
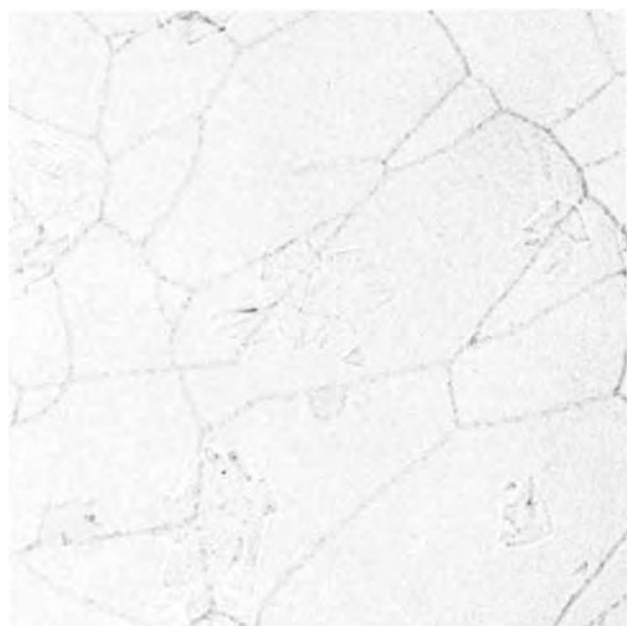

Fig. 4. Transmission electron micrograph of anodic oxide film after heating in argon at 350°C for 3 hr and after immersion in chromate solution for 1700 min (magnification 45,000X).

After fully thinning such a film in chromate solution, the capacitance increased to 1.31 $\mu F/cm^2$ indicating that 57Å of anodic γ-Al_2O_3 remain. The MgO crystals, accordingly, are positioned within this inner region which is in good agreement with the other results.

It is known that the anodic film formed on Al-3% Mg alloy contains the same ratio of aluminum to magnesium as exists in the metal (7). In order to ascertain if the magnesium in the oxide participates in the formation of MgO, anodic films were stripped from the alloy and heated in argon at 350°C for 20 hr. Examination of these films by electron microscopy did not reveal the presence of MgO, while transmission electron diffraction showed only the characteristic pattern of amorphous γ-Al_2O_3.

These results indicate that the crystals of MgO result from a solid-state reaction between the amorphous γ-Al_2O_3 and Mg from the underlying alloy according to the equation

$$Al_2O_3 + 3Mg \rightarrow 3MgO + 2Al$$

Such a reaction is to be expected at 350°C on the basis of free energy consideration (8). An alternative explanation, that the crystalline MgO results from the reaction between Mg and oxygen, would require the inward diffusion of oxygen ions through the anodic film. Such a mechanism is responsible for the formation of crystalline γ-Al_2O_3 at 425° to 575°C under anodic oxide films formed on high purity aluminum (5). The rate of formation of the crystals of γ-Al_2O_3 is very sensitive to oxygen pressure. The insensitivity of the rate of formation of the MgO crystals to oxygen pressure argues against such an explanation in the present work. Moreover, the reaction between Mg and oxygen would require a weight gain which was not observed.

The solid-state reaction described above also results in the formation of elemental aluminum which was never detected by transmission electron diffraction experiments. However, it is possible that during the reduction, Al and Mg diffuse in opposite directions through the MgO crystallites. This would result in the aluminum returning to the alloy. Alternatively, the aluminum might have been formed in a colloidally dispersed state which would not be detectable by electron diffraction. The slight volume increase accompanying the solid-state reaction would result in the MgO crystal protruding very slightly into the metal phase but growing primarily into the oxide phase as was observed in this work.

The above results clearly demonstrate that MgO results from the solid-state reaction between magnesium and amorphous γ-Al_2O_3. Such a reaction doubtless occurs at an early stage during the thermal oxidation of Al-Mg alloys. In this case, however, the initial protective film of amorphous γ-Al_2O_3 is only some 20 to 30Å thick. Consequently, depending on the conditions of oxidation, it can be completely reduced by magnesium to MgO and elemental aluminum, as will be shown in subsequent papers (1).

On the Electrochemistry of Porous Zinc Electrodes in Alkaline Solutions

Z. Nagy*,[1] and J. O'M. Bockris*,[2]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Porous zinc electrodes were discharged galvanostatically in aqueous potassium hydroxide solutions. The morphology of the zinc oxide film formed was investigated with a scanning electron microscope. The current distribution in the porous electrode, and its dependence on current density, was determined by microslicing the electrode after discharge and chemical analysis. The oxide film had a porous, "carpet-like" structure, consisting of long needle crystals with occasional sidearms. The formation of this type of film can be explained by a dissolution-precipitation mechanism. The current distribution in the porous electrode, and its dependence on current density could also be explained, based on a model of oxide film consisitng of a thin, high resistance compact film, beneath the porous oxide.

The behavior of porous electrodes is an important topic in electrochemistry since many practical electrode reactions (particularly those of energy conversion and storage) take place in porous matrices. The basic question is the distribution of current (and potential) in the porous body. The theory of porous electrodes has evolved to a considerable sophistication during the last decade. While the mathematics is complicated, analytical solutions have been obtained for a number of cases taking into account the *IR* drops in the electrolyte and the metal matrix, the diffusional processes of reactants and products, the kinetics of the charge transfer reaction, and the wetting characteristics of the metal by the electrolyte. A recent summary of these theories is available (1). None of these early theories have, however, taken into consideration the structural changes taking place in the porous matrix during the electrode process (*e.g.*, the anodic dissolution of a metal and the formation of insoluble reaction products) which are very common in electrochemical energy storage systems. Two recent theoretical papers began work in this area. The first one (2) treats the effects of structural changes due to the anodic dissolution of the matrix without product precipitation. The other (3) considers slightly soluble reactants and products on an inactive conducting matrix, and treats the structural effects as changes in mass transport parameters of the active materials. Both of these treatments result in differential equations solvable only numerically.

The experimental determination of current distribution can be carried out in three ways: (*i*) the measurement of potential distribution by using numerous probes along the electrode, as was carried out with MnO_2 electrodes (4), (*ii*) the direct measurement of the distribution by using sectioned electrode, and measuring the current separately to each section as was reported for MnO_2 (5), and the $Pb/PbSO_4$ system (6) and, (*iii*) sectioning the electrode after the experiment and analysis of the products as was recently carried out with cadmium electrode (7). The first two methods allow repeated cycling of the electrode while carrying out *in situ* measurements, and the determination of time dependence of the distribution is also possible, but the technique itself may interfere with the normal operation of the porous electrode thereby distorting the results. The third method is free of this objection, but it is limited to one observation per electrode, and is applicable only for processes with solid reaction products.

The zinc-zinc oxide alkaline electrode is an important system for which current distribution studies have not been reported as yet. This is surprising considering the fact that it is one of the more promising electrodes for high energy and power density energy storers (8, 9). Oxide film formation and passivation have been investigated by many workers on flat zinc electrodes in alkaline solutions. Recent reviews are available (10, 11). There is a controversy in the literature whether the passive film is formed directly on the surface or by a dissolution-precipitation mechanism (11-19). Recent results (11, 17-19) indicate, however, that there are two kinds of film formed during anodization of zinc in an alkaline solution. One, a precipitated film, appears before passivation occurs; while the second film, forming beneath it, is the cause of passivation. Correspondingly, the prevailing hydrodynamic conditions have been shown to have a strong influence on the formation of the films, and that the quiescent conditions inside a porous electrode will favor the precipitated oxide. Further, it has been shown by cathodic reduction studies (20), that the direct, solid-state, reduction of zinc oxide is energetically unfavorable compared to the dissolution-zincate reduction mechanism. Numerous reports also appeared (21-29) on the anodic behavior and passivation of porous zinc electrode in alkaline solutions, as a function of current density,

temperature, solution composition, and porosity of the electrode, but in none has the question of current distribution within the electrode been studied.

Experimental

Porous zinc electrodes were discharged galvanostatically in alkaline zincate electrolytes. The morphology of zinc oxide formed was examined with a scanning electron microscope. The penetration of current, and its dependence on current density, were determined at the end of the process by microslicing the electrode and chemical analysis. All tests were carried out at room temperature.

The cell.—The basic concept of the cell is illustrated in Fig. 1. The porous zinc pellet was pressfitted into the solution channel of the Teflon cell body, and the assembly covered tightly with a glass sheet. Current contact to the porous electrode was made using a 0.0075 cm thick zinc foil. The solution channel on the other side of the porous electrode led to a counterelectrode chamber, the counterelectrode was a platinum wire spiral immersed in KOH-ZnO slurry. The Teflon tubing Luggin led to a reference chamber holding a calomel electrode. Details of the cell design are given elsewhere (30).

Preparation of the porous electrodes.—The test electrodes were prepared from 99.9999% pure zinc powder (United Mineral and Chemicals Corporation) with a particle size less than 0.015 cm (−100 mesh). The powder was compressed into a 0.3 cm diameter, 0.1 cm thick pellet in a suitable mold, using a pressure of 8400 psi. The porosity of the electrodes was determined, from their calculated density, as 30%.

The electrolyte solutions.—High purity potassium hydroxide-zincate solutions were prepared with a technique described before (31). For all but one experiment, a solution composition of 2M KOH and 0.1M zincate was used. In one case, the solution was 8M KOH containing 0.5M zincate.

Experimental procedure.—After assembling the cell, it was blown free of air with purified nitrogen, and the solution was introduced by applying vacuum on the outlet side of the channel. Filling of the electrode could be observed with a microscope through the glass cell cover: if bubbles were observed the evacuation and filling was repeated. A constant current was applied, using an Elron galvanostat, in the range of 4-100 mA/cm^2 apparent current density (calculated on the geometric area) for a time duration of 2-40 hr. The electrode potential was measured with a Beckman digital pH meter. At the end of the test, the cell was opened, and the porous electrode transferred into ethyl alcohol. It was washed several times with fresh alcohol to remove all water and potassium hydroxide. Finally, it was dried in a vacuum desiccator, where it was stored for further examination.

Observation of oxide morphology.—Some electrodes were examined with a scanning electron microscope (JSM-U3, JOELCO, Japan) to determine the shape of the oxide particles formed during the discharge. Only the top surface (facing the glass cover in the cell) was examined.

Determination of current penetration.—Some electrodes were microsliced under a microscope, equipped with a calibrated scale, using stainless steel blades. First a 1 mm wide section was cut out longitudinally (in the direction of current flow), from the middle of the electrode to avoid the influence of edge effects. This 3 × 1 × 1 mm piece was then further cut into six, 0.5 mm wide, parts. The ZnO and Zn content of each part was then determined as follows. The oxide was dissolved in a solution of 1M NH_4OH and 1M NH_4Cl. This solution dissolves the oxide but attacks the zinc only negligibly during the 5 min contact time (32). The solution was then filtered and analyzed for zinc with an EDTA titration (33). The remaining zinc was dissolved in hydrochloric acid and the solution analyzed for zinc as above.

Results

Morphology of the oxide film.—Scanning electron microscopic investigation was carried out on electrodes discharged at 4 and 40 mA/cm^2 current densities with a charge range of 4 to 18 mA-hr. In the interior of the electrode, a very porous "carpet-like" oxide film, consisting of long needle crystals, was found on the zinc grains. Examples are shown in Fig. 2. The appearance of the film was the same everywhere in the interior of the electrode, independently of distance from the solution, current density, and depth of discharge, within the limits of the experiments. On areas less densely populated with growth, occasionally side arms were observed on the needles (Fig. 3). At the edge of the electrode, toward the electrolyte, the film was more compact as shown in Fig. 4. An experiment was carried out using an 8M KOH solution, and produced similar results (Fig. 5).

Current penetration into the porous electrode.—This experiment was carried out at five current densities ranging from 5 to 80 mA/cm^2. The duration of discharge was also varied so as to keep the total charge used constant, at a value of 25% over-all conversion of the porous electrode. From the chemical analysis of the sliced electrodes, the average conversion of zinc to zinc oxide was calculated for each section. The results are plotted in Fig. 6-10, as a function of distance from the electrolyte. The measured overpotentials are given in Table I.

Discussion

The morphology of the oxide film.—The dendritic appearance of the oxide, with all the needles pointing towards the solution, suggests the following mechanism for its formation. The dissolving zinc supersaturates

the solution in zincate [the stability of highly supersaturated zincate solutions is known (21)] until a concentration is reached when oxide nucleation suddenly begins. This will happen at the surface of the metal where the zincate concentration is the highest. Once nucleation occurred, crystallization will proceed very fast from the supersaturated solution and a concentration gradient is set up, creating a diffusion layer. If the radius of curvature of some of the nuclei is small enough, to allow spherical diffusion to take over, conditions for dendritic growth are fulfilled (34, 35). Apparently, due to the simultaneous nucleation of a large number of crystals, many nuclei will have the required small radius of curvature resulting in a dense, carpet-like, appearance of the film. The observation of occasional side branches (Fig. 3) supplies strong evidence for this mechanism. This mechanism is analogous to the dendritic solidification of a cylindrical mass of molten metal (36). Figure 2E affords a side view of the film which peeled off the zinc grain.[3]

[3] Peeling was observed only occasionally. From the present data it could not be decided whether this occurred during the electrode process, or afterwards during the vacuum drying.

Current distribution.—There is strong evidence to indicate that the reaction in a porous zinc electrode proceeds through the soluble zincate intermediate. Anodic studies on planar zinc electrodes have shown, that under hydrodynamic conditions most resembling that of the porous electrode, the oxide film was formed by a dissolution-precipitation mechanism (11, 17-19). The morphology of the zinc oxide film (see above) also supports this mechanism. Further, cathodic studies (20) have proven that the direct (solid-state) reduction of ZnO does not contribute in measurable amount to the over-all reaction. The first step in the discharge mechanism of a porous zinc electrode is, therefore, the electrochemical formation of zincate, a study of which reaction was reported earlier (31). The exchange current density of the reaction being high (80 mA/cm^2 for the solution concentration used in these experiments), the activation overpotential in the present case can be considered to be in the linear current density-overpotential range for all, except the highest, current density used, and even for the highest one it can be used as a good approximation (cf. also Table I). This considerably simplifies the problem. The sophisticated, and

mathematically complex, theories which use the Butler-Volmer equation (or the high overpotential approximation) in the description of the porous electrode behavior [cf. Bockris and Srinivasan (1)], can be now reduced to their simplest form, taking the linear relation between current and potential. This simple theory was considered earlier by Euler and Nonnenmacher (37) (without considering any structural changes during the reaction), and their equations will be used as a basis of approach for the present problem.

The porous electrode is considered as a network of series and parallel resistors as shown in Fig. 11. The current flowing through the metallic phase is $i_1(x)$, and that in the solution phase, $i_2(x)$. Current transfer between the two phases (through the surface resistance $1/\kappa$) results in faradaic reaction, the value of which is expressed as: di_1/dx, at any point x along the porous electrode. The current densities, and the potentials (E_1 in the metallic, and E_2 in the solution phase) are functions of distance (x) obeying the following relations

$$\frac{dE_1}{dx} = -\frac{1}{\sigma_m} i_1(x) \quad [1]^4$$

$$\frac{dE_2}{dx} = -\frac{1}{\sigma_{sol}} i_2(x) \quad [2]^4$$

$$\frac{di_1}{dx} = \kappa[E_2(x) - E_1(x)] \quad [3]$$

$$\frac{di_1}{dx} = -\frac{di_2}{dx} \quad [4]$$

Combining Eq. [1] through [4] gives the final differential equation

$$\frac{d^4E_1}{dx^4} - \kappa\left(\frac{1}{\sigma_m} + \frac{1}{\sigma_{sol}}\right)\frac{d^2E_1}{dx^2} = 0 \quad [5]$$

The following boundary conditions are relevant to the present problem

$$i_1(x=0) = 0; \qquad i_1(x=L) = i$$
$$i_2(x=0) = i; \qquad E_2(x=0) = 0$$

where L is the over-all length of the porous electrode and i ($=i_1$, at $x = L$) is the total current density. The solution for the distribution of the faradaic current (di_1/dy) as a function of fractional distance ($y = x/L$) is given by

$$\frac{di_1}{dy} = \frac{i \cdot \sigma_{sol} \cdot \nu}{(\sigma_{sol} + \sigma_m)\sinh \nu}\left[\frac{\sigma_m}{\sigma_{sol}}\cosh \nu(1-y) + \cosh \nu y\right] \quad [6]$$

where

$$\nu = L \cdot \sqrt{\kappa\frac{\sigma_{sol} + \sigma_m}{\sigma_{sol}\,\sigma_m}} \quad [7]$$

Note, that in accord with the linear i-η restriction the surface resistance ($1/\kappa$) was considered constant, independent of potential. In the general sense the surface resistance can include not only the faradaic resistance but also the electrical resistance of any film formed on the surface as shown schematically in Fig. 12 for a single pore.

[4] The metallic and solution conductivities (σ_m, σ_{sol}) used in Eq. [1] and [2] are not equal to the corresponding bulk values. They represent the respective contributions of the metallic and solution phases to the over-all conductivity of the solution filled porous electrode. For an electrode having p% porosity their values can be estimated, as a first approximation, as

$$\sigma_m = (\sigma_m^{bulk})\frac{100-p}{100}, \text{ and}$$

$$\sigma_{sol} = (\sigma_{sol}^{bulk})\frac{p}{100}$$

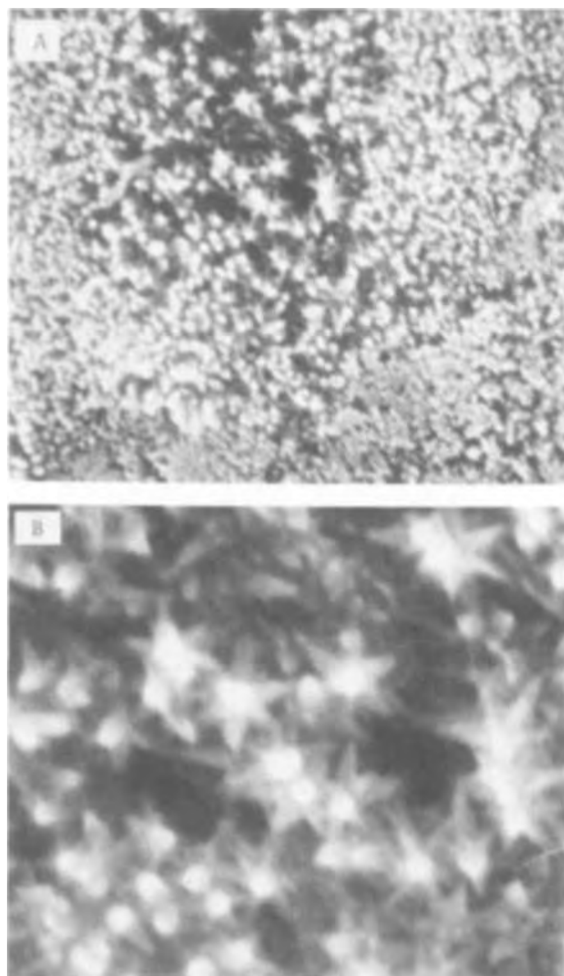

Fig. 3. Appearance of sidearms. 40 mA/cm², 28% discharge. Mark represents 3μ for A, and 1μ for B.

In the derivation of Eq. [6] σ_{sol}, σ_m, and κ were taken as constants, independent of distance within the electrode and time of discharge. In the case of an electrode where structural changes occur during the process, these assumptions have to be re-examined.

For the present electrode process the values of σ_{sol}, σ_m, and κ are known for the beginning of the process.[5] If these are substituted in Eq. [6] it can be shown that the current will drop off very quickly with distance, reaching 10% of the over-all current value at $y = 0.11$. This prediction, that practically all the faradaic current will go to a layer only one tenth of the electrode's depth, is not in agreement with the experimental data (Fig. 6-10) showing much greater penetration. The structural changes, dissolution of zinc, and precipitation of ZnO from the saturated zincate solution will have to be taken into account.

The dissolution of zinc will increase the resistance of the metallic phase ($1/\sigma_m$). However, since the experiments were limited to 25% conversion, the effect of this decrease in σ_m will be negligible on the current distribution, considering that the specific conductivity of the metal is six orders of magnitude greater than that of the solution.

The precipitation of ZnO will have two effects: (*i*) it will plug up the pores, decreasing σ_{sol}, and (*ii*) it will cover the surface of zinc, decreasing κ. The first effect (decrease of σ_{sol}) will not cause the current to

[5] $\sigma_{sol} = 0.32 \times 0.3$; $\sigma_m = 1.7 \times 10^5 \times 0.7$, where the values are corrected for 30% porosity. $\kappa = 575 \times 6.15$, where 575 is the area in cm² of one cm³ of porous electrode (calculated for a 100μ average particle diameter), and 6.15 is the reciprocal of the faradaic resistance.

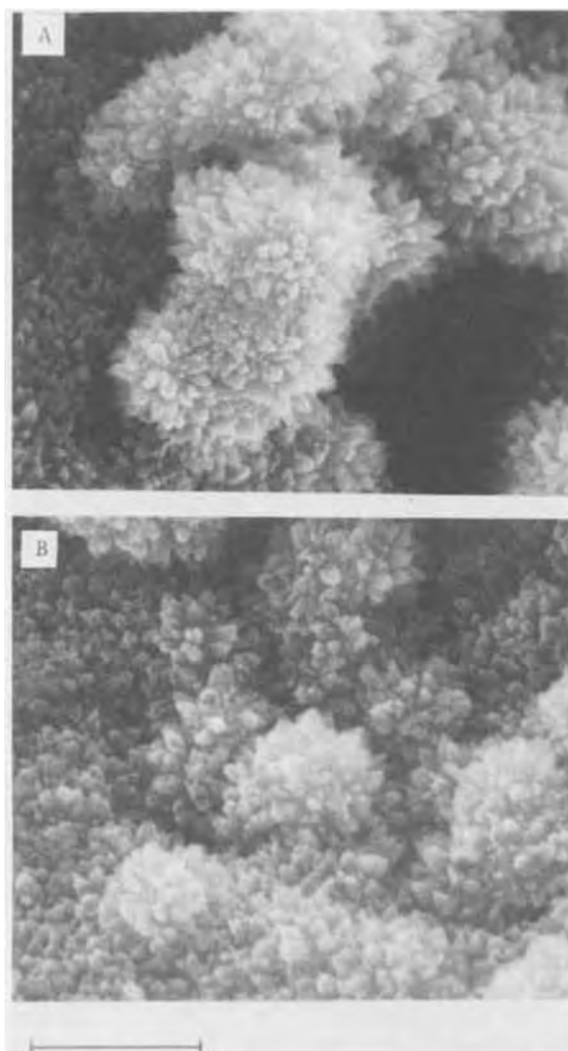

Fig. 4. Film at the edge of electrode. 40 mA/cm². Discharge: 25% for A, and 44% for B. Mark represents 3μ.

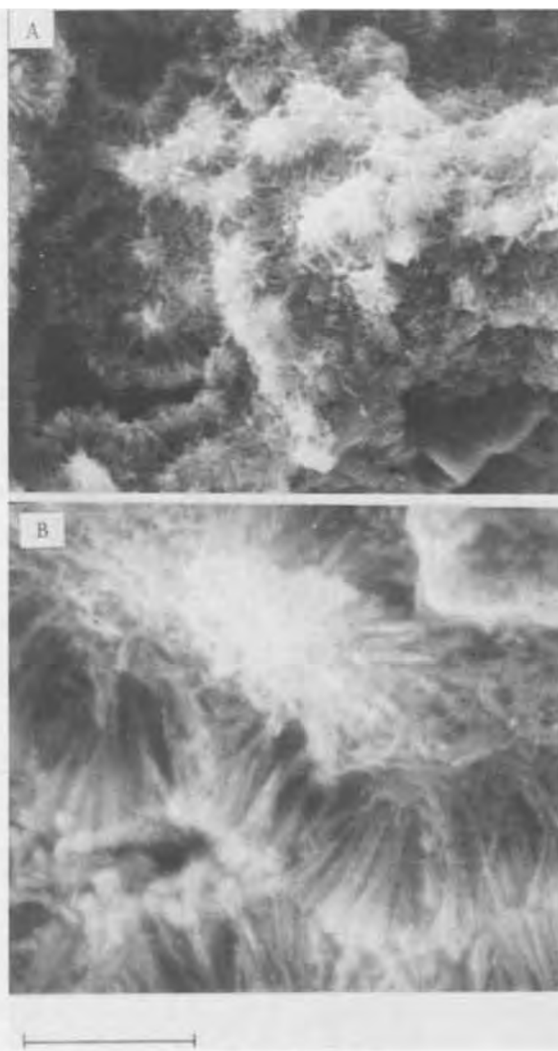

Fig. 5. Film formed in 8M KOH. 100 mA/cm², 31% discharge. Mark represents 10μ for A, and 3μ for B.

penetrate more deeply into the electrode. On the contrary, it can be seen, considering Fig. 11, that a decrease in σ_{sol} will cause the current to transfer, from the solution to the high conductivity metallic phase, closer to $x = 0$. This can be shown also numerically, using Eq. [6]. Taking a decreased σ_{sol} (corresponding to a porosity of 15% only) the 10% current level will now be reached at $y = 0.08$. It can be calculated that during the discharge of the present electrodes, the average porosity decreases from 30 to 20%.[6] Therefore, this effect will change the current distribution only slightly and in the direction to make it less in agreement with the experimental results.

There remains only the possibility that $1/\kappa$ represents not only the faradaic resistance, but, in fact overwhelmingly, a film caused resistance arising from the oxide formation. Immediately after the anodic current begins, during the free dissolution of the metal, κ can be considered constant. Then the oxide precipitation will suddenly decrease κ. The value of κ will continuously decrease, after the precipitation, due to the thickening of the film. The time of precipitation can be estimated as follows. The total volume of the electrolyte in the pores of the electrode is 2.1×10^{-3} cm³. The solubility of ZnO in 2M KOH solution is 0.33M (38) and, considering that 0.1M zincate is present in the original solution, it can be calculated that a charge of 0.026 mA-hr is needed to saturate all the electrolyte

[6] This was calculated for 25% discharge taking into consideration the density difference between Zn and ZnO (7.14 and 5.6, respectively).

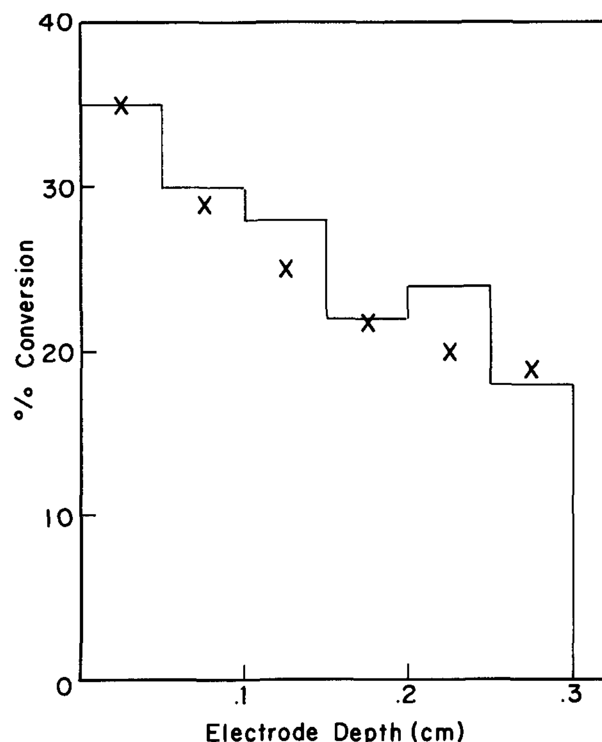

Fig. 6. Per cent conversion as function of distance. 5 mA/cm². x: values calculated with $\kappa = 0.6$.

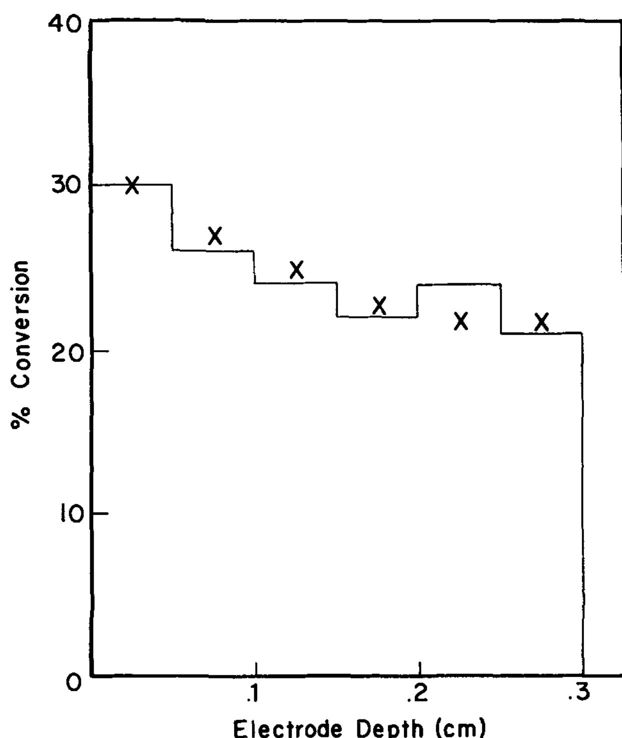

Fig. 7. Per cent conversion as a function of distance. 10 mA/cm². x: values calculated with $\kappa = 1.25$.

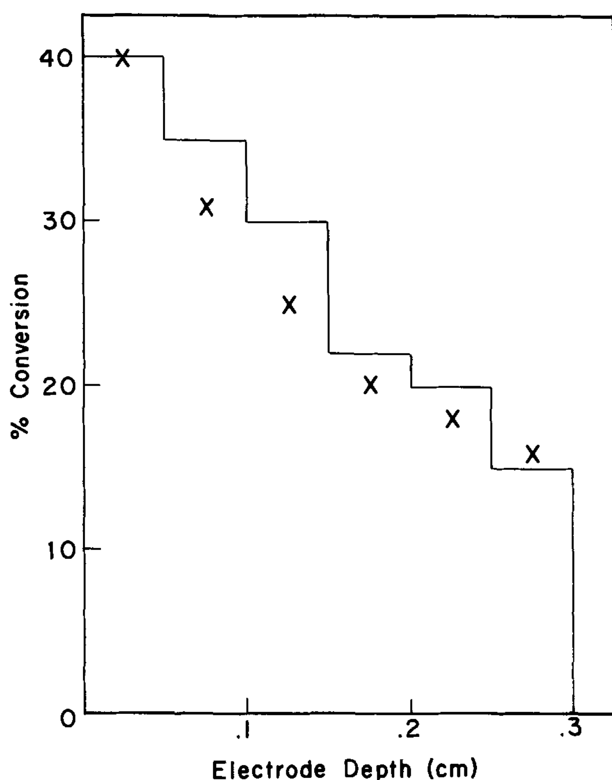

Fig. 8. Per cent conversion as a function of distance. 20 mA/cm². x: values calculated with $\kappa = 2.0$.

within the pores. This charge is negligible as compared to the total charge of 8 mA-hr used in these experiments, and therefore, it can be considered that film precipitation will occur everywhere in the electrode, instantaneously, at the beginning of discharge.[7] The

[7] Actually, at the beginning, practically all the current will go to the first one tenths of the electrode depth (as was shown earlier using Eq. [6] with the initial values of conductances), causing precipitation in this area and shifting the current to the next layer in the electrode until the solution becomes saturated there, and so on. This process sweeps across the electrode in a time duration negligible as compared to the total time of the experiment.

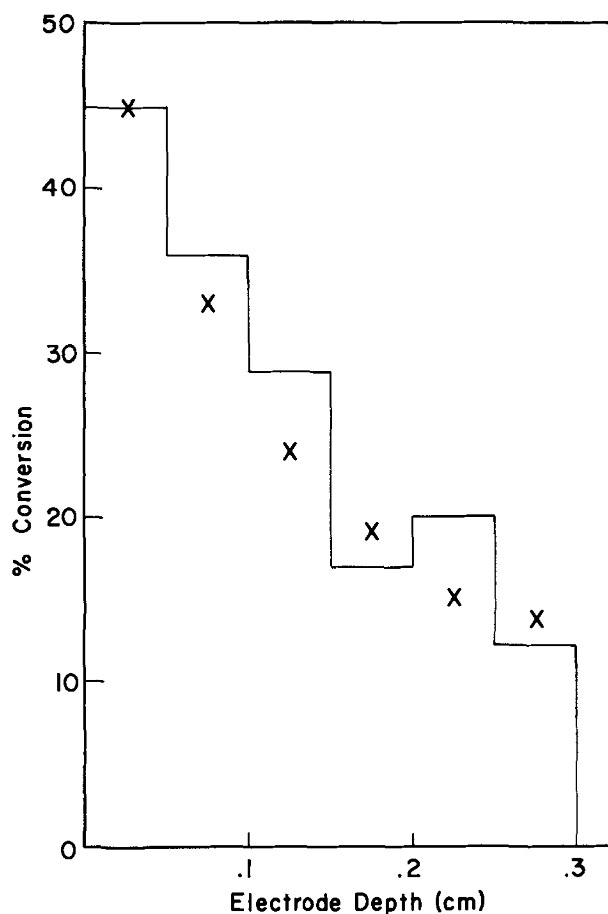

Fig. 9. Per cent conversion as a function of distance. 40 mA/cm². x: values calculated with $\kappa = 3.0$.

film then will thicken in time, causing κ to decrease further. As a first approximation, this change in time will be smoothed out, and an average κ will be considered in the following way.

An attempt was made to fit Eq. [6] to the experimental data (Fig. 6-10) with a suitable selection of the value of κ.[8] Reasonable agreement was obtained with the κ's indicated. These values, and their current dependence can then be examined to determine whether they are physically realistic, and whether their dependence on current density can be theoretically explained.

To arrive at an expected approximate dependence of κ on current density, the following extension of the present model for the operation of the porous electrode is used. The film is formed by precipitation from a saturated solution formed by galvanostatic dissolution of the metal, under conditions, when the reaction products can be removed only by diffusion. Under these conditions, the time of precipitation is related to the current density as

$$i\, t^{1/2} \approx \text{const} \quad [8]$$

The resistance of the film, on the other hand, will be proportional to its thickness, which depends on the total charge represented by the film

$$1/\kappa \approx \text{const} \cdot i \cdot t \quad [9]$$

Therefore, the dependence of "κ," the surface conductivity, on current can be approximated from [8] and [9] as

$$\kappa \approx \text{const} \cdot i \quad [10]$$

predicting a linear relation, which in fact was observed (Fig. 13).

[8] In these calculations, σ_m was taken as $1.7 \times 10^5 \times 0.7$ and σ_{sol} as 0.32×0.2. A decreased solution conductivity was used to account for the plugging of pores by ZnO.

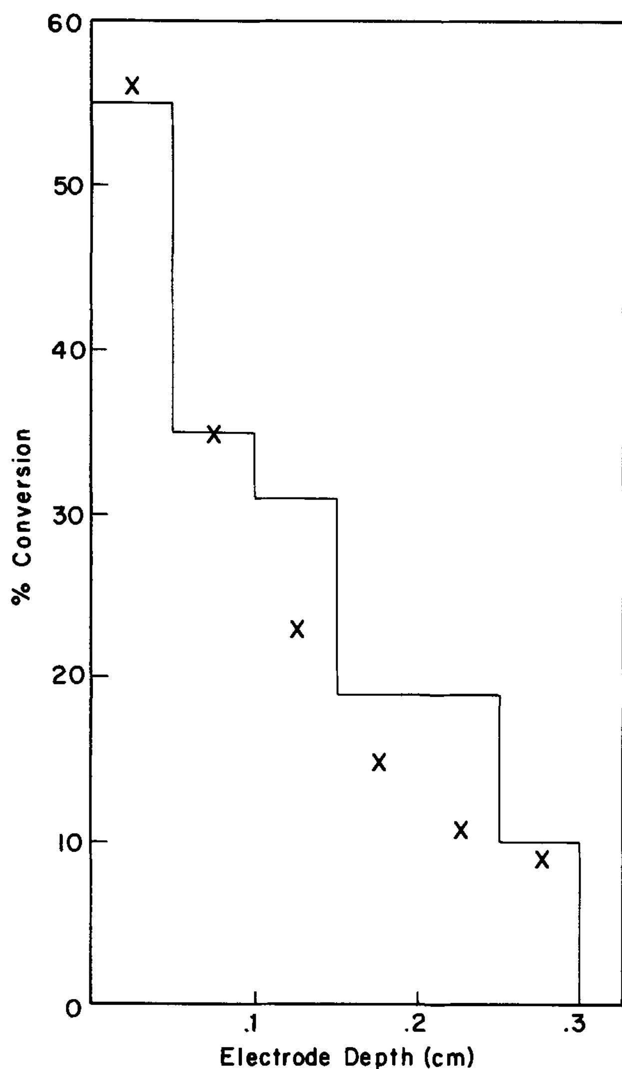

Fig. 10. Per cent conversion as a function of distance. 80 mA/cm². x: values calculated with $\kappa = 5.5$.

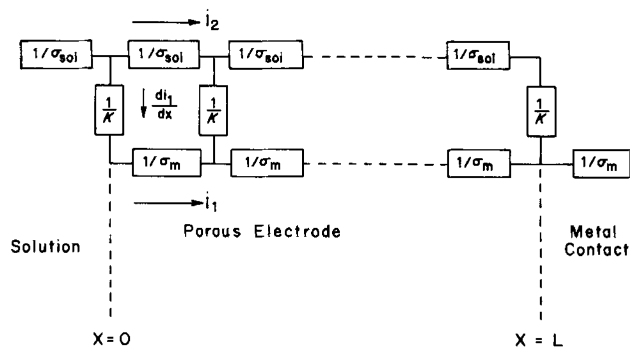

Fig. 11. Schematic representation of the porous electrode

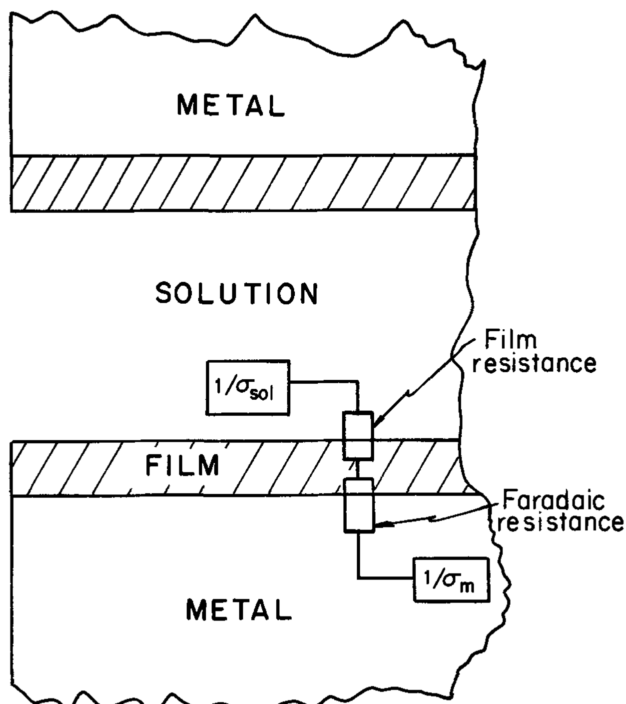

Fig. 12. Schematic representation of a single pore

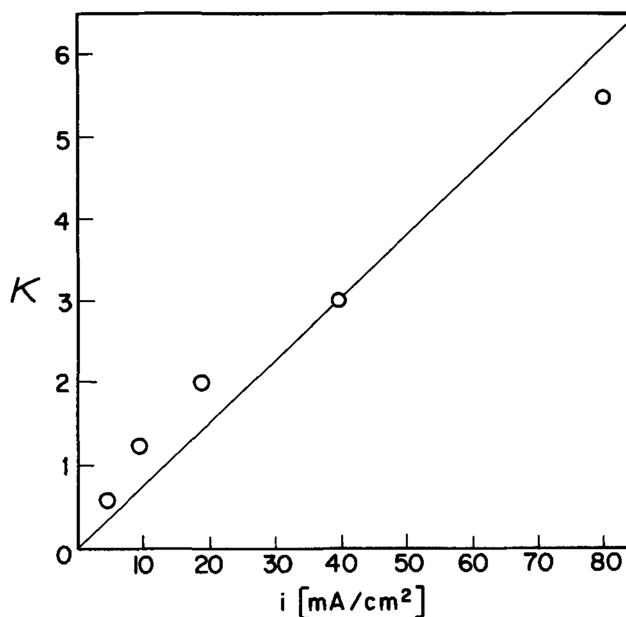

Fig. 13. Dependence of film conductivity on current density

The actual values of "κ" can also be compared to resistances calculated for different model of the film. The surface resistance ($1/\kappa$) is a sum of the terms: the faradaic resistance, the resistance of the porous zinc oxide film, and the resistance of any continuous film beneath the porous film. Assuming a surface area of 575 cm²/cm³ (calculated for an average particle size of 100μ) the surface resistance values giving the best fits to the experimental data range between 100 and 1000 ohms cm². Such a high value cannot be explained either by the decrease of apparent i_0 due to decrease of free area, or by the resistance of the porous film based on the observed film structures. It seems, therefore, that the assumption of the existence of a "compact" film underneath the "porous" one is necessary to explain the data. This is in agreement with the duplex films recently found on planar electrodes (11, 17-19). Since the specific resistance of zinc oxide can vary from 10^{-3} to 10^{17} ohm cm (39, 40) depending on stoichiometry of the oxide and on impurities, a very thin film could account for the observed resistances.

The resistance of the film will increase as the film thickens. While this will make the current distribution more uniform, it will also increase the *IR* losses in the electrode. This accounts for the decrease of the useful voltage of the battery as the discharge proceeds. This model, therefore, suggests a possible way to enhance the uniformity of current distribution in the porous electrode, namely the increase of oxide film resistance (possibly by suitable alloying of the zinc). This will, however, increase the *IR* losses, and the two effects will have to be optimized. On cathodic charging, the high resistance, compact film is expected to be reduced

fast, thereby altering the total resistance of the film and making the current distribution less uniform (as compared to that during discharge). On repeated cycling, this difference of the anodic and cathodic current distributions may cause physical distortion of the electrode structure.

The present results can be compared with the current penetration observation of Breiter (28). In that study, processes occurring in a porous zinc electrode were investigated using potential sweep technique. It was concluded that only a small portion of the interior of the electrode was active. Considering that the sweeps lasted a few minutes only, the result is in agreement with the present model, since the film formation may not have penetrated across the whole electrode during the experiments.

Thermal Conductivity Measurements of Nickel-Cadmium Aerospace Cells

Part II: Component Conductivities

E. W. Brooman* and J. McCallum*

Battelle Columbus Laboratories, Columbus, Ohio 43201

ABSTRACT

Thermal conductivities have been determined for the positive and negative electrodes from various 20 A-hr sealed, nickel-cadmium cells. The average value obtained for the discharged positives is 0.0014 ±0.0001 (cal/cm²/sec) (C/cm). The average value obtained for the discharged negatives is 0.0020 ±0.0001 (cal/cm²/sec)/(C/cm). The thermal conductivities of the three separator materials studied, nonwoven, calendered, and uncalendered nylon, and nonwoven polypropylene, are a function of porosity, electrolyte absorption, and amount of compression. Dry, uncalendered nylon felt, about 82% porous, compressed to about 72% porosity, has a conductivity of about 0.00014. Dry, calendered nylon felt, about 62% porous, reduced to about 49% porosity on compression, has a conductivity of about 0.00021. Dry polypropylene wettable paper, about 46% porous, reduced to about 34% porosity on compression, has a conductivity of about 0.00016 (cal/cm²/sec)/(C/cm). As electrolyte is added to the separator materials, the conductivity initially increases relatively little compared with the conductivity of the electrolyte itself. However, as the separator pores become filled with electrolyte then conductivity values approaching that of the electrolyte may be obtained.

Part I of this paper (1) described thermal conductivity values obtained for four types of 20 A-hr, nickel-cadmium aerospace cells. Thermal resistance networks were set up to explain the variations in conductivity observed between the four types of cells. Only semiquantitative correlation was obtained between the networks and the measurements, and one reason for this lack of precise agreement was attributed to the lack of reliable conductivity data for the materials comprising the cell elements. This present paper describes new experimental conductivity reference data for some of the principal components of the cells. Investigated were the conductivities of positive and negative electrodes from various types of the 20 A-hr cells described previously (1), and the conductivites of three separator materials as a function of electrolyte content. The three separator materials chosen were a nonwoven polypropylene, and a nonwoven nylon felt in the calendered and uncalendered conditions. These materials are candidate separator materials for use in sealed aerospace cells.

Experimental

Positive and negative electrodes from the 20 A-hr aerospace cells described previously (1), and samples from the manufacturers of the separator material (2), were used in this investigation. The basic experimental arrangement and procedures for the thermal conductivity measurements have been described elsewhere (1, 2). Briefly, the thermal comparison method was used with an acrylic block as the reference material. To prevent carbonation of the wetted electrodes or separator materials resulting from exposure to the air, and to prevent drying out of these components during the measurements, the components were sealed in envelopes fabricated from about 0.003 cm thick polyethylene film. The contribution of the film to the measured over-all conductivity was calculated each time, and an appropriate correction made to the experimental results.

For the conductivity measurements of positive or negative electrodes, the complete electrodes from the 20 A-hr cells, from manufacturers II, III, and IV were used after cell disassembly. The tabs were trimmed off, and the edges of the electrodes were inspected for any sharp protuberances which might have punctured the polyethylene envelopes.

For the conductivity measurements of the nylon and polypropylene separator materials, three or six pieces of material, depending on thickness, each about 10.0 × 5.0 cm, were cut and folded in half. These pieces were then interwoven to give a stack of six or twelve layers, each about 5.0 × 5.0 cm, before being sealed into the polyethylene envelopes. In the experiments where known amounts of electrolyte were added up to saturation, the required amount of electrolyte was added to the central layers of separator so that the electrolyte migrated to the outermost surfaces by capillary action. This procedure ensured that the separator materials were wetted throughout the stacks.

Results and Discussion

Positive and negative electrodes.—As the charge reaction of a nickel-cadmium cell is endothermic (3, 11), which may be or may not be offset by Joule heating effects depending on the charging rate and internal resistance of the cell; or offset by heat evolved in side reactions such as the evolution and recombination of oxygen) the thermal conductivity of the charged electrodes is relatively less important than the discharged-electrode conductivities. It is usually during discharge that the most heat is generated which, subsequently, has to be dissipated. Also, differences in thermal conductivity between 50% charged and discharged cells are less than 8% (2). For these reasons the conductivity values for discharged positive and negative electrodes only, are given in Table I. These conductivities were measured in a direction normal to the plane of the

electrodes (x-direction), and the units are ($cal/cm^2/sec)/(C/cm)$, which, hereinafter, are referred to as cgs units in the text.

Because of the similarity of the conductivities for all positive or all negative electrodes investigated, even though they were fabricated using different manufacturing techniques, as a first approximation a value of 0.0014 ± 0.0001 cgs units may be taken for the thermal conductivity of discharged nickel-hydroxide positive electrodes. A value of 0.0020 ± 0.0001 cgs units may be taken for the conductivity of discharged cadmium negative electrodes.

Separator materials.—The properties assigned by the manufacturers, or determined independently for the three separator materials chosen for this investigation, are given in Table II.

Dry separator materials.—The measured thermal conductivity of dry separator materials is a function of the bulk conductivity of the materials, the as-supplied porosity, and the amount of compression in the conductivity measuring apparatus. Thermal conductivities for bulk nylon materials average about 0.00055 cgs units, and an average value for bulk polypropylene is about 0.00026 cgs units (4).

Table II gives the apparent porosity of each of the fabricated materials. These porosities were based upon the weights and the uncompressed volumes of the materials. Upon assembly in the conductivity measuring apparatus, the materials were reduced in thickness, hence, apparent porosity by about 35, 25, and 18%, respectively. Therefore the actual porosities of the materials during measurement were of the order 72, 49, and 34%, respectively, assuming that the pore volume decreased while the volume of solid remained the same.

The range of anticipated conductivities for the dry separator materials can be estimated from Eq. [1] and [2], using the average bulk conductivity values mentioned above and assuming a thermal conductivity of 0.000062 cgs units for dry air.

$$k_{max} = \theta k_s + (1 - \theta) k_d \quad [1]$$

$$k_{min} = \frac{k_s k_d}{\theta k_d + (1 - \theta) k_s} \quad [2]$$

Equation [1] gives the maximum conductivity based on a simple parallel conduction thermal model. Equation [2] gives the minimum conductivity based on a simple series conduction model. In both Eq. [1] and [2], k_s refers to the bulk conductivity of the separator material, and k_d refers to the conductivity of dry air. The volume fraction of the separator material is denoted by θ, hence $(1 - \theta)$ is the porosity of the material.

Table III gives the estimated maximum and minimum conductivities for the separators using Eq. [1] and [2], and assuming that the compressed porosity value given is correct. The arithmetic mean of the maximum and minimum values calculated is seen to correspond very well with the measured values for both the nylon and the polypropylene materials.

Pratt (5) gives a discussion of heat transmission in fibrous materials, and states that, for some materials in the density range 0.283-0.531 g/cm^3, the "geometric" mean, Eq. [3], of the bulk material and air gives good agreement with measured values

$$k_{mean} = k_s^{\theta} \times k_d^{(1-\theta)} \quad [3]$$

The densities for nylon (max calendering) and the polypropylene fall within the above density range (see Table II); therefore, using Eq. [3] with $\theta = 0.51$ and $\theta = 0.66$ for the nylon and polypropylene, respectively, the dry conductivity of the nylon is predicted to be 1.89×10^{-4} cgs units and that of the polypropylene to be 1.60×10^{-4} cgs units. These "geometric" mean values differ only slightly from the arithmetic means given in Table III.

In general, therefore, the conductivity of a dry, porous separator material can be predicted to a first approximation by taking the arithmetic mean of the limiting values calculated from Eq. [1] and [2], or the geometric mean from Eq. [3]. However, good agreement using Eq. [3] is said to occur only if the density lies in the range 0.283-0.531 g/cm^3. An average value from Eq. [1] and [2] implies that heat transfer is occurring by both parallel and series paths formed by the separator and air. Values of about 0.00055, 0.00026, and 0.000062 cgs units should be used for the conductivity of bulk nylon, polypropylene, and dry air.

Wetted separator materials.—When the separator materials are wetted with electrolyte, the apparent thermal conductivity increases but cannot exceed the conductivity of the electrolyte itself if convection effects are absent. The International Critical Tables (6) give values for the thermal conductivity of several KOH solutions of different strengths. Interpolation of these data yields a value of 0.00135 cgs units for 30% KOH, compared with a value of 0.00140-0.00145 cgs units for pure water. Therefore, for the particular electrolyte in question (30% KOH), the measured conductivity of any of the separator materials investigated is not expected to exceed about 0.00135 cgs units.

The apparent conductivity value obtained for a wetted separator will be some function of (*i*) the porosity of the material; (*ii*) the conductivity of the bulk separator material; (*iii*) the electrolyte conductivity and amount of electrolyte available for absorption by the separator; and (*iv*) the electrolyte absorption value of the separator material (Table IV). In most applications, the porosity, the electrolyte absorption value, and the conductivity of the separator materials will be invariant. For a given application the conductivity of the electrolyte is also invariant. Even in unsealed flooded cells or vented cells, where there is the possibility of carbonation of the electrolyte, the over-all conductivity of the electrolyte will not change much because the thermal conductivity of potassium

Polypropylene wettable paper		0.48	0.37

carbonate solutions is similar to that of hydroxide solutions (6).

Thus, for any given application, the thermal conductivity of the wetted separator is fixed for a given cell electrolyte content. If the separator materials are not saturated with electrolyte, there is the possibility that changes in electrolyte content (due to cycling, orientation, and so on) may change the apparent conductivity. Changes in internal cell pressure may be responsible for changes in separator electrolyte content. Such changes in pressure can result from gas evolution or from changes in the volume of active materials on cycling, for example. Forces acting on the electrodes in nickel-cadmium cells are known to be sufficient to buckle 0.058 cm electrodes because this has been observed during cell disassembly (7). Any change in the shape or volume of the electrodes could result in electrolyte being displaced from the separator, giving a lower apparent thermal conductivity. Migration of active materials into the separator would also result in the displacement of electrolyte.

For a maximum effective thermal conductivity, the separators should be saturated with electrolyte. In fabricating sealed cells where gas recombination is important, however, this may not always be desirable because a saturated separator impedes the diffusion of the oxygen evolved during cycling to the negative electrodes where recombination occurs. In practice, therefore, the actual separator electrolyte content must be a compromise between that dictated by good thermal design and that dictated by the chemistry and operating profile of the cell.

The electrolyte absorption capability of a separator material is defined as the quotient of the weight of electrolyte absorbed and the dry weight of the separator (8). The procedure given in Ref. (8) was used to determine the electrolyte absorption of the separator materials listed in Table II, and the results are given in Table IV. These data were required for the experiments to investigate the effect of separator wetting on thermal conductivity. The electrolyte absorption figure given in Table IV defines the amount of electrolyte (30% KOH) present in the uncompressed, saturated separator materials. It should be noted that this method of measurement is somewhat arbitrary because individual observers may use different criteria for the absence of excess electrolyte after wiping the saturated separator materials across the glass plate.

Table V lists the conductivity values obtained for the separator materials wetted to various extents with the 30% potassium hydroxide electrolyte. These data, when plotted in Fig. 1, show similarity in behavior between the nylon and the polypropylene materials. The thermal conductivity of these separator materials remains relatively small, compared with the conductivity of the electrolyte, until nearly all the pore volume is filled. As the pore volume becomes filled, and the possibility of excess electrolyte in the polyethylene bags used in the measurements exists, then the conductivity value obtained can vary appreciably according to whether or not the excess electrolyte can provide a thermal-short across or around the apparatus. If a thermal-short (continuous electrolyte path) exists, then conductivity values are obtained for the wetted

Table V. Thermal conductivities of various nonwoven separator materials as a function of electrolyte content

[c] For comparison the thermal conductivity of 30% KOH is taken as 0.00135 cgs units.

separators which more closely resemble that of the electrolyte alone (0.00135 cgs units).

The maximum thermal conductivity calculated from Eq. [1], assuming all the pores are filled with electrolyte, is 0.00063 cgs units for the polypropylene material and about 0.00094-0.00113 cgs units for the nylon materials. The corresponding minimum conductivities calculated from Eq. [2] are 0.00036 and 0.00077-0.00096 cgs units, for the polypropylene and maximum calendered and maximum loft nylons, respectively. If the arithmetic mean of k_{max} and k_{min} is taken for the expected measured conductivity, as was done for the dry separators, then the predicted values are 0.00050, and 0.00085-0.00105 cgs units. Inspection of Fig. 1 shows that the value obtained by extrapolation of the polypropylene data to 100% pores filled is 0.00057 cgs units. Similarly, extrapolation of the data for the two nylons gives values of 0.00080 and 0.00102 cgs units. Reasonable agreement, therefore, exists between the predicted and measured values for the saturated separator materials if a parallel-series conduction model is used which gives the arithmetic mean of Eq. [1] and [2] as the over-all conductivity.

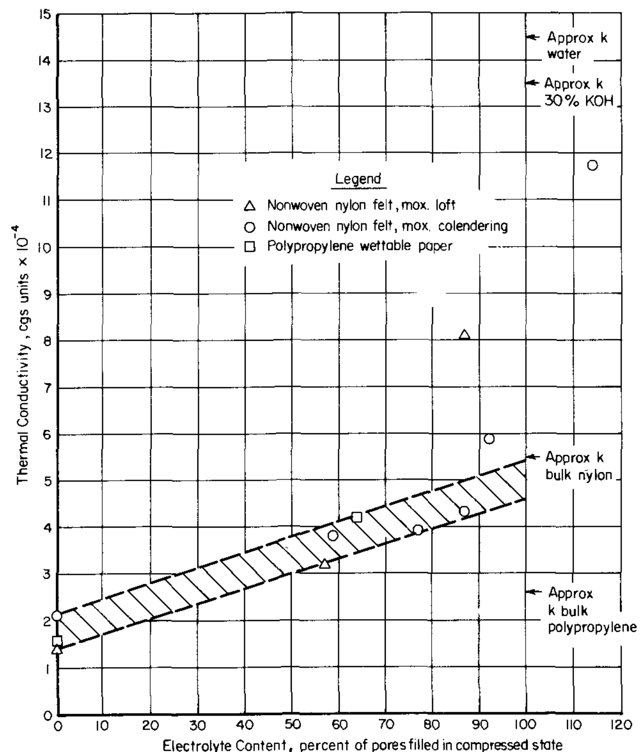

Fig. 1. Thermal conductivity of various separator materials as a function of electrolyte content.

Table VI. Calculation of tortuosity factor, *t*, for the wetted and dry separator materials

Material	Condition	Equation for tortuosity factor, t	t
Polypropylene wettable paper	Dry	$1.6 \times 10^{-4} = \frac{1.93 \times 10^{-4}}{t_1}$	$t_1 = 1.21$
	Wetted	$5.7 \times 10^{-4} = \frac{6.30 \times 10^{-4}}{t_2}$	$t_2 = 1.11$
Nylon felt, maximum calendering	Dry	$2.1 \times 10^{-4} = \frac{3.10 \times 10^{-4}}{t_3}$	$t_3 = 1.48$
	Wetted	$8.0 \times 10^{-4} = \frac{9.40 \times 10^{-4}}{t_4}$	$t_4 = 1.18$
Nylon felt, maximum loft	Dry	$1.4 \times 10^{-4} = \frac{1.99 \times 10^{-4}}{t_5}$	$t_5 = 1.42$
	Wetted	$10.2 \times 10^{-4} = \frac{11.3 \times 10^{-4}}{t_6}$	$t_6 = 1.11$

Another possible model for the thermal conductivity of separator materials is a collection of parallel pores having an unknown tortuosity factor. The tortuosity of both the wetted and dry separator materials should be identical for the same amount of compression, so that the measured conductivity would be equal to the calculated conductivity for the parallel mode from Eq. [1] divided by the tortuosity factor, t. Table VI gives the calculated values of t for the wetted and dry separator materials investigated. The calculations show reasonable agreement for the tortuosity of the wet and dry polypropylene material. The agreement is not as good for the nylon materials. However, as expected, the tortuosity factor for the felted nylon materials is greater than that of the less porous polypropylene material.

From another viewpoint, Krischer and Esdorn (9) summarize the four processes of heat transfer in a damp, porous or granular solid as follows: (*i*) heat transfer in the solid, k_s; (*ii*) heat transfer in the liquid, k_e; (*iii*) heat transfer by molecular conduction and as latent heat in air contained in pores with damp walls, $k_d + k_v$; (*iv*) molecular heat conduction in pores with dry walls, k_d. Krischer and Esdorn then constructed a model in which the above four processes were in parallel with each other; and then this network of parallel processes was in series with another network comprising each of the four processes above in series (5). While this model gave satisfactory agreement between theoretical and experimental values for certain lightweight concretes, it does not give good agreement for the wetted separator materials under consideration.

The separator materials under investigation must, therefore, be considered as consisting of fibers compacted together in a very open structure. In a discussion of the effect of moisture on the conductivity of porous insulating materials Joy proposed the following arrangements or models (10): (*i*) series arrangement—minimum conductivity with liquid located in layers perpendicular to the direction of heat flow; (*ii*) parallel arrangement—maximum conductivity with liquid forming continuous paths that bypass the less conducting air pockets; (*iii*) bead arrangement—liquid uniformly distributed through the material as small beads and considered as a dispersed phase; (*iv*) foam arrangement—material surrounded by liquid films which connect as in a foam so that liquid forms an irregular continuous phase. Joy found that the experimental data, when compared with the theoretical data, indicated the possibility of more than one of the above arrangements being applicable to a given amount of moisture. As discussed below, the present study indicates that one of two of the above arrangements probably predominates according to the electrolyte content of the separator material.

Joy's series arrangement (*i*) is thought not to apply as the predominant conductivity determining factor for separator materials. This is because there are no markedly planar surfaces in the separator material. Even if the electrolyte were concentrated at the separator/electrode interface (*i.e.*, under the action of thermal gradients (5) which are known to be small from the temperature differences observed in the conductivity measurements) a planar film need not be stable because of the capillary forces deriving from the porous electrode and separator material surfaces. Joy's bead arrangement (*iii*) is possible if the separator materials are not easily wettable and are relatively thick. Since the separator materials in this study are readily wettable, the existence of beads is unlikely. Thus the parallel arrangement, (*ii*), and the foam arrangement, (*iv*), appear most appropriate for describing the conductivity of wetted separators. These latter two arrangements appear to be related to each other in that the foam arrangement probably is more descriptive at low electrolyte contents, wherein pore walls are wetted while the parallel arrangement is more descriptive at higher electrolyte contents, wherein some, if not all, of the pores are completely filled. However, there is probably no well-defined transition between the two arrangements.

In summary, in sealed aerospace cells, because of the requirements for oxygen diffusion through the separator, the pores in the separator are probably only 60 to 80% filled with electrolyte. Therefore, Fig. 1 shows that a typical conductivity value for such a material is about 0.0004 cgs units.

Use of the measured conductivity data.—If the measured and calculated conductivity data from this work, namely:

Positive electrodes;	$k_x = 0.0014$ (measured)
	$k_y = 0.03$ (calculated)
Negative electrodes;	$k_x = 0.0020$ (measured)
	$k_y = 0.03$ (calculated)
Wetted separator;	$k_x = 0.0004$ (measured)
	$k_y = 0.0004$ (estimated)

are used in the thermal resistance networks for the four types of 20 A-hr nickel-cadmium cells described previously (1, 2), reasonable agreement is found between predicted and measured cell conductivities (2), as shown in Table VII. Knowing the dimensions of a cell and its components and their composition, it is now possible to calculate cell conductivities. Similarly, if the dimensions of a battery and its components, and their composition are known, then the heat transfer

Table VII. Predicted and measured cell conductivities

Cell type	k_x, cgs units		k_y, cgs units	
	Predicted	*Measured*	*Predicted*	*Measured*
I	0.0028	0.0027	0.0067	0.0071
II	0.0021	0.0038	0.0065	0.0067
III	0.0025	0.0026	0.0047	0.0056
IV	0.0024	0.0086	0.0036	

properties of that battery can be calculated and used to optimize thermal design.

Conclusions

To fill an apparent void in the literature, experimental thermal conductivity data have been obtained for discharged nickel hydroxide positive, and cadmium negative electrodes, and for three types of separator material considered for use in nickel-cadmium aerospace cells.

In the direction perpendicular to the plane of the electrodes the average value obtained for discharged positive electrodes is 0.0014 ± 0.0001 cgs units. The average value for discharged negative electrodes is 0.0020 ± 0.0001 cgs units. Measurements were not made in the parallel direction, but a calculated value of about 0.03 cgs units for the positives or negatives appears to be consistent with the measured and predicted cell conductivities.

The thermal conductivities of the three separator materials studied, nonwoven calendered and uncalendered nylon, and nonwoven polypropylene, are a function of the respective bulk conductivities, porosities, and electrolyte absorption values. The conductivity of a dry separator material may be estimated by taking the arithmetic mean of the values determined from Eq. [1] and [2] using values of 0.00055, 0.00026, and 0.000062 cgs units for the bulk conductivity of nylon, polypropylene, and dry air, respectively. Experimental values of 0.00014, 0.00021, and 0.00016 cgs units were obtained for dry noncalendered nylon felt about 72% porous after compression; dry calendered nylon felt about 49% porous after compression; and dry polypropylene wettable paper about 34% porous after compression, respectively.

As the electrolyte content of the separators is increased, the thermal conductivity increases up to about 0.0004 cgs units for a pore filling (60-80%) thought to be representative for sealed aerospace cells. The thermal conductivity of saturated separator materials (100% pores filled with electrolyte) can approach that of the electrolyte itself (0.00135 cgs units).

Effect of Chloride on the Anodic Dissolution of Titanium in Methanolic Solutions

E. P. Parry and D. H. Hern

North American Rockwell Science Center, Thousand Oaks, California 91360

ABSTRACT

A study of the polarographic characteristics of the Ti(IV)-Ti(III) couple in methanolic solutions containing various concentrations of HCl and LiCl has been the basis for the determination of the oxidation state of titanium during dissolution in these media. The Ti(IV) and Ti(III) complexes have been shown to have the same number of chloride ligands. It is also shown that titanium dissolves with an apparent oxidation number (n_{app}) between 3 and 4, with the value approaching 3 at high chloride concentrations. The acidity appears to have little effect at acidities greater than 0.10*M*. It is also shown that Ti(IV) in methanol solutions containing a high chloride ion concentration oxidizes Ti to form Ti(III). The nature of the complexes of titanium ion in solution and their effect on the titanium dissolution is discussed.

Considerable interest currently exists in the stress corrosion cracking mechanism of titanium and its alloys in methanol (1-4). However, very little is known about the chemistry of titanium dissolved in methanolic solutions. The importance of solution chemistry cannot be overlooked in mechanistic interpretations, and while electrochemical work has been reported (5, 6), very few studies about the nature of the titanium complexes present in solution have been made.

Studies of anodic dissolution of titanium have been reported. Thirsk and co-workers (7) have studied

Key words: oxidation state, polarography, solution formal potentials, solution equilibria.

the anodic dissolution of titanium in aqueous sulfuric acid solutions and have concluded, on the basis of some indirect evidence, that titanium is oxidized only to the +3 state during dissolution. On the other hand, Franz and Göhr (8) and Pourbaix (9) indicated that TiO_2 is formed when titanium dissolves anodically in aqueous sulfuric acid solutions which provides evidence that at least some Ti^{+4} is obtained. Franklin and Seklemian (10) have electrochemically oxidized titanium in a number of nonaqueous solvents with and without complexing agents present and have found oxidation numbers between 3 and 4. Johnson and Shreir (11) have found that in 3*M* $AlCl_3$ in diethyl ether titanium anodically dissolves to give Ti(III).

When titanium was chemically oxidized in various aqueous acids (*i.e.*, concentrated sulfuric, hydrochloric, hydrofluoric, and hydrochloric-acetic), Franklin and Seklemian found that Ti(III) is formed. Recent work by Harkins (12) showed that methanol vapor reacts directly with oxide free titanium to give $Ti(OCH_3)_4$.

Menzies and Averill (13) have studied the dissolution of titanium in anhydrous methanol solutions containing hydrogen chloride. They report that titanium dissolves with an oxidation state of 3.0 independent of chloride ion or hydrogen ion concentration, potential of the specimen, water content up to 1% and several other parameters. On the basis of the independence of the titanium oxidation state upon the chloride ion concentration, they postulated a dissolution reaction involving adsorption of chloride at the electrode surface.

In a program aimed at developing a better understanding of the role of solution chemistry in titanium corrosion and stress-corrosion cracking in methanol solutions, results for the anodic dissolution of titanium in methanol have been obtained which differ from those of Menzies and Averill (13). Preliminary results are presented here which suggest that the concentration of chloride ion is of considerable importance in determining the oxidation state of anodically dissolved titanium, and indicate the important role of chloride as a complexing agent.

Experimental

A multipurpose electrochemical instrument, using operational amplifiers designed and built in this laboratory, was used both for dissolution as well as for the electrochemical measurements. A glass cell was employed having a Teflon stopper, suitably bored for electrode access. Evaporated cryogenic nitrogen was used for oxygen purging after purification by passage through copper sponge in a tube furnace at approximately 400°C. The nitrogen was presaturated with methanol before bubbling into the cell containing the solution.

A low leakage, high-impedance aqueous saturated calomel electrode was used throughout this investigation. These electrodes have nominal leak rates of approximately 25 μliters/hr. For a 4 to 6 hr run, this changes the water and chloride content only by a negligible amount. For determination of oxidation states, the usual dropping mercury electrode (DME) having m and t values of 5.4 mg/sec and 7.05 sec, respectively, was used. In some cases, a Kemula hanging mercury drop electrode was employed. For the recording of polarization curves, a cell having a Luggin capillary placed within 2 mm of the specimen, was used. The anode and cathode compartments were not separated in this cell.

To integrate the current during potentiostatic runs to obtain the total coulombs, the voltage, measured by passing the current through a standard resistor, was integrated using a Vidar Model 241 (12470) voltage to frequency converter and a C.M.C. Model 726 BN counter. The titanium electrodes for dissolution were rods ¼ in. in diameter and 1 in. long, fitted into a Stern Makrides holder (14). The area of the electrode was 5.4 cm^2. Each electrode was degreased in boiling benzene for 5 min, then pickled in an acid mixture of 30% HNO_3-20% H_2SO_4-20% HF-H_2O for 30-45 sec. The electrode was then thoroughly washed in water, then in methanol, and inserted into the cell. Both Ti 75A and arc melted titanium specimens were used. The Ti 75A material has up to 4000 ppm of impurities, including about 2000 ppm of iron. The arc melted titanium has a typical analysis of less than 400 ppm of all metallic impurities.

Mallinkrodt "Nanograde" methyl alcohol was used without further purification or treatment. Analysis for water in this solvent gave values of approximately 0.02%. To make anhydrous acid solutions of methanol, anhydrous hydrogen chloride gas was passed into a given volume of methanol for a period of time to prepare a stock solution. Standardization of this solution was made by taking aliquots, diluting with water, and titrating with base. Subsequent solutions were made by appropriate dilution of this stock solution with methanol. Analysis of typical solution containing 0.02*M* HCl, showed a water content of approximately 0.05%. Reagent grade lithium chloride was added to some of the solutions to adjust the chloride concentration. Solutions were made both in which the salt was carefully dried just before use, as well as from the salt in the "as-received" condition from a freshly opened bottle.

The conductivity of the solutions of interest was determined by measuring the current and phase angle resulting from application of 1000 cycle a.c. to common conductivity cells, having cell constants near 0.4 or 0.01 depending on the conductivity measured.

The anhydrous stock titanium tetrachloride solution was prepared by adding reagent grade liquid $TiCl_4$ to an anhydrous methanol-0.1*M* hydrogen chloride solution slowly with stirring. The titanium content of the solution was then checked against the amount added by a complexometric titration (15). A back titration was performed, using cupric ion at *p*H of 5.5 and pyrocatechol violet as indicator.

In some experiments, the total titanium content of the solutions was determined using atomic absorption spectroscopy. The above standardized stock solution was used for calibration. To decrease ionization and, therefore, to increase sensitivity and linearity of the calibration plot, a large excess of alkali metal ion must be present. We found that sodium ion is better than the recommended potassium ion for this purpose.

Results

Because polarography is a convenient tool to monitor the titanium oxidation state upon dissolution, and may also yield information about the titanium ion complexes in solution, some discussion of the polarographic behavior of titanium ions in methanol-hydrogen chloride is desirable.

In HCl concentrations greater than 0.01*M*, titanium (IV) reduction to Ti(III) appears reversible by ordinary polarography. Reversibility was evaluated by the standard technique of using the slope of the E *vs.* log $i_d - i/i$ plot (0.059^{-1} V^{-1}) and by the fact that the reduction wave for the (IV) complex and oxidation wave of the (III) complex have the same half-wave potential. Additional work done with a stationary mercury drop electrode and a fast potential scan suggests that the electrode reaction for the Ti(IV)-Ti(III) couple in this medium may be quasi-reversible. With ordinary polarography, however, the wave can be considered to be reversible.

Figure 1 shows the polarographic wave for a solution which is $2 \times 10^{-4}M$ in Ti(IV) in a methanolic solution containing 0.01*M* HCl and 0.2*M* LiCl. The half-wave potential of the Ti(IV) reduction wave in this solution is −0.35V *vs.* SCE. The half-wave potential shifts approximately 18 mV in a positive direction with a tenfold increase in chloride content. This shift, however, is not corrected for ionic strength effects. The diffusion plateau is well-defined and the limiting current is

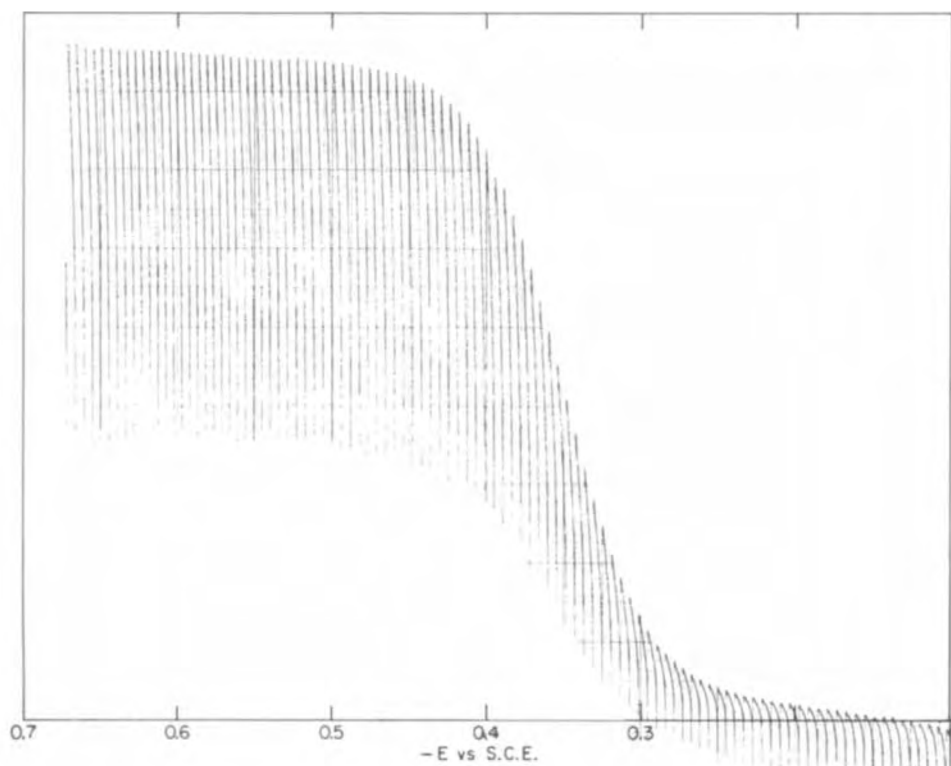

Fig. 1. Polarogram showing reduction of 2 x $10^{-4}M$ Ti(IV) in methanol solution containing 0.01*M* HCl and 0.20*M* LiCl.

diffusion controlled. Using the Ilkovic equation, the diffusion coefficient of the Ti(IV) complex is calculated to be 1.0×10^{-5} cm²/sec. The magnitude of the diffusion current is proportional to the concentration of Ti(IV) from 4 to at least 40 parts per million (ppm) Ti(IV). The temperature coefficient of the diffusion current is 3% per degree over the temperature range from 15° to 30°C.

The Ti(III) species is easily oxidized by air to the Ti(IV) complex. The diffusion coefficient of Ti(III) is more difficult to obtain using the Ilkovic equation because the Ti(III) salts available were partially air oxidized and did not completely dissolve in methanol, and so the concentration was not accurately known. In order to determine the diffusion coefficient of Ti(III), a polarogram of a solution containing a mixture of Ti(III) and Ti(IV), but where the Ti(III) wave was at least 80-90% of the total, was obtained. The total wave height [Ti(III) + Ti(IV)] was measured. The solution was air oxidized to give a solution of only Ti(IV), but where the total titanium concentration was the same. The diffusion current was again measured. Our experimental results showed that these total diffusion currents were the same. Such a technique becomes less precise the more Ti(IV) contamination in the originally measured solution. No mathematical evaluation of the accuracy which can be obtained by this method under these experimental conditions has been done. However, the reproducibility is about ±10% for the diffusion coefficient of Ti(III).

At acid concentrations smaller than 0.01*M*, the wave becomes irreversible. Addition of water to a 0.01*M*, HCl solution in methanol shifts the half-wave potential to more negative values (Fig. 2). Although at 5% water content the normal polarographic wave has the reversible slope, some unusual electrochemical behavior is noted. This will be discussed in more detail in a subsequent publication. Because of the well-defined nature of the wave, the ratio of Ti(IV) to Ti(III) in any solution can be determined readily from the polarographic wave. At potentials well anodic of the half-wave potential on the diffusion current plateau, where Ti(III) is oxidized, the concentration of Ti(III) can be determined. Similarly, at potentials cathodic of the half-wave potential on the diffusion plateau of Ti(IV) reduction, the concentration of Ti(IV) can be determined (see Fig. 3).

The apparent oxidation number (n_{app}) of the titanium species after anodic dissolution, for any mixture of Ti(IV) and Ti(IIII), can be obtained by application of the easily derived expression

$$n_{app} = \frac{3|i_{anod}| + 4|i_{cath}|}{|i_{anod}| + |i_{cath}|}$$

where $|i_{anod}|$ and $|i_{cath}|$ represent the absolute values of the anodic and cathodic diffusion currents, respectively. The polarographic technique can also be used to monitor the titanium oxidation state during the dissolution process. A direct measurement of the n_{app} values is thus possible which may be more precise than the coulometric technique. In this latter technique, because of the high oxidation state, a given relative error in the determination of total titanium concentration will cause a relative error four times as large in the n_{app} value.

To acquire some indication as to the effect of neglecting *IR* corrections in the medium, the conductivities of a methanol solution 0.02*M* in anhydrous HCl and one 0.02*M* in HCl, 0.48*M* in LiCl were measured. The conductivities were 2.1×10^{-3} and 1.3×10^{-2} ohm^{-1}

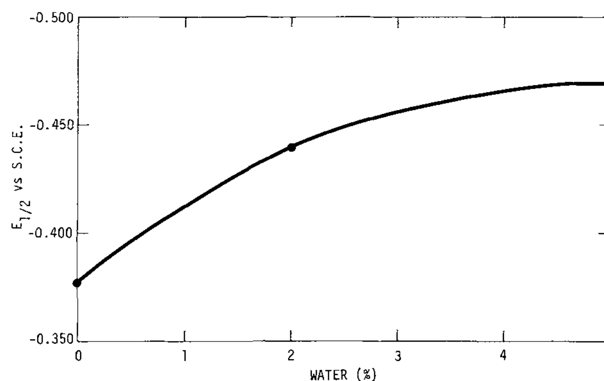

Fig. 2. Variation of normal polarographic half-wave potential with added water content in methanol solution containing 0.01*M* HCl.

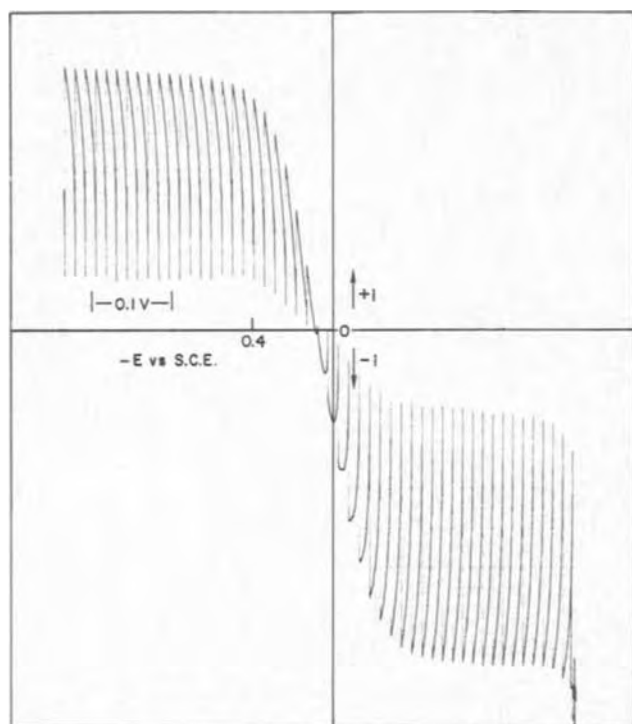

Fig. 3. Polarogram of solution after electrochemical dissolution of arc melted titanium specimen in methanol solution containing 0.02M HCl and 0.18M LiCl.

cm^{-1}, respectively. These values are both greater than would be found for an aqueous solution 0.01*M* in KCl.

After potentiostatic dissolution of a piece of arc melted titanium at −0.15V *vs.* SCE in a methanol solution containing 0.18*M* LiCl and 0.02*M* anhydrous HCl, the solution gave the polarographic behavior shown in Fig. 3. In this dissolution experiment, anodic and cathodic compartments were not separated. Both titanium (III) and (IV) species are formed upon dissolution. The $E_{1/2}$ value for the mixed polarographic wave is the same as that found for a solution where Ti(IV) was directly dissolved in another portion of this methanol-chloride medium. The same polarographic behavior and ratio of cathodic and anodic wave heights were obtained both when the indicator electrode (DME) was put directly into the cell in which the titanium was being dissolved (*in situ* technique), and when the polarographic measurement was made on an aliquot of the dissolution solution placed in a separate cell.

Although Ti(III) is very sensitive to air oxidation, it was shown that partial oxidation did not cause the mixture of oxidation states. After oxygen removal, it was found that the Ti(IV)/Ti(III) ratio was independent of time of purging, indicating no oxidation was caused by oxygen impurity in the purging gas. Moreover, simple calculations show that the amount of

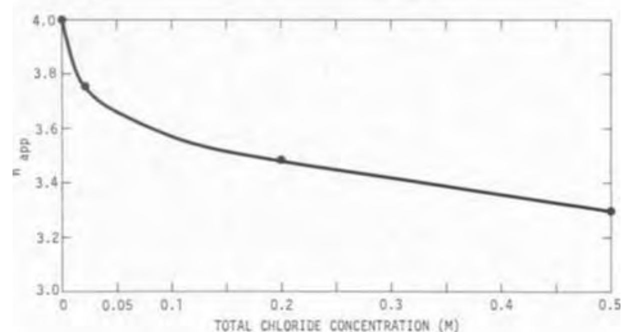

Fig. 4. Effect of chloride ion concentration on apparent oxidation number for electrochemical dissolution of titanium in methanol solutions.

oxygen which was found in the nitrogen after purification (1 ppm or less) was not sufficient to account for the oxidation.

In this same dissolution experiment, the coulombs expended were measured and the total concentration of titanium was determined using atomic absorption spectroscopy. After passing 58 coulombs and dissolving 0.166 moles of Ti, an average n_{app} value for the titanium in the solution was found to be 3.60. The polarographic data gave a value of 3.44. In other experiments, similar differences were found between coulometric and polarographic results with the polarographic result generally being lower. The reason for this discrepancy is not completely understood at present, but may be caused by less than 100% current efficiency in the oxidation process.

The *in situ* polarographic technique was used to determine the average oxidation state (n_{app} values) of titanium after dissolution at constant potential in solutions containing various concentrations of chloride. The results are given in Table I. The value of n_{app} is shown as a function of chloride ion concentration in Fig. 4. Dissolution in the absence of chloride was performed in 0.02*N* sulfuric acid in methanol. All data were obtained in a cell in which the cathodic and anodic compartments were separated by a glass frit. However, results for the oxidation state were the same for a cell with or without separated compartments. Both Ti 75A and arc melted titanium specimens gave similar results. The value of n_{app} also appears to be independent of electrode condition (*i.e.*, whether cold worked or annealed).

Results indicating the effect of acid concentration at constant chloride concentration are shown in Fig. 5. The results suggest that acidity has little effect on the n_{app} values, particularly at acid concentrations greater than 0.1*M*.

If a piece of titanium is placed into methanol containing 0.1*M* $TiCl_4$-0.48*M* LiCl-0.02*M* anhydrous HCl, a reaction occurs in which Ti(III) is formed. The titanium metal and Ti(IV) react according to

Table I. Effective n_{app} number for electrochemically oxidized titanium

Run	Medium	n_{app}	Electrode	Potential (V *vs.* SCE)	Remarks

$$3Ti(IV) + Ti \rightleftharpoons 4Ti(III)$$

Arc melted titanium, Ti 75A, Ti-6Al-4V, and Ti 50A have all, in time, shown significant reaction. With Ti 75A, Ti-6Al-4V, and others, the effective η_{app} number of the titanium in solution, after several hours reaction, is approximately 3.1, indicating that the reaction goes to the right almost completely. The high concentration of chloride appears to be essential to this reaction. At considerably lower concentrations of chloride and of Ti(IV), the reaction either does not go or was too slow for our observation (8 hr). While all titanium specimens tried underwent this reaction in time, the rate of the reaction varied considerably. A specimen of Ti 75A which was not annealed after machining and only moderately etched in the HNO_3-H_2SO_4-HF mixture, underwent rather rapid reaction, generating considerable blue color within 1 hr. On the other hand, an arc melted specimen, which was not annealed, but was etched the same way, appeared not to react. When the unannealed specimen was heavily etched in the etchant (10 min or longer), it would react. An arc melted specimen which was annealed, but only very lightly etched, reacted, but very slowly (color appears after 4 to 5 hr). The rate of the reaction appears to have a rather complex dependency on the oxide film on the specimen, surface cold work, and perhaps on the microstructure of the alloy. Experiments are planned to elucidate the important parameters in this reaction.

During both chemical and electrochemical dissolution with an active electrode, it was found that a black deposit formed on the electrode or flaked off into solution. The amount increased with time. This material was identified as α-Ti by x-ray diffraction as also found by Menzies and Averill (13).

In the initial work involving both electrochemical and chemical dissolution in the presence of lithium chloride, no special effort was made to dry the presumably anhydrous salt from a freshly opened bottle, since it was reported previously, by Menzies and Averill (13) that a water content less than 1% in methanol-HCl solutions "did not affect the oxidation state, the amount or nature of disintegration product, or the surface features of the titanium specimen after dissolution." However, Mansfeld (6) showed subsequently that as little as 0.6% water gives rise to a passive region in the titanium polarization curve in a methanol-HCl solution. The use of lithium chloride, that was not carefully dried and handled, gave solutions which contained from 0.3 to 0.5% water, as determined by a Karl Fischer titration. The n_{app} value obtained with these solutions was the same as that obtained in a solution containing 0.02-0.04% water, in agreement with the findings of Menzies and Averill. However, contrary to their data, we found that upon using the initial solutions wherein approximately 0.5% water was present in the methanol solution which contained 0.02*M* HCl and 0.48*M* LiCl, the electrode showed rather severe pitting after both chemical and electrochemical dissolution. The pits, micrographs of which are shown in Fig. 6 and 7, are typical of the classical pits formed by localized attack on a passive surface. The potential of the specimen in both methods of dissolution was more noble than the pitting potential [see Mansfeld (6)]. The potential of the specimens during dissolution in the work of Menzies and Averill was not specified, since they used galvanostatic techniques.

