It can be seen in Table VI that the polarographic results obtained in the present work and in other studies are in general significantly higher than those reported by other techniques, especially in the case of iodide. However, the nature and number of complexes formed are acceptable.

That the polarographically obtained stability constants are higher than "accepted" values is extremely interesting. The experimental errors involved in the present study are considerable. A recent paper by Momoki and Ogawa (59) discusses this aspect of indium(III) systems in detail. $(E_s)_f$ is an extrapolated value and the major contributions to the $F_0(X)$ function $[(E_s)_f - (E_{1/2})_c]$, could be in error by several millivolts. However, despite considerable uncertainty in the $F_0(X)$ functions the values of β_j calculated by polarographic procedures still do not appear to be in agreement with other data.

This apparent anomaly needs an explanation. The net conclusion one could draw from these data is that the summit potential is not in agreement with the thermodynamic standard potential, E^o, at least at some ligand concentrations. The number and nature of the complexes in the Lingane plot given in Fig. 9 is basically derived from data at high ligand concentrations. These are essentially correct so it would appear that E_s values at high ligand concentrations are in agreement with those calculated from complexation existing in the bulk solution. The magnitude of the β_n values however strongly depends on the $(E_s)_f$ value used. This value is an extrapolated one and is derived essentially from the data obtained at low ligand concentrations.

At low ligand concentrations, the major species present in the bulk solution is electroinactive $In(aq)^{3+}$, and the electrode process is assumed to occur through mechanism [2] via anion-induced adsorption. For the particular example of low thiocyanate concentration, Pospisil and De Levie (32) have shown that the electrode process is consistent with

$$In^{3+} + 2SCN^-_{(ads)} \xrightarrow{\text{slow}} In(SCN)_2{}^+{}_{(ads)} \quad [a]$$

$$In(SCN)_2{}^+{}_{(ads)} + 3e \overset{\text{fast}}{\rightleftharpoons} In(Hg) + 2SCN^- \quad [b]$$

where the adsorption step is much slower than charge transfer and presumably is rate determining near $E_{1/2}$.

Measurements in this work are consistent with rapid and reversible charge transfer because the shape of both a-c and d-c waves is close to Nernstian. However below the 10^{-2}M ligand concentration range the electrode process is kinetically controlled to varying degrees by the anion-induced adsorption step occurring prior to reduction of the complex as in scheme [2] or step [a] reported for the thiocyanate system (32). This could influence the E_s value so that it no longer reflects the thermodynamic value expected from bulk complexation existing in bulk solution.

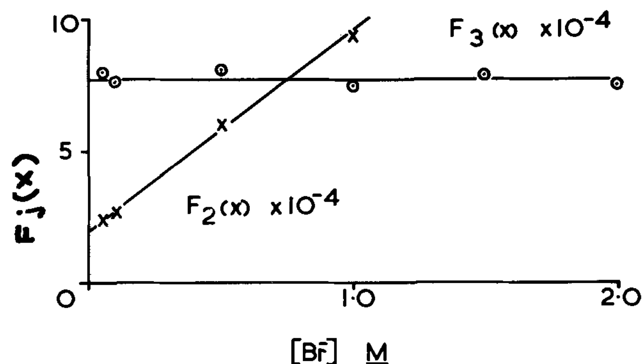

Fig. 6. Graphical analysis of the $F_2(X)$ and $F_3(X)$ functions for the bromide system.

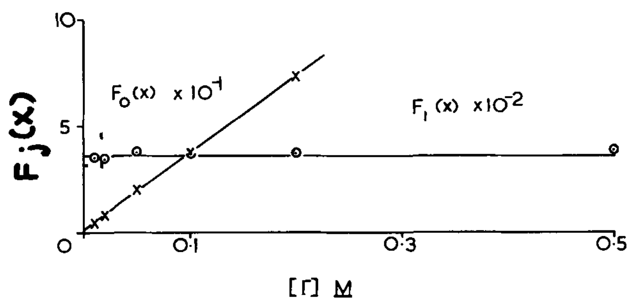

Fig. 7. Graphical analysis of the $F_0(X)$ and $F_1(X)$ functions for the iodide system.

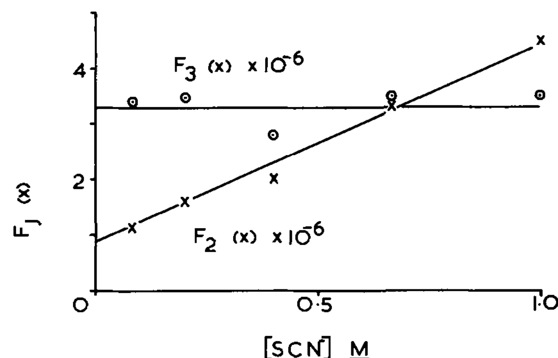

Fig. 8. Graphical analysis of the $F_2(X)$ and $F_3(X)$ functions for the thiocyanate system.

Calculations based on data presented in Ref. (36) suggest that the E_s value extrapolated to zero ligand concentration [similar to Cozzi and Vivarelli's d-c $E_{1/2}$ value (23, 24)] is more positive than the correct $(E_s)_f$ value and hence stability constant determinations using this value give rise to large β_n values: that is, when the influence of the anion-induced adsorption step becomes rate determining and is likened to a prior chemical reaction, the E_s value becomes more positive than the reversible half-wave potential.

However, if the extrapolation of $E_{1/2}$ to zero ligand concentration is limited to concentrations above 2 ×

[(e)] Log β_4 = 4.6 [$In(SCN)_4^-$]; log β_5 = 5.5 [$In(SCN)_5^{2-}$].

$10^{-2}M$ when kinetic considerations of the electrode process will not be as important [as was done by Momoki and Ogawa (59)] then in agreement with ideas presented in this paper it would appear that the correct $(E_{1/2})_f$ value is obtained for use in standard polarographic equations for determining stability constants. This work therefore clarifies some apparently anomalous results concerning stability constant determination by polarographic methods and shows how discrepancies have arisen.

In conclusion it can therefore be said that although some aspects need a more detailed explanation, the basic findings in this work appear to be consistent with the results and discussion given by other workers (20, 25-32). All studies show the importance of adsorption and complex formation on the polarography of indium(III).

Acknowledgment

The author wishes to express his appreciation to Mr. A. B. Waugh for assistance in obtaining some of the results reported in this paper.

Rotating Ring-Disk Electrode Studies of Corrosion Rates and Partial Currents: Cu and Cu30Zn in Oxygenated Chloride Solutions

Barry Miller* and Maria I. Bellavance

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The corrosion of copper and Cu30Zn in oxygenated 0.1M HCl-1M NaCl has been studied by ring-disk electrode methods. The corrosion rates at open circuit as a function of rotation speed and temperature have been measured on an instantaneous basis through ring currents for the oxidation of the copper(I) product. Results have been confirmed against solution analyses. Automatically recorded partial current curves have been obtained as a function of copper and alloy potential by scanning currents both anodic and cathodic to the open-circuit condition. The Tafel plots from the anodic partial currents of copper and alloy disks under immersion corrosion at several temperatures have been derived and compared to the predictions of a simultaneous dissolution model.

Aqueous corrosion processes at homogeneous metal surfaces with simultaneously applied external currents, i, may ideally be interpreted in terms of the additivity of all the coupled anodic, i_a, and cathodic, i_c, partial currents and their dependence on electrode potential (1). The dissolution rate of metal or alloy, $i_a = i - i_c$, and the (mixed) corrosion potential at open circuit can be determined from the summed partial current-potential curves. The necessary engineering information is chiefly the dependence of i_a at $i = 0$ on solution, temperature, surface, and mass transport parameters.

To these ends electrochemical techniques involving only the test specimen generally depend on passing external currents and relating the measured potentials, as by linear polarization (2), to the corrosion rate through Tafel parameters. More extensive perturbation of the electrode allows extrapolation of Tafel lines to the corrosion potential at the expense of altering the surface and conceding instant response. The corrosion current to a known oxidation state can, of course, be determined from the weight loss of metal or the equivalent analysis of the contacting solution. Limitations of these averaging procedures and others have been discussed by Stern and Weisert (3). A methodology for measuring instantaneous corrosion rates by soluble oxidants at an open circuited specimen is obviously of advantage and is an established experimental capability of the rotating ring-disk electrode (RRDE) system (4-6). This use simply involves special cases exploiting the general properties of the electrode pair which have been developed since the initial stimulus of Frumkin and Levich (7-9).

The $\omega^{1/2}$ dependence of results gained from rotating disk electrode (RDE) experiments alone has been used in corrosion studies to discriminate between mass transport and kinetic control, as shown particularly by Zembura and co-workers (10, 11, and *loc. cit.*) and by Heitz (12). Earlier work has been reviewed by Riddiford (13). In these investigations, however, chemical analysis of the solution was required to determine the equivalent disk dissolution current for comparison to the Levich equation for mass transport control (a linear $\omega^{1/2}$ dependence of the limiting current). Coupling the well-defined transport parameters of the disk and the geometrically determined collection properties of the ring allows a real-time monitoring of the disk processes which assists considerably in the interpretation of the corrosion system.

In this work we describe the acquisition of resolved partial current-potential curves and corrosion rate data for copper and Cu30Zn disks in oxygenated acidic chloride media by means of amperometry at ring electrodes. These corrosion rates have been compared to those obtained by atomic absorption spectroscopy on simultaneously sampled contacting solutions. The total applied current, the partial anodic component, and their logarithmic values have been automatically recorded on both sides of the corrosion potential. Data have been obtained over a range of temperatures and rotation speeds to interpret the results kinetically.

In the Cu-Zn binary alloy, significant work was done with the RRDE by Feller (14) and Pickering and Wagner (15) on the question of selective dissolution in sulfate media during the anodization of disks. Dezincification effects begin as β and higher zinc content phases appear. Confirmation of nonselective anodic dissolution for the α-alloy in ammoniacal solution was also obtained in this laboratory (6). In this latter work, a split ring-disk electrode capable of monitoring both copper and zinc dissolution at the same time was applied along with the conventional technique.

* Electrochemical Society Active Member.

Key words: anodic dissolution, alloy corrosion, brass, solid solutions.

For all these experiments, disk dissolution currents were above the critical 10^{-6} $\mu A/cm^2$ level below which Pickering and Byrne (16) found zinc preferentially dissolved from the α-brasses by colorimetric analysis of the solutions. In nonring studies, Marshakov and Bogdanov (17) found no dissolution selectivity from rotated α-phase alloy specimens in 0.5M NaCl or HCl, comparing anodic dissolution currents with polarographic analyses of the resulting solutions. Skorchelletti *et al.* (18) concluded from the hysteresis shifts in repetitive E-i traces of α-brasses more than 25% in zinc in NaCl solution that selective dissolution occurred. These effects, however, were superimposed on film formation in nonstirred solutions. The corrosion rates which could be reasonably measured with the ring electrode in the present work are all above those critical values (16) at which selectivity apparently ceases, and the alloy surface is thus expected to be removed uniformly unless there is specific interaction with the corrodent, products, or medium.

The anodic dissolution of binary homogeneous alloys considered as atomically dispersed heterogeneous alloys has been discussed with similar results by both Mueller (19) and Steigerwald and Greene (20). In situations where surface enrichment does not occur even though the component standard potentials are widely separated (for α-brass, when $i_a > 10^{-6}$ A/cm^2), they predict a limiting case in which the current-potential curves are dominated by the more noble component. Data relative to this conclusion where the currents are due both to soluble oxidants and anodic dissolution have been obtained in this work.

Experimental

Reagents.—The solution used in all experiments was 0.1M HCl-1M NaCl, prepared from reagent grade chemicals and triply distilled water.

Ring-disk electrodes and control circuitry.—Two ring-disk electrodes were employed, both with gold split rings. One was equipped with a pure copper disk, the second with a 70.1 atomic per cent (a/o) Cu-29.9 a/o Zn (α-brass) disk. The electrodes were normally operated in a shorted split-ring configuration equivalent to the conventional ring-disk electrode. Electrode construction and control circuitry are all described in detail elsewhere (6).

The geometric parameters of the two electrodes were as follows: Cu disk, $r_1 = 0.238$ cm, $r_2 = 0.263$ cm, $r_3 = 0.322$ cm, $A = 0.178$ cm^2, $N = 0.336$; α-brass disk, $r_1 = 0.236$ cm, $r_2 = 0.263$ cm, $r_3 = 0.319$ cm, $A = 0.176$ cm^2, $N = 0.323$. The inactive areas of the ring divisions were accounted for in determining N.

A third electrode containing a gold disk was amalgamated for use as a mercury surface ($r_1 = 0.238$ cm, $A = 0.178$ cm^2). The solid metal surfaces (including the amalgam prior to applying a drop of mercury) were polished down to a 0.3μ Linde A finish. Excess mercury on the amalgam electrode was spun off at 10,000 rpm.

In addition to the basic control circuitry, two logarithmic operators (Philbrick/Nexus 4350) were used to record log i and log i_a from their respective current follower sources at 5 V/decade. The electrode speed control scheme has been described elsewhere (21). The temperature of the solution was controlled by means of a jacketed cell and external thermostated bath. A central Luggin capillary underneath the disk surface led to a saturated calomel electrode at ambient temperature (effects on potential due to the Luggin tip-SCE temperature gradient have been ignored in this work). A Beckman RC-19 bridge was used to measure the conductivity of the electrolyte for correction of IR losses from the capillary position beneath the disk and the Newman theory (22).

Procedure and preliminary measurements.—An initial solution volume of 125 to 150 ml was used for each of the runs in which concurrent analyses were to be done. In such cases, 5 ml samples were withdrawn at known time intervals, typically every 30 min. The determinations of copper and zinc at the approximately 1 mg/liter levels involved were carried out by direct atomic absorption spectroscopy of the samples, using standards prepared by dilution in the pure cell electrolyte. Analytical accuracy at 1 ppm was estimated to be $\pm$ 5%, improving above that level. All the runs made for purposes of comparison to solution analyses were carried out under open-circuit conditions at the disk, using a zero current galvanostatic configuration. The ring current at an appropriate controlled potential was simultaneously monitored on a strip chart recorder.

In the chloride solutions, the dissolution of copper is to Cu(I), thus allowing monitoring of the partial anodic current of copper from the disk through the oxidation of Cu(I) to Cu(II) at the ring. For a pure copper disk and one-electron reactions at both ring and disk, $i_a = \dfrac{i_r}{NA}$. It was independently established that the loss of Cu(I) by reaction with oxygen during transit from disk to ring was negligible and that no intermediates in oxygen reduction at the disk were reoxidized at the applied ring monitoring potentials. The first was done with split ring measurements showing the equality of Cu(I) oxidation and reduction at the half rings when Cu(I) was generated at the disk with an applied current in the presence of oxygen, using a coulometric technique (23). The second was inferred from the identity of the anodic current potential curves observed at the gold ring during both applied disk current under nitrogen and open-circuit corrosion in the presence of oxygen. Only Cu(I) $\rightarrow$ Cu(II) waves were observed at the monitoring potentials of +0.40-0.45V *vs.* SCE. These conclusions are further substantiated by the comparison of solution analyses to electrochemical prediction, as reported below. It was further established that the gold rings are not anodically responsive to hydrogen generated by impressed cathodic currents in the experiments involving disk current scan.

In brass dissolution, the product Zn(II) does not interfere with the anodic reaction of Cu(I) at the ring, but since mercury-coated rings were not used with the brass disk as in an earlier study (6) and also because oxygen was present, the rate of zinc dissolution could not be directly measured. The collection efficiency for copper from the alloy, N_{Cu}, is, however, given by the ring current i_r for the Cu(I) $\rightarrow$ Cu(II) + e reaction divided by i_a, and for nonselective dissolution, N_{Cu} may be calculated from the geometric N, the atomic fractions f_{Cu} and f_{Zn}, and the number of electrons involved in the individual anodic dissolution reactions ($n_{Cu} = 1$, $n_{Zn} = 2$) as

$$N_{Cu} = N\left[\frac{f_{Cu}n_{Cu}}{f_{Cu}n_{Cu} + f_{Zn}n_{Zn}}\right] = (0.323)(0.540) = 0.174.$$

Experimental agreement with this value indicates nonselective dissolution and, in such circumstances, the zinc dissolution can be calculated by difference. From the above, the partial anodic current of zinc from the disk as determined from the Cu(I) oxidation ring current is $\left(\dfrac{i_r}{0.174}\right)(1-0.540)$. For comparison to the chemical analyses, the ring current-time integral was recorded on the strip chart with a Disc Chart integrator if necessary, but usually the current traces were either nearly constant or quite linearly changing with time and an average current was easy to determine. For both copper and alloy disks, the residual ring currents were estimated by cathodically protecting the disk with sufficient current to suppress any anodic reaction and measuring the resulting i_r, which was

then independent of any further increase in the cathodic protection current. The solution levels of copper ions were always kept low enough that Cu(II) etching of metal did not make a significant contribution to the corrosion rates.

For determining the current-potential curves, the applied disk current was scanned between anodic and cathodic limits which corresponded respectively to the end of the linear i_r *vs.* i traces and to the point where i_r reached a constant (residual) value. The linear trace extends to $i \cong i_a$, where oxygen reduction becomes negligible. The value of i_r at $i = 0$ read from these curves compared very well to the i_r obtained at a constant open-circuit condition when the surface changes due to corrosion or anodization had stabilized. Disk potentials were recorded with i and i_r on a two-pen XYY′ recorder, and when a logarithmic display of the current outputs was made, the residual ring current was subtracted from the total ring current before the log operator. The potential of the disk was corrected for *IR* drop before display by analog subtraction of the appropriate fraction of the voltage from the disk current follower from the measured potential between the SCE and disk electrode.

Results and Discussion

A current-potential curve for the reduction of oxygen saturated 0.1M HCl-1M NaCl at a rotating copper disk is given in Fig. 1 along with curves of nitrogen, air, and oxygen at an amalgamated disk. The mixed potential corrosion reaction for copper under oxygen is evident from the steep rise in the copper curve as it approaches the zero current axis. The limiting current for the well-defined oxygen step at mercury corresponds to a two-electron reduction, as is known from polarography. Satisfactory limiting currents on copper were not obtained in this acidic electrolyte, and therefore the corrosion current densities later obtained were compared to the oxygen-limiting current densities at the mercury disk for identical rotation speeds and temperatures.

In studying the open circuited copper disk under O_2, it was first necessary to establish that the limiting current for Cu(I) oxidation at the ring was related to the anodic partial current density by the expression $i_a = \frac{i_r}{NA}$. The electrochemical evidence for this has already been given. The comparison between currents and dissolved metal was then done with the $i_r - t$ integrals and the solution sample analyses. The collection efficiency N obtained under O_2 and N_2, as discussed earlier, was consistent with the geometrically calculated 0.336 for numerous combinations of rotation speed and temperature. An experimental value was obtained in each run and used in the $\frac{\int i_r dt}{NA}$ calculation. The results of the comparison are given in Tables I and II for two runs at different temperatures, showing total ppm Cu in the solution phase.

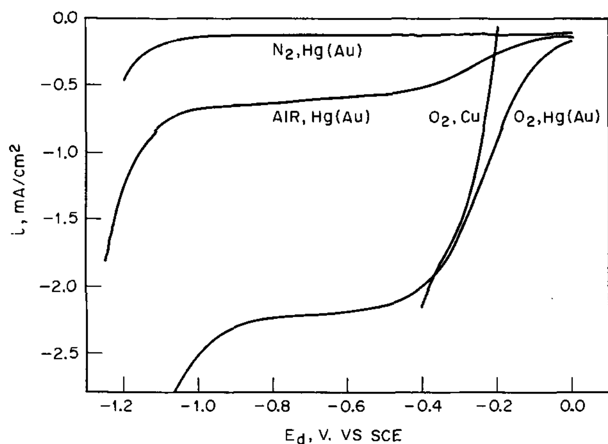

Fig. 1. Controlled potential cathodic sweeps in 0.1M HCl-1M NaCl for an amalgamated gold disk under N_2, air, or O_2 saturation (scan rate 10 mV/sec) and for a copper disk under O_2 saturation (scan rate 5 mV/sec). Rotation speed 1600 rpm, all scans.

These experiments were carried out for totals of 2 and 3 hr, respectively, so as to get several increments of copper sufficient for analysis by atomic absorption into solution. The quoted values of i_r are the averages during the sampling periods. The agreement between electrochemical and analytical results is generally within the experimental error. On this basis, we quote all other i_a results from ring data alone, except for some corresponding analytical comparisons for α-brass.

The increase in average corrosion rate during successive sampling periods, as indicated by the i_r values in Tables I and II, is typical of these experiments. A spread approaching a factor of 2 from the starting rate to a stabilized value was normal. Initial rates could usually be raised by pre-etching the polished surface with $CuCl_2$ solution on twill cloth before immersion. Data for the same temperature and rotation speed, but from different runs, will be seen to be subject to this drift in corrosion rate to varying degrees. However, where systematic changes in a variable were to be analyzed, the surfaces were allowed to stabilize before measurements were begun. Thus similar trends rather than exact reproducibility are to be expected depending on the exact surface condition.

The rotation speed dependence of i_a, calculated from ring currents, is given in Fig. 2 at several temperatures along with the 2 electron limiting current for O_2 reduction at amalgamated gold under the same conditions. The reduction at the limiting current at mercury shows the expected linear $\omega^{1/2}$, oxygen transport governed behavior. The corrosion current at the copper disk at open circuit, however, increases weakly and nonlinearly with $\omega^{1/2}$, indicating that control by a surface kinetic process is more important than control by transport.

The current due to oxygen transport to the mercury disk changes very little with temperature increase because of the near compensation of higher diffusion coefficient of oxygen and reduced concentration (solubility) in the Levich equation

$$i = 0.62\, n\mathbf{F}\, \nu^{-1/6}\omega^{1/2}D^{2/3}\, (C^b - C^s) \qquad [1]$$

The net corrosion rate at copper, however, is strongly

influenced by temperature, increasing by a factor of 4 or more at all speeds for a 20°-60°C change. At constant speed, these data give reasonably linear logarithmic plots *vs.* $\frac{1}{T}$, as shown in Fig. 3 for 1600 rpm. The magnitude of the resulting activation energy, 6.6 kcal/mole, represents the summation of effects of the several temperature dependent thermodynamic, kinetic, and diffusive processes which influence the corrosion rate.

At 60°C the percentage of the $2e$ limiting oxygen current represented by i_a is 72 at 20 rpm$^{1/2}$ and this decreases to 42 at 60 rpm$^{1/2}$. The net surface concentration of unreacted oxygen increases with rotation speed and anodic partial current, primarily because the activation overpotential of the oxygen reduction reaction more than compensates for the decrease in the cathodic concentration overpotential. The situation at lower temperatures is even more dominated by the kinetics of the cathodic reaction.

The anodic half-reaction may be studied independently under a nitrogen atmosphere, and dissolution curves for the copper disk are shown in Fig. 4 with both linear and log recording of the current over a range beyond both limits of the corrosion data in Fig. 2. The log slope at 30°C is 69 mV/decade of current. The theoretical shift due only to concentration overpotential at constant rotation speed is 60.1 mV, indicating that the $Cu/CuCl_2^-$ reaction has a sufficiently high exchange current that it contributes only a small activation overpotential at these current densities.

After establishing the behavior of the copper disk under nitrogen, comparable curves under oxygen were obtained using controlled current scans crossing zero applied current. At the same time, both the corresponding $Cu(I) \rightarrow Cu(II)$ limiting ring current and disk potential were recorded to derive plots of i_a *vs.* E_d at fixed speeds for the 20°-60°C range, and the results are shown in Fig. 5. The corrosion currents at open circuit are indicated and are within 10% of the range of rates expressed as ring currents in the longer term experiments of Tables I and II.

A more complete picture is given by a plot of i and i_a against E_d, as in Fig. 6. These curves are plotted from individual points taken from recorded traces and i_c calculated by difference. It is experimentally convenient to do the original recording with i and i_r on different axes so that the residual current region (true $i_a \simeq 0$) and the $i_a \propto i$ region ($i_c \simeq 0$) are immediately apparent. It should be emphasized that the corrosion current measurement depends only on knowing the oxidation state changes at the ring and the disk and the collection efficiency, and the same is true for the partial current curves. If the disk films over, as by corrosion product precipitation or a similar passivating mechanism, the steady-state ring current still measures the net corrosion rate. Complications are, of course, introduced by ring deactivation or reactions in transit.

Logarithmic recording provides an alternative presentation of these results, giving plots of log i and log i_a *vs.* E_d. An example at 40°C under oxygen is

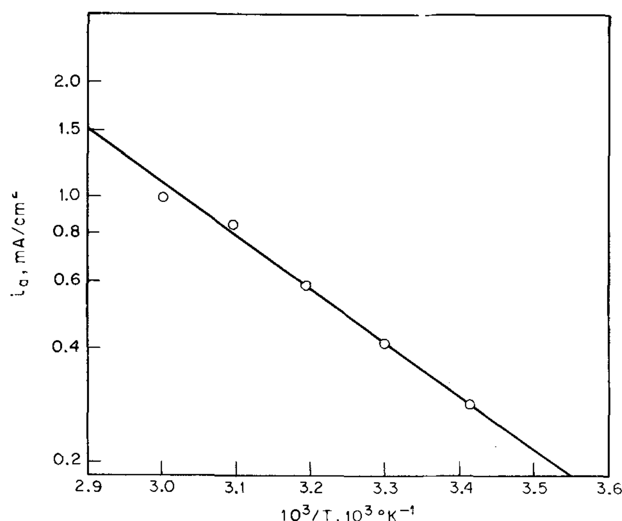

Fig. 3. Partial anodic current density at open-circuit copper disk under O_2 saturation *vs.* $10^3/T$; currents from ring current. Rotation speed 1600 rpm, 0.1M HCl-1M NaCl. T range 20°-60°C.

shown in Fig. 7. The slope of the log i_a tracing is 69 mV/decade $\left(\frac{2.303\,RT}{\mathbf{F}} = 62.1 \text{ mV}\right)$, consonant with the purely anodic and largely transport-controlled dissolution under N_2 at 30°C of Fig. 4.

The measurements in Fig. 7 have been carried 80 mV negative of the corrosion potential. The net ring current at this point was only about 3 μA, but with careful correction for residual current, linear log $i_a - E_d$ behavior is typically found down to this level. Such data

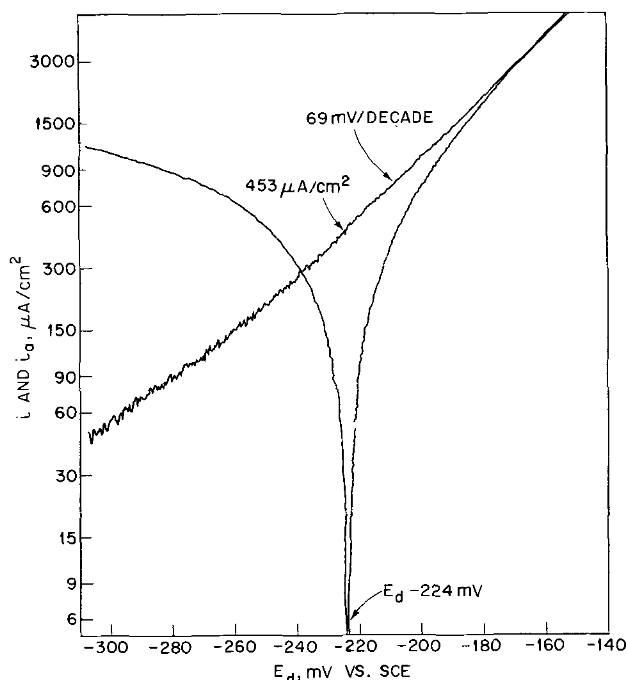

Fig. 7. Log i and log i_a for Cu disk under O_2 saturation and controlled current scan from anodic to cathodic limits. i_a from i_r at $E_r = +0.45$V vs. SCE. $di/dt = 0.9$ μA/sec, rotation speed 1600 rpm, temperature 40°C. Tafel slope, corrosion current, and corrosion potential indicated on figure.

are collected in a single sweep of a few minutes, and the corrosion potential and current are directly measured along with the anodic Tafel parameters. If desired, i_c or log i_c could be computed by an analog $i - i_a$ subtraction as well.

Tafel plots for the partial anodic currents accumulated from i_a-E_d data as shown above are presented in Fig. 8 for the 20°-60°C range. For this set of data the slopes run from 70 (20°C) to 75 (60°C) mV/decade $\left(\frac{2.303\,RT}{\mathbf{F}} \text{ gives 58-66 mV/decade}\right)$. A separate run at 40°C (Fig. 7) gave 69 compared to the 73 mV/decade in Fig. 8. A reproducibility within a 5 mV/decade span of the slope at each temperature was typical for all times of exposure and for log or linear recording in spite of the slow changes of corrosion rate in the initial period of exposure of the originally polished surface. It was, however, contingent upon keeping the scan rate $\frac{di}{dt}$ low enough to be a minimal factor in determining the slope; excessive rates produced high slopes. The nearly reversible slope (concentration overpotential) for the anodic reaction at all temperatures combined with the transport and current level dependent rates of Fig. 2 further substantiates cathodic activation overpotential as the dominant controlling factor in the corrosion rate.

Similar approaches may be taken with an alloy once it is established that dissolution is nonselective and that one component's product may be monitored to determine the over-all rate. Collection efficiencies for pure anodic dissolution in proportion to atomic composition have been confirmed for copper-zinc alloys similar to the present example in sulfate, chloride, and ammoniacal media (6, 14, 15, 24). Under open-circuit oxygen corrosion, where a collection efficiency cannot be measured in the usual electrochemical way $\left(\frac{i_r}{i}\right)$,

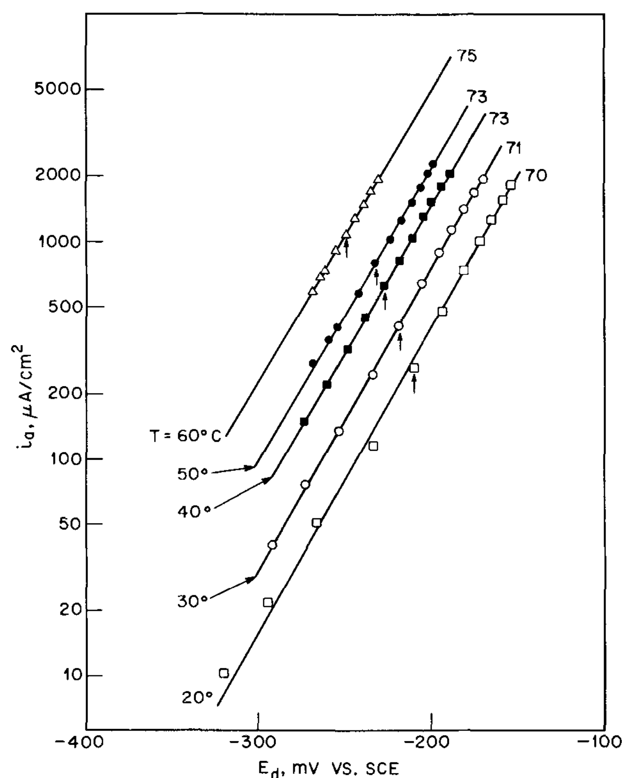

Fig. 8. Plots of partial anodic current density vs. potential for Cu disk under O_2 saturation as a function of indicated temperature. i_a from i_r. Tafel slopes in mV/decade i_a indicated on figure. Open-circuit condition indicated by arrows. Rotation speed 1600 rpm, 0.1M HCl-1M NaCl.

the absence of preferential dissolution effects can only be assured by independent analysis. Although it was earlier shown that with this alloy (6) the copper/zinc dissolution ratio can be measured directly with a split ring-disk electrode under nitrogen, such measurements in general would have to take into account the possible interfering reactions at the ring of the reduction of the oxidant (here oxygen) or the reoxidation of its product.

The results of ring current measurements for copper, of calculations for zinc on the basis of nonselective dissolution, and of atomic absorption analyses for both metals are shown for two runs in Tables III and IV. The agreement between the electrochemical and analytical results at the concentration levels involved is satisfactory. Considering especially the time spans involved in each run (170 and 375 min), the results confirm that no significant degree of preferential dissolution occurs at i_a values attributable to oxygen corrosion in these oxygen saturated solutions.

We thus calculate the total dissolution rates (as currents) for the Cu30Zn disk for other experiments solely on the basis of ring currents detecting copper. Measurements under nitrogen with anodic dissolution

gave an average copper collection efficiency of 0.171, as against the theoretical 0.176 for nonselective dissolution, in agreement with the corrosion results under oxygen at open circuit.

From simultaneously recorded disk and ring currents, the total anodic ($i_{a,Cu} + i_{a,Zn}$) partial current, the applied current, and the cathodic component (by subtraction) were obtained as a function of α-brass disk potential as shown in Fig. 9 for a 60°C run. When the current scan data are plotted in logarithmic form, the set of Tafel lines for the 20°-60°C range in Fig. 10 is obtained. These data may be compared to those in the equivalent plots for pure copper in Fig. 8. From the analytical data in Tables I-IV and from the anodic currents at the corrosion potential in the two groups of Tafel plots (Fig. 8 and 10), it is apparent that the brass disk electrodes corrode at slower rates than the copper, in spite of the negative shift of the corrosion potential relative to pure copper at each temperature and the consequent increase in activation overpotential for the cathodic process. This suggests that the exchange current for oxygen reduction at the 70/30 α-brass disk is lower than that at the high-purity

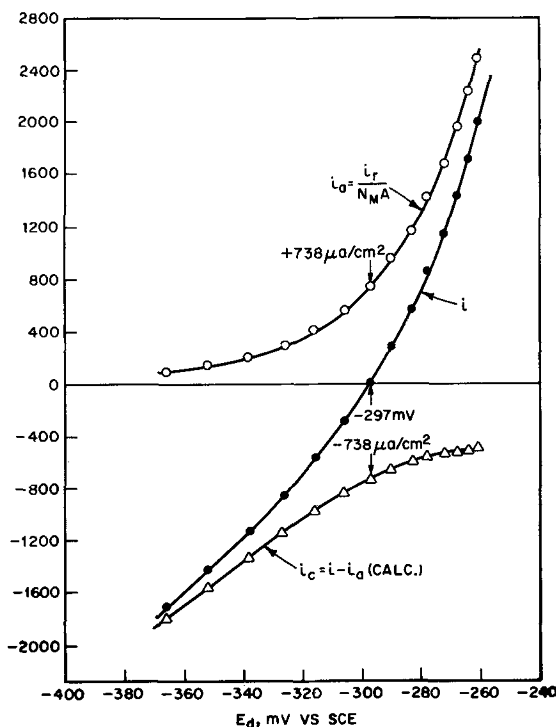

Fig. 9. Applied and partial anodic current density ($i_{a,Cu}+i_{a,Zn}$) for Cu30Zn under O_2 saturation. copper disk by more than enough to compensate for the more negative potential.

The slopes of the Tafel lines in Fig. 10 are only slightly lower than those of Fig. 8, show the same trend with temperature, and are each essentially equal to $\frac{2.303\,RT}{F}$. Similar and distinctly copper-like behavior of the α-phase alloys has been observed in a systematic study of the polarization curves of a spectrum of Cu-Zn compositions in sulfate solutions by Feller (14) as well as in chloride solutions (17, 18). In Feller's study all the α-brass electrode curves crossed the zero current axis within 50 mV of pure copper, and only the zinc rich ϵ-phases had zinc-like i-E curves which fell more than 800 mV negative of those of copper.

For single phase solid solutions dissolving at potentials so much more positive than the standard potential of the more electroactive component (zinc), the partial anodic behavior is dominated by the co-dissolving base metal (copper), but the corrosion rate itself is controlled by the exchange current of the alloy surface for the cathodic reaction, oxygen reduction. Tomashov (25) claims that, at comparable current densities, the oxygen overpotential at zinc is about 0.7V higher than that at copper. An effect in this direction would be consistent with the present results.

The constraint of nonselective dissolution

$$\frac{i_{Cu}}{i_{Zn}} = \frac{f_{Cu}n_{Cu}}{f_{Zn}n_{Zn}} \quad [2]$$

has been verified here by both ring-disk electrode and solution analysis results. If the total dissolution current at a given potential were written as that of a heterogeneous alloy, with the respective surface areas and appropriate partial current densities of the pure components, then (26)

$$Ai_a = a_{Cu}i_{Cu}^o + a_{Zn}i_{Zn}^o \quad [3]$$

It would be expected from the widely divergent standard potentials of copper and zinc that $i_{Zn}^o >> i_{Cu}^o$ and thus $i_a \simeq a_{Zn}i_{Zn}^o$, so there would be dezincification rather than uniform dissolution. Such "heterogeneous behavior" is found experimentally for the very low currents and the limited periods sustainable by solid-state transport mechanisms (15, 16).

However, it is apparent in the present experiments that both Eq. [2] and [3] have to hold simultaneously for the substitutional solid solution dissolving at the values of i_a observed here. Combining Eq. [2] and [3] with the relations $\Sigma\, a_i = A$ and $\Sigma\, f_i = 1$ (20), it is readily shown that

$$i_a = \frac{i_{Zn}^o i_{Cu}^o\,(f_{Cu}n_{Cu} + f_{Zn}n_{Zn})}{i_{Zn}^o f_{Cu}n_{Cu} + i_{Cu}^o f_{Zn}n_{Zn}} \quad [4]$$

Ignoring any interactions between copper and zinc, then the tendency of i_{Zn}^o to be much greater than i_{Cu}^o simplifies Eq. [4] to

$$i_a \simeq i_{Cu}^o \frac{(f_{Cu}n_{Cu} + f_{Zn}n_{Zn})}{f_{Cu}n_{Cu}} = 1.85\ i_{Cu}^o \quad [5]$$

Thus the same supposition that leads to surface enrichment at low currents requires that the alloy appear distinctly copper-like, but somewhat more active, when it is dissolved uniformly. Stated otherwise, when the alloy is forced to dissolve at the current levels caused by oxygen saturated, nonfilming acidic chloride media, the solid solution cannot act as a heterogeneous system and dezincify.

This simple approach suggests that the brass Tafel lines (Fig. 10) should lie negative to the copper lines (Fig. 8) at the same total anodic current and temperature by some $\frac{2.303RT}{F}$ log 1.85 mV or by 16-18 mV over the temperature range studied. The values of the average separations for three current densities (200, 500, and 2000 μA/cm²) are 34, 30, 28, 34, and 35 mV at 20°, 30°, 40°, 50°, and 60°C, respectively. The respective brass corrosion potentials are 43, 43, 42, 45, and 47 mV more negative than those of copper, while the ratios of corrosion currents at these temperatures are 1.51, 1.73, 1.79, 1.49, and 1.49, averaging about 1.6. This would give an additional separation of some $\frac{2.303RT}{F}$ log 1.6 or 12-13 mV, accounting well for the 42-47 mV separation of the corrosion potentials as compared with the 28-35 mV separation at equal total anodic currents.

The predictions by the naive model of a 16-18 mV separation and of identical Tafel behavior are thus qualitatively in line with the measurements at the several temperatures, especially when one considers that the standard potentials of copper and zinc in chloride solution are separated by ~1V and the reversible Nernst factors differ by a ratio of two. The relatively close correspondence is very likely largely dependent on well-controlled mass transport which has not been typical of most previous attempts at such correlations.

Summary and Conclusions

In the copper (disk)-gold (ring)-chloride-oxygen system, measurements of instantaneous corrosion rates at the disk have been made and demonstrated by independent solution analysis to be equivalent to mass or volume loss rates. With the geometric properties of the system, the ring measurements provide continuous monitoring of the partial anodic current at the disk. Instantaneous corrosion rates may be determined without the prior assumptions as to the shape of the partial curves in the vicinity of the corrosion potential that are characteristic of the usual electro-

chemical approaches and with considerably increased accuracy.

Such solution analyses were also carried out on an actively corroding alloy, Cu30Zn, where the corrosion reaction was determined to be nonselective toward the alloy components. The over-all corrosion rate could then be monitored by the oxidation at the ring of the copper product, Cu(I). For other metals or alloys, ring reaction schemes appropriate to the given case must necessarily be selected. For example, if the products are not electroactive in the potential range normally accessible to ring materials (as with Al or Mg disks), the decrease in flux of corrodent to the reacting disk or a corrodent product (such as H_2O_2 or H_2) might be measured. Thus i_c might be the directly monitored quantity and i_a calculated, instead of the reverse as applied in this study.

A major feature of the ring technique is the instantaneous feedback on corrosion rate. It is commonplace that corrosion rates of metallic samples often change with exposure time, even if the solution conditions are held constant, because of surface alterations. Ring measurements instantly respond to such behavior or any other system changes, such as inhibiting additives, as long as the monitoring ring reaction is not interfered with. Data reported in this paper show these surface effects when corrosion rate measurements under the same external conditions are repeated in different runs. Standard pretreatments, such as pre-etching the samples briefly after polishing, accelerate the achievement of the higher corrosion rates characteristic of longer exposures. For other physical examination studies, the advantage of measuring corrosion without externally perturbing the surface is desirable. The ring current gives a direct measure of the activity of the surface without the averaging necessary in integral techniques which might obscure the effects. The cathodic behavior of copper and copper-zinc alloys toward oxygen is an example of correlating partial current measurements with potential so as to understand surface controlled relative reaction rates toward a common oxidant.

Simple models of the dissolution behavior of a solid solution (19, 20) appear to give good correlation between the i-E curves of the more noble component and the alloy. Ring-disk electrode approaches to such problems offer the necessary control of concentration overpotential and detection of dissolution ratios that are required to obtain valid experimental data in this area.

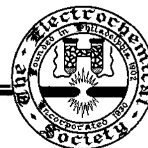
Technical Note



Electrochemistry of Sulfur in LiCl-KCl Eutectic

John H. Kennedy* and Frank Adamo*

Department of Chemistry, University of California, Santa Barbara, California 93106

The blue solution of sulfur is a well documented phenomenon. An intense blue solution is observed in fused KSCN upon decomposition of KSCN or after the introduction of sulfur or various sulfides (1, 2). A polarographic study of fused KSCN or KSCN-NaSCN eutectic has illustrated that SCN^- is reduced to S^{2-} and CN^- (3). The authors cited references to the blue color of sulfur, however their discussion did not reveal the development of the blue color during their study. It has been recently suggested (4) that impurities of sulfur and sulfide may cause the blue color in molten KSCN. The blue solution of sulfur has been observed many times in the LiCl-KCl eutectic. Greenberg, Sundheim, and Gruen (5) gave evidence that the blue solution in fused LiCl-KCl is caused by diatomic sulfur molecules in the triplet state. Delarue (6-9), in his electrochemical investigation of sulfur and sulfide salts in LiCl-KCl melt, observed an intense blue color when sulfur was added to the melt or when sulfide salts were oxidized by various metal ions. Although the blue color was not directly investigated, Delarue assumed that the blue solution was dissolved sulfur. Recently, Bodewig and Plambeck (4) reported the electrochemical behavior of sulfur and sulfide in the LiCl-KCl eutectic. They observed that a blue color was generated when sulfur, initially a colorless solution, was coulometrically reduced to sulfide. Further investigation showed that the blue color disappeared when chlorine was generated at the electrode, or when the potential was held at a constant value which was 0.3V more positive than the decomposition potential of sulfur, or when a vacuum was applied. The blue color reappeared upon addition of sulfur. It was ascertained that both sulfide and sulfur must be present to form the blue color. Bodewig and Plambeck subsequently concluded that the blue solution was a polysulfide formed from sulfur and sulfide, *i.e.*, $S^{2-} + S_x \rightleftarrows S_{x+1}^{2-}$. Further investigation using uv spectroscopy (10) seemed to confirm the authors' suggestion that the blue solution was a polysulfide. It was definitely shown that neither sulfur nor sulfide alone produced a blue solution.

Although many reasons for the formation of the blue solution of sulfur have been suggested, until recently no detailed investigation of the nature of the blue solution of sulfur had been reported. However, Giggenbach (11) recently gave evidence that the sulfur species producing the blue coloration in DMF and other aprotic polar organic solvents is the anion radical, S_2^-. UV spectroscopy of tetrasulfide, in 25% DMF-water mixture, showed two bands in the visible and near-uv region near 23.10×10^3 cm^{-1} and 36.2×10^3 cm^{-1}. A third absorption at 16.2×10^3 cm^{-1} developed and increased when more DMF was added. Subsequently, it was shown that the tetrasulfide was in equilibrium with S_2^-, and that the equilibrium favored the anion radical as the DMF content of the solvent mixture increased. More recently, Merritt and Sawyer (12) reported the electrochemistry of sulfur, S_8, in DMSO. Cyclic voltammetry and controlled potential electrolysis revealed that sulfur is reduced to S_8^{2-} in two reversible one-electron steps. The product of the first reduction step is S_8^-, a stable anion radical. Although the products of the reduction steps are easily oxidized, reoxidation of S_8^{2-} was shown not to be a simple two-step oxidation. Chronopotentiometry and uv spectroscopy established that S_8^- dimerizes, the formation constant of the dimer being 5×10^3 M^{-1}. That is, $S_8^=$ is electrochemically oxidized to S_8^-, and the S_8^- radical dimerizes to $(S_8)_2^=$. The dimer then is electrochemically oxidized to $2S_8^0$. Interestingly enough, although Merritt and Sawyer did not report the observance of a blue solution, S_8^- was found to absorb at 16.2×10^3 cm^{-1}, the same frequency Giggenbach (11) reported for the absorption of S_2^-. The similarity of these two studies seems to indicate that the blue solution of sulfur is caused by an anion radical of sulfur, but the number of molecules associated with the radical is uncertain or varies. Recent ESR investigations of sulfur in various media (13) support this supposition.

This paper presents additional electrochemical evidence for sulfur species in fused LiCl-KCl.

Experimental

Apparatus.—A Beckman Electroscan 30 was used for all electrochemical operations. The temperature of the melt was controlled by a Barber-Colman temperature controller, while a Glas-Col heating mantle for a 250 ml Griffin-type beaker was used to heat the melt.

As illustrated in Fig. 1, a 400 ml tall-form, lipless, Berzelius beaker was used as the electrolysis cell. The cell was covered by a 1 in. thick asbestos stopper in which appropriate standard tapered holes were drilled to accommodate the glassware. A 6 mm glass tubing encased the Chromel-Alumel thermocouple, while an asbestos-wick isolation compartment and a coil of platinum foil, 0.003 in. by 0.5 in. by 2.0 in. served as the reference electrode. A carbon rod ⅛ in. in diameter, enclosed in a 10 mm sealing tube with a medium porosity fritted disk, was used as the auxiliary electrode. When controlled potential electrolysis of sulfur was carried out, a 10 mm sealing tube with a medium porosity fritted disk, sealed to a straight vacuum adapter, served to isolate the sulfur and the working electrode, a gold foil 0.005 in. by 1 in. by 1 in., heat sealed to a gold wire. A stirring assembly was attached to the top of the vacuum adapter. A length of 12 mm glass tubing was substituted for the working electrode compartment, illustrated in Fig. 1, during cyclic voltammetry studies.

All experiments were carried out under a nitrogen atmosphere which was provided by way of a straight vacuum adapter with $\$$14/20 ground glass joints and an extended inner tube. A two-way stopcock was used to regulate the passage of nitrogen over or through the melt. A small air hole was blown in reference and auxiliary electrode compartments about 2 in. above

Key words: cyclic voltammetry, controlled potential electrolysis, molten salts, sulfur, lithium chloride-potassium chloride eutectic.

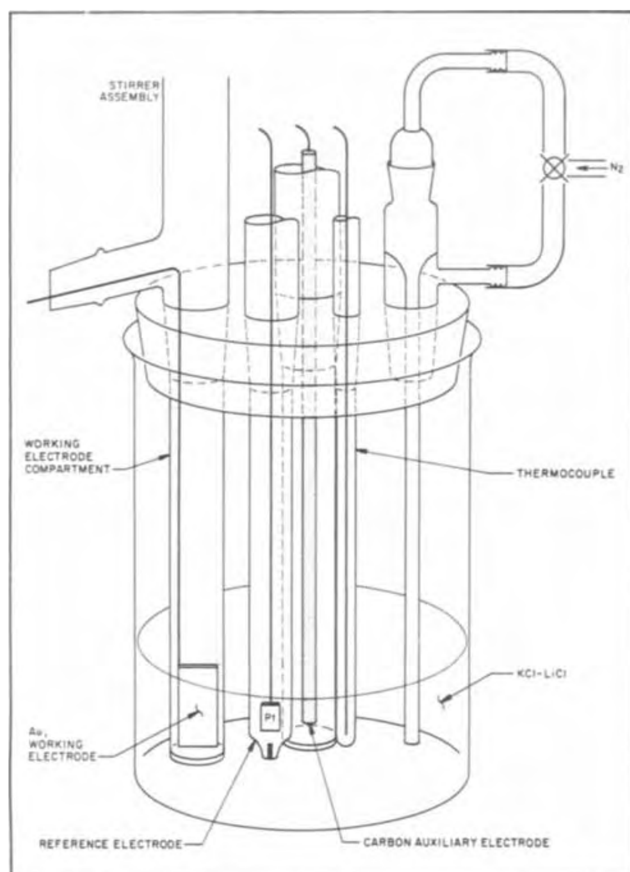

Fig. 1. Diagram of cell used for cyclic voltammetry

the level of the melt to accommodate a nitrogen atmosphere.

Reagents.—Reagent grade lithium chloride and potassium chloride were used. Small quantities of sulfur were heated in test tubes at 120°C overnight. Before using, a test tube was broken, and the lump of sulfur was used directly. Nitrogen was dried by passage through a column of Silica Gel.

Solvent.—The LiCl-KCl eutectic salt mixture was prepared by combining 400g of lithium chloride and 488g of potassium chloride in a large jar and tumbling the mixture overnight until homogeneous. About 600g of the mixture was then purified as described by Bodewig and Plambeck (4). Four Berzelius beakers were dried at 120°C for 2-3 hr and were placed in a vacuum desiccator. After quickly transferring 100–125 ml of the molten eutectic to each of the beakers, the desiccator was flushed with dry nitrogen. Upon cooling, the beakers were quickly sealed with Parafilm.

Procedure.—For each experiment, the glassware was cleaned with chromic acid cleaning solution, and the electrodes were appropriately assembled. The cell assembly was placed in an empty beaker and oven dried at 120°C for two or more hours. After the LiCl-KCl eutectic was allowed to become molten under a nitrogen atmosphere, the cell assembly was quickly transferred to the cell. The isolation compartments were then allowed to fill over a period of 2-6 hr. A Pt(II)/Pt reference electrode was coulometrically generated using a Sargent Coulometric Current Source. A current density of 7.5 mA/cm^2 was employed anodically, giving rise to a concentration of 0.01-0.02M in platinum (II). All measured potential values were converted to the 1.0M Pt(II)/Pt standard molar platinum electrode (SMPE). The temperature was adjusted to 420°C, and after purging the melt for a few minutes, a cyclic voltammogram of the blank solution was recorded.

Cyclic voltammetry of sulfur was begun after about 0.1g of a lump of sulfur was dropped through the isolation compartment. For controlled potential electrolysis of sulfur, the working electrode was previously fitted closely against the inner wall of the isolation compartment. The gold wire was extended out through the sidearm of the vacuum adapter. A constant potential was applied at a value more negative than the corresponding peak potentials of interest. Using a constant speed stirrer connected to a Variac to adjust the speed of rotation, the blank was electrolyzed until a constant residual current was obtained. A small lump of sulfur, about 0.015g, was added to the melt through the sidearm of the vacuum adapter and the sulfur was electrolyzed at an appropriate controlled potential. The n-value for the electrolysis was evaluated from the recorded current *vs.* time curve. On subsequent runs, the electrolysis was stopped and a cyclic voltammogram of the partially electrolyzed solution was recorded. Cyclic voltammetry of the completely electrolyzed solution was also carried out.

After each experiment, the reference electrode isolation compartment was removed and placed in a desiccator. After cooling to room temperature, the isolation tube was gently broken and the solid salt mixture analyzed according to procedures described by Bodewig and Plambeck (4).

Results

Cyclic voltammetry.—The cyclic voltammogram of sulfur in LiCl-KCl eutectic is shown in Fig. 2. The initial scan showed a sharp rise in current at -0.9V *vs.* SMPE, however, rather than the formation of a peak, a limiting current was observed. As the scan was continued, a peak at -1.37V *vs.* SMPE developed. Two anodic peaks, at -1.10 and -0.83V *vs.* SMPE, were observed when the scan was reversed. On the second and succeeding cycles, a peak at -1.13V *vs.* SMPE appeared where the initial rise in current was observed, as illustrated in Fig. 2. Coincidental with the initial rise in current, a blue color developed at the working electrode. As the cyclic voltammetry was continued, the blue color intensified until the entire solution was opaque. Cyclic voltammetry using a large gold foil electrode showed that the initial formation of the blue color occurred only at the electrode interface. The blue solutions were decolorized by standing for several hours, or more quickly by putting the melt under vacuum. This phenomenon indicates that the blue species or its decomposition product has a measurable vapor pressure at 420°C.

The curves in Fig. 2 show that two steps are involved in the electrochemical reduction of sulfur. At a scan rate of 200 mV/sec, the products of the reduction are easily reoxidized. However, the reactions are not strictly reversible, *i.e.*, the difference between the cathodic peak potential and anodic peak potential at 420°C was not equal to 132 mV/n where n is the num-

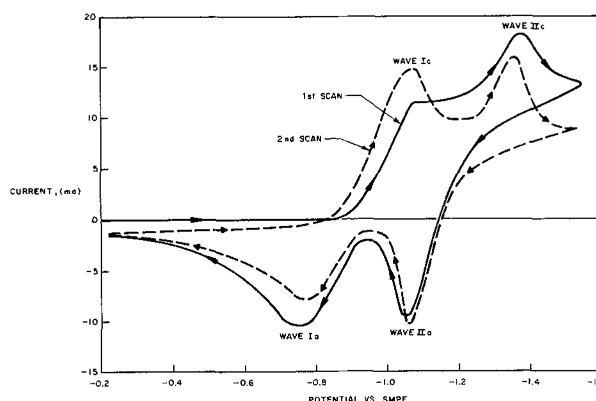

Fig. 2. Cyclic voltammetry of sulfur in 100 ml LiCl-KCl eutectic at 420°C. 0.3g S; sweep rate 200 mV/sec.

ber of electrons transferred. The separation between the peak potentials of the first wave did not vary with scan rate from 200 to 40 mV/sec. In contrast, the separation of the peak potential of wave II decreased as the scan rate was varied from 200 to 40 mV/sec. In fact, the separation of the peak potentials was 130 mV when the scan rate was set at 40 mV/sec; consequently, the second reduction step may be approaching electrochemical reversibility at slow scan rates, assuming that only one electron is involved in the reduction step. If the potential scan was reversed at -1.2V the anodic peak at -0.83V was identical to the peak observed after scanning to -1.6V. Thus, the anodic peak at -0.83V is directly associated with the cathodic peak at -1.13V.

When the solution was cathodically scanned to -1.8V *vs.* SMPE and held at that potential, the current increased. After holding the potential at -1.8V for 3-5 min, the solution was anodically scanned. The peak of wave II decreased slightly; while wave I increased severalfold. Also, the peak potential of Wave I was shifted approximately $+0.05$V. Reversing the scan showed only the normal development of the cathodic peaks.

Controlled potential electrolysis.—A weighed amount of sulfur was electrolyzed at a potential of -1.1V *vs.* SMPE. The current *vs.* time was recorded and then integrated (by counting squares) after the current reached the previously determined residual current value. The area above the residual current value was considered to be sulfur reduction and computed as Faradays/g-atom of sulfur or e^-/S atom. Since the sulfur was trapped in the electrode compartment, loss as vapor was minimized. The values reported are the largest obtained from several runs since the only major source of error was leakage of sulfur vapor from the electrolysis cell.

The current *vs.* time curve showed that the sulfur was not being reduced in the normal manner, *i.e.*, the current *vs.* time curve did not follow the normal exponential decay. The current remained constant for 2-3 min and then gradually dropped to a lower constant value. After another minute or so, the current again dropped to a lower constant value. This sequence continued throughout the electrolysis. Controlled potential electrolysis of the first reduction step, which took about 8 hr to complete, revealed that 0.265 e^-/S atom was involved in the first cathodic step. Controlled potential electrolysis of the second reduction step at -1.4V, which took about 1 hr, behaved in the normal manner, *i.e.*, the current decayed exponentially with time. The n-value was determined to be an additional 0.72 e^-/S atom. Anodic oxidations of the product of the reduction at controlled potential were rapid. Controlled potential electrolysis at -1.0V *vs.* SMPE gave an n-value of 0.833 e^-/S atom; while further oxidation at -0.7V *vs.* SMPE gave an n-value of 0.201 e^-/S atom.

A very intense blue solution was formed immediately after the initiation of the controlled potential electrolysis of the first reduction step. The cyclic voltammogram of the blue solution midway through the electrolysis is shown in Fig. 3. The initial rise in current did not develop into a peak, rather, a limiting current was observed. A peak, at -1.51V *vs.* SMPE developed as the scan was continued. The anodic scan revealed two peaks at -1.10V *vs.* SMPE and -0.85V *vs.* SMPE. Although the cyclic voltammogram is similar to the cyclic voltammogram of the elemental sulfur, the initial cathodic rise and the cathodic peak were shifted to more negative values. The blue color became less intense as the electrolysis at the first cathodic wave neared completion. When controlled potential electrolysis at the second cathodic wave was carried out, the blue color disappeared. The solution turned blue when oxidation at controlled potential was carried out, although the color was not intense. Sulfur vapors collected on the wall of the isolation tube above the level of the melt, when controlled potential electrolysis of the second anodic wave was carried out.

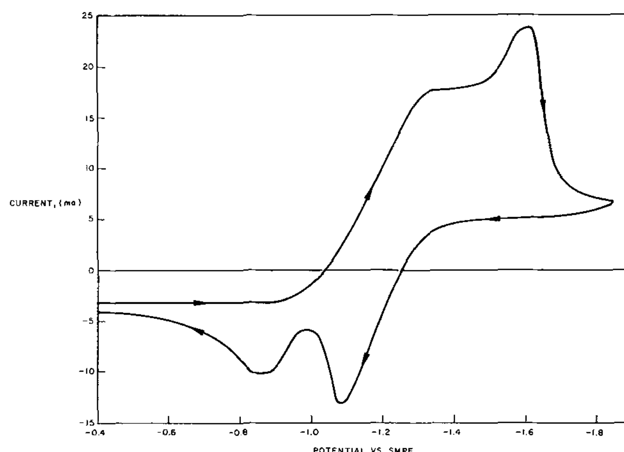

Fig. 3. Cyclic voltammetry of sulfur during controlled potential electrolysis at -1.15V *vs.* SMPE. 0.612g S; sweep rate 200 mV/sec. Electrolysis was about 50% completed when scan taken.

Discussion

The electrochemical reduction of sulfur proceeds through two steps. The curves in Fig. 2 indicate that the same number of electrons are involved in each step. Initial scans were somewhat different than succeeding scans because of undissolved sulfur present initially. After the sulfur dissolved, the cyclic voltammograms were reproducible. Based on the similarity of the results in LiCl-KCl to the results in DMSO (12), the two reduction steps can be described as follows

$$S_n \xrightarrow{+e^-} S_n^- \xrightarrow{+e^-} S_n^{2-}$$

where $n \geqq 2$.

Controlled potential electrolysis showed that 1e^-/S was involved during reduction or subsequent oxidation and, thus, the final reduction product can be described as S_m^{m-}. However, it cannot be concluded that $n = m$ since additional reactions could occur during the long-term controlled potential electrolysis which were not observed during cyclic voltammetry. In fact, the results of controlled potential electrolysis carried out at the first reduction step of -1.1V *vs.* SMPE indicate that n may be 3 or 4. Both cyclic voltammetry and controlled potential electrolysis have shown that the product of the first reduction step is the sulfur species producing the blue solution.

Lead Anode Deterioration as a Function of Depth of Operation

R. P. Hollandsworth and E. L. Littauer[*,1]

Electrochemistry Department, Lockheed Aircraft Service Company, Ontario, California 91761

In recent years, considerable attention has been devoted to the development of impressed current cathodic protection (ICCP) systems for ships and offshore structures. Significant economies accrue from the use of permanent anodes in such installations because of the cost and inconvenience of drydocking ships outside of normal maintenance schedules, and with offshore structures, the need to employ divers for servicing. In the latter case, such servicing can be extremely difficult with structures in deep water.

ICCP systems are generally self-regulating with the permanent anodes connected to the positive side of a power supply comprising a step down transformer from a 220 or 440V line, a rectifier, and with control frequently accomplished with a saturable-core reactor in conjunction with a silver-silver chloride reference electrode. The negative of the power supply is connected to the structure. In principle, the system is analogous to a potentiostat. Protective potential of steel in sea water is in the range -800 to -850 mV *vs.* Ag/AgCl, and this range is set on the controller.

Systems are designed in modular form with outputs ranging from 50-3500A. The protective current required is determined from data of water conductivity, flow by rate, bare area of steel, and anode position. Anodes range in size from 1-2 ft long to 16 ft and are mounted on a dielectric shield to assist in distribution of current to all areas of the structure. Anodes may be mounted on the structure or mounted remotely; the latter method assists current distribution but may introduce complications such as stray current effects.

The most often used permanent anode in ICCP systems of ocean structures has been Pb based, *e.g.*, Pb alloys such as Pb, 6% Sb, 1% Ag, and Pb-Pt bielectrodes. The latter are less expensive because the cost of Pt for microelectrodes is less than that of Ag in the alloy anode. Also the Pb-Pt bielectrode is capable of operating at somewhat higher current densities (C.D.) which leads to a smaller anode for the same duty.

With Pb based anodes the active surface becomes a layer of PbO_2 which forms over the original Pb surface upon anodic polarization in sea and fresh water. The mechanisms and conditions of formation of the chemically passivating PbO_2 have been extensively dealt with in the literature (1-3). Under normal conditions there is little further involvement of the underlying metal once a limiting thickness of PbO_2 has formed. The predominant electrode process becomes evolution of Cl_2 and/or O_2, depending on the C.D. and salinity of the electrolyte. Initial formation of PbO_2 follows a path similar to that manifested by Pb in SO_4^{2-} containing electrolytes, where an initial layer of essentially nonconducting crystallites of $PbSO_4$ are converted to PbO_2. This happens within interstices in the crystallite layer at points at the metal solution interface where the potential exceeds that of the $Pb_{aq}^{2+} \rightarrow PbO_2$ reaction.

* Electrochemical Society Active Member.

Key words: anode dissolution, pressure hydrostatic, lead anode, cathodic protection.

In fresh water the initial nonconducting layer is a lower oxide; in saline water this precursor to chemical passivation is $PbCl_2$. In both cases the layer is eventually converted to PbO_2 through a heterogeneous reaction (3).

Recent service experience with Pb-based anodes, operating at depths greater than 25m, has revealed a deterioration rate far greater than that observed in surface operation. Anode failures have been indicated by a gradual (or sudden) increase in resistance, and inspections of failed anodes have shown: (*i*) separation of the PbO_2 from the Pb, with a thick, intervening layer of $PbCl_2$ intermixed with lower oxides, and (*ii*) the thickness of PbO_2 growth is far greater than observed on anodes operating at modest depths for an equal length of time. No explanation for these deteriorating effects is to be found in prior literature which has considered the influence of alloy composition (4), effect of microelectrodes (1), temperature (5), and water velocity (6). Accordingly, the present study was undertaken to examine the problem in detail under controlled laboratory conditions, with the intention of discovering the mechanism of the depth effect as well as defining the pressure conditions under which Pb anodes can be expected to operate without deterioration.

Experimental

To simulate deep-ocean conditions in the laboratory, the experiments were performed in pressurized (316) stainless steel test vessels (Fig. 1) equipped with flanged top, anode receptacle, automatic pressure regulating valve, and pressure gauge. Prepressurization was accomplished with argon, which is inert towards the electrode processes and is relatively insoluble in sea water.

The production of hydrogen and chlorine was limited to less than 10% of the ullage volume by changing solutions regularly and by automatic pressure relief valves which maintained the pressure within 2 psi of the desired value. One liter of artificial sea water (ASTM D-1141-52) was contained in the vessel, the ullage volume being about 0.51.

Tantalum, which forms an insulating anodic oxide in sea water, was chosen as the anode support thus avoiding interferences in the electrode chemistry. Anodes were cast into cylinders 1.75 cm × 1 cm diameter. The Pb-Pt bielectrodes were made using 99.5% Pb, 0.5% Sb alloy (Bunker Hill Company). A piece of 0.76 mm (30 mil) diameter, 10% Ir/Pt wire, 0.4 cm long was inserted into an undersized hole in one end so that 0.15 cm protruded; into the other end a hole was tapped to accommodate the 0.125 cm diameter threaded tantalum rod. The Pb, 6% Sb, 1% Ag anodes were prepared from analytical grade Pb, Sb, and Ag. The ingredients were weighed, melted, and mixed in a porcelain crucible and cast. Analysis showed the composition to be 92.8% Pb, 6.2% Sb, and 1.0% Ag which conformed to MIL-A-23871 for lead silver anodes. Anodes were preformed for 7 days in artificial sea water at C.D. 5 mA/cm² above those to be used in their

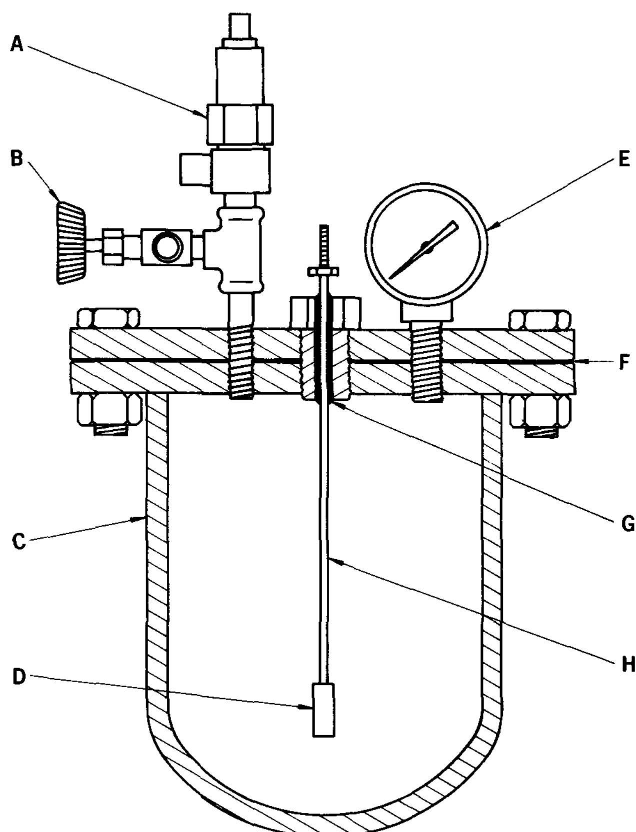

Fig. 1. Pressure test vessel. A: pressure control relief and valve; B: pressurization valve; C: pressure vessel; D: lead anode; E: pressure gauge; F: Teflon gasket; G: epoxy insulation; H: tantalum connecting rod.

respective long-term tests. This preforming period was arbitrarily chosen since measurements revealed very little change in the PbO_2 layer after 2 or 3 days.

During the pressure tests, the solution was changed at such intervals that the variation in Cl^- concentration was always less than 0.1*N*. A previous study (3) showed little difference in electrode behavior in the range 0.5*N* to 0.1*N* on preformed anodes, and it is thus believed that the variation occurring in the present experiments would not be a significant affector of the electrode processes of interest. It was also calculated that the hydrogen and chlorine evolved never occupied more than 10% of the ullage volume. The electrolyte became saturated with chlorine during the runs; however, earlier work (7) showed that dissolved chlorine has no significant influence on the anodic behavior.

The C.D.'s were chosen on the basis of the upper operating limits of the anodes, *i.e.*, 30 mA/cm² for the lead silver alloy (6) and 40 mA/cm² for bielectrodes (8). These limits have been established by laboratory and field experience over a number of years.

Constant d.c. (<0.1% a.c.) was supplied by an Electronic Measurements No. C614 instrument to a bank of the test vessels connected in series. Tests were run for 17, 30, 60, and 90 days at which time the thickness of the PbO_2 layers on the anodes were measured by slicing off cross sections and observing with a graticule equipped microscope.

Information on the actual weight of Pb converted to PbO_2 was obtained by physical removal of the dioxide followed by dissolution in an aqueous solution containing 2% KI, 10% CH_3COOH, and 5% CH_3COONa. Pb is not dissolved by this solution within the time required to dissolve the PbO_2. The PbO_2 quantity was determined by either titration against standard $Na_2S_2O_3$, or by atomic absorption spectrophotometry.

Results

Photographs 1-6 in Fig. 2 are characteristic of the series. Photographs 1-3 represent the Pb-Pt bielectrode at 40 mA/cm² and photographs 4-6 show the Pb, 6% Sb, 1% Ag anode at 30 mA/cm²; observations from all the experiments typically illustrated by the photographs are:

(*i*) Cracking and striations in the PbO_2 layer increase with depth.

(*ii*) Extent of blister formation and subsequent blister rupture and spalling of PbO_2 increases with depth. Blister formation is frequently associated with gassing but with Pb anodes in chloride solutions, blister formation is a way of relieving stresses at the Pb-PbO_2 interface. The PbO_2 formed in this system is quite porous and has a bulk volume about double that of the substrate.

(*iii*) Rate of growth, *i.e.*, continuing thickening of PbO_2 increases with increasing depth. This is further illustrated in Fig. 3 which was obtained by measurement of cross sections, accuracy being about 25%.

(*iv*) Failure of the lead silver anode, as shown in photograph 6 (Fig. 2) occurred after only about 0.3 to 0.6 cm of PbO_2 growth because the dioxide separated from the underlying Pb. This failure is depicted in the curve of applied voltage *vs.* time at constant C.D., Fig. 4, and is representative of failures observed in ICCP operations; *i.e.*, anode malfunction due to the onset of a large resistance increase.

From Fig. 4 it may be noted that the electrode shown in photograph 6 functioned normally at steady voltage for 7 days, but the voltage requirement increased at that time. With the high-voltage capability of the

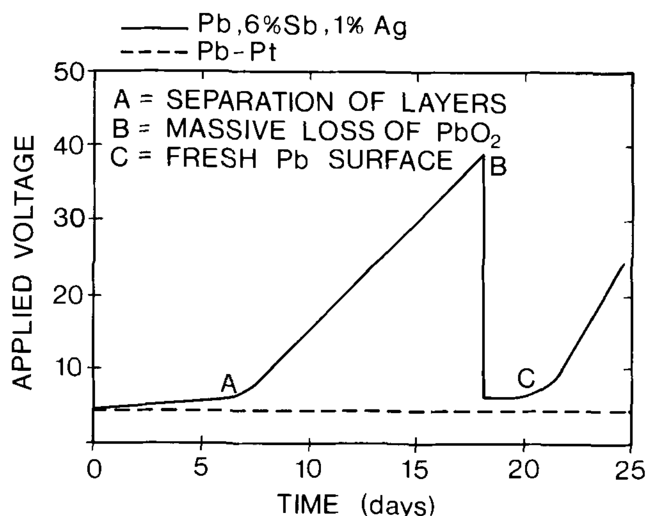

Fig. 4. Failure sequence of Pb, 6% Sb, 1% Ag alloy anode

power supply used in this study, it was found that a maximum was reached after about 17 days, and this maximum was associated with the total surface decrepitation shown. The voltage rise from day 7 onward reflected the gradually increasing separation of the PbO_2 from the underlying Pb, accompanied by the high resistance of the cavity formed between the two electrically conducting interfaces. The PbO_2 finally spalled off completely at 17 days exposing a fresh Pb surface. Then once a fresh adherent thin layer of PbO_2 had reformed, the anode reverted back to normal low-voltage behavior for a few days. This sequence of failure events was observed with the Pb alloy anode at depths greater than 30m regardless of the C.D., the anode functioning normally for a longer time as the C.D. was decreased.

The Pb-Pt bielectrode did not suffer from this type of failure even though the rate of PbO_2 growth was somewhat greater, but separation of the dioxide from the Pb also occurred at depths greater than about 30m. However, the Pt microelectrodes effectively provided a current path between the Pb and PbO_2 across the nonconducting cavity and permitted normal operation for long periods.

Discussion

In the first part of this discussion, the practical significance of the experimental data is considered. In the second part an hypothesis is presented which explains why depth of operation is an affector of anode deterioration independent of mechanical pressure forces.

Figure 3, obtained from the experimental data, shows the influence of depth on the rate of the conversion reaction Pb → PbO_2. Pb anodes will apparently function with an acceptably low-deterioration rate at depth to about 20m but at greater depths the conversion rate increases significantly. However, before operational limits can be established, it is necessary to calculate anode life as a function of depth. These data, obtained assuming a conventional Pb anode 1.3 cm (0.5 in.) thick, are shown in Fig. 5. The points were calculated by referring to the thickness of PbO_2 on controls run at atmospheric pressure alongside the pressure test specimens. Since a Pb-based anode operating at normal depths manifests very little conversion once a limiting thickness has formed, the additional growth at high pressures may be obtained by subtraction. To predict the life of Pb-Pt bielectrodes, we selected 75% conversion as representing a totally depleted anode since field experience has shown that these anodes will operate normally up to this level of conversion. On the other hand, with the Pb alloy, the criterion of useful anode life has to be determined differently. This is because at depths ≥30m the anode ceased to operate after about 30% conversion, (0.3 to 0.6 cm) of PbO_2, because the dioxide layer separated from the underlying metal, leaving a high-resistance cavity. This separation, due to abnormal stresses on the thick layers at depth, has been confirmed by field experience. Thus we selected the onset of high resistance as the criterion of lifetime for the alloy anodes in Fig. 5.

A phenomenological view of the problem may be obtained by considering the difference in electrochemical behavior of an anode at the surface and at the depth. Calculations based on data obtained with a fully formed bielectrode at 40 mA/cm² and at atmospheric pressure showed that 6×10^{-5}% of the current is used for oxidation of Pb → PbO_2 and that the remainder is involved in decomposition of the electrolyte. However, at a depth of 180m, 2×10^{-3}% of the current is used for Pb oxidation (30 × increase), which is reflected by the greatly reduced useful anode life. An explanation is not readily apparent from the literature since published data are sparse on the influence of pressure on heterogeneous inorganic electrochemical processes. Initially, when Pb or Pb alloys are made anodic in Cl containing electrolytes, the Pb corrodes as Pb_{aq}^{2+}. If the C.D. is sufficient, the plumbous ions react with Cl^- at or in close proximity to the corroding electrode and a mechanically passivating film of $PbCl_2$ develops. When passivation is complete or nearing completion, the current path is restricted to interstices and pores in the crystalline layer and the potential increases at constant current to a level sufficient that lead aquocations derived either from the metal surface or from dissolving $PbCl_2$ crystallites, may be oxidized through inter-

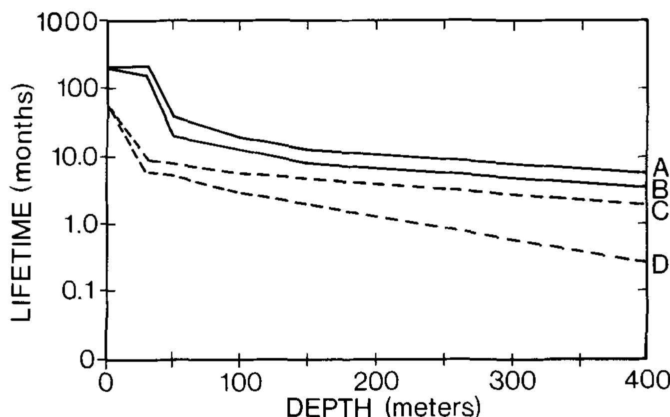

Fig. 5. Calculated anode lifetime. A: Pb-Pt bielectrode at 20 mA/cm²; B: Pb-Pt bielectrode at 40% mA/cm²; C: Pb, 6% Sb, 1% Ag alloy at 15 mA/cm²; D: Pb, 6% Sb, 1% Ag alloy at 30 mA/cm².

action with water dipoles or hydroxyl ions at the metal solution interface to PbO_2

$$Pb^{2+} + 2H_2O \rightarrow PbO_2 + 4H^+ + 2e$$

$$E = 1.455 - 0.1182\,pH - 0.0295 \log a_{Pb^{2+}} \quad [1]$$

The PbO_2 then grows within and over the $PbCl_2$. The exact mechanism is different for Pb alloys and bielectrodes, but so long as there is electrical continuity between the two conducting species (Pb and PbO_2), the surface becomes totally covered with the dioxide and eventually any underlying $PbCl_2$ is converted. Once PbO_2 has formed, oxidation of Cl^- to Cl_2, and to a smaller extent H_2O to O_2, is observed to occur on the chemically passivated PbO_2 surface. Actually, O_2 evolution is energetically favored over chlorine, but it is highly irreversible on PbO_2, and may be disregarded except at high C.D.'s or in low salinities. Thus, the alternate reaction to Pb oxidation is

$$2Cl^- \rightarrow Cl_2 + 2e$$

$$E = 1.359 + 0.0295 \log p_{Cl_2} - 0.059 \log a_{Cl^-} \quad [2]$$

By inserting values for $a_{Pb^{2+}}$ and pH into Eq. [1], one may show that the reversible potential is 1.04V. [The $a_{Pb^{2+}}$ and pH at the Pb/solution interface were previously determined in 0.5*M* NaCl to be 1.07×10^{-4} and 4.5, respectively (9)]. Also, the reversible potential for the Cl^-/Cl_2 reaction at a similar anode was calculated to be 1.33V (9). Thus, from reversible thermodynamic considerations, continued oxidation of Pb is to be expected, but this heterogeneous reaction is kinetically much slower and more irreversible than Cl_2 evolution which, therefore predominates. It will also be observed that there is no pressure sensitive term in Eq. [1], and that a pressure of 100 atm only increases the reversible potential of [2] by 59 mV. Thus, it becomes apparent that a reversible thermodynamic treatment is inadequate to explain the pressure responsiveness of the system, but it may be predicted from le Chatelier's principle that reaction [2] will be hindered with increasing pressure. A study of chemical reaction kinetics under pressure has been given by Hamann (10) who considered collision theory and transition state (or activated complex) theory and showed that hydrostatic pressure effects are best explained by transition state theory. However, to obtain specific quantitative data, it is necessary to have knowledge of the elementary intermediate reactions in oxidations [1] and [2], and such information is not yet available. Experiments to determine the kinetics of the reactions of interest will be the subject of a future paper. But, at the present time we believe that as depth increases, the Pb → PbO_2 reaction remains essentially constant, while the $Cl^- \rightarrow Cl_2$ reaction decreases, and this causes more coulombs to be available for the Pb conversion reaction.

Conclusions

Pb-based anodes have been shown to operate with normal low conversion of Pb → PbO_2 only to depths of about 30m. Below this depth, serious deterioration occurs, and such anodes cannot be recommended for deep-water use. Pb-Pt bielectrodes and Pb, 6% Sb, 1% Ag alloy also show a dramatic increase in conversion in comparison to surface operation. For example, with Pb-Pt bielectrode at 40 mA/cm^2 conversion increase rates at 176 and 352m were 30 and 41 ×, respectively.

The thick, chemically passive, PbO_2 layers developed cracks and fissures and separated from the underlying Pb but, with the bielectrode, electrical conductivity was shown to be maintained through the microelectrode, thus delaying failure. The mechanical forces causing the separation of Pb from PbO_2 probably also increase with depth and thus amplify the problem. The increasing conversion rate of Pb → PbO_2 with increasing depth is postulated to be due, at constant current, to the coulombs not used for the $Cl^- \rightarrow Cl_2$ reaction. These coulombs become available because the rate of the Cl_2 evolution reaction is believed to decrease under pressure while the Pb oxidation rate remains essentially constant.

Thermodynamic Activity of Na_2O-B_2O_3 Melt

Use of Stabilized Zirconia as an Electrode Constituent

Seichi Sato, Toshio Yokokawa, Hideaki Kita, and Kichizo Niwa

Department of Chemistry and The Research Institute for Catalysis, Hokkaido University, Sapporo 060, Japan

In the thermodynamic studies of the oxide melts such as borates, silicates, and phosphates, the electromotive force technique has been applied on various occasions. However, difficulties in the construction of the reference electrode and especially the selection of the electrode materials, which specifies the well-defined electrode reaction, have retarded a wide use of this method, aside from the problem of the liquid junction potential.

Meanwhile, CaO stabilized ZrO_2 has proven to be an excellent solid electrolyte (1), which can be used to measure oxygen pressure in gaseous atmosphere, oxygen content in liquid metals and so on (2). The present authors have shown this material to be very satisfactory for the measurement of the thermodynamic activity of Na_2O in Na_2O-B_2O_3 melt. The unique characteristics of this electrode are discussed.

Key words: $O_2/O^=$ reference electrode, acid-base of oxide melt, Na_2O-B_2O_3.

Experimental

The concentration cell is the type

(Pt) O_2|ZrO_2(CaO)|Na_2O-B_2O_3(I)

||Na_2O-B_2O_3(II)|ZrO_2(CaO)|O_2(Pt)

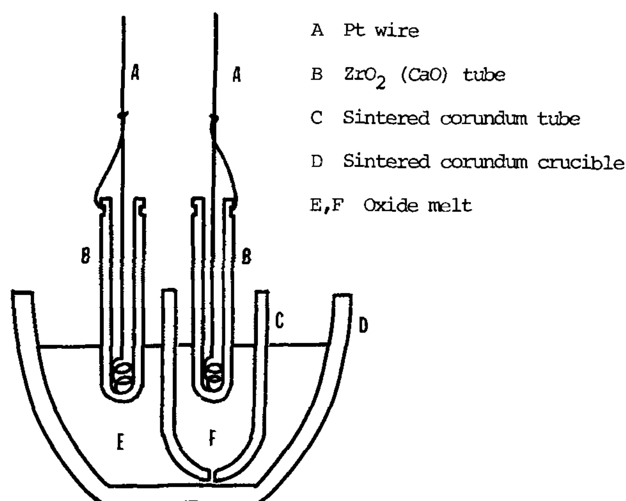

Fig. 1. Cell assembly

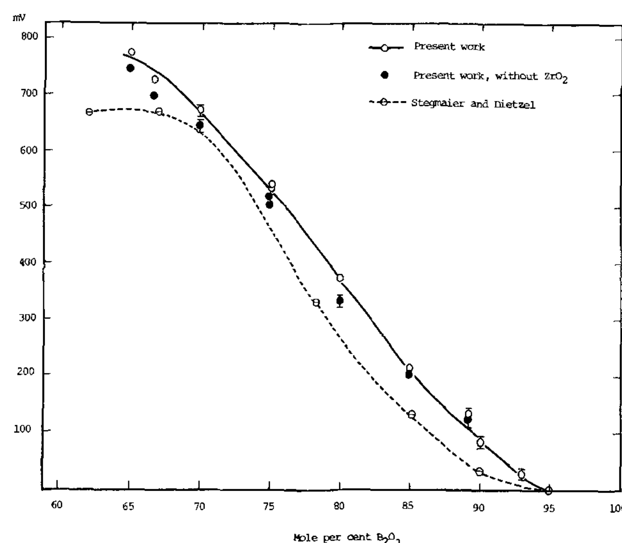

Fig. 2. Emf value as functions of composition at 850°C

and its construction is shown in Fig. 1. The electrode reaction is given by

$$O^{=} = \frac{1}{2} O_2 + 2e \qquad [1]$$

which proceeds in the forward direction at the left electrode and backward at the right electrode when a current of 2 Faradays passes from left to right in the cell. The potential gap across the ZrO_2-oxide melt interface is assumed to be set up so as to equalize the electrochemical potential of $O^{=}$ in both phases. Further, if it is assumed as usual that Na^+ is the sole carrier of the virtual electric current through the liquid junction, the liquid junction potential is given by

$$u_{ljp} = -(1/\mathbf{F})(\mu_{Na^+(I)} - \mu_{Na^+(II)}) \qquad [2]$$

where μ_{Na^+} is the chemical part of the electrochemical potential of Na^+ in the melt. Accordingly, the net electromotive force is represented as

$$E = \frac{1}{2\mathbf{F}}(\mu_{O^{=}(I)} - \mu_{O^{=}(II)}) + \frac{1}{\mathbf{F}}(\mu_{Na^+(I)} - \mu_{Na^+(II)})$$
$$= \frac{RT}{2\mathbf{F}} \ln \frac{a_{Na_2O(I)}}{a_{Na_2O(II)}} \qquad [3]$$

where a_{Na_2O} is the thermodynamic activity of Na_2O. In Fig. 1, platinum wire (A) is in electric contact with the inside bottom of the zirconia tube, the latter being grooved for suspension. The corundum tube (C) which separates the two melts is furnished with a hole of 0.3 mm diameter at the bottom. The assembly in a reaction tube was heated in a resistance furnace in air atmosphere. A stainless tube was introduced between the furnace tube and the reaction tube and was grounded. The voltage was measured both by an ordinary potentiometer and by a vibrating reed electrometer (Takeda Riken TR-84M type). It took about 4 hr for the emf to approach close to constant value. Usually the measurement was carried out in 12 hr after the charge. It remained constant for several days. The sample melt was prepared from H_3BO_3 and Na_2CO_3 of the guaranteed reagent grade.

Results and Discussion

The measurement was carried out for the Na_2O-B_2O_3 melt over the composition range 0.65-0.95 mole per cent (m/o) B_2O_3, the melt of 0.95 being used as a reference. The results are shown in Fig. 2. The data obtained from the measurement with the bare platinum wire without the zirconia tube are also plotted. Only small but systematic deviation is found in the two sets. Stegmaier and Dietzel (3) have measured the activities of Na_2O, K_2O, and Li_2O in the binary borates with a cell in which platinum wire electrodes were dipped into the melt. The data are reproduced in Fig. 2 where the emf value is shifted for easy comparison, although they measured it referred to 0.5-0.7 m/o alkali oxides. The order of magnitude and gradations of emf value are in fair agreement among the three sets of data. This suggests two facts. First, either the oxygen pressure in the melt at the platinum electrode without the ZrO_2 tube is in equilibrium with gaseous atmosphere or the electrode potential is determined practically at the gas-metal-oxide coexisting surface on the platinum wire. Second, the assumption that the electrochemical potential of $O^{=}$ is at the same level across the ZrO_2-melt interface is correct. In passing, one must note that the magnitude of emf corresponds to 10^7 of the activity ratio at 0.65 to 0.95 m/o B_2O_3 (Eq. [3]). This drastic change reminds one of the hydrogen ion concentration in an aqueous solution. This behavior is not observed in typical binary melts and will be understood better in terms of the acid-base character of the melt. Thus, while $O^{=}$ from Na_2O neutralizes B_2O_3 to various degrees depending upon the strengths of basicity and acidity of Na_2O and B_2O_3 respectively and upon their compositions, while Na^+ ion remains free.

The features of this electrode are the following. (*i*) The oxygen pressure is well defined. Although platinum or graphite rod electrodes have been used in the investigations of this kind, the pressure of O_2 or CO has not been specified except in a few cases (4). (*ii*) Since there is no electronic conduction through the ZrO_2 phase, the molecular oxygen dissolved in the melt cannot take part in the electrode reaction. This gives an advantage that the fugacity of molecular oxygen in the melt can be handled freely, being independent of the basic oxide content. A procedure of this sort becomes important, for example, when one wishes to measure the concentration ratio of Fe^{2+}/Fe^{3+} as functions of oxygen pressure and the basicity of an iron-containing melt separately. Parenthetically, the fugacity of molecular oxygen in the melt can be measured by the ordinary technique with ZrO_2 (2). (*iii*) The possible contamination due to ZrO_2-melt reaction is a shortcoming, as this might give rise to interference in reversibility of the emf with respect to $O^{=}$. In the present system zirconia showed a much higher resistance against contamination than sintered corundum.

The present method will widen the applicability of the emf technique to systems for which otherwise reversible electrode cannot be constructed. This electrode will function well as the reference electrode when one might want to measure a single electrode potential of an anode or a cathode in electrolysis of an oxide melt. There is no need of bubbling of O_2 gas

on the surface of the electrode (4). This electrode is in principle analogous to the glass electrode in a *p*H meter in which a thin glass layer functions reversibly only to hydrogen ion.

Oxidation Properties of a Zirconium-2.7 w/o Niobium Alloy in the Temperature Range 650°-1000°C

V. F. Urbanic and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The reaction kinetics and structures of the alloy/oxide composite system were determined for a Zr-2.7 weight per cent Nb alloy exposed at temperatures over the range 650°-1000°C in oxygen at 1 atm pressure. These kinetics may be represented by a parabolic-linear relationship. The zirconia scales contained small amounts of the intramolecular oxide, $6ZrO_2 \cdot Nb_2O_5$. An investigation was carried out on the morphological development of the columnar scale and the underlying layer of oxygen stabilized α-Zr plates in the β-Zr alloy during parabolic oxidation. The sequence of the reaction product layers was consistent with predictions from the Zr-Nb-O phase diagram.

Investigations on the oxidation properties of Zr-Nb alloys containing 2-3 w/o (weight per cent) Nb at elevated temperatures have been only carried out to a limited extent (1-5). The reaction kinetics over the temperature range 300°-1000°C are characterized initially by continuously decreasing rates followed by transitions to more rapid approximately constant rates. At temperatures less than the $\alpha + \beta$ eutectoid point at 610°C, a martensitic alloy oxidizes more rapidly than the Widmanstatten-structured alloy (2, 3). The zirconia scales may contain small amounts of the intramolecular oxide, $6ZrO_2 \cdot Nb_2O_5$ (2-5). At temperatures higher than 900°C, parabolic oxidation of a β-structured alloy gives rise to the formation of an oxygen stabilized columnar zone of α-Zr plates beneath the scale (4, 5). The objectives of this investigation, accordingly, were to determine the temperature dependence of the oxidation kinetics for the alloy in the $\alpha + \beta$ and β-Zr structures and to examine the morphological development of the scale and α-Zr columnar layer in the β-Zr alloy.

Experimental

A thermogravimetric technique was employed to measure the oxidation rates of alloy plates and spheres. The assembly which has been described contained an Ainsworth, Type AU-1, balance for continuously recording weight gains up to 400 mg to a sensitivity of 0.02 mg (6). Test temperatures were controlled to ±2°C. A specimen was lowered into the reaction zone and held for 15 min to ensure temperature equilibration after the assembly had been flushed with argon purified of oxygen and water vapor. The assembly was subsequently pumped down to less than 10^{-4} Torr and oxygen, 99.99% pure, then admitted to a pressure of 760 Torr. At the termination of a run, the specimen was quenched by rapidly raising it into the air-cooled portion of the assembly.

The material was a Zr-2.7 w/o Nb alloy received as a 2 mm thick sheet and as a bar. Analyses for impurities have been presented, the residual oxygen content in the alloy being 1100 ppm (2). Plates prepared from the sheet, 2 × 1 × 0.2 cm, were wet abraded on 220 to 600-grit silicon carbide papers, polished on 6 and 1μ diamond laps lubricated with kerosene followed by acetone washing and drying. Spherical specimens were prepared from the bar by machining pieces to a diameter of approximately 1 cm. They were then hand-abraded as above and lap-polished using a jig which permitted specimen rotation and polishing of the entire surface. The specimens, which were sealed in evacuated quartz capsules and annealed at 1000°C for 1 hr and furnace cooled, exhibited a typical β-cooled structure of coarse acicular α-grains.

Oxidized specimens were mounted in araldite self-setting epoxy resin. Abrasion was carried out to 600-grit silicon carbide with kerosene as lubricant. Final polishing at the 6 and ¼μ stages was completed on nylon cloths impregnated with diamond paste. Specimens used for metallographic examinations were etched in an aqueous solution containing 30 v/o (volume per cent) H_2SO_4, 30 v/o HNO_3, and 10 v/o HF. Oxides were identified by x-rays using the powder method and reflection diffraction with nickel filtered CuKα radiation. X-ray diffraction measurements of the oxide in the underside of a scale could be made by dissolving away metal in the etching solution held at approximately 70°C. A Cambridge scanning electron microscope was useful for distinguishing various phases in the scale and underlying metal. Variations of niobium concentration in the alloy and oxide phases were qualitatively determined using a Cameca electron probe microanalyzer.

Results

The results are classified into those obtained at temperatures in the range 650°-991°C using plate specimens and those obtained at 1000°C using the spherical specimens. It is evident from the Zr-Nb phase diagram (7) that these temperatures lie within the $\alpha + \beta$ phase field extending from 610° to 840°C or the high temperature β-Zr phase field.

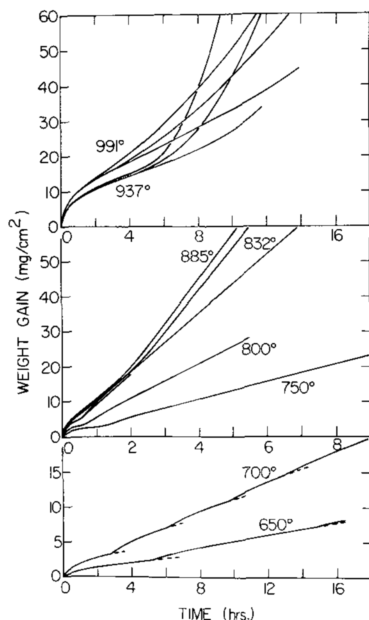

Fig. 1. Oxidation curves for the Zr-2.7 w/o Nb alloy plate specimens at temperatures over the range 650°-1000°C in oxygen at 1 atm pressure.

Oxidation curves for the plates are shown in Fig. 1. A continuously decreasing oxidation rate was observed during early exposure stages up to a transition to more rapid kinetics after approximately 5 hr at 650°C and within 2 hr at 885°C. The curves exhibited periodic discontinuities at 650° and 700°C which occurred more frequently at the latter temperature. At temperatures from 750° to 885°C, the transition led directly to linear kinetics. Specimens exposed at 937° and 991°C showed transitions within 4 hr to more rapid continuously increasing kinetics during the subsequent exposures examined.

A scale after the termination of a run at temperatures within the range 650°-885°C was colored white and extensively cracked. Specimens exposed at 937° and 991°C were covered predominantly by gray compact oxide and characterized by white cracked oxide at edges and corners. The powder x-ray patterns of the white and gray oxide were identical and similar to the pattern for monoclinic zirconia with the exception of one reflection at 2.97Å which corresponded to a spacing for the tetragonal oxide, $6ZrO_2 \cdot Nb_2O_5$. The alloy was composed of $\alpha + \beta$ phases at temperatures to 885°C. At 937° and 991°C, the alloy microstructure was characterized by a layer of α-Zr plates extending into the β-Zr substrate at areas covered by a gray compact scale. This columnar alloy structure was not present at regions where oxide cracking had caused enhanced localized scale growth. These latter observations correspond to those previously reported for alloys oxidized within the range 870°-990°C (4).

Continuous oxidation of the β-Zr alloy was extended to longer periods by employing the spherical specimens. As illustrated in Fig. 2, the shape of the oxidation curve at 1000°C is similar to that obtained upon oxidizing a plate specimen. The region of continuously decreasing oxidation rate, however, was extended beyond 16 hr. The adherent compact scales on the spheres, as shown in Fig. 3, were of lighter gray color with increasing exposure. White oxide was only observed at localized regions of cracked scale after the transition to more rapid oxidation.

A unique columnar structure of oxygen stabilized α-Zr plates existed under the compact scale formed on the β-Zr alloy. This structure is illustrated in Fig. 4. The martensitic matrix is a consequence of the transformation which occurs when a specimen is quenched. An interesting feature of the α-Zr layer,

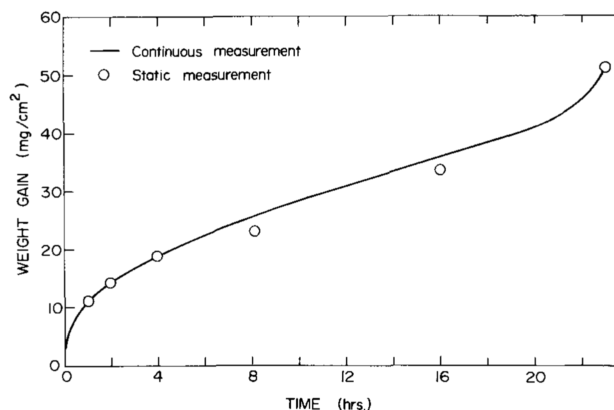

Fig. 2. Oxidation curve for the Zr-2.7 w/o Nb alloy spherical specimens at 1000°C in oxygen at 1 atm pressure obtained by the continuous gravimetric technique and by static tests involving specimen weighings before and after exposures.

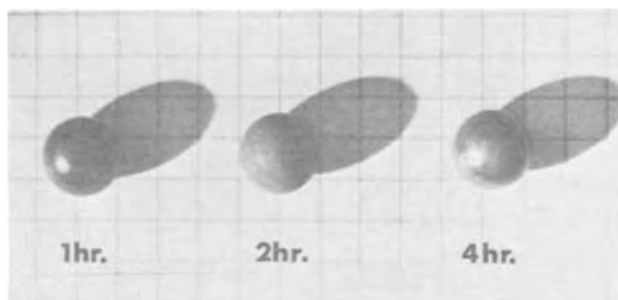

Fig. 3. Spherical specimens oxidized at 1000°C

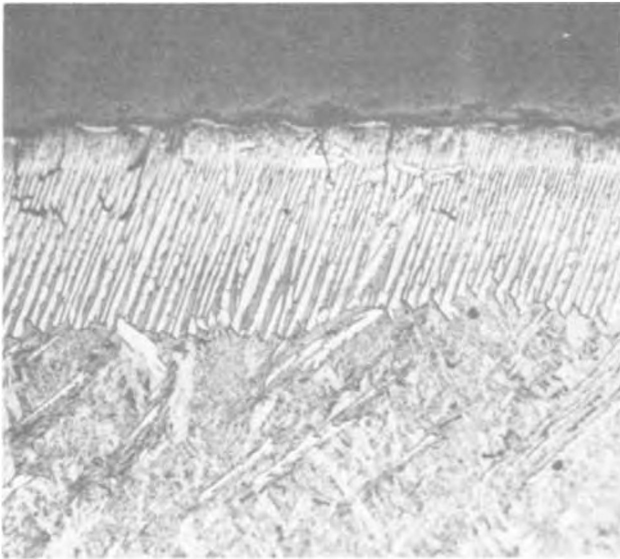
which is evident in Fig. 4 and readily apparent at higher magnifications as shown in Fig. 5, is the occurrence of a finer columnar structure near the metal/oxide interface. The coarse and fine structures differed from one another since they exhibited different etching properties. The intercolumnar regions of the coarse structure was simply transformed β-Zr whereas the material between the columnar plates of the fine structure was an oxide. Note that these oxide stringers extend inward right from the metal/oxide interface.

The external compact scale, α-Zr + oxide, and $\alpha + \beta$ layers formed in the alloy spheres grew at rates which continuously decreased with increasing exposure. As illustrated by the parabolic plots in Fig. 6, growth of these reaction product layers was determined by a diffusional mechanism involving inward oxygen migration.

Metallographic examination using the oil immersion technique of the oxide formed over the α-Zr plates demonstrated that the scale also exhibited a columnar structure not unlike that of the underlying alloy. This feature is illustrated in Fig. 7. An intercolumnar region generally appears to contain a lighter phase with the exception of a dark phase near the metal/oxide interface. The scale at the metal/oxide interface subjected to reflection x-ray diffraction only revealed monoclinic zirconia. Powder samples of the scales, nevertheless, exhibited a reflection corresponding to $6ZrO_2 \cdot Nb_2O_5$ which possibly arises from the lighter appearing discontinuous phase. Attempts were made using the electron-microprobe to determine the variations in niobium concentration across the columnar regions in the alloy and scale. It was only possible to conclude from lateral scans parallel to the alloy interface, however, that these regions were enriched in niobium since limitations were imposed on the validity of the results due to their small physical dimensions.

Discussion

The kinetics obeyed a parabolic relationship in the early stages of the reaction. This characteristic is



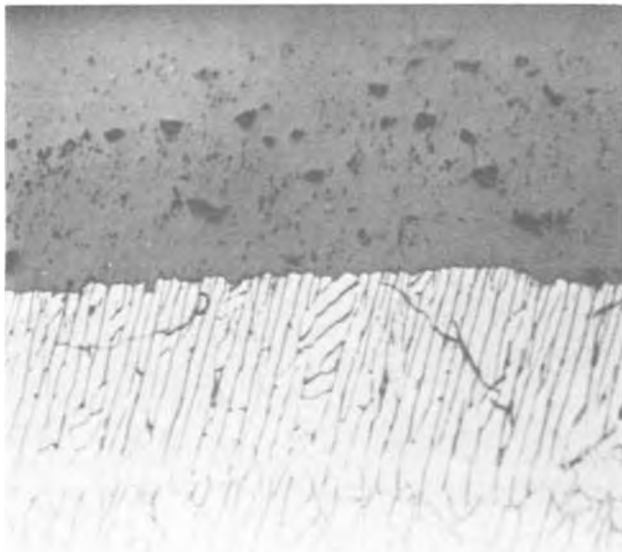


Fig. 4. Cross sections of spheres oxidized at 1000°C for 1 hr (upper) and 23 hr (lower) micrographs (140X). The micrographs illustrate the scales and the columnar zones beneath the scales in the β-Zr alloy.

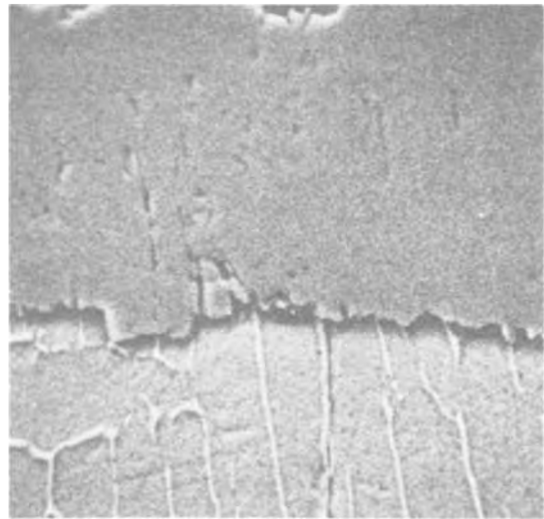

Fig. 5. Scanning electron micrograph of the scale and the α-Zr columnar alloy region formed at 1000°C exhibiting oxide stringers in the intercolumnar regions of the alloy (1000X). The metallographically polished specimen was chemically etched.

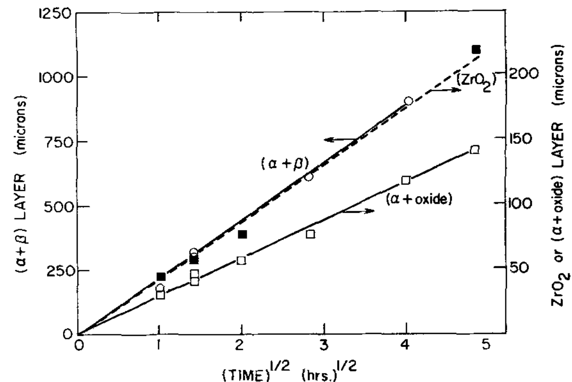

Fig. 6. Parabolic plots for the growth of the scale, α-Zr + oxide stringer layer, and $\alpha + \beta$ columnar layer in the alloy at 1000°C.

illustrated by the plots in Fig. 8 for oxidation of the plates at several temperatures and for the spheres at 1000°C. Scale growth, accordingly, was determined initially by a diffusional mechanism for inward migration of oxygen since zirconia is an oxygen-conducting oxide (8).

Arrhenius plots of the parabolic and linear oxidation constants are shown in Fig. 9. Values of the linear rate constants were determined from linear sections of the curves or from limiting tangents after the transitions from parabolic kinetics. The $\alpha + \beta$ alloy apparently oxidizes by a common mechanism over the temperature range 650°-885°C. The activation energies for parabolic and linear oxidation over this temperature range are 38 and 31 kcal/g-atom, respectively. Linear oxidation was associated with scale breakdown by cracking but the role of the scale as a barrier to oxidation remains undefined. Parabolic oxidation above 937°C nevertheless, proceeded at a lower rate than predicted from extrapolation of the Arrhenius relation. Oxygen dissolved in the alloy is known to cause an upward shift of the $\beta/\alpha + \beta$ phase boundary temperature (9). In particular an oxygen content of 1400 ppm in a 2½ w/o Nb alloy, which is approximately the impurity content of the alloy, raises this temperature to 925°C. Thus the transition in the kinetics to a lower value above 885°C was associated with a distinctly different morphological development involving concurrent formation of a scale and an unique columnar layer of α-Zr plates in the β-structured alloy.

A description of the oxidation properties of the β-Zr alloy at 1000°C may be formulated from the results for the spheres. Cross sections were characterized by a compact scale, a region of internal oxidation comprised of α-Zr plates and oxide stringers, and a layer of α-Zr as coarse columnar plates in the β-alloy matrix. Since growth of these reaction product layers followed parabolic relationships determined by a diffusional mechanism involving inward oxygen migration, the alloy-oxygen system may be considered as a diffusional couple.

The ternary isotherm available for 1500°C (10) is used to discuss the formation of the solid phases since the binary representations on the ternary diagram coincide with phase boundaries of the respective binary diagrams at 1000°C. A schematic representation for the compositions and microstructures of the oxidized alloy is shown in Fig. 10 by superimposing a path on the ternary phase diagram to correspond to the sequence of observed reaction product layers. This path which emerges into the β-phase at 2.7 w/o Nb defines the interior alloy matrix. On its emergence into the $\alpha + \beta$ phase field, the crossing of tie-lines represents precipitation of α-Zr and growth of the $\alpha + \beta$ coarse columnar

layer. Crossing of the $\alpha + \beta + ZrO_2$ phase field defines the interface between the $\alpha + \beta$ and $\alpha + ZrO_2$ layers. Formation of zirconia stringers as an internal oxide signified that the composition path must cut tie-lines in the $\alpha + ZrO_2$ field. This columnar layer was readily distinguishable in the cross sections due to its fine structure in comparison to that of the $\alpha + \beta$ layer. Since oxygen solubility in β-Zr decreases with increasing niobium concentration, niobium was segregated into the intercolumnar β-Zr regions as the primary α-Zr plates grew. Consequently, oxygen supersaturation created in the β-Zr was relieved by nucleation and growth of the finer secondary α-Zr plates. Niobium enrichment also led to formation of the observed dark niobium-enriched zirconia stringers extending up to the alloy/scale interface and into the adjacent scale. It was only feasible, however, to detect this niobium enrichment by the electron probe technique due to the small width of the intercolumnar regions. Subsequent emergence of the diffusion path from the zirconia field into the $ZrO_2 + 6ZrO_2 \cdot Nb_2O_5$ field at an angle incident to tie-lines is consistent with the x-ray and metallographic results for the presence of the intramolecular oxide within the scale.

Conclusions

A Zr-2.7 w/o Nb alloy exposed to oxygen at 1 atm pressure at temperatures in the range 650°-1000°C exhibits parabolic kinetics during early exposure stages followed by a transition to more rapid kinetics. The scale became extensively cracked in the post-transition interval. Small amounts of the intramolecular oxide, $6ZrO_2 \cdot Nb_2O_5$, were contained within the zirconia scales. The temperature coefficient of the parabolic oxidation constants changed to a lower value in the range 885°-937°C which was associated with the formation of a columnar zone of α-Zr plates in the β-structured alloy by inward diffusion of oxygen. The scale which formed over the α-Zr plates exhibited a similar columnar structure and zirconia stringers extended inward along the alloy intercolumnar boundaries. Diffusional growth of the reaction product layers was

consistent with predictions from the Zr-Nb-O phase diagram.

Electron Injection into Anodic Valve Metal Oxides

II. Further Experimental Results for Ta_2O_5, Nb_2O_5 and Al_2O_3

ABSTRACT

Electron injecting contacts can be formed at valve metal oxide/semiconducting metal oxide interfaces with applied fields of the order of some 10^6 V/cm. Electronic current injection as a function of time and applied field (activation) has been measured for Ta/Ta_2O_5, Nb/Nb_2O_5, and Al/Al_2O_3 electrodes in contact with Fe_2O_3 as the semiconducting transition metal oxide. The activation process is explained on the basis of interacting ionic and electronic processes with the ionic charge transport following the empirical field law for anodic oxide growth $i = A \exp (BF)$. The explicit dependence of the electronic process on parameters of the ionic conduction process has been confirmed by determining the ionic conduction parameters from the field and temperature dependence of the activation process. Quantitative agreement with values reported from measurements of the kinetics of anodic oxide growth has been obtained. The electronic current resulting from activation of $Nb/Nb_2O_5/Fe_2O_3$ and $Ta/Ta_2O_5/Fe_2O_3$ electrodes in contact with electrolytes showed a field dependence typical for thermionic emission. Linear log i *vs.* $F^{1/2}$ characteristics could be obtained extending over 4-5 decades with slopes in agreement with thermionic emission following a Poole-Frenkel mechanism. It appears that valve metal/valve metal oxide/semiconducting oxide electrodes with two oxides in intimate but initially blocking contact provide model systems for the generation of coulombic centers from which thermally activated electron emission with Poole-Frenkel characteristic can take place. The barrier height for the thermionic emission process and its change with progressing activation has been determined from measurements of the temperature dependence of the electronic current with applied field and state of activation as parameters. The barrier heights were found to be of the order of 1 eV.

In a recent publication (1) it has been shown that homogeneous electronic currents of the order of 10 mA/cm^2 could be injected into anodic tantalum oxide under high field conditions after inserting a thin layer of semiconducting transition metal oxide between the valve metal oxide and the electrolyte. The transition metal oxide layer restricted ionic migration while providing electronic equilibrium between the electrolyte and the surface of the valve metal oxide

Figure 1 shows a schematic of the experimental system. A thin layer of iron or manganese oxide was deposited on the valve metal oxide. Upon application of a constant voltage between metal substrate and counterelectrode equivalent to a field required for ionic migration, the level of electronic current injection was found to rise with time over several decades. A typical injecting $Ta/Ta_2O_5/Fe_2O_3$ electrode would consist of Ta substrate, anodic Ta_2O_5, and reactively-sputtered Fe_2O_3. In response to the applied field of the order of 5×10^6 V/cm an ionic current started to flow

Key words: electron injection, Poole-Frenkel mechanism, thin film conduction, ionic interface polarization, anodic aluminum oxide, niobium oxide, tantalum oxide.

in the anodic oxide. Migration of oxygen ions away from and metal ions towards the Ta_2O_5/Fe_2O_3 interface resulted in the accumulation of positive charge in the Ta_2O_5 near this interface due to the limited availability of oxygen ions from the electrolyte. This corresponds to a polarization of the interface in an electrochemical sense which causes increased electron injection from the contact. The semiconducting oxide with dominating electronic conductivity does not totally block the supply of oxygen ions from the electrolyte. In conjunction with the electrolyte the semiconducting oxide provides an electrical contact that is not plagued by destructive breakdowns as is common with metal counterelectrodes at the high applied fields.

In the case of $Ta/Ta_2O_5/Fe_2O_3$ electrodes the time-dependent increase of the electronic conductivity with constant applied field, the field dependence of this activation process, and the field dependence of the electronic current have been interpreted as Poole-Frenkel thermionic emission at the anodic oxide/iron oxide interface coupled with the high field ionic conduction mechanism of the anodic oxide.

The electronic current was found to follow a thermionic emission characteristic

$$i_{el} = i_{o,el} \exp (e\beta F^{1/2} - \phi)/kT \quad [1]$$

with e, charge of an electron; β, field-lowering coefficient in agreement with Poole-Frenkel emission; F, applied field, ϕ, energy barrier at zero field; k, Boltzmann constant; T, absolute temperature. The process of activation was interpreted in terms of a reduction of the energy barrier ϕ as a function of the ionic current resulting in a time-dependent increase of the electronic current at constant applied field

$$\phi = \phi_o - \text{const}\ t\ i_{ion} = \phi_o - \text{const}\ t\ A \exp (BF) \quad [2]$$

with ϕ_o, energy barrier at zero field prior to activation; t, time. The empirical relationship

$$i_{ion} = A \exp (BF) \quad [3]$$

with $A = i_o \exp (-W/kT)$, B, field constant of the ionic conductivity, was used to describe the field dependence of the ionic current for the high field case (2). As an approximation, the lowering of the emission barrier in Eq. [2] was assumed to be proportional to the polarization of the interface. Combination of Eq. [1] and [2] led to an expression for the increase of the electronic current with time (activation)

$$\log_{10} i_{el} = \text{const} - \text{const}\ t\ A \exp (BF) \quad [4]$$

with a slope of

$$s = \text{const}\ A \exp (BF) \quad [5]$$

In this paper additional experimental results obtained for the activation process of $Al/Al_2O_3/Fe_2O_3$ and $Nb/Nb_2O_5/Fe_2O_3$ electrodes, the electronic current-field characteristic of $Nb/Nb_2O_5/Fe_2O_3$ electrodes, as well as measurements of the temperature dependence of the activation process and the electronic conductivity of $Ta/Ta_2O_5/Fe_2O_3$ electrodes will be presented. The results support our model for homogeneous electronic current injection into anodic tantalum oxide and its applicability to valve metal oxides other than Ta_2O_5.

Experimental

Valve metal electrodes were prepared by anodic formation of the oxide following standard procedures. Capacitor grade Ta and Nb foil was degreased and chemically polished in a hot mixture of H_2SO_4 (98%): HNO_3 (70%):HF (49%)-5:2:2 followed by rinsing in HF (49%) and distilled water. The metals were vacuum annealed at 2000°C (Nb) and 2100°C (Ta) for 2 hr. The vacuum treatment was found to considerably reduce the number of electronically active impurity sites in the anodic oxides to be formed subsequently and became a prerequisite for the reliable measurement of controlled electronic current injection. Anodization at 1 mA/cm^2 was carried out in 0.1M H_3PO_4 or 0.1M H_2SO_4 at room temperature. The oxide films were aged for 30 min at voltage, back-etched in HF for up to 10 sec, reformed and again aged for 30 min. The procedure resulted in a significant decrease in the number of sites where localized electronic current injection into the anodic oxides in contact with the semiconducting oxides could be observed already at low voltages. The improvement is probably due to the removal of impurities accumulated in the surface of the anodic films during formation (3).

Aluminum foil (99.999%) was degreased, etched in 1M KOH for 30 min, rinsed in distilled water and formed at 0.3 mA/cm^2 to 100V in 0.1M potassium phosphate solutions (pH = 7).

Thin layers of semiconducting iron oxide (FeO_x with $x \leq 1.5$) were deposited by reactive sputtering in a rf sputtering system (Materials Research Corporation—Model SEM-8620) with water cooled target and substrate holders. Target to substrate distance was 9 cm. The target material consisted of 99.9% iron. Reactive sputtering was carried out in argon/oxygen mixtures containing between 1 and 20% oxygen. Typical sputtering conditions were: 100W power input and 6×10^{-3} Torr total gas pressure yielding deposition rates of 7-10 Å/min. Electron bombardment of Nb_2O_5 and Ta_2O_5 substrates during sputtering was found to cause irreversible changes in the anodic oxides effecting the reproducibility of subsequent measurements. This effect could be suppressed by a tantalum shield having the dimensions of the substrate (2.5 cm $\times$ 10 cm, for example) that was placed between target and substrate about 4 cm above the substrate. The deposition rate was lowered by about one third. Deviations in the thickness of the iron oxide film deposited in the shadow of the shield were only about 10% across a 2.5 cm wide substrate which indicated diffusion-controlled deposition of the sputtered material. Al/Al_2O_3 anodes were sputtered without shield.

Following the deposition of the iron oxide layer the specimens were returned to the electrolytic cell. To insure the insolubility of the iron oxide, measurements were carried out in 0.5M standard acetate buffer solutions. High resolution anodic printing (4) was used to determine the homogeneity of the electronic conductivity on a microscale during the activation process. Only $Nb/Nb_2O_5/Fe_2O_3$ and $Ta/Ta_2O_5/Fe_2O_3$ specimens which did not exhibit any appreciable electronic conductivity at point defects during a voltage scan from zero to the activation voltage were used in the experiments. The electrodes were masked with Mylar tape (Mystic No. 7003) and a series of experiments carried out with one area (0.07-0.3 cm^2) exposed at a time. In the case of $Al/Al_2O_3/Fe_2O_3$ electrodes the contribution of defect conduction to the homogeneous electronic conductivity established by activation could not be estimated from voltage scan anodic printing experiments. The anodes broke down in contact with the KI/starch printing gel electrolyte with about one half of the formation voltage applied. However, prints indicating homogeneous electronic current distribution similar to Ta and Nb-electrodes could be obtained from specimens following their activation in phosphate electrolytes.

The field dependence of the activation process of $Ta/Ta_2O_5/Fe_2O_3$ electrodes was measured at temperatures between 0° and 65°C.

The temperature dependence of the electronic current with constant applied field was measured in the temperature range from 5° to 75°C for various stages of the activation process. Activation was carried out at the highest temperature to be used in the temperature measurements. This was found to be necessary in order to avoid erroneous results due to continued activation during the temperature cycle. The temperature dependence was measured after terminating

the activation process at a desired electronic current level and decreasing the applied field sufficiently to stabilize the current. It was observed that the electronic current decreased somewhat with time and reached a constant value within minutes after the applied field had been lowered. This indicated a partial reversion of the activation process. The temperature was varied continuously at rates between 4°C/min and 12°C/min starting and ending at 75°C.

Measurements for different stages of the activation process were carried out either by activating different areas on the specimen to different levels or by continuing activation of the same area following one temperature cycle at the preceding level. Comparing Ta and Nb, the Ta system proved to be the more stable and reproducible of the two with respect to the temperature measurements.

Results and Discussion

Anodic activation.—Field and temperature dependence of the activation process.—The time dependent increase of the electronic current is shown in Fig. 2 for three different electrodes at 20°C: Ta/(1960Å)Ta_2O_5/Fe_2O_3, Nb/(1960Å)Nb_2O_5/Fe_2O_3, and Al/(1630Å)Al_2O_3/Fe_2O_3. A 200Å film of Fe_2O_3 was deposited by reactive sputtering using identical deposition conditions for all specimens (80% Ar + 20% O_2, 6×10^{-3} Torr, 100W). This was important in order to permit comparison of the results for different anodic oxides, since it had been found that the rate of activation and the detailed structure of the activation curve depended on the properties of the sputtered oxide which are sensitive to the deposition conditions.

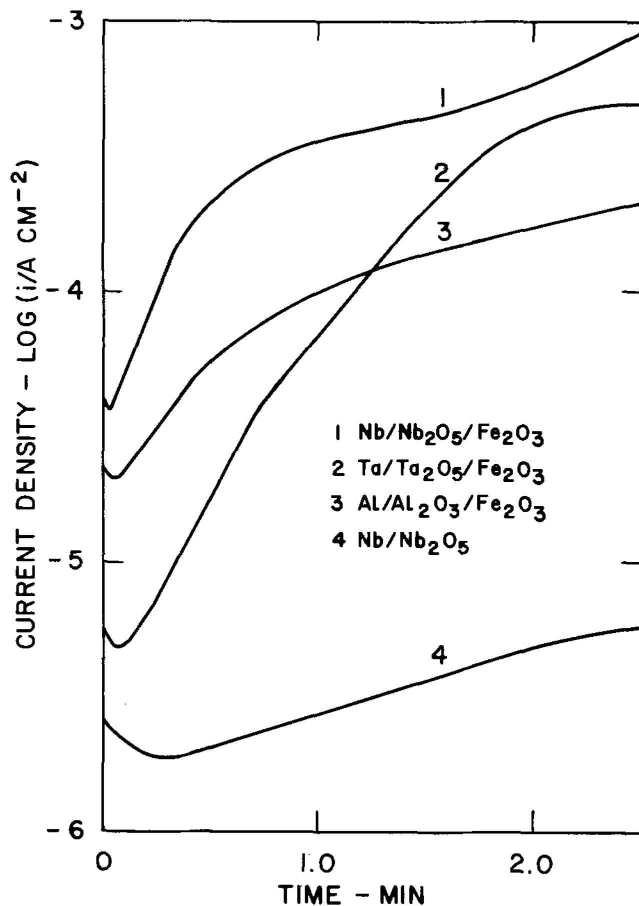

Fig. 2. Current-time characteristic of the activation process for: 1, Nb/1960Å Nb_2O_5/200Å Fe_2O_3 electrode, activation field $F' = 3.5$ mV/cm; 2, Ta/1960Å Ta_2O_5/200Å Fe_2O_3 electrode, activation field $F' = 5.2$ mV/cm ; 3, Al/1630Å Al_2O_3/200Å Fe_2O_3 electrode, activation field $F' = 6.2$ mV/cm; 4, reanodization curve of Nb/1960Å Nb_2O_5 anode following activation (curve 1) and subsequent dissolution of the Fe_2O_3 layer. $F' = 3.5$ mV/cm.

All measurements of the activation process refer to linear sections of the *i-t* curves, mostly the initial linear increase. The effect of the electronic properties of the sputtered transition metal oxide in conjunction with the redox electrolyte on the activation process will be discussed in a subsequent paper.

The activation curves have, approximately, the same initial slope indicating the same rate of ionic interface polarization, *i.e.*, an approximately equal ionic current flowing in all three anodic oxides. To obtain similar slopes the applied field had to be increased from 3.5 mV/cm for Nb_2O_5 to 5.2 mV/cm for Ta_2O_5, and 6.2 mV/cm for Al_2O_3, which corresponds to the decrease of the ionic conductivities of the anodic oxides given in the literature (5). Microscopic inspection of anodic Ta and Nb oxide and reanodization experiments following the dissolution of the Fe_2O_3 layer subsequent to activation had shown the activation process to be a surface effect that caused no apparent changes in the properties of the bulk of the oxide.

Curve 4 (Fig. 2) is the reanodization curve for the Nb/Nb_2O_5 anode measured after the dissolution of the iron oxide layer subsequent to activation (curve 1) with the same field applied. It also represents the normal reanodization curve at constant voltage following the anodic formation of oxide. The ionic current is likely to be smaller than the total reanodization current because of some residual electronic contribution. From the level of the current of the reanodization curve, it was concluded that the contribution of ionic current to the measured activation current (curves 1-3) was negligible even for early stages of the activation process. The rate of increase of the electronic current with time was found to be very sensitive to the applied field. Applied voltage was converted to field neglecting any voltage drop across Fe_2O_3 and polarization at the Fe_2O_3/electrolyte interface. This appears justified for the low current densities involved and at least for the linear regime of the activation curve, which is interpreted as current injection limited by coulombic centers at the valve metal oxide/Fe_2O_3 interface. Galvani potential differences between the various phases were estimated as described previously (1) and were taken into account when calculating the true field in Fig. 5, 6, and 8.

Figure 3 shows the field dependence of the activation process for a Nb/(1960Å)Nb_2O_5/(200Å)Fe_2O_3 electrode in the applied voltage range from 69 to 73.1V at 20°C. Figure 4 depicts a similar set of curves for a Ta/(1740Å)Ta_2O_5/(200Å)Fe_2O_3 electrode in the applied voltage range from 80 to 86V at the higher temperature of 41.5°C.

According to Eq. [5] $\log s \sim BF$ (s, slope of activation curve $\log i_{el}$ *vs.* t) which means that the field constant B of the ionic conductivity of the anodic oxide can be obtained from the slope of a plot of $\log s$ *vs.* the applied field. The initial linear slope s of the activation curves (Fig. 3 and 4) was used in these plots, but it was found that other linear parts of the activation curves could have been used as well.

The result obtained from the set of activation curves shown in Fig. 3 for a $Nb/Nb_2O_5/Fe_2O_3$ electrode is presented in Fig. 5. The plot of $\log s$ *vs.* the applied field is a straight line. From its slope the field constant B was calculated. The results for Nb_2O_5, Al_2O_3, and Ta_2O_5 (1) obtained at 20°C have been listed in Table I. Comparison with values reported in the literature (5) from direct measurements of the field dependence of the ionic conductivity of the respective anodic oxides indicates good agreement with our measurements.

The temperature dependence of the field constant B was determined for Ta_2O_5 by measuring the field dependence of the activation process at four temperatures between 0° and 65°C for Ta/(1740Å)Ta_2O_5/(200Å)Fe_2O_3 electrodes. Plots of $\log s$ *vs.* the applied field as observed for one electrode at four temperatures are shown in Fig. 6. The results of four independent mea-

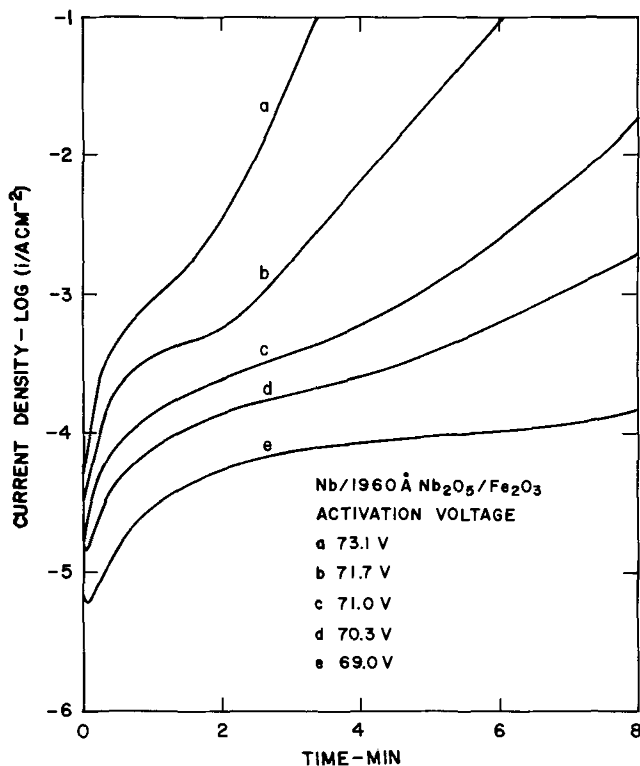

Fig. 3. Rate of activation as a function of the applied field $F' = V/d$ for Nb/1960Å Nb_2O_5/200Å Fe_2O_3 electrodes at 20°C; field range: 3.52-3.73 mV/cm.

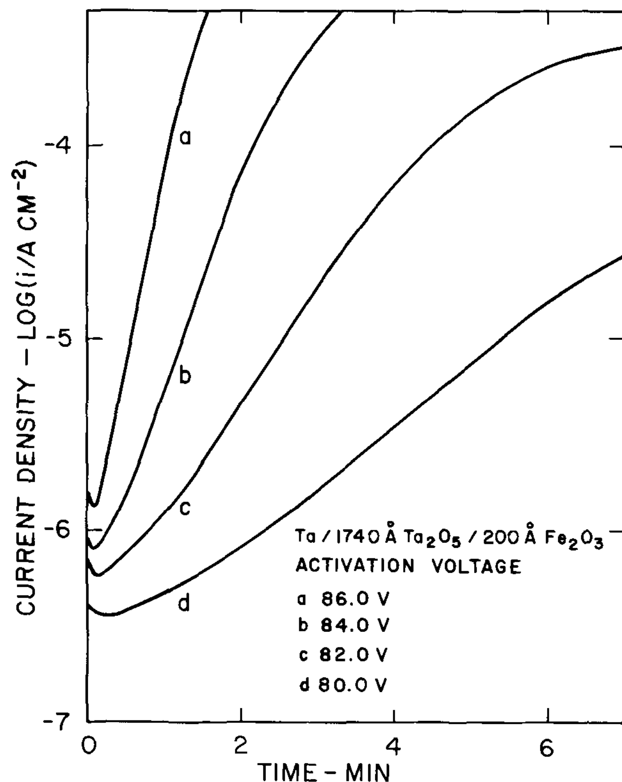

Fig. 4. Rate of activation as a function of the applied field $F' = V/d$ for Ta/1740Å Ta_2O_5/200Å Fe_2O_3 electrodes at 41.5°C; field range: 4.60-4.94 mV/cm.

surements at each temperature have been listed in Table II. They show B to be independent of temperature in the observed range. This is in agreement with results by Vermilyea (2) and Young (6) from studies of the temperature dependence of the Tafel slope for the anodic formation of tantalum oxide.

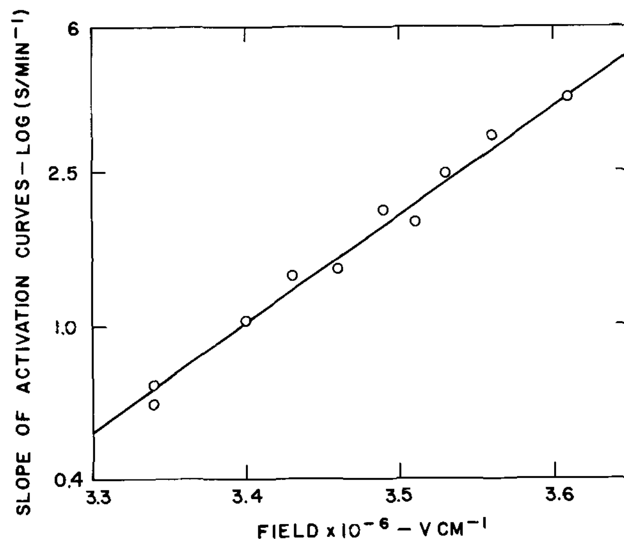

Fig. 5. Slope of activation curves (from Fig. 3) vs. the true field $F = \Delta V/d$ in Nb_2O_5. ΔV = applied voltage, V corrected for Galvani potential differences (1).

At constant applied field the rate of activation increased rapidly with temperature. Since B was found to be temperature independent, this result meant that the pre-exponential factor (Eq. [3]) was responsible for the temperature dependence. From our measurements, the activation energy W (Eq. [6]) for ionic conduction at zero field could be determined.

$$A = i_{o,\text{ion}} \exp\left(-\frac{W}{kT}\right) \quad [6]$$

Log s vs. $1/T$ was plotted in Fig. 7 for constant field F = 4.81 mV/cm in Ta_2O_5 using the data from Fig. 6. The rate of activation s was directly measured at 21° and 41°C, while values for 3.5° and 64°C were extrapolated from the respective log s vs. field plots, since at the given field the activation was either too slow or too fast to allow a correct determination of the rate of activation s to be made. A value of W = 0.75 eV was calculated from the slope of the log s vs. $1/T$ plot in Fig. 7 in close agreement with a value reported by Vermilyea (2) from measurements of the temperature dependence of the ionic conductivity (W = 0.71 eV). The results of the temperature measurements are subject to the same interpretations put forward in the literature and discussed by Young (5) to explain a lack of temperature dependence of the Tafel slope for the anodic formation of tantalum oxide.

Table I. Field constant B of the ionic conductivity from measurements of the field dependence of the activation process (B_{exp}) in comparison with values from measurements of the kinetics of anodic oxide growth (B_{ion})

	$B_{exp} \times 10^6$ (cm V⁻¹)	$B_{ion} \times 10^6$ (cm V⁻¹)
Ta_2O_5	4.95 ± 0.2	5.2
Nb_2O_5	6.6 ± 0.7	6.4
Al_2O_3	4.4 ± 0.5	4.9 ± 0.5

Table II. Field constant B of the ionic conductivity of Ta_2O_5 from measurements of the field dependence of the activation process in the temperature range 3°-60°C

°C	$B \times 10^6$ (cm V⁻¹)
3	4.9 ± 0.2
20	5.0 ± 0.2
40	5.2 ± 0.2
60	5.2 ± 0.2

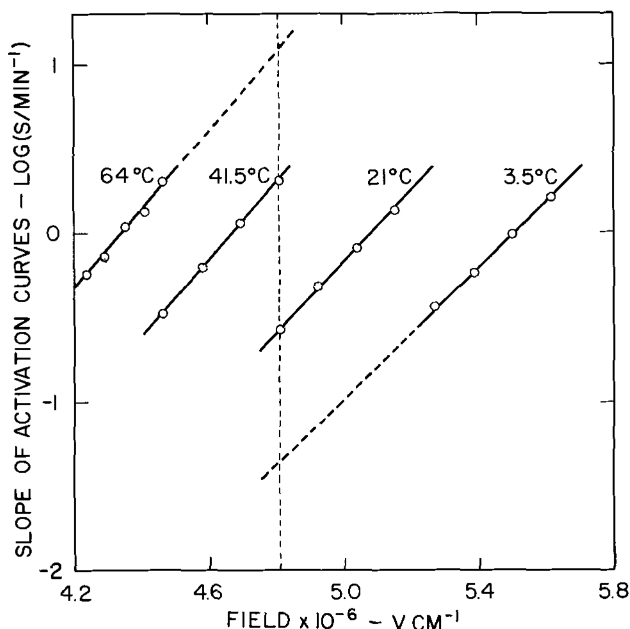

Fig. 6. Slope of activation curves (from Fig. 4 for 41.5°C) vs. the true field $F = \Delta V/d$ in Ta_2O_5. ΔV = applied voltage V corrected for Galvani potential differences (1).

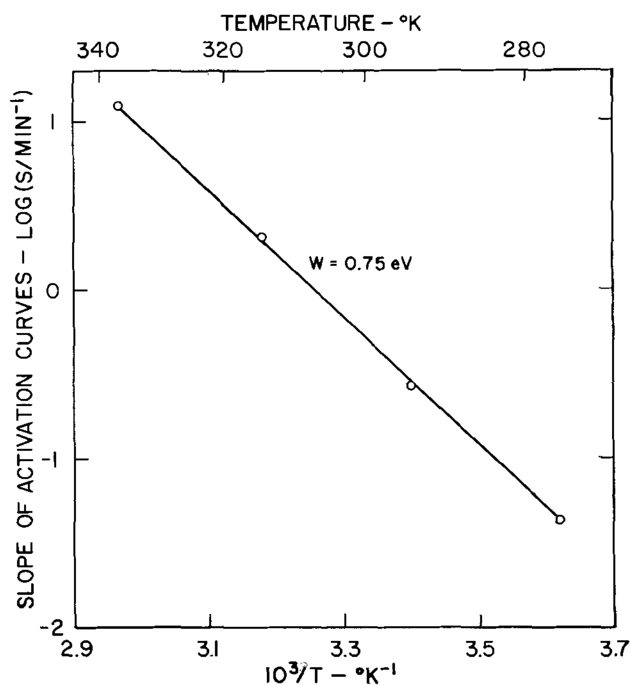

Fig. 7. Slope of activation curves at constant applied field (F = 4.81 mV/cm) vs. $1/T$ for Ta/1740Å Ta_2O_5/200Å Fe_2O_3 electrode. Temperature range 3.5°-64°C.

A direct coupling of ionic and electronic processes has been postulated to explain the observed behavior of the electronic current during activation experiments. From our measurements the characteristic parameters of the ionic processes were obtained in quantitative agreement with values from measurements of the kinetics of anodic film growth. In particular, the field and temperature dependence of the ionic processes were deduced correctly from the characteristics of the electronic process for three different oxides. This is considered conclusive evidence of the basic correctness of the assumptions underlying our model of the activation process.

Current-field characteristic of the electronic conduction process resulting from activation.—Current-field

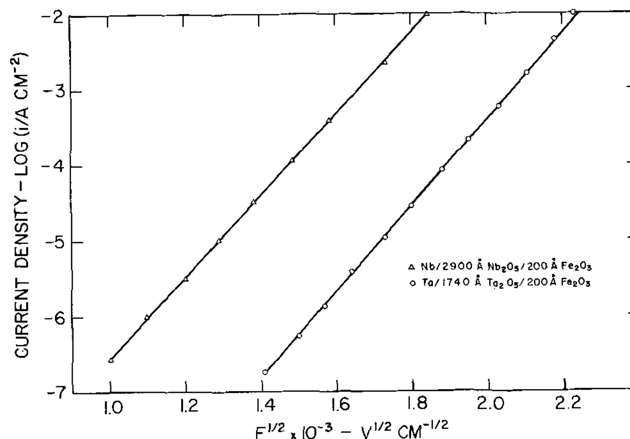

Fig. 8. Current-field characteristics of Ta/1740Å Ta_2O_5/200Å Fe_2O_3 electrode (○) and of Nb/2900Å Nb_2O_5/200Å Fe_2O_3 electrode (△) following activation to 10 mA/cm², 20°C. Field corrected for contribution of Galvani potential differences to applied voltage (1).

characteristics were measured after activation to different electronic current levels. The measurements were made at decreasing and increasing fields. Typical results are shown in Fig. 8 for two anodic oxide films: (2900Å)Nb_2O_5 and (1740Å)Ta_2O_5, both sputtered with 200Å films of Fe_2O_3. The dependence of the logarithm of the homogeneous electronic current density on the square root of the applied field was found to be a linear one over as many as 5 decades of current for any given state of activation.

The linear log i *vs.* $F^{1/2}$ dependence (Fig. 8) is characteristic for thermionic emission over a field-lowered barrier (Eq. [1]). Previous results showed agreement with the concept of electron emission from coulombic centers generated in the process of activation. This mechanism can be described by the simple Poole-Frenkel theory (7-10) which will be used here. The field lowering coefficient β (Eq. [1]) is given by

$$\beta = \left(\frac{e}{\pi\epsilon_0\epsilon}\right)^{1/2}$$

with e, electronic charge; ϵ_0, permittivity of vacuum; and ϵ, relative dielectric constant.

The slope of the log i *vs.* $F^{1/2}$ plots can be used to calculate the field lowering coefficient β. The dielectric constant is the only uncertain value in the formula for β. Some authors (7, 8) on the subject favor the use of the high frequency dielectric constant ($\epsilon_\infty = n^2$; n, refractive index). Recently, Hill (10) proposed to use a value of the form $\bar{\epsilon} = (\epsilon_1^{-1} - \epsilon_2^{-1})^{-1}$ with ϵ_1 and ϵ_2 the high and low frequency dielectric constants of the bulk material, respectively. Table III gives the values for the dielectric constants ϵ_{exp} as calculated from the slopes of log i *vs.* $F^{1/2}$ curves assuming Poole-Frenkel emission. For both Ta_2O_5 and Nb_2O_5 the high frequency dielectric constants computed from the respective refractive indices are in excellent agreement with experimental values obtained from the slopes of log i — $F^{1/2}$ curves when the Poole-Frenkel formula is used. $\bar{\epsilon} = (\epsilon_1^{-1} - \epsilon_2^{-1})^{-1}$ values were calculated using for the low frequency dielectric constants the values ϵ_2, (Ta_2O_5) = 27.6 and ϵ_2, (Nb_2O_5) = 41.4 (5). The

Table III. Dielectric constants ϵ_{exp} from log i vs. $F^{1/2}$ plots in comparison with ϵ_∞ and $\bar{\epsilon}$. ϵ_∞ was calculated from the indices of refraction (5). $\bar{\epsilon}$ was calculated according to Hill (10)

	ϵ_{exp}	$\epsilon_\infty = n^2$	$\bar{\epsilon}$
Ta_2O_5[1]	4.7	5.1	6.2
Nb_2O_5	6.0	6.0	7.0

agreement of ϵ_{exp} with $\bar{\epsilon}$ is less satisfactory and there appears no need to introduce an intermediate dielectric constant into the theory describing the experimental system. Within the limits of the simple Poole-Frenkel theory describing the field assisted emission of electrons from coulombic centers (traps), the results presented in this paper provide quantitative verification of that theory over a wide range of current densities (5 decades) and for two different materials.

Temperature dependence of the electronic conduction process.—Thermionic current emission according to Eq. [1] is characterized by an expression for the activation energy

$$\Delta E = e\beta F^{1/2} - \phi \quad [7]$$

which consists of the zero field barrier modified by the applied field. The mechanism of electronic activation, *i.e.*, the time-dependent increase of the electronic current with the applied field as parameter rests on the assumption that ionic interface polarization leads to a time dependent decrease of the activation energy. Consecutive states of activation should, therefore, be characterized by thermionic emission barriers ϕ reduced in the same sequence. Measurements of the temperature dependence of the electronic current at constant applied field should yield the barrier height as a function of the pre-established state of activation

$$\log_{10} i_{el} = \text{const} + \frac{e\beta F^{1/2} - \phi}{kT} \quad [8]$$

Such measurements are shown in Fig. 9 for a Ta/(1740Å)Ta_2O_5/(200Å)Fe_2O_3 electrode and three consecutive states of activation (electronic current levels). In Fig. 10 similar measurements for four consecutive states of activation of a Nb/(1590Å)Nb_2O_5/(200Å)Fe_2O_3 electrode are shown. In all cases, linear

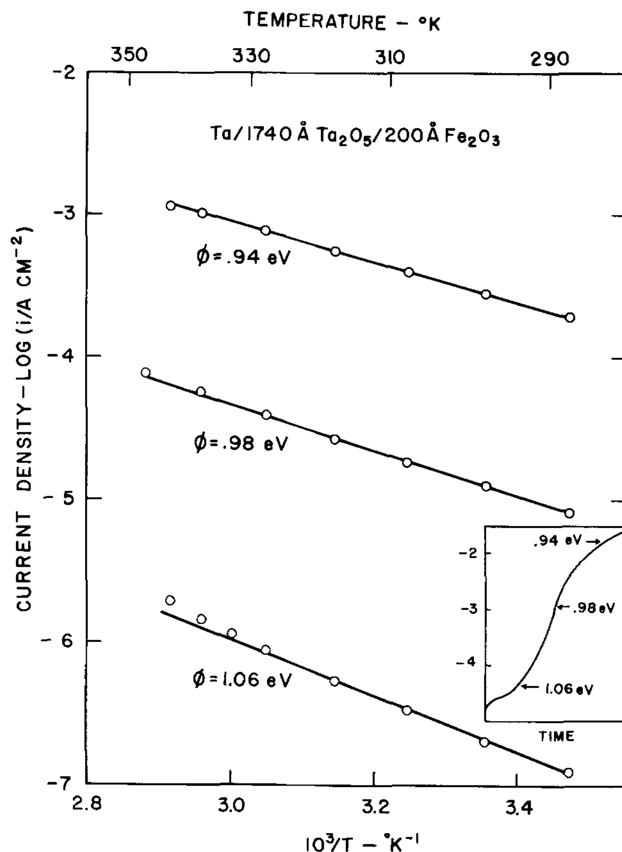

Fig. 9. Temperature dependence of electronic activation current for three consecutive states of activation at constant applied voltage (65V) in the temperature range 5°-75°C. Ta/1740Å Ta_2O_5/200Å Fe_2O_3 electrode was activated at 80V, 75°C. The activation curve is shown in insert.

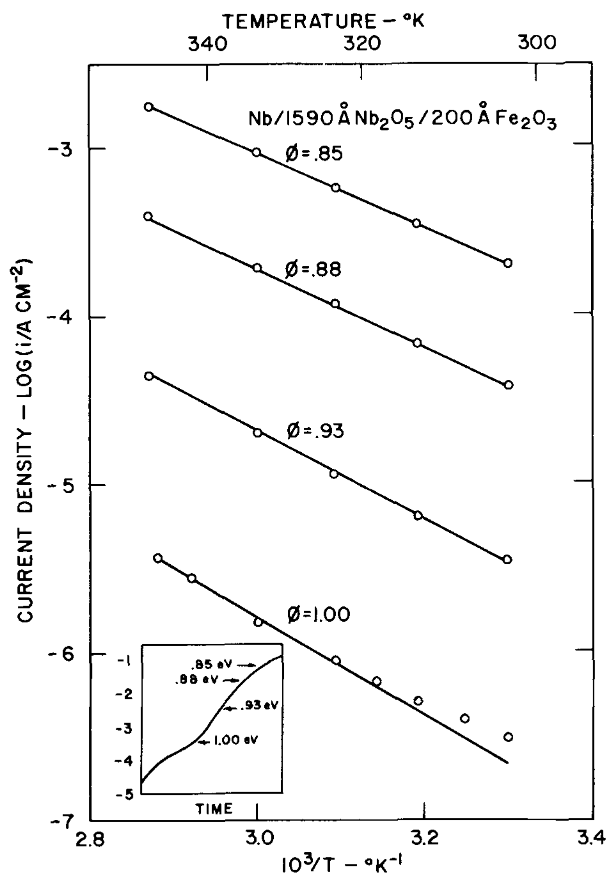

Fig. 10. Temperature dependence of electronic activation current for four consecutive states of activation at constant applied voltage (30V) of Nb/1590Å Nb_2O_5/200Å Fe_2O_3 electrode following activation at 50V, 75°C. Temperature range 20°-75°C. The activation curve is shown in insert.

log i_{el} *vs.* $1/T$ plots were obtained in a temperature range from 5° through 75°C.

The corresponding activation curves for Ta_2O_5 and Nb_2O_5 have been inserted in Fig. 9 and Fig. 10, respectively. Their particular structure is related to the specific electronic properties of the iron oxide deposited in these cases. The interface polarization process was found to proceed independently of the particular type of iron oxide which means that the lowering of the emission barrier could be considered a function of ionic charge transfer alone. Thermionic Poole-Frenkel characteristics were obtained at any point of the activation curves independent of the particular structure of the activation curve.

From the slopes of log i — $1/T$ lines in Fig. 9 ($Ta/Ta_2O_5/Fe_2O_3$) the activation energies for three consecutive states of activation were found to be in eV 1.06, 0.98, and 0.94 ± 0.02 from the lowest to the highest states of activation corresponding to 4.7×10^{-5}, 1.3×10^{-3}, and 1.8×10^{-2} A/cm², respectively, for activation at 80V, 74°C. For an increase of the electronic current level by three decades a decrease in the barrier height ϕ by 0.12 eV was measured. By extrapolating the barrier height linearly to zero activation, an initial barrier of 1.1 eV was found for the $Ta/Ta_2O_5/Fe_2O_3$ electrode (Fig. 11).

From Fig. 10 the activation energies for four consecutive states of activation of a $Nb/Nb_2O_5/Fe_2O_3$ electrode were found to be in eV 1.00, 0.93, 0.88, and 0.85 from the lowest to the highest state of activation corresponding to 3.8×10^{-4}, 3.8×10^{-3}, 2.2×10^{-2}, and 6.8×10^{-2} A/cm², respectively, for activation at 50V, 75°C. Linear extrapolation of the barrier height to zero activation is shown in Fig. 11 along with results obtained for another Nb/(1590Å)Nb_2O_5/FeO_x electrode activated under the same conditions. While the rate of

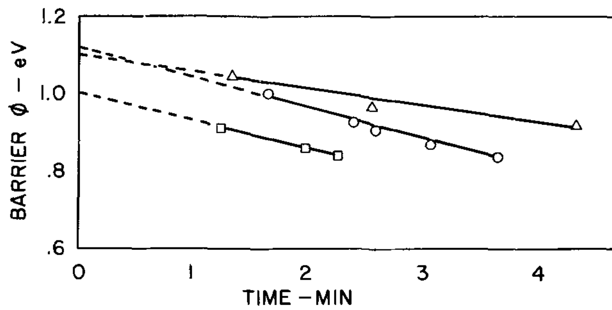

Fig. 11. Linear extrapolation of the barrier height ϕ to zero activation ($\triangle$), Ta/1740Å Ta_2O_5/200Å Fe_2O_3 electrode; ($\bigcirc$), Nb/1590Å Nb_2O_5/200Å Fe_2O_3 electrode; ($\square$), Nb/1590Å Nb_2O_5/200Å FeO_x electrode ($x < 1.5$).

barrier lowering was the same for both electrodes, the initial barrier heights (1.1 eV and 1.0 eV, respectively) were found to depend on the properties of the sputtered iron oxide, mainly its degree of oxidation. The lower initial barrier would correspond to the iron oxide with the lower oxidation state.

A further check of the thermionic log i_{el} — $F^{1/2}$ characteristic attributed to a Poole-Frenkel mechanism of electronic current injection follows from Eq. [7]. The activation energy ΔE would be expected to show a square root dependence on the applied field (11). In this case, the activation energy was obtained from log i_{el} — $1/T$ plots with the applied field as parameter. Measurements were carried out after a fixed state of activation had been established at 1.8×10^{-2} A/cm^2, 80V, 75°C. The results given in Fig. 12 show the expected linear dependence of ΔE on $F^{1/2}$.

Conclusions

Anodic oxides on valve metals such as Ta, Nb, and Al in contact with electrolytes behave as insulators because the rate of electron injection remains low even at field strengths sufficient for ionic migration. The normal reaction of valve metal/valve metal oxide electrodes in aqueous solutions and at fields of the order of some 10^6 V/cm is additional oxide formation with negligible electronic current. Several monolayers of semiconducting transition metal oxides like FeO_x, MnO_x, and others, deposited on top of the valve metal oxide sufficiently suppress the transfer of ions to the valve metal oxide/semiconducting oxide interface to cause the formation of an electron injecting contact. The results presented in this paper have demonstrated

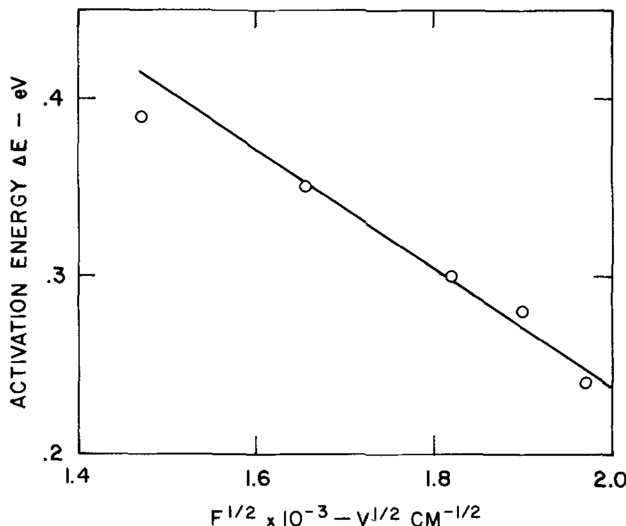

Fig. 12. Activation energy $\Delta E = e\,\beta\,F^{1/2} - \phi$ vs. $F^{1/2}$ for Ta/1740Å Ta_2O_5/200Å Fe_2O_3 electrode following activation at 80V, 75°C to 1.8×10^{-2} A/cm^2.

that this mechanism is common to at least three valve metal/valve metal oxide electrodes.

Electronic current injection as a function of time and applied field (activation) was measured for the Ta/Ta_2O_5, Nb/Nb_2O_5, and Al/Al_2O_3 electrodes with Fe_2O_3 as the semiconducting transition metal oxide.

Mechanism of activation.—The assumption of interacting ionic and electronic processes formed the basis of a model for the activation process of Ta/Ta_2O_5/Fe_2O_3 electrodes published earlier. By assuming that the underlying ionic charge transport followed the empirical current field law for anodic oxide growth ($i = A \exp BF$), a relationship for the time dependence of the activation process could be derived with explicit dependence of the electronic process on the parameters of the ionic conduction process. The validity of this model was confirmed by determining the parameters of the ionic process from measurements of the field and temperature dependence of the electronic activation for three valve metal oxides. Quantitative agreement was found for B values obtained from the field dependence of the rate of activation and values from measurements of the kinetics of film growth for Ta/Ta_2O_5, Nb/Nb_2O_5, and Al/Al_2O_3 electrodes. In addition, the temperature dependence of the activation process at constant applied field was found to follow from the temperature dependence of the ionic process with B independent of temperature, the temperature dependence arising from the pre-exponential factor A. From the temperature dependence of A the activation energy of ionic migration could be determined. It was found to agree well with data from kinetic measurements of the ionic process.

The data presented in this paper fully confirm earlier measurements and provide quantitative evidence of the coupling of ionic migration and electron injection in electrodes of the general type valve metal/valve metal oxide/semiconducting oxide.

Ionic polarization in the contact between solids, of which oxide/oxide contacts of the type investigated here are a characteristic example, can lead to conditions favorable to electron injection into the "insulating" oxide thus changing a blocking into an injecting contact. This general mechanism can lead to homogeneous electron injection, as was found to be the case in the systems studied, or to localized electron injection caused by impurities. Thermal effects or carrier multiplication may eventually lead to destructive breakdown of the dielectric in either case. The deposition of a homogeneous semiconducting oxide layer provided for an experimentally controllable system. The use of an electrolytic contact in our experiments is believed to contribute to the electrical stability of the valve metal/valve metal oxide/semiconducting oxide electrodes. The semiconducting oxide/electrolyte contact gives evidence of limiting the injection current at the higher activation levels in a way that prevents catastrophic breakdown and destruction of the specimen. The same is not true for semiconducting oxide/metal contacts. While indications of an initially similar activation mechanism were present in the latter case as well, catastrophic breakdowns destroyed the specimens before any detailed measurements could be made.

Mechanism of electron injection.—The electronic current resulting from activation of Nb/Nb_2O_5 and Ta/Ta_2O_5 electrodes with thin layers of Fe_2O_3 showed a field dependence typical for thermionic emission. Log i_{el} *vs.* $F^{1/2}$ characteristics could be measured extending over 4-5 decades of current density. The slopes of these current-field characteristics agreed closely with those predicted for thermionic conduction following a Poole-Frenkel mechanism. For both the Ta and Nb electrodes the dielectric constants determined from the slopes of log i *vs.* $F^{1/2}$ curves agreed well with the high frequency constants of the respective anodic oxides. The measurements presented in this paper are,

thus, in excellent agreement with the basic Poole-Frenkel theory.

Experimental systems of this kind with two oxides in intimate but initially blocking contact provide nearly perfect model systems for the generation of coulombic centers in the boundary region between the two oxides which become the source of thermally activated electron emission with Poole-Frenkel characteristic.

It should be noted that the usual distinction between interface and bulk mechanisms (*e.g.*, Schottky *vs.* Poole-Frenkel characteristic) cannot be applied to the experimental system valve metal oxide/semiconducting oxide. Even though the sources of electron emission into the valve metal oxide are being generated in the interface region between the two oxides, the physical reality would appear to match as close as possible the model situation of the Poole-Frenkel theory (10). In our case, this model situation can be described as the field assisted emission of electrons from coulombic centers, *e.g.*, oxygen vacancies as a result of local nonstoichiometry, into the conduction band of the valve metal oxide. It is the activation process which leads to the generation of such coulombic centers in a manner controlled by the ionic charge separation across the valve metal oxide/semiconducting oxide interface. Agreement of the measured value of the dielectric constant with the high frequency dielectric constant of the valve metal oxide demonstrated that the valve metal oxide provided the dielectric environment of the coulombic centers in conformity with the model situation of emission from centers located in the bulk of the oxide.

Measurements of the temperature dependence of the electronic current with the applied field and state of activation as parameters yielded activation energies of the Poole-Frenkel thermionic emission process. Both the original barrier height and its change with progressing activation could be determined. Typically, the barrier height prior to activation was close to 1 eV decreasing by several tenths of an electron volt with increasing polarization of the valve metal oxide/semiconducting oxide interface.

Devitrification of Steam-Grown Silicon Dioxide Films

R. L. Meek* and R. H. Braun

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Devitrification of steam-grown SiO_2 films has been studied as a function of time and temperature, with special attention to impurity effects, by monitoring the refractive index of the film and by examining the time, temperature, and impurity dependent degradation of the dielectric strength. Monitoring of the refractive index showed that partial devitrification may occur in a time scale of weeks at room temperature if the oxide was significantly [$\sim 2(10)^{15}$ cm^{-2}] sodium contaminated and had, in addition, a high-temperature ($\sim$1000°C) anneal while contaminated. As-grown slices, for which the sodium contamination level is $<10^{11}$ cm^{-2}, showed no evidence of devitrification. Electron diffraction observations confirmed the interpretation of the refractive index changes. Dielectric breakdown behavior indicated that the function of the high-temperature anneal was to modify the manner in which the sodium was incorporated into the silica film although nucleation phenomena may also be important. The activation energy for dielectric strength degradation is $\sim$0.1 eV which is much less than the activation energy for devitrification of pure bulk fused silica (2.2 eV).

Silicon dioxide films thermally grown on silicon form a cornerstone of the planar device technology and steam-grown oxides have found wide usage partly because the growth rate is much larger than is the case for films grown in dry oxygen, and because lower oxidation temperatures are possible. Here we report observations on the devitrification of initially amorphous, steam-grown silicon dioxide films.

It has, in fact, been known for a long time that silica films grown contaminated, by sodium or a number of other things, are apt to contain crystallites (1-5) and that such films possess inferior electrical properties. Sugano *et al.* (6) have carried out an electron diffraction study in which they found that the incidence of crystallinity in grown oxide films was increased by the incorporation of water (steam-grown) or boron and suppressed by the incorporation of P or Sb. They did not, however, consider changes with time explicitly.

Pavlov and Shitova (7) and Nagasima (8a) have also performed oxide structure analyses, using electron diffraction and infrared absorption, of films grown on silicon in clean, dry or wet ambients. The atomic

Key words: devitrification, silicon dioxide, sodium contamination, ellipsometry, dielectric breakdown.

arrangement as determined from the electron diffraction spacings and the infrared absorption spectrum is very similar to that of bulk fused silica. The structure was found to be independent of film thickness and whether the oxide was grown wet or dry. No crystallized regions were observed, although changes with time were again not dealt with. The apparent discrepancy between these results and those of Sugano *et al.* (6) for the case of wet oxides may be related to undetected differences in the level of other impurities, especially Na.

There is also a large literature [see Ref. (8b), for example] on devitrification of bulk glass which shows the devitrification rate to be dramatically increased by the addition of impurities (8b-13), especially water (12, 13) and sodium (11). Although fused silica is thermodynamically unstable relative to the crystalline phases, rearrangement is immeasurably slow at low temperatures; usually measurable devitrification does not take place below about 1000°C (10). [The activation energy for crystallization of pure SiO_2 glass is 51.2 kcal/mole (14) (2.2 eV) so that the rate at room temperature may be expected to be infinitesimally small compared to the rate at 1000°C, all other things being equal.]

The bulk glass devitrification product is cristobalite (10), as might be expected, even though quartz is the room temperature stable form, since the local arrangement of atoms in the SiO_4 tetrahedra in glass corresponds very closely to the arrangement in cristobalite (7, 8b, 15, 16). Impurities can, however, lead to other devitrification products (8b, 10) notably tridymite, but apparently only when present in concentrations greater than 0.5% (10, 11, 17). Sugano *et al.* (6) found a high incidence of tridymite, as is to be expected since their films contained large amounts of impurities. Balyagin (18) has reported that when fused silica was heated for 5 min in hydrogen at 1000°C, isolated microcrystallization took place. Steam-grown oxides are expected to contain significant amounts of hydrogen as OH or H_2O.

It might be supposed that grown silica films on silicon behave considerably differently with respect to reconstruction than does bulk glass. However, most previous studies have not revealed rapid crystallization of grown films even when contaminated. Revesz (19) found that films aged for 15 hr in dry N_2 at 1200°C remained noncrystalline. Stickler and Faust (4) observed some changes in intensity distribution in the electron diffraction patterns from samples held at 450°C in vacuum for 90 hr but they had not divitrified, since no sharp rings were seen, while Knopp and Stickler (20) found crystallized portions in films held at 1235°C in vacuum for several hours. Brodsky and Cubicciotti (21) found that the vitreous oxide formed on their samples exhibited x-ray diffraction lines corresponding to α-cristobalite and quartz after it had been heated overnight at 1200°C. Their oxide was doubtless very impure as the silicon used was only 98%. These results are consistent with the data on bulk glass. On the other hand, a recent electron diffraction study in this laboratory (22) showed that initially amorphous steam-grown oxides sometimes devitrified at room temperature within a few weeks after fabrication.

Experimental

Refractive index.—In order to monitor the occurrence of any devitrification or other structural or density changes in the films, the refractive index in the visible region has been measured as a function of time. This method has the advantage of simplicity and it is obvious that the measurement process cannot induce devitrification.

The refractive index was measured using a Gaertner Model L119 ellipsometer. Measurements were made in the first and third zones and the usual precision techniques were used (23). The refractive index and thickness were determined from the psi and delta derived from measured angles by comparison to computer calculated values.

Both structural changes and density changes may of course contribute to changes in the refractive index. In order to identify a refractive index change with devitrification, it is necessary to have other substantiating evidence; in this work, electron diffraction and optical microscopy. However, we expect that devitrification of fused silica, for which $n = 1.46$ at the mercury green line (5461Å) and room temperature, to either crystobalite, for which $n = 1.485$, or tridymite, for which $n = 1.47$, will result in an increased refractive index. In fact, if it is assumed that devitrification is the only change, we can compute the expected refractive index change from the relation between polarizability, index of refraction and density (24). In this way we estimate that an increase equal to the reproducibility of the measurements corresponds to about 1% devitrification. Of course, other changes, notably water content and density changes of the glass itself can also produce significant refractive index changes.

The oxides for refractive index measurements were grown at 1050°C in atmospheric pressure steam to thicknesses of either 1250 or 3700Å in order to utilize the maximum sensitivity for measurement of n. The substrates were <111>, 0.5 ohm-cm, p-type. Initial measurements of the refractive index and thickness were made at several points on the wafer. When variations over a wafer were greater than the reproducibility at a given point, the slice was discarded. The reproducibility of the settings at a given point corresponded to a precision in n of $\pm$ 0.0003 and in the thickness of $\pm$15Å.[1] The slices were then kept in various atmospheres at various temperatures and the refractive index and thickness were monitored for times beyond a month (700 hr).

Dielectric breakdown strength.—It is known (3, 5) that the presence of crystallites in silica films causes a degradation in dielectric properties. In particular, breakdown strengths fall around two principal values; about $2(10)^6$ V/cm (secondary breakdown) and about $8(10)^6$ V/cm (primary breakdown). [There are also sometimes a few tertiary breakdowns at $\lesssim (10)^6$ V/cm which correlate with gross visible defects and pinholes.] Only the primary breakdown voltage is found for clean grown oxides and the secondary breakdown voltage is thought to correlate with areas of the film which contain very small crystallites not detectable by optical microscopy. It might be expected then that the behavior of the distribution of breakdown voltages could be used to determine the extent of devitrification of the film. It can be shown (25) by some simple arguments that the number of defects per unit area, σ, is related to the fraction of secondary (and tertiary) breakdowns, f, by

$$\sigma = \frac{1}{A}\left(\frac{f}{1-f}\right) \qquad [1]$$

where A is the electrode area. Clearly σ is some function of the extent of devitrification of the film. It has previously been demonstrated (3, 5) that for a given oxide (constant σ) the appropriate relationship between f and A is obtained.[2]

Steam oxide films for these measurements, 1100 $\pm$ 100Å thick, were grown on <100> boron-doped p-type

[1] By reproducibility at a given point, we mean the difference in values obtained when the slice is removed from the instrument, replaced, and remeasured on nominally the same area of the wafer. If left in place, the reproducibility in simply resetting angles corresponds to a precision in n of $3(10)^{-4}$ and in thickness of 1Å. Since it was not possible to age and heat-treat the wafers *in situ*, the former error values are the significant ones; and we unfortunately lose the, potentially very interesting, data on changes in thickness (or density).

[2] Chou and Eldridge (3) and Fritzche (5) in fact use $\sigma = (1/A) \ln (1/1 - f)$ which, as Price (25) points out, is incorrect since the defects are indistinguishable and must be counted as such, *i.e.*, Bose-Einstein rather than Boltzmann statistics must be used. For small f, the calculated σ is, of course, essentially the same, for large f it is much different.

silicon having a resistivity of 10 ohm-cm. The electrode was a mercury probe (26) and the electrode area was 0.5 mm^2. A ramp voltage was applied in a sense so that the semiconductor surface was in accumulation, at a rate of 1 V/sec. [Chou and Eldridge (3) found the breakdown voltage distribution to be independent of ramp rate at least in the range 10^{-2} to 1 mV/cm-sec.] Breakdown is defined as the point of occurrence of the first current spike ($\sim 10^{-6}$ A-cm^{-2}). The breakdown voltage is determined at about 100 points on each slice and the data plotted *vs.* per cent less than the value. [Bar graphs may also be prepared as was done by Chou and Eldridge (3) and are in some respects more informative, especially when there are large fractions of secondary and tertiary breakdowns.]

Results

Refractive index changes.—A first set of experiments was carried out in a dry, nonoxidizing ambient (dry N_2). The results are given in Fig. 1 where the change in refractive index is plotted *vs.* the time since oxidation. n_o is the initial refractive index, and a positive Δn would likely correspond to devitrification. At room temperature (25°C), no significant refractive index changes were observed in a month's time. At 875°C the refractive index began to decrease at about 100 hr, dropping to a lower, nearly constant value at about 300 hr. This is not devitrification (Δn has the wrong sign) but is probably stabilization of the glass film. The stabilization time for bulk glass at this temperature is of the order of hundreds of hours (27) and the observed change is consistent with the fact that for bulk silica glass the refractive index increases with increasing fictive temperature below 1600°C (28). The thickness of the oxide in all experiments remained constant (±15Å) and is not discussed further.

A second set of experiments, the results of which appear as Fig. 2, was performed in room air where the water vapor partial pressure was about 10 Torr. Again at room temperature (25°C), the refractive index at first decreased to a minimum at about 15 hr, then increased to a maximum at 100 hr, followed by another minimum and maximum at 250 and 400 hr, respectively. The detailed origin of this behavior is not clear. It probably involves structural rearrangement of Si-O-H groups, absorption of water, and the aforementioned stabilization. [Incorporation of water probably reduces the refractive index as the index for opal, $SiO_2 \times H_2O$, is less than that of fused silica. Hetherington and Jack (29) have also shown that the refractive index of commercial fused silicas decreases with increasing "water" content. Typically, the refractive index of an oxide film grown in dry oxygen is greater than that of a film grown in wet oxygen or steam (30). Although the refractive index of high-pressure steam oxides is still greater; their structure is doubtless much different, as evidenced by their higher density (30). It should also be noted that the refractive indices of the complex sodium/alumina/boro/silicate glasses, as well as that for crystalline quartz, are greater than for cristobalite.] We must also expect a few monolayers of adsorbed water on the SiO_2 surface at room temperature and partial pressures greater than a few Torr (31). However, all films were exposed to the normal humid atmosphere during measurement so that this was a constant factor, since relative humidity and temperature were constant. Figure 3 presents some additional data taken for samples kept in nitrogen ambients with controlled water vapor partial pressures. The general behavior was similar to the samples of Fig. 2. There is, in summary, no evidence of devitrification.

The oxide has also been stripped in several hundred angstrom thick layers from slices kept at room temperature for many weeks and the refractive index measured as removal of the oxide progressed. The refractive index was found to be uniform within the precision of the measurements which, of course, varies with thickness. Also, these and other slices having had various treatments were partially etched and/or angle lapped, and then examined microscopically under polarized light in order to detect the incidence of any metastable internal crystallites as described by Wagstaff (16). None were found. A slice which had been kept at room temperature in room ambient for 2000 hr was examined by electron diffraction (32). The pattern obtained was characteristic of vitreous silica and no evidence of crystallization was seen, that is no diffraction rings were seen.

Finally, sodium contamination was considered as a cause of devitrification. Slices were boiled in a 0.25*N* NaCl solution for an hour and rinsed thoroughly in D. I. water upon removal. The sodium was diffused in by annealing the slice in dry N_2 at 600°C for about 20 hr. The refractive index change of a slice treated in this manner corresponds qualitatively to that of a slice which had not been sodium contaminated. The effect of the NaCl solution boil is to cause the refractive index to be very near 1.458 irrespective of its

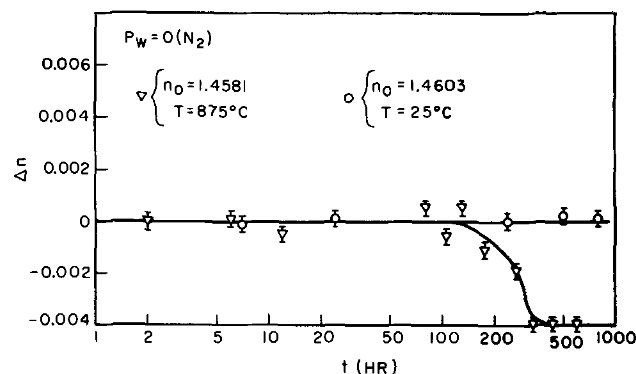

Fig. 1. Change in refractive index *vs.* time for samples aged in dry nitrogen, P_w is the water vapor partial pressure in the aging ambient.

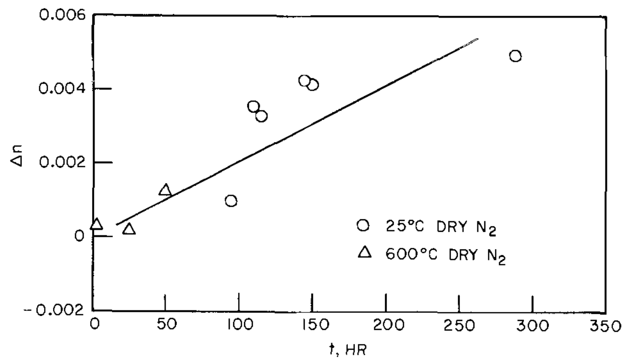

Fig. 4. Change in refractive index vs. time for sodium-contaminated samples aged in dry nitrogen.

initial value. After the 600°C treatment it returns to very near (±0.001) its initial value. A sodium contaminated slice was also examined by electron diffraction (32) after being aged at room temperature in room ambient for about 1000 hr. Some slight banding but no sharp lines were observed in the diffraction pattern. No crystallized regions could be detected by optical microscopy.

However, if the slice is annealed for 5 min at 1000°C in dry nitrogen after the 600°C drive-in, the behavior is markedly different. (The 5-min treatment is chosen as the longest time at 1000°C which causes no measurable refractive index change.) Refractive index *vs.* time data for two samples treated in this way are plotted in Fig. 4. At room temperature there was now a steady increase in refractive index, to $\Delta n = +0.005$ at 290 hr. A slice aged about 500 hr at room temperature was again examined by electron diffraction (32). Many very sharp rings were observed. Photomicrographs of samples aged for a longer time (about 2000 hr) show optically active, presumably crystallized areas, Fig. 5. If the drive-in step is omitted, but the slice is annealed for 5 min at 1000°C, larger features, Fig. 5c and d, are observed which are confined to the first 500Å or so of oxide. The smaller crystallites of Fig. 5a and b are apparent throughout the film.

Degradation of dielectric-breakdown strength.—In Fig. 6 are plotted measured breakdown voltage distributions. First, it may be noted that the distribution of primary breakdowns is decidedly not normal but is rather fairly represented by a straight line (to about 10%) on log-probability coordinates. That is, the distribution is skewed toward lower breakdown voltages. This is only to be expected as there should be a reasonably well-defined maximum breakdown voltage (the true dielectric strength) with some potential of breakdown at any smaller voltage corresponding to various structural imperfections.

Second, it can be seen that for an as-grown oxide there are essentially no secondary breakdowns and that sodium contamination (after growth) plus drive-in, does not materially affect the distribution. There is also no change with aging at least for up to 50 hr at temperature up to 500°C or for many days at room temperature. This is in agreement with the absence of crystallization indicated by the refractive index measurements.

However, after a 5-min anneal at 1000°C the mean breakdown strength is reduced by about 35% although there are still effectively no secondary breakdowns (curve 4, Fig. 6). This would seem to imply that the high-temperature treatment changes the manner in which the sodium is incorporated into the oxide so that, in fact, a somewhat different dielectric structure having a different dielectric strength is produced. Five minutes at 1000°C does not change the distribution for an uncontaminated oxide (Fig. 6, curve 5). Curves 1, 2, 3, and 5 agree, within slice to slice variations. It may be noted that a structure change producing such a large change in dielectric strength might also be expected to produce a refractive index change which is, of course, not observed. However, it may simply be

that compensating changes in refractive index due to two or more mechanisms have taken place.

In Fig. 7, breakdown voltage distributions of sodium-contaminated and 1000°C annealed oxides are plotted for various elapsed times at room temperature. The fraction of secondary breakdowns increased with time and at longer times tertiary breakdowns began to appear. Figures 8 and 9 present similar data for temperatures of 300° and 600°C.

Discussion

Refractive index changes.—It is seen that changes in refractive index attributable to devitrification occurred only if slices were sodium contaminated and then subjected briefly (5 min) to a high temperature (1000°C). As grown, the sodium contamination level is known to be $<10^{11}$ cm^{-2} from neutron activation analysis (33). The total sodium contamination introduced has been measured (34) using the flame photometry method (35) and found to be $\sim 2(10)^{15}$ cm^{-2}. The 600° or 1000°C treatments do not change this contamination level. After contamination by boiling in NaCl

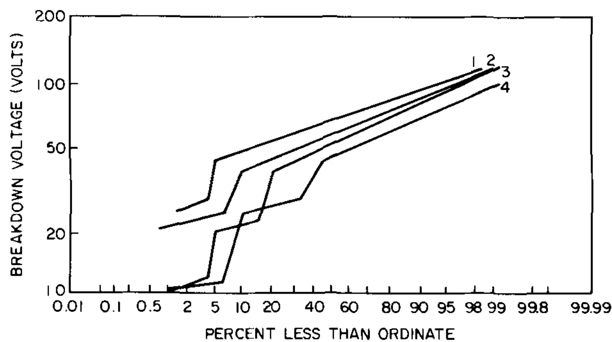

Fig. 7. Distribution of breakdown voltages for Na contaminated oxides aged at 25°C. Curve 1, 24 hr; curve 2, 48 hr; curve 3, 110 hr; and curve 4, 450 hr.

solution, the sodium has been driven into the oxide by diffusing at 600°C for about 24 hr in order to simulate a naturally occurring, grown-in sodium distribution. (Buck *et al.* (36) found in their tracer experiments that evaporating radioactive sodium on the oxide surface and then diffusing at 600°C for 22 hr produced Na profiles similar to those found in grown contaminated films.)

The need for a high-temperature step is consistent with the observations of previous investigators. Mathews *et al.* (37) found when oxides were contaminated with sodium and heated above 600°C that a visible change took place which was interpreted as devitrification and alkali glass formation. Below 600°C no visible reaction occurred. Chou and Eldridge (3) found that degraded dielectric breakdown behavior correlated with the existence of crystallized regions in the oxide and that it was more severe with a higher sodium content. However, they also observed, when $\sim 5(10)^{12}$ extra (mobile) sodiums per square centimeter were added to the oxide, by boiling in NaCl solution after growth, that very little additional devitrification and degradation of dielectric properties were observed, at least for heating up to 50 min at 500°C. Nagasima and Enari (38) observed visible crystallites of cristobalite when about a monolayer of Na atoms was deposited on a silicon surface before oxidation in the neighborhood of 1100°C.

The conclusion is, then, that sodium contamination can cause partial devitrification of grown oxide films to occur at room temperature in a few hundred hours. However, it is apparently necessary that the slices have had a high temperature treatment after being sodium contaminated. The sodium contamination may reduce the activation energy for devitrification. Some data for a sodium-contaminated and activated slice kept at 600°C are given in Fig. 4. It is not advantageous to monitor refractive index at elevated temperature beyond about 100 hr since the total refractive index change includes changes due to processes other than devitrification (compare Fig. 1 and 4). However, if it is assumed that Δn is due to devitrification, for the temperatures and times of Fig. 4, which seems reasonable since uncontaminated oxides showed no change in n (Fig. 1), we can estimate an upper limit for the activation energy. If $n \propto t$ is assumed, $E < 0.04$ eV and if $E \propto t^2$ is assumed, $E < 0.09$ eV. While sodium contamination may enhance the devitrification, the necessity of a brief high-temperature treatment suggests that either nuclei must first be present for any significant devitrification to take place at room temperature or that the high-temperature treatment changes the manner in which the sodium is incorporated into the oxide structure. This is likely related to the distinction between bound and unbound sodium in SiO_2 (39-41). It may also be expected that the enhanced devitrification will be more serious for wet oxides since it is well

known that water enhances sodium incorporation (42, 43).

Dielectric breakdown strength.—In Fig. 10 is plotted the equivalent surface defect density computed from the fraction of primary breakdowns according to Eq. [1]. The data may be represented for the range of times and temperatures covered by

$$\sigma = (a_0 e^{-E/kT})t \quad [2]$$

where t is the time, with $a_0 \simeq 10$ hr^{-1} and $E \simeq 0.1$ eV. Since we cannot propose a model relating the observed linear (in time) increase of σ to the microscopic details of the devitrification process, it is not clear that this activation energy is that for devitrification. A more direct quantitative determination of the devitrification is needed. A possibility might be a light scattering experiment where measurement of the scattering coefficient should give a direct measure of the extent of devitrification.

It would also be desirable to investigate the effect of the level of sodium contamination. For $<10^{11}$ Na atoms cm^{-2} devitrification does not occur while for $\sim10^{15}$ Na atoms cm^{-2} room-temperature devitrification does occur. Such measurements could also be valuable in deciding the importance of nucleation since, if that is the important step, the kinetics should go as the sodium concentration to some power, n, where n is the number of sodium atoms incorporated into a nucleus. It should be emphasized that the present experiments only show sufficient, although not perhaps necessary, conditions for room temperature devitrification to take place.

Conclusions

Monitoring of the refractive index of steam-grown silicon dioxide films on silicon indicates that, in agreement with prior electron diffraction studies (22), partial devitrification may occur in a time scale of weeks at room temperature; but the present study indicates this occurs only if the oxide is significantly sodium contaminated and, in addition, has had a high-temperature treatment while contaminated. Dielectric breakdown behavior indicates that the function of the high-temperature anneal is to modify the manner in which the sodium is incorporated into the silica film, although nucleation phenomena may also be important. The activation energy for dielectric strength degradation is $\sim$0.1 eV.

However, since devitrification of bulk silica glass even when grossly sodium contaminated, does not proceed at measurable rates at room temperature (8b) it must also be concluded that there may exist subtle structural and/or stoichiometric differences between bulk silica glass and amorphous-grown silica films. There is no real reason to believe that a grown amorphous film must have precisely the same structure as fused silica having a fictive temperature equal to the film-growth temperature since the grown film has never gone through a molten phase and therefore may not be able to relax to the same structure as the true glass. Stabilization studies on grown films would seem to be in order. Stoichiometrically, there are, of course, small gradients in oxygen and perhaps silicon concentration remaining from the growth process. Also, it may be noted that the oxide is under compressive stress as grown (44). Since cristobalite is more dense (2.3 g/cm^3 opposed to 2.2 g/cm^3) than fused silica this may be expected to enhance the devitrification of grown films compared to bulk glasses.

High Resistance Anodic Film Formation on Bismuth with or without Appearance of Induction Period

S. Ikonopisov and Ts. Nikolov

Department of Physical Chemistry, Higher Institute of Chemical Technology, Sofia 56 (Darvenitsa), Bulgaria

ABSTRACT

The galvanostatic oxidation of bismuth in aqueous oxalic acid solutions has been studied at various anodic current densities, J, electrolyte concentrations, N, and temperatures, T. An induction period was found to appear always when J is lower than a critical value, specific for given N and T. Relations considering the duration of the induction period as a function of J, N, and T, and the dependence of the linear potential rise on time in absence of induction period or after its expiration have been established. These relations are explained on the basis of a model considering the precipitation of crystals of a slightly soluble bismuth compound which isolates a part of electrode surface. When the current density on the rest (uncovered) surface reaches the critical value, an anodic film begins to grow on it, causing corresponding increase in the anodic potential.

The formation of anodic oxide films on bismuth has been studied until recently in neutral and alkaline media only (1-6). Masing and Young (3) have found that the steady-state kinetics of anodizing Bi in dilute NaOH solution are analogous to those of the typical valve metals, and the potential-transient behavior is somewhat different. De Smet and Hopper (6) reported that the usual relation between the current density and the change in overpotential with respect to charge passed (which may be considered to be proportional to the field) is not valid for the galvanostatic anodization of bismuth in Na_2CO_3 solution, while the open-circuit transient is similar to that of tantalum.

The anodic oxidation of Bi in H_2SO_4 solutions has been reported quite recently by Ammar and Khalil (7). They have shown that in dilute H_2SO_4 solutions bismuth could be anodized to voltages over 100V. It has been observed in our laboratory that high-resistance anodic films could be formed in a number of aqueous and nonaqueous solutions of acids. The kinetics of growth and the properties of the films appeared to be strongly affected by the composition and concentration of the electrolyte. The present investigation was undertaken to obtain quantitative data on the appearance of an induction period during the anodization of bismuth in aqueous oxalic acid solutions.

Experimental

The anodization was carried out under constant current conditions (using an electronic galvanostat), thermostatic regulation, and stirring of the electrolyte. A conventional one-compartment electrolytic cell without deaeration was employed. The specimens with a surface area of about 12 cm² were cut out in the form of plates from a block of high-purity bismuth (5 ppm). Electrical contact was made by soldering a wire to the specimen and insulating the wire with a glass tube. The tube penetrated into the metal and its edge was additionally insulated with epoxy resin. The electrodes were mechanically and electrochemically polished, brightened, and washed prior to anodization as described by Masing and Young (3). At the end of selected intervals of anodizing time the anodization was interrupted. The anodes were washed in conductivity water and dried and photomicrographs were taken by automatic microscope (Neophot 2, C. Z., Jena).

De Smet and Hopper (6) have found that visible light causes large changes in the overpotential of the bismuth electrode while undergoing galvanostatic anodization with low current densities. Our experiments have shown that the illumination with visible light did not noticeably influence the appearance and duration of the induction period or the rate of subsequent potential rise. Actually, the photoeffect was found by De Smet and Hopper to decrease with increasing applied current density and to disappear for current densities above 10^{-4} A/cm². Consequently, the lack of photoeffect in our experiments is probably due to the higher values of the current densities used. Therefore, a shadowed instead of a darkened room has been used. Each of the present data is an average value of many experiments.

Results

Formation of anodic films without induction period.—Under certain conditions (low temperatures and low concentration of the electrolyte and high current densities) the kinetics of the anodization of Bi in aqueous solutions of $(COOH)_2$ are similar to those in alkaline solutions (Fig. 1, curve A). Under galvano-

Key words: anodic, anodization, bismuth, oxide, film, induction period.

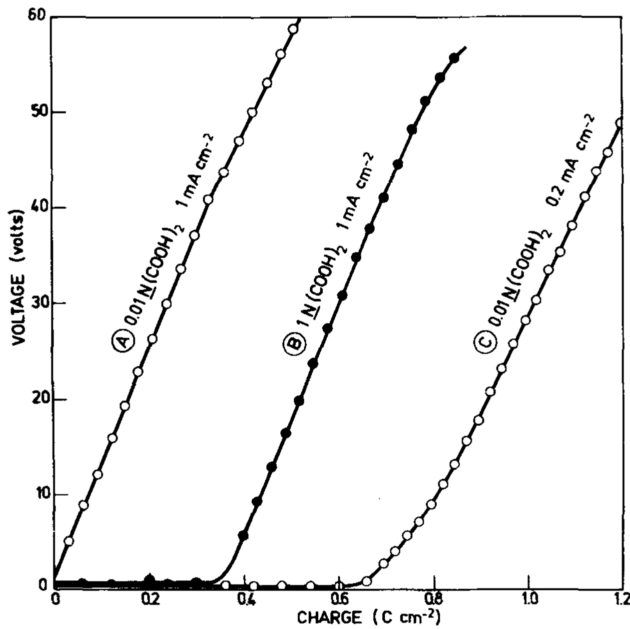

Fig. 1. Potential vs. charge at various concentrations and current densities. Temperature 293.2°K.

static conditions the potential drop, U_f, across the film increases linearly with time, thus with Q, the total charge density passed. The range of this linear potential rise depends on the anodizing current density, J, and temperature, T, and vary from 40 to 70 (V) for $J < 10$ mA cm^{-2} and $274 < T < 333$ (°K).

