considerable variations in orientation can be seen. The growth seems to occur by motion of ledges or facets, visible in Fig. 16, and whose orientation is approximately {320}.

It is remarkable that all areas close to <100> poles never develop {100} faces but orientations varying from

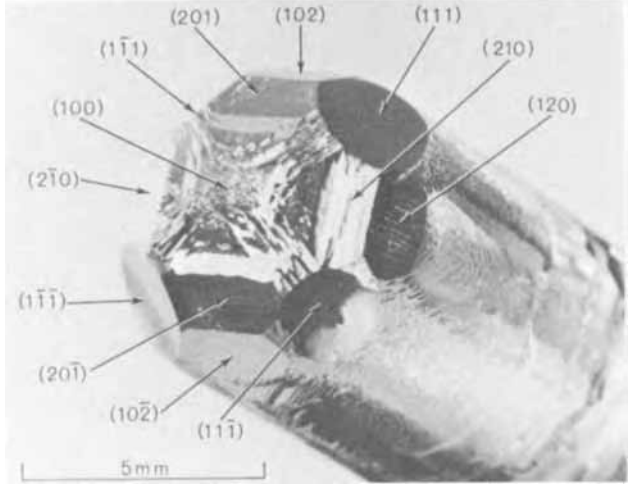

Fig. 14. Photomicrograph of deposit obtained on hemispherical crystal. Current density = 0.3 mA/cm^2. Average thickness 230 μm.

{710} to {15,1,0}. The goniometer reflections are rather diffuse, in agreement with the structure seen under the microscope: terraced pyramids tending to have {15,1,0} at the base and {710} at the tip (see Fig. 17). The pyramids very often have a core which is not epitaxially oriented, as was determined by x-ray examination.

Discussion

From the results presented it can be concluded that in carefully controlled conditions it is possible to electrodeposit copper from sulfate solutions in layers over 100 μm thick with a high degree of perfection. It is, however, clear that the orientation of the surface plays an important role, and so far only for orientations close to {111} have conditions leading to good deposits been found.

Since the sensitivity of a method for detecting defects varies with their nature, only correlating different results can give an accurate picture of the defect structure of a crystal. The measurement of the half-width of the 444 Bragg peak, although more sensitive than Borrmann topography in detecting mosaic structure (the half-width of the anomalously transmitted beam is of the order of 15" of arc) is little affected by individual defects. The broadening of the 444 peak is

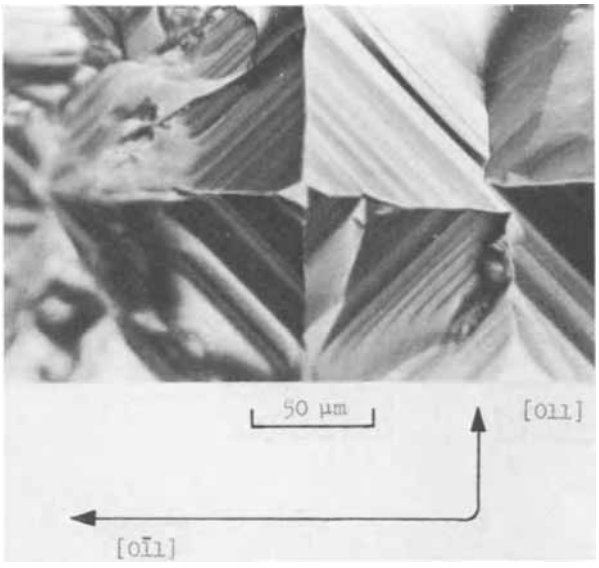

Fig. 17. Pyramidal growth bound by {710} and {15,1,0} facets. Deposition at 0.5 mA/cm². Nomarski interference contrast.

barely noticeable when Borrmann topographs show the presence of a substantial number of defects. Topography is extremely sensitive in detecting dislocations as well as small loops or point defect clusters having dimensions down to few μm. However, in the restricted case of a fairly flat and well-oriented surface, etch-pit observations have shown a density of defects of the order of 10^5 to 10^6 per cm² in crystals which appeared nearly perfect if examined by x-ray methods. Analogous results have been obtained in the case of copper specimens irradiated with fast neutrons (26); this leads to the conclusion that the defects detected here as etch-pits are mostly point defect clusters or very small dislocation loops.

In the rare instances where a dislocation line could be seen continuing in the deposit, the image in the topograph exhibited less contrast than in the substrate; this cannot be easily understood, since no change in the Burgers vector of the dislocation can be expected. This observation has to be left for the moment unexplained. It is, however, interesting that the faint lines extending from the dislocations in the deposit tend to be more or less perpendicular to the surface. This is in contrast with the observations in the electrolytic growth of silver (27), where it was reported that most dislocations tended to grow along <110>.

Among the factors affecting the perfection of the deposits, the defect density in the substrate does not seem to be as important as the presence of impurities in solution or the orientation of the surface; for misorientations of less than 1° from {111}, a substrate with a dislocation density up to about $5 \cdot 10^4$/cm² would contribute very little to Bragg peak broadening (28) or etch-pit density, compared with defects generated during deposition. As the deposit shown in Fig. 4 seems to indicate, however, the lowest defect density in the deposit might be achieved for misorientations in the range of 3° to 6° of arc.

It has been suggested that defects intersecting the surface influence the kinetics of electrodeposition, providing sources of steps (29). The present observations show that about 10^6 defects per square cm, as detected by etch-pits, should be expected on a growing {111} surface. When the misorientation is higher than 1° to 1°30′, that is when the step density $d \geqq 10^6$/cm, the surface appearance changes drastically, and the regularity of the step arrays suggests that steps due to misorientation are sufficient to maintain the current density. Since there is no indication that local current density is much higher than the average value, a step velocity between 10^{-6} and $2 \cdot 10^{-6}$ cm/sec can be deduced from the formula

$$v = \frac{i V_m}{zFdh}$$

where i is the current density, $V_m = 7.11$ cm³/mole is the molar volume, $z = 2$ is the charge, **F** is the Faraday constant, and $h = 2.09 \cdot 10^{-8}$ cm is the height of a step on a {111} plane. On the surfaces close to zero average misorientation such as those shown in Fig. 2 and 6, it is difficult to estimate step density; however, by measuring the slope of the hillocks a step density of the order of 10^5/cm can be deduced. Under the conservative assumption that local current density can be as low as 0.3 mA/cm², a step velocity of the order of $5 \cdot 10^{-6}$ cm/sec can be calculated. From studies on the interaction between random nucleation and step motion (30), the nucleation rate R_n which would insure a current density of about 0.3 mA/cm² on a perfect {111} is given by

$$R_n = \frac{vd^3}{2}$$

resulting in a value of the order of $2 \cdot 10^9$ nucleations/cm² sec. It is therefore unlikely that nucleation occurs only at defect sites; with a defect density of the order of 10^6/cm², about 10^3 close-packed layers per second would be generated at the same place, giving a vertical growth rate of $2 \cdot 10^5$ cm/sec. Since the horizontal rate v is smaller, very steep hillocks should be observed. On the contrary, even when a system of defects is capable of enhancing growth so that a large pyramid results (Fig. 11) the slopes measured never exceed 2°. Most of the nucleations therefore occur randomly, and relatively few result in extended defect formation. The evidence indicates that defects in electrodeposited copper are a consequence of the growth process rather than its cause.

From these considerations one would conclude that the range of conditions in which defect density in the substrate can influence the kinetics may be very limited; also the dependence of the reaction rate on misorientation postulated by the classical treatment of electrocrystallization kinetics (31) might be difficult to observe. Nevertheless, defects generated during deposition could influence anodic dissolution; it is interesting to remember that differences in anodic overvoltage between electrodeposited and grown from the melt material have been observed both in silver (32) and copper (33, 34). Also, isolated point defects would not have been detected in the present investigation, and their influence on the kinetics is unknown.

The principal mechanism for the formation of the defect clusters which can be detected by Borrmann topography seems to be interaction between steps meeting and annihilating; accordingly, higher defect density is found where the orientation is so near to a close-packed plane that new steps have to be generated by nucleation, moving then in every direction. Similarly, on slightly misoriented areas multi-atomic steps are sometimes pinned so that step pile-up occurs at one point. The steps then bend and bypass the obstacle, and so meet and annihilate locally. In these points both x-ray topographs and etching techniques show high defect concentration. On the other hand when the misorientation is larger than a few degrees, the chances of interaction between the moving multiatomic steps are high because of the small spacing, and defect concentration tends to increase again.

As comparison between Fig. 4 and 5 shows, the areas containing a high defect density do not continue indefinitely in the deposit and can be buried by a layer of more perfect crystal. This also shows that no long dislocation lines tend to be formed. The complexity of the situation and of the defects formed by deposition is further illustrated by Fig. 10 and 11; even in the case of well developed hillocks, the defect found in their center is not simply one or a few dislocation lines, but

a strain center giving an image several tens of μm in diameter.

Examination of the deposits of unsatisfactory perfection indicates also that hindered motion of steps on the {111} surface is responsible for the formation of defects, many of which are found in long lines where the steps had been blocked. The piling up of the steps is responsible for the development of {210} facets. There is evidence of overgrowth, presumably at the bottom of pits, leaving cavities and giving rise to considerable strains as Fig. 13 shows; prismatic loops are evidently punched out from these strain centers.

The observations about the crystal habit of copper are in general agreement with the findings of other workers (1, 35), although most previous depositions had been carried out at higher current density; the main differences are that in the present work a more pronounced tendency to form {210} facets was found and that {100} was never observed in d-c deposits. On this last point it is not clear, however, if the difference is due to different deposition conditions or if the measurement of the orientations was carried out in previous work carefully enough to distinguish between facets differing by a few degrees. Orientations similar to those observed here have been reported previously for both anodic attack and cathodic deposition in chloride solutions (33, 36).

Since convex crystals tend to be bound in growth by slowly growing faces, the {110} orientation has no tendency to develop because growth in this direction is fast, as shown by x-ray (11) and electron microscope observation (12) of the texture of polycrystalline deposits. Also exchange current densities on {110} have been found to be higher than on other close-packed orientations (7).

In the present work, periodic current reversal has not proved to be helpful in growing more perfect crystals. However, preliminary results seem to show that it can influence crystal habit; for instance, well-developed and smooth {100} facets have been produced by low frequency rectangular pulses. The method could, therefore, be interesting for developing surfaces of various orientations for the purpose of making kinetic measurements.

Acknowledgments

The authors wish to thank F. W. Young, Jr. and B. C. Larson for many helpful suggestions, and F. A. Sherrill for taking the x-ray topographs.

Laplace Plane Analysis of the Impedance of Faradaic and Nonfaradaic Electrode Processes

Arthur A. Pilla*

ESB Incorporated, Research Center, Yardley, Pennsylvania 19067

ABSTRACT

A unified theory of the impedance of electrode processes is presented. It is shown that the expression of impedance in terms of the Laplace variable, s, permits all cases of interest to be treated. The basic equations developed allow a finite rate for both charge transfer and adsorption, as well as mass transport, in a system of uniform potential distribution. The question of coupling of faradic and charging currents is treated in detail.

The use of impedance as a characteristic function of electrochemical systems has long been recognized (1, 2). It was recently pointed out (3) that its expression in terms of the Laplace transform variable, s, enables impedance to be considered as a real ($s = \sigma$) or complex ($s = j\omega$) function allowing both less ambiguity in mechanism detection and an increased frequency range to be achieved.

The necessary quantities can be obtained by starting with the following general relation

$$i_T(s) = i_f(s) + i_c(s) \qquad [1]$$

where $i_f(s)$ is the faradaic current (*i.e.*, that which involves the passage of charge across the interface) and $i_c(s)$ is the interfacial charging current (*i.e.*, that which does not require the passage of charge across the interface). Equation [1] can be misleading, as has recently been pointed out (4-11), since both partial currents may contain double-layer and faradaic parameters if strong reactant adsorption is present. However, their expression in terms of s to develop impedance clearly shows how coupling may or may not exist and allows some interesting and usable limiting cases to be determined, which heretofore do not appear to have been described.

General Theory

To illustrate this approach, it will be assumed that only the oxidized species need be taken into account (*e.g.*, metal-metal ion electrode). Extension to any number of electroactive species is a trivial matter.

The quantities $i_f(s)$ and $i_c(s)$ in [1] must first be written in explicit form. For the former, the most general approach would be to express it in terms of the appropriate independent variables. Since the treatment below will assume finite kinetics for both charge transfer and adsorption, it is rigorous to pick both C_0 and Γ_0 as well as E for these variables. However, since the (linearized) rate expression given below for Γ_0 allows its dependence on C_0 (as well as E) to be established, it is sufficient to use only C_0 and E to describe $i_f(s)$. (Note that this does not require C_0 and Γ_0 to be in equilibrium.) It is to be remembered, nevertheless, that the variation of C_0 at the interface can in fact be obtained only if both charge transfer and adsorption (finite or otherwise) are taken into account. For the purposes of this study, the standard linearized rate expression is employed realizing, however, that the most general form for $i_f(s)$ does in fact consist in its expansion involving the well-known partial derivative coefficients. Note that, in the latter case, the parameters are lumped in such a way that the frequency variation of C_0 is no longer separable from either the dependence of i_f on E (*i.e.*, charge transfer) or on C_0. In order to express $i_c(s)$ [$=s\,q(s)$] in an explicit manner, it is convenient (12) to consider it in terms of Γ_0 and E. This takes into account the fact that q may vary not only with E, as in classical systems, but also with Γ_0 when specific adsorption is present. Of course, Γ_0 is related to C_0 *via* the (linearized) rate expression given below.

Using the above considerations, [1] can now be written

$$i_T(s) = i_o[-\Delta C_0(0, s)] + n\mathbf{F}i_o\eta(s)/RT + q_{\Gamma_0}s\Delta\Gamma_0(s) + q_E s\eta(s) \qquad [2]$$

where

$$q_{\Gamma_0} = (\partial q/\partial\Gamma_0)_E \qquad [2a]$$

$$q_E = (\partial q/\partial E)_{C_0} \qquad [2b]$$

$$\Delta C_0(0, s) = (C_0(0, s) - C_0)/C_0 \qquad [2c]$$

$$\Delta\Gamma_0(s) = (\Gamma_0(s) - \Gamma_0)/\Gamma_0 \qquad [2d]$$

and $\Gamma_0(s)$ and $C_0(0,s)$ are, respectively, the frequency variation of the surface excess and interfacial concentration of the reacting species, and the other terms have their usual meaning.

Equation [2] can be solved to obtain an expression for the impedance of the system, provided both $\Delta\Gamma_0(s)$ and $\Delta C_0(0,s)$ are known. These quantities are related by allowing finite adsorption kinetics given by (3, 12)

$$\Delta\Gamma_0(s) = (v_0/s\Gamma_0)\,[\Delta C_0(0,s) - \Delta\Gamma_0(s) + a\eta(s)] \qquad [3]$$

where v_0 is the exchange adsorption rate and a is a coefficient representing the potential dependence of Γ_0. Note that [3] does not presuppose an *a priori* form of adsorption kinetics, merely that any kinetic expression can be linearized. Fick's second law can now be employed to obtain $\Delta C_0(0,s)$. For this, the remaining necessary equation (boundary condition) can be written as

$$s\Gamma_0\Delta\Gamma_0(s) = \sqrt{D_0}C_0\sqrt{s}\,\Delta C_0(0,s) + i_f(s)/n\mathbf{F} \qquad [4]$$

which simply states, as is well known (5), that the surface excess of the reacting species can vary either by mass transport (in this case semi-infinite linear diffusion), or by charge transfer, or by both.

Utilizing [2], [3], and [4], the following is obtained for the generalized faradaic [$Z_F(s)$] and charging [$Z_C(s)$] impedance

$$Z_F(s) = \frac{RT}{n\mathbf{F}i_o}\,\frac{b\sqrt{D_0}C_0\sqrt{s} + b\Gamma_0 s/(1 + \Gamma_0\, s/v_0)}{b\sqrt{D_0}C_0\sqrt{s} + (b\Gamma_0 + an\mathbf{F}\Gamma_0)\,s/(1 + \Gamma_0\, s/v_0)} + \frac{1}{b\sqrt{D_0}C_0\sqrt{s} + (b\Gamma_0 + an\mathbf{F}\Gamma_0)\,s/(1 + \Gamma_0\, s/v_0)} \qquad [5]$$

in which $b = n^2\mathbf{F}^2/RT$, and

* Electrochemical Society Active Member.

Key words: adsorption, double layer, electrode kinetics, frequency domain.

$$Y_C(s) = 1/Z_C(s) =$$

$$\frac{q_{\Gamma_0} s[nFi_o/RT + a(nF\sqrt{D_0}C_0\sqrt{s} + i_o)]}{(1 + \Gamma_0 s/v_0)(nF\sqrt{D_0}C\sqrt{s} + nF\Gamma_0 s(1 + \Gamma_0 s/v_0) + i_o) + q_E s} \quad [6]$$

Both Z_F and Z_C are in parallel and do not readily lend themselves to interpretation *via* aperiodic equivalent circuits, although the number of parameters is not too great for numerical analysis to be attempted. Some general observations can, however, be made as is shown below.

Negligible Adsorption Potential Dependence

Inspection of [5] shows that as $a \to 0$ (*i.e.*, as the potential dependence of adsorption becomes negligible), then [5] can be written

$$Z_F(s) = \frac{RT}{nFi_o} + \frac{1}{b\sqrt{D_0}C_0\sqrt{s} + b\Gamma_0 s/(1 + \Gamma_0 s/v_0)} \quad [7]$$

In addition, as $a \to 0$, $q_{\Gamma_0} \to 0$ as thermodynamics requires (13) for the conditions under which [3] is valid, and [6] reduces to

$$Z_C(s) = 1/q_E s \quad [8]$$

Comparison of [5] and [6] with [7] and [8] shows that in the latter cases Z_F depends only on charge transferred across the interface (*i.e.*, represents solely a faradaic process), while Z_C does not require faradaic current. In contrast, the former cases show how the faradaic and charging processes are intercoupled.

Use of [7] and [8] allows the aperiodic equivalent circuit shown in Fig. 1 to be constructed where R_e is the electrolyte resistance and

$$C_d = (\partial q/\partial E)_{\Gamma_0} \quad [9]$$

$$R_t = RT/nFi_o \quad [10]$$

$$Z_D = 1/b\sqrt{D_0}C_0\sqrt{s} \quad [11]$$

$$C_a = b\Gamma_0 \quad [12]$$

$$R_a = 1/b\,v_0 \quad [13]$$

This case differs from classical Randles-Ershler (1, 2) behavior by the presence of the adsorption terms R_a and C_a. In fact, if R_a and C_a are not present (*i.e.*, no reactant adsorption), then it can readily be seen how classical behavior is obtained, since in this case both $a = 0$ and $\Gamma_0 = 0$.

Equations [5] and [6] can also be used to establish the conditions for infinitely fast adsorption kinetics,

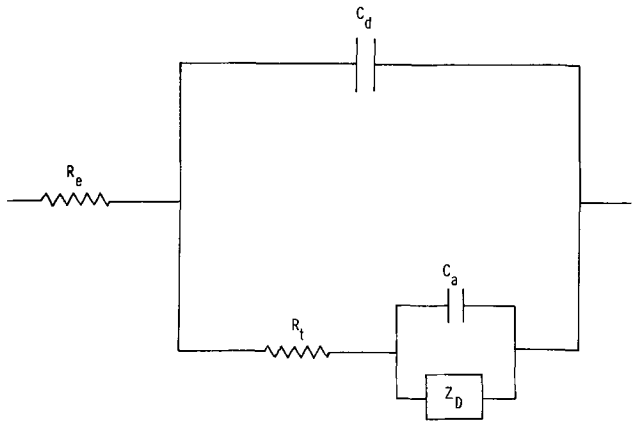

Fig. 2. As Fig. 1, except for infinite adsorption kinetics

since $v_0 \to \infty$ and $R_a \to 0$. If, in addition, $a \to 0$, then the aperiodic equivalent circuit shown in Fig. 2 may be employed. This is exactly the same result which would have been obtained if a kinetic expression for adsorption (Eq. [3]) had not been employed, but rather the expansion (6) for $d\Gamma_0/dt$, since Γ_0 is related to $(\partial\Gamma_0/\partial C_0)_E$ (*i.e.*, an isotherm) and a is similarly related to $(\partial\Gamma_0/\partial E)_{C_0}$. It can thus be seen that this is merely a special case of the more general approach given above, as expected.

Infinite Charge Transfer Kinetics

The case of infinitely fast charge transfer (*i.e.*, $i_o \to \infty$) can now be considered. Inspection of [5] and [6] shows that, when this limit is set, then

$$Z_F(s)_{i_o \to \infty} = \frac{1}{b\sqrt{D_0}C_0\sqrt{s} + (b\Gamma_0 + anF\Gamma_0)s/(1 + \Gamma_0 s/v_0)} \quad [14]$$

and

$$Z_C(s)_{i_o \to \infty} = \frac{1}{\frac{q_{\Gamma_0}(nF/RT + a)s}{1 + \Gamma_0 s/v_0} + q_E s} \quad [15]$$

which results in the aperiodic equivalent circuit shown in Fig. 3 where

$$C_a' = q_{\Gamma_0}(nF/RT + a) \quad [16]$$

and

$$R_a' = \Gamma_0/v_0\, q_{\Gamma_0}(nF/RT + a) \quad [17]$$

Diagnostic analysis is possible particularly if Z_D and C_d can be isolated by study over a wide frequency range, and the two remaining time constants are sufficiently different. It can easily be seen that, if adsorption is infinitely fast, $R_a \to 0$ and $R_a' \to 0$ and the cir-

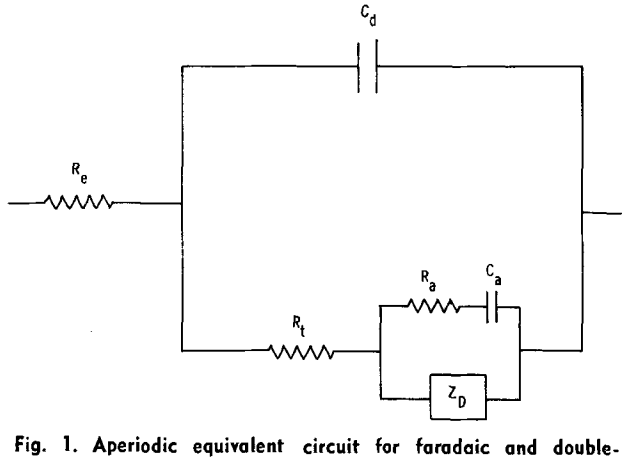

Fig. 1. Aperiodic equivalent circuit for faradaic and double-layer processes in the case of finite adsorption and charge transfer kinetics (potential dependence of adsorption negligible).

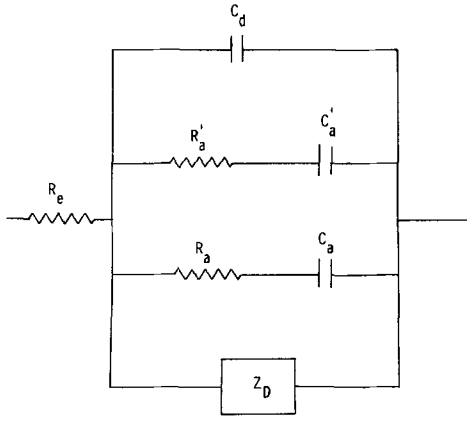

Fig. 3. Aperiodic equivalent circuit for infinite charge transfer and finite adsorption kinetics (potential dependence of adsorption not negligible).

cuit reduces to one which looks classical with the parallel capacitance composed of C_d, C_a, and C_a'.

Negligible Charge Transfer

The case of infinitely slow charge transfer $i_o \rightarrow 0$ can now be considered. With this restriction, $Z_F(s) \rightarrow \infty$ as can be seen by inspection of [5]. Equation [6], however, now becomes

$$Y_C(s) = 1/Z_C(s) = \frac{q_{\Gamma_0} s (an\mathbf{F}\sqrt{\bar{D}_0 C_0 \sqrt{s}})}{(1 + \Gamma_0 s/v_0)(n\mathbf{F}\sqrt{\bar{D}_0 C_0}\sqrt{s} + n\mathbf{F}\Gamma_0 s/(1 + \Gamma_0 s/v_0) + q_E(s)} \quad [18]$$

for which the aperiodic equivalent circuit is shown in Fig. 4, where

$$Z_D' = \Gamma_0/q_{\Gamma_0} an\mathbf{F}\sqrt{\bar{D}_0 C_0} \quad [19]$$

$$R_a'' = \Gamma_0/q_{\Gamma_0} av_0 \quad [20]$$

and

$$C_a'' = 1/q_{\Gamma_0} a \quad [21]$$

This is, of course, the well-known result for the adsorption of electroinactive species with a slow adsorption step (12, 14). Again, when adsorption is infinitely fast, $v_0 \rightarrow \infty$ and $R_a'' \rightarrow 0$ and the circuit reduces to that originally proposed for this situation (15).

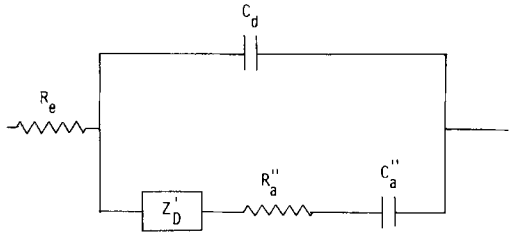

Fig. 4. Aperiodic equivalent circuit for adsorption of electroinactive species with slow adsorption step.

Negligible Mass Transport

Finally, it is of interest to consider the case for which mass transport is negligible (high reactant concentration). For this

$$Z_F(s) = \frac{RT}{n\mathbf{F}i_o} + \frac{1}{(b\Gamma_0 + an\mathbf{F}\Gamma_0)s/(1 + \Gamma_0 s/v_0)} \quad [22]$$

and

$$Z_C(s) = \frac{1}{q_{\Gamma_0} as/(1 + \Gamma_0 s/v_0) + q_E s} \quad [23]$$

Inspection of [22] and [23] shows that they can be represented by the aperiodic equivalent circuit given in Fig. 5 which shows adsorption with slow kinetics involved in both the faradaic and charging processes as expected. Similar to the above cases, if $a \rightarrow 0$, then the circuit becomes that given in Fig. 6 where R_T may be equal to R_t, R_a, or $R_t + R_a$ depending on the value of v_0. A circuit of this type has in fact been found for the Pt/1M H^+ system (16, 17) where diffusion is negligible.

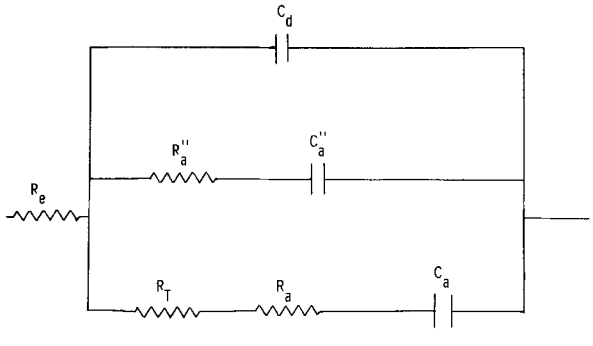

Fig. 5. Aperiodic equivalent circuit for finite charge transfer and adsorption kinetics and negligible diffusion (potential dependence of adsorption not negligible).

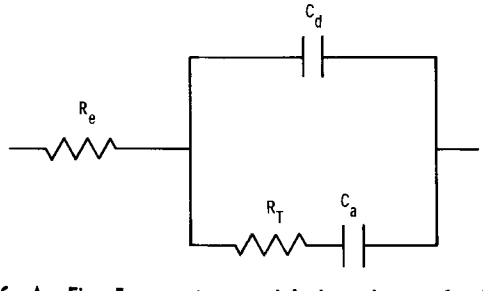

Fig. 6. As Fig. 5, except potential dependence of adsorption negligible.

Conclusion

In summary, the expression of impedance in terms of s starting with the general case allowing both finite charge transfer and adsorption, as well as mass transport in a system of uniform potential distribution, has been performed. The basic equations developed allow essentially all cases of interest in this general scheme to be treated. In particular, the coupling of faradaic and charging currents is clearly shown, as well as the manner in which relatively simple behavior can be obtained when the potential dependence of adsorption, which is the essential coupling parameter, is negligible.

The Electrode Potential of Zinc Amalgam in Alkaline Zincate Solutions

D. P. Boden,* R. B. Wylie, and V. J. Spera*

ESB Incorporated, Research Center, Yardley, Pennsylvania 19067

ABSTRACT

The electrode potential of zinc amalgams has been measured in potassium hydroxide solutions containing dissolved zincate. Curvature in the Nernst plots was observed at high zincate concentrations in agreement with the results of other workers. The curvature is explained as being due to the dependence of the hydroxyl and zincate ion activity on concentration in strong potassium hydroxide solutions. The data yield a value of −1.205V (*vs.* SHE) for the standard potential of the zinc, zincate ion electrode (I.U.P.A.C.—Stockholm convention) and −205.86 kcal for the free energy of formation of the zincate ion at 25°C.

The potential of the zinc electrode in alkaline solutions has been studied previously but there is still no general agreement as to the nature of the ionic species to which the electrode is reversible.

Bodländer (1) and Kunschert (2) measured the electrode potential of cells containing solutions of zinc in sodium hydroxide. Their data were interpreted to show that the zinc existed as the $Zn(OH)_4^{2-}$ ion in strongly alkaline solutions. Later, Dirkse (3) reported measurements on cells of the type

$$Zn(s)/KOH + ZnO/KOH, H_2, Pt \qquad [A]$$

It was concluded that the species existing in solution was the $Zn(OH)_4^{2-}$ ion and that water participated in the reaction to form an aquotetrahydroxy zincate ion. This conclusion was based on the observation that plots of E *vs.* log $a(OH^-)$ at constant zinc concentration showed curvature at high hydroxyl ion concentrations. Recently, Hampson, Herdman, and Taylor (4) studied the zinc amalgam electrode in KOH solutions containing zincate ion and confirmed the curvature in the logarithmic plots reported by Dirkse. They found that the curvature could be reduced by allowing for the participation of two to four water molecules in the reaction but, even then, a completely linear relationship was not obtained. It was suggested that the electroactive zinc species in solution was the six coordinated diaquotetrahydroxy zincate ion. It was also found that the electrode potential was insensitive to the zincate ion concentration from 0.2 to 1.0*M* (molar), the highest concentration studied. This led them to propose that, at high zincate concentrations, the zinc species becomes $[ZnO_2aq]^{2-}$.

Raman and infrared spectral studies (5) of solutions of zinc oxide in potassium hydroxide indicate that the predominant species is $Zn(OH)_4^{2-}$ in agreement with studies using proton magnetic resonance (6). However, Okinada (7) and Jost (8) do not rule out the presence of $Zn(OH)_3^-$ in dilute solutions.

In this work, the electrode potential of zinc amalgam electrodes has been measured as a function of the hydroxyl ion and zincate ion concentrations.

An attempt has been made to relate the potential dependence to the change in activity of the electroactive species as the concentration is changed.

Theory

When zinc oxide is dissolved in KOH solution, it is possible for the following solute species to be present: Zn^{++}, $Zn(OH)^+$, $Zn(OH)_2$, $Zn(OH)_3^-$, $Zn(OH)_4^=$ ----- $Zn(OH)_n^{(n-2)-}$.

These are formed according to the general equation

$$Zn^{++} + n\,OH^- = Zn(OH)_n^{(n-2)-} \qquad [1a]$$

$$\beta_n = [Zn(OH)_n^{(n-2)-}]/[Zn^{++}][OH^-]^n \qquad [1b]$$

Assuming that no complexes higher than $Zn(OH)_4^=$ are present, the mass balances are given by ($N = 4$)

$$C(Zn) \Big| = \sum_{n=0}^{N} \beta_n [Zn^{++}][OH^-]^n \qquad [2]$$

and

$$C(OH^-) \Big| = [OH^-] + \sum_{n=0}^{N} n\,\beta_n [Zn^{++}][OH^-]^n \qquad [3]$$

where $C(Zn)$ and $C(OH^-)$ are the analytical concentrations of zinc and hydroxyl ion, respectively, and $[OH^-]$ is the equilibrium concentration.

The equilibrium constants for zinc hydroxy complex formation are not known at high ionic strengths; therefore, the concentrations of the various zinc species cannot be calculated with a high degree of certainty. Approximate values can be obtained, however, by use of stepwise complex formation equilibrium constants at zero ionic strength. Butler (9) gives the constants for the stepwise complex formation equilibria of zinc hydroxy complexes

$$[Zn(OH)^+]/[Zn^{++}][OH^-] \qquad K_1 = 10^{4.15} \qquad [4]$$

$$[Zn(OH)_2]/[Zn(OH)^+][OH^-] \qquad K_2 = 10^{6.0} \qquad [5]$$

$$[Zn(OH)_3^-]/[Zn(OH)_2][OH^-] \qquad K_3 = 10^{4.1} \qquad [6]$$

$$[Zn(OH)_4^=]/[Zn(OH)_3^-][OH^-] \qquad K_4 = 10^{1.26} \qquad [7]$$

Therefore, the cumulative complex formation constants have the values $\beta_1 = 10^{4.15}$, $\beta_2 = 10^{10.15}$, $\beta_3 = 10^{14.25}$, $\beta_4 = 10^{15.51}$.

Assume, as a first approximation, that only OH^-, $Zn(OH)_3^-$, and $Zn(OH)_4^=$ are present to any appreciable extent; then

$$C(Zn) = \beta_3[Zn^{++}][OH^-]^3 + \beta_4[Zn^{++}][OH^-]^4 \qquad [8]$$

$$C(OH^-) = [OH^-] + 3\beta_3[Zn^{++}][OH^-]^3 + 4\beta_4[Zn^{++}][OH^-]^4 \qquad [9]$$

Since, in general, the concentration of $Zn(OH)_3^-$ is small compared to the concentration of $Zn(OH)_4^=$ and since the $[OH^-]$ is much larger than the concentration of zinc, Eq. [9] can be approximated by

$$C(OH^-) = [OH^-] + 4C(Zn) \qquad [10]$$

The solubility of zinc oxide in KOH has been deter-

* Electrochemical Society Active Member.

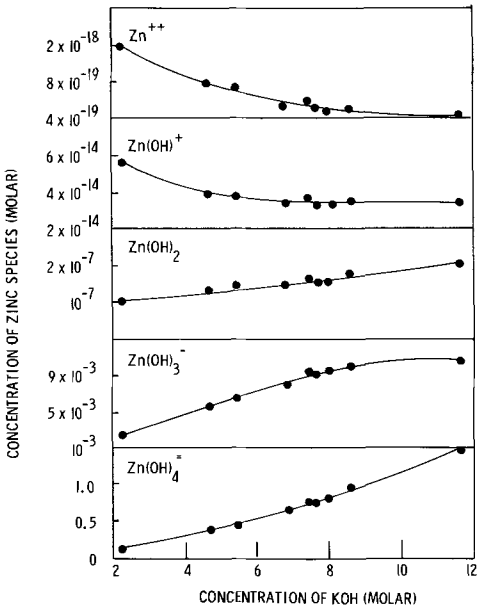

Fig. 1. Plot showing variation in concentration of various zinc hydroxy species in KOH solutions saturated with zincate.

mined (10, 11) and, therefore, it is possible to solve Eq. [8] and [10] and, by use of the mass action equilibria, obtain the concentrations of the various zinc hydroxy complexes as a function of the KOH concentration. The results are shown in Fig. 1. The only zinc species present to any appreciable extent is the $Zn(OH)_4^=$ ion. Therefore, even though the above calculations are only approximate, it was assumed that only $Zn(OH)_4^=$ is present.

In a cell of the type

$$Hg,HgO/KOH(a_1)//KOH(a_2),Zn(OH)_4^=/Zn(Hg) \quad [B]$$

the emf is given by

$$E = E^\circ(Zn) - E^\circ(HgO,Hg) - (RT/2\mathbf{F}) \ln \frac{a^4(OH^-)_2 \cdot a(Zn)}{a(Zn(OH)_4^=)} + (RT/2\mathbf{F}) \ln a^2(OH^-)_1 \quad [11]$$

Since the activity of the zinc in the amalgam and of the hydroxyl ion in the reference compartment remained constant during the experiment, Eq. [11] can be written as

$$E = E^{\circ *}(Zn) - (RT/2\mathbf{F}) \ln \left(a^4(OH^-)_2 / a\left(Zn(OH)_4^=\right) \right) \quad [12]$$

where

$$E^{\circ *}(Zn) = E^\circ(Zn) - E^\circ(HgO,Hg) - (RT/2\mathbf{F}) \ln a(Zn) + (RT/\mathbf{F}) \ln (OH^-)_1 \quad [13]$$

Therefore, a plot E *vs.* $\log \left(a^4(OH^-)_2 / a\left(Zn(OH)_4^=\right) \right)$ should be a straight line wtih a slope of 0.0295V and an intercept which can be used to obtain $E^\circ(Zn)$, provided that the activity of hydroxyl ion in the reference compartment and the activity of zinc in the amalgam are known.

Since the activity coefficients of zincate ion and hydroxyl ion in the presence of each other are not known, these were calculated from the Davies (12) equation. This equation which has the form

$$-\log \gamma_\pm = Az^+z^-[I^{1/2}/(1 + I^{1/2}) - BI] \quad [14]$$

has been successful in predicting the activity coefficients of a number of electrolytes up to fairly high concentrations. Here, A is the usual Debye-Hückel coefficient, 0.509, in aqueous solutions. I is the ionic strength, expressed in moles per liter of solution. Although this equation does not have a sound theoretical

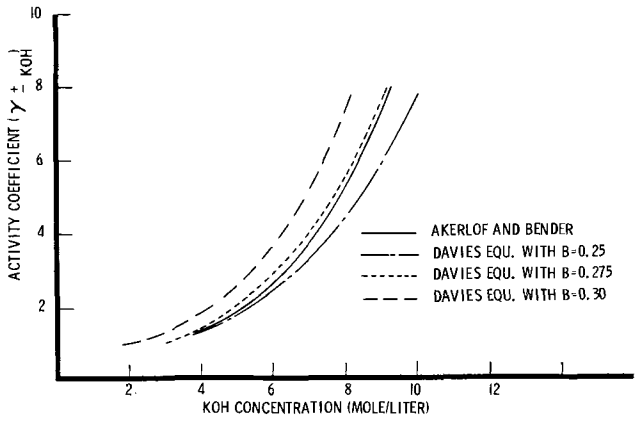

Fig. 2. Activity coefficients of concentrated KOH solutions calculated from the Davies equation with various values for *B* compared to the experimental values of Akerlof and Bender.

basis, it has been applied to a large number of electrolytes with good success. It has not been applied, however, to solutions having concentrations as high as those used in the present work. To gain some insight into the effectiveness of the equation in predicting the activity coefficients of concentrated KOH solutions, calculated activity coefficients have been compared to those determined experimentally by Akerlof and Bender (13). The results are shown in Fig. 2. In the concentration range of interest in this work, *i.e.* around 7.0M, the data of Akerlof and Bender are fitted quite well by the Davies equation with B = 0.275. It was therefore thought permissible to use this equation in calculating activity coefficients of zincate solutions in this range of ionic strengths.

Experimental

Materials.—The potassium hydroxide solutions were prepared by dissolving Fisher "Certified" reagent-grade pellets of KOH in twice-distilled water. A stock solution of 7.03M (moles KOH per liter of solution) was used for all the experiments. The zincate solution was prepared by saturating a KOH solution with zinc oxide (Baker Analyzed Reagent) so that the final concentration of free hydroxyl ion was 7.03M calculated by means of Eq. [10].

A 1% zinc amalgam was prepared by electrodeposition from a saturated zincate solution into triple-distilled, instrument-grade mercury.

Method.—The experiment was carried out in the cell shown in Fig. 3. The working electrode was 1% zinc amalgam which was placed in the working compartment of the cell. Solid zinc was not used because trouble was encountered with fluctuations in the electrode potential, caused apparently by the hydrogen generated as a result of the zinc dissolving.

The working compartment, salt bridge, and reference compartment were filled with 7.03M KOH solution and the zincate concentration was varied by adding a solution of 7.03M free KOH and 1.28M zincate from a burette. In this way, the concentration of KOH was kept constant during the experiment and only the zincate concentration was varied. The liquid junction potential due to the zincate was judged to be very small and was neglected. The reference electrode was Hg/HgO/7.03M KOH in water.

The measurements were made to ±0.01 mV using a Rubicon precision potentiometer. The test cell was immersed in a constant temperature bath controlled at 25° ± 0.1°C.

Results and Discussion

The results of a typical experiment are shown in Table I. In Fig. 4 the emf is plotted *vs.* the logarithm of the zincate ion concentration. At low concentrations, the graph is linear with a slope of 0.0275V. At higher concentrations, however, the plot shows con-

siderable curvature and eventually passes through a minimum. This curvature has been observed previously by Dirkse (3) and by Hampson *et al.* (4) although no minimum has been reported. It seems unlikely that the curvature in the data is caused by the presence of other hydroxy complexes apart from $Zn(OH)_4^=$ since their concentration is probably negligible. The curvature could be attributable to the participation of water in the reaction as proposed by Dirkse (3) or it could also be a consequence of the behavior of the activity coefficients of zincate and hydroxyl ion in the solution studied.

In making a plot of the emf *vs.* the logarithm of the concentration, a number of assumptions are made: first, that the activities in Eq. [12] can be replaced by concentrations and, second, that the activity of the hydroxyl ion in the working electrode compartment is constant. The first of these assumptions is probably not too bad at low zincate concentrations but it cannot be expected to hold over the entire concentration range studied. It is also incorrect to assume that the activity of the hydroxyl ion is constant, since, as the zincate is added, the ionic strength will change even though the hydroxyl ion concentration remains constant.

Activities calculated from concentrations *via* the Davies equation, Eq. [14], with $A = 0.509$ and $B = 0.275$. For zincate ion, the activity coefficient calculated from the Davies equation is that for the salt $K_2Zn(OH)_4$.

In order to determine whether the curvature results from the concentration dependence of the OH^- and $Zn(OH)_4^=$ ions, one would require the activities of zincate and hydroxyl ion in the presence of each other and, unfortunately, these have not been determined. Therefore, it was decided to attempt to calculate the activity coefficients by use of the Davies equation which, as has been shown earlier, gives fairly good agreement with experimental data for KOH alone with $B = 0.275$. This equation was used to calculate the activity coefficients of the hydroxyl and zincate ions [*i.e.*, of KOH and $K_2Zn(OH_4)$] from which the activities could readily be obtained. The calculated activities are shown in Table I and a plot of E *vs.* $\log a^4(OH^-)/a(Zn(OH)_4^=)$ is shown in Fig. 5. It can be seen that a straight line is obtained over the entire concentration range studied, giving an intercept of −1.207V and a slope of 0.030V. Furthermore, it can be seen from the activity values in Table I that the variation of $\log a^4(OH^-)/a(Zn(OH)_4^=)$ with concentration, passes through a minimum at 0.5680M in zincate concentration. That the electrode potential also passes through a minimum at this concentration gives additional confirmation that the activities calculated from the Davies equation are reasonably accurate. The intercept of −1.207V gives $E°$ for an electrode at unit activity of OH^- and zincate ions, referred to the Hg/HgO/7.03M KOH reference electrode. This intercept is $E°*(Zn)$ in Eq. [12].

Using the value $E°(HgO,Hg)$ given by Latimer (15), the data of Akerlof and Bender (13) for the activity of the hydroxyl ion in the reference compartment, and those of Walls and Upthegrove (14) for the activity of zinc in the amalgam, $E°(Zn)$ was calculated to be −1.205V from Eq. [13], referred to the SHE. This value is somewhat more positive (*i.e.*, more noble) than the values of −1.211 reported by Dirkse (3) and −1.216 reported by Latimer (15). Dirkse (16) has suggested that, in 7M KOH, the partial molal free energy of H_2O is about 0.2 kcal lower than in dilute solutions and that this would result in a shift in the reference electrode potential, making it about 6 mV more negative. If this correction is applied, our value

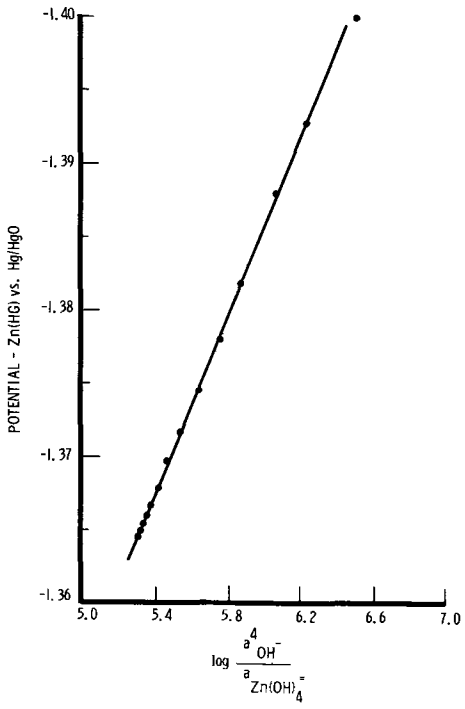

Fig. 5. Potential of zinc amalgam electrode as a function of log $a^4(OH^-)/a(Zn(OH)_4^=)$. The activity coefficients were calculated with the aid of the Davies equation with $B = 0.275$. Supporting electrolyte 7.03M KOH. Reference electrode: Hg/HgO/7.03M KOH.

of −1.205V is made to coincide exactly with Dirkse's.

The free energy of formation of the zincate ion is found to be −205.86 kcal. Previous values include −206.2 (Dirkse) and −206.41 (Latimer).

When the calculated activities are used in conjunction with the experimentally determined value of $E°$ to calculate the electrode potential as a function of the zincate ion concentration, the calculated points shown in Fig. 4 are obtained. The agreement between the experimental and calculated curves is generally within 1 mV over the whole concentration range studied. Thus, the curvature in the plot of the electrode potential *vs.* the log of the zincate ion concentration can be explained in terms of the variation in the activities of the hydroxyl and zincate ions with concentration. As was shown by Hampson *et al.* (4), the curvature in log plots of this type cannot be entirely explained by taking account of the participation of water in the electrode reaction as was suggested by Dirkse (3). It appears, therefore, that the behavior of the zinc amalgam electrode can be more adequately explained in terms of the values of the activities of the ions to which the electrode is reversible.

ABSTRACT

Electromotive force measurements were made of cells of the type Pt/H_2(g, 1 atm)/HCl(m), glycerol(X), H_2O(Y)/AgCl-Ag where X = 20, 40, 70, and 90 w/o (weight per cent) glycerol at 5°, 15°, 25°, 35°, and 45°C and also in 10 w/o glycerol at 25°C. The cell has been used to calculate, (*a*) the standard emf, (*b*) the mean molal activity coefficients of HCl, (c) the primary medium effect, (*d*) the relative partial molal enthalpy, and (*e*) the standard thermodynamic functions ($\Delta G°_t$, $\Delta S°_t$, and $\Delta H°_t$) for the transfer of HCl from the aqueous standard state to the standard state in the respective mixed solvents. The electrostatic part of the total free energy, entropy, and enthalpy of transfer has been computed using Born's model. The nonelectrostatic contribution (the chemical effect) of the thermodynamic quantities has been evaluated by subtracting the electrostatic contributions from the total values. The values of $E°_m$ obtained by a theoretically justified polynomial curve fitting technique have been expressed as a function of temperature. The significance of these results in relation to the acid-base behavior and the breakdown of the structure of water is discussed.

The properties of dilute strong electrolytes in mixed solvents have long been of interest. Standard potentials of the silver-silver chloride electrode in dipolar aprotic solvents such as tetrahydrofuran-water (1, 2) and in amphiprotic solvents like isopropanol-water (3) have been useful in the investigation of chemical equilibria. In the present work, the binary mixtures of water + glycerol were chosen, because these mixtures are often used as solvents in studies of ionization constants (4) and acid-base properties of compounds slightly soluble in water.

The emf measurements on hydrochloric acid solutions in 50 w/o (weight per cent) glycerol in the temperature range 0°-90°C have been reported earlier (5). The solvent mixtures containing 10 and 30 w/o glycerol were studied by Knight *et al.* (6), through the temperature range 0-40°C. Lucasse (7) also studied the same cell in 3.06 and 21.2 w/o glycerol at 25°C, but none of these investigators provided data for the associated thermodynamic quantities.

In the present work, measurements of the emf of the cell

$$Pt/H_2(g.\ 1\ atm)/HCl(m),\ glycerol(X),\ H_2O(Y)/AgCl\text{-}Ag \quad [A]$$

were made from 5° to 45°C at intervals of 10°C in several glycerol-water mixtures (X = 20, 40, 70, and 90 w/o) and also in 10 w/o glycerol at 25°C with the concentration range 0.005 to 0.2 molal hydrochloric acid. The present paper reports our results on the thermodynamic properties of dilute hydrochloric acid solutions. As is demonstrated below, the values of the standard electrode potential, the activity coefficient, primary medium effect, and the related thermodynamic quantities provide useful insights with regard to the acid-base behavior and the changes in structural aspects of the solvents.

Experimental

Glycerol (Fisher certified ACS) was used without further purification, after the preliminary measurements had shown that the difference in emf for solutions made with purified glycerol (8) and for solutions made from untreated glycerol was no greater than the experimental error (±0.1 mV). The stock solution of hydrochloric acid was prepared from a twice-distilled sample of the acid. The specific conductance of the water used in the preparation of the solutions was less than 0.7×10^{-6} mho/cm. The solvent mixtures of various percentages were made by weight. All solutions were freshly prepared before taking measurements. All concentrations are accurate to within ±0.02%.

The general experimental procedures employed in the present work were the same as those described previously (2). The silver-silver chloride electrodes were of thermal electrolytic type (9).

Measurements were made at 5°, 15°, 25°, 35°, and 45°C by means of a K-3 Universal Type Potentiometer. An Eppley standard cell having low temperature coefficient and the mirror-type galvanometer having a sensitivity of ±0.02 mV per division was used in conjunction with the potentiometer. The water bath in which the cells were immersed was regulated within ±0.01°C. The cell was constructed so as to permit the use of two Ag-AgCl electrodes and two hydrogen electrodes. The equilibrium was reached in 3-4 hr after the initiation of hydrogen bubbling. The criterion for equilibrium was a stable reading within ±0.1 mV over a period of about 1 hr. The emf at 25°C was recorded three times, namely at the start, middle, and end of the temperature run. The individual readings for the same solution, at 25°C, agreed within ±0.08 mV, and the average is given in Table I.

Total vapor pressures (p) of the solvents at the respective temperatures were obtained from data of Carr, Townsend, and Badger (10), and by the method of extrapolation and interpolation, which utilized the straight-line plots of log p as a function of $1/T$, where T is in Kelvin. The dielectric constants, D, of the solvent mixtures used for the calculation of the electrostatic free energy were derived from the data of Åkerlöf (11).

Key words: activity coefficient, glycerol, mixed solvent, thermodynamics, standard emf, medium effect.

Results

Standard electrode potentials.—Evaluation of the standard potential of the reversible cell reaction is the primary step in the computation of the thermodynamic quantities. The commonly used linear graphical extrapolation technique for the evaluation of the standard potentials, using the Gronwall, LaMer, and Sandved (12) extension of the Debye-Hückel theory involves data such as the density and dielectric constants of the mixed solvents, an appropriate estimate of the ion-size parameter for the linear plot (13), and the Debye-Hückel constants, whereas this information is not necessary when the extrapolation of emf data is made by a theoretically justified polynomial curve fitting technique as demonstrated below.

The emf of the cell studied is expressed by the Nernst equation

$$E + (2RT/\mathbf{F}) \ln m = E^\circ - (2RT/\mathbf{F}) \ln \gamma_\pm \quad [1]$$

For electrolytes of symmetrical valence types, the extended equation for ln $f_\pm$ is given by the equation (12, 14)

$$\ln f_\pm = -\frac{\epsilon^2 z^2}{kTDa}\,\frac{.1.}{2}\,\frac{x}{1+x} + \sum_{m=1}^{\infty}\left[\frac{\epsilon^2 z^2}{kTDa}\right]^{2m+1}\left[\frac{1}{2}X_{2m+1}(x) - 2mY_{2m+1}(x)\right] \quad [2]$$

where D is the dielectric constant of the solvent, T is in Kelvin, $x = \zeta a$ and $\zeta^2 = 8\pi N\epsilon^2 z^2 c/10^3 kTD$, N is Avogadro's number, k is the Boltzmann constant, ϵz is the charge on the ions, c is the molar concentration, and a the ion-size parameter. In the case of symmetrical valence type electrolytes, the even order terms vanish, and the contribution of the terms $X_{2m+1}(x)$ and $Y_{2m+1}(x)$ have been evaluated by Gronwall, LaMer, and Sandved (12) up to the fifth order. After appropriate expansions, integrations, and some tedious algebraic manipulations, Eq. [2] can be expressed as (15)

$$\ln f_\pm = A_1''x + A_2''x^2 + A_3''x^3 + \ldots \quad [3]$$

The use of the molality scale changes the molar activity coefficient by some constant value and Eq. [3] is rewritten as

$$\ln \gamma_\pm = A_1'm^{1/2} + A_2'm + A_3'm^{3/2} + \ldots \quad [4]$$

where the first term on the right hand side of Eq. [4] represents the Debye-Hückel limiting law. Substitution of Eq. [4] into Eq. [1] yields

$$E + (2RT/\mathbf{F}) \ln m = E^\circ + A_1m^{1/2} + A_2m + A_3m^{3/2} + \ldots \quad [5]$$

If a good set of experimental data is available, the coefficients E°, A_1, *etc.*, can be evaluated by means of a polynomial curve fitting program of the form

$$y = A_0 + A_1X + A_2X^2 + A_3X^3 + \ldots \quad [6]$$

Equations [5] and [6] are of identical form. Hence, such a method is theoretically sound and yields excellent results as was shown in our earlier paper (16) by comparison of E°_m data with those obtained from the best linear extrapolations for various solvent systems. The theoretical validity of Eq. [5] has been further corroborated by Dill *et al.* (17, 18).

The observed potentials for the cell, corrected to a hydrogen fugacity of 1 atm, are presented in Table I. Each value in the table indicates the mean value from three or four replicate cells. The lowest and highest values for replicate cells did not differ by more than 0.12 mV.

Table II gives the values of the standard potentials on the molality (m) and mole fraction (N) scales in glycerol-water mixtures. The standard cell potentials for water-glycerol (X weight per cent) solvent mixtures were found to fit the equations given below, together with the equation for water as the solvent (13)

[a] From the present study.
[b] From ref. (6).

$$E^\circ_m(X = 0) = 0.2224 - 6.396 \times 10^{-4}\,(t - 25) - 3.18 \times 10^{-6}\,(t - 25)^2 \quad [7]$$

$$E^\circ_m(X = 20) = 0.2090 - 7.300 \times 10^{-4}\,(t - 25) - 5.00 \times 10^{-6}\,(t - 25)^2 \quad [8]$$

$$E^\circ_m(X = 40) = 0.1900 - 8.010 \times 10^{-4}\,(t - 25) - 0.93 \times 10^{-6}\,(t - 25)^2 \quad [9]$$

$$E^\circ_m(X = 70) = 0.1490 - 9.999 \times 10^{-4}\,(t - 25) - 5.71 \times 10^{-6}\,(t - 25)^2 \quad [10]$$

$$E^\circ_m(X = 90) = 0.0947 - 10.526 \times 10^{-4}\,(t - 25) - 10.63 \times 10^{-6}\,(t - 25)^2 \quad [11]$$

The standard potentials on the mole fraction scale have been calculated with the equation

$$E^\circ_N = E^\circ_m - (2RT \ln 10/\mathbf{F}) \log_{10} (1000/M_{xy}) \quad [12]$$

where M_{xy} is the mean molecular weight of the solvent and is listed in Table II.

The stoichiometric mean activity coefficients of hydrochloric acid, $\gamma_\pm$, at round molalities were calculated from the following equation

$$\log_{10} \gamma_\pm = [E^\circ_m - \{E + (2RT/\mathbf{F}) \ln m\}]/(4.6052RT/\mathbf{F}) \quad [13]$$

using the values of E°_m given in Table II. The values of $\{E + (2RT/\mathbf{F}) \ln m\}$ at round molalities were obtained from Eq. [5]. The term $\gamma_\pm$ measures the difference in the "nonideal" part of the chemical potential of the HCl acid at finite concentration and at infinite dilution of the mixed solvent.

The primary medium effect is a measure of the energy involved in the transfer of HCl from infinite dilution in one solvent to infinite dilution in another solvent. This effect ($\log {}^s_w\gamma^\circ_\pm$(HCl)) of glycerol-water mixtures was computed by the equation

$$ {}^wE^\circ_m - {}^sE^\circ_m = \lim_{m \to 0} (4.6052RT/\mathbf{F}) \log_{10} {}^s_w\gamma_\pm \quad [14]$$

and the values are tabulated in Table III. The superscript, s, on the mean activity coefficient, $\gamma_\pm$, indicates that the measurements are carried out in a mixed solvent; whereas, the subscripts, w and s mean that $\gamma_\pm$ is measured relative to unit value at infinite dilution in water and in a mixed solvent, respectively. The limiting value ${}^s_w\gamma^\circ_\pm$ represents the activity coefficient of hydrochloric acid at infinite dilution in a mixed solvent (s) referred to unity at infinite dilution in water.

Relative partial molal quantities.—For each round molality in the respective media, $\log_{10} \gamma_\pm$ was fitted to a power series of the form

$$-\log_{10} \gamma_\pm = a + bT + cT^2 \quad [15]$$

where T is in Kelvin. The values of the relative partial molal enthalpy, $\bar{L}_2 = \bar{H}_2 - H_2^\circ$, of hydrochloric acid was evaluated by the equation

$$\bar{L}_2 = (-4.6052RT^2)\, d(\log_{10} \gamma_\pm)/dT \quad [16]$$

which after proper substitution of the constants of Eq. [15] yields

The values of $\bar{L}_2$ are shown in Table IV.

Thermodynamic quantities.—The standard thermodynamic quantities (ΔG°_t, ΔS°_t, and ΔH°_t) for the transfer process (t)

HCl (in H_2O) → HCl (in various glycerol-water media)

can be obtained from the standard emf of the cell in water and in the respective glycerol-water mixtures and the variation of E°_m with temperature together with Eq. [12] for E°_N. The use of the mole fraction scale eliminates the energy changes due to concentration changes.

For the transfer process, we can now calculate the thermodynamic functions by applying the customary thermodynamic relations to Eq. [8-11] in combination with Eq. [12]

$$\Delta G^\circ_t = \mathbf{F}({}^wE^\circ_N - {}^sE^\circ_N) \quad [18]$$

$$\Delta S^\circ_t = -\,d(\Delta G^\circ_t)/dT \quad [19]$$

and

$$\Delta H^\circ_t = \Delta G^\circ_t + T\Delta S^\circ_t \quad [20]$$

The values of these quantities are given in Table V.

For HCl, the protolytic reaction involves the transfer of protons from water to another amphiprotic solvent (SH)

$$H_3O^+ + SH \rightleftarrows SH_2^+ + H_2O$$

This reaction depends not only on the specific chemical interactions (nonelectrostatic effect or acid-base properties), but also depends on the change of the dielectric constant of the medium (electrostatic effect). The chemical interactions involve the destruction of one type of solvation shell and the creation of another (20). Thus, the related thermodynamic quantities comprise two parts: electrostatic (el) and chemical or nonelectrostatic (non). For the change of the free

Table V. Standard thermodynamic quantities[a] accompanying the transfer of HCl from water to glycerol-water mixtures

[a] ΔG° and ΔH° are in (cal/mole) and ΔS° in (cal/°K-mole).

energy of transfer

$$\Delta G^\circ_t = \Delta G^\circ_{t,el} + \Delta G^\circ_{t,non} \quad [21]$$

and similar equations exist for the other thermodynamic functions, ΔS°_t and ΔH°_t. The contribution to the electrostatic part of the free energy change can be calculated from the well-known Born equation

$$\Delta G^\circ_{t,el} = \{Ne^2/2\}\{1/D_s - 1/D_w\}\{1/r_+ + 1/r_-\} \quad [22]$$

where r_+ is the radius of the "solvated hydrogen ion" and is arbitrarily taken as 2.76Å (21) for all of the mixed solvents, and r_- is the radius of the chloride ion taken as 1.81Å (22). The values of $\Delta G^\circ_{t,non}$ have been obtained by the difference between ΔG°_t and $\Delta G^\circ_{t,el}$. All these data are shown in Table V.

The electrostatic contribution of the entropy change can be evaluated by differentiating Eq. [22] with respect to temperature and subsequent substitution of the resulting equation into the empirical equation (23)

$$D = D_0 e^{-T/\theta} \quad [23]$$

gives

$$\Delta S^\circ_{t,el} = (-Ne^2/2)(1/D_s\theta_s - 1/D_w\theta_w)(1/r_+ + 1/r_-) \quad [24]$$

In Eq. [23], D is the dielectric constant at temperature T, and D_0 and θ are the constants characteristic of the medium. To use Eq. [24], the values of $1/\theta_s$ and $1/\theta_w$ can be obtained by differentiating Eq. [23]

$$d(\ln D)/dT = -1/\theta \quad [25]$$

Thus, from the slopes of the linear plots of log D *vs.* T for the respective glycerol-water media, the following values of θ were calculated

w/o glycerol	0	20	40	70	90
θ	220	208	203	197	203

The chemical or nonelectrostatic contribution of the entropy of transfer, $\Delta S^\circ_{t,non}$, can then be obtained by subtracting $\Delta S^\circ_{t,el}$ from ΔS°_t. All these computed values are given in Table V.

From a knowledge of $\Delta G^\circ_{t,el}$ and $\Delta S^\circ_{t,el}$, the electrostatic part of the enthalpy change, $\Delta H^\circ_{t,el}$, has been evaluated and hence the nonelectrostatic part of the quantity, $\Delta H^\circ_{t,non}$, has also been obtained. The values so calculated at 25°C are presented in Table V.

Discussion

A direct comparison of the value of E°_m for $X = 10$ was made with that of ref. (6). Our value (at 25°C) of E°_m determined by the polynomial curve fitting technique is equal to 0.2166V compared to 0.2165V by Knight *et al.* The agreement is excellent.

The values of the activity coefficient for $X = 40$ and 90 at all experimental temperatures are given in Table VI. In a given system and at a given temperature the increase in the value of the mean activity coefficient corresponds to the decrease in the molality

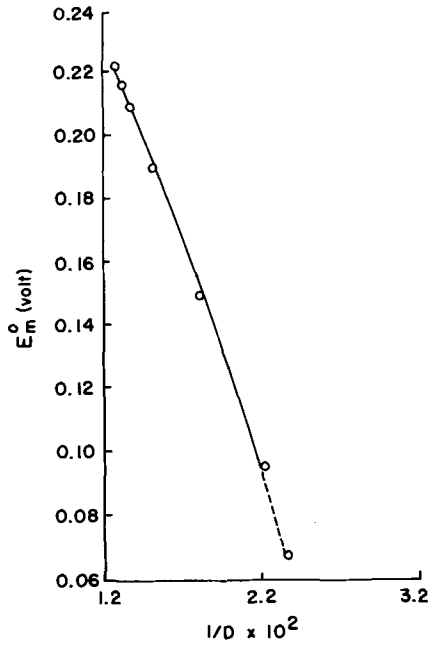

Fig. 1. Plots of the standard potential (E°_m) *vs.* $1/D$ at 25°C

of hydrochloric acid. As expected from Debye-Hückel theory, the value of $\gamma_\pm$ at a given molality decreases with increasing proportions of glycerol, because the dielectric constant of the medium is lowered. An average uncertainty of ±0.08 mV in emf values corresponds to an error of 0.003 in the values of $\gamma_\pm$.

It is evident from Table III that the primary medium effect (ion-solvent interaction) of glycerol-water mixtures on hydrochloric acid becomes greater as the concentration of glycerol is gradually increased. This also expresses the well-known fact that the escaping tendency of HCl is greater in glycerol-water mixtures than in the pure aqueous solutions.

It is interesting to see how the values of E°_m change with the dielectric constant of the media. The Born equation predicts that the plot of E°_m *vs.* $1/D$ should be linear. In Fig. 1, it is rather remarkable that the predictions of the Born equation are qualitatively correct. The dashed line represents the slight curvature for 95 w/o glycerol (24). It should be mentioned, however, that the Gibbs energy calculations based on the Born model may be acceptable, but the uncertainties in the computed values of the entropy and enthalpy are greater, mainly because of the arbitrary choice in the ionic radii and the dielectric constant of the medium. Hepler's equation (25), which takes into account the dielectric saturation in the ionic force field, may be better, but still the uncertainty factor in the radius of the solvated proton would remain. The values of ΔG°_t are presumably correct within ±8 cal.

It is evident from Table V that the transfer Gibbs energy appears to be positive for all solvent compositions in the glycerol-water systems, while the chemical part of the free energy change, $\Delta G^\circ_{t,non}$, is negative up to $X = 70$. The positive value of ΔG°_t indicates that HCl appears to be in a lower Gibbs energy state in water than in glycerol-water mixtures. The fairly uniform negative values of $\Delta G^\circ_{t,non}$, signify that it is favorable for the transfer process from water to glycerol-water mixtures as far as the chemical interaction or solvation is concerned. But, the electrostatic factors are important and predominate over the chemical interaction causing an unfavorable effect in the over-all transfer process. The nonelectrostatic contribution appears to be a solvent parameter which is possibly characterized as a measure of the increase in basicity of the medium as glycerol is added up to a composition of $X = 70$. The positive value of $\Delta G^\circ_{t,non}$ for $X = 90$ does have a real significance. This result shows that water

has a greater chemical affinity for the proton than the mixed solvent if it is assumed tentatively that very little free energy change (due to chemical interaction or solvation) is involved in the transfer of the accompanying chloride ion.

The dissociation behavior of some cation acids in methanol-water mixtures (26, 27) and in ethylene glycol-water mixtures (28), support the above view that as the respective alcohol is added to water, the basicity increases passing through a maximum ($X = 80$). The reason for this apparent anomaly was suggested by Braude and Stern (29) that the addition of alcohol may gradually destroy the water structure, thus the basic centers of the oxygen in water molecules become free for the attachment of incoming protons. This reasoning may apply equally well for glycerol-water media.

Beside the less discriminating free energy changes which are not affected by structural factors, the changes in enthalpy and entropy might offer some limited interpretation of structural changes (30, 31) involved in the over-all process. The values of ΔH^o_t and ΔS^o_t appear to be negative and decrease with the increasing proportion of glycerol up to $X = 70$ and indicate a gradual breakdown of the structure in water (30) with further addition of glycerol to highly polar water molecules. Moreover, the glycerol molecules decrease their rotational freedom in the high electric field of an ion and contract their volume due to electrostriction, giving negative values of entropy. The increasing values of ΔS^o_t (still negative) and ΔH^o_t for $X = 90$ might be due to a number of diverse phenomena. For instance, the order created by HCl in this solvent composition relative to pure water begins to increase (31) as far as the structural effect is concerned. Another factor might involve a proton solvation effect. The basicity falls off past the minimum and glycerol may begin substituting for water causing a serious disturbance in the hydration sphere of the ions (28).

When the electrostatic factors are taken into consideration, the contributions of $\Delta H^o_{t,non}$ and $\Delta S^o_{t,non}$ from the chemical interaction follow a general trend and appear to be negative up to $X = 70$ and then positive for $X = 90$. Further analysis of the results, however, should wait for similar studies in different amphiprotic solvent + water mixtures.

Acknowledgments

The authors thank Professor J. Greene for assistance with computer calculations, Mrs. Margaret Lindquist for assistance with preliminary experiments, and Dr. J. Padron for providing the facility for this experimental work as well as for his comments and criticisms about the manuscript.

Manuscript submitted Sept. 10, 1970; revised manuscript received Mar. 16, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Thermodynamics of the Molten AgCl-RbCl-NaCl System by Electromotive Force Measurements

A. D. Pelton and S. N. Flengas

Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario, Canada

ABSTRACT

Electromotive force measurements have been made using the reversible formation cell

$$\text{Ag} \mid \underset{\text{(liquid)}}{\text{AgCl-RbCl-NaCl}} \mid \text{graphite, } Cl_2$$

Partial molar excess free energies, enthalpies, and excess entropies of mixing of AgCl have been measured over the entire composition range of the AgCl-RbCl-NaCl ternary system. Partial properties of mixing of RbCl and NaCl and integral properties of mixing have been calculated using an analytical solution of the Gibbs-Duhem equation. The partial properties of RbCl and NaCl can be explained on the basis of simple considerations of regular solution behavior. The partial properties of AgCl, however, cannot be explained in this way.

There have been very few systematic studies made of ternary fused salt systems. In no such system are complete free energy, enthalpy, and entropy data simultaneously available.

In a previous publication (1), emf measurements using the cell

$$\text{Ag} \mid \underset{\text{(liquid)}}{\text{AgCl, alkali chloride}} \mid \text{graphite, } Cl_2 \qquad [A]$$

were described. Properties in the AgCl-*A*Cl (where A = Na, K, Rb, or Cs) binary systems were measured. In the present investigation, the formation cell was used to obtain partial molar excess free energies, enthalpies, and excess entropies of mixing of AgCl at several compositions over the entire composition range of the AgCl-RbCl-NaCl ternary system. Above 800°C, one homogeneous liquid phase exists at all compositions in this system.

In the AgCl-NaCl binary system (1), excess free energies, enthalpies, and excess entropies of mixing are all positive. In the AgCl-RbCl system (1), however, all these excess properties are negative. By studying the ternary system, it is possible to see how the properties vary between the two extremes as the ratio of NaCl to RbCl is changed, and so the competing effects of the RbCl and NaCl can be examined.

As is discussed later, if this ternary system is to be studied fully, it is necessary to have "end point" thermodynamic data in the RbCl-NaCl binary system. Enthalpies of mixing are available in this binary system from the calorimetric studies by Hersh and Kleppa (2). The phase diagram of the RbCl-NaCl system has been measured (3), and free energies of mixing have been calculated from the phase diagram with good precision (3). The availability of these "end point" data was one of the considerations in the decision to study the AgCl-RbCl-NaCl system.

Data Treatment

To be able properly to analyze the experimental data in a ternary system, it is essential that a method of applying the Gibbs-Duhem relation must be available so that partial properties of all components and integral properties of mixing can be calculated. In a previous publication (4), an analytical solution of the Gibbs-Duhem equation in ternary systems was developed. It was shown that the analytical method overcomes the many problems inherent in the older graphical Gibbs-Duhem integration techniques. The analytical method has also recently been extended (5) to apply to systems of any number of components.

The composition variables chosen (4) were designated y and t, where

$$y = (1 - X_1) \qquad [1]$$

$$t = X_3/(X_2 + X_3) \qquad [2]$$

where X_1, X_2, and X_3 are the mole fractions of the three components.

In the composition triangle of an isothermal ternary system, t is constant along quasi-binary lines of constant X_3/X_2 ratio. The variable can assume values from $t = 0$ in the 1-2 binary system to $t = 1$ in the 1-3 binary system. The variable y is constant along lines parallel to the 2-3 binary line, and can assume values from $y = 0$ for pure component 1 to $y = 1$ in the 2-3 binary system. This is shown on the ternary composition triangle in Fig. 1.

When the method is applied later to the AgCl-RbCl-NaCl ternary data, component 1 will be AgCl for which the partial molar properties have been measured. Components 2 and 3 will be RbCl and NaCl, respectively.

The partial and integral molar properties of mixing are expressed as power series in y and t as follows

$$f_1 = \sum_{j=2} \sum_{k=0} a_{jk} y^j t^k \qquad [3]$$

$$f_2 = \sum_{j=0} \sum_{k=0} b_{jk} y^j t^k \qquad [4]$$

$$f_3 = \sum_{j=0} \sum_{k=0} c_{jk} y^j t^k \qquad [5]$$

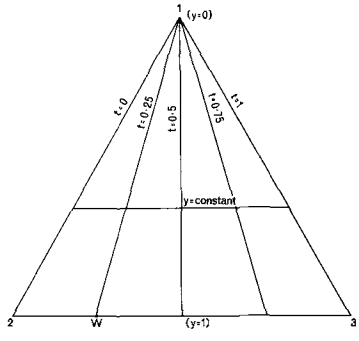

Fig. 1. Quasi-binary lines in a ternary system (in AgCl-RbCl-NaCl system: 1 = AgCl, 2 = RbCl, 3 = NaCl).

Key words: silver chloride, rubidium chloride, sodium chloride, fused salts, molten salts, ternary systems, thermodynamics, emf measurements, formation cell, silver electrode, chlorine electrode.

$$f = \sum_{j=1} \sum_{k=0} \phi_{jk} y^j t^k \quad [6]$$

where f_1, f_2, and f_3 are the partial molar properties of mixing of components 1, 2, and 3, and f is the integral property of mixing. In order that such series expansions can be written for f_1, f_2, f_3, and f, the properties and their derivatives must be continuous and finite functions in and on the boundaries of the entire composition range of the system. Excess properties of mixing will always satisfy these conditions.

Equation [3] may be written in expanded form as

$$f_1 = (a_{20} + a_{21}t + a_{22}t^2 + \ldots)y^2 + (a_{30} + a_{31}t + a_{32}t^2 + \ldots)y^3 + \ldots\ldots\ldots\ldots\ldots \quad [7]$$

Along a line of constant t, each of the bracketed factors in Eq. [7] becomes constant, and f_1 is simply a power series in $y = (1 - X_1)$ starting with the y^2 term, which is the well-known type of expansion first suggested by Margules (6) for binary systems. It is in this sense that the lines of constant t are called "quasi-binary" lines.

The expansion [3] for f_1 starts with the $j = 2$ term. That the missing coefficients a_{0k} are zero for all values of k follows from the condition that $f_1 = 0$ when $y = 0$. That the missing coefficients a_{1k} are all zero follows from the Gibbs-Duhem relation as is discussed shortly. In the expansion [6] for f, the missing coefficients ϕ_{0k} for $j = 0$ must all be zero because of the condition that $f = 0$ when $y = 0$.

Experimental values of f_1 may be fitted by a least-squares technique to an expansion of the form of Eq. [3]. In the present case, the partial molar excess free energies, enthalpies, and excess entropies of mixing of AgCl may be fitted to such an expansion. The coefficients b_{jk}, c_{jk}, and ϕ_{jk} in the expansions [4], [5], and [6] for f_2, f_3, and f may then be calculated from the following relationships which have been derived (4) from the Gibbs-Duhem equation

$$b_{jk} = a_{jk} - \frac{j + 1 - k}{j} a_{(j+1)k} \quad j \geqq 1 \quad [8]$$

$$c_{jk} = a_{jk} - \frac{j + 1 - k}{j} a_{(j+1)k} - \frac{k + 1}{j} a_{(j+1)(k+1)} \quad j \geqq 1 \quad [9]$$

$$a_{jk} = (1 - j)\,\phi_{jk} \quad [10]$$

(For $j = 1$, it may be seen from Eq. [10] that $a_{1k} = 0$ for all values of k, since the coefficients ϕ_{1k} must be finite. This proves the assertion made previously.)

The use of end point data.—From Eq. [8] and [9], the coefficients b_{jk} and c_{jk} of the expansions for f_2 and f_3 may be determined from a knowledge of the coefficients a_{jk} except when $j = 0$. The coefficients b_{0k} and c_{0k} cannot be calculated from the Gibbs-Duhem equation and must be determined from boundary values.

Equation [4] for f_2 may be expanded as follows

$$f_2 = \left(\sum_{k=0} b_{0k} t^k \right) + \sum_{j=1} \sum_{k=0} b_{jk} y^j t^k \quad [11]$$

The undetermined term, $\left(\sum_{k=0} b_{0k} t^k \right)$, is constant along a quasi-binary line where t is constant. The knowledge of one end point value of f_2 along a quasi-binary line is thus sufficient to give values of f_2 at any point on that line.

Consider the specific case in which values of f_2 in the 2-3 binary system are available from independent measurements in this system. (In the present case, partial molar properties of NaCl and RbCl in the RbCl-NaCl system are available as has been mentioned.) Let $f_{2(1,t)}$ be the value of f_2 at some value of t in the 2-3 binary system where $y = 1$. Then

$$f_{2(1,t)} = \left(\sum_{k=0} b_{0k} t^k \right) + \sum_{j=1} \sum_{k=0} b_{jk} t^k \quad [12]$$

Let $f_{2(y,t)}$ be the value of f_2 at any value of y for the same value of t. Substitution of Eq. [12] into Eq. [11] then gives

$$f_{2(y,t)} = f_{2(1,t)} + \sum_{j=1} \sum_{k=0} b_{jk}(y^j - 1)t^k \quad [13]$$

In Fig. 1, then, values of $f_{2(y,t)}$ at any point along the quasi-binary line 1-W are given from a knowledge of the end point value of f_2 at point W.

An equation completely analogous to Eq. [13] may be written for f_3

$$f_{3(y,t)} = f_{3(1,t)} + \sum_{j=1} \sum_{k=0} c_{jk}(y^j - 1)t^k \quad [14]$$

For calculating the integral property f, it may be seen from Eq. [10] that the coefficients ϕ_{jk} may be calculated from a knowledge of the coefficients a_{jk} for all values of j and k except for $j = 1$. The coefficients ϕ_{1k} cannot be determined from the Gibbs-Duhem equation, and end point values of f are required. By a derivation similar to that just given for f_2 and f_3, values of $f_{(y,t)}$ may be shown (4) to be given by the equation

$$f_{(y,t)} = y \cdot f_{(1,t)} + \sum_{j=2} \sum_{k=0} \phi_{jk}(y^j - y)t^k \quad [15]$$

where $f_{(1,t)}$ is an end point value of f in the 2-3 binary system.

If f_2, f_3, and f have been measured in the 2-3 binary system as functions of concentration, then $f_{2(1,t)}$, $f_{3(1,t)}$, and $f_{(1,t)}$ may be written as power series expansions in t (where $t = X_3$ in the 2-3 binary system from the definition [2]). Equations [13], [14], and [15] would then be complete analytical expressions for f_2, f_3, and f in the ternary system.

Experimental

The experimental apparatus and technique have been fully described elsewhere (1). An all-quartz experimental cell was used. The precision of the results obtained in the binary systems (1) was believed attributable in part to the use of a very high resistance "asbestos diaphragm" between the Ag and Cl_2 half cells.

Reagent-grade AgCl and NaCl were used. The RbCl (Matheson) was of 99+% purity. All salts were dried under vacuum and with dry HCl gas at 400°C in the case of AgCl and at 550°C for NaCl and RbCl. All salts were stored in a vacuum desiccator. The silver electrode was of 99.9+% purity. The graphite electrodes were special spectroscopic-grade graphite, pretreated [see ref. (1)] in chlorine gas. The chlorine was Matheson "high-purity" grade.

All readings reported have been corrected to a Cl_2 pressure of 1 std atm (101,325 newton/m^2), and all voltages are given in absolute volts.

Cell temperatures reported here have been shown (1) to have a probable accuracy of ±1°K.

The standard cell potential, $E°$, obtained with pure AgCl electrolyte, was found (1) to be given by the equation

$$E°\,(\text{mV}) = 1227.0 - 1.5973T + 0.182T\ln T - 4.48(10^{-5})T^2 \quad [16]$$

where T is in kelvins, and where the correction for the thermoelectric potential of the Ag-C couple has been applied.

AgCl, RbCl, and NaCl are numbered components 1, 2, and 3, respectively. Thus, $y = (1 - X_{AgCl})$, and $t =$

$X_{NaCl}/(X_{RbCl} + X_{NaCl})$; $t = 0$ in the AgCl-RbCl binary system, and $t = 1$ in the AgCl-NaCl binary system.

Results

Cell potentials, E, were measured with electrolytes at several compositions along quasi-binary lines where $t = 0.25$, $t = 0.50$, and $t = 0.75$. This was done primarily to facilitate presentation of the data. Values of $(E - E°)$ were calculated for each experimental point using Eq. [16] for $E°$. Results are shown in Fig. 2a-c. In all cases, the points were well fitted by straight lines. Least-squares lines are shown in Fig. 2a-c, and the equations of the lines are given in Table I along with the mean and maximum deviations for each line. The values of t for each composition, as in Table I, while not always exactly 0.2500, 0.5000, or 0.7500, differ only insignificantly from these values.

Also given in Table I are the equations of the least-squares lines for $(E - E°)$ *vs.* T obtained (1) at compositions in the AgCl-RbCl ($t = 0$) and AgCl-NaCl ($t = 1$) binary systems.

The partial molar excess free energy of mixing of AgCl at 800°C as well as the partial molar enthalpy and excess entropy of mixing of AgCl as calculated from the fitted curves are listed in Table I for each composition studied (1 cal is defined as 4.1840j). (For the composition at $X_{AgCl} = 0.1043$ in the AgCl-NaCl system, there are only two data points, and it was felt that the slope of this line is not sufficiently well defined for partial enthalpies and excess entropies to be calculated.)

Excess free energies of mixing.—Experimental values of the partial molar excess free energy of mixing of AgCl, $\Delta\bar{G}^E_{AgCl}$, at 800°C are plotted *vs.* X_{AgCl} along the three quasi-binary lines where $t = 0.25$, $t = 0.50$, and $t = 0.75$, as well as along the AgCl-RbCl ($t = 0$) and AgCl-NaCl ($t = 1$) real binary lines in Fig. 3. In Fig. 4 is a similar plot of the parameter $\Delta\bar{G}^E_{AgCl}/y^2$.

The 36 data points were fitted by a 9-coefficient equation of the form of Eq. [3]. The equation is given in Table II. Mean and maximum deviations were 17 and 54 cal. The fitted curves for the five lines of constant t are shown in Fig. 3, and as the solid lines in Fig. 4. It must be remembered when examining the

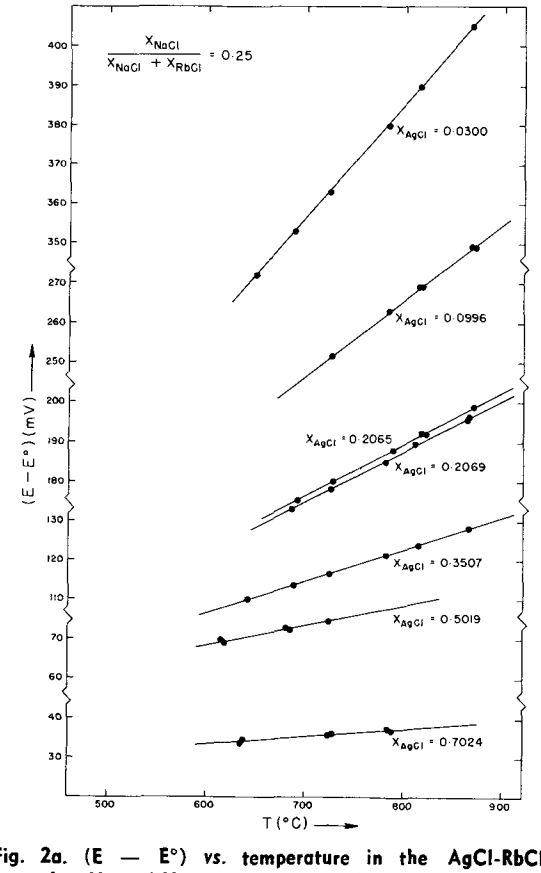

Fig. 2a. $(E - E°)$ *vs.* temperature in the AgCl-RbCl-NaCl system when $X_{NaCl}/(X_{RbCl} + X_{NaCl}) = 0.25$.

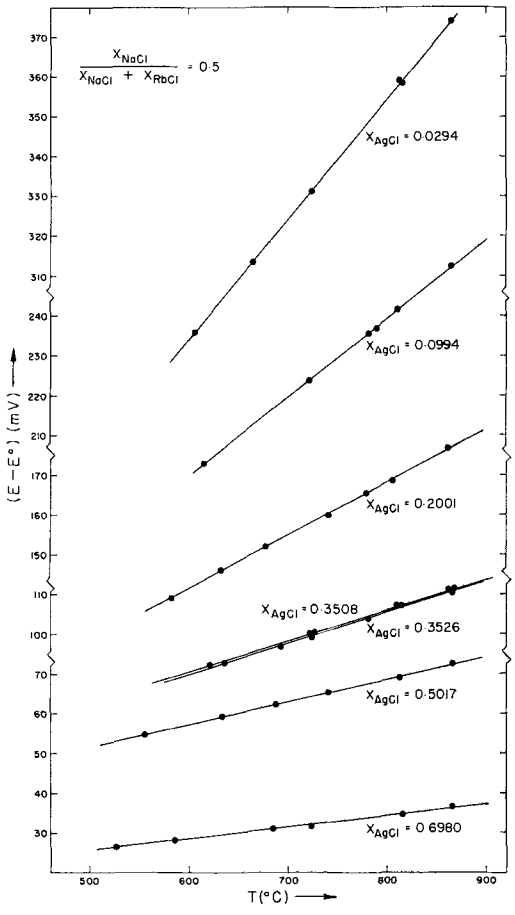

Fig. 2b. $(E - E°)$ *vs.* temperature in the AgCl-RbCl-NaCl system when $X_{NaCl}/(X_{RbCl} + X_{NaCl}) = 0.50$.

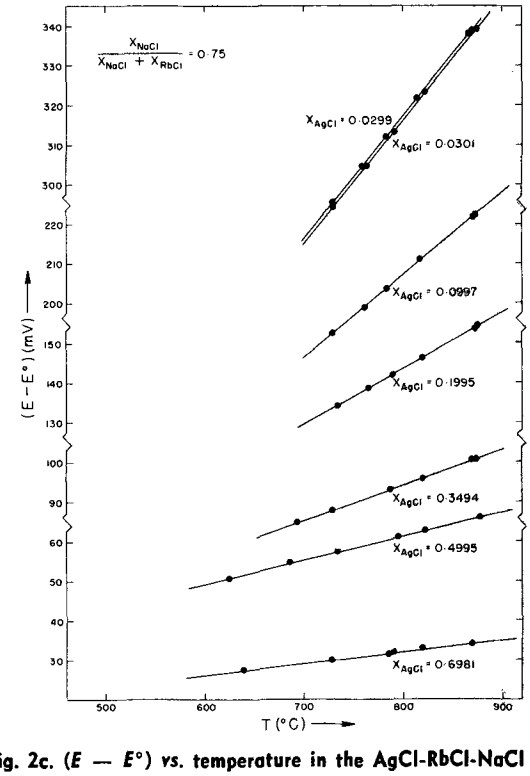

Fig. 2c. $(E - E°)$ *vs.* temperature in the AgCl-RbCl-NaCl system when $X_{NaCl}/(X_{RbCl} + X_{NaCl}) = 0.75$.

(1 cal = 4.1840 j).

plots of $\Delta\bar{G}^E_{AgCl}/y^2$ in Fig. 4 that dividing $\Delta\bar{G}^E_{AgCl}$ by y^2 greatly magnifies the discrepancy between the fitted curve and the experimental points when y is small. When $y = 0.3$, for instance, errors are magnified about 11 times more than when $y = 1$ ($X_{AgCl} = 0$). The least-squares fit is done on the values of $\Delta\bar{G}^E_{AgCl}$, not on the values of $\Delta\bar{G}^E_{AgCl}/y^2$. In Fig. 4, the fitted curves for small values of y (*i.e.*, large values of X_{AgCl}) are shown as broken lines to indicate this uncertainty.

In Fig. 4 are shown, as dashed lines, the curves which would result if $\Delta\bar{G}^E_{AgCl}$ varied linearly (additively) with t, as t varied from 0 to 1 at constant X_{AgCl}. That is, the three dashed lines in Fig. 4 are ¼, ½, and ¾ of the way between the two experimental curves for the binary systems at $t = 0$ and $t = 1$. It is seen that when $X_{AgCl} = 0$, such additive (linear) behavior is very closely followed by the experimental curves, but as the solutions become richer in AgCl there occur progressively larger positive deviations of the experimental curves from this additive behavior.

Enthalpies of mixing.—The experimental values of the partial molar enthalpy of mixing of AgCl, $\Delta\bar{H}_{AgCl}$, are plotted *vs.* X_{AgCl} for the five values of t in Fig. 5. In Fig. 6 are similar plots of the parameter $\Delta\bar{H}_{AgCl}/y^2$. The 35 data points were fitted by a 6-coefficient equation of the form of Eq. [3]. The equation is given in Table III. Mean and maximum deviations were 63 and 147 cal. Fitted curves are shown in Fig. 5 and as the solid curves in Fig. 6. For large values of X_{AgCl}, the curves are again shown as broken lines in Fig. 6 to

$$\Delta\bar{H}_{AgCl} = (-3714 + 5490t - 3411t^2 + 2476t^3)y^2 + (702 + 268t)y^3$$

$$\Delta\bar{H}_{RbCl} = [-690t^2 - 160t^3] + (7428 - 5490t + 0 + 2476t^3)[y - 1] + (-4767 + 5222t - 3411t^2 + 2476t^3)[y^2 - 1] + (702 + 268t)[y^3 - 1]$$

$$\Delta\bar{H}_{NaCl} = [-770 + 1380t - 450t^2 - 160t^3] + (1938 + 1332t - 7428t^2 + 2476t^3)[y - 1] + (-4901 + 5222t - 3411t^2 + 2476t^3)[y^2 - 1] + (702 + 268t)[y^3 - 1]$$

$$\Delta H = [-770t + 690t^2 + 80t^3]y + (3714 - 5490t + 3411t^2 - 2476t^3)[y^2 - y] + (-351 - 134t)[y^3 - y]$$

indicate the uncertainty resulting from division by y^2 when y is small. The lines which would result if $\Delta\bar{H}_{AgCl}$ varied linearly (additively) with t at constant X_{AgCl} are shown in Fig. 6 as the dashed lines. These lines lie ¼, ½, and ¾ of the way between the two experimental curves at $t = 0$ and $t = 1$.

Excess entropies of mixing.—Experimental values of the partial molar excess entropy of mixing of AgCl, $\Delta\bar{S}^E_{AgCl}$, are plotted *vs.* X_{AgCl} for the five values of t in

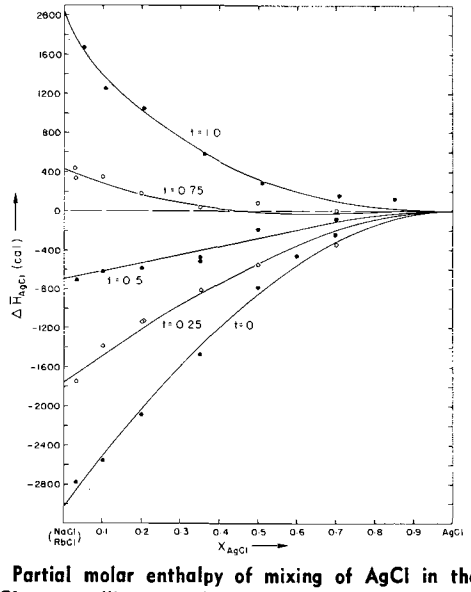

Fig. 5. Partial molar enthalpy of mixing of AgCl in the AgCl-RbCl-NaCl system (lines are from least-squares fit). $t = X_{NaCl}/(X_{RbCl} + X_{NaCl})$.

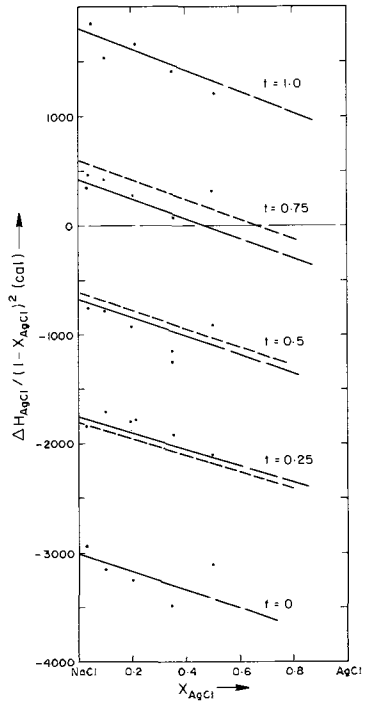

Fig. 6. $\Delta\bar{H}_{AgCl}/(1 - X_{AgCl})^2$ in the AgCl-RbCl-NaCl system. $t = X_{NaCl}/(X_{RbCl} + X_{NaCl})$. ———, Least-squares fit. – – –, Assuming linearity with t at constant X_{AgCl}.

Fig. 7. Also shown as solid lines are the fitted curves obtained using a 6-coefficient equation of the form of Eq. [3]. The equation is given in Table IV. Mean and maximum deviations were 0.05 and 0.17 cal/°K-mole. The lines which would result if $\Delta\bar{S}^E_{AgCl}$ varied linearly (additively) with t at constant X_{AgCl} are also shown in Fig. 7 as dashed lines. These lines represent entropies of mixing lying ¼, ½, and ¾ of the way between the two experimental curves for $t = 0$ and $t = 1$.

Calculation of partial properties of RbCl and NaCl and of integral molar properties.—The coefficients, (b_{jk}, c_{jk}, and ϕ_{jk}) in the expansions [4], [5], and [6] for the partial excess free energies $\Delta\bar{G}^E_{RbCl}$ and $\Delta\bar{G}^E_{NaCl}$, and for the integral molar excess free energy of mixing, ΔG^E, were calculated from the fitted coefficients, a_{jk}, of $\Delta\bar{G}^E_{AgCl}$ given in Table II. Equations [8], [9], and [10], respectively, were used for this purpose. The resulting expansions for $\Delta\bar{G}^E_{RbCl}$, $\Delta\bar{G}^E_{NaCl}$, and ΔG^E are given in Table II in the form of Eq. [13], [14], and [15]. In Table II, end point values, $\Delta\bar{G}^E_{RbCl(1,t)}$, $\Delta\bar{G}^E_{NaCl(1,t)}$, and $\Delta G^E_{(1,t)}$ as functions of t in the RbCl-

Table IV. Least-squares fit for $\Delta\bar{S}^E_{AgCl}$ vs. composition in the AgCl-RbCl-NaCl ternary system and other partial entropies and integral entropy of mixing as calculated analytically from the Gibbs-Duhem equation

$$\Delta\bar{S}^E_{AgCl} = (-1.049 + 1.418t - 3.079t^2 + 2.489t^3)y^2 + (0.482 + 0.576t)y^3$$

$$\Delta\bar{S}^E_{RbCl} = [-0.208t^2] + (2.098 - 1.418t + 0 + 2.489t^3)[y - 1] + (-1.772 + 0.942t - 3.079t^2 + 2.489t^3)[y^2 - 1] + (0.482 + 0.576t)[y^3 - 1]$$

$$\Delta\bar{S}^E_{NaCl} = [-0.208 + 0.416t - 0.208t^2] + (0.680 + 4.740t - 7.467t^2 + 2.489t^3)[y - 1] + (-2.060 + 0.842t - 3.079t^2 + 2.489t^3)[y^2 - 1] + (0.482 + 0.576t)[y^3 - 1]$$

$$\Delta S^E = [-0.208t + 0.208t^2]y + (1.049 - 1.418t + 3.079t^2 - 2.489t^3)[y^2 - y] + (-0.241 - 0.288t)[y^3 - y]$$

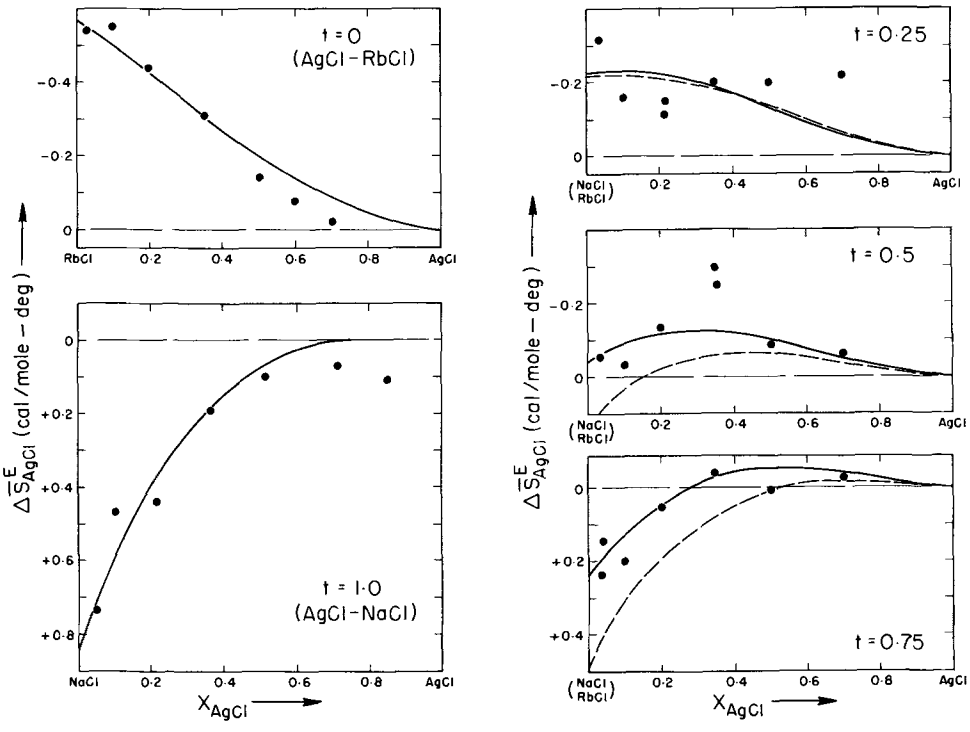

Fig. 7. $\Delta\bar{S}^E_{AgCl}$ in the AgCl-RbCl-NaCl system. $t = X_{NaCl}/(X_{RbCl} + X_{NaCl})$. ———, Least-squares fit. – – –, Assuming linearity with t at constant X_{AgCl}.

NaCl binary system are used. *Viz.*:

$$\Delta\bar{G}^E_{RbCl(1,t)} = -632t^2 \quad \text{cal/mole} \quad [17]$$

$$\Delta\bar{G}^E_{NaCl(1,t)} = -632(1-t)^2$$
$$= -632 + 1264t - 632t^2 \quad \text{cal/mole} \quad [18]$$

$$\Delta G^E_{(1,t)} = -632t(1-t)$$
$$= -632 + 632t^2 \quad \text{cal/mole} \quad [19]$$

(where $t = X_{NaCl}$ in the RbCl binary system from definition [2]). These are the values obtained from the phase diagram calculations (3).

Similar calculations were performed to give the partial molar enthalpies and excess entropies of mixing of RbCl and NaCl, and to give the integral molar enthalpies and excess entropies of mixing. The resulting equations are given in Tables III and IV. The end point values, $\Delta\bar{H}_{RbCl(1,t)}$, $\Delta\bar{H}_{NaCl(1,t)}$, and $\Delta H_{(1,t)}$ as functions of t in the RbCl-NaCl binary system were calculated from the data of Hersh and Kleppa (2). End point values of the excess entropies were calculated by combining the free energies calculated from the phase diagram with the calorimetric enthalpies (3).

The accuracy of all the end point data has been shown (3) to be quite good.

The calculated integral molar properties of mixing, ΔG^E, ΔH, and ΔS^E, are shown in Fig. 8, 9, and 10 in the form of iso-ΔG^E, iso-ΔH, and iso-ΔS^E plots. The analytical Gibbs-Duhem technique is very useful in the preparation of such 'iso-plots." With an equation for ΔG^E as in Table II, for example, one can calculate values of ΔG^E at hundreds of composition points within the ternary system using a computer, and one can then easily trace out lines of constant ΔG^E.

It may be noted that the lines of zero ΔG^E, zero ΔH, and zero ΔS^E in Fig. 8, 9, and 10 follow approximately the same composition path for all three properties.

Graphical plots of the partial molar properties of RbCl and NaCl are shown and discussed later.

As seen in Fig. 4, the quantity $\Delta\bar{G}^E_{AgCl}/y^2$ exhibits almost perfectly additive behavior as t varies from zero to unity at constant X_{AgCl} when$X_{AgCl} = 0$. Progressively increasing positive deviations from additivity occur, however, as X_{AgCl} increases. Guion *et al.* (7) made some similar measurements of $\Delta\bar{G}^E_{AgCl}$ using formation cells in the AgCl-KCl-NaCl and AgCl-CsCl-NaCl systems. Plots of $\Delta\bar{G}^E_{AgCl}/y^2$ at 800°C *vs.* X_{AgCl} at several values of t are shown in Fig. 11 (where t is defined as $t = X_{NaCl}/(X_{ACl} + X_{NaCl})$ where A = K or

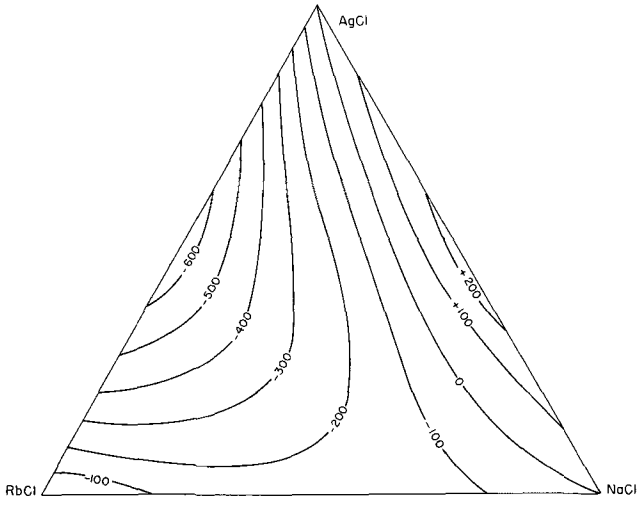

Fig. 8. Iso-ΔG^E lines at 800°C

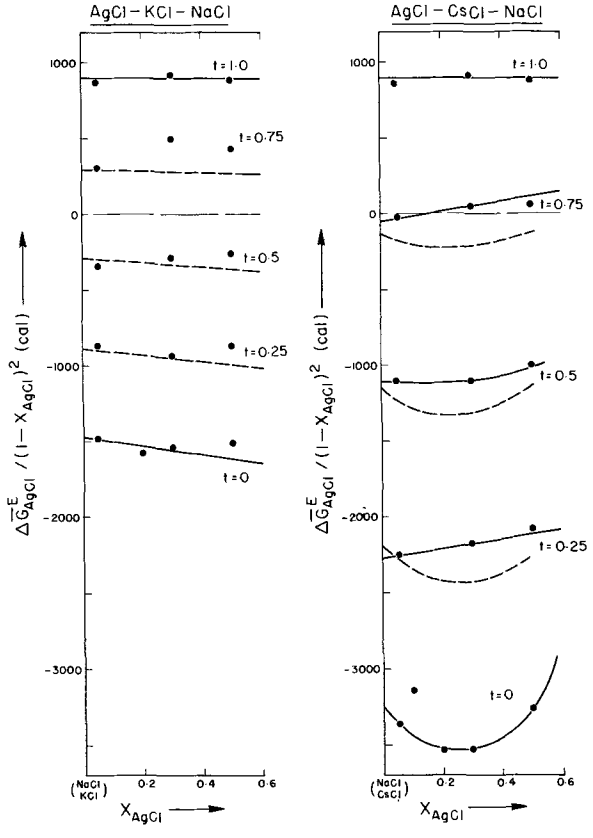

Fig. 11. $\Delta\bar{G}^E_{AgCl}/(1 - X_{AgCl})^2$ at 800°C in the AgCl-KCl-NaCl and AgCl-CsCl-NaCl systems [Guion et al. (7)]. $t = X_{NaCl}/(X_{ACl} + X_{NaCl})$ where A = K or Cs. – – –, Calculated assuming linearity with t at constant X_{AgCl}.

Cs). From the plots for the AgCl-CsCl-NaCl system, it is seen that behavior very similar to that observed in Fig. 4 is exhibited. For the AgCl-KCl-NaCl system, there is perhaps some evidence of positive deviations from additivity, although these deviations are certainly much less than in the other two systems.

In Fig. 4 is a plot of $\Delta\bar{G}^E_{AgCl}/y^2$ for the AgCl-KCl binary system (1). The shape of the curve for this real binary system is much different from the shape of the curve for the quasi-binary system where $t = 0.25$, even though the values of $\Delta\bar{G}^E_{AgCl}$ are similar in magnitude in the two cases.

In Fig. 6, it may be seen that $\Delta\bar{H}_{AgCl}/y^2$ exhibits nearly additive behavior within experimental error limits as t is varied at constant X_{AgCl}. In the plots of $\Delta\bar{S}^E_{AgCl}$ in Fig. 7, it is seen that there is evidence of quite large negative deviations from additivity in this property. A negative deviation from additivity in $\Delta\bar{S}^E_{AgCl}$ will, of course, cause a positive deviation in $\Delta\bar{G}^E_{AgCl}$. Thus, there is evidence that the deviations from additivity in $\Delta\bar{G}^E_{AgCl}$ as seen in Fig. 4 may be largely due to deviations from additivity in the excess entropy and not in the enthalpy. However, in attempting to separate the deviations from additivity in Fig. 4 into entropy and enthalpy effects, one is working near the limits of the experimental accuracy.

Enthalpies and excess entropies calculated from the results of Guion *et al.* (7) in the AgCl-KCl-NaCl and AgCl-CsCl-NaCl systems were too scattered for trends to be observable.

Discussion

In simple regular solution theory (8, 9) ΔG^E in a ternery system may be described by an equation of the form

$$\Delta G^E = X_1X_2b_{12} + X_1X_3b_{31} + X_2X_3b_{23} \quad [20]$$

where b_{12}, b_{31}, and b_{23} are concentration-independent parameters which have the same values in the ternary system as in the 1-2, 1-3, and 2-3 binary systems. Such an equation is usually derived assuming random mixing, and assuming constant, additive, pairwise interactions between particles. For simple molten salt solutions with a common anion, such as the AgCl-RbCl-NaCl system, the simple regular solution approach takes the major contribution to the energy of mixing to be due to second-nearest neighbor cation-cation pairwise interactions. For instance, in this theory (9), b_{23} is given by

$$b_{23} = \tfrac{1}{2}(2E_{23} - E_{22} - E_{33}) \quad [21]$$

where E_{23}, E_{22}, and E_{33} are the energies of 2-3, 2-2, and 3-3 second-nearest neighbor cation-cation "bonds," respectively.

From Eq. [20], the partial free energy of mixing of component 1 may be calculated, and is given by

$$\Delta\bar{G}^E_1 = y^2(1 - t)b_{12} + y^2tb_{31} - y_2t(1 - t)b_{23} \quad [22]$$

which may be written as

$$(\Delta\bar{G}^E_1/y^2) = y^{-2}[(1 - t)\Delta\bar{G}^E_{1(12)} + t\Delta\bar{G}^E_{1(13)})] - \Delta G^E_{23} \quad [23]$$

where $\Delta\bar{G}^E_{1(12)}$ and $\Delta\bar{G}^E_{1(13)}$ are values of $\Delta\bar{G}^E_1$ in the 1-2 and 1-3 binaries at the particular value of y in question, and ΔG^E_{23} is the integral excess free energy of mixing in the 2-3 binary at the end of the line of constant t in question. That is, in Fig. 12, $\Delta\bar{G}^E_1/y^2$ at point P is given by taking a linear variation in $\Delta\bar{G}^E_1$ between points a and b, and then subtracting the integral excess free energy of mixing at point c in the 2-3 binary. Equation [23] was first derived in the form given here by Alcock and Richardson (10), who had

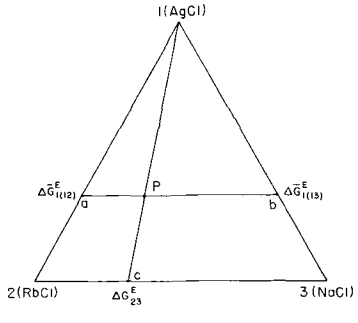

Fig. 12. Ternary relationships in Eq. [23]

much success with the equation in predicting the properties of liquid alloy systems dilute in component 1.

In most cases, the parameters b_{12}, b_{23}, and b_{31} will not be independent of concentration even in the binary systems. For instance, the present experimental results show that b_{12} and b_{31} in the AgCl-RbCl and AgCl-NaCl binary systems are not independent of concentration. Nevertheless, the geometrical relationship of Eq. [23] might still reasonably be expected to be a fairly good approximation.