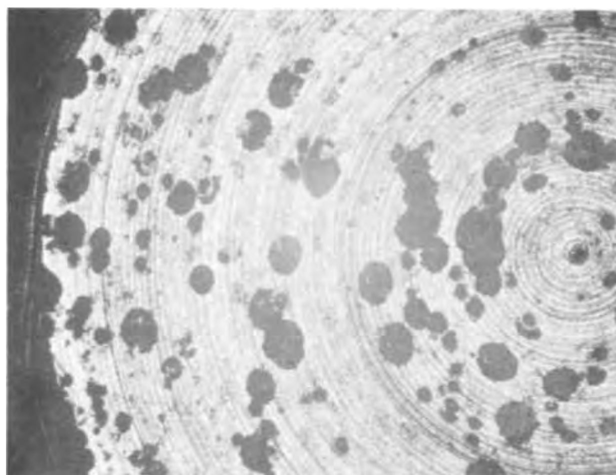

Fig. 6. Micrograph showing Ti-6A-4V specimen after 72 hr contact with methanol solution containing 0.1*M* $TiCl_4$, 0.02*M* HCl and 0.48*M* LiCl, water content about 0.5%. Magnification 32X.

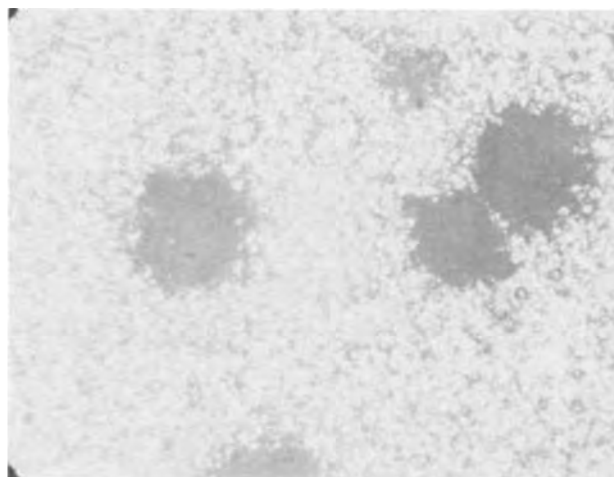

Fig. 7. Micrograph showing Ti 75A specimen after 17.5 hr electrochemical dissolution at —0.15V in methanol solution containing 0.02*M* HCl and 0.48*M* LiCl, water content about 0.5%. Magnification 100X.

Discussion

Even though methanol has a fairly low dielectric constant (32.6), it is still a relatively good ionizing solvent (16). Thus 0.01*M* HCl is about 85% ionized in methanol. It can also be shown by consideration of the autoprotolysis constant of methanol, that the concentration of methoxide ion is much too small to be considered as a significant ligand for the Ti species. The important ligands for both Ti(IV) and Ti(III) species, therefore, consist of chloride, water (where present), and methanol, as shown below.

The polarographic behavior gives a reasonable amount of information concerning the nature of titanium complexes. For a reversible polarographic wave, the difference in the number of ligands attached to the ions of higher and lower oxidation states can be obtained. Thus, for a reaction

$$ML_p + ae \rightleftharpoons ML_q + (p - q)L^{-b}$$

the half-wave potential of the polarographic wave, as a function of the ligand concentration, C_L, would be given by (17)

$$E_{1/2} = E^{01} - \frac{(p-q)}{a} 0.0591 \log C_L$$

where E^{01} is a term involving both the formal potential (E'_o) of the reaction, and the diffusion coefficients of oxidized and reduced species. In the above reaction, the charge on the complex ions is omitted for simplicity. If, in the reduction of a chloro complex of Ti(IV) to a chloro complex of Ti(III), $(p - q)$ is 1 [*i.e.*, if the Ti(III) complex has one less chloride than the Ti(IV) complex], the half-wave potential should shift by 60 mV per decade change in chloride ion concentration. If the difference in the number of chloride ligands between the Ti(IV) and Ti(III) species were even greater, then a proportionately greater shift would occur. Since the experimental shift of half-wave potential per decade change in chloride ion concentration was found to be 18 mV, it indicates that either polymeric titanium species are present in the solution and involved in the electrode reaction, or the small shift is caused by a change of the ionic strength of the solution with increased chloride ion concentration. Because the diffusion coefficients obtained for titanium (IV) and (III) ions in methanol are very close to those found for typical ions in aqueous solution (*e.g.*, PJ^{++} in $0.1M$ KCl: $D = 0.98 \times 10^{-5}$ cm^2/sec), polymerization does not seem likely. The small shifts obtained are typical of ionic strength effects and, although experiments would have been desirable at constant ionic strength, the likelihood is great that the change in ionic strength is responsible for the small shift in half-wave potential that is noted. Thus, it is concluded that the Ti(IV) and Ti(III) complexes in these solutions have the same number of chloride ligands.

Both Ti(IV) and Ti(III) are octahedral and have sixfold coordination. The six ligand positions are either occupied by chloride ion or solvent. From the above rationale, we know that both Ti(III) and Ti(IV) have the same number of chloride ligands, but we are unable to say if all ligands are chloride or only some chloride ions are present, with solvent molecules playing an important role in the coordination sphere. The fact that methanol is a strong base towards first row transition metals [as shown by a number of previous studies (18)] suggests that methanol could compete quite successfully with chloride ion as a coordinating ligand. We thus speculate that both titanium species have methanol and chloride ion coordinated in the complex in the "anhydrous" solutions, but the data we have available at present do not permit detailed elucidation of the nature of the titanium species.

Because both Ti(IV) and Ti(III) have the same number of chloride ligands, the reaction representing the polarographic reduction can be written as

$$TiCl_x^{4-x} + e \rightleftharpoons TiCl_x^{3-x}$$

The reversible polarographic half-wave potential in a given medium gives the formal potential for the above reaction, since the diffusion coefficients are the same (18). This value has been shown to be -0.35V in a methanolic solution containing $0.02M$ HCl and $0.18M$ LiCl. If we now consider the reactions in a solution of ionic strength of 0.2 (neglecting coordinating solvent molecules), we have

	E'_O
(a) $Ti + xCl^- \rightleftharpoons TiCl_x^{3-x} + 3e$	E'_O (a)
(b) $Ti + xCl^- \rightleftharpoons TiCl_x^{4-x} + 4e$	E'_O (b)
(c) $TiCl_x^{3-x} \rightleftharpoons TiCl_x^{4-x} + e$	-0.350

We can now calculate an expression relating the formal potentials for reactions (a) and (b) from the formal potential of reaction (c). Such calculations require that the free energies be used. Thus, we have

$$\Delta F_{(c)} = \Delta F_{(b)} - \Delta F_{(a)}$$

where $\Delta F = (-nFE'_O)$. Substitution of the appropriate values of n and solving we obtain the expression

$$E'_{O(b)} = -\frac{0.350}{4} + \tfrac{3}{4} E'_{O(a)} \text{ (volt)}$$

which gives the relationship between the formal potentials of the reactions (a) and (b). This indicates a very small difference between the formal potentials of reactions (a) and (b). For example, if $E'_{O(a)}$ were -0.500V, $E'_{O(b)}$ would equal -0.463V. This suggests an explanation for the mixture of oxidation states found in the dissolution experiments.

As described earlier, the reaction

$$\text{(d)}\quad 3Ti(IV) + Ti \rightleftharpoons 4Ti(III)$$

has been shown to occur and to go nearly to completion. Because the same number of chloride ions are found in the Ti(IV) and Ti(III) complexes, the equation representing the observed oxidation of titanium by titanium tetrachloride can be written

$$\text{(e)}\quad 3TiCl_x^{4-x} + Ti + xCl^- \rightleftharpoons 4TiCl_x^{3-x}$$

Inspection of this equation suggests the reason for requiring large concentrations of chloride ion and Ti(IV) for the reaction to go from left to right. Consideration of the two half-reactions

$$\text{(f)}\quad Ti + xCl^- \rightarrow TiCl_x^{3-x} + 3e$$

$$\text{(g)}\quad TiCl_x^{3-x} \rightarrow TiCl_x^{4-x} + e$$

which comprise reaction (e), and recognizing that the free energy for reaction (e) is considerably negative, we determine that the formal potential of reaction (f) is significantly more negative than -0.350V. However, with the data available we are unable to specify the value of the formal potential of this half-reaction.

The change in n_{app} value with chloride ion concentration seems unusual, since both the Ti(III) and Ti(IV) complexes contain the same number of chloride ligands. However, half-reactions (a) and (b) (see above) have different dependencies on the chloride ion concentration, as can be seen by consideration of the Nernst expression for the two half-reactions

$$E = E'_{O(a)} + \frac{0.06}{3} \log \frac{[TiCl_x^{3-x}]}{[Cl^-]^x} \quad \text{(volts)}$$

and

$$E = E'_{O(b)} + \frac{0.06}{4} \log \frac{[TiCl_x^{4-x}]}{[Cl^-]^x} \quad \text{(volt)}$$

In addition, because of the different charge on the complex ion, these expressions will also be affected differently by ionic strength.

While the Ti(IV)-Ti(III) couple is polarographically reversible, the dissolution of titanium is an activated process where the kinetics of the processes must be considered as well as the thermodynamics. The independence of the n_{app} value over a wide potential range was not evaluated, but the data (see Table I) do not indicate any significant dependence over a limited potential range. This would suggest that the log current-voltage curves for oxidation of Ti to the Ti(III) and Ti(IV) states, respectively, are essentially parallel over the potential range covered.

It has been generally assumed for titanium oxidation in aqueous sulfuric acid media, that titanium dissolves to give Ti(III) from an active surface and Ti(IV) from a passive surface (19) although there is no agreement on this point (7). Our data indicate that in methanol solutions containing chloride, the apparent oxidation number is independent of whether the electrode actively dissolves or dissolves under passive conditions where pitting occurs. For example, comparison of runs 5 and 6 with 7 shows that no significant difference is found in the n_{app} values for an electrode where extensive pitting occurred (runs 5 and 6), and where only

active dissolution was found (run 7). For solutions having the composition of run 12, a significant passive region exists (6) where pitting occurs, with the ratio of passive dissolution to dissolution by pitting estimated to be smaller than 1 to 100. Under these conditions, the n_{app} value is consistent with that which would be found under comparable conditions with an active electrode (compare run 12 and Fig. 4).

The use of the *in situ* technique might raise the question as to the effect of the presence of mercury in the solution on the dissolution process. It should be pointed out that mercury metal does not come directly in contact with the titanium specimen during the dissolution experiment. Thus, no alloy effect is possible. Moreover because the reversible potential of the Ti(IV-III) couple is more negative than mercury dissolution in this medium, the oxidation of mercury metal by Ti(IV) is thermodynamically unreasonable. No other reactions would appear to be feasible. Added evidence is found in the observation that the *in situ* determination of n_{app} during dissolution and the determination of n_{app} on a separate aliquot gave the same value within experimental error, although it was more difficult to prevent air oxidation upon removal of a separate aliquot.

The results reported here for the dissolution valence of titanium are not in agreement with those of Menzies and Averill (13) (M&A). Their data indicate that titanium dissolves with a valence of three independent of chloride ion, hydrogen ion, water content to 1%, etc. However, these results are in general agreement with those of Franklin and Seklemain (10) where titanium was electrochemically dissolved in a number of nonaqueous solvents to give an oxidation number between three and four (although methanol was not specifically studied).

To resolve unequivocally the difference in results between this work and that of M&A is not possible at this time because details of their experiments are not given. However, it is possible, based on their data, to indicate what the probable differences are. It does not appear to be caused by differences in water content, rate of stirring or small differences in the experimental set-up. Their analytical technique for determination of Ti is not described in sufficient detail to evaluate. Careful examination of their paper indicates that the biggest and most consistent difference between this work and that of M&A is the total coulombs passed. They used a galvanostatic technique and passed 900 coulombs. Their cell volume is not given but purely from inspection of the figure, it can be assumed to be about 50 ml. Under these conditions they would have slightly over $0.06M$ Ti in solution after the dissolution. As shown above, at this concentration of Ti(IV) a reaction with the Ti metal to give Ti(III) appears possible, particularly if the solution stood with the electrode in place after being exposed to air following dissolution. This reaction would lower the value of n. Such a hypothesis needs to be tested.

Our results indicate that the oxidation state is highly dependent on the complexation of the titanium ions. Thus, the dissolution process is influenced significantly by the type and nature of the complex ions in solution. The electrochemical behavior of titanium in various nonaqueous media and its passivation characteristics are of considerable current interest. While it cannot be denied that short-lived intermediates and surface reactions play a vital role in the metal dissolution behavior and passivation processes, the bulk properties and the electrochemical behavior of soluble couples may be of importance. We have, for example, some very preliminary indication at the present time that the presence of small amounts of water in these HCl methanol solutions gives rise to an additional Ti(III) species which appears short-lived. Because titanium begins to passivate in this medium with small amounts of water present, the formation of this different species may be related. Solution chemistry and the nature of both short- and long-lived species during metal dissolution may thus be of importance, not only in understanding passive behavior, but also stress-corrosion cracking.

Acknowledgment

The authors express their thanks to Drs. F. Mansfeld and I. Goldberg for many helpful discussions during this study.

Anodic Dissolution and Selective Etching of Gallium Phosphide

R. L. Meek* and N. E. Schumaker

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Current voltage curves and the effective dissolution valence have been determined for GaP electrodes in 3*N* NaOH solution. At electrode potentials of a few volts the current density for p-type ($N_A \sim 4(10)^{17} \cdot cm^{-3}$) is a factor of 10^4 greater than for n-type ($N_D \sim 4(10)^{17}$ cm^{-3}) electrodes. This difference allows selective removal of p material from p-n structures. Application of this selective etching to the fabrication of mesa structures for GaP light emitting diodes, and to junction delineation, is discussed. At large current densities, 6 charges are transferred per dissolved GaP molecule in distinction to the 3 transferred charges found previously in alkaline solution at low (< 2mA cm^{-2}) current densities.

As III-V compound semiconductor device technology is advanced, it becomes desirable to apply some of the electrochemical processing and evaluation techniques which have proven useful for silicon and germanium (1-3) to those materials. The present paper discusses anodic dissolution and selective etching of gallium phosphide.

In comparison to germanium and silicon, the electrochemistry of the III-V compounds has not been widely studied. The occurrence and nature of surface films (4, 5) and the morphology of the etched surface (5, 6) have been determined for InSb. Several authors have discussed the electrochemistry (7-12) and Nuese and Gannon have described selective etching (13) of GaAs. Memming (14, 15) has studied GaP, but not at the rather large anodic current densities desired for etching and shaping operations.

Experimental

Current density-potential relations were determined in the apparatus of Fig. 1. The electrolyte was 3*N* aqueous NaOH maintained at 20°C although the exact temperature is not critical. Measurements were made in the dark and potentials are relative to the saturated calomel reference electrode. The samples were of (111) orientation, and both the Ga (111) and P-($\bar{1}\bar{1}\bar{1}$) faces were studied. The faces were distinguished by their chemical etching characteristics in Cl_2 saturated methanol. This and equivalent techniques are ultimately traceable to x-ray evidence. N-type samples were Se doped and p-type samples were Zn doped to a level of about $4(10)^{17}$ cm^{-3} and were cut from LEC (Liquid Encapsulated Czochralski) pulled ingots. Ohmic contacts on p-type (n-type) were prepared by evaporating and alloying gold containing 1% Be (2% Si). Surfaces were chemically or mechanically polished, as applicable, before use as electrodes. The number of electronic charges passing through the external circuit per dissolved atom was determined by integrating the current for a certain time and measuring the weight loss with a microbalance.

Results

Current density *vs.* potential data are summarized in Fig. 2. As expected, n-type ($N_D = 3.5(10)^{17}$ cm^{-3}) shows current saturation. The value is about 20 μA cm^{-2}. The p-type material of about the same doping level, $N_A = 4.4(10)^{17}$ cm^{-3}, is readily dissolved and large currents ($\sim$100 mA cm^{-2}) are drawn at a few volts.

For both n- and p-type the rest potential is more positive for the Ga face. This is in line with Gatos' (6) observation that the (111) face of III-V compounds is less reactive than the ($\bar{1}\bar{1}\bar{1}$) face. The J-V curves cross, however, somewhere below the lowest current densities measured. This simply shows that the potential drop across the interface, including both the semiconductor and electrolyte space charge potentials, is different for the two surfaces. Since the arrangement of surface atoms is manifestly different (6), this is not unexpected and depends on the details of the kinetics involved. Below about 0.5 mA/cm^2 the data follow a Tafel slope of about 90 mV/decade (see insert in Fig. 2), rather different from the 120 mV/decade found by Memming and Schwandt (14). It is not wise to attach too much significance to such a Tafel slope since it is the slope on a plot of surface potential *vs.* current density which determines the surface carrier concentration. The electrode potential also includes the (variable) Helmholtz potential.

It is seen that, for p-type, the Ga face draws a larger current density at a given electrode potential than does the P-face. Note that plotting current den-

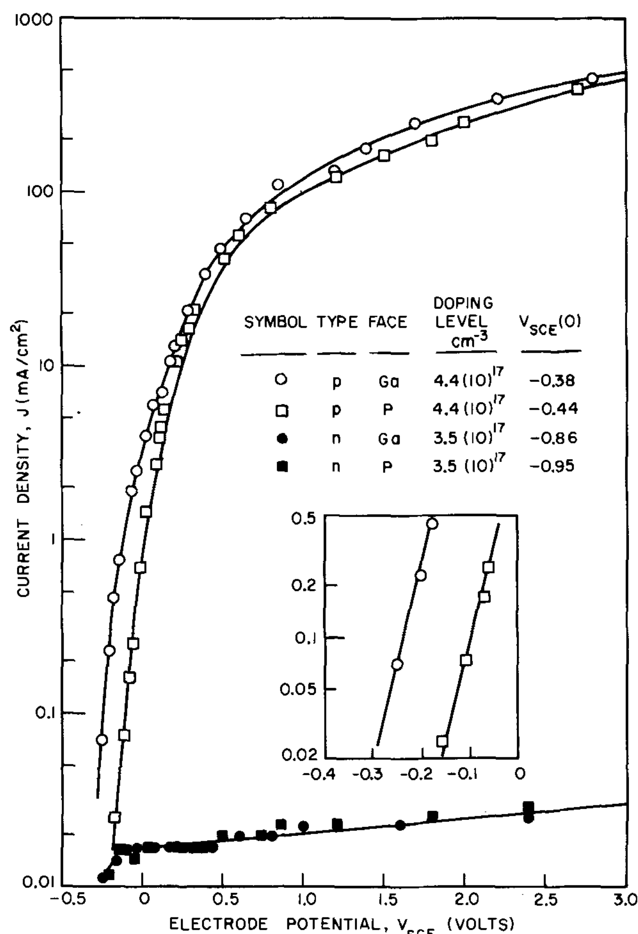

Fig. 2. Current density vs. electrode potential for n- and p-type gallium phosphide electrodes in 3N NaOH.

sity using rest potential as the arbitrary zero does not remove this difference but rather accentuates it. The rest potential is likely not the reversible potential, but rather a corrosion potential and is itself dependent on kinetic considerations.

The data plotted are for situations where no surface film growth is taking place. This is no problem on the P-surface where no film formation and consequent dropoff of current with time is observed. On the Ga face, however, above about 1 mA/cm^2 a film formation is observed and the current decreases by a factor of two in a few tens of minutes unless the nitrogen bubbler is implemented as shown in Fig. 1. An intense stream of bubbles is directed onto the electrode so that the solution is vigorously agitated near the electrode. (For the P-face the current is completely independent of whether the bubbler is on or off.) These observations suggest that the reaction on the Ga face is mass transfer limited. It is known that sparingly soluble $Ga(OH)_3$, or perhaps hydrated Ga_2O_3, is one of the dissolution products (14) so it is expected that a film will form to such a thickness that electrochemical oxidation and dissolution of the oxidation product are balanced. Vigorous agitation reduces the mass transfer boundary layer thickness and allows dissolution of the film. The data presented are well into the range where more intense agitation produces no change in steady current density. It is not at present clear why no film tends to form on the P-face, but it is no doubt related to differences in the detailed reaction paths for the two surfaces. Straumanis *et al.* (9) have also observed that on GaAs a thicker film of $Ga(OH)_3$ is formed on the Ga face than on the As face.

There is also a difference in structure of the surfaces produced as shown in Fig. 3. The Ga surface has an "orange peel" texture while the P-face is smoothly polished. The features apparent on the P-face are similar to those observed after etching or polishing by other methods and are likely due to bulk crystal defects. The difference in surface roughness is probably sufficient to produce agreement between current density-voltage curves on the two faces at large current densities.

An effective dissolution valence, or electron number, may be defined as the number of electronic charges passing through the external circuit per dissolved atom. The data determined from integrated current and weight loss measurements are plotted in Fig. 4. It is seen that at least for current densities greater than 50 mA/cm^2 the effective valence is 3; that is, 6 charges per GaP molecule, which is consistent with the supposition that a Ga atom and a P atom dissolve as a unit as suggested by Gerischer (16) for GaAs. However, it is very difficult to explain the film formation on the Ga, but not the P-face in terms of such a model of dissolution.

Gerisher (10) has shown that GaAs is oxidized with the consumption of 6 holes to Ga^{3+} and As^{3+}. Any contribution due to conduction band charge transfer is less than 0.1% of the total (11). Memming and Schwandt (14) conclude that, for GaP, dissolution is almost all (90+) per cent by holes. Here it will be assumed that only holes are involved.

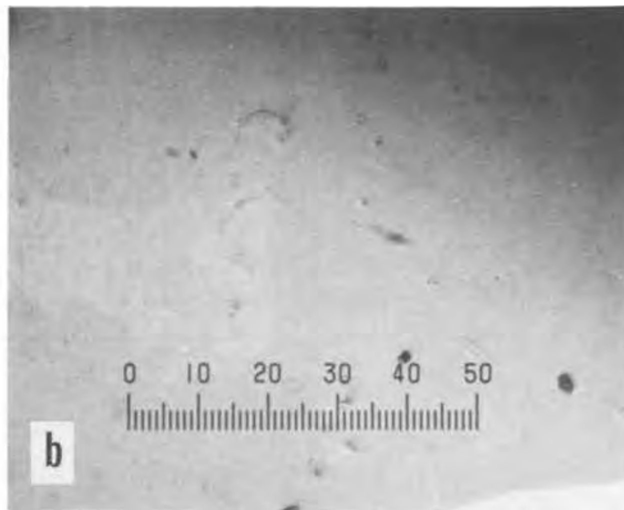

Fig. 3. Photomicrographs of electroetched surfaces after several minutes at $J \sim 200$ mA/cm^2: a, gallium face; b, phosphorus face ($10 = 100\mu$.).

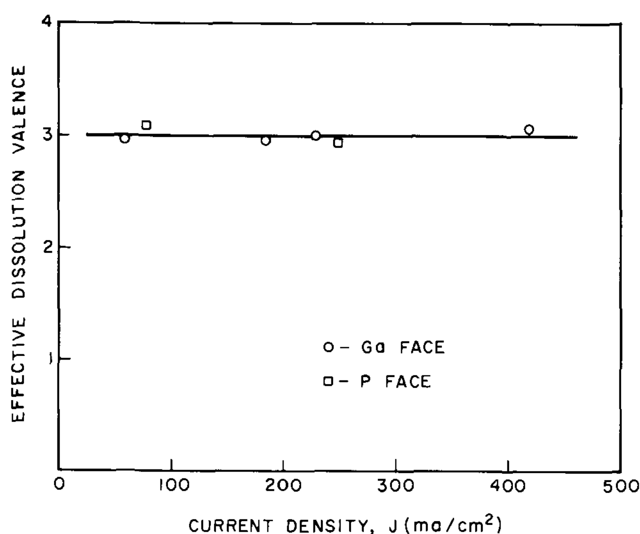

Fig. 4. Effective dissolution valence (or electron number) vs. current density. Symbol size is indicative of experimental uncertainty.

However, Memming and Schwandt (14) found that only 3 charges were transferred per GaP molecule in alkaline solution although 6 were involved in acid solution. Their measurements were based on colorimetric analysis of the solution and were for $J < 2$ mA/cm^2. They write the over-all reactions as (14)

$$GaP + 3H_2O + 6e^+ \rightarrow Ga^{3+} + H_3PO_3 + 3H^+ \quad [1]$$

in acid, and

$$GaP + 4\,OH^- + 3e^+ \rightarrow GaO_2^- + P + 2H_2O \quad [2]$$

in alkali. Presumably these are followed by reactions further oxidizing the phosphorus since the phosphorus is found as $PO_4^{\equiv}$ in either case. Ring-disk studies are in progress in an attempt to identify reaction products (see Appendix).

The fact that, in the present determinations, 6 rather than 3 charges are transferred per GaP molecule implies that some at present unknown reaction replaces Eq. [2]. The change from 3 to 6 cannot be explained on the basis of OH^- depletion at the electrode surface (and consequent reversion to Eq. [1]) since the limiting current for that to occur is expected to be several A cm^{-2}.

Selective Etching

It is seen from Fig. 2 that at potentials of two or three volts an etch rate ratio of $\sim 10^4$ exists between p- and n-type GaP doped to $\sim 4(10)^{17}$ cm^{-3}. This presents the possibility of selectively removing p-material from p-n structures. The p-n configuration is satisfactory for GaP since the diffusion length for holes is short and injection of holes from p to n and consequent dissolution of the n is unimportant. In silicon, where the diffusion length may be of the order of tenths of millimeters, this is a serious limitation (17) and it is in fact rather difficult to remove p from n without extensive etching of the n.

The samples used were liquid phase epitaxial Zn,O doped p-type layers grown on the (111) P-face of n-type substrates. The doping levels were near those for the bulk samples used for J-V determinations. The samples were waxed down to a sapphire plate with p-side up, that is away from the plate, and an evaporated ohmic contact was provided near one edge of the slice. A constant potential source was used and the p-type layer selectively stripped off by lowering the wafer into solution using the same apparatus, which lowers the sample into the solution at a controllable rate, as has been used for similar silicon work described elsewhere [see Fig. 2 and 3 in Ref. (17)].

Junction delineation.—The selective removal of the p-type layer represents an effective means for revealing the p-n interface in a fashion previously unavailable in the study of GaP. Lowering the GaP wafer into solution generates a wedge of p-type GaP with a sharply defined leading edge at the p-n junction as shown in Fig. 5a. This photomicrograph clearly shows the sharp delineation of the p-n interface and also reveals the surface structure of the n-type layer upon which the p-type layer was grown. Vapor etching of the n-layer, or partial dissolution before regrowth, may account for the rough surface exposed.

In addition, Fig. 5a shows gross striations in the p-layer which run parallel to the p-n junction. Higher magnification of the p-n junction region (Fig. 5b) reveals a multitude of small defect structures within 1-3 μm of the actual junction; and we expect that this etching technique will be a valuable tool for defect study and identification.

The nature and cause of the striations and defects revealed by this etching are not understood at the present time. However, the presence of these defects may be expected to have a deleterious effect on device performance and reliability.

Mesa formation for light emitting diodes.—Fabrication of the quasi-planar beam-lead GaP diode requires the formation of isolated p-type mesas from the zinc and oxygen doped p-layer (18). Presently this involves careful control of the p-layer thickness and subsequent chemical etching for times calculated from known etch rates to achieve the desired mesas (19). The preparation of the p-layer is laborious and is necessitated by the limitations of the current GaP liquid-phase epitaxy growth technology which results in nonuniform layers. The use of selective removal of the p-layer by electrochemical etching is an attractive alternative method of mesa formation which, because of its self-limiting nature, should reduce the requirements on layer thickness uniformity.

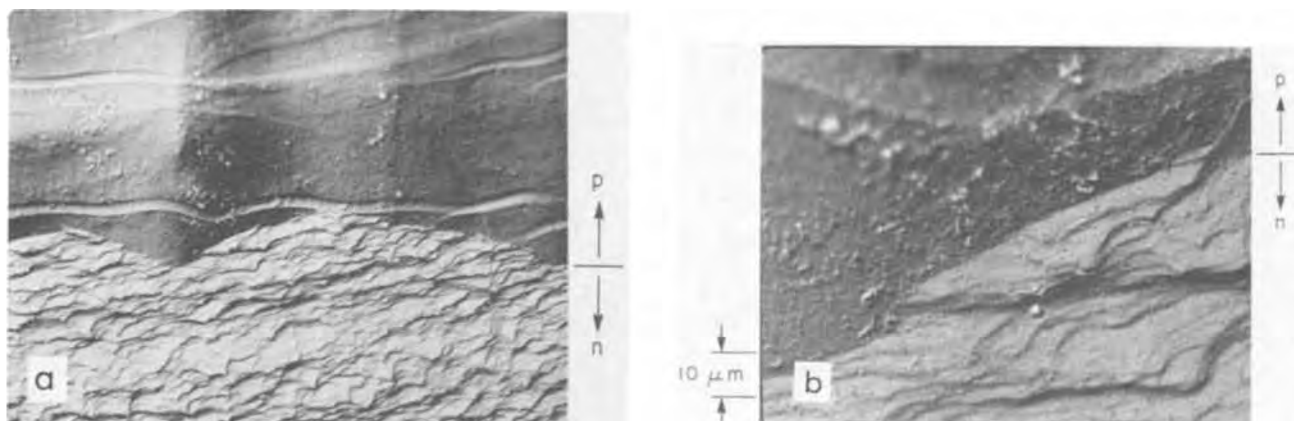

Fig. 5. Sample from which the p-epitaxial layer has been partially removed: a, 160X; b, 1000X.

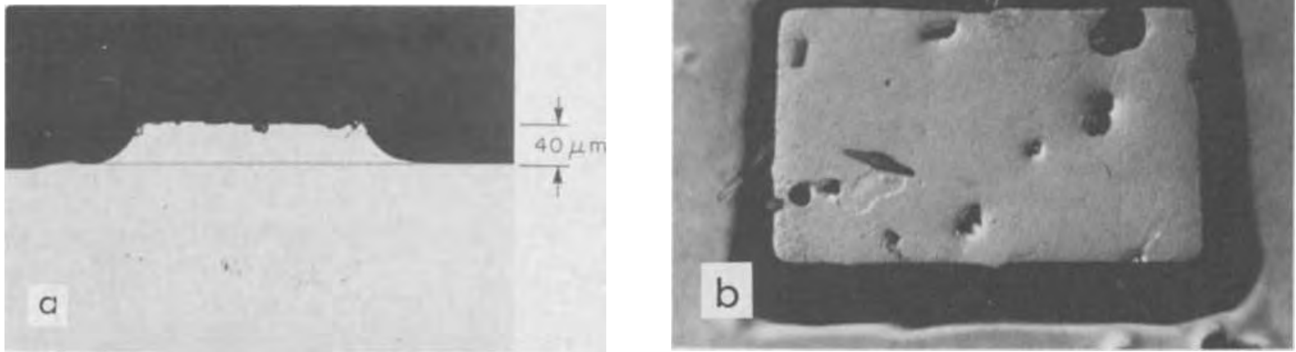

Fig. 6. Etched mesa structures for fabrication of gallium phosphide light emitting diodes: a, cross section view; b, top view

To demonstrate the feasibility of this technique a wafer of GaP with a p-layer ~40 μm thick, and an ohmic contact near one edge, was coated with a layer of SiO_2 and a mesa pattern defined by standard photoresist technique. The wafer was subsequently etched as described above. A representative mesa formed by electrochemical etching is shown in Fig. 6a and 6b. The cross-section view indicates a smoothly contoured surface on the sides of the mesa. The p-n junction has been delineated on the cleavage face by etching in warm HNO_3 and clearly indicates the selective removal of the p-layer. The top view of a mesa in Fig. 6b shows that the mesa is quite uniform in size. The mesa is smaller than the original mask size. The undercutting of the mask, U is expected to be equal to the etch rate times the total time etched; that is

$$U = E\,L/R$$

where E is the etch rate, L is the length of the wedge produced as the slice is lowered into solution (17), and R is the lowering rate. Since

$$R = LE/T$$

where T is the thickness of the layer removed (17)

$$U = T$$

That is, on the average, the mask is undercut by an amount equal to the layer thickness. That this is approximately true can be seen from Fig. 6. There is also a differential in the undercutting from one side of the mesa to the other since the slice is lowered into the solution. That is, there is a tendency to form a mesa with a trapezoidal rather than rectangular top. This differential is given by

$$\frac{\Delta U}{U} = \frac{WE}{RT}$$

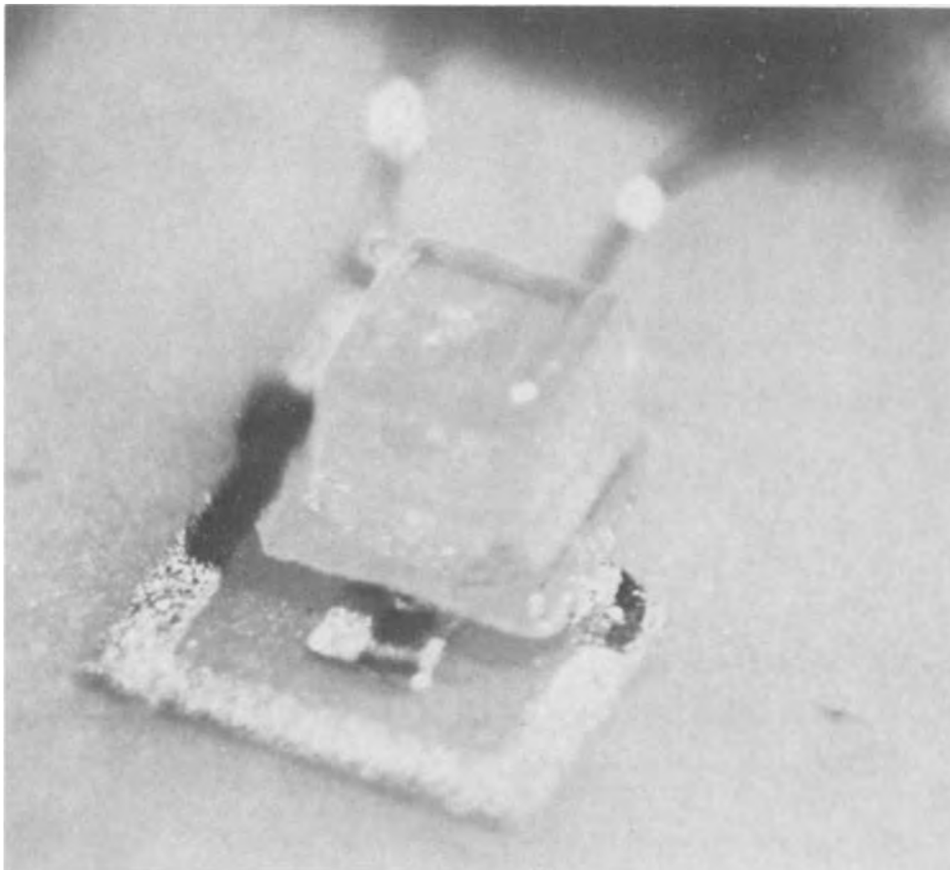

Fig. 7. Completed, quasi-planar beam lead diode.

where ΔU is the difference in undercutting from top to bottom and W is the mesa dimension in the lowering direction. Clearly, to minimize this, R should be large and E (or equivalently the potential) should be small. For $T = 25\mu$, typically $R = 3$ cm/hr and $V_{cell} = 4V$. Of course V_{cell} must not be too small or R too large or else potential drops down the tapered slice become large and etch through nearest the contact, and consequent premature isolation occurs. It is important to note that, since the etching is electrochemical rather than chemical, the undercutting stops as soon as the p-layer between mesas is etched away; or, more precisely, any further etching is limited by the current drawn through a reverse biased p-n junction.

The defects and entrapped crystallites apparent in Fig. 6 were due to the nature of the material before etching and do not appear in device quality material. Figure 7 is a photomicrograph of a completed, quasi-planar LED (Light Emitting Diode) bonded to a ceramic chip. The device is roughly 250μ on a side, and typical device parameters are 10 mA at a forward voltage of 2V with an unencapsulated quantum efficiency of 2%.

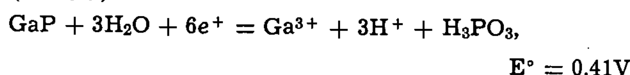
Manuscript submitted Nov. 22, 1971; revised manuscript received March 30, 1972. This was Paper 185 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

APPENDIX

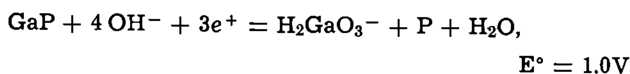
Consideration of the inorganic chemistry of gallium and phosphorus [W. M. Latimer, "The Oxidation States of the Elements and Their Potentials in Aqueous Solutions," Prentice-Hall, Inc., Englewood Cliffs, N. J., (1952)] in light of the above discussion, and the fact that phosphine is observed to be liberated in all cases, suggests that:

(In acid)



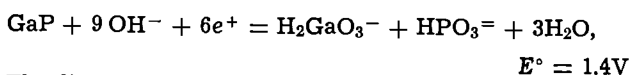
$$GaP + 3H_2O + 6e^+ = Ga^{3+} + 3H^+ + H_3PO_3, \quad E^\circ = 0.41V$$

(In alkali, $J \lesssim 10$ mA cm^{-2})



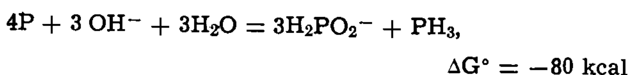
$$GaP + 4\,OH^- + 3e^+ = H_2GaO_3^- + P + H_2O, \quad E^\circ = 1.0V$$

(In alkali, $J \gtrsim 10$ mA cm^{-2})



$$GaP + 9\,OH^- + 6e^+ = H_2GaO_3^- + HPO_3^= + 3H_2O, \quad E^\circ = 1.4V$$

The disproportionation reactions



$$4P + 3\,OH^- + 3H_2O = 3H_2PO_2^- + PH_3, \quad \Delta G^\circ = -80 \text{ kcal}$$

and

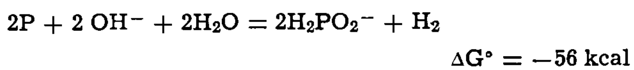
$$3H_3PO_2 = PH_3 + 2H_3PO_3, \quad \Delta G^\circ = -30 \text{ kcal}$$

have rather large negative free energies and may partially account for the further oxidation of P at low current densities in basic solution.

Since the phosphorus is finally found in the +5 oxidation state, and as phosphine, we presume that the reaction

$$4H_3PO_3 = PH_3 + 3H_3PO_4 \quad \Delta G^\circ = 0.9 \text{ kcal}$$

which has a small positive free energy is pushed to right because of evolution of phosphine from the solution. Some hydrogen is expected to be evolved in basic solution through



$$2P + 2\,OH^- + 2H_2O = 2H_2PO_2^- + H_2 \quad \Delta G^\circ = -56 \text{ kcal}$$

and

$$H_3PO_2 + H_2O = H_3PO_3 + H_2 \quad \Delta G^\circ = -23 \text{ kcal}$$

competing with the disproportionation reaction. Ring-disk studies (D. M. MacArthur, private communication) indicate 1 to 10% of the phosphorus follows this reaction path. The fact that 6 charges are transferred at larger potentials, current densities, indicates that there, for reasons not particularly apparent but perhaps related to the PH_3 concentration, the phosphorus is more likely to enter into a reaction involving further charge transfer than into the disproportionation reactions.

Organic Reactions in Gas Discharges Leading to Polymer Deposits

Arthur Bradley*

Surface Activation Corporation, Westbury, New York 11590

ABSTRACT

The ultimate products of static gas discharge in organic vapor are solid polymer deposits and inorganic gases. Analyses by gas chromatography of decomposition intermediates suggested common routes for many systems. Characteristic plasma reactions are decarbonylation and dehydrogenation, with solid resins arising via migration of ionized unsaturated species to the electrodes where they recombine as energetic neutral fragments. The last organic residue found in the vapor state after exhaustive discharge decomposition of any hydrocarbon is acetylene. Experimental evidence of the formation of the trifluoromethyl radical from perfluoroacetone is presented.

With very few exceptions, organic vapors subjected to excitation and ionization in an electrical discharge yield polymeric deposits on the electrodes. The process as a means for producing useful thin film coatings was patented in 1960 (1). The commercial possibilities which this new plasma technology suggested have provided the incentive for more than a decade of intensive applied research (2). There has been particular attention paid to fluorocarbon deposits, which may have utility as protective or water-repellent coatings, as dielectric layers, or release agents, but there are no substantial commercial applications at present.

Although the importance of normal chain propagation in gas discharge polymerization is doubtful, unsaturated "monomers" give the best adherent and coherent films. The deposits from aliphatic hydrocarbons and other simple organic compounds are brittle and of low utility. This paper attempts to explain these and related observations by considering the probable routes of decomposition and recombination of organic fragments in a plasma/electrode environment. There are no mechanisms presented but some apparently consistent and predictable reaction sequences are discussed.

Rates of conversion of organic vapor to solid polymer in terms of grams per kilowatt-hour have been determined for many compounds (3). Conventional monomers such as styrene and methyl methacrylate do not deposit films much faster than ethyl benzene or methyl acetate unless the electrodes are chilled to near the condensation point of the vapor. Direct-current discharges yield ten times as much polymer on the cathode as the anode. It seems likely that there is little or no polymerization in the vapor state and that molecules reach the electrode as positively charged fragments which are there converted to highly energetic neutral species.

We have speculated that polymerization results from random recombination of open bonds on the electrode surface, with no propagation in the ordinary sense (3). Nevertheless, the deposit from styrene shows many of the structural features of conventional polystyrene (*e.g.*, similar IR spectra); that from tetrafluoroethylene is not unlike Teflon.

A static discharge (no exhaust or inflow of gas) in certain monomers results in a gradual decrease in pressure, indicating that severe fragmentation does not occur before species are ionized and drawn to the cathode. In general, these give the better quality films, and are discussed in some detail later in this report. On the other hand, aliphatic hydrocarbons, even unsaturated ones, as well as simple alcohols, ketones, carboxylic acids and esters, tend to decompose in the plasma. Polymer deposits obtained from methane, methanol, ethane, propane, isobutylene, hexane, acetone, ethylene, and acetylene were all similar in appearance, chemical composition (low H to C ratio), and physical properties. In each case, the polymer formed nonadherent brittle flakes or crumbled to powder. It is proposed that these solids all had a common antecedent: plasma decomposition intermediates such as ethylene and acetylene.

There is no general agreement in the extensive gas discharge literature on even the broadest aspects of polymer formation, much less on a mechanism (4, 5). Some authors visualize the organic monomers condensing on the electrode and there polymerizing after initiation by electron or ion bombardment (6-8). This might be appropriate for styrene but not for benzene, acetylene, or a host of saturated hydrocarbons. Others have, like us, found evidence of decomposition of the parent molecule in the plasma followed by recombination at the electrode surface (9-12).

Some of our more specific findings have been previously described. The similarity of deposits from styrene and ethyl benzene was reported by Brick and Knox (4). McTaggert (10) detected ethylene and ethane as by-products of the plasma polymerization of all paraffins from methane to decane and noted that the polymer obtained was not physically distinguishable from that deposited from acetone or methanol.

Vastola and Wightman (12) found that methane, ethane, and ethylene all deposited hydrocarbon films of similar composition in a microwave discharge. In each experiment, the by-product gas mixture was about 95% hydrogen plus a mixture of all three hydrocarbons and acetylene in approximately equal quantities (by mass spectroscopic analysis). Furthermore, the infrared spectra of the films from ethane and ethylene were found to be superimposable. Unfortunately, no spectral comparison with the acetylene deposit was reported. These authors suggest that the CH fragment might be a common intermediate in the deposition of solid polymer films from hydrocarbon gas discharges.

Williams and Hayes (8) found that no polymerization occurs on the anode of a d-c discharge and so dismissed the importance of electron bombardment. They recognized the advantage of condensation on a chilled electrode and concluded that glow discharge polymerization probably occurs exclusively at the electrode surface. However, since they confined their work to conventional monomers, they were inclined to overlook routes which involved neither initiation nor propagation. These authors proposed a classification of monomers by rate of reaction based on their likelihood to be adsorbed on electrode surfaces. The favored monomers on their list could also be described as the

least likely to decompose in C_2 hydrocarbon intermediates.

Experimental Results

A large bell jar (18 in. diam) was used as the plasma reaction chamber. Pairs of clean tin-plated steel electrodes (0.006 × 4 × 6 in.) were mounted parallel and approximately 0.5 in. apart for each experiment. Gases were introduced via a feedthrough in the baseplate directly from commercial gas cylinders. Liquids were contained in a 250 ml round bottom flask attached by an O-ring seal "quick-coupling" to a fixture at the underside of the baseplate. A vapor pressure of at least 2 mm at room temperature was the only physical requirement of a "monomer." Alternating voltages of 3000-10,000 Hz were applied to the electrodes, approximately 300V being required (at 2 mm) to achieve a stable discharge covering the entire electrode surface. Discharge currents were maintained between 20 and 25 mA for the duration of experiments which lasted from 5 to 30 min.

Although a relatively small portion, much less than 1%, of the volume of gas contained in the bell jar was actually between the electrodes at any one instant, it appeared that circulation was excellent and that the body of gas was being acted upon uniformly. In many experiments, after 30 min there was only a trace of the original vapor left.

At the beginning of each experiment the bell jar was evacuated to below 0.05 mm with an oil pump. The gas or vapor from the liquid reservoir was admitted until the pressure reached 2 mm and then all valves were closed. Film depositions were carried out with no attempt made to maintain a constant pressure. It is characteristic of acrylonitrile and tetrafluoroethylene that the pressure decreases in such static discharges; with most materials there was a gradual pressure rise as hydrogen and other by-products accumulated.

Aliquots of the gas mixture were taken at intervals for analysis by an F & M Model 810 gas chromatograph. A sample of 25 cc at 2 mm was generally sufficient for identification of the major components on an activated charcoal column. The sampling chamber was opened to the column for 60 sec; 3 min later a programmed heating cycle began which raised the column from room temperature to 380°C in another 12 min. High-purity helium was employed as the carrier gas with a thermal conductivity detector registering each component as it emerged from the column. Most identifiable peaks were recorded on the chart by the time the heat cycle had reached its maximum temperature. It was kept hot for another 15 min to remove any residual components of the previous experiment before cooling to room temperature again for the next sampling.

Gases obtained for this investigation in standard cylinders from the Matheson Corporation included hydrogen, nitrogen, oxygen, carbon monoxide, carbon dioxide, methane, ethane, ethylene, acetylene, propane, isobutylene, tetrafluoromethane (Freon-14), fluoroform (Genetron-23), hexafluoroethane (Freon-116), and perfluoropropane. Hexafluoroacetone was obtained from the General Chemical Division of Allied Chemical Corporation, Baton Rouge. Tetrafluoroethylene was supplied by the Thiokol Corporation, Moss Point, Mississippi.

Reagent grade acetone, methanol, and hexane were obtained from a commercial laboratory supply house. Acrylonitrile, methyl methacrylate, and allyl methacrylate were supplied by the Monomer Polymer Laboratories, Philadelphia.

In a typical experiment, hydrogen appeared as a sharp peak on the descending shoulder of the initial sampling response, barely 30 sec after the sampling chamber was closed (detected at the 1.5 min mark in Fig. 1, for example).

Oxygen and nitrogen were indistinguishable, the "air" peak coming at 2.5 min, followed by carbon monoxide at 3, methane at 5, carbon dioxide at 8, and the family of C_2 hydrocarbons, usually acetylene> ethylene> ethane, between 10.5 and 13 min. Perfluorinated analogs appeared at almost the same intervals as the hydrocarbons. Fluoroform (trifluoromethane) was released from the column after tetrafluoromethane and before hexafluoroethane, as shown, for example, in Fig. 2.

Chromatograms under standard conditions were taken for each gas individually before they were identified as components of a mixture. Thus the peak for fluoroform alone was superimposable on the 8.5 min peak *found* in the hexafluoroacetone decomposition carried out with the electrodes wrapped with Mylar film.

Infrared absorption spectra for acrylonitrile film deposited on KBr pellets were recorded on the Perkin-Elmer Model 21 double-beam spectrophotometer. Peaks characteristic of primary, secondary, and tertiary amines with various hydrocarbon substituents were observed.

Powders and flakes of polymer removed from the electrodes (or gathered from where they had fallen) were submitted to the Schwarzkopf Analytical Laboratory, Woodside, Queens, New York. Some preparations were from a static gas phase and some had a continuous flow of fresh feed vapor and exhaust. Elemental analyses of C and H always totaled considerably less than 100% because of oxygen and some nitrogen absorbed by the polymer upon exposure to air. The oxygen take-up was not reduced by maintaining the bell jar vacuum for 6 hr after an experiment. Acrylonitrile polymer had lost about one-fifth of its nitrogen, indicating that perhaps 80% of the deposit was derived from intact monomer. The H/C ratio for acrylonitrile deposit suggests that many of the lost nitrogen atoms were fragmented as CN. Some typical analyses are given in Table I.

The absorption of oxygen by powdery organic polymers bristling with free radical sites was expected, but the trapping (or "fixation") of nitrogen by the same process was something of a surprise. Other workers who have detected nitrogen in glow discharge polymer have attributed it to air contamination of the hydrocarbon vapor (13).

The complete chromatogram records of this investigation would include some sixty readout charts. It is convenient to illustrate how these chromatograms were utilized with one chart for allyl methacrylate (Fig. 1) and two for hexafluoracetone (Fig. 2). Features of the various chromatogram readouts applicable to other compounds are introduced where the specific plasma experiments are discussed in the following paragraphs.

Discussion

Since most organic compounds decompose when thermally excited to a small fraction of 1 eV, it is not surprising that even "cold plasma" energies (14) up to 15 eV tend to disrupt molecules extremely rapidly. Under the conditions described in this report, only acetylene and certain perfluorinated hydrocarbons survived the equivalent of 10 sec continuous plasma exposure, and that spread out over a 30 min period.

Any compound that can remain intact long enough for its ion to reach an electrode surface will be incorporated into a polymeric deposit forming thereon.

Table I. Typical analyses

Polymer from	%C	%H	%N	H/C ratio
Methane, static	78.4	7.02	0.85	1.07
continuous flow	69.8	6.3	—	1.08
Ethylene, static	72.1	6.8	—	1.13
Isobutylene, static	81.7	8.07	0.11	1.19
continuous flow	78.9	7.8	0	1.18
Hexane, static	81.6	8.0	—	1.18
Acrylonitrile	68.8	6.4	20.4	1.12

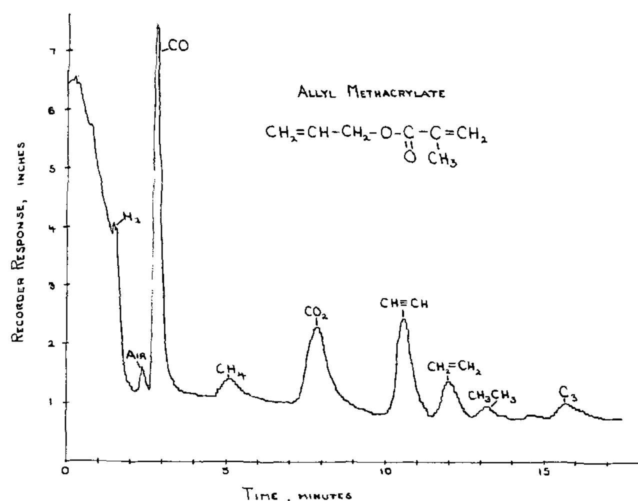

Fig. 1. Gas chromatogram of intermediate products from gas discharge in allyl methacrylate vapor (2 mm).

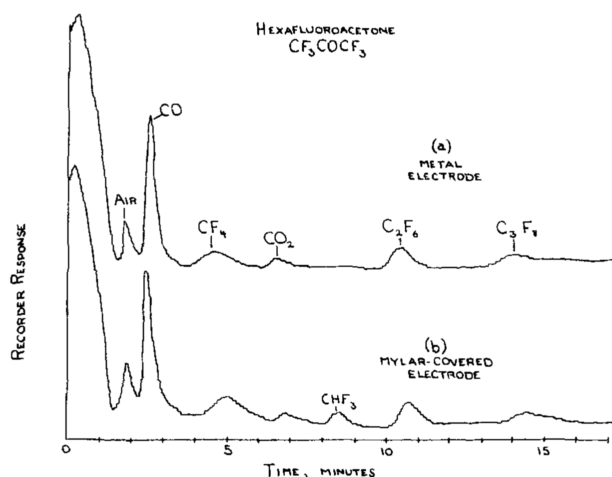

Fig. 2. Gas chromatogram of products from plasma decomposition of hexafluoroacetone vapor (3 mm) with (a) metal and (b) Mylar electrodes.

This type of molecule, even when unsaturated and presumably polymerizable, is rare. Thus isobutylene, C_4H_8, yielded a polymer $C_4H_{4.8}$. Hexane gave a deposit of the same composition. The methane polymer was approximately $CH_{1.1}$. We must begin to suspect a common intermediate. By what route does this intermediate arise? Is it related to the well-known plasma synthesis of acetylene from methane (12, 15)? Clearly, there must be some pattern to these observations.

Plasma decomposition reactions.—Dehydrogenation is the most rapid single decomposition step, even for methane, where CH_2 is the "radical species present in important concentration" (15). Since the concentration of hydrogen builds up rapidly under plasma conditions, a certain amount of the reverse reaction (hydrogenation) also occurs in all systems. The result is that regardless of the starting composition, all hydrocarbon residues tend toward the same (gradually disappearing) mixture of ethane, ethylene, and acetylene. These three peaks are characteristically accompanied by hydrogen and methane, as illustrated in Fig. 1. Oxygen from organic compounds is often found both as carbon monoxide and carbon dioxide. The free element may also be observed as a decomposition product of carbon dioxide or water.

The actual equilibrium concentrations of C_2H_2, C_2H_4, and C_2H_6 in the presence of excess hydrogen in a discharge plasma are unknown, but they would certainly favor the triple bond compound. Acetylene is the last surviving organic identifiable in the gas phase after exhaustive discharge of almost any compound containing carbon and hydrogen. Presumably it is consumed only by polymerization to C-H solid residues; elemental carbon was not observed as a product in this investigation, however long the plasma was sustained. It remains a possibility that ethylene or other unsaturated species could also yield polymer without breaking down to acetylene first, but H/C ratios in deposits from hydrocarbon plasmas consistently approach unity.

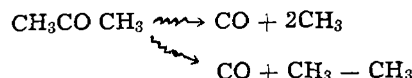
Ethane releases hydrogen faster than any other feed gas subjected to glow discharge. In one experiment, approximately 90% degraded in 15 min, at which time were observed 5% acetylene and lesser quantities of methane, ethylene, and a C_3 moiety. The hydrogen peak corresponded to 150% of the original volume of ethane.

Ethylene gives the same intermediate products during the course of its plasma degradation, although in different proportions. Methane and ethane peaks are barely more than traces. The yield of hydrogen from completely spent ethylene is half that obtained from similarly depleted ethane. The conversion to solid polymer is essentially quantitative in both cases. Unfortunately, the flaky, intractable solid bears no resemblance to polyethylene in any respect (unless the latter has been cross-linked and degraded by excessive radiation to a crumbly powder).

After dehydrogenation, the next most characteristic plasma reaction is decarbonylation. Carbon monoxide is one of the more stable species and one of the last survivors of exhaustive discharge treatment. The products observed in the early stages of glow discharge decomposition of acetone vapor indicate that the ketone decomposition quickly yields hydrocarbon fragments which then proceed via the ethane-ethylene-acetylene subsystem to polymeric deposits. Thus, after 10 min glow between metal plate electrodes, acetone yielded the products listed in Table II.

The high proportion of ethane suggests that there is a route from acetone to hydrocarbon that does not require free methyl radicals to be released, although some part of the C_2 concentration probably results from reactions of C_1 fragments. The consumption of methane certainly requires some such path. It is believed that once CO is released by the parent vapor it takes no significant part in the subsequent reaction scheme. Attempts to react CO with hydrocarbons in separate experiments have not been successful.

It is proposed that the initial decomposition of acetone follows both these routes



$$CH_3CO\,CH_3 \rightsquigarrow CO + 2CH_3$$
$$\searrow CO + CH_3 - CH_3$$

As the reactions continue on further discharge treatment, the proportions of C_2 fragments remain fairly constant and a C_3 peak appears. The parent ketone is completely depleted after 30 min and shortly thereafter all hydrocarbon peaks disappear, leaving solid deposit, hydrogen, carbon monoxide, some air from leakage, and traces of carbon dioxide. These are the same products, including the same quality polymer film, obtained from exhaustive plasma degradation of

Table II. Intermediate species identified in plasma degradation of acetone (% by volume)

Species	% by volume
Unreacted acetone	50
Hydrogen	About 30
Carbon monoxide	50
Methane	5
Ethane	9
Ethylene	3
Acetylene	7
Solid polymer (by weight)	About 25

ethane or ethylene, except for the carbon monoxide (which eventually begins to react with the hydrogen, see below).

It is of interest to review at this time the decomposition of the related perfluorinated ketone hexafluoroacetone. With this compound, decarbonylation is again the first degradation step. The reaction sequence is simpler, however, because C_2F_6 has little or no tendency to defluorinate. No significant amounts of C_2F_4 or C_2F_2 appear and only traces of solid can be found on the electrodes and these are probably due to impurities or leakage. This lends support to the hypothesis that the polymer in the hydrocarbon system is derived from unsaturated C_2 fragments.

The products observed after a 15-min discharge in hexafluoroacetone are CF_4, C_2F_6, and C_3F_8. An experiment was carried out in which one electrode was covered with plastic film (one-mil Mylar polyester), serving as a source of hydrogen. This led to formation of fluoroform CHF_3 as an additional product and confirms that the perfluoromethyl radical $\cdot CF_3$ was an intermediate and probably participated in the reaction sequences leading to the various fluorocarbon products. Figure 2 reproduces the chromatograph record of the discharge products from hexafluoroacetone on metal (a) and organic (b) electrodes.

The type of experiment in which discharge products are allowed to react with substrates covering the electrodes can be extremely informative. The possibilities were by no means adequately explored in this investigation. However, one reaction, unrelated to the main subject matter of this paper, was examined, and the results are presented here as an aside of possibly general interest.

Reactions of polymer surfaces with oxygen plasma.—Oxygen was introduced at pressures of 2-4 mm into an electrode chamber in which the electrodes were variously wrapped with polyethylene, polypropylene, polyester film, and polyester fabric. In all cases CO_2 peaks appeared soon after discharge commenced and steadily grew in height as the condition was maintained. The area of the peaks corresponded to about one-third conversion of O_2 to CO_2 in 30 min with no sign of slowing down (Table III).

It has long been known that a polymer film exposed to an air discharge experiences changes in wetting angle and printability, and it has been shown that oxygen is incorporated onto the surface in the form of ether, carbonyl, carboxyl, hydroxy, and peroxy groups (16). It was not anticipated, however, that so much carbon would be removed from the substrate by the excited oxygen species. Cleavage of polymer chains must contribute heavily to the disruption of the surface and, in fact, must generally precede the formation of new oxidized groups. The accompanying lowering of the average chain length of polymer molecules gives real meaning to the term "oxidative degradation" as applied to the effects of corona discharges in air.

Conversion of methanol to polymer.—Before discussing methanol reactions it is first necessary to refer again to the reduction of carbon monoxide with hydrogen. The results of a plasma study of these gases were disclosed by Blaustein and Fu in 1967 (17). Although previous workers had found only methane as a product,

Table III. CO_2 from O_2 discharge reactions with substrates

Peak heights, inches, from gas chromatograph

Electrode covering	CO_2, 10 min	CO_2, 30 min
None (control)	0.10	0.35
Polyethylene film (HD)	1.3	5.8
Polyethylene film (LD)	1.9	7.2
Polypropylene film	2.0	7.0
Polyester film (Mylar)	1.15	4.3
Scoured polyester fabric (Vycron)	2.3	7.6
Greige polyester fabric (Vycron)	2.4	8.4

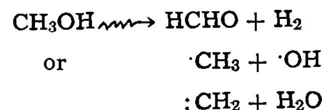
these workers identified the intermediates ethane and acetylene on the inevitable route to polymer, both in far greater quantity than could be accounted for by any specific reaction involving CO and H_2. Oddly, ethylene was not found. Nevertheless, it appears that the methane-to-polymer route followed the familiar pattern outlined above involving a set of C_2 hydrocarbons.

It will be noted that no methanol was found as a product of a CO-H_2 plasma, although this reaction readily occurs at high pressure and is of commercial importance. However, the reverse reaction

$$CH_3OH \rightsquigarrow CO + 2H_2$$

predominated when methanol was used as feed gas in our discharge experiments. It is not surprising that within the first 10% decomposition of methanol, traces of methane and ethane were detected as gaseous byproducts and the beginnings of polymer deposit observed. Longer treatment increased the peaks and added acetylene, and by the time the methanol was gone the usual organic residues had appeared in their typical proportions.

From what we know of the reactions in a CO-H_2 plasma (17), all of the products from methanol can be accounted for. There remain, however, possible minor contributions from alternate routes of decomposition, such as



$$CH_3OH \rightsquigarrow HCHO + H_2$$
$$\text{or} \quad \cdot CH_3 + \cdot OH$$
$$:CH_2 + H_2O$$

These modes of degradation could lead to the same hydrocarbon intermediates. Neither formaldehyde nor water would have been detected by the analytical technique employed.

Polymerization of other monomers.—The foregoing has presented a possible common-denominator route for polymerization of a number of simple organic compounds in a gas discharge. The remainder of this paper surveys larger and more unsaturated molecules which show some evidence of conversion to solids by alternate routes. It particularly refers to the importance of temperature control of the electrodes. If the comments tend toward over-generalization the author can only plead that he has tried to assimilate the collected impressions of a generation of affiliated workers while maintaining one consistent over-all point of view.

Aromatic "monomers" such as benzene, toluene, naphthalene, pinene, thiophene, and pyrrole were not investigated by gas chromatography. Their film properties (3, 18) suggest that they are not converted to polymer solely via unsaturated C_2 hydrocarbons. This group, which might also include butadiene and cyclopentadiene, probably polymerize via larger ionized fragments containing multiple unsaturation. Their vapors deposit stable, adherent films from a discharge plasma, although it is well to restrict the thickness to 1 or 2μ. In thicker layers they crack and peel away from the substrate; they lack the flexibility, tenacity, and cohesion necessary to form a protective coating, nor do they conform well to an unusual shape.

It might be expected that genuine organic monomers (vinyl or allyl compounds with mildly polar functional group substituents) would deposit polymer from a gas discharge without producing a family of degradation products. In actual practice, no monomer fulfills this ideal behavior, but acrylonitrile probably comes as close as any.

The pressure in a chamber containing acrylonitrile begins to drop the moment a discharge is turned on. Only minor by-products appear: small peaks attributable to nitrogen and acetylene are observed after a few minutes. No detectable hydrogen, methane, ethane, or ethylene are produced as the conversion to solid continues.

Table IV. Organic "monomers" classified by polymerization route

Category	Description	Examples	Remarks
I	Polymerization is essentially via whole molecule	Acrylonitrile Perfluorinated olefins	Yield and quality of film not directly related to temperature of electrodes
II a	Molecule has tendency to degrade into large fragments with conjugated unsaturation which also polymerize	Styrene Vinyl pyrrolidine	Chilling electrode to near condensation point of monomer improves yield, and properties of film approach those of "conventional" polymer
II b	There is competition between whole-molecule polymerization and the slow route via C_2 hydrocarbon intermediates	Allyl methacrylate Diallyl sulfide	Condensation conditions help in producing good quality films
III a	Principal route to polymer is via unsaturated fragments	Benzene Dicyclopentadiene	Control of electrode temperature probably has little or no effect
III b	Only route to polymer is via C_2 hydrocarbons	Methane Acetone	No decent film obtained under any conditions

Analytical results suggest that only about 20% of the acrylonitrile polymer is derived from degradation products. However, it is believed that much of the direct polymerization involves the nitrile group. Amines of all description have been detected by infrared analysis, and the richly colored deposit absorbs oxygen readily, suggesting conjugate unsaturation. These observations are consistent with a nonpropagation model for polymerization, new bonds forming according to the random orientation of the various species immediately after being neutralized at the electrode. An acrylonitrile cation, formed in the plasma by electron bombardment, might carry most of its charge on the nitrile carbon, decreasing the probability of the nitrile function remaining intact in the macromolecular film deposit.

Yield alone does not give a clue to the degree of fragmentation, but rapid film deposition monomers like acrylonitrile, styrene, and acrylic acid will be sure to rank with the best in preserving monomer integrity into the solid. On the other hand, the perfluorinated olefins, lacking a defluorination mechanism analogous to dehydrogenation, are also polymerized fairly intact, although at a much slower rate. Polytetrafluoroethylene films prepared for capacitance use had essentially the same dielectric constant as bulk commercial Teflon, and came within one order of magnitude of its extremely low power factor (2).

A number of organic monomers roughly classifiable as unsaturated esters have been successfully used for producing colorless protective films over metal surfaces (2). It was somewhat surprising and disturbing therefore to find that they released the same family of related decomposition products as the simple oxygen-containing feed gases methanol and acetone. Thus, allyl methacrylate and methyl methacrylate gave carbon monoxide, carbon dioxide, acetylene, ethylene, and ethane, in the opening minutes of glow, in this decreasing order of importance. After 10 min, the CO peak had increased disproportionately, towering five times above those of CO_2 and acetylene, which in turn overshadowed ethylene, ethane, and the newly appeared methane and C_3 peaks (Fig. 1). Considerable hydrogen was also indicated at this time. Further discharge treatment (15 to 30 min) resulted in exhaustion of the hydrocarbon fragments, leaving traces of acetylene as the last survivor.

It must be concluded that one or more decarbonylization mechanisms compete with direct polymerization, and therefore, the solid product obtainable from these monomers (above condensation, at least) must contain a significant proportion of the C_2-hydrocarbon polymer previously characterized as undesirable in this report. This work suggests the importance of temperature control in custom deposition beyond that of yield or thickness. Gas phase reactions probably generate hydrocarbon fragments under all conditions, but a chilled substrate attracting a swarm of neutral monomer molecules converts some of these charged fragments to good use as initiators, and others may be harmlessly incorporated as copolymer.

It has long been suspected that condensate and near-condensate films show better adhesion to substrate, more flexibility, and improved appearance because they represent a more conventional polymer, as if prepared under milder circumstances (8, 19). It is now somewhat clearer how this comes about, and why temperature control is so much more important in determining the properties of one polymer system and not another.

For example, acrylonitrile and perfluorinated monomers may be converted by glow discharge into polymer without undue concern about the substrate temperature. Styrene and allyl methacrylate, on the other hand, degrade significantly in the glow and should be deposited with careful attention to the role of condensation in excluding or diluting the undesirable decomposition fragments. The same considerations undoubtedly apply to most other useful monomers, possibly according to the categories suggested in Table IV. The brief descriptions of polymerization routes are presented as speculation, consistent with all observations in the laboratory but not yet rigorously proved.

By way of summary, it is our experience that useful films can be obtained from category I monomers as long as the electrodes are not allowed to overheat. Category II films benefit greatly from chilling the electrode to near the condensation temperature of the monomer. Category IIIa films are of generally inferior quality and IIIb films are not films in any real sense.

Manuscript submitted March 15, 1971; revised manuscript received April 27, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

The Reduction of Chlorine on Carbon in $AlCl_3$-KCl-NaCl Melts

Gerhard L. Holleck*

Tyco Laboratories, Inc., Bear Hill, Waltham, Massachusetts 02154

ABSTRACT

Using a rotating-vitreous, carbon disk electrode, the kinetic parameters for chlorine reduction in an $AlCl_3$-KCl-NaCl (57.5-12.5-30 mole per cent [m/o]) melt were determined. It was found that the reduction of chlorine occurs according to the paths

$$Cl_2 + e^- \rightleftharpoons Cl^- + Cl_{ads}$$

$$Cl_{ads} + e^- \rightleftharpoons Cl^-$$

with the first step being most probably rate determining. The apparent exchange currents were $(1 \pm 0.15) 10^{-4}$ A/cm^2 at 130°C and $(2.1 \pm 0.3) 10^{-4}$ A/cm^2 at 150.6°C.

The electrochemical reduction of chlorine in molten salts is of general interest to the development of high energy density batteries. One such proposed battery system is based on an aluminum anode and a chlorine cathode in a low melting aluminum chloride-alkali chloride eutectic (1). In a previous paper, we have dealt with the behavior of the aluminum electrode in $AlCl_3$-KCl-NaCl melts (2). This work is concerned with the kinetics of chlorine reduction in such melts.

Despite the use of the chlorine electrode for a number of years as a reference electrode in fused salts (3), kinetic and mechanistic studies have been quite limited. Treadwell and Terebessi conducted emf studies of the cell Al/$AlCl_3$-KCl-NaCl/Cl_2 (4). Skundin *et al.* carried out studies of chlorine reduction in $AlCl_3$-KCl-NaCl melts at 100°-150°C on Pt and Ir electrodes using linear sweep voltammetry (5). They estimated an exchange current of 10^{-4} A/cm^2 with no evidence of surface film formation. Drossbach and Piontelli both investigated the evolution of chlorine from chloride melts and found small polarizations (6, 7). The evolution of chlorine from LiCl-KCl melts in the temperature range of 425°-650°C was found to be resistance controlled primarily due to the gas film present on the electrode surface (8). Triaca *et al.* found that the dissolution of chlorine on graphite in molten LiCl was diffusion controlled at higher current densities which precluded mechanistic conclusions (9). Other studies of the reduction of chlorine on graphite electrodes in molten salts have been made by Ivanovskii *et al.* (10), Trusov and Borisova (11), and Swinkels (12).

In preliminary studies, we found that graphite-containing samples showed considerable swelling and disintegration in aluminum chloride-alkali chloride melts. Vitreous carbon, which did not show any attack, was chosen as a suitable electrode material for kinetic studies of chlorine reduction on carbon surfaces in $AlCl_3$-KCl-NaCl melts using the rotating disk electrode technique.

Experimental

The rotating disk arrangement consisted of a sturdy stand on which a 1/15-hp Bodine motor and a precision ball bearing for the 0.25 in. rotating shaft were mounted. The motor speed was controlled by a Minarik speed control (SL-52). The coupling of the motor and the electrode shaft was accomplished by a nonslip belt. The rotation rate of the electrode was continuously monitored by the frequency modulation resulting from magnetic coupling of an electromagnet with an iron gear mounted on the rotating shaft. This signal was amplified and displayed on a frequency counter. Electrical contact to the disk electrode was accomplished through a mercury pool in the top of the rotating shaft.

The electrochemical cell was made of a 50 mm Pyrex O-ring joint with a 30 mm-thick Teflon cover. The Teflon cover contained tapered holes to accommodate a liquid seal in the center with a 29/40 standard tapered joint surrounded by four 10/30 joints for the gas inlet and outlet as well as the counter and reference electrodes. A Teflon bell was fixed to the rotating shaft (Fig. 1). Silicone oil with a low vapor pressure was used as sealant liquid.

The rotating electrode consisted of a vitreous carbon rod (3 mm diameter, from Atomergic Chemicals Corporation) press fitted into hot Teflon. Details of the electrode construction are shown in Fig. 1. A vitreous carbon rod was used as counterelectrode and an Al electrode in the same melt, but in a separate compartment, served as reference electrode. The electrochemical cell was thermostated by a stirred silicone oil bath controlled to ±0.2°C by a Matheson Lab Stat

proportional temperature control unit and a two-stage heating arrangement. The chlorine from a gas cylinder was passed through a trap filled with molecular sieves (Linde No. 5A) which had been dried at 375°C, under dry argon overnight, before entering the cell.

The experiments were conducted in the $AlCl_3$-KCl-NaCl melt (57.5-12.5-30 m/o) at 130° and 150.6°C. The purification of $AlCl_3$, and the preparation of the melts, has been described in detail elsewhere (2). Before introducing Cl_2 gas into the cell, cyclic voltamograms were taken at the carbon disk electrode (these showed no detectable faradic background current). Following this, the argon was replaced by Cl_2, and a slow flow of Cl_2 was maintained above the melt surface. The progress of melt saturation was monitored by measuring the increase of the limiting current of the Cl_2 reduction with time at constant rotation speeds. Generally, the stirred melt was saturated with Cl_2 after 25 to 30 min.

Results

The open circuit potentials (measured *vs.* an aluminum reference electrode in a melt of the same composition and temperature) at 130° and 150°C were 2.10 and 2.06V, respectively. A typical current-voltage curve at 130°C, at a sweep rate of 200 mV/min, is shown in Fig. 2. A slight hysteresis was observed between the forward and the backward sweep. The hysteresis at low current densities was independent of rotation rate, whereas the differences between the forward and backward sweeps at, or close to, the limiting current region increased with increasing rotation rate. Figure 3 shows the change of current with time at constant potential at a rotation rate of 30 rps.

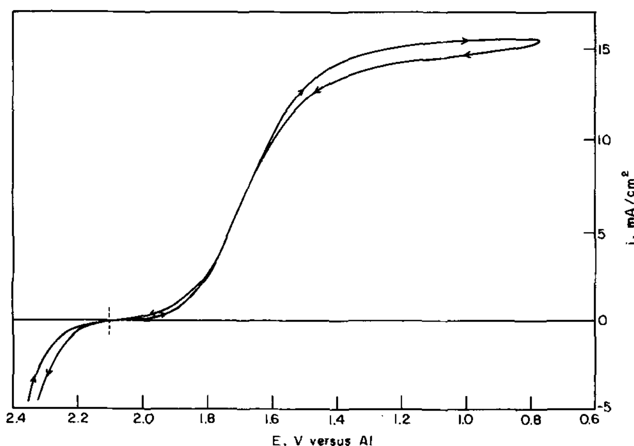

Fig. 2. Reduction of Cl_2 at rotating carbon disk electrode in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o) at 130°C, 20.8 rps, and 200 mV/min.

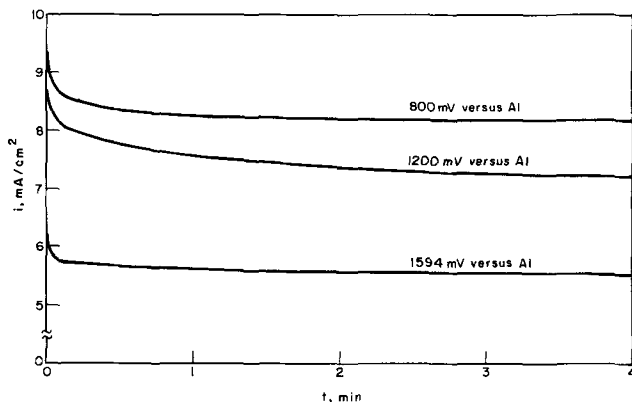

Fig. 3. Decay of Cl_2 reduction current with time upon potentiostatic steps to various potentials (vs. Al) at the rotating disk electrode in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o) at 130°C and 30 rps.

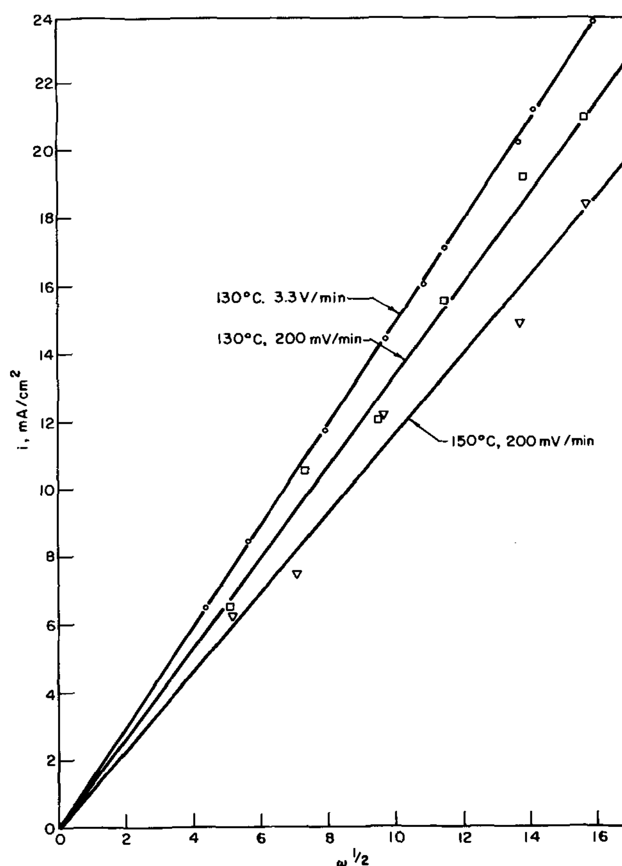

Fig. 4. Limiting currents for Cl_2 reduction vs. rotation rate at carbon electrode in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o).

Besides the buildup of the diffusion layer, we observed a relatively slow current decay which is clearly potential dependent. It is largest at 1.2V, in keeping with the current-voltage curves, and reaches a steady value after about 3 min. At 0.8 and 1.59V, steady-state values are more quickly established. This and the reproducibility of the current-voltage sweeps after returning to the open circuit potential suggest a potential dependent inhibition. The exact cause of this behavior is not yet known. However, it seems most likely that some melt impurity is involved.

Limiting currents of chlorine reduction as a function of rotation rate are shown in Fig. 4. The data show the linear relationship predicted for a mass transfer controlled reaction (13)

$$i_L = An\mathbf{F}D^{2/3}\nu^{-1/6}\omega^{1/2}C_o$$

where A = constant, D = diffusion coefficient, C_o = bulk concentration of the electroactive species, ν = kinematic viscosity, $\omega = 2\pi N$ where N = rotation rate.

The limiting currents obtained from cyclic current-voltage sweeps at 3.3 V/min follow a straight line with a slope of 1.48 $mA/cm^2\omega^{1/2}$. The limiting current values from the slow current-voltage sweeps show larger scatter and a somewhat smaller slope (1.37 $mA/cm^2\omega^{1/2}$), reflecting the slow current decay mentioned above. At 150.6°C, a slightly smaller slope resulted, indicating that the increase in the factor $D^{2/3}\nu^{-1/6}C_o$ is overcompensated by a decrease of the Cl_2 solubility. The transport parameter ($D^{2/3}\nu^{-1/6}C_o$) is approximately 1.4×10^{-8} [mole cm^{-2} $sec^{-1/2}$] at 130°C from which the chlorine solubility can be estimated to about 5 mmole/liter.

Figure 5 shows the current potential data in a diffusion corrected Tafel plot of the form

$$\eta = \frac{2.3\,RT}{\beta z\mathbf{F}} \log i_o - \frac{2.3\,RT}{\beta z\mathbf{F}} \log \frac{i}{1 - (i/i_L)} \quad [1]$$

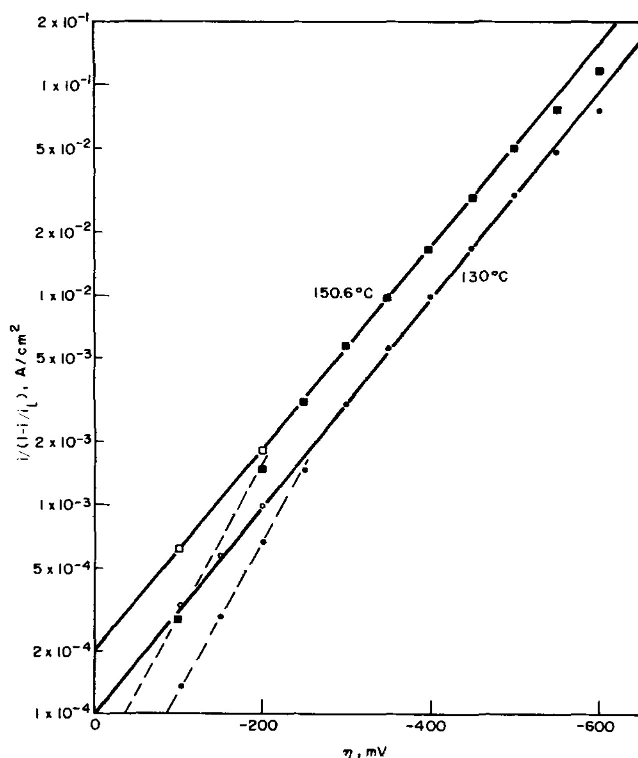

Fig. 5. Diffusion corrected Tafel plots for Cl_2 reduction, $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o); (open symbols at low η represent returning sweep).

where the symbols have their usual meaning. The equation is obtained by substituting $C/C_o = 1 - i/i_L$ in the expression for the cathodic current

$$i = -i_o \frac{C}{C_o} \exp\left(\frac{-\beta z \mathbf{F} \eta}{RT}\right)$$

It is applicable for a reaction with a simple rate determining step and of first order with respect to the diffusing species.

The experimental data in Fig. 5 show good Tafel behavior up to high overvoltages. The main Tafel slope was 200 mV at 130°C and 210 mV at 150.6°C. This suggests a one-electron transfer in the rate determining step with $\beta = 0.4$. At lower overvoltages (between $\eta = 50$ and 250 mV), the current of the cathodic going sweep follows a Tafel line with a decreased slope (130 mV/decade). On the returning potential sweep, no change in Tafel slope occurred. The exchange currents for chlorine reduction obtained from the main Tafel region were $(1.0 \pm 0.15)10^{-4}$ A/cm² at 130°C, and $(2.1 \pm 0.3)10^{-4}$ A/cm² at 150.6°C with an activation energy of 12 cal/mole.

The rotating disk electrode offers a particular advantage in determining the reaction order with respect to the reactants and products by studying the effect of rotation rate at a fixed potential as was illustrated by Frumkin and Aikazyan (14).

For the rate determining step, $qO + ze^- \rightarrow R$, we can write

$$\frac{i}{i^*} = \left(\frac{C_o{}^o}{C_o{}^\infty}\right)^q = \left(1 - \frac{i}{i_{L,c}}\right)^q \quad [2]$$

where i = measured current, i^* = activation controlled current, $C_o{}^\infty$ and $C_o{}^o$ are the concentration of species O in the bulk of the electrolyte, and at the electrode surface, respectively, and q = reaction order with respect to the diffusing species.

With $q = 1$, Eq. [2] converts to

$$\frac{l}{i} = \frac{l}{i^*} + \frac{l}{K\omega^{1/2}} \quad [3]$$

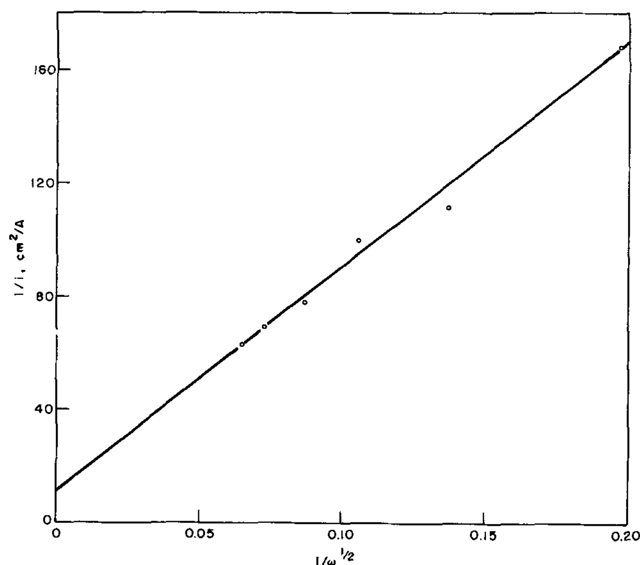

Fig. 6. Reduction of Cl_2 at constant potential (130°C, E = 1.5V vs. Al).

(K is the scope of the plot i_L vs. $\omega^{1/2}$) while $q = \frac{1}{2}$ (for instance) results in

$$i^2 = (i^*)^2 - \frac{(i^*)^2}{K} \frac{i}{\omega^{1/2}} \quad [4]$$

A typical plot of l/i vs. $l/\omega^{1/2}$, according to Eq. [3], is shown in Fig. 6. The linear relationship of the experimental data suggests a reaction order of one. From the intercept at $l/i = 0$, $i^* = 80$ μA/cm² was calculated as found in the Tafel plots. The slope $l/K = 780$ cm²$\omega^{1/2}$/A is in good agreement with K from Fig. 4.

From the initial slope of galvanostatic potential-time curves close to the open circuit potential, the double layer capacity was determined to 110 ± 15 μF/cm², which is larger than the 20 to 30 μF/cm² one would normally expect to find. The larger capacity values are most likely due to an increased roughness factor of the electrode and/or an adsorption capacitance.

Discussion

The over-all reaction

$$Cl_2 + 2e^- \rightleftharpoons 2Cl^-$$

can occur according to two paths

1 (a) $Cl_2 + e^- \rightleftharpoons Cl^- + Cl_{ads}$

(b) $Cl_{ads} + e^- \rightleftharpoons Cl^-$

2 (a) $Cl_2 \rightleftharpoons 2Cl_{ads}$

(b) $Cl_{ads} + e^- \rightleftharpoons Cl^-$

The fact that the reaction for the chlorine reduction was found to be first order excludes the second path.

A calculation of the theoretical Tafel slopes of the first path, depending on whether step (a) or step (b) is rate determining, results in the following values.

Rate determining	Langmuir adsorption		Temkin adsorption	
	$\theta \rightarrow 0$	$\theta \rightarrow 1$	nonactivated	activated
1a	$-2RT/\mathbf{F}$	$-2RT/3\mathbf{F}$	$-2RT/\mathbf{F}$ or $-2RT/3\mathbf{F}$	$-RT/\mathbf{F}$
1b	$-2RT/3\mathbf{F}$	$-2RT/\mathbf{F}$	$2RT/3\mathbf{F}$	$-RT/\mathbf{F}$

The experimentally determined main Tafel slope was 2.5 $RT/\mathbf{F}$. The above table shows that the value for the Tafel slope alone is not sufficient to distinguish between steps (a) and (b). The measured slope could reflect a rate-determining step according to 1a at low coverage of the electrode or according to 1b at large electrode coverage. Thus, additional information concerning the electrode coverage would be required.