A linear relationship was found between the rate of potential rise ($\partial U_f/\partial Q$) and the logarithm of current density J for the limited ranges of J in which the potential rise starts without any induction period. The results for three temperatures are shown in Fig. 2. Such a relationship

$$J = A_1 \exp\left[B_1 \left(\frac{\partial U_f}{\partial Q} \right)_{Q_{ind}=0} \right] \quad [1]$$

is typical for anodic formation of nonporous films. Nevertheless, the constants log A_1 and B_1 are not linear functions of $1/T$

$$\log A_1 = 26.28 - \frac{1.23 \times 10^4}{T} + \frac{8.9 \times 10^6}{T^2}, \quad \log (A/cm^2)$$

$$B_1 = -0.302 + \frac{1.37 \times 10^2}{T} - \frac{9.95 \times 10^3}{T^2}, \quad C\,cm^{-2}\,V^{-1}$$

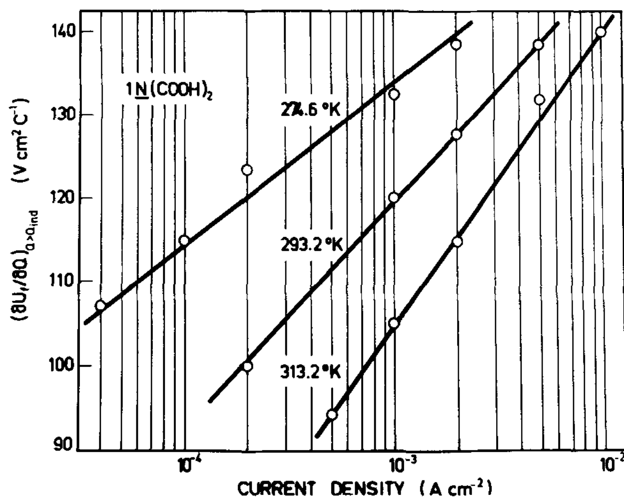

Fig. 2. Rate of change of potential as a function of the current density at different temperatures.

in contrast to the relationships usually found in the case of not very wide ranges of J and T.

Appearance and duration of the induction period.—Under suitable change of the conditions, *e.g.*, a reduction of the current density and (or) an increase of the electrolyte concentration, the type of $U_f(Q)$-relationship changes radically. After switching on the anodic polarization no increase in U_f is observed for a time defined as "induction period" (Fig. 1, curves B and C). The duration of this induction period can be conveniently represented under various conditions by the density of the "uneffective charge," Q_{ind}, that has passed during the induction period. After this period, U_f begins to increase rapidly and linearly up to high values (Fig. 1).

The appearance and duration of the induction period were found to depend mainly on three parameters: electrolyte concentration N, current density J, and temperature T. As can be seen from Fig. 3, the induction period does not appear when the solution of $(COOH)_2$ is sufficiently diluted. It appears at a certain concentration and increases rapidly with the increase of the concentration and simultaneously a wide scattering of the experimental results for Q_{ind} is observed. Above a certain electrolyte concentration the uneffective charge reaches a constant and reproducible value. All present results are obtained in that range of concentration that provides good reproducibility.

The duration of the induction period increases with the increase of temperature. Figure 4 illustrates the temperature dependence, under suitable conditions, of the induction period.

The increase of the current density shortens the induction period. It turns out that a linear dependence exists between $Q_{ind}^{2/3}$ and log J (Fig. 5), described by the expression

$$J = A_2 \exp - (B_2 Q_{ind}^{2/3}) \quad [2]$$

where the constants A_2 and B_2 are temperature functions

$$\log A_2 = -17.8 + \frac{1.1 \times 10^4}{T} - \frac{1.87 \times 10^6}{T^2}, \quad \log (A\,cm^{-2})$$

$$B_2 = 100 - \frac{6.68 \times 10^4}{T} + \frac{1.13 \times 10^7}{T^2}, \quad (C\,cm^{-2})^{-2/3}$$

After the induction period the anode potential begins to increase in a linear fashion with time, and thus

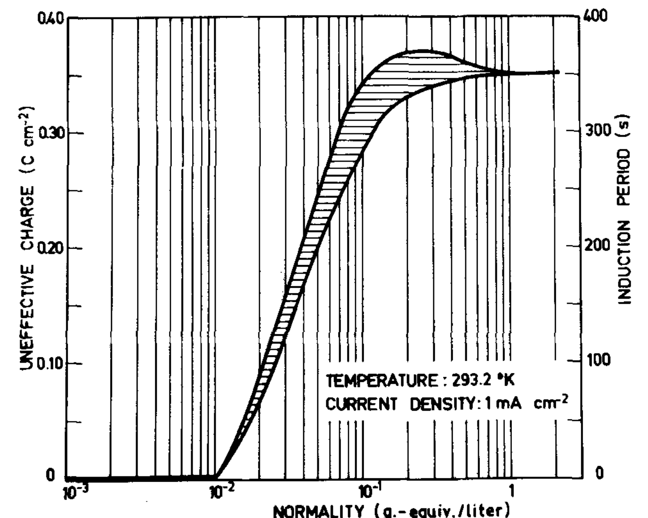

Fig. 3. Dependence of uneffective charge on the electrolyte concentration. The shaded area limits the dispersion of experimental results.

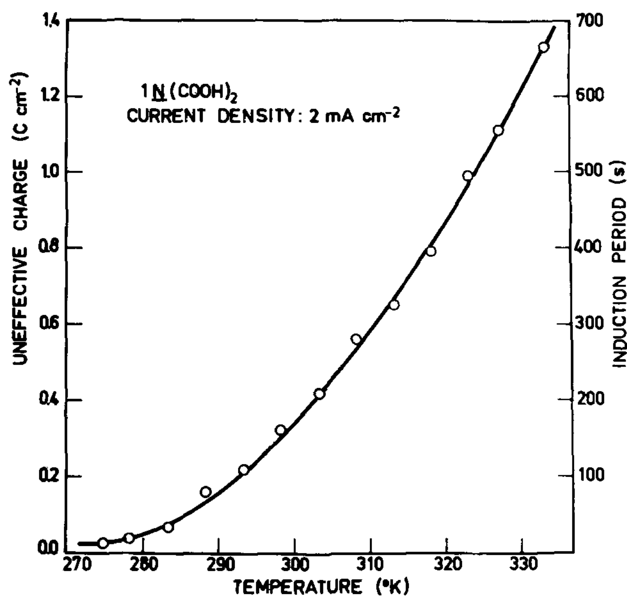

Fig. 4. Temperature dependence of induction period

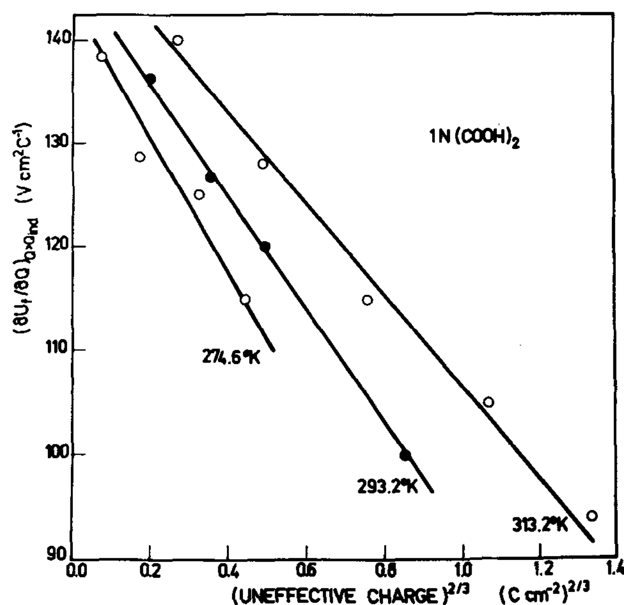

Fig. 6. Dependence between the rate of potential rise after the induction period and $Q^{2/3}$ at different temperatures.

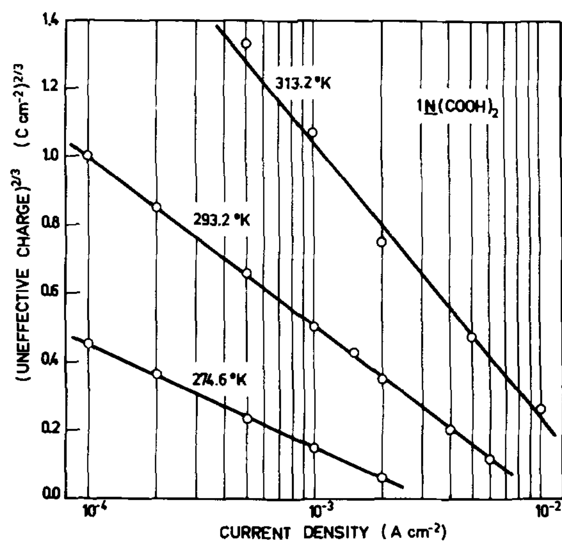

Fig. 5. Plot of $Q_{ind}^{2/3}$ vs. log J at different temperatures

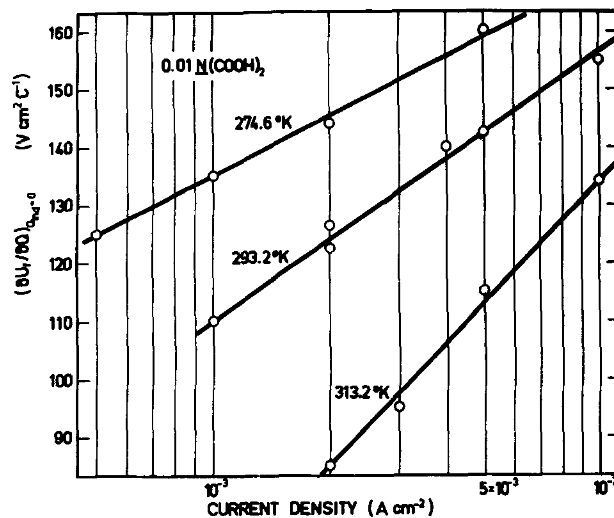

Fig. 7. Slope of $U_f(Q)$-curves after the induction period vs. current density at different temperatures.

with the electric charge Q, until film breakdown commenced (plots B and C of Fig. 1). Experimental results indicate that a linear relation exists between the slope of $U_f(Q)$-curves after the induction period and the quantity $Q_{ind}^{2/3}$. This relation is represented in Fig. 6 and is expressible in the form

$$\left(\frac{\partial U_f}{\partial Q}\right)_{Q>Q_{ind}} = A_3 - B_3 Q_{ind}^{2/3} \quad [3]$$

where

$$A_3 = 330 - \frac{9.02 \times 10^4}{T} + \frac{1.07 \times 10^7}{T^2}, \quad \text{V cm}^2\,\text{C}^{-1}$$

$$B_3 = -468 + \frac{2.58 \times 10^5}{T} - \frac{3.07 \times 10^7}{T^2}, \quad (\text{C cm}^{-2})^{-2/3}$$

Equations [2] and [3] suggest an exponential relation between J and the rate of linear potential increase (50-70V) after the induction period, $(\partial U_f/\partial Q)_{Q>Q_{ind}}$, analogous to the corresponding relationship when the potential rise commences without induction period (Eq. [1]). The experimental data are given in Fig. 7 and can be described by the expression

$$J = A_4 \exp\,[B_4 (\partial U_f/\partial Q)_{Q>Q_{ind}}] \quad [4]$$

however, the values of the constants A_4 and B_4 differ considerably from those in Eq. [1], viz.

$$\log A_4 = -101.3 + \frac{6.37 \times 10^4}{T} - \frac{1.06 \times 10^7}{T^2}, \quad \log\,(\text{A cm}^{-2})$$

$$B_4 = 1.36 - \frac{8.64 \times 10^2}{T} + \frac{1.43 \times 10^5}{T^2}, \quad \text{CV}^{-1}\,\text{cm}^{-2}$$

Direct observations of the electrode surface.—During the anodization without an induction period the overall anode surface remains flat and bright interference colors appear with the growth of the film. Small crystals appear and grow only at isolated surface sites. On the contrary, when the process begins with a prolonged induction period, the crystals occupy a considerable part of the surface. When the process was carried out at high temperatures (*e.g.*, 60°C) the crystals were well shaped with a clearly expressed hexagonal symmetry. At low temperatures the crystals grow as acicular druses.

In the beginning of the induction period, under conditions of high temperature and low current densities

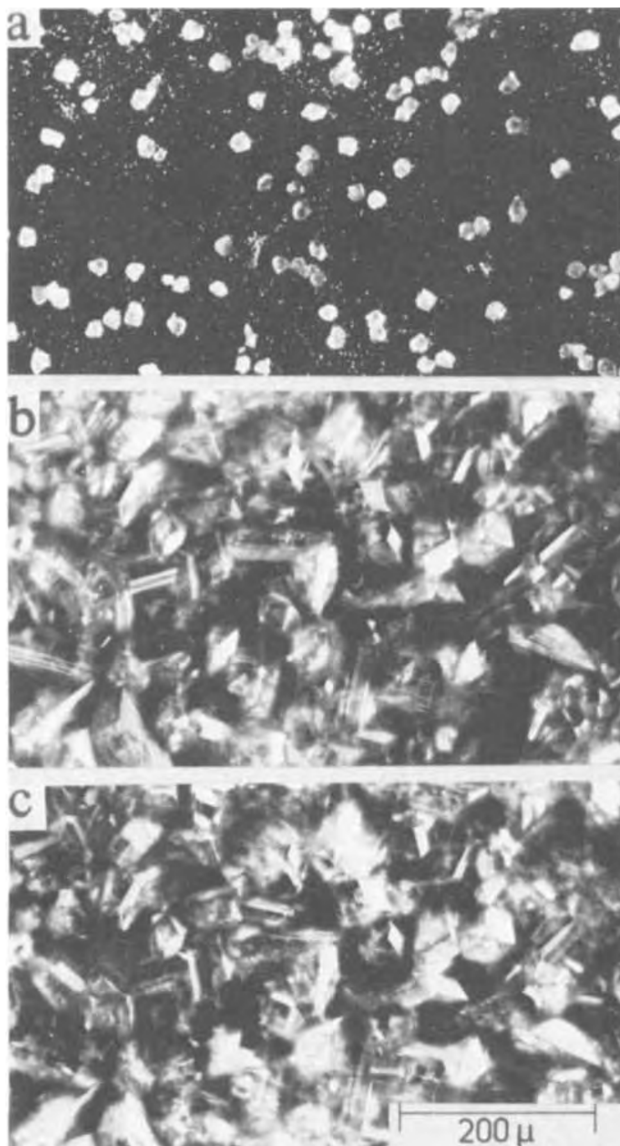

Fig. 8. Dark field photomicrograph of one and the same part of the surface of the electrode anodized in 1*N* $(COOH)_2$ with 1 mA/cm² at 60°C. a, In the beginning of the induction period (about 0.05 Q_{ind}); b, at the end of the induction period; and c, when the electrode potential has reached the value of 30V.

(providing high values for Q_{ind}), some crystals are formed (Fig. 8a), grow bigger and at last cover almost the total metal surface (Fig. 8b). The increase of U_f after the induction period does not change the surface picture (Fig. 8c).

Under conditions of a short induction period the crystals cover only a small part of the electrode surface (Fig. 9a). After completion of the induction period, the crystal size and number increased (Fig. 9b), together with the increase of the electrode potential.

It is worthwhile to mention that the electrodes were cut out of large-sized crystals of polycrystalline bismuth. It was observed that the number, size, and spatial orientation of the crystals grown during the induction period were different on the different substrate crystal faces; this effect was not investigated in detail.

Nature and structure of the films.— X-ray diffraction patterns of the crystal films mechanically removed from the electrode surfaces, and reflective electronograms of the anodized electrode surfaces, were taken. X-rayograms and electronograms showed the lack of lines typical for α- and β-Bi_2O_3. It turned out that the

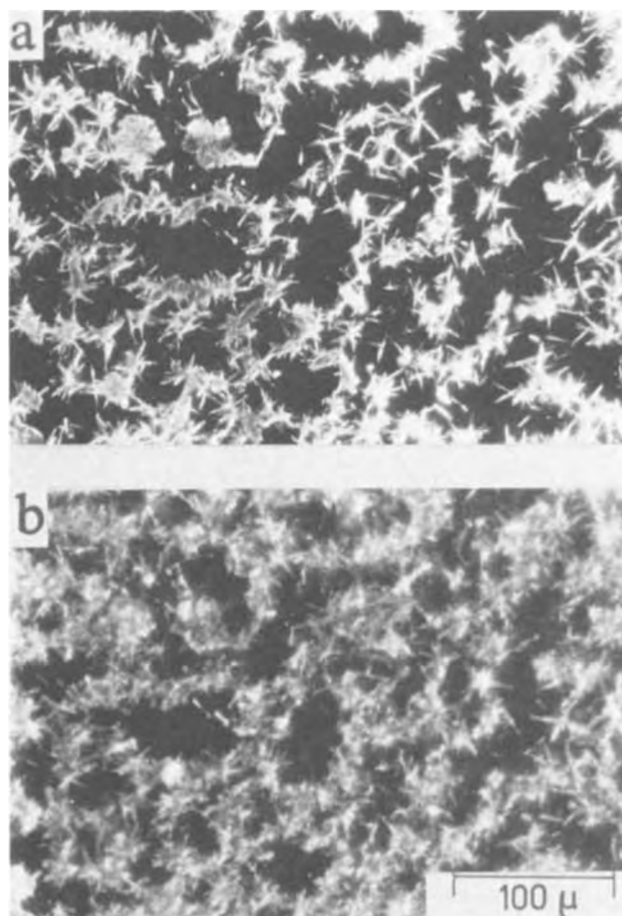

Fig. 9. Electrode surface anodized in 1*N* $(COOH)_2$ with 2 mA/cm² at 1.5°C. a, At the end of the induction period; and b, when the electrode potential has reached 30V.

films were composed from $Bi(OH)_3$ or $Bi_2O_3 \cdot CO_2 \cdot H_2O$, but it is difficult to distinguish these compounds by means of the electronographic and x-rayographic analysis because of the very close values of the interplanar distances.

Discussion

The appearance of induction time during anodic passivation of some metals [e.g., Cd, Pb, Zn (8), Fe (9), Cr (10), Sn (11), Hg (12), and Ni (13)] is well known, the mechanism of the phenomenon being under discussion (14-18). The passive state in all these cases is related with the formation of a very thin film bearing 1-2V only. Something of the sort of an induction period (a transition from a low to a higher rate of potential increase) have been observed in galvanostatic anodization to high voltages of bismuth (19) and of vanadium (20). A vividly outlined induction period followed by a linear potential rise to high voltages does not seem to be a specific phenomenon for bismuth only. Preliminary investigations have shown the appearance in some cases of a fairly well-expressed induction period during anodization of antimony (21) and molybdenum (22) to high voltages. An attempt for a semiquantitative interpretation of this phenomenon by considering the elementary processes is given below.

Elementary processes.—The possible elementary processes at the electrode surface both when the anodic polarization causes the growth of a continuous anodic film and when dissolution of the metal takes place, are schematically shown in Fig. 10.

Three simultaneous processes seem to occur when the electrode is completely covered with anodic film: (*I*) Formation of anodic film as a result of the flowing of ionic component J_{gr}, of the current. It is usually

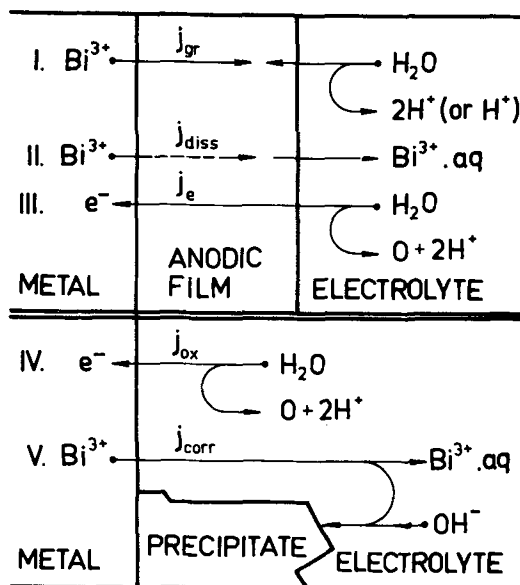

Fig. 10. Schematic representation of the possible processes during anodic polarization of Bi in solutions of $(COOH)_2$.

assumed that the metal ions move through the film, but the results would not be changed if the anion mobility is commensurable or higher. (*II*) The dissolution of the anodic film with a rate expressed by the ionic current J_{diss}. (*III*) Electronic conduction of the anodic film. This electronic component of the current, J_e, is connected with the oxygen evolution at the anode and does not influence the anodic film thickness.

There appear to be two processes of interest in the absence of continuous anodic film: (*IV*) Oxygen gas liberation at the metal (current density J_{ox}), and (*V*) Anodic dissolution of the metal with an ionic current density J_{corr}. A part of the bismuth ions formed deposit on the cathode, while the rest precipitate as crystals of a slightly soluble compound [$Bi(OH)_3$ or $Bi_2O_3 \cdot CO_2 \cdot H_2O$] on the anode surface.

The appearance and duration of the induction period are considered to result from variations in the relative rates of these elementary processes.

Anodic film formation without induction period.—This situation corresponds to the growth of anodic film which covers the electrode surface completely from the beginning of the process (a thin primary oxide film is supposed to exist before the anodic polarization). The continued growth of the anodic film requires satisfying the condition $J_{gr} > J_{diss}$.

The total current density, J, can be expressed as a sum of the three current components, $J = J_{gr} + J_{diss} + J_e$. Thus the efficiency Λ of anodic film formation is

$$\Lambda = \frac{J_{gr}}{J} = \frac{J_{gr}}{J_{gr} + J_{diss} + J_e} \qquad [5]$$

The current components J_{diss} and J_e are probably functions of N and T, hence Λ will also depend on N and T. The film thickness D can be obtained using Faraday's law

$$D = \frac{M_f}{6\mathbf{F}\rho_f} Q\Lambda \qquad [6]$$

where ρ_f is the density of the film, M_f is its molecular weight, $\mathbf{F}$ is Faraday's number, and Q is the charge density. Using Eq. [6], the potential drop U_f across the anodic film can be determined

$$U_f = DE = \frac{M_f E}{6\mathbf{F}\rho_f} Q\Lambda \qquad [7]$$

where E is the electric field strength. It is seen that the linear increase of U_f with Q, found in galvanostatic anodization at given N and T, and in the absence of an induction period, *i.e.*

$$\left(\frac{\partial U_f}{\partial Q}\right)_{J,T,N} = \text{const} \qquad [8]$$

requires both

$$(\Lambda)_{J,T,N} = \text{const and } (E)_{J,T,N} = \text{const} \qquad [9]$$

or

$$J_{gr} >> J_{diss} + J_e \qquad [10]$$

As will be shown, condition [10] contradicts the nonlinear dependence of the constants in Eq. [1] on $1/T$. For this reason it may be concluded that in the absence of the induction period the efficiency Λ and the field strength E are not functions of the film thickness (conditions [9] are satisfied).

The dependence J_{gr} (E, T) is represented by the well-known equation

$$J_{gr} = A \exp - \left(\frac{B - \alpha E}{kT}\right) \qquad [11]$$

which is theoretically a first approximation for not very wide E and T ranges, and is usually observed in formation of insulating anodic films (*e.g.*, [23]). A, B, and α are positive constants. From Eq. [5], [7], and [11] the total current density is obtained as

$$J = \frac{J_{gr}}{\Lambda} = \frac{A}{\Lambda} \exp - \left(\frac{B}{kT}\right) \exp\left[\frac{6\mathbf{F}\rho_f\alpha}{M_f kT\Lambda}\left(\frac{\partial U_f}{\partial Q}\right)\right] \qquad [12]$$

This equation is identical with the experimentally established Eq. [1]. Furthermore, expression [12] shows that the constants in Eq. [1]

$$A_1 = \frac{A}{\Lambda(N,T)} \exp - \left(\frac{B}{kT}\right)$$

$$\text{and } B_1 = \frac{6\mathbf{F}\rho_f\alpha}{M_f kT\Lambda(N,T)} \qquad [13]$$

must depend on T not only directly, but also through the function $\Lambda(N,T)$, *i.e.*, log A_1 and B_1 should be nonlinear functions of $1/T$, as was found experimentally. Moreover, this fact shows that $\Lambda < 1$ and the sum of the current components $J_{diss} + J_e$ is of the order of J_{gr}, *i.e.*, condition [10] is not satisfied and Λ and E are independent of D (condition [9] is valid).

Appearance of induction period.—During the induction period the electrode surface is not covered with continuous anodic film. In this case it is necessary for the rate of film dissolution to be higher than the rate of its growth

$$J_{diss} \geqq J_{gr} \qquad [14]$$

The result is a dissolution of the primary oxide film in the beginning of the process and subsequently metal dissolution and an oxygen evolution commence.

A quantitative description of the processes yielding Eq. [14] is difficult. Only a qualitative description based on the general properties of J_{gr} and J_{diss} are given. While the ionic conductivity J_{gr} of the film is a function of E and T, the dissolution rate J_{diss} is also dependent on the electrolyte concentration N, being greater for higher N. The absence of induction period ($Q_{ind} = 0$) at given J and T and low N become comprehensible, because at sufficiently low N the condition $J_{diss} < J_{gr}$ is satisfied. The current density J_{diss} increases with the increase of N and can reach the value of J_{gr} ($J_{diss} \approx J_{gr}$) under certain concentrations. In that range of concentrations small changes in the conditions may lead to partial or total dissolution or rebuilding of the anodic film, thus explaining the observed wide dispersion of the data for Q_{ind}. A further increase of N would make condition [14] valid, *i.e.*,

$J_{diss} > J_{gr}$, which leads to a reproducible induction period.

The current components J_{gr} and J_{diss} depend also on the total current density, J. A decrease of J causes the appearance of an induction period. Using this one may assume that J_{diss} decreases less rapidly with the decrease of J than does J_{gr}. Hence, the value of J must be lower than some boundary value J^* at given T and N in order to satisfy condition [14] and have an induction period appear.

Duration of the induction period.— The duration of the induction period (the uneffective charge Q_{ind}) may also be determined on the basis of the assumption for a minimum current density, J^*, necessary for a continuous growth of anodic film. If $J < J^*$ (for given T and N) an anodic film is not formed and $J = J_{ox} + J_{corr}$. The current component J_{corr} increases the concentration of bismuth ions around the anode and leads to a precipitation insoluble compound on the metal surface. The crystals of this compound isolate some part S_{is} of each square centimeter of the anode surface. Hence, the real current density J_{real} over the free surface $(1 - S_{is})$ increases. This process takes place until S_{is} becomes large enough, S_{is}^*, for J_{real} to become $J_{real} = J^*$, determining the end of the induction period and the magnitude of Q_{ind}.

Using this model, Q_{ind} may be determined as a function of J at given T and N. An increase in S_{is} of dS_{is} results in a change of J_{real} by dJ_{real}, which is proportional to the instantaneous value of J_{real} and to dS_{is}

$$dJ_{real} = C_{is} J_{real} dS_{is}$$

where C_{is} is a coefficient. Integration from the beginning of the process ($S_{is} = 0$ and $J_{real} = J$) to the end of the induction period ($S_{is} = S_{is}^*$ and $J_{real} = J^*$) yields

$$J = J^* \exp - (C_{is} S_{is}^*) \qquad [15]$$

where

$$(J^*)_{T,N} = \text{const}$$

The area covered with the crystals, S_{is}, depends on their volume V_{is}. If the anodic surface is large enough for the growth of a great number of precipitated crystals, which is the case in our experiments, and taking into account the chaotic orientation of the crystals, it is not difficult to show that the coated surface S_{is} at any moment and at the end of the induction period is, respectively

$$S_{is} = V_{is}^{2/3} \text{ and } S_{is}^* = V_{is}^{*2/3} \qquad [16]$$

On the other hand, we could assume that at given T and N the volume of the precipitated crystals is proportional to the charge Q that had been passed

$$V_{is} = K_{is}(T,N) Q \text{ i.e., } V_{is}^* = K_{is}(T,N) Q_{ind} \qquad [17]$$

where the constant K_{is} is a function of T and N. Substituting Eq. [16] and [17] into [15] yields

$$J = J^*(T,N) \exp - [C_{is} K_{is}(T,N) Q_{ind}^{2/3}] \qquad [18]$$

which is identical with the empirical relation [2] provided that

$$A_2 = J^*(T,N)$$

and

$$B_2 = C_{is} K_{is}(T,N)$$

It is difficult to determine how these constants (A_2 and B_2) depend on the temperature, because the change of T changes the rate of metal corrosion and the diffusion coefficient, consequently the relation between the metal deposits on the cathode and the precipitated crystals of bismuth compound on the anode. Even the crystal shape may be changed (the relative number of the acicular crystals increases with the decrease of the temperature). In general, the diffusion of the bismuth ions and their deposition on the cathode, the oxygen evolution on the anode, the solubility of the precipitated crystals, etc., increase with the increase of temperature at given J and N. Hence, a smaller amount of the precipitated crystals will correspond to unit charge at higher temperature, *i.e.*, the constant K_{is} in Eq. [17] will be lower. Correspondingly, a larger charge will be required in order to reach a current density $J_{real} \geqq J^*$ and to start the anodic film growth. Moreover, the value of J^* will also be higher at higher temperature, because of the reduction of the anodization efficiency with the increase of the temperature (see Eq. [6]). All this explains qualitatively the increase of Q_{ind} with T found in the experiments (Fig. 4).

Growth of anodic film after the induction period.— After the expiration of the induction period the electrode potential begins to increase linearly with the charge density Q that had passed (Fig. 1). This linear relation (condition [8]) proves that after the induction period, as it was in the case of the absence of the induction period, the film growth efficiency Λ and the field strength E are independent of the film thickness, *i.e.*, condition [9] is also satisfied. The fact that the slope $(\partial U_f/\partial Q)_{N,T,Q>Q_{ind}}$ is a function of the total current density or of the duration of induction period (Fig. 6 and 7, Eq. [3] and [4]), however, cannot be explained directly with the model proposed for interpretation of the duration of the induction period. According to this model at the end of the induction period the current J_{real} passing through the surface not covered with precipitated crystals $(1 - S_{is}^*)$ must reach a certain critical value J^*, independent of the total current density. Then the growth of anodic film on the free surface, leading to the increase of the electrode potential, will be realized always by the same current density, and from Eq. [12]

$$J = J^* = \frac{A}{\Lambda} \exp - \left(\frac{B}{kT}\right) \exp \frac{6\mathbf{F}\rho_f\alpha}{M_f kT\Lambda} \left(\frac{\partial U_f}{\partial Q}\right)_{Q=Q_{ind}} = \text{const} \qquad [19]$$

it follows that

$$(\partial U_f/\partial Q)_{Q=Q_{ind}} = \text{const}$$

Hence, if the surface covered with the precipitated crystals does not increase further after the expiration of the induction period, the slope $(\partial U_f/\partial Q)_{Q>Q_{ind}}$ should be independent of the total current density and Q_{ind} which is in contradiction to the experimental data.

The empirical data (Eq. [3] and [4]) require an assumption of an additional increase of the surface insulated by the precipitated crystals, causing an increase of the slope $(\partial U_f/\partial Q)$ proportional to the free surface $(1 - S_{is}^*)$ at the end of the induction period

$$\left(\frac{\partial U_f}{\partial Q}\right)_{Q>Q_{ind}} = \left(\frac{\partial U_f}{\partial Q}\right)_{Q=Q_{ind}} + b\,(1 - S_{is}^*) \qquad [20]$$

where b is a constant at given T and N.

Substituting [16] and [17] into [20] one may obtain an expression identical with the empirical equation [3]

$$\left(\frac{\partial U_f}{\partial Q}\right)_{Q>Q_{ind}} = \left(\frac{\partial U_f}{\partial Q}\right)_{Q=Q_{ind}} + b - bK_{is}^{2/3} Q_{ind}^{2/3} \qquad [21]$$

where the constants

$$A_3 = \left(\frac{\partial U_f}{\partial Q}\right)_{Q=Q_{ind}} + b \text{ and } B_3 = bK_{is}^{2/3}$$

should be functions of the temperature as it was found experimentally.

The dependence between the total current density, J, and the slope $(\partial U_f/\partial Q)_{Q>Q_{ind}}$ could be obtained from Eq. [21] and [18]

$$J = J^* \exp - \left\{ \frac{C_{is}K_{is}^{1/3}[(\partial U_f/\partial Q)_{Q=Q_{ind}} + b]}{b} \right\} \exp \frac{C_{is}K_{is}^{1/3}}{b} \left(\frac{\partial U_f}{\partial Q} \right)_{Q>Q_{ind}} \quad [22]$$

This Eq. [22] is identical with the empirical relation [4], where the quantities

$$A_4 = J^* \exp - \left\{ \frac{C_{is}K_{is}^{1/3}[(\partial U_f/\partial Q)_{Q=Q_{ind}} + b]}{b} \right\}$$

and

$$B_4 = \frac{C_{is}K_{is}^{1/3}}{b}$$

must have constant values at given T and N, which was confirmed by the experiment.

Conclusion

The established anodic behavior of bismuth in aqueous oxalic acid solutions can be explained by a model taking into account the existence of a critical current density determining the appearance of the induction period at each temperature and electrolyte concentration. An induction period does not appear if the anodic current density exceeds some critical value. A continuous anodic film grows from the beginning of the process causing a linear increase of the anode potential with time.

If the current density is lower than the critical one, the film growth is retarded. The current is used for metal dissolution and oxygen evolution. Crystals of a slightly soluble compound precipitate on the anode surface during this induction period. These crystals isolate some part of the surface and cause an increase of the current density on the free surface. When the current density reaches the critical value the induction period terminates and an anodic film begins to grow on the free surface, causing an increase of the anodic potential. In the beginning of this process, the surface insulated by precipitated crystals increases additionally and proportionally to the free surface in the end of the induction period, and after that a steady-state anodization is achieved.

The linear increase of the anodic potential with time in the absence of induction period or after its expiration suggests that the film growth efficiency and field strength across the anodic film are independent of the film thickness.

The found empirical dependences of this somehow unusual kinetics of anodization would be valuable even if the proposed explanations are not quite correct.

Oxidation State of Anodic Tantalum Oxide after Heat-Treatment

I. Galvanostatic Method as Applied after Heating in Vacuum

Gerhart P. Klein*

P. R. Mallory & Company Inc., Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

During heat-treatment of anodic Ta_2O_5 in vacuum (10^{-5} Torr) at temperatures in the range from 200° to 700°C oxygen exchange between the anodic oxide, the Ta substrate, and the atmosphere was observed. Galvanostatic reanodization experiments resulted in potential-time (charge) curves which could be used to determine the oxidation state of heat-treated TaO_n as a function of the distance from the electrolyte/oxide interface into the oxide. Profiles of the oxidation state across the oxide were measured for tantalum oxide anodized in 0.1M H_3PO_4 and 0.1M H_2SO_4 after heat-treatment at 10^{-5} Torr and 500°C. Of several experimental variables, the time of heat-treatment and the oxide thickness were chosen to illustrate the method of determining oxidation state profiles for the case of heat-treatment in vacuum. In all cases treated in this paper the reduction was carried out to the extent that the oxide as a whole exhibited high electronic conductivity.

Anodic tantalum oxide is amorphous as formed on its substrate (1). If stripped it can be recrystallized at temperatures above about 600°C (2, 3). Below this temperature no change in its structure was observed. Crystalline forms of tantalum oxide are formed during the thermal oxidation of tantalum in oxygen containing atmosphere in this lower temperature range. Also, special anodization conditions can lead to crystalline tantalum oxide [field crystallization (4)]. In the experiments presented in this paper only tantalum oxide in its amorphous form was involved.

Vermilyea (4, 5) had found an effect of heat-treatment on the dissolution rate of Ta_2O_5 and, at the same time, significant changes in the film capacitance upon heating in air, and more so in vacuum or hydrogen atmosphere. Later, Smyth *et al.* (6-10) studied in detail the effect of heat-treatment in air on the dielectric properties of Ta_2O_5. These authors interpreted their results in terms of interactions of the amorphous oxide both with the underlying Ta substrate and the surrounding gas phase.

The incorporation of anions from the electrolyte into the anodically grown oxide was demonstrated by Randall *et al.* (11) for electrolytes containing phosphate and sulfate ions. Incorporation of phosphorous and sulfur was limited to about the outer half of the oxide, indicating that the transport numbers were close to 0.5 for both tantalum and oxygen ions. Similar results were obtained from reanodization curves after heat-treatment of such films in vacuum (12).

This paper reports the results of experiments in which Ta/Ta_2O_5 specimens anodically formed in electrolytes containing phosphate and sulfate ions were heat-treated in vacuum followed by reanodization under constant current conditions. From potential-charge curves (reanodization curves, RAC) the charge required to restore partially reduced TaO_n to its original oxidation state (Ta_2O_5) was obtained while potential was used to measure distance into the oxide from the electrolyte/oxide interface. Thus, profiles of the oxidation state of TaO_n across the oxide film could be measured by electrochemical means.

Experimental

Specimen preparation and anodization.—Specimens used in this study were prepared in the usual way: capacitor grade Ta sheet (Berylco-Kawecki Company) was chemically polished in a mixture of 5 parts H_2SO_4, 2 parts HNO_3, and 1.5 parts HF (all reagent grade, concentrated), followed by dipping in HF for about 10 sec, rinsing in distilled water, and vacuum annealing at 2100°C for 1 to 3 hr at 10^{-5}-10^{-6} Torr. Anodization was done in Pyrex glass cells with Ta counter-electrodes. Solutions were prepared from A.R. reagents and distilled water. To standardize anodization rates independent of any electronic leakage currents or area variations anodization was done at programmed linearly increasing voltage corresponding to constant current anodization. Stabilization at the anodization voltage was avoided since the incorporation of anions from the electrolyte during anodization had been found to be current dependent (11). Stabilization at constant voltage would have led to a gradient in the foreign ion concentration near the oxide/electrolyte interface.

Heat-treatment.—Vacuum heat-treatment was carried out in a furnace inside a bell jar vacuum system. Constant pressure was maintained by means of an automatic pressure regulator (Granville Phillips). A furnace (Centorr Associates) with cylindrical resistance heated zone (2.5 in. diam × 5 in. high, Hoskins alloy heating element, Inconel heat shields) was mounted on an 18 in. diam vacuum feedthrough collar. The specimens were heated inside vertical quartz tubes which rested on the bottom heat shields. They could be lowered into the hot zone and raised out of it by means of wires operated by a rotary feedthrough. Temperature distribution was found to be within 5°C of the control thermocouple for a specimen 7.5 cm long × 1.25 cm wide.

Galvanostatic reanodization.—The loss of oxygen during heat-treatment was determined quantitatively from potential-charge (reanodization) curves (RAC's). After annealing the specimens were reanodized at constant current density and the voltage was recorded as a function of time. The schematic experimental electronic circuit is shown in Fig. 1A. It consisted of constant current supply (Electronic Measurements Model C633), electrometer (Keithley Model 610A), and strip chart recorder (Hewlett-Packard Model 7101). To make efficient use of the specimens after heat-treatment circular areas (0.3 cm²) were masked off with pressure sensitive tape with silicone adhesive (Mystic Company No. 7305). A specimen with several test areas masked off in this way was mounted on a support plate. The end was clamped against a copper block to provide electrical contact to the substrate. A drop of electrolyte (*e.g.*, 0.1M H_2SO_4) was placed on a test area and a platinum wire mesh, serving as counter-electrode, was brought in contact with the electrolyte (Fig. 1B). This experimental arrangement proved

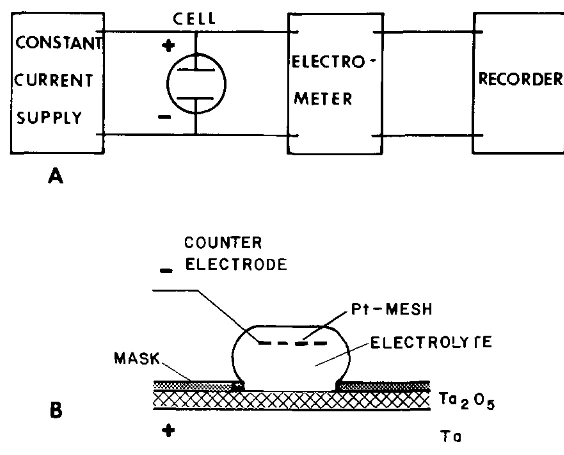

Fig. 1. A. Schematic of electronic circuit used to measure reanodization curves. B. Masked off test area on Ta/TaO_n specimen.

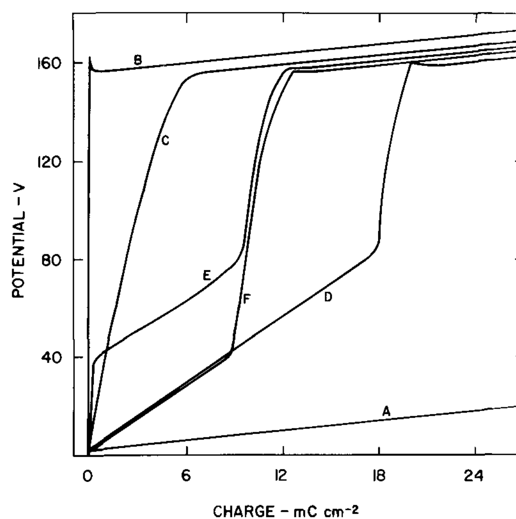

Fig. 2. Anodization (A) and reanodization (B-F) curves of anodic tantalum oxide. All curves were measured at 0.2 mA/cm^2. With the exception of A, all anodizations were done at 0.3 mA/cm^2 in the electrolytes given below. Heat-treatment of specimens C-F was carried out at 500°C, 10^{-5} Torr, for 120 min.

Curve	Electrolyte	Voltage, V
A	0.1M H_3PO_4	(Anodization of Ta)
B	0.1M H_3PO_4	0-160
C	0.1M H_2SO_4	0-160
D	0.1M H_3PO_4	0-160
E	0.1M H_3PO_4	0-80
	0.1M H_2SO_4	80-160
F	0.1M H_2SO_4	0-80
	0.1M H_3PO_4	80-160

highly advantageous as it permitted several tests to be performed on a given specimen. The test areas were sharply defined by the tape. No edge effect or electrolyte undercutting was observed.

Potential was measured against the platinum counterelectrode, *i.e.*, the potential of the hydrogen electrode in the same solution, approximately. No corrections for ohmic potential drop in the electrolyte and "pre-existing" oxide were applied since only thick oxides (typically 160V anodization voltage) and low current densities (typically 0.2 mA/cm^2) were used. Any error from these sources was within the general experimental inaccuracy.

Sectioning of tantalum oxide.—In some cases RAC's were measured after partial removal of tantalum oxide in 48% HF which was saturated with NH_4F at room temperature (13). The addition of NH_4F reduced the rate of attack and more uniform dissolution of the film resulted. The amount of oxide removed was measured by comparison with a color gauge. The difference in thickness could also be obtained from the difference in reanodization voltage, as is shown later.

Capacitance measurements.—Capacitance measurements were performed in an experimental setup similar to the one used for reanodization experiments. The electrolyte used was 5M H_2SO_4 and the counterelectrode was a platinized Pt grid. Capacitance was measured with a digital capacitance bridge (Micro Instruments Model 5300) at a frequency of 120 Hz.

Results and Discussion

Anodization and reanodization (RAC) curves.—Under the condition of negligible electronic charge transfer across the oxide/electrolyte interface the anodization of Ta at constant current density is characterized by a linear increase of voltage and oxide thickness with time. With suitably pretreated high-purity Ta the ratio $i_{ion}/i = 1 - i_{el}/i \approx 1$ (i_{ion} = ionic, i_{el} = electronic, i = total current), which means that under galvanostatic anodization conditions nearly all charge is used to form anodic oxide (1). Since the field is constant during constant current anodization, the thickness of the oxide is proportional to the anodization voltage.

Figure 2 shows characteristic reanodization curves C-F after heat-treatment in comparison with an original anodization curve A and the reanodization and continued anodization curve B of a specimen without heat-treatment. The linear rise of potential with charge in curve A for the anodization of Ta at 0.2 mA/cm^2 indicates that the rate of oxide growth is constant. The Ta/Ta_2O_5 specimen previously anodized to 160V showed a behavior as in curve B when subjected to further anodization at 0.2 mA/cm^2. The potential rose steeply exceeding the original formation voltage (V_A) in an overshoot, followed by a decay of the overshoot and a linear rise of potential, characteristic of the rate of further oxide formation. The slope of this section of curve B was identical to curve A.

When Ta/TaO_n specimens which had previously been anodized to 160V followed by heat-treatment at 10^{-5} Torr, 500°C were subjected to the same anodization conditions, the potential-charge curves C-F were obtained. Their slopes in the potential range to V_A fell between those of curves A and B indicating that substantial amounts of charge were required to reach the original anodization voltage. Beyond V_A the slope was again found to be identical to that of curve A. Curve C was obtained with a specimen which had been anodized in 0.1M H_2SO_4 to 160V followed by heat-treatment at 500°C, 10^{-5} Torr, for 120 min. A smooth rise of potential with charge without abrupt changes in slope (except near V_A) was found. Curve D shows the reanodization behavior of a specimen which had been anodized in 0.1M H_3PO_4 to 160V followed by heat-treatment under the same conditions as above. In this case the potential-charge curve to V_A showed two sections with different slopes: to about $V_A/2$ the slope was nearly linear and much shallower than that of curve C. Beyond $V_A/2$ the slope became steeper approaching that of the upper part of curve C. The remaining curves E and F were obtained with specimens that had been anodized, consecutively, in 0.1M H_3PO_4 and 0.1M H_2SO_4 followed by heat-treatment under the same conditions as before. In the case of curve E, anodization in 0.1M H_3PO_4 to 80V was followed by anodization in 0.1M H_2SO_4 from 80 to 160V. In the case of curve F, the sequence of anodizations in H_3PO_4 and H_2SO_4 was reversed. Curve E exhibited three distinctly different slopes before reaching V_A: to about $V_A/4$ the slope was steep and similar to curve C (anodization in 0.1M H_2SO_4), between $V_A/4$ and $V_A/2$ the shallower slope of curve D (anodization in 0.1M H_3PO_4) was evident, and above $V_A/2$ the slope was

again steep and similar to the upper parts of curves C and D. In curve F only two slopes were in evidence: to $V_A/4$ the slope was shallow and approached that of curve D (anodization in 0.1M H_3PO_4) while above $V_A/4$ curve F was nearly identical with the corresponding part of curve C.

The general shape of reanodization curves (RAC's) was found to be a function of variables relating to the anodization of the original oxide (type and concentration of electrolyte, rate of anodization, anodization voltage V_A, among others) and the conditions of heat-treatment (pressure, temperature, time). Depending on the conditions of heat-treatment, the reanodization charge expressed as a fraction of the anodization charge could vary between 0 and nearly 100%. At the given pressure the limiting temperatures for these conditions to be established were, approximately, 300° and 700°C.

The specific examples given in Fig. 2 illustrate the differences in RAC's arising from differences in the electrolyte used during anodization. The RAC's shown in Fig. 2 do not represent steady-state conditions in the oxide, however, at 500°C, 10^{-5} Torr, and 160V anodization the further change of their shape with time would be a slow one beyond times of the order of 120 min. For this reason, they can be considered to reflect quasi steady-state conditions. In the context of this paper no attempt is being made to systematically present results of the dependence of RAC's on the variables of anodization and heat-treatment. Instead, typical RAC's are used to illustrate the method of galvanostatic reanodization and its application to the measurement of profiles of the oxidation state across heat-treated TaO_n.

The RAC's C-F of Fig. 2 have in common that substantial quantities of charge, amounting to as much as 10% of the charge stored in oxide anodized to the same voltage V_A, were consumed during the process of reanodizing heat-treated oxide to the original anodization voltage, V_A. This charge consumed during reanodization could, in principle, be either ionic or electronic charge. It will be necessary to account for the charge consumed during reanodization and to establish the type of charge transfer in the oxide and across the oxide/electrolyte interface before an interpretation of the changes occurring during heat-treatment in vacuum can be attempted.

Initial potential drop.—A further common characteristic of curves C-F is the absence of a steep initial rise of potential immediately following the switching on of constant current. Any appreciable resistance in the experimental system would lead to a corresponding potential drop which would appear with a rate of increase determined by the rate of capacitor charging. An extreme case of this kind is illustrated by curve B which showed a potential drop equivalent of the ionic resistance of the original oxide. In this case, the presence also of an initial overshoot of potential beyond V_A indicated initial excess resistance to ionic migration as compared to the steady-state resistance. The absence of an initial potential drop showed that the anodic oxide film as a result of heat-treatment had lost its insulating properties. Whether this was due to changes at the oxide/electrolyte interface facilitating electron injection, or changes in the oxide itself increasing its electronic conductivity will have to be established.

Anodization electrolyte.—A comparison of RAC's C-F reveals the influence of the anodization electrolyte on the behavior of Ta_2O_5 during heat-treatment in vacuum and subsequent reanodization to V_A. From radiotracer experiments by Randall *et al.* (11), quantitative information is available concerning the incorporation of ions from the anodization electrolyte into an outer layer, extending to about the mid-point of the oxide. The outer layer is formed by tantalum ion migration and oxide formation at the electrolyte/oxide interface which explains the possibility of ionic inclusions during oxide growth. The inner half of the oxide remains unaffected by the electrolyte since it is the result of oxygen ion migration and oxide growth at the oxide/metal interface. According to Randall (11), the amount of phosphorous incorporated into anodic Ta_2O_5 from dilute H_3PO_4 was substantially greater than the amount of sulfur that was incorporated from dilute H_2SO_4, concentrations of the two acids being equal.

Curve C was obtained with Ta_2O_5 anodized in 0.1M H_2SO_4, while curve D was the result of anodization in 0.1M H_3PO_4. The presence of phosphorous in the latter case must have been responsible for the difference in reanodization curves, which showed a shallow slope to about $V_A/2$ for phosphorous-containing oxide. In separate experiments, it was established that this slope was dependent on the concentration of phosphorous in the anodic oxide showing a decrease with increasing concentration. By contrast, the slope of RAC's of oxide anodized in dilute H_2SO_4, as well as a large number of other electrolytes (*e.g.*, oxalic, nitric, hydrochloric acid, and their salts) was found to be independent of the concentration of the anodization electrolyte. For this reason, it seems justified to assume that curve C (H_2SO_4) was representative of anodic Ta_2O_5 which was not affected by inclusions from the electrolyte. The results shown in curves E and F for consecutive anodizations in 0.1M H_3PO_4 and 0.1M H_2SO_4 correspond directly to the additional duplex structure of the outer half of the oxide. With anodization in H_3PO_4 followed by H_2SO_4, the layer containing phosphorous was buried underneath a layer containing sulfur. Reversing the sequence of anodizations reversed the sequence of the layers. The inner half of the oxide again was not affected by incorporation of ions.

The fact that phosphorous incorporation was limited to the outer half of the oxide established by tracer experiments (10) together with the observation that the reduced slope of curve D (caused by anodization in H_3PO_4) was traversed first during reanodization lead to an important qualitative conclusion: in RAC's of the type shown in Fig. 2 the potential scale from zero to V_A can be related in the process of reanodization to a traversing of the oxide from the oxide/electrolyte interface to the oxide/metal interface. The results of curves E and F with consecutive anodizations confirm this conclusion in that the sequence of characteristic slopes in the RAC's corresponded directly to the sequence of layers in the oxide.

The close correspondence of those parts of the RAC's extending from $V_A/2$ to V_A for all anodization electrolytes indicates that this part of the oxide is unaffected by ionic inclusions from the electrolyte, in agreement with the results by Randall *et al* (10). The continuity in the slope of curve C between the outer and inner parts of the oxide is further confirmation for the previous conclusion that oxide anodized in dilute H_2SO_4 is unaffected by ionic inclusions as regards its behavior during heat-treamtent in vacuum under the given conditions.

Nature of charge consumed during reanodization.—For the correct interpretation of the RAC's of heat-treated tantalum oxide it is essential to determine the charge-consuming reactions during reanodization to V_A. In particular, the distribution of the total charge between electronic and ionic reactions must be established. Any electronic charge transferred across the oxide/electrolyte interface would be consumed in redox reactions, *i.e.*, under the given experimental conditions the evolution of oxygen. However, this was not observed during reanodization even though the total measured charge, if electronic, should have lead to visible gas evolution. For this reason, the major part of the charge could not have been electronic.

To determine the extent of any minor electronic contribution to the total charge and to establish the

ionic current efficiency of reanodization, the more sensitive redox print-out method (14) for detecting electronic current (e.c.) was used. Several such experiments were performed with heat-treated Ta/TaO_n specimens. With high purity Ta used in this study the results were negative. No uniformly and negligible nonuniformly distributed electron transfer across the oxide/electrolyte interface was detectable during reanodization.

When less pure Ta specimens were used increased nonuniformly distributed impurity conduction was found. Figure 3 illustrates a case where the effect of e.c. on the reanodization curve could not be neglected. A print-out of the e.c. distribution was obtained by reanodizing a specimen with KI/starch gel as the electrolyte. The specimen had been anodized to 160V in 0.1M H_3PO_4 followed by heat-treatment at 500°C, 10^{-5} Torr for 120 min. The gel was supported by Millipore paper and lifted off the specimen after constant current reanodization in steps of 10V. Fresh electrolyte was used in every voltage interval. The RAC shown in Fig. 3A was obtained during the print-out experiment. The anodic prints obtained in the indicated intervals are shown next to the corresponding segments of the RAC. There was no indication of any uniformly distributed e.c., however, random patterns of e.c. indicating the presence of impurities were observed. As was shown previously (14, 15), heat-treatment of Ta or Ta/Ta_2O_5 specimens may cause electronically active impurities to appear at the surface of the anodic oxide. No e.c. had been detected in the specimen of Fig. 3 prior to heat-treatment.

That surface impurities were the cause for e.c. in this case could be demonstrated by the following experiment which revealed, at the same time, the strong influence of the electrolyte on surface impurities and resulting e.c. It was noticed that areas on the same specimen adjacent to the one for which the prints of Fig. 3A were obtained gave the dashed reanodization curve when reanodized in 0.1M H_2SO_4. In a separate experiment adjacent areas were reanodized as indicated in Fig. 3B and C. One masked-off area was first anodized to 10V in 0.1 H_2SO_4 followed by print-out anodization in KI for which a clear print was obtained (Fig. 3B). Another area was first anodized in KI resulting in the intensely colored print and little rise in potential (Fig. 3C). This was followed by anodization to 10V in 0.1M

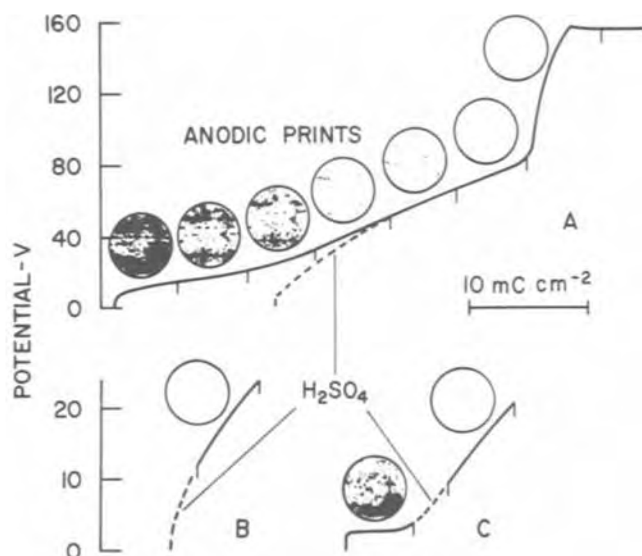

Fig. 3. Reanodization of heat-treated tantalum oxide combined with anodic print-out of electronic conductivity. Anodic prints were obtained by reanodizing in KI/starch printing electrolyte during 1 min intervals before exchange of printing medium. Diameter of original print 0.5 cm. Dashed RAC's indicate reanodization in 0.1M H_2SO_4. For further details, see text.

H_2SO_4 and a further print-out anodization. The second print was clear. Whatever impurities had been present after heat-treatment they were deactivated during reanodization in H_2SO_4, while KI/starch gel required much longer time to accomplish the same. Figure 3A showed that KI reanodization was seriously affected by e.c. to about 50V with slight impurity related nonuniform e.c. even above this level. Dissolution of impurities by an electrochemical mechanism tied to the passage of current was the most likely course of deactivation.

These results show that RAC's can be severely distorted in the presence of impurities and the resulting electronic charge transfer. These problems can be minimized by the use of high-purity materials and reanodization in dilute acid (*e.g.*, 0.1M H_2SO_4) which, as was shown, eliminated the effect of any remaining impurities. Anodic prints were used to detect any residual e.c. Comparison of the print-out intensity with a set of test patterns made it possible to estimate the fraction of electronic charge and thus current efficiency of reanodization. Specimens were rejected if the electronic charge exceeded a few per cent of the total charge.

These experiments demonstrated conclusively that the charge consumed during reanodization was ionic charge and that the ionic processes responsible for the reanodization behavior of heat-treated TaO_n proceeded with an ionic current efficiency approaching 1.0.

Restoration of heat-treated tantalum oxide.—The ionic charge consumed during reanodization to V_A must be related directly to the changes that took place in anodic tantalum oxide during heat-treatment. It is postulated that reanodization means restoration of partially reduced oxide TaO_n to its original oxidation state Ta_2O_5. This interpretation is suggested by the fact that the slopes of the reanodization curves C-F in Fig. 2 fall between those of the anodization of bare Ta (curve A) and the reanodization of 160V Ta_2O_5 without heat-treatment (curve B). With this assumption, the charge consumed during reanodization to V_A would measure the amount of oxygen lost during heat-treatment. If at the same time the potential scale can be related to position in the oxide, then it will be possible to determine the oxidation state of tantalum oxide after heat-treatment as a function of the distance from either the oxide/electrolyte or oxide/metal interface.

From previous experiments, the following conclusions pertain to this assumption:

1. The absence of an initial potential drop during reanodization at constant current showed that the oxide, after heat-treatment under the given experimental conditions, had become electronically conductive throughout.

2. Electron transfer across the oxide/electrolyte interface was found to be inhibited. This means that only ions could be transferred across this interface and that reanodization had to begin at the oxide/electrolyte interface and proceed inward toward the metal.

The following experiments are intended to provide additional evidence in support of the above assumptions.

Step-reanodization curves.—The relationship of charge required to reach a particular potential on the RAC with position in the oxide could be established experimentally by measuring reanodization curves after partial stripping of oxide. In Fig. 4 a series of RAC's is shown that were measured from different steps in the oxide. The step pattern dissolved into the oxide is illustrated schematically at the bottom of Fig. 4. The specimen used in this experiment was of the type shown in Fig. 2, curve D. It had been anodized in 0.1M H_3PO_4 to 160V and heat-treated at 10^{-5} Torr, 500°C for 120 min. The top curve (solid line, marked step O) represents the RAC of the oxide as a whole. The subsequent curves (marked steps 1-5) were measured at progressively deeper steps in the oxide. Their origins were shifted to the right to make the first tran-

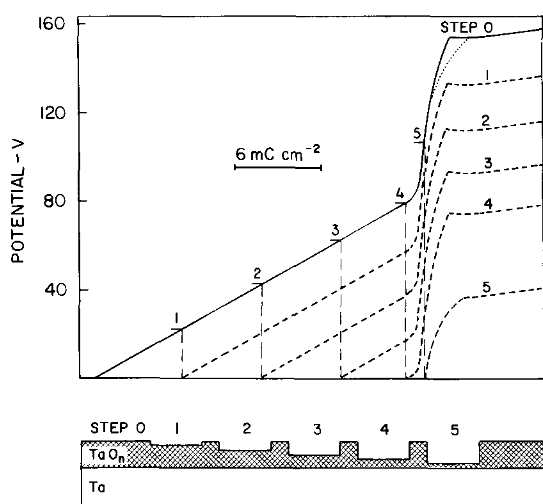

Fig. 4. Reanodization curves of heat-treated tantalum oxide from steps of different height dissolved into the oxide (see schematic at bottom). The origins of curves 1-5 were shifted to the right such that the steep sections of each curve coincided, on the abscissa, with that of the original RAC ("step O"). By upward shifting curves 1-5 could be superimposed on the original RAC. The only deviation occurred near V_A and was indicated by the dotted line. Anodization: 0.1M H_3PO_4, 0.3 mA/cm^2, 160V. Heat-treatment: 500°C, 10^{-5} Torr, 120 min.

sition points (from the shallow to the steep slope) coincide on the abscissa relative to the "step O" curve. With progressing penetration into the oxide, progressive removal of the shallow linear part of the RAC left of the transition point to the steeper slope was observed. Then the removal of the transition point itself and the subsequent steep curve segment followed. At their top end all curves showed a sharp transition to the shallow slope associated with further anodization, corresponding to the original V_A.

As the oxide was stripped increasing portions of the original RAC were cut off. The remaining curve segments were identical to corresponding sections of the original curve. By shifting curves 1-5 upward they could be superimposed on the original curve. They matched closely except at the top end where the slope of the last step RAC (step 5) deviated somewhat from the previous curves. This effect is believed to be related to the potential overshoot which was much more pronounced in Fig. 2, curve B, but still affected reanodization curves of the type shown in Fig. 4 in some small degree.

The magnitude of the potential overshoot and its effect on the shape of the transition region from the steep reanodization slope to the shallow anodization slope depends on the extent of reduction of the anodic oxide. The further the reduction goes, the smaller its effect. In the context of this paper the specimens used had been subjected to heat-treatment conditions sufficiently severe to minimize the overshoot and reduce its influence on the results to within the over-all experimental error.

The results of this experiment provided evidence for the previously stated assumption that reanodization of heat-treated tantalum oxide began at the electrolyte/oxide interface and continued toward the metal. At the same time it showed that the reanodization potential could be considered a direct measure of distance into the oxide from the oxide/electrolyte interface. In the following it will be shown that reanodization potential and distance into the oxide were linearly related.

It is assumed that in the process of reanodization partially reduced oxide is restored to its original oxidation state with properties similar to those of originally formed anodic oxide. The field required to move ions through restored oxide can then be expected to be of comparable magnitude as the field required for anodization. In addition, during anodization the field at constant current density is known to remain constant independent of anodization voltage, making voltage a linearly related measure of oxide thickness. It appears reasonable, therefore, to assume that the same holds true for the field in oxide restored to the maximum oxidation state after reanodization.

Field differences between anodization and reanodization could arise due to differences in the structure of as-anodized and heat-treated oxide and variations of the dielectric constant with inclusions of ions from the electrolyte. However, the available evidence suggests that these are minor effects which may affect the accuracy of the distance scale without changing either the qualitative picture or the charge-related quantitative aspect, *i.e.*, the determination of the oxidation state.

Comparison of thickness measurements from interference color and reanodization voltage.—During heat-treatment in vacuum with moderate partial reduction of tantalum oxide the interference color of the oxide did *not* change noticeably, a fact which had been noted by Vermilyea (4). Only when the reduction reached low oxidation states of TaO_n ($n < 1.5$) did the oxide interference color change to a metallic appearance. Interference color can, therefore, be used as a measure of thickness as long as the reduction has not been carried too far.

Reanodization experiments can also be used to measure oxide thickness. In Fig. 4 the voltage equivalent of the height of the steps dissolved into the oxide could be obtained from the vertical displacement of the step reanodization curves 1-5 with respect to the original RAC at a point beyond the steep section of the curves. Beyond the points on the RAC's corresponding to V_A reanodization had been completed and the difference in voltage was caused by the removal of the oxide over the corresponding step.

Figure 5, curve A shows a comparison of thickness measurements on a specimen similar to the one illustrated in Fig. 4, as determined by comparison with a color gauge and by reanodization. The color gauge was calibrated in terms of anodization voltage. The voltage equivalent of thickness was plotted against the duration of oxide dissolution in HF/NH_4F for a particular

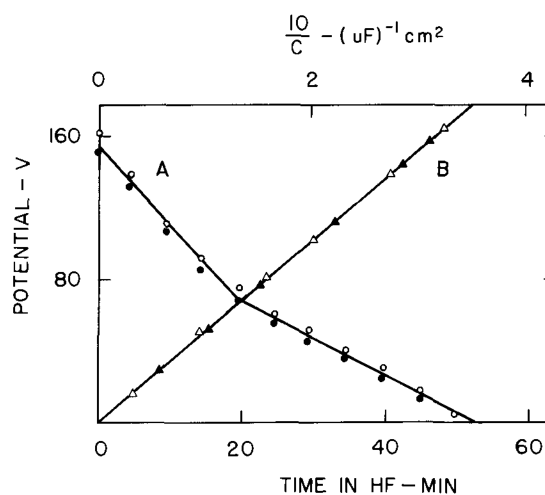

Fig. 5 A. Comparison of oxide thickness remaining after stepwise dissolution in HF/NH_4F. ○ Thickness (in volts) measured by reanodization (0.1 mA/cm^2); ● thickness by comparison with color gauge. B. Reciprocal capacitance vs. thickness (in volts). △ Ta specimen after anodization to given voltages (0.1 mA/cm^2); ▲ tantalum oxide heat-treated, dissolved in steps and reanodized to same point on original RAC (corresponding to anodization voltage V_A). Anodization: 0.1M H_3PO_4, 0.3 mA/cm^2, 160V. Heat-treatment: 500°C, 120 min, 10^{-5} Torr.

step. The rates of oxide dissolution of the outer and inner parts of the oxide were noticeably different which gave rise to a change in slope at about the midpoint of the oxide. However, for both sections color chart and reanodization yielded closely corresponding values for the thickness. The generally lower voltage readings from the color chart may have been caused in part by the lack of standardization between the two methods. Significantly, the displacement, within experimental error, was constant over the full range indicating that a linear relationship existed between the potential differences as obtained from reanodization curves after dissolution of steps into the oxide, and the corresponding changes in interference color.

Comparison of thickness measurements from capacitance measurements and reanodization voltage.—Capacitance measurements provide an alternative method for determining oxide thickness. Since substantially reduced oxide exhibited high electronic conductivity capacitance measurements could only be applied to reanodized oxide. Again, a step pattern was dissolved into heat-treated oxide of the same kind used in the previous experiment. The remaining oxide on each step was reanodized to a point on the step RAC equivalent to V_A on the original RAC (transition point between steep part of RAC and shallow slope of continued anodization). In Fig. 5, curve B the reciprocal of capacitance (top scale) was plotted *vs.* the thickness of oxide as measured by reanodization. For comparison, $1/C$ *vs.* anodization voltage was also measured for a Ta specimen anodized to various voltages. Both types of measurements fell on the same straight line indicating that $C \times V = \text{const}$, consequently $\epsilon \times F = \text{const}$ (V, voltage equivalent of oxide thickness; ϵ, relative dielectric constant; F, field), a result generally found for anodic oxides of the same chemical nature (11).

The linear relationship between $1/C$ and reanodization potential on the one hand, and thickness determined via interference colors and reanodization potential on the other substantiate the earlier conjecture about a linear relationship between reanodization potential and distance into the oxide measured from the electrolyte/oxide interface.

Dependence of RAC's on current density.—The amount of charge required to restore partially reduced tantalum oxide to its maximum oxidation state should be independent of the current density used in the galvanostatic experiment. It is assumed that electronic leakage currents can be neglected. Since potential is used as a measure of distance into the oxide, it is an additional requirement that the linear relationship between reanodization potential and distance be maintained independent of the current density used. In cases where initial potential drop and/or potential overshoot are observed, this condition may not be fulfilled. The observed potential has to be corrected before it can be used as a linear measure of distance into the oxide. While the corrections can be carried out, they were not necessary in the cases discussed in this paper.

In order to establish experimentally whether the above assumptions were justified, a group of RAC's were measured with current densities varying from 0.05 to 1.0 mA/cm^2. The specimen was of the type illustrated in Fig. 2, curve D (0.1M H_3PO_4, 160V, 10^{-5} Torr, 500°C, 120 min) and exhibited three sections with the characteristic slopes related to the outer, phosphorous-containing oxide, the inner phosphorous-free oxide, and continued anodization. The transition between different slopes occurred, on the potential scale, at points V_m and V_A with V_m indicating the boundary of the P-containing oxide and V_A the boundary of the previously formed anodic oxide. The charges required to reach these points were q_m and q_A, respectively. The experimental results have been summarized in Table I. The ratio V_m/V_A measuring the fraction of P-containing oxide was found to be close to 0.5 for all current

Table I. Characteristic voltage transition points and reanodization charge as a function of current density

C.D., mA/cm^2	V_m/V_A	q_m, mC/cm^2	q_A, mC/cm^2	q_m/q_A
0.05	0.50	11	12.7	0.86
0.1	0.50	11.3	13	0.87
0.2	0.50	10.8	12.2	0.88
0.5	0.505	10.3	12	0.86
1.0	0.505	10.1	11.8	0.86

densities. The charge required to reach V_m was $q_m = (10.7 \pm 0.44)$ mC/cm^2 and the charge to reach V_A was $q_A = (12.3 \pm 0.45)$ mC/cm^2. For five current densities varying by a factor of 20 (0.05-1 mA/cm^2), the charges q_m and q_A measured to V_m and V_A, respectively, were independent of current density within a standard deviation of less than $\pm 5\%$ of the average charge.

The constancy of the ratio of the charges q_m/q_A together with the constancy of the corresponding voltage ratio demonstrated that any current density dependent effects during reanodization acted equally on the outer and the inner oxide. The inclusion of phosphorous in the outer layer and its higher degree of reduction compared to the inner oxide had no effect on the measurement of position in the oxide by means of potential, as long as it was expressed as a fraction of V_A. Absolute distance measurements require a calibration of the potential scale by optical measurements, for example, since the determination of V_A from RAC's is dependent on current density.

Repeatability of the effect of heat-treatment.—It was shown that the incorporation of phosphorous into an outer part of the oxide film was responsible for a greater loss of oxygen during vacuum heat-treatment than would occur under similar conditions in the presence of sulfur, or the absence of any foreign ions. The increased loss of oxygen could not be accounted for by assuming that P was incorporated in the form of P_2O_5 and that it was the source of lost oxygen. The P content of Ta_2O_5 was found to be of the order of a few atom per cent (10) when anodization was done in dilute H_3PO_4, while the oxygen loss could amount to a much larger fraction of the total oxygen content of the oxide depending on the conditions of heat-treatment. In whatever form P was incorporated into the oxide during anodization causing increased oxygen loss during heat-treatment in vacuum, the effect should not repeat itself after the first heat-treatment and reanodization if P had been lost during the first vacuum treatment. Figure 6 shows the results of repeated cycles of heat-treatment and reanodization in 0.1M H_3PO_4 for 80 and 160V Ta_2O_5. The partial reduction of the oxide in the outer part of the film clearly repeated itself, even though differences were observed in the degree of reduction. For 160V Ta_2O_5 the trend was for the first heat-treatment to result in a slightly greater loss of oxygen than for subsequent cycles, while the opposite was found for 80V (and lower) oxides. The significance of these trends is not clear; however, the differences are significantly larger than the experimental uncertainty. The result of these experiments was that phosphorous which caused the increased loss of oxygen was not removed during repeated heat-treatments in vacuum.

Effect of heat-treatment on the structure of tantalum oxide.—Anodic tantalum oxide is amorphous and its structure has been described as glasslike (3). Electron and x-ray diffraction patterns show only very diffused rings from which an upper limit of about 10Å has been estimated as the size of microcrystals, if indeed there are any. Nothing is known about their structure and whether they can be considered as nuclei of any of the known crystalline modifications of Ta_2O_5. In the context of this study structural changes during heat-

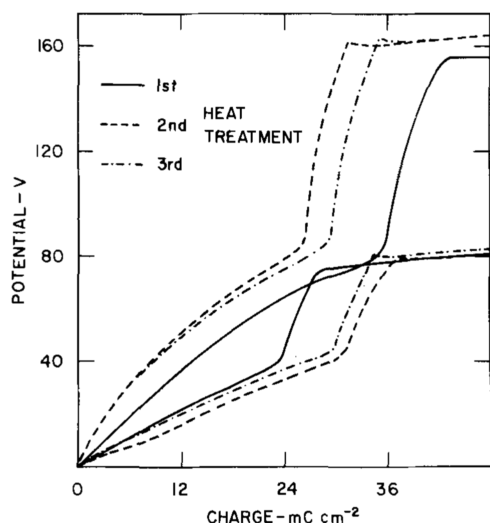

Fig. 6. RAC's for three cycles of heat-treatment and reanodization. Anodization: 0.1M H_3PO_4, 0.3 mA/cm$_2$, 80 and 160V, respectively. Heat-treatment: 500°C, 90 min, 10^{-5} Torr. Reanodization: 0.1M H_3PO_4, 0.2 mA/cm, 80 and 160V, respectively.

treatment had to be considered since the ionic charge consumed during reanodization could have been related to changes in the structure of the oxide. For example, if microcrystals were in fact present and could act as nuclei for the growth of crystalline oxide, then heat-treatment might lead to increased crystallinity of the oxide. The ionic charge might then be required to fill gaps between crystalline areas. If microcrystals were absent or could not act as nuclei, then nucleation would have to occur before any recrystallization could take place. In this case, there would be little reason for ionic charge consumption unless crystallization occurred during reanodization itself. Light and electron microscopy, as well as electron reflection diffraction, were applied to oxide films after heat-treatment at 10^{-5} Torr in the temperature range of 650°C for several hours. No changes in oxide topography or any significant sharpening of electron diffraction patterns could be observed which would indicate recrystallization of existing amorphous oxide. It was, therefore, concluded that no significant structural changes had taken place during heat-treatment in vacuum and that ionic charge could not have been consumed in any structure related phenomenon.

Mechanism of reanodization.—The formation of tantalum oxide is a high-field process and involves the migration of both oxygen and tantalum ions through the existing oxide (2, 16). The migration of the latter leads to oxide formation at the oxide/electrolyte interface and results in the incorporation of ions from the electrolyte into oxide growing at this interface (11). Oxygen migration leads to oxide formation at the oxide/metal interface. At constant current, the voltage increases linearly with thickness and the electric field is constant. After heat-treatment in vacuum and some loss of oxygen the anodic oxide as a whole becomes electronically conductive, as evidenced by reanodization curves starting from very low voltage. Reanodization starts at the electrolyte/oxide interface and proceeds inward toward the metal. Ionic migration can only occur in such parts of the oxide which have been restored or the required high field could not be established. The absence of homogeneous electron injection from the electrolyte shows that the properties of the electrolyte/oxide interface of restored and original oxide are the same.

It is proposed that the mechanism of reanodization may be similar to that of anodization with the difference that no tantalum ions enter the oxide from the tantalum substrate until the existing reduced oxide has been restored in its entirety. It can be assumed that both tantalum and oxygen ions migrate during reanodization. In this case Fig. 7 shows, schematically, the partially restored oxide. Distance is expressed as a fraction of the total oxide thickness, which extends from $x = O$ (electrolyte/oxide interface) to $x = 1$ (oxide/metal interface).

After partial reanodization to a depth x_2, the restored oxide consists of three layers: the outermost layer from $x = O$ to x_1 resulting from the migration of tantalum ions from the reduced oxide to the electrolyte/oxide interface (reaction I). These ions represent part of the metal excess in the reduced oxide over the stoichiometric composition of Ta_2O_5. The formation of "fresh" tantalum oxide at the electrolyte/oxide interface can be expected to proceed under further incorporation of ions from the electrolyte. The second layer consisting of restored stoichiometric oxide extending from x_1 to x_2 results from the migration of oxygen ions from the electrolyte/oxide interface inward (reaction II) and, at the same time, the migration of tantalum ions outward (reaction I). In reaction II oxygen ions combine with excess tantalum at the boundary x_2 between restored and reduced oxide. In the third layer consisting of reduced oxide and extending from x_2 to $x = 1$, the current is carried by electrons. The migration of oxygen does not lead to the formation of "fresh" oxide as does the migration of tantalum ions since it replaces oxygen in the existing oxide. For this reason no additional oxide free of inclusions is formed.

In the process of reanodization, the total oxide thickness remains constant until the restoration reaches the oxide/metal interface. At this point, additional oxide is formed and tantalum ions are added from the substrate. For these reasons, fresh oxide formed by tantalum ion migration during reanodization is oxide formed from metal excess in the reduced oxide by a change of place of metal ions between reduced oxide and the oxide/electrolyte interface. The charge that is measured as a function of potential is the result of the sum of the partial ionic current densities.

The measured voltage across the restored oxide is the sum of voltage drops across the fresh and the restored oxide. It appears reasonable to assume that the field in the two kinds of oxide is of comparable magnitude. In addition, it can be assumed that the transport number for cation migration during reanodization is similar to that during anodization ($n_{Ta} \approx 0.5$). This means that about half of the metal excess existing after heat-treatment would be converted into fresh oxide. Since the integral reanodization charge was, typically, of the order of one tenth or less of the corresponding anodization charge to the same voltage (see Fig. 2, curve D) one estimates the voltage equiva-

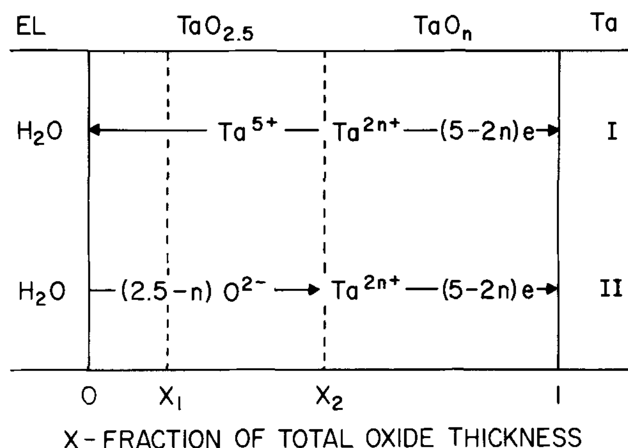

Fig. 7. Schematic diagram of reactions occurring during reanodization after heat-treatment in vacuum.

lent of the thickness of fresh oxide to about one twentieth or less of the total anodization voltage. This means that any differences in the potential scale arising from fresh oxide are completely negligible within the experimental error.

Oxidation state of tantalum oxide.—Reanodization curves of the type shown in Fig. 2, curves C-F can be used to establish the profile of the oxidation state n of heat-treated TaO_n. This is possible since the position in the oxide is related directly to the reanodization voltage while the measured charge represents the amount of oxygen lost during heat-treatment. It should be noted that corrections are required in the presence of initial potential drop and potential overshoot. However, this problem does arise in cases of strong reduction in vacuum which is the case for all examples presented in this paper.

The procedure for deriving the profile of the oxidation state of TaO_n as a function of distance from the outer interface into the oxide is straightforward once a correct potential-charge curve has been obtained. It is based on a point by point comparison of the slope y of a particular RAC with the slope y_o of the anodization curve. The rate of continued anodization after complete reanodization of the heat-treated oxide is identical with the rate of anodization of tantalum. (It is important to measure y_o sufficiently far from V_A to exclude any influence of oxygen dissolved in the substrate during heat-treatment.) The slope $y(V_i)$ of the reanodization curve at potential V_i was obtained by numerical differentiation of the reanodization curve. With V_A as a measure of total oxide thickness, the distance into the oxide was expressed as a fraction of the total oxide thickness $x = V/V_A$. The oxidation state was calculated from Eq. [1]

$$n(x) = 2.5(1 - y_o/y\ (x)) \qquad [1]$$

where y_o = rate of anodization ($Ta \rightarrow Ta_2O_5$) ($V\ mC^{-1}\ cm^2$), y = rate of reanodization ($TaO_n \rightarrow Ta_2O_5$) ($V\ mC^{-1}\ cm^2$), V_A = anodization voltage, and x = fraction of total oxide thickness (from el/ox interface) measured in terms of reanodization voltage.

Accuracy of oxidation state profiles.—The limitations on the accuracy of the electrochemical determination of reanodization potential and charge have already been discussed. Once potential-charge curves have been obtained the derivation of the oxidation state profile becomes a mathematical operation which can be done with the desired accuracy. For experimental reasons, the determination of the oxidation state becomes the more accurate the higher the oxidation state of TaO_n after heat-treatment is. [A reanodization slope which is double the anodization slope means that n has reached an oxidation state (n = 1.25) which is already half the maximum (n = 2.5). Compare this to the change in n from 2.25 to 2.47 for a change in the reanodization slope form 10 to 100 times the anodization slope.]

For constant current density, y and y_o are measured with about the same absolute error Δy, causing the greater uncertainty with low values of y. For this reason, relative changes at high oxidation states can be determined with high accuracy since y_o can then be considered constant, in spite of the relatively large error.

Somewhat greater uncertainty may exist at the outer and inner limits of the profile. Near the outer interface of the oxide, electronic current would be most noticeable which would result in an apparent decrease of oxidation state (Fig. 3). The absence of this condition has been confirmed by print-out tests for all profiles given in this paper. Near the inner interface, the accuracy may be affected by the presence of some residual effect of the potential overshoot even in cases of substantial reduction as defined earlier. This may increase the error in V_A slightly and, at the same time, make the gradient to appear somewhat steeper than it was in reality. It is estimated that because of the combined sources of error $x = V/V_A$ was accurate to within about 5% only and the profile became difficult to derive within about the same percentage of the oxide/metal interface.

Profiles of the Oxidation State of TaO_n after Heat-Treatment

Anodization in 0.1M H_3PO_4.—Ta/Ta_2O_5 specimens were prepared by anodization to 160V in 0.1M H_3PO_4. Heat-treatment was carried out at 500°C, 10^{-5} Torr, for 15, 90, 180, and 360 min. The profiles of the oxidation state shown in Fig. 8 were obtained from reanodization curves (*e.g.*, Fig. 2 curve D) measured at a current density of 0.2 mA/cm^2.

The sequence of four profiles illustrates the increasing loss of oxygen as a function of the time of heat-treatment. As was shown before, the presence of phosphorous in the outer half of the oxide caused the rate of loss of oxygen to increase over that observed in the inner oxide. For this reason, an abrupt change in oxidation state was observed near the center of the oxide and the segments of the oxidation state profiles of the two layers showed characteristic differences with time of heat-treatment. In the inner oxide a gradient of $n(x)$ toward the metal was observed which changed only slowly with time. The direction of the gradient indicated that oxygen was lost to the metal substrate.

In the outer oxide a steeper gradient toward the inside was found after 15 min of heat-treatment. The direction of the gradient again indicated loss of oxygen to the metal. The oxidation state at the electrolyte (atmosphere) oxide interface remained at its maximum, $n(x = O) = 2.5$. The oxidation state of the outer oxide was reduced in large part below that of the inner oxide because of the presence of phosphorous in the former. However, oxygen seemed to have diffused mainly to the substrate. The profile measured after 90 min of heat-treatment showed a further reduction of the oxidation state of the outer oxide. A gradient toward the inside remained while $n(x = O)$ dropped to a lower value than previously observed. After 180 min a gradient toward the atmosphere/oxide interface appeared in addition to the gradient toward the metal. At the same time part of the profile of the outer oxide became nearly horizontal, indicating constant $n(x)$. After 360 min $n(x)$ had become constant throughout the outer oxide with an oxidation state approaching TaO_2. It should be noted that this was not an equilibrium composition. Further changes in the profile and the oxidation state of both the outer and inner oxide occurred with continued heat-treatment. However, these further changes occurred much more slowly which gives reason to consider the profile

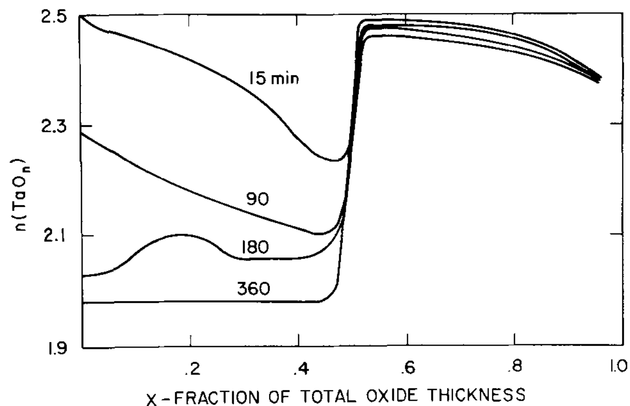

Fig. 8. Profiles of the oxidation state of TaO_n after heat-treatment in vacuum. Anodization: 0.1M H_3PO_4, 0.3 mA/cm^2, 160V. Heat-treatment: 500°C, 10^{-5} Torr, for times given in graph.

reached after 360 min as a quasi-stationary state. The time sequence of oxidation state profiles for anodic Ta_2O_5 anodized in 0.1M H_3PO_4 can serve as a basis for the elucidation of the kinetics of the reduction of tantalum oxide, a task which goes beyond the scope of this paper.

Anodization in 0.1M H_2SO_4.—Ta/Ta_2O_5 specimens were prepared by anodization in 0.1M H_2SO_4 to three different thicknesses: 40, 80, and 160V. The experimental conditions of heat-treatment were 500°C, 10^{-5} Torr, and 120 min. RAC's were measured as in the previous case and oxidation state profiles shown in Fig. 9 were computed from the potential-charge curves.

A major difference between the profiles of Fig. 8 and 9 is the absence of a duplex layer structure in the case of anodization in H_2SO_4. Even though some sulfur may be incorporated into the oxide, it appeared not to have any effect on the rate of oxygen loss during heat-treatment. For this reason, no discontinuity in the $n(x)$ profiles was observed near the center of the oxide.

The profiles shown in Fig. 9 for different oxide thickness after the same time at temperature are, in a way, comparable to profiles of one thickness after different times, such as shown in Fig. 8.

Since changes in the oxidation state result from the exchange of oxygen with the adjoining metal and gas phases, it can be expected that thicker oxides containing larger quantities of oxygen will require longer times than thinner ones to reach a similar profile of the oxidation state. For this reason, the loss of oxygen will have progressed farthest in the thinnest oxide for the same duration of heat-treatment.

The profile of the 160V oxide exhibited a shallow gradient of the oxidation state from the oxide/atmosphere to within a short distance of the oxide/metal interphase. At the former interphase, the oxidation state remained close to its maximum value $n(x = O) \approx 2.5$. Near the metal a steep gradient was observed as expected if oxygen was lost to the metal.

Both of the thinner oxides (80 and 40V) revealed a nearly symmetric profile with gradients of the oxidation state both to the metal and the atmosphere. At both interphases the oxidation state dropped to values below $TaO_{1.5}$. Loss of oxygen to both metal and atmosphere was indicated.

Consecutive anodizations in 0.1M H_3PO_4 and 0.1M H_2SO_4.—The set of three profiles shown in Fig. 10 was obtained from Ta/Ta_2O_5 specimens that had been anodized first in 0.1M H_3PO_4 to $V_A/2$ (20, 40, 80V, respectively), followed by anodization from $V_A/2$ to V_A in 0.1M H_2SO_4 (20 to 40, 40 to 80, and 80 to 160V, respectively). The conditions of heat-treatment were the same as in the previous case. It had been shown previously (11) that anodization of this kind resulted in multilayered structures with the inner half of the oxide free from inclusions while the outer half was made up of clearly separated layers with P and S incorporation in the sequence of anodization, *i.e.*, in this case P-containing oxide buried under S-containing oxide. The profiles of Fig. 10 correspond directly to this oxide structure.

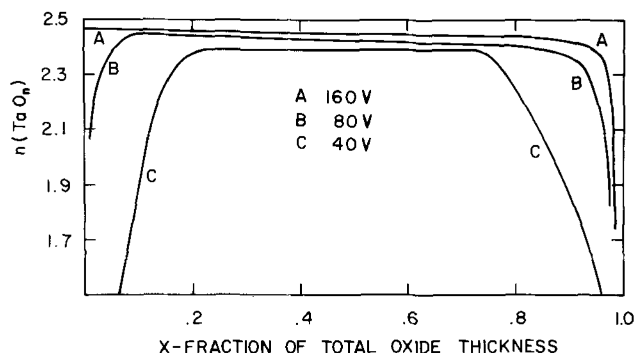

Fig. 9. Profiles of the oxidation state of TaO_n after heat-treatment in vacuum. Anodization: 0.1M H_2SO_4, 0.3 mA/cm^2, voltages as given in graph. Heat-treatment: 500°C, 10^{-5} Torr, 120 min.

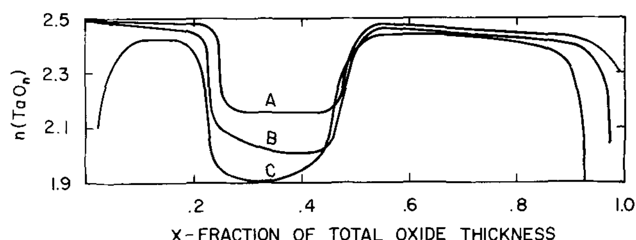

Fig. 10. Profiles of the oxidation state of TaO_n after heat-treatment in vacuum. Anodization (0.3 mA/cm^2): A 0-80V in 0.1M H_3PO_4; 80-160V in 0.1M H_2SO_4; B 0-40V in 0.1M H_3PO_4; 40-80V in 0.1M H_2SO_4; C 0-20V in 0.1M H_3PO_4; 20-40V in 0.1M H_2SO_4. Heat-treatment: 500°C, 10^{-5} Torr, 120 min.

The outermost quarter of the oxide showed the behavior typical of anodization in H_2SO_4, while the following quarter showed a behavior typical of anodization in H_3PO_4. Abrupt changes in the oxidation state were found between the P-containing oxide and both neighboring types of oxide. The inner oxide showed a gradient of the oxidation state toward the metal similar to the corresponding parts in both previous examples (Fig. 8 and 9). The 80-S/80-P oxide revealed a gradient of the oxidation state in the S-containing and inclusion-free oxide toward the metal indicating loss of oxygen to the metal. At the oxide/atmosphere interphase the oxidation state remained at its maximum $n(x = O) = 2.5$. The P-containing oxide sandwiched between these two layers again showed increased loss of oxygen, with constant $n(x)$. The 40-S/40-P oxide lead to a similar profile, with the oxidation state generally lower than in the previous case. In the 20-S/20-P oxide the same trend continued with the exception of a gradient of the oxidation state toward the atmosphere/oxide interphase. This trend paralleled that observed in Fig. 9 for both the 80 and 40V oxides. In the present case, the development of the gradient toward the atmosphere/oxide interphase was delayed and appeared only in the thinnest of the three oxides.

Mechanism of oxide reduction.—The examples of oxidation state profiles given in this paper are intended to illustrate the method of deriving such profiles from galvanostatic reanodization curves. The reaction of anodic tantalum oxide with the adjoining metal and gas phases is a dynamic process which precludes the establishment of true equilibrium conditions, except after very long times which would be impractical experimentally. For this reason none of the profiles given represent equilibrium conditions, at most they can be considered as quasi stationary after the initial more rapid changes.

The profiles given in this paper, for the most part, appear to be determined by the kinetic limitations of the decomposition of anodic tantalum oxide. They depended, in addition to the time of heat-treatment and the thickness of the oxide, on numerous other experimental variables, such as pressure and temperature of heat-treatment and the anodization conditions in cases where effects of incorporated ions were observed. The results of the study of these variables will be published in the future.

At this time, some qualitative conclusions can be drawn concerning the mechanism of oxide decomposition. The inner oxide, which can be considered free of inclusions from the anodization electrolyte, tended to lose oxygen to the metal substrate with the rate determined by diffusion. From the initial gradients of the oxidation state in the outer oxide it can also be concluded that oxygen was lost to the substrate from oxide further removed from the substrate. In the

case of P-inclusions substantial amounts of oxygen originating in the outer oxide had to be transported to the metal by diffusion. However, the profile of the oxidation state revealed that the profile was not determined by the gradient of the oxygen partial pressure in the oxide alone but depended also on the composition of the oxide, especially the presence or absence of phosphorous. This does not mean that different equilibrium oxidation states exist for oxide with phosphorous and without. Available evidence indicates that phosphorous affects only the rate of oxide decomposition, *i.e.*, its kinetics through a catalytic effect and that after sufficiently long times similar quasi-stationary states are reached in all cases.

For the oxide/atmosphere interphase the profiles presented in this paper lead to a surprising conclusion. In those profiles that were measured after short heat-treatment (Fig. 8, 15 min) in the case of anodization in H_3PO_4, or for thick oxides (Fig. 9 and 10: 160V) the oxidation state remained high at the interphase itself while a gradient toward the metal was in evidence. After longer time of heat-treatment, and with thinner oxides, the profiles revealed a pronounced gradient of the oxidation state toward the oxide/atmosphere interphase. These observations can only mean that anodic tantalum oxide can lose oxygen to the atmosphere at the temperature and pressure used during heat-treatment. The initially high oxidation state at the phase boundary itself suggests a rate-limiting phase boundary reaction. After a sufficient degree of reduction diffusion appeared to become rate limiting. In the case of P-containing oxide further complications seem to arise from the stability of transitory intermediate oxidation states as revealed by constant segments of the oxidation state profiles.

The observation of a loss of oxygen in anodic tantalum oxide at oxygen pressures of the order of 10^{-5} Torr and at 500°C shows that a significant difference exists between this oxide and any crystalline modifications of Ta_2O_5 (17). The results given here show that anodic tantalum oxide can under these conditions be reduced to lower oxides with an oxidation state n below 1.5. For β-Ta_2O_5 the deviation from stoichiometry was immeasurably small below 700°-800°C and still estimated to as low as $x = 10^{-9}$ for Ta_2O_{5-x} at about 1200°C and 10^{-11} Torr oxygen pressure (17).

Conclusions

1. Constant current reanodization of anodic tantalum oxide which had been subjected to heat-treatment in vacuum (*e.g.*, 10^{-5} Torr O_2, 500°C) lead to potential-charge curves which indicated that substantial amounts of charge were required to reach the original anodization potential of the oxide. It could be shown that this charge was ionic charge consumed in the restoration of partially reduced tantalum oxide (TaO_n) to its original oxidation state ($TaO_{2.5}$).

2. The restoration of the oxide was proceeding with ionic current efficiencies $i_{ion}/i \approx 1.0$, similar to the anodization of high-purity tantalum. Uniform or non-uniform electronic charge transfer could be shown to be negligible within the sensitivity of the KI-starch print-out method.

3. The rate of loss of oxygen during heat-treatment was found to be strongly dependent on ions which were incorporated into an outer half of the anodic oxide during anodization. Phosphorous incorporation led to increased rate of loss, in the outer part of the oxide, compared to oxide free of ions from the electrolyte (inner part). Oxide anodized in dilute H_2SO_4 showed a behavior similar to oxide free of ions. Oxide anodized, consecutively, in dilute H_3PO_4 and H_2SO_4 resulted in reanodization curves after heat-treatment which corresponded directly to the multilayered structure established by radiotracer experiments (11).

4. From reanodization curves at constant current charge as a function of reanodization potential could be determined. It was shown that reanodization potential was linearly related to distance into the oxide from the electrolyte/oxide interface. Thus, charge required to restore partially reduced tantalum oxide could be measured as a function of distance in the oxide. From such measurements the profile of the oxidation state of heat-treated tantalum oxide across its thickness could be derived.

5. The oxidation state n of partially reduced tantalum oxide was arrived at by comparing the slope of its reanodization curve with that obtained for the anodization of tantalum at the same current density. Several profiles of the oxidation state $n(x)$ (where $x = V/V_A$, distance from the electrolyte/oxide interface) of tantalum oxide anodized in dilute H_3PO_4 and H_2SO_4 were presented in this paper. Additional experimental variables were time of heat-treatment and oxide thickness.

None of the profiles given represented equilibrium conditions. Under certain conditions quasi-stationary states were reached. They represent typical examples of transitory oxidation state profiles after substantial reduction in vacuum.

6. During heat-treatment in vacuum (typically 500°C, 10^{-5} Torr, 120 min) the anodic oxide lost oxygen to the metal substrate, as well as to the atmosphere. This conclusion was based on the direction of the gradients of oxygen deficiency in the oxidation state profiles.

7. The observed deviations from stoichiometry in amorphous anodic tantalum oxide resulting from heat-treatment at temperatures between 300° and 700°C and at pressures of the order of 10^{-5} Torr are far larger than expected for tantalum oxide in the crystalline state (17). Little if any tendency for recrystallization was found for anodic oxide under the given experimental conditions. Both observations indicate that amorphous oxide may be more fundamentally different from crystalline oxide than was assumed in the past. It is expected that further investigations of its behavior during heat-treatment, especially the kinetics of reduction and oxidation, will help to further clarify some of these differences.

Acknowledgment

The author thanks Mr. P. Orthmann for his skillful assistance with the experiments and Dr. N. I. Jaeger for valuable comments on this paper.

$NaLnF_4$:Yb^{3+},Er^{3+} (Ln:Y,Gd,La): Efficient Green-Emitting Infrared-Excited Phosphors

Tsuyoshi Kano, Hajime Yamamoto, and Yoshiro Otomo

Central Research Laboratory of Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

Hexagonal $NaLnF_4$:Yb^{3+},Er^{3+} (Ln:Y,La,Gd) was found to be an efficient green-emitting phosphor with infrared excitation. It was prepared by firing a mixture of Na_2SiF_6 and coprecipitated $Ln_{1-y-z}Yb_yEr_zF_3$ at 630°C in an argon atmosphere. The optimum firing condition of $NaYF_4$:Yb^{3+},Er^{3+} was revealed to lie in the region where (*a*) the decomposition reaction $Na_2SiF_6 \rightarrow 2NaF + SiF_4$ is complete, (*b*) liquid NaF-$NaY_{1-y-z}Yb_yEr_zF_4$ and hexagonal $NaY_{1-y-z}Yb_yEr_zF_4$ are coexistent, and (*c*) the phase transition of $NaY_{1-y-z}Yb_yEr_zF_4$ from hexagonal to cubic does not occur. When pumped by a Si-doped GaAs diode, properly prepared $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ is 4 ~ 5 times as bright as the commercially available LaF_3:Yb^{3+},Er^{3+}.

Many visible-emitting, infrared-excited phosphors have been reported as candidates for up-conversion devices. Typical examples are LaF_3:Yb^{3+},Er^{3+} (1-3), YF_3:Yb^{3+},Er^{3+} (1, 2, 4), $BaYF_5$:Yb^{3+},Er^{3+} (5) as green-light emitting and YOCl:Yb^{3+},Er^{3+} (6), Y_2O_3:Yb^{3+},Er^{3+} (7) as red-light emitting phosphors. In Y_3OCl_7:Yb^{3+},Er^{3+} (6), red and yellow visual response have been reported at high and low Yb concentrations, respectively.

Among *IR*-to-visible converting phosphors, rare earth fluorides containing Yb^{3+} and Er^{3+} were the first efficient series studied and the improvement of efficiencies has been reported on BaF_2-YF_3 systems containing Yb^{3+} and Er^{3+}. A series of experiments in search of more efficient host materials on the binary fluorides doped with Yb^{3+} and Er^{3+} is a natural consequence in the course of the development of *IR*-to-visible converting phosphors. As constituent ions to be substituted by Yb^{3+} and Er^{3+}, Y^{3+}, Gd^{3+}, and La^{3+}, abbreviated as Ln, are admittedly the first candidates.

In selecting another constituent element besides Ln in binary fluorides, it is of experimental convenience to choose the elements of which fluorides are stable solids having melting points not too low to be used as starting materials or intermediate products for firing. The elements having higher valency than 3 are thus excluded in the first stage because the fluorides of these elements are mostly gases, liquids, or low melting solids at ordinary conditions. This aspect restricts the elements under consideration to monovalent, divalent, and trivalent ones. Of the binary fluorides of these ions and Ln, alkali metal-rare earth fluorides are the systems where few studies have been made on the *IR*-to-visible conversion using Yb^{3+} and Er^{3+}.[1] They have been reported as diluents to YbOCl and related compounds to have tunable emission of green to red depending on excitation intensities (8). *IR*-to-visible conversion in $LiYF_4$ has been reported using Yb^{3+} and Ho^{3+}. The measured efficiency, however, was an order of magnitude smaller than for YF_3:Yb^{3+},Er^{3+} (9). It is not clear whether the lack of efficient phosphors reported in this system is simply due to incomplete investigations or has some physical basis. One possible reason is that the alkali metal-rare earth fluoride systems generally have complex phase diagrams (10) which make it difficult to obtain well-crystallized single-phase materials. As is shown in the detailed phase diagram of NaF-YF_3 in Fig. 1 (11), for example, the transition in $NaYF_4$ between hexagonal and cubic phases occurs at 691°C. If one wants to fire phosphors at temperatures lower than the transition temperature in order to have purely single-phase materials, an elaborate technique will be required to obtain well-crystallized homogeneous products because of the low firing temperatures. This requirement is met by the use of the decomposition reaction of Na_2SiF_6 and the selection of correct firing temperature and mixing ratio as described in this paper.

The new synthetic method makes it possible to obtain fluoride phosphors at comparatively low firing temperature without using hydrofluoric acid gas. This firing condition contributes much to the ease of preparing fluoride phosphors, because conventional quartz tubes can be used. The characteristic firing condition of the method in this work is compared with the

reported methods of preparing typical *IR*-to-green converting phosphors in Table I.

Experimental

Powder samples were prepared by firing the mixtures of Na_2SiF_6 (Morita Chemical Industry Company, Ltd.) and $Ln_{1-y-z}Yb_yEr_zF_3$. The latter was coprecipitated from an aqueous nitrate or chloride solution of the proper composition by hydrofluoric acid and dried in air at 120°C for a day. The raw materials were fired in covered platinum crucibles contained in a quartz tube in a purified argon atmosphere. The purified argon was obtained by using a rare gas purifier (Japan Pure Hydrogen Company, Inc.). The gaseous SiF_4 evolved during the firing was trapped by aqueous NaOH solution. The aqueous Ln (containing Yb, Er) nitrate and chloride solutions were obtained by dissolving 99.999% pure oxides (Shin-Etsu Chemical Industry Company, Ltd.) in nitric acid and hydrochloric acid, respectively.

The relative luminescence intensities of the powder samples were measured under infrared excitation using a 1 kW tungsten-iodine lamp with a Toshiba *IR*-D1B filter as an exciting light source and RCA-1P22 photomultiplier as a detector. An interference filter with a window around 546 nm ($\Delta\lambda_{1/2} < 11$ nm) in front of the detector selected the green luminescence. For the comparison of luminescence intensities, thick powder layers (*ca.* 150 mg/cm²) were prepared on metal patches with a butyl acetate binder and were mounted at an identical position. The spectral energy distribution of the luminescence was measured with a Spex 1400 II grating monochromator using a RCA-7265 photomultiplier as a detector.

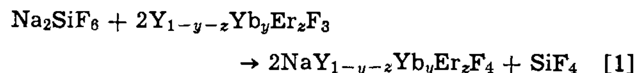
Differential thermal analysis was carried out by using the apparatus (M8006) made by Rigaku Denki Company, Ltd.

The power conversion efficiency of the phosphor-coated light-emitting diode was obtained relative to GaAsP light-emitting diode whose efficiency had been determined elsewhere in this laboratory. The ratio of visible light output of these two different types of light-emitting diodes was obtained by comparing the spectral energy distribution of the emission of diodes set in an integrating sphere.

The brightness of the phosphor-coated diodes was measured by using a Pritchard photometer (Photo Research Company).

Results and Discussion

We obtained $NaY_{1-y-z}Yb_yEr_zF_4$ by reacting Na_2SiF_6 with coprecipitated $Y_{1-y-z}Yb_yEr_zF_3$ in an argon atmosphere for 1 hr at various temperatures according to the reaction



$$Na_2SiF_6 + 2Y_{1-y-z}Yb_yEr_zF_3 \rightarrow 2NaY_{1-y-z}Yb_yEr_zF_4 + SiF_4 \quad [1]$$

With y and z arbitrarily chosen to be 0.19 and 0.01, respectively, the mixing ratio of Na_2SiF_6 and $Y_{0.80}Yb_{0.19}Er_{0.01}F_3$ and the firing temperature were varied to determine the optimum conditions. The relative green luminescence intensities of the fired mixtures upon *IR* excitation are shown on the NaF-YF_3 phase diagram (Fig. 1).[2] The cubic phase in the high-temperature regions was found, by x-ray analysis, not to be retained at room temperature with the cooling rate of about 50°C/hr that we employed. As is evident from Fig. 1, the most efficient phosphors can be prepared in region D where hexagonal $NaYF_4$ and the liquid are coexistent. Thermal charactersitics related to phosphor preparation in the temperature region concerned are shown in Fig. 2. In this figure, the thermal decomposition curve of Na_2SiF_6 (a) and the differential thermal analysis of the fired product (c) are compared with the dependence of the luminescence intensity of the fired products (optimum mixing ratio) on the firing temperature (b). The data shown in Fig. 2 (b) and (c) are on the phosphor samples having the optimum concentration of Yb^{3+} and Er^{3+} (see Fig. 3 and 4). As is shown in Fig. 2(a), the decomposition of Na_2SiF_6 begins around 500°C and is complete around

[2] It is to be pointed out that the temperature scale of Fig. 1 is shifted upward relative to the scale appropriate to the actual system studied. As the phase diagrams of the sodium fluoride rare earth trifluoride systems (10) show that the phase transition temperatures decrease with the decrease of the ionic radii of the rare earth elements, the phase transition temperatures of NaF-YF_3 systems are expected to decrease by the partial substitution of Yb and Er for Y. The actual location of the optimum point in the phase diagram was confirmed by the thermal measurement (Fig. 2).

(b) Relative luminescence intensity of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ under *IR* excitation *vs.* firing temperature at the optimum mixing ratio. (c) Differential thermal analysis of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ + 0.2NaF (10°C/min).

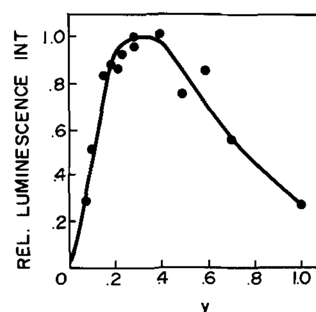


Fig. 3. Relative green luminescence intensities of $NaY_{(0.99-y)}Yb_yEr_{0.01}F_4$ with *IR* excitation.

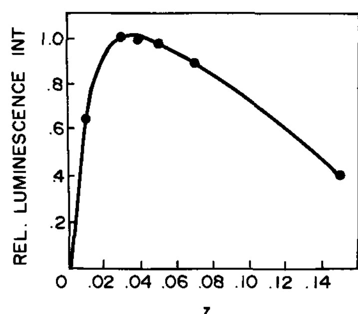

Fig. 4. Relative green luminescence intensities of $NaY_{(0.61-z)}Yb_{0.39}Er_zF_4$ with *IR* excitation.

650°C when the temperature is increased at the rate of 10°C/min. The observed weight loss closely corresponds to the calculated weight of SiF_4 gas evolved according to reaction [2]

$$Na_2SiF_6 \rightarrow 2NaF + SiF_4 \quad [2]$$

The endothermic peak around 610°C in Fig. 2(c) corresponds to the formation of eutectic liquid phase of $NaYF_4$ and NaF at 638°C. This correspondence was confirmed by the DTA experiment. When the same sample was etched by dilute HCl to remove NaF, the endothermic peak around 610°C was completely removed. The endothermic peak around 650°C corresponds to the transition from hexagonal $NaY_{1-y-z}Yb_yEr_zF_4$ to cubic $NaY_{1-y-z}Yb_yEr_zF_4$. Upon cooling, the inverse transition occurs around 540°C as is shown by the exothermic peak.[3] The observed exothermic transition (cubic-hexagonal) is consistent with the result of x-ray analysis described previously. In the case of $NaYF_4$, an endothermic peak at 690°C due to the phase transition from hexagonal to cubic has been reported (12). The comparison of the transition temperatures observed on $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$-NaF system with those reported on $NaYF_4$-NaF system shows that the transition temperatures are lower in the former than in the latter.

From the above discussions, it is concluded that the optimum firing temperature at 630°C lies in the temperature region where (*i*) the decomposition of Na_2SiF_6 is just complete, (*ii*) a liquid phase is formed, and (*iii*) a cubic phase is not formed.

These conditions may favor the formation of good luminescent crystals of the hexagonal phase because (*i*) the SiF_4 gas evolved is expected to remove oxygen impurities which are known to be strong quenchers of *IR*-excited green luminescence, (*ii*) the intermediate NaF would readily react with $Y_{1-y-z}Yb_yEr_zF_3$ as is usual for freshly formed products of decomposition reactions, (*iii*) the liquid phase would behave as a flux to help crystal growth, and (*iv*) the product is free from inhomogeneity arising from quenching of the high-temperature cubic phase and from imperfections produced by the phase transition in the cooling process. An experimental support of (*i*) is provided by the fact that efficient phosphors are obtained by firing mixtures of Na_2SiF_6 and $Y_{0.57}Yb_{0.39}Er_{0.04}F_3$ in platinum crucibles having extra Na_2SiF_6 at the bottom. The extra Na_2SiF_6 charged at the bottom of the crucible significantly contributes to the reproducible formation of efficient phosphors, although the decomposition product NaF at the bottom does not contact and react with $Y_{1-y-z}Yb_yEr_zF_3$.

In addition to the use of Na_2SiF_6 as a starting material, another essential point is to use coprecipitated $Y_{1-y-z}Yb_yEr_zF_3$. If one uses mixtures of separately precipitated YF_3, YbF_3, and ErF_3, one can obtain only gray-colored samples whose luminescence intensities are smaller by a factor of five than those of samples prepared from coprecipitated fluorides.

[3] The small exothermic peak observed around 590°C is probably due to the local solidification of the liquid because it is removed by etching the sample.

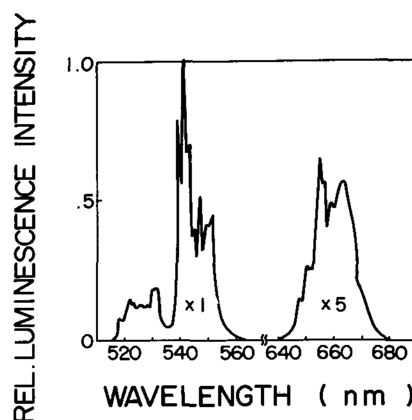

Fig. 5. Spectral energy distribution of the luminescence of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ with *IR* excitation at room temperature.

As is shown in Fig. 1, the most efficient phosphors can be prepared not from stoichiometric mixtures but from those having some excess Na_2SiF_6. The resulting excess NaF contributes to the formation of a liquid phase that helps crystal growth. The fired samples contain a small amount of NaF and its removal by solution in water or acids did not change the luminescence intensities significantly.

The efficiency of the fired products was found to be sensitive to the firing program which controls the decomposition rate of reaction [2]. A typical firing program is as follows: the starting mixtures (1.2 Na_2SiF_6 + 2$Y_{0.57}Yb_{0.39}Er_{0.04}F_3$ put in platinum crucibles having 0.3 Na_2SiF_6 at the bottom) are heated to 630°C in about 1 hr, kept at that temperature for 3 hr, and cooled to room temperature in about 10 hr.

The efficient phosphors obtained were found by x-ray analysis to have the hexagonal gagarinite structure in accord with the phase diagram of $NaYF_4$. A spectroscopic analysis of the phosphor revealed *ca.* 0.1 w/o (weight per cent) of Si as a major impurity.

The dependences of luminescence intensities of $NaYF_4$:Yb^{3+}, Er^{3+} on the concentration of Yb^{3+} and Er^{3+} are shown in Fig. 3 and Fig. 4. The optimum concentrations of Yb^{3+} and Er^{3+} are 30 ~ 40 m/o (mole per cent) and 3 ~ 4 m/o, respectively.

The spectral energy distribution of the luminescence of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ upon *IR* excitation is shown in Fig. 5. The ratio of the intensity of green luminescence to that of red luminescence decreases with the increase of exciting *IR* intensity. The data shown in Fig. 5 were measured on the phosphor coated on a domed Si-doped GaAs diode (10% eff.) operated with 50 mA current. The green and red emission originate from the electronic transitions, $^2H_{11/2}$, $^4S_{3/2} \rightarrow {}^4I_{15/2}$ and $^4F_{9/2} \rightarrow {}^4I_{15/2}$ of Er^{3+}, respectively. The emission around 540 nm due to the transition $^4S_{3/2} \rightarrow {}^4I_{15/2}$ is dominant and the resulting emission appears pure green. The lifetime of the green emission ($\tau_{1/e}$) was observed to be 1.2 msec under *IR* excitation with a Si-doped GaAs diode.

Table II. Relative luminescence intensities of $NaLnF_4$ (Ln:Y,Gd,La,Yb,Er,Ho) with *IR* excitation

Composition	Rel. lum. int.
$NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$	400-540
$NaY_{0.80}Yb_{0.19}Er_{0.01}F_4$	170
$NaLa_{0.80}Yb_{0.19}Er_{0.01}F_4$	155
$NaGd_{0.80}Yb_{0.19}Er_{0.01}F_4$	135
$NaY_{0.40}Gd_{0.40}Yb_{0.19}Er_{0.01}F_4$	140
$NaY_{0.32}Gd_{0.24}La_{0.24}Yb_{0.19}Er_{0.01}F_4$	145
$NaY_{0.80}Yb_{0.19}Ho_{0.01}F_4$	23
LaF_3:Yb, Er*	100

* The typical *IR*-to-visible conversion phosphor used on the commercially available green-emitting diode of the *IR*-to-visible conversion type (GE-SSL-3).

Table III. Variations of conversion efficiencies of phosphors kept in various conditions

Composition	Condition	Period	Luminescence intensity relative to the phosphor just fired (%)
$NaY_{0.80}Yb_{0.19}Er_{0.01}F_4$	Kept in descicator with silicagel	118 days	100
	Kept in closed vessel with water	118 days	100
$NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$	Kept at 100°C in air	4 days	97
	Boiled with water then kept at 100°C in air	20 min 1 day	88
	Treated with dil. HCl sol.	5 hr	98
	Coated with polystyrene binder on GaAs:Si diode operated with 50 mA current	4414 hr	86*
	Coated with epoxy resin on GaAs:Si diode operated with 100 mA current	3477 hr	91*

* These values include deterioration of GaAs:Si diodes and binders.

Relative luminescence intensities of $NaLnF_4$: Yb^{3+}, Er^{3+} or Ho^{3+} (Ln = Y,Gd,La) prepared by the method described for $NaYF_4$: Yb^{3+}, Er^{3+} are summarized in Table II. The phosphor having the composition of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ was found to be 4-5 times brighter than commercial LaF_3: Yb^{3+}, Er^{3+} on a Si-doped GaAs diode by comparing the green light output of the two phosphors coated on identical diodes. The resultant over-all power conversion efficiency of the green-emitting diode reaches 0.01% with 60 mW (1.2V, 50 mA) d-c power, when the phosphor is coated with polystyrene binder on a 0.6 × 0.6 mm Si-doped GaAs diode[4] having 3% conversion efficiency. When the phosphor is settled from aqueous suspension on a GaAs diode and covered with epoxy resin, the over-all power efficiency of the green-emitting diode increases to 0.02%. The brightness of the phosphor-coated diodes was measured to be 250-350 ft-L[5] at the brightest spot with 100 mA current. In comparing the values of brightness with those of direct light-emitting diodes, it should be taken into consideration that the emitting area of phosphor layers is an order of magnitude larger than that of Si-doped GaAs. The brightness is expected to increase 4-11 times by using 6-10% eff. Si-doped GaAs diodes (13) because the dependence of the green luminescence intensity on the exciting infrared light intensity is quadratic. By coating the phosphor on a 10% GaAs: Si domed diode with glycerin binder, we have obtained a green-emitting diode having over-all power efficiency of 0.2% with 470 mW input d-c power, which is the highest value so far reported on the green-emitting diode of the *IR*-to-visible conversion type.

The conversion efficiency of the phosphor-coated light-emitting diode decreases to ½ when the temperature increases from 25° to 65°C.

The results of test experiments on the stability of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ to heat-treatment in air are shown in Fig. 6. As shown in the figure, the efficiency of the phosphor is not affected by the heat-treatment lower than 400°C in air. Other results of stability tests of $NaYF_4$: Yb^{3+}, Er^{3+} are summarized in Table III. They show that there is no significant degradation of the phosphor under the conditions investigated.

In conclusion, we have succeeded in preparing a new class of efficient and stable infrared-excited phosphors using decomposition reactions. The decomposition reactions evolve nonoxidizing gases and provide intermediate products which are very useful for the formation of efficient fluoride phosphors.

[4] Emission peak: 957 nm.

[5] These values were obtained after thermal equilibrium was attained with the power supply on. The initial brightness was 2.6 times higher than that at thermal equilibrium. The efficiency of the GaAs diode decreased to 2% at thermal equilibrium with 100 mA current.

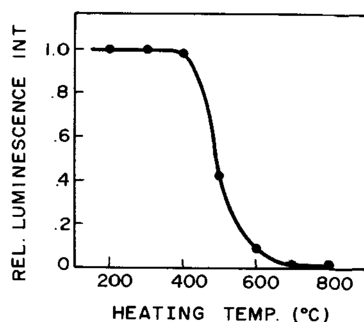

Fig. 6. Relative green luminescence intensities of $NaY_{0.57}Yb_{0.39}Er_{0.04}F_4$ after heating for 2 hr in air.

Acknowledgments

The authors are greatly indebted to A. Suzuki for most of the evaluation experiment, to T. Suzuki for coating phosphors on diodes and evaluating them, and to M. Nakano for preparation of many samples of the phosphors.

Chemical Vapor Deposited Polycrystalline Silicon

M. E. Cowher and T. O. Sedgwick*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Mirror smooth thin films of polycrystalline silicon suitable for FET device processing have been chemically vapor deposited from silane at 650°C on different insulating materials. Hall mobilities of p-type and n-type films have been measured for carrier concentrations between 10^{14}/cc and 10^{20}/cc. Unusually high mobilities, within a factor of two of bulk silicon, were obtained in the 10^{14}/cc to 10^{17}/cc carrier concentration range. *In situ* vapor doping control was irreproducible for carrier concentrations below 5×10^{18}/cc. Evidence from radiochemical analysis, electron microscopy, and x-ray analysis indicates that there is a large concentration of electrically inactive dopant which is postulated to be in the grain boundaries. Undoped polysilicon films could be deposited with resistivities greater than 10^6 ohm-cm.

Polycrystalline Si (poly Si) films are beginning to have a wide spread impact on semiconductor device technology. Bean *et al.* (1) first described the thermal conductivity of thick poly Si films which were to be used for a dielectric isolation scheme for single-crystal Si devices. More recently, poly Si has been used as the gate in a self-aligned gate process in field effect transistor (FET) fabrication (2). A direct antecedent of this paper was the report of the fabrication of a reasonably good FET in a poly Si film by Fa and Jew (3) which brought poly Si into the realm of active device materials. In all probability, poly Si devices will never compete with single-crystal Si devices in applications requiring high speed and high packing density. However, poly Si devices may fill a need in other applications requiring devices to be fabricated over large areas and where single-crystal substrates are not available.

There seems to be general agreement that the smoothest polycrystalline deposits are composed of extremely fine, randomly oriented grains (4-7). Such fine grain deposits have been made most successfully via the pyrolysis of silane at temperatures between 500° and 700°C. Ford *et al.* (6) reported that smaller grains were obtained on Si_3N_4- than on SiO_2-covered substrates in a H_2 atmosphere, but uniformly fine grains were found on both SiO_2 and Si_3N_4 using a He deposition ambient atmosphere. Most workers report an increasing degree of preferred grain orientation and crystallite size as the temperature is increased above 700°C, independent of the chemical deposition system.

There are little data in the literature on the variation of Hall mobility with carrier concentration, especially at low carrier concentration levels. The most extensive data are those of Kamins (8) who reported that in layers grown at 1035°C from silane, the mobility reached a maximum of 40 cm^2/V-sec in p-type samples doped with boron to the 10^{18}/cc level and decreased for both higher and lower doping levels. The mobility peaked similarly in arsenic-doped samples but the maximum mobility was only 30 cm^2/V-sec. With the exception of the diffused samples of Kamins, where a mobility approximately ½ that of bulk is obtained for samples above 10^{19}/cc, reported mobility values have been scarce, irreproducible, and usually a factor of 10 to 100 times below bulk values (1, 6, 9, 10).

Most workers (6, 8, 9, 10) have reported that doping control during growth was very difficult, and in some cases significant amounts of dopant were incorporated into the crystal in an inactive state.

The present study was undertaken to find first, a poly Si deposition process which would produce a very smooth film suitable for standard photoresist device processing, and thus avoid the thick film growth and polish-back technique used by Fa and Jew. Second, the potential for doping during growth and the Hall mobilities of the resulting doped films are evaluated. A model is proposed to account for the unusually high Hall mobilities and irreproducible doping levels found for our samples doped below 2×10^{17}/cc.

Key words: mobility, doping, grain structure, low temperature.

Experimental Procedure

Poly Si films were deposited from SiH_4-H_2 mixtures at temperatures between 600° and 750°C or from $SiBr_4$-H_2 mixtures at 750°-900°C in conventional vertical induction-heated reactors. For a summary of system conditions, see Table I. The set of conditions for each system termed "operating conditions" were employed to deposit all poly Si films for electrical, chemical, and crystallographical analysis. Layers typically 1-3 μm thick were grown on three different substrates; 1.3 μm thermal SiO_2 on Si, fused quartz, and sapphire. All the quantitative data reported in this study were taken on layers 2.0 ± 0.1 μm thick. The films were either undoped or were doped during growth with B_2H_6 (p-type) or with PH_3 (n-type) in the range 10^{14}-10^{20} atoms/cc. The surface quality of the deposited films depended markedly both on substrate preparation procedures and on deposition conditions. The crucial step in the preparation of all substrates was found to be an "aqueous oxidation" (11) in a solution of 3 parts 30% stabilized H_2O_2 to 97 parts H_2O at 90°C for about 20 min just prior to deposition. Since the crystallite size decreased with decreasing temperature, giving rise to smoother surfaces, most depositions were made at the lowest possible temperature. The smoothest films, comparable to good epitaxial Si, were deposited at 650°C in the SiH_4 system on SiO_2. In the $SiBr_4$-H_2 system, the best films (matte surface) were grown at 840°C; depositions below 840°C were avoided because of the tendency of submicron films to be discontinuous. There is a slight degradation of surface quality of the films deposited from SiH_4-H_2 with increasing dopant concentration at 650°C. However, there was no problem obtaining continuous submicron films in this system. Undoped poly Si films deposited from both systems exhibited a measured resistivity of $\geq 10^6$ ohm-cm and

Table I. System conditions for deposition of poly Si films from SiH_4-H_2 and $SiBr_4$-H_2 mixtures

* Operating conditions.

several high-concentration diffusions were made on these undoped samples.

Tallysurf measurements were made across an etched step to determine film thickness. To make electrical measurements on doped samples, six, terminal Hall bars were cut ultrasonically from the wafers, so that the current flow was parallel to the sample surface. Standard d-c Hall measurements were made to determine resistivity, mobility, and carrier concentration. A modified four-point-probe technique was used to measure the resistivity of the undoped samples. A selected number of n-type (phosphorus-doped) samples were analyzed for total phosphorus content using radiochemical analysis. Several p-type (boron-doped) samples were studied for crystallite size, boron precipitation, and preferred orientation using carbon surface replicas, glancing angle x-ray analysis, scanning electron microscopy (SEM), and high-voltage electron microscopy (HVEM).[1] The samples were either cleaved (for SEM) or the substrates were removed by chemical etching and ion milling for (HVEM).

Results

Film morphology and grain structure.—The most important factors in obtaining smooth poly Si films in the SiH_4 system were the use of careful cleaning procedures, especially the peroxide cleaning steps, and the use of low film-deposition temperature. The best deposits were obtained on thermal SiO_2. Of somewhat poorer quality were deposits on fused SiO_2, and the few deposits made on sapphire were distinctly less uniform. The surface quality of deposits on thermal SiO_2 was quite reproducible but any relaxation in the cleaning procedure or inadvertent contamination led to seriously degraded, nonuniform surfaces. Electron micrographs of two poly Si samples grown at 650°C on thermal SiO_2 and doped with boron, one lightly (10^{14}/cc) and another heavily (10^{19}/cc), are shown in Fig. 1. The electron micrographs of carbon surface replicas (A) show the extremely fine-grain texture of the lightly doped sample. This appears as a very highly reflecting surface to the naked eye comparable to good epitaxial Si layers. This photograph was taken in a slightly defected area to show the few large Si grains protruding above the surface which were occasionally seen and which represent the only obvious defects in the surface. A water mark on a wafer or an unclean wafer will give rise to a very high density of such grains. The heavily doped sample shows an over-all rough surface texture due to large grains. Electron diffraction patterns (B) and high-voltage electron transmission micrographs (C) show that the lightly doped sample consists of fairly uniform random grains 250-350Å in size and the heavily doped samples of slightly preferred <110> oriented grains 2000-3000Å in size. The scanning electron micrographs of a fractured edge of the poly Si films show essentially no texture in the lightly doped sample. However, columnar growth does appear in the heavily doped samples. No evidence of a boron-rich phase was observed in any sample using HVEM. These results are summarized in Table II along with data obtained on an intermediate doped sample which exhibited properties intermediate between those found above.

Phosphorus-doped samples deposited at 650°C appeared visually identical to the boron-doped samples

[1] The HVEM pictures were taken by R. M. Fischer and A. Szirmae at the U.S. Steel Fundamental Research Laboratory in Monroeville, Pennsylvania.

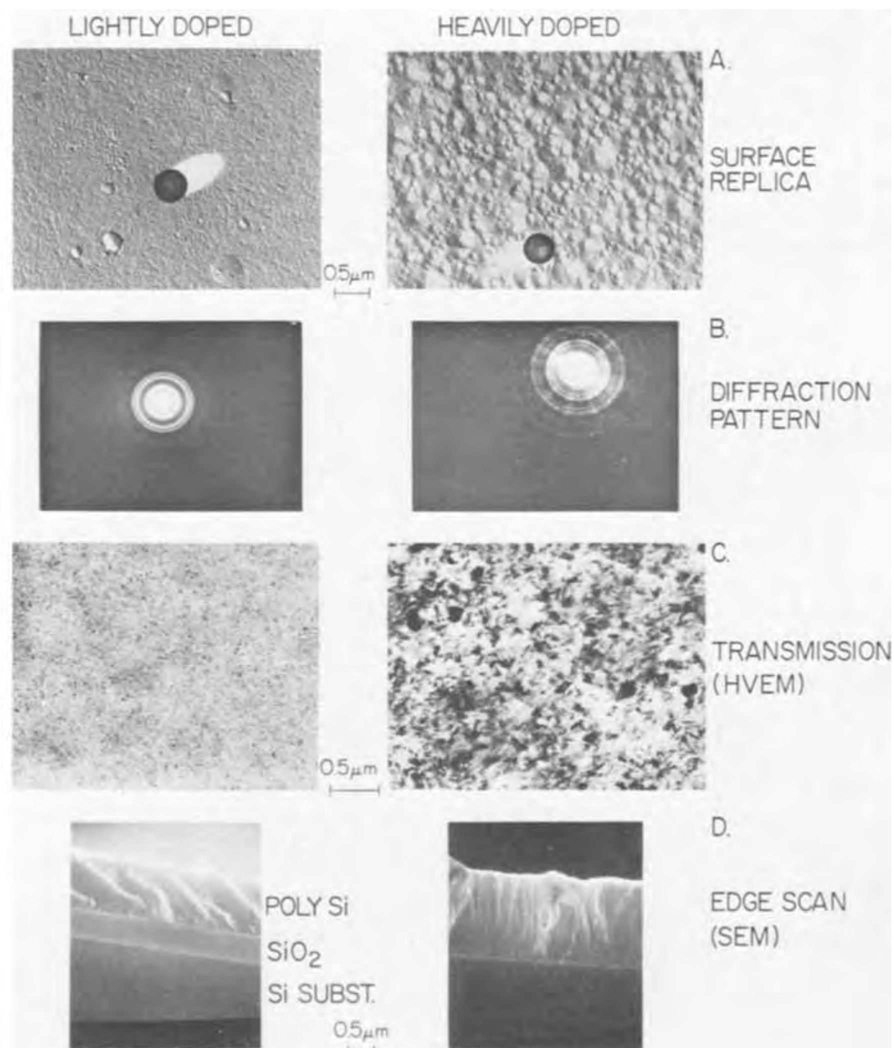

Fig. 1. Film morphology and grain structure of lightly (10^{14}/cc) and heavily (10^{19}/cc) boron-doped polycrystalline silicon grown at 650°C on thermal SiO_2.

Table II. Characteristics of boron-doped poly Si deposited on thermal SiO_2

Surface morphology	Mirror smooth	Slightly dull	Slightly matte
Carrier conc, N_A, cm^{-3}	10^{14}	10^{17}	10^{19}
Grain size, A	250-350	900-1100	2000-3000
Grain orientation	Random	Mostly random	Preferred <110>

as a function of doping level. Although no detailed electron microscope examination of the phosphorus samples was made, the visual similarity and similar results from glancing x-ray diffraction patterns of both phosphorus- and boron-doped samples lead us to believe that the grain structure is similar. The somewhat rougher surface of the phosphorus samples grown at 840°C is presumably associated with larger grain size. The grain structure of the diffused samples was not studied.

Doping during growth.—Most samples were doped during growth with either PH_3 or B_2H_6. Figure 2 shows the electrically active boron dopant or carrier concentration, N_A, of films deposited on both thermal SiO_2 and fused quartz substrates as a function of boron-to-silicon ratio, B/Si, in the vapor. (To avoid confusion in the following, the composition of the vapor is always referred to as a ratio, B/Si or P/Si, and is a pure number, *e.g.*, 10^{-5}. The concentration of carriers or electrically active dopant, N_A or N_D, in the crystal is always referred to on a concentration basis, *e.g.*, 10^{20}/cc.) The N_A values were obtained from Hall measurements. For high doping levels, 5×10^{18}/cc to 2×10^{19}/cc, N_A was proportional to the B/Si ratio as is usually the case and as is shown for boron-doped single-crystal Si grown at high temperature, as indicated by two different curves (Fig. 2, curves A and B) from the literature (11, 12). The highest doping concentration obtained, 4×10^{19}/cc, is close to the solubility limit (13) of boron in Si extrapolated to 650°C. The extremely rapid decrease in N_A below a B/Si atom ratio of $\sim 5 \times 10^{-5}$ is unprecedented as far as we know in a SiH_4 system. In this range it was not possible to predict or control the value of N_A within the range of values from 10^{14}/cc to 5×10^{18}/cc by setting the B/Si vapor phase ratio. The samples grown on fused quartz seem to show the same precipitous decrease of N_A with decreasing B/Si ratio but at a slightly higher B/Si value.

Figure 3 shows the variations of electrically active phosphorous dopant or carrier concentrations, N_D, deposited at 650° and 840°C as a function of the phosphorous to silicon ratio, P/Si, in the vapor. In a manner similar to the boron results, N_D, between 5×10^{18}/cc and 3×10^{19}/cc, is roughly proportional to P/Si. Above 3×10^{19}/cc, N_D is no longer proportional to P/Si but it does depend on P/Si in a manner closely parallel to single-crystal doping curves (Fig. 3, curves A and B) obtained at high temperature (12, 14). The values of N_D drop precipitously when the P/Si atom ratio is decreased below $\sim 5 \times 10^{-5}$. Therefore it was not possible to control doping levels below 5×10^{18}/cc by varying P/Si. There seems to be no essential difference between the data points obtained from deposits made at 840°C in the $SiBr_4$-H_2 system and those obtained at 650°C in the SiH_4-H_2 system. The maximum value of N_D observed agrees well with the solubility limit (15) of phosphorus in Si extrapolated to the two deposition temperatures.

Figure 4 shows the electrically active dopant concentration, N_D, and the total phosphorous dopant concentration, N_D^T, from neutron activation analysis of some samples as a function of P/Si. Some of the samples had N_D values too low to measure. The N_D and N_D^T points joined by dotted lines are for individual samples on which it was possible to make both measurements. N_D^T is found to be proportional to P/Si over the whole range and the data are fit by Eq. [1]

$$N_D^T = P/Si \cdot 35 \times 10^{22} \quad [1]$$

which is drawn as the solid line in Fig. 4. The dramatic drop off in N_D as N_D^T decreases linearly with P/Si is discussed later and a model is postulated (see dashed curve) to describe this phenomenon. The difference between N_D^T and N_D which is N_{GB} is referred to as the electrically "inactive" dopant concentration and is discussed in detail in the section on Doping during growth.

$$N_{GB} = N_D^T - N_D \quad [2]$$

Hall mobility of poly Si doped during growth.—The Hall mobility, μ_H, was obtained from the ratio of the Hall signal and the resistivity as measured at room temperature and is shown for p- and n-type samples respectively in Fig. 5 and 6.

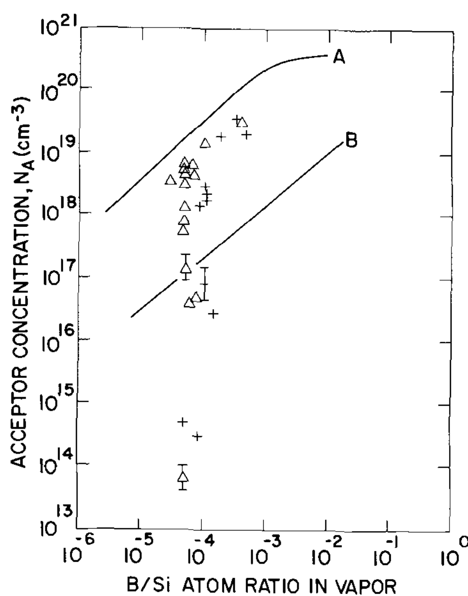

Fig. 2. Acceptor concentration, N_A, vs. B/Si atom ratio in vapor for poly Si samples deposited from SiH_4 at 650°C. △, Thermal SiO_2 substrates; +, fused quartz substrates. Single-crystal doping: -, boron doping of Si from B_2H_6 and $SiCl_4$-H_2 at 1500°K, A (11); B (12).

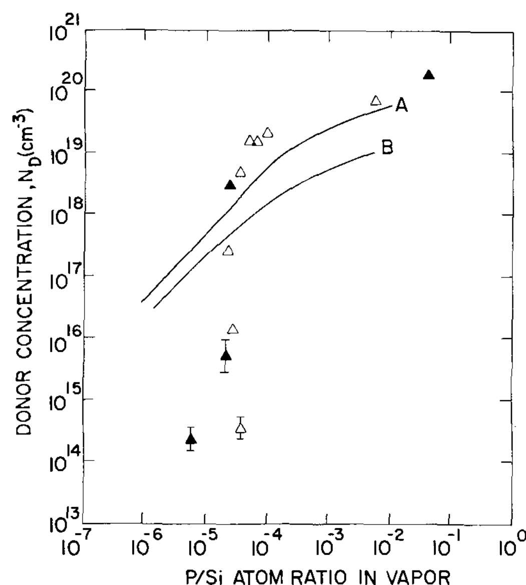

Fig. 3. Donor concentration, N_D, vs. P/Si atom ratio in vapor for poly Si samples deposited on thermal SiO_2 substrates. △ Deposited at 650°C from SiH_4, ▲ deposited at 840°C from $SiBr_4$-H_2. Phosphorous-doped single-crystal silicon, A (14); B (12).

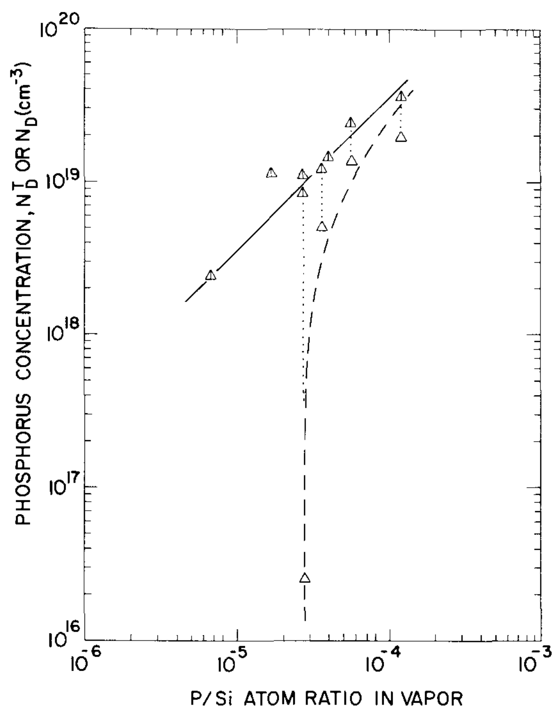

Fig. 4. Total phosphorous concentration, N_D^T, and donor concentration, N_D, vs. P/Si atom ratio in vapor for poly Si deposited from SiH_4 at 650°C. ⚠ Total phosphorous concentration, △ donor concentrations, ——— see Eq. [1] in text, - - - - calculated from Eq. [4] in text.

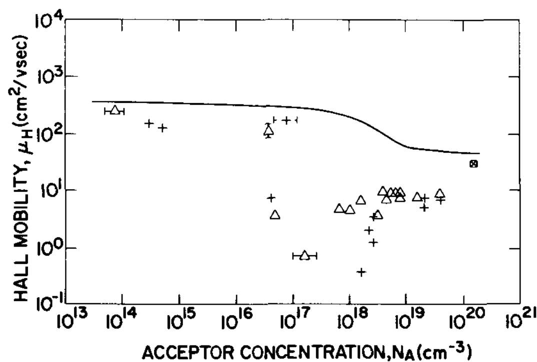

Fig. 5. Hall mobility, μ_H, vs. acceptor concentration, N_A, for poly Si samples doped with boron and deposited from SiH_4 at 650°C. ——— Single crystal mobility (16), △ thermal SiO_2 substrates, + fused quartz substrates, ⊠ sample diffused using BBr_3 at 1000° for 5 min.

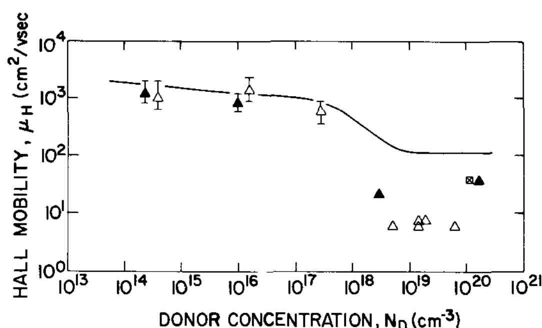

Fig. 6. Hall mobility, μ_H, vs. donor concentration, N_D, for poly Si samples doped with phosphorous and deposited on thermal SiO_2. ——— Single crystal mobility (16), △ deposited at 650°C from SiH_4, ▲ deposited from $SiBr_4$-H_2 at 840°C, ⊠ sample diffused using $POCL_3$ at 825°C for an 8-min cycle.

The variations of μ_H with carrier concentration, N_A, N_D, is quite similar for both p- and n-type samples. For carrier concentrations above 5 × 10^{18}/cc, the Hall mobility of poly Si grown at 650°C is 1/10 (p-type) to 1/30 (n-type) of bulk values (16). On the other hand, the two diffused samples and the one n-type sample, doped to 2 × 10^{20}/cc carrier concentration and grown at 840°C, exhibit values of μ_H ½ to ¼ of that of bulk. With decreasing carrier density from 5 × 10^{18}/cc down to about 2 × 10^{17}/cc, the mobility of p-type samples decreases and becomes more variable. Somewhat surprisingly, in the further decrease of doping below 10^{17}/cc, the Hall mobility of both n- and p-type samples rises and is 1/2 to 1/3 that of bulk samples down to 10^{14}/cc carrier density. At the lower doping levels, the Hall measurements become more difficult and are less reproducible. Data were included in Fig. 5 or 6 only if the Hall signal was greater than 60% of the current-voltage drop in the sample and only if all three Hall voltages were of correct sign and if the data were consistent in every other way. Even when employing these criteria, most of the data were included (8 out of 13 samples).

Undoped samples always had a resistivity > 10^6 ohm-cm, as measured by a modified four-point-probe method, but the Hall signals were too low to be measured by our apparatus.

Discussion

Structure.—With regard to surface smoothness of undoped samples, our results appear comparable to those of Ford *et al.* (6) and Deluca (4) who also grew poly Si at low temperatures. Our poly Si grains, like theirs, are around 300Å in diameter and are randomly oriented. Unlike Ford, who grew from SiH_4 in He, we find small grain size and highly uniform surfaces deposited from SiH_4 in a hydrogen ambient. This may be due to the peroxide cleaning step we employed which is so important in preparing substrates. The increase in particle size up to 3000Å as the doping increases up to 10^{19}/cc has not been reported previously. The simultaneous appearance of a slightly preferred <110> orientation with the larger grain size is curious because it has been observed that an increase in deposition temperature produces exactly the same two associated effects. The smooth and shiny films obtained on thermal SiO_2 show that it is the most uniform substrate of those used and that poly Si is extremely sensitive to variations in nucleating conditions.

Doping during growth.—Figure 4 shows that the sharp decrease in N_D for low P/Si values occurs even though the total phosphorous content of the samples remains proportional to P/Si. Thus, some of the phosphorous is present in the crystal in a form which does not contribute significantly to electrical conductivity.

Similarly, Kamins (8) has reported that in vapor-doped poly Si grown at 1035°C, N_D, the electrically active arsenic concentration, is less than the total As concentration below 10^{18}/cc. He has also inferred from an indirect method that boron-doped samples behave similarly. Although we have no data on total boron content of our boron-doped samples, we presume for the remainder of the discussion that they behave in the same manner as the one doped with phosphorous.

As regards the location of these electrically "inactive" atoms, we have considered several models: (*i*) preferential deposition in grain boundaries which we feel is most likely, (*ii*) distributed deposition in grain boundaries and in the bulk, and (*iii*) formation of interstitials or clusters in the bulk of the grains. We first present the most likely model (*i*) and finally make a few comments about why (*ii*) and (*iii*) are unsatisfactory. We feel the inactive atoms are deposited in the grain boundaries because the assumption that deposition occurs in the bulk of the grains leads to a contradiction as follows: from Fig. 4 it may be seen that the effective bulk concentration of inactive dopant atoms, N_{GB}, is high ~10^{19}/cc. If these atoms were in the bulk they would be ionized, although the carriers must be trapped somewhere to explain their inactivity. The

10^{19}/cc density of ionized impurities would necessarily limit the maximum mobility that could be measured to values of about 100 cm^2/V-sec (from bulk curve Fig. 6), which is an order of magnitude smaller than actually observed because of ionized impurity scattering. Therefore we conclude that the inactive atoms are in the grain boundaries. A distinct, separate, three-dimensional phase, *e.g.*, SiB_6 or SiP, was not observed in the HVEM examination of samples, and it probably was not formed because we are still more than an order of magnitude below the solubility limit for either boron or phosphorous in Si.

In order to account for the very rapid change of, say, N_D with P/Si ratio, it is necessary to postulate that no dopant atoms are deposited in the bulk of the crystallites until the grain boundaries are completely saturated. After the boundaries are saturated, any further increase in P/Si will result in dopant atoms being incorporated into the bulk of the crystallites. Quantitatively this model may be described as follows: the electrically inactive dopant concentration, N_{GB}, given by Eq. [2], is now defined to be the equivalent bulk density, (atoms/cm^3) of dopant atoms but which are located in the grain boundaries! For a simple grain geometry such as a cube

$$N_{GB} = \frac{3 \times A \times D_s \times S}{V} \quad [3]$$

where A is the area of one cubic grain face, V the volume, D_s the surface atom density of Si (1.35×10^{15}), S the fraction of surface atoms covered or associated with an electrically inactive dopant atom, and the factor 3 is the equivalent number of cube faces (½ the total) associated solely with this grain.

Combining [2] and [3] and assuming an average grain size of 1000Å, (or $A = 10^6$ Å^2, $V = 10^9$ Å^3) we have

$$N_D = N_D^T - 4.05 \times 10^{20} S \quad [4]$$

where N_D^T is given by Eq. [1] for the data in Fig. 4. We have fit Eq. [4] to the data of Fig. 4 using S as an adjustable parameter. The best fit (dashed curve) describes the N_D data very satisfactorily, with S equal to 0.024, and exhibits the rapid change of N_D with P/Si. From Eq. [3] then, N_{GB} equals 9.7×10^{18}/cc.

Let us now point out that the alternative model which postulates that dopant atoms are distributed in equilibrium concentrations between the grain boundaries and the bulk of the grains cannot explain the present result. Such a model would give a doping curve with N_D proportional to P/Si but with a lower intercept on the N_D axis. It would not predict the observed sharp decrease of N_D with decreasing P/Si below the value of 5×10^{-5}.

We also believe that the inactive dopant atoms are not present as interstitials or clusters in the bulk of the grains for the following two reasons: first, both interstitials and clusters would be expected to increase in concentration slowly with increasing total dopant concentration, which is not observed. Second, the concentration of such clusters would probably vary with temperature, which is not observed in Fig. 3 data.

Mobility.—The Hall mobility, μ_H, of poly Si samples in Fig. 5 and 6 is always observed to be less than that of the bulk. This is consistent with the expectation that grain boundaries will necessarily lower μ_H. Let us now consider various portions of the doping range separately.

At doping levels above 2×10^{18}/cc, we note that our results and those of Kamins, Ford, and Mai indicate that high-temperature processing either during growth or during diffusion is necessary to achieve high mobility. From 2×10^{18}/cc to 2×10^{17}/cc, no one reports very high mobilities but the trend of the mobility change with decreasing doping is different for different investigations. We do not have a satisfactory explanation for mobility in either of the above ranges and will not speculate further here on its cause.

We have developed, however, a basic explanation to account for the unusually high mobility[2] of most of our samples doped from 2×10^{17}/cc down to 10^{13}/cc. Historically, it is in this doping range where μ_H, measured in many different polycrystalline materials, has been found to be much lower than in bulk single crystals. The mobility lowering has usually been attributed to the presence of potential barriers at grain boundaries which have an increasingly detrimental effect on the mobility as the carrier concentration is decreased.

Now, because of the extremely small dimensions (200-1000Å) of the poly Si grains in this doping range, the usual band model of a potential barrier is inappropriate. For instance, at a doping level of 10^{16}/cc, the space charge width is much larger than the average diameter of the grains, which is about 1000Å. However, even if a potential barrier picture is inappropriate, trapped charges at surface states in the grain boundaries would still lower mobility, and trapped charges at grain boundaries are likely to be present in any case due to structural defects which are inevitably present due to random orientation of neighboring grains.

However, since we do not observe low mobility, it seems reasonable to suspect that such barriers or charge scattering centers are effectively removed or compensated in our films.

At this point we would like to speculate on two alternative mechanisms by which the trapped charge centers might be eliminated or compensated:

1. The hydrogen present at our low growth temperature eliminates surface states in the grain boundaries.

In support of this model we note that low-temperature, 300°-500°C, but not high-temperature hydrogen annealing has been very effective in removing fast surface states at Si-SiO_2 interfaces (18).

2. The presence of the large, $\sim 10^{19}$/cc, concentration of the previously described electrically inactive boron and phosphorous atoms compensates surface states in the grain boundaries.

With regard to this model, we note first that Dumin (19) has obtained significant evidence, in layers of single crystal Si grown on sapphire near 1200°C, for the presence of a high density of acceptors in the middle of the upper half of the bandgap and donors in the middle of the lower half of the bandgap. These centers increase in concentration near the Si-sapphire interface and may be due either to an impurity or a structural defect or both. Kamins postulated that similar defects are present in poly Si films.

Specifically, we postulate that the electrically inactive boron and phosphorous atoms may be pairing with and therefore compensating defects to produce either neutral pairs or localized dipoles in the grain boundaries. These pairs would be relatively ineffective in lowering mobility. The low temperature of our depositions would favor pair formation which would be less likely at higher deposition temperatures. In the same way, if the free energy of formation of such pairs were very high compared to the free energy of dissolving boron or phosphorous in Si, this would explain why the grain boundaries apparently become completely saturated with dopant before any dopant appears in the bulk of the crystallites, as already discussed. If there is a one-to-one pairing of inactive dopant atoms with defects, then the surface defect density is in the 10^{13} defects/cm^2 range. It is important to note that the relatively shallow acceptors and donors (boron and phosphorous) would be able to compensate any defect charge center of the opposite type

[2] The high mobility found here cannot be explained by the inhomogeneity effects discussed by Wolfe *et al* (17). In his model, anomalously high mobilities are observed only when the total amount of dopant greatly exceeds that which is present in our samples.

as long as the defect has the deeper electronic energy level.

Summary

It has been shown that thin polycrystalline silicon films having mirror smooth surfaces suitable for photoresist processing can be deposited at low deposition temperatures over large areas on thermal SiO_2. These films exhibit mobility values approximately 50% of bulk values in the concentration range between 10^{14}/cc to 10^{17}/cc and above 10^{19}/cc. This implies that fabrication of FET's in the 10^{16}/cc doping range and the use of heavily doped Si for gate material looks quite promising.

It is suggested that the irreproducible doping during growth and the unexpected high mobility of lightly doped samples are associated and caused by the selective deposition of dopant atoms in grain boundaries which compensate local structural defects. The resultant pairs are electrically neutral and therefore do not adversely affect the mobility. (Alternatively, hydrogen may compensate or eliminate the structural defects.)

Above 10^{19}/cc, diffusion processes yield samples with higher mobility and doping levels than does doping during growth.

The feasibility of fabricating FET's in poly Si is supported by the Hall mobility in the 10^{16}-10^{17}/cc carrier concentration range, reported in the present work, on the premise that some other doping process be employed other than doping during growth.

Acknowledgments

We would like to express our appreciation to the many members of the staff who have contributed to this work. We would especially like to acknowledge the assistance of H. Keller and J. F. Woods in measuring and interpreting the Hall measurements, and of J. E. Lewis in carrying out the neutron activation analyses. In addition we would like to thank T. B. Light, V. J. Silvestri, C. J. Kircher, and S. Lahiri for many helpful discussions.

Manuscript submitted April 25, 1972; revised manuscript received June 21, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Diffusion of Boron from Shallow Ion Implants in Silicon

Sigurd Wagner

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The use of shallow ion implants as diffusion sources was studied on bare (111) silicon wafers implanted at room temperature with 30 keV, $3 \cdot 10^{14}$ cm^{-2} boron. Samples were annealed in purified argon at 900°, 1000°, and 1100°C. The diffusion profiles of boron are determined by in-diffusion into the silicon and by dissolution, to equilibrium, in the thin oxide layer on the surface. The amount of boron retained in silicon decreases during the initial period of an anneal and then remains constant. More boron is retained the higher the temperature and the lower the oxygen content in the ambient gas. With ~10 ppm O_2 in argon, losses range from 15 to 35% of the implanted dose. Experimental results are reasonably well represented by the mathematical formalism developed. The experimental data indicate that the values listed in the literature for sheet conductivity mobilities of holes are too low.

The anneal of boron implanted at room temperature into silicon can be thought to proceed in two steps. The electrical activity of the dopant is developed during a brief heat-treatment at a relatively low temperature, typically (1, 2) 30 min at 850°C. Under these conditions the diffusion length, $2\sqrt{Dt}$, in undamaged silicon is small as compared to the standard deviation in the Gaussian distribution of the implanted boron. The concentration profile of the dopant can be expected to remain essentially that of the original implant, even if some damage-enhanced diffusion occurs initially.

Anneals at higher temperatures and for longer periods of time alter the concentration profile of the

Key words: ion implantation, diffusion, silicon.

implanted boron in addition to developing its electrical activity. This paper reports the characterization of such "diffusion anneals." (111) silicon was implanted at room temperature with a dose of $3 \cdot 10^{14}$ cm^{-2} boron ions of 30 keV energy in a random direction. The wafers were annealed in a purified argon atmosphere.

Analysis

The as-implanted distribution, after a 30-min anneal at 850°C, is well approximated by a Gaussian distribution with its maximum in the surface of the wafer (Fig. 1)

$$C(x,t=0) = C(x=0, t=0) \cdot e^{-x^2/4\alpha} = \frac{Q}{\sqrt{\pi\alpha}} \cdot e^{-x^2/4\alpha} \quad [1]$$

(A list of symbols is provided at the end of the paper.) This distribution represents the source for subsequent diffusion into the silicon and into the very thin oxide layer which grows on the silicon surface even in purified argon. As the experimental results will indicate, this SiO_2 layer is in equilibrium with the boron on the silicon side of the SiO_2/Si interface, and the loss of boron to the ambient gas is negligible (see Discussion section). Therefore, all "out-diffusion" can be accounted for by an infinitely thin sink, of growing capacity, and located at the SiO_2/Si interface. The movement of this interface relative to the bulk of the silicon can be neglected because the oxides grown are only up to a few hundred angstrom units thick.

An analytical expression for the rate by which the capacity of the boron sink increases is obtained from a characterization of the oxide growth. After ion implantation and cleaning a 10-30Å layer of oxide covers the silicon. During the anneal rapid initial oxidation occurs up to an oxide thickness of the order of 100Å. Then the growth begins to proceed according to the linear rate law (3)

$$u = A_1 + A_2 t \quad [2]$$

Recent experimental data (4) indicate that the onset of parabolic (after linear) growth occurs at thicknesses as low as 200Å. In any case no single existing theoretical expression fits the oxide growth from virgin oxide to a few hundred angstrom units. It is proposed to represent this region by a phenomenological parabolic law

$$u = \sqrt{Bt} \quad [3]$$

which neglects the oxide existing at $t = 0$, but takes the initial rapid growth and the subsequent slowdown into account.

The diffusion equation can now be derived in a manner similar to that of diffusion from a predeposited source into a thick oxide growing on the silicon, with negligible diffusivity in the oxide. This case was analyzed by Huang and Welliver (5).

Diffusion into the silicon from the ion implanted source, without net flux across the interface, is described by

$$C_+(x,t) = C_+(0,t) \cdot e^{-\frac{x^2}{4(\alpha+Dt)}} = \frac{Q}{\sqrt{\pi(\alpha+Dt)}} \cdot e^{-\frac{x^2}{4(\alpha+Dt)}} \quad [4]$$

However, the actual boundary condition at the interface results from diffusion into the growing oxide while equilibrium is maintained at the interface and within the oxide (for the oxide, boron implanted and boron incorporated by growth is neglected)

$$D\frac{\partial C}{\partial X}\bigg|_{x=0,t} = -k \cdot \left\{ C(0,t) \cdot \frac{\partial}{\partial t} u(t) + u(t) \cdot \frac{\partial}{\partial t} C(0,t) \right\} \quad [5]$$

The second term on the right-hand side of Eq. [5] is smaller than the first until $\partial \ln C(0,t)/\partial \ln t = -½$, when the net flux across the interface becomes zero, and the first term becomes small as compared to its initial value. Therefore the equation for out-diffusion from the silicon can be solved (6) approximately, by neglecting the second term, to give

$$C_-(x,t) = A(t) \operatorname{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) \quad [6]$$

$A(t)$ is found by combining the derivative of Eq. [6] with Eq. [5]

$$C_-(x,t) = -C(0,t) \cdot \frac{\sqrt{\pi}}{2} \cdot k \cdot \sqrt{\frac{B}{D}} \cdot \operatorname{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) \quad [7]$$

The diffusion equation and the boundary conditions are linear. Therefore the actual impurity profile can be obtained by adding $C_-(x,t)$, Eq. [7], to $C_+(x,t)$, Eq. [4], and by solving for $C(0,t)$ at $x = 0$

$$C(x,t) = C_+(x,t) + C_-(x,t) = \frac{Q}{\sqrt{\pi(\alpha+Dt)}} \left\{ e^{-\frac{x^2}{4(\alpha+Dt)}} - \frac{1}{1 + \frac{2}{\sqrt{\pi}} \cdot \frac{1}{k} \cdot \sqrt{\frac{D}{B}}} \cdot \operatorname{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) \right\} \quad [8]$$

The amount of boron retained in the silicon is

$$Q(t) = Q + \Delta Q(t) = \int_{x=0}^{\infty} C(x,t)\,dx = Q \left\{ 1 - \frac{1}{1 + \frac{2}{\sqrt{\pi}} \cdot \frac{1}{k} \cdot \sqrt{\frac{D}{B}}} \cdot \frac{2\sqrt{Dt}}{\pi\sqrt{\alpha+Dt}} \right\} \quad [9]$$

The latter equation has several important consequences. First, boron is lost only during an initial period; the amount of boron retained in the silicon remains virtually constant as soon as $Dt >> \alpha$. Second, the loss $\Delta Q(t)$ increases with decreasing $1/k \cdot \sqrt{D/B}$, that is, the larger $1/k \cdot \sqrt{D/B}$, the more boron is retained. $1/k \cdot \sqrt{D/B}$ can be made large by keeping the concentration of oxidant as low as possible, and by annealing at as high a temperature as possible: the enthalpy of activation for the oxidation (3), ~2 eV · $mole^{-1}$, is much smaller than that for diffusion which is ~3.5 eV · $mole^{-1}$. k appears to be independent of temperature. Therefore

$$\frac{\partial}{\partial T}\left(\frac{1}{k} \cdot \sqrt{\frac{D}{B}}\right) > 1 \quad [10]$$

In spite of the superposition of an erfc-profile on the Gaussian distribution, accurate coefficients of diffusion can be obtained when $x >> \sqrt{Dt}$ and $Dt >> \alpha$. Then D is calculated from the slope of a plot of ln C vs. x^2

$$\frac{\partial \ln C(x,t)}{\partial (x^2)} \cong -\frac{1}{4(\alpha + Dt)} + \frac{1}{\left(1 + \frac{2}{\sqrt{\pi}} \cdot \frac{1}{k} \cdot \sqrt{\frac{D}{B}}\right)\sqrt{\pi}} \frac{\sqrt{Dt}}{x^3} \cong -\frac{1}{4(\alpha + Dt)} \quad [11]$$

Experimental

7-14 ohm-cm As-doped silicon wafers (3.2 cm diam, ~0.025 cm thickness) with polished (111) surfaces were implanted with 30 keV boron ions in a random direction, ~7° off the {111} axis, at a dose of $3 \cdot 10^{14}$ cm^{-2}. Whole wafers, or chips, were cleaned consecutively in organic solvents, conc HF, conc HNO_3, conc HF, and water. Slices were annealed on a quartz boat in the quartz liner of a resistance-heated furnace. Purified argon (99.996%, nominally less than (in ppm) 7 O_2, 2 H_2 30 N_2, 2 CH_4, 2 CO_2, dew point −95°C $\triangleq$ 0.037 ppm H_2O) served as a protective gas; it was run through an acetone-dry ice trap to keep the maximum actual dew point at −78°C. The argon flux was 0.5 cm · sec^{-1} (STP) except during and for 3 min after insertion of a sample, when a flux of 5 cm · sec^{-1} (STP) was maintained.

Concentration profiles were determined mainly by anodization profiling and sheet conductivity measurements. Chips were anodized in a potassium nitrite-tetrahydrofurfurol solution (7) (2.8g KNO_2 in 100 ml THFol) while being irradiated with light from a tungsten-halogen lamp. A constant current-constant voltage automatic crossover power supply was set to deliver 15 mA cm^{-2} and voltages between 196V ($\triangleq$ 500Å Si) and 294V ($\triangleq$ 750Å Si). The anodization was stopped when the current had decayed to virtually zero. The thickness of anodic oxides was measured by visual comparison with an oxide chart calibrated by ellipsometry.

A square array four-point probe (point spacing 0.064 cm, 0.0025 cm tip radius, 50g load per point) was used for the sheet conductivity measurements. Linearity of signal voltage with applied current was frequently checked. The signal voltage ranged from ~1 to ~100 mV (8). A few sheet conductivities were also measured on a Van der Pauw configuration (9) with In-Sn soldered contacts. Agreement was to within 3%.

All samples were profiled to beyond the pn junction. When the junctions were deeper than 1 μm, x_j, calculated from the sum of the thickness of the anodic oxides were within 10% of x_j from angle lapping, staining, and interferometry.

$(\Delta\kappa_s/\Delta x)_n$ was calculated for each profiling step n, and, except for the first step $n = 1$, smoothed by arithmetically averaging over $n - 1, n, n + 1$. Then C was obtained from the equation

$$\left(\frac{\Delta\kappa_s}{\Delta x}\right)_x \cong \left(\frac{\partial\kappa_s}{\partial x}\right)_x = -C \cdot q \cdot \mu_h(C) \quad [12]$$

The hole mobility μ_h and its dependence on C are discussed in the Appendix.

Carrier concentrations were also obtained from Hall effect measurements on Van der Pauw patterns. Concentrations were measured on as-annealed chips, and on several specimens profiled by the copper-displacement technique ($2Cu^{2+} + Si = 2Cu + Si^{+4}$) with intermittent anodizations to smooth the silicon surface.

Thickness and refractive index of surface oxides were determined by ellipsometry.

Results

The concentration profiles of two implants annealed for 30 min at 850°C are plotted as log C *vs.* x^2 in Fig. 1. The experimental data are reasonably well approximated by a straight line (Gaussian distribution) corresponding to

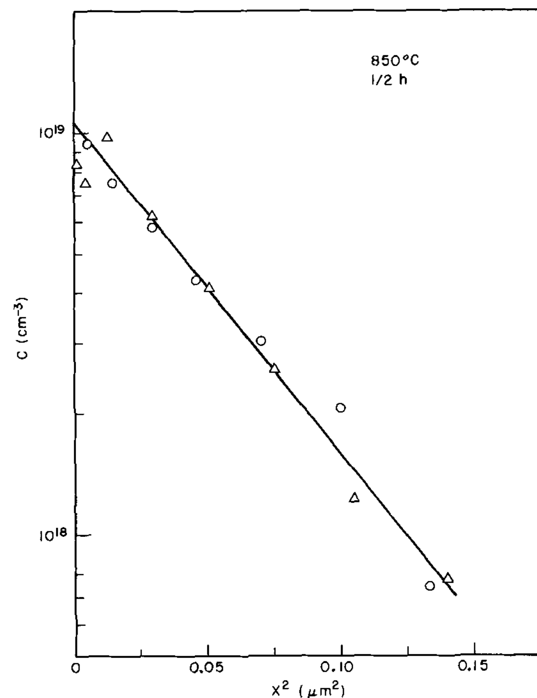

Fig. 1. Profile of implant after 30 min anneal at 850°C

$$C(x,t=0) = 1.05 \cdot 10^{19} \cdot e^{-\frac{x^2}{4 \cdot 1.36 \cdot 10^{-10}}} \quad [13]$$

The amount of active dopant

$$\int_0^\infty C(x, t=0)dx = C(x=0, t=0) \cdot \sqrt{\pi\alpha} = 2.1_2 \cdot 10^{14}\ cm^{-2} \quad [14]$$

indicates that not all of the implanted boron had yet developed its electrical activity. This activity develops most slowly in the high-concentration portion of an implant (10), thus in a narrow region near $x = 0$ in the present case. Consequently a further anneal to $3 \cdot 10^{14}$ carriers per square centimeter would not have had a significant effect on the slope of the implanted profile and on α.

Experimental profiles for the 900°, 1000°, and 1100°C anneals are presented in Fig. 2, 3, and 4, respectively. The diffusion coefficient at 1100°C (from the 4-, 9-, and 16-hr profiles) is $1.7 \cdot 10^{-13}$ cm^2 sec^{-1}, at 1000°C (from the 12- and 48-hr profiles) $1.7 \cdot 10^{-14}$ cm^2 sec^{-1}. The 900°C profiles are very steep at high x due to partial penetration of the probe points through the junction. Here D was derived from the difference in slope of the 42- and 168-hr profile at intermediate x^2

$$D_{2-1} = -\frac{1}{9.212(t_2 - t_1)}\left[\frac{\Delta(x^2)}{\Delta(\log C_2)} - \frac{\Delta(x^2)}{\Delta(\log C_1)}\right] \quad [15]$$

and was found to be $1.5 \cdot 10^{-15}$ cm^2 sec^{-1}. The diffusion coefficients are in very good agreement with those of Ref. (11) for diffusion from a doped oxide source, and with those of Ref. (12) for diffusion from a B_2O_3-saturated N_2 atmosphere.

The amount of boron retained in the silicon, $Q(t)$, was arrived at by integration of the C *vs.* x curves, and in part also by (uncorrected) Hall measurements. These data are shown in Fig. 5. The mobilities leading to two different sets for the sheet conductivity data are discussed in the Appendix.

In Fig. 6 the oxide growth at 1100°C is shown to proceed approximately by a parabolic law with $B = 8.9 \cdot 10^{-17}$ cm^2 sec^{-1}. At 900° and 1000°C the oxide growth was irregular, probably because of variations

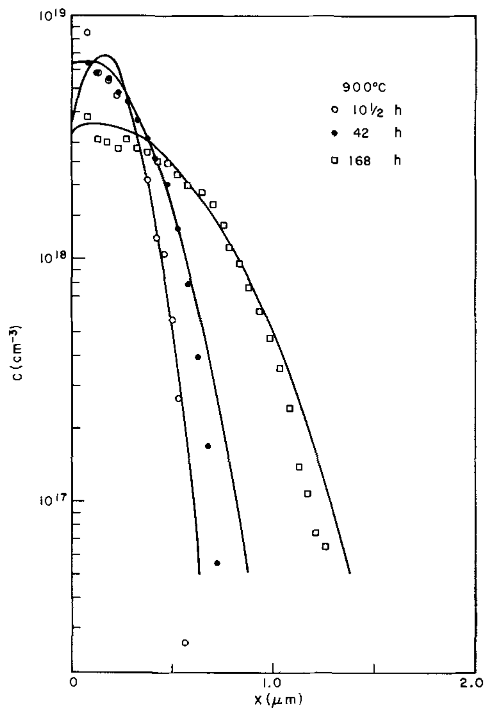

Fig. 2. 900°C diffusions; experimental points and calculated profiles.

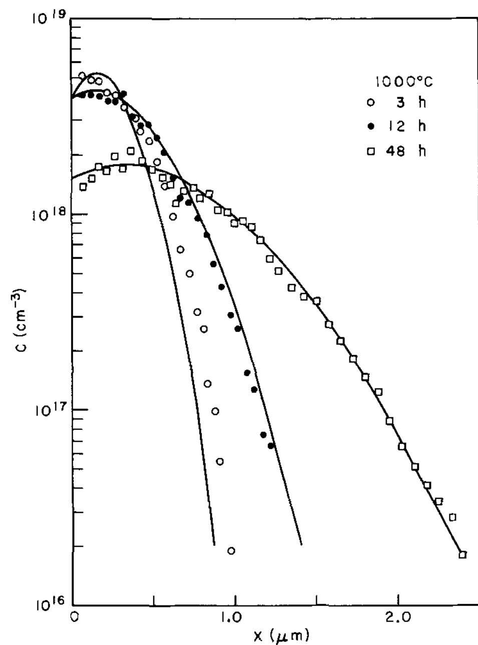

Fig. 3. 1000°C diffusions; experimental points and calculated profiles.

in the oxygen and water content (dew point) of the ambient gas during the long annealing times involved. For these cases B was calculated separately for each sample as $B = u^2/t$.

The distribution coefficient of boron between the oxide and the silicon, k, was derived from the amount of boron lost from the silicon, $\Delta Q(t)$, the thickness of the oxide, u, and the concentration of boron in silicon at the interface, $C(x = 0,t)$

$$k = \frac{\Delta Q(t)}{u \cdot C(0,t)} \quad [16]$$

Because of the scatter brought in with $\Delta Q(t)$, $C(0,t)$, and u, considerable scatter can be expected for k. The average value (from all but the shortest anneal at each

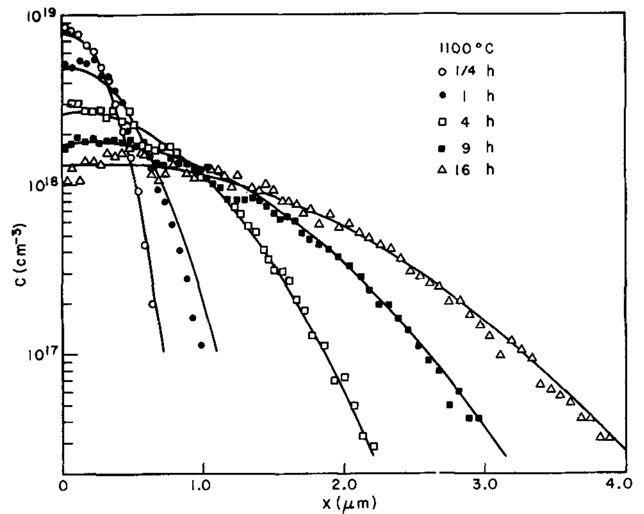

Fig. 4. 1100°C diffusions; experimental points and calculated profiles.

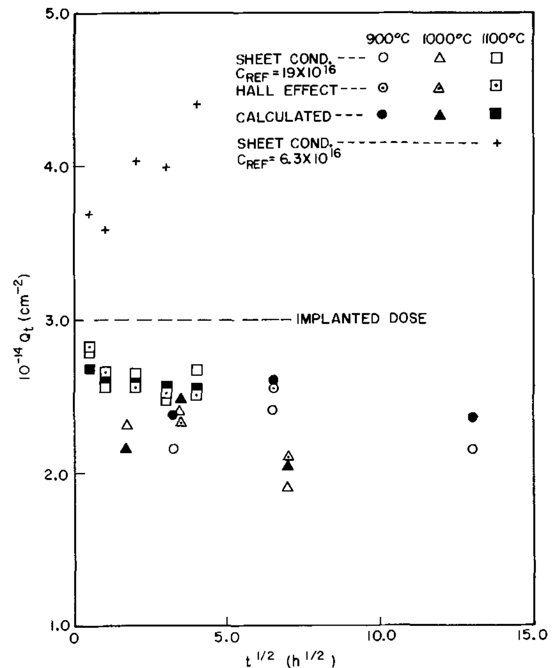

Fig. 5. Amount of boron retained in silicon

temperature) is $k = 16 \pm 5$. k is low for short anneals because the boron has not yet attained equilibrium within the oxide.

A summary of data is presented in Table I. The diffusion profiles calculated using Eq. [8] and the B and k values just discussed are shown as solid lines in Fig. 2, 3, and 4; the calculated retained doses, $Q(t)$, are given in Fig. 5.

Discussion

The experimental results were used as a basis for assumptions made for the analysis of the boron diffusion. The initial profile is well approximated by a Gaussian distribution with its maximum at $x = 0$ (Fig. 1). The growth of the oxide can be expressed in terms of a parabolic rate law (Fig. 6). A constant coefficient of distribution of boron between oxide and silicon, and equilibration within the oxide, is supported by the data of Table I, although with a considerable margin of error. However, the values for k are satisfactory in view of the possible errors in u, $C(0,t)$, and especially in the "lost" portion of boron, $\Delta Q(t)$, which is found as difference of two larger quantities, Q (implanted) and $Q(t)$. The complexity of the processes occurring in

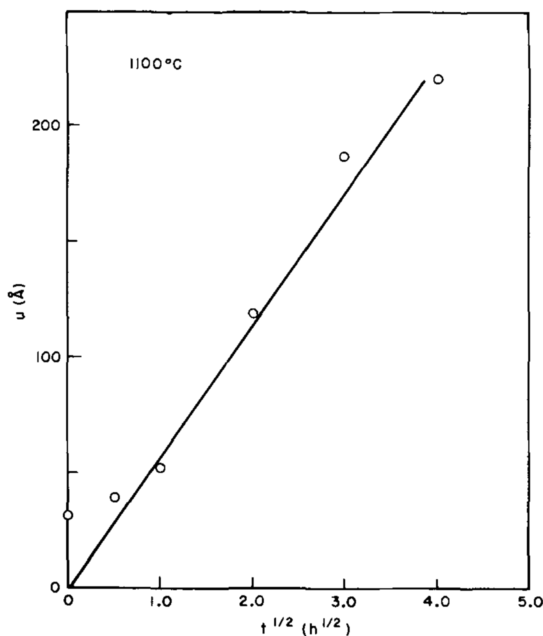

Fig. 6. Thickness of oxides, 1100°C anneals

the oxide must also be kept in mind: fresh oxide grows at the SiO_2/Si interface and displaces previously grown SiO_2 which has a higher content in boron. Boron will therefore diffuse toward the interface not only from the bulk silicon, but also from outer layers of the oxide. At 900°C, the growth rate B and the diffusion coefficient of boron in SiO_2 (13) are of comparable magnitude and nonuniformity of the boron concentration in SiO_2 might result. Of course, there is always the question whether such very thin oxide layers can be treated as bulk phases. Altogether the value of $k = 16 \pm 5$ compares favorably to values given in the literature for the case of thick oxides grown on bulk-doped silicon (14), $k = 3$, silicon with boron predeposits (5, 15), $k = 9$ and $k = 10$, and for the transfer of boron from a $SiO_2 + B_2O_3$ layer to silicon (11), $k \cong 50$.

The calculated profiles (Fig. 2, 3, and 4) and retained doses (Fig. 5) agree well with the experimental results and support the physical concept put forward. No significant losses of boron to the ambient gas did occur since the entire implanted dose is accounted for by the boron retained in the silicon plus that dissolved in the oxide.

One simplifying assumption for the present study was that the diffusion length of B in SiO_2 is at least comparable to the thickness of the SiO_2-layer. The capacity of the oxide for boron is then proportional to its thickness, and the key quantity determining the retained dose is $1/k \cdot \sqrt{D/B}$. There is another case of practical interest which can be approached in a similar manner: implantation through a thick layer of oxide, into the silicon and subsequent anneal without further growth of oxide. The oxide layer must be thick in comparison to the diffusion length of boron in the oxide. Let the maximum concentration of the implant be in the SiO_2/Si interface. During a brief anneal the boron will equilibrate across the interface and two essentially Gaussian profiles will be set up, one in SiO_2, the other in Si. If all secondary effects are neglected, the amounts of boron in Si, $Q(\text{Si})$, and in SiO_2, $Q(\text{SiO}_2)$, are then related to the respective concentrations at the interface, $C(\text{Si})$ and $C(\text{SiO}_2)$, by

$$Q(\text{Si}) = C(\text{Si}) \cdot \sqrt{\pi \cdot D(\text{Si}) \cdot t} \quad [17]$$

and

$$Q(\text{SiO}_2) = C(\text{SiO}_2) \cdot \sqrt{\pi \cdot D(\text{SiO}_2) \cdot t} \quad [18]$$

The maximum of both profiles will be in the interface, where

$$C(\text{SiO}_2) = k \cdot C(\text{Si}) \quad [19]$$

Combining Eq. [17], [18], and [19], one obtains

$$\frac{Q(\text{Si})}{Q(\text{SiO}_2)} = \frac{1}{k} \cdot \sqrt{\frac{D(\text{Si})}{D(\text{SiO}_2)}} \quad [20]$$

If $\sqrt{D(\text{Si})} > k\sqrt{D(\text{SiO}_2)}$, the boron tends to remain in the silicon. If $\sqrt{D(\text{Si})} < k\sqrt{D(\text{SiO}_2)}$, much of it will diffuse into the oxide. At 1100°C, with $D(\text{Si}) = 1.7 \cdot 10^{-13}$ cm² sec^{-1} and $k = 16$ from the present investigation, and $D(\text{SiO}_2) = 3.5 \cdot 10^{-17}$ cm² sec^{-1} from Ref. (13)

$$\frac{1}{k} \cdot \sqrt{\frac{D(\text{Si})}{D(\text{SiO}_2)}} \cong 4 \quad [21]$$

Thus it appears feasible to retain a major portion of the boron implanted through an oxide layer if the diffusion anneal is performed without any concurrent oxidation. The enthalpy of activation, $\Delta H^{\neq}$, for diffusion in Si, 3.5 eV · mole^{-1}, is slightly smaller than that for diffusion in SiO_2, 3.8 eV · mole^{-1} (13). As a result the tendency for diffusion into the oxide increases with increasing temperature. However, the difference in $\Delta H^{\neq}$ is small and diffusion at an elevated temperature is advisable for expediency.

Acknowledgments

The author thanks R. A. Moline and R. W. Treible for their active support in supplying the implants, and R. H. Kaiser for the ellipsometric measurements. He is indebted to C. F. Gibbon, J. C. C. Tsai, and T. E. Seidel for discussions, to E. I. Povilonis for much experimental advice, and to P. F. Schmidt for information about the anodizing equipment.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

APPENDIX

Hole Mobility $\mu_h(C)$

The amount of dopant retained in the silicon, $Q(t)$, was obtained by integration of the concentration profiles as described in the experimental section. Initially hole mobilities, μ_h, were taken from Ref. (16); they agree with the values used in Ref. (17). The mobility *vs.* concentration relationship has been shown to fit an empirical Fermi-distribution curve (18)

k		8.1	21.3	19.6	9.6	11.8	22.2	6.7	15.4	10.4	17.0	15.4

$$\mu_h(C) = \frac{\mu_{max} - \mu_{min}}{1 + (C/C_{ref})^\beta} + \mu_{min} \quad [22]$$

with $\mu_{max} = 495$ cm^2 sec^{-1} V^{-1}, $\mu_{min} = 47.7$ cm^2 sec^{-1} V^{-1}, $\beta = 0.76$, and $C_{ref} = 6.3 \cdot 10^{16}$ cm^{-3}.

Use of this equation with the constants given above resulted in integrated doses, $Q(t)$, considerably larger than the total implanted dose of $3 \cdot 10^{14}$ cm^{-2} which is considered to be accurate to $\pm 3\%$. $Q(t)$ for the 1100°C anneals is shown in the upper portion of Fig. 5. A similar observation has been made by Tsai (19) for a 100 keV boron implant with a dose of $1 \cdot 10^{15}$ cm^{-2}. (The wafer was capped, after implantation, with SiO_2 deposited from ethyl orthosilicate, and annealed in argon for 1 hr at 1050°C. The total dose found by integration of the concentration profile was $1.3 \cdot 10^{15}$ cm^{-2}.)

Errors in $(\Delta\kappa_s/\Delta x)$ can be ruled out as cause for this discrepancy because of the agreement of κ_s measured with the four-point probe with κ_s on a Van der Pauw pattern with soldered contacts, and because of the agreement of the junction depths, x_j, from anodization with those from angle lapping. In-diffusion of p-type impurities from the furnace can also be excluded: in case of in-diffusion no concentration maxima could appear at $x > 0$.

It was therefore concluded that the hole mobilities taken from the literature were too low in the concentration range of interest ($10^{17} < C < 10^{19}$ cm^{-3}). Extrapolation of $Q(t)$ of the 1100°C samples to $3 \cdot 10^{14}$ cm^{-2} at $t = 0$ was taken as criterion for correct mobilities. The assumption was made that the values for μ_{max} and μ_{min}, which are independent of C, are correct as well as the shape of the μ_h *vs.* C curve, which is determined by β. Thus a new μ_h-C relationship was established by merely shifting the existing curve parallel to the C-axis to a higher value of $C_{ref} = 19 \cdot 10^{16}$. μ_h and κ are plotted *vs.* C in Fig. 7 and 8, respectively.

Carrier concentrations from uncorrected Hall measurements now agree well with $Q(t)$ from sheet conductivity measurements (Fig. 5). A plot of the total amount of dopant under a given depth x

$$\int_x^{x_j} C\,dx$$

as calculated from (uncorrected) Hall measurements,

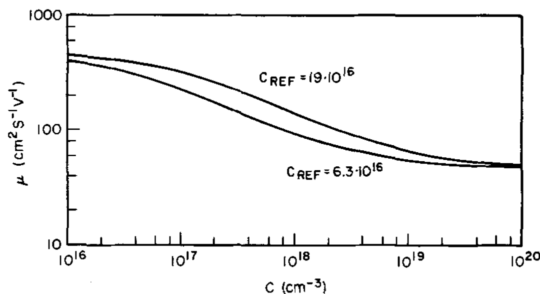

Fig. 7. Hole mobility *vs.* total boron concentration. $C_{REF} = 6.3 \cdot 10^{16}$ literature; $C_{REF} = 19 \cdot 10^{16}$ this study (25°C).

P-Type Dopants for GaP Green Light Emitting Diodes

O. G. Lorimor and M. E. Weiner*

Bell Telephone Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In an effort to reduce the red Zn-O emission in GaP green LED's, acceptors other than Zn were considered. Crystals were grown and green LED's fabricated from C- and Mg-doped material. In the C-doped crystals a half-power dependence of $N_a - N_d$ as a function of CH_4 partial pressure up to a maximum attainable $N_a - N_d$ of $\sim 1.5 \times 10^{17}$ cm^{-3} at 900°C was found. Mg-doped crystals were grown with $N_a - N_d$ up to 10^{19} cm^{-3}. In double LPE green LED's fabricated from a C,N-doped layer grown on a Te,N-doped layer, the external electroluminescent quantum efficiency, η, was as high as 0.1% at 200 A/cm^2. For single liquid phase epitaxy (LPE) diodes with a Mg,N-doped p-layer, $\eta = 0.006\%$. For the acceptors Be and Mg (and also for Si and Al) thermodynamic calculations are presented which consider the formation of the nitride of the dopant through the interaction with the NH_3 used to simultaneously dope the crystals with N. These calculations show that at typical LPE growth temperatures and under conditions where the Ga is saturated with N, the order of increasing solubility is Be $<$ Al $<$ Si $<$ Mg. The low solubility of Al precludes the growth of heavily N-doped $Ga_xAl_{1-x}P$ from Ga-rich melts. These calculations also predict the low $N_d - N_a$ which results with simultaneous Si and N doping. No such reaction involving the formation of a nitride limits the solubility of C during the LPE growth process.

One of the present problems in the growth of material for the fabrication of GaP green LED's is the elimination of the red Zn-O pair bound exciton emission which accompanies the green. Presently both n- and p-type LPE layers (1) grown by an open-flow dipping technique contain unintentionally added oxygen. All diodes in which the p-layer is Zn-doped emit some red light which indicates the presence of Zn-O pairs in the p-layer (2). In addition, the room temperature electroluminescent (EL) spectrum usually shows the $\sim$1.35 eV infrared emission band which has been identified as the bound-to-free transition at an isolated substitutional O atom (3). Diodes fabricated from Te,N-doped material where the junction is made by Zn diffusion (4) behave similarly (5).

The most obvious way to eliminate the red emission is to eliminate the O from the crystal. The possible sources of O include the Ga, the polycrystalline GaP used to saturate the melt, the fused quartz furnace tube and crucible, the H_2 gas stream and the NH_3 mixture used for N doping. The difficulty in determining the relative importance of such possible O sources and eliminating them is compounded by the lack of a simple, accurate method of measuring the O content of the LPE layers. Consequently, in addition to seeking methods of reducing or eliminating the O contamination, it is also attractive to seek other means of eliminating the red emission, in particular, the replacement of Zn by another acceptor. However, in doing so one must consider the interaction of the dopant with the NH_3 which is used as the source of N to obtain the green emission. For example, if one considers a dopant having a very stable oxide, (thus reducing O solubility in Ga) one must also consider whether that element also has a stable nitride.

The acceptors Be, C, and Mg, will be considered in detail. Because of the fast diffusivity of Be (6), only C and Mg have been used experimentally as dopants in this study. C does not form a stable nitride and thus its solubility is not expected to be significantly influenced by the simultaneous doping with N. Consequently only the interaction of NH_3 with Be and Mg will be considered in the calculations. Although not acceptors, the interaction of NH_3 with Al and Si will also be considered.

Experimental

C,N- and Mg,N-doped layers have been grown for use as the p-layers in LED's. The C-doped LPE layers were grown in an open-flow dipping system from 900°C (1). The layers were grown on {111}B oriented liquid encapsulated Czochralski grown (LEC) substrates or on a Te- or Te,N-doped n-type LPE layer which had previously been grown at 1000°C. C-doped layers, ranging in thickness from $\sim$½ to 1 mil, were grown by cooling the melt 11°C at a rate of 6°C/hr. Three of the C-doped layers were also doped with N to $\sim 1 \times 10^{19}$ cm^{-3} by the addition of NH_3 to the gas stream (1, 7).

Matheson ultra-high purity (99.97%) CH_4 gas was used as the source of C and introduced directly into the flowing gas stream. In order to give the melt time to saturate with C, growth of the crystal was not started until $\sim$40 min after the CH_4 was turned on.

* Electrochemical Society Active Member.

Key words: gallium phosphide, light-emitting diodes, liquid phase epitaxial growth.