In the RbCl-NaCl binary system, $\Delta G^E_{23} = -632 X_{NaCl} X_{RbCl}$ (1). In Fig. 4, then, Eq. [23] predicts a constant positive deviation from additivity at $t = 0.5$ of about +158 cal. This deviation should be independent of X_{AgCl}. No such constant deviation is seen in Fig. 4. In the solutions dilute in AgCl, where Eq. [23] should be expected to hold best (10), nearly perfectly additive behavior is observed, as if the final term in Eq. [23] were not present. As the concentration of AgCl is increased, positive deviations from additivity are observed, and these rapidly become much greater than 158 cal.

A similar relationship to Eq. [23] should also hold for the quantity $\Delta \overline{H}_{AgCl}/y^2$. In the RbCl-NaCl binary system at $X_{RbCl} = X_{NaCl} = 0.5$, ΔH_{23} is about −200 cal (2), and the model thus predicts a constant positive deviation from additivity of +200 cal at $t = 0.5$. Once more, as may be seen in Fig. 6, this behavior is not observed. Within the experimental error limits, actually, it would seem that the system exhibits nearly additive behavior everywhere.

So it is seen that Eq. [23] does not explain the observed partial properties of AgCl. This would indicate that the regular solution theory is not applicable to the present system. However, if the partial properties of RbCl and NaCl are examined, Eq. [23] does appear to explain the observations quite well, as will now be shown.

Behavior of partial properties of RbCl and NaCl.— In Fig. 13 are plots of $(\Delta \overline{G}^E_{RbCl}/(1 - X_{RbCl})^2)$ *vs.* the parameter $X_{AgCl}/(X_{NaCl} + X_{AgCl})$ at constant values of X_{RbCl}. The parameter $X_{AgCl}/(X_{NaCl} + X_{AgCl})$ assumes constant values along lines radiating from the "2-corner" of the composition triangle. It is seen that negative deviations from additivity occur along the paths of constant X_{RbCl}.

The Alcock-Richardson equation may be applied to component 2 (RbCl) to give an equation for $(\Delta \overline{G}^E_{RbCl}/(1 - X_{RbCl})^2)$ similar to Eq. [23]. This would predict

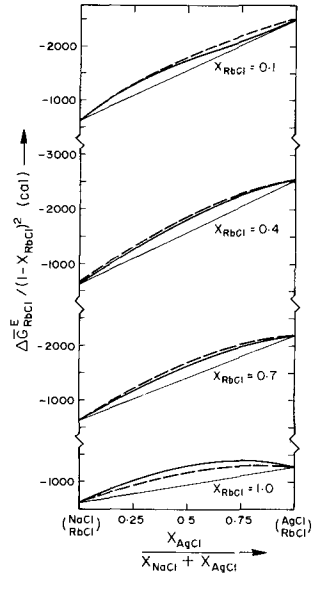

Fig. 13. $\Delta \overline{G}^E_{RbCl}/(1 - X_{RbCl})^2$ vs. $X_{AgCl}/(X_{NaCl} + X_{AgCl})$ at constant values of X_{RbCl} at 800°C. ———, Experimental. – – –, Calculated.

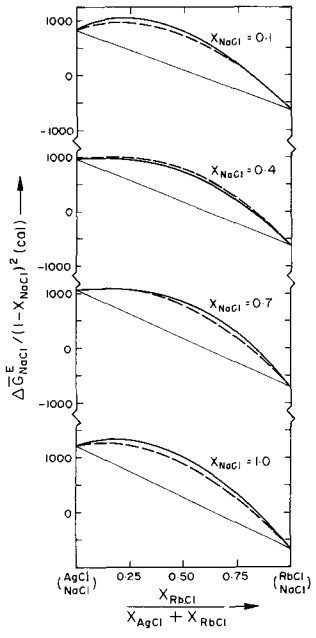

Fig. 14. $\Delta \overline{G}^E_{NaCl}/(1 - X_{NaCl})^2$ vs. $X_{RbCl}/(X_{AgCl} + X_{RbCl})$ at constant values of X_{NaCl} at 800°C. ———, Experimental. – – –, Calculated.

that in Fig. 13, at any value of $X_{AgCl}/(X_{NaCl} + X_{AgCl})$, there should be constant deviations from additivity, independent of X_{RbCl}, equal to $(-\Delta G^E_{13})$, where ΔG^E_{13} is the integral excess free energy of mixing in the 1-3 (AgCl-NaCl) binary system at the end of the line of constant $X_{AgCl}/(X_{NaCl} + X_{AgCl})$ ratio. Since ΔG^E_{13} in the AgCl-NaCl system is positive, negative deviations from additivity are expected. The actual predicted curves are shown in Fig. 13. Agreement with the experimental curves is very good.

In Fig. 14 are plots of $(\Delta \overline{G}^E_{NaCl}/(1 - X_{NaCl})^2)$ *vs.* the parameter $X_{RbCl}/(X_{AgCl} + X_{RbCl})$ at constant values of X_{NaCl}. Positive deviations from additivity occur. The Alcock-Richardson equation predicts that these deviations should be equal to $(-\Delta G^E_{12})$, where ΔG^E_{12} is the integral molar excess free energy of mixing in the 1-2 (AgCl-RbCl) binary system at the end of the line of constant $X_{RbCl}/(X_{AgCl} + X_{RbCl})$ ratio in question. The deviations should be positive, since ΔG^E_{12} in the AgCl-RbCl system is negative. Predicted curves are shown in Fig. 14, and are in very good agreement with the experimental curves.

In Fig. 15 and 16 are plots similar to those in Fig. 13 and 14, respectively, except that the partial enthalpy functions rather than the partial free energy functions are plotted. The curves predicted by the Alcock-Richardson equation are also shown. In view of the greater experimental errors in the enthalpy measurements, the agreement with experiment is good.

The experimental errors in the excess entropies are great enough that it is not possible to draw any conclusions regarding deviations from additivity in plots $\Delta \overline{S}^E_{RbCl}$ and $\Delta \overline{S}^E_{NaCl}$.

So, it may be seen that the simple considerations of regular solution behavior used in the derivation of Eq. [23] are sufficient to explain the observed partial properties of RbCl and NaCl quite satisfactorily, even though these same considerations completely fail to explain the partial properties of AgCl. This is evidence that the bonding of AgCl in these solutions is of different character than that of the alkali chlorides. Evidence from measurements on the binary systems that silver-chlorine bonds have a partially covalent nature has been presented previously (1).

The advantages of examining the partial properties of all the components when studying a ternary system can be seen.

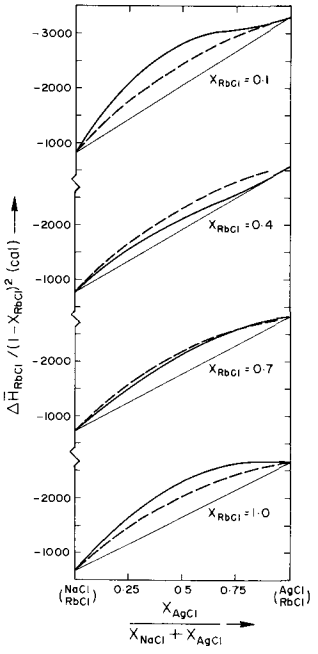

Fig. 15. $\Delta\bar{H}_{RbCl}/(1 - X_{RbCl})^2$ *vs.* $X_{AgCl}/(X_{NaCl} + X_{AgCl})$ **at constant values of** X_{RbCl}. ———, **Experimental.** – – –, **Calculated.**

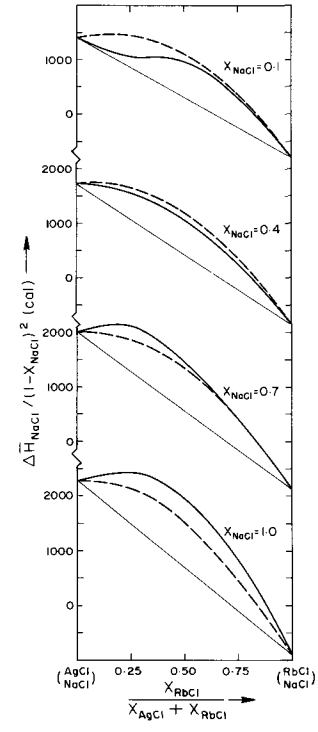

Fig. 16. $\Delta\bar{H}_{NaCl}/(1 - X_{NaCl})^2$ *vs.* $X_{RbCl}/(X_{AgCl} + X_{RbCl})$ **at constant values of** X_{NaCl}. ———, **Experimental.** – – –, **Calculated.**

At high dilutions in the RbCl-NaCl binary, it has been shown that $\Delta\bar{G}^E_{AgCl} = RT \ln \gamma_{AgCl}$ varies almost linearly with t (γ_{AgCl} = activity coefficient of AgCl). It may be noted, however, that a corresponding plot of γ_{AgCl} *vs.* t exhibits negative deviations from linearity. AgCl is more stable (γ_{AgCl} is lower) in dilute solution in RbCl than in NaCl. Because γ_{AgCl} exhibits negative deviations from linearity with t, AgCl dissolved, say, in an equimolar mixture of RbCl and NaCl will have an activity closer to that which it would have in pure RbCl. For any solute dissolved in a mixture of two solvents in which ($RT \ln \gamma_{solute}$) varies approximately linearly as t (where t is the molar ratio of the two solvents), γ_{solute} will show negative deviations from linearity. The greater the difference in the values of γ_{solute} in the two individual solvents, the greater will be the deviations. Therefore, if the solute were not particularly stable in solvent A, but were quite stable in solvent B, the addition of a relatively small amount of B to a solution of the solute in A would have a very large stabilizing effect.

The Effect of Competition with Water on the Kinetic Parameters in Electrode Reactions

ABSTRACT

The effect of competition with water on electrode kinetics as well as the kinetics of chemical reactions catalyzed by metals in solution has been determined theoretically. The model of Bockris, Devanathan, and Muller was taken into account and shown to play a considerable role for large molecules and for potentials far removed from the potential of zero charge.

The importance of adsorbed intermediates (*e.g.*, hydrogen atoms or OH radical) in the mechanism of electrode reactions has been recognized early in the development of mechanistic studies of electrode kinetics (1). Detailed discussions of the Tafel slopes which should be obtained under limitingly low or limitingly high values of the fractional surface coverage, where the Langmuir adsorption isotherm is applicable, are available (2-4). The case of intermediate values of the coverage on a heterogeneous surface, where the Temkin or Frumkin isotherm is applicable has also been worked out in detail for various reactions (5, 6).

Butler (7, 8) considered the role of the energy of adsorbed water molecules as important in the adsorption process. Replacement of adsorbed water on solid electrodes was treated by Barradas and Conway (9). Mott and Watts-Toben (10) introduced a model for the potential dependent orientation of water molecules which has been recently applied by Bockris, Devanathan, and Muller (11) and Muller (12) for the derivation of an isotherm. Thus, it is now realized that adsorption from solution onto the surface of an electrode is a replacement reaction, the energetics of which depend mainly on the difference between the energy of adsorption of the adsorbent and the energy of desorption of an appropriate number of water molecules (13). The potential dependence of adsorption of neutral organic molecules has been interpreted alternatively as being due to the change of energy of the double layer capacitor (14-16) and as due to the dependence of energy of adsorption of water molecules on the field across the metal/solution interface (11, 13). More recently it was shown (18) that this type of effect should be taken into consideration when discussing the charge-transfer adsorption of organic species. Changing the potential has two effects in this case: Equilibrium is shifted toward a higher degree of adsorption due to charge transfer, while competition with adsorbed water tends to decrease the extent of adsorption. In a study of the anodic oxidation of hydrazine on gold electrodes (19) this effect was also taken into account to explain the observed Tafel slope, which deviated markedly from any simple multiple of $(2.3\ RT/\mathbf{F})$.

In the present paper the value of the Tafel slope has been calculated for a number of commonly occurring mechanisms. Competition between adsorbed intermediates and water molecules for sites on the surface affects the kinetics of the reaction in two ways. On the one hand the degree of coverage by adsorbed intermediates and its rate of change with potentials $d\theta/d(\Delta\phi)$ is altered, and has been shown previously (18). On the other hand the specific rate constant for the rate-determining step (rds) is affected, increasing in the case of a desorption step and decreasing in the case of an adsorption step. The relationship between the dependence of the apparent standard free energy of adsorption and the apparent standard free energy of activation on potential (*i.e.*, between the dependence of the equilibrium constant and the specific rate constant on potential) is similar to that calculated for the dependence of the same quantities on coverage under Temkin conditions, as discussed elsewhere (5, 6).

The isotherm of Bockris, Devanathan, and Muller (11) has been employed. This was criticized recently by Damaskin (16) for not taking into account the contribution due to the change of energy of the double layer capacitor, as proposed by Frumkin (14). However, it was shown recently by Gileadi (20) that this is a relatively small contribution, which does not exceed *ca.* 10% in most cases of practical interest. Thus, including this correction does not alter the results presented below qualitatively.

Calculation of Tafel Slopes

The bromine evolution reaction.—General considerations.—A simple anodic process, the bromine evolution reaction has been chosen to exemplify the method of derivation of Tafel slope. This reaction takes place in two steps. The initial charge transfer

$$Br^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Br_{ads} + e \qquad [1]$$

followed by a surface recombination of two adsorbed atoms

$$2Br_{ads} \xrightarrow{k_2} Br_2 \qquad [2]$$

or by further charge transfer according to the equation

$$Br_{ads} + Br^- \xrightarrow{k_3} Br_2 + e \qquad [3]$$

Surface recombination rds.—If the surface recombination step (Eq. [2]) is assumed rate determining, with the preceding charge transfer step at quasi-equilibrium, the rate equation at limitingly low coverage is commonly written as

$$i = n\mathbf{F}k_2\theta^2 = n\mathbf{F}k_2 K_1^2 C_{Br}^2 - \exp(2\Delta\phi\mathbf{F}/RT) \qquad [4]$$

giving rise to a Tafel slope of $b = 2.3RT/2\mathbf{F}$.

The dependence of adsorption on potential at high values of the field is obtained from the equations de-

* Electrochemical Society Active Member.

Key words: adsorption, electrode kinetic, water competition.

rived by Bockris *et al.* (12) as a variation of the equilibrium constant K_1, with potential (18).

$$K_1 = K_{1,o} \exp - \left(\frac{m\mu}{e_o\nu}\right)\left(\frac{\Delta\phi \mathbf{F}}{RT}\right) \qquad [5]$$

where m is the number of water molecules replaced by each molecule of adsorbed intermediate, μ is the dipole moment of water, e_o is the electronic charge, and ν is the thickness of the compact part of the double layer, taken in this case to be equal to the diameter of a water molecule on the surface. The minus sign in the exponent arises from the assumption that the anodic oxidation takes place at a high positive rational potential, *i.e.*, far anodic to the potential of zero charge, where the competition with water causes a decrease in fractional coverage with increasing potential.

Equation [5] may also be written in the form

$$\Delta G^\circ = \Delta G^\circ_o + \left(\frac{m\mu}{e_o\nu}\right)\Delta\phi \mathbf{F} \qquad [6]$$

Where ΔG° is the apparent standard free energy for the adsorption equilibrium and ΔG°_o is its value at $\Delta\phi = 0$. It was shown both experimentally and theoretically (20, 21) that the change in apparent standard free energy of activation (22) for a given reaction is proportional to the change in the apparent standard free energy of the reaction. Thus

$$\Delta G^{\circ\neq} = G^{\circ\neq}_o - \left(\frac{m\mu}{e_o\nu}\right)\beta\Delta\phi \mathbf{F} \qquad [7]$$

where β is a symmetry factor the value of which is commonly taken to be near 0.5, and $\Delta G^{\circ\neq}$ and $\Delta G^{\circ\neq}_o$ are the apparent standard free energies of activation at some potential $\Delta\phi$ and at $\Delta\phi = 0$, respectively. Equation [7] has a negative sign because the energy of activation for the desorption process (Eq. [2]) is decreased with increasing potential.

From Eq. [7] one has for the rate constant k_2 the expression

$$k_2 = k_{2,o} \exp \frac{m\mu}{e_o\nu}\left(2\beta \frac{\Delta\phi \mathbf{F}}{RT}\right) \qquad [8]$$

where the factor 2 has been introduced because two adsorbed species are desorbed in each act of the rate-determining step. Using the values of K_1 and k_2 in Eq. [4] one has

$$i = K^1 C^2_{Br^-} \exp\left(\frac{2\Delta\phi \mathbf{F}}{RT}\right) \exp - \left(\frac{m\mu}{e_o\nu}\right)\left(\frac{2\Delta\phi \mathbf{F}}{RT}\right) \exp\left(\frac{m\mu}{e_o\nu}\right)\left(\frac{2\beta\Delta\phi \mathbf{F}}{RT}\right)$$

$$= K^1 C^2_{Br^-} \exp\left(\frac{2\Delta\phi \mathbf{F}}{RT}\right)\left[1 - \frac{m\mu}{e_o\nu}(1-\beta)\right] \qquad [9]$$

The numerical values to be used in Eq. [9] are: $\mu = 1.8 \times 10^{-18}$ esu; $e_o = 4.8 \times 10^{-10}$ esu; $\nu = 2.7 \times 10^{-8}$ cm, and $\beta = 0.5$. With these, Eq. [9] becomes

$$i = K^1 C_{Br^-} \exp(2\Delta\phi \mathbf{F}/RT)(1 - 0.07m) \qquad [10]$$

The Tafel slope will depend on the size and mode of adsorption of the intermediate species, which determines the number of water molecules replaced from the surface. For the case of bromine discussed here a value of $m = 2$ would seem reasonable, giving rise at room temperature to

$$b = (2.3RT/2\mathbf{F})(1 - 0.07m)^{-1} = 35 \text{ mV}$$

to be compared to a value of 30 mV obtained for the same mechanism, neglecting the effect of competition with water.

In the other extreme case, when θ approaches unity, the rate equation is commonly written as

$$i = n\mathbf{F}k_2 \qquad [11]$$

Table I. Values of the Tafel slope (in mV) calculated for different mechanisms in the bromine evolution reaction

Mechanism	$\theta \ll 1$		$0.2 < \theta < 0.8$		$\theta \to 1$	
	$m = 0$	$m = 2$	$m = 0$	$m = 2$	$m = 0$	$m = 2$
$Br^- \rightleftharpoons$ [Br] + e; 2 [Br] $\xrightarrow{rds}$ Br_2	30	35	60	60	∞	214
$Br^- \rightleftharpoons$ [Br] + e; [Br] + $Br^- \xrightarrow{rds} Br_2 + e$	40	42	60	64	120	93
$Br^- \xrightarrow{rds}$ [Br] + e; [Br] + [Br] $\rightarrow Br_2$	120	167	—	—	—	—

which leads to a limiting current behavior.[1] If the dependence of k_2 on potential according to Eq. [8] is taken into account one finds, however

$$i = K^1 \exp \frac{m\mu}{e_o\nu}\left(\frac{2\beta\Delta\phi \mathbf{F}}{RT}\right) \doteq K^1 \exp 0.14m(\Delta\phi \mathbf{F}/RT) \qquad [12]$$

yielding a Tafel slope of

$$b = (2.3RT/\mathbf{F})/0.14m = 214 \text{ mV}$$

At intermediate values of the coverage, assuming the Frumkin isotherm (23) to prevail, the rate equation will be written in the form (5, 6)

$$i = n\mathbf{F}K_1\theta^2 \exp(2\beta mr\theta/RT) \qquad [13][2]$$

and the equilibrium in step [1] can be represented by the isotherm

$$\frac{\theta}{1-\theta} \exp\left(\frac{mr\theta}{RT}\right) = K_1 C_{Br^-} \exp \frac{\Delta\phi \mathbf{F}}{RT} \qquad [14]$$

in which the pre-exponential term in θ may be neglected in comparison with the exponential term (Temkin's approximation). Thus from Eq. [14] one has

$$\exp \frac{r\theta}{RT} = K_1^{1/m} C_{Br^-}^{-1/m} \exp \frac{\Delta\phi \mathbf{F}}{mr\theta} \qquad [15]$$

combining Eq. [15] and [13], and introducing the potential dependence of K_1 and k_2 from Eq. [5] and [8], respectively, one has

$$i = K^1 C^2_{Br^-} \exp(\Delta\phi \mathbf{F}/2\beta RT) \qquad [16]$$

yielding a Tafel slope of

$$b = 2.3RT/2\beta\mathbf{F} = 60 \text{ mV}$$

It is thus found that for this mechanism under Temkin conditions the calculated Tafel slope is not affected by taking into account the competition with water. This, however, is not always the case under Temkin conditions, as shown in Table I.

Ion-atom step rate determining.—It will now be assumed that reaction [3] is rate determining, with reaction [1] still at quasi-equilibrium. The rate equation can be written under Langmuir conditions, in the form

$$i = n\mathbf{F}k_3 C_{Br^-}\theta \exp \beta\Delta\phi \mathbf{F}/RT \qquad [17]$$

and the rate constant will depend on potential according to the equation

$$k_3 = k_{3,o} \exp(0.14\beta m\Delta\phi \mathbf{F}/RT) \qquad [18]$$

[1] This is called the reaction limited current, to distinguish it from the diffusion limited current observed when the over-all reaction rate is controlled by the rate of mass transport of reactions to the surface.

[2] The parameter r in this paper is defined in a slightly different manner tnan in previous publications (5, 6). It is the rate of change of the apparent standard free energy of adsorption with coverage per mole of adsorption sites. The product mr is the same parameter per mole of adsorbed species.

Substituting θ for low coverage conditions as in Eq. [4] and taking into account the variation of k_3 and of K_1 with potential (Eq. [18] and [5], respectively), the rate equation becomes

$$i = K^1 C^2_{Br^-} \exp [0.14\beta m + (1 - 0.14m) + \beta]\Delta\phi\mathbf{F}/RT$$

$$= K^1 C^2_{Br^-} \exp [1 + \beta - 0.14m(1 - \beta)]\Delta\phi\mathbf{F}/RT \quad [19]$$

which gives rise to a Tafel slope of

$$b = (2.3RT/\mathbf{F})/(1.5 - 0.07m) = 42 \text{ mV}$$

to be compared with a value of 40 mV obtained for the same mechanism when the effect of competition with water is not taken into account.

Considering the same mechanism for limiting high coverage ($\theta \to 1$). The rate equation is obtained by combining [17] and [18]

$$i = K^1 \exp \frac{\beta\Delta\phi\mathbf{F}}{RT} [1 + 0.14m] \quad [20]$$

The resulting Tafel slope is

$$b = (2.3 \times 2RT/\mathbf{F})/(1 + 0.14m) = 93 \text{ mV}$$

to be compared with a slope of 0.12V obtained when m is put equal to zero.

In the intermediate coverage range, under Temkin conditions, the rate equation will take the form

$$i = n\mathbf{F}k_3\theta C_{Br^-} \exp (\beta mn\theta/RT) \exp (\beta\Delta\phi\mathbf{F}/RT) \quad [21]$$

The exponential term in θ is substituted from Eq. [15] and the potential dependence of K_1 and k_3 from Eq. [5] and [18], respectively, to give

$$i = K^1 C_{Br^-}{}^{1+\beta} \exp \frac{\Delta\phi\mathbf{F}}{RT} [0.14\beta m + \beta + (\beta - 0.14m)]$$

$$= K^1 C_{Br^-}{}^{1+\beta} \exp \frac{\Delta\phi\mathbf{F}}{RT} [2\beta - 0.14m(1 - \beta)] \quad [22]$$

hence

$$b = (2.3RT/\mathbf{F})/(1 - 0.07m) = 64 \text{ mV}$$

as compared to 60 mV for $m = 0$.

Initial discharge rate determining.—Consider now the case where the initial discharge step (Eq. [1]) is rate determining. The rate equation

$$i = n\mathbf{F}k_1 C_{Br^-}(1 - \theta) \exp (\beta\Delta\phi\mathbf{F}/RT) \quad [23]$$

The rate constant in this case decreases with increasing anodic potential because it relates to an adsorption process, thus

$$k_1 = k_{1,o} \exp - \left(\frac{m\mu}{e_o\nu}\right)\left(\frac{\beta\Delta\phi\mathbf{F}}{RT}\right) \quad [24]$$

Only the low coverage case needs to be considered when formation of the intermediate is the rds. Thus

$$i = n\mathbf{F}k_{1,o}C_{Br^-} \exp (\beta\Delta\phi\mathbf{F}/RT)(1 - m\mu/e_o\nu) \quad [25]$$

and hence

$$b = 2(2.3RT/\mathbf{F})/(1 - 0.14m) = 167 \text{ mV}$$

compared to 0.12V for $m = 0$.

It is interesting to note that this model can, for the first time, predict Tafel slopes that are higher than 2 x 2.3$RT/\mathbf{F}$ for a simple mechanism.

Table I summarizes the Tafel slopes obtainable for various mechanisms of the bromine evolution reaction assuming $m = 2$. The usual Tafel slopes calculated when the effect of change of free energy of adsorption due to competition with water is not taken into account ($m = 0$) are given for comparison.

Electroorganic reactions.—From the discussion above it can be seen that the effect of change of apparent standard free energy of adsorption with potential on the Tafel slope increases with the size of the molecule or the number of sites it occupies on the surface. Thus, it would seem most appropriate to apply the above considerations to the interpretation of kinetic parameters observed in the study of electrode reactions of organic compounds. In Table II a number of typical mechanisms for the stepwise anodic oxidation of an organic compound is shown with the corresponding Tafel slopes for low, intermediate, and high coverage. The numbers of water molecules replaced by the substrate, the first and the second intermediate are denoted m, l, and p, respectively. The method of derivation of these Tafel slopes is similar to that shown above for the bromine evolution reaction, and will not be reproduced here. The choice of mechanisms is somewhat arbitrary and Table II is mainly intended to illustrate the type of results which may be expected under somewhat more complex situations than the bromine evolution reaction. The usual Tafel slope can be obtained in each case by setting m, l, and p equal to zero.

Table II. Tafel slope derived for different typical organic oxidation reactions at an electrode

	Mechanism	$b/(2.3RT/\mathbf{F})$ $\theta << 1$	$0.2 < \theta < 0.8$	$\theta \to 1$
I.	$A \rightleftharpoons [A] + mH_2O$			
	$[A] \xrightarrow{rds} [B] + (m - l)H_2O$	$[0.07(m + l)]^{-1}$	∞	$[0.07(m - l)]^{-1}$
II.	$A \rightleftharpoons [A] + mH_2O$			
	$[A] \xrightarrow{rds} [B] + H^+ + e + (m - l)H_2O$	$2[1\cdot0.14(m + l)]^{-1}$	2	$2[1 + 0.14(m - l)]^{-1}$
III.	$A \rightleftharpoons [B] + H^+ + e = mH_2O$			
	$[B] \xrightarrow{rds} [C] + (m - l)H_2O$	$[1\text{-}0.07(m + l)]^{-1}$	$2\left[\frac{m - l}{m}\right]^{-1}$	$[0.07(m - l)]^{-1}$
IV.	$A \rightleftharpoons [B] + H^+ + e + mH_2O$			
	$[B] \xrightarrow{rds} [C] + H^+ + e + (m - l)H_2O$	$[1.5\text{-}0.07(m + l)]^{-1}$	$2\left[1 + \left(\frac{m - l}{m}\right)\right]^{-1}$	$2[1 + 0.14(m - l)]^{-1}$
V.	$A \rightleftharpoons [B] + H^+ + e + mH_2O$			
	$[B] \rightleftharpoons [C] + H^+ + e + (m - l)H_2O$			
	$[C] \xrightarrow{rds} [D] + (l - p)H_2O$	$[2\text{-}0.07(l + p)]^{-1}$	$\left[\frac{l - p}{l}\right]^{-1}$	$[0.07(l - p)]^{-1}$

Discussion

Scope and applicability of the method.—The theory for the calculation of Tafel slopes presented above applies to an anodic reaction taking place at potentials for anodic to the potential of maximum adsorption or for a cathodic process taking place at potentials for cathodic to the potential of maximum adsorption. In an inverse case, *i.e.*, a reduction taking place at very positive potentials or vice versa, the effect of competition with water will be just the opposite. The values of the Tafel slope can be calculated in this case in a straightforward manner following the derivations given above with a change in sign in the exponential dependence of the equilibrium constants and specific rate constants on potential. These equations will therefore not be derived here.

The competition with water affects the calculated value of the parameter b to a lesser degree if the reaction considered is taking place at potentials in the vicinity of the potential of maximum adsorption. The Tafel lines in this region are expected to be nonlinear, changing from the value derived when the competition with water is neglected to the values obtained in Table I and II.

Quasi Tafel relationship in heterogeneous catalysis in solution.—The first mechanism presented in Table II is of some special interest, since the reaction rate is potential dependent although no charge transfer occurs. A quasi Tafel slope can be defined in this case as $b \equiv \partial(\Delta\phi)/\partial \log r$, where r is the rate of the chemical reaction. Thus, chemical reactions catalyzed in solution by metals can be controlled by controlling the potential of the catalyst. The rate may be expected to depend strongly on potential at low values of the fractional surface coverage; it will be independent of potential at intermediate values of the coverage (under Temkin conditions); and it will depend somewhat on potential again at full coverage. Thus, changing the potential may serve as a convenient means of starting up or stopping a chemical reaction which occurs on the surface of an electronically conducting catalyst in solution.

Conclusions

The adsorption of intermediates formed in electrode processes is controlled on the one hand by the charge transfer process and on the other hand by competition with water. A new isotherm which takes into account both effects has been developed elsewhere (18). It is used here to calculate Tafel slopes for a number of typical mechanisms, particularly relevant to electrode reactions of organic compounds which replace a large number of water molecules from the surface per reactant molecule adsorbed. The Tafel slopes calculated are seen to depart markedly from simple multiples of $2.3RT/\mathbf{F}$. In particular a value of $b > 2 \times 2.3RT/\mathbf{F}$ is calculated when a first charge-transfer adsorption step is rate determining.

These considerations probably do not apply to the hydrogen and the oxygen evolution reactions because in these cases the reactant (i.e., H_3O^+, H_2O, or OH^-) does not have to replace water molecules from the surface.

The rate of purely chemical reactions catalyzed by metals in solution can be controlled by setting the potential with respect to an appropriate reference electrode in the same solution.

Technical Notes

Electrode Studies in Nonaqueous Solvents

II. Anion Effect on the Kinetics of Li/Li^+ in Propylene Carbonate

Stuart G. Meibuhr*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

A number of different electrolytes are being used in lithium organic electrolyte batteries. These include propylene carbonate (PC) (or mixtures containing it), as the organic solvent and a solute containing as anion either ClO_4^-, $AlCl_4^-$, or PF_6^- (1).

The electrochemical kinetics of a smooth lithium electrode in PC solutions of either $LiAlCl_4$, $LiPF_6$, or $LiBF_4$ at temperatures up to 60°C are reported here. Two types of experiments were performed. The lithium reference electrode in $LiAlCl_4$-PC solutions was evaluated by measuring the potential of a Li/Li^+ concentration cell at ambient temperature; and the Li/Li^+ electrode kinetics were studied by analyzing the anodic and cathodic polarization of Li electrodes.

Experimental

The PC solvent was vacuum distilled as described before (2) and contained < 20 ppm H_2O. The solutes were used as they were obtained without further attempt to purify or dry them. The $LiAlCl_4$ was obtained on special order from Lithium Corporation of America in a 14 lb lot. The elemental analysis provided by the manufacturer was 1.02, 0.97, and 0.86% theoretical for the Li, Al, and Cl, respectively. The $LiPF_6$ obtained from K & K Laboratories and Agri-Chemicals, Inc., was extremely hygroscopic. The $LiBF_4$ was from the Research Inorganic Chemical Corporation. Solutions of 1M were prepared by weighing in a dry box sufficient solute to add to 100 ml of PC. The $LiPF_6$ solution, after having been stored over Li for several weeks, contained 60 ppm water. The water content in the $AlCl_4^-$ solution could not be determined by the Karl Fischer method; however, because of the similarity of the i_o value and its behavior with immersion time for both $AlCl_4^-$ and ClO_4^- solutions, it will be assumed that the water content of 1M $LiAlCl_4$ was the same as in 1M $LiClO_4$—about 20 ppm. The 1M $LiBF_4$ solution contained 180 ppm water. Less concentrated solutions were prepared by dilution and contained less water than the more concentrated 1M solutions. Details regarding the solutions, electrode preparation, and equipment have already been given (3).

The experimental procedure was similar to that described previously (3), except that the polarization measurements were made within 1-2 min after the polished electrode was immersed into the solution. The solution resistance measurements were made in the previously described way but at the conclusion of the polarization run instead of before the run as was done in the earlier work (3). The exchange current densities were calculated with a computer program from the equation

$$i_o = IRT/\eta_{IR\text{-free}}\mathbf{F}$$

where

$$\eta_{IR\text{-free}} = E_{exptl} - E_{oc} - IR$$

Under all experimental conditions with all solutions, the C.D.-polarization plots were linear. In the several instances when cathodic data were taken, the polarization plot agreed with the anodic plot within 5%. Duplicate anodic runs on freshly repolished electrodes produced slopes that were within 10% of each other.

The value for the *IR* drop varied from 10-50% of either the measured voltage or the polarization value. For example, in 0.5 $LiAlCl_4$, a value for the *IR* drop was 1.6 mV whereas the measured voltage and the polarization was 4.75 and 3.0 mV, respectively, at 55 $\mu A/cm^2$. In the PF_6^- and BF_4^- solutions, the *IR* drop was regularly only 10% of the measured voltage and about 50% of the polarization value.

The potential of the concentration cell

$$Li/LiAlCl_4\ (c_1) - PC/LiAlCl_4\ (c_2) - PC/Li$$

was measured for values of c_1 = 1.0 and 0.5M and c_2 = 1.0, 0.5, 0.25, and 0.1M. Included in the measured emf was an unknown junction potential which was estimated using the Henderson equation (4)

$$E_j = RT/\mathbf{F}\,\frac{\lambda_+^\circ - \lambda_-^\circ}{\lambda_+^\circ + \lambda_-^\circ}\ln\frac{c_1}{c_2}$$

where λ_+° and λ_-° are the limiting ionic mobilities of Li^+ and $AlCl_4^-$, respectively. The value for λ_+° in PC solutions was calculated as 8.7 (3) and was reported as 7.3 (5); hence, in this equation, an average value of 8.0 was used for λ_+°. The value for λ_-° was calculated from

$$\Lambda_o = \lambda_+^\circ + \lambda_-^\circ$$

The value for Λ_o in $LiAlCl_4$ solutions was determined to be 32.5 at 25° (6), consequently, λ_-° is 24.5.

Results and Discussion

Concentration cell studies.—Table I shows the measured emf values for the cell together with the calculated E_j values and the corrected emf values. A plot of the concentration *vs.* the corrected emf values has a slope of 57 mV. Considering the assumptions that were made in calculating the E_j values, the potential responded to the changing Li^+ ion concentration in good agreement with the Nernst equation. Thus, a solid lithium electrode immersed in solutions of $LiAlCl_4$ behaved satisfactorily for a reference electrode. These results in $AlCl_4^-$ solutions agreed with similar results regarding the use of Li as a reference electrode in ClO_4^- solutions (3, 7). Because of the Nernstian agree-

ment for both $AlCl_4^-$ and ClO_4^- solution, it will be assumed that similar behavior exists in the other two Li^+ ion containing solutions used in this study.

Polarization studies.—The i_o variations with temperature, Li^+ ion concentration, and type of anion are summarized in Table II. From the results of the temperature effect on the polarization, the enthalpy of activation at zero polarization (ΔH_o^*) was calculated from the plot of the log i_o against $1/T$. These plots are displayed in Fig. 1 for $AlCl_4^-$ solutions and in Fig. 2 for PF_6^- and BF_4^- solutions. The ΔH_o^* values were 9.9 kcal/mole for $LiAlCl_4$ concentrations > 0.5M; 6.4 kcal/mole for the 0.1M $LiAlCl_4$, and 5.1 kcal/mole for the 0.05M $LiAlCl_4$. No such change of ΔH_o^* with Li^+ ion concentration occurred with the ClO_4^- solutions (3).

The ΔH_o^* value for 1M solutions of $LiPF_6$ and $LiBF_4$ was 3.5 kcal/mole, a value considerably lower than the ΔH_o^* value for 1M solutions of $LiAlCl_4$ or $LiClO_4$. Two possible reasons for this striking difference in ΔH_o^* value are: (*a*) the water contents of the $AlCl_4^-$ and the ClO_4^- solutions were lower (the solutions that were analyzed showed lower water and were stored over Li for long times), or (*b*) fluorine-containing anions clearly influence the kinetics of the lithium/lithium ion reaction to the extent that the observed difference in ΔH_o^* is real.

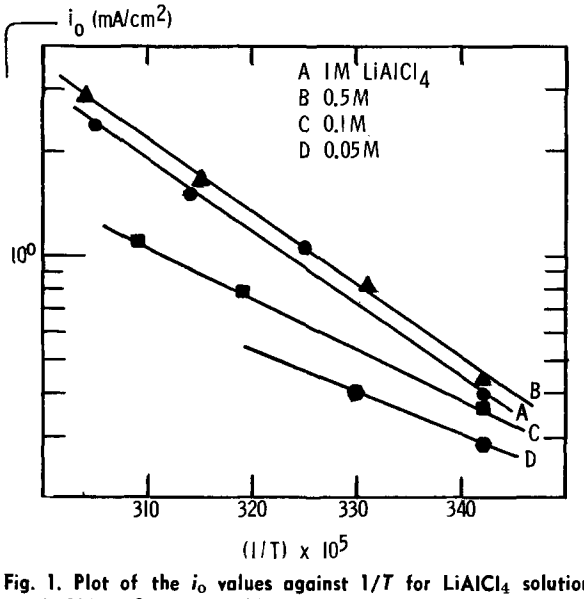

Fig. 1. Plot of the i_o values against $1/T$ for $LiAlCl_4$ solutions. Curve A, 1M; B, 0.5M; C, 0.1M; D, 0.05M.

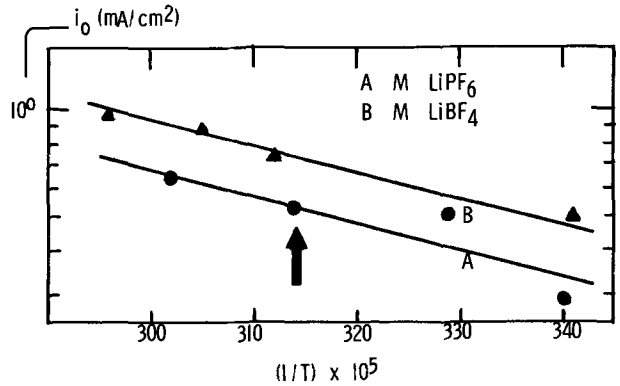

Fig. 2. Plot of the i_o values against $1/T$. Curve A, 1M $LiPF_6$; B, 1M $LiBF_4$.

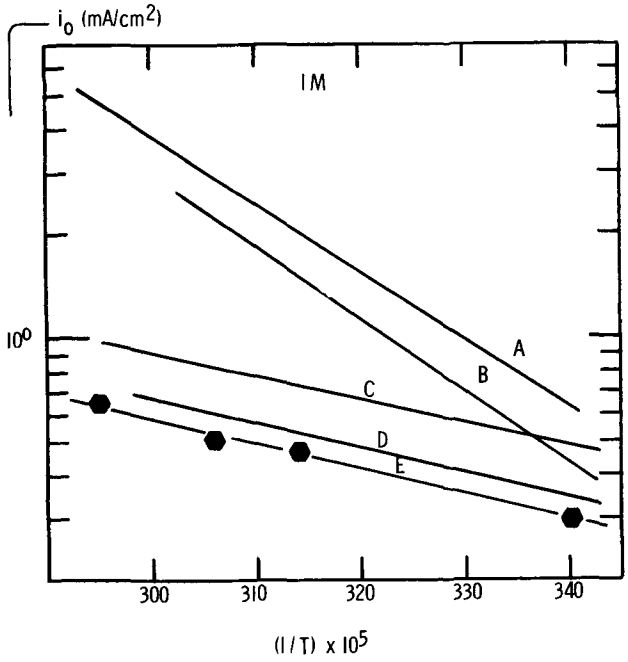

Fig. 3. Plot of the i_o values against $1/T$ for 1M solutions. Curve A, dry $LiClO_4$; B, $LiAlCl_4$; C, $LiBF_4$; D, $LiPF_6$; E, wet $LiClO_4$ (1800 ppm water).

To distinguish between these two causes, the following experiment was performed. To a solution of 1M $LiClO_4$ (containing about 20 ppm water) was deliberately added water to a concentration of 1800 ppm. The polarization runs were repeated in duplicate at 4 temperatures. The results (log i_o *vs.* $1/T$) appear in Fig. 3 where curve A corresponds to the dry 1M solution and curve E corresponds to the solution that contains the water. The other plots depict other 1M solutions shown in Fig. 1 and 2. Indeed, the wet solution exhibited a ΔH_o^* value virtually identical to the BF_4^- and PF_6^- anion containing solutions identified as curves C and D. The solute $LiPF_6$ is thermally unstable, and it etched the glass container in which it was stored. This etching implied the presence of water. The BF_4^- solution contained about 180 ppm water. These data confirm that the BF_4^- and PF_6^- solutions contained sufficient water to affect the electrode kinetics probably by film retardation of the electron transfer reaction (8). These data also suggest that in dry lithium salt solutions, the kinetics of the lithium/lithium ion reaction may be relatively independent of the nature of the anion of that salt. Hence, the selection of a specific solute (for a battery operation) should depend less on electrode kinetics, than on factors such as cost, ease of drying the solute, stability of the solution, and compatibility with other cell components.

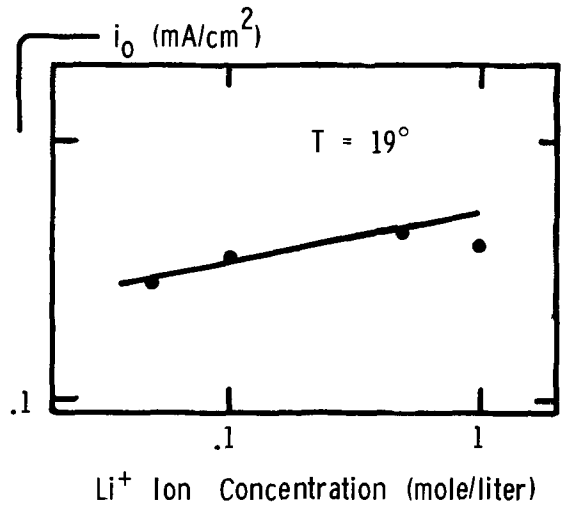

Fig. 4. Determination of the $(1 - \alpha)$ value from $LiAlCl_4$ solutions. Temperature = 19°C.

The transfer coefficient, α, was calculated indirectly from the slope of the plot $\partial \log i_0/\partial \log C_{Li}$ (9). Such data were taken only with $LiAlCl_4$ solutions. The data in Fig. 4 yielded a value for α of about 0.8. This value is somewhat higher than the 0.67 value reported for solid Li electrodes in $LiClO_4$-PC solutions (3, 10), or the 0.75 value reported for Li amalgams in LiCl-dimethylsulfoxide solutions (11). Whether these differences in value are real or whether the present value has been influenced by the presence of trace amounts of water in the dilute solutions of Li^+ ion, cannot be resolved.

Acknowledgments

On Causes of Error in Multiple Specular Reflection Studies

B. D. Cahan, Jean Horkans,* and Ernest Yeager**

Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

Recent studies in the laboratory have revealed that substantial errors were introduced in the earlier work (1) using multiple specular reflection to investigate the gold-electrolyte interface. While the earlier work was essentially correct in those trends which are independent of wavelength, significant errors occur in the wavelength dependence because of the large number of reflections used. These errors have been traced to scattering (primarily from imperfections in the electrode surface) and to impurity wavelengths from the monochromator. Both sources of error may become important when the number of reflections is sufficiently large and can be made negligible by using a small number of reflections. The purpose of this note is to call attention to these errors and to present some corrected results for gold.

Gold is of special interest for optical studies because of its absorption edge in the visible. The reflectivity of gold is close to unity in the red but drops off to ~30% in the blue. This edge can be used as a probe in studying the electronic properties of the metal surface (2).

The original work was done using mechanically polished bulk gold electrodes spaced to give 19-21 reflections. A large number of reflections was used to enhance the small relative change of light intensity occurring at each single reflection. Current work is being done using low numbers of reflections (1-7) from electrodes made by evaporating gold films onto smooth glass substrates.[1] The stability and noise level of the source and detection system have been improved to a point where a large number of reflections is no longer needed to enhance the sensitivity, and in fact, a single reflection is generally used.

Several factors contribute to the total intensity I of the light entering the photomultiplier after passing between two parallel electrodes spaced to give n reflections. These are represented as follows

$$I = R(\lambda_1)^n I_0(\lambda_1) + \int_{\lambda \neq \lambda_1} R(\lambda)^n I_0(\lambda)\, d\lambda + S_{eff} R(\lambda_1)^m I_0(\lambda_1) + C \quad [1]$$

where λ_1 represents the wavelength of interest, λ (unsubscripted) represents all other wavelengths, $R(\lambda)$ is the reflectivity of the surface at λ, and $I_0(\lambda)$ is the intensity of the incident light at λ.

The first term corresponds to the final intensity after an incident light of intensity I_0 undergoes n specular reflections, and is generally assumed to be the only significant term. However, recent work in this laboratory has shown that when a large number of reflections are used, other factors can become important. The second term represents the effects of any light impurity of other wavelengths, caused chiefly by scattering within the monochromator. The third term represents

Key words: electroreflectivity, electromodulation, specular reflection, gold.

[1] The two substrate materials used were microscope slides and slides cut from a drawn sheet of Corning 7059 glass. The results were found to be the same for both.

that fraction of the light which is scattered (rather than reflected) down the optical path between the electrodes such that it enters the photomultiplier. The symbol S_{eff} designates the fraction of the incident light scattered to the photomultiplier. The scattering originates primarily from nonspecular reflection caused by such things as scratches on the electrode surface, particulate matter that may be present in the solution, and small surface irregularities. Because of the geometry of the cell, light scattered from the entrance window undergoes essentially the same number of reflections as the direct light. The term C is included to represent all other stray light which does not pass through the optoelectrochemical system and hence is not electromodulated.

The scattering term is a gross oversimplification, since the number of reflections undergone by the scattered light is dependent on the scattering angle and where the scattering occurs. Some of the rationale for the form of this term may be seen from the following. Consider the scattering occurring at the j^{th} reflection. Let S_{eff} be the fraction of the light scattered so as to undergo k more reflections before entering the detection system. Then the intensity of this scattered component is

$$I_s = [R(\lambda_1)^j I_o(\lambda_1)]S_{eff}R(\lambda_1)^k$$
$$= S_{eff}R(\lambda_1)^m I_o(\lambda_1) \quad [2]$$

where $m = j + k$, and S_{eff} and m are to be viewed as effective average values and are wavelength dependent. Specific values of m can range from j to infinity, depending upon the angle the scattered light makes with the surface. The rapid attenuation of intensity with multiple reflection when $R(\lambda_1) < 1$, however, results in the lower values of m being much more heavily weighted than large values of m. Hence the effective average value for m would be expected to be substantially smaller than n. The scattered component of the light will still be electromodulated through the dependence of $R(\lambda_1)$ on potential.

Experimentally, the reflectivity is recorded while a triangular sweep is applied to the electrode. The quantity $(1/R)(\partial R/\partial E)_\lambda$ is sensitive to processes occurring at the electrode-electrolyte interface and is related to the shape of the reflectivity-potential (I *vs.* E) curves through

$$\frac{1}{R}\left(\frac{\partial R}{\partial E}\right)_{\lambda_1} = \frac{1}{n}\frac{1}{I}\left(\frac{\partial I}{\partial E}\right)_{\lambda_1} \quad [3]$$

with the assumption that only the first term in Eq. [1] is important. If other terms in Eq. [1] are also significant, Eq. [3] will no longer be valid. The way in which these other terms will affect the value of $(1/R)(\partial R/\partial E)_{\lambda_1}$ will now be examined for the case of a gold electrode with $n \simeq 19$.

Case I. High reflectivity region: $\lambda_1 > \lambda_{edge}$

For wavelengths in the red, where the reflectivity of gold is high (*e.g.* $R \simeq 0.9$), the intensity of the light reaching the photomultiplier after n reflections is still relatively large (*e.g.* $0.9^{19} = 0.135$) and the first term in Eq. [1] is generally predominant. Impurity wavelengths and the nonelectrochemically modulated stray light (*e.g.* light scattered from the cell windows) should be negligible. A significant contribution, however, can be made by the scattering term, particularly with mechanically polished or etched surfaces. As discussed above, scattering results in a lowering of the effective number of reflections to some value $m < n$. Thus, from Eq. [3], the value of $(1/R)(\partial R/\partial E)_\lambda$ found by assuming n reflections based on the geometry of the system is too small, since n is too large.

Case II. Low reflectivity region: $\lambda_1 < \lambda_{edge}$

For wavelengths in the blue, where the reflectivity is < 0.5, the quantity $R(\lambda_1)^n I_o(\lambda_1)$ is very small for large n (*e.g.* $0.5^{19} \simeq 10^{-6}$ and $0.25^{19} \simeq 10^{-12}$). With the emergent light being of such low intensity, the other terms in Eq. [1] can become significant.

Light impurities from the monochromator (caused chiefly by internal scattering) should also be considered. When the primary wavelength is heavily attenuated through many reflections, the impurity wavelengths can become important. The error is worst when the primary wavelength is in the blue, and there are impurity wavelengths in the red. The observed electromodulation will be caused by a distribution of wavelengths, and the value of $(1/R)(\partial R/\partial E)_\lambda$ will thus be in error.

The situation with respect to light scattered within the cell is the same in the blue as in the red. However, the magnitude of the effect is much larger in the blue due to the small size of the first term in Eq. [1]. Scattering causes the experimental values of the quantity $(1/R)(\partial R/\partial E)_\lambda$ to be too low in general. At wavelengths less than the wavelength of the absorption edge of gold (where R becomes small), the apparent $(1/R)(\partial R/\partial E)_\lambda$ drops off sharply.

When $\lambda_1 < \lambda_{edge}$, even such factors as incompletely compensated dark current and stray, nonelectromodulated light can become significant relative to the intensity of the specularly reflected light. In the evaluation of $(1/R)(\partial R/\partial E)_\lambda$ with Eq. [3], the experimental value for the total intensity I includes the background levels. When the background levels are small compared to the first term in Eq. [1], the error is negligible. When the background level is appreciable compared to the first term, as when $\lambda_1 < \lambda_{edge}$, the quantity I in the denominator of Eq. [3] is too large, and the apparent value of $(1/R)(\partial R/\partial E)_\lambda$ rapidly becomes much smaller than the true value.

The effects of these errors is illustrated in Fig. 1, which shows the dependence of $(1/R)(\partial R/\partial E)_\lambda$ on wavelength. The data were obtained for an evaporated gold film electrode using a single reflection. The data obtained with $\sim$ 19 reflections (1) are also included for comparison. The differences in shape between these two sets of data can be explained in terms of the above discussion. All of the values for $(1/R)(\partial R/\partial E)_\lambda$ obtained using multiple reflection are lower than those values from the single reflection data. The general shape of the two sets of curves is seen to differ most drastically at wavelengths where the reflectivity is no

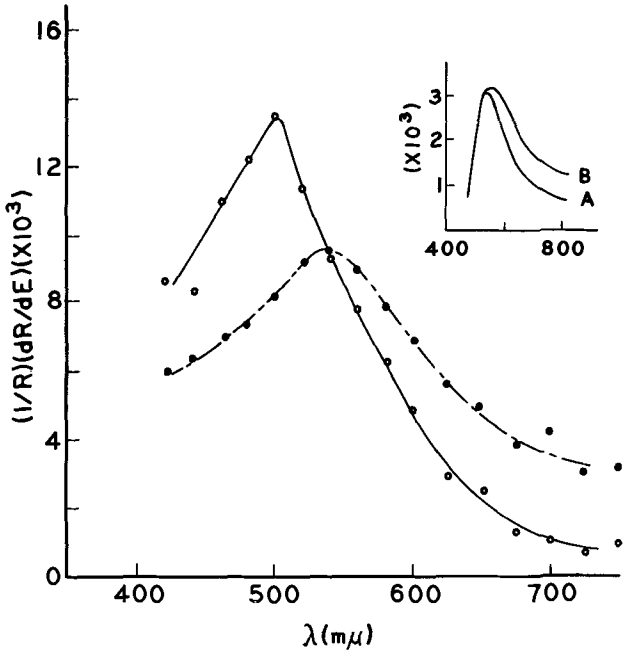

Fig. 1. $(1/R)(\partial R/\partial E)_\lambda$ at 0.2V (———) and 1.0V (———– – ———). The inset is the multiple reflection data of Ref. (1): A is at 0.52V, B is at 1.03V.

longer near unity. In the red the deviation is principally a result of a lowering of the effective number of reflections due to scattering. In the blue end of the spectrum even small amounts of light impurities, scattering, and background light levels can become important when the intensity of the reflected light is heavily attenuated through the use of a large number of reflections. Thus, the invariance of the peak in $(1/R)(\partial R/\partial E)_\lambda$ with respect to potential and the sharp dropoff in the blue obtained from the multiple reflection work appear to be artifacts.

Equation [3] can be used as a criterion for evaluating the importance of these spurious effects in a real system. If the only important term is the first term in Eq. [1], then for n reflections the slope of the reflectivity-potential curve, $(1/I)(\partial I/\partial E)_\lambda$, should be n times the slope of the curve obtained for a single reflection. Experimental data obtained using 1 to 7 reflections from evaporated films (2) showed that within experimental error the shape of the $(1/R)(\partial R/\partial E)_\lambda$ curve is independent of the number of reflections used.

The conclusions based on the multiple reflection work (1) need re-examination in light of the corrected $(1/R)(\partial R/\partial E)_\lambda$ data. As stated above, the peak at 550 mμ is artifactual. The position of the peak is actually dependent upon the potential at which the slope of the reflectivity-potential curves is obtained. The linearity of these curves at $\sim$ 550 mμ reported in the earlier work (1, 2) is fortuitous. This linearity is altered by adsorption of either ionic or nonionic species even at 550 mμ.

The actual peak in $(1/R)(\partial R/\partial E)_\lambda$ in Fig. 1 is much broader than that reported earlier using multiple reflection (1). The width of the peak casts doubt upon the hypothesis that a change in electrode potential produces a simple shift of the reflectivity curve along the wavelength scale as the electrode potential is changed. An attempt has been made (2) to observe this shift directly by recording the reflectivity *vs.* wavelength curve of an electrode potentiostated at various potentials from 0.0 to 1.4V *vs.* NHE. These curves were fitted to high order polynomials (5th to 15th degree), and the position of the inflection point was found to be invariant within $\sim$ 6 x 10^{-4} eV/V compared to the postulated shift (3) of 0.0108 eV/V. Present indications are that the primary effect of a change of potential is a distortion of the reflectivity-wavelength curve.

The Initial Oxidation Rates of Single-Crystal Copper and the Effect of Gaseous Pretreatment

A. W. Swanson** and H. H. Uhlig*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Submicroscopic faceting occurs when any Cu surface is heated in H_2 or N_2, favoring, according to oxidation rate data, the (111) and (100) faces, respectively. The subsequent thin film oxidation rate in O_2, 1 atm at 200°C, is determined by the rearranged surface rather than by the original orientation of the underlying single crystal. This accounts for an observed large effect of gaseous pretreatment on oxidation of single-crystal or polycrystalline Cu, and suggests one important reason for typical lack of agreement between previously reported thin film oxidation rates of many metals. Electropolished or faceted single-crystal Cu of original (100), (110), or (111) orientation follows the two-stage logarithmic oxidation equation. The present data are interpreted in terms of a model based on control of thin film oxidation rates by transfer of electrons from metal to oxide surface.

A review of the literature on oxidation behavior of Cu was presented by Rönnquist and Fischmeister (1). Although many papers on oxidation of Cu appear in the literature, only a limited number deal with quantitative data. This is especially true of results on the effect of crystal face. Furthermore some of the limited results previously reported are subject to question because of high-temperature surface treatment which may have seriously disturbed surface structure and orientation. Results are presented herewith in which such disturbing effects are both studied and avoided, and which serve as a more reliable basis for evaluating the mechanism of thin film oxidation kinetics.

The high-temperature pretreatment of Cu specimens in H_2 previous to oxidation studies is commonly practiced both to anneal specimens and to chemically reduce air-formed oxide films. It was shown by previous experiments (2), however, that pretreatment of this kind applied to a polycrystalline Cu surface at 450°C for 30 min can markedly influence the subsequent oxidation rate in O_2 at 200°C. The observed effects were found, on further examination, to depend on gas atmosphere and on crystal face. Nitrogen pretreatment of the (111) face increased the subsequent thickness of oxide formed in O_2 at 200°C (20 min) by a factor of 5, whereas pretreatment with H_2 had no effect within experimental error. For the (100) face, on the other hand, just the opposite effect resulted: N_2 pretreatment had no effect whereas H_2 pretreatment reduced the subsequently formed oxide thickness by a factor of 4. It was shown that the observed effects were not reasonably caused by (*a*) surface impurities or (*b*) by hydrogen dissolved in the Cu lattice. Instead it was proposed that submicroscopic faceting (not visible at 1000X) occurs during pretreatment schedules, the metal surface becoming rearranged so as to favor either rapidly or slowly oxidizing faces depending on the pretreatment atmosphere. The predominant face that develops is apparently that of lowest surface energy for the particular gas adsorbed on its surface. Accordingly, it was concluded that hydrogen adsorbed on Cu favors facets of slowly oxidizing approximate (111) orientation, whereas N_2 whose effect was ascribed to traces of oxygen in the metal or gas, favors the more rapidly oxidizing approximate (100) orientation.

Electron micrographs are now presented to show that faceting does indeed take place at pretreatment temperatures. The present investigation also carries out in further detail oxidation rate studies of the three close-packed faces (100), (110), and (111). These include thin film oxidation rates (up to 3500Å total oxide thickness) for untreated surfaces at 175°, 200°, and 225°C and for surfaces pretreated under a variety of temperatures and times.

Experimental

Copper single crystals (purchased from Virginia Institute of Scientific Research) were cut from a 2.5 cm diameter boule into specimens having a thickness of about 0.6 cm. Their final alignment was checked by x-ray. The specimens were mounted so that one face made contact with a spiral Nichrome wire heater employing mica sheet insulation and a back-up plate of thin 18-8 stainless steel. Temperature was measured by an insulated Chromel-Alumel thermocouple placed in a small hole carefully drilled in the side of the specimen.

Oxidation studies were carried out on the surface of the single crystal opposite to the side in contact with the heating element. Electropolishing a previously

Key words: logarithmic oxidation, single crystal copper, faceting, thin film oxidation.

metallographically polished surface (with heating element removed) provided a surface of essentially unit roughness factor. The electrolyte consisted of 70 v/o (volume per cent) of 85 w/o (weight per cent) orthophosphoric acid at 0°C to which 10 g/liter of cupric orthophosphate were added. Initial and final current densities ranged from 0.04 to 0.02 A/cm^2, respectively, over a period of about 20 min. The specimen was then taken out of the electrolyte without interrupting the current, immersed immediately in 10 v/o orthophosphoric acid, and subsequently washed in deaerated distilled water. The acid-water rinse was repeated until all copper reaction products remaining on the surface from the electropolishing operation were removed; final washing was carried out in five consecutive bottles of distilled H_2O through which CO_2 passed continuously. A stream of nitrogen gas was used to dry the specimens.

The oxidation runs, as described previously (2), were immediately carried out in a spherical Pyrex vessel measuring 9 cm diameter. This vessel containing the specimen was fitted by means of a ground glass joint (omitting grease) to a glass holder through which thermocouple and heating current wires were connected through tungsten seals. Nitrogen, O_2, or H_2 was admitted to the oxidation chamber by opening appropriate stopcocks. Nitrogen and H_2 were dried over $CaCl_2$, passed over Cu turnings at 400°C, and then through a liquid N_2 cold trap. Oxygen was only dried using $CaCl_2$.

Two oxidation procedures were followed. One involved pretreating the H_2-reduced electropolished specimen surface in N_2 or H_2 before oxidation in O_2 at 1 atm. The other involved direct oxidation in O_2 at 1 atm after electropolishing and cleaning; in this case the specimen surface was covered by a superficial oxide film which developed within the brief time the specimen was exposed to air at room temperature during assembly of the apparatus. In detail, the procedure was to rapidly heat the specimen to temperature (2 min to reach 200°C) in purified flowing N_2, then switch to O_2 at 1800 ml/min maintaining the temperature manually to within ±1°C. At the end of the oxidation period, the heating current was turned off and the cell flushed with purified N_2 at an initial flow rate of 4000 ml/min which was later reduced to 2000 ml/min. No visible surface changes occurred during heating in N_2 no matter how long the time, indicating that O_2 contamination was negligible.

Nitrogen pretreatment was carried out by heating to 450°C in purified N_2, switching to H_2 at 1 atm, 1000 ml/min at temperature for 5 min (to reduce the air-formed oxide film), shifting to the prescribed temperature in H_2, changing again to N_2 at 1000 ml/min, and holding for a definite time after which the temperature was lowered to 200°C and held. The cell was then flushed with O_2 at a rate of 1800 ml/min and oxidation allowed to proceed for 20 min. The cooling procedure was the same as that described previously for oxidation runs. Hydrogen pretreatment was carried out at specified temperatures and times analogous to N_2 pretreatment. Flushing with N_2 at 200°C previous to O_2 exposure, which was necessary for H_2 pretreatment in order to avoid explosive mixtures, was shown by experiment to be too low a temperature for occurrence of any surface rearrangement subsequent to faceting produced by H_2 at higher temperatures.

Oxide thickness was determined by coulometric reduction in N_2-saturated 0.1N KCl in accord with the technique described by Campbell and Thomas (3). The oxdized specimen was attached by springs to a small inverted glass cell separated by a rubber gasket lightly covered with stopcock grease. A silver-silver chloride reference electrode was mounted inside the cell near the specimen surface. The potential change of the specimen surface during reduction at constant current (0.2-0.8 mA/cm^2) was followed using a d-c amplifier and a chart recorder. From the time required to completely reduce the Cu_2O film (density = 6.0 g/cm^3), the oxide thickness was calculated, assuming a roughness factor of unity, to within ±10Å. Although the roughness factor was undoubtedly often greater than unity, the primary effects of gaseous pretreatment far overshadowed any accompanying effects on oxidation introduced by surface roughening.

Electron micrographs of the Cu surfaces were prepared from replicas obtained by applying a 1% Parlodion solution in distilled n-butyl acetate. To assure that the replicas reproduced the actual pretreated metal surface and not an air-formed oxide film, the plastic solution was applied to the specimen surface in the pretreatment cell at room temperature under a purified N_2 atmosphere and then dried in flowing N_2. The replicas were shadowed with Cr at an angle of 15° before photographing using a Siemens electron microscope.

Results

Oxidation rate data for the (100), (110), and (111) faces follow the direct logarithmic equation $y = k_1 \log (t/\tau + 1)$ where y is oxide thickness, t is time, and k_1 and τ are constants. Specifically, the three faces all show two-stage logarithmic behavior as shown in Fig. 1-3. Two-stage logarithmic behavior was shown previously to apply to single-crystal Cu by Lustman and Mehl (4), to single-crystal and to

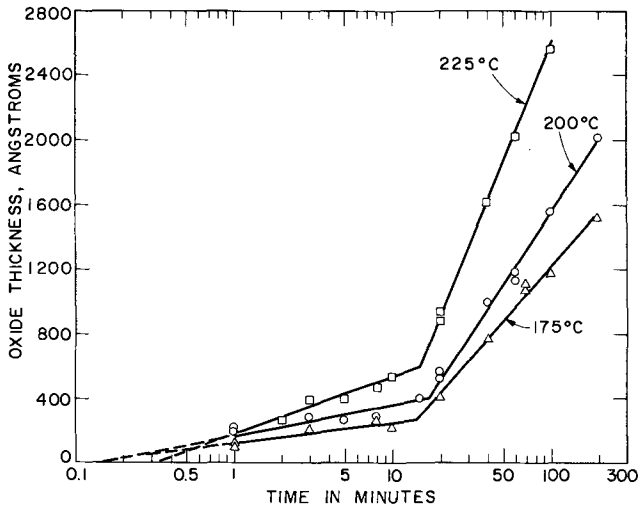

Fig. 3. Oxidation of electropolished (110) Cu in O_2, 1 atm, at various temperatures (air-exposed specimens).

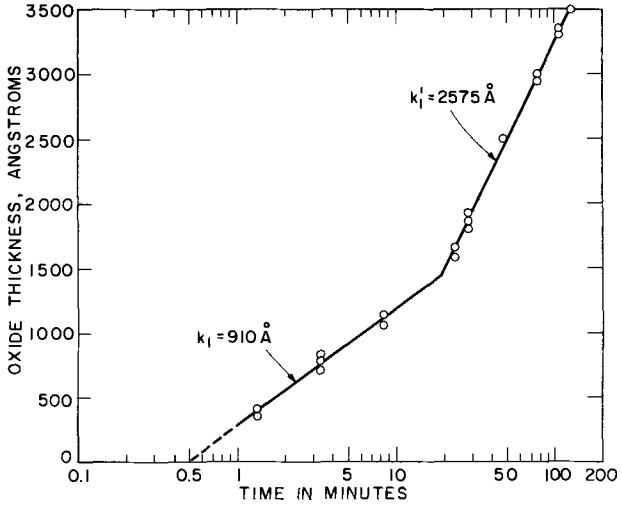

Fig. 4. Oxidation of electropolished (100) Cu in O_2, 1 atm, 200°C, plotting log $(t + \tau)$ and log $(t + \tau')$ instead of log t. Data from Fig. 1.

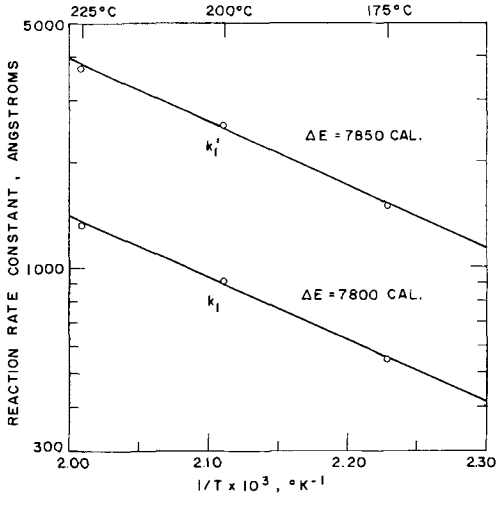

Fig. 5. Log first- and second-stage reaction rate constants for (100) Cu plotted with reciprocal absolute temperature.

polycrystalline copper by Bradley and Uhlig (2), and to polycrystalline Cu by Tylecoat (5), and by MacNairn and Uhlig (6). Two-stage logarithmic behavior can also be found in thin film oxidation data reported for Zn (7), Ni (8), and Fe (9).

Values of τ are obtained from data of Fig. 1-3 by extrapolating y *vs.* log t plots to $y = 0$, emphasizing points for which $t >> \tau$. Values of τ' for second-stage oxidation can be obtained on the basis that the following relation holds: $y - L = k_1' \log (t/\tau' + 1)$ where L is the thickness of oxide at the transition to second-stage kinetics. The value τ' is then the time at which y equals L. Values of k_1 and k_1', in turn, are obtained by plotting y *vs.* $k_1 \log (t + \tau)$ or y *vs.* $k_1' \log (t + \tau')$ which are also linear as shown by a typical plot of oxidation rate data for the (100) face at 200°C (Fig. 4) taking data from Fig. 1. Values of k_1 or k_1' obtained in this way are more precise, although not much different from corresponding values obtained by the usual plot of y *vs.* log t. Values of k_1, k_1', τ, and τ' as well as L [obtained from y *vs.* log $(t + \tau)$ plots] are listed in Table I.

By plotting log k_1 *vs.* $1/T$, where T is the absolute temperature, the activation energy of oxidation is obtained for each crystal face. A typical plot is shown in Fig. 5. Activation energies so obtained for 1st and 2nd stage oxidation are listed in Table I. From these values, it is apparent that the activation energies for first-stage oxidation decrease in the order of (100) > (110) > (111). Differences between (111) and (110) are small, but it is of interest to note that the reverse order of oxidation rates for these two faces is obtained comparing actual oxide thickness at a given time (see Fig. 2 and 3; also Table II). Oxide thickness leads to the order of oxidation rate: (100) > (111) > (110) in accord with the order previously reported by Gwathmey and co-workers (10-12), by Ali and Wood (13), and by Bradley and Uhlig (2). This suggests that the pre-exponential factor of the Arrhenius rate equation also differs with crystal face, accounting for an order of oxide thickness differing from the order of activation energies. It should be noted that activation energies for second-stage oxidation are approximately the same for all crystal faces. Accordingly values of k_1' also do not vary greatly with crystal face.

Oxide thickness plotted with log time in O_2 at 200°C for the (100) face pretreated 30 min in H_2 at 450°C is shown in Fig. 6. Note that the data accurately follow

Table I. Oxidation rate parameters

Face	Temp, °C	k_1 (Å)	τ (min)	k_1' (Å)	τ' (min)	L (Å)	ΔE, cal/mole 1st Stage	ΔE, cal/mole 2nd Stage
(100)	175	550	0.32	1520	13.0	1000	7800	7850
	200	910	0.34	2575	8.8	1440

Table II. Effect of H_2 pretreatment at 450°C, 30 min on oxide thickness formed subsequently at 1 atm O_2, 200°C, 20 min

Crystal face	No pretreatment, A*	H_2 pretreated, A*
(100)	1860 ± 59	715 ± 40
(111)	580 ± 51	620 ± 37
(110)	400 ± 13	585 ± 25

* Averaged for three or four specimens. Deviations are maximum values.

two-stage logarithmic kinetics and that the parameters of oxidation parallel those of the slowly oxidizing (111) face at the same temperature (Table I). Similarly, the (111) face pretreated 30 min in N_2 at 450°C follows two-stage logarithmic kinetics paralleling that of the (100) face. Pretreated surfaces accurately follow the two-stage logarithmic equation up to and including a total oxide thickness of 3200Å. In this connection, it should be noted that similarly pretreating the (100) face in N_2 or the (111) face in H_2 at 450°C (Table II) has no effect on subsequent oxidation rates in O_2 within experimental error of such measurements. On the other hand, pretreating the (110) face in H_2 increases the subsequent oxidation rate to that characteristic of (111) (Table II). Hence in accord with previous conclusions, N_2 pretreatment produces surface facets favoring the (100) orientation whereas H_2 pretreatment produces surface facets favoring the (111) orientation.

Electron Micrographs of Faceted Surfaces

The appearance of facets on Cu surfaces after low-temperature heat treatment in the order of 350°-450°C was missed in early work by other investigators probably because the facets are not visible under an optical microscope. Any observed effect of pretreatment on oxidation rate was typically ascribed to surface impurities. However, Parlodion replicas of electropolished (111) Cu, which show a smooth surface at 100,000X, show definite reproducible roughening typical of striations or faceting after N_2 pretreatment (Fig. 7). Similarly, H_2-pretreated (100) Cu also shows roughening with formation of facets of somewhat smaller dimensions than those produced in N_2-pretreated (111) (Fig. 8). The background facets for either face have dimensions in the order of 100Å; N_2-pretreated (111) shows a superimposed formation of larger areas in the order of 500Å. Their over-all small dimensions account for lack of sharp definition at 100,000X. Important was the observation that surface roughening accompanying facet formation is reversible, depending on the adsorbed gas, as is shown in the micrograph of Fig. 9. Here (100) Cu

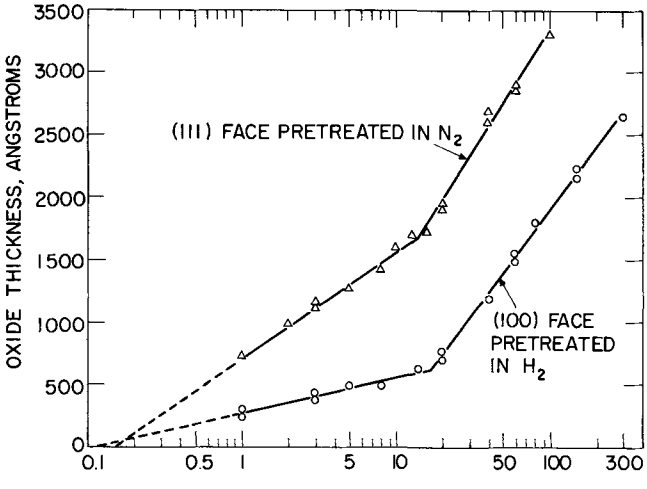

Fig. 6. Oxidation in O_2, 1 atm, 200°C, of electropolished (111) Cu pretreated in N_2 and of (100) Cu pretreated in H_2, 450°C, 30 min. (Initially H_2-reduced surfaces, not air-exposed.)

Fig. 7. Electronmicrograph of electropolished (111) Cu pretreated in N_2, 1 atm, 450°C, 30 min.

Fig. 8. Electronmicrograph of electropolished (100) Cu pretreated in H_2, 1 atm, 450°C, 30 min.

Fig. 9. Electronmicrograph of electropolished (100) Cu pretreated in H_2, 1 atm, 450°C, 30 min, then in N_2, 1 atm, 450°C, 30 min, showing reversible faceting.

was first faceted in H_2 at 450°C for 30 min, followed immediately by exposure to N_2 at 450°C for 30 min. The first gas produced faceting as in Fig. 8, but the latter gas favoring the original (100) face again produced a relatively smooth surface. The relatively larger oxide crystals which form on H_2-pretreated (100) Cu oxidized in O_2, 1 atm, at 200°C for 20 min is shown in Fig. 10. Electron micrographs, therefore, support the premise that faceting results from gaseous pretreatment; in turn, the large effect of gaseous pretreatment on subsequent oxidation rates leaves little doubt that faceting is the cause.

Faceting produced at temperatures in the order of 450°C is plausibly the result of surface rearrangement resulting from surface diffusion of Cu atoms. The effect

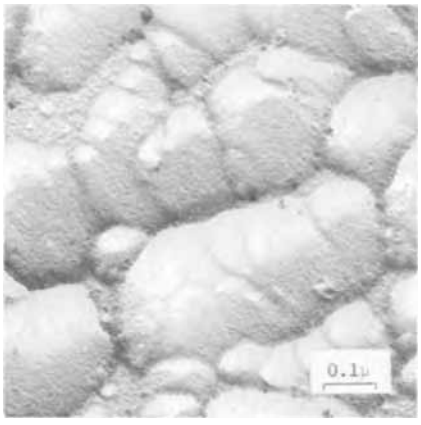

Fig. 10. Electronmicrograph of electropolished (100) Cu pretreated in H_2, 1 atm, 450°C, 30 min then oxidized in O_2, 1 atm, 200°C, 20 min.

of temperature and time on faceting, as measured by oxidation rates of pretreated surfaces, is shown in Fig. 11 and 12. It is apparent that surface rearrangement or faceting does not occur appreciably below 300°C within 30 min. Comparatively, at 450°C, it requires 10 min for optimum faceting of (111) in N_2 or analogously 20 min for (100) in H_2. The data for N_2 pretreatment provide a calculated activation energy of 9700 cal/mole and a similar but higher value for pretreatment in H_2. These low values are consistent with a surface diffusion process. It was also concluded by Tucker (14) that faceting of (210) Rh in 10^{-6} Torr O_2 at 350°C to form (100) and (110) surfaces, as revealed by low energy electron diffraction, occurs by surface diffusion.

Discussion

The close correspondence of the reaction rate constants k_1 and k_1', at 200°C for the H_2-treated (100) face with those for the untreated (111) face (Table I) plus the effects of H_2 pretreatment of all faces (Table II) indicate that (*a*) the oxidation rate is established by the specifically oriented facets that form during gaseous pretreatment and (*b*) the predominant orientation of the facets which form on exposure to H_2 at 350°-450°C is (111). Similar conclusions are drawn on comparing the oxidation parameters for the N_2-treated (111) face and the untreated (100) face, the corresponding predominant orientation of facets being (100). Not only do the faceted surfaces exhibit two-stage logarithmic behavior, similar to untreated surfaces, but the linear relation between oxide thickness and logarithm of time is valid up to oxide thicknesses of at least 3200Å which lie well beyond the equivalent dimensions of facets (100-500Å) as estimated from Fig. 7 and 8. The thickness of copper consumed in forming a 3200Å film of Cu_2O, for example, is 1920Å. Hence, it appears that the oxidation rate established by a faceted surface may continue beyond the time that the facets themselves are consumed. This suggests that the oxide-metal orientation relationships at the interface become stabilized soon after oxidation begins and hence orientation of facets dominates the oxidation process for an appreciable time within the thin film region. If the interface were not stabilized, the oxidation rate should gradually revert to that characteristic of the original crystal orientation, which rate can be either higher or lower than the initial rate. There is no evidence from thickness *vs.* log time plots that this reversion occurs.

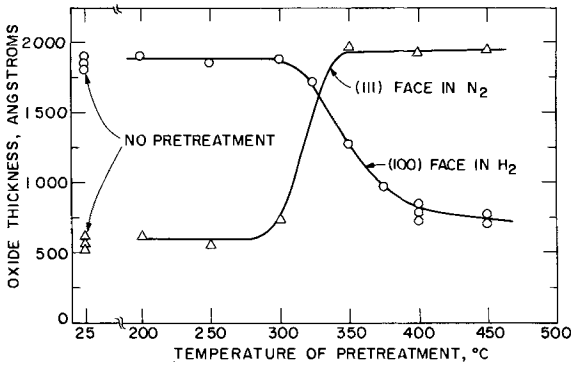

Fig. 11. Effect of temperature of pretreatment for 30 min on subsequent oxidation of Cu in O_2, 1 atm, 200°C, 20 min.

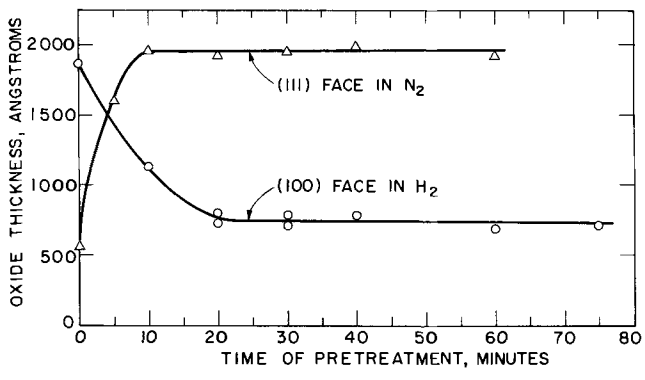

Fig. 12. Effect of time of pretreatment at 450°C on subsequent oxidation of Cu in O_2, 1 atm, 200°C, 20 min.

Actually, since the rates in second-stage oxidation tend to be the same and independent of crystal face, the influence of a faceted surface need extend only to the maximum oxide thickness characteristic of first-stage oxidation or to a thickness equal to L. Maximum values of L at 225°C range from 720Å for (110) to 2290Å for (100). Differences of roughness factor of the faceted compared to the equivalent nonfaceted surfaces may account for an increase in values of L for treated surfaces, but experimental variations of L are too large for any quantitative interpretation.

The reversible nature of faceting presently observed for copper surfaces, and which was also observed by Moreau and Bénard (15) for an 18% Cr-Fe alloy in H_2-H_2O atmospheres, reasonably results from a surface diffusion process stimulated by gas absorbed on the metal surface. The tendency is to form a surface of adsorbed gas-metal atoms of lowest free energy, the orientation of the resulting surface depending on the gas. The rate at which such a surface forms probably also depends on the nature of the adsorbed gas. This is suggested by results of Rhead (16) who reported that surface diffusion of Ag and Cu is enhanced by adsorbed oxygen. The apparently larger dimensions of facets which form on N_2-treated Cu compared to H_2-treated Cu (Fig. 7 and 8) can be explained accordingly by a higher surface diffusion rate of the Cu-O complex compared to the Cu-H complex.

After such time as oxide nuclei form and grow into a continuous film [within seconds at 500°C, 1 Torr O_2 (17); still less time at 200°C, 1 atm O_2], the surface orientation of metal with respect to oxide probably becomes "frozen," effectively blocking any further tendency for the surface to rearrange itself to form facets of orientation differing from that of the metal in contact with oxide. Hence, the oxidation rate is firmly established by the orientation relationships which exist at such time as the three-dimensional oxide film becomes continuous and the two-stage logarithmic equation is found to apply. After the oxide film grows to a thickness such that diffusion of ions or vacancies through the oxide becomes rate determining, the effect of metal face is no longer an important factor in establishing the oxidation rate, and the usual parabolic equation applies instead. This was shown by similar oxidation rates (within 20%) of various Cu faces at 900°C reported by Bénard and Talbot (18). The differing rates for Cu crystal faces at 600°C,

1 Torr O_2, reported by Ali and Wood (13), despite the parabolic equation being obeyed, suggest that conditions were intermediate between logarithmic and parabolic kinetics, and hence some of the effects of crystal orientation persisted.

The large effect of faceting on thin film oxidation behavior of Cu suggests that faceting should exert important effects quite generally. In this regard, it is of interest to note that work functions measured by Underwood (19) for the (100) Cu surface, on continued heating in vacuum approached the work function of (111) Cu presumably because facets of approximate (111) orientation slowly developed on the (100) face. Similarly, work function measurements by Köhler (20) on a copper single-crystal sphere cooled from the melting point in high vacuum showing no effect of crystal face, is probably explained by a faceted surface, all portions of the sphere having the same approximate orientation. The lack of good agreement in the thin film region for oxidation rates of metals in general, as reported by various investigators, suggests that uncontrolled faceting was probably a contributary cause in addition to any important effects of impurities. It is probable in the case of Cu that perturbations caused by surface treatment were sometimes minimized by a usual final vacuum treatment which reversed in part any faceting caused by an initial pretreatment of specimens in hydrogen. The observed effect of pretreatment of Cu surfaces with CO_2 at 250°C causing accelerated oxidation rates of the (111) face in O_2, as reported by Cathcart *et al.* (21), suggests that the effect of pre-exposure may have been one of submicroscopic faceting produced by the CO_2 atmosphere. The temperature in this case was somewhat below the minimum temperature found presently to produce faceting in H_2 or N_2 atmospheres. Similarly, the accelerated oxidation rate of pure Zr reported by Demant and Wanklyn (22) following vacuum annealing at 800°C for ½ to 48 hr, an effect which could be erased by electropolishing less than 10μ from the metal surface, is plausibly ascribed to faceting produced by the vacuum anneal. The authors sought in vain for a likely surface contaminant.

Based on the model of logarithmic oxidation kinetics according to which the rate is controlled by electron transfer from metal to oxide (6) it is possible to calculate the work function (w.f.) ϕ for each Cu face at the oxide-metal interface, as well as the density n of imperfections in Cu_2O at which electrons become trapped. The latter produce a growing uniform density negative space charge within the growing oxide next to the metal surface which impedes electron transfer, accounting for a slowing down of oxidation. The w.f. is calculated from the derived relation ΔE (activation energy, 1st stage) $= \phi - 3.6$ (electron volts) where ϕ is the metal w.f. as modified by contact with oxide and 3.6 eV is the electron affinity of O adsorbed on Cu_2O. The density of sites n at which electrons become trapped can be calculated from the reaction rate constant $k_0 = k_1/2.3 = \epsilon kT/4\pi nle^2$ and $3.6 = 2\pi nel^2/\epsilon$ where ϵ is the dielectric constant of Cu_2O (equals 10.5), e is the charge on the electron (4.80×10^{-10} esu), l is a parameter, which cancels out, equal to the calculated thickness of uniform charge density oxide at which the Fermi levels in oxide and metal become equal, k and T are the Boltzmann constant and absolute temperature, respectively. Calculated values of ϕ and n are listed in Table III using values of ΔE and k_1 listed in Table I.

Table III. Calculated values of Cu work function ϕ at oxide-Cu interface, and density n of electron trap sites in Cu_2O

Face	ϕ (V)	n (cm^{-3}) 175°C	200°C	225°C
(100)	3.95	2.1×10^{14}	0.86×10^{14}	0.47×10^{14}
(111)	4.08	34.5	9.8	2.5
(110)	4.16	44.5	17.8	4.7

The w.f. for polycrystalline Cu in vacuum (4.47V) is about 0.6V higher than for the value modified by contact of metal with oxide as calculated from oxidation rate data (8). The corresponding modification of present values, however, is expected to vary with crystal face. This can be seen from the fact that, since ΔE is the work necessary to transfer an electron from metal to oxygen absorbed on oxide, ϕ is made up of several terms, *e.g.*, $\phi_0 + X_0 - X_1 + X_2$ where ϕ_0 is the w.f. of metal in vacuum, X_0 is the increase of w.f. caused by immediate contact of metal with oxygen atoms, X_1 is the w.f. of oxide at the metal-oxide interface, and X_2 is the w.f. of oxide at the oxide-O_2 interface. Under equilibrium conditions, $X_1 = X_2$, but, in an actively growing oxide, defect structure differs at the two interfaces, altering corresponding values of w.f. Since crystal face determines the oxidation rate, which in turn influences the defect structure, it is logical to expect that X_1 and X_2 will also vary with crystal face. The value X_0 probably also varies with crystal face as was shown for Ni by MacRae (23). A fractional ¼ coverage of O on (111) Ni increased the w.f. by 1.2V whereas on (100) Ni the same ¼ coverage by O increased the w.f. by only 0.25V, indicating that (111) Ni in contact with O has a higher w.f. than (100) Ni similarly exposed to O. The modified w.f. probably explains why (111) is the face of Ni which oxidizes least in the thin film region as reported by Lawless *et al.* (24). A similar effect may explain why the order of w.f. for Cu in vacuum: $\phi_0(100) > \phi_0(111)$ as measured by Underwood (19) and Rose (25) is opposite to the order shown in Table III: $\phi(111) > \phi(100)$, and that (111) Cu correspondingly oxidizes at a lower rate than (100) Cu despite the order of w.f. values in vacuum.

Values of n, the density of electron trapping centers in Cu_2O, also vary with crystal face, being much larger for the slowly oxidizing (110) and (111) faces than for the more rapidly oxidizing (100) face. The average values are consistent with 10^{14} to 10^{15} holes or defect sites per cubic centimeter at >100°C in Cu_2O formed from commercial copper as calculated by Brattain (26) from conductivity and mobility measurements, although the values reported in Table III are obviously kinetic values and do not refer to an equilibrium state. For this reason, the observed imperfection densities in Table III vary with oxidation rates which in turn vary with crystal face.

The observed activation energies for second-stage oxidation, corresponding to growth of a diffuse space charge oxide, are largely independent of crystal face, being in the range 0.32 to 0.34 eV. According to the theory cited earlier (6) the activation energy for second-stage oxidation is equal to

$$-4\pi ne^2lL/\epsilon - e(\phi - v) + 4\pi e^2/\epsilon kT\left(\frac{d\,nlL}{d\,1/T}\right)$$

where v equals the electron affinity of adsorbed O (3.6V), and other terms have already been defined. In the original derivation, the third term above was inadvertently omitted. In view of the fact that observed values of nl decrease whereas observed values of L increase with temperature, the third term can sometimes be neglected, but this is probably not true generally. Since the values of ϕ, l, n, and L are all dependent on crystal face, the assumption can be made that these factors interact in such a manner as to result in the same approximate second-stage activation energy for the three crystal faces. One can also assume that continued oxidation beyond the first stage produces surface rearrangement and hence essentially the same metal-oxide orientation relations; the operating work function ϕ may then become independent of crystal face. Further consideration of Cu_2O semiconducting properties and of the detailed nature of the energy barrier at the Cu_2O-Cu interface are needed for further useful evaluation of such effects on the mechanism of thin film oxidation.

Conclusions

1. Submicroscopic faceting of Cu surfaces occurs during gaseous pretreatment, having a major effect on subsequent oxidation rates. Electron micrographs confirm that faceting occurs and that it is a reversible process.

2. Gaseous pretreatment in H_2 favors facets of slowly oxidizing predominately (111) orientation, whereas in N_2, the effects of which are ascribed to traces of O_2, the rapidly oxidizing predominately (100) orientation is favored.

Activation energies (9700 cal/mole) for facet formation are in accord with a surface diffusion process.

3. Oxidation rates, according to oxide thickness measurements, decrease in the order: (100) > (111) > (110), but, according to activation energies, in the order: (100) > (110) > (111).

4. All three faces follow two-stage logarithmic kinetics at 175°, 200°, and 225°C. This is also true of treated (100) and (111) faces oxidized at 200°C.

5. Work functions calculated from activation energies of oxidation indicate that modification of the metal work function at the metal-oxide interface is orientation dependent.

The Chlorination Kinetics of Tungsten, Molybdenum, and their Alloys

A. Landsberg, C. L. Hoatson, and F. E. Block

Albany Metallurgy Research Center, Bureau of Mines, U. S. Department of the Interior, Albany, Oregon 97321

ABSTRACT

The chlorination kinetics of tungsten, molybdenum, and three of their binary alloys have been studied as part of a Bureau of Mines effort to provide information of value when considering chlorine metallurgy processes. Tungsten and molybdenum were used for this initial investigation of alloys because they are chemically similar, form a complete range of solid solutions, and have been shown to chlorinate at temperatures sufficiently different so as to facilitate the determination of temperature dependency of reactivity by experiments based on the measurement of weight loss as the volatile chlorides are formed. Both the pure metals and alloys containing 22, 48, and 72 atomic per cent (a/o) molybdenum were found to chlorinate between 400° and 775°C at rates of 10^{-7} to 10^{-5} mole per square centimeter per minute, with the reaction rate dependent upon the 0.6 power of chlorine pressure. Molybdenum exhibited the highest reactivity, tungsten was the least reactive, and the alloys showed intermediate reactivity with respect to temperature. Single crystals of the pure metals showed marked anisotropy upon chlorination. When chlorinated, the polycrystalline alloy specimens of 22 and 72% molybdenum tended to show the crystalline anisotropy exhibited by the major component, while the 48% molybdenum specimen developed no pattern similarity to the pure metals.

Chlorine reacts with all metals at appropriate temperatures and pressures. Some of the chloride products of such reactions volatilize at the temperatures at which detectable reaction occurs, leaving a clean metal surface during chlorination. Tungsten and molybdenum exhibit this characteristic. Their chlorination kinetics, studied previously in our laboratory (3), show a temperature difference of over 200°C for equal chlorination rates of the two pure metals. Simple removal of reaction products, a wide range of reaction

Key words: alloy chlorination, tungsten-molybdenum chlorination, molybdenum-tungsten chlorination, morphology of chlorination.

No analysis was made for nonmetallic impurities.

temperatures, and the fact that these chemically similar metals form solid solutions in all proportions (2) suggest that the determination of temperature dependency of chlorination rate might be used conveniently for studying the effects of alloying on reactivity.

Experimental Work

Sample preparation.—The starting materials for the samples used in this study were metal powders supplied by the General Electric Company with average particle diameters of 3μ for the tungsten powder and 5μ for the molybdenum powder. Preweighed powders for each sample composition were mixed in a twin-V-shell blender for 15 min, passed through a 60-mesh screen, again mixed for 15 min, screened for a second time, and finally mixed for a third 15 min. Each blended composition was compacted isostatically, and the compacts were sintered in hydrogen at 2200°C for 10 hr. The resulting sintered bars of 90 to 95% of theoretical density were then consumable-arc-melted into ingots which were machined to a diameter of 1.5 in. and extruded at 1900°C to rectangular bars ⅜ x ¾ in. in cross section. These bars, after being conditioned by sand blasting to remove surface defects, were hot-rolled. A rolling temperature of 1450°C was used for the tungsten and the alloys, with a reduction of 20% per pass. The molybdenum was hot-rolled at 800°C, with a reduction schedule of 10% per pass. The final rolled thickness was 0.25 cm on all specimens. To reduce oxidation, all heating was done in an argon atmosphere. Sample specimens measuring 2.5 x 2.0 x 0.25 cm were machined from this rolled stock. Table I shows the impurity analysis for the samples used, and Table II shows the variation of sample composition from point to point as determined by an electron microprobe.

Single-crystal specimens were obtained from Materials Research Corporation. These materials were pure tungsten and molybdenum which contained no spectrographically detectable impurities. Crystal orientation was determined by x-ray reflection methods.

* These analyses were made randomly on highly polished sample surfaces with the electron beam of 1μ diameter to a depth of approximately 1000A. After reaction the surfaces were slightly roughened. Chemical analysis of large portions of the samples gave 22, 48, and 72 a/o molybdenum which reflect the composition changes in samples fabricated from the same ingot.

Procedure.—Chlorination-rate measurements were begun by weighing and measuring a metal sample. Weights were determined to the nearest 0.1 mg, and the rectangular measurements were made to the nearest 0.01 cm. The sample was then placed horizontally so that it rested slightly below center in a 28-mm Vycor[1] reaction tube which was held in a 3 x 30 cm tube furnace. C. P. grade argon and chlorine passing through control needle valves and calibrated rotameters were scrubbed in a bubbler containing sulfuric acid before entering the reaction tube. Gases leaving the reaction tube passed through another such bubbler and were vented via a laboratory hood. With the metal sample in place, argon was passed through the apparatus at the rate of 500 cc/min while the furnace was brought to operating temperature. The reaction-zone temperature was measured by a Chromel-Alumel thermocouple in a small Vycor tube positioned directly over the sample. After the reaction zone had been held at the desired operating temperature for several minutes, the reaction was started by substituting chlorine for part of the argon to give the desired chlorine concentration at a total gas flow of 500 cc/min. All work was done at 20% chlorine (approximately 152 Torr) except where noted. Reaction times ran from 15 min to 1 hr, during which the temperature remained constant to within ±2°C, and the gas flows were held to within 2% of the desired values. At the end of a run the chlorine flow was stopped and the argon flow increased while the entire reaction tube was cooled. When cool, the sample was removed and weighed. The weight loss was used to calculate the rate of reaction as moles of metal per minute per cm^2 of surface based on the geometric area and the average tungsten-molybdenum composition of the sample.

Results

The measured rates of chlorination, as moles of metal/cm^2 min, are shown graphically in Fig. 1. Data for each of the metal compositions given by open, filled, and partially filled symbols represent the experimental results from the three samples of each metal composition. Also each data point is the average of at least three replicate runs using an individual sample. The data show reproducibility from sample to sample, and the lines derived from a least squares analysis of the data according to the Arrhenius relationship agree quite well with our previous work on commercially prepared sheets of the pure metals. The least squares analyses are given in Table III. All samples changed in appearance as chlorination proceeded. Initially the surfaces appeared dull because of their sandblasted finish but became shiny as they reacted. The reaction rates increased during the two or three initial reaction experiments and then remained constant for an extended period of chlorination during which the experiments were made for the reported data. After the constant rate period of chlorination the samples were rough on all surfaces and very jagged on the edges in the direction of rolling and the reaction rate decreased slightly. These decreasing-rate data are not reported here. The composition of the sample sur-

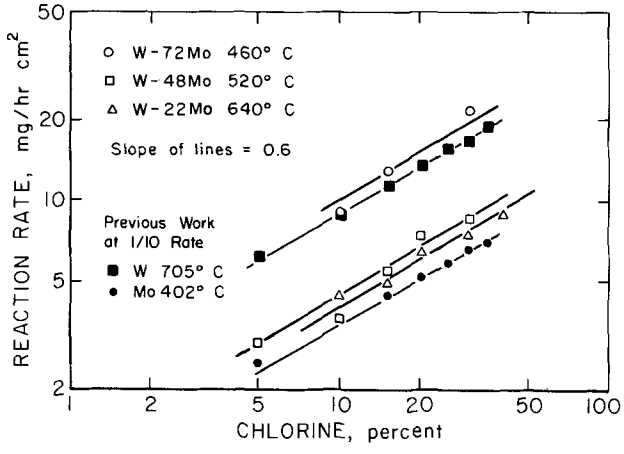

Fig. 2. Effect of chlorine pressure on reaction rate

faces showed slight preferential loss of molybdenum upon chlorination, as indicated by the electron microprobe measurements in Table II. The data, although presented in the table in pairs of analyses for before and after reaction, do not necessarily represent exactly the same location on the surface before and after reacting. These surfaces were only slightly reacted before the final microprobe analyses were made. Other tests in which over half of the entire sample was removed by chlorination showed no depletion of molybdenum. The resulting, very rough surfaces hindered accurate microprobe analyses.

The effect of chlorine pressure on the reaction rate is shown in Fig. 2. As in our previous work with the pure metals, the alloys showed a rate of chlorination

where R is the chlorination rate in moles per cm² min with 20% chlorine and T is the absolute temperature in °K.

approximately dependent upon the 0.6 power of chlorine concentration. At the highest rates of chlorination measured, changes of total gas flow rates from 500 to 1000 cc/min produced no change in measured chlorination rates demonstrating that true chemical reaction was the rate-limiting factor.

Upon chlorination all samples changed in appearance because of the anisotropic attack of chlorine. The polycrystalline metals and alloys developed ridges and troughs running in the direction in which the samples had been hot-rolled. Figure 3 shows the trimmed ends of the molybdenum sample before and after chlorination. Interestingly, a sample which had been reacted at 1200°C did not develop the deep ridges and troughs but remained rather smooth with the individual grains becoming very evident. Microscopic views of these reacted samples are not of high quality because of the deep etching and low depth of field at high magnification. Nevertheless, in Fig. 4 these views do reveal a similarity between the reacted textures of tungsten and tungsten-22 molybdenum, and between molybdenum and tungsten-72 molybdenum with the tungsten-48 molybdenum texture being distinct. The molybdenum after chlorination at higher temperatures shows

reaction produced rows of small circles running in different directions on adjacent crystals. This produces crystal differentiation on a macroscopic scale.

Single crystal samples show the anisotropic attack of chlorine quite clearly. Figure 5 is a photograph of two tungsten single crystals which have been extensively chlorinated at 700°C and a molybdenum crystal chlorinated at 1200°C. These specimens were cylindrical before reaction occurred. Because of the high reaction rate of molybdenum at 1200°C, gaseous diffusion limited the reaction rate, causing the somewhat rounded corners on the single crystal; however, close examination shows distinctive surface characteristics at 90° intervals. Electron microscope views in Fig. 6 of a molybdenum single crystal show surfaces in the early stages of attack by chlorine, and Fig. 7 and 8 show surfaces parallel or nearly parallel to the {100}, {110}, and {410} planes which have developed after extensive chlorination. Nomarski interference-contrast microscopic views of similar surfaces are shown in Fig. 9. Similar surface configuration resulted from chlorination at all chlorine concentrations and temperatures studied (except for the high-temperature experiments specifically noted).

Tungsten single-crystal surfaces developed similarly upon extensive chlorination. Two planar surfaces which formed on an originally cylindrical crystal were parallel to the {100} and {210} planes. Electron microscope

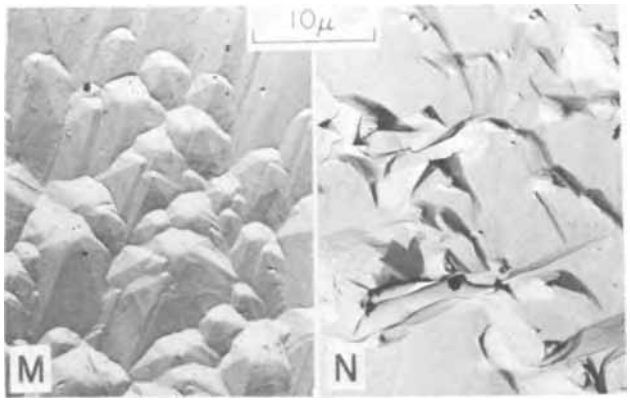

Fig 6. Electron micrographs of single-crystal molybdenum at the onset of chlorination. M. Reacting surface, N. Nonreacting area.

views of these surfaces are shown in Fig. 10. Optical microscope views of the surfaces which developed parallel to the {100}, {210}, and {320} planes are shown in Fig. 11.

The molybdenum crystal reacted with chlorine at 1200°C showed a series of microscopic rod-like depressions over the entire surface. These cylindrical pits were all parallel. Viewing the crystal microscopically from various angles revealed that the pit spacing varied periodically every 90° on surfaces parallel to their length, but perpendicular to their length the pits appeared as round holes in the metal surface.

Discussion

The chlorination of tungsten and molybdenum in the temperature range studied shows striking similarity to certain oxidation reactions of these metals. Perkins, Price and Crooks (5) have shown that within boundaries defined by temperature and oxygen pressure tungsten is oxidized without formation of an oxide scale at a rate proportional to the 0.59 power of the oxygen pressure. Single-crystal tungsten used by these investigators shows anisotropic attack by oxygen in this region. Other investigations (4, 7) have shown that oxygen attacks both tungsten and molybdenum with a similar fractional exponential dependence on oxygen pressure. Like the oxidation of these metals, the appearance of the chlorination-reaction-produced surfaces changes as the temperature rises. This was shown clearly for molybdenum chlorinated at 1200°C, the maximum temperature obtainable in our equipment (see Fig. 3 and 5). Tungsten surfaces chlorinated at 1200°C showed some dissimilarity to surfaces chlorinated at lower temperatures.

The marked anisotropy of the chlorination of tungsten and molybdenum as evidenced by the resulting morphology of single crystals demonstrates that certain crystal surfaces are reactive and also the fact that certain crystal planes are not chlorinated. This

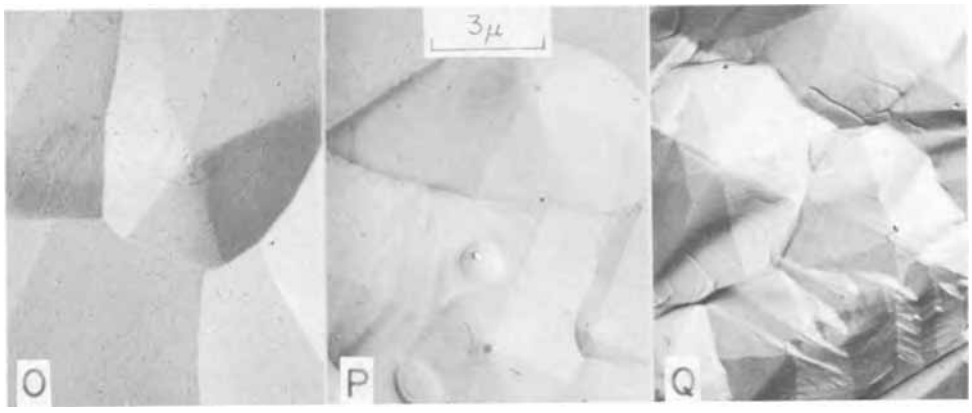

Fig. 7. Electron micrographs of chlorinated molybdenum single-crystal surfaces parallel to the {100} plane.

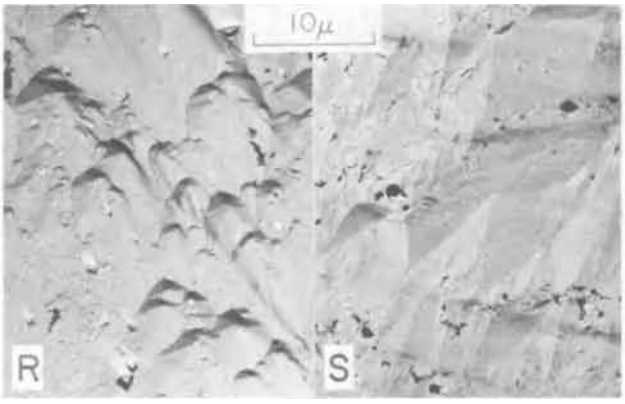

Fig. 8. Electron micrographs of chlorinated molybdenum single crystal surfaces. R is a {410} surface; S is a {110} surface.

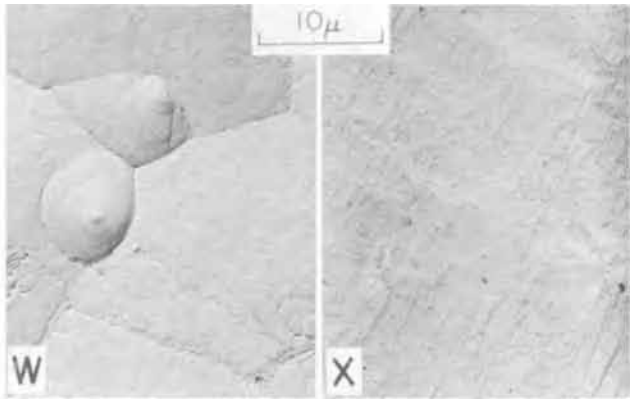

Fig. 10. Electron micrograph of chlorinated tungsten single-crystal surfaces. W is a {100} surface; X is a {210} surface.

is clearly shown in Fig. 5 by the very sharp corners on the reacted tungsten single crystals. Figure 6 also illustrates a contrast between the reactive and nonreactive faces of a single crystal. Even though the surfaces shown had only been exposed to chlorine for a few minutes, it is very clear that a marked pattern had already developed on one face while an adjacent area showed no change from the unreacted surface. Such areas alternated around the cylindrical crystal every 45°.

Examination of Fig. 7, 8, and 9 reveals a system of pyramids developed by chlorination on {100} molybdenum surfaces and surfaces close to {100}. The large surface area resulting from these pyramids (*e.g.* frame T) gives an indication as to why molybdenum upon chlorination recedes rapidly perpendicular to {100} planes. On some higher order planes similar pyramids appear slanted, and a pencillike structure is noted with the pyramid being in the sharpened-point position. A trisoctahedron form best correlates with the single-crystal morphology developed as the result of molybdenum chlorination.

Tungsten crystals also produce an octahedral form when chlorinated. The square pyramids shown in the electron photomicrograph of Fig. 10, W are severely rounded, but photomicrographs in Fig. 11 of the chlorinated {100} and {320} surfaces depict a sharper series of angular faces. The {210} faces, which reacted rather rapidly, show no clearly defined geometric pattern other than a series of shallow lines. The best geometrical shape that conforms to these chlorination-developed surfaces is a tetrahexahedron with faces made up of {210} planes.

From these tentative identifications of the reactive planes of tungsten and molybdenum, a difference in surface reactive geometry may be postulated for the two metals even though the over-all chemical mechanism may be similar. Indeed, this is observed in the chlorination-produced faceting under equal magnification and developed on materials which had a similar crystal texture due to rolling. [Reference (1) gives a rolled texture of (100) <011> for both tungsten and molybdenum.] The alloys rich in one metal develop a chlorination faceting similar to that of the pure metal and show a chlorination dependency on temperature similar to that of the high-content metal, but the alloy with nearly equal numbers of tungsten and molybdenum atoms develops a surface quite different from either of the pure metals. Dependency of chlorination rate on the nearly half power of the chlorine pressure may be attributed to the breakup of the chlorine molecule on the metal surface, and others (6) have shown that atomic chlorine is more reactive towards molybdenum; indeed it may be the only reactive chlorination species.

Positive identification of the reacting metal surfaces needs to be made, and a correlation between the various temperature-dependent regions of chlorination and the role of the metal surface must be determined before a complete understanding of the chlorination of tungsten and molybdenum and their binary alloys is realized. Such determinations would answer the question as to whether a certain crystal-oriented morphology develops on tungsten, molybdenum, and their alloys because of the atoms present or because of the temperature-chlorine pressure region of the reaction.

Mechanism of Sulfidation of Nickel-Chromium Alloys at 700°C as Inferred from Inert and Radioactive Marker Techniques

G. Romeo,*,[1] W. W. Smeltzer,* and J. S. Kirkaldy

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Sulfidation experiments have been carried out on a Ni-20 w/o Cr alloy using platinum markers and the tracer S^{35} to elucidate the transport mechanism for the diffusion-controlled formation of the duplex sulfide scale. It is concluded that outward diffusion of nickel and chromium accounts entirely for the growth of both layers. Chromium sulfide, being more stable than nickel sulfide, is formed by decomposition of the latter at the boundary between the two layers. This process is compensated for by a rapid growth of nickel sulfide at the gas-scale interface. It has been unequivocally demonstrated that sulfur diffusion does not contribute significantly to scale growth.