Studies of the mechanism of chlorine evolution on graphite (9) in molten lithium chloride suggests, as the rate determining step, the combination of chlorine atoms on a surface with appreciable coverage. In fact, when scanning the rotating carbon electrode from the region of chlorine evolution to more cathodic potentials, one indeed observes, up to overvoltages of 250 mV, a lower Tafel slope which changes to $2RT/F$ at higher overvoltages probably indicating the change from an intermediate to low coverage. On the anodic going sweep, this low coverage is maintained until reaching anodic potentials.

Thus, we can conclude that the chlorine reduction on vitreous carbon in $AlCl_3$-KCl-NaCl melts occurs according to path 1 with step 1a being most probably rate determining at higher polarizations with a low chlorine coverage on the electrode.

Acknowledgments

The Aluminum Electrode in $AlCl_3$-Alkali-Halide Melts

Gerhard L. Holleck* and José Giner*

Tyco Laboratories, Inc., Bear Hill, Waltham, Massachusetts 02154

ABSTRACT

Passivation phenomena have been observed upon cathodic and anodic polarization of the Al electrode in $AlCl_3$-KCl-NaCl melts between 100° and 160°C. They are caused by formation of a solid salt layer at the electrode surface resulting from concentration changes upon current flow. The anodic limiting currents increased with temperature and with decreasing $AlCl_3$ content of the melt. Current voltage curves obtained on a rotating aluminum disk showed a linear relationship between the anodic limiting current and $\omega^{-1/2}$. Upon cathodic polarization, dendrite formation occurs at the Al electrode. The activation overvoltage in $AlCl_3$-KCl-NaCl (57.5-12.5-20 mole per cent [m/o]) was determined by galvanostatic current step methods. An apparent exchange current density of 270 mA/cm² at 130°C and a double layer capacity of 40 ± 10 μF/cm² were measured.

Molten salts have been investigated as electrolytes for high energy density batteries. The main disadvantage of the molten electrolyte batteries is the necessity for high temperature operation, which introduces many problems related to materials, construction, safety, etc. Furthermore, the insulation necessary in these high temperature batteries leads to a degradation of their energy density.

In this context, we have carried out studies of a high energy density battery based on an aluminum anode and a chlorine cathode with a molten $AlCl_3$-electrolyte (1). Aluminum is a low cost, readily available material which is easy to handle and has a low equivalent weight. The use of low melting aluminum chloride-alkali-halide mixtures should overcome the problems associated with the high working temperatures of the present molten salt systems, while still retaining the advantages of high energy density and relatively efficient electrode processes. The operating temperature of this system would be in the range of 120°-150°C, with a theoretical energy density of 650 Whr/lb. Furthermore, using an $AlCl_3$-KCl-NaCl eutectic the battery can be started at 90°C and the addition of LiCl (2) could reduce the starting temperature to 61°C.

In this paper, we will discuss the processes occurring at the aluminum electrode in $AlCl_3$-KCl-NaCl melts containing more than 50 m/o $AlCl_3$. The behavior of the chlorine electrode is discussed elsewhere (3).

Preparation and Purification of $AlCl_3$-KCl-NaCl Melts

Thermal analysis of the $AlCl_3$-KCl-NaCl system has been carried out by Fischer and Simon (4) and by Midorikawa (5). The $AlCl_3$-rich region (>50% $AlCl_3$) constitutes the low temperature region of the phase diagram and is of specific interest for the investigations reported here. Different melting points and com-

* Electrochemical Society Active Member.

Key words: molten salts, aluminum-chlorine battery, passivation.

positions have been reported (4-8) for the ternary eutectic ranging from 70°C for $AlCl_3$-KCl-NaCl (66-14-20 m/o) to 94°C for $AlCl_3$-KCl-NaCl (62.13, 12.7-25.17 m/o). The most reliable value is probably 89°C for $AlCl_3$-KCl-NaCl 63.5-16.5-20. Aside from the pseudobinary eutectics, $NaAlCl_4/AlCl_3$ (108°C), $KAlCl_4/AlCl_3$ (128°C), and $NaAlCl_4/KAlCl_4$ (125°C), very little is known about the actual phase diagram in this region and about the species present in the melt.

All experimental work was carried out in the argon atmosphere of a purge-type glove box. The melts were prepared with Baker "analyzed" KCl and NaCl. In exploratory experiments, $AlCl_3$-KCl-NaCl, 66-14-20 m/o melts were prepared using $AlCl_3$ from eight different manufacturers. Upon heating, grayish brown melts were readily formed. Other investigators (9) have also observed this coloration and attribute it to carbonaceous material and to the presence of $FeCl_3$ impurity in the $AlCl_3$. By investigating the effect of intentional additions of $FeCl_3$, it was confirmed that iron was the major impurity in all melts even where the $AlCl_3$ label stated "iron free" (10). $AlCl_3$ obtained from Fluka Chemicals (Switzerland) was found to contain the lowest impurity level, and was, thus, used as starting material for further purification.

After exploring several purification methods, we settled for the following procedure: a quartz rack containing three electrodes (an Al wire in the center, an Al sheet cylinder as counterelectrodes, and a Pt wire electrode) and a baffle were introduced into a heated 2 liter Pyrex resin reaction kettle containing a Teflon-coated, magnetic stirring bar. A 1500g batch of $AlCl_3$-KCl-NaCl (67.5-13.38-19.12 weight per cent [w/o]) was introduced into the vessel and heated to 130°-140°C. At this temperature, the resulting melt had only a moderate $AlCl_3$ vapor pressure.

A high current (~10A) was passed between the Al electrodes with the wire as cathode for several minutes and aluminum dendrites were formed. These dendrites were partially separated from the wire electrode by reversing the current. Thus, clean high surface Al was produced *in situ*. (We found that, when using Al turnings, the effectiveness of this treatment varied from case to case probably due to the presence of an aluminum oxide layer.) The melt was kept under constant stirring at 140°C for 24 to 36 hr.

The progress of the exchange of Fe^{3+} for Al^{3+} was monitored by cyclic potential sweeps at the Pt wire electrode. A reduction in the ionic iron content by more than a factor of 25 was obtained. The temperature was then raised and the $AlCl_3$ evaporated into an air-cooled, 1 liter reaction kettle placed upside down on top of the reaction vessel. The material so treated was clear and produced virtually transparent eutectics without detectable residual current in the cyclic voltammetric curves obtained on Pt.

The Quasi-Steady-State Behavior of the Al Electrode

Experimental.—The investigations were carried out at three different $AlCl_3$-KCl-NaCl compositions (melt I, 67-13.6-19.4 m/o; melt II, 59-17-24 m/o; and melt III, 57.5-12.5-30 m/o) and at three different temperatures (157°, 126°, and 105°C).

For the measurements on stationary wire electrodes, an electrochemical cell was constructed using two O-ring joints of 50-mm ID. The electrodes and the gas in and outlet tubes were connected with Teflon Swagelok fittings. The working electrode consisted of a pure Al wire of 1 mm diam covered with several layers of shrinkable Teflon tubing except for a length of 1.2 cm. The reference electrode, also an Al wire, was contained in a separate compartment with a narrow opening to protect it from changes in electrolyte concentration.[1] An Al wire spiral around the inside of the vessel served as counterelectrode. A platinum electrode sealed into glass was also included in the cell for measurements of the electrolyte background.

A pressure control, consisting of an electromagnetic valve and a mercury contact manometer, was used to maintain a constant argon pressure (normally, a positive pressure of 10 to 20 Torr was used). The cell was filled and assembled tightly in the glove box, then transferred into an air oven (temperature control ±1°C), and connected to the argon line. No gas was passed through the cell to avoid concentration changes resulting from the appreciable vapor pressure of $AlCl_3$ over the melt. The appearance of the melt was clear, but it turned slightly grayish with time.

The rotating disk assembly and cell are described in detail elsewhere (3).

Results and discussion.—Melts I and II contained varying amounts of $AlCl_3$ at the KCl/NaCl ratio of the ternary eutectic. The KCl/NaCl ratio in melt III is the same as in the pseudobinary eutectic between $NaAlCl_4$ and $KAlCl_4$. These melts promise to be more favorable for practical application than the composition of the ternary eutectic since they stay liquid over a wider concentration range at temperatures around 130°C.

Qualitatively the current voltage curves at an aluminum electrode are very similar in all melts. Typical examples are shown in Fig. 1-3. Figure 4 shows the

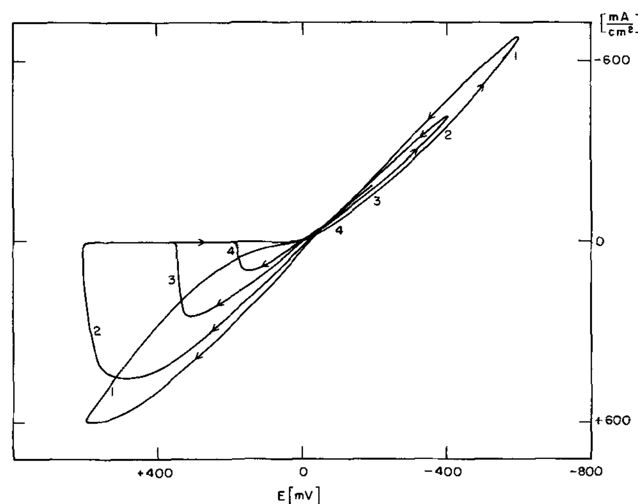

Fig. 1. Triangular potential scans at Al electrode, $AlCl_3$-KCl-NaCl (67-13.6-19.4 m/o) 105°C, 400 mV/min (from 0.0 mV to E_{cath} to E_{anode} back to 0.0 mV, no IR correction).

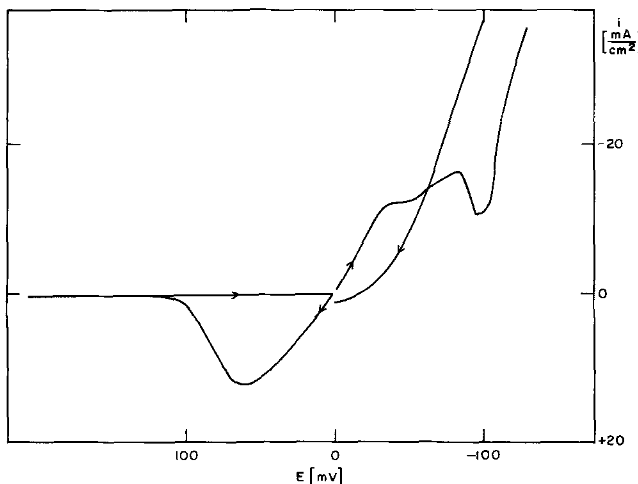

Fig. 2. Separate anodic and cathodic potential scans at an Al electrode. $AlCl_3$-KCl-NaCl (59-17-24 m/o), 105°C, 20 mV/min (no IR correction).

[1] It had been established (11, 12) that an Al electrode is a stable reference in these melts, and all potentials are referred to this electrode in the particular melt investigated.

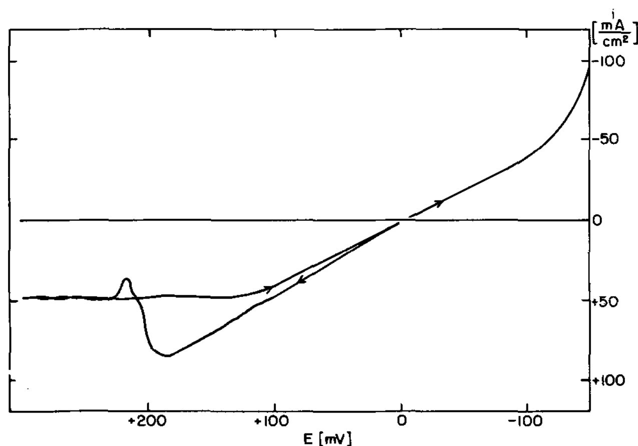

Fig. 3. Separate anodic and cathodic potential scans at an Al electrode. $AlCl_3$-KCl-NaCl (59-17-24 m/o) 157°C, 20 mV/min (no IR correction).

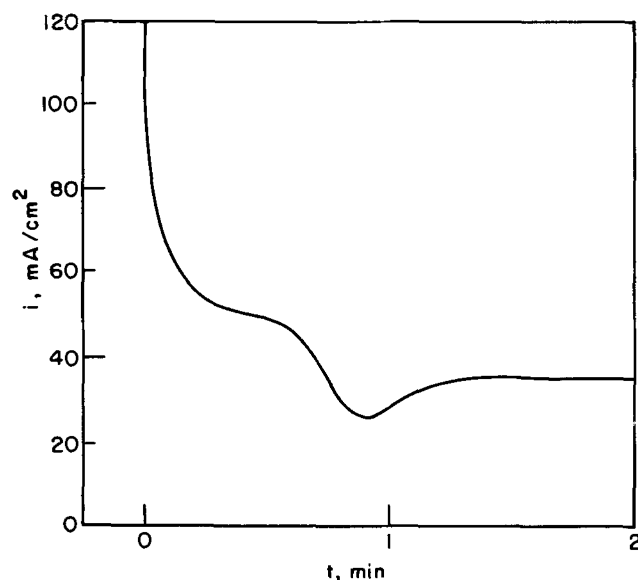

Fig. 4. Anodic current as a function of time upon potentiostatic polarization of Al electrode at 150 mV *vs.* Al in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o) at 126°C (no IR correction).

anodic current as a function of time upon potentiostatic polarization of the Al electrode.

Anodic behavior.—The anodic potential sweeps in Fig. 1-3 show passivation phenomena. This anodic passivation of the Al electrode does not occur at a constant, defined potential. A closer examination reveals that the sudden current drop can be related to the charge passed (current and time) rather than to the potential. Figure 1 shows the correlation between anodic passivation and cathodic prepolarization for a low temperature with melt I. Comparison of the anodic and cathodic charges (represented by the area underneath the i-t curve) shows that they are nearly equal. This is even more obvious for cathodic and anodic current *vs.* time curves upon potentiostatic polarization for periods of varying length (not shown). This behavior seems to indicate that melt I (which is $AlCl_3$-rich) cannot tolerate much more anodic formation of $AlCl_3$ at this temperature without precipitating it in solid passivating form. On the other hand, if by cathodic pretreatment we form a diffusion layer close to the electrode which is poor in $AlCl_3$, then we are able to polarize the electrode anodically for a time necessary to replenish the initial $AlCl_3$ concentration until passivation occurs. Parallel to the current voltage behavior of Fig. 1, it can be seen by microscopic *in situ* observation of the Al electrode (1) that it is shiny after cathodic polarization and becomes dull upon passivation. The fact that the anodic and cathodic charges are almost equal indicates a rather compact diffusion layer with practically no convection. As the cathodic prepolarization time is increased, the charge obtained prior to anodic passivation becomes smaller than the cathodic charge, as one would expect.

Cathodic behavior.—If the above explanation holds, we should expect a similar passivation effect at cathodic currents due to salt precipitation. In fact, current-voltage sweeps show indications of such behavior (for example, Fig. 2). In all cases, however, a subsequent current increase is found after indications of passivation. This is due to dendrite formation at the Al electrode. Long, shiny, Al dendrites can easily be seen growing into the electrolyte, thus enlarging the surface area.

The initiation of dendrite growth is a function of current and time. There seems to be a current value below which little dendrite formation is noticeable. This critical current value changes with conditions. Although more detailed information on the parameters governing dendrite formation is required, our results indicate a strong effect of concentration polarization and ionic conductivity on dendrite formation.

Effect of melt composition.—The most obvious difference between the potential scans of the different melts is a much higher, steady-state, anodic current after passivation in melts II and III compared to melt I. For example, at 156°C, the anodic limiting currents are approximately 2 mA/cm^2 for melt I, 50 mA/cm^2 for melt II, and 100 mA/cm^2 for melt III.

On the cathodic side, a deviation from the linear current-potential behavior appears at much larger current densities in melt I than in melt II. This again confirms our explanations of solid salt formation at the electrode. Melt II, which is less concentrated in $AlCl_3$, can support higher anodic current densities (that means it can accept more Al^{3+} without forming undissolved $AlCl_3$) than melt I. The latter, however, since it is more concentrated in $AlCl_3$, will be able to support higher cathodic currents before forming a passivating salt layer due to X-$AlCl_4$ precipitation (we disregard for the moment the additional complication of dendrite formation). The anodic current maxima (Fig. 3) are very likely due to supersaturation of the melt close to the electrode. After the first crystals have formed, the supersaturation breaks down. This is responsible for the following current dip.

The same effect can be seen in Fig. 4 which shows the anodic current as a function of time upon potentiostatic polarization. Thus, the limiting value of the steady-state current, besides depending on the usual transport properties, also depends on the capacity of the melt to accommodate concentration changes without surpassing the liquidus line of the phase diagram. This is clearly a function of melt composition.

Effect of temperature.—The effect of temperature on the current-voltage behavior of the Al electrode in the molten salt electrolyte, can be seen by comparing Fig. 2 and 3 obtained using the same melt. Although a considerable steady-state current can be obtained at 157°C ($\sim$50 mA/cm^2 in melt II), this steady-state current is practically zero at 105°C. Melt III shows limiting currents of approximately 100 mA/cm^2 at 157°C, and 34 mA/cm^2 at 126°C.

The temperature affects the results in several ways. First, there is the temperature dependence of the usual transport phenomena; for example, the viscosity decreases, and the diffusion coefficients increase with rising temperature. Much more important in our case, however, are considerations concerning the $AlCl_3$-KCl-NaCl phase diagram. We mentioned earlier the key role of solid salt formation. How large a concentration

change is necessary to surpass the liquidus line of the phase diagram is, to a large extent, a function of temperature (besides initial melt composition).

The temperature will surely have an effect on dendrite growth since this is controlled by diffusion and ohmic polarization. Further changes in conductivity, due to varying dissociation constants and changes in complex formation with temperature, are to be expected. These problems cannot, however, be discussed more closely on the basis of presently available data.

Effect of mass transport.—All results of our stationary polarization measurements at Al electrodes indicate that the anodic limiting currents are a function of the mass transport in the melt. We, therefore, expect the anodic limiting currents to depend on the diffusion layer thickness and, thus, on the rotation rate of a rotating Al disk electrode. The current which is controlled only by mass transfer is given by Levich (13)

$$i_L = A \cdot n\mathbf{F}D^{2/3}\upsilon^{-1/6}\omega^{1/2}\Delta C$$

where A is a constant, D is the diffusion coefficient, ΔC is the concentration difference of the electroactive species in the bulk of the electrolyte, and at the electrode surface, υ is the kinematic viscosity, and $\omega = 2\pi$ (rps), where rps = rotations per second. This equation implies a linear relationship between i_L and $\omega^{1/2}$ under diffusion controlled conditions.

As Fig. 5 shows, the experimental data can, indeed, be represented very well by a straight line in such a plot. The slight deviations from linearity and some variations in the individual current densities were to be expected. One must keep in mind that here we are actually dealing with the dissolution of a passivating solid salt layer at the rotating electrode, which is in many respects quite different from the idealized conditions for which the above equation is strictly valid. Further, at the high current densities observed, changes in the electrode itself cannot be avoided.

These results show clearly, however, the role of transport phenomena in removing reaction products from the electrode surface. They show further that high current densities can be obtained at Al electrodes at relatively low temperature if the transport limitations can be overcome.

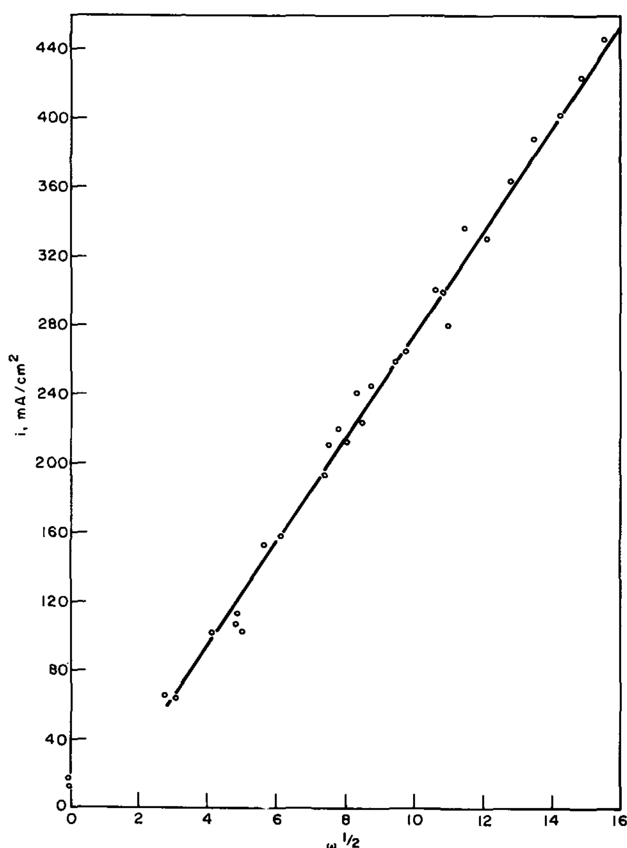

Fig. 5. Anodic limiting current at rotating Al disk electrode in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o) at 125°C.

The Transient Behavior of the Al Electrode

Previous measurements suggested that the charge-transfer processes at the Al electrode are quite fast. It is, therefore, necessary, in order to exclude the effect of concentration polarization, to use transient methods to investigate the electrode kinetics. We chose galvanostatic pulse measurements for this purpose.

Galvanostatic current step methods.—The galvanostatic technique, considering the double layer charging, was originally discussed by Berzins and Delahay (14) and, since then, has been used in several investigations. Following Graves, Hills, and Inman (15) we can write for small overvoltages ($\eta < 0.1\ RT/n\mathbf{F}$); and for sufficiently long times the potential transient as a function of a galvanostatic current pulse

$$\eta = \frac{-2RTit^{1/2}}{\pi^{1/2}n^2\mathbf{F}^2C_o^0D^{1/2}} + \frac{RTi}{n\mathbf{F}}\left[\frac{RTC_{dl}}{n^3\mathbf{F}^3(C_o^0)^2D} - \frac{1}{i_o}\right] \quad [1]$$

Hence, a plot of $\eta/t^{1/2}$ should give a straight line of slope

$$\frac{d\eta}{d(t^{1/2})} = \frac{-2RTi}{\pi^{1/2}n^2\mathbf{F}^2C_o^0D^{1/2}} \quad [2]$$

from which a value for $C_o^0D^{1/2}$ can be calculated.

When $t^{1/2} = 0$, then

$$\eta = \frac{RTi}{n\mathbf{F}}\left[\frac{RTC_{dl}}{n^3\mathbf{F}^3(C_o^0)^2D} - \frac{1}{i_o}\right] \quad [3]$$

and the intercept on the η axis, together with the value for $D(C_o^0)^2$ calculated above, will give a value for i_o from Eq. [3].

An alternative method for calculating i_o is the use of a special value of $t^{1/2}$ given by

$$t_c^{1/2} = \frac{\pi C_{dl}}{4i} \times \frac{d\eta}{d(t^{1/2})} \quad [4]$$

The corresponding overpotential, η_c, can be found from the curve, and a value for i_o calculated.

Both methods require the determination of the differential double layer capacity which can be obtained from the initial slope of the potential time trace at sufficiently short times (16).

Experimental.—In view of the facts mentioned above, it was necessary to use pulses with a short rise time and high current density. It was also necessary to be able to record small potential changes with time, which required a low noise level in the experimental setup and compensation of the ohmic drop in the solution. For the constant current pulses, the output of a Wavetek function generator (gated by a Tyco-built pulse generator to allow multiple pulse application) was used directly. The *IR* compensated, potential-time traces were obtained by feeding the potential of the two-electrode cell and the output of the *IR* compensation into the inputs of the differential amplifier of a Tektronic dual trace oscilloscope. The measurements were conducted at an Al disk electrode ($0.385\ cm^2$). A sheet of pure Al ($15\ cm^2$) served as the counterelectrode. The experimental setup, including the cell, showed a response time of about 1 μsec. The melt $AlCl_3$-KCl-NaCl (57.5-12.5-5-30 m/o) was thermostated by a temperature controlled silicone oil bath. Again, a slightly positive argon pressure was kept in the cell at all times.

Results and discussions.—From the initial slope of the potential-time traces at anodic and cathodic current pulses, a double layer capacity of $40 \pm 10\ \mu F/cm^2$

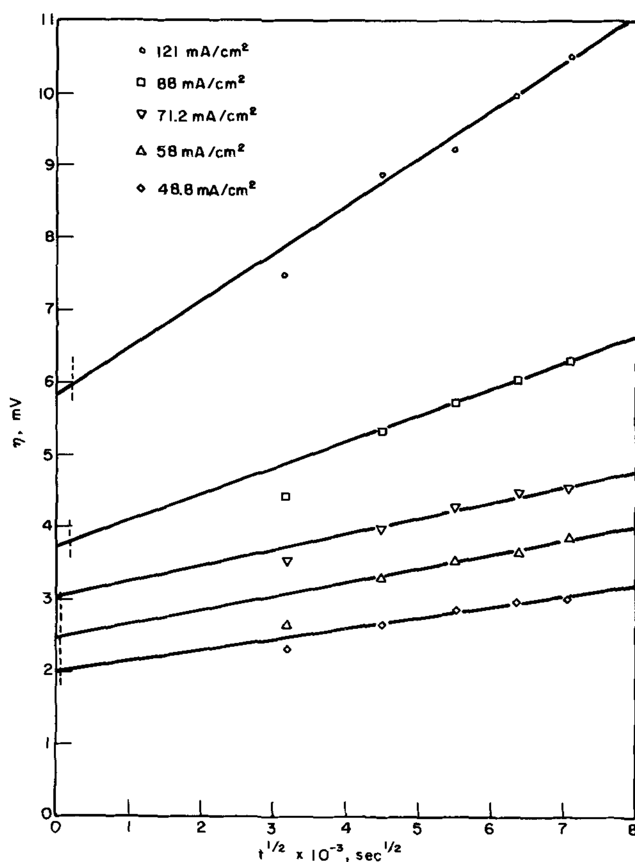

Fig. 6. Variation of overvoltage with time at Al electrode upon galvanostatic current step in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o) at 130°C.

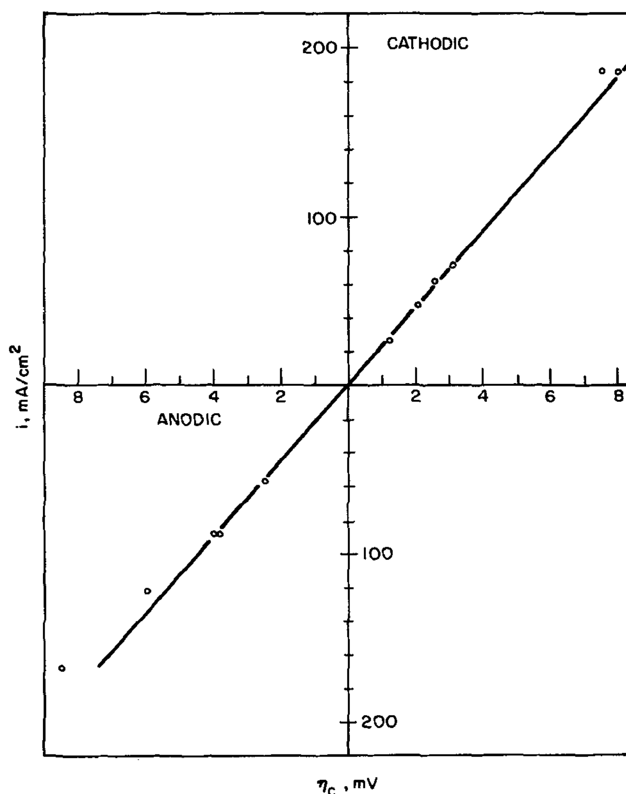

Fig. 7. Current density vs. activation overvoltage at Al electrode in $AlCl_3$-KCl-NaCl (57.5-12.5-30 m/o) at 130°C.

was determined. Considering the surface roughness, this suggests the absence of specific absorption effects.

Figure 6 shows a typical overvoltage *vs.* square root of time plot for various current densities. At times larger than 10 μsec, the potential varies linearily with $t^{1/2}$. As expected, the slope of these lines increases with increasing current density. The times, $t_c^{1/2}$, according to Eq. [4] are also included in Fig. 6. Figure 7 shows a plot of i *vs.* activation overvoltage. At low overvoltages, one finds a linear relationship between current density and potential. With $n = 3$, the apparent exchange current at the Al electrode was determined as $i_o = 268$ mA/cm² at 130°C in the melt $AlCl_3$-KCl-NaCl (57.5-12.5-5-30 m/o).

Schulze and Hoff (17) recently investigated the transference of aluminum in a temperature gradient. From these measurements they deducted similar values for the exchange current at aluminum electrodes in $AlCl_3$-KCl-NaCl (66-14-20 m/o) between 160° and 230°C [i_o (490°K) 0.86A, $Q = 9.7$ kcal/mole]. They also assume that $n = 3$. Despite reports of multiple electron transfer in molten salts (18), a three-electron transfer as rate determining step for the aluminum electrode is not established. Thus, the available data are not sufficient to decide upon a detailed electrode mechanism. The aluminum electrode has been investigated also in molten $AlCl_3$-NaCl and $AlCl_3$ (LiCl-KCl) by Del Duca (19). The results are, however, too different in order to allow a meaningful comparison with the present investigation.

Finally, it is interesting to examine more closely the values obtained for the transport parameter, $C_o^0 D^{1/2}$. These values were found to be approximately 1.4×10^{-8}. Assuming a diffusion coefficient of 10^{-6} cm²/sec in the melt, one obtains for the concentration of the electroactive species $C_o^0 \approx 1.4 \times 10^{-5}$ mole/cm³. This is about two orders of magnitude less than the excess $AlCl_3$ assuming 50 m/o $AlCl_3$ to be complexed as $(AlCl_4)^-$. Unfortunately, practically nothing is known about the nature of the species present in the melt and about the complex formation in $AlCl_3$-rich melts.

Conclusions

The behavior discussed above in detail leads us to the following conclusions.

1. The passivation effect is due to the formation of a solid salt layer at the electrode surface caused by concentration changes during current flow.
2. The occurrence of passivation is not dependent on potential, but rather on current and time, *i.e.*, on charge passed through the electrode. It also depends on the transport properties of the melt.
3. The occurrence of salt formation depends on the compositional stability of the melt towards concentration changes. It is strongly dependent on melt composition and on temperature.
4. At cathodic currents, dendrite formation occurs at the Al electrode.
5. The Al electrode itself is highly reversible and able to support large current densities at low activation overvoltage.
6. The polarization observed in the experiments is, to a large extent, ohmic in nature. It again depends on melt composition and temperature.

Acknowledgments

The authors wish to thank Dr. B. Burrows and Mr. M. Turchan for contributions to this investigation. This research was supported by the Electronics Research Center, U. S. National Aeronautics and Space Administration, under Contract No. NAS 12-688.

Ring-Disk Electrode Study of the Reduction and Oxidation of Bismuth on Gold

S. H. Cadle and Stanley Bruckenstein*

Chemistry Department, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

The deposition and stripping of bismuth at a gold electrode was studied in 0.12*M* perchloric acid. Current-potential curves show four cathodic and four anodic processes at $E_D < +0.40V$ *vs.* SCE. Three of these processes correspond to the deposition and stripping of Bi(O) at underpotential. A maximum of one monolayer of Bi(O), corresponding to 590 μcoulombs/cm^2 at $-0.05V$, was deposited on the electrode at underpotential. The fourth process was the deposition and stripping of bulk bismuth. The diffusion coefficient of Bi(III) was found to be 5.8×10^{-6} cm^2/sec. No Bi-Au alloy formation was observed. Bi(III) was found to adsorb on gold oxide. The quantity adsorbed is a function of the oxidation potential of the electrode and the concentration of Bi(III).

The deposition and stripping of bismuth on platinum electrodes was studied initially by Bowles (1) in perchloric acid media. In this study, he reported that bismuth deposits at underpotential on platinum. Recently we reinvestigated the deposition and stripping of bismuth on platinum using the rotating platinum ring-disk electrode (2). This work showed that the underpotential deposition of bismuth on platinum in 0.12*M* perchloric acid media was markedly irreversible in that underpotential bismuth oxidation occurred over the potential region 0.0 to +1.2V *vs.* SCE. We also found that bismuth (III) is adsorbed on platinum oxide. Because of the overlap in the potential regions of adsorption of bismuth (III) and underpotential deposition and stripping of bismuth (O), there is no electrode potential for which the surface of a platinum electrode is free of bismuth in one or another of its oxidation states. After deposition of multilayers of bismuth, oxidation resulted in the formation of five additional stripping peaks which were shown to be associated with four monolayers of bismuth and an alloy several monolayers deep.

Schmidt, Gygax, and Cramer (3) studied the deposition of bismuth on gold from hydrochloric acid media. They found that deposition at underpotential occurred in two potential regions, resulting in the plating of a single monolayer of bismuth. No alloy formation or adsorption was observed.

We felt that it would be valuable to study the plating and stripping of bismuth on gold from perchloric acid media using a rotating gold ring-disk electrode (RGRDE) and contrast the behavior at gold with that observed at platinum.

It will be shown below that a monolayer of bismuth is deposited at underpotential on a gold electrode from perchloric acid media. A full monolayer of underpotential Bi(O) must be deposited before bulk deposition occurs. Also Bi(III) adsorbs on gold oxide but not on reduced gold.

* Electrochemical Society Active Member.
Key words: ring-disk electrode, adsorption, bismuth, gold, underpotential deposition.

Experimental

Solutions and equipment.—All solutions were prepared using triply distilled water. B and A reagent grade perchloric acid was used to prepare the 0.12*M* supporting electrolyte. Stock solutions of Bi(III) were prepared by dissolving Fisher reagent grade bismuth trioxide in perchloric acid solution. All solutions were deoxygenated by passing nitrogen through and over the solution. The nitrogen was passed through a hot column of finely divided copper dispersed on diatomaceous earth to remove any traces of oxygen from the gas.

The circuit for the ring-disk potentiostat (4) has been previously described, as has the electrochemical cell, the X-Y-Y' recorder and the rotator (4).

The projected area of the gold ring-disk electrode was 0.46 cm^2. The electrode parameters, N, $B^{2/3}$, and S were 0.42, 1.22, and 0.66 respectively (4).

All potentials are reported *vs.* the saturated calomel electrode (SCE). Values of the number of μcoulombs passed per cm^2 are reported using the projected area of the electrode, uncorrected for roughness factor.

Electrode pretreatment.—The gold ring and disk electrodes were pretreated in the following manner:

(*i*) The electrode was polished with Buehler 0.05μ gamma micropolish. (*ii*) Next it was oxidized at +1.6V for 5 min and reduced at −0.3V for 5 min. (*iii*) The electrode potential was then cycled repeatedly between +1.6 and −0.30V until a reproducible current-potential curve was obtained.

The electrode was reactivated periodically during the course of an experiment by oxidizing it at +1.6V, and then cycling its potential from +1.6 to −0.3V several times.

Results and Discussion

Bi(III) reduction.—The plating and stripping of bismuth on a gold ring-gold disk electrode was studied in 0.12*M* perchloric acid solution. Figure 1 shows the disk current-disk potential curve (I_D-E_D) and the corresponding ring current-disk potential (I_R-E_D) curve in a $2 \times 10^{-5}M$ Bi(III) solution for a ring potential, E_R, equal to −0.30V. The ring electrode potential chosen produces a convective-diffusion controlled-limiting wave for the reduction of Bi(III). Curves 1-3 correspond to increasing disk potential scan rates of 5, 20, and 50 mV/sec respectively.

Shielding of the ring electrode occurs for $E_D < +0.35V$, indicating the consumption of Bi(III) at the disk electrode. The shielding and the disk current are seen to be a function of the potential scan rate at $+0.35V \leq E_D \leq -0.23V$. In the disk electrode potential range $+0.35V \leq E_D \leq -0.05V$, I_D falls to zero if the potential scan is stopped indicating that only a finite quantity of bismuth can be deposited in this potential region. This bismuth is shown below to be underpotential deposited Bi(O). Figure 1, curve 1 demonstrates that the deposition of Bi(O) at underpotential occurs in three distinct potential regions labeled A-C, in contrast to the behavior observed by Schmidt *et al.* (3) in hydrochloric acid where only two underpotential deposition regions were observed. Peaks A-C disappear at higher scan rates because the deposition of Bi(O) becomes convective-diffusion controlled.

A steady-state Bi(III) reduction current is observed at the disk electrode $E_D = -0.05V$ (Fig. 1). A plot of the steady-state current at −0.25V *vs.* $\omega^{1/2}$, the square root of the rotation velocity, is linear with a zero intercept proving that the limiting current is convective-diffusion controlled. The diffusion coefficient of Bi(III) was calculated using the Newman version (5) of the Levich equation to be 5.8×10^{-6} cm²/sec, the same as was found at the platinum disk electrode (2).

Bi(O) oxidation.—The oxidation of Bi(O) from a gold electrode exhibits current peaks at +0.30, +0.15, +0.10, and +0.05V, peaks A-D in Fig. 2. The corresponding ring collection curves yielded the theoretical value of the collection efficiency for all four stripping peaks. The Bi(O) which strips at peaks A-C deposits before the Bi(O) which is oxidized at D. This fact was established by depositing various amounts of Bi(O), and oxidizing these films. Peak D is due to the oxidation of bulk deposits of Bi(O), while peaks A-C represent the stripping of underpotential Bi(O).

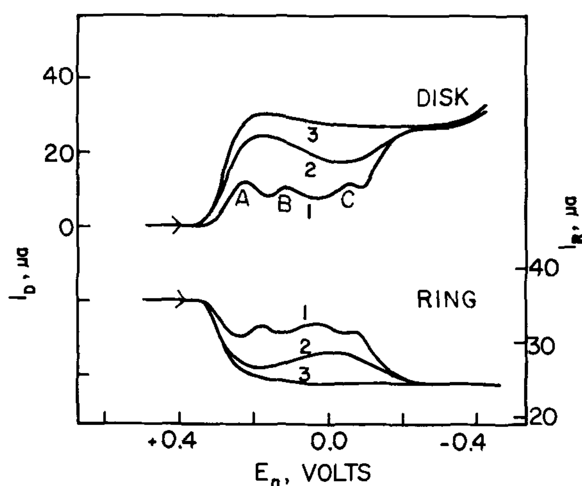

Fig. 1. Cathodic current-potential curve for a Bi(III) solution at a RGRDE. 0.12M $HClO_4$, $2 \times 10^{-5}M$ Bi(III), rotation speed 2500 rpm, ring potential −0.300V, potential scan rate curve (1), 5 mV/sec; curve (2), 20 mV/sec; curve (3), 50 mV/sec.

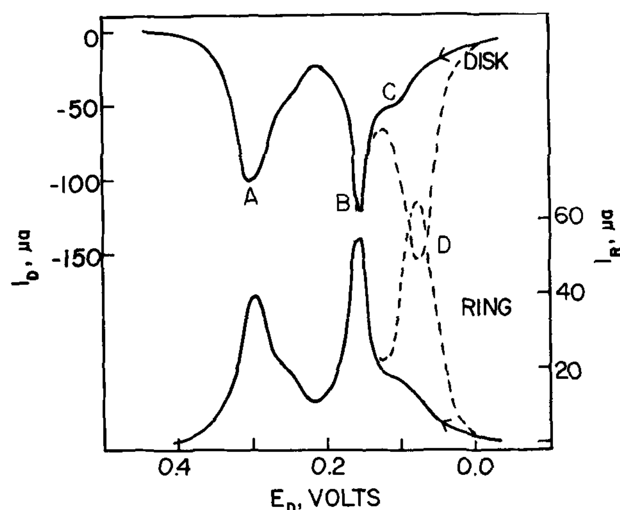

Fig. 2. Oxidation of Bi(III) from a gold electrode. 0.12M $HClO_4$, $2 \times 10^{-5}M$ Bi(III). — *Disk electrode scanned anodic after a 15 min potential hold at* −0.050V. - - - Disk held at −0.100V for 40 sec, rotation speed 2500 rpm, ring potential −0.300V, potential scan rate 50 mV/sec.

No Bi-Au alloy formation was observed electrochemically, in contradistinction to the situation for Pt-Bi(2). Also, no oxidizable species was detected by the ring electrode during the stripping process for ring potentials of +1.6 to −0.3V.

The quantity of Bi(O) deposited at underpotential on the disk electrode was determined as a function of potential from ring collection curves (Table I). The disk was potentiostated at various potentials in $2 \times 10^{-5}M$ Bi(III) solution for 15 min before scanning to anodic potentials in the range −0.05 to +0.4V to strip the Bi(O) deposited at underpotential. Potentiostating the electrode for longer periods of time did not increase the amount of Bi(III) collected. A maximum of 290 μcoulombs/cm² was oxidized at peak A. The maximum amount of Bi(O) plated at underpotential peaks A, B, and C ($E_D \geq -0.05V$) was 590 μcoulombs/cm².

Roughness factor.—The roughness factor of the gold disk electrode was estimated in three ways. Two of the methods have been reported previously, *i.e.*, the method of Brummer and Makrides (6), the method used by Woods (7), and the third is one we developed.

Brummer and Makrides suggest that a complete monolayer of oxygen is adsorbed on a gold electrode at +1.20V in 1*M* perchloric acid and corresponds to 400 μcoulombs/cm². One oxygen is adsorbed for each gold atom exposed on the surface. On our electrode we found that 596 μcoulombs/cm² of charge was required to reduce the electrode after oxidation at +1.20V, corresponding to a roughness factor of 1.49.

Table I. Underpotential deposition of bismuth on gold

Disk potential volts *vs.* SCE	Bismuth μcoulomb/cm²	Surface coverage
−0.050	590	0.98
0.000	582	0.96
0.050	475	0.79
0.100	368	0.61
0.150	284	0.47
0.200	241	0.40
0.250	129	0.21
0.300	3.9	0.01

Woods estimated the true surface area of exposed gold in platinum-gold alloy electrodes by assuming that 300 μcoulombs/cm^2 of charge is required to reduce a gold electrode when it is continuously cycled between −0.25 and +1.25V at 40 mV/sec in 1*M* perchloric acid. Since the current-voltage curves for platinum-gold alloys are the sum of current-voltage curves for pure platinum and pure gold (7), Woods method for calculating the gold surface area of Pt/Au alloys should be as valid for calculating the roughness factor of gold electrodes as for gold-platinum alloys. We found that 402 μcoulombs/cm^2 was required to reduce our electrode under Woods' conditions, yielding a roughness factor of 1.34.

In order to obtain a third estimate of the roughness factor of the gold disk electrode, Cu(O) was deposited at underpotential on the electrode from 0.12*M* perchloric acid solution. The deposition of Cu(O) on gold has been studied by Schmidt (8, 9). Assuming that copper deposits at underpotential on gold in the same manner that it deposits on platinum, *i.e.*, in a single uniform monolayer where one copper atom is associated with one platinum atom (10), 400 μcoulombs/cm^2 of the Cu(O), should be deposited at underpotential on a gold electrode with a roughness factor of one. For our electrode 556 μcoulombs/cm^2 of Cu(O) was deposited at underpotential, corresponding to a roughness factor of 1.39.

The average of the roughness factors determined by the three different techniques was 1.41 ± 0.10, and all our results were obtained, either with an electrode having a roughness factor of 1.41, or the results were corrected to a roughness of 1.41, using the roughness factor determined from the deposition of copper at underpotential.

The last column in Table I gives the fractional surface coverage of Bi(O) on gold as a function of potential. These data were calculated from the second column of Table I assuming that 605 μcoulombs/cm^2 Bi(O) constitute a single monolayer of close packed Bi atoms on a gold electrode with a roughness factor of 1.41.

Monolayer coverage charge.—The quantity of Bi(O) which constitutes monolayer coverage on a gold electrode was calculated assuming: (*i*) a 3 electron reduction of Bi(III) to Bi(O), (*ii*) that a monolayer of oxygen adsorbed on gold, one oxygen atom per gold atom, is equal to 400 μcoulombs/cm^2 for a roughness factor of 1.0 (5), and (*iii*) the atomic radii of gold and bismuth are 1.44 and 1.70Å respectively. Since 400 μcoulombs/cm^2 is the charge required for a 2 electron reduction to occur at every gold atom exposed at the surface of a gold electrode, 600 μcoulombs/cm^2 would be required for the 3 electron reduction of Bi(III) to Bi(O) at every gold atom. However, since Bi(O) is larger than Au(O) it is necessary to multiply 600 μcoulombs/cm^2 by the square of the ratio of the atomic radii of Au(O) to Bi(O). Using this procedure, which has also been used by Bowles (11), we calculate that 430 μcoulombs/cm^2 Bi(O) constitutes a monolayer on a gold electrode with a roughness factor of 1.

Adsorption of Bi(III).—Figure 3 is an I_D-E_D curve in 0.12*M* perchloric acid in the presence and absence of 2 × 10^{-5}*M* Bi(III). The plating and stripping of underpotential bismuth is evident at E_D = +0.40V. The introduction of Bi(III) into the supporting electrolyte causes a small decrease in the quantity of surface gold which is oxidized during the anodic scan. During the cathodic scan, the presence of Bi(III) causes a marked shift in the cathodic direction, and a broadening of the gold oxide reduction peak.

The anodic I_D-E_D curve can be rationalized by assuming (*i*) that Bi(III) adsorbs on an oxidized gold electrode, and that (*ii*) this has an inhibiting effect on the oxidation of a small amount of remaining reduced gold, thus causing the decrease in the anodic current. The cathodic I_D-E_D curve demonstrates that the presence of adsorbed Bi(III) on the oxidized gold surface has a stabilizing effect on the oxidized gold causing the shift of the reduction peaks in the cathodic direction. The fact that the adsorbed Bi(III) has both an inhibiting effect and a stabilization effect on the oxidized gold appears to be inconsistent, unless we assume that the inhibition of the gold oxide formation is due to the physical blocking of the surface by the adsorbed Bi(III).

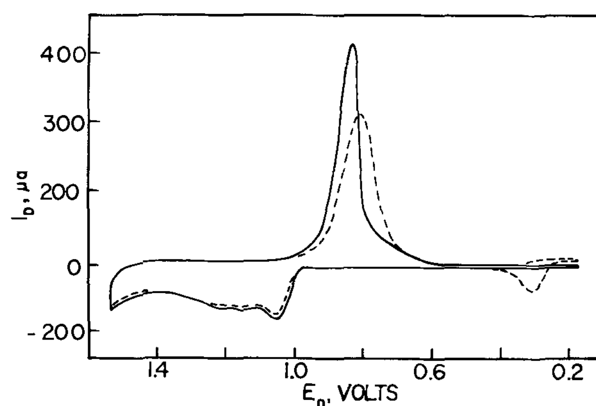

Fig. 3. Current-potential curve at a rotating gold disk electrode ——— 0.12*M* $HClO_4$, ---- 0.12*M* $HClO_4$ + 2 x 10^{-5}*M* Bi(III), rotation speed 2500 rpm, potential scan rate 100 mV/sec.

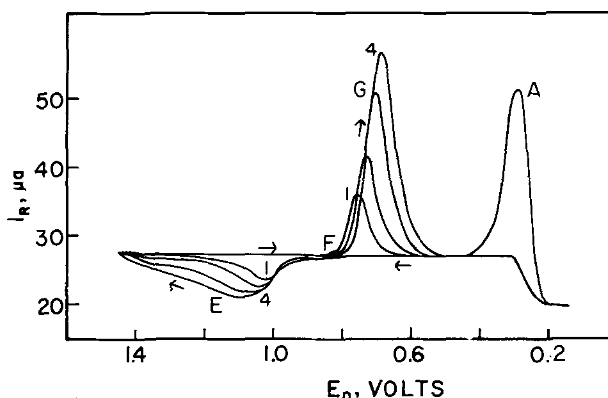

Fig. 4. Ring current-disk potential curves at a RGRDE 0.12*M* $HClO_4$, 2 x 10^{-5}*M* Bi (III), rotation speed 2500 rpm, ring potential −0.300V. Potential scan rate curve (1), 25 mV/sec; curve (2), 50 mV/sec; curve (3), 100 mV/sec; curve (4), 200 mV/sec.

Figure 4 presents a series of I_R-E_D curves obtained in a 2 × 10^{-5}*M* Bi(III) solution at different potential scan rates. Curves 1-4 represent disk potential scan rates of 25, 50, 100, and 200 mV/sec, respectively. In this discussion we are not particularly concerned with the behavior of the ring electrode at potential cathodic of +0.4V, since this has been previously discussed (see Fig. 1 and 2). We merely note that peak A in Fig. 4 corresponds to peak A in Fig. 2, and its independence of scan rate confirms the convective-diffusion controlled nature of the process leading to the deposition of underpotential bismuth (see Fig. 1).

During the anodic scan, at peak E, there is a decrease in the ring current for E_D > 1.0V, indicating the consumption of Bi(III) at the disk electrode. As the disk potential scan rate is increased to 200 mV/sec, the ring current becomes completely shielded. Since Bi(III) is not reduced in this potential region, the ring shielding can only be attributed to the adsorption of Bi(III) on gold oxide.

The adsorbed Bi(III) desorbs when the gold oxide is reduced and is collected at the ring giving a ring current peak at +0.75V (peak G). The small peak F, at +0.82V is due to the collection of a soluble gold

species which is also found to be collected in this supporting electrolyte solution (12). The charge involved in the shielding curve and the stripping peaks are equal, proving that all of the Bi(III) adsorbed on the anodic scan was desorbed during the cathodic sweep.

The shift in the ring collection peak potential in the cathodic direction with increasing disk potential scan rate is attributed to a slow kinetic step in the desorption process, since a corresponding shift in the gold oxide reduction peak at the disk was not observed.

The quantity of Bi(III) adsorbed at the disk electrode was determined as a function of disk potential by integration of ring collection curves. For this study the disk electrode was potentiostated, successively, at 0.10V intervals in the range 1.10-1.60V for 15 min in a $2 \times 10^{-5}M$ Bi(III) solution before scanning E_D in a cathodic direction. No adsorption experiments were conducted at potentials greater than +1.6V because surface roughening of the gold electrode occurs readily at these potentials (9).

The results of the adsorption experiments are given in Table II. A maximum of 0.28 monolayers of Bi(III) was adsorbed at +1.6V from a $2 \times 10^{-5}M$ Bi(III) solution.

Not unexpectedly, the adsorption of Bi(III) was also found to be concentration dependent. Table II lists the quantity of Bi(III) adsorbed at 1.4V as a function of concentration. An eightyfold increase in concentration resulted in a 2.3-fold increase in the quantity of Bi(III) adsorbed.

Table II. Adsorption of bismuth on gold

Disk potential volts *vs.* SCE	Bi(III) conc moles/l	Bi(III) adsorbed μcoulomb/cm^2	Surface[a] coverage
1.100	2.0×10^{-5}	85	0.14
1.200	2.0×10^{-5}	124	0.20
1.300	2.0×10^{-5}	125	0.21
1.400	2.0×10^{-5}	149	0.25
1.500	2.0×10^{-5}	169	0.28
1.600	2.0×10^{-5}	170	0.28
1.400	2.0×10^{-6}	94	0.15
1.400	6.0×10^{-6}	123	0.22
1.400	1.6×10^{-5}	147	0.24
1.400	5.6×10^{-5}	186	0.31
1.400	1.6×10^{-4}	212	0.35

[a] Based on our earlier calculation that 605 μcoulombs/cm^2 is required for monolayer coverage on our gold electrode.

Conclusion

In marked contrast to the case of bismuth deposited on platinum, we find that there are potential regions at the gold disk electrode where the electrode surface is free of plated or adsorbed bismuth. Furthermore, again in marked contrast to the behavior of Bi(O) films on platinum, on gold no difficult-to-oxidize bulk alloy forms when bismuth deposits. With the use of gold electrodes the stripping of submonolayer and multimonolayer films of bismuth can be recovered quantitatively after deposition.

Thus, gold should prove to be far superior to platinum as an electrode material for the anodic stripping analysis of Bi(III) solutions. For the latter purpose, in 0.12*M* $HClO_4$, deposition at −0.25V, and oxidation at +0.40V should prove satisfactory.

Thermodynamic Properties of Manganous Chloride in Alkali Chloride Melts by Electromotive Force Measurements

A. S. Kucharski and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario, Canada

ABSTRACT

Electromotive force measurements on the $MnCl_2$-ACl systems where A = Li, Na, K, and Cs were made using cells of the type

$$\text{Mn} \;(-) \;\Big|\; MnCl_2\text{-ACl (liquid)} \;\Big|\; \text{graphite, } Cl_2 \text{ (1 atm)} \;(+)$$

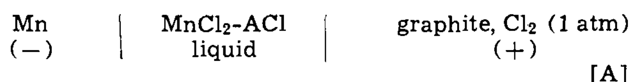
largely in the temperature range 600°-900°C. The partial molar free energies, enthalpies, and entropies of mixing have been calculated from the emf results. The systems indicate negative deviations from ideality which are increasing from Li throughout to Cs. The concentration dependence of the partial molar enthalpies and entropies of mixing has been interpreted on the basis of the "complex ion" model previously developed which is applicable to reactive change asymmetrical fused salt mixtures. The entropy of mixing has been treated by postulating vibrational as well as a configurational contributions. The vibrational contributions have the largest negative values in the $MnCl_2$-CsCl system. The effect of the vibrational contribution on the partial molar properties is also discussed.

The thermodynamic properties of a number of transition metal chlorides dissolved in alkali chlorides have been determined recently by calorimetric and electrochemical methods.

Papatheodorou and Kleppa have measured the calorimetric heats of mixing in the binary systems $MnCl_2$-ACl, $FeCl_2$-ACl, $CoCl_2$-ACl (1), and $NiCl_2$-ACl (2), where, A represents the alkali metal cations Li, Na, K, Rb, and Cs, here and throughout the paper. A common trend in these systems is that they have pronounced exothermic heats of mixing which increase as the size of the alkali metal cation in the binary mixtures becomes larger. Electrochemical measurements by Hamby *et al.* (3, 4) on the systems $NiCl_2$-ACl and $CoCl_2$-ACl, where A represents Li, Na, and K, also indicate pronounced negative deviations from ideality and exothermic heat effects. The concentration dependence of the interaction parameters in the systems MCl_2-ACl (M = Mn, Fe, Co, and N) $\Delta H_M/X_1X_2$, determined from the calorimetric measurements by Papatheodorou and Kleppa (1, 2), indicated a minimum at about 33 m/o (mole per cent) MCl_2. The authors attributed this effect to the possible formation of a tetrahedrally coordinated MCl_4^{-2} species (1, 2). Thus, the heat of mixing was thought to originate from a heat of reaction and other heat effects resulting from the transformation of the covalently bonded pure salt to an ionic species, followed by changes in the coulombic and dispersion interactions during mixing.

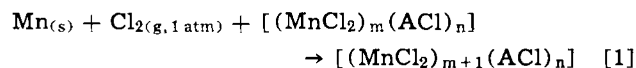
The formation of tetrahedrally coordinated complexes in divalent metal chlorides was first suggested by Flood and Urnes (5) in their analysis of the phase diagrams of the systems $MgCl_2$-ACl (A = Na, K, and Rb), where the liquidus tie lines were predicted using activities calculated on the basis of the complete formation of the $MgCl_4^{2-}$ complex species. The calculations, however, were entirely based on configurational entropies and ignored the enthalpy contributions (6) which are now known to be quite significant.

In the present investigation the thermodynamic properties of the binary systems $MnCl_2$-ACl where A = Li, Na, K, and Cs, were studied by emf measurements using formation cells of the type



$$\text{Mn} \;(-) \;\Big|\; MnCl_2\text{-ACl liquid} \;\Big|\; \text{graphite, } Cl_2 \text{ (1 atm)} \;(+) \qquad [A]$$

for which, the cell reaction is represented by



$$Mn_{(s)} + Cl_{2(g,\,1\,atm)} + [(MnCl_2)_m(ACl)_n] \rightarrow [(MnCl_2)_{m+1}(ACl)_n] \qquad [1]$$

The results are interpreted in terms of the "complex ion model" presented previously (7) which is further extended to account for the unusual concentration dependence of the partial molar entropies of mixing.

There have been two previous electrochemical studies of the $MnCl_2$-KCl, and the $MnCl_2$-NaCl systems by Bruneau *et al.* (8, 9). However, these authors have not measured the standard formation potential for pure $MnCl_2$, and in addition, only a few measured points are reported for the $MnCl_2$-NaCl system. The reported emf values indicate significant scatter and the uncertainties can be attributed to experimental difficulties associated with the use of graphite as an electrode in $MnCl_2$ melts, which are discussed in detail in the Experimental section.

Experimental

Anhydrous manganous chloride was prepared by a method similar to that employed by Corbett *et al.* (10). Reagent grade manganous chloride tetrahydrate was dehydrated in vacuum at 210°C for 24 hr. To insure final dehydration, the pink solid was ground to a fine powder and slowly fused under a stream of anhydrous hydrogen chloride gas (Matheson Research Grade). In order to insure that no oxide would remain in the melt, anhydrous chlorine gas was also bubbled through the melt for 15 min followed by flushing with argon gas to remove the dissolved chlorine. After cooling under argon, the quartz glass container with the salt was transferred to a dry box. The glass was then broken under an inert gas atmosphere and the salt was stored in sealed containers until used. The chemical analysis of the purified manganous chloride indicated an average chlorine to manganese mole ratio of 2.005 ± 0.005.

For all the alkali chlorides used in these experiments the dehydration procedure was essentially the same. The reagent grade alkali chlorides were purified initially by drying in vacuum for several days at 110°C,

Key words: manganous chloride thermodynamic properties, complex ions; molten salts, manganous chloride emf measurements.

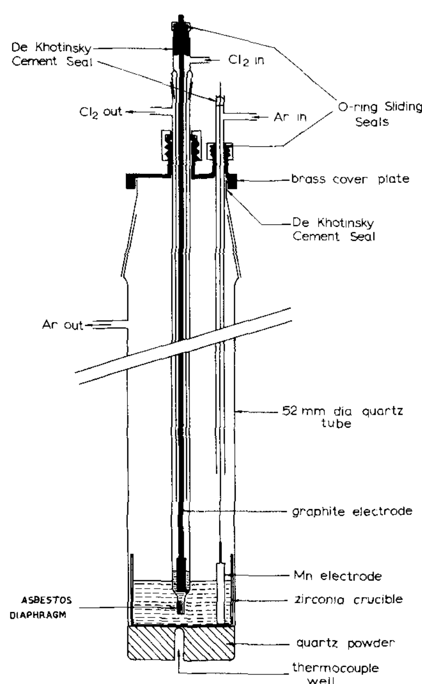

Fig. 1. EMF formation cell

followed by melting under a stream of anhydrous hydrogen chloride gas. When the salts were molten, the hydrogen chloride atmosphere was flushed out with argon. Chlorine gas was then bubbled through the melt for approximately 20 min, and finally, the melt was sparged with dry argon and allowed to solidify under an argon atmosphere. These purified salts were also stored in tightly sealed containers until used.

The design of the electrochemical cell used in these measurements is given in Fig. 1.

The cell consists of two half-cell compartments separated by an asbestos diaphragm. The purpose of the diaphragm was to hinder the diffusion of chlorine gas into the metal electrode compartment while allowing ionic transfer. The stability of the measured emf's in cells employing gaseous chlorine or sulfur vapor electrodes (11, 12) investigated previously in this laboratory has been attributed to the high resistance and the general chemical stability of these diaphragms.

The manganese metal electrode was prepared by melting electrolytic manganese (99.9%) in a closed-end alumina tube under an atmosphere of purified argon. A 1/8 in. diam rod of tungsten, used for the electrical connections, was introduced into the molten metal and the liquid was allowed to solidify slowly. A flexible platinum wire was then welded to the tungsten rod and served as the final electrical lead to the potentiometer.

The chlorine electrode consisted of a graphite rod immersed in an atmosphere of pure chlorine gas (Matheson Research grade) as shown in Fig. 1. The graphite electrode was prepared in the standard manner (13). The electrodes were heated to 900°C and held at this temperature for 8 hr. Chlorine gas was then passed over the graphite for 12 hr and finally the system was evacuated for 8 hr. It was found that the electrolyte and particularly the manganous chloride-rich concentrations reacted with the graphite, since upon long immerison an electrode would become swollen and brittle.

An electron scanning photomicrograph was taken on such swollen graphite samples and indicated the presence of salt inclusions within the graphite matrix. The attack on graphite appears to be related to the chemical composition of the salt phase. For example, pure molten $MnCl_2$ caused more severe damage to the electrode than the dilute solutions of $MnCl_2$ in alkali chlorides. Porous graphite was also more severely affected than the dense variety. It appears that upon long exposure to the melt manganese ions are capable of penetrating the bonded layer structure of graphite thus creating a volume increase accompanied by a loss of mechanical strength. This effect caused a serious deterioration in the electrochemical behavior of the chlorine electrode resulting in a drift of the potentials toward lower values.

Accordingly, to prevent the deterioration of the graphite electrode, the electrode was constructed from dense graphite, an experiment was always started at the lowest temperature, and the graphite electrode was connected to a vacuum sliding seal and could be withdrawn from the melt when not in use.

Graphite swelling due to chemical attack in $CdCl_2$-NaCl melts has also been reported by Dijkhuis (14). Graphite is also known to form electrically conducting lamellar compounds with gaseous Br_2, Cl_2, and a variety of halides (15).

It has been stated that a formation cell using a Mn electrode (13) cannot be used to determine the thermodynamic properties of $MnCl_2$ because manganese metal is soluble in the salt phase. Corbett *et al.* (10) have determined the solubility of Mn in $MnCl_2$ indirectly using the freezing point depression method. Because of the reactivity of manganese metal with Vycor, tantalum containers were used which also reacted to form a thin layer of $TaMn_2$. It was found that the solubility of manganese metal depresses the freezing point of $MnCl_2$ by 1.5° ± 1°C, corresponding to a Mn solubility of only 0.8 ± 0.5 m/o. Such small solubilities are not expected to affect the emf measurements as is demonstrated by the good agreement between the experimental and calculated standard potentials in the present work and by the reproducibility of the results upon heating and cooling.

At the beginning of a run, the cell was assembled, charged with the salts, and immediately evacuated. The system was heated slowly under vacuum to approximately 350°C to remove any trace of moisture present. At this point, the chlorine electrode and the manganese electrode compartments were flushed with chlorine and argon gas, respectively, and slowly heated to the fusion temperature of the salts.

Initial saturation of the molten solution with chlorine took about 1 hr during which the cell potential rose slowly. But once saturated with chlorine gas, the cell potential was stable and responded immediately to changes in temperature or chlorine gas pressure. The potentials obtained during heating over a period of 24 hr could be retraced on cooling indicating the reproducibility of the results. The reversibility of the measured emf's was also verified by polarization tests whereby a current from an external dry cell was passed through the cell. On disconnecting the applied potential the cell emf returned to its former equilibrium value to within ±0.1 mV. The volatility of the salts did not have any significant effect on the results, since the cell potentials obtained during a heating cycle (to 850°C) could be reproduced on cooling, even at high manganous chloride concentrations. In order to compare the present results with values calculated from the available thermochemical data, the thermoelectric Pt-C junction potential was measured separately by short circuiting the ends of the carbon and platinum electrodes together at the hot junction. It was found that the carbon was positive with respect to the platinum and thus aided the electrochemical voltage. Therefore, this additional voltage was subtracted from the measured cell emf to give the true value.

The thermoelectric effect was fitted to a straight line given by the equation

$$E_{TE}\ (\text{mV}) = -3.98 + 0.01289T\ (\text{in Kelvins}) \quad [2]$$

with a standard deviation of 0.06 mV. This thermo-

electric correction is only needed for the standard potential since it cancels when the data are used to calculate solution properties.

Results

Standard potential $E°$.—The free energy change for Reaction [1] is

$$\Delta\overline{G}_R = -ZFE \qquad [3]$$

where E is the measured emf of a cell containing a solution as the electrolyte, and $\Delta\overline{G}_R$ is the free energy change for the reaction. If pure $MnCl_2$ is used as the electrolyte the cell potential, designated as $E°$, allows the direct calculation of the free energy of formation of pure $MnCl_2$ as given by Reaction [4]

$$Mn_{(s)} + Cl_{2(g,\,1\,atm)} \rightarrow MnCl_{2(l,\,pure)} \qquad [4]$$

through the relationship

$$\Delta G°_R = -ZFE° \qquad [5]$$

From Eq. [3] and [5], and from the well-known expression for the activity, the equation relating the measured cell potential to the activity A_{MnCl_2} of $MnCl_2$ in solution is given as

$$E_{cell} = E° - (RT/2F) \ln A_{MnCl_2} \qquad [6]$$

The standard states for this calculation are, respectively, pure liquid $MnCl_2$ at all temperatures, pure solid Mn metal, and chlorine gas at 1 atm pressure. The experimentally measured $E°$ values in the temperature range 660°-820°C corrected for the thermoelectric emf's are presented in Fig. 2.

These data may be compared with the standard potential calculated from free energy data tabulated by Kubaschewski *et al.* (16), Kellogg *et al.* (17), and Wicks and Block (18). It may be seen that good agreement to within ±1 mV is obtained with the thermochemical calculation from the compilation of Wicks and Block (18).

At 990°K, α-Mn will transform to β-Mn with an endothermic heat effect of 535 cal. The free energy of the transformation and the heat capacities given by Wicks and Block (18) have been taken into account in the calculation of the standard cell potentials as a function of temperature using the Σ-function method. The experimental results are well represented by the following equations. For 990°K > T > 923°K

$$E° = 2387.7 + 0.4043T \log T - 0.3729 \times 10^{-4} T^2 - 1.1138 \times 10^3 T^{-1} - 1.7179T \text{ (in mV)} \qquad [7]$$

and for 1200°K > T > 990°K

$$E° = 2372.6 + 0.2721T \log T - 0.78 \times 10^{-5} T^2 + 7.32 \times 10^2 T^{-1} - 1.3381T \text{ (in mV)} \qquad [8]$$

Emf's obtained with a cell containing the $MnCl_2$-ACl solutions represent Reaction [1]. The partial molar free energy of mixing for $MnCl_2$, $\Delta\overline{G}_{MnCl_2}$, is given as

$$\Delta\overline{G}_{MnCl_2} = -ZF(E - E°) \qquad [9]$$

The partial molar free energies are related to the partial molar enthalpies and entropies of mixing by the Gibbs-Helmholtz relationship

$$\Delta\overline{G}_{MnCl_2} = \Delta\overline{H}_{MnCl_2} - T\Delta\overline{S}_{MnCl_2} \qquad [10]$$

If the enthalpy and entropy of mixing are taken to be temperature independent the quantity $E - E°$ can be expressed as a linear function of temperature over a narrow temperature range.

Partial molar enthalpies and entropies of mixing for $MnCl_2$ were obtained from the intercepts and slopes of the linear plots of $E - E°$ *vs.* temperature for the four binary systems, as given in Fig. 3-6. The data are well represented by the least square lines shown. The maximum standard deviation in all four binary systems is 1.4 mV and the largest deviation of an individual experimental point is 2.6 mV. The equations of these lines are given in Table I, along with the standard and maximum deviations for each line. The partial molar excess free energies of mixing of $MnCl_2$, $\Delta\overline{G}^{XS}_{MnCl_2}$ at 800°C are also listed in Table I, along with the partial molar enthalpies and partial molar entropies of mixing for $MnCl_2$. These two properties are temperature independent within experimental errors as shown by the linearity of the plots.

Figure 7 shows the plot of E_{cell} *vs.* log X_{MnCl_2} for the four binary systems investigated.

The ideal line is drawn as a dashed line and corresponds to $A_{MnCl_2} = X_{MCl_2}$. It is readily seen that the negative deviations increase as the size of the alkali metal cation becomes larger from Li through to Cs. The emf's reported by Bruneaux *et al.* (9) for the $MnCl_2$-KCl system are also included as solid circles and indicate rather poor agreement with the present results. The activity isotherms at 800°C for $MnCl_2$ are shown in Fig. 8. The $MnCl_2$-LiCl system shows the least negative deviation from ideality while the $MnCl_2$-KCl and $MnCl_2$-CsCl systems have the greatest negative

deviations. The activities of the alkali chlorides shown in Fig. 9 were determined by the Gibbs-Duhem integration method from the corresponding partial molar excess free energies of $MnCl_2$.

Partial molar heats of mixing for the alkali chlorides in the four binary systems were calculated by the Gibbs-Duhem equation applicable to partial molar heats of mixing.

The results of these calculations are shown in Fig. 10-13 and in Table II. Partial molar heats of mixing for $MnCl_2$ and the corresponding integral heats for each binary are also given.

From the standard deviations given in Table I the uncertainty in the calculated partial molar heats of mixing for $MnCl_2$ is estimated to be between 150 and 240 cal/mole. The uncertainty in the partial molar heats of mixing for ACl calculated by the graphical Gibbs-Duhem integration method cannot be given with any confidence because of the approximate nature of this method. However, if the partial molar heats of mixing for ACl are given uncertainties at least equal to those estimated for the $MnCl_2$ component, then the integral heats of mixing obtained from the well-known expression

$$\Delta H_M = X_1 \, \Delta \overline{H}_1 + X_2 \, \Delta \overline{H}_2 \quad [11]$$

should also have an uncertainty between 150 and 240 cal/mole of solution. For the $MnCl_2$-LiCl system this

uncertainty is significant but becomes less important in the more reactive systems $MnCl_2$-CsCl.

The approximate integral heats of mixing obtained by this method are also given in Fig. 10-13 and are compared with the direct calorimetric measurements by Papatheodorou and Kleppa (1). It is apparent that the integral heats of mixing obtained by the emf method are at the most about 10% lower than the calorimetric results, with the exception of the $MnCl_2$-LiCl system, for which, however, the disagreement appears to be within the uncertainty limits. It should be noted, however, that in the latter system the enthalpies of mixing are small and the errors which are inherent in the emf method become more significant. The agreement between the calorimetric and the electrochemical integral heats of mixing for the systems $MnCl_2$-NaCl, $MnCl_2$-KCl, and $MnCl_2$-CsCl is within the experimental error for the latter. The partial entropies of mixing for $MnCl_2$ were calculated from the temperature dependence of $E - E°$ as stated earlier and are also given in Table I. From the uncertainties in the free energy and enthalpy data, the partial molar entropies of mixing reported herein are given with confidence to within ±0.5 cal/°K. For the $MnCl_2$-CsCl melts the slight negative entropies of mixing at $X_{MnCl_2} = 0.1957$ and $X_{MnCl_2} = 0.498$, appear to be inconsistent with the general trends.

Discussion

The thermodynamic properties of the $MnCl_2$-ACl solutions and particularly the concentration dependence of the enthalpy and entropy of mixing may be understood through the application of the quasichemi-

* Average enthalpies in the temperature range 550°-850°C.
The partial molar enthalpies of mixing for $MnCl_2$ represents points taken from smooth curves drawn through the experimental results given in Table I. The partial molar properties for the ACl component were calculated by the Gibbs-Duhem integration method.

cal model for charge asymmetrical solutions presented in a previous publication (7).

The model is based on the concept that "complex ions" exist in molten salt solutions. However, the concept of complex ions in molten salts presented here is entirely different from that generally accepted in aqueous solutions. In dilute aqueous solutions because of the high dielectric constant of water, complex ionic species having a discrete structure may be considered to exist and the properties of the solutions may be interpreted by considering the behavior of point electrical charges in a dielectric medium.

In molten salts, the medium is totally ionic and because of the existence of strong short range electrostatic forces the requirement of local electrical neutrality is satisfied through the concept of interlocking anionic and cationic quasi lattices.

In this sense the liquid structure is continuous and the existence of discrete complex species is conceptually difficult. It is most likely that a "complex anion" in molten salts should be best represented by a configuration of a cation M^{n+} surrounded by anions X^- having a given coordination number within which the bond distances MX, and accordingly their energies, should be different from those expected to represent a noncomplexed dissociated ionic state. It is also convenient to take the noncomplexed state of the salt MX as that of the "pure MX." Accordingly, the "complex" is expected to form only in the presence of a second salt AX which is considered to act as the ligand donor. Thus, the formation of the complex species is assumed to be the result of reactions of the type

$$MX + (n-1)\,AX \rightarrow A_{n-1}MX_n \qquad [12]$$

and the strength of the complex shall depend on the magnitude of the competing interactions of the A^+ and M^+ cations for the same ligand anions X^-.

In a melt containing both AX and MX, it is conceivable that two kinds of MX bonds could exist. M-X bonds having the bond distance describing the "complex" state, and M-X bonds describing the "free" MX species. The pure material is expected to have only bonds of the second type.

It is also evident that the continuity of the medium imposes the restriction that the "complex" anions are not discrete isolated species but are part of the ionic liquid structure and therefore their central M cations interact with other surrounding cations through bridging X^- anions. In a melt containing MX and AX components, it is meaningless to postulate a structure based on the MX_n anions occupying single anion lattice sites in addition to other free anions and cations. The structure should still be one represented by arrays of positive and negative ions in a continuous sequence in such a manner that positive ions are always surrounded by negative ones.

Since the only characteristic of a "complex" anion is the bond distance MX, its coordination configuration MX_n may be treated as a separate statistical entity. When MX is added to AX a "reaction" may be postulated according to the stoichiometry indicating the preferred coordination within the complex anion. For example, for a tetrahedrally coordinated complex between a divalent metal chloride and an alkali metal chloride, the reaction is represent by

$$MCl_2 + 2ACl \rightarrow A_2MCl_4 \qquad [13]$$

Regarding the preferred coordination of complex ions in fused salts, the accumulated experimental evidence indicates that such coordinations are relatively simple. Thus, mixtures of monovalent cations appear to prefer the two-ligand configuration representing a linear or angular structure as in $Ag(CN)_2^-$ (19). Mixtures of mono- with divalent cations appear to follow the tetrahederal coordination as in $MgCl_4^{-2}$. Finally, mixtures of mono- and tetravalent cations as in the systems, $ZrCl_4$, $TiCl_4$, $HfCl_4$, with alkali chlorides (20) prefer to form octahedrally coordinated complexes of the type $ZrCl_6^{2-}$, $TiCl_6^{2-}$, and $HfCl_6^{2-}$. In these systems it has been shown that the thermodynamic properties of the solutions can be accounted for on the basis of the MCl_6^{2-} complex ion (21, 22).

From the previous discussion it follows that "complex" species in fused salts are not expected to dissociate in the same manner as their counterparts in aqueous solutions. The formation of the new type of M-Cl bond distances is initiated by the presence of the A^+ cations. Each added A^+ cation is expected to disturb one M-Cl bond and the "complex" should form "stoichiometrically."

Accordingly, the difference between the effects of various kinds of ACl ligand donors on the same MCl_2 salt shall be manifested as a heat effect, and the introduction of a dissociation constant into the treatment is not necessary for the mathematical treatment. In a solution containing various proportions of ACl to MCl_2, the changes in the bond energies which may result from the replacement of one kind of neighboring ion by another, should result in changes in the over-all heat effect of mixing, and may be accounted for by assigning different values to the bond energies representing the various possible ionic combinations. Again the concept of a "dissociating complex" is not necessary.

However, if two or more "complex" coordinations are energetically favorable, then the concepts of equilibrium between "complex" species, and of dissociation, become significant.

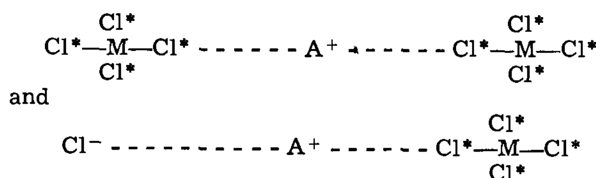
The present treatment is applicable to salt systems which appear to conform with the concept of a single complex configuration.

Theory of mixing of charge asymmetrical system forming complex anions.—Considering the binary mixture MCl_2-ACl over the entire composition range, from pure MCl_2 to pure ACl, the complex A_2MCl_4 is expected to form quantitatively at a composition $X_{MCl_2} = 0.333$.

For compositions rich in ACl; namely for $0.333 > X_{MCl_2} > 0$, the melt is taken to consist of unreacted ACl and the complex compound A_2MCl_4. For com-

positions rich in MCl_2, namely for $1.00 > X_{MCl_2} > 0.333$, the melt may be taken to consist of unreacted MCl_2, and the complex compound A_2MCl_4.

The ionic compositions, assuming that the complex only dissociates into A^+ cations and MCl_4^{2-} anions, may be calculated from the original mole fractions by a mass balance calculation and are given in Table III. For the common cation subsystem, ACl-A_2MCl_4, if the ability of the M^{2+} ions for interaction is considered as having been nearly satisfied through the formation of the "complex" anion MCl_4^{-2}, it is reasonable to expect that the species present should be randomly distributed and that only next nearest neighbor type interactions should be significant. The solutions could then be treated as regular. Thus, the bond energies to be considered in the "pure" components ACl and A_2MCl_4 are characterized by the energies of the next nearest neighbor interactions, Cl^-—A^+—Cl^- and MCl_4^{-2}—A^+—MCl_4^{-2}, respectively. The solution, in addition to the above interactions is also characterized by interactions of the type Cl^-—A^+—MCl_4^{-2}. However, the concept of continuity in the structure of the ionic melt discussed earlier, requires that the MCl_4^{-2} species be nonexistent as an isolated entity. The A^+ cations are expected to interact with the M^{2+} central cations in the "complex" species via bridging Cl^- anions. Thus, it is more realistic to describe the MCl_4^{-2} type interactions in pure A_2MCl_4 and the Cl^-—A^+—MCl_4^{-2} type interactions in the solution, as interactions between a central A^+ cation and two chloride species representing ionic arrays of the type



where Cl^- and Cl^* describe the states of chlorine in pure ACl and in the "complex" species, MCl_4^{-2}, respectively.

It should be noted that although the number of MCl_4^{-2} configurations in the system is fixed by stoichiometry, the two types of chloride ions in the solution can readily exchange positions so that the probability of finding a chloride species of the Cl^* type in any position is approximated by the fraction of the anionic positions occupied by the configuration MCl_4^{-2}.

The "significant" interactions for the pure components and for their mixture are therefore best represented by the following energy terms. For pure ACl, the Cl^-—A^+—Cl^- type interaction is described by $E_{Cl-A-Cl}$; for pure A_2MCl_4, the Cl^*—A^+—Cl^* type interaction is described by $E_{Cl^*-A-Cl^*}$, and in the binary solution ACl-A_2MCl_4, the bond energies are the $E_{Cl-A-Cl}$, $E_{Cl-A-Cl^*}$, and $E_{Cl^*-A-Cl^*}$, where E_{Cl^*-A-Cl} describes the new type of interaction discussed previously.

Since we are only concerned with the chloride ion coordination of the A^+ cations the nearest neighbor coordination number for A^+ should not be affected by mixing the charge asymmetrical system ACl-A_2MCl_4.

In this composition range, for a melt represented by the nominal mole fractions X_{ACl} and X_{MCl_2}, respectively, the "true" composition is given in Table III.

Within the subsystem ACl-A_2MCl_4 as the complex anions present in the mixture have originated from the total reaction of X_{MCl_2} gram-moles of MCl_2, the first part of the heat effect or the "reaction part" is simply proportional to the amount of complex formed, and is given by the equation

$$\Delta H_1 = X_{MCl_2}\, b_R \quad [14]$$

The constant b_R represents the heat of formation per gram-mole of complex according to

Table III. Mass balance for the MCl_2-ACl system

A^+, Cl^- (at 0, ACl) — MCl_4^{2-}, Cl^-, A^+ — MCl_4^{2-}, A^+ (at 0.333, A_2MCl_4) — M^{+2}, Cl^-, A^+, MCl_4^{2-} — M^{+2}, Cl^- (at 1.0, MCl_2)

X_{MCl_2} ⟶

$1.0 > X_{MCl_2} > 0.333$
$n_{MCl_2} = X_{MCl_2} - 0.5X_{ACl} = n_1,\ n_{ACl} = 0$
$n_{A_2MCl_4} = 0.5X_{ACl} = n_2$

Ionic composition	Ionic fraction
$n_{M^{+2}} = X_{MCl_2} - 0.5X_{ACl}$	$N_{M^{+2}} = \dfrac{2X_{MCl_2} - X_{ACl}}{1 + X_{MCl_2}}$
$n_{A^+} = X_{ACl}$	$N_{A^+} = \dfrac{2X_{ACl}}{1 + X_{MCl_2}}$
$n_{Cl^-} = 2X_{MCl_2} - X_{ACl}$	$N_{Cl^-} = \dfrac{4X_{MCl_2} - 2X_{ACl}}{4X_{MCl_2} - X_{ACl}}$
$n_{MCl_4^{-2}} = 0.5X_{ACl}$	$N_{MCl_4^{-2}} = \dfrac{X_{ACl}}{4X_{MCl_2} - X_{ACl}}$

$n_{M^{+2}} = 0$	$N_{M^{+2}} = 0$
$n_{A^+} = X_{ACl}$	$N_{A^+} = 1.0$
$n_{Cl^-} = X_{ACl} - 2X_{MCl_2}$	$N_{Cl^-} = \dfrac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}}$
$n_{MCl_4^{-2}} = X_{MCl_2}$	$N_{MCl_4^{-2}} = \dfrac{X_{MCl_2}}{X_{ACl} - X_{MCl_2}}$

X indicates the original mole fractions in the solution which is prepared by mixing the components ACl and MCl_2.
n indicates the g·moles of a component.
N indicates ionic fractions after the complex forming reaction has taken place.

$$MCl_2 + 2ACl \rightarrow A_2MCl_4 \quad [15]$$

The second part or the "mixing part" of the total heat originates by the regular solution type mixing of the charge asymmetrical mixture containing n_1 g-moles of ACl and n_2 g-moles of A_2MCl_4 according to the reaction

$$n_1\, ACl + n_2\, A_2MCl_4 \rightarrow [(ACl)_{n_1}\, (A_2MCl_4)_{n_2}] \quad [16]$$

This "mixing" part may be calculated by interpreting the energy of mixing as the difference between the internal energy of the solution from that of the pure components, where the previously described interactions are the only ones which are considered as being significant. Pair interactions of the same kind are taken to have the same energy in the pure components as in solution and cancel out.

The energy change in the mixing reaction is therefore

$$\Delta E^{int}_{mix} = E_{mix} - n_1\, E_{ACl} - n_2\, E_{A_2MCl_4} \quad [17]$$

The total number of next nearest neighbor interactions originating from a central A^+ cation is given by $\frac{1}{2}N(n_1 + 2n_2)Z_1$ where N is the Avogadro number and Z_1 is the coordination number for ACl. In pure ACl and A_2MCl_4, the total numbers of such interactions are $\frac{1}{2}n_1\, NZ_1$ and $n_2\, NZ_1$, respectively. Hence, using the above relationships and taking the probability of finding a bonded Cl^* as being the same as that of finding the entity MCl_4^{-2}, the following expression has been derived (7) according to the method which is followed for regular solutions.

$$\Delta E_M = \frac{(X_{ACl} - 2X_{MCl_2})X_{MCl_2}}{X_{ACl} - X_{MCl_2}} \left[\frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} b_1 + b_2 \right] \quad [18]$$

where

$$b_1 = \tfrac{1}{2}NZ_1 [E_{Cl^*-A-Cl^*} + E_{Cl-A-Cl} - 2E_{Cl^*-A-Cl}]$$

and

$$b_2 = \tfrac{1}{2}NZ_1 [4E_{Cl-A-Cl^*} - 3E_{Cl^*-A-Cl^*} - E_{Cl-A-Cl}]$$

are parameters to be determined from experimental results. By assuming that pressure-volume work is negligible, Eq. [18] can be used to represent the enthalpy of mixing ($\Delta E_M = \Delta H_M$). Thus, the total enthalpy will be given by the sum of Eq. [13] and [18], as shown below

$$\Delta H_M = X_{MCl_2}b_R + \frac{(X_{ACl} - 2X_{MCl_2})X_{MCl_2}}{X_{ACl} - X_{MCl_2}} \left[\frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} b_1 + b_2 \right]$$

for

$$0.333 > X_{MCl_2} > 0 \quad [19]$$

It should be noted that the parameter b_2 is similar to that obtained from regular solution theory for a charge asymmetrical reciprocal salt mixture. The parameter b_1 is the result of charge asymmetry. Hence, the total integral heat of mixing in the reacting system is determined by the heat contribution due to the complex ion forming reaction, by a heat effect due to an exchange reaction between next nearest neighbor anions, and by asymmetry.

Considering the composition range in the subsystem $MCl_2 - A_2MCl_4$ from, $1.0 > X_{MCl_2} > 0.333$, the "true" composition of the solution is given in Table II. In this range the "reaction" part of the total mixing reaction is given by

$$\Delta H'_1 = 0.5X_{ACl}b_R \quad [20]$$

Once the complex has been formed the second part of the reaction involves mixing of the unreacted MCl_2 with A_2MCl_4 according to

$$n_1MCl_2 + n_2A_2MCl_4 \rightarrow [(MCl_2)_{n1}(A_2MCl_4)_{n2}].$$

Again, in this system the following different kinds of chloride ions should be considered: chloride ions which surround "free" M^{2+} or A^+ cations, and chloride ions bonded in the complex ionic configuration $[MCl_4^*]^{-2}$. Also, the cation M^{2+} in the complex $[MCl_4^*]^{-2}$ is bonded to the surrounding M^{2+} or A^+ "free" cations through bridging Cl^* ions. Accordingly, in a reciprocal salt mixture where the complex ion configuration is already present the significant interactions are the nearest neighbor cation to anion attractions. The various energy contributions are given as: E_{Cl-A}, E_{Cl^*-A}, E_{Cl-M}, E_{Cl^*-M} where the interactions E_{Cl-A} and E_{Cl-M} are also common in the pure components ACl and MCl_2. It is also expected that if the nearest neighbor coordination number of the "free" M^{2+} cations is Z_1, then the nearest neighbor coordination number of the A^+ cations should be $0.5Z_1$.