At a CH_4 partial pressure $p_{CH_4} \lesssim 0.50$ atm, no blackening of the furnace tube due to decomposition of the CH_4 was noticed. At an unknown p_{CH_4} but larger than $p_{CH_4} = 0.7$ atm, the furnace tube was heavily coated with C due to CH_4 decomposition. Consequently, the study was restricted to $p_{CH_4} \leq 0.50$ atm.

The Mg-doped LPE layers were grown in an open-tube modified version of the slider system described by Panish *et al.* (8). The slider assembly was graphite while the furnace tube was quartz. Elemental Mg of 99.99% purity cleaned by etching in dilute HCl was used as a source of Mg. It was found that when the melt was not capped with a graphite lid, the quartz tube above the melt was severely attacked by the Mg vapor. Even with the lid covering the melt a white substance, assumed to be MgO, formed on the melt surface.

The Mg-doped layers were grown from 950°C by cooling 20°C at a rate of 20°C/hr. The surfaces of the layers appeared to be of high quality. They had small "terraces," but were smoother than layers grown in the dipping system. However, they were nonuniform in thickness. Frequently little or no growth was found over part of the substrate while ~1 mil was found in other areas. This large thickness nonuniformity was not observed when undoped or Te doped layers were grown in the same system.

The net acceptor concentrations, $N_a - N_d$ were determined by surface barrier capacitance measurements using a Copeland profiler (9). The measurements were primarily made on the surface of the layers. An in-depth profile of one of the C-doped layers showed no decrease in $N_a - N_d$ with increasing depth from the surface verifying that sufficient time was given for the melt to come into equilibrium with the CH_4.

Results

Figure 1 shows the net acceptor concentration as a function of the CH_4 partial pressure in the gas stream for the C-doped LPE layers. Although very few data points were taken, they fall reasonably well on a straight line with a slope of ½. In all cases the background $N_d - N_a \simeq 6 \times 10^{15}$ n-type is considerably exceeded. Figure 2 shows $N_a - N_d$ as a function of Mg concentration in the Ga + GaP melt. Because some of the Mg added to the melt was removed as MgO, the Mg dissolved in the melt for a crystal growth run was actually less than that added and shown as the abscissa in Fig. 2. Consequently, for any given Mg concentration the value of $N_a - N_d$ shown is only a lower limit on what one would measure if no MgO formed. However, this data does show that one can easily Mg-dope GaP to 1×10^{19} cm^{-3} and gives a lower bound of 0.02 for the distribution coefficient at 950°C. Consequently, Mg can be used to give the needed $N_a - N_d$ for green LED's.

Two of the C-doped layers were grown on n-type LPE layers previously grown at 1000°C (1). Diodes were fabricated from both of these LPE structures. The characteristics of these diodes are shown as samples 1 and 2 in Table I.

The n-layers in samples 1 and 2 are comparable both in $N_d - N_a$ and minority carrier lifetime

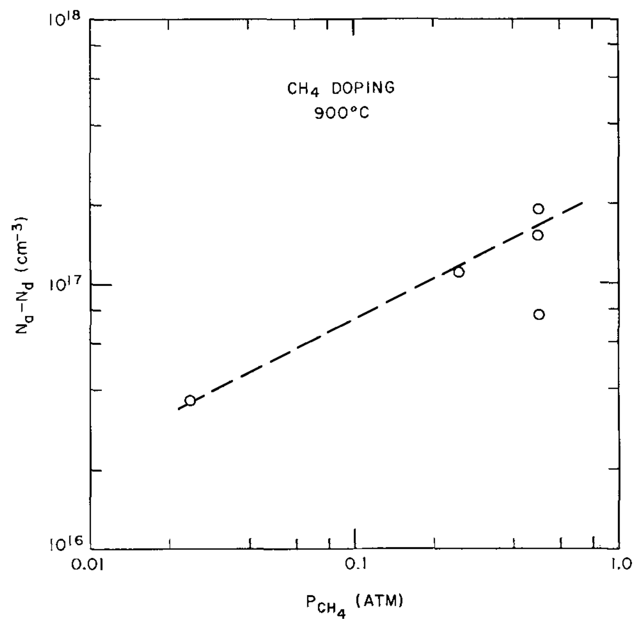

Fig. 1. Net acceptor concentration as a function of CH_4 partial pressure for GaP LPE layers grown near 900°C.

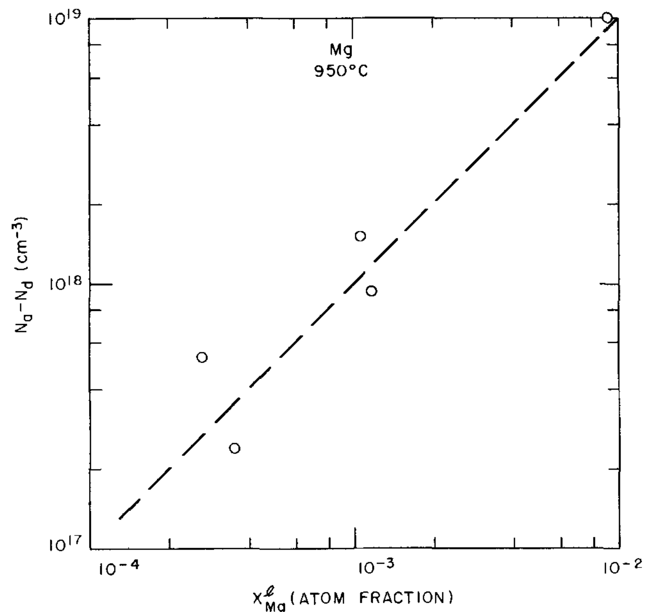

Fig. 2. Net acceptor concentration as a function of Mg concentration in the liquid for GaP LPE layers grown near 950°C.

to those which have produced diodes of $\eta \gtrsim 0.1\%$ with Zn,N-doped p-layers. The minority carrier lifetime of the p-layer in sample 1 is comparable to that found in Zn-doped layers. However, the $N_a - N_d$ of both p-layers is lower than that usually needed (~5×10^{17} cm^{-3}) to produce efficient diodes.

Table I

Diode number	N-Layer			P-Layer				
	Dopant	$N_d - N_a$ (cm^{-3})	τ_{mc} (ns)	Dopants	$N_a - N_d$ (cm^{-3})	τ_{mc} (ns)	η_{EL}	Diode type
1	Te	3.5×10^{17}	54	C, N	1.5×10^{17}	39	0.019, 50 mA AC (100 A/cm^2)	mesa
2	Te, N	7.5×10^{16}	86	C, N	7.5×10^{16}	—	0.1, 100 mA AC (75 A/cm^2)	die
3	Sn	3×10^{17}	LEC substrate	Mg, N	1.5×10^{18}	12	0.006, 50 mA AC (100 A/cm^2)	mesa

Properties of layers composing the diodes discussed in this study. τ_{mc} is the minority carrier lifetime as measured by the green PL decay time.

Thus, considering that the n-layer in sample 1 contains no intentionally added N, the encapsulated quantum efficiencies of these samples are quite good. The value of 0.10% at 100 mA (75 A/cm^2) pulsed for sample 2 is larger than that measured for many Zn,N/Te,N-doped diodes. Consequently, C itself appears to be an acceptable acceptor from a luminescent point of view. Its actual usefulness is limited because of its low solubility in Ga at 900°C.

Sample 3 is a diode fabricated from a Mg,N doped layer grown directly onto an n-type LEC substrate. The efficiency, although low, is comparable to that observed by Logan *et al.* (7) for single LPE structures on LEC substrates. In addition, in the slider system the lid, and possibly the MgO layer, over the melt probably inhibited the NH_3 from saturating the melt with N.

Figure 3 shows the EL spectrum of diode 1 at 100 mA (200 A/cm^2). The energy positions of the nitrogen bound exciton and its phonon replicas are indicated by the arrows (10). The arrow at 1.78 eV indicates the position of the red Zn-O emission if it were present (2). The low energy rise in emission is due to the free-to-bound transition involving oxygen which peaks near 1.35 eV (3). The broad, weak peak near 1.75 eV is presently unidentified but has been observed previously (11-13). The spectrum from diode 3 was found to be very similar to that of diode 1.

At current densities of 50 to 100 A/cm^{-2}, green-to-red ratios of 30:1 to 100:1 were obtained for all three samples. Thus, the use of C or Mg as a p-type dopant is a satisfactory way of obtaining large green-to-red ratios.

Interaction of Dopants with NH_3

The elements, Be, Mg, Al, and Si form stable nitrides. Thus, when simultaneously doping with one of these elements and N, the nitride of the element may form reducing the concentration of the element in the melt. The following calculations consider these reactions in such simultaneous doping.

The only nitrogen source considered in these calculations is NH_3. It is the purpose of this analysis to find what combinations of ammonia partial pressure, p_{NH_3}, and concentration of dopant in the liquid, X^l_{dopant}, are permissible. Thus the following reactions must be considered

$$3Be(l) + 2NH_3(g) \overset{K_1}{=} Be_3N_2(s) + 3H_2(g) \quad [1]$$

$$3Mg(l) + 2NH_3(g) \overset{K_2}{=} Mg_3N_2(s) + 3H_2(g) \quad [2]$$

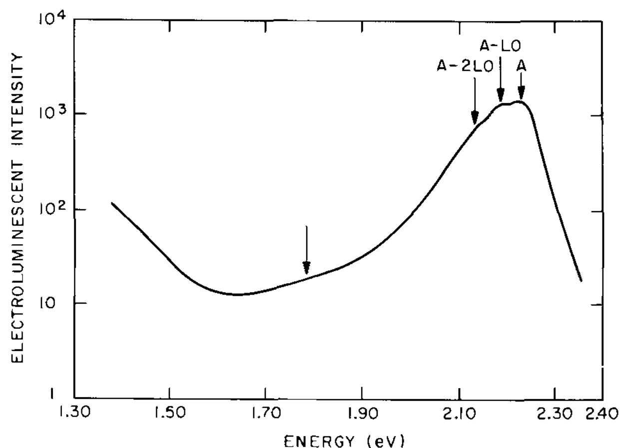

Fig. 3. Room temperature electroluminescent intensity as a function of photon energy for C,N/Te-doped, diode 1. The energy positions of the N bound exciton A-line and its phonon replicas as determined from optical absorption are noted. The arrow near 1.78 eV denotes where the peak energy position of the Zn-O red emission would fall if it were present.

$$Al(l) + NH_3(g) \overset{K_3}{=} AlN(s) + 3/2H_2(g) \quad [3]$$

$$3Si(l) + 4NH_3(g) \overset{K_4}{=} Si_3N_4(s) + 6H_2(g) \quad [4]$$

It is assumed that $p_{H_2} = 1$ atm and that solutions containing Mg and Al are ideal, *i.e.*, the activity coefficients γ_{Mg} and γ_{Al} are unity. Activity coefficients for Be and Si are attainable from the Be-Ga and Si-Ga binary phase diagrams (14), if it is assumed that phosphorus and nitrogen do not influence these coefficients. These activity coefficients are listed in Table II. Thus

$$X^l{}_{Be}{}^{3/2} p_{NH_3} = \frac{1}{K_1{}^{1/2} \gamma_{Be}{}^{3/2}} \quad [5]$$

$$X^l{}_{Mg}{}^{3/2} p_{NH_3} = \frac{1}{\sqrt{K_2}} \quad [6]$$

$$X^l{}_{Al} p_{NH_3} = \frac{1}{K_3} \quad [7]$$

$$X^l{}_{Si}{}^{3/4} p_{NH_3} = \frac{1}{K_4{}^{1/4} \gamma_{Si}{}^{3/4}} \quad [8]$$

Note that it is assumed that the solid nitride exists only at unit activity. This may not be valid for Al since $Ga_{1-x}Al_xN$ could form. In this case, the allowed concentration of Al in the solution is less than the value calculated. The equilibrium constants K_1, K_2, K_3, and K_4 were calculated from data in the JANAF tables (15) and are listed in Table III.

In addition to interacting with certain dopants, NH_3 also reacts with Ga to form GaN. The minimum pressure of NH_3 at which GaN forms is the maximum equilibrium pressure of NH_3 in the system. If the activity coefficient of nitrogen in Ga is independent of concentration, the presence of dopants, and if no nitrides form, the concentration of nitrogen in the solution is proportional to the NH_3 pressure.

In Fig. 4, the maximum dopant concentrations for which the nitrides of Be, Mg, Si, and Al do not form are plotted *vs.* the NH_3 partial pressure. In addition, the value of p_{NH_3} at which GaN forms is shown (16).

The permissible dopant concentrations and NH_3 pressures lie in the area to the left of the dopant curve and below the GaN line. In the region above the dopant curve and below the GaN line, the dopant will be removed from the solution as a nitride until the dopant curve is reached. Thus, from Fig. 4, it may be seen that only very small amounts of Al can exist in solution at a reasonable NH_3 pressure. Clearly, one will not be able to produce heavily N-doped $Ga_xAl_{1-x}P$ by growth from Ga rich melts.

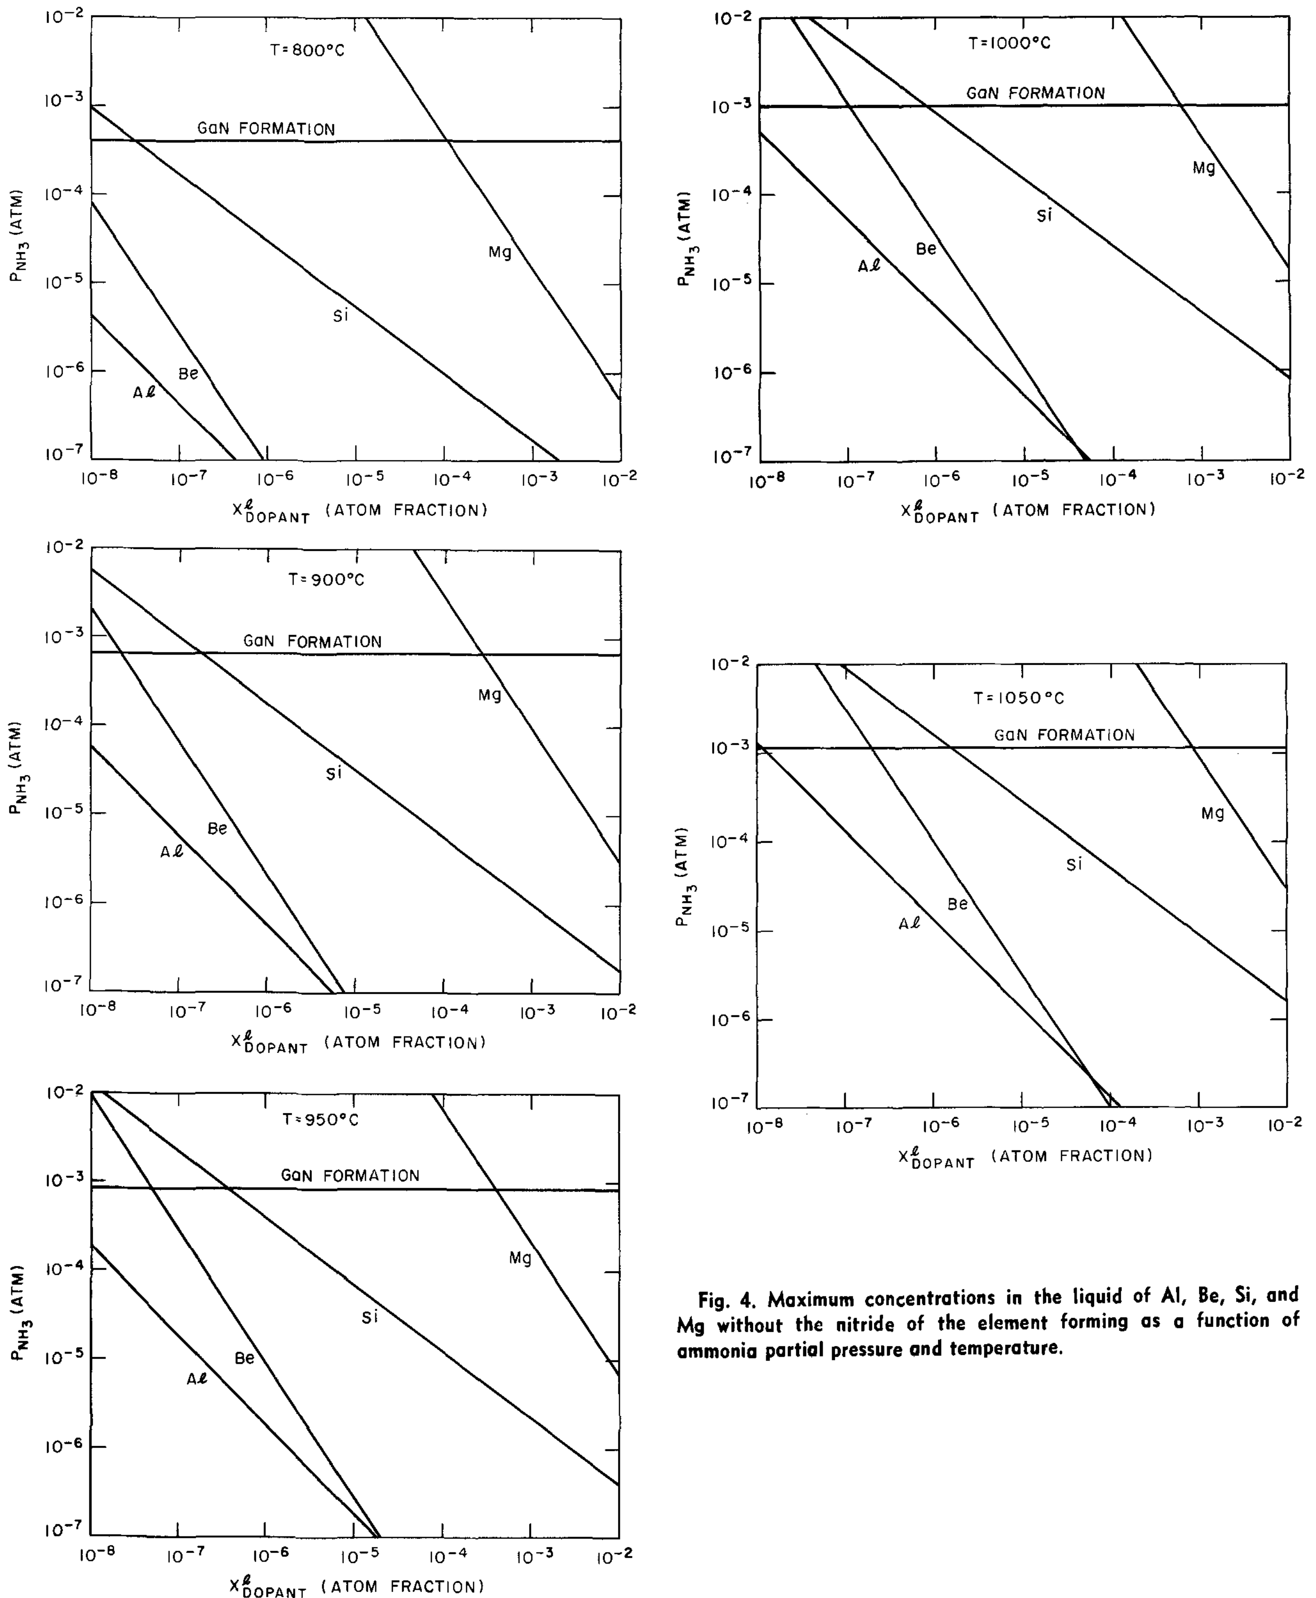

Fig. 4. Maximum concentrations in the liquid of Al, Be, Si, and Mg without the nitride of the element forming as a function of ammonia partial pressure and temperature.

Silicon has been used as an n-type dopant. In a typical experiment an LPE layer was grown at 1000°C with zero NH_3 partial pressure and X^{l}_{Si} (added to melt) $\approx 2.5 \times 10^{-5}$. From surface barrier capacitance measurements $N_d - N_a = 1.4 \times 10^{17}$ cm^{-3} in this layer. In another layer, grown under the same conditions except for the ammonia partial pressure being held constant at $p_{NH_3} = 7 \times 10^{-4}$ atm, $N_d - N_a = 3 \times 10^{16}$ cm^{-3}. This result is consistent with the data in Fig. 4. The Si added to the melt would be expected to react with the NH_3 forming Si_3N_4 until an actual Si concentration in the liquid of $X^{l}_{Si} \approx 1.3 \times 10^{-6}$ is reached. If it is assumed that the $N_d - N_a = 3 \times 10^{16}$ cm^{-3} is the total Si concentration in the solid, a value for the distribution coefficient of 0.5 is obtained. This value compares favorably with a value of ~0.7 estimated from the low Si concentration end of the calculated curve for the Si solubility for 1040°C from Trumbore *et al.* (17).

Magnesium appears to be a suitable dopant from the viewpoint of its reaction with NH_3. Only at very high doping levels should problems with the NH_3 interaction occur.

Conclusions

LPE layers have been grown using C and Mg as p-type dopants. The spectra of diodes fabricated from material where the p-layer was doped with one or the

other showed green-to-red ratios >30:1 at 100 mA. This ratio is considerably larger than ~10:1 ratio that has been found in many diodes where the p-type dopant is Zn (7).

At 900°C the maximum $N_a - N_d$ in the C-doped crystals that could be achieved was $\lesssim 2 \times 10^{17}$ cm^{-3}. In one case a Te,N-C,N diode with a quantum efficiency of 0.10% at 100 mA pulsed was measured. This efficiency is quite good in view of the low p-type doping attainable with C compared to the doping level of ~5×10^{17} cm^{-3} in high-efficiency green LED's where Zn is the p-type dopant. Consequently, although C appears to be a satisfactory acceptor from a luminescence point of view, it is presently not felt to be a suitable dopant when LPE growth is at 900°C for use in these diodes because of its low solubility. However, at higher growth temperatures it is possible that the solubility of C would increase.

Mg, on the other hand, is amply soluble in GaP to provide the optimum doping level. However, its strong affinity for O makes this dopant difficult to use during crystal growth. Consequently, further studies using Mg as a dopant are dependent upon developing more nearly O free systems.

Thermodynamic calculations show that when one simultaneously dopes with NH_3 and an element having a stable nitride, the nitride of the element may form and reduce the concentration of the doping element in the melt. This process can be particularly important at the ($10^{-4} \lesssim p_{NH_3} \lesssim 10^{-3}$ atmospheres) pressures of NH_3 needed to heavily N-dope the LPE layers. Such a reaction precludes the simultaneous heavy doping of GaP with N and Al or Be. While such a reaction is expected for Mg, it is not likely at the doping levels of interest. No such reaction may occur for C. Experimental results for LPE layers where heavy Si and N doping were attempted are consistent with the thermodynamic calculations.

Acknowledgments

We wish to thank D. D. Roccasecca for his assistance in the materials growth, R. Z. Bachrach for the spectra and diode efficiencies, and J. Mann and R. Furnanage for the diode fabrication. The assistance of G. Forsyth for the $|N_d - N_a|$ measurements, and F. A. Trumbore for helpful discussions is much appreciated.

Manuscript submitted Feb. 18, 1972; revised manuscript received July 31, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Lifetimes and Diode Characteristics in Epitaxial Silicon

P. Rai-Choudhury* and D. K. Schroder

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

The lifetime in epitaxially grown silicon p- and n-layers and the reverse I-V characteristics of diodes fabricated in such layers, were measured as a function of various growth temperatures and substrates of different dopants and doping concentrations. The epitaxial layers were grown by the hydrogen reduction of silicon tetrachloride. It was found that layers grown at 1100°C had significantly higher lifetimes (up to 200 μsec) and higher breakdown voltages than those grown at higher temperatures. Furthermore, layers grown on heavily phosphorus-doped substrates had much better characteristics than those grown on antimony- or lightly phosphorus-doped substrates. Chelating of the substrates prior to epitaxial growth had the effect of reducing the scatter as well as increasing the value of the lifetime. Gettering with P_2O_5 had a lesser effect on the diode characteristics than it did on the lifetime.

Recent comparisons of microinhomogeneities in epitaxial silicon with those in melt grown silicon indicate that conventional epitaxial silicon from the $SiCl_4$-H_2 system is comparable to the best melt grown materials (1). In terms of oxygen content, epitaxial silicon is comparable to float-zoned silicon. However, devices fabricated in vapor grown silicon often have poor junction characteristics (2). The substrate surface is frequently contaminated with metallic impurities before epitaxial layers can be grown. Unless these contaminants are more soluble in the substrate (such as Au in P-doped n^+ Si) or pinned strongly by the substrate, these metals will diffuse into the growing layer reducing the minority carrier lifetime. Recent

work by Kern and Puotinen (3) on the effectiveness of peroxide cleaning in reducing organic, ionic, and metallic impurities, and the work of Robinson *et al.* (4) on HCl gettering to increase the minority carrier lifetime, give some indication of the effects of surface contamination. Chang (5) has observed by the Leed-Auger method that heat-treatments above 1000°C were accompanied by the appearance of metallic impurities at the surface, which sometimes totaled over 1×10^{14} atoms/cm^2 for a 5 min heat-treatment at 1250°C. Thus, metallic impurities that are usually present as surface contaminants and as rejected solutes from the bulk during heat-treatment, often decide the fate of the device. It is generally found that p-n junctions involving epitaxial silicon, such as epitaxial-substrate junctions, epitaxial-epitaxial junctions, or diffused junctions into expitaxial silicon, give either high-reverse leakage current or considerably lower junction breakdown voltage than diffused junctions in melt grown silicon. The epitaxial junction is located either near the substrate-epitaxial interface, where the substrate surface has been extensively treated, or in the epitaxial material grown on such a treated surface. In either case, there is the possibility that significant contamination of the junction or of the entire epitaxial layer exists. Thus the importance of cleaning the substrates effectively before epitaxial growth cannot be overemphasized.

Epitaxial structures are more susceptible to postgrowth contamination than diffused structures. The dislocations generated in the epitaxial reactor are thermally induced (6), relatively clean, extend over larger thicknesses, and are widely separated. Any post-heat-treatment operation, such as base or emitter diffusion of transistors, could decorate these dislocations with heavy metals, which might develop shorted or extremely leaky junctions. The dislocations generated in a diffusion furnace are impurity induced, already decorated (being located in the heavily doped diffused region), and are usually more dense. Both types of dislocations are essentially edge in character and slip on the system (111)[110]. While the mobility of the diffusion induced dislocations may be different from those induced thermally (7), the latter type may be more harmful.

The reason for the inferior performance of devices fabricated in epitaxial silicon, in spite of their high structural perfection, is not clear. The present investigation was undertaken with the hope of gaining a better understanding of this problem and improving the epitaxial silicon. In this study the carrier lifetime and diode characteristics in the epitaxial silicon are measured under various processing conditions. Some of the important variables considered are cleaning procedure, growth temperature, and substrate material.

Experimental Procedure

The silicon substrates used were n-type, 2° off the (111) orientation, float zoned as well as Czochralski grown. The dopants in the heavily doped substrates were deliberately chosen as phosphorus (1×10^{20} atoms/cm^3) which causes lattice contraction, and antimony (5×10^{18} atoms/cm^3) which may slightly dilate the silicon lattice. The substrates were either chemically polished or chem-mechanically polished by the silicon dioxide polishing technique (8) and were free of any mechanical damage. Three methods of substrate cleaning were followed. The first consisted of degreasing in acetone and trichloroethylene followed by boiling in H_2SO_4:HNO_3::3:1. Each step was followed by extensive rinsing in Super Q water, *i.e.*, continuously recycled deionized water. This method will be designated for convenience as DSN. The second method consisted of an additional final step of treating the wafers with ammoniumethylenediaminetetracetate (EDTA), a complexing agent for metals, followed by repeated rinsing in Super Q water. This second method is designated as DSNE. In the third method, the EDTA was replaced by an H_2O-H_2O_2-NH_4OH treatment to remove organic contaminants and by an H_2O-H_2O_2-HCl treatment to remove metallic impurities. This method is designated as DSNP and is described in detail by Kern *et al.* (3).

The epitaxial layers of silicon were grown on these substrates following an *in situ* HCl etch. Epitaxial growth was carried out in a conventional horizontal rf heated system, having a silicon-coated graphite susceptor. The $SiCl_4$ partial pressure was typically 8×10^{-3} atm, the gas velocity was 41 cm/sec, and the reactor was of rectangular cross section 8 cm $\times$ 5 cm. Six wafers were normally used for each run, and to eliminate any run-to-run or day-to-day variability in the data, a given run always included two wafers of each of three substrates, rendering the results more meaningful. Silicon was deposited from the H_2-$SiCl_4$ system and doped with B_2H_6 and AsH_3 as desired. Hydrogen was Pd-purified and all materials were of ultrapure grade. Epitaxial layers were grown at three temperatures 1100°, 1150°, and 1250°C.

The carrier concentration profiles and thicknesses of the grown layers were determined by the spreading resistance technique (9). They were typically 20-30μ thick. To measure the lifetime it is undesirable to use techniques that require a p-n junction, since the formation of a junction can alter the very properties we want to measure. Methods that rely on the decay of excess carriers are also not suitable since they involve the minority carrier diffusion length. This can be much longer than the epi-layer thickness and the measured lifetime in that case is an epi-layer/substrate combination.

For these reasons we chose the pulsed MOS capacitor technique (10) in which the generation lifetime (11) is determined. Here, the generation of carriers in the space-charge region is measured. Hence, small volumes are sampled and the sample volume can be easily controlled through the appropriate choice of gate diameter and gate voltage step. The gate diameter was 12 mil and the depleting voltage step was between 50 and 100V creating a silicon space-charge region width of about 10μ for a 2500Å thick oxide.

The MOS capacitors were formed by chemical vapor deposition of SiO_2 at 750°C using the silane-oxygen process. Aluminum dots were evaporated through a metal mask. The effect of the Si-SiO_2 interface on the pulsed MOS-C response is made negligible by hydrogen annealing (12) and a proper analysis of the data (13).

Diode measurements were made on p-n junctions which were of three types, (*i*) shallow diffused junctions into the epitaxial layers (boron diffusion into n-epitaxial layers); (*ii*) substrate-epitaxial junctions (only used for boron-doped epitaxial layers on n-type substrates); (*iii*) epitaxial-epitaxial junctions formed by growing a layer of opposite conductivity on the first epitaxial layer. Mesa diodes were fabricated which were subsequently passivated by the 750°C deposited oxide and hydrogen annealed. Some diodes were gettered in a two-zone P_2O_5 furnace with the source at 250°C and the silicon wafers at 950°C for 45 min in an argon ambient to see if the lifetime could be improved.

We found that the p-n junctions were more difficult to analyze than the lifetimes, since they involve not only the epitaxial layer, but also a second region of opposite conductivity, plus the added complexity of the junction itself. Therefore, the interpretation of the I-V measurements is more complicated.

Results

Lifetimes.—N-epitaxial layers.—The lifetime data for n-epitaxial layers are presented first. These layers were grown on three types of substrates: (*i*) 0.0009 ohm-cm phosphorus-doped, (*ii*) 10 ohm-cm phos-

phorus-doped, and (*iii*) 0.008 ohm-cm antimony-doped; at three temperatures: 1100°, 1150°, and 1250°C. In addition, a comparison was made between the DSN cleaning procedure and cleaning using a chelating agent.

The effect of the cleaning procedure is seen in Fig. 1 by comparing the lifetime values at 1150°C for the three substrates. It is quite obvious that the chelated wafers had significantly higher lifetimes than those cleaned in the same manner, but not chelated. This points out the heavy metal complexing property of the chelating agent. Although it is not obvious from the data points in that figure—each point is the average of 10 measurements—the scatter in the data for wafers treated with the EDTA chelating agent is considerably less than that for wafers not chelated. For example when the substrate was not chelated, the lifetime in the layer grown on heavily phosphorus doped substrate at 1150°C varied from 1.6 to 28 μsec; using chelated substrates the lifetimes improved to 91 to 120 μsec. A comparison of these two sets of data points at 1150°C, which were the first to be done in these experiments, prompted us to use a chelating agent for all other runs.

The second, very important observation to be made on Fig. 1 is that the lifetime increases for lower growth temperatures. Although the lifetime values do not all change by the same amount, the trend of higher lifetimes for lower temperatures is certainly obvious.

The third observation is that consistently higher lifetimes were obtained on layers grown on degenerately phosphorus-doped substrates. We have found this to be the case for all layers grown during this investigation—n and p-type.

In an attempt to improve the lifetime of those layers grown on the lightly phosphorus-doped or degenerately antimony-doped substrates, they were gettered, using the conditions described earlier. This treatment had essentially no effect on the lifetime, indicating that the impurities responsible for the lifetime degradation cannot be easily removed by this gettering procedure.

P-epitaxial layers.—The lifetime data for p-epitaxial layers are shown in Fig. 2. Having found on n-layers that chelating had a significant effect on the lifetime, all substrates were chelated prior to p-epitaxial growth. The substrates were identical to those used for the n-layers.

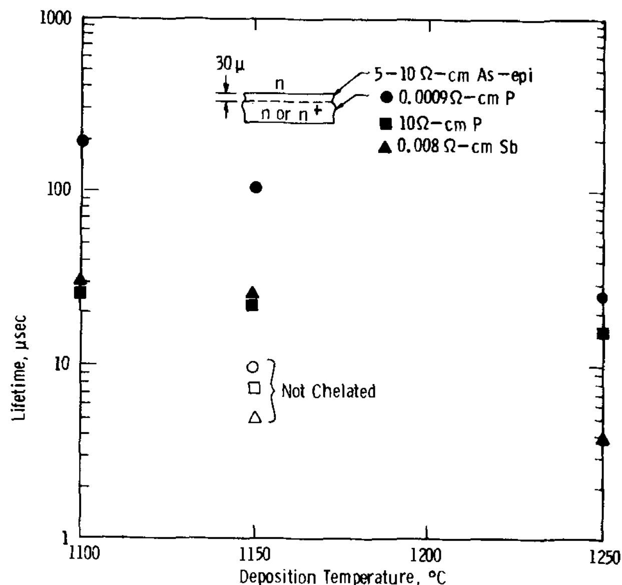

Fig. 1. Lifetimes in n-epitaxial layers as a function of deposition temperature. For 1150°C lifetimes with and without chelating are shown. All others are chelated.

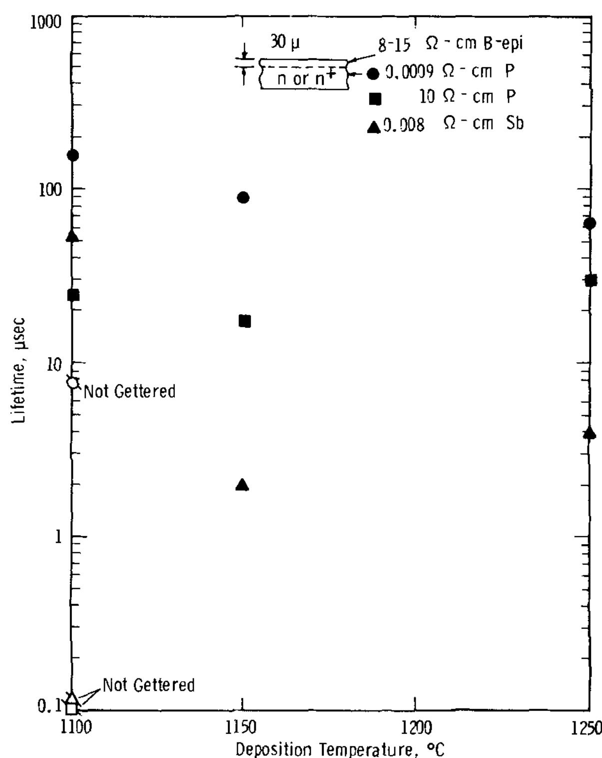

Fig. 2. Lifetimes in p-epitaxial layers as a function of deposition temperature. For 1100°C lifetimes before and after gettering are shown. All others are gettered.

However, in contrast to the results of Fig. 1, where P_2O_5 gettering had little effect on the lifetimes, very significant lifetime improvements were observed on the p-layers following the P_2O_5 gettering cycle. For example, for the 1100°C deposition temperature, values before and after gettering are shown and lifetime increases by a factor of over 100 were observed. Similar effects were measured at the other deposition temperatures, but for these temperatures only the lifetimes after gettering are shown. During the gettering cycle, both surfaces of the wafers were exposed to the phosphorus ambient and the thin n^+ skin on the p-epitaxial layer was etched off prior to the low temperature oxide deposition.

Similar to the observations on n-layers, the p-layers also showed an increase in lifetime values for lower epitaxial growth temperatures, and the layers grown on the heavily phosphorus-doped substrates again yielded the highest lifetime.

I-V characteristics.—The lifetime results showed the following definitive trends: the lower the deposition temperature, the higher the lifetime; layers grown on heavily phosphorus-doped substrates gave consistently better lifetimes. It is known that impurities that influence the lifetime, *e.g.*, heavy metals, can also have a pronounced effect on the I-V behavior of reverse-biased diodes (14). They can cause microplasmas which result in excessive leakage currents or low breakdown voltage. To correlate our lifetime data with junction behavior, we measured the breakdown voltage of p-n junctions formed in the epitaxial layers.

N-epitaxial layers.—A typical impurity concentration profile of an n-layer on a heavily phosphorus-doped substrate is shown in Fig. 3 indicating absence of any doping nonuniformity arising either from poor system control or contamination. The layer thickness was around 30μ and the doping varied between 5×10^{14} and 2×10^{15} cm^{-3} insuring bulk and not punch-through breakdown for all but the lowest dopant concentrations.

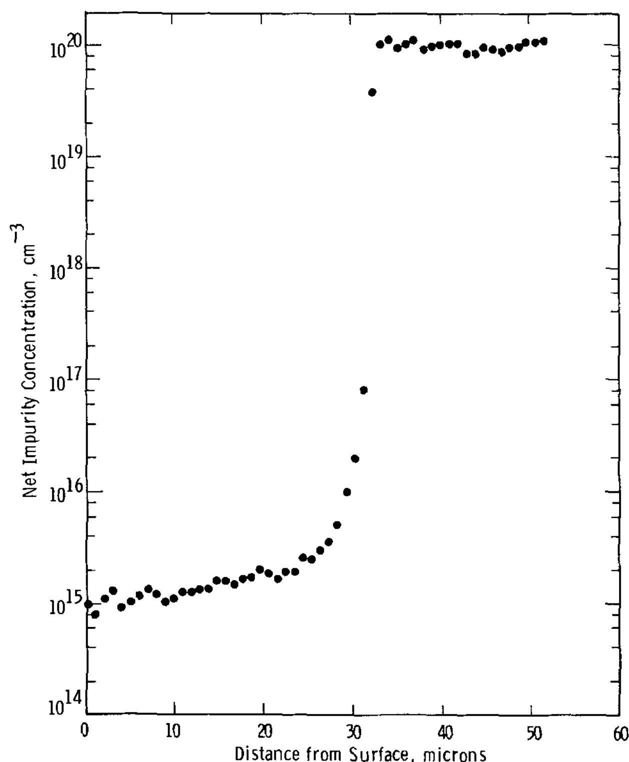

Fig. 3. Typical impurity concentration profile of an n-epitaxial layer on a heavily phosphorus-doped substrate.

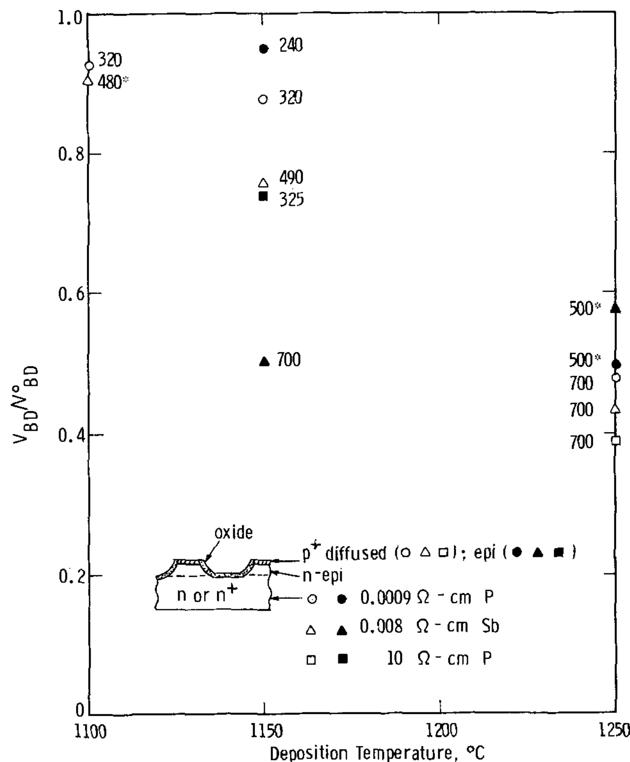

Fig. 4. Ratio of measured to theoretical breakdown voltage of diodes in n-epitaxial layers as a function of deposition temperature. The open points are for diffused and the solid points for epitaxial diodes. The numbers beside the points are the theoretical breakdown voltages, where the starred numbers indicate breakdown under punch-through conditions.

The diodes were formed by either a shallow boron diffusion into the layer or growing a p^+ epitaxial layer on top of the n-layer. 40 mil diameter mesa diodes were then etched which were subsequently passivated by an oxide deposition as shown in the insert of Fig. 4. The results of voltage breakdown measurements are shown in Fig. 4 and Tables I and II. The ratio of measured breakdown to the theoretical values, corresponding to the layer doping, is plotted as a function of the deposition temperature. The open points refer to diffused diodes and the solid ones to epitaxial-epitaxial diodes. The numbers beside the points are the theoretical breakdown voltages, with the starred quantities indicating that the breakdown is determined by punch-through of the space-charge region to the n^+ substrate.

P 50 ohm-cm	DSNE	1150	1×10^{15}	240 @ 20μA	325

[a] Indicates theoretical punch-through breakdown voltage.

The processing and growth conditions as well as doping concentrations of the layers are given in Table I. The reverse voltage values are given for two values of current, less than 20 μA and 5 mA, where the 5 mA value was used as the breakdown voltage measure. Also shown are the theoretical breakdown voltages (15). Similar data for the epitaxial-epitaxial diodes are shown in Table II.

The general trend of these measurements is in accord with the lifetime data, *i.e.*, lower growth temperatures yielded devices with breakdown voltages closer to the theoretical values. Also, diodes fabricated on heavily phosphorus-doped substrates had higher breakdown values than the other two substrates. These diodes also exhibited harder I-V characteristics, while the others frequently had a very soft breakdown. The very low V_{BD} of the lightly doped layers ($2\text{-}4 \times 10^{14}$ cm^{-3}, with their correspondingly high V^{o}_{BD}) may be partly due to surface effects.

Contrary to the lifetime data, the cleaning procedure had little influence on the breakdown characteristics, as evidenced by the data in Table I. The chelating and H_2O_2 cleaning of the substrates did not give significantly different results than those of the substrates not so cleaned.

The epitaxial-epitaxial diodes behaved very much like the diffused ones. This indicates that such junctions are not inherently poor, but that the junction characteristics are much more dependent on the quality of the layer with the lower doping.

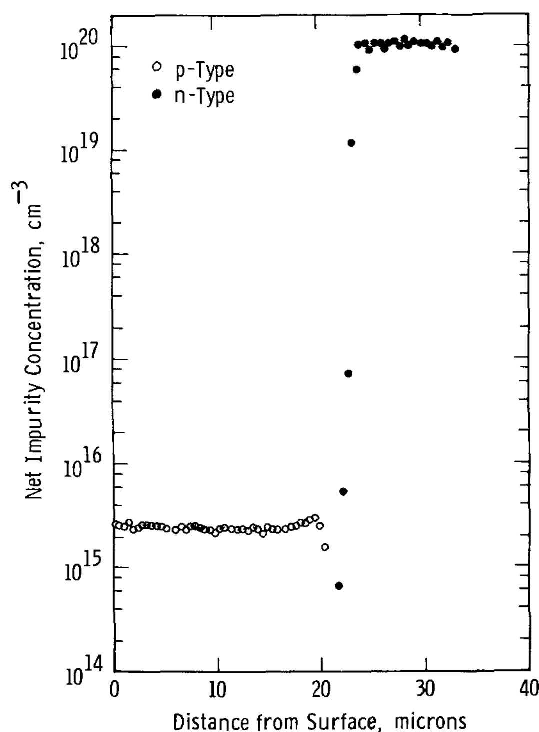

Fig. 5. Typical impurity concentration profile of a p-epitaxial layer on a heavily phosphorus-doped substrate.

P-epitaxial layers.—An impurity concentration profile of a p-layer on a heavily phosphorus-doped substrate is shown in Fig. 5. This is typical of the p-epitaxial layers showing the doping uniformity and a well-defined step junction. Since a natural junction is formed when a p-layer is grown on an n-type substrate, only the substrate-epitaxial junctions were evaluated for these layers. The results for 1100°C growth temperature and DSNE chelating are shown in Table III. The diodes fabricated on phosphorus-doped substrates had higher breakdown voltages than those on antimony-doped substrates, as measured on n-layers. However, there was no notable difference between the lightly and heavily phosphorus-doped substrates. We tried to improve the reverse-characteristics by phosphorus gettering, the process which had a noticeable effect on the lifetime of p-layers. But, as is evident in Table III, gettering had little effect on the breakdown voltage.

Similar to n-layers, higher growth temperatures yielded junctions with poorer reverse characteristics. Those measurements, however, were not as conclusive as the n-layer results, and are not shown in Table III.

Discussion

From Fig. 1 and 2 it is obvious that the highest lifetimes were obtained on both n- and p-type layers grown on heavily phosphorus-doped substrates. These substrates were characterized by the presence of considerable inhomogeneities, such as, impurity striations, phosphorus-induced precipitates, and dislocations. However, an examination in transmission electron microscopy indicated that the epitaxial layers grown on these substrates were of good quality, and comparable to layers grown on dislocation-free, high perfection, high resistivity substrates. Sirtl etching (16) of the layers grown on these substrates revealed only a few dislocations, the number of which decreased with decreasing growth temperature. However, x-ray topographs of the epitaxial layers with and without the substrates indicated the apparent presence of strain which Sirtl etch failed to reveal. Although the origin of these apparent strain effects is not known, their presence in layers grown on degenerate phosphorus-doped substrates at all temperatures, reduces their importance as lifetime controlling factors, since the lifetime in these layers was very high. Thus, with the exception of a slight variation in the dislocation density at a very low level, the layers on all substrates were free from any precipitates and stacking faults. Hence, an explanation of the lifetime results should primarily come from point defect considerations. Point defects, such as, vacancies, carbon, oxygen, heavy metals, and various complexes can form numerous deep energy levels (17), reducing the carrier lifetime.

Table III. Characteristics of substrate-epitaxial diodes on p-epitaxial layers grown at 1100°C

Substrate	Gettering	Layer doping	Rev. voltage at current <20 μA	Rev. voltage at current 5 mA	V°_{BD}

	P_2O_5	1×10^{15}	280	315	320

The high values of the lifetime in the n-type layers can be taken as an indication that the deposition system was free of lifetime-killing impurities. The fact that the lifetime in the p-type layers before gettering was low is probably connected with the B_2H_6 doping system. Although gettering improved the lifetime in the p-layers near the top surface, the p-n junction, *i.e.*, the epitaxial layer-substrate interface region was not effectively cleaned.

The reason for such high lifetimes in the epitaxial layers grown on heavily phosphorus-doped substrates is not clearly understood. We offer the following conjecture as a possible explanation. The type and location of the impurity-pinning centers in epitaxial silicon (*e.g.*, thermally induced dislocations extending the entire thickness of the wafer) are such, that the impurities cannot be gettered as effectively as in diffused junctions in bulk material. The diffusion induced dislocations on the other hand are formed in the heavily doped side of the junction, with a maximum dislocation density located away from the junction plane (18, 19) and are decorated with the diffusing dopant. Thus the epitaxial silicon is generally more susceptible to contamination, and once contaminated, affects the device behavior adversely. The diode characteristics and the lifetime results together with the observed effects of chelating indicate that the lifetime-killing impurities originate primarily from the substrate surface, rather than from the epitaxial growth system. High phosphorus concentration contracts the silicon lattice and increases the affinity and solubility of heavy metals, such as Cu, Ag, and Au. Any heavy metal contamination introduced during substrate preparation may be held more effectively by degenerate phosphorus-doped substrates than by antimony or lightly phosphorus-doped substrates during subsequent epitaxial growth. If the growth temperature is sufficiently high so as to render these adsorbed impurities mobile then the grown layer becomes contaminated causing a decrease in the measured lifetime. The metallic impurities probably constitute the primary mode of layer contamination, either as individual point defects or as complexes with other point defects, such as vacancies. Decoration of dislocations with metallic is most likely only a secondary mode of contamination.

Summary

Epitaxial n- (arsenic-doped) and p-layers (boron-doped) were grown on phosphorus and antimony-doped substrates at temperatures from 1100°-1250°C. The generation lifetime was measured in these layers

by the pulsed MOS-C technique and the reverse junction characteristics were obtained on diodes formed in these layers.

The lifetimes in both types of layers were comparable. They improved when the substrates were cleaned using a heavy metal complexing chelating solution. Lifetimes of several hundred microseconds were measured on layers grown at 1100°C, but higher growth temperatures caused the lifetimes to decrease. The layers grown on heavily phosphorus-doped substrates had higher lifetimes than those grown on lightly phosphorus-doped or heavily antimony-doped substrates. Phosphorus pentoxide gettering had little effect on the lifetimes in the n-layers but resulted in a significant increase for the p-layers. This is probably due to lifetime killing impurities of the B_2H_6 doping system.

The trend of the lifetime results was generally also observed when the breakdown voltage of the diodes was measured. The layers grown at the lower temperature (1100°C) had breakdown voltages closer to theoretical values than those grown at higher temperatures. The diodes formed in layers grown on heavily phosphorus-doped substrates had better characteristics than those grown on the other two substrates. Gettering had a lesser effect on the diode characteristics than it did on the lifetimes.

There was no significant difference between diodes formed by boron diffusion into the n-layers and those fabricated by growing a p-layer on the n-layer. This shows that epitaxial-epitaxial junctions can be as good as diffused-epitaxial junctions. For the epitaxial p-layers on the n-substrates, the epitaxial-substrate junctions showed some good behavior but on the whole gave poorer results than those above.

$Zn(PO_3)_2$ Glass as a Doping Source for GaP(Zn,O)

A. S. Jordan, L. Derick, R. Caruso, and M. Kowalchik

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

As an alternative to elemental Zn and Ga_2O_3 powder, $Zn(PO_3)_2$ glass has been utilized as a convenient simultaneous source of Zn and O to dope GaP. The synthesis of $Zn(PO_3)_2$ from ZnO and $(NH_4)_2HPO_4$ is described together with some of its advantageous properties (low melting point, compactness, small surface area for adsorption). $Zn(PO_3)_2$ was employed in the preparation of GaP liquid-phase epitaxial layers (on vapor grown substrates) and of solution-grown (SG) platelets, for which red electroluminescence and photoluminescence efficiency maximization curves were determined, respectively. The results are comparable to those obtained previously by using Zn and Ga_2O_3. Analysis of the photoluminescence measurements, absorption spectra, and below-gap excitation spectra on SG platelets indicates that the incorporation chemistry of Zn and O from $Zn(PO_3)_2$ is in accord with previous findings using Zn and Ga_2O_3. Since the nonradiative shunt path component of the minority carrier lifetime in SG platelets is hole concentration dependent for growth solutions containing $Zn(PO_3)_2$ as well as for those containing Zn and Ga_2O_3, it seems unlikely that the "killer center" associated with the shunt path is related to the background impurities introduced by these dopants.

The early work of Starkiewicz and Allen (1) on GaP red light-emitting diodes (LED's) demonstrated the key role of Zn and O in the generation of the red light, which is now known to arise from the decay of excitons bound to Zn-O nearest neighbor pairs (2, 3). The usual sources of Zn and O are Zn pellets and Ga_2O_3 powder, although ZnO (4, 5), $Zn_3(PO_4)_2$ (5), and $GaPO_4$ (5) have also been used or considered. In this paper we report on the use of $Zn(PO_3)_2$ glass as a promising dopant with certain advantages over these sources, and we consider the luminescent properties

Key words: light-emitting diodes, crystal growth, compound semiconductors, photoluminescence.

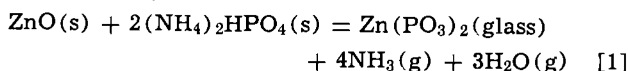
of Zn,O-doped GaP crystals grown from solutions containing $Zn(PO_3)_2$.

Our search for an alternative approach was motivated by several considerations. First, the use of a glass should be advantageous due to the reduced adsorption of impurities from the atmosphere as compared with Ga_2O_3 powder, which has a large surface area.[1] Second, a single compact dopant was sought to eliminate the cumbersome handling of Zn pellets and Ga_2O_3 powder. Third, a source was desired with a melting point below the typical growth temperature (~1040°C) (7) of GaP by liquid-phase epitaxy (LPE), in order to achieve rapid mixing and dissolution of the dopants in the solution during the warmup cycle. $Zn(PO_3)_2$ glass, which melts at ~870°C (8), seemed to satisfy these requirements. Finally, in order to determine whether impurities contaminating Ga_2O_3 powder introduce nonradiative "shunt path" (9, 10) centers, $Zn(PO_3)_2$ was chosen because it can be synthesized without using Ga or Ga_2O_3.

It was shown earlier that the incorporation of Zn in GaP pulled by the liquid encapsulation Czochralski (LEC) technique from melts containing $Zn(PO_3)_2$ follows the calculated solid solubility for Zn at 1465°C (11). Recently, the photoluminescent properties of GaP pulled by LEC from stoichiometric melts and nonstoichiometric solutions with $Zn(PO_3)_2$ additions have been given (12). Electroluminescence efficiencies as high as 2.7% have been reported on annealed and encapsulated diodes prepared by double LPE on n-type LEC substrates, where the p-type LPE layer was grown from a solution containing $Zn(PO_3)_2$ (13). The major objective of this paper is to describe our experiments concerning the utilization of $Zn(PO_3)_2$ for doping GaP grown either by LPE on vapor-grown (VG) substrates (Work done prior to the availability of LEC substrates.) or by slow cooling of unseeded solutions of Ga saturated with GaP.

Experimental Procedure

Synthesis of $Zn(PO_3)_2$.—$Zn(PO_3)_2$ was synthesized from ZnO and $(NH_4)_2HPO_4$, both with 99.999% nominal purity, by the reaction



$$ZnO(s) + 2(NH_4)_2HPO_4(s) = Zn(PO_3)_2(glass) + 4NH_3(g) + 3H_2O(g) \quad [1]$$

In a typical run stoichiometric proportions of the powdered ingredients were mixed thoroughly and loaded into a shallow Pt dish.[2] The mixture was placed in a box-type furnace, slowly heated to ~1000°C, and held there for at least 1 hr. Reaction [1] proceeded to completion, yielding only $Zn(PO_3)_2$ glass and gaseous H_2O and NH_3 which were exhausted via an inverted quartz casserole (covering the Pt dish) that served as a chimney. Finally, the liquid glass was poured onto a clean quartz plate to solidify, crushed into convenient size pieces, and stored in a N_2 dry box to prevent hydration.

GaP crystal growth.—The feasibility of using $Zn(PO_3)_2$ was first demonstrated by the sealed-tube single LPE growth of Zn,O-doped GaP layers on S-doped n-type VG GaP substrates with a net donor concentration of $\sim 6 \times 10^{17}$ cm^{-3}. The substrates were deposited by the wet hydrogen vapor transport method (14) on GaAs seeds, removed from the seeds, and mechanically polished on the {111} P-face to a thickness of ~0.3 mm. A modification of the sealed-tube tipping technique (15) was used to grow a series of LPE layers from GaP-saturated Ga solutions containing between ~0.02 and 0.25 mole per cent (m/o) $Zn(PO_3)_2$. The VG substrate, sometimes as large as 12 mm by 20 mm, was pinned by a quartz rod to a quartz pedestal before the evacuation and sealing of the fused quartz capsule. The pin permitted the termination of LPE growth at will by a 180° rotation of the capsule along its horizontal axis. Usually ~40 μm thick films were deposited by cooling from 1050° to 600°C at 10°C/min.

In addition, Zn,O-doped GaP platelets were grown by cooling saturated solutions of GaP in Ga (SG). Typically, unseeded solutions containing 6.9 m/o GaP and between $\sim 10^{-3}$ and $\sim 2 \times 10^{-1}$ m/o $Zn(PO_3)_2$ in a BN crucible were placed in a fused quartz tube which was then evacuated and sealed. The ampoule was heated to ~1160°C, held for 2 hr, and cooled to 900°C at 5°C/hr.

Experimental Results and Discussion

Point contact electroluminescence measurements were performed at 2 and 10 mA on several 250 μm mesa diodes fabricated from each p-type LPE, n-type VG structure. The variation of η_{EL} at 10 mA as a function of the nominal $Zn(PO_3)_2$ concentration in the LPE solution is presented in Fig. 1. The maximum value of η_{EL} is achieved between ~0.1 and ~0.15 m/o $Zn(PO_3)_2$. By bonding and encapsulating in epoxy, the η_{EL} of the "best" diode was increased from its point contact values of 0.60% at 2 mA and 0.52 at 10 mA[3] to 1.20 and 1.05%, respectively.

Trumbore *et al.* (16) reported point contact η_{EL} for similar unannealed diodes prepared by depositing a Zn,O-doped p-type layer from a Zn, Ga_2O_3-containing tipping solution onto VG substrates. Their η_{EL} values were 0.11% and 0.23% for S- and Te-doped substrates,[4] respectively ($N_D - N_A = \sim 4 \times 10^{17}$ cm^{-3}). With respect to Zn, their solution composition of 0.15 m/o Zn is the same as the composition leading to our maximum η_{EL}. These workers added only 0.05 m/o Ga_2O_3 to their solution whereas we provided an amount equivalent to 0.3 m/o Ga_2O_3 (0.15 m/o $Zn(PO_3)_2$). However, additions in excess of 0.008 m/o Ga_2O_3 at ~1040°C lead

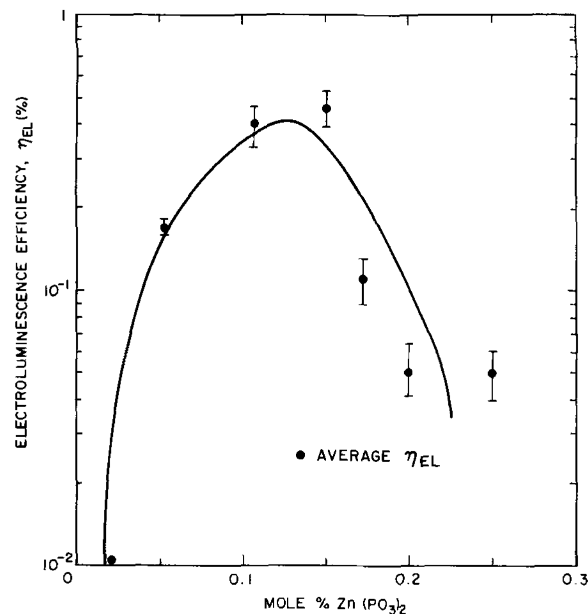


Fig. 1. Point contact electroluminescence efficiency, η_{EL}, of GaP mesa diodes at 10 mA as a function of $Zn(PO_3)_2$ concentration in the LPE solution. The net donor concentration of the S-doped VG substrates is $\sim 6 \times 10^{17}$ cm^{-3}. The top and bottom of each error bar represent the highest and lowest efficiency mesa diodes fabricated from the same slice.

[1] Recently S, a shallow donor impurity, was found to be introduced with Ga_2O_3 additions in some GaP crystals (6).

[2] Although these powdered ingredients may contain adsorbed impurities, most of these are expected to be removed by volatilization during the high temperature synthesis.

[3] The η_{EL} at 2 mA of annealed and encapsulated diodes prepared identically but replacing $Zn(PO_3)_2$ with Zn and Ga_2O_3 in our LPE system is 1.3%. All the values of η_{EL} in Fig. 1 are for unannealed LPE layers. Although no detailed study of annealing was undertaken here, the diodes with the maximum efficiency showed no improvement with annealing, in agreement with previous findings at similar Zn concentrations in the tipping solution (7).

[4] It should be noted, however, that in the work of Trumbore *et al.* (16) η_{EL} of 0.5% was reported for a presumably Si-contaminated n-type VG substrate.

to the saturation of the Ga-GaP-Ga_2O_3 ternary solution (13), and it seems likely that both results were obtained on GaP layers of comparable oxygen concentration.

We also studied the photoluminescence properties of the $Zn(PO_3)_2$-doped SG unannealed platelets. To prepare planar, parallel specular surfaces the platelets were polished on the {111} Ga and P faces on a tin lap with a 0.1 μm diamond polish. For two runs, although the platelets were polished, their small size precluded the preparation of parallel surfaces. For every crystal the red (7000Å) internal photoluminescence quantum efficiency (9), η_{PL}, was measured at 25°C under excitation with the 4880Å line of an argon laser. The dependence of η_{PL} on $Zn(PO_3)_2$ concentrations in the solution is shown in Fig. 2.

Recent experimental and theoretical results concerning the optical properties of Zn,O-doped GaP (9, 12, 17-19) provide a model for a self-consistent estimation of the total substitutional oxygen concentration, $N_{O,t}$, the total zinc concentration, $N_{Zn,t}$, and the nonradiative shunt path component, τ_n, of the total minority carrier lifetime. For the platelets with planar and parallel surfaces we obtained absorption spectra and below-bandgap excited photoluminescence spectra, the latter with the 5682Å line of a krypton laser. These measurements, in connection with η_{PL}, led to the determination of the minority carrier lifetimes, τ_m (17). Then, from a previously established correlation (18) of the absorption coefficient at 0.8 eV with hole concentration, we estimated the hole concentration and $N_A - N_D$. A knowledge of $N_A - N_D$ and η_{PL} permits the calculation of the branching ratio, s (9, 18).

Appropriate combinations of s and τ_m yield τ_n (9, 12) and the concentration of Zn-O complexes, N_{ZnO}

$$1/\tau_n = (1 - s)/\tau_m \quad [2]$$

and

$$N_{ZnO} = s/v\sigma_{nt}\tau_m \quad [3]$$

where v is the thermal velocity of the electrons and σ_{nt} is the cross section for the capture of minority carrier electrons by the Zn-O center. In addition, the relative concentration of unpaired substitutional oxygen can be estimated by a combination of N_{ZnO}, η_{PL}, s, and the ratio of the infrared (1.32 eV) to red (1.77 eV) signal strengths, obtained from the below-gap photoluminescence spectra (18). This relative value in comparison with the optical properties of a previously characterized standard SG crystal (9) yields an absolute value for the concentration of unpaired substitutional oxygen, N_{O^+}.

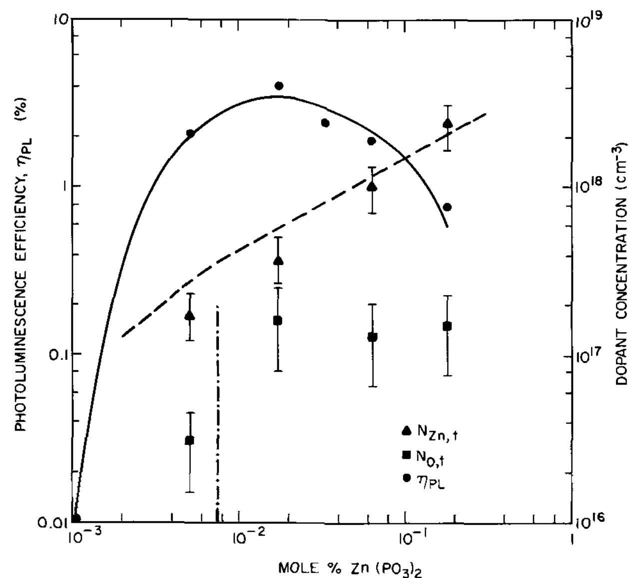

Fig. 2. Photoluminescence quantum efficiency, η_{PL}, of SG platelets as a function of $Zn(PO_3)_2$ concentration in the growth solution. The estimated total dopant concentrations $N_{O,t}$ and $N_{Zn,t}$ are also shown. The dashed line is the calculated Zn solubility isotherm for GaP at 1100°C (11). The vertical line represents the estimated O solubility in the solution of the Ga-GaP-Ga_2O_3 system at 1100°C, converted to m/o $Zn(PO_3)_2$ (13). The error bars for $N_{O,t}$ and $N_{Zn,t}$ are consistent with Ref. (9) and (18), respectively. The η_{PL} of 0.01% for 10^{-3} m/o $Zn(PO_3)_2$ is an upper limit.

If Zn and O are the only electrically active impurities in these SG platelets, then a knowledge of $N_A - N_D$, N_{O^+}, and N_{ZnO} permits the calculation of $N_{O,t}$ and $N_{Zn,t}$ (18). In Fig. 2 we present $N_{O,t}$ and $N_{Zn,t}$ as a function of $Zn(PO_3)_2$ concentration in the solution. The calculated Zn solid solubility isotherm in GaP (11) and the estimated O solubility in liquid Ga saturated with Ga_2O_3 and GaP (13), both for 1100°C, are also shown. It can be seen that the experimental $N_{Zn,t}$ values for SG crystals grown between 1160° and 900°C can be reasonably well represented by the theoretical 1100°C solubility isotherm. $N_{Zn,t}$ for the platelet with maximum efficiency ($\eta_{PL} = 4\%$) is comparable with the net acceptor concentration reported by Saul *et al.* (7) for high efficiency p-n junctions.

It has been previously mentioned that the Zn solubility in GaP pulled by LEC from $Zn(PO_3)_2$-containing melts also follows the theoretical 1465°C curve. For these crystals the experimental and calculated distribution coefficients derived from Ref. (11) are 0.16 and 0.19, respectively, which should be compared with the distribution coefficient of 0.096 reported for GaP pulled by LEC from melts containing metallic Zn (20). Evidently, in contrast to Zn, when $Zn(PO_3)_2$ is used in this open system, the loss of Zn from the LEC charge during heating to the melting point of GaP is almost negligible.

According to Fig. 2, in agreement with thermodynamic considerations (13) and recent results on LPE growth (21), $N_{O,t}$ remains constant above the ternary solubility limit (13) in the solution. Very recent measurements using prompt α-particle nuclear microanalysis to directly determine $N_{O,t}$ in LPE layers grown at ~1100°C (22) and electrical data on SG crystals (23) are in accord with the indicated lower limits (7×10^{16} cm^{-3}) of the estimated values shown in Fig. 2 along the plateau.

In Fig. 3, we show the variation of $1/\tau_n$ (obtained by using Eq. [2]) with hole concentration. The data strongly support a linear dependence of $1/\tau_n$ on hole concentration, as has been suggested elsewhere (9, 24). According to Dishman *et al.* (9), this relationship is consistent with the presence of a killer center in SG GaP which is a deep acceptor impurity with a concentration independent of the Zn doping level. Because the capture of electrons by this center proceeds via an Auger process by moving a free hole deep into the valence band, a linear relationship between $1/\tau_n$ and hole concentration results. Since our growth solutions were doped with $Zn(PO_3)_2$ whereas those of Dishman *et al.* (9) were doped with Zn and Ga_2O_3, it seems unlikely that the killer center is related to the chemical contaminants present in either doping source.

In previous work a correlation has been established between $1/\tau_n$ and relative Ga-vacancy concentration for Zn,O-doped GaP pulled by LEC from stoichiometric and nonstoichiometric solutions (12). In stoichiometric LEC samples, $1/\tau_n$ appeared to be independent of hole concentration (18). As all the SG crystals in the present study were grown in the same temperature range, their Ga-vacancy concentration is expected to be reasonably constant. Thus, we may speculate that an additional killer center is present in SG crystals, such as a Ga-vacancy-O complex (25), which may be responsible for SG crystals not having a higher η_{PL}.

Some qualitative considerations are in order concerning the shape and position of the η_{PL} curve in Fig. 2. Initially, η_{PL} increases from 2.1 to 4.0% with increas-

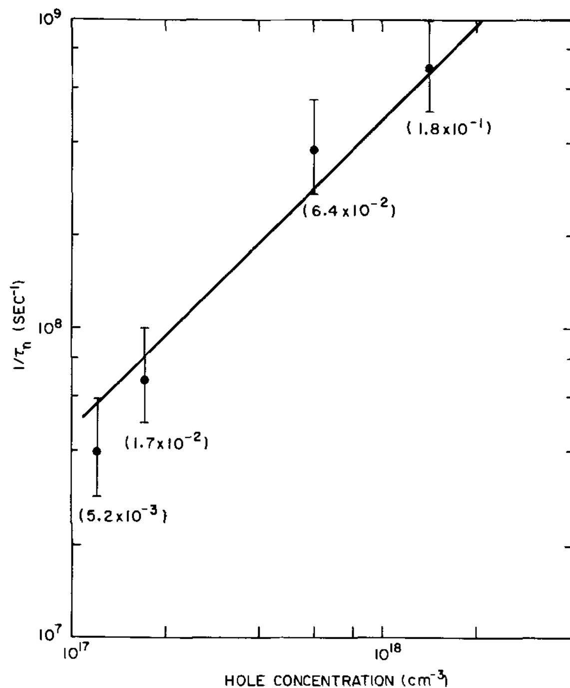

Fig. 3. Reciprocal of nonradiative shunt path component of electron lifetime, $1/\tau_n$, vs. hole concentration for the SG platelets shown in Fig. 2. The error bars for $1/\tau_n$ are based on Ref (17). The $Zn(PO_3)_2$ concentration in the growth solution corresponding to each platelet is given in parenthesis in m/o.

ing $Zn(PO_3)_2$ concentration. This is largely due to a rise of N_{ZnO} from $\sim 6 \times 10^{15}$ to 1.6×10^{16} cm^{-3}, which is only partially counteracted by the decrease of τ_n. On the other hand, since the decrease of η_{PL} from 1.9 to 0.76% [with greater $Zn(PO_3)_2$ additions] is accompanied by a slight increase of N_{ZnO} from 3.2×10^{16} to 3.6×10^{16} cm^{-3}, this decrease is mainly due to the drop in τ_n. A similar η_{PL} curve has recently been presented by Dishman *et al.* (9) for unannealed SG crystals grown in the same temperature range as ours from solutions doped with Zn and Ga_2O_3. Somewhat similar η_{PL} curves have also been obtained by Gershenzon *et al.* (26) for SG platelets prepared from solutions containing various amounts of Zn and Ga_2O_3. However, Gershenzon *et al.* (26) achieved their peak efficiency at 0.1 a/o Zn, whereas we find a maximum at 0.02 m/o $Zn(PO_3)_2$. Since their SG platelets were grown by cooling from 1050°C, the composition shift is in accord with the known solid solubility behavior of Zn in GaP (11). To incorporate equal amounts of Zn in GaP, less Zn is required in the solution for the higher temperature growth than for the lower temperature one. This explanation also applies to the composition shift between the η_{EL} curve of Fig. 1 and the η_{PL} curve of Fig. 2.

In conclusion, the present study demonstrates that $Zn(PO_3)_2$ glass is a convenient alternative to Zn and Ga_2O_3 as a source of Zn,O-doping in GaP. The luminescence efficiencies of GaP LED's and SG platelets grown from solutions containing $Zn(PO_3)_2$ are comparable to those of samples grown from solutions doped with Zn and Ga_2O_3. An analysis of the optical measurements for SG crystals suggests that the incorporation chemistry of Zn and O from a $Zn(PO_3)_2$ source is in accord with previous results using Zn and Ga_2O_3 and that the killer center is not related to the background impurities introduced by either of these dopants. Further systematic work on the preparation of annealed single and double LPE structures on LEC substrates is required to determine whether the use of $Zn(PO_3)_2$ can lead to a significant improvement in doping control and device performance.

Acknowledgments

We acknowledge the assistance of E. A. Sigety in the initial preparation of $Zn(PO_3)_2$. We are grateful to F. A. Trumbore for his continuing interest in this work and for many helpful discussions. Beneficial comments by J. M. Dishman and J. S. Jayson are also acknowledged.

Manuscript submitted Jan. 24, 1972; revised manuscript received *ca.* June 23, 1972. This was Paper 49 presented at the Houston, Texas, Meeting of the Society, May 7-11, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Nonuniform Lateral Ionic Impurity Distributions at Si-SiO_2 Interfaces

D. J. Silversmith

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The transport of mobile sodium ions to the Si-SiO_2 interface in a metal-oxide-semiconductor capacitor causes gross distortions of the capacitance-voltage characteristics. While these changes might be interpreted as increased surface-state densities, this paper shows experimentally that the surface-state densities are unchanged by mobile ion concentrations in the $10^{12}/cm^2$ range. By comparison of high- and low-frequency capacitance *vs.* voltage measurements and conductance *vs.* voltage measurements, it is shown that the distortion of C-V curves can be explained by fluctuations imposed on the surface potential by a nonuniform pileup of sodium ions at the Si-SiO_2 interface. This argument is further supported by a theoretical reproduction of the experimental C-V curves obtained by a statistical summation of ideal curves.

Although the theoretical nature of the voltage dependence of capacitance in metal-oxide-silicon (MOS) structures is well-understood, experimental measurements generally show significant deviations from the ideal curves. In addition to flatband voltage shifts caused by fixed charge in the oxide and metal contact potentials, deviations from the ideal capacitance structure in the depletion domain have been ascribed to surface states, N_{ss}, at the Si-SiO_2 interface (1). We have observed a change of structure in the capacitance-voltage (C-V) structure when sodium impurities, introduced during device fabrication, are driven to the Si-SiO_2 interface. Related measurements, however, indicate no change in the surface-state density with changes in location of ionized impurities in the oxide. These changes in the capacitance structure are reversible and appear to be caused by potential variations due to a nonuniform distribution of sodium at the Si-SiO_2 interface.

This physical hypothesis was studied by comparing quasi-static and high frequency surface-state measurements with conductance measurements. These comparisons have allowed us to distinguish between distortion caused by charge inhomogeneities introduced by sodium ions near the interface and distortions caused by carrier trapping sites (fast surface states) which might have been introduced by drifted sodium.

C-V Measurements

The experimental data in Fig. 1 is typical of the MOS C-V data. The pair of curves on the right are the quasi-static ramp and 1 mHz high-frequency curves with sodium ions accumulated under the field plate. The two curves on the left are the quasi-static and high-frequency curves with ions at the silicon interface, with all measurements taken at room temperature. The high- and low-frequency curves were aligned by matching zero capacitance at high frequency with zero displacement current (quasi-static) and setting the oxide capacitance to coincide with the quasi-static displacement current in accumulation. This test device consisted of a nominal 2000Å SiO_2 grown in a dry thermal O_2 ambient at 1100°C on a 10 ohm-cm N-type substrate. After oxidation, wafers were given a 15 min nitrogen *in situ* anneal at 1100°C and then removed from the furnace. Field plates were 20 mil diameter dots of 200Å Cr and 2000Å Au. The pair of curves with flatband voltages (V_{FB}) near $-0.5V$ correspond to the sodium ions quenched at the metal-SiO_2 interface, while the pair of curves with V_{FB} at $-1.5V$ had the ions quenched at the Si-SiO_2 interface. "Quenching" is accomplished by a $\pm 10V$ bias stress at 250°-300°C for 3 min and a rapid quench to room temperature under bias. The bias stress procedure is compatible with an ion-surface density measurement by the high-temperature quasi-static method (2). In addition to a ΔV_{FB} corresponding to 1.1×10^{11} ions/cm^2, the pair of curves corresponding to ions at the Si-SiO_2 interface show an extension along the voltage axis near flatbands.

Key words: MOS devices, sodium contamination, interface charge distribution, apparent surface states.

Surface-state density (N_{ss}) was determined for both sets of C-V measurements using a method based on the uniform MOS device model which compares the high- and low-frequency curves (3), and is given in Fig. 2. The voltage dependence of the surface potential is found from the quasi-static curve, and the dispersion between this curve and the high-frequency curve from accumulation through depletion gives the surface-state density as a function of energy from the band edge appropriate to the Si doping type. The surface-state densities for this MOS device with sodium at either side of the oxide is the same (within experimental accuracy) and has a minimum value of 7.5×10^{10} cm^{-2}/eV at 0.3 eV below the conduction band edge. Since the N_{ss} appears to be unchanged by sodium position, the change in capacitance structure appears to be caused by ion pileup at the Si-SiO_2 interface.

Conductance Measurements

Nicollian and Goetzberger (4) have performed definitive measurements of surface states by the con-

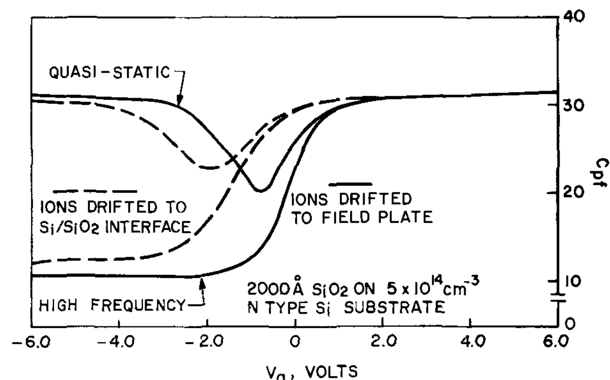

Fig. 1. High frequency and quasi-static C-V characteristics from an MOS device with ions frozen in at one, and then the other, of both oxide interfaces. For sufficiently negative bias, both quasi-static curves correspond to the same value of C_{ox} as in accumulation. At $-10V$, both high-frequency curves have the same value of C_{min} in inversion.

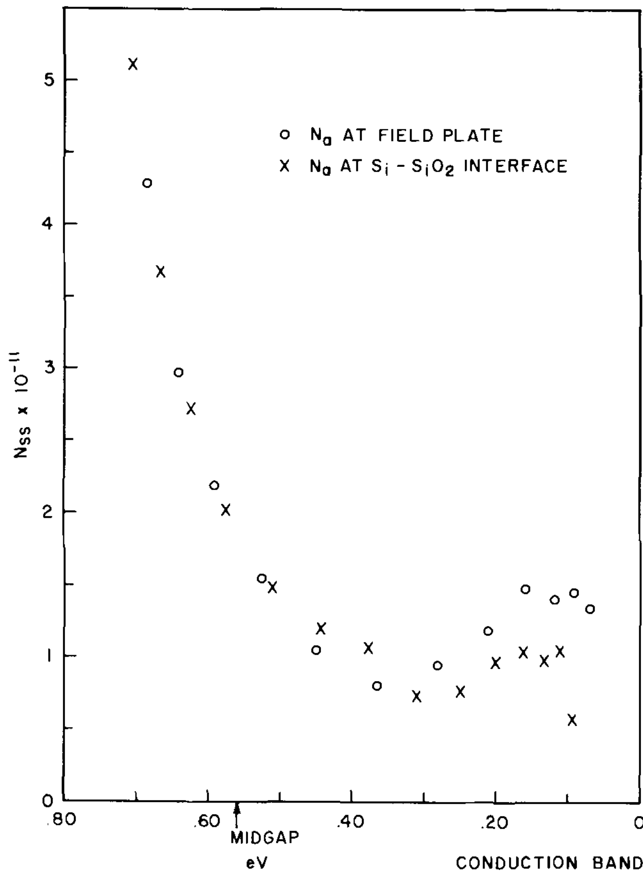

Fig. 2. Si-SiO$_2$ surface-state density as a function of energy from the Si conduction band edge determined from data of Fig. 1. The field plate consisted of a 20 mil diameter Cr-Au dot.

ductance technique and have shown that the measured equivalent parallel conductance is dominated by surface states. The magnitude of the conductance peak is related to N_{ss} since the loss mechanism is controlled by majority carrier capture and emission at surface states. Figure 3 illustrates simultaneous high-frequency

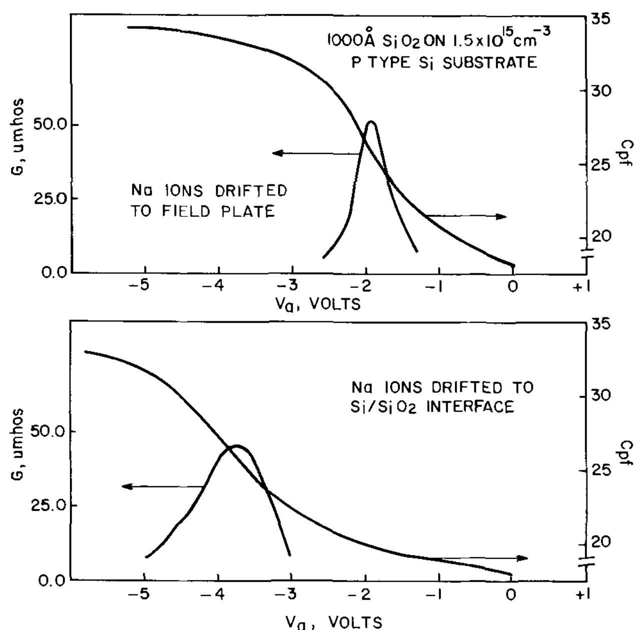

Fig. 3. Simultaneous measurements of high-frequency capacitance and conductance for an MOS device with ions frozen in at both oxide interfaces.

capacitance and conductance measurements for a device with ions quenched at both interfaces in the MOS structure. The device was 1000Å SiO_2 grown in a dry thermal furnace at 1100°C on a substrate of 1 ohm · cm P-type Si, and given a 15 min *in situ* nitrogen anneal at 1100°C. To avoid problems due to sodium drift under bias, measurements were taken using the pulse method (5). Pulse length was 3 msec with a 6% duty cycle, and the measurement frequency was 10 kHz. The measurements in Fig. 3 were taken at room temperature, but related curves have been taken down to 160°K. Because of the use of the pulse method, the capacitance near zero volts corresponds to deep depletion, not inversion. With ions at the Si-SiO_2 interface the depletion domain appears to extend an additional volt on the capacitance curve. The flatband shift is equivalent to 3.5×10^{11} ions/cm^2. The decrease in conductance peak with sodium at the Si-SiO_2 interface as seen in Fig. 3 may indicate, in fact, a slight decrease in N_{ss}, but this decrease is not significant as it is more probably due to statistical broadening caused by the nonuniform sodium surface distribution.

If $G_{p\,MAX}$, the magnitude of the conductance peak with ions at the Si-SiO_2 interface were significantly greater than $G_{p\,MAX}$ without ions at this interface, we would have proven that N_{ss} increases with ions at the Si-SiO_2 interface. Our experiment, on the contrary, indicates that within experimental accuracy N_{ss} remains the same—with or without Na ions at the Si-SiO_2 interface. We would expect a large increase in N_{ss} if structural changes in the C-V curves were due to sodium-induced surface states; consequently the spreading of the C-V curve along the voltage axis is attributable to statistical fluctuations in the local surface potential caused by lateral nonuniformities in the surface distribution of sodium ions. The effect of the nonuniform distribution of ions near the Si-SiO_2 interface increases as they are drifted to this interface because of straight-forward electrostatic considerations The observed C-V and G-V curves are attributable to a summation of ideal MOS curves, with their effective flatband voltages distributed about the mean, according to the statistical variations in local charge density. This model is developed in the rest of this paper for low surface sodium densities ($<10^{12}$/cm^2).

Theoretical Models

Nicollian and Goetzberger (4) have discussed effects of small local variations in surface potential caused by a random distribution of fixed oxide changes under conditions of negligible sodium contamination. The C-V characteristic was calculated for the two dimensional case where the potential in the Si varies both in a direction perpendicular to the semiconductor surface as well as along the surface. In this model the oxide charges influence the capacitance by introducing ripples in the surface potential. The crux of this model is the subdivision of each MOS device into a parallel network of smaller devices, each with a characteristic area α. Within each area the capacitance is independent of the distribution of charge, and the surface potential is uniform. The problem is then transformed from a distribution of charge to one of a distribution of surface potential values over an ensemble of devices connected in parallel. This point of view has been corroborated by the work of DiStefano (6). DiStefano has observed the formation of inhomogeneities in the Si-SiO_2 barrier contact potential as sodium ions are drifted to this interface.

For the case of sodium ions, which may introduce large variations, the mathematics of this model must be modified by appeal to a number of experimental observations. Because the density of charged interface states is small compared to the image charge induced by ions at the Si-SiO_2 interface, there is no need to be specifically concerned with changes in surface potential fluctuations due to interface states. Within the oxide

it is assumed that all transportable sodium is ionized, and in the vicinity of the $Si\text{-}SiO_2$ interface the ions appear as a fixed charge distribution (7). A uniform fixed charge distribution manifests itself as a voltage shift on the C-V characteristic. The amount of shift is linear with fixed charge density and is inversely proportional to distance from the $Si\text{-}SiO_2$ interface as expected from effective charge arguments. Snow *et al.* (7) have shown that the distribution of ions perpendicular to the interface is very narrow when ions have been driven to the silicon interface. When ions are quenched at the $Si\text{-}SiO_2$ interface, the distribution does not extend deeply into the bulk and a lateral distribution of sodium ions is sufficient to describe the distribution of flatband voltages. This is a less detailed approach than in Ref. (4).

Castangne and Vapaille have discussed the fluctuations in capacitance structure in terms of a fluctuation of the effective charge (8). Their point of view is different from ours as they consider fluctuations in the surface potentials at the $Si\text{-}SiO_2$ interface rather than local flatband voltage shifts caused by fluctuations in the local ion density. The formalism with respect to variance as a statistical fitting parameter is, however, virtually the same and good agreement with experiment is obtained. Although conductance measurements confirm that little change in N_{ss} takes place—within the sensitivity of the measurement—on drifting ions to the $Si\text{-}SiO_2$ interface, visual comparison of the structural changes in the depletion region for high frequency and quasi-static curves indicate a change in the dispersion in many cases. Because the Gaussian distribution, as used by Castangne and Vapaille, is symmetrical about the mean, the apparent dispersion cannot be reproduced in this model. Castangne and Vapaille, in fact, are unable to reproduce any dispersion in their calculation although it is quite obvious in their experimental data.

Gamma Distribution Statistics

We have attempted to reproduce the observed distortion by a statistical summation of ideal MOS C-V curves. The model assumes that a one-dimensional parallel capacitor array represents a MOS device with a slowly varying distribution of ions along the $Si\text{-}SiO_2$ interface. Consider subdividing the area of a hypothetical $Si\text{-}SiO_2$ interface under the field plate into an array of N equal areas. Suppose that we could determine the number of ions in each of the N areas. From this information we could plot a histogram with the number of ions per unit area on the abscissa and the number of such areas on the ordinate. This histogram represents the distribution of ions along the surface of a MOS capacitor.

Figure 4 shows continuous variable distributions we have found applicable in this work to sodium ions along the $Si\text{-}SiO_2$ interface. This is a Gamma distribution of the form

$$f_\Gamma(x) = \frac{x}{\beta^2} e^{-x/\beta}$$

where β is the fitting parameter. x corresponds to the number of ions per unit area. The mean μ and variance σ^2 are related by $\sigma^2 = \mu^2/2 = 2\beta^2$. As seen in Fig. 4, the distribution cuts off abruptly at $x = 0$ with first derivative $f_\Gamma'(0) = 1/\beta^2$, peaks at $x = \beta$, and the integral from $x = 0$ to 6.65β is 0.99. The distribution is skewed toward values of $x > \beta$ with a point of inflection at $x = 2\beta$. The sharp cutoff at $x = 0$ is equivalent to having no negative charges. The skewed behavior is what would be expected for low level ionic contamination. Even with 10^{12} ions/cm^2 there would be only one sodium ion for every 1000 silica molecules.

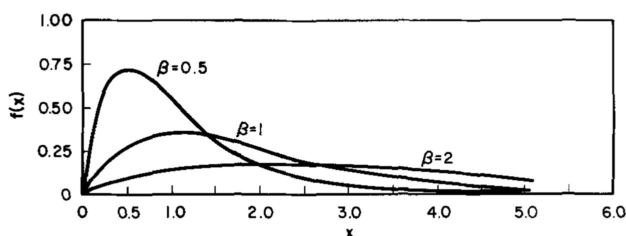

Fig. 4. Gamma distributions with different values of β

The Gamma distribution as used in our calculation has had values skewed to the left, that is $x \rightarrow -x$, because the free variable in this distribution model is the relative flatband shift. Boulin (9) has shown that the transformation from distributed surface charge to relative flatband shift is linear, but with an inversion of the horizontal axis. Since the free variable in this distribution calculation is the relative flatband shift, β is in units of volts. The sharp cutoff of the Gamma distribution with a proper choice of β insures that we have no positive ΔV_{FB} contributions to the statistics; such contributions would be inconsistent with positive sodium ions.

Results from Model Calculations

Calculations for typical N- and P-type materials are described in a pictorial algorithm in Fig. 5. The calculations proceed from computer-generated theoretical high- and low-frequency curves. For purposes of illustration, the ideal quasi-static curve is shown in Fig. 5. For a value on the voltage axis mesh, say V_o, the zero of the Gamma distribution—skewed toward negative voltage values—is aligned with ideal curve. The entire high- and low-frequency curves are multiplied point by point with the aligned Gamma distribution, and the product is integrated from $V = -6.65\beta$ to $V = 0$. The resulting value

$$C_o = \int_{-6.65\beta}^{0} C(V) f_{\Gamma,\beta}(V - V_o)\, dV$$

is the averaged capacitance for the point V_o, which is

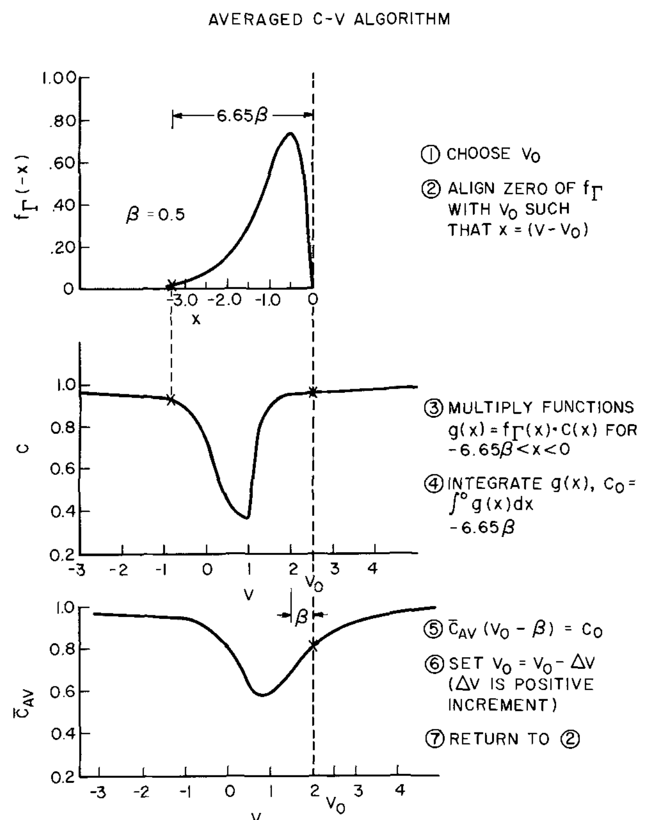

Fig. 5. Illustrated algorithm for obtaining "averaged" C-V curve from the convolution of the ideal curve with the Gamma distribution.

a point on the statistical C-V characteristic corresponding to the starting voltage. For purposes of comparison, values of C_o, as in the lowest curve of Fig. 5, are arbitrarily plotted at $V_o - \beta$ because the maximum of the Gamma distribution is at β. For clarity, the linear shift in the voltage due to the over-all flatband shift has not been included. The calculation gives only the relative structural changes due to lateral variations; the linear voltage shift along the V axis has to be determined separately from

$$\Delta V_{FB} = \frac{1}{C_{ox}d} \int_0^d Z\rho(z)\,dz$$

as in Ref. (6).

Figure 6 shows a comparison between the ideal C-V characteristics, dashed line, and the statistically summed calculations, solid line, for both low and high frequencies for a typical P-type device. The distortion caused by fluctuations superimposed on the surface potential is clearly evident and resembles the experimentally observed reversible distortion. A more suitable fitting procedure for experimental data would be to commence the mapping from the measured C-V characteristic with ions at the metal-oxide interface, instead of from the ideal C-V curve. In this way one can conveniently account for the effect of N_{ss} initially present. An initial calculation of this type (9), also with $\beta = 0.5$, indicates excellent agreement, and is given in Fig. 7. $\beta = 0.5$ corresponds, roughly, to a $\pm 50\%$ local deviation in the ion density. For example, one could consider an average ion density of 10^{11} ions/cm^2 as measured by the over-all flatband shift, but with a local deviation of about 5×10^{10}/cm^2.

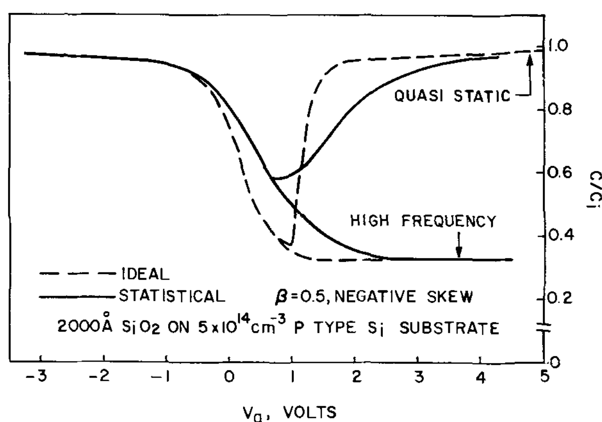

Fig. 6. Model calculation for statistical fluctuations on typical P-type substrate MOS devices.

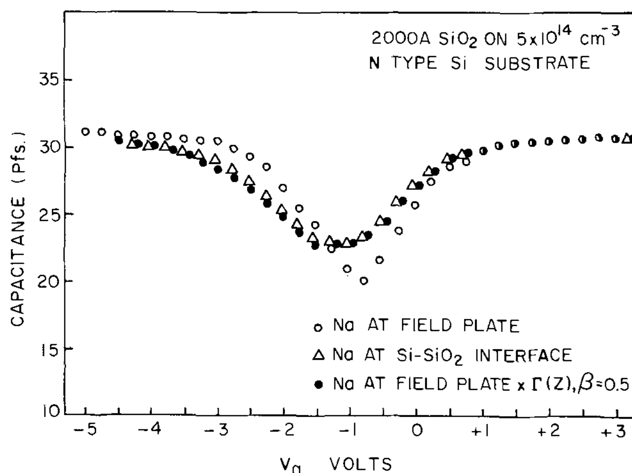

Fig. 7. Quasi-static data of Fig. 1. showing a comparison between the C-V curve with sodium ions at the Si-SiO2 interface and the corresponding "averaged" C-V curve using the C-V curve (for the same device) with ions at the field plate as "ideal" data.

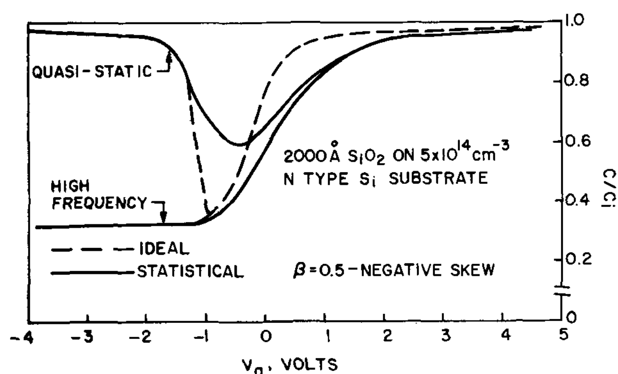

Fig. 8. Model calculation for statistical fluctuations on typical N-type substrate MOS devices.

Figure 8 shows similar comparative results for a typical N-type device. In addition to the distortion noted for the P-type substrate in the previous figure, there is a dispersion evident about flatbands. The apparent surface-state density as indicated by the dispersion would amount to about 10^{11}cm^{-2}/eV if it were real. But this dispersion is an artifact of the algorithm we have used. This artifact is related to the use of a skewed distribution for the local relative flatband voltage shifts. It would be difficult to determine if this artifact exists in real data because the actual surface-state densities are also on the order of at least 10^{11}cm^{-2}/eV. This effect may have been noted in the literature (10-12) and may account for the recurring concern about interaction between surface states and low-level inherent ionic contaminants.

The success of this statistical model in describing the effect of sodium drift on the C-V characteristic substantiates the applicability of the parallel capacitor array model. Since this simple model would be invalid if the surface charge were, in fact, randomly distributed, the need for further study of the appropriateness of the random distribution approach is indicated.

Conclusions

For sodium impurity levels of less than 10^{12} cm^{-2}, the transport of ions from one oxide interface to the other in an MOS device results in a marked change in the measured C-V and G-V characteristics, in addition to the flatband voltage shift. Measurements of surface-state density, N_{ss}, indicate no changes with ion location. The structural changes in capacitance and conductance are ascribed to statistical fluctuations in the surface density of sodium ions at the Si-SiO_2 interface. In the absence of a sufficiently simple and straightforward *a priori* calculation of the ion surface distribution, a model is devised which maps an ideal C-V characteristic into a distribution of flatband voltages and results in the "averaged" C-V characteristic. Although a special form of the Gamma distribution has been used in the model because it appeared to be particularly applicable, other similarly skewed distributions may be applicable. While this model applies specifically to long range nonuniformities, it is sufficient to demonstrate that a nonuniform distribution of ions can cause an apparent distortion of the C-V structure.

Acknowledgments

During the course of this work, I have had a number of helpful conversations with R. J. Strain and E. H. Nicollian. D. McE. Boulin contributed his programming expertise. R. C. Beairsto spent many tedious hours taking data, and I appreciate his patience.

The Thermal Decomposition of Germane

Lou H. Hall*

Texas Instruments, Incorporated, Dallas, Texas 75222

ABSTRACT

The kinetics of the thermal decomposition of germane were studied in a dynamic system. The effect of substrate temperature on growth rate in the range of 300°-450°C was investigated. The effect of germane concentration on the growth rate of germanium was also studied. The mole fraction of germane was varied from 3 to 30 (x10^{-3}). The carrier and diluent were nitrogen. Both zero and first order reactions were observed. Activation energies were found to be 0.75 eV (17 kcal) and 1.20 eV (28 kcal) for the zero and first order reactions, respectively. The zero order is ascribed to a heterogeneous reaction while the first order is ascribed to a homogeneous reaction. Comparisons with results obtained from other studies are made.

The use of chemical vapor deposition (CVD) techniques to grow films for use as coatings is well known. Recently, we employed this technique to grow germanium films for use as anti-reflection coatings for application in aviation optical systems.

Germane, GeH_4, is a gas which thermally decomposes irreversibly on any surface heated above about 280°C to yield a germanium deposit (1-3). Hogness and Johnson (2), and Tamaru *et al.* (3) have reported studies on the kinetics of the thermal decomposition of germane by a static method. This method consists of using an isothermal vessel which is evacuated to less than 10^{-4} mm Hg. This vessel is attached to a mercury manometer and enables the decomposition of germane to be followed by measuring the initial pressure of germane as well as the final pressure (unreacted germane and hydrogen). Hogness and Johnson found the rate to be proportional to the one-third power of germane pressure at the higher temperatures (275°-375°C) with an inhibition by hydrogen in a lower temperature range (2). However, Tamaru *et al.* found zero and first order reactions (3). The zero and first order reactions were ascribed to heterogeneous and homogeneous decomposition processes, respectively.

Dumin (4), and Papazian and Reisman (5) have reported the epitaxial growth of germanium from the decomposition of germane on spinel and gallium arsenide substrates, respectively. Our germanium films were to be used as coatings on infrared glasses for application in the 8-14 μm region. These glasses have low softening temperatures, below 400°C, so it was necessary to have a low-temperature film growth. Single-crystal materials are obviously desirable; however, amorphous or small polycrystalline material can also have low loss due to surface or grain boundary scattering. If large-grain polycrystalline material is used the surface is rough and scattering is large.

This paper presents data on the kinetics of the thermal decomposition of germane in a dynamic system in a temperature range of 300°-450°C.

Key words: chemical vapor deposition, thin films, germanium, kinetics.

Experimental

The decomposition of germane was studied by measuring the rate of deposition of germanium as a function of substrate temperature and concentration of germane. The substrates used were single-crystal silicon wafers (<111> oriented; mechanically polished) and silicon wafers which had a 1000Å oxide coating. The substrates were cleaned prior to use by Caro's acid (mixture of 280 ml H_2SO_4 and 120 ml H_2O_2) and then rinsed thoroughly with deionized water. The wafers were left in deionized water until ready for loading into the reactor. The wafers were removed one at a time and blown dry with high-pressure nitrogen. The procedure is similar to that reported by Berkenblit *et al.* for the low temperature disproportionation of GeI_2 (6).

The thicknesses of the germanium films were obtained by partial masking of the film and removing the unmasked portion by use of a 35% solution of hydrogen peroxide at 50°C. The thicknesses were mechanically measured by use of the Talystep I. In general, the film thicknesses ranged from 2000 to over 20,000Å with the majority being between 10,000 and 20,000Å.

The reactor used was a horizontal quartz tube with an ID of 2 in. and approximately 12 in. in length. The system was rf heated by loading into a 5½ in. × 1¾ in. × ⅜ in. carbide-coated graphite susceptor. The substrate temperatures were measured by use of an infrared radiation thermometer. Emissivity and absorption corrections were made for the silicon substrates and quartz tube (7, 8). Substrate temperatures ranged from 300° to 450°C. Uncertainty in temperature was less than ±5°C. Nitrogen was used as the carrier and diluent gas and was kept at a flow of 1 liter/min for most of the studies. Pure germane (99.999%) was obtained from Matheson and was used without additional purification. The mole fraction was varied from approximately 3×10^{-3} to 30×10^{-3}, 3 to 30 cc/min.

Results and Discussion

At low temperatures (300°C) there was a difference in the growth rate on the oxidized and nonoxidized

silicon substrates. The growth rates are 70 and 50 Å/min, respectively. The films were approximately 1000Å thick. This may be due to a difference in nucleation on the two surfaces. However, at higher temperatures and concentrations (and much thicker films) there was no significant difference in growth rate on the two surfaces.

Figure 1 shows the effect of germane concentration on the growth rate at four different temperatures (300°, 350°, 375°, and 400°C). The log *C* *vs.* log *R* graph (concentration *vs.* growth rate) shows both zero and first order zones. Each data point represents at least two depositions. The deviation from the average growth rate was typically ±5% or less. At 300°C the slope is zero even at the highest concentration used; however, the higher the substrate temperature the lower the germane concentration need to obtain a zero slope. Growth rates varied from 70 Å/min at a low temperature and concentration to over 2600 Å/min at the highest temperature and concentration. At the higher temperatures and concentrations the decomposition becomes uncontrollable and "cracking or fallout" occurs. For depositions at 450°C and 1.6% germane concentration, the germane had decomposed on the walls of the reactor prior to reaching the monitor slice. This premature decomposition is ascribed as the reason for the bending of the first zero order curves towards zero slope at higher temperatures and concentrations. The data suggest that two kinds of reactions are taking place, zero and first order, with the former predominate at low temperature and/or low concentration and the latter predominate at high temperature and high concentration.

Figure 2 shows the effect of temperature on the deposition rate. The log *R* *vs.* $1/T$ plot provides an activation energy for both the zero and first order reactions. Applying the Arrhenius equation, activation energies of 0.75 ± 0.02 and 1.20 ± 0.02 eV (17 and 28 kcal) were obtained for the zero and first order reactions, respectively.

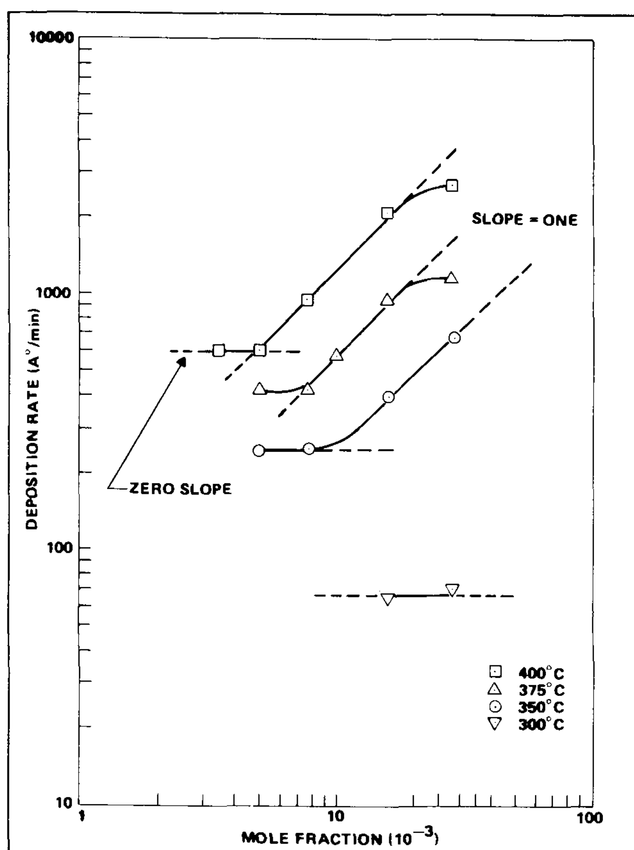

Fig. 1. Effect of germane concentration on deposition rate

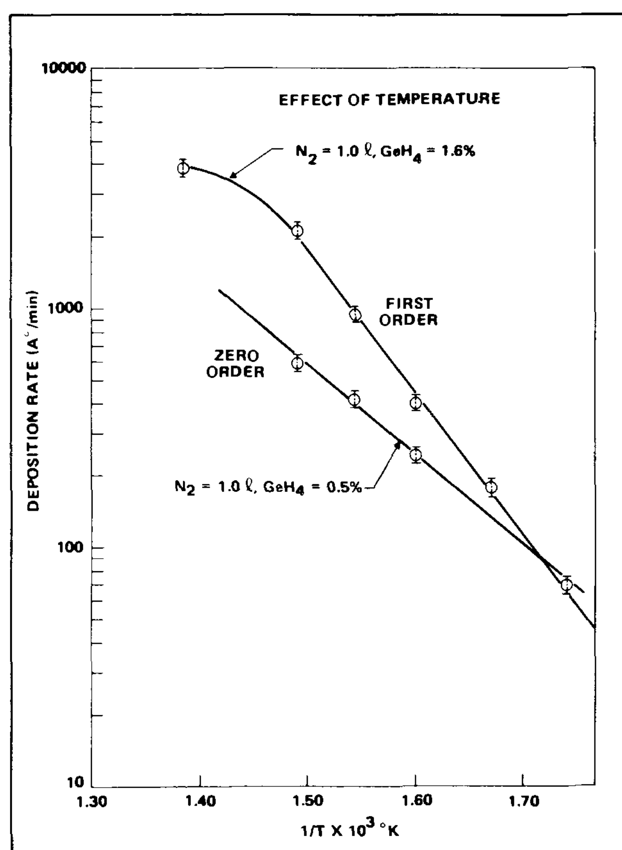

Fig. 2. Effect of substrate temperature on deposition rate

Tamaru *et al.* (3) suggested that in the static system the zero and first order reactions are taking place simultaneously and showed that the zero order reaction was heterogeneous decomposition at the substrate surface and the first order reaction was homogeneous decomposition in the gas stream (3). These conclusions appear to be valid for the dynamic system also. Figure 3a shows the surface smoothness of a film whose growth is predominately controlled by the zero order reaction. In Fig. 3b droplets are seen on the surface of a film whose growth is predominately controlled by the first order reaction; however, films with smooth surfaces could also be obtained from depositions which were predominately controlled by the first order (homogeneous) reaction.

This behavior may be understood by the following considerations. The following diagram (Fig. 4) shows a substrate with a heterogeneous and homogeneous reaction zone.

As long as the substrate surface is properly prepared (cleaned, etc.), a heterogeneous-controlled reaction will provide films with smooth surfaces. It is interesting that films obtained from conditions which indicate a homogeneous reaction have very smooth surfaces. If gas phase decomposition occurs sufficiently close to the surface then the decomposed germanium atoms can diffuse to the surface before large clusters are formed or "fallout" occurs. The quality of films obtained from this homogeneous reaction depends on the germane concentration and total flow rate.

The heterogeneous reaction is zero order. In addition, an increase in linear gas stream velocity has no effect on growth rate. The latter is in accordance with a surface controlled reaction as described by Reisman and Berkenblit (9). The fact that the homogeneous and heterogeneous reactions are proceeding simultaneously makes it difficult to determine the rate controlling process for the homogeneous reaction. If an isothermal reactor is used to study the homogeneous decomposition of germane, it is expected that the amount of

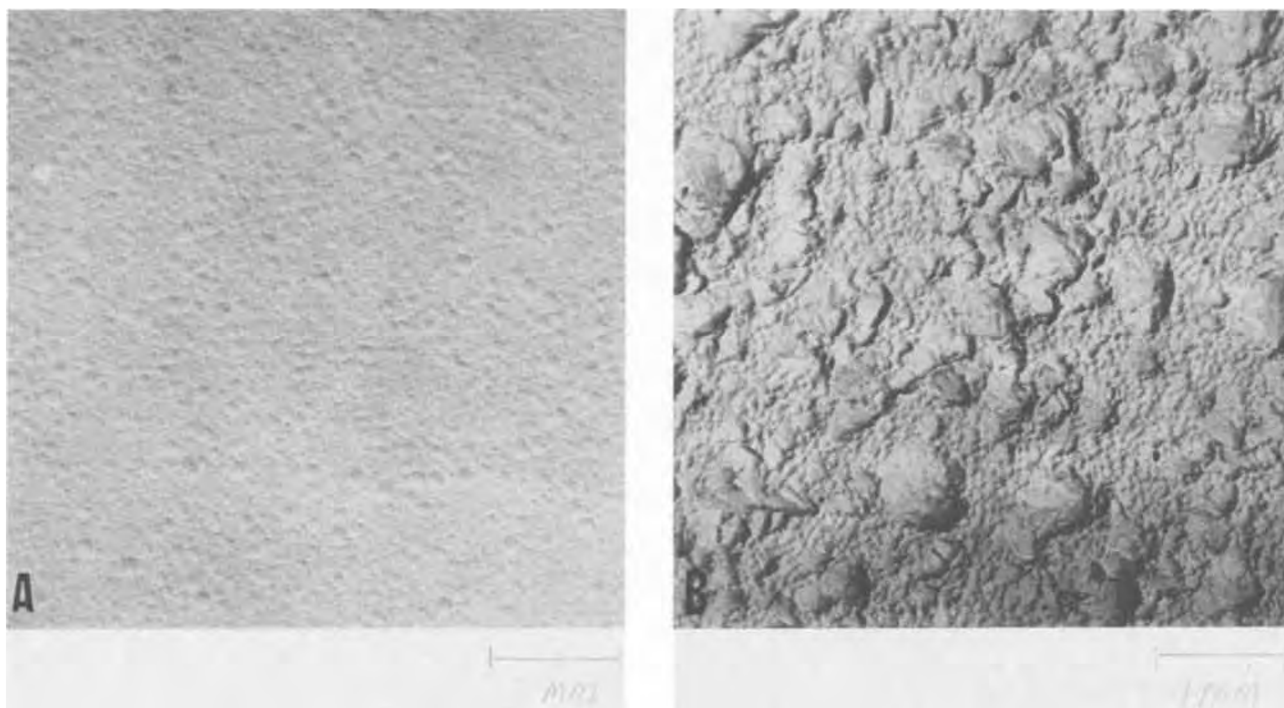

Fig. 3. Electron micrographs showing the surface of germanium films deposited on single crystal silicon substrates. Replica techniques were used. A, 300°C substrate temperature, 1.6% Ge, 7500Å; B, 375°C substrate temperature, 1.6% Ge, 7500Å.

germane decomposed would be a function of both the temperature and germane concentration. However, in the present study there is a temperature gradient from the susceptor to the walls of the reactor, T_s (substrate temperature) and T_w' (a temperature d distance away from the substrate) (see Fig. 4). Decomposition begins for any gas which passes through this zone (for the homogeneous case). The greater the flux of germane into this zone the faster the decomposition. Several factors can lead to an increase in decomposition rate of germane in the homogeneous zone. These are: (*i*) an increase in total flow, keeping the germane concentration constant, (*ii*) an increase in germane concentration, keeping the total flow constant, and (*iii*) an increase in the zone dimensions, *i.e.*, d in Fig. 4. However, the total flow can also affect the size and shape of the homogeneous zone, *e.g.*, through cooling. Depending upon several factors, *e.g.*, total flow rate and geometry of homogeneous zone, the decomposed germanium may not reach the substrate. The germanium could be deposited either upstream or downstream of the monitor wafer. Experimentally we have observed both an increase and decrease in growth rate with increase in total flow.

As long as the homogeneous zone has a small d, decomposed germanium atoms apparently can diffuse to the surface and become part of the deposited film before large clusters are formed or "fallout" occurs.

A large difference was noted in activation energies reported here and by Tamaru *et al.* for the static studies (3). The differences between activation energies $[(E_a^1 - E_a^0)_{static} = (E_a^1 - E_a^0)_{dynamic}]$ for the zero and first order reactions are the same for both the static and dynamic system, but there is a significant difference between activation energies ($E_a{}^1{}_{static}$ = 51 kcal/mole, $E_a{}^1{}_{dynamic}$ = 28 kcal/mole). Dumin has studied the decomposition of germane in hydrogen in a temperature region of 575°-750°C and reported an activation energy of 47.5 kcal/mole (4).

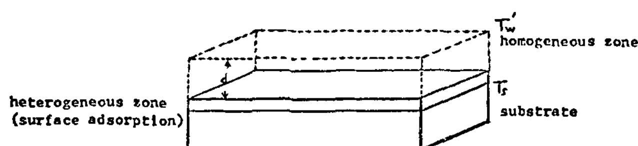

Fig. 4. Heterogeneous and homogeneous reaction zones

The decomposition of germane, GeH_4, has the products of solid germanium and hydrogen gas. Both the static decomposition of germane and the epitaxial growth of germanium from germane and hydrogen are similar in that hydrogen might be expected to act in a similar fashion. A flowing nitrogen ambient may condition the surface differently than H_2, and in addition sweep the hydrogen by-products away from the surface. Also, nitrogen gas occupies the major portion of the gases in the reaction zones in this study and certain normal or activated properties of N_2 may have a definite effect on the activation energy. We have observed an increase in growth rate of approximately 30% for silicon dioxide films when grown in nitrogen as compared to growth in argon (10).

The data presented supports an effect of nitrogen, impurity less than 5 ppm combined H_2O and O_2, on either the mechanism of decomposition, or through an activated species, the activation energy.

Still, the effect of impurities, or the possibility that the homogeneous (or heterogeneous) process may not be kinetically controlled and mass transport is occurring cannot be completely eliminated as factors in the lowering of the activation energies relative to previous work.

Conclusion

The growth of germanium films from the thermal decomposition of germane in nitrogen was studied and the decomposition was found to proceed by two different reactions, a zero and first order reaction. These were ascribed to heterogeneous and homogeneous processes. Activation energies were calculated and found to be 0.75 eV and 1.2 eV, respectively, for the zero and first order reactions. The decomposition obtained by a static method (3) was compared to that obtained in the dynamic system, and the results are similar.

Acknowledgments

Nitride Layer Growths on Liquid Thorium and on Solid Thorium Carbon Alloys

R. Benz

Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico 87544

ABSTRACT

Nitride layers were formed on thorium-carbon alloys by reaction with nitrogen (1-1600 Torr) at temperatures between 1400° and 2400°C. Values of scale thicknesses of face-centered cubic (fcc) ThN on liquid thorium and of Th(C,N) on solid alloys with C/Th = 0.10, 0.20, and 0.30 were found to be proportional to the square-root of time of reaction indicating growth rates are controlled by diffusion. Calculated composition-average values of concentration-gradient type interdiffusion coefficients in pure ThN at 1900°, 2100°, and 2400°C can be represented by the equation $\overline{D} = 254 \exp(-99.4 \pm 30$ kcal/mole$)/RT$. Diffusion coefficients in the Th(C,N) layers are approximated by the same method: cross effects due to presence of carbon are neglected. The results show that the nitrogen diffusion rate in Th(C,N) increases with carbon content and with decreasing nitrogen pressure. Nitrogen-rich Th(C,N) layers formed on alloys with C/Th ratio $\geqq$ 0.4 are preceded by a carbon-rich front containing ThC_2 precipitate. This observation together with the assumption of negligible mobility of thorium atoms leads to the conclusion that carbon diffuses "uphill" against a concentration gradient. The phenomena also occurs in the analogous U(C,N) phase during reaction under similar conditions. With increasing carbon content, nitrogen diffusion is suggested to change from a vacancy mechanism in pure ThN to a substitution mechanism in carbon-rich Th(C,N).

In a recent investigation of the Th-C-N system (1), equilibration of thorium-carbon alloys with nitrogen was observed to be extremely slow under certain conditions. The usual solution to an equilibration problem of increasing the anneal time proved unsuccessful. For example, increasing the holding time of 1-mm chips of ThC in 1 atm N_2 at 1800°C from 6 to 600 hr did not give products perceptibly closer to equilibrium. Explanation of this difficulty, as may be seen in the results of this investigation, is that atomic fluxes during the reaction are coupled causing an "uphill" diffusion of carbon (diffusion up a concentration gradient) and consequently to segregation of carbon and thorium. Darken first reported having observed "uphill" diffusion in austenitic steels (2). It also occurs in uranium-carbon alloys reacting with nitrogen. The phenomena, which can occur in systems with three or more components, may be more prevalent than has been previously supposed.

In what follows, nitride layers are described which form on thorium-carbon alloys by reaction with nitrogen. At nitrogen pressures below the decomposition pressure of Th_3N_4, the reaction rate is controlled by diffusion and no evidence for outward migration of thorium is observed. Under this condition, the growing nitride layer may be either single-phase face-centered cubic, fcc, Th-ThC-ThN solid solution, denoted Th(C,N), two distinct Th(C,N) phases, or a mixture of Th(C,N) and monoclinic ThC_2 and/or ThCN. Important for interpretation of diffusion processes occurring in the growing layer is a knowledge of the thorium-carbon-nitrogen phase diagram (1) and the composition at the outer surface of the growing layer. The latter information was obtained from results of equilibration experiments which are described first.

Key words: diffusion in ThN, diffusion in ThN-ThC solid solutions, uphill diffusion, decomposition pressure of Th_3N_4, decomposition pressure of ThCN.

Experimental

Materials.—Alloys were prepared with crystal-bar thorium metal (Metal Hydrides, Division of Ventron Corporation, Beverly, Massachusetts), spectroscopic graphite (National Carbon Company, Union Carbide Corporation, Fostoria, Ohio), and prepurified nitrogen (Big Three Industrial Gas and Equipment Company, Houston). Thorium metal specimens and thorium-carbon alloys were arc melted by P. L. Stone as previously described (3). Powder ThN was obtained by vacuum decomposition of Th_3N_4 (4).

Apparatus and procedure.—Specimens were placed in a tungsten crucible which was heated by induction in a vacuum chamber. Equilibration experiments were thus made with finely divided powders of the appropriate thorium-carbon alloy. The powder was equilibrated with nitrogen at selected pressures and quenched in a stream of helium. Compositions of the fcc Th(C,N) phase coexisting with ThC_2 and with ThCN were determined from unit cell dimensions with the assump-

tion of a linear variation from the value of 5.159Å in pure ThN to 5.346Å in pure ThC. Nitrogen decomposition pressures of Th_3N_4, carbon-rich Th_3N_4, and ThCN were determined with powder ThN, $ThC_{0.20}$, and $ThC_{1.00}$, respectively. The experiments were carried out at a series of different nitrogen pressures for a given temperature and the decomposition pressure was deduced from x-ray diffraction pattern determinations of the presence or absence of the respective phases in samples of the products. Layer growths of ThN on liquid thorium were made with the thorium spheroids supported on a bed of ThN powder. They were reacted in nitrogen at selected temperatures and quenched in a stream of helium. Ternary nitride layer growths were made with alloy chips having dimensions of 3 × 3 × 4 mm. Each specimen was heated for a selected period of time in nitrogen at a fixed pressure and quenched in the same way. Layer thicknesses were measured with a microscope disk calibrated with a vernier.

Results

Equilibration experiments.—Room temperature unit cell dimensions, a_o, of powders which had been equilibrated with various nitrogen pressures and at various temperatures are listed in column 3 of Table I. Values of x in the formula $ThC_{1-x}N_x$ were calculated with the assumption of a linear dependence on a_o and are shown in column 4. As seen in the phase diagrams illustrated in Fig. 1 and 2, the extent of solution of nitrogen in ThC_2 is less than 1% and the amount of carbon that can precipitate (as ThC_2) from the nonmetal saturated Th(C,N) on cooling is comparatively small too. Thus the Th(C,N) phase at temperature can also be represented to a good approximation by the formula $ThC_{1-x}N_x$ with the same room temperature values of x.

The nitrogen decomposition pressure at a given temperature was taken as the lowest nitrogen pressure at which the nitrogen-rich phase was identified in quenched products. The thus determined decomposition pressures of pure Th_3N_4, of Th_3N_4[+ ThCN + Th(C,N)], *i.e.*, Th_3N_4 coexisting with ThCN + Th(C,N), and of ThCN[+ ThC_2 + Th(C,N)], *i.e.*, ThCN coexisting with ThC_2 + Th(C,N), are plotted in Fig. 3. Based on the results listed in Table I and Fig. 3, pressure isotherms at 1600° and 1800°C were deduced. These are shown schematically in Fig. 1 and 2 respectively.

Fig. 4. Photomicrograph of a typical ThN scale growth that was formed on liquid thorium in 1520 Torr nitrogen at 2100°C (X100).

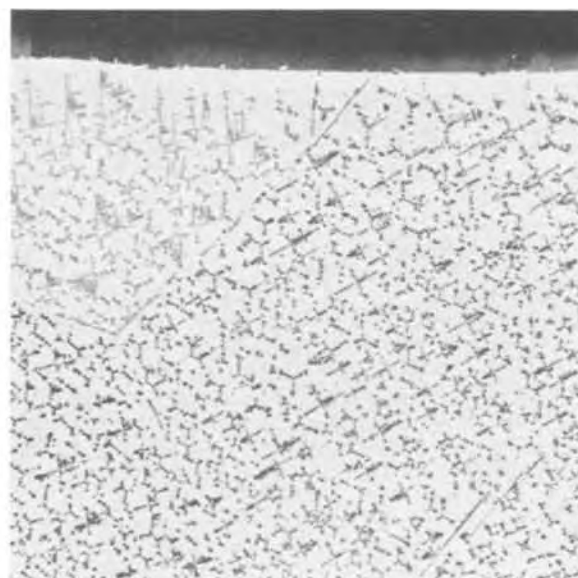

Fig. 5. Photomicrograph of a scale growth on a thorium-carbon alloy with C/Th = 0.1 after annealing in 90 Torr nitrogen at 1750°C. No porosities are seen in the faintly visible surface fcc Th(C,N) phase (top). Precipitate particles of Th(C,N) are seen in the central thorium-rich phase (bottom area) (X100).

ThN scales formed on liquid thorium.—At first attempts were made to form diffusion-controlled scale growths of ThN on solid thorium. ThN scales which were formed on thorium at temperatures of 1400°-1700°C were found, however, always to be porous indicating that ThN scales do not grow by diffusion.

Next, experiments were made to produce diffusion-controlled ThN scale growths on liquid thorium analogous to those previously described to produce diffusion-controlled UN layer growths on liquid uranium metal (5). The resulting ThN scales were dense. A typical scale growth is illustrated in Fig. 4. Layer thicknesses, x_s, corrected for a small thermal contraction as calculated with high-temperature x-ray diffraction data (6) are listed in column 4 of Table II. The nitrogen pressures and times at temperature, t, are listed in columns 2 and 3, respectively.

Th(C,N) scales formed on solid alloys with C/Th = 0.10, 0.20, and 0.30.—Based on high-temperature x-ray diffraction results (6) and the thorium-carbon-nitrogen phase diagram (1), volume difference between Th(C,N) and coexisting α-thorium is expected to diminish with increasing carbon content. The difference, of course, becomes zero at a critical composition where the two phases merge into a single phase, *e.g.*, where the carbon atom fraction reaches the value of about 0.3 at 1800°C as seen in Fig. 1. Simultaneously, lattice strains induced by volume change when thorium-carbon alloys react with nitrogen may be expected to diminish with increasing C/Th ratio and eventually yield scales free of voids.

Experiments were made to form nitride scales on rectangular-shaped thorium-carbon alloys with the dimensions 3 × 3 × 4 mm. The scales formed on alloys with C/Th = 0.05 were found to be porous but the porosity was less than that formed on carbon-free solid thorium metal. No porosity was at all perceptible in scales grown on alloys with C/Th = 0.10 to 0.40 providing the nitrogen pressure during reaction did not exceed the decomposition pressure of Th_3N_4[+ ThCN + Th(C,N)]. Microstructure of a typical scale is seen in Fig. 5. Th(C,N) scales were grown on alloys with C/Th = 0.10, 0.20, 0.30 by reaction with nitrogen at the ThCN[+ ThC_2 + Th(C,N)] decomposition pressure and the temperatures of 1400°, 1500°, 1600°, 1700°, 1750°, and 1800°C. The anneal times and resulting layer thicknesses are listed in columns 4 and 5 of Table III. In addition, one measurement was made with the lower pressure of 2 mm at 1600°C and the results are listed in row 15 of Table III. The scale thicknesses grown in 19 Torr N_2 at 1600°C are proportional to the square root of time at temperature. Other conditions being the same, the thicknesses are greater in alloys with higher C/Th ratios. This effect results, in part, from

decreasing width of the thorium Th(C,N), two-phase region and, in part, from subsequently described increasing rate of diffusion with increasing C/Th ratios.

Information on the direction of nitrogen diffusion was obtained by comparison of x-ray diffraction powder patterns of samples taken from the outer surfaces with those taken from the centers of reacted specimens. The results revealed no evidence for carbon to redistribute during the reaction. The direction of nitrogen flux in Th(C,N) scales is concluded to coincide with directions of nearly constant C/Th ratio. The directions are presumably parallel to isochemical potential curves of carbon. Representative nitrogen paths are illustrated in Fig. 6 on the 1600°C isotherm. The diffusion paths in alloys with C/Th ratio up to 0.40 begin on the nitrogen-rich boundary of Th(C,N). The diffusion paths in Fig. 6 cross the Th(C,N) phase in a skewed path deviating slightly from paths of the constant C/Th ratio as previously inferred from lattice parameter data. The slight skewing is suggested on the basis of the course of the ThCN[+ ThC_2 + Th(C,N)] decomposition pressure isotherm according to which the most stable and equilibrium composition of Th(C,N) assumed to prevail at the outer surface of the reaction layer is $ThC_{0.35}N_{0.65}$. The diffusion paths in Fig. 6 terminate in the nitrogen-rich boundary of α-thorium in accord with the observation that composition gradients level rapidly in the latter phase.

Reaction layers formed on alloys with C/Th > 0.4.— Observations with alloys in this composition region are mostly qualitative but cover a wide range of composition in the ternary phase diagram and form an important basis for an interpretation of the diffusion mechanism in Th(C,N). Reaction layers very often consisted of complex mixtures of phases. Unless stated otherwise, only reactions in nitrogen at the ThCN[+ ThC_2 + Th(C,N)] decomposition pressure are described. Reaction with alloys having C/Th = 0.4 to 1.0 produce a surface layer of nitrogen-rich Th(C,N) having a nitrogen content only slightly lower than that which was found on the previously described alloys with lower carbon content. Microstructures of the reaction layers differ from the previously described ones in having ThC_2 precipitate present in the Th(C,N) forming a continuous series of solid solutions between the outer surface and the central alloy composition. Reaction in nitrogen at lower pressures yielded surface Th(C,N) with lower nitrogen content and the ThC_2 precipitate was distributed over a broader region. Based on these observations representative nitrogen diffusion paths were drawn as illustrated in Fig. 6. In specimens with the lower C/Th ratios of 0.4 to 0.8 nitrogen penetration depths were greater and the ThC_2 precipitate appeared as small particles in relatively minor proportions as illustrated in Fig. 7. In alloys with the higher carbon contents of C/Th = 0.9 and 1.0 the ThC_2 precipitate appeared as a continuous layer such as seen in Fig. 8.

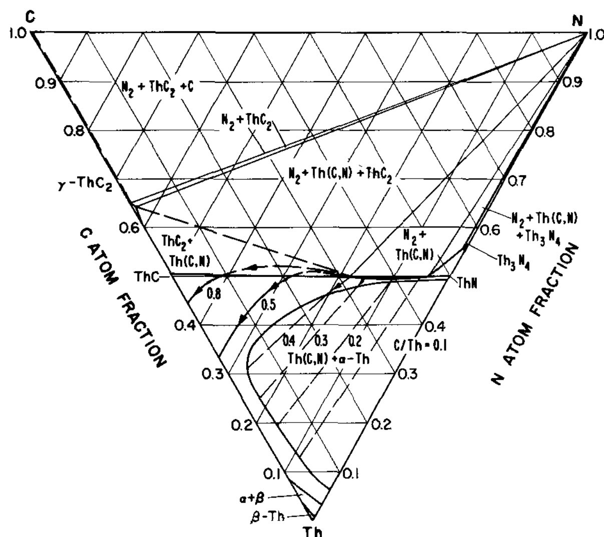

Fig. 6. Typical nitrogen diffusion paths in 19 Torr nitrogen on the thorium-carbon-nitrogen 1600°C isotherm.

Net nitrogen uptake by $ThC_{1.00}$ in 1 and in 100 Torr nitrogen was determined. The specimens experienced weight gains of 5.0 and 4.2 mg nitrogen, respectively, in ½ hr at 1800°C. Microscopic examination of the products revealed a small amount of ThC_2 at the Th(C,N) grain boundaries.

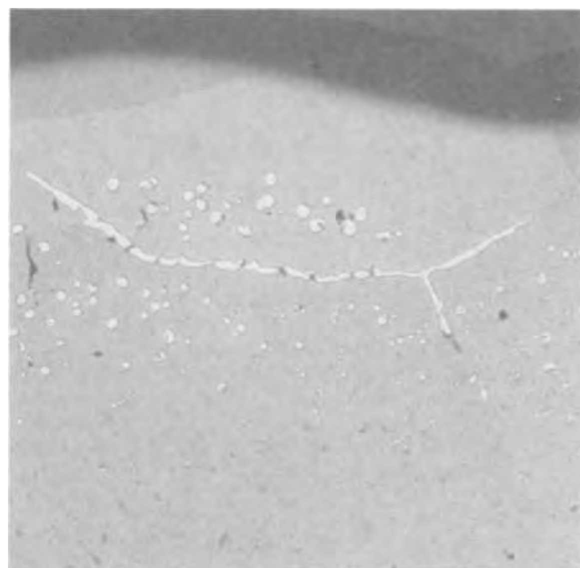

Fig. 7. Photomicrograph of an alloy with C/Th = 0.40 after annealing in 150 Torr nitrogen at 1800°C and quenching. The nitrogen is near the ThCN + Th(C,N) + ThC_2, three-phase, equilibrium pressure. Precipitate particles of ThC_2 (light area) are seen embedded in Th(C,N). The ThC_2 particles formed at temperature showing that carbon was displaced inward by flux of nitrogen in the Th(C,N) phase (X100).

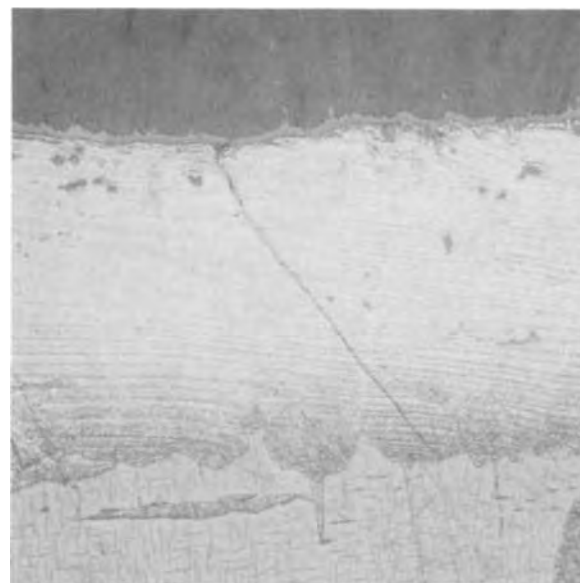

Fig. 8. Photomicrograph of an alloy with C/Th = 1.00 after annealing for 9 hr in 1520 Torr nitrogen at 1500°C and quenching. The nitrogen pressure exceeds the ThCN + ThC_2 + Th(C,N) and the Th_3N_4 + Th(C,N) + ThCN equilibrium pressures. The sequence of phase layers beginning with the outer layer at top (dark area) is Th_3N_4 + ThCN → Th(C,N) → ThC_2 (+ small amount of ThCN) → ThC (X300).

Discussion

Diffusion coefficients in the binary ThN phase.—Concentration-gradient type interdiffusion coefficients were calculated with the equation

$$\overline{D} = x_s^2/4tu^2 \quad [1]$$

as previously described (5) [see also Jost (7a)]. Values of the parameter u, as listed in column 5 of Table II, were calculated from the equation

$$(X_N'' - X_N')/(X_N' - X_N^o) = \pi u \exp u^2 \operatorname{erf} u \quad [2]$$

in which the value of the nitrogen atom fraction in ThN at the gas-scale interface was taken as $X_N'' = 0.500$, that in ThN at the scale-liquid interface was taken as $X_N' = 0.494$ corresponding to N/Th = 0.975 (4), and values of the nitrogen atom fraction in the liquid thorium-nitrogen alloys, X_N^o, were calculated from published liquidus data (4). According to Wagner (8), the symbol $\overline{D}$ represents an average value

$$\overline{D} = \frac{1}{X_N'' - X_N'} \int_{X_N'}^{X_N''} \tilde{D}\, dX_N \quad [3]$$

of the local interdiffusion coefficient $\tilde{D}$. The calculated $\overline{D}$ values as listed in column 6 of Table II can be represented by the equation

$$\overline{D}(\text{cm}^2/\text{sec}) = 254 \exp(-99.4 \pm 30 \text{ kcal/mole})/RT \quad [4]$$

where T denotes temperature in degrees Kelvin, indicating an effective activation energy for diffusion of 99.4 kcal/mole. The latter value may be compared with 120 ± 25 kcal/mole reported for the analogous UN phase (5).

The $\overline{D}$ values for ThN at 2100°C are seen in Table II to be essentially the same for 0.20 as for 2.00 atm nitrogen, a ten-fold difference in nitrogen pressure (p_{N_2}). Values of $\overline{D}$ for the analogous UN phase at elevated temperatures have also been reported to be insensitive to changes in p_{N_2} in the same pressure range (5). This is consistent with our observations that the composition of neither ThN nor UN changes appreciably with equilibrium p_{N_2} in the stated pressure range. It is also compatible with a vacancy mechanism for nitrogen diffusion as proposed for UN (5) and as suggested for the ThN phase, if one assumes in accord with observations, that the N/metal ratio does not exceed the stoichiometric value of one in 2 atm nitrogen. Flux rate of nitrogen in a binary phase can be written

$$j_N = -\frac{D^S_N C_N}{RT} \frac{d}{dx} \mu_N \quad [5]$$

where D^S_N denotes nitrogen self-diffusion coefficient and C_N is the nitrogen concentration (gram-atoms/cubic centimeter). Other things being equal, a ten-fold increase in p_{N_2} corresponding to an increase in μ_N by some 5 kcal/mole might be expected to appreciably increase the observed j_N value, whereas j_N is in fact insensitive to changes in p_{N_2} from 0.20 to 2.00 atm. Qualitatively, this comes about because, according to the vacancy theory of diffusion, D^S_N is proportional to the concentration of nitrogen vacancies (N_v) and an increase in p_{N_2} decreases N_v and, therefore, decreases D^S_N so as to compensate for the increase in the effective $d/dx\ \mu_N$. Reported composition average values of D^S_N [denoted $\overline{D}^s{}_{oN}$ in Ref. (5)] as deduced with the aid of Eq. [5] for UN are lower in value for $p_{N_2} = 2.00$ than for $p_{N_2} = 0.20$ atm by a factor of about 5 (5).

Diffusion coefficients in the ternary Th(C,N) solid.—The Onsager equations describing one-dimensional isothermal fluxes (gram-atom/square centimeter-second) of carbon and nitrogen relative to thorium are, respectively

$$j_C = -k_{C,C} \frac{\partial}{\partial x} \mu_C - k_{C,N} \frac{\partial}{\partial x} \mu_N \quad [6]$$

$$j_N = -k_{N,C} \frac{\partial}{\partial x} \mu_C - k_{N,N} \frac{\partial}{\partial x} \mu_N \quad [7]$$

at each point in the isotropic solid. The instantaneous chemical potential gradient of the general component i representing either carbon or nitrogen in the direction of flow is $\partial/\partial x\ \mu_i$ and the coefficients k_{ij} are generally functions of composition, pressure, and temperature. Transformations to other reference coordinate systems, as is well known, do not change the form of the flux equations, but do generally change the k_{ij} values.

Acquisition of data to integrate the flux equations is a formidable task and, as usual, simplifying assumptions are made to describe behavior under limiting conditions. With assumptions of negligible drift velocity of thorium and of negligible volume change,[1] flux of thorium relative to an ordinary coordinate system such as one fixed to the outer surface of the solid can be written

$$J_{Th} = -K_{Th,C} \frac{\partial}{\partial x} \mu_C - K_{Th,N} \frac{\partial}{\partial x} \mu_N = 0 \quad [8]$$

It follows that measurements of j_C and j_N, defined relative to thorium, are identical to those measured relative to the surface coordinate system of reference. Thus, $k_{ij} = K_{ij}$ and fluxes referred to the coordinate system fixed at the system's surface can be written

$$j_C = -K_{C,C} \frac{\partial}{\partial x} \mu_C - K_{C,N} \frac{\partial}{\partial x} \mu_N \quad [9]$$

$$j_N = -K_{N,C} \frac{\partial}{\partial x} \mu_C - K_{N,N} \frac{\partial}{\partial x} \mu_N \quad [10]$$

Only Eq. [10] is used in the subsequent analysis. It simplifies in the two limiting cases that nitrogen diffuses in directions parallel to the thorium or to the carbon isochemical potential curves. When nitrogen diffuses at all points in directions of constant μ_{Th}, Eq. [10] becomes

$$j_N = -D' \frac{\partial}{\partial x} X_N \quad [11]$$

where $D' = [K_{N,N} - K_{N,C}\, X_N/X_C]\ \partial/\partial X_N\ \mu_N$, X_C and X_N are the carbon and nitrogen atom fractions, and μ_N is a function of the single composition variable X_N in view of the pseudobinary character of the system. In the second case, nitrogen diffuses in a direction sufficiently close to curves of constant μ_C and Eq. [10] can be written

$$j_N = -D \frac{\partial}{\partial x} X_N \quad [12]$$

where $D = K_{N,N}\ \partial/\partial X_N\ \mu_N$.

Along the diffusion paths in nitrogen-rich Th(C,N) the fcc unit cell dimensions change only very little so that volume changes can be neglected. Equation [12] with D a constant is assumed to describe the diffusion of nitrogen in the nitrogen-rich Th(C,N) scales. Solution to the diffusion problem is analogous to that previously described for nitrogen diffusion in pure ThN. Value of $\overline{D}$ were calculated from observed scale thicknesses with Eq. [1] and u values were calculated with Eq. [2]. The nitrogen atom fractions in Th(C,N) at the Th(C,N)-gas interface was obtained with the formula $X_N'' = ½(1 - [\text{C/Th}])$, where C/Th denotes the carbon-to-metal ratio of the initial alloy. The nitrogen atom fraction in Th(C,N) at the alloy-scale interface,

[1] The discussion has to be qualified because volume changes in Th(C,N) can be finite. Extreme fractional change in volume that can occur on the ThC-ThN tie line is given by the fractional volume difference between pure ThC and ThN: $\frac{V_{ThC} - V_{ThN}}{V_{ThN}} = 0.11$

X_N', and that in the central alloy, X_N^o, were calculated for the initial C/Th ratios and published phase diagrams (1). $\overline{D}$ values thus deduced for alloys having various initial C/Th ratios are listed in column 7 of Table III and are plotted in Fig. 9 where results obtained with pure ThN are also shown. The $\overline{D}$ values for the alloys have a greater uncertainty than those for pure ThN because of greater uncertainty in the X_N values. Precision of the results, however, shows that the $\overline{D}$ tend to higher values in alloys with higher C/Th ratios. The results in rows 7 and 15 of Table III show that the effect of lowering the nitrogen pressure at 1600°C is to increase the $\overline{D}$ value from 4.2×10^{-10} cm^2/sec (row 7) in 19 Torr to 9×10^{-10} cm^2/sec (row 15) in 2 Torr nitrogen. Increase of $\overline{D}$ with decreasing nitrogen pressures is in accord with the postulated vacancy diffusion mechanism because an increase in nonmetal vacancy concentration occurs in the Th(C,N) phase in nitrogen at lower pressures and this can increase rate of transport. The vacancy mechanism explains the very high rates of diffusion in the extreme metal-rich alloys.

Reaction of an alloy with C/Th = 0.4 at the same low nitrogen pressure of 2 Torr at 1600°C produced a distinct enrichment of carbon in the outer part of the Th (C,N) scale. Based on lattice parameter values obtained with samples, the C/Th ratios are roughly estimated as 0.55 in the surface and 0.25 in the center of the specimen. Redistribution of carbon was not observed in scales formed on alloys with C/Th = 0.1 and 0.2 that had been reacted under otherwise the same conditions. Based on an extension of the analysis of Wagner (9) and reported free energy of mixing ThC and ThN (10) valid at more elevated temperatures, the redistribution of carbon in the Th(C,N) scale leads to the conclusion that $D^s{}_C > D^s{}_N$. This result has to be regarded as tentative, however, because the composition of Th(C,N) scales produced under the described conditions deviates considerably from that of a dilute solution of thorium in the monocompound $ThC_{1-x}N_x$.

Rates of diffusion of nitrogen in nonmetal-rich Th(C,N) can be calculated from the nitrogen uptake data at 1800°C. Nitrogen diffusion in nonmetal-saturated Th(C,N) is tentatively assumed to be described by Eq. [11] with D' constant. The assumption of constant μ_{Th} leading to Eq. [11] may not be strictly correct. In justification, one can argue on physical grounds that variation of μ_{Th} is probably not large. As may be seen in the final results, D' is not constant but varies with composition. The values to be determined, therefore, are composition averages and are denoted by $\overline{D'}$. As previously noted the composition of Th(C,N) coexisting with ThC_2 is close to the ThC-ThN tie line. Thus, the surface composition in the diffusion specimens can be described to a good approximation as a ThC-ThN solid solution and, based on Table I, consists of 54.1 and 35.5 m/o (mole per cent) ThC in 1 and 100 Torr N_2, respectively. Values of $\overline{D'}$ were calculated on the assumption of semi-infinite diffusion with the equation $\overline{D'} = \pi/t\ (q/2aC^s)^2$ (7b), where q is the gram atoms of nitrogen absorbed in time t and C^s is the surface concentration of nitrogen (gram-atom/cubic centimeter). The $\overline{D'}$ values thus obtained are 5.3×10^{-8} cm^2/sec in 1 Torr and 1.0×10^{-8} cm^2/sec in 100 Torr nitrogen. These values are somewhat low due to the growth of reaction produced ThC_2 precipitate that reduces the effective area, a. This effect, however, influences both values by approximately the same factor because q and, hence, the quantity of ThC_2 precipitate are about the same in both experiments. The $\overline{D'}$ value is higher for the Th(C,N) phase with 54.1 m/o ThC than that with 35.5 m/o ThC. This trend can be expected to continue with increasing carbon contents approaching pure ThC.

$j_C - j_N$ coupling.—The ThC_2 precipitate always appears in layer growths at a position displaced appreciably inward from the specimen outer surface. This observation cannot be attributed to migration of the precipitated ThC_2 particles *per se* because unreasonable assumptions would be required. The displacement of carbon is concluded to be caused by diffusion of carbon, during reaction, "uphill" against a carbon concentration gradient in Th(C,N).

We have observed that similar phenomena occur when the analogous UC phase is reacted with low-pressure CO and/or nitrogen. Evidently, carbon diffuses "uphill" in U(C,N) too. Carbon-rich fronts thus formed can be seen in published photomicrographs of products of reaction of UC with CO as reported by Erwin (11) and of UC with nitrogen as reported by Leitnaker, Lindemer, and Fitzpatrick (12). The solid solutions, $ThC_{1-x}N_x$, have been reported to be regular with respect to the components ThC and ThN at temperatures above 2500°C (10). It is reasonable to assume that stoichiometric $ThC_{1-x}N_x$ is a regular solution at the temperatures under discussion too. One may not conclude, however, that nonmetal-saturated Th(C,N) with very slightly greater nonmetal content is a regular solution. Component chemical potentials generally show a strong variation with composition having inflections near stoichiometric compositions. Thus, μ_{ThC} and μ_{ThN} can be expected to change considerably in magnitude with small deviations from the stoichiometric regular-solution monocompound $ThC_{1-x}N_x$, *i.e.*, with a small increase in (C + N)/Th ratio above unity. The "uphill" diffusion must, therefore, be ascribed to a change in sign of $\partial/\partial x_{ThC}\ \mu_C$ from negative in the regular solution $ThC_{1-x}N_x$ to positive in the nonmetal saturated Th(C,N) at a (C + N)/Th ratio only slightly greater than unity, *e.g.*, between 1.00 and 1.03 at 1800°C. Evidence for this can be seen by examination of phase relations in Fig. 2 where the composition of Th(C,N) coexisting with ThC_2 + ThCN is $ThC_{0.35}N_{0.65}$. At this composition μ_C must have a value approaching $\mu_C{}^o$, the value in pure graphite, and μ_C must decrease in the ThC_2-saturated Th(C,N) phase boundary in the direction of ThC. Based on well-established phase relations in the U-C-N system, and the fact that $\mu_C = \mu_C{}^o$ in nitrogen-rich U(C,N) where it coexists with

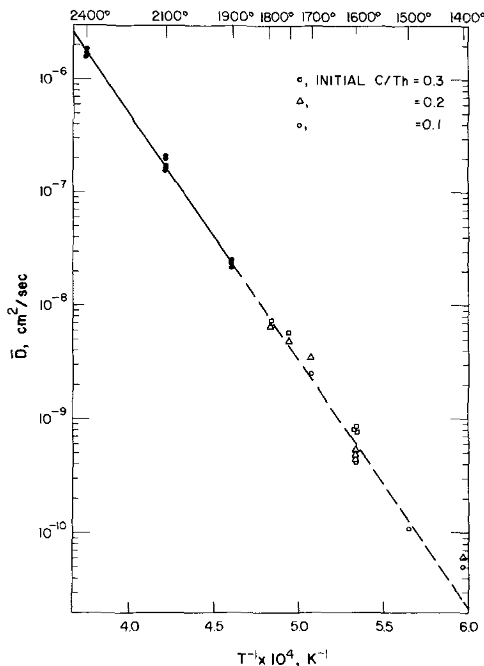

Fig. 9. Composition average chemical interdiffusion coefficients in pure ThN and in Th(C,N) as calculated from layer growth rates. For comparison, a line drawn through the results for pure ThN is extrapolated to lower temperatures as a broken line.

graphite one can show analogously that $\partial/\partial x\ \mu_C$ and $\partial/\partial x\ X_C$ have opposite signs in the greater part of the nonmetal-saturated U(C,N) phase boundary too (1200°-1800°C and 5-1000 Torr N_2). Thus, observed phase relations are qualitatively in accord with first principles in showing that carbon "uphill" diffusion is accompanied by a decrease in μ_C in both the Th(C,N) and the analogous U(C,N) phase.

Interpretation of the diffusion data.—Migration of nitrogen atoms through the intact thorium sublattice in the ThN layer growths requires a vacancy mechanism whence flux of nitrogen atoms is accompanied by an equal and opposite flux of vacancies on the nonmetal sublattice. In accordance with this mechanism, $\overline{D}$ values in nitrogen-rich ternary Th(C,N) are observed to increase with decreasing nitrogen pressure. Values of $\overline{D}$ increase with increasing carbon content (and with increasing unit cell dimensions) in the ternary monocompound phase $ThC_{1-x}N_x$, *i.e.*, near the ThN-ThC tie line. With increasing C/Th ratio above about 0.35 ($x < 0.65$), coupling between j_C and j_N becomes appreciable resulting in carbon "uphill" diffusion. A mechanism leading to such a coupling is obtained with the reasonable assumption that carbon atoms have to move off lattice sites in order to make room for oncoming nitrogen atoms. A carbon atom does not have to wait for a sublattice vacancy to come along, however, because at these compositions it is energetically possible for it to join a neighboring carbon to form a C_2 group. Excess carbon thus built up in front of the nitride layer eventually precipitates as ThC_2. At compositions intermediate to that of pure ThN and $ThC_{1-x}N_x$ with $x < 0.65$, a transition between the two diffusion mechanisms evidently occurs.

Summary

The following measurements were made: (*a*) compositions of $ThC_{1-x}N_x$ coexisting with ThC_2 and with ThCN in nitrogen at various pressures and at various temperatures; (*b*) nitrogen decomposition pressures of Th_3N_4, $Th_3(N,C)_4$, and of ThCN; and (*c*) nitrogen diffusion coefficients in the binary ThN phase and in the ternary Th(C,N) solid solutions at compositions near the monocompound.

Evidence is presented for "uphill" diffusion of carbon in the ternary solid solution Th(C,N) and some thermodynamic implications are discussed. The observations explain the observed tendency for carbon and thorium to segregate in the course of reaction of thorium-carbon alloys with nitrogen at moderate pressures.

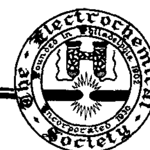
Technical Note



Dislocation Etchants for β′-$Gd_2(MoO_4)_3$

A. S. Bhalla[1]

National Physical Laboratory of India, Delhi, India

Gadolinium molybdate $Gd_2(MoO_4)_3$, an important rare-earth molybdate, exhibits both the ferroelectric and ferroelastic properties (1-3). The ferroelectric phase below 159°C has an orthorhombic structure with mm2 point group (4, 5) symmetry. Recent interest in its potentialities as an acoustooptic and as ferroelectric laser host call for studies on the imperfection in the crystal and their role in its properties. So far no dislocation etching studies have been reported on the single crystal of $Gd_2(MoO_4)_3$. In this note some chemical etchants are reported which could be useful for revealing the dislocation sites and to study the interaction of the dislocations with the domain walls and their movement.

Samples were cut in the shape of a rectangular plate with edges parallel to the crystallographic *a*, *b*, *c* axes. The *c*-face was polished with 0.3 and 0.1μ Al_2O_3 powders in succession. Samples were then etched at room temperature, using various alkalis, acids, and salts. Hydrochloric and nitric acids were found to be the best etchants to reveal the dislocation sites in the crystal with the etching times 10 sec and 45 sec, respectively. Different concentrations of these acids were tried and practically all dilutions produced the pits equally well on the faces of the crystals (Fig. 1). The pits are considered to be dislocation etch pits on the following grounds:

[1] Present address: Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802.

Key words: chemical etching, crystal defects, ferroelectric materials.

Fig. 1. Dislocation etch pits produced on the (001) face by dilute HNO_3 (40%), × 400.

Fig. 2. Low-angle grain boundary and the pile up of dislocations against it, were revealed by HNO_3:H_2O (1:3), × 350.

(*i*) The prominent etch pits were point-bottomed and continued etching did not alter this feature but only made the pits deeper and larger.

(*ii*) If HNO_3 was first used to produce the pits on the sample, subsequent etching with HCl just made the pits bigger and deeper.

(*iii*) When the samples were polished after etching and re-etched, the pits reappeared at the same locations.

(*iv*) Grain boundaries were revealed by the etchants (Fig. 2).

The above observations justify the conclusion that the pits were at the dislocation sites and these acids can be used to detect and study the dislocation in (001) face of the β'-$Gd_2(MoO_4)_3$.

Further investigations in the mobility of the dislocations and the influence of the electric field in it are in progress and the detailed results will be reported elsewhere.

The Low-Temperature Polarization of Platinum-Catalyzed Air Cathodes in Alkaline Electrolyte

K. F. Blurton*

Energetics Science Inc., New York, New York 10470

ABSTRACT

Polarization curves have been determined for oxygen reduction on Teflon-bonded platinum black diffusion electrodes in 30% KOH solution in the temperature range of 25° to −40°C. From this data the exchange current densities as a function of temperature and the activation energy at zero overpotential for oxygen reduction on platinum-catalyzed electrodes have been calculated and it was shown that the cathode potential at any current *vs.* a standard hydrogen electrode increased (became more anodic) with decreasing temperature.

Recent observations (1, 2) have indicated that the performance of zinc/air batteries decreases markedly at temperatures below 0°C. The purpose of this study, therefore, was to determine the influence of temperature on the polarization of the air cathodes.

Polarization curves were determined for oxygen reduction on Teflon-bonded platinum black diffusion electrodes in 30% KOH solution at temperatures from 25° to −40°C in the current density range of zero to 200 mA/cm^2. From this data the exchange current densities as a function of temperature and the activation energy at zero overpotential for oxygen reduction on Pt electrodes have been calculated. In addition it has been shown that, although the cathode polarization increased with decreasing temperature, the cathode potential at any current *vs.* a temperature-independent standard hydrogen electrode increased (became more anodic) with decreasing temperature.

Experimental

Steady-state polarization curves for oxygen reduction on Teflon-bonded platinum black electrodes were determined galvanostatically in oxygen-saturated and in air-saturated 30% KOH solution at temperatures of 25°, 5°, −10°, and −40°C.

The electrodes were tested in a floating electrode cell (3). The working electrode (geometric area 1 cm^2) was supported in a gold spring and it was floated on the surface of the electrolyte. Current collection from the gold spring to the external circuit was made via a platinum wire. The counterelectrode was a platinum gauze on which platinum was electrodeposited. The reference electrode was a mercury/mercuric oxide electrode which was placed in a Luggin capillary and immersed in the test electrolyte. The *IR* drop between the floating electrode and the tip of the Luggin capillary was determined using an interrupter technique and all potentials given in this paper have been corrected for *IR* drop.

It is essential when determining the kinetic parameters for oxygen reduction that Teflon-bonded electrodes are made so that a change in the catalyst loading does not change the electrode structure. We were able to prepare reproducible platinum electrodes by the same procedure as that of Vogel and Lundquist (4). These electrodes were prepared with Pt (Engelhard Industries) loadings of 2.9, 4.7, 6.8, and 10.0 mg/cm^2, 30 w/o (weight per cent) of Teflon 30 (E.I. du Pont de Nemours) and gold-plated tantalum as the current collector. The current due to oxygen reduction on the current collector and electrode holder was negligible (less than 1 mA/cm^2) at all potentials.

The 30% KOH solution was prepared from Baker Analyzed Reagent grade chemical and triply distilled water. Oxygen, which was obtained from cylinders, and laboratory air were used without purification. The cell temperature was maintained at 25°C with a water bath, at 5°C with ice and water, at −10°C with ice and salt water, and at −40°C with dry ice and acetone.

The polarization curves were determined both by increasing the current density stepwise from open circuit to 200 mA/cm^2 and by decreasing the current density stepwise from this current density to open circuit. There was no significant difference in the potentials at a given current when either increasing or decreasing the applied current and this indicates that the steady-state potential was attained. At each applied current, the cathode potential was steady within 2-3 min at all temperatures.

The platinum area of the Teflon-bonded diffusion electrodes was measured by determining the charge due to the oxidation of adsorbed hydrogen using the periodic triangular voltage sweep technique on submerged electrodes (5). This technique gave a value of 24 m^2/g for the Pt surface area.

Results

The potential of the mercury/mercuric oxide electrode is temperature dependent (6) and therefore, the polarization data is recorded *vs.* the overpotential for oxygen reduction and *vs.* the cathode potential with respect to the standard hydrogen electrode (SHE).

The cathode overpotential was calculated from the experimental cathode potentials *vs.* Hg/HgO electrode and the reversible oxygen electrode potential *vs.* Hg/HgO. The cathode potential with respect to SHE was

Table I. Calculated electrode potentials as a function of temperature

Temperature (°C)	Oxygen electrode potential (V) vs. Hg/HgO	Oxygen electrode potential (V) vs. SHE
25	0.303	0.316
5	0.315	0.355
−10	0.323	0.385
−40	0.339	0.450

calculated from the overpotential and the reversible oxygen electrode potential *vs.* SHE. The calculated values of the reversible oxygen electrode potential *vs.* Hg/HgO and *vs.* SHE are given in Table I.

The reversible oxygen electrode potential *vs.* Hg/HgO is independent of the KOH concentration and therefore, these potentials at each temperature (Table I) were calculated from the standard potentials and temperature coefficients of the oxygen and mercury/mercuric oxide electrodes (6).

The reversible oxygen electrode potential *vs.* SHE was calculated from the Nernst relationship

$$e = e^o + RT/4\mathbf{F} \ln a^2_{H_2O}/a^4_{OH^-} \qquad [1]$$

The values of e^o at each temperature were calculated from the standard potential at 25°C and the temperature coefficient of the oxygen electrode, and the water activity was calculated from the ratio of the vapor pressure of the KOH solution (7) to the saturated water vapor pressure (8). The activity of the hydroxyl ion was calculated from the KOH concentration and the activity coefficient at 25°C (9), since the activity of KOH solutions is essentially independent of temperature over the range 25° to −40°C (7).

Semilogarithmic plots of current per unit weight of platinum (milliamperes per milligram of Pt) *vs.* overpotential and *vs.* cathode potential with respect to SHE are shown in Fig. 1-4 for oxygen reduction on Teflon-

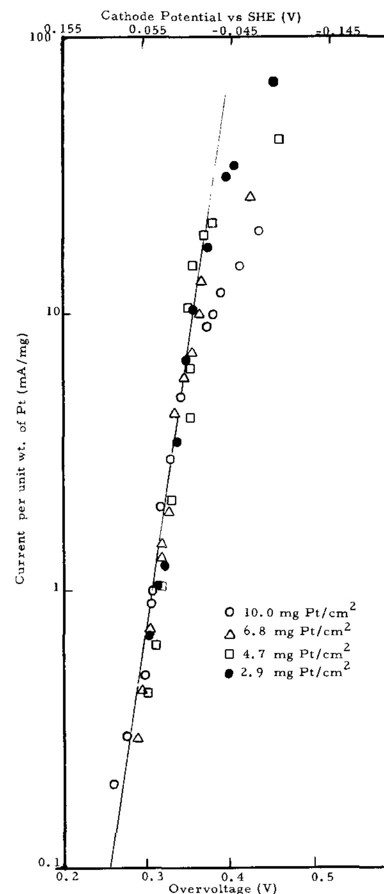

Fig. 2. Polarization curve for oxygen, 30% KOH solution at 5°C

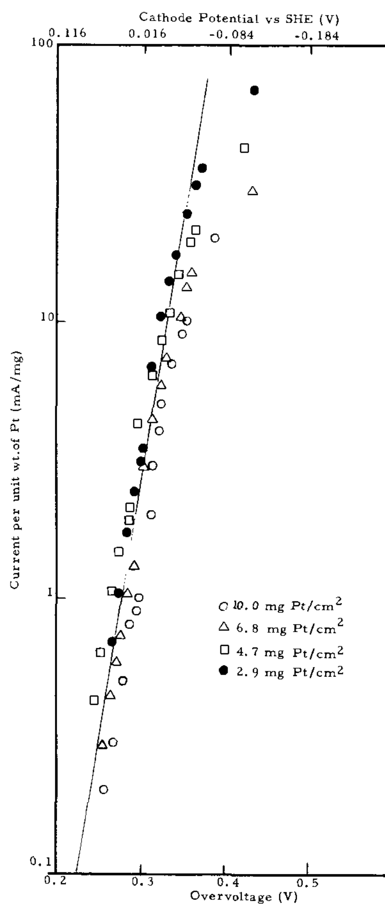

Fig. 1. Polarization curve for oxygen, 30% KOH solution at 25°C

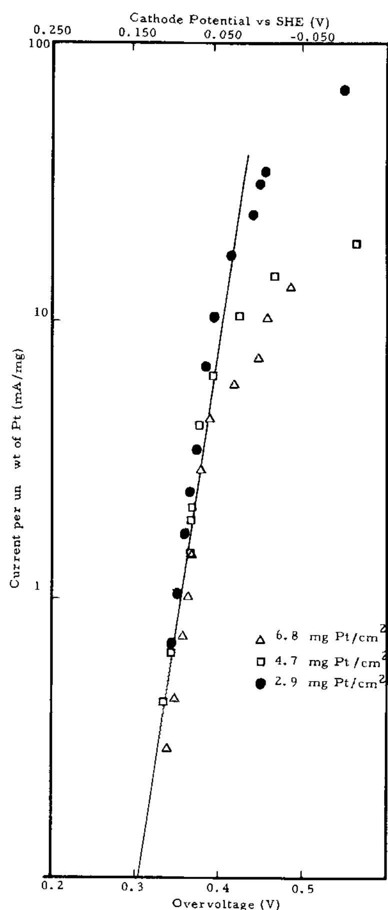

Fig. 4. Polarization curve for oxygen, 30% KOH solution at −40°C.

bonded platinum black electrodes in oxygen-saturated 30% KOH solution at 25°, 5°, −10°, and −40°C, respectively. These plots refer to polarization data obtained with several Pt electrodes and the applied current density can be obtained from the values of milliamperes per milligram of Pt and the electrode loadings. The Tafel plots were linear over approximately two decades of current, and the current per unit weight of Pt in the Tafel region was independent of the Pt loading (Fig. 1-4). The value of the current per unit weight of Pt at which the semilogarithmic plots deviated from linearity decreased with increasing Pt loading and with decreasing temperature.

The linearity of the Tafel plots, and the independence of the current per unit weight of platinum in the Tafel region on the platinum loading, indicate (4, 10, 11) that gas concentration polarization is absent, that the internal ohmic polarization across the electrode is negligible, and that the electrode structure did not change when the electrode loading was varied. Thus, the exchange current densities can be calculated as a function of temperature from these polarization curves (Fig. 1-4).

The values of the exchange current per unit weight of Pt (amperes per milligram), the exchange current density based on the real Pt area (amperes per square centimeter), the Tafel slope ($\partial V/\partial \log i$), and the vapor pressure (7) of 30% KOH solution (p) are given in Table II. The exchange currents per unit weight of Pt were calculated by extrapolating the semilogarithmic plots to the reversible oxygen potential at each temperature, while those based on the real Pt area were calculated from the exchange current per unit weight of Pt and the experimentally determined value of the Pt surface area of 24 m²/g.

These values of the exchange currents are for an oxygen partial pressure of (1-p) atm. However the values of p are so small (Table II) that the exchange

currents are essentially those for O_2 at 1 atm pressure. The value of the exchange current density at 25°C on Pt black electrodes in 30% KOH solution (Table II) was comparable with that determined for oxygen reduction on Pt foil electrodes at 25°C in 0.1N KOH solution (5×10^{-11} A/cm²) (12), but differed by an order of magnitude from those determined in 0.1N NaOH solution (1×10^{-10} A/cm²) (13) or in 1N KOH solution (3×10^{-12} A/cm²) (14). This difference may be due to the lower effect of electrolyte impurities on high area Pt black than on low area Pt foil electrodes or to differences in the oxidation states of the platinum surfaces (15).

The expected variation of the Tafel slope with temperature was found (Table II) and the value of the Tafel slope was equal to RT/F. Similar values of the Tafel slope at 25°C were also found for oxygen reduction on Pt foil electrodes in dilute alkaline solutions (12-14).

Figure 5 shows the semilogarithmic plot of current density *vs.* overvoltage and *vs.* cathode potential with respect to SHE for oxygen reduction on a Pt electrode (loading 4.7 mg of Pt/cm²) in oxygen- and in air-saturated KOH solution at −10°C. The overvoltage for

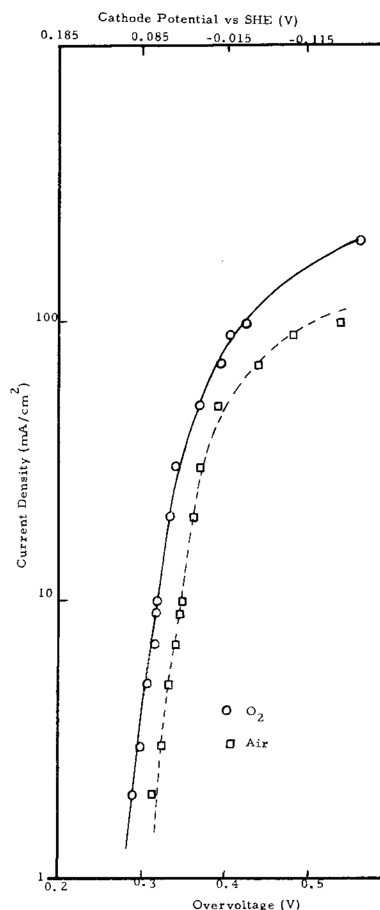

Fig. 5. Polarization curve for air, 30% KOH solution at −10°C, electrode loading 4.7 mg of Pt/cm².

oxygen reduction in the Tafel region increased by approximately 28 mV on switching from oxygen at 1 atm to air at 1 atm (Fig. 5).

The polarization increase ($\Delta\eta$) at a constant current density in the Tafel region on changing from oxygen to air at the same total pressure is given by (10)

$$\Delta\eta = \frac{\partial V}{\partial \log i} \log \frac{P\,\text{air}}{P_{O_2}} \quad [2]$$

where P_{air} and P_{O_2} are the oxygen partial pressures in air and oxygen, respectively.

At $-10°C$ the calculated value (Eq. [2]) of $\Delta\eta$ is 36 mV and this is in satisfactory agreement with the experimental value of 28 mV. There was good agreement between the calculated and experimental values of $\Delta\eta$ with other electrodes and at the other temperatures.

At applied current densities greater than 100 mA/ cm^2, droplets of electrolyte were observed on the gas side of the electrode (i.e., electrode "weeping" occurred). Electrode weeping was not observed at current densities in the activation polarization region. The amount of electrolyte exuded by the electrode increased with increasing current density and the gas side of the electrode dried very quickly on decreasing the applied current density below 100 mA/ cm^2. The electrodes could not be observed at low temperatures and, therefore, it is not known whether the current density at which weeping occurs is temperature dependent.

Electrode weeping in alkaline electrolyte has been observed by other workers (4, 16). This behavior indicates that the electrolyte is under a current dependent force which is sufficiently large to overcome the surface tension within the electrode pores, and it has been claimed (16) that this force is due to the mutual diffusion of water and electrolyte in the electrode pores. It is eliminated in metal/air batteries by coating the gas side of the cathode with a hydrophobic barrier.

Discussion

Comparison of the polarization data at each temperature (Fig. 1-4) shows that the overvoltage for oxygen reduction increases with decreasing temperature. However the variation in the reversible oxygen electrode potential with temperature is included in these measurements of overvoltage. In order to analyze the low-temperature behavior of metal/air cells, the cathode potential with respect to a temperature-independent electrode must be known. It was for this reason that the cathode potential at each applied current density was calculated with respect to SHE, since this potential is, by definition, zero at all temperatures (17).

The comparison of the semilogarithmic plots of current per unit weight of Pt at each temperature (Fig. 1-4) shows that the cathode potential with respect to SHE at each current density increased (became more anodic) with decreasing temperature. Thus this variation of cathode potential with temperature acts to increase the voltage of metal/air cells with decreasing temperature.

The difference between the cathode potentials with respect to SHE at two temperatures was greater at current densities in the Tafel region (activation control) than at higher current densities [activation and gas diffusion control (11)]. For example with a Pt loading of 2.9 mg/cm^2, the cathode potential at 10 mA/cm^2 was 65 mV more anodic at $-40°C$ than at 25°C, whereas at 200 mA/cm^2 it was 22 mV more anodic at $-40°C$ than at 25°C. This change is due to the influence of the mass transport parameters (oxygen solubility and diffusion coefficient) on the electrode polarization at the higher current densities.

The present results in the Tafel region can be used to analyze metal/air battery performance curves since the polarization is independent of electrode structure and the current at any potential is proportional to the Pt loading. However the results at higher current densities (activation and gas diffusion control) only indicate the general trend in the variation of cathode potential with temperature and this data is not directly comparable with other Pt loading electrodes since the current at a given potential is not proportional to Pt loading. Furthermore the cathode polarization at higher current densities was complicated by electrode weeping and this results in an increase in electrode polarization since gas diffusion to the electrode/electrolyte interface then occurs through an electrolyte film on the gas side of the electrode.

Figure 6 shows the Arrhenius plot of the logarithm of the exchange current density *vs.* the reciprocal of temperature. The value of the activation energy at zero overpotential for the oxygen electrode calculated from this plot was 11.3 kcal/mole. No correction was made for changes in the oxygen solubility with temperature but this correction would be small.

The present value for the energy of activation is significantly lower than those determined with Pt foil electrodes in 1*N* KOH solution (22.5 kcal/mole) (18) and in 0.1*N* NaOH solution (15.4 kcal/mole) (19). The variation in these values is probably due to the different conditions under which the measurements were made. Thus the present values were obtained from cathode polarization data on oxide-free Pt electrodes, whereas the previous values (18, 19) were calculated from oxygen evolution data on oxide-covered Pt surfaces.

Thus in alkaline electrolyte the energy of activation for the oxygen electrode is less on oxide-free Pt electrodes than on oxide-covered Pt electrodes whereas in acid electrolyte the energy of activation is greater on oxide-free Pt electrodes (20, 21). This difference in the energy of activation on oxide-free and oxide-covered Pt surfaces in alkaline and acid electrolyte may be associated with the higher coulombic efficiency for hydrogen peroxide formation in alkaline electrolyte compared with that in acid electrolyte (12, 22-24).

Conductivity of Beta-Alumina and Its Dependence on Sodium and Magnesium Content

John H. Kennedy* and Anthony F. Sammells*

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

The relationship between conductivity and sodium content has been investigated for sintered beta-alumina containing MgO. Conductivities of 3.5×10^{-3}, 8.0×10^{-3}, and 4.4×10^{-3} ohm^{-1}-cm^{-1} were found for material containing 1, 2, and 4% MgO, respectively, with optimum sodium content. Experimental conductivities for 1 and 2% MgO agree well with calculated values assuming one additional sodium ion for each magnesium ion present. Resistance measurements were made in the frequency range 0.75-10 kHz, and conductivities were calculated from resistances extrapolated to infinite frequency. Electrode contact was made using thin films of silver and gold following glow discharge cleaning techniques.

Beta alumina has been known for a considerable time and was originally thought to be a crystallographic variation of alumina (1). It was soon established that sodium oxide was essential to the synthesis of beta-alumina from aluminum oxide and that it is in fact an alkali aluminate of ideal stoichiometry $Na_2O \cdot 11Al_2O_3$ (2). The x-ray analysis (3, 4) has proven conclusively that beta-alumina consists of a hexagonal layer-type structure of spinel-type blocks containing four layers of cubic close-packed oxygen atoms with aluminum ions occupying all of the sites normally occupied by the aluminum and magnesium ions in $MgAl_2O_4$ spinel. The sodium-containing layers are separated from the spinel blocks by Al-O-Al bonds. More recently, single crystals of beta-alumina were shown to exhibit rapid sodium ion diffusion in the plane perpendicular to the c-axis (5) and that the sodium could be almost completely exchanged in suitable molten salts for Ag, K, Li, Rb, and, to a lesser extent, Cs ions. Sodium ions have exhibited the largest diffusion coefficient, and the mechanism of diffusion has been shown conclusively to be interstitialcy (5, 6). Beta-alumina normally is found with an excess of sodium when compared to the ideal stoichiometry, and it has been suggested (7) that this excess can be stabilized by the presence of Al^{3+} vacancies in the spinel.

For beta-alumina to be of utility as an electrolyte in a battery system, practical ceramic-type shapes must be formed from the single crystals. This necessitates the sintering of pressed material under strictly controlled conditions so that the sintered product will have a final density close to that of the single crystal. Sintered compacts of beta-alumina for use as an electrolyte have been reported previously (8-10) and have been used in the experimental sodium-sulfur battery. This battery operates in excess of 300°C so as to keep the reactants molten, and at such temperatures, beta-alumina has a very high conductivity of approximately 0.2 (ohm-cm)$^{-1}$. The conductivities reported at room temperature by various workers have not only been relatively low, but erratic and dependent on the type of electrode contact used as well as on the sintering conditions.

Sintering conditions reported (8-11) have varied between 1600° and 1900°C with times ranging between 15 min and several hours. It has always been found necessary to use coarse beta-alumina packing so as to provide an alkaline atmosphere to reduce sodium loss.

It has been shown (5, 7) that the interstitialcy mechanism of migration of ions through beta-alumina depends on an excess of sodium present and that the incorporation of MgO into the sintered material in-

* Electrochemical Society Active Member.

Key words: beta-alumina, ionic conductivity, magnesium oxide, thin films.

creases the ionic conductivity of the sintered material (9, 12). This suggests that there might be some relation between the amount of MgO present in the sintered material and sodium content required for optimum conductivity. Before any comparison can be made however, a method for achieving reproducible satisfactory electrode contacts must be established.

Several approaches have been made to achieve good electrode contacts to both single crystals and sintered compacts of beta-alumina. The reported ionic resistivities in most cases have been made at high frequency so as to minimize the faradaic impedance at the electrode-electrolyte interface. Yao and Kummer (5) while working with single crystals of beta-alumina and indium electrodes reported resistivity values at room temperature of 30 ohm-cm at 500 kHz and 46 ohm-cm at 50 kHz, and the resistivity value was found to be frequency independent between 0.5 and 1.5 mHz. Whittingham and Huggins (7) used a silver resinate solution on single crystals of silver beta-alumina in conjunction with mechanically pressed silver electrodes to achieve a resistivity of 150 ohm-cm at room temperature and a frequency independent range of 0.1-100 kHz. Using sintered beta-alumina containing 2% MgO, Wynn Jones and Miles (9) reported ionic resistivities between 400 and 600 ohm-cm with a 4-probe d-c technique using silver metal in contact with the ceramic via solid sodium hydroxide. Recently, Armstrong *et al.* (10) illustrated the necessity for determining frequency dependence when resistivities were measured on sintered material and worked with a variety of electrodes and, in particular, reported resistivities at room temperature of the order of 550 ohm-cm at a frequency of 1.592 kHz when using sodium electrodes.

It is quite evident from the literature that electrode contact to single crystals of beta-alumina is easier to achieve than to sintered compacts. This is because there is a greater roughness factor in the sintered material, and therefore it is more difficult to make good contact with the entire surface. In single crystals, contact can be made by initial mechanical contact followed by high-temperature annealing so as to bond the electrode to the crystal. Whittingham and Huggins (6) also reported achieving good contact to single crystals by the novel use of tungsten bronze electrodes. Such techniques have not been satisfactory with sintered material. Satisfactory electrode contacts can be made to sintered pellets using thin-film techniques only if the substrate is perfectly clean before evaporation. One method for cleaning sintered pellets *in situ* which we used in this study was glow discharge. Such cleaning techniques minimize any possible contact resistance that might result so that the final extrapolated resistivity should closely represent the true bulk resistivity of the electrolyte.

The frequency dependence of the faradaic impedance has been known for some time (13, 14). It is also well known that such impedance is proportional to the reciprocal of the square root of frequency

$$\Delta R = k\omega^{-1/2}$$

where ΔR is the faradaic impedance, ω is the frequency, and k is a proportionality constant. The measured resistance, R_m, consists of both bulk resistance, R, and the faradaic impedance at the interface

$$R_m = R + \Delta R = R + k\omega^{-1/2}$$

A linear extrapolation of resistances measured at different frequencies to infinite frequency by plotting R_m against $\omega^{-1/2}$ will eliminate or at least minimize the error due to faradaic impedance. Resistance measurements were made in the frequency range 0.75-10 kHz in this study. The use of higher frequencies can lead to additional complications in the interpretation of results (15). The dependence of the infinite frequency resistivity on sodium content was determined using sintered pellets of beta-alumina with fixed percentages of MgO and thin-film electrodes of gold or silver. The sintering conditions were strictly controlled so as to produce final sintered densities in a narrow range so that a valid comparison could be made from one pellet to another in each run.

As has been observed by others, the final sodium content of beta-alumina after sintering was always less than the initial content, and in order to correlate the measured resistivity with sodium content, a sodium analysis on each pellet after sintering was necessary. The sodium content was determined by ion-exchanging sodium by silver with silver nitrate and subsequent analysis for sodium in the silver nitrate by atomic absorption.

Experimental

Preparation of samples prior to sintering.—Alcoa beta-alumina (325 mesh) (11) was ground to particle size 0.5-1μ in a grinding mill using alumina balls. Ethylene glycol was used as a grinding aid, and the final particle size was determined with a Unitron U11 microscope. The MgO and Na_2CO_3 of similar particle size were mixed with the ground beta-alumina in a Fisher mechanical mortar and pestle (alumina). To this powder was then added a binder (2% carbowax 1000 as a 10% aqueous solution) and the material allowed to dry at 110°C over a 24-hr period. Pellets were made in a KBr-type press at 16,000 psi, and the binder was removed by slowly heating to 400°C and leaving 24 hr.

Sintering conditions.—Pellets were sintered in an Astro ultra-high temperature graphite resistance furnace Model No. 1000A-2560 under oxidizing conditions with the use of a muffle tube assembly. The graphite heating elements surrounding the alumina muffle tube were protected by a nitrogen atmosphere. Pellets were kept covered with a coarse 325 mesh beta-alumina during the sintering process so as to maintain an alkaline atmosphere and hence reduce the loss of sodium. The pellets, together with the beta-alumina packing, were kept in a covered alumina crucible during the sintering. Slow heating rates of 250°C/hr were maintained so as to prolong the muffle tube life. Temperatures of 1700°-1800°C were achieved over extended periods of time. Temperature control was maintained by a boron-graphite thermocouple connected to a L&N 6261 Electromax C.A.T. controller. Recorded temperatures were measured directly by use of a Micro Optical pyrometer (Pyrometer Instrument Company) through a viewing port in the side of the furnace.

Application of thin-film electrodes.—Evaporations of silver and gold were performed in a Veeco 776 automatic high vacuum evaporator. Electrode contact was improved with the use of glow discharge cleaning of the substrate with oxygen at 10^{-3} Torr using low potentials. If too high a potential was used in the glow discharge process the first electrode became oxidized during cleaning of the second face of the pellet. This oxidation was eliminated by the use of nitrogen in the second cleaning process. Nitrogen was not as effective in cleaning the substrate as oxygen, but the pellet was thoroughly cleaned on the first cleaning so that nitrogen was satisfactory for the second cleaning.

Resistivity measurements.—Measurements of pellet resistance were made with a General Radio 1650A impedance bridge at frequencies between 10^{+4} and 500 Hz by the use of a Wavetek Model 111 voltage-controlled generator. Resistivity values were calculated from resistance measurements extrapolated to infinite frequency and the pellet dimensions.

Atomic absorption spectrophotometry.—Sodium analysis was accomplished by first ion-exchanging the sodium for silver by heating pellets at 220°C for 24 hr with $AgNO_3$. The exchange process was carried out twice to ensure complete exchange of sodium. A third exchange did not indicate any more exchangeable

sodium in the sintered pellets. Sodium in the silver nitrate was then analyzed on a Jarrell-Ash 82-270 Atomsorb atomic absorption spectrophotometer by comparing with an appropriate calibration curve.

X-ray diffraction.—Surface x-ray diffraction of sintered beta-alumina pellets was accomplished with a Philips x-ray diffraction instrument with CuKα radiation, a Philips Type 52572 scintillation counter, and a chart recorder.

Results

It was found that particle size and homogeneity were critical in preparing beta-alumina containing MgO. A particle size of 0.5-1μ gave a suitable final density. Variation in the sodium content was achieved by thoroughly mixing sodium carbonate of similar particle size to the starting material prior to pellet formation. Pellets were made at pressures of 16,000 psi giving a "green" density of 1.91. When pressures greater than this were used, laminations occurred in the green pellet and it readily fell apart. The binder was removed slowly in a conventional tube furnace by heating slowly to 400°C and leaving at this temperature for 24 hr. Attempts to remove the binder more rapidly than this in the sintering furnace gave noticeably lower final densities. Although it is unlikely that any sodium loss would occur at such low temperatures the pellets were covered with coarse beta-alumina during the binder removal. The pellets were covered to a depth of ½ in. in coarse 325 mesh beta-alumina in the alumina crucible prior to sintering, and a thin layer of packing was also placed between individual pellets since without such separation there was a tendency for the pellets to sinter together. The sintering furnace was heated up at a rate of 250°C/hr (the recommended rate for the alumina muffle tube). The sintering temperatures and times varied significantly between pure beta-alumina and that containing MgO. With pure beta-alumina, final densities close to theoretical could be achieved with temperatures of 1720°C for 2 hr, but when 1 or 2% MgO was added, the required sintering conditions were 1750°C for 7 hr. With 4% MgO, the best sintering conditions were 1830°C for 6 hr but were not completely satisfactory in achieving maximum density. It has been noted before that the rate of sintering of ceramic material, alumina in particular, is reduced when MgO is added (16) due to its effect on the grain boundary mobility. However, other authors (9) report that lower temperatures were sufficient for beta-alumina doped with 2% MgO, but this has not been our experience.

Two other crystalline forms of beta-alumina containing MgO have been reported and designated β''-(17) and β'''-alumina (18). However, there was no indication of β''-, or β'''-, or α-alumina in our sintered pellets from x-ray analysis. There was an indication of a small amount of a second phase of sodium aluminate (possibly microdispersed) in many samples. No preferred orientation was observed in the sintered pellets.

Several types of electrodes were investigated including silver paint, sodium amalgam, and metal thin films. A large frequency dependence for the silver paint indicated poor electrode contact to the beta-alumina, and in the case of sodium amalgam, difficulty was found in even achieving contact. Most satisfactory results were obtained with thin films of silver and gold, and only the results obtained with these electrodes are reported here. Silver was found to make a better electrode contact to the beta-alumina than did gold. This was determined by the larger frequency dependence of the measured resistance on samples containing gold electrodes when compared to those samples having silver electrodes as shown on Fig. 1 and 2. Electrode contact was also improved by the use of glow discharge cleaning prior to electrode deposition, and samples treated in this manner exhibited a lower frequency dependence of the measured resistance than those not treated by this cleaning process.

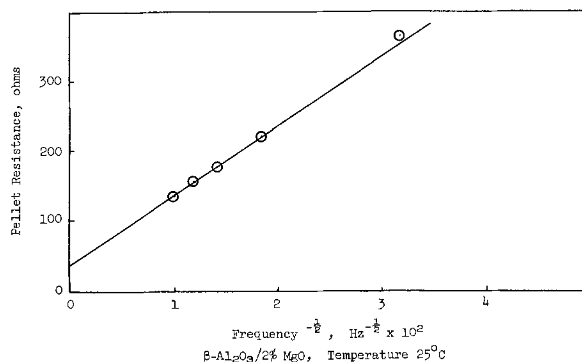

Fig. 1. Frequency dependence for β-Al_2O_3 pellets with evaporated gold thin-film electrodes.

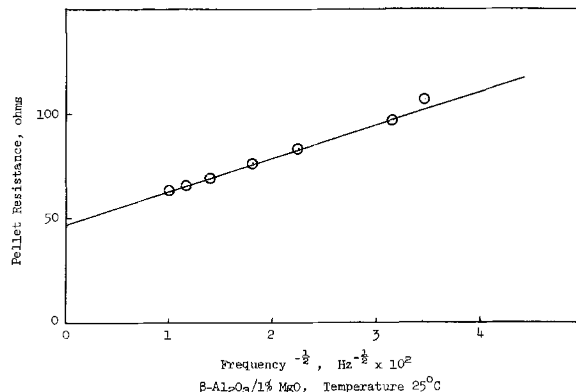

Fig. 2. Frequency dependence for β-Al_2O_3 pellets with evaporated silver thin-film electrodes.