The results of a kinetic and morphological study of the scale formation on nickel-20 w/o (weight per cent) chromium alloys in hydrogen sulfide-hydrogen atmospheres were presented in an earlier publication (1). We report in this paper the results of a further series of experiments designed to elucidate the mechanism of the process. In particular, platinum markers and radioactive sulfur have been used to establish the contribution of the different species to the net transport of matter across the sulfide scale formed as a corrosion product. Such techniques have been widely employed in the past few years. We refer the reader to the papers by Mrowec and Werber (2-4) for further information and to an extensive and up-to-date bibliography on this subject in a recent paper by Holt and Himmel (5).

Experimental

Platinum marker experiments.—Specimens approximately 1.5 x 0.5 x 0.1 cm were cut from sheets of Ni-20 w/o Cr alloys. Details on composition and metallographical preparation prior to sulfidation have been reported in our earlier publication (1). In the same publication, the assembly was described for the concurrent sulfidation in hydrogen sulfide-hydrogen atmospheres of four specimens. The specimens could be raised to a relatively cold zone of the assembly and quenched after different reaction times. All experiments were carried out at 700°C which, as discussed in the previous work, was convenient for avoidance of the formation of a liquid phase. H_2S/H_2 atmospheres were used that ranged from 5 to 60 v/o (volume per cent) in hydrogen sulfide it being previously established that the pressure of sulfur has a negligible effect on the reaction mechanism.

Short pieces of 50μ diameter platinum wire were stretched across the surface of the specimens and electrically spot welded at several points and to the edges. Satisfactory adhesion to the surface of most markers was attained and the specimens could be sulfidized in the upright position. During later examinations of scale cross sections comparison of the relative positions of

Key words: sulfidation, nickel-chromium, markers.

the different markers in a given specimen allowed one to recognize those with poor adhesion and to ignore them in the subsequent analysis. Specimens were mounted in epoxy resin as cross sections, polished, and examined metallographically.

Radioactive marker experiments.—Radioactive sulfur S^{35} is a convenient isotope for studies on the mechanism of sulfide scale formation. The advantages consist in its commercial availability, its comparatively long half-life (~90 days), and its decay with the emission of β^- radiation only. The latter characteristic sensibly reduces the number of precautions that have to be taken in handling the radioactive material.

The experiments consisted in first sulfidizing the alloy specimens with normal sulfur and subsequently with the radioactive isotope, or vice versa. It is assumed that the mechanism of reaction is the same for sulfur obtained from the decomposition of H_2S or directly from sulfur vapor (1, 7).

An assembly was designed (Fig. 1) similar to that used by Meussner and Birchenall (6) in which the specimens could be exposed to a sulfur atmosphere containing a small amount of S^{35}. A few coils of platinum wire were wound around the specimens to prevent contact with their containers. One or more specimens could be located in pockets at one end of a Vycor cell. At the opposite end was located a bulb containing remelted sulfur flowers. Some drops of a benzene solution of S^{35}, supplied by Amersham/Searle Company, corresponding to a total activity of approximately 1 mC were added to the normal sulfur. The reaction vessel was then sealed off in vacuo, and the sulfur-containing bulb was rapidly heated up to about 200°C, corresponding to a sulfur vapor pressure of roughly 3×10^{-3} atm. Finally the end of the vessel bearing the specimens was inserted into a furnace previously brought up to 700°C. The sulfidation was allowed to proceed for a selected time at the end of which the Vycor cell was quickly cooled down to room temperature and opened. The specimens could then be given further treatment with ordinary sulfur at the same temperature, either in a similar cell or in the assembly used for the platinum marker experiments.

Alternatively, sulfidation with normal sulfur could be followed by treatment with the radioactive isotope. In this experiment the reaction had to be stopped for a time at the end of the first stage for transfer of the specimens from the reaction vessel containing the isotope to the one containing ordinary sulfur or vice versa. This could have affected the experiments insofar as the thermal shocks may have caused strains and cracks in the sulfide scales. However, a critical appraisal of the results indicates that these artifacts do not seriously confuse the interpretations.

Cross sections of the specimens were prepared metallographically and their autoradiographs taken, exposing Kodak "contrast process ortho" films by contact with the radioactive surface. This technique is in general use and details can be found in several publications (8).

Results

In Fig. 2, micrographs are given of the cross sections of four specimens sulfidized at $\sim 10^{-7}$ atm sulfur for

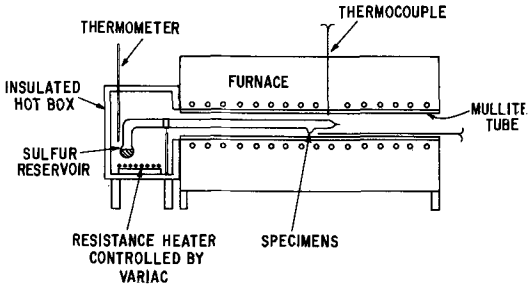

Fig. 1. Apparatus for sulfidation with radioactive sulfur

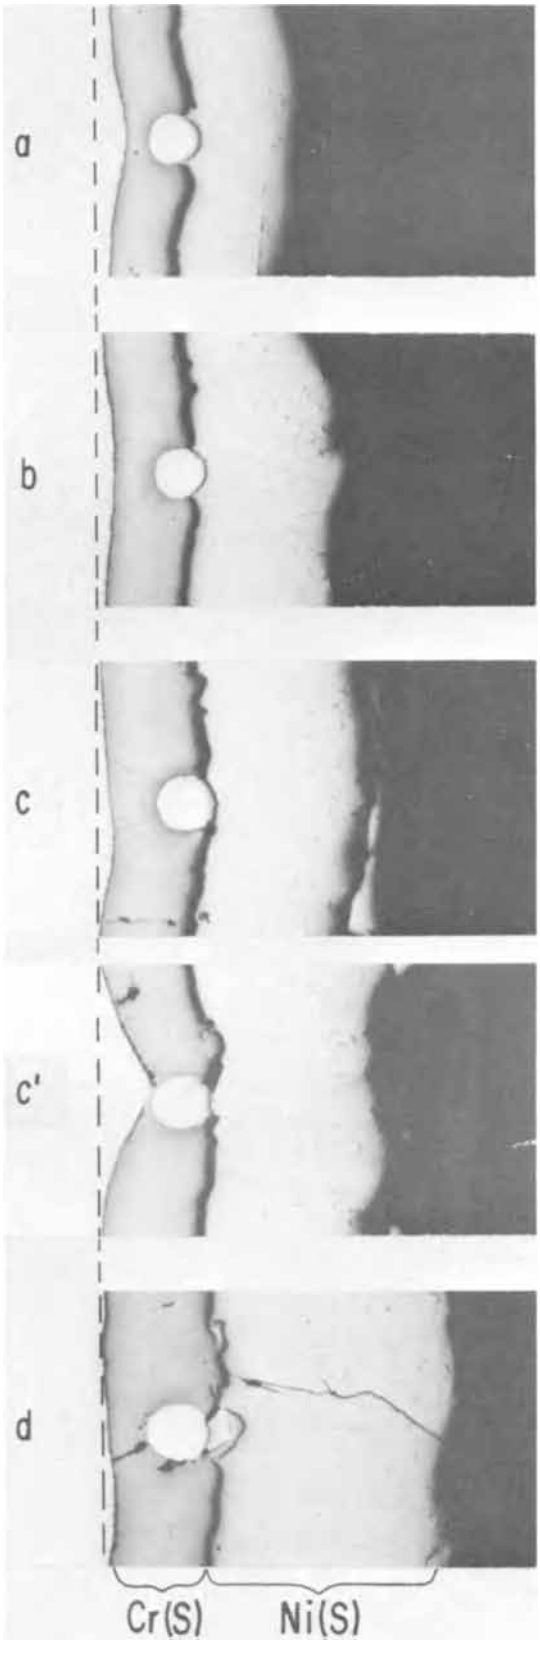

Fig. 2. Positions of the platinum markers after different reaction times. Micrographs a, b, c and c', d correspond to 5, 7, 10, 15 hr sulfidation at 700°C and $\sim 10^{-7}$ atm sulfur, respectively. Micrograph c' is indicative of the "undercutting mechanism." Magnification 135X.

5, 7, 10, and 15 hr, respectively. In addition to the remarkable compactness of the scale, one can observe that the platinum markers are situated in the inner chromium sulfide layer close to the adjacent nickel sulfide layer. This position leaves some space between

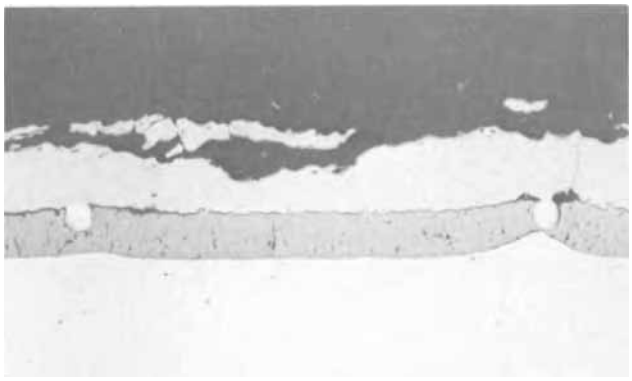

Fig. 3. Morphology of alloy and sulfide scale with relation to two platinum markers. Specimen sulfidized for 15 hr. Magnification 85X.

the bottom of the platinum marker and the metal interface. The thickness of this space is constant with the time within the limits of accuracy of our metallographical observations as suggested by the dashed line. Micrograph c' in Fig. 2, and Fig. 3, exemplify the "undercutting mechanism" (6) that takes place during the scaling of the alloy. The platinum marker acts as a barrier to the outward transport of metal ions thus impeding scale formation at this point. The space progressively made available by lateral depletion of the metal is apparently filled with chromium sulfide by plastic deformation until the "hill" under the marker disappears. The marker is gradually imbedded in chromium sulfide as the reaction proceeds. This observation indicates that thickening of the inner layer involves outward diffusion of chromium. It is also evident that the faster growth of the outer nickel sulfide layer must occur above the platinum marker by the outward diffusion of nickel.

The results of the tracer tests are perhaps even more definitive. Using the assembly of Fig. 1, specimens were sulfidized first with normal sulfur and then with the radioactive isotope. Figure 4 shows a beveled section of one of these specimens, which underwent treatment for 5 hr with normal sulfur and for 7 hr with S^{35} at 700°C. The layer of nickel sulfide grown during the second stage of the reaction on top of the pre-existing scale can be clearly seen. In Fig. 5, the micrograph of a specimen which had reacted for 6 hr with normal sulfur and for 10 hr with S^{35} is exhibited together with the corresponding autoradiograph.

Radioactive tracers have an advantage over other types of markers, primarily because they do not cause surface damage and take part in the reaction without interfering mechanically with the growth of corrosion products. However, this kind of macro-autoradiography has its limitation in the diffuseness of the radioactive trace. This is due to the fact that not all the radiation coming out of the specimen cross section hits the film perpendicularly. It is nonetheless clear from Fig. 5 that the radioactive isotope does not move into the layer of nickel sulfide grown in the first stage of the reaction except when, through cracks in the scale, it can reach and react with the metal core.

The results of the reverse two-stage sulfidation experiment are presented in Fig. 6. Here the ends of the cross sections of three specimens are shown, their characteristic features being easily comparable with the corresponding autoradiographs mounted opposite in a mirror-like arrangement. A comparatively low magnification has been chosen in order to include in the micrograph a large area of the specimen and at the same time keep the enlargement of the original autoradiograph within suitable limits. The magnification is identical for specimens and autoradiographs. All three scales exhibit under the optical microscope the familiar duplex structure, although this does not show in the picture for specimen (a). An intermittent gap

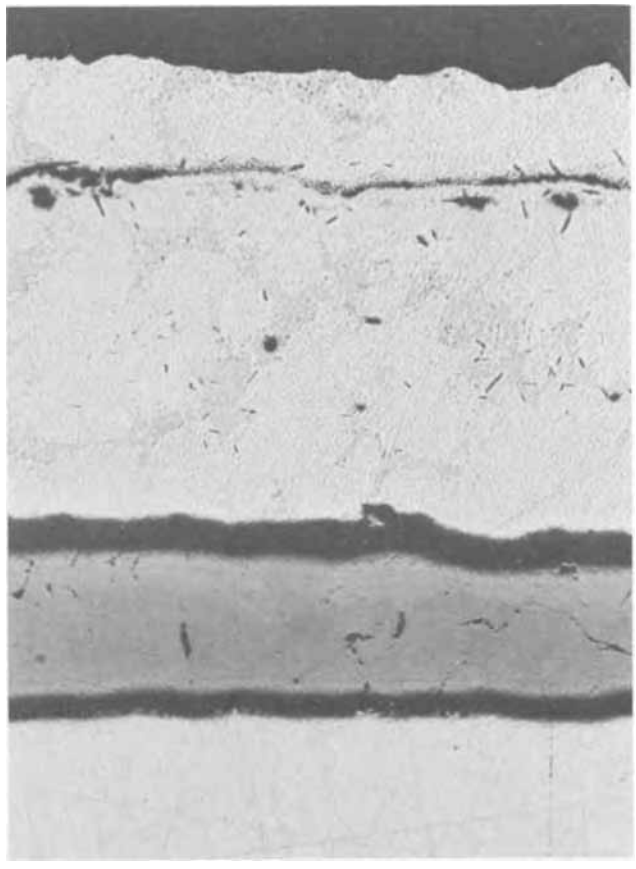

Fig. 4. Beveled section of a specimen treated for 5 hr with normal sulfur and 7 hr with radioactive sulfur at 700°C. At the top is the nickel sulfide layer grown in the second stage of the reaction. The inner layer boundaries are not properly focused, due to pronounced rounding off of this area during polishing. Magnification approx. 160X.

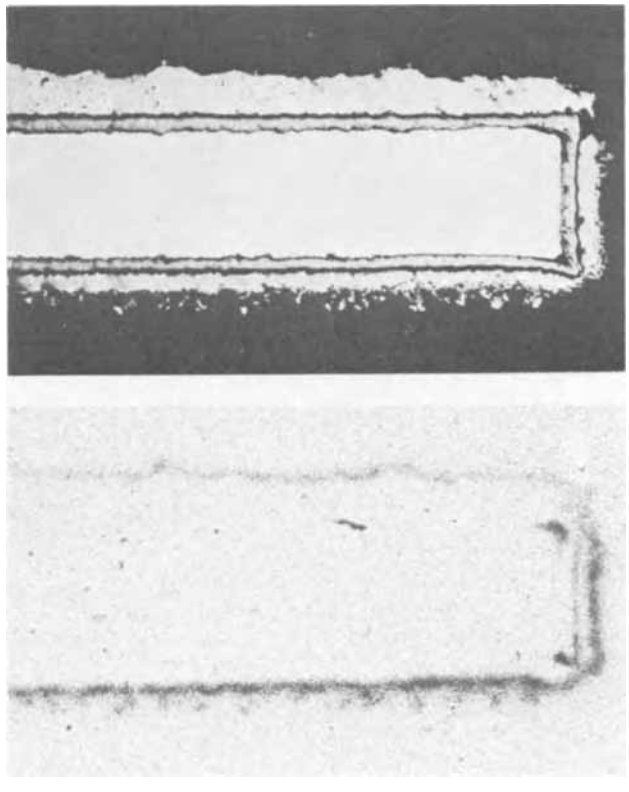

Fig. 5. Cross section of specimen treated for 6 hr with normal sulfur followed by 10 hr with radioactive sulfur at 700°C. At the bottom is the corresponding autoradiograph. Magnification 21X.

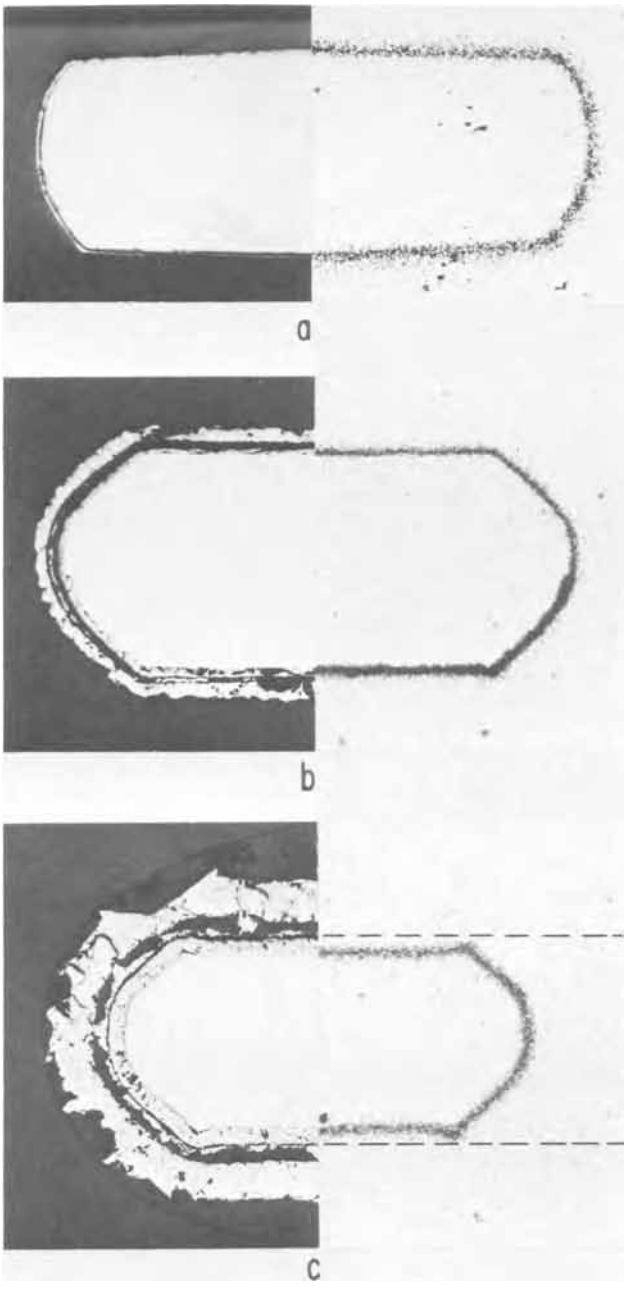

Fig. 6. Micrographs and autoradiographs of specimens sulfidized first with radioactive, then with normal sulfur. The three specimens have been treated for 15 min with S^{35}. Subsequently specimens (b) and (c) have been sulfidized with normal sulfur for 2 and 8 hr, respectively. Mounted opposite to the cross sections are the corresponding autoradiographic traces. Inner and outer layer in (b) and (c) are separated by an intermittent gap. This gap formed not as a general sulfidation feature but during the final quench in this particular type of experiment. Magnification 27X.

between the two scale layers has developed, as seen in specimens (b) and (c). Specimen (a) was treated for 15 min at 700°C with only radioactive sulfur, while specimens (b) and (c) after identical treatment underwent further sulfidation at the same temperature in H_2S/H_2 atmosphere (sulfur pressure $\cong 10^{-6}$ atm) for 2 and 8 hr, respectively. It is evident, upon comparing (a) and (c), that after 8 hr the tracer is no longer present in the outer nickel sulfide layer. The thickness of trace (a) looks wider than that of the other two traces because in this case no layer of inactive sulfide is absorbing the side scattered radiations. It can be seen that the inner border of the radioactive traces always coincides with the metal interface. Moreover, for specimen (c) part of the chromium sulfide layer lies outside the tracer perimeter, as indicated by the dashed lines. In conclusion, the distribution of radioactive sulfur remains essentially of constant width in the vicinity of the alloy surface, irrespective of scale thickness, clearly indicating that sulfur anions do not ostensibly diffuse in either of the sulfide phases.

Discussion

This section aims to synthesize a reaction mechanism for the formation of sulfide scales on nickel-chromium alloys. We shall base our arguments on the analysis of kinetic data, metallography, platinum marker positions, and radioactive sulfur distribution in the scales.

In our previous investigation (1), it was shown that parabolic relationships describe the growth of the individual sulfide layers and the duplex scales. Prerequisites for this type of kinetics are compactness and adherence of individual sulfide layers. Although in our case these conditions were satisfied, a certain amount of mechanical breakdown of the scale did occur, especially where the specimen geometry restricted plastic deformation. This led, after a prolonged reaction time, to the formation of preferential channels at the edges of specimens through which sulfur reached the metal surface by transport through the gas phase. Nonetheless, on the basis of our observations it appears valid to set up a model for the scale growth over a flat alloy surface in terms of solid diffusion of its components alone.

The stoichiometries of the nickel and chromium sulfide phases, have been shown to vary with sulfur pressure within somewhat large ranges (1, 9). We shall assume, in agreement with these results, that the composition of the outer layer is Ni_3S_2 or NiS if the reacting sulfur pressure is below or above 10^{-5} atm, respectively. We ascribe the formula CrS to the inner chromium sulfide layer, although phases lying within the composition range $CrS\text{-}Cr_2S_3$ could possibly be present in this region.

It is evident from Fig. 2, 5, and 6 that outward movement of nickel ions is entirely responsible for the growth of the outer nickel sulfide layer. Diffusion probably occurs via vacancies in the cation sublattice, since both NiS (10-12) and Ni_3S_2 (13) exhibit characteristics of metal deficit (p-type) semiconductors. The formation of these lattice defects, nickel vacancies and positive holes, can be expressed by the equations

$$S \rightleftarrows NiS + Ni\square'' + 2\oplus \qquad [1]$$

and

$$2S \rightleftarrows Ni_3S_2 + 3Ni\square'' + 6\oplus \qquad [2]$$

Since we have no evidence of a nickel sulfide phase dispersed in the chromium sulfide layer, we assume that a similar mechanism accounts for the transfer of nickel ions across the inner chromium sulfide layer, with nickel-substituting chromium ions in the cation sublattice. Microprobe analysis has in fact shown nickel in solution to about 3 a/o (atom per cent) (1). Therefore, the diffusion of nickel through the chromium sulfide layer must be a rather fast process.

The growth of the inner layer must be controlled by a similar mechanism. Microscopic examination has shown that from the very beginning of the reaction the corrosion product has the duplex structure. The position of the inert platinum markers, taking into account the above-mentioned "undercutting mechanism," indicates concurrent outward diffusion of chromium and nickel ions. The anion lattice being everywhere inert, Fig. 6 and its interpretation in Fig. 7 make this conclusion unassailable.

Figure 5 shows clearly that radioactive sulfur did not penetrate into the compact outer layer. Furthermore, it has been reported that the diffusivity of nickel in nickel sulfide is much higher than that of sulfur (14). Our observations show that the boundary between the inner and the outer layer in Fig. 3 moves outward with respect to the platinum marker and the metal interface with increasing reaction time. We con-

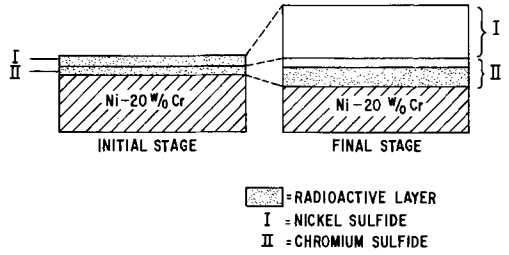

Fig. 7. Schematic representation of the two-stage sulfidation depicted in Fig. 6. The dashed lines connecting the two models show the relative displacement of the interfaces during the reaction.

clude therefore, that the inner layer grows at the expense of the nickel sulfide layer, with the displacement reaction NiS + Cr $\rightleftarrows$ CrS + Ni occurring at its inner boundary. This process results in a decrease in thickness of the outer layer, but it is balanced by a much faster growth rate at the gas phase interface.

The driving force for the conversion of nickel sulfide into chromium sulfide is the difference in the free energy of formation of these compounds. Extrapolated standard free energy variations for the formation of 1 mole of reaction product from pure metal and S_2 at 1 atm are, respectively, $\Delta G°_{NiS} = -17{,}775$ cal/mole, $\Delta G°_{Ni_3S_2} = -42{,}450$ cal/mole at 727°C (10), and $\Delta G°_{CrS} = -35{,}360$ cal/mole at 700°C (15). The growth of chromium sulfide at the expense of nickel sulfide is clearly favored. If this reaction occurs at the inner-outer layer interface, chromium must be transferred to this region. Unfortunately no data are available, to our knowledge, on the defect structure of CrS. Assuming that this compound is a p-type semiconductor, chromium from the alloy could reach the interface via cation vacancies, formed according to the equation

$$S \rightleftarrows CrS + Cr\square'' + 2\oplus \qquad [3]$$

where sulfur is supplied by the dissociation of nickel sulfide.

The proposed over-all reaction mechanism is summarized in Fig. 8. The nickel ions and electrons are transported across the scale from the alloy to the gas phase interface, where they react with adsorbed sulfur to form the nickel sulfide layer. This transport occurs via cation vacancies in the inner and in the outer layer, both of which are supposed to have a p-type structure (16). This model does not require the presence of a second nickel sulfide phase within the chromium sulfide layer, as previously reported in the literature (7). Although the composition of this layer has not been characterized generally for our experimental conditions the formula CrS can be adopted. The growth of this layer is attributed to outward diffusion of chromium to react with nickel sulfide at the interface between the two layers.

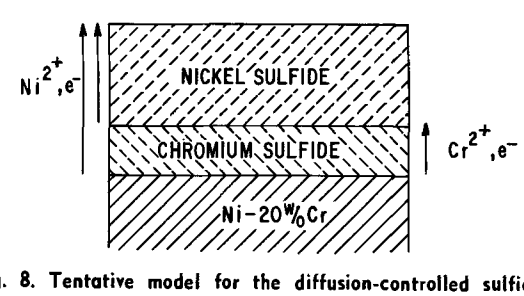

Fig. 8. Tentative model for the diffusion-controlled sulfidation of a Ni-20 w/o Cr alloy at 700°C.

Summary

On the basis of kinetic and morphological data and with the help of markers, we have been led to propose a mechanism for the sulfidation of a Ni-20 w/o Cr alloy. The model is based entirely on diffusion of metal across the scale under conditions for high-temperature corrosion phenomena, although concurrent mechanisms can contribute to the scaling of the alloy when mechanical breakdown of the scale takes place. This model stands on a few hypotheses which should be checked by further experimentation. Information should be gathered on the composition and the defect structure of the phases involved in the sulfidation, as well as on the lattice and boundary diffusivities of the scale components. Notwithstanding, the results of this investigation disprove the prevalent view that nickel sulfide stringers in chromium sulfide are essential for transfer of nickel across the scale and that sulfur migrates as sulfur vapor or hydrogen sulfide through fissures in the nickel sulfide and chromium sulfide layers to form chromium sulfide at the alloy interface.

Acknowledgment

This research was supported by a grant from Falconbridge Nickel Mines Ltd. to J. S. Kirkaldy. The authors are grateful to Falconbridge Metallurgical Laboratories for providing materials. A number of useful and encouraging discussions were held with Dr. L. A. Morris and Dr. M. J. Lavigne of that company.

Manuscript received Feb. 8, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Characterization of Silicon Nitride Films

E. A. Taft

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

Various "silicon nitride" films have been prepared from SiH_4, N_2, NH_3, and N_2O in an rf-promoted glow discharge reaction. These films are described primarily through the use of infrared absorption. Aided by ultraviolet absorption, the inclusion of excess silicon or of oxygen in the films is readily followed. Changes in index of refraction, etch rates in HF acid, and electrical conductivity of the films are correlated with the optical absorption study. Comparisons of these films with those formed by pyrolysis or by reactive sputtering are made. Some reproducible physical properties of an amorphous Si_3N_4 film are stated.

After an initial group of manuscripts on silicon nitride thin films in 1967, there have appeared reports on new processes or variations of old processes in preparing these amorphous layers. Evaluations of the prepared films have been made through physical, chemical, or electronic methods depending on the particular interest of the investigator. The general interest has been toward the development of an impervious dielectric film to replace or to supplement silicon oxide films which serve in various capacities in silicon device technology. Because of these different methods of preparation and the individual emphasis on a property of a film, there has been on real basis for assuming that only one material was undergoing investigation. On the other hand, a common set of evaluations of variously prepared films could serve to establish an identity for silicon nitride.

Three general methods are used to form these nitride films. The most used system is the pyrolytic decomposition of mixtures of gases of silicon compounds and nitrogen compounds (1-5); typically these gases are SiH_4 and NH_3 decomposed on a substrate at 1000°C (6-8). Other work describes the reactive sputtering of silicon in nitrogen onto a cold or heated substrate (9-11). Radio-frequency (rf) sputtering of Si_3N_4 is not generally used as high-purity cathodes are not readily available. The third method utilizes a rf glow discharge to ionize gases and form films on cold or heated substrates (12-14). A more recent report describes the action of ultraviolet light on SiH_4 and H_4N_2 mixtures (15). The general properties of many of these films have been described in terms of their surface structure, optical absorption, or x-ray diffraction. An interest in mechanical stresses, etch rate in HF acid, or resistance at elevated temperatures to diffusion of specific atoms through the films appears in some papers (16-20). The electrical conductivity or "leakage" of these dielectric films is discussed in other papers (21-23), and the silicon-silicon nitride interface has received much study (3, 7, 23, 25).

This report is based on optical absorption studies of silicon nitride films formed in a glow discharge of $SiH_4 + NH_3$ or $SiH_4 + N_2$. (Pyrolytic films from $SiH_4 + NH_3$ prepared by F. K. Heumann and reactively sputtered films of Si in N_2 prepared by L. F. Cordes were available for comparison.) The index of refraction and the etch rate in HF acid is determined for many of the films. Variations in properties of glow discharge films are explained and an amorphous Si_3N_4 film is identified. Silicon oxynitride films obtained from glow discharges in SiH_4, N_2O, and N_2 are also measured. In addition, comparisons are made with other nitride and oxynitride (25-29) films to show a continuous variation in properties as the composition of the amorphous film is changed. [X-ray and electron diffraction work (7, 25) especially that of Tombs *et al.* (28) shows no long range order on ½μ thick deposited films. The films used here, deposited at low temperatures, are therefore also described as amorphous.]

Key words: thin dielectric films, rf glow discharge, infrared absorption.

Experimental

The reaction chamber was a 2-in. ID Pyrex tube which was initially evacuated to less than 1×10^{-3} Torr with a mechanical pump. The flow of gases was controlled by needle valves or by capillaries. A simple nichrome wire spiral heater supported a carbon sample holder. Several turns of copper wire or tubing were wound over the Pyrex tube and rf current was passed through the coil. At the usual gas pressure of 0.05-1 Torr, monitored by a thermistor vacuum gauge, a discharge was readily started with a small oscillator at frequencies from 0.5 to 30 MHz. Power absorbed by the discharge was usually less than 10W, and an unheated substrate was warmed slightly. The experimental setup used appears to be much like that described by Joyce (30). The procedure was normally limited to fixing a flow rate of SiH_4, setting a substrate temperature, adjusting the flow of NH_3, N_2, or N_2O, and then starting a discharge. Substrates were either thin silicon wafers for infrared absorption or disks of sapphire for the ultraviolet absorption. The thickness and the index of refraction of the films on silicon were determined from the wavelengths of interference minima for reflected light. While this method requires measurement at two different angles of incidence and films at least several fringes thick, the substrate need not be an optical flat. A Cahn electrobalance was used for density measurements.

The infrared absorption spectrum was recorded on a Perkin-Elmer 337 grating spectrophotometer. Films on sapphire disks were observed in ultraviolet absorption on a Perkin-Elmer 202 grating spectrophotometer. The etch rate in 48% hydrofluoric acid was recorded for some films.

Results

Glow discharge SiH_4-N_2-NH_3.—As most of the discussion will include data from infrared absorption, a composite spectrum is drawn in Fig. 1 to indicate the bands which are observed and band strengths which may be encountered. The Si-N bonds (31) appear in absorption at 11.5 and 21μ and are typically of the strength shown. The N-H and Si-H modes have been seen with absorption coefficients as high as those shown, but they are often not detectable. The log scale emphasizes the sharpness of the bands. Figure 2 shows only the region of major absorption for the Si-N bonds on a linear absorption scale. Si_3N_4 crystalline powder (β-phase) in a KBr pressed disk exhibits sharp structure in comparison to amorphous silicon nitride films formed by any of the three different methods. These spectra shown are typical, though variations will be shown later, and the slightly sharper peaks of the pyrolytic material formed at 1000°C is perhaps the only notable feature. The absorption coefficients of the

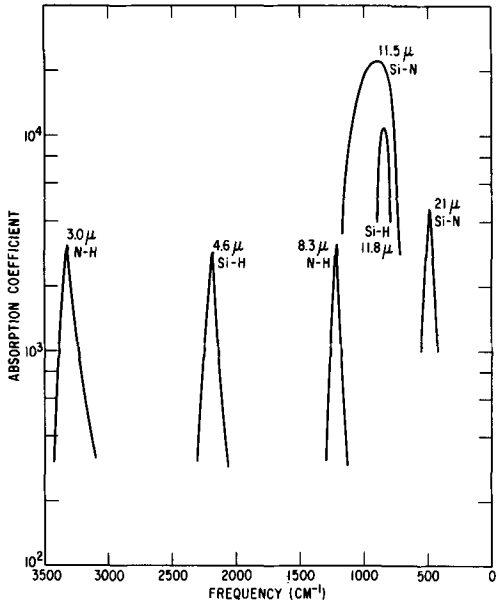

Fig. 1. Infrared absorption bands in silicon nitride films formed in a rf glow discharge.

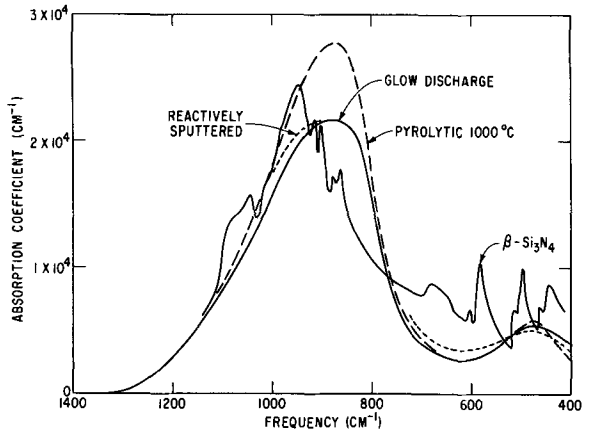

Fig. 2. Comparison of crystalline and amorphous silicon nitride infrared absorption.

films are not accurately determined but they should be within 20% of these values.

Starting with a fixed silane pressure in the glow discharge system, anhydrous ammonia was run through at different rates in a series of runs. The substrate was held at approximately 400°C while films of ½ to 1μ in thickness were deposited. Variations of the peak amplitudes of the infrared absorption coefficients in three different bands are given in Fig. 3 for changing ammonia pressure. When nitrogen rather than ammonia is used, quite a different pattern is obtained, as seen in Fig. 4. The index of refraction and deposition rate variations for the nitrogen runs appear in Fig. 5. It was found that moving the position of the rf coil, changing the temperature of the substrate, or moving the injection point of the silane caused changes in the curves presented in Fig. 3, 4, and 5. Therefore, these data are shown to illustrate the variations which do occur, but which cannot be readily reproduced in detail in a separate system. They do serve to emphasize the ease with which films of different properties can be formed. Even the main Si-N band absorption is subject to considerable shift in peak position and to change in intensity. Figure 6 shows this change with three examples and the index of refraction for each. The Si-N absorption at 21μ in 1μ thick films is even more variable as indicated in the spectrograph tracings in Fig. 7. The pyrolytic deposit of curve B contains the well-defined

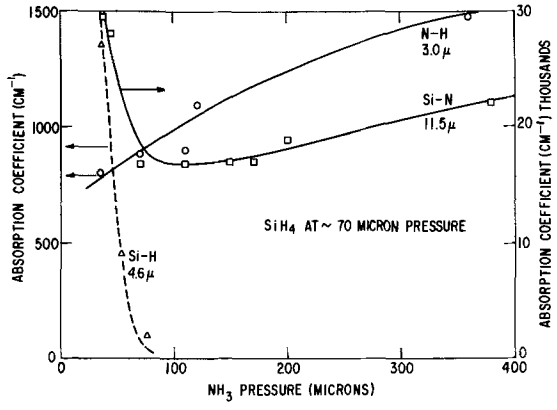

Fig. 3. Change in infrared absorption coefficients with ammonia gas pressure.

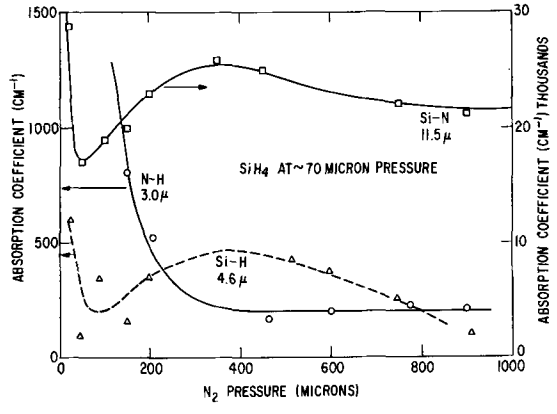

Fig. 4. Change in infrared absorption coefficients with nitrogen gas pressure.

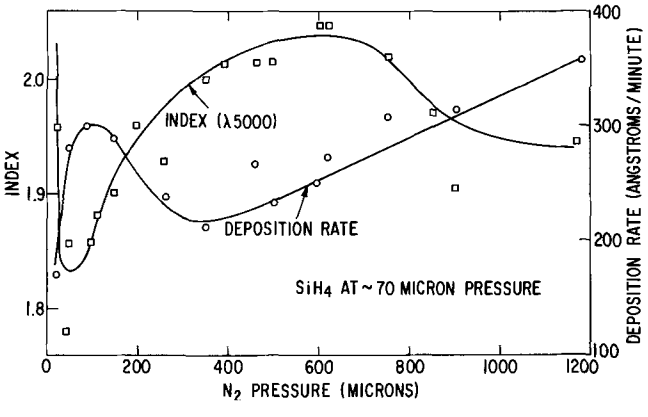

Fig. 5. Variation of index of refraction and deposition rate with nitrogen pressure.

absorption at 21μ typical of films formed at 1000°C. Curve A represents a low-temperature glow discharge film containing large N-H fractions. In curve C the 21μ absorption peak is nearly obliterated. The film giving curve C, also from a low-temperature glow discharge, shows small N-H but large Si-H absorption bands. The 21μ peak is the symmetric stretching mode in Si-N absorption (31), and it is clear that there is enough Si-H bonding (the absorption coefficient at 4.6μ is 3000 cm^{-1}) made at the expense of Si-N bonds to greatly disturb the Si-N absorption normally localized in this region.

Figure 8 shows tracings of a portion of spectrographs for 1μ thick films in the higher energy range. Absorption coefficients as high as 3000 cm^{-1} have been observed in each of the bands shown. The 4.6μ band, while a little sharper than the one at 3.0μ, does not

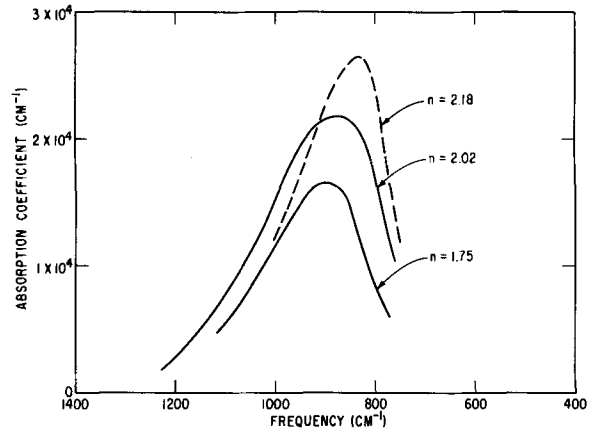

Fig. 6. Shift of peak position and index of refraction in silicon nitride glow discharge films.

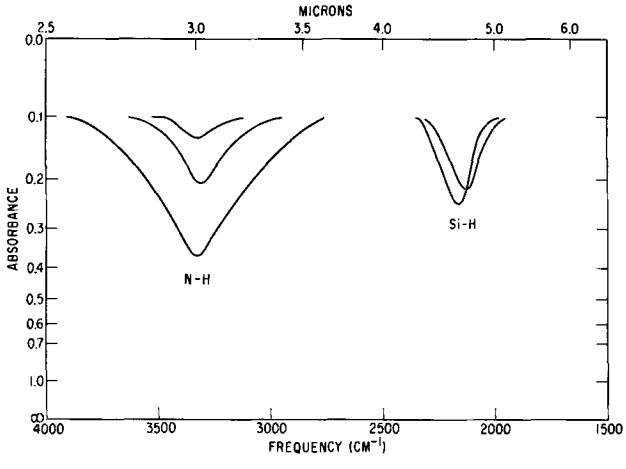

Fig. 8. Tracings of the hydrogen bond absorbance in glow discharge films of silicon nitride.

appear to be so definitely fixed in peak position. The 3.0μ band seems always to be accompanied by an absorption of about the same strength at 8.3μ in the tail of the main Si-N band. The 4.6μ band also seems to be accompanied by absorption near 11.8μ indicating a second stronger Si-H mode. This mode is often evidenced through an apparent shift in the peak position of the main Si-N band, as for example in curve C of Fig. 7. This shift toward lower energy has been found in all films having appreciable 4.6μ absorption. The observation of this second absorption of Si-H was initially made on films formed from SiH_4 and N_2O.

Glow discharge SiH_4-N_2O.—In film formation from SiH_4 and N_2O gases there is observed, in addition to

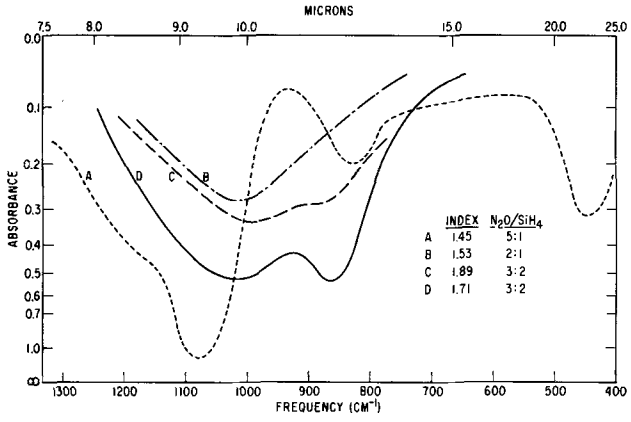

Fig. 9. Infrared absorbance with change in nitrous oxide/silane ratio in glow discharge.

the bands previously discussed, absorption of O-H at 2.74μ, and the prominent Si-O bands at 9.3, 12.4, and 22μ. Figure 9 gives the trend in infrared absorption of ½-1μ thick films as the SiH_4/N_2O ratio is increased. Curve A appears to be much like that for normal absorption of a silicon dioxide film, and the index of refraction is that expected of the oxide. Curve B (for a film of different thickness) appears to belong to an intermediate of silicon oxide and silicon nitride. This film has a small band at 2.98μ—apparently the N-H absorption slightly shifted; whereas curve A has a small O-H absorption at 2.74μ. The index of refraction of the film of curve C approaches that of a nitride, but the absorption still indicates an intermediate oxynitride composition, although a second peak near 11.8μ is beginning to rise. The film of curve D was deposited under the same gas conditions as film C, but the substrate was not heated. The second peak is now much larger. The absorption at 4.6μ is also found to be larger. In this series of films, the second peak near 11.8μ always corresponds in strength to the Si-H absorption at 4.6μ. At higher SiH_4/N_2O ratios the films become more and more silicon rich.

Glow discharge SiH_4-N_2-N_2O.—Some films were deposited in SiH_4 and N_2 or SiH_4 and NH_3 with small amounts of N_2O added. An illustration of the effect of the added oxidizing gas is given in Fig. 10 for films 1½μ thick. Curves A and B show a shifting and broadening in the 9-12μ region of absorption as oxygen is incorporated in the film. Curve C shows features of the sharper and stronger bands associated with silicon oxide. However, a small absorption occurs at 2.95μ and indicates that the N-H band is still present but slightly shifted in position. When coupled with the index of refraction value, it appears that there is still a fraction of silicon-nitrogen bonding in the composite film.

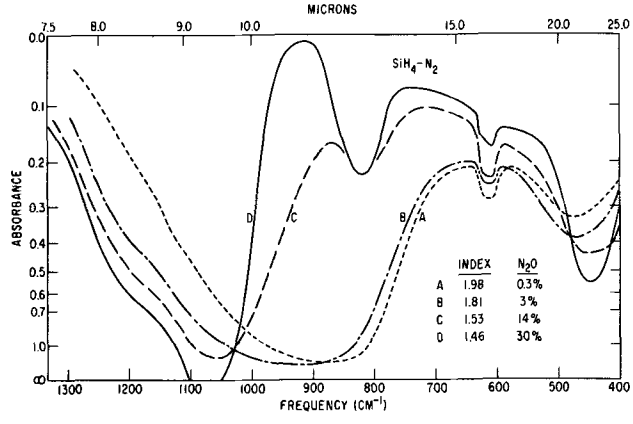

Fig. 10. Infrared absorbance with added nitrous oxide in silane-nitrogen glow discharge.

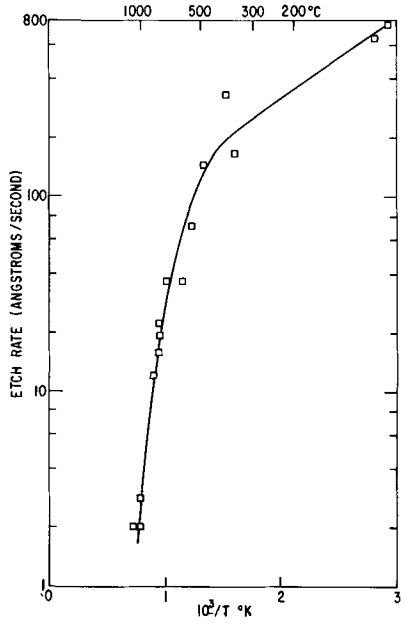

Fig. 11. Etch rate in 48% hydrofluoric acid vs. substrate temperature for silane-ammonia glow discharge films.

In curve D, the Si-O absorption bands are clearly separated and the greater peak values of absorption are evident. The N-H band near 3.0μ has now disappeared to be replaced by the O-H band at 2.74μ.

Etching in hydrofluoric acid.—Some of the samples deposited at various substrate temperatures from the SiH_4-NH_3 glow discharge were placed in 48% hydrofluoric acid and the film removal rate observed. For films with low deposition temperatures the etch rates are very high, but the rates decrease to about 6000 Å/min for substrate temperatures of 500°C. (See Fig. 11.) The rates then drop rapidly with increasing temperatures until at temperatures above 800°C the films are, of course, indistinguishable from pyrolytic films formed without the glow discharge. The infrared absorption at 3.0μ indicative of N-H bonds was found to exhibit some correlation with the etch rate. The general trend is given in Fig. 12, although some films prepared at other gas pressures or other gas ratios did not fit this curve well. The films formed in the SiH_4-N_2 system appear to fit to an entirely different curve with respect to the 3.0μ absorption strength. This curve

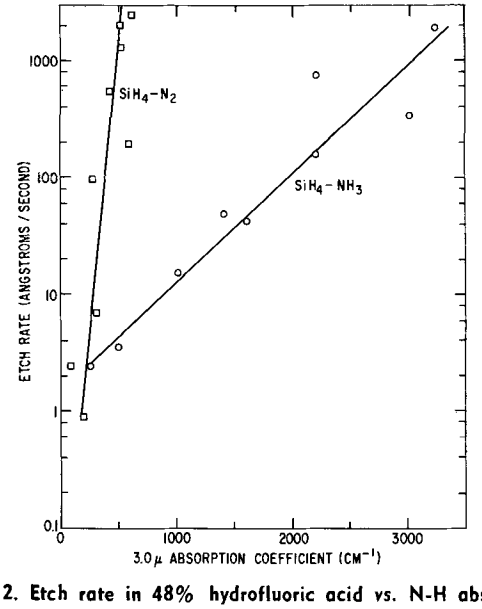

Fig. 12. Etch rate in 48% hydrofluoric acid vs. N-H absorption coefficient at 3.0μ for silane-ammonia and silane-nitrogen glow discharge films.

is also shown in Fig. 12 and again represents the general trend.

Data on the index of refraction and the density were taken for films deposited at various substrate temperatures from SiH_4 and NH_3. Deposition at room temperature produced films with a density of 2.4. This density is much lower than the 3.1 found for high-temperature films. The decreased density and the usual high hydrogen content accompanying it are factors in the lack of resistance of these films to hydrofluoric acid attack. The index of refraction of a film is much easier to obtain than the density. These index values were found to range from 1.8 to 2.1 for the same group of films which varied in density from 2.4 to 3.2. A change of this order is predicted by the Lorenz-Lorentz law (32), so the index can be used (at least for silicon nitride films in this range) to estimate the density.

Ultraviolet absorption.—A number of films were deposited on sapphire substrates. Tracings of data from the spectrophotometer are shown in Fig. 13. For films about 1μ thick the absorption coefficient where the curves intersect the base line (absorbance = 1.5) is 3×10^4 cm^{-1}. Curve 1 is typical for a film containing excess silicon. The reactively sputtered films of Cordes (11) show curves of this shape and near this wavelength position. Pyrolytically formed films (25) at high NH_3/SiH_4 ratios show absorption at higher energies near curve 2. The more rapid increase in absorption at higher energies as compared with curve 1 is always observed. Curves 3 and 4 are included to show the smooth shift of the absorption edge to higher energies as small amounts of oxygen are added to the film. Continuous shifts to lower energies are observed as the N_2/SiH_4 ratio is reduced in the glow discharge. A film having an index of 2.8 gives a base line intercept at 420 mμ and an amorphous film prepared from pure SiH_4 has moved to 570 mμ.

Discussion

Resistance to corrosion, great hardness, and low thermal expansion made crystalline Si_3N_4 an attractive high-temperature refractory (33). The work of Turkdogan *et al.* (34) firmly established the formula as Si_3N_4 and set the density at 3.19 ± 0.01. Additional work on the properties was reported by Popper and Ruddlesden (35). The solubility and electrical activity of nitrogen in silicon have been studied by Kaiser and Thurmond (36). These few papers on crystalline material are a background to the many papers on the amorphous thin film. To summarize a few figures on crystalline Si_3N_4, first the old density figure of 3.44 (37) should be replaced by 3.19 (34). The dielectric constant value of 9.4 often appears, but the source is not apparent. If the Lorenz-Lorentz approximation (32) is made using the measured density (3.11) and the dielectric constant (7.4) of amorphous material (25), a value of 8.0 is obtained for the dielectric constant of crystalline material. Also, if the index of re-

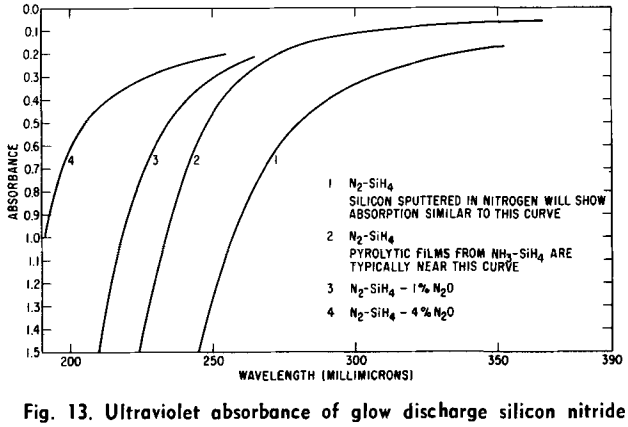

Fig. 13. Ultraviolet absorbance of glow discharge silicon nitride films 1μ thick.

fraction of the film at 4500Å is 2.03 (25), the index of the crystal is calculated to be 2.06. These numbers will be considered as those representing crystalline Si_3N_4 and an amorphous material with similar bonding.

The reactively sputtered films deposited by Cordes (11) were highly reproducible and quite insensitive to system parameters. Because of this invariable behavior, it was first assumed that this must be the stoichiometric material. This assumption was in part based on the observation that the pyrolytic films of Heumann (25) contained hydrogen and were of slightly lower index of refraction. However, the conclusions of Cordes (11) seem valid, and a slight excess of bonded Si is built into the lower substrate temperature sputtered deposits. Cordes found that high-temperature annealing decreased the index but not the thickness of the film. This observation agrees with the assumption that Si-Si bonds were replaced with Si-N bonds. The etch rate of the reactively sputtered films moved from ~120 to 150 Å/min after heating and the index of refraction changed from 2.06 to 2.03. These values are like those of a pyrolytic film. As the sputtered film does not contain hydrogen, the small amount of N-H bonding seen in infrared absorption in the higher temperature pyrolytic films therefore has no discernible effect on the index or the etch rate.

If excess conductivity is assumed to indicate Si-Si bonding in films, again the pyrolytic film with the lowest conductivity should be more nearly the Si_3N_4 composition. Cordes (11) uses conductivity to describe Si excess in a sputtered silicon nitride lattice by comparing to the pyrolytic films of D. M. Brown (25). Hu (24) also used sputtered films. Doo (16), G. A. Brown (22), and Yeargan (21) show pyrolytic film conductivity. Deal (23) measured a slightly different film formed from $SiCl_4$ and NH_3. Parnell (38) gives a comparable conductivity for rf glow discharge dielectrics in capacitors. A comparison of these data (Fig. 14) shows that the pyrolytic deposits of many investigators seem to approach a common minimum conductivity at voltages near the breakdown strength of the dielectric. Doo (16) and G. A. Brown (22) found their curves to represent the minimum conduction observed as the ratio of silane to ammonia was decreased.

The ultraviolet absorption edge also appears to be a relatively sensitive indicator of excess silicon or of oxygen contamination, and an absorption increase accompanies a conductivity increase. The addition of small amounts of oxygen to either the pyrolytic or glow discharge systems gives a continuous shift of the ultraviolet edge to higher energies. This again indicates that the assignment of the 2290Å wavelength to a 10^4 cm^{-1} absorption coefficient for amorphous silicon nitride is approximately correct.

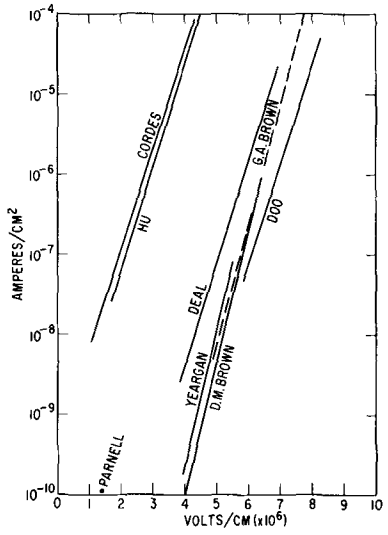

Fig. 14. Conductance in pyrolytic and sputtered silicon nitride films.

Two types of investigation which have received some attention are film structure (28, 39, 40) and the electrical behavior of the film with a silicon interface. Because of the already diverse properties of films prepared in this work and early recognition of silicon nitride as a leaky insulator (25), no use of the C-V behavior of the films was attempted in this study. Throughout the infrared work when the effects of quantities of oxygen, hydrogen, or silicon could be observed as part of the silicon nitride film, there gradually built up the impression that the composition of these films can be made continuously variable. The data on the oxynitrides, in particular, appears to agree with the work of Tombs *et al.* (28), and their description of the films as solid solutions appears to fit as well to the wider range of films discussed here. Drum and Rand (29) also suggest this continuous range of properties and refer to their films as oxynitride polymers.

Conclusions

An amorphous film of silicon nitride of Si_3N_4 composition has an index of refraction of 2.03 at a wavelength of 4500Å, a dielectric constant of 7.4, and ultraviolet absorption edge with an absorption coefficient of 10^4 cm^{-1} at wavelength 2290Å. Its broad infrared absorption band with an absorption coefficient of 2 x 10^4 cm^{-1} peaks near 11.5μ with a smaller band at 21μ. The etch rate, in 48% hydrofluoric acid at room temperature, is 150 Å/min, and the resistivity is 10^{16} ohm-cm at 4 x 10^6 V/cm.

Pyrolytic films formed at 900°-1100°C with very dilute SiH_4 in NH_3 appear to approach this description except for the small added hydrogen content. At formation temperatures below 900° most of the hydrogen remaining in the film is correlated with a lowering of the index of refraction and an increase in the etch rate. With low (<10:1) ammonia-silane ratios excess silicon appears in the films. Reactively sputtered films always form with a slight silicon excess indicated by the increased index of refraction of 2.06 and lowered etch rate of 120 Å/min. No hydrogen appears in these films. Glow-discharge-promoted deposits can be made at room temperature, but the resultant films have a high hydrogen content accompanied by a greatly lowered index of refraction and almost no etch resistance. Films formed at higher temperatures can be made which approach pyrolytic material in etch resistance and dielectric strength. These films are usually obtained by adjusting the gas ratio and allowing the films to become slightly silicon rich. The hydrogen content then appears to switch from the N-H bond to the Si-H bond and the dielectric constant increases while the etch rate decreases.

If N_2O is added to the gases, a range of oxynitrides can be made using the glow discharge. These films also retain hydrogen, especially at the lower substrate temperatures, and can be made to contain excess silicon. The range of index of refraction is from that of silica at 1.45 to that of silicon-rich films at >3.

Evaluation of a New Polish for Gallium Arsenide Using a Peroxide-Alkaline Solution

J. C. Dyment and G. A. Rozgonyi

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

It has recently become necessary to obtain a high-quality, strain-free polish on the (111) Ga-face of GaAs. Previous techniques using a bromine-methanol (BM) solution or a Syton-bromine-methanol (SBM) solution were found to be inadequate. The BM and SBM solutions were also subject to undesirable aging characteristics which resulted in nonreproducible polishing rates with time. In this report we show that a new solution containing H_2O_2 and NH_4OH, referred to as the PA solution for peroxide-alkaline, overcomes the limitations of the BM and SBM solutions. A comparative study of the three polishes has been made relating the optical quality, crystal orientation dependence, polishing rates and stability, ohmic contact resistance to the polished surfaces, and residual surface damage, as determined by high-resolution x-ray topography of polished surfaces and cleaved cross sections. In each case the PA solution equals or improves on the BM or SBM solutions. In addition, it is found that PA polished substrates yield diffused junction lasers with threshold current densities comparable to the best BM and SBM data.

Chemical polishing of GaAs wafers is recognized as a crucial step in the fabrication of many device structures. Because of the excellent results obtained on the (100) face and the $(\bar{1}\bar{1}\bar{1})$ As-face of GaAs with the bromine-methanol solution (BM), first described by Sullivan and Kolb (1) in 1963, it has been widely used in GaAs technology. However, several limitations still exist with the BM solution that are becoming increasingly important in order to meet the stringent requirements of recent advances in GaAs devices. For example, the single-heterostructure junction laser (2-4) often requires that the n-type substrates of these devices be polished on the (111) Ga-face to within a few microns of the p-n junction. These procedures are employed to reduce the thermal resistance between the junction and a suitable heat sink and thereby permit improved continuous or high duty-cycle operation.

Two of the limitations of the BM solution are its inability to polish the (111) Ga-face nonpreferentially, and its aging characteristics which result in nonreproducible polishing rates with time. It was found that adding Syton to the BM solution, hereafter SBM, improved the optical quality of the (111) face, but it still was not completely satisfactory for many devices, and its aging characteristics were worse than the BM solution. We have therefore made a detailed study of a

Key words: gallium arsenide, polishing, x-ray topography.

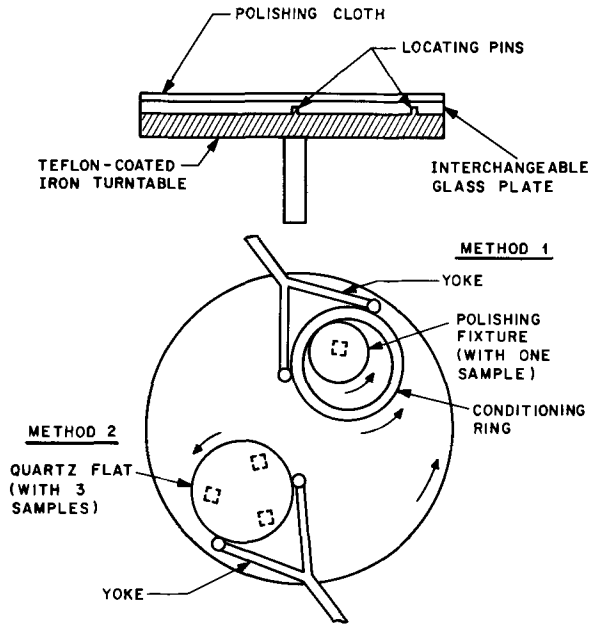

Fig. 1. Top: Schematic of polishing machine turntable and interchangeable glass plate. Bottom: Diagram illustrating the two methods used for polishing samples. In method 1, the single sample rotates about its own center. The sample and polishing fixture turn inside a conditioning ring which is positioned by a yoke. In method 2, several samples are polished simultaneously by mounting them on a large quartz flat. As the flat turns inside the yoke, samples receive a translational motion across polishing cloth.

new polishing solution for GaAs which contains H_2O_2 and NH_4OH and was first used by Sayko (5) of these laboratories. In the present paper, we show that this peroxide-alkaline (PA) solution overcomes the limitations associated with both the BM and SBM solutions.

Several properties of the PA solution were investigated as follows:

a. Optical quality and crystallographic dependence.
b. Polishing rates and reproducibility.
c. Surface damage and residual strain due to polishing.
d. Metallic contact resistance to polished layer.
e. Fabrication of diffused junction lasers from PA-polished substrates.

The results of these studies are reported and, where applicable, comparisons are made with the BM and SBM polishes. Finally, a critical evaluation of the PA solution and some areas which still require further investigation are outlined.

Experimental Procedures

The apparatus used for polishing is shown schematically in Fig. 1. It consists of a Teflon-coated iron turntable and several interchangeable flat Pyrex glass plates. These plates can be used with any desired polishing cloth or, alternately, without a cloth during lapping operations. For PA and SBM polishing we used Politex Supreme cloths,[1] while PAW scientific cloths[2] were employed for BM polishing. Both of these cloths have adhesive backings which are pressed onto the Pyrex plates.

Two methods of mounting wafers are used depending on the number of available samples as illustrated in Fig. 1 (bottom). In method 1, a single wafer is mounted in a polishing fixture similar to one reported by Mash *et al.* (6). The wafer is first waxed to a flat quartz or stainless steel disk which is then attached to a plunger. The movement of the plunger is constrained by a linear bearing to maintain the surface of the wafer parallel to the plane of the turntable. The polishing pressure is varied by adjusting a compression spring located inside the center shaft of the plunger. With method 2, on the other hand, three or more wafers must be mounted simultaneously on a large quartz flat. Although it is not possible to polish one wafer at a time, method 2 does have the advantage of producing a more desirable polishing motion since each sample is translated back and forth across the polishing cloth rather than turning only about its own center as in method 1. Further discussion of these aspects is given in Experimental Results.

Most of our polishing experiments have been performed on n-type wafers with electron concentrations in the low 10^{18} cm^{-3} range, which is a typical doping for junction lasers. Before polishing, the wafers were always lapped with 5 μm alumina abrasive. Each of the polishing solutions was mixed in the proportions given in Table I and applied at rates of 800-1400 ml/hr. The pressure applied during polishing with methods 1 and 2 was approximately 400 and 120 g/cm^2, respectively. After the removal of a few microns of material the lapping damage was usually not visible, but the polishing was always continued until about 50 μm of material had been removed.

Experimental Results

Optical quality and crystallographic dependence.— Polishing of the (100), (111) Ga-rich, and $(\bar{1}\bar{1}\bar{1})$ As-rich faces has been investigated. For all three solutions, highly polished surfaces were achieved on the (100) and $(\bar{1}\bar{1}\bar{1})$ faces with little evidence of any preferential etching, although the BM polished surfaces sometimes revealed a slight lemon-peel undulation[3] which was not observed with either the PA or SBM surfaces. On the other hand, only the PA and SBM solutions polished the (111) face nonpreferentially. Initial results with a scanning electron microscope failed to reveal any features of the surface topography. Additional measurements with a Talysurf[4] showed the PA topography to be flat and uniform with no elevated features greater than about 100Å which is the resolution limit of the instrument. This value is also consistent with

* Chemical assays NH_4OH (29.5%), H_2O_2 (29-32%, superoxol), bromine (99.8%), methanol (99.9%), Syton (Monsanto Company).
** Final rate determined 8 hr after preparation of polishing solution.

another measurement obtained with a multiple beam interferometer.

In order to achieve a nonpreferential polish on the (111) face with the PA solution, we found that the motion of the samples on the polishing cloth is an important factor. In this regard, method 2 is notably superior to method 1 apparently because the samples have increased translational motion and a correspondingly increased contact with the polishing cloth. To understand the importance of the motion, it is first necessary to describe how the PA polishing mechanism differs from conventional etching mechanisms. When a GaAs wafer is in contact with the PA solution, a thin film, which probably contains gallium and/or arsenic oxides, forms on the GaAs surface. The exact composition of the film is still undetermined but, since the film is very soft, it is continually removed by the cloth during polishing. In contrast with most etching solutions, the PA solution contains no second component which chemically dissolves the film as it forms. Thus, the PA solution by itself cannot be used to etch a GaAs substrate and polishing will only proceed when the GaAs is in contact with the cloth. This has two advantages. First, the film is removed from the high regions of the wafer before the low regions and this improves the over-all flatness. Second, the formation of any preferential polishing effects, which are sometimes observed on the (111) face, will also be inhibited.

The lack of translational motion associated with method 1 sometimes leads to a situation where small preferential pimples are observed near the center of the (111) slice being polished. In accordance with the above discussion, these pimples are not usually observed at the outer edges of the slice which do have some translational motion. With method 1, a nonpreferential (111) surface can still be obtained by slightly increasing the amount of NH_4OH to raise the *p*H value from its initially measured value of about 7.0. However it is important not to increase the *p*H value too much since this may cause a shallow pitting of the surface. Therefore, in summary, the (111) orientation of GaAs can be polished with the PA solution, but both the sample motion and NH_4OH concentration are important factors which determine the quality of the polished surface.

Polishing rates and reproducibility.—Initial observations with the PA solution indicated that the polishing rate was essentially constant over durations of several hours which is in marked contrast with either of the solutions containing bromine. To substantiate these results, three identical $(\bar{1}\bar{1}\bar{1})$ wafers were selected and then individually polished by method 1, using one wafer for each solution. All solutions were mixed as in Table I and applied at a constant rate (1000 ml/hr). The turntable speed was maintained at 70 rpm and each wafer was polished at a pressure of approximately 400 g/cm^2. The results of these controlled experiments are plotted in Fig. 2. Each point represents 30 min of polishing time with the exception of the initial points which are for 20 min of polishing beginning with the lapped surfaces. These initial points have been plotted for completeness only and are not indicative of the true polishing rates since a lapped surface polishes more rapidly. The main conclusion from Fig. 2 is that the polishing rate for the PA solution is remarkably stable during the 8-hr test period, whereas the rates for BM and SBM solutions are reduced by factors of 3 and 12, respectively. The evaporation of bromine is believed to be the main cause of these reduced polishing rates.

Surface damage and residual strain due to polishing.—A further evaluation of the three solutions has been made using a series of high resolution reflection x-ray topographs of the actual polished surfaces. Again, $(\bar{1}\bar{1}\bar{1})$ wafers were examined so that the BM solution could be included. X-ray topographs were obtained

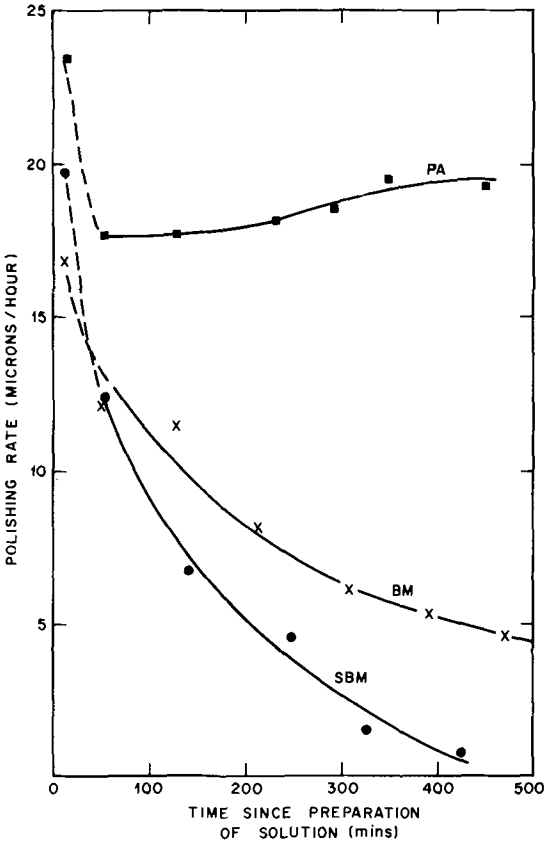

Fig. 2. Polishing rate as a function of time for each of the three solutions (see Table I for composition). All solutions were applied at a constant rate (1000 ml/hr) and each of the identical $(\bar{1}\bar{1}\bar{1})$ wafers was polished at a pressure of ≃400 g/cm^2. The initial point where curve is dashed is for a 20 min polish on a lapped surface. All other points present 30 min of polish. Estimated accuracy on each rate is ±1.5 μm/hr.

with Cu $K_{\alpha 1}$ radiation using a (422) reflection from samples polished with PA, BM, and SBM solutions. The results are presented in Fig. 3a, b, and c, respectively. Notice in Fig. 3a and b that there is excellent diffraction contrast between the perfect or defect-free regions of the polished surface (*i.e.*, the uniform gray background) and the defect dislocations (*i.e.*, the short dark lines uniformly distributed throughout the bulk of the sample). These observations are typical for Czochralski-grown ingots (8) and, from these topographs, it is estimated that there are approximately 5 x 10^4 dislocation lines per square centimeter. In marked contrast to Fig. 3a and b, Fig. 3c shows that, due to the residual strain present in the SBM surface, contrast at the dislocations has essentially been eliminated. Note, however, that some heavy tweezer damage does show up very clearly in three places in the lower central portion of Fig. 3c. These photographs clearly demonstrate the superior quality of the PA and BM polished surfaces.

A qualitative explanation for the loss of contrast in Fig. 3c is presented in Fig. 4 where we schematically compare the diffracted X-ray intensity expected from a "perfect" strain-free area, I_p, containing a dislocation line, I_d, with a comparable region on a strained surface, I_s. It can be seen that, because damaged surfaces give rise to enhanced diffracted intensity, *i.e.*, $I_s > I_p$, the contrast difference $(I_d - I_s)$ will suffer when compared to the perfect region where it is $(I_d - I_p)$. In the extreme cases, when $I_s \simeq I_d$, the reflection topographs are uniformly dark and featureless.

The residual strain fields at the surfaces of the above samples have also been examined by obtaining x-ray topographs from (110) cleavage faces using procedures described by Rozgonyi and Haszko (9). The cleavage

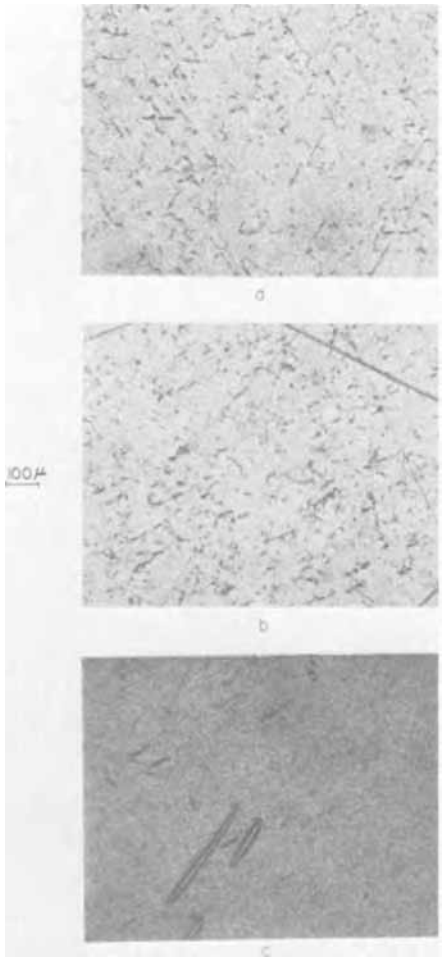

Fig. 3. High resolution reflection x-ray topographs of (a) PA, (b) BM, and (c) SBM polished GaAs wafers. See text and Fig. 4 for explanation of these photographs.

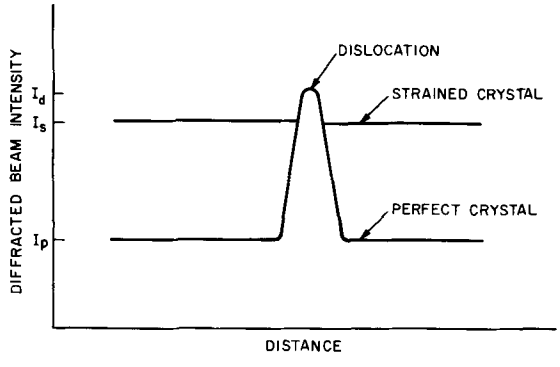

Fig. 4. Schematic representation of diffracted x-ray intensities I_p at a perfect strain-free surface compared to I_s at a strained surface and I_d for a bulk dislocation. The contrast difference ($I_d - I_p$) is greater than ($I_d - I_s$) which accounts for the increased contrast found in Fig. 3a and b compared to Fig. 3c.

face x-ray topographs of PA and BM polished surfaces showed excellent dislocation contrast uniformly distributed from the interior of the wafers to the outer (polished) edge of the cleavage face, see Fig. 5a and b. However, for the SBM polished sample, see Fig. 5c, a thin uniformly black area was observed at the edge of the cleavage face corresponding to the polished surface at the right-hand edge of the photograph. The black area again indicates there is residual surface damage associated with the SBM polish. The enhanced diffraction at the left-hand edge of these topographs is primarily due to the saw cutting and lapping operation.

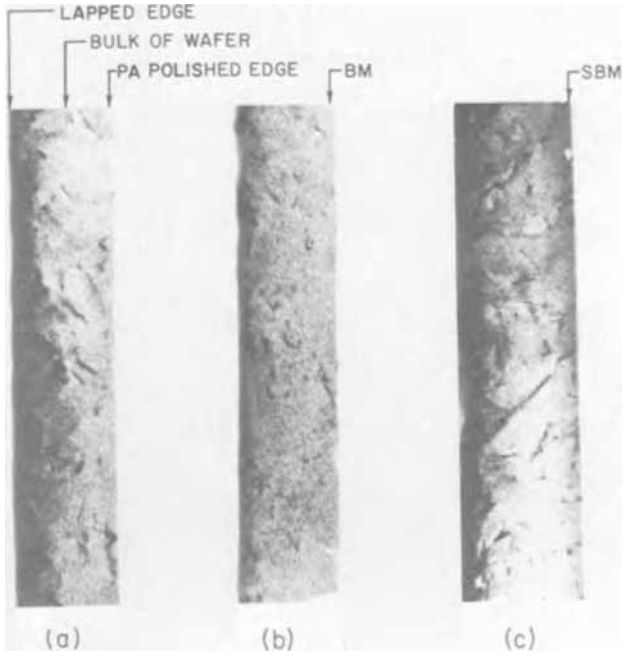

Fig. 5. Cleavage face x-ray topographs for the three samples of Fig. 3.

Thus the cleavage face topographs are consistent with the $(\bar{1}\bar{1}\bar{1})$ surface topographs presented in Fig. 3.

We believe that the results reported here explain some of our previous data regarding the threshold current densities of diffused junction laser diodes. These lasers were prepared by diffusing Zn to a depth of 2 μm into BM and SBM polished surfaces using procedures described previously (10). The standard stripe geometry contacts (11) were then applied. It was found that the threshold current densities were at least 30% higher for SBM than for BM polished wafers. This was observed for three separate ingots. One possible explanation for the higher thresholds associated with SBM would be increased diffraction losses due to photons propagating through the strained material near the surface. Another explanation might be that the strained surface somehow affects the diffusion of the Zn to produce a more ragged junction or one that does not have the optimum gradient. After the discovery that it required higher thresholds, the SBM polish was discontinued as a prediffusion substrate polish. However, until the discovery of the PA solution, the SBM solution was still used whenever the (111) surface had to be polished, *e.g.*, to thin the n-GaAs substrates of single-heterostructure lasers.

Metallic contact resistance to polished layer.—In view of the above discussion, it seems probable that some film which is not completely removed by the cloth will remain on the GaAs surface after PA polishing. The thickness of this residual film has been estimated (12) to be about 70Å from ellipsometer measurements. This is to be compared to a film thickness of only 20Å on a BM polished slice. It is found, however, that the PA film thickness is reduced to less than 20Å after HF cleaning. Nevertheless, for any device application, it is essential to determine whether the remaining layer prevents the achievement of a good ohmic electrical contact to the polished slice. We performed several contact resistance experiments using our standard contact to n-type GaAs which is an alloy containing Sn-Pd-Sn (13). With the polished GaAs substrate held in vacuum at 150°C, 2000Å of Sn and 500Å of Pd were successively evaporated onto the surface. These two metals were then alloyed in vacuum at 525°C for 30 sec. On cooling the substrate to 150°C again, the final 7000Å thick layer of Sn was evaporated. Good ohmic contacts were reliably formed on

PA polished slices with the Sn-Pd-Sn contact and the results are virtually the same as found for the BM case. The numerical values given in Table I were obtained by measuring the total resistance of several n-type GaAs samples of known dimensions and subtracting off the bulk contributions. We conclude, therefore, that any layer which does remain on the surface after PA polishing does not prevent an ohmic contact.

Fabrication of diffused junction lasers from PA polished substrates.—Since PA and BM polished ($\bar{1}\bar{1}\bar{1}$) surfaces both appear to be of comparable quality, it was expected that diffused junction lasers should also be comparable in performance. At the present time, two different sets of PA and BM polished wafers have been compared. For each set, shallow 2 μm junctions were diffused (10) and stripe geometry contacts (11) applied in the usual manner. It was found that the average laser threshold current densities were essentially equal. Some devices from the PA polished substrates had slightly lower thresholds but this is not thought to be significant due to the complicated nature of the junction laser. Nevertheless, these results support our findings and again indicate that the PA solution produces a high quality surface.

Discussion

Our results, which are tabulated in Table I, demonstrate that the new PA polish is highly useful for GaAs technology. In summary, the PA solution provides satisfactory microtopography for all GaAs orientations of interest to device engineers, constant polishing rates, essentially strain-free surfaces, and ohmic metallic contact characteristics. The PA solution is much more predictable than either the BM or SBM solutions since these both deplete rapidly with time. In addition, the PA solution would be preferred over the BM solution because the latter will not polish the (111) faces. Sullivan and Kolb (1) have shown that if the bromine content is reduced to 0.0025% (*i.e.*, a factor of 20 smaller than used in this paper) then the (111) faces can be polished. However, as Iiyama *et al.* (14) have noted, the polishing rate is then so slow that it is no longer practical. Although the SBM solution will polish the (111) faces, it has the disadvantage that it is somewhat messy to use and leaves a strained surface which we believe has contributed to higher thresholds in diffused junction lasers. The presence of strain in a substrate may also be detrimental if one subsequently deposits vapor or liquid phase epitaxial layers. Such a situation has been reported by Weinstein *et al.* (15) for GaAs and Rozgonyi and Saul (16) for GaP.

There are several areas which we feel warrant further investigation. For example, we have not tried to optimize the over-all flatness of our wafers. In some cases with polishing method 1 of Fig. 1 we have achieved flatnesses of approximately 1 μm over a linear dimension of 1 cm. In this measurement a fairly large wafer is required since a rounding effect occurs at the outer 2 or 3 mm of the wafer. This rounding is considerably reduced by polishing method 2. However, it is expected that further improvements in flatness could be achieved by using some of the recently reported discal polishing techniques (14).

It would also seem important to determine optical quality and polishing rates as the volume percentage of NH_4OH is varied up or down from the value used by us which provides an essentially neutral solution ($pH \simeq 7.0$). In addition to the experimental results reported in this paper, we have performed two additional experiments using NaOH and KOH in place of NH_4OH. These were mixed with H_2O_2 to again produce a $pH \simeq 7.0$. In each case a test slice of n-type GaAs yielded a polish which appeared comparable in quality to the PA results of this paper when examined microscopically. These two solutions have not been investigated in detail but many possibilities are suggested of using these and other alkalines in conjunction with oxidizers other than H_2O_2.

It may also be of interest to study the effects of PA solutions on n-type and p-type GaAs as functions of the substrate doping levels. We can report that 10^{16} cm^{-3} n-type GaAs has been polished in addition to the $\simeq 10^{18}$ cm^{-3} GaAs used in most of the above experiments. We have also polished p-type $Ga_xAl_{1-x}As$ but extensive measurements on flatness, rate of removal, etc., are still to be made. Finally, it should be verified whether III-V compounds other than GaAs can be polished in PA solutions.

Acknowledgments

The authors thank R. E. Albano for expert technical assistance during the course of these investigations including the effects of motion and solution *p*H on the optical quality of the polished surface. We also thank A. P. Pisarchik and V. Decker for furnishing the original designs of the polishing machine and polishing fixture, A. J. Sayko for informing us of the existence of the PA solution, W. R. Costello for the scanning electron microscope study, V. J. Albano for assistance with the *p*H measurements, and S. E. Haszko for the x-ray topographs. Useful discussions have also been held with F. Vratny and M. V. Sullivan during the course of this work. Finally, we thank J. H. Rowen, L. A. D'Asaro, B. Schwartz, J. E. Ripper, and E. A. Ulmer for comments on the manuscript.

Manuscript received Nov. 30, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Neutron Activation Analysis of Epitaxial Silicon

Graydon B. Larrabee* and Joseph A. Keenan

Texas Instruments Incorporated, Central Research Laboratories, Dallas, Texas 75222

ABSTRACT

A neutron activation analysis technique has been developed for the analysis of epitaxial silicon. The technique is described in detail along with a table of detection limits. Impurity and dopant concentrations have been profiled through epitaxial films on boron- and antimony-doped substrates. These data along with experience in routine analyses show a factor of 10 to 40 higher impurity concentrations in the outer layer of silicon epitaxial films. Autoradiography combined with profiling has been shown to be a powerful tool for studying doping uniformity.

The production of epitaxial silicon for device fabrication has increased markedly in the last few years. Marketing personnel estimate that close to 80% of the total dollar production of single-crystal silicon will be epitaxial material in the 1972-1974 time period. This pronounced change in the mix of silicon product has focused attention on the development of new techniques for the characterization of this material.

The characterization of epitaxial material, for any parameter, is complicated by the physical form and size of the sample. Epitaxial silicon samples can generally be described as thin, lightly doped, single-crystal films, 2-30μ in thickness, on heavily doped 200-300μ thick single-crystal substrates. There are many techniques available for growing these single-crystal films (1, 2) but usually they are vapor grown at high temperatures (1050°-1250°C) on highly polished substrates from $SiCl_4$ as shown in Eq. [1]

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \qquad [1]$$

Current silicon production is on 2-in. slices, which means that the amount of epitaxial silicon sample available for analysis ranges from 1 to 15 mg, depending on the thickness of the film. Both intentionally added and adventitious impurities in these films range in concentration from about 1 ppm down to the sub-ppb level. As can be seen a highly sensitive characterization technique is required to analyze these films because of the combined effects of sample size and small impurity concentration.

Neutron activation analysis meets both of these requirements and has been used for the analysis of bulk silicon (3, 4). However, bulk silicon is readily available as large single crystals with samples in the 1-10g size. Further, there is no problem in sample handling whereas with epitaxial silicon it is necessary, before radioassay, to physically separate the film from the substrate without sampling the substrate as part of the film. This is accomplished by masking and etching techniques.

Abe and Sato (5) used activation analysis to determine the distribution of arsenic atoms in epitaxial films deposited on heavily doped arsenic substrates. Interpretation of the data which they obtained was difficult because the distribution could not be fitted to an error-function diffusion profile. Perezhogin and Meshcheryakov (6) determined the distribution of phosphorus in an epitaxial film on a boron-doped substrate and antimony in an epitaxial film on an antimony-doped substrate. This work is concerned with the determination of adventitious impurities in epitaxial films.

Experimental

Neutron activation analysis of epitaxial silicon can be described as a three-step process; irradiation, source preparation, and radioassay. Most of the radioactive isotopes produced in neutron bombardment decay by β-γ emission. Some pure β-emitters such as ^{32}P must be studied by β-spectroscopy. Chemical separations are usually required for β-spectroscopy both because of the polyenergetic β spectrum and because a thin source must be counted in order to minimize absorption of β particles within the source. The greater penetrating power of γ-rays makes it possible to identify impurities in solutions and solid samples by γ-ray spectroscopy. Since γ-rays are monoenergetic and specific for the isotope considered, most elements can be identified in a single sample without resorting to chemical separations. The simplicity of source preparation for γ-ray spectroscopy is counterbalanced, however, by the complexity of data reduction. In this laboratory computer reduction of data is used to achieve rapid analysis by γ-ray spectroscopy.

Irradiation

In earlier work (7) on the neutron activation analysis of SiO_2 films and silicon for sodium it was shown that both the amount and the location of this impurity in the sample was strongly dependent on the pre-irradiation packaging. As a result of that work, a standard quartz dish was designed, as shown in Fig. 1. These dishes have an inside diameter slightly larger than a 2-in. silicon slice and are approximately 0.5 in. in height.

In this work, epitaxial silicon samples were stacked into the dishes with specially cleaned ultrapure silicon spacers between them. Flux monitors were included with the slices. The dishes were fitted with quartz tops, wrapped in aluminum foil, and shipped to the reactor.

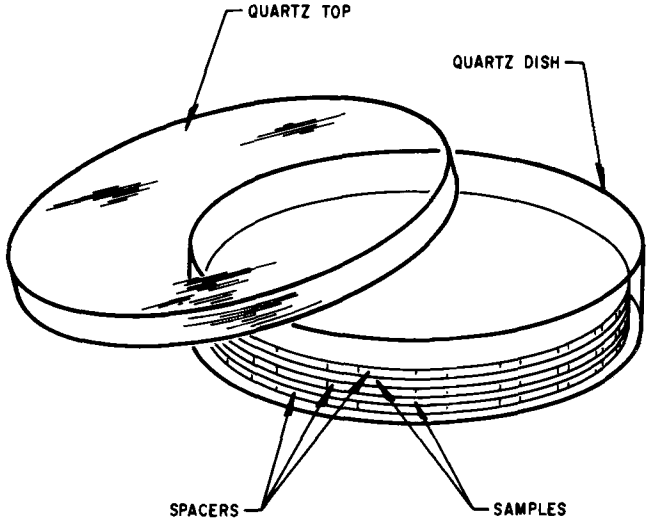

Fig. 1. Quartz dish used for the irradiation of silicon samples

* Electrochemical Society Active Member.

Key words: impurities, neutron activation, epitaxy, silicon, autoradiography.

Irradiations were performed in a fixed position on the face of the Texas A&M University reactor at a flux of 1.5 x 10^{13} n/sec/cm^2 for 14 hr. Normally the irradiation ended at midnight. The samples were shipped to our laboratory the following morning, processed for counting that afternoon, and counted the following morning. This 36 hr delay allowed the 2.6 hr ^{31}Si arising from activation of the matrix to decay sufficiently to make a negligible contribution to the γ-spectrum.

Source Preparation

Once returned to our laboratory, the quartz dish was opened, the monitors were placed to one side, the spacers were discarded, and the samples were stored in individual plastic boxes. Each slice was given three successive 2-min washes in 50 ml of 50:50 HCl:CH_3OH in plastic beakers to remove surface contamination. After these washings, the slices were rinsed twice in methanol, once in acetone, and air dried. The back of each slice was then masked with 2-in. polyethylene tape.[1]

It should be pointed out at this time that when the epitaxial film is grown on the substrate it effectively "wraps around" the edges of the slice. This "wrap-around" has been confirmed by angle lap and stain techniques. Therefore, the substrate is completely isolated from the etch solution once the tape has been applied to the back.

The masked slices were etched to remove the desired thickness of epitaxial material. The etches used were either an 8 μ/min "planar" etch ($HF:HNO_3:CH_3COOH$, 2:15:5, vol/vol) or a 1μ/min etch ($HF:HNO_3:CH_3COOH$, 1:40:1, vol/vol). The amount of material removed is readily determined by infrared interferometry spectroscopy (8). The etch rate for each etch composition has been found to be constant and reproducible.

In order to minimize sample handling and retain constant counting geometry, the slices were etched in the same 250 ml beaker in which the etchant was to be γ-counted. After the desired amount of epitaxial silicon had been removed the slice was taken from the solution with tweezers and rinsed with water into the same beaker. Finally the etch solution was diluted to a standard volume of 20 ml and the beaker was sealed for counting.

Monitors that were included in the irradiation were processed in the standard manner after all samples had been prepared for radioassay. Generally this involved crushing the small quartz vial with the monitor in the acid solution that was to be used to dissolve the monitor. After dissolution, the solution was diluted to volume in a volumetric flask, an aliquot removed and diluted to 20 ml in a 250 ml plastic beaker. This assures the same counting geometry for monitors and samples.

Gamma-ray Spectroscopy

Both low-resolution NaI(Tl) and high-resolution Ge(Li) γ-ray spectrometers were used in this work. The less efficient Ge(Li) system was used predominately as a pilot detector in order to identify the components of complex spectra for the linear-least squares computer analysis of the NaI(Tl) data.

The Ge(Li) system consisted of a 16 cc coaxial lithium-drifted germanium detector, a Tennelec TC135 preamplifier, TC200 shaping amplifier, and a Nuclear Data Model 2200 4096-channel multichannel analyzer. Energy resolution for the system was 3.7 keV at the 1333 keV peak of ^{60}Co. The multichannel analyzer was equipped with CRT display and teletype print and punched paper tape output.

All the detectors had plastic collars fitted to them to ensure that the 250 ml beakers containing the 20 ml of etch solution were held in a fixed-reproducible geometry. Typically NaI(Tl) spectra were accumulated for 100 min. Due to the lower efficiency of Ge(Li) detectors, these spectra were accumulated for as long as the intensity of the sources permitted (typically 20 hr) in order to obtain the best possible counting statistics.

Data Reduction

An IBM Model 047 tape to card converter was used to convert the BCD paper tape information from the NaI(Tl) detectors to IBM cards. For the bulk of the time covered by this work, the data from the Ge(Li) detector were analyzed by hand. More recently Ge(Li) data have been analyzed on a Texas Instruments Model 861 computer via a direct interface between the Nuclear Data Model 2200 and the computer.

The computer programs used to analyze the NaI(Tl) data were operated in a multiprogramming mode in a CDC 6400 computer. The two program system is outlined in Fig. 2. The first program (H 137) is a modified form of a linear least squares analysis developed by Helmer *et al.* (9). The second program converts the γ-intensities obtained from H137 to concentrations of the impurities in the sample.

In addition to the selection of various options, the input required for H137 consists of a background spectrum, the experimental data, and standard spectra of all the elements contributing to the experimental spectrum. These standard spectra are kept in a library which is updated at frequent intervals.

In order to derive impurity concentrations, H092 uses the γ-intensity from the monitor to account for

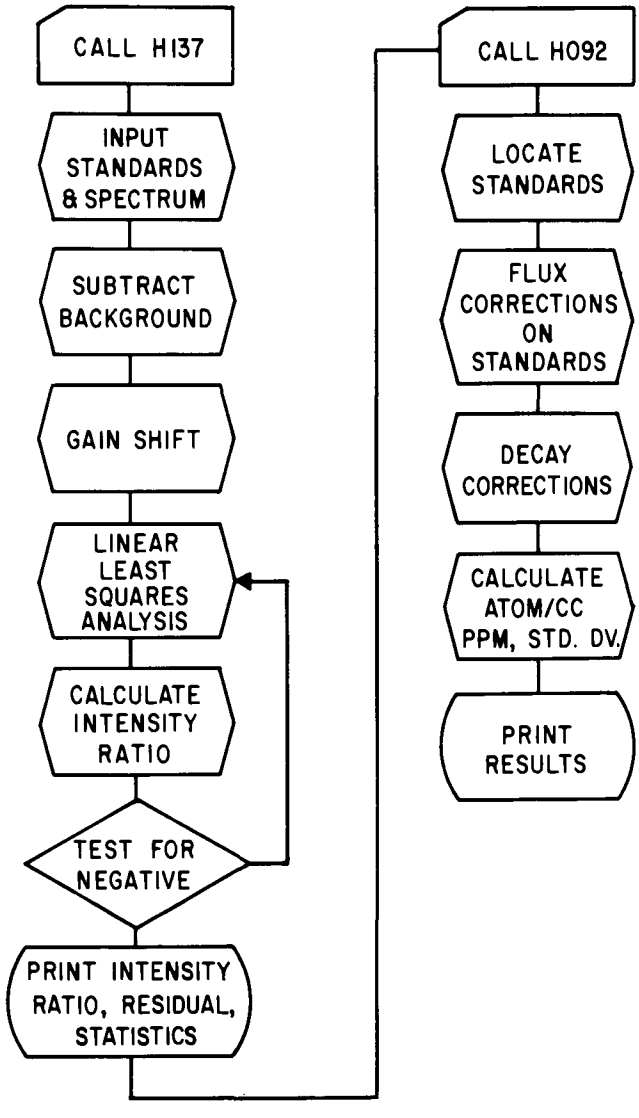

Fig. 2. Outline of the computer programs used to analyze the gamma spectra.

[1] Arno Adhesive Company, Fort Worth, Texas.

the difference in flux for the standards and for the experimental source. The additional inputs required by H092 are γ-intensity of the monitor, the weight of the sample, and the time after irradiation at which the sample was counted. Typically eight to ten samples can be processed through these computer programs to obtain final results as parts per million or atoms per cubic centimeter in 20 to 30 sec of central processor computer time.

The γ-intensities derived by H137 are expressed as the ratio of the experimental intensity to the standard intensity. Ratios as small as 0.001 have been detected with highly consistent results. The detection limits for a 100 min count, 36 hr after a 14-hr irradiation, at 1.5 x 10^{13} n/sec/cm^2 are given in Table I. These limits are based on counting a 10μ film etched off a 2-in. slice. A 10μ film was used in the calculations to simplify normalization of these detection limits to any other thickness removed. As can be seen the detection limits are good, with 50 elements having sensitivities less than one ppma and 33 less than 10 ppba. It must be remembered that these sensitivities are based on a 10μ film and any change in the thickness analyzed will proportionally affect the sensitivity. These sensitivities can be readily improved by an order of magnitude by going to a higher flux in another reactor and/or increasing the irradiation time.

A relative standard deviation of $\pm$5.3% for five impurities over a concentration range of 0.65 ppb to 415 ppm has been established for this technique applied to bulk silicon (3). The absolute accuracy was shown to be in the $\pm$6.1 to $\pm$35% range when compared to electrical measurements. There is no reason to believe that this precision and accuracy should change significantly, if at all, for epitaxial material.

Results

Epitaxial silicon.—Neutron activation analysis of epitaxial silicon has been in routine use in these laboratories for about 18 months. The most commonly observed impurities are those generally seen in all semiconductor grade silicon; gold, copper, sodium, arsenic, and antimony. A statistical analysis of the gold, copper, and sodium contents of the surface (outer 4μ) and epitaxial film (remaining film after removal of the outer 4μ) gives clear evidence that the surface concentrations are a factor of 10 to 40 higher than in the film. An example of this is shown in Table II.

Table II. Concentrations of three impurities in epitaxial silicon showing distribution

Impurity	Concentration (atoms/cc) Surface (4μ)	Epitaxial film (>4μ)
Gold	1 x 10^{13}	1 x 10^{12}
Copper	7 x 10^{14}	6 x 10^{13}
Sodium	3 x 10^{15}	7 x 10^{13}

Other impurities have been observed in epitaxial films including those elements present in the lapping compounds such as zirconium and hafnium. This occurs when the slices have not been properly cleaned. Other impurities that have been observed sporadically include molybdenum, tungsten, lanthanum, bromine, chromium, gallium, cerium, and the rare earths. There appears to be no explanation for the random appearance of these latter impurities but the evidence for their presence is strong since they were confirmed by both NaI(Tl) and Ge(Li) gamma-ray spectroscopy.

Impurity Profile Through the Film

Impurities.—The distribution of impurities through two epitaxial films was determined by incremental etching followed by gamma-ray spectral analysis of the etch solutions. The results of these profile analyses are shown in Fig. 3 for a 20μ film on a boron substrate and in Fig. 4 for a 20μ film on an antimony-doped substrate. As can be seen the concentration of impurities tends to be high at the surface and then becomes level through the epitaxial film. In the case of the film on the antimony substrate, the outdiffusion of the antimony into the film is easily seen. Since boron does not have a detectable radioactive species, similar data are not available for the boron-doped substrate.

An understanding of the location of the impurities in epitaxial film could provide valuable insight for device processing (10). Generally, devices are fabricated in the first few microns of the epitaxial film where the highest concentration of impurities exist. This would suggest that a cleanup procedure which removes a micron or more of the epitaxial film might be beneficial.

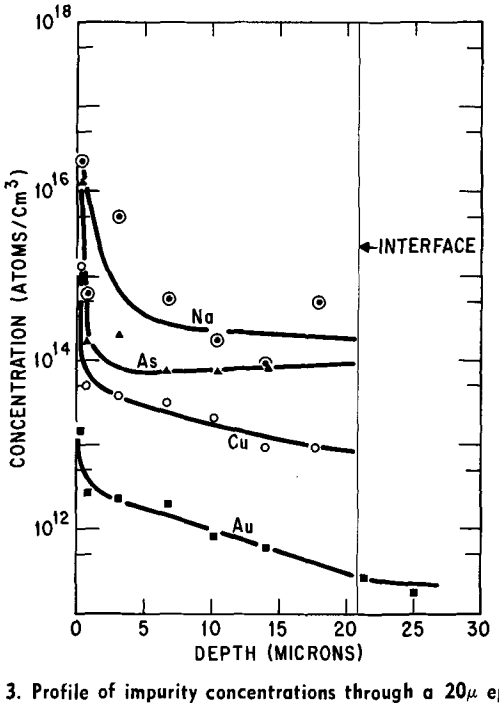

Fig. 3. Profile of impurity concentrations through a 20μ epitaxial film on a boron-doped substrate.

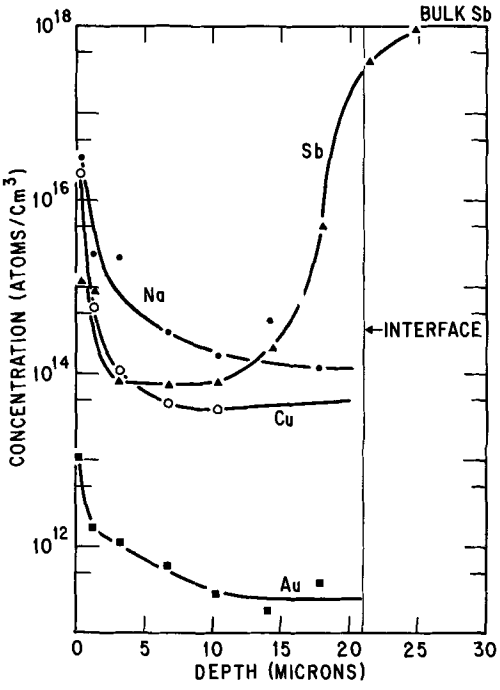

Fig. 4. Profile of impurity concentrations through a 20μ epitaxial film on an antimony-doped substrate.

Dopant.—Two samples of 0.11 ohm-cm arsenic-doped epitaxial film (12.5μ thick) on a p-type boron-doped substrate were irradiated and profiled. The arsenic distributions for both slices are shown in Fig. 5. As can be seen good agreement was obtained. The depth of penetration of arsenic was considerably deeper than anticipated and may have been caused by indiffusion of the arsenic dopant during epitaxial deposition.

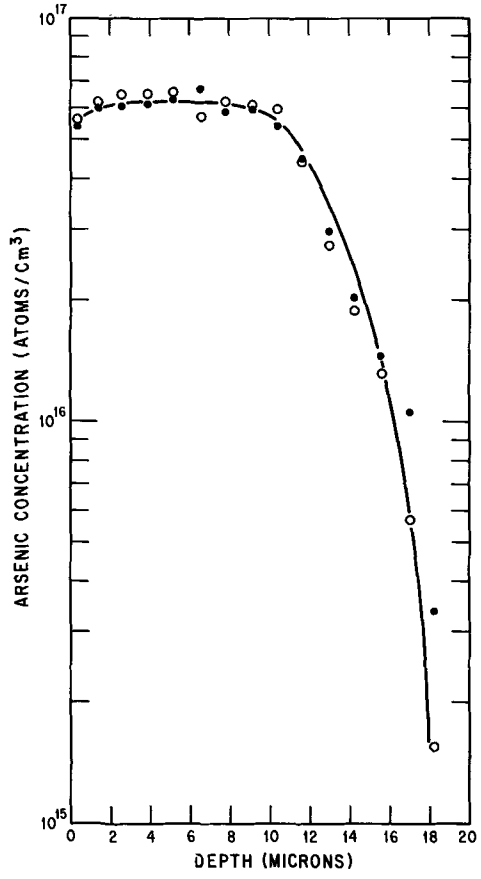

Fig. 5. Profile of arsenic distribution through a nominal 12.5μ arsenic-doped epitaxial film.

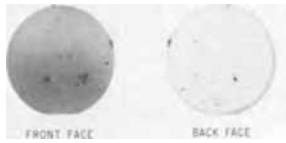

Fig. 6. Autoradiogram of arsenic distribution on the front and back face of a silicon slice with a 12.5μ arsenic-doped epitaxial film.

The surface distribution of the arsenic was also studied using autoradiography. A typical autoradiogram is shown in Fig. 6. By simultaneously taking autoradiograms of the front and back of the slice it is possible to differentiate between front and back face radioactivity. Activity exposing the film through the slice will form a diffuse image. Notice that on the back face autoradiogram the arsenic distribution shows that the epitaxial film, when grown, wraps around the edges. It can also be seen that, on this particular slice, there are areas of high arsenic concentration in the epitaxial film.

This combination of autoradiography and profiling provides a valuable tool for the study of doping uniformity in epitaxial films. Information can be obtained on the doping uniformity both across the slice and through the film.

Conclusions

Neutron activation analysis is a powerful characterization technique with high sensitivity and with the capability to analyze epitaxial films for chemical impurities in depth. The analytical procedure described in this work, utilizing computer reduction of the gamma spectra immediately followed by the calculation and print out of impurity concentrations, has been shown to be a versatile and efficient method. While the irradiations must be performed at a remote location, a 36-hr wait is required to allow the 2.6-hr ^{31}Si matrix activity to decay. This allows adequate time for the return of the samples from the reactor to the laboratory and sample preparation for radioassay. Sample preparation, including masking the back of the slice, etching and diluting to volume for counting takes typically 2 hr for six to eight samples. Radioassay generally takes 100 min to acquire sufficient counting statistics in the gamma spectrum.

A profile of the impurity concentrations through the epitaxial films indicate higher concentrations at the surface. This observation is supported by the historical data on the routine analyses and shows about 10 to 40 times higher concentrations on the surface than in the bulk. This phenomenon is particularly important in device fabrication because all devices are built in the outer surface of the epitaxial film. Doping uniformity, both radially and in depth can be readily studied by combining autoradiography and these profiling techniques.

Impurities that do not form detectable isotopes in (n,γ) reactions, *e.g.*, boron, carbon, oxygen, aluminum, etc., cannot be determined by neutron activation. These elements can be detected by other techniques such as charged particle activation, ion microprobe mass analysis, and spark source mass spectroscopy (11).

Acknowledgments

This work would not have been possible without the assistance of personnel from both the Components and Materials Groups. T. George originated much of this work and has generously provided samples. O. Cecil grew the epitaxial films used for the profiling work and has given us substantial help in the interpretation of the results. We are especially indebted to J. King for his diligence in performing the radiochemistry involved with this work.

Vapor Growth and Properties of AlAs[1]

M. Ettenberg, A. G. Sigai,* A. Dreeben,* and S. L. Gilbert

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Aluminum arsenide epitaxial layers on GaAs substrates have been prepared by a continuous flow vapor transport technique employing AlCl and AsH_3. It has been found that for all practical experimental conditions the reaction of AsH_3 and AlCl takes place at the point of mixing of the reactive gases. This behavior is consistent with a thermochemical analysis of the AlAs growth. The bandgap of AlAs was determined by optical absorption to be 2.17 eV and indirect. Hall and resistivity measurements made on epitaxial layers removed from the substrates indicate that the as-grown material is n-type with electron concentrations ranging from 6×10^{18} to 4×10^{17} cm^{-3} with corresponding room-temperature mobilities varying between 75 and 280 cm^2/V-sec. The value of 280 cm^2/V-sec is the highest measured electron mobility yet reported for AlAs. While the material does degrade in air, it has been found stable enough to allow ample time for device fabrication and protection.

The large bandgap (> 2.1 eV) (1) of AlAs makes it an especially interesting material for high-temperature device applications or optical applications in the visible region of the spectrum. The high melting point of this compound and the reactivity of aluminum have created problems in its high-purity preparation. The major limitation to material characterization or device fabrication, however, has been the instability of AlAs in air. Reported complete degradation of grown layers in 10 min (2) would indicate a limited usefulness.

This study was made using the open flow vapor growth system (3) employing the Group V hydride and the Group III chloride, modified to accommodate the growth of aluminum III-V compounds. In this system growth takes place at temperatures significantly below the melting point of the compound grown, thus reducing many of the problems associated with the reactivity of aluminum and general contamination. This technique has yielded n-type AlAs having increased stability and the highest electron mobilities yet reported (4, 5).

Experimental

The growth system, shown in Fig. 1, consists of a quartz tube which accommodates a pure alumina liner containing alumina boats filled with 99.999% aluminum. The alumina is 99.7% Al_2O_3 with 0.05% SiO_2, 0.1% Fe_2O_3, 0.2% Na_2O, and 0.05% K_2O as major impurities. Aluminum monochloride is formed by passing Pd-diffused H_2 carrier gas containing 0.2% HCl by volume over the liquid aluminum at 1000°-1050°C. The AlCl is then mixed with AsH_3, and the AlAs formed was deposited on GaAs substrates at a temperature between 1000°-1050°C. The AsH_3, which contains < 1 ppm total impurities determined by mass spectrometry, is 2% by volume in the H_2 carrier gas. This configuration (Fig. 1) includes provision for a gallium boat so that $Al_xGa_{1-x}As$ alloys may be grown as well as pure AlAs by simultaneously passing HCl over gallium. This basic system may also be employed to grow AlN using NH_3 instead of AsH_3 and AlP using PH_3. The long aluminum zone, containing up to six aluminum-filled boats, allows the first two aluminum boats to act as getters removing any traces of H_2O, O_2, or other impurities contained in the HCl and H_2 stream. The remaining boats serve to insure complete equilibration of the HCl with aluminum. The exposed quartz in the deposition zone is protected from attack by the initial deposits of AlAs. More recently, a tungsten liner has

Cr-doped GaAs	Mass spec[1]	0.1	2	0.5	0.1

[1] In all the mass spectrographic analyses, impurity levels of C, O, and F were consistently observed. These levels are thought to be associated with surface contamination since their concentrations decreased as more of the surface is removed during analysis.

been employed in the deposition region to facilitate cleaning and to further reduce Si contamination.

Reaction of the AsH_3 and AlCl to form AlAs takes place at the point of mixing of the two gases, independent of reactive gas concentrations up to at least changes of a factor of five in AlCl or AsH_3 concentrations. Furthermore, the location of the reaction zone does not change for various combinations of aluminum and reaction zone temperature between 850° and 1050°C. In order to move the reaction zone from the mouth of the alumina tube, an alumina plug (99.7% Al_2O_3), with small holes (1/16 in. diam) drilled through it, was added to the mouth of the alumina tube, decreasing the effective cross section and thus increasing the gas velocity at the point of reaction. This spread the reaction over a 4 in. length, allowing a suitable substrate to be conveniently placed in the reaction zone.

Growths were usually made on chemically polished GaAs substrates oriented 3° from the (100) plane. Substrates were cleaned for 20 min in Caro's acid etch (5 H_2SO_4, 1 H_2O, 1 H_2O_2) and 1 min in 1% Br-methanol solution just prior to insertion in the system. Growth rates could be varied between 10 and 100 μm/hr depending on reactant concentrations and volumes. Depositions at growth rates less than 60 μm/hr on GaAs substrates at temperatures exceeding 980°C were invariably good single-crystalline layers as evidenced by Laue back-reflection photographs. Layers grown at temperatures below 980°C or at high growth rates (> 60 μm/hr) were usually highly oriented large-grain polycrystals.