In a random system, the total number of bonds which emanate from the "free" A^+ and M^{+2} ions may be calculated from the average coordination number of the solution defined as

$$\overline{Z} = \frac{n_1}{n_1 + 2n_2} Z_1 + \frac{2n_2}{n_1 + 2n_2} 0.5Z_1 = \frac{n_1 + n_2}{n_1 + 2n_2} Z_1 \quad [21]$$

The total number of significant nearest neighbor type bonds in the solution is readily calculated as

$$\tfrac{1}{2}N(n_1 + 2n_2)\overline{Z} = \tfrac{1}{2}N(n_1 + n_2)Z_1$$

On the basis of the same assumptions as for the ACl rich solutions, the integral energy of mixing has been derived as (7)

$$\Delta E_M = \frac{(X_{MCl_2} - 0.5X_{ACl})0.5X_{ACl}}{(2X_{MCl_2} - 0.5X_{ACl})} \left[\frac{X_{MCl_2} - 0.5X_{ACl}}{X_{MCl_2} + 0.5X_{ACl}} b'_1 + b'_2 \right] \quad [22]$$

where

$$b'_1 = \tfrac{1}{2}NZ_1[2E_{ACl} + 0.5E_{MCl^*} - 2E_{MCl} - 0.5E_{ACl^*}]$$

$$b'_2 = \tfrac{1}{2}NZ_1[2E_{ACl} + 0.5E_{MCl^*} - E_{MCl} - 1.5E_{A-Cl^*}] \quad [23]$$

are interaction parameters.

The total integral heat of mixing is given as

$$\Delta H_M = 0.5X_{ACl}b_R + \frac{(X_{MCl_2} - 0.5X_{ACl})0.5X_{ACl}}{(2X_{MCl_2} - 0.5X_{ACl})} \left[\frac{X_{MCl_2} - 0.5X_{ACl}}{X_{MCl_2} - 0.5X_{ACl}} b'_1 + b'_2 \right]$$

for

$$1.0 > X_{MCl_2} > 0.333 \quad [24]$$

The second part of Eq. [25], is of the form

$$\Delta E_M = \frac{n_1n_2}{2n_1 + n_2} \left[\frac{n_1}{n_1 + 2n_2} b'_1 + b'_2 \right] \quad [25]$$

and accordingly, the parameter b'_2 describes the regular behavior of the solution when asymmetry effects are not accounted for. The effect of variable coordination number is represented by the asymmetric parameter b'_1.

The above calculations indicate that the concentration dependence of the integral heat of mixing is a complex function of the concentration and that the entire heat of mixing curve may be accounted for by five parameters, b_R, b_1, b_2, b'_1, and b'_2. The application of this method to 27 reactive charge asymmetrical binary fused salt systems presented in the previous publication (7) shows that the interaction parameters are physically meaningful as they are related to the ionic radii of the ionic species in these melts.

Determination of energetic parameters.—The "reaction" parameter b_R may be obtained from an experimentally measured heat of mixing curve by substituting for $X_{MCl_2} = 0.333$ and solving either Eq. [19] or [24]. Thus

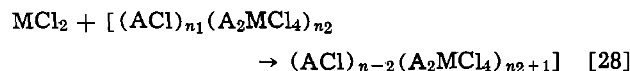
$$b_R = 3(\Delta H_M) \text{ at } X_{MCl_2} = 0.333 \quad [26]$$

The parameters b_1 and b'_2 may be determined from the partial molar heats of mixing.

In the $ACl - A_2MCl_4$ subsystem at $0.333 > X_{MCl_2} > 0$ the partial molar heats of mixing for ACl and MCl_2 may be represented by the following mixing reactions

$$ACl + [(ACl)_{n1}(A_2MCl)_{n2} \rightarrow (ACl)_{n1+1}(A_2MCl_4)_{n2+1}] \quad [27]$$

and



$$MCl_2 + [(ACl)_{n1}(A_2MCl_4)_{n2} \rightarrow (ACl)_{n-2}(A_2MCl_4)_{n2+1}] \quad [28]$$

The corresponding equations for the partial molar heats of mixing are derived by partial differentiation of Eq. [19] as

$$\Delta\overline{H}_{MCl_2} = b_R + \frac{(X^3_{ACl} - 4X^3_{MCl_2} - 7X_{MCl_2}X^2_{ACl} + 12X_{ACl}X^2_{MCl_2})}{(X_{ACl} - X_{MCl_2})^3} b_1 - \frac{2X^2_{MCl_2} - (X_{ACl} - 2X_{MCl_2})^2}{(X_{ACl} - X_{MCl_2})^2} b_2 \quad [29]$$

and

$$\Delta\overline{H}_{ACl} = \frac{X^2_{MCl_2}}{(X_{ACl} - X_{MCl_2})^2} \left[b_2 + \frac{2(X_{ACl} - 2X_{MCl_2})}{(X_{ACl} - X_{MCl_2})} b_1 \right] \quad [30]$$

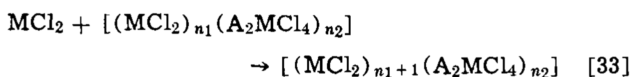
At $X_{ACl} = 2X_{MCl_2}$, or at the composition $X_{MCl_2} = 0.333$, Eq. [29] and [30] yield

$$b_2 = (\Delta\overline{H}_{ACl}) \quad [31]$$

or

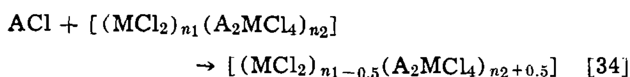
$$b_2 = \frac{b_R - (\Delta\overline{H}_{MCl_2})}{2} \quad [32]$$

In the $MCl_2 - A_2MCl_4$ subsystem, at $1.0 > X_{MCl_2} > 0.333$ the mixing reactions for ACl and MCl_2 are respectively



$$MCl_2 + [(MCl_2)_{n1}(A_2MCl_4)_{n2}] \rightarrow [(MCl_2)_{n1+1}(A_2MCl_4)_{n2}] \quad [33]$$

and



$$ACl + [(MCl_2)_{n1}(A_2MCl_4)_{n2}] \rightarrow [(MCl_2)_{n1-0.5}(A_2MCl_4)_{n2+0.5}] \quad [34]$$

The partial molar heats of mixing for ACl and MCl_2 are obtained by partial differentiation of Eq. [24], and are, respectively

$$\Delta\overline{H}_{MCl_2} = \frac{0.0625X^4_{ACl} + 1.25X^2_{MCl_2}X^2_{ACl} - 0.75X^3_{ACl}X_{MCl_2}}{((2X_{MCl_2} - 0.5X_{ACl})(X_{MCl_2} + 0.5X_{ACl}))^2} b'_1 + \frac{X^2_{ACl}}{4(2X_{MCl_2} - 0.5X_{ACl})^2} b'_2 \quad [35]$$

and

$$\Delta\overline{H}_{ACl} = 0.5b_R + \left[\frac{0.5^2_{MCl_2} - X_{MCl_2}X_{ACl} + 0.375X^2_{ACl}}{(2X_{MCl_2} - 0.5X_{ACl})(X_{MCl_2} + 0.5X_{ACl})} - \frac{0.25X_{ACl}(X_{MCl_2} - 0.5X_{ACl})^2(X_{MCl_2} - X_{ACl})}{(2X_{MCl_2} - 0.5X_{ACl})^2(X_{MCl_2} + 0.5X_{ACl})^2} \right] b'_1 + \frac{(X^2_{MCl_2} - X_{ACl}X_{MCl_2} - 0.125X^2_{ACl})}{(2X_{MCl_2} - 0.5X_{ACl})^2} b'_2 \quad [36]$$

From Eq. [36] at a composition $X_{MCl_2} = 0.333$

$$(\Delta\overline{H}_{ACl}) = (b_R - b'_2)/2 \quad [37]$$

and from Eq. [35]

$$(\Delta\overline{H}_{MCl_2}) = b'_2 \quad [38]$$

From Eq. [31] and [37], it follows that

$$b_R = 2b_2 + b'_2 \quad [39]$$

Hence, the parameters b'_2 and b_2 may be determined directly from experimentally obtained partial molar heats of mixing of either ACl or MCl_2 at the stoichiometric composition of $MCl_2 = 0.333$.

The parameters b_1 and b'_1 may be determined from the equations for the integral heats of mixing [18] and [24] written in the following forms:
For the composition range

$$0.333 > X_{MCl_2} > 0$$

$$\frac{(\Delta H_M - X_{MCl_2}b_R)(X_{ACl} - X_{MCl_2})}{(X_{ACl} - 2X_{MCl_2})X_{MCl_2}} = \frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} b_1 + b_2 \quad [40]$$

which is of the linear form

$$I = P\,b_1 + b_2$$

Similarly, from Eq. [24]

$$\frac{(\Delta H_M - 0.5X_{ACl}b_R)(8X_{MCl_2} - 2X_{ACl})}{(2X_{MCl_2} - X_{ACl})X_{ACl}} = \frac{2X_{MCl_2} - X_{ACl}}{2X_{MCl_2} + X_{ACl}} b'_1 + b'_2 \quad [41]$$

which is of the linear form

$$I' = Q\,b'_1 + b'_2 \quad [42]$$

Because the calculations involve small difference between large numbers, it is best to obtain the parameters b_2 and b'_2 from the partial molar heats of mixing, and then use the linear plots predicted by Eq. [40] and [41] to evaluate the slopes b_1 and b'_1. Alternatively, b_1 and b'_1 may be calculated by solving Eq. [19] and [24], for various points along the curve where b_R, b_2, and b'_1 are known using the previously described methods.

Calculation of Entropies of Mixing

Following the same general method as previously, the entropy of mixing in a reactive binary salt mixture is calculated on the basis of the two main contributions. The "reaction" part which is simply proportional to the amount of the complex species formed in accordance with reaction [14], and a "random mixing" part which is calculated on the basis of ionic fractions.

The formation of a "complex" species is expected to be accompanied by changes in vibrational entropy while the mixing part should be entirely configurational.

In the compositional range, $1.0 > X_{MCl_2} > 0.333$ application of these concepts leads to the equation for the integral entropy of mixing which is of the form

$$\Delta S^{Int}_M = 0.5X_{ACl}\,\epsilon - R[n_{A^+} \ln N^2_{A^+} + n_{Cl^-} N^2_{Cl^-} + n_{MCl_2^-} \ln N_{MCl_4^{2-}} + n_{M^{2+}} \ln N_{M^{2+}}] \quad [43]$$

The expressions for the mole numbers n and for the ionic fractions N in terms of primary mole fractions are given in Table III. Similarly, in the composition range, $0.333 > X_{MCl_2} > 0$ the corresponding expression is

$$\Delta S^{Int}_M = X_{MCl_2}\,\epsilon + R[n_{Cl^-} \ln N_{Cl^-} + n_{MCl_4^{2-}} \ln N_{MCl_4^{2-}}] \quad [44]$$

The parameter ϵ represents the change in vibrational entropy connected with Reaction [15].

The partial molar entropies of mixing for MCl_2 and ACl may be calculated from Eq. [43] and [44] by partial differentiation with respect to the corresponding mole fractions. In the concentration range $1.0 > X_{MCl_2} > 0.333$ the final equations expressed in terms of primary mole fractions are

$$\Delta\overline{S}_{MCl_2} = -R \ln \frac{4(2X_{MCl_2} - X_{ACl})^3}{(1 + X_{MCl_2}) \cdot (4X_{MCl_2} - X_{ACl})^2} \quad [45]$$

and

$$\Delta\overline{S}_{ACl} = 0.5\epsilon - \frac{R}{2} \left[\ln \frac{2(2X_{MCl_2} - X_{ACl})^3(1 + X_{MCl_2})}{X^3_{ACl}(4X_{MCl_2} - X_{ACl})} \right] \quad [46]$$

It is significant that the partial molar entropy of mixing for MCl_2 does not include any vibrational contributions. In this concentration range the solution process for a partial property of MCl_2 is represented by Reaction [33] and it is evident that the reaction does not include the formation of new complex species other than these already in existence. However, for the ACl component the solution process is given by Reaction

[34] and clearly involves the formation of one additional mole of complex species.

In the composition range $0.333 > X_{MCl_2} > 0$, the partial molar entropies of mixing for ACl and MCl_2 are given, respectively, as

$$\Delta\bar{S}_{MCl_2} = \epsilon - R \ln \frac{X_{MCl_2}(X_{ACl} - X_{MCl_2})}{(X_{ACl} - 2X_{MCl_2})^2} \quad [47]$$

and

$$\Delta\bar{S}_{ACl} = R \ln \frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} \quad [48]$$

In this concentration range it is significant that the partial entropy of mixing for MCl_2 includes vibrational contributions. The logarithmic term in Eq. [47] represents the configurational part to the total partial molar entropy of mixing. The partial molar entropy of mixing for ACl is entirely configurational because the addition of ACl to these ACl-rich solutions is not accompanied by the formation of additional moles of complex species.

The "configurational" part of the partial molar entropy of mixing from Eq. [45] and [47] was calculated and the results are presented in Fig. 14. Figure 14 also includes so-called "ideal" partial molar entropies of mixing given as $-R \ln X_{MCl_2}$.

It is characteristic that the present calculation predicts the concentration dependence of the molar entropies of mixing which changes from positive to negative and then again to positive values. This behavior may be described as typical of complex ion fused salt systems.

Application of the complex ion model to the $MnCl_2$-ACl systems.—From the integral heats of mixing for the binary systems $MnCl_2$-LiCl, $MnCl_2$-NaCl, $MnCl_2$-KCl, and $MnCl_2$-CsCl, the reaction parameters b_R, b_1 and b'_1 were obtained and are given in Table IV. Similarly, the interaction parameters b_2, b'_2 were determined from the experimental partial molar heats of mixing of $MnCl_2$ and of the corresponding alkali chloride at $X_{MnCl_2} = 0.333$, and are also included in Table III. From Eq. [29] and [35] and the parameters in Table III the partial enthalpy of mixing of $MnCl_2$ was calculated over the entire concentration range and the results are compared with the experimental partial enthalpies of $MnCl_2$ in Fig. 10-13. The parameters b_R for the $MnCl_2$-ACl systems are plotted in Fig. 15 *vs.* the radii of the alkali metal cations and the plot indicates a linear relationship. Good agreement is also obtained with the b_R parameter determined from the calorimetric data of Papatheodorou and Kleppa (1, 7).

Table IV. Enthalpy and entropy parameters for $MnCl_2$-ACl system (cal/mol, cal/K·mol)

	CsCl	KCl	NaCl	LiCl
b_R	−14,700	−10,700	−5900	−720
b'_2	−9,500	−6,150	−3350	−350
b_2	−2,500	−2,200	−1250	−175
b'_1	−31,500	−20,750	+1875	−1770
b_1	−377	−501	+107	−415
ϵ	(−1.0)	(−0.2)	(+1.0)	—

The entropy of mixing can also be used to test the model that has been proposed. The partial molar entropies of mixing obtained from the emf results are included in Fig. 14 for comparison with the calculated values.

It is evident that within the experimental uncertainty of ±0.5 cal/°K the theoretical calculations are in fair agreement with the experimental results, particularly for the systems $MnCl_2$-NaCl, $MnCl_2$-KCl, and $MnCl_2$-CsCl for compositions rich in alkali chloride. The $MnCl_2$-LiCl system with the exception of one point appears to follow the "ideal" entropy curve and therefore its thermodynamic behavior should be described as "regular."

For solutions rich in ACl the difference between the experimental points and the configurational entropy curve may be attributed to vibrational contributions. Approximate values for ϵ in the various systems were calculated and are given in Table III. Similarly, for solutions rich in $MnCl_2$ where the partial molar entropies of mixing are entirely configurational the agreement is within experimental error, with the exception of two points at $X_{MCl_2} = 0.5$ which correspond to the two systems $MnCl_2$-KCl and $MnCl_2$-CsCl.

It is evident that the model describes quite well the general trend in the concentration dependence of the excess partial molar entropies and enthalpies of mixing except for the LiCl system.

It is characteristic that the model predicts positive entropies in the $MnCl_2$-rich compositions and entropies of mixing which change from positive to negative for the alkali chloride-rich compositions. In addition the transition from positive to negative values is occurring at about $X_{MnCl_2} = 0.333$, where the complex $MnCl_4^{2-}$ is expected to form stoichiometrically.

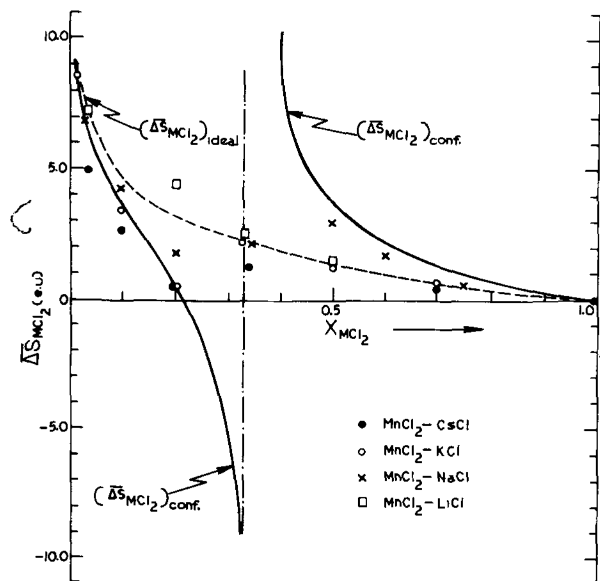


Fig. 14. Partial molar entropies of $MnCl_2$ in the alkali chloride systems. Comparison between theoretical and experimental values.

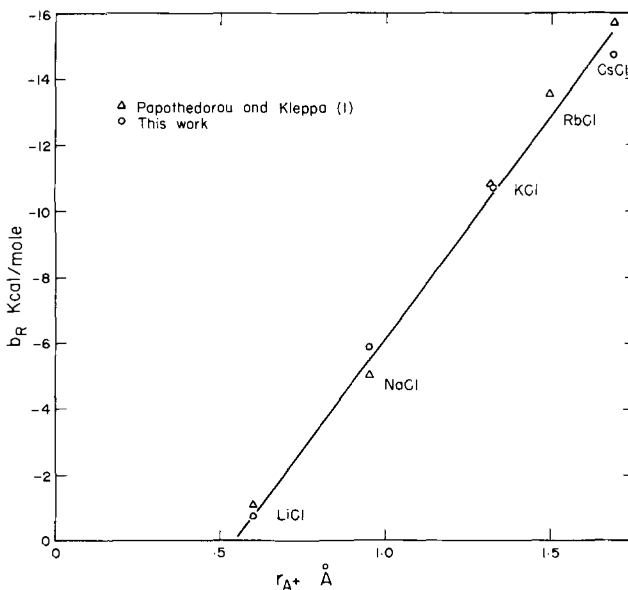

Fig. 15. Plot of b_R vs. the radii of alkali metal cations in the ACl-$MnCl_2$ binary systems.

The calculated values for the vibrational contributions ϵ given in Table III are consistent with the magnitude of the reaction parameters b_R. For example, the $MnCl_2$-CsCl system which has a large negative heat of formation b_R is also characterized by the most negative vibrational entropy. The $MnCl_2$-LiCl system which is characterized by a small enthalpy of formation b_R is best represented by configurational entropy only.

It is worthwhile to note that for dilute solutions at $X_{MCl_2} \rightarrow 0$, the partial molar entropy of mixing given by Eq. [47] reduces to

$$\Delta\bar{S}_{MCl_2} = \epsilon - R \ln X_{MCl_2} \quad [49]$$

and accordingly, the excess partial molar entropies in this range may be identified with vibrational contributions.

Anodic Films in ECM Electrolytes: Onset of Passivation of Mild Steel in Nitrate Solution

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A potentiostatic transient study was made of the passivation of mild steel in $NaNO_3$ solution. The current-time relation in the initial stage of the passivation process agreed with a model involving two-dimensional progressive nucleation and growth of a monolayer of oxide on the electrode surface. The rate of film formation was found to increase with the rate of electrode dissolution and with the nitrate concentration.

Since the discovery (1) that the quality of surface finish and dimensional control obtained in electrochemical machining (ECM) of steel is directly related to anodic film formation, a series of tests have been made in this laboratory to ascertain the nature of the film in various ECM electrolytes (2, 3). It has been found that in NaCl and $NaClO_4$ solutions the passive film is initiated by the formation of a salt layer resulting from supersaturation of dissolution products in the immediate vicinity of the anode. Although such a film is capable of giving good surface finishes at high current densities, it lacks the ability to protect the metal surface located some distance from the machining area facing the cathode. In $NaClO_3$ solution, a porous film resulting from anodic oxidation has been identified. This film not only gives excellent dimensional control, but also brings about mirror-like surface finishes on the machined area. In the present work, such testing has been extended to $NaNO_3$ solution.

Though numerous studies have been made on the passivation of iron or steel in nitrate solutions, most of them are confined to either acidic or alkaline conditions such as in HNO_3 or NH_3-NH_4NO_3-H_2O systems. There are only a few studies reported in the literature concerning neutral nitrate solutions. Cowley, Robinson, and Kerrich (4) measured anodic polarization curves for mild steel in 10% NH_4NO_3 solution, and the effect

of *p*H on the polarization curves was reported by Mieluch (5), who found that passivation occurred most easily at *p*H 7.5. In a later report, Mieluch (6) also described a study of the effect of crystallographic orientation on the passivation of Fe in concentrated NH_4NO_3. The influence of fatty acids on the passivation of iron and steel in neutral nitrate solutions was investigated by Smialowski and Ostrowska (7).

This paper describes a potentiostatic transient study of a mild steel electrode in neutral $NaNO_3$ solutions. The mechanism of passivation is discussed with a two-dimensional nucleation and growth model for the formation of an oxide film on the electrode.

Experimental

A rotating hemispherical electrode was used for the study. The electrode consisted of a replaceable mild steel hemispherical head[1] mounted on one end of a cylindrical Teflon rod; the other end of the rod was attached to the spindle shaft of a high speed rotator. The mild steel head was 0.317 cm in radius and had a surface area of 0.628 cm^2 exposed to the electrolyte. Details of the experimental setup are given in previous reports (2, 3), and will not be repeated here.

Before the transient measurement, the surface of the mild steel electrode was degreased in isopropanol, cleaned in dilute HCl, and rinsed in distilled water. The clean electrode was then installed on the rotator and transferred into a cell filled with the test electrolyte. To remove any remaining trace of oxide on the surface, the electrode was further treated cathodically at −1.2V *vs.* SCE for one minute, and the system was permitted to rest for several minutes to allow the electrode potential to return to the steady-state value at open circuit. A constant anodic potential pulse was then applied to the electrode, and the current transient was recorded.

The electrolytes used were 1 to 4M $NaNO_3$. The solutions were prepared by dissolving Baker analyzed-grade chemicals in distilled water; the *p*H of these solutions varied from 6.5 to 7.5 at room temperature. Before the start of each test the electrolyte was presaturated with nitrogen; and, during the run, a nitrogen atmosphere was maintained by passing the gas through the cell. All the experiments were performed at a constant room temperature of 24° ± 1°C.

Results

Figure 1 shows the recorder traces of current transients for two different passivity potentials in a 2M $NaNO_3$ solution. For each potential pulse, the curves are given for two different rotational speeds: curves a and c at 0 rpm, and curves b and d at 2500 rpm. These curves are typical of the results obtained; so the raw data with other passivity potentials and other concentrations are not shown here.

It is seen for each curve, the current jumps to a large value at $t = 0$, and then drops smoothly to a small value. Stirring of the solution apparently has no effect on the current transient. It should be noted that, though the current drop between the initial value and the tail portion occurred within a few seconds, the time required to reach a steady-state value was very long. In this tail portion, the current continued to drop slowly, and often it took 30-60 min before a steady value was observed.

It has been found that during this initial current drop period, the logarithm of the current varied linearly with the cube of time. Figure 2 is a plot of I *vs.* t^3 on semilogarithmic scales for various potential pulses in 2M $NaNO_3$ solution. The effect of nitrate concentrations on the current transient is shown in Fig. 3, where the current obtained from a potential pulse of 1.0V *vs.* SCE is also plotted against the cube of time on semilogarithmic scales for three nitrate concentrations. It is seen that the rate of current drop increases with increase in both anodic potential and solution concentration.

The relationship between the initial current density and the steady-state polarization curve is shown in Fig. 4. The steady-state current densities for various nitrate concentrations and anode revolution rates are represented by the symbols, ○, △, ▭, etc. The dashed curves are the initial current densities obtained from the current transient curves. This figure demonstrates that the passive region lies between anode potentials from 0 to 1.2V *vs.* SCE. The current densities on the left of 0.0V *vs.* SCE represent the rate of active dissolution of iron into the electrolyte, and those on the right of 1.2V *vs.* SCE are the transpassive current densities. Variation in the nitrate concentration and stirring of the solution have no effect on the steady-state measurements. The initial current densities of the potentiostatic pulses appear to be smooth extensions of the steady-state current densities of the active dissolution states into the passive potentials.

Discussion

The behavior of current transients can be explained by a model of two-dimensional nucleation and growth for an anodic film on the electrode surface. The model involves the following assumptions: (*i*) the film nuclei

[1] Composition of the mild steel: Fe, 98.4%; Mn, 0.98% S, 0.29%; C, 0.1%; P, 0.06%; Si, 0.005%.

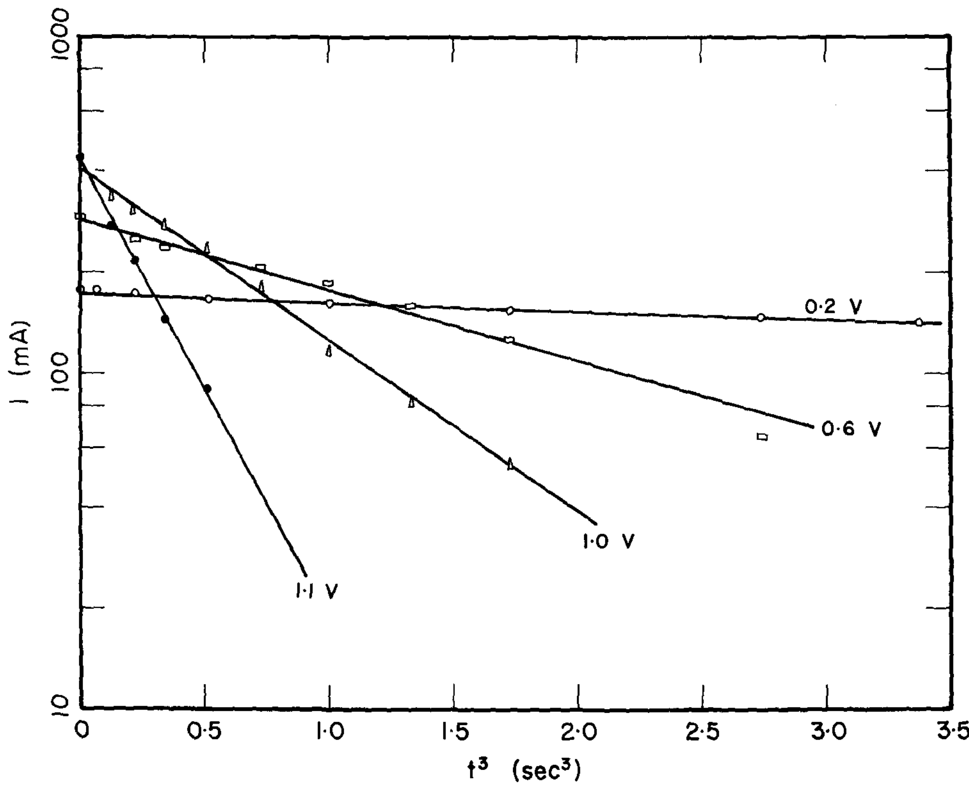

Fig. 2. I vs. t^3 for various potentiostatic pulses (vs. SCE) in 2M $NaNO_3$.

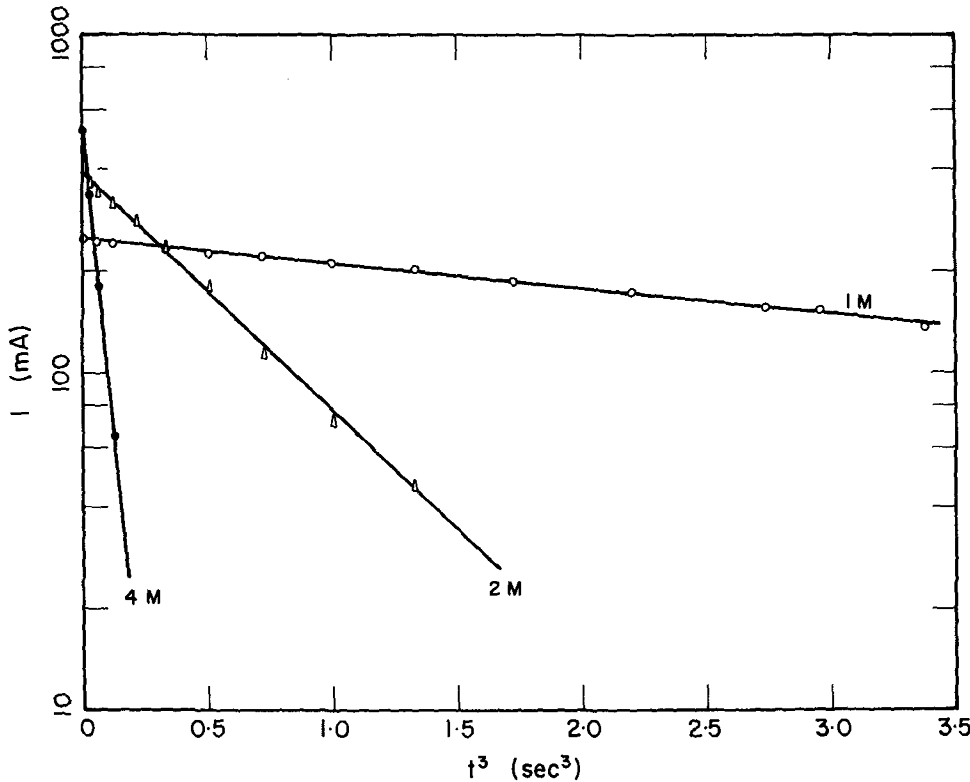

Fig. 3. I vs. t^3 for a potentiostatic pulse of 1.0V (vs. SCE) in three different concentrations of $NaNO_3$ solution.

occur randomly on the surface; (*ii*) only a monomolecular layer of the passive film is formed on the surface, and the growth of such a layer results in a decrease in the dissolution current; and (*iii*) the film is permeable to the metal ion, in other words, electrode dissolution can take place by diffusion of metal ions through the film. Under these circumstances, the current density/time relationships have been given by Armstrong, Porter, Bulman, and Thirsk (8, 9):

(a) formation of the passive film

$$i_F = q_{mon}\pi v^2 N t^2 \exp\left(-\frac{\pi}{3} v^2 N t^3\right) \quad [1]$$

(b) dissolution on the bare electrode surface

$$i_D = i_o \exp\left(-\frac{\pi}{3} v^2 N t^3\right) \quad [2]$$

(c) dissolution by diffusion through the film

$$i'_D = i'_o \left\{1 - \exp\left(-\frac{\pi}{3} v^2 N t^3\right)\right\} \quad [3]$$

Here i_o and i'_o are the exchange current densities for the dissolution reactions occurring on the bare electrode surface and on the surface covered with the pas-

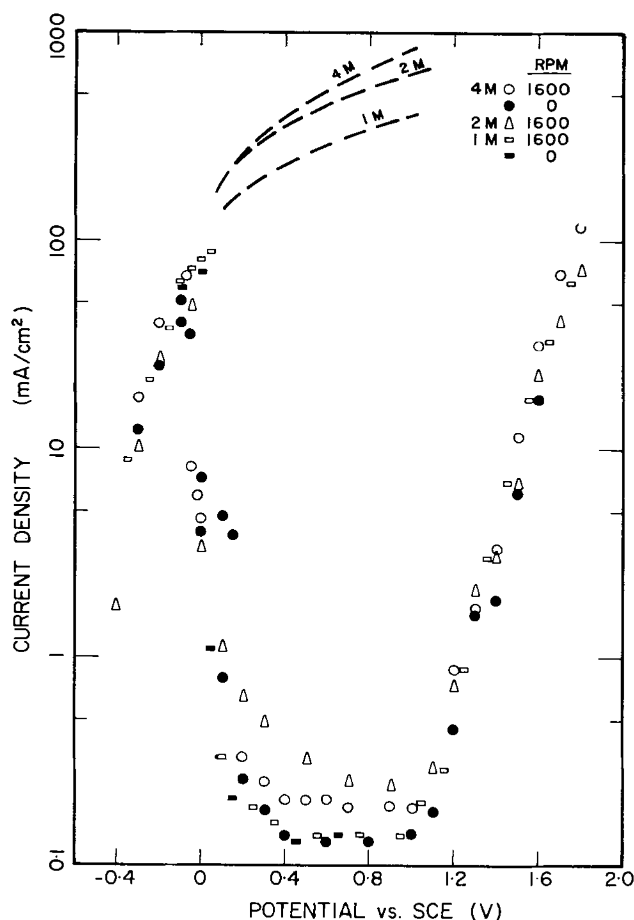

Fig. 4. Initial current density of the potentiostatic transient and the steady-state polarization curves for mild steel in $NaNO_3$ solution. The steady-state measurements are represented by the symbols, ○, Δ, ▭, etc. The dashed curves are the initial current densities obtained from the recorder output.

sive film, respectively; q_{mon} is the charge density for the formation of the monomolecular layer; N is the rate of nucleation of two dimensional centers; and v is the rate of film spreading from the nuclear centers.

The total current density is the sum of Eq. [1]-[3]. For the present study, one may assume that i_F and i'_D are too small to be observed under the experimental conditions. Thus, the current measured is contributed mostly by the dissolution on the bare metal surface. Equation [2] suggests that a plot of the logarithm of the current against the cube of time would give a straight line. The results given in Fig. 2 and 3 demonstrate that the current transient for a mild steel electrode in sodium nitrate solutions agrees precisely with this model. Figure 4 further shows that the initial current density of the transient represents the rate of dissolution on the bare electrode surface and, thus, corresponds to i_o in Eq. [2]. The cube root of the product, v^2N, can be regarded as an average rate of film formation on the electrode surface. Figure 5 is a semi-logarithmic plot of $\sqrt[3]{v^2N}$ *vs.* i_o as calculated from the experimental data. It is seen that the film formation rate increases with the metal dissolution rate as well as with the nitrate concentration.

This film formation mechanism is further supported by Mieluch's (6) galvanostatic study of iron in concentrated ammonium nitrate solutions. His results give a charge density of 1.3 mcoulomb/cm² needed for the formation of an initial passive layer on the electrode surface. If one assumes that this initial layer is composed of Fe_3O_4, as suggested in the literature (10), this amount of charge density would correspond to an oxide layer of monomolecular thickness on the electrode surface.

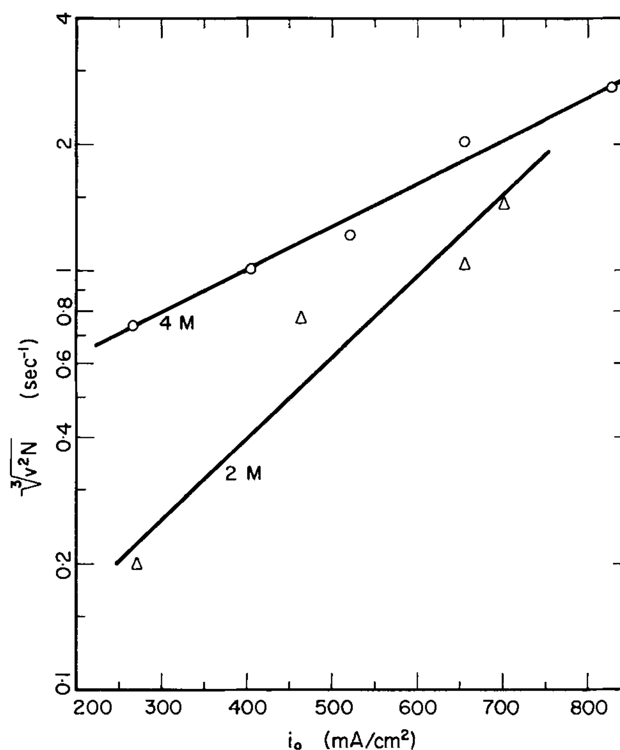

Fig. 5. Average rate of film formation *vs.* dissolution current density for two different $NaNO_3$ concentrations.

It should be noted that the transient data presented here represent only the initial stage of the passivation process. The present results do not account for thickening of the film, nor for possible transformation of phase layers in later stages of the passivation process. Further study is needed to resolve these problems.

Conclusions

The onset of passivity for mild steel in neutral nitrate solutions is characterized by formation of a monolayer of oxide on the electrode surface. The rate of formation increases with the rate of dissolution reaction as well as with nitrate concentration.

Technical Notes

h-Pits Produced by Hydrating and Annealing Aluminum Foil

Cecil G. Dunn*[1]

Research and Development Center, General Electric Company, Schenectady, New York 12301

and Donald R. Witter[2]

Electronic Capacitor and Battery Department, General Electric Company, Columbia, South Carolina 29202

This note reports some surface phenomena, including the formation of relatively large crystallographically oriented pits, on aluminum reacted with boiling water prior to heating in air. For identification purposes and to distinguish them from thermal pits or vacancy condensation pits (VC-pits) we call the present pits, h-pits. Although other studies have been reported of *in situ* dehydration of boehmite films (1), and high temperature reactions between boehmite films and the substrate aluminum (2), the present h-pit observations appear to be new.

The surface phenomena described in the following experiments were obtained using suitable hard (H19 temper) commercial grade 99.99% Al foil. The phenomena include: (*i*) crystallographically oriented pits, both within the aluminum grains and at the grain boundaries, that arise due to recrystallization and grain growth; (*ii*) networks of pits and occasionally gigantic grooves at grain boundaries; and (*iii*) partial networks of pits within grains.

Regarding pits within grains, samples of the hard foil were observed visually during relatively fast heating to about 600°C, since it was known that suitable foil, heated at a relatively high rate of temperature rise in the 200° to 300°C range (3-5) produced relatively large grains. Under oblique illumination, the grain structure was not visible in a sample given no pretreatment; but after a few minutes at about 600°C, grains ½ to 1 cm in size became visible in a sample given a pretreatment of 5 min in boiling water. The individual grains were visible prior to cooling. On the other hand, samples cooled to room temperature could be studied more thoroughly. Figure 1 shows the appearance of a sample held 30 min in air at 550°C after about a 1 min heating-up time. The large-grained structure was revealed by differences in reflected light intensity due to crystallographically oriented pits of about 5μ size and density near 10^5 pits/cm^2. The uneven light reflections from some of the grains suggests the presence of a coarse subgrain structure. Incidentally, support for this view was obtained using the sink property that sub-boundaries (and boundaries) have for vacancies (6). Thus, samples of either the annealed foil or the hard foil were electropolished to provide smoother surfaces, then held for 10 min in air at 600°C, and finally cooled at a suitable rate for VC-pit formation within the large subgrains.

From the above results one may conclude that the development of the h-pits is a consequence of the hydration treatment; and h-pits, since they can form at temperature, are unlike VC-pits, which form only after a drop in temperature.

Grain boundaries generally provided preferred sites for h-pits. This feature will be illustrated using a fine-grained structure developed in samples from the same lot of hard foil by holding them for 16 hr at 350°C after a low rate of temperature rise. At this point, some samples were given a 5 min hydration treatment at 100°C while others were given no treatment. Both kinds of samples were then held 30 min in air, at 550°C, as before. Again h-pits were abundantly present in samples given the hydration treatment and essentially absent

Fig. 2. Soft aluminum foil (after a 16-hr anneal at 350°C) given a 5 min dip in boiling water prior to a 550°C anneal in air. (X250).

in samples given no hydration treatment. Figure 2 is a typical micrograph showing a network structure due to a preferential formation of pits at grain boundaries. This feature is similar to results observed previously for hydrogen-doped aluminum involving no hydration treatments (7).

Another observation was that some grain growth occurred at 550°C including instances of relatively fast grain boundary migration. When this occurred after grain boundary pits had already formed, chains of pits and partial networks of pits were left within grains as might be expected. When pits along a grain boundary grew in size until they came together, "gigantic" grain boundary grooving occurred. Some instances of this phenomenon appear in Fig. 2. Careful inspection of the sample (and others using film lifting techniques) revealed the presence of a transparent oxide film over the entire surface. The h-pits, accordingly, are voids at the oxide metal interface. Individual h-pit voids within a grain have a rather unique morphology and this is also evident to some degree in Fig. 2. Noting that {111} planes and {100} planes of the aluminum matrix are the preferred boundary planes for both hydrogen pores (8) and VC-pits (9), we suggest that the crystallographic orientations referred to earlier may involve the same {h k l} planes.

Using another lot of H19 commercial grade 99.99% Al, which had the property of recrystallizing to a fine-grained structure on heating rapidly (3-5), it was shown that the network pattern of grain boundary pits does not depend on the presence of a fine-grained structure at the time of hydrating the foil, which was the situation above. For example, the second lot of hard foil was given a 5 min hydration treatment at 100°C and the 30 min treatment in air, at 550°C, as before. Results were similar to those illustrated in Fig. 2.

Mention may be made of some limited studies on the effect of holding temperature on samples given the hydration pretreatment. Holding 16 hr at 400°C, for example, produced h-pits. However, a similar treatment at 300°C produced no large pits, or pits that could be easily seen.

Other studies showed that the removal of the hydrate layer prior to annealing, by means of a boiling aqueous solution of CrO_3 and phosphoric acid (10, 11), essentially eliminated the formation of large h-pits. Thus, the presence of a hydrated film during the holding at 400°C and higher appears to be necessary for abundant h-pit formation.

For the most part, the above phenomena may be explained by the assumption that the h-pits actually are hydrogen pits (H-pits), with the hydrogen probably originating in an Al-hydrate film reaction (2). The literature is extensive on H-pores and surface blisters, the latter due to hydrogen precipitation within the aluminum but near the surface. Instances of hydrogen precipitation at a metal-oxide interface, undoubtedly, have been seen. In fact, based on proton injection results, Milacek *et al.* (12) conclude that "pitting is the result of accumulation of protons as hydrogen in voids which form at the oxide-metal interface." Also, previous work (7), involving superpurity aluminum with and without added hydrogen introduced during recasting, demonstrated the formation of H-pits in the hydrogen-doped samples annealed in air. A surface oxide film plays an important role in these instances because it prevents the escape of hydrogen, which, in turn, provides the driving force for the formation of voids at the oxide-metal interface.

An Interpretation of Anodic Dissolution and Corrosion of Some Film-Covered Electrodes

Ashok K. Vijh*

Hydro-Quebec Institute of Research, Varennes, P.Q., Canada

Consider anodic dissolution of metals in anhydrous hydrogen fluoride (AHF) proceeding via fluoride corrosion films (1, 2). Following Gerischer (3), anodic discharge of F^- ions of the AHF on the fluoride covered metal, MF, may occur either by participation of the conduction band of MF as

$$MF + F^- \rightarrow MF_2 + e \qquad [1]$$

or, by involvement of the valence band as

$$MF + F^- + p_s \rightarrow MF_2 \qquad [2]$$

The ratio of the two rate equations is given by (3)

$$\frac{v_2}{v_1} = \frac{p_s}{N_c} \exp - \left(\frac{\gamma Eg}{kT} \right) \qquad [3]$$

where v_1 and v_2 are the rates for reactions [1] and [2], respectively; p_s is the hole concentration in the surface of MF at equilibrium; N_c is the effective density of states in the conduction band of MF; γ is a constant having value between 0.5 and 1, depending on the system; Eg is the band gap. Assuming value of $\gamma = 0.5$, and noting that $Eg \simeq -2\Delta H_e$ where ΔH_e is the heat of formation per equivalent (4) of the MF, one has

$$v_2 \simeq v_1 \frac{p_s}{N_c} \exp \left(\frac{\Delta H_e}{kT} \right) \qquad [4]$$

For highly ionic fluoride films, Eg is large so that the dissolution proceeds almost entirely by a hole mechanism (3). One may, therefore, take v_1 as a negligible and relatively *constant* fraction of the over-all rate $(v_1 + v_2)$. This would then give

$$\log v \propto K \left(\frac{\Delta H_e}{2.3\, kT} \right) \qquad [5]$$

* Electrochemical Society Active Member.

Key words: anodic dissolution, film-covered electrodes, hydrogen fluoride, fluoride films.

where v is the total rate of anodic dissolution and K is a constant. Application of Eq. [5] to the data (1, 2, 5) on anodic dissolution of metals in AHF shows its approximate validity (Fig. 1); *i.e.*, as ΔH_e of MF becomes higher (more endothermic), log v increases. Similar considerations appear to be valid for anodic dissolution of metals in sulfamic acid-formamide solutions occurring via corrosion reaction films (6, 7).

Noting that, for electrode reactions log rate is proportional to electrode potential V, and that, for some cases of open-circuit corrosion, one conjugate reaction determines almost exclusively the corrosion potential E_h (so that $V \simeq E_h$) one gets

$$E_h \propto K \left(\frac{\Delta H_e}{2.3\, kT} \right) \qquad [6]$$

Examination of Eq. [6], in relation to the data given in Ref. (8) and (9), roughly supports its validity.

Electrochemical Preparation of Cadmium and Mercury Tellurides

M. H. Miles*

Department of Chemistry, Middle Tennessee State University, Murfreesboro, Tennessee 37130

and W. S. McEwan

Telluride compounds are of growing interest due to their properties as semiconductors and semimetals. The solid solution system $Cd_xHg_{1-x}Te$ is an outstanding infrared detector material (1). Cadmium telluride is useful for windows in infrared lasers and infrared modulators and also as a nuclear radiation detector (2). Although telluride compounds are often prepared by direct union of the elements at high temperatures, a convenient electrolytic method for preparing tellurides from aqueous solution at room temperature has been described (3). The application of electrochemical methods is investigated for the preparation of CdTe and HgTe.

Experimental

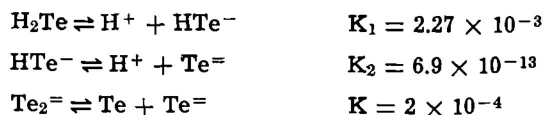
The tellurium electrodes used as the source of $Te^{=}$ ions were prepared by sealing a piece of this substance in glass tubing using Bipax epoxy (BA-2112) and making a mercury contact to a copper lead. The total resistance of this electrode was usually about 5-15 ohms. A cadmium rod was used as the source of Cd^{++} ions in the preparation of CdTe. Reagent mercury (II) acetate was used as the source of Hg^{++} ions in the preparation of HgTe. The quoted purities are 99.99% for the cadmium rod (Alfa Inorganics), and at least 99.5% for the tellurium stick (A. D. Mackay).

The ammonium acetate-acetic acid buffer solution used as the electrolyte was prepared from reagent chemicals by adding acetic acid to 1M NH_4OH to give a pH of 4.5. Electrochemical experiments were performed using the Beckman Electroscan 30 instrument and a one-compartment, beaker type, electrochemical cell containing the buffer solution and the appropriate electrodes. Nitrogen purified by bubbling through Fieser's solution was used to remove oxygen from the electrolyte solution (4). The closed electrochemical cell was placed in a plastic bag and kept under positive nitrogen pressure during electrolysis as an added precaution against oxygen.

The CdTe or HgTe precipitate formed during constant current electrolysis was washed, centrifuged, and dried under vacuum at 100°C for at least 12 hr. Atomic absorption spectroscopy, electrode weight losses, and precipitate weights were used to determine the composition of the material.

Results and Discussion

Knowledge of the products formed at the tellurium cathode is vital in this method. In aqueous solution we have the following equilibria (3, 5)



$$H_2Te \rightleftharpoons H^+ + HTe^- \qquad K_1 = 2.27 \times 10^{-3}$$

$$HTe^- \rightleftharpoons H^+ + Te^= \qquad K_2 = 6.9 \times 10^{-13}$$

$$Te_2^= \rightleftharpoons Te + Te^= \qquad K = 2 \times 10^{-4}$$

According to Panson (5), the major product of the tellurium cathode is $Te_2^=$ above *p*H 12, and $Te^=$ below *p*H 9. Figure 1 shows a cyclic voltamogram for the tellurium electrode in the *p*H 4.5 buffer solution. Reduction of tellurium occurs as the potential becomes more negative than $-0.8V$ (*vs.* SCE). The telluride ions produced are readily oxidized during the anodic sweep as the potential increases beyond $-0.8V$. In slightly acidic solution the net reaction involved is likely

$$Te + H^+ + 2e^- \rightleftharpoons HTe^- \qquad [1]$$

A brownish product was observed streaming from the electrode during the oxidation, probably due to Te particles formed. The ease of oxidation of the telluride ion reflects the concern for rigid precautions to exclude oxygen from the solution (3). Further electrochemical oxidation is observed as the potential sweeps beyond 0.2V; the oxidized substance formed is reduced during the following cathodic sweep at a peak potential of about $-0.45V$. The oxidation product is fairly insoluble as determined from the effects of stirring the solution and delaying the cathodic sweep. From the potential $-p$H equilibrium diagram for the tellurium-water system (6), these reactions probably involve the formation and corresponding reduction of TeO_2. Uncompensated *IR* effects are present in the cyclic voltamograms, largely due to the 15 ohm resistance through the tellurium electrode. Slightly irregular behavior at the extreme potentials in Fig. 1 is due to the manual potential reversal switch of the Beckman instrument.

Cadmium telluride was produced by using a cadmium anode and a tellurium cathode in the *p*H 4.5

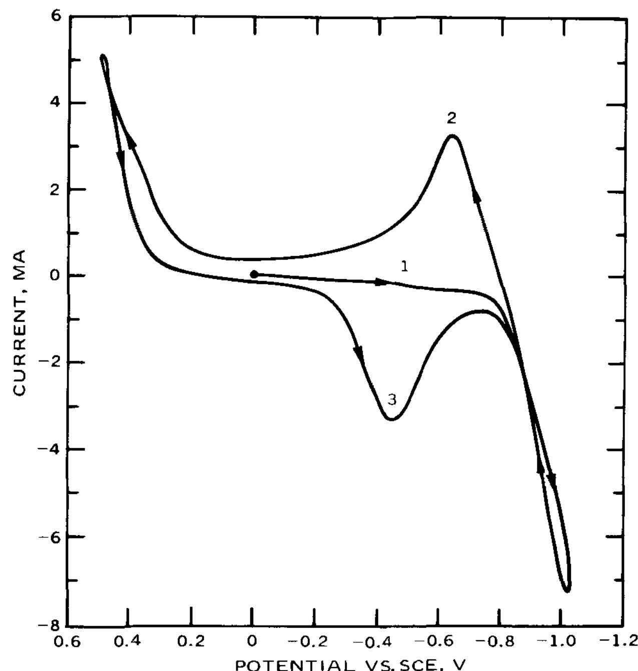


Fig. 1. Cyclic voltamogram for a tellurium electrode in a 1.0M $NH_4C_2H_3O_2$ + $HC_2H_3O_2$ buffer solution of *p*H 4.5. Order of potential sweeps: 1. Cathodic direction beginning at 0.0 V; 2. Following sweep in the anodic direction; 3. Following cathodic sweep. Potential sweep rate = 100 mV/sec; geometrical electrode area = 0.5 cm²; T = 27°C.

Table I. Experimental and theoretical results for the formation of CdTe by the passage of 801 coulombs

	Electrode weight loss, g	Precipitate weight, g	Atomic absorbtion analysis Lab A	Lab B
Experiment 1:	0.459 Cd	0.977	42.66% Cd	45.2% Cd
	0.517 Te		55.84% Te	55.5% Te
Experiment 2:	0.480 Cd	0.992	44.79% Cd	42.5% Cd
	0.514 Te		53.32% Te	58.5% Te
Experiment 3:	0.478 Cd		45.63% Cd	47.2% Cd
	0.513 Te		46.58% Te	53.6% Te
Theoretical:	0.467 Cd	0.997	46.83% Cd	
	0.530 Te		53.17% Te	

buffer solution stirred both by the bubbling N_2 and a magnetic stirrer. The Cd^{++} and $Te^{=}$ ions generated, combine to form a fine, dark precipitate of CdTe. The potential of the tellurium electrode with 0.5 cm^2 geometrical area, during constant reduction currents of 1, 10, and 100 mA, was $-0.86V$, $-1.05V$, and $-1.65V$ (*vs.* SCE), respectively, reflecting the uncompensated *IR* effects and the various types of overvoltage. The potential of the cadmium electrode, with 10 cm^2 geometrical area during constant anodic currents of 1, 10, and 100 mA, was $-0.77V$, $-0.72V$, and $-0.41V$, respectively.

Table I shows the results for three separate experiments, each involving the passage of 0.010A for 100 sec followed by 0.100A for 8000 sec between the cadmium anode and tellurium cathode to form the CdTe precipitate. Each product was analyzed by two independent laboratories using atomic absorption spectroscopy. Assuming that the lack of reproducibility is due to random errors in the analyses, the arithmetic means are 44.7 ± 1.9% for cadmium and 53.9 ± 4.3% for tellurium where the limits express the 95% confidence interval of the "Student t" statistical test (7). Identical samples tested by the same laboratory showed similar lack of reproducibility. The statistical test for the total (% Cd + % Te) gives 98.6 ± 3.5% at the 95% confidence interval. Slight oxidation of the precipitate due to exposure to air during washing and centrifuging may occur; however, this effect is not statistically significant at the 95% confidence level.

Significant deviations from the expected theoretical values, which indicate possible systematic error sources in the experiments, are found for the low cadmium composition of the product and for the low weight loss at the tellurium electrode.

The low analyses for cadmium are just significant at the 95% confidence level. A possible systematic error source is the reaction with oxygen

$$HTe^- + H^+ + \tfrac{1}{2}O_2 \rightarrow Te + H_2O \quad [2]$$

which would result in Te metal present in the precipitate and Cd^{++} ions left in solution without partners for precipitation. These Cd^{++} ions would, therefore, be lost during the washing and centrifuging operations. Apparently, the extreme precautions taken to exclude oxygen during electrolysis were not sufficient to completely eliminate the interfering reaction of the telluride ion with oxygen. In one experiment, where the solution was accidently exposed to air during the electrolysis, the results of the analysis changed dramatically to 79.1% Te and 20.5% Cd indicating that the above reaction takes place very readily if any oxygen is available.

Any occurrence of reaction [2] would lead to high analyses for tellurium. Although many of the analyses for Te in Table I are higher than the theoretical value, the results are not statistically significant due to the large uncertainty in the atomic absorption results for this metal. Also, the questionable low value reported by Lab A for experiment 3 (Table I) tends to greatly reduce the arithmetic mean of these analyses.

The CdTe product is composed of black powder and lumps, very similar in appearance to particles of coal. Under the microscope, however, some fibrous material having a metallic luster is observed. Possibly such fibers consist of tellurium metal produced by reaction [2]. It is roughly estimated that these fibers represent less than 1% of the total product.

The low weight loss at the tellurium electrode is significant at the 99% confidence level indicating that systematic error sources are highly probable. Possible error sources include the reactions

$$2H^+ + 2e^- \rightarrow H_2 \quad [3]$$

$$Cd^{++} + 2e^- \rightarrow Cd \quad [4]$$

occurring at the tellurium cathode in addition to the expected reaction [1]. Both of these reactions are thermodynamically possible in the potential region where tellurium reduction occurs.

Reaction [3] would be expected to occur readily at the large negative potentials required for the electrochemical reduction of tellurium. Fortunately, however, the overvoltage for H_2 evolution on tellurium is high. Also, telluride ions tend to have a poisoning effect on the hydrogen evolution reaction (8). Any occurrence of reaction [3] will directly reduce the weight loss of the tellurium cathode but will have no effect on the composition of the precipitate since an equivalent amount of Cd^{++} ions will be left without $Te^{=}$ partners. Any occurrence of either reaction [2] or [3] would result in excess Cd^{++} ions left in solution, which may then be reduced and deposited at the tellurium cathode (reaction [4]) giving less than the expected weight loss for this electrode.

There is some controversy over the existence of the adsorbed monovalent cadmium ion, Cd^+ or Cd_2^{++}, as an intermediate in the cadmium electrode reaction (9, 10). One may speculate that such an intermediate might react chemically with other adsorbed species such as water

$$Cd^+ + H_2O \rightarrow Cd^{++} + OH^- + \tfrac{1}{2} H_2$$

which would result in the electrode weight loss being larger than theoretical. Although the data in Table I is not statistically significant on this point, both experiments 2 and 3 gave larger than theoretical weight losses for the cadmium electrode. Further experiments established that this is due to slight chemical reaction of the cadmium during the experiment with the weakly acidic solution. Carefully designed experiments did not show any significant difference between the behavior of zinc and cadmium anodes. Both are electrochemically oxidized in the *p*H 4.5 buffer solutions by a two electron step to form the divalent ion.

Formation of the mercury double ion, Hg_2^{++}, prevents a satisfactory electrochemical preparation of HgTe. Use of a mercury anode and a tellurium cathode in the $NH_4C_2H_3O_2/HC_2H_3O_2$ buffer solution results in a white column of precipitate forming above the electrode cup containing the mercury, while a black precipitate forms in solution. Apparently the mercury oxidizes to Hg_2^{++} which then precipitates upon the electrode as $Hg_2(C_2H_3O_2)_2$. Since mercury (I) acetate is sparingly soluble, the electrolytically produced $Te^{=}$ ions likely cause disproportionation of Hg_2^{++}

$$Hg_2^{++} + Te^{=} \rightarrow Hg + HgTe \quad [5]$$

similar to the reaction with $S^{=}$ ion (11). Metallic films were observed in the electrochemical cell indicating contamination of the black HgTe formed with free mercury as suggested by reaction [5]. Atomic absorption analysis also showed excessive mercury in the product.

Preparation of HgTe is also possible by electrochemically generating $Te^{=}$ ions in solution by using a platinum anode with the tellurium cathode and then directly adding a soluble mercury (II) salt such as

mercury (II) acetate. Atomic absorption analyses of such a preparation by two separate laboratories gave 63.17%, 61.7% for mercury, and 35.78%, 38.9% for tellurium. This compares favorably with the theoretical values of 61.12% Hg and 38.88% Te for HgTe. However, it is experimentally difficult to prevent oxygen produced at the anode during electrolysis from mixing with the solution and oxidizing $Te^{=}$ ions. This particular problem could be avoided by using liquid ammonia solutions since N_2 is formed at the anode; however, in NH_3-NH_4NO_3 solutions (12), it was found from the electrode weight loss that the ditelluride ion, $Te_2^{=}$, is the major product at the cathode.

Conclusions

Cadmium telluride can be prepared by a simple electrochemical method. The purity of the CdTe is determined primarily by the extent of oxygen exclusion during electrolysis. Any oxygen present reacts with the electrochemically produced telluride ions resulting in contamination of the product with tellurium metal.

Formation of Hg_2^{++} at the anode complicates the electrochemical preparation of HgTe. However, addition of a mercury (II) salt to a solution of electrochemically generated telluride ions produces a precipitate of the desired product.

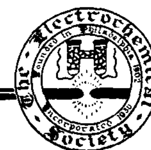
Brief Communication



Characterization of Passivating Films on Fe-Cr Alloys by Soft X-Ray Spectroscopy

J. E. Holliday[1] and R. P. Frankenthal*

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation Research Center, Monroeville, Pennsylvania 15146

It is well known that chromium steels radically change their corrosion and electrochemical properties at about 12% chromium content (1). The low-Cr steels have properties similar to iron, while the stainless steels (Cr > 12%) behave similarly to chromium. It is probable that the composition, structure, and/or thickness of the passivating film on the stainless steels is different from that on the low-Cr steels. Few studies have been made of these properties of passivating films formed at room temperature on chromium steels, primarily because the films are thin (2-4 nm).[2] An electron diffraction study (2) of a series of iron-chromium alloys indicates that the film on alloys with Cr-content $\leq$ 12% is an Fe-Cr spinel, the lattice parameter of which increases with increasing Cr-content; the film on alloys with Cr-content > 12% is amorphous in character. The passivating film on iron is γ-Fe_2O_3 and may include some Fe_3O_4 (3).

[1] Present address: McDonnell Douglas Research Laboratory, St. Louis, Missouri 63166.
Key words: iron, iron-chromium alloys, oxide, passivating film, thin film.
[2] 1 nm = 10A.

The applicability of soft x-ray spectroscopy to the characterization of relatively thick oxide films (> 10 nm) on transition metals has recently been reported (4). We wish to report a method of characterizing very thin films, *e.g.*, passivating films, *in situ* on iron and iron-chromium alloys by soft x-ray spectroscopy. When a metal, alloy, or compound is bombarded with electrons of energy up to 3 kV, soft x-rays originating near the surface are emitted; the depth from which the x-rays come decreases with decreasing electron energy. The wavelength and intensity distribution of the x-ray band spectra are sensitive functions of the electronic structure of the emitter, *i.e.*, ionization state. The effect of compound formation on the shape and wavelength of characteristic emission bands from the elements, as well as experimental techniques, has recently been reviewed by Holliday (5). In the present study the system was evacuated to 1×10^{-7} Torr and the target was cooled to reduce the probability of oxide growth.

For iron and chromium the L_{II} and L_{III} bands (4s + 3d $\rightarrow$ 2p transition) occur in the soft x-ray region. The L_{II} band is a (4s + 3d $\rightarrow$ 2p $J_{1/2}$) transition and

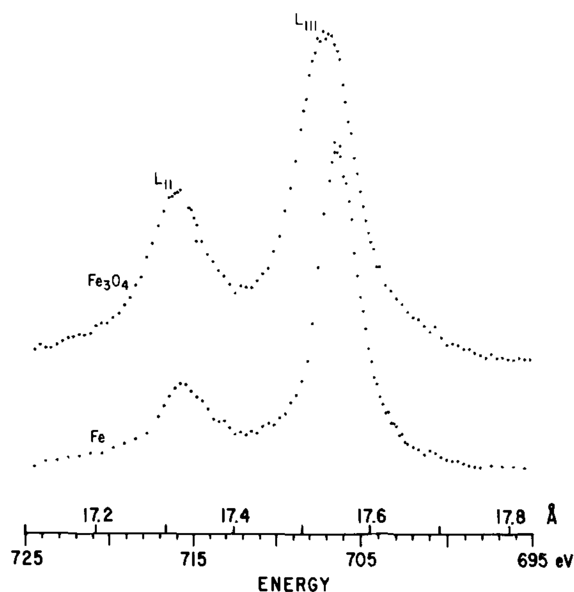

Fig. 1. $FeL_{II,III}$ bands from iron and from Fe_3O_4 measured at 2.5 kV. Spectrum of Fe_2O_3 is almost the same as that of Fe_3O_4.

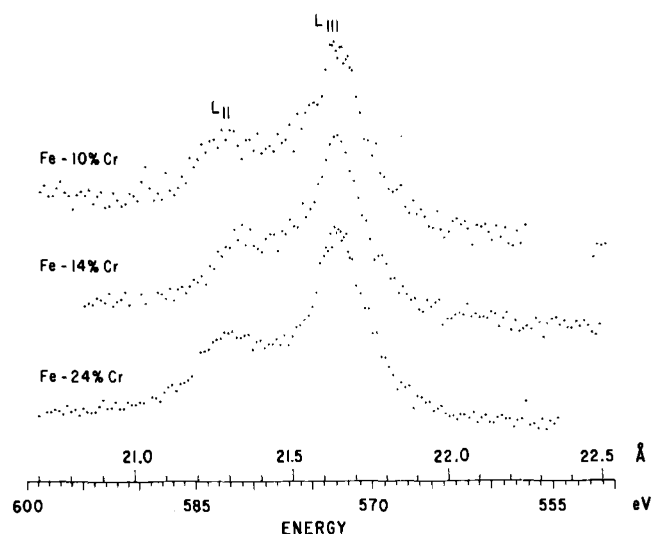

Fig. 2. $CrL_{II,III}$ bands from three passivated iron-chromium alloys measured at 3.0 kV.

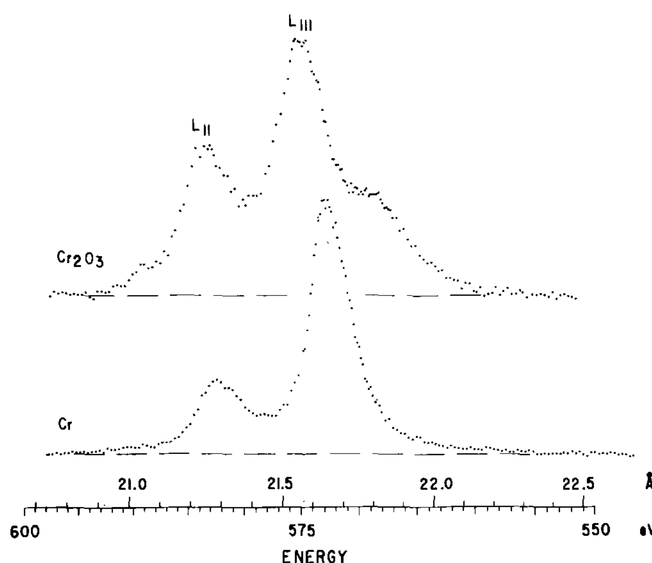

Fig. 3. $CrL_{II,III}$ bands from chromium and from Cr_2O_3.

the L_{III} band is a ($4s + 3d \rightarrow 2p\ J_{3/2}$) transition. The spectrum consisting of both bands is usually designated Fe $L_{II,III}$ for iron and Cr $L_{II,III}$ for chromium. For this paper a superscript above the symbol of the element indicates the ionization state; the absence of a superscript indicates the band results from more than one ionization state.

A series of ferritic iron-chromium alloys from pure iron to Fe-24Cr has been examined. The specimens were passivated potentiostatically in 1*N* H_2SO_4 at 0.85V *vs.* SHE until a steady state was achieved. Frankenthal (6) has shown that this potential is sufficiently high so that the preferential-dissolution/-adsorption mechanism (7) is no longer important; instead passivity results from an oxide film. The Fe $L_{II,III}$ and the Cr $L_{II,III}$ band spectra of the passivated specimens were measured using a blazed grating analyzer of 3600 grooves/mm in a spectrometer with a 0.5m radius of curvature and a flow proportional counter as detector (8).[3] To obtain accurate peak positions and intensity values, at least three runs were made for each spectrum.

The $L_{II,III}$ bands of the spectra of Fe, Fe_3O_4, and Fe_2O_3 (Fig. 1) overlap to such an extent that their resolution is difficult. However, the ratio of the intensities of the Fe L_{II} and Fe L_{III} bands {$Fe(L_{II}/L_{III})$} is greater for the oxides than for the metal (Fig. 1). Holliday (9) has shown that the change in the $Fe(L_{II}/L_{III})$ intensity ratio is a property of the surface oxide rather than self-absorption and that the ratio increases with increasing oxide thickness at constant accelerating voltage; for example, at 2.5 kV the ratio is 0.24 on oxide free iron and 0.45 on Fe_3O_4 and on Fe_2O_3. For each alloy the $Fe(L_{II}/L_{III})$ ratio was determined from the spectra measured at 1.5 kV (Table I) and will be related to the thickness of the passivating film.

The Cr $L_{II,III}$ band spectrum of each passivated alloy was measured at 3.0 kV; three spectra are shown in Fig. 2. It will be observed that there is a hump on the high energy side of the Cr L_{III} peak from the Fe-10Cr alloy. This hump could be due to self-absorption, electronic structure, or surface oxide. Self-absorption can be ruled out because chromium and iron are adjacent in the periodic table and iron has no emission or absorption edges in the vicinity of the Cr $L_{II,III}$ band. The fact that the energy separation of the hump and main peak (Fig. 2) is the same as that for the Cr L_{III} bands from Cr_2O_3 and chromium metal (Fig. 3) indicates that the hump is due to Cr_2O_3 rather than a change in electronic structure. Further evidence that the hump is due to Cr_2O_3 rather than a change in electronic structure is obtained by measuring the Cr $L_{II,III}$ band from the Fe-10Cr alloy at 2 kV accelerating potential; the intensity of the hump relative to the main peak increased at 2 kV over that at 3 kV. This is expected if the hump is due to surface oxide since at lower accelerating voltages a greater portion of the x-rays come from nearer the surface. A more extensive treatment showing that the changes in Fig. 2 are due to surface oxide is given by Holliday (10).

From the above evidence it can be assumed that the Cr $L_{II,III}$ band spectra in Fig. 2 are composites from Cr_2O_3 and chromium metal. By knowing the relative heights, half-widths, and peak energy positions of the Cr $L_{II,III}$ bands from chromium and from Cr_2O_3 (Fig. 3), it was possible to resolve the Cr $L_{II,III}$ bands in Fig. 2 into the Cr $L_{II,III}$ bands from chromium metal and from Cr_2O_3 on a du Pont 310 Curve Resolver; two resolved spectra are shown in Fig. 4. They have been normalized to a constant Cr^0L_{III} peak intensity. The peak intensity ratio $Cr^{3+}L_{III}/Cr^0L_{III}$, as calculated from the resolved spectra, is given in Table I for each

[3] The Cr $L_{II,III}$ band spectra of the passivated 5Cr alloy was measured with a spectrometer with a 1m radius of curvature for greater resolution.

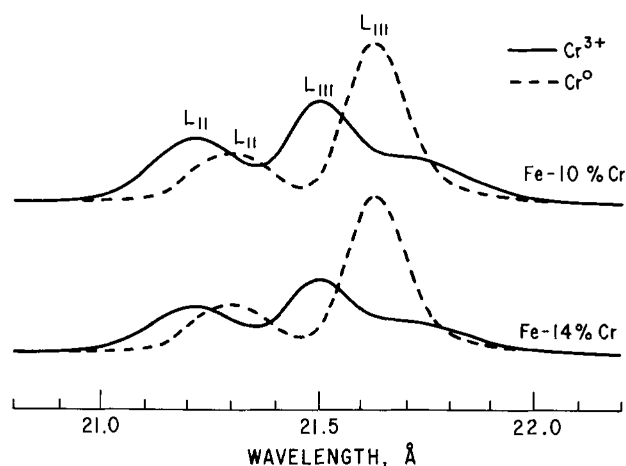

Fig. 4. Resolved $L_{II,III}$ bands of Cr° and Cr^{3+} from two iron-chromium alloys measured at 3 kV. Spectra have been normalized for constant $Cr^{o}L_{III}$ intensity.

alloy. The precision of the ratios is limited by the precision with which the curves can be resolved.

To determine that the chromium oxide was not changed during electron bombardment, a 50Å film of chromium and Cr_2O_3 was electrodeposited onto an iron substrate. The thickness of the chromium oxide on the 50Å film, as determined by chemical analysis, was approximately 10Å. The relative intensities of the Cr L_{III} bands from chromium and Cr_2O_3 were in agreement with chemical analysis data showing that electron bombardment in the present vacuum system does not change the film.

The changes in the Fe(L_{II}/L_{III}) and in the $Cr^{3+}L_{III}/Cr^{o}L_{III}$ intensity ratios (Table I) can be associated with major changes in oxide film thickness and composition over the alloy composition range from 10 to 14% chromium, the same range over which major changes occur in the electrochemical, corrosion (1), and crystallographic (2) properties of the alloys.

Assuming that the dilution of iron and its oxide by chromium and Cr^{3+}, respectively, does not appreciably effect the determination of the quantity of iron oxide from the Fe(L_{II}/L_{III}) intensity ratio, the change in this ratio between 10 and 14% chromium can be accounted for by a decrease in the oxide film thickness (9). Using this relationship and the fact that the oxide film on iron is 4 nm thick (11), the oxide on the high-Cr alloys is estimated to be about 2 nm thick. Although the above assumption may not be strictly valid, the results are qualitatively reasonable, inasmuch as the oxide film thickness on passivated chromium metal has been reported to be 1 nm (12).

Assuming the validity of the film thickness calculations and that changes in the $Cr^{3+}L_{III}/Cr^{o}L_{III}$ intensity

Table I. Fe(L_{II}/L_{III}) and $Cr^{3+}L_{III}/Cr^{o}L_{III}$ intensity ratios of Fe-Cr alloys

%C in alloy	Fe(L_{II}/L_{III})	$Cr^{3+}L_{III}/Cr^{o}L_{III}$
0	0.35 ± 0.005	—
5	0.34	1.1 ± 0.05
10	0.35	0.6
14	0.32	0.4
19	0.32	—
24	0.32	0.4

ratio should be determined primarily by changes in the quantity of Cr^{3+} in the oxide and/or Cr^{o} in the alloy, the changes in this ratio with alloy composition (Table I) may be explained. The change in the ratio between the 5Cr and the 10Cr alloys is most likely due to the increase in Cr-content of the alloy with relatively small changes in oxide composition and/or thickness. The change in the ratio between 14Cr and the 24Cr alloys can best be accounted for by assuming an increase in the Cr^{3+} concentration of the oxide equal to the increase of chromium in the alloy, the oxide thickness remaining relatively constant. The change in the ratio between the 10Cr and the 14Cr alloys indicates that the Cr^{3+} concentration in the film is increasing approximately proportionately to the decrease in film thickness, *i.e.*, the concentration doubles if the film thickness decreases from 4 to 2 nm. The changes in the Cr^{3+}/Fe^{3+} concentration ratio in the oxide with alloy composition will be even greater than the changes in Cr^{3+} concentration because each additional chromic ion in the oxide replaces a ferric ion, the densities of Cr_2O_3, Fe_2O_3, and Fe_3O_4 being equal.

The results of this initial study show that there are distinct differences in the spectra obtained from the different passivated alloys. While the interpretation of the present data is not unambiguous, it is consistent with significant changes in the oxide film thickness and composition in the alloy composition range from 10 to 14% chromium, in which range the major changes in the electrochemical and corrosion properties occur.

Acknowledgments

The authors wish to thank Dr. R. A. Oriani for helpful discussions and Mr. W. A. Hester for performing the soft x-ray measurements.

Successive Adsorptions of Hydrogen Bromide and Hydrogen Sulfide on Vapor-Deposited Lead Monoxide Layers

A. H. Boonstra and R. M. A. Sidler

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven, The Netherlands

ABSTRACT

The chemisorption of HBr on vapor-deposited PbO layers was investigated at different temperatures. At room temperature the reaction of HBr with the PbO surface molecules is followed by a fast reaction with the underlying molecules. At −160°C only the surface reaction was measured, resulting in an adsorption of HBr of 60% of a monolayer. Taking into account the decrease of the surface area caused by the adsorption of HBr, we conclude that a monolayer of HBr is chemisorbed. This means that as a result of this reaction the compound Pb_2OBr_2 is formed on the surface of the crystallites. Chemisorption of H_2S at room temperature on such a layer shows a coverage of H_2S of 40% of a monolayer. Optical measurements on these layers show an absorption edge of about 1.75 eV.

The photoconductive layer in the Plumbicon television pick-up tube consists mainly of polycrystalline PbO of the red modification.[1] These vapor-deposited layers have a specific surface area of about 50 m^2g^{-1} and are therefore particularly suitable for chemisorption experiments. It is known that after vapor-deposition of the PbO, the absorption edge of these layers can be shifted toward the red if the layer is treated with H_2S (1, 2). It is shown that by the adsorption of H_2S, at temperatures below −120°C, the oxygen atoms can be replaced, in stages, by sulfur atoms, resulting in the formation of surface compounds with bandgaps of 1.45, 1.05, and 0.80 eV corresponding to a chemisorption of H_2S to a surface coverage of about 0.25, 0.5, and 1 monolayer, respectively (3). The purpose of our investigations was to find out if this replacement of the oxygen atoms by steps is specific for sulfur atoms or whether it is also possible in the case of the reaction of HBr with PbO. Another possibility in this stepped process is a successive substitution by atoms of different elements.

Experimental Techniques

The primary PbO layers used in our investigations were prepared in the following way. An amount of about 0.5g PbO was evaporated from a platinum crucible. The PbO vapor passed through a gas atmosphere consisting of water vapor and oxygen, and condensed on a Pyrex substrate, maintained at a constant temperature. A detailed description of the evaporation technique is given elsewhere (3, 4).

After evaporation the tube was evacuated and transferred to an adsorption apparatus. In this apparatus the surface area of the PbO layer was measured by the BET method (5) at 78°K using krypton. The specific area of these layers strongly depends on the temperature of the Pyrex substrate during the preparation. For example it is about 40 m^2g^{-1} at a substrate temperature of 120°C and about 60 m^2g^{-1} at a substrate temperature of 90°C. For our investigations we preferred to use PbO layers deposited at 90°C, in order to determine more accurately the changes of the surface area caused by chemisorption of gases. These layers have a typical thickness of 20 μm and consist of crystal plates (6) with dimensions of about $2 \times 0.5 \times 3.5 \cdot 10^{-3}$ μm, orientated perpendicularly to the substrate surface.

According to Dickens (7) the structure of red PbO can be described as a sandwich structure containing a plane of oxygen atoms flanked by two planes, each containing half the number of Pb atoms. The lone pairs of electrons of the lead atoms hold the sandwiches together by van der Waals forces. Therefore red PbO is expected to crystallize mainly in the form of plates parallel to the sandwich plane.

Assuming that this also occurs in our vapor-deposited PbO layers, the surface density of lead and of oxygen atoms is $1.25 \cdot 10^{15}$ cm^{-2} (8, 9).

PbO layers prepared by our evaporation technique have a porosity of 50% and a mean space between the crystal plates of 5 nm. These properties of the layer make it possible for the gas molecules to penetrate readily into the spaces throughout the entire thickness of the layer. Therefore the depth of penetration of the gas molecules is only restricted by the reactivity of the gas with the surface of the solid.

A description of the chemisorption apparatus is given elsewhere (10). The chemisorption experiments were carried out as follows. A known amount of HBr was added to the PbO layer and the change of the HBr pressure was measured as a function of the adsorption time. The water vapor liberated during the reaction was frozen out of the gas mixture by cooling part of the system to −95°C using melting acetone.

Key words: chemisorption, photoconductivity, phosphors, adsorption, compound formation.

[1] Plumbicon is a trade-mark of N. V. Philips' Gloeilampenfabrieken, Eindhoven.

An interesting point is the adsorption of HBr at temperatures below room temperature, for example at about −160°C, at which in addition to chemisorption a physical adsorption of HBr also takes place. This temperature can be kept constant during the reaction, using melting 2-methylbutane. The change in the surface area of layers treated in this way was determined. The reactivity of these layers with H_2S was also investigated.

For the optical measurements, the windows with the PbO layers were removed from the tubes, after which the total (diffuse + specular) reflection spectra, R, and total transmission spectra, T, of the layer, illuminated with normal incident light, were measured on a Beckman DK 2A spectrophotometer with a special integrating sphere accessory. From these measurements the optical absorption spectra can be determined. As a result of the H_2S adsorption the color of the PbO layer was changed. After fracturing the layer the depth of penetration of H_2S into the PbO layer was examined under the microscope.

Adsorption Results

The chemisorption of HBr on a vapor-deposited PbO layer was measured as a function of the adsorption time at different temperatures. Some typical results are given in Fig. 1. We see that the adsorption velocity strongly depends on the temperature. At room temperature the pressure of the HBr decreased from 1 Torr to about 10^{-1} Torr as a result of the adsorption.

At −160°C the HBr pressure decreased to less than 10^{-4} Torr because in addition to a fast chemisorption there was also a physical adsorption. The latter amount could be readily desorbed from the PbO layer by cooling part of the apparatus with liquid N_2. After desorption of this amount, the quantity of HBr which remains on the PbO layer was about 60% of a monolayer, independent of the adsorption time and the excess of HBr.

In this paper a monolayer adsorption means an adsorption of one gas molecule per PbO surface molecule. It is possible to chemisorb more HBr at −160°C if the layer is warmed up to room temperature after the first chemisorption, $\theta = 0.6$, and cooled down again to about −160°C. This chemisorption process can be repeated several times. The results of these processes are given in Fig. 2.

To get an impression of the value of θ_{HBr} as a function of the depth of penetration of HBr into the PbO layer, a number of PbO layers was covered with different quantities of HBr (Q_{HBr}) at −160°C. At room temperature, such a quantity of H_2S (Q_{H_2S}) was added to each of these layers so that the depth of penetration of H_2S (D_{H_2S}) into the PbO layer was larger than the

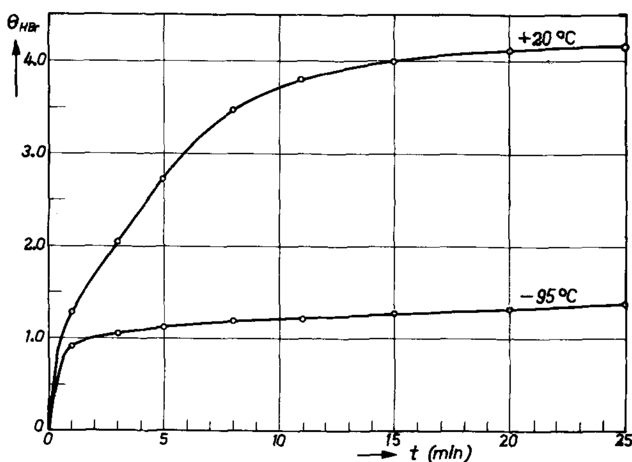

Fig. 1. Adsorption of HBr on the surface of a PbO layer at +20°C and −95°C, expressed in monolayers (θ_{HBr}), as a function of the adsorption time.

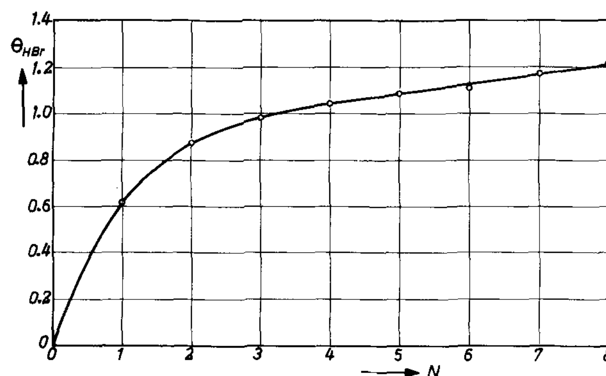

Fig. 2. Adsorption of HBr on the surface of a PbO layer at −160°C vs. the number of processes (N). Each process consists of cooling to −160°C, adsorbing HBr, and warming up the layer to room temperature.

depth of penetration of HBr (D_{HBr}). The water vapor liberated during this reaction was frozen out at −95°C with melting acetone. As a result of such a treatment, the part of the PbO layer covered with HBr and H_2S became deep red; that covered with H_2S only black; and the remaining part retained its original yellow-orange color.

After the adsorption measurements the layers were broken and the location of the boundaries of the colored parts measured under the microscope. A photograph of such a layer is given in Fig. 3.

Using these data and the known quantities of the adsorbed amounts of HBr the θ_{HBr} was calculated.

From previous experiments (3) we know that the θ_{H_2S} of a PbO layer is about 0.90. Therefore the coverage of H_2S of the part of the PbO layer covered with HBr ($\theta_{HBr}{}^{H_2S}$) can also be calculated using the formula

$$\theta_{HBr}{}^{H_2S} = \frac{Q_{H_2S} - (D_{H_2S} - D_{HBr})\theta_{H_2S}}{D_{HBr}} \qquad [1]$$

The results are given in Table I. We see that the θ_{HBr} is about 0.60 and the $\theta_{HBr}{}^{H_2S}$ about 0.40.

To gain insight into the significance of a $\theta_{HBr} = 0.60$, the influence of HBr adsorption on the surface area was determined. Therefore, the surface area of a number of PbO layers was measured, they were then treated at −160°C with an amount of HBr smaller than 60% of a monolayer, after which the surface area was again determined. The results are given in Fig. 4.

We see, that the surface area strongly diminishes as a result of the HBr adsorption. Assuming that the part of the layer on which HBr is adsorbed, is covered with a $\theta_{HBr} = 0.60$, and that the uncovered part of the layer

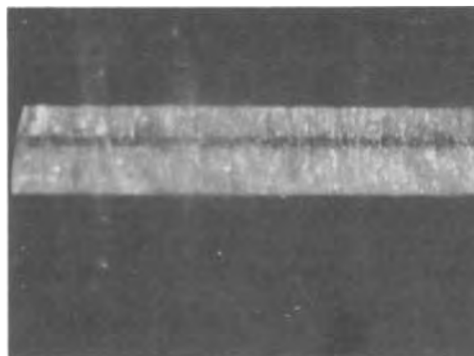

Fig. 3. Photograph of a PbO layer in which the small light-colored part is treated with 0.60 of a monolayer of HBr and 0.40 of a monolayer of H_2S, the dark-colored part being treated with a monolayer of H_2S only and the other light-colored part being the uncovered part of the layer.

4	53.4	62.7	54.0	1.11
5	45.5	65.8	54.5	1.10
6	38.0	72.4	57.0	1.06
7	30.1	78.5	57.5	1.05
8	22.1	84.0	56.5	1.06
9	12.1	90.8	54.5	1.10

does not undergo a change in surface area, we can calculate the change in surface area of the PbO layer on which HBr is adsorbed. In Table II the results of these calculations are given for a number of PbO layers. In the fourth column of this table the ratio is given between the surface area of the covered part of the layer and that of the same part of the layer before HBr has been adsorbed (A'/A). We see that as a result of the HBr adsorption the surface area of the covered part of the layer decreases to 55-60% of its original value. This decrease of the surface area occurs during chemisorption and not during the warming up of the tube to room temperature. This was determined by cooling some tubes to 78°K, directly after the chemisorption of HBr at −160°C, at which temperature the surface area was measured once again. This indicates that at −160°C, there is a surface recrystallization, made possible by the energy which is liberated as a result of the chemisorption of HBr. A calculation of the coverage of HBr based on the newly formed surface gives a θ'_{HBr} of about one monolayer at all times, assuming the same density of Pb atoms per square centimeter. This means that half of the oxygen atoms of the PbO surface molecules are replaced by twice the number of bromine atoms.