The final densities of 1 and 2% MgO samples ranged between 3.0 and 3.1 with the majority in the range 3.0 and 3.05. The density of 4% MgO material was only 2.9, and attempts to obtain greater density than this with longer sintering times or higher temperatures did not succeed. In this case, smaller particle sizes might provide greater green densities prior to sintering. However, since the main purpose of this investigation was to determine the optimum stoichiometry of sodium for maximum conductivity, the lower density pellets were satisfactory.

Resistivity measurements were made *vs.* frequency using a pellet holder with gold contacts, and no change in the resistance values was observed with change in pressure. Typical measurements are shown in Fig. 1 for silver electrodes and Fig. 2 for gold electrodes. The resistivity was measured from the pellet thickness and area occupied by the electrode. The electrode contact was not found to deteriorate with time in a vacuum system but when exposed to the atmosphere some deterioration with time was observed as shown in Fig. 3. This deterioration with time was attributed to the slow oxidation of the silver electrode thus increasing the contact resistance between electrode and electrolyte. Sintered pellets kept in a reasonably dry atmosphere for several months before applying electrodes exhibited essentially the same conductivity as fresh pellets. All resistance measurements on the pellets reported here were made immediately after electrode deposition.

The correlation between extrapolated resistivity and sodium content for a fixed percentage of MgO is shown in Fig. 4, 5, and 6. The minimum resistivity values were: 288 ohm-cm for 1% MgO at 6.8% Na_2O, 125 ohm-cm for 2% MgO at 7.4% Na_2O, and 227 ohm-cm for 4% MgO at 9.5% Na_2O. Conductivity values, calculated from resistivities, were 3.5×10^{-3} (ohm-cm)$^{-1}$ for 1% MgO at 6.8% Na_2O, 8.0×10^{-3} (ohm-cm)$^{-1}$ for 2% MgO at 7.4% Na_2O, and 4.4×10^{-3} (ohm-cm)$^{-1}$ for 4% MgO at 9.5% Na_2O.

Discussion

From consideration of charge neutrality it can be hypothesized that magnesium which becomes incorporated into the beta-alumina structure on Al^{3+} sites will increase the number of interstitial sodium ions that can be stabilized. This hypothesis is reasonable when one recalls that the spinel-type blocks of beta-alumina have the same structure as the spinel $MgAl_2O_4$. From this possible correlation between magnesium substitution and sodium ion interstitials, an optimum sodium content and maximum conductivity for any given MgO content can be calculated.

The theoretical Na_2O content for pure beta-alumina is 5.24%, but our studies and those of other investigators (3-5) have shown that "pure" beta-alumina contains excess sodium. Our beta-alumina was found to contain an average sodium content of 6.1% and had a conductivity of 6.7×10^{-4} (ohm-cm)$^{-1}$ at 25°C. This represents a 16% excess Na_2O content which may be stabilized by Al^{3+} vacancies or other defects present in the "pure" material. The addition of 2 w/o (weight per cent) MgO to the beta-alumina is equivalent to 0.59 mole of Mg^{2+} per mole of beta-alumina and should stabilize an additional 0.59 mole of interstitial sodium ions. This would amount to an additional 1.5 w/o Na_2O giving an expected optimum sodium content of $6.1 + 1.5 = 7.6$ w/o Na_2O. There is no requirement that when 2% MgO is incorporated the material will still contain the same number of other defects, but Fig. 5 shows that a maximum conductivity was found at 7.4% MgO, quite close to the calculated value.

Similar calculations for material containing 1 and 4% MgO give expected Na_2O contents of 6.85 and 9.1 w/o. Again, Fig. 4 and 6 show that maximum conductivity was achieved at a Na_2O content of 6.8 w/o for the material containing 1% MgO and 9.5 w/o for material containing 4% MgO, both values being close to the values calculated above.

Conductivity values for undoped β-Al_2O_3 sintered to a density similar to the doped materials were in the range $5.3\text{-}7.1 \times 10^{-4}$ ohm^{-1}-cm^{-1}. If the median value of 6.6×10^{-4} ohm^{-1}-cm^{-1} is used as a base reference value, then any increase in conductivity resulting from the additional interstitial sodium ions can be calculated assuming additivity with this base reference value

$$\sigma_{tot} = \sigma_o + \sigma_{MgO}$$

where σ_{tot} = total conductivity, σ_o = base reference conductivity contribution, and σ_{MgO} = conductivity contribution from addition of MgO stabilizing higher concentrations of interstitial sodium ions.

If we assume for the moment that the additional sodium ions will have a mobility equal to that measured for pure beta-alumina (1.56×10^{-5} cm^2/sec-V at 25°C) the σ_{MgO} contribution can be calculated using

the equation

$$\sigma_{MgO} = N_{MgO}\mu q$$

where N_{MgO} is the concentration of magnesium atoms (which equals the additional concentration of sodium ions incorporated into the β-Al_2O_3), μ is the mobility of the additional sodium ions in β-Al_2O_3, and q is the unit of charge. The number of conductive sodium ion interstitials will equal the number of magnesium ions introduced, and for 2% MgO this is

$$N_{MgO}(\text{ions/cm}^3) = \frac{3.0\text{g } \beta\text{-}Al_2O_3 \times 0.02\text{g MgO/g } \beta\text{-}Al_2O_3 \times 6.02 \times 10^{23}}{\text{cm}^3\ 40\text{g MgO/mole}} = 9 \times 10^{20}$$

Therefore

$$\sigma_{MgO} = 9 \times 10^{20} \times 1.56 \times 10^{-5} \times 1.6 \times 10^{-16} = 2.25 \times 10^{-3} (\text{ohm-cm})^{-1}$$

for 2% MgO at 25°C. Consideration of tortuosity in the polycrystalline material would suggest that the measured conductivity based on pellet geometry should be smaller than the calculated value. The true tortuosity factor is unknown, but Wynn Jones and Miles (9) concluded it might be as high as 3-5.

Another possible difference between conductivity in single crystals and observed conductivity in polycrystalline materials is the contribution of grain boundaries. Some solid electrolytes such as silver bromide exhibit enhanced conductivity from grain boundary conduction and a lower activation energy (19). However, Wynn Jones and Miles suggest a grain boundary contact resistance with a higher activation energy which may impede conductivity (9). We have observed various values of activation energy from conductivity measurements over the temperature range $-50°$ to $+70°$C of 3-5 kcal/mole compared to the single crystal value of 3.8 kcal/mole (5). This would seem to indicate that possibly some contact resistance was present in some of our sintered pellets, but its contribution was small. Therefore, it is reasonable to compare our conductivity measurements with those on single crystals keeping in mind these differences.

On the other hand, this calculated value of conductivity based on tracer diffusion coefficient (from which the mobility was calculated) must be increased by the correlation factor for the interstitialcy type mechanism accepted for beta-alumina (5). There is still some debate as to the correct correlation factor to use for the polycrystalline material, but recent evidence (20) suggests that 3 is an appropriate value at room temperature. In fact, with higher sodium contents found in β'', correlation factors as high as 7-8 have been observed at room temperature. Neglecting the unknown tortuosity factor and possible increased correlation factor above 3, we expect a contribution to conductivity from the interstitial sodium stabilized by the 2% MgO of 6.75×10^{-3} (ohm-cm)$^{-1}$. The total conductivity would then be

$$\sigma_{tot} = 6.6 \times 10^{-4} + 6.75 \times 10^{-3} = 7.41 \times 10^{-3} (\text{ohm-cm})^{-1}$$

which compares well with the observed value of 8.0 $\times 10^{-3}$ (ohm-cm)$^{-1}$ at 7.4 w/o Na_2O. This agreement may be somewhat fortuitous because of the uncertainties in tortuosity, correlation factor, and mobility of the additional sodium ions. The additional sodium ions in magnesium-containing β-Al_2O_3 may actually be more mobile by occupying alternate sites and/or exhibit higher correlation factors which would counteract the tortuosity effect expected for polycrystalline materials. Aside from these uncertainties, the measured values are consistent with the proposed model for magnesium doping of β-Al_2O_3.

The calculated value for 1% MgO is 4.1×10^{-3} (ohm-cm)$^{-1}$ compared to the observed value of 3.5 $\times 10^{-3}$ (ohm-cm)$^{-1}$. The observed conductivity of beta-alumina containing 4% MgO was considerably lower than the predicted value of 14.2×10^{-3} (ohm-cm)$^{-1}$ and is attributed to the low density of these pellets. There appears to be a limit to the amount of MgO that can be incorporated into the beta-alumina structure and lies between 2 and 4% MgO.

Pellets containing larger amounts of sodium than the optimum value showed a decreased conductivity. This, we believe, was caused by the excess sodium leading to increased amounts of sodium aluminate since the beta-alumina structure cannot accommodate the additional sodium ions. A quantitative correlation between sodium aluminate content and conductivity could not be made because the amount in all samples was extremely small, and x-ray analysis could not conveniently be performed on pellets used for conductivity studies.

In conclusion, it has been shown that magnesium oxide will stabilize additional sodium ions in beta-alumina leading to increased conductivity, and the increase in conductivity is proportional to MgO content up to at least 2 w/o.

ABSTRACT

High-resolution electron micrographs and diffraction patterns of thin discontinuous cobalt and nickel films deposited electrolessly under various conditions are presented. It is concluded that nickel, when deposited from strongly alkaline solutions assumes a fcc structure. Evidence is presented that the structure of cobalt deposits can be either fcc or hcp depending on the chemistry of the metalizing solution. Mixed cobalt-nickel films appear to form a fcc structure like nickel.

Chemically (electrolessly) deposited nickel films can be considered as a binary system of nickel and phosphorus. Some previous studies (1) have suggested that the initial structure of as-deposited Ni-P film is metastable. Heat-treatment, it was found, will transform it to a more stable state of a two-phase system consisting of fcc nickel and tetragonal Ni_3P. In the as-deposited state we are dealing with a "liquid like" material (2). By this one means a solid solution of phosphorus in a very fine polycrystalline nickel system. The average size of the crystallites was recently estimated (3) to be about 10-20Å. It should be remembered that the catalytic sites on which the film growth is initiated were stated (2) to be of about the same dimensions. This state of affairs is quite well established for nickel deposited from acidic metalizing solutions. Films deposited from alkaline solutions, in the as-deposited state, exhibit a degree of crystallinity depending on their phosphorus content. It is the aim of the present communication to study this crystallinity in some detail. It will become evident that a comparison between Ni-P, Ni-Co-P, and Co-P, all grown chemically, yields important information concerning this crystalline state.

Experimental

The films in this investigation were grown on microscope slide glasses coated with Formvar (4g polyvinylformal in one liter of ethylene dichloride). They were floated off the glass substrate in distilled water.

The detailed compositions of the sensitizing, activating, and acidic metalizing solutions for the deposition of nickel were given in Ref. (2).

The compositions of the alkaline metalizing solution for the deposition of electroless nickel is given in Table I, along with the compositions of the solutions used for mixed Co-Ni-P films (with a 65% nickel content) and for Co-P films. The technique of transmission electron microscopy was used throughout the present work. Our instrument is a Hitachi HU-12 electron microscope operated at 100 kV.

All chemicals used in the present work were supplied by Fisher or Canlab and were used without further purification.

Experimental Results

In Fig. 1 we present the electron micrographs of electrolessly deposited nickel from different alkaline solutions (see Table I). The *p*H values of the different solutions corresponding to the figure are (a) *p*H = 7, (b) *p*H = 8, (c) *p*H = 9, (d) *p*H = 10, and (e) *p*H = 11.

In Fig. 2 we present the corresponding electron diffraction patterns of these films. The deposition times had to be varied (see figure captions) as change of the *p*H does affect the deposition rate, and our aim here was to compare films of similar thicknesses. The effect of increased *p*H is best seen by comparing the corresponding diffraction patterns. In order to ensure that these effects were due to change in *p*H (and hence phosphorus content) and not merely an effect of the different deposition rates, the following was done. We prepared some films using a hot (85°C) metalizing bath. At an elevated temperature the deposition rate is markedly enhanced. We found that for a given *p*H, raising the temperature from 20° to 85°C had about the same effect on the rate as increasing the *p*H at room temperature by 1. The diffraction pattern, however, is not affected by temperature, and is thus determined by the *p*H (and phosphorus content).

Next we investigated the mixed Ni-Co-P films (see Table I). Here too, the *p*H of the metalizing solutions was varied. In Fig. 3 we present the micrographs for films grown from solutions with (a) *p*H = 7.5, (b) *p*H = 8.5, and (c) *p*H = 10.5. Figure 4 depicts the corresponding electron diffraction patterns. Here again

Table I. Composition of metalizing solution for deposition of electroless nickel and for mixed Co-Ni-P and Co-P films

	Ni-P,* g/l	Ni-Co-P* (65% Ni), g/l	Co-P,* g/l
Nickel sulfate, $NiSO_4 \cdot 6H_2O$	30	30	—

the pH affects the deposition rate, so different deposition times were employed as given in the figure captions.

Finally we took up the study of Co-P films. Here again, initially the effect of the pH of the metalizing solution was investigated. It must be noted, however, that in the case of Co-P one can, essentially, change the pH and the phosphorus content independently. The latter is done by simply varying the concentration of the sodium hypophosphite.

In Fig. 5 we present the effect of these variables on the nucleation and growth of thin electroless Co-P films. Specifically, Fig. 5(a)I is the electron micrograph of a Co-P film grown from a metalizing solution with pH = 7 and a hypophosphite concentration of 40 g/liter. Figure 5(b) is the same except with pH = 10 and Fig. 5(c) with pH = 12. In order to show the effects of hypophosphite concentration, Fig. 5(a)II corresponds to 5g of hypophosphite/liter, with pH = 7. The corresponding electron diffraction patterns are shown in Fig. 6(a)I to 6(c), and 6(a)II. It will be noted that essentially no changes can be observed in comparing the patterns in Fig. 6. The hexagonal shaped

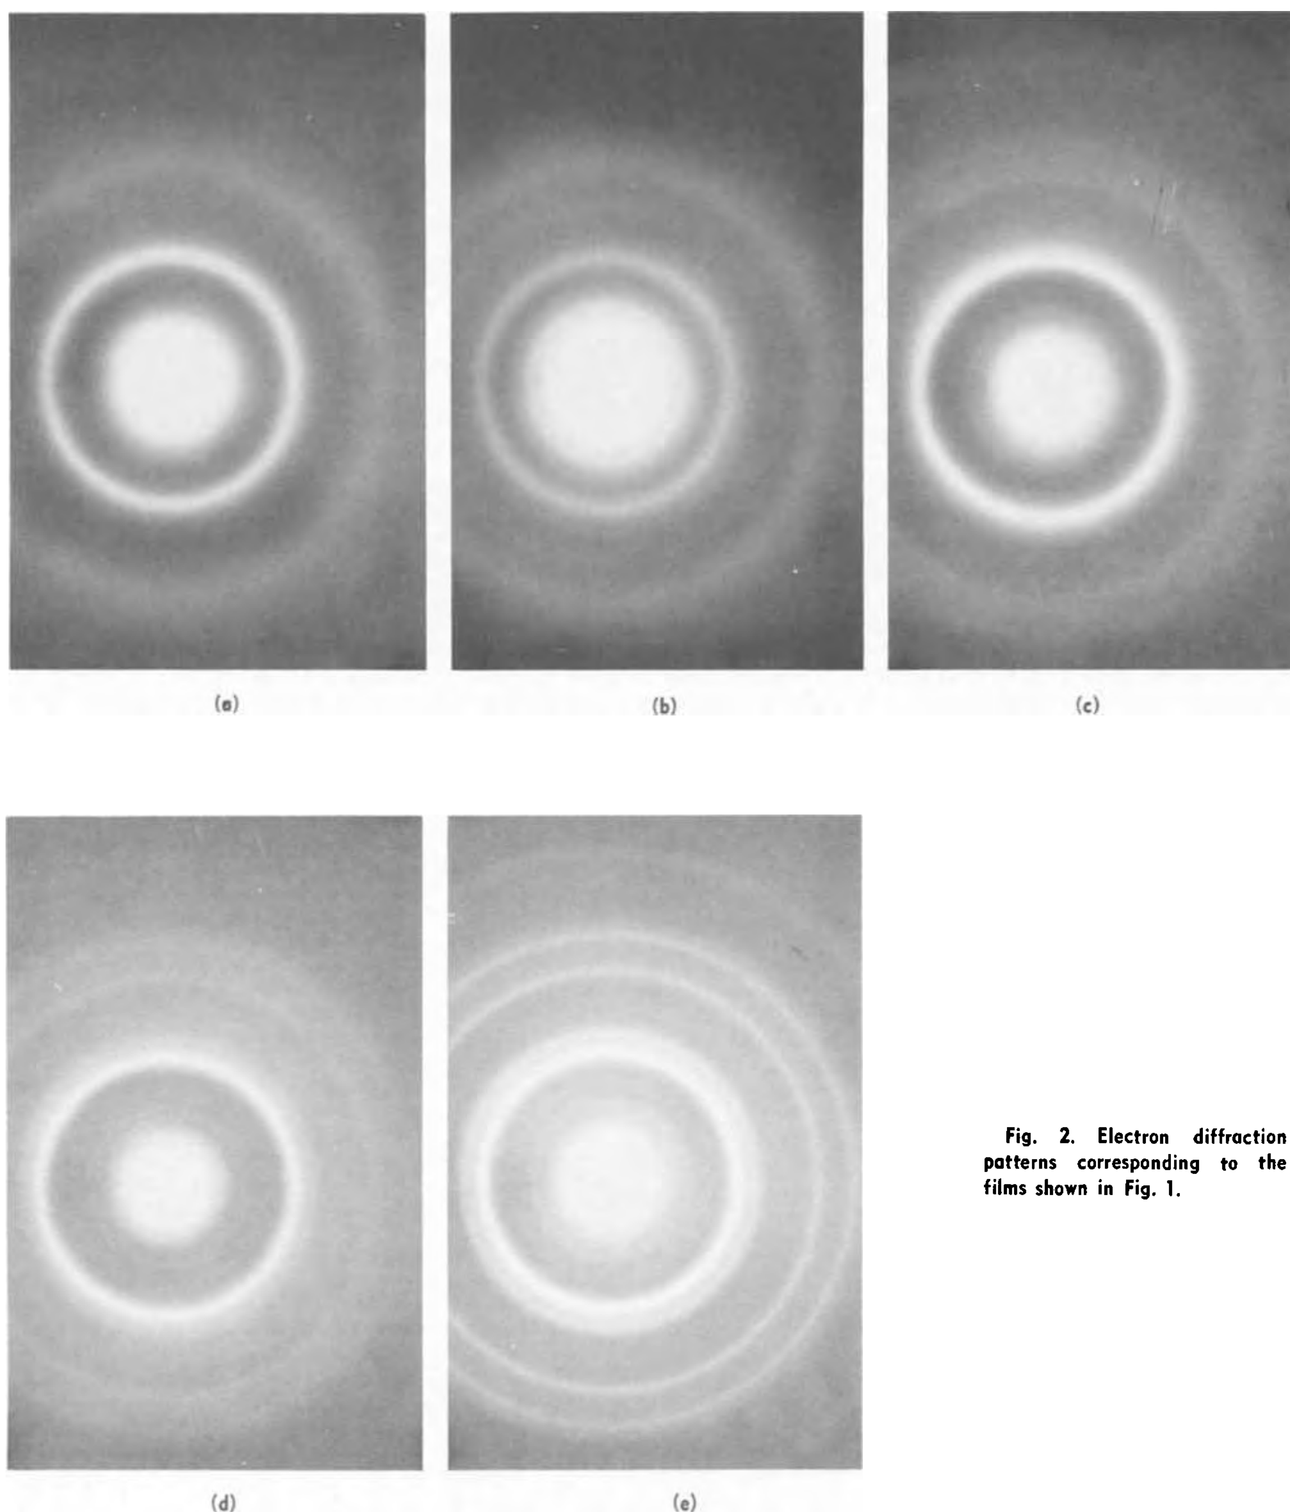

Fig. 2. Electron diffraction patterns corresponding to the films shown in Fig. 1.

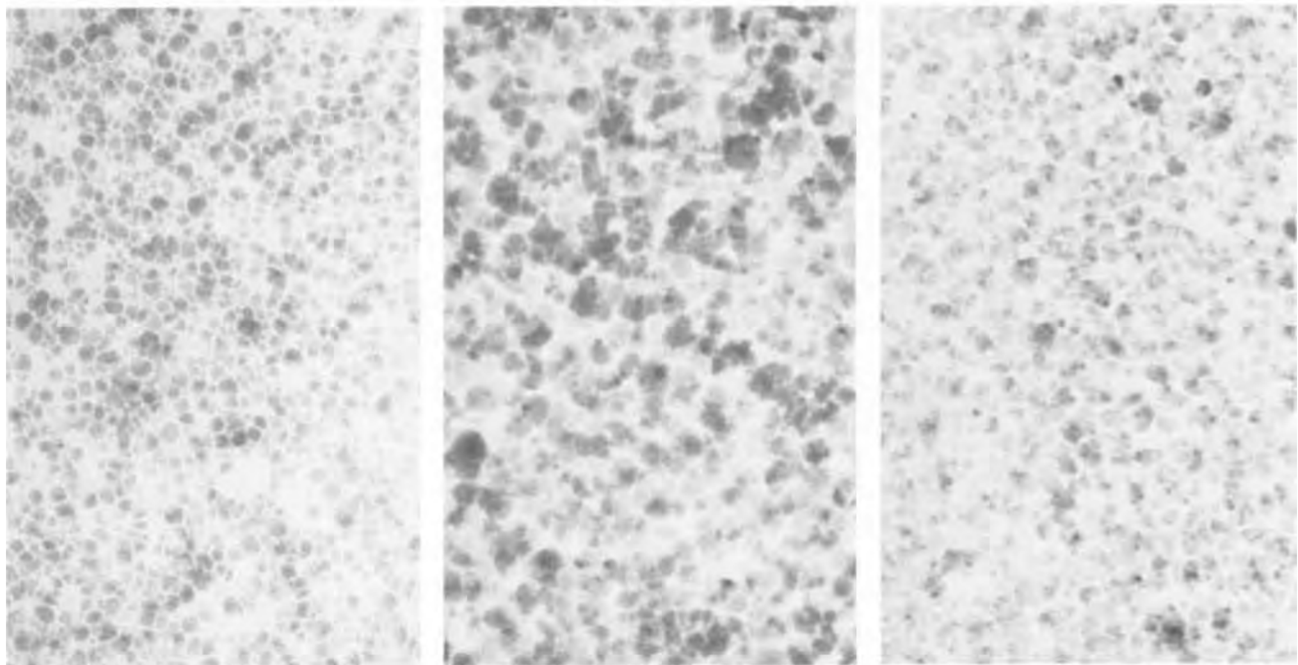
islands in Fig. 5(a)I are perhaps indicative of the hcp structure of as-deposited Co-P. The time of deposition varied and is given in the corresponding captions.

Discussion

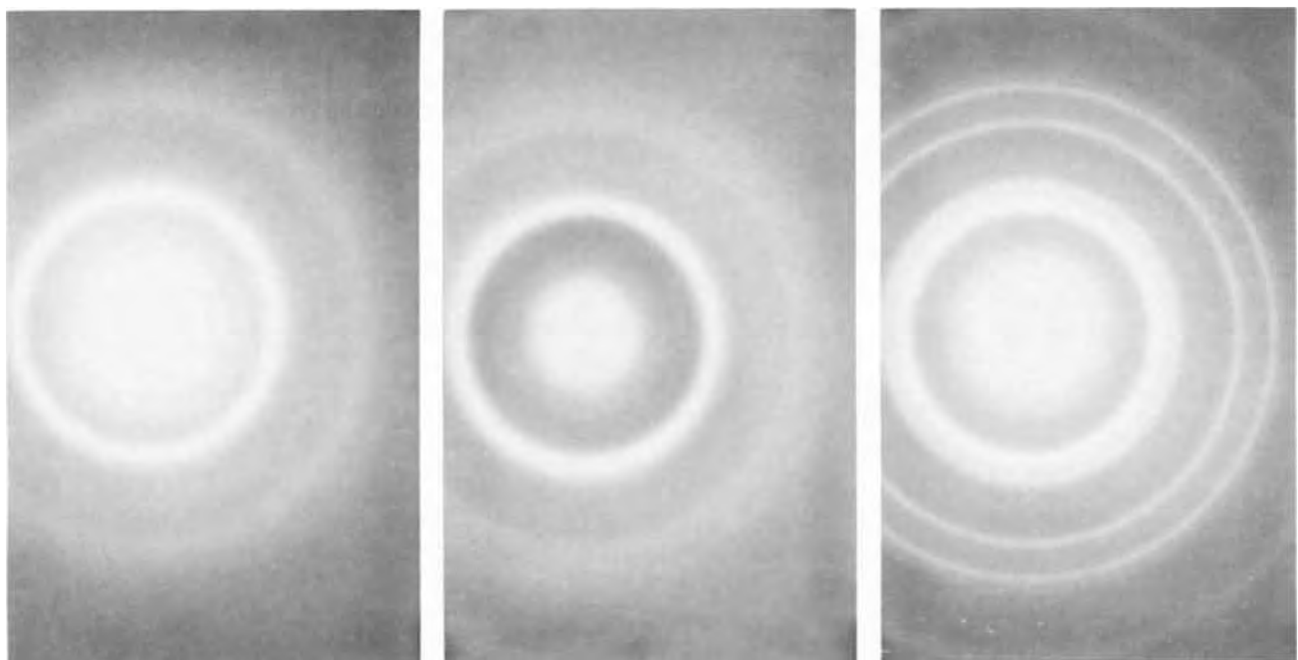
Effects of the amounts of phosphorus on the magnetization of nickel were studied by Albert *et al.* (4). They too controlled the level of phosphorus by changing the pH of the metalizing bath. This they did since the amount of phosphorus incorporated into the films increases as the pH of the bath decreases.

Consequently in our case on "passing" from Fig. 1(a) to 1(e) the amount of phosphorus in the films decreases. Assuming the as-deposited films to be (see above) a solid solution of phosphorus in a very fine polycrystalline system, it is not unreasonable to expect that decreasing the phosphorus content should result in an increase in the average size of crystallites. This is not immediately observable by comparing the micrographs in Fig. 1. The electron diffraction patterns shown in Fig. 2, however, demonstrate this point very clearly.



(a) $pH = 7.5$, deposition time 8 min (b) $pH = 8.5$, deposition time 4 min (c) $pH = 10.5$, deposition time 2½ min

Fig. 3. Transmission electron micrographs of electrolessly deposited mixed nickel-cobalt (65% nickel) films.



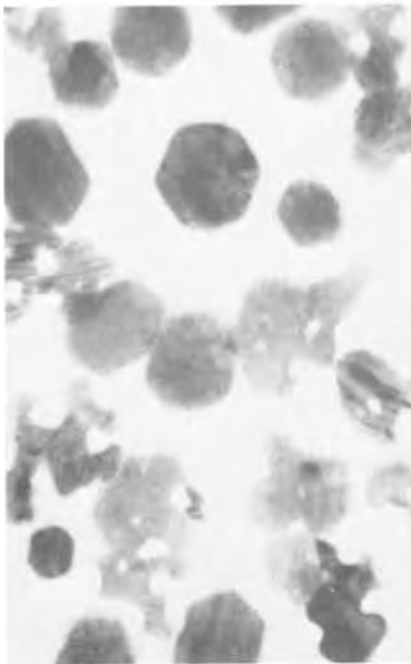
(a) (b) (c)

Fig. 4. Electron diffraction patterns corresponding to the films shown in Fig. 3

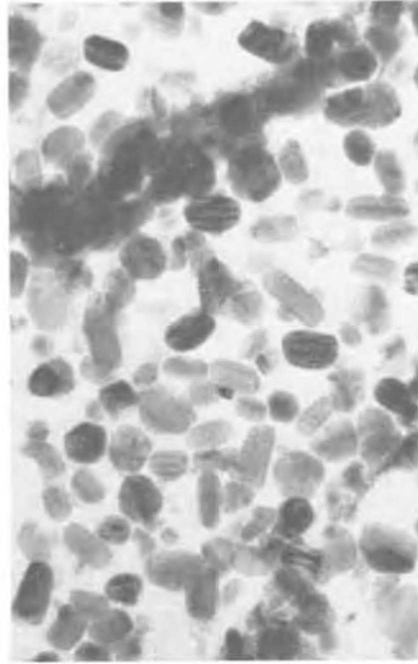
Further, assuming in Fig. 2 fcc symmetry, one can infer a lattice constant for the nickel of 3.554Å. While this number can be considered somewhat too large (ordinary nickel has a lattice constant of 3.517Å), it might be indicative of a "strained fcc lattice" (4).

The influence of the change of pH in the metalizing solution for mixed nickel and cobalt is shown in Fig. 3 and 4. Here too the decrease in P content seems to result in larger average sizes of the crystallites. The crystallographic symmetry of these can be attributed to a fcc structure. It must indeed be remembered that this is known to be one of the simplest systems formed by cobalt, and nickel can form a complete series of solid solutions with fcc cobalt.

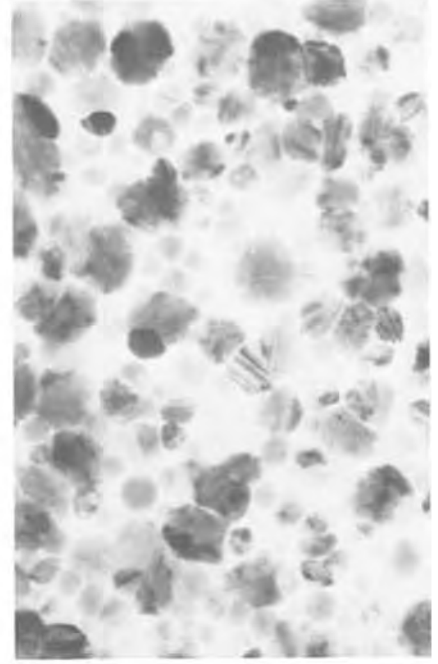
Of more complexity is the series of micrographs and patterns presented in Fig. 5 and 6. Here it is likely



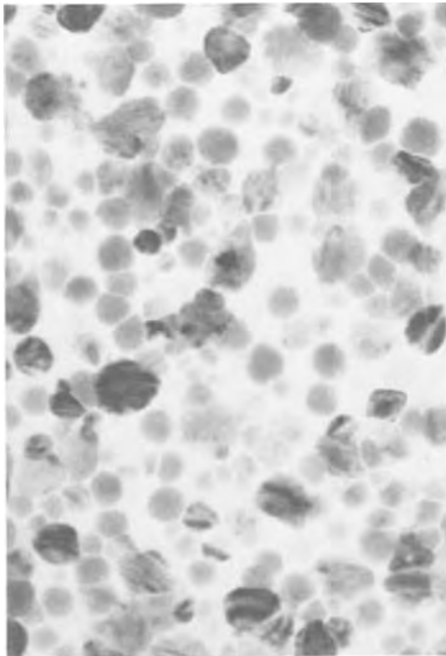
(a)I pH = 7, [hypophosphite] = 40 g/liter, deposition time 1 min



(a)II pH = 7, [hypophosphite] = 5 g/liter, deposition time 1 min



(b) pH = 10, [hypophosphite] = 40 g/liter, deposition time 5 min



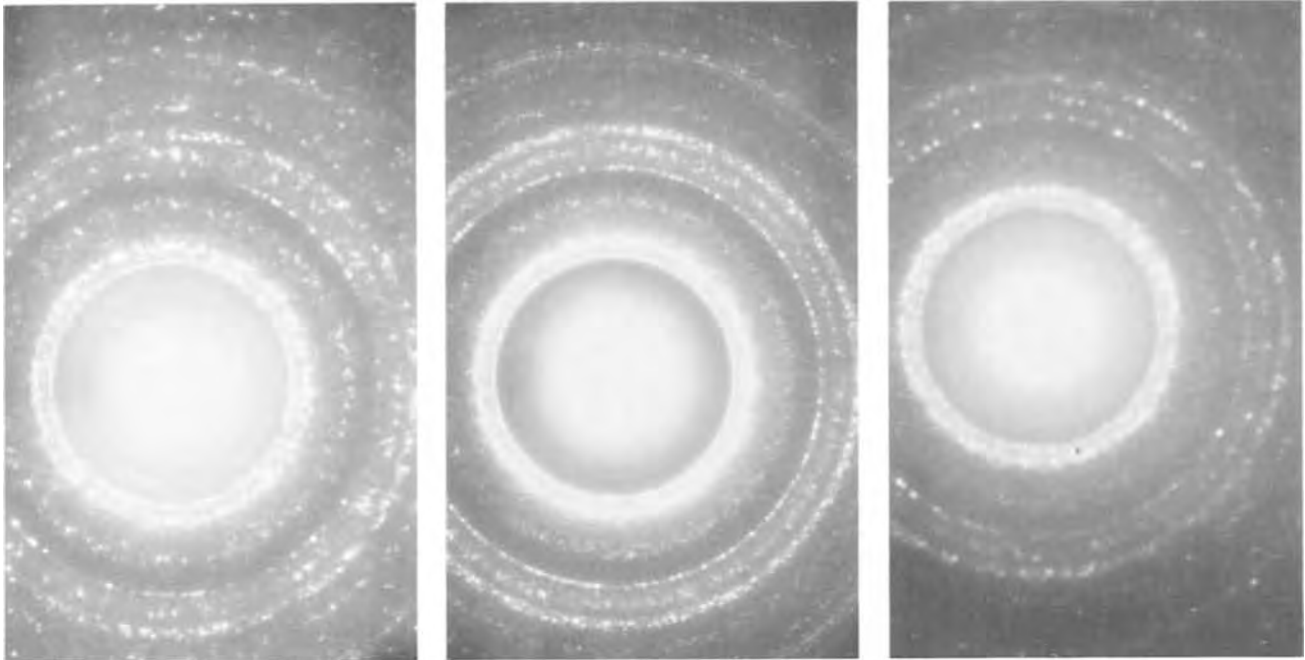
(c) pH = 12, [hypophosphite] = 40 g/liter, deposition time 5 min

Fig. 5. Transmission electron micrographs of electrolessly deposited cobalt from different metalizing solutions.

1000Å

that for low pH but high phosphorus content, the crystal symmetry of Co-P films is predominantly hexagonal [see shapes of "islands" in Fig. 5(a)I]. Decreasing the phosphorus content [see Fig. 5(a)II] or increasing the pH changes the general appearance of islands. Comparison of Fig. 2(e) with the patterns in Fig. 6 reveals a significant difference. In principle it should be possible to distinguish between fcc and hcp on the basis of the strength of the [200] ring, but it is difficult to give an unambiguous assignment to the rings in Fig. 6. Not much can be inferred quantitatively in this case (at least at present) from the diffraction patterns. Our assumption, however, is that to begin with the Co films constitute a mixture of fcc and hcp phases. Increasing the pH or decreasing phosphorus content tips the ratio more toward the fcc phase.

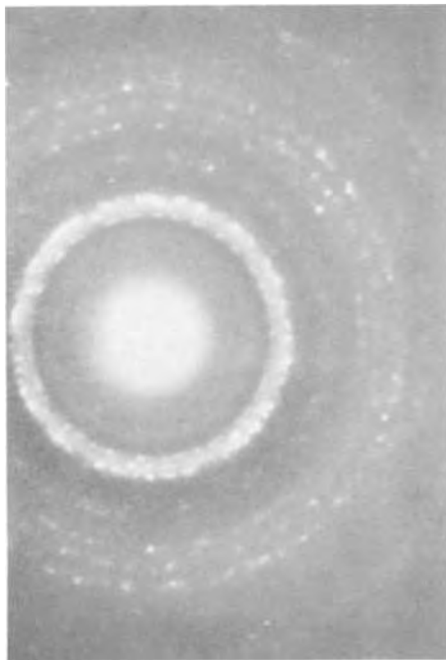
Frieze, Sard, and Weil (5) have studied the morphology of thin Co-P films in some detail. The film thickness range covered by their experiments is 500-20,000Å



(a)I pH = 7, [hypophosphite] = 40 g/liter, deposition time 1 min

(a)II pH = 7, [hypophosphite] = 5 g/liter, deposition time 1 min

(b) pH = 10, [hypophosphite] = 40 g/liter, deposition time 5 min



(c) pH = 12, [hypophosphite] = 40 g/liter, deposition time 5 min

Fig. 6. Electron diffraction patterns corresponding to the films shown in Fig. 5.

while we are interested here in much thinner samples. In addition, the resolution of our micrographs is at least ten times better than theirs. Nonetheless, we also agree about the role of the co-deposited P as a "growth inhibitor," both for cobalt and nickel. As we see from our work the influence of P content will show at much lower thickness than 1000Å, and an alternative explanation for the difference between Fig. 5(a) and 5(c), for instance, might be the change in fiber axis from $<0001>$ to $<10\bar{1}0>$. This will, of course, explain also the lack of change in passing from Fig. 6(a) to 6(c). The difficulty in accepting this approach lies in the fact that in very thin films like ours, one would expect the initial deposition on the palladium-activated surface to have its basal plane of the hexagonal lattice predominantly parallel to the substrate. Only thicker samples would be expected to have their fiber axis orientation dependent on the phosphorus content [see Ref. (5)]. This difficulty returns us to the first suggestion of a mixed hcp-fcc phase.

Zinc Electrode Shape Change in Secondary Cells

James McBreen*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Shape change, the reduction in zinc electrode area with cycling, is a limiting factor in the life of most secondary zinc batteries. This investigation was an attempt to elucidate the mechanism of shape change by monitoring the pattern of current and potential distribution over the surface of a zinc electrode during cycling. This was done while keeping all electrode and cell parameters similar to those found in conventional cells. Differences in the secondary current distribution during charge and discharge result in exhaustion of the reducible zinc species at the plate periphery in the early stages of cycling. This generates a concentration cell which corrodes zinc off the plate edge and deposits it in the plate center. Shape change is a result of these concentration cell effects and the transfer of zincate from the plate periphery to the plate center in the early stages of discharge. Many other hitherto unexplained phenomena related to shape change were rationalized on the basis of these findings and mechanism.

Shape change, the reduction of the zinc electrode geometric area with cycling, is the limiting factor in the life of most secondary zinc batteries (1). On cycling the zinc active material is removed from the plate edges and agglomerates toward the plate center. The movement of zinc continues as cycle life progresses and results in a reduction of the capacity and useful life of the cell (2).

In the past, numerous correlations have been made between the shape-change phenomena and the various operating and construction parameters of secondary zinc cells. Both electroosmotic effects, which cause fluctuations in the anolyte level with cycling, and gravitational effects have been ruled out as being major contributors to shape change in tightly packed cells (3, 4). Shape change occurs more slowly in a tightly packed cell than in a loosely fitting cell pack (5-7). The rate at which shape change occurs with cycling is reduced by decreasing the depth of discharge (2), lowering the KOH concentration in the electrolyte (8), and increasing the stoichiometric ratio of the negative to positive active material in a cell (4). The rate of shape change is increased by amalgamation of zinc plates and is directly proportional to the mercury content of the plate. Other factors which increase the rate of shape change are high resistivity membranes, bare spots or cracks in "green" negative plates (3, 4), and nonalignment of positive and negative plates in the cell pack (4).

Developments which mitigate shape change to some extent are the addition of binders such as Teflon (9, 10) or polyvinyl alcohol (4) to the zinc plate, the extension of the negative plate edges beyond the edges of the positive plate (1, 11), the use of contoured zinc negatives which have more zinc oxide at the plate periphery than the plate center (1, 10, 12), or zinc negatives which are thicker at the plate top than the plate bottom (13).

No proven mechanism of shape change has been reported. A mechanism based on gravitational effects has been proposed (14), but this mechanism is not consistent with the fact that sometimes zinc also moves away from the plate bottom (2). It has been suggested that shape change is due to concentration cell effects (3, 4). However, Lander (2) has pointed out that the remote causes of shape change are still uncertain.

This investigation was an attempt to elucidate the mechanism of shape change. The analytical approach in this investigation was to determine the patterns of potential and current distribution over the surface of a zinc electrode during cycling. All negative electrode and cell parameters corresponded as closely as possible to those found in an actual operating cell. The current distribution on the zinc electrode was determined by monitoring the current to a sectioned cadmium counterelectrode. The basic assumption underlying the experimental approach was that the current flow through a section of the cadmium counterelectrode was a good indication of the flow through the portion of the zinc electrode just opposite the section.

Experimental

Apparatus and method.—The test cell (Fig. 1) comprised a standard zinc electrode, a separator system, a sectioned cadmium counterelectrode, an array of Hg/HgO reference electrodes, and a third electrode for cycling the counterelectrode independently of the zinc electrode. Current distribution was determined by monitoring the current to the various sections of the cadmium electrode.

Zinc electrode.—The zinc electrode was made by evenly distributing and pressing 15g of electrode mix (94.5 w/o (weight per cent) ZnO + 0.5 w/o HgO + 5 w/o binder) onto an expanded silver screen. The final plate dimensions were 11.1 × 11.1 × 0.051 cm. In the assembled cell, the screen was on the side of the electrode remote from the counterelectrode.

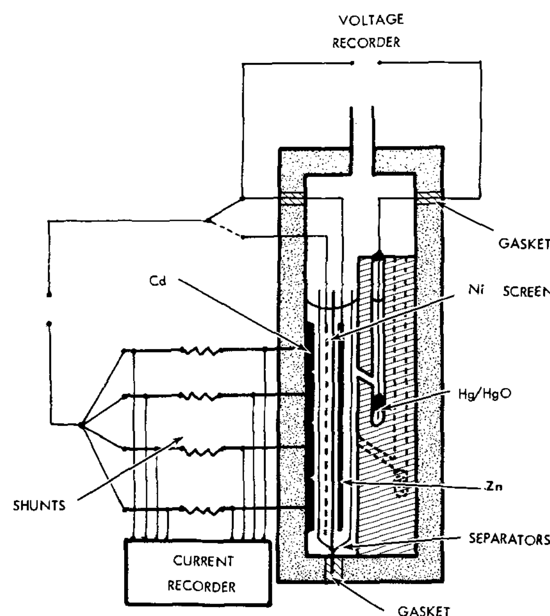

Fig. 1. Test cell and electric circuit

* Electrochemical Society Active Member.

Key words: battery, current distribution, potential distribution, concentration cell.

Counterelectrode.—The cadmium counterelectrode support structure comprised of 16 sections of nickel battery plaque (0.089 cm thick), with coined edges and spot-welded nickel tabs. These sections were arranged on an acrylic plastic sheet as shown in Fig. 2. The spaces between each section were filled with epoxy and the coined edges were masked with epoxy. The finished sectioned electrode was perfectly flat; the uncoined exposed area of each section was 2.54 × 2.54 cm and the space between each section was 0.12 cm. Cadmium was incorporated in the plaque sections by the standard impregnation method (15). Afterward, the electrode was lightly pressed while still wet and then given four formation cycles against a nickel sheet counterelectrode.

Reference electrodes.—The reference electrode compartments were 0.4 cm diam holes drilled vertically in an acrylic plastic block (11.4 × 14.0 × 1.6 cm) as shown in Fig. 3. The reference electrode capillaries were 0.1 cm diam holes from the reference compartments to one face of the plastic block. These holes were drilled at a 20° angle to the normal of the block face and were packed with cellophane to prevent dewetting. These compartments were used for the fabrication of the array of Hg/HgO electrodes. The relative position of these electrodes with respect to the cell pack is shown in Fig. 1, and the relative position of the capillary exits with respect to the sections of the counterelectrode is shown in Fig. 2.

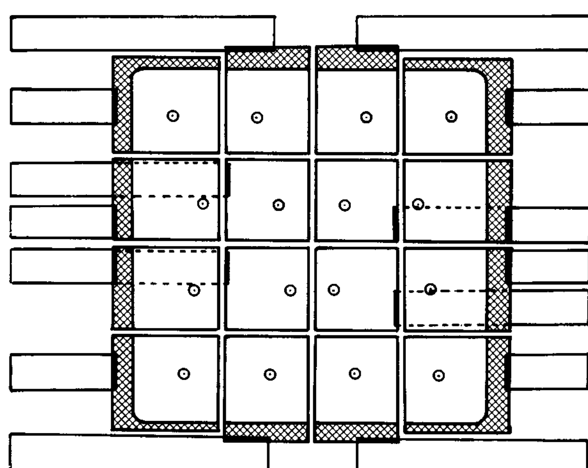

Fig. 2. Arrangement of counterelectrode sections. The relative position of the reference capillaries are also shown. These are on the side of the zinc electrode opposite to the cadmium electrode.

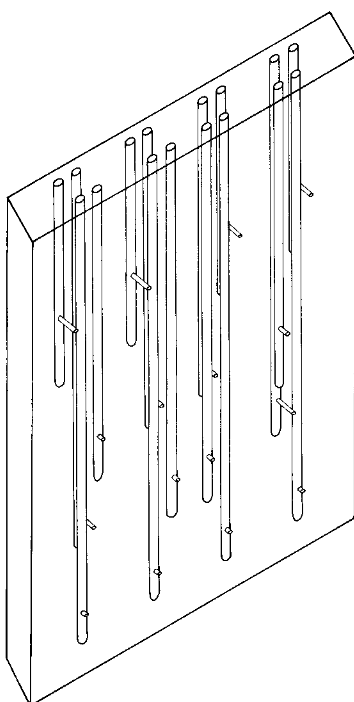

Fig. 3. Reference electrode compartments

Third electrode.—The third electrode was an electroformed nickel screen with a 0.25 cm reticulated pattern. The screen thickness was 0.01 cm and the spacing between openings was 0.05 cm. The screen area dimensions were the same as the sectioned cadmium electrode.

Apparatus assembly.—A schematic drawing of the complete cell assembly and circuitry is shown in Fig. 1. The cell separator system for the work reported in this paper was

Cd/1T,F-120/2T,C-25/1T,F-200/Ni screen/1T,F-120/2T,

FSC-76/1T,P-30/Zn/1T,P-30/KOH/HgO/Hg

where 1T = one layer of separator, 2T = two layers of separator, F-120 = 0.012 cm polyamide felt, C-25 = 0.0025 cm unplasticized cellophane, F-200 = 0.020 cm polyamide felt, FSC-76 = 0.0076 cm Fibrous Sausage casing, and P-30 = 0.003 cm acrylic acid grafted polyethylene (RAI, P-2291).

Provisions were made to have the zinc and cadmium electrodes parallel to one another with a spacing of 0.114 cm between the faces of the cadmium and zinc electrodes, thus ensuring a snug fitting cell pack when the cell was filled with electrolyte. The leads from the cadmium counterelectrodes were bolted to 0.050 ohm shunts.

Experimental procedure.—After the cell was wet down with 44 cc of electrolyte (37.5 w/o KOH + 70 mg ZnO/ml), soaked for 72 hr, vacuum treated to remove gas bubbles, the sectioned counterelectrode was deep cycled four times against the nickel screen at a current of 1.0A. The cadmium electrode was then charged to within 100 mV of the zinc deposition potential and the zinc electrode was immediately charged for 4 hr against the cadmium electrode. The counterelectrode was then back-charged at 1.0A against the nickel screen for 2.5 hr and cycling of the zinc electrode against the sectioned electrode was continued on an automatic cycler which had a filtered power supply. During cycling, the current to each section was monitored by measuring the voltage across the shunts on a multipoint recorder that had a zero center scale and a range of −12.5 to +12.5 mV full scale. The potential was recorded on a multipoint recorder with a range of 0-2V full scale. Occasionally the potential relaxation at the end of charge and discharge was monitored by a scanning switch in conjunction with a high impedance amplifier and a digital voltmeter.

If the cycling regime consisted of a zinc overcharge, the cadmium electrode was occasionally back-charged against the nickel screen before the cadmium capacity became exhausted. Whenever the nickel screen was used to charge the counterelectrode, the cell was vacuum-treated afterward to remove gas bubbles from the vicinity of the nickel screen. The cadmium electrode sections were monitored from time to time to ensure that they were still charged.

The cycling regime for the run reported in this paper was a 1.0A charge for 105 min followed by a 102-min discharge at the same current. Provisions were made also to terminate the charge if the zinc polarization exceeded 200 mV; thus, the cycling regime of the zinc electrode was similar to that encountered in a cell with an efficient positive electrode such as silver oxide. Other runs were made with as much as 15% overcharge each cycle to simulate the conditions encountered in a nickel-zinc cell (16).

Requirements and choice of the experimental method.—The cell components and configuration were chosen to facilitate application of the findings of this investigation to a practical battery. Cadmium was chosen as the counterelectrode since (*a*) fabrication of a flat sectioned electrode was easy; (*b*) gas bubble formation or (*c*) bridging between sections was unlikely; and (*d*) complications due to separator oxidation were avoided. The cadmium electrode has the additional advantage of having low polarizability on charge and discharge, and thus does not have an overriding effect on the current distribution in the cell.

The cellulose separators expand on wetting, thus facilitating construction of a snug-fitting cell pack. The layer of grafted polyethylene separator prevented the growth of zinc dendrites to the cadmium electrode. Shorting to the sectioned cadmium electrode would vitiate any current or potential distribution measurement. The other layer of grafted polyethylene between the zinc anode and the reference electrode capillaries prevented the growth of zinc into the capillaries during overcharge. This was a problem in some preliminary cell tests where there was no membrane between the zinc electrode and the reference capillaries.

The positioning of the reference electrodes on the back of the zinc electrode was possible since the electrodes were thin and porous. This juxtaposition of the reference electrodes and the zinc plate did not interfere with the cell current distribution, ensured that all capillary exits were equidistant from the zinc electrode, and facilitated prevention of dendritic growth into the capillaries.

The counterelectrode capacity was not allowed to become discharged for the simple reason that limiting factors at the cadmium electrode would complicate interpretation of the current distribution results. This consideration outweighed any effects the charging screen might have on the current distribution.

The sectioned counterelectrode technique was used since this method gives the most direct measurement and has minimum effect on the current distribution cell. Further sectioning at the electrode edges would be desirable, but it was felt that the effects generated by such sectioning would nullify any increase in resolution that might accrue from this method.

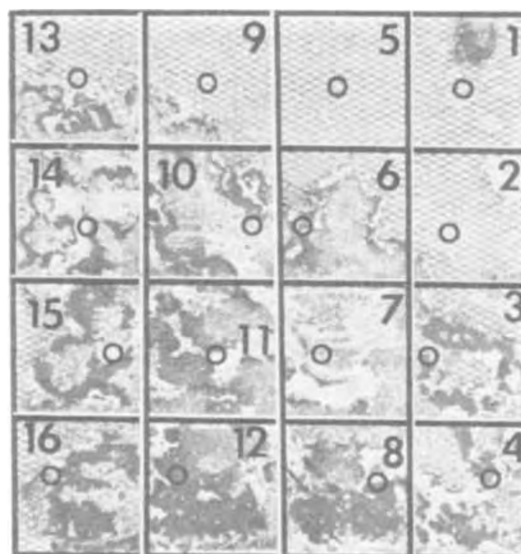

Fig. 4. Photograph of the zinc electrode after 120 cycles; relative positions of the counterelectrode sections and the reference capillaries are also shown. The numbers refer to the portions of the cadmium electrode and the reference capillaries. Sections 1, 5, 9, 13 are along the top of the cell.

Results

Post-test analysis of cell.—After 120 cycles the cell was taken apart in the charged condition and examined. No visible deterioration of the separators, the cadmium electrode, the charging screen, or the reference electrodes had occurred during cycling. Zinc did not penetrate any of the separator layers. A photograph of the zinc electrode is shown in Fig. 4. The zinc electrode underwent a loss of 45% in geometric area with the zinc agglomerating toward the lower part of the plate. No zinc grew beyond the edges of the current collector screen. In the areas where the zinc agglomerated, the plate thickness increased by as much as a factor of two in some places. The front face (*i.e.*, the face nearest the counterelectrode) of the zinc deposit consisted compacted gray sponge zinc. Underneath this deposit was a cake of uncharged zinc oxide, embedded in the electrode grid. At the edge of the thick zinc deposit, additional zinc was deposited directly on the grid forming a border about 3 mm wide around the zinc oxide cake. Between this border and the zinc oxide cake, small traces of blue zinc material were observed on the back side of the electrode. In the electrode regions beyond the continuous zinc deposit, small scattered deposits of crystalline zinc dendrites were found.

Figure 4 also shows the relative positions of the sixteen counterelectrode sections and the reference electrode capillaries. All of sections No. 1 and 5 were denuded of zinc. Little zinc remained in sections No. 9, 13, and 2. Considerable zinc loss occurred in sections No. 3, 14, 15, and 16. The greatest gain in zinc deposit thickness occurred in sections No. 7, 8, 10, 11, and 12.

Current distribution on the cadmium electrode.—In the formation process, the current to each cadmium electrode section stabilized to a value of 62 $\pm$4 mA after two formation cycles. The current distribution was equally even on charge and discharge. The over-all electrode capacity was 4.5 A-hr on the fourth formation cycle.

During the preliminary cycling of the cadmium electrode in the cell against the nickel screen, the electrode capacity stabilized at 4.25 A-hr. The section current on charge was 62 $\pm$5 mA. The heterogeneous deposition of zinc on the nickel screen in the initial stages of discharge caused wide variations in the section current during discharge. This zinc was stripped from the screen in the first few minutes of charge. The cadmium electrode capacity was checked at the end of each run and no significant deterioration of the capacity was found.

Reference electrodes.—After the cell was wet down and vacuum-treated a few times, the reference electrode potentials stabilized at values that varied by no more than 1 mV of one another.

Current and potential distribution on the zinc electrode.—The current and potential distribution for cycles No. 3, 19, 31, 60, 75, 100, and 120 are shown in Fig. 5-11, respectively. Initially, the current distribution between sections was relatively even. However, the current distribution between sections on discharge bore no apparent relationship to the current distribution between the sections when the cadmium electrode was charged with the nickel screen. In the early stages of cycling, there was a greater variation in the current distribution during charge than during discharge. Also, in the early stages of cycling, the current distribution on charge tended to diverge with time whereas the current distribution on discharge tended to converge with time. These trends may be seen in Fig. 12 for sections No. 5, 7, 9, and 10 in cycle No. 2. In the initial stages of cycling, the potential distribution was even on both charge and discharge. However, after about 15 cycles, sections No. 1, 5, 9, and 13 polarized more at the end of charge than any of the

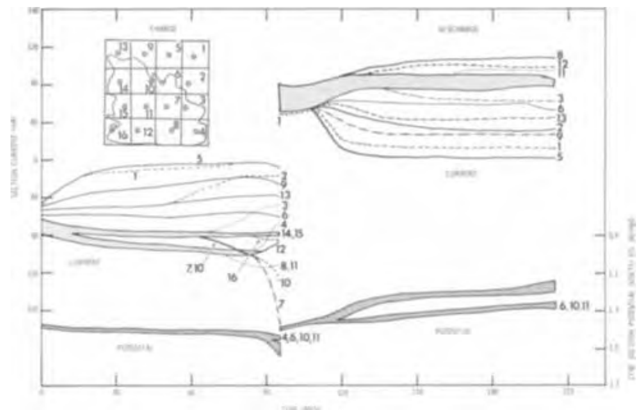

Fig. 10. Current and potential distribution on the zinc electrode, cycle No. 100. Explanation of inset is given in Fig. 5 caption.

other sections. With this polarization, there was a concomitant drop in current to these sections. After about 25 cycles, these same sections also had lower currents in the latter stages of discharge (Fig. 7). This type of trend continued throughout cycling until eventually most of the current was being carried by sections No. 7, 8, 10, 11, and 12 (Fig. 8-11). Toward the end of cycling, the low current areas of the zinc electrode tended to polarize on discharge (Fig. 11). The external *IR* correction, as determined by a 60-cycle Kordesch-Marko interrupter, was negligible (about 2 mV).

In some runs, the cell was cycled in the horizontal position periodically. The various cell orientations produced no changes in current or potential distribution that could be distinguished from the normal slight variations in these parameters that occurred from cycle to cycle. This was true even when these experiments were repeated with different open-circuit stand times of up to 24 hr in each position before cycling.

Similar potential distribution patterns were observed in two electrode nickel-zinc cells, thus indicating that the results obtained in these experiments were not an artifact of the sectioned electrode. Furthermore, the shape-change patterns in these experiments were similar to those found in nickel-zinc cells with similar separator systems and electrode geometries.

Current interruption.—One salient feature of the current distribution in the latter stages of cycling was

that the current distribution was relatively uniform for about the first 7 min of discharge (Fig. 9-11), whereas on charge the current distribution immediately diverged after switching to charge. However, if the current was interrupted after one or two minutes of discharge, and the cell allowed to stand overnight on open circuit, the current distribution on resumption of discharge had a spread similar to that found after half an hour of steady discharge. On the other hand if the current was similarly interrupted after an hour of charge, the current distribution on resumption of charge showed a spread similar to that found at the beginning of charge. Thus, interruption of the current in the initial stages of discharge leads to a divergence in current distribution on switch *on*, whereas the interruption of the current in the latter stages of charge leads to a convergence of current distribution on switch *on*.

Potential relaxation.—Figure 13 shows the potential relaxation on the electrode when the current was shut off at the end of charge and discharge during cycle No. 75. Figure 14 shows similar data in another run where the cell was overcharged each cycle. At the end of charge, the potentials initially have a wide spread and eventually, with time, the potentials converge to a common value. At the end of discharge, however, there are little differences in the potential across the surface of the electrode.

Overvoltage on the zinc anode.—Figure 15 shows zinc polarization measurements in a two-electrode nickel-zinc cell with similar anode construction parameters to the zinc electrode used in the current distribution measurements. These data were obtained at the same stage of electrode charge. Polarization measurements on charge were reproducible; and at each current density, the polarization reached a plateau value. At the higher current densities, on charge, the polarization went through a maximum before reaching a plateau. This type of behavior is not unknown (17, 18). The plateau values are shown in Fig. 15. On

discharge, the polarization continually increased with time at the higher current densities. The variation of the polarization with current density was greater on discharge than on charge.

Discussion

Significance of potential distribution.—Secondary zinc electrodes usually have a silver grid and are cycled in such a way so as to maintain an excess of metallic zinc in the electrode at all times. Hence, the potential in the metal will be constant throughout the whole area of the electrode, even when current is passed through the cell. If the zincate concentration does not vary over the surface of the electrode, the open-circuit potential, as measured by a reference electrode capillary, will be constant irrespective of where the measurement is made on the surface of the electrode. However, if the concentration of zincate varies from one position to another, a potential difference will exist between these points on the electrode surface. This potential difference will not be the usual Nernstian potential difference. Local differences in zincate activity will result in concentration cells across the surfaces of the electrode. In these concentration cells, the areas with high concentrations of zincate are the cathodes; and the areas with low concentrations of zincate are the anodes. The situation here is a complex example of the thin-film corrosion problem that has been discussed by Waber and his co-workers (19, 21). Accordingly, the measured differences in interfacial potential depend on the relative magnitude of a number of parameters that have the dimensions of length, viz., the separator thickness (t), the radial parameter for the anode area (R_a), the radial parameter for the cathode area (R_c), together with the lengths of the Wagner parameters (22) for the anode and the cathode. The Wagner parameters for the anode and cathode are, respectively, $k_a = \sigma(\partial\eta_a/\partial i)$ and $k_c = \sigma(\partial\eta_c/\partial i)$ where η is the overvoltage and i the current density; σ, in this case, is a complex function of the conductivity of the electrolyte and the separator. The radial parameters R_a and R_c will be the radii of anodic or cathodic areas if they are circular, or the half widths of such areas if they are strips along the edge or middle of the electrode. If R_a and R_c are large in comparison to t, k_a, and k_c, then differences in potential can be measured over the surfaces of the electrode. If one assumes $\sigma = 0.1$ mho cm^{-1}, then both k_a and k_c at low current densities will be 0.6 cm, and at higher current densities, $k_c \simeq 0.02$ cm and $k_a \simeq 0.06$ cm. Consequently, the only requirement then for locating anodic and cathodic sites on a zinc electrode, by means of a closely placed reference probe, is to have anodic and cathodic sites a few millimeters in diameter and a reference probe that has a capillary diameter of a millimeter or less. The measured interfacial potentials will include anodic and cathodic polarizations together with the ohmic drops in the electrolyte (23). So, even though the electrolyte has a high conductivity, interfacial potential measurements can locate concentration cell anodes and cathodes if they are large enough in area.

When current is passed through the cell, differences in overvoltage can exist over the surface of the electrode either because of differences in the local current density or variations in the zincate concentration at various points on the electrode. Ideally, for these measurements, the reference capillary exits should be at the face of the zinc electrode, that is toward the counterelectrode (24). Since such an arrangement is virtually impossible here, the measured polarization values in these experiments will differ from those found at the plate face. The external IR correction to the measured potential can be isolated by standard interrupter techniques. On interruption of current, however, concentration cell effects can occur, thus rendering absolute measurements impossible.

It is, therefore, evident that potential distribution measurements yield only qualitative data. Such measurements can locate anodic and cathodic sites on an electrode on open circuit (23), detect the position of concentration polarization on charge, and identify local passive areas on discharge.

Significance of the current distribution.—In the later stages of cycling, the current to the areas without zinc (section No. 1 and 5) was essentially zero throughout most of the charge and discharge cycles (Fig. 10 and 11). This strongly indicates that any particular section current was a good quantitative measurement of the current to the zinc electrode area that was in exact register to that counterelectrode section. Since the electrode was amalgamated and no excessive hydrogen evolution was observed, the current distribution on charge is a very direct measurement of the metal deposition distribution.

The predicted current distribution, with no polarization at the electrodes, is the primary current distribution (25); and this is determined by the geometry of the electrodes, the electrolyte, and any other conductive or nonconductive objects in the electrolyte. However, high current density points polarize and some of the current is rerouted to other positions of the electrode, thus yielding the secondary or actual current distribution (25-28). The magnitude of the corrective effect of electrode kinetics on the current distribution is described by the Wagner parameter, $k = \sigma(\partial\eta/\partial i)$. Increasing the value of k results in a more uniform current distribution (22). So, for a given KOH concentration and separator system, the current distribution depends on $\partial\eta/\partial i$, the electrode polarizability (29).

Since the polarizability of the cadmium electrode is low (30), the measured current distribution in the cell was a good indication of the current distribution that is inherent to a zinc electrode operating in a secondary cell with a prismatic construction.

Mechanism for shape change.—In a thin plate prismatic secondary zinc cell, the primary current distribution should be the same for both charge and discharge. However, because the polarization behavior of zinc electrodes is different on charge and discharge (Fig. 15), the secondary current distribution will be different during the anodic and cathodic process. The closest approach to the primary current distribution will be expected the instant the cell is switched to discharge after charging in the early stages of cycling. At the beginning of discharge, in a fresh cell, there will be plenty of active sponge zinc throughout the plate, and the electrode at this stage will have a low polarizability. The increase of this initial low polarizability with time would explain the convergence of the current distribution to more uniform values (Fig. 5, 6, and 12) as the discharge progresses. This increase in polarizability may be due to the formation of the prepassive films that have been described by Powers and Breiter (31, 32) and by Hull *et al.* (33). At the beginning of charge, however, the current distribution will not be as close to the primary current distribution as at the beginning discharge because high current density points are temporarily highly polarized in the initial stages of charge (17, 18). Further on in the charge, in the initial stages of cycling, the zinc electrode operates under conditions where the substrate area increases continuously and metal deposition occurs in a milieu with an excess of reducible material. Hence, the electrode polarizability is low (Fig. 15); and, thus, the nonuniformity and divergence of the current distribution on charge (Fig. 5 and 12) may be explained.

In a cell with plane parallel electrodes, the primary current distribution will be high at the plate edges since the current lines can pass outside the space between the electrodes (22). In a secondary zinc cell, the edge effect will be greatest at the top and sides of the electrode. Here, the corrective effects of the electrode polarizability on charge and discharge will be greatest. The net effect is that at the beginning of cycling more

zinc is deposited at the edges than is deplated in the subsequent discharge. Because of this, the zinc oxide and zincate supply at the plate edges becomes rapidly depleted in the early stages of cycling; so, after a short period of cycling, some of these positions polarize at the end of charge. This concentration polarization results in a concomitant drop in the current (Fig. 6 and 7) to these positions.

The question arises as to how the depletion of zinc oxide and zincate at the plate edges results eventually in the removal of zinc from these positions (Fig. 4). A plausible explanation is that zinc is removed by a concentration cell which dissolves zinc off the plate edges and deposits it at the center of the plate. The results in Fig. 13 and 14 indicate that, after charging, the edge positions are negative to the center positions of the electrode. The relaxation of these potentials to a common value must occur via a concentration cell rather than by the much slower diffusion process. It is easy to demonstrate that zinc can be plated and deplated by such a process at a reasonable rate by simply shorting one zinc electrode in KOH electrolyte and another electrode in a zincate electrolyte while having both electrolytes in contact with one another. The results of such a test are shown in Fig. 16. Concentration cell effects also explain the divergence in the current distribution after interruption of current at the beginning of discharge and the convergence of the current distribution after current interruption toward the end of charge. In the former case, the concentration cell exhausts the zinc supply at the plate top edges whereas in the latter case, the concentration cell generates a fresh supply of reducible material at these same positions. These concentration cells can occur on termination of charge or may even possibly occur on charge if there is a drop in the over-all electrode polarization during charge.

Very direct evidence of such concentration cell effects was found in one of the early runs in this investigation. The sectioned cadmium electrode was accidently overcharged, against the nickel screen, to potentials negative to the zinc deposition potential. When the current was interrupted, anodic and cathodic current transients were observed in different sections. Initially, these currents were 30-60 mA, and the currents decayed to zero in about 5 min after opening the cell circuit. Undoubtedly, these currents were due to zinc concentration cell effects since the sectioned electrode remained at the zinc potential after termination of charge. The currents were much larger than those that could be attributed to pH gradients (34), and the relative positions of the screen and sectioned electrode does not facilitate the formation of pH gradients.

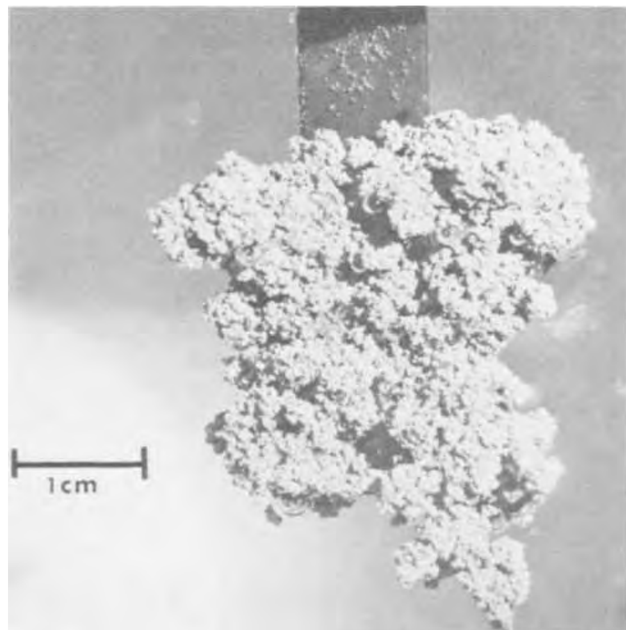

Fig. 16. Zinc concentration cell, 100 hr after shorting. Cell case (12 x 13 x 2.5 cm) was half filled with 37.5 w/o KOH + 70g ZnO/liter, and then filled to the top with 37.5 w/o KOH without mixing. The anode (10 x 5 x 0.050 cm) was electroplated dendritic zinc and the cathode was sheet zinc (2 x 1 cm).

After discharging the electrode, the electrolyte will be supersaturated with zincate (35-38); hence, the small differences in the potentials across the surface of the electrode (Fig. 13 and 14).

With the onset of shape change, the edge positions will start to passivate toward the end of discharge. This passivation will result in a divergence in the current distribution in the latter part of the discharge cycle (Fig. 7-11).

Because the current distribution at the beginning of discharge, in a fresh cell, closely approaches the primary current distribution, the anolyte at the plate periphery will become supersaturated with zincate before the center positions. This will generate a concentration gradient between the edge and center of the electrode and transfer zincate toward the center of the plate. This transfer of zincate toward the plate center together with the erosion of the plate periphery by concentration cells results in shape change.

The sequence of events that has been postulated above to explain the current and potential distribution patterns, as well as the remote and immediate causes of shape change, is consistent with prior visual observations of the onset and progress of shape change. When a secondary zinc cell is cycled, it is observed that after some cycles, some edge position will charge up completely. At the end of charge, this position will consist entirely of zinc whereas other positions will have both gray zinc metal and white zinc oxide. After some more cycling (say, 10 cycles), this area will become bare of zinc; and at the end of charge only a few scattered dendrites will be found here on the grid, thus indicating a position of high polarization on charge (37). Other positions like this will develop, and the electrode will start to lose geometric area rapidly. Then, at the end of a deep discharge, the edges of active material will have a blue tinge. This blue color is due to the passive zinc films that have been described by numerous authors (31-33).

The fact that shape change occurs in cells that are cycled horizontally, and since cell orientation does not affect the current distribution, it is doubtful if gravity has any major effect on shape change. The frequent occurrence of shape change at the plate top is more likely due to the extended current paths that are available in the separator folds and to the fact that conventional cell construction techniques, where cathodes are wrapped in separator "U" folds, tend to raise the top edge of the positive plate above the edge of the zinc electrode. Convection effects can carry zincate to the bottom of a cell with widely spaced electrodes (14), but the possibility of convection in a tightly fitting cell pack is limited.

Consistent interpretation of factors that affect shape change.—Any factor that causes nonuniform current distribution will result in an increase in the rate of shape change. Thus, the bad effects of (*a*) high resistivity membranes, (*b*) wrinkling separators, (*c*) nonalignment of positive and negative plates, and (*d*) plate defects and bare spots can be readily explained. The decrease in the rate of shape change by the reduction of the KOH concentration from 45 to 30 w/o (8) can be explained on the basis of the improvement in current distribution by the higher conductivity of the electrolyte at lower KOH concentrations. In a secondary zinc-air cell with a third electrode (40), the current distribution will be very poor once shape change starts, since, here, one has a relatively reversible zinc electrode out of alignment with a highly polarizable counterelectrode. Thus, the current distribution will

be quite uniform over the third electrode whereas the edge of the zinc active material, beyond which the third electrode extends, will be a high current density point (41). Hence, shape change should proceed rapidly once it starts.

If the supply of zinc oxide at the plate edges is increased, the number of cycles required to exhaust the zincate supply and thus set up a concentration cell, will be increased. Hence, the onset of shape change will be delayed. Thus, the beneficial effects of increasing the stoichiometric ratio of negative to positive active material, extending the plate edges, and the use of dish-shaped negatives can be readily explained.

Reduction of the zinc plating efficiency will improve the metal distribution on the plate and will mitigate shape change. The beneficial effect of removing mercury from the zinc can thus be rationalized.

The mechanism for shape change also explains why shape change is independent of the grid structure, and why the addition of mechanical barriers, such as fibers, does not mitigate shape change. A possible explanation for the beneficial effect of binders is that they maintain the integrity of the plate during cell construction and prevent the shedding of zinc oxide. The loss of zinc oxide from the grid would generate a site from where shape change could start and proceed by the above mechanism. In electrodes without binders, no shape change occurs at the plate bottom or at the lower part of the plate sides. The shed zinc oxide in the lower part of the cell is a reservoir of zincate that prevents shape change at these positions. Binders reduce the degree of shed and in such electrodes shape change can occur at the plate bottom.

In cells with large electrodes and wrinkling separators, bare spots can occur at random throughout the zinc plate. The mechanism for the occurrence of these spots must be the same as that described above for shape change.

The electrochemical nature of the shape-change phenomena explains why zinc can build up with such enormous pressures at the plate center. In some instances, both the centers of the zinc electrode and the positive electrode become densified and mechanical stresses sufficient to rupture cell cases are generated.

According to this mechanism, cycling is a necessary condition for the occurrence of shape change. This is in agreement with the fact that shape change does not occur on wet stand or when the cell is kept on float.

The current distribution effects which eventually result in concentration cells do not occur until later on in the discharge cycle (Fig. 12). This is in concordance with the fact that shape change occurs more slowly when a cell is cycled at shallow depths of discharge.

Summary

The patterns of current and potential distribution on a cycling zinc electrode have been monitored while keeping the electrode and cell parameters as similar as possible to those found in a conventional secondary zinc cell.

Differences in current distribution throughout cycling have been explained in terms of changes in the secondary current distribution resulting from variations in electrode polarizability. Differences in the secondary current distribution during charge and discharge result in the exhaustion of the reducible zinc species at the plate periphery in the early stages of cycling. The initiation and progress of shape change have been explained on the basis of concentration cells that corrode zinc off the plate edges and deposit metal at the plate center, and current distribution effects at the beginning of discharge. Further variations in the current distribution throughout cycling have been interpreted in terms of local concentration polarization on charge and local areas of passivity on discharge.

Although the electrolyte conductivity was high, the concentration cells could be detected by potential measurements because the anodic and cathodic polarizabilities were low and the electrolyte path in the separator was thin in comparison to the radial dimensions of the anodic and cathodic sites.

The data from this investigation together with the postulated mechanism for shape change were used to rationalize most of the reported phenomena related to zinc shape change in secondary cells.

Surface Preparation and Pit Propagation in Stainless Steels

H. S. Isaacs*[,1] and G. Kissel

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

A scanning reference electrode has been used to measure the number of active pits on 304 stainless steels in ferric chloride solution with time. The probability of a pit deactivating has been discussed in terms of the physical and chemical properties of solid oxide films over the pit which were originally on the steel and undermined by the dissolution process. The properties of these films were varied by different surface preparations.

The pitting of metals has been described as a highly localized form of crevice corrosion (1-3) and this analogy is further emphasized by the presence of a film over pits (1, 2, 4, 5) which restricts the flow of solute and solution in the pit cavity. It has been suggested that the film was the passive oxide layer which remained over the pit after the metal beneath it has been dissolved away during pit growth (4, 5). The presence of the film over the pit was found to play a decisive role during the early stages of the pitting process as any disruption of the film rapidly led to passivation of the pit walls (4). The properties of the passive oxide layer would depend on surface preparation and this investigation set out to determine whether surface preparation in turn influenced the propagation of actively pitting sites.

Experimental

The apparatus used in this study to locate active pitting sites and monitor them during exposure to ferric chloride solution has been described in detail elsewhere (4). Basically the method consists of measuring potential variations in a pitting environment with a fine capillary probe leading from a reference electrode. The tip of the probe scans a plane in solution close to and parallel with the pitting surface. The potential variations in the solution close to the surface arise from the ohmic potential differences which exist between the anodic areas (the pits) and cathodic areas (the passive metal surface) as current flows between them. The variations of potential in the solution are recorded on an X-Y recorder and arranged to show a three-dimensional potential surface with anodic sites as peaks and cathodic sites as troughs. Figure 1 shows examples of the appearance of the X-Y recordings during pitting corrosion of stainless steel in ferric chloride.

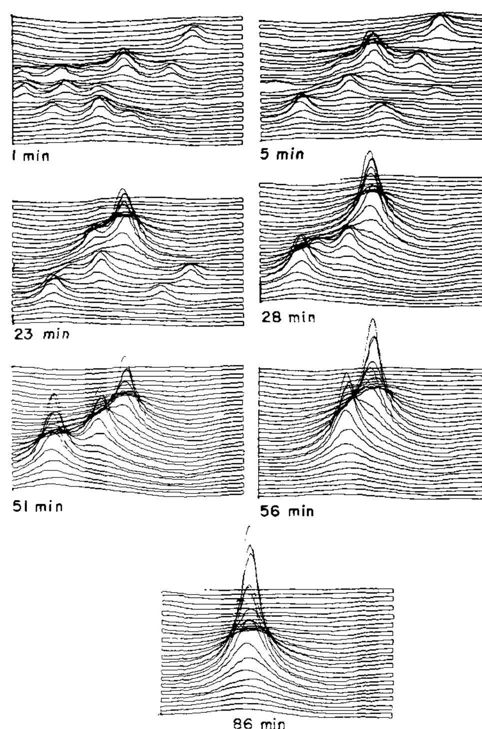

Fig. 1. Potential scans above an electropolished surface initiated at the times shown.

Specimens 15 × 30 mm were cut from a single sheet of Type 304 stainless steel, having a composition shown in Table I. The specimens were masked with silicone rubber after surface preparation. Surfaces in an abraded and electropolished condition were tested. The abraded surface was prepared by polishing down to a 600 grade silicon carbide paper. Electropolishing was performed for 10 min in a mixture of 60% phosphoric acid, 20% sulfuric acid, and 20% water at 25°-45°C, at a current density of about 1 A/cm² and 10V across the cell. The electropolished surfaces were in addition (*a*) oxidized in air at elevated temperature and (*b*) cathodically polarized in the polishing solution for 10 min. Specimens were also prepared with one part of the surface having a different preparation from the remaining area. For example, an area of an abraded

surface was masked and the surrounding area electropolished. The mask was then removed, the specimen degreased, and prepared for testing in the usual manner by applying silicone rubber to the electropolished area leaving both an abraded and electropolished surface exposed.

The ferric chloride solution used for all the tests consisted of 0.4M $FeCl_3$ with approximately 0.03M HCl giving a pH of 0.9. The tests were conducted at 25° ± 1°C with the solution unstirred and exposed to air.

Results

Recordings of the potential variations over the electropolished steel surface are shown in Fig. 1. The first scan, initiated 1 min after contact between the specimen and the chloride solution, showed 14 peaks indicating an equal number of active pits on the surface. The second scan initiated 5 min after contact showed that 10 pits were active. Subsequent scans showed that the number of peaks or active pitting sites decreased until after about 86 min only one active pit was present. Figure 2 gives a plot of the number of active pits as a function of time for the results shown in Fig. 1 and for a second test with an "as-electropolished" surface. The latter results are included to show the variations occurring between tests as replicate tests were conducted for all surface preparations. Figure 2 also includes results for different surface treatments of electropolished specimens. Specimens cathodically polarized showed that any pits on the exposed metal surface rapidly deactivated as no active pits could be seen on scanning for 1 min or less after contact between metal and the chloride solution. However, about 10 pits/cm² were present on the exposed surface after removing the specimen from the solution, indicating that pitting did take place and what may be termed crevice corrosion developed extremely rapidly at the specimen-insulation interface. These crevices were initiated by pits which "fanned" out under the protective insulation. The broken line in Fig. 2 for the cathodically polarized specimen is only approximate, giving the minimum rate of pit decay deduced from the observations that 10 pits were observed after exposure and no active pits were present during the first scan which took 3 min.

Air oxidation for 24 hr above 100°C increased the number of active pits and decreased the rate at which these pits deactivated as shown in Fig. 2. These effects became more pronounced as the temperature of oxidation was increased to 240°C. Recordings of scans for a specimen oxidized at 240°C is shown in Fig. 3. When the density of active peaks was high (>30 pits/cm²) difficulty in counting small peaks was encountered. Amplification of the potential variations did not help as this gave overlapping of the larger peaks to an extent that their number could not be counted. The procedure that was adopted involved a low amplification so that the larger peaks could easily be counted, but necessitated the assumption that peaks which developed after a period of time resulted from pits which were initiated when the specimen was immersed in the ferric chloride, but grew slowly. The corrosion potentials of the specimens were also recorded (4) and when high densities of pits were present the potential dropped rapidly during the first 20 min of exposure to less than 0.1V relative to the saturated calomel electrode (*i.e.*, less than 0.15V relative to hydrogen). This value is below that for the critical pitting potential of Type 304 stainless steel in 1.2*N* chloride solutions (6), and pits would therefore not be expected to initiate during the test.

The effect of higher oxidation temperatures for short times were also studied. These results are shown in Fig. 4 for specimens heated at 250°, 300°, and 375°C for 2 hr. The shorter oxidation period gave essentially the same behavior as may be seen on comparison of the 2-hr oxidation at 250°C with the results of heating at 240°C for 24 hr. The rate of decay of active pits on specimens heated at 375°C was significantly different from those oxidized at lower temperatures. This specimen also showed a first-order straw interference color that disappeared during exposure to ferric chloride, suggesting that the oxide had dissolved.

The results for abraded stainless steel surfaces were similar to those for the cathodically polarized electropolished surface, as the pits which formed on the exposed surface deactivated within a few minutes and crevice corrosion developed. Oxidation of abraded surfaces at 240°C also increased the life of pits but

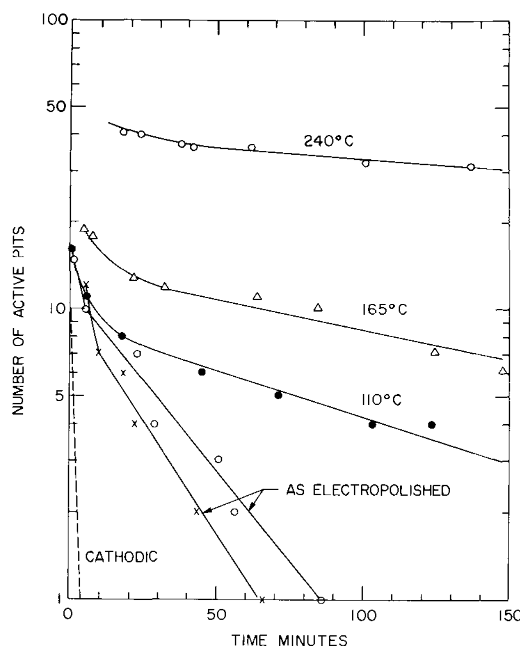

Fig. 2. Influence of surface treatment on the variation of active pits with time for electropolished surfaces. Specimens were oxidized for 24 hr at the temperatures shown. The "cathodic" curve for a cathodically treated surface is an approximation.

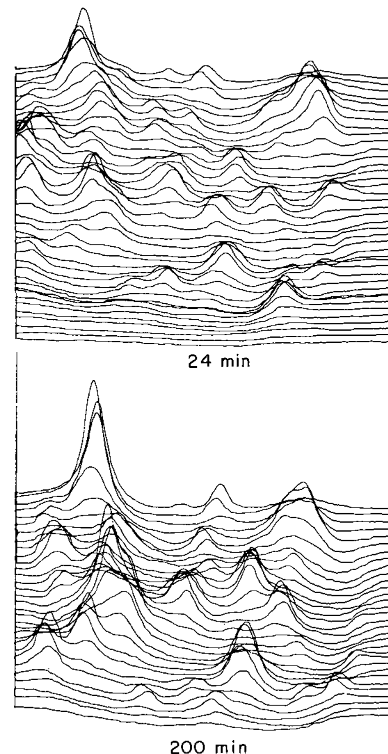

Fig. 3. Potential scans above an electropolished surface oxidized for 24 hr at 240°C initiated at the times shown.

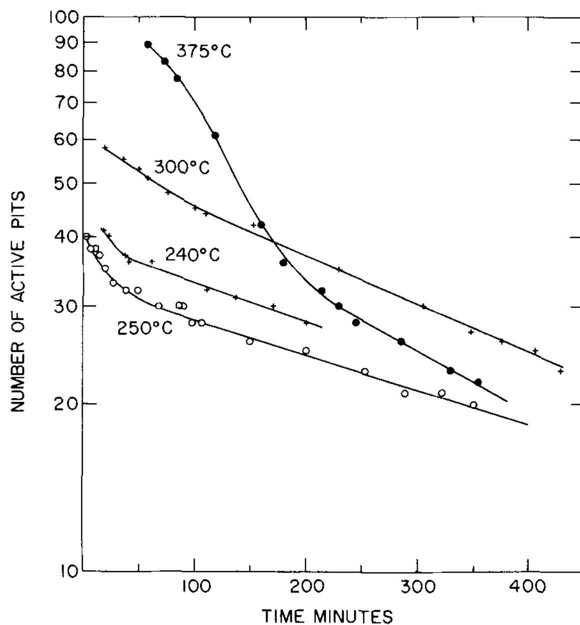

Fig. 4. Influence of oxidation temperature on the variation of active pits with time. ○, +, ●, oxidized for 2 hr at temperatures shown; + oxidized at 240°C for 24 hr.

even these pits deactivated within a relatively short period.

The behavior of active pits on a surface with areas having different preparations was simply an extension of the above results. For example, when the surface had one area which was electropolished and a second area that was abraded active pits propagated only on the electropolished area. The abraded area showed no active pits but was distinctly more cathodic than the unpitted electropolished area. This was clearly indicated by a trough on the X-Y recordings which corresponded to the abraded surface. In another test with a cathodically treated electropolished area and a second as-electropolished area, active pits were again present only on the latter area. In this case, the unpitted area did not show the marked cathodic behavior. An air oxidized electropolished area also showed a higher density of pits than an as-electropolished area on which all the pits decayed after about 40 min.

Discussion

The results in Fig. 2 and 4 clearly show that both the number of active pits and the rate at which they decrease with time depends markedly on surface treatment of the steel. If the probability of pits deactivating remained constant for a given surface preparation, the curves would be linear. This appears to be the case for the majority of the results at longer times after some initial curvature. The linear portions of the curve which are the more important in assessing corrosion resistance from a practical point of view, may be related to a half-life of active pits. The half-life is equal to the time taken for half of a given number of active pits to passivate. Table II gives the half-lives for each of the surface preparations investigated. The smaller the half-life, the greater will be the probability of an active pit on the exposed surface deactivating and the greater will be the resistance to pitting corrosion. From Table II it is, therefore, concluded that the abraded surfaces and the cathodically polarized electropolished surfaces are the more pit-resistant surface preparations. Similar conclusions have been reached by other investigators using different techniques (6, 7).

The variations in pit life result from changes brought about during pitting by the different surface preparations. These changes were not the result of electrochemical kinetics. The electrochemical properties of

Table II. Variation of pit half-life with surface preparation

Surface treatment	Pit half-life,[a] min

[a] Maximum variation of 20%.

the metal surface within the pit would not, per se, be influenced by surface preparation, specifically, when the surface treatment did not involve heating the steel and probably when the heating was conducted for only a few hours at temperatures below 400°C. Tests with specimens prepared with one part of the surface having a different preparation from the remaining area, showed that the pit life depended on the surface treatment of the particular area. The lives of these pits were similar to those in Table II and were independent of the treatment of the remaining area. These observations also indicate that neither the cathodic reduction kinetics nor variations in the corrosion potential (which would be expected to influence pitting or interactions of small pits), played any major part in the life span of active pits in ferric chloride. The influence of surface preparation, however, would be expected to influence the properties of the passive oxide layer.

It has been shown that the perpetuation of small active pits depended on the presence of a solid film over the pit. When these films were purposefully disrupted during the early stages of growth, the pitting action ceased (1, 4). The presence of the film, therefore, played a decisive role in the perpetuation of pitting probably by restricting the diffusion of the high chloride concentration from the pit cavity. The importance of a physical barrier preventing diffusion of chloride away from the pit may be seen on considering the factors which influence the concentration in the active pit. Changes in chloride concentration result from the differences in fluxes of chloride to and away from the pit, carried by the current (8) and diffusion, respectively.

If a pit is small and open to the bulk solution, the concentration gradient down which chloride diffuses away from the pit will be large and the rate of chloride loss will be high. The diffusion gradients would decrease as the pit radius increased, *i.e.*, the rate of concentration change would be inversely related to the radius. Assuming that the current density at the pit walls is constant the flow of current and hence the flow of chloride to the pit will be proportional to the square of the radius. The difference between these rates, as a function of pit radius, indicates that when the pit is small and open, loss of chloride will predominate and the pit would passivate. However, if the radius is greater than some critical value, an open pit would then remain active. In agreement with this model, earlier investigations did show two stages in the propagation of pitting. The second stage was reached after a pit had grown on electropolished surfaces for over an hour and did not deactivate on removing the film (4).

On the basis of this approach, during the early stages of pit growth (when the pit is small), the integrity of the film over the pit plays an important role in determining whether a pit will remain active or passivate, *e.g.*, weak films which are easily disrupted or perforated give a rapid rate at which pits passivate. The results in Fig. 2 and 4 may then be interpreted in terms of the properties of the film on the steel. However, owing to the meager amount of in-

formation available relating to the chemical and physical properties of thin oxides (<500Å) it has not, in general, been possible to predict the relationship between surface treatment and the behavior of pitting once it has initiated. A large number of factors play a role in the complex behavior of the oxide (9) prior to and after it has been separated from the metal by the pitting process.

The integrity of the film depends on the stress acting on it. Stresses will arise from both internal and external forces. The external forces that result from convection currents in the solution and possibly pressure buildup within the pit may be considered to remain approximately constant and independent of surface preparation.

The influence of the external forces on the breakdown of the film over pits depends on the film thickness as the resulting stresses would be inversely proportional to the thickness. Changes in the intrinsic mechanical properties of the oxide (*e.g.*, plasticity and fracture stress) with thickness do take place but if these were not marked, the thinner film would be more susceptible to breakdown and the half-lives would be shorter. This is, in general, borne out experimentally as shown in Fig. 2. The thinnest films on the cathodically polarized surface gave the shortest half-life (<1 min). The film thickness on the as-electropolished surface would be intermediate between the cathodically polarized surface and that formed by air oxidation above 100°C, and the thickness would be expected to increase with increased oxidation temperatures. The half-life of the active pits does vary in accord (Table II) and for the specimen oxidized at 240°C it was 430 min. These results show that the probability of pits deactivating can be varied by over two orders of magnitude by changes in the thickness of the oxide. Rhodin (10) has also shown that the pitting of Type 304 stainless steel in 10% ferric chloride (0.67M $FeCl_3$) depended on the oxide thickness. His results give a linear dependence between the estimated oxide thickness and weight loss. However, with films formed by oxidation, there is a change in the characteristics of the film when grown above 300°C.

The composition of the oxide formed on stainless steel varies with surface preparation, as shown by Rhodin (9), and these variations could also lead to changes in the physical and chemical properties of the oxide. For example, oxides grown in oxygen at 100°C had substantially higher chromium concentrations (37.2%) than oxides grown in an oxidizing aqueous solution (5% HNO_3 + 0.5% $K_2Cr_2O_7$ at 60°C) which contained 20% chromium. These changes would be expected to influence the point defect concentrations in the oxide which in turn would alter the plasticity of the oxide (12) and the pitting characteristics, as has been clearly demonstrated by Bianchi *et al.* (13) for annealed oxide films. Variations in composition may also lead to changes in the dissolution rate of the film. It was clear that the oxide formed after oxidation at 375°C did dissolve on exposure to ferric chloride as the interference color disappeared. In this test the pit behavior was also markedly different (Fig. 4) and no definite slope was observed for up to 200 min. These observations suggest that above about 250°C chemical changes take place in the oxide film which render it more soluble and increase the probability of pits deactivating. This effect reverses the trend of increased pit stability with increased oxide thickness as observed up to 250°C.

During the first few minutes of exposure of the steel to the ferric chloride solution the results in Fig. 2 and 4 indicate that the number of active pits increased with increased oxide thickness. This observation contrasts with that of Bianchi *et al.* (13) whose results for oxidized surfaces showed a maximum density of pits after exposure at 300°C. Nevertheless, in view of the different behavior of active pits on the surface oxidized at 375°C (Fig. 4) from those at lower temperatures, the different solutions used for pitting the steels and the method of measuring the presence of pitting, the two sets of results are not in conflict. Both illustrate marked changes in the characteristics of the oxide when oxidized above 300°C.

Internal forces within the film will depend on processes during its formation. The ratio of the volume of oxide formed from a given volume of metal (the Pilling-Bedworth ratio) would be greater than unity and there is the possibility that high compressive stresses could develop. However, the development of the stress depends on the diffusing species in the oxide and as these are predominantly cationic (11), low or no compressive stresses will be present in the film on the metal (12). Compressive stresses in the oxide, even if present, would lead to the oxide blistering when undermined by pitting and would be less likely to result in rupture of the film during pitting than tensile forces, unless the film showed a sufficient degree of plasticity to relieve the tensile stress. Abrading the surface of the steel would be expected to introduce both defects and stresses in the oxide grown on the surface (9). The results in Table II do show that the active pits on the abraded surfaces even after oxidation at 250°C have very small half-lives and probably reflect both the presence of internal stresses and disruption of the metal surface.

The results obtained at times less than 50 min show that the number of active pits increased as the rate of their decays decreased. This suggests that the number of initiated pits on contacting the steel and the ferric chloride solution may not differ markedly with surface treatment. If this was the case then the influence of the properties of the oxide on the steel plays the major part in determining the number and growth of pits rather than factors involved in pit initiation. Hence, the scanning technique, as do other techniques which depend on current flow from a pit of greater than 10^{-10}A (corresponding to approximately a 100Å pit), gives information only about the presence of an active pit and conjecture relating to its initiation.

Summary

1. The propagation of active pits is highly dependent on the surface preparation of stainless steel specimens which reflects the properties of the oxide film on the surface.

2. The half-lives of active pits increase with increased thickness of the oxide when grown thermally below 300°C. At and above this temperature significant dissolution of the oxide occurs reflecting changes in the chemical properties of the oxide, and reducing the life of active pits.

3. The number of active pits is more readily related to the properties of the film than to factors that relate to their initiation.

ABSTRACT

A "Z-shaped" current voltage curve is shown to be controllable with a new device which is equivalent to a voltage source in series with a negative resistance, both being adjustable. The latter was built with an operational amplifier. Using this original regulating device, the steady-state anodic polarization curve of an iron rotating disk in molar sulfuric acid was studied as a function of the rotation speed. The Z-shaped curve thus obtained exhibits a continuous and reversible transition between active and passive states. This particular shape of the polarization curve explains the steep transitions observed with a potentiostatic regulation. In the passive to active state transition the dissolution of the disk is localized to a ring part of the surface, the dimensions of which were followed as a function of the total current and of the rotation speed. The explanation of this quite heterogeneous distribution of current density can be found in the coupling between the convective-diffusive mass transfer and a very steep variation of current density *vs.* potential.

The anodic behavior of iron in molar sulfuric acid solution, when controlled by a potentiostat, is characterized by a current-voltage curve which exhibits two steep transitions between active and passive state. When the potential is increased toward more anodic values, a sudden drop of current takes place at a passivation potential, V_P. When decreasing the potential, from values more anodic than V_P, a jump of current takes place at an activation potential, V_A, less anodic than V_P. The activation potential has been considered to be identical with the Flade potential (1), as defined by the potential decay method. This idea seems to us more valid than the alternative one which identifies V_P with the Flade potential, because the high current densities in the active state, at potential V_P, lead to considerable overvoltages which originate from ohmic drop and concentration gradients. Moreover, the presence of crystalline $FeSO_4 \cdot 7H_2O$ layers on the electrode surface (2) may induce oscillations in the system.

According to some authors, ohmic drop (3) and/or mass transfer (4) might induce such steep transition as mentioned above, between active and passive state, as well as oscillations of the electrochemical system, which could be explained by a breaking down of control. The observed potentiostatic behavior would thus not be a fundamental property of the iron-sulfuric acid solution interface. In order to verify this assumption, we devised an electronic control apparatus different from the potentiostat.

Polarization Control

Principle.—Let I be the current flowing through an electrochemical cell from a counterelectrode E_2 to a working electrode E_1 (Fig. 1a). The latter may be connected to ground either directly (position 1) or through a resistor R (position 2). If I is a positive current, E_1 is an anode, in the opposite case it is a cathode. If U is the voltage between E_2 and ground, and if the cell is fed by a voltage source E in series with a resistance ρ, then, whatever the behavior of the cell may be, we can write

$$U = E - \rho I \qquad [1]$$

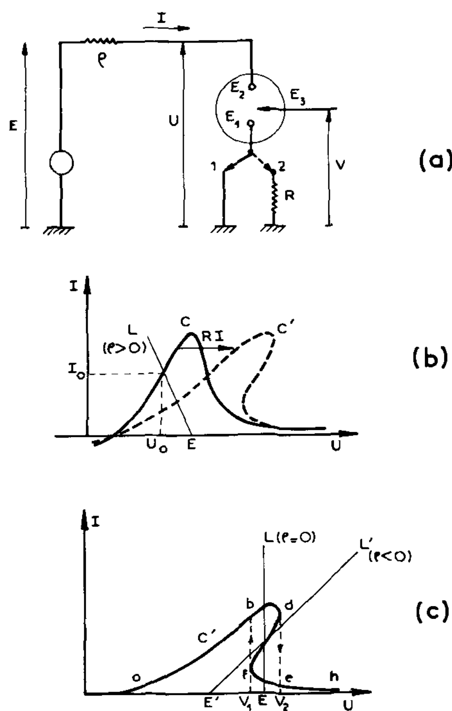

Fig. 1 (a). Electrochemical cell fed by a voltage source E in series with a resistance ρ. E_1, working electrode; E_2, counterelectrode; E_3, reference electrode. E_1 can be connected to ground either directly at 1, or through a resistor R at 2. (b). Current-voltage curve refering to (a) with working electrode grounded (curve C) or connected to ground through R (curve C′). L is the load line corresponding to $U = E - \rho I$, $\rho > 0$. (c) Curve C′ of (b) with L, load line with $\rho = 0$ and L′, load line with $\rho < 0$.

* Electrochemical Society Active Member.

Key words: anodic dissolution, convective-diffusion, disk electrode, discontinuous current distribution, regulation.

The related "load line" L, in the U-I plane, is drawn on Fig. 1b. Its slope is $-1/\rho$. On the other hand, the electrochemical cell, with the working electrode connected to ground may be characterized by a curve such as C in the U-I plane. If L crosses C in one point (U_o, I_o), this point is an equilibrium one for the system consisting in the cell and the polarization device. In many circumstances, it is possible, with a proper choice of ρ, to determine C only by varying E. The electrochemical cell is then said to be controllable by the polarization device. The current I being a steady one, the voltage V between the working- and counterelectrode can be measured independently by means of a reference electrode, E_3, so that one gets the usual plot of current-voltage curves in the V-I plane.

In the particular case when one value of I corresponds to a value of U, the resistance ρ can be chosen as zero (L parallel to the I axis). But this requirement is not always met, as it can be seen on Fig. 1b where the curve C′ corresponds to the same cell as before, but with a resistor R between working electrode and ground. This situation may also arise from an ohmic drop between working- and counterelectrode. A load line parallel to the I axis ($\rho = 0$) crosses C′ in three points if $V_1 < E < V_2$ (Fig. 1c). We shall call "Z-shaped" this kind of curve. With this regulation device, the part a-b-d of C′ is obtained at increasing voltage. If U is further increased, I drops from d to e, then e-h is obtained. At decreasing voltage, starting from h, h-e-f is obtained, then I jumps from f to b. An analogous situation is met when using a potentiostat, if the current-voltage curve in the V-I plane is Z-shaped. Whenever the load line is tangent to the curve in a point such as d or f, this point is unstable (5) and a steep transition of current takes place from the corresponding value of the current to another one. We shall recall this remark later, when discussing the transitions which are observed with an anode of iron in sulfuric acid solution.

Coming back to the control device of Fig. 1, it is easy to see that an electrochemical system, with a curve such as C′, can be controlled if the load line L′ has a positive slope (Fig. 1c), *i.e.*, if ρ has a negative value. This can be achieved by using a negative impedance converter (NIC), a two port device which has the property that the impedance seen at its output is the negative of the impedance connected across its input.

Polarization control using a NIC.—A NIC can be defined in terms of the two port variables (E', I'), (U, I) shown in Fig. 2, by the equations

$$U' = U$$
$$I' = -KI \quad K > 0 \qquad [2]$$

If a voltage source E, in series with a resistance ρ, is connected across the input

$$U' = E - \rho I'$$

Using Eq. [2], this equation is written

$$U = E + K\rho I \qquad [3]$$

In the U-I plane, the corresponding load line has a positive slope $1/K\rho$. In other words, the control device acts as a voltage source E in series with a negative resistance $-K\rho$.

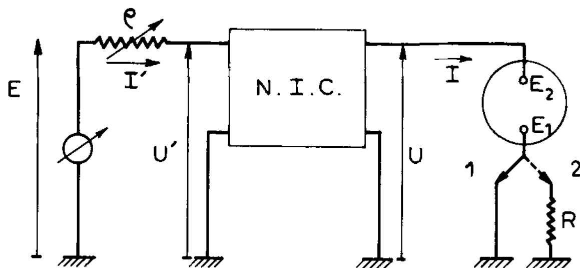

Fig. 2. Negative impedance converter. Sign conventions for currents and voltages.

The NIC, the properties of which have been known for a long time (6), may be realized by using a differential-input operational amplifier as the active element (7), as shown on Fig. 3 which gives the whole set-up used to record current voltage curves in the V-I plane. With the usual simplifying assumptions used when dealing with operational amplifiers, the constant K equals R_2/R_1 (full details are given in the Appendix). The values of ρ and E can be adjusted in order to get any load line with positive slope in the U-I plane, and the current-voltage curve in the V-I plane is obtained by varying either E, or ρ, or both, as necessary. As no current flows into the negative input point of the amplifier, the current flowing through the cell is the same as the current flowing through R_2. It is measured with the help of a differential amplifier D.

Test of the polarization control device.—The test has been carried out with an austenitic stainless steel disk electrode, rotated at 2000 rpm in $2N$ H_2SO_4. The composition of the alloy is 16% Cr, 14% Ni, 4.2% Si. The experiment covers the transpassive region. The same curve 1 (Fig. 4) has been obtained, using a potentiostat (8) or the present polarization control device with $\rho = 0$. This result holds with a grounded working electrode. A 50-ohm resistor is then inserted between

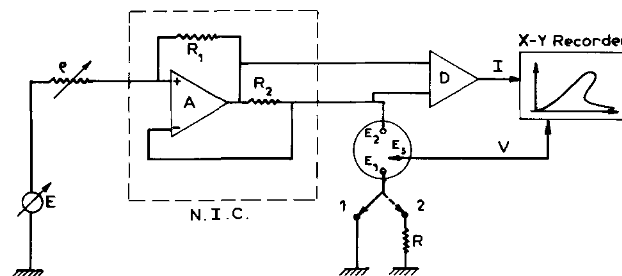

Fig. 3. Experimental set-up. E, adjustable voltage source ($-5V \leq E \leq 5V$); ρ, adjustable resistor ($0 \leq \rho \leq 10$ kohms). The operational amplifier is Analog Devices, 406 Model, with $A \geq 95$ db; $R_1 = 100$ ohms; $R_2 = 1$ ohm. The frequency compensating circuits are not shown. D is a differential amplifier.

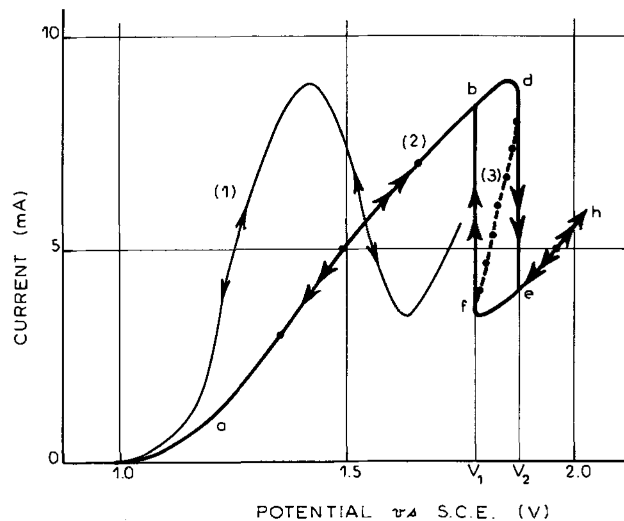

Fig. 4. Test of the NIC control device, carried out with a stainless steel rotating disk electrode (diameter 4 mm). Curve 1 is current voltage curve of the working electrode connected to ground, drawn either with a potentiostat or the NIC control device with $\rho = 0$. Curve 2 is current voltage curve of the working electrode connected to ground through 50 ohms (the voltage is taken between reference electrode and ground). Same polarization device as in curve 1. Curve 3 is current voltage curve of the same system as curve 2, drawn with the NIC control device with $\rho \neq 0$.

this electrode and ground. With a potentiostat, as well as with the present control device with $\rho = 0$, curve 2 is obtained. It exhibits two steep transitions d-e and f-b, and the current is not the same at increasing (a-b-d-e-h) or decreasing (h-e-f-b-a) voltage, as shown by the arrows on Fig. 4. With the polarization control device using a NIC, and a value of ρ different from zero, a continuous curve 3 (a-b-d-f-e-h) is obtained. The dashed part d-f cannot be drawn with a potentiostat, while the remaining parts coincide with the corresponding potentiostatic drawing. This curve does not depend on the value of E and ρ used to draw it. It is perfectly reproducible and reversible. Moreover it coincides with the theoretical curve which can be deduced from curve 1 by adding the ohmic drop corresponding to the resistance $R = 50$ ohms. The same curve is also obtained when the current I is not measured in the way shown in Fig. 3 (*i.e.*, from the voltage across R_2) but from the voltage across a resistance in series with the counterelectrode. With this last procedure, the experimental data is free from any possible artifact coming from the polarization control device, as long as each point of the curve is an equilibrium point, since the measured current is the very current which flows through the interface.

Results

The rotating electrode, which may be disk- or square-shaped, is the cross section of an iron rod (Johnson-Matthey), embedded in an insulating acrylic resin cylinder of circular cross section. The molar electrolyte solution is prepared from Merck Suprapur sulfuric acid, and water purified with ion-exchange resins. Oxygen is removed from the solution by argon bubbling (Air Liquide, "U" quality). The temperature of electrolyte is 25°C controlled within ±0.1°C.

Current voltage curves.—Figure 5 shows the steady-state behavior of a disk electrode (5 mm in diameter) rotated at 750 rpm. The curve in Fig. 5(a) refers to potentiostatic conditions, the curve in Fig. 5(b) to polarization control with the device using a NIC. The voltage V is measured between the working electrode and a reference electrode (SCE). With a potentiostat, the curve is described through the points a-b-d-e-h at increasing potential, h-e-f-b-a at decreasing potential. When the rate of potential sweep is too fast, a maximum of current is observed in the vicinity of point b (2, 9), but it disappears under steady-state conditions. The steep transitions which take place at V_A and V_P do not occur when the NIC device is used (curve b). The dashed part d-d' of the line corresponds to the average value of a fluctuating current which cannot be controlled. The magnitude of these fluctuations is not negligible, they are rather slow, but have no well-defined frequency. They are not to be mistaken for the oscillations which are known to occur with certain potentiometric polarization conditions (3, 4). The a-b-d and h-e-f part of the curves (a) and (b) are identical with both techniques, but, when using a NIC, any point can be reached at either increasing or decreasing potential. The continuous transition d'-f between active and passive state is also reversible. However in the vicinity of point f, at currents lower than a few milliamperes (not visible on the scale of the drawing), it is difficult to ascertain the reversibility of the curve. We shall ignore this point because all the results to be presented here have been obtained at much higher currents. Anyhow, the shape of curve (b) in the vicinity of f explains the jump of current f-b observed with a potentiostat, as discussed above (see Fig. 1c). The transition d-e (curve a) is probably induced by the coming of the fluctuation observed in d-d' (curve b).

Experiments have been carried out at various rotation speed Ω (Fig. 6). In regions such as b-d (see Fig. 5), the current is limited by diffusion. It increases as $\Omega^{1/2}$, in agreement with Levich's theory (10), extended in this laboratory to concentrated solutions (11).

Localized dissolution of the electrode.—Figure 7 shows photographs of a rotating disk electrode after it has been polarized in the transition region between passive and active state [part of d'-f of curve (b), Fig. 5], with a schematic drawing of the corresponding sections. The general case (12) corresponds to the dissolution of a ring-shaped part of the surface (Fig. 7c). The depth of field of a conventional microscope is small enough for the depth of attack to be determined within ±1 μm. The edges of the ring are sharp, and its diameters are determined easily with a micrometer. The remaining part of the electrode is not attacked as it can be seen by referring to the insulated part of the disk. An actual profile is given in Fig. 8. It has been tested independently by direct observation after the electrode has been cut along its axis.

The inner and outer diameters of the ring, d_i and d_e, vary with current and rotation speed (Fig. 9). As limiting cases, d_i reduces to zero (Fig. 7b), or d_e becomes identical with the diameter of the disk (Fig. 7a). At a given rotation speed, dissolution takes place

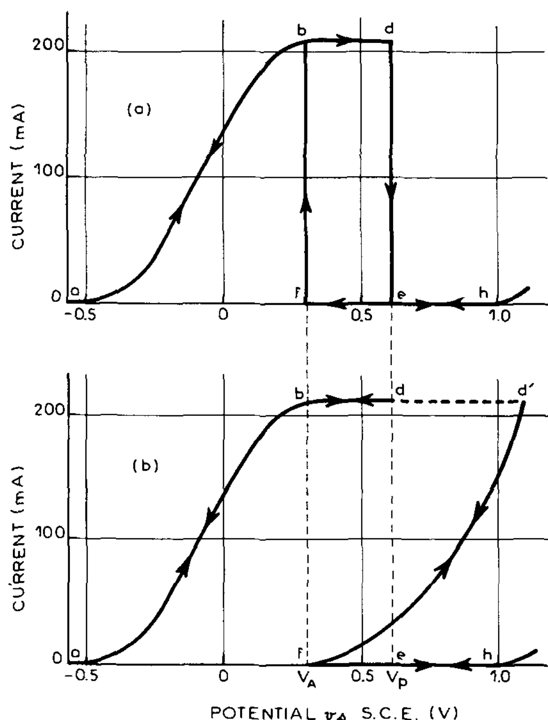

Fig. 5. Current-voltage curves of a disk electrode (diameter 5 mm) rotated at 750 rpm: (a) using a potentiostat, (b) using the device of Fig. 3.

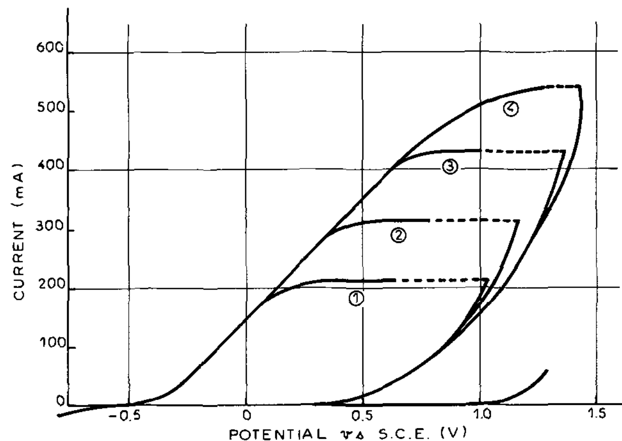

Fig. 6. Current-voltage curve of a disk electrode (diameter 5 mm), at rotation speeds: curve 1, 750 rpm; curve 2, 1600 rpm; curve 3, 3000 rpm; curve 4, 4500 rpm.

on an increasing area when current increases, until the whole disk is attacked.

Experiments have also been carried out with rotating square-shaped electrodes. From the hydrodynamical point of view, the rotating body behaves in the same way as in the previous experiments since the electrode is embedded in an insulating coating of circular cross section, but the boundary conditions are different. A localized dissolution is again observed. The attacked part may have many different shapes, depending on rotation speed and current. The limiting cases are given in Fig. 10. At low speed, the undissolved part is a square, the sides of which are parallel to the sides of the electrode (Fig. 10a). At high rotation speed, the attacked region is a circular ring (Fig. 10b). Its center coincides with the center of rotation of the system even if the latter is not the center of the square.

In the transition region between passive and active state, the total current is used to dissolve metal with valency 2, as it has been verified by a spectrophotometric titration of Fe^{++}, with o-phenantroline as an indicator. It proves that no electrochemical reaction of appreciable rate takes place on the part of the

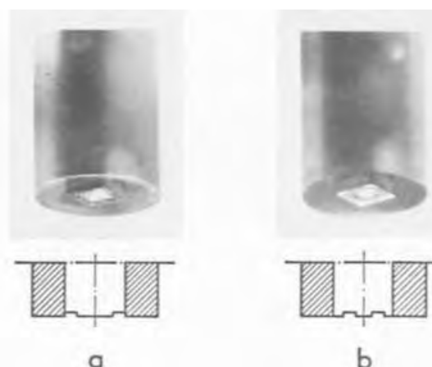

Fig. 10. Localized dissolution of a square shaped electrode. (a) $\Omega = 750$ rpm; $I = 20$ mA; $V = 500$ mV/SCE. (b) $\Omega = 3000$ rpm; $I = 60$ mA; $V = 740$ mV/SCE. Under each photograph, schematic section of the electrode.

electrode which is not attacked. Then it is possible to derive the average dissolution current density from the current and the area of the attacked surface (Fig. 11).

Discussion

As shown by using a new polarization control device, a continuous and reversible transition does exist between the active and passive state of iron in 2*N* sulfuric acid solutions. The steep transitions which can be observed when using a potentiostat are not related to merely electrochemical processes, as they are generally thought to be (13). They result from the fact that a potentiostatic regulation is not appropriate when dealing with Z-shaped polarization curves.

The decrease of current from a limiting value to zero (d′ to f in Fig. 5) is due, not only to a decrease of the active area, but also to a decrease of current density (Fig. 11). As far as we know, this is the first example of an electrochemical system for which several over-all reaction rates can exist for a given potential. To be sure that it is a fundamental property of the iron-sulfuric acid interface, it is necessary to estimate the ohmic drop, which, if large enough, is able to transform a bell-shaped curve into a Z-shaped curve [(8) and Fig. 1b]. The ohmic term is not proportional to the current, since the active area is not constant.

The ohmic drop has been measured with the interrupter technique at the point d′ (Fig. 5b) where the whole area of the electrode is active. After correction, this point is more cathodic than the point f if the rotation speed is higher than 1600 rpm. But it is more

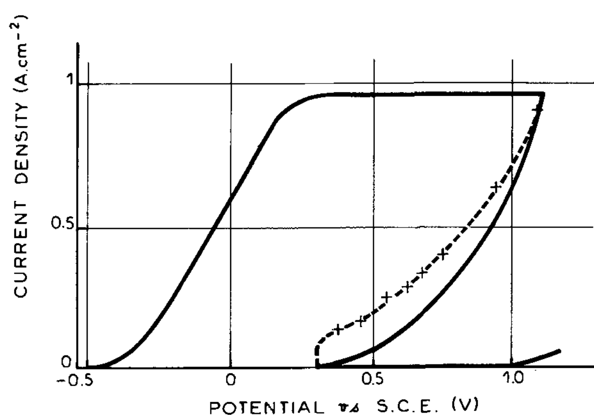

Fig. 11. Full line: experimental current density, *i.e.*, total measured current, divided by the total area of the disk. Dashed line: average current density for the attacked surface, *i.e.*, total measured current, divided by the area of the attacked part of the electrode.

anodic at lower rotation speeds. Then the ohmic drop cannot completely explain the shape of the polarization curve. Mass transfer has also to be taken into account, in particular for the point d′. It also plays a part in the localized dissolution of the electrode, as shown by the above experiments, since the shape and the size of the attacked region depend not only on the shape of the electrode, but also on the rotation speed. Coupling between mass transfer by convective diffusion, ohmic drop in the electrolyte, and charge transfer have been studied by Newman (14) from a theoretical point of view in the case of a rotating disk electrode. According to the author, who assumes an exponential relationship to exist between the charge transfer reaction rate and the potential, a maximum of current can take place at a distance from the center of the disk. It results in a lack of uniformity in the dissolution of the electrode. This is not in quantitative agreement with the present case. However, if the charge transfer reaction rate is not assumed to vary according to an exponential law, but rather steeply in a narrow range of voltage, the main features of Newman's model could explain the localized dissolution of the electrode: a continuous distribution of potential along the radius of the disk would result in discontinuous variations of current density. Further experimental and theoretical work is in progress to support this interpretation.

APPENDIX

Equations of the Negative Impedance Converter

Figure A-1 shows the NIC realized with a differential input operational amplifier. The latter is characterized by a gain A, an input impedance Z_i, and an output impedance Z_o. The three quantities refer to open-loop conditions. Since a voltage $U' - U$ is applied across the amplifier input, its output (between B_2 and ground) acts as a voltage source $A(U' - U)$ in series with Z_o. The circuit of Fig. A-1 is then equivalent to the circuit of Fig. A-2. Kirchoff's laws, applied to U, U', I, I', and the auxiliary current I_2, lead to

$$U' = R_1(I' + I_2) + Z_o(I' - I) + A(U' - U)$$
$$A(U' - U) = Z_o(I - I') + R_2(I + I_2) + U$$
$$0 = Z_iI_2 + (I_2 + I')R_1 + (I_2 + I)R_2$$

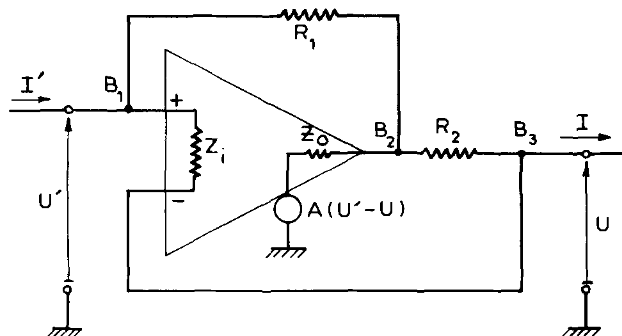

Fig. A-1. Schematic drawing of the NIC. A, open loop gain; Z_o, open loop output impedance; Z_i, open loop input impedance.

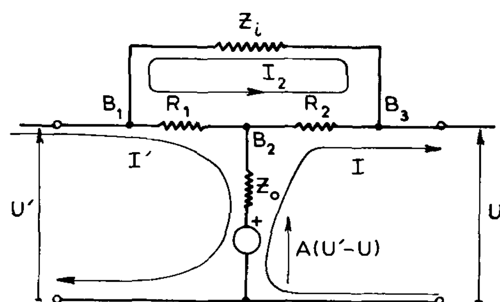

Fig. A-2. Electrical network corresponding to Fig. A-1 showing the currents used to write down Kirchhoff's law.

Eliminating I_2 between these equations leads to the NIC equations

$$(A - 1)U' + \left[\frac{R_1}{Z_t}(R_2 + Z_i) + Z_o\right]I' = AU + \left(\frac{R_1R_2}{Z_t} + Z_o\right)I$$

$$AU' + \left(\frac{R_1R_2}{Z_t} + Z_o\right)I' = (A + 1)U + \left[\frac{R_2}{Z_t}(R_1 + Z_i) + Z_o\right]I$$

where $Z_t = R_1 + R_2 + Z_i$.

Solved for U′ and I′, they are written

$$U' = \frac{U\left[1 - \frac{1}{A}\left(1 - \frac{R_2}{Z_i} - \frac{Z_o Z_t}{R_1 Z_i}\right)\right] - \frac{1}{A}\left(1 + \frac{Z_o}{R_1} + \frac{Z_o}{R_2}\right)R_2I}{1 + \frac{1}{A}\left(\frac{R_2}{Z_i} + \frac{Z_oZ_t}{R_1Z_i}\right)}$$

$$I' = \frac{-\frac{R_2}{R_1}I\left[1 - \frac{1}{A}\left(1 + \frac{R_1}{Z_i} + \frac{Z_o Z_t}{R_2 Z_i}\right)\right] + \frac{1}{A}\frac{Z_t}{Z_i}\frac{U}{R_1}}{1 + \frac{1}{A}\left(\frac{R_2}{Z_i} + \frac{Z_oZ_t}{R_1Z_i}\right)}$$

The equation for the load line in the U-I plane is then written

$$E\left[1 + \frac{1}{A}\left(\frac{R_2}{Z_i} + \frac{Z_oZ_t}{R_1Z_i}\right)\right] = U\left[1 - \frac{1}{A}\left(1 - \frac{R_2}{Z_i} - \frac{Z_o Z_t}{R_1 Z_i} - \frac{Z_t}{Z_i}\frac{1}{R_1}\right)\right]$$
$$- I\left[\frac{\rho R_2}{R_1} + \frac{1}{A}R_2\left(1 + \frac{Z_o}{R_1} + \frac{Z_o}{R_2}\right) - \frac{R_2}{R_1}\left(1 + \frac{R_1}{Z_i} + \frac{Z_o Z_t}{R_2 Z_i}\right)\right]$$

As Z_o is very small and Z_i very large, R_1 and R_2 can be chosen so that the following approximations hold

$$R_1 + R_2 << Z_i \qquad R_1 >> Z_o \qquad R_2 >> Z_o$$

They lead to

$$U = \frac{E}{1 - \frac{1}{A}\left(1 - \frac{\rho}{R_1}\right)} + I\frac{\rho R_2}{R_1}\left[1 + \frac{1}{A}\frac{R_1}{\rho}\left(1 - \frac{\rho}{R_1}\right)\right]$$

The open loop gain A can be chosen large enough for these equations to be written, in accordance to Eq. [2] and [3]

$$U' = U; \qquad I' = -\frac{R_2}{R_1}I; \qquad U = E + I\rho\frac{R_2}{R_1}$$

The Polarization Behavior of Fe-Ni-Cr Alloys in Concentrated Sodium Hydroxide Solutions in the Temperature Range 25° to 150°C

ABSTRACT

Results are reported for the potentiodynamic polarization at 600 mV/hr of Fe, Ni, Cr, and seven Fe-Ni-Cr alloys in concentrated NaOH solutions in the temperature range 25°C to the boiling point. Iron and nickel, as well as the Fe-Ni-Cr alloys, showed an active-passive transition which correlates very well with the predictions of the Pourbaix diagram both with respect to M/HMO_2^- dissolution and oxide formations. Chromium on the other hand exhibited a transpassive Tafel behavior with an inflection corresponding to the CrO_3^{---}/CrO_4^{--} equilibrium. The HER and OER follow generally predicted behavior. The corrosion rates increased with an increase in the temperature and NaOH concentration. In the sodium hydroxide environment nickel is the most corrosion resistant and desirable componet in the Fe-Ni-Cr alloys, whereas Cr is generally deleterious.

The purpose of this study was to survey the polarization behavior of Fe-Ni-Cr alloys in caustic solutions in the temperature range 25° to the boiling point and in NaOH concentrations from 1 to 19.5*N* (saturated). Anodic and cathodic scans were conducted all at the same scan rate, 600 mV/hr.

Compared to the numerous polarization studies in acid solutions, only a few studies have been conducted in alkaline solutions: Fe (1-8), Cr (9-11), Ni (12-14), and Fe-Ni-Cr (15-17). The behavior of Ni in alkaline solutions is also given in some detail by Hoare (18). In summary, the previous work of this alloy system in caustic environments has not been extensive. The work reported here is the first broad survey. This study was conducted potentiodynamically to rapidly obtain the broadest view of the problem. Certainly, future studies must examine regions of special interest more intensively.

Experimental

Three high-purity metals Fe, Ni, and Cr, and seven of their alloys were investigated in this study. Sources of metals and alloy preparations are described elsewhere (19). The caustic solutions were prepared by using double-distilled water and carbonate-free saturated NaOH solution. High-purity nitrogen was used for deaerating the solution in the cell. The instruments used were Wenking potentiostat Model 68TS3, Keithley electrometer Model 602, Erwin Halstrup motorpotentiometer Model MP165, and Esterline Angus recorder Model S-601-S or Hewlett Packard x-y recorder Model 7001A.

The specimens were cylindrical with a 0.32 cm diam. The exposed surface area was 1.0 cm^2. One end of the specimen was threaded as shown in Fig. 1A. A stainless steel rod which was fitted into a Teflon tubing was threaded at one end and was then screwed into the specimen. Before mounting, the specimen was abraded with emery paper ranging from 200- to 600-grit finish, washed with distilled water, and dried with acetone. This treatment of the specimens gave fairly reproducible results.

A schematic arrangement of the equipment is shown in Fig. 1B. The cell was made of Teflon and heated by heating tapes wrapped around its outer surface. Nitrogen was bubbled continuously through the solution in the cell. The counterelectrode was a circular Pt gauze. A Luggin probe was made from a Teflon U-tube with a nylon wick running inside it. One end of the probe was positioned near the specimen in the cell and the opposite end was connected, via a NaOH bridge, to a saturated calomel reference electrode in saturated KCl at room temperature. All the potential measurements were made against this reference electrode

and subsequently converted, by adding 242 mV, to the standard hydrogen electrode scale for reporting.

After the cell was assembled and proper connections were made, the open-circuit potential was measured. In most cases it took approximately 30 min to obtain the steady-state value. The potential was scanned at 600 mV/hr either in the noble direction for the anodic curve, or in the active direction for the cathodic curve. [This scan rate was arbitrarily chosen after a preliminary survey at various scan rates showed no significant changes in the over-all pattern of the polarization curves, although the current density did vary. A similar observation is reported for 18-8 stainless steel in 1N H_2SO_4 by Green *et al.* (20).] Only one polarization curve (anodic or cathodic) was obtained at a time. For the other curve, the specimen was reabraded and the cell reassembled with a fresh caustic solution.

Results

The anodic and the cathodic polarization curves of Fe-Ni-Cr alloys in NaOH solutions are shown in Fig. 2-8. Figures 2-4 show the effect of increasing temperature on the polarization behavior while Fig. 5-8 show effects of changing the NaOH concentration and the alloy composition.

The corrosion potential, E_c, of the specimens as functions of temperature and caustic concentration is shown in Fig. 9 and 10, respectively. The corrosion potential of the specimens became more negative (active) with an increase in temperature or caustic concentration. The E_c of Fe, Ni, and Cr in 10N NaOH changed from −900, −180, and −150 at 25°C to −950, −720, and −270 mV (SHE) at 118°C, respectively. Similarly, the change in E_c with an increase in caustic

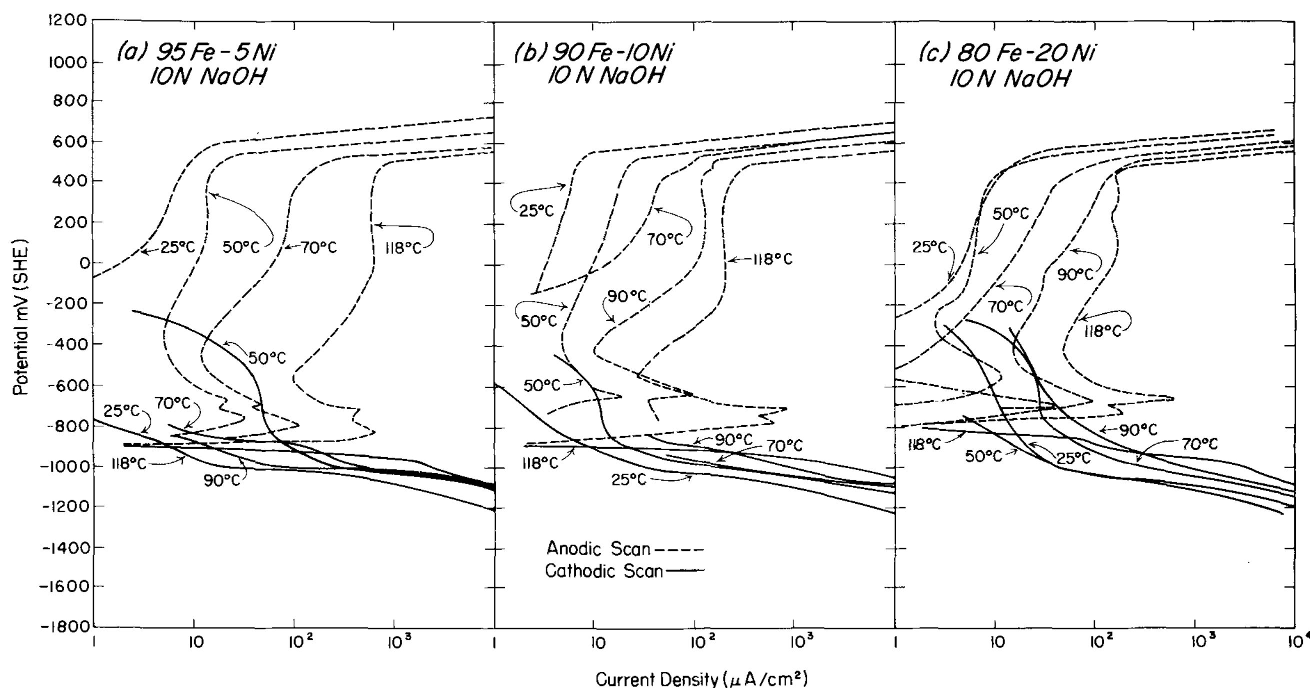

Fig. 3. Polarization behavior of the Fe-Ni binaries in 10N NaOH in the temperature range 25°-118°C.

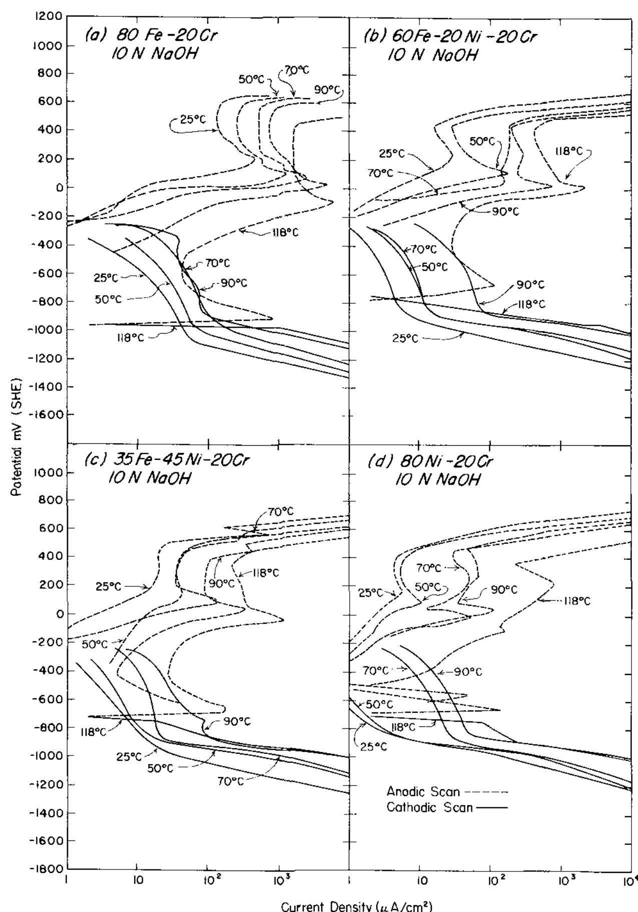

Fig. 4. Polarization behavior of the Fe-Ni-Cr alloys in 10*N* NaOH in the temperature range 25°-118°C.

concentration from 1 to 10*N* NaOH at 70°C for Fe, Ni, and Cr was from −220, −40, and 100 to −830, −180, and −190 mV (SHE), respectively. The E_c of alloys, in general, lies intermediately between those of their pure components. The addition of Ni and/or Cr shifted the corrosion potential of Fe alloys to more noble values.

The anodic polarization curves of Fe and Ni in caustic solutions showed conventional active-passive behavior, Fig. 2, 5, and 7. However, the anodic scan of Fe in both 1 and 5*N* NaOH at 70°C showed only the passive and transpassive part of the polarization curve, Fig. 5. This occurred because the corrosion potential in these cases was in the passive region. The critical peak of Fe in 10*N* NaOH between 25° and 118°C lies within 40 mV of its corresponding corrosion potential. The current density in the post-passive region in certain instances is higher than that at the critical peak; *e.g.*, in Fig. 7a an anodic hump, which is 750 mV above (noble) the critical peak, has one order of magnitude higher current density than at the critical peak. Jones *et al.* (7) have reported similar observations with mild steel polarization in 1 and 5*N* NaOH at 300°C.

The critical anodic peak in the polarization curves of Ni does not appear below 90°C in solutions of concentration less than 10*N* NaOH, Fig. 2 and 5. Nickel, like Fe, shows a hump in the post-passive region; with an increase in temperature or caustic concentration, the value of current density at the hump approximately equals that at its critical peak, see Fig. 2c and 7a.

Chromium in caustic solutions did not exhibit an active-passive behavior, Fig. 2, 6, and 8. The anodic scan produced a Tafel-like increase of the current density from its corrosion potential to the end of the scan 450 mV (SHE). A change in the slope of log i *vs.* E plot occurred, depending on the caustic concentration and temperature, at 50-100 mV from its corrosion potential.

The effects of increases in the NaOH concentration and in temperature on the passive current density of pure metals at a fixed potential are summarized in Fig. 11 and 12. An approximately linear dependence of log i *vs.* $1/T$ is clearly seen for Fe and Ni which corresponds to an apparent energy of activation of 6.1 kcal. Log i is also directly proportional to the log of NaOH concentration. The slope of log i *vs.* log N is one for Fe and Ni but ~2 for Cr. In identical environments the current density of Cr is a decade or more higher than that of Fe which in turn is approximately a decade higher than that of Ni.

The anodic current density of alloys is intermediate between those of their pure components. The anodic kinetics in the passive region in 10*N* NaOH at 70°C for 95Fe-5Ni is ~½ decade less, and that for 80Fe-

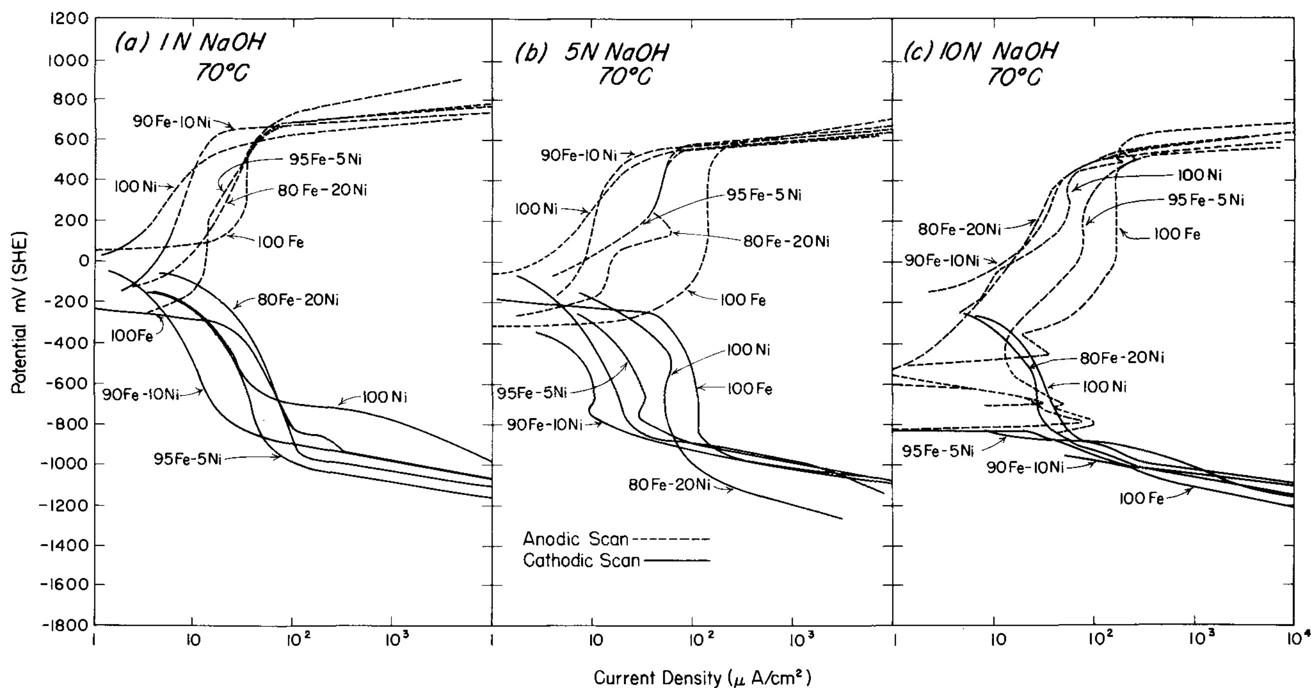

Fig. 5. Polarization behavior of Fe, Ni, and the Fe-Ni binaries in 1, 5, and 10*N* NaOH at 70°C.

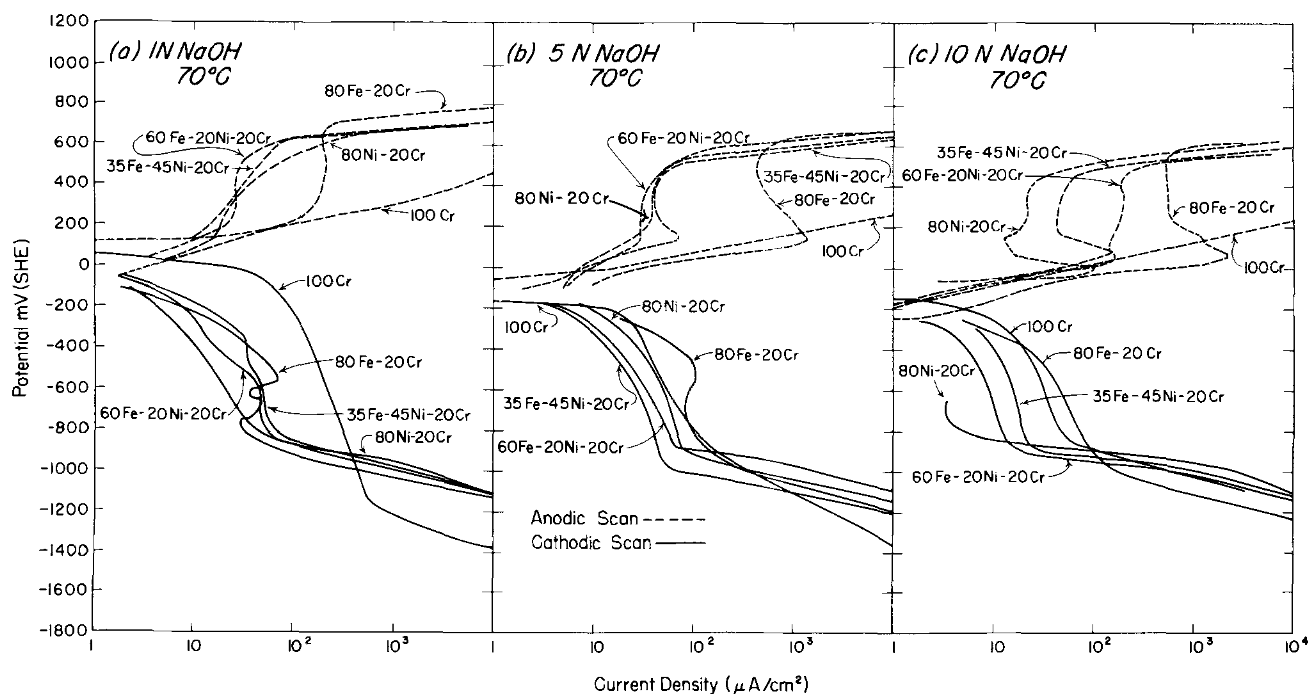

Fig. 6. Polarization behavior of Cr and the Fe-Ni-Cr alloys in 1, 5, and 10N NaOH at 70°C.

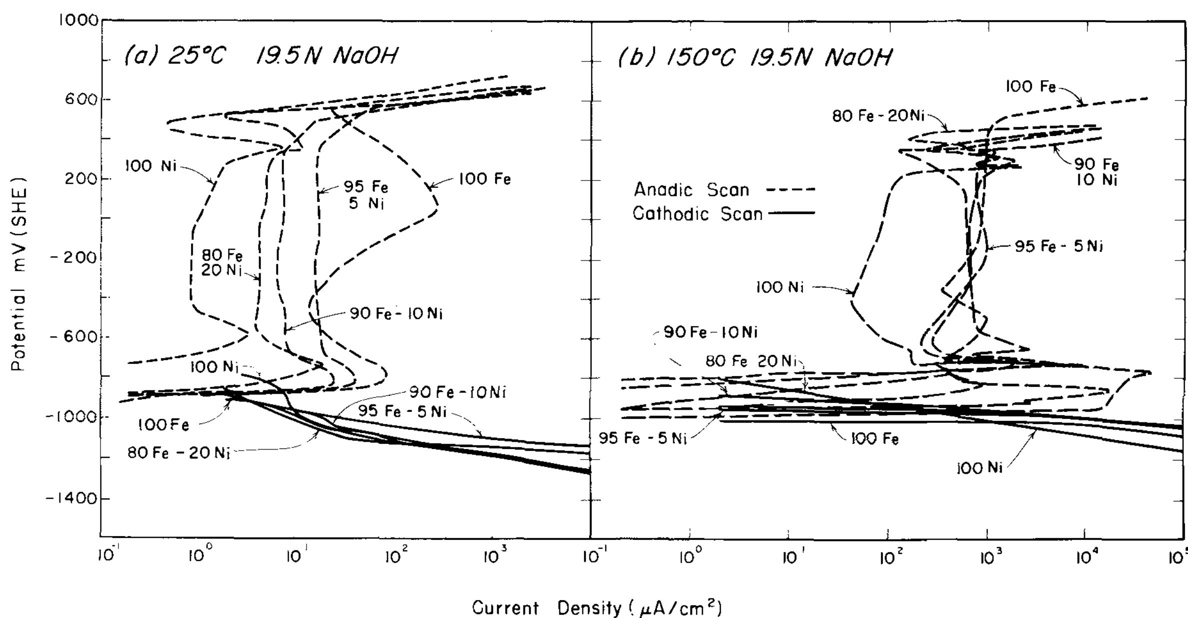

Fig. 7. Polarization behavior of Fe, Ni, and the Fe-Ni binaries in 19.5N NaOH at 25°-150°C.

20Ni is ~1 decade less than that of Fe. At elevated temperature in concentrated caustic the results are not as significant; *e.g.*, in 19.5*N* NaOH at 25°C Fe-Ni binaries show the above-mentioned trend but at 150°C the current densities in the passive region are approximately the same as that of Fe, Fig. 7.

The anodic polarization curves of Cr alloys in concentrated solutions (≥10*N* NaOH) or at high temperatures (>70°C) show two distinct anodic peaks below the oxygen evolution potential, Fig. 4 and 8. At lower temperatures (≤70°C) in 1-10*N* NaOH, since the corrosion potential of Cr alloys lies closer to that of Cr, the anodic polarization curves exhibit only the second peak region. A comparison of the polarization curves of Cr alloys with those of pure metals Fe, Ni, and Cr indicates that the current density in the first active-passive region is controlled by Fe-Ni dissolution and formation of their oxides. The second peak in alloys is due to Cr. The current density at the second anodic peak matches closely with the corresponding current density of pure Cr. The current density at the second anodic peak, depending on the caustic concentration and temperature, is ~½ to 2 decades higher than that at the first active peak.

The oxygen evolution region of the anodic polarization curves of Fe, Ni, and all their alloys exhibit Tafel behavior, Fig. 2-8. The average value of the OER Tafel slope in caustic solutions used in this study between temperatures of 25° and 150°C is 45 ± 10 mV for the majority of the specimens. This value is in full agreement with that reported in the literature (18). In a few exceptional cases, the observed Tafel slope is quite high, *e.g.*, 90 mV for Fe in 1*N* NaOH at 70°C, and also for 80Ni-20Cr in 10*N* NaOH at 118°C.

The OER potential is slightly lowered with an increase in the caustic concentration or temperature. The OER potential for Ni, depending on the concentration and temperature, is 50-100 mV less noble than for Fe, and that for all their alloys is intermediate between the two. The effects of the NaOH concentration and

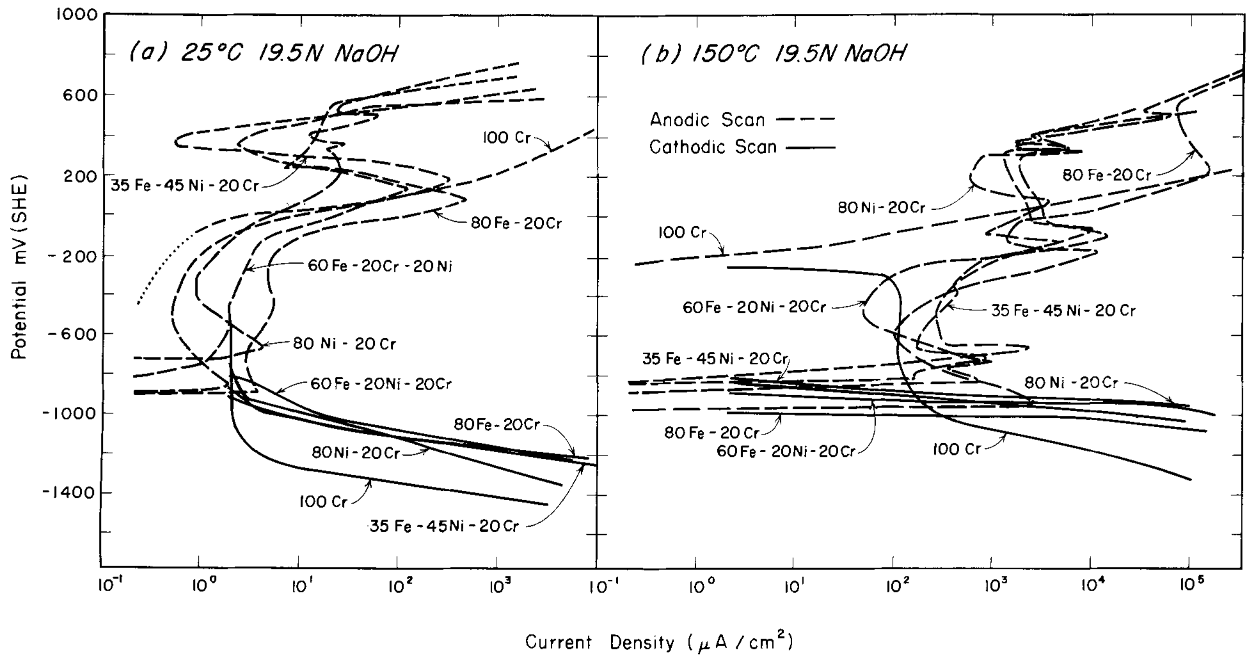

Fig. 8. Polarization behavior of Cr and the Fe-Ni-Cr alloys in 19.5N NaOH at 25°-150°C.

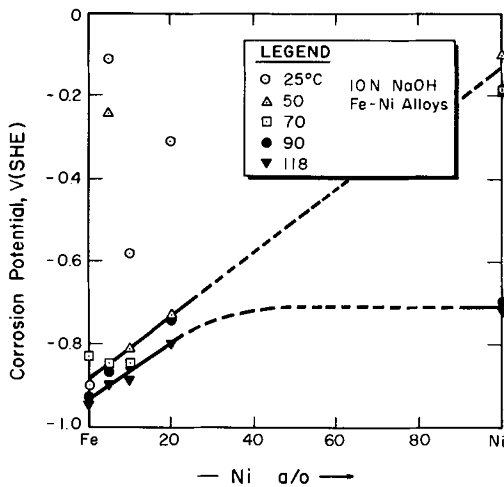

Fig. 9. Corrosion potential of the Fe-Ni alloys in 10N NaOH in the temperature range 25°-118°C.

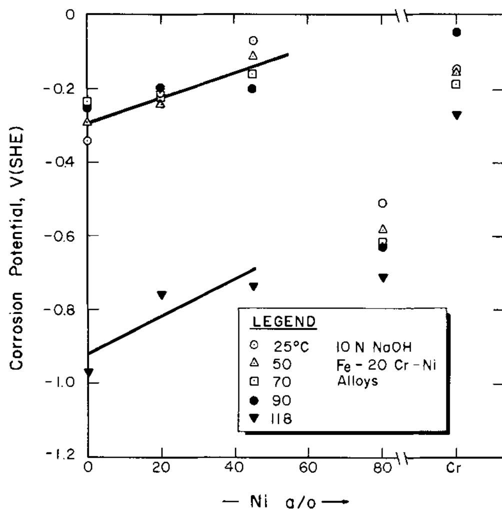

Fig. 10. Corrosion potential of Cr and the Fe-Ni-20Cr alloys in 10N NaOH in the temperature range 25°-118°C.

the temperature on OER kinetics over Fe and Ni is summarized in Fig. 13 and 14, respectively. The OER rates increased directly in proportion to the NaOH concentration with a reaction order of two. The apparent energy of activation for the OER on Fe and Ni is approximately 25.6 and 14.5 kcal, respectively, in 10*N* NaOH.

The cathodic polarization curves of specimens in Fig. 2-8 all show similar behavior. There are two distinct regions in each curve. During the cathodic scan the surface oxide and oxyanion reduction occur at high potential. As the potential decreases the hydrogen evolution reaction (HER) occurs and exhibits Tafel-type behavior. The oxide and the oxyanion reduction in caustic solutions $\leq$10*N* NaOH at temperatures 25°-118°C appears complete, in all cases except Cr, when

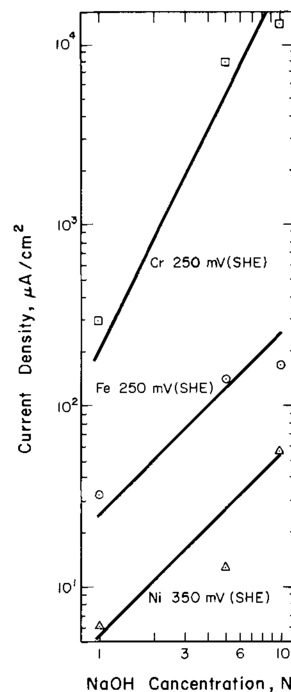

Fig. 11. Current density of Fe, Ni, and Cr at 70°C in the passive or transpassive region as a function of NaOH concentration.

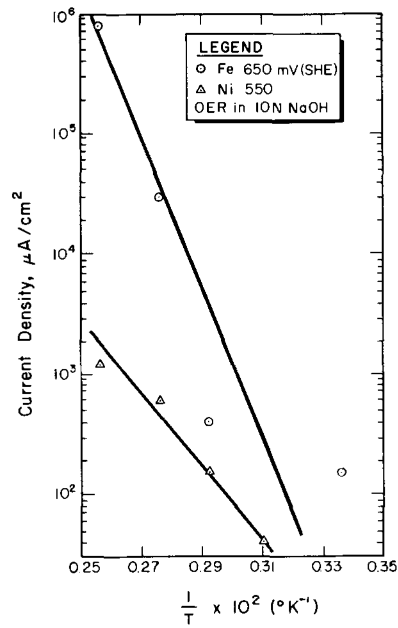

Fig. 14. Arrhenius plot for OER on Fe and Ni in 10*N* NaOH

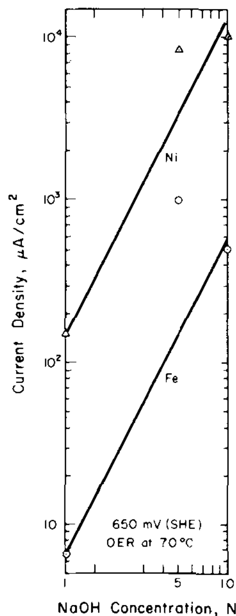

Fig. 13. OER current density on Fe and Ni at 70°C as a function of NaOH concentration.

the cathodic current density reaches ~100 $\mu A/cm^2$ at -950 ± 50 mV (SHE). The current density and the potential in 19.5*N* NaOH at 25°C are, except for Cr, ~50 $\mu A/cm^2$ and -1050 ± 50 mV (SHE). The cathodic scan in 19.5*N* NaOH at 150°C was done over a very limited potential range because of experimental difficulties; therefore, the above region is not identifiable in the polarization curves.

In the case of Cr, the oxide and oxyanion reduction in 5 and 10*N* NaOH at various temperatures appears complete at ~100 $\mu A/cm^2$ as shown in Fig. 2 and 6. The corresponding potential values vary considerable, *e.g.*, in 10*N* NaOH the approximate values at 25° and 90° are -1450 and -900 mV (SHE), respectively. The potential and the current density in 1*N* NaOH at 70°C are -1150 mV (SHE) and ~500 $\mu A/cm^2$, while in 19.5*N* NaOH the respective values at 25°C are -1250 mV (SHE) with 10 $\mu A/cm^2$, and at 150°C -110 mV (SHE) with ~400 $\mu A/cm^2$.

The value of the Tafel slope for HER on Fe-Ni-Cr alloys as a function of temperature and caustic concentration is listed in Tables I and II. There is no specific effect of temperature or caustic concentration on the HER Tafel slope. The slopes on Fe and Ni are approximately 75 and 100 mV, respectively. The slope for Cr varies irregularly with temperature and caustic concentration from 75 to 325 mV.

Figures 15 and 16 show the effects of NaOH concentration and temperature on the HER kinetics. The rate of the HER on Fe and Ni decreased with an increase in the caustic concentration except for Cr where the opposite effect was observed. The apparent energy of activation for all three metals is approximately 11 kcal in 10*N* NaOH.

Discussion

For convenience in relating the features of the polarization curves with the thermodynamic boundary con-

ditions we show on the polarization curves of the pure components the location of the relevant equilibria in Fig. 17. Where a soluble species is involved we take its concentration as 10^{-6}M and the pH is taken as 14. The equilibrium data for Fe and Cr was taken from the Pourbaix Atlas (21) and that for Ni at 100°C was taken from Cowan and Staehle (22).

With respect to correlating the potentiodynamic determination with the Pourbaix diagram the OER and HER occur in potential ranges where they are expected.

For iron the anodic peak occurs in the region just above the $Fe/HFeO_2^-$ equilibrium as expected. The passivity observed at higher potentials is possibly due to the formation of Fe_3O_4 and then Fe_2O_3. The curves for pure iron show also a sharp depression at −550 mV. The current dropped below 1 μA in one case (curve shown as discontinuous because of the scale limitation), Fig. 2a. This is probably due to the partial anodic and cathodic current densities being of the same order of magnitude, although the HER potential is more negative at −825 mV. It would seem then that the initially formed Fe_3O_4 is very protective but the subsequent Fe_2O_3 is less so.

For pure nickel, like iron, the anodic peak occurs in the region defined by the $Ni/HNiO_2^-$ equilibrium. Despite the broad range of stability of $HNiO_2^-$, a protective film forms above the anodic peak and extends for several hundred millivolts. At approximately the potential where Ni_3O_4 is stable the film becomes less protective.

In the case of pure Cr while the Cr/CrO_3^{---} equilibrium occurs at about −1400 mV the anodic region for chromium is not observed until −200 mV. This may simply result from a submerged anodic region rendered inaccessible by the additivity of partial currents. These partial currents appear to result primarily from the reduction of Cr_2O_3 previously present on the surface. An inflection in anodic kinetics is observed in Fig. 2 where the product changes from CrO_3^{---} to CrO_4^{--}. The inflection occurred at −50 mV compared to the predicted −190 mV from the Pourbaix diagram. Second, for alloys containing Cr, see Fig. 4, the film loses its integrity where CrO_4^{--} becomes stable although at a slightly higher potential a new but less stable film forms. In the 80Ni-20Cr alloys in Fig. 4d it is possible to observe peaks at 0 and 220 mV. The

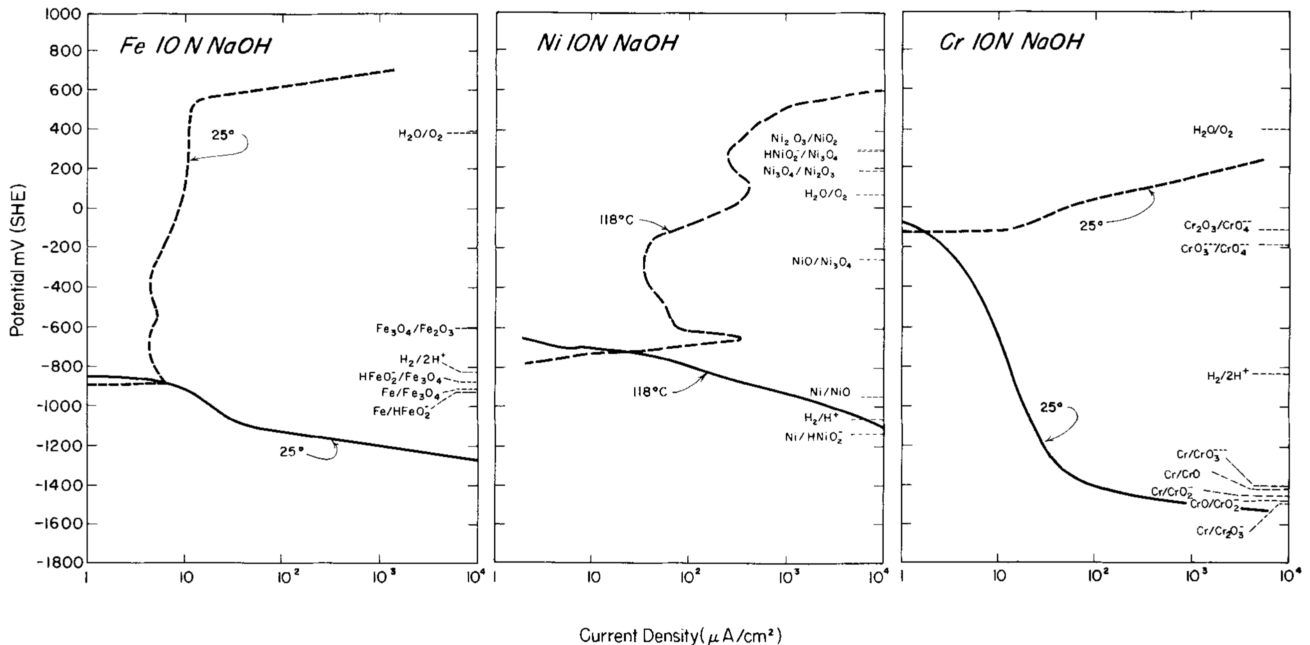

Fig. 17. Polarization behavior of Fe, Ni, and Cr in 10*N* NaOH and the thermodynamic equilibrium of various species in pH 14 solution

lower peak is due to CrO_4^{--} formation and the higher peak is due to the formation of Ni_3O_4.

The significant features of the curves for the alloys clearly depend on the characteristic features of the pure components. One has only to compare the pure Fe and Ni curves with that for Fe-Ni alloys in Fig. 2 and 3.

It is interesting that an "anomalous" passivity is obtained in the caustic solution as in the acidic solution which is more extensively described in the literature. In particular for Ni while the soluble oxyanion $HNiO_2^-$ is the most stable species the specimen exhibits excellent passivity.

Since the purpose of this study was a broad survey no detailed mechanistic arguments are advanced. The kinetic parameters obtained are not sufficient for mechanistic interpretation of the results. A careful analysis of the partial currents, obtained by chemical analysis of the electrolyte for dissolved components, both in the active and the passive regions, would be required to supplement the present study. Such a study is underway in our laboratory.

With respect to using these alloys in caustic service, the already well-known desirability of nickel is vindicated. In particular see Fig. 5 and 6. In Fig. 5 the pure nickel is at least one order of magnitude more corrosion resistant than the pure iron. In Fig. 6 the 80Ni-20Cr alloy is over an order of magnitude better than the 80Fe-20Cr binary. Polarization in 1-10*N* concentrations of caustic solutions show generally similar patterns. However, in the saturated solution (19.5*N*) all alloys exhibit approximately the same features below -250 mV while above this value the superior behavior of the Ni-Cr is again evident.

Conclusions

1. The dominant effects of the alloy composition for Fe-Ni-Cr in caustic solutions at the boiling point and below are the following: (*a*) The presence of nickel in iron or chromium alloys produces significant improvement in corrosion resistance. (*b*) Adding chromium to nickel or iron is generally deleterious.

2. Increasing the temperature from room temperature to the boiling point increased the reaction rate by 1-3 orders of magnitude.

3. Increasing the NaOH concentration from 1 to 10*N* at constant temperature increased the reaction rate about one order of magnitude.

4. Fe-Ni-Cr alloys in the caustic solution exhibit an active-passive behavior. Pure chromium exhibits only the transpassive behavior.

5. Significant features of the polarization curves correlate very well with predictions of the Pourbaix diagram both with respect to M/HMO_2^- dissolution and oxide formations.

6. HER and OER reactions follow generally predicted behavior.

7. The corrosion potential shifts to negative values with an increase in temperature and caustic concentration.

Electrolytically Formed Polyimide Films and Coatings

I. Electrodeposition from Colloidal Dispersions

D. Colin Phillips

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

A process was developed for the electrophoretic deposition of polyamic acids onto metal electrodes and subsequent conversion to the corresponding polyimide. Polyamic acids were electrodeposited from colloidal dispersions of amine salts of the corresponding acids contained in a mixed organic solvent system. The tough, adherent, pin-hole free coatings have excellent mechanical, physical, and thermal properties. Correlations of coating thickness with current density, bath composition, and electrodeposition time are discussed and a mechanism for polymer electrodeposition is postulated.

Most electrophoretic deposition studies (1) have been involved with aqueous systems. For industrial scale-up of the process, these systems present obvious advantages, such as lack of dangerous fumes, minimized fire hazard, and inexpensive bath media. However, aqueous depositions are adversely affected by gas evolution (from water electrolysis) at the electrodes. Often, in such systems, gas bubbles prevent good film formation at the electrode by rupturing and dislodging the deposit. Electrophoretic deposition is also possible from nonaqueous solvents (2) and, in this instance, the solution conductivity is governed by laws different from those valid in aqueous solutions. In nonaqueous solvent systems, solution conductance is often very low, but may be compensated by applying high voltages at low currents without incurring solvent electrolysis or high heating effects.

The process of organic electrodeposition is thought to be highly complex (3). During electrocoating, several mechanisms are believed to occur to varying degrees. These are generally thought to be electrophoresis, electrocoagulation, electro-osmosis, and electrode reactions (4).

Electrophoresis involves the movement of charged particles or ions, dispersed or dissolved in a liquid medium, toward an electrode under the influence of an electric field. Whereas simple ions have only one to four units of charge, colloidal particles carry a large number of unit charges on their surfaces. Each of these particles is thought to be surrounded by a cloud of counterions. The charge of these particles gives rise to the electrokinetic potential or the zeta potential, which is defined as a measure of the electrokinetic charge that surrounds suspended particulate matter. Because of this charge, there is a mutual repulsion of these particles and this is why these dispersions are stable. The charges on the colloidal particles are probably due to a combination of adsorbed ions from the solution, from adsorbed surfactant groups, and from the particle itself having ionized groups at the liquid-particle interface. The mobility is affected by the viscosity of the medium and the size, shape, and concentration of particles, pH and concentration of electrolyte.

Electrocoagulation is the coalescence of charged moving particles in the vicinity of the electrode. The densification is a highly complex reaction. There is not complete agreement as to the actual process which occurs at this point in the electrodeposition when the particle loses its charge and coagulates. The resin particle has several adsorbed ions distributed on its surface. These negatively charged ions surrounding the resin particle will attract positively charged ions, and thereby create a secondary region encompassing the resin particle. This effect is known as the cloud layer or double layer. Each particle finds itself in an atmosphere of ions of opposite sign, with a concentration gradient depending essentially on the charge of the particle and on the composition of the dispersing medium. The double layer is thought to be diffuse, with the outer layer possessing an electric density falling off according to an exponential law. The repelling effect exerted when two charged particles approach each other exists only if the liquid medium possesses some degree of ionizing action. Electrophoresis involves a tangential motion of one phase of the double layer with respect to the other, and it occurs only if the two phases carry free charges of opposite sign.

Electro-osmosis is the movement of the liquid phase under the influence of the electric field and is often referred to as the reverse mechanism of electrophoresis. The medium in which the resin particles are dispersed moves in the opposite direction, that is, away from the film forming on the electrode. This seems to be caused by the counterions of the deposited particles which move away from the film.

Numerous organic and inorganic electrochemical reactions occur at or around the electrodes (4). The importance of the significant role played by the electro-dissolved metal has been indicated by Fink (5) and Tawn *et al.* (6). A more comprehensive study of the electrode reactions occurring during electrodeposition has been made by Smith and May (7, 8) and substantiated by Mercouris *et al.* (4).

Prior to this work, polypyromellitimide (polyimide) films have been produced by solution casting, followed by a heat cure. One major problem with producing polyimide films by the solution casting technique is that only relatively thin films can be produced in a one coat process. Heavier coating or film thickness must be made as a multicoat system, with each coat being dried (solvent removal) and cured before applying the subsequent coat. Also, polyimide coverage of irregular-shaped objects has proven to be impossible by solution casting. Most, if not all, of the above-mentioned problems are eliminated or become quite insignificant if the polypyromellitamic (polyamic) acid precursor is electrodeposited directly onto the substrate. Solution viscosity becomes irrelevant; solvent problems are greatly minimized; much heavier single coat thicknesses are achievable; and the resulting corner and edge coverage is more than adequate.

In the present work, commercially available polyamic acids have been successfully electrodeposited from colloidal dispersions of amine salts of the corresponding acids in mixed organic solvent systems.

Experimental

Materials.—Commercially available polyamic acid solutions, such as, Pyre-M.L. wire enamel (E.I. du Pont de Nemours Company), Dynimel (3M Company), and

Key words: electrodeposition, polyimides, polyamic acids, electrocoating, coatings.

AI-8 wire enamel (Westinghouse Electric) were used as received. The solvents (Fisher Scientific Company), acetone (containing 0.5% water), dimethylsulfoxide (containing 0.2% water), dimethylacetamide (containing 0.2% water), N-methyl-2-pyrrolidone (containing 0.5% water), and the bases (Aldrich Chemical Company), trimethylamine, triethylamine, N,N-dimethylbenzylamine, 1-methylimidazole, were used without further purification.

Apparatus.—Briefly, the apparatus consists of a 1000 ml glass reaction vessel with cover. From the cover, two stainless steel rods are suspended. These are sealed into two glass tubes by means of Teflon insert rings. Normally, two aluminum or copper electrodes were suspended from the lower ends of the steel rods, each electrode having a surface area of approximately 44 in.^{2}. The size of electrode or metallic composition could be varied, depending on the parameter being investigated. Approximately 600 ml of colloidal dispersion was placed in the vessel and connection to a d-c power supply (Kepco, Model SM160-4) was made through the two stainless steel bars.

Procedure.—Formation of a colloidal dispersion, suitable for electrodeposition, initially involves dissolving the commercially available polyamic acid in a solvent, such as dimethylsulfoxide. An amine is added to this solution to produce the organic salt of the free carboxyl groups, present in the polyamic acid. The solutions is heated to approximately 40°C and maintained at this temperature for 15 min. Finally, the resulting solution is added to a nonsolvent, such as acetone, during which time the acetone is stirred vigorously. This results in the production of a colloidal suspension of the salt, contained in a mixed organic solvent system, comprised of acetone and dimethylsulfoxide.

Suitable commercially available polyamic acids are Pyre-M.L. wire enamel, Dynimel, and AI-8 resins. Organic bases, such as trimethylamine, triethylamine, N,N-dimethylbenzylamine, and 1-methylimidazole were used for salt formation. Alternative solvents for the resins were dimethylacetamide and N-methyl-2-pyrrolidine and higher boiling ketones could be substituted for acetone. Nonsolvents which electrolyzed during the passage of current were not suitable, since most of these produced gaseous products which prevented good film formation at the electrode.

After electrodeposition, the polyamic acid films and coatings, which were produced at the anode, were heat cured to ~300°C in a convection oven over a period of 30 min. This led to the formation of smooth, uniform, pin-hole free polyimide coatings over the entire anode surface.

Results and Discussion

Parameters investigated.—The relatively large number of parameters involved in this type of system present many difficulties. In general, only the parameters involved in the optimization of electrodeposition were investigated. These were solution composition, electrodeposition time, electrode material, and current density.

Correlations of final, cured coating thickness with base, dimethlylsulfoxide, and acetone bath content have been made. No apparent interaction occurred between the amine component and the acetone/dimethylsulfoxide solution. The variation of coating thickness with triethylamine:Pyre-M.L. ratios is shown in Fig. 1. In these experiments all variables, other than the one under investigation, were kept constant. The current density was varied for each concentration and the final coating thicknesses were determined by means of a Permascope film thickness measuring device. Aluminum electrodes having a total surface area of 44 in.^{2} with a 1-in. separation were used. It can be seen that each current density curve flattens when the triethylamine:Pyre-M.L. ratio is approximately 0.2:1. Hence, in this instance, optimum coating properties are achieved when the polyamic acid concentration is five times that of the base. In dispersions having polyamic acid/amine ratios of greater than 5:1, film thickness is variable because complete salt formation between all the available carboxyl groups, along the polymer chain, has not occurred. Dispersions having polyamic acid/amine ratios of ≤ 5 gave, essentially, the same coating properties. At these values, all the available carboxyl groups, along the polymer chain, have reacted to give the salt. Hence, film thickness is invariant when the amine is in excess of that needed for salt formation.

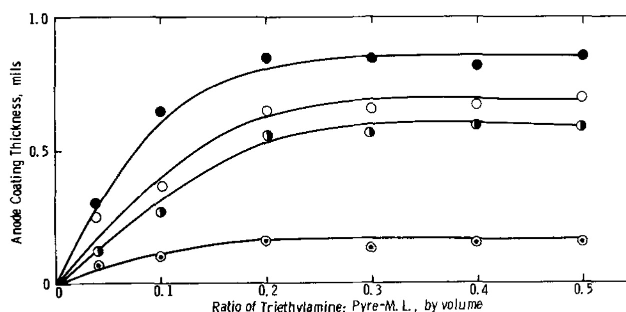

Fig. 1. Variation of coating thickness with triethylamine: Pyre-M.L. ratios. ● Current density 4.6 mA/in.^{2}, ○ current density 3.4 mA/in.^{2}, ◑ current density 2.3 mA/in.^{2}, ⊙ current density 1.1 mA/in.^{2}. Electrodeposition time 20 sec. Total aluminum electrode area 44 in.^{2}. Electrode separation 1 in.

Figure 2 shows the variation of coating thickness with acetone:dimethylsulfoxide ratios. Constant electrodeposition times of 20 sec were employed for each set of current densities. In this case, optimum coating thicknesses were achieved when the acetone to dimethylsulfoxide ratio is five to one. Whereas the organic salt is soluble in dimethylsulfoxide it is not soluble in acetone. In solutions having acetone/dimethylsulfoxide ratios <5, some of the organic salt was soluble in the solvent system. As the solution strengthened in dimethylsulfoxide content, this reduced the concentration of colloidal particles within the over-all dispersion. Hence, less particles are available for electrodeposition and coating thickness is reduced as the amount of acetone decreases in the acetone/dimethylsulfoxide ratio. The salt is not soluble in solutions having acetone/dimethylsulfoxide ratios ≥ 5 and at these values the coating thickness is invariant with acetone concentration.

Utilizing the results found in Fig. 1 and 2, the bath composition giving rise to optimum coating properties was considerd to be: 50 ml Pyre-M.L., 10 ml triethylamine, 200 ml dimethylsulfoxide, and 1000 ml acetone.

An additional series of experiments was done to determine the effect which deposition time and current

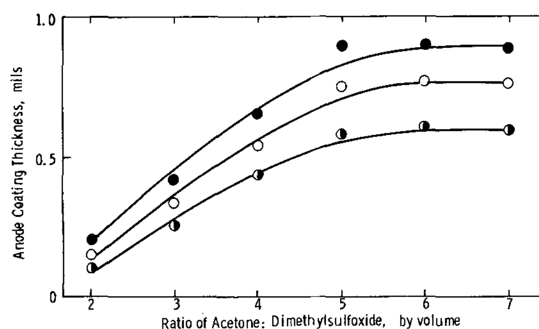

Fig. 2. Variation of coating thickness with acetone:dimethylsulfoxide ratios. ● Current density 3.4 mA/in.^{2}, ○ current density 2.3 mA/in.^{2}, ◑ current density 1.1 mA/in.^{2}. Electrodeposition time 20 sec. Total aluminum electrode area 44 in.^{2}. Electrode separation 1 in.

density had on the final coating thicknesses. The results are shown in Fig. 3, which depicts the variation of coating thickness with the former parameters. Again, identical bath composition, electrode area, and separation were used. Thicker coatings were obtained at longer deposition times and a linear relationship existed between applied current density and final coating thickness. Wet (uncured) coatings of >10 mils could be obtained when the current density was applied for a sufficiently long period of time. Similar results were discovered in a series of experiments in which the effect of applied voltage was studied. Figure 4 shows the effect of applied voltage and electrodeposition time. Again, when other variables were kept constant, a linear relationship existed between anode coating thickness and applied voltage over a time interval range of 20-60 sec.

The decay of current density with electrodeposition time at constant applied voltage was observed in another series of experiments. Some observations were made using a copper anode and cathode, whereas others were made with an aluminum anode and cathode. For similar current densities, very similar coating thicknesses were obtained on both aluminum and copper anodes. Figure 5 shows different current density fall-off curves for each electrode pair. An identical electrodeposition set-up was used in each instance,

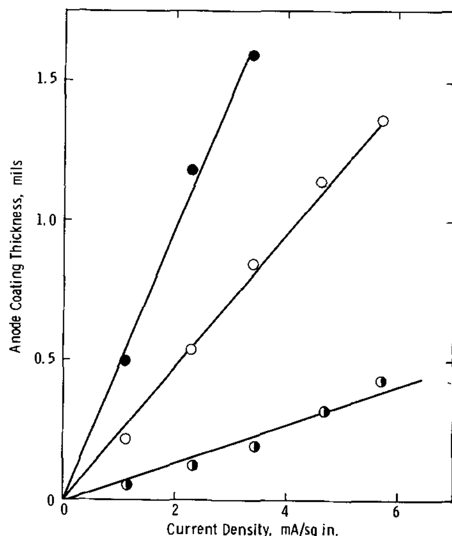

Fig. 3. Variation of coating thickness with current density and electrodeposition time. ● Bath time 70 sec, ○ bath time 40 sec, ◑ bath time 10 sec. Fig. 4. Variation of coating thickness with applied voltage and electrodeposition time. ● Bath time 60 sec, ○ bath time 40 sec, ◑ bath time 20 sec. Total aluminum electrode area 40 in.^{2}. Electrode separation 1.5 in. Bath composition: 200 ml Pyre-M.L., 300 ml dimethylacetamide, 40 ml 1-methylimidazole, 75 ml methyl isobutyl ketone.

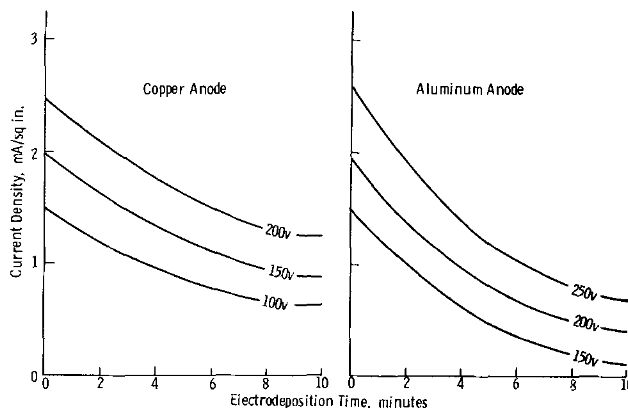

Fig. 5. Constant voltage, current-time plots for colloidal solutions using copper and aluminum anodes. Electrode separation 2 in. Bath composition: 200 ml Pyre-M.L., 40 ml 1-methylimidazole, 300 ml DMSO, 3200 ml acetone.

only the electrode material was varied. The current density fall-off was found to be much more rapid when an aluminum anode and cathode were used. Lower peak current densities were found on aluminum than on copper. This is consistent with the possibility of an oxide layer being present on the aluminum.

Finally, a comparison of the electrocoating capabilities of various commercially available polyamic acids was made. The solutions had identical bath compositions, electrode area, and separation. The electrodeposition time, in each instance, was kept constant at 20 sec and the results are given in Fig. 6. The variation of anode coating thickness with applied current density is shown. Surprisingly, the electrocoating capability is almost identical for Pyre-M.L., Dynimel, and AI-8 resin. This seems to suggest that the basic composition of each of these polyamic acids is very similar. All give rise to approximately a 1 mil coating thickness after applying a current density of 5 mA/in.^{2} for an electrodeposition time of 20 sec. It would appear that the slight differences which were observed were due to the small variations in the solid contents of the original polyamic acid resins.

Under conventional electrodeposition times, increased bath temperature was not observable. Only when the bath was run continuously for more than 3 hr was an appreciable rise in temperature noticed. Bath pH was always in the 8-9 region and for short

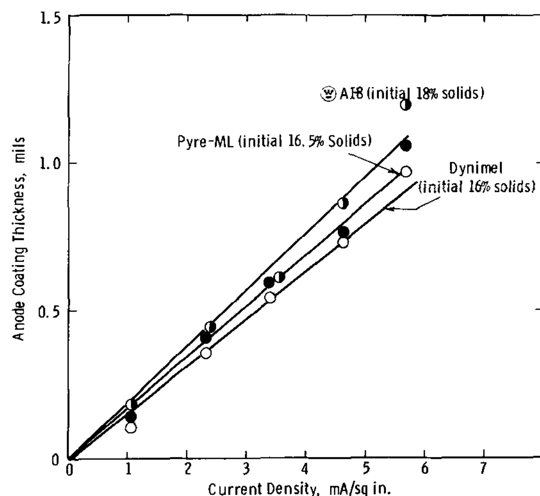

Fig. 6. Variation of coating thickness with current density. Electrodeposition time 20 sec, aluminum electrode separation 1.25 in. Bath composition: 50 ml resin, 10 ml 1-methylimidazole, 200 ml dimethylsulfoxide, 1000 ml acetone.

electrolysis times (*i.e.*, 15 min and under), there was no necessity to stir the solution, as no precipitation or agglomeration of the resin was observed.

Analysis of coatings.—Infrared and emission spectra analyses were made on the "wet" (uncured) and final coatings in order to better understand the electrodeposition process mechanism. The conversion of the free polyamic acid to the polyimide can be followed spectroscopically by the disappearance of the —NH band at 3.1μ (3230 cm^{-1}) and the appearance of imide bands at 5.64μ (1770 cm^{-1}) and 13.9μ (722 cm^{-1}). The appearance of these same bands can be seen in the spectra in Fig. 7, which show the conversion of polyimide from wet electrodeposited polyamic acid films.

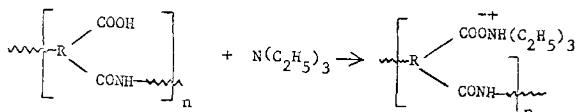
A comparison was also made between the infrared spectra of a polyamic acid cast from dimethylsulfoxide solution and the same acid electrodeposited from colloidal dispersion. The spectra are essentially identical. The corresponding spectra of the cured polyimide were also the same. Hence, no amine component (used in salt formation) is present in the wet electrodeposited film. The identical nature of the spectra is substantiated by the fact that the electrical and mechanical properties of polyimides cast from solution and electrodeposited are very similar.

Emission spectra analyses of cured coatings, which had been carefully stripped from aluminum and copper substrates, were determined. Aluminum content of the coatings was <10 ppm, whereas copper content varied from 0.1 to 2.9% depending on electrolysis time, bath concentration, etc. By comparison with the emf series in aqueous solutions, such behavior is expected. The latter range for copper compares with iron content figures of 0.13-0.27% and 0.01-2.0% found in electrophoretically deposited resin coatings by May (8) and Mercouris (4), respectively. Mercouris was concerned with polyacrylic acid deposition and May with epoxy deposition, both from aqueous media. The iron content in these coatings has not yet been successfully explained. Explanations, for the existence of iron, vary from stable iron oxides (9) to organometallic salts (4, 10) of the form [(Colloid-R)COO]$_2$Fe.

A copper compound, similar to the above organo-iron salt, does not appear to be a feasible suggestion to explain the copper contents of the electrodeposited polyamic acid films, since such a compound would have been detected by infrared analysis, which showed normal polyamic acid films. At this time, the formation of stable inorganic copper salts cannot be ignored, but further work appears necessary to elucidate the true role of copper in this system.

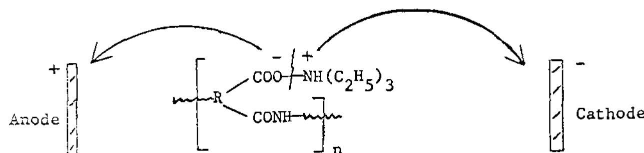
Mechanism.—From analysis studies and the various parameters investigated, the following over-all mechanism for electrodeposition is postulated.

Polymer salt formation



The polyamic acid is depicted by a polymer chain containing carboxyl and amide groups. Addition of a base, such as triethylamine, produces the triethylammonium salt of the free carboxyl group.

Ionization and migration

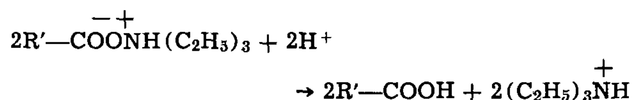


Under the influence of the electric field, it is envisaged that the salt ionizes to produce the triethylammonium ion and the carboxyl ion of the polymer, which subsequently migrate to cathode and anode, respectively.

Anode and cathode reactions.—At the anode, trace amounts of water (present in acetone dimethylsulfoxide, etc.) are thought to be involved in the electrodeposition

$$H_2O \rightarrow 2H^+ + \frac{1}{2} O_2 \text{ (gas)} + 2e$$

followed by hydrolysis of the salt at the anode surface



$$2R'\text{—}\overset{-+}{COONH}(C_2H_5)_3 + 2H^+ \rightarrow 2R'\text{—}COOH + 2(C_2H_5)_3\overset{+}{N}H$$

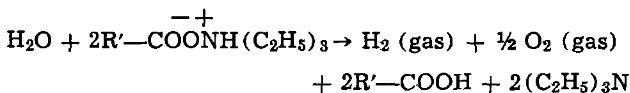
where the remainder of the polymer chain is written as R′.

At the cathode, the following reactions are thought to occur

$$2H_2O + 2e \rightarrow H_2 \text{ (gas)} + 2(OH)$$

$$2(C_2H_5)_3\overset{+}{N}H + 2(OH)^- \rightarrow 2(C_2H_5)_3N + 2H_2O$$

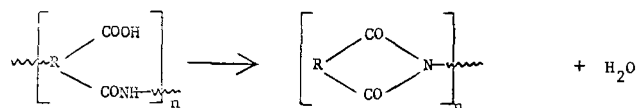
The over-all cell reaction becomes



$$H_2O + 2R'\text{—}\overset{-+}{COONH}(C_2H_5)_3 \rightarrow H_2 \text{ (gas)} + \frac{1}{2} O_2 \text{ (gas)} + 2R'\text{—}COOH + 2(C_2H_5)_3N$$

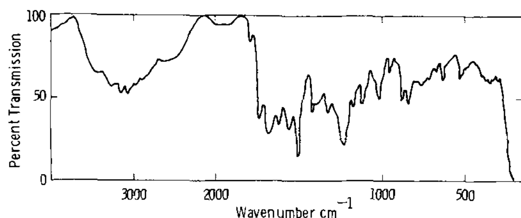
Hence, the formation of the polyamic acid film on the anode would appear to be the consequence of the increased local acidity of the region immediately adjacent to the anode which results from the electrolysis of water.

Heat cure

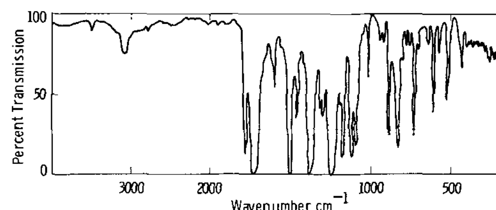


Subsequent heat cure at 300°C gives rise to the loss of water and produces the characteristic polyimide ring structure.

Coating properties.—It appears that, using the solution formulations previously described, polyamic acids can be successfully electrodeposited on any metallic



a. Infrared spectrum of uncured Pyre-M.L. film (electrodeposited from colloidal solution).



b. Infrared spectrum of cured Pyre-M.L. film (electrodeposited from colloidal solution).

Fig. 7. Infrared spectra of uncured and cured electrodeposited films

surface. Adherent polyimide electrocoatings have been produced on such metals as aluminum, copper, nickel, iron, zinc, titanium, lead, chromium, tin, and platinum. Aromatic polyimides are extremely heat-stable organic polymers and maintain their mechanical and physical properties over a wide temperature range ($\sim -60°$ to $+400°C$). A summary of some of these properties is shown in Table I. Some tests were made on films, which had been carefully stripped from the metallic substrate, whereas others were performed on coatings adherent to the metal.