AlAs Properties

One of the significant factors limiting the potential usefulness of AlAs is its reported instability in air (2); contrary to this report, some of the single-crystalline epitaxial layers reported here were stable in air for periods of up to 1 month and could be maintained in vacuum indefinitely. Unprotected diffused diodes fabricated from this material (6) maintained their I-V characteristics for several weeks. This stability is attributed to the higher purity and good crystallinity of the AlAs prepared by this technique.

The optical bandgap for the material has been ascertained to be indirect and 2.17 ± 0.02 eV at 300°K, in good agreement with prior studies (1, 6, 7). This value has been obtained by analysis of optical absorption data from several AlAs layers from which the GaAs substrate was removed. Similar results were obtained with polycrystalline layers grown on (0001) sapphire substrates.

Hall effect and resistivity measurements made on epitaxial aluminum arsenide layers, while still on semi-insulating Cr-doped GaAs substrates (> 10^5 ohm-cm), yielded mobility values which were inordinantly high for a large indirect bandgap material (in excess of 3000 cm²/V-sec). Attempts to remove the AlAs from the substrate were hampered by cracking of the sample as it was thinned. By preferential removal of the AlAs in aqueous HCl, it was ascertained from Hall measurements that there existed, in some samples, a thin layer of highly conducting GaAs at the surface of the semi-insulating GaAs substrate. The Hall mobility of such a layer was measured to be ~ 2000 cm²/V-sec. By sandblasting the GaAs surface with alumina powder, the conducting GaAs layer could be removed; it was estimated, by further etching, that the thickness of these interfacial layers were between 2 and 10 μm. In Table I the impurity concentrations at the surface of a Cr-doped GaAs substrate are compared before and after removal of the interfacial conducting layer by sandblasting.

As can be seen from the table, there is a high concentration of impurities at the interfacial layer. These impurities probably have diffused into the GaAs from the AlAs during growth. The impurity concentration of silicon is sufficiently in excess of the Cr compensation to make the semi-insulating Cr-doped GaAs n-type. Furthermore, calculations, assuming a reasonable value for the diffusivity, have shown that typical growth rates may be comparable to the diffusion rate of Si at growth temperatures, indicating that the Si contamination of the semi-insulating GaAs substrate could arise from Si impurities present in the AlAs. Thus, it may be concluded that, contrary to the results for other III-V compounds, electrical measurements on vapor-grown AlAs cannot be made on compensated semi-insulating substrates when diffusion of impurities is likely.

As a result, emphasis was placed on electrical data derived from thicker AlAs layers (> 4 mils) from which the GaAs substrates could be removed. Ohmic contacts were made to the AlAs by a combination of ultrasonic soldering with indium followed by an anneal in H_2 at 800°C for 2 min. In Table II are listed electrical properties and impurity analyses of AlAs epitaxial layers with the GaAs substrates removed. Table II indicates that silicon is the main donor in this vapor-grown AlAs.

The room-temperature electron mobility of 280 cm²/V-sec obtained for sample C is higher than the highest previously reported value of 180 cm²/V-sec obtained by Whitaker (5). The higher mobility value found in this study may still be representative of compensated material, perhaps due to Si self-compensation such as found in $Al_{1-x}Ga_xAs$ grown from Ga solution (8). This hypothesis is consistent with the mass spectrographic analysis which shows that the amounts of species which are probably compensators (Fe, Cu, Mg) are quite low in sample B, while the silicon contamination is quite high.

The cracking of the thinner epitaxial AlAs layers upon attempts to remove the GaAs substrate is indicative of strain at the interface. It is noteworthy that at the growth temperature the lattice match between AlAs and GaAs is almost perfect (9), indicating that this is not the source of the strains. Instead, the strain is probably due to the differential thermal contraction

[1] In all the mass spectrographic analyses, impurity levels of C, O, and F were consistently observed. These levels are thought to be associated with surface contamination since their concentrations decrease as more of the surface is removed during analysis.

(9). This hypothesis is consistent with the fact that the dislocation densities found by electron microscopy in the grown AlAs layers are comparable to that of the starting substrates ($\sim 10^5/cm^2$).

Thermochemical Analysis

Analysis of the thermochemistry of the aluminum arsenide vapor growth was made to better understand the growth of AlAs and provide a compiled data source to give insight for the future growth of $Al_xGa_{1-x}As$ and other mixed aluminum compounds.

Three primary sources of data were employed. The JANAF tables (10) were used for data on AlCl, $AlCl_3$, and HCl; the values derived from this source for the important reactions present in the system are shown as solid lines in Fig. 2 and 3. Values derived from recent work by Kikuchi *et al.* (11), more in agreement with the bulk of previous measurements, are indicated as dashed lines in Fig. 2 and 3. The free energy of formation of AlAs is given by Hoch and Hinge (12), who used a Knudsen effusion cell to measure vapor pressures between 1350° and 1530°K. On this basis, the extrapolated values are estimated to be reliable within ± 50°C about the measured temperature range. The free energy of formation was reduced to the liquid aluminum standard state by taking values for the free energy of evaporation from Hultgren *et al.* (13).

Although there are some discrepancies between the various sources of thermodynamic data, certain conclusions may still be drawn. It is assumed that the volume fractions of the various gases, in the growth tube, are equal to their partial pressures. This is a valid assumption since the system is held at a constant pressure of 1 atm by a small head of silicone oil at the gas exit, and the volume fractions of the gases are all measured at room temperature.

It must first be ascertained what gaseous species enter the growth or mixing chamber. If it is assumed that the various species have come to equilibrium, according to data accumulated by Ruehrwein, at 1000°C and an incoming AsH_3 pressure of 2×10^{-2} atm (14), the AsH_3 has completely decomposed ($<<$ 0.01% undecomposed) and the amounts of As_2 and As_4 coexisting are 20 and 80%, respectively. Employing the data of Stull and Sinke (15), 70% As_2 and 30% As_4 exist at 1000°C at equilibrium. In both cases, little of the As species is present ($<$ 0.1%). Even though the calculations do not clearly indicate the predominant arsenic species, As_2 is used as the standard state for the reactions considered in Fig. 2 and 3. The assumption is justified because departures from equilibrium will tend to favor the simpler As_2 molecule; also, as shown in Fig. 2, there is only a small difference in free energy of formation of AlAs between the As_2 and As_4 standard states.

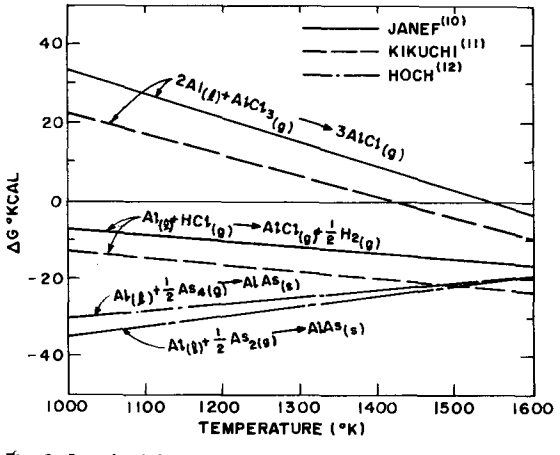

Fig. 2. Standard free energy changes for aluminum reactions

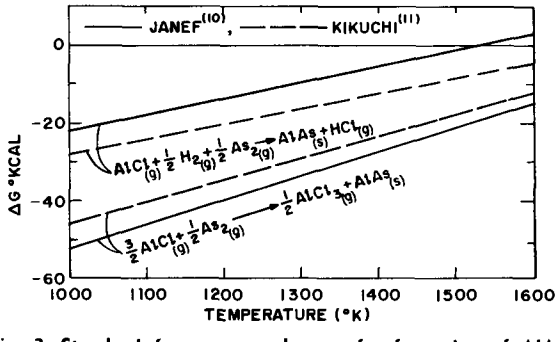

Fig. 3. Standard free energy changes for formation of AlAs in vapor-growth system.

In the aluminum zone, the picture is much clearer; in equilibrium at 1000°C and an incoming HCl pressure of 2×10^{-3} atm, AlCl is the predominant species. Using the JANAF tables, calculations show that 99.5% is AlCl and 0.5% is $AlCl_3$, while from the data of Kikuci 99.8% of the reactive gas is AlCl. Calculations with both data indicate that a negligible amount of HCl will remain unreacted at equilibrium.

The equilibrium products for the reactions taking place on mixing of the As_2 and AlCl at 1000°C can now be calculated. The two possible reactions forming AlAs are

$$AlCl + \frac{1}{2}H_2 + \frac{1}{2}As_2 \rightarrow AlAs + HCl \quad [1]$$

$$3AlCl + As_2 \rightarrow 2AlAs + AlCl_3 \quad [2]$$

Ignoring the small diluent effect of mixing the As_2 and AlCl from the JANAF data, both reactions will result in almost complete reaction of AlCl to form AlAs, 85% if HCl is the only product and 96% for $AlCl_3$ product. Kikuchi's data indicate 99% conversion for HCl and 90% for an $AlCl_3$ product. Due to the differences in free energies from the two sources, a dominant reaction cannot be chosen. The over-all reaction in the mixing zone is

$$5AlCl + 2As_2 + H_2 \rightarrow 4AlAs + 2HCl + AlCl_3 \quad [3]$$

This reaction does go to completion but the ratio of HCl to $AlCl_3$ is ambiguous from the available data.

It should be noted that, for the various reactions taking place in the AlAs growth system, an examination of the signs of the free energy changes alone will not lead to proper conclusions about the gaseous species involved. One of the major factors controlling these reactions is the low partial pressures of the reactive gaseous compounds. Only if all the gases are in their standard states, 1 atm, can the sign or magnitude of the various free energy changes be used as a criterion for choosing dominant reaction.

Although it is difficult to make precise quantitative statements from the available data, it should be possible to predict some temperature range where, at the present flow rates, the reactants forming AlAs should not react completely. The reactive gases may then be mixed in one temperature zone and the product deposited at some lower temperature as is done for the growth of GaAs. By examination of Fig. 3, it may be seen that at temperatures in excess of 1300°K the dominant reaction is the one that yields HCl as the product. An arbitrary temperature to employ as a mixing temperature would be the point at which the reaction only proceeds 25% to completion. This temperature is ~1160°C from the JANAF data and ~1300°C from Kikuchi's data. The temperatures necessary to test this hypothesis were not attainable in the present growth system; and, in use, equilibrium was only approached. Although quantitative data are difficult to derive from this growth system, it has nevertheless been observed that as the temperature is raised in the reaction zone the growth region tends to spread out. Thus, as indicated by the equilibrium anal-

ysis, complete reaction is not taking place at the point of mixing of reactive gases.

In summary, the vapor growth of AlAs from AsH_3 and AlCl, in the temperature range accessible in the present experiments and reactant concentration necessary for single-crystal growth, occurs at the point of mixing of the two reactant gases. This is distinct from GaAs vapor growth where mixing occurs at one temperature and deposition occurs at some lower temperature. This immediate deposition of AlAs is consistent with the given thermochemical analysis. Furthermore, AlAs has been shown to be a wide band gap semiconductor with a higher electron mobility than GaP and a stability which allows sufficient time for device fabrication and protection.

The Phase Diagrams of the Systems $PbCl_2$-UCl_4 and $PbCl_2$-UCl_3

J. L. Borowitz, R. Rafaeloff,[1] and A. Roy[2,*]

Soreq Nuclear Research Centre, Yavne, Israel

ABSTRACT

The phase diagrams of the salt mixtures UCl_4-$PbCl_2$ and UCl_3-$PbCl_2$ have been investigated by means of thermal analysis. There is a single eutectic at 50 mole per cent (m/o) UCl_4 and 346°C in the UCl_4-$PbCl_2$ system. A compound with incongruent melting point, of a composition $6PbCl_2$:$1UCl_4$ decomposing at 386°C is apparent. The melting points of the pure salts, as measured, are 503°C for $PbCl_2$, 590°C for UCl_4. The UCl_3-$PbCl_2$ system has a single eutectic at 11 m/o UCl_3 and 470°C, with no peritectic reaction. A heat effect at 342°C was noted. The melting points of the pure salts, as measured are for $PbCl_2$ 502°C for UCl_3 841°C. X-ray diffraction analyses gave no indication of solid solution in either system. Analysis of both the phase diagrams according to the Van't Hoff equation indicates that both systems behave like ideal mixtures [in accordance with Temkin's (1) model] oversignificant concentration ranges.

Phase diagrams of mixtures of UCl_4 and alkali metal chlorides have been investigated by Barton *et al.* (2), by Kuroda and Suzuki (3), and by Bogacz and Trzebiatowski (4). The last showed the mixtures to be nonideal due to the formation of complexes in the melt. Kuroda and Suzuki also examined the UCl_4-alkaline earth chloride systems.

The present research shows that melts of uranium and lead chlorides approach ideality, indicating that the different charges on the cations do not cause irregularity in the molten salt structure (5).

Experimental

Materials.—Reagent grade (Baker Analyzed) $PbCl_2$ of specified purity 99.5% was dried by heating under vacuum. The temperature was raised at approximately 100°C per hr until just below the melting point.

UCl_4 specified as chemically pure, obtained from A. D. Mackay, Inc., U.S.A., was purified by vacuum sublimation. This was done in an apparatus consisting of four tubes 250 mm long and 36 mm in diameter joined end-to-end horizontally by tubing of smaller diameter. The UCl_4 was placed in one end tube, and this end was sealed. The apparatus was evacuated from the other end to 10^{-3}-10^{-4} mm Hg. The tube containing the UCl_4 was heated to 500°C, the second tube to 325°C, and the third to 250°C, and the sublimation carried out at these temperatures. UCl_4 sublimed into the second tube, while more volatile impurities condensed mainly after the third tube. A 120g batch could be purified in this way in 6-8 hr, dark green crystals of UCl_4 being obtained. At the end of the run the tube containing the sublimed UCl_4 was sealed at both ends and opened in a dry box. This material normally had

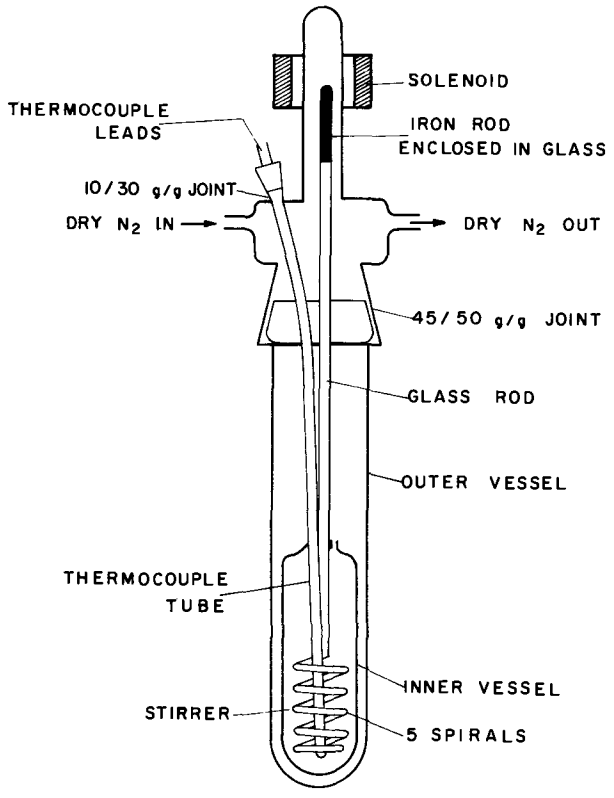

Fig. 1. Thermal analysis cell

a chlorine to uranium ratio of 4.00 ± 0.02. The original material, analyzed spectroscopically contained less than 0.07% metal elements other than uranium. UCl_3, obtained from the same source, was used as received, after analysis.

Nitrogen gas for the inert atmosphere was passed through a column of copper chips at 550°C to remove traces of oxygen, and then through a drying tube containing Linde "Molecular Sieve 5A."

Apparatus.—The thermal analysis cell used was very similar to that described by Solomons and Janz (6), and is shown in Fig. 1. The melt was contained in a Pyrex test tube, 25 mm in diameter and 70 mm long, closed except for a 9 mm hole at the top through which the stirrer passed. The space between the stirrer and the hole was used for filling the test tube, and was afterwards closed by wrapping a piece of platinum foil around the opening, in order to prevent loss of UCl_4 by sublimation. The thermocouple well was sealed into the top of the test tube, as shown.

The stirrer was a glass helix with five spirals extending over a length of 30 mm. A piece of iron rod was encased completely in glass at the top of the stirrer extension rod, and by means of a solenoid a vigorous up-and-down movement of the stirrer could be induced, thus overcoming the high viscosity of the melts.

The test tube was kept in an atmosphere of dry nitrogen gas in the outer vessel. This gas was dried and purified by passing over copper chips at 550°C to remove traces of oxygen, and then through a drying tube containing Linde molecular sieve 5A.

The test tube was made of Pyrex for the UCl_4 experiment and of quartz for experiments with the higher melting UCl_3. The melts did not appear to affect the test tube in any way, even after a few days contact, provided moisture was rigidly excluded.

Temperature measurement.—The temperature of the melt was measured by a Chromel-Alumel thermocouple. The thermocouple was calibrated before, during, and after the measurements at the freezing points of tin, cadmium, lead, and zinc. The melting points of these metals were obtained with a reproducibility of ±0.5°C. Both temperature-time cooling and heating curves were obtained on most samples. The liquidus temperature of a salt mixture was usually taken by extrapolation across the supercooled region. Reproducibility was approximately ±1°C. The temperature was continuously recorded on a recording potentiometer and the thermocouple electromotive force was periodically checked on a Leeds and Northrup precision potentiometer.

Analysis of melts.—A freshly prepared mixture was used for the determination of each temperature-composition point on the phase diagram. After recording cooling curves some mixtures were analyzed using the procedure detailed below. The compositions were found to correspond, within the limits of accuracy of the analysis, to those based on the known weights of the compounds introduced into the reaction vessel. The latter were thus taken as the compositions of the mixtures.

The analytical procedure was to dissolve the mixture in nitric acid and to determine the chloride by the Votocek and Volhard titration methods (7).

For determination of lead and uranium, another sample was dissolved in nitric acid and evaporated twice to white fumes. The lead was then precipitated as lead sulfate by sulfuric acid. Since nitric acid dissolves lead sulfate, the solution was evaporated twice with sulfuric acid until dense white fumes were evolved. In order to separate the lead from coprecipitated UO_2Cl_2, the sulfate was dissolved in ammonium acetate solution, and reprecipitated with ammonium para-molybdate. The lead was weighed as $PbMoO_4$ (8). The separated uranium was precipitated from solution as ammonium uranate (9).

Experimental procedure.—The apparatus, which had been filled in a dry box, was placed in a tube furnace. It was evacuated at 10^{-3}-10^{-4} mm for one hour, purged with dry nitrogen for an hour, and then heated to 150°C under vacuum for one hour. After this the apparatus was cooled to room temperature under vacuum and flushed again with nitrogen. While heating and cooling curves were being obtained, a very small flow of nitrogen was maintained so that the vessel was always slightly above atmospheric pressure.

The mixture was slowly heated until it became liquid, when the stirrer was turned on. After adequate agitation to homogenize the melt, a cooling curve was obtained by lowering the power input to the furnace. Liquidus and transition points were deduced from breaks in the cooling curves. Repeated cooling curves confirmed the points with variation not greater than ±1°C.

Results and Discussion

Figure 2 is the phase diagram for the UCl_4-$PbCl_2$ system. The melting point of the pure compounds as given on the figure were found at 503°C for $PbCl_2$ and 590°C for UCl_4. A eutectic of composition 50 mole per cent (m/o) of UCl_4 is evident at 346°C, and a peritectic line at 388°C was found. This line is due to a compound of incongruent melting point and composition near 6 $PbCl_2$:1 UCl_4. The existence of this compound was confirmed by x-ray diffraction. Solidified melts of composition between 14% and 50% UCl_4 revealed diffraction lines corresponding to *d*-values of 4.08, 4.00, 2.45, and 2.05Å. These are quite distinct from the lines of pure UCl_4 and pure $PbCl_2$ as checked by us.

An attempt to isolate the $PbCl_2$-rich compound was made as follows. A mixture of 40% UCl_4, 60% $PbCl_2$ was placed in a vessel similar to the ordinary phase diagram vessel, but for two changes: (*i*) The inner vessel, containing the mixture, had a perforated bottom. (*ii*) This vessel was inserted into a close-fitting test tube. The fit here was good enough to prevent molten material leaving the vessel to any large extent until the vessel was lifted out of the test tube.

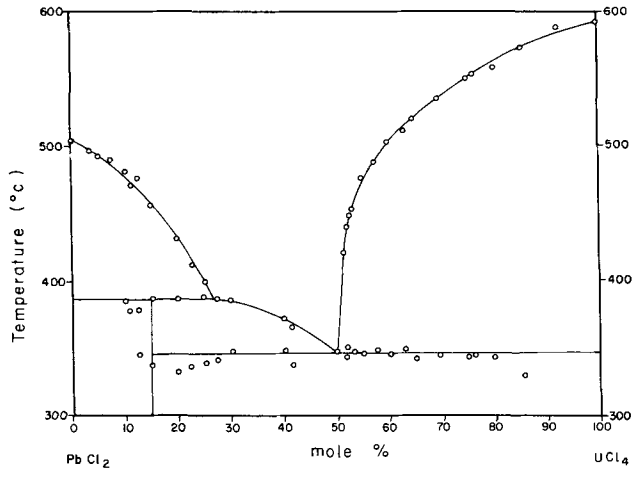

Fig. 2. Phase diagram—UCl_4-$PbCl_2$

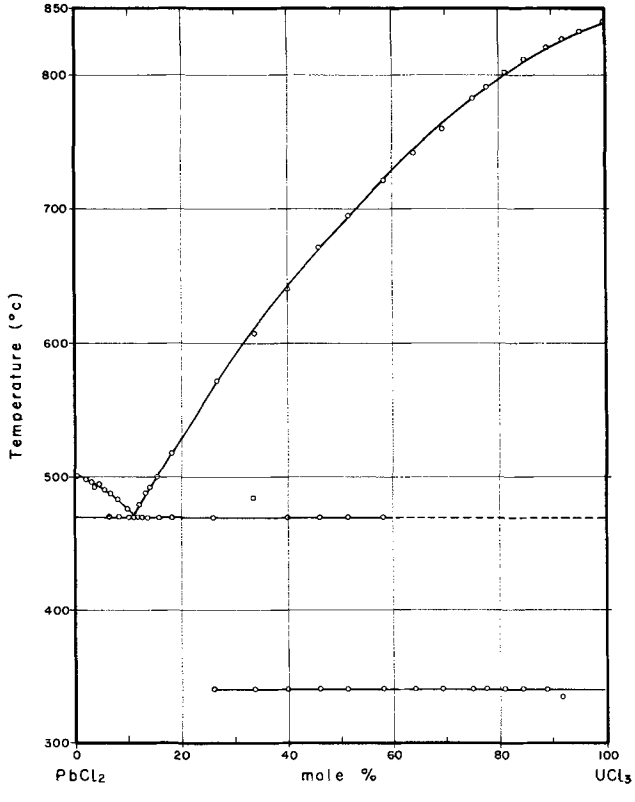

Fig. 3—Phase diagram—UCl_3-$PbCl_2$

The material was melted under the conditions used for cooling curves, stirred, and then held at a temperature between its liquidus and the eutectic temperature for two hours, while stirring. At the end of this period the inner vessel was lifted out of the test tube, filtration took place, and the system was then cooled rapidly.

An analysis of the material left in the vessel indicated a composition of 14.4% molar UCl_4, or an approximate ratio of UCl_4 to $PbCl_2$ of 1 to 6.

Comparison of the lines characteristic of $PbCl_2$ and UCl_4 obtained from solidified melts, with those of the pure compounds gave no indication of solid solution.

The phase diagram of the UCl_3-$PbCl_2$ system is shown in Fig. 3. A single eutectic at 11 m/o UCl_3 and 470°C was found. X-ray diffraction analyses on solidified melts showed no signs of solid solutions.

The heat effect at 342°C does not appear in the literature. It is shown on the diagram as it was a marked effect, but the possibility that it is an impurity (UCl_4) effect may not be excluded.

A simple thermodynamic analysis of the two phase diagrams investigated was attempted using the Van't Hoff equation.

$$\ln a_A = \frac{\Delta H_A}{R}\left(\frac{1}{T_o} - \frac{1}{T_m}\right) + \frac{\Delta C_p}{R}\left(\frac{T_o}{T_m} - 1 - \ln\frac{T_o}{T_m}\right)$$

where a_A is the activity of component A

ΔH_A is the latent heat of fusion of pure A

T_o is the melting point of pure A

T_m is the liquidus temperature.

$$\Delta C_p = C_L - C_S$$

where C_L is the specific heat of the liquid at T_m

C_S is the specific heat of the solid at T_m.

The ΔC_p correction has been neglected in the analyses on the basis that, within the concentration ranges considered, it is unlikely to exceed significantly the experimental error (10).

Figures 4 and 5 are plots of $\ln X_A$ against $1/T_m \cdot 10^3$.

Ideal behavior is seen in the UCl_4-$PbCl_2$ system between 100% and 88% $PbCl_2$ and between 100% and 85% UCl_4. In the UCl_3-$PbCl_2$ system the mixtures are approximately ideal from 100% to about 48% UCl_3.

The ideal behavior found shows the activity a_A to be equal or almost equal to the concentration X_A. This equality is in accord with Temkin's (1) model for ideal behavior of molten salts. In this model the charge of a cation does not affect its distribution on cation sites which is random. The activity thus tends to equal the concentration.

Allowing for vacancies introduced into the "lattice" of the melt by the inequality of the cation valencies,

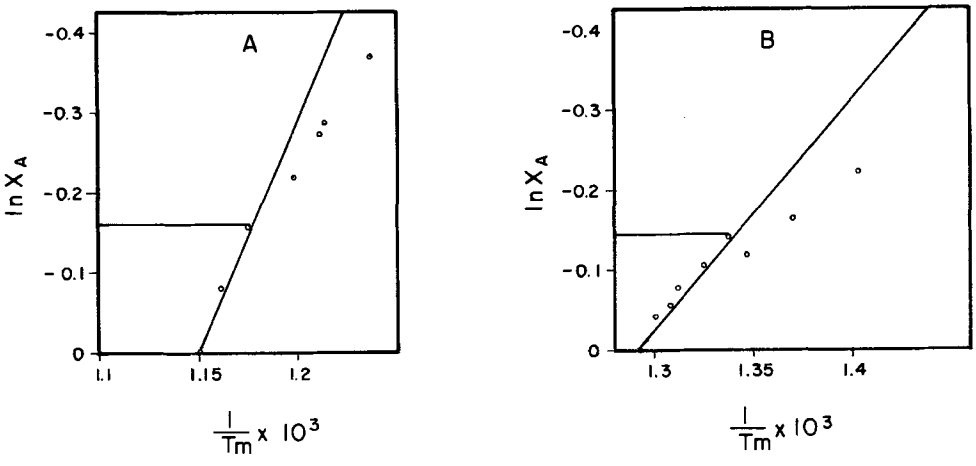

Fig. 4. Analysis of UCl_4-$PbCl_2$ for ideality. (A) $A = UCl_4$, slope $= \Delta H_f/R = 5400$ (11). Horizontal line segment denotes limit of ideality which corresponds to $PbCl_2 = 15$ m/o. (B) $A = PbCl_2$, slope $= \Delta H_f/R = 2930$ (12). Horizontal line segment denotes limit of ideality which corresponds to $UCl_4 = 12.5$ m/o.

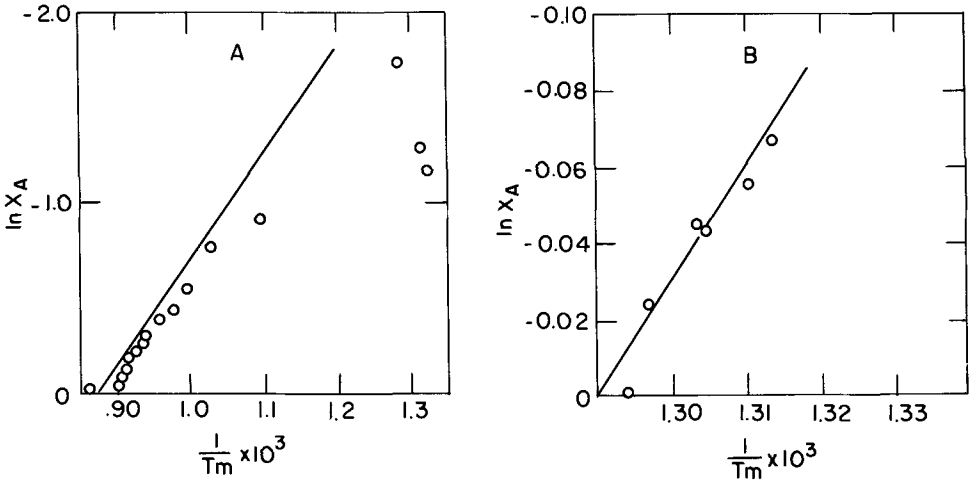

Fig. 5. Analysis of UCl_3-$PbCl_2$ for ideality. (A) $A = UCl_3$, slope $= \Delta H_f/R = 5600$ (11). (B) $A = PbCl_2$.

according to Flood, Forland, and Grjotheim (5), one arrives at the equation

$$a_{PbCl_2} = \frac{X_{PbCl_2}}{X_{PbCl_2} + 2X_{UCl_4}}$$

for the $PbCl_2$-UCl_4 system. The "equivalent" activity is thus lower than the ordinary activity. It is clear from Fig. 5 that the experimental concentrations of UCl_3 are almost always larger than the ideal concentrations, *i.e.* the activity is greater than 1. In other words, even when the behavior is not ideal, it does not tend in the direction of the "equivalent" model but in the opposite direction.

The systems investigated thus behave in a more-or-less ideal fashion, indicating that the different valencies of the cations do not cause vacancies in the lattice, *i.e.* the lead and uranium cation positions in the lattice should be interchangeable.

Some Thermodynamic Properties of Zn_3As_2, Cd_3As_2, and ZnP_2

A. S. Jordan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

By analogy with the known mode of vaporization of Zn_3P_2, Cd_3As_2 and Cd_3P_2, the Knudsen cell pressure measurements on Zn_3As_2 of Nesmeyanov *et al.* between 601° and 751°K have been reinterpreted according to the reaction

$$Zn_3As_2(s) = 3Zn(g) + \tfrac{1}{2}As_4(g)$$

The derived free energy change for this reaction, given by

$$\Delta G^\circ(\text{kcal}) = 139 - 99.8 \times 10^{-3}T$$

is consistent with the fragmentary thermochemical data for Zn_3As_2. In addition, the free energy change for the dissociation reaction

$$ZnP_2(s) = 1/3\ Zn_3P_2(s) + 1/3\ P_4(g)$$

has been estimated as

$$\Delta G^\circ(\text{kcal}) = 21.4 - 18.4 \times 10^{-3}T$$

Finally, the entropies of fusion of Zn_3As_2 and Cd_3As_2 have been evaluated by applying the Clausius-Clapeyron equation to recent data, yielding 28.7 and 29.5 eu/g-mole, respectively.

The importance of the group II-V compounds $ZnAs_2$, Zn_3As_2, ZnP_2, and Zn_3P_2 in the interpretation of the Ga-As-Zn and Ga-P-Zn ternary phase diagrams has been emphasized by Panish (1, 2). Recently, Casey and Panish (3) lacked thermodynamic data for Zn_3As_2 in their analysis of Zn diffusion in GaAs from an invariant ternary source. Moreover, thermodynamic data for Zn_3P_2 and ZnP_2, if available, are thought to be useful to design and interpret Zn diffusion experiments in GaP from a ternary source. The diffusion of Zn into $Ga_xIn_{1-x}P$ from Zn_3P_2 has been accomplished by Hakki (4).

In addition, there is also an intrinsic interest in the properties of the II-V compounds. For example, Rubenstein and Dean (5) have very recently observed the luminescence of ZnP_2. Other semiconducting II-V compounds such as $ZnAs_2$, $CdAs_2$, Zn_3As_2, and Cd_3As_2 have also been investigated (6-8).

The volatilities of $ZnAs_2$, $CdAs_2$, Cd_3As_2, and Zn_3P_2 have been the subjects of several thermochemical studies. However, there are no thermodynamic data for ZnP_2 and the information on Zn_3As_2 is fragmentary and incorrectly interpreted. The primary objective of this paper is the derivation of consistent thermodynamic data for Zn_3As_2 by the reinterpretation of available measurements. Then, the standard heat of formation and entropy of ZnP_2 are estimated by comparison with the properties of other arsenides and phosphides. These thermodynamic data for Zn_3As_2 and ZnP_2 were found to be useful in recent work (9) concerned with the solid solubility of Zn in GaP and GaAs. In addition, the entropies of fusion of Zn_3As_2 and Cd_3As_2 are evaluated by the Clausius-Clapeyron equation from existing pressure-temperature and density data. Finally, the entropies of fusion of $ZnAs_2$, ZnP_2, and Zn_3P_2 are estimated.

The Vaporization and Some Thermodynamic Properties of Zn_3As_2

Nesmeyanov *et al.* (10) have measured the vapor pressure of Zn_3As_2 between 601° and 751°K by means of a Knudsen cell. The analysis of the resulting condensate, containing radioactive Zn and As, led these authors to believe that the predominant mode of evaporation of Zn_3As_2 proceeds according to

$$Zn_3As_2(s) = Zn_3As_2(g) \qquad [1]$$

Consequently, Nesmeyanov and his associates (10) expressed the observed pressure of $Zn_3As_2(g)$, denoted by p_{obs}[1] in the present paper, in the usual form as

$$-RT \ln p_{obs} = 39.7 - 28.3 \times 10^{-3}T \qquad [2]$$

in units of kcal. These authors have also proposed a mode of evaporation similar to Eq. [1] for Cd_3As_2.

However, comparing Bourdon gauge and dew-point measurements on Cd_3As_2, it was demonstrated by Lyons and Silvestri (11) that this compound, which is also in the group II-V family together with Zn_3As_2, thermally dissociates according to the reaction

$$Cd_3As_2(s) = 3Cd(g) + \tfrac{1}{2}As_4(g) \qquad [3]$$

The mass spectrometric work of Westmore *et al.* (12) has confirmed the above result.

Recently, mass spectrometric studies by Schoonmaker *et al.* (13) have revealed that at elevated temperatures Zn_3P_2 also decomposes into the component gases (*i.e.*, into $\tfrac{1}{2}P_4(g)$ and $3Zn(g)$. Likewise, Cd_3P_2 (14) follows the aforementioned sublimation process.

Therefore, it is reasonable to propose that, contrary to the interpretation of Nesmeyanov *et al.* (10), Zn_3As_2 dissociates according to

$$Zn_3As_2(s) = 3Zn(g) + \tfrac{1}{2}As_4(g) \qquad [4]$$

The reinterpretation of Nesmeyanov *et al.*'s data, represented by Eq. [1], for the correct mode of evaporation, as expressed above, is possible by the extension of a procedure established by McCabe (15) and also by Goldfinger and Jeunehomme (16) for the analysis of the Knudsen evaporation of II-VI compounds. Ac-

Key words: II-V compounds, vaporization, heat of fusion, heat of formation.

[1] Nesmeyanov *et al.* (10) utilized the usual Knudsen equation to calculate p_{obs} from their experimental data. Although the actual orifice area for each vapor pressure determination was not tabulated, these authors have emphasized that the orifice area was varied from run to run and, in addition, the sample area was at least 1000 times larger than the orifice area. The resulting ln p_{obs} plotted as a function of reciprocal temperature showed no systematic variation from a straight line, indicating that the measurements were insensitive to changes in the orifice area. Hence, even if the condensation coefficient departs from unity, it is reasonable to assume that the experimental arrangement of Nesmeyanov *et al.* (10) leads to p_{obs} which nearly equals the equilibrium pressure in the temperature range under study.

cordingly, if the effusing species were $Zn_3As_2(g)$, then in Knudsen evaporation p_{obs} would be given by

$$p_{obs} = \frac{\alpha w}{\sqrt{M}} \quad [5]$$

where α is a constant of proportionality incorporating T, the time of the experiment and the "effective" orifice area, and M is the molecular weight of Zn_3As_2 of total weight loss w. However, if the predominant effusing species, as suggested in Eq. [4], are Zn(g) and $As_4(g)$, then the partial pressures of these species, denoted by p_{Zn} and p_{As4}, respectively, are of the form

$$p_{Zn} = \frac{\alpha}{\sqrt{M_{Zn}}} \frac{3M_{Zn}w}{M} = 3\left(\frac{M_{Zn}}{M}\right)^{1/2} p_{obs}$$

and

$$p_{As4} = \frac{\alpha}{\sqrt{M_{As4}}} \frac{M_{As4}w}{2M} = \frac{1}{2}\left(\frac{M_{As4}}{M}\right)^{1/2} p_{obs} \quad [6]$$

where the M_i's are the molecular weights of the designated species.

The equilibrium constant, K, for Eq. [4] is given by

$$K = p_{Zn}{}^3 p_{As4}{}^{1/2} \quad [7]$$

Substituting Eq. [6] into Eq. [7] and taking the logarithms of both sides, one finds

$$-RT \ln K = -3.5\, RT \ln p_{obs} - RT \ln \frac{27 M_{Zn}{}^{3/2} M_{As}{}^{1/4}}{M^{7/4}} \quad [8]$$

Introducing the p_{obs} of Nesmeyanov *et al.* (10) from Eq. 2 into Eq. [8], one obtains the following free energy change, $\Delta G°$, for Eq. [4]

$$\Delta G°\,(\text{kcal}) = 139 - 99.8 \times 10^{-3} T \quad [9]$$

where $\Delta H° = 139$ kcal and $\Delta S° = 99.8$ eu are the second law enthalpy and entropy changes for Eq. [4], respectively, at 676°K (mid-temperature of Nesmeyanov *et al.*) (10).

The free energy equation given in Eq. [9] is reasonable in comparison with the free energy determination of Schoonmaker *et al.* (13) by means of torsion effusion and torsion surface vaporization measurements between 620°-820°K for the reaction

$$Zn_3P_2(s) = 3Zn(g) + \tfrac{1}{2}P_4(g)$$

which was reported to be

$$\Delta G°\,(\text{kcal}) = 144 - 107 \times 10^{-3} T \quad [10]$$

In particular, one finds combining the values of $\Delta S°$ in Eq. [9] and [10] with the standard entropies of gaseous species involved, obtained from Stull and Sinke (17), that the standard entropies of $Zn_3As_2(s)$ and $Zn_3P_2(s)$ at 676°K are 73 and 61.2 eu/g-mole, respectively. The corresponding entropies derived by the Neumann-Kopp rule are 72.9 and 65.9 eu/g-mole, respectively. Therefore, taking into account the reported ±6 eu uncertainty in the entropy given by Schoonmaker *et al.* (13), one concludes that the entropy of Zn_3As_2 is consistent with that of Zn_3P_2.

It can further be shown that Eq. [9] is also consistent with the available fragmentary thermodynamic data for Zn_3As_2. According to the calorimetric measurement of Ariya *et al.* (18), the enthalpy change at 298°K for the reaction

$$Zn_3As_2 = 3Zn(s) + 2As(s) \quad [11]$$

is 30.5 kcal. $\Delta H°$ for Eq. [4] at 298°K can be readily calculated by means of Kirchhoff's equation from the known $\Delta H°$ at 676°K and the appropriate heat capacity functions. If it is assumed that the heat capacity of Zn_3As_2 obeys the Neumann-Kopp rule,[2] then taking the heat capacity functions for the solid and gaseous elements from Kelley (19), one obtains 141.9 kcal for $\Delta H°$ of Eq. [4] at 298°K by an essentially second law procedure. Adding the heats of condensation of 3Zn(g) and $\tfrac{1}{2}As_4(g)$, tabulated by Stull and Sinke (17), to this result, one finds that $\Delta H°$ at 298°K for Eq. [11] is 31.1 kcal, in very good agreement with Ariya *et al.*'s (18) measurement. An alternative third law treatment of the raw data of Nesmeyanov *et al.* (10) results in $\Delta H° = 30.4 \pm 1$ kcal for Eq. [11] at 298°K.[3] By an analogous second law procedure, starting with the $\Delta S°$ for Eq. [4] taken from Eq. [9], one gets $\Delta S° = 0.5$ eu for Eq. [11] at 298°K, in almost complete accord with the Neumann-Kopp rule; hence, the recommended $S°$ of Zn_3As_2 is 47 eu/g-mole at 298°K.

Sirota and Smolyarenko (20) have recently reported that emf measurements between 700°-800°K for the reaction $3Zn(l) + 2As(s) = Zn_3As_2(s)$ yield $\Delta G° = -31.0 \pm 4$ kcal. This result presumably refers to the middle of their temperature range, 750°K. An extrapolation of Eq. [9] to 750°K in combination with the pertinent free energies of condensation as tabulated by Stull and Sinke (17) gives $\Delta G° = 29.2$ kcal for the above reaction, in reasonable agreement with the value of Sirota and Smolyarenko (20). Unfortunately, the derived $\Delta H°$ and $\Delta S°$ values of these authors are inconsistent; hence, in the absence of any information on the temperature dependence of the emf, no further comparisons can be made.

Estimated Thermodynamic Properties of ZnP_2

Having analyzed the dissociation pressure of $ZnAs_2$ as determined by Bourdon gauge and dew-point techniques, Lyons (21) has concluded that this compound dissociates according to

$$ZnAs_2(s) = 1/3\, Zn_3As_2(s) + 1/3\, As_4(g) \quad [12]$$

and

$$\Delta G°\,(\text{kcal}) = 18.8 - 18.5 \times 10^{-3} T$$

between 885°-1013°K. Likewise, it has been demonstrated by Lyons and Silvestri (11) that the decomposition of $CdAs_2(s)$ follows the above reaction.

Unfortunately, as yet there have not been any measurements either on the mode of decomposition or the thermodynamic properties of ZnP_2. However, there is no reason to doubt that its decomposition in analogy with Eq. [12] proceeds according to

$$ZnP_2(s) = 1/3\, Zn_3P_2(s) + 1/3\, P_4(g) \quad [13]$$

In order to estimate the free energy change at elevated temperatures, say at 700°K, for Eq. [13], it is at first necessary to estimate the heat of formation and standard entropy of ZnP_2 at 298°K.

In Table I the heats of formation per g-atom at 298°K, $\Delta H°$, of $CdAs_2$, $ZnAs_2$, Cd_3As_2, Zn_3As_2, and Zn_3P_2 from their solid elements are listed together with their respective standard entropies per g-atom, $S°$. Noting that the atoms in the semiconducting compounds ZnP_2 and $ZnAs_2$ are tetrahedrally coordinated (22), one would expect periodic trends in the thermodynamic properties of $CdAs_2$, $ZnAs_2$, and ZnP_2, in comparison with the III-V compounds obtained by replacing Cd and Zn with group III elements in the same row of the periodic system. Therefore, the most recent or best values of $\Delta H°$ and $S°$ for InAs, GaAs, and GaP are also listed in Table I. In addition, $\Delta H°$ and $S°$ for the II-VI compounds CdSe, ZnSe, and ZnS are given.

The tabulated values of $\Delta H°$ and $S°$ for the Zn and Cd arsenides and phosphides had to be derived from the available high-temperature data. $\Delta H°$ and $S°$

[2] According to Robinson and Bever (33), this assumption holds within better than 4% for Mg_3Sb_2, a similar II-V compound.

[3] As the free energy function ($FEF = G°(T) - H°(298)/T$) of Zn_3As_2 is not known, a rough estimate of the FEF had to be obtained. By a combination of the known heat capacity equation of Zn_3N_2 (19) with an *a priori* estimate of the $S°$ of Zn_3As_2 at 298°K, the FEF was computed following the usual thermodynamic procedure (34). The $S°$ was estimated by the averaging of the $S°$'s of Zn_3Sb_2 (19) (63.6 eu/g-mole) and Zn_3P_2 (36 eu/g-mole from Table I) at 298°K. Taking the FEF's for the gaseous species from Stull and Sinke (17), the third law method yields the $\Delta H°$ for Eq. [4] at 298°K which can be readily converted to the desired $\Delta H°$ for Eq. [11].

Table I. Enthalpies of formation and standard entropies at 298°K of some arsenides and phosphides

	$-\Delta H°$ (kcal/g-atom)	Ref.	$S°$ (eu/g-atom)	Ref.
$CdAs_2$	1.6		9.8	
$ZnAs_2$	6.5		6.7	
ZnP_2	8.1[a]		4.8[a]	
Cd_3As_2	2.6		11.4	
Zn_3As_2	6.2		9.4	
Zn_3P_2	7.6		7.2	
InAs	7.4	(32)	9.05	(28)
GaAs	10.4	(31)	7.67	(28)
GaP	12.2	(29)	5.98	(29)
CdSe	16.2	(16)	11.5	(16)
ZnSe	19.5	(30)	9.9[b]	(16)
ZnS	24.6	(30)	6.9	(25)

[a] Estimated.
[b] May be 1.5 eu/g-atom too high as in the case of ZnTe (34).

for Zn_3As_2 have been evaluated in the previous section. A similar procedure has been followed in the calculation of the standard values for Cd_3As_2 and Zn_3P_2. In the case of $ZnAs_2$, Lyons' (21) pressure data between 885°-1013°K yield $\Delta H° = 18.8$ kcal and $\Delta S° = 18.5$ eu for Eq. [12] at 950°K. Assuming the validity of the Neumann-Kopp rule for the specific heat of $ZnAs_2$ and Zn_3As_2 and taking the C_p of $As_4(g)$ from Kelley (19), one obtains $\Delta H° = 20.3$ kcal and $\Delta S° = 21$ eu for Eq. [12] at 298°K by an application of Kirchhoff's equation. This in combination with the data for Eq. [11] and the heat of condensation and standard entropy of 1/3 $As_4(g)$ yields $\Delta H° = 19.5$ kcal at 298°K for the reaction

$$ZnAs_2(s) = Zn(s) + 2As(s) \qquad [14]$$

and $S° = 20.1$ eu/g-mole. The data of Lyons and Silvestri (11) for $CdAs_2$ have been analyzed by a similar procedure.

The periodic trends in $\Delta H°$ and $S°$ per g-atom of the triads of compounds listed in Table I are immediately obvious. Therefore, it is suggested that $\Delta H°$ for

$$ZnP_2(s) = Zn(s) + 2P(s) \qquad [15]$$

at 298°K should be estimated by adding to the $\Delta H°$ per g-atom of $ZnAs_2$ the average of the $\Delta H°$ differences between Zn_3As_2 and Zn_3P_2 and between GaAs and GaP. An analogous procedure is proposed for the estimation of $S°$ of ZnP_2. Carrying out the calculations, one finds $\Delta H° = 24.3$ kcal for Eq. [15] and $S° = 14.4$ eu/g-mole.

Finally, based on the above values for Eq. [15] and the data of Schoonmaker *et al.* (13) for Zn_3P_2, reversing the method used to evaluate $\Delta H°$ and $S°$ for Eq. [14] from Eq. [12], one obtains for Eq. [13] at 700°K

$$\Delta G°(\text{kcal}) = 21.4 - 18.4 \times 10^{-3}T \qquad [16]$$

which is comparable with Lyons' (21) $\Delta G°$ (Eq. [12]) for $ZnAs_2$.

The Entropies of Fusion of Zn_3As_2 and Cd_3As_2

Recently, Jayaraman *et al.* (23) have investigated the dependence of the melting points, T_f, of Zn_3As_2 and Cd_3As_2 on the total pressure, p, and have given measured values of dT_f/dp for these compounds. In addition, Glazov and Kasymova (24) have reported the densities of solid Zn_3As_2 and Cd_3As_2 and of their respective melts. Thus, the entropy of fusion, ΔS_f, of these compounds can be readily computed from the Clausius-Clapeyron equation written in the form

$$\Delta S_f = \frac{dp}{dT_f}\Delta V_f = \frac{dp}{dT_f}\left(\frac{M}{d_l} - \frac{M}{d_s}\right) \qquad [17]$$

where ΔV_f is the volume change of fusion, d_l and d_s are the liquid and solid densities, and M is the molecular weight of the compound. Substituting the required variables into Eq. [17], one obtains

Table II. Heats and entropies of fusion of some arsenides and phosphides

	ΔS_f (eu/g-atom)	ΔH_f (kcal/g-mole)
Zn_3As_2	5.74,[a] 5.30[b]	36.9[a]
Zn_3P_2	5.3[c]	40.0[c]
Cd_3As_2	5.94,[a] 5.25[b]	28.6[a]
$ZnAs_2$	6.5[c]	20.4[c]
ZnP_2	5.9[c]	22.2[c]

[a] Experimentally determined, based on Eq. [17].
[b] Calculated from Eq. [19].
[c] Estimated by adding 0.3 eu/g-atom to Eq. [19].

$$\Delta S_f = 28.7 \text{ eu/g-mole} = 5.74 \text{ eu/g-atom} \quad \text{for } Zn_3As_2 \qquad [18]$$

and

$$\Delta S_f = 29.5 \text{ eu/g-mole} = 5.90 \text{ eu/g-atom} \quad \text{for } Cd_3As_2$$

The corresponding heats of fusion, ΔH_f, taking T_f from Jayaraman *et al.* (23), are

$$\Delta H_f = 36.9 \text{ kcal/g-mole} \quad \text{for } Zn_3As_2$$

and

$$\Delta H_f = 28.6 \text{ kcal/g-mole} \quad \text{for } Cd_3As_2$$

The above ΔS_f's seem to be reasonable in comparison with the theoretical estimate calculated by a method recommended by Kubaschewski *et al.* (25). According to these authors, the entropy of fusion/g-atom for an ordered compound of formula A_mB_n is given by

$$\Delta S_f = \frac{m\Delta S_f(A) + n\Delta S_f(B)}{m+n} - R\left(\frac{m}{m+n}\ln\frac{m}{m+n} + \frac{n}{m+n}\ln\frac{n}{m+n}\right) \qquad [19]$$

in units of eu/g-atom where $\Delta S_f(A)$ and $\Delta S_f(B)$ are the entropies of fusion of the pure elements A and B, respectively. Substituting the ΔS_f's of the elements from Stull and Sinke (17) into Eq. [19], one finds $\Delta S_f = 5.30$ eu/g-atom and 5.25 eu/g-atom for Zn_3As_2 and Cd_3As_2, respectively, which compare favorably with the values in Eq. [18].

Estimated Entropies of Fusion of $ZnAs_2$, ZnP_2, and Zn_3P_2

Noting that the above-calculated ΔS_f of Zn_3As_2 based on Eq. [19] is approximately 0.3 eu/g-atom less than the experimentally determined result (Eq. [17] and [18]), it is suggested that the ΔS_f's of ZnP_2, $ZnAs_2$, and Zn_3P_2 should be estimated by adding $\approx$0.3 eu/g-atom to the theoretical value calculated from Eq. [19]. The estimated ΔS_f's and ΔH_f's of ZnP_2, $ZnAs_2$, and Zn_3P_2 are presented in Table II together with the experimentally determined quantities of Zn_3As_2 and Cd_3As_2. In performing these calculations, the ΔS_f of P(red) was taken from the JANAF (26) tables. The melting points of $ZnAs_2$ and ZnP_2 were obtained from Hansen (27) and the recent work of Rubenstein and Dean (5). Finally, the melting point of Zn_3P_2 was estimated to be 1240° $\pm$ 20°C by adding to the melting point of Zn_3As_2 the average of the relatively constant difference between the melting points of ZnP_2 and $ZnAs_2$ (214°C) and of GaP and GaAs (227°C).

Manuscript submitted Aug. 21, 1970; revised manuscript received Feb. 24, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Vaporization in the PbTe-SnTe System[1]

David A. Northrop

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

The vaporization of three alloys in the PbTe-SnTe system has been investigated thermogravimetrically. The vaporization is noncongruent as SnTe, the more volatile component, is lost preferentially. Due to the similarity of the PbTe and SnTe vapor pressures, the observed differences in total effusion rates between the alloys and changes in rate expected due to noncongruency are of the magnitude of the experimental error and the vaporization appears to be congruent in gravimetric experiments. Effusion rates, composition changes, and approximate vapor pressures have been determined with the results falling between the limits given by PbTe and SnTe. The results for a commercial, (Pb,Sn)Te thermoelement are given for comparison with this work and previously published investigations.

Vaporization of alloys in the PbTe-SnTe system has been investigated as part of a continuing study of vaporization in the (Pb,Sn,Ge)Te system (1). Considerable interest has been shown in the PbTe-SnTe pseudobinary system as these alloy compositions are in use as the p-junction in several isotope power generator systems. The vaporization of three compositions was studied: $Pb_{0.91}Sn_{0.09}Te$, $Pb_{0.72}Sn_{0.28}Te$, and $Pb_{0.50}Sn_{0.50}Te$. In addition, the results for a commercial, p-type thermoelement are given which were obtained with the same effusion cells and procedures so that a direct comparison could be made.

Commercial p-type thermoelements of nominal $Pb_{0.50}Sn_{0.50}Te$ composition were used for the free surface vaporization rates given by Bates and Weinstein (2), and in the mass spectrometric effusion studies by Winchell (3). The latter investigator concluded that the vaporization was either congruent or "pseudocongruent" and occurs by the loss of SnTe and PbTe molecules in the same relative concentrations as in the solid. Sokolov *et al.* (4), on the other hand, found a SnTe-rich vapor over a $Pb_{0.52}Sn_{0.48}Te$ material, which would indicate noncongruency and a progressively Pb-enriched alloy composition. These studies are discussed in more detail later in this report.

Other studies in the PbTe-SnTe system have been concerned with determination of the phase relations (5-8), examination of the variation of lattice parameter with composition (5-7, 9-12), growth and characterization of single crystals (7, 8, 13), and investigation of electrical properties (6-8, 14, 15). The over-all results show that PbTe and SnTe form a complete range of solid solutions which exhibit nearly ideal behavior. The temperature-composition phase relations are in the shape of a simple lens with end points given by the melting points of 917° and 806°C for pure PbTe and SnTe, respectively, and a maximum difference between the liquidus and solidus of ~18°C at 45 m/o (mole per cent) SnTe (5). Lattice parameters show slight positive deviations from Vegard's law when the exact tellurium concentration is considered. The single-phase (Pb,Sn)Te compositions are all p-type and thus the field lies on the Te-rich side of the PbTe-

Key words: lead telluride, tin telluride, vapor pressure, effusion, thermoelement.

SnTe binary join (13). The liquidus surface of the Pb-Sn-Te ternary system has also been determined (16).

Experimental Details and Results

General.—A detailed description of the apparatus, methods, and sources of error is given elsewhere (1), and only specific details are reported here. An automatic recording balance was used and its continuous weight, time, and temperature record is particularly suited for the investigation of noncongruent vaporizations where changing rates of loss are expected.

Three alloys were made from the elements (of stated purity > 99.99%) by reaction at 950°C in evacuated quartz ampoules. The ampoules were air quenched from this temperature, and the samples were reground finer than 240 mesh and annealed at 600°C for 48 hr, also in evacuated quartz ampoules. The lead concentration was determined by polarography and the alloy composition was calculated assuming an exact $Pb_xSn_{1-x}Te$ stoichiometry. The initial alloy compositions are, to ±0.01 a/o (atomic per cent), $Pb_{0.91}Sn_{0.09}Te$, $Pb_{0.72}Sn_{0.28}Te$, and $Pb_{0.50}Sn_{0.50}Te$. Powder x-ray diffraction analyses indicated that only the alloy phase was present.

Graphite and alumina effusion cells were used, and their effective orifice areas were determined by effusion of a lead standard (1). Three types of effusion experiments were made: Type 1: Isothermal runs in which ~80 mg were effused until a constant cell weight was observed. Type 2: isothermal runs which were quenched at successive stages of vaporization and samples taken for x-ray and polarographic analyses. The initial amount of sample was ~1200 mg and two cuts and a final residue were obtained for each run. For each cut, the sample was removed from the cell, reground and mixed thoroughly, ~100 mg removed permanently for analysis, and the remainder replaced in the cell for further vaporization. Type 3: effusion runs of ~20 rate-temperature data points for the vapor pressure calculations. The initial sample weight was 800-900 mg and no more than a third was vaporized in a single run.

Vapor species.—No direct determination of the vapor species was made in this investigation. It is assumed that (Pb,Sn)Te vaporizes by the loss of molecular SnTe(g) and PbTe(g), and this assumption is based on the results for the pure end members and the following reported mass spectrometric data for the alloys. Winchell (3) observed approximately equal intensities of $SnTe^+$ and $PbTe^+$ but no Te_2^+ or higher molecular weight ions for a thermoelement of approximate composition $Pb_{0.5}Sn_{0.5}Te$. Sokolov *et al.* (4) examined the effusion of a $Pb_{0.52}Sn_{0.48}Te$ sample at 760°C and identified the following parent ions with relative intensities given in parentheses: $SnTe^+$ (132), $PbTe^+$ (100), Te_2^+ (~1), $SnTe_2^+$ (~1), and lesser amounts of $Sn_2Te_2^+$, $PbSnTe_2^+$, and $PbSnTe^+$. Unambiguous determination of the equilibrium vapor is hindered by electron impact dissociation in the mass spectrometer ion source, and atomic ions produced by fragmentation were observed in both studies.

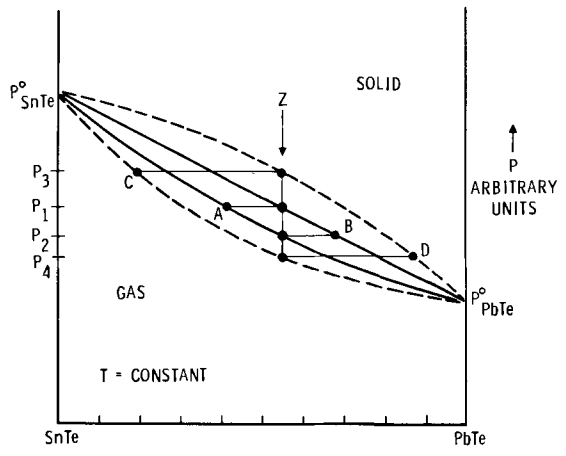

Fig. 1. Possible pressure-composition phase relations for the PbTe-SnTe system showing the compositional relations for the ideal (solid lines) and a typical nonideal (dashed lines) solid solution.

Congruency.—A noncongruent vaporization of (Pb,Sn)Te alloys was expected and was confirmed by several experiments. The prediction was made by examination of the schematic pressure-composition phase relations shown in Fig. 1 for a binary alloy system exhibiting a complete range of solid solutions. In addition, while PbTe vaporizes congruently, SnTe vaporizes noncongruently with the loss of a slight excess of Te which first produces a two-phase, Sn-SnTe assemblage, and then a very small amount of pure Sn as a final phase (1). Thus noncongruency has to be examined from two standpoints: the relative loss of SnTe with respect to PbTe and also the possibility of the formation of a metal second phase.

The results for the type 2 effusion runs are given in Table I. Each cut was analyzed polarographically for total lead content and an alloy composition was calculated on the assumption that only a stoichiometric $Pb_xSn_{1-x}Te$ phase was present. The results are semiquantitative with the uncertainty arising from both the analytical technique and possible inhomogeneities and minor phases present in the cut. Each alloy was investigated at 625°, 700°, and 825°C, but the three results were averaged in each case as no general temperature dependence could be observed.

A small portion of each cut (<1 mg) was examined by x-ray diffraction utilizing the Debye-Scherrer technique and Ni-filtered, CuKα radiation. From published reports (9), the alloy lattice constant can be related to its composition provided that the exact Te stoichiometry is known from the carrier concentration or other measurements. The lack of this information and the uncertainty that such a small portion of the total sample would accurately reflect the bulk composition precluded any quantitative analysis by x-ray methods. Qualitatively, however, comparative line shifts in the back-reflection region indicated that in every case the observed *d*-spacings became greater (increased PbTe concentration) with increased vaporization.

Table I. Alloy composition as a function of amount vaporized

Material	Initial composition	Cut A		Cut B		Residue	
		Amt lost, w/o	Composition	Amt lost, w/o	Composition	Amt lost, w/o	Composition
Type 2 effusion runs:

The residues from the type 3 effusion experiments were also analyzed by the two methods. The results are also given in Table I and the same trend is found.

The possibility of the formation of a metallic second phase is more difficult to assess. If the original stoichiometric concentrations of the elements were maintained, the initial alloys should be two-phase, (Pb,Sn) and (Pb,Sn)Te, as the single-phase alloy compositions lie on the Te-rich side of the PbTe-SnTe binary join (13). However, a metal second phase could not be detected in x-ray powder patterns of either the initial alloys or any cuts from the special effusion runs. Isothermal effusion runs (type 1) to constant weight with pure SnTe resulted in a Sn residue of ~0.3 w/o. Similar experiments with the $Pb_{0.50}Sn_{0.50}Te$ alloy produced a trace residue (<0.1 w/o) which was identified by x-ray diffraction as SnO_2, and its exact origin is unknown. Pb would not be expected in the residue at a constant observed weight as its vapor pressure is of the same order of magnitude as lead telluride. In the type 1 effusion runs, care was taken to insure that the cell temperature did not overshoot the intended run temperature. During the first 5 w/o of loss, the maximum observed rate decreased by ~7% to an essentially constant rate for the balance of the run. In the noncongruent vaporization of GeTe, this rate-time behavior was interpreted as the rapid loss of excess Te to drive the over-all composition into a Ge-GeTe two-phase region (1). The same interpretation could be applied in this case, and further evidence is found in the parent Te_2^+ contribution reported by Sokolov *et al.* (4).

To summarize, the vaporization of (Pb,Sn)Te is noncongruent. The primary composition change is a decrease in the SnTe/PbTe ratio due to the preferential loss of SnTe(g). There is inconclusive evidence for the loss of additional tellurium but in amounts that should not affect the results and discussions in this report.

Effusion rates.—Two type 3 effusion runs were made with different graphite cells for each alloy. Unless assumptions are made concerning the relative vapor composition and its change due to noncongruency, the total vapor pressure cannot be calculated from the total rate of weight loss as is usually done *via* the Knudsen equation

$$P_T = \sum_i P_i = \sum_i \left(\frac{1}{A}\right) x_i \left(\frac{dw}{dt}\right)_T \sqrt{\frac{2\pi RT}{M_i}} \quad [1]$$

where A is the effective orifice area, $(dw/dt)_T$ is the total observed rate of weight loss, and x_i and M_i are the weight fraction and molecular weight of the ith vapor species. Alternatively, a quantity Q_T has been defined

$$Q_T = \left(\frac{1}{A}\right)\left(\frac{dw}{dt}\right)_T \sqrt{2\pi RT} \quad [2]$$

which is essentially proportional to the observed effusion rate and is related to the total vapor pressure by

$$P_T = Q_T \sum_i x_i \sqrt{\frac{1}{M_i}} \quad [3]$$

The reason for presenting the data in terms of Q_T is to emphasize the similarity of the observed effusion rates for this alloy system.

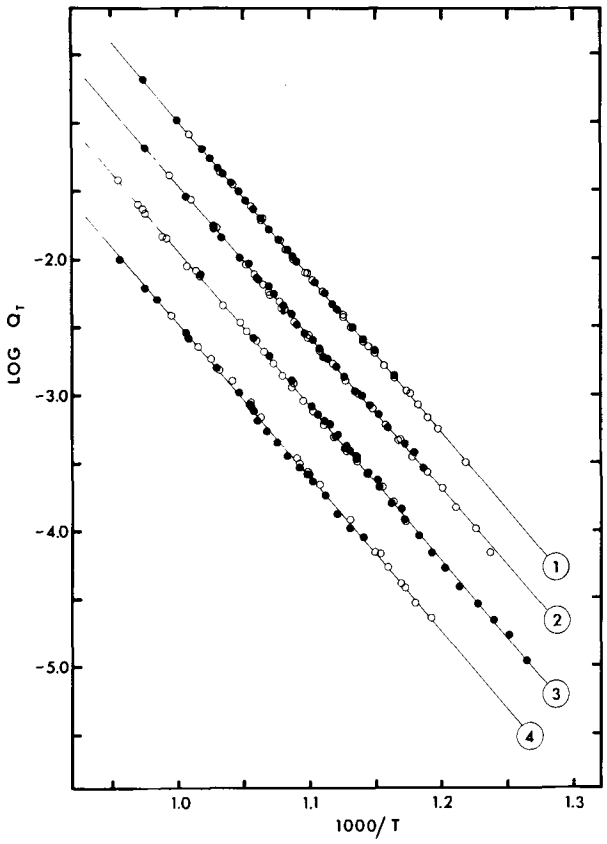

Fig. 2. Experimental data for the type 3 effusion runs expressed as log Q_T *vs.* reciprocal temperature: curve 1, $Pb_{0.91}Sn_{0.09}Te$; curve 2, $Pb_{0.72}Sn_{0.28}Te$; curve 3, $Pb_{0.50}Sn_{0.50}Te$; curve 4, thermoelement. Ordinate scale applies to curve 4; each of the other curves has been offset from the other by log Q_T = 0.50 for clarity.

If the summed term is relatively constant during an effusion run, as in the case of a large sample and small over-all weight change, then Q_T is directly proportional to P_T and a plot of log Q_T *vs.* reciprocal temperature should be essentially linear with a slope equal to the enthalpy of vaporization. Linear least-squares fit of log Q_T as a function of $1/T$ resulted in equations of the form

$$\log Q_T = (A \pm \sigma_A) + (B \pm \sigma_B)(1000/T) \quad [4]$$

where σ_i are the standard deviations associated with the constants. The results for the two effusion runs for each of the three alloys and the thermoelement are shown in Fig. 2 and summarized in Table II. Values of Q_T for PbTe and SnTe have been calculated from the average summary equation given in Tables III and V, respectively, of Ref. (1).

Steady state and equilibrium.—In these experiments, the effective orifice areas of the effusion cells ranged from 4.49 x 10^{-4} to 5.64 x 10^{-3} cm^2 and the sample was

Table II. Effusion results expressed in terms of log Q_T and the experimental enthalpy of vaporization

Material	Average temp (°C)	log $Q_T = A + B(1000/T)$ A	B	ΔH_{vap} (kcal/mole)
PbTe[1]	634	8.837 ± 0.058	−11.294 ± 0.177	51.68 ± 0.81

Table III. Calculated values of log Q_T and specific effusion rates at 650°C

Material	log Q_T	Specific effusion rate (g/cm² sec)	σ[1]	$\sigma\%$[2]
PbTe[3]	−3.394	5.89×10^{-4}	0.037	±9
$Pb_{0.91}Sn_{0.09}Te$	−3.435	5.36×10^{-4}	0.009	±2
$Pb_{0.72}Sn_{0.28}Te$	−3.388	5.97×10^{-4}	0.016	±4
$Pb_{0.50}Sn_{0.50}Te$	−3.385	6.01×10^{-4}	0.021	±5
SnTe[3]	−3.331	6.81×10^{-4}	0.045	±11
Thermoelement	−3.413	5.64×10^{-4}	0.024	±6

[1] σ is the standard error of the estimate of the linear least-squares fit of log Q_T *vs.* reciprocal temperature. σ applies to the log Q_T values shown.
[2] $\sigma\%$ is σ expressed as a per cent difference between Q_{calc} and Q_{obs} and applies to the rates shown.
[3] Calculated from data given in Ref. (1).

always ground finer than 340 mesh (<75μ). The vaporization coefficients for PbTe and SnTe are greater than 0.2 (1) and the attainment of steady-state conditions is not hindered by a low α_v or a low sample surface area/orifice area ratio as discussed by Motzfeldt (17). The observed effusion rates for all compositions were essentially constant during the type 1 effusion runs to greater than a 99 w/o loss. The rates then broke essentially discontinuously to zero (a constant cell weight). Thus, as little as 1 mg of material was sufficient to produce steady-state conditions in the cell. Surface enrichment of the less volatile phase (PbTe in this case) would normally tend to hinder vaporization and the attainment of steady-state conditions and would increase the apparent activity and vapor pressure of this phase. The results of the type 1 effusion experiments and the similar vapor pressures of PbTe and SnTe show that such effects are not detectable in these gravimetric experiments. In addition, the observed effusion rates and calculated pressures appear to be independent of orifice area within the range given above and, thus, a case can be made that these results represent the equilibrium values.

Discussion

The alloy vaporization can be described in terms of the P-X phase relations given in Fig. 1, where the solid and dashed lines indicate the phase boundaries for an ideal and a typical nonideal solid solution, respectively. In the ideal case, the exact boundaries can be calculated from the solid composition and the vapor pressures of the pure end members since, by definition, $P_i = x_i P_i^\circ$. The initial equilibrium vapor composition over an alloy of composition Z is given by A at a total pressure of P_1. As vaporization proceeds, both the vapor and solid compositions shift toward the less volatile component with Z and B becoming the concentrations of vapor and solid as the last solid vaporizes. Note that the vapor is always rich in the more volatile component and has the initial alloy composition only at the end of vaporization. The equilibrium total pressure decreases from P_1 to P_2 in the course of the vaporization. The representative nonideal case shown indicates that greater compositional and pressure changes would be expected: C going to Z for the vapor, Z going to D for the solid, and P_3 decreasing to P_4.

Table III gives values of log Q_T and specific, total rates of weight loss (g/cm² sec) calculated at 650°C. The similarity in these values is striking and can perhaps explain why these alloys have been interpreted as vaporizing congruently or "pseudocongruently" (3). The rate-temperature effusion data gave no systematic changes in observed rate with total weight loss up to losses of ~30 w/o. Furthermore, in the type 1 effusion runs, a continuous, over-all decrease in rate could not be definitely identified for any of the alloy compositions outside of the small initial decrease described earlier in the congruency discussion.

Several factors combine to explain this apparent congruency in these gravimetric experiments, and the over-all result is that the expected decrease in rate due to noncongruency is less than the over-all precision of the experimental procedure. First, the standard error of the estimates between log Q_{calc} and log Q_{obs} range from 0.009 to 0.045 which correspond to uncertainties of approximately ±2 to ±11% in Q_T. These uncertainties in themselves practically cover the entire range of calculated values given in Table III. Second, the temperature can be controlled to ±½°C during the isothermal effusion runs, and a 1° temperature change varies the observed rate by ~2.5% at these values of ΔH and temperature. Finally, only small changes in observed total rate are expected due to the similar vapor pressures of SnTe and PbTe. At a given temperature, the relative effusion rates for pure SnTe and PbTe are given by

$$\frac{\left(\frac{dw}{dt}\right)_{SnTe}}{\left(\frac{dw}{dt}\right)_{PbTe}} = \frac{P^\circ_{SnTe}}{P^\circ_{PbTe}}\sqrt{\frac{M_{SnTe}}{M_{PbTe}}} \qquad [5]$$

This rate ratio has the values of 1.133 and 1.171 at 550° and 725°C, respectively. Thus, an approximate 15% decrease in rate would occur during a hypothetical effusion run in which the solid composition would change from SnTe to PbTe. It is clear from Fig. 1 that a considerably smaller decrease would be observed during the vaporization of a given alloy composition. This change during a complete isothermal effusion can be calculated exactly if it is assumed that the system behaves ideally. For a 50/50 m/o alloy at 700°C (where $P^\circ_{SnTe}/P^\circ_{PbTe} = 1.359$), the ratio of initial to final rate is 1.0222; this is a decrease of approximately 2%.

Table IV shows the maximum composition changes that can be expected for a complete equilibrium vaporization if the alloy system is ideal. In every case, the observed composition changes are greater, suggesting nonideality and phase relations similar to those given by the dashed lines in Fig. 1. The observed changes eliminate the possibility of a more complicated double-lens type of phase diagram in the composition range $Pb_{0.5}Sn_{0.5}Te$ to PbTe. However, the possibility of a pressure maxima and a congruently subliming indifferent point (18) at the SnTe-rich end of the phase diagram is still compatible with the data.

It is desirable to calculate apparent total vapor pressures from the experimental data. As the vapor composition is continuously changing and has not been measured directly at any point in these experiments, an arbitrary, "average" molecular weight has been selected for this calculation. The initial vapor composition for an ideal alloy (Table IV) was selected and

Table IV. Calculated and observed composition changes at 700°C

Material	Calculated for an ideal solid solution[1]		Observed solid composition (from Table I)
	Initial vapor composition	Final solid composition at end of a complete vaporization	
$Pb_{0.91}Sn_{0.09}Te$	88/12	93/07	99/01 after a 59 w/o loss
$Pb_{0.72}Sn_{0.28}Te$	65/35	78/22	82/18 after a 63 w/o loss
$Pb_{0.50}Sn_{0.50}Te$	42/58	58/42	64/36 after a 75 w/o loss

[1] $P^\circ_{SnTe}/P^\circ_{PbTe} = 1.359$ at 700°C.

Table V. Approximate total vapor pressures based on an arbitrary average molecular weight

Material	Selected vapor composition	Average molecular weight	Log $P_T = A + B(1000/T)$ A	B	Calculated pressure at 650°C (atm)	σ%[2]
PbTe[1]	—	—	7.575	−11.294	2.21×10^{-5}	±9
$Pb_{0.91}Sn_{0.09}Te$	88/12	324.2	7.771	−11.506	2.04×10^{-5}	±2
$Pb_{0.72}Sn_{0.28}Te$	65/35	303.8	7.540	−11.236	2.35×10^{-5}	±4
$Pb_{0.50}Sn_{0.50}Te$	42/58	283.5	7.763	−11.426	2.45×10^{-5}	±5
SnTe[1]	—	—	7.776	−11.360	2.97×10^{-5}	±11
Thermoelement	42/58	283.5	7.610	−11.310	2.30×10^{-5}	±6

[2] See Table III.

the total weight loss has been ascribed to a vapor with this average molecular weight. For this comparative calculation, the error introduced by the arbitrary choice of vapor composition and not treating the data rigorously by Eq. [1] is less than the over-all experimental uncertainty. The equations for log Q_T in Table II can then be converted to log P_T by the addition of log $(M^{-1/2})$ to the A term. The results are given in Table V and the total vapor pressure curves presented in Fig. 3. Pressures calculated at 650°C given in Table V show more clearly the relative total vapor pressures for these materials. While a variation of pressure with alloy composition is evident, these pressures are practically indistinguishable within the limits set by the pure PbTe and SnTe when the experimental uncertainties are considered. It should be emphasized that the observed effusion rates are even more similar (see Table III) than the pressure curves given in Fig. 3; the molecular weight in the pressure calculation produces much of the vertical separation.

Thermoelements

3P,[2] p-type thermoelements were used in the studies of Winchell (3) and Bates and Weinstein (4), and were examined for comparative purposes in this work. While the exact composition is proprietary, this p-type material contains PbTe, SnTe, and MnTe in approximately 47/47/06 m/o proportions. MnTe is less volatile than the other two tellurides and can be identified as a residue in both effusion and free surface vaporizations. However, its accumulation did not affect the effusion results as seen in Fig. 2, curve 4. As for the alloy compositions discussed in an earlier section, no systematic variation of rate with time or amount vaporized was observed. Winchell did not detect any form of Mn in the vapor during his investigation (3).

The results have been calculated and presented along with the "pure" alloy materials, and they are closest to those for the 72/28 and 50/50 compositions. The approximate vapor pressure curve is given in Fig. 4 relative to pure SnTe and PbTe and the previously reported results of Winchell (3), Bates and Weinstein (2), and Sokolov *et al.* (4). Thus, the near-equilibrium vaporization behavior of this complex material is determined by the behavior of the major constituent and is relatively unaffected by minor phases or dopants added to enhance its electrical properties. Unpublished data from this laboratory indicate that this is also true for 3N[3] and TAGS[4] thermoelements where the near-equilibrium vaporization behavior is essentially identical to that of the major phase, PbTe and GeTe, respectively.

Technical Notes

Formation of 20-25Å Thermal Oxide Films on Silicon at 950°-1140°C

J. A. Aboaf*

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

Recent papers on MNOS (metal-Si_3N_4-SiO_2-Si) memory transistors, in which charge can be stored at or near the interface between the two insulators (1-6), classify them as either Fowler-Nordheim devices or direct tunneling devices, the only difference being that the latter have thinner oxide layers. For oxide layer thicknesses up to 37Å (3), the interface traps are charged by direct tunneling through the SiO_2 layer. Direct tunneling devices consequently exhibit great sensitivity of the so-called "write" characteristics to the oxide layer thickness (4, 7). Since the growth rate of SiO_2 on silicon is relatively high in oxygen or water vapor ambients (8) at high temperatures, low temperatures and/or diluted oxygen atmospheres should be used when very thin (about 20Å) films are necessary. While Wallmark and Scott (3), in their MNOS studies, prepared SiO_2 films in steam at 600°C, the present paper shows that very thin films of SiO_2 (less than 50Å) can be formed on silicon in ambient mixtures of NO and H_2 at 950°-1140°C.

P-type silicon wafers (<100>, 10 ohm-cm) were first cleaned in ammonia, hydrochloric acid, hydrofluoric acid, and deionized water, and then blown dry in nitrogen. The residual SiO_2 covering the wafers was then measured by ellipsometry (9, 10) and found to be 10 ± 1Å. The reactions were carried out using rf induction heating of a conventional horizontal quartz tube (59 mm in diameter) with a graphite susceptor encased in a fused silica envelope and attached to the cap of the reactor. High-purity hydrogen and nitric oxide gases (Matheson Corporation) were used without further purification.

The growth of oxide on these silicon wafers at 1000°C in various gas ambients is shown in Fig. 1. The oxide thickness, measured by ellipsometry, increased linearly above 25Å but probably logarithmically below 25Å.

The oxidation of Si by NO (curve A) probably occurs by the reaction of silicon with the oxygen formed while the NO gas is decomposing. The mechanism of thermal decomposition of NO in nitrogen and

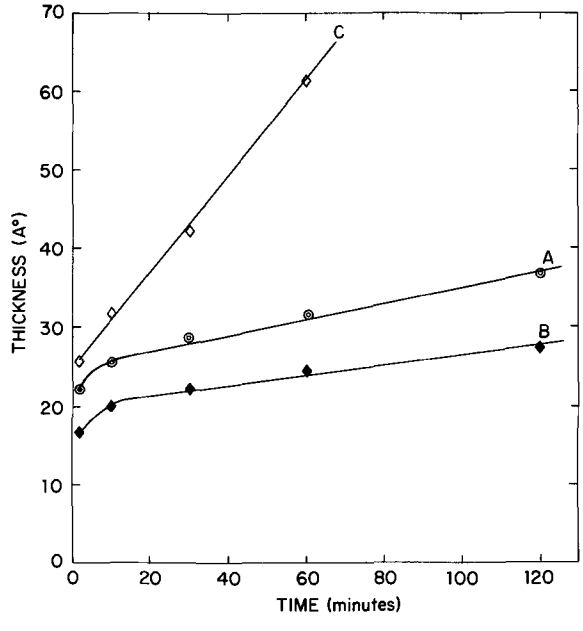

Fig. 1. Oxide growth as a function of time at 1000°C in the following gas ambients: A—6%NO, 94% N_2 in volume (total flow: 4.5 liters/min); B—6% NO, 94% H_2 in volume (total flow: 4.5 liters/min); C—0.3% O_2, 99.7% N_2 in volume.

* Electrochemical Society Active Member.

Key words: oxidation, silicon, thin films.

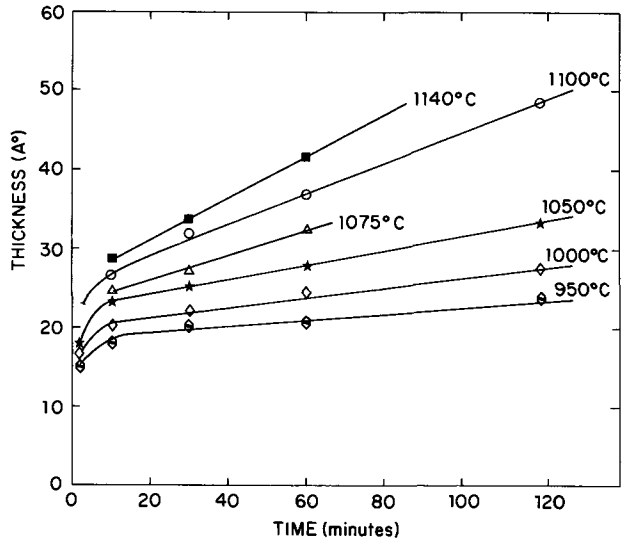

Fig. 2. Oxide thickness as a function of time at several temperatures: 6% NO, 94% H_2 in volume (total flow: 4.5 liters/min).

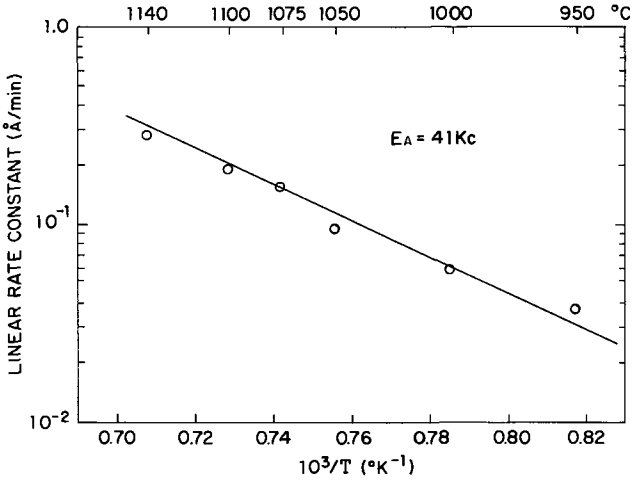

Fig. 3. Effect of temperature on the linear rate constant

oxygen involves a complex chain propagated by the atomic species (O, N) formed during the reaction (11, 12).

In the 6% in-volume NO + 94% in-volume H_2 ambient (curve B), the growth rate in the linear region is very nearly the same as in the NO + N_2 ambient, but lower absolute values of oxide thickness are obtained. For comparison, note the much faster oxide growth rate in even a very dilute oxygen ambient, 0.3% in-volume O_2 + 99.7% in-volume N_2 (curve C).

Oxide growth rate in NO + H_2 mixtures is strongly thermally activated. Figure 2 shows the thicknesses of oxide films at various temperatures, between 950°C and 1140°C as a function of time. The growth rate is linear with time except for the earliest stages of the oxidation process. Reproducibility of the thickness measurements was ± 1Å for the lowest temperature of oxidation and ± 2Å for the highest temperature of oxidation. Figure 3 shows the effect of temperature on the linear rate constant. An activation energy value of about 41 kcal/mole was calculated from the slope of the line. This energy value approximates the 45.3 kcal/mole obtained by Deal and Grove (8) for the direct oxidation of silicon in oxygen and/or water vapor.

The kinetics of the NO + H_2 reaction were studied by Graven (13) in the range of 840°-1060°C, and a homogeneous chain mechanism including intermediates such as NOH, O_2H, and OH was proposed. Kohout and Lange (14), using a mass spectrometric method, showed that NOH was the primary product of the H_2-NO reaction, and that N_2O and small amounts of NH_2OH were also formed. The films grown in the present study were not oxynitrides, no nitrogen was detected at the electron microprobe, and the index of refraction of 1000Å thick films grown at 1100°C was found to be that of thermal oxide of silicon, 1.46.

Acknowledgments

The author is grateful for the cooperation and support of J. F. Shepard and Dr. J. M. Eldridge, as well as the technical assistance of S. Neumann. He also wishes to thank Drs. B. Vromen and Y. van de Muelen for their helpful discussions concerning the ellipsometrical measurements.

Electric Field Effects on the System Oleyl Cholesteryl Carbonate-Cholesteryl Chloride

Werner Haas* and James Adams

Xerox Research Laboratories, Webster, New York 14580

The study of induced phase transitions from the cholesteric to the nematic mesophase has recently been of interest to a number of investigators. Sackmann, Meiboom, and Snyder (1) reported a magnetically induced phase transition, and Wysocki *et al.* (2, 3) described an electric field induced phase transition. Theoretical work by De Gennes (4) and Meyer (5) resulted in mathematical expressions which described the fields required to induce the phase transition, and the threshold fields were found to be inversely proportional to the pitch of the unperturbed cholesteric helix. Experimental work designed to confirm the theory was carried out by Durand (6) for magnetic fields and Baessler and Labes (7) for electric fields.

In the experiments described here, the electric fields required to induce the cholesteric-nematic phase transition were measured in the system cholesteryl chloride (right handed)-oleyl cholesteryl carbonate (left handed) and were correlated with the reciprocal pitch which is a function of composition.

Mixtures in 10% steps ranging from 0 to 100% content by weight of cholesteryl chloride (CC) were prepared by dissolving the components in petroleum ether. The films were cast from the solvent and heated in order to remove as much solvent as possible.

A preliminary examination of the mixtures under the polarizing microscope showed that mixtures with contents higher than 70% cholesteryl chloride crystallize quickly and mixtures with oleyl cholesteryl carbonate contents larger than 90% were isotropic at room temperature. Somewhat surprising was the observation that 50-50% mixtures deposited onto a slide without cover glass spontaneously adopted a uniaxial configuration with positive sign. Oriented areas as large as 1.0 cm^2 were observed. Positive signs are characteristic of smectics and nematics, but the textures which were observable at the borders of the preparation appeared nematic in nature.

The pitch of the mixtures was measured at room temperature on aligned free surface liquid crystals. Monochromatic light was incident at an angle ϕ_i measured from the normal, and the maximum reflection was detected by a photodiode at an angle ϕ_s also measured from the normal; ϕ_i, ϕ_s and the index of refraction n of the liquid crystal were correlated by Fergason's (8) formula with the pitch of the helical structure. Details of the instrumentation were given elsewhere (9).

A plot of the reciprocal pitch *vs.* composition is shown in Fig. 1; around the 50% point, the reciprocal pitch value approaches zero which is in agreement with the observed positive conoscopic figure.

The electric field strengths required to induce the phase transition were measured with cells as shown schematically in Fig. 2. The gap between the electrodes was about 200μ and was measured for each cell with a micrometer. Results were checked by focusing the microscope on the lower and upper slides. The accuracy of these measurements was $\pm 10\%$.

The geometry of the cell is such that pressure effects are largely eliminated. The liquid crystal material after introduction into the gap generally assumed, after some relaxation time, a texture of optically active areas surrounded by birefringent regions which

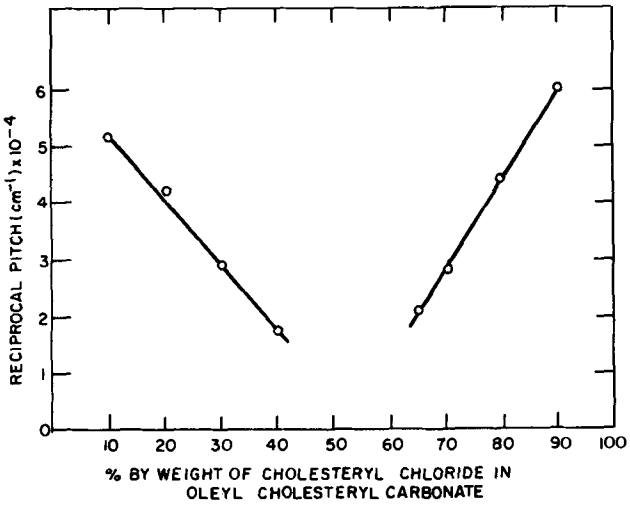

Fig. 1. Reciprocal pitch *vs.* composition

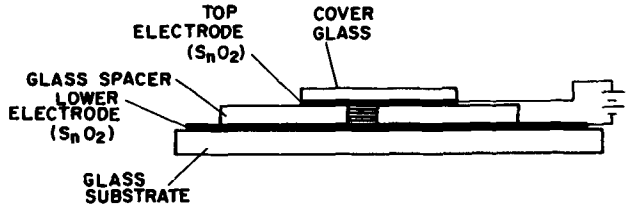

Fig. 2. Measuring cell

form a focal-conic-like texture. In the optically active areas, the liquid crystal adopted the Grandjean plane texture which is optically negative. This is somewhat surprising for the 50% mixture which, as mentioned previously, was optically positive on an uncovered slide. The film on the open glass slide, however, was about 50 times thinner than the layer in the cell, and deposition of a "thick" film on an uncovered slide also produced a cholesteric texture. The conclusion drawn from this experiment was that in the compensated region the liquid crystal is very labile and, depending on film thickness, substrate, or other factors affecting the ordering, can adopt either the cholesteric or nematic molecular arrangement.

When an electric field was applied to the mixed cholesterics in the measuring cell at field strengths substantially below the transition field, the optically active areas disappeared (2) and the film broke off into a number of small birefringent domains. The film became totally focal-conic and scattered light strongly. Without a microscope, the film appeared frosted and the over-all aspect was similar to dynamic scattering (10) without the violent turbulence associated with that effect.

The disappearance of the optically active areas is associated with a realignment of the optic or helical axes to a position perpendicular to the electric field and is due to the sign of the anisotropy of the dielectric susceptibility. This type of realignment is not only observed in the system studied but is characteristic of many other cholesteric systems.

* Electrochemical Society Active Member.

Key words: liquid crystals, mesomorphism, phase transition.

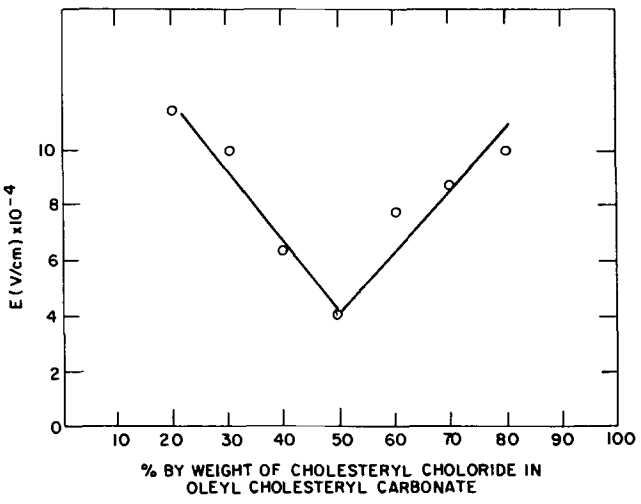

Fig. 3. Transition field vs. composition

This effect precludes the observation of the transition for the case in which the electric field is applied parallel to the optic axis. Thus, Meyer's formula (5) $F_c = 2\pi/Z_0 \ (K_{22}/\Delta\epsilon)^{1/2}$, where F_c is the critical electric field, Z_0 the pitch of the unperturbed cholesteric helix, K_{22} an elastic constant, and $\Delta\epsilon$ the anisotropy of the dielectric constant, is not applicable. The appropriate formula to be used is the electric analog of the prediction by De Gennes, $H_c = \pi^2/2Z_0 \ (K_{22}/\Delta\chi)^{1/2}$, for magnetic fields applied perpendicular to the helical axis. H_c is the critical magnetic field and $\Delta\chi$ the anisotropy of the magnetic susceptibility. This expression probably also applies to the measurements by Baessler and Labes (7).

In the measurements described here, once the layer had become focal-conic, the field was always normal to the helical axes. With increasing voltages, scattering and domain sizes underwent quantitative changes. Below the transition, turbulence increased and dark regions appeared which correspond to areas in which the film was already nematic and aligned. In time the film became darker until the field was totally extinguished. At this point the interference figure was very sharp and scattering ceased completely.

The criterion used in the measurements of the field strength required to produce the transition was total darkness 2 min after application of the field. The results are plotted *vs.* composition in Fig. 3. The threshold field is linear in reciprocal pitch as predicted by the theory for the magnetic analog (4). From the reciprocal pitch measurements or from the thin film experiment, one would have expected that the value for the 50% composition would have been very small. This was not the case. The value is relatively low but still considerable. Since the data were taken in 10% steps, the absolute minimum was, of course, not precisely determined.

If the field is removed when the liquid crystal is in the aligned nematic state, the film breaks into a number of unaligned domains. The conoscopic figure appears to become temporarily biaxial and then vanishes rapidly. In parallel light between crossed polarizers, the light output increases and a number of colors appear in sequence. These phenomena were recently studied in detail by Wysocki *et al.* (11). Scattering increases strongly as the film settles into the focal-conic texture and after 20 min the first optically active areas become visible again.

In summary, the pitch of cholesteryl chloride-oleyl cholesteryl carbonate mixtures was measured and correlated with critical fields required to induce the cholesteric-nematic phase transition. The critical field was found to vary linearly with reciprocal pitch for the case of field perpendicular to the helical axis which is in agreement with the magnetic analog (4). Optically active areas whose helical axes are parallel to the field realign at fields smaller than required for the transition. The realignment is due to the sign of the anisotropy of the dielectric susceptibility.

Ge-Esperite—A New Mn-Activated Phosphor

A. Wachtel* and C. K. Lui Wei

Westinghouse Electric Corporation, Bloomfield, New Jersey 07003

A recent paper by Ito (1) describes a number of Zn, Ca, Pb silicates, among which $Zn(Ca_{1-x}Pb_x)SiO_4$ (Calarsenite, recently renamed esperite) is known for its bright Mn-activated luminescence in the yellow-green (2). Owing to low stability, however, this compound is difficult to prepare in pure form, especially as a well-crystallized phosphor. In this connection, we noted that the analogous germanate which we propose to call Ge-esperite (GESP) is considerably more stable and amenable to synthesis.

The purpose of this note is to report on some of the properties of GESP and to describe efforts to ascertain its composition.

* Electrochemical Society Active Member.

Key words: luminescence, phosphors, germanates, calcium larsenite, esperite.

Experimental

Compounds activated by 0.01 Mn replacing Zn were prepared by appropriate heat treatment of raw materials obtained by different techniques as will be described. Luminescence under 254 nm excitation was

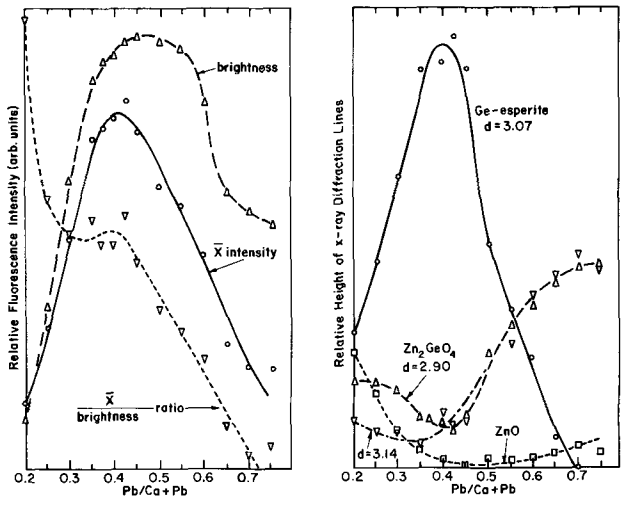

Fig. 2. Luminescence (left) and x-ray powder diffraction analyses (right) of hydroxide slurries, dried and fired at 820°C, as a function of composition. Use of $\bar{x}$ and $\bar{y}$ filters was to distinguish between the luminescence of different phases.

observed microscopically as well as measured in powder plaques. X-ray powder diffraction analyses were performed with a Philips x-ray diffractometer, operated at 35 kV and 15 mA, using a Cu target and Ni filter.

Results

Solid-state reaction between component oxides and carbonates proceeds *via* formation of Zn_2GeO_4 above 750°C, followed by GESP above 800°C. Above 950°C, GESP begins to decompose to Zn_2GeO_4 and other products, at least one of which displays a weak orange-red luminescence and is unidentified. Prolonged annealing of the fused (1000°C) product at lower temperatures, *e.g.* 850°C, again causes formation of GESP. Microscopic examination of the luminescence showed that the Pb/Ca+Pb ratio (x) of the compositions strongly influences the relative yield of the various phases obtained: below $x = 0.25$, a red luminescent phase[1] is noted together with GESP even at moderate temperatures; while, above $x = 0.25$, it disappears but the amount of Zn_2GeO_4, which is always present, increases. Maximum formation of GESP (about 50%) obtains at $x = 0.25$. Figure 1 shows the course of the reaction, as monitored by x-ray diffraction analyses, on products obtained from this composition in heating steps of 30 min and 50° increments. To avoid crowding, the figure is divided in two portions, and unidentified phases are indicated only by the most prominent d-spacing. It essentially confirms the results already noted by microscopic examination of activated materials. The extremely complex pattern obtained on high-temperature decomposition products was not suitable to identify the red luminescent phase, as this was often associated with d-spacings other than that at 5.08Å. Note that Zn_2GeO_4 goes through a minimum at the temperature of maximum GESP formation, at which point the initially strongest reflection at 2.69Å disappeared, while the second strongest reflection at 2.90Å has increased in relative intensity. This curious observation was reproducible in similar experiments.

Considerably higher yields of GESP resulted from wet slurries of component hydroxides which seemed to partially react prior to drying and firing. Figure 2 shows the luminescence (left) and x-ray diffraction line heights (right) of products obtained at 820°C as a function of x. Note that, in contrast to previous results, x is clearly optimized at 0.4. The relative concentration of side products is lower, and is also minimized at $x = 0.4$; however, their presence still casts some doubt on the actual composition of GESP at this point.

[1] Presumably some Zn,Ca germanate, and not necessarily the same orange-red emitting phase previously mentioned.

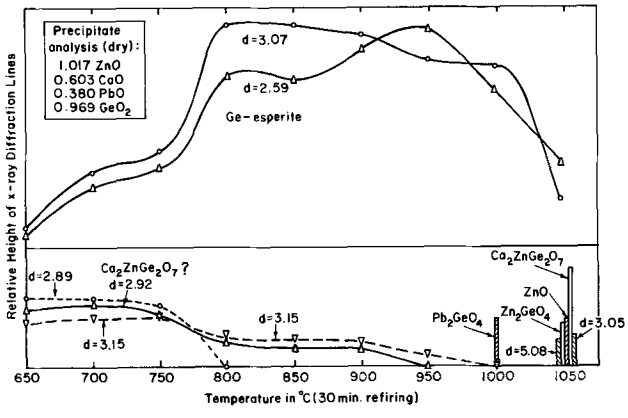

Fig. 3. X-ray powder diffraction analyses of a coprecipitate after 30 min firings at increasing temperatures. Bars denote phases observed at only one temperature.

The most rapid formation of GESP resulted from firing of coprecipitates derived from mixed nitrates and Na_4GeO_4. The purest and most strongly luminescent preparations resulted from initial compositions of $x = 0.35$ and Ge = 1.04 but, owing to small losses of Ca and Ge, the final compositions were somewhat richer in Pb and more stoichiometric in Ge. Figure 3 shows the thermal reaction of a typical precipitate of this composition. Comparison with Fig. 1 shows some important differences: GESP is observed already at 650°C and reaches maximum near 800°C, and no Zn_2GeO_4 is formed prior to decomposition of GESP at higher temperatures. The small amount of side products between 800° and 1000°C is due only to the short firing times employed, and single-phase preparations of GESP were readily obtainable by this technique by firing at 850°-900°C for a few hours. Table I shows the powder diffraction pattern of one of these in comparison to that of esperite as reported by Moore and Ribbe (3). It can be seen that the agreement is excellent, and also that the observed specific gravity was in good agreement with that calculated from the x-ray data on the basis of 12 Ge atoms/unit cell. It was, however, interesting to note that within the precision afforded by the sharpness of the lines our d-spacings were independent of x; *i.e.*, no lattice expansion due to Pb replacing Ca could be observed.

Figure 4 shows the emission and excitation spectra of GESP as compared to those of two specimens of esperite from Franklin, New Jersey. It can be seen

that, within the range displayed by the minerals, the emission is not significantly different. Despite the high luminosity of the emission, however, we could obtain only about 40% of the brightness of Zn_2GeO_4:Mn in our best samples.

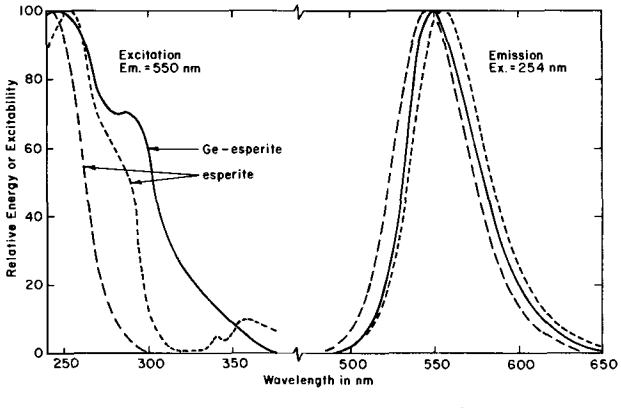

Fig. 4. Excitation and emission spectra of GESP (solid lines), and of two specimens of esperite from Franklin, New Jersey (dashed lines).

Discussion

The present data show that, unlike esperite, GESP can form by solid-state reaction between conventional oxide or carbonate raw materials, although the much better results with homogeneous coprecipitates suggest that the reaction is slow. This, as well as comparison of the decomposition temperature with that of esperite (1), shows that the germanate is considerably more stable.

Comparison between the germanate and silicate concerning their x-ray diffraction patterns, and their agreement between actual and calculated specific gravities when both are calculated on the basis of the same number (12) of Si or Ge atoms/unit cell, shows that the two substances are isomorphous.

The unit cell model proposed by Moore and Ribbe (3) contains 16 Ca sites, 4 Pb sites, and 4 sites which may be occupied by either ion. This corresponds to a range of 4-8 Pb/24 cation sites ($x = 1/6$ to $1/3$). Our values of x, leading to maximum formation of GESP depended on the technique of preparation: in solid-state reactions, it was 0.25 which is the mean of this range; while, in the more homogeneous wet preparations, the much higher values (0.35-0.4) would require that some of the sites proposed for Ca alone be occupied by Pb. However, our data are uncertain, either because the presence of side products makes it impossible to equate the composition of GESP with the over-all composition or, in the case of homogeneous preparations, because of the formation of single-phase solid solutions over a range of compositions. Finally, the value of $x = 0.4$, suggested by Fig. 2, would require a basic unit cell according to $Ca_3Pb_2(ZnGeO_4)_5$, in violation of the presently assumed model (3).

In the near future, we hope to resolve this question by means of reaction products obtained by fluxing component oxides with KCl at 850°C and leaching in water. Microscopic examination of such powders, under 254 nm excitation, reveals well-crystallized needles of Zn_2GeO_4:Mn (green), plates of GESP (green-yellow), and aggregates of inert and weak red luminescent matter. Using the cathodoluminescence of the particles for identification, we expect to be able to ascertain the composition of GESP by electronmicroprobe analyses and, in particular, to note whether it is a function of the over-all raw material composition. These results will be reported in a separate communication.

Acknowledgments

Oxidation of Vapor Deposited Aluminum in Air at 23°C

D. L. Kinosz and D. L. Belitskus

Aluminum Company of America, Alcoa Research Laboratories, New Kensington, Pennsylvania 15068

Hart (1) has summarized early work on oxidation of nascent aluminum surfaces in air or oxygen at room temperature. The quartz crystal microbalance provides a method of obtaining rapid, accurate oxidation data for vapor deposited metal films from early stages of oxidation. Kirk and Huber (2) used this technique to study the oxidation of aluminum in dry oxygen at

Key words: quartz, crystal, microbalance, kinetics, dew point.

pressures ranging from 10^{-3} to 10 Torr, finding a pressure dependent, direct logarithmic film growth. The present work employed this method to determine the growth laws applicable in dry and moist air at atmospheric pressure.

Experimental

Weight gains were measured with a Westinghouse Model 701 Quartz Crystal Microbalance coupled with a Hewlett-Packard Model 521C Counter. The crystal head was mounted in a conventional bell jar assembly in a room held at 23° ± 1°C (−5° to 0°C dew point). Aluminum films were evaporated onto the exposed gold covered quartz crystal from 99.999% Al on a tungsten helix fitted with a beam collimator. A shutter between the exposed crystal and the vaporization source was kept closed until the vaporization was constant to minimize any radiant heat effects. Films averaging 1000Å were deposited at 15 Å/sec. The pressure, maintained by an oil diffusion pump and a liquid nitrogen trap, was typically 3-5 x 10^{-7} Torr, as measured by a hot filament cathode gauge before the start of vaporization. After film deposition, about 10 min was required for the balance to stabilize.

For four experiments in −75°C dew point air, a ballast tank was filled from a commercial cylinder to sufficient pressure to equal one atmosphere when the gas was expanded into the bell jar assembly. Gas expansion required about 90 sec. Four experiments at −5° to 0°C dew point used room air vented into the system. Finally, two experiments were conducted in 23°C dew point air produced by bubbling air through water before entering the ballast tank.

The reversible correction in balance beat frequency produced by admitting an air atmosphere to a gold coated crystal (3) was determined and applied to the oxidation data.

Results and Discussion

Average weight gains per unit geometric area are shown in Fig. 1 as a function of the log of oxidation time. There is no significant difference between the kinetics in air at −75°C dew point and in air at 0°C dew point for up to 10 hr (3.6 x 10^4 sec). Only one run in air at 0°C dew point was carried out beyond 5 x 10^3 sec. Weight gain in moisture-saturated air was more rapid but is also best represented by a direct logarithmic oxidation rate.

The direct logarithmic oxidation rate in moisture-saturated air agrees with the results of Hart (1), who studied the oxidation of electropolished aluminum by anodic polarization. The direct logarithmic oxidation rate in dry air agrees with the results of Kirk and Huber (2) and Eley and Wilkinson (4) in dry oxygen at reduced pressures and with Boggio and Plumb (5) in dry air at one atmosphere but is contrary to the results of Hart in dry oxygen at one atmosphere. While the mechanism of oxide formation may differ in dry air and dry oxygen at atmospheric pressure, it is possible that because of the absence of data during very early oxidation in the investigation of Hart [*cf.* Fig. 5 of Ref. (1)], an incorrect assignment of the oxidation kinetics was made. After about 10 hr, oxidation in air at either −75°C or 0°C dew point oxidation became more rapid, departing from a direct logarithmic rate. While data were insufficient to determine the rate law beyond this point, it may be the inverse logarithmic rate found by Hart. Boggio and Plumb (5) found no deviation from a direct logarithmic law in up to 10^6 seconds. The reason for this difference is not obvious but may be related to differences in substrate or in aluminum film thickness, purity, or porosity.

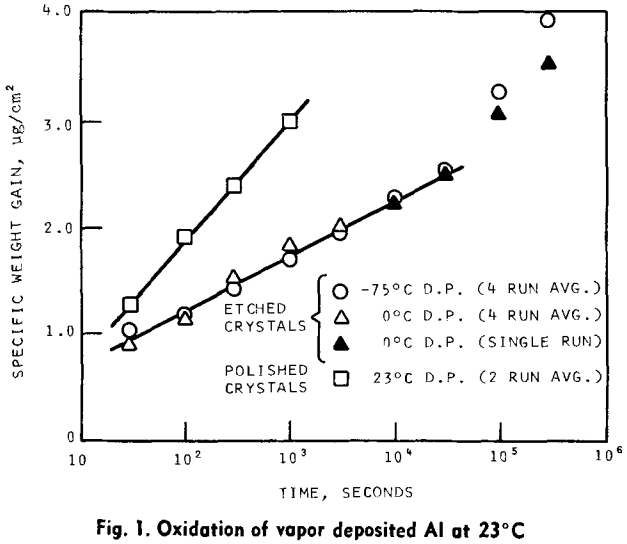

Fig. 1. Oxidation of vapor deposited Al at 23°C

Several theories predict a logarithmic time law for the initial oxidation. Hauffe and Ilschner (6) assume that the rate of electron tunnelling determines the initial rate, resulting in a direct logarithmic law, and that the rate of ionic transfer determines the rate with thicker films, resulting in an inverse logarithmic law. Lanyon and Trapnell (7) assume a two-stage reaction involving oxygen chemisorption and a place-exchange reaction between the chemisorbed oxygen and the underlying aluminum atoms which leads to the pressure-dependent, direct logarithmic law found by Kirk and Huber (2) and Eley and Wilkinson (4). Boggio (8) showed that electron tunnelling and reaction with adsorbed oxygen atoms leads to the same growth law.