To get an impression of the adsorption of H_2S on an HBr-covered PbO layer as a function of the depth of penetration, a number of PbO layers were covered at

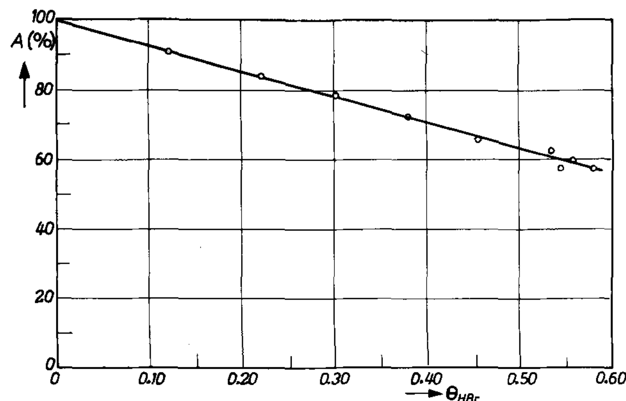

Fig. 4. Total surface area of PbO layers after the adsorption of HBr at −160°C, expressed in percentage of the total original surface area, *vs.* the amount of adsorbed HBr in monolayers.

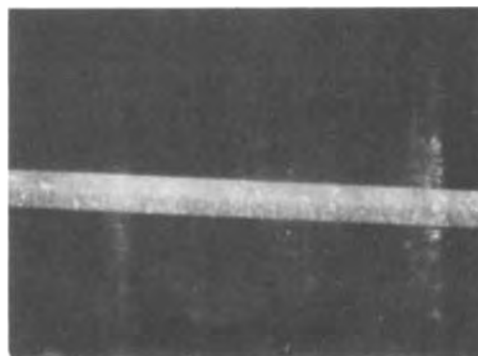

Fig. 5. Photograph of a PbO layer in which the dark-colored part is treated with HBr to a coverage of 0.60 and with H_2S to a coverage of 0.40. The rest of the layer is only treated with HBr to a coverage of 0.60.

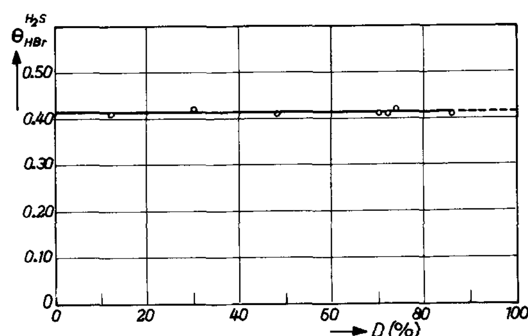

Fig. 6. H_2S adsorption at +20°C on a PbO layer previously treated with HBr at −160°C, *vs.* the depth of penetration *(D)* of H_2S into the PbO layer, expressed in percentages.

−160°C with an amount of HBr equivalent to about 60% of a monolayer. Different quantities of H_2S were added to these layers at room temperature. Determination of the surface area showed that the decrease of the area caused by the adsorption of H_2S was less than 10%. After fracturing the layers the depth of penetration of the H_2S in each of these layers was determined under a microscope. The determination of the boundary was possible because of the deep red color of the part of the PbO layer covered with HBr and H_2S, while the rest of the layer retained its yellow color. An example of such a layer is given in Fig. 5 The results of these measurements are given in Table III and Fig. 6. For each of the layers $\theta_{HBr}{}^{H_2S} = 0.40$ is found. This value of 0.40 is based on the original surface area. Taking into account the 40% decrease of the surface area caused by the chemisorption of HBr and the 10% decrease caused by the chemisorption of H_2S on such a layer, the coverage of H_2S, $\theta'_{HBr}{}^{H_2S}$, is then equal to 0.75.

This means that not only the oxygen of the surface layer of Pb_2OBr_2 is replaced by the sulfur of the H_2S but also a part of the oxygen of the second layer, because no desorption of a bromine compound was detected as a result of H_2S adsorption. When all the oxygen of the first monolayer is replaced by sulfur atoms

Table III. Depth of penetration of H_2S on HBr-covered PbO layer

Sample No.	Amount of HBr adsorbed at −160°C in % of a monolayer	Amount of H_2S adsorbed at +20°C in % of a monolayer	Depth of penetration of H_2S (%)	$\theta_{HBr}{}^{H_2S}$
1	53.2	4.8	12	0.41
2	55.9	10.6	25	0.42
3	50.6	19.6	48	0.41
4	52.3	28.4	70	0.41
5	54.3	29.5	72	0.41
6	52.1	31.0	74	0.42
7	54.0	35.6	86	0.41

then about a quarter of the oxygen of the second layer must also be replaced by sulfur atoms. This suggests the formation of two different sulfur compounds. More information about this can be obtained with the aid of optical measurements.

Optical Results

A property of the PbO layers covered successively with HBr at $-160°C$ and H_2S at $+20°C$ that interests us particularly is the wavelength at which the optical absorption of these layers becomes small and ultimately drops to zero.

In determining the absorption spectra one has to bear in mind that these vapor-deposited PbO layers scatter the incident light rather strongly. The form of the crystallites makes it impossible to handle the scattering rigorously. Therefore one has to fall back on the phenomenological reflection theory of Kubelka and Munk (11) on the basis of which Matzinger (12) shows, that the optical absorption (O) in the bandgap region can be approximated by

$$1 - R - T = O = \frac{\alpha D \left(1 + \frac{1}{2}\alpha D + \sigma D\right)}{1 + \left[\alpha + \sigma + \frac{1}{3}\alpha D(\alpha + 2\sigma)\right] D} \quad [2]$$

where D is the layer thickness, α is the absorption coefficient, and σ is the Kubelka-Munk scattering coefficient. Expression [2] is valid for $\alpha D(\alpha D + 2\sigma D)$ not exceeding one.

The product σD can be estimated from the reflection spectrum. For our layers this is generally somewhat smaller than one. Therefore, in the region of the bandgap ($\alpha D << 1$) the term $\alpha D(\alpha D + 2\sigma D)$ is also $<< 1$. Hence expression [2] reduces to simply

$$O = \alpha D \frac{1 + \sigma D}{1 + \sigma D} = \alpha D \quad [3]$$

Our measurements showed that $O^{1/2}$ is linearly dependent on photon energy (Fig. 9), as is characteristic for indirect energy gap media. For very small values of O, deviations from the straight line show up. This absorption tail is always found in our vapor-deposited PbO layers and is probably caused by impurities. After subtraction of this absorption tail the energy bandgap is easily found.

Figure 7 shows the total reflection spectra, R, and the total transmission spectra, T, of a layer covered with 72% HBr at $-160°C$ and one covered with 56% HBr at $-160°C$ and 25% H_2S at $+20°C$, while in Fig. 8 the superimposed spectra of these layers are shown.

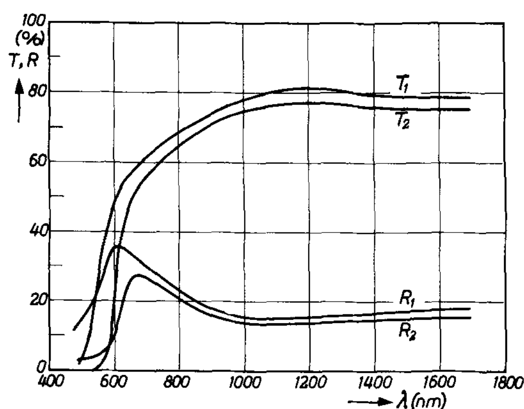

Fig. 7. Total reflection spectra (R) and total transmission spectra (T) as a function of the wavelength of the incident light, denoted by 1 for a PbO layer treated with HBr (sample 1 of Table IV) and by 2 for a PbO layer treated with HBr and H_2S (sample 4 of Table IV).

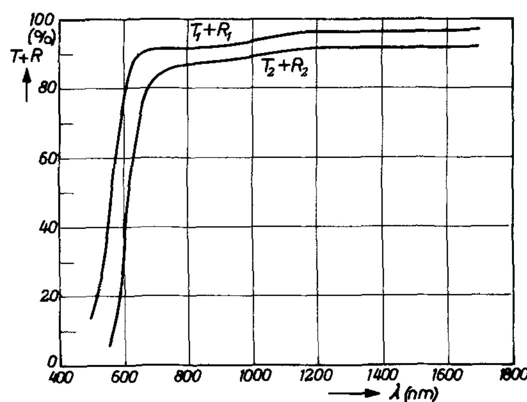

Fig. 8. Superposition of the total transmission and total reflection spectra ($T+R$) as a function of the wavelength of the incident light, 1 being used to denote sample 1 of Table IV, and 2 to denote sample 4 of Table IV.

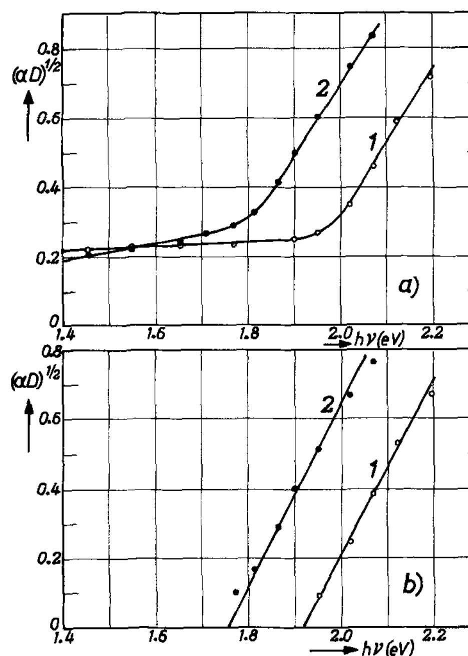

Fig. 9. (a) The absorption spectra of sample 1 (1) and sample 4 (2) of Table IV, vs $h\nu$. (b) The above absorption spectra after subtraction of an absorption tail found in our vapor-deposited PbO layers and probably caused by impurities.

The square root of the absorption curves of these layers, showing the bandgap energy, are given in Fig. 9. In Table IV the results of these measurements are given for a number of PbO layers treated in this way. Special care was taken to ensure that the depth of penetration of H_2S was less than that of HBr. For all the layers we found a value of the bandgap of about 1.75 eV. For some of the layers a bandgap of 1.55 eV was also found, but the intensity of the second branch was small.

Table IV. Bandgap energy of PbO layer

Sample No.	Amount of HBr adsorbed at $-160°C$ in % of a monolayer	Amount of H_2S adsorbed at $+20°C$ in % of a monolayer	E_{e_1} (eV)	E_{e_2} (eV)	E_{e_3} (eV)
1	72.2	—	1.92		
2	55.1	19.8		1.79	
3	51.0	20.0		1.77	
4	55.9	24.5		1.76	
5	55.8	25.5		1.77	1.56
6	54.3	29.5		1.74	
7	58.1	32.0		1.77	1.55
8	57.5	33.5		1.75	1.53

According to Matzinger (12) a good approximation of the value of the bandgap energy is also given by the wavelength at which the reflection curve shows its maximum value. In Fig. 7 we see that the values thus derived are 1.98 and 1.81 eV for a PbO layer covered with HBr and one covered with HBr and H_2S, respectively.

Conclusions

From the adsorption measurements of HBr on a PbO layer we may conclude that, at room temperature, the chemisorption of HBr is not restricted to the PbO of the surface layer but that HBr also reacts with the underlying PbO molecules. The reaction of the HBr with the bulk PbO molecules of the crystal plates can be suppressed by lowering the adsorption temperature. At $-160°C$ only a surface reaction is measured, which results in a θ_{HBr} of 0.60.

As a result of this chemisorption the surface area of the layer is decreased. This reduction of the surface area can be understood when we remember that a PbO layer with a thickness of 20 μm is prepared in less than 5 min. Therefore besides large crystal plates a lot of plates with very small dimensions are also formed. By the energy liberated during chemisorption of HBr the large crystallites can grow at the cost of the small crystallites resulting in a decrease of the surface area of the layer.

Assuming that the surface area of the uncovered part of the layer does not alter, we see that the surface area of the part of the layer covered with a $\theta_{HBr} = 0.60$ diminishes to 60% of the original surface area. This suggests a surface recrystallization caused by the HBr adsorption. Assuming the same density of Pb atoms per square centimeter, we see a $\theta'_{HBr} = 1.0$ based on the newly formed surface. This means that half of the oxygen atoms of the surface molecules have been replaced by bromine atoms. In this process two bromine atoms are necessary to replace one oxygen surface atom. This is indicative of the formation of a new surface molecule having the formula of Pb_2OBr_2. A partial replacement of oxygen atoms of the PbO surface molecules by atoms of another element has already been found in the case of H_2S adsorption on a PbO layer, at a temperature of about $-120°C$ (3).

It proves possible to replace the oxygen atom of the surface molecule Pb_2OBr_2 not only by bromine atoms but also by a sulfur atom. The adsorption of H_2S at $+20°C$ results in a coverage of about 0.40 of a monolayer, calculated at the value of the original surface area, or in a coverage of H_2S of 0.75 calculated at the value of the surface area measured after the HBr and H_2S chemisorption.

This means that more oxygen atoms are replaced by sulfur atoms than are present in the Pb_2OBr_2 surface layer, so that a proportion of the oxygen atoms of the second layer must also be replaced by sulfur atoms.

For the replacement of the oxygen atoms of the first layer by sulfur atoms only an amount of H_2S of 0.50 of a monolayer is necessary. The rest of the H_2S will replace a quarter of the oxygen of the second layer. This suggests the formation of more than one sulfur compound.

However, from optical measurements we must conclude that only one new compound is formed because only one bandgap is found which has an energy of 1.75 eV. No bandgap energy of about 1.45 eV is measured which is expected if in the second layer the compound Pb_4O_3S was formed.

Therefore our hypothesis is that the first and the second monolayer interact to form a new surface layer consisting of a complex compound of lead, oxygen, sulfur, and bromine, which has the formula of $Pb_8O_3S_3Br_4$, instead of the formation of the compound Pb_2SBr_2 in the first layer and of the compound Pb_4O_3S in the second layer.

We hope that the existing techniques available for the study of surfaces will make it possible to confirm our conclusion concerning the structure of this surface compound.

Acknowledgments

We are indebted to Mr. B. H. Matzinger for many valuable discussions concerning the optical part of this work and to Mr. C. G. A. Kregting for his assistance with our experiments.

Effects of Scale Porosity, Second-Phase Oxides, and Doping in the High-Temperature Oxidation of Cobalt and Dilute Cobalt-Chromium Alloys

Fred R. Billman

Alcoa Research Laboratories, Aluminum Company of America, Cleveland, Ohio 44105

ABSTRACT

The oxidation mechanisms of high-purity cobalt and dilute Co-Cr alloys have been investigated over a 950°-1350°C temperature range in oxygen atmospheres of 10-760 Torr. The 99.999% cobalt exhibited parabolic oxidation behavior for weight gains of up to 30 mg oxygen/cm^2 rectangular specimen surface. Parabolic kinetics were interrupted when fissures developed in the oxide scale as a result of mechanical stresses at the metal/scale interface or through anisotropic decomposition along CoO grain boundaries. Molecular oxygen then short-circuited to the porous inner scaling layer in accelerated attack of fresh Co surfaces. Diffusion of Co^{2+} through the CoO scale is considered to be the primary rate determining process during periods of steady-state oxidation. The effect of porosity at the metal/scale interface prior to perforation of the outer scaling layer is slight, but is believed to result in a small reduction of the oxidation rate due to a reduction in the CoO/Co contact surface through which cations enter the oxide. Co alloys containing 0.5, 3, 7, and 10 w/o (weight per cent) Cr also obey parabolic kinetics during formation of thinner scaling layers. Porosity and localized loss of scale adherence are aggravated by the presence of $CoCr_2O_4$ and Cr_2O_3 particles in the inner scaling layer to the extent that scale rupture mechanisms quickly obscure parabolic kinetics for chromium contents greater than 3 w/o at temperatures of 1150°C and above in 100 Torr oxygen. Under conditions where initial periods of steady-state parabolic oxidation were discernible on thermobalance curves, maximum reaction kinetics are associated with 1-2 w/o Cr additions (which approach the Cr^{3+} solubility limit in CoO) as rationalized by Wagner's semiconductor valence theories.

Previous oxidation studies of high-purity cobalt have been reported in the literature (1-8). Linear kinetics are observed during the growth of very thin oxide films, with a subsequent transition to parabolic growth kinetics for thicker oxide layers. At elevated temperatures CoO is a metal deficient, p-type semiconductor (9, 10) and the electrical conductivity of CoO at near atmospheric pressures, where singly charged cation vacancies supposedly predominate (9), is proportional to $P_{O_2}{}^{1/4}$ (9, 10). The self-diffusion of Co in CoO is reported to be proportional to $P_{O_2}{}^{1/n}$, where n varies from values of ~ 4 at 10^{-3} atm to ~ 3 at 1 atm oxygen over a 950°-1350°C temperature range (11). The parabolic rate constant for the high-temperature oxidation of cobalt has also been reported to obey a $P_{O_2}{}^{1/n}$ dependence where $4 > n > 3$ (1-4). Parabolic oxidation of cobalt is rationalized according to the Wagner theory (12). Cobalt cations diffuse from the metal/oxide interface via cation vacancies in the oxide lattice to combine with oxygen at the oxide/gas interface and cation diffusion through the oxide is considered to be the rate-controlling process.

Incremental additions of chromium have been reported to increase the Co-Cr alloy oxidation rate to a maximum value at approximately 10 w/o (weight per cent) chromium (6, 7). Further chromium additions decrease the alloy oxidation rate to a minimum value at approximately 20-30 w/o chromium, with increasing chromium concentrations above 30 w/o then increasing the oxidation rate up to that of unalloyed chromium (7, 13-16).

The rate-controlling process for oxidation of the dilute Co-Cr alloys (Cr $<$ 10 w/o), like that for pure cobalt, is held to be diffusion of cations via cation vacancies in the CoO scale. Continuous increases in alloy oxidation rate with increasing chromium contents of up to 10 w/o have been attributed to Cr^{3+} doping of the CoO scale according to the semiconductor valence approach proposed by Wagner (12). If the effect of doping is to be significant in the over-all oxidation rate of a dilute alloy, the solubility of the dopant in the matrix oxide must be greater than the native-defect concentration of that oxide at the ambient oxygen pressure.

The native-defect concentration of CoO is thought to be approximately 1% at 1200°C in oxygen at 1 atm (9). Although no data for Cr solubility in CoO are available, analogies with respect to a measured solubility of only 1-2% Cr in NiO (17) have been discussed (13) by Kofstad and Hed who argued that semiconductor valence effects would not be significant in explaining the differences in oxidation behavior between pure cobalt and the Co-10 w/o Cr alloy. They postulated that anisotropic CoO decomposition and rapid transport of gaseous oxygen across pores in the oxide serve to partially short-circuit the diffusion of cations through the scale.

Metallographic examinations of cross sections of partially oxidized dilute Co-Cr alloy specimens have revealed a duplex scale formation similar to that observed for dilute Ni-Cr alloys (18). A dense outer layer of CoO is separated from the metal by a porous inner layer of CoO containing dispersed particles of Cr_2O_3 and the spinel $CoCr_2O_4$. Internal oxide particles of Cr_2O_3 are also seen in a chromium-depleted region of the alloy, just beneath the metal/scale interface (7, 13). Kofstad and Hed have proposed that the presence of a sufficient volume fraction of dispersed spinel particles (Cr_2O_3 particles were not observed in the inner CoO layer in their investigation) can effectively reduce the cross-sectional area of the inner CoO scale available for cation diffusion, because diffusion of Co is several orders of magnitude slower in $CoCr_2O_4$ than in CoO (19, 20). This reduction in the diffusion path cross section would therefore explain the decreased

oxidation rate of a 10 w/o chromium alloy relative to an alloy of lesser chromium content.

In order to clarify some of these features, further study of the oxidation of pure cobalt and dilute cobalt-chromium alloys containing up to 7 w/o chromium was considered necessary. Comparison of results of these additional studies with the reported behavior of the Co-10 w/o Cr alloy permits a more thorough analysis of the processes by which the high-temperature oxidation of dilute Co-Cr alloys is enhanced relative to that of pure cobalt. Similar interpretations are thought applicable to dilute Ni-Cr alloys and other related systems in which the solubility of the aliovalent solute element in the oxide scale is small.

Experimental Procedure

Rectangular specimens of approximately 10 cm^2 surface area were cut from cold-rolled sheets of *99.999%* cobalt and cobalt-chromium alloys prepared at Battelle Memorial Institute by vacuum-melting techniques. Chemical analyses of the material components are given in Table I. Specimens were polished through 600 metallographic paper, 0.5μ diamond, ultrasonically cleaned, washed in water, and rinsed in trichloroethylene prior to each test.

The experimental apparatus has been described in detail in a previous report (13). As in previous studies reported by Kofstad and Hed (13), continuous kinetic weight measurements commenced with 1-2 min exposure of the specimen to furnace temperature, and after equilibration of the system to the desired oxygen pressure. Specimens did therefore experience an initial 1-2 min unrecorded oxidation interval during which specimen temperature and oxygen pressure were increasing to the regulated conditions at which kinetic measurements were taken. At completion of a test, specimens were lifted out of the hot zone, oxygen pressure was increased to 1 atm, and specimens were removed from the apparatus. Oxide scales on alloys containing less than 3 w/o chromium were comparatively adherent to the metal even after cooling in still air. However, the 3 and 7 w/o chromium alloy scales often separated from the remaining metal when cooled slowly from temperatures above 1050°C, necessitating quenching the oxidized coupon in a molten Pb-Bi alloy immediately after removal from the reaction chamber.

Oxidized specimens were mounted in epoxy and polished through 600 metallographic paper, 0.5μ diamond, and Linde B alumina. A 1-5-min etch in 80 parts lactic acid, 5 parts HCl, 10 parts hydrogen peroxide, and 10 parts HNO_3 was utilized to accent the oxidized cross sections.

Results

Pure cobalt.—Figure 1 is a typical (weight-gain)^2 *vs.* time plot for the oxidation of 99.999% pure cobalt in 100 Torr oxygen over the 950°-1350°C temperature range (16).[1] Parabolic behavior is observed even within the first few minutes of exposure. Figure 2 summarizes the oxygen pressure dependence of the

parabolic rate constant over a P_{O_2} range of 10-760 Torr (16).[1] Values of the parabolic rate constant at 1250°C have been inferred from the observed temperature dependence. The negative deviation in slope at 950°C in 760 Torr oxygen is attributed to the formation of a surface layer of Co_3O_4. At all other temperatures and pressures investigated, CoO is the only stable oxide formed on pure cobalt. Within the accuracy of the data (k_p values were generally reproducible within $\pm 5\%$) a $k_p \propto P_{O_2}{}^{1/n}$ dependence was noted with $n = 3.3$.

Figure 3 is an Arrhenius plot of the parabolic rate constant for the oxidation of pure cobalt (16). A least squares analysis results in values of 36.0, 37.8, and 38.7 kcal/mole for the activation energy for oxidation in 10, 100, and 760 Torr oxygen, respectively.

Metallographic examination of cross sections through the oxidized cobalt specimens invariably revealed a region of porosity at the metal/oxide interface as shown in Fig. 4 for an oxidizing temperature of 1150°C. Co_3O_4, which precipitates during cooling of the oxidized specimen to room temperature, outlines grain boundaries in the outer CoO scale.

Previous investigators (2, 4) have reported the presence of porous inner layers on oxidized specimens of cobalt, which heretofore have been largely attributed to impurity effects or polishing artifacts. That such porosity does not result entirely from "metallographic pull-out" of the fine-grained oxide at the metal/oxide interface is verified by Fig. 5a and b. In this instance a crack developed in the external CoO oxide after 4 hr

exposure in 100 Torr O_2 at 1150°C (as evidenced by the pronounced increase in the weight-gain data shown in Fig. 5a) and molecular oxygen penetrated the semicontinuous network of pores at the metal/oxide interface. Formation of a new and compact CoO layer occurred subsequently on the fresh metal surface. The position of the metal/oxide interface at the time of the scale rupture is delineated by a few remaining pores as shown in Fig. 5b.

Dilute cobalt-chromium alloys.—Figure 6 shows parabolic plots of the gravimetric data for the oxidation in 100 Torr oxygen of cobalt containing 0.5, 3, and 7 w/o chromium. The over-all oxidation behavior might be described as "approximately parabolic," although oscillations in the parabolic kinetics are common as the reaction proceeds. These oscillations become slightly more pronounced at higher temperatures for a given composition and oxygen pressure as shown in Fig. 7a-c. Scale spallation upon cooling an oxidized specimen of a given alloy content was much more pronounced after oxidation at the higher temperatures. Scales for alloys containing $\geq 3\%$ chromium which cooled in still air generated cracks evenly around the perimeters of the rectangular specimens and nearly perfect sheets of oxide cleanly separated from the specimen faces.

The data from Fig. 7a-c in typical parabolic plots as shown in Fig. 8a-c reveal that the breaks in the kinetics occur at similar weight gain intervals (similar increments of scale thickness) at 1150° and 1350°C. Reproducibility of these oscillations was demonstrated for Co-10% Cr alloys in the previous report (13).

Irregularities in the oxidation rate can be correlated to the chromium content of a Co-Cr alloy. As demonstrated in Fig. 9, the scale thickness at which interruptions in the parabolic behavior occur decreases with increasing chromium contents. Oxidation of Co-Cr alloys with chromium concentrations of 3 w/o or greater, at temperatures of about 1150°C, produces interrupted kinetics within the first 10 mg of O_2 uptake/cm^2 specimen surface area. It therefore becomes very difficult to determine the initial parabolic oxidation rate, exclusive of any scale rupture effects, at the higher temperature.

Mechanisms by which oscillations in the parabolic behavior might occur during alloy oxidation may be rationalized through metallographic examination of the oxidized specimens. Figure 10a is a parabolic plot of the weight gain data for a Co-3% Cr alloy oxidized at 950°C in 760 Torr oxygen. Two distinct breaks in the parabolic kinetics are noted. At this temperature and pressure both Co_3O_4 and CoO are stable oxide phases, and the oxygen-rich Co_3O_4 phase will exist only in direct contact with oxygen at or near 1 atm pressure. In Fig. 10b, which is a photomicrograph of this same specimen, a white Co_3O_4 layer is visible at the gas/oxide interface directly above an adherent CoO layer. A region of porosity midway through the inner oxide is also outlined with Co_3O_4. The presence of continuous Co_3O_4 oxide layers, as distinguished from cooling precipitates, implies that the pores were in direct contact with the furnace environment after the interruption in kinetics. The absence of Co_3O_4 around

the vast majority of irregularly shaped pores in the outer CoO layer also verifies that molecular oxygen at ambient pressure is not easily transmitted through this layer. There was some evidence of molecular transport of oxygen from the furnace atmosphere to the porous inner layer via a few isolated grain boundaries or microcracks in the CoO oxide as shown in Fig. 10c.

Figure 11a is a parabolic plot of the weight gain data for the oxidation of a Co-7% alloy at 1150°C in 760 Torr oxygen and Fig. 11b is a photomicrograph of the same specimen. There is an apparent correlation between the number of line segments in the parabolic kinetics and the number of distinguishable layers in the porous inner oxide. Delineation of the separate inner layers results from the pronounced accumulation of spinel particles at the metal/scale interface until a loss of scale adherence occurs. In these experimental conditions, Co_3O_4 is not a stable oxide and only cooling precipitates of this more oxygen-enriched phase are seen. Frequently, the number of striations in the porous inner oxide is greater than the number of distinguishable portions of the weight gain *vs.* time curves, especially at specimen corners. Localized losses of scale adhesion do not significantly affect the over-all kinetics unless scale lifting is propagated across an appreciable portion of the specimen surface. Extensive metallographic examination of many different cross-sectional areas of a single oxidized coupon would therefore be necessary before a

definite correlation between a particular curve segment and a given inner oxide layer could be made.

Figure 12 summarizes the effect of dilute chromium additions on the parabolic oxidation rate constant over a 950°-1350°C temperature range in 100 Torr oxygen. Data points are intended to represent the initial parabolic rate constants as determined graphically prior to the onset of any distinguishable scale rupture effects.

Discussion

Pure cobalt.—These results are in very good agreement with the empirical relation determined by Snide, Myers, and Saxer (1) for the oxidation of pure cobalt cylinders at 950°-1250°C in oxygen atmospheres of 15-727 Torr. The pressure dependence obtained in this study was also reported by Mrowec, Walec, and Werber (2) for the oxidation of pure cobalt at 1000°C. Carter and Richardson obtained a $P_{O_2}{}^{0.29}$ dependence for pure cobalt oxidation at 1150°C (3) and $P_{O_2}{}^{0.28}$, $P_{O_2}{}^{0.30}$, and $P_{O_2}{}^{0.35}$ dependences for the diffusion of Co^{60} in CoO at 1000°, 1150°, and 1350°C, respectively (11).

The tracer diffusion data determined by Carter and Richardson (11) were corrected for the correlation factor (f) according to the equation $D_{Co^*} = f\ D_{Co}$ where $f = 0.78$ as suggested by Kofstad (10). Wagner's parabolic oxidation theory was then used to compare the calculated and experimental values of the parabolic rate constants for the oxidation of pure cobalt at 1000°, 1150°, and 1350°C. These data are given in Table II. Agreement between the calculated and experimental rate constants is similar with that of previous investigations at 1000°C (2, 3) and at 1150°C (1, 3) if the earlier data are also corrected with the corre-

lation factor. Negative deviations from the calculated k_p values were noted in all four investigations, the magnitude of the deviation being slightly greater in this study. Note that the deviation increases with increasing oxygen pressure (*i.e.*, increasing oxidation rate) at temperatures of 1000° and 1150°C, but is nearly independent of oxygen pressure at 1350°C.

Results of this investigation do not correlate the presence of a porous inner CoO layer on pure cobalt with an enhancement of the parabolic oxidation, in the exposure intervals prior to the development of cracks or fissures in the outer CoO scale. In fact, the slightly larger negative deviations of the experimental from the calculated k_p values [these data *vs.* results of other investigations (1, 2) in which no porosity was observed] suggest that porosity decreases the oxidation rate slightly by reducing the effective diffusion cross section of the scale, or by a reduction in the metal/scale contact surface through which cations leave the metal substrate. Further evidence for this interpretation is provided by a comparison of the density of oxide scales formed at 1150° and 1350°C.

Cross sections of several specimens oxidized at 1150° and 1350°C were examined metallographically. Some twenty separate scale thickness measurements were taken around the perimeter of each oxidized coupon, an average scale thickness was calculated, and the volume of oxide for each specimen was estimated using the original surface area of the sample and a geometrical correction for the additional volume of oxide formed at specimen corners. Relative oxide density approximations (average measured volume/measured weight-gain) revealed that after oxidizing pure cobalt at 1350°C in 100 Torr oxygen, the scale was approximately 20% less dense than when oxidized at 1150°C in 100 Torr oxygen. Original specimen size was identical in all cases, specimens had been exposed for approximately equal weight gains, and the external scale surfaces were found to be quite smooth and free of facets so that the measured scale thickness was very nearly equal around the entire perimeter of each oxidized coupon.

Although these density determinations are not sufficiently precise to offer conclusive proof that scale porosity increases as the reaction temperature increases, this is a distinct possibility which is intuitively satisfactory. The accumulation of vacancies at the metal/scale interface would be expected to increase (and the ability of the scale to undergo plastic deformation should decrease) as the flux of cation vacancies to the interface increases. However, the plasticity of the oxide might be expected to increase with increasing temperature and thereby counteract the effects of a more rapidly receding metal surface. This point has not been demonstrated in oxidation studies, and Van Den Broek and Meijering (21) argue that the ductility of high-melting-point oxides such as NiO (and CoO) does not increase very much with rising temperature in the vicinity of 950°C. An increasing rate of oxidation may therefore result in greater scale adhesion difficulties.

One additional feature was indicative of the presence of gross porosity in the inner CoO layer; comparison of the calculated oxide densities of different specimens oxidized under the same environmental conditions (1350°F in 100 Torr oxygen) revealed that scale was up to 15% more dense if an acceleration in the weight-gain kinetics had occurred. This increased scale density after a period of accelerated attack can be explained by a scale rupture mechanism. Porosity increases at the metal/oxide interface until a crack resulting from mechanical stresses occurs in the outer CoO layer, or until anisotropic dissociation along CoO grain boundaries perforates the scale thickness. In either case, molecular oxygen is suddenly transported from the ambient atmosphere through the semicontinuous network of pores along the metal/scale interface. Oxidation of the freshly exposed Co surfaces occurs until the pores are at least partially closed and the supply of molecular oxygen from the atmosphere is terminated. Parabolic weight-gain kinetics are then restored and the cycle begins anew. There are many indications of such scale rupture effects in the literature (2, 4, 27, 21-30).

Dilute cobalt-chromium alloys.—At least three seemingly different modes of scaling behavior occur as a function of temperature, oxygen pressure, and chromium content over the 0-10 w/o Cr range. As shown in Fig. 12 the parabolic oxidation rate increases rapidly with increasing chromium concentrations up to 1-2 w/o Cr and then remains relatively constant with additional chromium concentration. This "parabolic rate plateau" is sensitive to temperature and oxygen pressure. If the oxidation reaction remains diffusion controlled, further chromium additions produce a decrease in k_p due to $CoCr_2O_4$ and/or Cr_2O_3 blocking of the Co^{2+} diffusing species. Such is the case at 950° and 1050°C at 100 Torr oxygen for chromium concentrations greater than 3 and 7 w/o, respectively. Analogous behavior has been found in the Ni-Cr system (31-33).

Local fractures or fissures in the scale and periods of accelerated attack become more frequent with increasing temperature and oxygen pressure in these dilute Co-Cr alloys due to the more rapid accumulation of mechanical stresses, porosity, and internal oxide particles at the metal/scale interface. At reaction temperatures above 1150°C in 100 Torr oxygen, alloys of greater than 3% Cr undergo these scale rupturing cycles even from the very early stages of oxidation. Positive deviations from the dashed "parabolic rate plateaus" at temperatures of 1150°C and above are thought to result from such scale rupture effects. At each temperature the plateau representing the maximum alloy oxidation rate (disregarding scale rupture effects) is very nearly equal to two times the oxidation rate of the cobalt base metal. The gross oxidation rate, which includes the combined effects of diffusion-controlled reaction and accelerated attack resulting from losses of scale adherence, increases with increasing chromium content to a maximum of approximately three times the oxidation rate of the cobalt base metal. The over-all enhancement factor of three was also found by Phalnikar *et al.* (7). The position of the maximum absolute oxidation rate as a function of chromium content is related to the temperature, the environment, degree of cold work, specimen geometry, and the proximity of the oxide composition to the equilibrium state as has also been found in the dilute Ni-Cr system (23).

In Fig. 8a-c a limited number of data points representing approximately equal increments of scale thickness have been denoted by a "+" symbol. It is significant to note that a straight line might reasonably fit these points and would, in fact, describe the gross oxidation kinetics; but, any mechanistic interpretation of a single rate constant calculated from this limited amount of data would be very misleading. Similar results are obtained if weight measurements are taken at equal time increments. The use of sensitive, continuous weight-gain measuring devices therefore seems imperative. Recent experimental techniques developed by Bruce and Hancock (28) indicate that scale rupture effects may be operative even when thermobalance charts show a smooth parabolic curve.

Oscillations in the weight-gain kinetics have been reported by Phalnikar, Evans, and Baldwin (7) for Co-Cr alloy oxidation, by Whittle and Wood (24) for Fe-Cr alloy oxidation, by Ali and Wood (27) for the oxidation of cold-worked Cu, Ni, and Fe, and by Van Den Broek and Meijering (21) for the oxidation of nickel and Ni-Cr alloys.

As discussed by Wood, Hodgkiess, and Whittle, (23) second-phase particles and Cr^{3+} ions in the host oxide

lattice affect the plasticity, strength, and adhesion of the scale and thereby tend to promote cracking, porosity, and a loss of scale adherence to the receding metal surface. Van Den Broek and Meijering (2) reported oscillations in the oxidation kinetics of dilute Ni-Cr alloys in which the wavelength of the oscillation always increased with increasing oxidation time. The increase in the oscillation period was attributed to the increasing relaxation possibilities when the absolute oxidation rate decreases. Although semiconductor valence effects in the CoO matrix do not solely determine the absolute alloy oxidation rate (accelerated attack resulting from loss of scale adherence dominates the over-all scaling rate for long-term exposures for alloys of greater than 3%Cr), they cannot be entirely discounted in rationalizing the sharp increases in the steady-state alloy oxidation rate with very small chromium additions.

Metallographic examination of the morphologies of the oxide scales on the 0.5-7 w/o chromium alloys indicated duplex scale formation of the same nature as those described in detail for the Co-10%Cr alloy. Spinel particles were not visible in the oxide scales on the 0.5%Cr alloy, except in a very narrow layer immediately at the metal/scale interface, whereas spinel particles were normally seen throughout the inner oxide layer for alloys of higher chromium content. This suggests a Cr solubility limit between 0.5 and 3% in CoO, over the 950°-1350°C temperature range. Alloys of this concentration fall within the zone of rapid, steady-state parabolic oxidation over exposure intervals equal to the periods of diffusion-controlled oxidation observed for pure cobalt.

The alloy oxidation enhancement factor (k_p alloy/k_p cobalt) of two which was nearly constant for alloys of 3-10%Cr, where initial periods of steady-state parabolic oxidation were discernible, is probably the result of combined doping effects in the CoO lattice of Cr^{3+} and other impurity ions (such as Si, Mn, Fe, etc.) in the 99.90% cobalt base material.

Summary and Conclusions

The high-temperature oxidation of pure cobalt follows parabolic weight-gain kinetics until fissures in the oxide scale develop from mechanical stresses at the metal/scale interface and/or anisotropic decomposition along CoO grain boundaries after extended reaction times (*i.e.*, after a weight gain of approximately 30 mg oxygen/cm^2 specimen surface under the conditions of this investigation). Molecular oxygen then flows through the porous inner scaling layer, formed by vacancy coalescence and loss of adhesion at the metal/scale interface, to attack fresh Co surfaces. The effect of porosity at the metal/scale interface prior to scale perforation is slight; but is believed to result in a small reduction in the oxidation rate due to a reduction in the CoO/Co contact surface through which cations enter the oxide. Diffusion of Co cations through the CoO scale is considered to be the primary rate determining process during periods of steady-state oxidation.

Oxidation of dilute Co-Cr alloys in the 950°-1350°C temperature range, like that of pure Co, is controlled primarily by the diffusion of Co^{2+} through the outer CoO scale as long as parabolic kinetics prevail. Porosity and localized loss of scale adherence are aggravated by the presence of $CoCr_2O_4$ and Cr_2O_3 particles in the inner scaling layer. As long as the outer CoO remains impervious to gaseous oxygen, porosity and the Cr_2O_3 and spinel oxide particles act as barriers to the transport of the Co cations. The presence of small amounts of trivalent cations in the CoO lattice (Cr^{3+} solubility ~ 1-2 w/o in CoO) does produce a factor of two increase in the parabolic oxidation of cobalt. These semiconductor valence effects become of lesser significance for Co-Cr alloys whose chromium content falls between 3 and 10 w/o, due to accelerated attack of the metal substrate following rupture of the outer CoO scale and gaseous transport of oxygen through the porous inner layer.

As stated by Bruckman (22), the mechanism of scale growth of metals and alloys can be explained by Wagner oxidation theory provided that additional processes resulting from geometrical alterations of the metal/scale system are taken into account. In many instances these features are indistinguishable. The formation of blisters and microcracks in the oxide are not necessarily reflected in kinetic curves because of their very localized nature. Cracking which occurs so reproducibly and with such strong influence on thermobalance curves as found in this study affects extensive areas of the specimen surface. Vibrational frequency techniques for measuring oxidation rates (28) are reportedly much more sensitive to the formation of microcracks. In cases where duplex scales are formed, development of more sophisticated methods for separating mechanical effects from diffusion processes is necessary before more meaningful quantitative analyses of alloy oxidation mechanisms may be formulated.

Effect of Cold Work on the Oxidation of Nickel at High Temperature

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR9

ABSTRACT

The oxidation of cold-worked and annealed pure Ni in 1 atm O_2 was investigated from 700° to 1270°C in continuous weighing experiments for periods from 1 min to 20 hr and the oxidized specimens examined by diffraction, electron-optical techniques, and metallographic cross sections. Cold-worked Ni was found to oxidize faster than annealed Ni and form finer-grained oxide. Plots of the apparent parabolic rate constant, Kp, for cold-worked Ni show an initial high value that decreases rapidly as the oxide coarsens with time. For annealed Ni, Kp is lower, grain size larger, and both change little with time. Accordingly, a range of Kp values is obtained at each temperature and, on an Arrhenius plot of Ni oxidation, there is a corresponding variation in apparent activation energy, E_A. These results can be plausibly interpreted on the basis of oxide grain boundaries acting as easy diffusion paths for Ni through the NiO layer: for fine-grained oxide, Kp is higher and E_A lower. The oxide is thinnest (and the derived E_A highest) on Ni grains which form a single crystal overgrowth. A break in the Arrhenius plot around 1000°C is the result of transport below 1000° being largely by leakage paths while at higher temperatures volume transport is more important. The estimated activation energy for growth of the oxide layer is 54 ± 2 kcal/mol for transport by lattice diffusion and appreciably less for transport by grain boundary diffusion.

In previous studies of the oxidation of Fe(1, 2) it had been found that cold-worked Fe oxidized considerably faster than annealed Fe. The explanation proposed was that cold work suppressed the formation of diffusion cavities at the Fe_3O_4-Fe interface (cavities which otherwise would block cation transfer) and, in addition, that cation diffusion through Fe_3O_4 was faster through Fe_3O_4 formed on cold-worked Fe. At temperatures above 600°C, *i.e.*, where a layer of FeO developed between the Fe_3O_4 and Fe, the effect disappeared: cold-worked and annealed Fe oxidized at the same rate with no diffusion cavities in either case.

The purpose of the present work was to obtain further information on the growth mechanism of oxide layers by studying the effect of cold work on the oxidation of Ni. Ni was chosen because only one oxide phase is formed, a factor expected to simplify interpretation of the results. The NiO is similar in structure to FeO, thickens via cation vacancy diffusion as in FeO and Fe_3O_4, and can be investigated over a broad temperature range.

* Electrochemical Society Active Member.

Key words: kinetics, oxide grain structure, oxide growth mechanism.

Experimental

Specimens 1 × 5 cm were cut from two grades of Ni strip, commercially pure (C.P.) Ni 0.035 cm thick and zone refined (Z.R.) Ni 0.025 cm thick. Table I shows the composition as determined by spark source mass spectroscopy on the as-received cold-rolled strip after electropolishing to remove surface contamination.

Specimens were prepared for oxidation by chemical polishing for 30 sec at 85°C in mixed concentrated acids (30 ml nitric, 10 ml sulfuric, 10 ml phosphoric, and 50 ml acetic), electropolishing for 30 sec at 17°C and 0.6 A/cm^2 in a 1:4 (by volume) solution of 71% perchloric acid in glacial acetic acid, annealing 1 hr at 1100°C in 30 Torr of purified Ar in a quartz tube, chemical and electropolishing as before, and etching

[a] Instantaneous values of the apparent parabolic rate constant calculated as $2w\ dw/dt$ from slope of oxidation curves at 0.1, 0.2, 1, and 20 hr. Units are ($mg^2\ cm^{-4}\ hr^{-1}$); multiply by 2.78×10^{-10} to change to $g^2\ cm^{-4}\ sec^{-1}$.
[b] Local values of the apparent parabolic rate constant calculated as w^2/t from measurements of the thinnest oxide on metallographic cross sections.
[c] Average oxide thickness calculated from wt. gain at end of run; diameter of average grain of outer oxide measured by Heyn intercept procedure.
[d] Cold worked by shot peening with glass microspheres.
[e] Cold rolled; standard procedure (chemical polish, electropolish, etch) except anneal omitted.

immediately in 0.8N nitric acid for 30 sec. The combination of chemical and electropolishing removed 13μ of Ni before annealing and 9μ after; etching removed 250A. Average grain diameter after annealing was 0.1 mm for C.P. Ni and 0.6 mm for Z. R. Ni; the latter showed wide variations with some grains as large as 10 mm. Cold-worked (C.W.) specimens were prepared by the following additional treatment: abrasion for 7 min with 600-grit SiC paper lubricated with methanol, 3 min with 6μ diamond on nylon cloth lubricated with lapping oil, then ultrasonic cleaning in benzene, ether, and redistilled methanol. The abrasive treatment removed 4μ of Ni. An alternative cold-working procedure was shot-peening for 2 min with 50μ diam glass microspheres.

Oxidation runs at 700°-1270°C were carried out for times from 1 min to 20 hr in 1 atm of purified oxygen flowing up through a 3 cm ID vertical furnace tube at 100 ml/min. Runs were started 1 hr after specimen preparation by hanging the specimen on a sapphire hook, lowering into the hot zone of the mullite furnace tube, and connecting to an automatic balance of 0.1 mg sensitivity. Specimens reached temperature in 30 sec. Weight recording began at 20 sec but was judged reliable only after about 2 min when a steady state had been achieved. The hot weight at zero time was determined from before and after weighings at room temperature. Runs were ended by removing the specimens to cool in Ar. No oxide was lost during oxidation or cooling. Table II summarizes the experimental details; a number of variations from the procedure described are included.

Results

Oxidation curves.—Figures 1 and 2 show the 20 hr oxidation curves of cold-worked and annealed Z.R. Ni and C.P. Ni at 700°, 900°, 1100°, and 1270°C. Cold-worked metal oxidizes faster at each temperature for both materials. An intermediate degree of cold work yields an intermediate oxidation rate (curve 25 *vs.* 22 and 23, Fig. 2). Cold working by a different method (shot peening, curve 24) gives the same rapid rate as the standard abrasion procedure (curve 23). Reproducibility is good within each grade of Ni (*e.g.*, curves

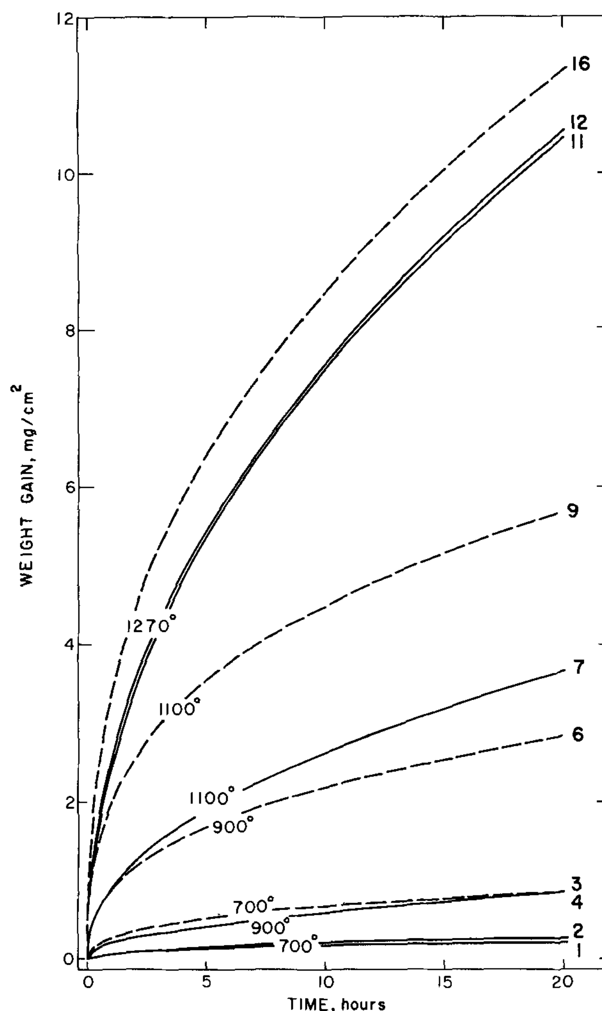

Fig. 1. Oxidation curves for Z.R.Ni from 700° to 1270°C. Oxidation is greater at each temperature for cold-worked Ni (broken lines) than annealed Ni (solid lines).

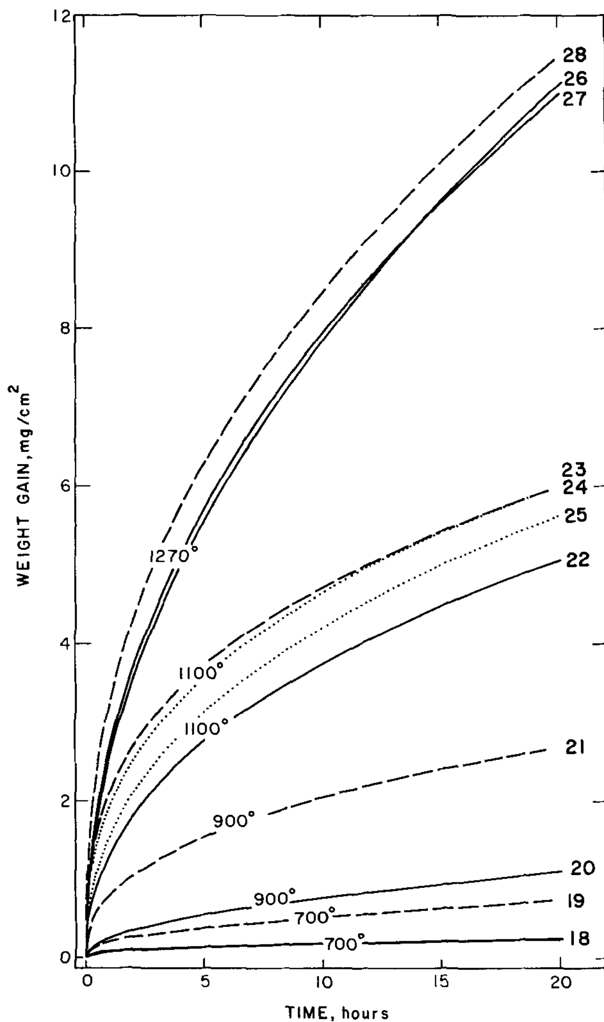

Fig. 2. Oxidation of C.P.Ni from 700° to 1270°C. Oxidation is greater for cold-worked Ni (broken lines) than annealed Ni (solid lines). Different methods of cold working give similar results (curve 24, shot-peened; curve 23, abraded). A lesser degree of cold work yields an intermediate oxidation rate—curve 25 (cold rolled) vs. curve 23 (abraded) and curve 22 (annealed).

1 and 2 or 11 and 12 for Z.R. Ni and 26 and 27 for C.P. Ni) but less so between grades: annealed C.P. Ni oxidizes faster than Z.R. Ni; in the cold-worked condition, however, the two grades oxidize at the same rate.

Rate constants.—Figures 3 and 4a show the instantaneous apparent parabolic rate constants, *Kp*, calculated from the oxidation data as $2w\ dw/dt$, plotted against time. (The data were processed by digitizing the weight gain strip charts from the recording balance and applying a computer program to yield plots of rate constants and oxidation curves directly.) For clarity, single representative runs are plotted; *Kp* values for all runs taken from the computer print-out at 0.1, 0.2, 1, and 20 hr are listed in Table II.

The *Kp* curves for cold-worked Ni differ in kind from those of annealed Ni: for the former, *Kp* is initially very high, decreases rapidly with time, and approaches a constant value at long times; for annealed Ni, *Kp* is comparatively constant throughout. The degree of convergence with time depends on temperature: after 20 hr at 700° and 900°, *Kp* remains appreciably higher for cold-worked than annealed Ni (Fig. 3), at 1100° it is slightly higher, but after 20 hr at 1270° *Kp* for cold-worked Ni has dropped to the value for annealed Ni (Fig. 4a). Figure 4b, c, d, and e are photomicrographs of the outer oxide surface (located on Fig. 4a by arrows) showing that the oxide

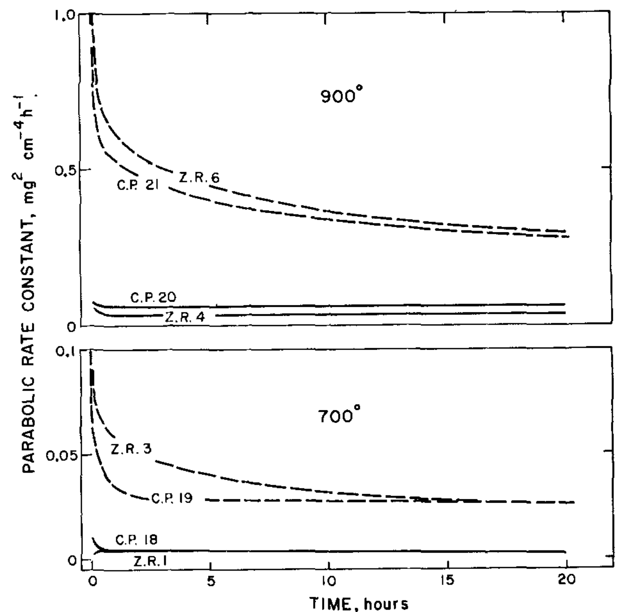

Fig. 3. Apparent parabolic rate constants, $2w\ dw/dt$, plotted against time for Z.R. and C.P.Ni at 700° and 900°. For cold-worked Ni (broken lines) *Kp* is high initially and decreases rapidly; for annealed Ni (solid lines) *Kp* is relatively constant. After 20 hr *Kp* still is appreciably higher for cold-worked than annealed Ni.

on cold-worked Ni is fine-grained initially, finer at lower temperature, and coarsens with time.

The variations in *Kp* are conveniently summarized on an Arrhenius plot, Fig. 5. The high values for cold-worked Ni at short times (0.1 hr) fall on a straight line over the full temperature range of 700°-1270° with a slope indicating a low apparent activation energy (E_A) of 28 kcal/mole. After 20 hr, E_A for cold-worked Ni at 700°-900°, despite the drop in *Kp* values, is still 28 kcal; at 1100°-1270° E_A for cold-worked Ni has increased from 28 to 41 kcal after 20 hr. The highest E_A is for annealed Ni from 1100° to 1270°—53 cal for Z.R. Ni and 49 kcal for C.P. Ni after 20 hr. *Kp* values for annealed Ni at 700° and 900° are high relative to the 1100°-1270° data for annealed Ni, giving rise to a break in the Arrhenius plot and a low apparent E_A (~34 kcal).

Oxide structure.—Figures 6-9 show the microstructure of the NiO layers formed at 700° and 900°. On cold-worked Ni an inner layer of small equiaxed NiO grains next to the metal (Fig. 6e, 7e, f, 8d, 9c, d) is overlaid with relatively coarse, columnar oxide. Grain size of the outer oxide after 20 hr is 0.0015 mm at 700° and 0.0033 at 900°C (Table II shows grain sizes at 700°-1270°). The layer is of uniform thickness, with small cavities distributed throughout, but in good contact with the metal (Fig. 7d, 8c).[1] The outer oxide surface is finely crystalline and at 700° shows a network of ridges that gives a cellular appearance (Fig. 6f, 10a).

Annealed Ni at 700° and 900° exhibits marked anisotropy of oxidation (Fig. 6-10). Over many metal grains the oxide is thin, smooth, and apparently monocrystalline (Fig. 6a,c, 8a,b, 9a,b); (111)Ni forms a thin, strongly epitaxed oxide layer with (111)NiO||(111)Ni. Etching reveals no oxide grain boundaries (Fig. 8a) and single crystal patterns are obtained by x-ray and electron diffraction. On other substrate grains the oxide is thick and polycrystalline, approaching the fine-grained structure formed on cold-worked Ni. A ridge of thick polycrystalline oxide, and a corresponding trench in the metal, forms over Ni grain boundaries

[1] Various artifacts are created during etching of the metallographic sections, *e.g.*, exaggeration of cavities in the oxide (Fig. 7e, 8d, 12c), a dark band between oxide and metal (Fig. 6a, d, 7a, 11c, 13c, 14c), pitting of the metal (Fig. 14a), and enhanced attack on fine oxide grains at the NiO-Ni interface (Fig. 8d, 9c).

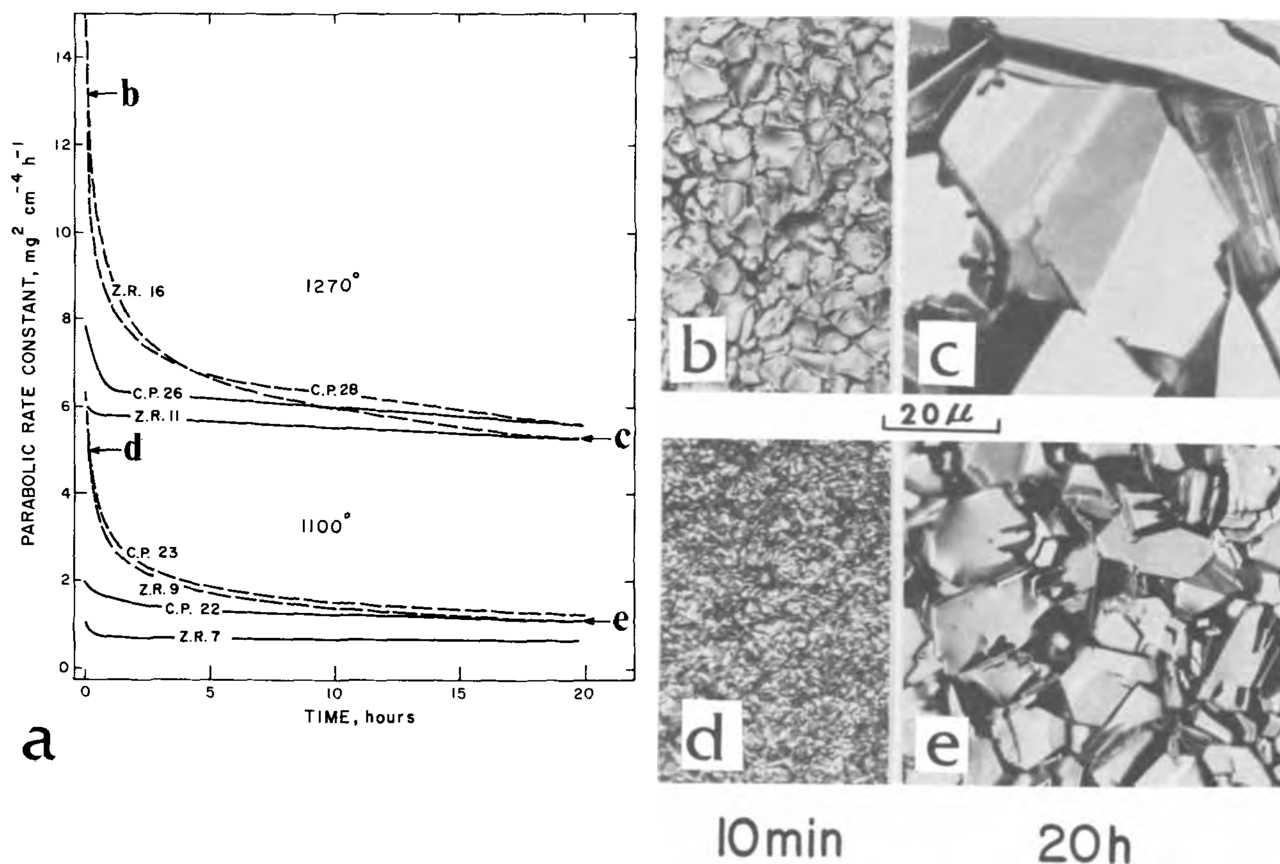

Fig. 4. (a) Apparent parabolic rate constants, $2w\ dw/dt$, for Z.R. and C.P.Ni at 1100° and 1270°. For cold-worked Ni (broken lines) Kp is high initially and decreases rapidly; for annealed Ni (solid lines) Kp is relatively constant. After 20 hr Kp becomes the same for cold-worked and annealed Ni at 1270°, but remains slightly higher at 1100°. (b), (c), (d), and (e) are photomicrographs at X750 of the outer oxide surface of cold-worked Z.R.Ni after 10 min and 20 hr at 1270° and 1100° [located on (a) by arrows; runs 17, 16, 10 and 9] showing the increase of oxide grain size on cold-worked Ni with time and temperature.

(Fig. 6-10). A similar ridge and trench develops, as expected, where a line of local cold work had been produced by lightly scratching the Ni surface before oxidation (Fig. 8b, 10d). The topography of the outer oxide surface at 700° and 900° is revealed more clearly by the SEM stereopairs in Fig. 10; details are given in the caption.

On annealed Ni at 700° and 900° cavities develop in the oxide on some areas and not on others. The oxide-metal interface is usually plane under thin oxide and rugged under thick oxide. When cavities occur in thick oxide, including oxide ridges, they are concentrated at the oxide-metal interface (Fig. 6a,b, 9a) suggesting cavity formation by condensation of cation vacancies. Since such cavities do not form on cold-worked Ni (Fig. 7d, 8c), where the oxide is as thick or thicker, presumably the cold-worked metal suppresses the nucleation of cavities by providing sinks for cation vacancies as was proposed for Fe (1).

Experiments in this program carried out at temperatures below 700° (650°, 400°, 375°, and 300°) displayed both the oxidation anisotropy of annealed Ni and the greater oxidation due to cold work, but specific results are not reported because the thermobalance was too insensitive to provide reliable kinetic data.

Figures 4 and 11 to 14 show the structure of the oxide formed at 1100° and 1270°C. On annealed Ni the layer is made up of columnar single grains with a plane outer surface parallel to the surface of the specimen. The thickness is uniform except that especially large oxide grains are somewhat thinner (Fig. 11a, 12b). The outer surface of each grain is concave or dished, *i.e.*, thicker near the grain boundaries (Fig. 11b, 12a,b). Oxide grains are larger at 1270° than 1100° and larger on Z.R. Ni than C.P. Ni. (The metal grain size is also larger for Z.R. Ni than C.P. Ni; the average oxide grain size is always less than that of the substrate metal but larger the coarser the metal.)

On cold-worked Ni the oxide at 1100° and 1270° is a uniform layer two or three grains thick made up of smaller, more equiaxed grains unrelated to the substrate grain structure (Fig. 11c, 12c, 13c, 14c). The outer oxide surface is randomly facetted rather than plane-parallel. (The latter is expected for a layer growing by a uniform diffusion-controlled process; randomly inclined facets indicate a nonuniform flux of reactant.) The oxide grain size is the same on C.P. Ni and Z.R. Ni, 0.009 mm at 1100° and 0.022 mm at 1270° after 20 hr. At short times the oxide grains are considerably smaller (Fig. 4b,d and Table II) whereas with annealed Ni little variation with time was found by microscopic examination of the short and long runs.

At 1100° and 1270° cavities develop in the Ni, both annealed and cold-worked, predominantly at the grain boundaries (Fig. 13a), and sometimes accompanied by internal oxidation (Fig. 12a). Isolated cavities are distributed throughout the oxide layer; good contact is maintained at the oxide-metal interface (Fig. 12a). The inner porous oxide layer observed in some other investigations (3, 4) is not evident. (The general subject of cavities in Ni oxidation will be part of a subsequent report.)

Discussion

The above experiments demonstrate that cold work affects both the grain size and growth rate of the oxide layer. Cold-worked Ni oxidizes faster than annealed Ni and forms finer-grained oxide which coarsens with time while the oxidation rate constant, Kp, decreases. On annealed Ni the oxide grain size and Kp change little with time. Noteworthy also is the anisotropy of oxidation below 1000° on annealed but not on cold-worked Ni, and the variation in the activation energy

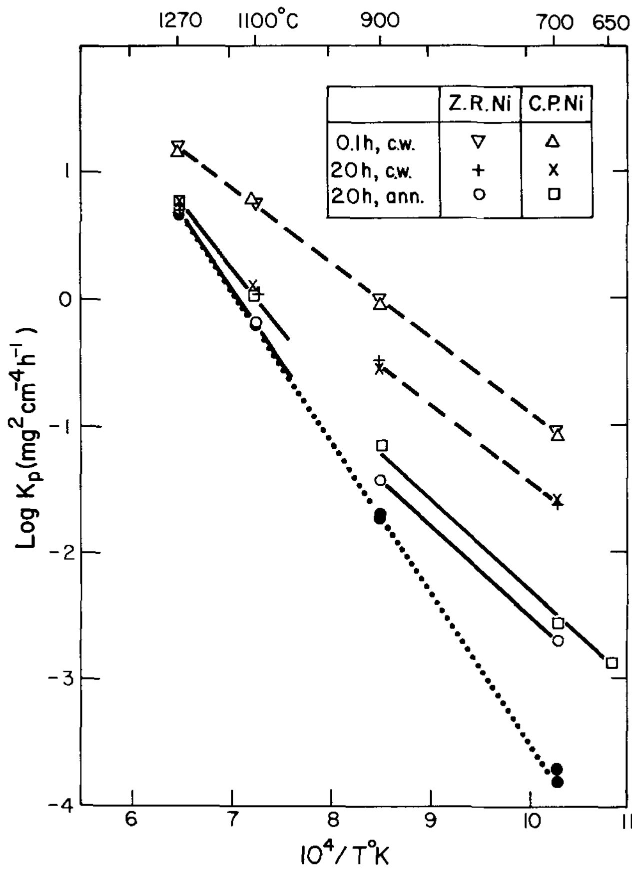

Fig. 5. Arrhenius plot of Kp calculated as $2w\ dw/dt$ for the oxidation of Z.R. and C.P.Ni, annealed (solid lines) and cold-worked (broken lines). Also shown are values of Kp calculated as w^2/t (filled circles—dotted line) from measurements of the thinnest oxide on annealed Ni at each temperature.

for oxidation E_A—high above 1000°, low below 1000°, and low at all temperatures for cold-worked Ni at short times. All these observations can be plausibly interpreted on the basis of oxide grain boundaries serving as easy diffusion paths for Ni through the NiO layer: with fine-grained oxide, Kp is higher and E_A lower.

The evidence for oxide grain boundaries acting as high-diffusivity paths is as follows: (*i*) Cold-worked Ni forms a finer-grained oxide layer than annealed Ni and oxidizes faster. (*ii*) Kp decreases with time for cold-worked Ni with an accompanying increase in oxide grain size. (*iii*) E_A is lower for fine-grained oxide as anticipated for a grain-boundary diffusion process. (*iv*) Oxidation anisotropy correlates with oxide grain size: the layer is thicker on substrate grains forming finer-grained oxide, and is especially thin for a single crystal oxide overgrowth.[2] (*v*) The oxide is thicker near oxide grain boundaries: at low temperature, ridges form where oxide grain boundaries emerge at the outer oxide surface; at high temperature, the leakage diffusion at the grain boundaries causes the outer surface of each oxide grain to be concave.

In a manner similar to Fe(2), cold-worked Ni, because of surface roughness, lattice mismatch, or polygonization during heating, develops a fine-grained oxide layer high in leakage paths and shows correspondingly high values of Kp. The coarse-grained oxide formed on annealed Ni provides few grain boundaries for leakage-enhanced diffusion and Kp values are consequently low. At high temperature the initially fine grains on cold-worked Ni coarsen rapidly causing Kp to decrease: after 20 hr Kp is the same for cold-worked and annealed Ni at 1270° and nearly the same at 1100°. Sufficient oxide grain growth has occurred to make the leakage path populations comparable. At 700° and 900° the initial fine-grained layer

[2] This has now been confirmed with some work here on oxidation of single crystals of various orientations.

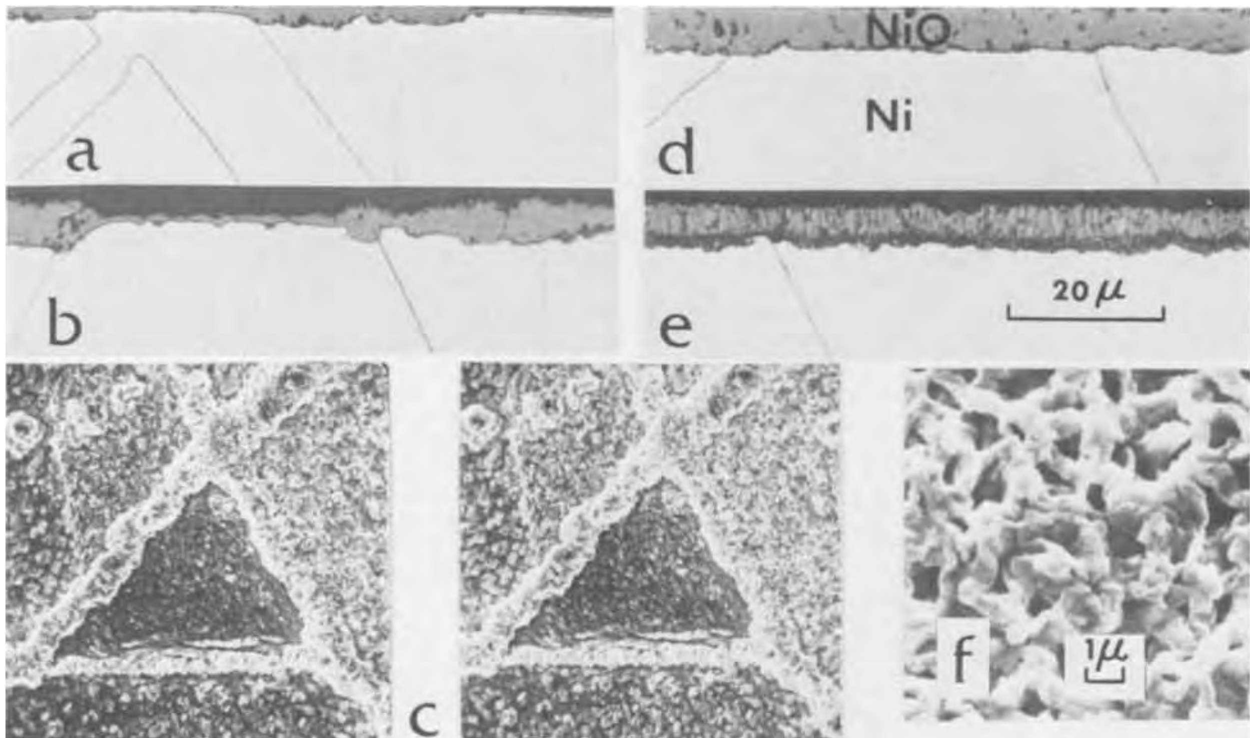

Fig. 6. Oxide structures formed on C.P.Ni in 20 hr at 700°. (a), (b), and (c) run 18, annealed. (d), (e), and (f) run 19, cold worked. (f) is SEM photo at X5000 of fracture section showing as in (e) the inner fine-grained layer and outer coarser columnar layer on cold-worked Ni (metal deformed during fracture).

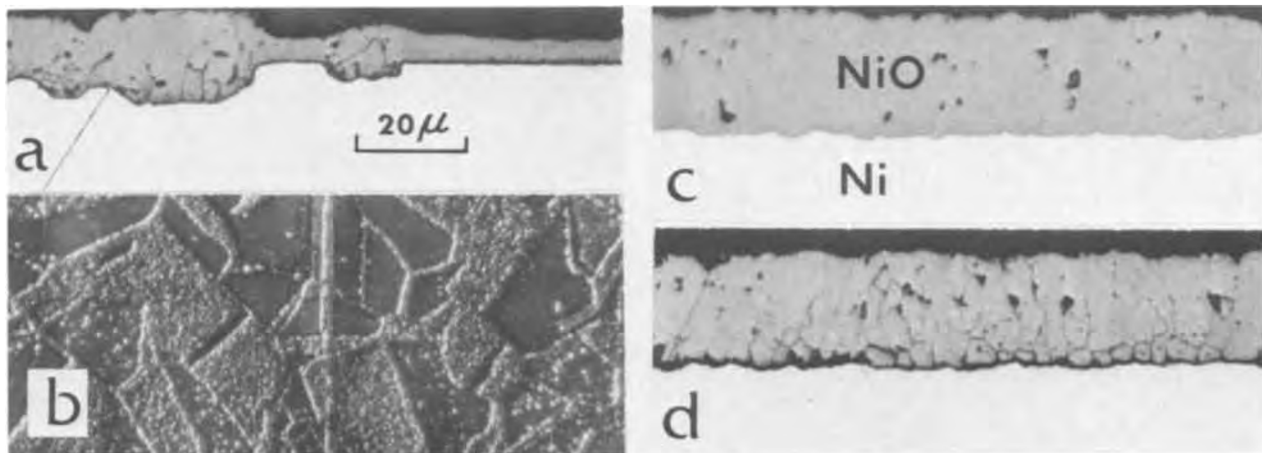

Fig. 8. Oxide structures formed on C.P.Ni in 20 hr at 900°. (a) and (b) run 20, annealed. (c) and (d) run 21, cold worked. In cross sections (at X750) Ni and NiO are etched in (a) and (d). (c) is unetched to illustrate good oxide-metal contact. Large cavities in fine-grained inner oxide in (d) are etching artifact. (b) is oxide outer surface at X60 showing oxidation anisotropy and ridging over Ni grain boundaries; central vertical bar is ridge of oxide formed over metal scratch.

persists and becomes overlaid with coarser columnar oxide. Kp decreases as the latter becomes a larger fraction of the total layer (and probably because of some grain growth in the inner layer, especially at 900°) and, though essentially constant after 20 hr, remains appreciably higher than the Kp for the coarse-grained layer on annealed Ni.

The anisotropy of oxidation on annealed Ni at 700° and 900° is related directly to the effect of substrate metal grains on the oxide grain size: thick oxide over Ni grains which develop fine polycrystalline oxide, intermediate when the polycrystalline oxide is coarser, and thin on Ni grains which form a single crystal overgrowth. Modification of the Ni surface by cold-working masks any effect of substrate orientation and yields a uniformly thick oxide unrelated to the structure of the underlying Ni.

Oxidation anisotropy is less evident at high temperature where grain coarsening eliminates the fine-grained oxide formed initially on some Ni orientations. The small early decrease in Kp with time of annealed Ni at 1270° and 1100° (Fig. 4a) results from this grain growth. Differences in thickness of the layer still remain after 20 hr. The thickness is least for the largest grains which presumably were a single crystal type of overgrowth from the start. That oxide grain boundaries are effective leakage paths even at 1100° and 1270° is demonstrated by the dished outer surface of the oxide grains that arises from the higher cation flux at the grain boundaries. This acts to maintain the thickness differential between different areas. For the largest grains surface mobility is inadequate to transport NiO far enough from the grain boundaries and thickening is solely by volume diffusion (which is al-

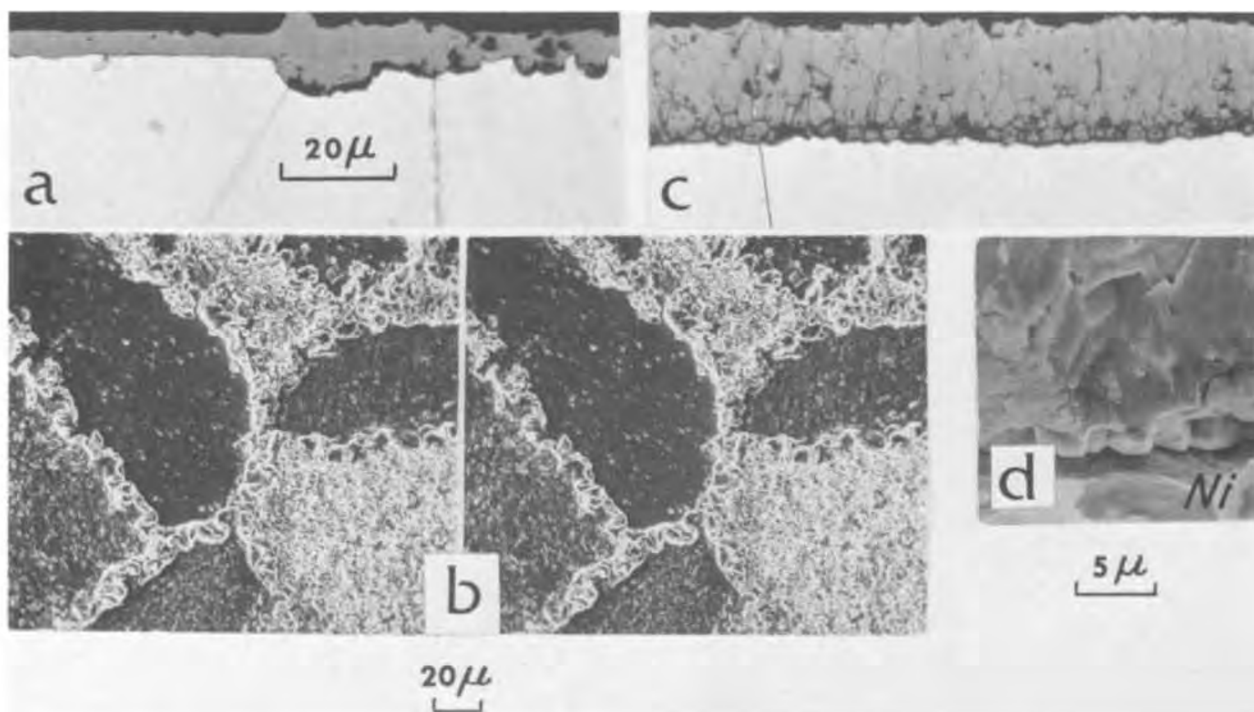

Fig. 9. Oxide structures formed on Z.R.Ni in 20 hr at 900°. (a) and (b) run 4, annealed. (c) and (d) run 6, cold worked. In polished sections (a) and (c) at X750, Ni is etched in (a) and Ni and NiO etched in (c). (b) is SEM stereopair of oxide outer surface at X300 showing oxidation anisotropy and ridging on annealed Ni. (d) is SEM photo of fracture section at X2000 showing small oxide grains near metal (bottom) seen in (c) as fine-grained inner layer (metal deformed during fracture).

ways occurring, irrespective of the presence or density of leakage paths). This mechanism for the dished outer oxide surface is consistent with the other observations and does not require the plastic deformation by compressive stresses in the oxide proposed by Rhines and Wolf (5).

Grain size can also explain the differences in Kp between annealed Z.R. and C.P. Ni. The oxide is finer-grained on C.P. Ni (as is the substrate metal), and Kp values are correspondingly higher. In the cold-worked condition the two materials, presumably because both are fine-grained, form oxide of the same grain size and no differences in Kp are found.

Activation energy.—The interrelationship between grain size and oxidation rate leads to a range of Kp values at each temperature and hence to the spread of apparent E_A values (Fig. 5) from 28 kcal/mol for cold-worked Ni at 0.1 hr to 53 kcal/mol for annealed Z.R. Ni after 20 hr at 1100° to 1270°. Ideally, two meaningful E_A values could be deduced, a high value for oxide growth via volume diffusion, and low for growth via leakage paths (6). In practice, uncertainty arises because transport is not exclusively by one or the other process and because of oxide layer variations that depend on time and temperature.

Although Kp values for cold-worked Ni at 0.1 hr lie on a straight line from 700° to 1270° (Fig. 5) representing an E_A of 28 kcal/mol, the true value is uncertain because the Kp values at the different temperatures should be for equal grain size, not equal times; as can be seen from Table II the grain size is larger at higher temperatures. Other perturbations are that the contribution from volume diffusion is greater at higher temperatures, and that at low temperature (700° and 900°) ridging at oxide grain boundaries means that the path length for leakage diffusion is longer than for the ideally uniform layer assumed in the calculation of Kp. In a subsequent publication (7) a treatment of the data to eliminate the contribution from lattice diffusion and decrease the influence of grain size yields a value of 38 kcal/mol, in agreement with values obtained from work at 300°-700° (8, 9) where growth was almost exclusively by leakage diffusion.

At 1100° and 1270° the lowest Kp values are for annealed Z.R. Ni after 20 hr and, with the associated E_A of 53 kcal/mole, appear to best represent oxide layer growth by volume diffusion. However, from the local thickening at grain boundaries seen in the metallographic sections, it is evident that there still is some contribution from leakage path transport. Such a contribution is evident also in the higher Kp values, because of finer oxide grain size, of cold-worked Ni and annealed C.P. Ni after 20 hr at 1100° and 1270°; the lower apparent E_A of 49 kcal for annealed C.P. Ni indicates that, in contrast to Z.R. Ni, the oxide grain size is significantly finer at 1100° than 1270°.

Some guidance to the validity of 53 kcal/mol as representative of volume transport can be obtained by directing attention to the thinnest oxide formed on annealed Ni at each temperature, *i.e.*, where the oxide layer is an extensive single crystal free of grain boundary leakage paths, and calculating local values of Kp as w^2/t by measuring the oxide thickness in cross section (1). Making the necessary but reasonable assumptions that a single growth process and good oxide-metal contact have existed from zero time, these minimum values of Kp (Table II) and the associated E_A best represent oxide growth by lattice diffusion only. (Note that Z.R. and C.P. Ni yield similar local Kp values; *i.e.*, volume diffusion in the NiO does not depend on the specimen material used.) Kp values so obtained are plotted as filled circles in Fig. 5 (dotted line) and indicate an E_A value of 54 kcal/mol. The measurements are less reliable for the thinner oxides at 700° and 900°, but the data points lie adequately along the extrapolation from the 1270° and 1100° data. Values of Kp from single crystal experiments at 650° and 600° in a separate investigation (9) also lie satisfactorily along this extrapolation. A value of 54 ± 2 kcal/mol thus appears to be a realistic estimate of E_A for oxide growth by volume diffusion and applies over a temperature range from 600°-1270°, the corresponding oxide thicknesses being 100 to 10^6Å.

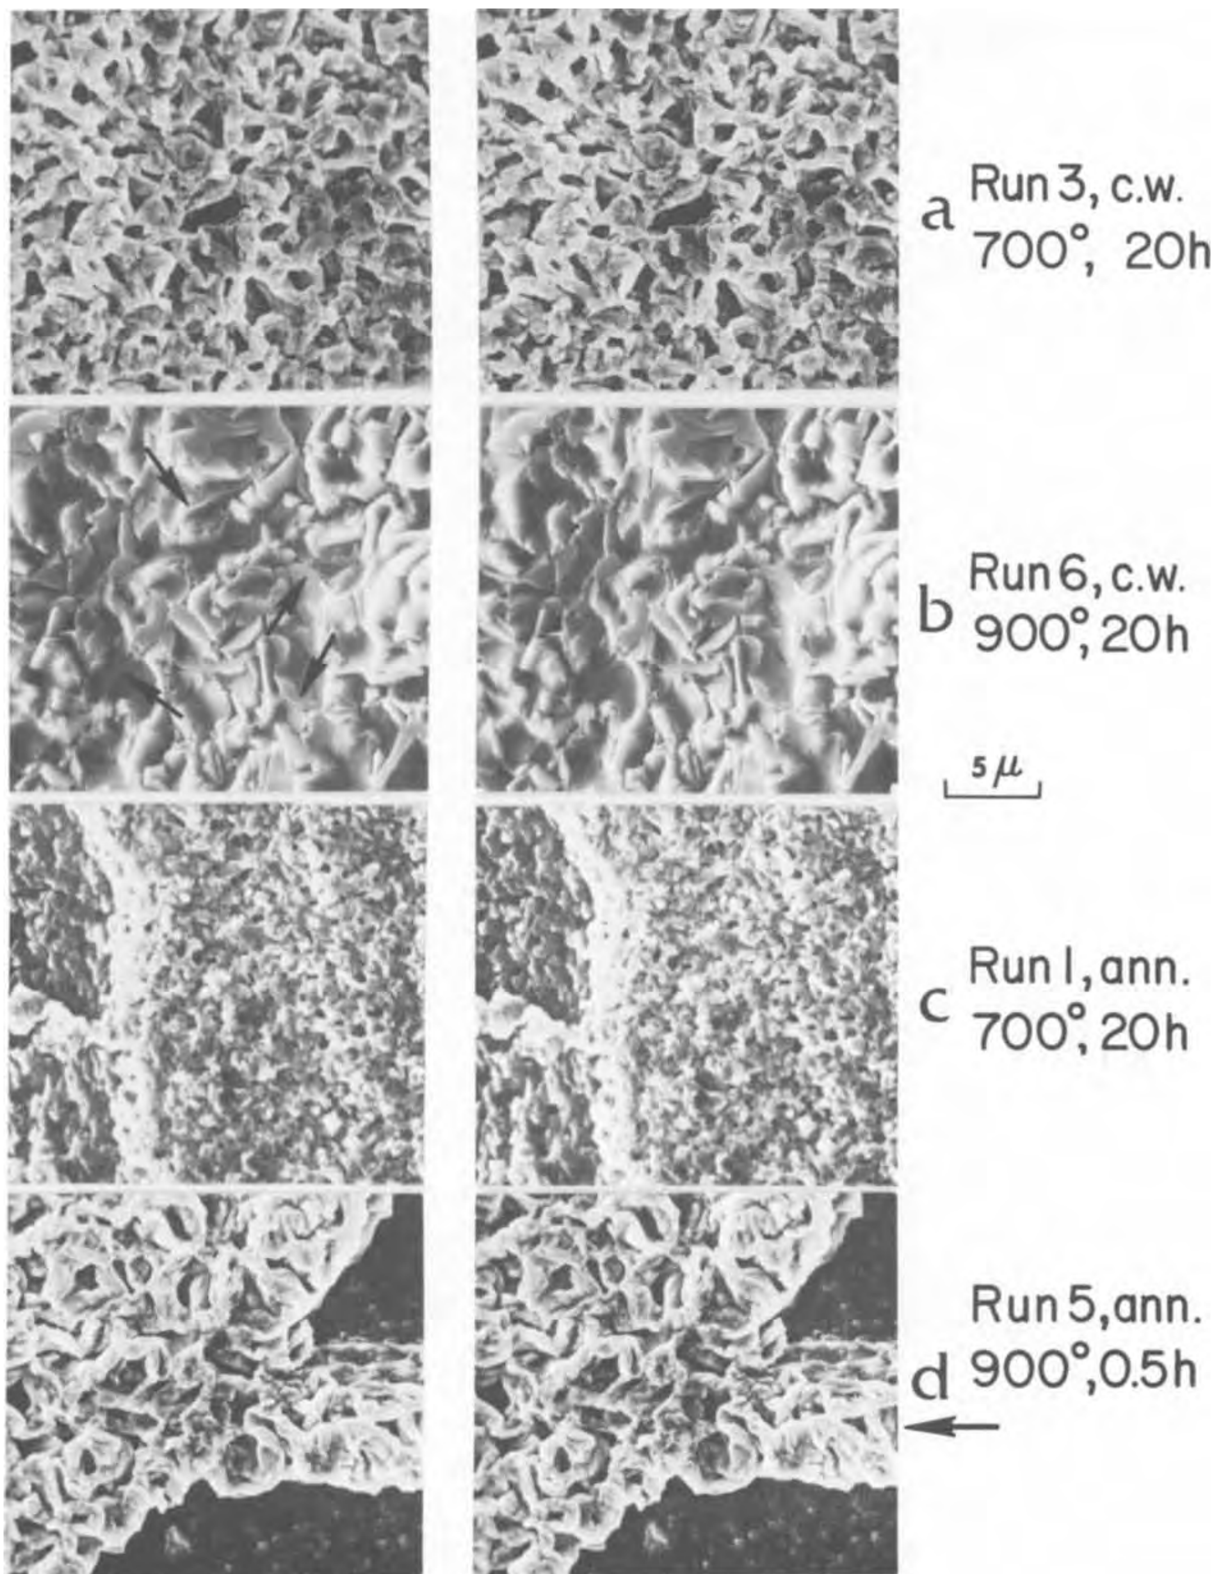

Fig. 10. Outer surface of oxide formed on Z.R.Ni at 700° and 900°. SEM stereopairs at X2500. (a) at 700°, honeycomb structure develops on cold-worked Ni from oxide ridges produced by preferential diffusion at oxide grain boundaries. (b) at 900°, oxide grain growth and greater surface mobility lead to replacement of ridges and honeycomb by finely-facetted, coarser-grained oxide; arrows indicate oxide grain boundaries [evident also on fracture section 9(d)]. (c) at 700°, annealed Ni also develops honeycomb structure at areas of thickest (polycrystalline) oxide. (d) Honeycomb structure forms at early stage on thick areas of annealed Ni at 900° also (but changes to structure of (b) at longer times); photo shows thick cellular oxide (left), thin oxide (right), and thick cellular oxide formed at metal scratch (arrow).