The electrical properties of the electrodeposited coatings are virtually identical with the same polyimide, which has been cast from solution in the conventional manner. From Table II, it can be seen that the coatings have a high dielectric strength (~5-6 kV/mil), low dissipation factor (~0.0007 at 60 Hz), and moderately high dielectric constant (~3-3.5 at 60 Hz).

Table I. Mechanical, physical, and thermal properties of electrodeposited Pyre-M.L.

Property	Typical value at 25°C	Test method
Folding endurance*	>30,000 cycles	ASTM D-2176-63T
Ultimate elongation*	60-70%	ASTM D-882-64T
Impact test†	80 in-lb (direct and reverse)	Falling ball impact
Abrasion resistance†	>400g	Hoffman scratch test
Adhesion & flexibility†	No cracking or loss of adhesion (1/16 in. bend)	Conical mandrel
Thermal aging†	Expected life >10,000 hr at 250°C	AIEE Method 57
Tensile strength*	24,000	ASTM D-882
Coefficient of friction*	0.42	ASTM D-1505

* Test evaluated on stripped film.
† Test evaluated on substrate (Cu and Al).

Table II. Electrical properties of electrodeposited Pyre-M.L. at 25°C

Property	Typical value	ASTM test method
Dielectric strength at 60 Hz (kv/mil)	5-6	D149
Dissipation factor at 60 Hz	0.0007	D150
Dielectric constant at 60 Hz	3-3.5	D150
Volume resistivity (ohm-cm)	10^{17}	D257
Surface resistivity at 1 kV, 50% RH (ohms)	10^{16}	D257

Insulation resistance is infinite when dry, and $\sim 5 \times 10^5$ megohms after boiling 10 min in water. These properties manifest themselves over a wide temperature range.

Conclusions

The work reported here shows that an electrophoretic technique can be utilized to produce polyamic acid coatings, which subsequently can be heat cured to produce the corresponding polyimide coatings. The technique seems to be applicable to all metallic surfaces and gives rise to defect-free coatings, having strong adherence to the metallic substrate.

The parameters, which were investigated show that reproducible electrodeposition rates can be achieved, under a variety of experimental conditions. By these means, coating thickness can be predicted to a high degree of accuracy.

Thin and thick polyamic acid coatings can be heat processed to effect ring closure without any apparent deterioration of the film properties. The electrical, mechanical, and thermal properties of the electrodeposited polyimide films manifest themselves over a wide temperature range.

Manuscript submitted May 1, 1972; revised manuscript received July 17, 1972. This was Paper 191 presented at the Cleveland Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussions Section to be published in the June 1973 JOURNAL.

The Inhibition of the Dendritic Electrocrystallization of Zinc from Doped Alkaline Zincate Solutions

John W. Diggle*,[1] and A. Damjanovic[2]

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The effect on zinc dendrite initiation and propagation in 10% KOH of the inhibitors lead, quaternary alkyl ammonium salts, Emulphogene BC-420, Triton X-15 and X-100 is examined. All these are found to affect zinc morphology to varying degrees, lead and quaternary salts being the most effective dendrite inhibitors. The role and type of adsorption, either specific or nonspecific, is discussed and related to the effectiveness of inhibition.

Much interest has been shown recently (1-3) in the use of polyethoxylated aliphatic and phenyl hydroxyl compounds as inhibitors in electrochemical power systems with rechargeable zinc electrodes to prevent the occurrence of zinc densification, and so-called shape change, and hence extend useful cell cycle life (4). Such inhibitors include the compounds with trade names, Emulphogene, Triton, and Igepal, in which ethylene oxide is combined with an aliphatic grouping (Emulphogene), or a substituted aromatic grouping (Triton and Igepal) in various proportions ranging

from about 10 to 70% ethylene oxide content. Adsorption of such compounds on zinc was reported (5) to affect zinc morphology in the potential range in which a zinc electrode is recharged. Emulphogene members are shown to be especially effective in retarding zinc densification and related zinc capacity losses (1, 6).

It is the aim of this work to examine the effect of Emulphogenes, Tritons, and some other compounds on another problem of the solid zinc electrode, that of the initiation and propagation of zinc dendrites. For this purpose, the effect of the following three classes of compounds was examined:

1. The $Pb(OH)_6^{=}$ ions in alkaline solutions. Lead was chosen since it has been shown to affect zinc morphology (7) and reduce the corrosion rate of zinc (8). The addition of metal cations has long been known to affect zinc morphology (9, 10) but little has been offered in the way of explanation apart from the obvious codeposition.

2. A series of the quaternary alkyl ammonium cations ranging from methyl to pentyl. These cations are reported to remain adsorbed even at low negative potentials far below the assumed potential of zero charge (11, 12) and they are thought to be preferentially adsorbed on dendrites (13).

3. The polar molecules (2) Emulphogene BC-420, Triton X-15, and Triton X-100. These compounds were chosen to elucidate the effect of their molecular structure on zinc deposition and inhibition of dendrite growth. Such an effect is expected on the basis of the studies of Blomgren, Bockris, and Jesch (14), and Meibhur (15) according to which aromatic compounds are adsorbed more strongly than aliphatic ones. Emulphogene BC-420 has the given formula tri-decyl-O-$(CH_3CH_2O)_{n-1}$-CH_3CH_2OH, Triton X-15 is $C_8H_{17} \cdot C_6H_4 \cdot O \cdot CH_3CH_2OH$, and Triton X-100 C_8H_{17}-$C_6H_4 \cdot O \cdot (CH_3CH_2O)_9CH_3CH_2OH$. Any structural effect can be ascertained by (*a*) comparing Emulphogene BC-420 (with estimated $n = 1$) with Triton X-15 ($n = 1$), this will ascertain the influence of the aromatic or aliphatic fragment at approximately constant ethylene oxide content; and (*b*) comparing Triton X-15 with Triton X-100 ($n = 10$), this will ascertain the influence of the ethylene oxide content which is 18 and 70%, respectively.

Experimental

Solution preparation.—The solution used throughout this work was a 10% w/v potassium hydroxide containing 0.1M ZnO. No special purification of the solution was made, since it has been shown that extended purification produces no significant effect on the experimental results (16).

The inhibitor was added to the zincate solution in the as-received condition. The quaternary alkyl ammonium salts were supplied by Eastman Organic Chemicals, and lead, as Pb_3O_4, was of the Baker analyzed purity. The Emulphogene and Triton compounds were kindly presented by the General Aniline and Film Corporation, and Rohm and Haas, respectively. Addition of the Pb_3O_4, Triton X-100, and quaternary salts to the alkaline zincate solution did not present any difficulties. However, some difficulties were experienced with the addition of Emulphogene BC-420 and Triton X-15 due to the low solubilities of these compounds in the alkaline zincate solutions. The solution preparation for these two compounds was as follows: to the required amount of Emulphogene and conductivity water a sufficient amount of acetone was added to render the Emulphogene soluble. This solution was then added to a concentrated alkaline zincate solution, followed by dilution with conductivity water to near the required zincate-KOH concentration. Occasionally, it was necessary to add more acetone to solubilize the Emulphogene.[3] The final solution was opaque, thus making difficult the microscopic *in-situ* observation of the propagation rate of dendrites. Therefore, measurements with the Emulphogene and Triton are somewhat more approximate than was previously the case with other additives or in pure zincate solutions (17). The effect of lead was studied in the concentration range 10^{-3} to 10^{-6}M, of quaternary salts in the range 1M to 10^{-5}M, depending upon the individual member, and of the Emulphogene[4] and Triton in the range 1.5×10^{-4} (this being, under present conditions, saturated for BC-420) to 1.5×10^{-5}M, and 1.8×10^{-4} to 1.8×10^{-5}M, respectively.

Electrode preparation.—Preparation of the zinc electrodes was the same as reported previously (17).

Procedure.—Potentiostatic control (Wenking potentiostat) was used throughout this work. The cell for deposition was similar in design to that used in a previous work (17). The volume of the present cell (70 cm^3) was, however, smaller than in the previous cell (500 cm^3). The illumination for microscopic observation was provided via two ⅛ in. diam fiber light pipes inserted into glass guide tubes which projected through the cell walls to within 1 cm of the opposite sides of the electrode. Fiber light pipe illumination was supplied through a quartz iodine bulb housed in an illuminator source (Ealing Corporation).

Experimental procedures were identical to those outlined in a previous work (17). Cathodic polarization curves, when determined, were obtained with freshly prepared electrodes which, after the polarization experiments, were not used any further. All potentials reported here are with respect to the zinc electrodes in the same solution.

The effect of inhibitors on dendrite propagation was determined in "solution exchange" experiments. In this procedure, dendrites were initiated in zincate solution without an inhibitor and the ensuing propagation was allowed to continue for some time, then the length of several dendrites was measured (17). The zincate solution was then withdrawn and quickly (30 sec) replaced by the zincate solution containing an inhibitor and the same dendrites were then observed in the microscope to ascertain if, and to what extent, the inhibitor affected their growth and rate of propagation. The potentiostat was in the off position during the exchange of the solution and 2 min following the exchange. This was done because some irregular behavior in the total current-time was observed for a short period (about 1 min) following the exchange.[5]

Results

Effect of Lead Ions on Dendritic Growth

Initiation time.—Figure 1 illustrates the effect of lead ion concentration on the total current density-time behavior.[6] The effect is negligible at 10^{-6}M, and completely effective at 10^{-4}M lead. At the latter concentration the *i-t* relationship is indicative (16) of compact zinc deposition. At 10^{-5}M, the behavior is indicative neither of dendritic nor of compact growth, but reflects the observed disk-like morphology (Fig. 2) where the real surface is apparently increasing faster than in the case of dendritic growth.

Table I summarizes the influence of lead concentration on the initiation of dendrites and the morphology of zinc deposits at various overpotentials. At the over-

[3] Concentration of acetone was usually 200 cm^3/1000 cm^3 of the final solution. This concentration of acetone in pure zincate electrolyte, i.e., in the absence of Emulphogene or Triton, was found to have no significant effect on either the initiation time or the dendrite propagation rate. In this respect, acetone is as ineffective as benzene (16), probably due to negligible adsorption at potentials far negative with respect to the zero charge potential of zinc.

[4] In the case of Emulphogene BC-420 1.5×10^{-4}M, was equivalent to 7.4×10^{-3}% w/v.

[5] The essential effects of the inhibitor were unaffected by similar exchange procedures.

[6] In all material that follows reference to a total C.D. implies the total current flowing divided by the initial cathode area 3×10^{-2} cm^2. Thus as the surface area of the cathode changes during deposition, so the total C.D. reflects such changes.

Fig. 2. Disk-type zinc morphology produced under the following conditions: 10% KOH, 0.1M ZnO, 10^{-5}M Pb, $\eta = -100$ mV, $T = 35°C$. Magnification X22.

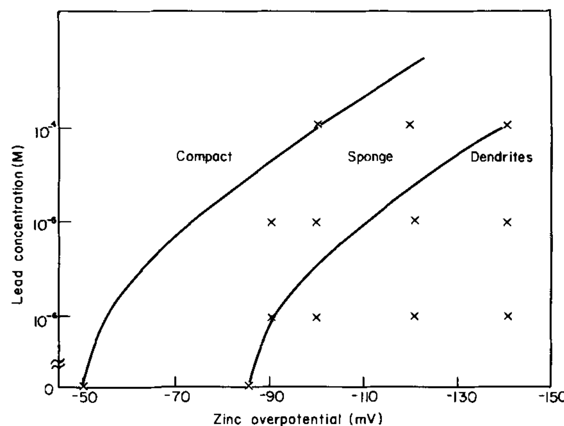

Fig. 4. Zinc morphology profiles with respect to overpotential and dopant lead concentration. Basic electrolyte 10% KOH + 0.1M ZnO. $T = 35°C$.

potential of -100 mV, the morphology changes from dendritic through a disk type of deposit (Fig. 2), to a spongy (Fig. 3), and finally to a compact zinc deposit as the concentration of lead ions increases from 10^{-6} to 10^{-4}M. When the lead ion concentration was increased further to 10^{-3}M, lead dendrites, instead of zinc dendrites, appeared to have formed. The lead dendrites are distinguished from zinc dendrites by the angle that the side branches subtend to the main dendrite axis, this being 90° for lead and 120° for zinc (18). From the same table it is evident that the effectiveness of lead ions in preventing the formation of dendrites decreases as the zinc deposition overpotential becomes more negative. Thus, at the concentration of lead of 10^{-5}M, no dendrites are formed at overpotentials of -90 or -100 mV, but they do form at -120 or -140 mV. The higher the concentration of lead ions, the more negative is the potential (higher overpotential) at which dendrites will appear (Fig. 4).

Propagation of dendrites.—Table I summarizes also the effect of the presence of lead ions in the zincate solution on the rate of propagation of dendrites found in solution exchange experiments. The trend observed parallels that found for the initiation of dendrites, *i.e.*, when the zincate solution with no lead ions is replaced

Table I. Influence of lead concentration on the initiation and propagation of zinc dendrites. Basic electrolyte throughout: 0.10 molar zincate in 10% w/v potassium hydroxide. Temperature 30°C

Lead concentration (molar)	Zinc overpotential (mV)	Initiation: Effective in preventing initiation	Initiation: Morphology observed	Propagation (solution exchange): Effective in stopping propagation	Propagation (solution exchange): Morphology produced after solution exchange
10^{-4}	-100	Yes	Compact	Yes	Compact
	-140	Yes	Sponge	Yes	Sponge
10^{-5}	-90	Yes	Compact & Sponge	Yes	Sponge
	-100	Yes	Disks	Yes	Disks
	-120	No	Dendrites	No	—
	-140	No	Dendrites	No	—
10^{-6}	-90	Partially	Dendrites & sponge	Very slightly effective	—
	-100	No	Dendrites	No	—

by the solution containing lead ions in the concentration of 10^{-6}M, the dendrites which had initially grown in pure zincate solution continued to grow, whereas when the solution was replaced by the one containing 10^{-4}M lead ions dendrites stop propagating. Figure 5 shows the total current density at overpotential of -100 mV before and after solution exchange with 10^{-4}M lead ion solution. The data on the exchange of pure zincate solution with 10^{-6}M lead ion solution are also shown. It is evident that the lead ion concentration of 10^{-6}M does not retard dendrite propagation to any extent (the *i-t* behavior being identical to that obtained in the zincate solution without lead) whereas in the presence of lead ions in the concentration of 10^{-4}M any further dendrite growth is completely prevented, as observed in the microscope. Consequently, as already formed dendrites stop propagating and new dendrites are not nucleated, any further rapid increase in total current ceases. Double exchange of solution, *i.e.*, zincate solution with no lead, followed by the solution with 10^{-4}M lead ion and then followed again by zincate solution, shows the *i-t* behavior as in Fig. 6. Upon subsequent removal of the solution containing

lead ions, dendrites recommence to propagate at a rate close to the original rate as judged from the similar slopes of the *i-t* curve at points of the same currents, and microscopic observations.

Figure 7 shows the dendrite tip before and after solution exchange with 10^{-4}M lead ion solution.[7] After the exchange, the tip appears to have lost the radius of curvature which was considered to be essential for the fast rate of dendrite propagation (17).

Effect of Quaternary Ammonium Salts on Dendritic Growth

Initiation time.—Figure 8 illustrates the effect of the addition of tetrabutyl ammonium bromide on the *i-t* behavior as a function of concentration of tetrabutyl ammonium bromide in the range 10^{-5}-10^{-2}M.[8] The effectiveness in suppressing the dendritic growth and producing a compact zinc deposit, as indicated by the *i-t* behavior (cf. Fig. 8) and confirmed by microscopic observations, increases as the concentration of tetrabutyl ammonium bromide increases. In the solutions with more than 10^{-3}M of the salt, the total current at the overpotential of -100 mV is nearly invariant with time and is less than that obtained in

[7] These photomicrographs were obtained in two separate experiments.

[8] Concentrations in this range of KBr have been ascertained as having no influence on either the initiation or propagation of zinc dendrites.

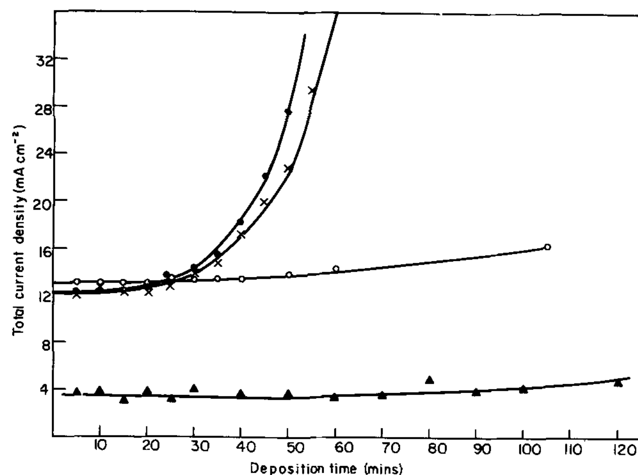

Fig. 8. Total current density-time behavior observed for zinc deposition from ● pure alkaline zincate solution 10% KOH + 0.1M ZnO, $\eta = -100$ mV. $T = 30°C$. x Doped with $10^{-4}M$ $(C_4H_9)_4N \cdot Br$, ○ $10^{-3}M$ $(C_4H_9)_4N \cdot Br$, ▲ $10^{-2}M$ $(C_4H_9)_4N \cdot Br$.

the undoped system or in those corresponding to 10^{-3} and $10^{-4}M$ of the salt.

The polarization curves reported here in Fig. 9, 11, 14, and 15 were obtained using a steady-state potentiostatic technique allowing minimum time at each potential for current stabilization. In all experiments reported graphically in Fig. 9, 11, 14, and 15, the polarization curves could be constructed within 5 min. In such a time, according to Diggle and Lovrecek (19), cathode surface area changes should have been minimal and thus the real area relevant to Fig. 9, 11, 14, and 15 can be considered equal to the original cathode area 3×10^{-2} cm^2.

A corresponding trend to that depicted in Fig. 8, namely the decrease in the current at -100 mV overpotential, is evident from the polarization curves for zinc deposition in the presence of tetrabutyl ammonium bromide (Fig. 9). There is a negligible effect of $10^{-4}M$ tetrabutyl ammonium bromide on the log i-η behavior when the latter is compared with that of the uninhibited systems. With $10^{-3}M$, however, a nearly linear region of η-log i is observed at overpotential less than -80 mV; at overpotentials greater than -100 mV, the limiting current density is observed; in $10^{-2}M$ inhibited solutions, Tafel relationship is evident with the slope close to 0.11V in the region of $\eta > 100$ mV. It is apparent, from Fig. 9, that the deposition of zinc at the overpotential of -100 mV becomes more activation controlled as the concentration of tetrabutyl ammonium bromide increases.

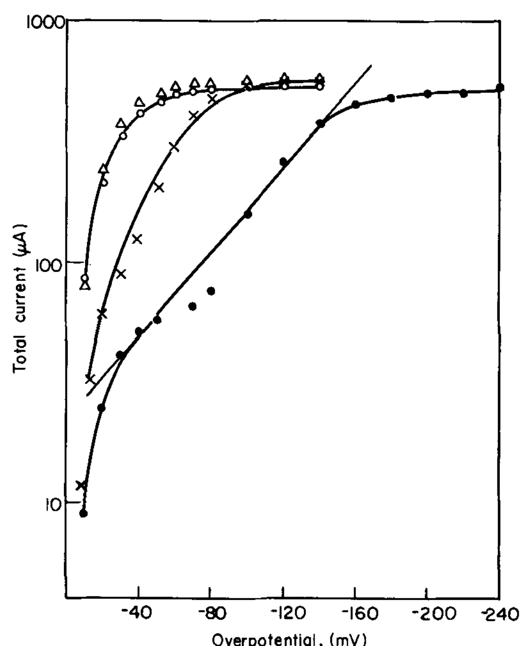

Fig. 9. Polarization curve for the deposition of zinc from pure and doped 10% KOH + 0.1M ZnO. $T = 30°C$. ○ Pure system, △ $10^{-4}M$ $(C_4H_9)_4N \cdot Br$, x $10^{-3}M$ $(C_4H_9)_4N \cdot Br$, ● $10^{-2}M$ $(C_4H_9)_4N \cdot Br$.

Table II. Influence of quaternary ammonium cations on the initiation of zinc dendrites from an electrolyte of 0.1 molar zincate, 10% KOH at 30°C and −100 mV

Quaternary salt	Minimum molar concentration for complete effectiveness in preventing zinc dendrites*
$(CH_3)_4NOH$	1
$(C_2H_5)_4NBr$	10^{-1}
$(C_3H_7)_4NBr$	10^{-2}
$(C_4H_9)_4NBr$	10^{-3}
$(C_5H_{11})_4NI$	10^{-4}

* At the quoted concentration, and above, the morphology of the zinc electrodeposit was always compact, except for tetramethyl where the zinc deposit was of a spongy nature.

No dendrite initiation was observed at $\eta = -100$ mV for tetrabutyl concentrations greater than or equal to $10^{-3}M$. In Table II the concentrations are given of tetrabutyl ammonium bromide, along with other quaternary salts, which are required to suppress dendrite initiation at overpotential of -100 mV; a definite dependence on the structure of the tetra-alkyl group is evident. The effectiveness, at the same concentration, in eliminating dendrites increases from tetramethyl to tetrapentyl. The minimum concentration required to suppress the dendrites initiation decreases by about one order of magnitude on passing from one member to the next in the range of compounds examined. At the minimum concentration of each member, except tetramethyl, compact zinc is deposited. In the presence of tetramethyl, a spongy type of deposit is formed.

Propagation rate.—For any quaternary salt, except tetramethyl, there is a minimum concentration at which, in solution-exchange experiments, dendrites stop growing (*cf.* Table II). Figure 10 shows the i-t behavior for solution exchange with $10^{-3}M$ tetrabutyl ammonium bromide (*cf.* Fig. 5, $10^{-4}M$ lead). As in the lead inhibited system, changes in the dendrite tip

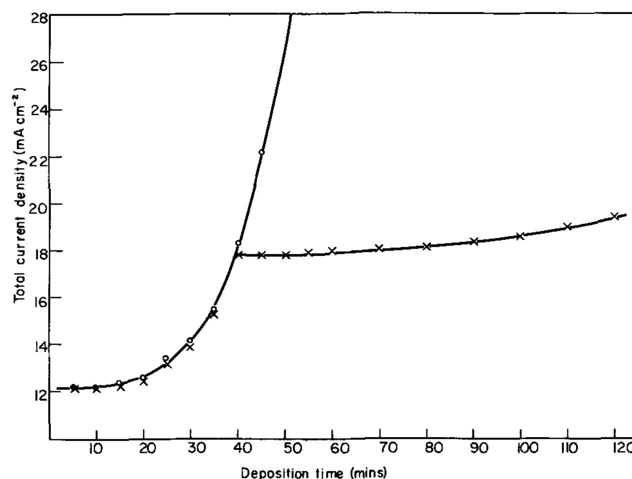

Fig. 10. Total current density-time behavior observed during solution exchange experiments. ○ represents the behavior of pure 10% KOH + 0.1M ZnO, $\eta = -100$ mV. $T = 30°C$. x Exchange solution containing $10^{-3}M$ $(C_4H_9)_4NBr$. Solutions exchange after 40 min.

radius of curvature are observed on the addition of inhibitor.

Effect of Polyethoxylated Hydroxyl-Compounds on Dendrite Growth

Emulphogene BC-420.—Figure 11 illustrates the η-log *i* polarization curves in zincate solution to which Emulphogene BC-420 was added to concentrations of 7.4 and 3.7 $\times$ 10^{-5}M for both increasing and decreasing overpotential. As the overpotential was made increasingly negative, starting from −50 mV, there is a gradual increase in current until an overpotential is reached at which a large increase in the current occurs. This latter overpotential is −110 mV and −240 mV for 3.7 $\times$ 10^{-5}M and 7.4 $\times$ 10^{-5}M solutions, respectively. For the 7.4 $\times$ 10^{-5}M doped solutions at these high potentials, substantial hydrogen evolution was noted. When the overpotential became more positive, a different η-log *i* relationship was observed and a strong hysteresis in η-log *i* was evident (*cf.* Fig. 11).

At overpotentials of −50 mV, or less negative, the current at a given overpotential becomes unstable and decreases with time, as indicated in Fig. 11 by the descending arrows. Figure 12 shows the total current on an electrode which was initially held at an overpotential more negative than that at which sudden increase in current is observed and then brought to −50 mV. The decrease in the current is the more rapid the more concentrated the inhibitor; the slope *di/dt* increases approximately 2.3 times for a two-fold increase in the Emulphogene concentration. Steady-state current density is established in about 500 and 1000 sec for 7.4 and 3.7 $\times$ 10^{-5}M solutions, respectively, in unstirred solutions. In stirred solution the steady state is established faster.

The above phenomenon is indicative of slow adsorption-fast desorption of the Emulphogene, in conformity with the findings of Payne, Tachikawa, and Bard (2) at similar concentrations.

Initiation Process in the Presence of Emulphogene BC-420

In systems containing Emulphogene, at an overpotential of −100 mV, two different total current-time relationships are found depending on whether the

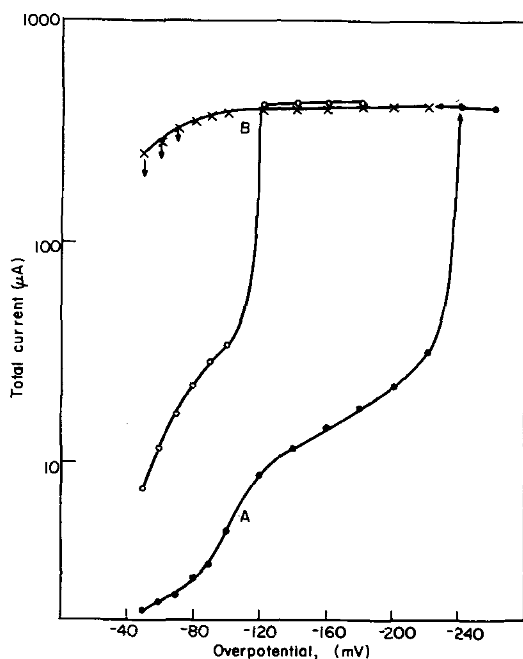

Fig. 11. Polarization curves for the deposition of zinc from 10% KOH + 0.1M ZnO, T = 33°C containing ○ 3.7 x 10^{-5}M and ● 7.4 x 10^{-5}M. Emulphogene BC-420. The points ○ and ● were determined with potentials moving cathodic, and the points x, illustrating the hysteresis, were determined with potentials moving anodic.

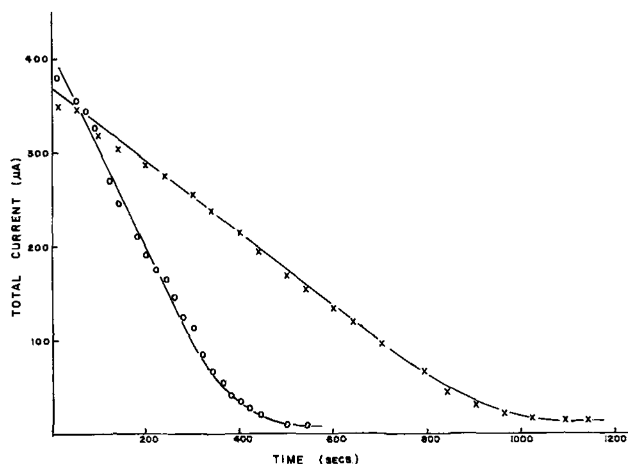

Fig. 12. Total current-time behavior representing Emulphogene BC-420 readsorption at η = −50 mV following desorption at high potentials 10% KOH + 0.1M ZnO. T = 33°C doped with x 3.7 x 10^{-5}M and ○ 7.4 x 10^{-5}M Emulphogene BC-420.

initiation was attempted before or after the apparent desorption of the Emulphogene. The initiation did not occur within 180 min when the electrode was maintained at the potential corresponding to point A in Fig. 11 (compared to normal initiation times in identical uninhibited systems of 10 min), whereas initiation proceeded normally when the electrode was initially kept at the potential corresponding to point B in the same figure. Two *i-t* dependences were found only when the Emulphogene concentration was higher than 1.5 $\times$ 10^{-5}M. Below this concentration, the cathodic polarization curve and the initiation times were found essentially to duplicate those in the uninhibited system.

Comparison of photographs obtained in the inhibited system (containing 1.5 $\times$ 10^{-5}M Emulphogene BC-420) with those from the uninhibited system, at the same deposition time, shows that an apparent higher initiation rate exists for the inhibited system (Fig. 13). It was observed that although dendrites do initiate in the inhibited system, and propagate in the main axis direction at a rate close to that observed in the uninhibited system, they do so only for a short period. This period of "free" growth appeared to depend on the Emulphogene concentration, being the shorter the higher the concentration. At the cessation of propagation, side branching and tip splitting occur (*cf.* Fig. 13). This phenomenon of tip splitting to produce side branches has been observed by the present authors occasionally in the uninhibited system and is well documented in other dendritic systems (20-22).

Triton X-15.—The polarization curve for zinc deposition in the presence of 1.5 $\times$ 10^{-4}M Triton X-15 is shown in Fig. 14. Again, as in the case of the Emulphogene, as the potential is made more cathodic the current increases at first gradually and then, at a given potential, a larger increase in current occurs. Initiation and growth of zinc dendrites at η = −100 mV proceeds as in the uninhibited system. Readsorption of Triton X-15 following 5 min desorption at −80 mV is considerably faster than for Emulphogene BC-420, being essentially complete in seconds rather than in minutes (*cf.* Fig. 11). At the concentration of 1.5 $\times$ 10^{-4}M (the highest used for Emulphogene BC-420), Triton X-15 is less effective in preventing dendrites than Emulphogene BC-420.

Triton X-100.—Figure 15 shows the cathodic polarization curves for the deposition on zinc in the presence of 1.8 $\times$ 10^{-4}, 1.4 $\times$ 10^{-4}, and 8.8 $\times$ 10^{-5}M Triton X-100. A rapid increase in current occurs at overpotentials in the range −270 to −290 mV, which is somewhat smaller than the value reported by

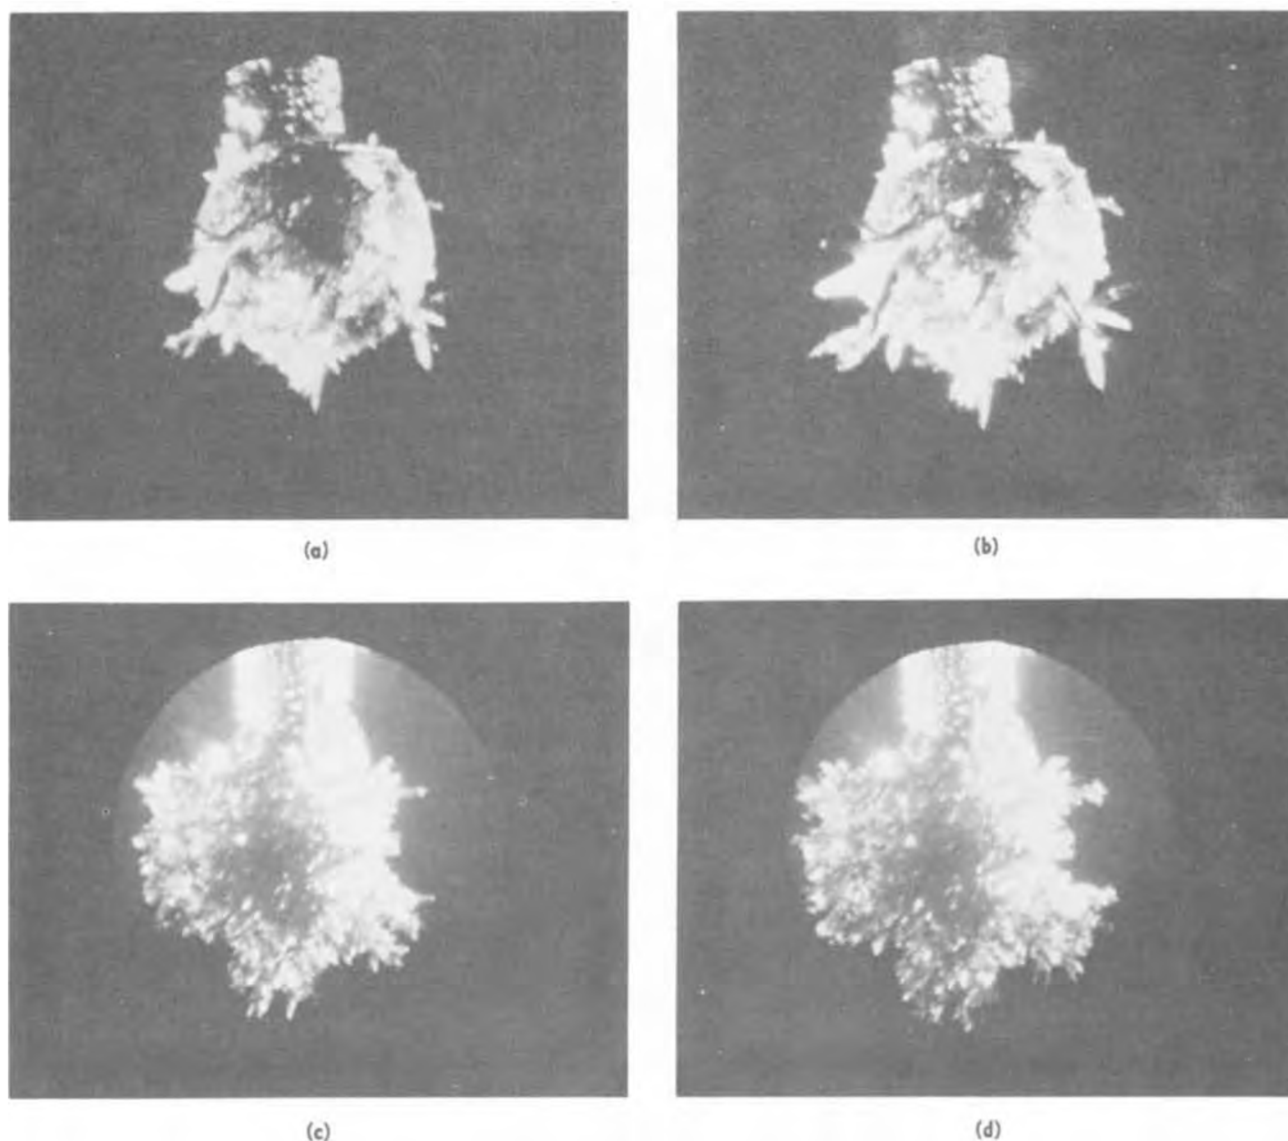

Fig. 13. Typical zinc morphology for the deposition of zinc from pure 10% KOH + 0.1M ZnO, η = −100 mV, T = 30°C after 35 (a) and 40 (b) min and from Emulphogene BC-420 doped solution (1.5 x 10^{-5}M) also after 35 (c) and 40 (d) min Magnification in all cases X22.

Stachurski (5). Some evidence exists as to a concentration dependence of this potential, but this is not so marked as for Emulphogene BC-420 (Fig. 11). Hysteresis in the η-log i relationship was observed on reducing the cathodic potential, but it is considerably less than that observed for the zincate system doped with Emulphogene. Inhibitor readsorption is more rapid for Triton X-100 than for Emulphogene BC-420, but not as rapid as for Triton X-15.

Discussion

In any investigation of inhibition the action of an inhibitor by two basic processes must be considered, (*a*) inhibition by pure blocking action and (*b*) inhibition arising from a change in electrode kinetic parameters, *e.g.*, specific adsorption of ions could cause a change in the difuse layer P.D. and thus produce either an increased or decreased P.D. across the reaction plane, *i.e.* the Helmholtz double layer. This latter effect has been reported (23) as being unable to account fully for some electrode reactions in the presence of specific adsorption. In the presence of specific adsorption a displacement of the discharge reaction plane position, being outward from the metal for retarded cathodic reactions (23), and a change in the activity coefficient for the activated complex (24) have been proposed as refinements to process (*b*).

In the following discussion an attempt will be made to discuss the applicability of these possible inhibition mechanisms.

Inhibition due to lead-bearing species.—Lead ions are well known in their influence on the morphology of crystallizing solids (25, 26), blockage by codeposition usually being invoked as an explanation. Figure 4 shows a summary of the influence of lead as a zinc morphology modifier, the degree of modification being dependent both on the lead concentration and the electrode potential. This potential dependence suggests that the inhibiting species is, at least, partially charged as an ion or adion.

A change in morphology from dendritic to compact zinc at η = −100 mV by the addition of 10^{-4} molar lead has been observed (*cf.* Fig. 4), *i.e.*, the initiation overpotential for zinc dendrites is now >/−100/mV. According to previous theory (17), a lowering of i_o leads to an increase in the numerical value of the critical overpotential η_{crit} required for dendrite initiation. Thus, if the addition of lead ions lowered the i_o for zinc deposition, then compact zinc, rather than dendrites, might be expected at −100 mV. Furthermore, with any one lead concentration, increasing the cathodic overpotential should eventually produce dendrites (as Fig. 4 shows). An alternative explana-

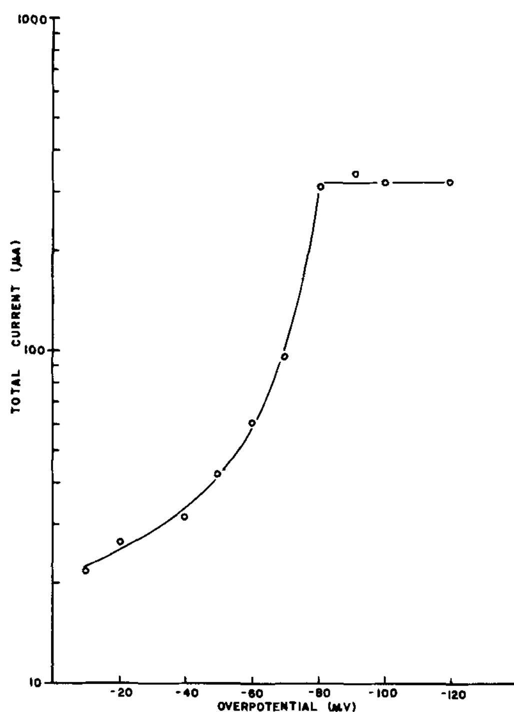

Fig. 14. Polarization curve for 10% KOH + 0.1M ZnO doped with 1.5×10^{-4}M, Triton X-15, $T = 25°C$.

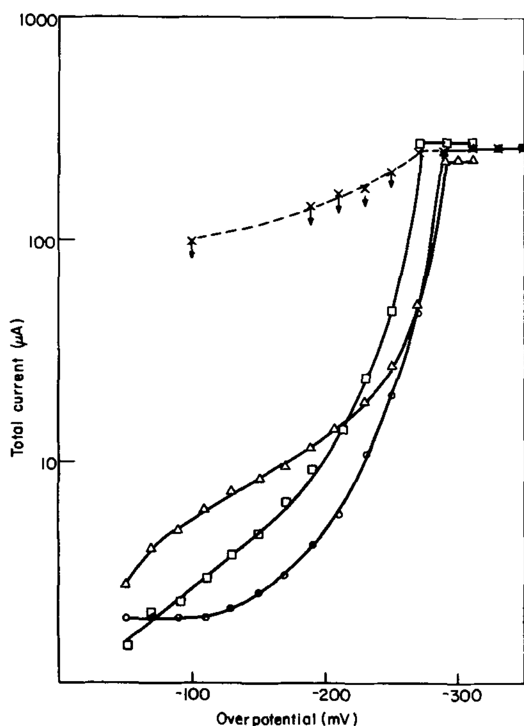

Fig. 15. Polarization curves for Triton X-100 doped 10% KOH + 0.1M ZnO. $T = 25°C$. □ 8.8×10^{-5}M, △ 1.4×10^{-4}M, ○ 1.8×10^{-4}M. A typical polarization hysteresis is indicated by the points x being, in this case, for the concentration 1.8×10^{-4}M. The hysteresis (marked by the downward arrows) observed here is much more short-lived than that in Fig. 11.

tion could be that although the applied overpotential remains constant, the essential driving force for the discharge of a zinc ion, *i.e.*, the electrostatic field, decreases. This could occur when an adsorbed lead species displaces the zinc ion discharge plane outward due to its large ionic size (see later discussion).

Inhibition due to tetra-alkyl ammonium salts.—From Fig. 9 it can be seen that the character of the E-log i plot changes from diffusion to activation control at $\eta = -100$ mV as the concentration of tetrabutyl ammonium bromide increases. The potential at which the polarization curve, in the presence of tetrabutyl, merges with the uninhibited curve becomes more cathodic as the tetrabutyl concentration increases. This is in agreement with the results of Chuang-Hshin and Iofa (27) who further reported a "desorption potential" for 10^{-3}M tetrabutyl ammonium chloride in 1M KCl of -1.6V (NHE), *i.e.*, approximately -1.0V relative to zpc. In the present work, a value for this "desorption potential" is found to be approximately -1.3V (NHE) for 10^{-3}M tetrabutyl doped zincate solution.

Inhibition mechanism.—Specific adsorption of tetra-alkyl cations is well known (28) and has been shown to produce both accelerating and retarding influences on the discharge of ions (29). From Gierst (29) and other workers (30-32) it may be concluded that the discharge of cations will be retarded by tetra-alkyl cation adsorption due to process (*b*) outlined earlier, and further retarded due to the blockage process (*a*) of the electrode surface. However in the present experiments where the KOH electrolyte concentration is 2M, inhibition processes based on changes in diffuse layer P.D. are considered unlikely.

Since specific adsorption of both lead ions and tetra-alkyl cations appear to be involved, a process other than simple electrode surface blockage may be involved. This may take the form of an increasingly outward displacement of the discharge plane as discussed by Elliott (23) and Fawcett (33). If the inhibition were due to simple blockage then the results shown in Fig. 9 are surprising, since electrode blockage would lead to a decrease in current (as observed) without the apparent change from diffusion to activation control as the tetra-alkyl ion concentration increases. Thus, the tentative conclusion is that the dendrite inhibition observed here on addition of tetra-alkyl ammonium salts (and perhaps lead) is that specific adsorption leads to a lowering of the electrostatic field promoting zinc ion discharge arising from an outward movement of the discharge plane. This conclusion is in no way invalidated by the recent work of Bockris, Nagy, and Damjanovic (34) who have concluded that the discharging species is a hydroxy-zinc anion. Only in the case of simple inhibition by process (*b*) could one say that adsorbed cations inhibit the discharge of a zinc cationic species. The knowledge that a retarding effect is observed for tetra-alkyls, in the case of anionic discharge, itself indicates something other than process (*b*), process (*a*) being over-ruled on previous evidence.

Inhibition due to polyethoxylated hydroxy compounds.—Facts are: (*i*) dendrite initiation, in the presence of Emulphogene, was found to occur following the process of inhibitor desorption, (*ii*) in the presence of inhibitor adsorption on the zinc substrate [adsorption occurring under diffusion control due to the low inhibitor concentration (2)] no initiation is observed, (*iii*) the propagation of dendrites in the presence of inhibitor above a certain concentration, proceeds only for a short time before cessation.

The occurrence of initiation, after inhibitor desorption, could be due to the fact that the initiation time is less than the time required for complete inhibitor adsorption, *e.g.*, compare adsorption time for 7.4×10^{-5}M Emulphogene (Fig. 12) with the initiation period for the system, in the absence of Emulphogene, of 10 min (17). Since the dendrites, when initiated, possess a low radius of curvature (10^{-4}-10^{-5} cm) compared to $\delta_0 = 10^{-2}$ cm the diffusive flux of inhibitor to the tip is greatly enhanced. Thus, propagation proceeds unimpeded for only a short time until complete adsorption of the inhibitor reduces further charge transfer, and hence, growth, to a low level. The time

of unimpeded or "free" growth should decrease as the inhibitor concentration increases, as observed. The higher frequency of dendrite initiation in Emulphogene doped zincate solutions, compared to that in the uninhibited system, is possibly due to the higher linear diffusive flux of zincate which will flow to the substrate surface in the absence of a larger number of spherical diffusive flux points, *i.e.*, propagating dendrites. In the uninhibited systems the presence of these spherical diffusive flux points, *i.e.*, continually propagating dendrites, the linear diffusive flux of zincate ions to the substrate could be considerably reduced and thereby reducing the dendrite initiation rate.

The conclusion that Emulphogene BC-420 is more effective as a morphology modifier than Triton X-15 is somewhat surprising since aromatic compounds are reported to be more strongly adsorbed, and hence, should influence morphology more, than aliphatic compounds (14). This conclusion, however, assumes that the hydrocarbon end lies adjacent to the metal surface. For Emulphogene compounds, Payne, Tachikawa, and Bard (2) have suggested, and have evidence to show, that the negatively charged ethylene oxide grouping lies adjacent to the metal surface, *i.e.*, they have shown that the electrocapillary maximum moves cathodic as the Emulphogene concentration increases. In contrast, Meibhur (15) has reported that the electrocapillary maximum moves anodic for polyethoxylated naphthyl hydroxyl compounds, from which it may be concluded that in the aromatic compounds there is a positive charge adjacent to the metal.

It is suggested that in the case of Emulphogene the molecule is oriented with negatively charged ethylene oxide groups adjacent to the metal,[9] whereas in Triton, although ethylene oxide groups are still adjacent to the metal, they are positively charged due to the electron withdrawing power of the aromatic ring. This situation is analogous to that of methanol and phenol (35) when one considers only static inductive effects

This would perhaps suggest that the orientation of these polyethoxylated hydroxyl compounds is controlled more by steric than by polarity considerations. The faster readsorption of Triton X-15 would appear to confirm the suggestion that Triton is adsorbed with a positive grouping adjacent to the metal (hence there is a migration term, as well as a diffusion term, assisting readsorption) whereas Emulphogene has a negative grouping adjacent to the metal (hence readsorption occurs only when diffusion supplies sufficient adsorbate). Decreasing the charge density of the positively charged ethylene oxide grouping in Triton may be expected to (*a*) increase the time required for adsorption, and (*b*) move the electrocapillary maximum more cathodic, resulting in a shift of the desorption potential in the cathodic direction. Results reported for Triton X-100 suggest that both (*a*) and (*b*) are observed.

Polarization curves (Fig. 11) in the presence of Emulphogene show that, providing the Emulphogene remains adsorbed, only a small current flows (region A); in this condition morphology is affected. Desorption of the Emulphogene at high cathodic overpotentials is accompanied by the appearance of the morphology observed in the absence of Emulphogene, and the occurrence of substantial H_2 evolution.

One reason for the large difference in the desorption potentials between Emulphogene BC-420 (Fig. 11) and Triton X-15 (Fig. 14) may be due to the fact that the zinc zpc, in the presence of Emulphogene, is much more cathodic than the zinc zpc in the presence of Triton. Another consideration must be that the cathodic desorption of a molecule with a positive end adjacent to the metal may be more difficult than the desorption of a molecule with a negative end adjacent to the metal.

[9] This conclusion differs from that of Meibhur (15) who concluded from surface excess measurements, assuming $\theta = 1$, that the hydrocarbon and either a part, or all, of the ethylene oxide chain lie parallel to the metal surface. This conclusion depends on the validity of the assumption that full coverage of the metal surface is unity.

Since a dependence of the shift of the zpc of a metal on the adsorbed inhibitor concentration is known (14), and has been observed for Emulphogene (2), the desorption potential will be expected to move cathodic for Emulphogene and anodic for Triton as the added inhibitor concentration increases providing all other factors are constant. Figure 11 shows this to be valid for Emulphogene BC-420.

From the work with Triton X-15 and X-100 it would seem that the higher the value of n, the more cathodic the desorption potential. This is in agreement with a decreasing charge density on the positively charged ethylene oxide chain, and a subsequent cathodic shift in the zinc zpc, as the value of n increases.

Triton X-100 shows some small concentration dependence (Fig. 15) of the desorption potential. It does, however, appear to be in the opposite direction to that expected from the above argument.

Triton X-15 is found to be ineffective as a morphology modifier since it is desorbed at $\eta = -80$ mV (Fig. 14). Triton X-100, which possesses higher ethylene oxide content, is much more effective than X-15 and as equally effective as Emulphogene BC-420.

In contrast to the tetra-alkyl inhibitors, polarization curves in the presence of polyethoxylated compounds do not exhibit any marked Tafel region, but do exhibit a marked desorption potential. Therefore, it is suggested that the influence, as inhibitors, of polyethoxylated compounds is due to a blockage, or other related effect, and is unrelated to specific adsorption. Adsorption of polyethoxylated inhibitor compounds on zinc effectively reduces the area available for deposition and consequently the total current, under potentiostatic control, decreases. Thus in conclusion, the polyethoxylated compounds do lead to some small improvement in the recharging processes of the zinc electrode, but are inferior to both lead and tetra-alkyls.

Conclusions

1. The addition of 10^{-4}M lead to alkaline zincate solutions was found to effectively suppress zinc dendrite initiation and propagation. Lead concentrations 10^{-4}M were partially effective or completely ineffective. At lead concentrations greater than 10^{-4}M, lead dendrites were formed preferentially.

2. The potential dependence of the lead inhibition process suggests that the inhibiting species is, at least, partially charged.

3. The influence on zinc morphology of the tetra-alkyl salts was found to be directly analogous to that of lead. Specific adsorption is tentatively proposed as an explanation.

4. Emulphogene BC-420 and Tritons X-15 and X-100 were found to be inferior as dendritic inhibitors to both lead and the tetra-alkyls. All three polyethoxylated compounds exhibited desorption potentials which were a function of the inhibitor concentration.

5. The desorption potentials observed for Emulphogene BC-420 were cathodic with respect to those for Triton X-15. This was suggested as being due to the zinc zpc, in the presence of Emulphogene, being cathodic with respect to the zinc zpc in the presence of Triton X-15. Since the shift in the zpc is dependent on the inhibitor concentration, the desorption potential may also be expected to exhibit an inhibitor concentration dependence.

6. Cathodic shift in zpc for Emulphogene, and the anodic shift for Triton is suggested to be due to the ethylene oxide grouping, adjacent to the zinc surface, possessing a negative charge in the case of Emulphogene and a positive charge in the case of the Tritons.

7. The inhibition of zinc dendrite morphology by lead and tetra-alkyl ammonium salt additions is tentatively suggested as being due to an outward shift in the discharge plane, following specific adsorption, and the consequent lowering of the electrostatic field facilitating discharge.

8. The influence on zinc morphology of the Emulphogene and Triton inhibitors was suggested as being largely a blocking action, and effective in preventing dendrite initiation only when adsorbed. Desorption of the Emulphogene, at high cathodic potentials, results in substantial H_2 evolution.

Electrochemical Oxidation of Uric Acid and Xanthine at the Pyrolytic Graphite Electrode

Mechanistic Interpretation of Electrochemistry

Glenn Dryhurst

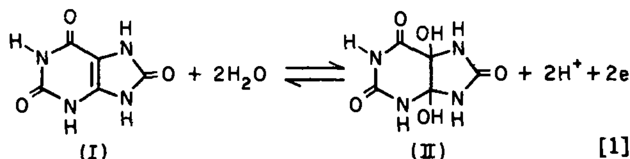
Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

The quantitative course of electrochemical oxidation of uric acid and xanthine at the pyrolytic graphite electrode has been examined between *p*H 1-7, the most commonly encountered *p*H range in biological systems. Basically, uric acid is oxidized in a primary $2e$-$2H^+$ oxidation of the $C_4{=}C_5$ bond to give a readily reducible and highly reactive bis-imine. The bis-imine can be detected as a cathodic peak by fast sweep cyclic voltammetry. Complete hydration of the bis-imine gives rise to uric acid-4,5-diol that breaks down to alloxan and urea at *p*H 1, allantoin and a small amount of urea at *p*H 7, and at intermediate *p*H values mixtures of alloxan, allantoin, urea, and occasionally traces of parabanic acid are formed. Xanthine undergoes a $4e$-$4H^+$ oxidation that proceeds by two $2e$-$2H^+$ stages. The first involves oxidation of the $—C_8{=}N_9—$ bond to give uric acid which, being more easily oxidized than xanthine, is immediately further oxidized ($2e$-$2H^+$) to the uric acid bis-imine. This then hydrates and fragments in essentially the same way as described for uric acid, the same products being observed. Mechanisms are developed which explain the observed electrochemistry and over-all formation of products from this reaction. The nature and yields of products formed electrochemically and the effect of *p*H on the reaction parallels the biological (enzymatic) oxidation of these compounds.

Over the past five to six years several reports have appeared concerned with the electrochemical oxidation of naturally occurring biologically important purines (1-11). All of these reports, however, are primarily concerned with qualitative identification and quantitative measurement of the products of the reactions and with detection of possible intermediates using fast sweep cyclic voltammetry. Detailed electrochemical and related chemical mechanisms have not been developed.

The first modern report of the electrochemical oxidation of a purine is that of Struck and Elving (1) who indicated that uric acid is oxidized at a wax-impregnated spectroscopic graphite electrode in 1M HOAc in a process that involves about $2.2e$ per mole of uric acid oxidized. The products formed were CO_2 (0.25 mole), allantoin or an allantoin precurser (0.25 mole), urea (0.75 mole), parabanic acid (0.3 mole), and alloxan (0.3 mole) per mole of uric acid oxidized. On the basis of these products a scheme was proposed whereby uric acid was oxidized in a primary $2e$ process to a short-lived dicarbonium ion, with the positive charge localized on the C_4 and C_5 carbon atoms, which was unstable and underwent hydrolysis to allantoin or its precurser, alloxan and urea and further secondary oxidation to parabanic acid and urea. There are however several objections to this scheme. First, the peak for oxidation of uric acid at both spectroscopic and pyrolytic graphite electrodes is strongly *p*H dependent (1, 5) and hence protons must be involved in the electrode reaction. The earlier scheme does not indicate the involvement of protons in the primary electrochemical step. Second, the dicarbonium ion formed in the primary electrode reaction was claimed to be further oxidized to parabanic acid at potentials where uric acid is oxidized. The probability of a doubly positively charged species readily losing the two further electrons required to give parabanic acid is obviously remote. In addition, oxidation of the dicarbonium ion intermediate to parabanic acid, theoretically a $2e$ process, and formation of 0.3 mole of parabanic acid on complete oxidation of uric acid should result in a total transfer of $2.6e$ per mole of uric acid not $2.2e$ as claimed (1). Thus, serious questions are raised as to the actual amount of parabanic acid formed and/or electrons transferred on electrochemical oxidation of uric acid, and to the actual nature of the primary product formed. Dryhurst (4) subsequently claimed that in order to account for the *p*H dependence of the oxidation peak of uric acid (I, Eq. [1]) at the PGE that the primary product of the oxidation was a uric acid-4,5-diol (II, Eq. [1]).



Fast sweep cyclic voltammetry of uric acid also reveals that the primary electrode product is very readily reducible, and that it is very unstable so that at slow scan rates (*i.e.*, < 300 mV-sec^{-1}) the reducible intermediate cannot be detected by cyclic voltammetry (4). It was proposed that the uric acid-4,5-diol (II, Eq. [1]) was the unstable highly reducible primary product (4), and that it very rapidly decomposed to the observed products proposed by Struck and Elving (1), one of which was parabanic acid. The latter was thought to be the cause of a second cathodic peak observed on cyclic voltammetry of uric acid at the PGE. However, the major objection to this scheme is that the uric acid-4,5-diol would not be expected to be very readily reducible, there being no electrochemically reducible sites in the molecule. Similar 4,5-diol products have been proposed to be formed upon electrochemical oxidation of adenine (2), guanine (5), xanthine (7), methylated xanthines (7-9) as well as uric acid (4, 7, 10). Clearly, neither of the primary products (dicarbonium ion or uric acid-4,5-diol) proposed for oxidation of these compounds fits the observed experimental data.

Complete product analysis and characterization in 1M HOAc has been carried out for all the purines mentioned above using pyrolytic graphite as the electrode material with the exception of uric acid, where

Key words: 2,6,8-trihydroxypurine, 2,8-dihydroxypurine, purine-2,6,8-triol, purine,2,6-diol, bioelectrochemistry.

spectroscopic graphite was used, and xanthine which has not previously been examined in detail. In view of the uncertainty regarding the n-value and yield of parabanic acid formed on oxidation of uric acid, the difference in electrode material used for macroscale oxidation (1) and cyclic voltammetry (4, 8) of uric acid, and the lack of quantitative data on xanthine, and the obviously incorrect assignment of the structures of the primary electrochemical product of these and other purines, a complete reinvestigation of the uric acid-xanthine systems at the PGE has been carried out. On the basis of the data reported here a different and plausible primary electrode product is proposed and detailed follow-up chemical and electrochemical mechanisms are proposed. In order better to compare the mechanisms and products of electro-oxidation of uric acid and xanthine to known biological oxidations the electrochemical oxidation of these two compounds was studied over a fairly wide pH range.

Experimental

Apparatus employed for d-c voltammetry, cyclic voltammetry, coulometry, and controlled potential electrolysis has been described in detail elsewhere (2, 4, 5, 7-10). The pyrolytic graphite used in this study was obtained from the Super-Temp Company (Santa Fe Springs, California). The fabrication of the micro PGE for voltammetry and massive electrodes for controlled potential electrolysis have been outlined in earlier reports (2, 12). Analytical methods for the detection and determination of parabanic acid, allantoin, urea, and alloxan have also been detailed previously (1, 5, 7-10). All potentials are referred to the SCE at 25°C.

Results and Discussion

Voltammetry.—Uric acid and xanthine both give rise to a single pH-dependent voltammetric oxidation peak at the PGE in aqueous solution. For uric acid the peak potential (E_p) is described by the equation $E_p = 0.755-0.069\ p\text{H}$ between pH 0-12 (*Fig.* 1A). For xanthine $E_p = 1.034-0.056\ p\text{H}$ over the same pH range (Fig. 1A). These equations are based on voltammograms obtained at a scan rate of 5 mV-sec^{-1} and under such conditions indicate that the peak of xanthine occurs 300-400 mV more positive than the peak of uric acid. The observed peak currents for uric acid and xanthine are largest at low pH and decrease more or less continuously with increasing pH (Fig. 1B). The reason for the very large peak current values at low pH is no doubt related to the very strong adsorption of these compounds. This is evidenced by the very sharp spike-like appearance of the peaks for both compounds, by increases in the peak current function with increasing voltage scan rate, and depressions of the base current in alternating current voltammetry; the latter two studies have been reported elsewhere (13). Assuming a value for the diffusion coefficient of uric acid and xanthine of 10^{-6} cm^2-sec^{-1} and n values of 2 and 4, respectively, (*vide infra*) the theoretical reversible peak current for uric acid under the conditions outlined in Fig. 1 is 1.11 μA and for xanthine 3.5 μA. These values are considerably smaller than the experimentally observed peak currents which may indicate that both uric acid and xanthine are appreciably adsorbed even at pH 12. The effect of pH on the extent of adsorption of these compounds and hence the magnitude of the peak current is no doubt related to their very low solubility at low pH and increasing solubility at higher pH.

By use of fast-sweep cyclic voltammetry, it is shown that oxidation of uric acid (peak I_a, Fig. 2A) gives rise to a very reactive yet very easily reducible product (peak I_c, Fig. 2A). The latter peak cannot be observed unless the scan rate exceeds about 300 mV-sec^{-1} (4, 7). A further cathodic peak at more negative potential (peak II_c, Fig. 2A) is also observed.

The involvement of uric acid in the electrochemical oxidation of xanthine is clearly established by fast-

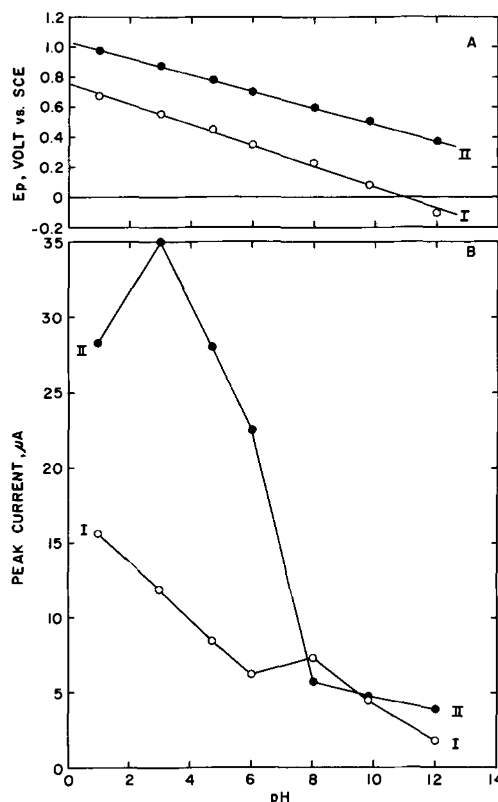


Fig. 1. (A) Variation of peak potential with pH for electro-oxidation uric acid (I) and xanthine (II) at the PGE. (B) Variation of peak current with pH for uric acid (I) and xanthine (II). Data taken at a uric acid concentration of 0.164 mM and xanthine 0.183 mM. Scan rate 5 mV-sec^{-1}.

sweep cyclic voltammetry. After having scanned the primary oxidation peak of xanthine (designated peak II_a, Fig. 2B) a very readily reducible product can be detected (peak I_c, Fig. 2B) and a second product reduced with greater difficulty (peak II_c, Fig. 2B). The peak potentials for cathodic peaks I_c and II_c of xanthine (Fig. 2B) are the same as for peaks I_c and II_c of uric acid (Fig. 2A). On the second positive-going sweep xanthine exhibits a second and new anodic peak (peak I_a, Fig. 2B). This peak occurs at almost the same peak potential as peak I_a of uric acid. As further confirmation of the fact that peaks I_a, I_c, and II_c observed on cyclic voltammetry of xanthine are identical to the corresponding uric acid peaks a cyclic voltammogram of a mixture of the two compounds was taken (Fig. 2C). The very small differences in peak potentials observed in peak I_a (the uric acid oxidation peak) shown in Fig. 2A, B, and C are caused by differences in concentration of uric acid which must be smaller in the situation extant in Fig. 2B than in Fig. 2A or 2C (*vide infra*). This is so because the peak potential for peak I_a of uric acid (and indeed peak II_a of xanthine) is strongly concentration- and scan-rate dependent. Thus, for a 0.2 mM solution of uric acid in acetate buffer pH 4.7, E_p for peak I_a is 0.45V at 0.005 V-sec^{-1} and 0.65V at 5.0 V-sec^{-1}. In the same medium but 0.01 mM in uric acid, E_p = 0.50V at 5.0 V-sec^{-1}. These shifts of peak potential are due to adsorption effects and to some extent to uncompensated ohmic drop in the instrumentation employed (14). As further evidence that peaks I_c, II_c, and II_a of xanthine are identical to those of uric acid the value of the peak potentials for these peaks of both compounds were measured as a function of pH and scan rate (Fig. 3). Clearly, the pH dependence of all peaks can be described by a single straight line indicating that the species giving rise to each peak from uric acid and xanthine are identical. This information confirms that oxidation of xanthine

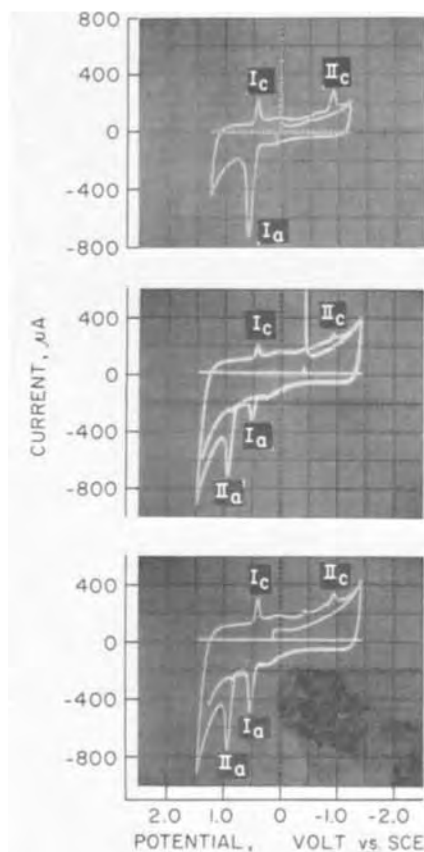

Fig. 2. Cyclic voltammograms at a clean PGE in acetate buffer pH 4.7. (A) 0.075 mM uric acid; scan pattern: 0.00 → −1.20 V → 1.30V → −120V → 0.00V. Scan rate 5.0 V-sec^{-1}. (B) 0.03 mM xanthine; scan pattern −0.40V → −1.40V → 1.50V → −1.40V → 1.50V. Scan rate 5.0 V-sec^{-1}. (C) 0.03 mM uric acid plus 0.03 mM xanthine; scan pattern: 0.00V → −1.40V → 1.50V → −1.40V → 0.00V. Scan rate 5.0 V-sec^{-1}.

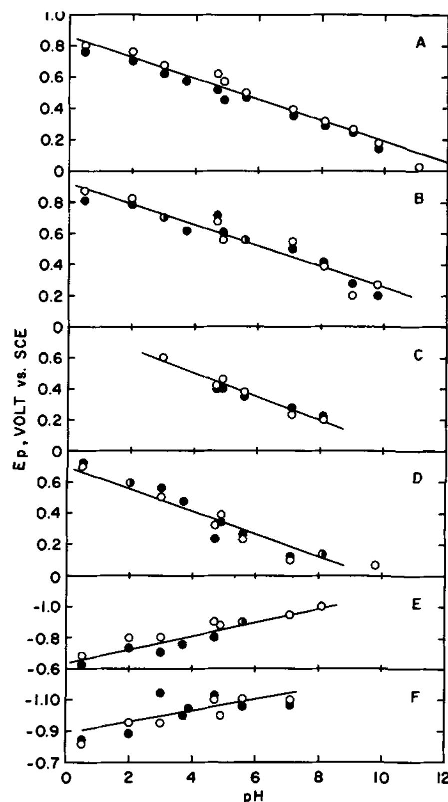

Fig. 3. Comparison of peak potentials for peaks I_a, I_c, and II_c of uric acid and xanthine as a function of scan rate and pH. (A) Peak I_a; scan rate 5 V-sec^{-1}. (B) Peak I_a; scan rate 50 V-sec^{-1}. (C) Peak I_c; scan rate 5 V-sec^{-1}. (D) Peak I_c; scan rate 50 V-sec^{-1}. (E) Peak II_c; scan rate 5 V-sec^{-1}. (F) Peak II_c; scan rate 50 V-sec^{-1}. gives rise to the same readily reducible product obtained on oxidation of uric acid (peak I_c), the reduction product of which is uric acid which can be detected by cyclic voltammetry as peak I_a. Peak II_c is also due to the same product as evidenced by the agreement between the peak potentials of the peak observed from both uric acid and xanthine.

Coulometry and mass electrolysis.—Coulometry of uric acid and xanthine was carried out at various pH values between pH 1-7, the most commonly encountered pH range in biological systems. Typical coulometric data is presented in Table I which clearly indicates that at all pH values examined the *n* value for uric acid is 2 and for xanthine is 4.

Table I. Coulometric *n*-values for the controlled potential electrolysis of uric acid and xanthine at the PGE

pH	Buffer system	Millimoles[a] electrolyzed	Applied potential, V *vs.* SCE	*n*-Value
		Uric acid		
1.0	Chloride	0.253	0.80	2.08
2.3	1M acetic acid	0.169	0.70	1.95
4.7	Acetate	0.203	0.55	2.30
7.0	McIlvaine	0.220	0.40	2.01
		Xanthine

2.3	1M acetic acid	0.181	1.10	3.90
4.7	Acetate	0.215	0.85	3.85
7.0	McIlvaine	0.108	0.80	3.93

[a] All electrolyses were continued until all uric acid or xanthine was oxidized.

After complete electro-oxidation of solutions of uric acid or xanthine in various background media between pH 1-7 qualitative and quantitative analyses of the electrolysis products were carried out. The various analytical data are presented in Table II. The notable difference between these data and those reported earlier by Struck and Elving (1) at pH 2.3 (1M HOAc) is that alloxan and urea are by far the major products. Much less allantoin is formed and only minute traces of parabanic acid.

It is also clear that at low pH the only products of oxidation of both uric acid and xanthine are alloxan and urea. With increasing pH the amount of alloxan decreases while the yield of allantoin correspondingly

Table II. Quantitative analytical data on products of electrochemical oxidation of uric acid and xanthine at the PGE

		Product, moles/mole of uric acid or xanthine electro-oxidized[a]

[b] Not detected.

increases. At pH 7 the major product is allantoin with smaller amounts of urea and alloxanic acid (not analyzed quantitatively but detected by thin layer chromatography). The change in major product from alloxan at low pH to allantoin in weakly acid and neutral solution is most interesting because it parallels the effect of pH on the products observed on oxidation of uric acid in the presence of peroxidase enzymes (15, 16). Parabanic acid could only be detected in exceedingly small amounts in the products of electrooxidation of uric acid and xanthine in 1M HOAc pH 2.3.

It should also be noted that the relative yields of products obtained at any pH were somewhat variable from one electrolysis to another, the values quoted in Table II are simply typical values. It can also be seen that on occasion the sum of total products does not total 100% of the initial uric acid or xanthine oxidized. The product yields however can be regarded as equivalent to a complete material balance in view of the analytical accuracy achieved by this worker.

Mechanisms

In summary, the electrochemical and analytical data reported here reveal that uric acid is oxidized in a 2*e*, pH-dependent process at the PGE. A very unstable, very reducible product is formed (peak I_c, Fig. 2). The species giving rise to peak II_c cannot be due to reduction of parabanic acid to 5-hydroxyhydantoin (17) as proposed earlier (4, 5, 7) because there is insufficient parabanic acid formed to account for the relatively large peak observed by cyclic voltammetry.

Cyclic voltammetry and analytical data clearly reveal that xanthine is initially oxidized to uric acid which is then further oxidized to the same products obtained with uric acid as the starting material.

As noted earlier, the product giving rise to peak I_c cannot be uric acid-4,5-diol as proposed earlier (4, 5, 7-9). However a diol is formed at some stage in the reactions following electron-transfer as evidenced by the fact that in the presence of methanol, oxidation of uric acid appears to give a 4,5-dimethoxy derivative (10).

In view of these facts, a mechanism is proposed where uric acid (I, Fig. 4) is initially electrochemically oxidized in a $2e$-$2H^+$ process to give the species designated II (Fig. 4) which will be referred to in subsequent discussion as a bis-imine. The bis-imine formed from uric acid could exist in two tautomeric forms (II_a, II_b, Fig. 4). Such a system of conjugated double bonds would be expected to be very readily electrochemically reducible, indeed molecules having somewhat similar bis-imine structures such as riboflavin (18-23), quinoxalines (24), and bis-quinazolines (25) are rather readily reduced electrochemically. Aldimines and ketimines are also very easily electrochemically reduced (26-28). The expected ease of reduction of structures II_a and/or II_b along with their expected facile hydration across the imine-N=C-double bonds to give a 4,5-diol accounts nicely for part of the observed cyclic voltammetry of uric acid. Thus, provided the sweep rate is fast enough, II_a or II_b formed as the primary products of oxidation of uric acid can be detected as a very reducible species (peak I_c, Fig. 2). At slow scan rates II_a or II_b cannot be detected because they are hydrated too rapidly to uric acid-4,5-diol or other species (*vide infra*). Cathodic peak II_c is observed at slower scan rates than is peak I_c (10) and occurs at potentials very close to those expected for reduction of parabanic acid. However, at completion of an exhaustive electrolysis of uric acid only a very small quantity of parabanic acid is detected (and that only in 1M HOAc solution), quite insufficient to account for the relative peak current observed for peak II_c. Accordingly it is proposed, without any direct supporting evidence, that the bis-imine formed on oxidation of uric acid hydrates in two stages, the first fast, the second slower. Addition of the elements of one molecule of

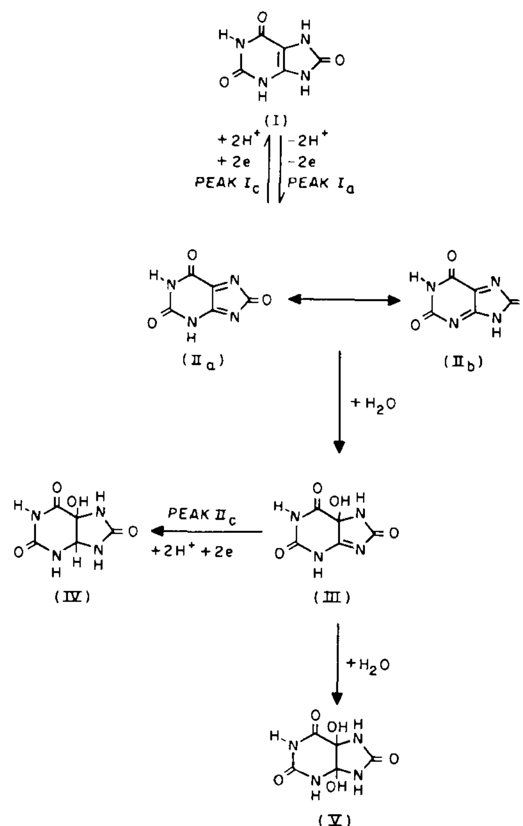

Fig. 4. Primary electrochemical oxidation, and reactions of cyclic voltammetric peaks observed for uric acid.

water gives rise to III (Fig. 4). It may be this compound that gives rise to peak II_c of uric acid being due to reduction of III possibly to IV (Fig. 4). Addition of a second molecule of water to III would give rise to the formation of uric acid-4,5-diol (V, Fig. 4). This diol is a typical intermediate of an imine-like hydrolysis and would be expected to readily fragment to the observed products. A plausible mechanism for formation of allantoin from uric acid-4,5-diol involves cleavage of the C_5—C_6 bond of the diol (I, Fig. 5) giving an imidazole isocyanate (II, Fig. 5). A hydrogen shift reaction must occur in compound II to give III which on hydrolysis would readily form CO_2 and allantoin (V, Fig. 5). A simple fragmentation of the 4,5-diol to alloxan (VI, Fig. 5) and urea (VII, Fig. 5) can also be written. Although only very minor amounts of parabanic acid are formed on electrochemcial oxidation of uric acid at the PGE in 1M HOAc, large amounts are claimed to be formed at spectroscopic graphite electrodes in the same medium (1). Formation of parabanic acid necessarily involves some secondary electrochemical oxidation. A mechanism is proposed in Fig. 5 where uric acid-4,5-diol undergoes a ring opening reaction to give the structures $VIII_a$ or $VIII_b$. In acid solution $VIII_a$ should readily cleave across the original C_5—C_6 bond to give an isocyanate (IX) and 2-oxy-4,5-dihydroxyimidazole (X). Alternatively the compound $VIII_b$ could undergo a ring closure to give XI, which in turn should cleave to X and IX. Simple hydrolysis of the isocyanate IX would give urea and CO_2. 2-Oxy-4,5-dihydroxyimidazole (X, Fig. 5) is an enediol. Enediols are normally very readily oxidizable to α-diketones even by such weak oxidizing agents as cupric ion and, on occasion, oxygen (29). Accordingly it is proposed that the parabanic acid (XIV, Fig. 5) which sometimes appears during the electro-oxidation of uric acid is formed as a result of electrochemical oxidation of the enediol (X) in a $2e$-$2H^+$ process. The very pronounced difference between the amount of parabanic acid formed on electro-oxidation of uric acid at spec-

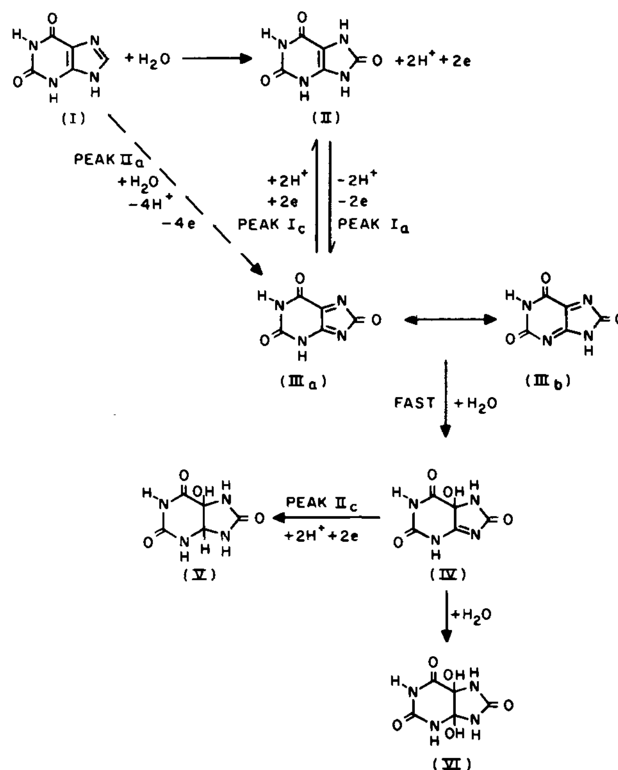

Fig. 6. Primary electrochemical oxidation and reactions of cyclic voltammetric peaks observed for xanthine.

troscopic graphite (1) and pyrolytic graphite can only be rationalized by invoking some specific electrode effects related to the nature of the electrode materials.

The mechanism of electrochemical oxidation of xanthine (I, Fig. 6) clearly proceeds by an initial $2e$-$2H^+$ oxidation of the $C_8{=}N_9$ (or $N_7{=}C_8$) bond to give uric acid (II, Fig. 6). Since uric acid is more readily oxidized than xanthine (Fig. 1A) it is immediately oxidized in a further $2e$-$2H^+$ process to the uric acid bis-imine (III_a, III_b, Fig. 6). Thus, the single initial voltammetric peak of xanthine (peak II_a, Fig. 2B) corresponds to the $4e$-$4H^+$ oxidation to the bis-imine (III_a, III_b, Fig. 6). Cathodic peak I_c observed cyclic voltammetrically is due to reduction of the bis-imine back to uric acid (III_a, or $III_b \rightarrow$ II, Fig. 6). Partial hydration of the bis-imine gives IV which is possibly the species giving rise to cathodic peak II_c resulting perhaps in compound V. Complete hydration of the bis-imine gives uric acid-4,5-diol which decomposes by exactly the same route as shown in Fig. 5. The anodic peak (peak II_a) observed on the second positive-going sweep of xanthine is simply reoxidation of uric acid, formed in the peak I_c process, back to the bis-imine.

It should perhaps be noted here that there is insufficient evidence at this time to definitively explain the effect of pH on the yield products. It is likely however that the various decomposition reactions of uric acid-4,5-diol are acid or base catalyzed hence changing the yields and nature of products with pH. The mechanisms actually proposed for the decomposition of the uric acid-4,5-diol (Fig. 5) should accordingly be regarded as tentative since actually several equally plausible mechanisms could be written. However, the basic mechanism presented here can be used to satisfactorily account for the electrochemistry and products formed on electro-oxidation of other purines (11).

Conclusions

At the single pH (1M HOAc, pH 2.3) where the electro-oxidation of uric acid has been examined at both the PGE and spectroscopic graphite electrodes (1M HOAc, pH 2.3) the products obtained are qualitatively similar but quantitatively quite different. More extensive product analyses over pH 1-7 reveals that at the PGE the major products in solutions between about pH 1-3 are alloxan and urea. With increasing pH the yield of alloxan and urea decreases and allantoin becomes the major product.

Product analysis, cyclic and linear sweep voltammetry allow a detailed mechanism for the primary electro-oxidation and follow-up chemical and electrochemical processes to be written. Combination of data obtained from linear and cyclic sweep voltammetry with controlled potential electrolysis and product analysis data to develop a mechanism is always based on the assumption that the electrochemical and related mechanisms are identical. There is no way in which one can confirm this assumption. Nevertheless the data obtained in this study are all consistent with a common mechanism. Although oxidation of uric acid and reduction of its primary $2e$-$2H^+$ product, a bis-imine, form an almost reversible couple as evidencd by cyclic voltammetry (Fig. 1), meaningful interpretation of the kinetics of the electron-transfer process and the rates of chemical follow-up reactions is not possible. This is so because uric acid is very strongly adsorbed at the PGE (13) which results in shifts of the anodic and cathodic peak potentials with concentration. In addition, there are clearly on occasion three parallel follow-up reactions which are very complex and are

not amenable to study by, for example, cyclic voltammetric methods.

The products and their yields obtained on electrochemical oxidation of uric acid almost exactly parallel those reported for the enzymatic oxidation of uric acid, particularly with the peroxidase enzymes (15, 16). Accordingly it is propsed that the mechanisms developed here for the electrochemical and related chemical reactions of uric acid can be used to describe the biological oxidation of this compound.

The mechanism of oxidation of xanthine, once the initial $2e$-$2H^+$ oxidation to uric acid has occurred, almost exactly parallels the mechanism for the latter compound.

The mechanism of oxidation of other naturally occurring biologically important purines can also be nicely explained by advocating that the primary electro-oxidations proceed through sequential $2e$-$2H^+$ oxidations of available unsubstituted ring —C=N— bonds leading ultimately to oxidation of the C_4=C_5 bond to give a bis-imine or on occasion a bis-iminium ion (*e.g.*, in the case of 3,7-dimethylxanthine, methylation at N_3 and N_7 results in formation of a cationic bis-iminium ion intermediate). Hydration to a 4,5-diol then occurs followed by its decomposition to the various products. Details of these mechanisms and their relationship to biological oxidations of these purines will appear elsewhere (11).

The Mechanism of the Zinc(II)-Zinc Amalgam Electrode Reaction in Alkaline Media As Studied by Chronocoulometric and Voltammetric Techniques

DeWitt A. Payne[1] and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The reduction of zinc(II) and the oxidation of zinc amalgam was studied in 0.18-4.0*M* KOH solutions. The primary electrochemical technique employed was potential step chronocoulometry with data acquisition on a small digital computer. The kinetic parameters were obtained by fitting the experimental charge-time curves to the complete theoretical equation for a stepwise electron transfer mechanism. The sytem was also studied by d-c and a-c polarography and linear scan voltammetry. The results of this study were compared to those of previous workers and shown to be consistent with a mechanism based on stepwise electron transfer

$Zn(OH)_4^{2-} \rightleftarrows Zn(OH)_2 + 2\,OH^-$

$Zn(OH)_2 + e \rightleftarrows Zn(OH)_2^-$

$Zn(OH)_2^- \rightleftarrows Zn(OH) + OH^-$

$Zn(OH) + Hg + e \rightleftarrows Zn(Hg) + OH^-$

One of the most significant features of the study of electrochemical kinetics during the last 20 years has been the evolution of theoretical and experimental procedures which are useful in uncovering the different stages in the complex series of processes which comprise an electrode reaction. An investigation of the kinetics of an electrochemical reaction would ideally lead to the elucidation of the nature of the various steps and a determination of their rate constants, the identification of the intermediates and products, and the determination of the adsorption isotherm for all adsorbed species. Usually, because of experimental and theoretical limitations, only part of the information is accessible for a given system. Although characterization of intermediates is of prime importance, direct observation of these may not be possible if their concentrations are too low or their lifetimes are too short. However, analysis of the current-potential relationship obtained by several nonsteady-state methods can yield further information on complex mechanisms and faster processes.

Of particular interest in this work is the study of electrode processes involving more than one electron transfer step (1). Vetter (2-4), Hurd (5), and Mohilner (6) have calculated the steady-state polarization curves for a set of two or more consecutive single electron transfer steps. Some reactions for which consecutive electron transfer mechanisms have been proposed on the basis of steady state-measurements are Tl(III)/Tl(I) (7) and quinone/hydroquinone (8). The theory of consecutive electron transfer mechanisms for electrochemical techniques involving potential steps, current steps, and a-c polarography has also been given (9-15).

The establishment of the mechanisms of an electrode reaction often requires acquiring large amounts of accurate experimental data and fitting this data to complicated theoretical equations. Digital data acquisition systems (16-21), especially those based on general purpose programmable digital computers (20, 21), have been very useful, particularly for experimental times in the sub-second region, in obtaining this data. The data obtained by these methods can be fitted to the equations in their complete form, without the necessity of approximations or linearizations sometimes required to make the analysis of data tractable. We report here a study of the zinc(II)-zinc amalgam system using several electrochemical methods and digital data acquisition techniques.

A number of studies of the alkaline zinc electrode reaction have been made. A significant part of this effort has come from the space program's search for high energy-density primary and secondary batteries and the important role of silver/zinc and zinc/air primary batteries in this connection. Although studies of the alkaline zinc electrode reaction often are concerned with reactions at the pure metal electrode, it is common practice in batteries to amalgamate the zinc plates. Hence, we deemed a study of the alkaline zinc(I)-zinc amalgam electrode reaction justified. Moreover, the reaction at the amalgam electrode is easier to understand than the reaction at the pure metal electrode, which may be complicated by the crystallization process and more difficult surface preparation.

A number of workers (22-31) have studied the alkaline zinc(II)-zinc amalgam electrode reaction with somewhat different results. Gerischer (22, 23) determined reaction orders of hydroxide, zinc, and zincate by measuring the change of the charge transfer resistance with concentration and expressed the exchange current, i_o, as

$$i_o = 2FAk^o[Zn(OH)_4^{=}]^{0.5}[Zn(Hg)]^{0.5}[OH^-]^{0.0} \quad [1]$$

This result led to the reaction mechanism in Eq. [2] and [3]

$$Zn(OH)_4^{2-} \overset{fast}{\rightleftarrows} Zn(OH)_2 + 2\,OH^- \quad [2]$$

$$Zn(OH)_2 + 2e \rightleftarrows Zn(Hg) + 2\,OH^- \quad [3]$$

Farr and Hampson (24) duplicated Gerischer's results in ultrapure solutions by faradaic impedance measurements. Matsuda and Ayabe (25) studied the reduction

* Electrochemical Society Active Member.

[1] Present address: Tennessee Eastman Company, Kingsport, Tennessee 37660.

Key words: potential step chronocoulometry, electrode reaction kinetics, polarography, digital data acquisition, consecutive electron transfer reactions.

process by d-c polarography and found that the mechanism was the same as that of Gerischer, but that α was 0.42 Behr *et al.* (26) and Morinaga (27) also obtained results which were consistent with the above mechanism. Stromberg and co-workers (28-31) obtained results which were similar to those of Matsuda and Ayabe (25) for the reduction process but found that the oxidation process did not fit the mechanism proposed from the study of the reduction reaction. They proposed that the reduction and the oxidation involved two different, totally irreversible reactions, each involving a single two-electron transfer step. Their mechanism for the oxidation reaction was

$$Zn(Hg) + OH^- \rightarrow Zn(OH)^+ + 2e \quad [4]$$

$$Zn(OH)^+ + 3\ OH^- \rightarrow Zn(OH)_4^{2-} \quad [5]$$

with $\alpha_R = 0.39$ (for [3]) and $1 - \alpha_O = 0.23$ (for [4]).

The measurements of Gerischer, Morinaga, and Farr and Hampson showed that there was essentially no dependence of the exchange current on hydroxide concentration, while the mechanism of Popova and Stromberg (31) would predict a fairly large variation of exchange current with hydroxide concentration. The mechanism we propose, based on the results shown below, involves consecutive one-electron transfer steps.

Experimental

Chemicals.—Stock solutions of 4.0*M* KOH and 4.0*M* KF were prepared from "Baker Analyzed" Reagent grade KOH and KF obtained from the J. T. Baker Chemical Company. The KOH solution was standardized by titrating a known amount of reagent grade potassium biphthalate using phenolphthalein as an end-point indicator. A stock solution of 0.05*M* zinc(II) was made by dissolving "Baker Analyzed" ZnO in 50 ml of stock KOH solution. The Zn(II) solution was standardized by titrating with EDTA buffered to pH 10. Purification of experimental solutions with acid washed activated charcoal (Barker's method) was tried, but the results were the same with or without this step, so this procedure was not used regularly. Solutions were prepared by pipeting a known amount of KOH stock solution into a volumetric flask and then diluting with the stock KF solution, so that all solutions were at the same ionic strength. Zinc amalgam was prepared from 99.9% zinc wire and purified mercury. The zinc wire was amalgamated by dipping in mercuric chloride solution for a few seconds before it was placed in the mercury to aid in more rapid dissolution of the zinc. The amalgam was stored under vacuum and removed from the storage vessel under a blanket of prepurified helium. Under these conditions, the concentration of zinc in the amalgam would remain stable for more than a week.

All experiments were carried out under a blanket of nitrogen. Commercial water-pumped nitrogen was purified by first bubbling it through distilled water, then through a solution of vanadous chloride standing over saturated zinc amalgam, then passing over copper strands heated to at least 350°C, and finally through distilled water again. The copper strands had previously been exposed to oxygen at high temperature and then been reduced by passage of hydrogen gas at high temperature in order to assure an active surface. The water used in all experiments and in preparation of solutions was deionized water that had been further purified by distillation from alkaline potassium permanganate in a Barnstead water still; its conductivity was less than 10^{-7} (ohm-cm)$^{-1}$. Potassium hydroxide, potassium fluoride dihydrate, and zinc oxide were reagent grade chemicals and were used without further purification. Commercial mercury was washed in 5% HNO_3 with air bubbling for several days, then splashed at least twice through a 5% HNO_3 scrubbing tower. After drying, the mercury was distilled twice under vacuum.

Apparatus.—A single compartment electrolytic cell manufactured by Metrohm Ltd. (Model EA664) and obtained from Brinkmann Instruments was used for all experiments. The working electrode was either a hanging mercury drop electrode (h.m.d.e.) or a dropping mercury electrode (d.m.e.). The auxiliary or counterelectrode was a piece of platinum wire immersed directly in the solution. The reference electrode was a saturated calomel electrode (SCE) which was separated from the solution by a Luggin-Haber capillary. The tip of the capillary was placed as close as possible to the working electrode to minimize uncompensated resistance. The hanging mercury drop electrode was manufactured by Metrohm Ltd. (Model E-410). A fresh drop of 0.032 cm^2 theoretical area was used for each run. The capillary tip had to be cut off at intervals since the strong alkali solution attacked the glass, and eventually the tip would not hold a drop of the proper size. Electrical contact to the drop was made by inserting a platinum wire into the reservoir through the pumping nipple.

The d.m.e. was constructed from a length of Sargent 6-12 second capillary. The mercury flow rate of the d.m.e. was measured before each experiment since the capillary did not last long before the tip had to be cut off, changing the flow rate.

Potential step chronocoulometry was performed with an instrument previously described (32) constructed from Philbrick solid-state operational amplifiers. A fraction of the voltage generated by the current follower could be fed back to the potentiostat for resistance compensation; the stabilization scheme of Brown *et al.* (33) was used. A-C and d-c polarography were performed using a Princeton Applied Research Corporation, Princeton, New Jersey, Model 170 electrochemical instrument. Data from potential step experiments were taken using a PDP-12A computer system (Digital Equipment Corporation, Maynard, Massachusetts). Data for potential sweep experiments at sweep rates below 300 mV/sec were recorded on a Moseley 2D-2 X-Y recorder. For sweep rates above 300 mV/sec, a Tektronix Model 564 storage oscilloscope was used with Type 2A3 (Y axis) and Type 2A63 (X-axis) plug-ins. Permanent records of oscilloscope data were made with a Polaroid camera mounted on the oscilloscope using 3000 speed film.

Initial and final potentials for potential step experiments and initial potentials for potential sweep experiments were measured with a United Systems Corporation Model 204 voltmeter to an accuracy of ±1 mV. Two of the relays in the relay register of the PDP-12 computer were used to control the potentiostat and integrator. Timing of data acquisition was controlled by internal computer cycle counting; the time scale was calibrated by acquiring data from a function generator (Wavetek Model 114).

Data were taken at the same potentials and the same time scales with and without zinc present. Different time scales were used at different potentials so that the charge measured with zinc was significantly larger than that without zinc, but at short enough times that sufficient kinetic information was still present. The quantity $nFAD^{1/2}C/\pi^{1/2}$, which is the slope of a Q *vs.* $t^{1/2}$ plot when the potential is stepped far enough so that the reaction rate is controlled by mass transfer, was evaluated for the reduction of zinc(II) by stepping from -1.0 to -1.7V and for the oxidation of zinc amalgam by stepping from -1.7 to -1.0V and least squares analysis on the $Q - t^{1/2}$ data. Three or four steps were averaged for each potential using a fresh drop each time.

The data acquisition system was checked by recording a current-time curve with a simple *RC* dummy cell ($R = 5$ kohm, $C = 1\ \mu f$) for the potential stepped from 0 to $+0.400$V. The accuracy of measurement was 1.2% or better. Further details about the apparatus, procedures, and calibrations are available (34).

Theory

The best method of proving that a charge transfer reaction consists of more than one electron transfer step is to demonstrate the existence of the intermediate products by some unambiguous technique (1).

Consider the case

$$O + n_1 e \rightleftarrows Y \quad E_1^{o'} \qquad [6]$$

$$Y + n_2 e \rightleftarrows R \quad E_2^{o'} \qquad [7]$$

At equilibrium, from the Nernst equations for [6] and [7]

$$\frac{C_Y^{n_1+n_2}}{C_R^{n_1} C_O^{n_2}} = K = \exp\left\{\frac{n_1 n_2 \mathbf{F}}{RT}(E_1^{o'} - E_2^{o'})\right\} \qquad [8]$$

Hence, for a given total concentration of O and R, C^*, the maximum amount of Y is present when $C_R = C_O$. If $E_1^{o'}$ is much greater than $E_2^{o'}$, then solutions containing essentially only Y can be made. If $E_1^{o'} = E_2^{o'}$, then $K = 1$ and for $n_1 = n_2 = 1$, the maximum C_Y is given by $C_O = C_Y = C_R$. As the quantity $E_1^{o'} - E_2^{o'}$ becomes more negative, the maximum amount of Y that can be present decreases rapidly. For example, for $n_1 = n_2 = 1$, and $C_O = C_R = C^*$, if $E_1^{o'} - E_2^{o'} = -0.2V$, then $C_Y \approx 0.03\ C^*$, while if $E_1^{o'} - E_2^{o'} = -0.4V$, $C_Y \approx (4 \times 10^{-4})C^*$.

However, depending upon the values of the rate constants for steps [6] and [7], the existence of stepwise electron transfer and transient formation of an intermediate, Y, can be deduced from electrochemical measurements [see Ref. (1) and general treatment of Albery and Hitchman (35)].

Potential step chronocoulometry (33, 34) was chosen as the principal electrochemical investigative procedure in this research, because integration of the current signal removes most of the high-frequency noise from this signal. Moreover, the integrated signal always starts from zero and can always be adjusted to stay on a given scale, while in chronoamperometry initial double-layer charging current may be several orders of magnitude larger than the faradaic current so that to obtain sufficient precision in the region of interest, the signal must be allowed to overdrive the amplifiers of the measuring instrument. Chronocoulometry can also be used to obtain information about the double layer (36, 37). Although the theoretical equations for stepwise electron transfers in chronocoulometry have not been presented previously, they can be obtained quite easily by integration of the appropriate equations of chronoamperometry.

Potentiostatic current-time behavior for systems involving a quasi-reversible two-step charge transfer was first derived by Hung and Smith (10) for the analytical solution for this case in a-c polarography. The partial differential equations and boundary conditions used by these authors in obtaining the following results are given in the Appendix. For the reaction given in Eq. [6] and [7] and following the notation of Hung and Smith (10), let

$$\psi_1(t) = \frac{i_1(t)}{n_i \mathbf{F} A C^*_O D_O^{1/2}} \qquad [9]$$

$$\beta_i = 1 - \alpha_i \ (i = 1,2) \qquad [10]$$

$$D_1 = D_O^{\beta_1} D_Y^{\alpha_1} \quad D_2 = D_Y^{\beta_2} D_R^{\alpha_2} \qquad [11]$$

$$f_1 = f_O^{\beta_1} f_Y^{\alpha_1} \quad f_2 = f_Y^{\beta_2} f_R^{\alpha_2} \qquad [12]$$

$$E^r_{1/2,1} = E_1^{o'} - \frac{RT}{n_1 \mathbf{F}} \ln\left(\frac{f_Y}{f_O}\right)\left(\frac{D_O}{D_Y}\right)^{1/2} \qquad [13]$$

$$E^r_{1/2,2} = E_2^{o'} - \frac{RT}{n_2 \mathbf{F}} \ln\left(\frac{f_R}{f_Y}\right)\left(\frac{D_Y}{D_R}\right)^{1/2} \qquad [14]$$

$$j_i = \frac{n_i \mathbf{F}}{RT}(E - E^r_{1/2,i}) \ (i = 1,2) \qquad [15]$$

These authors showed that the current during a step to potential E is given by Eq. [16].

$$i(t) = \mathbf{F} A C^*_O D_O^{1/2} [n_1 \psi_1(t) + n_2 \psi_2(t)] \qquad [16]$$

where

$$\psi_1(t) = \frac{\lambda_1}{(1 + e^{j_1})(\chi_+ + \chi_-)} [(\chi_- - \lambda_2) \exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2}) - (\chi_+ - \lambda_2) \exp(\chi_+^2 t) \operatorname{erfc}(\chi_+ t^{1/2})] \qquad [17]$$

$$\psi_2(t) = \frac{\lambda_1 \lambda_2}{(1 + e^{j_1})(1 + e^{j_2})(\chi_- - \chi_+)} [\exp(\chi_+^2 t) \operatorname{erfc}(\chi_+ t^{1/2}) - \exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2})] \qquad [18]$$

$$\chi_\pm = \frac{\lambda_1 + \lambda_2 \pm [(\lambda_1 + \lambda_2)^2 - 4K]^{1/2}}{2} \qquad [19]$$

$$K = \lambda_1 \lambda_2 \left[\frac{e^{j_2} + e^{-j_1} + e^{(j_2 - j_1)}}{(1 + e^{j_2})(1 + e^{j_1})}\right] \qquad [20]$$

$$\lambda_i = \frac{k^o_i f_i}{D_i^{1/2}} (e^{-\alpha_i j_i} + e^{\beta_i j_i}) \qquad (i = 1,2) \qquad [21]$$

Since we are interested here only in the case where $E_1^{o'} << E_2^{o'}$, and because $E \approx E^r_{1/2} = (E^r_{1/2,1} + E^r_{1/2,2})/2$, some simplifications can be made in these equations, yielding

$$\psi_1(t) = \frac{\lambda_1}{(1 + e^{j_1})(\lambda_1 + \lambda_2)} [\lambda_2 \exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2}) + \lambda_1 \exp(\chi_+^2 t) \operatorname{erfc}(\chi_+ t^{1/2})] \qquad [22]$$

$$\psi_2(t) = \frac{\lambda_1 \lambda_2}{(1 + e^{j_1})(\lambda_1 + \lambda_2)} [\exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2}) - \exp(\chi_+^2 t) \operatorname{erfc}(\chi_+ t^{1/2})] \qquad [23]$$

The expression for $Q(t)$ is obtained by integrating the above equations to obtain Eq. [24] and [25]

$$\int \psi_1(t) dt = \frac{\lambda_1}{(1 + e^{j_1})(\lambda_1 + \lambda_2)} \left[\frac{\lambda_2}{\chi_-^2}\left(\exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2}) + \frac{2\chi_- t^{1/2}}{\pi^{1/2}} - 1\right) + \frac{\lambda_1}{\chi_+^2}\left(\exp(\chi_+^2 t) \operatorname{erfc}(\chi_+ t^{1/2}) + \frac{2\chi_+ t^{1/2}}{\pi^{1/2}} - 1\right)\right] \qquad [24]$$

$$\int \psi_2(t) = \frac{\lambda_1 \lambda_2}{(1 + e^{j_1})(\lambda_1 + \lambda_2)} \left[\frac{1}{\chi_-^2}\left(\exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2}) + \frac{2\chi_- t^{1/2}}{\pi^{1/2}} - 1\right) - \frac{1}{\chi_+^2}\left(\exp(\chi_+^2 t) \operatorname{erfc}(\chi_+ t^{1/2}) + \frac{2\chi_+ t^{1/2}}{\pi^{1/2}} - 1\right)\right] \qquad [25]$$

Since χ_+ is much greater than χ_-, the term in the above equations in χ_+ can be neglected compared to the term in χ_-. Under these conditions, then

$$\int \psi_1(t) dt = \int \psi_2(t) dt \qquad [26]$$

and, defining Z_c as in Eq. [27]

$$Z_c = \frac{(n_1 + n_2) \mathbf{F} A D_O^{1/2} C^*_O \lambda_1 \lambda_2}{(1 + e^{j_1})(\lambda_1 + \lambda_2)} \qquad [27]$$

then

$$Q(t) = \frac{Z_c}{\chi_-^2}\left(\exp(\chi_-^2 t) \operatorname{erfc}(\chi_- t^{1/2}) + \frac{2\chi_- t^{1/2}}{\pi^{1/2}} - 1\right) \qquad [28]$$

For the case where R is initially present but not O and the potential is stepped in the positive direction, the expression for $Q(t)$ is the same as that in [28] except that Z_c is replaced by Z_a

$$Z_a = \frac{(n_1 + n_2)FAD_R{}^{1/2}C^*{}_R\lambda_1\lambda_2}{(1 + e^{-j_2})(\lambda_1 + \lambda_2)} \quad [29]$$

Thus, for a two-step electron transfer reaction, the equation for $Q(t)$ is identical in form to the expression for $Q(t)$ for single-step charge transfer, Eq. [30] (36, 37)

$$Q(t) = \frac{K}{\lambda^2}\left(\exp(\lambda^2 t)\ \mathrm{erfc}(\lambda t^{1/2}) + \frac{2\lambda t^{1/2}}{\pi^{1/2}} - 1\right) \quad [30]$$

$$\lambda = \frac{k^o}{D^{1/2}}(e^{-\alpha j} + e^{\beta j}) \quad [31]$$

$$j = \frac{nF}{RT}(E - E^{o\prime}) \quad [32]$$

$$K = nFAk^o(C^*{}_O e^{-\alpha j} - C^*{}_R e^{\beta j}) \quad [33]$$

To use Eq. [28] or [29] to determine kinetic parameters and reaction mechanisms, one steps from a potential where no appreciable current flows to one where a measurable cathodic or anodic current is obtained and measures the Q *vs.* t behavior. From this data K and λ are determined. These values are determined at a number of potentials and then the logarithm of K and λ are plotted *vs.* the potential. For a single-step charge transfer case, the plot of ln K *vs.* E is a straight line with a slope equal to $-\alpha nF/RT$. The plot of ln λ *vs.* E is a curve which has a minimum near $E^{o\prime}$ and asymptotically approaches straight lines for E greater than and less than $E^{o\prime}$. The slope of the asymptote for E less than $E^{o\prime}$ is $-\alpha nF/RT$, while for E greater than $E^{o\prime}$, it is $\beta nF/RT$.

In the case of a two-step charge transfer reaction, Z and χ_- can be determined from Q *vs.* t (or i *vs.* t) data in the same manner as K and λ in a one-step reaction. However, the behavior of the plots of ln Z and ln χ_- *vs.* E can be more complex than in the one-step case. It is this difference in behavior that can sometimes allow one to demonstrate the existence of a two-step mechanism. The behavior of ln χ_- *vs.* E and ln Z *vs.* E can be illustrated by some examples:

(*i*) If $k^o{}_1$ and $k^o{}_2$ are very large, then the over-all rate of the reaction may be so fast that the reaction appears to be Nernstian. In this case, it is not possible to calculate χ_- and Z and the reaction is indistinguishable from a one-step multi-electron transfer reaction (10).

(ii) For $k^o{}_1 >> k^o{}_2$, when $(RT/F)\ln(k^o{}_2/k^o{}_1) < E < E^r{}_{1/2,2}$, then $\partial \ln Z_c/\partial E = -(1 + \alpha_2)F/RT$ [see Fig. 1 (Z_c,1)] and ln χ_- has a minimum near $E = 0$ (where $E^r{}_{1/2,1}$ is taken as -0.2V, and $E^r{}_{1/2,2}$ is $+0.2$V). When $(RT/F)\ln(k^o{}_2/k^o{}_1) < E < O$, then $\partial \ln(\chi_-)/\partial E = -(1 + \alpha_2)F/RT$ [Fig. 1 ($\chi_{-,2}$)]. When $O < E < E^r{}_{1/2,2}$ $\partial \ln(\chi_-)/\partial E = (1 - \alpha)F/RT$ [Fig.1 ($\chi_{-,1}$)] and $\partial \ln Z_a/\partial E = \beta_2F/RT$ [Fig. 1 (Z_a,1)]. When $E^r{}_{1/2,1} < E < (RT/F)\ln(k^o{}_2/k^o{}_1)$, then $\partial \ln Z_c/\partial E = -\alpha_1F/RT$ [Fig. 1 (Z_c,2)], $\partial \ln Z/\partial E = (2 - \alpha_1)F/RT$ [Fig. 1 (Z_a,2)] and $\partial \ln(\chi_-)/\partial E = -\alpha_1F/RT$ [Fig. 1 (χ_-,3)].

(*iii*) For $k^o{}_2 >> k^o{}_1$, the results are the mirror image of those for case (*ii*) above.

(*iv*) The results for $k^o{}_2 = k^o{}_1$ are shown in Fig. 2. Therefore, to determine whether a reaction is single step or multi-step, not only must the over-all reaction be slow enough to be measurable, but also the rate must be slow enough to be measurable in the vicinity of

$$E' = \frac{E^r{}_{1/2,1} + E^r{}_{1/2,2}}{2} + \frac{RT}{F}\ln\frac{k^o{}_2}{k^o{}_1} \quad [34]$$

Otherwise, the reaction is indistinguishable from a single-step reaction. For example, for $k^o{}_2 >> k^o{}_1$, if the most positive potential at which measurements of Z and χ_- can be made is less than E' in 38, then $\partial \ln Z_a/\partial E = (2 - \alpha_1)F/RT$ and $\partial \ln Z_c/\partial E = -\alpha_1F/RT$. Under these conditions $\partial \ln Z_a/\partial E - \partial \ln Z_c/\partial E = 2F/RT$ and the results cannot be distinguished from a single-step reaction with the same over-all rate and $\alpha = \alpha_1/2$. The behavior of ln (χ_-) is similarly indistinguishable.

In order to assign values to both α_1 and α_2, both cathodic and anodic plots of ln Z and ln χ_- *vs.* E must have linear segments whose slope is less than n_iF/RT.

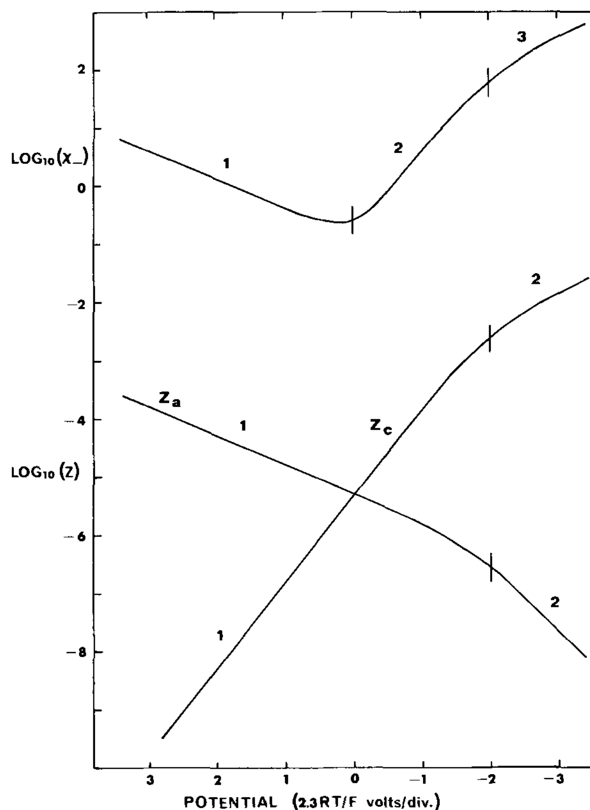

Fig. 1. Log χ_- and log Z vs. E for case (*ii*). $\alpha_1 = \alpha_2 = 0.5$, $E^r{}_{1/2,1} = -0.2$V, $E^r{}_{1/2,2} = +0.2$, $k^o{}_1 = 2.0$, $k^o{}_2 = 0.02$, $n_1 = n_2 = 1$, $D_1{}^{1/2} = D_2{}^{1/2} = 0.00316$, $f_1 = f_2 = 1.0$, $C_O = C_R = 2.03 \times 10^{-6}$ moles/cm^3, $A = 0.032$ cm^2.

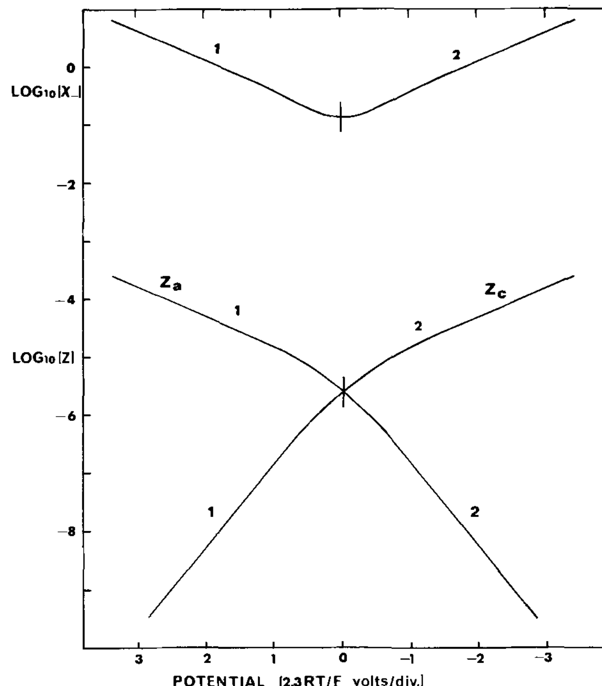

Fig. 2. Log χ_- and log Z vs. E from case (*iv*). The conditions are the same as in Fig. 1 except $k^o{}_1 = 0.02$.

Then α_1 can be obtained from the slope of the cathodic plot and α_2 can be obtained from the slope of the anodic plot. $(E^r{}_{1/2,1} + E^r{}_{1/2,2})/2$ can be determined from the potential where $Z_a = Z_c$

$$E_{Z_a=Z_c} = \frac{n_1E^r{}_{1/2,1} + n_2E^r{}_{1/2,2}}{n_1 + n_2} + \frac{RT}{(n_1 + n_2)\mathbf{F}} \ln \frac{C^*{}_O}{C^*{}_R} \quad [35]$$

Even here $k^o{}_1$, $k^o{}_2$, $E^r{}_{1/2,1}$, and $E^r{}_{1/2,2}$ cannot be assigned absolute values, since the value of $E^r{}_{1/2,2} - E^r{}_{1/2,1}$ is not known. We can, however, measure k_1' and k_2' at $(E^r{}_{1/2,1} + E^r{}_{1/2,2})/2$.

For $n_1 = n_2 = 1$

$$k_1' = \frac{k^o{}_1}{\exp\left[\frac{-\alpha_1\mathbf{F}}{RT}\left(\frac{E^r{}_{1/2,2} - E^r{}_{1/2,1}}{2}\right)\right]} \quad [36]$$

$$k_2' = \frac{k^o{}_2}{\exp\left[\frac{(1-\alpha_2)\mathbf{F}}{RT}\left(\frac{E^r{}_{1/2,2} - E^r{}_{1/2,1}}{2}\right)\right]} \quad [37]$$

If we could measure the concentration of Y at equilibrium, we could then determine the value of $E^r{}_{1/2,2} - E^r{}_{1/2,1}$. For purposes of calculation it is sufficient to select a value of $E_2 - E_1$ greater than 0.2V and use that to calculate $k^o{}_1$ and $k^o{}_2$ from the observed k_1' and k_2'. Using the values determined above for α_1, α_2, $E^r{}_{1/2,1}$, $E^r{}_{1/2,2}$, n_1, n_2, $k^o{}_1$, and $k^o{}_2$, one can calculate Z and χ_- over the whole potential range and see if these values give a good fit in the nonlinear portions of the ln Z and ln χ_- *vs.* E plots. If the fit is good, one can say with confidence that the charge transfer is multi-step.

Clearly, potential step techniques are particularly useful for distinguishing between single-step and multi-step electron transfer. Hurd (5) has stated that unequivocal proof of a two-step consecutive electron transfer mechanism can only be obtained from steady-state polarization curves if the exchange currents of the two steps differ by a factor of 100 or more while still being less than the mass transfer limited current. Hence, if rate constants are about equal, concentration ratios would have to be very large in order to achieve the necessary exchange currents. Large concentration ratios usually mean large concentrations, high currents, and problems from solution resistance. Potential step techniques allow examination of the current-potential behavior over a wider range of potentials and larger rates than is possible with steady-state techniques since the effects of mass transfer can be accounted for by proper application of potential step theory.

Results

Potential step chronocoulometry.—Kinetic parameters are usually determined by linearization of Eq. [30] by taking Q values only at times where $\lambda t^{1/2} > 5$, so that $\exp(\lambda^2 t)\,\text{erfc}(\lambda t^{1/2})$ is negligible compared to the other terms in this equation (36). A similar procedure is often followed in chronoamperometric experiments (38, 39) where current values at times corresponding to $\lambda t^{1/2} < 0.1$ are used. The difficulty of using these approximations in practice has been discussed [see, for example (40, 41)] and is based on the necessity of knowing the value of λ, the parameter to be determined by the experiment, before the valid approximation zone is established. Moreover, the zone of the approximation may be located where perturbations caused by double layer charging or convection are important. However, the best use of the data is made by fitting the experimental results to the complete theoretical Eq. [30] using a high speed digital computer, and this procedure was followed here. Because digital data acquisition was employed, the data were in a particularly convenient form for further processing on the computer. The procedure followed consisted of guessing initial values of K and λ and calculating values of Q for each t using [30], Q_{calc}. These values are compared to the experimental ones, Q_{exp}, and the total variance, which is the sum of $(Q_{exp} - Q_{calc})^2$, determined. The values of K and λ are changed until the variance has been minimized. Details of this procedure and the method for calculating $\exp(y^2)\,\text{erfc}(y)$ are discussed elsewhere (34). Preliminary chronocoulometric measurements showed that neither reactant (zincate) or product (zinc in mercury) were adsorbed, so that the number of coulombs required to charge the double layer capacitance, Q_{dl}, was determined on a test solution lacking zinc(II) with a pure mercury electrode; Q_{exp} was then taken as $Q_{meas} - Q_{dl}$, where Q_{meas} is the measured charge. This procedure assumes that Q_{dl} is not affected significantly by the presence of the small amounts of zinc in solution or mercury.

The log λ and log K values at various potentials and various hydroxide concentrations determined by this procedure are given in Table I. These values were plotted *vs.* E and αn and βn were determined from the slopes of the linear parts of the cathodic and anodic branches of the plots at constant hydroxide concentration. The dependence on hydroxide ion concentration was determined from plots of log K at constant potential *vs.* log $[OH^-]$. The results are given in Table II. The diffusion coefficients of zinc(II) and Zn(Hg) were determined by measuring K/λ when $|E - E^r{}_{1/2}|$ was large. For the reduction process, this gives the value of $nFAC^*{}_O D_O{}^{1/2}$, while for the oxidation $nFAC^*{}_R D_R{}^{1/2}$. The effective surface area of the Kemula type Metrohm h.m.d.e. has been shown to be about 90% of the geometrical area (42) yielding a value for our electrode of 0.0291 cm^2. With this value for A, $C^*{}_O = 2.03 \times 10^{-6}$ moles/cm^3 and $K_c/\lambda = 2.82 \times 10^{-5}$, we obtain a $D_O{}^{1/2} = 2.47 \times 10^{-3}$ cm/sec$^{1/2}$. Similarly, with $K_a/\lambda = 2.66 \times 10^{-5}$ and $D_R{}^{1/2} = 3.98 \times 10^{-3}$ cm/sec$^{1/2}$ (43), the concentration of zinc in the amalgam, $C^*{}_R$, was found to be 1.19 m*M*. The potentials for the intersection of K_a and K_c and the concentrations of Zn(II) Zn(Hg), and OH^- can be used to calculate $E^r{}_{1/2}$ for the over-all reaction. A plot of $E^r{}_{1/2}$ *vs.* log $[OH^-]$ had a slope of -0.118V and an intercept of -1.445V *vs.* SCE.

D-C polarography.—The zinc(II)/zinc amalgam system in alkaline media exhibits a quasi-reversible polarographic reduction wave. The treatment of the data follows the treatment of Meites and Israel (44) and is similar to that of Matsuda and Ayabe (25). From the Ilkovic equation and the values $m = 1.07$ mg/sec, $t = 1.0$ sec, $i_d = 7.64$ μA and $C^*{}_O = 2.03$ m*M*, we find a value of $D_O{}^{1/2} = 2.53 \times 10^{-3}$ cm/sec$^{1/2}$, in good agreement with the value obtained from the potential step experiment. To determine kinetic data, a plot of $\log[i/(i_d - i)]$ *vs.* E according to the equation for a totally irreversible reaction (44)

$$E = E^{o\prime} + \frac{0.059}{\alpha n}\log\frac{1.349k^o t^{1/2}}{D_O{}^{1/2}} - \frac{0.0542}{\alpha n}\log\frac{i}{i_d - i} \quad [38]$$

was made for values of E sufficiently negative as to make the reverse reaction slow enough to be negligible. Results are given in Table II.

A-C polarography.—Measurement of kinetic parameters by a-c polarography involved phase-sensitive detection of the current, so that the phase angle of the current as well as its magnitude was measured. From this data the cotangent of the phase angle, θ, was determined and used to calculate λ at different values of E (45)

$$\text{Cot}(\theta) = I_{0^o}/I_{90^o} = 1 + (2\omega)^{1/2}/\lambda \quad [39]$$

The kinetic parameters can be obtained from a plot of log λ *vs.* E or directly from a plot of $\cot(\theta)$ *vs.* E by measuring the potential and magnitude of the maximum value of $\cot(\theta)$ (45)

$$[E]_{\max} = E^r_{1/2} + \frac{RT}{n\mathbf{F}} \ln(\alpha/\beta) \quad [40]$$

$$[\cot(\theta)]_{\max} = 1 + \frac{(2\omega D)^{1/2}}{k^o[(\alpha/\beta)^{-\alpha} + (\alpha/\beta)^{\beta}]} \quad [41]$$

The results are shown in Table II.

Potential sweep voltammetry.—Kinetic parameters can be obtained from linear potential sweep voltammetry at a stationary electrode by observing the variation of E_p or of $E_p - E_{p/2}$ with scan rate, v (46). Kinetic parameters for the cathode reaction were obtained from experiments in a 1.0M KOH solution containing 2.03 mM zinc(II) at a mercury electrode while those for the anodic reaction used a zinc amalgam electrode, [Zn] = 1.2 mM and 1.0M KOH (34). Kinetic parameters obtained from these measurements are shown in Table II.

Discussion

The results obtained by the different electrochemical methods in Table II are in fair agreement with each other. These results show that the electrode reaction of zinc in alkaline media is not a simple quasi-reversible two-electron transfer. First, the quantity $\alpha n + \beta n$ is much less than two, when α and β are calculated from the appropriate slopes measures well away from $E^r_{1/2}$. Second, the log K *vs.* E plots show definite curvature in the region near $E^r_{1/2}$. This curvature cannot be due to double-layer effects, since the rate of change of potential at the outer Helmholtz plane with electrode potential is nearly constant in the region of interest, which is far negative of the potential of zero charge, and the solution has a high ionic strength. Nor can it be explained by uncompensated resistance, since the region of maximum curvature is in the region where K was less than 100 μA, and the uncompensated resistance was less than 10 ohms, *i.e.*, where the curvature was most pronounced, contributions from IR effects were at a minimum. These features correspond quite closely to a consecutive electron transfer mechanism, however, and the following mechanism appears to fit the experimental data quite well

$$Zn(OH)_4^{2-} \rightleftarrows Zn(OH)_2 + 2\,OH^- \quad [42]$$

$$Zn(OH)_2 + e \rightleftarrows Zn(OH)_2^- \quad [43]$$

$$Zn(OH)_2^- \rightleftarrows Zn(OH) + OH^- \quad [44]$$

$$Hg + Zn(OH) + e \rightleftarrows Zn(Hg) + OH^- \quad [45]$$

Comparison of this model to the experimental results is simplified by using a modification of the notation of Hung and Smith (10), with O representing $Zn(OH)_2$; YO, $Zn(OH)_2^-$; YR, $Zn(OH)$; and R, $Zn(Hg)$. With $f_O = [OH^-]^2, f_{YO} = 1.0, f_{YR} = [OH^-]^{-1}$, and $f_R = [OH^-]$, the following equations hold for $E^r_{1/2,1}$ and $E^r_{1/2,2}$

$$E^r_{1/2,1} = E_1^{o\prime} + \frac{RT}{2\mathbf{F}} \ln \frac{D_O}{D_{YO}} + \frac{RT}{\mathbf{F}} \ln \frac{f_O}{f_{YO}} \quad [46]$$

$$E^r_{1/2,1} = E_1^{o\prime} + \frac{RT}{2\mathbf{F}} \ln \frac{D_O}{D_{YO}} - \frac{RT}{\mathbf{F}} \ln[OH^-]^2 \quad [47]$$

$$E^r_{1/2,2} = E_2^{o\prime} + \frac{RT}{2\mathbf{F}} \ln \frac{D_{YR}}{D_R} - \frac{RT}{\mathbf{F}} \ln[OH^-]^2 \quad [48]$$

At constant $E - E^r_{1/2}$, the hydroxide dependence of λ_1 is proportional to f_1 and λ_2 to f_2, where f_1 and f_2 are given by Eq. [49] and [50]

$$f_1 = f_O^{\beta_1} f_{YO}^{\alpha_1} = [OH^-]^{-0.36} \quad [49]$$

$$f_2 = [OH^-]^{-0.32} \quad [50]$$

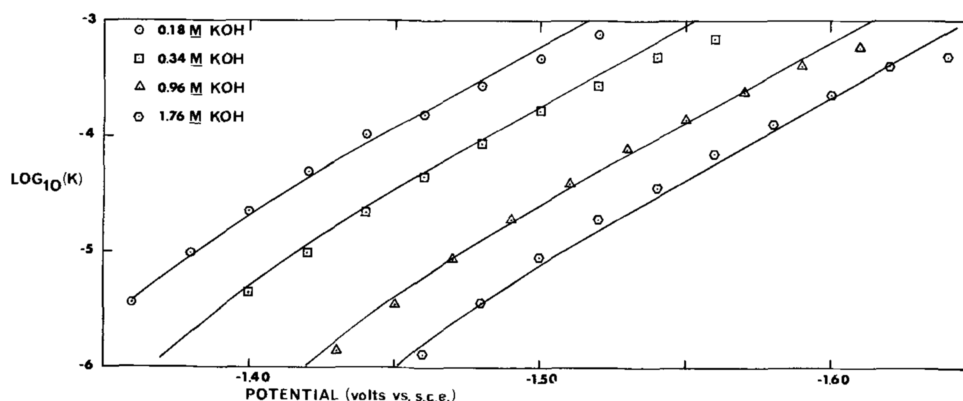

Fig. 3. Log K_c vs. E for reduction reaction. Comparison of experimental data from potential-step chronocoulometry ($[Zn(OH)_4^{2-}]$ = 2.03 mM) with values calculated from consecutive-electron transfer theory.

This means that for any given value of $E - E^r_{1/2}$, the hydroxide dependence will be small. In particular, when λ_1 is nearly equal to λ_2, and the hydroxide concentration is about 1.0*M*, the hydroxide dependence of log K and log λ will be zero. Since the region where λ_1 is equal to λ_2 is also the region of curvature of the log K *vs.* E plot, the apparent α measured in this region will be between the values for the high and low slope linear regions; for the Zn(II)/Zn(Hg) reaction αn would be equal to about 1.0 in this region.

The measured values of the hydroxide dependence of log K at constant potential yield the following values for f_1 and f_2: $f_1 = [OH^-]^{-0.21}$ and $f_2 = [OH^-]^{+0.15}$. To obtain a quantitative comparison between model and results, we take $\alpha_1 = 0.82$, $\alpha_2 = 0.66$, $k^o_1 = 0.228$, $k^o_2 = 0.0209$, and use these parameters to calculate values for log K and log λ from consecutive electron transfer theory

$$E^r_{1/2,1} = -1.645 - \frac{RT}{\mathbf{F}} \ln[OH^-]^2 \quad [51]$$

$$E^r_{1/2,2} = -1.245 - \frac{RT}{\mathbf{F}} \ln[OH^-]^2 \quad [52]$$

We find that the potential step data fits the theoretical curves quite well (Fig. 3-6). In particular, in the plot of log K_a *vs.* E where the curvature is most pronounced, the fit is excellent.

These same parameters can also be used to calculate a-c and d-c polarograms using Hung and Smith's equations (10). In calculating polarograms, the Matsuda function (47) was used instead of exp $(\lambda^2 t)$ erfc $(\lambda t^{1/2})$, because a d.m.e. is used for polarography and planar diffusion no longer occurs. The fit between the theoretical a-c polarographic data (cot θ *vs.* E) and d-c polarographic data [log$(i/i_d - i)$ *vs.* E] and the experimental results are shown in Fig. 7 and 8. The agreement between theory and experiment for a-c polarography is not too good, but Delmastro and Smith (48) pointed out that amalgam formation reactions may show large distortions of the current because of spherical diffusion inside the drop. Since the theoretical curves in these figures were calculated with parameters from the potential step experiment, the agreement must be considered satisfactory.

It is of interest to compare our results with those of previous studies (Table III). Gerischer (22, 23) and later Farr and Hampson (24) determined the exchange current i_o by measuring the charge transfer resistance ($R_T = RT/n\mathbf{F}i_o$) at the equilibrium potential of a solution and thus determining the variation of i_o with reactant concentration. From i_o, one can determine α and k^o from the relation

$$i_o = n\mathbf{F}Ak^oC_O^{1-\alpha}C_R^{\alpha} \quad [53]$$

The exchange current can also be determined from consecutive electron transfer theory, either from the equation derived by Vetter (2-4) or from the treatment of Hung and Smith (10)

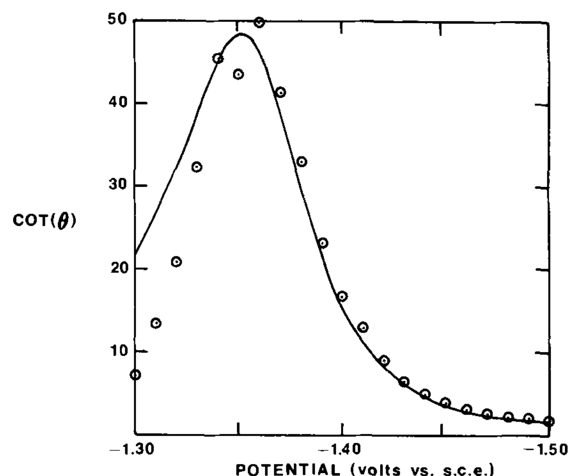

Fig. 7. Comparison of Cot(θ) vs. E data from a-c polarographic measurements with theoretical calculations. The solution contained $[Zn(OH)_4^{2-}] = 2.03$ mM and $[OH^-] = 0.18M$. The d.m.e. was mercury with a drop time of 1 sec. $\omega = 11.0$ Hz.

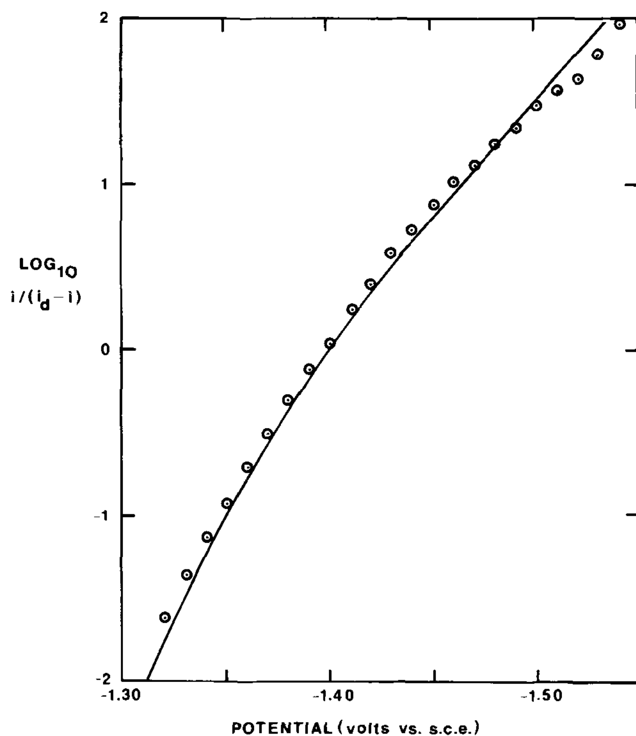

Fig. 8. Comparison of log $i/(i_d - i)$ vs. E data from d-c polarography with theoretical calculations. Conditions same as in Fig. 7.

$$i_o = 2FAC^*_O D_O^{1/2} \frac{\lambda_1\lambda_2}{(1 + e^{j_1})(\lambda_1 + \lambda_2)}$$

$$= 2FAC^*_R D_R^{1/2} \frac{\lambda_1\lambda_2}{(1 + e^{-j_2})(\lambda_1 + \lambda_2)} \quad [54]$$

Using the kinetic parameters obtained from potential step measurements to calculate i_o and R_T and comparing these results with the data in Fig. 2 of Farr and Hampson (24), we calculate an R_T which is larger than their values by a factor of 3.5. This difference may be attributed to differences in the conditions of measurement in the two studies; for example, the ionic strength of Farr and Hampson's solutions was 3.0M, while in the present work, it was 4.0M. They used NaOH and $NaClO_4$ while KOH and KF were used in the present work, and the solutions used by Farr and Hampson were purified by circulation over activated charcoal for at least 28 days. However, when the R_T values calculated from potential step data are divided by 3.5, the values at different Zn(Hg) and OH^- concentrations agree fairly well with those of Farr and Hampson (Fig. 9).

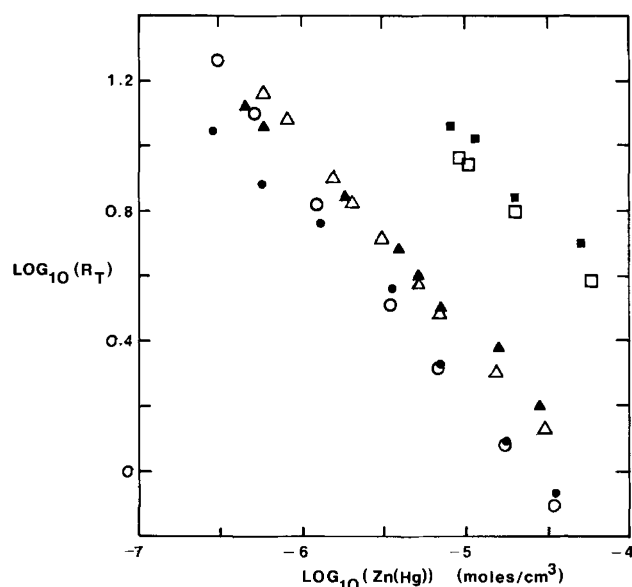

Fig. 9. Log R_T vs. log [Zn(Hg)] for different concentrations of $Zn(OH)_4^{2-}$. Comparison of theoretical calculations with experimental data from Farr and Hampson (24). Squares, $[Zn(OH)_4^{2-}] = 5.05 \times 10^{-6}$ moles/cm^3; triangles, $[Zn(OH)_4^{2-}] = 6.8 \times 10^{-5}$ moles/cm^3; circles, $[Zn(OH)_4^{2-}] = 1.834 \times 10^{-4}$ moles/cm^3. Open symbols are data from this work, solid symbols are from Farr and Hampson.

Matsuda and Ayabe (25) studied the reduction process by d-c polarography. Using the treatment for quasi-reversible polarographic waves they obtained the results shown in Table III, which agree very well with ours for the reduction process.

Stromberg and Popova (29-31) studied both the oxidation and reduction reactions by d-c polarography with a dropping zinc amalgam electrode used to study the oxidation reaction. Their results do not agree very well with the results of the present work for the oxidation reaction, although the agreement is fairly good for the reduction reaction (Table III). However, their results still lead to the conclusion that one hydroxide is involved in the oxidation reaction rate limiting step, since the oxidation rate shows a dependence on the first power of the hydroxide concentration. This observation led Stromberg and Popova to conclude that the oxidation reaction was a two-electron reaction which occurred by a completely different path than that of the reduction reaction (Eq. [4] and [5]). However, if they were correct, then a plot of log K vs. E for any one

hydroxide concentration should be linear over the whole potential range (except for curvature due to double layer effects and distortion due to uncompensated resistance); this is not the case. Moreover, this mechanism does not predict the negligible variation of the exchange current with hydroxide concentration at equilibrium which several other researchers have reported (22-24, 26, 27). The consecutive electron transfer mechanism explains all the observed features.

Recently Despic and co-workers (49) demonstrated that the Cd(II)/Cd(Hg) system in H_2SO_4 solutions, long thought to represent a mechanism involving a simple two-electron charge transfer step, probably occurs by a two-step single electron exchange mechanism. The findings here on the Zn(II)/Zn(Hg) system parallel these results and suggest that other electrode reaction mechanisms previously thought to involve multiple electron transfer steps bear reinvestigation.

The Kinetics of the p-Toluquinhydrone Electrode

F. Kornfeil*

Electronics Technology and Devices Laboratory,
United States Army Electronics Command, Fort Monmouth, New Jersey 07703

ABSTRACT

The reaction mechanism of the redox system p-toluquinone/toluhydroquinone (toluquinhydrone electrode) on smooth platinum was elucidated with the aid of the electrochemical reaction order method. It was found that in the pH range 0.1-3.2 the reaction proceeds according to the scheme $Q + H^+ \rightleftarrows HQ^+$, $HQ^+ + e^- \rightleftarrows HQ$, $HQ + H^+ \rightleftarrows H_2Q^+$, $H_2Q^+ + e^- \rightleftarrows H_2Q$. This mechanism is identical with the HeHe sequence determined by Vetter for the benzoquinone electrode. The relatively fast rate of the charge-transfer steps, however, necessitated measurements of the electrode polarization in the nonsteady state. A method is described to determine the individual exchange current densities in moderately fast consecutive charge-transfer reactions.

The reaction mechanism of the redox couple p-benzoquinone/hydroquinone (quinhydrone electrode) was first elucidated by Vetter (1) who interpreted the steady-state overpotential on smooth platinum with the aid of the electrochemical reaction order method. He showed that, in the over-all electrode reaction $H_2Q \rightleftarrows Q + 2H^+ + 2e^-$, the electrons are exchanged in two different charge-transfer steps. Hale and Parsons (2), using the Koutecky method on dropping mercury, and Eggins and Chambers (3), employing cyclic voltammetry on polished platinum electrodes, arrived at essentially similar conclusions in more recent studies of the reduction of benzoquinone and other p-quinones. The consecutive charge-transfer mechanism is, however, challenged by Loshkarev and Tomilov who account for their experimental results obtained on Pt (4, 5) and other metals (6) by postulating that both electrons are transferred simultaneously in a single charge-transfer step.

The present paper describes an investigation of the kinetics of the redox system methyl-p-benzoquinone/methyl-hydroquinone (toluquinhydrone electrode). The aim of this study has been (*i*) to clarify the situation with respect to the reaction mechanism and (*ii*) to ascertain what effect, if any, the addition of the CH_3-group to the benzene ring may have on the kinetic parameters of the quinhydrone electrode reaction.

Experimental Procedure

All measurements of the overpotential were made at the same constant temperature (25° ± 0.5°C) in solutions of equal ionic strength $\frac{1}{2}\Sigma c_j n_j^2 = 1.0$. The excess of supporting electrolyte accomplished, as usual, the suppression of the ζ-potential to negligible values, minimal tranference numbers t_j, and the virtual constancy of the activity coefficients of all reacting species S_j, thereby making the substitution of c_j for a_j possible.

Electrolyte solutions.—Both the toluquinone and the toluhydroquinone used were obtained from Eastman Kodak "practical grade" reagents. The toluquinone was purified by sublimation under atmospheric pressure and the sublimate collected as canary-yellow needles (mp 68.0°C). The toluhydroquinone, however, required repeated recrystallization from benzene and had to be subsequently twice sublimed in vacuo before snow-white crystals could be obtained (mp 126.5°C). All other reagents used in the electrolyte solutions were of C.P. quality and were used without further purification. Triply distilled water served as the solvent. The toluquinone and toluhydroquinone concentrations varied from 10^{-2} to 10^{-4} molar.

Because of the known vulnerability of aqueous solutions of toluquinhydrone to photodecomposition (7) the toluquinone and toluhydroquinone were dissolved in the electrolyte immediately before the start of each experiment. No decomposition could be detected within a 6-hr period, provided that the solutions were kept free of dissolved oxygen. Purified argon was, therefore, bubbled through the electrolyte at the start of each series and also, intermittently, between individual measurements within a series of determinations of the overpotential. This procedure insured sufficient stability during the 2-3 hr normally required for establishing the anodic and cathodic current density-potential relation at a given concentration.

Reference electrodes.—The values of all electrode potentials ϵ are referred to the SHE and were measured against a Ag/AgCl/KCl(1M) electrode ($\epsilon_0 = +0.2387$ V). Highly stable reference electrodes were prepared by the electrolytic formation of AgCl on thermally reduced spheres ($r \sim 0.2$ cm) of Ag_2O (8) attached to small Pt spirals. The scatter of potential differences among these electrodes never exceeded 0.05 mV.

Electrolysis cell.—A Pyrex cell as shown in Fig. 1 was used in all the polarization measurements described in this paper. The working electrode, a smooth Pt wire ($r \sim 0.25$ mm), was sealed into a glass tube leaving 2.55 cm exposed to the electrolyte solution, and was located along the axis of a cylindrical Pt counter-electrode through which a small hole had been drilled to accommodate the Haber-Luggin capillary of the

* Electrochemical Society Active Member.

Key words: toluquinhydrone electrode, reaction mechanism, exchange current densities, electrochemical reaction order.

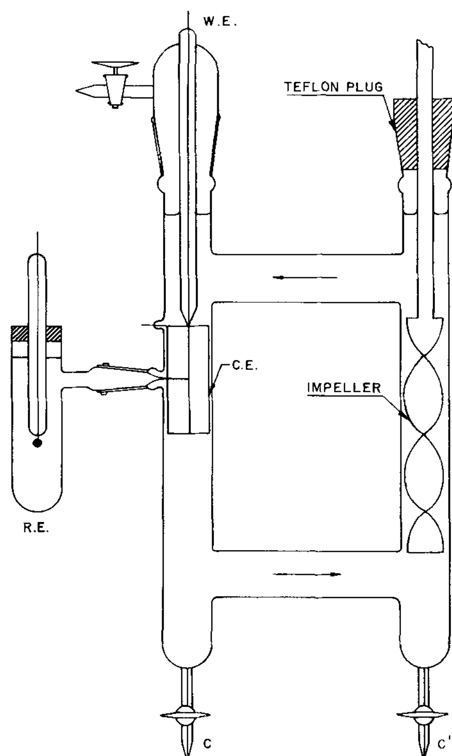

Fig. 1. Electrolysis cell. W.E., working electrode; C.E., counter-electrode; R.E., reference electrode; C,C', argon inlets.

reference electrode. A machined Teflon plug served as the bearing of a Lucite impeller which, driven by a synchronous motor, circulated the electrolyte solution through the cell in the direction indicated by the arrows in order to realize conditions of controlled mass transport during the steady-state electrolysis. The speed of flow (25 cm/sec) was the same as the one reported by Vetter (1) in his work on the benzoquinhydrone electrode and was chosen to facilitate the direct comparison of the test results.

The electrolyte could be drained from the apparatus through stopcocks C and C' which also served as the inlets for the argon. Keeping the working electrode immersed in chromosulfuric acid when not in use and thorough rinsing with distilled water before each series of polarization measurements were the only other precautions necessary to attain a reproducibility of about ±5 mV over the major portion of the current potential curves.

Electrical.—In the measurements of the steady-state overpotential under forced convection the polarizing current $i \times A$ (i = current density in amperes/square centimeters, A = apparent surface area of the working electrode in square centimeters) was controlled[1] by switching in various portions of a high-ohmic network of induction-free resistors connected to a d-c power source[2] of about 400V. The resistance network was designed so that successive switch positions resulted in logarithmic increases of the polarizing current. The potential difference between the working and reference electrodes was measured using the Poggendorff compensation method.[3]

The same circuit was also used in the galvanostatic pulse measurements except that in this case the potentiometer circuit was replaced by a cathode-ray oscilloscope[4] connected to a mercury wetted relay[5] in the triggering circuit. This relay was a new type of high contact resistance ($> 5 \times 10^7$ ohm) and capable of rapid ($< 10^{-9}$ sec), chatter-free closing of the contact. The same milliammeter served to preset the circuit for each desired current density, the electrolysis cell having been temporarily replaced by a suitable resistor.

The electrolyte solution was kept at rest during pulse polarization but was circulated between recordings of the potential-time traces in order to expedite the re-establishment of the equilibrium potential ϵ_o. Extrapolation of the potential transients for $t \to 0$ and correction for the iR-drop between the working electrode and the tip of the Haber-Luggin capillary were carried out according to the method of Gerischer (9).

Results and Discussion

General.—Throughout this discussion i and η will be reckoned positive for the anodic and negative for the cathodic branches of the polarization curves.

The over-all redox electrode reaction can be written as a net oxidation process in the generalized form

$$\Sigma \nu_j S_j + ne^- = 0 \qquad [1]$$

with the equilibrium potential given by

$$\epsilon_o = E_o + RT/n\mathbf{F}\Sigma\nu_j \ln a_j \qquad [2]$$

where ν_j is the stoichiometric coefficient of the species S_j ($\nu_j < 0$ for a reduced, $\nu_j > 0$ for an oxidized species), E_o is the standard electrode potential and the remaining symbols have their usual significance. In the case of the toluquinone electrode (E_o = 0.623V, n = 2) the ν_j's have, therefore, the following values: $\nu_{H_2Q} = -1$, $\nu_Q = +1$, $\nu_{H^+} = +2$.

For the sake of brevity the following indices will be used for ν_j, S_j, and later for the electrochemical reaction order z_j: toluquinone (Q) = 1, toluhydroquinone (H_2Q) = 2, hydrogen ion (H^+) = 3.

The theoretical relationship between the transfer overpotential of a redox electrode and the current density in the stationary state was first derived by Vetter (10, 11) for an electrode reaction of the type $S_r \rightleftarrows S_o + 2e^-$ proceeding via two consecutive charge transfer steps under the formation of an intermediate S_m

$$S_r \rightleftarrows S_m + e^- \quad \text{(transfer step 1)} \qquad [3]$$

$$S_m \rightleftarrows S_o + e^- \quad \text{(transfer step 2)} \qquad [4]$$

each charge transfer step having its own characteristic transfer coefficient (α_1, α_2) and exchange current density ($i_{o,1}$, $i_{o,2}$). Moreover, each species appearing in Eq. [3] and [4] may itself be involved in sufficiently fast chemical reactions.

Under these conditions the i-η relationship is, in its most perspicuous form

$$i = 2i_{o,1} \exp\left(\frac{\alpha_1 \mathbf{F}}{RT}\eta\right) \times \frac{1 - \exp\left(-\frac{2\mathbf{F}}{RT}\eta\right)}{1 + (i_{o,1}/i_{o,2}) \exp\left(-\frac{1 + \alpha_2 - \alpha_1}{RT}\mathbf{F}\eta\right)} \qquad [5]$$

$$i = -2i_{o,2} \exp\left(-\frac{1 - \alpha_2}{RT}\mathbf{F}\eta\right) \times \frac{1 - \exp\left(\frac{2\mathbf{F}}{RT}\mathbf{F}\eta\right)}{1 + (i_{o,2}/i_{o,1}) \exp\left(\frac{1 + \alpha_2 - \alpha_1}{RT}\mathbf{F}\eta\right)} \qquad [5a]$$

Equations [5] and [5a] are identical. However, the consequences of large overpotentials (Tafel lines) and high values of the ratios of the exchange current densities in the intermediate range of η (pseudo-Tafel lines) can be seen more clearly when Eq. [5] is used for anodic ($\eta > 0$) and Eq. [5a] for cathodic ($\eta < 0$) polarizations. The complete theoretical polarization

curves have been systematically examined more recently by Hurd (12) who also investigated the general case of n consecutive transfer steps with numerical solutions supplied for $n = 3$.

In the experimental determination of the i-η relationship the concentrations of toluquinone (c_1) and toluhydroquinone (c_2) were varied in the following electrolyte solutions: 1M HCl (pH = 0.1), 0.01M HCl + 0.99M KCl (pH = 2.14), and 0.03M CH_3COOH + 1M KCl (pH = 3.15).

Steady-state polarization.—Figure 2 shows a typical polarization curve obtained at $c_1 = c_2 = 10^{-2}$ molar in 1M HCl. In all steady-state measurements the irregular (~1 Hz) fluctuations of the electrode potential due to the variations in the mean thickness of the diffusion layer in turbulent flow, characteristic of a diffusion current, were observed when the current density approached the limiting value i_L. The limiting anodic current density was found to be proportional to the toluhydroquinone concentration

$$(i_L)_a = 0.8\, c_2 \quad (A/cm^2) \qquad [6]$$

and the limiting cathodic current density proportional to the toluquinone concentration according to

$$(i_L)_c = 0.9\, c_1 \quad (A/cm^2) \qquad [7]$$

The values of these proportionality constants are somewhat lower than those determined by Vetter (1) under identical conditions, as would be expected from the larger size of the methyl-substituted molecules. It follows (13) from the above that the overpotential associated with the limiting currents is pure diffusion overpotential η_d with no measurable reaction overpotential η_r present.

It can also be seen from Fig. 2 that the contribution of the charge-transfer overpotential to the total overpotential is not nearly large enough for Tafel lines to be drawn with a sufficient degree of accuracy. In addition, the rather steep anodic slope of the polarization curve suggests strongly the possibility of mistaking a pseudo-Tafel line for a true Tafel line. It was for these reasons that the contribution of η_d was eliminated by employing the nonsteady-state method (pulse polarization).

Pulse Polarization.—The appearance of the factor 2 immediately following the equality signs in Eq. [5] and [5a] is due to the fact that, by definition of the stationary state, both charge-transfer reactions proceed at the same rate ($i_1 = i_2 = 0.5i$), otherwise there would occur a net accumulation or depletion of S_m. This condition does, of course, not necessarily prevail at any time before the system has reached the stationary state. It is, therefore, necessary to introduce a "current distribution coefficient" γ in the derivation of the corresponding equation reflecting the condition of the nonsteady-state. The factor γ is then defined as that fraction of the total current density giving rise to the first charge-transfer reaction (Eq. [3]): $\gamma \equiv i_1/i$, $1 - \gamma \equiv i_2/i$. Following the arguments (10) used in the derivation of Eq. [5] and [5a] one obtains

$$i = i_{o,1}/\gamma \exp\left(\frac{\alpha_1 \mathbf{F}}{RT}\eta\right) \times \frac{1 - \exp\left(-\frac{2\mathbf{F}}{RT}\eta\right)}{1 + \frac{(1-\gamma) i_{o,1}}{\gamma\, i_{o,2}} \exp\left(-\frac{1 + \alpha_2 - \alpha_1}{RT}\mathbf{F}\eta\right)} \qquad [6]$$

$$i = -\, i_{o,2}/(1-\gamma) \exp\left(-\frac{1-\alpha_2}{RT}\mathbf{F}\eta\right) \times \frac{1 - \exp\left(\frac{2\mathbf{F}}{RT}\eta\right)}{1 + \frac{\gamma i_{o,2}}{(1-\gamma) i_{o,1}} \exp\left(\frac{1 + \alpha_2 - \alpha_1}{RT}\mathbf{F}\eta\right)} \qquad [6a]$$

of which the steady-state equations are the special case for $\gamma = 0.5$.

At sufficiently large overpotentials Eq. [6] and [6a] simplify to

$$i = i_{o,1}/\gamma \exp\left(\frac{\alpha_1 \mathbf{F}}{RT}\eta\right)$$

$$\text{and } i = -\, i_{o,2}/(1-\gamma) \exp\left(-\frac{1-\alpha_2}{RT}\mathbf{F}\eta\right) \qquad [7]$$

In a plot of log i *vs.* η one ought therefore obtain Tafel lines with intercepts $I_a = i_{o,1}/\gamma$ and $I_c = i_{o,2}/(1-\gamma)$ and anodic and cathodic slopes determined by the values of α_1 and $(1 - \alpha_2)$, respectively, provided that γ remains reasonably constant over the range of overpotentials under consideration. That this is indeed the case can be seen in Fig. 3-5 which were taken by varying the concentration of only one species at a time, keeping all other concentrations constant. A comparison of corresponding pairs of polarization curves demonstrates that the anodic and cathodic Tafel lines have different intercepts. From the slopes of the Tafel lines the transfer coefficients were calculated as $\alpha_1 = 0.40$ and $\alpha_2 = 0.55$, independently of the concentration. Both criteria for the occurrence of consecutive charge-transfer reactions ($I_a \neq I_c$, $\alpha_1 \neq \alpha_2$) are therefore fulfilled.

Figure 4 also shows the appearance of a pseudo-Tafel line in the intermediate range of the anodic overpotential before the true Tafel region is reached at still larger overpotentials. This phenomenon occurs when the concentrations are chosen so that $I_a >> I_c$ (10, 12). Under this condition, and at sufficiently large overpotentials (exp $2\mathbf{F}\eta/RT >> 1$) Eq. [6a] assumes

the pseudo-Tafel form

$$i = i_{o,2}/(1-\gamma)\exp\left(\frac{1+\alpha_2}{RT}\mathbf{F}\eta\right) \quad [8]$$

with an apparent anodic transfer coefficient $\alpha_a = (1 + \alpha_2)$ whose magnitude $1 < \alpha_a < 2$ simulates the existence of a transferred particle of charge $2e^-$. If one further considers that the intercept $i_{o,2}/(1 - \gamma)$ is identical with the cathodic intercept I_c then it is easily appreciated that in a steady-state experiment under the same conditions, where the anodic limiting current density is approximately 1 mA, the true Tafel line could never be observed. One would then be forced to conclude that the two electrons are indeed transferred in a single step. It seems most likely that these difficulties led Loshkarev *et al.* (4-6) to postulate a single-step mechanism. Such a mechanism is, in any event, difficult to accept unless one is prepared to assume the existence of a dimer electron.

Electrochemical reaction orders, reaction mechanism.—It is well known that the electrochemical reaction order method provides a convenient and powerful means of identifying the stoichiometry of the species S_r and S_o participating directly in the charge-transfer reactions (14), provided that these substances are virtually in thermodynamic equilibrium with other species S_j (*i.e.*, $\eta_r \rightarrow 0$)

$$z_{r,1}S_1 + z_{r,2}S_2 + \ldots \rightleftarrows \ldots + (-z_{r,p})S_p + \ldots (-z_{r,q})S_q + S_r \quad [9]$$

$$z_{o,1}S_1 + z_{o,2}S_2 + \ldots \rightleftarrows \ldots + (-z_{o,p})S_p + \ldots (-z_{o,q})S_q + S_o \quad [9a]$$

In the presence of a large excess of supporting electrolyte the expressions for c_r and c_o follow from the law of mass action as

$$c_r = K_r \Pi c_j z_{r,j} \quad [10]$$

$$c_o = K_o \Pi c_j z_{o,j} \quad [10a]$$

Substitution of Eq. [10] in the expression for the exchange current density of transfer step 1 results in

$$i_{o,1} = k_1 c_r \exp\left(\frac{\alpha_1 \mathbf{F}}{RT}\epsilon_o\right) = K_1 \Pi c_j z_{r,j} \exp\left(\frac{\alpha_1 \mathbf{F}}{RT}\epsilon_o\right) \quad [11]$$

and, analogously, using Eq. [10a] for transfer step 2

$$i_{o,2} = k_2 c_o \exp\left(-\frac{1-\alpha_2}{RT}\mathbf{F}\epsilon_o\right) = K_2 \Pi c_j z_{o,j} \exp\left(-\frac{1-\alpha_2}{RT}\mathbf{F}\epsilon_o\right) \quad [11a]$$

where the rate and equilibrium constants have been taken together to form the new constants K_1 and K_2. The stoichiometric coefficients of the equilibria [9] and [9a] reappear now as the anodic and cathodic electrochemical reaction orders $z_{r,j}$ and $z_{o,j}$, respectively, whose knowledge allows the computation of the stoichiometric formulas of S_r and S_o according to the equations

$$S_r = \Sigma z_{r,j} S_j \text{ and } S_o = \Sigma z_{o,j} S_j \quad [12]$$

which follow at once from Eq. [9] and [9a].

Introducing the Tafel line intercepts $I_a = i_{o,1}/\gamma$ and $I_c = i_{o,2}/(1 - \gamma)$ and taking logarithms, Eq. [11] and [11a] become

$$\ln I_a = -\ln\gamma + \Sigma z_{r,j}\ln c_j + \frac{\alpha_1 \mathbf{F}}{RT}\epsilon_o + \ln K_1 \quad [13]$$

$$\ln I_c = -\ln(1-\gamma) + \Sigma z_{o,j}\ln c_j - \frac{1-\alpha_2}{RT}\mathbf{F}\epsilon_o + \ln K_2 \quad [13a]$$

The electrochemical reaction orders can now be calculated by partial differentiation of $\ln I_a$ and $\ln I_c$ with respect to the equilibrium potential ϵ_o, varying the concentration c_k of the species S_k at a time, keeping all other concentrations constant

$$2.303\left(\frac{\partial \log I_a}{\partial \epsilon_o}\right)_{c_{j\neq k}} = \frac{\mathbf{F}}{RT}\left(\alpha_1 + 2\frac{z_{r,k}}{\nu_k}\right) \quad [14]$$

$$2.303\left(\frac{\partial \log I_c}{\partial \epsilon_o}\right)_{c_{j\neq k}} = \frac{\mathbf{F}}{RT}\left(\alpha_2 + 2\frac{z_{o,k}}{\nu_k} - 1\right) \quad [14a]$$

where Eq. [2] has been used to obtain $\partial \log c_k/\partial\epsilon_o$.

In the present case a plot of $\log I_{a,c}$ *vs.* ϵ_o is preferable to the more frequently used $\partial \log i/\partial \log c_k$ because the actual concentration of S_j may not accurately be known owing to the holoquinone/meriquinone equilibria (15) present in the electrolyte solutions. The meriquinone is believed to be the source of the intermediate to sustain the second charge-transfer reaction at $t = 0$ in the nonsteady-state experiments.

In Fig. 6 and 7 the dependence of the anodic and cathodic intercepts is shown as a function of the equilibrium potential ϵ_o, using the variable c_k as the parameter. With the aid of Eq. [14] and [14a] the $z_{r,j}$'s are calculated from $\partial \log I_a/\partial\epsilon_o$ and the $z_{o,j}$'s from $\partial \log I_c/\partial\epsilon_o$ as

$$z_{r,1} = 0, \quad z_{r,2} = +1, \quad z_{r,3} = 0$$

$$z_{o,1} = +1, \quad z_{o,2} = 0, \quad z_{o,3} = +1 \quad [15]$$

Substituting these values in Eq. [12] it follows immediately that $S_r = H_2Q$, the toluhydroquinone molecule

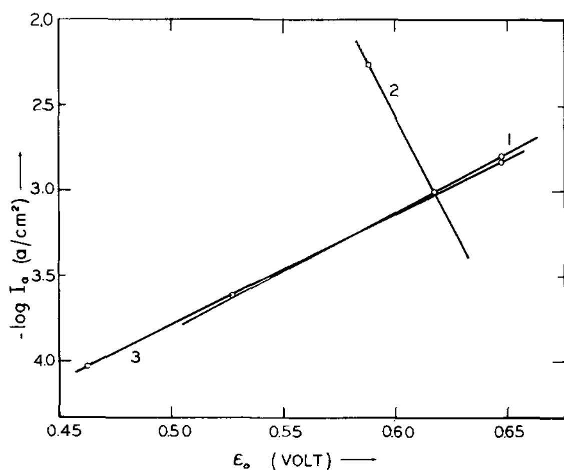

Fig. 6. Determination of the anodic electrochemical reaction orders. Curve 1, $z_{r,1}$; curve 2, $z_{r,2}$; curve 3, $z_{r,3}$.

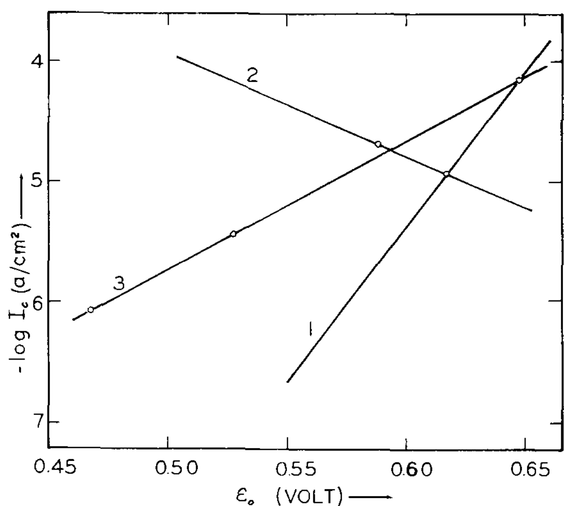

Fig. 7. Determination of the cathodic electrochemical reaction orders. Curve 1, $z_{o,1}$; curve 2, $z_{o,2}$; curve 3, $z_{o,3}$.

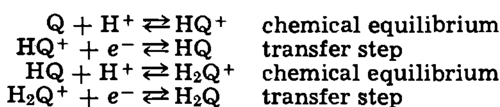
itself, while $S_o = HQ^+$, the protonated toluquinone. Since the charge exchanged in each transfer step is obviously e^-, it is clear that the over-all electrode reaction proceeds according to the scheme



$Q + H^+ \rightleftarrows HQ^+$	chemical equilibrium
$HQ^+ + e^- \rightleftarrows HQ$	transfer step
$HQ + H^+ \rightleftarrows H_2Q^+$	chemical equilibrium
$H_2Q^+ + e^- \rightleftarrows H_2Q$	transfer step

$Q + 2H^+ + 2e^- \rightleftarrows H_2Q$	over-all electrode reaction

Thus, the mechanism of the toluquinhydrone electrode is the same as the HeHe mechanism of the benzoquinhydrone electrode as determined by Vetter (1).

Determination of the individual exchange current densities.—Although the elucidation of the electrode mechanism has been shown not to depend on the knowledge of the individual exchange current densities $i_{o,1}$ and $i_{o,2}$, it would still be desirable to ascertain their values in order to be able to see the influence of the substituent on the rates of the charge-transfer reactions.

When the transfer steps are too fast the Tafel lines become obscured by the early development of limiting current densities in steady-state measurements. On the other hand, inspection of Eq. [6] and [6a] demonstrates that, using the current pulse method alone, the three unknowns $i_{o,1}$, $i_{o,2}$, and γ cannot be separated because they invariably occur in the same combination $i_{o,1}/\gamma$ and $i_{o,2}/(1-\gamma)$, *i.e.*, the Tafel line intercepts. It is, however, possible to measure γ, and hence the exchange current densities, by combining the results of the pulse experiments with measurements of the steady-state overpotential in the vicinity ($-10 < \eta < +10$ mV) of the equilibrium potential in the following way: the pulse measurements yield directly the values of the intercepts $I_a = i_{o,1}/\gamma$ and $I_c = i_{o,2}/(1-\gamma)$. Now, differentiation of Eq. [5] or [5a] with respect to η for $\eta \to 0$ gives the expression for the charge-transfer resistance R_t (13)

$$R_t = \left(\frac{\partial\eta}{\partial i}\right)_{\eta\to 0} = \frac{RT}{4F}\left(\frac{1}{i_{o,1}} + \frac{1}{i_{o,2}}\right) \quad [16]$$

independently of the values of the transfer coefficients (10). One can, therefore, calculate γ by combining the expressions for the intercepts I_a and I_c with the slope R_t at the origin of the i-η curve. This leads at once to the equation

$$\gamma = -A/2 \pm \left(\frac{A^2}{4} - \frac{1}{I_a B}\right)^{1/2} \quad [17]$$

with $A = \frac{1}{I_c B} - \frac{1}{I_a B} - 1$, and $B = \frac{4F}{RT} R_t$.

The results of measurements taken near the equilibrium potential are presented in Fig. 8 and 9. In Fig. 8 the experimental conditions were $c_1 = 10^{-3}$, $c_2 = 10^{-2}$, pH $= 0.10$ for which the intercepts had been determined as $\log I_a = -2.26$ and $\log I_c = -4.68$ (cf. Fig. 4). Using Eq. [17] with $R_t = 0.6$ mV/μA, γ is calculated as $\gamma_1 = 0.47$ and $\gamma_2 = 0.005$. For the experiment performed with $c_1 = 10^{-2}$, $c_2 = 10^{-3}$, pH $= 3.14$ (Fig. 9) the corresponding intercepts are

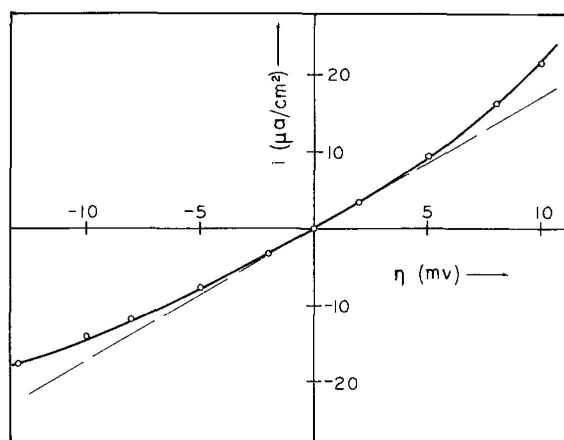


Fig. 8. Determination of the charge-transfer resistance R_t at the equilibrium potential. Experimental conditions: $c_1 = 10^{-3}$M, $c_2 = 10^{-2}$M, pH $= 0.10$.

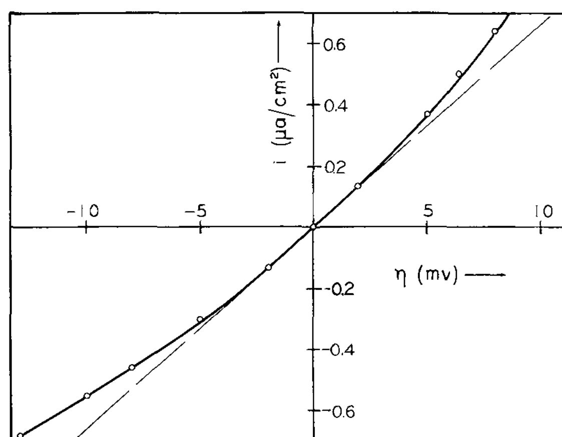

Fig. 9. Determination of the charge-transfer resistance R_t at the equilibrium potential. Experimental conditions: $c_1 = 10^{-2}$M, $c_2 = 10^{-3}$M, pH $= 3.14$.

$\log I_a = -4.03$, $\log I_c = -6.05$ (cf. Fig. 5), and $R_t = 15$ mV/μA, resulting in $\gamma_1 = 0.52$ and $\gamma_2 = 0.007$.

Although it is much more probable that $\gamma \sim 0.5$ is the correct value the ambiguity arising from Eq. [17] having two roots can be removed by employing Eq. [16] with the values of the Tafel line intercepts and charge-transfer resistances obtained in two different sets of experiments. In this case

$$R_t = \frac{RT}{4\mathbf{F}}\left(\frac{1}{I_a\gamma} + \frac{1}{I_c(1-\gamma)}\right),$$

$$R_t' = \frac{RT}{4\mathbf{F}}\left(\frac{1}{I_a'\gamma} + \frac{1}{I_c'(1-\gamma)}\right) \quad [18]$$

and

$$\gamma = \frac{I_c - KI_c'}{K(I_a' - I_c') - (I_a - I_c)} \quad [19]$$

where $K = R_t I_a I_c / R_t' I_a' I_c'$.

Making use of the same experimental data as in the calculations above one finds $\gamma = 0.5$. Apart from the need of two separate sets of polarization data it is preferable to use Eq. [17] because the error in the calculation of γ using Eq. [19] can become quite appreciable due to the presence, in both numerator and denominator, of ΔI's. It should also be pointed out that the close agreement between the values of γ obtained with the two methods is, therefore, somewhat misleading and is attributable to the choice of suitable pairs of polarization curves. Equation [19] can, however, serve a useful purpose in deciding between the roots of Eq. [17]. The fact that γ is found to be so close to 0.5 demonstrates that on the time scale of the Gerischer extrapolation the current distribution of the steady state is rapidly reached and that the stationary concentration of S_m can differ only slightly from its thermodynamic equilibrium concentration.

Having thus ascertained the numerical value of γ it is now an easy matter to make a direct comparison between the exchange current densities of the toluquinhydrone and benzoquinhydrone electrodes. Taking Vetter's results and the data presented in this paper it is seen that, at corresponding concentrations, the exchange current densities of the toluquinhydrone electrode are invariably higher, at some concentrations by as much as a factor of about 300. It seems therefore that the toluquinhydrone electrode should function as the superior indicator and reference electrodes from the point of view of its greater reversibility. This advantage will, however, in most practical cases be negated by the easy photodecomposition of its electrolyte solution.

Acknowledgments

The author wishes to express his gratitude to C. F. Cook for his help in setting up the triggering circuit for the oscilloscopic measurements, and to W. F. Nye for his continued interest and encouragement.

The Electrochemistry of the Liquid Crystal N-(p-Methoxybenzylidene)-p-n-butylaniline (MBBA)

The Role of Electrode Reactions in Dynamic Scattering

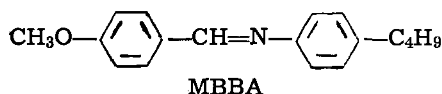
Ann Lomax, Ryo Hirasawa, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The electrochemical reduction and oxidation of MBBA were studied by cyclic voltammetry and by controlled potential coulometry. The reduction in DMF leads to the formation of the radical anion which decomposes with a half-life of about 4 sec, apparently by both ec and ece pathways. The oxidation product was unstable on the time scale of this study. The possible importance of electrode reactions in interpreting the dynamic scattering phenomenon in nematic liquid crystals is suggested.

The liquid crystal (LC) Schiff base N-(p-methoxybenzylidene)-p-n-butylaniline (MBBA) has been of much recent interest because it undergoes "dynamic



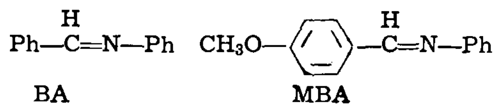
MBBA

scattering" (DS) when subjected to d-c or a-c electrical fields; this electrooptic effect forms the basis of LC display devices. Dynamic scattering has been shown to occur when the LC, sandwiched between two closely spaced (e.g., 10-100 μm) electrodes above a certain threshold voltage, begins to undergo first laminar and then turbulent flow (1). The mechanism of this phenomenon has been the subject of a number of recent studies (2-8) and is apparently different for d-c and low frequency a-c excitations, where the electrodes

* Electrochemical Society Active Member.
Key words: electro-organic chemistry, cyclic voltammetry, coulometry, electron spin resonance, Schiff base.

must contact the LC phase, and for high frequency a-c excitations, where the electrodes may be insulated or "blocked" from the LC. The d-c low frequency mechanism is based on the "injection of electrons" into the low conductivity LC leading to space charges; transfer of momentum from the resulting moving ions under the influence of the field to the aligned LC molecules results in cellular hydrodynamic flow (1-3). In an alternate model the space charges in the nematic LC originate in the anisotropic conductivity of the LC (4-6). These models generally ignore the electrochemical processes occurring at the electrode-LC interface and the nature of the ionic species formed in the process. Because these processes can affect the threshold voltage for the onset of dynamic scattering and have important ramifications in the occurrence of secondary chemical reactions which may limit the life of the LC device, we have undertaken a study of the electrochemical behavior of LC materials.

Most of the electrochemical studies of MBBA described here were performed using the aprotic solvents N,N-dimethylformamide (DMF) or acetonitrile (ACN) as reaction media; a few preliminary studies in neat MBBA were also attempted, however. Previous electrochemical studies on the reduction of the related molecule, N-benzylideneaniline (BA) (9-12) and the oxidation of N-(p-methoxybenzylidene)aniline (MBA) (13) have been described.



Experimental

The MBBA was special, high-purity material obtained from Texas Instruments. The supporting electrolyte materials, tetra-n-butylammonium perchlorate (TBAP) and iodide (TBAI), were polarographic grade (Southwestern Analytical Chemicals) and were dried in a vacuum oven before use. Purification of the solvents DMF and ACN followed previous practice (14, 15).

All electrochemical data were obtained with a Princeton Applied Research Corporation (PAR) Model 170 electrochemical system. Solution preparation on a vacuum line and freeze-pump-thaw techniques were as previously described (14, 15). The cell for voltammetric studies contained either a platinum disk or a hanging mercury drop working electrode, a platinum auxiliary electrode in a separate chamber, and an aqueous saturated calomel electrode (SCE) connected to the test solution by an agar bridge with its tip positioned near the working electrode. The coulometric studies were done in the same cell with a platinum gauze working electrode. Electron spin resonance (ESR) spectra were obtained on a Varian V-4502 spectrometer and electrolytic cell accessory. The solutions were degassed by the freeze-pump-thaw method and transferred to a reservoir above the ESR electrolytic cell. The cell was flushed with nitrogen and fresh solution from the reservoir was employed for each experiment.

Results

Electrochemical reduction.—The reduction of MBBA at a platinum electrode was studied by both cyclic voltammetry and controlled potential coulometry to obtain information about the electrochemical behavior of the system on both a short and a long time scale. A typical cyclic voltammogram for the reduction in DMF is shown in Fig. 1. The first reduction wave occurs at $-2.06V$ *vs.* SCE and is nearly reversible at scan rates above 5 V/sec. The second reduction wave occurs at $-2.60V$ and shows no reversal current even at high scan rate. The reduction potential of the first wave is more negative than that of BA ($-1.83V$) (9) as expected for the introduction of an electron-donating group into the molecule, and is close to that for MBA ($-2.15V$) (10) in DMF solutions.

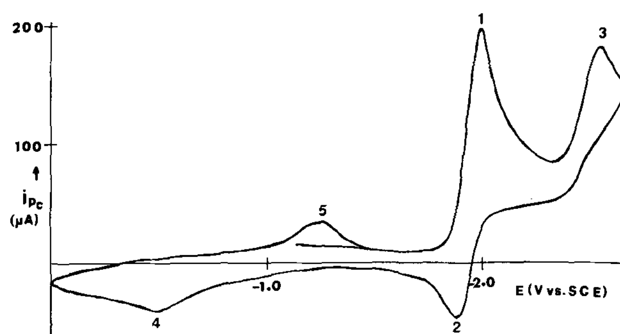


Fig. 1. Cyclic voltammogram at a Pt disk electrode of 6.65 mM MBBA in DMF, 0.1M TBAP. The scan rate was 2 V/sec.

Figure 1 shows, in addition to the two major reduction waves of MBBA (1, 3) and the oxidation of $MBBA^{\cdot-}$ (2), two waves of lesser height. An anodic wave (at $-0.54V$) (4) appears to a slight extent after scanning through only the first wave, and to a greater degree if the scan is continued beyond the second main reduction wave. The small cathodic wave (at $-1.38V$) (5) appears only after having scanned through wave 4. Neither the nature nor the source of these waves was investigated. The anodic wave 4 was found to be the only wave remaining after exhaustive electrolysis of the solution at a potential on the plateau of the first wave. The behavior of the diagnostic criteria, i_{pa}/i_{pc} and $i_{pc}/v_{1/2}$, for the first reduction wave is shown as a function of scan rate, v, in Fig. 2 (i_{pc} and i_{pa} are the cathodic and anodic (reversal) peak currents, respectively). The peak height and peak potential separation, as well as the coulometric and ESR results below, show that the first reduction wave leads to the production of the radical anion in a one-electron reaction. The upper curve (Fig. 2a) illustrates the extent of reaction of the radical anion; the reaction is nearly complete at slow scan rates, while at fast scan rates it has scarcely begun. The qualitative shape of curve 2a is characteristic of both the ec and ece mechanisms, where an ec mech-

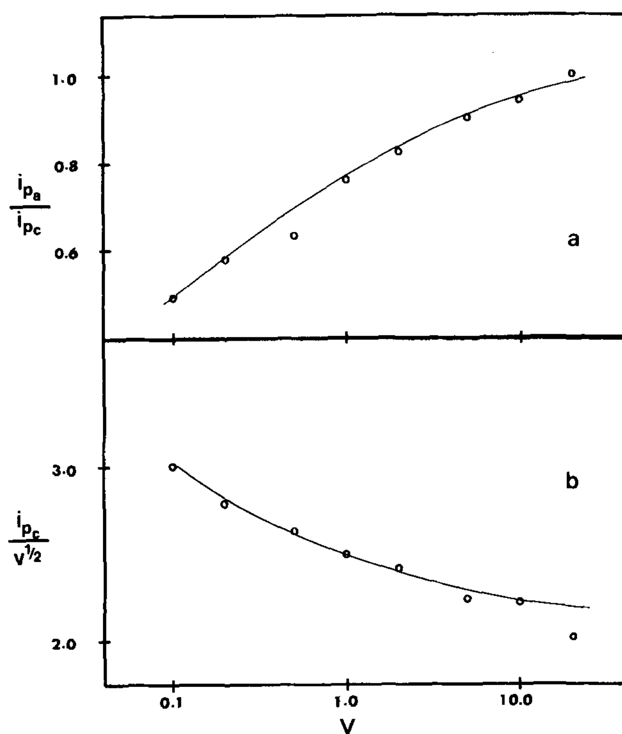

Fig. 2. (a) The peak current ratio, and (b) the normalized cathodic peak current vs. scan rate for the reduction at a hanging mercury drop electrode of 1.66 mM MBBA in DMF, 0.01M TBAP. v is in V/sec, $i_{pc}/v^{1/2}$ in μA sec$^{1/2}$/v$^{1/2}$.

anism involves reaction of the electrogenerated product to a nonelectroactive species, while an ece mechanism implies that the product of the chemical reaction is reduced at potentials where MBBA is reduced. The data in Fig. 2b are useful in distinguishing between the two. In the ec case, the maximum change is about 10% while for the ece case, in which the product of the reaction is more easily reduced than the starting material, a maximum change of 50% can be observed (16, 17). The change of about 33% observed in the reduction of MBBA indicates a significant degree of ece behavior. The effect of v on the peak potential (Table I) is to shift the peak to more negative values at faster scan rates, as would be expected for an irreversible chemical reaction following electron transfer.

Exhaustive controlled potential coulometric reduction on the plateau of the first reduction wave gave an apparent number of faradays per mole of MBBA, n_{app}, of 1.2 to 1.9.

In ACN only the first reduction wave of MBBA was observed. Its peak potential was more negative (−2.15V) than in DMF (−2.06V); no reversal current was detected, even at scan rates of 20 V/sec.

Electrochemical oxidation.—The oxidation of MBBA in ACN occurs in two steps; a typical cyclic voltammogram is shown in Fig. 3. Waves 1 (1.45V) and 2 (2.0V) correspond to the oxidation of MBBA, while wave 3 is present in the solvent-supporting electrolyte medium before the addition of the depolarizer. Similar two-step oxidations have been reported for other Schiff bases (13). A small wave at 0.8V is also evident and is presumably caused by an impurity in the MBBA.

Though the occurrence of the second wave at a potential where the residual current is large makes its analysis difficult, a study of the peak characteristics of the first wave indicated that both the peak potential and the normalized peak current were dependent on the scan rate; the behavior is shown in Fig. 4, with the poor reproducibility of the current and potential measurements probably resulting from electrode filming. Neither wave yielded a detectable reversal current at scan rates up to 20 V/sec.

An n_{app} value determined by controlled potential coulometry at the first wave ranged from 0.88 to 1.2 electrons/molecule; the major electroactive product of the oxidation was reducible at −0.8V.

Attempts to investigate the electrochemical behavior of neat MBBA using TBAP or octadecyldimethylbenzylammonium bromide as supporting electrolytes in a small three-electrode cell were thwarted by the low solubility of the salts in MBBA and the concomitant low conductivity. The solution of MBBA with 15 volume per cent (v/o) DMF and TBAP had background limits of −1.8V corresponding to the reduction of MBBA, and +0.8V, probably the oxidation of the impurity noted in the oxidation of MBBA; there was no significant electrochemical process detected between the two limits.

Electron spin resonance results.—*Intra muros* electrolysis of a 1.5 mM MBBA solution in 0.1*M* TBAI-DMF at a constant current of 0.2 mA resulted in the ESR spectrum shown in Fig. 5. Attempts to simulate the spectrum and extract coupling constants have thus far been unsuccessful. Alkali metal reduction in MTHF did not produce a radical sufficiently stable to be detected.

Table I. Peak potentials for reduction waves of MBBA[a]

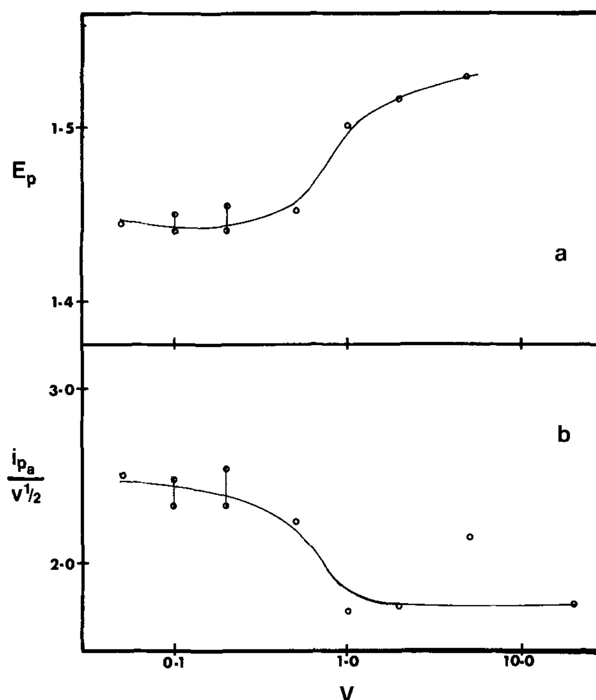

Fig. 4. (a) The peak potential, and (b) the normalized anodic peak current *vs.* scan rate for the oxidation at a Pt disk electrode of 2.24 *mM* MBBA in ACN, 0.1*M* TBAP. v is in V/sec, E_p in V *vs.* sce; $i_{pa}/v^{1/2}$ in μA sec$^{1/2}$/V$^{1/2}$.

A few experiments were performed in the SEESR cell (18) to determine the stability of the radical anion and the potentials where it is formed. For a constant-current pulse where the potential remained on the first voltammetric wave, the ESR signal showed a linear increase during the pulse, and a slow decay when the current was off. Constant-current steps where the potential reached those of the second wave showed a decrease of ESR signal at these potentials.

Discussion

The electrochemical and ESR results for the reduction provide evidence for initial formation of the anion radical of MBBA with a half-life in DMF of approximately 4 sec. The evidence suggests that the radical anion reacts in following ece and ec reactions. Similar behavior has been reported for the reduction of BA (9-12), where both protonation (in the ece pathway) leading to conversion of the —HC=N— structure to —CH_2—NH—, and dimerization (in the ec pathway) occur. Andrieux and Saveant (9) and Kononenko *et al.* (11) concluded that both pathways were important and occurred simultaneously. Note that by labeling the protonation reaction as ece we only imply a reac-

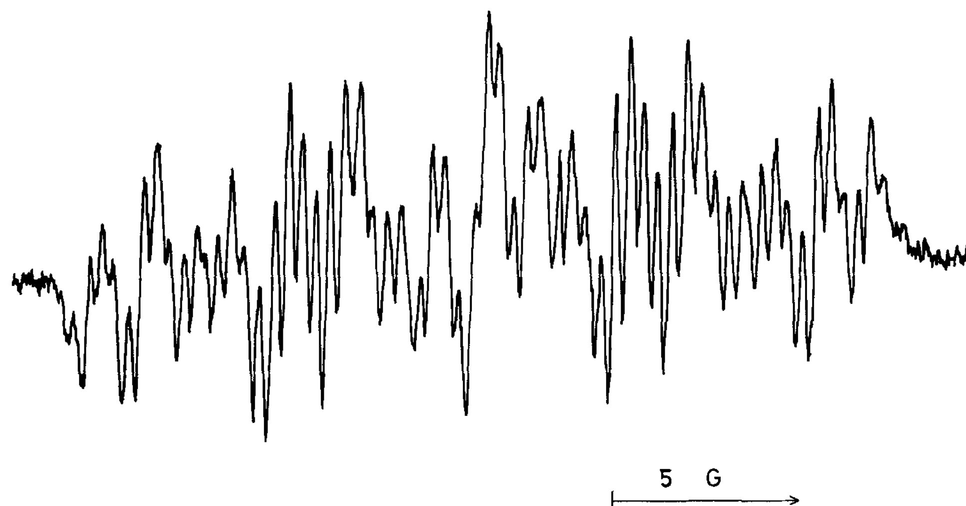

Fig. 5. The ESR spectrum of the MBBA radical anion in DMF, 0.1M TBAI.

tion pathway leading to ultimate consumption of two electrons per molecule and do not reject other possible paths (*e.g.*, disproportionation followed by protonation of the dianion) which may yield similar voltammetric and coulometric behavior.

The oxidation of MBBA in ACN parallels a previous study (13) and suggests that the oxidation product (perhaps the cation radical) is very unstable within the voltammetric time scale of these experiments.

Although these experiments were conducted in dilute solutions of MBBA in DMF and ACN rather than in pure MBBA, the results should have some relevance to dynamic scattering studies in MBBA. The measured potentials for reduction and oxidation here are probably somewhat smaller than those for the same processes in MBBA, since the polar solvents DMF and ACN probably solvate the MBBA ions more strongly than MBBA itself. Moreover, the fast reaction following the oxidation electron transfer reaction in ACN shifts the E_{pa} to values less positive than its reversible value. As a first approximation, however, we can take the "decomposition voltage" of MBBA as at least $E_{pa}(ACN) - E_{pc}(DMF)$, or about 3.5V. The threshold voltage of dynamic scattering must be above this value and include the *IR*-drop through the MBBA liquid layer at currents (or ion flows) sufficient to induce turbulence. Although previous explanations of DS were given in terms of charge injection and Schottky emission of carriers (1), the current-voltage behavior was independent of the work functions of the metal used for the electrodes. Descriptions in terms of electrogeneration of radical ions and a cell current-voltage characteristic determined by the electrode kinetic equations (which bear a close resemblance to the Schottky emission equation) (19) and resistive drop in the liquid bear consideration. In a recent investigation (20), it was found that trace amounts of water are necessary in an anisylidene-p-aminophenylacetate (APAPA) LC device to promote conduction and DS; this was explained by a model in which water molecules assist the APAPA molecule in accepting an electron from the cathode. A more probable explanation in terms of our study is that ions from water (or hydrolysis products of APAPA) increase the conductivity of the LC material and improve the nature of the electrochemical cell. Doping of the LC with small amounts of different salts should serve the same purpose and decrease the possibility of attack of water molecules on the radical ions. Decomposition of the radical ions, particularly the radical cation, into products which decrease the purity and disrupt the alignment of the molecules in the nematic LC may also be of importance in limiting the life of LC display devices. Finally, although migration of the ions is probably the major mode of conduction through the liquid medium, direct electronic conduction by means of rapid electron exchange between radical ion and parent molecule is also a possibility, especially in a solvent composed of pure parent molecules where the parent concentration is very high (21, 22). This conduction mode may be of less importance in this LC system, however, where the alignment of the molecules and structural considerations (*i.e.*, the presence of the nonconjugated n-butyl group) decrease the rate of the intermolecular electron transfer reaction.

Acknowledgments

The support of this research by the National Science Foundation (GP-31414X) and the Robert A. Welch Foundation is gratefully acknowledged. We are indebted to Drs. Isaac Trachtenberg, Linda Creagh, and Allen R. Kmetz of Texas Instruments for helpful discussions concerning this research and for pure samples of MBBA.