The experiments in dry air and in air of 0°C dew point employed etched gold coated quartz crystals as received from the manufacturer. Reproducibility was good for the four runs in air of 0°C dew point, with the highest rate about 15% greater than the lowest, but poor for the runs in dry air, with the highest rate nearly 100% greater than the lowest. Nonetheless, each of the individual curves followed the direct logarithmic time law and the average curve is considered reasonable. Lack of reproducibility is attributed primarily to variability in surface roughness of the quartz crystals, which may have been accidentally greater for the runs in dry air. An attempt to measure surface roughness by stripping the oxide film from aluminum coated crystals by a radioactive chromate-phosphate solution (9) failed when the vapor deposited aluminum coating was also removed. Handy and Waters (10) have estimated the surface area of similar crystals as 2.5± 0.2 times the geometric area.

The two runs in moisture-saturated air used polished crystals obtained from Reeves-Hoffman (Carlisle, Pennsylvania). Scanning electron micrographs (2000X) of oxidized aluminum surfaces on an etched and on a polished crystal are shown in Fig. 2. The difference in slopes of the two curves in Fig. 1 increases from twofold to fivefold after correction for surface roughness (taking the roughness of a polished crystal as unity). This should not be taken as quantitative since part of the difference could be due to the change in the base crystals. In air at 23°C dew point some condensation may occur on the crystal, giving rise to higher oxidation rates. More experiments using a common type of quartz crystal substrate (preferably polished) are required.

Assuming the oxide formed in dry air is amorphous Al_2O_3 of density 3.5 g/cc and a 2.5 roughness factor, oxide thickness after 24 hr is about 35Å. This is close to the 30-40Å range found by Hart (1) in 1 atm of dry oxygen and the 30Å found by Madden, Canfield, and Hass (11) in 1 atm of air but is higher than the 19Å found by Boggio and Plumb (5). The thickness of the oxide cannot be accurately determined with a quartz crystal microbalance until information on the identity and density of the film is available. Quartz crystal microbalance studies in conjunction with tech-

The Response of the Stabilized Zirconia Galvanic Cell to Methane-Oxygen Mixtures

Y. L. Sandler*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

The voltage response of the stabilized zirconia galvanic cell to varying concentrations of methane-air mixtures in their combustion products was studied, using air as a reference gas. It is shown that the cell can be operated in two distinct ways, the equilibrium and the nonequilibrium mode. In the former case, the electrode equilibrates the mixture completely and registers a Nernst potential corresponding to the oxygen partial pressure in the equilibrated mixture. With active porous platinum electrodes, this condition is realized. In the nonequilibrium case, the cell registers the Nernst potential corresponding to the true oxygen partial pressure in the mixture. This condition is realized with silver electrodes; exact oxygen potentials were obtained at temperatures as high as 800°C with mixtures containing up to 27% methane in air. By means of a combination of nonequilibrium and equilibrium electrodes, both oxygen and methane concentrations can be determined. A methane gauge is described that can measure methane in air without the use of a reference gas.

The solid electrolyte high-temperature cell is ideally suited for the rapid and accurate potentiometeric determination of oxygen in gas mixtures. The electrolyte used in the present study is a stabilized zirconia tube containing 15 m/o (mole per cent) calcia. Within wide limits of temperature and oxygen pressure, the conductivity (1) of the electrolyte is due solely to the mobility of the oxygen ions. With suitable electrodes, reversible oxygen potentials are obtained at open circuit. Cells of this type have therefore come into use as oxygen gauges (2, 3) for determining oxygen pressures or oxygen partial pressures in inert gas mixtures. In equilibrium mixtures (4, 5), such as H_2/H_2O, CH_4/H_2O, or CO/CO_2, the cell is capable of indicating accurately the potential corresponding to the equilibrium oxygen partial pressure. An air or oxygen electrode is usually used as a reference electrode.

In the present paper, the response of the cell is more closely examined when a nonequilibrium mixture containing both oxygen and a fuel, methane, passes the cell. The complete equilibration of the mixture and the correct response to the oxygen partial pressure cannot be taken for granted under all conditions. The response will depend on the catalytic activity of the electrode material as well as on physical characteristics, such as porosity and size, flow rate, and temperature. In the present work, methane-air mixtures were used with and without combustion products present. As will be shown, the proper choice of the electrode makes it possible to operate the cells under conditions of either complete equilibrium or complete nonequilibrium. In intermediate cases, the cell voltage is often difficult to interpret.

Experimental

The electrolytic tubes were made of zirconia doped with 7 w/o (weight per cent) calcia and were supplied by the Zirconium Company of America. Their dimensions were 4 mm ID, 5 mm OD, and 18 cm length. Platinum or silver electrodes were made from metal paste as provided by Engelhard Industries. The outside electrode was in contact with the atmosphere as a source of constant oxygen partial pressure. The gas to be analyzed was passed through the inside.

The furnace heating the electrolyte tube had a temperature zone constant to 3°C over about 2 cm length. When platinum was used, to maximize the catalytically active area, the electrode extended over almost the entire length of the electrolyte tube, as shown in Fig. 1(a). No voltage deviation due to the colder parts of the tube (having a higher ohmic resistance) was noticed. When no catalytic activity was desired, with

Key words: oxygen, methane, catalyst, silver, zirconia, gauge, electrode.

silver electrodes, a small electrode of about 1 cm length at the center of the tube was used. Electrical connections to the cold end of the tube were made by narrow lines consisting of the same material [Fig. 1(b)].

The pure or premixed gases were taken from cylinders supplied by Matheson Company. After passing through separate flowmeters, the combined gases passed a water vapor saturator which was kept in an oil bath thermostated to within 10^{-2}°C. The gas lines beyond the saturator were kept hot by means of a heating tape to prevent the condensation of water vapor. Gas samples were taken off before and after passage of the gas through the furnace. Analyses were carried out by means of a mass spectrometer, Consolidated Electrodynamics, Model 620-A. Cell voltages were measured with a Keithley 660 Differential Voltmeter.

The partial pressure of water vapor was determined from the temperature of the water saturator and by taking into account the water formed in the cell by oxidation of the fuel. Control experiments were performed to check the reliability of this procedure. Water and carbon dioxide were absorbed by passing gas mixtures through two absorption tubes containing Drierite and Ascarite, respectively. The molar ratio of water to carbon dioxide absorbed agreed to at least 5% with the ratio calculated from the water saturation temperature and the mass spectrometric value for the CO_2 concentration, corrected for the presence of the water vapor.

Results and Discussion

The equilibrium potential, E, of the oxygen electrode with respect to an air reference electrode is given by the Nernst equation

$$E \text{ (in volt)} = 4.95 \times 10^{-5} \times T \log (0.20/p) \quad [1]$$

p is the oxygen pressure in atmospheres at the electrode-electrolyte interface. 0.20 was the partial pressure of oxygen in the air at the reference electrode[1]; T is the absolute temperature.

When possible, the output voltage was compared directly to the oxygen partial pressure as found by mass spectrometric analysis. With fuel in excess, in the equilibrium experiments, p was calculated from the known equilibrium constants for the oxidation of the fuels.

Platinum electrodes.—Two typical results with platinum electrodes are summarized in examples 1 and 2 of Table I. Dilute methane-oxygen mixtures were used that contained an excess of nitrogen, carbon dioxide, and water vapor. Given are the temperature and the flow rate; the water vapor pressure given is the equilibrium vapor pressure at a certain measured temperature of the water saturator (see Experimental section). The mass spectrometric analyses are given for samples entering and leaving the cell and do not include the water vapor. The partial pressures of the individual gases are obtained by multiplying the given concentrations by a factor $(1 - p_{H_2O}) \times 10^{-2}$. In the last two columns of the table, the measured cell output is compared with the output calculated from the oxygen partial pressure of the outgoing gas unless indicated otherwise.

Generally, good agreement was obtained between measured and calculated values as demonstrated in examples 1 and 2; this was expected on the basis of previous work (4, 5). In the first example, there was an excess of oxygen in the fuel mixture; in the second, an excess of methane. In either case, the methane was consumed completely within the error of the mass analysis for methane. In example 1, an excess of oxygen was left in the emerging gas. In example 2, no measurable amount of oxygen was left and hydrogen was found. It may be formed by the two reactions

$$CH_4 + 1H_2O = CO + 3H_2 \quad [2a]$$

and

$$CH_4 + 2H_2O = CO_2 + 4H_2 \quad [2b]$$

Both reactions are of importance at 800°C where the equilibrium constant for the water gas shift reaction $CO + H_2O = CO_2 + H_2$ is approximately equal to 1.[2]

Silver electrodes.—When it is desired to measure the correct partial pressure of oxygen in the presence of a reactive gas, an electrode material must be used that does not catalyze the oxidation of the fuel. Obviously such factors as contact time, temperature, electrode porosity, and surface area will also affect the degree of oxidation during passage of the gas through the cell.

Relatively little information is available on the catalytic oxidation of saturated hydrocarbons (6) at high temperatures. On general grounds, one would expect that the transition metals are not suited for the present purpose. In view of the vacancies in their d-orbitals, they strongly chemisorb hydrogen and they also chemisorb methane dissociatively because enough energy is gained for breaking the C-H bond by the bonding of the split off hydrogen. On the other hand, silver is an s-metal and does not chemisorb hydrogen at low temperatures. [Strictly, this holds true only for oxygen-free silver (7).] The chemisorption of methane on silver would be expected to be very slow. On the other hand, silver is known to provide an excellent oxygen electrode. The reason for this is that the oxygen chemisorption, as well as the diffusion to the electrode-electrolyte interface, is fast. This also holds for electrodes of low porosity because of the relatively high diffusion rates of oxygen through the bulk or along the grain boundaries of the silver film.[3]

No oxidation of methane was observed in any experiment with silver electrodes up to 800°C. The gas analyses of samples taken before and after transfer of the mixtures through the cell were the same.

In Tables II and III, some typical results are presented. In Table II, a single oxygen mixture was used containing 0.85% methane and 2.34% oxygen (excluding water), at temperatures between 550° and 800°C, with and without water present. The only slightly lower oxygen concentration found in the "out"-sample at the highest temperature of 795°C is at least partly

[1] Strictly, the fraction of oxygen in dry air is 0.2094. The value 0.200 was used in the calculations for the oxygen reference pressure. It is an empirical average value chosen to offset the effect of humidity in the reference air and of the excess pressure of the gas to be analyzed over atmospheric pressure at an average flow rate.

[2] The CO formed in example 2 of Table I could not be reliably analyzed. It contributed less than 1% to the mass peak 28 which it shares with N_2. With $K = [CO_2][H_2]/[CO][H_2O] = 0.877$, the CO formed is found to be 0.6%. The error in the analyses is up to 3% and is higher for the low methane concentrations.

[3] These properties are important even at open circuit; otherwise, in the presence of a reducing gas, cell voltages may be observed that seem abnormally high. (Y. L. Sandler, Unpublished results; also cf. Abs. 328, p. 732, Electrochem. Soc. Extended Abstracts, Spring Meeting, Los Angeles, May 10-15, 1970.)

due to fluctuations in the gas composition that occurred in this set of experiments.

In Table III, similar experiments are presented with relatively high concentrations of methane in "air," actually a mixture of 20% oxygen in nitrogen. Three different mixtures were used near 700°C at flow rates varying from 15 to 100 cc/min. The results appear particularly striking[4]: with mixtures containing up to 27% methane, the gauge indicated the correct oxygen partial pressure in the mixture entering the gauge, with and without the presence of water vapor. As may be seen, the ratio of oxygen to nitrogen is the same before and after passage through the gauge, showing that no oxidation of methane occurred. The maximum deviation of only 0.2 mV between measured and calculated voltages corresponds to an error of about 1% in the oxygen concentration, which is below the error of the mass spectrometric oxygen determination.

When the gas supply was stopped and the exit of the tube was closed by a plug, the potential gradually rose, as shown in Fig. 2 for one example. This is caused by slow catalytic combustion of the methane and the resulting loss in oxygen.

The experiment sets the approximate temperature limit of 700°C at which silver can be used as a nonequilibrium electrode in static systems. In the present flow system, accurate voltages were obtained to 800°C. Small positive deviations from theoretical voltages were observed at 850°C at low flow rates indicating some catalytic activity. At any rate, the use of such high temperatures is not practical because of the high vapor pressure of silver and the resulting short life of the electrodes.

[4] Methane is explosive in concentrations above 5.5% in air. The absence of any gas phase reaction is due to the large surface-to-volume ratio in the narrow electrolyte tube. [F. B. Lewis and G. von Elbe, "Combustion, Flames and Explosions of Gases," Second Ed., p. 103, Academic Press, New York (1961).]

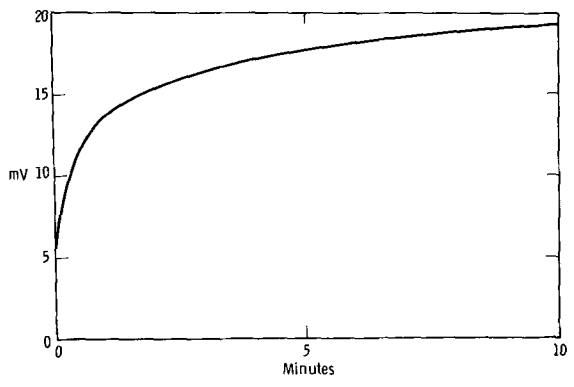

Fig. 2. Change in cell voltage with time for a stationary mixture of 19.7% CH_4 and 80.3% air at 696°C.

A methane gauge.—It has been demonstrated for methane-air mixtures that, by the use of appropriate electrodes, the zirconia high-temperature cell can accurately indicate the chemical potential of the oxygen either in the totally equilibrated state or in the totally unequilibrated state. The nonequilibrium cell measures the true oxygen partial pressure, or concentration, in the mixture, while the equilibrium cell indicates the excess oxygen pressure or concentration after complete equilibration of the mixture. Thus, the difference in the oxygen content indicated by the two cells gives the oxygen required for the combustion of the methane, which is equal to one half the amount of the methane in the mixture. The combination of the two cells therefore allows the determination of both the oxygen and the methane in the mixture.

The situation may arise that the amount of oxygen in the mixture is known, for example, when methane is present as an impurity in air. Then a single measurement is sufficient to determine the methane concentration. This can be achieved by the use of a cell having one equilibrium and one nonequilibrium electrode. One version of this type of cell is indicated in Fig. 3. The air stream containing methane is split in two parts. One part passes through a catalyst bed where the mixture is equilibrated and subsequently comes in contact with one silver electrode, the anodes of the cell. The other part passes directly over the cathode which is also made of silver. The same metal is used for both electrodes to avoid the thermoelectric potential set up between dissimilar metals. (The potential of a platinum-silver couple was measured to be 13 mV at 800°C.)

Suppose that the mixture initially consists of a moles CH_4 and b moles O_2. At the equilibrium electrode, the mixture will be

$$a\,CO_2 + 2a\,H_2O + (b - 2a)\,O_2$$

The cell voltage then is

$$\Delta E = (RT/4F)\ 2.30 \log [b/(b - 2a)] \qquad [3]$$

The ratio of the partial pressures in the Nernst equation can be replaced by the number of moles or by concentrations because the number of molecules does not change during the combustion of methane.

Then,

$$b/(b - a) = \log^{-1}[(4\mathbf{F}/2.30\,RT)\,\Delta E] = A$$

or

$$a = b/2\,[(A - 1)/A] \qquad [4]$$

giving the methane concentration in terms of the known oxygen concentration and the measured cell voltage.

It is desirable to use a catalyst that is effective in small amounts so that it can be inserted directly into the electrolyte tube. A platinum catalyst supported on porous alumina fragments of 2-3 mm diameter was found adequate. The support was soaked in chloroplatinic acid and reduced with borohydride to give a platinum content of 1% by weight. After careful washing and steaming, the catalyst was densely packed into the electrolyte tube between two retaining nickel nets about 4 cm apart.

The method was tried out in a system shown in Fig. 4 which allowed the test of different combinations. It consists of a nonequilibrium gauge and an equilibrium gauge in series. All electrodes were made of silver paste. The outer electrodes, the cathodes, were exposed to air and were electrically connected. The gas mixtures used consisted of methane and a premixed gas containing 19.8% oxygen in nitrogen. The results are presented in Table IV. Only the mixture emerging from the second cell was analyzed by mass spectrometer. The analyses, as given in column 2 of the table, already include the water content; it must be twice the amount of CO_2 which is formed by the reaction $CH_4 + 2\,O_2 = CO_2 + 2H_2O$. The concentration of methane initially present, as given in column 3, is equal to the amount of CO_2 formed plus the small amount of residual methane found in some of the exit samples. Columns 4-7 give the nonequilibrium and the equilibrium voltages, E_1 and E_2, and the oxygen concentrations derived from these voltages. ΔE in column 8 is the voltage between equilibrium and nonequilibrium electrode which is equal to the difference between the two cell voltages, E_1 and E_2. The methane concentrations given in the last column are one half of the difference of the oxygen concentrations in the two cells (columns 5 and 7). The same methane concentrations are obtained when calculated from the initial oxygen concentrations and ΔE by the use of Eq. [4], without the use of E_1 and E_2 individually. As may be seen, the methane concentrations obtained from the cell measurements are in satisfactory agreement with the data derived from the mass-spectrometric analyses (column 3).

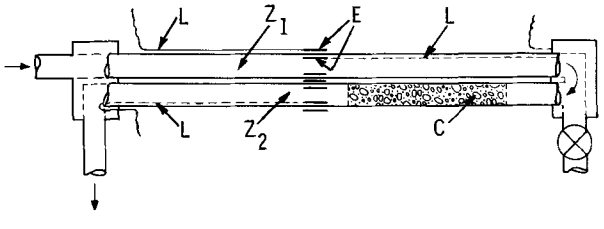

Fig. 4. Combination gauge. Z_1 = nonequilibrium cell, Z_2 = equilibrium cell, E = electrodes, L = leads to cold end of Z, C = catalyst.

It should be possible to improve further the sensitivity and accuracy of the method, particularly at low methane concentrations, by the use of a larger amount of catalyst, to oxidize the methane more completely before it reaches the anode, and by compensating for asymmetries in the cell with the use of pure air or oxygen on both sides of the cell.

No pure air or oxygen is required when determining the methane content of air from ΔE and the known initial-oxygen concentration. A device as depicted in Fig. 3 therefore should be well suited as a methane detector in applications such as coal mine safety devices or gas leak detectors.

An Intercell Planar Heat Pipe for the Removal of Heat During the Cycling of a High Rate Nickel Cadmium Battery[1]

and M. M. Kreitman[2]

Physics Department, University of Dayton, Dayton, Ohio 45409

ABSTRACT

Two 22 A-h nickel-cadmium cells were continuously cycled at a 1c charge rate and a 2c discharge rate, with cooling provided by an intercell planar (rectangular cross section) heat pipe. For purposes of comparison, thermocouple measurements were also taken with an aluminum conduction fin substituting for the heat pipe. The aluminum fin and heat pipe were cooled, by room temperature forced air. Thermally insulated cells were also cycled at the same rates. Cell case temperatures were measured during cycling, and a maximum of 29°C with a 5°C thermal excursion was noted with the heat pipe under conditions of thermal equilibrium which were observed after 3 complete cycles. For the aluminum fin configuration a maximum of 42°C with a 7°C thermal excursion was obtained near thermal equilibrium after 5 complete cycles. The insulated configuration yielded a battery case temperature of 83°C after 5 cycles, and thermal equilibrium was never reached. Coulombic efficiency values for the heat pipe cooled battery were found to be several per cent greater than ~95% which was recorded for the aluminum fin configuration. The specific heat of the cells was measured to be 0.27 cal/g°C. From this and the measured values of the total heat generated per cycle, the effectiveness of the heat pipe in removing battery heat was calculated to be approximately 26% greater than the aluminum fin at or near equilibrium. It is surmised that the significantly lower operating temperatures produced by the heat pipe should lead to an important lengthening of battery cycle life and an associated reduction of capacity degradation.

The use of a heat pipe for the transfer of a large amount of heat with a small temperature drop is well known (1) and it has shown promise of being immediately useful in many areas of technology (2). High thermal conductance is achieved by transferring heat via evaporation and condensation of a fluid within a wick lined pressure vessel (see Fig. 1). The evaporation of the fluid (termed working fluid) occurs at one end of the device and vapor transport carries the heat (of vaporization) to another section where condensation and heat rejection occur. The condensed vapor is returned to the evaporator section via wick forces (capillary pumping). The heat pipe is closely analogous to the ordinary steam heating-radiator system, where the wick serves as the condensate return mechanism rather than gravity. Within certain limits, the heat pipe is capable of transferring heat energy from one point to another point with very small temperature differences.

One of the most important technological applications of a heat pipe is the efficient removal of waste heat from power sources. In the following paragraphs, we wish to discuss and compare the cooling of an advanced two cell nickel cadmium battery at high charge and discharge rates by (*a*) the use of a planar heat pipe; and (*b*) an aluminum conduction fin.

Although the literature on heat pipes deals chiefly with cylindrical geometry, planar type heat pipes are not only important because their flat configuration is highly adaptable to many requirements, but in addition, since their rectangular cross section can offer much more perimeter than circular cross sections of the same area, they can offset significant limitations on the thermal conductance of cylindrical heat pipes by presenting much larger surface areas to the heat source. In this way, lower thermal fluxes through the heat pipe surface can be realized and the possibility of local overheated areas is decreased. Recently, in discussing thermal control of spacecraft batteries, Coggi (3) has considered the optimization of the conduction path between the battery and the heat sink. In order to be compatible with rectangular case configurations of battery cells, and to achieve maximum heat transfer between the cell case wall and the heat pipe, a planar heat pipe was developed and tested with electrical heaters serving to simulate the battery heat source (4). We now report on measurements associated with the application of this heat pipe to the removal of battery waste heat.

Apparatus

Heat Pipe.—The planar heat pipe employed for these experiments was fabricated from thin (0.635 mm) Type 304 stainless steel sheet with over-all dimensions of 12.7 mm x 88.9 mm x 304.8 mm. In addition to its outer shell, a heat pipe normally consists of a porous wick and enough working fluid to saturate the entire wick. Although a variety of working fluids, ranging, for example, from ammonia to silver, have been found suitable (5), water was used for the working fluid

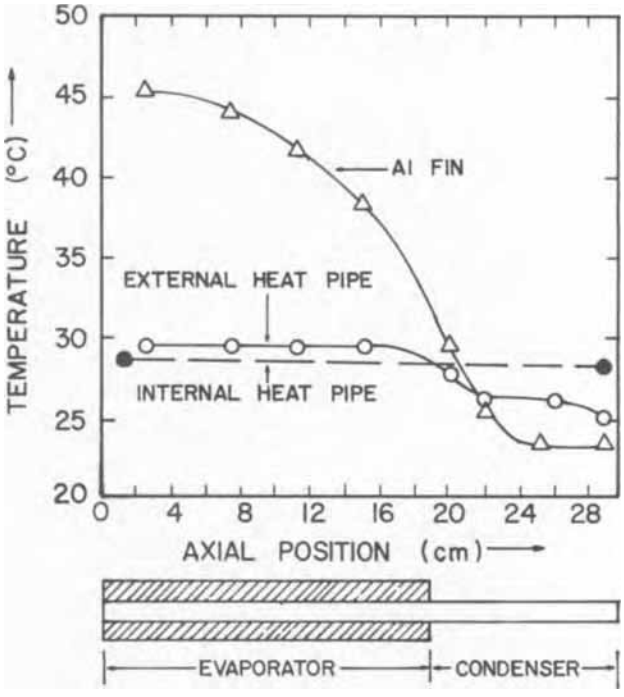

Fig. 3. Axial temperature profile of battery-heat pipe and battery-aluminum fin after five continuous cycles.

because it presented fewer experimental difficulties and offered an abundance of thermophysical data. Thirty grams of singly distilled, deionized, demineralized water was introduced into the heat pipe through the fill valve shown in Fig. 2. Two unbonded layers of 100 mesh stainless steel screen were used as capillary material. The stainless steel surfaces were passivated by soaking in 10% Na-OH solution for 12 hr prior to loading the working fluid. The heat pipe weighed approximately 570g. No attempt was made to minimize weight or volume of this prototype device. Further construction details of the heat pipe have been described in Ref. (4).

Battery.—The two nickel cadmium cells employed for these tests were new, unsealed, and flooded. Nominal capacity of each cell was 22 A-h, although the actual capacity was approximately 26 A-h. Design features of the cell (6) included thin (0.508 mm) plates, with a nickel, rather than iron, current-carrying substrate. The plate combs and terminals were nickel plated heavy copper. Cell internal resistance was 0.5-0.8 milliohms. The cell case material was nylon and the separator material was nonwoven nylon. Over-all dimensions of each cell were 26.7 mm x 79.4 mm x 194.1 mm and each weighed 1139g.

Assembly.—The heat pipe was located between the cells and held in place by two 9.5 mm thick Plexiglas retainer plates, which were bolted together. See Fig. 2. A thin layer of heat sink compound was spread on the cell face to promote good thermal contact. With the exception of the heat pipe condenser section (the part of the heat pipe protruding above the cells), the cell-heat pipe-Plexiglas assembly was insulated with a 15 cm thickness of ceramic fiber insulation. The top of each cell was uninsulated, but was covered with a 1.6 mm thick Teflon cover plate (not shown in Fig. 2) to minimize heat losses. For comparative purposes, the two cell battery was also tested with a 3.18 mm thick intercell aluminum thermal conduction fin which was assembled in the same manner as the heat pipe. The heat rejection portion of the fin (3.18 mm x 88.9 mm x 101.6 mm) was similar to that of the condenser end of the heat pipe (12.7 mm x 88.9 mm x 101.6 mm). Cooling was provided by placing the uninsulated part of the fin or heat pipe condenser section into an air duct into which a small centrifugal blower supplied room temperature (20°-22°C) cooling air.

Instrumentation.—Instrumentation of the heat pipe included internal and external copper-constantan thermocouples (±0.5°C accuracy) and a pressure transducer to monitor working fluid vapor pressure (±0.01 psia). Four No. 36 copper-constantan thermocouples were attached to the centerline of the evaporator (heat input) section of the heat pipe at axial positions corresponding to the abscissa values of data plotted in Fig. 3. The aluminum fin was instrumented in a similar fashion. For measurements on a third configuration (in which neither the heat pipe nor the aluminum fin were included), five thermocouples were located between the cells at approximately the same axial positions (see Fig. 4), and the heat accumulation without cooling was investigated with a 15 cm thick blanket of ceramic fiber insulation surrounding the battery assembly.

Procedure

The cells were cycled at nearly constant current conditions, 26A charge and 48A discharge. Charge and discharge currents were manually controlled by adjustment of individual power supplies. Cell case (heat pipe evaporator) temperatures and internal heat pipe temperatures were measured and recorded during cycling, as were charge and discharge currents and voltages. The 26A charge was terminated at one hour and discharge was initiated immediately. Discharge was terminated when the battery voltage reached 1.8V (0.9V/cell). Thus, the depth of discharge was nearly 100%. Five continuous cycles were run for each configuration in an attempt to establish equilibrium conditions in the cell.

The heat pipe and batteries were tested in both the vertical position (reflux mode), with condenser section uppermost and in the near horizontal position. In the near horizontal position, the evaporator section was purposely elevated one inch with respect to the condenser to insure liquid return was by capillary pumping. In preliminary experiments, the effect of gravity had little influence on heat pipe or battery performance for these test conditions. However, some difficulty was experienced due to leakage of electrolyte

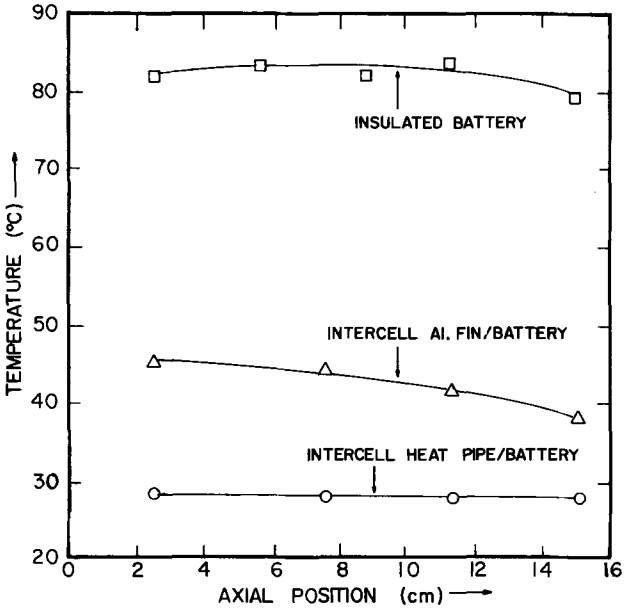

Fig. 4. Axial temperature profile of Ni-Cd cell case after 5 continuous cycles. (Cell case temperature ≡ temperature of the portion of the heat pipe or the aluminum fin in contact with the cell case.)

through the battery outgassing seals, and it was decided to limit further experiments to the vertical position only.

In general, the heat pipe may be designed to operate in a gravity environment, such as encountered in a spinning spacecraft. The effect of gravity is to reduce the maximum transportable heat flux, therefore, the device is more attractive for zero gravity or reflux mode (condensate return aided by gravity) applications.

Results

Figure 4 shows the cell case temperature profile at the end of discharge after five continuous cycles for the three configurations investigated. Table I summarizes the measured electrical parameters for the cycles indicated. Current and voltage data given are average values. These results show the heat pipe cooled battery efficiency to be several per cent better than that of the aluminum fin cooled configuration. Both the heat pipe and aluminum fin cooled configurations are markedly superior in efficiency to that of the uncooled, insulated battery.

The axial temperature profile of the entire length after 5 complete cycles with the aluminum fin and heat pipe are shown in Fig. 3. Characteristically the heat pipe cooled cells exhibit a near isothermal axial temperature profile, while the aluminum fin cooled cells are subjected to a 15°C axial temperature gradient. It may be noted that the evaporator section of the heat pipe is significantly cooler than the aluminum fin, while the condenser section of the heat pipe is hotter.

To assist in the analysis of the results, the specific heat of the cell was measured using a water calorimeter. The cell was heated in a furnace to a known temperature, typically between 50° and 60°C, then removed from the furnace and immersed in a water bath which was initially at a temperature of 5° to 10°C. The equilibrium temperature of the cell and bath were measured and the cell specific heat was calculated. Five separate determinations were performed and the mean specific heat of the cell was found within 3.4% to be 0.27 cal/g°C at approximately 25°C. The specific heat of a brass sample was measured in the same manner and found to be within 4% of the accepted value.

Table I. Electrical performance of battery at or near thermal equilibrium

Cycle description	Cycle number	Charge Amps (avg)	Charge Volts (avg)	Discharge Amps (avg)	Discharge Volts (avg)	Efficiency η_{A-h} %	Efficiency η_{W-h} %

	Cycle 5	26.4	2.82	48.4	2.47	98.4	86.0

Discussion

Two important thermal related properties of battery performance are cell cycle life and cell capacity (7). Reference (7) discusses the logarithmic decrease of cell cycle life with an increase of depth of discharge for different temperatures. For an 80% depth of discharge, it has been observed that the cell cycle life is approximately doubled when the operating temperature is decreased from 49° to 24°C. Based on the temperature dependence of the cell cycle life given in Ref. (7), the data in Fig. 4 indicate that operation of the battery at the lower temperatures provided by the heat pipe should yield significant improvements in cell cycle life.

Another temperature dependent property of cell operation is cell capacity, the ability of a cell to store charge. Marked decreases in cell capacity have been observed with these cells as a result of extended cycling at elevated (>40°-50°C) temperatures (8). In Fig. 5, the end of charge heating observed for the in-

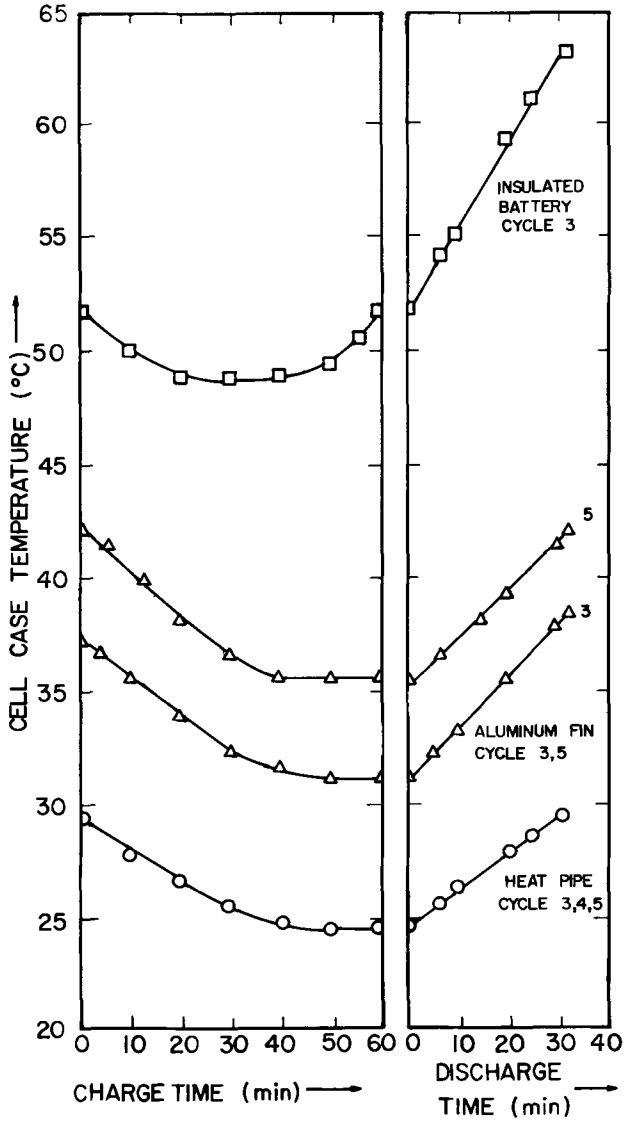

Fig. 5. Comparison of mean cell case temperature during charge and discharge.

sulated battery configuration can be partly attributed to faradaic inefficiency (reduction in cell capacity) because of operation at higher temperatures. Similar end of charge heating was also observed for cycles 4 and 5, but, these data are not shown because they lie beyond the scale of the graph.

Mean battery case temperatures (average of ordinate values of Fig. 4) were also plotted as a function of charge time in Fig. 5 for the heat pipe and aluminum fin cooled battery configurations and a nearly linear temperature change was observed during the first 40 min of charge. The cell temperatures were then observed to remain nearly constant until completion of the 26A, 1 hr charge. Cycle 4 for the aluminum fin configuration is omitted in Fig. 5 (and in Table I) because the cells were deliberately overcharged by 10% (~6 min) in an attempt to examine the thermal response. Rapid end of charge heating was observed similar to that noted above with the insulated battery configuration, and this was used as a check on the actual A-h capacity of the battery. Similar overcharge results were obtained in separate experiments (not reported here) with the heat pipe configuration.

On discharge, the mean cell case temperature change as a function of time was linear for all three configurations. It was observed that the thermal excursion undergone by the heat pipe cooled cell is approximately 5°C as compared to 7°C for the aluminum fin configuration. It is expected that reduction in the thermal excursion (with the heat pipe configuration) could be realized by various improvements of the heat pipe design, specifically, by employing a sintered screen or porous metal capillary wick instead of an unbonded layered wick (4). No such attempts were made. It was found that the thermal excursions of the heat pipe-cooled battery reached dynamic equilibrium after 3 cycles, while the aluminum fin cooled battery appeared to approach equilibrium after 5 cycles. Dynamic equilibrium was assumed when the temperature dependence of the charge discharge results for successive cycles was found to be approximately identical.

In order to estimate the net heat transferred by the heat pipe and aluminum fin, the heat generated by the cells was compared to the heat accumulated in the cells. The heat generated during charge is given by the first and second laws of thermodynamics (9)

$$Q_C = \int_C I\Delta E dt + T\Delta S \Big|_C \quad [1]$$

The heat generated during discharge is given by

$$Q_D = \int_D I\Delta E dt + T\Delta S \Big|_D \quad [2]$$

For high A-h efficiencies, the chemical reaction can be assumed reversible such that

$$T\Delta S \Big|_C \simeq -T\Delta S \Big|_D \quad [3]$$

Adding Eq. [1] and [2] and integrating yields the total heat generated per cycle, given by

$$Q_{\Delta E} = I_C \Delta E_C t_C + I_D \Delta E_D t_D \quad [4]$$

where recorded charge and discharge current and voltage data was averaged and used to calculate $Q_{\Delta E}$. The heat accumulated in the cells per cycle is given by

$$Q_{\Delta T} = m\, C_P\, \Delta T \quad [5]$$

and the net heat transferred per cycle by the heat pipe and aluminum fin is

$$Q_R = Q_{\Delta E} - Q_{\Delta T} \quad [6]$$

The above analysis neglects end of charge heating and thermal losses through the power leads and insulation. A small amount of end of charge heating was observed on some cycles, characterized by a slight (0.5°-1.0°C) increase in cell case temperature. For the first two cycles of the insulated battery configuration where it was assumed that $Q_R \approx 0$ and where the measured amp hour efficiencies were greater than 95%, it was found that $Q_{\Delta E}$ exceeded $Q_{\Delta T}$ (calculated from the measured specific heat) by only 8%. This result indicates that the effects of thermal lag and external heat losses cannot be more than 8%. Thus, the Q_R for the heat pipe and aluminum fin configuration can be computed to within 8%.

Table II. Comparison of heat transferred and fin effectiveness for the heat pipe and aluminum fin for heat accumulated over n cycles (where $1 \leq n \leq 5$)

	$\Sigma Q_{\Delta E}$	$\Sigma Q_{\Delta T}$	ΣQ_R	ξ
Aluminum fin/battery				
Cycle 1	11.42	8.54	2.88	0.252
Cycle 2	22.12	11.90	10.22	0.462
Cycle 3	32.32	12.70	19.62	0.607
Cycle 4	44.02	15.30	28.72	0.652
Cycle 5	53.76	15.85	37.91	0.705
Heat pipe/battery				
Cycle 1	11.93	4.56	7.37	0.618
Cycle 2	22.60	5.55	17.05	0.754
Cycle 3	32.48	5.84	26.64	0.820
Cycle 4	42.92	5.84	37.08	0.864
Cycle 5	52.81	5.84	46.97	0.889

Table II summarizes the thermal performance of the heat pipe and aluminum fin battery configurations during cycling. These data are based on the total heating values, obtained by addition of the per cycle heating parameters described by Eq. [4], [5], and [6] respectively. Comparison at equilibrium conditions, cycle 5, shows the heat pipe to be approximately 26% greater in fin effectiveness, or relative heat transfer capability, as compared to the aluminum fin. Heat accumulated in the cells with heat pipe cooling was approximately 11% (5.84 W-h) of the total heat generated in 5 cycles, as compared with 29% (15.85 W-h) for the aluminum fin cooled configuration.

Conclusions

It was demonstrated that the heat pipe limited maximum temperatures of the cell case during cycling to 29°C for the 1C/2C charge/discharge rates. Thermal equilibrium was achieved after three complete cycles, during which the thermal excursion of the cell case was limited to 5°C. By comparison, after five complete cycles the temperature of the aluminum fin cooled battery case reached 42°C, near thermal equilibrium was achieved, and the thermal excursion was 7°C. However, for the insulated battery, the case temperature ascended to 83°C after five cycles, and thermal equilibrium was never attained.

At or near thermal equilibrium, the electrical efficiency of the heat pipe cooled battery was found to be several per cent greater than approximately 95% which was recorded for the aluminum fin configuration. After two cycles the efficiency of the uncooled, insulated battery, decreased rapidly due to heat accumulation, and at 5 cycles it was measured approximately 52%.

The mean specific heat of the cell was measured to be 0.27 cal/g°C and this result was used to show that the fin heat transfer effectiveness with the heat pipe is approximately 26% greater than that with the aluminum fin at or near equilibrium. It is surmised that the heat transfer effectiveness of the heat pipe could be improved further by capillary design refinements, thus lowering the evaporator and condenser radial temperature gradients. It is expected that the weight and volume of the prototype heat pipe (570g, 344 cc) could be halved by such design optimization with no adverse effects on heat transport capability. These experiments demonstrate the ability of the heat pipe to minimize heat accumulation and thermal excursion in the battery during cycling, thereby allowing operating conditions at significantly lower temperatures. Such improved operating conditions should lead to an important lengthening of the battery cycle life and an associated reduction of capacity degradation.

Sintered Zirconia Electrolyte Films in High-Temperature Fuel Cells

N. J. Maskalick* and C. C. Sun

Energy Storage Department, Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Thin-film fuel cells employing stabilized cubic zirconia as an oxygen anion-conducting electrolyte depend on an effective separation of fuel gas and air by the dense zirconia electrolyte layer. Fully stabilized solid-zirconia electrolyte films have been prepared by reactive sintering of zirconia, ZrO_2, and calcium zirconate, $CaZrO_3$. Such films are employed as the electrolyte in high-temperature fuel cells. Electrolyte film conductivity is at least 50% of that expected from the geometry of test cells. The films are sufficiently pure and gastight to allow near-theoretical open-circuit voltages to be displayed.

The high electrical conductivity of the oxide mixture $(ZrO_2)_{0.85}(Y_2O_3)_{0.15}$ was first observed by Nernst (1) in 1900. Solid electrolytes were studied in oxygen concentration cells by Haber (2) in 1905. The electromotive force, E, of an oxygen concentration cell having a solid zirconia electrolyte, as derived from the work of Wagner (3), is

$$E = -\frac{1}{4\mathbf{F}}\int_{\mu'_{O_2}}^{\mu''_{O_2}} (t_{ion})\, d\mu_{O_2}$$

where $\mathbf{F}$ is Faraday's constant; μ'_{O_2} and μ''_{O_2} are the chemical potentials of oxygen in the reversible cathode and anode, respectively. Assuming ideality, the chemical potentials, μ_i, are related to partial pressures, p_i, by

$$\mu_i = \mu^\circ_i + RT \ln p_i$$

where R is the gas constant per mole and T is the absolute temperature. The maximum emf of such cells, as defined by the ratios of the oxygen partial pressures

$$E = (t_{ion})\frac{RT}{4\mathbf{F}} \ln \frac{p'}{p''}$$

is not obtained unless t_{ion}, the oxygen ion transference number, is equal to unity. As shown by Neuimin *et al.* (4) dispersed electronically conductive phases, such as NiO, and dissolved compounds, such as Fe_2O_3, can each contribute to considerable lowering of t_{ion} in calcia-stabilized zirconia electrolyte if present in sufficient quantities.

The transference number of the oxygen ion in the pure electrolyte is near unity for $(ZrO_2)_{0.85}(CaO)_{0.15}$, as demonstrated by Kingery *et al.* (5). The same electrolyte was used in a fuel cell by Weissbart and Ruka (6) to measure near-theoretical voltages for the hydrogen-oxygen reaction. Archer *et al.* (7) demonstrated that 20-cell batteries using stabilized zirconia electrolyte could develop open-circuit voltages within 3% of theoretical values using hydrogen as fuel. Twenty of these batteries were assembled into a unit which employed coal gas as fuel (8). Maximum power, when loaded so that its terminal voltage was 50% of open-circuit voltage, was 110W.

The electrolyte employed by Archer was in self-supported bell-and-spigot geometry. To decrease internal resistance as much as possible, the active cell region of the electrolyte was machined to a minimum practical thickness of approximately 0.04 cm. White

Key words: solid electrolytes, zirconia, fuel cells, thin films, sintering.

(9) has reported the successful plasma-arc spray fabrication of fuel cells with electrolyte having comparable electrolyte thickness. White employed an iron-oxide-doped, Y_2O_3-stabilized zirconia and a final sintering step to accomplish densification. Both the machined electrolyte and the plasma-sprayed electrolyte are comparatively thick structures, wasteful of power due to excessive voltage dropped across large internal resistances.

Recent work has employed electrolyte having considerably less thickness to further decrease internal resistance and also to minimize the cost of dense zirconia for the particular case where yttria rather than calcia is the stabilizing agent. Maskalick (10) constructed sputtered cells with stabilized zirconia electrolyte less than 5μ thick. Low sputtering rates limited the economic feasibility of this type of cell. Isenberg (11) evaluated a fuel cell with zirconia-yttria electrolyte formed by chemical vapor deposition approximately 30μ thick which developed near-theoretical open-circuit voltage and 0.45 W/cm^2 when loaded to a terminal voltage which was 50% of open-circuit voltage. Thickness control, high-temperature masking, chemical attack of cell materials, and a temperature limitation of 1100°C for processing of subsequently applied layers all contributed to make adoption of this technique in mass production difficult.

To overcome these disadvantages, Maskalick investigated sintering of thin films using layers of fine-particle, fully stabilized zirconia with and without iron oxide additions. Such films, if doped with iron oxide, were dense, though cracked and poorly bonded to the porous zirconia substrate. Extensive and rapid migration of iron led to contamination and volume changes in the porous support tube itself. Containment of iron solely in the sintering electrolyte film did not appear to be feasible, so that component structures applied in later sintering operations (*e.g.*, interconnections and air electrodes) could also be subject to iron contamination. Without iron oxide, adequate densification of fully stabilized zirconia did not occur.

The reactive sintering process $x\ ZrO_2 + y\ CaZrO_3 \xrightarrow{\Delta} (ZrO_2)_{x+y}\ (CaO)y$ was developed to form dense, well-bonded, and continuous thin films of stabilized zirconia electrolyte. This electrolyte contributes no contaminants to the surrounding fuel cell components and can be cycled repeatedly up to 1400°C for sinter-processing of successively applied component layers. Fuel cells employing this electrolyte were constructed and tested. This paper discusses the performance of such cells and aspects of the fabrication method.

Experimental

Preparation of electrolyte films.—Zirconia and calcium zirconate react quickly and completely at 1400°C to yield a dense, sintered film suitable for use as the electrolyte. The term reactive sintering is used because of the phase changes consequent to the mechanism: monoclinic zirconia and calcium zirconate in the proper proportions can react to form stabilized cubic zirconia. This is a specific example of the general reaction between monoclinic zirconia and zirconia containing stabilizing agents, *e.g.* CaO, Y_2O_3, to form cubic zirconia. Such reactions, if they occur during sintering, improve the densification of the electrolyte layer with enhanced grain growth and improved bonding to the substrate.

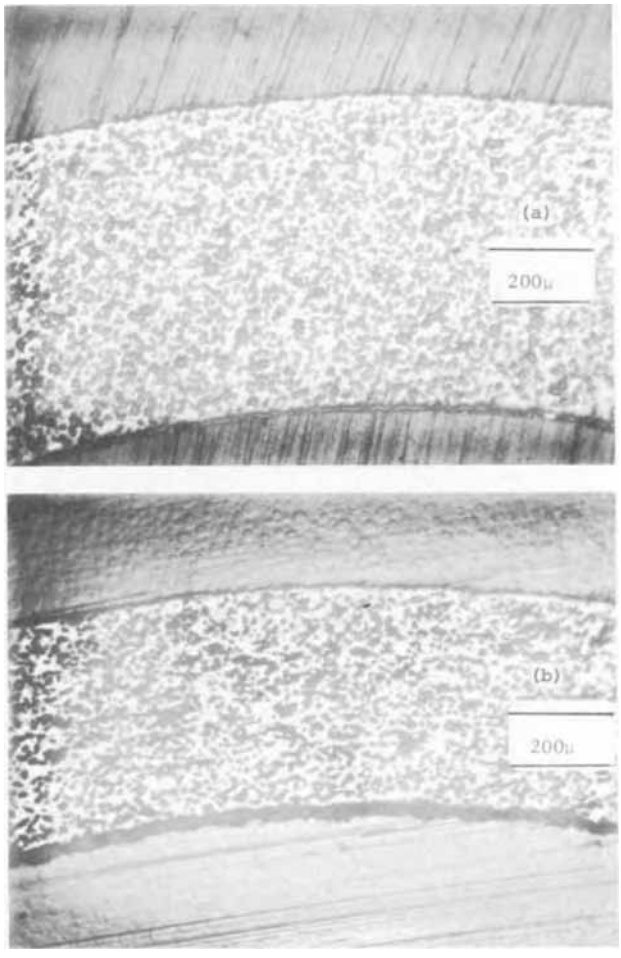

Fig. 1. Typical cross section through one wall of (a) extruded tube and (b) slip-cast tube of calcia-stabilized zirconia.

Slurries of the reactive mixture equivalent to an over-all composition of $(ZrO_2)_{0.85}(CaO)_{0.15}$ can be made by ball-milling 76 w/o (weight per cent) of submicron ZrO_2 with 24 w/o of −325 mesh $CaZrO_3$ and sufficient butyl acetate to produce a free-flowing suspension. Ball-milling times vary from 1 to 20 hr. With longer ball-milling times, the probability of the appearance of flaws due to the presence of coarse agglomerates is diminished.

Preparation of fuel cells.—The electrolyte and the working electrodes are all fabricated in sequence on the outer surface of a porous zirconia support tube. The throughgoing porosity of these tubes is displayed in Fig. 1.

In order to realize a cell geometry, the porous support tube is first coated with a sintered layer consisting of a coarse two-phase mixture of cobalt and stabilized zirconia (Fig. 2). Sintering of this layer is

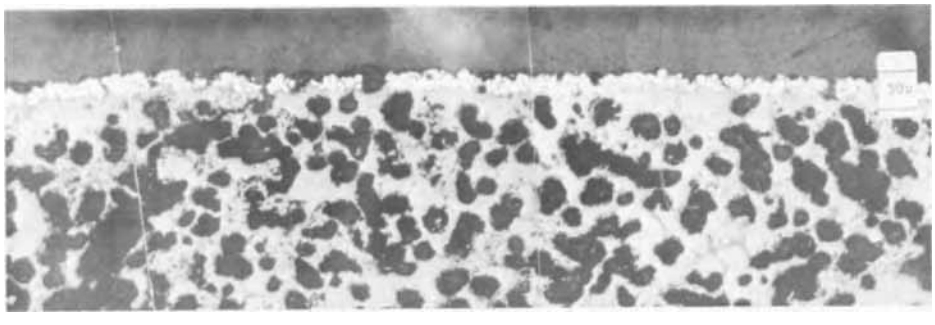

Fig. 2. Slip cast cobalt-zirconia fuel electrode over porous zirconia tube.

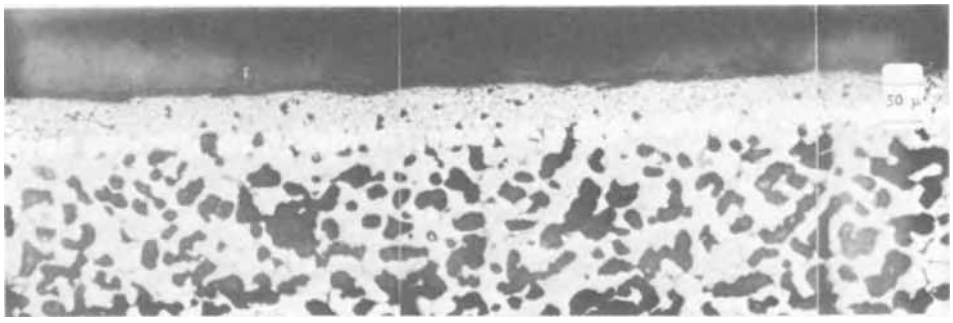

Fig. 3. Reactively sintered stabilized zirconia electrolyte over fuel electrode.

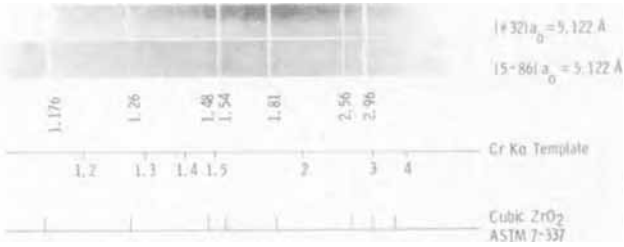

Fig. 4. Cubic structure demonstrated by thin-film reactively sintered ZrO_2-CaO electrolyte. Two-radian Debye-Scherrer powder pattern.

carried out in N_2, 5% H_2 saturated with H_2O at 26°C. This layer functions as a porous, electronically conductive fuel electrode and as the surface to which the electrolyte must sinter. The stabilized zirconia electrolyte layer must form a thin, dense, adherent film over this fuel electrode.

Electrolyte slurries may be applied to the tube and to the fuel electrode surface either by slip-casting or by spraying. Typical weight gains, after the butyl acetate has been completely removed, are 10-30 mg/cm².

Sintering is conducted in atmospheres which do not tend to oxidize the metal in the fuel electrode, so that disruptive phase changes are avoided. Either reducing mixtures of H_2/H_2O in an inert carrier gas or inert gases scrubbed to low oxygen content are employed. Sintering is carried out at temperatures which do not permit excessive migration of the cobalt metal in the fuel electrode. Experience has shown that this constraint establishes a practical limit at approximately 1430°C. Sintering times at 1400°C have been varied from 1 to 15 hr. Film grain sizes of 5-10μ are observed after 1 hr and up to 50μ after 10-15 hr.

The microstructure of a reactively sintered zirconia electrolyte film is displayed in Fig. 3. This film covers the fuel electrode layer which, in turn, is sintered to the base tube of porous zirconia. The electrolyte films at present are produced with approximately 5% apparent pore volume. Air (S.T.P.) leak rates of 6×10^{-7} moles/min at present can be demonstrated over 40 cm² with a 10^{-2} Torr initial vacuum on one side of the sintered electrolyte film. The reactively sintered electrolyte crystal structure is cubic as determined by powder method x-ray diffraction (Fig. 4). The observed range of lattice parameter is 5.122-5.123Å for films containing 17 m/o (mole per cent) calcia over-all. These data are compared with a lattice parameter of 5.11Å observed by Duwez *et al.* (12) who cooled their specimens rapidly from 2000°C. Since the lattice parameter is a function of sintering history as well as calcia content, no attempt is made to claim a particular stoichiometry for these films. They are completely cubic within a 5% limit of detection for the x-ray method. Therefore, $t_{ion} \rightarrow 1$ should be demonstrated if bulk electrolyte properties are obtained. Two test specimens were prepared, specimen A embodying two separate cells, and specimen B, also with two separate cells. In the tests reported here, the electrolyte was applied and fired on in four successive steps. Total weight gain of applied electrolyte was 33 mg/cm² and total time at 1400°C was 6 hr (specimen B) and 7.5 hr (specimen A). The sintered electrolyte films were about 60μ thick.

Electronically conducting interconnection oxide material was applied in two bands and sintered concurrently with the electrolyte. The interconnection bands served as potential taps to determine fuel electrode ρ/δ (resistivity/thickness) by the four-terminal method.

The air electrode structure of specimen A consisted of plasma-sprayed In_2O_3, 2 m/o SnO_2. The air electrode structure of specimen B was more complex, consisting of 24 mg/cm² of an intermediate porous layer of submicron $(ZrO_2)_{0.9}(Y_2O_3)_{0.1}$ fired on at 1400°C for 2 hr. This layer was then covered with plasma-sprayed In_2O_3, 2 m/o SnO_2, and finally impregnated with 0.5-1.0 mg/cm² of $CoPrO_3$.

A summary of the processed layers is given in Table I. A schematic of these layers, and their orientation on the completed device, is given in Fig. 5.

Testing of fuel cells.—Figure 6 shows the individual load circuits for each of the two cells on the test device. Contacts were established with platinum wires. Pt, Pt 10% Rh thermocouples were employed on all cells as potential taps. The geometry permits the testing of two independent cells on each specimen device. The oxide potential taps are employed to measure the voltage drop in the fuel electrode. Gold gaskets contacted the fuel electrode at both ends of the test specimen.

Cell operation was conducted with air flowing on the outside of the tubular cells and hydrogen saturated with water at 68°C flowing through the inside of the tube as depicted schematically in Fig. 6(a). Calculations of the theoretical emf are based on the H_2/H_2O ratio obtained by assuming the fuel gas mixture to be hydrogen at 0.7 psi gauge pressure containing water at the partial pressure expected at equilibrium over $H_2O(l)$ at 68°C. Two oxygen gauges served to detect

system leaks both upstream and downstream of the test cells.

Results

Both cells of specimen A developed open-circuit voltages which were 96% of theoretical over a period of 12 days. The test was terminated prematurely due to test equipment malfunction in which fracture of the upstream oxygen gauge led to contamination of the fuel stream and oxidation of the fuel electrode. Performance of these cells is displayed in Fig. 7 and 8. The cell resistances were high due to the high resistance ($\rho/\delta = 5$ ohms) of the flame-sprayed indium oxide air electrode. As a consequence, effective cell area was much less than the over-all area which was used to compute current density.

Specimen B employed an improved air electrode with a greater proportion of active cell area. The high surface area porous zirconia component of the air electrode served to increase the area of contact with the In_2O_3. The $CoPrO_3$, a conductor of both electrons and oxygen anions, was provided to improve the introduction of oxygen anions into the zirconia lattice and reduce air electrode polarization. The resulting cells developed 100% of the theoretical open-circuit voltage and showed significantly improved performances (Fig. 9 and 10). Fast and slow polarization processes observed during interruption of the current in the cell test circuits were recorded by photographing oscilloscope traces of voltage change *vs.* time. Analysis showed that the air electrode resistance and fuel electrode polarization are the two most significant voltage losses.

By measuring the fast portion of the current interruption pictures using an oscilloscope, individual contributions of total cell resistance were obtained. Referring to Fig. 6, the total cell resistance is equal to the sum of the resistance measured from the air side and the resistance on the fuel side. The resistance on the air side consists of air electrode resistance (R_a) and one half of the electrolyte resistance ($\frac{1}{2} R_b$), and the resistance measured from the fuel side includes the fuel electrode resistance (R_f) plus one half of the electrolyte resistance. Table II compares the measured resistances with values expected from the geometry of the cells on samples A and B. Cell resistances are computed assuming that the electrode resistances are low compared with that of the electrolyte. However, as pointed out earlier, due to the high air electrode resistance, $(\rho_e/\delta_e)_a = 5$ ohms, the effective cell area is lessened. This is in agreement with the higher cell resistance and polarization losses observed.

The test of specimen B was terminated on the fourth day when the open-cell voltage dropped below 0.3V. Axial cracks in the electrolyte were observed after testing. Cross sections showed that the electrolyte was lifted up from the cobalt fuel electrodes and had axial cracks where it was lifted but, in the intercell area where no fuel electrode was underneath, the electrolyte remained dense and well attached to the support tube.

A circumferential crack broke the tube open on cell No. 2. A microscopically visible circumferential crack on cell No. 1 appeared to be directly underneath the

Definition of Symbols:
D — Diameter of support tube (centimeters).
δ_b — Thickness of electrolyte (centimeters).
δ_e — Thickness of electrode (centimeters).
ρ_b — Resistivity of the electrolyte (ohm-centimeters).
l_c — Length of active cell (centimeters).
l_f — Length of fuel electrode lead (centimeters).
ρ_e — Resistivity of the electrode (ohm-centimeters).
R_a — Resistance of the air electrode (ohms).
R_f — Resistance of the fuel electrode (ohms).
R_b — Resistance of the electrolyte (ohms).

platinum wire leads. Because of the poor In_2O_3 current collector ($\rho/\delta \simeq 5$ ohms) employed on these cells, high current densities prevailed in the immediate contacted region of the platinum wire, causing hot spots and mechanical stresses.

From the test results of the four cells comprising specimens A and B, one can conclude the following:

1. Hydrogen-oxygen cells generating full theoretical open-circuit voltage at 960°C may be prepared using reactively sintered $(ZrO_2)_{0.85}(CaO)_{0.15}$ electrolyte 60μ thick. Such films must therefore have an oxygen ion transference number which approaches unity.
2. Electrolyte film resistivity approaches 50% of bulk, fully stabilized resistivity.
3. Air electrode resistance and fuel electrode polarization limit cell performance.
4. Mechanical stability of the entire structure also limits cell performance. The observed stresses were due to nonuniform current distribution arising from a poorly conductive air electrode.

Summary

A reactive sintering process has been developed to produce films of calcia-stabilized zirconia. This process involves spraying of a butyl acetate slurry of fine particle monoclinic zirconia and calcium zirconate. Subsequent sintering at 1400°C causes the formation of fully cubic electrolyte films of sufficient purity, density, and impermeability to gas flow to allow near-theoretical open-circuit voltages to be obtained in complete cell structures. The ability to display theoretical voltages implies that t_{ion} approaches unity, a critical property of fully stabilized bulk zirconia electrolyte. Initial measurements also indicate that sintered electrolyte film resistivity agrees with bulk resistivity values within the uncertainty introduced by estimates of active cell area.

By employing the reactive sintering process to fabricate the thin-film analog of bulk stabilized zirconia, the problems of thickness uniformity, high-temperature masking, and restrictive temperature limitations in processing are avoided. The economies associated with producing all-sintered practical fuel-cell batteries become available, though further development of all component structures is needed to improve device performance.

Reactive sintering is an effective and economical way to form thin-film electrolyte in a dense, well-bonded cubic structure.

Technical Note

High-Stability Cathodes for Fuel Batteries

D. C. Constable

CSIRO, Division of Mineral Chemistry, P.O. Box 124, Port Melbourne, Victoria 3207, Australia

The use of noble metals, notably platinum, for the cathodic reduction of oxygen in acid electrolyte fuel cells is well known, and many methods of catalyst preparation and electrode fabrication have been published. Catalysts of two main types have been used—unsupported metal blacks (1-3) and metal blacks deposited on an inert support (3-6).

The electrodes are fabricated by mixing the catalyst material with a polymeric binder, spreading onto a conducting substrate material, and pressing at a temperature sufficient to accomplish sintering of the binding material. In some cases a wetproofing layer of polymer is applied to the surface by spraying or applying a coherent polymer film.

Commercial electrodes[1] of the PTFE and platinum black sinter type have been available for some time, but supply was uncertain and their long-term performance was found to be poor. For these reasons it was necessary to initiate a program to develop and produce electrodes for our own use.

We have found that electrodes prepared by a method similar to the above (3) but using Adams' Catalyst (7) (platinum dioxide) have shown excellent stability for over 2000 hr when used as cathodes in low-temperature fuel cell batteries employing ion exchange membrane separators and water-soluble fuel. The use of Adams' Catalyst was suggested by the work of Cairns and McInerney (8), who found that electrodes of reduced platinum oxide and sintered PTFE showed a 3.5-fold increase in activity for propane oxidation over electrodes prepared with commercial platinum black. For oxygen reduction, we found a two-fold increase in activity, using platinum dioxide in place of commercial platinum black.[2]

Electrode Fabrication

Electrodes were prepared by a method similar to that described by Christopher (3). The required quantity of platinum dioxide was blended with an aliquot of Fluon GP30[3] (PTFE) dispersion to form a doughlike mass which was spread uniformly onto a 145 cm^2 degreased 4/0 or niobium mesh,[4] using a metal blade. After drying, the electrodes were pressed between aluminum foils for 2 min at 2000 lb and 300°C. The aluminum foils were dissolved in sodium hydroxide solution (400 g/liter) and the electrodes washed with distilled water. Finally, reduction of the platinum dioxide was carried out in 5% formaldehyde solution.

[3] John Crane, Mauri, Melbourne, Australia.
[4] Exmet. Corp., Tuckahoe, N. Y.

When using an ion exchange membrane, the application of polymer to the electrode surface is unnecessary.

The first electrodes prepared by this method performed erratically. Generally poor performance could be correlated with a high ohmic loss attributable to surface oxide on the metal substrate, an effect previously observed by Christopher (3).

Two methods have been tried in an attempt to overcome this difficulty: (*a*) chemically etching the substrate using 10% hydrofluoric acid before spreading the catalyst layer and (*b*) plating an inert metal onto a cleaned substrate.

The first method yielded substrates that had low ohmic losses but became brittle after etching, thus limiting substrate life. The second method, employing a gold coating, yielded substrates with low ohmic losses without affecting substrate life. This approach was also taken by Christopher (3), who used electroplated gold at 4 mg/cm^2. The gold was applied by vacuum evaporation onto the substrate cleaned by heating to 1200°C at a pressure of 2×10^{-4} Torr. A coherent gold deposit was obtained at a loading of 0.5 mg/cm^2. In the case of low platinum loadings, to enable an even spread of the small quantity of catalyst involved, a layer of graphite (10 mg/cm^2) and PTFE (2.8 mg/cm^2) was spread on the substrate and pressed for 1 min at 300°C and 10,000 lb before application of the catalyst.

Electrode Testing

To check reproducibility electrodes were tested as cathodes in a half-cell (Fig. 1) based on the design of Cathro *et al.* (9). The materials and components of the test module were polypropylene frames, chlorobutyl rubber seals, and tantalum bipolar plates and current collectors. These same components were used for the construction of the fuel cell batteries used for the long-term testing of the electrodes. To enable comparison of data, all half-cell tests were carried out using an electrolyte containing formaldehyde. The electrolyte, maintained at a temperature of 60°C by a glass-sheathed immersion heater, was circulated by a Hypalon-lined oscillating pump. Air was supplied at atmospheric pressure, and flow rate was measured by a laboratory flowmeter. Polarizing current was supplied from a direct current source, and the potential of the cathode was measured *vs.* a mercury/mercurous sulfate reference electrode in contact with the circulating electrolyte. The ohmic contribution to the potential was determined by a current interrupter technique and the appropriate correction made.

Electrodes, selected at random from each batch prepared, were tested in the half-cell before and after extended fuel battery operation; the polarization values reported are mean values for electrodes when tested in the half-cell.

Results and Discussion

The platinum and PTFE loadings, together with the type of substrate used for the electrodes tested, are

shown in Table I. In order to determine the effect of platinum loading on performance, two sets of electrodes were prepared, using a graphited substrate with Pt loadings of 10 and 20 mg/cm^2 (Preparations 1 and 2). These six electrodes were tested for 1293 hr at a current density of 30 mA/cm^2 in a methanol-fueled battery at 60°C, using air.

The initial and final performance curves for these electrodes are shown in Fig. 2. It can be seen that increased platinum loading decreases electrode polarization and improves stability. The loss in performance of these electrodes, however, indicates a definite limitation in useful life. This decline in performance was attributed to either a change in PTFE character with a consequent change in wettability or to a change in electrode structure due to oxidation of the graphite substrate or to both factors. To ascertain which of these effects controls electrode stability, forty electrodes were prepared for use in a formaldehyde-fueled battery, using platinum and PTFE loadings as shown in Table I. The formaldehyde battery was operated as a fully self-contained system for a period of 2250 hr, after which the cathodes were retested in the half cell.

The initial and final polarization curves of the electrodes tested are shown in Fig. 3-6. In all cases except one, the stability of these electrodes was superior to that of Preparations 1 and 2 electrodes. The exception was Preparation 4 (Fig. 4) which was prepared for comparison with Preparation 2, using PTFE loading of 7.5 mg/cm^2 on a graphitized substrate to determine whether higher concentrations of PTFE would decrease the rate of loss of wetproofing. It appears in fact that an excessive concentration of PTFE was used and loss of catalyst surface has occurred due to occlusion, since these electrodes still appeared to be hydrophobic after 2250 hr use. It is possible that a synergistic effect, due

fuel has been demonstrated. A high platinum loading has been shown to contribute markedly to the long-term stability of electrodes under battery-operating conditions. Results show that electrodes prepared with only platinum and PTFE show stable performance with a PTFE content of 2.8–6.7 mg/cm². Electrodes prepared on a graphited substrate show inferior stability especially when high PTFE loadings are used.

Electroluminescent II-VI Heterojunctions[1]

A. G. Fischer*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

D-C electroluminescence in II-VI films is still in its infancy and could become of great technical importance if the problem of efficient hole injection in the absence of p-n homojunctions can be solved, which is possible through systematic efforts. A survey is given of the existing methods of hole injection and of the available materials combinations. Their advantages and shortcomings are listed, and as a conclusion a new method is proposed.

The Present Situation of Industrial Electroluminescence

The industrial significance of electroluminescence in America has undergone some metamorphoses. In the fifties, when the internal mechanism of the a-c electroluminescence of ZnS type embedded powders (Destriau effect), then in its heyday, was not yet fully understood but when brightness and efficiency figures improved almost daily due to empirical development, we thought of electroluminescence as the light source of the future. Prematurely, production facilities were set up. When this rapid progress reached an unexpected plateau, and when the mechanism was begun to be understood, II-VI electroluminescence work (mainly carried out by phosphor chemists) fell into undeserved oblivion, including the work on some promising still-undeveloped aspects of it.

With the upsurge of III-V semiconductor research (mainly carried out by another group, the semiconductor scientists), electroluminescence took a different turn. Whereas before one had aimed for large-area panels for general illumination purposes, the new light sources were tiny single-crystalline p-n diodes emitting infrared and red light, to be used for punch card readouts, control lights, and small alphanumeric displays. An enormous amount of research was expended and impressive progress was made, especially recently with gallium phosphide lamps, but it is clear that this is a relatively limited application. By analyzing the market, one finds that there is only one potential big-scale application of electroluminescence which can justify the large previous and coming research expenditures: multielement image display panels.

With this in mind, the outlook is different. To compete with other displays which dominate the market, the cost of one electroluminescent element, plus addressing and storage circuitry, has to be far less than one penny. This prosaic requirement deflates the exaggerated expectations for individually fabricated monolithic p-n junction diodes, even the simplified mass-production versions which we have explored (1), and brings back the former II-VI electroluminescence in its various forms.

From past mistakes, we have now learned to look at the whole intended system, not just at electroluminescence *per se*. In a separate study, we have concluded that the best way to provide addressing and storage for a multielement display system (the most desirable system would be flat television) is by large-scale-integrated thin-film-transistor (TFT) circuitry (2). Since the Destriau type of a-c electroluminescence requires high-voltage, audio-frequency drive power which presents impedance matching problems to TFT circuitry (which, admittedly, could be overcome), the most favorable type of electroluminescence would be low-voltage, d-c electroluminescence. Since we ruled out the single-crystal approach, we have to investigate polycrystalline layers. III-V polycrystalline layers do not luminesce well and cannot easily be made by vacuum deposition. Therefore, we have to concentrate on polycrystalline II-VI layer structures, which is the topic of this paper. II-VI layer structures have the well-known advantage that they can be produced easily and cheaply and that they show highly efficient photo- and cathodoluminescence throughout the visible spectral range, even at low excitation densities, which shows that they do not have many nonradiative transitions which have to be swamped before luminescence can occur. The task is to achieve the luminescence we now have by photo- or cathodoexcitation by minority carrier injection through contacts. This is a very worthwhile task and should be pursued even though progress so far has been slow, and even though the spectacular success of monolithic III-V diodes tends to divert attention from it at the present time.

Minority Carrier Injection in II-VI Compounds

Difficulties of producing II-VI p-n homojunctions.— Due to the phenomenon of self-compensation of added doping impurity ions by the formation of lattice vacancies on nearby lattice sites (3), wide-band gap semiconductors with partially ionic ("soft") lattices can be prepared only n- or p-type depending on the material, but not in both types. This inherent tendency can be combated by using thermodynamic nonequilibrium methods. Procedures tried or suggested so far are: squeezing out the compensating vacancies under extreme pressure (*e.g.*, 10^4 atm) at elevated temperature and then cooling while still under hydrostatic pressure (4), doping at low temperature using ion implantation (5), and film preparation by means of reactive sputtering with simultaneous incorporation of acceptor ions (6). These methods have, however, not yet been reduced to practice sufficiently, and some may be too expensive to become of industrial importance. Therefore, we consider in this paper only

those methods where the properties of existing materials in thermodynamic equilibrium are utilized.

Problems with II-VI quasihomojunctions.— A quasihomojunction is defined as a p-n junction between two materials, one being n-type, the other p-type, which form a complete series of alloys so that there is no abrupt transition from one material to the other, but a gradual one. This is in contrast to a heterojunction in our nomenclature, where the two materials are not, or not completely, miscible, so that a vertical step occurs within the junction. Commonly, the word heterojunction is used to cover both types.

We have the following II-VI materials at our disposal, with their (direct) bandgaps listed: ZnS (3.7 eV), ZnSe (2.7 eV), ZnTe (2.2 eV), CdS (2.4 eV), and BeS (5.5 eV), BeSe (4.5 eV), BeTe (3.5 eV) (7), and MgTe (4.7 eV) (8). (The other alkaline-earth-chalcogenides are very humidity-sensitive, and not of zinc blende or wurtzite structure.)

Since ZnTe, and possibly BeTe and MgTe, are the only materials with native p-type properties, only a limited number of combinations are feasible. This is the first comprehensive review.

n-CdS/p-ZnTe junction.—This junction is self-suggestive since CdS readily comes n-type and ZnTe is natively p-type. It is unworkable, however, because CdS and ZnTe do not form a continuous alloy series (9) and hence form an abrupt heterojunction full of nonradiative interface states (Fig. 1). Besides, injection into ZnTe is predominant due to the bandgap relations, and ZnTe films are known to be poorly luminescent at room temperature for reasons not fully understood. This junction is mentioned mainly as a negative example.

n-ZnSe/p-ZnTe quasihomojunctions.—ZnSe and ZnTe are fully miscible (10). Polycrystalline ZnSe films cannot be made as highly n-type conducting as CdS films, notwithstanding the high n-type conductivity obtainable in ZnSe:Al, Zn single crystals (0.1 ohm-cm). This is due to high intergranular Schottky barriers (11) in ZnSe films. These are much shallower, or completely absent, in CdS films since CdS has a higher work function than ZnSe (11).

We have found that, even with highly n-type ZnSe single-crystal substrates, epitaxially grown n-ZnSe/p-ZnTe junctions, although light emitting (12), are inherently inefficient. This may be caused by the 8% lattice mismatch between ZnSe and ZnTe leading to a high concentration of lattice defects in the junction and by the anomalous dip in the bandgap of these alloys (10). The latter is now explained by intermediate bands formed by isoelectronic traps (13) which form a "sump" within the junction coinciding with the disturbed crystal area (Fig. 2), thus enhancing nonradiative recombination. In addition, it is known that even homogeneous $ZnSe_{0.60}Te_{0.40}$ single crystals are poorly luminescent at room temperature (14).

n-CdS/i-ZnSe/p-ZnTe n-i-p quasihomojunctions.—In this sandwich structure, designed to avoid the former pitfalls, one can envision electrons being injected into the central ZnSe layer from the CdS electroding layer, and holes from the ZnTe electroding layer, with radiative recombination occurring in the insulating ZnSe layer which can be doped optimally for efficient luminescence since it does not have to compromise with conductivity requirements.

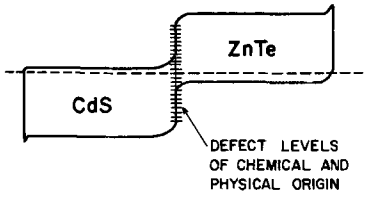

Fig. 1. n-CdS/p-ZnTe heterojunction

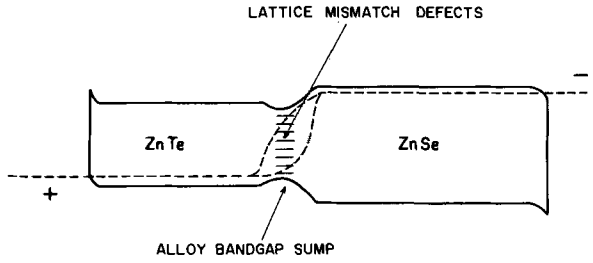

Fig. 2. n-ZnSe/p-ZnTe quasihomojunction (forward voltage applied).

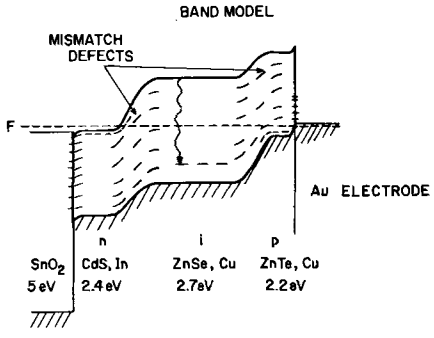

Fig. 3. n-CdS/i-ZnSe/p-ZnTe quasihomojunction

We found that a true p-i-n structure with an i-layer thicker than a diffusion length (about 2μ) tends to be blocking and then breaks down suddenly at increasing voltage, with current constriction at points, revealing a strongly negative I-V characteristics. This is a basic, not much publicized, flaw which even follows from theory in any space-charge-limited double-injection p-i-n structure with deep traps and strong recombination, especially in the case of "uphill" injection where the i-part has a higher bandgap than the n- and p-electrodes. It occurs even if the junctions are made gradual, not steep (15).

This undesirable condition can be avoided by making the i-layer so thin that currents through it are diffusion limited, not field driven, and/or by giving the central ZnSe layer a weak conductivity. This structure has been suggested recently by Lehmann (16) (Fig. 3).

A possible drawback of this structure is that the ZnTe electrode absorbs that emission of the ZnSe which has a shorter wavelength than red light.

n-ZnSe/i-$ZnSe_{0.4}Te_{0.6}$/p-ZnTe n-i-p quasihomojunctions.—In the desire to overcome the previously recognized obstacles by a suitable materials combination, the following structure was conceived (Fig. 4). Starting with a polycrystalline ZnSe:Al,Zn layer (bandgap 2.7 eV) in which the n-type conductivity has been enforced by heating in Zn vapor, we superimpose an almost intrinsic $ZnSe_{0.4}Te_{0.6}$ layer (bandgap 2 eV) by flash evaporation, to be followed by a p-type ZnTe layer (bandgap 2.2 eV). Thus, we have the converse case of a graded p-i-n junction, namely one where carriers are injected "downhill." Theory shows that such a structure allows very high double-injection carrier density in the i-region (17), a condition which is essential in order to "swamp" nonradiative recombination centers and to avoid negative resistance regions with the concomitant current constriction into filaments resulting in burnout. This structure also permits easy escape of the bandgap radiation of the i-layer through the electroding layers which act as "windows" (17).

However, an important shortcoming of this structure is that light emission is limited to 2 eV and that

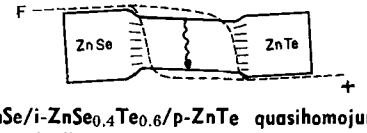

Fig. 4. n-ZnSe/i-$ZnSe_{0.4}Te_{0.6}$/p-ZnTe quasihomojunction. Band model (voltage applied).

$ZnSe_{0.4}Te_{0.6}$, in its present state of perfection, is a poor phosphor at room temperature.

Abrupt II-VI heterojunctions.—Carrier injection from sharp spikes.—The a-c electroluminescence of ZnS type powder particles (Destriau effect) is caused by the fortunate peculiarity of the ZnS-Cu_2S composite system that ZnS, due to its zinc blende-wurtzite polymorphism, develops linear defects. These act as nucleation sites for excess copper sulfide as the crystals are slowly cooled during preparation. The copper sulfide forms conductive thin long needle-shaped precipitates. (These can now be made directly visible by transmission electron microscopy. Before, they could only be seen by optical microscopy at very high copper concentration where the electroluminescence was almost concentration quenched.)

When an a-c field is applied, it relaxes in the conducting needles and concentrates at the tips, where bipolar nonohmic carrier injection into the surrounding near-insulating phosphor matrix takes place, with trapping of the holes in the deep luminescence centers for half a cycle, and recombination with the then injected electrons, in the form of comet-shaped sheaths around the conducting needles, in the next half cycle (18).

A remarkable fact has to be emphasized here, since it gives strong support to our contention that d-c electroluminescence in II-VI compounds has a promising future: the local brightness in these light-emitting comets (which constitute only about 1/1000th of the total volume of the electroluminescent capacitor) is on the order of 100,000 ft-L (19). The quantum efficiency is near unity (18) and can actually exceed 100% if particles are arranged in a string between the electrodes (20). The over-all power efficiency is low (but still on the order of 1%), due to the high ohmic losses of the currents oscillating back and forth in the near-insulating crystallites.

"All we have to do" is to achieve these conditions in contiguous large areas, in low-resistivity layers driven by d-c current.

Impact-excitation or impact-ionization electroluminescence in back-biased Schottky barriers.—Impact-ionization of the lattice by electrons emerging from a superficial copper sulfide precipitate, and accelerated in the high field of a back-biased Schottky barrier between the n-type ZnS interior and the Cu_2S surface, was postulated early to be the acting mechanism of the Destriau effect. Electroluminescence occurs as the impact-created excess electrons return to their ionized centers at field reversal (21, 22). D-C electroluminescence based on this effect (Fig. 5) was observed early in SiC and was found also in electrolyte-ZnO contacts (green EL) (23) and in silver paint or Aquadag-(n)ZnS:Al contacts (blue EL), from 5-7V on (24), always with the metal electrode negative. [Strangely, n-type CdS does not exhibit this effect, possibly due to a peculiarity in the conduction band structure which prevents electrons from heating up (25).]

Cusano found strong d-c electroluminescence (1000 ft-L) in his n-type, vapor-deposited ZnS, CdS, ZnSe, and ZnCdS films when the superficially applied Cu_2S surface layer was biased negatively (26). The half life of these films was too short for practical applications, probably due to copper migration.

Vecht prepared bright d-c electroluminescent cells using ZnS:Cu, Mn powder particles with Cu-rich surfaces, embedded into a minimum of organic binder (20). Since electrolytic currents are unavoidable in this scheme and copper is used, the life of these cells is limited, even though several hundred hours are claimed. The acting mechanism is probably a combination of several of the effects described here.

Though easy to obtain, impact ionization electroluminescence is inherently inefficient: only a very small fraction of the electrons passing the high-field region is accelerated up to ionization energy (about 3/2 bandgap energy); the rest produce nothing but heat. In cases where impact ionization was clearly the active mechanism, electroluminescent efficiencies never exceeded 10^{-4} photons/electron, as theory demands. Inversely, if higher efficiencies are observed, impact ionization cannot be the sole acting mechanism. Therefore, impact ionization or impact excitation schemes have no practical importance.

Minority carrier injection through physical inversion layers.—By placing a very high work function metal electrode such as Pt (5.4 eV), Au (5.1 eV), or C (4.6 eV), onto an n-type conducting luminescent crystal of low electron affinity (ZnS and ZnSe about 3 eV, CdS 4 eV), the resulting Schottky barrier becomes so steep that a physically induced p-type surface layer is formed (Fig. 6). For instance, carbon deposited onto an n-type ZnSe:Al crystal leads to light emission (yellow, hv ~ 2.1 eV) from only 1.5V on (contact positive) (27). The effect is enhanced if a thin insulating film is interposed, for instance by using Aquadag (graphite dust which has a trace of silicate binder). Green light emission has ben obtained in an electrolyte-ZnS contact using fuming sulfuric acid (oleum), which has a "work function" of 7 eV and does not attack ZnS (28).

We have obtained blue injection electroluminescence ($h\nu$ ~ 2.6 eV) from only 2V on when we contacted

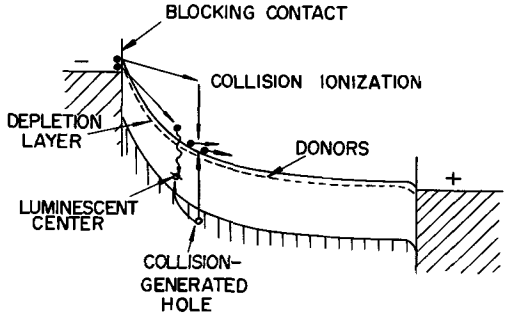

Fig. 5. Impact ionization electroluminescence in back-biased Schottky barrier.

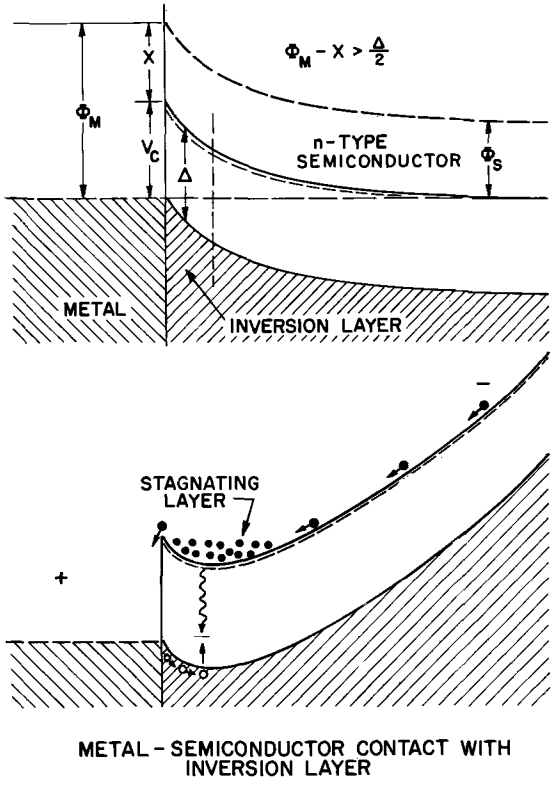

METAL - SEMICONDUCTOR CONTACT WITH INVERSION LAYER

Fig. 6. (a)—top and (b)—bottom, Electroluminescent physical inversion layer.

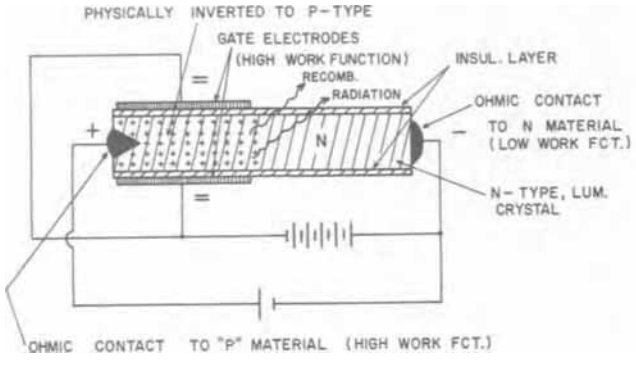

Fig. 7. Field-effect electroluminescent device

highly n-type ZnS:Al crystals (1 ohm-cm)[2] with Aquadag. The blue light emission was brighter, and the efficiency higher, than similar blue light obtained from GaAs LED's coated with up-conversion phosphors. The discrepancy between the energy of the emitted light and the applied voltage is explained in Ref. (27).

If one uses a p-type luminescent semiconductor such as ZnTe, the relations are inversed: by contacting the crystal with a low work function metal such as Ba (2.5 eV), light emission is obtained from very low voltages on (metal negative). Again, the effect is enhanced if a thin insulating layer is interposed, which can be an intrinsic surface layer of the host crystal itself (30). The efficiency is lower than with n-type crystals since ZnTe has poor luminescent properties at room temperature in its present state of development.

The decisive shortcoming of this scheme is that the number of injected minority carriers is by far exceeded by the number of majority carriers which flow out of the crystal into the metal electrode.

Field-effect electroluminescence.—The formation of a superficial physical inversion layer due to the work function difference between contacting metal and luminescent semiconductor can be enhanced artificially by using the field effect. If one interposes an insulating film between metal and semiconductor, one can apply an external potential in the same way as it is done in MOS and TFT transistors, except that one has to make the field effect so strong that conversion to the opposite type, not just to the insulating state, is achieved.

Whereas an a-c scheme based on this idea has been proposed by Kahng (31), a d-c structure which holds definite promise has been proposed, and reduced to practice using silicon as a model substance, by A. M. Goodman[3] (Fig. 7). A strong depletion layer induced by the negatively biased gate electrodes drives the n-type conducting luminescent semiconductor layer toward p-type. A high work function "source" electrode injects holes into this inverted channel. As soon as these holes drift toward the "drain" electrode and emerge from the inverted region into the n-type region, they recombine with electrons radiatively. A structure simpler than shown in Fig. 7 has been designed so that, in principle, a multielement panel could be fabricated by successive vapor deposition through masks.

A drawback of this interesting scheme is that the carrier density of the injected holes can at best come close to that of the charge on the gate, due to $Q = C \cdot V$.

Thornton's method.—An amazingly bright d-c electroluminescent structure (more than 1000 ft-L) was empirically developed by Thornton (32). At the present time it is still the best II-VI d-c EL scheme available, even though it was abandoned due to its limited half life. Only now, after a long dormancy period, is work on this scheme being resumed.

A ZnS:Mn,Cu,Cl film is vacuum deposited onto a heated or after-baked transparent conducting glass substrate. The back electrode must be applied in such a way that there is a very thin insulating interlayer. Aluminum or Mg is best, because they form this interlayer by solid-state electrolysis. After a "forming period," bright yellow light typical of the manganese center is emitted at the anodic metal contact. This is an indication that hole injection takes place, even though the I-V characteristics show that this is not the "ohmic" injection known from p-n junctions. Rather, it is a form of high-field injection in which the insulating film and the needle-shaped copper sulfide precipitates play an important role. Aging occurs if the insulating film becomes too thick (33) and is due to migration of copper ions which are mobile in high fields even at room temperature.

Light emission has been observed from 2V on (32), which rules out impact ionization as the sole mechanism.

Thin-film tunnel injection electroluminescence.—This scheme is a logical development from the preceding one. If a very thin insulating film is interposed between the luminescent semiconductor and the metal electrode, the potential drop across this film leads to a shift between the Fermi levels in such a way that holes from the metal can now tunnel through the insulating film into the valence band of the semiconductor, where they can recombine with electrons from the conduction band [Fig. 8(a)]. Light emission is observed, but this principle (34, 35) never became very popular due to low quantum efficiency and frequent breakdown of the insulating film. The reasons for this failure are scrutinized here for the first time.

The main shortcoming which must be explained is the low ratio of minority carrier injection over majority carrier extraction. The relations of the bandgaps and electron affinities of the materials in contact play an important role. Figure 8(a) shows a case

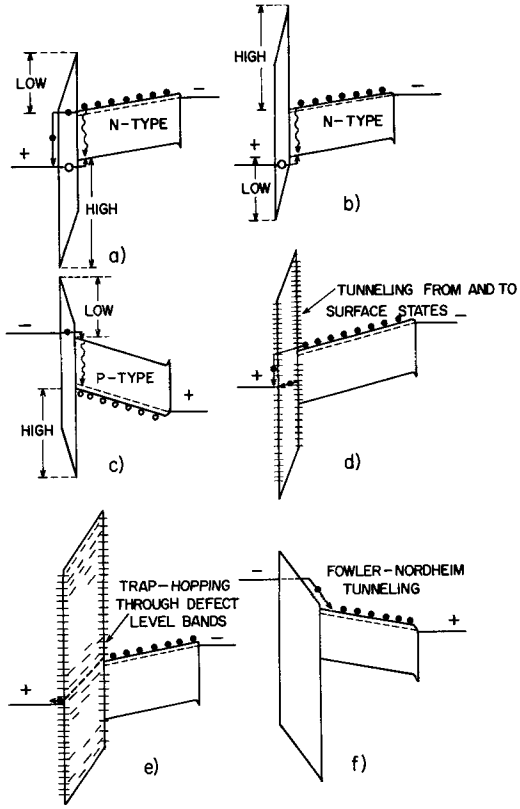

Fig. 8. Possible conditions in thin-film tunnel-injection electroluminescence.

[2] Insulating ZnS:5000 ppm Al (Eagle Picher Company) crystals were treated in Zn using the Aven method (29): the crystals were heated for 12 hr at 850°C submerged in Zn in a sealed quartz ampoule, the liquid Zn shaken off the crystal before solidification to prevent cracking of the crystals.

[3] Personal communication.

where majority carrier out-tunneling is stronger than minority carrier in-tunneling, simply because the barrier for holes is higher than that for electrons. The case in Fig. 8(b) is more desirable. These relations at the contact can now be determined experimentally by the use of internal photoemission (36).

However, Fig. 8(a),(b),(c) describe an idealized situation which may never occur in reality. It is more likely that the thin insulator film is thoroughly disturbed: Fig. 8(d) shows tunneling to and from surface states within the forbidden gap of the luminescent semiconductor; Fig. 8(e) shows tunneling through defect level bands. Apparently, these situations in which the injected carriers do not arrive in the respective conduction or valence band but somewhere within the bandgap occur most of the time. It was always a puzzle why tunnel injection electroluminescence could only be obtained with films of 300Å thickness or more, which should be completely impervious to tunneling (theory demands that 80Å be the maximum thickness).

Apart from the possibility of injection through defect level bands, another explanation for the penetration through relatively thick films may be "Fowler-Nordheim tunneling" [Fig. 8(f)]: if the applied voltage is high enough, the carriers do not have to penetrate the whole film but emerge from the tunnel into the conduction band of the insulator. There they are accelerated by the field and then penetrate into the luminescent semiconductor conduction or valence band.

Improved II-VI heterojunction structures.—As we have seen, all the successful schemes described so far have been developed quite empirically. With the better surview that we now have gained, we should be able to design a better structure which avoids the recognized pitfalls and uses all the advantages.

The envisioned optimized structure should have the following features.

(*a*) Use a highly n-type luminescent layer, to avoid ohmic losses. ZnS:Mn,Al,Cl, ZnSe:Al,Zn, and $Cd_xZn_{1-x}S$:In,Cl can be made quite conducting while retaining their luminescent properties (37).

(*b*) Avoid strong copper doping to prevent rapid deterioration.

(c) For hole injection, use a high-work-function back electrode with a superimposed thin film with low electron affinity to build a barrier for harmful electron extraction and a bandgap which eases hole injection. The material must be chemically very stable to prevent changes by solid-state electrolysis.

(*d*) The transparent conducting front electrode must make good ohmic contact to the conduction band of the luminescent layer.

As a result of this study, we have conceived a new structure, "semibarrier injection electroluminescence," for which several possible materials combinations exist (38). One possible configuration is shown in Fig. 9 (2).

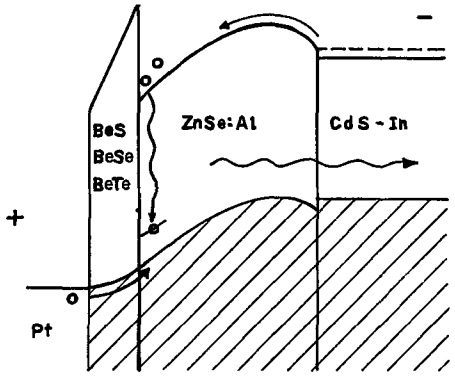

Fig. 9. One possible configuration of our new semibarrier electroluminescent structure. The Be-chalcogenide film can be prepared by reactive sputtering.

The insulating film is made so thick (*e.g.*, 5000Å) that tunneling through it, even by means of defect level bands, becomes impossible. The electron affinity is so low that this barrier also becomes insurmountable. In this way, majority carrier extraction is curbed.

To ease hole injection, the bandgap of the insulator and the work function of the contacting metal are so chosen that the holes can flow through this film as single-carrier, space-charge-limited current. Thereby, they attain a high velocity so that they penetrate into the luminescent layer, away from the surface states. The materials have to be selected so that these surface states are harmless.[4] Active work is in progress to realize this structure.

Conclusion

The problem of injecting holes into n-type, luminescent II-VI films in the absence of p-n junctions is still not solved in a satisfactory way. The solution is of great technical importance. For the first time, the many existing attempts are surveyed here systematically and their advantages and shortcomings discussed. New solutions are proposed. It is hoped that this will stimulate further progress. The most important requirement is a consistent well-staffed, long-term research effort. Up until now, work in this field has lingered along in many scattered, one-man, part-time programs, mainly depending on serendipity.

Acknowledgment

The author wishes to express his gratitude to Dr. W. Lehmann of Westinghouse Research Laboratories, Pittsburgh, Pennsylvania, for his competent review of this paper.

Manuscript submitted Oct. 13, 1970; revised manuscript received Feb. 9, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

[4] We have found, for instance, that the interface n-CdS/i-ZnS, which has a step of 0.8 eV between the respective conduction bands, does not introduce radiationless transitions, despite the mismatch in lattice constants (1). This test was made observing photoluminescence at a ZnS-covered CdS interface excited by 4200Å radiation.

Connections between Color Center Phenomena and Luminescence Phenomena in General

Herbert N. Hersh*

Zenith Radio Corporation Laboratories, Chicago, Illinois 60639

ABSTRACT

Alkali halide research has occupied a central position in solid-state physics. Its teachings are transferable to other fields. A modern synthesis of alkali halide research relevant to luminescence phenomena in general is presented. The relationship between the mechanisms of coloration and luminescence in alkali halides is described. The concepts of nonmoving excitons and of self-trapping are discussed and used to explain intrinsic luminescence in all alkali halides and the scintillation mechanism in thallium-activated alkali halides in an atomistic way. The possible importance of self-trapping, lattice relaxation, internal metastable states, molecules in crystals, *etc.*, in the luminescence of some conventional phosphors is pointed out.

When preparing this paper, I thought it might be of interest to choose a topic that bordered on luminescence but was one field away. For almost 30 years, physicists and physical chemists have spent millions of dollars per year and millions of man-hours studying color centers in alkali halides. The sponsors of this research have supported it, not because color centers are beautiful (which they are) or useful (which they are not), but on the grounds that what they would learn about them would be applicable to technologically more useful materials. By and large, the research has gone on but the implicit promise to apply the acquired knowledge was never really kept. I would like to examine some of the outcomes of alkali halide research and point out those concepts which come through strongly in this field and may have relevance to luminescence in general. This will touch on the detailed work of many people in a wide but selected variety of topics (1) but, more importantly, I shall be striving to extract broad but simple ideas which may be useful in other fields of work.

We start with a definition of an *F* center: an electron trapped at a halide ion vacancy (1). In the first approximation, this is an ionic model, since the electron occupies a lattice site of positive potential. In reality, however, the electron is shared among surrounding neighbors. This latter picture of the *F* center is absolutely established by EPR and ENDOR experiments. The *F* center gives rise to a characteristic absorption in the crystal which is responsible for the various colors and other properties seen in different alkali halides. *F* centers may be made in a number of ways, such as irradiating the crystal with neutrons, x-rays, or electrons, or chemically doping with a stoichiometric excess of alkali.

When ionizing radiation is used, holes are also generated and these give rise to additional absorption at shorter wavelengths than the *F* band which do not appear when only electron-donating alkali atoms are chemically added. After being colored, the crystals exhibit such properties as photoconductivity, paramagnetism, luminescence and optical absorption, photochromism, *etc.* Figure 1 shows a typical absorption spectrum of an x-rayed crystal.

Although a lot of effort has successfully gone into identifying and explaining the properties of color centers, the big problem plaguing color center workers is not how electrons and holes are shuffled around by the radiation; it is the fact that the radiation produces halogen ion *vacancies*. The generation of these vacancies would be conceptionally simple if neutrons had been used to knock halogen ions into the interstices, but x-ray photons and low-energy electrons are also effective and these have almost no momentum to transfer to the heavy halogen ion to cause it to move to an interstitial position. We shall come back to this point, but first I would like to make a few general comments.

It is well known that most alkali halides crystallize in the NaCl structure, are good insulators, have large binding energies and bandgaps, and are transparent

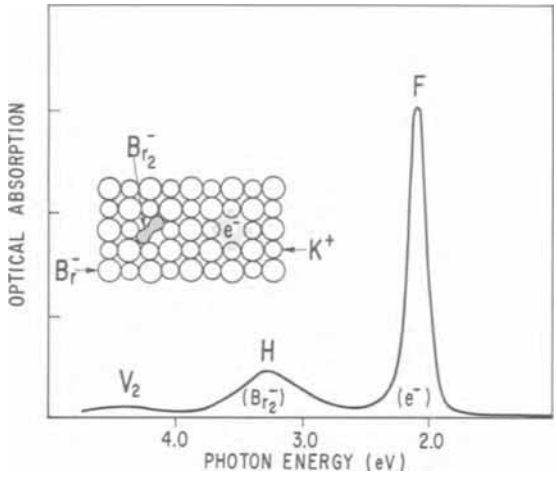

Fig. 1. Absorption bands produced by x-raying KBr at 2°K. The x-rays result in *(a)* the displacement of a bromide atom which then forms an interstitial Br_2^- molecule (called the *H* center), and *(b)* the simultaneous formation of a bromide vacancy which traps an electron to form the *F* center.

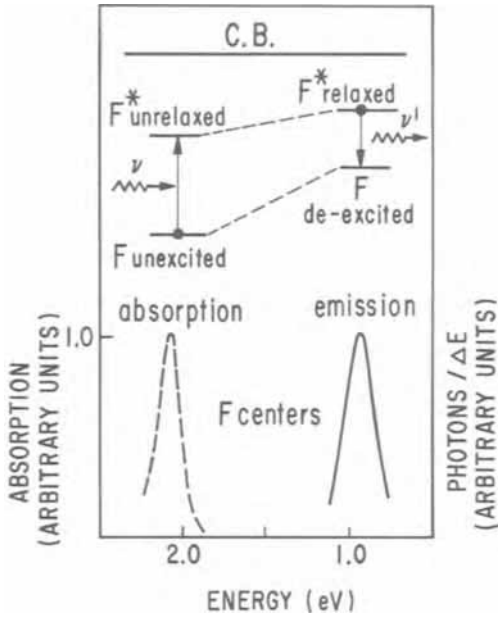

Fig. 2. Excitation and emission spectra (lower), and schematic representation of the luminescence of a relaxed *F* center. The relaxation is caused by the outward motion of neighboring ions and the delocalization of the excited electron.

from the near ultraviolet to the far infrared. Simplified representations of the energy bands of an alkali halide have been used to explain many of the optical and electrical properties of these insulators (*1*). The transitions to the exciton levels and the conduction band are believed to be responsible for the strong absorptions in the ultraviolet region. However, we note (*a*) that the energy band representation has not been a very useful one in explaining coloration processes or in predicting or understanding the nature of the intrinsic luminescence, and (*b*) it is more useful to regard the positive hole as a halogen atom (as will be seen).

The most decisive experimental technique in the radiation physics of alkali halide has been electron spin resonance, developed only in the later stages of the long history of color center studies. The most radical departure from conventional points of view has been the idea that not all color centers are ionic as formerly supposed; some of them, the so-called *V* centers, are stabilized by strong covalent forces which operate between atoms and ions in ionic crystals.

As shown below, *F*-center luminescence studies have revealed the importance of *relaxed* excited states, while impurity luminescence studies have exposed the nature of so-called metastable states; and studies of the intrinsic luminescence of undoped alkali halides have illustrated the importance of covalent bonding and of the competitive relationship between luminescence and one kind of nonradiative de-excitation (*viz.*, color center formation).

F Center Luminescence and Relaxed Excited States

The luminescence properties of an electron trapped at an unoccupied lattice site are quite pertinent to the general theory of solid-state luminescence. The usual EPR studies describe the *F* center electron only in its ground state (*2*). It is the optical excitation of the electron from this S-like state to higher excited states that gives rise to the characteristic colors of the various alkali halides. At low temperatures, irradiation in the *F* band efficiently excites luminescence at longer wavelengths (*3*). In KBr, the emission spectrum has a maximum at about 1.2μ, corresponding to a Stokes shift of almost 1 eV. The luminescence is very easily quenched by other impurities and by *F* centers themselves. In KCl, the quantum efficiency is approximately unity at temperatures below 78°K but drops off sharply with temperature in a small temperature region between 90° and 125°K. In this same temperature region, there is a sharp increase in photoconductivity due to the fact that the *F* center can either be thermally ionized from its excited state or emit light.

Faraday rotation experiments (*4*) show that the excited state of the *F* center is P-like but the individual P states are unresolved. However, the fluorescence lifetime of 1 μsec is too long for a simple allowed P-to-S downward transition. It is therefore generally believed that the *F* center in its excited state strongly interacts with the surrounding ions to form a new, *relaxed-excited state,* as indicated in Fig. 2. It is presumed that, after excitation to the bound P state, the surrounding positive ions immediately move outward to new equilibrium positions; and, during this process, the P state crosses an excited state quite different in physical character and symmetry, from which the transition, a quasi-S-to-S transition, proceeds with lower probability and hence longer lifetime. The concept which has been developed is this: an excited electronic system in a polarizable crystal will, in general, give rise to dynamic adjustments of the ions (as well as the electrons) resulting in relaxed-excited states; these states may be physically different from the initial excited states in character and symmetry. Thus, *two* configuration coordinate models are needed (as in Fig. 2), one to describe the absorption and the second to describe the emission. Substances like Ge or GaAs are not sufficiently polar to give rise to obvious effects caused by lattice relaxation but sulfides and oxides might be. Substances having radical ions such as molybdates, tungstates, and vanadates are probably important candidates for built-in nuclear relaxation processes and relaxed-excited states.

It is interesting that one can distinguish two kinds of electron centers in alkali halide crystals, exemplified by the *F* center (intrinsic to the pure crystal) and by the electron which is trapped at an impurity (and which is often the basis of photochromism in inorganic materials). Chemically speaking, they both correspond to the reduction of a cation. In the case of the *F* center, the electron resonates among identical alkali ions; in the case of an impurity, *e.g.* Tl^+ or Ag^+, the electron is in the immediate vicinity of one impurity ion and usually more tightly bound. The *F*-center electron (whose center-of-charge is at a halide ion site) is shared among the neighboring surrounding alkali ions; it is thus an "inside-out" atom as contrasted, say, to a silver atom in an alkali halide, where the electron

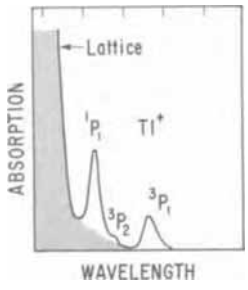

Fig. 3. Absorption bands of Tl^+ in an alkali halide. The cross-hatching indicates the lattice absorption (after Seitz).

surrounds (or is on the outside of) the Ag ion. Unlike the alkali atoms, the $P_{1/2}$ level is above the $P_{3/2}$ in the *F* center. This inversion of the P levels is a property of an electron in a cage of surrounding nuclei rather than of an electron surrounding a nucleus (as in the case of Tl^o or Ag^o) and gives rise to a negative spin-orbit coupling which has been inferred from Faraday rotation and circular dichroism experiments (5). (In the case of the cesium halides, the spin-orbit splitting is sufficiently large to give rise to resolved structure in the *F*-band optical absorption which is absent in the other alkali halides.)

Impurity Luminescence and Metastable States

The phosphor usually described as archetypical in most solid-state physics books is KCl:Tl. Thallium-activated bromides and iodides are completely analogous in their properties, and similar phenomena occur in a variety of doped crystals such as KBr:In, KCl:Ag, *etc.* Figure 3 shows the well-known schematic optical absorption spectra of a thallium-activated alkali halide. The energy levels of Tl^+ are analogous to those of atomic Hg and are split by spin-orbit interactions in the crystal. The ground state is $^1S_0$ and the first excited states are $^3P_{0,1,2}$ (the $J = 0, 2$ states being metastable) and $^1P_1$. The $^1S_0$-$^1P_1$ transition is ordinarily the strongest (*C* band). The selection rules are not strictly obeyed and the $^1S_0$-$^3P_1$ is also a strong transition as in the case of Hg (*A* band absorption); the $^1S_0$-$^3P_2$ also is weakly allowed (*B* band). When excited optically in the *A*, *B*, or *C* bands or with x-rays, fluorescent emissions occur at longer wavelengths. KCl:Tl is usually classified as a nonphotoconducting phosphor (6) but it is not; in some luminescence processes, free electrons and holes play a major part (as will be seen). The object of this section is to show that recent research does away with the idea of internal metastable states such as the $^3P_0$ and $^3P_2$ functioning as traps, a concept which had been invoked to explain phosphorescence effects noticed at low temperatures (7). Extensive and very detailed experiments prove that such intra-atomic states are not responsible for the phosphorescence and that there is a real separation of charge giving rise to this energy storage (8). This is illustrated by the following example in which an infrared image is converted to a visible one in a KI:Tl crystal without electro-optic scanning or high voltages.