The intermediate values of Kp in Fig. 5 and the associated range of E_A values are of minor significance. They reflect the relative contributions of volume and leakage diffusion. The Kp values for cold-worked Ni after 20 hr at 700° and 900° are considerably lower than at 0.1 hr but the E_A is the same, indicating merely that the concentration of leakage paths has decreased equally at the two temperatures and leakage transport still predominates. After 20 hr at 1100° and 1270° the decrease in Kp values and increased E_A for cold-

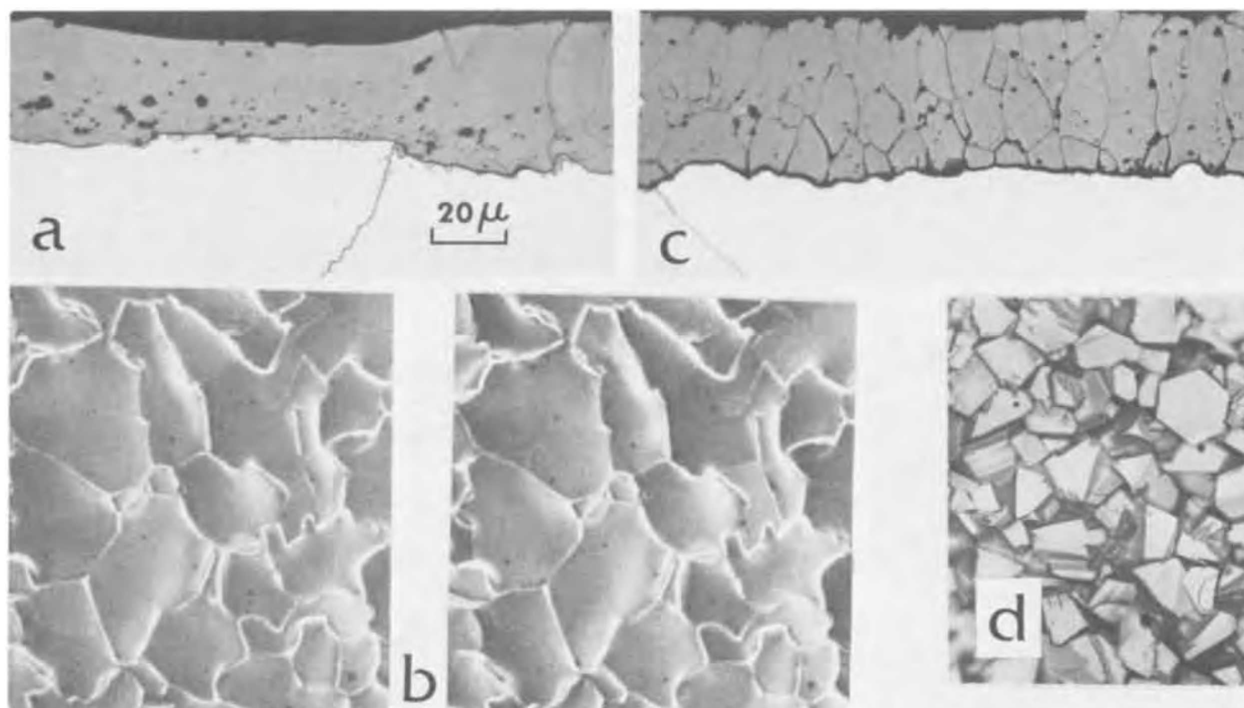

Fig. 11. Oxide structures formed on C.P. Ni in 20 hr at 1100°. (a) and (b) run 22, annealed. (c) and (d) run 23, cold worked. (d) shows random facets on oxide outer surface on cold-worked Ni. X500.

worked Ni, compared to 0.1 hr, indicates that the progressive elimination of leakage paths by oxide grain growth has made volume diffusion a significant part of the transport process; the apparent E_A of 40 kcal/mol is an intermediate value reflecting the presence of fewer leakage paths at 1270° than 1100°. For annealed Ni at 700° and 900° the high Kp values, compared to an extrapolation of the 1270° and 1100° data, and lower E_A values (which causes a break in slope of the Arrhenius plot) again indicate transport mainly via leakage paths. Such breaks in Arrhenius plots have been reported previously for the oxidation of Ni (10-13) and other metals (14-18). It is reasonable that leakage-enhanced diffusion may explain anomalies in Arrhenius plots of metal oxidation generally, not just for Ni.

Implications

The rate constant for the oxidation of Ni is as much as 1000 times smaller when the NiO barrier layer is in the form of a single crystal, *i.e.*, free of easy diffusion paths. The same phenomenon may apply as well to Co, Mn, Cu, and other metals. This has obvious potential practical importance for metals and alloys generally, provided that suitable oxidation procedures or surface treatments could be devised to form protective layers with few leakage paths.

A second point that arises from the observed major effect of leakage paths on oxidation resistance is that it may be necessary to reassess some prior work on the effect of alloying. If, as demonstrated here, two grades of pure Ni treated similarly can yield appreciably different oxidation rates because of differences in oxide grain size, the results of investigations into the effect of alloying additions, in which changes in oxidation rate have been ascribed to Wagner-Hauffe valency effects, could have been misinterpreted by unrecognized variations in oxide grain size produced by the alloying additives. Observations in the literature that the oxidation resistance of Ni increases with purity may similarly be an effect of oxide grain size, not impurities per se.

Conclusions

1. Cold-worked Ni oxidizes faster than annealed Ni because the oxide formed on cold-worked Ni is finer-grained and the oxide grain boundaries act as easy diffusion paths for Ni through the NiO barrier layer.

2. The apparent parabolic rate constant for cold-worked Ni is high initially but decreases rapidly as the oxide grain size increases with time. On annealed Ni the rate constant is lower, the oxide grain size larger, and both change little with time.

3. The activation energy for growth of the oxide layer is 54 ± 2 kcal/mol for transport by volume dif-

fusion and appreciably lower for transport via grain boundary leakage paths.

4. Marked anisotropy of oxidation occurs with annealed Ni below 1000°C because the substrate orientation affects the grain size and hence thickness of the oxide overgrowth. The oxide is thinnest on Ni grains which form a single crystal overgrowth.

5. The Arrhenius plot for Ni oxidation shows a break around 1000°C as a result of transport below 1000° being largely via leakage paths and because above 1000° there is extensive oxide grain growth and volume transport becomes more important.

6. An apparent difference in oxidation rate between zone-refined and commercially pure Ni is due to differences in grain size of the oxide layers. The oxidation rates are the same for the two materials if the oxide grain size is the same.

The Correlation Between Temperature Coefficient of Capacitance and Dielectric Loss in Tantalum and Tantalum-Aluminum Anodic Oxides

J. M. Schoen, R. C. Pitetti, and D. Jaffe

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

A semi-empirical formula for temperature coefficient of capacitance (TCC) as a function of dielectric constant and loss (tan δ) is developed for isotropic oxides. Comparison is made between this formula and experimental values of TCC and tan δ for the anodic oxides of sputtered tantalum and tantalum-aluminum alloy films. Tan δ was a function of alloy content and in addition was varied by heat treatments during interrupted anodization. Agreement between theory and experiment is considered adequate. It is concluded that the major contribution to TCC in Ta and Ta-Al anodic oxides comes from the dielectric loss, so that materials processing changes that reduce the loss should also reduce TCC.

Thin film capacitors based on anodic oxides of tantalum and tantalum-aluminum alloys are of interest for temperature compensating R-C network applications. An understanding of the factors contributing to the temperature coefficient of capacitance (TCC) of anodic oxides is necessary to insure proper control of the electrical properties of these components. Existing equations which attempt to relate TCC, dissipation factor (tan δ), and dielectric constant (κ) in various oxides do not predict these relationships satisfactorily for anodic oxides of tantalum and tantalum-aluminum alloys.

There is considerable literature devoted to the underlying processes governing the temperature coefficient of capacitance in bulk, solid dielectrics (1-7). Harrop and Campbell (8, 9) have made notable progress in applying these theories to thin films. In the present paper we refine Harrop and Campbell's work to the specific problem of TCC in thin oxide films with the dielectric constant in the range from 10 to 100. A semi-empirical formula for TCC as a function of κ and tan δ is developed. Comparison is made between this formula and experimental measurements made on anodically formed oxides of tantalum and tantalum-aluminum [atomic per cent (a/o) Al $\lesssim$ 52].

Theory

Harrop and Campbell (8, 9) have expressed the temperature coefficient of capacitance (TCC) of thin film capacitors in terms of the dielectric constant (κ), linear coefficient of thermal expansion (λ), dielectric loss (tan δ), and electrical polarizability (α) of a macroscopic volume (V) of the dielectric. Their expression is

$$\mathrm{TCC} = \frac{(\kappa - 1)(\kappa + 2)}{\kappa}[X + Y + Z] + \lambda + A \tan\delta \quad [1]$$

where

$$X = -\lambda = -\frac{1}{3V}\left(\frac{\partial V}{\partial T}\right)_P \quad [2]$$

$$Y = \frac{1}{3\alpha}\left(\frac{\partial \alpha}{\partial V}\right)_T\left(\frac{\partial V}{\partial T}\right)_P \quad [3]$$

$$Z = \frac{1}{3\alpha}\left(\frac{\partial \alpha}{\partial T}\right)_V \quad [4]$$

$$A = (5.0 \pm 1) \times 10^4\ \mathrm{ppm/°C} \quad [5]$$

Harrop and Campbell then define regions of κ and tan δ in which one or two terms of Eq. [1] dominate. In these regions they obtain approximations to Eq. [1], plot TCC as a function of κ and/or tan δ, and compare the results with experiment. In most cases the agreement is quite good; however, a number of thin film dielectrics exist, notably the amorphous, anodic oxides of tantalum and tantalum-aluminum alloys for which the Harrop and Campbell approximations do not agree with experiment. In this paper it is demonstrated that this lack of agreement results from inappropriate approximations to Eq. [1], and not from a deficiency in the theory that leads to Eq. [1].

The approach taken in the present work is to start with Eq. [1] and, instead of defining regions in which

Key words: temperature coefficient of capacitance, dielectric loss, tantalum and tantalum-aluminum, anodic oxides.

some terms dominate, to obtain a reasonable approximation to the entire equation. Attention is restricted specifically to amorphous, isotropic oxides. Bosman and Havinga (4) have made an extensive study of the variation of κ with temperature and pressure in cubic oxides and plot $X + Y$ and Z as a function of κ. In the range $10 \leq \kappa \leq 100$, these quantities closely follow the empirical formulas

$$X + Y = \{10 - 3 \log_{10} \kappa\} \text{ ppm/°C} \quad [6]$$

$$Z = \{37 - 30 \log_{10} \kappa\} \text{ ppm/°C} \quad [7]$$

Equations [6] and [7] should be representative of amorphous, isotropic oxides as well. Moreover, Hersping (5) finds for oxides

$$\lambda \approx 7.5 \text{ ppm/°C} \quad [8]$$

Substituting Eq. [5] to [8] into Eq. [1] yields

$$\text{TCC} \cong \left\{ \frac{(\kappa - 1)(\kappa + 2)}{\kappa} (47 - 33 \log_{10} \kappa) + 7.5 + 5.0 \times 10^4 \tan \delta \right\} \text{ ppm/°C} \quad [9]$$

Equation [9] thus represents our approximation for TCC of amorphous isotropic oxides as a function of tan δ and κ in the range $10 \leq \kappa \leq 100$. It is plotted in Fig. 1 as a function of $\kappa (10 \leq \kappa \leq 30)$ with tan δ as a parameter. To determine the theoretical TCC for a given κ and tan δ, it is only necessary to find the intersection of the TCC curve for the proper tan δ with a vertical line extending from the abscissa at the proper value of κ. In the section on Comparison of Theory and Experiment, TCC values predicted by Eq. [9] are compared to experiment.

Experimental

4500Å β-Ta and Ta-Al films were obtained by d-c, diode sputtering in an argon atmosphere onto Corning 7059 glass slides with thermally oxidized Ta_2O_5 underlays. The cathode configurations used to obtain the various alloy films have been described previously (10, 11). The composition was determined using a spectrophotometric technique (12). Groups of films with average compositions of 52, 42, 36, and 25 a/o Al were processed into capacitors. X-ray determination of the alloy film structures showed that the 25 and 36 a/o Al films exhibited the β-Ta (13) phase, whereas the 42 and 52 a/o Al films were microcrystalline. No measurable amount of bcc phase was detected in any of the alloy films. β-Ta films were obtained from three different sources as indicated in Table I. X-ray diffraction patterns indicated the films were predominantly β-Ta with estimated amounts of bcc of 30, 8 to 10, and 8 to 10% for source 1, 2, and 3, respectively.

* NHT = no heat-treatment.
** κ = 25 for β-Ta_2O_5 and as given in Table II for anodic Ta-Al oxides.
λ = 7.5 ppm/°C for all oxides.

The films were photolithographically etched into a 15 capacitor test pattern (14) (capacitor area = 0.1 cm^2) and then anodized to 200V. β-Ta films were anodized in 0.01% citric acid solution, while the alloy films were anodized in a 1:1 solution of ethylene glycol: oxalic acid. After reaching the prescribed voltage, the films were allowed to soak for 1 hr. However, some films were removed from the electrolyte after a half-hour soak, heat-treated for 1 hr at 250° or 350°C, and then returned to the electrolyte to soak for an additional half hour. Capacitor fabrication was completed by evaporating 200Å NiCr-8000Å Au counterelectrodes through a mechanical mask.

Capacitance and tan δ for capacitors situated in a Delta environmental chamber were measured at 1 kHz on a GR 1615-A capacitance bridge. Typical capacitance density was 0.065 μF/cm^2 for β-Ta capacitors measured between 60° and 85°C. Capacitance densities of alloy capacitors measured between 25° and 65°C are given in Table II. Auxiliary measurements as a function of frequency indicated that there was no significant external series resistance contribution to tan δ at 1 kHz.

Comparison of Theory and Experiment

In this section a comparison is made between the predictions of Eq. [9] and measurements of TCC and tan δ for the anodic oxides of tantalum and tantalum-aluminum alloys. In addition, the experimental results are compared to Harrop and Campbell's expression for TCC in the appropriate range ($\kappa > 2$, $\tan \delta > 0.001$) (8, 9), which is

$$\text{TCC} = \{5.0 \times 10^4 \tan \delta - \lambda\kappa\} \text{ ppm/°C} \quad [10]$$

Table II. Dielectric constant, capacitance density, theoretical intrinsic TCC, and anodization constant of tantalum and tantalum-aluminum alloy anodic oxides

48% Ta-52% Al	0.049	16.7	200	18.5	106

* Ref. (18).

It will be demonstrated that Eq. [9] leads to better agreement with experiment than does the Harrop and Campbell formula.

Equations [9] and [10] are two different approximations to the same theoretical expression, Eq. [1]. They differ only in their prediction of the intrinsic value of TCC. In Eq. [10] the intrinsic TCC is equal to $-\lambda\kappa$ and hence is always negative.

To check the validity of either Eq. [9] or [10] for a particular material, it is necessary to obtain measurements of TCC for different values of tan δ. Generally the range of tan δ values for capacitors fabricated from the same material in the same fashion is quite limited. However, heat-treatments during anodization of β-Ta and Ta-Al films generally increased the tan δ of the resulting oxide as is shown in Table I. The data obtained relative to the variation of TCC and tan δ in β-Ta and Ta-Al films subjected to heat-treatments during anodization allowed the validity of Eq. [9] and [10] to be checked over a reasonable range of values.

A final parameter needed to make theoretical calculations of TCC is the dielectric constant of the material. For β-Ta_2O_5 this has been reported to range from 21.7 (15) to 27 (16, 17) and depends on whether mechanical or optical techniques are used to determine oxide film thickness. For the anodic oxides of Ta-Al, the capacitance density, forming voltage, and anodization constant (18) have been used to calculate κ. The results are given in Table II.

A TCC *vs.* tan δ plot for β-Ta_2O_5 is illustrated in Fig. 2. The straight lines are plots of Eq. [9] for κ = 22 and 27. The experimental points are found to be distributed reasonably well between these lines.

In Fig. 3 TCC predicted by Eq. [9] for the anodic oxides of β-Ta (κ is taken at an intermediate value of 25) and Ta-Al is plotted against the experimental TCC. The straight line represents perfect correlation between theory and experiment. Note that the experimental points are generally, uniformly distributed about this line. In view of the uncertainties in the values of A in Eq. [1] and κ in Eq. [9], it is felt that the validity of the formula is adequately established. The results in Fig. 3 are additionally encouraging because Eq. [9] was derived without the use of data on either Al_2O_3 or Ta_2O_5. The values for TCC predicted by the Harrop and Campbell expression [Eq. (10)] are shown in Table I. Clearly the correlation between experiment and Eq. [10] is not good. The points from Fig. 3 are also included in Table I.

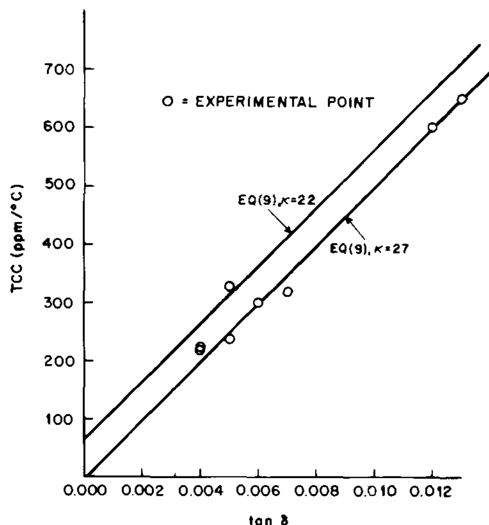

Fig. 2. TCC *vs.* tan δ for β-Ta_2O_5

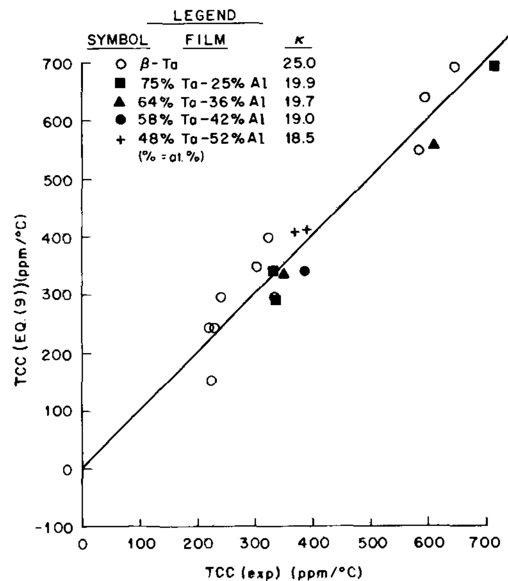

Fig. 3. TCC as calculated from Eq. [9] *vs.* TCC experimental

The intrinsic (tan δ = 0) values of TCC predicted by Eq. [9] for the materials studies are all positive and are presented in Table II. Note that they never exceed 106 ppm/°C. On the other hand the experimental values of TCC never fall below 220 ppm/°C. This indicates that the tan δ contribution to TCC is predominant for both β-Ta and Ta-Al anodic oxides and implies that changes in material processing steps which reduce tan δ will reduce TCC as well.

Crystal Growth from the Melt under Destabilizing Thermal Gradients

K. M. Kim, A. F. Witt,* and H. C. Gatos*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Direct time correspondence between crystal growth behavior and the thermal characteristics of the melt under destabilizing gradients was established by means of "time markers" which were introduced into the growing crystals and simultaneously registered on the continuous recording of the thermal behavior of the melt. Employing Te-doped InSb, it was found that as solidification progressed, the melt exhibited successively turbulent convection, oscillatory thermal instabilities, and, finally, thermal stability. During turbulent convection, the crystals underwent pronounced transient back-melting and the average microscopic growth rate was found to be independent of, and about 20 times greater than, the average macroscopic growth rate; this microscopic growth rate was controlled by the convection characteristics of the melt and the thermal gradients in the solid. With the onset of oscillatory thermal instabilities, back-melting became less pronounced and then ceased. In this region the average microscopic and macroscopic growth rates were equal and the crystals exhibited fluctuations in dopant concentration with a periodicity identical to that of the thermal oscillations in the melt. Finally, under stabilized thermal conditions, the microscopic and macroscopic growth rates were identical and no localized fluctuations in dopant concentration could be detected. The Rayleigh numbers of the melt during a growth experiment ranged from 3×10^5 to 0. In view of the fact that the vertical thermal gradient changed only by a factor of about two during the entire growth, the wide range of Rayleigh numbers was the result of the changes in melt height. In the turbulent convection region, the Rayleigh numbers ranged from about 3×10^5 to about 4×10^3, in the oscillatory region from 3×10^3 to 2×10^3, and in the region of thermal stability from 10^3 to 0.

Single crystals grown from the melt under destabilizing gradients, as is the case of Czochralski-type arrangements, usually exhibit nonsteady-state growth characteristics (1) and inhomogeneous dopant segregation (2). This behavior has been attributed to temperature changes in the melt resulting from fluid dynamic effects associated with destabilizing thermal gradients (3). Most melt-grown single crystals exhibit in addition, other types of striations (dopant heterogeneities) which could be attributed to various origins, such as rotation in the presence of thermal asymmetry, to vibration, to deficient pulling mechanisms, and others. The nature of these heterogeneities has been extensively discussed in the literature (1). In this investigation the experimental conditions were such that none of the above-mentioned striations could occur and all dopant heterogeneities observed could be attributed to temperature variations in the melt. Theoretical models predict that, for a given fluid system, thermal instability may lead to either turbulent convection or thermal oscillations (4) depending on the acting forces and geometric and thermal configuration of the system. Both types of instabilities have been observed and their transient character has been studied primarily by varying the thermal gradients under fixed geometric conditions (5). A limited number of thermo-hydrodynamic studies in actual growth systems with horizontal and vertical arrangements have been carried out in the same way (6). Although impurity heterogeneities in crystals have been attributed to thermal fluctuations in the melt (7) (which lead to changes in the microscopic growth rate and thus to changes in the effective dopant segregation), their unambiguous cause and effect relationship has as yet not been established.

In view of the fact that the melt height changes continuously during crystal growth and in view of the fourth power dependence of the Rayleigh number on the melt height (12), the present work was undertaken to study the thermal behavior of the melt as its height decreases continuously during actual crystal growth. Furthermore, the thermal behavior of the melt and its changes were directly correlated with growth characteristics including interface morphology, microscopic growth rate, and dopant segregation in the resulting crystal.

Experimental Apparatus and Procedure

The apparatus used in the present investigation is shown in Fig. 1. Polycrystalline InSb doped with Te (1×10^{18} cm^{-3}) was placed into the inner quartz tube, 1.33 cm ID and 10 cm long (referred to as the growth tube). This tube had a graphite insert at the bottom capable of accommodating the volume expansion during solidification and was mounted on a Lava pedestal. A 3 cm long InSb seed of (111) orientation was machined, etched to a diameter of 1.3 cm, and mounted to a water-cooled seed holder assembly which was then positioned in the apparatus and properly aligned. An outer quartz tube provided for a hydrogen ambient at about 1 mm Hg overpressure. A tube furnace 12 cm long, operated with proportional power control, was located coaxially around the outer tube. After flushing with hydrogen, the polycrystalline ingot was heated to above its melting point. Subsequently, the seed was lowered and after thermal equilibration brought in contact with the melt. The desired thermal gradient along the growth direction was established by adjusting the vertical position of the furnace and the flow of the coolant in the seed holder. Crystal growth was initiated and allowed to proceed at the desired rate by means of controlled power reduction. A linear decrease of the furnace temperature was obtained through a steadily increasing bucking voltage (motor-driven servosystem) in series with the output of the controlling thermocouple which was located in the

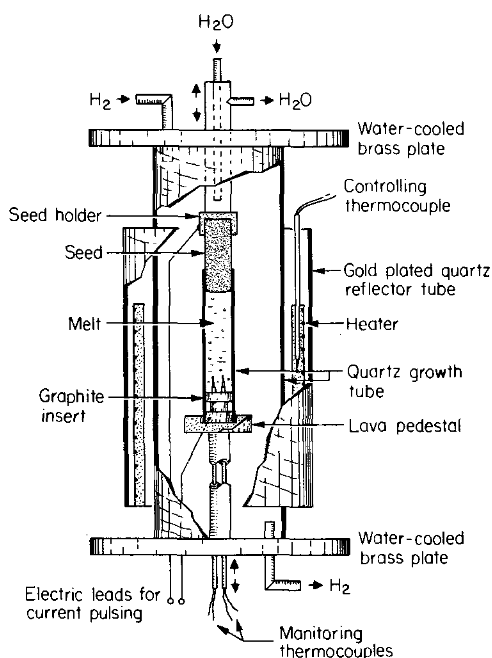

Fig. 1. Schematic diagram of the apparatus used for the study of crystal growth under destabilizing thermal gradients.

furnace. The experiments were carried out with a linear furnace temperature decrease of 0.27°C/min resulting in an average macroscopic growth rate of 2 μm/sec. Temperature measurements in the melt were obtained with two Chromel-Alumel thermocouples (made of 75 μm diameter wire) each mounted in a 1 mm ceramic tube and inserted through the bottom into the growth tube. The thermocouples were movable and the junctions could be positioned at any desired height in the melt during a growth experiment. The bare sensing junctions were protected with a thin insulating layer of "Insa-Lute" and showed high thermal response.

To permit the transmission of controlled current pulses across the crystal melt interface for introducing "time markers" and "rate striations" during growth, electrical contacts were made to the insulated seed holder and the graphite block in the bottom of the melt. Current pulses of the desired frequency and duration (ranging in the present experiments from 10 to 50 msec) were obtained from a function generator and programmable d-c power supply (8). During growth, each current pulse across the crystal-melt interface resulted in a readily detectable time marker in the crystal. Furthermore, each pulse was simultaneously registered by the temperature monitoring thermocouples in the melt and recorded as an instantaneous pen deflection on the temperature tracing. Thus, through the time markers any segment of the grown crystal could be correlated in time with the measured thermal fluctuations in the melt. A schematic diagram of the circuitry and the components used is shown in Fig. 2.

After each growth experiment, the crystal was cut along the <111> growth axis to expose a (211) plane. This plane was polished and appropriately etched (9) to reveal the growth and segregation characteristics. In most instances the crystals grown were single for a length of 10 to 15 mm and twinned for the remaining length. Since twinning does not interfere with the analysis of the growth characteristics, no attempt was made to eliminate it.

Experimental Results and Discussion

Thermal characterization of the melt.—In view of the dependence of the thermo-hydrodynamic behavior of fluids on thermal gradients (6), a series of experiments

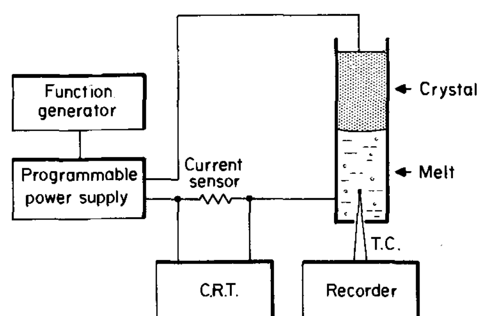

Fig. 2. Block diagram of the electronic arrangement for introducing time markers into the growing crystal and on the temperature recording.

was conducted in which the vertical thermal gradients in the melt were determined as a function of melt height. The measurements were performed under growth conditions by employing a thermocouple introduced into the melt through the bottom of the growth tube. This thermocouple could be moved vertically in the melt, as desired. In order to determine the vertical thermal gradients at various melt heights, crystal growth was arrested at predetermined intervals. At each arrest, the height of the melt level was determined and the temperature along the vertical growth direction up to the crystal-melt interface measured.

The results are shown in Fig. 3. It can be seen that the gradients were essentially constant for each given crystal-melt interface position (melt height). Their values decreased from 19°C/cm at a melt height of 33 mm to 8°C/cm at a melt height of 12 mm. Thermal fluctuations in the melt were most pronounced at the original growth interface position (33 mm melt height) and decreased discontinuously with decreasing melt height (see Fig. 4b).

No attempt was made to determine the prevailing lateral thermal gradients. Actually, in the presence of thermal fluctuations exceeding ±10°C, at melt heights greater than 15 mm, such measurements would be of no particular significance; on the other hand, at melt heights ranging from 15 mm to zero, the growth interface was essentially horizontal (with only a slight curvature upward at the periphery), thus indicating that the prevailing lateral gradients were rather small.

It is of interest to point out that the thermal gradients and their changes with melt height observed under

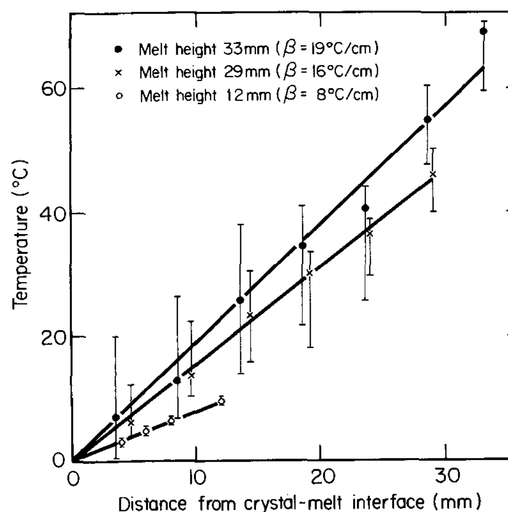

Fig. 3. Vertical temperature distribution in the melt for different crystal-melt interface positions (melt heights). The vertical bars represent the magnitude of the temperature fluctuations. The zero point in temperature corresponds to the melting point of InSb, 525°C.

the present conditions are of the same magnitude as those encountered in Czochralski-type systems.

Relationship between thermal characteristics in the melt and crystal growth on the macroscale.—The following experiment was designed to study the cause and effect relationship between the macroscopic growth behavior and the concurrent thermal conditions in the melt. An InSb crystal was grown at an average "macroscopic" growth rate of 2 μm/sec. This growth rate was determined from the time required (at the indicated rate of furnace temperature decrease) to displace the crystal-melt interface by 30 mm (original melt height) in the downward direction. The thermal conditions prevailing during growth in the melt were continuously monitored by two stationary thermocouples (4 mm apart) located at the same height, 5 mm from the bottom of the melt. The thermocouple outputs were recorded at slow speed and with low sensitivity to permit comparison with the grown crystal on a macroscale. An etched section of the crystal cut along its growth axis and the corresponding thermal history of the melt are shown in Fig. 4. The temperature recordings (Fig. 4b) indicate three distinct regions with fundamentally different hydrodynamic behavior. On the top region, corresponding to melt heights ranging from 30 mm to about 15 mm, and with thermal gradients from 18°C/cm to about 12°C/cm, pronounced random temperature fluctuations of about ±10°C were present. The mean temperature of these fluctuations is modulated with an average period of about 3 min and is phase shifted by about 180° in the two tracings. This thermal behavior is indicative of turbulent convection in the melt.

With continuing growth, the amplitude of the thermal fluctuations decreases sharply and minor perturbations of apparently constant frequency persist over a narrow region. In this region, (as is shown in detail below), the melt exhibits periodic thermal oscillations. The last portion of the temperature recordings shows only gradual temperature changes and no temperature fluctuations, indicating a high degree of thermal stability.

Thus, under the present conditions, solidification occurs first under the influence of turbulent convection, then under oscillatory thermal instability, and finally under thermal stability.

The growth and segregation behavior of the crystal, as revealed by high resolution etching, are shown in Fig. 4a. The effects of the changing thermal conditions in the melt are clearly visible; three distinctly different regions can readily be identified. On the top region, growth (to a crystal length of about 15 mm) is char-

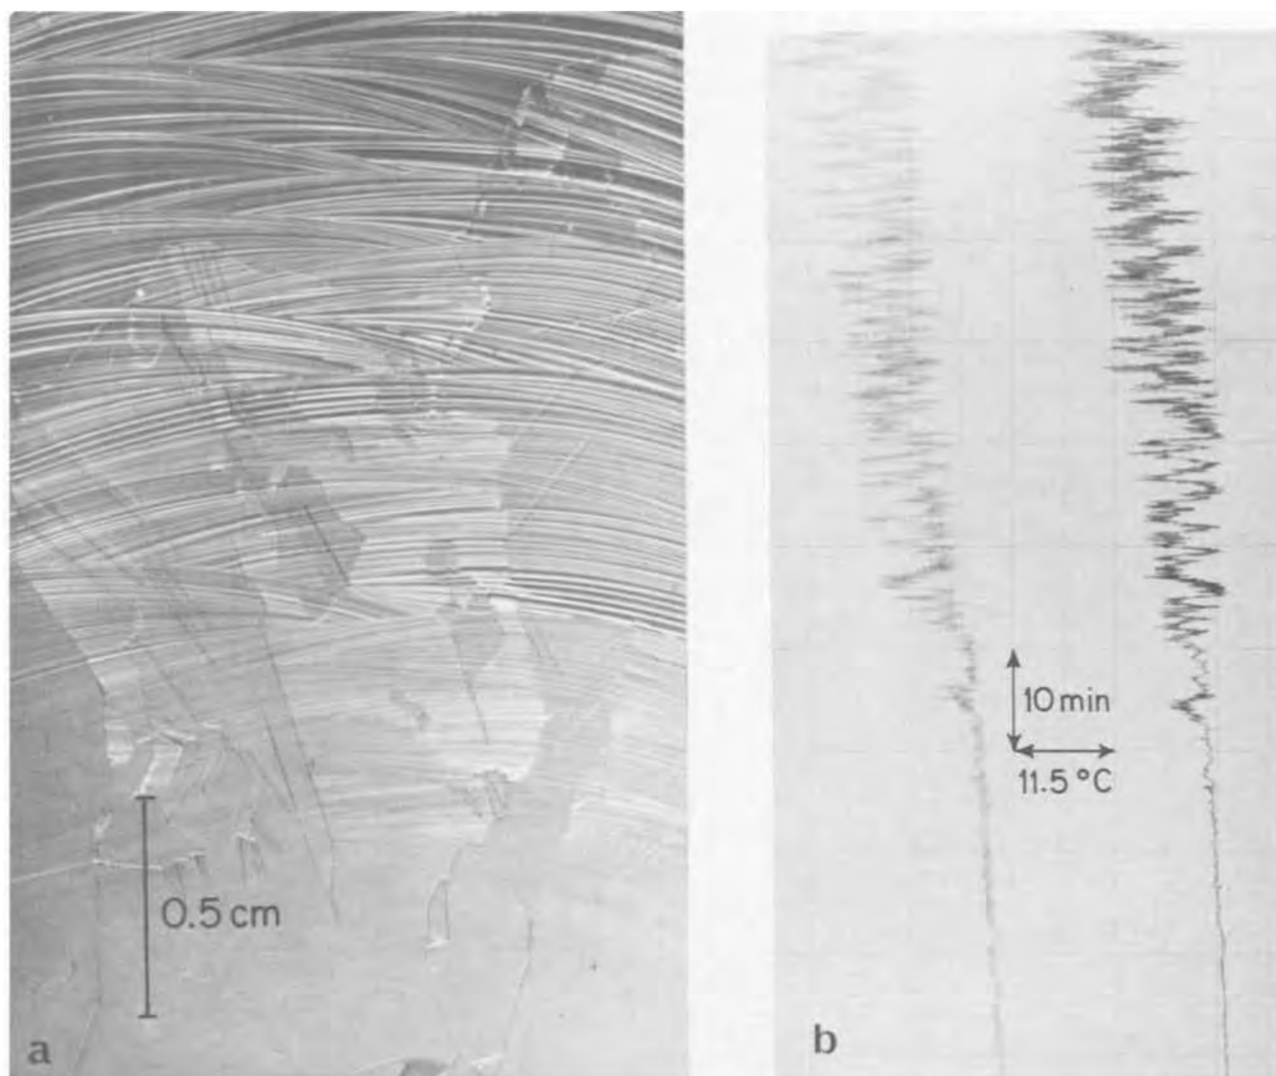

Fig. 4. (a) Photograph of etched crystal cut along the growth axis. The decreasing complexity of impurity striations from top to bottom reflects the thermo-hydrodynamic transition of the melt from turbulent convection to thermal stability. Note that the dopant striations are continuous across all twin boundaries indicating that twinning does not influence the over-all growth characteristics. (b) Recording of the temperature in the melt during the growth of the crystal depicted in Fig. 4(a). The two thermocouples were 4 mm apart and 5 mm from the bottom of the melt.

acterized by pronounced transient remelting (caused by turbulent convection in the melt). The clearly visible remelt lines indicate that the convective pattern is continuously changing with a frequency corresponding to that of the modulated mean temperature fluctuations (see below). The remelt lines further reflect complex changes in the growth interface morphology. With continuing growth, the intensity of dopant heterogeneities decreases abruptly and back-melting no longer takes place; the crystal exhibits a rather flat growth interface and only closely spaced dopant heterogeneities. The intensity of the dopant heterogeneities decreases continuously until in the bottom region (thermal stability region), homogeneous dopant segregation is encountered.

A detailed analysis of the three regions on a microscale is given below.

Direct time correspondence between crystal growth and the thermal characteristics of the melt on a microscale.—In order to study the relationship between the thermal melt-characteristics and crystal growth on a microscale, the melt behavior was monitored by two thermocouples, maintained (by periodic repositioning) at a distance of 3-6 mm from the advancing crystal-melt interface. The thermocouple signals were continuously recorded at high sensitivity (1 mV full scale) and at high speed (1 in./min).

Direct correspondence in time between the thermal behavior of the melt and crystal growth was obtained as indicated, by means of the time markers which were incorporated in the crystal during growth and simultaneously registered through the monitoring thermocouples. In this way, any point on a longitudinal section of the crystal could be directly related to the thermal behavior of the melt recorded at the time of growth.

The results of the growth behavior on a microscale are presented in three sections corresponding to the growth regions previously identified on a macroscale. These sections are presented in order of increasing complexity beginning with the region of thermal stability.

Growth under thermal stability in the melt.—Thermal stability in the melt during growth prevailed at melt heights ranging from about 10 mm to zero. A representative section of the grown crystal (about 6 mm from the end) together with the corresponding thermal recording is shown in Fig. 5. The photomicrograph of the etched specimen of Fig. 5a clearly shows the time markers introduced during growth by current pulses (15A) of 50 msec duration at intervals of 21.0 sec. To obtain a reference point for establishing an unambiguous direct time correspondence between the time markers in the crystal and on the temperature

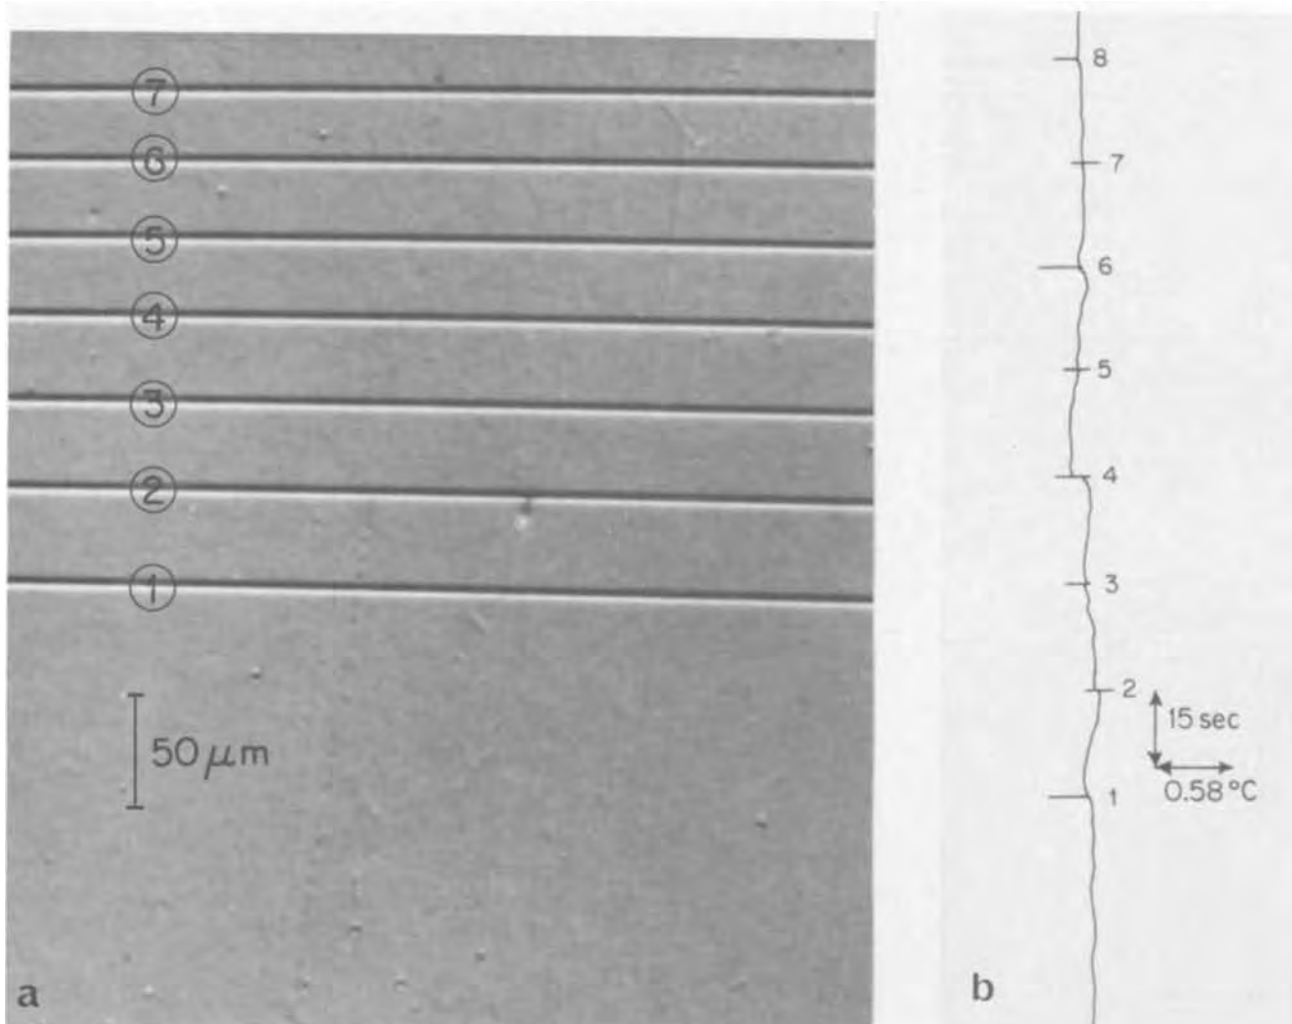

Fig. 5. (a) Section of crystal (cut along the growth axis) grown under thermal stability. No dopant heterogeneities can be seen. The horizontal lines (time markers) resulted from the current pulses applied at intervals of 21 sec. Line 1 corresponds to the last current pulse and serves as time reference. (b) Recording of the temperature in the melt during growth of the crystal segment depicted in Fig. 5(a). The thermocouple was located about 5 mm from the growth interface. The pen deflections are caused by the current pulses and allow establishing direct time correspondence with the grown crystal.

recording, the last current pulse was applied prior to the termination of growth. Thus, the last time marker in the crystal could be readily identified and was used as the absolute time reference.[1]

The temperature recording containing the last pen deflection corresponding to the last current pulse, is shown in Fig. 5b. It is seen that no thermal perturbations were present and that the temperature was stable to within ±0.1°C. The uniform appearance of the etched sample clearly indicates that the dopant distribution is homogeneous.

Each time marker was formed across the entire crystal-melt interface within the time duration of the current pulse (50 msec in the present case). Consequently, the time markers delineate the growth interface morphology at the time of their formation. The time markers in Fig. 5a show that the growth interface in the depicted section was essentially flat under conditions of thermal stability. The average microscopic growth rate calculated from the frequency and the spacing of the time markers is 1.8 μm/sec for the depicted region.

Growth under oscillatory thermal instability.—The condition of thermal stability encountered at small melt heights was preceded by oscillatory thermal instability at melt heights ranging from 15 to 10 mm. Figure 6 shows the last section of the crystal grown under temperature oscillations (at melt height of about 11 mm) together with the corresponding temperature recording. Direct time correspondence between the temperature recording and the depicted crystal was achieved by identifying the corresponding time markers.

It is seen in the photomicrograph of Fig. 6a that thermal oscillations result in faint lines (dopant heterogeneities) parallel to the time markers. The repetition rate of the dopant heterogeneities in the crystal (determined from the spacing of successive time markers which appear 21.0 sec apart) is 0.38/sec and, thus, identical to the frequency of the concurrent temperature oscillations (Fig. 6b).

It is of interest to note that the dopant heterogeneities caused by thermal oscillations are at all times continuous across the entire crystal and exactly parallel to the slightly curved time markers. Each time marker is formed across the growth interface with an interval of 50 msec which is significantly smaller than the period of the thermal oscillations (2.6 sec). Since each dopant striation is continuous and at a constant distance from the time markers across the entire crystal, the thermal perturbation must be "in phase" at all times across the crystal-melt interface.

[1] It should be pointed out that current pulsing (introduction of time markers) in no way alters the over-all solidification characteristics.

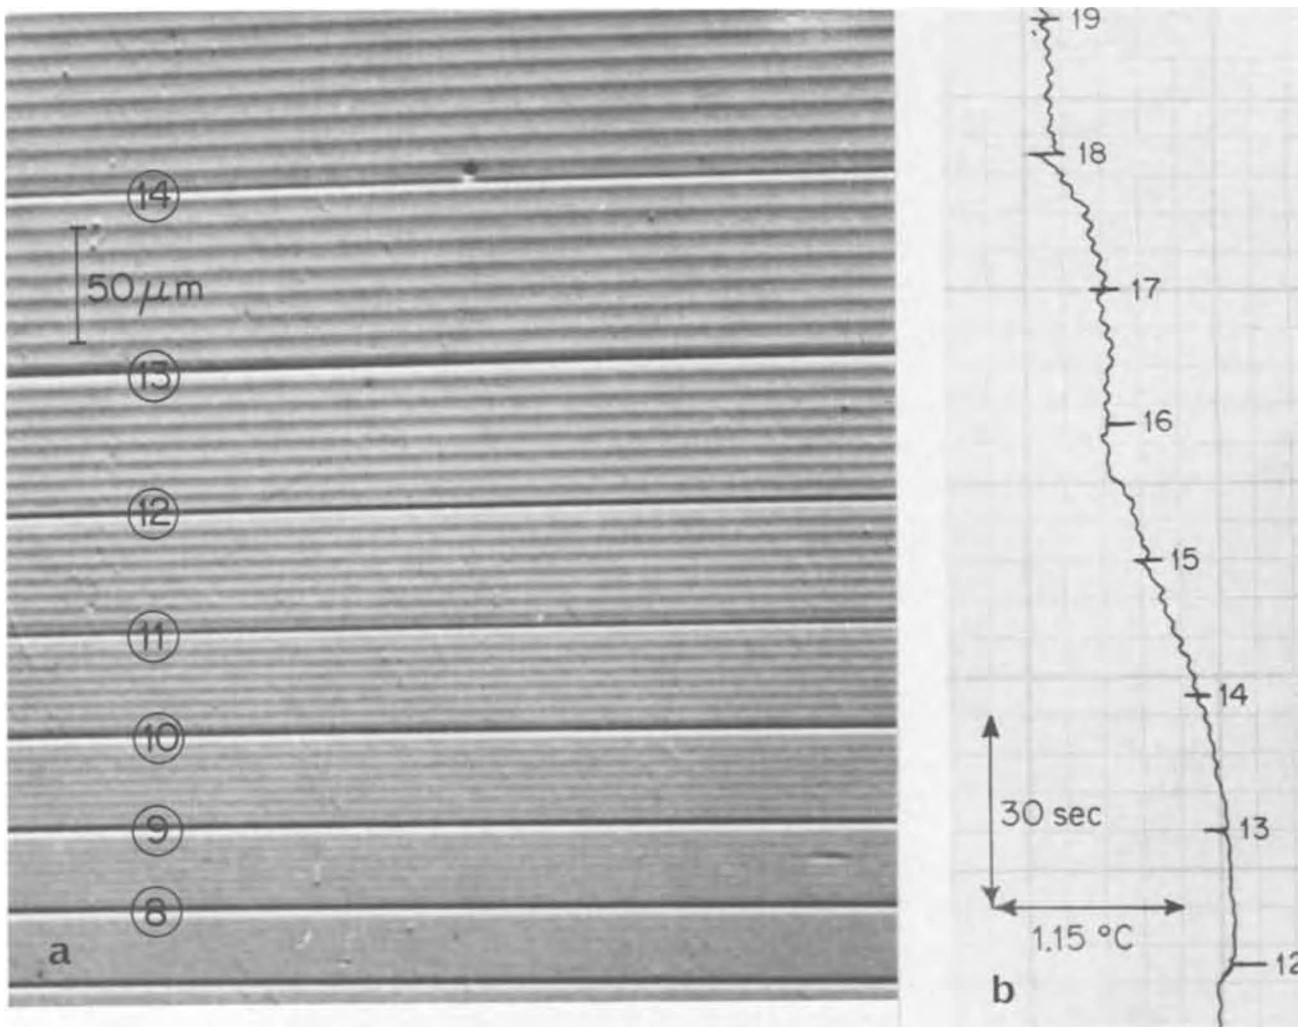

Fig. 6. (a) Section of crystal grown in the presence of thermal oscillations in the melt. The dopant heterogeneities caused by the thermal oscillations are clearly visible. Note that their spacing decreases from top to bottom. The time markers make it possible to establish that the frequency of the thermal perturbations is constant over the depicted region (the number of dopant heterogeneities between successive time markers is constant) and that the microscopic growth rate decreases from top to bottom (the spacing of successive time markers decreases). (b) Recording of the temperature in the melt during growth of the crystal segment depicted in Fig. 6(a).

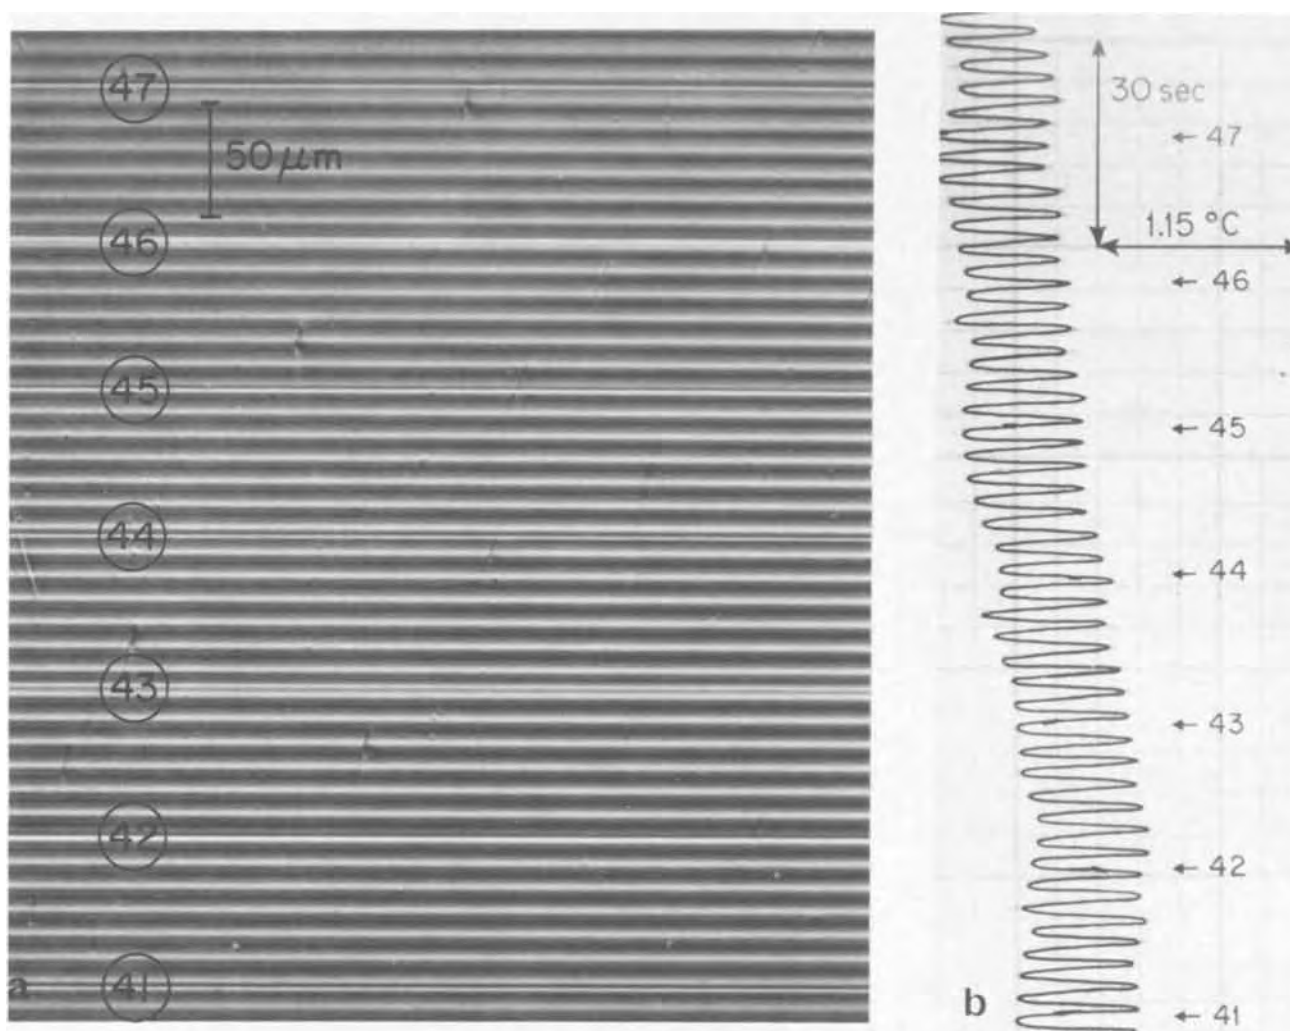

Fig. 7. (a) Section of crystal grown in the presence of thermal oscillations in the melt. Comparison with Fig. 6(a) shows that the dopant heterogeneities are here more pronounced, their frequency is decreased, and the microscopic growth rate is constant. Incipient remelting can be observed. (b) Recording of the temperature in the melt during growth of the crystal sement depicted in Fig. 7(a).

As seen in Fig. 6a, the frequency of the periodic dopant heterogeneities is constant over the depicted area. Their "intensity" decreases with decreasing melt height and can no longer be observed between the time markers 7 and 8. At the same time, the amplitude of the corresponding temperature oscillations decreases continuously (from its original value of $\pm 0.1°C$) with decreasing melt height and becomes zero between the time markers 13 and 14. It appears that the striations between the time markers 14 and 8 are caused by temperature oscillations which lie below the detection limit of the temperature sensors ($\pm 0.01°C$). Alternatively, it is possible that the temperature fluctuations are attenuated with distance from the growth interface, although other investigations (10) have found no evidence of attenuation in oscillatory thermal instabilities. In either case, these results demonstrate the extreme sensitivity of dopant segregation to small temperature fluctuations and the high resolving power of chemical etching for dopant heterogeneities.

At melt levels ranging from about 15 to 12 mm, the frequency of the thermal oscillations was found to be 0.29/sec and their amplitude higher but constant over a wide range. A representative photomicrograph and the corresponding temperature recording are shown in Fig. 7. Here also the frequency of the periodic dopant heterogeneities is identical with that of the thermal oscillations but their intensity indicates incipient remelting due to the higher amplitude of the thermal oscillations. The frequency change of the thermal oscillations from 0.29/sec to 0.38/sec occurred abruptly within two time markers.

Growth under turbulent convection.—At melt heights ranging from 30 mm (start of growth) to about 20 mm, thermal instability appears in the form of random temperature fluctuations (Fig. 8b) with no discernable periodicity and widely varying amplitudes assuming peak values in excess of $\pm 5°C$. These fluctuations of short duration are superimposed to pronounced variations ($\sim \pm 10°C$) of the mean melt temperature which occur at relatively longer periods ranging from 2 to 4 min. The tracings of the two monitoring thermocouples (positioned symmetrically about the axis of the melt at equal height and 4 mm apart) indicate that the variations of the mean temperature are phase shifted by 180°; *i.e.*, while the one thermocouple registers a mean temperature "high" the other registers a mean temperature "low." There is however no apparent amplitude or phase relationship between the high frequency temperature fluctuations of the two temperature tracings.

The effects of this thermal behavior of the melt on the crystal growth characteristics and dopant segregation are shown in Fig. 8a. The pronounced segregation heterogeneities, identified as "remelt" striations, indicate a complex pattern of transient back-melting. The morphology of the intersecting remelt striations shows that growth occurred alternatingly on the left and right side of the crystal with a period of about 3 min,

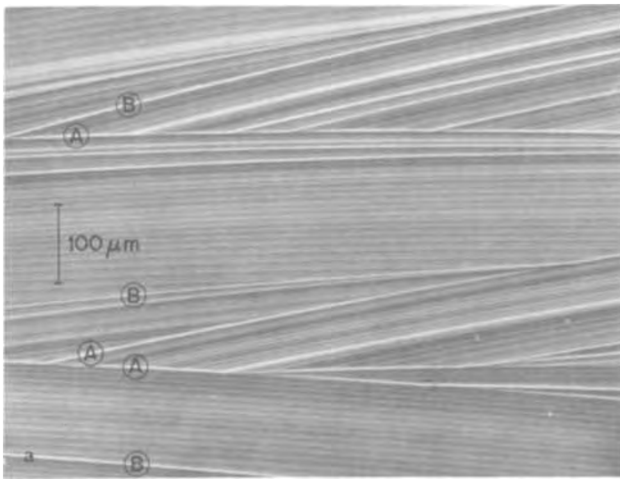

Fig. 8(a). Section of crystal grown in the presence of turbulent convection in the melt. Alternating regrowth and remelting on the left-hand side and the right-hand side are reflected in the morphology of the remelt striations (A). Brief remelting within the regrowth regions is evident from remelt striations (B). The faint lines throughout the depicted region are rate striations.

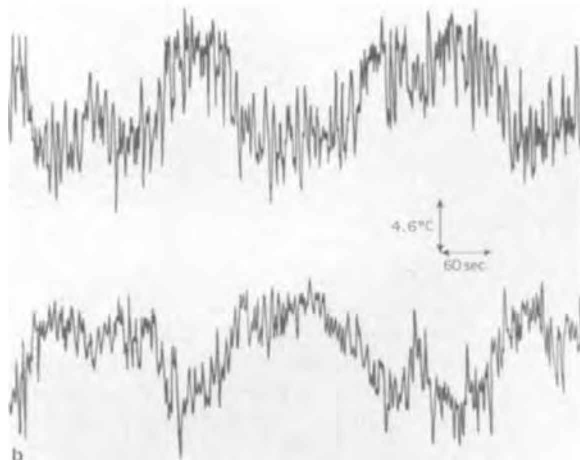

Fig. 8(b). Recording of the temperature in the melt during growth of the crystal segment depicted in Fig. 8(a). Note that the mean temperature variation of the melt, as recorded by two thermocouples positioned symmetrically about the axis of the melt, is phase shifted (see text).

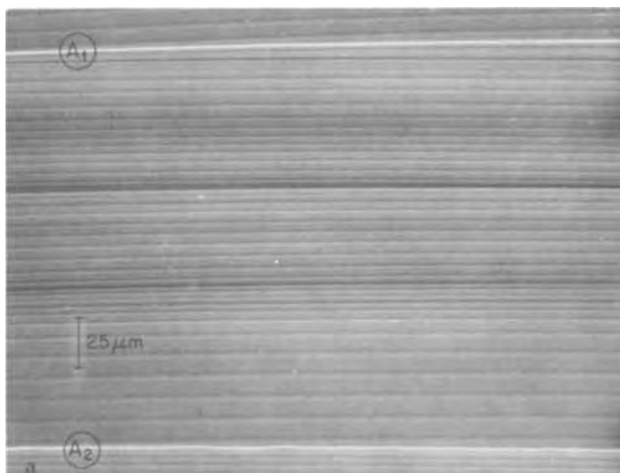
corresponding to that of the mean temperature variations.

To permit the determination of the microscopic growth characteristics associated with this thermal behavior of the melt, rate striations with a frequency of 5/sec were introduced during growth (for a period of 5 min) at a melt height of approximately 25 mm, by applying current pulses (10A) of 20 msec duration. Representative microscopic growth behavior between two successive remelt striations is shown in the photomicrograph of Fig. 9a. The microscopic growth rates for this area were calculated from the known frequency and the measured spacing of the rate striations and are shown in Fig. 9b. It can be seen that the growth rate is irregular and reaches peak values in excess of 55 μm/sec. For the depicted region (between A_1 and A_2) the average microscopic growth rate is found to be about 28 μm/sec. Over a larger crystal region the average growth rate was found to be about 38 μm/sec and thus about 20 times greater than the "average macroscopic growth rate." This striking discrepancy between microscopic and macroscopic rates was found throughout the crystal region grown under extensive transient back-melting.

The growth and segregation characteristics in this region can be explained from the morphology of the remelt striations, the microscopic growth rates, and the recorded thermal behavior of the melt. During each interval of increasing mean melt temperature (see Fig. 8b), extensive remelting takes place and the crystal-melt interface recesses. The terminal remelt growth interface, delineated by a remelt striation, is always concave and not normal to the growth direction. This morphology differs considerably from that expected under the prevailing vertical and horizontal thermal gradients. It clearly reflects the presence of pronounced convective melt flow; *i.e.*, melt of higher temperature flows upward on one side of the growth tube while melt of lower temperature flows downward on the other side. This finding is consistent with the phase shift of the mean melt temperature variations registered by the monitoring thermocouples. Alternating remelting (and growth) on the left and right side of the crystal is attributed to a continuous rotational displacement of the convective flow about the vertical axis of the melt (11). Thus, upon a 360° rotation of the flow pattern ("shear flow"), the major portion of the region regrown during the period of decreasing mean melt temperature at this part of the interface is again remelted and only a small portion remains in the crystal.

The rate striations reveal clearly that, at the portion of the crystal-melt interface subjected to a decreasing



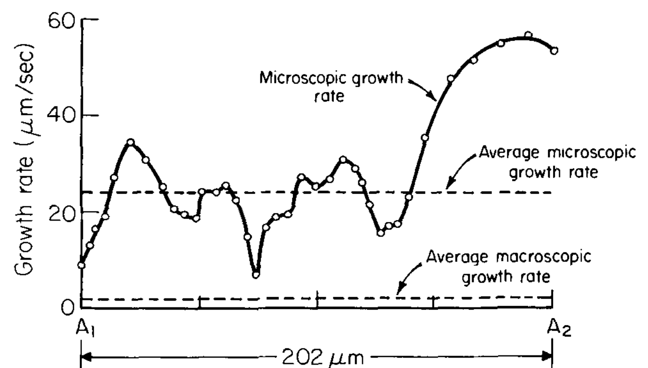


Fig. 9. (a) Photomicrograph of region regrown under turbulent convection in the melt. The rate striations introduced at a rate of 5/sec show pronounced variations of the microscopic growth rate within successive remelt lines. (b) Microscopic growth rates, as a function of time within remelt lines (A1) and (A2) of Fig. 9(a) as determined from the spacing and frequency of the rate striations.

mean melt temperature, the crystal undergoes accelerated growth. Its rate is unrelated to the average macroscopic growth rate imposed by the power reduction. The microscopic growth rate is indeed controlled by the rate of the mean melt temperature decrease (associated with the low frequency temperature fluctuations, shown in Fig. 8b) and is modulated by the superimposed temperature fluctuations; in fact, for pronounced fluctuations, brief remelting takes place within the regrowth period.

With continuing growth, the peak values of the mean melt temperature variations decreased and appeared at longer intervals. At melt heights of less than about 18 mm, mean melt temperature variations are absent and the amplitude of the random temperature fluctuations is considerably decreased. Under these thermal conditions, random and intermittent backmelting of short duration is observed. With a further decrease in melt height the temperature fluctuations continue to exhibit a varying amplitude but assume distinct and constant periodicity (Fig. 10b). In this region, remelt striations are irregularly spaced indicating irregular growth rate modulations associated with the varying amplitude of the periodic thermal fluctuations (Fig. 10a). All dopant striations become continuous across the crystal, indicating that the thermal perturbations are "in phase" across the entire growth interface.

In this growth period, it is not possible to use time markers for establishing time correspondence between the recorded temperature oscillations and the dopant striations because some of the current pulses coincide with remelting and do not form time markers in the crystal. However, since each recorded temperature fluctuation results in a continuous striation, it becomes possible to establish time correspondence by counting the striations and the temperature fluctuations starting with the first time marker after transient remelting ceases.

Thermo-hydrodynamic behavior of the melt.—The present results indicate that under destabilizing thermal gradients, the thermo-hydrodynamics of the melt control the growth and dopant segregation behavior. They further show that turbulent convection, oscillatory instability, and thermal stability are successively present during solidification. Since the vertical thermal gradients did not change significantly during the entire solidification and were virtually constant within each hydrodynamic transition region, it is suggested that the continuous decrease in melt height is responsible for the observed changes in thermo-hydrodynamic behavior of the melt.

The Rayleigh number (12), R, which is often used as a criterion for hydrodynamic behavior, exhibits linear dependence on the vertical thermal gradient, β, and fourth power dependence on the melt height, h

$$R = \frac{g\alpha\beta h^4}{\nu\kappa}$$

where g is the gravitational constant, α is the coefficient of volume expansion, ν the kinematic viscosity, and κ is the thermal diffusivity. Using the values $\alpha = 0.95 \times 10^{-4}/°C$ (13), $\nu = 3.02 \times 10^{-3}$ cm²/sec (13),

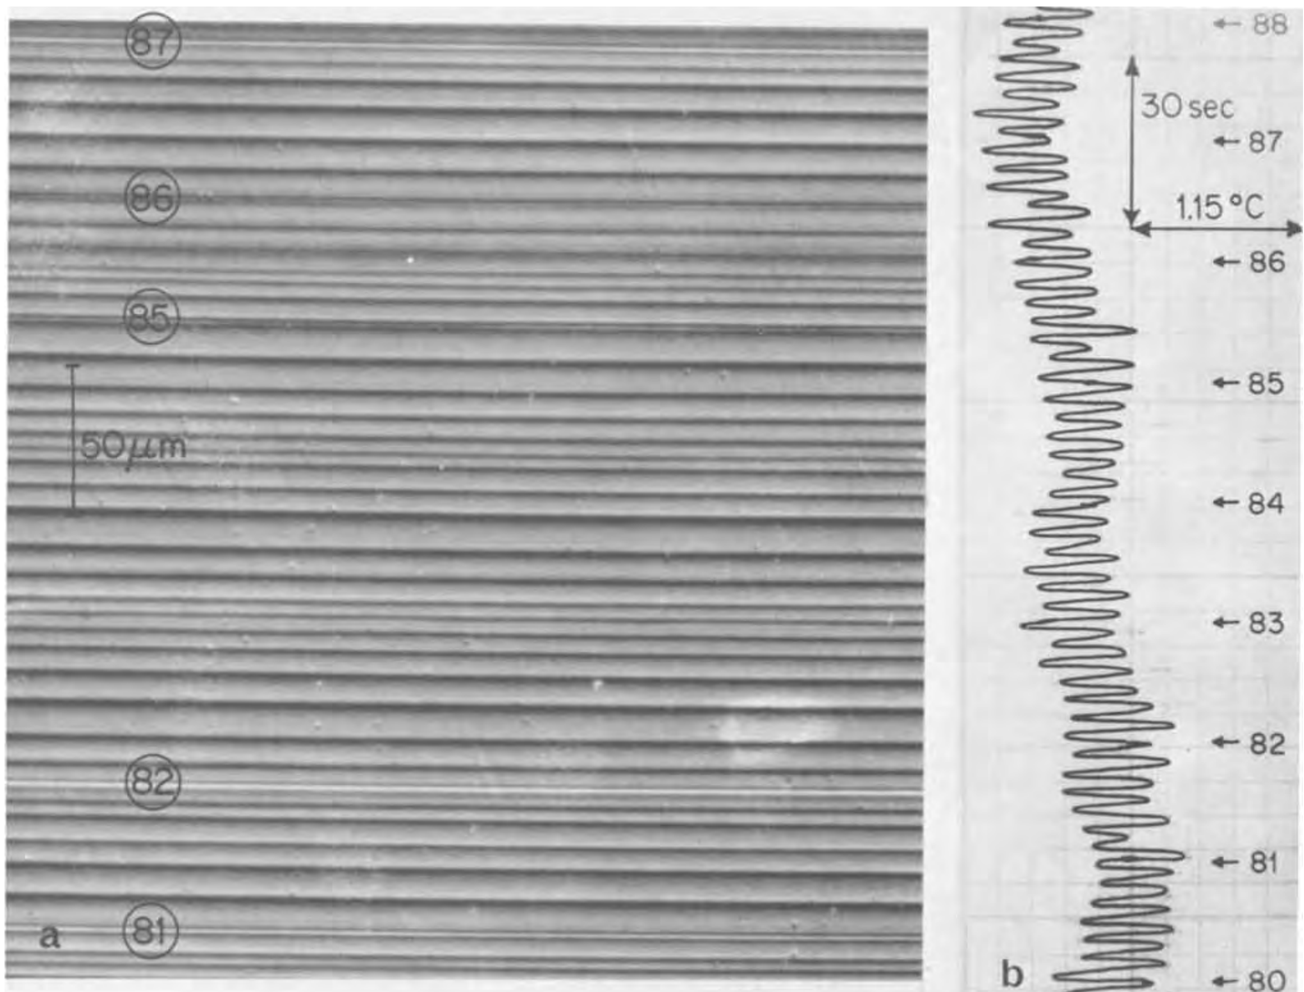

Fig. 10. (a) Photomicrograph of region grown after turbulent convection in the melt ceased and temperature fluctuations of varying amplitude but constant frequency prevailed. Intermittent remelting prevented the appearance of some of the time markers. (b) Recording of the temperature in the melt during growth of the crystal segment depicted in Fig. 10(a).

$\kappa = 0.2$ cm²/sec (14), and the experimentally determined values of β and h, it is found that for the reported experiments, R ranges from about 3×10^5, at the start of solidification, to zero at the end. The Rayleigh numbers characterizing the three regions of different thermo-hydrodynamic behavior, discussed above, are about 3×10^5 to about 4×10^3 for turbulent convection, 3×10^3 to 2×10^3 for oscillatory thermal instability, and 10^3 to 0 for thermal stability.

It is of interest to note that the transition from thermal instability to stability occurs at $R \cong 2 \times 10^3$ which is surprisingly close to the value of 1700 predicted for the onset of convective instability from theoretical considerations (15) where the assumed boundary conditions differ substantially from those in the present experiments. It is furthermore noteworthy that oscillatory thermal instability rather than a stationary pattern of convection in the form of Bénard cells (16) is observed upon the transition from thermal stability to thermal instability. Oscillatory thermal instability has been predicted (17) and has been found under destabilizing thermal gradients in the presence of transverse magnetic fields and/or rotation. More recently, temperature oscillations have also been observed in the absence of stabilizing forces and their origin has been attributed to horizontal thermal gradients (18). The present findings appears to be consistent with this point of view. Through the use of time markers it was shown that the temperature oscillations are "in phase" across the entire growth interface. This finding is of particular significance since the interface was detectably curved and appreciably deformed at twin boundaries. The present results gave no indication of a phase shift between the effects of the thermal perturbations at the steadily advancing growth interface and the thermal perturbations measured by the stationary thermocouple in the melt. Furthermore, it should be noted that no detectable phase shift was observed between the signals (oscillations) at the two monitoring thermocouples.

The presence of turbulent convection at large melt heights was confirmed through the growth and segregation behavior as well as through the recorded thermal behavior of the melt. Segregation effects in the grown crystal suggest further that, under the influence of horizontal gradients, the convective flow pattern undergoes a continuous rotational displacement along the axis of the melt. With decreasing melt height (decreasing Rayleigh number), convective flow gradually ceases and the random temperature fluctuations change first to periodic fluctuations of varying amplitude and ultimately to oscillations of constant frequency and amplitude. The present findings show clearly that time markers are not only valuable for investigating the microscopic growth behavior, but that they also constitute a powerful tool in establishing reference points in thermo-hydrodynamic studies.

The present study demonstrates the paramount importance of thermo-hydrodynamics in crystal growth, which has been widely recognized and has become the subject of numerous investigations in recent years. The approach used in this study relates directly the hydrodynamic behavior of the melt to crystal growth and segregation characteristics. It is hoped that it will serve to bridge the existing gap between theoretical and experimental investigations.

Anodic Oxide Hydration Measured by Ion Probe Mass Spectrometry

G. A. Dorsey, Jr.

Kaiser Aluminum & Chemical Corporation, Center for Technology, Pleasanton, California 94566

ABSTRACT

The water content of barrier layer anodic alumina films was measured using the ion probe mass spectrometer: a method of sputtered ion mass analysis. Film thicknesses ranged from 100 to 2000Å, with the oxides left intact on the basis metal during the analysis. The analytical procedure was first calibrated against standard samples of aluminum trihydroxides and monohydroxides. Then data were obtained for different thicknesses of boric-acid-anodized barrier layer oxides. The various aspects of the fragmentation patterns that were obtained are suggestive of a trihydroxide composition. Representative spectra are included, to illustrate the use of this method of surface analysis.

The ion probe mass spectrometer is a recent innovation for the inorganic analysis of thin films and other surface-related phenomena. It is also an equally useful instrument for the analysis of bulk inorganic materials, yielding a measure of compositional changes that take place as a function of the increased distance of beam penetration below the outer surface of the sample.

The sputter ion source technique was first developed by Herzog and Viehbock (1) but did not come into much use until 1966. Socha (2) recently reviewed the instrument and its related theory while Evens and Pemsler (3) have been among the many investigators to employ the technique; in this case, to the examination of tantala films.

The unique feature of the ion probe is in its use of an energetic plasma beam of accelerated ions: positively charged argon ions, for example, at 5-15 keV. This primary beam is directed onto the surface of the sample, with the resultant sputtering of secondary ions from the sample. Neutral, negative, and positively charged secondary particles are formed, but only the positive ion yield is commonly analyzed via the detection system: mass spectrometry.

The sputtering process gives a geometrically uniform erosion pattern at low rates (~ 100 Å/min), for thin film analyses, or the erosion rate can be increased several hundred fold for bulk analyses, but at the sacrifice of erosion pattern uniformity. In either case, the advantage of the ion probe lies in its ability to provide a composition profile of sample components beginning at the outer surface of the specimen: at slow erosion rates, an almost monolayer-like sampling process.

Erosion rates and secondary ion yields are dependent on the species of bombarding ion and on the structural characteristics of the sample itself; this is aside from variations in instrumental parameters themselves. It therefore follows that, before a quantitative interpretation can be made from these data, a suitable experimental procedure must first be established, with standardized materials that are representative of the type of sample involved. Hydroxides present still another experimental complication, since the ion probe analysis is performed at a vacuum of 10^{-6} Torr. There is then the need to establish that a working equilibrium can indeed be attained, with respect to the water content of these samples, so that the experimental data can have significance in terms of the initial hydration of the sample. Unbound molecular water would be expected to be quickly lost during the initial stages of evacuation, prior to sample analysis. However, sorbed water and structural hydroxides might arrive at a working equilibrium with respect to the vacuum environment imposed by the analysis. Such a condition, if sufficiently reproducible, might then allow relevant data to be interpreted in terms of the initial water content of the oxide. This might partly resolve a discrepancy in data previously reported (4) for the degree of hydration of the anodic alumina barrier layer. Erdey *et al.* (5-7), Bogoyavlenskii (8) and Shreider (9) are also among those who found at least some degree of hydration in barrier layer aluminas formed in aqueous electrolytes. However many others, notably Burghers *et al.* (10), Vedder and Vermilyea (11), and Alwitt (12) present opposing data. While this lack of agreement can be partly attributed to differences in sample preparation and techniques of experimental measurement, there is still an obvious need for additional data to support either contention.

Key words: anodic aluminas, sputter ion source mass spectrometry, hydration.

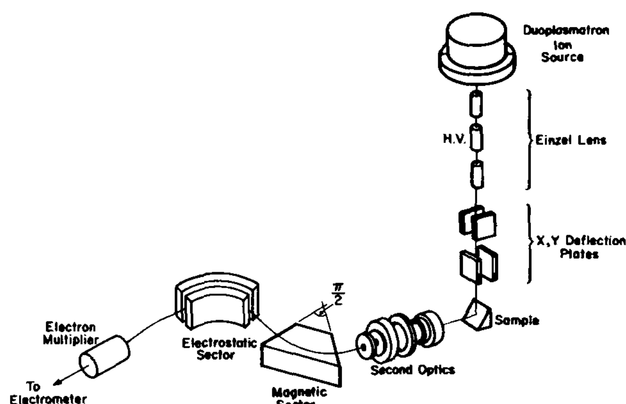
Experimental

Sample preparation.—Four reference samples of aluminum trihydroxides (2 of gibbsite and 2 of bayerite) and four reference samples of monohydroxide (all boehmites) were obtained through our Chemicals Division. These had been previously identified as suitable for use as standards, via x-ray diffraction and thermal analysis techniques. Approximately 0.5g of each alumina was compressed into a thin wafer, using 30 Ksi and a standard x-ray pelletizing die; no binder was employed, nor was any required. The result was a translucent wafer, with a hard and highly glazed surface. A dust-free section from a wafer was then mounted in a clean gold foil envelope, one side of which had a rectangular opening to expose the wafer surface during ion probe analysis; the gold foil allowed normal charge compensation procedures to be used.

Anodic oxides were prepared on clean alloy 1199 foil, using a 2M boric acid electrolyte at 60°C and 0.1 A/dm² current density. Forming voltages were varied from 6.7 to 101V. Total coating thicknesses, including both primary and secondary phases of the barrier layer oxide (4), ranged from 100 to 2000Å; thicknesses were measured by coating impedance, infrared absorption, and electronoptical methods (4). After anodizing, the foils were thoroughly rinsed in flowing distilled water (cold) then air dried. Some were analyzed immediately, with the ion probe, while others (including remaining portions of earlier samples) were analyzed up to three weeks later; storage was under clean but ambient atmospheric conditions. Such delays, between sample preparation and analysis, did not alter the ion probe data in any detectable manner. However, the auxiliary methods of thickness measurement (impedance, ir) were performed immediately in each case.

The anodic oxides were left intact on the foil substrates, for ion probe analysis.

Ion probe mass spectrometer.—The commercial instrument employed (manufactured by GCA Technology Division, Bedford, Massachusetts) has been described in detail elsewhere (13) and is diagrammed in the following illustration, using a figure adapted from



Ref. (3). Research grade argon (Union Carbide—Linde Division) was used in the ion source, creating the primary ion beam (positively charged) which was directed toward the sample under a 10 keV potential. The beam diameter at the surface of the sample was 8 mm, the narrow diameter of the elliptical pattern produced by the beam. The instrument was adjusted to enhance the detection of molecular fragmentation patterns via an adjustment to the energy discriminating function governed by the target potential and the electrostatic analyzer of the instrument, a setting of 205V, to the "energy window" (13). Charge-up effects were eliminated through the use of a heated filament mounted close to the sample surface, ahead of the secondary extraction optics. Each analysis was begun at a vacuum of 10^{-6} Torr, including argon pressure, with both anodic oxides and compressed pellets of alumina standards.

With the glazed pellets of alumina standards, the pressure in the sample chamber immediately rose as the beam worked into the sample. An eightfold increase in pressure (to 8×10^{-6} Torr) was often observed, with approximately 2 hr required for the vacuum to be restored to its initially low value, either with or without the ion beam bombardment being continued. Perhaps this outgassing may partly have been due to the rupturing of the outer glazed surface of the compacted alumina pellet, exposing the entrained molecular water of the porous inner bulk to degassing. Spectra obtained during this degassing period showed, largely, molecular water ($^{18}H_2O^+$) indicating that the energy of the primary beam may have been partly dissipated by an outgassed layer of water vapor above the surface of the sample (Fig. 1). Coincident with the return to initial vacuum (10^{-6} Torr), the spectra stabilized and were then unchanging with respect to further erosion time. Erosion rate itself had no apparent effect on the time to equilibrium, nor did it alter the stability of the spectrum once equilibrium was obtained. It is thus possible to define experimental equilibrium, with respect to sample outgassing, by: (*i*) the return to initial vacuum level, (*ii*) the quantitative repeatability of spectral scans, and (*iii*) the quantitative stability of relevant peak intensities, in this case $^{16}O^+$ and $^{17}OH^+$, on a time scan basis. It follows naturally, however, that equilibrium conditions are most quickly met when sample quantity is kept to a minimum.

Owing to the comparatively small quantity of oxide involved, most anodized samples presented no measurable delay toward the establishment of experimental equilibrium, the exception being with those films whose

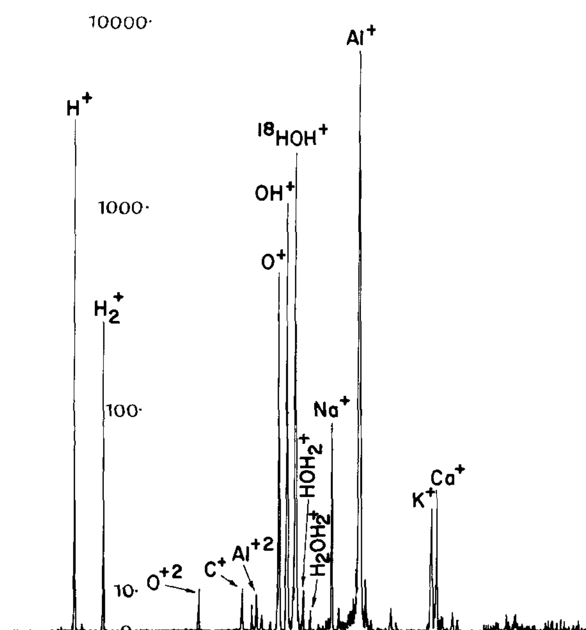


Fig. 1. Ion probe spectrum of gibbsite during initial stage of degassing, sample chamber pressure eightfold higher than initial value. Note intensity of $^{18}HOH^+$ species (5 decade intensity scale).

thickness was in excess of 1000Å. There, some amounts of residual surface (sorbed) water was found to a depth of *ca.* 150Å beneath the surface; afterward, these samples also met all criterion for experimental equilibrium.

Results and Discussion

Representative spectra of the various samples are included here, as an illustration of the type of data available with the instrument. In many cases, these spectra also contain data that are not part of the textual discussion, but which may interest those seeking additional detail.

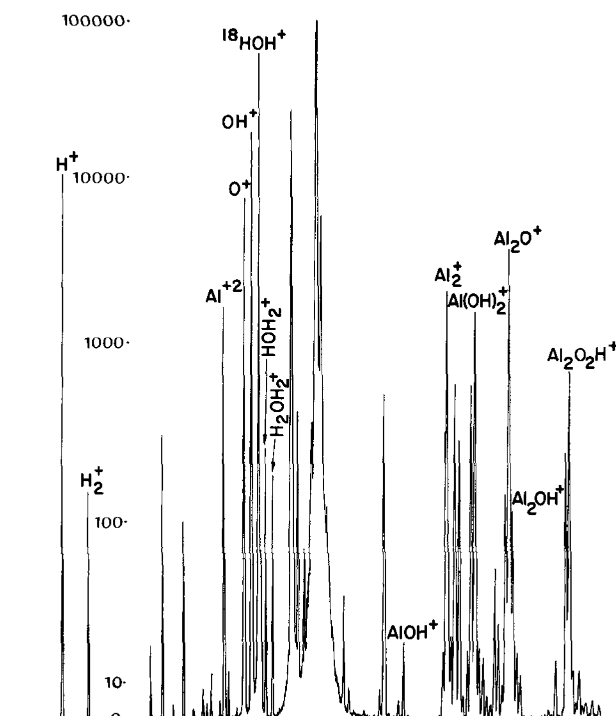

Fig. 2. Gibbsite prior to establishment of equilibrium. Note that more alumina fragmentation patterns are seen here, vs. Fig. 1, but $^{18}HOH^+$ intensity is still strong (5 decade intensity scale).