Transient Mass Transfer at the Rotating Disk Electrode

Leonard Nanis*

and Irving Klein

Carothers Research Laboratory, Experimental Station, E. I. du Pont de Nemours, Wilmington, Delaware 19800

ABSTRACT

Transient mass transfer at the rotating disk has been investigated theoretically and experimentally for cathodic reduction of ferricyanide in the redox system ferricyanide-ferrocyanide with potassium hydroxide supporting electrolyte. It has been shown that overpotential-time predictions for the rotating disk are fitted very well for decay (current interruption) but poorly for build-up following switching on of constant current. As an explanation for this behavior, attention is directed to the inadequacy of the assumption that a radially independent concentration profile exists at the disk surface just at the start of galvanostatic current passage.

Of great importance in the design of electrodes for practical electrolytic processes is knowledge of the current distribution. Predictive methods based on concepts of "throwing power" have been devised for several geometries and types of electrode reaction. These developments are all related to the steady state, *i.e.*, constant current density and overpotential. The question of current distribution during nonsteady electrode processes appears to be hitherto untouched theoretically. Transient electrode processes such as double layer charging, slow kinetic and diffusion steps are of course associated with electrode system impedance. Relatively little attention has been directed to the problem of current distribution during transient electrode response. However, it is essential to know the redistribution of current over an electrode surface during the unsteady portion of the electrode behavior in practical systems such as periodic reverse plating and pulsed battery charging sequences.

The method chosen for investigating the possible existence of nonuniform transient current distribution was the time varying behavior of overpotential for a cathodic redox reaction on a rotating disk electrode. This is of advantage since no change in the roughness of the surface occurs and because the hydrodynamics controlling convection transport are well known. The ferrocyanide-ferricyanide-potassium hydroxide system was selected since the exchange current density is known (1) to be sufficiently large so as to ensure purely diffusion-controlled kinetics and also because transport parameter data are well known (2). The study was based on comparison of overpotential relaxation following current steps of simple on or off switching. To this end, the decay problem was solved to provide a match for the well-studied build-up transient. Both build-up and decay were determined experimentally for comparison with theory.

Theoretical

Because of disk symmetry, the time-dependent convective diffusion equation based on the axial and radial directional coordinates (cf. Eq. [1]) theoretically describes mass transfer in the concentration boundary layer adjacent to a rotating disk

$$\frac{\partial C}{\partial t} + V_r \frac{\partial C}{\partial r} + V_Z \frac{\partial C}{\partial Z} = D \left[\frac{\partial^2 C}{\partial Z^2} + \frac{\partial^2 C}{\partial r^2} + \frac{1}{r}\frac{\partial C}{\partial r} \right] \quad [1]$$

* Electrochemical Society Active Member.

Key words: rotation disk, transient overpotential, mass transfer, current distribution, galvanostatic.

Previous theoretical developments (3, 9-11) for nonsteady mass transfer during galvanostatic overpotential build-up have all been based on the assumption that the disk acts as a uniformly accessible surface throughout the transient interval. On the basis of this assumption, all derivatives of the concentration with respect to the radial coordinate can be set equal to zero, resulting in the following simplified version of Eq. [1], *i.e.*

$$\frac{\partial C}{\partial t} + V_Z \frac{\partial C}{\partial Z} = D \frac{\partial^2 C}{\partial Z^2} \quad [2]$$

It should be noted that Levich first introduced the concept of uniform accessibility in terms of a zero concentration of depleted species all along the disk at the maximum rate of steady-state mass transfer. This radially independent boundary condition facilitated the calculation of the steady-state concentration profile developed in the boundary layer (Eq. [2] with time derivative equal to zero). Thus, the concept of uniform accessibility during nonsteady mass transfer (implying a concentration which varies with time but not with radial position) is merely a convenient assumption used to simplify the mathematics.

If uniform accessibility is assumed for nonsteady mass transfer, the following dimensionless variables may be introduced

$$\psi = \frac{C - C_b}{C_{o,o} - C_b}, \quad \tau = \frac{Dt}{\delta_c^2}, \quad \xi = \frac{Z}{\delta_c} \quad [3]$$

where δ_c is the steady-state concentration boundary layer thickness arbitrarily defined as the point at which 99% of the bulk conditions are achieved, C_b is the time independent bulk concentration, and $C_{o,o}$ is the concentration at the electrode surface at time zero. A model for V_Z has been based on well-known rotating disk hydrodynamics (12) which approximates a parabolic axial velocity distribution in the concentration boundary layer corresponding to laminar flow in a solution of large Schmidt number. Thus

$$V_Z = -0.51\omega^{3/2}\nu^{-1/2}Z^2 \quad [4]$$

Following the approach developed by Levich (13), δ_c is described as

$$\delta_c = 2.54D^{1/3}\nu^{1/6}\omega^{-1/2} \quad [5]$$

Substituting Eq. [3], [4], and [5] into Eq. [2] yield the dimensionless result

$$\frac{\partial \psi}{\partial \tau} - 8.361\xi^2 \frac{\partial \psi}{\partial \xi} - \frac{\partial^2 \psi}{\partial \xi^2} = 0 \quad [6]$$

In order to theoretically predict mass transfer behavior occurring during overpotential build-up, Eq. [6] was numerically solved in conjunction with boundary conditions specifying a constant mass flux at $\xi = 0$ (Eq. [7]) and a constant bulk concentration at $\xi = 1$ (Eq. [8]) and in conjunction with an initial condition specifying a uniform concentration, C_b throughout the boundary layer (Eq. [9]).

$$\frac{\partial \psi(0,\tau)}{\partial \xi} = 1.572 \quad [7]$$

$$\psi(1,\tau) = 0 \quad [8]$$

$$\psi(\xi,0) = 0 \quad [9]$$

Mass transfer occurring during overpotential decay was theoretically solved using Eq. [6] together with boundary conditions specifying a zero flux at $\xi = 0$ (Eq. [10]) and a constant bulk concentration at $\xi = 1$ (Eq. [8]). The initial condition was obtained following the method of Levich (13), the concentration distribution in the boundary layer being expressed in terms of an incomplete gamma function (Eq. [11]).

$$\frac{\partial \psi(0,\tau)}{\partial \xi} = 0 \quad [10]$$

$$\psi(\xi,0) = 1 - 1.572 \int_0^{\xi} e^{-2.759g^3}\, dg \quad [11]$$

where g represents a dummy variable of integration.

Build-up: Previous Solutions

The theory of unsteady-state processes on the rotating disk electrode has already received considerable attention. Levich (3) presented a solution to the nonsteady convective diffusion equation (cf. Eq. [2]) in his treatment of transient mass transfer during galvanostatic overpotential build-up. His first order approximation for the concentration gradient in the convective term (based on a solution for diffusion-controlled mass transfer) however, severely restricts the time interval, *i.e.*, $\tau < 0.15$, over which reasonable correlation between theory and experiment may be expected. Subsequently, theoretical problems related to nonstationary disk processes were solved using the hydrodynamics of the system only to specify a constant concentration boundary condition at $Z = \delta_c$, while neglecting the convective mass transfer term (4,8). Filinovskii (9) solved Eq. [2] using Laplace transforms and an appropriate change of variables together with approximations to permit inversion. The approximations were based on consideration of a narrow region within the concentration boundary layer, immediately adjacent to the disk surface. Within this region a term proportional to the fourth power of the distance was omitted which reduced the problem to the canonical equation for Airy functions. As a result, Filinovskii's analytical solution does not correctly describe the mass transfer behavior occurring at relatively long dimensionless times, *i.e.*, $\tau > 0.4$ of the transient interval. Hale (10) has used a Crank-Nicholson finite difference technique to numerically solve for the concentration distributions occurring during galvanostatic overpotential build-ups. His solution can be used to describe mass transfer behavior occurring throughout the transient interval.

Recently, Krylov (11) has developed an analytical technique for determining a complete solution to the problem in terms of a series of parabolic cylinder functions. The major drawback of his technique is that it becomes exceedingly cumbersome at long times since a large number of terms are necessary in order to describe the concentration behavior.

Build-up and Decay: Present Solutions

Numerical solutions of Eq. [6], [7], [8], and [9] (build-up) and [6], [8], [10], and [11] (decay) were obtained using a machine computed relaxation technique modified as suggested by Allen (14) to allow for solution of parabolic partial differential equations. The grid spacing and the error criterion were systematically reduced until less than a 1% variation in successively calculated values for $\psi(0,\tau)$ was obtained. A square grid spacing of 0.02 and an error criterion of 0.001 produced the desired convergence and the computed values for $\psi(0,\tau)$ during build-up and decay are shown in Table I. The electrode-electrolyte interface concentration $\psi(0,\tau)$ has been compared with Hale's numerically computed results. Of all the build-up solutions available in the literature, Hale's values for $\psi(0,\tau)$ are the most comprehensive. Good agreement, *i.e.*, within 3%, is shown compared with the present results throughout the transient interval, $\tau < 0.8$. It should be noted that the present treatment provides a spatial bound (Eq. [8]) not present in the Hale treatment based on the Crank-Nicholson finite difference procedure applied to Eq. [6], [7], and [9]. The agreement of $\psi(0,\tau)$ build-up obtained by the present relaxation technique provides a degree of certainty that a correct solution has been obtained using this technique for the new, yet mathematically analogous, problem of nonsteady mass transfer during overpotential decay (cf. Eq. [2], [8], [10], and [11]).

Relation of Concentration and Overpotential

Time-concentration behavior is only implicitly related to the directly measured overvoltage transient, so that the Nernst equation has been used to link the functional behavior of the predicted overpotential to the concentration at the electrode-electrolyte interface. Using concentrations in place of activities for a redox reaction at 25°C, $n = 1$, the Nernst equation gives for a net cathodic reaction overvoltage

$$\eta_c = 0.059 \log \frac{(C_{OX})_{0,\tau}(C_{RED})_b}{(C_{OX})_b(C_{RED})_{0,\tau}} \quad [12]$$

where OX and RED refer to the oxidized and reduced species, respectively. Substituting in Eq. [12] for $(C_j)_{0,\tau}$ in terms of $(\psi_j)_{0,\tau}$ (cf. Eq. [3]) and relating the galvanostatic current density to the steady-state concentration at the electrode surface yields

$$(\eta_c)_\tau = 0.059 \log \left[\frac{1 - (\psi_{OX})_{0,\tau}(J/J_{OX,lim})}{1 + (\psi_{RED})_{0,\tau}(J/J_{OX,lim})\,(D_{OX}/D_{RED})^{2/3}(C_{OX})_b(C_{RED})_b^{-1}} \right] \quad [13]$$

Equation [13] permits computation of concentration overvoltage, for both build-up and decay in terms of

the theoretical time dependent dimensionless concentrations, $(\psi)_{0,T}$ (cf. Table I), the fraction of the limiting current passing through the system during the electrochemical reaction, $J/J_{OX,lim}$, and the diffusion coefficients, D, and the bulk concentrations, C_b, of the redox species. The limiting current, J_{lim}, is related (Fick's first law) to the maximum mass flux at the electrode as

$$J_{lim} = -n\mathbf{F}D \left.\frac{\partial C}{\partial Z}\right|_{max} = n\mathbf{F}D \frac{C_b}{\delta_c} \quad [14]$$

Experimental

The disk consisted of a cylindrical nickel plug (0.5 in. × 0.625 in. diam) imbedded in a 1.25 in. diam Teflon cylinder. The nickel disk was polished smooth using standard metallographic equipment so that projections greater than 1μ were eliminated. The Teflon cylinder was attached to a glass epoxy shaft which was rotated by a rubber belt driven by a variable speed Bodine ⅛ hp d-c motor (Model NSH-54RL). A Minarik Electric Company control unit (Model SH 63W) was used to regulate the motor speed. Disk speeds were preferably selected by a series of gear trains enabling the motor to operate near its maximum speed rating, thereby eliminating major speed fluctuations. Disk speed fluctuations were usually less than 1% of set value.

The rotating disk was made the cathodic working electrode. An anodic counterelectrode consisting of a circular piece of nickel foil placed atop an adjustable Teflon platform served to complete the electrochemical cell. Its area was more than twenty times that of the disk, so that concentration overpotentials of the anode were small when compared with those occurring at the disk. Potential for an electrochemical reaction at the disk surface was provided by low voltage power supply (battery eliminator).

The electrolyte was equimolar (5×10^{-6}gmole/cm^3) $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ in excess KOH (2×10^{-3}gmole/cm^3). The supporting KOH electrolyte rendered negligible the contribution of migration to the over-all mass transport of the reacting species, and minimized the resistive (ohmic) potential drop in the cell. The potential of the working electrode was continuously measured with respect to a saturated calomel reference electrode connected to the electrolyte by means of a KCl salt bridge. The location of the bridge was found to have no influence on the measured potentials for the currents used, *i.e.*, there was a negligible resistive potential included in the overpotential measurement. The disk-reference potential was monitored by a high impedance electrometer (Keithley 610B) whose output signal was fed into a Tektronix (Model 555) oscilloscope. A permanent record of the transient voltage was obtained with a Model C-12 Tektronix camera using Polaroid film (Type 47). Time-dependent cathodic build-up and decays were obtained for fractional current densities (J/J_{lim}) ranging from 0.225 and 0.995. The rotational Reynolds number was varied between 130 and 8500 so as to produce corresponding relaxation times of about 50-0.5 sec.

Results

Typical data for transient decays are shown in Fig. 1 and for build-ups in Fig. 2 where the solid lines represent theoretical prediction based on Eq. [13]. In a typical sequence at each rotational speed, the current fraction, J/J_{lim}, was chosen by adjusting the current until a desired steady-state overpotential, $(\eta_c)_\infty$, was obtained, based on Eq. [13] for $(\psi_{OX})_{0,\infty} = (\psi_{RED})_{0,\infty} = 1$. Data of Arvia (2) were used for the ratio of diffusion currents of the redox species.

The experimental overpotentials have been conveniently replotted as discrete points *vs.* log dimensionless time based on D_{OX} according to Eq. [3]. The correlation of the experimental data with theory as shown in Fig. 1 and 2 is typical of a general trend indicating that transient overpotential decay data for a given solution, speed of rotation, and current density fraction exhibits better agreement with theory than overpotential build-ups obtained under the same conditions.

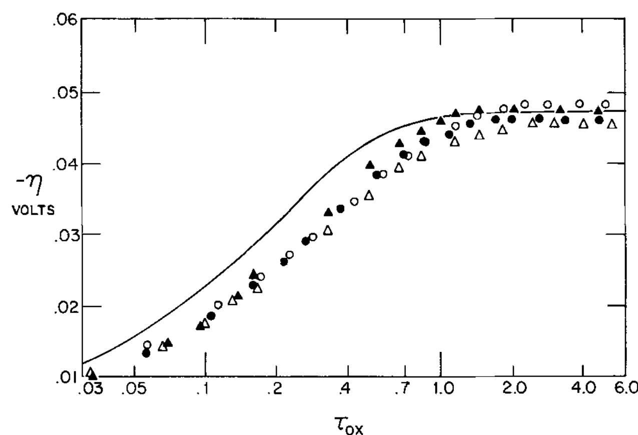

Fig. 2. Transient build-up of overpotential for $J = 0.715\ J_{lim}$. Solution: 2M KOH, 0.005M $K_4Fe(CN)_6$, 0.005M $K_3Fe(CN)_6$. Symbols: ▲ 2.6 rad/sec, Re = 132; ● 8.4 rad/sec, Re = 429; △ 26 rad/sec, Re = 1320; ○ 45 rad/sec, Re = 2290.

Discussion

The poor fit of the build-up data obtained for experimental hydrodynamic conditions essentially identical to those present during decay suggests that previous treatments have oversimplified the model necessary to describe overpotential build-ups. Since the present treatment also includes the assumption of constant concentration at the electrode-electrolyte interface, *i.e.*, $\psi(0,\tau)$ independent of radial position, the discrepancy can be related to the theoretical interpretation of the boundary condition at the disk surface during the build-up period.

In order to utilize a one-dimensional model to describe mass transfer, a uniformly accessible surface has been assumed. In fact, however, at the start of the transient, the overpotential build-up has not had time to develop; therefore a nonuniform, *i.e.*, primary, current distribution must be present at the electrode surface. When there is no overpotential on the electrode, the potential distribution in the electrolyte of course still satisfies the Laplace equation

$$\nabla^2\phi = 0 \quad [15]$$

The solution of Eq. [15] for disk geometry is well known (15) with the current density distribution given as

$$J/J_{AVG} = 0.5/\sqrt{1 - (r/a)^2} \quad [16]$$

The boundary condition at $\xi = 0$ is, therefore, more complicated than initially considered, and must be a function of the radial coordinate and time, *i.e.*, $\partial C/\partial Z = f(r,t)$. Using a general representation of Fick's first law, cf. Eq. [14], to relate this mass flux at the disk surface to the current density, together with the relation describing the primary current distribution initially present at the disk during build-up yields

$$\left.\frac{\partial C}{\partial Z}\right|_{Z=0} = -0.5\, J_{AVG}/nFD\sqrt{1-(r/a)^2} \quad [17]$$

However, as steady-state conditions are approached ($\tau = \infty$), a uniform current distribution can be assumed for near limiting current densities, so that

$$\left.\frac{\partial C}{\partial Z}\right|_{Z=0} = -J_{AVG}/nFD \quad [18]$$

A mathematical solution based on this time-varying boundary condition is difficult to obtain. However, the solution may be bounded for $\tau = 0$ and $\tau = \infty$. At long times, one may expect the development of a significant amount of overpotential at near limiting current densities so that a uniformly accessible surface is closely approximated (16) and Eq. [18] is an appropriate bounding condition. Indeed, it may be seen (cf. Fig. 2) that at $J/J_{lim} = 0.715$, a bounding constraint based on a uniformly accessible surface is a good approximation at long times, since the potential attains the value predicted from steady-state, radially independent considerations.

At short times, however, there is marked deviation from a theoretical model based on uniform accessibility and a bounding condition represented by Eq. [17] is appropriate.

For the inclusion of a radially dependent boundary condition, the two-dimensional Eq. [1] is an appropriate statement of the nonsteady convective diffusion equation. As a first approximation, mass transfer due to radial convection may be considered to be greater than mass transfer due to radial diffusion, so that Eq. [1] reduces to

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial Z^2} - V_Z\frac{\partial C}{\partial Z} - V_r\frac{\partial C}{\partial r} \quad [19]$$

For a substance depleted at a cathode, *i.e.*, ferricyanide, the rate of accumulation in the boundary layer must be negative, and $\partial C/\partial t$ in Eq. [19] is a negative quantity. The contribution of the term $-V_r\, \partial C/\partial r$ to the total rate of accumulation is always positive for a species undergoing cathodic reduction, because: (*a*) $\partial C/\partial r < 0$ throughout the boundary layer [current density at an electrode is always greater at the edges (cf. Eq. [15] for $\tau = 0$) than at the center forcing the concentration to be less at the edges], and (*b*) $V_r > 0$ throughout the boundary layer. Therefore, the surface concentration calculated on the basis of Eq. [19] must be greater (at any given time) than the surface concentration calculated when neglecting the radial term (cf. Eq. [2]), causing a slower attainment of steady-state conditions. Similarly, if a substance is built up at a cathode, *i.e.*, ferrocyanide, its rate of accumulation in the boundary layer is positive, $\partial C/\partial t$ is positive, and the contribution of the term $-V_r\, \partial C/\partial r$ is negative. The surface concentration calculated on the basis of Eq. [19] is less (at any given time) than the surface concentration calculated when neglecting the radial term, also contributing to slower attainment of steady-state conditions.

The good agreement of the decay data with a theory (cf. Fig. 1) which omits radial terms suggests that a uniformly accessible surface, *i.e.*, radial independence of surface concentration, does exist throughout the overpotential decay interval. This is to be expected since a significantly large amount of overvoltage is initially present during decay when $J/J_{lim} = 0.715$ essentially producing a radially independent surface concentration at $\tau = 0$. The subsequent decay behavior is not controlled by electrochemical reaction so that a radially independent concentration behavior continues to exist.

A quantitative basis for estimating the relative uniformity of current distribution at steady state may be simply obtained from the familiar throwing-power parameter. The relation of this dimensionless group to the ratio between interface and ohmic resistance has been discussed by Nanis and Kesselman (17). Uniform current density distribution is generally obtained when the dimensionless group in Eq. [20] is numerically greater than unity. Equation [13] may be used to obtain an estimate for $\partial\eta/\partial J$ at steady state by setting $\psi = 1$. Simplification is possible by considering $D_{OX} = D_{RED}$ and $C_{OX} = C_{RED}$. Thus, a criterion for uniform current density at 25°C is a large value of the quantity

$$\frac{\kappa}{a}\left|\frac{\partial\eta}{\partial J}\right| = 0.0513\,\frac{\kappa}{aJ_L}\,\frac{1}{(1-J/J_L)(1+J/J_L)} \quad [20]$$

In general, Eq. [20] indicates that uniformity is enhanced by reducing disk size and increasing electrolyte conductivity. In addition, uniformity is seen to be promoted with small values of J_L. In turn, Eq. [14] and [5] may be used to indicate that the greatest control for diminishing the limiting current density is afforded by proportional decrease in the concentration and decrease in the square root of the rotational speed. The J/J_L factor in Eq. [20] strongly influences current uniformity. As J/J_L approaches unity, the denominator factor $(1 - J/J_L)$ goes to zero, causing a large increase in the throwing power parameter. For the conditions shown in Fig. 2, Re = 2290 (430 rpm) represents the least favorable current distribution situation, according to the above discussion. Using the limiting current density, 1.4 mA cm^{-2}, together with $\kappa = 0.375$ ohm^{-1} cm^{-1}, $a = 0.794$ cm and $J/J_L = 0.715$, Eq. [20] is equal to 35, thus assuring uniformity of current in the steady state. At very small current densities (J/J_L approaching zero), Eq. [20] becomes numerically equal to 17, more than satisfying the criterion for uniformity for Re = 2290. As discussed above, present results for slower speeds must therefore also be associated with steady-state uniformity of current. In equivalent terms, the boundary layer thickness is uniform at steady state in the present study.

In order to relate the poor fit of build-up data to theory in terms of the good fit for decay, it is helpful to consider the time behavior of this mass transport boundary layer. Initially, the depletion layer does not yet exist and commences growth with the initiation of current. According to the primary current distribution given in Eq. [16], a stable boundary layer thickness should be reached first at the edge of the disk, followed by radial spreading inward to the center. This behavior is not taken into account in the mathematical statement of Eq. [2] since radial terms have been omitted. Since, as indicated above, the steady-state boundary layer thickness was independent of radial position, *i.e.*, uniform current density prevailed, the assumption of radially independent initial condition (Eq. [11]) for decay was valid. Likewise, the radial terms are reasonably omitted from Eq. [1] applied to decay. It should be noted that the boundary condition given in Eq. [8] describes a model meant to approximate the actual behavior of the concentration profile at the outer edge of the boundary layer. During actual decay following current interruption, the thickness of the concentration depletion layer may increase but certainly will not become smaller, since this would correspond to increased stirring. Thus, the present solution (Table I) for the decay of concentration overpotential with time corresponds to a limiting bound of fastest possible decay. Finally, since transient current distribution is a most generally applicable concept, re-

newed attention should be directed to related technical implications in cyclic plating and pulse battery charging (macro and porous electrode size scales) as well as to the rotating disk electrode.

Summary

Experimental mass transport controlled overpotential decay data exhibit better correlation with a theory based on uniform accessibility at the rotating disk electrode than do overpotential build-up data. The discrepancy of the build-up data may be associated with nonuniform current distribution (nonuniform accessibility) present at the disk during the initial stages of build-up.

SYMBOLS

a	disk radius, cm

Transient Behavior During Reactant Depletion in Porous Electrodes

Richard Alkire* and Barry Place**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Transient behavior of porous electrodes during reactant depletion is modeled by a one-dimensional pseudo steady-state calculation based on transport equations. Numerical results are presented for both constant current and constant potential electrolysis.

Withdrawal of energy from a battery is a batch process in which the chemical energy initially available as reactant species is converted into electrical energy upon discharge by electrochemical reaction. Porous electrodes are used in batteries in order to achieve a high reaction rate per unit volume. Since most reactants and/or products are usually incorporated in the solid electrode phase, the conduct of electrolysis will lead to changes in the composition and configuration of the electrode material itself. Although extensive fundamental studies have been conducted on porous electrode systems of invariant structure (1, 2), rather few analyses have treated transient behavior during discharge of the electrode phase (3-5).

The following study provides an analysis of transient behavior during discharge owing to depletion of a limited quantity of solid reactant from favorable reaction regions within the porous electrode structure. The study represents a step toward the analysis of practical systems which are usually complex. In many electrochemical systems, the local reaction rate is highest on certain portions of the porous electrode surface. During operation, reactive material in these regions would be consumed and subsequent reaction would take place elsewhere within the porous electrode.

* Electrochemical Society Active Member.
** Electrochemical Society Student Associate.

Key words: porous electrode, transient behavior, mathematical model, reactant depletion.

Eventually reactants even in the inaccessible regions would be discharged by reaction. Determination both of the electrode regions which are most accessible and of the rate at which active material becomes depleted depends on the current distribution throughout the porous electrode.

The reactant depletion process involves a straightforward type of composition change in the solid phase in which a local region is either reactive or not depending on the quantity of reactant that is locally available. In actual battery systems, more complicated phenomena take place such as crystallization or precipitation of insoluble product salts on the reacting surface which can lead to gradual insulation of the surface and obstruction of the pore cross-section (6-8). The investigation of the somewhat pristine model which follows will provide a basic approach which may be extended toward the more complex systems once sufficient kinetic data become available.

Model Formulation

The theoretical model is based on consideration of a slab of porous electrode material of high conductivity, of uniform specific surface area, a, and of thickness, l. The porous electrode is contacted on one side ($y = 0$) by a metallic plate, and on the other ($y = l$) by the electrolytic solution which also fills the void volume within the electrode. The pores are sufficiently small that the potential and solute concentrations vary along the pores in essentially one dimension alone. There is no convection of electrolyte within the pores.

Prior to discharge, a limited quantity of solid reactant is uniformly dispersed throughout the interior surface of the porous electrode. During discharge, the distribution of solid reactant within the electrode is changed owing to electrolysis and is determined from Faraday's law

$$q(y,t) = q_o - \int_0^t j(y,t)\,dt \qquad [1]$$

(The notation is provided at the end of the text.) The current distribution, $j(y,t)$ varies in time during the discharge process and is to be calculated by application of transport laws to the movement of solute species within the porous electrode.

Under many practical circumstances, concentration gradients will become established during electrolysis. As reactive species become depleted, however, the concentration distributions within the porous electrode will vary. In order to take into account the effect of concentration variations during discharge, an approximate method of analysis has been chosen which avoids excessive investment in computation time. It is assumed that the concentration profiles adjust themselves rapidly to small changes in the reactivity distribution within the electrode. That is, a pseudo steady-state condition is said to prevail under which the concentration distributions change during depletion; but at any given moment the concentration distributions are at the steady state which corresponds to the reactivity conditions prevailing at that moment. During the initial moments of discharge, concentration gradients will achieve a steady state before depletion sets in if

$$\frac{alq_o i^*}{n^2\mathbf{F}^2 c_r^2 D_r} > 1$$

The model may now be formulated from the one-dimensional pseudo steady-state conservation equation for each solute species

$$D_i\frac{d^2c_i}{dy^2} + \frac{z_iD_i\mathbf{F}}{RT}\frac{d}{dy}\left(c_i\frac{d\phi}{dy}\right) = \frac{\nu_i\sigma a}{n\mathbf{F}}j \qquad [2]$$

The homogeneous species source term is related to the rate of the electrochemical reaction

$$\sum_i \nu_i M_i^{z_i} = ne^- \qquad [3]$$

through the reaction rate expression. The example calculations presented here are intended for comparison with experimental data on a system for which the Butler-Volmer form applies. Upon discharge, the solid reactant begets a soluble ion (species 3) so that the cathodic partial reaction is concentration dependent.

$$j = i_o \left\{ e^{-\frac{\alpha n\mathbf{F}}{RT}(\phi - \phi_e)} - \frac{c_3}{c_3^o} e^{-\frac{(\alpha - 1)n\mathbf{F}}{RT}(\phi - \phi_e)} \right\} \qquad [4]$$

In addition, electrical neutrality is assumed to prevail throughout the pore region

$$\sum_i z_i c_i = 0 \qquad [5]$$

Two sets of boundary conditions have been chosen for study: galvanostatic discharge and potentiostatic discharge. In both cases, the boundary conditions at the metal backing plate ($y = 0$) are the same since no current passes through the rear plane

$$\frac{d\phi}{dy} = \frac{dc_i}{dy} = 0 \qquad [6]$$

At the boundary which faces the electrolyte solution, the solute concentrations are equal to their values in the bulk of the electrolyte

$$c_i(l,t) = c_i^o \qquad [7]$$

Under potentiostatic discharge, the potential in the solution at the pore entrance is maintained at a constant value

$$\phi(l,t) = \phi^o \qquad [8]$$

Under galvanostatic discharge, however, the flux of product ions (species 3) released during discharge is constant

$$D_3\frac{dc_3}{dy} + \frac{z_3D_3\mathbf{F}c_3}{RT}\frac{d\phi}{dy} = \frac{i_o}{z_3\mathbf{F}} \qquad [9]$$

In order to render the mathematical model more compact, the variables may be written in dimensionless form

$$Y = \frac{y}{l} \qquad C_i = \frac{c_i}{c_r}$$

$$\Phi = \frac{\mathbf{F}}{RT}(\phi - \phi_e) \qquad J = \frac{al^2 j}{n\mathbf{F}c_rD_r}$$

$$Q = \frac{q}{q_o} \qquad \tau = \frac{n\mathbf{F}c_rD_rt}{al^2q_o}$$

The equations become

$$\frac{d^2C_i}{dY^2} + z_i\frac{d}{dY}\left(C_i\frac{d}{dY}\right) = \frac{\sigma\nu_i\xi}{\pi_i}\left\{ e^{-\alpha n\Phi} - \frac{C_i}{\gamma_i} e^{-(\alpha - 1)n\Phi} \right\} \qquad [10]$$

$$\sum_i z_iC_i = 0 \qquad [11]$$

$$Q = 1 - \int_0^\tau J\,d\tau \qquad [12]$$

For constant potential discharge the boundary conditions are

$$\frac{dC_i}{dY} = \frac{d\Phi}{dY} = 0 \text{ at } Y = 0$$

$$C_i = C_i^o \text{ at } Y = 1 \qquad [13]$$

$$\Phi = \Phi^o \text{ at } Y = 1$$

For constant current discharge the boundary conditions are

$$\frac{dC_i}{dY} = \frac{d\Phi}{dY} = 0 \text{ at } Y = 0$$

$$C_i = C_i^o \text{ at } Y = 1 \quad [14]$$

$$\frac{dC_3}{dY} + z_3 C_3 \frac{d\Phi}{dY} = -\frac{n\beta}{z_3 \pi_3} \text{ at } Y = 1$$

The dimensionless parameters which arise in the foregoing development are

$$\xi = \frac{i_o a l^2}{n\mathbf{F} c_r D_r}$$

$$\gamma_i = \frac{c_i^o}{c_r}$$

$$\beta = \frac{i^* l^2}{n\mathbf{F} c_r D_r}$$

$$\pi_i = \frac{D_i}{D_r}$$

Method of Calculation

The calculation of transient behavior during discharge was carried out in a stepwise manner. At each time step, the electroneutrality and conservation equations, [10] and [11] were solved by using finite difference techniques. The electrode region was divided into segments of equal size and linearized forms of Eq. [10] and [11] were written for each segment; the coupled tridiagonal matrices thus obtained were inverted by a computer-implemented method (9). Calculation of discharge behavior was started by solving the electroneutrality and conservation equations, as described above, to obtain the steady-state current distribution under the condition of uniform reactivity throughout the electrode. The steady-state distribution was assumed to prevail throughout the first moments of electrolysis until sufficient charge passed to deplete reactants from the electrode segment where the reaction rate was highest. A new current distribution was then determined for which the electrode was reactive throughout except for the one exhausted segment. With the revised current distribution, the time necessary for depletion of the second electrode segment was determined. In a like manner, the time needed for depletion of each successive portion of the electrode was computed with use of the prevailing steady-state current distribution.

The numerical results presented below were found not to change appreciably below electrode segments of width 0.005. Calculations were conducted on an IBM 360 computer with FORTRAN IV programming complied in FORTRAN G language.

Results and Discussion

The calculations reported below are intended for comparison with data from experiments on copper-coated porous stainless steel electrodes. Upon dissolution in acid sulfate electrolyte, the copper will dissolve to form the soluble cupric ion; local depletion of copper will be followed by passivation of the stainless steel substrate. The physical properties of the acid copper sulfate system, given in Table I, have therefore been chosen in order to conduct calculations.

Prior to any depletion whatsoever, the steady-state current distribution for a given current or potential depends on the value of the dimensionless parameter ξ as indicated in the lower portion of Fig. 1. For large values of ξ, the electrode reaction is relatively reversible and takes place mainly near the electrolyte side of the porous electrode. For sluggish reactions in thin electrodes (small ξ), charge transfer overpotential near the pore entrance region forces current to penetrate into the porous electrode so that for a given applied potential the reaction is more uniformly distributed at the expense of a lower total current. The concentration distributions within the porous electrode are also affected by the value of ξ as indicated in the upper portion of Fig.1. For large values of ξ, the current is large so that significant concentration differences arise between the bulk and the "pore" solutions in order to transport reaction products out of the pores. For small values of ξ, smaller concentration differences are encountered. For a given applied potential, the concentration gradient at the pore entrance increases with ξ since the total current increases.

Table I. Physical properties of the acid copper sulfate system chosen for calculations

Species	z_i	γ_i	π_i	ν_i

Cu^{++}	+2	0.10	0.7188	−1

Constant Potential Discharge

Transient behavior during battery depletion depends on whether discharge proceeds under conditions of constant potential or of constant current. The constant potential conditions, specified by the boundary conditions of Eq. [13]), are reported first. All calculations are reported for a dimensionless depletion potential of $\Phi^o = -1.0$. Figure 2 indicates how the total current varies during discharge for various values of ξ. It may be seen that the time required for depletion of the first segment of the electrode depends on the uniformity of the current distribution, that is, on ξ. For large values of ξ, the current is large but drops off rapidly since the forward portions of the electrode are rapidly depleted owing to the highly nonuniform current distribution. For small values of ξ, a much lower current is withdrawn from the device owing to charge-transfer overpotential, but the current distribution is more uniform with the result that a uniform current may be withdrawn for longer periods of time.

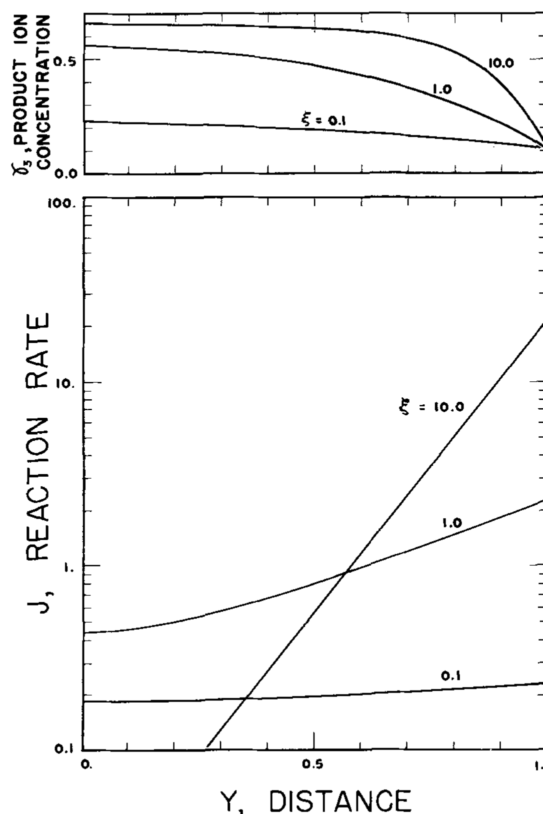

Fig. 1. Steady-state current and concentration distributions in porous electrode prior to reactant depletion for $\Phi^o = -1.0$.

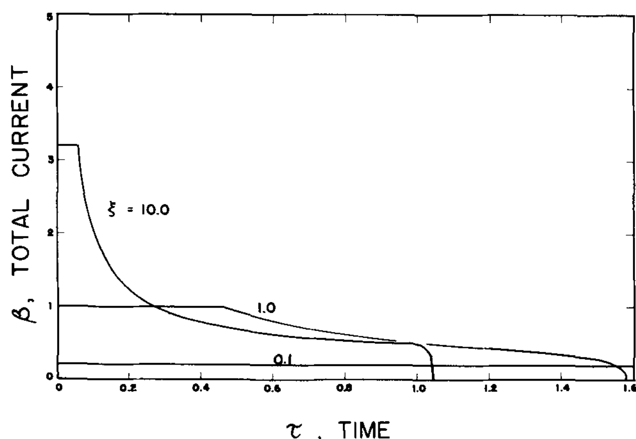

Fig. 2. Current variation during depletion in porous copper electrode for a constant applied potential of $\Phi^o = -1.0$.

Figure 3 provides the coulombic state of charge distribution during constant potential depletion for $\xi = 1.0$. At the onset of electrolysis, the coulombic distribution (of copper) is uniform throughout the porous electrode. For the example shown here, the reactant nearest the electrolyte side of the porous electrode becomes completely consumed at a dimensionless time of $\tau = 0.432$. Subsequent consumption proceeds in the interior regions; the variation of total current during the depletion process has already been presented in Fig. 2.

During the depletion process depicted by Fig. 3, the current and concentration distributions vary as shown in Fig. 4. From the upper portion it is seen that concentration gradients become established but that they decrease during the course of depletion; the mass transfer driving force decreases as the current drops off during depletion. The lower portion of Fig. 4 shows the current distributions within the electrode at various times during depletion. The dashed line in the lower portion gives the local reaction rate at the "leading edge" of the reaction zone, J_f, as it recedes within the electrode during depletion. It may be seen that J_f is initially large and that it decreases during initial stages of depletion. The dashed line in the upper portion of Fig. 4 gives the cupric ion concentration at the leading edge of the reaction zone as depletion sets in; it is seen that during initial moments of depletion the concentration at the leading edge increases in order to provide a greater diffusion driving force for removal of product ions. When depletion first sets in, a portion of the applied (constant) potential is consumed by concentration overpotential so that the potential available for reaction decreases. However, the concentration overpotential cannot increase indefinitely, since the total quantity of product species retained within the pores is decreasing during depletion. Eventually, the

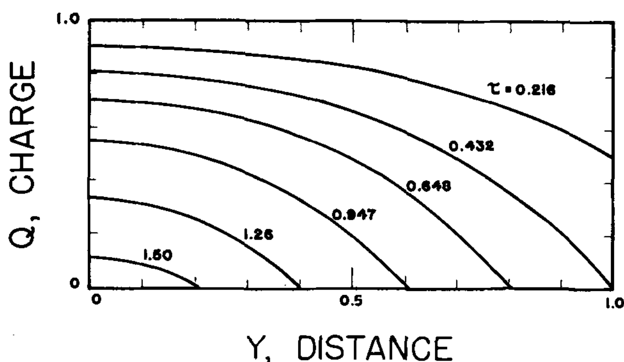

Fig. 3. Coulombic state of charge distribution during anodic depletion of copper from a porous electrode at constant potential, $\Phi^o = -1.0$ and $\xi = 1$.

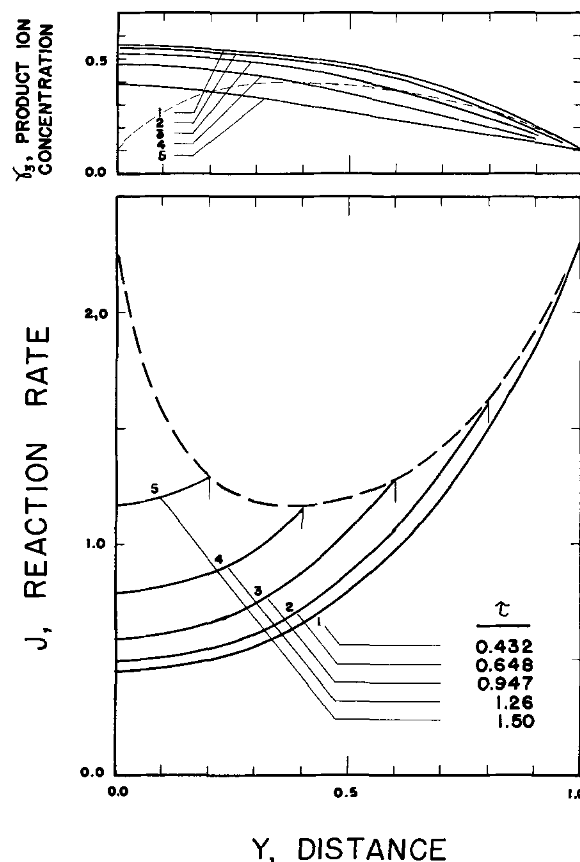

Fig. 4. Current and concentration distributions during potentiostatic anodic depletion of copper from a porous electrode, $\Phi^o = -1.0$ and $\xi = 1$.

concentration at the leading edge of the reaction zone attains a maximum value and subsequently decreases. Similarly, the potential at the leading edge attains a minimum value and subsequently increases. Thus J_f attains a minimum value during depletion. During the initial moments of depletion, the decrease in current is due primarily to the appearance of a diffusion resistance associated with the unreactive zone of the electrode. During latter stages of depletion, the decrease in current is due to the reduced surface area available for electrolysis in the active region which remains. The current distribution becomes more uniform during depletion because the electrode can produce more product species than the depleted (diffusion) zone can disperse.

Constant Current Discharge

When current is applied to the electrode at a constant rate, the electrode overpotential will increase during depletion with the result that the useful cell voltage decreases. The constant current calculations reported below for the acidified copper sulfate system were carried out for $\beta = 1$. Figure 5 illustrates the variation of potential at the electrolyte side of the porous electrode during depletion. For small values of ξ, the beginning charge-transfer overpotential is large and the useful cell potential is small, but the current distribution is uniform so that the potential plateau is long. During constant current operation, the solute concentration increases within the electrode since an ever larger driving force is needed for removal of product species through the discharged zone.

The current distributions during constant current depletion are shown at various stages of discharge in Fig. 6. Since

$$\beta = \int_0^1 J\, dY = \text{constant}$$

the area under each distribution curve is the same.

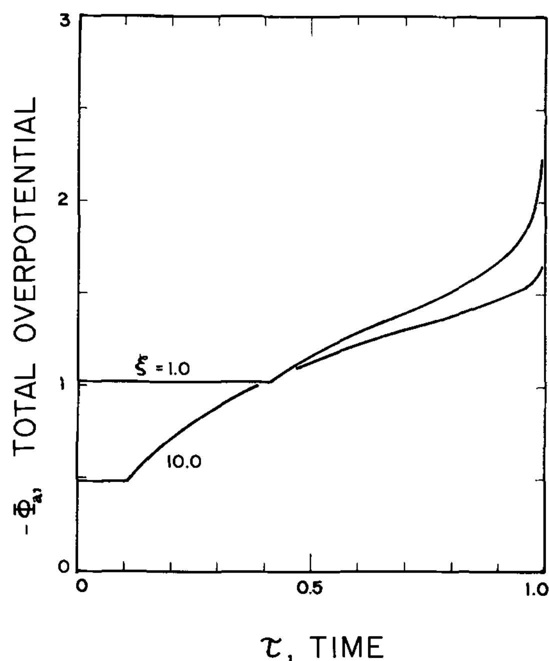

Fig. 5. Overpotential variation during constant current anodic depletion of copper from a porous electrode at $\beta = 1$.

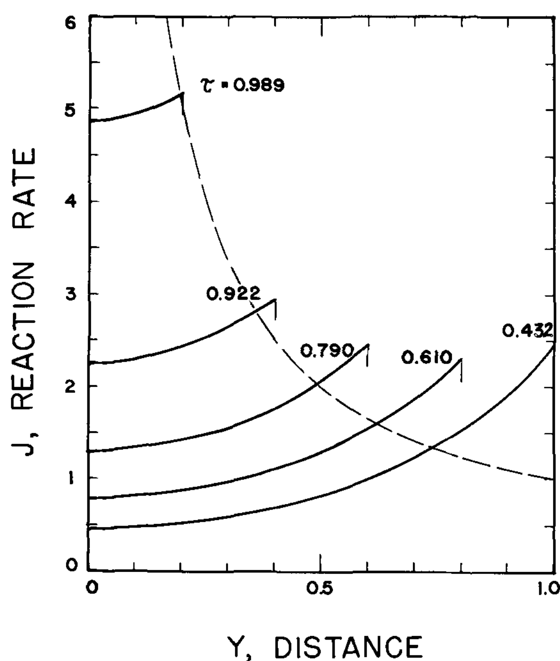

Fig. 6. Current and concentration distributions during anodic depletion of copper from a porous electrode at constant current, $\beta = 1$ and $\xi = 1$.

The dashed line corresponds to the reaction rate at the leading edge which would be observed if the current distribution were uniform throughout depletion. It may be seen that the current distribution over the active zone becomes always more uniform as depletion proceeds.

Concluding Remarks

The calculations presented here, although limited in scope, demonstrate that a simple conceptual model can serve as a basis for approaching transient phenomena in porous electrode systems. The results are capable of verification by somewhat simple experiments which avoid the complicated phenomena which occur in most secondary battery systems. An especially interesting interplay occurs during constant potential depletion in which the reactivity of the leading edge of the reactive zone passes through a minimum.

The model examined above has some features in common with the treatment of Dunning *et al.* (5), which ascribes transient behavior to mass transfer limitations between crystallites of sparingly soluble reactants. In contradistinction, the present model centers attention on variation of surface reactivity during operation.

The analysis of more complex systems can be accomplished by a straightforward extension of the foregoing pristine model. The pseudo steady-state assumption, although economical, is not necessary and could be discarded in favor of more rigorous unsteady-state calculation methods. Chemical interaction between solute species within the porous electrode may be accounted for easily by superposition of equilibrium-constant constraints on the equation network. Multiple electrode reactions, such as occur during gassing, could be incorporated into the present model without additional complication. Different forms of reaction rate expressions could also be employed were they available; in particular, a rate expression which reflected gradual insulation and blocking of the surface during discharge could be used for examining the role of insoluble products and/or reactant species upon behavior during cycling of secondary battery systems.

Technical Note

Synergistic Effects of Anions in the Corrosion of Aluminum Alloys

A. A. Adams,* K. E. Eagle, and R. T. Foley*

Department of Chemistry, The American University, Washington, D. C. 20016

In a preliminary note (1) it was reported that in specific electrolyte mixtures, *i.e.*, specific concentrations and specific NaCl-$NaNO_3$ ratios, the corrosion of aluminum alloys Type 7075 and 2024 was increased by an order of magnitude over that in NaCl solutions of the same concentration. This was unexpected as it was known that $NaNO_3$ inhibits the corrosion of aluminum alloys and, although it was recognized that a lower critical amount was required to achieve passivation (2), no accelerating effect had been reported. We have studied this phenomenon in more detail with chloride-nitrate mixtures of other cations. We have also conducted supporting experiments with the objective of throwing light on the mechanism by which these electrolyte mixtures accelerate the corrosion of aluminum alloys.

Experimental

The experimental procedure was similar to that reported previously (1). Three aluminum alloys, Types 1199-H14, 2024-T3, and 7075-T6, in sheet form were used. The specimens were prepared by standard methods and, following corrosion, were stripped of corrosion products, also by standard procedures. Corrosion products and corroded surfaces were examined by x-ray diffraction and x-ray fluorescence techniques. Metallographic cross sections of selected specimens were examined microscopically. The pH's of the solutions in which the samples were corroded were measured before and after sample exposure. Because it was very pertinent to follow the fate of the NO_3^- ion during the course of the reaction the solutions were qualitatively analyzed for nitrite ion and ammonia, reduction products of nitrate. The benzidine test (3) was used for nitrite detection and the p-nitrobenzene diazonium test (4) for ammonia.

Results and Discussion

Some selected but representative data obtained with alloy Type 2024 are given in Table I. Some general observations can be made with respect to data not shown. The first has to do with the dependence on alloy composition. There was no evidence of accelerated corrosion of alloy 1199 with any electrolyte mixture. The behavior of alloys Type 2024 and 7075 were similar semiquantitatively. The second observation has to do with solutions containing NO_3^- without Cl^-. The corrosion was low in every case so these figures are not tabulated here.

The results in Table I for the sodium-salt mixtures, wherein corrosion is enhanced by a factor of 8-9, is consistent with previously reported results and those obtained with alloy Type 7075 in which case there is a tenfold increase in corrosion in a 0.01*N* NaCl-0.007*N* $NaNO_3$ solution compared to that in a 0.01*N* NaCl solution. In the earlier work mixtures of potassium and lithium salts in this same concentration range were examined but no synergistic mixture was disclosed. However, when the concentration range was extended and other ratios were studied it was found that there existed for these two systems a specific mixture in which corrosion was accelerated. These mixtures are shown in Table I; the same mixture applies to alloy Type 7075. For the potassium-salt solutions a mixture

Table I. Immersion tests with alloy 2024 in potassium, lithium, and sodium solutions

Solution	Duration (days)	Wt. loss (average) mg/cm²
0.1*N* KCl	13	0.83
0.1*N* KCl/0.005*N* KNO_3	13	11.94
0.1*N* KCl/0.001*N* KNO_3	13	10.49
0.1*N* KCl/0.01*N* KNO_3	13	0.64
0.1*N* KCl/0.05*N* KNO_3	13	1.14
0.1*N* LiCl	18	0.22
0.1*N* LiCl/0.005*N* $LiNO_3$	18	0.55
0.1*N* LiCl/0.01*N* $LiNO_3$	18	1.03
0.1*N* LiCl/0.02*N* $LiNO_3$	18	0.48
0.1*N* LiCl/0.05*N* $LiNO_3$	18	0.23
0.1*N* LiCl/0.1*N* $LiNO_3$	18	0.13
0.01*N* NaCl	14	1.03
0.01*N* NaCl/0.003*N* $NaNO_3$	14	3.72
0.01*N* NaCl/0.005*N* $NaNO_3$	14	7.98
0.01*N* NaCl/0.007*N* $NaNO_3$	14	8.72
0.01*N* NaCl/0.01*N* $NaNO_3$	14	8.44
0.01*N* NaCl/0.05*N* $NaNO_3$	14	0.13

Key words: aluminum alloy 7075, aluminum alloy 2024, accelerated corrosion, pitting, complexions.

of 0.1*N* KCl and 0.005N KNO_3 yields a fourteenfold increase in rate while for the lithium-salt solutions a mixture of 0.1*N* LiCl and 0.01*N* $LiNO_3$ gives about a fivefold increase in rate. It is possible that there are other synergistic mixtures, but it is apparent that for each of the alkali metals there is at least one specific mixture which accelerates corrosion, usually by an order of magnitude. With the sodium-salt system the concentration as well as the ratio appear to be specific. There was no accelerated corrosion when the same ratio was used at other concentrations. Furthermore, when electrolyte mixtures outside the alkali metal group were investigated, it was observed that synergistic mixtures with Al^{+++}, Be^{++}, and NH_4^+ also exist. In certain ammonium-salt solutions corrosion reaches a catastrophic stage during 1-2 week exposures. Specifically, in mixtures of 1.0*N* NH_4Cl-0.5*N* NH_4NO_3 and 1.0*N* NH_4Cl-0.2*N* NH_4NO_3, the corrosion rate is enhanced by a factor of 100 and 600, respectively, over a 14 day period.

The corrosion in the alkali-salt solutions starts with many small pits scattered over the surface. The attack spreads rapidly, covering the entire surface and producing a thick layer of corrosion product. In the ammonium-salt solutions the attack appears to be concentrated at fewer, deeper pits which leads to the complete penetration of a 0.8 mm strip in 14 days. Where attack commences at an edge, the strip is exfoliated in several days (Fig. 1).

The kinetics of the reaction of alloy Type 2024 in 0.01*N* NaCl-0.005*N* $NaNO_3$ and 0.1*N* KCl-0.005*N* KNO_3

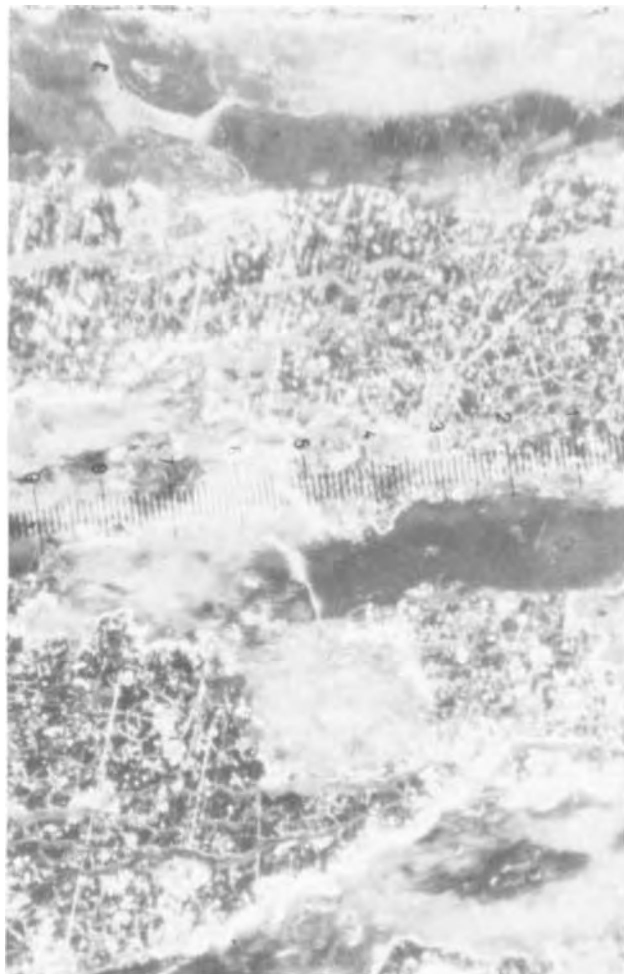

Fig. 1. Cross section of aluminum alloy Type 2024-T3 coupon corroded in 1.0*N* NH_4Cl-0.2*N* NH_4NO_3 solution. Magnification, 52×. Duration of test, 14 days. Dark bands are fissures in the metal. Located within fissures are white and blue colored precipitates.

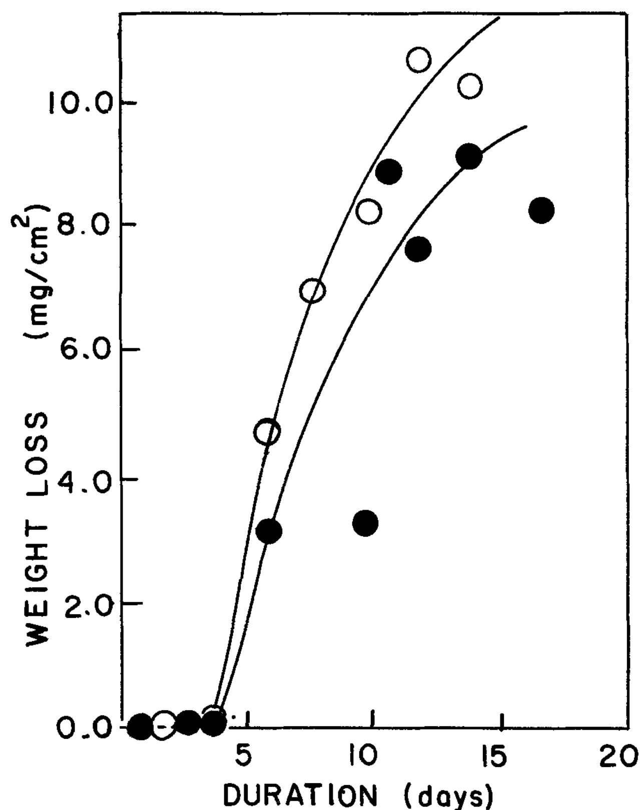

Fig. 2. Reaction of aluminum alloy Type 2024-T3 with synergistic mixtures. ○ = corrosion in 0.01*N* NaCl-0.005*N* $NaNO_3$ solution; ● = corrosion in 0.1*N* KCl-0.005*N* KNO_3 solution.

is shown in Fig. 2. The incubation period is characteristic of sodium and potassium salt solutions but not for ammonium in which corrosion commences during the first day.

In addition to the corrosion data there are other observations that are useful in developing a mechanism to explain how these synergistic solutions accelerate corrosion.

The test for nitrite ion was negative in the K^+, Na^+, and NH_4^+ synergistic mixtures before immersion of the coupons. After one day the test was positive and persisted for the duration of the experiment.

The test for ammonia in the K^+ and Na^+ synergistic solutions was negative at the start and remained negative during the incubation period (Fig. 2). The test became positive coincident with the increase in reaction rate.

The *p*H's of the solutions of the alkali-metal salts rose during the reaction proportional to the weight loss. For the synergistic mixture the rise was about 5 *p*H units, *e.g.*, from 5.73 to 10.78. For the ammonium solutions the increase was less, usually about 2 units, *e.g.*, from 5.18 to 7.52, never exceeding 8.

X-ray diffraction examination indicated that the main corrosion product from NaCl solutions and from NaCl-$NaNo_3$ synergistic mixtures was the same, γ-$Al_2O_3 \cdot 3H_2O$.

X-ray fluorescence measurements on samples corroded in synergistic solutions and stripped in the chromic-phosphoric acid stripping solution showed a depletion of alloying element, Cu or Zn, on the metal surface. Specimens corroded in a similar fashion but with the main corrosion layers scraped from the surface indicated an enrichment of the alloying element at the surface. In the case of alloy Type 2024 this consisted of what appeared to be a layer of Cu stratified between the metal and the corrosion scale.

It is obvious from the foregoing that a number of reactions are taking place simultaneously, and the cor-

rosion reaction must be a multistep process. However, the following sequence of steps may be postulated.

The first step, preceding any electrochemical or chemical step, is the adsorption of Cl^-, NO_3^-, H_2O, and O_2 at the oxide-solution interface. This process and the effect of specific anions on the properties of the oxide film related to subsequent transport processes has been described by Pryor (5). Following adsorption, reactions take place affecting either the anodic or cathodic process.

Anodic Reactions

(*i*) *Initiation of pitting by Cl^-.*

$$Al + 4Cl^- \rightarrow AlCl_4^-$$

The evidence for this step has been given by Bogar and Foley (6) and takes place with all three alloys.

(*ii*) *Hydrolysis of aluminum chloride complex.*

$$AlCl_4^- + H_2O \rightarrow \gamma\text{-}Al_2O_3 \cdot 3H_2O + H^+ + Cl^-$$

The main product is the hydrated oxide observed here by x-ray diffraction. At points of local acidity protons can be reduced to H_2.

Cathodic Reactions

(*iii*) *Reduction of O_2.*

$$O_2 + 2H_2O + 4e \rightarrow 4\,OH^-$$

During active corrosion the pH of the solution will rise as indicated above.

(*iv*) *Reduction of NO_3^-, when available, simultaneous with (iii).*

$$NO_3^- + 2e = NO_2^- \quad E°_B = 0.01V \ (7)$$

$$NO_2^- + 6e = NH_3 \quad E°_B = -0.48V \ (8)$$

Nitrite is produced at the start of the reaction. Ammonia is produced after the incubation period.

(*v*) *Chemical reactions between NH_3 and intermetallic compounds (9).*

in alloy 2024[1] $CuAl_2 + 4NH_3 = Cu(NH_3)_4^{++}$
$K_{instability} = 2.4 \times 10^{-13}$ (10)

in alloy 7075[2] $MgZn_2 + 4NH_3 = Zn(NH_3)_4^{++}$
$K_{instability} = 3.46 \times 10^{-10}$ (10)

[1] Nominal Cu content = 4.4%.
[2] Nominal composition = 5.6% Zn, 2.5% Mg, 1.6% Cu.

Both complexes are very soluble and will accelerate the attack.

(*vi*) *Dissociation of soluble complexes in sites of high alkalinity.*

$$Cu(NH_3)_4^{++} = Cu^{++} + 4NH_3$$

This leads to deposition of either Cu° or CuO as a red layer at metal-oxide interface as indicated by x-ray fluorescence. Alloy Type 1199 is immune to this type of accelerated attack because it contains neither Cu nor Zn as alloying elements.

The existence of specific concentrations and anion ratios in solutions with different cations is difficult to explain. However, it appears reasonable that the cations of different polarizability will be adsorbed in the electric double layer to different degrees and influence the composition of the oxide-solution interface. This in turn would influence the relative adsorption of Cl^-, NO_3^-, H_2O, or O_2.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of the Electrochemical Society*, Vol. 118, No. 7, 9, 11, and 12; July, September, November, and December 1971; Vol. 119, No. 1 and 4; January and April 1972.

Hydrogen Embrittlement and Hydrogen Traps

J.O'M. Bockris and P.K. Subramanyan (pp. 1114-1119, Vol. 118, No. 7)

G. Dubpernell:[1] It is good to see the consideration given to the possible spreading of microcracks in the metal. This theory was suggested by Ferguson and Dubpernell a long time ago,[2] in an investigation of the behavior of platinum and palladium membranes.

[1] M&T Chemicals Inc., 1700 East Nine Mile Road, Ferndale, Michigan 48220.
[2] A. L. Ferguson and G. Dubpernell, *Trans. Electrochem. Soc.*, **64**, 221 (1933).

A number of questions or comments occurred during reading the paper under discussion. Why were the membranes annealed for 3 hr at 600°C prior to the experiment? What results are obtained if this treatment is omitted?

The deposition of a thin layer of palladium on the back of the Armco iron membranes seems unnecessary and unimportant in this instance. Iron would show little anodic dissolution in 0.1N NaOH. Was the rate of dissolution checked? It would seem better to use platinum for this purpose if anything is needed, as palladium has a greater tendency to anodic dissolution. What was the visual appearance of the 1.13 cm² area of the back of the membranes after the experiments? Was any corrosion evident compared to the unexposed

parts of the membranes, since the back is subjected to anodic treatment?

One would expect these experiments to be made at room temperature. Why was a temperature of 50° and 60°C used, and in one case 70°C?

On page 1116 of the paper by Bockris and Subramanyan there is a discussion of "H damage." Hydrogen is sometimes referred to as H_2. Is the H in "H damage" merely H_2, and could the expression just as well be "H_2 damage," or is a different form of hydrogen intended to be indicated by the plain "H"?

This writer feels that the results of these experiments are due to the porosity of the membranes, and not to hydrogen diffusion at all. Gross porosity of the membranes could readily be checked by the method which has been suggested[2] of reversing the polarity of the charging current on the front of the membrane and seeing if there is an immediate change in the polarity of the back of the membrane. This method depends upon the presence of thin threads of solution through the capillaries in the metal of the membrane, from front to back.

If the capillaries in the metal of the membrane are small enough and few enough, it is conceivable that the threads of solution in them might make a poor and irregular connection from the front to the back of the membrane which could easily be broken as by hydrogen bubbles, and easily be re-established when the current was shut off as during the decay tests shown in Fig. 3 and 4 in the paper under discussion. Such re-establishment of solution connections would permit any residual cathode polarization on the front of the membrane to affect the potential on the back, and this would be an explanation of the effects noted in Fig. 3 and 4.

The closely-connected report of Beck, Bockris, Genshaw, and Subramanyan[3] is also of considerable interest. The solubility of hydrogen in nickel is given as almost 1000 times the solubility in iron, and yet the permeability of iron-nickel alloys falls to about one thousandth of that of iron at about 40% or more of nickel. This contradiction does not seem adequately explained.

An excellent correlation is noted between the permeability of the membranes and their corrosion resistance, the membranes with 40% or more of nickel having about 1000 times the corrosion resistance of iron. The authors suggest that the higher permeability of iron may be due to the formation of pits caused by corrosion and the spreading of cracks to the surface. Is not this tantamount to saying that iron membranes may become more porous than 40% nickel membranes due to corrosion, and that the permeability of iron membranes in which hydrogen is less soluble, is due to porosity?

The writer again wishes to bring into question the validity of the method proposed by Devanathan, Stachurski, and Beck[4] for determining the permeability of metal membranes to hydrogen.

Adsorption of Thiourea and its Derivatives at the In-Hg/Electrolyte Interface.

R. Narayan and N. Hackerman (pp. 1426-1430, Vol. 118, No. 9)

A. N. Frumkin and N. B. Grigoryev:[5] Starting from 1928[6] the adsorption of thiourea at the metal/electrolyte solution interface has attracted the attention of electrochemists as an example of a reversible adsorption process resulting from a chemisorptive interaction of the functional group and the metal surface. This problem is also treated in the interesting paper under discussion of Narayan and Hackerman, who considered the case of thiourea adsorption on indium amalgams.[7] The aim of this note is to fill up some gaps in their paper.

Adsorption of thiourea leads to a shift of pzc towards negative potentials, which is due to the orientation of the C-S bond with the negatively charged sulfur atom to the metal surface. This conclusion, first obtained from electrocapillary curves,[6] was confirmed by the determination of pzc from the minimum on the C,E curves in diluted electrolyte solutions.[9] Analysis of these curves showed that unlike the desorption maxima of many aliphatic and aromatic compounds, the desorption maximum for solutions with thiourea additions is due to the strong shift of pzc in the negative direction, rather than to the effect of thiourea on the double layer capacity. The adsorption of thiourea on a dropping gallium[10] and on a lead electrode was investigated.[11,12] The adsorption potential shifts on gallium are greater, and on lead smaller, than on mercury. Experimental data on thiourea adsorption on mercury[9] and gallium[11] were used for verification of the theory of the discrete double layer at the metal/solution interface in the presence of specific adsorption of dipole molecules and adsorption of solvent molecules.[13] The Esin-Markov coefficient, calculated with the use of reasonable values of the double layer parameters, agreed well with the experimental values and, in conformity with the theory, decreased when passing from mercury to gallium.

It was shown[14] that the influence of thiourea adsorption on the kinetics of electrochemical processes on mercury and on thallium amalgams can be well accounted for by taking into consideration the ψ-effect. Meurée and Gierst[14] described for the first time the interesting phenomenon, which is also considered in the paper under discussion, *viz.*, the appearance of sharp peaks on the C,E curves during simultaneous adsorption of thiourea and halogen ions. Such sharp peaks point to a drastic change of the surface charge in a narrow potential range and to the presence of attractive interactions between adsorbed particles at more positive potentials. Narayan and Hackerman, in the paper under discussion, suppose that in this case at anodic potentials thiourea molecules turn towards the amalgam surface with their positive nitrogen end. We think that, considering that urea shows practically no surface activity at the mercury/solution interface,[6] this concept is unlikely. However, this problem cannot be cleared up without a more thorough examination of the characteristics of the adsorption layer of thiourea in the presence of halogen ions. The C,E curves with such peaks were obtained at our laboratory during thiourea adsorption on mercury in the presence of I^-, but we decided not to publish them until they could be investigated in more detail.

[7] The choice of indium amalgams as adsorbent is perhaps not optimum owing to the change in the surface layer composition with changing potential. In the quantitative interpretation of this dependence there are some discrepancies between Butler's results, which are used by Narayan and Hackerman, and those obtained by Frumkin *et al.*[8] We shall not dwell on this problem here since recently it was thoroughly dealt with.

[9] A. Morozov, N. Grigoryev, and I. Bagotskaya, *Elektrokhimiya*, 3, 585 (1967).
[10] On a stationary gallium electrode[11] in the presence of thiourea, the capacity was found to depend on the a-c frequency and on the age of the electrode/solution interface, which points to a slow chemical interaction of gallium with thiourea (with a dropping gallium electrode such phenomena are not observed). In this connection it would perhaps be useful to carry out measurements with a dropping In-Hg electrode.

Finally we should like to mention that there are rather numerous data in literature[15,16] on the effect of thiourea and its derivatives as corrosion inhibitors, mentioned in the paper under discussion.

R. Narayan and N. Hackerman: We thank the authors of the above discussion for bringing to our attention the extensive Russian literature on the subject. However, our paper was presented at the 1967 October meeting of The Electrochemical Society held in Chicago, and triangular correspondence across 10,000 miles delayed the publication. So, in effect, the paper was written prior to the appearance of the recent references noted by Frumkin and Grigoryev. Therefore, the recent references were not included.

There are at least two points of major difference between the results of Butler[17,18] and that of the Russian school:[19] (*i*) variation of the negative surface excess of indium with the potential calculated from electrocapillary measurements and (*ii*) the presence of the hump in the capacitance curves. Our measurements show the second observation and the results are in general agreement with those of Butler.

The sharp peaks in the capacitance curves in the presence of thiourea and chloride ions could be observed only with the amalgam electrodes of 20 mole per cent In or more. The negative surface excess of indium also shows a maximum at this concentration[17,18] and hence this result was emphasized. However, the suggestion by Frumkin and Grigoryev regarding possibility of compound formation was also included.

The literature[20] available shows that thiourea invariably enhances the double-layer capacitance for the Hg, Pb, and Ga electrodes. Our results show that with In-Hg electrodes there is a region of potentials in which the capacitance is depressed by the presence of thiourea. A transition hump is also obtained with amalgams of higher indium concentrations. This hump apparently becomes a peak in the presence of chloride ions. The mechanism for the peak formation is not clear. As Frumkin and Grigoryev point out strong attractive interactions come into play. Our suggestion was that the adsorbed anions reduce the mutual repulsions between adsorbed thiourea species and that the positive end of the dipole may be oriented towards the amalgam. This suggestion is based on the fact that interfacial composition of indium increases with positive polarization. The absence of surface activity of urea at the Hg solution interface probably indicates the absence of Hg-N interaction. Would this also mean the absence of In-N interaction?

An important fact which we did not consider was that thiourea is present to a large extent as the protonated species in acid solutions. The proton is attached to the sulfur atom. We have evidence of this based on studies with Fe and Hg electrodes in solutions of varying *p*H containing thiourea and N-substituted thioureas.[21] What would be the nature of the metal-thiourea interaction under these conditions? It is also worthwhile carrying out investigations with a dropping amalgam electrode.

We described perhaps for the first time the appearance of peaks in the C-E curves during simultaneous adsorption of thiourea and chloride ions, when presenting the paper in Chicago. Gierst and co-worker observed such peaks in the presence of bromide ions. Frumkin and Grigoryev claim such observations in the presence of iodide ions. Recent studies in the Indian Institute of Technology, Madras, by tensammetry showed that such peaks, rather small and sharp, can be obtained in the presence of chloride ion also using a d.m.e. The minimum chloride ion concentration corresponds to 0.25M KCl or 0.2M HCl. Further work is in progress.

The reference in our paper regarding data on corrosion inhibition was only an illustration of work which emphasizes the cumulative effects of anion and thiourea derivatives on the process of corrosion.

The Electrochemical Behavior of Technetium and Iron Containing Technetium.

G.H. Cartledge (pp. 1752-1758, Vol. 118, No. 11)

S. Trasatti:[22] In the paper under discussion, the author reports the value of about 9×10^{-5} A cm^{-2} for the exchange current of the electrolytic hydrogen evolution reaction on Tc. To my knowledge, this is the first measurement of this kind reported for Tc, a metal for which data regarding surface properties are indeed almost nonexistent. As an example, in the most recent review by Hayward[23] on chemisorption from the gas phase, Tc is tabulated always in brackets because of lack of any data for characterization. At first sight, it would therefore appear impossible to ascertain the reliability of the $i_{o,H}$ value reported by Cartledge, without repeating experimental measurements. However, I will here attempt to undertake this task by making use of a number of correlations I have recently developed[24-27] between electrochemical properties and work function of metals. Conversely, this attempt, if positive, will constitute in turn a valuable test of the reliability of such correlations originally devised to predict unknown properties of metals or metallic materials.

The ground datum from which this analysis will start is the value of Pauling's electronegativity,[28] (x_M). Recent considerations[26] show that Pauling's values are generally dependable also in the case of less common metals. Correlation exists between x_M and the work function Φ which in the case of transition metals is expressed by the equation[26]

$$x_M = 0.50\Phi - 0.55 \qquad [1]$$

Using for Tc $x_M = 1.9$, we obtain $\Phi = 4.9$ eV. Now, this value can in turn be used in the correlation between $i_{o,H}$ and Φ which, for transition metals, is given[27] by

$$\log i_{o,H} = 6.7\Phi - 36.6 \qquad [2]$$

Thus, from Eq. [2] the value of 1.6×10^{-4} A cm^{-2} is derived for $i_{o,H}$ of Tc. In view of the factors which may affect exchange current measurements and the fact that the value of x_M given by Pauling is approximate to the first figure[26,28] the agreement between observed and calculated values of $i_{o,H}$ for Tc can be considered as very satisfactory. It may be noted that coincidence of the two values is obtained with a x_M value of 1.88. Once established that the $i_{o,H}$ obtained by Cartledge is basically correct, it is more reasonable to refine the value of x_M from the experimental value of $i_{o,H}$ than the reverse, as the experimental uncertainty of electrochemical measurements is intrinsically lower than that pertaining to x_M values as claimed by Pauling.[28]

While a disagreement between observed and calculated values of $i_{o,H}$ for Tc would not reveal in principle which value is to be considered as incorrect (however, reliability of the correlation is already supported by the fact that it has been derived from data for more than 30 metals), the resulting agreement between the two values should be regarded in my opinion, as a reciprocal check of the reliability of both the experimental result and the derivation of the correlations.

I would also like to consider along the same lines some more aspects of that part of Cartledge's paper which deals with the Tc/H_2 system. The very high rapidity of hydrogen ionization observed by the author should indicate a nonactivated hydrogen adsorption on Tc, which, together with a Tafel slope for the cathodic reaction of about 40 mV would suggest, along the lines of Thomas' analysis,[29] a fast proton discharge followed by a rate determining ion + atom reaction. This mechanism is conceivable in the light of the correlations mentioned above. In fact, from Parsons' analysis[30] it is known that the relationship between $i_{o,H}$ and the strength of the M-H surface bond should pass through a maximum. This has been verified[27,31] and transition metals as a result located in the descending branch of the resulting volcano-shaped curve. Cartledge's value of $i_{o,H}$ places Tc between Pt, Pd, Rh, Ir, for which the combination is the rate-determining step, and those metals for which the ion + atom reaction is rate determining, about in the same position of Re which in fact belongs to the same group and behaves similarly. It should be of interest to note that Ru and Os[32] present about the same $i_{o,H}$ as that of Tc and the reaction is governed by the ion + atom mechanism.

A value of 64 kcal mol^{-1} for the strength of the Tc-H surface bond in solution during hydrogen evolution at $\eta \rightarrow 0$ can be derived from the volcano curve. According to arguments given by Krishtalik[31] this value should be capable of being ascertained from experimental data. Such a check would definitely prove the reliability and usefulness of correlations proposed elsewhere.[25-27] It should be added that the value of 64 kcal mol^{-1} for E(M-H) and the experimental value of $i_{o,H}$ for Tc are compatible with a rather high equilibrium coverage with atomic hydrogen, so that the combination reaction should possess a rate comparable to that of the ion + atom reaction.

I would like to emphasize here the fact that, albeit Mn belongs to group VIIA like Re and Tc and therefore all of them possess 7 electrons in the valency band, the behavior of Mn is quite peculiar. Practically, Cartledge's results demonstrate that Mn is the sole transition metal (more likely, the sole metal) which does not take the expected place in correlations. This would suggest a quite particular structure (or property) of 3d band in respect of other outer d bands.

G. H. Cartledge: Professor Trasatti has developed correlations among several properties of metals which are also related to their behavior as cathodes for the evolution of hydrogen. He observes that the exchange current density which I reported for the technetium cathode is in close agreement with the calculation he makes on the basis of his equations and the estimated electronegativity value of Pauling. For his calculation, Trasatti used the $j_{0,H}$ value given for a cathode of technetium plated over gold, whereas for massive technetium or technetium rather heavily plated over platinum the value is 10^{-3} A cm^2 His Eq. [2] is not very sensitive to differences in $j_{0,H}$, but use of the better value gives $\phi = 5.02$ and, by Eq. [1], $x_M = 1.96$. It is gratifying to note the consistency of the results.

Trasatti points out, also, the close similarity of the electrochemical behavior of technetium to that of platinum. This was apparent, not only in the ready response of the technetium electrode to hydrogen, as shown in my paper, but also by reference to the correlation between the heat of adsorption of atomic hydrogen on a metal and the overvoltage for liberation of hydrogen at a fixed current density, as given by Bonhoeffer in 1923. This also indicated a ΔH_{ads} of *ca.* 64 kcal $mole^{-1}$, in agreement with Trasatti's comments.

Professor Trasatti concludes, further, that my data indicate the probable mechanism of the discharge of hydrogen on technetium. It is to be noted, however, that the diagnostic properties of the plated electrodes were rather sensitive both to the nature of the substrate and to the presence of slowly reducible surface films. In addition, earlier work[33] suggested strongly that the behavior of technetium electrodes may be affected by their radioactivity, though circumstances did not permit further investigation of this point. Because of these uncertainties, I chose not to discuss the mechanism of the discharge of hydrogen, though I agree that the data, so far as they go, are in accord with the Heyrovsky mechanism, as Trasatti suggests. Such a conclusion is consistent also with the observation (cf. p. 1754 of the paper under discussion) that the cathodic current density at a given overvoltage is temporarily decreased when the degree of coverage by adsorbed hydrogen is reduced.

I am grateful to Professor Trasatti for his interesting discussion.

A Secondary, Nonaqueous Solvent Battery

J. S. Dunning, W. H. Tiedemann, L. Hsueh, and D. N. Bennion (pp. 1886-1890, Vol. 118, No. 12)

J. Besenhard and H. P. Fritz:[34] The authors describe a secondary, nonaqueous battery, consisting of a lithium negative and a graphite compound positive electrode, $LiClO_4$/dimethyl sulfite being the electrolyte; they suggest the formation of lamellar graphite compounds, *e.g.*, C_nClO_4, in the aprotic system. n is estimated to be 89 and in contrast to the results in acids,[35] no color change, no stage formation, and unlimited, irreversible expansion of graphite on oxidation is reported.

We, however, found a fair accord with the behavior of graphite oxidized in conc. acids, particularly with respect to stoichiometry and ionic structure.[36]

Formation of stages.—On oxidation in aprotic solvents the potential of a graphite electrode slowly rises to a constant value. Galvanostatic oxidation of graphite foils (~0.2 mm thick) in 1M solutions of $LiClO_4$ or KPF_6 in propylene carbonate (PC) with low-current densities (30-50 $\mu A \cdot cm^{-2}$ geometrical surface) yields a constant final value of about 2.2V *vs.* SCE after a current passage corresponding to the stoichiometry $C_{24}X$; with higher current densities this constant potential is attained before the graphite has reacted completely. Further stages $n > 24$ can be detected, however, they cannot be assigned unambiguously due to their "unsharpness." On further oxidation no stages $n < 24$ were as yet observed; the products formed, however, are reversibly reducible, so that in suitable solvents a markedly higher maximum charge storage capacity is obtained than that calculated on the basis of $C_{24}X$, in analogy to the

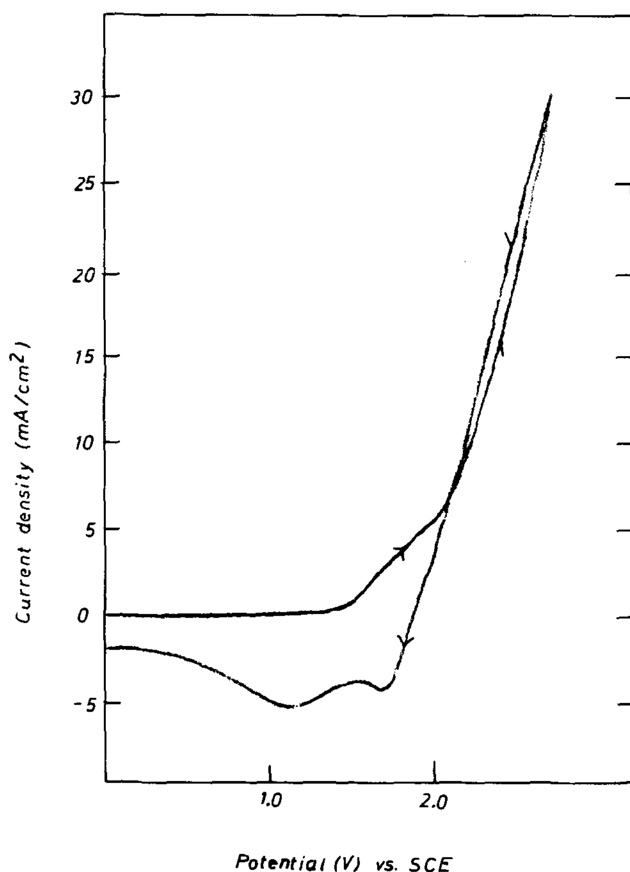

Fig. 1. Cyclic voltammogram at a graphite electrode (foil, 0.2 mm) in $LiClO_4$/dimethyl sulfite (1*M*). Scan rate 300 mV/min; first cycle.

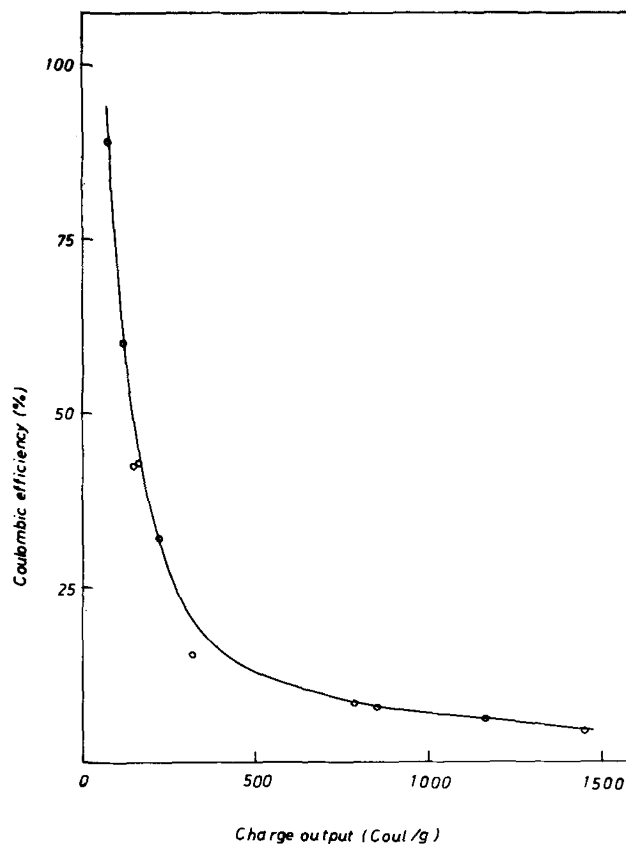

Fig. 2. Coulombic efficiency (charge output/charge input) of graphite foil in $LiClO_4$/PC (1*M*); first cycle. Current density (discharge) $\approx$ 1 mA/cm^2; cutoff potential 3.5V vs. Li/Li$^+$(1*M*).

situation in conc. H_2SO_4. We found the reaction following the oxidative formation of $C_{24}HSO_4 \cdot 2H_2SO_4$ (the so-called "build-up of an oxygen overvoltage"[35]) to be reversible and leading to charge storage capacity five times higher than for the C_{24}-stage.

The steps in the oxidation current and several close-lying reduction peaks can be easily detected by cyclic voltammograms; especially on cycling with increasing amplitude in many organic electrolyte solutions, among them $LiClO_4$/dimethyl sulfite, several consecutive reduction peaks were observed.

Existence of electrolytic lamellar compounds.—The postulate of ionic graphite compounds in aprotic solvents was proved by conductivity measurements; on cycling a "Li/graphite" cell in 0.1*N* $LiClO_4$/PC the conductivity of the electrolyte solution changed to about 60% of the theoretical value expected for the reaction

$$LiClO_4 + nC \rightleftharpoons C_nClO_4 + Li$$

For the discharged cell the electrolyte conductivity decreased after cyclization only slightly. During these measurements the size of the graphite electrode was such, that only compounds with $n > 24$ were formed, which was checked by measuring the potential *vs.* a reference electrode.

Maximum coulombic capacity.—Trying to find a maximum oxidation stage of graphite in $LiClO_4$/PC we as yet had no success in establishing a definite upper limit. With increasing charge input the coulombic efficiency decreases (see Fig. 2), since mainly solvent is decomposed; however, a charge output of more than 1000 coulomb g^{-1} was obtained with a current density of about 1 mA cm^{-2} and a cutoff potential of 3.5V *vs.* Li/Li$^+$ (1*M*). The discharge characteristics of these oxidation products are rather flat over a wide range; however, the break downward

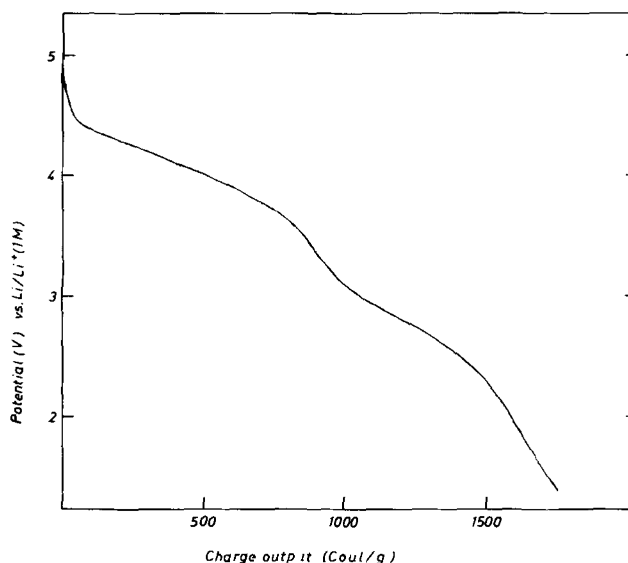

Fig. 3. Typical galvanostatic discharge curve for a graphite electrode (foil sandwiched between porous glass) in $LiClO_4$/PC (1*M*). Current density 1 mA/cm^2; previous charge input 10,150 coulomb g^{-1} at 2 mA/cm^2; first cycle.

in the curve is getting less sharp with increasing charge input (Fig. 3).

In many other organic solvents we were able to obtain charge outputs of $\gg$335 coulomb g^{-1} ($\hat{=}$ $C_{24}X$). The reported very low maximum coulombic capacity of graphite in $LiClO_4$/dimethyl sulfite was also observed during our study, although with extreme charge input we obtained a higher charge output than 90 coulomb g^{-1}. Since $LiClO_4$/dimethyl sulfite

shows a markedly lower oxidation stability at platinum electrodes, the ease of oxidation of dimethyl sulfite possibly causes the low-charge storage capacity. The grave loss of cell capacity on wet stand is certainly due to solvent oxidation; graphite electrodes vacuum-dried immediately after anodic oxidation could be stored remarkably well.

Cycling tests.—When cycling a half cell in $LiClO_4$/PC (charge current 2 mA cm^{-2}, discharge current 1 mA cm^{-2}, charge input 167.5 coulomb g^{-1}) we observed after 13 cycles no essential changes in the charge as well as the discharge curves, if the discharge was complete, *i.e.*, until starting reduction of PC at graphite.[37] Under these conditions a charge efficiency of about 90% is obtained. With higher cutoff potentials the graphite electrode is discharged only incompletely; increasing coulombic efficiencies during the first cycles are due to this fact.

Expansion of graphite.—The expansion of graphite is strongly dependent on external pressure and therefore caused not only chemically, but mainly mechanically; the solvent also influences the degree of expansion. In order to be able to work quantitatively with high charge input, our investigations were done with graphite foils sandwiched under pressure between porous glass plates.

J. S. Dunning, W. H. Tiedemann, L. Hsueh, and D. N. Bennion: The result of Besenhard and Fritz appear to confirm the results we found. The closer agreement which they observed between their results and the behavior of lamellar compounds of graphite formed in pure acids might be attributed to two causes. (*i*) We used dimethyl sulfite as a solvent rather than propylene carbonate in most of our experiments. Apparently propylene carbonate is somewhat more stable under these strong oxidizing conditions than dimethyl sulfite. (*ii*) We used polycrystalline graphite rather than large, well-defined pyrolytic graphite in most of our experiments. Thus, the blue might not have been easily seen and the stages averaged out. In spite of the discrepancies noted, it has been our general opinion that lamellar compounds of graphite, similar to those formed by oxidation in strong acids, are formed by oxidation in selected aprotic, electrolyte solutions. It is gratifying to see that the results of Besenhard and Fritz tend to confirm that opinion. However, the low-current efficiencies observed in some of their tests will require further investigation. It might be noted that we did observe some long cathodic current plateaus at between 2 and 2.5V *vs.* lithium. However, we were concerned that such plateaus might be due to previously formed solvent decomposition products or other impurities.

Mass Transfer to a Rotating Sphere at High Schmidt Numbers

J. Newman (pp. 69-71, Vol. 119, No. 1)

D. T. Chin:[38] In the paper under discussion, Newman used the Lighthill transformation to calculate the rate of mass transfer to a rotating sphere at high Schmidt numbers. He made use of Manohar's numerical results[39] of the meridional velocity gradient at the surface, $(\partial V_\theta/\partial r)_{r=r_o}$, as the shear stress in the transformation, and integrated the resulting equation numerically to give a correction to Chin's θ-expression theory[40] for the rate of mass transfer at large θ.

Manohar's results for the tangential velocity gradient, $(\partial V_\phi/\partial r)_{r=r_o}$, can also be used for such calculations provided that the Chilton-Colburn analogy[41]

$$\mathrm{Sh}_x = \mathrm{Re}_x\,\mathrm{Sc}^{1/3}\,(f_x/2) \qquad [1]$$

is used for the analysis. Here Sc is the Schmidt number; Sh_x, Re_x, and f_x are the local Sherwood number, the local Reynolds number, and the local friction coefficient, respectively, based upon the surface distance, x, from the leading edge of the boundary layer flow.

Although the Chilton-Colburn relation is empirical in nature, it is a simpler method. It has been found to give a reasonably accurate estimate of the rate of heat and mass transfer for flow over a flat plate[42] and for channel flows.[43] In the case of a rotating-disk electrode, the use of Eq. [1] leads to the following relation for mass transfer at high Schmidt numbers[44]

$$\mathrm{Sh} = 0.616\,\mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3} \qquad [2]$$

This equation agrees to within 1% with Levich's exact solution,[45] which predicts a 0.620 $\mathrm{Re}^{1/2}\mathrm{Sc}^{1/3}$ dependence for the Sherwood number.

For flow induced by a rotating sphere, the leading edge of the boundary layer occurs at the pole of rotation, and x should be taken as $r_o\theta$. Thus, using $r_o\omega\sin\theta$ as a characteristic velocity for every local point on the sphere surface, Sh_x, Re_x, and f_x can be calculated from the following relations

$$\mathrm{Sh}_x = \frac{kr_o\theta}{D} \qquad [3]$$

$$\mathrm{Re}_x = \frac{r_o^2\omega\theta\sin\theta}{\nu} \qquad [4]$$

$$f_x \simeq -\frac{\mu\left(\dfrac{\partial V_\phi}{\partial r}\right)_{r=r_o}}{\frac{1}{2}\,\rho r_o^2\omega^2\sin^2\theta} \qquad [5]$$

Substituting Eq. [3]-[5] into Eq. [1], and making use of the dimensionless tangential velocity and the dimensionless radial coordinates defined as $G = V_\phi/r_o\omega$ and $\eta = (r - r_o)\,(\omega/\nu)^{1/2}$, respectively, we have

$$\mathrm{Sh}_{loc} = \left(\frac{kr_o}{D}\right) = -\,\mathrm{Re}^{1/2}\mathrm{Sc}^{1/3}\,\frac{(\partial G/\partial\eta)_{\eta=0}}{\sin\theta} \qquad [6]$$

Here, Re is the Reynolds number, $r_o^2\omega/\nu$, based on the sphere radius.

The tangential shear stress distribution, $(\partial G/\partial\eta)_{\eta=0}$, has been obtained numerically by Manohar.[39] A curve fitting of his results indicates that $(\partial G/\partial\eta)_{\eta=0}$ can be expressed as

$$-\left(\frac{\partial G}{\partial\eta}\right)_{\eta=0} = 0.61592\theta - 0.18946\theta^3 - 0.05819\sin^3\theta \qquad [7]$$

Substituting the above relation into Eq. [6], we immediately arrive at a correlation for the local rate of mass transfer to the sphere surface

$$\mathrm{Sh}_{loc} = \mathrm{Re}^{1/2}\mathrm{Sc}^{1/3}\,\frac{0.61592\theta - 0.18946\theta^3 - 0.05819\sin^3\theta}{\sin\theta} \qquad [8]$$

Equation [8] is plotted in Fig. 1 as the thick curve for $\mathrm{Sh}_{loc}/\mathrm{Re}^{1/2}\mathrm{Sc}^{1/3}$ *vs.* θ. For comparison, Newman's results in the paper under discussion based on the meridional shear stress distribution are given as the thin curve. The dashed curve is calculated from Chin's

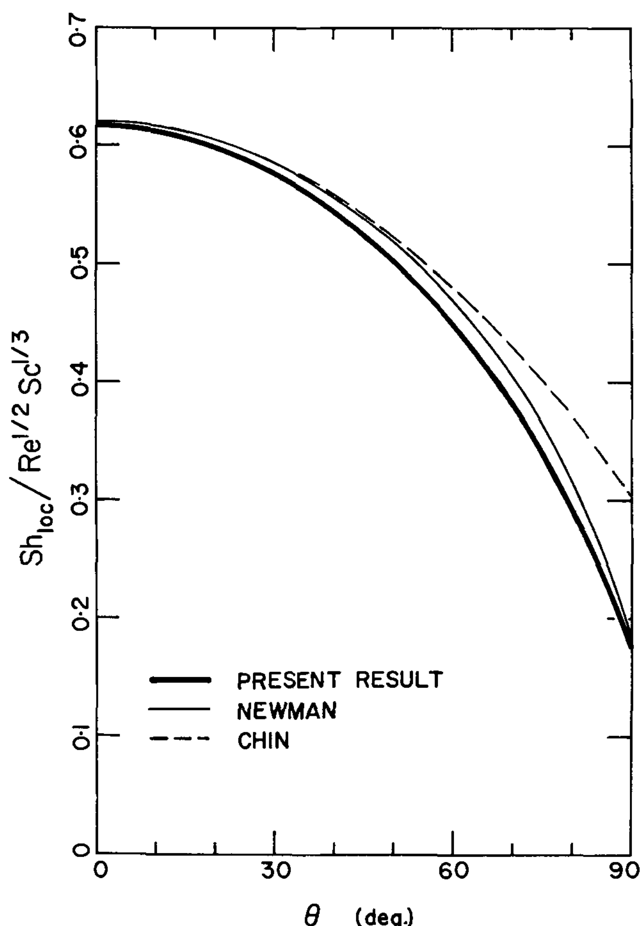

Fig. 1. Local mass transfer rate on the surface of a rotating sphere. The thick curve is the result of the present analysis as calculated from Eq. [8]. Newman's results based on the meridional shear stress distribution are given as the thin curve. The dashed curve represents Chin's θ-expansion theory for small θ.

θ-expansion solution[40] for small values of θ. It is seen that in spite of being empirical in nature, the present results obtained with the Chilton-Colburn analogy are in good agreement with the two previous theories based on more rigorous mathematical treatment. Whereas Chin's θ-expansion solution considerably overestimates the rate of transfer at large θ, the present results give a good approximation for the rate of transfer in the equatorial region. The maximum deviation of Eq. [8] from Newman's curve, which occurs approximately at $\theta = 80°$, is less than 9%. At the pole of rotation ($\theta = 0°$) and at the equator ($\theta = 90°$), the accuracy of the present results is better than 99%.

Equation [8] can be integrated to give the average rate of mass tranfser to the spherical surface

$$Sh = \frac{Re^{1/2}Sc^{1/3}}{1 - \cos\theta}\{0.30796\theta^2 - 0.047365\theta^4 + 0.019397\,(\sin^2\theta + 2)\cos\theta - 0.03879\} \quad [9]$$

For a sphere or a hemisphere whose entire surface is subject to mass transfer, Eq. [9] gives a 0.433 $Re^{1/2}Sc^{1/3}$ dependence for the average Sherwood number; this correlation is only 4% smaller than Newman's results which predict a value of 0.451 for the numerical coefficient.

In conclusion, we have used the Chilton-Colburn analogy to discuss laminar mass transfer on a rotating spherical electrode. It is shown that in spite of its empirical nature, the Chilton-Colburn relation is a simple and powerful tool to give a good approximation of the rate of ionic transfer on a complicated electrode geometry (such as the rotating sphere), where the exact solution is difficult to obtain. The procedures illustrated in this work can also be used for other rotating surfaces, such as a cone or an ellipsoid.

LIST OF SYMBOLS

D	diffusivity of diffusing species, cm^2/sec
f_x	local friction coefficient based upon the surface distance, x, from the leading edge of the flow boundary layer, dimensionless
G	dimensionless azimuthal (or tangential) velocity defined as $V_\phi/r_o\omega$
k	local mass transfer coefficient, cm/sec
K	average mass transfer coefficient, cm/sec
r	radial coordinate, cm
r_o	radius of spherical electrode, cm
Re	Reynolds number defined as $r_o^2\omega/\nu$, dimensionless
Re_x	local Reynolds number based upon the surface distance, x, from the leading edge of the flow boundary layer, dimensionless
Sc	Schmidt number defined as ν/D, dimensionless
Sh	average Sherwood number defined as Kr_o/D, dimensionless
Sh_{loc}	local Sherwood number defined as kr_o/D, dimensionless
Sh_x	local Sherwood number based upon the surface distance, x, from the leading edge of the boundary layer, dimensionless
V_θ	meridional velocity component, cm/sec
V_ϕ	azimuthal (or tangential) velocity component, cm/sec
x	surface distance from the leading edge of the boundary layer, cm
η	dimensionless radial distance defined as $(r - r_o)(\omega/\nu)^{1/2}$
θ	latitude coordinate, rad
ν	kinematic viscosity, cm^2/sec
ρ	density of electrolyte, g/cm^3
ϕ	azimuthal coordinate, rad
ω	angular velocity, rad/sec

Electrolytic Determination of Porosity in Gold Electroplates

R. J. Morrissey (pp. 446-450, Vol. 119, No. 4)

F. Mansfeld:[46] In the paper discussed here and elsewhere[47] Morrissey uses an expression derived by Stern[48] for an electrochemical determination of porosity in gold electroplates. Several corrections are necessary for Eq. [1] in Morrissey's paper. The exact (and complete) expression for the galvanic current I_g flowing between two dissimilar metals is[49]

$$\log I_g = \frac{\phi^C - \phi^A}{\beta_a + \beta_c} + \frac{\beta_c}{\beta_a + \beta_c}\log A^C i^C_{corr} + \frac{\beta_a}{\beta_a + \beta_c}\log A^A i^A_{corr} \quad [1]$$

where ϕ^C and ϕ^A are the corrosion potentials and i^C_{corr} and i^A_{corr} are the corrosion C.D. (not exchange C.D. for the anodic and cathodic processes) of anode and cathode before galvanic coupling. A^C and A^A are the respective areas of the two dissimilar metals (not area fractions). Under Morrissey's assumption[47] Eq. [1] can be simplified to

$$I_g = C_1 (A^A)^{\frac{\beta_a}{\beta_a + \beta_c}} \quad [2]$$

The form of Eq. [2] (and Eq. [4]) in this paper[47] seems to result from a typographical error.

It will be noted that ϕ^C and ϕ^A are the corrosion potentials of the uncoupled metals. No information can therefore be obtained for the potential ϕ_g of coupled metals. This relationship has been shown by Stern[48] and later by Mansfeld[49], to be

[48] M. Stern, *Corrosion*, 14, 329t (1958).
[49] F. Mansfeld, ibid., 27, 436 (1971).

$$\phi_g = k + \frac{\beta_c\beta_a}{\beta_a + \beta_c} \log \frac{A^C}{A^A} \quad [3]$$

If the area fraction of the anode $A_A = \frac{A^A}{A^C + A^A}$ is used instead of the area ratio A^C/A^A, Eq. [3] can be written as

$$\phi_g = k + \frac{\beta_c\beta_a}{\beta_a + \beta_c} \log \frac{1 - A_A}{A_A} \quad [3a]$$

Since the area fraction of Cu is very small ($A_A << 1$) under the conditions of Morrissey's experiments, Eq. [3a] can also be written in the form

$$\phi_g = k - \frac{\beta_c\beta_a}{\beta_a + \beta_c} \log A_A \quad [3b]$$

which predicts that the potential of gold plated Cu becomes more negative as the area fraction of Cu increases.

The derivation by Stern assumes that only an oxidation process occurs on the anode and only a reduction process occurs on the cathode. It is further assumed that the reactions are completely under charge transfer control. It is unlikely that the latter assumption is true for a Cu-Au couple in aerated 0.1*N* KCl or 0.1*N* NH_4Cl. In these solutions the cathodic reaction is more likely controlled by diffusion of oxygen. In this case the potential of the galvanic couple was shown by Mansfeld[49] to be related to the area ratio A^C/A^A by

$$\phi_g = \phi^A + \beta_a \log \left(\frac{A^C}{A^A} + 1 \right) \quad [4]$$

Upon introduction of the area fraction of the anode (Cu) $A_A = \frac{A^A}{A^A + A^C}$, Eq. [4] can be written as

$$\phi_g = \phi^A - \beta_a \log A_A \quad [5]$$

A plot of the potential of a Cu-Au couple *vs.* area fraction of Cu should therefore result in a straight line with a slope of $-\beta_a$. The plots by Morrissey have slopes of −34 to −36 mV (Fig. 2, 3[47]), while a Tafel slope $\beta_a = 51$ mV is reported for Cu. Luborsky *et al.*[50] on the other hand, show plots of log $A^C/A^A = A_C/A_A$ *vs.* galvanic potential ϕ_g of Cu-Au couples in 1M NH_4Cl which result in a straight line with a slope of 58 mV. The results of Luborsky also suggest that the cathodic reaction is under diffusion control since the potential of the couple becomes independent of the area ratio for $A^{Cu}/A^{Au} > 0.05$. This behavior is predicted by Eq. [4] which shows that for $A^C/A^A << 1$

$$\phi_g \approx \phi^A = \text{constant}$$

An interpretation of the results of Fig. 3 in the paper under discussion cannot be given since the author does not state clearly how he calculated the "gross area C.D." in the expression $\Delta J/\Delta V$ (mho · cm²). Under the assumption that charge transfer control occurs, which is doubtful as pointed out above, Eq. [1] and Eq. [3] can be combined to give a correlation between the galvanic potential ϕ_g and the galvanic current I_g

$$\phi_g = \phi^A - \beta_a \log i^A_{corr} A^A + \beta_a \log I_g \quad [6]$$

A correlation can also be given between ϕ_g and the galvanic current density $i_g^A = I_g/A^A$ with respect to the area of the anode (Cu)

$$\phi_g = \phi^A - \beta_a \log i^A_{corr} + \beta_a \log i_g^A \quad [7]$$

From Eq. [6] and Eq. [1] it follows

$$\frac{\partial \phi_g}{\partial \log I_g} = \beta_a - \beta_a \frac{\partial \log A^A}{\partial \log I_g} = -\beta_c \quad [8]$$

[50] F. E. Luborsky, M. W. Breiter, and B. J. Drummond, *This Journal*, 119, 92 (1972).

while from Eq. [7], one derives

$$\frac{\partial \phi_g}{\partial \log i_g^A} = +\beta_a \quad [9]$$

Since both I_g and i_g are proportional to the polarization admittance, one would expect that a logarithmic plot of $\Delta J/\Delta V \approx i_g^A$ *vs.* ϕ_g results in a straight line with a slope of $+\beta_a$, while a similar plot of $\Delta I/\Delta V \approx I_g$ should lead to a slope of $-\beta_c$. If the current density in Fig. 3 were based on the exposed area of Cu, then one would expect a slope of +51 mV according to Morrissey's data. Instead a line with a slope of −73 mV is reported.

All derivations above do not take account of potential (*IR*) drops in the pores, which could significantly affect current-potential relationships. It could also affect linear polarization measurements. The results of Fig. 2 which indicate a linear relationship between current and potential over a potential range of more than 50 mV are rather surprising in light of recent considerations[53] and might very well be significantly influenced by *IR* drops in the pores.

A further treatment of the dependence of galvanic current and galvanic potential on porosity of a metallic coating can be found in the paper by Oldham and Mansfeld.[51]

Morrissey also mentions leakage current measurements for determination of porosity in electrodeposits. A similar technique has recently been described by Mansfeld and Parry.[52] Using a potential sweep technique a quantitative electrochemical test for porosity in permalloy plated memory wire was described. In this test, which should also be of value for Au plated Cu, a potential sweep is applied to the metal couple immersed in 3.5% NaCl in a potential region where the dissolution rate of the cathode (Au, Permalloy) is very low, while that of the anode (Cu) is high. From integration of the resulting current peak, the area of Cu exposed through pinholes can be determined after suitable calibration.

R. J. Morrissey: As has been pointed out in the foregoing discussion, the mathematics appearing in the paper under discussion and also in our previous reference[47] are based on expressions originally given by Stern.[48] These expressions were derived under the assumptions that only oxidation was proceeding at the anode and only reduction at the cathode, and that the over-all process was under activation control. Mansfeld[49] has recently derived a series of general expressions describing the variation of the corrosion potential and the corrosion current with the respective anodic and cathodic areas. For the case of activation control, the results of the Stern and Mansfeld treatments are consistent, and Mansfeld's Eq. [3b] above is identical to Eq. [2] in Morrissey.[47]

Mansfeld expresses the opinion that for gold-copper couples in 0.1M NH_4Cl or 0.1M KCl, the cathode reaction is probably controlled by the diffusion of oxygen. He then derives expression [5], showing that for this case, a plot of corrosion potential *vs.* the logarithm of the anode area fraction should yield a slope equal to β_A, rather than to $(\beta_A\beta_C/\beta_A + \beta_C)$, which would be the case under activation control. He then cites data from Luborsky *et al.*,[50] purportedly in support of this hypothesis.

In our own previous work,[47] plots of corrosion potential *vs.* the logarithm of the anode area fraction yielded slopes of 34-36 mV, which was felt to be in excellent agreement with the value of $(\beta_A\beta_C/\beta_A + \beta_C)$, and thus indicative of activation-controlled kinetics. Luborsky *et al.* plot corrosion potential *vs.* the

[53] K. B. Oldham and F. Mansfeld, *ibid.*, 27, 434 (1971).

logarithm of the ratio of the anodic and cathodic area fractions (not of the areas, as implied by Mansfeld). At small values of the anode area fraction, this reduces to a plot of corrosion potential *vs.* the logarithm of the anode area fraction alone; and in 0.1M NH_4Cl Luborsky *et al.* obtain a slope of approximately 32 mV, which is in close agreement with our own data. In 1.0M NH_4Cl, these authors obtain a slope of greater than 50 mV. This value approximates that of β_A, implying that in this latter electrolyte the cathode reaction is diffusion-controlled. This is quite reasonable, in view of the reduced oxygen solubility in more concentrated electrolytes. It is also significant that the data of Luborsky *et al.* show that the curve for 1.0M NH_4Cl begins to depart from linearity at smaller values of the anode area fraction than does that for 0.1M NH_4Cl. One can thus make a strong case for diffusion control of the cathode reaction for gold-copper couples in 1.0M NH_4Cl. It seems equally clear, however, that at small values of the anode area fraction, the kinetics in 0.1M NH_4Cl are activation-controlled.

Mansfeld questions the significance of plotting values of $(\Delta J/\Delta V)$ in Fig. 3 of the paper under discussion, and derives Eq. [8], which shows that in the case of activation control, a plot of corrosion potential *vs.* the logarithm of the galvanic current (or, by extension, of $\Delta I/\Delta V$) should yield a slope of $-\beta_C$. He also expresses surprise at the linearity of the polarization curves obtained, citing a previous publication by Oldham and himself[51] which states that polarization curves should ordinarily show curvature in the vicinity of the corrosion potential in order for the Stern-Geary relationship to apply. He then suggests that the apparent linearity might be indicative of ohmic control by the *IR* drops in the pore channels.

The values of $(\Delta J/\Delta V)$ obtained in this work were arrived at by dividing the experimentally determined values of $(\Delta I/\Delta V)$ by the total geometric areas of the various specimens. These were 2.5 cm^2 for the gold-plated copper specimens and 10.8 cm^2 for the solid gold specimens. Figure 3 was presented in the form shown because, plotted in this form, the data points for the solid gold specimens fall nicely along the line extrapolated from the data points for the various gold-plated specimens, whereas in a plot of corrosion potential *vs.* the logarithm of $(\Delta I/\Delta V)$ they fall well off the line. Such a plot is shown in Fig. 3a. The slope of this plot is -90 mV, which is in excellent agreement with the value of 93.5 mV obtained for β_C and in accordance with Mansfeld's Eq. [8]. It had been shown in the paper under discussion that, also in the case of activation control, a plot of the logarithm of $(\Delta I/\Delta V)$ *vs.* the logarithm of the anode area fraction should yield a slope equal to $(\beta_A/\beta_A + \beta_C)$. Figure 4 of the paper under discussion is such a plot, and the slope obtained is in close agreement with the predicted value.

As to the linearity of the polarization curves obtained, I can only cite the wealth of instances in the literature of polarization data which are linear or, as noted by Jones,[54] at least approximately so within the discrimination capabilities of available instrumentation, even over extended ranges of potential.[55] It remains the opinion of this writer that since the

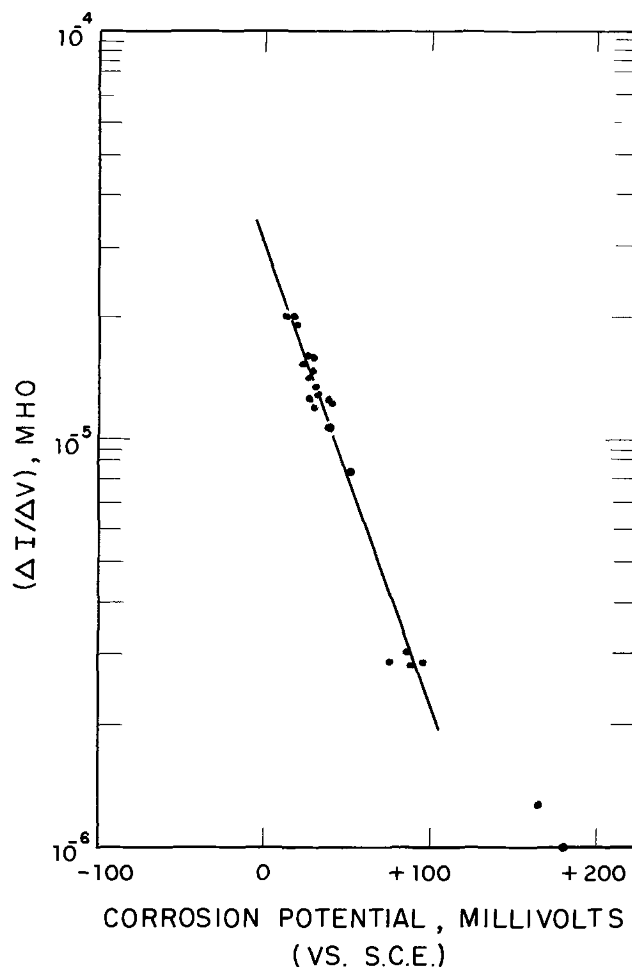

Fig. 3a. Comparison of corrosion potential and polarization admittance values.

Stern-Geary expression represents an approximation, ordinarily applicable over only a relatively limited range of potential, any attempt to ascribe physical significance to what amounts to the derivative of such a function should be approached with caution.

The question of ohmic control by electrolyte in the pore channels has been raised previously,[47] and is the basis of Clarke and Britton's original treatment[56] of linear polarization data obtained on specimens coated with porous electroplates. As has been reiterated in these comments, all of the evidence available for gold-copper couples in 0.1M NH_4Cl electrolyte is indicative of activation-controlled kinetics at small overpotentials and for small values of the anode area fraction. A direct test of the effects of concentration and resistance polarization on the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl has been described.[47] The results, shown in Table II in that paper, indicated that such effects were negligible for copper specimens plated with gold deposits of 50, 100, 200, and 400 μin. (1.27, 2.54, 5.08, and 10.16 μm) thickness.

High-Resolution Negative Photoresist

R. M. Walters and R. Brecher

Bayside Research Center, GTE Laboratories Incorporated, Bayside, New York 11360

ABSTRACT

A negative-working high-resolution photoresist system is described. The preparation of the polymer and sensitizer components of the photoresist is outlined. The importance of the molecular weight distribution of the polymer on the properties of the photoresists is discussed. Consideration of this, and other, parameters has lead to a resist formulation capable of functioning in film thicknesses of 2000-3000Å, showing an acceptably low pinhole density and having a resolution capability of 400 lines/mm.

Negative-working photoresists are materials of fundamental importance in the fabrication of semiconductor devices by means of photolithographic procedures. In recent years there has been a trend toward microimage device geometries, and the fabrication of these devices calls for etching in silicon dioxide linewidths in the range 1-5 μm. The advent of large scale integrated circuit devices has also occurred in recent years, and these two factors have placed increasingly severe demands on the available photoresist technology.

Kodak Thin Film Resist (KTFR) has received much attention in this field and Clark and Turner (1) have investigated the high-resolution capabilities of this resist. However when used in film thicknesses of 5000Å or less, which are necessary to achieve a resolution of $\geq$ 400 lines/mm, the tendency of this resist to pinhole can present problems (1, 2).

In view of the need for a photoresist with the capability of giving 1 μm lines on 1 μm spaces (a resolution of 500 lines/mm) using appropriately thin resist films with acceptably low pinhole densities (*i.e.*, $\leq$ 30 pinholes/in.^{2}), the negative resist system described by Kornfeld (3) was investigated. This resist consists of an ultraviolet-sensitive diazido compound which is used as the photo-initiator (or sensitizer) for the cross-linking of an unsaturated alkyd resin. This system is attractive since the polymer and sensitizer components of the resist are prepared initially as separate species and can then be combined over a wide range of ratios in photoresist formulations. This system was considered to offer a greater probability of giving a resist with the required resolution capabilities than attempts to modify chemically any of the commercially available negative resists.

Experimental

The sensitizer is 4,4′ diazido benzophenone-p-carboxyphenylhydrazone; a pale yellow crystalline solid, designated (ABH). This compound is prepared, in a three step synthesis, from 4,4′ diamino diphenylmethane. Initially the amino groups are converted to azide groups via diazonium salt intermediates. Oxidation of the central methylene group to carbonyl is then accomplished with chromium (VI) to give 4,4′ diazidobenzophenone. Reaction of this species with p-carboxy phenylhydrazine gives ABH. The over-all yield of ABH is 40%. The ultraviolet absorption spectrum shows a maximum at 360 nm, and ABH shows good photoresponse to a high-pressure mercury arc.

The polymer component of the resist is the commercial alkyd Rezyl 387-5 obtainable from Koppers Company. A fractional precipitation method was used to obtain polymer samples with different molecular weight distribution (4). The standard fractionating procedure was to dissolve 100g of raw alkyd in 2.28 moles of trichloroethylene followed by the addition of 10 moles isopropanol. This solution was stirred at a constant rate and water (*i.e.*, the nonsolvent) was added at a constant rate of 10 g/min until the required amount of water had been added. The bottom resin phase which separates is drawn off and the solid polymer precipitated with petroleum ether. After several washings with petroleum ether the polymer is dissolved in methylethylketone (MEK) and then reprecipitated with petroleum ether. The polymer is again washed with petroleum ether and again dissolved in MEK. Vacuum distillation of this solution served to distill off all the petroleum ether. The polymer solids content of the solution was estimated gravimetrically and then suitably dilute polymer stock solutions were prepared by adding the required solvents. Molecular size distribution data were obtained using a Waters Model 200 gel permeation chromatograph. Photoresist solutions were prepared on a weight/weight basis, by dissolving ABH in a quantity of polymer stock solution.

Resist films were applied to the wafers by spinning. Film thickness was measured with a Talysurf Profilometer. This method proved to be quick and convenient and acceptably accurate (5) for resist thicknesses down to 2000Å. The Talysurf data correlated well with a series of resist film thicknesses measured by an interferometric method (6). The Talysurf method was also used to gain information on the surface quality, *i.e.*, the flatness of the resist films after having first established the flatness of the wafer substrates.

The silicon dioxide films of the various thicknesses used were grown on the silicon wafers as follows: 10,000Å SiO_2 films were grown by using a 1¼-hr steam oxidation at 1200°C followed by a 5-min dry oxidation at the same temperature. The 4000Å SiO_2 films were grown using a 4-hr dry oxidation at 1200°C.

Key words: photolithography, micro-imaging, resist-composition.

The pinhole densities were measured in the following way. A blank measurement was made on the original SiO_2 layers, after which the wafers were prepared and coated with resist and then given the same exposure as was used for imaging in the resist. The mask used in the exposure was a 5.0 × 5.0 cm glass blank, with no opaque areas on it, so that the entire resist film area was exposed. The exposed wafer was put through the development and post bake cycle followed by an etch in buffered hydrofluoric acid. The etching time was that known to be required for the particular silicon dioxide thickness being used. The etched and stripped wafers were examined by scanning the wafer at 200X magnification and counting the number of circular pinholes, of 1 μm diameter or greater, occurring randomly in the silicon dioxide layer. Clusters of pinholes around obvious oxide defects were not included nor were pinholes occurring at the very periphery of the wafer.

The two masks of main interest used were obtained from Qualitron Corporation and were 5 × 5 cm chrome on glass. The repeat unit patterns of these two masks are shown in Fig. 1 and 2. In Fig. 1 the narrowest set of L shaped lines are 2.5 μm lines on 2.5 μm spaces. The interdigitated finger pattern of lines are also 2.5 μm lines on 2.5 μm spaces. In Fig. 2 the numbers on the mask refer to microinches and the narrowest line geometries on this mask (50 μin.) are 1.25 μm lines on 1.25 μm spaces. The photolithographic work was done in a class 100 clean room.

A typical photoresist process cycle would be as follows.

1. Substrates are cleaned with a cycle of various organic solvents. Before coating a 5-min bake at 1200°C is given.
2. Spin coat on Headway spinner, 4000 rpm for 30 sec typically. The resists were filtered at point of use by dispensing the resist onto the wafer from a glass syringe fitted with a Millipore 1 μm "Duralon" filter.

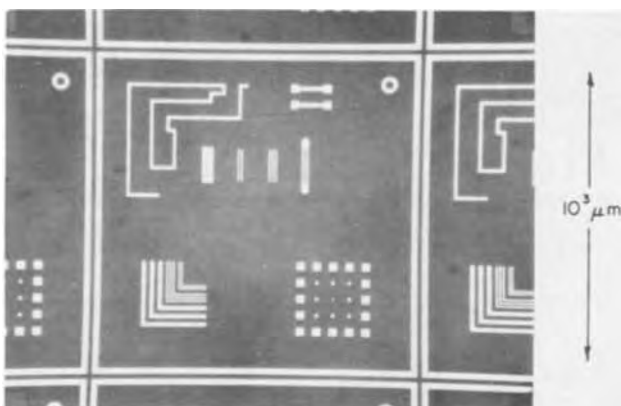

Fig. 1. Unit pattern of Qualitron mask

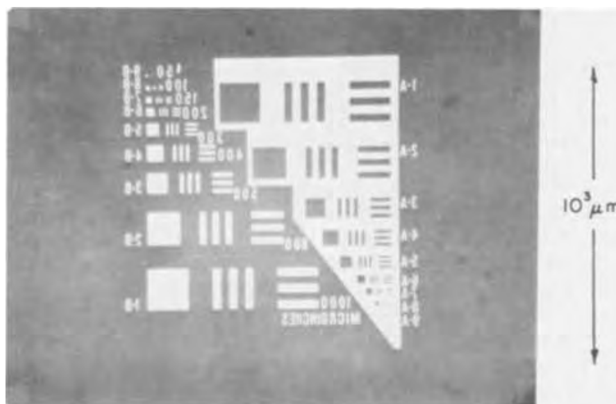

Fig. 2. Unit pattern of Qualitron mask

The wafer surface was flooded with resist immediately prior to spinning.

3. Air dry for at least 10 min. The use of a prebake is not necessary and is in fact deleterious to the behavior of the resist in the development and etching steps.
4. Expose. A Kulicke and Soffa Model 6822 alignment tool was used.
5. Dip development in xylene for 2 min followed by a 20 sec isopropanol rinse. Spray development and rinsing can be used with equal effect.
6. Postbake for 10 min at 250°C.
7. Etch.
8. Strip off photoresist film with J-100 (Indust-Ri-Chem Laboratory) 15 min at 140°C followed by a similar treatment with fresh J-100.

Results and Discussion

The occurrence of pinholes in the silicon dioxide layer during the various photolithographic steps, in the manufacture of integrated circuits, is one of the major factors governing the yield of the devices (7). In general, pinholes of greater than 1 μm diameter present the most serious problems. The occurrence of pinholes etched into the oxide arise from pinholes in the resist film which occur during the photomasking process from a variety of distinct causes. Pinholes in the resist film can occur as the resist is being applied onto the wafer; the presence of silicon spikes through the oxide, particulate matter on the oxide surface during spinning, and the inherent film-forming qualities of the resist (at the particular resist thickness being used) are important factors at this point of the process. Immediately before, and during, the exposure step the presence of opaque particulate matter on the resist surface, or on either surface of the mask, will tend to interfere with the insolubilization of the resist and result in the formation of pinholes in the resist and subsequently in the oxide.

The above factors will always operate to some degree but can be minimized by close control of the processing procedures. A further source of pinholes, which is more difficult to control, lies in the nature of the chemistry of negative working photoresists. The commercial negative resists used in microcircuitry, and the system under discussion, all appear to be based on the crosslinking of polymer molecules initiated by a light-sensitive sensitizer species which furnishes free radicals upon irradiation with uv light (8). The exposure of such a film is thus a process whereby the normally soluble polymer molecules are crosslinked and become insoluble, by virtue of the increase in molecular weight which has occurred. Thus in those areas of the resist film where the photocrosslinking does not occur to a sufficient extent to withstand the solvent action of the developer, a pinhole is likely to result. This effect is the major source of pinholes in high-resolution work since achieving adequate crosslinking in the necessary thin resist films becomes increasingly more difficult (1). The pinhole data presented later were derived from experiments where every effort was taken to exclude pinholes from other sources and the pinhole density data obtained are, in the main, a measure of the ability of the resist to crosslink effectively and so withstand the processing conditions.

The resolution capabilities of the resist has been measured in terms of the image structure etched into the silicon dioxide layer. A pattern of lines on spaces, of any particular width, was used since it is generally more difficult to achieve such an etched pattern rather than a single line of the same dimension. The resolution attainable is dependent, among other parameters, on both the thickness of the photoresist layer and the thickness of the silicon dioxide film to be etched through. Both of these films must be as thin as possible to achieve maximum resolution. The silicon dioxide

must be of sufficient thickness to constitute an effective diffusion mask and 4000Å of silicon dioxide was used since this fulfills the diffusion mask criteria and yet still allows the etching of line patterns of 500 lines/mm, *i.e.*, 1 μm lines on 1 μm spaces. The resist film must be as thin as possible commensurate with good adhesion, etch resistance, imaging properties, and pinhole behavior.

Molecular weight distribution.—The molecular weight distribution of the polymer component of the photoresist is one of the major factors governing such properties of the resist as adhesion, etch resistance, image line quality, the tendency to pinhole, and also the ease of handling of the resist. Experiments were therefore carried out to investigate the effect of varying the molecular weight distribution of the Rezyl alkyd on the resist properties. Fractions of the Rezyl 387-5 of different molecular weight distribution were obtained using the fractional precipitation method described previously. In the various fractionations different amounts of water were added to the reaction mixture, at a constant rate of 10 g/min, to isolate fractions with different molecular weight distributions. Stock solutions were prepared from each quantity of polymer using a 1:1(wt:wt) mixture of MEK and cyclohexanone as the solvent system. The fractions were characterized quantitatively with respect to their molecular weight distributions by the gel permeation chromatograph (GPC) method (9). The instrument was calibrated with a series of polystyrene standards (Waters Associates). The raw data from the GPC are in terms of molecular size, or polymer chain length, and from these data apparent number average chain lengths, $\overline{A}_N$, and weight average chain lengths, $\overline{A}_W$, can be calculated and expressed as angstrom unit values. The data are presented in this way since the molecular weight of the polymer per angstrom unit of chain length, (*i.e.*, the *Q* factor) is not known with any precision.

Table I shows the $\overline{A}_N$ and $\overline{A}_W$ values obtained by the GPC characterization of six samples of fractionated Rezyl. The different fractions were obtained by adding different numbers of moles of water to the standard fractionation mixture.

The $\overline{A}_N$ values are probably more reliable than the $\overline{A}_W$ values due to the marked sensitivity of $\overline{A}_W$ to errors in the estimation of the highest molecular weight species in the samples. Figure 3 shows the $\overline{A}_N$ values plotted as a function of the number of moles of water used in the fractionation. These values fall on a smooth curve which becomes asymptotic to the measured value of 210 for the number average chain length of the raw Rezyl alkyd.

In view of the necessity of working with as thin a resist film as possible, it became of interest to determine how the polymer solids content and the spinning speed influenced the thickness of the resist film obtained. Figure 4 shows the resist film thickness obtained on our apparatus using 20, 15, and 10% polymer solids in 1:1 MEK/cyclohexanone as solvent, with spinning speeds in the range 4000 to 9000 rpm. The solutions were prepared using polymer fractionation 4 in Table I. The curves show that the polymer solids content of

Table I. $\overline{A}_N$ and $\overline{A}_W$ values obtained by GPC characterization

Fraction-ation No.	Moles water added to reaction mixture	$\overline{A}_N$	$\overline{A}_W$	Polydispersity ratio, $\overline{A}_W/\overline{A}_N$

2	19.5	354	7,650	21.3
3	16.7	370	9,540	25.7
4	13.9	433	10,010	18.2
5	11.1	599	11,720	19.5
6	8.3	1,012	15,420	15.2

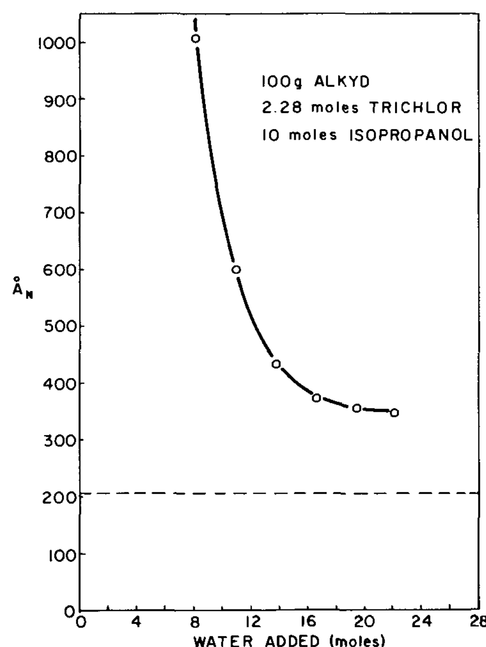

Fig. 3. Number average chain length vs. moles of water added

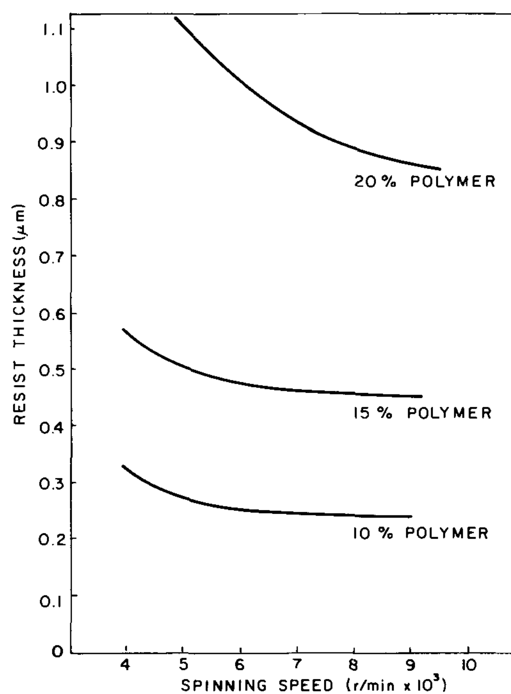

Fig. 4. Resist film thickness vs. spinning speed

the resist is the most important parameter to be varied to achieve film thicknesses of <3000Å and that the final spinning speed is less important as a parameter since the curves for the 15 and 10% solutions are essentially parallel to the abscissa above a spinning speed of 5000 rpm. Therefore adjusting the polymer solids content of the resist solution was the method used to vary the resist film thickness.

Accordingly a series of ten photoresist solutions was prepared from each of the six polymer fractions with the polymer concentration going in 1% increments over the range 1-10% polymer. A constant ratio of polymer solids to sensitizer was maintained; the sensitizer concentration being 8% of the amount of polymer present. It was found that below 5% polymer, for all the fractions, the resist films pinholed badly in all cases during development; varying the sensitizer concentration could not correct this condition. For the polymer fractions of

$\bar{A}_N > 550$ the resist solutions became increasingly difficult to filter down to the 1 μm level as the polymer concentration increased above 5%. Also the resist images became increasingly difficult to develop out and the line quality of the images consequently deteriorated. For the polymer fractions of $\bar{A}_N < 400$, the trends observed were reduced adhesion of the resist during etching and an increasing tendency for the resist to pinhole during the development step. This tendency to pinhole could not be corrected for resists up to 10% polymer and 8% sensitizer.

Thus, the optimum region for photoresist behavior, for the fractionation procedure described, was judged to be where $\bar{A}_N$ is between 400 and 500 with $\bar{A}_W$ in the region of 10,000.

High-resolution capabilities of the resist.—The high-resolution capabilites of photoresist solutions prepared with polymer from fractionation 4, in Table I, were evaluated. The chrome mask whose repeat unit is shown in Fig. 1 was used. Figure 5 shows sets of L-shaped lines of 5.0 and 2.5 μm width etched in 4000Å of SiO_2. Figure 6 shows the interdigitated pattern of 2.5 μm lines again etched in 4000Å of SiO_2. These patterns were obtained with virtually 100% yield over the wafer. The photoresist solution used was 10% in polymer solids with a sensitizer concentration 8% of the polymer solids. This solution had a viscosity of 3.7 cp and yielded 2800Å films when spun on at 4000 rpm. Exposure time was 2 sec, otherwise the processing was as described previously. Attention was then turned to the chrome mask whose repeat unit is shown in Fig. 2 since this mask contains patterns of lines on spaces down to 1.25 μm. It was found that the narrowest line patterns that could be etched satisfactorily into 4000Å of silicon dioxide, with 100% yield over the wafer, were the 100 μin. lines or 2.5 μm lines on 2.5 μm spaces. Figure 7 shows such patterns. Although the patterns of 1.25 μm lines were present in the developed photoresist layer, these images had not been etched into the oxide and they occurred only irreproducibly over the wafer.

The problem in etching out these lines was found to be due to incomplete development of the resist from the 1.25 μm line areas which caused a subsequent interference with the etching step. Careful microscopic

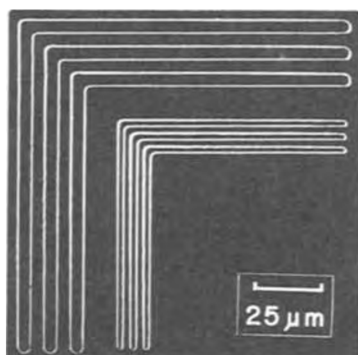

Fig. 5. Dark-field light micrograph of 2.5 and 5.0 μm lines etched in 4000Å of SiO_2.

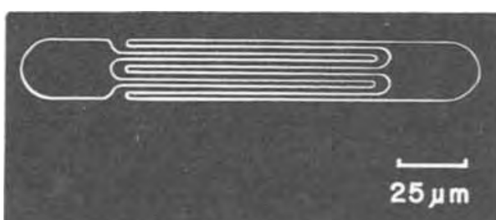

Fig. 6. Dark-field light micrograph of interdigitated 2.5 μm lines etched in 4000Å of SiO_2.

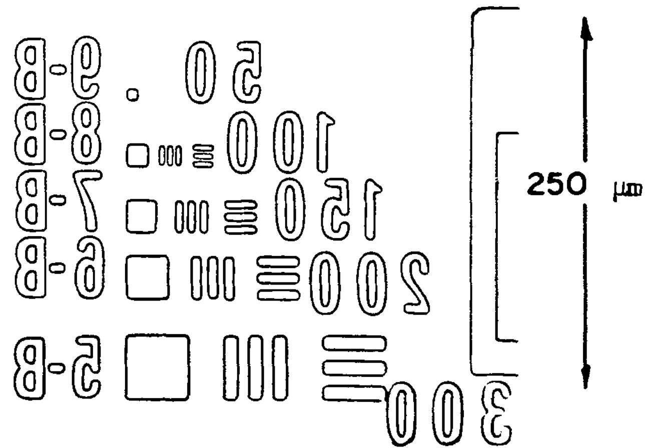

Fig. 7. Resolution test pattern etched in 4000Å of SiO_2

examination indicated the presence of a very thin layer of resist, remaining after development, in the 1.25 μm line areas, whereas the unexposed resist was completely removed down to the oxide, from the 2.5 μm, and larger, image areas. The presence of resist in the 1.25 μm lines is presumably due to partial crosslinking of the resist by scattered light to a sufficient extent to prevent clean development.

Various approaches were taken to circumvent this problem; these included increasing the developing time, extending the etching time, using lower sensitizer concentrations, and the use of more powerful developing solvents. In addition, the polymer solids content of the resist was lowered to allow the use of films approximately 2000Å thick. Although these approaches often resulted in a higher proportion of the 1.25 μm lines being etched out, there was often either an increase in pinhole density, to an unacceptable level, or a deterioration of the image quality. None of the approaches, then, constituted a satisfactory solution to the problem.

The resists prepared from fractionations 5 and 6 in Table I had shown quite strikingly that the ease of development of unexposed photoresist areas is strongly dependent on the molecular weight distribution of the polymer. The highest molecular weight species were more difficultly soluble in the developer. Also the effects of scattered light over the wafer surface during the exposure step, will be most pronounced with high molecular weight polymer molecules since relatively few chemical crosslinks are needed to give a species which shows much reduced solubility in the developer. Thus, it was reasoned that the removal of the highest molecular weight components of the polymer might enable a photoresist to be prepared which would develop cleanly from unexposed 1.25 μm line areas, due to the reduced effects of scattered light.

Table II shows the results obtained in three fractionations of the raw Rezyl where a first addition of water was used to separate out the highest molecular weight polymer. This was separated off and discarded. A second addition of water caused a further quantity of polymer to separate out. This was isolated and processed by the usual procedure. The total amount of water used in these three fractionations was 13.9 moles in each case.

Table II. Results of three fractionations of raw Rezyl

Fractionation No.	Moles water added in first addition	Moles water added in second addition	$\bar{A}_N$	$\bar{A}_W$	Polydispersity ratio
7	5.00	8.90	430	8,063	18.7
8	5.56	8.34	392	4,999	12.0
9	6.12	7.78	361	3,089	8.5

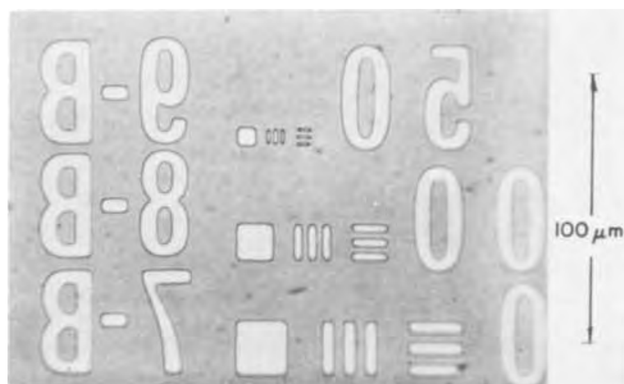

Fig. 8. Resolution test pattern etched in 4000Å of SiO_2

It is apparent from the $\bar{A}_W$ values shown that this modified fractionation procedure has effectively removed the higher molecular weight polymer species to a degree depending on the amount of water used in the first addition.

Photoresist solutions were prepared from these three fractions and examined. The trend toward easier development of the 1.25 μm lines as the $\bar{A}_N$ and $\bar{A}_W$ values decrease was immediately evident. Fractionations 7 and 8 gave less than 100% yields of the 1.25 μm lines, but no development problems were experienced with the resists prepared from Fractionation 9, and 100% yields of the 1.25 μm lines on space patterns were consistently obtained with the normal xylene development. Figure 8 shows the 1.25 μm lines etched through 4000Å of silicon dioxide. The lines on spaces are clearly resolved and correspond to a resolution capability of 400 lines/mm. The processing conditions were as described previously and the 1.25 μm lines were obtained using photoresist solutions containing 10 and 8% polymer solids, respectively, with a sensitizer concentration of 8% of the polymer solids in both cases. The solvent system was the usual 1:1 MEK/cyclohexanone. The resist film thicknesses obtained at 4000 rpm spinning speed were 3000 and 2200Å from the 10 and 8% polymer solutions, respectively. The other important features of the resist such as acid resistance, adhesion, and image quality were judged to be comparable to when polymer of $\bar{A}_N = 430$ and $\bar{A}_W = 10{,}000$ was used.

Pinhole data comparison with KTFR.—The pinhole data accumulated for the two Rezyl fractions of main interest are shown in Table III together with comparative data for KTFR. The pinhole data are also presented as a function of the percentage of polymer solids, and hence film thickness, of the resist. The KTFR was centrifuged initially and then all the photoresist systems were filtered to the same 1 μm level.

The photoresists of various types prepared from the Rezyl polymer, and described in Table III, are thus capable of functioning in films in the thickness range of 2000 to 3000Å with an acceptably low pinhole density of 30 pinholes/in.^{2}. At a film thickness of 3000Å, KTFR shows an unacceptably high pinhole density, and it is only when a KTFR thickness of 10,000Å is used that the pinhole density becomes approximately equal to the pinhole densities exhibited by the resists described.

Table III. Pinhole data for two Rezyl fractions and KTFR

Photoresist	$\bar{A}_N$	$\bar{A}_W$	Polymer solids in the resist (%)	Viscosity (cp)	Film thickness (Å)	Pinhole density (pinholes/in.^{2})
Rezyl fraction No. 4	433	10,015	10	3.7	2,800	10
			8	2.7	1,800	20
Rezyl fraction No. 9	361	3,089	10	1.6	3,000	20
			8	1.4	2,200	30
KTFR	—	—	7	—	3,000	$\approx$1,000
			12		10,000	30

It will be noted, however, that no pinhole data are presented for any Rezyl photoresist solutions of less than 8% polymer solids. For all the Rezyl fractions no useful photoresist of less than 5% polymer could be prepared since all developed a large number of pinholes in the development step. Initial pinhole measurements made on photoresist films obtained from 6% polymer photoresist solutions prepared using both Rezyl fractionations 4 and 9 gave acceptably low pinhole densities in films ~1400Å thick. The use of these resists on a day-to-day basis, however, showed that the successful functioning of these resists depended markedly on rigorous control of the processing conditions; otherwise the resists pinholed badly. It was observed for instance that on days when the humidity in the laboratory was toward the high end of the allowed limits, the resist tended to behave in a nonreproducible manner (10). This nonreproducibility negated the routine use of 6% polymer resists. A polymer solids content of at least 8% produced a completely reproducible behavior, within the errors of evaluation, on a day to day basis. The somewhat thicker resist film allowed for the necessary latitude in the processing conditions.

The use of photoresists on phosphorus-doped silicon dioxide surfaces often presents adhesion problems (11). Acordingly a series of silicon wafers were steam oxidized at 1200°C to give a 10,000Å film of silicon dioxide followed by a 7-min doping with phosphorus oxychloride at 1050°C. Patterns of various geometries (down to 10 μm) were etched into the doped oxide using a photoresist prepared from Rezyl fractionation 4 in Table I. The line quality was judged to be not quite as good as obtained with undoped oxide and so the usual techniques, taken with KTFR, etc., to prevent loss of adhesion on phosphorus-doped surfaces, such as a steam leach or the deposition of a thin film of pyrolytic oxide, are probably also appropriate for the Rezyl-based photoresists to insure good adhesion.

Photoresist stability.—The stability of the photoresists with respect to time, *i.e.*, the shelf life, is of great practical importance. The stability of the individual chemical components of the resist is of almost equal importance to the stability of sensitized photoresist solutions. The ABH sensitizer, in the solid crystalline state, is stable when stored under appropriate conditions, *i.e.*, protected from light and in a cool place ($\approx$20°C). Solid sensitizer stored for eighteen months showed no signs of decomposition as evidenced by the appearance of the crystals, infrared spectra, and the behavior of photoresists prepared from it.

Photoresist solutions prepared from polymer having $\bar{A}_N = 433$ and $\bar{A}_W = 10{,}015$ were used on a day-to-day basis for six months with reproducible resist properties; beyond this period, some deterioration in line quality was observed. The use of butylated hydroxy toluene (an anti-oxidant) (12) is currently under investigation as a stabilizing additive. The data accumulated so far indicate that this compound is an effective stabilizer, for polymer stock solutions and sensitized photoresist solutions, with no adverse effects otherwise on the performance of the resist.

Conclusions

The foregoing discussion has covered various photoresist parameters with emphasis on the molecular weight distribution of the polymer. Variation of this latter parameter has allowed the formulation of a photoresist capable of functioning in films in the thickness range of 2000-3000Å, which allows 1.25 μm lines to be etched through an appropriate thickness, *i.e.*, 4000Å of silicon dioxide, and which yields an acceptably low pinhole density. The resolution capability demonstrated is therefore 400 lines/mm. Although

masks with lines-on-spaces patterns smaller than 1.25 μm were not readily available, single 1 μm lines were obtained and the resist formulation described probably possesses a resolution capability of 500 lines/mm.

The Interaction of Photoresists with Metals and Oxides during RF Sputter-Etching

J. L. Vossen* and E. B. Davidson[1]

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

When photoresists are used as masks for rf sputter-etching of various materials, interactions between the material being etched and the photoresist occur as a result of backscattering of some of the ejected material. We have studied these interactions in a variety of ways. Most of the interactions are similar to the interactions of the materials with carbon, and the intrinsic sputter-etch rate of photoresists is the same as that of carbon. When metals and photoresists are etched simultaneously, both materials are eroded at the same rate because backscattering converts the surface to a uniform mixture of all materials present. The etch rate of the composite surface increases over the intrinsic etch rate of the photoresist if metal carbide intermetallics can form. When only solid solutions can form, the composite etch rate decreases with decreasing solubility of carbon in the metal. When oxides are backscattered onto photoresists, the etch rate of the composite surface varies in a way which we cannot explain, and the photoresist is etched preferentially because of oxide decomposition followed by "chemical sputtering." The ability of a photoresist to mask oxides varies from one photoresist material to another. It is not possible to correlate the performance of a sputter-etch resist to its structure at this time, but it is clear that different materials behave differently in every respect.

Radio frequency (rf) sputter-etching has been used extensively to clean substrate surfaces prior to film deposition (1) and to delineate patterns in film surfaces using sacrifical photoresist masks (2-8). The latter application is the subject of this paper. Specifically, we shall describe the techniques required to prepare photoresist layers for sputter-etching and certain observed interactions between photoresists and other materials during sputter-etching.

In rf sputter-etching, the photoresist mask and the material being etched are both eroded. The maximum etch depth is limited by the thickness and quality of the photoresist mask (2, 3, 5, 7). The definition of etched patterns is limited only by the definition of the photoresist mask and there is no undercutting (2-8). Therefore, nearly all the limitations of rf sputter-etching are related to the photoresist.

Preparation of Photoresist for Sputter-Etching

Commercially available photoresist materials are intended primarily for chemical etch masking, not for masking energetic ions. One might well inquire as to how the resist layer should be prepared for sputter-etching as compared to chemical etching.

It has long been recognized that reactive gases can cause "chemical sputtering" of certain materials (9). Chemical sputtering refers to the formation of a volatile compound at the target surface under the influence of reactive gas ion bombardment. If a photoresist is bombarded by oxidizing gas ions, the photoresist is much more rapidly eroded than it would be by inert gas ion bombardment (physical sputtering) (3, 10). Indeed, this process is often used to strip photoresist materials after etching processes (11-13). Clearly this implies that reactive gases should be excluded from the sputtering system during rf sputter-etching. To accomplish complete solvent removal from the photoresist layer and to avoid oxidation of the layer, we have found that the post-development heat-treatment of the photoresist layer is critical. Figure 1 shows the apparatus used. The substrates are heated on a hotplate while the photoresisted surface is convectively cooled in a gas jet. The photoresist is thus heated from the bottom of the film, allowing all solvent to escape before the top surface of the film becomes too dense.

Key words: etching, films, polymers, ion bombardment.

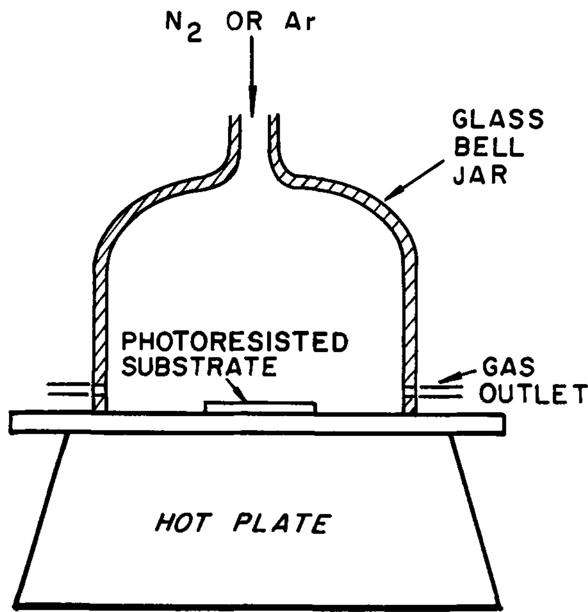

Fig. 1. Apparatus for baking photoresist films

We have observed that oven-baked photoresists tend to develop large holes under mild ion bombardment, whereas hot-plate-baked photoresist layers can withstand higher bombarding voltages. Presumably, the holes are a result of exploding pockets of trapped solvent.

The atmosphere used during the heat-treatment should be inert. Figure 2 illustrates the maximum sputter-etch depth into a photoresist patterned SiO_2 surface which was obtained for fixed initial photoresist thickness and fixed sputtering conditions. The detrimental effect of heating in oxidizing atmospheres is evident. The data plotted in Fig. 2 are for an experimental photoresist that will be described later. The temperatures at which the maxima occur vary from one photoresist to another. These temperatures are given in Table I. The time of the heat-treatment for the data given in Fig. 2 and Table I was 20 min. There was little difference observed if the time was extended.

Reproducibility of the Sputter-Etch System

Assuming that the photoresist layers are prepared in optimum fashion, it was necessary to check the reproducibility of the rf-sputtering system, as nonreproducibility would invalidate results requiring run-to-run repeatability. The system used has been described previously (5).

Six 3 cm diameter silicon wafers were photoresisted with the experimental resist. The photoresist pattern consisted of 1 mm lines and 1 mm spaces. The wafers were sputter-etched one at a time on backing plate smaller than the wafer diameter under the following conditions:

Table I. Optimum post-development bake temperature for various photoresist materials in N_2

Material	Temperature (°C)
Shipley AZ-111 and 1350	100
Shipley 1350H	125
Kodak KPR®, KTFR®, and KMER®	150
RCA Experimental	200

Residual pumpdown pressure	1×10^{-6} Torr
Argon pressure	15 mTorr
Average target potential	−700V
Peak-to-peak rf voltage	2700V
Magnetic flux density	50 gauss
Etch time	20 min

This target configuration was purposely chosen to yield a nonuniform etch profile across the silicon wafer since this provides the most severe test for reproducibility in the sputtering system. After sputter-etching, the etch depth was measured at every step across the wafer using multiple beam interferometry. The results are plotted in Fig. 3. The total spread in measured depths from wafer to wafer is about 10%, which is within the accuracy of the thickness measuring technique. It was concluded that the system and the photoresist preparation techniques used were reproducible.

Limiting Bombarding Voltages and Etch Rates for Various Photoresists

As we shall show later, the presence of other materials on target surfaces has a profound influence on the etch rate of photoresists. To eliminate this variable, all data reported in this section refer to the rf sputter-etching of 1.7 μm thick optical filters which consist of many alternate layers of ZnS and ThF_4. The same photoresist pattern was applied to the films, but the

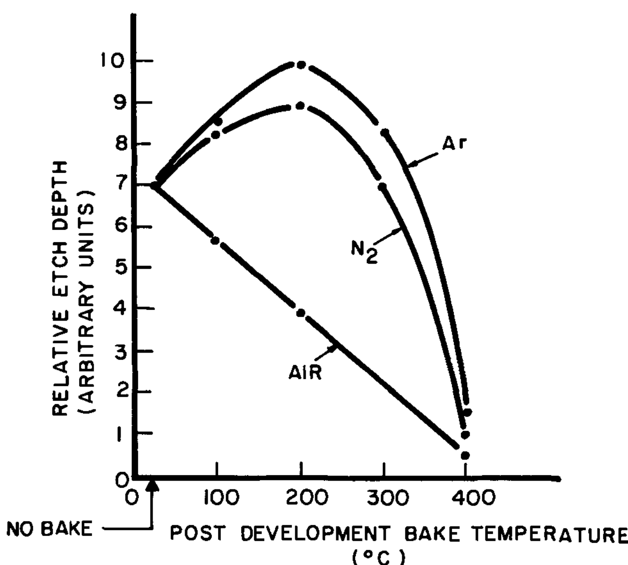

Fig. 2. The effect of post-development photoresist bake temperature and atmosphere on the maximum sputter-etch depth into SiO_2.

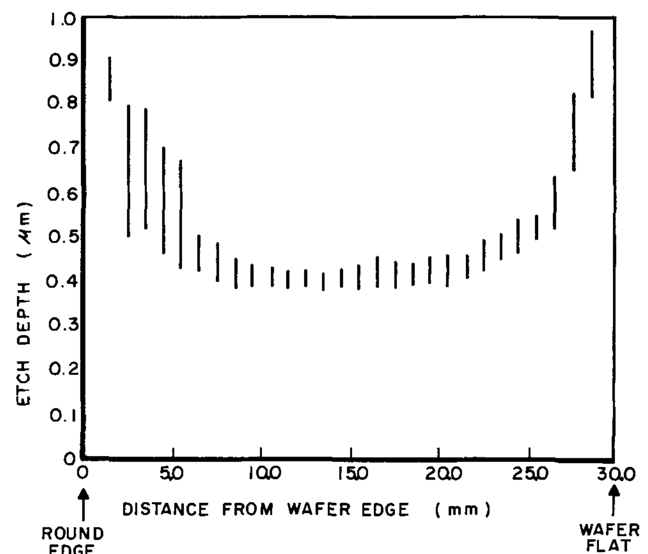

Fig. 3. Range of sputter-etch depths into Si measured at regular intervals across the Si surface for six different Si wafers. The photoresist films used to mask the Si were deposited at different times.

Table II. Maximum bombarding voltages for various photoresists

Material	Voltage (V)
Shipley AZ-111 and 1350	600
Shipley 1350H	700
Kodak KPR® and KTFR®	900
Kodak KMER®	1,000
RCA Experimental	1,400

photoresist materials were varied. Each photoresist was bombarded at successively higher voltages until a threshold for large crack and/or hole formation was observed. These threshold voltages are given in Table II. These are the average d-c target sheath potentials and should be taken as being relative to each other rather than absolute, since different materials being etched, different discharge conditions, or different backing plates can change the absolute values. The advantage of higher bombarding potentials is a higher etch rate as shown in Fig. 4.

All further experiments were conducted at bombarding potentials substantially lower than the thresholds given in Table II.

Interaction of Metals with Photoresists

It has been noted in the past (5) that "the" sputter-etch rate of a photoresist has little meaning. When a film is patterned with photoresist and sputter-etched, both the film and the resist are sputtered. Whenever a surface is ion-bombarded in a glow discharge, some of the sputtered material is reflected back to the target surface (14). Recently, the amount and spatial distribution of the back-scattered material has been measured (1, 14). The spatial distributions determined were surprisingly uniform over fairly large areas (up to 5 cm^2). As a result of this phenomenon, some resist material is back-scattered onto the film surface and *vice versa* until a new and uniform surface composition comprising film and photoresist material or fragments of photoresist material is present everywhere on the surface being etched. When metals are sputter-etched with photoresist patterns, the composite surface formed by backscattering results in a uniform etch rate for all species on the surface. That is, there is no preferential removal of photoresist or metal regardless of the metal used. This implies that the photoresist thickness needed to mask for a given etch depth into a metal surface is only slightly greater than the etch depth (to account for nonuniformities in photoresist thickness). For example, in Fig. 3, the photoresist thickness averaged 10,000Å, and the wafers were sputter-etched until the photoresist was almost completely removed near the wafer edges. The etch depth near the wafer edge averages about 9000Å, which is very close to the original photoresist thickness. Similar observations have been made for a variety of metal-photoresist combinations.

These interactions affect the over-all sputter-etch rate of the composite surface. In an attempt to determine the magnitude of these interactions, Si wafers were completely coated with the experimental photoresist, flood exposed, and baked in N_2 at 200°C for 20 min. The wafers were all spin-coated with approximately the same thickness of photoresist, but the actual thickness was measured using spectrophotometric techniques (15), and all data were normalized for thickness variation. The wafers were sputter-etched while resting on 7.5 cm diameter target backing plates of various metals. The backing plates were pre-sputtered for at least 2 hr in Ar before the sputter-etching runs. The sputtering conditions used to etch the photoresist are:

Residual pumpout pressure	1×10^{-6} Torr
Argon pressure	5 mTorr
Target sheath potential	−700V
Peak-to-peak rf voltage	2800V
Axial magnetic flux density	50 gauss

The wafers were sputtered until all the photoresist was removed. The time to removal and the measured resist thickness were used to calculate the effective etch rate. The data thus obtained for metal backing plates are plotted in Fig. 5 as a function of the sputtering yield of the metal backing plate. Two features of the curve are evident. The relationship displays a maximum etch rate for the Pt-photoresist combination and the Cu-photoresist combination is anomalously low. This behavior is suggestive of specific, but different, chemical interactions between the backscattered materials.

Since the major constituent element of photoresist is carbon, it was expected that the interactions were between the metals and carbon. Several experiments supported the expectation.

First, a glass target backing plate was completely covered with a thick layer of photoresist, flood exposed and baked. A photoresisted silicon wafer was then sputter-etched using this "photoresist backing plate." The etch rate of the photoresist in this configuration was the same as the etch rate of the photoresist resting on a C backing plate within the limits of

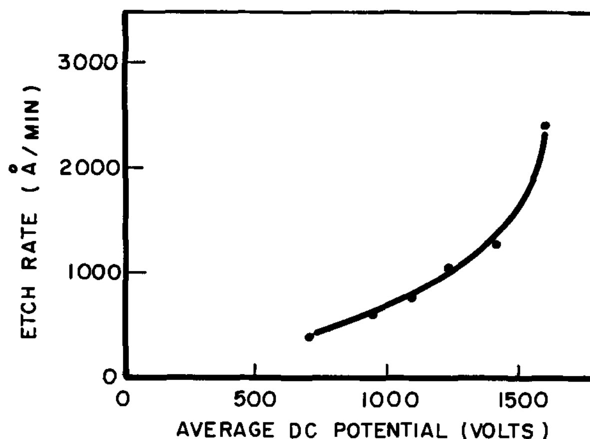

Fig. 4. RF sputter-etch rate of ZnS-ThF$_4$ optical filters vs. target sheath potential.

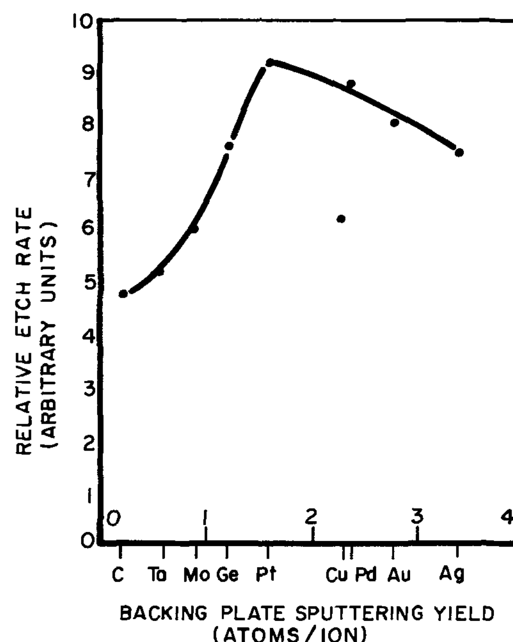

Fig. 5. Relative sputter-etch rate of experimental photoresist films vs. the sputtering yield of the metal backing plate upon which the sample was resting. Each point represents an average of 3 runs.

experimental error. Hence, the intrinsic etch rate of the photoresist is the same as that of carbon.

Next, carbon films were rf sputtered from a vitreous carbon target onto silicon wafers. These carbon films were then rf sputter-etched while resting on backing plates of the same metals used in the earlier experiments. Figure 6 shows the resulting etch rates and compares the carbon and photoresist etch rates. The shapes of the curves are qualitatively the same and the anomalously low Cu point is evident.

All of the metals having sputtering yields lower than that of Pt form inter-metallic carbides (16, 17), while the metals having sputtering yields equal to or higher than Pt form solid solutions of varying degrees of solubility with C (18). If carbide formation in the photoresist is the operable mechanism for the increased etch rates observed, then one must assume that the carbides are formed uniformly over the photoresist surface. This further implies that the sputtering rate of the metal carbides and the metal-photoresist composites are the same. If the entire surface being sputtered is for all practical purposes metal carbide, then the ratio of the sputtering yield of the carbides to that of carbon should be the same as the ratio of the etch rates of the metal-photoresist combinations to the intrinsic etch rate of the photoresist. We have measured the effective sputtering yield of TaC and Mo_2C, by the method of comparing the rf sputter-deposition rate of these materials with metals of known sputtering yield in a system with fixed geometry and using fixed sputtering conditions (19, 20). In this technique, metals of known sputtering yield and the unknown materials are deposited and their thicknesses measured, yielding sputtering rates (R). The "effective yield" or the relative sputtering rate (S) is then given by the simple proportion

$$S_x = S_{Me}(R_x/R_{Me})$$

where the subscripts x and Me refer to the unknown and the metal standard respectively. The metals used as standards were Ta and Mo. As has been pointed out by Maissel (20), this method of measuring yields is subject to various uncertainties (different secondary electron yields, re-emission coefficients, etc.). Therefore, it is advisable to use more than one standard to average out these effects. In this case, the ratios of

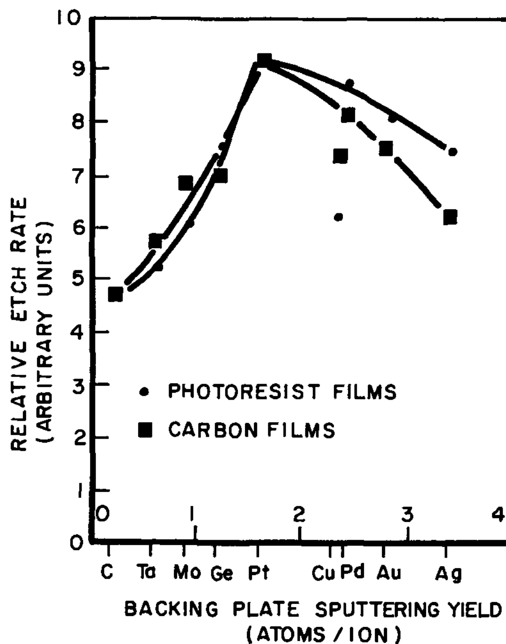

Fig. 6. Relative sputter-etch rate of carbon films *vs.* the sputtering yield of the metal backing plate upon which the sample was resting. The data for photoresist films are also shown for comparison. Each point represents an average of 3 runs.

Table III. Effect of intermetallic carbide formation on rf sputter-etch rate

Metal or carbide	Sputtering yield (19) (atoms/ion)	Effective sputtering yield (atoms/ion)	(Yield of metal or carbide / Yield of carbon)
C	0.12	—	1.00
Ta	0.57	—	4.75
TaC	—	0.13	1.08
Mo	0.80	—	6.67
Mo_2C	—	0.15	1.25

the measured deposition rate to the known sputtering yield of Ta and Mo differed by less than 10%. The results are tabulated in Table III. The sputtering yields given are for 600 eV Ar^+ bombardment at normal incidence on polycrystalline targets (21). The ratio of the sputter-etch rates for the photoresist on Ta and Mo backing plates to the intrinsic etch rate of the photoresist are 1.10 and 1.25, respectively (Fig. 5). The agreement with the carbide data in Table III is quite close, implying that carbides are formed in the photoresist such that the effective etch rate is increased.

For metals that form solid solutions with carbon, a decrease in etch rate with increasing sputtering yield is observed. The apparently anomalous Cu points fit reasonably well in a plot of etch rate *vs.* solid solubility of C in metals (Fig. 7).

The general tendency toward lower etch rates for these metal-photoresist or metal carbon combinations may be explained qualitatively based on the backscattering data presented for metals on Si earlier (1). The amount of material backscattered generally decreases with increasing sputtering yield, thus leaving more low yield photoresist exposed to the ion bombardment. For the limiting case of an infinite sputtering yield, no backscattering would occur and there would be no interactions with the photoresist. Hence, the etch rate of the surface would revert to the intrinsic (low) etch rate of the photoresist.

Similar results to those given in Fig. 5 and 6 have been obtained for other photoresists. Figure 8 illustrates the etch rate of a photoresist similar to Kodak KTFR® as a function of the sputtering yield of the backing plate metal. Here, the variation is distinctly resolved into two separate modes of interaction, the formation of intermetallic carbides or solid solutions of the metals and carbon.

Interaction of Inorganic Oxides with Photoresist

To determine the effects of sputter-etching photoresists in the presence of inorganic oxides, experiments similar to those with metals were conducted using 16 hot-pressed oxide backing plates. Before each run the backing plates were pre-sputtered in pure O_2 for at least 3 hr to ensure that a stoichiometric,

clean surface was present. The photoresist films were prepared in the same manner as before.

Since there are no data available on the "sputtering yield" of oxides, it was necessary to measure the "yields" for each of the oxides used in the study. This was done by the method of deposition rate comparison as described earlier. Caution should be exercised in using these yield data (Table IV). Many of these materials are known to reduce, chemically, under the influence of Ar ion bombardment (5). Therefore, the surface composition changes continually during ion bombardment. Furthermore, the meaning of "yield" for compounds is not clear since one has no way to determine the nature of the ejected species (atoms, molecules, clusters). Therefore, we shall refer to the "relative deposition rate" of the oxides. These relative deposition rates are normalized to the sputtering rate of metals having known sputtering yields. The metals used as standards were Si, Pt, Cr, and Au. The ratios of the measured deposition rates to the known sputtering yields of these metals differed by less than 10%. The average of these ratios was used to normalize the oxide deposition rates to the sputtering yield of the metals.

The variation of photoresist etch rate with the relative deposition rate of oxides is shown in Fig. 9. The

Table IV. Relative deposition rate of inorganic oxides (Normalized to the sputtering yield of metals)

Oxide	Relative deposition rate $\left(\frac{\text{A/min}}{\text{A/min}}\right)$

etch rate for the metal backing plates is replotted in the same figure for reference. We have no satisfactory explanation for the shape of the oxide curve. It does not relate to any thermodynamic or thermochemical property of the oxide backing plate, nor to the possibility of chemical reduction followed by either carbide or solid solution formation by backing plate cations with C in the photoresist. All that can be said with certainty is that the etch rates for oxide backing plates are generally higher than those for metals. This leads to the possibility that oxygen is being released from the backing plates into the discharge, thus superimposing chemical sputter-etching on physical sputtering. Because chemical sputtering, resulting from partial chemical reduction of oxides, may cause preferential etching of photoresists when compounds are etched, it is necessary to determine the ratio of photoresist thickness to etch depth required for oxides.

"Protection Factor" for SiO_2

N-type (111) silicon wafers with 10,000Å of steam oxide were whirl-coated with photoresist and exposed through a mask so that one-half of the wafer was protected by photoresist after development. The wafer was placed on a SiO_2 backing plate in the sputtering system and half of it was shielded by a second oxidized silicon wafer (Fig. 10).

The oxide was sputter-etched for 20 min under the following conditions:

Residual pumpdown pressure	1×10^{-6} Torr
Argon sputtering pressure	5 mTorr
Target sheath potential	−700V
Axial magnetic flux density	25 gauss

The wafer was then removed, a thin layer of chromium was evaporated onto it, and the resulting sur-

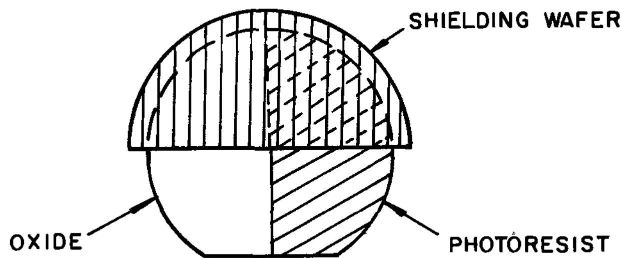

Fig. 10. Sample configuration for sputter-etching of photoresist on SiO_2 for determination of oxide etch rate and protection factor.

face was examined with a Bendix Proficorder®. The arrangement permitted determination of (*i*) the original oxide thickness, (*ii*) the amount of photoresist removed, and (*iii*) the amount of oxide removed (Fig. 11a). The resist was then characterized for the rate of removal of oxide in Å/min and for the protection it afforded in terms of the ratio of photoresist sputtered to oxide sputtered. A good sputter-etch resist is characterized by a large value for the rate (of oxide removal) and a small value for the protection factor (P.F.).

The sputtering conditions were chosen so that the photoresist was not completely removed after 20 min of sputtering. Occasionally a run did result in complete removal of the photoresist resulting in the condition pictured in Fig. 11b. In this case the effective time of sputtering must be calculated since during a portion of the 20 min period oxide was being sputtered off at an equal rate from both sides of d resulting in no change in height. In these cases, the rate (Å/min) is calculated as

$$\text{Rate (Å/min)} = \frac{d}{20 - \left[\frac{c + d}{90}\right]}$$

where the value 90 Å/min is the intrinsic sputter-etch rate of SiO_2. The P.F. value in this case is a/d.

In either case, an internal check on the measurements is available since $(a + c)$ should equal $(b + d)$. Table V lists the rate of oxide removal and the protection factor for the materials evaluated. Individual step heights are not given, however, the per cent deviation of the individual sums $(a + c)$ and $(b + d)$ from the average $[(a + c) + (b + d)]/2$ is listed for each material.

A variety of materials were examined including commercially available photoresists and other materials which could be formulated into photoresists.

This latter group, which includes the RCA experimental resist, was made up of drying oil alkyd resins of the class reported by Walters and Mocsary-Weisz (22).

Species Sputtered from Photoresists

Spark source mass spectroscopy was employed in an attempt to determine the nature of the species sputtered from photoresists. Films were deposited from a photoresist-covered sputtering target, yielding information on the manner in which the photoresist is removed from the target. This film was compared with a photoresist film that had not been ion bombarded and with an rf sputtered C film.

The photoresist layer that was not bombarded showed a preponderance of high molecular weight species. The sputter deposited photoresist film shows hydrocarbons to the extent of the mass scale (280), but species above C_4, C_5 C_6 are very weak, indicating that the polymer has been thoroughly fragemented by the ion bombardment. The films deposited from the vitreous carbon target showed mainly C clusters, with traces of hydrocarbons.

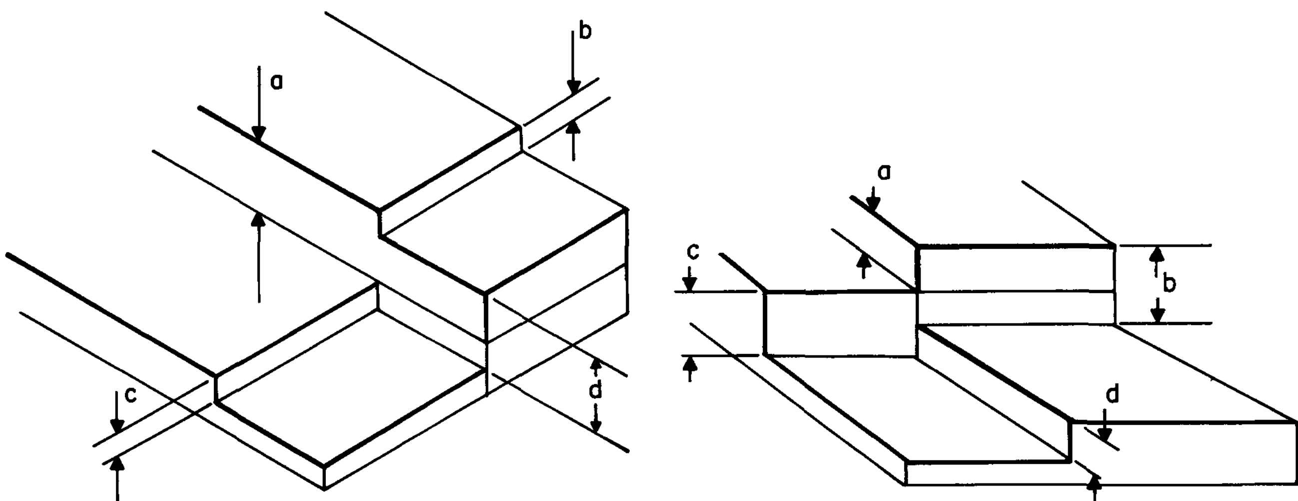

Fig. 11. Substrate configuration after sputter-etching (a, left) with photoresist remaining, (b, right) with photoresist entirely removed

Summary and Conclusions

The main conclusions that may be drawn from this work are as follows:

1. The pretreatment of the photoresist before sputter-etching clearly affects its performance. Baking in an inert atmosphere improves the performance relative to no-baking up to a point; then the performance declines. The performance of the resist when baked in air is always poorer than if no-bake were employed.
2. When prepared under optimum conditions, there is a limit to the maximum bombarding voltage that the photoresist can withstand. This maximum varies from one material to another.
3. The mass spectra of sputtered photoresist differs from that of unsputtered photoresist and carbon. The unsputtered photoresist shows the presence of masses to the limit of the instrument ($M=280$) with a preponderance of high-mass species. Films deposited from a "photoresist target" showed masses to the extent of the mass scale, but species above C_6 were very weak. The films of rf sputtered carbon showed mainly C clusters with traces of hydrocarbons.
4. The intrinsic sputter-etch rate of photoresists is very close to that of C.
5. When metals and photoresists are sputter-etched simultaneously, the entire target surface is eroded at the same rate, presumably because backscattering converts the surface to a mixture of the materials present.
6. Metal-carbon combinations sputter-etch in a way that is very similar to metal photoresist combinations.
7. The interaction of backscattered metals with carbon or photoresist depends upon whether an intermetallic carbide or a solid solution with carbon is formed. When carbides are formed, the etch rate of the composite surface is increased over the intrinsic etch rate of the photoresist by an amount approximately proportional to the ratio of carbide to carbon sputtering yields. When solid solutions are formed, the etch rate decreases with decreasing solubility of carbon in the metal.
8. When oxides are backscattered onto photoresist, the etch rate of the composite surface varies from one oxide to another in a way which we cannot explain.
9. In the photoresist-oxide case, photoresist is etched preferentially, probably because of oxide decomposition followed by chemical sputtering. The ability of a photoresist to mask oxides varies from one photoresist material to another.
10. It is impossible to correlate the performance of a sputter-etch resist to its structure at this time. It is clear, however, that different materials behave differently in every respect.

Acknowledgments

L. DiMarco prepared most of the photoresist films used in this study. J. J. O'Neill and E. S. Poliniak conducted many of the sputtering runs. The mass spectrometric analyses were done by W. L. Harrington.

Nuclear Study of the Fluorine Contamination of Tantalum by Various Polishing Procedures and of Its Behavior during Subsequent Anodic Oxidation

B. Maurel, D. Dieumegard,[1] and G. Amsel*

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Tour 23; 11 quai St. Bernard, Paris 5e, France

ABSTRACT

The fixation of fluorine in the film left on tantalum by chemical polishing in a H_2SO_4-HNO_3-HF mixture was studied using microanalysis by the nuclear reactions $F^{19}(p,\alpha)O^{16}$ and $O^{16}(d,p)O^{17}$. Typically 2×10^{15} atoms/cm^2 of fluorine is found in films containing 20×10^{15} atoms/cm^2 of oxygen. Leaching in boiling water decreases the amount of fluorine by about 50%. On the other hand, the dissolution of these films in a NH_4F saturated 40% HF solution reduces the fluorine contamination to less than 1.5×10^{14} atoms/cm^2. Hence this double chemical treatment appears to be an effective procedure to obtain low fluorine contaminations on polished tantalum. Leached samples were anodically oxidized in a 5% ammonium citrate aqueous solution up to 90V at 1 mA/cm^2. It was found both by dissolution techniques and by the observation of the 872 keV narrow resonance of the $F^{19}(p,\alpha\gamma)O^{16}$ reaction, that, after oxide growth, the fluorine remains near the metal-oxide interface. The oxide growth laws for the various surface preparation procedures described were investigated. The presence of F^{19} on the surface of tantalum seems to have little influence on the growth laws; the small changes induced are discussed in detail.

It is well known that a metal is subject to contamination by various elements during the process of surface treatment by chemical, electrochemical, or mechanical polishing procedures. The present paper is devoted to an investigation of the contamination with fluorine of the surface of tantalum samples subjected to various treatments in fluorine-containing baths. Attention was paid to the localization, as a function of depth, of fluorine atoms after anodic oxidation of the specimens. The oxide growth laws on various tantalum surfaces were also investigated. The results will be discussed mainly with reference to the work of Young (1) and to several papers (2-4) from this laboratory, the present work being a continuation of the latter. Anodic oxidation leads in most electrolytes, except those with high fluorine content (5), to the formation of nonporous, amorphous, highly insulating films. Young (1) has shown that the thin layer of tantalum oxide which remains after chemical polishing has properties different from those of anodic tantalum oxide; he has explained this fact by a possible introduction of fluorine impurities due to the polishing treatment. However, to the best of our knowledge, no direct evidence, either quantitative or qualitative, has yet been obtained for the existence of such traces of residual fluorine. In the present paper, we made use of a recently developed method for determining the absolute quantities of fluorine and oxygen on the surface of tantalum: that of microanalysis by direct observation of nuclear reactions.

Analytical Techniques

The method of microanalysis used for the measurement of fluorine traces and of oxygen (O^{16}) contents of oxide layers consists in the direct observation of charged particles coming from the nuclear reactions $F^{19}(p,\alpha)O^{16}$ and $O^{16}(d,p)O^{17}$. One millimeter diameter proton or deuteron beams were produced by the 2 MeV Van de Graaff accelerator of the Ecole Normale Supérieure of Paris. A detailed description of this method has been reported in Ref. (6-9), Ref. (6) being devoted to the general technical details of the method, Ref. (7) mainly to O^{16}, and Ref. (8) and (9) to F^{19}. It will be recalled here that the counting rates reach the order of 100 counts for a duration of measurement of 15 min (*i.e.*, 10% statistical accuracy) for layers of thickness

$$1.5 \times 10^{13}\ O^{16}\ \text{atoms/cm}^2\ (\sim 4 \times 10^{-4}\ \mu g/cm^2)$$
$$10^{14}\ F^{19}\ \text{atoms/cm}^2\ (\sim 3 \times 10^{-3}\ \mu g/cm^2)$$

under the experimental conditions used (intensity of the beam 1 μA; detection of charged particles by three identical 3 cm^2 silicon-surface barrier detectors, at an angle of 150° with respect to the direction of the beam, subtending a total solid angle of detection of 0.36 steradian). These figures relate to bombarding energies near the plateaus of the cross-section curves at 900 keV for O^{16} and 1270 keV for F^{19} [using the broad resonance of $F^{19}(p,\alpha)O^{16}$ at 1348 keV, the above-counting may be reached in the same conditions for 2×10^{13} atoms/cm^2 F^{19}; this procedure, somewhat more critical, was not necessary in the present experiments]. Since the standard error varies as the square root of the counts, it is clear that accuracy improves rapidly for oxygen or fluorine contents exceeding the above-orders of magnitude. For instance, the oxygen contents dealt with in the present investigation, which were of the order of 10^{16} atoms/cm^2, were determined within 1 min with a statistical precision of the order of 1%.

The absolute oxygen standard was provided by a film of anodic oxide grown on tantalum under well-defined conditions. (3). It has been shown in the latter paper that precise coulometric measurements permit in this case the absolute determination of the number of O^{16} atoms per cm^2 with an accuracy of about 3%. The absolute fluorine standard was a vacuum deposited film of CaF_2 on a tantalum backing, known with an accuracy of about 7% (8, 9).

Quantitative Results on the Contamination Phenomena

Unannealed, rolled tantalum specimens (from Kawecki-Berylco Ind.) (rated bulk purity 99.95%) were used in this investigation, with a thickness of 0.2 mm. Before use, they were carefully degreased in acetone (3, 4). Investigations of specimens which had not been subjected to any treatment except for de-

Key words: tantalum, polishing, fluorine, contamination, anodic oxidation, nuclear reactions.

greasing showed a surface contamination with fluorine varying from 1.4×10^{14} to 3×10^{14} F^{19} atoms/cm^2. As measurements of F^{19} on high-purity silicon yield zero counts, for measurement times equal to those used for tantalum (5 min), it appears improbable that the presence of the measured quantities of fluorine on tantalum specimens of high purity is caused by contamination in the vacuum of the nuclear reaction detection chamber. This contamination of the raw-rolled tantalum surface remains as yet unexplained. Measurements of O^{16} did not allow us to find a correlation between the observed quantities of O^{16} and F^{19}. The results are shown in Fig. 1 where the number of F^{19} atoms is plotted *vs.* that of O^{16} atoms contained within the surface layer of natural oxide (the two measurements refer to the same beam impact point of the specimen). It is seen that the quantities of oxygen vary between 3×10^{16} and 8×10^{16} atoms/cm^2, which corresponds to natural oxide layers of the order of 50-150Å [considering this oxide to be Ta_2O_5, the equivalence is 5.45×10^{14} atoms/cm^2 of oxygen for 1Å, assuming a density of 8.0 as in Ref. (4)].

The residual fluorine contamination was investigated on tantalum specimens 11 by 20 mm polished chemically for 15 sec in a mixture of 5 parts of H_2SO_4 (95%), 2 parts of HNO_3 (53%), and 2 parts of HF (40%), as in Ref. (2-4), a classical mixture similar to that used previously by Young [Ref. (1), p 46]. After washing with triply-distilled water at room temperature for 10 min, the specimen surfaces showed an appreciable fluorine content, which was rather variable. It may be noted that measurements at various points of the same sample yield a similar spread of the results as that obtained for different samples. These results (Fig. 1) show that the contamination amounts on the average to 23×10^{14} F^{19} atoms/cm^2. Figure 1 also shows that the F^{19} content is statistically independent of the thickness of the oxide layer, *i.e.*, its oxygen content. The thickness of this natural oxide layer is of the order of 20-45Å. Washing the specimens in boiling triply-distilled water for 5 min eliminates a large fraction of the fluorine (about 50%), which partly confirms the statements of Young [(1), p 67]. Prolonged washing with boiling water (1 hr) does not lead to any noticeable further decrease in the fluorine content, which is hence on the average near 10^{15} F^{19} atoms/cm^2.

The influence of the relative proportions of the constituents of the polishing bath on the extent of fluorine contamination after boiling in water was next investigated in particular as a function of the HF proportion. No noticeable change in contamination was observed, in both the alteration of the polishing bath by an excess or the defect of HF by as much as ±50%.

If one assumes that the 10^{15} F^{19} atoms/cm^2 are contained in a pure uniform compound of composition TaF_5 (density 4.7), taking a roughness factor for the polished tantalum near unity (10), the corresponding thickness is near 2Å. Hence, the two extreme possibilities are that the fluorine is contained either in a pure submonomolecular fluoride layer, or dispersed throughout the residual oxide layer of thickness near 40Å, *i.e.*, containing about 5 fluorine atoms per 100 oxygen atoms.

In order to attempt to reduce the fluorine contamination of the polished tantalum specimens, they were immersed for 5 min in a bath of NH_4F-HF (about 300g NH_4F per liter of 40% HF) which is generally used for dissolving the oxide. The use of such a solution was suggested by Pringle (Private communication, 1966) and the technique was applied in our laboratory (2-4). Recently Pringle published this method (11), where he also describes a double treatment similar to that investigated here for its effects on F^{19} contamination. This operation was performed at 27.5°C, as usual for oxide dissolution. The samples were then washed for 5 min with boiling triply-distilled water. As seen from Fig. 1, the fluorine content drops to an average value of 1.5×10^{14} atoms/cm^2. The best results were obtained with a solution saturated with NH_4F. Figure 2 shows the spectra recorded during the measurements of the fluorine content by means of the $F^{19}(p,\alpha)O^{16}$ reaction

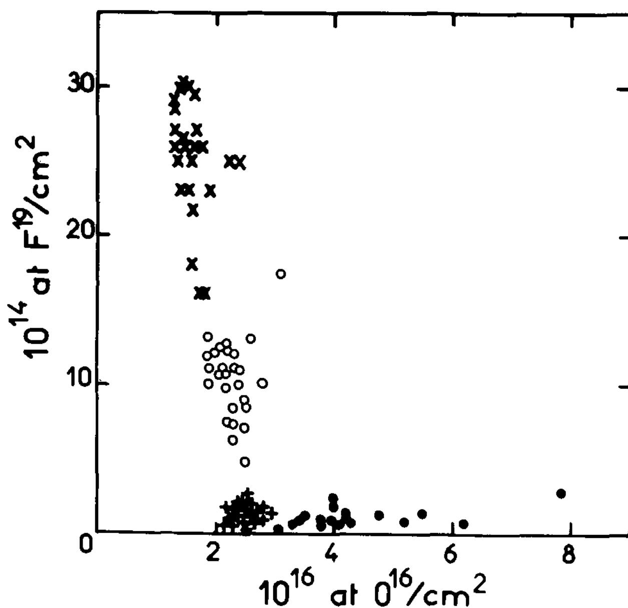

Fig. 1. Correlegram of the F^{19} and O^{16} contents found on the surface of Ta specimens. (●), raw tantalum; (×), polished and washed with cold water; (○), polished and washed with boiling water; (+). polished, treated in the NH_4F-HF bath and washed with boiling water.