If one takes a transparent crystalline plate of a Tl-activated alkali halide at dry ice or liquid nitrogen temperature, energy can be stored in it by irradiating for a few seconds with x-rays. Then the crystal is in the infrared-stimulable or "pumped" state. If an infrared image is focused on the surface of the crystal, it is transduced to a visible image with high sensitivity and resolution (Fig. 4). So long as the temperature is maintained below a certain value, the crystal remains in the "pumped" state and is ready for use. The color of the emission depends on the activating impurity and the host. What is the physical nature of such a light-storing crystal? It was previously thought this was due to some metastable states of Tl^+ but this is not so. In the case of KI:Tl, work has been performed (9) which yields the following answer:

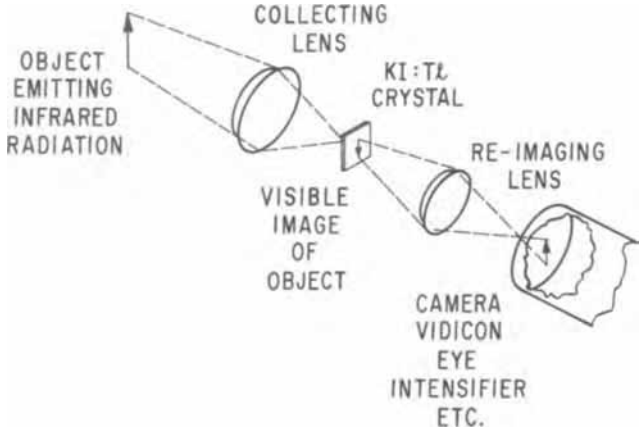

Fig. 4. Schematic of *IR* image converter using a thallium-activated alkali halide.

1. Before pumping, the crystal contains K^+, I^-, and a small percentage [say 1 a/o (atom per cent)] of Tl^+ occupying K^+ sites. After pumping, there are some neutral thallium atoms as a result of electron trapping and some Tl^{+2} as a result of hole trapping.

2. Irradiation with infrared light releases electrons from the Tl atoms which recombine with the trapped holes, restoring the crystal to its former condition with the emission of light (Fig. 5). These processes of storage and infrared stimulation may be summarized by the following equations:

$$\text{KI:Tl} \xrightarrow{\sim} e + h \qquad [1]$$

$$\vec{e} + Tl^+ \rightarrow Tl \qquad [2a]$$

storage

$$h + Tl^+ \rightarrow Tl^{+2} \qquad [2b]$$

$$Tl + h\nu_{IR} \xrightarrow{\sim} Tl^+ + e \qquad [3a]$$

stimulation

$$\vec{e} + Tl^{+2} \rightarrow Tl^{+*} \rightarrow Tl^+ + h\nu \qquad [3b]$$

(The broken arrow indicates a photoreaction.)

This picture of what happens is supported by detailed studies of the energy-storing state, using techniques of optical absorption, electron spin resonance, thermoluminescence, photoconductivity, and emission and excitation spectroscopy (10). The above over-all reaction is the direct antithesis of the concept that internal metastable states of the Tl^{+1} ion ($^3P_0$ and $^3P_2$) are responsible for energy storage.

On the basis of these detailed low-temperature studies, which isolate the individual recombination and retrapping steps, the atomistic mechanism by which thallium-activated gamma ray detectors operate at room temperature has been pieced together (11). This is based on the reasonable assumption that the scintillation mechanism at room temperature is simply

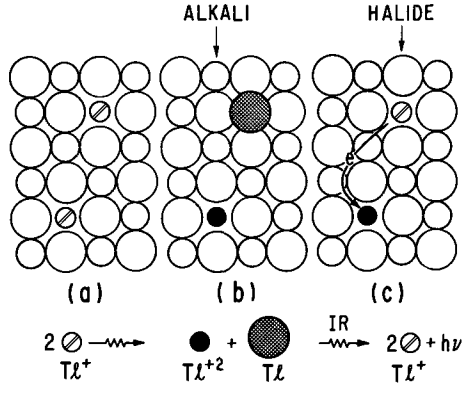

Fig. 5. Heavily doped KI:Tl crystal *(a)* before x-irradiation, *(b)* after x-irradiation, and *(c)* during *IR* excitation, at 78°K.

the appropriate time-sequential composite of the steps frozen out and studied at low temperatures which lead to emission.

The above reactions apply only to a heavily doped phosphor, *e.g.* 10^{-1}-1 a/o Tl^+. If more lightly doped, the hole is not only trapped at a Tl^{+1} but is self-trapped as well, *i.e.* trapped at an I^- ion. The hole (which is chemically equivalent to a halogen atom) immediately forms a molecular bond with a halide ion; the resulting X_2^- molecule (where X is any halogen) has been unambiguously identified by EPR. Electrons may recombine with X_2^- centers as well as Tl^{+2} ions. The generation of the self-trapped hole (X_2^- center) is of great significance. The over-all reaction is indicated by the following for a lightly doped KCl:Ag crystal exposed to x-rays or cathode rays (12).

$$KCl{:}Ag^+ \xrightarrow{\sim} Ag + Cl_2^- \qquad [4]$$

It is basically an electron transfer followed by a dark reaction between the chlorine atom and a neighboring chlorine ion, *viz.*

$$Cl^- \xrightarrow{\sim} Cl^0 + e \text{ (electron transfer)} \qquad [5a]$$

$$\vec{e} + Ag^+ \rightarrow Ag \qquad [5b]$$

$$Cl^0 + Cl^- \rightarrow Cl_2^- \qquad [6]$$

The identification of this center (also called the V_K center) was the first positive proof (*a*) that molecules could exist in ionic crystals and (*b*) that simple holes cannot exist in alkali halides. The molecule formed by the atom and a neighboring ion has a unit positive charge with respect to the crystal and occupies ordinary substitutional lattice sites of the halide sublattice (although it is pulled together by the covalent bond) (13). With alkali halides, the concept of self-trapping is seen in very simple terms as the forming of a chemical bond with a neighboring ion. It is easy to see that a moving electron trapped by the molecular center will restore the crystal to its original condition: *i.e.*, the X_2^- acts like a hole. The reason simple holes cannot stably exist is that they are trapped by surrounding halogen and impurity ions.

The important concepts to arise from these studies of impurity luminescence in alkali halides are these: (*a*) internal metastable states of atoms do not act as long-lived traps: (*b*) for all practical purposes, holes in alkali halides are equivalent to halogen atoms; and (c) covalently bonded atoms can exist in ionic crystals.

Intrinsic Luminescence

Only a few years ago, it was shown conclusively that undoped alkali halides are phosphors, excitable by ultraviolet radiation and x-rays (14). The existence of this intrinsic luminescence (which occurs only at very low temperatures) is of fundamental significance and leads to some interesting concepts, the most provocative of which is that in alkali halides simple excitons cannot move far and probably cannot move at all.

It has been shown that, when electrons interact with self-trapped holes (X_2^- molecules), there is a characteristic luminescence which is identical to that produced by ultraviolet irradiation (15, 16) in accordance with

$$\vec{e} + X_2^- \rightarrow 2X^- \pm h\nu \qquad [7]$$

Process [7] occurs only at sufficiently low temperatures. The recombination has been conceived to be due to a transitory excited molecule, $X_2^{=*}$, composed of an X_2^- molecule and a more loosely bound electron, as indicated in [7]. This has been conclusively proved using EPR and polarized luminescence techniques (15) (since the X_2^- is anisotropic as well as paramagnetic).

It is useful to consider the various ways in which the $X_2^{=*}$ center can be formed. Theoretically, an $X_2^=$ molecule must be derived from two nonequivalent X^- ions for there to be net binding (*i.e.*, one of the X^- ions must be excited); it follows therefore that it can be formed without first forming a free electron (*i.e., without recombination*). We may thus write down the process of intrinsic luminescence in undoped alkali halides excited by ultraviolet, nonionizing light as

$$X^- + h\nu \xrightarrow{\sim} X^{-*} \text{ (Frenkel exciton)} \qquad [8]$$

$$X^{-*} + X^- \rightarrow X_2^{=*} \rightarrow 2X^- + h\nu \text{ (intrinsic luminescence)} \qquad [9]$$

The exciton is thus explicitly identified atomistically as an excited (localized) X^- ion. Because there is always an unexcited halide ion next to it, the exciton in such polar crystals will probably *never* move but be trapped instead. The $X_2^{=*}$ molecule is thus a self-trapped excitonic molecule. When self-trapped at low temperatures, it relaxes radiatively and the constituent halide ions simultaneously resume their normal separation on the halide sublattice. An interesting fact about the intrinsic luminescence center in the alkali halides is that it is produced *by* the irradiation, and does not exist prior to it. Its existence points up the importance of ionic relaxation processes as well as exchange forces in luminescence processes. It has even been suggested that the onset of photoconductivity in a solid does not necessarily imply the onset of interband transitions because relaxation can take a bound excited state, *i.e.* an excitonic state, above the conduction band (17).

Intrinsic Luminescence and Coloration

The recognition of the existence and origin of intrinsic excitonic luminescence in alkali halides has played a very important role in studies of color center formation. As stated above, when F centers are produced by x-rays, halogen ion vacancies are also produced. Now vacancies can only be produced by vacating lattice ions. X-ray photons have insufficient momentum to cause this motion, even though they have plenty of energy. Thus, creating a negative-ion vacancy is like moving a billiard ball by hitting it with a pea. EPR studies show that an interstitial halogen atom is ejected and forms a molecule with a neighboring ion somewhat like the X_2^- center. This interstitial molecule is called the H center (18). Chemically, the H center, like the self-trapped hole, is composed of a halogen atom and ion but occupies one halide site rather than two (see Fig. 1). The important fact is that the interstitial atom leaves behind a vacancy plus an electron, *i.e.* an F center. How does this come about? In particular, where does the momentum come from (19)? A reasonable mechanism is now available based on the observation made only a few years ago that there is an inverse relationship between intrinsic luminescence and coloration (20, 21).

In KI, in a certain temperature region it is now known (22) that, while the radiation is on, the most pronounced phenomenon is the generation of intrinsic luminescence; after the radiation is turned off, stable color centers, such as F and the X_2^- interstitial center, are seen, the characteristic luminescence centers having disappeared.

It was natural to ask if the luminescence centers are responsible in any way for the color centers which are produced. The answer is, they are. In many photochemical systems, the onset of reaction is accompanied by a drop-off in luminescence. KI exhibits this characteristic. There is virtually no color center formation below 90°K and the luminescence is very high; above 90°, there is no luminescence and the coloration rate is high. In photochemical systems, a luminescence center is often known to be the first product of photon absorption and then the source of subsequent photochemical products. In the same way, the luminescence center in KI can be looked on as the generator of the color center, leading to the following description of color center formation:

During x-ray (and even ultraviolet excitation as described above), there exists in the crystal a high

steady-state population of $X_2^{=*}$ luminescent molecules, some of which radiatively decay to the ground state. What happens to those that do not? It has been proposed that the $X_2^{=*}$ molecules are all initially formed in, or excited to, a predissociative state, that the successful dissociation of *some* of them generates vacancies and halogen interstitials with sufficient kinetic energy that they are separated, and that radiative transitions of *undissociated molecules* generate the intrinsic emissions. At very low temperatures, we get intrinsic luminescence; at high temperatures, color centers instead, as is found experimentally.

It is explicit in the mechanism (21) that alkali halides can be colored by *nonionizing* light as well as by ionizing rays; *i.e.*, the threshold energy is of the order of 6-10 eV, and not thousands of electron volts as previously thought. Near ultraviolet light is nonionizing. Ultraviolet colorability experiments are in accord with this (22). EPR evidence has recently come forth (23) which shows directly that, when an electron combines with a self-trapped hole (X_2^-) at sufficiently high temperatures, an interstitial halogen atom and a vacancy are formed. This provides fairly conclusive evidence for an excitonic mechanism in accordance with the following (21)

$$X^- + X^- \xrightarrow{\text{uv}} X_2^{=*}$$

formation of self-trapped exciton [10]

$$X_2^{=*} \rightarrow X_i + \boxed{e} + X^- \quad \text{formation of } H \text{ and } F \text{ centers} \quad [11]$$

Thus, through the formation of a covalent bond between the excited and a normal halide ion, the potential energy imparted to the ion by an almost momentless photon can be converted into kinetic energy: sufficient momentum has been gained to move a massive ion. We can thereby explain both color center formation (a special type of nonradiative process) and intrinsic luminescence by one general mechanism and see clearly the relationships between them.

Applications of Alkali Halide Research

We now know a good deal about color centers in alkali halides. The proof of this is that, as described above, we know what atoms are involved and their configurations; also how the atomic configurations come about and how they give rise to the observed electrical and optical properties. Thus, a good understanding of color center production and intrinsic luminescence in alkali halides has been achieved. How can this knowledge be used? The following points suggest some possible relevance to other fields.

1. Excitons and self-trapping.—In alkali halides, it has been shown that excitons intrinsically do not move because of self-trapping. Self-trapping has been hypothesized in oxygen-dominated phosphors (24) and recently has been observed in tungstates (25).

2. Lattice relaxation.—The luminescence of F centers and the existence of the X_2^- molecule show the importance of lattice relaxation. In these cases, even the symmetry of the excited state is changed by lattice ion relaxation. Relaxation phenomena certainly play a role in the excited states of groups such as vanadate ions, and the concept of a relaxed-excited state probably has general applicability in luminescence.

3. Covalent bonding in ionic crystals.—The existence of color centers and luminescence centers that are molecular indicates the importance of covalent bonding in ionic solids and in luminescence processes. Even a trapped electron is bound partially covalently in a defect.

4. Cathodoluminescence at low electron energies.—It has been shown in alkali halides and also in YVO_4 that uv photons can produce the same excited state for luminescence as electrons. Thus, it is clear that energy packets too much in excess of the necessary minimum will lead to inefficiency; *i.e.*, it is obvious that the threshold energy is physically more significant than the average energy to produce an event (which for high-energy excitation is about 3 E_g per electron-hole pair). It has recently been shown (26) that electrons having only bandgap energy (1 E_g) above the conduction band of CdS can give rise to direct individual pair production and recombination luminescence in which the momentum is conserved without phonon participation. Low-voltage cathodoluminescence (below the plasmon energy) is not only an intrinsic expectation of solids but an experimentally rewarding research area.

5. Isoelectronic traps.—Even when they come from the same group in the periodic table, impurities such as Ag^+ and Br^- added to alkali halides can act as electron and hole traps (27) (as well as activators). This is because of their electron affinity relative to the host ions. Similar effects may occur in sulfide phosphors at very low doping levels, as the properties of oxygen-containing ZnSe scintillators suggest (28).

6. Internal metastable states.—Such states exist in Tl^+ but they do not play any role as trapping states in low-temperature phosphorescence. It is likely that all long-lived metastable states in inorganic phosphors involve separation of charge; this is entirely different physically from an internal metastable state of an impurity.

7. Penetration of fast electrons with matter.—This has been studied experimentally by examining the profiles of luminescence generated as a function of electron energy. Even using good photographic techniques, it is difficult to get precise data because of internal reflections, *etc.* (29). Color center generation should provide a good way of examining electron penetration in matter and of having a permanent record of the experiments.

8. MOS and MIS devices.—It is known that metal oxide semiconductor devices are affected by radiation. Trapped charges in the oxide can affect the electrical properties. It should be possible to compare the radiation effects in bulk silica (amorphous and crystalline) and alumina with effects in the oxide layer of the device and then, just as with alkali halides, one can do experiments such as measuring thermally stimulated current and luminescence on MOS devices themselves, and determine imperfection content, propose models to explain radiation effects, and devise ways of decreasing radiation sensitivity.

9. Electroluminescence.—A frequently proposed model for a-c-excited electroluminescence in ZnS is based on field-released primary electrons from imbedded specks of Cu_2S. Recently it has been possible to obtain electroluminescence from single crystals of KI at low temperatures as well as from KI:Tl at room temperature (30). It is possible to prepare heat-treated, additively colored alkali halide single crystals in such a manner that they contain evenly dispersed colloidal specks of alkali metal. These could serve as sites of field emission and it should be possible in such a well-characterized specimen to excite electroluminescence and test the validity of proposed mechanisms (31).

Conclusion

An attempt has been made to present an eclectic picture of alkali halide research in highly abbreviated form, that might be relevant to luminescence and other fields. In alkali halides, the mechanics of intrinsic luminescence and color center formation are competitive. Self-trapping of holes and excitons is a prominent feature and it leads to the probability that, in alkali halides at least, excitons do not and cannot move. Considering the great variety of materials and phenomena many of us are working on, it is possible that these ideas which come through so strongly in alkali halide research may be applicable to other fields.

JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS

JULY 1971

The Scientific Society and National Materials Problems[1]

N. E. Promisel

National Materials Advisory Board, National Research Council, Washington, D. C. 20418

For some years now, I have been absorbed with the need for viewing, in broad perspective, materials science and engineering as an interdisciplinary force involved in a very significant way in our major national issues and our individual interests. Now this statement can be made about other subjects, for example, chemistry. Chemistry, however, is a relatively cleanly bounded area, recognized in its fullest interactions by everyone. This is not true about materials, for which there is not even a generally accepted definition. For the most part, the subject of materials is described by a nondefinition; *i.e.*, it is defined as "everything except," and the exceptions depend on the immediate purpose at hand. Electrochemistry is certainly an important aspect of materials, and I was encouraged to think that it would be appropriate and provide an opportunity to discuss materials science and engineering, particularly in terms of national issues and problems, and the related importance of a learned society such as this.

It may be useful to review briefly, at least as I see it, the genesis of materials science and engineering as it is recognized today. I would then like to discuss relevant national issues; some efforts toward providing a national forum, if not a national policy, with respect to materials; and, finally, the position and role of the learned and professional societies in this scenario. Please keep in mind that, whenever I use the word "materials," I consider that the word "electrochemistry" may either be substituted for it or forms a vital part of it.

First, to build up our ego a bit, I will quote from Sir George Thomson, who won the Nobel Prize in Physics in 1937. He said: "We have for some time labeled civilizations by the main material which they have used: The Stone Age, The Bronze Age, and The Iron Age. . . . . A civilization is both developed and limited by the materials at its disposal . . . . Today, man lives on the boundary between The Iron Age and a New Materials Age."

As a result of the impressive developments in electrochemistry, chemistry, physics, solid state science, metallurgy, ceramics, and other disciplines (all of which, when integrated, become the field of materials), there has grown up a materials science and a materials engineering which are having a profound impact on industry, government, and academia, and are, therefore, receiving more and more attention at all levels. We must recognize, however, that materials as a total concept, or as an identifiable segment of science and engineering, is really relatively new.

In the United States, materials science and engineering were given their stimulus in World War II, primarily with Federal funding. We had, of course, the mono-disciplines of metallurgy, chemistry, physics, *etc.*, and a storehouse of fairly classical materials from which the designer and product developer drew. Background and experience were major influences on his material selection. Those with metal backgrounds stayed with metals, those with chemical backgrounds stayed with plastics when they could, *etc.* For example, asked how to protect steel from corrosion, an electrochemist would recommend electrochemical protection and a chemist would recommend an organic coating. The boundaries of the disciplines were barriers rather than interfaces. Communication between designers and metallurgists or chemical engineers was grossly inadequate.

The drastic demands of defense and, later, nuclear energy and space forced a change in this attitude. Now the requirements tended to be expressed in terms of performance; for example, a *material design* to withstand "*x*" temperature degrees, for "*y*" hours, with "*z*" creep under "*s*" stress, without specifying whether it be metal, ceramics, intermetallic compounds, a combination of these, or these combined with built-in cooling; or one would specify a certain electrical performance, whether it use vacuum tubes, solid state devices, or special electronic concepts. Thus there grew the concept of materials as a system and the concept of the multidisciplined materials engineering. Simultaneously, inspired by such demanding fields as electronics and progress in solid-state science as in single crystals and synthetic polymers, a clearer understanding was being developed of the relation between the properties or behavior of a substance and its basic electronic, atomic, and molecular structure. It became evident that this relationship was essentially fundamental, thus establishing a kind of commonality in certain attributes of various materials and minimizing the real differences between various types of materials. There also grew a materials science, indigenous to the behavior of many kinds of materials, that tended to break down the barriers between metallurgy, chemistry, and other disciplines.

It was natural that a concern for increasing the availability of material scientists and engineers should also develop. Obviously, universities had not been producing this type of individual. Attention was focused on promoting university courses, curricula, and research for educating and training students in this direction. The first step was a major effort by the United States Government to create interdisciplinary laboratories in 17 universities. Approximately a 10-year program was created, which cost in the neighborhood of a quarter of a billion dollars. This program is now nearing its end. Clearly the Ph.D.'s and other graduates in this field have increased substantially, at least a fewfold. Some universities have created very effective materials science departments, in many cases, as an outgrowth of their metallurgy departments. At the same time, the interdisciplinary efforts in some uni-

[1] This paper is based on the Plenary Electrochemical Society Lecture presented at the Atlantic City, N. J., Meeting of the Society, October 5, 1970.

versities have been only in name; the old barriers between departments really still existed.

It is interesting to note that the onset and trend toward materials science and engineering also had their impact on industry, where diversification has become common and materials-producing and materials-system industries have grown. Many of the larger companies, as in aerospace, also have established their own laboratories of materials science and engineering.

The effect has been felt even in technical and professional societies: our metal societies deal with plastics; our chemical societies include metals; our electrical societies include materials; *etc.* The Electrochemical Society could, as justifiably as some others, be termed a materials society; a review of the Society Divisions shows coverage of many materials, material processes, and material behavior phenomena.

It is worth emphasizing also that, while enormous contributions have continued to be made by the more conventional materials industries (such as those concerned with metals, ceramics, and textiles), recent progress in solid-state science and engineering has shown that the most subtle new insights (such as quantum electronics concepts, statistical mechanics applied to changes in polymers, and the lattice-defect theories of metallic aggregates) can be applied effectively to a host of practical problems which were heretofore treated only with empiricism.

In summarizing the above, I would say that the past 20 years have seen a transition from the single disciplines of metallurgy, chemistry, *etc.*, to the multidiscipline concept of materials, which includes all of these subjects and more. The single disciplines, of course, still exist (as they should) because they are vital. This change has had profound effect in industry, government, and universities. It has been an important step forward in optimizing design and production, by forcing open-minded consideration of many competitive materials, techniques, and concepts, permitting wider choice based on both improved performance and improved economy. It has established communication and transition between science and engineering. Finally, and of extreme importance, it has made possible the concept of tailor-making or custom-making materials to satisfy very difficult and complex requirements which could not be satisfied by the more conventional approaches.

Electrochemists, as such, perhaps may be referred to as a vanishing group. This may be an exaggeration; I have not attempted to document it. But my "gut" feeling is supported, for example, by some correspondence. As a further example, in the hundreds of contacts representing a wide variety of disciplines which we annually make in our own Advisory Board, I cannot recall a single individual who calls himself an electrochemist. I myself, although basically an electrochemist by training and many years of practice, call myself either a materials scientist or a materials engineer, depending on my audience and what I want to achieve. Yet, as I have already indicated, electrochemistry has many of the same interdisciplinary aspects as materials science, although not on so comprehensive a scale. Just as the devotees of materials have felt (at least until fairly recently) that their subject was not being appreciated in terms of its true significance and importance, that it was being neglected and not being assigned an adequate priority in the family of scientific and technological subjects, so the charge is now being made that electrochemistry as a field is waning both in terms of academic interest and industrial support. It is claimed that the annual production of only 5-10 Ph.D.'s in electrochemistry in this country is far out of balance with the annual production of about $4 billion of electrochemical products; that, under these conditions, the United States will fall behind in industrial disciplines as compared to Europe, where electrochemistry still commands substantial interest and respect in universities and laboratories; that the United States will deprive itself of important technical contributions to our societal problems. This is an important indictment of science in our country which, if completely real, could have far-reaching implications. At the same time one can ask, without meaning to imply any bias whatsoever, a number of questions: Is much or even most of the work that should be done in electrochemistry actually being done but not under the name of electrochemistry; for example, under the heading of materials science, or physical chemistry, or surface chemistry? If so, should we let these trends continue their course so that eventually electrochemistry will exist primarily as a concept and series of principles serving as important adjuncts of other fields of science and technology but not in itself be classed as a separate, identifiable entity in the same sense as metallurgy, chemistry, or physics? If this is not desirable, what priority should be given this field, considering the financial strain currently being imposed on science as a whole and the needs of other scientific and engineering fields? Where are the opportunities and potential payoffs greatest? For we hear the same plaint in other technical areas. For example, in the recent Orton Memorial Lecture of the American Ceramic Society, Dr. Osborn stated: "The position of the U. S. in ceramic science and technology rose to one of world leadership during the past few decades. . . . A recent study . . . concludes that the U. S. is rapidly losing this leadership. . . . How in the future will we fund the basic research our industry will need . . . . ? Basic research in ceramics has at present a precarious future." I do not pretend to have adequate answers to these and similar questions but I believe they are important, and I suggest that this Society is a logical place to start developing some facets of a national, documented position for consideration. Perhaps you are already doing so.

I have injected this topic at this stage because I believe it is a fitting introduction to the next subject, namely, national problems which interface with materials and related topics. The question of the status and future policy with respect to electrochemistry is but one of a series of major issues with which this country is not organized to cope in a deliberate, efficient, comprehensive manner. So I would now like to spend some minutes on these national situations and the related importance of materials and, directly or indirectly, electrochemistry. These issues are tabulated in Table I.

The materials problems of societal needs.—By societal needs is meant those now quite commonly recognized: pollution and environment control, transportation, low-cost housing, urban development, *etc.* Examples of materials problems in these areas are numerous. Already millions of pieces of metal are being implanted in human beings annually and yet there has been no major concerted effort to develop optimum materials for these specialized and literally vital applications. Mostly, implant materials have been "borrowed" from other technologies, and such effects as corrosion and electrochemical behavior under the particular conditions obtaining in the body still need vigorous attack. Many of the biological interactions involved depend on electrochemical reactions. Progress in high-speed transportation by trains is being hampered by materials problems in wear, friction, and brake applications; aggressive approaches through surface chemistry and coatings are obviously needed. Environment control demands refined approaches to proc-

Table I. Some major national materials issues

essing materials, utilizing them, converting from one form of energy and power to another (batteries and fuel cells are important approaches), minimizing waste and reclaiming value from it, perhaps designing the ultimate industrial products to facilitate salvage or disposition. These are only a few of the more obvious material and electrochemical aspects of societal problems.

The challenge of the materials explosion.—The materials explosion of the past two decades has contributed to probably all branches of science and engineering: from cryogenics to ultrahigh temperatures; from automobiles to space travel; in computer technology, food processing, communications, man-made fibers for textiles, clothing, and massive structures; *etc.* The challenge is to take advantage of this explosion now and to insure its continuation in the future. The scientific understanding must be converted to engineering application; the technology in sophisticated areas—in the United States notably in defense, space, and nuclear energy—must be transferred to other areas. Recognition must be given to the tremendous potentials in the ever-increasing nonmetallics areas such as plastics, inorganic engineering materials, ceramics and glass for industry and for the nation. Electrochemical syntheses are often basic to some of these products.

National security and national posture in technology.—I have grouped under this heading such pursuits as defense, space technology, commerical nuclear power, and other items which require strong government involvement and support and are often inter-related in other ways. Government involvement is justified when industrial risks are too high (as in the SST), when there is political or military significance (*e.g.* space and computers), or when there is lack of profit incentive (as in electric cars). As an illustration, let me cite the birth and development of a whole new industry, titanium, in less than two decades, as a result of close government/industry interaction springing from a deliberate national policy. Many features of this industry are electrochemical in nature; for example, the electrochemical production of magnesium (the main reducing agent for titanium tetrachloride) and the electrode processes in melting.

Material life cycle.—This topic has been mentioned earlier. We consider this cycle as proceeding from natural resources (raw materials), to preparation and transformation into products, to utilization, to disposal (waste), to recovery for reuse, thus closing the cycle. Such a cycle does, in fact, include all the problems I have enumerated: materials availability, pollution, efficient use of resources, export/import balance and economics, and many more. There is an international aspect as well, since all countries are in some respects "have-not" nations and must depend on imports and exchange of commodities to meet their internal needs. The increasing industrialization in so many countries will create extreme competition for these materials throughout the world, with peculiar situations possible. For example, it is conceivable that a country some day might be faced by the unpleasant necessity of choosing between a mineral shortage and a food shortage, since one can be bartered for the other.

Mobilization, operation, and control of materials research and development (R&D).—The U. S. is spending on the order of $1 billion per year in materials research and development. The estimate of this amount varies depending on how one defines the scope of materials. Perhaps half of this amount is furnished by the government directly or indirectly, and the rest is mainly provided by industry.

If we normalize the budgets over the last five years to correct for inflation, the annual effort is not increasing and probably is tending to decrease.

A number of questions, therefore, can immediately be asked. Is this annual rate adequate? How was the government effort determined? Is it properly distributed in proportion to priorities and defined goals? Is the technical manpower adequate? How about equipment and facilities? What is the relation to university educational programs? And many more questions. You see, the previous question of the adequacy of the national effort in electrochemistry and its priority fits into this category of issues.

I wish I could say that years ago we defined our national goals and priorities in materials and were now following an up-to-date grand plan. Unfortunately, this is not the case. I am not saying that our present fragmented programs are not good or logical. Perhaps they are; but I am emphasizing that we have not had a mechanism in the past for forecasting needs in materials and processes in such a way, and with such conviction, that we could define our goals and design national programs to achieve these goals most efficiently.

Other problems.—There are a number of other problem areas that could be presented if time were available. Now there is the need to define (forecast) both our opportunities and major problem areas in the next 10 to 20 years; to establish long range strategies, necessary for guidance of university curricula, for industry operation, and indeed to maintain our economic position in the world; the problem of optimizing the exchange and use of information generated by the annual billion dollar effort, and the important role that the professional society should play here; the task of improving public safety by taking advantage of new understanding of material behavior; the challenge to take advantage of electronic data processing to deal adequately with materials as a system on a national basis. And there are many more issues requiring a national forum for planning.

Thus, over the years, materials have moved from being an individual problem, to an industrial problem, to a government involvement problem. There is hardly any major national situation in which materials do not play a significant role. Therefore, no piecemeal, fragmented, haphazard activities can provide the answers and actions that are needed to deal nationally with these situations. There must be a national mechanism for focusing on these problems and creating policy. Otherwise, there is confusion, inefficiency, and big, unfilled gaps demanding attention. My earlier statements about assessing the needs for national action in the field of electrochemistry, *vis-à-vis* other national scientific needs, is an example of such a gap.

At the moment, I see three important contributory assists to this situation: one is at the Federal Government level; the second is the organization which I represent, namely, the National Materials Advisory Board; the third is the scientific and professional society, working either as an individual society or in consort with other societies, preferably the latter. These approaches, by the way, are not mutually exclusive; in fact, I see them as a strong coalition. Let me discuss them in a little detail.

Mainly as a result of the Government's concern with pollution, waste, recovery, and control of the environment in general, it has been possible to stimulate, in the Senate, a bill for the formation of a Presidential Commission on Materials. Some of you will recall that in the early fifties there was a Presidential Commission on natural resources, chaired by Mr. W. M. Paley of the Columbia Broadcasting System. The resulting Paley Report dealt with a number of resource issues in the country and included recommendations, some of which were implemented, and others, including the establishment of a continuing national body to monitor problems, which were not. In any case, the Paley studies are certainly out of date, and many of us have felt for several years that a new, comprehensive study was needed. The bill that was introduced in the Senate in mid-1970 was designed to set up a seven-man commission, to be appointed by the President, to conduct a study to be completed within three years, financed by

Table II. Proposed subjects for a national commission on materials policy

- Materials requirements, priorities, objectives and economic projections
- Relationship of materials policy to population size and environmental quality
- Recommended means for extraction, development and use of materials susceptible to recycling, reuse, or self-destruction, to enhance environmental quality and conserve materials
- Means of exploiting scientific knowledge in the life cycle of materials and encouraging research and education
- Means to enhance coordination and cooperation among Federal agencies
- Feasibility and desirability of establishing computer inventories of materials requirements, supplies and alternatives
- Other subjects as may be developed

Congress up to $2,000,000, with the objectives shown in Table II. The bill has now become law. In the meantime, another group has been authorized to inventory United States requirements and supplies of raw materials until the year 2000. Another act is also in process which would require annual reporting on mining, minerals reclamation, utilization trends, *etc.* Clearly Congress and the Executive Department are worried about materials resources for the next 30 years.

The second force that I mentioned in connection with national materials problems was my own organization, the National Materials Advisory Board (NMAB); and I would like to briefly describe this. The NMAB is a unit of the National Academy of Sciences and the National Academy of Engineering (which essentially are honorary groups of distinguished scientists and engineers), and the National Research Council (which is the operating arm of these two academies). In accordance with the principles and charter of the two academies, NMAB, therefore, is a nongovernment activity, supported by both government and private funds, for the advancement of the science and engineering of materials in the best interests of the country. It works with government agencies, industry, professional societies, universities, and trade associations. For national problems and opportunities in materials, and for transfer of technology to nonmaterials areas, it provides the functions of analyzing, defining, planning, balancing, cross-fertilizing, integrating, monitoring and coordinating, both for government and nongovernment. It operates mainly by assembling the best available talent in the country, and sometimes from abroad, for a given problem or objective. The functions of NMAB are abbreviated in Table III. The NMAB, therefore, provides a neutral, unbiased forum and focal point for discussing and providing implementable

Table III. Objectives and functions of NMAB

- Provide assistance to government and non-government
- Provide studies on national problems and opportunities and on action to be taken
- Identify problems and approaches in interacting materials with other functions
- Cooperate in development of advanced educational approaches
- Promote cooperation among professional societies
- Disseminate information
- Be aware of advancing technology, emphasize opportunities and roadblocks, and promote advanced concepts

approaches to national issues, embracing the three major sectors of the materials community: government, industry, and academia. Its role with respect to technical societies will become clear in a moment.

The Board itself, besides its permanent staff, consists of between 25 and 30 outstanding, top level scientists and engineers, representing many professional views: metallurgy, chemistry, physics, ceramics, economics, management, *etc.* They come from industry, government, and universities throughout the country.

The organization of NMAB is shown in Fig. 1. I do not intend to discuss this organization in detail but do want to emphasize a few of its facets. First, note that there are three councils, to permit focusing on the problems and interests of each of the three sectors I have mentioned. However, each council contains representatives of all three sectors, to insure balanced input and interaction. In addition to these three councils, we have an Interagency Council which includes all the government agencies concerned with materials; that is, not only DoD, AEC, and NASA, but the National Science Foundation, Department of Transportation, the National Institutes of Health, Housing, and Urban Development and a half dozen more, thus assuring good interaction between materials and other government problems.

Note also that we have essentially three types of operational groups or committees, not including various administrative committees. These are the Ad Hoc Technical Committees, dealing with fairly specific technical studies of limited duration, such as a year or two. The Standing Committees are intended to deal with broad issues and have no finite termination date. The third group are special committees of finite life but dealing with broad subjects, not specifically technical. Let me illustrate these three types. In Fig. 1 are examples of some technical topics that the Ad Hoc Technical Committees deal with. The Standing Committees or Technical Councils could deal with fracture prevention or corrosion, for example, on a continuing,

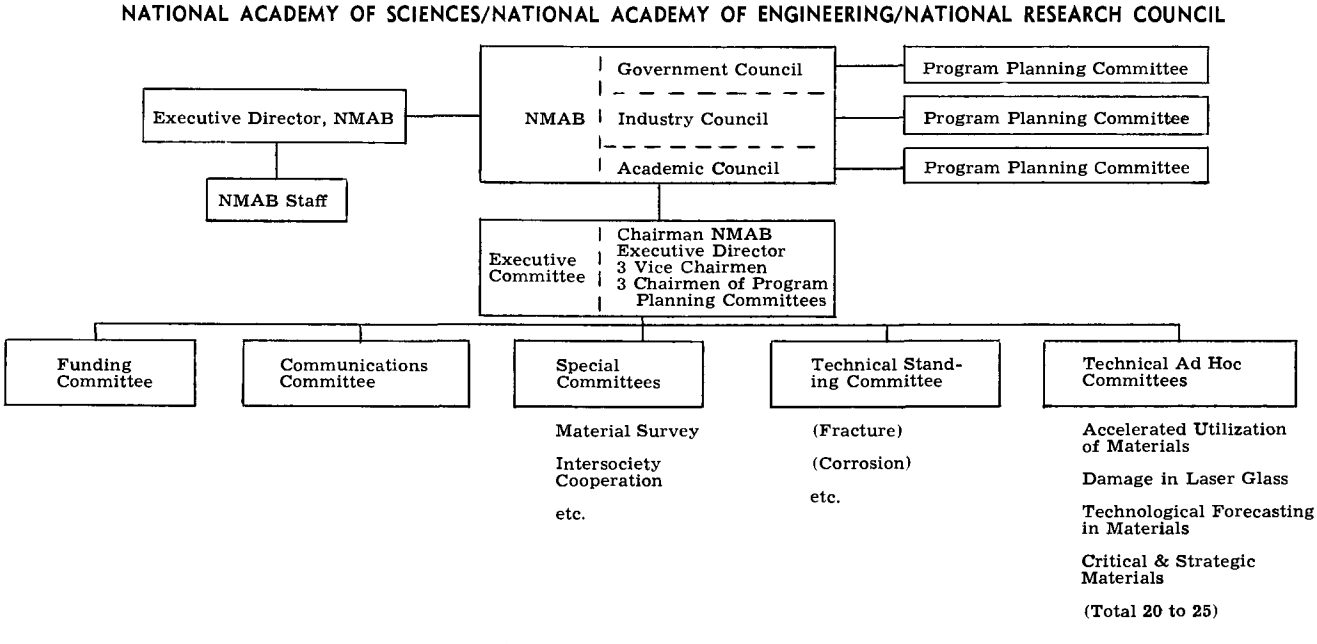

Fig. 1. The organization of NMAB

Table IV. Tentative objectives of national materials survey

- Identify and define the field of materials science and engineering.
- Identify past accomplishments and future potential and role.
- Determine gaps in materials R&D
- Examine national manpower needs.
- Examine educational structure in this field.
- Identify approaches for improving interaction between science and engineering.
- Plan future goals, strategies and priorities.

comprehensive basis. For the Special Committees, I want to mention two subjects in particular.

Some of you may be familiar with a series of reports produced by the National Academy of Sciences covering broad surveys of technical areas. There is such a report on chemistry (The Westheimer Report), on physics (The Pake Report), on life sciences, *etc.* The NMAB has been active in stimulating and planning such a survey on materials, with the objectives shown in Table IV. Certainly as one component of materials, a number of aspects of electrochemistry will be included. Nevertheless, you might want to consider a separate survey of electrochemistry as such, with objectives parallel to those described, if indeed you are concerned about the status and future direction of electrochemistry.

The second special topic I want to describe has to do with the broad group of scientific, technical, and professional societies.

In the United States we have about 35 technical and professional societies significantly concerned with materials in one way or another. The Electrochemical Society is one of these. Without questioning at this time the justification for all of these societies (although I have personal reservations), it is clear that this multiplicity does result in unnecessary duplication of meetings, lectures, symposia, *etc.*, on the one hand; and, on the other hand, no one society is able to cope with certain broad national problems, providing an integrated view on national materials issues when such a view is sought, *etc.*

A few years ago, during the annual meeting of the National Research Council on which are represented most of the societies involved, we decided to explore with these representatives several possibilities for concerted action. From this beginning, through a sequence of task forces, committees, and individual actions, there has evolved the conclusion that these societies can work best and to mutual advantage in the form of a society federation, analogous but not identical to the American Institute of Physics, the American Geological Institute, and others.

Let me emphasize immediately certain basic tenets of this proposal for a federation. No new society is intended here, only the voluntary cooperative effort of existing societies. No merger of any societies is being sought; conceivably, in the future, something in this direction could spontaneously occur. No society is being asked to yield its autonomy, its prerogatives, or its individuality. The federation will in no sense be a political lobby but it could respond technically and in a coordinated way to government requests. The major thrust of this effort is to provide a deliberate, positive opportunity and mechanism for a number of societies to work together, efficiently, toward common goals and to mutual advantages, with better service resulting to the scientific and technical community and to the nation as a whole. The NMAB is serving only in a catalytic role in this activity; once the objective is achieved in whatever form is desired by the societies, it does not intend to have any continuing function.

At a meeting called at the NMAB in August 1970 to discuss plans for a conference to determine the next moves toward forming such a federation, 18 selected societies were invited with almost 100% response; rather amazing and quite significant, in my opinion. Although no commitments were requested and none made, the group reaction was most favorable and encouraging, with a decision to proceed with the drafting of a charter. This has been done and drafts of a Constitution and Bylaws have been circulated to all of the societies involved. At the planned conference, held on February 11, 1971 at the National Academy of Sciences, the society representatives formed a steering group to define available options for an intersociety operating mechanism or federation. In the meantime, the steering group itself is authorized to plan appropriate coordinating and cooperative society activities. I continue to be hopeful, therefore, that by this or other means we can move forward to expanded intersociety activity on a firm, deliberate, continuing basis.

I personally consider that the scientific and professional societies in the fields we are discussing have been too modest for too long. The talent and technical resources which reside in the hundreds of thousands of members could make valuable contributions to the many vital problems and situations which confront the nation. More than one member of Congress, for example, has exhorted societies to act in this way. The societies are needed to help in these national issues and, in turn, can demonstrate the significance and importance of the technical areas they represent. In a sense, I think we can look on a society such as this one as a fourth dimension, a vital adjunct and contributor to the other three: industry, academia, and government.

In conclusion, I would recapitulate by stating that materials science and engineering, including electrochemistry under this broad spectrum, have made dramatic strides in the past few decades. Simultaneously, however, this country has awakened to, or has created, some massive national issues to which materials can make valuable contributions. The expanded National Materials Advisory Board is providing a forum and a mechanism to assist in making these contributions feasible and in providing guidance. In addition to this national effort of NMAB, one or more President's Commissions are being established. In every sense, a society such as The Electrochemical Society can provide valuable inputs and accomplishments, simultaneously ensuring that the field for which it is responsible to its membership receives proper attention and priority. Particularly today, when science and technology have lost some of their luster in the public's mind and yet, ironically, when the public needs science and technology perhaps more than ever before, it is important that each society assess its position and capability and join in an integrated effort for the common good.

AUGUST 1971

Anion Bridging and Anion Electrocatalysis on Mercury

Robert de Levie

Department of Chemistry, Georgetown University, Washington, D. C. 20007

ABSTRACT

The rate-enhancing effect of some specifically adsorbed anions on the kinetics of several electrode reactions greatly exceeds that predicted by the Frumkin correction. The literature on this effect is critically reviewed, including Heyrovský's 1947 hypothesis of ligand bridging and the pioneering work of Aikens and Ross on the oxidation of Cr(II). Two current theoretical interpretations are discussed and several related comments are made regarding ionic adsorption.

The double layer at the electrode-electrolyte interface has long been known to exert a significant effect on the kinetics of electrode reactions. Frumkin (1) was the first to point out that electrode reactions are driven by the effective potential $E - \phi$ (where ϕ is usually associated with the so-called "outer" Helmholtz potential) rather than by the applied potential E. He also introduced a Boltzmann correction for the interfacial reactant concentrations, which are modified by coulombic attraction or repulsion of ions by the double-layer field. Since anion specific adsorption alters the value of ϕ, such adsorption may significantly change the rates of electrode reactions.

A second type of double-layer influence is that of blocking. Adsorbed organic molecules often severely suppress electrode reactions. This interference is usually much larger than can be accounted for on the basis of a mere change of ϕ resulting from the adsorption. Of course, the influence of ϕ is present as well, and the two effects can sometimes be distinguished when they work in opposite directions (2).

Many adsorbed organic molecules, like proteins, alkaloids, and pyridines, are known to catalyze the reduction of hydrogen on mercury. This effect has been studied extensively for several decades, and the reader is referred to recent reviews (3, 4) for details.

Of more recent date is the realization that adsorbed inorganic ions can act as catalysts as well. The ion adsorption is of course accompanied by a change in ϕ, but the observed acceleration of electrode reaction rates is often much too large to be accounted for solely on that basis. Another factor which sometimes complicates the interpretation is the possibility of complex formation between the reduced cation and the added anion. However, the rate enhancement is often much more pronounced with I^- than with Cl^-, even when the tendency for the cation to form complexes is greater with Cl^- than with I^-.

Heyrovský was the first to notice the pronounced effect of halides on the reduction of Sn(II), Bi(III), Sb(III), and In(III) (5). These observations he explained, as early as 1947, with electron transfer through a bridge mechanism. Many more examples have since been reported, and it now appears that electrocatalysis by adsorbed anions is a fairly general phenomenon.

Key words: adsorption, catalysis, isotherms, kinetics, ligand bridging.

In this review, discussion is restricted to electrode processes on mercury. This should not be taken to imply that similar effects are not operative on other electrodes, but merely to reflect the fact that, for a variety of reasons, sufficiently detailed double-layer data on solid electrodes are virtually nonexistent. Our present understanding of both electrode kinetics and double-layer structure stems largely from experiments on mercury, and the same applies to electrocatalysis, which represents a close interplay between kinetics and double-layer structure.

So far, two cases of rate enhancement by anion bridging have been worked out in fair detail: the oxidation of Cr(II) and the reduction of In(III). Since quite different and largely complementary approaches were taken in these two cases, we will consider them separately. Subsequently, some more or less scattered data from the literature and from our own research are discussed in order to illustrate the fairly common occurrence of such effects on mercury.

Chromium(II)

After several investigators (6, 7) had noticed that the addition of chloride accelerates the oxidation of Cr(II), Aikens and Ross (8) examined this reaction in detail. They measured the oxidation rate constants as a function of solution composition and electrode potential. The oxidation rate is enhanced more by I^- than by Br^-, and Br^- in turn is a more efficient accelerator than Cl^-. This sequence runs parallel with the adsorbabilities of these anions, but counter to the tendency of Cr(II) to form complexes with halides. Also, the rate enhancement is much more pronounced at more positive potentials, where halide anions are more strongly adsorbed, suggesting again that the adsorbed rather than the bulk anions cause the effect.

Aikens and Ross (8) also performed large-scale electrolytic oxidation of Cr(II) in the presence of chloride, and found that the electrolysis, when performed at rather positive potentials, almost exclusively produced chloropentaquochromium(III). All the above data are consistent with two parallel oxidation pathways in the presence of chloride ions:

$$Cr^{2+} \rightarrow Cr^{3+} + e^- \qquad [1]$$

and

$$Cr^{2+} + Cl^-_{ads} \rightarrow CrCl^{2+} + e^- \qquad [2]$$

Finally, Aikens and Ross (8) pointed out that $CrCl_2^+$, even if initially formed, would react rapidly with Cr^{2+} as long as there would still be some Cr^{2+} left:

$$Cr^{2+} + CrCl_2^+ \rightarrow Cr^{2+} + CrCl^{2+} + Cl^- \quad [3]$$

Consequently, product analysis in this case cannot indicate whether one or two adsorbed halides are involved in the halide-assisted charge transfer.

The observations of Aikens and Ross (8) have been confirmed extensively by Kemula and Rakowska (9), Anson *et al.* (10, 11), and Watanabe *et al.* (12). Recently, Anson *et al.* (13) have extended the measurements to the oxidation of Cr(II) in the presence of thiocyanate ions. In this case, $Cr(NCS)_2^+$ and $Cr(NCS)_3$ are the predominant oxidation products over a wide range of conditions. The dependence of the product distribution on potential, and the preferential formation of the cis-isomer of $Cr(NCS)_2^+$, are clear evidence that adsorbed SCN^- is involved in the oxidation, and apparently acts as ligand bridge between cation and electrode.

In the oxidation of Cr(II), direct chemical product analysis provides convincing evidence for the involvement of adsorbed ions in the electrode process, because the reaction products are quite substitution-inert, *i.e.*, they do not quickly exchange coordinated solvent molecules or ions with the surrounding solution. In the case of substitution-labile products, we must rely on less direct evidence, an example of which will be given in the next section.

Indium(III)

Heyrovský (5) noticed that the presence of halides rendered the oscillopolarographic reduction of indium reversible, and explained this observation in terms of electron transfer through a halide bridge. Earlier, Lingane (14) had observed a minimum on the polarographic wave for In(III) in halide solutions; but it remained for Cozzi and Vivarelli (15) to correlate the occurrence of this minimum with anion desorption. Similar minima (*i.e.*, regions in which the polarographic reduction current decreases as the potential is made more negative) are observed also with, e.g., tartrate (15), oxalate (16), thiocyanate (17, 18), and with several organic sulfur and nitrogen compounds (19).

Shirai (17) noticed that the a-c polarogram of In(III) in thiocyanate solutions exhibits a negative admittance. Tanaka *et al.* (20) pointed out that the sign of the faradaic admittance is determined by the sign of dk/dE, where k is the reduction rate constant and E the applied potential. This correlation was given a more precise formulation by de Levie and Husovsky (21), who also demonstrated that the polarographic minimum and the negative faradaic admittance are indeed manifestations of the same phenomenon, namely a decrease of the over-all reduction rate when the electrode potential is made more negative. Finally, Pospíšil and de Levie (22) showed that all data can be accounted for quantitatively by the following reaction sequence

$$In^{3+} + 2\,SCN^-_{ads} \xrightarrow[\text{slow}]{} In(SCN)_2^+{}_{ads} \xrightarrow[\text{fast}]{+\,3e^-} In^\circ + 2\,SCN^-_{ads} \quad [4]$$

This represents a truly electrocatalytic mechanism, since there is no net consumption of the bridging ligands. Whether the thiocyanate ions act as electron conductors (5) or merely labilize the hydration shell of the hexaquo indium ions is not yet clear. Hexaquo indium(III) itself, in the absence of hydrolysis or electrocatalysis, appears not to be reducible polarographically.

That two adsorbed thiocyanate ions partake in reaction [4] follows from the dependence of the reduction rate constants on the surface activity of adsorbed SCN^-, see below. That the reacting indium(III) species is probably In^{3+} rather than one or more indium-thiocyanate complexes, can be deduced from measurements at very low thiocyanate concentrations (22) and also from the dependence of the rate constants on bulk thiocyanate concentration, at constant surface activity. In view of the equilibrium data of Sundén (23), the Frumkin correction (1) does not affect the analysis since the average charge of thiocyanato-indium complexes is essentially zero for $[SCN^-] \geq 1M$.

The polarographic minimum, then, is caused by the gradual desorption of the electrocatalyst, SCN^-_{ads}, as the potential is progressively made more negative (15). In more concentrated NaSCN solutions, the minimum becomes more pronounced, despite the larger amount of adsorbed SCN^-, because extensive bulk complexation sharply reduces the availability of hexaquo In(III).

The polarographic minimum in chloride solutions is not quite as pronounced as that in thiocyanate. Analysis similar to that for SCN^- indicates (24) that, most probably, two chlorides are involved in the electrocatalytic reduction of In(III) in solutions containing 0.1-2.5M NaCl. In much more dilute (10^{-4}-10^{-2}M) NaCl solutions there are indications that the reduction can also proceed through one adsorbed halide, though not as efficiently.

In bromide and iodide solutions, the data (24) are not so simple to interpret, with slopes of log rate constant *vs.* log βa of 1.5 to 2. It is not yet clear whether this is an indication of more than one catalytic pathway or whether it is merely a reflection of the imprecision of available surface activity data.

Surface Activity

In the preceding section, the concept of surface activity (22) was introduced. We will now show how it is defined, and subsequently how it can be obtained experimentally. Assuming equilibrium between adsorbed and bulk particles (indicated by subscripts a and b, respectively), one can write for their electrochemical potentials, μ

$$\mu^\circ_a + RT \ln a_a = \mu_a = \mu_b = \mu^\circ_b + RT \ln a_b \quad [5]$$

where a denotes an activity ratio and the superscript $^\circ$ a standard state. Consequently

$$a_a = a_b \exp\left[\frac{\mu^\circ_b - \mu^\circ_a}{RT}\right] \quad [6]$$

which can be written in a more compact notation as

$$a_a = a_b\beta \quad [7]$$

$$\beta \equiv \exp\left[\frac{\mu^\circ_b - \mu^\circ_a}{RT}\right] = \exp\left[\frac{-\Delta G^\circ_{ads}}{RT}\right] \quad [8]$$

The above formalism is extremely simple, yet the application of Eq. [7] is not all that straightforward, and several difficulties arise, especially with adsorption of ionic species.

In the case of ion adsorption, a_a represents the bulk ion activity. As long as no reliable methods have been developed to estimate single ion activities, we have to resort to the conceptually less satisfactory, but at least measurable, salt activities or related mean salt activities. Secondly, thermodynamic measurements of surface tension, surface charge density or double layer capacitance yield surface excesses rather than surface activities, in contrast with thermodynamic measurements of bulk properties, which yield activities rather than concentrations. Ion adsorption is further complicated by the fact that the measured surface excesses contain contributions from both short-range and long-range interactions with the electrode. Since we are interested here in specific ("contact") adsorption, the contribution due to long-range, coulombic forces must be corrected for, using a theoretical model (*e.g.* that

of Gouy-Chapman) for the diffuse double layer contribution. The resulting specifically adsorbed surface excess still varies with the chosen electrical parameter: applied potential, surface charge density, etc. There is still considerable controversy about the most meaningful choice of electrical parameter but, within the framework of any such choice, β could in principle be estimated from Eq. [7] by using

$$\lim_{\Gamma \to 0} a_a = \Gamma \qquad [9]$$

so that

$$\beta = \frac{a_a}{a_b} = \lim_{\Gamma \to 0} \frac{\Gamma}{a_b} \qquad [10]$$

if, in this limit, β were to depend solely on adsorbate-adsorber interactions. For ions, this appears not to be the case and, moreover, the experimental precision needed for the direct application of Eq. [10] is not yet available, so that less straightforward techniques must be used. See the Appendix for some related comments.

For only relatively few ions, has the specific adsorption onto mercury been studied quantitatively. For these ions, to a first approximation, β appears to be (25) an exponential function of both the electrode charge density Q and of the effective electrode potential, $E - \phi$. This is a very useful property, since it allows us to extrapolate β values to regions where direct measurements are not available. The uncertainties inherent in such an extrapolation should of course be appreciated.

Zinc

Randles and Somerton (26) observed that the presence of halides or thiocyanate significantly increased the rates of the reactions

$$Zn(II) + 2e^- \rightleftharpoons Zn(Hg) \qquad [11]$$

Such behavior cannot be explained by a simple ϕ effect.

Oscillopolarographic measurements by Heyrovský (27) established the presence of two quite distinct reduction peaks in fairly concentrated KI solutions; one at the potential at which zinc is oxidized from its amalgam, the other at that at which Zn(II) is reduced from acidic sulfate solution. Polarographic measurements on a streaming mercury electrode (28) confirmed the presence of two separate reduction waves in the presence of I^-. Consequently, two separate processes must be considered, one related to the presence of I^- and the other not. Since Zn(II) has a greater tendency to form complexes with Cl^- than with I^-, whereas the rate enhancing effect is larger with I^-, Tamamushi *et al.* (29, 30) concluded that anion adsorption rather than complex formation is involved in the halide-related process. A similar conclusion was reached by Blackledge and Hush (31).

More recently, Sluyters *et al.* (32-36) have published extensively on the Zn(II)/Zn reaction. They found that the standard rate constant is an exponential function of the amount of specifically adsorbed halide ions (35, 36). However, Sluyters *et al.* considered only one single reaction pathway. The observed (35) exponential dependence of the rate constant on the amount of specifically adsorbed anions is quite compatible with a linear dependence on βa similar to that found for indium. Another explanation, in terms of the activity coefficient of the activated complex, was given by Parsons (37).

In summary, the available evidence strongly suggests the presence of halide electrocatalysis in the reduction of Zn(II), although no satisfactory quantitative analysis has yet been given.

Other Cations

The reduction of nickel(II) to some extent resembles that of In(III): the reduction of the hexaquo ion appears to involve a preceding destabilization of the hydration shell (38) and, in the presence of SCN^-, a polarographic minimum and the associated negative faradaic admittance are observed (39-41). Quantitative measurements are hindered, however, by the appearance of a polarographic maximum which is possibly related to the the formation of a nickel film on the mercury surface rather than amalgamation. Adsorbed organic amines (42-45) and thiourea (46) can also catalyze the reduction of Ni(II).

Moorhead *et al.* have reported extensively (47-50) on the SCN^- catalyzed reduction of Ga(III) in aqueous solutions of high ionic strength. Their experiment with competitive adsorption (49) clearly suggests that adsorbed rather than bulk thiocyanate is involved.

Polarographic minima have been observed in the reduction of Sn(IV) (51), V(V) (52), and Mo(VI) (53), and these systems have been shown to exhibit negative faradaic admittances (54), see Fig. 1 and 2. It is highly probable that bridging by adsorbed ligands is involved in these instances.

The reduction of Bi(III) from a noncomplexing medium like 1M $HClO_4$ takes place at a positively charged electrode, so that the addition of small amounts of halides changes ϕ considerably. However, the reduction of Bi(III) is accelerated so much (55)

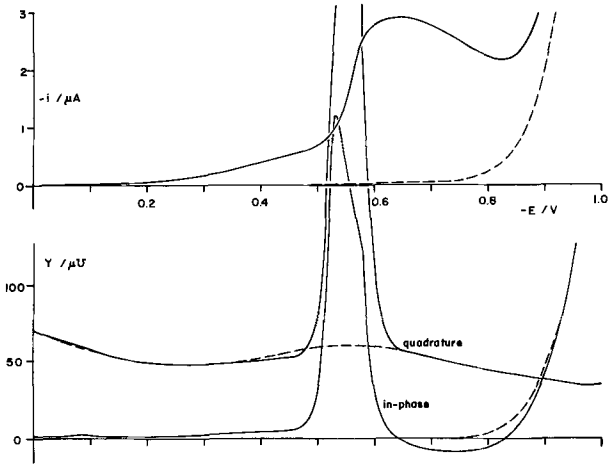

Fig. 1. D-C (top) and a-c (bottom) polarograms of 1 mM $SnCl_4$ in 0.5M oxalic acid, 0.45M Li_2SO_4 and 0.05M H_2SO_4, showing a negative faradaic admittance (54). Replacing all or part of the Li_2SO_4 by H_2SO_4 does not affect the curves, which appears to indicate that the electrocatalyst in this case is the undissociated acid, $C_2O_4H_2$. A-C signal: 5 mV top-to-top at 15.9 Hz. Note that the capacitive component of the faradaic admittance around −0.55V exceeds the resistive component, indicating pronounced reactant specific adsorption. Dashed line: same curves in absence of electroactive species.

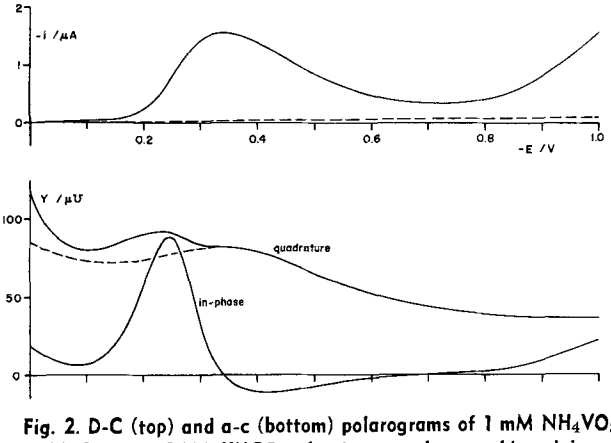

Fig. 2. D-C (top) and a-c (bottom) polarograms of 1 mM NH_4VO_3 in 0.5M $C_2O_4K_2$, 0.5M $KHCO_3$ showing a polarographic minimum (52) and the associated negative faradaic admittance (54). A-C signal: 5 mV top-to-top at 15.9 Hz. In this case, as well as that of Fig. 1, the negative faradaic impedance coincides with the decreasing part of the polarographic minimum, as one would expect for a negative charge transfer resistance (21).

that ligand bridging appears likely. Quantitative analysis is complicated (24) however, by uncertainty about the chemical species present in solution (needed for reliable application of the Frumkin correction) and especially, by coupling (56) of kinetic and adsorption phenomena. The latter leads to extremely complicated mathematical analysis when, as in this case, the electrode reactions are not "infinitely fast." Vlček and Kůta (57) showed that the polarographic reduction of pentamine cobalt(III) is catalyzed by adsorbed halides. This catalysis is complicated by the direct, chemical involvement of Hg in the reduction process (58), in a reaction sequence like (59)

$$2Co(NH_3)_5^{3+} + 10\,H^+ + 2X^-_{ads} + 2Hg \xrightarrow[\text{slow}]{} 2Co^{2+} + 10\,NH_4^+ + Hg_2X_2 \quad [12]$$

$$Hg_2X_2 + 2e^- \xrightarrow[\text{fast}]{} 2Hg + 2X^-_{ads} \quad [13]$$

A somewhat similar mechanism had been suggested as early as 1953 by Laitinen *et al.* (60) for the halide-catalyzed polarographic reduction of $Co(NH_3)_6^{3+}$. In these cases, the actual reduction process is a heterogeneous chemical reaction, whereas the electrochemical step [13] serves to remove Hg_2X_2 and to regenerate the catalyst, X^-_{ads}. Such a situation can readily be distinguished from the cases discussed earlier since reaction [13] yields a reduction wave which rises, without inflection, from the anodic mercury oxidation wave (59).

Interesting but not yet quite understood results were obtained by Anson (61) in the oxidation of the Co(II)-EDTA complex at Pt, the rate of which is greatly enhanced by the presence of halides. This paper (61) serves to illustrate some of the difficulties involved in explaining, even if only qualitatively, results obtained on electrodes other than Hg.

Finally, halide electrocatalysis has also been indicated in the reduction of protons on mercury (62). Especially noteworthy was the observation that the basic rate constant for the halide-catalyzed reaction pathway is the same for Cl^-, Br^- or I^-, within the accuracy of the data. This suggests a common slow mechanism, probably labilization or loss of coordinated water.

An Alternative Interpretation

An interesting alternative explanation for the effects of halides on, *e.g.*, the reduction of hydrogen and zinc ions on Hg, was given by Parsons (37). He interprets the rate enhancement as resulting from the effect of specifically adsorbed ions on the activity coefficient of the activated complex of the charge transfer reaction. This model requires that the activated complex be present inside the compact (Helmholtz) double layer. Of course, such a physical interpretation cannot account for the chemical incorporation of halides during the oxidation of Cr(II). Also, the physical nature and especially, the charge of the activated complex invoked in this model, are rather undefined as a consequence of the Franck-Condon principle. On the other hand, the model yields behavior which may often be rather similar to that predicted by our chemical interpretation, making it difficult to distinguish experimentally between the two (101). Interestingly, Parsons' model also provides for an interpretation of the blocking effect of organic compounds (37, 101).

Discussion

(A) In the foregoing, the term anion bridging has been used to describe a molecular mechanism whereby the anion adsorbed in the electrode/solution interface appears to be involved directly in the electron transfer between metal ion and electrode. On the other hand, anion electrocatalysis is used to denote an over-all stoichiometry. Thus, in all examples given, anion bridging is presumed to be present, but only in some are the bridging anions incorporated into the final reaction products. In the oxidation of Cr(II), adsorbed anions are built into the resulting substitution-inert species, and therefore the reaction is not really catalytic. In such a reaction, chemical analysis of the reaction products provides an unambiguous indication of the chemical involvement of adsorbed ions in the reaction process. Such direct chemical evidence is not available when the reaction product is either a metal atom or a substitution-labile ion, and less straightforward electrochemical evidence must be used. In the latter case, the term "bridging" is not to be taken in the strict sense of Libby (103) and Taube (104), since no distinction between, *e.g.*, inner or outer sphere activated complexes can yet be made.

(B) When the reaction rate increases markedly in the presence of some strongly adsorbed anions, ligand bridging may be involved. However, the observed effects might also be due to a change in ϕ or to complex formation, or both. It is therefore likely that cases of weak halide bridging will not be readily distinguishable, especially when the tendency of the cation towards complexation with anions parallels the tendency for anion adsorption, *e.g.*, $Cl^- < Br^- < I^-$.

(C) When the rate-enhancement resulting from ligand bridging is very pronounced, and especially when the reaction in the absence of bridging is very slow, polarographic minima and associated negative faradaic admittances may be observed, as with In(III), Ni(II), and Sn(IV). Such minima are not likely to be due to double layer repulsion when they occur at potentials far away from the potential of zero charge, and when they persist at high ionic strengths. This criterion must of course be applied with caution since at least one minimum (63) and the associated negative faradaic resistance (64) is known to be caused by still another quite different mechanism.

(D) The concept of surface activity, as defined in the section on Surface Activity, can be used to obtain more precise, stoichiometric information on the reaction mechanisms. So far its application has been restricted to only a few relatively simple cases (22, 62), although it could readily be extended to more complicated situations in which, *e.g.*, several complexes are reduced simultaneously, as soon as more and better surface activity data become available. However, as the number of adjustable parameters (standard rate constants, transfer coefficients, stoichiometric numbers) increases, so does the speculative nature of the interpretation, and one quickly reaches the point of futility, especially in view of the large inherent uncertainties of surface activity data.

(E) The reaction sequence during electrocatalysis can be represented by a scheme like

$$M^{m+} + pX^-_{ads} \rightarrow MX_p^{(m-p)+} \quad [14]$$

$$MX_p^{(m-p)+} + ne^- \rightarrow M^{(m-n)+} + pX^-_{ads} \quad [15]$$

with possible modifications including metal complexes as starting material and or product. For oxidations, n is a negative quantity.

When the chemical reaction [14] is much slower than the electron transfer step [15], then the over-all reaction rate will be simply proportional to the activity of M^{m+} and to the pth power of the surface activity of X^-_{ads}. Thus, the rate is given by

$$\text{rate} = k\beta^p a_x^p a_M \quad [16]$$

where k is the rate constant of the chemical reaction [14] and is independent of the electrical parameter, whereas β usually varies as an exponential function of potential (or charge density). Thus, the formalism for an oxidation with rate-determining ligand bridging, Eq. [14], and fast subsequent charge transfer [15], misleadingly resembles that for a slow electron transfer step!

The reduction of hexaquo indium(III) from thiocyanate solutions is an example of rate-determining

ligand bridging, quite analogous to several bulk chemical reactions of hexaquo vanadium(II) which are also limited by the rate of formation of the "precursor complex" (65, 66, 102).

When reaction [14] is much faster than [15], then [14] may be considered to be in equilibrium. The overall rate equation will then follow the usual electrochemical formalism, but in terms of the interfacial activity of MX_p, which in turn is proportional to the activities a_M and $(\beta a_x)^p$, so that

$$\text{rate} = kK\beta^p a_x^p a_M \exp\left[\frac{\alpha n\mathbf{F}(E - E^\circ)}{RT}\right] \quad [17]$$

where

$$K = \frac{a_{XM_p}}{a_M\,(\beta a_x)^p} \quad [18]$$

This is the situation observed in the reduction of hydrogen ions (62).

(F) Electrocatalysis or ligand bridging, if present, will go unnoticed when the uncatalyzed reaction is already near the limit of accurate measurements (at present, $k_{sh} \gtrsim 0.1$-1 cm sec^{-1}). The fact that electrocatalysis or ligand bridging has so far been established mostly in cases in which the uncatalyzed reactions are very slow [In(III), Cr(II), Ni(II), H(I)], may therefore be merely a reflection of the limitations of our present measurement techniques. On the other hand, it is tempting to speculate that many electrode reactions involving a drastic change in coordination are slow because the cations involved have low rates of exchange of coordinated water (67), and that the ligand-bridging pathway is effective in labilizing the hydration shell. Such a hypothesis is quite compatible with the observation that the reduction of Zn(II) becomes faster in concentrated perchlorate solutions (68), in which the "inert" electrolyte competes for coordination water, or with somewhat similar observations with Ni(II) (69).

(G) By its very nature, ligand bridging depends strongly on the adsorbability of the bridging anions. However, there seems to be no direct relation between the effectiveness of ligand bridging and the adsorbability of the cations or cationic complexes involved (73). For instance, cis-$Cr(NCS)_2(H_2O)_4^+$ is very strongly adsorbed on mercury (13), like its tetramine analog, cis-$Cr(NCS)_2(NH_3)_4^+$ (70), but there is no evidence that $CrCl(H_2O)_5^{2+}$ or $CrBr(H_2O)_5^{2+}$ are strongly adsorbed, although the oxidation pathways are similar. Likewise, In(III) is not measurably adsorbed on Hg in chloride solutions (71, 72), yet the reaction mechanism seems to be quite similar to that in thiocyanate, where In(III) is markedly adsorbed (72, 73).

(H) In the foregoing we have tried to emphasize some purely chemical double layer effects, as distinct from the well-known, more physical influences like those of the ϕ potential or of blocking. Somewhat analogous cation-bridging effects have been proposed by, *e.g.*, Delahay and Mattax (105) and Schmid and Reilley (106). Clearly, ligand bridging in homogeneous solution has its interfacial analog, the study of which is interesting both for our fundamental understanding of charge transfer processes and for its obvious practical applications.

APPENDIX 1: THE ELECTROCHEMICAL PARAMETER

Experimentally, adsorption on electrodes varies with the applied potential. Consequently, in order to study e.g. the dependence of the amount adsorbed on the bulk activity of the adsorbable material, the analysis must be made at constant electrochemical parameter. Stern (74) proposed to use as such the effective potential $E - \phi$, which, incidentally, is the same parameter introduced subsequently by Frumkin (1) in the description of electrode kinetics. Grahame (75, 76), in his work confirming and extending the ideas of Stern, used electrode charge density Q as the electrochemical parameter, a choice later rationalized by Parsons (77).

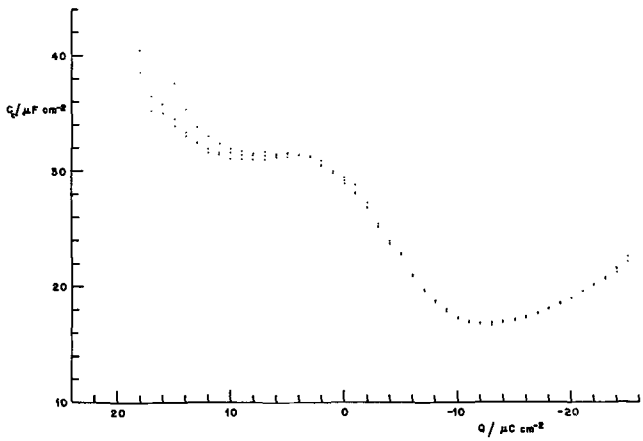

Fig. 3. The compact double-layer capacitance, C_c, as a function of electronic charge density, Q, from Grahame's experimental data (87) of Hg in 0.01, 0.10, and 0.916 M NaF, calculated from the measured capacitance, C, according to $C^{-1} = C_c^{-1} + C_d^{-1}$ where the diffuse double-layer capacitance, C_d, is given by $C_d^2 = (zFQ/2RT)^2 + (\epsilon\kappa/4\pi)^2$ and κ is the Gouy-Chapman reciprocal length, ϵ the macroscopic solvent dielectric constant.

Several arguments pro and con this choice have been given (78-81) and need not be repeated here. A few observations may be added.

The potential ϕ of the (outer) Helmholtz plane is not directly measurable, and its calculation depends on the model chosen for the description of the diffuse double layer. Consequently, the values of the effective potential, $E - \phi$, also depend on such model assumptions,[1] though to a lesser extent since the range of values of ϕ is about an order of magnitude smaller than that of E.

In the absence of electrode reactions, the electrode charge density Q is a directly measurable, "thermodynamic" quantity. However, Q becomes thermodynamically undefined when adsorbable species are involved in electrode reactions (82-86). Under those circumstances, ϕ can still be evaluated from the surface excess of a nonadsorbed ion which is not participating in the electrode reactions, like *e.g.* Na^+ or K^+ from the inert electrolyte. In the case of anion bridging or electrocatalysis, where adsorption phenomena and kinetics are intertwined, the measurability of the electrochemical parameter is obviously important, quite apart from the convenience of using the same parameter, $E - \phi$, for the description of both adsorption and kinetics.

Experimentally, the two choices, $E - \phi$ and Q, appear to be rather equivalent (25). For instance, Grahame showed (75, 76, 87) that, for Hg in aqueous NaF solutions, the capacitance C_c of the compact double layer is independent of the NaF concentration, but that C_c still is a function of Q, see Fig. 3. The same conclusion holds when Q is replaced by $E - \phi$, see Fig. 4. Similarly, adsorption isotherms which are congruent (see below) when plotted at constant Q are equally congruent, though not necessarily of the same shape, when considered at constant $E - \phi$, unless the argument is changed halfway from $E - \phi$ to E (88).

APPENDIX 2: THE ISOTHERM FOR ADSORPTION OF IONS

Adsorption is conveniently described by the adsorption isotherm, *i.e.* the dependence, at constant temperature, pressure and electrochemical parameter, of the surface excess Γ on the logarithm of the bulk activity a of the adsorbable material. Often, neutral molecules exhibit so-called "congruent" isotherms, that is, the isotherms obtained for the same substance but at different values of the chosen electrochemical parameter ($E - \phi$ or Q) can be made to superimpose by a mere shift along the log a axis. Of course, congruence applies likewise to the integrated form of the

[1] For ion adsorption, the dependence of $E - \phi$ on a diffuse double layer model does not introduce any additional uncertainty, since the necessary prior subtraction of the contribution of ions "non-specifically" held in the diffuse double layer depends on the very same model.

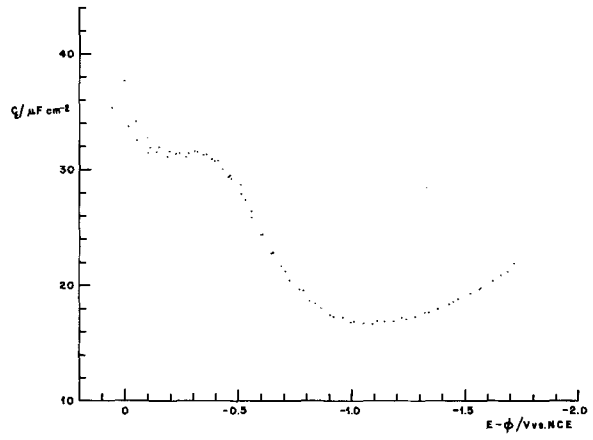

Fig. 4. The same compact double-layer capacitance data as in Fig. 3, but now plotted as a function of the effective potential $E - \phi$. The potential ϕ was calculated using $\phi = 0.05139$ arcsinh $[Q/11.74\ c^{1/2}]$. Note that the data for the three NaF concentrations fit equally well for both choices of the electrical parameters, $E - \phi$ or Q. A similar plot as a function of the applied potential, E, leads to clearly noncoinciding curves.

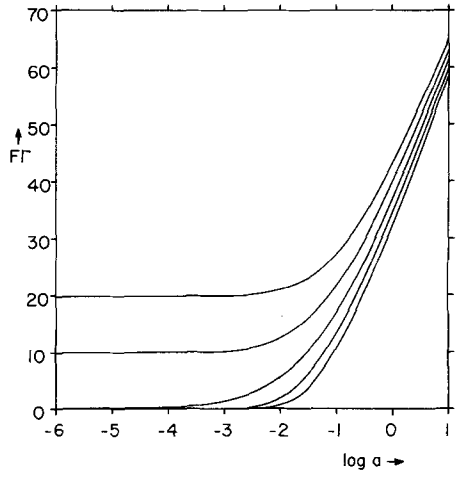

Fig. 5. Adsorption isotherms, at constant electrode charge density, Q, calculated from Eq. [19] using the following parameters: $\beta = 10^{-6}$ cm, $\Gamma_s = 10^{-9}$ moles cm^{-2}, and $A = 10^{10}$ cm^2 mole^{-1}. Curves calculated for electrode charge densities of (from top to bottom) +20, +10, 0, −10, and −20 μC cm^{-2}, respectively. For ease of comparison, β is kept constant despite the variation of Q. The potential ϕ is calculated according to $\phi = 0.05139$ arcsinh $[(Q + zF\Gamma)/11.74\ c^{1/2}]$. In the calculation of ϕ, the difference between bulk concentration, c, and bulk ionic activity, a (both in moles liter^{-1}), is neglected. For $Q > 0$, the curves tend to approach $F\Gamma \approx Q$ at low salt activities, and no Henry region (where Γ is proportional to a) is observed in the activity range shown. Units: $F\Gamma$ in μC cm^{-2}, a in M.

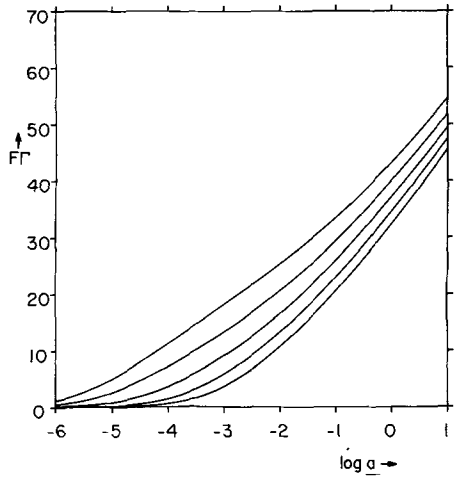

Fig. 6. The same adsorption isotherms as in Fig. 5, but at constant ionic strength (1M) maintained with a nonspecifically adsorbed electrolyte. Note that the curves differ substantially from those in Fig. 5, and appear to be much more congruent, since the double-layer influence has been reduced significantly for the larger part of the curves (log c < 0).

adsorption isotherm, *viz.* the plot of surface pressure, $\pi = RT\int P\ d\ \ln a$, *vs.* log a, for which it was first observed (89). This fairly general rule of congruence is reflected in the fact that many of the proposed equations for adsorption isotherms, *e.g.* all those listed in Ref. (90), correspond to congruent ones, *i.e.*, βa is a function solely of Γ.

Experimentally, ionic adsorption isotherms are usually noncongruent. There is one apparent exception, that of I^-, which is congruent over the entire range studied by Grahame (91), although noncongruence shows up even here when the measurements are extended to lower concentrations (92). A typical example of a noncongruent ionic adsorption isotherm is that of chloride (93).

The noncongruence shows most clearly at low bulk activities, with correspondingly small values of Γ. This rules out effects due to changing mutual interaction of adsorbed ions. The only interactions which do not tend to vanish at low bulk activities, and which also are not accounted for by any of the congruent adsorption isotherms, are those between specifically adsorbed and nonspecifically adsorbed ions.

Adsorption isotherms which include a Boltzmann term in ϕ, like those of Stern (74), Levine *et al.* (94, 95), and Devanathan and Tilak (96), sometimes fit the trends of ionic adsorption isotherms better than do congruent adsorption isotherms (25). Extension could of course be made to Flory-Huggins statistics (97, 98) if the introduction of still another adjustable parameter is warranted. Figures 5 and 6 show the Frumkin isotherm (99) as modified by the inclusion of the Boltzmann term

$$\beta a = \frac{\Gamma_s\Gamma}{\Gamma_s - \Gamma} \exp\left[A\Gamma + \frac{z\mathbf{F}\phi}{RT}\right] \qquad [19]$$

Note that Frumkin (99) proposed his isotherm for adsorption of uncharged substances, and that Eq. [19] indeed reduces to that isotherm for $z = 0$. An isotherm similar to Eq. [19], but using the "inner Helmholtz" potential ϕ_i instead, was used by Grahame (91) and by Parry and Parsons (107).

In some cases, as with chloride, Eq. [19] appears to overemphasize the effect of the diffuse double layer; and better agreement with experiment is obtained with only a fraction of the term $z\mathbf{F}\phi/RT$ in the exponent.

Interestingly, the inclusion in the isotherm of a term in ϕ leads to behavior like that observed by Dutkiewicz and Parsons (100), without the need to invoke salt activities rather than ionic ones, as can clearly be seen by comparison of Fig. 5 and 6.

APPENDIX 3: THE DETERMINATION OF β

For systems exhibiting congruent adsorption isotherms, β, and consequent surface activity βa, and surface activity coefficient $\beta a/\Gamma$, can be obtained from the surface pressure either at constant effective potential or at constant electrode charge density. When the isotherm is not congruent, then curve fitting to a theoretical or empirical adsorption isotherm appears to be the only available alternative. Although ΔG°_{ads} would seem to be a thermodynamic quantity, there is as yet no purely thermodynamic way to determine ΔG°_{ads} or β for ions.

Acknowledgments

Extensive assistance with various aspects of this work by Dr. L. Pospíšil, Miss J. C. Kreuser, and Mr. J. K. Corless, and helpful discussions with Dr. Roger Parsons and Professor Fred C. Anson are gratefully acknowledged, as is the financial support of this work by the National Science Foundation (Grant GP 8575), the Air Force Office of Scientific Research (OAR,

USAF, Grant 68-1344), and the Office of Naval Research.

Manuscript submitted Nov. 6, 1970; revised manuscript received ca. Feb. 26, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Formation of $PbSO_4$ Crystallites on Pb in the Lead-Acid Cell

Takewo Chiku* and Koichi Nakajima

Toyota Central Research and Development Laboratories, Inc., Nagoya, Japan

ABSTRACT

Formation of lead sulfate crystallites on lead during the electrochemical reaction has been examined by electron microscopy and x-ray diffraction techniques. It was found (*i*) that lead sulfate as the active material nucleates preferentially on the crystal surface of lead and grows dendritically, depending on the condition of discharging; also that the crystallographical relation shows a tendency to have Pb [100]//$PbSO_4$ [100] for the (001) plane and Pb [$1\bar{1}0$]// $PbSO_4$ [010] or [111] for the (111) plane of Pb, and (*ii*) that the morphology of the lead sulfate as the active material seems to be different from the lead sulfate not transformed to Pb, even in a fully charged condition.

Burbank (1, 2) studied lead oxide and the three basic sulfates of the lead-acid cell by x-ray and electron microscope techniques and found that these basic sulfates were transformed into prismatic and nodular particles of PbO_2 by anodic oxidation. She (2) also observed that crystals of PbO_2 in a state of discharge varied from prismatic individuals to complex spherulitic formations, depending on how the electrode plates were prepared and the progress of the electrochemical reaction.

The electrochemical reaction which occurs on the positive plate is characterized by the formation and consumption of H_2O during the reaction. It may be important to consider this in the mechanism of nucleation and formation or decomposition of PbO_2 and the basic sulfates in the positive plate, since it suggests that the characteristics of the reaction process produce complicated substances similar to those obtained by Burbank.

Formation of active material in the negative plate during anodic oxidation depends directly on the existence of sulfate ions; therefore, the formation of lead sulfate should depend considerably on the concentration of sulfate ions along the surface of the plate during the progressive reaction.

Recently it has been shown (3, 4) that lead sulfate crystallites grow dendritically on lead crystal surfaces, especially on the (100) and (111) planes. The purpose of this study was to determine how lead sulfate crystallites nucleate and grow onto Pb during the process of discharging.

Experimental Procedure

Single crystals of Pb were prepared in the form of cylindrical rods 10 mm in diameter, which were cut parallel to the (111) and (100) planes by the modified Bridgman method. A Servomet spark erosion machine was used for the cutting. Part of the cut surface was then removed by chemical polishing in a solution containing four volumes of CH_3COOH and one volume of H_2O_2 (30%).

* Electrochemical Society Active Member.

Key words: electron microscopy, x-ray diffraction, nucleation.

The specimens were annealed at 300°C for 3 hr in vacuum and then used as electrode plates which were charged and discharged under conditions shown in Table I. The specific gravity of the electrolyte was 1.260 at 20°C. These electrode plates were then washed thoroughly with distilled water and dried at room temperature under reduced pressure.

Extraction replicas were prepared from the surfaces by a standard two-stage plastic carbon replication technique. Chromium was used as the replica shadowing material to determine the crystallographical relationship between $PbSO_4$ and Pb as the active material. Electron microscopic observations were made with a JEOL (JAPAN) JEM-6A electron microscope at 100 kV.

Crystallographic orientation was determined by the x-ray diffraction technique. Shadowing by chromium was carried out from the direction of the projection parallel to [100] direction for the specimen cut parallel to (001) and [110] direction for the specimen cut parallel to (111). The glancing angle was 28.5°.

Samples used for x-ray measurements were taken from a commercial battery at various stages of discharge (Fig. 1). At each stage they were put into a small polyethylene bag together with the electrolyte solution of the battery and then mounted on a specimen holder.

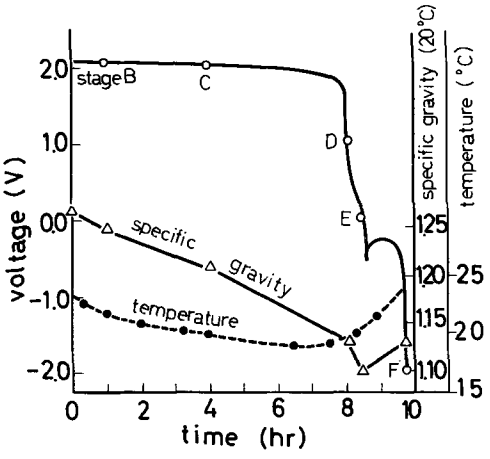

Fig. 1. Characteristic curves of discharge (at 4A) in the battery examined.

Results

Observation of the crystal surface of lead crystal dipped in the electrolytic solution.—Figure 2 shows an example of the electron micrographs and the selected area diffraction patterns obtained from the (001) plane dipped in the electrolytic solution for 2 hr. From the diffraction patterns, the materials extracted were found to be $PbSO_4$. Prismatic individuals of $PbSO_4$ are observed irrespective of the orientation of the surface of the lead crystal.

To obtain a clean surface of Pb single crystals, the surfaces of each of the specimens were polished chemically and then reduced cathodically at 200 or 800 μA for 30 sec. No extracted materials were observed after this treatment, but in some cases small amounts of the materials were found to exist on the surface and were determined to be $PbSO_4$ crystallites. These were thought to be caused by the deoxidization of the lead oxides during the cathodic charging.

Nucleation and growth of lead sulfate crystallites during discharging.—Figures 3-6 show morphological changes of the $PbSO_4$ crystallites. Results obtained after discharging at 200 μA for 30 sec and 800 μA are shown in Fig. 3 and 4, respectively. These electron micrographs show a dendritic $PbSO_4$ formed from Pb during the process of discharging. The formation condition of the $PbSO_4$ dendrite on a definite lattice plane of a Pb crystal can be determined from the analysis of an electron micrograph and the corresponding diffraction pattern. It should be noted first that the electrochemical reaction does not proceed homogeneously over the whole surface of the electrode plate but locally, depending on the crystal orientation. Second, the relationship between crystallographical orientation of the surface of the lead crystals and the

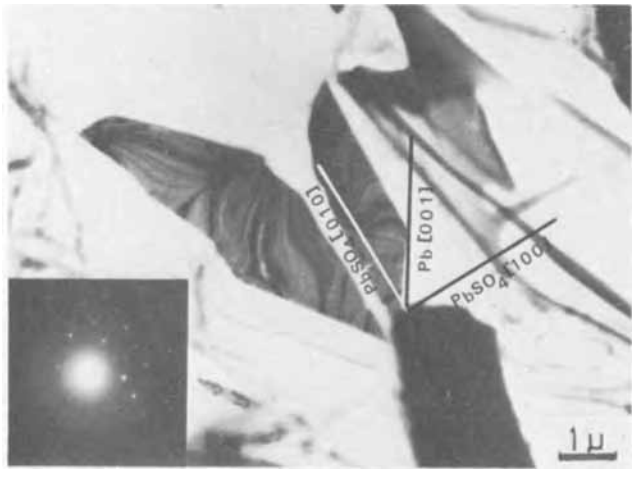

Fig. 5. Electron micrograph of an extraction replica taken from (100) plane of Pb single crystal discharged at 100 μA for 60 sec in the electrolyte solution.

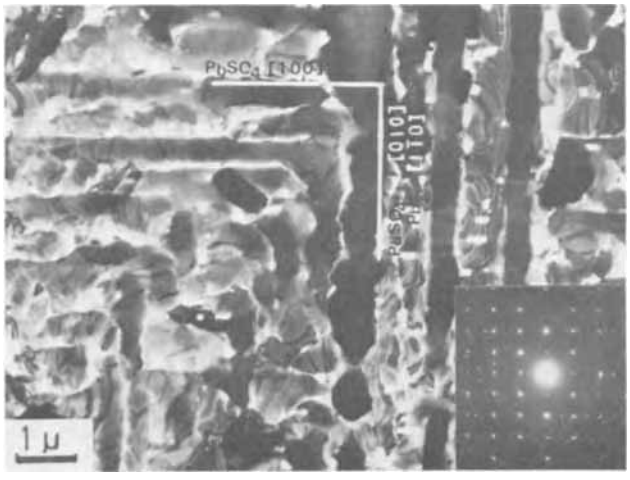

Fig. 6a. Electron micrograph of an extraction replica taken from (111) plane of Pb single crystal discharged at 200 μA for 300 sec in the electrolyte solution.

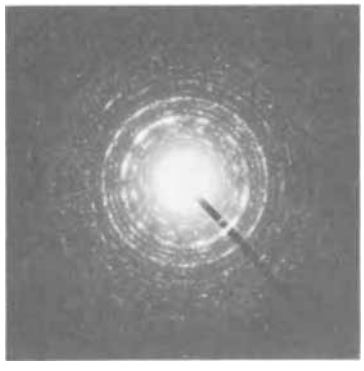

Fig. 6b. Diffraction photograph of the same sample obtained by using a high resolution diffraction technique. The area irradiated was taken to be about 0.1 mm in diameter.

$PbSO_4$ clearly depends on the condition of anodic oxidation. Figure 5 shows the result obtained with the (001) plane of Pb crystals after discharging at 100 μA for 60 sec; dendritic growth of $PbSO_4$ crystallites can hardly be observed.

With an increase of discharge current, the formation of $PbSO_4$ crystallites appears to give rise to a typical dendrite having an immediate connection with the crystal orientation of Pb. Figure 4 is an example of the type of formation of $PbSO_4$ referred to as the dendritic growth. This is found more frequently on the (001) plane of Pb crystal and results from discharging at 800 μA for 20 sec. The crystallographic relation yields to Pb [100] // $PbSO_4$ [100], and in some cases to Pb [100] // $PbSO_4$ [211]. Figure 6a illustrates the dendritic growth of $PbSO_4$ on the (111) plane of Pb crystals, showing a somewhat different crystallographic relation compared with that in the (001) plane. The relationship is determined by Pb [$1\bar{1}0$] // $PbSO_4$ [010] or Pb [$1\bar{1}0$] // $PbSO_4$ [111].

To correlate these crystallographic relationships with crystal structures it is necessary to know the detailed structure of the $PbSO_4$ crystal. It is orthorhombic in structure, having $a_o = 8.48$Å, $b_o = 5.40$Å, and $c_o = 6.96$Å, and contains four molecules per cell. The positions of Pb and S in the unit cell are given (7) but those of the O atoms are not as yet clear.

A high resolution diffraction technique was applied in order to investigate a wide region of the extraction replica. Figure 6b shows the diffraction obtained. The area irradiated was approximately 100μ in diameter. It can be seen that the $PbSO_4$ crystallites cluster around

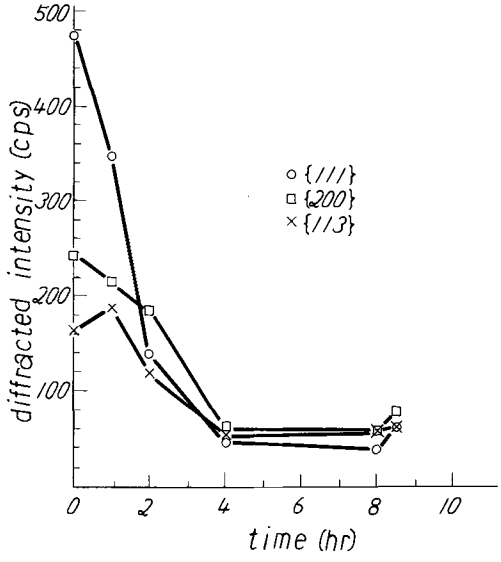

Fig. 7. Changes in the negative plate of the diffracted intensity of some diffraction lines of Pb and $PbSO_4$.

certain orientations. It is interesting to note that the diffraction pattern shown is identical with that of $PbSO_4$, but the selected area diffraction pattern obtained from the same specimen shows some extra diffraction where the spots correspond to the forbidden reflection, *i.e.*, (100), (010), and (100). This suggests that these spots appear due to double reflection.

X-ray diffraction analysis for the transformation of Pb to $PbSO_4$.—Figure 7 shows the change in diffracted intensity of the {111}, {200}, and {113} planes in Pb with increase in time of discharging. It can be clearly seen that (*i*) the diffracted intensity from each plane decreases rapidly and (*ii*) the relative intensity of these reflecting planes deviate greatly from that in the normal state. For example, the relative $I_{111}:I_{200}:I_{113} = 100:50:32$ in the initial stage becomes 8:12:11 after discharging at 4A for 8 hr, indicating that the nucleation and growth of $PbSO_4$ on the surface of Pb becomes more dense on the crystal surface of a definite orientation.

The diffracted intensity from each plane decreases with the time of discharging, but the rate of decreasing depends on the crystal orientation. The results obtained here were about 1/12 for {111}, 1/4 for {200}, and 1/3 for {113}, respectively, in the nearly zero terminal voltage stage. This suggests that the {111} plane of Pb may be a habit plane for the nucleation of $PbSO_4$ during discharging. The electron micrographic observations also show that the lead sulfate grew dendritically on the Pb crystal surface, especially on the (100) and (111) planes.

An interesting result was obtained by analysis of diffracted intensity from various planes of Pb composed of the negative plates of new and old fully charged batteries. As shown in Table II, the intensity of {111} reflection from the new battery differs greatly from that in the old battery, but not for those of other

Table II. Diffracted intensity from various lattice planes of Pb and $PbSO_4$ crystallites in fully charged batteries

Pb	111	100	100	(820 Hz)	100	(210 Hz)
	200	50	58	(476 Hz)	116	(244 Hz)
	311	32	26	(213 Hz)	125	(262 Hz)
$PbSO_4$	112	35	13	(13 Hz)	39	(82 Hz)
	020	46	13	(13 Hz)	64	(134 Hz)
	211	100	100	(100 Hz)	100	(210 Hz)
	102	71	52	(52 Hz)	85	(179 Hz)
	210	86	74	(74 Hz)	106	(223 Hz)
	002	33	65	(65 Hz)	37	(78 Hz)
	201	23	17	(17 Hz)	29	(61 Hz)

reflecting planes. This was probably caused by preferential nucleation and growth of $PbSO_4$ on the {111} plane of Pb. Diffracted intensities from various lattice planes of $PbSO_4$ and age of the battery are given in Table II. It can be seen from this table that $PbSO_4$ crystallites formed on Pb with a preferred orientation.

X-ray examinations were carefully carried out to distinguish crystallographically between $PbSO_4$ as the active material and the other type of $PbSO_4$ not being transformed to Pb. No change of crystal structure could be observed in either of them. The present study points up an important lead in determining how the amounts of $PbSO_4$ in the electrode plate increase with the age of batteries, even in the fully charged state. The morphological change of $PbSO_4$ crystallites on the electrode plate must be intimately related as to whether or not the $PbSO_4$ formed is effective as the active material. Lead sulfate formed in connection with the crystallographic relation (Fig. 3) transforms completely to Pb as a result of cathodic charging, while the other type of $PbSO_4$ formed during soaking in electrolytic solution (Fig. 2) keeps its configuration, even in the fully charged state.

As shown in Table II, a considerable decrease of diffracted intensity is clearly seen in the {111} and {200} planes of Pb in the negative plate, depending on how much the battery is used. This suggests that these planes in Pb crystallites are exhausted with the aging of the battery by the formation of $PbSO_4$. In other words, the age of the battery is estimated roughly from the total residual area of {111} or {100} planes in each particle composing the electrode plate.

The integral breadth of diffraction lines of Pb as the active material was observed to increase [or decrease (3)] gradually with the time of charging (or discharging), approaching the value of metallic Pb when the terminal voltage became nearly zero. The highly strained state produced during cathodic charging may be explained in terms of hydrogen impregnation occurring during the charging. The elastic stored energy was estimated to be about 0.05 cal/g (3). In fact, hydrogen adsorption is known (5) to reduce the surface tension of metal, and the adsorbed hydrogen slows down the discharge of metallic ions (6) with increasing polarization and results in occurrence of a strained state in the matrix.

Summary

Nucleation and growth of lead sulfate crystallites as the active material on an electrode plate were examined by electron microscopy and x-ray diffraction techniques. The results were as follows:

1. In the early stage of anodic oxidation, lead sulfate crystallites nucleate preferentially on the crystal surfaces of Pb having low indices, especially the (001) and (111) planes, and grow dendritically depending on the condition of discharging. The crystallographic relation between them is given by $Pb[100]//PbSO_4[100]$ for the (001) plane of Pb, and $Pb[1\bar{1}0]//PbSO_4[010]$ or [111] for the (111) plane of Pb.
2. The crystal structure of lead sulfate as the active material could not be distinguished from that of the other type of $PbSO_4$. It was not transformed to Pb even in the fully charged state, but a morphological change could be seen in both forms of $PbSO_4$.

Acknowledgment

The authors wish to express their thanks and appreciation to Mr. A. Isogai, Mr. T. Ishiguro, and Mr. and Mrs. H. Kojima for their diligent aid throughout the course of the work.

Performance Characteristics of Solid Electrolytes under Steady-State Conditions

N. S. Choudhury* and J. W. Patterson**

Deparmtent of Metallurgy and Engineering Research Institute, Iowa State University, Ames, Iowa 50010

ABSTRACT

Parametric integral equations for the steady-state terminal voltage and external current of a solid electrolyte energy conversion device are derived under the assumption that the anode and cathode chemical potentials remain invariant. Plots of terminal voltage, power delivered, and efficiency *vs.* external current are generated for yttria-doped thoria at 1600°C by first inserting the appropriate functional dependencies for the ionic and electronic conductivities into the parametric equations and then systematically eliminating the common parameter. The formulas are also used to calculate and plot the chemical potential profiles inside the yttria-doped thoria solid electrolyte under applied voltage (charging) as well as under load (discharging) conditions.

The feasibility of an electrochemical energy conversion device (*e.g.* battery, fuel cell, etc.) for any particular application depends on its voltage-current characteristics. Once the relationship between terminal voltage and external current is known, the delivered power and efficiency of the device may be estimated for proposed operating conditions. Such operating characteristics are usually obtained empirically by merely observing device response to preselected charge and discharge conditions.

Observed variations in terminal voltage with external current may be rationalized in terms of various

polarization effects associated with (*a*) mass and charge transport through the electrodes and electrolyte, and (*b*) transfer reaction kinetics at the electrodes. Although extensive experimental and theoretical effort has been directed to the polarization effects associated with electrodes and electrode-electrolyte interfaces, polarization effects within the bulk of the electrolyte have received much less attention.

The present paper concerns polarization effects within solid electrolytes. In particular, Wagner's theory of mixed conduction (1, 2) is used to obtain quantitative methods for calculating terminal voltage, external current, delivered power, efficiency, and chemical potential profiles (3) for virtually stoichiometric solid electrolytes under steady-state conditions of charge and discharge.

Expressions for Current and Voltage for Solid Mixed Conductors at Steady-State

Consider the electrochemical system depicted schematically in Fig. 1. For generality the M_aX_b solid electrolyte is presumed to exhibit a perceptible amount of electronic conductivity σ_3 in addition to the cationic and anionic conductivities σ_1 and σ_2. Chemical conditions in electrodes 1 and 2 serve to fix the nonmetal chemical potentials μ_{X_2}' and μ_{X_2}'' in the respective electrode compartments.

The chemical potentials $\mu_{X_2}(O)$ and $\mu_{X_2}(L)$ prevail just inside the electrolyte at the corresponding electrode-electrolyte interfaces. If mass transfer polarization effects external to the electrolyte can be neglected, $\mu_{X_2}(O) = \mu_{X_2}'$ and $\mu_{X_2}(L) = \mu_{X_2}''$ even under load or discharge conditions. Because we are considering only losses within the electrolyte, this assumption of completely reversible behavior is employed below. Departures from these equalities are the subject of electrode and interface polarization effects external to the electrolyte (4).

The electronic leads connecting the electrode-electrolyte interfaces to the external circuit in Fig. 1 are assumed to be of identical composition so that the electrochemical potential difference $\eta_3'' = \eta_3'$ for electrons in leads 2 and 1 is related to the terminal voltage V_T by

$$\eta_3'' - \eta_3' = -\mathbf{F}\,V_T \qquad [1]$$

where $\mathbf{F}$ is Faraday's constant. Electronic polarization effects outside the solid electrolyte are neglected by assuming the electrochemical potential of electrons $\eta_3(O)$ and $\eta_3(L)$ just inside the electrolyte at the O and L interfaces are respectively equal to η_3' and η_3''.

According to Wagner's theories (1, 2), the local charge fluxes I_1 (due to cations), I_2 (due to anions), and I_3 (due to electrons) may be written in terms of the corresponding partial conductivities σ_i, electrochemical potential gradients $\nabla\eta_i$ and valences Z_i as follows

$$I_i = -A(\sigma_i/Z_i\mathbf{F})\nabla\eta_i; \quad i = 1, 2, 3 \qquad [2]$$

where $\mathbf{F}$ is Faraday's constant, and A is the cross sectional area of the solid electrolyte. The assumptions of local equilibria involving neutral atoms, ions, and electrons—and the condition of virtual stoichiometry combined with the Gibbs-Duhem relation between the species M and X—facilitates the elimination of the nonmeasurables η_1 and η_2 in favor of the variables μ_{X_2} and η_3 whose differences can be measured and controlled in physical systems. There results

$$I_{ion} = -A\,\sigma_{ion}(\nabla\mu_{X_2}/2Z_2\mathbf{F} + \nabla\eta_3/Z_3\mathbf{F}) \qquad [3]$$

and

$$I_3 = -A\,\sigma_3\,\nabla\eta_3/Z_3\mathbf{F} \qquad [4]$$

where $I_{ion} = I_1 + I_2$ and $\sigma_{ion} = \sigma_1 + \sigma_2$.

The condition of steady-state requires that I_1, I_2, and I_3 must individually be independent of location. Therefore the ratio

$$r = I_{ion}/I_3 \qquad [5]$$

is also independent of location. In this paper the parameter r is used to characterize the steady-state condition of the solid electrolyte because for fixed values of μ_{X_2}', μ_{X_2}'', and temperature T, each value of r corresponds uniquely to a particular external current I_{ext} and terminal voltage V_T. The quantitative formulas for I_{ext} and V_T in terms of σ_i, μ_{X_2}', μ_{X_2}'', and r may be readily derived by appropriate integration under the assumptions of steady-state conditions and negligible polarization outside the electrolyte phase.

Substitution of Eq. [3] and [4] into [5] solved for $\nabla\eta_3$ gives

$$\nabla\eta_3 = \frac{Z_3}{2Z_2}\left(\frac{\sigma_{ion}}{r\sigma_3 - \sigma_{ion}}\right)\nabla\mu_{X_2} \qquad [6]$$

Integration of Eq. [6] from one end of the electrolyte to the other, division by $\mathbf{F}$, and use of Eq. [1] yields

$$V_T = \int_{\mu_{X_2}'}^{\mu_{X_2}''}\left(\frac{\sigma_{ion}}{r\sigma_3 - \sigma_{ion}}\right)\frac{d\mu_{X_2}}{2Z_2\mathbf{F}} \qquad [7]$$

as the explicit formula for the terminal voltage in terms of r, μ_{X_2}', μ_{X_2}'' and appropriate transport parameters for the M_aX_b phase. For any given value of r the integrand in Eq. [7] is a function of μ_{X_2} only and the integral may be evaluated explicitly when the dependence of σ_{ion} and σ_3 on μ_{X_2} are known for the electrolyte in question.

The external current I_{ext} is simply the sum of I_{ion} and I_3. Thus I_{ext} may be written as

$$I_{ext} = I_3 + I_{ion} = -\frac{A(1 + r)\sigma_{ion}\sigma_3}{(r\sigma_3 - \sigma_{ion})}\frac{\nabla\mu_{X_2}}{2Z_2\mathbf{F}} \qquad [8]$$

where Eq. [3], [4], [5], and [6] have been used to eliminate I_{ion}, I_3, and $\nabla\eta_3$ in favor of the variables σ_{ion}, σ_3, $\nabla\mu_{X_2}$ and the parameters A, Z_2, r, and $\mathbf{F}$. Integration of Eq. [8] under the assumption of linear flux geometry and the steady-state implication that I_3 and I_{ion} are independent of location in the electrolyte yields

$$I_{ext} = -\frac{A}{L}\int_{\mu_{X_2}'}^{\mu_{X_2}''}\frac{[1 + r]\sigma_{ion}\sigma_3}{(r\sigma_3 - \sigma_{ion})}\frac{d\mu_{X_2}}{2Z_2\mathbf{F}} \qquad [9]$$

In Eq. [9] as in [7] the integral may be evaluated explicitly if the dependences of σ_{ion} and σ_3 on μ_{X_2} are known from independent measurements and if the values of μ_{X_2}', μ_{X_2}'', and r are specified.

The functional dependences of σ_{ion} and σ_3 on μ_{X_2} (or equivalently log P_{X_2}) may be determined experimentally from a-c conductivity, d-c polarization, and open circuit emf measurements on appropriate cell arrangements involving M_aX_b specimens (2, 5). Alternately the dependences may at least in part be inferred from law of mass action considerations involving the species believed to dominate the defect struc-

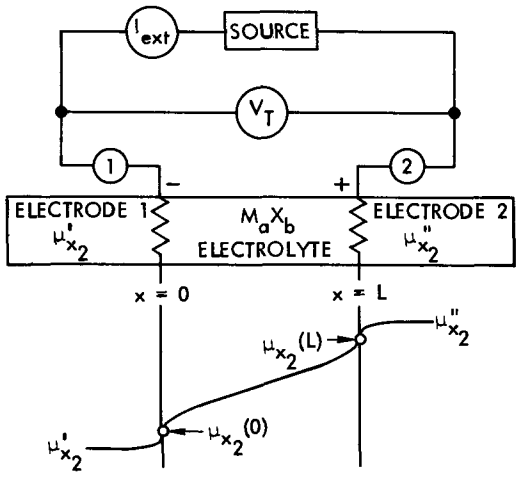

Fig. 1. Schematic representation of a solid electrolyte energy conversion device.

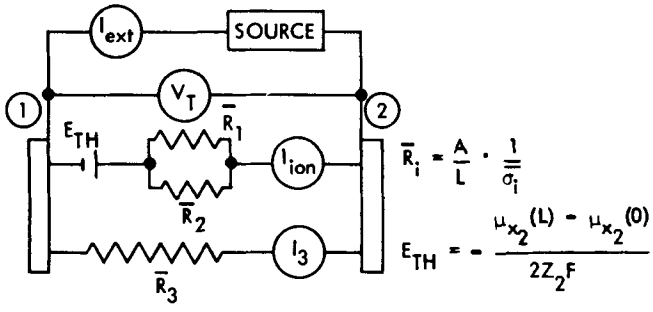

Fig. 2. Linear circuit analog for a solid electrolyte energy conversion device.

ture of the M_aX_b compound (6-9); in the present context, however, the dependences of σ_{ion} and σ_3 on μ_{X2} are assumed to be available from independent sources. We may therefore turn to the task of generating the voltage-current characteristics with the help of Eq. [7] and [9] which are parametric in r.

In principle the procedure is quite simple. One merely ranges r over as many values as desired. For each r, V_T and I_{ext} are evaluated from Eq. [7] and [9] and then plotted *vs.* one another to form the voltage-current characteristic curve. However, the range of r values to be chosen for a given assessment may not be too obvious at first glance. Thus the equivalent circuit shown in Fig. 2 is offered for assistance. Because the values of $\bar{\sigma}_i$ and hence of $\bar{R}_i$ may depend on the applied current and voltage, the equivalent linear circuit shown in Fig. 2 is only a very crude way to approximate the behavior of the physical system depicted in Fig. 1. Nevertheless, Fig. 2 provides some insight into the ranges of r that correspond to particular modes of steady-state behavior.

If the source is a load resistor of infinite impedance or a battery with an appropriate bucking emf, I_{ext} vanishes, and the electrolyte is said to be functioning in the open circuit mode. Inspection of the circuit diagram in Fig. 2 indicates that neither I_{ion} nor I_3 vanish in the open circuit case but rather $I_{ion} = -I_3$, *i.e.* $r = -1$. Figure 2 also indicates that the open circuit magnitudes of I_3 and I_{ion} depend not only on the overall ionic and electronic resistances but also on the magnitude of the thermodynamic voltage E_{TH} (indicated as a battery in Fig. 2) generated by chemical conditions of the electrodes. The magnitude of E_{TH} is given by

$$E_{TH} = -(\mu_{X_2}'' - \mu_{X_2}')/2Z_2F \qquad [10]$$

It is easy to demonstrate that the above assertions are in accordance with Wagner's tarnishing theory by substituting $r = -1$ into Eq. [9] to get $I_{ext} = 0$ and into Eq. [7] to get Wagner's well-known result

$$E_W = -\int_{\mu_{X_2}''}^{\mu_{X_2}''} \frac{t_{ion}}{2Z_2F} d\mu_{X_2} \qquad [11]$$

where the ionic transference number t_{ion} is defined as $t_{ion} = \sigma_{ion}/[\sigma_{ion} + \sigma_3]$.