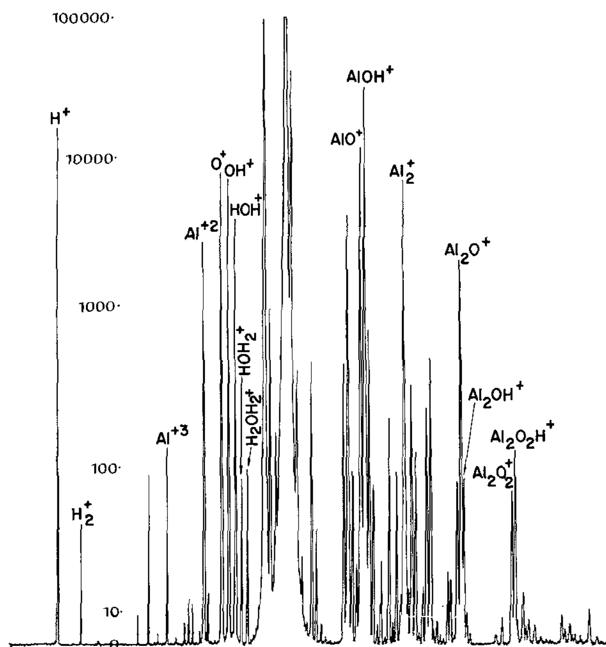

Fig. 3. Gibbsite approaching instrumental equilibrium, sample chamber pressure now fourfold higher than initial value. Note that the $^{18}HOH^+$ intensity is decreasing with respect to other species in the spectrum (5 decade intensity scale).

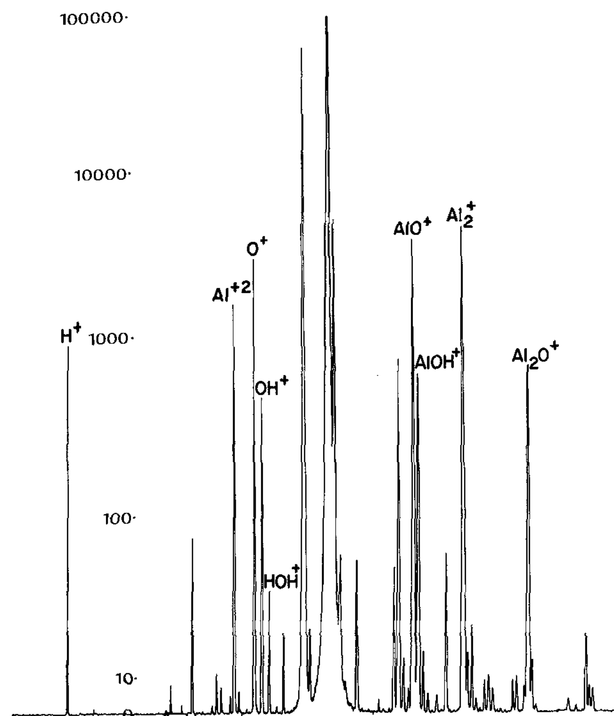

Fig. 4. Gibbsite at instrumental equilibrium. Note the absence of hydrous fragment species that characterized the spectra obtained prior to equilibrium (5 decade intensity scale).

Figures 1-3 show the type of spectra encountered during the initial stages, prior to the establishment of experimental equilibrium, with compressed pellets of aluminum hydroxides. Initially, one of the strongest features in the spectrum is the peak of amu 18 due to $^{18}HOH^+$, as outgassing commences. Later (Fig. 2 and 3) aluminum-bearing fragmentation patterns become more pronounced, as outgassing decreases with a return toward initial vacuum in the sample chamber; these spectra are still obviously "wet," however, with such species as HOH_2^+, $H_2OH_2^+$, O_2H^+, $O_2H_2^+$, etc. All such peaks disappear from the spectrum of the same hydroxide when equilibrium conditions, as defined earlier, are established (Fig. 4).

Figure 5 shows the effect on the ratio of $^{17}OH^+$ to $^{16}O^+$, as equilibrium is attained: slowly for the comparatively large quantities of sample employed with the standard hydroxide pellets, and quickly with the considerably lesser quantities sampled in the case of the anodic oxides. This also illustrates the importance of obtaining data only in the equilibrium region of the sample. And though we have not done so, it would be reasonable to expect that an extreme delay in data collection, beyond the time-to-"equilibrium" for the particular sample, would result in the measurement of a lesser degree of apparent hydroxide in the sample.

It is reasonable to assume that the ratio of $^{17}OH^+$ to $^{16}O^+$ intensity would be a valid measure of the initial water content of the sample, exclusive of the unbound molecular water lost, to the vacuum, prior to analysis. But this assumption cannot be made until ion yields have been established with representative standards, in this case, aluminum trihydroxide (gibbsite and bayerite) and the monohydroxide/boehmite. Figure 6 shows the ion yield calibration, in this instance, for the $^{17}OH^+$ to $^{16}O^+$ ratio with these standards. At equilibrium, trihydroxides gave a ratio of 0.15 while the monohydroxide gave a ratio of 0.05. Figure 6 also shows companion data for anodic oxides, for comparison with these standards. The anodic oxides are represented by fourteen different thicknesses of anodic oxide barrier layer films. The average ratio of $^{17}OH^+$ to $^{16}O^+$, for the barrier layer, was also 0.15 ± 0.01, with the more scattered data points belonging to oxide thicknesses less than 500Å. It was experimentally difficult to measure the ratio accurately with the thinner films, especially those films with thicknesses less than 200Å. Nevertheless, the apparent mole per cent water in these anodic oxide barrier layers was near 34%, basis the prior calibration against reference aluminas.

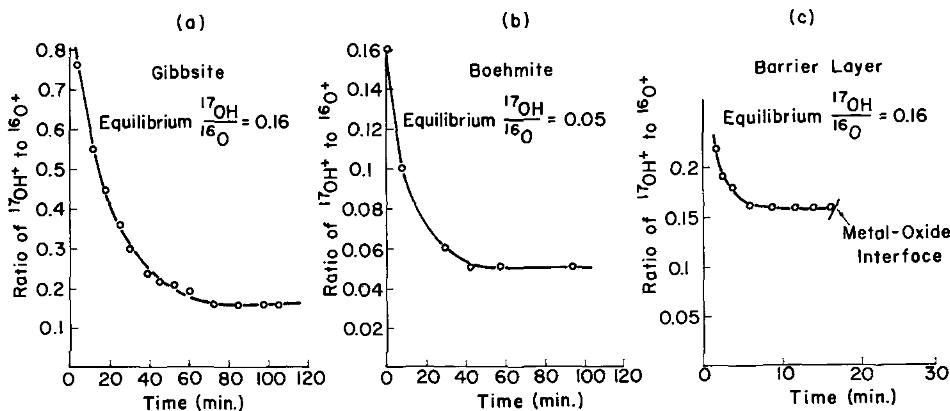

Fig. 5. Establishment of equilibrium conditions, as judged by the stability of the $^{17}OH^+$ to $^{16}O^+$ ratio, for (a) gibbsite, (b) boehmite, and (c) barrier layer anodic oxides. Thick barrier oxides require equilibrium conditioning but for a much shorter duration than with the massive quantities of alumina bulk standards. This time-to-equilibrium period was too brief to be measured with oxides thinner than 1000Å.

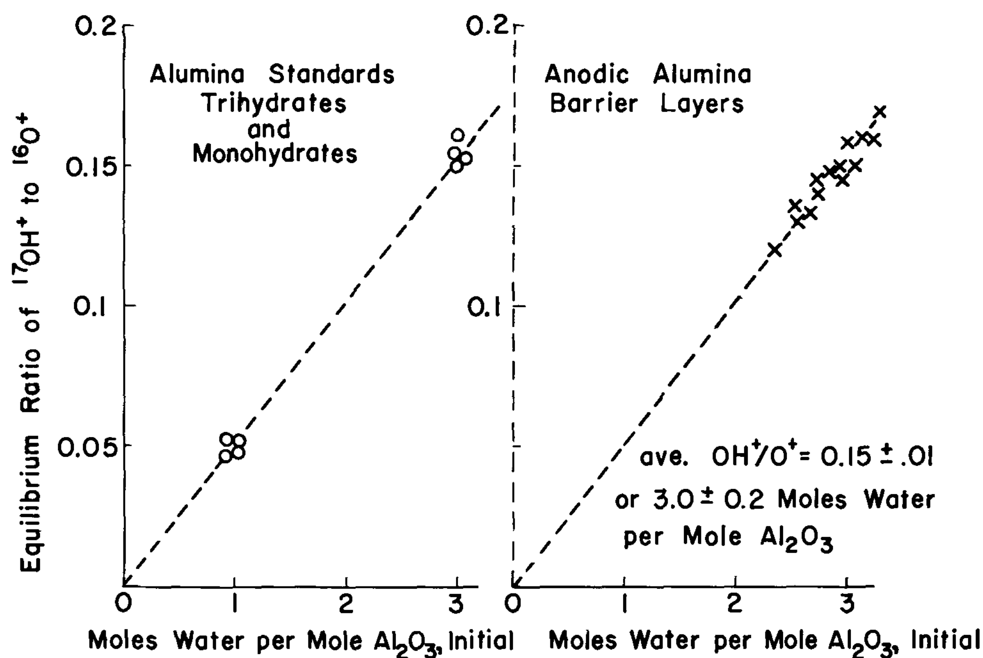

Fig. 6. Ion probe mass spectrometer determination of: (a) alumina standards, an ion yield calibration for $^{17}OH^+$ to $^{16}O^+$ ratio, and (b) anodic aluminas, 14 samples with film thicknesses ranging from 100 to 2000Å, showing ratio of $^{17}OH^+$ to $^{16}O^+$.

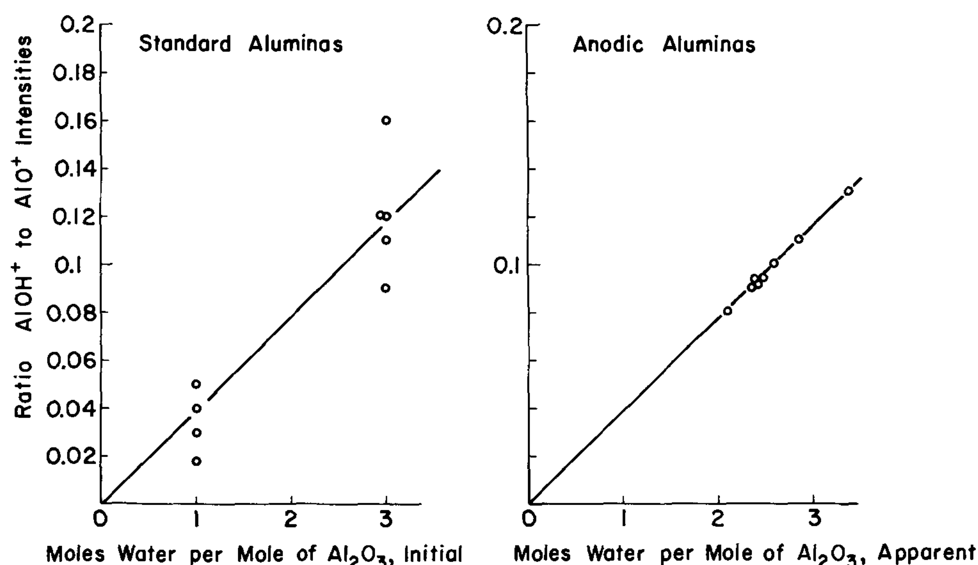

Fig. 7. Ion probe data for standard alumina hydroxides and barrier layer anodic oxides showing equilibrium ratios of $^{44}AlOH^+$ to $^{43}AlO^+$.

The ratio of $^{44}AlOH^+$ to $^{43}AlO^+$ also supports the measurement, as may be seen in Fig. 7; however, these results are experimentally less precise than the measurement of the ratio $^{17}OH^+$ to $^{16}O^+$. This difference in precision is largely due to the approximately tenfold lesser intensity of the $^{43}AlO^+$ species (*vs.* the $^{16}O^+$ species) which contributes quantitative error when employing the "fast scan" conditions (3 min, to amu 70) needed for a complete analysis of thin barrier layer anodic oxides. Then too, we might expect some degree of variation in molecular fragmentation pattern to be characteristic of the structural differences (*i.e.*, crystallinity differences) between bayerite, gibbsite, and barrier layer anodic oxides. All this not withstanding, the results shown in Fig. 7 are still consistent with the data obtained with the ^{17}OH to $^{16}O^+$ ratio (Fig. 6). Numerically, the $^{44}AlOH^+$ to ^{43}AlO ratio data gave the following average values: monohydroxides, 0.03 ± 0.01; trihydroxides, 0.12 ± 0.02; barrier layer oxides, 0.10 ± 0.02.

Also in this regard, we can compare the ion yield data for these aluminas with the data adjusted with

Table I. Summary of adjusted ion yield data for standard alumina references and barrier layer anodic oxides

Sample	Adjusted ion ratios			
	$^{16}O^+/Al^{+3}$	$^{16}O^+/Al^{+2}$	$^{17}OH^+/Al^{+3}$	$^{17}OH^+/Al^{+2}$
Monohydrate reference (4 samples)	33.0 ± 4	1.7 ± 0.1	1.3 ± 0.3	0.07 ± 0.04
Trihydrate reference (5 samples)	34.0 ± 3	2.0 ± 0.1	5.0 ± 0.8	0.29 ± 0.03
Barrier layer oxides (10 samples)	39.0 ± 9	2.1 ± 0.3	5.7 ± 2.4	0.30 ± 0.09

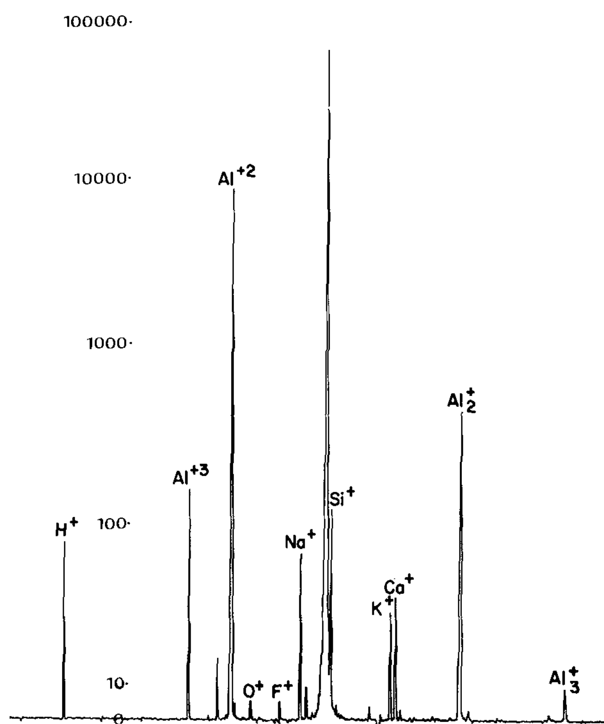

Fig. 8. Ion probe spectrum of basis alloy 1199 foil after beam-stripping of surface oxide (5 decade intensity scale).

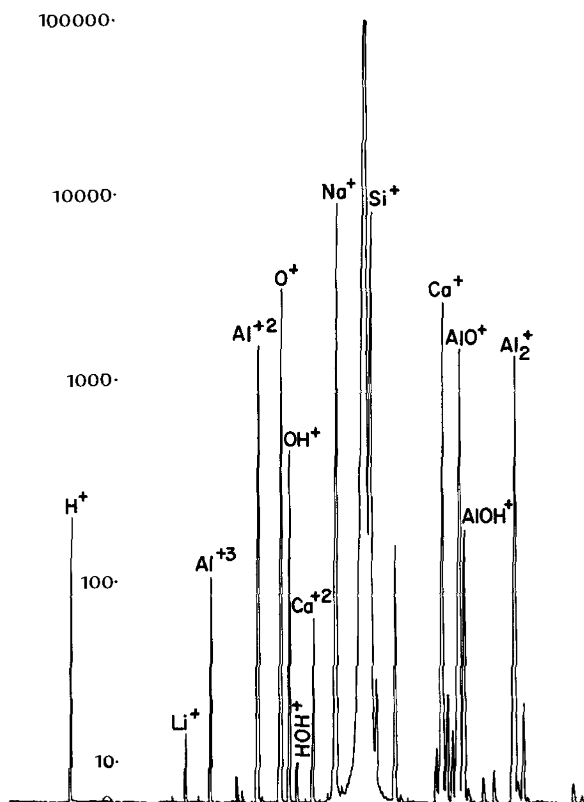

Fig. 9. Gibbsite at instrumental equilibrium, with spectrum prepared using same "fast scan" conditions employed with anodic oxides (5 decade intensity scale).

respect to the ion intensities of $^{9}Al^{+3}$ and $^{13.5}Al^{+2}$ species: "internal standards," to compensate for variations in instrumental operating parameters and differences in sample density. (The $^{27}Al^{+}$ species is the most intense in the spectrum of these oxides, and is always off-scale with the type of measurement sensitivity

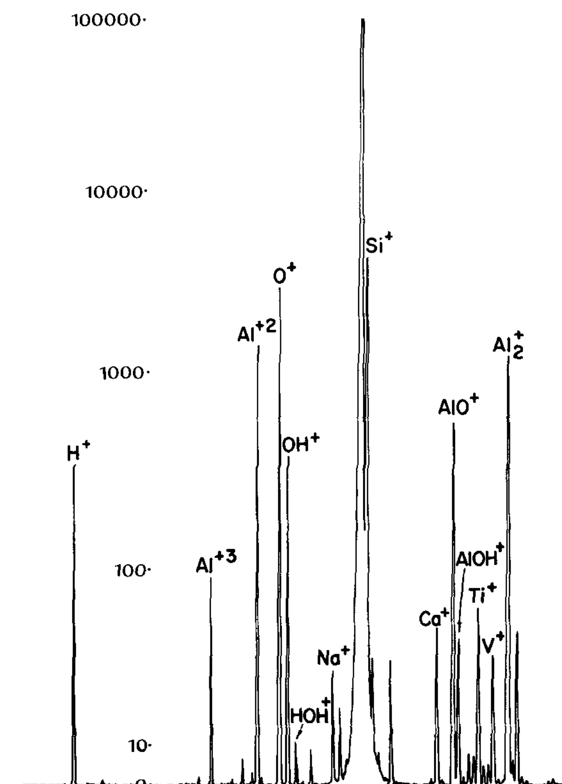

Fig. 10. Bayerite at instrumental equilibrium, with spectrum prepared using same "fast scan" conditions employed with anodic oxides (5 decade intensity scale).

employed here.) These adjusted data are best for the $^{13.5}Al^{+2}$ reference peak, which has approximately equal intensity with the $^{16}O^{+}$ and $^{17}OH^{+}$ peaks. It is also a measurement that is made within the same ~100Å increment of sample thickness that produced the measured $^{16}O^{+}$ and $^{17}OH^{+}$ peak intensities. The $^{9}Al^{+3}$ reference is of considerably lesser intensity, and is a measurement that is made ~200Å earlier in the film.

Table I shows these data, using $^{9}Al^{+3}$ and $^{13.5}Al^{+2}$ peak intensities as internal standard within the oxide. As would be expected, on a bulk-increment mole per cent basis, the oxygen-to-aluminum ratios are essentially the same for each alumina. Only the hydroxide-to-aluminum ratios are characteristic of the initial hydroxide composition of the samples.

Additional illustrations are seen in Fig. 8-12, Fig. 8 shows a spectrum of the substrate metal (alloy 1199 foil) essentially free of oxide in the area sampled by the ion beam erosion. This illustrates the negligible oxygen and hydroxide background in the instrument. Prepared in the same manner are representative spectra of gibbsite, bayerite, and barrier layer anodic oxides: Fig. 9-11, respectively. These illustrate the structural features, such as the $^{17}OH^{+}$ to $^{16}O^{+}$ ratio, already discussed. Figure 12 shows a time scan plot of $^{17}OH^{+}$ and $^{16}O^{+}$ intensities *vs.* erosion time (at 128 Å/min erosion rate) into a barrier layer anodic oxide, to further illustrate the consistency of composition as a function of film thickness. As would be expected, the intensity of both species remains constant until the oxide-metal interface is encountered. Thereafter, the intensity of both species falls off sharply.

Dicing Induced Damage in GaP Electroluminescent Diodes

N. E. Schumaker and G. A. Rozgonyi*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Batch processing of GaP electroluminescent (EL) diodes requires that the GaP wafer be separated into individual devices before lead bonding and final packaging. This paper describes an investigation of the effects of this mechanical dicing operation on the EL characteristics of GaP diodes. Chemical etching of the diced GaP diode after lead bonding has been found to be essential in achieving the maximum quantum efficiency of the completed device. The etchant used is a 3:1:1 solution of H_2SO_4, 33% H_2O_2, and H_2O at 60°C. The quantum efficiency is found to be dependent on the etching time with the efficiency reaching a maximum after approximately 5 min.

Efficiency and current-voltage measurements on unetched devices indicate the presence of surface leakage currents which decrease the external quantum efficiency of the completed device. Since it is believed that the presence of a damaged surface layer and its associated strain field can provide nonradiative leakage current paths, x-ray topography has been used to detect the existence of dicing-induced strain fields and to follow their removal as a function of etch time. X-ray topographs have also been obtained for samples initially cut with a wire saw and a diamond saw. Etching of the completed GaP diode effectively relieves the dicing-induced strain field and eliminates the surface leakage paths. This results in a device with maximum quantum efficiency and with reproducible current-voltage characteristics.

Batch processing of GaP wafers, essential for providing large quantities of GaP electroluminescent (EL) diodes, requires that the wafers be separated or diced into individual devices of uniform size and shape (1). This paper describes an investigation of the effects of this mechanical dicing operation on the EL characteristics of GaP diodes.

Empirically it had been observed that chemical etching improved the external EL efficiency of the completed GaP diode. This behavior suggested the presence of a damaged surface layer and an associated strain field which could provide nonradiative leakage current paths. This analysis has been confirmed by electrical measurements and by the use of x-ray topography to detect the existence of dicing-induced strain fields and to follow their removal as a function of etch time. The paper is divided into three sections. First, the dicing operation and the empirically observed effects of etching on the device will be described. Then the changes that occur in the device characteristics as a function of etch time are presented. Finally, the results of the x-ray topographs taken of step-etched GaP wafers cut by various techniques are analyzed and compared with the EL device data.

Dicing Operation and Device Etching

The procedure for batch processing GaP wafers is shown schematically in Fig. 1. The GaP wafer, after the growth of the two liquid phase epitaxial (LPE) layers, is lapped and polished to a uniform thickness of 0.25 mm. A distributed dot contact of 2% Si in Au is evaporated onto the n-type substrate, and 125 μm diameter dots of 1% Be in Au are evaporated onto the p-type LPE layer. After a high temperature alloy cycle to form ohmic contacts, the wafer is ready for separation into individual devices (0.4 × 0.4 mm) for bonding and inclusion in display packages. Although each step in the processing to obtain a completed GaP light emitting diode is being studied, only the dicing operation will be evaluated in this paper.

The external quantum efficiency of a completed GaP diode is dependent on the current density in the device. Similarly the radiation pattern of the device is strongly affected by the shape of the diode. For these two reasons it is important that the technique for separating or dicing the GaP wafer yield devices of uniform size and shape. At the same time, the technique used should be rapid, reproducible, and reliable for application to large volume production.

Since the GaP wafers have {111} orientation and cleave in the <110> direction, conventional "scribe and cleave" techniques cannot be efficiently used to

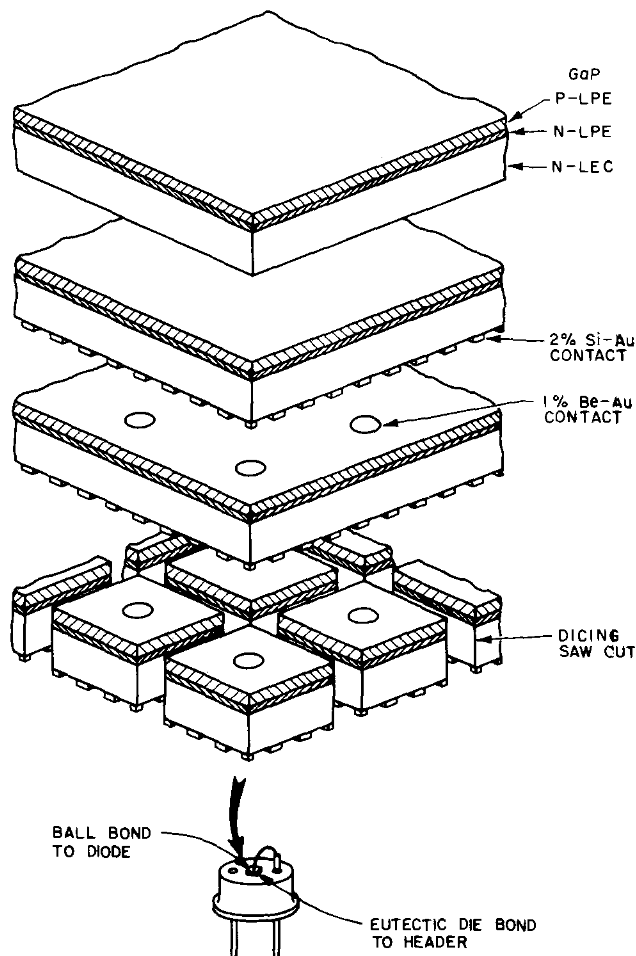

Fig. 1. Schematic drawing of batch process for GaP electroluminescent diodes.

Key words: x-ray topography, strain, surface currents.

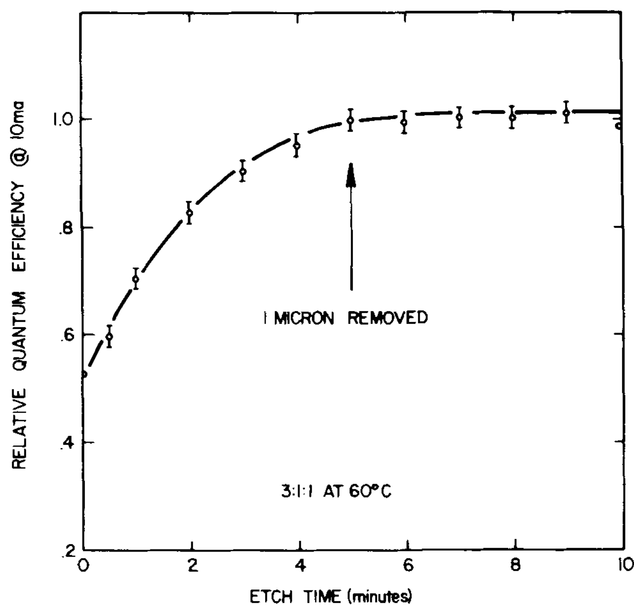

Fig. 2. Relative quantum efficiency at 10 mA as a function of the etch time for a sampling of slurry cut diodes.

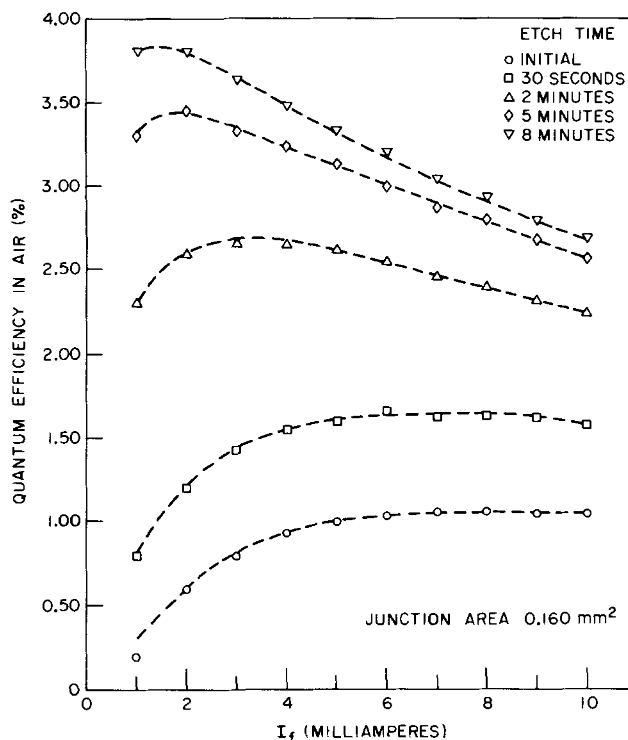

Fig. 3. Quantum efficiency in air as a function of forward current for various etch times for a slurry cut diode.

provide the square shaped devices desired. Hence, mechanical dicing machines were considered as alternate means of obtaining discrete devices. A diamond saw, a wire saw, and a multiple blade slurry dicing machine[1] were examined in this study.

The dicing machine uses a mandrel consisting of numerous 50 μm thick stainless-steel blades separated by precision ground spacers which determine the size of the final device. The mandrel rotates at 10,000 rpm and is bathed in a water slurry containing 10-12 μm diameter silicon-carbide abrasive. The rotating mandrel directs the abrasive slurry against the GaP wafer. The thin stainless-steel blades do not contact the wafer at any time, and only the slurry abrades through the wafer. This cutting action results in a kerf loss of only 120 μm. The operation of the machine is fully automatic and a complete dicing cycle, requiring two cuts perpendicular to each other, is accomplished in 90 sec. The device dimensions across a wafer are maintained to within ± 3 μm.

As mentioned in the introduction, devices fabricated using this dicing technique required chemical etching to achieve maximum EL efficiency. In particular, etching in a solution of H_2SO_4, 33% H_2O_2, and H_2O in a ratio of 3:1:1 at 60°C, improved the device properties significantly. The increase in EL efficiency at 10 mA forward current as a function of each etch time is shown in Fig. 2. This curve represents the behavior of a group of twenty devices from a single GaP wafer. The devices were etched for successively longer times and EL efficiency measured at the times indicated. In this group of devices a twofold increase in efficiency is found after etching for 5 min. Longer etch times do not significantly improve the efficiency, and excessive etching degrades device performance by undercutting contact areas.

Careful determination of the etch rate for the 3:1:1 solution at 60°C indicates that after 5 min about 1 μm of GaP would be removed. This has been subsequently confirmed by scanning electron microscope photographs of etched and unetched GaP diodes (2).

Electrical and Optical Measurements

The fact that such striking results were obtained by the removal of such a small amount of material from the GaP device, indicated the presence of a surface controlled effect. To demonstrate the magnitude of this effect, the quantum efficiency *vs.* current for a particular device after various etch times is shown in Fig. 3. This device was obtained from a different wafer of GaP than that used to generate the curve of Fig. 2 and indicates an even greater effect of etching. Note that the efficiency at 10 mA more than doubles when 1μ is removed and the peak efficiency shifts to lower current density.

Since the presence of an absorbing surface film would require an absorption coefficient $\sim 10^3$ cm^{-1} to account for the magnitude of this effect, and, since one would expect no change in the shape of the efficiency *vs.* current curve due to an absorbing layer, a current leakage path in the diced GaP diode that was removed by etching was suspected. This was confirmed by the current-voltage data shown in Fig. 4 and 5.

In Fig. 4 the logarithm of the forward current *vs.* the forward voltage is shown for various etch times. One sees that for the unetched device the current-voltage dependence

$$I \propto I_0 e^{-\frac{qV_f}{nkT}}$$

at low bias gives an $n > 2$. However, as the diode is etched for successively longer periods of time, the value for n decreases and after 5 min $n \simeq 2$. The current-voltage behavior of the unetched GaP diode with $n > 2$ is consistent with the presence of nonradiative recombination centers at the surface as discussed by Sah and others (3-5).

The reverse characteristics shown in Fig. 5 also change with etching. The unetched device is quite "leaky" and shows a soft reverse breakdown. Again, as the etching proceeds for longer times, the reverse leakage decreases to less than 1 nA at 10V and the diode exhibits a hard reverse breakdown.

Surface leakage currents can arise from a number of causes, principally surface contamination and surface damage. Since care was taken to avoid contamination on the device, the damage introduced during the dicing operation was expected to dominate the surface effect.

X-Ray Topographic Results

Since x-ray topography represents a sensitive technique for examining strain gradients in single crystals, it was used to evaluate the extent of the dicing-induced damage and its associated strain field. The samples which were evaluated by this method were prepared as shown schematically in Fig. 6. The {111} P-

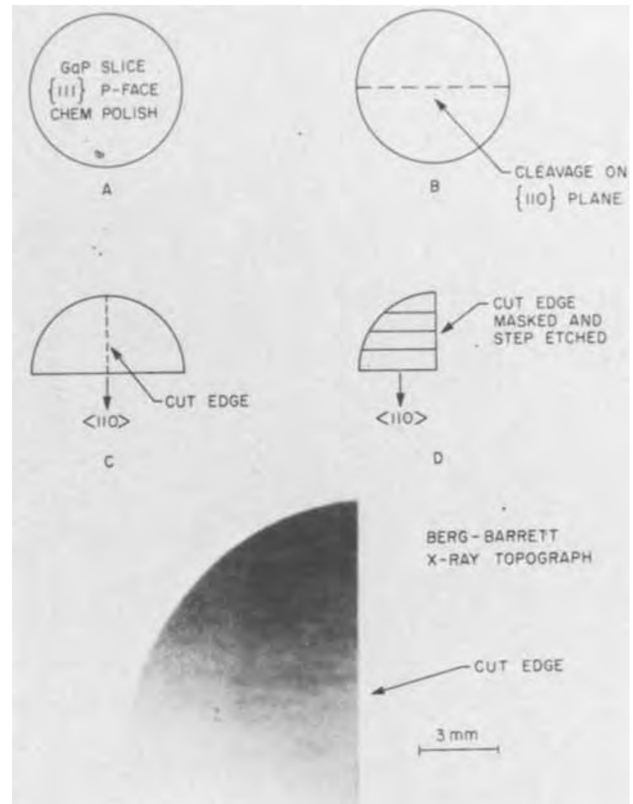

Fig. 6. Schematic showing procedure used to examine the effects of etching on cut and damaged wafer edges.

face of a substrate wafer cut from a GaP ingot grown by the liquid encapsulation Czochralski (LEC) technique was chemically polished using the polishing procedures described previously (6). The substrate wafer was then cleaved and a single cut was made in the <110> direction perpendicular to the cleavage plane. The cut edge and surface were then carefully masked with wax and successively etched to provide regions with different amounts of surface damage removal on the same sample. Berg-Barrett (reflection) topographs were then obtained using either {242} or {440} reflections; see Fig. 6e where the dark edge at the lower right edge represents the dicing-induced strain field.

The effectiveness of the etching procedure for a GaP substrate wafer, which was prepared in this fashion with etch periods sufficient to remove ~1 μm, 5 μm, and 15 μm of GaP from the slurry cut edge, is shown in the enlarged topograph of the cut edge in Fig. 7. The arrows point to various masked regions on the cut edge and the approximate amount of material removed is indicated. The lower right-hand edge of Fig. 7 clearly shows enhanced diffraction of the x-rays in the unetched region and indicates that the elastic strain field, due to dicing damage, extends for ~ 100 μm. The region directly above this in the figure has been etched for 5 min in 3:1:1 at 60°C to remove ~1 μm of GaP. Essentially, no enhanced diffraction is observed here indicating that the strain field has been relieved by the etching procedure. Note that the etch has been sufficiently light so that the rough chipped edge is still readily apparent. Further etching to remove ~5 μm and ~15 μm merely rounds and smooths the edge.

To correlate the removal of the damage and strain from the diced wafer with typical device measurements, *e.g.*, those shown in Fig. 2, a second substrate of GaP was prepared and step-etched. In this case, etch periods of 30 sec, 1, 2, and 5 min were used and the resulting topograph is shown in Fig. 8. This figure confirms the rapid removal of the damage and strain in the GaP wafer and should be compared with the

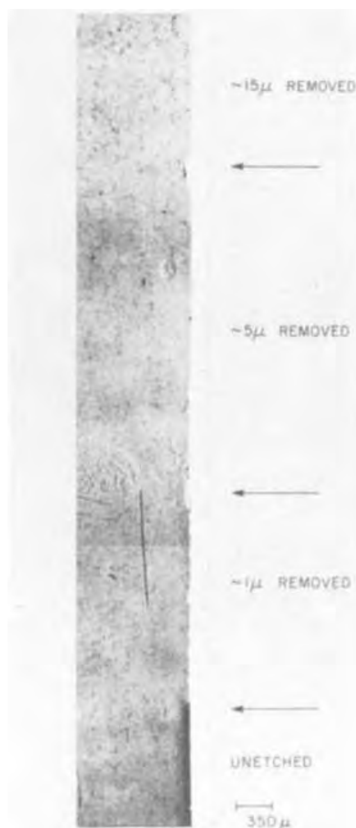

Fig. 7. X-ray topograph of a step-etched GaP wafer, slurry cut

Fig. 9. X-ray topograph of a step-etched GaP wafer, diamond saw cut.

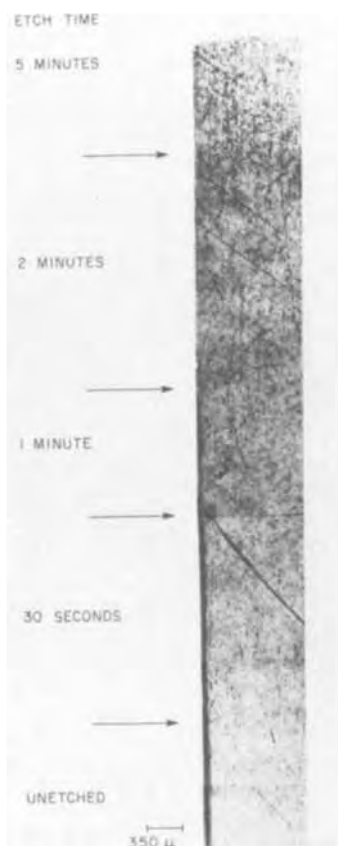

Fig. 8. X-ray topograph of a step-etched GaP wafer for short etch times, slurry cut.

efficiency *vs.* etch-time curve in Fig. 2. One sees that the extent of the dicing-induced strain fields is progressively reduced as the etch times are increased. After 5 min of etching there is no apparent enhanced diffraction which is in qualitative agreement with the device results of Fig. 2.

Similar topographs were obtained for samples initially cut with a wire saw and a diamond saw. The results with a wire saw, using a silicon carbide abrasive, were essentially the same as those observed for the slurry dicing machine. However the topograph in Fig. 9, obtained on a step-etched GaP substrate wafer cut by a diamond saw, shows that enhanced diffraction is still present on the edge after the 1 μm deep etch has been used. In this case, after 5 μm of material is removed, there is no dicing-induced strain field remaining.

Conclusions

Using x-ray topography, mechanical dicing operations such as slurry cutting and diamond or wire sawing have been shown to introduce a shallow damaged layer on a GaP substrate wafer. The elastic strain field associated with this damage may extend as far as 100 μm into the wafer. Chemical etching to remove as little as 1 μm of material has been shown to relieve this elastic strain field. Efficiency and current-voltage measurements on devices prepared using slurry dicing indicate the presence of surface leakage currents which have a deleterious effect on the external quantum efficiency of the completed device. However, etching the diced device for 5 min in a solution of H_2SO_4:33% H_2O_2:H_2O a ratio of 3:1:1 at 60° removes ~1 μm of material from the device which effectively relieves the strain field and eliminates the surface leakage paths. This results in a device with maximum quantum efficiency and with reproducible current-voltage characteristics.

Luminescence of Alkaline Earth Zirconium Silicates

W. L. Wanmaker,* J. W. ter Vrugt, and E. P. J. Meester

N.V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

The luminescence of alkaline earth zirconium silicates has been investigated. The unactivated compounds show an ultraviolet emission band, which can be excited by cathode rays or by short-wavelength (190-210 nm) ultraviolet radiation. The excitation and emission can be ascribed to charge-transfer transitions between the oxygen and the zirconium ions. Activation of the alkaline earth zirconium silicates with various activators has been tried, lead giving the most efficient luminescence, *e.g.*, in $Ca_2ZrSi_4O_{12}$-Pb (λ_{max} of the emission at 355 nm) a quantum efficiency (with 254 nm excitation) of 52% was observed. Excitation and emission spectra, efficiencies, and temperature dependence of the lead-activated phosphors are presented.

In the MeO-ZrO_2-SiO_2 system (Me = Ca, Sr, Ba) various compounds have been described in the literature, *viz.*, with Me = Ca the 2-1-4 and the 3-1-2 compounds (1, 2), with Me = Sr the 6-1-5 compound (3), and with Me = Ba the 1-1-3 and the 2-2-3 compounds (4).

The crystal structure of most of the alkaline earth zirconium silicates has not been determined up until now. The only exception is $BaZrSi_3O_9$ with a hexagonal unit cell (a = 6.75Å and c = 10.00Å). In this compound Si_3O_9-rings are present, with the Ba^{2+} and Zr^{4+} ions in trigonally distorted octahedra. $BaZrSi_3O_9$ is isomorphous with benitoite-$BaTiSi_3O_9$ (5). With the other alkaline earth zirconium silicates no isomorphous titanium silicates or zirconium titanates exist. Even the chemical composition of the compounds found in the three classes differs strongly, as follows from Table I (6-8).

Up until now only the luminescence of $BaZrSi_3O_9$ has been studied (5, 9, 10). For instance Blasse and Bril (5) found an efficient luminescence with Eu^{2+}- and with Ti^{4+}-activation. In the present investigation we tried to activate the alkaline earth zirconium silicates, mentioned above, with various activators, *viz.*, Ce^{3+}, Eu^{2+}, Eu^{3+}, Tb^{3+}, Dy^{3+}, Sn^{2+}, Pb^{2+}, Ti^{4+}, Sb^{3+}, and Mn^{2+}.

Experimental

Powder samples were prepared by heating intimate mixtures of $CaCO_3$, $SrCO_3$, $BaCO_3$, ZrO_2, and SiO_2 at temperatures between 1100° and 1350°C. Two or more heatings lasting 2-4 hr were carried out. The activator elements were mostly added in an amount of 0.05-0.15 mole per mole of the host compound.

In many cases a two-step method was used to prepare the zirconium silicate phosphors. Tak and van Klinken (11) found this to be a useful procedure for the synthesis of $BaZrSi_3O_9$-Eu^{2+}, leading to a higher quantum efficiency of the phosphor as compared with the normal one-step preparation method. For instance, in the preparation of $BaZrSi_3O_9$-Pb first $BaSi_2O_5$-Pb is made at a temperature of 1100°C and the reaction product is refired twice at a temperature of 1350°C after the addition of 2 moles of ZrO_2 (*i.e.*, 1 mole in excess) and 1 mole of SiO_2 per mole of $BaSi_2O_5$-Pb.

It pointed out that it is difficult to obtain the pure alkaline earth zirconium silicates, especially the strontium compound. Optical measurements as given in this paper were done, however, in the compounds corresponding to the formulas given. In these compounds no second phase could be detected by x-ray analysis.

X-ray powder diffraction patterns were taken on a Philips diffractometer using CuKα radiation.

Fluorescence, excitation, and reflection spectra were measured on a spectrofluorometer built in our laboratory. Two Jarrel-Ash ¼ meter monochromators with 600 grooves/mm gratings, blazed for 300 nm, are used as the excitation and as the fluorescence monochromator respectively. A 30W deuterium source with a suprasil window is used for the spectral range from 185 to about 400 nm, while a 55W halogen motorcar lamp covers the near-ultraviolet and visible regions. The source radiation is chopped with a frequency of 12 Hz and focused on the entrance slit of the excitation monochromator with the aid of a concave mirror.

The exit slit of the first monochromator is focused on the phosphor plaque, the reflected and the fluorescent radiation being concentrated on the entrance slit of the second monochromator. The intermonochromator optics consists of flat and concave mirrors to eliminate chromatic aberrations. The spectral bandwidth, both for excitation and fluorescence, was equal to or less than 6 nm.

The current from the photomultiplier (Philips XP 1003 with extended S-20 spectral response and with a quartz window) behind the exit slit of the fluores-

cence monochromator, is amplified with a phase-sensitive 12 Hz amplifier and recorded. Reflection spectra may be recorded by scanning both monochromators synchronously.

Excitation spectra are corrected with the aid of the measured excitation spectra of sodium salicylate (12) (up to 350 nm), or in the near-ultraviolet and visible spectral range with that of 2,2'-dihydroxy-1,1'-naphtaldiazine (Lumogen LT-hellgelb from BASF) (13). Both phosphors show a constant quantum efficiency in a broad spectral region. The fluorescence spectra were calibrated with various NBS standard phosphors (14). As a reflection standard CaF_2 or $BaSO_4$ is appropriate.

Results and Discussion

Optical properties of the unactivated alkaline earth zirconium silicates.—On exciting $BaZrSi_3O_9$ with cathode rays, Blasse and Bril (5) found an ultraviolet emission band peaking at 285 nm. With ultraviolet excitation at wavelengths shorter than 220 nm a similar emission band could be detected. Excitation and emission of this compound were ascribed to charge-transfer transitions between the O^{2-} ions and the Zr^{4+} ions. Ultraviolet emission of the same type was found before in ZrP_2O_7 (15), and it might be expected in other Zr^{4+}-compounds as well (5).

Therefore we looked for a similar emission band in the other alkaline earth zirconium silicates prepared in the present investigation. As shown in Fig. 1 an ultraviolet emission band is present also in other alkaline earth zirconium silicates. Its maximum ranges from 285-340 nm when excited with cathode rays. With short-wavelength ultraviolet excitation (190-210 nm) this emission band is found at a slightly different wavelength, *e.g.*, with the Ba compounds the emission maximum shifts from 285 to 330 nm, as may be seen from Fig. 2.

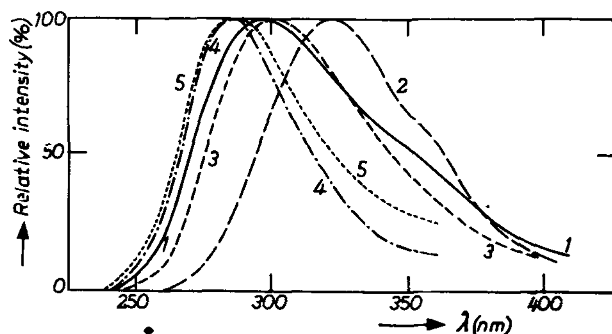

Fig. 1. Spectral energy distribution of the emission of alkaline earth zirconium silicates with cathode-ray excitation; curve 1, $Ca_2ZrSi_4O_{12}$; curve 2, $Ca_3ZrSi_2O_9$; curve 3, $Sr_6ZrSi_5O_{18}$; curve 4, $BaZrSi_3O_9$; curve 5, $Ba_2Zr_2Si_3O_{12}$.

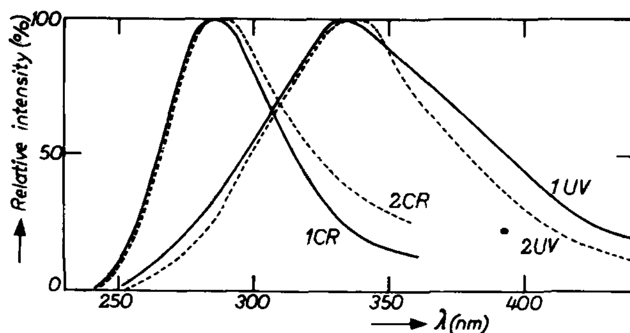

Fig. 2. Spectral energy distribution of the emission of barium zirconium silicates under cathode-ray and under 190 nm excitation respectively. Curve 1CR, $BaZrSi_3O_9$, cathode rays; curve 1UV, $BaZrSi_3O_9$, 190 nm; curve 2CR, $Ba_2Zr_2Si_3O_{12}$, cathode rays; curve 2UV, $Ba_2Zr_2Si_3O_{12}$, 190 nm.

The conclusion may be drawn that in both $BaZrSi_3O_9$ and $Ba_2Zr_2Si_3O_{12}$ the luminescence is connected with two kinds of transitions. This phenomenon could be similar to the occurrence of two emission bands in niobates and tantalates, *e.g.*, $Mg_4Nb_2O_9$ and $Mg_4Ta_2O_9$ (16), depending on the wavelength of the exciting radiation and on the temperature. These two bands are ascribed to the appearance of singlet-singlet and triplet-singlet transitions (16). Just as in the above-mentioned niobates and tantalates the shift of the emission maxima in the zirconium silicates is about 5500 cm^{-1}.

Activated compounds.—In addition to the Eu^{2+}- and the Ti^{4+}-luminescence in $BaZrSi_3O_9$, as described before (5), in several of the host lattices investigated by us luminescence was observed with activator ions like Eu^{3+}, Eu^{2+}, Sn^{2+}, Ti^{4+}, Ce^{3+}, Tb^{3+}, Dy^{3+}, and Pb^{2+}. For instance with Ti^{4+}-activation in $Ca_2ZrSi_4O_{12}$ a broad emission band with a maximum at 480 nm and with a bandwidth at half-maximum intensity of 125 nm was observed and in $Ba_2Zr_2Si_3O_{12}$-Eu^{2+} an emission band at 490 nm with a bandwidth of 80 nm. With Eu^{3+}-activation emission lines characteristic for transitions in the Eu^{3+} ion were observed, *e.g.*, in $Ca_3ZrSi_2O_9$. In $Ca_2ZrSi_4O_{12}$-Pb, Mn a Mn emission band (λ_{max} = 610 nm) could be observed in addition to the Pb emission band at 355 nm.

The quantum efficiency (254 nm excitation) of most of these phosphors does not exceed a value of about 10%, with the exception of activation with lead, giving rise to values up to 50%. Therefore we will restrict ourselves in the following to Pb-activated phosphors.

Lead-activated compounds.—Spectral energy distribution curves (254 nm excitation) of the various lead-activated phosphors are given in Fig. 3. The maximum of the emission band shifts to longer wavelengths and broadens in the sequence Ca-Sr-Ba. With $Ca_3ZrSi_2O_9$-Pb the emission band is nearly identical to that of the unactivated compound, but there exists a large difference between the excitation spectra. The unactivated compound can only be excited by radiation of wavelengths shorter than 210 nm, while the Pb-activated phosphor shows a strong narrow excitation band at 260 nm (Fig. 6), which is typical for that of the activator ion.

When measuring the emission spectra at 77K, the Ba compounds show a second narrow emission band at 330 nm, as is illustrated in Fig. 4. A second emission band does not occur in the other lead-activated alkaline earth zirconium silicates, the only effect observed with excitation at 77K being an increase in peak height of about 20-70% as compared with the value at room temperature.

The decay-time (1/e-value) of the 400 nm emission band in both Pb-activated barium zirconium silicates is 6 μsec, while that of the 330 nm band showed to be 8.5 μsec (ultraviolet excitation at 77K). These values

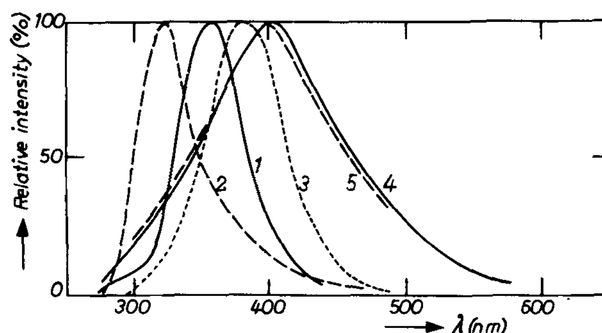

Fig. 3. Spectral energy distribution of the emission of $Ca_2ZrSi_4O_{12}$-Pb (curve 1), $Ca_3ZrSi_2O_9$-Pb (curve 2), $Sr_6ZrSi_5O_{18}$-Pb (curve 3), $BaZrSi_3O_9$-Pb (curve 4), and $Ba_2Zr_2Si_3O_{12}$-Pb (curve 5). Mainly 254 nm excitation.

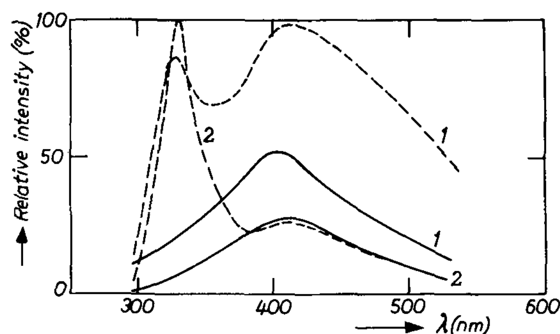

Fig. 4. Spectral energy distribution of the emission of $Ba_2Zr_2Si_3O_{12}$-Pb and $BaZrSi_3O_9$-Pb as measured at 77 and 293K respectively. Mainly 254 nm excitation. Curves 1, $Ba_2Zr_2Si_3O_{12}$-Pb. curves 2, $BaZrSi_3O_9$-Pb. Full curves, emission at 293K relative to that at 77K; dashed curves, emission at 77K.

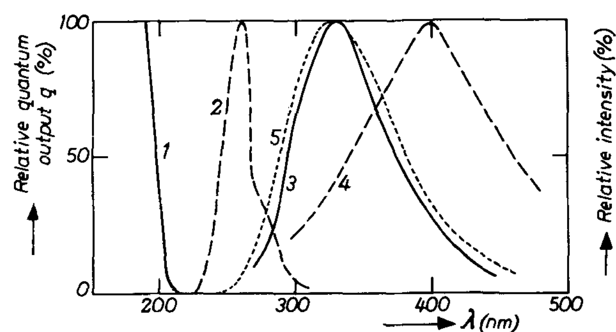

Fig. 5. Excitation spectra (relative quantum output) and spectral energy distribution of the emission of $Ba_2Zr_2Si_3O_{12}$-Pb, as measured at room temperature. Curve 1, excitation spectrum of the emission at 330 nm; curve 2, excitation spectrum of the emission at 400 nm; curve 3, emission spectrum under 190 nm excitation; curve 4, emission spectrum under 260 nm excitation; curve 5, emission spectrum under cathode-ray excitation.

are comparable to those found with other Pb-activated phosphors, indicating that both bands are due to transitions in the Pb ions.

One could assume, that the 330 nm emission band should have its origin in a host lattice transition, but the two following arguments support the explanation that a transition in a Pb-center is much more probable, *viz.*:

(*i*) The 330 nm emission band observed at 77K can be excited with 254 nm radiation; its excitation band coincides with that of the 400 nm emission band at room temperature. At 77K the excitation band of the 400 nm emission band, however, is very narrow and peaks at 245 nm. The host lattice emission of the alkaline earth zirconium silicates, on the contrary, can only be excited with radiation at wavelengths shorter than 210 nm (see Fig. 5).

(*ii*) When exciting $Ba_2Zr_2Si_3O_{12}$-Pb with cathode rays or with 190-210 nm radiation (both giving rise to host lattice excitation, see above) a broad emission band at 330 nm occurs (see Fig. 5), differing in shape from the emission band excited by 254 nm radiation at 77K.

The occurrence of two lead-emission bands in $BaZrSi_3O_9$-Pb and in $Ba_2Zr_2Si_3O_{12}$-Pb might be due to transitions from different levels to the ground level (*e.g.*, from $^3P_1$ or $^3P_0$ to the $^1S_0$ state) (17) in analogy to two excited levels in $BaZrSi_3O_9$-Ti (5). The presence of lead in both Ba^{2+}- and Zr^{4+}-sites as Pb^{2+}, or as a combination of Pb^{2+} and Pb^{4+}, might be another explanation. The two emission bands might also be attributed to the existence of Pb-Pb pairs, as assumed by Schulman *et al.* in order to explain the occurrence of more emission bands in $CaSiO_3$-Pb (18).

The luminescence intensity of the lead-activated alkaline earth zirconium silicates decreases rapidly (especially of the Ba-compounds) when heating the phosphors above room temperature. With the Ca- and Sr-compounds the luminescence has decreased to 50% of that at room temperature at 200°-250°C, while for the Ba-compounds this already occurs at 100°C.

The excitation and reflection spectra of the lead-activated alkaline earth zirconium silicates are presented in Fig. 6. All phosphors show a narrow excita-

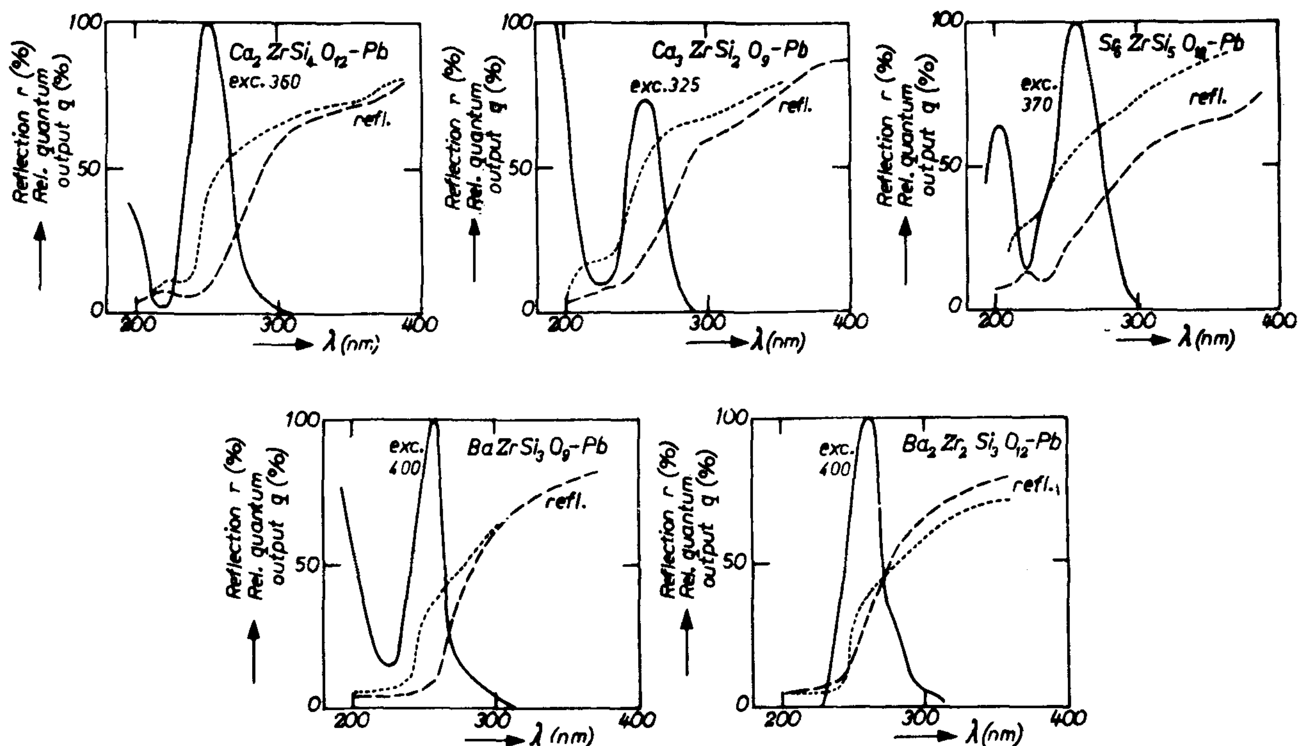

Fig. 6. Excitation spectra (relative quantum output *q*) (full curves) at the lead-emission band and diffuse reflection spectra (*r*) of the host compounds (dotted curves) and of the lead-activated phosphors (dashed curves). Numbers in the figure denote wavelength (nm) of measured emission.

Table II. Some properties of lead-activated alkaline earth zirconium silicates

Composition	Emission maximum (nm)	254 nm excitation		Cathode-ray excitation
		q (%)	Refl. (%)	η (%)
$Ca_2ZrSi_4O_{12}$	355	52	14	1.5
$Ca_3ZrSi_2O_9$	325	28	19	1
$Sr_6ZrSi_5O_{18}$	380	32	25	0.5
$BaZrSi_3O_9$	410	34	9	4
$Ba_2Zr_2Si_3O_{12}$	405	4	23	3

q = quantum efficiency for 254 nm excitation.
η = radiant efficiency for cathode-ray excitation (20 kV).
The lead concentration amounts to 0.1 mole per mole for the Ca and Sr compounds and to 0.15 mole per mole for the Ba compounds, as added to the firing mixture.

tion band; the band maxima show some change with composition from 250 to 265 nm. In most cases excitation occurs also at shorter wavelengths, *viz.*, at about 200 nm, leading to the same emission spectrum as excitation with 250 nm. The shoulders observed in some excitation bands might be due to crystal field splitting of the $^3P_1$ level of the lead ions. Due to partial or total overlap of activator and host lattice emission, in some cases excitation at 200 nm (of the emission at the wavelengths labeled in the figure) must be partly attributed to the host lattice. The shape of the excitation bands in all relevant phosphors, *viz.*, a sharp band at about 250 nm with a band width of 30-40 nm, is typical for lead-activated phosphors. Recently we found similar excitation bands with lead-activated alkaline earth germanates (19). A narrowing of the excitation bands and a slight shift to shorter wavelengths is found with some phosphors when measuring at 77K.

It follows from the excitation spectra, that in the region of a strong absorption of the host lattice (*i.e.*, at wavelengths shorter than 230 nm) mostly a weak excitation of the lead-emission band only occurs. An exception to this is constituted by $Ca_3ZrSi_2O_9$-Pb, for which compound host lattice and activator emission bands coincide. Therefore the conclusion may be drawn that in the relevant host lattices the energy transfer from the host lattice to the lead activator ions is negligible. This is confirmed by the measurements on $Ba_2Zr_2Si_3O_{12}$-Pb given in Fig. 5, showing that with 190 nm and with cathode-ray excitation only host lattice emission was found; the lead-emission band appears when exciting at 254 nm, corresponding to a specific absorption in the activator ions.

In Fig. 6 the reflection spectra both of the host lattices and of the lead-activated phosphors are given. With $Ba_2Zr_2Si_3O_{12}$-Pb we found only a very weak extra absorption band at 250 nm, when compared with the unactivated compound. The strong host lattice absorption of $Ba_2Zr_2Si_3O_{12}$, however, must be responsible for the low quantum efficiency of its lead emission (Table II). The poor energy transfer in the alkaline earth zirconium silicates may be ascribed to the small spectral overlap of the host-lattice emission band and the lead-activator absorption band. With $BaZrSi_3O_9$-Ti, on the contrary, a very efficient energy transfer to the titanium center was found (5) due to the broad spectral overlap of the respective emission and absorption bands.

It follows from the excitation spectra, that most of the phosphors should be suitable for 254 nm excitation, as present in a low pressure mercury vapor discharge. Their quantum efficiency, however, is rather low (Table II), *viz.*, a highest value of 52% was measured with $Ca_2ZrSi_4O_{12}$-Pb. The latter phosphor, with a maximum emission wavelength at 355 nm, might be applied in lamps with a specific photochemical action, such as copying lamps.

Acknowledgments

The authors are indebted to Mr. J. G. Verlijsdonk for his assistance in preparing the phosphors, to Dr. A. Bril for the measurements with cathode rays, and to Mr. C. Bakker for measuring the reflection, excitation, and fluorescence spectra.

A New Method for Revealing Striations in High-Resistive Floating-Zone Silicon Crystals

A. J. R. de Kock and P. G. T. Boonen

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

Striations were revealed by preferential etching of preannealed longitudinal crystal slices taken from high-resistive floating-zone silicon crystals. The required preannealing treatment was carried out at a temperature between 1000° and 1200°C in a tubular furnace. A model for the mechanism of striation revealing is proposed. The influence of such striations on the performance of planar diodes is briefly discussed.

Several methods have been developed during the past decade for revealing impurity striations in silicon crystals. These striations, which reflect the shape of the solid-liquid interface present during crystal growth, can easily be made visible in heavily doped material by means of the pulsed copper-plating technique (1) or by preferential etching (2). For intermediate resistivities (1-100 ohm-cm) some special etching techniques with mixtures of HF-HNO_3 have been described (3, 4). Recently Kämper (5) has reported on a rather complicated method consisting of a series of successive etching treatments which can be applied to high-resistive floating-zone silicon.

In the present paper a new and simple method is described for revealing striations in high-resistive silicon crystals.

Experimental Procedure

The experimental procedure for revealing striations is as follows. Longitudinal slices, cut from the crystals to be investigated, are polished or chemically etched in order to remove any surface damage and subsequently annealed for a few hours in a tubular furnace at a temperature of between 1000° and 1200°C. After annealing a surface layer is removed from the slices by chemical etching or polishing. This is done in order to prevent the formation of a haze during the final step of the process, which consists of preferential etching for a few minutes with the CrO_3 etchant described by Sirtl and Adler (6). The preferential etching treatment reveals striations on the longitudinal sections, which are clearly visible under a normal optical microscope. No striations become visible if no annealing treatment is carried out prior to etching. The related spiral pattern formed on the surface of cross-sectional slices is less sharply defined, however. In those regions where the solid-liquid interface is nearly parallel to the cross-sectional surface no spiral pattern is formed during etching.

Results

The striations in a variety of floating-zone crystals have been examined. The electrical resistivity of the available crystals was in the range of 5-1500 ohm-cm, whether n-type or p-type. Crystals with high dislocation densities as well as dislocation-free crystals were used. The dislocation-free material contained either a striated distribution of vacancy clusters (7, 8) or was grown under such conditions that cluster formation was prevented (8). Independent of the level of doping, striations could be revealed in all those crystals. Some examples are shown in Fig. 1 and 2. Although clearly visible, the striation etch pattern in heavily dislocated crystals was less pronounced than in dislocation-free material. Furthermore, preferential etching also reveals dislocations. The dislocation etch pits formed disturb the striation pattern in crystals containing high dislocation densities ($> 10^4$ cm^{-2}).

The environment in which the annealing treatment can be carried out was found to be of minor importance. In most experiments nitrogen was used, but comparable results were obtained with argon or a mixture of nitrogen and water vapor, the latter causing oxidation of the samples. Good results were obtained with an annealing temperature of 1150°C. The minimum annealing time necessary for revealing of the striations was found to depend on the typical crystal, but not on the level of doping. However, a

Key words: silicon, single crystals, impurity striations, planar devices.

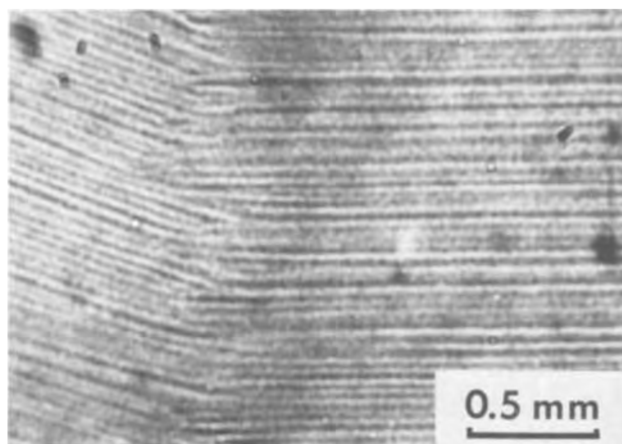

Fig. 2. Longitudinal section of a dislocation-free pedestal-pulled crystal grown in argon. Average distance grown per revolution: 0.03 mm. Resistivity: 208 ohm-cm, p-type. Anneal at 1150°C in nitrogen for 4 hr. Preferential etching (10 min). The solid-liquid interface exhibits a central (111) facet.

4-hr annealing treatment was found to be sufficient for all the crystals investigated. Although the cooling rate after annealing was not critical, the best results were obtained if the samples were cooled at a relatively slow rate (*e.g.*, from 1150° to 700°C in 15 min).

If the slices are coated with a layer of phosphorus glass prior to annealing, no striations are observed. It is well known (9) that such a glass layer prevents the penetration of metallic impurities, which are always present in a resistance-heated furnace, into the samples. If the annealing treatment is carried out in a rf-heated epitaxial reactor in an atmosphere of purified hydrogen, again no striations are revealed after subsequent preferential etching. In an epitaxial reactor contamination of the samples with metallic impurities is much less than in a resistance-heated furnace.

The method was also applied to a number of Czochralski-grown crystals with resistivities between 5 and 10 ohm-cm, whether n-type or p-type. In some of these crystals the striation pattern could be revealed easily, whereas this pattern was completely absent in some others.

Discussion

Neither the level of doping nor the type of dope used has any significant influence on the visibility of the striation etch pattern. It seems likely, therefore, that other impurities with distribution coefficients differing from unity, such as oxygen [$k \sim 0.5$ (10)] or carbon [$k \sim 0.1$ (11, 12)], play an essential part in the mechanism of striation revealing. Furthermore no striations were detectable if the samples were coated with phosphorus glass or if the annealing treatment was carried out under very clean conditions in a rf-heated epitaxial reactor. This indicates that metallic impurities are essential as well.

Accordingly the following explanation for the striation formation is proposed. During annealing at the temperatures indicated, point defects, in particular vacancies, are thermally generated. These point defects will associate with impurity atoms present in the as-grown material. As discussed previously (7, 8) association of vacancies and oxygen atoms may occur, resulting in the formation of vacancy-oxygen complexes. Such complexes can only be stable, at the anneal temperatures involved, if they contain more than three oxygen atoms (7, 8, 13). The oxygen concentration exhibits a periodic variation (striations) along the growth axis, caused by the periodic variation in growth rate usually occurring. Consequently the vacancy-oxygen complexes are formed in a similarly striated pattern, although the variation in complex concentration is much more pronounced (7, 8). During cooling of the samples after annealing, the complexes partly remain unchanged, whereas some of them capture vacancies, giving rise to the formation of tiny vacancy clusters (7, 8).

It has been established that a strong interaction exists between vacancy clusters and metallic impurities such as copper (7, 8, 14) and lithium (15). Furthermore evidence has been obtained of an interaction between metallic impurities, for instance lithium, and small vacancy-oxygen complexes such as the A-center (15-17). It seems likely, therefore, that interaction takes place also between the vacancy-oxygen complexes, formed during annealing, and the metallic impurities introduced. Because of these interactions the metallic impurities are mainly concentrated in the direct neighborhood of the above-mentioned clusters and complexes. Consequently these impurities are distributed in a striated configuration similar to that of these microdefects. It is assumed that this striated distribution of metallic impurities is finally revealed by the preferential etching treatment. These striations again reflect the shape of the original solid-liquid interface which was present during crystal growth.

This model explains the absence of striations if insufficient amounts of metallic impurities are introduced during annealing. Furthermore during annealing in hydrogen this element rapidly diffuses into the silicon slices, resulting in a decreased rate of formation of vacancy-oxygen complexes (8). In heavily dislocated material a large amount of the metallic impurities are concentrated near the line defects, because of the strong interaction between dislocations and these impurities. This partly counteracts the formation of the striations. Differences in oxygen concentration in the various crystals as well as differences in the periodic variation of the oxygen concentration result in different rates of the diffusion-limited formation of the vacancy-oxygen complexes. This explains the material

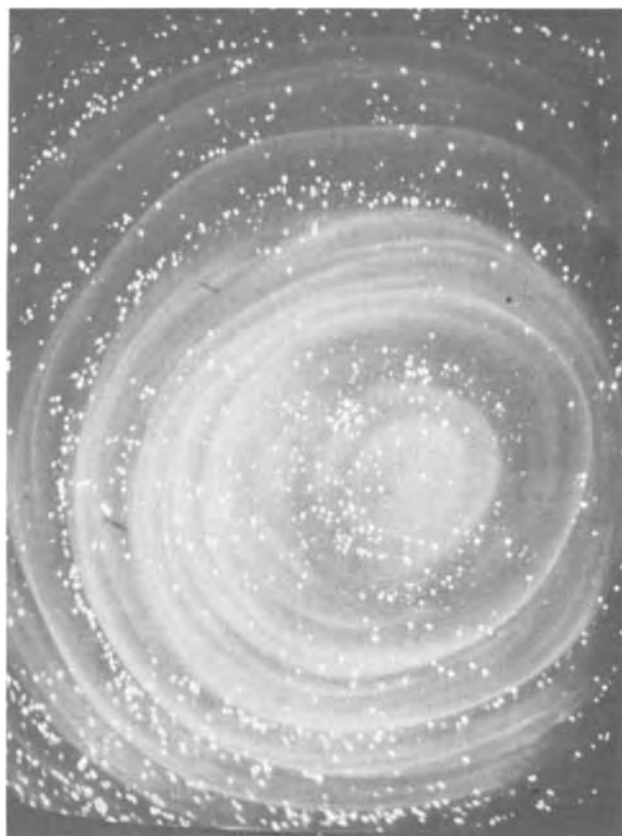

Fig. 3. TV picture obtained with a silicon-vidicon containing a target of dislocation-free floating-zone silicon. Target not illuminated. Target voltage: 10V.

dependence of the minimum annealing time required for the formation of striations.

The irreproducible results obtained with crystals grown from the crucible are not well understood, but may be due to the high impurity content of these crystals. It is well known (18-20) that during high-temperature annealing precipitation of oxygen and carbon takes place in these crystals. This interferes with the vacancy-oxygen complex formation.

Influence of Striation Formation on the Performance of Planar Diodes

Planar devices are made by successive oxidation and diffusion processes. These processes are generally carried out in resistance-heated furnaces at temperatures similar to those at which the described metallic impurity striations are formed. Consequently such striations will form during the fabrication of the devices. Because the metallic impurities will partly be electrically active, these striations will particularly influence the performance of those devices made on silicon slices on which no epitaxial layer has been grown. An example of such a device is the silicon-vidicon.

Figure 3 shows the monitor picture obtained with such a silicon-vidicon TV pick-up tube. The target is made of a dislocation-free silicon slice containing vacancy clusters. As reported previously (7) the large white spots represent regions with leaky diodes caused by an interaction between metallic impurities and the grown-in vacancy clusters. However, at target voltages near the flatband voltage, slight variations in the diode leakage current occur, resulting in a clearly visible background spiral pattern. This pattern seems to be closely related to the described striated distribution of metallic impurities. It has been found (21) that an adequate getter diffusion greatly reduces the background pattern. This observation produces conclusive evidence that indeed metallic impurities are involved.

Ion Implantation and Annealing Effects in SiO_2 Layers on Silicon Studied by Optical Measurements

C. R. Fritzsche* and W. Rothemund

Institut für Angewandte Festkoerperphysik, Freiburg i. Br., Germany

ABSTRACT

Phosphorus, arsenic, and argon ions were implanted into thermally grown SiO_2 layers with energies up to 115 keV. The effect of the implantations, its dependence upon dose, and the anneal behavior were studied by *IR* absorption and ellipsometric measurements. Observed effects are mainly due to radiation damage. A saturation of the damage is observed in the amorphous silica which up to now has only been observed in crystalline materials. Two annealing processes can be distinguished beginning near 100° and near 300°C. Results are compared with the annealing of SiO_2 produced by implantation. Models are proposed to describe the observed shift of absorption bands and the anneal behavior.

The effect of ion implantation on the properties of silicon dioxide layers is of interest in semiconductor device technology and studies of this topic may help to promote the basic research in amorphous materials. Some investigations have already been published reporting on ion migration, creation of traps and surface states, the improvement of the dielectric strength, and changes of the refractive index (1-4). Results show that radiation damage causes the observed effects in many cases.

* Electrochemical Society Active Member.

Key words: silicon dioxide, ion implantation, radiation damage, *IR* absorption.

Radiation damage in 40 keV xenon implanted amorphous SiO_2 has already been studied by Matzke (5) using electron diffraction and gas release techniques, but his work is more concerned with the behavior of damaged quartz. No information on changes in the atomic arrangements was provided by the electron diffraction measurements, and gas release studies are inherently difficult to combine with annealing.

We have therefore used optical methods, such as *IR* transmission spectroscopy and ellipsometry, to study how implantation and annealing alter the SiO_2 layers. This paper reports mainly on the behavior of ther-

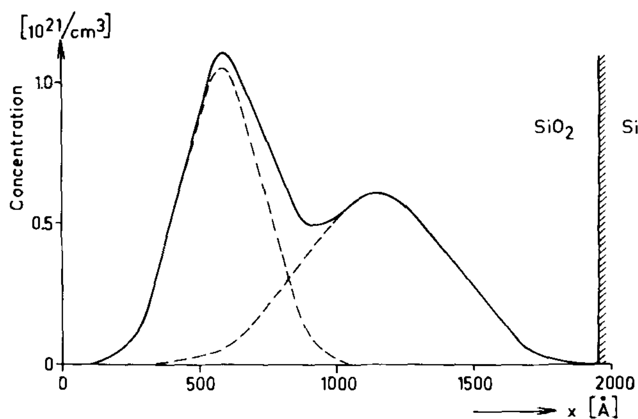

Fig. 1. Ion concentration profile after standard phosphorus implantation as calculated from LSS theory.

mally grown oxides after implantation of phosphorus. At first the dose dependence of damage production by 115 keV ions is studied. Then we describe annealing damage when 115 and 60 keV implants are made to yield an ion distribution like that shown in Fig. 1. Very high doses were chosen so that possibly formed compounds could be observed. Implantations with a lower dose or of other ions are reported also. In addition to the annealing studies we describe the formation of SiO_2 by implantation of oxygen into silicon.

While the behavior of the *IR* absorption after implantation can be fairly well explained, some of the annealing effects are not yet well understood.

Experimental

Silicon dioxide layers were grown thermally in dry oxygen at 1140°C on single crystal 10 ohm · cm p-type silicon wafers. The wafers were polished on both sides before oxidation, and both oxide layers were used for the optical absorption measurements. Layer thicknesses were chosen according to the penetration depth of the implanted ions as described below.

Implantations were made into both oxide layers of every sample, but half the area of the wafer was covered by an impermeable metal sheet so that a comparison of implanted and unimplanted material with otherwise identical properties was possible. The standard implantation used in most of the experiments was made in two steps with 115 and 60 keV, resulting in a profile as shown in Fig. 1 for phosphorus. This double implantation enlarges the range where the ion concentration is in the order of 10^{20} cm^{-3}, and simultaneously keeps the concentration in the silicon low. The different heights of the two peaks resulting from the use of equal doses in both implantations is believed to be less important than the decay near the surface and the oxide silicon interface where the concentration is 2 to 3 orders of magnitude below the peak. Although no severe influence of the profiles on the results has been noticed, one should be aware that our results refer to two special profiles, the Gaussian and the one shown in Fig. 1. The optical properties were expected to depend primarily upon radiation damage. Normally the shape of the damage profile is similar to that of the ion concentration profile (6) but the peaks may be cut off by saturation.

Since the projected range R_p and the standard deviation ΔR_p, and hence the peak concentration at given energy and dose, depend upon the mass of the incident ion, it is, in principle, impossible to implant different ion species with completely identical parameters. We implanted phosphorus, arsenic, and argon and decided to keep the ion energy and the peak concentration C_R constant but to change the oxide thickness D and the implanted dose. Values were chosen so that calculated from LSS theory approximately

$$D = R_p + 3\Delta R_p \quad C_R = 6 \times 10^{20} [\text{cm}^{-3}]$$

for the 115 keV implantation. Thus the profiles for arsenic and argon can be taken from Fig. 1 by contraction in the abscissa direction proportional to R_p. In the experiments with variable dose the 60 keV implantation was omitted.

Dose was determined from the product of time and current at a beam control electrode taking into account the secondary emission of negative particles at the target as well as at the control electrode by multiplication with a correction factor. The correction was calculated from measurements with and without suppression of secondary emission before implantation. This procedure was tested by a variety of experiments with ion implanted semiconductors from which we conclude that 20% is the upper limit for discrepancies between calculated doses and real doses. The relative accuracy within a set of implantations is much better.

In all implantations with exception of the O^+-implantation for the oxide production described later the flux was 9.3×10^{15} ions/cm^2 · sec inside the beam and 1.7×10^{13} ions/cm^2 · sec with respect to the implanted area. The exposure time of any point of the target during one sweep was about 5×10^{-5} sec.

No consideration was given to the charge built up in the insulating oxide. Its upper limit is given by the intrinsic breakdown voltage which is between 80 and 160V and will scarcely be reached because of the ionizing effect of the beam.

Infrared spectra were measured with a Beckman IR 9 spectrometer and the absorbance of the implanted and the unimplanted side of the sample was recorded alternately several times until the mean square deviation of the mean half width $\Delta\nu$ of the band near 9μ was close to $\pm$ 1 cm^{-1}. This was necessary because the magnitude of some effects was very close to the experimental error.

At the beginning of this work layer thicknesses were measured with an interference microscope after etching away part of the oxide and evaporation of aluminum over the etched step. Later, we used an ellipsometer and obtained in this way additional information on the refractive index. The difficulties in interpretation of both the interferometric as well as the ellipsometric measurements will be mentioned in the next section.

Results

A general demonstration of the effects of implantation and annealing is given in Fig. 2 and 3. The absorption bands normally found at 1083 and 459 cm^{-1} are shifted to lower wave numbers and broadened by the implantation of phosphorus (figures) as well as arsenic and argon. The weak band at 810 cm^{-1} is slightly shifted to higher wave numbers. Since this is important for interpretation and no further data are given in the figures, we present single and mean values for standard phosphorus and argon implantation in Table I.

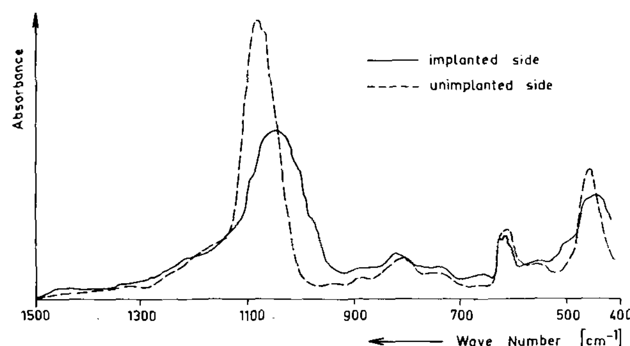

Fig. 2. Effect of phosphorus implantation on *IR* spectrum of SiO_2. Room temperature implantation according to Fig. 1.

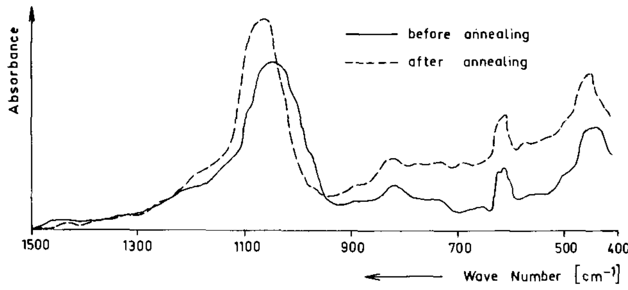

Fig. 3. Effect of 45 min 500°C annealing on *IR* spectrum of P^+ implanted SiO_2. Same sample as in Fig. 2.

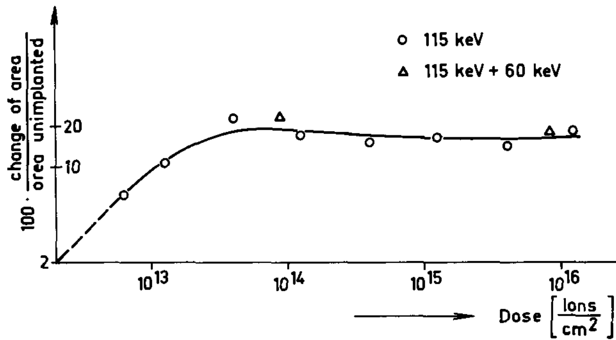

Fig. 4. Dose dependence of change in 1083 cm^{-1} band area. P^+ implantations.

Further effects of implantation are a decrease of the area of the 1083 cm^{-1} band, an increase in layer thickness, and decrease of the refractive index. Annealing at several hundred degrees C alters the properties in the opposite direction as the implantation. The background absorption of the dashed curve in Fig. 3, which increases with decreasing wave number, will not be discussed in detail here. Until now it has only been observed after phosphorus implantations, and is caused by free-carrier absorption in the silicon substrate as can easily be checked after removal of the oxide. Formation of a phosphorus glass should result in an additional absorption band at 1335 cm^{-1} (7). None of the investigated spectra showed this band even after annealing in air up to 700°C. We concentrate now on the strongest band near 1083 cm^{-1} to which we refer as the 9μ band.

The influence of the phosphorus dose on the changes in area, peak location, and half width is shown in Fig. 4 and 5. All three curves show a saturation of the implantation effect near 10^{14} ions per square cm. The dashed line in Fig. 4 is purposely drawn according to proportionality of dose and loss of area. Measurements at a still lower dose would have been of little use because of the relatively high ratio of fluctuations to real change. The curve of the peak wavenumber ν_{max} resembles closely the dependence of dielectric breakdown upon dose, described elsewhere (3). The dose at which the peak appears is also in excellent agreement with reference (3).

The increase in peak wave number at very high doses is believed to be real, since it was well pronounced in a series of samples with small layer thicknesses. Inaccuracies in layer thickness seem to cause the spreading of measurements in Fig. 5 because ΔR_p is only 268Å, and near the oxide silicon interface a path of 0.6 R_p is sufficient to change the concentration by a factor of 10 so that in the thicker layers a larger range of very low concentration exists than in the thinner ones. The little dashes at the measurement points in Fig. 5 indicate samples with thicknesses markedly different from $R_p + 3\Delta R_p$ (maximum difference 298Å). They are at the left of the points if the thickness was too high.

Table I. Shift of the 808 to 812 cm^{-1} band by implantation

	Phosphorus Unimplanted	Phosphorus Implanted	Argon Unimplanted	Argon Implanted
Single values	811 814	819 822 818	812 811	813 818 814
Mean value	812.5	819.7	811.5	815.0

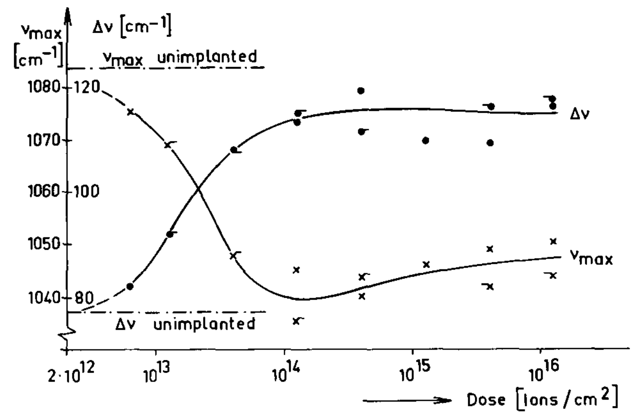

Fig. 5. Dose dependence of peak wave number ν_{max} and half width of the 9μ band. 115 keV P^+ implantations.