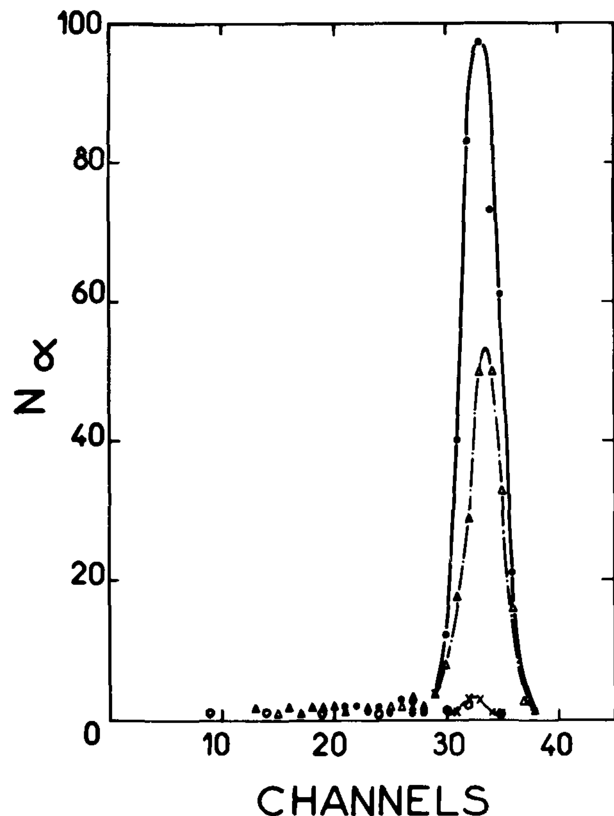

Fig. 2. α particle energy spectra from the reaction $F^{19}(p,\alpha)O^{16}$ recorded for Ta specimens subjected to various treatments. (○), raw tantalum; (●), polished and washed with cold water; (△), polished and washed with boiling water; (×), polished, treated in the NH_4F-HF bath, and washed with boiling water.

on the same tantalum specimen subjected, after polishing, to the various successive treatments described above. It clearly appears that this double treatment provides a method for effectively minimizing the fluorine content of the surface of polished tantalum. Moreover, it is seen from Fig. 1 that the thickness of the spontaneous oxide which results from this double treatment is the same as that encountered after washing in boiling triply-distilled water only.

From these results it may be inferred that the mechanism of polishing leads to the formation of an oxide heavily contaminated with fluorine, which then undergoes gradual dissolution. The fluorine atoms seem to be located within the spontaneous oxide layer (or in a region close to the metal) which remains on the material after stopping the polishing process. The NH_4F saturated bath dissolves this film while introducing much less fluorine contamination. The spontaneous reoxidation of the sample leads to an oxide layer of similar thickness as before.

Location of Fluorine after Anodic Oxidation of Polished Tantalum

When the polished tantalum samples are subjected to anodic oxidation, the fluorine atoms located on the specimen surface or within the spontaneous residual tantalum oxide undergo a transport phenomenon under the effect of the electric field. After anodic oxidation, the fluorine atoms may be located at the metal-oxide interface, near the oxide surface or may be distributed throughout the bulk of the oxide. Tantalum samples polished as above and washed for 5 min in boiling triply-distilled water were anodically oxidized in an aqueous solution according to a procedure similar to that used in Ref. (2-4), *i.e.*, a *p*H 6 buffer solution of high purity (Merck) ammonium citrate (5% by weight) in triply-distilled water of resistivity 0.5 megohm-cm. The oxidations were carried out at a temperature of 26.5°C at a constant current of 1 mA/cm^2, up to a final potential of 90V between anode and platinum cathode.

The location of fluorine in this oxide layer was first studied by successive dissolution of anodic oxide layers in the above used NH_4-HF bath; the remaining number of O^{16} and F^{19} atoms per cm^2 was recorded as a function of the time of dissolution. The results are shown in Fig. 3. They correspond to a series of initially identically prepared samples. The initial oxide layer contained 7.8×10^{17} atoms of oxygen per cm^2 (*i.e.*, equivalent to 1410Å). From the linear decrease with time of the oxygen content of the remaining film one can calculate the dissolution rate under our experimental conditions, *i.e.*, 4.1×10^{16} atoms/cm^2 (or 75Å) per minute. The oxygen content becomes stationary for dissolution times above about 18 min; this level of stabilization corresponds to the spontaneous formation of a thin oxide layer about 40Å thick. The fluorine measurements show that the concentration remains stationary during the dissolution (around 1.4×10^{15} fluorine atoms/cm^2); when the oxide is completely dissolved, one observes a sharp drop in the fluorine content (factor 4). This means that the fluorine which remains after polishing is found in a region close to the metal-oxide interface. A complete dissolution of the oxide allows one to eliminate most of the fluorine, while the residual contamination is probably due to the dissolution bath itself. Complementary experiments showed that the total amount of F^{19} before and after anodic oxidation is, on the average, the same. Hence the F^{19} content is conserved during anodic oxidation.

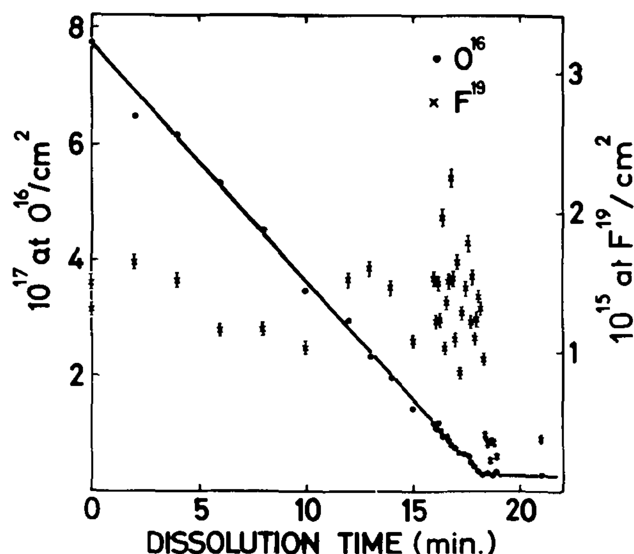

Fig. 3. F^{19} and O^{16} contents found on the surface of polished Ta specimens first subjected to anodic oxidation up to 90V and immersed for various times in the dissolution bath: (●), O^{16}; (×), F^{19}. Statistical error is indicated for F^{19}; it is negligible for O^{16}.

In order to further confirm the location of the fluorine atoms in the oxide near the oxide-metal interface, we resorted to a second technique in which the ambiguity of the first method (*i.e.*, that the dissolution bath itself contained fluorine) was avoided. The localization was achieved here by the observation of a narrow resonance in the $F^{19}(p,\alpha\gamma)O^{16}$ reaction, according to a method described in Ref. (6), (8), and (9). The 4.2 keV wide resonance at 872 keV was used, the γ rays being detected with a 3 in. by 3 in. NaI(Tl) scintillation detector. Such a measurement is based on the principle that if the fluorine is detected on the surface, the resonance occurs at the energy E_0 which is the actual energy of the resonance. However, if the fluorine is found at a certain depth, the incident protons must lose an energy ΔE before reaching the fluorine atoms; consequently, the resonance occurs at an energy $E_0 + \Delta E$. Knowing the stopping power of the matrix material to incoming particles (9), one is able to calculate the depth of penetration. The resulting excitation curves are shown in Fig. 4. Curve (a) shows the resonance at 872 keV observed by automatic energy scanning (6) (768 eV/channel) on a tantalum sample chemically polished and then washed for 5 min with boiling triply-distilled water. Total content measurements using the $F^{19}(p,\alpha)O^{16}$ reaction showed that 5×10^{14} F^{19} atoms/cm^2 were on the surface of this specimen. Curve (a) was taken as the reference excitation curve. Curve (b) shows the same resonance observed in identical conditions for the same sample, but further subjected to anodic oxidation up to 90V, as above. This curve is shifted by about $\Delta E = 11$ keV and is somewhat broader than the reference curve (a). The shape of curve (b) may be fully interpreted by assuming that the fluorine atoms remain, after anodic oxidation, in a thin layer near the oxide-metal interface, thus confirming the results obtained by the dissolution method. Full theoretical calculations of the shape of curve (b) according to this assumption are published in Ref. (9). The broadening of curve (b) is well explained by the energy straggling of the incident protons in the F^{19} free anodic oxide. The combination of the results of Fig. 3 and 4 allows us to conclude that the F^{19} is contained, after further anodic oxidation by the order of 1400Å, in a film less than 50Å, near the oxide-metal interface.

Anodic Oxide Growth Laws for Various Surface Treatments of Tantalum

The investigation by Siejka *et al.* (4) of the oxide growth laws on tantalum, as a function of the applied voltage V_{ox} at various current densities, was achieved with samples polished and washed in boiling water, as above. The question arose whether the presence of

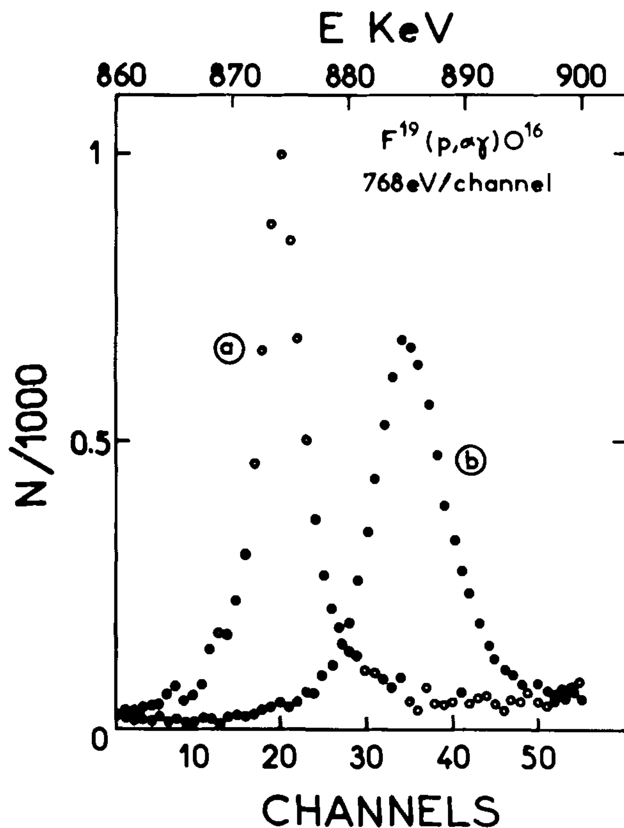

Fig. 4. Excitation curve for γ rays near the 872 keV resonance of the $F^{19}(p,\alpha\gamma)O^{16}$ reaction: (a) Ta specimen polished and washed with boiling water, (b) same specimen, anodically oxidized up to 90V.

F^{19} on the surface of these samples, as evidenced in what precedes, has a noticeable influence on these growth laws. In the experimental conditions of Ref. (4) used here, these laws $N_O = f(V_{ox})$ are straight lines relating V_{ox}, N_O, and $V_{ox}(O)$, N_O being the number of oxygen atoms per cm^2, and $V_{ox}(O)$ the extrapolated value of V_{ox} for $N_O = 0$. This basic relation and its implications, in particular the meaning of $V_{ox}(O)$, are fully discussed in Ref. (4), to which we refer here systematically. The study of the influence of the various surface preparation techniques described here on the values of $V_{ox}(O)$ and of the slope dN_O/dV_{ox} was undertaken.

All samples were cut in the form of rectangles of 2.2 cm^2 by using a special cutting tool (3,4) in order to ensure an effective reproducibility of their areas. Electrical contact with the specimens was achieved by a special tantalum clamp (12), as in Ref. (4). Anodic oxidation was performed as described above, except for greater care in the measurement of the applied potentials, using a calomel reference electrode, as in Ref. (4). In the following, the potentials are expressed in the hydrogen scale.

Figure 5 shows the results; it appears that, at a given potential, the quantity of oxygen in films grown on polished Ta is the same, for samples washed in either cold or boiling water. Moreover, the oxygen content, at a given potential, of films grown on specimens subjected to the double chemical treatment described above systematically exceeds that found on specimens which were only polished. The latter effect results, on the one hand, in a shift of $V_{ox}(O)$ towards negative potentials by about 0.5V, on the other hand, in an increased slope of the curve $N_O = f(V_{ox})$. It should be noted that this slope is even greater for raw tantalum, while $V_{ox}(O)$ is further shifted in this case towards negative potentials by about 0.3V. Figure

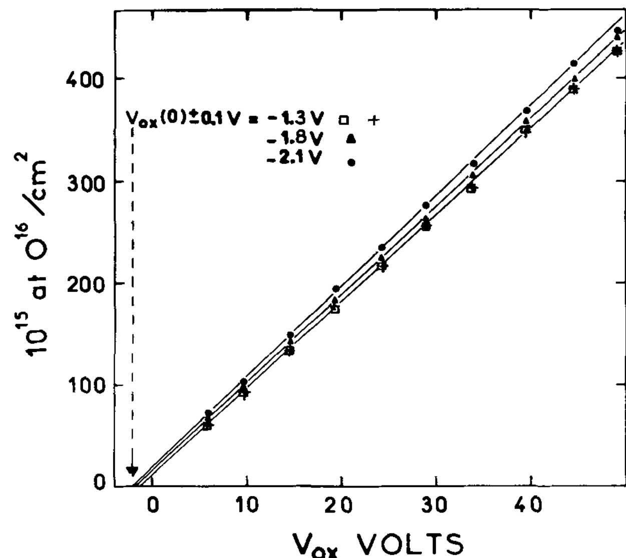

Fig. 5. Growth laws $N_O = f(V_{ox})$ of anodic oxide on Ta. (●), Unpolished; (+), polished, washed with cold water; (□), polished, washed with boiling water; (▲), polished, treated in the NH_4F-HF bath, and washed with boiling water.

6 shows in more detail the data from Fig. 5, represented so as to emphasize the slopes of the growth laws. The corresponding values for raw, doubly-treated and only polished Ta are respectively (in 10^{15} atoms/cm^2 V): 8.9, 8.6, 8.5, with errors illustrated by Fig. 6. The average slope represented being nearly constant, so is the local slope dN_O/dV_{ox}.

It appears that the influence of F^{19} on the oxide growth laws is only slight. The small observed differences will be discussed in the next section. Moreover the presence of fluorine on the surface of Ta seems to have little effect on the breakdown voltage for anodic oxidation in the above used solution, this voltage being around 200V.

Discussion

Tantalum seems to behave with respect to fluorine in sharp contrast to silicon, which was studied by Croset and Dieumegard (13). These authors found, using the same analytical techniques as in this paper, that the fluorine contamination of silicon after etching in HF and washing in cold water is below 10^{13} atoms/cm^2, *i.e.*, about a hundred times less than here. More-

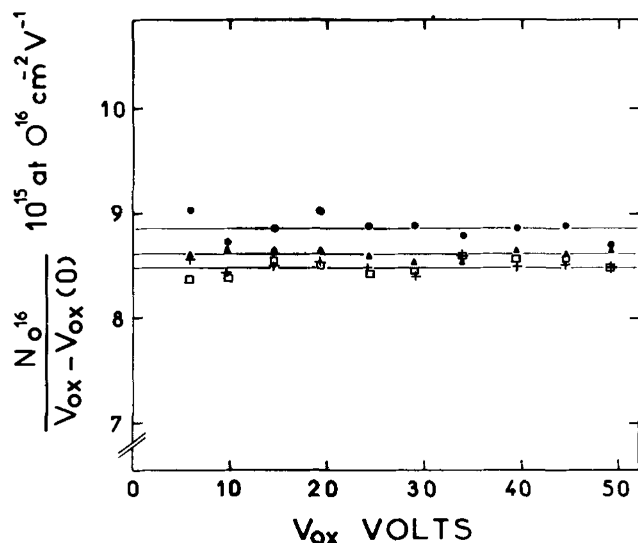

Fig. 6. $N_O/(V_{ox} - V_{ox}$ (□)) as a function of V_{ox} for anodic oxides on Ta submitted to various treatments (same symbols as in Fig. 5).

over, the presence of 1.5×10^{14} fluorine atoms per cm^2 in anodic oxide films on silicon (formed in diethylene glycol) leads to a breakdown voltage smaller by at least a factor of 3 than without fluorine contamination of the oxide, whereas the effect of even higher contaminations on the breakdown voltage seems to be small if any for tantalum. Möller and Starfelt (14) [using a $F^{19}(p,\alpha\gamma)O^{16}$ broad resonance with a quoted sensitivity of 0.01 $\mu g/cm^2$] observed, on the other hand, comparable fluorine contaminations of Zircaloy for various polishing procedures. Barrandon (15) [using the $F^{19}(p,\alpha)O^{16}$ reaction] found very high fluorine contaminations, of the order of 10^{16} atoms/cm^2, of zirconium polished chemically in a $HF\text{-}HNO_3$ bath, the washing procedure being not specified. No other direct measurement of low level fluorine contaminations of metals or semiconductors seems to have appeared in the literature.

The fact that the fluorine left by chemical polishing on the surface of tantalum remains near the oxide-metal interface after anodic oxidation is in good agreement with the observations of Pawel *et al.* (16). These authors demonstrated, using an ion microprobe, that fluorine introduced in the oxide film in the course of anodic oxidation in a fluorine containing aqueous bath has a tendency to migrate towards the oxide-metal interface and to accumulate there. Although the way in which fluorine is introduced here in the film is different, the analogy between the two observations is strong; further experiments are in progress to establish whether fluorine originating in chemical polishing or incorporated during anodic oxidation in fluorine containing solutions behave in a completely similar way from the point of view of atomic transport.

The value found for $V_{ox}(O)$ for chemically polished tantalum at 1 mA/cm^2, -1.3V, is in good agreement with that of Siejka *et al.* (4), i.e., -1.15 ± 0.06V, taking into account our estimated error, ± 0.1V. The identity of the curves $N_O = f(V_{ox})$ for samples washed in cold or boiling water is on the other hand in contrast to the results of Young [Ref. (1), p. 66] who reports capacity measurements and who observes a shift towards negative potentials of the curve $1/C = f(V_{ox})$ for samples not leached in boiling water. This might be due to the presence on the surface of a fluorine containing, oxygen-poor compound, which is practically soluble in hot water only, and which, while causing a negligible potential drop at a current density of 1 mA/cm^2 still contributes to the total capacitance of the film as measured in the frequency region of 1 kHz. The increased adhesion of the oxide films after leaching in boiling water, reported by Young [Ref. (1), p. 68] is clearly not associated with a complete elimination of fluorine. It might be due to a diffusion effect which would change the distribution and (or) chemical state of fluorine in the spontaneous oxide layer. The above-mentioned experiments in progress might shed light on this point.

The behavior of $N_O = f(V_{ox})$ for raw tantalum observed here is similar to that observed by Siejka *et al.* (4). The higher slope of $N_O = f(V_{ox})$ and the shift of $V_{ox}(O)$ for the samples subjected to the double chemical treatment, as compared to those only polished, might be explained by the observation of Halbritter (17), who used the $NH_4F\text{-}HF$ bath described here to treat niobium surfaces. This author observed higher residual skin effect rf-losses in superconducting niobium cavities treated in this way and attributed this effect to grain boundary etching of the metal. In fact, this bath does not seem to attack the metal but might do so preferentially at defects like grain boundaries inducing rather narrow and deep microfissure type corrosion figures. This would increase by the order of 1% the roughness factor and increase from 8.5 to 8.6 dN_O/dV_{ox} (4). This might also explain the shift of $V_{ox}(O)$ by -0.5V, by the effect of filling the narrowest microfissures by oxide at the early stage of the oxidation; this would appear as an increase of the oxygen coverage by a constant ΔN_O, which by shifting $N_O = f(V_{ox})$ upwards results in a shift of $V_{ox}(O)$ towards negative potentials (4) ($\Delta N_O \sim 4 \times 10^{15}$ at.oxygen/cm^2 being equivalent to -0.5V). Scanning microscope measurements might confirm this interpretation. It may be concluded that the presence of 10^{15} at.fluorine/cm^2 near the metal-oxide interface has negligible influence on the oxide growth laws and that the observation of Siejka *et al.* (4) are correct. In particular, the fact that for tantalum $V_{ox}(O)$ is very near to the thermodynamic equilibrium potential for the formation of tantalum oxide is confirmed, the observed shifts of $V_{ox}(O)$ for some surface treatment procedures being probably artifacts.

Work is in progress to improve the double chemical treatment above so as to obtain in a simple fashion fluorine free and still satisfactorily flat tantalum surfaces. The electrochemical polishing procedure described by Diepers *et al.* (18), which seems to give such surfaces for niobium, will be investigated for fluorine contamination. Extension of the present work to niobium is considered with potential applications to the preparation of the surface of niobium superconducting rf-cavities as studied, among others, by Kneisel *et al.* (19).

Acknowledgments

The authors would like to thank Dr. J. Siejka for his continuous interest in this work and for enlightening discussions. They are indebted to Dr. J. Halbritter for the private communication of the results quoted. The contribution of Dr. J. P. Nadai to the interpretation of the excitation curves in Fig. 4 was most appreciated. Mrs. E. d'Artemare and E. Girard provided valuable assistance for the handling of problems related to the automatic energy scanning of the beam and to the electronic set up.

This work was supported by the Centre National de la Recherche Scientifique (RCP No. 157), the DRME, and the DGRST.

Manuscript submitted May 22, 1972; revised manuscript received July 24, 1972. This was Paper 88 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Luminescent Properties of Thiogallate Phosphors

II. Ce^{3+}-Activated Phosphors for Flying Spot Scanner Applications

T. E. Peters*

GTE Laboratories Incorporated, Waltham, Massachusetts 02154

ABSTRACT

The cathodoluminescence emission and decay properties of MGa_2S_4:Ce,Na (M^{2+} = Ca, Sr, Ba) phosphors were investigated to determine their suitability for use in flying spot cathode ray tubes. The thiogallate phosphors exhibit radiant efficiencies as high as 7.0% and their fluorescence decays to 1% of initial brightness in 1.3-1.55 μsec. Strontium thiogallate phosphors with decay times as short as 0.6 μsec were obtained by compositional modifications. Maintenance measurements indicate that $SrGa_2S_4$:Ce, Na is more stable in CRT applications than $Ca_2Al_2SiO_7$:Ce.

A previous publication (1) presented crystallographic data for thiogallate compounds of the general formula MGa_2S_4 (where M = Ca^{2+}, Sr^{2+}, Ba^{2+}, Pb^{2+}, Eu^{2+}, [Na^{1+}, La^{3+}] and [Na^{1+}, Ce^{3+}]) and described some of the luminescence properties of the unactivated and the Ce^{3+} or Eu^{2+} activated alkaline earth compounds. In this report the cathodoluminescence emission and decay characteristics of the Ce^{3+}-activated phosphors are described, particularly as they relate to the use of these materials in flying spot cathode ray tubes.

The fluorescence decay times of Ce^{3+}-phosphors are always very short (~0.1 μsec) because allowed $^2D \rightarrow {}^2F$ electric dipole transitions are involved in the emission process. Short decay phosphors that fluoresce in the visible region of the spectrum are of particular interest for use in certain types of flying spot scanner tubes that are employed as playback transducers for color television (2). As reported previously (1) the Ce^{3+}-activated alkaline earth thiogallates fluoresce in the blue spectral region and consequently an investigation of their cathodoluminescence emission and decay properties was conducted to determine their suitability for use in this type of device.

Experimental

Phosphor preparation.—The starting materials employed in the preparation of the Ce^{3+}-phosphors were high purity alkaline earth carbonates, Ga_2O_3 (99.99%) and CeO_2 (99.9%). All reagents were subsequently converted to their respective sulfides by reaction at 900°-1200°C in a stream of H_2S gas.

It was found desirable to provide valence compensation for the Ce^{3+} ion when it substitutes for the divalent alkaline earth in the thiogallate lattice. Initially, monovalent sodium was introduced in the form of NaCl to provide compensation according to the general formula $M_{1-2x}Ce_xNa_xGa_2S_4$. In later experiments it was found that the use of 0.035 moles Na_2SO_4/mole MGa_2S_4 in excess of that required for electroneutrality resulted in improved activator incorporation and valence compensation.

Stoichiometric quantities of the various sulfides, together with NaCl or Na_2SO_4, were thoroughly mixed by grinding in a glass mortar and the resulting blend was subjected to a solid-state reaction at 900°-950°C for 2 hr in H_2S. The phosphor cake was then mortared (NaCl compensation) or washed (Na_2SO_4 compensation) and sieved prior to evaluation.

Measurements.—Standard analytical techniques were employed to monitor the purity and stoichiometry of the sulfide reagents and finished phosphors. X-ray powder diffraction was used to ascertain formation of the thiogallate compounds.

Emission and excitation spectra are given in terms of relative energy and relative energy efficiency. Absolute radiant efficiencies under cathode ray excitation (η_{cr}) were determined in a manner analogous to that described by Bril and Klassens (3).

Relative efficiency values (η_{cr} Rel.) were obtained by comparing the integrated area under the spectral energy distribution curves to that of selected thiogallate and NBS-1021 phosphors of known absolute efficiency.

Blue brightness levels were measured under conditions simulating those found in a color video playback system employing flying spot scanners (2). Phosphor-coated conducting glass slides were placed in a demountable CRT and excited with a 25 kV-100 μA electron beam which was scanned at the normal TV rate over a 2¼ × 3 in. raster. The emission was detected by a Gamma photometer equipped with a Wratten No. 47B filter.

Cathodoluminescence decay times were measured by pulsing a 20 kV electron beam of a 5 in. cathode ray tube at a rate of 60 Hz with a pulse duration of 100 nsec. The fluorescence was detected by a photomultiplier tube and displayed on an oscilloscope.

Phosphor maintenance studies were also conducted on the sealed 5 in. CRT's using excitation conditions identical to those employed for the blue brightness measurements.

Thermoluminescence curves were obtained by cooling the phosphor to liquid nitrogen temperatures in an evacuated quartz chamber, irradiating with a 3650Å lamp and then increasing the temperature at ~8°C/min, while monitoring the emission with a photomultiplier tube.

Results and Discussion

The cathodoluminescence properties of NaCl (Na/Ce = 1) compensated $M^{2+}Ga_2S_4$:Ce,Na phosphors are compared to those of $Ca_2Al_2SiO_7$:Ce, a commercial flying spot scanner material (Table I). The radiant efficiencies of the calcium and strontium thiogallates are greater than that of the barium analog and are comparable to that of the $Ca_2Al_2SiO_7$:Ce. It is to be emphasized that the η_{cr} values given in Table I were obtained on samples whose syntheses were not optimized and are intended only to illustrate the relative performance of analogous alkaline earth compositions. Later in the text it will be pointed out that the η_{cr}

Key words: fast decay, short persistence.

of $SrGa_2S_4$:Ce,Na can be improved substantially by modifications in the preparation method.

Two decay times, τ and β, are given in the last two columns of Table I. The fluorescent lifetime τ, is the time required for the fluorescence to decrease from its initial value I_0 to I_0/e. This assumes that the decay curve is represented by an exponential decay $I \propto e^{-at}$ (where $a = \tau^{-1}$). In many cases, however, the decay curves of Ce^{3+}-phosphors exhibit a nonexponential tail. A more meaningful decay value, particularly for the application in question, is one which includes the nonexponential part of the curve, *i.e.*, the time required for the fluorescence to decrease to 1% I_0. This value is designated as β in Table I and in the subsequent text. Although the β values in Table I show the thiogallates to have significantly longer decay times than the aluminosilicate, this characteristic alone does not preclude their use in flying spot scanner tubes. The decay times are of a magnitude which would permit electronic compensation to obtain acceptable performance (2). Thus the Ce^{3+}-activated alkaline earth thiogallates are potentially useful flying spot scanner materials.

The τ values in Table I indicate that the exponential portions of the decay curves are similar for the aluminosilicate and thiogallate phosphors. Larger differences in the decay rates of the phosphors occur in the nonexponential part of the curve. This is evident from the divergence of the β values and can be clearly seen in the representative decay curves given in Fig. 1. Figure 1 also indicates that the decay of $Ca_2Al_2SiO_7$:Ce is not entirely exponential. Bril *et al.* (4) have shown that $Ca_2Al_2SiO_7$:Ce and many other Ce^{3+}-activated phosphors exhibit long decay components that deviate significantly from the exponential law. They suggested that the afterglow might be due to the storage of excitation energy in traps provided by defects or impurities. In order to test this hypothesis as it relates to the thiogallate phosphors, thermoluminescence measurements were performed on $Ca_2Al_2SiO_7$:Ce and several $SrGa_2S_4$:Ce,Na phosphors and the results are presented in Fig. 2. In the figure the relative heights of the thermoluminescence peaks do not constitute a meaningful measure of the concentration of trapping species because the surface area and quantity of phosphor varied from sample to sample. However, the curves do yield qualitative information as to trap depth and distribution. In accord with the hypothesis the thermoluminescence curve for the aluminosilicate phosphor indicates a broad distribution of deep lying traps centered around 80°C. The curves for the thiogallate phosphors, on the other hand, exhibit only one thermoluminescence peak centered at −140°C. This indicates that only shallow traps are present that should not be populated at room temperature. Thus a simple trapping process does not seem to explain the nonexponential behavior of the decay of Ce^{3+} fluorescence in $SrGa_2S_4$.

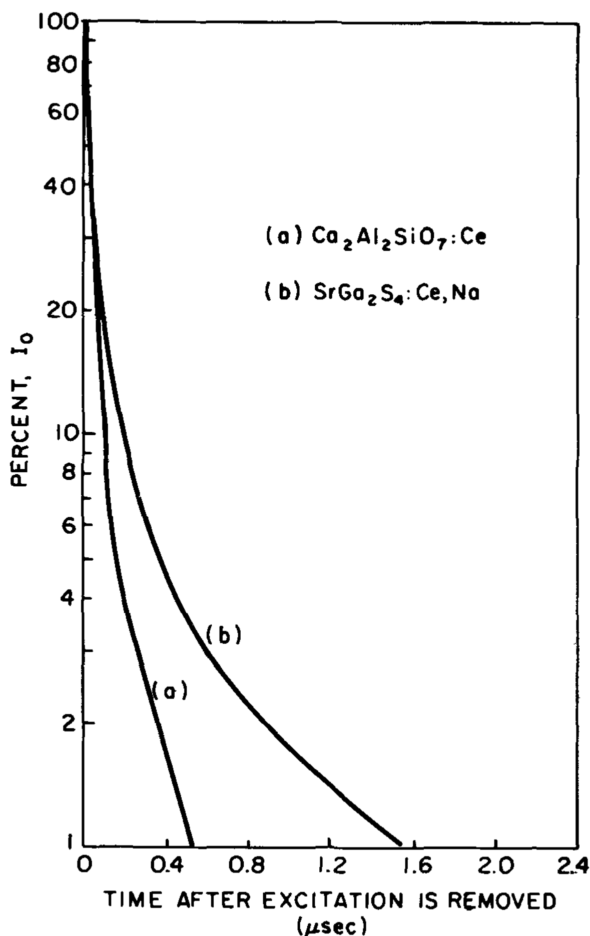

Fig. 1. Decay of fluorescence of Ce^{3+} phosphors

The decay of the Ce^{3+} fluorescence in the $SrGa_2S_4$:Ce,Na phosphor can be shortened by (*i*) concentration quenching, (*ii*) improved valence compensation, (*iii*) energy transfer to Nd^{3+}, and (*iv*) transition metal quenching. This is shown in Fig. 3 where the decay to 1% I_0 (β) is presented as a function of [Ce^{3+}] for $SrGa_2S_4$:Ce,Na, $SrGa_2S_4$:Ce,Nd,Na, and $SrGa_2S_4$:Ce,Na,Co. In all of the phosphors examined a reduction in the decay was effected by increasing the [Ce^{3+}] beyond 2 atomic per cent (a/o) which is optimum for brightness; the reduction in decay attributed to concentration quenching is also accompanied by a decrease in emission intensity and a slight shift in λ_{max} to lower energy.

The effect of improved valence compensation on the Ce^{3+} decay is indicated by a comparison of (a) and (b) in Fig. 3. These data are for two series of $SrGa_2S_4$:Ce,Na phosphors prepared with NaCl (Na/Ce = 1) and Na_2SO_4 (Na/Ce = 1 + 0.07/Ce) respectively, as the source of the monovalent compensating ion. It can be seen that substantially smaller β values result when an excess of the compensating ion is included in the phosphor formulation. Similar reductions in β have been observed when other sodium compounds have been employed in the synthesis provided there is an excess of Na^+ over that required for electroneutrality. Sodium sulfate is preferred, however, because it also serves as a mineralizer which improves the uniformity and crystallinity of the phosphor.

The effect of Nd^{3+} coactivation on the decay of Ce^{3+} fluorescence in $SrGa_2S_4$:Ce,Nd,Na is given by (c) in Fig. 3. The observed shortening of the decay time is attributed to $Ce^{3+} \rightarrow Nd^{3+}$ energy transfer. Energy transfer between these ions has been reported by Gandy *et al.* (5) in a Ce,Nd coactivated silicate glass.

Evidence for the $Ce^{3+} \rightarrow Nd^{3+}$ energy transfer in $SrGa_2S_4$:Ce,Nd,Na is given in the excitation spectra shown in Fig. 4(a-c). Comparison of the excitation spectra for Nd^{3+} emission at 900 nm shows that there

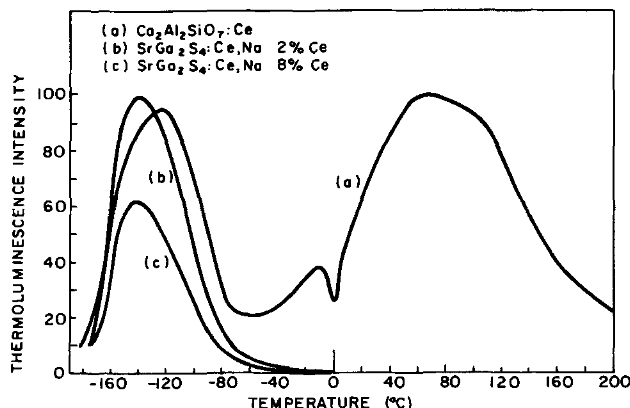

Fig. 2. Thermoluminescence of Ce^{3+} phosphors

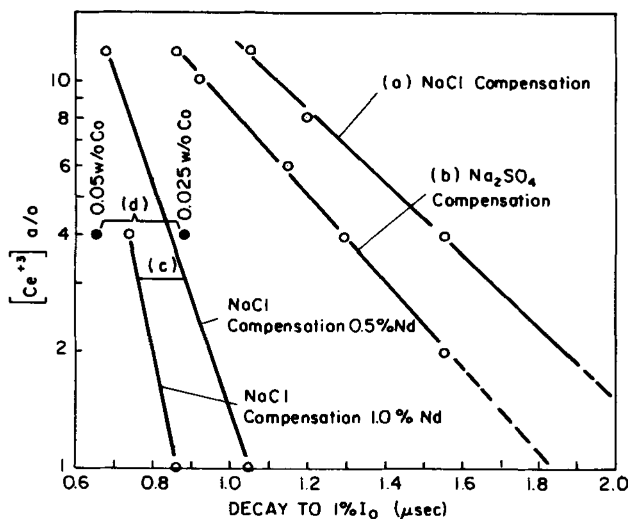

Fig. 3. Decay time β vs. $[Ce^{3+}]$ for $SrGa_2S_4$:Ce,Na phosphors

is a strong absorption band at 410 nm in the coactivated phosphor (Fig. 4a) which is absent in the material activated only by Nd^{3+} (Fig. 4b). That this band is due to Ce^{3+} absorption can be seen in the excitation spectra for the 460 nm Ce^{3+} emission of $SrGa_2S_4$:Ce,Na (Fig. 4c). Thus excitation into the Ce^{3+} band at 410 nm produces Nd^{3+} emission at 900 nm confirming $Ce^{3+} \rightarrow Nd^{3+}$ transfer in the $SrGa_2S_4$:Ce, Nd,Na phosphor.

Figure 3(d) depicts the β values for sodium sulfate compensated $SrGa_2S_4$:Ce,Na(4 a/o) phosphors containing 0.025 and 0.05 w/o cobalt. A comparison of these values with that of the cobalt free 4 a/o Ce^{3+} phosphor shows that extremely small concentrations of cobalt can reduce the decay time of $SrGa_2S_4$:Ce,Na by approximately 50-70%. Similar reductions in decay resulted when phosphors were prepared with 0.01-0.1 w/o of iron or nickel.

It is believed that the principal effect of the transition metal ion is to increase the probability of radiationless transitions to the ground state. In support of this contention it is noted that the decay curves of the cobalt quenched phosphors exhibit a nonexponential tail similar to that of the unquenched $SrGa_2S_4$:Ce, Na and that the increase in decay rate manifested itself in both the exponential and nonexponential parts of the curve. Furthermore, the intensity of the Ce^{3+} fluorescence, for phosphors containing up to 0.1 w/o Co, was found to decrease in proportion to the increase in decay rate.

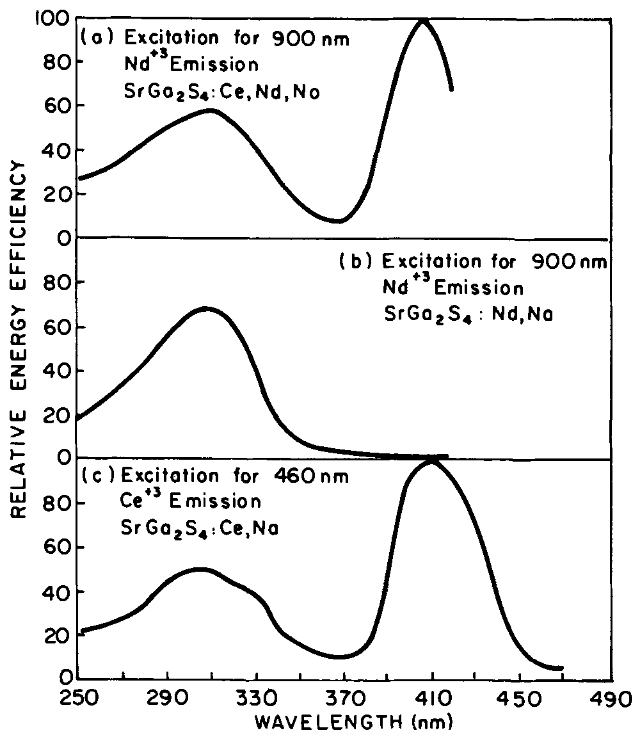

Fig. 4. $Ce^{3+} \rightarrow Nd^{3+}$ energy transfer in $SrGa_2S_4$:Ce,Nd,Na

Of the four methods found effective in reducing the decay of $SrGa_2S_4$:Ce,Na only improved valence compensation results in an increase rather than a decrease in cathodoluminescence efficiency. For example, a $SrGa_2S_4$:Ce,Na (4 a/o Ce) phosphor prepared with excess Na_2SO_4 exhibits an η_{cr} Rel. of 6.5% as compared to 5.0% for a similar phosphor (see Table I) compensated with NaCl (Na/Ce = 1).

In a color flying spot scanner system both the efficiency and spectral energy distribution of the phosphor must be considered because it is the response of the systems' photodetectors that constitute the TV signal in video playbacks. Relative brightness measurements were made under conditions simulating the blue detector response in a color flying spot scanner system and the results are given in Table II.

In Table II the blue brightness of several of the phosphors described in Fig. 3 are compared to that of a sodium sulfate compensated $SrGa_2S_4$:Ce,Na (η_{cr} Rel. = 7.0%). Similar data is reported for a $Ca_2Al_2SiO_7$:Ce phosphor that is employed as the blue screen component in a commercial color flying spot scanner tube. The best brightness levels were recorded for the $SrGa_2S_4$:Ce,Na phosphors activated with 2-4 a/o Ce^{3+}. These materials yield a blue detector response which is 1.5-2.0 times that of the $Ca_2Al_2SiO_7$: Ce. The remaining thiogallates in the table provide examples of the brightness levels available from phosphors that employ concentration quenching, transition metal quenching, or energy transfer to improve their decay properties. In general these materials exhibit somewhat lower brightness levels than the $Ca_2Al_2SiO_7$: Ce.

Trivalent cerium-activated phosphors are frequently found to be unstable in cathode ray tube operation. For example, losses in efficiency have been reported for $Ca_2Al_2SiO_7$:Ce (6), $Ca_2MgSi_2O_7$:Ce (7), and (Y,Gd,La)PO_4:Ce (8) and we have observed similar losses for the recently described Y_2SiO_5:Ce (9). The $SrGa_2S_4$:Ce,Na phosphor is remarkably stable in this respect as illustrated by the maintenance data given in Fig. 5. In this figure the initial intensity of each of the phosphors has been normalized to 100%. The thiogallate phosphor loses only 10% of its initial intensity in 10 hr, while the aluminosilicate phosphor, shown here for comparison, suffers an intensity loss of 50% in the same time period.

Phosphor stability is an important consideration in the manufacture of a flying spot scanner tube because drastic changes in brightness frequently make it necessary to age the tube until a relatively stable level of emission intensity is achieved. Use of the $SrGa_2S_4$:Ce,Na phosphor could eliminate or curtail this costly process. Furthermore, the thiogallate phos-

phors exhibit an even greater brightness advantage when compared to an aged $Ca_2Al_2SiO_7$:Ce. Considering the data in Table II it is apparent that some of this brightness advantage could easily be traded for a somewhat faster decay by employing transition metal or concentration quenching.

Summary

The cathodoluminescence emission and decay properties of $M^{2+}Ga_2S_4$:Ce,Na (M^{2+} = Ca,Sr,Ba) phosphors have been investigated to determine their suitability for use in a version of the flying spot scanner tube that is employed as a playback transducer for color television. Relative efficiencies (η_{cr} Rel.) as high as 7.0% have been recorded for optimum $SrGa_2S_4$:Ce,Na compositions. The fluorescence of the $M^{2+}Ga_2S_4$:Ce,Na phosphors decays to 1% of initial intensity (β) in 1.3-1.55 μsec. The decay of Ce^{3+} fluorescence in $SrGa_2S_4$ can be shortened by (*i*) improved valence compensation, (*ii*) concentration quenching, (*iii*) energy transfer to Nd^{3+}, and (*iv*) transition metal quenching. Fluorescence decay times (β) as short as 0.6 μsec have been achieved by application of one or more of these mechanisms. Measurements conducted under conditions simulating the blue detector response in a color flying spot scanner system indicate that the brightness of several $SrGa_2S_4$:Ce,Na compositions exceeds that of the blue screen component, $Ca_2Al_2SiO_7$:Ce, employed in a commercial color flying spot scanner tube. Phosphor maintenance measurements also show the $SrGa_2S_4$:Ce,Na to be much more stable than the aluminosilicate in CRT operation.

Acknowedgments

The author wishes to express his appreciation to R. Amster who initiated work on $Ce^{3+} \rightarrow Nd^{3+}$ energy transfer, to T. Sisneros for brightness measurements, and to J. Ragusin for technical assistance. Thanks are also due to K. Speigel of GTE Sylvania's Electronic Tube Division who provided much of the decay data and to F. Palilla and S. Natansohn for manuscript review.

Manuscript submitted May 19, 1972; revised manuscript received July 24, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Formation of Ultrathin Oxide Films on Silicon

Francis P. Fehlner*

Corning Glass Works, Research and Development Laboratories, Corning, New York 14830

ABSTRACT

Thin silicon dioxide films on silicon have been grown by thermal oxidation in dry oxygen at 400°C. The kinetics of the process and the effect of both impurities and ultraviolet irradiation have been examined and compared with models of the oxidation process.

Silicon dioxide films, in the range of 5-50Å thick, are useful in the fabrication of silicon tunneling devices. Examples of such devices include the memory field effect transistor (1), and the tunneling-mode transistor (2). In both cases, one needs a uniform, high-quality film which is essentially transparent to electrons under the influence of a high electric field.

Prior work (3) has shown that the thermal oxidation of silicon at one atmosphere occurs very slowly when compared with that of metals. As a result, temperatures in the range of 600°C have been utilized (4) to obtain oxide thicknesses in the range 15-60Å. Higher temperatures have also been used in conjunction with a reduced partial pressure of oxygen (5, 6) or with an oxide of nitrogen (7, 8).

Thin oxide films have been observed to grow on silicon at temperatures lower than those noted above. At room temperature, approximately one and one-half monolayers of oxide grow in 2000 min at 40 Torr oxygen (9). In air, a thicker film is formed (10). Boiling, deionized water containing dissolved oxygen forms films approximately 13Å thick (11). Nitric acid has also been found useful in forming 10-20Å thick oxide films on silicon (12).

No reports on the rate of oxidation in the temperature range 100°-600°C have been found in the literature. Since it appears to be the range in which 15-30Å films can be conveniently grown in oxygen, an investigation of the growth rate of silicon dioxide on silicon at 400°C in one atmosphere of dry oxygen has been carried out. The results are reported below as a function of impurity content and ultraviolet irradiation.

Key words: oxidation, silicon surfaces, silicon dioxide, low-temperature oxidation, MNOS devices, tunnel transistors.

Experimental Procedure

MOS-quality silicon wafers [6-9 ohm-cm, n-type, (111)], as supplied by Monsanto Corporation, were cleaned as follows. Approximately 1μ of oxide was grown by wet oxidation at 1050°C in an MOS-quality tube furnace. The wafers were stored in this form until needed. The oxide was eventually stripped in a solution of four parts deionized (DI) water to one part 48% hydrofluoric acid (electronic grade) until clean as determined by ellipsometer measurements. The final rinse was for 15 min in DI water, after which the ellipsometer showed a 4.9 ± 0.5Å film remaining on the silicon surface.

A saturated iodine-anhydrous methanol solution (13) was substituted for the water rinse in some cases, in an attempt to remove the residual fluorine which is known to adhere to silicon wafers cleaned in HF (14). The iodine, in turn, was removed by a 25 min bake at 550°C in dry argon.

After an experiment had been completed, the wafers were reclaimed by a one minute dip in 1:4 HF/H_2O and a 15 min rinse in DI water.

Oxidation was carried out in one of two reactors. Both utilized rf-heated, silicon carbide coated, graphite susceptors. They differed in the construction of the surrounding quartz tube.

The first reactor, shown in Fig. 1A, consisted of a quartz tube closed at the ends with steel plates and silicone rubber gaskets. The adhesive (Dow Corning 732RTV) used to attach the rubber to the steel later proved to be a source of acetic acid (HAc), so a second system was constructed. This is shown in Fig. 1B. The closures on this quartz tube were quartz end caps.

The thermocouple which controlled the susceptor temperature was Chromel-Alumel encased in a stainless-steel sheath.

Gas was supplied via stainless steel tubing as shown in Fig. 1C. Matheson ultrahigh purity argon and oxygen were used. A 2 liter water bubbler held at room temperature was used to humidify the gas for some experiments.

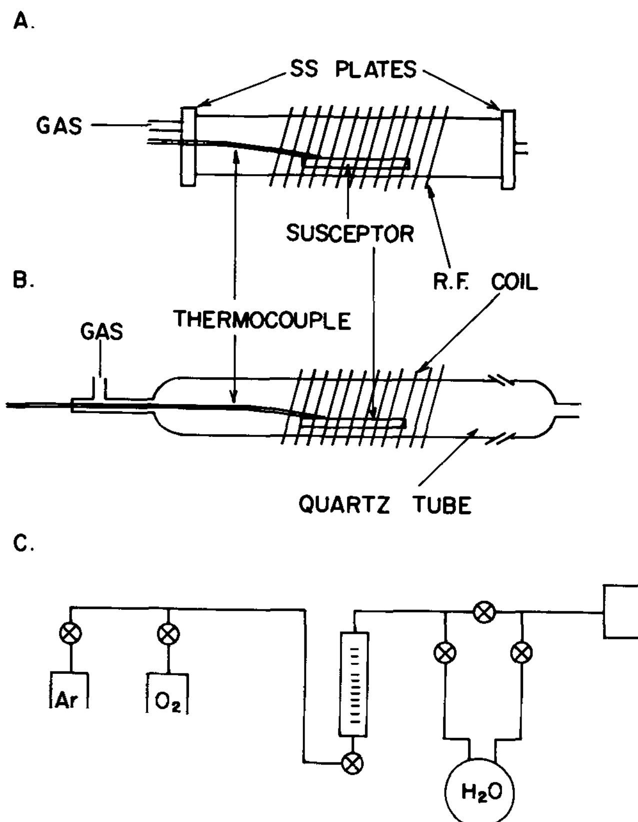

Fig. 1. Apparatus used for oxide growth at 400°C. A, Initial setup; B, final setup; C, gas inlet assembly.

Film thicknesses were measured with an ellipsometer, a Rudolph Model 43603-200E, using 546 mμ radiation and 70° angle of incidence. Polarizer-analyzer readings were reduced using a time-shared computer program written by J. Conragan. The measurements were reproducible to ±1Å.

The silicon substrate optical constants were taken to be 4.05-0.027 i (15). The refractive index of bulk SiO_2, 1.46, was rounded off to 1.5 on the assumption that the silicon-rich interface layer would have a higher refractive index than bulk silica. However, it proved difficult to check this assumption, since the oxide thickness determined from the ellipsometer data was insensitive to small changes in refractive index.

Results

The study of silicon oxidation at 400°C proceeded only after the question of clean, reproducible starting conditions had been settled. The first apparatus used, shown in Fig. 1A, turned out to be contaminated with acetic acid vapors emanating from the silicone rubber cement used to attach the gaskets to the metal end plates. Although deemed unfortunate at the time, this event later proved useful in showing that silicon oxidation can be an impurity-controlled process, as concluded by Revesz and Evans (16).

The presence of acetic acid was detected by a change in the rate of oxidation after continued use of the apparatus. The initial results are shown in Fig. 2 by X's and squares. An induction period of 60 min was followed by a logarithmic growth rate. Irradiation of the silicon using a medium-pressure mercury arc (Illumination Industries Inc. 202) resulted in an accelerated rate of film growth, perhaps due to acetic acid photolysis and the incorporation of hydrocarbons in the oxide film. Acetic acid is known to yield methyl radicals during photolysis (17).

An increase in water vapor content caused an increase in the photolytic effect. This behavior can be explained by the fact that moisture leads to faster curing of the silicone rubber cement, with concomitant faster release of acetic acid.

After a time, the initial results could not be reproduced, due to depletion of the source of contamination. The induction period lengthened to 100 min and the rate of logarithmic oxidation decreased. Little or no effect due to water vapor or irradiation could be found. This result is shown by the circles in Fig. 2.

The sudden change in behavior was difficult to explain, until every variable in the system had been checked. Water vapor, cleaning procedures, and gas purity were all discounted as causes. The initial results could be reproduced only when the gaskets were reglued. The presence of fresh acetic acid vapor from the silicone cement was the only addition to the system which gave the original results.

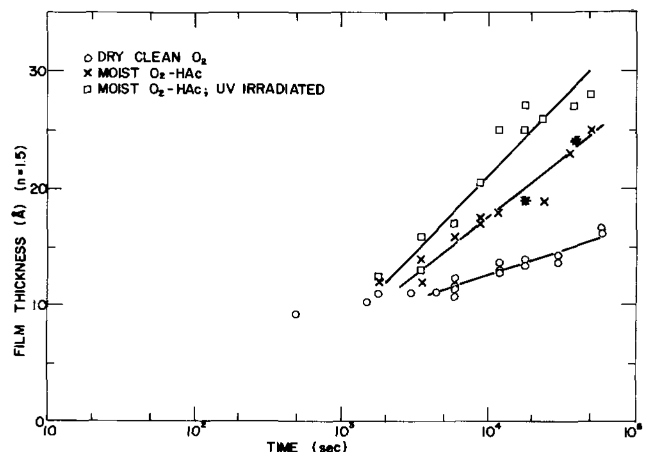

Fig. 2. Oxidation of silicon at 400°C

The problem, once found, was eliminated by constructing a new system as shown in Fig. 1B. Quartz end caps eliminated the problem of silicone rubber. All other parts of the system remained the same.

Excellent results were obtained at 400°C, as shown in Fig. 3. No point on the graph is more than 1Å off the line. The use of (100) n-type or (111) p-type wafers gave the same results at 1200 sec as (111) n-type silicon. Even the displacement of the original fluoride layer by an iodine-dip-and-bake gave no change in oxidation rate, as also found by van der Meulen (5).

It should be noted though, that even the oxide film grown under the more carefully controlled conditions contained impurities. Preliminary results of Auger spectroscopy showed that ~0.01 monolayers of fluorine and a trace of copper were present in the oxide films studied in the present work. Presumably, hydrogen and carbon were also present.

Discussion

Revesz and Evans (16) conclude that the oxidation of silicon is an impurity-controlled process. Their work is confirmed by the results of the present study. The greater the degree of contamination, as shown in Fig. 2, the greater the rate of film growth. Dry, clean oxygen gave a growth rate at 400°C of 4.2 Å/decade. The addition of a small amount of moisture and acetic acid raised the rate to 6.8Å/decade. The combination of moist acetic acid and ultraviolet radiation gave a rate of 13.1 Å/decade.

The results of the reaction of silicon with oxygen under clean dry conditions at 400°C are compared in Fig. 3 with the results of Goodman and Breece (4) at 600°C and Archer and Gobeli (9) at 25°C. Goodman and Breece originally interpreted their work in terms of a linear process, but it will be shown below that a logarithmic plot fits just as well for dry oxidation.

Cabrera and Mott (18) give an expression for estimating the upper temperature limit for application of the inverse logarithmic growth law. For aluminum, they found an upper temperature limit of approximately 300°C. For silicon, the limit is higher.

A graph of current density *vs.* applied field for anodized silicon (19) was compared with the theoretical expression of Cabrera and Mott [p. 180 of Ref. (18)]. An upper temperature limit for inverse logarithmic growth of approximately 500°C was calculated using only data at the highest fields (where anodization was occurring) and an oxidation efficiency of 1%. An ionic jump distance of 2.8Å was also calculated. As a result of these findings, an attempt to present the results of Goodman and Breece in inverse logarithmic form seemed justified.

However, direct logarithmic kinetics also had to be considered. Since silicon dioxide is an excellent network former in glassy systems, the work of Fehlner and Mott (20) would predict growth by anion transport at constant field, leading to direct logarithmic kinetics

$$x = C + D \log (t + t_o) \quad [1]$$

where $C = \frac{(qaF/2) - W}{\mu} + \frac{2.3\, kT}{\mu} \log \frac{(\mu N \Omega \nu)}{kT}$, $D = \frac{2.3\, kT}{\mu}$, x = oxide thickness, t = time, T = temperature, N = the number of anions in position to move across the oxide, Ω = volume of oxide per ion, ν = frequency of vibration, W = barrier to ion motion, q = charge on the ion, a = jump distance of the ion, F = field across the oxide (V/x), μ, k, t_o = constants.

The data from Fig. 3 have been plotted according to Eq. [1] and are shown in Fig. 4. The value of t_o corresponding to the initial oxide thickness was estimated to be 1200 sec. Although reasonable straight-line plots resulted and an increase in μ with T was found, it proved impossible to calculate a positive value of $W - qaF/2$ in Eq. [1] from the data in Fig. 4. As pointed out by Fehlner and Mott, straight-line plots are insufficient to prove the validity of any particular rate law. One must be able to calculate physical parameters which have reasonable values.

Since the direct logarithmic expression was not completely applicable, an inverse logarithmic plot was tried. This is shown in Fig. 5 for the expression

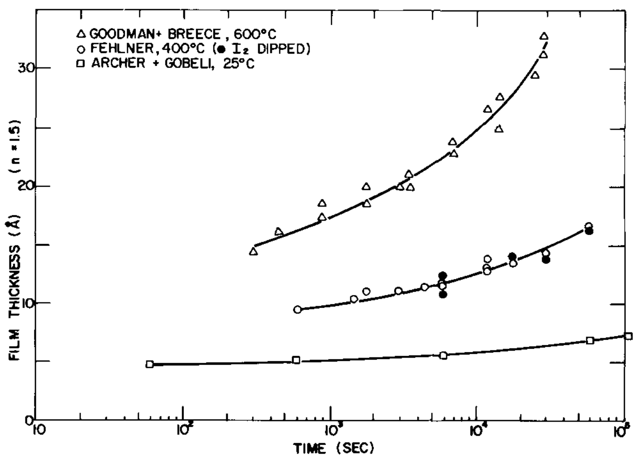

Fig. 3. Dry oxidation of silicon

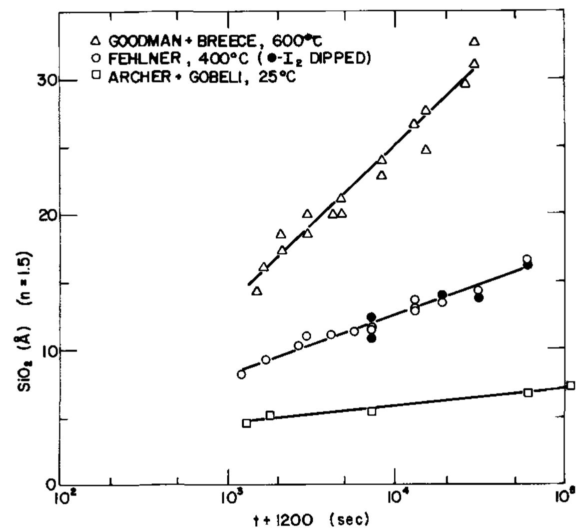

Fig. 4. Figure 3 replotted according to direct logarithmic kinetics, taking into consideration the presence of an initial film.

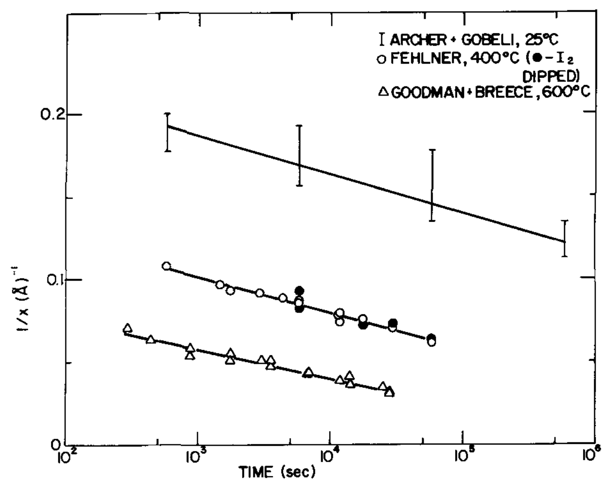

Fig. 5. Data for the dry oxidation of silicon plotted according to the inverse logarithmic law.

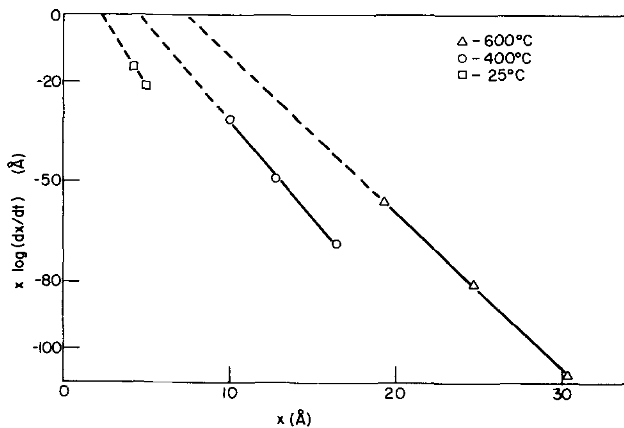

Fig. 6. Rate data for the low-temperature oxidation of silicon tested against the inverse logarithmic law.

$$\frac{1}{x} = A - B \log t \quad [2]$$

where $A = \frac{4.6W}{qaV} + \frac{4.6kT}{qaV} \log\left(\frac{x}{N\Omega\nu}\right)$

and $B = \frac{4.6kT}{qaV}$

as derived by Hauffe (21).

Again, reasonable straight-line plots resulted, similar to those found by Ligenza (22) for the low-temperature oxidation of germanium. Following Ligenza, a plot of $x \log (dx/dt)$ *vs.* x (see Fig. 6) was used to find a value of V assuming $q = 4e$ and $a = 5$Å. This value was checked by determining V directly from Eq. [2] and the data in Fig. 5. The results are shown in Table I. The values calculated from Fig. 5 are considered to be more accurate, since the determination of dx/dt was done graphically. The room-temperature values are only approximate due to scatter in the data of Archer and Gobeli. The values of V so determined agree with work function changes found for a similar system, oxygen on germanium (23).

Again following Ligenza, an attempt to determine the activation energy W was made from a plot of the slopes in Fig. 6 *vs.* $1/T$. The three points which were available did not fall on a straight line. This would agree with the results found by Ligenza for germanium, which implies that the activation energy is temperature dependent. However, it should be noted in Eq. [2] that W is also a function of x and V. As such, it is not a simple matter to graphically find the temperature dependence of W.

Since it was possible to calculate reasonable values of V from the data presented in inverse logarithmic form, it appears that the Cabrera-Mott mechanism is applicable. It is probable then that the oxidation of silicon at low temperatures proceeds mainly by cation migration under conditions of constant voltage (20).

At high temperatures, anions are the mobile species (24, 25) during silicon oxidation, but during anodization at low temperatures, anions and/or cations can be mobile (26). The determining factor appears to be the field applied across the oxide. At low fields, Schmidt and Ashner (26) have shown that hydroxyl ions move from the oxide surface into the oxide. Conversely, at high fields, cations move from the silicon interface through the oxide. A less striking example of the same type of behavior is found with aluminum (27) in which a greater fraction of cations move as the field is increased. Brook *et al.* (28) have discussed a similar phenomenon, observed during the anodization of zirconium and aluminum. They propose that the relative rates of movement of two differently charged ions in a growing oxide invert as a function of applied field.

Table I. Calculated values of voltage across thin oxide films on silicon

Oxidation temperature, °C	Voltage across oxide	
	Calculated from the slope of Fig. 5 (18)	Calculated from the differential plot (22)
25	0.2	0.11
400	0.25	0.35
600	0.33	0.60

The same reasoning may explain the behavior of silicon during low-temperature oxidation. At low temperatures, charge separation induces a large field across the oxide such that cation migration would be favored. At higher temperatures, the effect of the field is lessened when compared with thermal effects, so that anion movement can predominate. It must not be overlooked though, that as with aluminum, both anions and cations may be mobile and only the ratio of the two changes as a function of temperature and applied field. Even so, theories which treat only one mobile species would still be valid in the extremes.

The absence of any noticeable effect of ultraviolet irradiation on the oxidation rate of silicon under dry, clean conditions may also be related to the thesis that oxidation is an impurity-controlled process. However, Cabrera (29) reported that the rate of aluminum oxidation in air at room temperature is doubled under the influence of ultraviolet irradiation. Oren and Ghandhi (30) have also shown that ultraviolet light can affect the oxidation of silicon at high temperatures. Apparently, both sets of experiments were done under clean, dry conditions. No explanation for the discrepancy between these results and the present work is yet available.

Conclusions

The kinetics of the oxidation of silicon at relatively low temperatures have been analyzed according to the models of anion and cation movement. The best agreement has been found with the cation model, which implies that both cations and anions can be mobile in silicon dioxide depending on the temperature and applied field. The present work cannot resolve this question completely, especially in view of the effect of impurities. It will be necessary to perform marker experiments similar to those of Davis *et al.* (27) and Siejka *et al.* (31) before the complete mechanism of oxide growth on silicon can be resolved.

Acknowledgments

The aid of J. Conragan and O. W. Kendall in carrying out this project is greatly appreciated.

The experimental portion of this work was carried out at the Signetics Corporation, Sunnyvale, California.

Heteroepitaxial Thermal Gradient Solution Growth of GaN

R. A. Logan and C. D. Thurmond*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The growth of single-crystal epitaxial layers of GaN onto (0001) oriented sapphire substrates from the liquid phase is shown to require three conditions: (*i*) the partial pressure of NH_3 in the H_2 ambient, P_{NH_3}, greater than the equilibrium pressure, (*ii*) the growth melt positioned in a thermal gradient to transport the dissolved GaN to the growth interface, and (*iii*) the control of nucleation by the addition of Bi to the growth melt. Studies of growth at temperatures from 850° to 1050°C show that the layer thickness, t, is approximately linear in time and varies with growth temperature and atom fraction of Ga, x_{Ga}, in the growth melt. When $t \gtrsim 30\mu$, internal cracks in the $[1\bar{1}0]$ basal plane hexagonal directions develop at the layer-substrate interface and for $t \gtrsim 75\mu$ they propagate to the surface and are thermally etched. A description is given of the interaction of liquid Ga with NH_3 as a function of T and P_{NH_3}. The low solubility of GaN in Ga (3×10^{-5} mole fraction at 1150°C) prevents useful growth by slow cooling of the melt. The inability to change the electron concentration, n, with Zn doping and the decrease of n with x_{Ga} in the growth melt support but do not unambiguously confirm the model that the native donor is a nitrogen vacancy.

The bandgap of GaN is both wide (~3.4 eV at 300K) and direct (1), so that GaN is potentially an extremely useful electroluminescent material. Single-crystal growth has been achieved by several vapor deposition techniques: by reacting the volatile Ga species GaCl with NH_3 to form epitaxial layers on sapphire (2), by heating GaN in an atmosphere of NH_3 to form GaN needles possibly by virtue of the volatile oxide Ga_2O (3), by thermally decomposing a volatile gallium bromide ammonia complex (4), or by reacting Ga with N generated from N_2 by gaseous discharge (5) or rf fields (6). The failure to obtain p-type crystals to date may imply a limited solubility of the common acceptors in the face of a highly soluble unidentified donor impurity or of compensation of the acceptors by a native donor defect as is observed in the II-VI semiconductors (7).

GaN can be formed by reacting NH_3 with Ga when the partial pressure of NH_3 in H_2, P_{NH_3}, is greater than the equilibrium pressure, P^*. At 1000°C, $P^* = 1 \times 10^{-3}$ atm and has a shallow temperature dependence (8) (0.53 eV). Growth of GaN has been obtained by reacting NH_3 with Ga (9) or with Ga compounds (10) that dissociated at the growth temperatures, to form small crystals of GaN with dimensions of a few microns. The extension of this growth process to the epitaxial growth of GaN on sapphire substrates has been limited by the extensive nucleation of small crystallites on the substrates, so that, in general, only dense, unconnected, small crystals are typically obtained.

It has been found that two modifications are required for epitaxial growth. By addition of Bi to the growth solution, nucleation is inhibited and by imposition of a thermal gradient across the growth melt, dissolved nitrogen is transported to regions of lower temperature where growth occurs. While there is no detailed understanding of the effect of Bi upon the nucleation, a similar effect was observed (11) in the solution growth of GaP where the addition of Bi to the growth melt both increased the crystal size and reduced the number of crystals obtained in a given growth procedure. The low solubility of GaN in the liquid phase does not permit useful amounts of crystals to grow by slow cooling. The thermal gradient produces a concentration gradient of dissolved GaN and thereby a transport mechanism.

In this paper, a description is given of the growth procedures used to grow reproducibly epitaxial layers of GaN on sapphire substrates from the liquid phase. In addition, a description is given of the interaction of liquid Ga with NH_3 at high temperatures as a function of P_{NH_3}. Two features of this interaction, which are encountered under some growth conditions, are described and explained: (*i*) the flow of Ga out of

* Electrochemical Society Active Member.
Key words: gallium, bismuth, ammonia, zinc, electrons.

the growth boat and (*ii*) the spattering or propelling of Ga droplets out of the growth crucible onto the furnace wall directly over the crucible.

Experiments performed in attempts to clarify the source of the high-electron concentration in the crystals are described. The inability to change the electron concentration, n, with Zn doping and the decrease in n with reduced atom fraction of Ga in the growth melt support the suggestion that the native donor is a nitrogen vacancy.

Apparatus and Procedures

Epitaxial layers of GaN were grown onto single crystal sapphire substrates from Ga (or Ga diluted with Bi) solutions heated under a partial pressure of NH_3 in H_2. The growth occurred in a horizontal furnace system in which the spontaneous dissociation of NH_3 was negligible and the NH_3 pressure could be monitored and remained constant during growth. The basic design of the furnace system has been described because of its previous usage to grow (12) epitaxial layers of N-doped GaP and to determine (8) the equilibrium pressure of N_2 over GaN. The principal features of the furnace are: (*i*) a low level of oxygen (and water vapor) in the ambient which was achieved by the use of stainless steel, Pyrex, and Teflon tubing connecting the gas sources to the main furnace tubing and contributed to the prevention of spontaneous dissociation of NH_3 in the heated furnace ($850°C < T < 1150°C$); and (*ii*) an easily replaceable quartz liner inside the main quartz furnace tube so that each growth occurred under reproducible conditions. The exit gas from the furnace could be titrated with a dilute solution of HCl of known volume and normality, containing methyl red indicator. By observation of the titration time, the NH_3 pressure could be monitored closely. The gas flow rate was generally 140 cc/min.

Spontaneous dissociation of NH_3 in the heated-empty furnace was caused by contaminants in the furnace (devitrified quartz or an inadvertent leak in the gas flow system) and was easily detected by the observation of a variation of P_{NH_3} with furnace temperature. When such dissociation was detected it could easily be eliminated. Devitrified quartz was replaced with new quartz, cleaned in de-ionized H_2O and alcohol prior to use. No bake out was necessary.

The epitaxial layers were grown in pyrolytic graphite boats, of dimensions 7.8 cm × 1.3 cm × 1.3 cm. These boats did not cause NH_3 decomposition and the weight loss during growth was negligible (<1 mg for heatings at 850°-1150°C for 20 hr). Quartz and boron nitride boats were also used but the former were more difficult to clean between runs due to wetting by the melts and the latter are relatively expensive.

The single-crystal, Czochralski-grown sapphire substrates were optically polished, oriented slices, 250μ thick. While several substrate orientations were investigated, the best growth was achieved with the (0001) orientation. Prior to use, the sapphire substrates were cleaned in hot aqua regia and rinsed in de-ionized water and alcohol. In some instances, the sapphire substrate was first covered with a vapor-deposited layer of GaN, a few microns thick, provided by M. Ilegems (13).

The growth solution consisted of 10-20g of 6-9's purity Ga or Ga-Bi alloys. Because of the wetting action of the Ga in the presence of NH_3 (to be described in the following section) the substrates, each of area ~1 cm², were placed on top of the melt for atom fractions of Bi, x_{Bi}, in the melt $\lesssim 0.5$. At higher values of x_{Bi}, where wetting was less, improved large area layer growth was obtained by placing the substrates just below the surface of the melt. This was accomplished by loading the growth boat with about 75% of the small particles of Bi and Ga, placing the substrates into the boat and covering them with the remaining Bi-Ga mixture. After the growth run, the substrates were generally covered with a thin layer of melt, with GaN growth on both sides of the substrate, but with much thicker growth on the upper side.

The crystal-growth cycle consisted of inserting the loaded boat into the cold furnace, flushing the furnace for 1 hr, and then heating at the growth temperature for typically 20 hr. Approximately 30 min were required to reach the growth temperature and after the growth another 30 min to lower the furnace temperature to ~600°C when the boat was removed. The substrates and melt were then soaked in both HNO_3 and aqua regia. In addition to recovering the substrates with their epitaxial layers in this digestion, approximately 250 mg of small crystals of GaN, which grew away from the substrates, was also obtained.

It was observed that the layer growth was dramatically improved in area coverage when growth occurred in a temperature gradient rather than in the flat zone of the furnace. The crystal growth described here was obtained with about 1/2 of the length of the boat extended into the uniform temperature zone of the furnace and a carbon rod heat sink attached to the downstream colder end of the boat and extending about 10 cm to the end of the furnace. The carbon heat sink was 1.7 × 1.2 cm in cross section and had a 1.5 cm long cutout that closely fitted around one end of the growth boat. The temperature of growth reported in this work corresponds to that read by a Pt-Pt, 10% Rh thermocouple contained in a quartz protection tube inserted into the growth melt.

Zinc as a dopant was added to the growth melt by vapor transport from an independently heated upstream source. Since similar procedures were used to grow epitaxial layers of Zn-doped GaP from Ga solutions in a 30 min growth cycle (12) the Zn concentration in the melt is expected to be at a steady-state value during most of the 20 hr growth cycle. Less volatile impurities such as Ge, were added directly to the melt. Carbon doping was achieved by adding methane to the gas ambient.

Results and Discussion

NH_3-Ga(l) reaction.—When the NH_3 pressure is less than the equilibrium pressure, P^*, Ga may be heated without visible reaction; the Ga remains shiny and clean. Since there is no evidence for volatile nitride species (14), any weight loss beyond that expected from the vapor pressure of Ga would be due to oxides contaminating the gas phase and reacting with Ga to form Ga_2O. Heating 40g of Ga at 1150°C for 16 hr, with $P_{NH_3} = 4.7 \times 10^{-4}$ atm ($< P^*$), and a gas flow of 280 cc/min resulted in a weight loss of 0.135g. This weight loss is about a factor of 2 higher than expected from the vapor pressure of Ga. The additional weight loss can be used to estimate the partial pressure of H_2O in the carrier gas by assuming that the water reacts with Ga to equilibrium producing Ga_2O. A partial pressure of 5×10^{-5} atm would be required to account for the additional weight loss of the Ga. We do not believe that this rather high pressure of H_2O is present in the carrier gas entering the furnace. We believe the reaction of H_2 with SiO_2 in the furnace is the probable source of the contamination. The equilibrium pressures of H_2O and SiO from the H_2-SiO_2 reaction at 1150°C gives about 2×10^{-5} atm of each as calculated from available thermodynamic information (15). The excess weight loss of our sample can be accounted for within 50% by this reaction.

Digestion of the Ga in HNO_3 and filtration of the residue through filters of 0.8μ porosity yielded residuals of ~1 mg. In three determinations the amount of residual varied approximately linearly with $P_{NH_3} < P^*$. If one assumes that the nitrogen dissolved in the Ga formed GaN during the cooling of the melt, then the extrapolation of the three experimental points to

$P_{NH_3} = P^*$ (1.5×10^{-3} atm) (8) gives a solubility of 3×10^{-5} mole fraction of GaN in Ga at 1150°C.

As the NH_3 pressure is increased beyond P^*, visible reaction with the Ga occurs for heating at temperatures in the range 1000°-1150°C. A striking feature of this reaction is the flow of the Ga melt. With $P_{NH_3} \sim 2P^*$, the melt flows up the inside walls of the boat but is contained inside the boat for heating times as long as 20 hr and will overflow in longer heating times (*e.g.*, 60 hr). The rate of Ga flow increases with P_{NH_3} and at $P_{NH_3} = 10\ P^*$, most of the melt will flow out of the boat in about 1 hr, and collect predominantly upstream. In all of the above cases, the Ga reacts with NH_3 to form small crystals of GaN. The crystal color and dimensions vary with P_{NH_3}, with black crystals of dimensions 75-500μ at low pressures and smaller, gray crystals 20-100μ in dimensions formed at higher pressures.

A qualitative explanation for the flow of Ga will now be offered, together with observations that test and support this explanation. It is proposed that Ga evaporates and reacts with NH_3 to form a film of GaN on the surfaces adjacent to the melt. The Ga wets and spreads over the GaN vapor deposited film until the Ga supply is either exhausted or completely reacted. With a large Ga supply at 1025°C and $P_{NH_3} = 0.03$ atm, the Ga has been observed to flow upstream about 20 cm, where it stopped at a region where the local temperature was ~850°C, while there was negligible flow downstream.

The following two observations support this explanation. A drop of Ga was placed on a large area vapor deposited GaN crystal and heated in H_2 on a strip heater and watched. At room temperature no wetting was observed but as the temperature was increased to ~800°C, the Ga wetted the surface as a thin film. Upon cooling to room temperature, the Ga drew back into a droplet. In the second experiment, a quartz boat 2 cm × 2.5 cm × 0.7 cm deep containing 3g of Ga was heated for 1 hr at 1025°C with $P_{NH_3} = 0.02$ atm. The Ga flowed so that all walls of the boat, both inside and out, were wetted, as well as the quartz furnace liner in the vicinity of the boat. Weight loss of the boat indicated that about 50% of the Ga had left the boat. The Ga contained small crystals of GaN, and was covered with a gray GaN film. Three more grams of Ga were added to the boat and reheated using a new quartz furnace liner and a hydrogen ambient. Again 2.2g of Ga flowed over the sides of the boat, confirming that the presence of the GaN was essential to the Ga flow.

At lower temperatures ($T \lesssim 950$°C) no apparent reaction occurs when Ga is heated in a uniform temperature zone of the furnace, even with P_{NH_3} as high as 0.2 atm. This is due to the formation of a thin crust of GaN over the melt which blocks further reaction. If the melt is agitated by mechanical vibration or placed in a temperature gradient (using the carbon heat sink described above), the reaction characteristics are similar to those described above for heating at higher temperatures.

The growth of GaN epitaxial layers on sapphire substrates was studied under conditions where the melt was contained in the growth crucible and this was generally achieved with $P_{NH_3} \sim 2P^*$. A phenomenon, termed spattering, was usually observed. This was characterized by the formation of droplets of Ga or crystallites of GaN directly over the boat on the quartz furnace liner. The amount of spattered Ga and GaN was generally far greater than that vapor transported to the downstream cold end of the furnace, as discussed above. The spattering is attributed to dissociation of GaN, releasing N_2 filled bubbles in the melt, which form at the surface or rise to the surface and burst, causing drops of melt to be propelled out of the boat. N_2 pressures greater than 1 atm can be formed by dissociation of GaN to Ga and N_2 since the equilibrium N_2 pressure is ~100 atm at 1025°C (8). If the spattering occurred during the early part of the growth cycle, the Ga drops would react with NH_3 to form GaN. The spattering phenomenon was reproduced by heating GaN crystallites under Ga in a He ambient with a heating cycle used in layer growth (20 hr at 1025°C). Ga drops were formed over the growth crucible on the quartz furnace liner as observed during growth.

Epitaxial layer growth.—Growth from Ga melts produced GaN crystals predominantly on the top sides of the sapphire substrates. Numerous, well-faceted crystallites were formed along with occasional small areas (1-3 mm in dimension) of epitaxial growth. There usually were evident regions of thermal etching or local dissociation after growth in the small areas of epitaxial layer growth. The small crystallites also grew off of the substrate, predominantly on the walls of the boat and were recovered after digestion of the growth melt. Crystallites, 120μ thick on the top surface and a few microns thick on the bottom side were obtained after growth for 16 hr at 1000°C (with $P_{NH_3} = 2 \times 10^{-3}$ atm). Growth thickness was roughly proportional to the growth time. After 64 hr at 1000°C, (with $P_{NH_3} = 1.3 \times 10^{-3}$ atm), the top surface crystallites were ~300μ thick while the bottom side contained a continuous epitaxial layer 6μ thick. The dissociation rate of GaN to Ga + N_2 at temperature $\lesssim$1050°C is small compared to the growth rate (16).

While there was a possibility that the addition of Bi to the growth melt might increase the solubility of N (and hence the growth rate), the dominant effect was the suppression of spurious nucleation so that growth occurred predominantly on the sapphire substrate. With melts containing 10-90 atomic per cent (a/o) Bi, the epitaxial growth extended over large areas of the sapphire substrate, typically from 50 to 100% of the total area. In those areas where layer growth was incomplete, the surface was covered with closely spaced crystallites. The effect of the Bi is apparently to suppress nucleation so that the initially nucleated crystallites grow laterally, as well as in thickness, to give complete coverage. The nucleation could be further assisted by using substrates containing a thin vapor deposited film of GaN. Using vapor deposited films (13), a few microns thick, generally with featureless surfaces, solution growth produced clear layers with faceted surfaces, grown reproducibly over the entire substrate area. While the double layer growth procedure was quite successful, it was not routinely used since single layer growth was also quite reproducible in supplying large area epitaxial layers.

The single-crystal epitaxial layers grow in the [0001] direction, the same orientation as the substrates generally used. However, the layer growth orientation was unchanged with $(11\bar{2}0)$ oriented substrates, a phenomena previously observed in GaN vapor growth by Wickenden *et al.* (2).

The epitaxial layer surfaces were sharply faceted and representative surfaces are shown in Fig. 1a and 2a. The surface structure ranged from flat-topped hexagonal platelets (Fig. 1a) to surface patterns containing the three $[1\bar{1}0]$ basal plane hexagonal directions of the sides of the hexagonal platelets (Fig. 2a). The small black regions in Fig. 1a are small crystals that grew above the layer, and were randomly oriented. They were found on many layers.

As the atom fraction of Bi, x_{Bi}, in the growth melt increased, a proportionate increase in P_{NH_3} was required to achieve growth. With GaN in equilibrium with the melt, the NH_3 pressure will increase as a result of a decrease in Ga activity with Bi addition. Using data where good layer growth occurred in growth times of ~20 hr at 1000°C (Fig. 1a and 2a being typical of the surfaces of such layers), the NH_3

Fig. 1. (a) The surface of a (0001) GaN epitaxial layer containing hexagonal facets with [1$\bar{1}$0] edges, viewed with incident illumination. The layer was grown at 1000°C in 24 hr with $x_{Ga} = 0.13$ and $P_{NH_3} = 0.02$ atm on a (0001) sapphire substrate containing a predeposited GaN layer and is 40μ thick. (b) The same area, below the surface of the layer viewed with transmitted light revealing subsurface cracks at the layer-substrate interface. The cracks lie predominantly in the [$\bar{1}$10] directions of the edges of the surface hexagonal facets.

input pressure is plotted in Fig. 3 against the atom fraction of Ga, $x_{Ga} = 1 - x_{Bi}$ in the growth melt. The variation in x_{Ga}, due to Bi evaporation during the growth, is indicated. The layer thickness, t, grown directly onto the (0001) sapphire substrates is also plotted against x_{Ga}. If it is assumed that Ga and Bi form an ideal liquid solution, and that GaN is only slightly soluble in it, the dependence of the NH_3 pressure on the Ga atom fraction can be obtained from the reaction

$$GaN + 3/2\,H_2 = Ga + NH_3 \quad [1]$$

with the equilibrium constant, K, given by

$$x_{Ga}P_{NH_3} = K \quad [2]$$

The equilibrium constant of the above reaction contains the observed inverse linear relationship between P_{NH_3} and x_{Ga}. The fact that the layer thickness decreased with decreasing Ga atom fraction indicates that the N atom fraction decreases as Bi is added to the melt, as would be expected if the solubility of GaN is less in Bi than in Ga.

Figure 1b shows the same region of the layer of Fig. 1a but viewed with transmitted light. The series of lines which generally follow the [1$\bar{1}$0] directions of the hexagonal surface structure are cracks which appear to originate at the interface of the layer and the substrate. It is noted that the cracks do not propagate to the surface of this 40μ thick layer, or to the back of the substrate. For thicker layers ($\sim$100μ thick) grown with higher x_{Ga} in an otherwise similar growth cycle, many of the cracks propagate to the surface and cause the thermal etching (or dissociation) shown in Fig. 1b. From observation of the surface structure, it is evident that the thermally dissociated regions were formed near the end of the layer growth. Surface dissociation effects were generally not observed in layers $\lesssim 75\mu$ thick nor were subsurface cracks observed in layers $\lesssim 30\mu$ thick.

Chemical doping.—The small GaN crystals that nucleated and grew away from the substrate were routinely recovered from the growth melt after digestion in aqua regia. Spectroscopic analysis of undoped crystallites gave impurity concentrations at the level of 10 parts per million or less. Hall measurements on the undoped layers yielded electron concentrations $\sim 3 \times 10^{19}$ cm^{-3}, approximately 2 orders of magnitude larger than the detected impurity levels.

Atomic absorption analysis of the small crystals obtained with Zn doping showed that the Zn concentration was primarily determined by the growth temperature provided the Zn was distilled into the gas stream from a source boat at $T \gtrsim 600$°C. For growth with $x_{Ga} = 0.1$, $P_{NH_3} = 0.02$ atm, Fig. 4 shows a plot of Zn concentration against growth temperature with the Zn source temperature indicated at each experimental point. Also shown are the electron concentrations determined by Hall measurements obtained using epitaxial layers grown under similar conditions. While the

Fig. 2. (a) The surface of a (0001) epitaxial GaN layer grown on a (0001)-oriented sapphire substrate in 20 hr at 1000°C with $x_{Ga} = 0.88$ and $P_{NH_3} = 0.006$ atm and is 100μ thick. The three $[1\bar{1}0]$ directions are evident in the surface facets. (b) Another region of the surface where grooves have developed in the surface during the latter part of the growth by thermal dissociation of cracks that propagated to the layer surface.

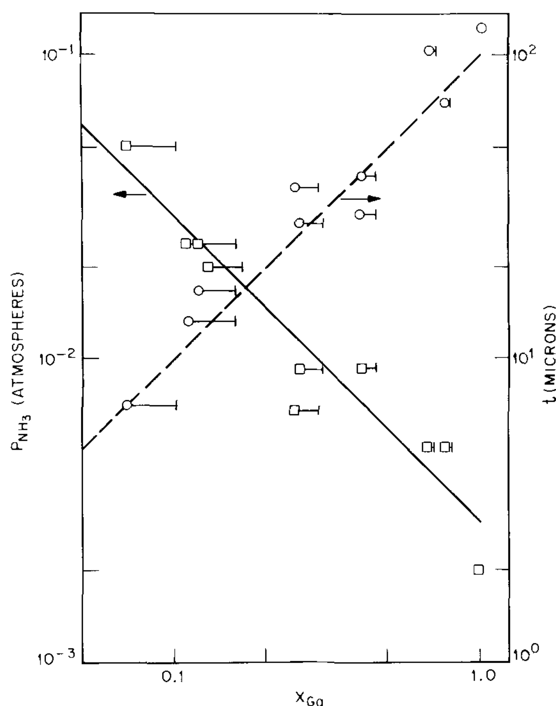

Fig. 3. The NH_3 input pressure and the epitaxial layer thickness as a function of x_{Ga} in the growth melt for 20 hr growth at 1000°C.

Zn concentration ranged up to 3.5×10^{20} cm^{-3}, the electron concentrations did not vary significantly from $\sim 3 \times 10^{19}$ cm^{-3}. The indicated variation in the latter concentrations are due to the local variations in the layer thickness, which ranged from average values of 4-17μ depending on the growth T, and by examination of the edge of the layers, the thickness fluctuated ±2μ about average values. The trends expected in Fig. 4 are approximately seen. At constant growth temperature the Zn concentration should increase with Zn pressure and therefore with Zn boat temperature; at constant Zn pressure and therefore Zn boat temperature, the Zn concentration is expected to decrease with increasing growth temperature since the heat of solution of Zn should be positive. The electron concentrations are nearly constant at about the value found when no Zn is added suggesting that most of the zinc has precipitated.

Precipitates were generally observed in the Zn-doped layers, and a representative sample is shown in Fig. 5. The layer was grown at 850°C with $x_{Ga} = 0.1$, $P_{NH_3} = 0.02$ atm, and $t \sim 5\mu$. Figure 5a, viewed with incident illumination, shows the hexagonal platelet structure often observed whereas Fig. 5b shows the same area viewed with transmitted light with precipitates in the form of fine lines and inclusions. The lines appear similar to decorated dislocations which have been observed and identified in other semiconductors (17). It is noted that the lines, which are generally not observed in undoped layers, lie in the $[1\bar{1}0]$ directions of the edges of

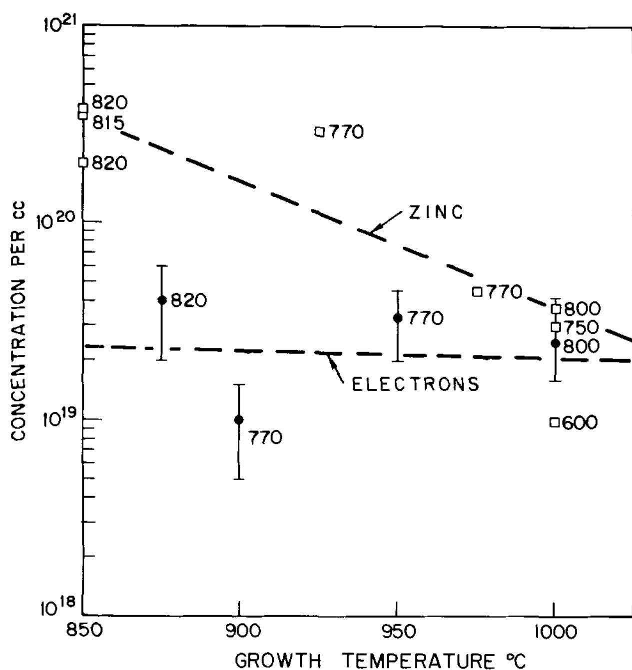

Fig. 4. The concentration of Zn (-□- from atomic absorption analysis) and of electrons (-●- from Hall effect measurement) plotted against the growth temperature with the Zn-source boat temperature indicated at each experimental point. The dashed lines indicate the general trend of the variation of the zinc and electron concentrations with the growth parameters, as discussed in the text. The layers were grown in 20 hr with x_{Ga} = 0.01 and P_{NH_3} = 0.02 atm and are 4-17μ thick. The error bars on the Hall results are due to the estimated variation in the layer thickness.

the hexagonal surface structure similar to the cracks observed in thick layers. Hall measurements indicated that while the electron concentration was unaffected by the Zn doping, the room temperature Hall mobility decreased, however, from ~75 cm^2/V-sec in undoped layers to ~4 cm^2/V-sec in the Zn-doped layers. The evidence of precipitation accounts for the ability to dope with high Zn concentrations without observing the electrical behavior expected for the substitutional Zn acceptors.

Atomic absorption analysis of crystals grown from Ga-Bi solutions at 1000°C give a limit on Bi at $\sim 10^{19}$ cm^{-3}. After the digestion of these crystals from the growth melt in aqua regia, the white precipitate bismuth oxychloride forms when the crystals are rinsed in water. While the analyzed crystals were recleaned in aqua regia, the presence of the precipitate qualifies the results of this analysis. The photoluminescent spectra of undoped crystals grown from Ga-Bi solutions were indistinguishable from those grown from Ga solution. Carbon doping was achieved by adding methane gas to the growth ambient. The growth properties were unaffected by the presence of methane, but decomposition of the methane (with black carbon deposits) was observed when the fraction of methane in the ambient exceeded 20%. Decomposition is expected when the CH_4 pressure in H_2 is greater than about 1% (15). While the addition of these impurities did not cause changes in the electron concentration, as compared to undoped layers grown under similar conditions, luminescence studies indicated characteristic spectral features that will be discussed elsewhere (18).

Dependence of n upon x_{Ga}.—It has been suggested (2) that nitrogen vacancies are the source of the electron carriers in GaN. In principle, the suggestion can be tested by annealing GaN under various pressures of NH_3 in H_2. If electrons come from the ionization of a nitrogen vacancy, the relationship between the electron concentration and the ammonia pressure can be calculated

$$3/2\, H_2 + N_N = NH_3 + V^+{}_N + e^- \quad [3]$$

The equilibrium relationship follows

$$\frac{P_{NH_3}}{P_{H_2}{}^{3/2}} [V^+{}_N][e^-] = K \quad [4]$$

and since the electron and vacancy concentrations are equal

$$[e^-] = K^{1/2} P_{H_2}{}^{3/4} P_{NH_3}{}^{-1/2} \quad [5]$$

That is, for $P_{NH_3} << P_{H_2}$, $[e^-] \propto P_{NH_3}{}^{-1/2}$.

Experiments by Montgomery (19) have shown that no resistivity changes occur in GaN epitaxial crystals annealed at 900°C under NH_3 pressures up to ½ atm. It was suggested that no changes were observed because diffusion processes were too slow.

We have been able to grow GaN crystals from melts containing Bi. As a result it has been possible to grow crystals under various NH_3 pressures simply by varying the Bi atom fraction in the melt. The fact that Bi in GaN is an isoelectronic center keeps it from being an electrically active center. It has been shown (Eq. [2]) that P_{NH_3} is inversely proportional to the Ga atom fraction. Consequently the electron concentration and the Ga atom fraction are related by the expression

$$n = [e^-] \propto x_{Ga}{}^{1/2}$$

While n may be determined by Hall measurements, growth thickness variation discussed above, place a large experimental uncertainty on n in thin layers ($t \lesssim 10\mu$). Reflectivity measurements by Barker and Ilegems (20) are found to be independent of t (provided $t \gtrsim 5\mu$) and the spectral position of the reflectivity minimum is a function of n that can be established independently by Hall measurements. The experimental precision of this method, applied to GaN layers, has not been assessed and the effect upon the reflectivity measurement of surface treatment (polished, as-grown, etc.) and sample uniformity is currently being investigated (20). Reflectivity measurements on our as-grown epitaxial layers have been used to complement the Hall measurements.

Using a group of layers grown at 1000°C in 20 hr with various values of x_{Ga} in the growth melt (and with P_{NH_3} correspondingly adjusted as in obtaining the data of Fig. 3) n obtained from reflectivity and Hall effect data is plotted against x_{Ga} in Fig. 6. The pairs of experimental points at the same value of x_{Ga} were measured by both procedures and scaled to match at $x_{Ga} = 1$. Due to evaporation of relatively small amounts of Bi during the layer growth, the plotted values of x_{Ga} are average values. Since it is believed that the experimental uncertainty in n, in all cases, exceeds that of x_{Ga}, the latter variation has not been indicated (but is identical to that in the data of Fig. 3).

Due to the large experimental uncertainty in the measured n, the results support but do not unambiguously confirm the dependence $n \propto x_{Ga}{}^{1/2}$. It is noted that results from three doped layers are plotted in Fig. 6. The Zn-doped sample contained 6.2×10^{18} Zn/cm^3 and the two carbon-doped layers were grown under a partial pressure of methane (with 8% CH_4, $n = 4.5 \times 10^{19}$ cm^{-3} and with 25.6% CH_4, $n = 3.0 \times 10^{19}$ cm^{-3}). To within the experimental scatter of the data, the values of n are indistinguishable from those in undoped layers.

If one assumes that vapor growth of GaN occurs under near equilibrium conditions, then from the dependence in n upon $P_{H_2}{}^{3/4} P_{NH_3}{}^{-1/2}$ in Eq. [5], one would expect a decrease in n by 10^3 from the value of 3×10^{19} cm^{-3} observed here. While values of n approach this value occasionally in vapor grown layers (13, 21), n is generally comparable to the high values observed here.

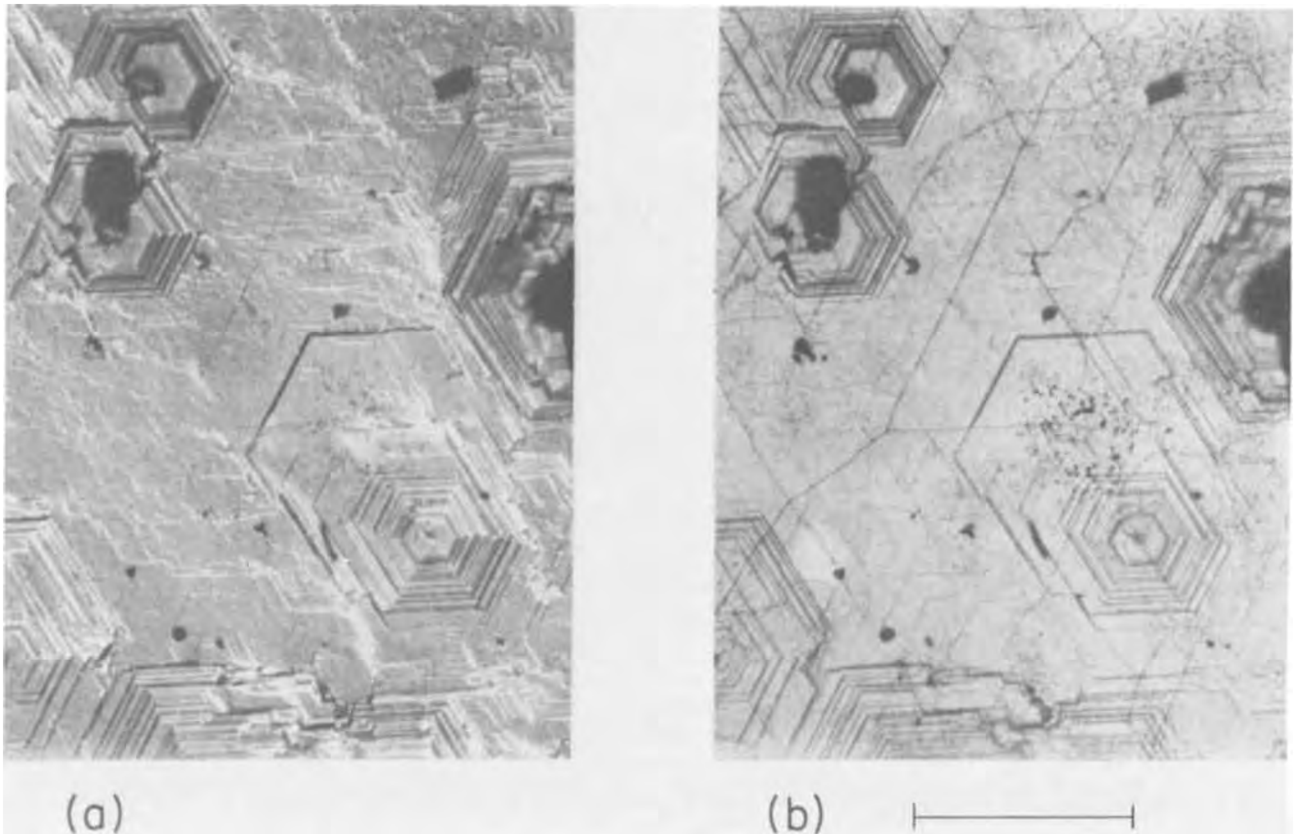

Fig. 5. (a) The surface of a (0001) epitaxial GaN layer grown on a (0001) sapphire substrate, viewed with incident illumination. The layer was grown in 20 hr at 850°C with $x_{Ga} = 0.1$ and $P_{NH_3} = 0.02$ atm with the Zn boat temperature at 815°C. The layer is ~5μ thick and from atomic absorption analysis, contains Zn = 3.5×10^{20} cm^{-3}. (b) The same area of the layer, viewed below the surface with transmitted light showing precipitates in the form of both lines and inclusions.

Temperature dependence of growth.—Most of the layers obtained in these studies were obtained at a growth temperature of 1000°C. The layer-growth characteristics did not change appreciably over the temperature range 875°-1050°C. For the 20 hr growth cycle used, Bi evaporation became appreciable at 1050°C (~40% of the original melt) and at higher temperatures severe dissociation of the GaN to Ga and N_2 is anticipated (16).

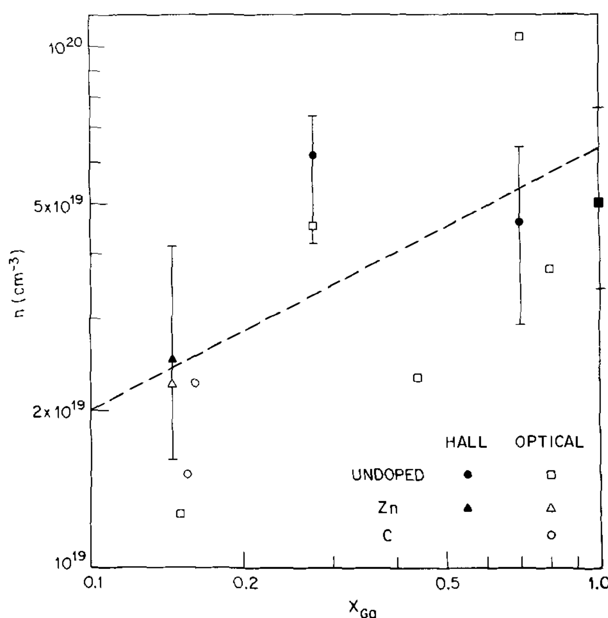

Fig. 6. Carrier concentration determined by Hall effect and reflectivity measurements vs. x_{Ga} in epitaxial layers grown in 20 hr at 1000°C. The dashed line indicates the expected dependence of $n \propto x_{Ga}^{1/2}$.

The layer thickness was observed to vary with growth temperature, and log t is plotted against $10^4/T$ K in Fig. 7 for a series of layers grown for 20 hr with $x_{Ga} = 0.12$ and 0.40. The variation in t is indicated. The increased t obtained at a fixed temperature with increased x_{Ga} is consistent with the data of Fig. 3. The slope of the lines drawn through the data is 1.5 eV and if the growth rate is primarily dependent upon the N concentration, this value may tentatively be ascribed to the heat of solution of GaN in Ga-Bi alloys and in Ga.

Reflectivity measurements on three samples grown at 900°, 1000°, and 1050°C, with $x_{Ga} = 0.4$ showed n between 2.5×10^{19} and 1.5×10^{20} cm^{-3}, uncorrelated with T and evidencing the same unexpected scatter obtained in the data of Fig. 6.

Summary and Discussion

Because of the low solubility of GaN in Ga (mole fraction approximately 3×10^{-5} at 1150°C) it has not been possible to grow GaN with useful crystal dimensions from the liquid phase by cooling of saturated melts. However, in a thermal gradient, with $P_{NH_3} > P^*$, the equilibrium pressure, epitaxial layers of GaN may be reproducibly grown onto oriented sapphire substrates from the liquid phase if the nucleation is controlled by addition of Bi to the growth melt.

The heating of Ga in an NH_3 ambient, with $P_{NH_3} > 2P^*$ at high temperature ($T > 950$°C) forms a vapor deposited film of GaN adjacent to the melt which is wetted by the melt and causes the melt to flow out of

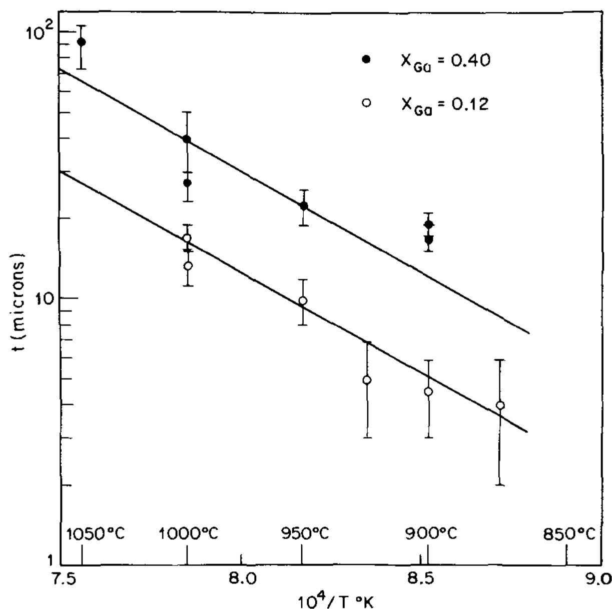

Fig. 7. The layer thickness vs. growth temperature for two sets of layers grown for 20 hr with $x_{Ga} = 0.12$ and 0.40 with corresponding $P_{NH_3} = 0.02$ and 0.009 atm respectively.

the growth boat. At low levels of $P_{NH_3} \sim 2P^*$, this effect is sufficiently reduced so that the melt is contained during growth (20 hr at temperatures in the range 850°-1050°C). At $T < 950°C$, a crust of GaN inhibits the reaction of Ga with the NH_3 ambient even up to very high NH_3 pressures. By mechanical vibration or by placing the melt in a temperature gradient the GaN crust is disturbed and the reaction characteristics are similar to those at higher T. A second interesting reaction observed during growth was termed spattering. This was characterized by the formation of droplets of Ga directly over the boat and shown to be due to dissociation of GaN to Ga and N_2 in the melt, with the bubbles of N_2 rising to the surface and bursting, propelling Ga droplets out of the boat. While the competing process of GaN dissociation to Ga + N_2 can only be suppressed at very high N_2 pressures [$P_{N_2} > 10^2$ atm at 1000°C (8)], this dissociation rate is small compared to the growth rate for growth temperature $\lesssim$ 1050°C (16).

The suppression of spontaneous nucleation of crystal growth by Bi is not understood but the phenomena appears similar to that encountered in the solution growth of GaP (11). The variation of growth thickness with growth time, temperature, and x_{Ga} are consistent with experience for solution growth. The growth mechanism appears to depend on the transport by diffusion of dissolved N, from the melt-ambient interface through a thin film of melt to the substrate, in a region of slightly lower temperature. We conclude that the single-crystal GaN layers are grown by heteroepitaxial solution growth in a thermal gradient.

It has been noted that even though sapphire and GaN possess different crystal lattices, in the c-axis or (0001) orientation of the epitaxial layer and substrate, the [$1\bar{1}0$] basal plane hexagons are mismatched in dimensions by 13% (5). Evidence of strain at the epitaxial layer-substrate interface is given by the appearance of internal cracks in the [$1\bar{1}0$] basal plane directions, when the layer thickness exceeds $\sim 30\mu$. In thicker layers ($t \gtrsim 75\mu$), the cracks propagate through the layer and are thermally etched by dissociation during the latter part of the growth cycle.

Addition of Zn impurities at concentrations as high as 3×10^{20} cm^{-3} did not appreciably change the electron concentration of $\sim 3 \times 10^{19}$ cm^{-3} measured in undoped crystals. Zn precipitates were visually observed in most Zn-doped layers. While similar negative results with Zn doping were observed in vapor grown layers by Ilegems (18, 21), high-resistivity, Zn-doped GaN ($\rho > 10^9$ ohm-cm) has been grown by Maruska and Tietjen (2) also using vapor-growth procedures, but with H_2 carrier gas instead of He and a 200°C lower growth temperature of 825°C. Since there is presently no information available about the Zn concentration and physical characteristics of the high-resistivity layers, it is not possible to give a detailed comparison with the present growth. The decrease in n with decreased x_{Ga} in the growth melt supports, but does not unambiguously confirm, the model that the crystals contain a native donor defect, a nitrogen vacancy, because of the large experimental uncertainty in the determination of n. The inability to reproducibly change n with Zn doping and the variations in n obtained with differing growth procedures indicate that n is dominantly influenced by growth details that are currently not understood. There is no evidence yet that GaN can be doped to low resistivity, p-type.

Acknowledgments

The Hall-effect measurements were performed by H. C. Montgomery and the optical reflectivity results were obtained by A. S. Barker and M. Ilegems. We also thank M. Ilegems for helpful comments and for providing the sapphire substrates containing GaN vapor deposited epitaxial layers. The atomic absorption and spectrographic analysis were obtained by J. P. Wright. We acknowledge the assistance of H. G. White in performing many of these experiments.

Solid-State Ionics–Mixed Ionic and Electronic Conduction in Ag_2Se-Ag_3PO_4 Solid Solutions

Takehiko Takahashi* and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

New solid solutions, the conduction in which is partly ionic and partly electronic, have been prepared in the Ag_2Se-Ag_3PO_4 system. Solutions containing 5-10 mole per cent (m/o) Ag_3PO_4 have the α-Ag_2Se structure and high ionic conductivity at room temperature. For example, $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ has an ionic conductivity of 0.13 $(ohm\text{-}cm)^{-1}$ at 25°C. The electronic conductivity and Hall coefficient have been measured as a function of the cation-to-anion ratio. The excess electron concentration varies linearly with the change in the cation-to-anion ratio. The solid solution containing 7.5 m/o Ag_3PO_4 which has been equilibrated with metallic silver has an excess electron concentration of 4.3×10^{19} cm^{-3} at 18°C. Coulometric titration, carried out with the galvanic cell Ag/$RbAg_4I_5$/specimen/Pt, gives the ratio of the effective mass to the free electron mass. At constant temperature, the effective mass increases with increasing electron concentration.

We may distinguish three types of solid conductors, namely, pure electronic, pure ionic, and mixed (partly electronic and partly ionic). Pure electronic conductors such as metals and semiconductors are well known. Silver halides are typical pure ionic conductors, which generally have extremely low conductivities at room temperature. In recent years, however, some ionic conductors such as Ag_3SI (1, 2) and $RbAg_4I_5$ (3, 4) with high conductivities, comparable with those of aqueous electrolytes, have been reported. Silver chalcogenides and copper chalcogenides are mixed conductors. Solids having both high ionic and high electronic conductivity have not been reported, except for high temperature modifications such as α-Ag_2S (>175°C), α-Ag_2Se (>133°C), α-Ag_2Te (>143°C), $Na_{0.4}WO_3$ (5), and $Na_2O \cdot 5\,(Fe_{0.95}Ti_{0.05}AlO_3)$ (6).

Ionic conduction in solids is of interest both because of its effect on their electrical properties and because of its role in their application to electrochemical elements (7-9). The purpose of this study has been to discover mixed conductors with high ionic and electronic conductivity at or near room temperature. The ionic conductivities of the mixed conductors known so far are summarized in Table I. This table shows that the high temperature (α-phase) modifications have extremely high ionic conductivity and the low temperature (β-phase) modifications very low. Crystal structure analysis (14-16) indicates that all the α-phases have the same type of structure, in which cations apparently move freely through a large number of sites. Therefore, if a compound exists which has this structure at room temperature, it should have high ionic conductivity at room temperature. In order to search for such compounds, we have undertaken studies on various systems of silver compounds. It has been found that some solid solutions obtained by thermal reaction in the Ag_2Se-Ag_3PO_4 system have a structure like α-Ag_2Se and as expected have extremely high ionic conductivities at room temperature. This paper reports the results of x-ray diffraction, differential thermal analysis, electrical conductivity, and coulometric titration investigations on this system.

Key words: α-Ag_2Se, ionic conductivity, electronic conductivity, coulometric titration.

Experimental Procedure

Preparation of samples.—Silver selenide was prepared from the elements. Stoichiometric quantities of silver powder (99.999% purity) and selenium powder (99.999% purity) were weighed, thoroughly ground together, sealed under vacuum in a Pyrex tube, and heated at 350°C for 48 hr. Silver phosphate was prepared by mixing aqueous solutions of silver nitrate (reagent grade) and sodium hydrogen phosphate (reagent grade). The precipitate was washed by decantation, filtered, dried *in vacuo* over phosphorous pentoxide, and then heated in flowing nitrogen gas at 100°C.

To react Ag_2Se and Ag_3PO_4, weighed quantities of these materials were thoroughly ground together, and the mixture was heated at various temperatures between 400° ± 5°C and 800° ± 5°C for 17 hr in a sealed-evacuated silica tube. The dependence of the nature of the reaction products on the reaction temperature was studied. It was found in the preliminary experiments that the melting points of the solid solutions were 830°C for 5 mole per cent (m/o), Ag_3PO_4, 750°C for 10 m/o Ag_3PO_4, and 650°C for 15 m/o Ag_3PO_4. The solid electrolyte, $RbAg_4I_5$, was prepared by Owens' procedure (3) for combining AgI with RbI.

X-ray diffraction investigation.—X-ray diffraction patterns for powdered samples were obtained with a

Table I. Ionic conductivity of mixed conductors

Compound	Temperature (°C)	Conductivity $(ohm\text{-}cm)^{-1}$	Reference
Cu_2S	400	2×10^{-1}	(10)
α-Ag_2Se	150	2.7	(11)
α-Ag_2Te	160	7×10^{-1}	(11)

	150	1.6×10^{-2}	(11)
β-Ag_2Se	105	$0.3\text{-}7 \times 10^{-4}$	(13)
β-Ag_2Te	97	$4\text{-}5 \times 10^{-4}$	(13)

Gigerflex D-3P diffractometer (Rigaku Denki Company, Ltd.) using CuK_α radiation. The scanning speeds were 1°/min for structure analysis and ¼°/min for lattice constant determinations.

Differential thermal analysis.—Differential thermal analysis was used to determine the phase transition temperature as a function of Ag_3PO_4 content. Each sample (about 1g) was sealed in a Vycor tube under vacuum, preheated to 800°C, cooled gradually to room temperature, and kept at room temperature for several days before the experiment. It was then heated and cooled at an automatically controlled rate of 3.5°C/min while the temperature difference between the sample and an α-Al_2O_3 standard was measured with a Chromel-Alumel thermocouple.

Ionic conductivity measurements.—The ionic conductivity was measured by the method described in a previous paper (13). The configuration is shown in Fig. 1. Since the ionic conductivity of the material studied was relatively high, a cylindrical sample 2-3 mm in diameter and 12-13 mm long was used, and $Ag/RbAg_4I_5$ probes were used for potential difference measurements. With this arrangement the effects of electrode polarization were negligible. When it was desired to change the cation-to-anion ratio in the sample, current was passed between the lower silver electrode and the platinum electrode wound around the sample.

Electronic conductivity and Hall coefficient measurements.—The material was rolled under a pressure of about 2000 kg/cm² to form a slab 1-2 mm thick and a six-arm bridge-type sample was cut out. The length-to-width ratio was 3.2. The cell assembly used to measure the electronic conductivity and Hall coefficient is shown in Fig. 2. The sample was placed between two silver ion transfer electrodes, $Ag/RbAg_4I_5$, which were used to change the cation-to-anion ratio of the sample by passing direct current between electrodes 3 and 7 or 8 in Fig. 2.

Measurements of the Hall coefficient and resistance were made by standard d-c methods. A constant sample current of about 100 mA was supplied between electrodes 1 and 5 in Fig. 2. The Hall voltage was measured between 3 and 6. The adopted voltage was the arithmetic mean of the four values obtained by reversing directions of both the magnetic field and sample current in order to cancel errors due to, for example, the thermoelectric effect and probe misalignment. Fields of 1900 and 3750G were used. The resistance was calculated from the voltage drop between 2 and 4. The electronic conductivity is equal to the electrical conductivity measured by the arrangement shown in Fig. 2 because the contribution to the sample current due to ionic conductivity is negligible in this case.

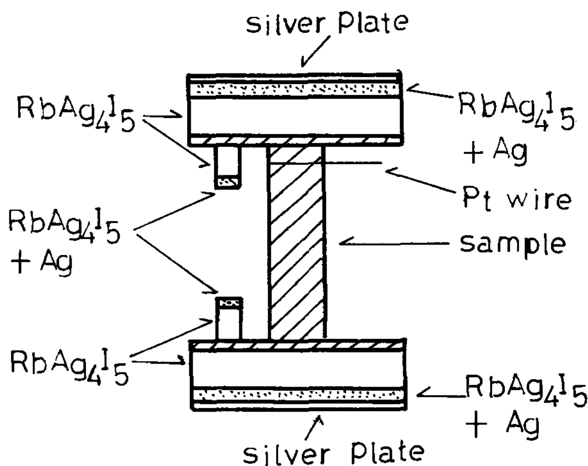

Fig. 1. Arrangement for ionic conductivity measurements

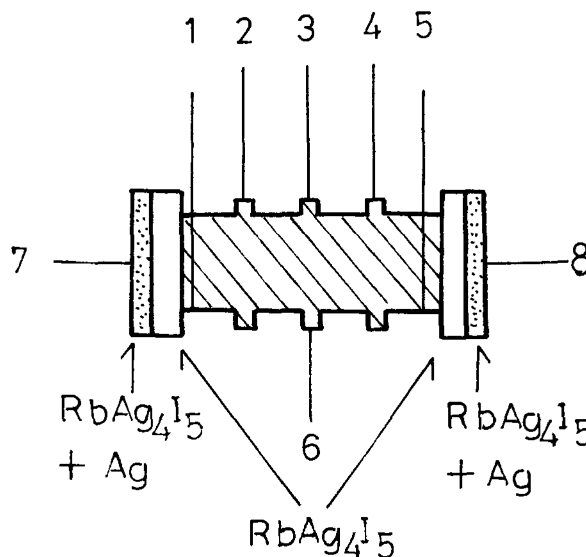

Fig. 2. Arrangement for Hall coefficient and electronic conductivity measurements. Numbers 1-8 represent platinum electrodes.

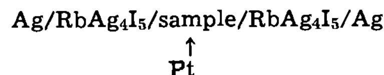
Coulometric titrations.—The activity of silver in the sample was determined as a function of the cation-to-anion ratio by means of coulometric titrations using the cell



$$Ag/RbAg_4I_5/\text{sample}/RbAg_4I_5/Ag$$
$$\uparrow$$
$$Pt$$

which is analogous to that for silver sulfide (17). The solid electrolyte $RbAg_4I_5$ is essentially a silver ion conductor and a well-defined amount of silver may be removed from the sample by passing a current across the cell. The sample was a pressed plate, 0.2-0.5 mm thick, contacted on the edge by a platinum wire. At each temperature the potential difference between the platinum and the silver electrode was first maintained at about 100 mV for several hours, after which the coulometric titration was carried out. A constant current of 50-100 μA was passed between the platinum and the left hand silver electrode, and the cell voltage was measured using the platinum and the right hand silver electrode.

Experimental Results and Discussion

Crystal structure of Ag_2Se-Ag_3PO_4 solid solutions.—Mixtures of Ag_2Se and Ag_3PO_4 in various proportions were heated at a number of temperatures for 17 hr and furnace-cooled to room temperature. The x-ray diffraction patterns indicated that the reaction products containing 5 to 10 m/o Ag_3PO_4 prepared above 400°C were single-phase solid solutions with a body-centered cubic structure like that of α-Ag_2Se. There was a difference in relative intensities of x-ray lines between α-Ag_2Se and the solid solutions. For α-Ag_2Se the intensities of the (200) and (211) lines were the same, but for the solid solutions the intensity of the (200) line was the strongest. The detailed crystal structure of the solid solutions could not be determined because no single crystals have been obtained. Samples in the composition range of 5 to 10 m/o Ag_3PO_4 which had been kept at room temperature for 6 months or more showed the same x-ray diffraction pattern as those which had been cooled abruptly from 800°C to room temperature. This result indicated that the α-Ag_2Se structure was stable at ambient temperature.

Samples containing 4 m/o Ag_3PO_4 or less gave two-phase patterns corresponding to the β-Ag_2Se and α-Ag_2Se structures. In the range 15-40 m/o Ag_3PO_4, the samples prepared above 500°C gave only broad lines at $2\theta = 34°$. Above 40 m/o Ag_3PO_4, both the broad lines and lines due to Ag_3PO_4 were observed.

In order to determine the range over which the α-Ag_2Se phase exists at room temperature, the variation of lattice constant of this phase with over-all sample composition was measured. The results, as shown in Fig. 3, indicate that the upper limit for the α-Ag_2Se phase is 12 m/o Ag_3PO_4. The lower limit could not be established from these data because the diffraction lines for this phase were broad below 3 m/o Ag_3PO_4.

The $\beta \rightarrow \alpha$ transition in Ag_2Se, which occurs at 133°C (15), is an endothermic process. The transition temperature as a function of composition in the Ag_2Se-Ag_3PO_4 system was determined by differential thermal analysis performed while the samples were heated from room temperature. The results are shown in Fig. 4. The transition temperature is lowered by the addition of Ag_3PO_4 and no thermal arrest was observed for samples containing more than 3 m/o Ag_3PO_4. This result confirms 4 m/o Ag_3PO_4 as the lower limit of the composition range over which the α-Ag_2Se phase is stable at room temperature.

The melting point in the Ag_2Se-Ag_3PO_4 system decreased as the Ag_3PO_4 content was increased from 0 to 50 m/o. The melting point was about 400°C for 50 m/o Ag_3PO_4. The phase diagram for the entire Ag_2Se-

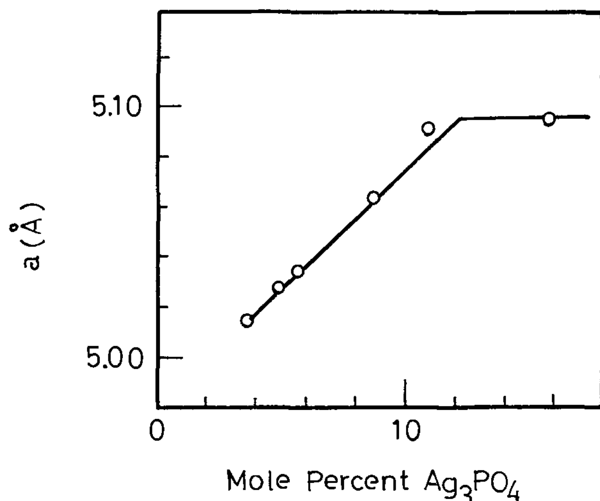


Fig. 3. Lattice constant, a, at 25°C as a function of over-all composition for solid solutions with the α-Ag_2Se structure in the Ag_2Se-Ag_3PO_4 system.

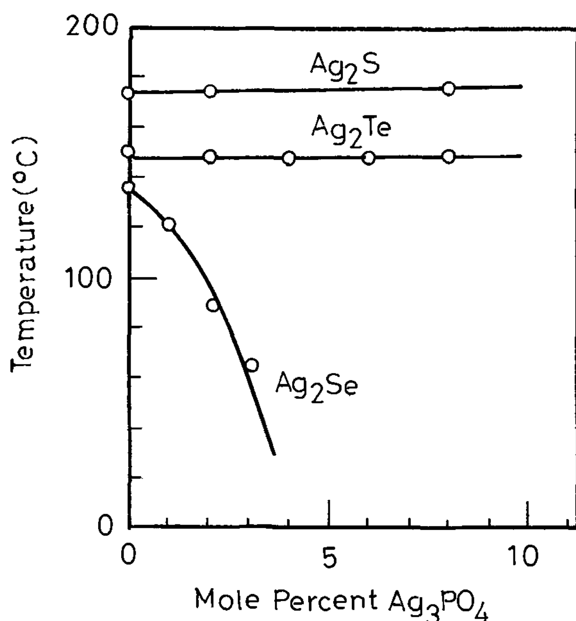

Fig. 4. $\beta \rightleftharpoons \alpha$ transition temperature as a function of composition for the Ag_2X (X = S, Se, Te)-Ag_3PO_4 systems.

Ag_3PO_4 system is too complex to be determined by thermal analysis alone.

Both Ag_2S and Ag_2Te exhibit $\beta \rightarrow \alpha$ transitions with increasing temperature. Their α phases have structures similar to that of α-Ag_2Se and show high ionic conductivity. In order to compare the Ag_2S-Ag_3PO_4 and Ag_2Te-Ag_3PO_4 systems with the Ag_2Se-Ag_3PO_4 system, their $\beta \rightarrow \alpha$ transition temperatures were measured as a function of Ag_3PO_4 content. The results are shown in Fig. 4. In both cases, the transition temperature is independent of composition, indicating that solid solutions are not formed. This was confirmed by the x-ray diffraction patterns of the thermal reaction products in these systems, which showed only two-phase mixtures of Ag_3PO_4 and Ag_2S or Ag_3PO_4 and Ag_2Te at room temperature.

Ionic conductivity.—The ionic conductivity was measured by means of the cell shown in Fig. 1. The relation between the current passed between the two silver plates and the voltage measured between the two $Ag/RbAg_4I_5$ probes obeyed Ohm's law, and the ionic conductivity was calculated from the slope of the current-voltage curve and the dimensions of the sample. The variation in ionic conductivity at 30°C with Ag_3PO_4 content is shown in Fig. 5 for samples prepared at 800°C, cooled to room temperature, and equilibrated with pure silver by connecting the platinum and silver electrodes for about 10 hr at 30°C before making the conductivity measurements. Samples containing 5-10 m/o Ag_3PO_4 show very high ionic conductivity, about 0.1 $(ohm\text{-}cm)^{-1}$ at 30°C. This value is comparable with that of $RbAg_4I_5$, 0.28 $(ohm\text{-}cm)^{-1}$ at 25°C. In Fig. 6, the ionic conductivity of $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ equilibrated with silver at each measurement temperature is plotted as a function of temperature. The energy of activation computed from the graph is 4.0 kcal mol^{-1}. The high ionic conductivity and low energy of activation are consistent with the α-Ag_2Se structure assigned to the composition on the basis of x-ray diffraction analysis and differential thermal analysis.

The α-phase solid solutions exhibit deviations from stoichiometry, and their ionic conductivity changes with the cation-to-anion ratio, as observed for β-Ag_2Se and β-Ag_2Te (13). However the stoichiometric composition of the α-phase solid solutions cannot be determined by means of the theory of Wagner and Schottky

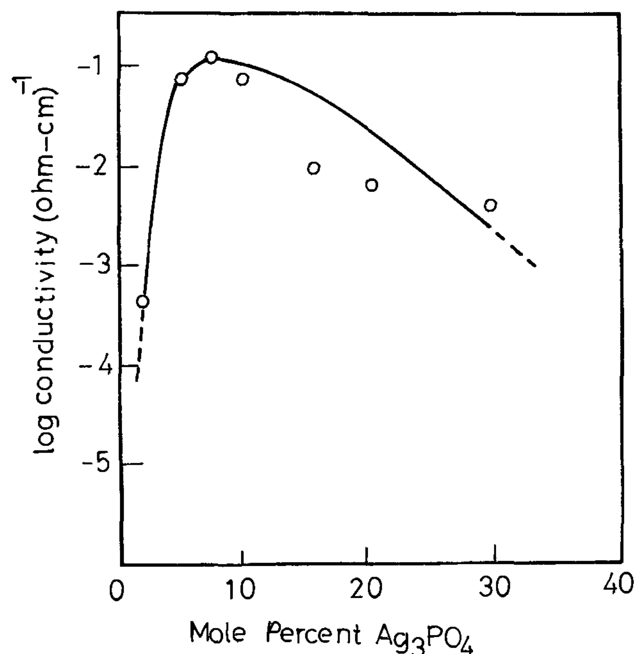

Fig. 5. Ionic conductivity at 30°C as a function of composition for Ag_2Se-Ag_3PO_4 samples equilibrated with pure silver at 30°C.

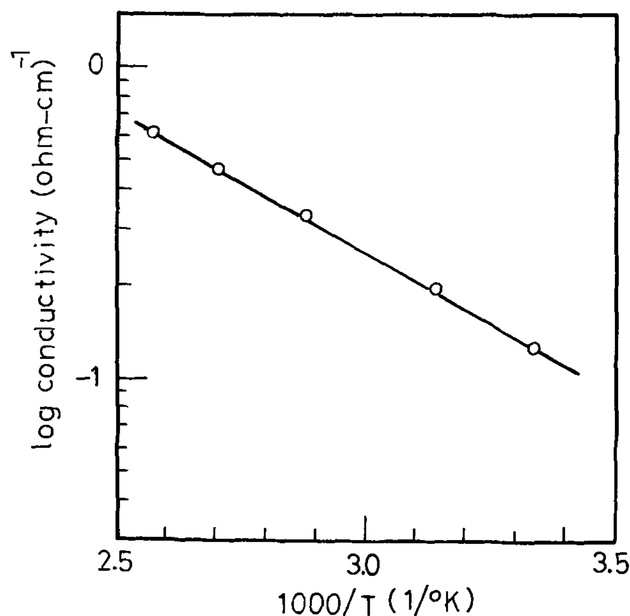

Fig. 6. Ionic conductivity as a function of temperature for $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ equilibrated with pure silver at each measurement temperature.

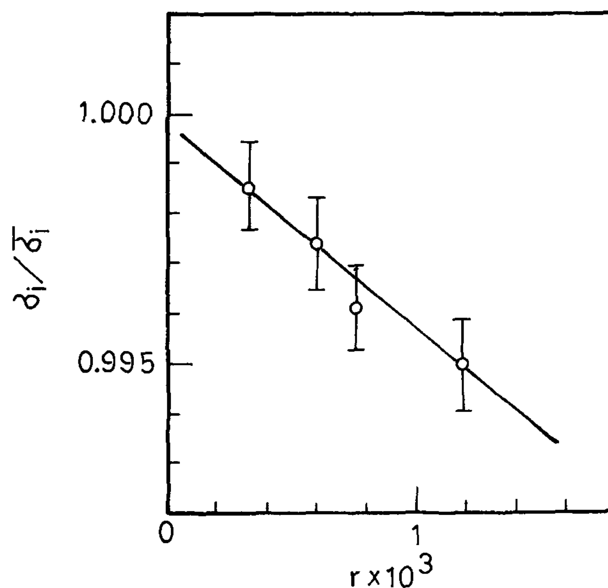

Fig. 7. Relative ionic conductivity, $\sigma_i/\overline{\sigma_i}$, of $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ at 110°C as a function of the deviation, r, from the composition equilibrated with pure silver at 110°C.

(18), which was used for β-Ag_2Se and β-Ag_2Te (13), because the α-phases contain high concentrations of both mobile ions and electrons. In this case, therefore, the composition equilibrated with pure silver was chosen as reference state.

The ionic conductivity (σ_i) of a sample containing 7.5 m/o Ag_3PO_4 was measured at 110°C as a function of the amount of silver (r) removed from the sample after it had been equilibrated with pure silver at 110°C. The reduction in silver content, which was produced by passing current between the platinum electrode and the lower silver electrode, was calculated from

$$r = \frac{q}{x\mathbf{F}} \quad [1]$$

where q is the number of coulombs passed, x the number of moles of anion in the sample, and $\mathbf{F}$ the Faraday constant. The relative conductivity, $\sigma_i/\overline{\sigma_i}$, where $\overline{\sigma_i}$ is the ionic conductivity of the sample equilibrated with pure silver, is plotted as a function of r in Fig. 7. The change in σ_i with r is small, and the experimental error in $\sigma_i/\overline{\sigma_i}$ is about ± 0.001.

Silver ions in a solid like α-Ag_2Se may be free to move through a large number of sites within the crystal. In that case

$$\sigma_i = en_i\mu_i \quad [2]$$

where n_i is the concentration of silver ion, μ_i the ion mobility, and e the electronic charge. If it is assumed that all the silver is ionized, the relation between n_i and r may be expressed by

$$n_i = \overline{n_i} - r(N_o/V_m) \quad [3]$$

where $\overline{n_i}$ is the concentration of silver ion for the sample equilibrated with pure silver, V_m the molar volume of the material, and N_o Avogadro's number. From Eq. [2] and [3], if μ_i is independent of n_i, we have

$$\frac{\sigma_i}{\overline{\sigma_i}} = 1 - \frac{rN_o/V_m}{\overline{n_i}} \quad [4]$$

According to this equation, the value of $\overline{n_i}$ may be determined from the slope of the $\sigma_i/\overline{\sigma_i}$ *vs.* r curve. From the slope of the curve in Fig. 7, one obtains 3.5×10^{21} cm^{-3} for $\overline{n_i}$. The ionic mobility calculated from $\overline{\sigma_i}$ and $\overline{n_i}$ is about 5×10^{-3} cm^2/V-sec. The total concentration of silver ion calculated from V_m (= 40 cm^3) is 3.1×10^{22} cm^{-3} in $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$, which is about ten times larger than the experimental value of $\overline{n_i}$. A possible explanation of this difference is that the transport of ions in solids with an α-Ag_2Se type structure differs from transport in liquids, due to interactions between the mobile ions and the other ions.

The concentration of mobile silver ions in the α-Ag_2Se solid solution cannot be compared with that in α-Ag_2Se, because the latter has not been reported. It may be concluded, however, from the experimental results that the concentration of mobile silver ion in the solid solution is extremely high compared with that in β-Ag_2Se, which is only 3.5×10^{17} cm^{-3} at 105°C (13).

Hall coefficient and electronic conductivity.—The Hall coefficient and electronic conductivity of the Ag_2Se-Ag_3PO_4 solid solutions have also been measured as functions of r. The Hall coefficient R was negative over the whole range of r. The excess electron concentration, n_e, was calculated by using the one-carrier equation

$$n_e = \frac{1}{eR} \quad [5]$$

The excess electron concentrations in $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ are shown in Fig. 8 as a function of r. The concentrations are fairly large and comparable to those in α-Ag_2Se, which were found by Miyatani *et al.* (19) to be in the range from 0.6×10^{19} to 6×10^{19} cm^{-3} at 150°C. In the range in which the hole concentrations in $(Ag_2Se)_{0.925}(Ag_3O_4)_{0.075}$ are negligible compared to those of excess electrons, the relation between n_e and r is given by

$$n_e = \overline{n_e} - r(N_o/V_m) \quad [6]$$

where $\overline{n_e}$ is the excess electron concentration when the sample is equilibrated with pure silver. According to this equation the slope of the n_e *vs.* r curve is N_o/V_m. The experimental slope in Fig. 8 is 1.3×10^{19} cm^{-3} at each temperature investigated, in good agreement with the calculated value of 1.5×10^{19} cm^{-3} for N_o/V_m.

The dependence of electronic conductivity on r for $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ is shown in Fig. 9. The Hall mobility calculated from $\mu_e = \sigma_e/en_e$ is shown in Fig. 10. It depends fairly strongly on r, that is, on the excess electron concentration.

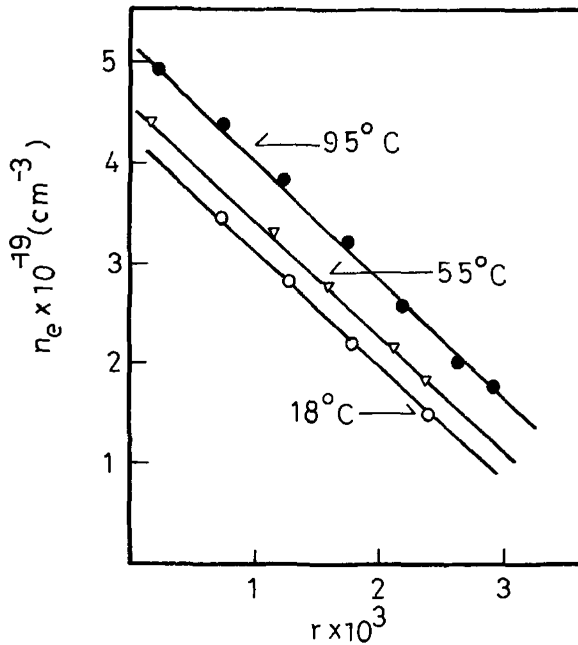

Fig. 8. Electron concentration, n_e, in $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ as a function of the deviation, r, from the composition equilibrated with pure silver at each measurement temperature.

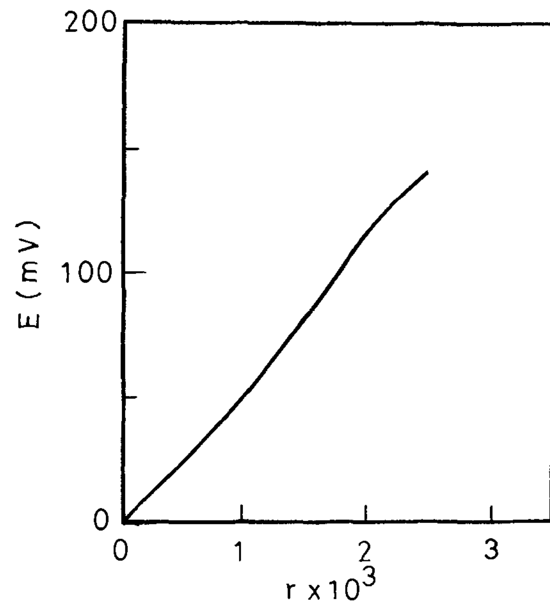

Fig. 11. Coulometric titration curve for $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ at 95°C.

Coulometric titration.—The potential difference (E) between the platinum electrode and one of the silver electrodes was measured while a constant current of 50-100 μA was being passed between the platinum electrode and the other silver electrode. Reproducible results were obtained up to a potential of 160 mV for both addition and removal of silver. Above 160 mV, a slow decay of the open-circuit potential was observed, possibly because of a slow decomposition of the Ag_2Se-Ag_3PO_4 solid solution to β-Ag_2Se and Ag_3PO_4. Typical results for E as a function of r, obtained at 95°C for the sample containing 7.5 m/o Ag_3PO_4, are shown in Fig. 11. The curves obtained in the temperature range from room temperature to 100°C for samples containing 5 to 10 m/o Ag_3PO_4 are similar to the one shown in Fig. 11.

For excess electron concentrations (n_e) as high as those in the present samples, n_e is given by Fermi statistics as

$$n_e = \frac{\pi(8m^*_e kT)^{3/2}}{2h^3} F(\mu_e/RT) \quad [7]$$

where m^*_e is the effective mass of an excess electron, k the Boltzmann constant, h Planck's constant, μ_e the chemical potential of the electrons, and $F(\mu_e/RT)$ the Fermi-Dirac function. By combining Eq. [6] and [7], and differentiating the resulting equation with respect to μ_e, we obtain

$$-\frac{N_o}{V_m}\frac{dr}{d\mu_e} = \frac{\pi(8m^*_e kT)^{3/2}}{2h^3RT} F'(\mu_e/RT) \quad [8]$$

Dividing Eq. [8] by Eq. [7] gives

$$-\frac{N_o}{V_m}\cdot\frac{dr}{d\mu_e} = \frac{n_e}{RT}\,\frac{F'(\mu_e/RT)}{F(\mu_e/RT)} \quad [9]$$

The chemical potential of silver, μ_{Ag}, is related to the electromotive force, E, by

$$\mu_{Ag} - \mu^o_{Ag} = -E\mathbf{F} \quad [10]$$

where μ^o_{Ag} is the chemical potential of silver in its pure state and $\mathbf{F}$ the Faraday constant. Denoting the chemical potential of silver ion by μ_{Ag^+}, we have

$$\mu_{Ag^+} + \mu_e = \mu_{Ag} \quad [11]$$

In view of the high degree of disorder of silver ions in the sample, the chemical potential of silver ions is essentially independent of small variations in the cation-to-anion ratio. Hence, it follows from Eq. [10] and [11] that

$$d\mu_e = d\mu_{Ag} = -d(E\mathbf{F}) \quad [12]$$

From Eq. [12], Eq. [9] is rewritten as

$$\frac{dr}{dE} = n_e(\mathbf{F}/RT)(V_m/N_o)\,\frac{F'(\mu_e/RT)}{F(\mu_e/RT)} \quad [13]$$

By using the values of dr/dE and n_e obtained respectively by coulometric titration and Hall coefficient measurements together with tabulated values of F and F' (20), $F(\mu_e/RT)$ can be evaluated for each value of n_e, and m^*_e is then found by using Eq. [7]. The values of m^*_e/m_o obtained in this way for $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ at 75° and 95°C are shown as a function of r in Fig. 12. These results are comparable with the values of m^*_e/m_o (0.1-0.15) for α-Ag_2Se measured by Miyatani *et al.* (19).

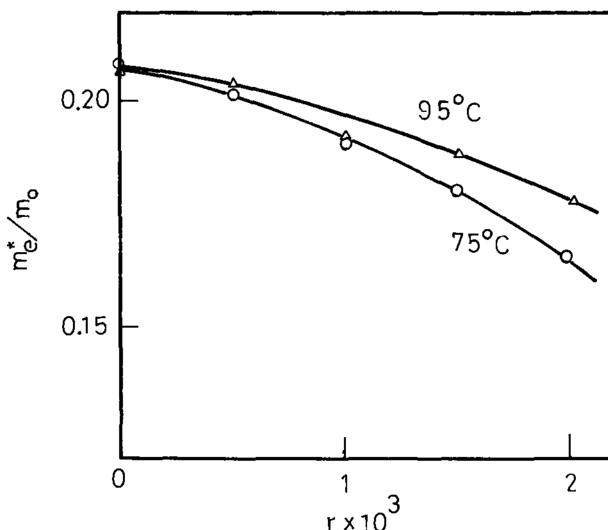

Fig. 12. Ratio of the effective mass, m^*_e, to the free electron mass, m_o, in $(Ag_2Se)_{0.925}(Ag_3PO_4)_{0.075}$ as a function of the deviation, r, from the composition equilibrated with pure silver at 75° and 95°C.

Summary

The properties of Ag_2Se-Ag_3PO_4 solid solutions with the α-Ag_2Se structure are summarized in Table II, together with the corresponding values for α-Ag_2Se. This table shows that the characteristic quantities for these solid solutions are comparable with those for α-Ag_2Se.

The solid solutions with α-Ag_2Se structure are mixed conductors which have both high ionic and high electronic conductivity at room temperature. These mixed conductors are suitable electrode materials for the electrochemical analog memory element proposed by the present authors (13), because the silver ion diffuses sufficiently fast to maintain a homogeneous activity in the solid phase.

A Thorough Thermodynamic Evaluation of the Silicon-Hydrogen-Chlorine System

L. P. Hunt and E. Sirtl

Dow Corning Corporation, Solid State Research and Development, Hemlock, Michigan 48626

ABSTRACT

A sensitive computational method allowed the determination of $\Delta Hf°_{298}(SiHCl_3,g) = -116.9 \pm 0.7$ kcal/mol based on various previously reported experimental investigations. For the first time the gaseous compounds $SiCl_3$ and Si_2Cl_6 were included in a thermodynamic evaluation of the Si-H-Cl system. Diagrams relating Cl/H (0.01-10) to Si/Cl over the temperature range of 400°-1700°K indicate the equilibrium state of the system with respect to the corresponding increase or decrease of silicon in the gaseous phase.

Many papers have appeared in the literature which have used thermodynamically calculated equilibrium states to aid in explaining experimental data from the synthesis, hydrogenation, pyrolysis, and reduction of various chlorosilanes. Some of these publications contain individual solutions for thermodynamically describing the Si-H-Cl system. More detailed analyses have been made by Lever (1), Niederkorn and Wohl (2), and Harper and Lewis (3). Since the various thermodynamic analyses lead to widely varying results, a recent article (4) critically evaluated the thermodynamic data used in the equilibrium calculations and presented results based on the suggested values. This article also provides a detailed survey of pertinent thermodynamic literature.

The current work thoroughly examines the standard enthalpy of formation of trichlorosilane since prior calculations had indicated that the calculated equilibrium molar ratio of $SiCl_4/SiHCl_3$ was highly sensitive to the $SiHCl_3$ enthalpy used, relative to a fixed enthalpy value of $SiCl_4$. The purpose of this paper, based on the revised $SiHCl_3$ enthalpy and the evaluation of other pertinent thermodynamic data, is to graphically present the equilibrium Si-H-Cl system in a form that depends only upon the initial and final states of the system. We have selected, similar to Lever (1), the temperature variation of the Si/Cl ratio as a function of the Cl/H ratio.

Computational Techniques

Modified versions of a computer program, similar to that described by Cruise (5), were used for all equilibrium calculations. The generalized program minimizes the free energy of a system through an iterative technique in which the concentration of specified species is varied in a controlled manner. A condensed phase species is automatically excluded from the computational process when its concentration reached a preset lower limit. Any number of probable species may be included in the program since input is in the form of a matrix representing the elemental distribution among the species.

The only restraint on the initial estimate of species concentrations is that the species concentrations represent the ratios of the atoms contained in the reactants. The final equilibrium state of a system is independent of the original distribution of the atoms among the species as long as the initial atomic ratios are the same. For example, one reaches the same equilibrium mixture from either 1 mole of SiH_2Cl_2 or from ½ mole each of SiH_4 and $SiCl_4$. Therefore, the Cl/H ratio is used to uniquely define the gas-phase composition of the Si-H-Cl system since it represents an infinite number of conditions made possible by using different proportions of starting materials.

Since the once selected Cl/H ratio has to remain constant for a reaction in this system, the Si/Cl ratio is used to represent the changing composition of the gas phase due to silicon either entering or leaving it via the condensed phase of elemental silicon.

In addition to using the temperature and total pressure of the system as input to the computer program, the physical state of each species must be noted along with its basic thermodynamic values. It is the deviations in these values, the standard enthalpy of formation, $\Delta Hf°_{298}$, standard entropy, $S°_{298}$, and the temperature function of the heat capacity equation, $C°_p(T)$, that cause different results to be obtained for the final computed equilibrium state of a system.

Thermodynamic Data

Discussed below are chemical species for which the thermodynamic data have been revised since our previous publication (4), or species that have been added to more thoroughly complete this analysis of the Si-H-Cl system. Data for the species Cl(g), Cl_2(g), and Si(g) are considered well enough characterized to be taken directly from the literature (see Table I).

Standard Enthalpy of Formation

Trichlorosilane.—Scrutinization of $\Delta Hf°_{298}(SiHCl_{3,g})$ is necessary since the only two experimental determinations in the literature differ by 13 kcal/mol. Reuther (6) stated that his value of −112 kcal/mol probably was too positive due to partial reaction of elemental chlorine, liberated by the combustion process, with the calorimeter. On the other hand, the enthalpy of −125 kcal/mol, determined by Wolf (7) and corrected for the revised SiO_2 enthalpy, seemed incompatible with experimental data close to equilibrium conditions (8). Similar to the case of several determinations of the standard enthalpy of $SiCl_4$, as discussed by Schäfer and Heine (9), the supposed experimental error in Wolf's data may likewise be due to incomplete hydrolysis, and would therefore lead to a negative deviation from the most probable $SiHCl_3$ enthalpy. Although past estimates (8) of the enthalpy of formation of $SiHCl_3$ appeared to yield satisfactory results when comparing calculated and experimental data (4, 8), the value of −116 kcal/mol had no direct experimental basis, since it had been obtained by linear interpolation between the enthalpies of SiH_4(g) and $SiCl_4$(g).

During the course of our studies, it became obvious that the enthalpy of formation of trichlorosilane could be determined from already existing experimental data. This is possible because the equilibrium molar ratio n_{SiCl_4}/n_{SiHCl_3} is very sensitive (Fig. 1) to the

Key words: silicon, thermochemical equilibrium, transport, enthalpy, vapor deposition.

standard enthalpy of formation of $SiHCl_3$, assuming the enthalpy of $SiCl_4$ as fixed, and because a less complex chemical equilibria exists at lower temperatures. Below about 1250°K, a negligibly small partial pressure of $SiCl_2$ exists such that the gas phase essentially contains only the molecules $SiCl_4$, $SiHCl_3$, HCl, and H_2.[1] Therefore, the only uncertain enthalpy is that of

[1] The variation of the interpolated standard enthalpy for SiH_2Cl_2 (g) by ±2 kcal/mol showed no major influence on the calculated partial pressures of the above-mentioned species.

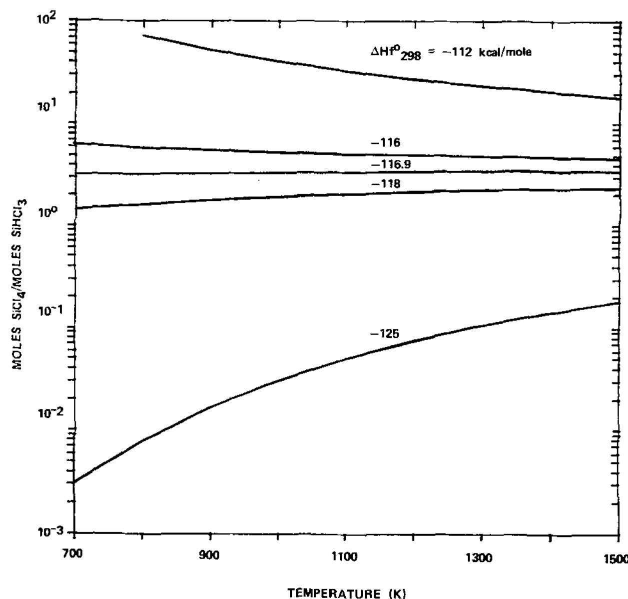

Fig. 1. Temperature variation of the equilibrium $SiCl_4/SiHCl_3$ ratio for various values of $\Delta Hf^\circ_{298}(SiHCl_3,g)$ at Cl/H = 1.0, 1 atm total pressure, and $\Delta Hf^\circ_{298}(SiCl_4,g)$ = −156.7 kcal/mol.

$SiHCl_3$ since the work by Schäfer and Heine (9) has given high reliability to $\Delta Hf^\circ_{298}(SiCl_4)$.

Ashen *et al.* (10) pursued the same problem in a similar way, based on their data obtained from the thermal decomposition of $SiHCl_3$ and $SiCl_4$ in presence of hydrogen. However, they accepted the $SiHCl_3$ value (uncorrected) as the point of reference and varied the $SiCl_4$ value until agreement was found with their kinetic data.

There are several experimental studies available which allow comparison of the different $SiCl_4/SiHCl_3$ ratios close to or extrapolated toward infinite residence time. These data, and others, compiled in Table II, show our calculated values of $\Delta Hf^\circ_{298}(SiHCl_3,g)$ from reactions involving the decomposition of $SiCl_4$ or $SiHCl_3$, the hydrogenation of $SiCl_4$, and the formation of chlorosilanes by hydrochlorination of silicon. The most probable enthalpy value of −116.9 ± 0.7 kcal/mol deviates only slightly from the value −116 obtained from the linear relationship within the sequence $SiH_4 \rightarrow SiCl_4$ proposed earlier (8). The data given by Hata *et al.* (11) must be weighted lightly due to their experimental difficulty of trapping the product gases.

Due to the large concentration of gaseous silicon dichloride in a high-temperature reaction zone the analysis of exhaust gases in any known silicon deposition reactor system must lead to erroneous thermodynamic conclusions. The major reason for this is the recombination of the dichloride with hydrogen chloride to form trichlorosilane in the downstream area. Depending on the quenching rate, polymer subchlorides of very low volatility also may be formed additionally influencing the results and the meaning of any gas analysis.

Silicon subchlorides.—A thorough study of the Si-$SiCl_4$ system up to 1575°K by Schäfer and Nickl (12), and supported by more recent studies (13, 14), indi-

cates that $SiCl_4$ and $SiCl_2$ are the only gases present to within less than the 2% experimental error in the measured partial pressures. Nevertheless, for theoretical as well as practical reasons, we wanted to complete our thermodynamic analysis of the Si-H-Cl system by also including the gaseous compounds SiCl, $SiCl_3$, and Si_2Cl_6. Although $SiCl_3$ has not been regarded as an equilibrium species by authors (1, 2) who have considered SiCl, recent EPR measurements (15) have shown the relative concentrations of species in the Si-Cl system to be $SiCl_2 > SiCl_3 >$ SiCl at temperatures greater than 600°K. Equilibrium calculations in our subsequent paper (16) are found to agree with these experimental observations in the lower temperature area.

The standard enthalpy value for SiCl(g) was taken from the JANAF Tables (17). The appreciable uncertainty (+45.7 ± 15 kcal/mol) is the result of two different spectroscopic evaluations. However, calculations at 1500°K using even the lowest value (+30.7) show that the amount of SiCl is $<8 \times 10^{-2}\%$ in the Si-Cl system.

A small change has been made in the enthalpy of $SiCl_2(g)$ based on the work by Schäfer *et al.* (13).

There is no literature concerning the standard enthalpy of formation of $SiCl_3(g)$. Unfortunately, a simple linear interpolation, as it was applied successfully to the sequence of "saturated" compounds in the series $SiH_4 \rightarrow SiCl_4$, is no longer meaningful in the case of $Si(g) \rightarrow SiCl_4(g)$. The energy states of the unbonded valence electrons are different in each case, as are the bonding angles of the ligands. It can be assumed that the compounds having an unpaired electron deviate from incremental linearity in an endothermal sense (more positive enthalpy of formation). This is demonstrated by the diagram shown in Fig. 2. The standard enthalpy of silicon trichloride was obtained from a computational analysis of the Si-Cl system where, based on studies by Schäfer and Nickl (12), the partial pressure of $SiCl_3(g)$ was not allowed to exceed 0.3%. This gave a minimum enthalpy value of −78 kcal/mol which supported our hypothesis.

A basic estimate leads to the chosen value of $\Delta Hf°_{298}(Si_2Cl_6,g)$. When one mole of $Si_2Cl_6(g)$ is synthesized from 2 moles $SiCl_3(g)$, the heat of reaction consists of the sum of the heat of formation of a silicon-silicon bond plus a "rearrangement energy," ΔH_R, of the $SiCl_3$ molecules characterized by the spatial deviation of the Si-Cl bond orbitals from their tetrahedral arrangement in $SiCl_4$. Since the term $\Delta H(SiCl_3,g) + \Delta H_R$, by definition, is nothing else but the hypothetical value of an "ideal" $SiCl_3$ molecule obtained by linear interpolation (Fig. 2), the standard enthalpy of gaseous Si_2Cl_6 can be calculated directly as follows

$$\begin{aligned} \Delta Hf°_{298}(Si_2Cl_6,g) &= 2[\Delta H(SiCl_3,g) + \Delta H_R] + \Delta H_{Si\text{-}Si} \\ &= 2(-91) + (-54) \\ &= -236 \text{ kcal/mol.} \end{aligned}$$

According to Pauling (18), $\Delta H_{Si\text{-}Si}$ is the negative value of one-half of the atomic sublimation energy $\Delta H°_{298}$(subl) of silicon. The limit of accuracy is estimated to be less than ±2 kcal/mol.

The catalytic thermal decomposition of Si_2Cl_6 has been reported (19) to be complete at temperatures between 350° and 400°C according to the reaction

$$2Si_2Cl_6(g) \rightarrow 3SiCl_4(g) + Si(s)$$

This is in agreement with our calculations and, thus, supports the validity of the proposed enthalpy of formation of hexachlorodisilane.

Standard Entropy

The entropy of $SiCl_3(g)$ taken from recently tabulated data (20) is nearly 2 kcal/mol higher than that of $AlCl_3(g)$ or $PCl_3(g)$. Since the entropy values of both $AlCl_3(g)$ and $PCl_3(g)$ are well established, we accepted the entropy of $SiCl_3(g)$ to be equal to that of $PCl_3(g)$.

No entropy data appears in the literature in the case of $Si_2Cl_6(g)$. The only compound related to Si_2Cl_6 is C_2Cl_6 (Al_2Cl_6 has a different molecular structure). Fortunately, entropy data for hexachloroethane are tabulated (17). Thus, comparisons within a homologous group can be used to make fairly accurate estimates. It is our experience that, within a homologous series of reactions, the difference in reaction entropies between the first and the second element in a group of the Periodic System generally amounts to 1 or 2 eu. Using the reaction $M_2Cl_6(g) \rightarrow 2MCl_3(g)$, a value of 101 ± 1 eu (cal/deg mol) was calculated for $S°_{298}(Si_2Cl_6,g)$.

Molar Heat Capacity, $C°_p(T)$

The heat capacity data for HCl(g) and Si(s) reported (4) earlier have been replaced by more accurate values.

The coefficients of the terms in the heat capacity equation were determined in many cases by regression analysis of the original data cited over a temperature range of 298°-2000°K. The maximum deviation of the calculated from the original data is <2% for the compounds predominate under normal conditions. A single form of the heat capacity equation was chosen because of convenience and of its more general use in compilations (21-23).

Results and Discussion

Computations over the Cl/H range of 0.01-10 and over temperature and total pressure spans of 300°-1700°K and 0.1-1.0 atm were carried out with the data compiled in Table I. The thermodynamic analysis indicates that the following species can be ignored at equilibrium due to their low partial pressures while maintaining ≥99% accuracy: SiH_4 SiCl, $SiCl_3$, Si_2Cl_6, Cl, Cl_2, and Si(g). A comparative discussion of the experimental and calculated behavior of individual species is given in a subsequent article (16).

The Si-H-Cl equilibrium system is well illustrated by Fig. 3 and 4 which show the variation of the final silicon content of the gas phase (Si/Cl ratio) with the initial chlorosilane concentration (and, therefore, Cl/H ratio) at various temperatures. There are three Si/Cl values in this system that are approached asymptotically in the diagrams; 0, 0.25, and 0.50. Total conversion to elemental silicon (Si/Cl = 0) is the ultimate case to be reached at very low Cl/H ratios and increasing tem-

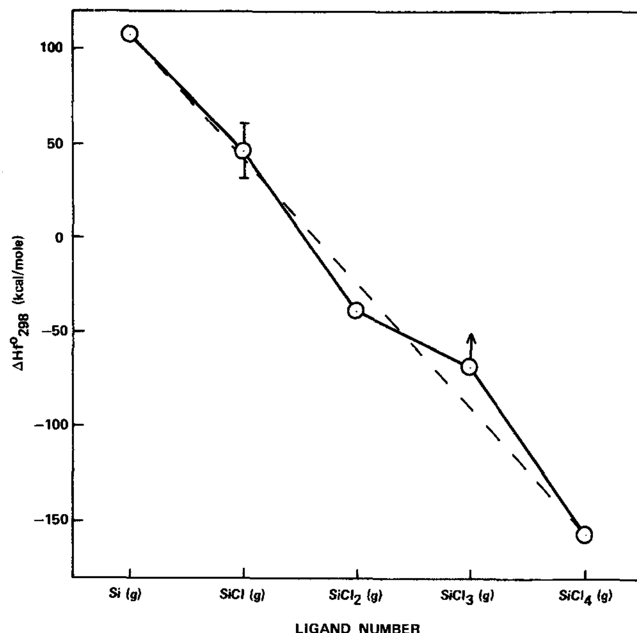

Fig. 2. Enthalpy relationship for the series $Si(g) \rightarrow SiCl_4(g)$

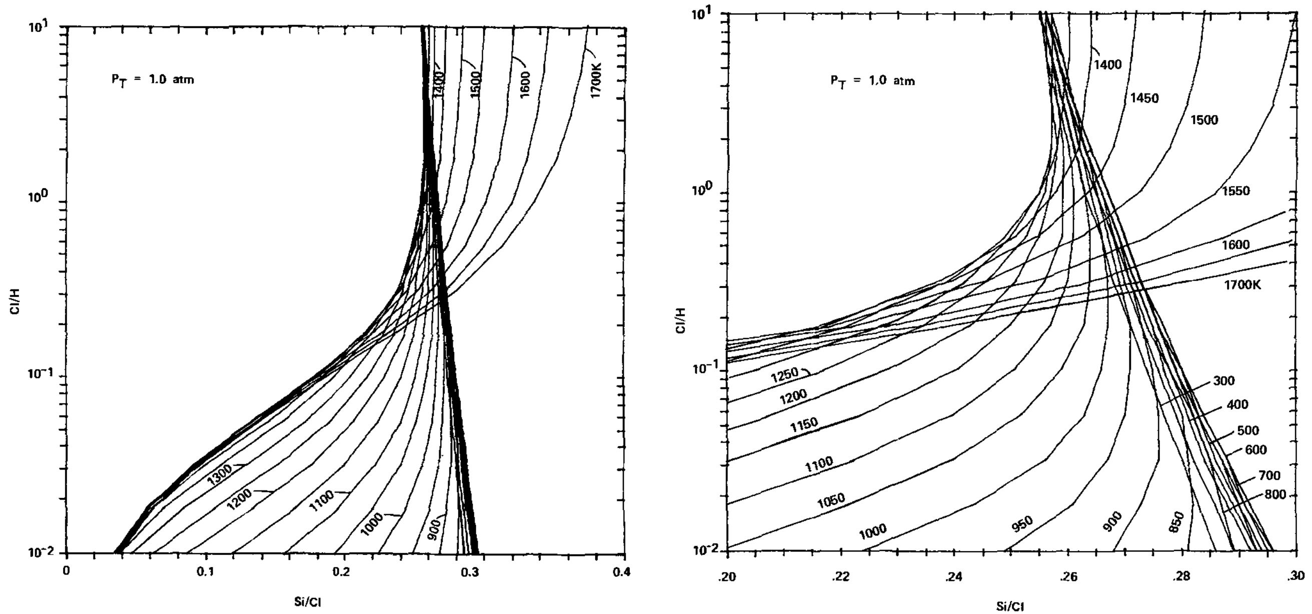

Fig. 3. (a, left) The silicon content of the gas phase as a function of the Cl/H ratio at 1 atm total pressure for 50 degree temperature increments. (b, right) An enlargement of a portion of (a).

peratures. Silicon tetrachloride (Si/Cl = 0.25) is the major compound of significance at high Cl/H values and at temperatures up to approximately 1300°K. At lower temperatures and decreasing Cl/H ratios, the silicon content of the gas phase is changed due to the relative importance of trichlorosilane (Si/Cl = 0.33) with respect to silicon tetrachloride. Both high temperatures and increasing Cl/H ratios strongly favor the formation of silicon dichloride (Si/Cl = 0.50), the most stable of the gaseous subchlorides below the melting point of silicon.

Figures 3 and 4 are particularly useful in determining the maximum yield of silicon from chlorosilane decomposition, or the direction and magnitude of silicon transport reactions. Negative yields, preferably obtained with HCl, $HCl\text{-}H_2$, or $SiCl_4/H_2$ mixtures indicate the dissolution (etching) of silicon.

In the first case, the theoretical silicon yield (η) can be easily calculated from the equation $\eta = (V - V')/V$, where V is the Si/Cl ratio of the starting mixture and V' is the ratio at equilibrium. The transport direction of silicon in a temperature gradient for a given Cl/H ratio, can be determined from the equilibrium Si/Cl ratios (V_1', V_2') existing at two silicon subsystems. Transport will occur by diffusion in the direction of the lower Si/Cl ratio. The transport driving force can be formulated according to $\Delta P_{Si} = V_1' - V_2'$. In the case of $T_1 > T_2$ a positive value of ΔP_{Si} corresponds to a silicon transport to higher temperatures. For a quantitative treatment of a diffusion-limited transport process, equations given in Schäfer's book (24) may be used.

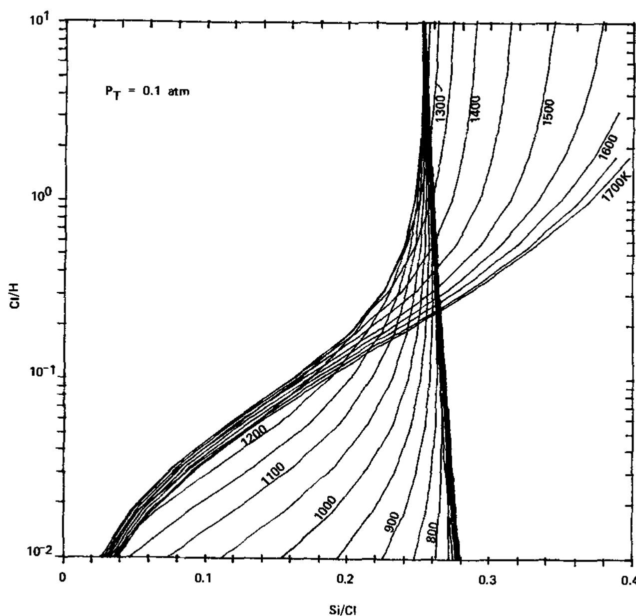

Fig. 4. The silicon content of the gas phase as a function of the Cl/H ratio at 0.1 atm total pressure for 50 degree temperature increments.

The application of the different diagrams to a number of practical cases will be demonstrated in a subsequent paper (16).

Acknowledgment

The authors wish to thank D. H. Sawyer for his experimental studies of transport reactions.

Light Scattering from Photoresist Films

F. P. Laming[1] and R. E. Straile

Bell Telephone Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Nonfluorescent light scattering at 6328Å from films of Kodak Metal Etch Resist and Kodak Thin Film Resist has been measured over an angular range of 1°-75° from the incident direction. A correlation is made between these measurements and resolution loss due to scattering which can occur when the resists are used for photolithography. It is found that such resolution loss can occur if certain limits on thickness or exposure are exceeded.

When high resolution is not an essential requirement there are few unsolved problems in the technology of pattern generation for thin-film circuits. However, when it is required to generate a pattern in which components are separated by distances of the order of only one micron, not only do problems become acute but the origins of many difficulties are as yet undetermined. Although a number of factors contributing to resolution loss can be postulated, they cannot be placed in order of precedence until they have been quantitatively evaluated. The results reported here will allow the relative importance of light scattering to be assessed when other contributing factors (such as edge diffraction, reflection, etc.) have been similarly determined.

Light scattered by a resist film consists of three distinct factors: (*i*) inelastic scattering, such as fluorescence, (*ii*) elastic scattering of absorbed light or resonance fluorescence, and (*iii*) elastic but nonabsorbed scattering, such as that considered by Mie or Rayleigh. In this report we are concerned only with type (*iii*).

Nonfluorescent scattered light from thin-film materials can originate either at interfacial boundaries or within the film material. The relative contribution from the two sources depends on the nature of the film material and the refractive index differences at the interfaces. In most studies of thin films, interfacial effects are eliminated as far as possible since information on the structure of film material is obtained primarily from the bulk-film scattering (1). In the present work it is the total nonfluorescent light scattering which is of interest. Our measurements, therefore, include the contribution of boundary scattering as a significant factor.

Figure 1 shows the interaction between a photoresist film and an incident perfectly collimated beam of light of intensity I. For simplicity, only scattering originating at the film surface is illustrated, but similar diagrams could have been drawn at any depth within the film material. The scattered light intensity will, of course, be greatest when the scattering angle θ is small, diminishing to a minimum at $\theta = 90°$. Backscattering will not be considerd. If the scattered intensity at a given angle θ is sufficient to expose the photo-

[1] Present address: International Business Machines Corporation, East Fishkill Facility, Hopewell Junction, New York 12533.

Key words: light, scattering, photoresist, Rayleigh.

resist, then loss in resolution will occur. Our present purpose was to determine at what angle θ such resolution loss first begins to occur under the conditions of normal photolithographic practice.

Experimental

Kodak Metal Etch Resist (KMER) was chosen as the material of primary interest since it is known to give poor resolution (2) and is the least purified resist supplied by Kodak. It should, therefore, present more of a scattering problem than any other resist. Kodak Thin Film Resist (KTFR) was also studied.

The resists were deposited as films on glass microscope slides by spinning, without purification by filtration. Thickness measurements were made using a Talysurf Model 4. Each film was baked at 100°C for 30 min prior to use.

A diagram of the scattering apparatus is presented in Fig. 2. The design is similar to that described by Lundberg *et al.* (3) for measuring light scattering from molecular solutions.

The output of a 25 mW He/Ne laser was interrupted at a rate of 400 Hz by a PAR* Model BZ-1 light chopper, positioned inside the laser cavity to eliminate edge diffraction from the chopper blades. The primary beam was deflected so as to pass at normal incidence through the sample under investigation, which was mounted on a fixed stage above a rotatory table. The beam met the sample at a point precisely above the center of the table. Scattered light was observed with the primary photomultiplier fixed to a rigid arm attached to the center of the table. The arm was motor-driven at a rate of 6° per min.

The apparatus was used as described for measurements down to 15°, and with some care down to 10°. Below 10°, however, a slight modification was necessary because the extension tube attached to the primary photomultiplier began to contact the main laser beam. For low-angle measurements, therefore, the long extension tube was replaced by a short tube with a ⅛ in. circular aperture. This "pin-hole" arrangement enabled measurements to be extended to 1°, though the wider acceptance angle of such an arrangement resulted in some loss of accuracy. The motor drive for the detector arm was not used in this mode of operation. Accuracy of the data decreased with decreasing angle and was approximately ±5% above 15°, ±10% down to 3°, and ±20% at 1°.

In order to eliminate minor fluctuations due to small daily changes in experimental conditions all scattering measurements were made with respect to a fixed standard; a 3 mm thick sample of Mylar[2] was found to be appropriate. Scattering from this sample at 45° was observed after each determination of resist scattering, and the ratio between the latter and the former taken as a measure of absolute scattering intensity. The ratio

[2] A commercial polyester resin.

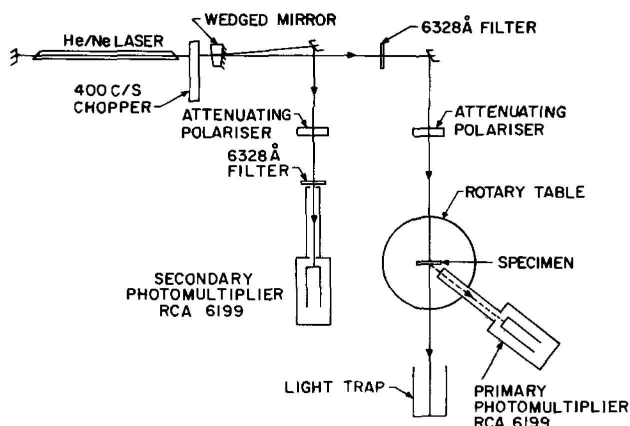

Fig. 2. Light scattering apparatus

obtained in this way also includes a contribution from the microscope-slide substrate. This contribution arises mainly from one surface of the glass slide (neglecting scattering within the bulk of the glass) since the other glass face presents an almost index-matched surface to the resist. The required resist scattering is, therefore, given by the expression

$$I_R = \frac{I_{OBS} - \dfrac{I_{SUB}}{2}}{I_{MYL}}$$

where I_R = scattering measurement required; I_{OBS} = observed scattering intensity at angle θ; I_{SUB} = observed scattering from substrate alone at angle θ; I_{MYL} = observed scattering from Mylar standard at 45°.

Table I lists values of I_R obtained for two sets of KMER films down to 15°. Although no specific attempt was made to vary film thickness, one set of slides was 4.37μ thick and the other 4.20μ. The precision of these measurements was sufficient to show clearly the difference in scattering between the two thicknesses; the difference, ΔI_R, must arise from the bulk film material. Values of ΔI_R are also quoted in Table I. Each figure quoted is an average value taken from a minimum of 12 separate measurements on six specimens of each sample.

Below 15° a further correction to the above expression is required because in this region the main laser beam begins to contact the primary photomultiplier housing resulting in an increasingly significant contribution to the measured intensity from unwanted reflections. A measure of this contribution, I_i, was obtained by scanning down to 1° in the absence of either microscope slide or sample. The revised equation is then

$$I_R = \frac{I_{OBS} - \left(\dfrac{I_{SUB}}{2} + I_i\right)}{I_{MYL}}$$

Because measurements in this region were not so precise, changes in scattering due to small variations in film thickness were not apparent. Table II lists the results obtained for KMER and KTFR films together with substrate measurements over the range 15° to 1°. The difference between KMER and KTFR can best be seen in Fig. 3. Both sets of data were taken from films approximately 4μ thick. It is apparent that the intensity of scattered light from films of KMER exceeds that from KTFR by approximately 40 times.

In order to convert I_R values to absolute units (as percentages of incident intensity), the intensity of the

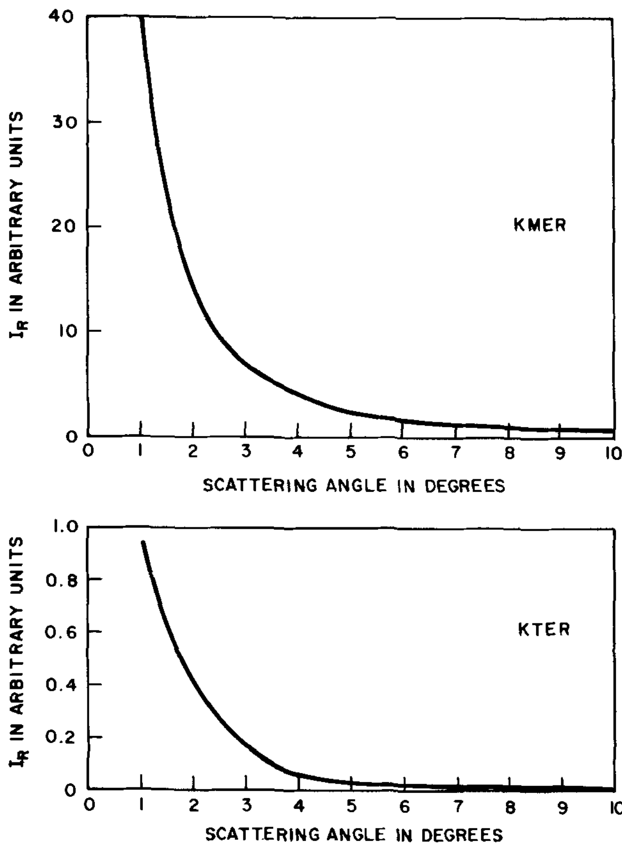

Fig. 3. Light scattering below 10° from films of KMER and KTFR.

incident beam relative to the Mylar standard was measured by scanning through 0°. To do this the incident intensity was reduced with a neutral density filter of transmittance 0.1%. Figure 4 illustrates the scattering profile of the incident beam as observed through (A) a plane glass slide, (B) a slide coated with KTFR, and (C) a slide coated with KMER. Measured values of I incident at 0° are 7900, 7600, and 7500 for A, B, and C, respectively. The observed difference between these values is largely due to the absorption of the films at 6328Å which in each case is approximately 5%. Clearly, the total scattered intensity over a solid angle of 4π steradians is an insignificant contribution to the loss in forward intensity.

The observed I_R value of 6.8 (see Table II) for a KMER slide at 3° is therefore equivalent to 0.086% of the incident intensity, while that of 0.16 for KTFR at the same angle is equivalent to 0.002% of incident.

Exposure of photoresist materials to light results in structural changes in the resist material which alter its solubility in the developing solvent. For negative resists, such as KTFR and KMER, unexposed areas are thus preferentially removed from the substrate during development. Since the development process is differential there can be some areas where the solubility has been decreased only sufficiently for partial removal to occur. Normal photolithographic procedure attempts to eliminate the effect of partially exposed areas by fairly severe washing techniques, taking advantage of the lower adhesion of the film in these areas. A characteristic curve applicable to this practical approach is represented by the solid line of Fig. 5. This curve is analogous to a photographic H&D curve. Below point A adhesion of the resist to the surface breaks down and the material can be completely removed by the developing agent.

We have extended this characteristic curve for KMER by using a less vigorous development technique so as to retain even the less adherent film. Each slide was exposed to an illumination of 1800 lumens/ft^2 from a 100W Black Light Eastern high pressure mercury lamp. Exposure times varied between 5-60 sec. After exposure, each slide was developed using KMER developer as follows. The exposed slide was immersed photoresist upwards in a shallow Petri dish containing rapidly stirred solvent. During the final 10 sec of the 3 min wash the upper surface of the slide was subjected to a jet of solvent applied with a syringe. The slide was then removed and dried in a stream of warm air. A measure of the amount of photoresist retained on the glass slide was obtained by measuring the absorption of the retained film at 400 mμ with a Beckman DU2 spectrometer.

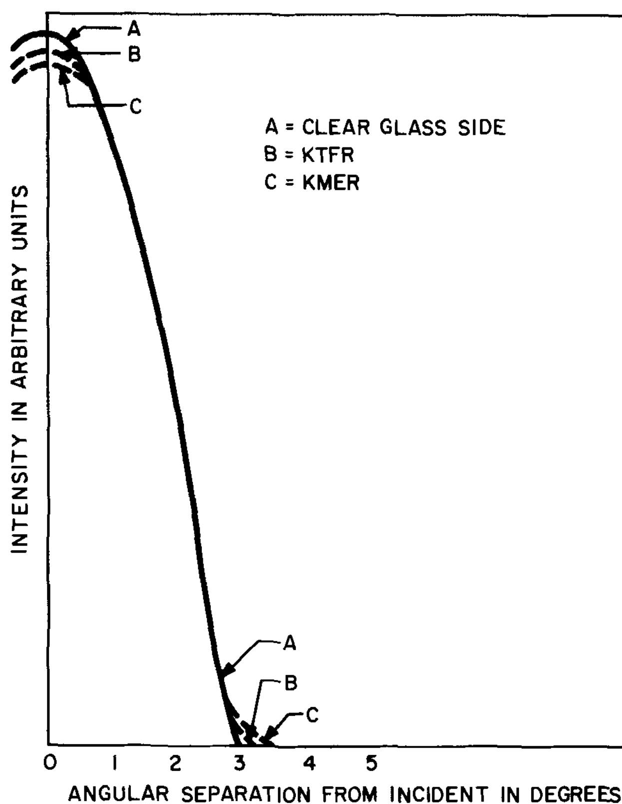

Fig. 4. Incident beam profiles close to 0°

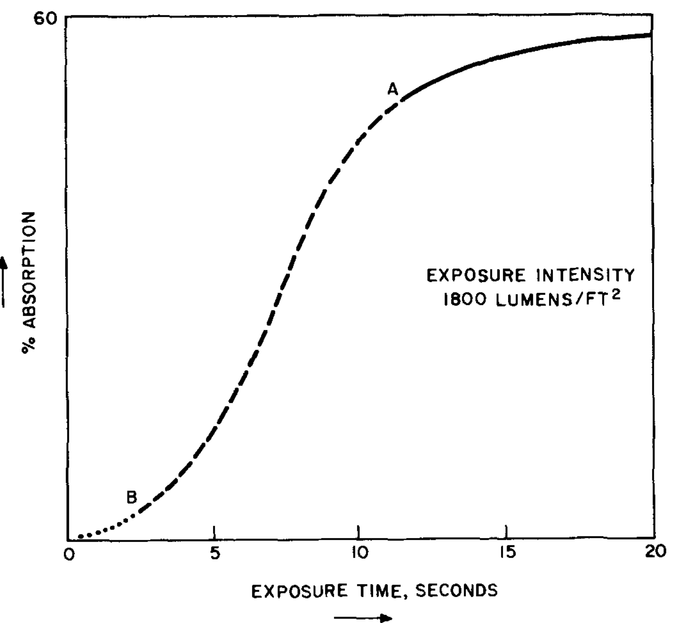

Fig. 5. Characteristic curve of KMER

The resulting characteristic curve is shown as the solid and dashed lines of Fig. 5 down to point B. At B, resist adhesion broke down even under the mild conditions described above. The dotted curve is an extrapolation.

Results and Discussion

The prime purpose of this work was to determine whether the intensity of nonfluorescent light scattered from a photoresist material is a significant factor in determining the resolution of the photolithographic process. The highest scattering value determined from the above measurements was for the KMER film at 1°, and amounted to only 0.51% of the incident intensity. It must be remembered, however, that this figure was determined using light of wavelength 6328Å. Normally, these resists are exposed to a high pressure mercury lamp with a peak emission at about 3600Å. A correction for this discrepancy can be made if the scattering follows Rayleigh theory, when the intensity of scattering will vary inversely as the fourth power of the wavelength. A scattered intensity of 0.51% at 6328Å is therefore equivalent to a scattered intensity of 4.9% at 3600Å, and it is this which would be encountered in pratcice. Whether this will result in a significant resolution loss depends on the intensity of light used in the exposure step.

Typically, exposure times of 60 sec are used for films of KTFR and KMER 1500Å thick at an intensity of 4500 lumens/ft^2. Assuming a linear relationship between exposure intensity and exposure time, this is equivalent to an exposure time of 150 sec with our intensity of 1800 lumens/ft^2. Four and nine-tenths per cent of the typical exposure used in practice would, therefore, be equivalent to an exposure time of approximately 7.5 sec under our conditions. This corresponds to a point between A and B on our sensitivity curve and would therefore result in resolution loss if a mild development procedure were used. But no effect would be observed using the more vigorous conventional development technique.

It is now possible to calculate the amount of overexposure necessary to produce a known resolution loss due to scattering. From Fig. 6 it can be seen that a perfectly collimated beam of light will be broadened by an amount $2x = 2t \cdot \tan \phi$ after passing through a resist layer of thickness t (actually this assumes that the total measured scattered intensity arises at the initial resist-air interface; the calculated resolution loss is therefore an over-estimate). The true scattering angle ϕ is related to the measured angle by Snell's Law (for a good index match between resist and glass slide). Measured values of θ = 15°, 10°, 5°, 3°, and 1° are therefore equivalent to ϕ values of 9°56′, 5°39′, 3°20′, 2°0′, and 0°40′ respectively.

It can thus be seen that if the scattering intensity at, say, θ = 10° is sufficient to produce adherence in the photoresist, then a 1μ line will be broadened to a 1.23μ line for a resist layer 1μ thick, and to a 1.03μ line for a resist layer only 1500Å thick. For this to occur the intensity at θ = 10 must be equivalent to an exposure of 12 sec at 1800 lumens/ft^2 (see Fig. 5). Since the scattered intensity at this angle is only 0.067% of the incident intensity exposure to an illumination of 4500 lumens/ft^2 would have to be continued for 6.5×10^3 sec for the resolution loss to be real. Such gross overexposure is not likely to occur in practice. Figure 7 illustrates values which have been calculated in this way for KMER and KTFR films 4μ thick. For thinner resist films the resolution loss would be less than that shown because (*i*) there is a linear relationship between line broadening and film thickness, and (*ii*) the intensity of scattered light will decrease with film thickness.

It should be remembered that the scattering measurements reported here do not include any contribution from resonance fluorescence. Since a 1μ film of resist will absorb approximately 50% of the incident 3600Å light, this fluorescence may be an appreciable factor, although much of this energy will no doubt be dissipated thermally. Reflectivity of the substrate has also been ignored for the present, but it should be borne in mind that this may increase scattering resolution loss slightly because of multiple reflections. The effect may not be severe, however, because of the high resist extinction coefficient.

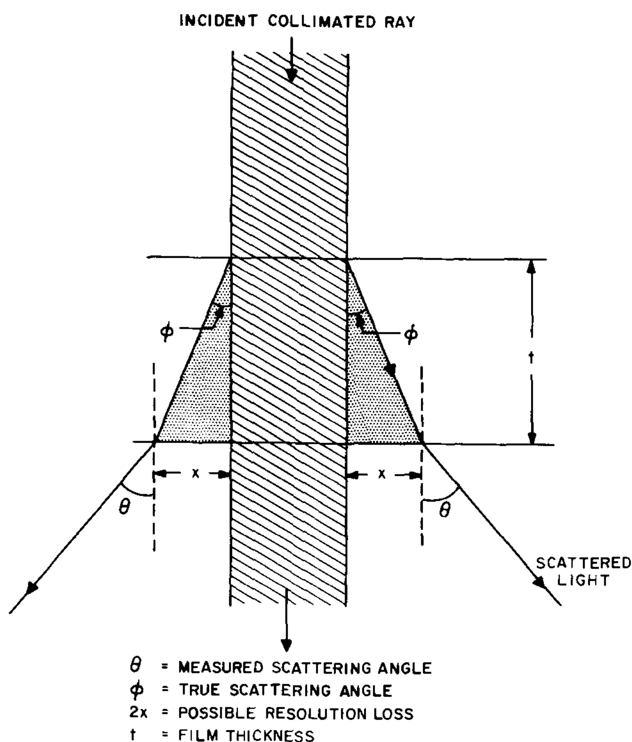

Fig. 6. Resolution loss

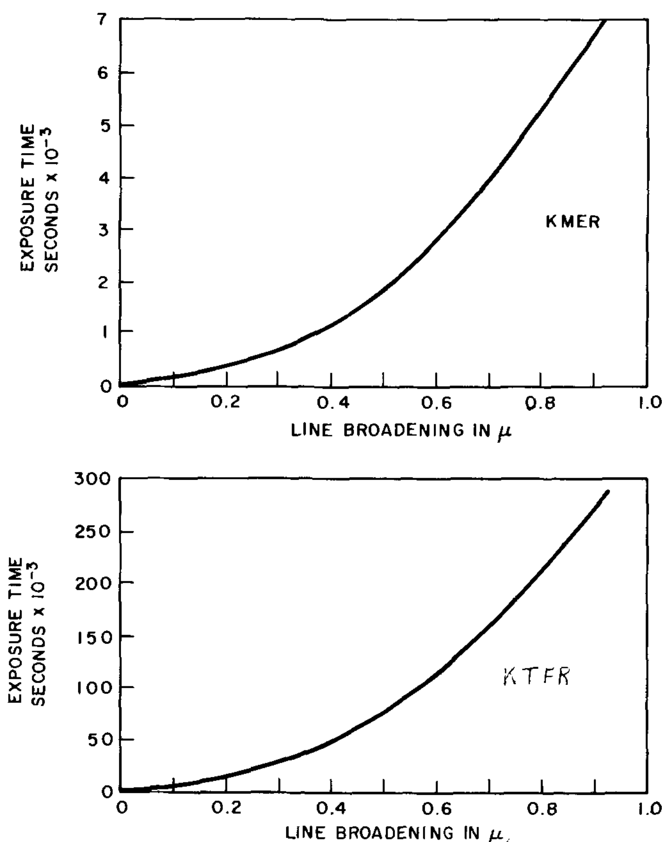

Fig 7. Degradation as a function of exposure time at an exposure intensity of 4500 lu/ft^2.

Conclusion

Nonfluorescent light scattering from films of Kodak Metal Etch Resist (KMER) has been measured over an angular range of 1°-75° and from films of Kodak Thin Film Resist (KTFR) over an angular range of 1°-15°. Scattering from KMER is approximately 40 times that from KTFR.

The intensity measurements reported here are used to determine to what extent nonfluorescent light scattering from resists will contribute towards image degradation in high-resolution photolithography. It is concluded that such scattering will not contribute to resolution loss providing the exposure employed does not exceed certain limits which are specified.

Manuscript received June 16, 1972. This was Paper 319RNP presented at the Boston Meeting of the Society, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Silicon Epitaxial Growth by Rotating Disk Method

Katsuro Sugawara*

Semiconductor and Integrated Circuits Division, Hitachi, Ltd., Kodaira, Tokyo, Japan

ABSTRACT

By a rotating disk method which had quantitatively been treated in fluid motion, silicon epitaxial deposition using the $SiCl_4$-H_2 system was effected at various susceptor rotation speeds and various pressures. Calculation of the growth rate was initially made with a one-dimensional model of an infinite diameter disk without considering natural convection caused by local heating. This was followed by a numerical solution of Navier-Stokes equations, continuity equation, and equation of energy of cylindrical coordinates, using a three-dimensional model and taking natural convection into consideration. With the three-dimensional model including natural convection, a quantitative description can be given of the influence of susceptor rotation speed and pressure on the growth rate at a temperature higher than 1150°C.