If the source in Fig. 1 is a battery with the same polarity and emf as E_{TH}, I_{ion} vanishes and $I_{ext} = I_3$ only. In this case $r = 0$, and the physical situation corresponds to the stopping voltage for scaling of metals (9, 10) or to the conditions corresponding to the Hebb-Wagner (2, 11, 12) d-c polarization technique for studying the electronic conductivity of mixed conductors. If the source battery polarity remains the same but its emf is increased, the M_aX_b electrolyte is said to be in the charging mode. By inspection, the charging mode corresponds to r values greater than zero.[1]

If the source voltage is less than E_W as given by Eq. [11] the electrolyte is said to be discharging under load.

[1] Because it is of such little interest in practical cases, we omit consideration of another $r > 0$ mode that results when the polarities of the source voltage and E_{TH} are not opposed.

By inspection of Fig. 2 it is seen that I_{ion} and I_3 will flow in opposite directions, and it is found that the range of r from -1 (open circuit) to $-\infty$ (dead short) covers all possible load conditions. This mode of operation (*i.e.* steady-state discharge) will be examined below to demonstrate the use of Eq. [7] and [9] to calculate current, voltage, power, and efficiency.

Analogous calculations and characteristic curves can also be made for the charging mode ($r > 0$) of operation but this case is not analyzed in detail. Chemical potential profiles are calculated and plotted below for linear geometry solid electrolytes in the charge ($r > 0$), discharge ($r < -1$), and open circuit ($r = -1$) modes.

Calculations for Special Cases

Specific calculations for a given electrolyte require that the dependences of σ_3 and σ_{ion} on μ_{X2} (or equivalently on log P_{X_2}) be known in some detail for the temperature and electrolyte of interest. Unfortunately, information of this type is available for only a few solid electrolytes and for only limited temperature ranges (5, 13). Furthermore, because of the discrepancies reported from investigator to investigator, those data which now exist can only yield an approximation to the functional dependences required. Nevertheless it is useful to demonstrate the calculation of the various characteristic curves by analyzing a solid electrolyte for which the required data (however approximate) are presently available.

The oxide solid electrolyte YDT (yttria-doped thoria $= Th_{0.85}\ Y_{0.15}\ O_{1.925}$) has been chosen for the calculations. By combining the results of various conductivity measurements (8), emf measurements (14), and assumptions regarding the defect structure of YDT, the following dependences of σ_3 and σ_{ion} for YDT may be used

$$\sigma_3 = \sigma_{ion}[(P_{O_2}/P_\oplus)^{1/4} + (P_{O_2}/P_\ominus)^{-1/4}] \qquad [12]$$

The ionic conductivity σ_{ion} is due to oxygen ion vacancies and is fixed at a given temperature by the dopant. Hence σ_{ion} is independent of P_{O_2} but exhibits an Arrhenius temperature dependence which at 1600°C gives a value of

$$\sigma_{ion}(1600°C) = 0.10\ \text{ohm}^{-1}\ \text{cm}^{-1} \qquad [13]$$

The Schmalzried parameters $P_\oplus$ and $P_\ominus$ in Eq. [12] also exhibit an Arrhenius temperature dependence (13) and for YDT at 1600°C they have the values

$$P_\oplus(1600°C) = 100\ \text{atm} \qquad [14]$$

and

$$P_\ominus(1600°C) = 10^{-19}\ \text{atm} \qquad [15]$$

Equations [7] and [9] may be evaluated for any r value by substituting Eq. [12] and [13] into the integrands and changing the variable of integration to P_{O_2}. Calculations at other temperatures merely require knowledge of the temperature dependences of σ_{ion}, $P_\oplus$, $P_\ominus$ and the end points of integration P_{O_2}' and P_{O_2}''.

Calculation of Discharge Characteristic Curves

Under load conditions the power P_d delivered by the electrolyte is simply I_{ext} times V_T which may be readily evaluated from Eq. [7] and [9] for various values of r. The consumption rate P_c of chemical energy stored in the electrodes is simply $I_{ion} = I_{ext}\ r/(r+1)$ times the thermodynamic emf E_{TH}. Thus the power P_d, the efficiency $e = P_d/P_c$, and the terminal voltage V_T for the electrolyte under steady-state discharge conditions may be calculated along with I_{ext} for any values of r in the range -1 to $-\infty$. The plots of P_d, e, and V_T *vs.* I_{ext} in this range of r values comprise the discharging characteristic curves for the electrolyte in question.

Figure 3 shows the results of the calculations for P_{O_2}' and P_{O_2}'' values corresponding to $P_\ominus$ and $P_\oplus$ respectively. Because the electrode chemical potentials extend well beyond the electrolytic domain (5, 13) for the electrolyte, the parasitic effects of electronic conduction on the efficiency add significantly to the in-

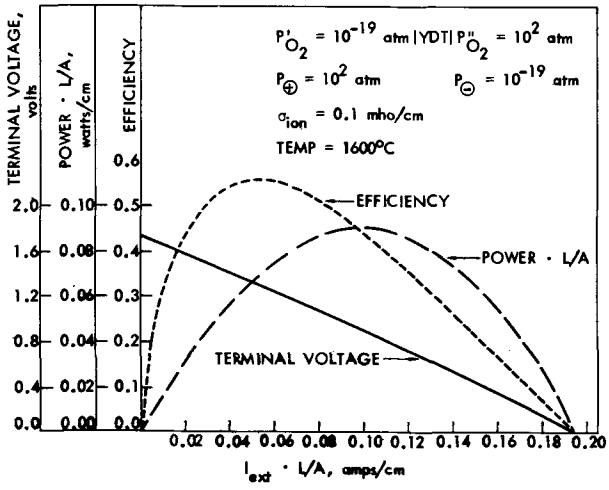

Fig. 3. Plot of terminal voltage, power, and efficiency vs. external current for yttria-doped thoria electrochemical cell having cathode $P_{O_2} = P_\oplus$ and anode $P_{O_2} = P_\ominus$.

escapable loss associated with the ionic resistance of the YDT solid electrolyte. In order to avoid special assumptions regarding the geometric factor L/A, external current and power quantities were calculated and plotted as $I_{ext}(L/A)$ A/cm and $P_d(L/A)$ W/cm. The efficiency e and terminal voltage V_T are independent of the L/A ratio.

In order to demonstrate the parasitic effects of electronic conduction the following four pairs of end points of integration were investigated:

	P_{O_2}' atm	P_{O_2}'' atm
Case 1	$10^{-10.5}$	$10^{-6.5}$
Case 2	$10^{-14.5}$	$10^{-10.5}$
Case 3	$10^{-18.5}$	$10^{-14.5}$
Case 4	$10^{-22.5}$	$10^{-18.5}$

In Fig. 4-6 respectively, the power delivered, the efficiency, and the terminal voltage *vs.* the external current are shown for each of the above cases. Although the thermodynamic voltage is the same for each of the cases, the figures show that P_d L/A, e, and V_T all decrease as the electrode P_{O_2}' and P_{O_2}'' values are shifted to lower values. This is due to the increase in excess electronic conduction in YDT at reducing conditions. A symmetric effect would also result if the P_{O_2}' and P_{O_2}'' value were similarly shifted upward, due

to increased positive hole conduction at oxidizing conditions. Because both these forms of electronic conduction detract significantly from the efficiency, the most efficient operation results (for a given difference between log P_{O_2}'' and log P_{O_2}') if the values of log P_{O_2}' and log P_{O_2}'' are chosen symmetrically about the log P_{O_2} at which the excess electron conductivity $\sigma_\ominus$ equals the positive hole conductivity $\sigma_\oplus$; *i.e.* the point of minimum electronic conductivity log P_{np}.

Chemical Potential Profile Calculation

In a recent paper Choudhury and Patterson (3) demonstrated a method for calculating chemical potential profiles in solid electrolytes under open circuit ($r = -1$) and ion blocking ($r = 0$) steady-state conditions. To supplement those results the chemical potential profiles for a range of charging ($r > 1$) and discharging ($r < -1$) conditions are given below for YDT at 1600°C.

The basic idea in generating these profiles is the conservation of some appropriate flux throughout the electrolyte's interior. Conserving I_{ion} yields

$$I_{ion} = -\frac{A}{x}\int_0^x \sigma_{ion}\,\nabla\eta_2 dx \qquad [16]$$

where

$$\eta_2 = \mu_{X2} + (Z_2/Z_3)\,\eta_3 \qquad [17]$$

Substitution of Eq. [17] into [16], integrating from O to x and then from O to L, and assuming σ_{ion} to be constant yields

$$I_{ion} = \frac{\sigma_{ion} A}{x} \{[\mu_{X_2}(x) - \mu_{X_2}'] + 2\mathbf{Z}_2\mathbf{F}V_T(r,x)\} \quad [18]$$

and

$$I_{ion} = \frac{\sigma_{ion} A}{L} [(\mu_{X_2}'' - \mu_{X_2}') + 2\mathbf{Z}_2\mathbf{F}V_T(r,L)] \quad [19]$$

where $V_T(r, x)$, the voltage drop from $x = 0$ to x, and $V_T(r, L)$, the voltage drop across the entire length, are evaluated for a particular value of r with the help of Eq. [7]. Division of Eq. [18] by Eq. [19], rearrangement, replacement of X_2 with O_2, and elimination of μ_{O_2} in favor of P_{O_2} yields

$$\frac{x}{L} = \left[\frac{\log|P_{O_2}/P_{O_2}'| - 4\mathbf{F}V_T(r,x)/RT}{\log|P_{O_2}''/P_{O_2}'| - 4\mathbf{F}V_T(r,L)/RT}\right] \quad [20]$$

where R is the gas constant and T the absolute temperature. By selecting r and any value of P_{O_2} between the endpoint values P_{O_2}' and P_{O_2}'', the corresponding x/L value is readily calculated with the help of Eq. [7]. Repeating this procedure for a constant r and plotting the corresponding log P_{O_2}, x/L values yields the desired chemical potential profile in the form of a log P_{O_2} *vs.* x/L plot.

The profiles shown in Fig. 7 were generated in this way for the values of r indicated. The value of V_T for each r is also shown. Figure 7 supplements the earlier results of Choudhury and Patterson (3) which applied only to the open circuit ($r = -1$) and ion blocking ($r = 0$) conditions. It is seen that a dead short ($V_T = 0$) over the electrolyte yields a linear chemical potential profile. Applying an emf V_T of the same polarity

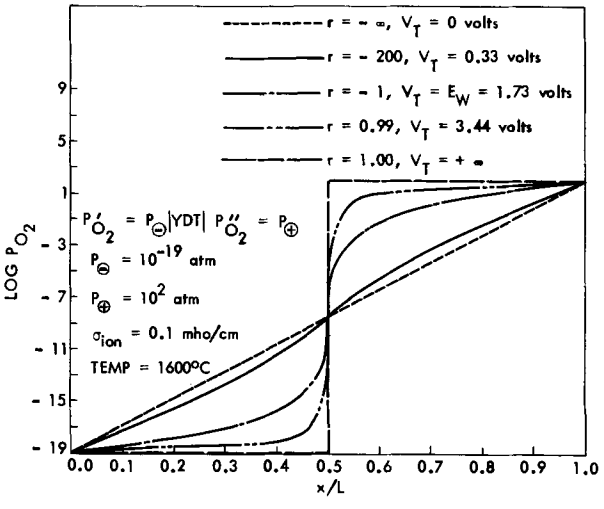

Fig. 7. Steady-state chemical potential profiles in yttria-doped thoria while holding $P_{O_2}' = P_\ominus$ and $P_{O_2}'' = P_\oplus$ constant.

as E_W but much greater in magnitude causes the profile to become increasingly abrupt. The limiting profile is a step function.

Interestingly, the inflection points (which always occur at log P_{np}) all superpose at $x/L = 0.5$ in Fig. 7. This somewhat fortuitous circumstance is a result of the symmetrically chosen endpoints of integration as well as the linear cell geometry. However, when the values of log P_{O_2}' and log P_{O_2}'' are not chosen symmetrically about log P_{np}, the inflection points are displaced for each value of r. Figure 8 shows a family of profiles for which this is the case. As an extreme case of asymmetry, P_{np} may not lie between P_{O_2}' and P_{O_2}''. In these cases the profiles exhibit no inflection points but will possess a maximum slope either at $x = 0$ or $x = L$. Figure 9 shows a family of profiles for which P_{np} does not lie intermediate between P_{O_2}' and P_{O_2}''. The general rule (1) according to Eq. [8] and the assumption of steady state, is that the profile slope (or equivalently $\nabla\mu_{X_2}$) is a maximum at the point where the "conductivity factor" $(1 + r)\sigma_{ion}\sigma_3/(r\sigma_3 - \sigma_{ion})$ is a minimum and *vice versa*.

APPENDIX: INTEGRATED FORMULAS

Evaluation of the parametric Eq. [7] and [9] for special assumptions regarding the P_{X_2} dependences of σ_{ion}, $\sigma_\oplus$, and $\sigma_\ominus$ leads to somewhat awkwardly integrated formulas and requires that attention be restricted to r values that have physical meaning. Let us assume σ_{ion} is a constant, and σ_3 is given by Eq. [12] where exponents $\pm\frac{1}{4}$ are replaced by $\pm 1/n$ and where P_{O_2} is replaced by P_{X_2}. In this case Eq. [7] may be transformed to a standard form and integrated to yield

$$V_T = -\left(\frac{RT}{2Z_2\mathbf{F}}\right)\cdot\left(\frac{n}{\sqrt{w}}\right) \cdot\left[\ln\left|\frac{1-2r(P_{X_2}/P_\oplus)^{1/n}-\sqrt{w}}{1-2r(P_{X_2}/P_\oplus)^{1/n}+\sqrt{w}}\right|\right]_{P_{X_2}'}^{P_{X_2}''};\ w>0 \quad [21]$$

or

$$V_T = \left(\frac{RT}{2Z_2\mathbf{F}}\right)\cdot\left(\frac{2n}{\sqrt{-w}}\right) \cdot\left\{\arctan\left[\frac{2r(P_{X_2}/P_\oplus)^{1/n}+1}{\sqrt{-w}}\right]\right\}_{P_{X_2}'}^{P_{X_2}''};\ w<0 \quad [22]$$

where

$$w = 1 - 4r^2(P_\ominus/P_\oplus)^{1/n} \quad [23]$$

Also under these assumptions, I_{ext} $[L/A]$ may be written in terms of V_T as follows

$$I_{ext}(L/A) = \sigma_{ion}\left(\frac{r+1}{r}\right)\cdot(E_{TH} - V_T) \quad [24]$$

where E_{TH} is given by Eq. [10] above. Numerous limiting cases may be used to simplify Eq. [21] and [22] for practical applications.

It may appear that evaluation of Eq. [21]-[24] can be carried out for any r values in the interval from $-\infty$ to $+\infty$. However, physically meaningful results are found only for those ranges of r in which the denominator of the integrand in Eq. [7] cannot vanish. For the functional dependences assumed above, two such ranges, R_1 and R_2, exist

$$R_1:\ -\infty \leqq r < \frac{\sigma_{ion}}{\sigma_3(\max)} \quad [25]$$

and

$$R_2:\ \frac{\sigma_{ion}}{\sigma_3(\min)} < r \leqq \infty \quad [26]$$

In these relationships, $\sigma_3(\max)$ and $\sigma_3(\min)$ are respectively the maximum and the minimum values of $\sigma_3 = \sigma_\oplus + \sigma_\ominus$ occurring between the limits of integration P_{X_2}' and P_{X_2}''. $\sigma_3(\max)$ will be $\sigma_3(P_{X_2}'')$ or $\sigma_3(P_{X_2}')$, whichever is larger. $\sigma_3(\min)$ will be the smaller of these two values unless P_{np} (the P_{X_2} where $\sigma_\oplus = \sigma_\ominus$) lies between P_{X_2}' and P_{X_2}''. In the latter case $\sigma_3(\min)$ is given by $\sigma_3(P_{np})$.

Only calculations for r values in the range R_1 have been considered above because this range covers all the cases of practical interest within the scope of this paper. Values of r in R_2 correspond to the uninteresting cases where E_{TH} and V_T are not bucking each other. Calculations for r values in the interval $[\sigma_{ion}/\sigma_3(\max)] < r < [\sigma_{ion}/\sigma_3(\min)]$ are without physical meaning in the present context.

Aggressive Ion Accessibility and the Morphology of Corrosion Pits

T. Tokuda[1] and M. B. Ives

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Corrosion pits were formed under potentiostatic conditions on {100}, {111}, and {110} surfaces of nickel in 1*N* H_2SO_4 or (0.5*N* $NiSO_4$ + 0.01*N* H_2SO_4) solution by adding Cl^- ions at passive potentials. The morphologies of the pits obtained were analyzed using a model based on the atomistic mechanics of dissolution. It is found that a simulation, which removed atoms one by one according to the principle that atoms more accessible to the aggressive ions are removed more easily, approximates the morphologies of pits obtained experimentally. Observed morphological changes with the reaction rate (dependent on the degree of passivation, the potential of chloride addition and the acidity of the solution) could also be accounted for by appropriate modification of the simulation procedure. The simulation also is shown to predict the morphology of corrosion pits in body-centered cubic metals reported by other workers. It is proposed that the state of close-packing of a crystal surface is not the only factor to be considered in determining the relative dissolution rates of crystallographic surfaces when aggressive ions are present.

The pitting corrosion of metals has usually been investigated from the standpoint of electrochemistry and very rarely from the standpoint of surface morphology. However, a morphological study can provide important clues to the mechanisms of crystal dissolution, evaporation, and growth. For example, evaporation spirals have been accounted for by a mechanism in which atoms are removed from the surface step emanating from the intersection of a screw dislocation with a free crystal surface (1, 2). The pitting of single crystal metal surfaces under potentiostatic control usually results in a small number of pits which grow to sizes sufficient for ready observation of their morphology. Also, these pits are obtained on most crystal orientations due to the fact that the surface outside the pits is always in a more passive state than the interior of the pits. This is in contrast to those etch pits which can be obtained at defects on a wide variety of materials, but usually only on crystal orientations within a small angle of low-index planes (3-6). Analysis of the morphology of etch pits has been attempted by considering the relative dissolution rates of various crystal orientations (7-11). For example, Batterman (7) and Irving (8) have considered the conditions for the stability of etch hillocks and pits on germanium. Frank (9) developed a kinematic theory to relate the orientation dependence of crystal dissolution rate to the dissolution morphology obtained, and this was successfully applied (10) to the dissolution morphologies obtained by Batterman (7). This approach to the morphology of dissolution features requires, however, a large number of dissolution measurements and is applicable only to dissolution shapes resulting from starting conditions of macroscopic dimensions.

The approach used in this work is closer to the principles employed to analyze dissolution at screw dislocations (2), and extends the approach to account for the atom-atom relationships resulting from the crystal structure. This truly atomistic model of pitting provides an opportunity to simulate the removal sequences of atoms subject to specific constraints, supposed to be appropriate to the particular experimental conditions existing during pitting corrosion under potentiostatic control. The extent to which a particular simulation approaches the pit morphologies observed is taken as a measure of the appropriateness of the assumed conditions.

Morphology of Corrosion Pits on Nickel

Garz *et al.* (12) have studied the morphology of corrosion pits formed in 0.5*N* $NiCl_2$ on {111}, {100}, and {110} surfaces of nickel. They state that faces of high atomic density constitute the facets of pits obtained at high anodic potentials. They observed pit facets to be composed of {310}, {110}, and {111}. No other definitive study of corrosion pits on nickel has come to our attention.

For the present work, 99.9% nickel was used to grow single crystals of <110> and <111> axes by the Czochralski technique under argon atmosphere. Disk samples of approximately 8 mm diam were prepared of {100}, {111}, and {110} orientations by cutting the crystals in a multiple-wire seesaw system and polishing to a 0.1μ diamond finish. The polarization cell has been described in detail elsewhere (13) and consisted of a Wenking potentiostat, platinum counterelectrode, Luggin capillary connected to a saturated calomel reference electrode, and Teflon specimen holder arranged for *in situ* microscopic observation.

Pits were formed by passivating the samples in 1*N* H_2SO_4 or in (0.5*N* $NiSO_4$ + 0.01*N* H_2SO_4) for 30 min at various potentials followed by the incremental addition of chloride ion (as NaCl solution) until pitting was initiated at the chosen potential for pitting. The two electrolytes were adopted to permit a study of morphological change with acidity.

In addition to the *in situ* optical observations, scanning electron microscopy was performed on samples after removal from the cell and goniomicroscopy was used to assist the determination of pit facet orientation.

The shape and structure of typical pits observed on the various crystallographic surfaces and at both low and high "reaction rates" (*i.e.* high and low anodic current during pitting) are presented in Fig. 1-6. Pit densities were always low, being less than 20 cm^{-2}. In many cases pit facets were stepped and the orientations quoted below are the mean crystallographic orientations.

Figure 1 is representative of the only type of pit morphology observed on {100} nickel surfaces in this work. The side facets of the pits were determined to be {111} orientations and the pit bottoms were usually mottled. All efforts to change the morphology by changing the reaction rate (*e.g.* changing the degree of passivation; adopting different activation potentials)

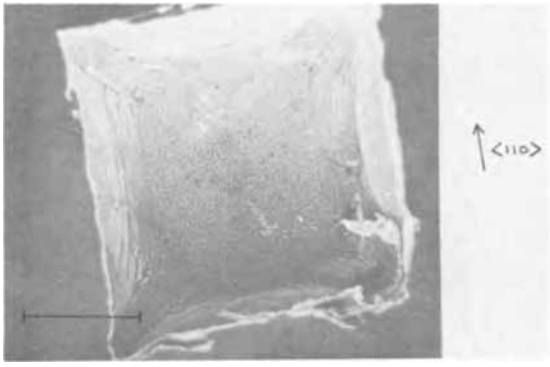

Fig. 1. Scanning electron micrograph of a typical pit formed on the {100} surface of nickel following passivation in 1*N* H_2SO_4 for 30 min at 500 mV, and activation with NaCl addition at 500 mV. The marker represents 50 μm.

were unsuccessful and only one morphology could be obtained on this orientation.

The {111} surfaces developed pits which tended to vary in external geometry from hexagonal toward triangular as the reaction rate was decreased. For example, Fig. 2 shows a pit formed in 1*N* H_2SO_4 at 800 mV after passivating at 500 mV and Fig. 3 a pit formed in (0.5*N* $NiSO_4$ + 0.01*N* H_2SO_4) at 500 mV after passivating at 500 mV. In the latter case the dissolution rate within the pit should be less, since the potential of activation is lower and the degree of passivation is higher in the less acidic solution. In Fig. 3 the pit facets are close to {111} and {210}.

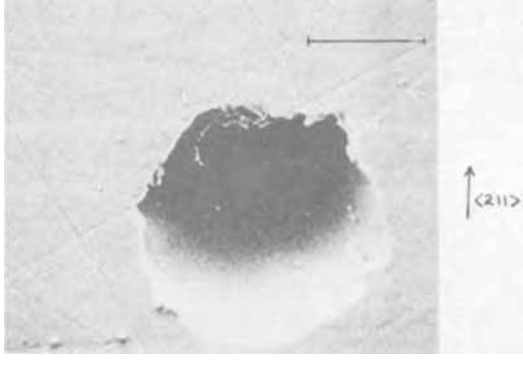

Fig. 2. Scanning electron micrograph of a pit on {111} nickel following passivation in 1*N* H_2SO_4 for 30 min at 500 mV, and activation with NaCl addition at 800 mV ("high reaction rate"). The marker represents 50 μm.

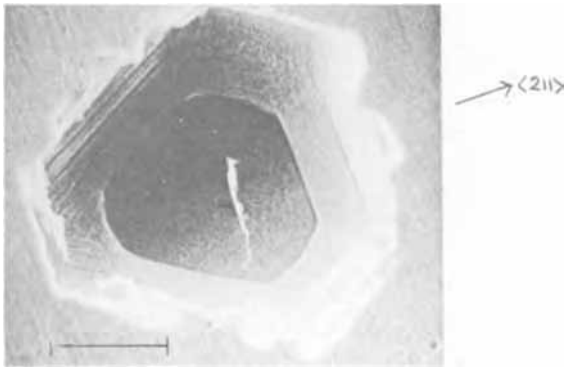

Fig. 3. Scanning electron micrograph of a pit on {111} nickel following passivation in (0.01*N* H_2SO_4 + 0.5*N* $NiSO_4$) for 30 min at 500 mV, and activation after NaCl addition at 500 mV ("low reaction rate"). The marker represents 50 μm.

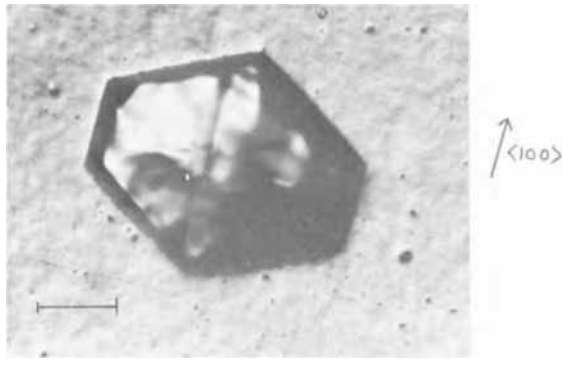

Fig. 4. Optical micrograph of pit observed during formation in the electrolytic cell on {110} nickel surface following passivation in 1*N* H_2SO_4 for 30 min at 500 mV, and activation after NaCl addition at 800 mV ("high reaction rate"). The marker represents 50 μm.

Fig. 5. Optical micrograph of a pit formed on {110} nickel surface following passivation in 1*N* H_2SO_4 for 30 min at 800 mV, and activation following NaCl addition at 500 mV (low reaction rate). The marker represents 50 μm.

Pits obtained on {110} surfaces also exhibited a dependence on the passivating potential, and an independence of the activation potential. The external geometry changed from hexagonal toward rhombohedral when the passivating potential was increased. For example, Fig. 4 shows a pit formed at 800 mV after passivation at 500 mV in 1*N* H_2SO_4 and Fig. 5 a pit obtained at 500 mV after passivation at 800 mV. The reaction rate would be lower in the latter case, due to the greater degree of passivation (13). On the {110} surfaces regular faceting of the pits was rare.

Certain of the crystals prepared for this study were found to be much more susceptible to pitting than most. Such crystals showed no difference in the shape of pits on {100}, and {111} surfaces but, on {100} surfaces rectangular pits (Fig. 6) were obtained at low potentials in less acidic solution, although in other conditions pit shapes were as in Fig. 4. These samples exhibited Laue x-ray diffraction patterns which suggested a mosaic subgrain structure. Whereas Garz *et al.* (12) reported observing rectangular pits on {110} regularly, in the present work only the "anomalous" crystals exhibited pits of this shape.

Simulation of Pitting

Simulation of pitting on the three major low-index planes of the face-centered cubic structure was carried out by a process of atom-by-atom removal, following the arbitrary subtraction of a single surface atom. It is supposed that this arbitrary subtraction corresponds to the point at which the passivating film is broken and pitting initiated. We assume that the extent of the phenomenon is such that in the area simulated there will be no further such surface nucleation event, since all other atoms remain covered with the passivating

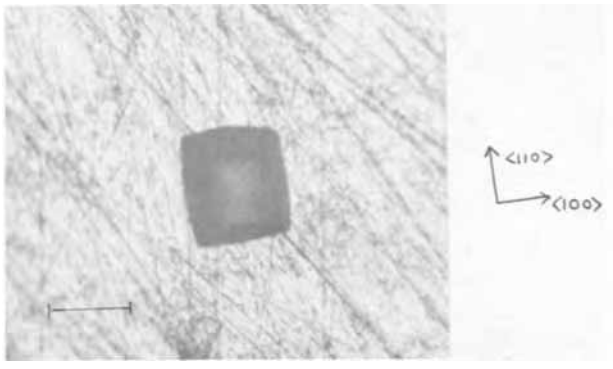

Fig. 6. Optical micrograph of a rectangular pit typical of those observed on {110} nickel surfaces of some crystals following passivation in (0.01*N* H_2SO_4 + 0.5*N* $NiSO_4$) for 30 min at 300 mV, and activation after NaCl addition at 150 mV. The marker represents 50 μm.

film until they are removed as a consequence of the expanding pit.

Simulation based on bonding.—The simplest model for the removal of surface atoms is that which assumes that an atom is removed preferentially if it has less bonds (nearest neighbors) than all other atoms. It is necessary to suppose that initially all the atoms, including the surface atoms in contact with the passive film, have the same number of bonds. Thus, the number of bonds broken is used as the criterion for priority of removal. After the initial arbitrary removal it is possible to simulate pit formation by atom-by-atom removal. The result of this procedure for the {100} surface of a face-centered cubic crystal is shown in Fig. 7. Only two layers are considered because it was found that a second layer atom is never in a position

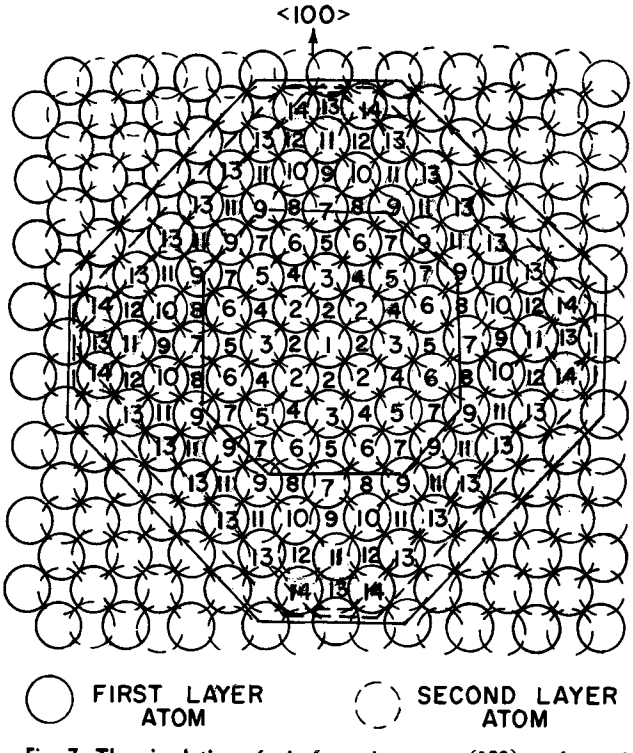

Fig. 7. The simulation of pit formation on a {100} surface of a face-centered cubic crystal, incorporating removal priorities dependent on the number of nearest neighbors. Atoms are designated with numbers corresponding to the removal sequence. The continuous lines refer to the removal boundaries for the first layer atoms following removal sequences 6 and 14: outer and inner dotted lines indicate removal boundaries for the second and third layer, respectively, following removal sequence 14.

to lose a bond with a third layer atom before it is itself removed. The numbers assigned to the atoms correspond to the order in which they were removed during the simulation. If more than one atom has the same number, these atoms had at one time the same number of nearest neighbors and, therefore, were removed simultaneously. The shape of the pit immediately following the fourteenth removal sequence is shown by the heavy solid line for first layer atoms and the outer dotted line for second layer atoms. Comparing this shape with that existing following the sixth removal sequence, (inner full line) it can be supposed that when grown to macroscopic dimensions the pit will appear square with sides along <110> directions.

Third layer removal for this case would commence, if the simulation rules are followed, by removal of the third layer atom immediately below atom "1" after the removal of atoms "2." The third layer removal will then be continued simultaneously with the upper layer removal.

The relative positions of the removal boundaries for each layer permits a prediction of the orientation of the pit facets which will be developed to macroscopic size, presumably when additional layers are subsequently removed. Thus the pit so simulated in the {100} surface has four {111} facets. The macroscopic morphology of such a pit is shown schematically in Fig. 8 (a).

In a similar manner, morphologies of pits developed on {111} and {110} surfaces can be readily obtained using the same "rules." Pits simulated for these two surfaces are shown in Fig. 8 (b) and 8 (c) respectively.

Comparing these morphologies with those obtained experimentally it is seen that there is some correspondence in the case of {100} and {111} pits, but there is considerable discrepancy for {110}.

Simulation based on the accessibility of aggressive ions.—The inability of the simple bonding model to generate the observed pit morphologies suggests that the factors controlling dissolution morphology during pitting are more complex, and we conclude the previous model is too simple. Kolotyrkin (14, 15) has considered the part played by anions in anodic dissolution and has suggested that the aggressive ions (in this case Cl^-) play an important part in assisting the removal of atoms. This concept leads to dissolution control through the ability of such aggressive ions to bond effectively with the atoms to be removed. Access of the aggressive ions during pitting corrosion is obtained only through the spaces produced by previous atom removal, and this factor must be considered in any simulation.

Since the number of spaces is coincident with the number of bonds broken, a simulation taking the number of spaces for the criterion of removal would give the same morphologies as those obtained in the "bond breaking" simulation already discussed. But the aggressive ions are unlikely to be of the same size as the metal ions of the lattice (called "atoms" here to avoid confusion) and could well be hydrated. What-

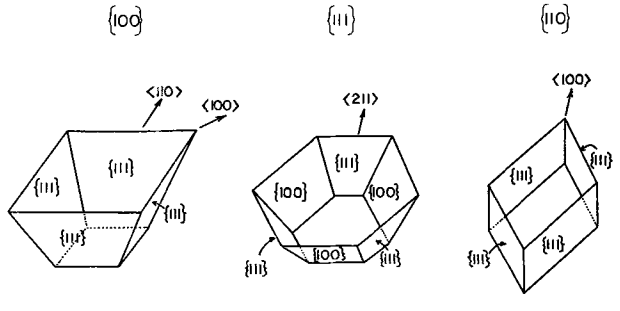

Fig. 8. Morphologies obtained by simulation using the "broken bond model" on {100}, {111}, and {110} surfaces.

ever form they may take, the configuration of those spaces adjacent to an atom will play an important role, if accessibility is the controlling factor. Hereafter the accessibility has been taken as the sole criterion of the ease of removal of atoms, since it successfully predicts the observed shapes. This necessitates considerable refinement to the rules of removal during simulation.

At low reaction rate.—At low reaction rates we assume time not to be important and that if there is a space large enough to accommodate the aggressive ions they will have time to reach that space. This leads to the following factors determining the accessibility:

(*A*) The total number of spaces adjacent to a given atom is the primary consideration (this factor corresponds to that used in the simple bonding simulation).

(*B*) There is a decrease in the contribution of a space if that space is shared among more than one adjacent atom.

(*C*) If a space is overlapped by an atom or atoms on an upper layer the accessibility of that space is reduced (In the simulation it is discounted completely for the atoms lying on the same layer as the space).

(*D*) The geometric configuration of a given number of spaces can determine the effective space they provide.

Factor (*B*) considers that when a space is shared among more than one atom the ability of the aggressive ion to remove these atoms is less than if it were adjacent to only a single atom. Factor (*C*) supposes the aggressive ions will have more difficulty in penetrating beneath an existing atom, and though this will render the lower layer space ineffective for the removal of atoms in that layer, the existence of that space does contribute to the removal of the upper (overlapping) atom. Factor (*D*) takes account of the effective volume of a set of adjacent spaces, and will be further elaborated when the individual simulations are described.

The factors noted above must be translated into "rules" which govern the progress of the simulation. We denote these rules for low reaction rates below:

L-1: Let N_1 be the number of spaces adjacent to an atom [factor (*A*)].

L-2: Let N_2 be the number of the adjacent spaces which lie on the same layer as the atom and are subject to overlap of atoms remaining in the upper layer [factor (*C*)].

L-3: Remove the atom with the largest $(N_1 - N_2)$. If more than one atom has the same $(N_1 - N_2)$ distinguish between them as follows:

L-4: Let n be the number of those $(N_1 - N_2)$ spaces which are shared with other atoms having $(N_1 - N_2)$ spaces [factor (*B*)].

L-5: Remove the atom with smallest n. If more than one atom has the same n, proceed as follows:

L-6: Let m be the number of those $(N_1 - N_2)$ spaces which have two of the other $(N_1 - N_2)$ spaces for the same atom adjacent to them [factor (*D*)].

L-7: Remove the atom with the smallest m.

These rules were applied to each of the three low-index fcc surfaces and if an appropriate morphology was not obtained, modifications were made to the rules consistent with the general factors (*B*), (*C*), (*D*) which are dependent on the specific surface structure and can be expected to result in different rules for different surfaces. It was found for all surfaces that only two layers need be considered in the simulation because second layer atoms are never in a position to possess spaces on the third layer, though the first layer atoms do possess spaces on the second layer. The morphology is determined by the first two layers.

The removal sequence for a pit in the {100} surface is summarized in Table I which also shows the instantaneous values of the various parameters used in applying the removal rules. In this case factor (*B*) (or the value of n) has no effect throughout the simulation. Until the sequence 7 the atoms with largest $(N_1 - N_2)$ have the same n, m values and are removed simultaneously. At sequence 8, atoms "8" and "9" have the same $(N_1 - N_2)$ and n values but different values of m. Thus, atoms "8" are removed in preference to atoms "9" by involving factor D. Figure 9 shows the development of this simulation and notes the removal boundaries after sequence 8 by full and dotted lines for the first and second layers respectively. The removal boundary for the third layer is indicated by the inner dotted line if the same simulation is applied to the third layer atoms. It is readily seen that the square shape is maintained as the pit expands. The simulation also predicts the development of {111} pit facets if successive layers are removed in a uniform manner. Such a macroscopic morphology appears to be coincident with the morphology obtained experimentally on {100} surfaces at low reaction rates.

Table I. Simulation 100-L

Removal sequence	Atoms Z(N_1,N_2,N_1-N_2,n,m) prior to removal
1	1 (arbitrary removal)
2	*2(1,0,1,1,0)*, 3(0,0,0,ND,ND)
3	*3(3,0,3,2,1)*, 4(2,1,1,ND,ND)
4	*4(3,0,3,3,3)*, 5(1,0,1,ND,ND)
5	*5(3,0,3,0,3)*, 6(2,0,2,ND,ND)
6	*6(3,0,3,2,1)*, 7(3,2,1,ND,ND)
7	*7(5,0,5,0,3)*, 8(2,0,2,ND,ND)
8	*8(3,0,3,2,1)*, 9(3,0,3,2,3), 9(2,1,1,ND,ND)

Atoms removed at each sequence are in italics.
Z is designation of atom in Fig. 10.
N_1,N_2,n,m are defined in text.
ND indicates that the value was not determined.

The same removal rules, "L," when applied to a {111} surface predict the triangular pit on the left hand side (a) of Fig. 10. The simulation sequence for this surface is summarized in Table II. (Atom designation for this surface has been modified for clarity.) In this case, factor (*D*) (the value of m) has no influence throughout the simulation, but factor (*B*) (value of n) is required at sequences 9, 10, and 12. This simulation suggests {111} pit facets and can be considered an effective simulation for the morphology approached by pits on {111} at low reaction rates, although no triangular pit has in fact been observed on the nickel surfaces in this work.

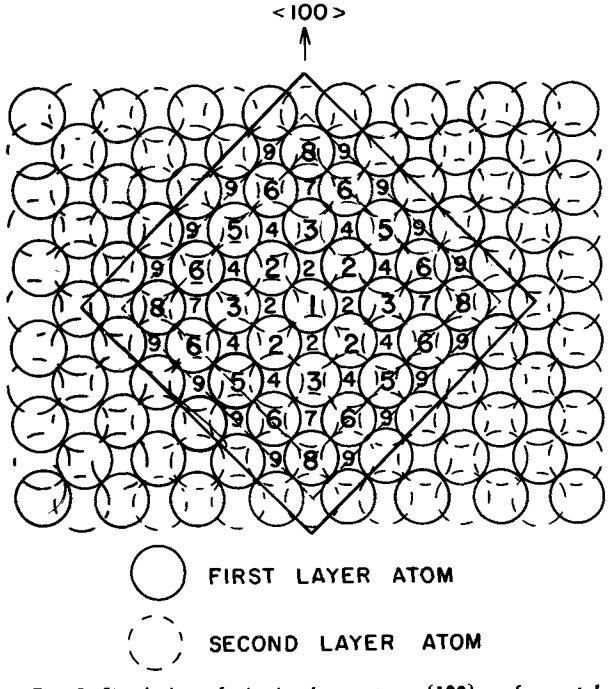

Fig. 9. Simulation of pit development on {100} surface at both low and high reaction rates. Removal boundaries are shown for the first, second, and third layers following removal sequence 8 (Tables I and IV).

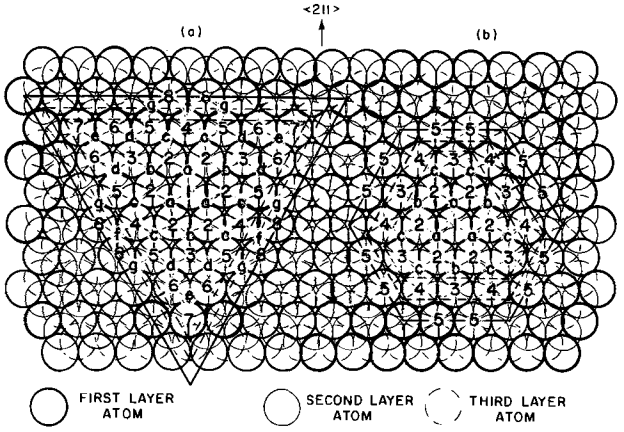

Fig. 10. Pit development on {111} surfaces at (a) low reaction rate with removal boundaries shown following removal sequence 12 (Table II); (b) at high reaction rate with removal boundaries shown following removal sequence 5 (Table V).

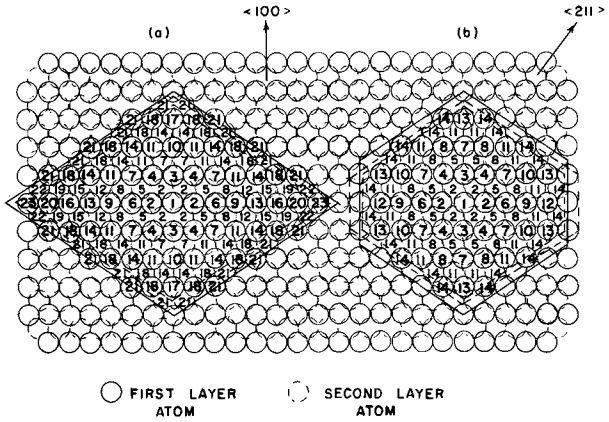

Fig. 11. Pit development on {110} surfaces for (a) low reaction rate, with removal boundaries shown following removal sequence 20 (Table III), and (b) for high reaction rate, and removal boundaries following removal sequence 14 (Table VI).

The results of the simulation of pitting on {110} surfaces at low reaction rates are summarized in Table III and the left hand side (a) of Fig. 11. In this case, in order to simulate the observed rhombohedral shape of the pits, it was found necessary to interpret rule L-5 in a less rigid manner than originally formulated. In order to simulate the observed shape it was necessary to make no distinction with respect to the accessibility of aggressive ions if $n = 1$ or 2. Therefore $n = 0$ was always taken in preference to any other value of n, but no distinction was made between $n = 1$ and $n = 2$. This modification appears at sequences 7, 10, 14, and 17 in Table III. The removal boundaries in the case of the simulated pits at low reaction rate in {110} surfaces predict pit facets to be composed of other {110} orientations.

The simulations at low reaction rate predict well the observed pits on {100} and {110} surfaces, and in the case of {111} indicate, at least, the tendency exhibited by pit shapes at low reaction rates. The prediction of the pit facets also seems accurate, subject to the complicating factor of ledges observed within the pits which will be discussed later.

At high reaction rate.—In order to simulate the pit morphologies observed at high reaction rate, it was necessary to modify the rules for atom removal which, in hindsight, result in the following amendments to the factors being considered.

At high reaction rates, it is reasonable to suppose that the accessibility of the aggressive ions to the spaces adjacent to lower layer atoms will be reduced more than that for the upper layer atoms. We have already assumed, even at low reaction rate, that the accessibility to lower layer atoms will always be less than that to the upper layer atoms [factor (C)], and it is now supposed that at high reaction rates an additional blocking effect will be provided by aggressive ions already adsorbed at the upper layer spaces. Consequently, we replace factor (C) with a new factor, namely,

(E) spaces occupied by adsorbed ions in upper layers will block spaces in lower layers, and consequently the latter will not be counted.

Table II. Simulation 111-L

Removal sequence	Atoms Z(N_1,N_2,N_1-N_2,n,m) prior to removal
1	*1* (arbitrary removal)
2	*2(1,0,1,0,0)*, *a(1,0,1,0,0)*, 3(0,0,0,ND,ND)

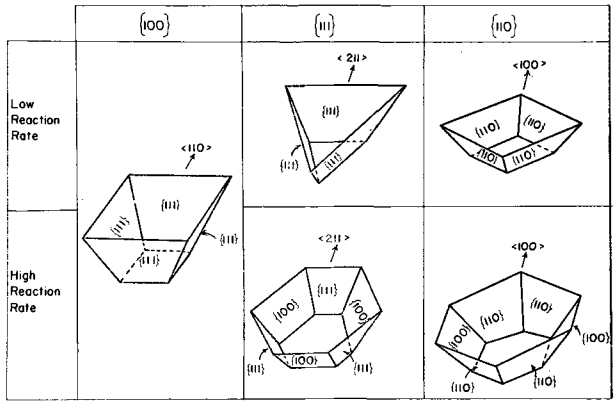

Fig. 12. Summary of pit morphologies obtained by simulation for {100}, {111}, and {110} fcc surfaces at low and high reaction rates. All simulations assume uniform deepening of a pit until it is arrested and a planar base is formed.

Also, at high reaction rates factor (D) is ignored on the assumption that small changes in the effective volume of an array of spaces are insignificant in this case.

Only factors (A), (B), and (E) are therefore considered relevant at high reaction rates and permit the following general rules for removal during the simulations:

H-1: Let N_1 be the number of spaces adjacent to an atom [factor (A)].

H-2: Let N_3 be the number of the adjacent spaces which are overlapped by a space or spaces in an upper layer [factor (E)].

H-3: Remove the atom with the largest ($N_1 - N_3$). If more than one atom has the same ($N_1 - N_3$), proceed as follows:

H-4: Let n be the number of the ($N_1 - N_3$) spaces which are shared amongst other atoms with ($N_1 - N_3$) spaces [factor (B)].

H-5: Remove the atom with the smallest n.

In applying these rules, it was realized that the factor (E) must be interpreted a little differently for less close-packed surfaces ({100} and {110}). In rules H-2 and H-3 spaces overlapped by upper layer spaces are discounted completely. But in the less close-packed surfaces, those spaces are never completely overlapped and could contribute to the ease of removing adjacent atoms on the upper layer. With this modification the correspondence between the morphologies obtained by simulation and in experiment was attained.

Simulations for the three low-index surfaces at high reaction rate are shown in Fig. 9 and the right hand sides (b) of Fig. 10 and 11. In {100} and {110} surfaces, the second layer spaces overlapped by the first layer spaces were considered to contribute to the ease of removing the adjacent first layer atoms, as described above, and so N_3 was always taken as zero for the first layer atoms. For {111} these spaces were completely discounted according to rules H-2 and H-3. Factor (B) was again interpreted differently for {110} as at low reaction rate.

It is seen that the increased reaction rate produces no change in the morphology on {100} surfaces but results in different types of six-sided pits in the other two surfaces, as observed experimentally (Fig. 2 and 4).

Figure 12 summarizes the simulated shapes for the three low-index surfaces at both low and high reaction rates.

Simulation for metal-oxygen bonding stronger than metal-metal bonding.—In all the simulations noted above no account has been taken of the possible effect of the bonding of the oxygen, present in the passivating film, with metal atoms of the first layer. It is possible that such bonding could be sufficiently strong to change the priorities of bond breaking under the influence of aggressive ions. Consequently, additional simulations were carried out in which the rules were modified such that atoms would always be removed from the second layer in preference to the first provided they had a finite number of spaces which are not discounted due to the overlap by any upper layer atoms. First layer atoms were only removed when there was no such second layer atoms available for removal.

The pit on the left hand side (a) of Fig. 13 shows the result of the application of these rules on {110}. It is seen that they develop what is almost a one dimensional pit which increases in length but not in width. But atoms such as 3′ in (a) could reasonably be expected to be removed in due course, although atoms 1,3,5,7---- always keep ahead of them. If it is supposed that the atom 3′ is removed after 6 and before 7, then the resulting shape would be as shown in the pit situated on the right hand side (b) of Fig. 13. One concludes, therefore, that rectangular pits will be developed on {110} surfaces subject to these conditions.

Using the same modified rules on {110} and {111} surfaces did not change the simulations from those obtained earlier. This result may be significant in that the anomalous samples only exhibited different pits on the {110} surfaces and they were, in fact, rectangular.

Application to Body-Centered Cubic Metals

In order to test the aggressive ion accessibility criterion for other crystal structures, the simulation method was used to predict pit morphologies on passivated low-index surfaces of body-centered cubic crystals, although few detailed studies of corrosion pit morphologies on body-centered cubic crystals have been reported.

Janik-Czachor and Szklarska-Smialowska (16) investigated the morphologies of corrosion pits on Fe-16% Cr formed under galvanostatic conditions. On all surfaces studied the pits exhibited regular polyhedral shapes and contained facets composed of {110} and {100} planes.

Taoka *et al.* (17) report similar shapes for corrosion pits produced chemically on the surfaces of Fe-3% Si. The existence of {110} and {100} facets on similar pits produced by the same etch procedure in Ferrovac E iron has also been confirmed by Spink and Ives (18). There is good reason to suppose that the surface condition existing during these chemical etch treatments involves the presence and breakdown of surface films, and the results can presumably be included with those in which the passive state is induced electrochemically.

A summary of the pit morphologies observed experimentally (16-18) in body-centered cubic metals is presented schematically in Fig. 14.

In accord with the experience with fcc surfaces, the accessibility factors (A), (B), (C), and (D) were considered of major importance at low reaction rates (*i.e.* low anodic current). At high reaction rates (or high anodic currents) the factor (E) was adopted in preference to factors (C) and (D).

In applying the rules for removal formulated previously, it was found necessary in bcc to consider both first and second nearest neighbor spaces for factor (A), whereas in fcc only nearest neighbors needed to be

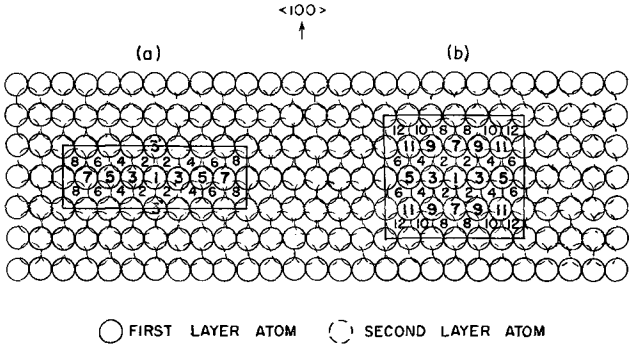

Fig. 13. Consequences of simulation on {110} surface assuming metal-oxygen bond strength to be greater than metal-metal bond strength.

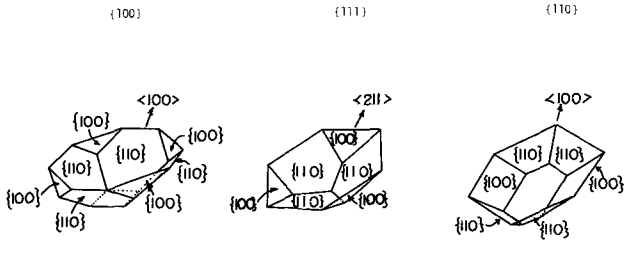

Fig. 14. Summary of pit morphologies in Fe, Fe-16% Cr, and Fe-3% Si, for {100}, {111}, and {110} surfaces, as reported in the literature.

considered. This makes factor (D) unimportant for bcc crystals.

The rules which govern the progress of the simulation for low reaction rate can be stated as follows:

L-1: Let N_1 be the number of the nearest neighbor spaces adjacent to an atom and N_2 be the number of the second nearest neighbor spaces adjacent to that atom [factor (A)].

L-2: Let $N_1°$ be the number of nearest neighbor spaces on the same layer as the atom which are subject to overlap of an atom or atoms remaining in an upper layer, and let $N_2°$ be the number of second nearest neighbor spaces in the same layer which are subject to overlap from above [factor (C)].

L-3: Remove the atom with the largest $(N_1 + N_2 - N_1° - N_2°) \equiv M_L$ (effective space). If more than one atom has the same M_L, proceed as follows:

L-4: Remove the atom with the largest $(N_1 - N_1°)$ (effective nearest neighbor space). If more than one atom has the same $(N_1 - N_1°)$, proceed as follows:

L-5: Let n be the number of the M_L spaces which are shared with other atoms having M_L spaces [factor (B)].

L-6: Remove the atom with the smallest n. L-4 distinguishes between the contribution of first and second nearest neighbor spaces.

At high reaction rates the specific rules for removal during simulation incorporate factors (A), (B), and (E), and are summarized as follows:

H-1: Let N_1 be the number of nearest neighbor spaces adjacent to an atom and N_2 be the number of second nearest neighbor spaces [factor (A)].

H-2: Let N_1^s be the number of nearest neighbor spaces on the same layer as the atom which are subject to overlap by a space or spaces existing on a layer above, and let N_2^s be the equivalent parameter for the second nearest neighbor spaces [factor (E)].

H-3: Remove the atom with the largest $(N_1 + N_2 - N_1^s - N_2^s) \equiv M_H$ (effective space). If more than one atom has the same M_H, proceed as follows:

H-4: Remove the atom with largest $(N_1 - N_1^s)$ (effective nearest neighbor space). If more than one atom has the same $(N_1 - N_1^s)$, proceed as follows:

H-5: Let n be the number of those M_H spaces which are shared with any of the other atoms having M_H spaces [factor (B)].

H-6: Remove the atom with the smallest n.

The above working rules permit the simulation of pit formation by atom-by-atom removal, and as an example the sequence for {110} at low reaction rate is summarized in Table IV. The individual simulations for low index bcc surfaces are shown in Fig. 15-17. The resulting pit morphologies are summarized in Fig. 18.

The agreement between the simulations (Fig. 18) and the experimental observations (Fig. 14) is good. The observed morphologies are predicted for {111} and {110} surfaces, and a combination of the low and high reaction rate is necessary to describe the {110} observations.

Table IV. Simulation 110-L (bcc)

Removal sequence	Atoms Z ($N_1 + N_2, N_1° + N_2°, M_L, N_1 - N_1°, n$) prior to removal

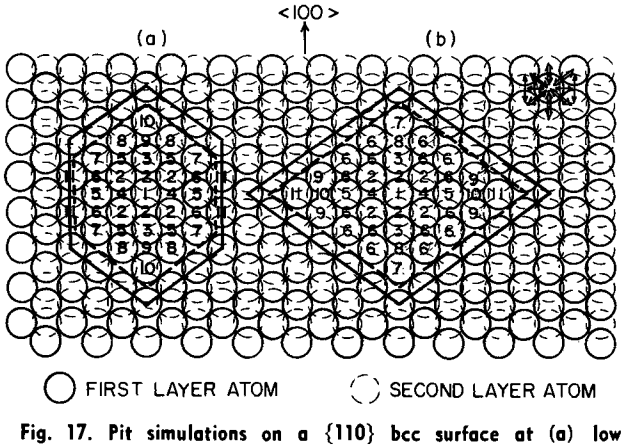

Fig. 17. Pit simulations on a {110} bcc surface at (a) low reaction rate (rules L) and (b) high reaction rate (rules H).

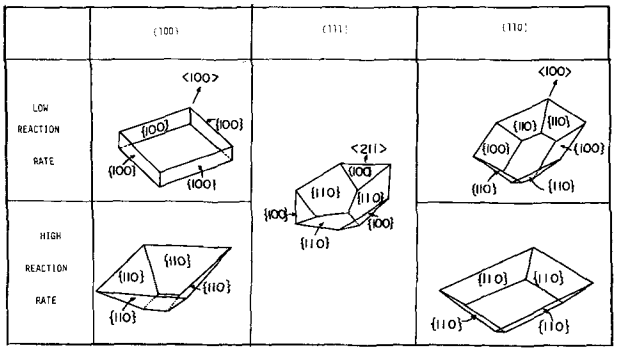

Fig. 18. Summary of pit morphologies predicted by the simulations for {100}, {111}, and {110} bcc surfaces at low and high reaction rates.

These simulations can also be related to the changes with time under galvanostatic conditions reported by Janik-Czachor and Szklarska-Smialowska (16) for Fe-16% Cr. They reported changes in pit morphology with time for pits on {100} and {110} surfaces. In particular, pits on {100} changed in superficial shape from square to octagonal and on {110} the shape of the base of pits changed from rhombohedral to hexagonal. Since the size and number of pits were observed to increase with time, the current density in a given pit must be reduced with time under galvanostatic control. Consequently the reaction rate in the pit is reduced. The morphological changes predicted by the simulations on {100} and {110} in making the transition from high to low reaction rate are therefore consistent with the experimental observations. No changes are either predicted or reported for {111} surfaces.

Discussion

A review of the factors which were necessary in order for the simulations to approximate the experimentally observed pitting morphologies suggests that the important consideration determining atom removal during pit development is the configuration of the spaces adjacent to each atom. When allowance is made for blockage of spaces and the sharing of spaces between equally unbonded atoms, we have seen that the simulations developed the appropriate morphologies if atoms with more adjacent space were removed in preference to those with less. Furthermore, those rules which required modification from one crystallographic surface to another could be related to the differences in the atom-atom configuration in these surfaces.

The realization that the simple "bond-breaking" model does not develop correct morphologies (nor would the equivalent "adjacent space" model) and the success of the simulations which were achieved suggests that the important factor is the accessibility of the aggressive ions in placing themselves close to metal atoms within the pit in order to remove them. This model is consistent with the suggestions of Kolotyrkin (14, 15) and is also supported by independent observations that during pitting corrosion the interior of pits are in the active state, while the remainder of the surface is passivated (19) and the realization that the susceptibility for pitting of nickel single crystal surfaces is directly proportional to the reactivity of that surface during active dissolution (13).

The necessity for introducing the blocking effect of already adsorbed aggressive ions on upper layers when pitting occurs at high reaction rates also substantiates this model. It is difficult to envisage a process involving only the metal substrate that would explain the morphological dependence on reaction rate.

The apparent success of the simulation in which second layer atom removal takes preference over first layer removal in reproducing the pit morphologies observed on the anomalous samples suggests that the effect of metal-oxygen bonding could certainly modify the aggressive ion capability of removing atoms. If these anomalous crystals were more defective (for example, have high impurity content) it is possible that the dissolution rate of the metal substrate would be increased, accentuating the effect of oxygen in bonding the surface layer. In addition, the {110} surface on which pits of different morphology were observed both experimentally and by simulation is far more readily passivated than are the {100} and {111} surfaces (13).

Much of the complication involving the description of the simulation method employed in this study has been due to the need for an effective means of describing the simulation process in written form. It is much simpler to appreciate the relative priorities for atom removal when the simulation is carried out by hand using models of spheres with the appropriate packing and surface orientation. Such a procedure leads the experimenter with no doubt as to the conclusions quoted above.

The prediction of the crystallographic orientation of the facets occurring within the corrosion pits has also been provided by the simulation. Of course, the development of macroscopic facets of these orientations supposes that the third and successive atom layers are removed at the same rate as the first two layers but slightly behind them. However, in the real situation when many atom layers are removed to form a macroscopic pit, delays in the initiation of layer removal can be expected due, for example, to the accumulation of corrosion product in the pit, resulting in a random variation of removal boundary spacing. The subsequent development of the removal boundaries may then be subject to interactions leading to combinations of monatomic steps which coalesce to form macroscopic ledges, in a manner similar to that proposed by Gilman (20) and Ramachandran and Ives (21) for etch pits on lithium fluoride. In this case the risers of such macroscopic ledges will have the crystallographic orientation already suggested by the simulation, and the macroscopic orientation of the pit sides will differ from the crystallographic orientation predicted by an amount dependent on the density of ledges.

Both the simulations for fcc and for bcc surfaces suggest the aggressive ion accessibility criterion to be relevant for determining dissolution morphologies within corrosion pits. A mechanism is thereby provided to explain why various crystallographic facets are stabilized under various corrosion conditions—a fact stated many times before but only rationalized vaguely in terms of the relative close-packing of the various crystal orientations. From the studies reported here it is possible to appreciate how different crystallographic surfaces are stabilized under different conditions and that their degree of close-packing is not the only factor to be considered.

The Effect of Water on Passivity and Pitting of Titanium in Solutions of Methanol and Hydrogen Chloride

F. Mansfeld*

North American Rockwell Science Center, Thousand Oaks, California 91360

ABSTRACT

The effect of water on passivity and breakdown of passivity by pitting of titanium in solutions of methanol and hydrogen chloride has been studied. In anhydrous solutions no passivation occurs. Small additions of water lead to passivation, the region of passivity being limited by the pitting potential to noble values. The critical pitting potential becomes more noble with increasing water content of the electrolyte. Values obtained under steady-state conditions (V_c) seem to level off at higher water contents, while values obtained under nonstationary conditions (V_c') increase linearly with water content. No passivation occurs when 12*N* aqueous HCl was added to pure methanol to produce an aqueous solution of CH_3OH + 0.01*N* HCl, but passivation was observed when an aqueous solution of CH_3OH + 1.0*N* HCl was produced. This is explained by the higher water content of the latter solution, which is sufficient to passivate the surface at potentials below the pitting potential.

In studies of passivity or breakdown of passivity through pitting, the effect of the electrolyte composition has been studied extensively. Since most of these studies have been carried out in aqueous solutions, the effect of water could not be investigated, although there is a general accord that the water molecule plays an important role in passivity of the transition metals and alloys in acid solutions.

One of the few studies of passivity in nonaqueous solutions was carried out by Kolotyrkin and Kossyi (1) who studied the effect of water on the anodic behavior of chromium in methanol solutions of hydrogen chloride. Potentiostatic polarization curves were measured in solutions of methanol which had been saturated with dry gaseous hydrogen chloride, then diluted with methanol to which certain amounts of H_2O were added. It was found that active anodic dissolution in CH_3OH-1*N* HCl-H_2O proceeds without participation of H_2O molecules, while increasing amounts of H_2O lead to a more and more extended region of passivity, which was not observed in the absence of water. The passive film was destroyed at higher anodic potentials by pitting and it was found that the critical potential for pitting was a linear function of the water content of the electrolyte at a constant concentration of HCl. Tsinman *et al.* (2) studied the anodic behavior of Ti in water-methanol solutions containing chloride ions and found that at constant HCl concentration pitting occurred at low H_2O concentration, and not at higher H_2O concentrations. Pitting was also observed during the anodic polarization of titanium in methanol solutions of NaBr (3). Tsinman *et al.* (4) studied the influence of water and the nature of the electrolyte on the anodic activation of a Ti alloy (VT-1) in methanol solutions by a galvanostatic method. They found that the critical pitting potential did not depend on the acidity of the solution, which is in contrast to what was found by Kolotyrkin and Kossyi (1). They also found that the pitting potential became more noble with increasing water content and varied in the series Cl^-, $Br^- < I^- << ClO_4^- << NO_3^-$. Meshcheryakova *et al.* (5) studied the behavior of titanium (VT-1) in ethanol-water solutions of hydrochloric acid. They found that titanium is not passive in anhydrous 20% HCl-ethanol solutions and corrodes with a rate of about 5 mm per year (about 630 mdd). The corrosion rate dropped to half of this value when 1% water was added and became rather small when 6-32% water was added (0.01 mm per year or 1.2 mdd). Corrosion was uniform except in solutions containing 4-6% H_2O where pitting occurred after 300 hr. The pitting potential was found to be proportional to the logarithm of the water concentration.

Levy and Seitz (6) also found that the pitting potential of a Ti-8Al-1Mo-1V alloy in CH_3OH + 0.4% HCl + H_2O became more noble with increasing water content. From their data (linear plot of potential *vs.* current density) no information about the effect of water on the active dissolution of this alloy can be obtained.

Schwabe and Schmidt (7) and Schmidt (8) studied the effect of water content on the anodic behavior of Ni in 2*N* H_2SO_4-dimethyl formamide-water and 2*N* H_2SO_4-acetonitrile-water solutions. It was found that passivation occurred only in the presence of water, the critical concentration of H_2O being $\approx$ 0.1% in dimethyl formamide and $\approx$ 3% in acetonitrile solutions.

Since only a few data concerning the effect of H_2O on passivity of Ti in CH_3OH-HCl solutions exist (2, 4, 6) and this effect is also of practical importance in stress corrosion cracking of Ti alloys (9), a sys-

Key words: anhydrous solutions, aqueous solutions, critical pitting potential, corrosion rates.

tematic study of the anodic behavior of Ti in CH_3OH-HCl-H_2O solutions has been carried out.

Experimental Procedures

Anhydrous solutions of CH_3OH-HCl were prepared by saturating methyl alcohol (nanograde, Mallinckrodt) with HCl gas. These solutions were then diluted by adding more methyl alcohol to give a certain concentration of HCl which was measured by titration. Aqueous solutions of CH_3OH-HCl were prepared by adding water to anhydrous solutions of CH_3OH-HCl or by adding certain amounts of concentrated hydrochloric acid to pure methanol. Commercially pure Ti (Ti-75A containing about 4000 ppm total interstitial impurities) was machined to a cylindrical electrode (about 2 cm^2 geometric surface) and connected to a holder so that only the electrode, Teflon, and glass were in contact with the solution. The electrode was degreased in boiling benzene at 80°C for 5 min, then etched in a solution of 40% HNO_3-2% HF-H_2O for 1 min, washed thoroughly in pure methanol, and then immediately immersed in the test solution, which had been deaerated with argon for 1 hr. The reference electrode was an aqueous saturated calomel electrode (SCE), except for solutions containing 0.01*N* HCl, where a reversible hydrogen electrode was used in a separate compartment and the same solution. All potentials refer to SCE. After the rest potential had become constant the potential was increased in steps of 10 mV/min using a Wenking potentiostat. At higher potentials when no pitting was observed, the rate of potential change was 50 mV/5 min. Since methanol solutions of hydrogen chloride have high electrical conductivity due to the anomalously high mobility of the methoxonium ion $CH_3OH_2^+$, no major experimental problems concerning iR-drops were encountered.

Results

Figure 1 shows potentiostatic polarization curves for Ti-75A in anhydrous CH_3OH + xN HCl for x = 1.0, 0.1, or 0.01.[1] The effect of HCl concentration is clearly seen. The curves are shifted parallel in the noble direction with decreasing HCl concentration, and no active-passive transition is observed up to the highest currents studied. For comparison, Fig. 2 shows polarization curves in methanol to which sufficient concentrated HCl was added to give aqueous solutions of CH_3OH + xN HCl for x = 1.0, 0.1, or 0.01. Again, the rest potential has the most noble value for the lowest HCl concentration, but surprisingly, passivity is observed in the solution with the highest HCl concentration (1.0*N*) but not for the solution with the lowest HCl concentration (0.01*N*). For the solution which contains 0.1*N* HCl, the region of passivity is small due to pitting, the occurrence of which was confirmed by microscopical observation. In these aqueous HCl-CH_3OH solutions the H_2O content increases with increase of the HCl content, because of the water content of concentrated HCl (37% HCl).

[1] Due to the water content of pure methanol (≈0.02%) these "anhydrous solutions" contain a small amount of H_2O.

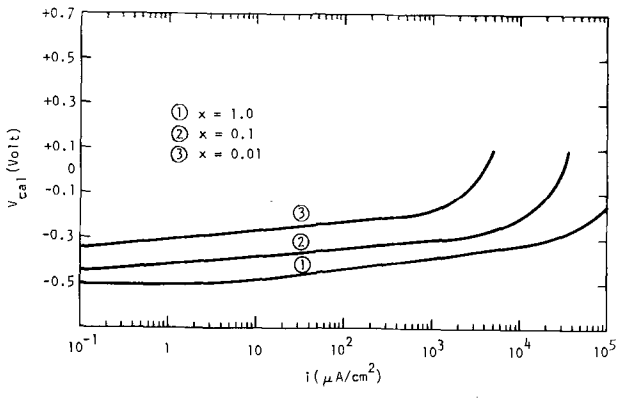

Fig. 1. Potentiostatic anodic polarization curves for Ti 75A in solutions of CH_3OH + xN HCl anhydrous (x = 1.0, 0.1, or 0.01).

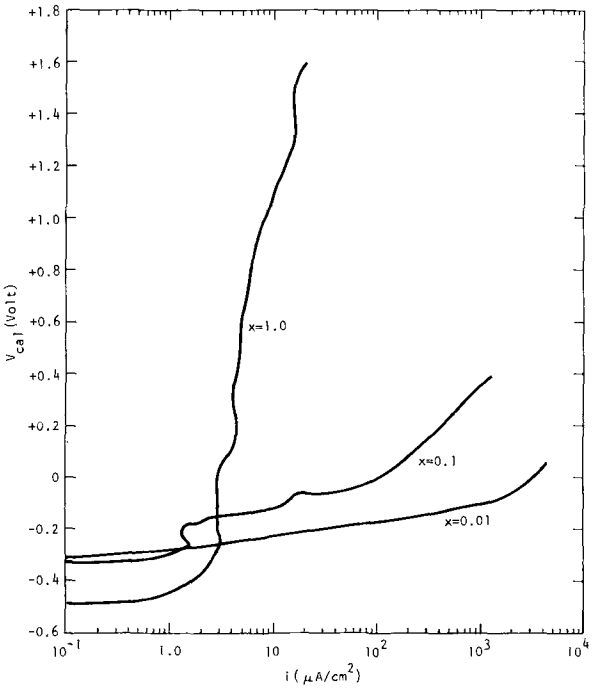

Fig. 2. Potentiostatic anodic polarization curves for Ti 75A in solutions of CH_3OH + xN HCl aqueous (x = 1.0, 0.1, or 0.01).

In the experiments of Fig. 3 increasing amounts of H_2O were added to a solution of anhydrous 1*N* HCl-CH_3OH. In the absence of H_2O no active-passive transition is observed; addition of 0.63% H_2O shifts the polarization curve in the noble direction, a small region of passivity is observed limited by breakdown of passivity through pitting. With increase in H_2O-content the region of passivity is extended, the passive C.D. being about 1.3 μA/cm^2. The passive region is limited by the critical potential for pitting V_c' which becomes more noble as the H_2O content increases. After each run the specimen was investigated under a microscope to make sure that pitting has indeed occurred. At higher water contents, establishment of V_c' from polarization curves was very difficult. In aqueous 1*N* HCl-CH_3OH (about 6.3% H_2O) no precise value of V_c' could be established. For this reason, the following two different experiments were carried out to determine more precisely the steady-state value, V_c, of the

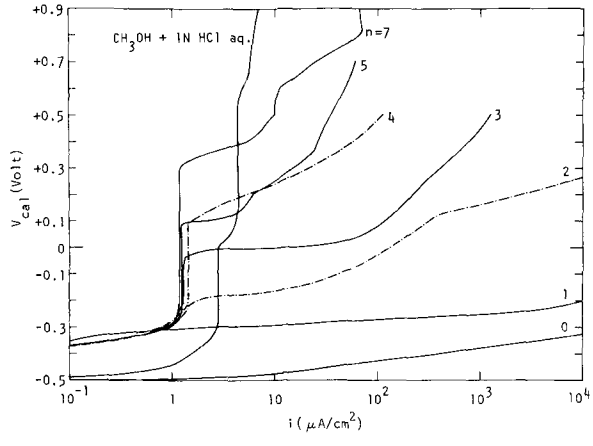

Fig. 3. Potentiostatic anodic polarization curves for Ti 75A in solutions of CH_3OH + 1*N* HCl anhydrous + n × 0.63% H_2O (n = 0-7).

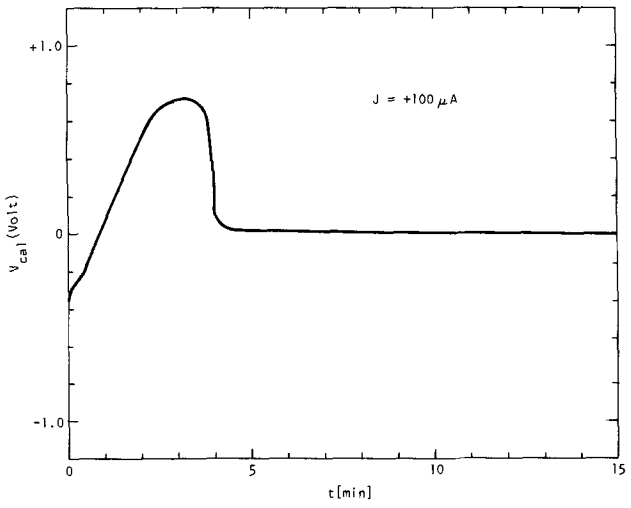

Fig. 4. Changes of potential at a constant anodic current of 100 μA in CH_3OH + 1*N* HCl anhydrous + 4.4% H_2O.

critical pitting potential.[2] In the first experiment, a constant C.D. of about 50 μA/cm^2 was applied to the test electrode and the potential *vs.* time curve recorded. This technique has recently been used by Tsinman *et al.* (4). Figure 4 shows the results for CH_3OH + 1*N* HCl + 4.4% H_2O. After application of the constant C.D. the potential increased slowly to more noble values. When the maximum value was reached, small fluctuations of the potential, which were probably due to formation of the first pits, were observed. The potential then decayed fast to a constant value, which has been called the activation potential by Tsinman (4). Microscopic observation of the electrode after the test showed occurrence of a number of pits. In the next experiment this constant potential was applied to a fresh electrode immediately after immersion into a fresh solution and the current *vs.* time curve recorded. If the potentiostatically applied potential was below the critical pitting potential V_c, the current decayed continuously due to passivation of the surface and no pits were observed (curve A, Fig. 5). The potential was then increased by 15 or 25 mV. If V_c was exceeded, the current increased after an initial decrease and pitting was observed (curve B). Critical pitting potentials estimated from polarization curves

[2] The notation by Leckie and Uhlig (10) is used here to distinguish between short-time (V_c') and steady-state (V_c) critical pitting potentials.

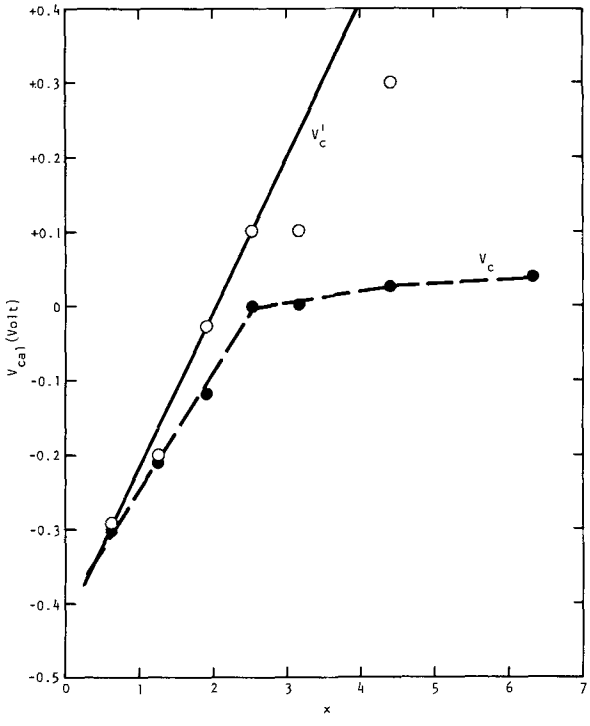

Fig. 6. Dependence of pitting potential on water content of CH_3OH + 1*N* HCl anhydrous + *x*% H_2O.

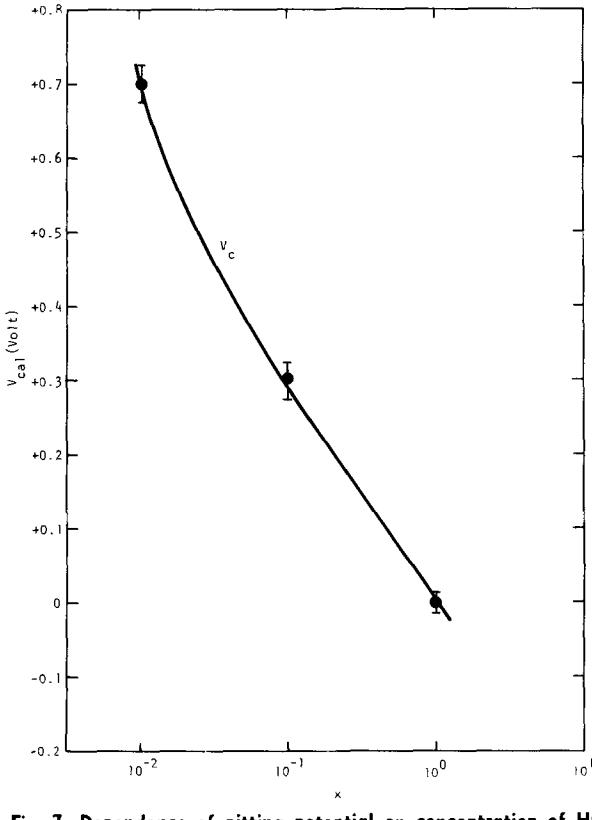

Fig. 7. Dependence of pitting potential on concentration of HCl anhydrous in solutions of CH_3OH + 3.15% H_2O + *x*N HCl (*x* = 1.0, 0.1, or 0.01).

(V_c') and measured more precisely at a constant potential (V_c) are plotted in Fig. 6. While V_c' seems to increase linearly with water content, values for V_c seem to level off after a H_2O content of 2.5% H_2O. Values of V_c in solutions of CH_3OH + 3.15% H_2O + *x*N HCl (x = 0.01, 0.1, 1.0) are shown in Fig. 7, which

shows an increase of about 0.3V when [HCl] is decreased by a factor of 10.

Discussion

The results obtained in this investigation have shown clearly that passivation of Ti cannot occur in CH_3OH-HCl in the absence of water. In "anhydrous" solutions anodic dissolution occurs following Tafel behavior. The polarization curves are shifted parallel in the noble direction as the HCl concentration decreases. Addition of water to the anhydrous electrolyte leads to passivation at a concentration as low as 0.6% water although the extent of the passive region is very small. This results from the fact that the critical pitting potential V_c' is only slightly noble to the corrosion (and passivation) potential. It has to be considered at this point that the surface concentration of water might be different from that in the bulk due to double-layer effects and due to solvation of dissolved metal ions. The latter effect would decrease the amount of water available for passivation. No information is available concerning double-layer effects in the solutions studied. Increasing additions of water lead to a broader region of passivity in which the current is independent of potential. At a certain potential (the critical pitting potential) chloride ions are adsorbed strongly enough to displace the adsorbed water molecules and penetrate the passive film. As more water is added to the electrolyte the passivating species (presumably the oxygen of water) is more strongly adsorbed and V_c is shifted to more positive values. When a sufficient amount of water is added to produce a sufficient concentration of the passivating species at the surface of the metal, the critical pitting potential increases only very slightly. This is seen better in experiments at constant current or potential (Fig. 4 and 5). At a sufficiently high, constant water content, the pitting potential becomes more noble as the chloride ion concentration decreases, as observed for many metals in aqueous electrolytes.

These findings also explain the initially surprising results of Fig. 2, where the electrode was polarized in the anodic direction in solutions prepared from pure methanol and concentrated hydrochloric acid containing a constant ratio of water to chloride ion. In the solution of CH_3OH + 0.01*N* HCl the water content is too small to allow formation of a passive film. In the solution containing 0.1*N* HCl, enough water is present in the bulk to passivate the surface. The passive film is, however, not very stable and therefore penetrated by chloride ions at a relatively low potential. In CH_3OH + 1*N* HCl, enough water is present to protect the surface from pitting up to rather noble values. The film becomes more and more stable when the electrode is polarized slowly in the noble direction. A precise value of V_c' is then difficult to detect. In the experiments of Fig. 4 and 5 an active electrode was used for determination of the pitting potential, values of V_c are therefore considerably more active than those of V_c'. This might also apply to the results of Kolotyrkin and Kossyi (1) who found a linear relationship between the pitting potential and water content from potentiodynamic curves in aqueous CH_3OH-HCl solutions.

The present results might also explain the observation of Meshcheryakova *et al.* (5) that pitting occurs only in a narrow concentration range of H_2O additions (4-6% H_2O) to ethanol-hydrochloric acid solutions. Presumably below 4% H_2O titanium did not become passive and no pitting would occur while above 6% H_2O the passive film was stable enough so that the critical pitting potential as determined by nonstationary methods was outside the range of potentials studied. The effect of water addition on corrosion rates observed by Meshcheryakova *et al.* (5) was also found in the present work where titanium specimens corroded at a rate of 3.1 mdd in anhydrous CH_3OH + 0.01*N* HCl as determined by weight loss after eight days, but only at a rate of 0.12 mdd when 0.3% H_2O was added to the solution.

The fact that the surface of titanium is free of a passivating film in anhydrous solutions of CH_3OH-HCl but covered with a passivating film in aqueous solutions of CH_3OH-HCl is interesting insofar as it will allow ellipsometric investigations and comparison of film-free and filmed surfaces. It is also interesting for studies of the mechanism of stress corrosion cracking (SCC) of Ti and Ti alloys, since SCC in anhydrous solutions, where the walls of a crack and crack tip are not covered by a passive film and are therefore active, can be compared with SCC in solution containing enough water for passivation. Under these latter conditions a potential difference is expected between the passive walls of the crack and the crack tip leading to the establishment of a galvanic couple. Preliminary results (11, 12) concerning SCC of Ti 75A in anhydrous and aqueous CH_3OH-HCl solutions have been obtained, ellipsometric investigations on the same material in the same solutions have been started (13).

The Solubility of Meta-Dinitrobenzene in Dimethyl Sulfoxide

John S. Dunning* and Douglas N. Bennion*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The solubility of meta-dinitrobenzene (m-DNB) in dimethyl sulfoxide (DMSO) was determined as a function of temperature in a dry nitrogen atmosphere glove box. Water content of the solutions was below 100 ppm as measured by Karl Fischer titration. The m-DNB saturation concentrations were determined by absorbance measurements of diluted sample solutions. The solubility was found to vary from 3.51 molal at 24.00°C to 4.64 molal at 49.75°C. From a plot of the logarithm of the saturation molality *vs.* the inverse of the absolute temperature the differential heat of solution was determined to be 2053 cal/mole in the temperature range considered if the activity coefficient correction is neglected.

Meta-dinitrobenzene (m-DNB) has been used as the cathode depolarizer in certain nonaqueous primary cells (1). The activated life of such cells depends upon the cell design and the diffusivity and solubility of the electrode depolarizer. Dimethyl sulfoxide (DMSO) may be useful as a solvent for nonaqueous electrochemical systems (2). The diffusion coefficient of m-DNB in a DMSO solution has previously been reported (3) to be 6.15 x 10^{-6} cm^2/sec. The solubility of m-DNB in DMSO will be considered here.

Experimental

The solubility was determined as a function of temperature at atmospheric pressure. Experiments were carried out in a dry nitrogen atmosphere maintained in a glove box. As received DMSO was purified by vacuum distillation using a packed column. Only DMSO with water content below 100 ppm as determined by Karl Fischer titration was used for the experimental study. The detailed procedure for the purification of m-DNB and DMSO and Karl Fischer titration is described elsewhere (3, 4). The temperature of the solution was controlled by placing it in a double walled vessel through which a fluid of constant temperature was passed. The fluid temperature was controlled by a mercury contact temperature bath to ±0.01°C. Temperatures of the solution were measured with a copper-constantan thermocouple as well as with a calibrated thermometer. Stirring of the solution was accomplished by means of glass-coated magnetic stirring bar.

The temperature of the solution was raised to approximately 50°C to start the experiment. A period of one week was allowed initially for the solution to reach equilibrium before samples were taken. The temperature was lowered after each sample was taken and the system was allowed to equilibrate for at least 24 hr. About half of the samples were taken in this manner. Then the temperature was raised after each sampling and the system was again allowed 24 hr to come to equilibrium. There was no systematic variation of the measured solubilities between the two methods of changing temperature.

Samples were withdrawn using a 10 ml pipet equipped with a glass wool particle filter and maintained at the temperature of the solution. The samples were diluted to either 1/20 or 1/40 of the saturation concentrations for convenient analysis. The concentration was determined using a Beckman Model DU spectrophotometer. Details of the spectrophotometric method used are reported elsewhere (4).

Table II. Density of meta-dinitrobenzene/DMSO solutions at 25°C

m-DNB concentration (mg/ml)	Density of solution (g/ml)
0	1.0961
4.316	1.0968
10.204	1.0976
18.938	1.1000
27.229	1.1022
36.532	1.1046
50.610	1.1073

Preliminary solubility measurements of 2,4 dinitroanaline in DMSO indicate a range of solubilities from 1.8 molal at 27.5°C to 2.6 molal at 46.8°C. The value of R $(\partial \ln m/\partial\ 1/T)_{sat}$ is approximately −2770 cal/mole.

The densities of various solutions of m-DNB in DMSO were determined by weighing of the solution contained in a 100 ml volumetric flask at 25°C. Tests of the solubility of 2,4 dinitroaniline (Eastman) in DMSO were also conducted.

Results

It was found that the solubility of m-DNB in DMSO increased from 3.51 molal at 25.00°C to 4.64 molal at 49.75°C. The data are shown in Table I. At saturation, the equality of chemical potentials of the solute in solution and in the solid phase yields the following relation

$$\left(\frac{\partial \ln m_i}{\partial\ 1/T}\right)_{sat} = -\frac{\Delta H_s}{R}\left(1 + \left(\frac{\partial \ln \gamma_i}{\partial \ln m_i}\right)_T\right)$$

where m_i is the saturation concentration, ΔH_s is the differential heat of solution for m-DNB in a saturated solution, and γ_i is the activity coefficient of m-DNB in DMSO.

Figure 1 shows a plot of the experimental values of the logarithm of the molality *vs.* the inverse of the absolute temperature. The slope of the line times R is −2053 cal/mole. An empirical equation for molality $m = 112.8 \exp(-2053/RT)$ fits the data quite well in the temperature range considered.

The densities of various solutions of m-DNB in DMSO are shown in Table II. A plot of the data shows a nearly linear relationship between density and concentration in this dilute region.

Electrochemical Dissolution of ZnO Single Crystals

D. D. Justice*,[1] and R. M. Hurd*,[2]

Department of Chemistry, North Texas State University, Denton, Texas 76203

ABSTRACT

Dissolution rates for the zinc face of ZnO single crystals were measured as a function of potential in KOH solutions. In the absence of light, there was no potential dependency between −1.2 and +3.0V *vs.* SCE. Upon irradiation with light of sufficient energy to produce electron-hole pairs, a potential dependent dissolution process was superimposed on the continuing potential independent process. The results are interpreted on the basis of a combination of both electrochemical and chemical dissolution processes.

Dissolution of the ionic crystalline state to form solvated ions involves oxidation-reduction reactions for metallic conductors, surface solvation and bond breaking for insulators, and probably some of each for semiconductors. The dissolution mechanism for metals is well known; however, the mechanism by which nonconducting crystals lose ions to the solution has been studied only slightly. The dissolution processes occurring on substances that span the "conductivity gap" between conductors and insulators have also been little studied; however, from the work that has been done, the existence of oxidation-reduction steps has been demonstrated on germanium (1) and silicon (2).

Germanium and silicon can be thought of as forming one type of "bridge" between conductors (metals) and insulators. Compound semiconductors, such as ZnO, can be thought of as forming a second bridge. The potential dependency of the dissolution rates of this first bridge has already been examined (3). The purpose of this investigation was to determine if the dissolution rates of single-crystal ZnO were a function of potential and, if possible, to measure these rates as a function of potential and correlate them with existing theories of electrochemical dissolution.

Key words: semiconduction, photopotential, electron-hole pairs, potentiostatic polarization, atomic absorption.

Experimental

A Magna 4700 potentiostat in a typical three-electrode circuit was used to maintain constant potentials over the long periods of time required to obtain the dissolution rates. These rates were measured with a Perkin-Elmer 303 atomic absorption spectrophotometer from accumulations of zinc ions in solution as a function of time. ZnO single crystals were obtained from Electronic Space Products, Inc., and had resistivity values between 2.0 and 10.0 ohm-cm. Etching characteristics (4) were used to identify the faces; only the zinc face was exposed to solution. Apparent surface areas were measured by a microscope and ranged from 0.026 to 0.042 cm^2. Ohmic contacts were obtained by the method used by Dewald (5). Thermostating at 26° ± 1°C was maintained by the air-conditioning in the laboratory; all room lights and other heat producing equipment were continuously operated. All solutions were bubbled with nitrogen for

several hours before the ZnO electrode was inserted in the cell. During measurements bubbling was discontinued and the outlet to the atmosphere was turned off. Currents were small enough so that IR drops between the ZnO electrode and the Luggin capillary could be neglected; IR drops in the semiconductor could be neglected except during high cathodic polarization.

A high-intensity microscope lamp was used to generate electron-hole pairs; glass filters were used to obtain a band of light between 360 and 400 mμ with the transmission maximum at 365 mμ. When a thermometer was placed directly in the solution, no change in temperature was measured in the presence or absence of light. As the intensity of light was increased (either by increasing the voltage to the lamp or by placing the lamp closer to the ZnO electrode), open-circuit potentials shifted in the cathodic direction from −150 mV *vs.* SCE (dark) to as much as −850 mV; thus, open-circuit potentials were an indication of light intensity.

Results

Dark dissolution rates were essentially independent of potential between −1.2 and +3.0V *vs.* SCE. In Fig. 1 dissolution rates for an 8.5 ohm-cm crystal in 1.0*N* KOH in the dark are shown on the same figure with the current-potential relation. The open-circuit dissolution rate is plotted to correspond to zero current, and anodic and cathodic dissolution rates are plotted relative to this point. Even though there was a sharp increase in cathodic currents around −1.2V, the dissolution rate did not measurably change. For an area of 10^{-4} cm², the 0.068 mg/hr cm² measured in this study for 1.0*N* KOH corresponds to the dissolution of about 4 x 10^{-12}g of ZnO in a 2-sec etch compared to about 2 x 10^{-10}g measured by Dewald (5) in 3.0*N* KOH.

From capacity values of ZnO in electrolyte systems (6), the space charge within the crystal is minimum at potentials near 600-700 mV cathodic to SCE (flat band potential). In this work, light intensity could be adjusted to easily attain an open-circuit potential of −650 mV which was chosen as the potential from which to begin measurements. During the first hour the lamp was adjusted slightly in order to maintain a constant open circuit, but then the potential remained essentially constant for 50 hr or longer; thus, light intensity was adjusted for an hour before any external voltage was applied. Open-circuit dissolution rates in light at −650 mV were almost twice those in the dark. Upon anodic polarization these rates increased; upon cathodic polarization they decreased. In Fig. 2 rates for an 8.5 ohm-cm crystal in 1.0*N* KOH are plotted on the same figure with the current-potential relation in order to show the close correlation between the two types of data. Around −1.2V the dark dissolution rates did not change but in light decreased and closely paralleled the polarization curve. Regardless of the polarization, the dissolution rates in light never became smaller than those in the dark.

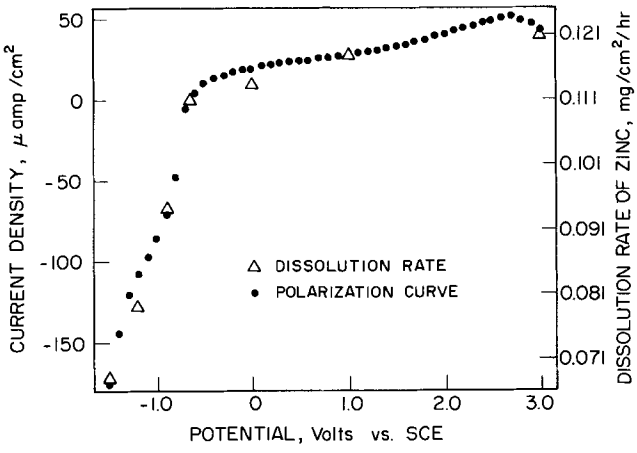

Fig. 2. Correlation of zinc dissolution rates with the current-potential relation for the zinc face of an 8.5 ohm-cm ZnO single crystal in 1.0*N* KOH. For each rate light was used to obtain an open-circuit potential of −650 mV *vs.* SCE.

As the hydroxide ion concentration decreased, larger anodic currents were obtained during polarization measurements. As shown in Fig. 3, the dissolution rates for an 8.5 ohm-cm crystal in 0.5*N* KOH still parallelled the polarization curve. For a given hydroxide ion concentration, the increase in dissolution upon anodic polarization became smaller as the resistivity of the crystal decreased. In Fig. 4 the polarization curve and dissolution rates are shown for a 2.0 ohm-cm crystal in 0.5*N* KOH. These data can be compared to those in Fig. 3 for an 8.5 ohm-cm crystal in 0.5*N* KOH. As shown in Fig. 2, 3, and 4, a passive type of peak was observed in light at approximately +3.0V. This peak was not examined in detail but became more pronounced as the current density of the polarization curves increased. Dissolution rates are summarized in Table I.

Assuming that electrons were released to the conduction band as zinc atoms passed into solution and that these electrons were measured as an external current flow, the weights of zinc expected after 100 hr were calculated, first on the basis of one and then two electrons per atom. In Table II these values are compared to the weights found by analyses. Experimental

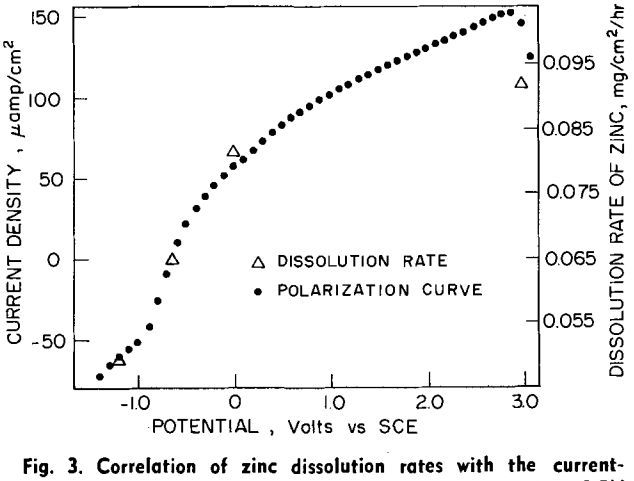

Fig. 3. Correlation of zinc dissolution rates with the current-potential relation for an 8.5 ohm-cm ZnO single crystal in 0.5*N* KOH. For each rate light was used to obtain an open-circuit potential of −650 mV *vs.* SCE.

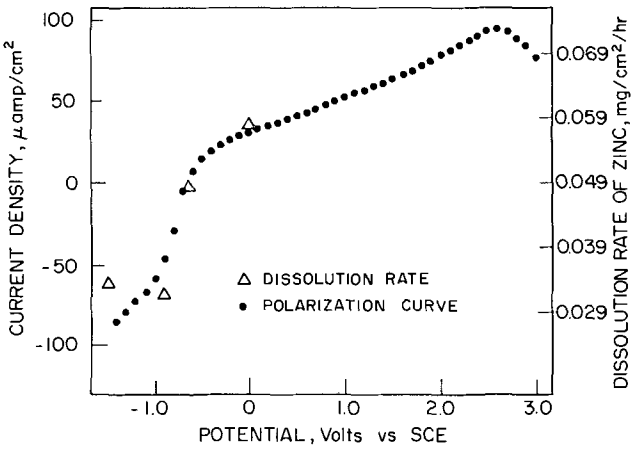

Fig. 4. Correlation of zinc dissolution rates with the current-potential relation for the zinc face of a 2.0 ohm-cm ZnO single crystal in 0.5*N* KOH. For each rate light was used to obtain an open-circuit potential of −650 mV vs. SCE.

amounts were always larger than those expected from current measurements.

In all the figures and more noticeable in Fig. 1, a "plateau" was found at −1.0V. This was most likely due to the slow desorption of hydroxide ions or to the reorientation of water dipoles with the more positive end toward the surface; *i.e.*, surface coverage by hydroxide ions or water dipoles was changing with potential.

Discussion

Dark dissolution rates between −1.2 and +3.0V were independent of potential and thus essentially chemical in nature. Large photovoltages indicated that large numbers of electron-hole pairs were produced; the increase in dissolution indicated that one of the delocalized charge carriers (holes) was involved in the dissolution process.

The open-circuit potential of −650 mV for the 8.5 ohm-cm crystal in 1.0*N* KOH was about 50 mV anodic to flat band potential (6). An anodic space charge existed in the crystal, and the holes produced and separated in this region were forced to the surface even at open circuit (7). Upon anodic polarization the surface hole density was additionally increased by increasing the depth from which holes were separated by the electrical field. The anodic current and dissolution rates parallel the increased surface hole density. Cathodic polarization resulted in a large decrease in surface hole density which paralleled a sharp decrease in the measured cathodic dissolution rates.

Since the flat band potential becomes more anodic as the *p*H decreases (6), a smaller anodic space charge region existed in 0.5*N* KOH, and a higher light intensity was needed to generate the current necessary to obtain the open-circuit potential of −650 mV. As seen from a comparison of Fig. 2 and 3, more holes were available to be forced to the surface by anodic polarization; upon cathodic polarization; a smaller proportion was forced back from the surface. In 0.5*N* KOH total dissolution was smaller, due to a decrease in the chemical rate with a decrease in hydroxide ion concentration, down to a solubility minimum near *p*H 9 (8) for powdered ZnO.

The flat band potential also becomes more anodic as resistivities increase (6). Compared to an 8.5 ohm-cm crystal, a larger proportion of holes was separated and forced to the surface in a 2.0 ohm-cm crystal. The influence of light and anodic polarization was less for the 2.0 ohm-cm crystal, as seen from a comparison of Fig. 3 and 4.

Conclusions

The over-all potential independent process can be described by

$$ZnO + 2\,OH^- + H_2O \rightarrow Zn(OH)_4^{-2} \qquad [1]$$

In this proposed chemical dissolution process, an electron is transferred from zinc to oxygen by a strong localized electrical field established by adsorbed hydroxide ions. This is a direct transfer because most of the electrons do not have enough energy to be delocalized to the higher lying conduction band. The small portion which has enough energy to make the transition can be considered to be electron-hole pair production which causes the mixed potential measured at open circuit even in the dark. Applied potentials cannot add enough energy to measurably increase the portion of electrons that has enough energy to make the transition. In addition applied voltages influence mainly the space charge region of the semiconductor and appear only to a limited extent across the semiconductor-solution interface. The composition of the phase at the semiconductor-solution interface therefore does not change, and thus the localized electrical field established by adsorbed ions is not changed.

Since the weight of zinc actually measured in solution was always greater than the amount expected from current measurements, a chemical dissolution process continues even in light; however, an additional dissolution process involving holes increases the total dissolution process. The following reactions (9) have previously been presented for this potential dependent (electrochemical) process

$$ZnO + 2(e'\sim/e'/) + 4\,OH^- \rightarrow Zn(OH)_4^{-2} + 2e' \qquad [2]$$

$$2H_2O + 2e' \rightarrow H_2 + 2\,OH^- \qquad [3]$$

$$ZnO + 2\,OH^- + 2H_2O + 2(e'\sim/e'/) \rightarrow Zn(OH)_4^{-2} + \tfrac{1}{2}\,O_2 + H_2 \qquad [4]$$

where ($e'\sim/e'/$) represents an electron-hole pair. Electrons are delocalized to the conduction band; the potential dependent step is the arrival of holes at the semiconductor surface.

The proposed electrochemical dissolution process for ZnO actually is analogous to the electrochemical dissolution of germanium (1) and silicon (2) except that in the proposed reactions for ZnO, light energy decomposes a mole of water into its constituent elements for each mole of ZnO that dissolves electrochemically. Electron-hole pairs are necessary for the electrochemical dissolution of all three semiconductors; however, in germanium and silicon the forbidden gap is small enough so that applied potentials can generate electron-hole pairs, whereas in ZnO the forbidden gap is so large that applied potentials of the magnitude used in this study cannot generate electron-hole pairs but can only alter the distribution of those produced by light.

Additional chemical data are needed to establish these proposed chemical and electrochemical reactions; in particular, precise measurements of the rates of evolution of hydrogen and oxygen gases are needed, as it is these data that will establish the fraction of the total dissolution rate which occurs by the electrochemical process.

Electrochemistry of Aziridinium Salts–Reduction of Alkyl Radicals to Anions as Function of Solvent

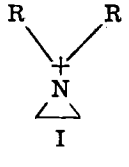
Donald A. Tyssee and Manuel M. Baizer*

Central Research Department, Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

The reductive degradation of aziridinium salts has been shown to follow different pathways depending on whether the solvent is protic (water) or aprotic (acetonitrile). Of prime importance is the variation in potential required for the reduction of an alkyl radical to an anion in the two solvents. The failure to recognize this fact in the electrolysis of compounds whose reduction potentials are subject to similar solvent shifts is discussed.

Mantsavinos and Christian (1) have examined the polarographic behavior of aziridinium salts and report that aziridinium ions of the general structure I undergo a single two electron reduction at approximately -1.2V (SCE) in aqueous solutions to give a trialkylamine, $R_2NCH_2CH_3$. In contrast, Mayell and Bard (2) exam-



I

$R = CH_2CH_2Cl$

ined the electrochemical behavior of benzyldimethylanilinium bromide and concluded that in either water or acetonitrile there is an initial one electron uptake at -1.6V (SCE) followed or accompanied by cleavage of a C-N bond to give dimethylaniline and the benzyl radical which then abstracts a hydrogen atom from the solvent to give toluene or dimerizes to give bibenzyl. Similarly, a radical pathway has been invoked to account for the observed behavior upon bulk electrolysis of benzyltrialkylammonium salts in water at -2.2V (3). In this case, toluene was formed upon bulk electrolysis in water, whereas in aprotic solvents a mixture of toluene and bibenzyl was formed. The use of active *d*-α-phenylethyltrimethylammonium nitrate demonstrated the presence of radical intermediates in aprotic solvents since upon bulk electrolysis only inactive coupled products were formed. The preparative utility of ammonium salt cleavage has been studied extensively by Horner (4).

Aziridinium salts reduce at easily accessible potentials. This allows one to investigate their electrochemical properties in solvent-electrolyte systems in which phenomena associated with electrolyte discharge are not of consequence. Namely, attention can be directed to the influence of solvent and/or electrolyte on 1 *vs.* 2 electron uptake and the mode of decomposition of intermediates to products. It is the purpose of this paper to report on the electrochemical behavior of aziridinium salts and to compare this behavior under conditions of both micro- and macro-electrolyses.

Experimental

Materials.—Acetonitrile (Matheson, Coleman and Bell-spectro-quality) was passed through Linde Type 3A molecular sieves and stored under nitrogen until used. Tetraethylammonium, tetramethylammonium, and lithium perchlorates were recrystallized from water and dried in a vacuum oven.

Aziridinium salts.—The aziridinium salts were prepared either as described previously (5) using silver

* Electrochemical Society Active Member.
Key words: bond cleavage, radical intermediates, ring opening, isotope effect.

perchlorate or generated *in situ* from the suitable 2-chloroethyldialkylamine liberated by neutralization of the commercially available amine hydrochlorides.

Polarography.—All polarograms were obtained with a Sargent Model XXI polarograph. Standard polarographic H cells were used throughout. The polarograms were recorded against a saturated calomel electrode as the reference using 0.1M supporting electrolyte. The concentration of depolarizer was 5×10^{-4} to 10^{-3}M. No correction was made for *IR* drop. Electrode constants were $m = 1.54$ mg sec^{-1}, $t = 5$ sec and $m^{2/3}t^{1/6} = 1.74$ at an Hg column height of 67 cm.

Cyclic voltammetry.—The cyclic voltammograms were obtained using a Wenking Model 66TA1 potentiostat and an Exact Model 505 function generator. Recording of the current-voltage curves was accomplished with a Tektronix 502-A Dual Beam Oscilloscope and a C-27 camera attachment. A three-compartment cell fitted with a Luggin capillary was used. The working electrode was a mercury drop suspended on a mercury-coated platinum wire. The reference electrode was a saturated calomel electrode and the auxiliary electrode a platinum wire. Solutions were 0.1M in supporting electrolyte and 5×10^{-4} to 10^{-3}M in depolarizer.

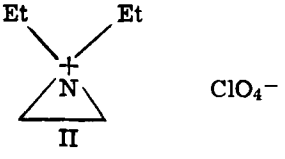
Bulk electrolysis.—Electrolyses were done at a mercury pool using a standard H cell with a glass frit divider. The potential was controlled using a saturated calomel electrode positioned at the mercury surface and a suitable potentiostat. Solutions were 0.2M in electrolyte. The aziridinium salt was either added initially in one portion or portion-wise over the duration of the run to keep its concentration in the bulk of the solution low. Electrolyses were carried out on sufficiently small quantities so that pH control was not necessary. The solvent/electrolyte mixture was pre-electrolyzed prior to the coulometric runs and deaerated continuously.

Isolation of amine products.—Typically the aqueous solution was made basic, extracted with ether, and analyzed by gas chromatography (Ucon/KOH). For runs in acetonitrile, the work-up procedure involved acidification, removal of acetonitrile *in vacuo*, and ether extraction after neutralization of the acidic residue.

Product identification.—Products were identified by the combined techniques of NMR, gas chromatographic retention times compared to authentic samples, and mass spectroscopy compared to authentic samples. Ethylene was identified in the off-gas by mass spectroscopy. Mercury was detected using the dithizone test—the samples having previously been oxidatively degraded with fuming nitric acid followed by aqueous bicarbonate neutralization.

Results

Polarography and coulometry.—Polarograms of N,N-diethylaziridinium perchlorate (II) in various solvent-electrolyte



II

systems are shown in Fig. 1. The variation of diffusion current with the height of the mercury column is illustrated in Fig. 2. The influence of phenol on the total diffusion current as well as on the presence of a polarographic maxima is illustrated in the polarograms of Fig. 3.

Because of the ease of removing acetonitrile during work-up, this solvent was used instead of dimethylformamide for coulometric and preparative studies. The aziridinium salts show identical behavior polarographically in either acetonitrile or dimethylformamide.

Coulometry of the aziridinium salt (II) at −1.8 to −1.9V in acetonitrile using tetraethylammonium perchlorate was consistent with a one-electron uptake at this potential. In contrast, coulometry at the same potential in water with tetraethylammonium perchlorate as the supporting electrolyte gave a two-electron uptake as did coulometry at −1.7V in water using lithium perchlorate as the supporting electrolyte.

Cyclic voltammetry.—The cyclic voltammogram of N,N-diethylaziridinium perchlorate in dimethylformamide is shown in Fig. 4. Included for comparison is the polarographic wave shape.

Bulk electrolyses.—Attempts to isolate products from the bulk electrolyses at controlled potential of N,N-diethylaziridinium perchlorate were complicated by the chemical reactivity of the starting material. Although coulometry allowed a distinction to be made between one- and two-electron reductions, increasing the concentration of the depolarizer to a scale (*i.e.* 10^{-1} to 1M) sufficient for product isolation resulted in low current efficiencies (*i.e.* less than 50% in most cases). Secondary products arising from competing chemical reactions included N,N,N',N'-tetraethylethylenediamine, polymeric quaternary ammonium salts, and 2-diethylaminoethanol (from hydrolysis of the original aziridinium salt).

Electrolysis in water (−1.6V to −1.9V).—Data relative to the electrolyses of aziridinium salts in aqueous solutions are given in Table I.

Careful examination by gas chromatography combined with rapid scan mass spectroscopy of the reaction mixture formed upon electrolysis of N,N-diethylaziridinium perchlorate (II) suggested that the peak eluting as triethylamine is actually a mixture of triethylamine and trace amounts of an amine of molecular weight 99.