The $SiCl_4$-H_2 system is most widely used for silicon epitaxial growth. As pointed out by Bylander (1), epitaxial growth is mass-transfer controlled in the higher temperature region, with about 1150°C as the dividing line; while in the lower temperature region, chemical reaction on the substrate surface is the rate-determining step. For a better quality of crystallinity required for semiconductor devices, the reaction is desirably performed in the higher temperature region. Consequently, the growth is closely connected with the concentration of supplied gas, its flow pattern, and the flow-rate control. For this reason, the gas-flow pattern was observed in a horizontal reactor in relation to the pressure, flow rate, and natural convection, using TiO_2 fumes as a tracer (2-3). Then the relation of gas-flow pattern to the epitaxial deposition rate distribution was investigated. This was followed by consideration of a boundary layer of certain thickness on the susceptor, which was determined by the gas-flow rate and pressure. Then a diffusion equation that took into account the diffusion and natural convection of the reactant gases was solved and a comparison with the experimental value was attempted (4). However, since the thickness of the boundary layer was substituted by the value estimated from the experiment, it lacked accuracy. Eversteyn *et al.* (5) similarly treated SiH_4 epitaxial growth, and found an agreement between boundary layer thickness from gas-flow pattern observation and that derived from their model.

Thus, attention was given to the rotating disk method, by which fluid velocity distribution and thickness of the boundary layer could be quantitatively obtained due to its axial symmetry, and the deposition rate was acquired by changing the rotation speed of the susceptor and the gas pressure. Then calculations were made with the one-dimensional model of an infinite diameter disk without considering natural convection. This was followed by a numerical solution of the Navier-Stokes equations, the equation of continuity, and the equation of energy of cylindrical coordinates, taking natural convection into consideration. In the following pages, theoretical considerations, the experimental method, and the results are presented, and a comparative examination of the experiment and calculations is sought.

Theory

As shown in Fig. 1, a susceptor acts as a rotating disk and silicon epitaxial deposition is effected on its surface.

Velocity and temperature distribution.—In cylindrical coordinates, the Navier-Stokes and continuity equations take these forms (6)

$$V_r \frac{\partial V_r}{\partial r} - \frac{V_\phi^2}{r} + V_y \frac{\partial V_r}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial r} + \nu\left(\frac{\partial^2 V_r}{\partial r^2} + \frac{1}{r}\frac{\partial V_r}{\partial r} - \frac{V_r}{r^2} + \frac{\partial^2 V_r}{\partial y^2}\right) \quad [1]$$

$$V_r \frac{\partial V_\phi}{\partial r} + \frac{V_r V_\phi}{r} + V_y \frac{\partial V_\phi}{\partial y} = \nu\left(\frac{\partial^2 V_\phi}{\partial r^2} + \frac{1}{r}\frac{\partial V_\phi}{\partial r} - \frac{V_\phi}{r^2} + \frac{\partial^2 V_\phi}{\partial y^2}\right) \quad [2]$$

$$V_r \frac{\partial V_y}{\partial r} + V_y \frac{\partial V_y}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \nu\left(\frac{\partial^2 V_y}{\partial r^2} + \frac{1}{r}\frac{\partial V_y}{\partial r} + \frac{\partial^2 V_y}{\partial y^2}\right) - fg\beta\Delta T \quad [3]$$

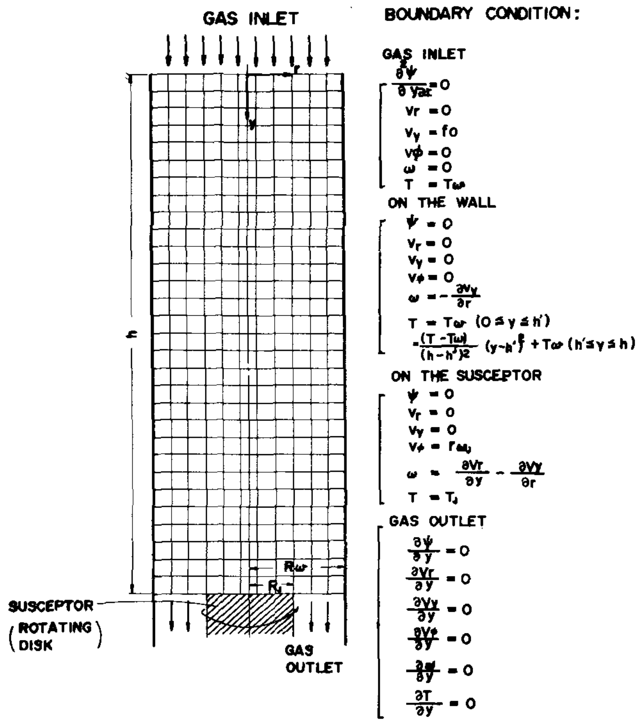

Fig. 1. Model system in the analysis of silicon epitaxial deposition by the rotating disk method and its boundary conditions.

$$\frac{\partial V_r}{\partial r} + \frac{V_r}{r} + \frac{\partial V_y}{\partial y} = 0 \qquad [4]$$

where V_r, V_ϕ, and V_y are the radial, tangential, and axial velocity components respectively and f is a correction factor of the natural convection.

To eliminate the terms of the pressure in [1] and [3], $\partial/\partial y$ [1] $-$ $\partial/\partial r$ [3] is calculated as

$$\frac{\partial}{\partial y}\left(V_r \frac{\partial V_r}{\partial r} - \frac{V_\phi{}^2}{r} + V_y \frac{\partial V_r}{\partial y} \right) - \frac{\partial}{\partial r}\left(V_r \frac{\partial V_y}{\partial r} + V_y \frac{\partial V_y}{\partial y} \right)$$
$$= \nu \frac{\partial}{\partial y}\left(\frac{\partial^2 V_r}{\partial r^2} + \frac{1}{r}\frac{\partial V_r}{\partial r} - \frac{V_r}{r^2} + \frac{\partial^2 V_r}{\partial y^2} \right) - \nu \frac{\partial}{\partial r}\left(\frac{\partial^2 V_y}{\partial r^2} + \frac{1}{r}\frac{\partial V_y}{\partial r} + \frac{\partial^2 V_y}{\partial y^2} \right) \qquad [5]$$

$$\text{Left side} = V_r \frac{\partial}{\partial r}\left(\frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} \right) + \frac{\partial V_r}{\partial r}\left(\frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} \right) + \frac{\partial V_y}{\partial y}\left(\frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} \right)$$
$$- V_y \frac{\partial}{\partial y}\left(\frac{\partial V_y}{\partial r} - \frac{\partial V_r}{\partial y} \right) = V_r \frac{\partial \omega}{\partial r} + \frac{\partial V_r}{\partial r}\omega + \frac{\partial V_y}{\partial y}\omega + V_y \frac{\partial \omega}{\partial y} - \frac{\partial}{\partial y}\left(\frac{V_\phi{}^2}{r} \right) \qquad [6]$$

$$\text{Right side} = \nu \left\{ \frac{\partial^2}{\partial r^2}\left(\frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} \right) + \frac{\partial^2}{\partial y^2}\left(\frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} \right) + \frac{1}{r^2}\left(\frac{\partial V_y}{\partial r} - \frac{\partial V_r}{\partial y} \right) + \frac{1}{r}\frac{\partial}{\partial r}\left(\frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} \right) \right\} + fg\beta \frac{\partial \Delta T}{\partial r}$$
$$= \nu \left(\frac{\partial^2 \omega}{\partial r^2} + \frac{\partial^2 \omega}{\partial y^2} - \frac{\omega}{r^2} + \frac{1}{r}\frac{\partial \omega}{\partial y} \right) + fg\beta \frac{\partial \Delta T}{\partial r} \qquad [7]$$

Then, the Navier-Stokes equations can be given in the forms of

$$V_r \frac{\partial \omega}{\partial r} - \frac{V_r \omega}{r} + V_y \frac{\partial \omega}{\partial y} - 2\frac{V_\phi}{r}\frac{\partial V_\phi}{\partial y} = \nu \left(\frac{\partial^2 \omega}{\partial r^2} + \frac{\partial^2 \omega}{\partial y^2} - \frac{\omega}{r^2} + \frac{1}{r}\frac{\partial \omega}{\partial r} \right) + fg\beta \frac{\partial \Delta T}{\partial r} \qquad [8]$$

$$V_r \frac{\partial V_\phi}{\partial r} + \frac{V_\phi V_r}{r} + V_y \frac{\partial V_\phi}{\partial y} = \nu \left(\frac{\partial^2 V_\phi}{\partial r^2} + \frac{1}{r}\frac{\partial V_\phi}{\partial r} - \frac{V_\phi}{r^2} + \frac{\partial^2 V_\phi}{\partial y^2} \right) \qquad [2]$$

where ω, a term relating to the rotation, is defined as

$$\omega = \frac{\partial V_r}{\partial y} - \frac{\partial V_y}{\partial r} = -\frac{1}{r}\frac{\partial^2 \psi}{\partial y^2} + \frac{1}{r^2}\frac{\partial \psi}{\partial r} - \frac{1}{r}\frac{\partial^2 \psi}{\partial r^2} \qquad [9]$$

A stream function ψ is introduced in such a way that the equation of continuity is automatically satisfied. In cylindrical coordinates, the velocity components can be expressed as derivatives of ψ (7)

$$V_y = -\frac{1}{r}\frac{\partial \psi}{\partial r} \qquad [10]$$

$$V_r = \frac{1}{r}\frac{\partial \psi}{\partial y} \qquad [11]$$

The equation of energy in terms of the gaseous transport properties is given as [12], taking axial symmetry and small viscosity coefficient into account

$$\rho C_p \left(V_r \frac{\partial T}{\partial r} + V_y \frac{\partial T}{\partial y} \right) = k \left\{ \frac{1}{r}\frac{\partial}{\partial r}\left(r \frac{\partial T}{\partial r} \right) + \frac{\partial^2 T}{\partial y^2} \right\} \qquad [12]$$

where C_p and k are the specific heat at constant pressure and the thermal conductivity of hydrogen respectively.

The boundary conditions are determined as follows, referring to the calculation of temperature distribution of the Czochralski pulling crystal (8) in solving the six partial differential equations [2], [8], [9], [10], [11], and [12]:

at the gas inlet $(y = 0, \quad -R_W \leqq r \leqq R_W)$

$$\left.\begin{array}{ll} \omega = 0 & V_\phi = 0 \\ V_r = 0 & T = T_W \\ V_y = f_o & \dfrac{\partial^2 \psi}{\partial y \partial r} = 0 \end{array}\right\} \qquad [13]$$

on the wall $(0 \leqq y \leqq h, \ r = \pm R_W)$

$$\left.\begin{array}{ll} \omega = -\dfrac{\partial V_y}{\partial r} & T = T_W \ (0 \leqq y \leqq h') \\ & T = \dfrac{(y - h)^2}{(h - h')^2}(T_{Wo} - T_W) + T_W \\ V_r = 0 & \\ V_y = 0 & \qquad (h' \leqq y \leqq h) \\ V_\phi = 0 & \psi = \psi_o = 0 \end{array}\right\} \qquad [14]$$

on the susceptor $(y = h, \ -R_J \leqq r \leqq R_J)$

$$\left.\begin{array}{ll} \omega = \dfrac{\partial V_r}{\partial y} - \dfrac{\partial V_y}{\partial r} & V_\phi = r\omega_J \\ V_r = 0 & T = T_J \\ V_y = 0 & \psi = \psi_o = 0 \end{array}\right\} \qquad [15]$$

at the gas outlet

$$(y = h,\ R_J \leqq r \leqq R_W,\ -R_W \leqq r \leqq -R_J)$$

$$\left.\begin{array}{ll} \dfrac{\partial \omega}{\partial y} = 0 & \dfrac{\partial V_\phi}{\partial y} = 0 \\ \dfrac{\partial V_r}{\partial y} = 0 & \dfrac{\partial T}{\partial y} = 0 \\ \dfrac{\partial V_y}{\partial y} = 0 & \dfrac{\partial \psi}{\partial y} = 0 \end{array}\right\} \quad [16]$$

Concentration distribution.—Following the calculation of the velocity and temperature distribution, the concentration distribution of $SiCl_4$ can be obtained by using the following convective diffusion equation in cylindrical coordinates

$$V_r \frac{\partial C}{\partial r} + V_y \frac{\partial C}{\partial y} = D_1 \left(\frac{\partial^2 C}{\partial y^2} + \frac{\partial^2 C}{\partial r^2} + \frac{1}{r}\frac{\partial C}{\partial r} \right) \quad [17]$$

The boundary conditions are:

$$\left.\begin{array}{ll} \text{at the gas inlet} & C = C_o \text{ (Const)} \\ \text{on the wall} & \dfrac{\partial C}{\partial r} = 0 \\ \text{on the susceptor} & C = a - x^1 \\ \text{at the gas outlet} & \dfrac{\partial C}{\partial y} = 0 \end{array}\right\} \quad [18]$$

Growth rate.—Deposition rate of silicon is

$$G(r) = -\frac{m}{M\rho_1} F \text{ (cm/sec)} \quad [19]$$

where

$$F = -D_2 \left(\frac{\partial C(r)}{\partial y} \right)_{y = h} \text{ (g/sec} \cdot \text{cm}^2) \quad [20]$$

m = atomic weight of Si, M = molecular weight of $SiCl_4$, ρ_1 = density of Si, D_2 = diffusion constant at the substrate temperature, shown in Appendix II. Symbols and numerical values used in this calculation are summarized in a List of Symbols at the end of this paper.

These partial differential equations were rewritten in calculus of finite differences, and both the y and r directions were divided into meshes at every 1 cm interval—y direction and r direction: 31 × 12. Following the flow chart given in Fig. 2, the stream function ψ, flow velocities V_r, V_y, and V_ϕ, temperature T, and ω connected with rotation were calculated successively, and while judging the convergence by the values of V_r and V_y, numerical calculations were effected. The computer used was the HITAC 8500 and 20 repetitions required about 90 sec.

In order to speed up convergence

$$V_r = \frac{0.181\, r\omega_J}{h\left(1 - \frac{1}{m}\right)} y \quad \left(0 \leqq y \leqq h\left(1 - \frac{1}{m}\right)\right)$$

where m is number of divisions made of h, 0.181 is the maximum value of F in Eq [24a] of the infinite rotating disk method (6), $V_r = 0$ at $y = 0$, satisfying the boundary condition of Eq. [13], $V_y = f_o$, $V_\phi = \dfrac{r\omega_J}{h} y$ [21]

were given and the first calculation was made. In Fig. 1, calculations commenced from the upper, left-hand corner. Also, gas velocity components V_r, V_y, and V_ϕ, density ρ, and kinematic viscosity coefficient ν were corrected by considering temperature dependence of high temperature H_2 as an ideal gas.

[1] a-x is calculated from the equilibrium constant of the reaction between $SiCl_4$ asd H_2, as shown in Appendix I.

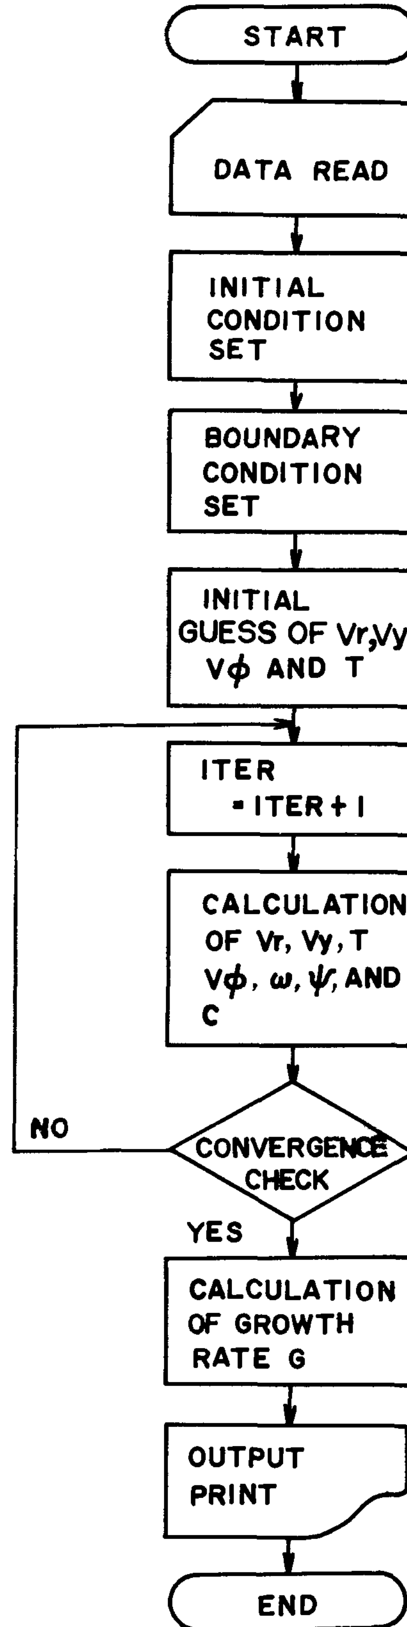

Fig. 2. Flow chart at the numerical calculation of silicon epitaxial deposition by the rotating disk method.

Experimental

As shown in Fig. 3, a quartz tube with an I.D. of 110 mm was used as a reactor for silicon epitaxial deposition. The susceptor was heated in the reactor by using a 400 kHz rf generator. The susceptor was rotated with a variable speed changer at a speed for rotation, 0-300 rpm, combined with a 1:5 pulley. The reactant gas

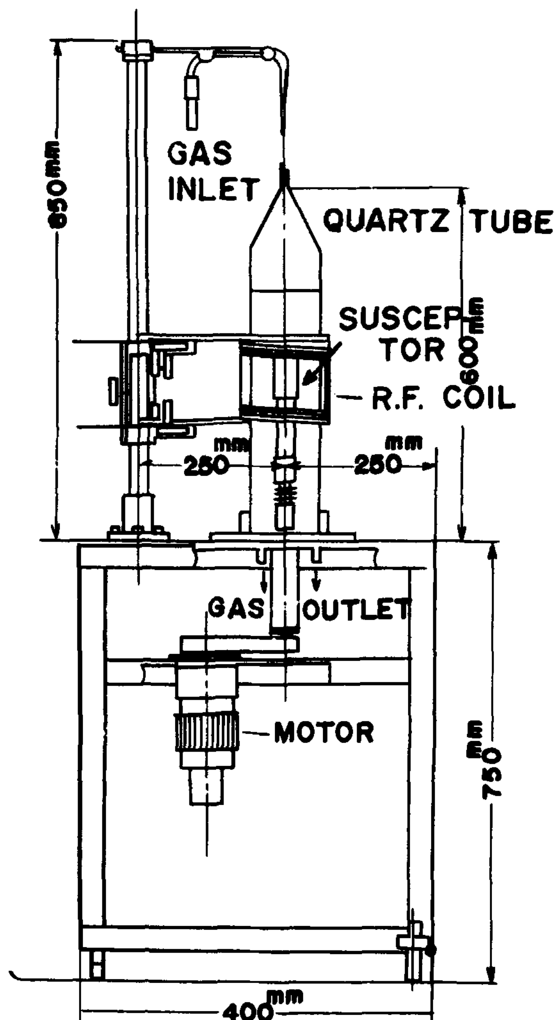

Fig. 3. Schematic diagram for the reactor of silicon epitaxial growth by the rotating disk method.

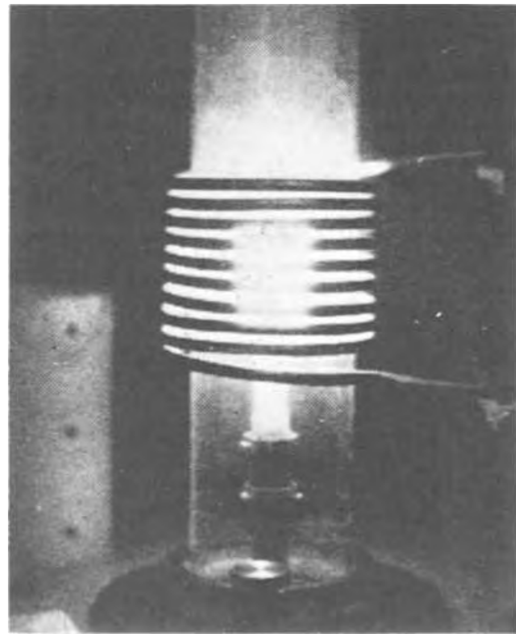

Fig. 4. Reactor of the epitaxial growth by the rotating disk method.

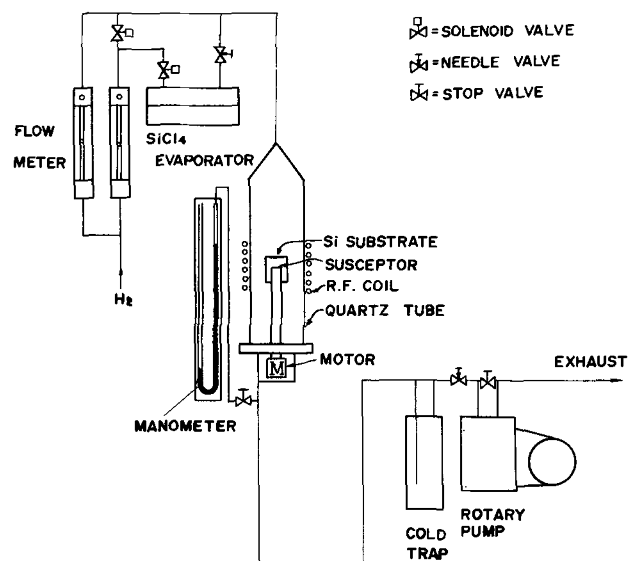

Fig. 5. Layout of the silicon epitaxial reactor system by the rotating disk method.

flowed from the upper part of the reactor. When desired, pressure was reduced to the regulation level by a rotary pump. A liquid nitrogen trap was provided between the reactor and the pump for absorbing unreacted $SiCl_4$ gas. Figure 4 is a photograph of the reactor; the layout of the reactor system by the rotating disk method appears in Fig. 5.

Silicon substrates used for the experiment were Czochralski-grown, Sb-doped, and (111)-oriented crystals with resistivity of 6×10^{-3}-2×10^{-2} ohm-cm; these were sliced, lapped, and chemically/mechanically polished. Their thickness was 250μ. A susceptor 50 mm in diameter was used, made of high-purity graphite and having a 300μ coating of SiC. The lower part was scooped out for achieving uniform temperature distribution in the radial direction of the susceptor during rf heating. A slight protrusion was made on the upper part to prevent scattering of the wafer by the centrifugal force generated during rotation.

A cleaned substrate wafer was placed on the susceptor which had been rotated in advance to suppress eccentricity. Then the quartz tube was fixed, 40 liters/min of H_2 was inserted, and rf heating was effected. After reaching the set temperature for the epitaxial reaction, a 5 min interval was taken before feeding $SiCl_4$ together with H_2. Reading the wafer temperature with an optical pyrometer, emissivity was corrected according to Allen's data (9) and the real temperature was obtained. The mole fraction of $SiCl_4$ and H_2 had been obtained in advance by the method given below.[2] After 10-15 min reaction, power was cut off and the wafer was taken out when it was cooled.

Thickness of the epitaxial layer was measured by the infrared interference method (10-12). The infrared spectrophotometer used was the Hitachi EPI-G2 with a wavelength range of 2.5-25μ.

Results

Temperature dependence of epitaxial growth rate.—The relation of growth rates to temperature at $SiCi_4/H_2$ mole fractions of 0.005, 0.01, and 0.02 at 760 Torr is given in Fig. 6, while the result of pressure change at the mole fraction of 0.005 appears in Fig. 7.

In the figures, hyphenated lines represent calculated values of the one-dimensional model in the case of a

[2] The $SiCl_4/H_2$ mole fraction was measured with a Perkin Elmer's atomic absorption spectrophotometer (Model 303). The $SiCl_4$-H_2 mixture is bubbled through a 4% water solution of NaOH. The atomic absorption measuring wavelength was 2516A and analysis was made in N_2O and C_2H_3 gases. The calibration curve was derived from a standard sample of Si fused in alkali.

Fig. 6. disk of infinite diameter; for details of calculations refer to Appendix III. The chain lines represent the case of a finite diameter disk without considering natural convection, and the thick, solid lines represent calculated values with natural convection considered as calculated under the method cited in the theory. As the equilibrium constant of Eq. [28] diminishes in the lower temperature range, the calculation displays a diminishing growth rate when the temperature drops below 1000°C; while in the higher temperature region above this, the equilibrium constant and the growth rate are approximately constant.

In the experiments the temperature, where the rate-determining step of the reaction was shifted from surface reaction at the substrate to diffusion in the gaseous phase was higher than the calculated value; it was approximately 1150°C. The difference in the lower temperature region between theory and experiment was caused by neglecting the surface reaction because only mass transfer of the reactant species in the gaseous phase and the chemical equilibrium of the reaction at the substrate surface were considered in the calculating process. Calculation of activation energies was sought from Arrhenius plots in Fig. 6 and 7. In the diffusion-limited, higher temperature range, they were about 1-3 kcal/mol; while in the reaction-limited, lower temperature range, the average value is 20-30 kcal/mol.

The actual growth rate at a higher temperature and 760 Torr, in the one-dimensional model, represents an approximate matching of the calculated and actually measured values. However, as pressure was reduced, the actually measured value became larger than that calculated. The calculated value of a three-dimensional model of the finite diameter disk approximately coincided with the experimental value.

Pressure dependence of epitaxial growth rate.—Figure 8 represents experimental results at 1200°C and mole fractions of 0.005, 0.01, and 0.02 rendered into a dual logarithm graph; Fig. 9 gives the growth rates when the susceptor rotation was changed under the mole fraction of 0.005. At 120 rpm and normal pressure, the growth rate of the one-dimensional model approximately coincides with the calculated value. The pressure (P) dependence is not proportional to $P^{1/2}$ as was calculated, but it is approximately propor-

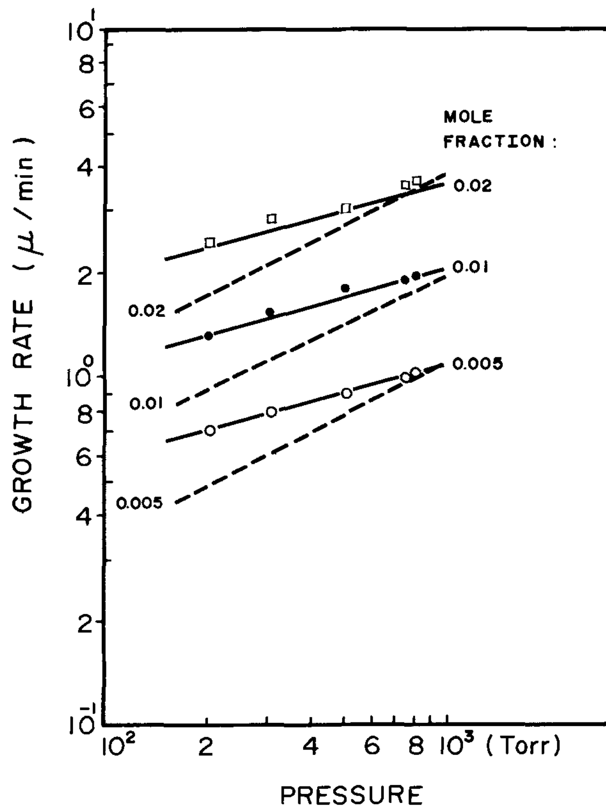

Fig. 8. Pressure dependence of silicon epitaxial growth rate at various $SiCl_4/H_2$ mole fractions. Growth temperature, 1200°C; speed of susceptor rotation. 120 rpm.

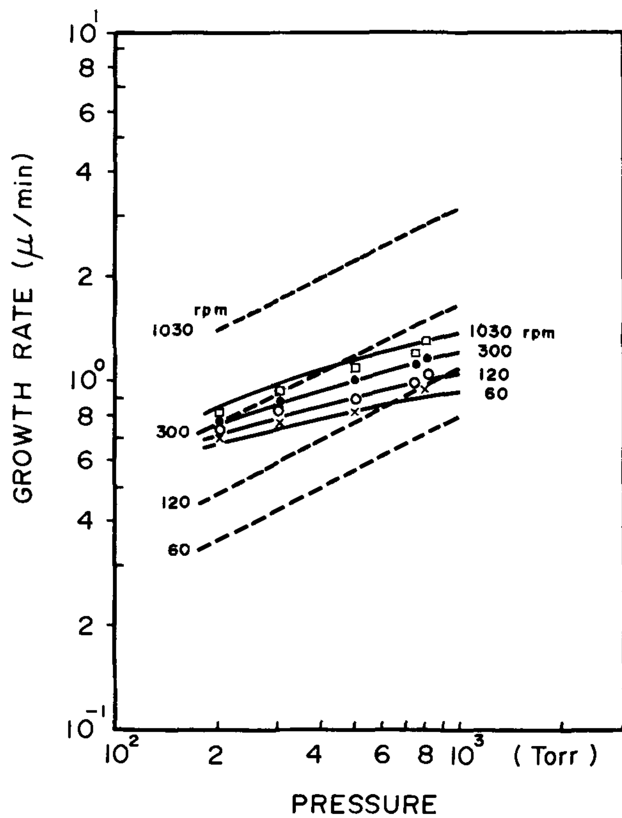

Fig. 9. Pressure dependence of silicon epitaxial growth rate at various speeds of susceptor rotation. Growth temperature, 1200°C; $SiCl_4/H_2$ mole fraction, 0.005.

tional to $P^{1/5}$ to $P^{1/3}$ dependent on rotation speed which is not to be expected from the theory belonging to the oversimplified model.

Under pressure changes, the three-dimensional model produced results close to the actually measured values.

Susceptor rotation dependence of epitaxial growth rate.—The results of investigation by varying the rotation between 60 and 1030 rpm and the mole fraction at the epitaxial temperature of 1200°C are given in Fig. 10. Figure 11 gives the experimental results obtained by varying the pressure at the mole fraction of 0.005.

With the one-dimensional model, the differences in rotation speed dependence are large between the measured and calculated values; but with the three-dimensional model of finite diameter disk, these values match well.

Discussion

Difference of diameter in a rotating disk system.—The motion of the fluid in relation to the infinite diameter rotating disk was first clarified by von Karman (13) and subsequently by Cochran (14). Assuming that the disk diameter was large enough to ignore the effect of disk edges, solutions to the Navier-Stokes and continuity equations were obtained as below, and the results were as given in Fig. 12. Incidentally, $y = 0$ on the axis of abscissa of this figure is on the disk, corresponding to the $h = 30$ cm point in this numerical calculation.

$$V_r = r\omega F(\xi) \quad [24a]$$

$$V_\phi = r\omega G(\xi) \quad [24b]$$

$$V_y = \sqrt{\nu\omega} H(\xi) \quad [24c]$$

$$\xi = \sqrt{\frac{\omega}{\nu}}\, y \quad [24d]$$

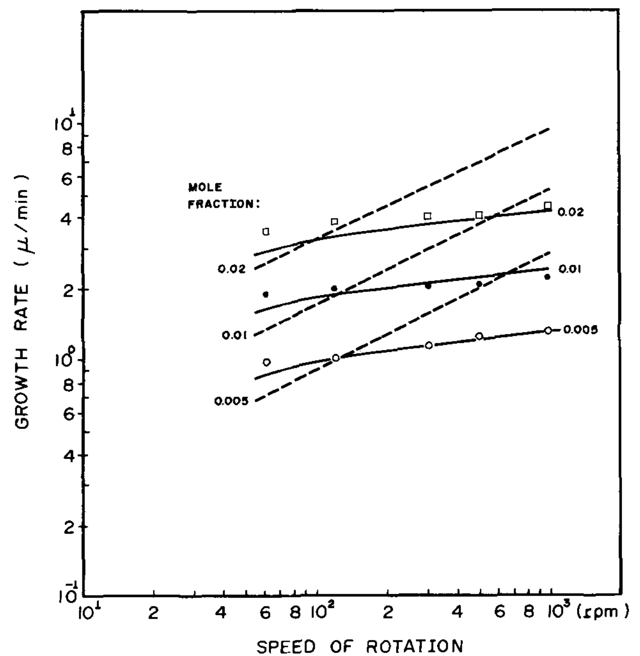

Fig. 10. Growth rate as a function of susceptor rotation speed at various $SiCl_4/H_2$ mole fractions. Growth temperature, 1200°C; pressure, 760 Torr.

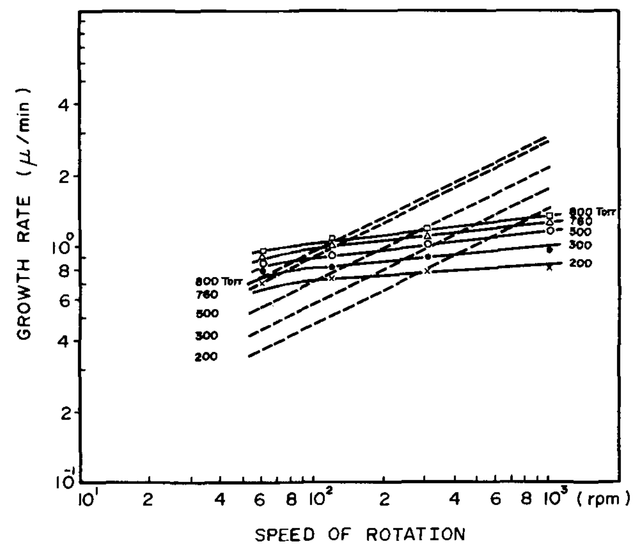

Fig. 11. Growth rate as a function of susceptor rotation speed under various pressures. Growth temperature, 1200°C; $SiCl_4/H_2$ mole fraction, 0.005.

Meanwhile, numerical solutions obtained by the method of calculus of finite differences are diagrammatically indicated in the order of V_r, V_y, V_ϕ, T, and C in Fig. 13(a)-(e) with and without natural convection. In the figures, the hyphenated lines represent the case where the effect of nautral convection was not considered, while the solid lines represent the case where natural convection was taken into account. For reference, the calculated value of the infinite diameter disk mentioned above—calculated for 800°C in Fig. 12—has been included in the chain lines.

The difference between finite and infinite diameter was as follows: (*i*) In the case of finite diameter, flow velocities V_r, V_y, and V_ϕ were larger by about one digit. (*ii*) In the case of V_r, with finite diameter, diminution occurred from the maximum value, although in some places, the flow direction was reversed, possibly due to effect of the disk edge. (*iii*) In the case of the finite disk, V_y increased for a time by the effect of ro-

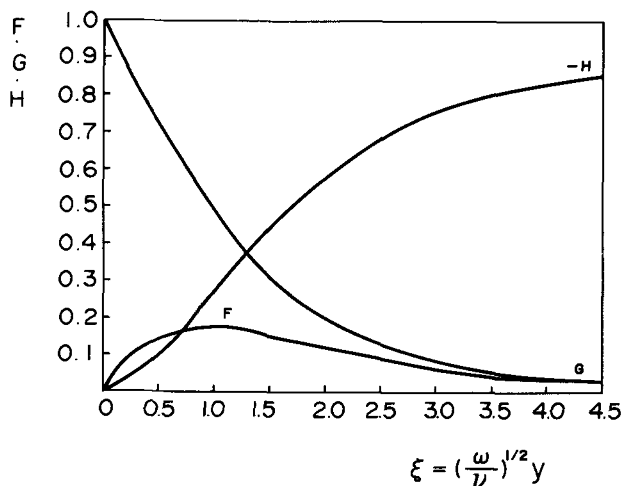

Fig. 12. Values of the functions *F, G,* and *H* in the rotating disk system of one-dimensional model calculated for 800°C.

$$V_r = r\,\omega\,F\,(\xi)$$
$$V_\phi = r\,\omega\,G\,(\xi)$$
$$V_y = \sqrt{\nu\,\omega}\,H\,(\xi)$$

tating disk, and after reaching the maximum value, it diminished, approaching the flow velocity at the gas inlet. (*iv*) With V_ϕ, after the rate was determined by the susceptor rotation speed on the disk, a monotonous decrease occurred. As shown above, the edge effect appeared conspicuously when the disk was finite revealing a broad difference from the former analysis of infinite diameter disk.

Influence of natural convection.—Figure 13(a)-(e) gives the flow velocities, temperature, and concentration distributions for the presence or absence of natural convection. From this figure, the following conclusions may be drawn: (*i*) The flow velocities, V_r and, V_y, directly above the susceptor decreased when convection was considered. (*ii*) Changes in flow velocity distributions appeared as changes occurred in the concentration distribution, resulting in differences in the growth rates.

Figure 14 gives the calculated growth rate, when natural convection is represented as a temperature difference of $\Delta T = 200$°C and the correction factor f is changed. The growth rate is the calculated value of $y = 0.5$ cm. Since diminution which occurred along with an increase of f from 2.05 μ/min in the case of $f = 0$, and 1.15 μ/min at $f = 0.025$ became approximately equal to the experimental value, the correction factor was used to undertake numerical calculations at the pressure of 760 Torr.

A variation of correction factor f along with pressure change is conceivable. Here natural convection is proportional to Gr, the Grashof number; but since it is through kinematic viscosity $\nu \propto 1/\rho$ that the relation arises with pressure, a correction factor of 0.025 at normal pressure having the linear function of pressure was assumed as shown in Fig. 15, and calculations were made for cases of pressure variation.

Pressure dependence of epitaxial growth rate.—As of this date, Bradshaw's paper (16) is the only study made of epitaxial growth rate in relation to pressure. He stated that the growth rate was proportional to half the square of pressure. This conclusion was arrived at from the fact that the thickness L of the boundary layer from the leading edge was

$$L \propto \rho^{-1/2} = \left(\frac{\overline{M}P}{RT} \right)^{-1/2} \quad [25]$$

where $\overline{M}$ indicated the mean molecular weight in the boundary layer. The growth rate became

$$G \propto \frac{1}{L} \propto P^{1/2} \quad [26]$$

His experiment was conducted with a vertical reactor provided with a special nozzle. The result was proportional to $P^{0.44}$.

With the one-dimensional model under the rotating disk method also, $D^{1/3}\nu^{-1/6}$—actually $D^{1/3}\rho^{1/6}$—in the equation for the boundary layer δ was related to pressure, and the calculated value was proportional to $P^{1/2}$. This is identical with that which Bradshaw obtained, though the procedure for calculation is different.

With the three-dimensional model, although a definite implication of meaning is difficult, concentration C and diffusion coefficient D respectively are proportional and inversely proportional to the pressure. The flow velocities are obtained by complicated calculations, and as in the case of V_y shown in Fig. 16, they increase together with the pressure but are not necessarily proportional to it. As over-all results, therefore, calculations from the concentration distribution given in Fig. 16(a) and (b) produce the results shown in Fig. 8 and 9. As the disk is finite, the effects of the edge and natural convection double up, rendering the experimental and calculated value closer to each other.

Susceptor rotation dependence of epitaxial growth rate.—Olander experimented with epitaxial growth under the rotating disk method, using Ge — I_2, which proved easier in treating the system thermodynamically and which grew at low temperature (17). Applying the gas from below and holding the Ge substrate face down, which differed from this experiment, he experimented with reaction temperatures up to 450°C. He showed that the effect of rotation was proportional to $\omega^{1/2}$ theoretically anticipated at 450°C and 900 rpm, but that below this value the dependence of the experimental value diminished. He concluded that failure to follow the trend of calculated values under 900 rpm arose from the influence of natural convection.

In the silicon epitaxial growth, using $SiCl_4$, the effect of natural convection is more easily exerted due to temperatures as high as 1200°C. Also, because of problems arising from the shape and rotating mechanism of the susceptor, the above tendency is conceivably magnified compared with the case of Ge — I_2, since it is not possible to raise the rotation above 1000 rpm. The effect of the periphery of the susceptor is also added.

With the three-dimensional model, the effect of susceptor edge and natural convection is exerted because of the susceptor rotation, and V_y and C distributions become as shown in Fig. 17(a) and (b), thus ultimately explaining the experimental result.

Conclusions

Taking note of the rotating disk method, which allows a quantitative treatment of fluid motion, the solid and gaseous phase boundary layer of an infinite diameter disk was calculated and the growth rate was sought through calculations of a one-dimensional model. However, matching of the actually measured values of pressure dependence and susceptor rotation dependence of the growth rate was unsatisfactory. Therefore, Navier-Stokes equations of the cylindrical coordinates, taking natural convection into account, were numerically solved under the calculus of finite differences—for a three-dimensional model—and the results were compared with the actually measured value.

1. The calculated, both one- and three-dimensional model, and actually measured values of epitaxial growth rate matched in the order tendency at normal pressure and at temperatures higher than 1150°C. Below this temperature, the experimental value was inexplainable.

2. With the one-dimensional model, pressure (P) dependence of the epitaxial growth rate was propor-

tional to $P^{1/2}$ in the calculated value, but in the experimental value, it was proportional to $P^{1/5} - P^{1/3}$.

3. Susceptor rotation speed (ω) dependence of the growth rate was the calculated result of the one-dimensional model, which was proportional to $\omega^{1/2}$, but the experimental value was proportional to $\omega^{1/20} - \omega^{1/10}$.

4. The difference between experimental and calculated values of presure and rotation speed dependence of the growth rate conceivably arose from diminish-

ing of the boundary layer calculated under the rotating disk method, due to the effect of a finite diameter disk and natural convection. In other words, because of the finite rotating disk diameter, the pressure and susceptor rotation dependence of the growth rate became smaller than in the case of the one-dimensional model. Also, because of the effect of natural convection, the flow velocities on the susceptor diminished, thus diminishing the growth rate and coinciding with the actual measured value.

Acknowledgments

To Prof. H. Inokuchi of Tokyo University for his critical review of and his sincere advice on this manuscript, and to Dr. N. Kobayashi of Toyama University for his helpful suggestion to set boundary conditions of the partial differential equations, I express my sincere gratitude. Appreciation is also due to the continued support of this work by Dr. S. Tauchi and Mr. S. Nishida, the helpful discussions with Mr. R. Takahashi, and the assistance in computer programming and numerical calculations rendered by Mr. Y. Ishikawa and Mr. H. Tochikubo.

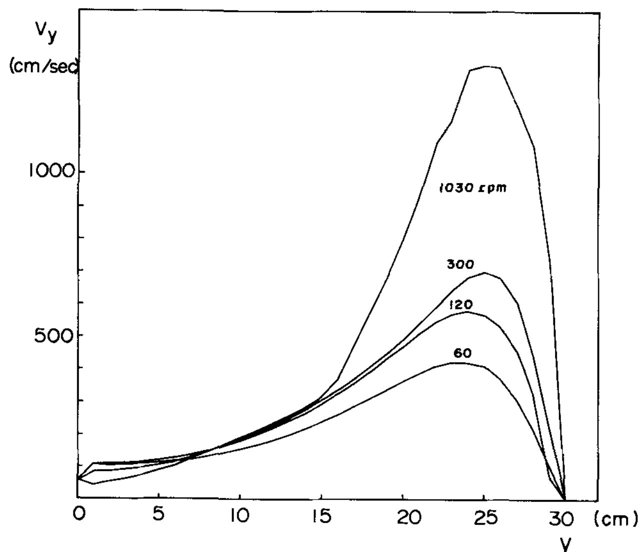
Manuscript submitted Feb. 15, 1972; revised manuscript received June 23, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

APPENDIX I

Concentration of $SiCl_4$ at the Surface of the Susceptor—Calculated Values from the Equilibrium Constant of $SiCl_4$-H_2 Reaction

The equilibrium constant of Eq. [27] is given by the following equation



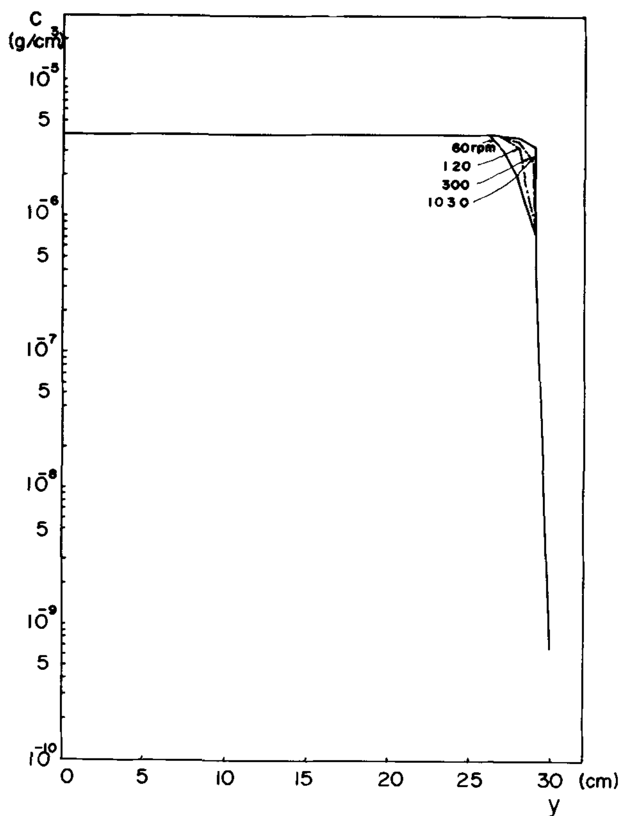


Fig. 17. Calculated values of the velocity and concentration distributions, considering the influence of the natural convection. Pressure, 760 Torr; temperature of the substrate, 1200°C; position, r = 0.5 cm. (a, upper) V_y distribution, (b, lower) concentration distribution.

$$SiCl_4(g) + 2H_2(g) \rightleftharpoons Si(s) + 4HCl(g) \quad [27]$$

$$K_p = \frac{P_{HCl}{}^4}{P_{SiCl_4} \cdot P_{H_2}{}^2} = \frac{(4x)^4}{(a-x)(1-2x)^2} \cdot \frac{P}{N} \quad [28]$$

where P_{HCl} = partial pressure of HCl, a = mole number of input $SiCl_4$, x = mole number of reacted $SiCl_4$, N = mole number of all gases, P = total pressure. The concentration of $SiCl_4$ at the surface of the susceptor was calculated and tabulated in Table I. The equilibrium constant K_p of $SiCl_4$-H_2 reaction in Eq. [28] was calculated by using the free energy in "JANAF Thermochemical Data" (18).

APPENDIX II

Diffusion Constants in the Gaseous Phase

Fujita's diffusion equation (19-20) and Wilke's formula (21-22) were used to evaluate the diffusion constants in the binary system and in the multicomponent system of gaseous phase respectively.

Fujita's formula

$$D_{SiCl_4 \cdot HCl} = \frac{0.00070T^{1.833}}{\left[\left(\frac{T_c}{P_c}\right)^{1/3}_{SiCl_4} + \left(\frac{T_c}{P_c}\right)^{1/3}_{HCl}\right]^3} \sqrt{\frac{1}{M_{SiCl_4}} + \frac{1}{M_{HCl}}} \quad [29]$$

Wilke's formula

$$D_{A'} = \frac{1 - y_A}{\frac{y_B}{D_{AB}} + \frac{y_C}{D_{AC}} + \frac{y_D}{D_{AD}} + \cdots\cdots} \quad [30]$$

where T_c = critical temperature (°K), P_c = critical pressure (atm), M = molecular weight, D_{AB} = diffusion constant of a component A in B gas, y_A = mole fraction of a component A in the mixed gas. Values thus obtained are plotted in Fig. 18.

APPENDIX III

Deposition Rate Calculation of Epitaxial Growth by Rotating Disk Method Using One-Dimensional Model

In computing, the following assumptions were made: (*i*) On the susceptor there is a boundary layer produced by the rotating disk with an infinite diameter. (*ii*) Temperature of the boundary layer is the same as that of Si substrate. (*iii*) Epitaxial reaction occurs only at the susceptor. (*iv*) Only the reaction

$$SiCl_4(g) + 2H_2(g) \rightleftharpoons Si(s) + 4HCl(g) \qquad [27]$$

occurs at the susceptor as Lever (23) and Bradshaw (16) have calculated due to a very low concentration of $SiCl_4$. (*v*) Hydrogen is stagnant. $SiCl_4$ and HCl move in the boundary layer by molecular diffusion. (*vi*) Consideration of natural convection is not given.

Thickness of boundary layer.—The thickness of the boundary layer is expressed by the following equation, when the rotating disk with an infinite diameter is used (6)

$$\delta = 1.60 D^{1/3} \nu^{1/6} \omega^{-1/2} \qquad [31]$$

where δ is thickness of the boundary layer.

Mass transfer coefficient.—When H_2 is stagnant in three component system H_2-$SiCl_4$-HCl, mass transfer coefficient takes the form of

$$k_g = \frac{D_{SiCl_4 \cdot HCl}}{\delta RT} P \qquad [32]$$

where k_g = mass transfer coefficient (mole/cm²sec) and $D_{SiCl_4 \cdot HCl}$ = diffusion constant which is for ternary nonequimolal counterdiffusion with one component H_2 stagnant (24).

Diffusion potential.—In the ternary system with one component stagnant, diffusion potential is given by

$$\Delta y = \frac{1}{1-x} \ln \left\{ \frac{\left(\frac{1}{D_{SiCl_4 \cdot HCl}} - \frac{1}{D_{HCl \cdot H_2}}\right) y_{SiCl_4 \cdot i} + \left(\frac{1}{D_{SiCl_4 \cdot HCl}} - \frac{1}{D_{SiCl_4 \cdot H_2}}\right) \frac{y_{HCl \cdot i}}{x} + \left(\frac{1}{D_{SiCl_4 \cdot H_2}} - \frac{1}{D_{HCl \cdot H_2}}\right) \frac{1}{x-1}}{\left(\frac{1}{D_{SiCl_4 \cdot HCl}} - \frac{1}{D_{HCl \cdot H_2}}\right) y_{SiCl_4} + \left(\frac{1}{D_{SiCl_4 \cdot HCl}} - \frac{1}{D_{SiCl_4 \cdot H_2}}\right) \frac{y_{HCl}}{x} + \left(\frac{1}{D_{SiCl_4 \cdot H_2}} - \frac{1}{D_{HCl \cdot H_2}}\right) \frac{1}{x-1}} \right\} \qquad [33]$$

where $D_{A \cdot B}$ = molecular diffusion constant of A and B component (cm²/sec), y_{Ai} = mole fraction of A component at the surface of the susceptor, y_A = mole fraction of A component in the gaseous phase, $y_{HCl} = 0$ for HCl, x = ratio of mole number out of the surface to that towards the surface; in this case $x = 4$, because of the stagnant hydrogen. The value of y_{Ai} was computed by using Eq. [28].

Growth rate of Si.—Growth rate is expressed under the above-mentioned assumptions

$$G = \frac{M_{Si}}{\rho_1} k_g \cdot \Delta y \qquad [34]$$

Thermal Oxidation of Silicon and Iron-Coated Silicon in the Temperature Range 692°-1003°C

Rong Yau Wang and Owen F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Polycrystalline silicon wafers, both clean and with a thin coating of metallic iron, have been oxidized in steam and in moist air (P_{H_2O} = 24 mm) in the temperature range 692°-1003°C. Data were analyzed in terms of a linear-parabolic rate equation. For clean silicon oxidized in steam, the parabolic rate constant displays an activation energy for the process of 26.9 kcal/mole below 903°C, and 16 kcal/mole above this temperature. The iron coating was assumed to oxidize and diffuse homogeneously in the oxide film within a relatively short period of oxidation; no evidence to the contrary could be found. In steam, the effect of iron was to extend the "high temperature" Arrhenius behavior to lower temperatures. In moist air, a single Arrhenius line corresponding to the "low temperature" behavior of clean silicon was seen. The activation energies of the "high temperature" and "low temperature" regions of silicon oxidation correspond to those reported for wet and dry oxidation, respectively. An interpretation of these phenomena in terms of a short range order transition in the vicinity of 900°C is postulated.

In their critical survey of their own and previous work, Deal and Grove (1) established that thermal oxidation of silicon in dry or wet oxygen could be described by the relation

$$x^2 + Ax = B\,(t + \tau) \qquad [1]$$

where x is film thickness, t is oxidation time, and τ is a factor to correct for the presence of an oxide film at $t=0$, or for an early stage of oxidation not described by this relation. Thus, early oxidation is linear in time, with a rate constant B/A, while later oxidation is diffusion-controlled, with a parabolic constant, B.

In their studies, Deal and Grove found an activation energy for parabolic oxidation of 16.3 kcal/mole under wet conditions and 28.5 kcal/mole under dry conditions, while the linear oxidation had an activation energy of 46 kcal/mole in either case. The values of the activation energy for B were found to be in accord with those for diffusion of the oxidizing species, hydroxyl ion (2), and superoxide ion (3), respectively. The parabolic constant, B, was found to be proportional to the partial pressure of the oxidant. The time constant, τ, was found to be zero under wet conditions, and to correspond to a positive oxide thickness under dry conditions, reflecting a dependence of the shape of the diffuse charge distribution in the oxide on the ionic content. Many of these observations were confirmed in a very careful study by Pliskin (4).

The mechanism of oxidation is less well established. This question is discussed at some length by Nakayama and Collins (5), who cite market studies indicating that the oxidant is the diffusing species. Jorgensen (6) studied the effect of an external field on oxidation, concluding that the diffusing species was ionic. However, Raleigh (7) demonstrated that these results were also consistent with an electrolytic reaction involving diffusion of a neutral species. The flow of another charged species in the film, required in the case of ionic diffusion to maintain a zero net charge flux, is discussed by Collins and Nakayama (8), but there are no definitive data dealing with this aspect of the mechanism.

More recently Revesz and Evans (9) have described the very significant effect of sodium (~1%) incorporated in the oxide film during oxidation. In brief, they postulated an interstitialcy mechanism for oxygen diffusion in the oxide in a dry oxygen environment, with both molecular and ionic transport occurring. The presence of sodium in the amorphous silica structure increases the density of broken Si-O-Si bridges, increasing the pre-exponential portion of the diffusion coefficient, but hinders the motion of oxygen, thus increasing the activation energy. They held oxidation by water to be very complex, with silanol (Si-OH), interstitial H_2, and interstitial H_2O possible as defects. An increase in the pressure of water vapor leads both to an increase in the pre-exponential constant and a decrease in the activation energy due to an increased density of broken Si-O-Si bridges. Inclusion of sodium in the structure increases the degree to which OH^- can be incorporated, but also hinders the movement of this species, thus increasing the activation energy.

In a recent paper Devereux, Wang, and Chien (10) reported on the oxidation of silicon through films containing significant quantities of sodium oxide (10-20%). They found that oxidation was cubic in its early stage, but became parabolic at longer times. Both cubic and parabolic constants exhibited an activation energy of 40.8 kcal/mole in wet air (P_{H_2O} = 24 mm). These data were found to be consistent with two proposed models. In one, transport rate (diffusion coefficient) decreased in proportion to the increase in viscosity (decrease in broken Si-O-Si bridges) occasioned by addition of silica to a phase containing a fixed quantity of sodium oxide. The alternative proposal was similar, but considered two phases, with the high sodium phase

decreasing in proportion to the extent of oxidation. As this phase would conduct the major part of the mass transport, this would lead to cubic kinetics. Although in either case the proposed dilution of the sodium content was continuous, the cubic kinetic behavior did not proceed indefinitely, in accord with the autocatalytic mechanism described by Charles (11) wherein a relatively small amount of sodium ion in glass produces a disproportionate amount of hydroxyl ion.

In the work reported herein, the authors have contaminated the growing film on oxidizing silicon with the oxide of a more refractory metal, iron, in order to establish a comparison to the effect of the low melting, highly soluble sodium oxide described above. In view of the large radii of both ferrous and ferric ions (0.83 and 0.67Å, respectively) compared to that of Si^{+4} (0.39Å) it was not expected that iron would substitute for silicon in the tetrahedral oxygen structure, but would enter interstitially, as does Na^+ (0.98Å), contributing its oxygens to neighboring SiO_4^{-4} tetrahedra, thus breaking Si-O-Si bridges (12). However, although iron would contribute more oxygen per cation than would sodium, the degree of ionization is much less, and less breaking of the structure would be expected than in the case of the sodium-contaminated film.

Experimental

Specimen preparation and experimental technique were essentially that described previously save in the method of introduction of the contaminating impurity (10). Silicon wafers were prepared from a 1 in. diameter polycrystalline ingot of nine 9's purity.[1] After slicing and lapping the wafers were degreased in hot trichloroethylene followed by hot nitric acid and rinsed in deionized water. The wafers were then polished in a solution of 60 parts nitric acid, 20 parts acetic acid, and 8 parts hydrofluoric acid. After polishing the wafers were rinsed in deionized water and stored under methanol. Final thickness was approximately 200μ. Clean, control specimens were oxidized as prepared; iron-contaminated specimens were coated on both sides with a vacuum-deposited layer of metallic iron (99.95%) prior to oxidation. Amounts of iron applied are shown in Table I.

Specimens were oxidized in both steam (1 atm) and wet air (P_{H_2O} = 24 mm). Oxidation was conducted in a refractory tube with a flowing environment, using a resistance furnace with current proportioning control that maintained temperature at the specimen within 1°C. Oxidation rate was determined by periodically removing the specimens and weighing them. For this purpose a Cahn RG electrobalance with a Varian G-1000 recorder as null indicator was used, yielding a typical weighing accuracy of 10^{-6}g. This technique was used previously (10) and was found to be more accurate than a continuous recording of the specimen weight. The effect of the thermal cycles on removing and reinserting the specimens was evaluated by comparison to specimens left in the furnace for extended periods of oxidation; the mean deviation between continuous and discontinuous terminal weight gain was 2.25% of the mean weight gain and the RMS value was 11.3%. There was no pattern to the sign or magnitude of the deviation, which was thus neglected in this treatment. Use of a direct weight measurement was preferred over an optical film thickness determination because of the complex nature of the binary oxide film.

Results

Kinetic data.—Weight gain data for clean silicon specimens in steam in the temperature range 692°-1003°C are shown in Fig. 1; data are presented as Δw *vs.* $t^{1/2}$ for convenience and clarity. Oxide film thickness, assuming an oxygen density of 1.0 g/cm³ in the film, is also indicated. Data for iron-coated silicon in moist air are shown in Fig. 2, and data for iron-coated silicon in steam are shown in Fig. 3.

Since the graphical representation used in Fig. 1, 2, 3 will be a straight line corresponding to the diffusion-limited region of oxidation only if the earlier linear and other nonparabolic weight gain is negligible, the appearance of linearity or lack of it in these figures is not proof of parabolic behavior. These data were analyzed by a least squares technique corresponding to Eq. [1]. Although there was no reason, *a priori*, to assume that oxidation of iron-coated silicon would follow the linear-parabolic relation, use of Eq. [1] did provide a means for correcting for early nonparabolic behavior in determining the kinetic constants for the parabolic region. An independent evaluation of the parabolic constants was made graphically from simple Δw^2 *vs.* t plots. On these plots all experiments save the iron-coated silicon in wet air at 692°C, with the slowest rate observed in the study, did exhibit at least a terminal parabolic region. Parabolic constants from both of these evaluations are compared in Table II. Arrhenius plots of these constants, using the graphical evaluation, are shown in Fig. 4. Preliminary experiments with clean silicon in moist air, not reported here, showed a reproducibility of the parabolic constant of 2%.

Pre-exponential constants and activation energies determined from this figure, together with values from the literature for comparison, are given in Table III. The parabolic constants for clean silicon oxidation show a behavior not previously reported. In the temperature range 692°-903°C a clearly linear de-

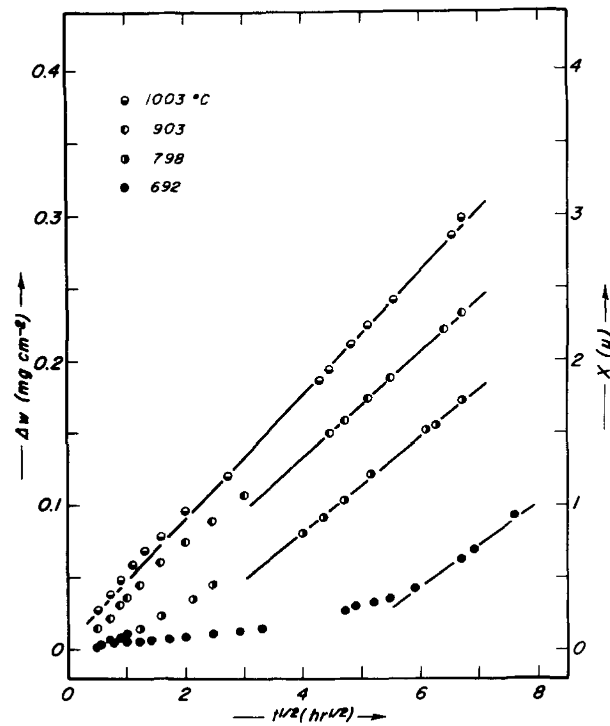

Fig. 3. Weight gain due to oxidation of iron-coated silicon in steam.

pendence is seen in steam ($P_{H_2O} = 1$ atm), but with an activation energy characteristic of that seen in dry, or nearly dry, oxygen, 26.9 kcal/mole. (See results of Deal and Grove, Nakayama and Collins, and Revesz and Evans cited in Table III.) The slope changes above that temperature; as shown in the figure an exact correspondence to the results of Pliskin (4) and of Deal and Grove (1) is seen. The plot for iron-coated silicon oxidized in steam shows a behavior similar to the high-temperature region of the clean silicon plot; however, it is not clear whether the high-temperature behavior is followed over the whole range of data, or a break, as for clean silicon, exists. The pre-exponential constant is not significantly different from that for clean silicon at high temperature. The behavior of iron-coated silicon in wet air, however, parallels the low-temperature clean silicon behavior, with a slope corresponding to 26.9 kcal/mole. Approximately a first order dependence on water vapor pressure is seen.

Microscopy.—Optical examination of the oxidized specimens was made directly and in tapered section.

* $B = k_o \exp(-\Delta H_k/RT)$.

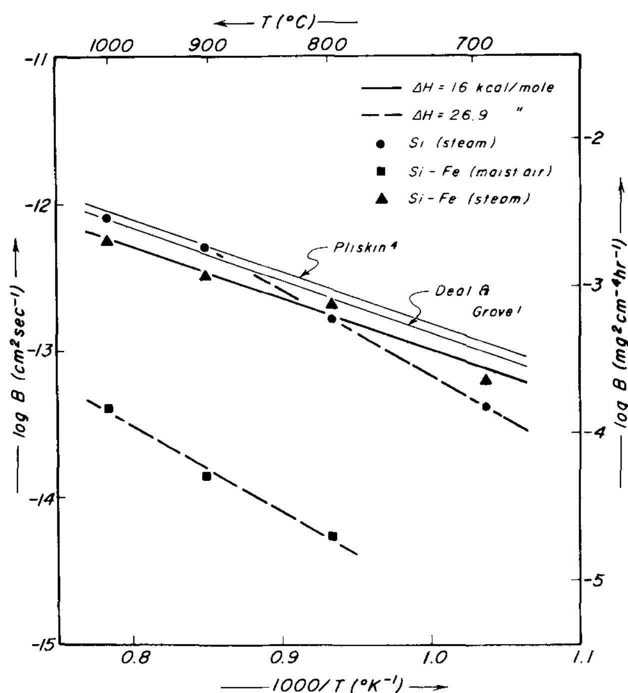

Fig. 4. Arrhenius plot of parabolic rate constants for clean silicon in steam, and for iron-coated silicon, in moist air and in steam. Extrapolated data of Pliskin (4) and Deal and Grove (1) shown for silicon in steam.

Typical observations are shown in Fig. 5, representing the final surface of the iron-coated silicon specimens oxidized in wet air at (a) 692°C, (b) 798°C, and

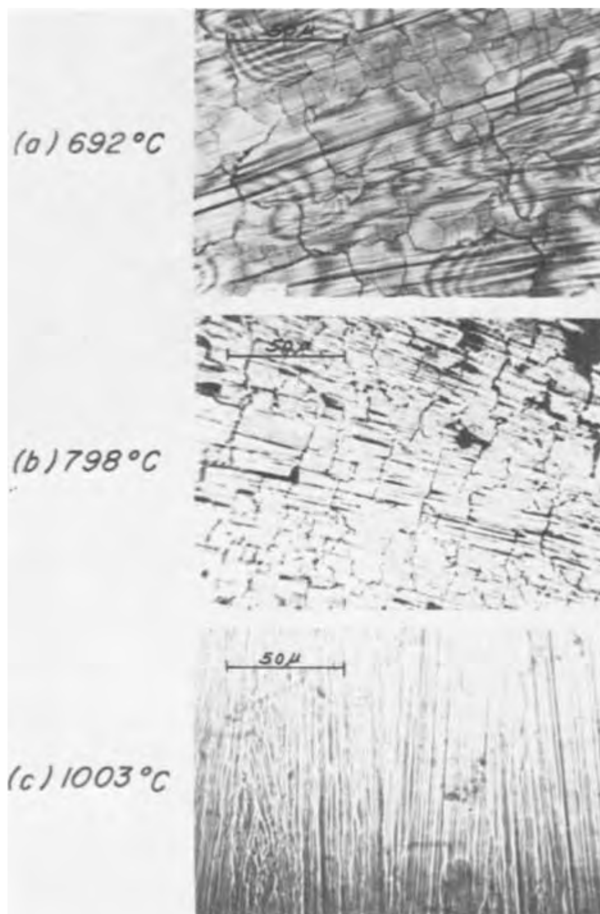

Fig. 5. Microstructure of the film on iron-coated silicon oxidized in moist air at (a) 692°C, (b) 798°C, and (c) 1003°C.

(c) 1003°C. A similar sequence of characteristics was seen for the iron-coated silicon oxidized in steam and, surprisingly, for clean silicon oxidized in steam. The lower temperature specimens display a random crack or grain boundary pattern, an effect which progressively disappears with increase in oxidizing temperature, being only suggested at 1003°C. Similar patterns were seen on examination of the tapered sections. These sections provided the additional information of a marked decrease in roughness at the silicon/oxide interface with increasing temperatures, demonstrating the increasing significance of diffusion control. Scanning electron microscopy of a clean, unoxidized specimen revealed a slight "orange peel" effect due to preparation; this was of a smaller order of magnitude than the pattern shown in Fig. 5 and gradually disappeared with increasing oxidizing time.

While these specimens were removed from the furnace at regular intervals for weighing in order to establish the oxidation rate, it is apparent, due to concurrence with weight gain data for specimens removed only after a terminal period of oxidation, that the observed pattern is not one of thermal-shock-produced cracks in either the metal or the oxide film. Alternatively, if the possibility of thermally produced cracks is admitted, then the conclusion must be reached that such cracking had no effect on oxidation rate.

X-ray diffraction.—X-ray diffraction analyses of the oxidized specimens were made, in which the wafer was employed essentially as a powder sample. Other than a weak diffraction peak from the oxidized iron-coated silicon specimens corresponding to a lattice spacing of 4.1068Å, no diffraction lines other than those from silicon were seen.

Discussion

The technique used to contaminate the silica film with iron oxide offered a controllable, clean means of putting a quantity of iron on the surface, but has a disadvantage in that the distribution and oxidation state of the iron in the oxide film are not known and that the concentration of iron in the film, and possibly the distribution, is a function of the thickness of the oxide film. It has been assumed by the authors that the iron in each case save one was fully oxidized very early in the experiment. Justification is given in Table I, wherein on assuming oxidation to Fe_2O_3, it is shown that the weight gain necessary for complete oxidation is attained in a relatively short time. The exception, the experiment performed in wet air at 692°C, was the one with the slowest oxidation rate and the only experiment failing to show a clear parabolic region. Supporting this assumption is the failure to observe a discrete iron or iron oxide phase by x-ray diffraction. A qualitative analysis made of the iron-coated sample oxidized at 798°C in steam by x-ray fluorescence in a scanning electron microscope at 20 kV revealed a Fe/Si count ratio of 0.04, fortuitously approximately the weight ratio of Fe to Si in the oxidized film if all iron applied were retained in the film and uniformly distributed. No iron was seen in an uncoated, oxidized sample.

A surprising aspect of Fig. 4 is the demonstration of a low-temperature oxidation behavior of clean silicon in steam that differs from the well-established behavior at higher temperature. Although the onset of purely parabolic behavior occurs in the vicinity of 1000°C, as opposed to the linear parabolic behavior seen at lower temperatures, the authors are confident that their analysis of the data, in view of the concurrence of both graphical and statistical methods, have yielded true parabolic constants as shown. The data in the range 692°-903°C show a very clear Arrhenius behavior that is quite distinct from that in the interval 903°-1003°C which, although defined only by two points, is in excellent agreement with the work of Deal and Grove (1) and of Pliskin (4). The authors have not seen previous mention of such an effect, but, on the other hand, the silicon/steam oxida-

tion system does not seem to have been studied previously in this temperature interval (Table III). An attempt was made, using a digital nonlinear regression program, to fit all of the oxidation data reported herein for a given system to a single relation, with both linear and parabolic constants expressed in terms of an activation energy and a pre-exponential constant, Eq. [2]

$$t = \frac{1}{a_0} \exp(\Delta H_a/RT) + \frac{1}{k_0} \exp(\Delta H_k/RT) \qquad [2]$$

It was not possible, however, to make a satisfactory correlation, further substantiating the change in slope depicted in Fig. 4.

Thermal oxide films on silicon are normally regarded as amorphous, in accord with the observation that devitrification of silica in this temperature range is exceedingly slow and with the absence of any evidence of crystallinity. While it has been reported that water does not alter the relative phase stability in silica significantly at other than very high pressure (13), water does dissolve in silica in appreciable quantity and more recent work has suggested that this might lead to an altered stability diagram (14, 15). Such water would enter the silica structure by replacement of bridging oxygen atoms by nonbridging hydroxyl groups, thus greatly increasing structural mobility. It might be reasoned that such a structure would possess short range order characteristics more nearly akin to those of the thermodynamically stable crystal. Supporting this argument, the temperature at which a change in kinetic behavior is seen is very nearly that of the quartz/tridymite transition, 867°C (15). As the transition to cristobalite occurs at 1470°C, a comparable effect due to this transition would not have been seen in the previously reported work. The resemblance of the "low-temperature" behavior of silicon oxidation in steam to that in dry oxygen is in accord with the relative openness of the tridymite structure in comparison to that of quartz, the densities being 2.30 and 2.655 g/cm^3, respectively (16). That is, in the absence of definitive data, it may be anticipated that the solubility of water in the low temperature structure is less than in the high temperature structure, giving corresponding greater importance to the "dry" transport mechanism during low-temperature oxidation.

The introduction of iron into a silica film oxidizing in steam does not appear to alter its behavior significantly. Despite obvious concentration variation during film growth, parabolic behavior is still seen for long-term oxidation. The kinetic parameters are not significantly different from those for clean silicon except that the high temperature behavior may, in steam, extend over the entire temperature range of the experiments. This might be interpreted as an effect of the solute on a short range structure transition as postulated above, thus stabilizing the more open structure at lower temperatures. In moist air, again a similarity between clean and iron-coated silicon is shown with, however, the "low temperature" or "dry oxygen" activation energy being displayed for the iron-coated case.

Conclusions

Clean silicon appears to exhibit different kinetic behavior during oxidation in steam below 900°C from that observed at higher temperatures. It is suggested that this might be due to a change in short-range structure corresponding to the quartz/tridymite transition. The quartz structure is less open than the higher temperature tridymite, suggesting a reduced solubility for water at lower temperatures, in accord with the observation that the activation energy for the parabolic constant at low temperatures in steam is characteristic of that seen during "dry" oxidation.

The effect of iron in the oxide film in steam oxidation is to extend the range of high-temperature behavior; in terms of above model, this would resemble a solute-lowered transition temperature. In moist air in which clean silicon already approaches the behavior seen in dry oxygen, iron-coated silicon exhibits a behavior characteristic of "dry" oxidation.

The authors have no other evidence to suggest the occurrence of a short range order transition in amorphous silica and, thus, at this point are merely suggesting such a transition as a model to explain the behavior reported.

The Etch Rate and Deterioration of Magnesium Aluminum Spinel in Hydrogen

J. M. Green*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Magnesium aluminum spinel is commonly used as a substrate for the heteroepitaxial chemical vapor deposition of silicon. Hydrogen is usually used as a carrier gas, and a high-temperature pretreatment in hydrogen is typically performed on the substrate with the idea that abrasion polishing damage will either be annealed or removed. In this paper the rate of material removal in hydrogen of stoichiometric spinel is presented as a function of crystallographic orientation, time, and temperature. For example, at 1000°C the rate is ~1 Å/min; at 1300°C, ~100 Å/min. However, it was found that such a hydrogen ambient promotes crazing of the substrate surface, thus degrading its suitability for heteroepitaxy. This phenomenon was studied, and it is suggested that the cause is due to a preferential out-diffusion of magnesium from the surface, which induces a strain large enough to result in brittle fracture. It has been shown that the crazing is obviated by the use of helium as a carrier gas.

The heteroepitaxial deposition of silicon on insulating substrates has been under investigation by several workers. Good reviews together with bibliographies are given in references (1-3). Sapphire was the first material to be used successfully (4); however, magnesium aluminum spinel has been thought to have some advantages over other materials where consideration is given to compatibility with silicon with respect to crystal class, lattice parameter, temperature coefficient of expansion, and tendency to incorporate constituents into the silicon film.

The silicon heteroepitaxy technologies for both sapphire and spinel have been extensively studied. Nonetheless, preparation of the substrate surface remains a critical consideration for improvement of the epitaxial film quality. At present the wafers are usually abrasion (mechanically) polished. This process induces considerable damage into the wafer surface, which must be removed. Several wet etches have been proposed for both sapphire and spinel (1, 2, 5-8), but a gaseous etch *in situ* would be advantageous. In this regard, oxide reduction by hydrogen clearly suggests itself: it does not contribute baneful reaction products; and it is the usual carrier gas used in the chemical vapor deposition of silicon, and, therefore, convenient to use. The etch rate of sapphire in hydrogen was studied by Zeveke *et al.* (7); the etch rate of spinel is reported in this paper.

Hydrogen is commonly used to prepare sapphire wafers for epitaxial deposition of silicon, and there has been no report of deleterious effects due to this procedure. However, a pernicious phenomenon is attendant to the polishing of spinel by this method: the wafers tend to craze (or crack) by brittle fracture. This is also discussed below.

Etch Rate Determination

The material removal rate of the spinel was determined by gravimetry using a Mettler Micro Gram-Atic Balance. The etch rate was calculated using a value of 3.58 for specific gravity (3, 6). The heat-treatments were effected in a relatively standard horizontal epitaxial reaction chamber (60 cm long by 5 cm in diameter) which was fabricated from fused silica. The wafers were supported by an uncoated graphite susceptor which was heated by rf induction. The hydrogen was purified in an Englehard Industries Palladium Diffusion Unit, and it flowed through the chamber with a gas stream velocity of ~10 cm/sec. The temperature was measured using a Pyrometer Instrument Company Micro Optical Pyrometer which had been calibrated for this particular series of experiments at the melting points of germanium, copper, and silicon. The starting substrates were fabricated from Czochralski grown, single-crystal, stoichiometric, magnesium aluminum spinel by the Crystal Products Division of Union Carbide. They measured 1 in. in diameter and 20 mils in thickness. The face being investigated was, in each case, abrasion polished to a specification of 1 μ in. absolute; the reverse face, 1 μ in. C.L.A. (center line average). There was no noticeable evidence of reaction between the wafer's reverse side and either the hydrogen or the carbon susceptor.

The etch rate data were collected for wafer orientations of (111), (110), and (100), at each of four temperatures which lie within the usual silicon deposition range (1000°-1400°C), and for two to five intervals of time at each temperature. As an example the data for 1320°C are given in Fig. 1. Here the intervals were 9, 10, 10, 10, and 26 min, and the average rate for each interval was plotted at the mid-interval time. All the data are summarized in the Arrhenius plot of Fig. 2. Here the etch rates were averaged at

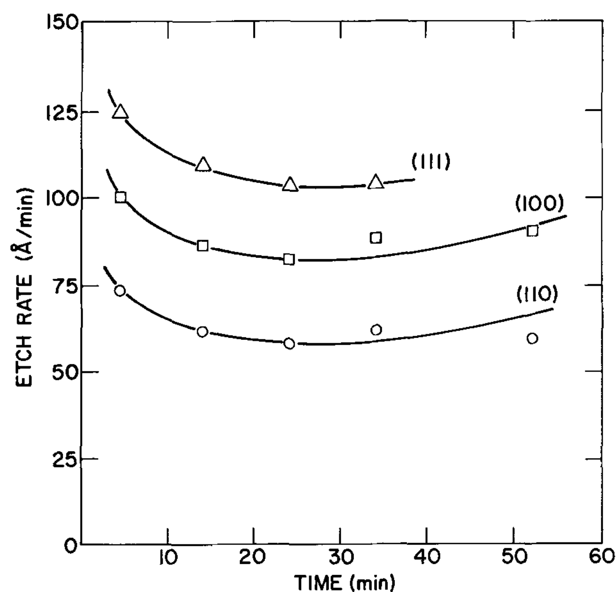

Fig. 1. The etch rate of magnesium aluminum spinel in hydrogen at 1320°C as a function of duration of heat-treatment.

Key words: substrates, polishing, spinel, etch rate.

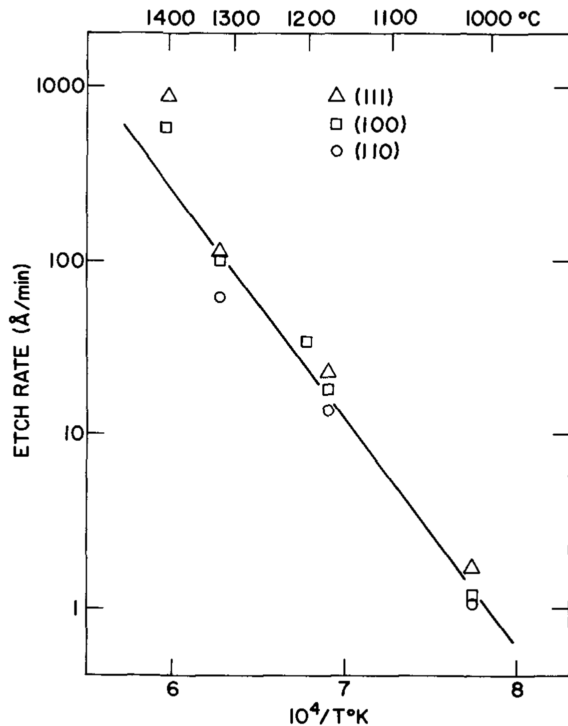

Fig. 2. The etch rate of magnesium aluminum spinel in hydrogen as a function of temperature.

each temperature for each orientation. The associated activation energy for the curve as shown is ~3 eV.

The submicroscopic character of the surface of a (100) wafer after moderate hydrogen etching (10 min at 1250°C) can be seen in the replica electron micrographs of Fig. 3. The rectanguloid etch figures are depressions (Fig. 3b); the largest are ~170Å deep and ~600Å across. Note further that deep spike-like wells are formed during hydrogen heat-treatment (Fig. 3a). These wells have been seen to extend to a depth of more than 3 μm. The typical density of occurrence as exhibited in Fig. 3a is of the order of 10^8 per cm^2. The diameter of the latex spheres is 5000Å. Note that the surface before hydrogen etching would appear featureless by comparison.

Deterioration

A phenomenon which accompanies the hydrogen etching of spinel substrates is the cracking or crazing of the surface of the wafer. The crazing is evident when observed in the optical microscope at 100X. And it can be seen to initiate at the sample periphery after it has been heated in hydrogen at >1000°C for a period as short as 5 min. A severe example is shown in the photographs of Fig. 4. A magnification of the cracks is seen in Fig. 5. Typically they are 1 mil deep; this depends of course on the extent of the heat-treatment, but the cracks do not extend through the thickness of the wafer. They initiate principally from the periphery of the wafer, and align themselves in low-index crystallographic directions. Occasionally a small surface section of the crazed wafer will break off and quit the wafer bulk; this leaves a depression of the order of 1 mil deep. Also a small elongated section may break off at one end and appear as if it were a curled shaving like those that might be left by a wood plane. None of the above evidence of deterioration has been seen after lengthy heat-treatments in a nitrogen or a helium ambient.

Two possible causes of the crazing were briefly investigated and discounted because of negative results:

1. Thermal shock during rapid heating or cooling. Wafers which were heated briefly to ~1500°C and cooled to room temperature for a few cycles in hydrogen or for >30 cycles in nitrogen ambient did not experience crazing.

2. Relief of asymmetric stress. The two faces of the wafers as received have been polished to different finishes, and hence have different induced strain due to the abrasion-polish damage. However, wafers with some 3 mils etched from each face in hot phosphoric acid and then exposed to hydrogen exhibited similar crazing to that of untreated wafers.

However, the following tentative mechanism does account for the crazing: magnesium is preferentially depleted at the wafer surface. This results in a composition gradient. And in as much as the lattice parameter is a function of the composition (9), a lattice parameter gradient is created, thereby inducing a strain large enough to produce brittle fracture of the

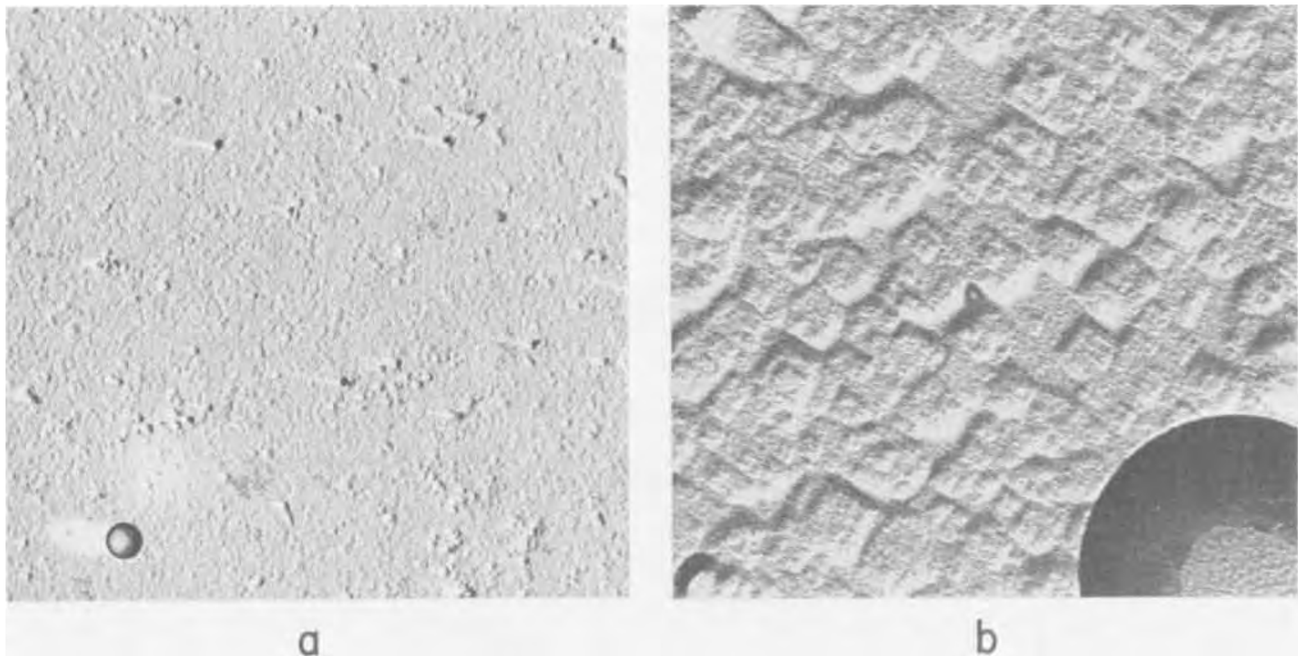

Fig. 3. Replica electron micrographs of a (100) spinel surface after heat-treatment in hydrogen at 1250°C for 10 min. The diameter of the latex spheres is 5000Å.

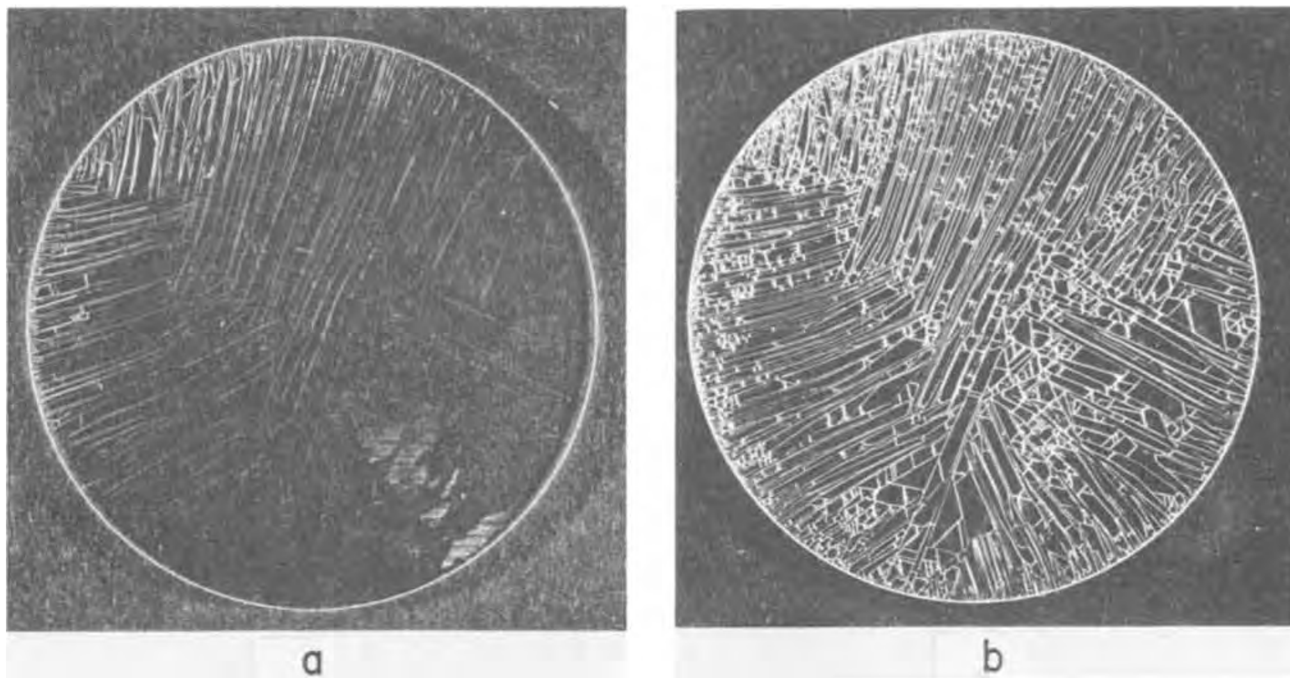

Fig. 4. Photomicrograph of a crazed (111) spinel wafer after heat-treatment in hydrogen at 1350°C (a) for 20 min and (b) for an additional 20 min. The wafer is 1 in. in diameter.

crystal at its surface. To investigate this hypothesis three experiments were performed:

1. Electron microprobe analyses were made on three wafers to determine the chemical composition (*i*) on the surface of an "as received" wafer, (*ii*) after extensive heat-treatment in nitrogen (16 hr at 1300°C), (*iii*) after heat-treatment in hydrogen on the surface of a wafer "shaving," and (*iv*) underneath the same shaving. The results, which are presented in Table Ia, show a composition gradient normal to the surface. Note that the theoretical weight fractions for a perfectly stoichiometric spinel are 17.1% magnesium and 37.9% aluminum.

2. Another electron microprobe analysis was performed on a single wafer after each of various treatments: (*i*) on the "as received" wafer, (*ii*) after the wafer had been heat-treated in hydrogen at a normal processing temperature (1200°C) and period (1 hr), (*iii*) after an additional 2 hr heat-treatment in hydrogen, (*iv*) after a subsequent etch in a mixture of sulfuric and phosphoric acids (3:1) (8) at 265°C for 60 min, which removed ~1 mil from each face. The results are presented in Table Ib and again show a composition gradient. At each step of the analysis, the wafer was scanned with the microprobe in an attempt to detect inclusions or precipitates, however, no evidence of such inhomogeneity was found. The accuracy of these analyses is better than ±5% of the amount of the element detected (*i.e.*, ±¾% for Mg and ±2% for Al). Pure stoichiometric MgO and Al_2O_3 were used as standards.

3. The relative etch rates in hydrogen of wafers of magnesia (MgO), spinel ($MgO \cdot Al_2O_3$), and sapphire (Al_2O_3) were determined at 1200°C. This was accomplished using the same gravimetric method used for spinel which was discussed above. The magnesia and spinel wafers were heat-treated for 2 hr; the sapphire, for 11.8 hr. The data are presented in Table II.

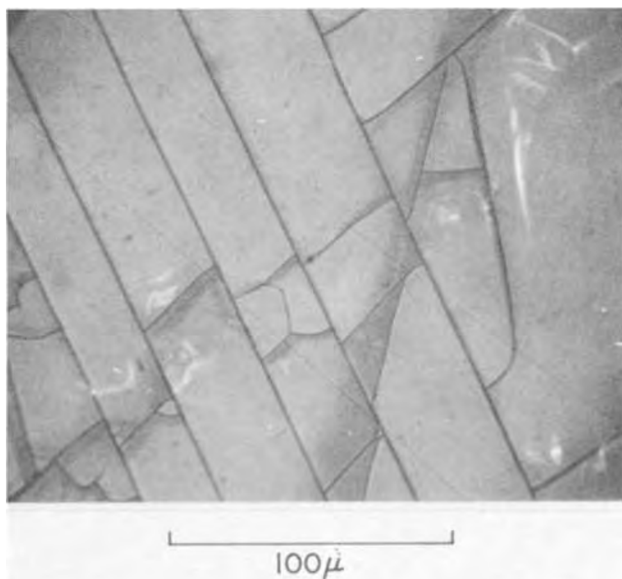

Fig. 5. An interference contrast photomicrograph of the wafer shown in Fig. 4b.

Discussion

The data seem to support the preferential-depletion-of-magnesium hypotheses. After 3 hr of hydrogen heat-treatment, the spinel wafers do indeed have a composition gradient within a mil or two of the surface.

Table I. The magnesium and aluminum concentrations as determined by electron microprobe analysis of spinel wafers after various treatments

(a)

Sample	Treatment	w/o Mg	w/o Al
D5 (111)	As received	17.2	39.4
D2 (111)	After 16 hr in N_2 at 1300°C	16.7	40.5
D3 (111)	After 40 min in H_2 at 1300°C		
	On shaving	15.3	41.7
	Under shaving	16.8	40.2

(b)

Sample	Treatment	w/o Mg	w/o Al
L2 (100)	As received	17.8	39.0
L2 (100)	After 1 hr in H_2 at 1200°C	17.1	39.0
L2 (100)	After an additional 2 hr in H_2 at 1200°C	15.9	42.4
L2 (100)	After subsequent acid etch to remove ~1 mil.	16.9	41.8

Table II. The etch rates of magnesia, spinel, and sapphire in Å/min

[Note that the sapphire etch rate given here is more than an order of magnitude lower than that given by Ref. (7).]

In H_2 at 1200°C			In N_2 at 1300°C	
MgO (100)	$MgO \cdot Al_2O_3$ (100)	Al_2O_3 60° off c-axis	$MgO \cdot Al_2O_3$ (100)	(111)
278	35	1.5	3.9	2.7

The lattice parameter differential at the surface as calculated from the compositions given in Table I and the data of Wang *et al.* (9) indicate that a tensile strain as high as 0.3% could have been achieved. This level of strain in all probability is in excess of that needed to cause brittle fracture. This is especially true, since the abrasion polishing of the wafers induces considerable surface damage (10, 11), which serves as Griffith cracks and lowers the brittle-fracture strength of the material. In this regard it should be noted that wafers which have been more gently abrasion polished show less tendency to craze. It has also been shown that near 1200°C the rate of the hydrogen reduction of magnesia is more than two orders of magnitude higher than that of sapphire (cf. Table II). It is therefore suggested that the etching of spinel can be considered as essentially two separate reactions

$$MgO + H_2 \rightarrow Mg\uparrow + H_2O\uparrow$$

and

$$Al_2O_3 + 2H_2 \rightarrow Al_2O\uparrow + 2H_2O\uparrow$$

In addition to Al_2O, Al_2O_3 may decompose to other suboxides or to the metal. This is discussed by Readey and Kuczynski (12). The above aluminum equation is representative of the rate-controlling step, reduction reaction of Al_2O_3. And it is assumed that this reaction is much slower than that for the reduction of magnesium. Note that in equilibrium all these reactions are thermodynamically unfavorable. However, in an open-tube system such as is used for the present work, the reaction products are rapidly swept away, and, therefore, the reaction is likely far from equilibrium.

Now hydrogen is known to diffuse rapidly through various materials (13-16), hence it can be expected to diffuse with high mobility through the spinel wafer. It is therefore reasonable to believe that the magnesium ions are preferentially reduced to the neutral metal, leached from the wafer by out-diffusion, and evaporated from the surface. This process is consistent with the very high vapor pressure of magnesium as compared to that of aluminum and its oxides (12, 17). A similar leaching process was observed by Komarek *et al.* while they were studying the reactions of carbon with magnesia, spinel, alumina, and other oxides (18).

The decreasing etch rate with time shown in Fig. 1 corresponds to the establishing of a steady-state diffusion of magnesium; the rate decreases because of the depletion of magnesium. This rate decrease could be augmented by the concomitant removal of the damaged layer which is left after abrasion polishing and may exhibit an increased etch rate. The increase in rate beginning at ~20 min can be attributed to an increase in the surface area due to crack formation. The data of Table I also shows that even for nitrogen heat-treatments there is a slight tendency for the magnesium to leach out.

The spike wells of Fig. 3a could be due to preferential etching along dislocation lines. If this is the case then the dislocation density would be a surprising 10^8 per cm^2. This is in contrast to values of 10^3-10^5 per cm^2 determined in conjunction with hot, liquid etches (5-7).

Summary

The etch rate of magnesium aluminum spinel in hydrogen has been established for purposes of substrate preparation. However, as a general practice hydrogen should be used with caution as an ambient for processes which use spinel as a substrate. Its use either as a pretreatment etch or as a carrier gas for silicon heteroepitaxy is liable to cause surface deterioration through crazing.

Recently helium was reported to have been used as a carrier gas for silicon iso-epitaxy (19). We have seen that spinel wafers processed in such a fashion do not craze. Also the use of essentially hydrogen-free reaction gases should have the beneficial side effect of lowering the autodoping by minimizing the liberation of metal atoms by oxide reduction.

A Novel Method for Fabrication of Ultrafine Metal Lines by Electron Beams

T. O. Sedgwick,* A. N. Broers, and B. J. Agule

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The minimum width of metal lines fabricated by means of electron-beam resist technology has steadily decreased during the last five years. The most important reduction in line width was achieved by the development of a high-resolution electron resist, polymethylmethacrylate. With this resist metal lines down to 1000Å in width can be routinely fabricated using the following procedure developed by Hatzakis (1, 2): apply electron resist, expose, develop, evaporate metal, and finally strip excess metal and unexposed resist.

The limiting factor now in obtaining still narrower metal lines is due to the lateral exposure (Fig. 1a) of the resist from electrons scattered in the substrate (dashed line area). Since most of these electrons from a 15 kV beam are scattered within a depth of about

* Electrochemical Society Active Member.
Key words: silicon nitride, resolution, substrate preferential etching.

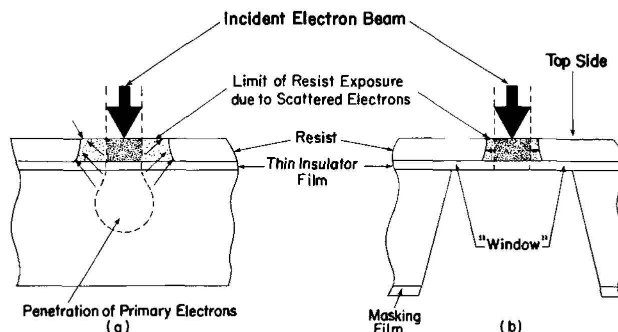

Fig. 1. Schematic diagram of (a) lateral electron resist exposure using a conventional substrate, and (b) reduced lateral resist exposure using a thin-film "window" substrate.

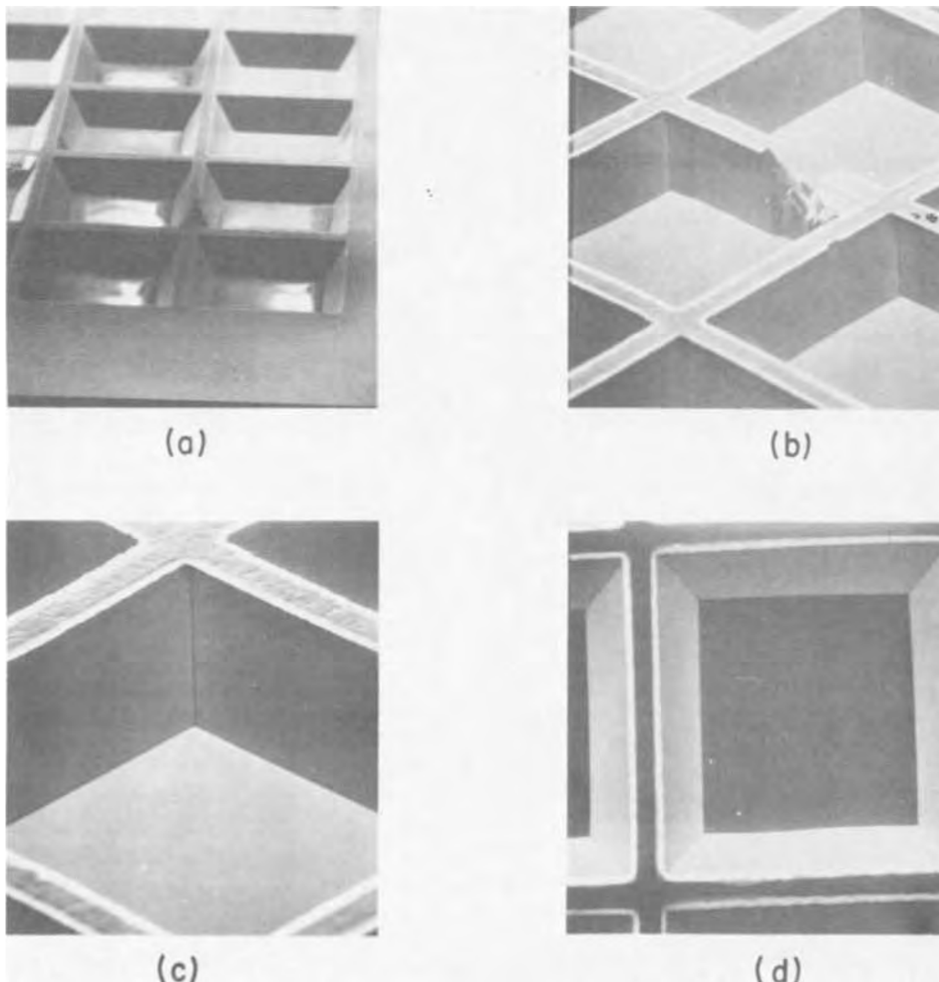

Fig. 2. SEM photographs of etched Si window structure. Masking film opening (top of photo) is 27 mils on a side (a), (b), (c) angle view, (d) top view; (b), (c), (d) metalized before photographing.

2μ in the substrate, presumably the lateral resist exposure could be greatly reduced by removing most of the substrate in the region to be electron-beam exposed. This note describes experiments which show that if the usual thick (compared to 2μ) substrate is replaced by a very thin substrate, *e.g.*, a 1500Å thick insulating film, as in Fig. 1b, the degree of lateral resist exposure is significantly reduced.

The "window-like" structure of Fig. 1b was fabricated by selective etching of a Si wafer (1 in. diameter, 5-10 mils thick, n-type 2-3 ohm-cm, <100>) as follows. The polished (top) side of the wafer was coated with a thin insulator film of vapor deposited 300-1500Å Si_3N_4 (3) or sputtered or thermal SiO_2. The lapped (bottom) side was coated with 1500Å Si_3N_4 for use as a masking film. A pattern of square openings was developed in the masking film with sides oriented along the (110) directions in the wafer. The Si wafers were etched using aqueous 33.5 weight per cent (w/o) NaOH at 90°C (4) or ethylene diamine 31.5 w/o, pyrocatechol 3.7 w/o, water 61.2 w/o at 110°C (5) to remove the Si under the "window." The NaOH did not etch the Si_3N_4 films noticeably during removal of the Si. However the NaOH etched SiO_2 films so fast that SiO_2 was not useful as the masking film. The ethylenediamine-pyrocatechol solution etched both the SiO_2 and the Si_3N_4 films at about 100 Å/hr. The Si etchants were highly preferential and exposed near perfect reflecting <110> planes as walls of the holes. The size of the openings in the masking films was calculated to give a window size at the bottom of the hole varying from about 4 mils square up to 36 mils square. An opening 14 mils on a side would etch down through a 5 mils thick wafer to produce a window about 4 mils on a side.

Figure 2 is a series of scanning electron micrographs (SEM) of a pattern of etched window structures all shown from the bottom or masking film side of the Si wafer. (View Fig. 1b from the bottom.) The wafer is 8-10 mils thick and the masking pattern is 27 mils wide. The exceptional smoothness of the exposed <110> Si planes which constitute the sides of the holes is apparent. The edges of the crossed pattern of masking film appear white in the photos because they are no longer supported by Si which was undercut during the etching. Several defects are apparent in Fig. 2a and 2b showing Si walls that have been etched away probably due to defects in the masking film. The insulator windows (hole bottoms) are very flat as seen in Fig. 2b, 2c, and 2d which were metalized to prevent charging while taking the SEM photos. Figure 2a was not metalized and shows an apparent, but not real, irregular bottom surface due to charging while taking the SEM photo.

The SiO_2 windows were fragile and easily broken if larger than 10 mils on a side. The sputtered SiO_2 films gave slightly dimpled or stretched windows, while the thermal SiO_2 gave clearly wrinkled windows, both of which made it difficult to spin on thin uniform electron resist layers for metal line fabrication. On the other hand, the Si_3N_4 windows were extremely flat and relatively strong. Windows as large as 36 mils on a side and only 1500Å thick were made. The windows used for the electron-beam resist exposure and metal line fabrication described below were only 4 mils on a side and 1500Å thick and most windows were not broken during normal handling procedures. It was even possible to make Si_3N_4 windows about 4 mils on a side down to a thickness of 300Å. In order to test the notion that a thin substrate would enable ultrafine line fabrication due to reduced electron backscattering, the following experiment was performed: several 1500Å thick Si_3N_4 window structures were coated with polymethylmethacrylate resist and exposed with a 100Å diameter electron beam (25 kV) at a line-charge density of 1.2×10^{-10} coulombs/cm.

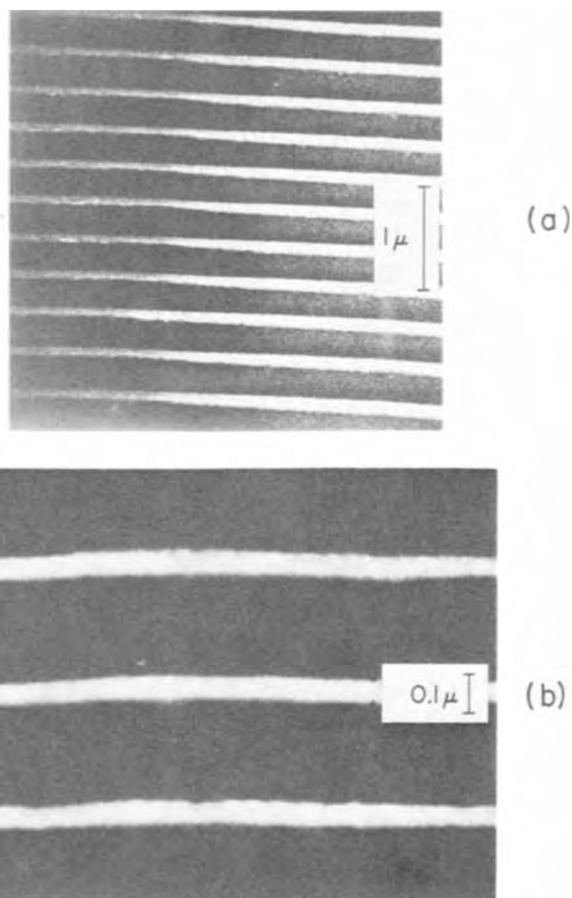

Fig. 3. (a) Metal line pattern fabricated over Si wafer (light, right portion) and over 4 mils Si_3N_4 window (dark, left portion); (b) higher magnification view of metal lines over window.

The beam current was 1.5×10^{-10}A. Aluminum metal lines (*ca.* 600Å thick) were fabricated both over the bulk (light portion of Fig. 3a) and over the window (dark portion of Fig. 3a). The fact that the SEM image is darker over the window is direct evidence that fewer electrons are scattered back out of the thin window-like substrate. From Fig. 3a it can be seen that the width of the metal lines is about 1000Å over the Si (light portion) and only 600Å over the Si_3N_4 window (dark portion). The smaller line width over the window (shown more clearly in Fig. 3b) is apparently due to the reduced intensity of scattered electrons which cause lateral exposure of the resist. The reduction in line width described here was repeated in several experiments. A systematic study of metal-line width as a function of substrate "window" thickness has not yet been undertaken. It should be noted, however, that the metal-line width is reduced gradually, as would be expected, as the lines pass from right to left in Fig. 3a over the edge of the Si substrate which is tapered due to the etching process (see Fig. 1b) and onto the "window" proper.

The Rate of the Reaction of Nickel with Gaseous Phosphorus and the Profiles of the Scales Formed

Yoshinori Sasaki and Shiro Ueda

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba, Japan

Many studies on nickel phosphides have been reported previously. Recently the catalytic activity of nickel phosphides has been of interest, *e.g.*, the reduction of nitrobenzene (1), the polymerization of α-olefins (2), and the hydrogenation of acetylene hydrocarbons (3).

In an earlier paper (4), the kinetics and mechanism of an attack of phosphorus vapor on nickel sheets were studied by gravimetric means. However, only a few morphological observations were made. The present paper deals with the profiles of the scales produced, together with the kinetics on an increase of the thickness of the phosphide layer.

The specimens phosphidized in a preceding research (4) were used in this study. They were embedded in a polyester resin, and then their cross sections were mirror-polished with a very fine powder of Cr_2O_3.

Thicknesses of these phosphide layers were determined by microscopic observation, and plotted against a square root of the elapsed time. Figure 1 shows that the reactions have a tendency to follow a parabolic behavior. The scatter in the data may result from the difference in porosity of the layers. Even on the same phosphidized specimen, the thickness is not necessarily the same for the position chosen. All the phosphide phases obtained are very stable at room temperature.

Key words: phosphidation of Ni, scale morphology.

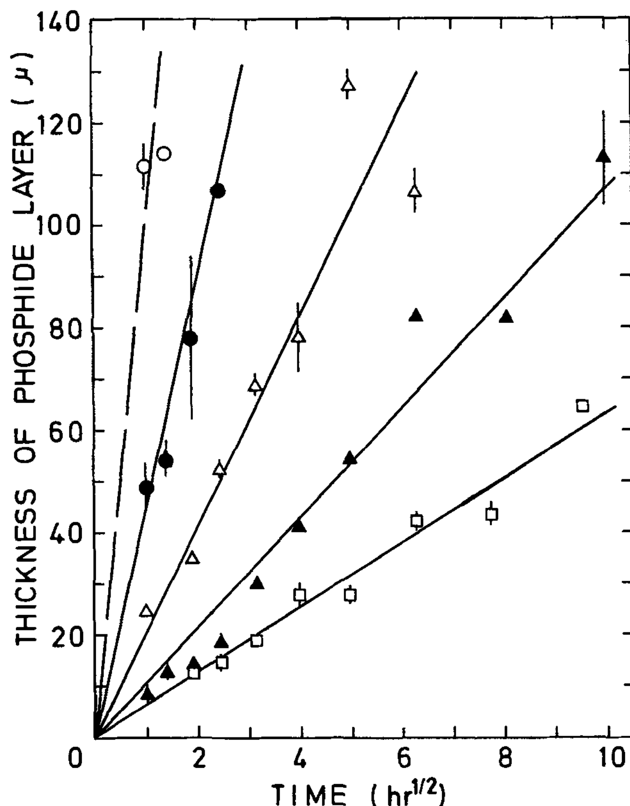

Fig. 1. Parabolic phosphidation of nickel in 2 atm phosphorus: ○ 600°, ● 550°, △ 500°, ▲ 450°, □ 400°C.

The parabolic-rate constants obtained at the 2 atm-reactions were as follows: 39 $\pm$ 10 μ^2/hr, 400°C; 114 $\pm$ 27 μ^2/hr, 450°C; 455 $\pm$ 108 μ^2/hr, 500°C; 2000 $\pm$ 400 μ^2/hr, 550°C; 10,400 $\pm$ 4,000 μ^2/hr, 600°C. Their Arrhenius plot yielded the activation energies of 26 $\pm$ 5 kcal/mole (400°-500°C) and 42 $\pm$ 9 kcal/mole (500°-600°C).

The x-ray patterns showed that the Ni_2P compound is certainly formed under all the conditions. The x-ray peaks of NiP_2 were surely observed at 400° and 450°C, but not at 500°C and above. The peaks of Ni_6P_5 were very low, but were recognized in the early stages through 400°-600°C, and, especially at 400° and 450°C, were comparatively higher (4).

Faceted phosphide grains developed over large parts of the surface are shown in Fig. 2, which reveals the crystals to grow stepwise. Its x-ray diffraction peaks (4) were identified as belonging to those of Ni_2P, showing the epitaxial growth of a (111) plane ($2\theta_{CuK\alpha} = 40.8$) and (300) + (002) planes ($2\theta_{CuK\alpha} = 54.2$). Faceted grains were not formed except at 500°C in 1 Torr phosphorus for 3-11 hr.

Phosphide whiskers were frequently observed on reactions in 2 atm phosphorus at 450°, 500°, 550°, and 600°C, and in 1 and 4 Torr at 500°C, but not at 400°C.

The growth of platelets was a common phenomenon at 500°C in 1-1520 Torr phosphorus, but was not observed except for these conditions. It is not clear, why such phenomenon took place at 500°C alone. It is not evident by x-ray-spectrography whether the different phase has been formed.

Typical platelets and whiskers, which developed at 500°C, are shown in Fig. 3: a platelet having corners

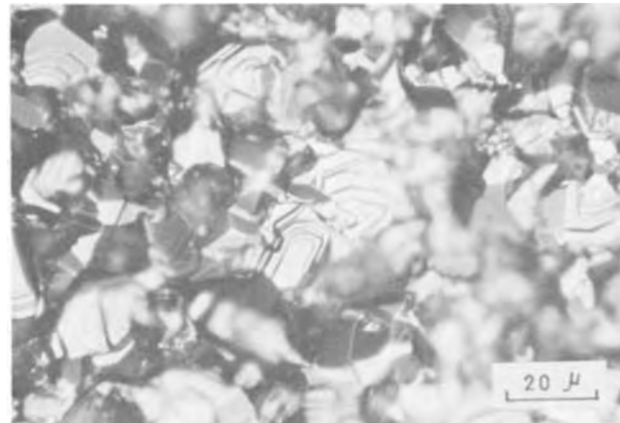

Fig. 2. Faceted phosphide grains formed at 500°C for 11 hr in 1 Torr phosphorus.

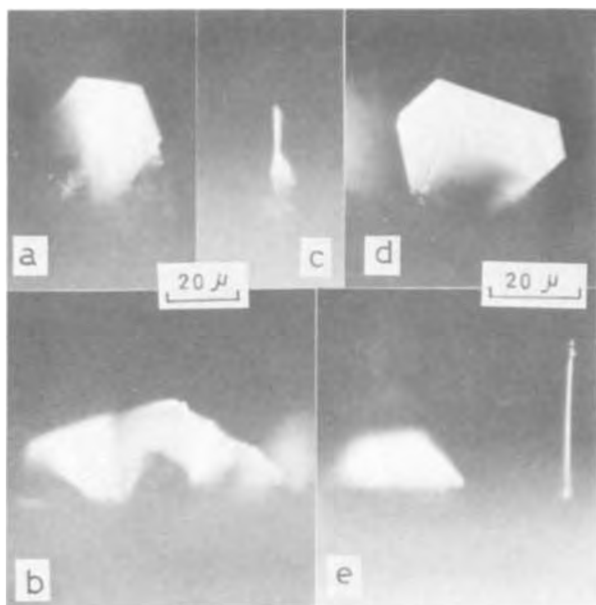

Fig. 3. The nickel-phosphide platelets and the whiskers grown on surfaces of specimens phosphidized at 500°C at (a) 4 Torr for 1 hr, (b) 4 Torr for 8 hr, and (c), (d), and (e) 1 Torr for 8 hr.

of an angle of 120° (Fig. 3a); a platelet possessing several creases (Fig. 3b); a whisker growing on the top of a platelet (Fig. 3c); a stepwise growing platelet (Fig. 3d); and the coexistence of a platelet and a whisker (Fig. 3e). The last three platelets (Fig. 3c, d, e) have grown at different parts of the same specimen.

Cross sections of phosphide-tarnishing layers formed at 400°C (Fig. 4) indicate the formation of thick, continuous phosphide films which appear to be in very close contact with the underlying metal. Long lines of fine pores are visible. In particular, it is of interest

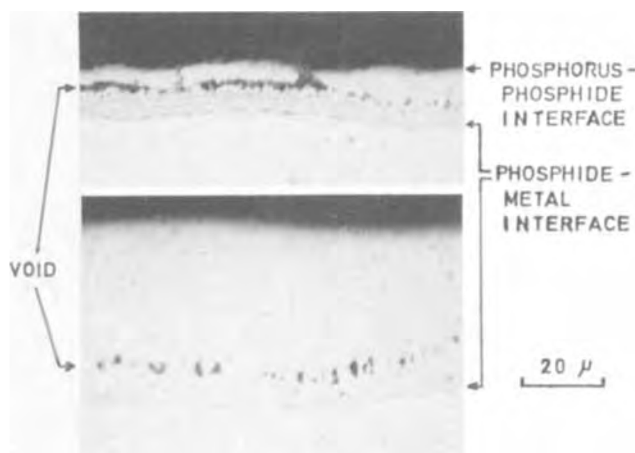

Fig. 4. Cross sections of specimens phosphidized at 400°C in 2 atm phosphorus for 3.5 hr (top) and for 60 hr (bottom).

that the position of voids from the unchanged nickel was not altered significantly throughout the reaction time at 400°C. The formation of voids might be due to the collapse of cation vacancies. Although the cross sections of a series of specimens phosphidized at 400°C were etched with conc nitric acid at room temperature, this treatment did not cause an appearance of a new phase.

Figure 5b shows some phase boundaries on the etching-treatment appearing in the same way, namely, showing an existence of two or three phases. After reaction for 65 hr (Fig. 5c), there is a double line of large elongated voids, parallel to the phosphide/metal interface. This double line was more plainly viewed at lower magnification in a microscope.

In the 500°C reaction, the inner layer (Fig. 6a) corresponds to Ni_2P, and the outer to higher phosphides. The same etching showed that the phases near the

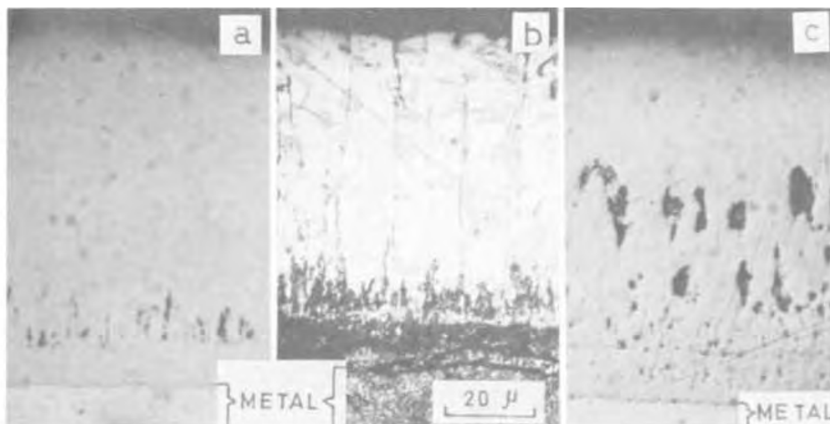

Fig. 5. Transverse sections of specimens phosphidized at 450°C in 2 atm phosphorus for (a) 40 hr, (b) 40 hr, etched with conc HNO_3, and (c) 65 hr.

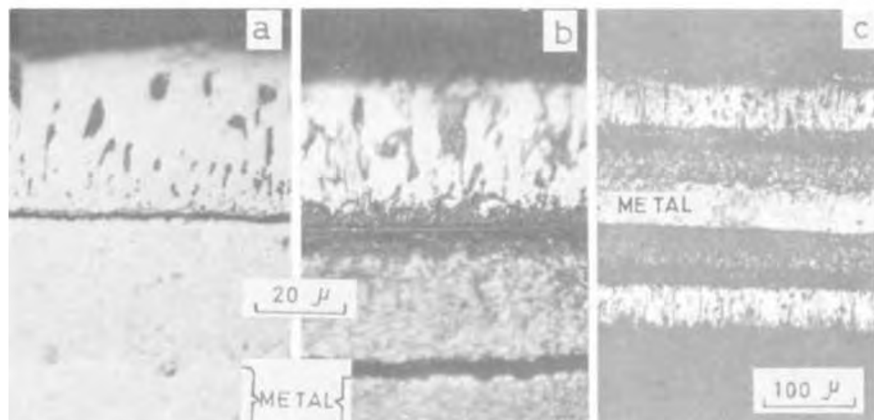

Fig. 6. Transverse sections of specimens phosphidized at 500°C in 2 atm phosphorus for (a) 16 hr, (b) 16 hr, and (c) 40 hr; (b) and (c) etched with conc HNO_3.

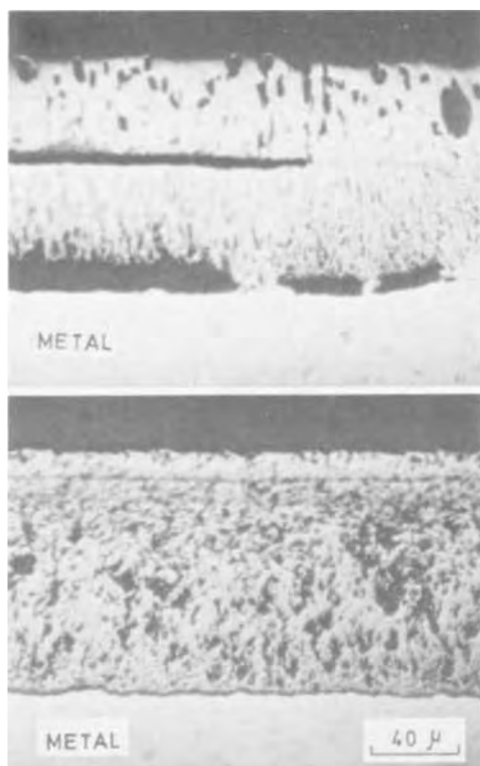

Fig. 7. Transverse sections of specimens phosphidized in 2 atm phosphorus. Upper micrograph, phosphidized at 550°C for 6 hr; lower micrograph, at 600°C for 1 hr.

solid-solid interfaces are corroded much more quickly than bulk phases (Fig. 6b), and that at least three layers exist (Fig. 6c), being consistent with the phosphorus distribution curve obtained by an electron microprobe (4). The transverse sections in the case of lower phosphorus pressures, namely, 1, 4, and 20 Torr at 500°C, were almost similar to those in 2 atm phosphorus at the same temperature.

In the case of the 550°C reaction too (Fig. 7), the outer layer is obviously porous and the inner is comparatively dense. The dark portions near the solid-solid interfaces are a groove which appeared during polishing, probably because of brittle layers. When the layers of Fig. 7 were etched by conc nitric acid, the aspects similar to Fig. 6c were observed.

When the nickel sheets were phosphidized to completion at 500°, 550°, and 600°C, numerous large voids were observed at the centers of their transverse sections.

The phosphidation rates which were determined by the measurement of the change of both the weight and the thickness were parabolic, and the factor governing the reaction appears to be diffusion processes complicated with the generation of a large number of voids and with the growth of various crystals.

Nondestructive Photovoltaic Technique for the Measurement of Resistivity Gradients in Circular Semiconductor Wafers

and L. J. Swartzendruber

Institute for Materials Research, National Bureau of Standards, Washington, D. C. 20234

Resistivity gradients in a semiconductor wafer can adversely affect the characteristics, yield, and reliability of devices fabricated from such a wafer. It is therefore of critical importance to be able to identify and cull out wafers with unacceptably large resistivity gradients. The method (1) commonly used to measure resistivity variations in semiconductor wafers involves six four-probe resistivity measurements: two at the wafer center, and four, 3.2 mm from the edge, 90° apart. Several problems are encountered with this method. Swartzendruber (2) has discussed a basic limitation in the application of the four-probe method to the measurement of resistivity variations due to the relatively large sampling region of the probes. Recently, Vieweg-Gutberlet and Schönhofer (3) have examined this limitation in greater detail and have recommended that to obtain more exact information about the radial resistivity profile along a diameter of a wafer, two-probe measurements should be made on a bar cut along that diameter of the wafer. Another problem is that the off-center correction factor (4) is very sensitive to the location of the probe near the wafer edge. As a result, small uncertainties in the probe placement produce large errors in the apparent resistivity. Another drawback to the standard method is the lack of information about the resistivity variations between the center and the measurement points near the edge of the wafer. Perhaps the most critical difficulty with the four-probe technique results from the placement of the probes on the wafer surface. The damage caused by the probes may of itself be detrimental to the reliability and yield of devices fabricated in the region of the damage.

A practical alternative to the four-probe technique for making resistivity gradient measurements along the diameter of a circular semiconductor wafer is described in this paper. This technique, which is based upon the bulk photovoltaic effect of Tauc (5), requires no contact with the flat surface of the wafer and permits a continuous measurement of the resistivity gradient along the wafer diameter to be made. Oroshnik and Many (6, 7) and Baev and Valyashko

Key words: germanium, inhomogeneities, measurement method, photovoltaic effect, resistivity, semiconductors, silicon.

(8, 9) have described photovoltaic techniques for measuring resistivity variations in bar-shaped germanium specimens and in rectangular germanium wafers. Munakata (10) has described an electron voltaic effect which might also be applied to the measurement of resistivity gradients in semiconductors. Oroshnik and Many (11) have also described a photovoltaic technique for making qualitative resistivity gradient measurements on circular silicon and germanium wafers, but no practical application of the photovoltaic effect to the quantitative measurement of resistivity gradients of circular semiconductor wafers has been attempted.

In this paper, a mathematical expression is derived which relates the resistivity gradient along a wafer diameter to the photovoltage measured at the diameter ends on the rim of the wafer. A measurement technique is described which allows one to determine the radial resistivity profile along a wafer diameter using the derived mathematical relation. Resistivity profiles as determined by the photovoltaic technique are compared with four-probe resistivity profiles made on the same wafer diameter and with two-probe resistivity profiles made on bars cut along that wafer diameter.

Theory

Tauc (5) has derived the underlying physical law of the photovoltaic phenomenon and has discussed its physical aspects. The bulk photovoltaic effect is a physical phenomenon which occurs when electron-hole pairs are photogenerated in a region of an impurity-density gradient. In the region of an impurity-density gradient, or equivalently a resistivity gradient, an internal electric field exists in the semiconductor. This is much like the situation at a p-n junction, only one is concerned here with a much smaller impurity-density gradient and thus a much smaller electric field. When excess electron-hole pairs are generated in this region, they are separated by the internal electric field. The steady-state distribution of the separated carriers is such that the magnitude of the net internal field is reduced. It is the reduction in magnitude of the net internal field which results in the photovoltage which can be measured at contacts made to the specimen. It is possible to relate this measured photovoltage to the resistivity gradient in the region where the excess electron-hole pairs are distributed.

The theory of Tauc (5) is basically a one-dimensional theory, valid for a narrow semiconductor bar. In the measurements which have been performed on bar shaped specimens (6-9), a narrow line of light illuminates the entire width of the bar and the photovoltage is measured at the ends of the bar. The photovoltage which is measured is proportional to the number of excess electron-hole pairs generated as well as the local resistivity gradient. Thus a determination of the number of excess carrier pairs generated is also needed in order to calculate the resistivity gradient. This can be accomplished by measuring the photoinduced change in specimen resistance, ΔR, as measured at the same contacts as the photovoltage, if one knows the relation between ΔR and the photoinduced change in resistivity, $\Delta\rho$, in the region of the excess carrier concentration. The change in resistivity is related to the change in carrier density by the equation

$$\Delta\rho = \rho^2|q|(\mu_n\Delta n + \mu_p\Delta p) \quad [1]$$

where Δn is the excess electron density and Δp the excess hole density. The relation between ΔR and $\Delta\rho$ for the case of a narrow semiconductor bar is trivial, but the development of the relation for the case of a circular wafer is somewhat more involved. An outline of this development appears later in this section. Numerous, not fully controllable, factors such as surface reflectivity and effective carrier lifetime, affect the number of excess carriers generated. Since these may, and probably will, vary as a function of position on the specimen, it has been recognized (6) that it is important to measure ΔR as a function of position along the specimen.

The extension of the photovoltaic technique to the measurement of resistivity gradients along the diameter of circular wafers required that expressions be developed which describe how the circular geometry affects both the measured photovoltage, V, and ΔR. The assumptions made in the derivation are: (*i*) the excess carrier concentration is essentially uniform with depth in a cross section beneath the area illuminated by the light; (*ii*) the excess carrier concentration is always zero at a measurement contact; (*iii*) the excess carrier concentration is always much less than the equilibrium carrier concentration; (*iv*) the resistivity gradient is only radial (that is, along a diameter); (*v*) the light is always several light spot diameters removed from a measurement contact. Except for (*iv*) and (*v*), these assumptions are the same as for the case of bar-shaped specimens. Condition (*iv*) is required so that excess carrier pairs are not separated in a direction perpendicular to the measurement diameter. Such carrier pairs contribute to the measured ΔR but contribute only second order effects to V. Condition (*v*) is required because of the breakdown of geometrical correction factors as the light spot nears the edge of the wafer. Contrary to the case for bars, a current shunting the illuminated region exists in the wafer when the photovoltage is generated. The specimen geometry appropriate for deriving the expressions describing the effect of the circular geometry on V and ΔR is illustrated in Fig. 1. The wafer is illuminated by a circular spot of light located at a point on the X (measurement) axis.

To obtain the desired expressions, the artifact of replacing the charge separation in the region of the light spot by a potential dipole $<U\epsilon>$, is used, where U is the voltage and ϵ the distance between the positive and negative poles. To facilitate the derivation of the relation between $<U\epsilon>$ and the potential difference at the contacts at the wafer rim, a current dipole is placed inside the potential dipole such that the proper potential dipole is obtained. The relation, obtained by the method of conformal transformation, is

$$V = \frac{2<U\epsilon>}{b}\frac{1}{1-(x/b)^2} \quad [2]$$

where b is the wafer radius and x is the light spot position with respect to the wafer center. To obtain

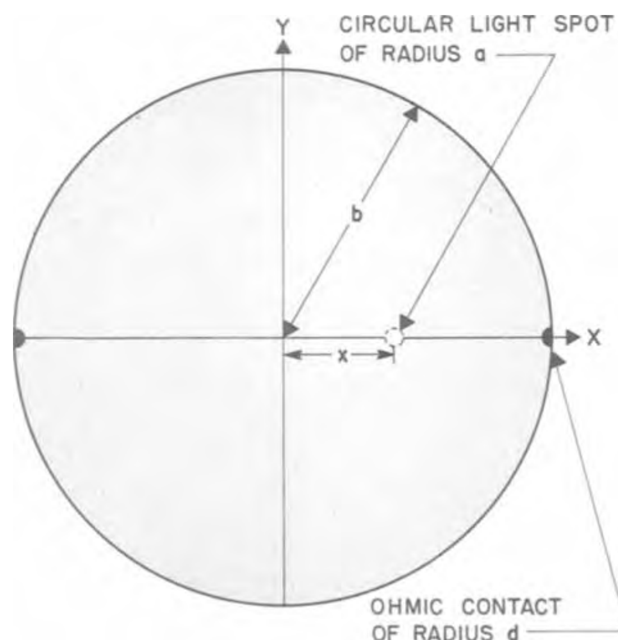

Fig. 1. The specimen geometry for which Eq. [9] applies

the appropriate dipole strength, the expression given by Tauc (5) for the photovoltage measured at the ends of a narrow bar when illuminated by a narrow line of light is used

$$U = \frac{2kT}{q} \frac{1}{(1 + \mu_M/\mu_m)} \frac{d\rho}{dx} L_o \Delta\sigma \quad [3]$$

where L_o is the length of the illuminated segment. For $\Delta\sigma << \sigma_o$, this can be written

$$U = -\frac{2kT}{q} \frac{1}{(1 + \mu_M/\mu_m)} \frac{1}{\rho} \frac{d\rho}{dx} \frac{\Delta\rho}{\rho} L_o \quad [4]$$

where ρ is the resistivity at the region illuminated. To simplify the measurement, ρ is replaced by $\bar{\rho}$, the average specimen resistivity, in this expression. Using Eq. [4] and appropriately averaging over a circle of radius a, the average voltage dipole strength for a circular spot of radius a becomes

$$<U_\epsilon> = -\frac{4kT}{3q} \frac{1}{(1 + \mu_M/\mu_m)} \frac{1}{\bar{\rho}} \frac{d\rho}{dx} \frac{\Delta\rho}{\bar{\rho}} a^2 \quad [5]$$

Included is a factor of ½ to account for the potential drop within the illuminated region which is a result of the current generated by the shunting of the separated charge by the surrounding material. The factor of ½ is an approximation based upon the fact that, for a circular spot on an infinite sheet, the resistance of the spot as measured at points at the ends of a diameter of the spot assuming the remainder of the infinite sheet removed, is equal to the resistance of the infinite sheet as measured at the same two points with the spot removed.

For contacts as shown in Fig. 1, the resistance of the wafer is

$$R_O = \frac{2\bar{\rho}}{\pi t} \ln\left(\frac{2 - d/b}{d/b}\right) \quad [6]$$

where d is the radius of the contact, $\bar{\rho}$ is the average specimen resistivity, t is the thickness of the wafer, and the contacts are assumed to be ohmic. The perturbation in R_O caused by a spot of radius a and resistivity $\rho + \Delta\rho$ can be calculated if it is assumed that $a << b$ and $d << b$. The contacts are replaced by current sources of values $+2I$ and $-2I$ and it is assumed the spot lies on an infinite sheet. This yields a problem which can be solved analytically by conformal transformation to yield

$$\frac{\Delta R}{R_O} = \frac{\Delta\rho}{\bar{\rho}} \frac{(a/b)^2}{\ln\left[\frac{2 - (d/b)}{d/b}\right]} \frac{1}{[1 - (x/b)^2]^2} \quad [7]$$

To eliminate the need to know d, Eq. [6] and [7] can be combined to give

$$\Delta\rho a^2 = \Delta R b^2 \frac{\pi t}{2} \left[1 - \left(\frac{x}{b}\right)^2\right]^2 \quad [8]$$

Equations [2], [5], and [8] can be combined to give the relationship of the resistivity gradient at the light spot to V and ΔR.

$$\frac{d\rho}{dx} = -\frac{3q}{4\pi kT} \frac{\left(1 + \frac{\mu_M}{\mu_m}\right)}{1 - (x/b)^2} \frac{\bar{\rho}^2}{bt} \frac{V(x)}{\Delta R(x)} \quad [9]$$

Apparatus

The electrical circuit used to make measurements of the photovoltage and photoinduced change in specimen resistance is shown in Fig. 2. The lock-in amplifier was used because the magnitudes of the photovoltaic signals were generally 1 μV or less. The rate at which the light is chopped must be adjusted so that the on-time of the light is long enough to achieve a steady-state excess carrier distribution. The X-Y recorder produces continuous plots of the photovoltage or photoconductivity as a function of position along the wafer diameter.

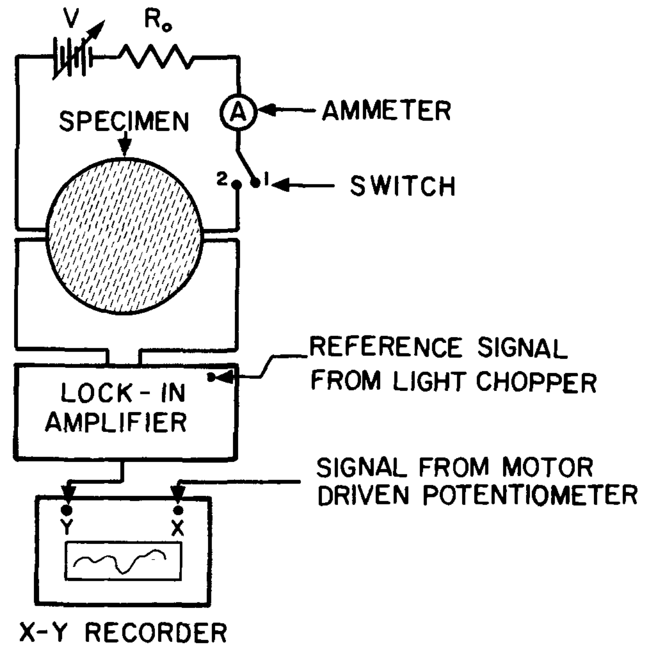

Fig. 2. Schematic of electrical circuitry used to measure the photovoltage and photoinduced change in specimen resistance. With the switch in position 1, the photovoltage can be measured; in position 2, the photoinduced change in specimen resistance can be measured.

The light source was a tungsten filament lamp. The light was concentrated on a circular aperture of variable diameter which was focused by a lens-mirror system onto the wafer surface to form the light spot.

The specimen holder used in this study is shown in Fig. 3. There are four sets of double knife-edge contact elements. The four contact elements permit the measurement of the average wafer resistivity, $\bar{\rho}$, by the van der Pauw technique (12, 13). It is this value

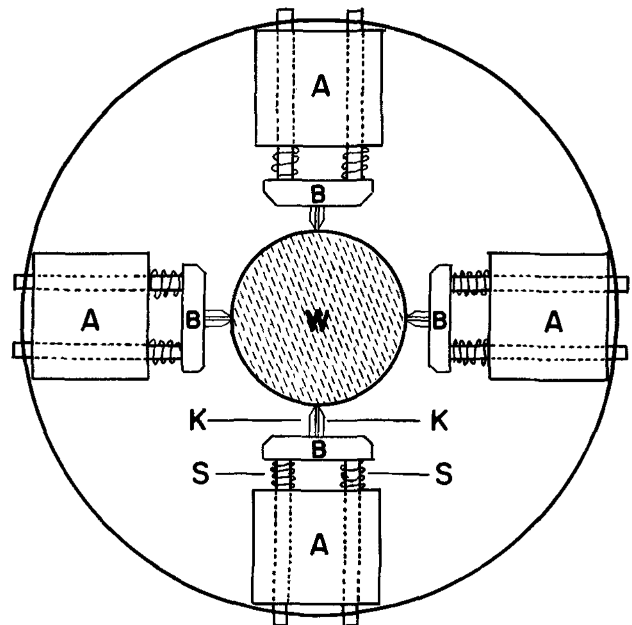

Fig. 3. Schematic illustration of specimen holder, where W is the wafer and K the knife edge. The springs, S, allow a variable knife-edge contact pressure to be applied. The knife-edge holders, B, are insulated from the knife edges. A is a moveable carriage to accommodate various wafer sizes and to allow knife-edge pressure adjustments.

of average specimen resistivity which is used in the evaluation of Eq. [9]. When the photovoltage or photoinduced change in specimen resistance is being measured, only the two contact elements at the ends of the measurement diameter are in contact with the wafer; the other two are retracted. When the photovoltage is measured, only one knife-edge at each contact element is used. When the change in specimen resistance is measured, both knife-edges at the contact element are used, one to carry the current, the other to measure the small, photoinduced change in potential across the specimen. This eliminates the problems associated with trying to measure a small change in potential with a nonohmic, current-carrying contact.

Results and Discussion

Both n- and p-type silicon and germanium wafers were measured in this study. The average resistivities ranged from about 1 ohm-cm to over 5000 ohm-cm. Most of the measurements were made on wafer surfaces lapped with 5 μm alumina abrasive. Preliminary measurements indicate that photovoltaic measurements made on chemically-mechanically polished surfaces differ little from measurements made on lapped surfaces.

To use Eq. [9] to determine the resistivity at points along the measurement diameter, an integration is required. In practice, values for $V(x)$ and $\Delta R(x)$ are determined for small segments of equal but arbitrary length for the entire diameter and a summation is performed. An absolute determination of $\rho(x)$ is not obtained, but the value obtained differs from $\rho(x)$ by the constant of integration, ρ_0, the value of the resistivity at the point on the diameter where the summation begins. The photovoltaic profiles in the figures have been adjusted to give a best fit to the two-probe or four-probe profiles, since, for this study, it was important to establish how well the photovoltaic technique was able to determine resistivity variations. Since one also measures $\bar{\rho}$, the average specimen resistivity, a good indication of the range of absolute resistivity values is obtained.

A comparison of a photovoltaic and four-probe resistivity profile made along a diameter of a 1 ohm-cm, n-type silicon wafer is shown in Fig. 4.

It has been found that, in general, the agreement between the photovoltaic profiles and the four-probe and two-probe profiles has been very good in the central region but deteriorates somewhat beyond approximately one-half the radius. The deterioration in agreement can partially be explained by the presence of nonohmic measurement contacts. Since the metal knife-edges are simply making a pressure contact with the wafer rim, the contact is not ohmic. Carriers which are photogenerated and which can diffuse to the metal-semiconductor contact without recombining, in violation of assumption (*ii*), generate a barrier photovoltage which is superposed on the bulk photovoltage. This does not appear to affect the photovoltaic measurement until the light probe is within a few carrier diffusion lengths of the contact if the wafer rim has been abraded or if the wafer has been cut from a centerless ground crystal.

An indication of the effect of varying the ohmic quality of a measurement contact can be seen in Fig. 5. The apparent increase in resistivity as measured by the photovoltaic method on an as-grown rim, as one approaches the edge of the wafer, results from diffusion of carriers to this highly nonohmic contact. When the rim is abraded, the contact becomes more ohmic and the photovoltaic and four-probe profile are in much better agreement. The nonohmic nature of the contacts was determined by measuring the specimen resistance between the contacts and comparing the magnitude for current in both directions between the contacts. A large difference in measured resistance for the two directions of current with the as-grown rim indicated that one of the contacts was much less ohmic than the other. This is also indicated by the asymmetry of the photovoltaic profile for the as-grown case in Fig. 5.

Three different resistivity profiles for the same wafer diameter are shown in Fig. 6. A four-probe profile and a photovoltaic profile were made on the circular wafer and a two-probe profile was made on a bar cut from the measurement diameter of the wafer. As mentioned previously, it has been recommended that to obtain more exact information about the resistivity gradient of a semiconductor wafer, particularly when steep gradients are present, a two-probe resistivity profile should be made in place of a four-probe profile (3). Note the agreement of the photovoltaic profile with the two-probe profile at the wafer center compared to the agreement between the four-probe and two-probe profiles at the center. It is not uncommon for the four-probe measurement to underestimate the depth of the valley in the resistivity profile at the wafer center when a steep gradient is present, as in Fig. 6. This is due primarily to the large area over which the four-probe measurement averages the resistivity. It is obvious that in this particular instance the resolution of the photovoltaic technique is superior to that of the four-probe technique.

Another difficulty encountered with making four-probe measurements is the sensitivity of the measure-

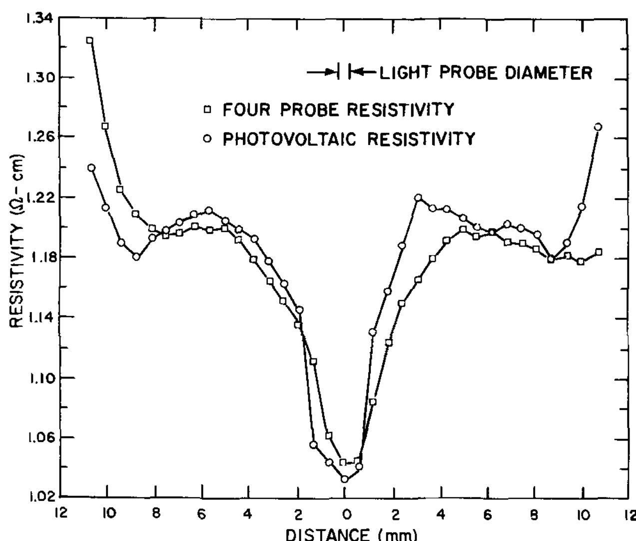

Fig. 4. Photovoltaic and four-probe resistivity profiles made along the diameter of an n-type silicon wafer.

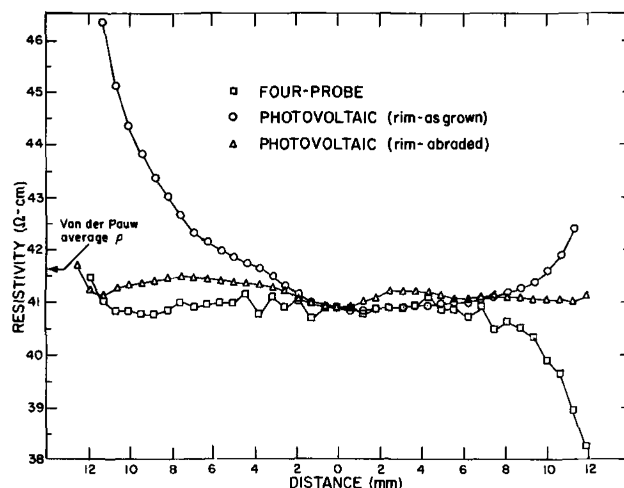

Fig. 5. Photovoltaic and four-probe resistivity profiles made along the diameter of a p-type silicon wafer. The effect of the nonohmic nature of the measurement contact on the photovoltaic profile is shown.

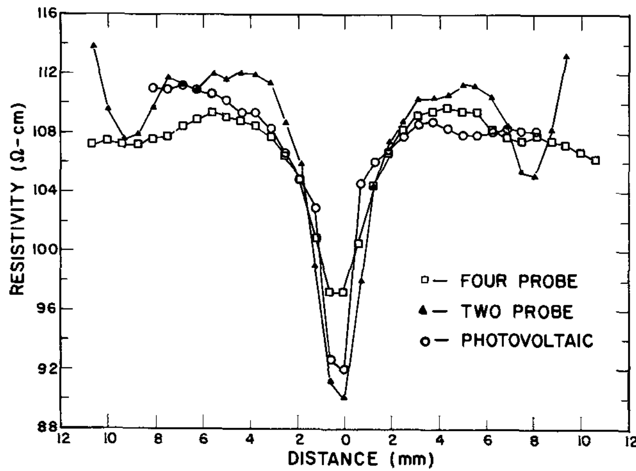

Fig. 6. Photovoltaic, four-probe, and two-probe resistivity profiles made along the same diameter of an n-type silicon wafer. The photovoltaic and four-probe profiles were made on the circular wafer while the two-probe profile was made on a bar cut from along the measurement diameter.

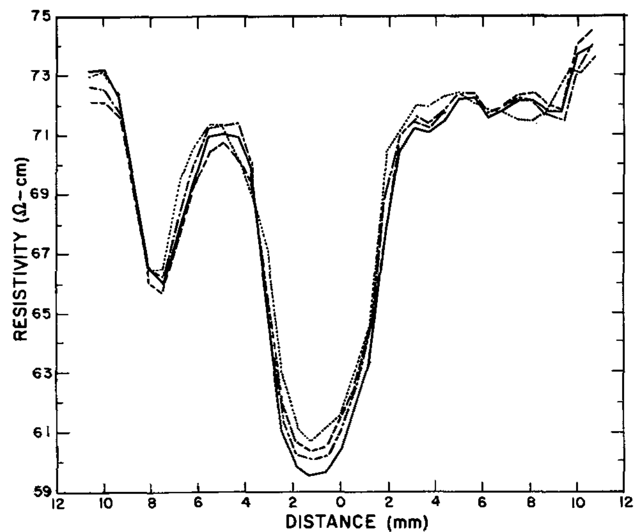

Fig. 8. Four independent photovoltaic resistivity profiles made along the same diameter of an n-type silicon wafer.

ment near the wafer edge to the placement of the probes. A small error in probe placement may result in a large error in the measured resistivity. This effect can be seen in Fig. 7 where the original four-probe profile was made with an error in the placement of the probes of approximately 0.3 mm. The photovoltaic measurement is relatively insensitive to slight errors in the location of the moving light spot. An error of 0.3 mm in light spot location would be barely detectable for the profile seen in Fig. 7.

In order to obtain an indication of the reproducibility of the photovoltaic technique, four independent photovoltaic resistivity profiles were made along the diameter of an n-type 65 ohm-cm silicon wafer. The results of these measurements can be seen in Fig. 8. The maximum difference at any point between any of the four profiles is less than 2% of the average specimen resistivity. Since the wafer had a large nonradial resistivity gradient along the chosen measurement diameter, and since the apparent resistivity profile of the wafer varied considerably as the measurement diameter was changed slightly, the reproducibility is considered to be indicative of that which could be obtained under less than ideal conditions.

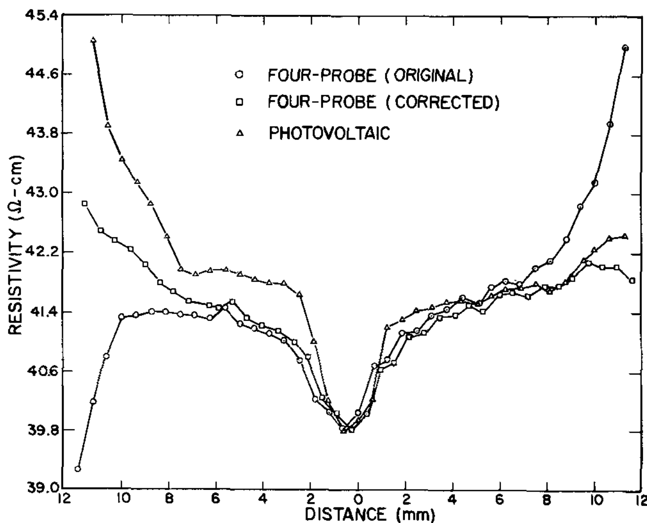

Fig. 7. Photovoltaic and four-probe resistivity profiles made along the diameter of a p-type silicon wafer. The effect on the four-probe resistivity measurement of a slight misplacement of the probes near a wafer edge is shown.

Since the magnitude of the photovoltage is proportional to the resistivity gradient, generally the higher the material resistivity the larger the photovoltage. For example, the magnitude of a 1% gradient in 10 ohm-cm material is 10 times the magnitude of a 1% gradient in 1 ohm-cm material. It is this fact which has not made it possible with the apparatus and technique described to measure resistivity gradients in material of resistivity less than 1 ohm-cm. Experiments indicate that the resistivity gradients of specimens with resistivities of less than 0.1 ohm-cm may be measured using the same measurement technique with a 25 mW He-Ne laser in place of the tungsten filament light source.

Conclusion

The theoretical and experimental basis has been provided for a quantitative, nondestructive measurement of the resistivity variations along the diameter of a circular semiconductor wafer. The measurement technique requires little or no special specimen preparation and requires contact only with the rim of the wafer.

It has been shown that resistivity variations in the central portion of a wafer as determined by the photovoltaic technique generally agree very well with those determined by the two-probe technique and with those determined by the four-probe technique when steep resistivity gradients are not present. When steep gradients exist in the central portion, it has been found that the photovoltaic resistivity profiles agree better with the two-probe profiles than the four-probe profiles do, indicating that the spatial resolution of the photovoltaic technique in these instances is superior to that of the four-probe technique. The ability of the photovoltaic technique for making resistivity gradient measurements within a few carrier diffusion lengths of a contact is limited by the nonohmic nature of the measurement contacts used.

The relative insensitivity of the photovoltaic measurement to light-spot location is contrasted with the extreme sensitivity of the four-probe technique near the edge of a wafer to the placement of the probes. The photovoltaic measurement has been found to be repeatable to within a few per cent of the average specimen resistivity, even under less than ideal conditions.

Acknowledgments

The authors thank Mr. M. Cosman for the preparation of the specimens, Mr. A. W. Stallings and Mr. G. P. Spurlock for construction of much of the apparatus, Dr. W. M. Bullis for his many helpful suggestions, and Mr. J. C. French and Dr. A. H. Sher for reviewing the manuscript.

This work was conducted as part of the Joint Program on Methods of Measurement for Semiconductor Materials, Process Control, and Devices at the National Bureau of Standards. Portions of this work were supported by the Defense Nuclear Agency and the National Bureau of Standards.

Manuscript received April 13, 1972.

An Improved Polishing Technique for GaAs

V. L. Rideout

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Certain electronic device applications that involve single-crystal GaAs are critically dependent on the substrate condition, *i.e.*, surface finish and flatness. In particular, the surface flatness of GaAs wafers is important in the fabrication of: (*i*) ultrathin epitaxial-layer devices such as semiconductor superlattices (1) or multilayered acoustic transducers; (*ii*) surface-wave acoustic devices using electron-beam exposure; and (*iii*) microwave-integrated circuits, metal-semiconductor field-effect transistors, and other device structures that involve photolithographic processing.

Since its development by Reisman and Rohr (2, 3), the NaOCl chemical-polishing technique has become a popular technique in the semiconductor industry for obtaining smooth mirror-finish surfaces on GaAs. Recently, another chemical polishing technique using H_2O_2 and NH_4OH has been developed by Dyment and Rozgonyi (4). All of these researchers, however, employed the same mechanical means to distribute the chemical etchant over the wafer surfaces, and we find that this can introduce certain undesirable effects.

The procedure employed until now is that the wafers to be polished are affixed to a disk which is allowed to rotate freely about a fixed point near the edge of a polishing plate which is covered by a polishing cloth. The rotation of the wafer-disk assembly is caused by the friction between the wafers and the liquid layer between the wafers and the polishing cloth (3). During rotation the etchant distributes itself over the wafer surfaces. Pressure on the wafers is provided by the weight of the wafer-disk assembly alone. In using this procedure we observed that the wafer-disk assembly often rotated nonuniformly which invariably resulted in poor quality surfaces. Initially the etchant was applied periodically at 1 min intervals. During this interval the liquid is dispersed by the polishing action and hence the coefficient of friction varies during the time period. Thus we assumed that conversion to a more uniform feed rate would solve the problem; however, nonuniform rotation still often occurred, particularly when square-shaped or large-area samples were used. Increasing the weight of the disk led to more uniform rotation, but then edge rounding was greatly enhanced. To circumvent the problem we used an electric motor to drive the wafer-disk assembly at a constant rotational speed in the natural direction of free rotation. Subsequently it was found that if the wafer-disk assembly was motor driven at a speed slightly higher than the natural speed of rotation due to friction alone, then edge rounding of the polished wafers was significantly decreased, and surface flatness enhanced.

Experimental conditions for a typical polishing operation are as follows. The samples are affixed to a 4 in. diameter ¼ in. thick glass disk (weight, 140g) with wax, and lapped using 6μ garnet powder in a water slurry. About 3-4 mils of material are removed. After careful rinsing and washing with a mild soap solution to remove particles, the disk is placed on a 12 in. diameter polishing plate. The center of the disk is positioned 3 in. from the center of the plate. Motor speed of the plate is 60 rpm while that of the disk is 30 rpm (the free rotational speed of the disk is about 20 rpm). The disk motor is constrained by a stop that prevents any downward force from being applied to

Key words: GaAs, chemical polishing, surface flatness, NaOCl.

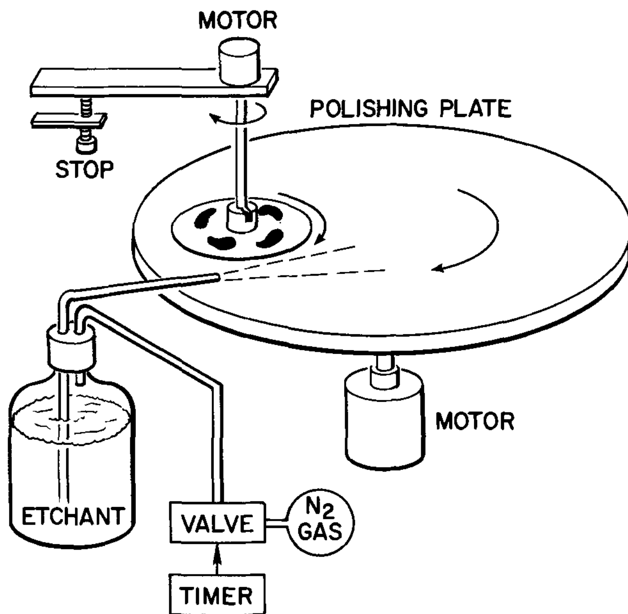

Fig. 1. Chemical polishing apparatus

the disk (see Fig. 1). The Politex PS Supreme polishing cloth (Geoscience Instruments Corporation) was found to be superior to the Pellon PAN-W for our applications. The etchant solution is 20:1 H_2O:NaOCl (Fisher reagent grade) and is replenished every hour. The feed rate is 4 ml of solution every 30 sec and the total polishing time is approximately 3 hr during which time about 1 mil of material is removed.

Both Cr-doped (semi-insulating) and Te-doped (4×10^{17} cm^{-3} n-type) single-crystal <100>, <111>A, and <111>B GaAs surfaces have been successfully polished with our apparatus. Measurements with a Talysurf instrument showed a surface flatness of better than ± 500Å over 250 mils of surface. Dyment and Rozgonyi (4) achieved flatnesses of approximately 10,000Å over a linear dimension of 1 cm, however, they made no attempts to optimize the over-all flatness of their wafers. To explain the improved surface flatness with our technique we propose that since the NaOCl polishing process is primarily chemical rather than mechanical, the primary purpose of mechanical motion is to distribute the etchant as uniformly as possible over the wafer surface. Thus mechanically driving the wafer-disk assembly in its natural direction of free rotation, but at a speed somewhat higher than its natural speed of free rotation, results in a more even exposure of the wafer surfaces to the etchant, and hence achieves flatter surfaces.

The Variation of the Solid Composition During the LPE Growth of $Ga_{1-x}Al_xAs$

W. G. Rado and R. L. Crawley

Ford Motor Company, Scientific Research Staff, Dearborn, Michigan 48121

The phase diagram of the Ga-Al-As ternary system has been calculated and explored experimentally by Ilegems and Pearson (1) and Panish and Sumski (2). Recently additional experimental data were presented by Alferov *et al.* (3) and by Rado, Johnson, and Crawley (4) on the variation of the AlAs concentration in LPE-grown $Ga_{1-x}Al_xAs$ with the Al concentration in the Ga-rich growth solution, as a function of growth temperature. Although these data were in moderately good agreement with the calculated isotherms, deviations as high as 30% in the solid composition were found for solution compositions in the 0.003-0.006 atom fraction Al range for growth temperatures between 800° and 950°C. The purpose of this note is to present experimental data on the variation of the solid $Ga_{1-x}Al_xAs$ composition with temperature during LPE growth runs.

The LPE growth apparatus and the technique for determining the relationship between layer thickness and instantaneous growth temperature have been described previously (5). Briefly, after the initial contact between a Ga-Al-As solution and a GaAs substrate was established, at each of two lower temperatures the solution was pushed off ¼ of the substrate, terminating growth on that part, so that a three-step growth profile was obtained. The temperature interval between successive pushes ranged from 20°-70°C.

Key words: solution growth, ternary systems, phase diagrams, III-IV alloys, LED.

Each grown layer was analyzed by slicing the wafer parallel to the push direction, lapping, polishing, and finally staining with 8 $K_3Fe(CN)_6$: 12 KOH: 100 H_2O by weight to reveal the substrate-layer interface. The thicknesses of the growth steps were measured from photomicrographs and by using the "push" temperatures a correlation between thickness and temperature was established.

The alloy composition was determined by electron-microprobe analysis. Measurements were made along the direction of growth in 2-20 μm steps. The error in these measurements was estimated to be ±2%. The variation of the solid $Ga_{1-x}Al_xAs$ composition with the grown layer thickness was converted to a variation with temperature by using the correlation between thickness and temperature established for the same layer earlier. The data for 8 runs are shown in Fig. 1. For comparison, curves calculated by Ilegems and Pearson (1) are also included. The growth parameters of the individual runs are given in Table I.

The values of the initial AlAs concentration in the LPE-grown solid next to the GaAs substrate, given in Table I, are in good agreement with previous experimental observations (4) except for run 4, which has a value slightly higher than expected.

The experimentally determined variations of the solid composition with instantaneous growth temperature plotted in Fig. 1 are in very good agreement with the corresponding calculations of Ilegems and Pear-

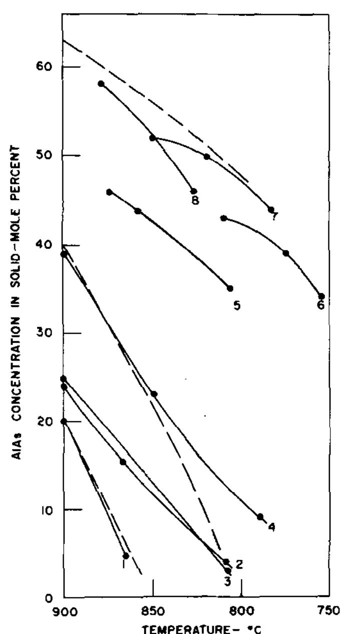

Fig. 1. The measured temperature variation of the solid $Ga_{1-x}Al_xAs$ composition during growth from a Ga-Al-As solution (solid lines). The numbers correspond to the run numbers in Table I. The dashed lines are curves calculated by Ilegems and Pearson (1).

son (1). Therefore, although the solid-liquid equilibrium concentrations calculated by Ilegems and Pearson (1) for specific temperatures deviate somewhat from experimental observations (3, 4), once an initial composition of the solid is determined, the variation of the solid's composition with temperature during a growth run can be predicted reliably by using the calculations of Ilegems and Pearson (1).

Calculation of the Solubility and Solid-Gas Distribution Coefficient of N in GaP

G. B. Stringfellow

Hewlett-Packard Company, Palo Alto, California 94304

Several investigators have found that the presence of N in GaP increases the efficiency of green electroluminescent diodes (1-4). Logan *et al.* (4) found that N could be incorporated into GaP during liquid-phase epitaxial (LPE) growth at 1000°-1100°C by using a mixture of NH_3 and H_2 at atmospheric pressure as the N source. The following is a list of phenomena observed by Logan *et al.* (4), Lorimer and Dawson (5), and Thurmond and Logan (6): (*i*) The N concentration in GaP increased linearly with NH_3 partial pressure (P_{NH3}) up to a concentration[1] of $\sim 2.5 \times 10^{18}$ cm^{-3} at $P_{NH3} = 10^{-3}$ atm; (*ii*) The efficiency of LED's fabricated in this material increased monotonically with P_{NH3} below 10^{-3} atm; (*iii*) With $P_{NH3} > 10^{-3}$ atm the crystal growth became disturbed and the efficiency of LED's began to decrease with increasing NH_3 partial pressure; (*iv*) Lorimer and Dawson found that at 1000°C increasing P_{NH3} above 10^{-3} atm produced no increase in the N content of the GaP and caused GaN precipitation in the liquid.

Key words: GaP-GaN system, thermodynamics, phase diagrams, solution theory, solidus calculation.

[1] The N concentrations reported by Logan *et al.* (4) were obtained from measured optical absorption coefficients by using a proportionality constant which Lightowlers (7) found to be too high by a factor of four. Therefore, their reported concentrations have been divided by four before being used in this paper.

From this information it is clear that the solid solubility of N in GaP and the solid-gas distribution coefficient, defined as the ratio of the GaN content in GaP to P_{NH3}, are important parameters in determining the crystal-growth conditions for GaP:N to be used for the fabrication of green LED's. The purpose of the present paper is to calculate the temperature dependence of these parameters by using the Phillips-Van Vechten model (8, 9) for the solid-pseudobinary alloy $GaP_{1-x}N_x$.

The reaction for incorporation of N during LPE growth of GaP may be written

$$NH_3(g) + Ga(l) = GaN(s) + 3/2\, H_2(g) \quad [1]$$

The standard Gibbs free energy of reaction is given by

$$\Delta G^\circ = -RT \ln \left[\frac{a_{GaN}{}^{(s)} \, (a_{H_2}{}^{(g)})^{3/2}}{a_{NH_3}{}^{(g)} \, a_{Ga}{}^{(l)}} \right] \quad [2]$$

where $a_i{}^{(j)}$ is the activity of component i in phase *j*. ΔG° may be obtained by considering the reaction to be the sum of two reactions

$$NH_3(g) = 3/2\, H_2(g) + 1/2\, N_2(g); \Delta G^\circ_1 \quad [3]$$

and

$$1/2\,N_2(g) + Ga(l) = GaN(s); \Delta G^\circ_2 \quad [4]$$

Both ΔG°_1(10) and ΔG°_2(6) have been determined as functions of temperature and thus $\Delta G^\circ = \Delta G^\circ_1 + \Delta G^\circ_2$ can be evaluated.

Two approximations can be made to simplify the calculation: (*i*) At temperatures below 1100°C $X_{Ga}^{(l)} \sim 1$, thus $a_{Ga}^{l} \sim 1$; (*ii*) For the conditions of interest $P_{NH_3} << P_{H_2}$, giving $a_{H_2} \approx 1$ and $a_{NH_3} \approx P_{NH_3}$.

The only other parameter needed to calculate the solid-gas distribution coefficient from Eq. [2] is $a_{GaN}^{(s)}$ which is equal to $x\gamma_{GaN}$, where x is the mole fraction of GaN and γ_{GaN} is the activity coefficient of GaN in the solid. The activity coefficient may be written

$$\gamma_{GaN} = \exp\,(\overline{G}_{GaN}^{xs}/RT) \quad [5]$$

where $\overline{G}_{GaN}^{xs}$ is the partial molar excess free energy of GaN in GaP. The excess free energy of the solid solution is

$$G^{xs} = \Delta H^M - T\Delta S^{M,xs} \quad [6]$$

where ΔH^M is the enthalpy of mixing and $\Delta S^{M,xs}$ is the excess entropy of mixing. For the GaP-GaN system where the solubility limit of GaN in GaP is small, indicating a very large positive ΔH^M, $\Delta H^M >> T\Delta S^{M,xs}$ and

$$\overline{G}_{GaN}^{xs} \equiv \left.\frac{\partial\,(N_o\,\Delta H^M)}{\partial\,N_{GaN}}\right|_{N_{GaN}=0} = \left.\frac{d\Delta H^M}{dx}\right|_{x=0} \quad [7]$$

which is the partial molar enthalpy of mixing at infinite dilution, denoted $\overline{H}^*_{GaN}$. N_o in Eq. [7] is the total moles of GaP and GaN. From Eq. [5] and [7], $a_{GaN}^{(s)} = x \exp\,(\overline{H}^*_{GaN}/RT)$.

Substituting the values of ΔG° and the 4 activities into Eq. [2] gives the following expression for the solid-gas distribution coefficient

$$x/P_{NH_3} = \exp\,[-(\Delta G^\circ_1 + \Delta G^\circ_2 + \overline{H}^*_{GaN})/RT] \quad [8]$$

The procedure for the calculation of $\overline{H}^*_{GaN}$ is a modification of a method developed in detail previously (11). It consists of using the Phillips-Van Vechten model (8, 9) to calculate ΔH°_f, the standard enthalpy of formation of the alloy, as a function of alloy composition. This is used to determine the dependence of ΔH on x, from which $\overline{H}^*_{GaN}$ may be obtained.

The Phillips-Van Vechten expression for the enthalpy of formation of the pure compounds and their pseudobinary alloys is

$$\Delta H^\circ_f = \Delta H_o a_o^{-3} f_i P \quad [9]$$

where ΔH_o is a scaling parameter equal to 1.24×10^4 Å^3-kcal/mole, and a_o and f_i are the lattice parameter and fraction of ionic character, both of which are taken as linear in composition. P is the dehybridization factor, which is related to the direct valence to-conduction-bandgaps E_o, E_1, and E_2 by the expression

$$P = 1 - [0.432\,E_2/(E_o + E_1)]^2 \quad [10]$$

For the $GaP_{1-x}N_x$ alloys the variation of each energy gap with composition is assumed to be parabolic

$$E_j = E_{GaP,j}\,(1-x) + E_{GaN,j}x - c_jx(1-x) \quad [11]$$

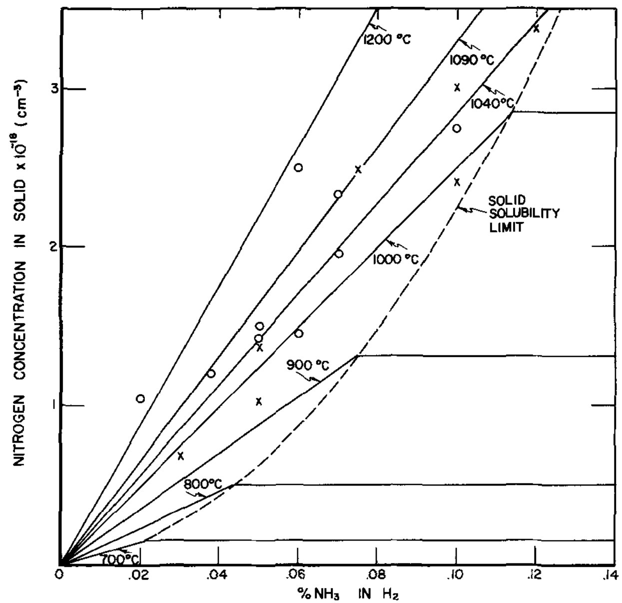

Fig. 1. Nitrogen concentration in GaP vs. P_{NH_3} at various temperatures. The experimental points are based on the data of Logan et al. (4) at 1090°C (○) and 1040°C (×). The solid lines were calculated as described in the text.

with j = 0, 1, 2. The values of E_o, E_1, and E_2 have been measured for GaP (12, 8). GaN has the wurtzite lattice, but the bandgaps as well as a_o can be calculated for a hypothetical zincblende GaN as explained in (8, 13). The bowing parameter, c_j, may also be calculated as described in (13). It is the sum of two components

$$c_j = c_{i,j} + c_e \quad [12]$$

where $c_{i,j}$ is the intrinsic component due to the nonlinear dependence of E_j on crystal potential, which is linear in x, and c_e is the extrinsic component due to the electronegativity difference between N and P (13)

$$c_e = (C_{NP})^2 = [1.5e\,Z(1/r_N - 1/r_P)\,e^{-k_sR}]^2 \quad [13]$$

Due to the large difference in the radii of N and P, $c_e = 21.9$ eV.

The compositional dependence of ΔH^M can now be calculated by using the relation

$$\Delta H^M = (1-x)\,\Delta H^\circ_{f,GaP} + x\Delta H^\circ_{f,GaN} - \Delta H^\circ_f \quad [14]$$

where $\Delta H^\circ_{f,GaP}$, $\Delta H^\circ_{f,GaN}$, and ΔH°_f for the alloy are calculated using Eq. [9-11] and the parameters listed in Table I.[2] From the calculated ΔH^M vs. x, $\overline{H}^*_{GaN}$ was determined from Eq. [7] to be 23 kcal/mole.

The concentration of N in GaP vs. P_{NH_3} at various temperatures can now be calculated with no adjustable parameters by using Eq. [8]. The results, which are plotted as solid lines in Fig. 1, are in excellent agreement with experimental points at 1090° and 1040°C based on the data of Logan et al. (4). It should

[2] The value of ΔH°_f, GaN calculated using the Phillips-Van Vechten model is 52 kcal/mole. This is much higher than the experimental value of 26.4 kcal/mole (6) because of the strong N-N triple bond in the gas phase, which tends to make the GaN less stable relative to Ga liquid plus N_2 gas. Since we are concerned only with bonding in the solid, this discrepancy has no effect on our calculation.

Table I. Parameters used in the calculation of $\overline{H}^*_{GaN}$

Compound	f_i	a_o (A)	E_o (eV)	E_1 (eV)	E_2 (eV)	$c_{i,0}$ (eV)	$C_{i,1}$ (eV)	$c_{i,2}$ (eV)
GaP	0.330	5.45	2.77	3.73	5.27			
GaN	0.500	4.49	2.95[a]	6.16[a]	10.38[a]			
GaN-GaP						−1.6	−0.6	0.7

[a] Calculated by the procedure described in Ref. (8) using D_{av}. As discussed in footnote 2 of this paper, D_{av} gives better agreement with experiment than the refined value of D. Thus the values do not agree with those quoted in Table VII of Ref. (18).

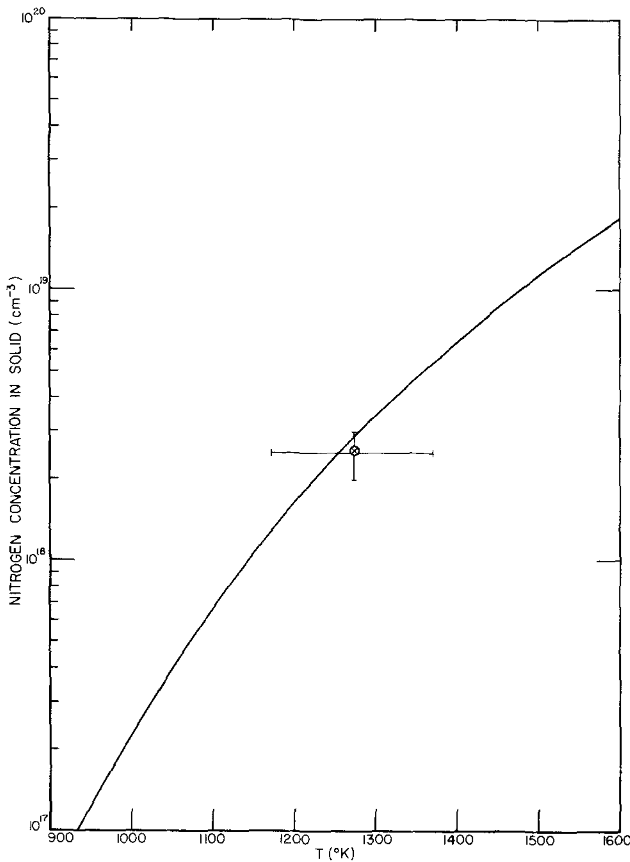

Fig. 2. Solid solubility of N in GaP vs. T. The solid line was calculated as described in the text. The data are taken from Logan et al. (4) (⊢┼⊣) and Lorimer and Dawson (5, 6) (⊗).

be mentioned that a comparison of their results with our calculated results assumes their NH_3 pressures to be equilibrium pressures, which would be the case if the NH_3 did not decompose. Thurmond and Logan (6) report negligible decomposition if the NH_3 contacts only clean fused SiO_2 and graphite while it is at high temperatures. However, they found that devitrified SiO_2 furnace tubes catalyzed the decomposition of NH_3. In that case the NH_3 pressure required to produce a given N concentration in the solid would be larger.

Also included in Fig. 1 is the solubility limit of N in GaP, which makes the N concentration independent of P_{NH_3} above a given pressure at each temperature. At the solubility limit, N-saturated GaP is in equilibrium with P-saturated GaN. The solubility limit was calculated by equating the chemical potential of GaN in the two solid phases

$$\mu_{GaN}^{(I)} = \mu_{GaN}^{(II)} \quad [15]$$

where the superscripts I and II represent the GaP- and GaN-rich solid phases respectively. Since the standard state is the same for both phases and $\mu = \mu_o + RT \ln a$

$$x\gamma_{GaN} = a_{GaN}^{(II)} \cong 1 \quad [16]$$

assuming that the GaN-rich phase is nearly pure GaN. Thus the temperature dependence of the solid solubility of GaN in GaP may be written

$$x = \exp(-\overline{H}^{*}_{GaN}/RT) \quad [17]$$

Figure 2 is a plot of calculated N solubility *vs.* *T*. It includes estimates of the solid solubility at 1000°C, based on the data of Logan *et al.* (4) and Lorimer and Dawson (5, 6), which are in excellent agreement with the calculated curve.

The results of the calculations are useful for determining the conditions under which N can be incorporated into GaP crystals during LPE growth. In the experiments of Logan *et al.*, the efficiency of light emitting diodes increased with increasing N concentration up to the solubility limit. Since the calculations indicate that the solubility of N increases significantly with increasing temperature, they suggest that diodes with higher efficiencies might be obtained by LPE growth at temperatures above 1100°C.

Brief Communication

Preparation of X-Ray Sensitive Monoclinic $BaYb_2F_8$:Er Upconversion Phosphor

Lyuji Ozawa*

Zenith Radio Corporation, Chicago, Illinois 60639

It has been recently reported (1) that the upconversion efficiency for infrared to green light of monoclinic $BaYb_2F_8$:Er markedly changes upon x-ray irradiation and that no x-ray sensitivity is found with other efficient upconversion phosphors. A screen of $BaYb_2F_8$:Er has a possibility of being used as the screen of an inversion viewer of negative film and as the screen for nondestructive inspection by x-ray.

This brief communication describes the preparation of this x-ray sensitive monoclinc $BaYb_2F_8$:Er upconversion phosphor. It was found that the x-ray sensitivity only occurred when the monoclinic $BaYb_2F_8$:Er was prepared with $BaCl_2$ flux (which was coprecipitated with BaF_2 from $BaCl_2$ solution).

The phase diagram of the Ba-Yb fluorides is given by Zhigarnovskii and Ippolitov (2) who characterized monoclinic $BaYb_2F_8$. The samples prepared were examined by x-ray diffraction analysis to make sure the crystal forms. Our experimental results, however, indicated that the firing of the proper mixture of BaF_2 and YbF_3 at 950°C in nitrogen atmosphere always resulted in a mixture of crystals, predominantly of cubic phase. The same results (mainly cubic crystals) were obtained even after firing was repeated several times with hard grinding between the refirings. However, an addition of 20-30 weight per cent (w/o) $BaCl_2$ to the BaF_2 resulted in monoclinic $BaYb_2F_8$ crystal.

Alternatively, the BaF_2, which was precipitated from $BaCl_2$ solution with an addition of HF solution, usually contained about 30 w/o $BaCl_2$ by chemical determination. This coprecipitated BaF_2 and $BaCl_2$ mixture was preferable in making the x-ray sensitive monoclinic $BaYb_2F_8$:Er upconversion phosphor.

The most efficient and x-ray sensitive upconversion phosphor was obtained as follows: the mixture of BaF_2 precipitated from $BaCl_2$ solution and of $(Yb,Er)F_3$, mixing ratio one-to-one, was fired at 950°C for 2 hr in an oxygen-free nitrogen atmosphere. The fired sample was washed with deionized water to remove the excess $BaCl_2$. The sample was dried at 105°C and then the x-ray sensitive monoclinic $BaYb_2F_8$:Er upconversion phosphor was obtained. Chemical determination indicated that the amount of chlorine in the $BaYb_2F_8$:Er washed was less than 1 w/o. The upconversion efficiency of monoclinic phosphor obtained was comparable to that of cubic $Ba(Y,Yb,Er)F_5$ phosphor which had been reported as ten times more efficient than the monoclinic phosphor (3). Monoclinic $BaYb_2F_8$:Er upconversion phosphor was also prepared with other chloride fluxes (such as NH_4Cl), but the phosphor was not sensitive to x-ray irradiation and did not have high efficiency.

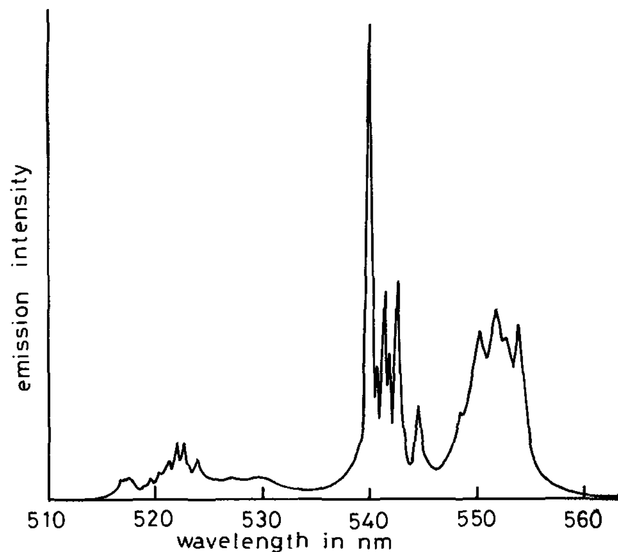

Fig. 1. Luminescent spectrum in green color region of monoclinic $BaYb_2F_8$:Er phosphor under infrared excitation.

The luminescent spectrum in the green color region of monoclinic $BaYb_2F_8$:Er phosphor under the infrared excitation is shown in Fig. 1. All of the luminescent lines indicated in the figure were identified as transitions from $^4S_{3/2}$ to $^4I_{15/2}$.

Preparation of Beta-Rhombohedral Boron Whiskers

I. Ahmad and W. J. Heffernan (pp. 1670-1675, Vol. 118, No. 10)

K. Ploog:[1] The purpose of this note is to indicate, that it is impossible to prepare whiskers of tetragonal boron, $B_{48}B_2$, in a pure form, because this cited boron modification investigated by Hoard *et al.*[2] is not a true polymorph of pure elementary boron.

In our investigations we found[3] that the II-tetragonal boron, B_{192}, (a = 10.12Å, c = 14.14Å, d = 2.36 g/ml, space group: $P4_122$, structure as yet unknown) is the only boron modification formed by the reduction of BBr_3 and BCl_3 with hydrogen at 950°-1400°C on an inert substrate. On the other hand we have now developed a new method to produce the tetragonal lattice of $B_{48}B_2$ in a reproducible manner by preparing a tetragonal boron carbide of composition $B_{48}B_2C_2$ and a tetragonal boron nitride of composition $B_{48}B_2N_2$.[4] In these tetragonal B-C and B-N phases (space group: $P4_2/nnm$) the unstable lattice $B_{48}B_2$ is stabilized by C- resp. N-atoms, which occupy holes in the tetragonal icosahedral framework.

The authors report that especially on graphite leads whiskers of tetragonal boron, $B_{48}B_2$, are formed. I suggest that the formation of this boron "modification" in the reported experiments is induced in the following way: the deposited boron picks up some carbon from the substrate and reacts on the surface, resulting in the nucleation and growth of whiskers, which actually are tetragonal boron carbide and not pure tetragonal boron. A decision between $B_{48}B_2$ and $B_{48}B_2C_2$ only by x-ray diffraction methods is difficult, but it is easily accomplished by determining the density of the material and by analyzing the carbon content.

Activity Coefficients for a Regular Multicomponent Solution

A. S. Jordan (pp. 123-124, Vol. 119, No. 1)

K. Yoshida[5] and E. W. Dewing:[6] Jordan has given the activity coefficient for a regular multicomponent solution in the form

$$RT \ln \gamma_i = \sum_{\substack{j=1\\ i\neq j}}^{m} \alpha_{ij} x_j^2 + \sum_{\substack{k=1\\ k<j, i\neq k, i\neq j}}^{m} \sum_{j=1}^{m} x_k x_j (\alpha_{ij} + \alpha_{ik} - \alpha_{kj}) \quad [1]$$

(his Eq. [8]). This is inconvenient since the coefficients α_{ij} and α_{ik} in the second summation also appear as α_{ij} in the first. Part of the second sum can be replaced by

$$\sum_{\substack{k=1\\ k<j, i\neq k, i\neq j}}^{m} \sum_{j=1}^{m} x_k x_j (\alpha_{ij} + \alpha_{ik}) = \sum_{\substack{j=1\\ i\neq j}}^{m} x_j \alpha_{ij} \sum_{\substack{k=1\\ k\neq j, k\neq i}}^{m} x_k \quad [2]$$

since

$$\sum_{\substack{k=1\\ k<j, i\neq k, i\neq j}}^{m} \sum_{j=1}^{m} x_k x_j \alpha_{ik} = \sum_{\substack{k=1\\ k>j, i\neq k, j\neq k}}^{m} \sum_{j=1}^{m} x_j x_k \alpha_{ij} \quad [3]$$

by interchanging j and k.

Combining Eq. [2] with [1] yields

$$RT \ln \gamma_i = \sum_{\substack{j=1\\ i\neq j}}^{m} \alpha_{ij} x_j (1 - x_i) - \sum_{\substack{k=1\\ k<j, i\neq j, i\neq k}}^{m} \sum_{j=1}^{m} \alpha_{kj} x_k x_j \quad [4]$$

since

$$\sum_{\substack{k=1\\ k\neq j, i\neq k}}^{m} x_k + x_j = 1 - x_i \quad [5]$$

Each coefficient now only appears once. For m = 4 and i = 1, for example

$$RT \ln \gamma_1 = \alpha_{12} x_2 (1 - x_1) + \alpha_{13} x_3 (1 - x_1) + \alpha_{14} x_4 (1 - x_1) - \alpha_{23} x_2 x_3 - \alpha_{24} x_2 x_4 - \alpha_{34} x_3 x_4 \quad [6]$$

and it can readily be verified by inspection of Jordan's Eq. [9] that the two are identical.

Equation [6] is inherently suitable for finding the coefficients α by linear regression analysis, whereas Jordan's equation is not. Furthermore, if experimental values are available for the activity coefficients of several components they can all be treated simultaneously in the same analysis.

A. S. Jordan: Yoshida and Dewing present the derivation of an alternative form to Eq. [8] (their Eq. [1]) of my paper concerned with the activity coefficients for a regular multicomponent solution. A careful reading of the paper under discussion reveals that the final result of Yoshida and Dewing (their Eq. [4]) was implicitly stated in the original work. To show this, I quote the following section from the paper

$$RT \ln \gamma_i = \sum_{\substack{j=1\\ i\neq j}}^{m} \alpha_{ij} x_j - \frac{1}{2} \sum_{\substack{k=1\\ k\neq j}}^{m} \sum_{j=1}^{m} \alpha_{kj} x_k x_j \quad [6]$$

By separating the quadratic terms present in Eq. [6], a more convenient expression for $\ln \gamma_i$ can be derived. Let us exclude the terms from the double sum in Eq. [6] for which $k = i$ and $j = i$ and absorb the resulting single sum

$$-\frac{1}{2} \sum_{\substack{j=1\\ i\neq j}}^{m} \alpha_{ij} x_i x_j - \frac{1}{2} \sum_{\substack{k=1\\ i\neq k}}^{m} \alpha_{ki} x_k x_i = - \sum_{\substack{j=1\\ i\neq j}}^{m} \alpha_{ij} x_i x_j$$

in the single sum in Eq. [6].

For the sake of brevity, this indicated substitution leading to my Eq. [7] was not explicitly given in the printed text, but the operation yields

$$RT \ln \gamma_i = \sum_{\substack{j=1\\ i=j}}^{m} \alpha_{ij} x_j (1 - x_i) - \frac{1}{2} \sum_{\substack{k=1\\ k\neq j, i\neq k, i\neq j}}^{m} \sum_{j=1}^{m} \alpha_{kj} x_k x_j \quad [6.5]$$

which is identical with Eq. [4] of Yoshida and Dewing apart from a notational difference (1/2 of the double sum and $k \neq j$ being equivalent to the whole sum and $k < j$). It should also be noted that the derivation of

Yoshida and Dewing's Eq. [4] from my Eq. [8] is a reversal of my procedure to obtain Eq. [8] from Eq. [6.5].

My aim in presenting Eq. [8] instead of Eq. [6, 5] as the final result is to some extent a matter of esthetic preference. Certainly, the quadratic (in composition) representation explicit in Eq. [8] is very much in accord with the previously published forms of activity coefficients for regular binary and ternary solutions. Moreover, a rapid straightforward generation of activity coefficients for a regular solution of any number of components can be realized from my Eq. [8].

However, I agree with Yoshida and Dewing that grouping terms with the same α_{ij}'s is the practical way to treat problems by linear regression analysis. Nevertheless, to obtain for a quaternary solution their Eq. [6] from my Eq. [9] which is given in a quadratic form requires only elementary algebraic manipulations.