During the electrolysis of II, secondary products formed as a result of subsequent chemical reactions included N,N,N',N'-tetraethylethylenediamine and a polymeric ammonium salt (V).

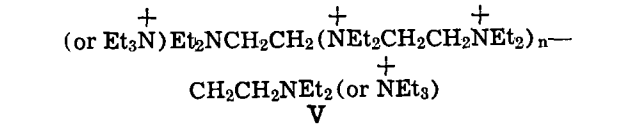
Table I. Preparative electrolysis of aziridinium salts in water

Salt[a]	Solvent/electrolyte	Products (ratio)
	$H_2O/LiClO_4$ H_2O/Et_4NClO_4	Et_2NH[b] Et_3N $Et_2NCH_2CH_2NEt_2$
	$H_2O(l)/D_2O(l)/Me_4NClO_4$	$Et_2N—CH=CH_2$ polymeric ammonium salts $CH_2=CH_2$ $Et_2NCH_2CH_3$(l) $Et_2NCH_2CH_2D$(l)
	H_2O/Me_4NClO_4	$Me_2NCH_2CH_2CH_3$[c] $Me_2NCH_2CH(Me)NMe_2$

[a] The initial concentration of the aziridinium salt was 1M when all of the salt to be electrolyzed was added at the beginning of the electrolysis. Several electrolyses were done in which the concentration of aziridinium salt was maintained at a lower level (*i.e.* 0.1M) by portion-wise addition to the cell. The same products were obtained regardless of the method of addition.

[b] The mole ratio of products formed was extremely variable. Attempts to establish a trend in product distribution with method of addition of II (*i.e.* portion-wise addition or adding all of II to be electrolyzed initially), current density, or electrolyte used were not successful.

[c] These were major products. No 2-dimethylaminopropane was detected.



V

The polymeric ammonium salt was characterized by NMR spectroscopy of the aqueous solution remaining after ether extraction of the basic electrolysis mixture. In the case of electrolyses in which $LiClO_4$ was used as the electrolyte, NMR spectra were run directly on the aqueous solution. In the case of electrolyses in which Me_4NClO_4 was used as the electrolyte, the tetramethylammonium cation was precipitated as the hexafluorophosphate salt prior to NMR analysis. Terminal triethylammonium groups were identified by comparing the shift of the methyl triplet relative to water. The salt $Et_3\overset{+}{N}CH_2CH_2NEt_2$ (prepared by the addition of N,N-diethylaziridinium perchlorate to a large excess of triethylamine) was used as a standard. The separations from water for the methyl triplet are 204 and 218 Hz respectively for the ammonium and neutral amine function. The water soluble product obtained upon exhaustive electrolysis of N,N-diethylaziridinium perchlorate showed only a triplet centered at 202 Hz. In addition, the expected quartet was observed (centered at 92 Hz upfield from H_2O) for $\overset{+}{N}CH_2CH_3$ as well as a singlet (85 Hz upfield from H_2O) for the internal methylenes.

Electrolysis in acetonitrile (−1.8V to −1.9V).—Electrolysis at controlled potential of N,N-diethylaziridinium perchlorate using either tetraethyl or tetraethylammonium perchlorate as the supporting electrolyte gave a variety of products. These included products of the primary electrochemical process (*i.e.* triethylamine, diethylamine and organo-mercury compounds) as well as products of subsequent chemical reactions between the aziridinium salt and electrochemically derived compounds. Again, as in the case of water, electrolysis on a preparative scale resulted in diminished current efficiencies as a result of competitive chemical reactions.

Evidence for the presence of radical intermediates in the form of organo-mercury compounds was obtained by the dithizone test (*cf.* Experimental). By analogy with other compounds which have been shown to undergo a one-electron reduction to a radical species which reacts with the mercury electrode (6, 7), it is assumed that a similar organo-mercury product is also

formed here. Attempts to trap the diethylaminoethyl radical with known radical scavengers including styrene, butadiene, or acrylonitrile were without success. This is in contrast to previous work which has shown that alkyl radicals generated electrochemically from alkyltriphenylphosphonium or sulfonium salts add to styrene in addition to reacting with the mercury electrode (6). In addition, gas chromatographic analysis of the amine products showed no evidence of the compound expected from coupling of two diethylaminoethyl radicals [*i.e.* $Et_2N(CH_2)_4NEt_2$].

Gas chromatographic analysis of the total reaction mixture suggested that a product was formed in barely detectable amounts whose retention time was the same as that of succinonitrile possibly formed by the coupling of $\cdot CH_2CN$. Previously it has been shown (6, 7) that reduction of this radical occurs more negatively than −1.7V, and therefore the absence of significant amounts of succinonitrile is expected.

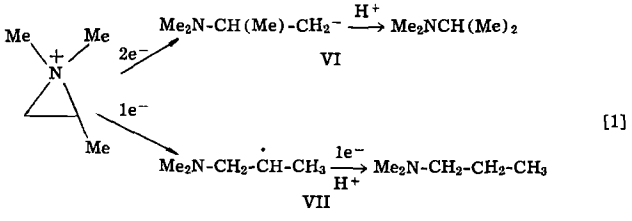
Discussion

Aqueous electrochemistry.—The polarographic and coulometric data are consistent with one two-electron reduction of N,N-diethylaziridinium perchlorate (II) at *ca.* −1.5V in water using a $LiClO_4$ electrolyte. Changing the electrolyte to $Et_4N\ ClO_4$ results in an apparent shift in half-wave of *ca.* −0.32V as well as in removal of the polarographic maximum.

As mentioned previously, the data obtained from bulk electrolyses were complicated by side chemical reactions in which products of the electrochemical reaction react chemically with the aziridinium salt to give nonactive product. The rates of such bimolecular chemical reactions were sufficiently depressed on a microscale so that reliable coulometric data could be obtained.

Several factors point to the conclusion that the first step in the reduction of II is addition of one electron followed by ring opening to a radical intermediate which, in aqueous solutions, is reduced to a carbanion at the applied potential. The diethylaminoethyl carbanion thus formed may abstract a proton from water (or unreduced aziridinium salt) or undergo an elimination to yield the diethylamine anion and ethylene.

The step-wise nature of the reduction is demonstrated by the reduction of N,N-dimethyl-2-methylaziridinium perchlorate (Table I). If a direct two-electron reduction were occurring initially or simultaneous with ring opening, the expected product would be the more stable primary anion (VI). A one-electron reduction followed by ring opening would yield the more stable secondary radical (VII). Reduction of VII followed by protonation would give 1-dimethylaminopropane (Eq. [1]).



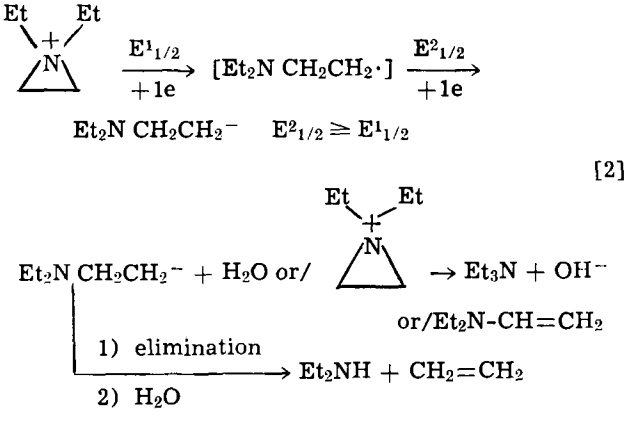
[1]

The exclusive product obtained (Table I) upon electrolysis of N,N-dimethyl-2-methylaziridinium perchlorate was that corresponding to a one electron reduction followed by ring opening to a radical intermediate (*i.e.* 1-dimethylaminopropane).

In order to distinguish between a radical or anionic precursor of triethylamine, an electrolysis of II was conducted in a 1/1 molar mixture of D_2O and H_2O, using tetramethylammonium perchlorate as the supporting electrolyte. Analysis of the isotopic enrichment in triethylamine by mass spectroscopy gave an isotope effect of 1 (*i.e.* $Et_3N/Et_2NCH_2CH_2D$). This is the value expected for anion protonation. Radical abstraction would be expected to give an isotope effect (k_H/k_D) greater than one as a consequence of the greater strength of the O-D bond (8). Although the isotopic enrichment in the electrolysis products of compounds previously reported to lead to products arising from hydrogen radical abstraction from water were not investigated, it is likely that a similar anionic intermediate rather than radical intermediate is involved, as has been reported (2-3). The known inability of water to quench radical polymerization as well as the unfavorable energetics required in the homolytic cleavage of an OH bond relative to forming a CH bond (*i.e.* 118 kcal for H_2O *vs.* 98 kcal for a CH bond) are also consistent with an anionic intermediate and serve to strengthen the argument against a radical intermediate being formed in aqueous solution.

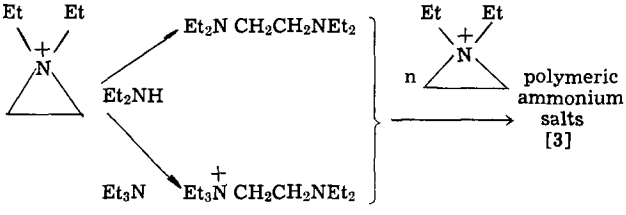
During the electrolysis of II a substantial amount of diethylamine was formed (Table I). This, taken with the observation that ethylene is formed, suggests that in the region of the electrode surface sufficiently anhydrous conditions exist so that prior to diffusion of the diethylaminoethyl anion into the bulk of the solution elimination occurs to give ethylene and the diethylamino anion. The formation of detectable amounts of diethylvinyl amine further supports the argument that a sufficiently basic species exists at or near the electrode surface to abstract a proton from unreduced aziridinium salt. The existence of an anhydrous layer at the electrode surface during aqueous electrolysis using quaternary ammonium electrolytes has been reported previously (9, 10). It thus appears that aziridinium salts behave in a similar fashion (*i.e.* to other ammonium salts) even to the extent that an "anhydrous" electrode layer exists when they are electrolyzed in the presence of a lithium containing electrolyte.

The following scheme is consistent with the aqueous electrolysis of aziridinium salts (Eq. [2]).



[2]

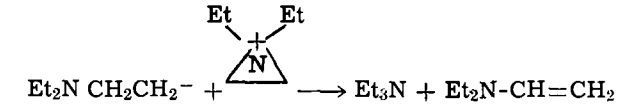
Because of the chemical reactivity of aziridinium salts, products formed initially *via* an electrochemical pathway accumulate in the cell during a bulk electrolysis and subsequently consume a portion of the aziridinium cation resulting in the observed decrease in current efficiency (Eq. [3]).



[3]

Nonaqueous electrochemistry.—Polarographic and coulometric results indicate that the reduction of N,N-diethylaziridinium perchlorate occurs in two one-electron steps. The first reduction is diffusion controlled (Fig. 2) and occurs at approximately −1.5 to −1.65V (SCE) depending on the electrolyte whereas the second reduction step occurs in the region *ca.* −1.9 to −2.1V (SCE) and exhibits a large maximum. The total dif-

fusion current constant (after the maximum) of the combined waves appears to be concentration dependent (Fig. 1b and 3) and is sensitive to the presence of proton donors (Fig. 3). It has been shown previously (6) that such an event occurs when an anion formed in the second reduction step reacts with depolarizer diffusing to the dropping electrode and is consistent with the behavior observed in aqueous electrolyses in which diethylvinylamine was detected in the products (Eq. [4]). Addition of phenol protonates the diethylaminoethyl anion so that all of the aziridinium salt diffusing to the electrode is available for reduction. The net result is to increase the total diffusion current.



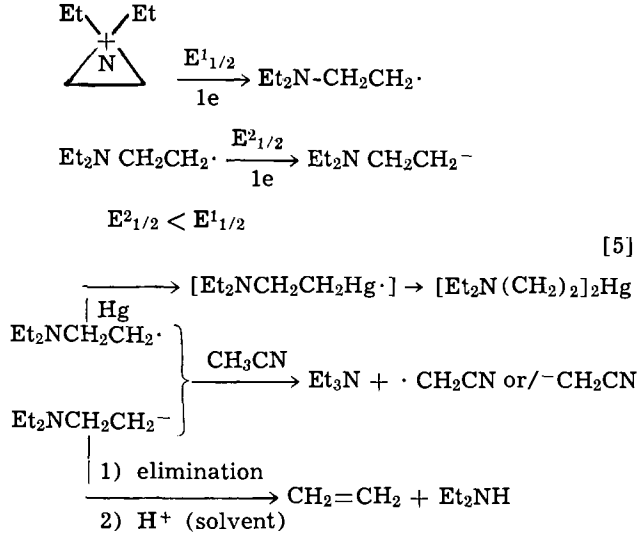
[4]

Numerous attempts to isolate radical products (other than organo-mercury compounds) by electrolyzing II at the first wave in the presence of known radical acceptors (*i.e.* butadiene, styrene, and acrylonitrile) were unsuccessful. However, the qualitative features (Fig. 4) of the cyclic voltammogram (11) as well as the detection of organo-mercury products are evidence for the formation of radical intermediates. The absence of radical coupling to give N,N,N',N'-tetraethylbutanediamine (VIII)

$$Et_2N(CH_2)_4NEt_2$$
VIII

is surprising in view of the reported formation of bibenzyl in the electrolysis of trimethylbenzylammonium salts (3). At present we have no explanation for this other than to note that dibenzylmercury is thermally converted to bibenzyl (12). As in the case of water, the formation of both diethylamine and triethylamine was observed indicating the potential control was not sufficient to prevent partial reduction to the anion followed by elimination or that radical abstraction by the diethylaminoethyl radical from acetonitrile is occurring. As discussed above, possibly trace amounts of succinonitrile were formed.

The following scheme is consistent with aziridinium salt electrolyses in aprotic solvents (Eq. [5])



[5]

Conclusions

The shift in half-wave potential of the second reduction step with solvent is of prime importance and resolves the question of the fate of alkyl radicals under varying electrolysis conditions. The extreme shifts observed in this study are shown in Fig. 1c. In water the radical (as R· or RHg·) is reduced at a potential as positive as or more positive than that required to form it initially. Changing to an aprotic solvent (dimethylformamide or acetonitrile) shifts the potential for the reduction of this radical to more negative values so that two distinct electron transfers occur.

The product distribution obtained upon bulk electrolysis of the aziridinium salts in aqueous solution is consistent with an anhydrous region being present at the electrode surface. In view of this, it might be expected that polarographic data obtained in aqueous and nonaqueous solutions would be the same. It is clear that they are not. This apparent contradiction is resolved if one compares the changes occurring at an electrode under conditions of micro- and macro-electrolysis. Polarographic current densities are of a sufficiently small magnitude such that the solution pH is maintained at the electrode whereas under the conditions of a bulk electrolysis in which protons are involved, the higher current densities result in a highly basic electrode region. This is especially true when only a limited amount of water is available initially as a consequence of the presence of the ammonium salt. The observed effect under aqueous conditions is a product distribution indicative of an anhydrous electrode region.

Earlier work (2, 3) postulating reduction to a radical intermediate in protic solvents followed by homolytic cleavage of an OH bond from the solvent to give the observed product is perhaps better described in terms of a direct two electron reduction to an anionic fragment which then reacts with the solvent. In aprotic solvents the reduction apparently proceeds in the stepwise manner previously reported for similar reductive cleavages.

Adsorption of Thiourea and Derivatives at the In-Hg Electrolyte Interface

R. Narayan[1] and Norman Hackerman*,[2]

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The double layer capacitance and interfacial tension of polarized Hg, In, and In-Hg (10 to 60 mole percent [m/o] In) electrodes were measured in 0.1M perchloric acid in a mixture of potassium chloride and hydrochloric acid (pH 1.6) and in the electrolytes containing thiourea and derivatives using the galvanostatic charging technique. Addition of thiourea increases the capacitance of the mercury electrode over the whole range of potentials. With the In-Hg electrodes, thiourea addition depresses the capacitance over a range of anodic potentials and increases the values over a range of cathodic potentials. A pronounced hump in the capacitance curve is observed; the nature of the hump and the depression of the capacitance are markedly influenced by the presence of Cl^-. These results are interpreted in terms of a reorientation of the adsorbed species in the interface. Effects of substituent groups on the above behavior were investigated using S-methyl isothiourea and tetramethyl thiourea.

The adsorption of thiourea from aqueous solutions at a mercury electrode has been investigated recently by capacity measurements (1) and tensammetric studies (2). Double layer capacity measurements with a mercury electrode in aqueous solutions containing thiourea have been very useful in the understanding of metal/solution interfaces. The results have been variously interpreted by Parsons (3) and Devanathan (4); the former investigating the dielectric behavior of the inner layer based on these results. Dutkiewicz and Parsons (5) studied the adsorption of thiourea from formamide at a mercury electrode, and observed that a direct interpretation of the capacity curves is rather difficult. The present investigation was undertaken to study the influence of the material of the electrode on the adsorption behavior of thiourea. Amalgams of compositions varying from 0-60 m/o can be easily prepared and handled. Butler (6,7) obtained electrocapillary curves for indium amalgams in 0.1M $HClO_4$ using the sessile drop method and double layer capacitances for the same system with a fast dropping amalgam electrode and a capacitance bridge. The In-Hg/0.1M $HClO_4$ system behaves like an ideally polarizable system over a range of potentials and the characteristic capacitance "hump" is also seen with amalgams of higher concentration (40%). It was believed worthwhile to obtain evidence by using the alternative charging curve technique and a hanging drop electrode, and to study adsorption characteristics at the interface. The use of a hanging drop electrode would also prove useful to achieve near equilibrium for any slow adsorption processes.

Experimental

All chemicals were analytical grade materials. The solutions were prepared using conductivity water. Supporting electrolyte solutions were treated with purified activated charcoal prior to use. The mercury was double distilled under vacuum and indium was 99.99% pure. The amalgams were prepared by adding the requisite amount of indium to weighed quantities of mercury kept under acidified water. The amalgams were stored in closed glass containers and kept in a vacuum desiccator.

The microelectrode was a hanging drop electrode, supplied by Metroohm Instruments and worked satisfactorily both with mercury and with amalgams. The areas were checked from weight measurements (assuming the small drop to be nearly a sphere) and capacitance measurements for mercury in 0.1M KCl. Agreement between the two methods was satisfactory. The counterelectrode was a large cylindrical platinum gauze. Attempts were also made to use indium rods as microelectrodes but with only partial success.

Cells were designed to accommodate a saturated calomel electrode with an intervening bridge of the experimental solution. A flat surface was incorporated into the main body of the cell for observation of the meniscus in the electrocapillary measurements.

Pure helium was used for degassing in the capacitance measurements and cylinder N_2, after passing through a purification train, was used for degassing and maintenance of pressure in the electrocapillary studies.

Capacitance measurements were made by the method developed earlier in this laboratory by Riney *et al.* (8). Potential time curves were obtained on a Tektronix oscilloscope 535A with a plug-in D type preamplifier and recorded using a Polaroid camera. The initial linear region (the first 5-10 μsec in the potential time trace) was used for calculations.

Results

Capacitance values for indium amalgam electrodes in 0.1M $HClO_4$ show satisfactory agreement with those obtained by Butler (7) who used an a-c bridge for his measurements. Capacitance-potential variations in KCl-HCl are similar to those in 0.1M $HClO_4$ but the capacitance values are generally higher. The hump is also observed in KCl-HCl medium. Capacitance curves with addition of Cl^- ions to $HClO_4$ are similar to those in $HClO_4$ but with larger capacitance values, significantly large with electrodes of higher amalgam concentration (greater than 20% amalgam concentration).

Addition of thiourea results in a depression of the capacitance of the amalgam electrode over a range of potentials (Fig. 1 and 2), the range depending on amalgam concentration. At cathodic potentials the capacitance increases to a value above that in the supporting electrolyte and the transition is marked by a rounded hump in the curves (Fig. 2). A sharp peak is observed when Cl^- ions are present in small quantity (Fig. 3) and the depression in the capacitance at anodic potentials is also greater. This observation is restricted to electrodes with 20% or more of indium in the amalgam.

In a chloride solution, the influence of amalgam concentration is even more marked; sharp peaks being

obtained instead of humps with 25% or higher amalgams (Fig. 4, 5, and 6). Electrocapillary studies (Fig. 7) indicate that thiourea and tetramethyl thiourea are very strongly adsorbed and shift the potential of zero charge (pzc) to more cathodic potentials. The capacitance in the presence of tetramethyl thiourea is decreased over a large range of potentials. No sharp desorption peaks are observed (Fig. 1, 2, 4, and 5). With

S-methyl isothiourea both capacitance (Fig. 1, 4, 5, and 7) and interfacial tension values are lowered to a very small extent over the whole range of potentials.

Discussion

The characteristic humps of capacitance curves are evident in the In-Hg/electrolyte system. In 0.1M $HClO_4$ the maximum of the hump occurs at approximately 100 mV more anodic than the potential of zero charge for mercury and amalgams of 50 and 60 m/o respectively. The charge q_m is different for the three electrodes at this potential. Thus the processes causing the humps seem to be potential dependent. The hump is perhaps absent in the case of amalgams of lower concentrations due to dissolution of indium from the amalgam at cathodic potentials. The pzc is known to be close to the potential for reversible dissolution of indium in the concentration range 1 to 20 m/o.

Parsons (3) explained the increased capacitance of mercury electrodes in the presence of thiourea as being due to the constant orientation of this species with the negative end of its dipole toward the mercury. With the amalgam electrodes the capacitance is increased over a range of potentials in the presence of thiourea, probably resulting from a similar orientation of the dipole. However, the capacitance is lowered when the electrode is anodically polarized beyond a certain potential, the transition being marked by a hump in the capacitance curve.

The potential range and height of this hump depend on the concentration of the amalgam and, to a lesser extent, on the concentration of thiourea. Electrocapillary studies by us indicate that the maxima of these humps for the higher concentrations occur at potentials practically coinciding with the respective pzc and that thiourea is strongly adsorbed in this region, as shown by a lowering of the interfacial tension. Thus these humps do not result from a slow desorption of thiourea.

The constant orientation of thiourea can be the result of strong Hg-S interaction. The capacitance

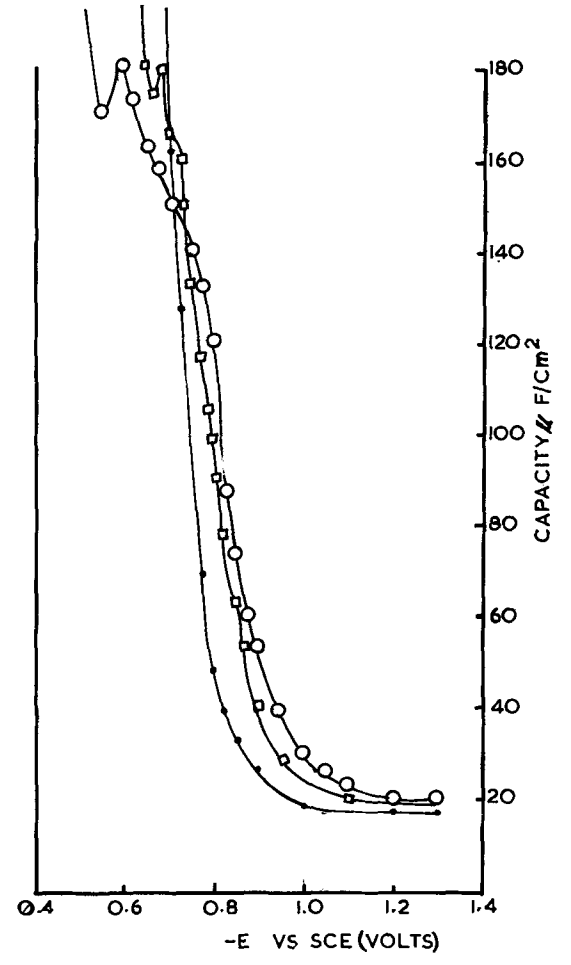

Fig. 6. Double layer capacitance of 20 m/o indium amalgam in a solution of KCl + HCl (pH = 1.6) with additions of thiourea and derivatives. ●—KCl + HCl (pH = 1.6), □—0.0105M thiourea, ○—0.0210M thiourea.

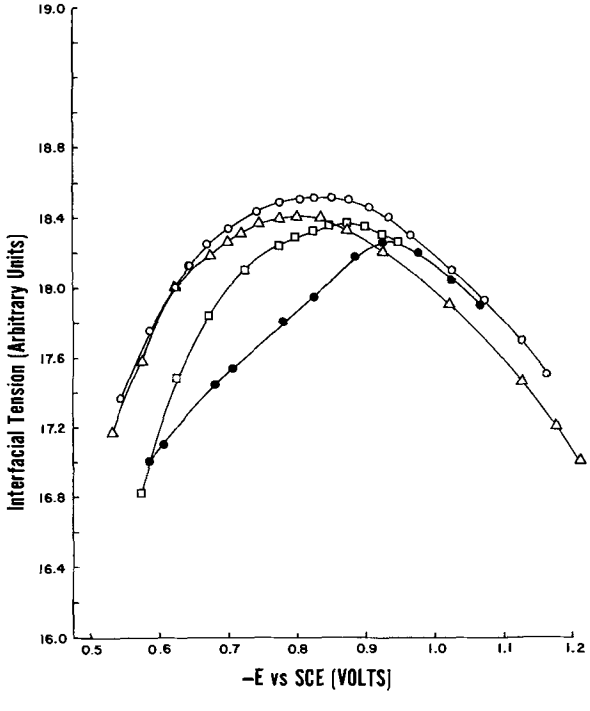

Fig. 7. Electrocapillary curves for 50 m/o indium amalgam in 0.1M $HClO_4$. ○—0.1M $HClO_4$, △—0.1M $HClO_4$ + 0.0063M S-methyl isothiourea, □—0.1M $HClO_4$ + 0.0052M thiourea, ●—0.1M $HClO_4$ + 0.0016M tetramethyl thiourea.

being lowered below the values in the supporting electrolyte at anodic potentials is indicative of a change in the adsorption layer. Electrocapillary studies with indium amalgams (6, 9) show that the interfacial composition of indium increases with anodic polarization. Curves for lower concentrations of amalgams show that indium is even positively adsorbed at potentials anodic to the pzc. Such positive adsorption is observed for higher concentrations of amalgams (<10.3%) in the presence of bromide ions (9). Thiourea with its specific adsorptive character can exert a similar influence, increasing the interfacial concentration of indium. Thus we expect with positive polarization an increased interaction involving indium, possibly as an $In-N^+$ interaction. This in turn should result in reorientation of the adsorbed species and hence a different capacitance. With increasing positive polarization the state where all dipoles were oriented with S toward Hg will change to a state with more and more dipoles oriented with N^+ toward In, the transition being marked by a hump in the capacitance curves. Information, at present lacking, regarding complexes of thiourea will prove useful in this context. We have to also consider relative changes in the electronegativities of Hg and In and any compound formation as the interfacial composition of In is increased.

In the presence of small concentrations of Cl^-, sharp peaks are obtained instead of humps. In a solution with chloride as the only anion, additional peaks at more anodic potentials are seen. Further, the lowering of capacitance due to thiourea becomes greater and a flat region extending over 50 mV is obtained. The capacitance at more cathodic potentials (−1.0V) is not affected. Lastly, the formation of peaks instead of humps in the presence of Cl^- ions is seen only when the concentrations of indium exceed 20 m/o in the amalgam.

The electrocapillary studies showed that Cl^- is adsorbed from a solution of 0.1M $HClO_4$. The pzc is shifted cathodically to a small extent due to this adsorption. To some extent Cl^- also increases the double layer capacitance of amalgam electrodes of composition exceeding 20 m/o of indium.

The calculations of Parsons (3) show that lateral interactions (repulsive) are very strong in the adsorbed layer containing thiourea dipoles. Hence if repulsive forces are considerable, then the adsorbed Cl^- ions act as bridges to reduce these forces, a more likely process with the positive ends of the dipoles oriented toward the metals. Additional dipoles can thus be accommodated and a greater depression in capacitance would result, as observed. The process of reorientation may also take place readily over a short range of potentials leading to the sharp peaks rather than humps.

It is more difficult to understand the critical composition of 20 m/o of indium in the amalgam to bring about the influence of the Cl^- ions. The adsorption of Cl^- ion is obviously the result of specific interaction forces between the metal and Cl^- and hence would depend on the interfacial composition of the amalgam. Upon specific adsorption Cl^- can indeed change the relative surface excess of In and may have an even greater influence in the presence of thiourea. One can further point to a relevant observation of Butler (6). The negative surface excess or surface deficiency of indium passes through a maximum in 0.1M $HClO_4$ for all potentials at approximately 20 m/o indium in the bulk of the amalgam. Frumkin (9), however, has indicated the necessity of keeping in mind possibilities of compound formation, for example, $InHg_3$ at 26 m/o In.

A 10% amalgam electrode obviously behaves like a mercury electrode. The adsorption of thiourea increases the capacitance over the entire ideally polarizable region, and the increase is greater with increased adsorption or concentration of thiourea. The dissolution of indium from this amalgam takes place at potentials more positive than approximately −0.65V and thiourea has some influence on this dissolution. The measurement of the capacitance becomes less accurate at such positive potentials and hence curves extending over the same potential range could not always be obtained. However, we observe from Fig. 2 and 3 that thiourea with its differential effects does not unduly affect the dissolution of indium from the amalgams with higher indium concentrations. Thus all the arguments given are truly restricted to the ideally polarizable region. In a purely chloride medium (Fig. 4, 5, and 6) there is a gross change in the behavior of indium of dissolution in the presence of thiourea, particularly for the lower concentration of amalgam (25% indium). Further studies have to be made before offering any explanation.

Tetramethyl thiourea, even in very small concentrations, adsorbs strongly at the Hg-solution and amalgam-solution interface. From electrocapillary studies, the desorption potential is taken to be about −1.0V. There is a considerable lowering of the interfacial tension and, to a lesser extent, the capacitance. This behavior resembles most surfactants except that a depression peak is absent in the capacitance. Kumler and Fahler (10) report that symmetrical substitution of the four hydrogens in thiourea decreases the dipole moment because steric hindrance prevents occurrence of forms with separation of charges which would make an appreciable contribution to the structure. As compared with thiourea, the decreased dipole moment may be reflected in a lowering of the capacitance. Any increase of the thickness of the double layer due to adsorption will also lead to a lowering. Steric factors appear to prevent N^+ to metal interaction so this derivative is always adsorbed with the S adjacent to the metal, no reorientation being possible. Thus the capacitance curves would be similar with both mercury and amalgam electrodes. Further, in the absence of reorientation, effects due to Cl^- are not expected.

The weak adsorption of the S-methyl derivative, as indicated by the very small lowering of capacitance and interfacial tensions, the nearly symmetrical nature of the electrocapillary curves, and the absence of any effect on the overvoltage for hydrogen discharge (thiourea and tetramethyl thiourea considerably reduce this factor), indicate that the mechanism of adsorption is different from that of the other two. By blocking the $-S$ by a $-CH_3$ group, it is likely that adsorption even at a mercury solution interface is through the nitrogen over the whole range of potentials and as a less dipolar species. Thus reorientation is unlikely and interaction forces are reduced. Hence the presence of Cl^- will not bring about any great changes in the adsorption except as a competing species.

More light can probably be shed on these forces of interaction by similar measurements using other metals for electrodes and also electrochemical polarization techniques. One approach would be to study the corrosion inhibition behavior of thiourea and derivatives. Some such studies have been done (11). It is known that thiourea in small concentrations (1 to 3 mM) inhibits corrosion but that it promotes the process when present in higher concentrations. Further investigations by one of us (RN) have shown that S-methyl and S-benzyl derivatives inhibit the corrosion of iron, the efficiency increasing with the concentration of the inhibitor (CE is 90% at 40 mM concentration).

The Low-Temperature Activity of Water in Concentrated KOH Solutions

P. Bro* and H. Y. Kang*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

The vapor pressures of H_2O-KOH solutions were measured manometrically between −40° and 25°C for concentrations between 2*M* KOH and 15*M* KOH. The effect of the temperature on the vapor pressure agreed with that predicted from the Clapeyron equation. An increase in the KOH concentration decreased the vapor pressure. The logarithm of the relative activity of KOH increased almost linearly with the KOH concentration, but it changed little with temperature. The data suggest that KOH hydrates occur as solid phases in the low concentration portion of the phase diagram. Furthermore, the existence of a eutectic point in the system was reflected in the properties of the solutions at temperatures far above the eutectic point.

The thermodynamic properties of concentrated potassium hydroxide solutions are of interest because they affect the operation of alkaline batteries. Water is consumed at metal oxide cathodes with the formation of hydroxyl ions, *e.g.*

$$HgO + 2e^- + H_2O \rightarrow Hg + 2\,OH^-$$

and, at low temperatures in particular, the kinetics of this reaction are affected by the activity of the water. The hydroxide formed at a zinc anode is in equilibrium with water

$$Zn(OH)_2 \rightleftharpoons ZnO + H_2O$$

and the state of the reaction product depends on the activity of the water. The activity of the potassium hydroxide is also of paramount importance, but that is not discussed here. Note that we employ $Zn(OH)_2$ and ZnO to designate the zinc ion species present in the system without implying that they are the species actually present (1). The reduction of water by zinc, with the formation of hydrogen, is also of interest, but it is of less importance at low temperatures.

There is a paucity of thermodynamic data on the H_2O-KOH system at low temperatures. The phase diagram of the H_2O-KOH system has been published (2), and its utility for the analysis of the performance of alkaline batteries is well recognized (3). Data are available on the activity of KOH in aqueous KOH solutions to concentrations of 4.0*M* KOH between 0° and 35°C (4) and to 17.0*M* KOH between 0° and 70°C (5). The activity of the water in KOH-H_2O solutions are available at 0°C (6) and 25°C (7), but no activity data are available for temperatures below 0°C which is a region of great interest for battery applications because of the severe low-temperature limitations on battery performance. The activity of the water in H_2O-KOH solutions is reported in this paper.

* Electrochemical Society Active Member.

Key words: H_2O-KOH system, H_2O-KOH-ZnO system, concentrated electrolytes, thermodynamic properties, low-temperature activity, vapor pressure, heat of vaporization, Gibbs-Duhem equation, phase diagram, eutectic behavior.

Experimental Methods

The activity of the water in the alkaline solutions was determined by measuring the vapor pressure of water above the solutions using the all-glass high-vacuum apparatus shown schematically in Fig. 1. The system was evacuated with S1 closed and S2-S4 open. Then, the sample container was connected to the vacuum line, the sample being located inside the low-temperature chamber (Associated Testing Laboratories, Model No. SW-5101), and the solution was frozen in a liquid nitrogen trap. S4 was then closed and S1 opened. When the pressure had decreased to about 10^{-5} mm Hg, S1 was closed and the sample warmed to room temperature. The same procedure was repeated three times to remove residual gases from the solution. Then, S1 was closed, S4 opened, and the system brought to about 10^{-5} mm Hg. When the sample had reached the desired temperature, as judged from the temperature of an identical sample container located near the

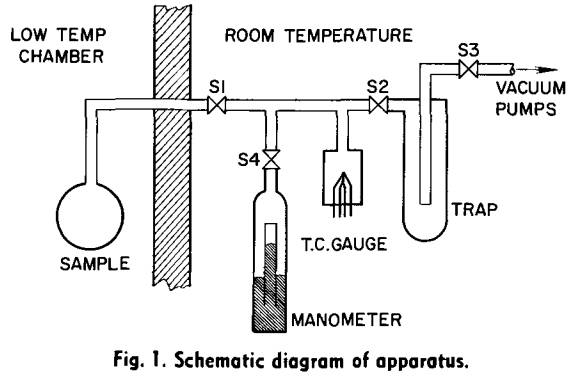

Fig. 1. Schematic diagram of apparatus.

shielded window of the low-temperature chamber, S2 was closed and S1 opened. The system was kept in this state until a constant pressure was observed on the pressure gauges (NRC thermocouple gauge No. 501 and a homemade Dubrovin gauge reading to 0.10 mm Hg). The gauges were calibrated using triply distilled water in the sample container instead of KOH solutions, and literature values (8) were used for the vapor pressure of ice and water.

The low-temperature chamber maintained the desired temperatures within ±0.5°C, and the sample temperatures were read with liquid-filled thermometers from a batch of thermometers having a standard deviation of 1.5°C from an NBS certified temperature over the entire temperature range. Replication of the pressure measurements indicated a precision of ±0.11 mm Hg at 10.0 mm Hg and ±0.0035 mm Hg at 0.300 mm Hg.

The potassium hydroxide solutions were prepared from Fisher Polypac 45.2% KOH solutions by dilution with triply distilled water. All the solutions were stored under argon atmospheres and all the solutions were prepared in argon-filled glove bags to eliminate CO_2 contamination.

Experimental Results

The observed vapor pressures are given in Table I for the KOH-H_2O system. The reported values were obtained on single-phase systems. At low-temperatures phase separations occurred with some of the solutions, but since phase separation gives rise to changes in the composition of the solutions the observed vapor pressures of the two-phase systems is of little interest, except as noted later.

The values reported in Table I were obtained in the chronological sequence shown. There appears to be a good agreement between the values obtained when the measurement temperatures were approached from above and from below and this agreement is taken as evidence that equilibrium prevailed in the system. It may be seen that the vapor pressures decreased markedly with a decrease in the temperature and with an increase in the KOH concentration.

In order to facilitate the comparison of the data, the least square values were computed using the correlation

$$P = A \exp(-B/T) \quad [1]$$

and the smoothed data are given in Table II together with the constants A and B.

Discussion

Our results may be compared with the values reported in the literature for the KOH-H_2O solutions at 25°, 20°, and 0°C; no values were found in the literature for lower temperatures. The comparison is illustrated in Fig. 2. It may be noted that the Kangro and Groeneveld (7) and the Dieterici (6) results were obtained by direct measurements of the vapor pressures and the Kobayashi (9) and the Robinson and Stokes (10) values were obtained by calculation from emf measurements. The latter used the data of Harned and Cook (4) and of Akerlof and Bender (5). All the 25°C values from the literature are in good agreement. It may be seen that our data fall slightly below the literature values at 25°C for the more concentrated KOH solutions, but otherwise they agree reasonably well. The 20°C data of Kangro and Groeneveld lie very close to their 25°C data, but slightly below the 25°C points shown in Fig. 2. Our 20°C data likewise fall slightly below our 25°C data. They are not shown in Fig. 2 to avoid cluttering the graph. At 0°C our data lie a little further below the 25°C data points, as may be seen in Fig. 2, but the 0°C water activity-KOH concentration curve generally follows the course of the 25°C curves. The data reported by Dieterici for 0°C lie considerably above all the other values shown in Fig. 2 and may be considered, at least provisionally, to be in error.

The consistency between the literature values and our results lends support to the belief that our results

* From data of Cohen-Adad and Michaud (2).
** From ref. (8).

at the lower temperatures provide a reliable set of values for the vapor pressure of the KOH solutions.

The $KOH-H_2O$ phase diagram presented by Cohen-Adad and Michaud (2) indicates the formation of ice in solutions containing less than 30.9 w/o (weight per cent) KOH and of $KOH \cdot 5H_2O$ in more concentrated solutions upon cooling. This being the case, it is to be expected that the observed vapor pressure data should extrapolate to values close to but slightly greater than those of pure ice and $KOH \cdot 5H_2O$, respectively, at the temperatures reported to be the freezing points of the solutions. This comparison is made in Table III for the $KOH-H_2O$ solutions. It may be seen that the solution vapor pressures are consistently lower than that of ice. In the case of the 14.7M KOH solution it is known that the solid phase is $KOH \cdot 5H_2O$ and its vapor pressure would be expected to be lower than that of ice at the same temperature. For the less concentrated solutions the experimental data indicate that the solid phase in equilibrium with the solutions, if ice, would have a greater water activity than the solutions and this appears to be unreasonable. The results suggest that the H_2O is more strongly bound in the solutions than in ice at the same temperatures. It follows that the solid phases may not be ice at all but some hydrates of KOH. Although the published $KOH-H_2O$ phase diagram does not indicate any solid phases other than ice for the less concentrated solutions some work of O'Nan (11) indicates that solid KOH hydrates do indeed form in the less concentrated $KOH-H_2O$ solutions. This matter is of some importance for the low-temperature operation of alkaline cells where alkali depletion occurs in the anodes, and their operability depends on whether pure ice forms or a more KOH-rich phase. The relevant considerations have been discussed by Gomis *et al.* (3).

The vapor pressure correlation represented by Eq. [1] is the integrated form of the Clapeyron equation for an ideal vapor with neglect of the liquid volume, and we have

$$\Delta H_{vap} = BR \qquad [2]$$

(R is the gas constant)

The experimental data gave the heats of vaporization shown in Table IV. It was independent of temperature between −40° and 25°C, and changes in the concentration of KOH did not affect it perceptibly. The average heat of vaporization was 11.2 kcal/mole. This value may be compared with the literature values of 10.4 kcal/mole at 30°C and 10.7 kcal/mole at 0°C (12) for the heat of vaporization of pure water. The good agreement between the two sets of values suggests that the water is present in the alkaline solutions in the same thermodynamic state as it is in pure water, except for possible differences in its state of order.

The vapor pressure of the H_2O-KOH solutions may be used to calculate the activity coefficient of the KOH by means of the Gibbs-Duhem equation. However, two problems arise which require that the usual integration path be replaced by a more appropriate choice. The Gibbs-Duhem equation is generally integrated by the use of the osmotic coefficient of the solution, and it is necessary to integrate from the state where the osmotic coefficient approaches unity; the standard state. At temperatures below 0°C it is not possible to measure the vapor pressure of very dilute KOH solutions, since a phase change occurs, and the osmotic coefficient cannot be determined. Another problem concerns the accuracy of the osmotic coefficients calculated from solution vapor pressures of dilute solutions. A tremendous error magnification occurs for dilute solutions, and vapor pressure data are not suitable for the calculation of electrolyte activity coefficients for dilute solutions. The dilemma posed by the two problems can be resolved by selecting an experimentally accessible reference state. The choice of reference state is quite arbitrary, but convenience dictates that the same reference state be used for all the temperatures of interest. We selected, therefore, the eutectic composition as the reference state for the H_2O-KOH system, and integration of the Gibbs-Duhem equation gives the activity of the KOH solution of any composition relative to the KOH activity of a solution at the same temperature having the eutectic composition. The relative activities are given in Table V, and the data available from the literature have been included for comparison. No data are available at temperatures other than 25°C, but it may be seen that our results agree well with the published data at 25°C. Some discrepancies occur in the most dilute and the most concentrated solutions where the vapor pressure measurements are recognized to be a poor means for obtaining electrolyte activity data.

* Relative mean molal activity with reference to an 8.0M KOH solution.
** Reference (10), recalculated to 8M KOH reference state.

The good agreement between our results and the published values at 25°C suggests that our results at the lower temperatures provide a valid measure of the relative activity of KOH in aqueous solutions at the lower temperatures as well. It may be noted that the KOH activity of the solutions increases very strongly with the KOH concentration. The logarithm of the relative activity increases almost linearly with the KOH concentration at all the temperatures shown. The rate of increase appeared to be nearly independent of temperature.

The Gibbs-Duhem equation was integrated via the term $(M \cdot P)$, *i.e.*, the product of the KOH concentration and the vapor pressure, and it was observed that plots of $(M \cdot P)$ *vs.* M displayed well defined maxima, Table VI. All the maxima occurred at the eutectic composition of the H_2O-KOH system regardless of the solution temperature. The maxima in these curves are equivalent to inflection points in the chemical potentials of KOH at the eutectic composition of the solutions at the various temperatures. Such inflection points are normally associated with stability regions, and it is interesting that the stabilizing influences responsible for the formation of a eutectic point should be discernible at temperatures much above the eutectic temperature.

It is well known (13) that the concentration of zinc oxide in electrolytically generated zincate solutions in H_2O-KOH have zinc oxide concentrations in excess of the reported equilibrium values (14), and it was of interest to examine the effect of the zinc oxide on the vapor pressure of the H_2O-KOH solutions likely to occur in alkaline cells with zinc anodes. We prepared some H_2O-KOH-ZnO solutions with a ZnO concentration exceeding the equilibrium values and measured their vapor pressures with the results shown in Table VII. It may be seen by comparing the results with the data in Table II that the addition of ZnO led to a decrease of the vapor pressure of all the H_2O-KOH solutions at room temperature. At lower temperatures the same effect persisted but only in the dilute KOH solutions. As the temperature decreased the vapor pressure of the H_2O-KOH-ZnO solutions approached that of the H_2O-KOH solutions with the same KOH concentration. In the most concentrated KOH solutions at low temperatures the vapor pressure of the H_2O-KOH-ZnO solutions exceeded that of the H_2O-KOH solutions.

Although the thermodynamic state of the H_2O-KOH-ZnO solutions we used is undefined [see (1)], the solutions are nevertheless of practical interest in battery technology. As a first approximation, the activity of the water in the H_2O-KOH solutions may be used for the analysis of the behavior of both alkaline cells with cadmium anodes and alkaline cells with zinc anodes.

Conclusions

Manometric techniques were found to be satisfactory for the measurement of the vapor pressure of potassium hydroxide solutions between −40° and 25°C.

The vapor pressure of the solutions decreased markedly with the temperature in accordance with the Clapeyron equation, and the experimental data led to a heat of vaporization of water of 11.2 kcal/mole for the H_2O-KOH solution between −40° and 25°C. The heat of vaporization was not affected noticeably by the concentration of the alkaline solutions. The vapor pressure decreased markedly with an increase in the KOH concentration, as expected.

The vapor pressures of the solutions at their freezing points were less than those of pure ice. This is inconsistent with the published phase diagrams which show solid ice to form in solutions less concentrated than 8.0*M* KOH. It is thought that hydrates of KOH must be present rather than ice.

The low-temperature activity coefficients of KOH cannot be calculated from the vapor pressure data by the Gibbs-Duhem equation since dilute solutions cannot be prepared at the low temperatures. Instead, the activities of KOH in the various solutions were calculated relative to those of KOH solutions with the eutectic composition. The logarithm of the relative activity increased almost linearly with the KOH concentration at all the temperatures, but it changed very little with temperature at constant composition.

Inflection points were observed in the chemical potentials of the electrolyte expressed as a function of the KOH concentration at a constant temperature. The inflection points occurred at the eutectic composition of the system over the entire temperature range, and their existence indicated the presence of eutectic precursor interactions in the system far above the eutectic temperature.

The addition of ZnO to the aqueous KOH solutions changed their vapor pressures, but the changes were sufficiently small that as a first approximation the vapor pressure of the H_2O-KOH solutions may be used for the analysis of the behavior of alkaline cells with zinc anodes as well as alkaline cells with cadmium anodes.

Convective Diffusion on a Rotating Spherical Electrode

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The Levich theory of the rotating disk has been extended to the case of rotating spherical electrodes by means of a series expansion method. It is shown that the rate of mass transfer near the pole of rotation is the same as on a rotating disk. It decreases, however, in meridional direction toward the equator. Results for a sphere or hemispherical electrode can be summarized as

$$Sh = 0.474\, Re^{1/2}\, Sc^{1/3}$$

$$I_{lim} = 0.474\, nFC_{\infty} D^{2/3}\, \nu^{-1/6}\, \omega^{1/2}$$

where Sh and Re are the Sherwood and the Reynolds numbers based on the sphere radius, and Sc is the Schmidt number.

Study of the transport process on a rotating spherical cap is of interest to the electrochemist. In the first place it could provide an insight regarding the effect of surface curvature on the rate of ionic transfer to a rotating disk electrode (RDE). Second, such a study would extend the application of RDE to corrosion and high-rate metal dissolution studies. The RDE is generally made of a circular disk electrode mounted concentrically on the surface of an electrically inert rotating disk. Since theoretical considerations require the RDE to have a perfectly flat surface, the RDE made this way is always polished carefully until the central disk electrode becomes flush with the nonconductive surface. For high rate dissolution studies (such as in the case of electrochemical machining), it is, however, extremely difficult to maintain a flat surface during the experimental runs, for the disk electrode made of the metal being dissolved would recede from the surface of the RDE and subsequently cause an irregular feature on the surface of the disk. This surface irregularity would then generate secondary flows, which in turn would interrupt the hydrodynamic boundary layer over the rotating disk. The Levich theory (1, 2) is therefore no longer valid, and access to the quantitative study of reaction kinetics becomes impossible.

One way to overcome the problem is to replace the disk electrode on the RDE with an electrode having a spherical surface as illustrated in Fig. 1. The electrode now has a spherical head fastened on one end of a rotating rod coated with nonconducting material and will be called a rotating spherical electrode (RSE). The advantage of this combination is that the spherical head is less subject to a change of surface geometry due to dissolution of electrode material into the electrolyte; the problem associated with the induced secondary flows as in the case of RDE could therefore be minimized.

Experimental investigation of laminar boundary layer flow induced by a sphere rotating in an infinite fluid has been performed by Kobashi (3), Kreith, Roberts, Sullivan, and Sinha (4), and by Bowden and Lord (5). Using smoke and hot wire techniques, these investigators found that the boundary layer originates at the pole and develops with increasing thickness toward the equator. The fluid is drawn in toward the sphere along the axis of rotation, as shown in Fig. 1, and moves over the spherical surface toward the equator where a radial outflow jet is formed. Bowden and Lord's photographic study revealed that the outflow in the vicinity of the equator is confined to a very narrow zone, and the flow of the radial jet is laminar within a short distance from the sphere surface. For Reynolds numbers, based on the sphere radius, of less than 1.25×10^4, the result of the study by Kreith *et al.* indicates that this outflow zone is less than 2° latitude in width. Theoretical analysis of this flow problem was first considered by Howarth (6), who introduced appropriate boundary layer equations and obtained an approximate solution by means of the Karman-Pohlhausen momentum integral method. Owing to the limitation of the boundary layer assumptions, he was unable to predict the outflow of fluid at the equator. Despite this shortcoming, however, his model has been used successfully to predict the torque required to maintain a constant speed of rotation (5), and to describe the velocity distribution and the thickness of the boundary layer along the surface except in the vicinity of the equator (4). Recently, Banks (7) and Manohar (8) have obtained the exact solution of Howarth's boundary layer equations by means of numerical integrations with the help of digital computers. A second theoretical model is proposed by Nigam (9), who assumes that the boundary layer thickness is uniform over the sphere surface, and that

Convective Diffusion on a Rotating Spherical Electrode

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The Levich theory of the rotating disk has been extended to the case of rotating spherical electrodes by means of a series expansion method. It is shown that the rate of mass transfer near the pole of rotation is the same as on a rotating disk. It decreases, however, in meridional direction toward the equator. Results for a sphere or hemispherical electrode can be summarized as

$$Sh = 0.474\, Re^{1/2}\, Sc^{1/3}$$

$$I_{lim} = 0.474\, nFC_{\infty} D^{2/3}\, \nu^{-1/6}\, \omega^{1/2}$$

where Sh and Re are the Sherwood and the Reynolds numbers based on the sphere radius, and Sc is the Schmidt number.

Study of the transport process on a rotating spherical cap is of interest to the electrochemist. In the first place it could provide an insight regarding the effect of surface curvature on the rate of ionic transfer to a rotating disk electrode (RDE). Second, such a study would extend the application of RDE to corrosion and high-rate metal dissolution studies. The RDE is generally made of a circular disk electrode mounted concentrically on the surface of an electrically inert rotating disk. Since theoretical considerations require the RDE to have a perfectly flat surface, the RDE made this way is always polished carefully until the central disk electrode becomes flush with the nonconductive surface. For high rate dissolution studies (such as in the case of electrochemical machining), it is, however, extremely difficult to maintain a flat surface during the experimental runs, for the disk electrode made of the metal being dissolved would recede from the surface of the RDE and subsequently cause an irregular feature on the surface of the disk. This surface irregularity would then generate secondary flows, which in turn would interrupt the hydrodynamic boundary layer over the rotating disk. The Levich theory (1, 2) is therefore no longer valid, and access to the quantitative study of reaction kinetics becomes impossible.

One way to overcome the problem is to replace the disk electrode on the RDE with an electrode having a spherical surface as illustrated in Fig. 1. The electrode now has a spherical head fastened on one end of a rotating rod coated with nonconducting material and will be called a rotating spherical electrode (RSE). The advantage of this combination is that the spherical head is less subject to a change of surface geometry due to dissolution of electrode material into the electrolyte; the problem associated with the induced secondary flows as in the case of RDE could therefore be minimized.

Experimental investigation of laminar boundary layer flow induced by a sphere rotating in an infinite fluid has been performed by Kobashi (3), Kreith, Roberts, Sullivan, and Sinha (4), and by Bowden and Lord (5). Using smoke and hot wire techniques, these investigators found that the boundary layer originates at the pole and develops with increasing thickness toward the equator. The fluid is drawn in toward the sphere along the axis of rotation, as shown in Fig. 1, and moves over the spherical surface toward the equator where a radial outflow jet is formed. Bowden and Lord's photographic study revealed that the outflow in the vicinity of the equator is confined to a very narrow zone, and the flow of the radial jet is laminar within a short distance from the sphere surface. For Reynolds numbers, based on the sphere radius, of less than 1.25×10^4, the result of the study by Kreith *et al.* indicates that this outflow zone is less than 2° latitude in width. Theoretical analysis of this flow problem was first considered by Howarth (6), who introduced appropriate boundary layer equations and obtained an approximate solution by means of the Karman-Pohlhausen momentum integral method. Owing to the limitation of the boundary layer assumptions, he was unable to predict the outflow of fluid at the equator. Despite this shortcoming, however, his model has been used successfully to predict the torque required to maintain a constant speed of rotation (5), and to describe the velocity distribution and the thickness of the boundary layer along the surface except in the vicinity of the equator (4). Recently, Banks (7) and Manohar (8) have obtained the exact solution of Howarth's boundary layer equations by means of numerical integrations with the help of digital computers. A second theoretical model is proposed by Nigam (9), who assumes that the boundary layer thickness is uniform over the sphere surface, and that

the assumption of the boundary layer does not break down at the equator. Though Nigam is able to predict an outflow in the region between latitude 54.75° and the equator, his solutions have been repeatedly proved to be incorrect from both theoretical and phenomenological points of view (4, 5, 8).

The problem of heat transfer from a rotating sphere has been studied experimentally by Kreith *et al.* (4) for Prandtl numbers between 0.024 and 217, and theoretically by Singh (10), Banks (11), and Baxter and Davies (12). Singh's computation is trivial because he employs Nigam's velocity result in the analysis. Banks calculates the thermal boundary layer numerically at Prandtl numbers equal to 0.7 and 1.0. Baxter and Davies' study is confined to high Prandtl numbers; they obtain an implicit approximate solution based on Howarth's approximate momentum solutions.

For the quantitative application of RSE to the study of electrochemical processes, one requires knowledge regarding the nature of ionic transfer on the spherical electrode. The object of this report is to discuss in detail the theoretical background behind such a problem. A mathematical model based on Howarth's and Banks' momentum results will be described. It will be shown that, at high Schmidt numbers, Levich's theory of the rotating disk electrode can be extended to the case of a rotating sphere by means of a series expansion method.

Boundary layer equations.—In the following analysis we shall use spherical polar coordinates, r, θ, ϕ, with r measured radially outward from the center of the sphere, θ measured from the axis of rotation, and ϕ the azimuth. The spherical electrode is assumed to be rotating at a sufficiently high speed to permit application of the boundary layer approximations, and the motion of the fluid is assumed to be symmetrical about the axis of rotation. Also, the physical properties of the fluid will be assumed to be constant. Neglecting the effect of external forces, the equations (4, 6, 11) of fluid motion and convective diffusion on a rotating spherical electrode of radius r_o are given as

Continuity

$$\frac{\partial V_r}{\partial r} + \frac{1}{r_o}\frac{\partial V_\theta}{\partial \theta} + \frac{\cot\theta}{r_o} V_\theta = 0 \qquad [1]$$

θ-momentum

$$V_r \frac{\partial V_\theta}{\partial r} + \frac{V_\theta}{r_o}\frac{\partial V_\theta}{\partial \theta} - \frac{V_\phi^2 \cot\theta}{r_o} = \nu \frac{\partial^2 V_\theta}{\partial r^2} \qquad [2]$$

ϕ-momentum

$$V_r \frac{\partial V_\phi}{\partial r} + \frac{V_\theta}{r_o}\frac{\partial V_\phi}{\partial \theta} + \frac{V_\theta V_\phi}{r_o}\cot\theta = \nu \frac{\partial^2 V_\phi}{\partial r^2} \qquad [3]$$

Convective-diffusion

$$V_r \frac{\partial C}{\partial r} + \frac{V_\theta}{r_o}\frac{\partial C}{\partial \theta} = D \frac{\partial^2 C}{\partial r^2} \qquad [4]$$

Boundary conditions

$$\left.\begin{array}{ll} \text{at } r = r_o, & V_r = V_\theta = 0 \\ & V_\phi = r_o\omega \sin\theta \\ & C = C_o \\ \text{at } r \to \infty, & V_\theta = V_\phi = 0 \\ & C = C_\infty \end{array}\right\} \qquad [5]$$

We may normalize the above equations with the following dimensionless variables and by expanding the dependent variables in a power series of θ

$$Re = \frac{r_o^2 \omega}{\nu}, \quad Sc = \frac{\nu}{D} \qquad [6]$$

$$\eta = \left(\frac{\omega}{\nu}\right)^{1/2} (r - r_o) \qquad [7]$$

$$V_r = (\nu\omega)^{1/2} \{H_1 + \theta^2 H_3 + \theta^4 H_5 + \ldots\} \qquad [8]$$

$$V_\theta = r_o\omega \{\theta F_1 + \theta^3 F_3 + \theta^5 F_5 + \ldots\} \qquad [9]$$

$$V_\phi = r_o\omega \{\theta G_1 + \theta^3 G_3 + \theta^5 G_5 + \ldots\} \qquad [10]$$

$$C = C_\infty + (C_o - C_\infty)\{\Phi_1 + \theta^2\Phi_3 + \theta^4\Phi_5 + \ldots\} \qquad [11]$$

Here the dependent variables F_i, G_i, H_i, and Φ_i with $i = 1, 2, 3, \ldots$, are functions of η only. Details of this lengthy substitution are illustrated in ref. (6) and (11) and will not be discussed here. The results for the first two terms in the series expansions are

Zeroth order equations

$$H_1' + 2F_1 = 0 \qquad [12]$$

$$H_1F_1' + F_1^2 - G_1^2 = F_1'' \qquad [13]$$

$$H_1G_1' + 2F_1G_1 = G_1'' \qquad [14]$$

$$H_1\Phi_1' = \frac{1}{Sc}\Phi_1'' \qquad [15]$$

$$\left.\begin{array}{l} \text{b.c. at } \eta = 0,\ F_1 = H_1 = 0,\ G_1 = \Phi_1 = 1 \\ \text{at } \eta \to \infty,\ F_1 = G_1 = \Phi_1 = 0 \end{array}\right\} \qquad [16]$$

First order equations

$$H_3' + 4F_3 - (1/3)F_1 = 0 \qquad [17]$$

$$H_1F_3' + H_3F_1' + 4F_1F_3 - 2G_1G_3 + (1/3)G_1^2 = F_3'' \qquad [18]$$

$$H_1G_3' + H_3G_1' + 4F_1G_3 + 2F_3G_1 - (1/3)F_1G_1 = G_3'' \qquad [19]$$

$$H_3\Phi_1' + H_1\Phi_3' + 2F_1\Phi_3 = \frac{1}{Sc}\Phi_3'' \qquad [20]$$

$$\left.\begin{array}{l} \text{b.c. at } \eta = 0,\ F_3 = H_3 = \Phi_3 = 0,\ G_3 = -1/6 \\ \text{at } \eta \to \infty,\ F_3 = G_3 = \Phi_3 = 0 \end{array}\right\} \qquad [21]$$

It is seen that the zeroth order equations are the same as the well-known transfer problem on a rotating disk (2, 13). Thus, for small values of η, we may immediately apply Cochran's result (14), and write the zeroth order solutions for the velocity distributions near the spherical surface

$$F_1 = a\eta - (1/2)\eta^2 - (b/3)\eta^3 - (b^2/12)\eta^4 + \ldots \qquad [22]$$

$$G_1 = 1 + b\eta + (a/3)\eta^3 + (1/12)(ab - 1)\eta^4 + \ldots \qquad [23]$$

$$H_1 = -a\eta^2 + (1/3)\eta^3 + (b/6)\eta^4 + \ldots \qquad [24]$$

The values of the constants, a and b, have been computed by a number of investigators (14-17); the most accurate ones, however, are those of Rogers and Lance (17)

$$\left.\begin{array}{l} a = 0.51023 \\ b = -0.61592 \end{array}\right\} \qquad [25]$$

For large Schmidt numbers, the zeroth order diffusion solution is described by Levich's theory of the rotating disk (2, 18). Using the present notation, it can be expressed as

$$\Phi_1 = 1 - 0.62045\, Sc^{1/3} \int_0^\eta \exp\left(-\frac{aSc}{3}\eta^3\right) d\eta \qquad [26]$$

It seems, therefore, that with an additional term characterized by Φ_3, it is possible to extend the Levich theory to the case of a rotating spherical electrode. To find the function, Φ_3, one needs information about the first order velocity distributions. However, no analytical solution has been available in the literature. In the next section our analysis is started with an attempt to develop appropriate expressions for the first order velocity distributions near the electrode surface.

Series solution for the first order momentum equations.—Equations [17-19] describing the first order velocity distributions are a set of linear, second order differential equations. An analytical expression can

be made possible if we expand F_3, G_3, and H_3 in a Taylor series about $\eta = 0$

$$F_3 = f_0 + \eta f_1 + \eta^2 f_2 + \eta^3 f_3 + \dots \quad [27]$$

$$G_3 = g_0 + \eta g_1 + \eta^2 g_2 + \eta^3 g_3 + \dots \quad [28]$$

$$H_3 = h_0 + \eta h_1 + \eta^2 h_2 + \eta^3 h_3 + \dots \quad [29]$$

Inserting these expressions into Eq. [17]-[19], and making use of Eq. [21]-[24], leads to the following expressions for the first order velocity components near the surface

$$F_3 = f_1\eta + (1/3)\eta^2 + (1/6)(b - 2g_1)\eta^3 + \dots \quad [30]$$

$$G_3 = -1/6 + g_1\eta + (1/6)(2f_1 - a)\eta^3 + \dots \quad [31]$$

$$H_3 = (a/6 - 2f_1)\eta^2 - (1/2)\eta^3 + \dots \quad [32]$$

Here, f_1 and g_1 are the values of the radial velocity gradients contributed by the first order velocity components at the sphere surface. These values have been computed numerically by Banks (7). His result is given as

$$\left.\begin{aligned} f_1 &= -0.22129 \\ g_1 &= 0.24765 \end{aligned}\right\} \quad [33]$$

Equations [30]-[33] can be used where required for the appropriate convection terms in the first order diffusion equation.

Method of solution of the first order diffusion equation.—In this section we proceed with an analysis that could lead to simplification of the first order diffusion equation. An analytical solution is then given for the case of high Schmidt numbers. Since, for the transfer process occurring at high Schmidt numbers, the thickness of the concentration boundary is much thinner than that of the momentum boundary layer, we would therefore start with stretching the mass transfer domain by introducing a new variable defined as

$$Z = Sc^{1/3}\eta \quad [34]$$

Substituting the new variable into Eq. [20], and making use of Eq. [22], [24], and [32] for the appropriate convection terms, we have

$$(a/6 - 2f_1)Z^2\frac{d\Phi_1}{dZ} - aZ^2\frac{d\Phi_3}{dZ} + 2aZ\Phi_3 - \frac{d^2\Phi_3}{dZ^2} = Sc^{-1/3}\left\{(1/2)Z^3\frac{d\Phi_1}{dZ} - (1/3)Z^3\frac{d\Phi_3}{dZ} + Z^2\Phi_3\right\} + 0(Sc^{-2/3}) \quad [35]$$

We note that the left hand side of this equation is independent of Sc, while the leading terms on the right vary inversely with the cube root of the Schmidt number. Thus, for the transfer process occurring at large Schmidt numbers, we may neglect the right hand side, and by replacing $d\Phi_1/dZ$ with an expression evaluated from Eq. [26], Eq. [35] can now be simplified to

$$\frac{d^2\Phi_3}{dZ^2} + aZ^2\frac{d\Phi_3}{dZ} - 2aZ\Phi_3 = -0.62045(a/6 - 2f_1)Z^2e^{-(a/3)Z^3} \quad [36]$$

The boundary conditions are

$$\left.\begin{aligned} &\text{at } Z = 0, \Phi_3 = 0 \\ &Z \to \infty, \Phi_3 = 0 \end{aligned}\right\} \quad [37]$$

A solution that satisfies both Eq. [36] and [37] can be found as

$$\Phi_3 = \frac{0.62045}{5a}(a/6 - 2f_1)Ze^{-(a/3)Z^3} \quad [38]$$

Substituting Eq. [26] and [38] into Eq. [11] we arrive at a concentration distribution over the rotating spherical electrode

$$\Phi = \frac{C - C_\infty}{C_0 - C_\infty} = 1 - 0.62045\int_0^Z e^{-(a/3)Z^3}dZ + 0.12833\,\theta^2Ze^{-(a/3)Z^3} + \dots \quad [39]$$

where

$$Z = Sc^{1/3}\eta = Sc^{1/3}(\omega/\nu)^{1/2}(r - r_0)$$

To obtain a generalized expression for the rate of transport process over the electrode, we now define a mass transfer coefficient, K, as

N = average mass flux on the electrode surface

$$= \frac{-\int_0^{2\pi}\int_0^{\theta} r_0^2\sin\theta\, D\left(\frac{\partial C}{\partial r}\right)_{r=r_0}d\theta d\phi}{\int_0^{2\pi}\int_0^{\theta} r_0^2\sin\theta d\theta d\phi} = K(C_0 - C_\infty) \quad [40]$$

Carrying out integration for the denominator and introducing the dimensionless variables, the Sherwood number defined as (Kr_0/D) can be evaluated from the following equation

$$Sh = \left(\frac{Kr_0}{D}\right) = -\frac{Re^{1/2}Sc^{1/3}}{1 - \cos\theta}\int_0^{\theta}\left(\frac{\partial\Phi}{\partial Z}\right)_{Z=0}\sin\theta d\theta \quad [41]$$

Substituting Eq. [39] into Eq. [41] and carrying out the integration, we obtain the dimensionless rate of transfer to a spherical electrode having an active surface specified by the angle θ

$$Sh = Re^{1/2}Sc^{1/3}\left\{0.62045 - 0.12833\frac{2(\cos\theta - 1) + 2\theta\sin\theta - \theta^2\cos\theta}{1 - \cos\theta}\right\} \quad [42]$$

For a hemispherical electrode, or a sphere whose entire surface is subject to the mass transfer, we have $\theta = \pi/2$; thus

$$Sh = 0.474\,Re^{1/2}Sc^{1/3} \quad [43]$$

In an excess supporting electrolyte, the average current density due to flux of mass to the electrode surface is related to the mass transfer coefficient, K, by

$$I = -n\mathbf{F}N = n\mathbf{F}K(C_\infty - C_0) \quad [44]$$

Substituting this relation into Eq. [42], and rearranging the equation in dimensional form, we have

$$I = n\mathbf{F}(C_\infty - C_0)D^{2/3}\nu^{-1/6}\omega^{1/2}\left\{0.62045 - 0.12833\frac{2(\cos\theta - 1) + 2\theta\sin\theta - \theta^2\cos\theta}{1 - \cos\theta}\right\} \quad [45]$$

For a sphere or a hemispherical electrode, $\theta = \pi/2$, and Eq. [45] becomes

$$I = 0.474\,n\mathbf{F}(C_\infty - C_0)D^{2/3}\nu^{-1/6}\omega^{1/2} \quad [46]$$

The limiting current density may be obtained by setting $C_0 = 0$

$$I_{\text{lim}} = 0.474\,n\mathbf{F}C_\infty D^{2/3}\nu^{-1/6}\omega^{1/2}, \text{ (for } \theta = \pi/2) \quad [47]$$

Discussion of Results

The correlations given by Eq. [42]-[43] and [45]-[47] would allow one to estimate the rate of mass flux and the diffusion current density on a rotating spherical electrode. Essentially, these results represent only the asymptotic behavior of a transport process occurring at large Schmidt numbers, and only the main region solution that disregards the boundary layer eruption at the equator. Here we discuss some implications of the theory, particularly as they bear on the various simplifications made in obtaining the solution.

The Sherwood number given by Eq. [42] differs from that of a rotating disk only by a correction func-

tion of θ. This implies that the correlation is actually an extension of Levich's theory. It would, therefore, be of theoretical interest to compare this rate of mass transfer to that of a rotating disk. From such a comparison, one would also be able to gain an insight regarding the effect of surface curvature for the rotating disk experiment. Using the present notation, the Levich theory (1, 2) of transfer on a rotating disk electrode can be expressed as

$$Sh_D = 0.62045\, Re^{1/2}\, Sc^{1/3} \qquad [48]$$

The ratio of average mass flux on a spherical electrode to that on a disk electrode can be obtained by dividing Eq. [42] by Eq. [48]

$$\frac{Sh}{Sh_D} = \frac{I}{I_D} = 1 - 0.207\left\{\frac{2\theta \sin\theta - \theta^2\cos\theta}{1-\cos\theta} - 2\right\} \qquad [49]$$

where the subscript, D, implies the process occurring at the disk electrode. Equation [49] is plotted in Fig. 2 as a solid curve. It is seen that the rate of transfer at the pole ($\theta = 0$) is the same as the disk electrode; however, it decreases with increasing θ toward the equator. In the polar region, the effect of curvature is not significant; for θ less than 0.7 (about 40°) the value of the Sherwood number estimated from Levich's equation is only 5% greater than the value given by Eq. [42]. However, for a sphere or a hemispherical electrode ($\theta = \pi/2$), the average rate is reduced to about 76% of the flux at the disk electrode. Also given in Fig. 2 are the values of approximate calculations made by Baxter and Davies (12); these are represented by the circular dots. Owing to the nature of the equation used, these authors were not able to perform the calculation for $\theta = \pi/2$. In spite of the approximate nature, their values agree reasonably well with the present analysis; the maximum deviation occurring at $\theta = 1.4$ (80°) is only 2.5%.

We now demonstrate that the solution is consistent with the notion that the concentration boundary layer is well within the hydrodynamic boundary layer, and that the application of Taylor's series expansions for the first order velocity distributions is valid for the case of large Schmidt numbers. Using the Nernst diffusion concept (19), the thickness of the concentration boundary layer can be defined as

$$\delta_c = -\frac{D(C_0 - C_\infty)}{D\left(\frac{\partial C}{\partial r}\right)_{r=r_0}} \qquad [50]$$

Substituting Eq. [39] into Eq. [50] we have

$$\delta_c = \frac{1.61}{1 - 0.207\theta^2}\left(\frac{\nu}{\omega}\right)^{1/2} Sc^{-1/3} \qquad [51]$$

Thus the thickness of the concentration boundary layers varies from $1.6(\nu/\omega)^{1/2}Sc^{-1/3}$ at the pole to $3.3(\nu/\omega)^{1/2}Sc^{-1/3}$ near the equator. The analysis of Cochran (13, 14), Banks (7), and Manohar (8) indicates that the thickness of the hydrodynamic boundary layer, δ_m, would vary approximately from $4(\nu/\omega)^{1/2}$ at the pole to $10(\nu/\omega)^{1/2}$ in the vicinity of the equator. Thus

$$\frac{\delta_c}{\delta_m} \sim \frac{0.4}{Sc^{1/3}} \qquad [52]$$

In a liquid system, a typical value for the Schmidt number is on the order of 1000; the concentration boundary layer is therefore about 20 times smaller.

The flux of mass contributed from the equatorial region itself has thus far been neglected. The fluid flow in the region is characterized by eruption of the boundary layer into a swirling, flat radial jet. The velocity distribution in the jet has not been resolved, and there is presently no knowledge of the nature of convective diffusion near the equator. However, the experimental work performed by Kreith and his associates (4) has shown that for Reynolds numbers less than 1.25×10^4, this region occupies less than 2% of the total surface area over the sphere. The extrapolation of the main region solution to the equatorial region would therefore not result in a significant error. The maximum discrepancy would be less than 2%. Another factor that deserves consideration is the effect of the second order term, Φ_5, in the series expansion for the concentration profile, Eq. [11]. Banks (11) has computed numerically the thermal boundary layers for Prandtl numbers between 0.7 and 1.0. His results indicate that the contribution of $\Phi_5'(0)$ to the local flux at the surface is about 0.5%. For practical applications this difference is negligible. Perhaps of greater importance is the effect of neglecting the higher order terms of Sc^{-1} in obtaining the diffusion solution. The Levich theory that has been used as the zeroth order solution for the rotating sphere is subject to an error on the order of $Sc^{-1/3}$ (20). Also, as shown in Eq. [35], the first order solution is made possible only by dropping the leading correction terms that vary inversely with the 1/3 power of the Schmidt number. We would therefore expect that the result given in this analysis is subject to an error on the order of $Sc^{-1/3}$; for a typical liquid system with a Schmidt number of 1000, this would be about 10%.

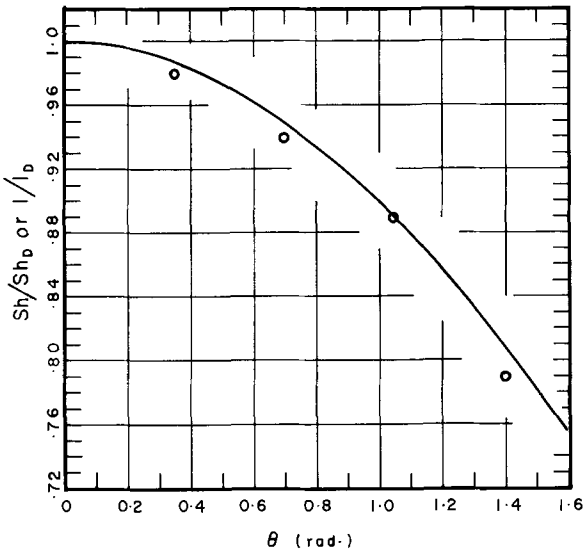

Fig. 2. Comparison with disk electrode. The solid line is the result of this analysis, Eq. [49]. The circular dots are Baxter and Davies' approximate calculations [ref. (12)].

Based on the above discussions, we may conclude that the diffusion solution expressed in the forms of Eq. [42]-[43] and [45]-[47] should give a reasonably accurate estimate of the mass transfer rate to the rotating sphere. For electrochemical applications, these equations should provide access to the quantitative study of diffusion coefficients and reaction kinetics of electrode processes.

Technical Note

Induced Osteogenesis by Electrical Stimulation

Didya D. Levy

Bioengineering Division, Polytechnic Institute of Brooklyn, Brooklyn, New York 11201

The ability of bone to act as a transducing element, converting a mechanical deformation into an electrical signal, is probably in part responsible for its remodeling capability. By monitoring the voltage response of cortical bone to a mechanical step deformation, Becker, Bassett, and Bachman (1), and Cochran (2) have provided a means for quantitatively investigating the remodeling system of bone. These response curves can be fitted to an equation containing two exponential terms of the form

$$V_o(t) = V_p(t)[K + (1 - K)\, e^{-t/\tau_2} - e^{-t/\tau_1}]$$

where V_o is the output voltage of the system when loaded by a step deformation, V_p the peak voltage, K a d-c multiplicative factor, and τ_1 and τ_2 the system's two time constants. In order to ascertain the resonant frequency of the system, *i.e.* the frequency at which the system response would be maximal, the fitted response curve must first be transferred to the Laplace domain where it has the form

Key words: bone growth, electrical stimulation, *in vivo* studies.

$$V_o(S) = V_p(S)[K/S + (1 - K)/(S + \tau_2) - 1/(S + \tau_1)]$$

The system's transfer function, defined as

$$H(S) = \frac{V_O(S)}{V_p(S)}$$

has the form

$$H(S) = \frac{AS + B}{S^2 + CS + D}$$

where A, B, C, and D are obtainable from analysis and, for the curve cited in (1), have the values 19.34, 0.677, 20.69, and 13.84 respectively (3). Substituting for S and squaring both sides, one can plot the square of the transfer function *vs.* frequency and arrive at a frequency value for which the system transfer function is a maximum. Figure 1 illustrates this maxima as occurring at a frequency of approximately 4.5 rad/sec (0.7 Hz). Inasmuch as previous investigators have demonstrated an osteogenic response to stimulation by

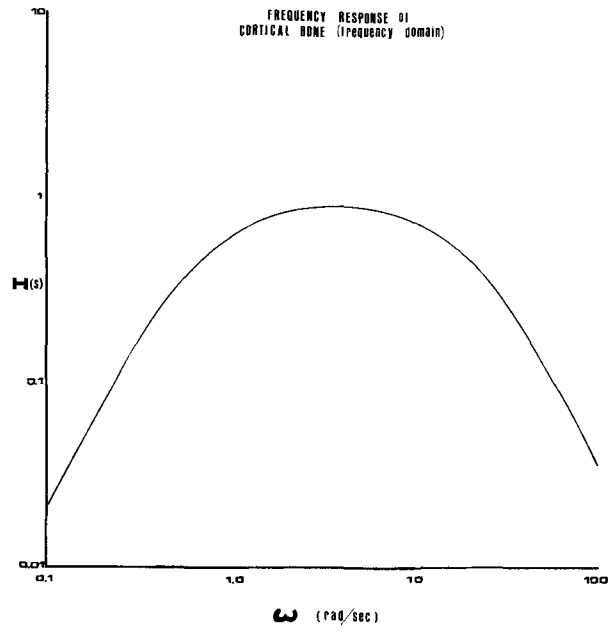

Fig. 1. System transfer function plotted on log-log scales as a function of input frequency. The transfer function is maximum at an input frequency of 4.5 rad/sec (about 0.7 Hz).

a d-c (voltage) source (4-6), an effort was made to determine if this response could be improved upon by use of a pulsed d-c current source operating at this frequency.

Experimental Techniques

Initial attempts at using a unijunction transistor oscillator as a pulsing source proved to be unsatisfactory primarily owing to its relatively large size. An astable multivibrator (AMV) was then designed to meet the size and reliability requirements imposed by surgical considerations. The circuit, shown schematically in Fig. 2, was encapsulated first in a clear epoxy and then in a pharmaceutical grade beeswax to minimize toxicological effects. The driving electrodes were Teflon coated platinum-iridium.

In each instance a pulsing source was used to drive a bone, a control device was implanted in the contralateral bone. Control units, similar to the pulsing units in both shape and weight, were of two basic types: passive and d.c. These control units were fabricated of the same materials as were the pulsing units and, in the

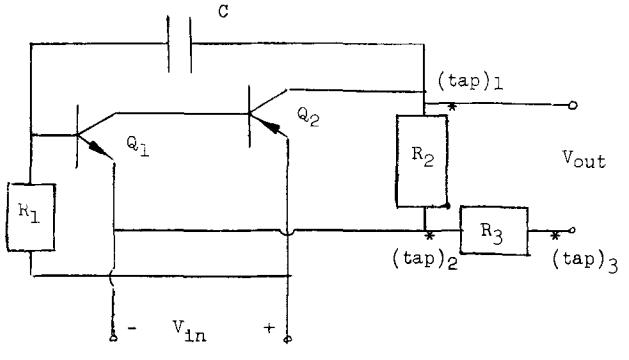

Fig. 2. A schematic representation of an AMV. The three taps were used to note potential drops across two portions of the circuit and, in so doing, provide information on the amount of energy delivered to the bone. The potential drop from points 3 to 1 (through the bone) is the difference between the drop from 1 to 2 and from 2 to 3. The current through the bone is equal to the drop from 2 to 3 divided by the known resistance R_3. The product of these two values is approximately the energy input to the bone; total energy input being this value multiplied by the product of pulsewidth, firing rate, and total time in operation.

case of the d-c control, operated at the same voltage level as was reported in the literature by O'Connor (4), Bassett (6), and Lavine (7), *viz.* 1-1.4V.

Because of their relatively small size, several of these units could be implanted in the rib cage and femurs of a subject dog. Thus 48 devices (12 passive, 6 d.c., and 20 AMV's) were implanted in eight dogs. A typical sterile procedure involved making an incision above the target femur, dissecting away the underlying fascia, and exposing the *biceps femoris*. The surgical plane between it and the underlying *vastus lateralis* was uncovered permitting rapid access to the femur with a minimum of trauma. An incision was made through the periosteum and a high-speed drill with a number 57 bit was used to drill two holes through the cortex. Electrodes, extending midway into the lumen, were seated in these holes and the entire unit was then anchored to the bone with a surgical silk (00). After a four-day recovery period, the dogs were returned to their kennels where they were then free to function normally.

Active stimulators contained Teflon coated cable leads that were extended through the skin of the subject dog and could be connected to an oscilloscope where its operating mode could be continuously monitored. Typically, the output characteristics of a pulsing source, monitored *in vivo*, were such that the unit fired a rectangular d-c pulse at a rate of 0.5 Hz, a pulsewidth of 5 msec, and a delivered peak current of approximately 1 mA. The total potential drop between the two electrodes was on the order of 1.1V and so

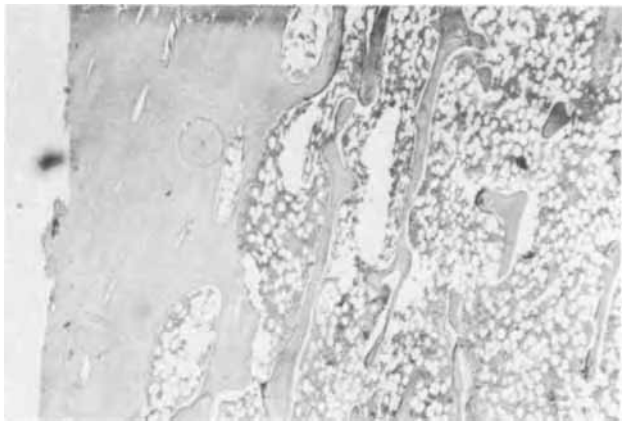

Fig. 3. Photomicrograph, at approximately 40 diameters, of a longitudinal section of a rib 2-10 mm from the point of electrode insertion. This section shows no unusual cellular activity despite the proximity of the passive control.

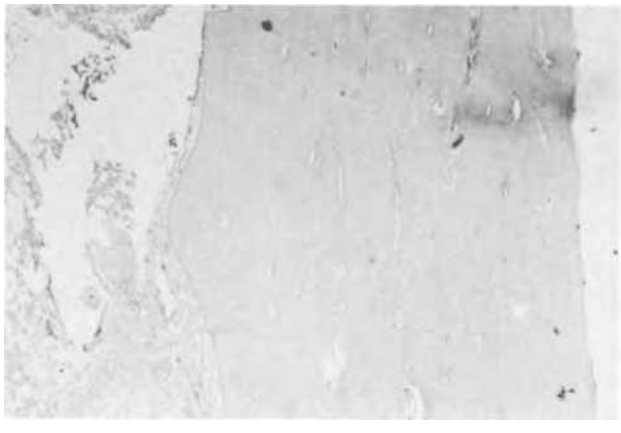

Fig. 4a. A longitudinal section through a rib at X40 showing the cortex and a portion of the lumen. No cellular activity is evident on the periosteal surface. There is, however, some activity along a portion of the endosteal surface.

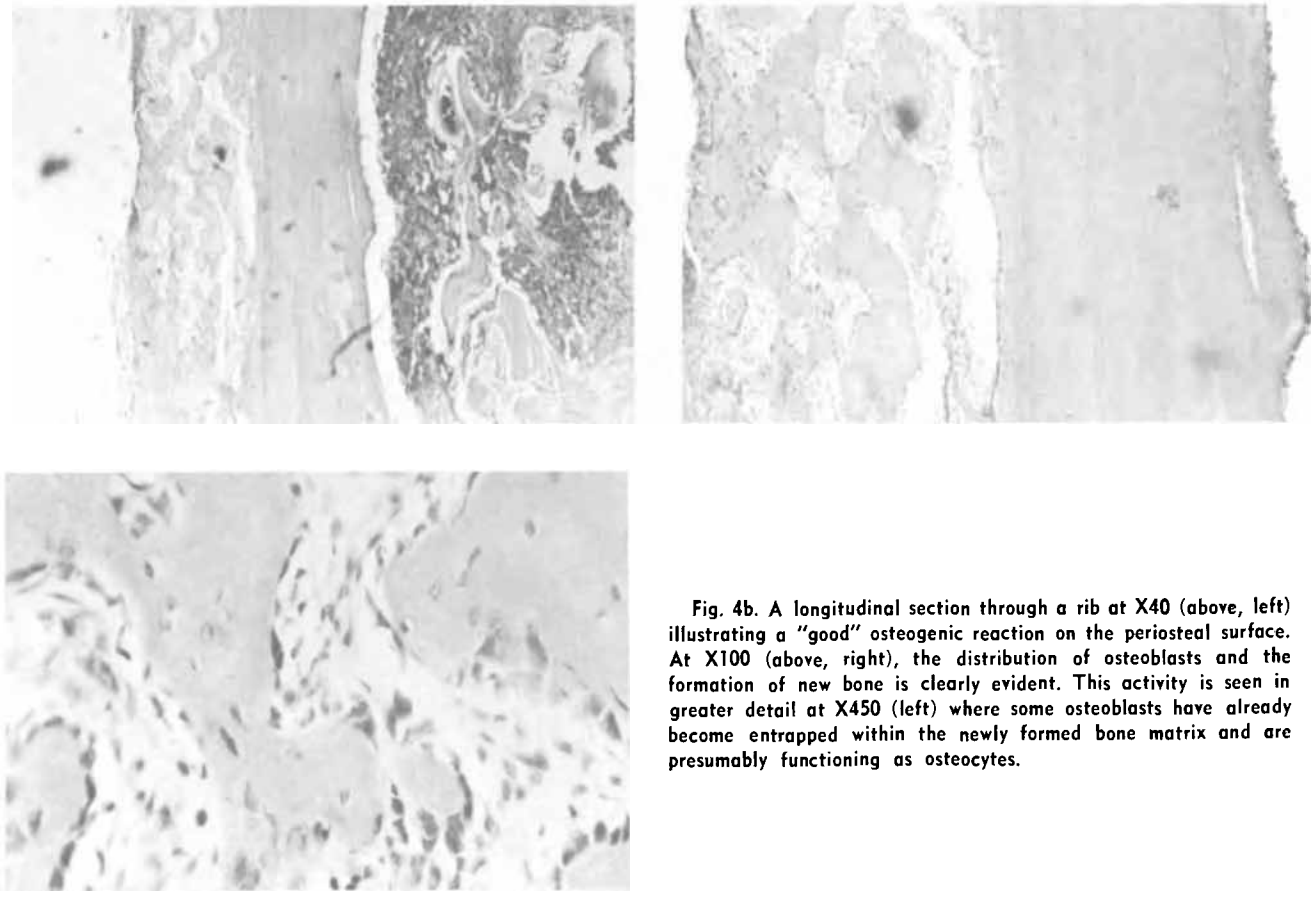

Fig. 4b. A longitudinal section through a rib at X40 (above, left) illustrating a "good" osteogenic reaction on the periosteal surface. At X100 (above, right), the distribution of osteoblasts and the formation of new bone is clearly evident. This activity is seen in greater detail at X450 (left) where some osteoblasts have already become entrapped within the newly formed bone matrix and are presumably functioning as osteocytes.

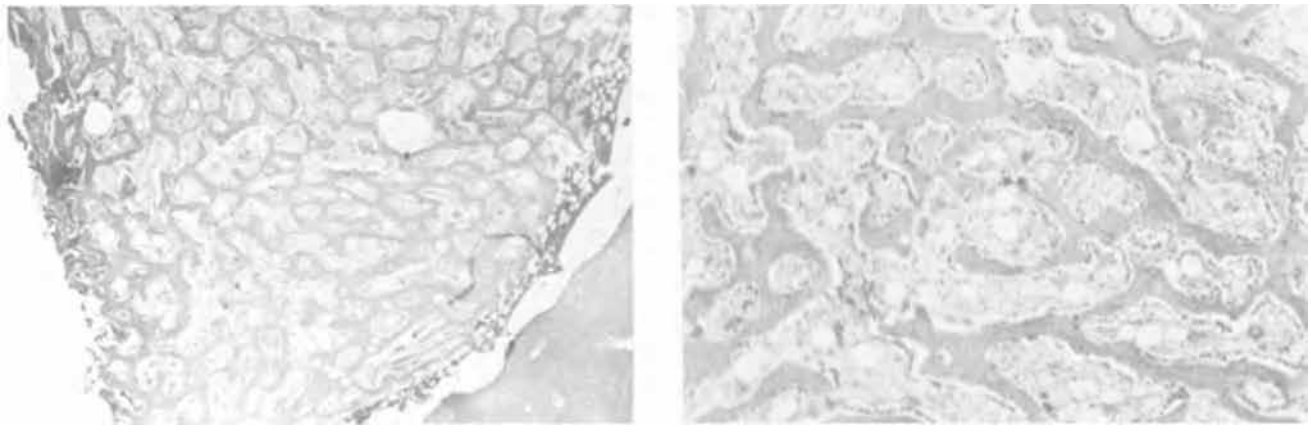

Fig. 5a. Photomicrographs at X40 (left) of a cross section through a femur driven by an AMV. The entire marrow space is filled with a dense mesh-like array of trabecula. This callus extended 5-6 cm in either direction from the point of stimulation. Detail at X100 (right) illustrates the process of laying down more new bone, increasing the trabecula thickness, is proceeding at a rapid pace.

the total energy delivered to the tissue during the two-week duration of an experiment was approximately 3.3W-sec. D-C voltage sources similar to those cited previously delivered approximately 144 W-sec during a like period.

Results and Conclusions

The use of passive control devices established that no significant histological changes were caused by the trauma associated with drilling through the cortices of bones and the subsequent electrode emplacement in these holes (Fig. 3).

In most instances where a d-c device was used to stimulate bone, there were no gross changes visible on the outer surface of the bone. There were, however, some changes in the marrow space that were characterized by variations in color and texture. Microscopic observations indicated that results were not consistent and could not necessarily be correlated with either total energy input or implant location. There was, though, a definite osteogenic response in every *in*stance that a d-c device was used. These responses varied from no apparent response on either the periosteal (outer) or endosteal (inner) cortical surface (Fig. 4a) to a considerable response on the periosteal surface and a good response in the medulla (Fig. 4b).

The response of bone to pulsed stimulation was consistent. Tissue reaction occurred in the central lumen (Fig. 5a) and on both the periosteal and endosteal surfaces (Fig. 5b). Newly formed bone appeared most often as a consequence of direct osteoblastic activity although in several instances new bone was noted as forming from a cartilagenous precursor (Fig. 6).

A summary of the tissue response evoked by a d-c source *vis-a-vis* a non-d-c source in the contralateral

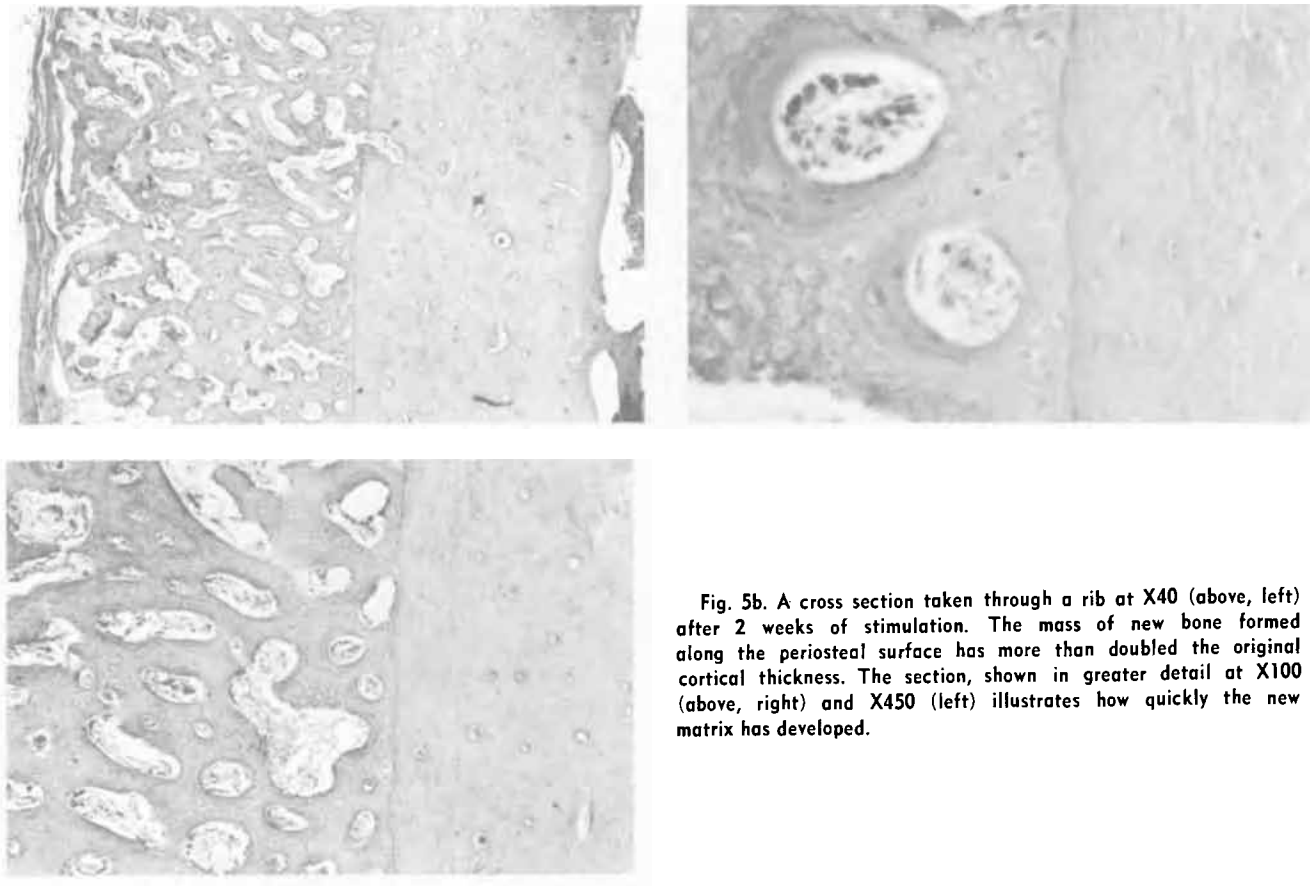

Fig. 5b. A cross section taken through a rib at X40 (above, left) after 2 weeks of stimulation. The mass of new bone formed along the periosteal surface has more than doubled the original cortical thickness. The section, shown in greater detail at X100 (above, right) and X450 (left) illustrates how quickly the new matrix has developed.

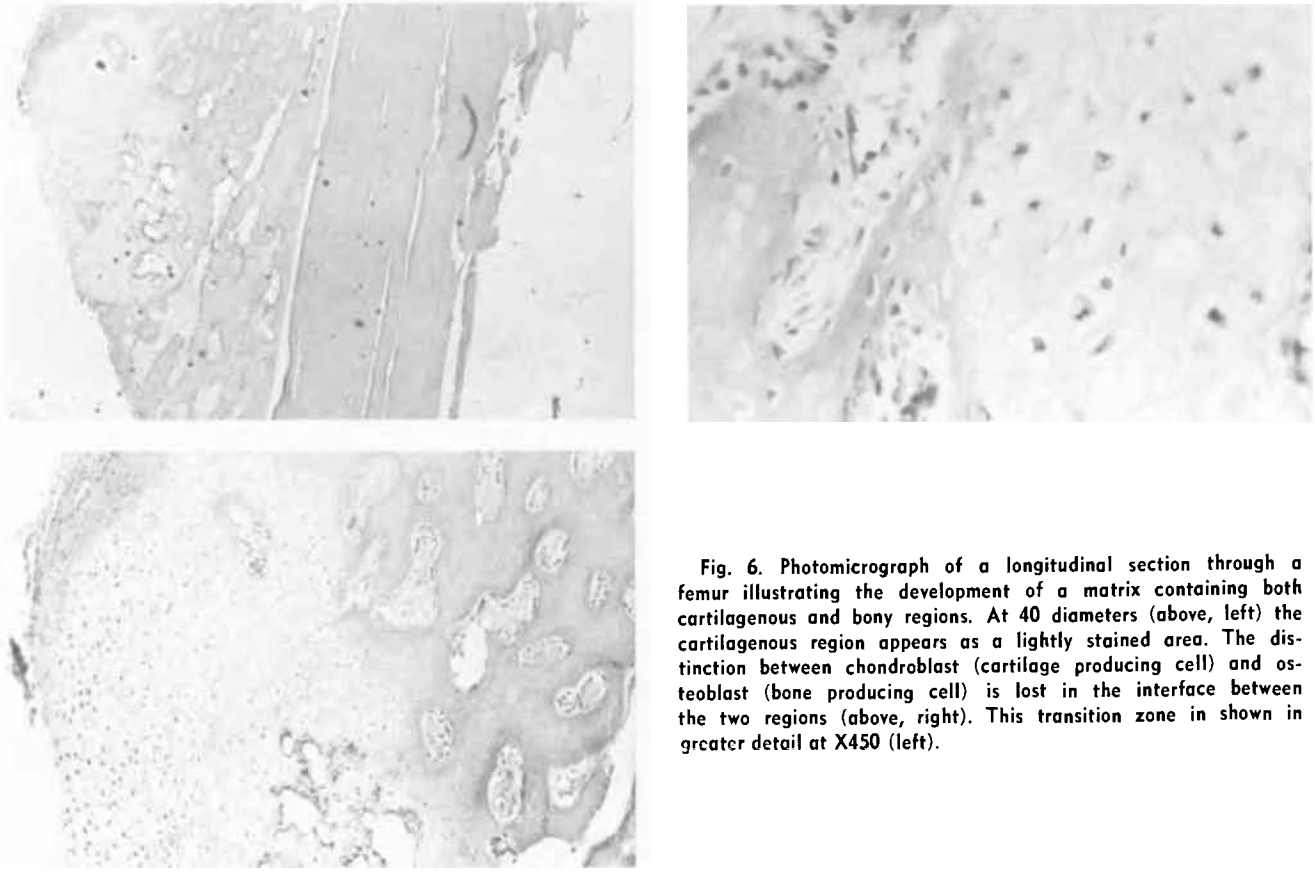

Fig. 6. Photomicrograph of a longitudinal section through a femur illustrating the development of a matrix containing both cartilagenous and bony regions. At 40 diameters (above, left) the cartilagenous region appears as a lightly stained area. The distinction between chondroblast (cartilage producing cell) and osteoblast (bone producing cell) is lost in the interface between the two regions (above, right). This transition zone in shown in greater detail at X450 (left).

bone is offered in Table I. The criterion for judging the qualitative tissue response was based upon the total area of newly formed bone when slide-mounted samples were analyzed. Of the five sets of data presented in the table, there was only one instance of a considerable osteogenic response to d-c stimulation. In almost every instance where contralateral sections were compared, more bone was laid down in response

Table I. Response of contralateral bones to both d-c and pulsed stimulation

Rt. femur	AMV	1.2	5	5	considerable	0.22

to pulsed stimulation than to d-c stimulation despite the fact that the total energy delivered to the bone by a d-c source was as much as 3800 times greater than the energy delivered by a pulsing source. Thus on the basis of data obtained during these experiments, it seems reasonable to conclude that a greater osteogenic response can be elicited by a pulsing source than by a d-c source.

The Influence of the Complexing Agent Concentration on the Etch Rate of Germanium

Michael F. Ehman*,[1], J. W. Faust, Jr.**,[2], and William B. White[3]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

This paper reports the effect of the concentration of the complexing agent in an etching solution on the etch rate and surface morphology. The {100} surface of germanium was etched in a solution of the basic composition $X:H_2O_2:H_2O$ in the volume ratio 1:1:4, where X was tartaric, acetic, citric, oxalic, HCl and HF acids, and mannitol. There was no change in the shape or orientation of the etch figures with variation of the type or orientation of the complexants. It was found that the etch rate was a function of the concentration of the complexant when the concentration of the oxidizing agent was held constant. The variation in etch rates and activation energies with the complexing agent concentration indicated that the reactions are diffusion controlled. A model is proposed for the crystal-solution interface which is consistent with the interdependence of the etch rates and the complexing ratio of the germanium.

The rapid development of the solid-state device industry in the decades of the 1950's and 60's was also accompanied by a multifold increase in the number and types of chemical etchants and polishes available for the resultant modern materials. The etchants and polishes are used not only for defect characterization and removing damaged layers, but also for preparing surfaces for orientation by optical goniometric techniques and thinning for transmission electron microscopy. In the case of elemental semiconductors, almost every etchant consists of two basic components and usually a third: (*a*) an oxidizing agent to place the surface atoms in a state suitable for being taken into solution; (*b*) a complexing agent to take the species into solution; and (c) usually a modifier. On the basis of these functions, two major etching systems have been developed for germanium. One is based on the use of HNO_3 as the oxidizing agent, and the second uses H_2O_2. The system Ge:HNO_3:complexant has been studied by several investigators in order to determine the etching mechanisms (1-4). An example of a polish-etchant in this system is CP-4A [HF:HNO_3: acetic acid (3:5:3)]. In this case both HF and acetic acid are reported to act as complexing agents. This system is characterized by high etch rates and activation energies, and variable induction periods making basic mechanism studies difficult. The system Ge:HF:H_2O_2 has also been studied by numerous approaches in order to determine the effects of various parameters on the etching characteristics. Two separate reaction schemes have been proposed for the oxidation processes in hydrogen peroxide solution. One is based on the oxidation of Ge to the divalent state in the form of GeO and further oxidation to the tetravalent state (5-7), whereas the second involves the formation of $Ge(OH)_2^{++}$ at the surface and dissolution as H_2GeO_3 (8, 9). Neither of these reaction schemes has been able to ascribe a general role to the complexing and oxidizing agents in etching processes. Faust (4) studied the reaction rates and the effect on the surface morphology of several oxidizing and complexing agents common to the HNO_3 and H_2O_2 etching systems. He found that the oxidizing agent controlled the mode of attack, *i.e.* the initial development, shape, and orientation of the etch figures, whereas the rate of attack varied with the type of complexing agent present in the solution. Since the shape and orientation of the pits appeared to be constant for a given oxidizing agent, it was decided to examine the variation of etching behavior with the type and concentration of the complexing agents in the solution.

Sample Preparation and Experimental Procedures

The samples used in this study were cut from an ingot of approximately 40 ohm-cm resistivity with the major crystallographic orientation parallel to the {100} planes. The samples were cut into rectangles measuring approximately 12 mm x 6 mm x 3 mm in order to minimize the effects of etch rates on the side areas with respect to those on the main face area. After being cut on an abrasive string saw using a SiC slurry, the samples were then lapped in a water slurry of 5μ Alundum on a glass flat until the surface was uniformly matted and the damaged material from the cutting processes had been removed. The samples were then pre-etched in the etchant to be studied to remove the damaged layer produced by the mechanical processes discussed above (3).

Key words: mechanism, hydrogen peroxide, activation energy, morphology, etch pits.

The base etchant used in this investigation was the Superoxol etch developed by Theurer (10). The etchant has the following composition: 48% HF:30% H_2O_2:H_2O in a volume ratio of 1:1:4. The complexing agents used were oxalic, citric, acetic, tartaric, hydrochloric, and hydrofluoric acids, and mannitol. In each case the oxidizing agent was 30% H_2O_2. The reference state for the concentration of the complexing agents was chosen to be a 0.75 molar solution of oxalic acid. This concentration was selected since oxalic acid is the least soluble of the above reagents in distilled water. A saturated solution at 15°C contains 0.75 moles of the acid per liter. The complexing agents were added in the ratio shown above, *i.e.* 1 part of a 0.75M solution of oxalic: 1 part of 30% H_2O_2: 4 parts of water. The chemicals used in the etchants were reagent grade and were prepared by dilution of saturated solutions at room temperature. Distilled water was used throughout the study for dilutions, etchant components, and washing of samples. The reagents were stored separately in polyethylene bottles until one hour before use. The etchant was then mixed in quantities large enough for a complete run and placed in the temperature bath. Camp (6) found that solutions stored this way are stable for long periods of time; however, in this study they were used within 24 hr of mixing.

The etching was carried out in a constant temperature bath with the temperature controlled to ±0.5°C. The etch rates were measured at five temperatures between room temperature and 70°C. The temperatures were read at the start and finish of each run; in each system the reactions did not change the temperature of the solution more than one degree contigrade. Fresh solutions of the etchants were used for each run and were allowed to equilibrate thermally with the bath before each run. The surface area of the sample to solution-volume ratio was approximately 2 cm^2: 600 ml.

The variation in etch rate with mechanical motion of the sample in the solution was minimized by rapid agitation of the sample in a perforated Teflon basket up and down in the beaker. It was found that the ratio increased with increased movement of the sample, as would be expected, and leveled off at approximately three movements per second over a distance of 3.5 cm. Teflon was used since some metal ions present in other plastics catalytically decompose H_2O_2.

Results and Discussion

The etch rate data for the Ge:complexing agent: H_2O_2:H_2O systems are shown in Fig. 1-6 as a function of the concentration of the following complexing agents: oxalic acid, acetic acid, tartaric acid, citric acid, HCl, HF, and mannitol, respectively. The data shown are for the {100} surface. The reaction rates on the {110} and {111} surfaces were not measured since the relationship between the rates on the major crystallographic surfaces have been thoroughly investi-

gated. Camp (6) has shown that in the system Ge: HF: H_2O_2: H_2O plots of the etch rate as a function of $1/T$ for the three surfaces had similar slopes, but the {110} and {111} surfaces had slightly lower rates. The rates shown in the plots are for 20°, 40°, and 60°C. In general the rates were measured at five temperatures between room temperature and 60°C. However, for simplicity, the complete data are not shown.

Microscopic examination of the surfaces showed that there was no variation in the shape or orientation of the etch figures between the types of complexing agents or over the range in concentrations as was predicted by Faust (4).

The most striking feature of the plots of the etch rate as a function of the concentration of the complexing agent is the leveling off of the rate between 0.3 and 0.4M solutions at a given temperature in the systems containing tartaric acid and mannitol and approximately 0.7M in the oxalate, citrate, HCl, acetate, and HF systems. Several investigators have shown that in aqueous solutions with low pH values, tartaric acid reacts with germanium to form a complex with a tartrate-to-Ge ratio of 1:1. Using potentiometric titrations and conductivity measurements Pflugmacher and Rohrmann (11) were able to show that the complex formed in aqueous GeO_2 solutions in a strong monobasic acid contained one germanium to one hydroxy-acid molecule. In aqueous solutions Gmelin (12) suggests that GeO_2 reacts with water as follows

$$GeO_2 + H_2O \rightleftarrows H_2GeO_3\ (aq) \qquad [1]$$

This suggests that the tartrate radical would then react with metagermanic acid. Using ion-exchange techniques Everest and Salmon (13) were able to confirm the presence of $HGeO_3^-$ in low pH solutions when GeO_2 was dissolved in water. Vartapetian (14) suggested that a complex of the type $GeO[O_2CCH(OH)CH(OH)CO_2H]$ is formed in acid media, and was able to isolate the pyridine salt $GeC_4O_7H_4$ in a crystalline form from the solution. The 1:1 complexing ratio was later verified by Vartapetian and Tchakirian (15) and Mattock (16). In an etching system one would expect that at a given concentration (since there is a 1:1 complexing ratio) when a state is reached where for every germanium atom dissolving there was one tartrate radical present at the crystal-solution interface, the etch rate would approach a constant value. This constant rate should not change if further amounts of tartaric acid were present in the solution. Looking at Fig. 1, 3, and 5, we can see that this behavior is observed. These rates, however, are significantly lower than those reported by Faust (4) even though the activation energies at concentrations in this saturated range compare favorably with those reported in the same study. This apparent increase in rate at the higher concentrations of tartaric acid might be related to the change in complexing ratio with increasing amounts of acid reported by Everest and Harrison (17). They reported that in concentrated solutions the complexes formed were of the type Ge_xTr_{x-1}, where $X \simeq 5$.

The complexing ratio of mannitol to monogermanic acid in very dilute solutions of low pH was reported to be 1:1 (18). Therefore we would expect the etch rate *vs.* concentration curves to be in a form similar to those of tartaric acid. Looking at Fig. 1, 3, and 5, one can see that indeed this behavior is observed.