In the annealing experiments the double implantation illustrated in Fig. 1 was used. The dose was 4.1 $\times$ 10^{15} ions/cm^2 each for the two phosphorus implantations and thus beyond the saturation shown in Fig. 4 and 5. Possibly this is the reason, why the ν_{max} and $\Delta\nu$ values after implantation do not distinctly depend upon the profile as can be seen by comparison of the 4 $\times$ 10^{15} cm^{-2} values in Fig. 5 (single implantation) and the initial values of Fig. 6 and 7 (double implantation). Figures 6 and 7 show isothermal annealing. After 45 min at 690°C in air the implantation effects have vanished to a high degree. Only the half width is still slightly increased. At 176°C and annealing times up to 140 min no changes in ν_{max} outside the experimental error can be observed. This was also true for arsenic and argon implantations. The half width, however, changes at this temperature. After phosphorus implantation it runs through a maximum at 176°C, while after argon and arsenic (similar to argon in Fig. 7) implantation $\Delta\nu$ decreases with increasing time even at 149°C. At a glance the result for phosphorus

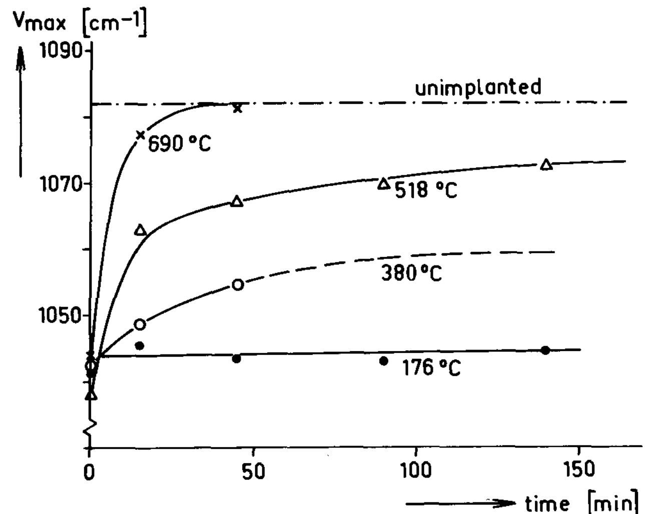

Fig. 6. Isothermal annealing after P^+ implantation shown by the peak wave number of the 9μ band. Implantation according to Fig. 1.

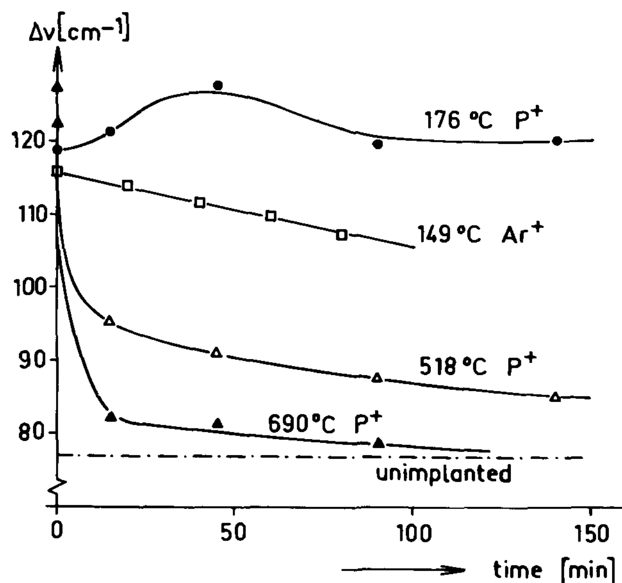

Fig. 7. Isothermal annealing after P^+ and Ar^+ implantation shown by the half width of the 9μ band. P^+ implantation according to Fig. 1. Argon dose 3 x 10^{15} each for the 115 and 60 keV implantation.

at 176°C may appear somewhat dubious, particularly since an accidentally very low initial value could account for the shape of the curve. This, however, cannot happen in the case of isochronal annealing which is shown in Fig. 8. Here all points at different temperatures must be taken from different samples. We have plotted the remaining change in per cent of the initial change. For high dose phosphorus implantations all points (x and o) up to 541°C lie above the 100% line with no exception. It is very unlikely that this had happened accidentally. The argon and arsenic implanted samples show the decrease mentioned above.

The low dose phosphorus implanted sample (•) does not exceed the 100% line but lies between high dose phosphorus and argon. Some samples with single phosphorus implantation were also annealed, and part of the results has already been published (3). No significant difference between single and double implanted layers was noticed in the behavior of ν_{max} and $\Delta\nu$.

The anneal behavior of the band area is similar to that of the peak wave number shown in Fig. 6. At 700°C the initial area is reached after 45 min. At 518°C still 65% of the initial change are retained after 140 min. At 176°C the area increases very slowly but, in contrast to ν_{max}, distinctly.

Interferometric measurements seem to indicate that the thickness increases with increasing dose up to 1.25 $\times$ 10^{14} ions/cm². However, at the high doses a substantial amount of ions reach the silicon and this can

268	1037	Not performed
380	1041	1033
500	1047	1048
700	1074	1063

lead to considerable errors. The implanted silicon was found to be attacked by the hydrofluoric acid used for the step etching described above at least if the calculated surface concentration reaches 6 · 10^{18} cm^{-3} and then the step to be measured is higher than the layer thickness. If the refractive index of the silicon surface changes, the ellipsometric measurements will be wrong also. We restrict ourselves therefore to the presentation of data obtained at low dose or with layer thicknesses of at least $R_p + 3.2\ \Delta R_p$. Interference measurements on such samples implanted with 115 keV phosphorus showed an increase in thickness of 1.8 and 3.6% at 6.25 $\times$ 10^{12} and 1.25 $\times$ 10^{14} ions/cm² respectively.

Results of ellipsometric measurements after standard argon implantation are shown in Table II. The implantation has increased the thickness. Annealing at 176°C results in a further increase. Thus interferometric as well as ellipsometric measurements show that implantation increases the thickness markedly. The refractive index is diminished on the implanted side and decreases during annealing.

As a supplement we have investigated the annealing of SiO_2 layers produced by ion implantation. O^+ ions where implanted with 70; 40; 20 keV and 1.3 $\times$ 10^{18}; 8.5 $\times$ 10^{17}; 5.0 $\times$ 10^{17} ions/cm² respectively into n-type silicon substrates. A low current density of 7.2 μA/cm² at maximum was chosen because a high density may possibly result in effects similar to annealing. The peak wave number of the 9μ band after implantation as well as after annealing is given in Table III. Two samples were annealed one in air and one in nitrogen for 30 min at different temperatures. The spectra of the original and the 700°C air annealed sample are shown in Fig. 9. The shift of the 9μ peak towards higher wave numbers begins at 268°C which is about the same temperature at which the annealing anomalies of P^+ implanted layers disappear (Fig. 8).

Discussion

The effect of implantation on the optical properties of thermally grown SiO_2 films can partially be under-

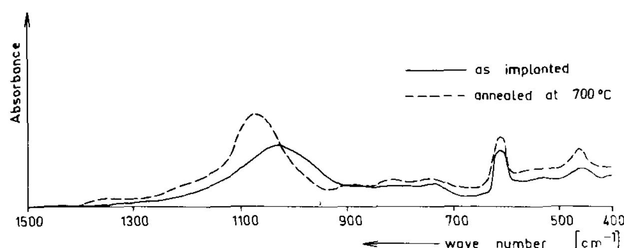

Fig. 9. IR spectra of implantation produced SiO_2. Annealing in steps of 30 min according to Table III (air).

stood as a consequence of a decrease in density. The increase in thickness indicated in the first line of Table II is about 6%. The total implanted dose was 6×10^{15} ions/cm^2 into a layer containing about 10^{18} silicon and oxygen atoms/cm^2. Hence the increase in thickness is one order of magnitude above the increase in number of atoms/cm^2 and indicates a decrease in density. Pliskin and Lehman (8) investigated the optical properties of thermally grown as well as of pyrolytically deposited and heat-treated oxide layers with densities between 2.09 and 2.23 g/cm^3 and found that the less dense oxides have a lower refractive index and show the 9μ band at lower wave numbers in agreement with our observations. Besides the density broken bonds may immediately contribute to the band shift as discussed below. Pliskin and Lehman describe the relationship between density ρ and refractive index n by

$$\rho = -4.784 + 4.785\, n \quad [1]$$

If the volume changes only by the thickness D and the mass is constant, Eq. [1] means that in very good approximation one should find

$$(n - 1) D = C \quad [2]$$

where C is a constant. From the first and the third column of Table II we find that in the annealing experiments at 176°C our data fulfill Eq. [2] excellently with deviations in C of less than one tenth of a per cent. This shows that during 176°C annealing n is simply controled by the density.

Primak *et al.* (9) have reported that after exposure within a nuclear reactor the density and refractive index of vitreous silica are increased in contrast to our results after ion implantation into thermally grown layers. This discrepancy may be caused by differences in the structure of the materials rather than by the different masses of the irradiated particles since Bayly and Townsed (4) found an increased refractive index independent of the ion species implanted into silica glass. On the other hand Primak et al. (9) report a decrease of density and refractive index in quartz after irradiation in contrast to their own results with vitreous silica. That means that even qualitatively the radiation effects depend strongly upon the structure of the solid. The loss in band area after implantation can be interpreted as a loss of absorbing oscillators because the area is proportional to the integral

$$\int \alpha_\nu d\nu = N \cdot \frac{\pi e^2 (n^2 + 2)^2}{3\mu c \cdot 9n} \quad [3]$$

where α_ν is the absorption coefficient at wave number ν, N the number of oscillators, μ the reduced mass, e the net electronic charge, and n the refractive index (11). From Table II and Eq. [3] we find, that even at the high concentrations reached by the standard implantation the change of n would change the integral by 4% while according to Fig. 4 the area changes by 19% at a dose of 6×10^{13} cm^{-2}. Hence most of the change can be attributed to N. Since the area increases during annealing the loss of oscillators is not due to sputtering of the oxide and may be understood as a consequence of broken bonds.

By the concept of broken bonds we get an interpretation of the opposite shift of the 1083 and 810 cm^{-1} bands. Matossi (12) has shown that connected SiO_4 groups give two active frequencies which can be derived from a frequency of a single group by changing the mass m of the connecting atom to $m/2$ or to $m = \infty$ and that the 810 cm^{-1} band may be derived with $m = \infty$ from the 900 cm^{-1} due to single SiO_4 systems, while 1083 cm^{-1} corresponds to $m/2$. Thus, if connecting oxygen atoms are thrown to interstitial sites during implantation both bands should move towards an intermediate frequency in agreement with our observations. Displacement of silicon may also contribute to the shift. Arsenic as well as argon implantations show qualitatively the same effect as phosphorus implantations but no indication was seen that the spectra depend upon the implanted species. Therefore the curves in Fig. 4 and 5 mean that with increasing dose an increasing number of displacements is produced until at about 10^{14} incident ions per square cm, the damage saturates. Such a saturation is well known from crystalline materials but there it is accompanied by a loss of long range order and this condition was defined as "amorphous" [see Mayer *et al.* (6), pp. 98 and 99]. Our layers are amorphous already before implantation but in another sense. Their structure is glassy and can still be damaged. Nevertheless, our investigations indicate that the saturation can be caused by the impossibility of breaking all bonds or of keeping them broken and is not necessarily related to the loss of long range order. It is commonly assumed that in amorphous silica the SiO_4 tetrahedrons form rings and the number of sides of the resulting polygons is close to 5 (13). From the maximum loss of about 20% shown in Fig. 4 and from Eq. [3] one may guess that saturation is reached when approximately every ring contains one damaged tetrahedron. From the specific weight of 2.2 g/cm^3 and the layer thickness of 1950Å a number of about $4 \cdot 10^{17}$ SiO_2 groups per cm^2 results. Thus, below saturation the number of displacements per incident 115 keV phosphorus ion is in the order of 10^3 which is the value to be expected (6).

The annealing experiments show at least two different processes. Figures 7 and 8, Table II, and the measurements of band area show that slightly above 100°C the atoms begin to change their places while Fig. 6 shows no indication that the network reorders to its initial structure. Possibly it is a recombination of interstitials and vacancies which is going on at these low temperatures. An annealing process in the same temperature range was also observed by Fahrner and Goetzberger (2) who found that surface states produced by 30 keV implantation of 10^{13} cm^{-2} N^+ ions into *MOS* structures begin to anneal at about 130°C and disappear at 300°C within 2 hr. We hesitate to interpret the increase in $\Delta\nu$ observed in phosphorus implanted samples since the determination of $\Delta\nu$ needs the assumption of a zero level which may be influenced by the overlap of bands and the free carrier absorption shown in Fig. 3. But, whatever the reason for the broadening may be, it is a special feature of the phosphorus implantation. Possibly the phosphorus is transiently incorporated into the silicon oxygen network while arsenic and argon are not.

In all annealing experiments above 268°C, all the investigated properties of the oxide alter in direction to their initial values. The behavior suggests that in amorphous silica the SiO_4 tetrahedrons tend to an arrangement which is not completely at random. The partial order may break down with increasing damage in a certain analogy to the formation of an amorphous layer in implanted crystals. The order is probably not yet present in implantation produced or in anodically grown oxides. The latter show a spectrum similar to that of damaged thermal SiO_2 and are not much influenced by implantation (3). The temperature at which the rearrangement begins is surprisingly low and demonstrates the necessity of using low beam currents if one wants to study the process of oxide formation by the ion beam itself separately from the effect of heat. From other work (2) where our implantation machine was used and distinct annealing effects were observed between 100° and 150°C we estimate that 130°C is an upper limit for the wafer temperature reached during our implantations. Freeman *et al.* (10) have used 1 mA/cm^2 and reached a wafer temperature of 600°C. They find the 9μ band at about 1059 cm^{-1} in good agreement with our data in Table III.

As to the formation of phosphorus glass by implantation three reasons for the nondetection of the $P = 0$ band at wave number 1335 cm^{-1} are taken into con-

sideration. Either the range where the phosphorus concentration is sufficiently high was too small, the anneal temperatures were too low, or additional oxygen is necessary. We do not believe that the nondetection is caused by the choice of transmission instead of reflectance measurements because this choice was made in accordance with the work of Fraenz *et al.* (7) who found the band very pronounced in transmission.

Results

The interdependence of density, refractive index and *IR* absorption of thermally grown SiO_2 layers on silicon after ion implantation or subsequent annealing above 300°C resemble the results of Pliskin and Lehmann (8) in the sense that implantation decreases, and high temperature annealing increases the density. The opposite shift of the bands at 1083 cm^{-1} and 810 cm^{-1} supports the Matossi model (12) for the vibration of linked groups of atoms. The number of bonds which remain broken after implantation is restricted. In the damaged material single atoms can move at temperatures near 100°C. Rearrangement of the initial structure begins slowly near 300°C, and at 700°C most of the change is finished within 45 min. High dose phosphorus implantations do not result in the formation of a phosphorus glass but at slightly elevated temperature transient reactions of the phosphorus with the damaged oxygen-silicon network seem to take place.

Acknowledgments

Thanks are expressed to H. Seelewind and G. Sixt for their assistance and aid in the optical measurements, to A. Axmann and J. Schaub who carried out the implantations, K. Eisele who took care of the oxidations and to W. Haydl for his suggestions concerning the manuscript.

Manuscript submitted Oct. 7, 1971; revised manuscript received May 10, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Properties of Ammonia-Free Nitrogen-Si_3N_4 Films Produced at Low Temperatures

R. Gereth and W. Scherber

AEG-Telefunken, Semiconductor Division, Heilbronn, Germany

ABSTRACT

Thin Si_3N_4 films are deposited on silicon substrates by the reaction of SiH_4 and N_2 in an rf glow discharge at substrate temperatures between 25° and 500°C. These films are hereafter referred to as "nitrogen-Si_3N_4 films." At optimum growth conditions an index of refraction of 2, a breakdown field strength of 10^7 V/cm, a flatband surface charge of 1.5×10^{12} cm^{-2}, and a very high stability against bias temperature stress is obtained. With changing SiH_4 concentration the stoichiometry of the nitride films can be varied between highly nitrogen-rich and silicon-rich films resulting in a corresponding wide variation of physical and electrical film properties. Hysteresis-free and highly stable MNS varactors can be accomplished by an *in situ* glow discharge exposure in H_2 and N_2 atmosphere, respectively.

During the past years many publications (1-8) have been concerned with the outstanding properties of Si_3N_4 films for semiconductor applications. Most Si_3N_4 films investigated thus far have been fabricated from ammonia and silane or another appropriate Si-compound. It is surprising that nobody tried to produce Si_3N_4 films by simply starting from N_2 and SiH_4, since handling and purification of ammonia is very difficult. The gases N_2 and SiH_4 are easily available in an extremely pure grade. Therefore, they should represent the ideal starting materials for the fabrication of ultra-clean Si_3N_4 films.

After completion of the present investigation it was learned that Kuwano (9) mentioned in 1968 that Si_3N_4 could possibly be formed out of SiH_4 and N_2. Off hand, the reaction looks rather simple but it does not take place under normal conditions. To overcome this difficulty the reaction was allowed to proceed in the presence of an rf glow discharge. This way, very good Si_3N_4 films could be fabricated at temperatures below 400°C starting from SiH_4 and N_2.

It is the purpose of the present paper to describe the new low-temperature Si_3N_4 films which for the sake of

Key words: silicon nitride films, semiconductor technology, low-temperature device passivation, glow discharge, chemical vapor deposition.

simplicity are referred to as "nitrogen-Si_3N_4 films." Using the equivalent terminology the standard pyrolytic Si_3N_4 films made out of SiH_4 and NH_3 are referred to as "ammonia-Si_3N_4 films."

The first part of the paper deals with the experimental results. Both the physical and the electrical properties of the nitrogen-Si_3N_4 films and their dependence on deposition parameters are described. The second part discusses the experimental film data. A comparison between ammonia- and nitrogen-Si_3N_4 films is made. A summary of the most interesting features of the new nitrogen-Si_3N_4 films concludes the paper. A preliminary brief report about the present work has been published (10).

Experimental Results

Deposition apparatus.—The standard pyrolytic deposition of Si_3N_4 films requires relatively high reaction temperatures in the range from 600° to 900°C and the use of ammonia, which cannot easily be purified from water residues and alkali contaminants. The new Si_3N_4 deposition method employs only SiH_4 and N_2 as reaction partners. The nitrogen-Si_3N_4 films are deposited in an rf glow discharge at temperatures below 500°C.

Figure 1 illustrates the nitrogen-Si_3N_4 deposition reactor. It is a high vacuum-tight apparatus because the affinity of SiH_4 to O_2 is many orders of magnitude greater than the affinity of SiH_4 to N_2, meaning that small amounts of O_2 in the apparatus are completely deposited in the nitride layer. The entire gas flow system is made of welded stainless steel pipes with high vacuum connections. A diffusion pump is used to check the tightness of the system at any time. The system can be pumped down to an ultimate pressure of 10^{-6} Torr.

The gases SiH_4, N_2, and H_2 contain less than 1.5 ppm H_2O or O_2. SiH_4 was used in two different dilutions, namely 1.5% SiH_4 in He and 2% SiH_4 in N_2. These two gas mixtures are characterized by the following notations: SiH_4 (He) and SiH_4 (N_2), respectively. The volume ratio SiH_4/N_2 in the reaction chamber can be varied from 10^{-4} to 0.15 by mixing the SiH_4 gas with a separate N_2 stream. The working pressure during nitride deposition is controlled by the inlet valves while the rotary pump is running at constant pumping rate.

The reaction chamber consists of a horizontal quartz tube, 90 cm long with a diameter of 7 cm. The wafer carrier also is made of quartz. It is resistance heated and covers an area of 4 × 11 cm. The glow discharge inside the reaction chamber is excited by an rf coil or two capacitor plates located outside the quartz tube. The rf generator is operating at a frequency of 500 kHz. The heating filament of the wafer carrier is arranged perpendicular to the direction of the electric field in both modes avoiding variation of substrate temperature with the rf field strength.

The nitride films are deposited on polished p-type silicon wafers cut parallel to the (111) plane and having a resistivity of 500 ohm-cm. The wafers are precleaned in HF and hot HNO_3 with intermediate rinses in deionized water.

Measuring techniques.—Nitride thickness and index of refraction are measured by means of an ellipsometer. Nearly all experiments are conducted with 600-1000Å thick films. Samples for electrical evaluation are supplied with evaporated aluminum dots having a diameter of 0.4 mm on the nitride side. Capacitance measurements are made using a 100 kHz bridge with 10 Hz bias sweep. The C-V plots are automatically displayed on a cathode-ray tube.

Growth rate.—The growth rate of the nitrogen-Si_3N_4 films is a linear function of the rf power. Between 100 and 700W the growth rate increases from zero to 400 Å/min. For the present investigations an rf power slightly above 100W is used. Substrate temperature and total pressure have no remarkable influence on the growth rate.

Figure 2 shows the rate of film deposition *vs.* SiH_4/N_2 ratio at constant rf power for the $SiH_4(N_2)$ (results denoted by solid circles) and the SiH_4(He) system (results denoted by open circles). If SiH_4 is diluted in He an increase of the SiH_4/N_2 ratio means a dilution of both reaction partners. Therefore, the growth rate remains nearly constant.

The growth rate can be enhanced substantially by an addition of a small amount of hydrogen to the gas mixture. The effect is not yet completely understood but it is very useful to get sufficient growth rate at extreme low power setting. No variation of film properties with presence of hydrogen could be observed.

The uniformity of film thickness across the wafers is excellent if the glow discharge is induced by two parallel field plates. Variation of film thickness across a 1 in. wafer is typically ±5%. Using the cylindrical rf coil rather good uniformity can be achieved only by an optimum combination of rf power and gas pressure.

Pinhole density.—Pinholes in the nitride films are detected by a special etchant consisting of 17 ml ethylenediamine, 3g pyrocatechol, and 8 ml water. The etchant penetrates the nitride films through smallest pinholes and attacks the silicon substrate. The pinhole density is extremely sensitive to the preceding cleaning procedures. *In situ* glow discharge treatments in N_2, A, H_2, or O_2 are most effective. Furthermore the pinhole density can be reduced with decreasing rf power. The extreme increase of deposition time at low power setting can be compensated by the addition of hydrogen mentioned above.

The nitrogen-Si_3N_4 films deposited at minimum power exhibit less than 10 pinholes per mm². This value depends strongly on the preceding fabrication steps like polishing, cleaning, and rinsing procedures.

Substrate temperature, silane concentration, dilution, pressure, and film thickness do not affect the pinhole density.

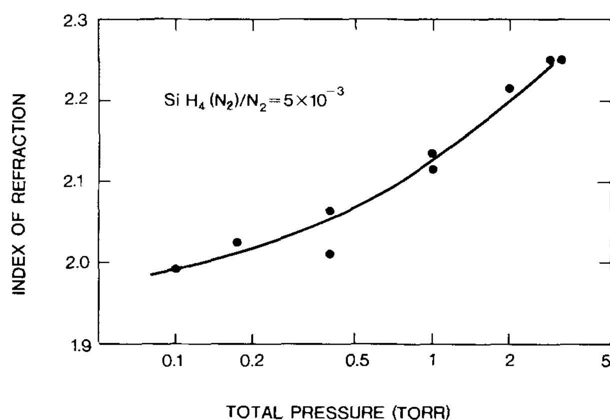

Fig. 4. Index of refraction as a function of total pressure

Optical properties.—The index of refraction of the nitrogen-Si_3N_4 films has been measured as a function of the SiH_4/N_2-ratio (Fig. 3), total pressure in the reaction chamber (Fig. 4), and substrate temperature (Fig. 5). The rising index of refraction for SiH_4/N_2 ratios above 2×10^{-3} is thought to be caused by the increasing Si content as is discussed later. Because of the strong dependence of the index of refraction on the total gas pressure, most of the films employed in the present experiments have been produced at a constant pressure of 1 Torr. Figure 5 suggests that nitrogen-Si_3N_4 films produced at substrate temperatures between 350° and 500°C have the same index of refraction. Unless otherwise noted constant substrate temperature of 350°C has been chosen.

The infrared transmission spectrum between 2.5 and 20μ is shown in Fig. 6. A broad absorption peak lies between 9.5 and 14μ with a maximum at 12μ. This is very similar to the IR absorption peak of pyrolytic nitride films deposited from SiH_4 and NH_3 at 700°C. Ammonia-free nitride films seem to be very pure. No SiO_2 component at 9.4μ could be detected on any sample, unless the reactor was leaky. Other possible compounds like Si ≡ N at 4.7μ, Si-H at 4.7μ, N-H at 3.0 and 6.4μ, and Si-NH-Si at 8.6μ cannot be detected by IR in the nitrogen-Si_3N_4 film. This simplicity in structure is not usual in films starting from ammonia or in sputtered silicon nitride films.

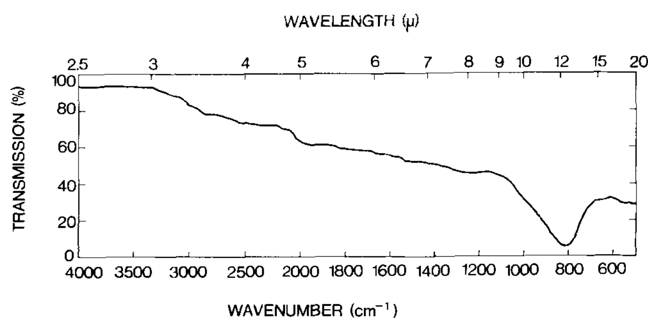

Fig. 6. Typical infrared transmission spectrum

A shift of the maximum absorption peak to shorter wavelengths is observed with increasing substrate temperature and decreasing SiH_4/N_2 ratio. Our data on this subject are fully comparable to those given by Kuwano (12).

Etch rate.—Similar to ammonia-Si_3N_4 films the etch rate of nitrogen-Si_3N_4 films produced in the glow discharge is strongly dependent on the highest temperature the films are subjected to. The etch rates in buffered and diluted HF are shown in Fig. 7 as a function of substrate temperature. The strong apparent densification effect can be usefully employed in device fabrication: deposition temperatures up to 300°C guarantee easy etching of the nitride film and post-annealing steps at temperatures as high as 1000°C produce adequate chemical resistance. The variation of etch rate with the SiH_4/N_2 ratio is shown in Fig. 8 by the open circles. Maximum values are obtained at 1.5×10^{-3} $SiH_4(N_2)/N_2$. The solid line in Fig. 8 gives the ratio of nitrogen to silicon atoms in the films as determined from back-scattering experiments (11). The higher the silane concentration in the reaction chamber, the higher is the Si concentration in the deposited nitride film. A SiH_4/N_2 ratio of 1.5×10^{-3} results in films with a N/Si value of 1.33 as calculated for Si_3N_4. It is interesting to note that a decrease in etch rate was observed for both silicon-rich and nitrogen-rich nitride films.

Dielectric breakdown.—The breakdown field strength of the nitrogen-Si_3N_4 films prepared at 350°C has a value of 10^7 V/cm (Fig. 9). It is constant over a wide variation of gas composition. Above 2×10^{-2} $SiH_4(He)/N_2$ it deteriorates due to the Si enrichment

in the film. An increase in substrate temperature from room temperature to 400°C drastically improves the breakdown field strength (Fig. 10).

C-V measurements.—The capacitance of metal-nitride-silicon (MNS) structures monitored as a function of applied bias yields the well-known C-V curves illustrated in Fig. 11. The flatband voltage is a measure of the electrical charge contained in the entire system. One talks about a hysteresis effect if the C-V curve is split during the sweeping cycle. During the present experiments the bias was automatically varied 10 times per second between minus and plus 50V. The hysteresis effect is normally related in the literature (13) to the existence of a thin natural oxide layer between Si_3N_4 and Si. Traps are located at the interface between oxide and nitride. These traps are charged and discharged during the C-V measurement causing the hysteresis of the C-V curve. The charge transport through such thin oxide layers occurs by tunneling (14).

C-V measurements have been employed to explore the influence of an *in situ* glow discharge precleaning step on the properties of the nitrogen-Si_3N_4 films. Prior to the actual deposition cycle the wafers are exposed to a glow discharge treatment of 30 min at temperatures of 350°C. Interesting results are obtained by this treatment. Figure 12 lists some of them. The empty rectangles illustrate the flatband voltages measured on samples pretreated in N_2, A, H_2, O_2, and those without pretreatment. There is no major effect visible. Only an O_2 glow discharge pretreatment reduces the flatband voltage to values corresponding to a flatband charge below 10^{12} cm^{-2}.

The picture is different for the hysteresis effect. No hysteresis can be observed on samples whose surface has been treated in a H_2 glow discharge just prior to the nitride deposition. The O_2 glow discharge produces a rather pronounced hysteresis of opposite sign. The resulting C-V curve resembles that one shown in Fig. 11 if the directions of starting and returning curve are interchanged.

Figure 12 also contains the results of a bias stress test. The shift of the flatband voltage was registered after a potential of −30V has been applied for 1 min to the metal contact of the MNS structures. Essentially no shift of the flatband voltage was observed on N_2 treated samples. Again after an O_2 treatment the behavior of the test sample is inverted, the shift of the flatband voltage being in the opposite direction.

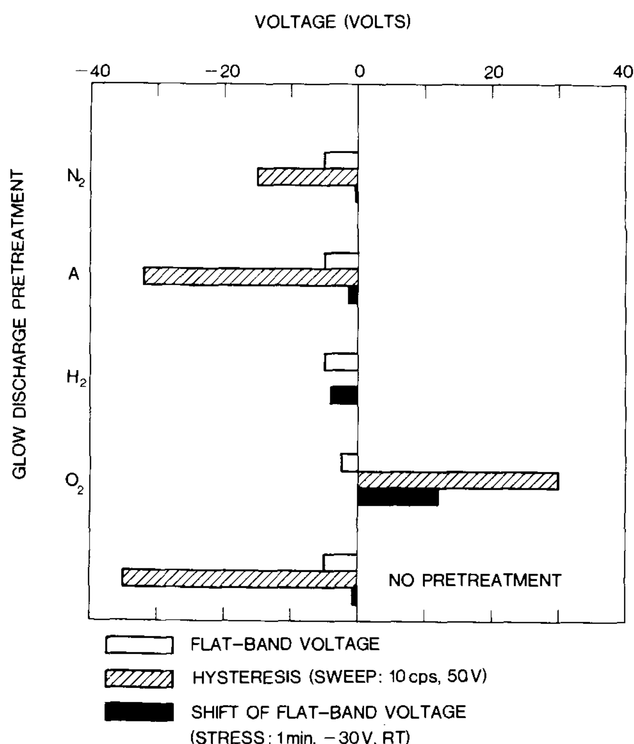

Fig. 12. Effect of glow discharge pretreatment on flatband voltage, hysteresis, and stability of different discharge atmospheres.

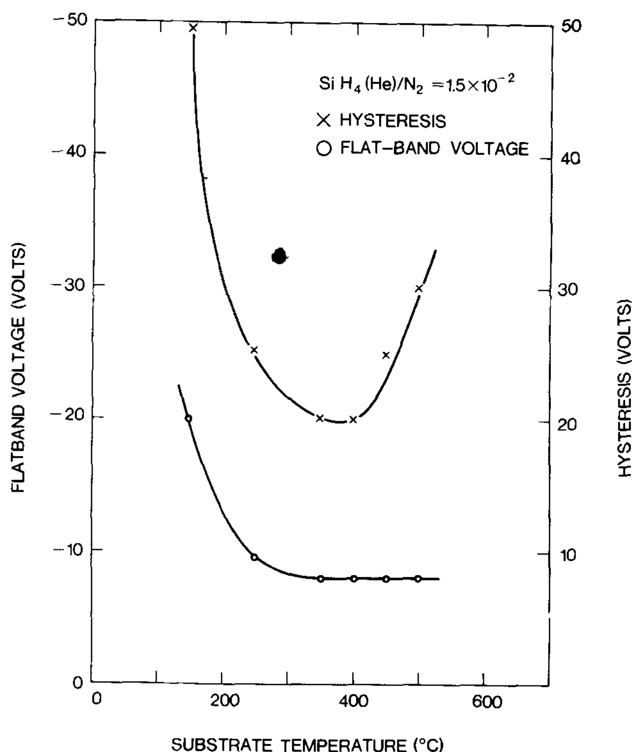

Fig. 13. Flatband voltage and hysteresis as a function of substrate temperature.

Figure 13 reveals the relationship between flatband voltage, hysteresis, and substrate temperature during film production. Temperatures of 350° to 400°C are necessary to bring hysteresis and flatband voltage to their minimum values. A variation of the SiH_4/N_2 ratio has no influence on the flatband voltage. The hysteresis, however, exhibits a maximum value in the range between 10^{-3} and $5 \cdot 10^{-3}$ SiH_4 content (see Fig. 14). In Fig. 15 results of bias temperature stress tests on MNS samples fabricated with different SiH_4/N_2 ratios are shown. The shift of flatband voltage was measured after a negative field of 2×10^6 V/cm has been applied to the metal contact for 10 min at 200°C. Again the SiH_4/N_2 ratios between 10^{-3} and 4×10^{-3} yield optimum results in analogy to the above described measurements of physical film properties.

Discussion

The various experimental results are widely consistent among each other and allow a clear picture to be drawn of the investigated nitrogen-Si_3N_4 films. The most striking fact is the strong dependence of nearly every film property on the gas composition. Therefore, controlling of gas flow and pressure must be done very carefully and reliably to achieve constant film deposition. In the pure $SiH_4(N_2)$ system, SiH_4/N_2 ratios of 10^{-3} to 3×10^{-3} yield N/Si ratios in the film of 1.25 to 1.4 and maximum etch rates (Fig. 8) both revealing good Si_3N_4 stoichiometry. The measurements of index of refraction, infrared absorption, electrical stability, and C-V hysteresis confirm this result. In comparison, the pyrolytic deposition of Si_3N_4 out of SiH_4 and NH_3 is less sensitive to gas composition: the silane concentration can be increased up to nearly 10% without changing the film qualities (5, 8). The required greater excess of N_2 in the ammonia-free deposition method results from the higher activation energy of N_2 compared to NH_3.

In the SiH_4(He) system, both the SiH_4 and the N_2 partial pressures are reduced, which decreases the nitride growth rate as can be seen in Fig. 2. Both curves of growth rate in Fig. 2 cannot be extrapolated to the origin. For the $SiH_4(N_2)$ system this behavior can only be interpreted as follows. Already at the lowest silane concentration the reaction is limited by the nitrogen concentration or, strictly speaking, by the concentration of activated nitrogen atoms.

Substrate temperature is an important deposition parameter. The minimum temperature necessary to grow good quality films lies around 350°C. This conclusion can best be derived from the measurements of the index of refraction (Fig. 5). At higher substrate temperatures the films become denser. The etch rate reduces and the infrared absorption peak shifts to shorter wavelengths. The hysteresis, however, increases (Fig. 13). This latter effect is not yet fully understood. Kuwano (12) also observed an increased hysteresis effect while using a substrate temperature of 500°C instead of 300°C. He suggested that ionized Si atoms might be responsible for the increased hysteresis effect. In light of the present new results which show that the index of refraction remains constant above 350°C (Fig. 5) and the hysteresis drops at higher silane concentrations (Fig. 14) the above explanation must be reconsidered.

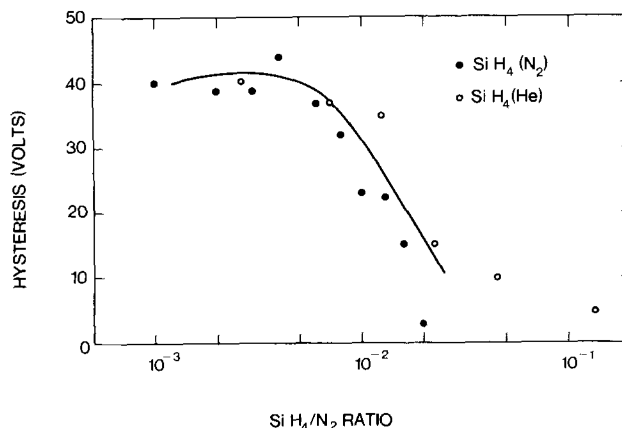

Fig. 14. Hysteresis as a function of SiH_4/N_2 ratio for the $SiH_4(N_2)$ and the SiH_4(He) system.

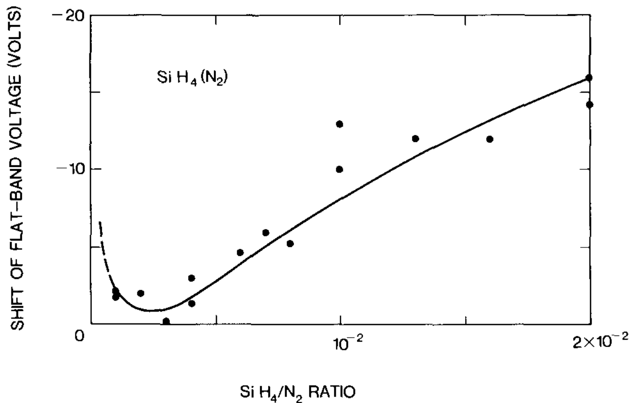

Fig. 15. MNS stability as a function of SiH_4/N_2 ratio. BT stress conditions: 10 min, 20V, 200°C.

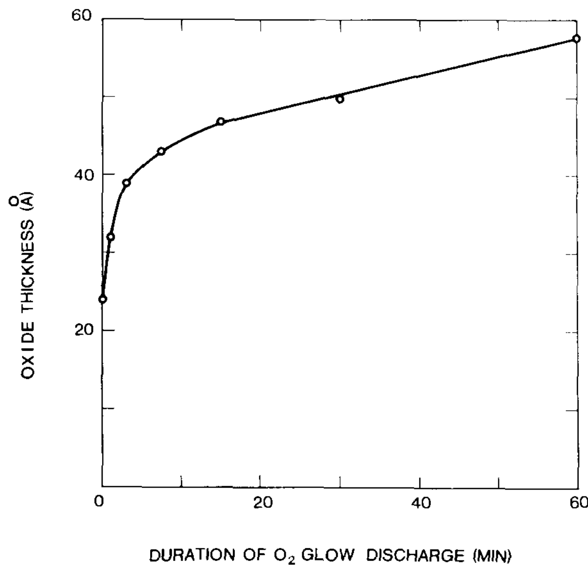

Fig. 16. Oxide growth as a function of duration of O_2 glow discharge.

The complete absence of hysteresis on H_2-treated silicon surfaces means that the natural oxide layer is removed. The nitride layer directly borders the silicon. In this structure no field-induced charge transport is possible within one sweeping cycle of the C-V curve. However, great instability occurs under long time stress even at room temperature.

The N_2 treatment lowers the hysteresis and improves the stability in contrast to an A treatment: the number of traps is reduced if N_2 can act on the surface. Perhaps the N_2 glow discharge allows a very slow but perfect growing of the first nitride molecules. The threshold voltage above which hysteresis occurs does not change either by the N_2 or by the A treatment, meaning that the oxide thickness remains unaffected. This is different after the O_2 treatment where the threshold voltage rises from approximately 10V up to 20V which could be explained by an increase of oxide thickness. Ellipsometric measurements (Fig. 16) demonstrate that an O_2 glow discharge of 30 min indeed produces an oxide thickness of 50Å, twice its original thickness.

The effect that the sign of the hysteresis and of the instability are inverted after O_2 treatment (Fig. 12) is not easy to explain. One might speculate that the plasma-grown oxide layer polarizes easily when an electric field is applied.

Summary and Conclusions

Nitrogen-Si_3N_4 films have been deposited on p-type silicon wafers by initiating the reaction between SiH_4 and N_2 with the help of a glow discharge. The film properties are in general comparable to those of pyrolytic nitride films deposited from SiH_4 and NH_3. They offer, however, additional advantages. The absence of ammonia makes it easier to deposit oxide- and sodium-free nitride films. Deposition is possible at temperatures well below 400°C. The substrate surface can be cleaned *in situ* by a suitable gas discharge treatment to achieve better stability or to tailor special properties of the films. The nitride properties can be widely varied by the deposition parameters, especially by the silane concentration in the plasma. Nitrogen-rich, silicon-rich, or even pure silicon films can be produced deliberately.

The properties of ammonia-free nitrogen-Si_3N_4 films can be summarized as follows:

(*a*) Predicted nitride stoichiometry is obtained at a substrate temperature of 350°C and a SiH_4/N_2 ratio of 1.5×10^{-3} related to a total gas pressure of 1 Torr during deposition.

(*b*) At substrate temperatures below 350°C the nitride films become less dense showing higher etch rate, larger flatband voltage, increased hysteresis, smaller index of refraction, reduced breakdown field strength, and an infrared absorption peak occurring at lower frequencies.

(*c*) At substrate temperatures above 350°C, hysteresis increases again, but no silicon enrichment can be detected in the film.

(*d*) The SiH_4/N_2 ratio directly determines the stoichiometry of the nitride films. Between 10^{-4} and 2×10^{-2} SiH_4 content the atomic ratio N/Si in the film varies from 1.7 to 0.9.

(*e*) The index of refraction increases with the silicon content of the film. Nitrogen-rich films have constant index of refraction with a value slightly above 2.

(*f*) Nitride films with theoretical Si_3N_4 stoichiometry exhibit maximum HF etch rate and maximum C-V hysteresis. Both effects are useful to optimize deposition parameters.

(*g*) The hysteresis can be avoided entirely by exposing the silicon surface to an H_2 glow discharge just prior to nitride deposition. Stability of MNS varactors can be improved by a N_2 glow discharge treatment.

(*h*) Shallow oxide layers on silicon surfaces from 20 to 60Å can be obtained reproducibly and at low temperatures by a glow discharge treatment in an oxygen atmosphere.

(*i*) The nitride deposition rate can be increased by a factor of two or more by adding some per cent hydrogen to the reactive gas mixture.

The optimum deposition temperature for the nitrogen-Si_3N_4 films lies nearly 500°C below that for ammonia-Si_3N_4 films. Even at room temperature, nitride films with reasonable quality can be produced which are suitable for the passivation of temperature-sensitive device structures.

The absence of ammonia is an obvious bonus. Working with ammonia means higher risk of getting water and alkali contaminants which are the cause of deleterious instabilities in SiO_2 films. Nitrogen-Si_3N_4 films are, therefore, perfectly tailored for the low-temperature passivation of clean oxide layers in connection with MOS and planar devices. Further applications are the hermetic sealing of metalized devices and the Ge and GaAs technology. The nitrogen-Si_3N_4 films are an excellent diffusion barrier against Zn and Ga. For example, a nitrogen Si_3N_4-film of 400Å thickness masks against a 5 hr Zn diffusion step carried out at 860°C.

Voltage-Controlled Multicolor CRT Phosphors: Preparation and Characteristics

J. S. Prener* and J. D. Kingsley*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Since the range of electrons in a solid is a function of their initial energy it is possible to construct high-resolution multicolor cathode-ray phosphor screens in which the color is determined by the accelerating potential. A nonluminescent layer of controlled thickness is formed upon the surface of each grain of a green or cyan phosphor. This coating is prepared either by the diffusion of a killer impurity such as cobalt from the surface into the bulk or by the homogeneous precipitation of undoped ZnS upon each phosphor grain. The coated phosphor is then intimately mixed with any efficient standard red emitting phosphor such as YVO_4:Eu or Gd_2O_3:Eu. A screen consisting of an intimate mixture of two component phosphors is then deposited by the same method used to prepare monochrome screens. Four distinct colors, useful for information display, can be observed in the red-green system. Quite acceptable two-primary-color television pictures have been demonstrated in the red-cyan phosphor system.

A beam of electrons impinging upon a phosphor excites each particle from the surface to some maximum depth. The distance in the solid at which the beam energy is reduced essentially to zero is called the ultimate or maximum range of electrons. The range of an electron is a function of its initial energy (1). Many different types of multicolor cathode ray tube (CRT) screens have been constructed based on the control of the penetration of the electrons into the phosphor. These screens emit radiation of different colors at different accelerating potentials.

In one early version (2) of such a screen, two or more phosphors, each emitting a different color under cathode-ray excitation, were laid down in successive thin layers upon the glass substrate. This geometry requires that the phosphor layers have thicknesses less than one micrometer if the CRT is to operate at convenient accelerating potentials (less than 30 kV). If particulate phosphors are used, the layers must consist of particles having diameters of a few tenths of a micrometer. These layers are very difficult to form and the small phosphor particles tend to be inefficient. The use of thin layers of transparent phosphor films has also been proposed (3), but such films are noteworthy for their low luminescence efficiency. These thin film screens are also substantially more difficult, and consequently more expensive, to produce than conventional screens. The required film thickness depends on the angle of incidence of the electron beam, thus on the distance from the center of the screen.

Another geometry has been proposed by Messineo *et al.* (4). They proposed coating one or more layers of submicrometer size phosphor particles upon the surface of a larger phosphor particle emitting light of a different color, using a gelatin absorption process described by Kell (5). Thus a multilayered structure occurs within each phosphor grain rather than over the area of the screen. The requirement that the coating phosphor particles be submicrometer in size limits the usefulness of this type of screen since such small particles are difficult to obtain and, as previously indicated, generally exhibit a low luminescence efficiency.

The various difficulties discussed can be avoided by using normal size phosphor particles and preparing a mixed two-component phosphor screen by the same method used for monochrome television picture tubes. One of the phosphors (*e.g.*, a green or cyan one) is prepared with a nonluminescent surface layer of a given thickness upon each grain. The other component (*e.g.*, a red or orange one) may be any efficient phosphor. A CRT having a two-component screen of this type emits red or orange light for all values of the accelerating potential. The green or cyan phosphor contributes to the tube emission only if the accelerating potential exceeds a threshold value which is determined by the energy required for the ultimate range to exceed the "dead" layer thickness. Since the electron beam encompasses a large number of phosphor grains, any inhomogeneities within a grain or differences among grains are averaged over the area of the beam. In order to be useful and economical the nonluminescent or dead layers must be produced in a controlled, reproducible and preferably simple manner.

We have produced nonluminescent surface coatings upon individual (ZnCd)S phosphor grains by two different methods and measured the dependence of the

* Electrochemical Society Active Member.

Key words: phosphors, luminescence, cathode-rays, color.

luminescence intensity under cathode ray excitation on accelerating voltage for changes in process variables. These methods are:

(*i*) A nonluminescent layer of undoped ZnS or CdS of a specified thickness is deposited on the surface of each phosphor grain by homogeneous precipitation.

(*ii*) A luminescence "killer" impurity, Co, is diffused in from the surface of each grain to a specified depth.

These processes and the properties of the multicolor CRT displays achieved using these phosphors are the subjects of this paper.

Messineo *et al.* (4) described the use of Co for producing a nonluminescent barrier layer between a phosphor grain emitting one color and very small phosphor particles of another emission color absorbed on the surface of the larger particle. They gave little information, however, on the luminescent properties of the Co-diffused phosphor. We found that the Co diffusion into a thin surface layer completely quenched the afterglow of the entire particle. Presumably a small fraction of the Co diffused into the entire phosphor grain in amounts sufficient to quench the normally long afterglow without decreasing the luminescence efficiency to any large extent (6). The first method above for producing nonluminescent surface layers permitted us to make a multicolor display screen with a long afterglow. The luminescence intensity of these ZnS-coated phosphors as a function of the accelerating voltage has been analyzed and shown to be consistent with the power loss of an electron beam in traversing a solid (7).

ZnS-Coated ZnS:Cu

Experimental

Coatings of undoped ZnS on ZnS:Cu phosphor grains were produced by homogeneous precipitation (8). The coating thickness could be controlled by varying the ratio of phosphor to zinc ions in solution, since all the zinc was precipitated after a sufficient time. After the precipitation of ZnS was complete, the phosphor was filtered, washed, and dried. The large number of ZnS:Cu crystallites provided efficient nucleating sites so that precipitation of ZnS occurred primarily on these rather than upon the container walls or on other nucleating particles present. Microscopic examination showed the presence of only the original ZnS:Cu grains and less than 1% of the precipitation took place upon the container walls. Furthermore, upon the precipitation of CdS coatings, microscopic examination showed that the normally colorless, transparent ZnS grains were still transparent but orange in color. The coating thicknesses, ranging from 0.051 to 0.51 μm, were calculated from the quantity of ZnS precipitated and the particle size distribution of the uncoated ZnS:Cu phosphors as measured with a Coulter Counter [see Ref. (7)]. The coated phosphor samples were settled on Ag plates using dilute barium acetate and potassium silicate as a binder. Four Ag plates were

mounted on a rotating head of a demountable CRT and the luminescence intensity was measured at constant beam current with varying accelerating potential (9). The intensity of the emitted light was measured with a monochromator and photomultiplier.

Results

Plots of the luminescence intensity as a function of accelerating potential are shown in Fig. 1a and 1b. With the coating thickness varying from 0.051 to 0.51 μm the "dead voltages" obtained by extrapolating the straight portion of each curve to zero intensity varied from 3.0 to 9.5 kV; the dead voltage of the uncoated phosphor was 1.5 kV. A log-log plot of coating thickness against dead voltage in Fig. 2 indicates that the thickness is related to the dead voltage by

$$d = 7.3 \times 10^{-7} V_0^{1.77} \quad [1]$$

when d is measured in cm and V_0 in kV. Measurements on many samples showed the process to be quite reproducible and the duration of the long green afterglow was not affected by the ZnS coatings. Some coated samples were fired in a flowing H_2S atmosphere for one hour at 500°C. There was a slight reduction in the dead voltage values after firing.

Screens having two phosphor components were made up by mixing the ZnS-coated ZnS:Cu with a red emitting phosphor and settling the mixture on a Ag substrate. The color variation with accelerating potential of a screen made by mixing ZnS:Cu having a coating thickness of 0.25 μm with YVO_4:Eu in a weight ratio of 3:1 was studied. The emitted light was red at 5 kV, red-orange at 8 kV, orange at 11 kV, yellow at 13 kV, and green at 17 kV.

Cobalt-Diffused (ZnCd)S:Ag

Experimental

Two phosphors were used: (*i*) a $(Zn_{0.69}Cd_{0.31})S$:Ag phosphor of the type used as the green component (color coordinates $x = 0.29$, $y = 0.61$) of the P22 phosphor commonly used in the aperture mask color television CRT's and (*ii*) a $(Zn_{0.82}Cd_{0.18})S$:Ag cyan phosphor with color coordinates $x = 0.16$, $y = 0.39$. The former was used for constructing multicolor information display CRT's and the latter for building a two-primary-color television picture tube.

The phosphor was agitated in a water suspension and cobalt sulfide was precipitated on the particles in a manner similar to that described by Messineo *et al.* (4). The phosphor was then filtered, washed, and dried.

Small batches were fired in a neutral argon or nitrogen atmosphere at temperatures ranging from 550° to 800°C for either 10 min or 2 hr at temperature. The furnace was regulated to ±2°C and the temperature was determined by a thermocouple located very close to the sample. Samples of the Co-diffused phosphor were sieved through a 200 mesh nylon screen, settled on Ag plates, and measured as described above.

Results

Some typical intensity-voltage curves are shown in Fig. 3. The dead voltage is a function of the thickness of the "killed" region of the phosphor grain due to Co diffusion. It depends on both the annealing time and temperature.[1] The dead voltages are shown in Fig. 4 and vary linearly with temperature over the range studied. Firing for 10 min at a given temperature yields the same result as firing for 2 hr at a temperature 75°C lower.

The diffusion coefficient of Co in $Zn_xCd_{1-x}S$ fired in argon can be estimated from the dead voltage values. It is assumed that the thickness of the nonluminescent region, d, is given by $d = \sqrt{Dt}$ where D is the diffusion coefficient, $D_0\exp(-E/kT)$, at temperature T and t is the diffusion anneal time. From the results discussed above (Fig. 2), the relationship between the thickness of the dead layer and the dead voltage V_0

[1] A (ZnCd)S phosphor was also measured without a binder by pressing it into a shallow depression in an Al block. The measured dead voltage was identical to that found using a binder.

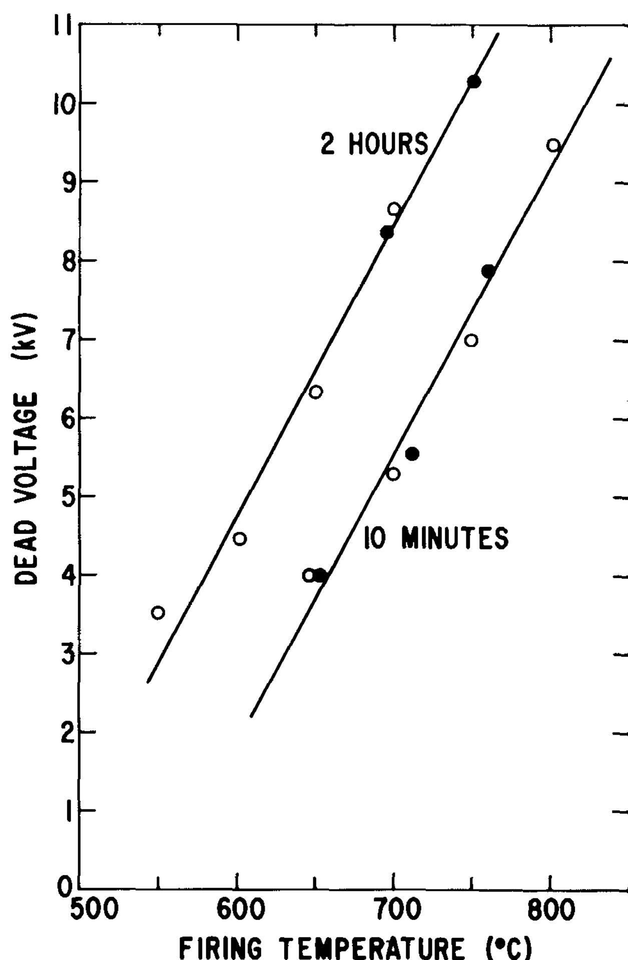

Fig. 4. Dead voltage of Co-diffused (ZnCd)S:Ag phosphors as a function of the firing temperature for a 10 min and a 2 hr anneal: $Zn_{0.69}Cd_{0.31}S$:Ag green phosphor (●); $Zn_{0.82}Cd_{0.18}S$:Ag cyan phosphor (○).

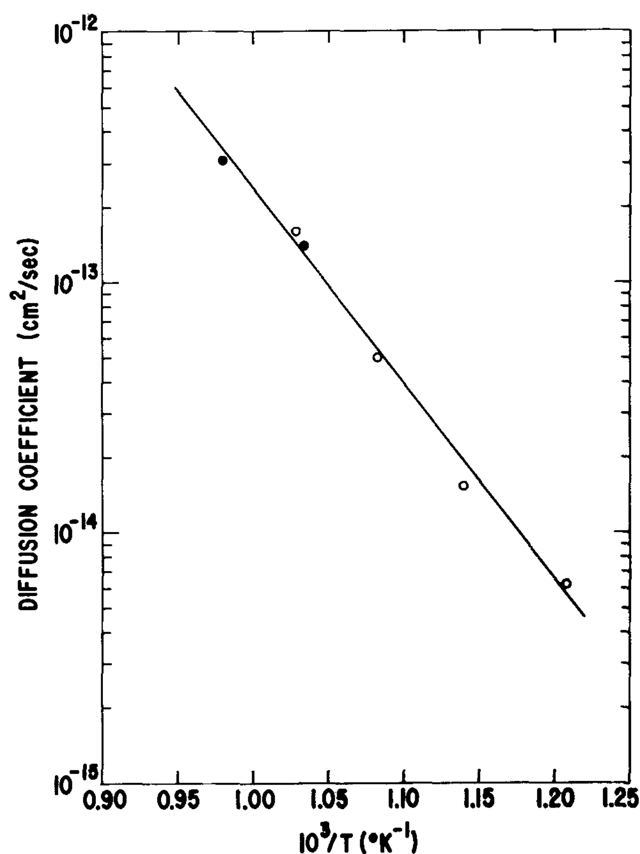

Fig. 5. The computed values of the diffusion coefficients of Co in $Zn_xCd_{1-x}S$ plotted against $10^3/T$. $Zn_{0.69}Cd_{0.31}S$:Ag green phosphor (●); $Zn_{0.82}Cd_{0.18}S$:Ag cyan phosphor (○).

for ZnS is given by Eq. [1]. Assuming that the relationship is the same for (ZnCd)S, the diffusion coefficient is given by

$$D = 53 \times 10^{-14} V_o^{3.54}/t \quad [2]$$

where D is in cm²/sec, V_o in kV, and t in seconds.

In determining D from Eq. [2], we have used the V_o data of Fig. 4 from the 2 hr anneals. The true anneal time is uncertain for the runs in which the samples were kept 10 min at temperature. Since the sample and fused quartz firing tube were cold when placed in the hot furnace, the time required for the sample temperature to rise to the furnace temperature was itself of the order of 10 min. For the 10 min data, therefore we would, in Eq. [2], have to use some value of t greater than 600 sec. In Fig. 5, log D is plotted against $10^3/T$. A least squares fit gives the activation energy E = 1.54 eV and $D_o = 1.30 \times 10^{-5}$ cm²/sec. The values of d as determined from Eq. [1] ranged from 0.07 μm for the 2 hr anneal at 554°C to 0.48 μm for the 2 hr anneal at 750°C.

We observed that Co is a much better "killer" impurity than either Fe or Ni for obtaining controlled thicknesses of nonluminescent layers. Both Fe and Ni gave products of very low efficiency even for low temperature anneals. The findings of Weakliem (10), that substantial amounts (0.1%) of Ni can be introduced into ZnS and CdS at 800°C in a few hours whereas several days were required to introduce an equivalent amount of Co, might very well explain the difference in behavior observed with Ni and Co. Even a 10 min anneal may be sufficient to introduce Ni concentrations sufficiently high to markedly decrease the luminescence efficiency throughout the bulk of the phosphor grains rather than just in a surface layer. There appear to be no data on the diffusion of Fe in ZnS or CdS.

Information Display Screens

The Co-diffused phosphor was mixed by tumbling with a red emitting phosphor (Gd_2O_3:Eu or YVO_4:Eu), and the two-component phosphor was settled on Ag plates as before. The dependence of the color coordinates of the emitted light on accelerating potential was determined from the emission spectra corrected for spectral sensitivity of the detector. In Fig. 6, this dependence is shown on a C.I.E. plot for a mixture of one part by weight of YVO_4:Eu and four parts of $Zn_{0.69}Cd_{0.31}S$:Ag into which Co had been diffused at 710°C for 10 min. The YVO_4:Eu and four-to-one ratio were chosen so that four distinct colors could be displayed with a total accelerating potential variation of two to one. Clearly distinguishable shades of red, orange, yellow, and green were obtained at 4, 5, 6, and 8 kV. The brightness was adequate, even at the lowest operating potential, to display computer-generated graphics and alphanumerics.

If fewer than four distinguishable colors are desired one can reduce the required accelerating voltage change or alternatively enhance the brightness at the lower operating potentials either by increasing the fraction of the red component or by using a phosphor whose emission color is more orange.

Two-Primary-Color Television Screens

The basic requirements on a two-primary-color TV system are first that it be capable of showing pictures in black and white and second that fleshtones be accurately reproduced, since we are most aware of any lack of color fidelity in the appearance of human skin. If one requires that the screen can display "pure" white, (i.e., Illuminant C) and fleshtones, then the

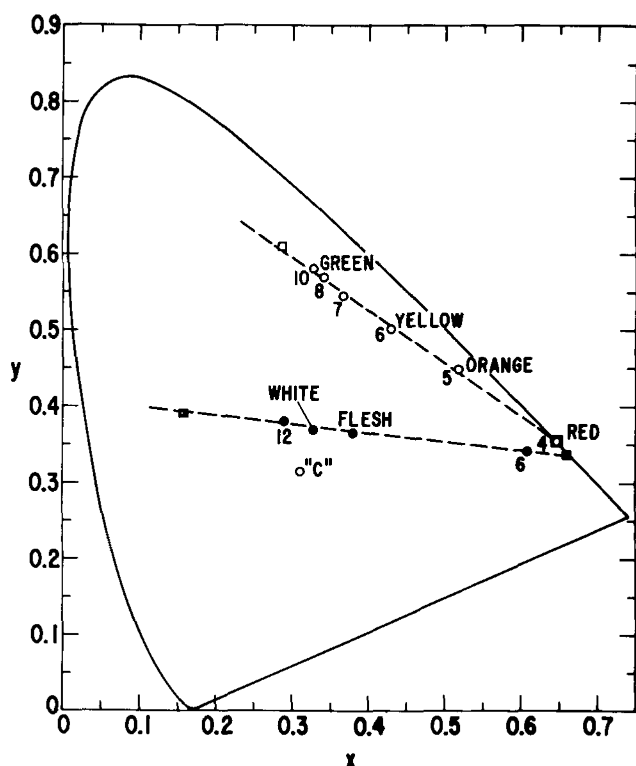

Fig. 6. Color coordinates of two-component phosphor screens operated at various accelerating potentials indicated by the numbers. The color coordinates of the component phosphors are shown by (■) and (□) and the color coordinates of Standard Illuminant C are given by point "C". One part by weight of YVO_4:Eu and four parts by weight of $Zn_{0.69}Cd_{0.31}S$:Ag into which Co was diffused for 10 min at 710°C (○). One part by weight of Gd_2O_3:Eu and four parts by weight of $Zn_{0.82}Cd_{0.18}S$:Ag into which Co was diffused at 700°C for 2 hr (●).

primary colors must be orange and a bluish cyan. It was determined experimentally that a more pleasing display resulted from using the red Gd_2O_3:Eu phosphor as one primary color and a greenish cyan for the second primary color. The cyan phosphor, $Zn_{0.82}Cd_{0.18}S$:Ag with color coordinates $x = 0.16$ and $y = 0.39$, was chosen to maintain the capability of displaying flesh-tones while compromising the white purity.

Since a moderately high average brightness of 50 ft-L was desired, the saturation of the high voltage primary color was also compromised. The two primary colors are indicated on Fig. 6 by their respective operating potentials of 6 and 12 kV. With a 12 in. diagonal, single-gun CRT, an average beam current of 0.5 mA, a 100% faceplate transmission, and a 50% duty cycle for each operating potential, we obtained a brightness of 49 ft-L for white ($x = 0.33$, $y = 0.37$), 43 ft-L for cyan ($x = 0.29$, $y = 0.38$), and 6 ft-L for red ($x = 0.61$, $y = 0.34$). Even though the high voltage primary is quite desaturated one obtained the impression of an essentially "full-color" picture although there were obviously no brilliant blues or greens.

$GaAs_{1-x}P_x$ Electroluminescent Diodes Made by Zn Diffusion in an Open-Tube System

K. K. Shih* and J. M. Blum*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

An open-tube process has been used for Zn diffusion in $GaAs_{1-x}P_x$ coated with SiO_2 films to form p-n junctions. Electroluminescent diodes made by this method have a brightness of 600 ft-L at 5 A/cm^2 with no etching of the surface required. The effects of temperature, time, and SiO_2 thickness on junction depth, efficiency, and brightness of the diodes are described.

Zn diffusion into III-V compounds such as GaAs, $GaAs_{1-x}P_x$ has commonly been carried out in sealed quartz tubes (1). The quality of the vacuum in the ampoule and the arsenic pressure in the system are critical factors in the control of junction depth and surface concentration, and therefore make reproducibility difficult. In addition, it was found that Zn and As vapors attack the window openings when the process is used on an oxide masked wafer. This makes

* Electrochemical Society Active Member.

Key words: $GaAs_{1-x}P_x$, electroluminescent diode, Zn diffusion, III-V alloy.

subsequent processes difficult to control. It was found that by depositing a thin additional layer of SiO_2 on the surface of the wafer, the surface erosion can be avoided. Shorts *et al.* (2) and Becke *et al.* (3) have studied Zn diffusion in GaAs coated with SiO_2 in a closed-tube system. They found that SiO_2 proved effective in lowering surface concentrations and preventing surface deterioration during diffusion. Since a thin protecting film of SiO_2 is necessary to protect the surface from erosion, the open-tube process was used instead of the conventional closed-tube system. We will describe here the effects of the Zn source temperature, the diffusion temperature, the oxide thickness, and the diffusion time using the open-tube diffusion of Zn into $GaAs_{1-x}As_xP$ on light emitting diode characteristics.

Experimental

Tellurium-doped $GaAs_{1-x}P_x$ wafers obtained from Monsanto Company were used in this work. Most of the wafers, according to the vendors specifications, were within the following specifications: x, in the formula $GaAs_{1-x}P_x$ was 0.39 ± 0.01; $n \cong 2 \pm 1 \times 10^{17}$, and the total thickness of the vapor-grown epitaxial layer on GaAs was about 80 μm with approximately the first 36 μm graded in composition with the remaining portion having constant composition. These wafers were selected on the basis that they all had similar epitaxial layer characteristics so that the effects of various diffusion parameters could be evaluated. It should be noted that more efficient diodes have been made here from other material.

The SiO_2 layers which were used to protect the semiconductor surface from erosion were deposited by a pyrolytic decomposition process. Before deposition, the wafers were cleaned in toluene, acetone, and alcohol. The deposition occurs at 500°C as a result of the decomposition of tetraethylorthosilicate (TEOS) in an oxygen atmosphere. SiO_2 films with a thickness of 500-4000Å have been produced with a deposition rate of about 60 Å/min.

The diffusion apparatus is shown in Fig. 1 and consists of a two-zone furnace so that the temperature of the source and wafers can be adjusted independently. A flow of N_2 was maintained through the system between diffusion runs. Zn pellets of 6-9's purity were loaded in a boat at the entrance of the source end of the tube and wafers were loaded in a flat plate at the other end. The nitrogen gas was turned off and forming gas was then turned on to flow at a rate of about 400 cc/min for 30 min to flush the system. After that, the Zn boat was first pushed into the source region zone 1 and after 10 min the wafers were pushed into the diffusion region zone 2 of the furnace. The diffusion of Zn into $GaAs_{1-x}P_x$ was investigated with the wafer temperature (T_w) maintained at the same temperature as the source (T_{Zn}). Temperatures of 700°, 750°, 800°, and 850°C were used with diffusion times ranging from 30 min to 4 hr. Diffusions at a fixed wafer temperature (T_w) of 800°C but with different source temperatures (T_{Zn}) of 700°, 750°, and 800°C for 1 hr have also been carried out.

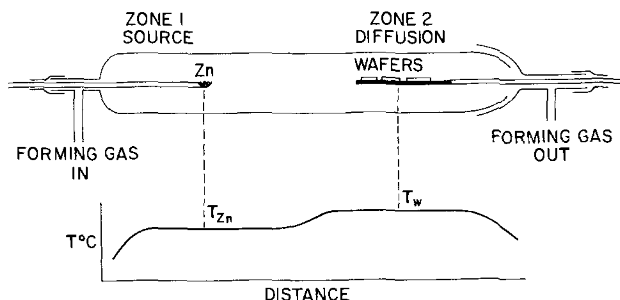

Fig. 1. Furnace system and temperature profile for diffusions

After diffusion, the wafers were removed from the diffusion zone. The forming gas was then turned off and the nitrogen turned on prior to removing the wafers from the furnace. The SiO_2 films were removed after the diffusion. The junction depth was measured by developing the junction interface with a $HF:H_2O_2:3H_2O$ etch in a cleavage plane normal to the junction. Diodes were made by electroplating Au-Sn on the substrate side of the wafer after the substrate is thinned to reduce series resistance. Small cleaved sections with an area of about 10^{-3} cm^2 were mounted on a header and an aluminum wire was ultrasonically bonded directly to the top p surface. The external quantum efficiencies and brightnesses of these diodes were then measured. The external quantum efficiencies were measured with an integrating sphere type of apparatus using Si photodiodes as detectors. The brightness was measured with a Spectra Brightness Spot Meter viewing an 8 mil diameter area.

Results and Discussion

Initially, the effects of oxide thickness on the diffusion were studied. It was found that with oxide thicknesses less than 500Å, a nonuniform junction depth often resulted. On the other hand, if the oxide thickness was about 4000Å the oxide sometimes cracked and gave erratic junction depths. Hence, most of our data were from wafers deposited with 1000 and 2000Å SiO_2 films. Examination of these wafers after diffusion indicated smooth clean surfaces with junction depth uniformity within ±5%.

The junction depth X_j for various Zn diffusions with the same source and wafer temperatures between 700° and 850°C and for 1000 and 2000Å thick SiO_2 films was found to vary almost linearly with the square root of the diffusion time while the diffusion times ranged from 30 min to 4 hr. This relationship indicates that open-tube Zn diffusion into $GaAs_{1-x}P_x$ obeys Fick's law (4). In the case where the wafer temperature is kept constant at 800°C for 1 hr, the junction depth can be decreased by a factor or two by reducing the source temperature from 800° to 700°C.

Figure 2 shows the junction depth X_j *vs.* the SiO_2 thickness for temperatures between 700° and 850°C when $T_{Zn} = T_w$ for a 1-hr Zn diffusion. This figure indicates that at the lowest temperature (700°C) the junction depth is almost independent of oxide thickness, while at a higher temperature (850°C), the junction depth decreases drastically with increasing

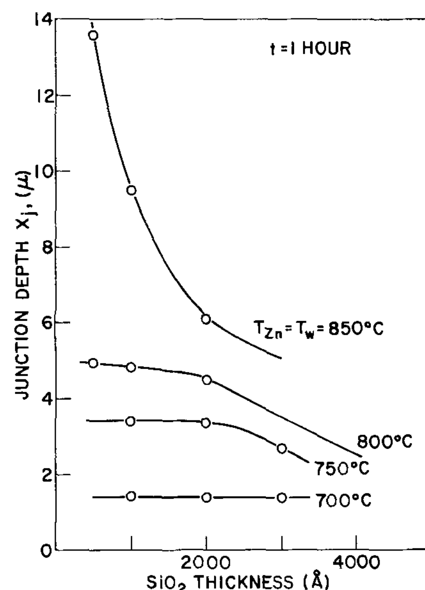

Fig. 2. Junction depth as a function of SiO_2 thickness for a 1-hr diffusion when $T_{Zn} = T_w$.

oxide thickness. The reason for the anomalous results in Fig. 2 is not understood and we cannot conjecture any theory without additional experimental data.

The junction depth also decreases with increasing donor concentration and increasing phosphorous concentration in the wafers. Because of the limited number of experiments done in this area, no quantitative results are reported here.

The sheet resistance of the diffused layers has been measured by the four point probe method. It was found that at a given junction depth, the sheet resistance of the layers diffused in the open-tube system is at least an order of magnitude higher than that using a $ZnAs_2$ source in a closed-tube system. This suggests that the Zn concentration in the oxide-coated $GaAs_{1-x}P_x$ layers diffused by the open-tube method must be lower than in layers diffused by the conventional $ZnAs_2$-source closed-tube method (5).

These results are confirmed by surface concentration (C_o) measurements made on the same wafers using the plasma resonance method (6). For the wafers diffused at $T_{Zn} = T_w = 800°C$ with a 2000Å thick SiO_2 film on the surface, C_o is approximately equal to 3.5×10^{19} cm^{-3}. The lowest C_o measured is about 1.4×10^{19} cm^{-3} when $T_{Zn} = T_w = 700°C$ with a 1000Å thick SiO_2 film on the surface during diffusion. C_o is approximately equal to 1.1×10^{20} cm^{-3} if $ZnAs_2$ source is used in a closed ampoule diffused at 800°C.

The external quantum efficiency and wavelength of the diffused $GaAs_{1-x}P_x$ diodes have been measured. It was found that the efficiency did not vary very much in our diffusion studies even though the temperatures of the source and wafers were changed between 700° and 850°C. The results show that the efficiency of diodes made with an SiO_2 thickness of 2000Å is about 20% better than that of 1000Å. The average efficiency was about 10^{-3} at 6600Å for uncoated diodes. The highest value obtained so far was about 2.4×10^{-3} at 6650Å for an uncoated diode.

Brightness measurements were made on hundreds of diodes whose areas varied from about 0.8×10^{-3} cm^2 to 1.2×10^{-3} cm^2. Figure 3 demonstrates the effects of diffusion time on brightness when the wafer temperature and source temperature are equal. Each point on the curves represents the average of several diodes. The brightness at current density = 10 A/cm^2 is plotted for comparison. When the temperature was increased from 700° to 800°C, the brightness also increased. A maximum value is obtained at 800°C for 1-hr diffusion. When the temperature increases further to 850°C, an adverse result was obtained which could have been caused by an increase in nonradiative recombination centers formed at the higher temperature. When the wafer temperature was kept constant at 800°C, some improvement in brightness can be obtained at a lower source temperature because the junction depth decreases with decreasing source temperature and this results in less light absorption at the surface.

The effect of junction depth on the brightness of the diodes was studied and the results are shown in Table I. At about the same shallow junction depths (under ~ 2.5 μm, runs A, A' and B, B' in Table I), the brightness of the diodes can be off by a factor of 3-4 depending on the diffusion conditions. When the junction depth is about 4-5 μm deep (see C and C' in Table I), the difference in brightness can still be large depending on diffusion conditions. However, when the junction depths are deeper as in runs D, E, and F the brightness drops substantially. This shows that for junction depths of less than ~ 5 μm the specific diffusion conditions (*i.e.*, time and temperature) play a significant role in determining the luminance characteristics. However, as the diffusion depth increases, the particular diffusion conditions have less influence. The luminance of these devices has been improved by removing part of the diffused region by etching the surface.

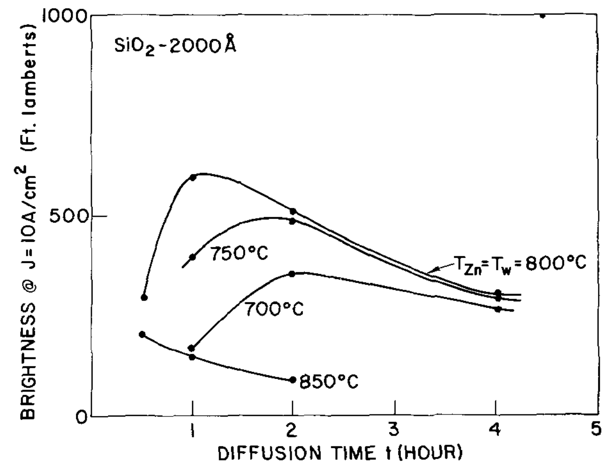

Fig. 3. Luminance of $GaAs_{1-x}P_x$ diodes at 300°K at current density = 10 A/cm^2 as a function of diffusion time at different temperatures when $T_{Zn} = T_w$.

We have performed a closed-tube diffusion on the same wafer used in the above studies using a $ZnAs_2$ source and a diffusion at 800°C for 45 min [*i.e.*, the same method described by Herzog *et al.* (5)]. The junction depth was about 5 μm. Without etching the surface the brightness of the diodes measured at 10 A/cm^2 was about 200 ft-L. This low brightness is probably due to the higher Zn concentration in the diodes made by closed-tube diffusion without an SiO_2 film. Besides, it is possible that a thin surface film could form during the diffusion process which has high absorption coefficient for red emission. Surface etching is required on diodes made from that type of diffusion in order to achieve maximum brightness.

Run B in Table I corresponds to a 1-hr diffusion at $T_{Zn} = T_w = 800°C$ with a 4000Å SiO_2 deposited on the surface, and run A corresponds to a 1-hr diffusion at $T_{Zn} = 700°C$ and $T_w = 800°C$ with a 2000Å SiO_2 film on the surface. These two diffusions gave comparable brightness and junction depth results. Since a 4000Å SiO_2 film usually cracks during the diffusion process the diffusion conditions corresponding to run A are preferred. The shallow junction may cause high sheet resistance which is not desirable for some applications. If lower sheet resistance is required, the diffusion condition corresponding to run C which has a deeper junction depth (~ 4.5 μm) and higher surface

Table I. Table of luminance characteristics for various diffusion conditions and junction depths

Run No.	Source temp, T_{Zn} (°C)	Wafer temp, T_w (°C)	Diffusion time, t (hr)	SiO_2 thickness, d (Å)	Junction depth, X_j	Brightness at current density = 10 A/cm^2, B (ft-L)
A	700	800	1	2000	1.5	700
A'	700	700	1	2000	1.4	150
B	800	800	1	4000	2.5	650
B'	800	800	0.5	2000	2.1	220
C	800	800	1	2000	4.5	600
C'	850	850	0.5	2000	4.8	200
D	750	750	4	2000	6.1	250
E	800	800	4	2000	8.8	250
F	850	850	2	2000	12	75

Zn concentration can be used. The diffusion conditions for both runs A and C are the same except the source temperature. Hence it appears that the best diffusion conditions for attaining high brightness are to deposit 2000Å thick SiO_2 films on $GaAs_{1-x}P_x$ wafers and to diffuse for 1 hr at 800°C while keeping the Zn source temperature between 700° and 800°C.

From measurements made on many diodes from many different wafers other than those particular ones used in this work it is evident that in addition to diffusion conditions wafer quality plays a very important role in the resulting ultimate diode characteristics. Superior luminance characteristics were achieved using the optimum open-tube diffusion conditions found in this work from wafers not used in this series of experiments. Typically the results from better quality wafers at 10 A/cm^2 were between 700 and 900 ft-L. The best wafer measured produced 55, 600, and 1050 ft-L at current densities of 1, 5, and 10 A/cm^2, respectively. All of these results were achieved without any surface etching.

In conclusion, it has been shown that SiO_2 films on the surface during diffusion offers surface protection allowing the retention of smooth surfaces. With this protection, open-tube diffusions can be used. The surface zinc concentration is lowered by the SiO_2 film. High brightness results are achieved in these diodes with no etching of the surface required. These results produce a true planar process. In addition, the open-tube approach enables many diffusions to be carried out in quick succession avoiding the complications associated with encapsulation under vacuum which is necessary in the closed-tube system. While only work on $GaAs_{1-x}P_x$ is reported here, the process has been successfully applied to other III-V semiconductor materials such as $Al_xGa_{1-x}As$, GaP, and GaAs.

Determination of the Component Activities in the System In-Ga Using a Solid Oxide Electrolyte Technique

K. A. Klinedinst, M. V. Rao, and D. A. Stevenson*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

An electrolytic technique utilizing the cell, Pt|W|Ga, β-Ga_2O_3| calcia stabilized zirconia|Ga-In, β-Ga_2O_3|W|Pt, has been used to measure activities of Ga in liquid In-Ga alloys in the temperature range 800°-950°C. The Ga activities and the In activities, calculated from the Gibbs-Duhem equation, show modest positive deviation from Raoult's law. The activities are compared with previously measured and computed values. The parameter α_{GaIn} (defined by $\ln \gamma_{Ga}/[1 - N_{Ga}]^2$) is seen to have a very small composition dependence in the temperature range studied. The partial molar excess entropies of solution of Ga, calculated using the measured free energies and previously measured values for the heats of mixing, are demonstrated to be negative and small.

There is both practical and fundamental interest in the thermochemistry of the Ga-In system. The system comprises one binary of a number of ternary systems of practical interest. For example, the compounds $Ga_xIn_{1-x}As$ and $Ga_xIn_{1-x}P$ are of current interest because of their potential applications as infrared and visible light emitting diodes, respectively. In the growth of ternary mixed crystals in the systems using liquid phase epitaxial growth techniques, knowledge of the ternary phase diagrams is essential. Because sufficient information of this type is unavailable, investigators have endeavored to estimate portions of the ternary phase diagrams using thermochemical data for the respective binaries, together with some information on the pseudobinaries (1). A recent study has employed an interpolative technique, using a limited amount of experimental information about the ternary (2).

A recent review of the Ga-In system (3) has described a number of inconsistencies in the present information in the literature concerning the phase diagram, the calorimetric measurement of the heats of mixing in the liquid (4-6), and the Gibbs free energy of mixing in the liquid, determined from activity measurements (7). It was proposed that the free energies were in error (3). Other information in the current literature also suggests that the previously measured activities may be incompatible with the other thermochemical information, and in particular, may be a bit high. An analysis of the available heat of mixing and the phase diagram information using a linear programming optimization technique (8) resulted in α_{InGa} values (with α defined as $\ln \gamma_{In}/[1 - N_{In}]^2$) that were considerably smaller than those obtained from the existing activity data (7). Furthermore, several investigators have successfully applied a quasichemical model to the In-Ga-As, In-Ga-Sb, and In-Ga-P systems using a value of α which was fortuitously taken

* Electrochemical Society Active Member.
Key words: solution thermodynamics, liquid alloys, free energy.

to be smaller by a factor of 2.303 than the reported experimental value (owing to a misinterpretation of the data) (9-13).

In light of the present uncertainty about the thermochemistry of this system, particularly concerning the free energies of mixing, a direct measurement of activities appeared desirable. The activities of Ga in liquid Ga-In solutions were measured using an electrochemical cell employing a solid oxide electrolyte. The electrochemical cell can be represented as

Pt|W|Ga, β-Ga_2O_3| calcia stabilized zirconia|Ga-In, β-Ga_2O_3|W|Pt

The equilibrium reactions at each electrode may be written as

$$2\,Ga(l) + \frac{3}{2} O_2\,(g) = \beta\text{-}Ga_2O_3\,(s) \quad [1]$$

$$K = \frac{a_{Ga_2O_3}}{a_{Ga}^2\, P_{O_2}^{3/2}} \quad [2]$$

with K being a constant for a given temperature. Assuming unit activities for Ga_2O_3 and pure Ga

$$a_{Ga}^{-4/3} = \frac{P_{O_2}\,(\text{Ga-In}, Ga_2O_3)}{P_{O_2}\,(\text{Ga}, Ga_2O_3)} \quad [3]$$

where a_{Ga} is the activity of Ga in the Ga-In alloy. The partial pressures of O_2 are related to the cell emf by the relation

$$E = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}\,(\text{Ga-In}, Ga_2O_3)}{P_{O_2}\,(\text{Ga}, Ga_2O_3)} \quad [4]$$

Thus one obtains

$$\ln a_{Ga} = -\frac{3\,E\mathbf{F}}{RT} \quad [5]$$

where E is the cell emf and $\mathbf{F}$ is the Faraday constant.

Experimental

A schematic diagram of the cell is given in Fig. 1. The Ga, β-Ga_2O_3 reference electrode was contained in the bottom of a calcia-stabilized zirconia (CSZ) vacuum-tight tube, ¼ in. in diameter and 18 in. long. Small pieces of solid gallium were placed in the bottom of the tube and melted with a heat gun. β-Ga_2O_3 powder was placed on top of the pool of liquid gallium. The Ga-In, β-Ga_2O_3 electrode was contained in the bottom of an alumina tube, 1⅛ in. in diameter and 14 in. long. A layer of β-Ga_2O_3 powder was placed in the bottom of the tube, and weighed pieces of gallium and indium were placed on top of the β-Ga_2O_3 powder.

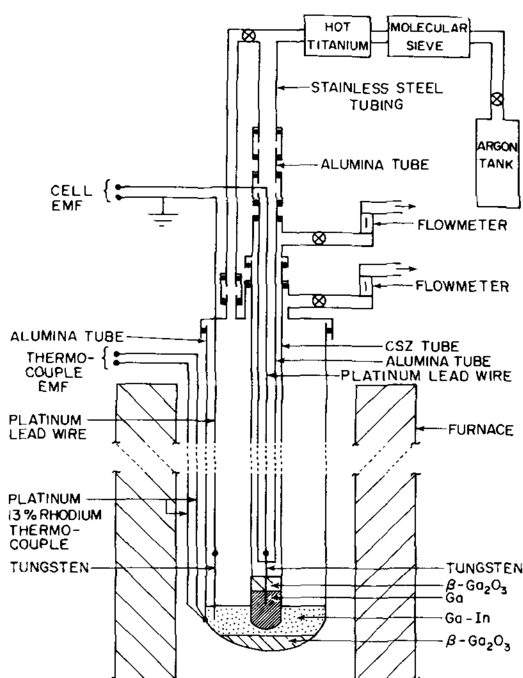

Fig. 1. Schematic diagram of the experimental apparatus

Pure argon gas was used to blanket both electrodes. It was purified by passing through activated Linde 4-A molecular sieve and titanium metal sponge (heated to 850°C). The argon line was constructed of stainless steel tubing with stainless steel Swagelok connectors. The argon was transported to the reference electrode via a ⅛ in. diameter alumina tube. The lead wires to the electrodes were 0.010 in. platinum wire, with short pieces of tungsten wire spot welded to them just above the surfaces of the two electrodes. The tungsten thus provided the contact between the liquid metals and the platinum wires, and was found not to dissolve in the liquid gallium or gallium-indium alloys. The lead wire from the alloy electrode was grounded.

The cell was assembled with Viton O-ring connectors and was positioned so that the electrodes were in the constant temperature zone of a resistance-heated Marshall furnace. The temperature profile of the furnace was adjusted so that it was uniform to within ±1°C from the bottom of the alumina tube to a point well above the platinum-tungsten junctions in the electrode lead wires. The cell temperature was measured with a Pt-13% Rh thermocouple in thermal contact with the outside of the alumina tube containing the alloy electrode. The cell temperature was controlled with a Barber-Colman Model 357A Digiset null balance controller. The cell potential and the Pt-13% Rh thermocouple potential were measured with a L&N K-3 potentiometer and a L&N 9834 null detector.

At the start of each experiment, the cell was heated and alternately evacuated and flushed with the purified argon gas. When the cell temperature exceeded 200°C, the cell was filled with the argon, and a slow flow was maintained over both electrodes throughout the duration of the experiment. The CSZ tube was positioned so as to dip below the surface of the alloy electrodes.

The cell was heated slowly to 900°C and maintained at this temperature for several hours for the equilibration of the alloy components and for the saturation of the electrodes with oxygen by the dissolution of the β-Ga_2O_3 powder in the liquid metals. The temperature was then raised to 950°C and the cell was again allowed to equilibrate until the cell emf was constant with time (about 2 hr). The emf was then recorded and the temperature was lowered in increments of 50° to 800°C. At each temperature, the cell was allowed to equilibrate before the emf value was recorded. In some cases, in order to test the reversibility of the electrode reactions, readings were taken during both ascending and descending temperature cycles. The equilibrium cell voltages at a given temperature always agreed to within ±0.5 mV.

To be certain that the alternating current in the furnace windings was not inducing stray voltages in the cell circuit, the power supply to the furnace was occasionally turned off just before the cell emf was recorded. No indication of such interference was ever observed. Further, no significant differences in cell voltages were observed to result from using different CSZ tubes or different reference electrode samples. Similarly, the emf values for identical samples at corresponding temperatures agreed to within ±0.5 mV.

The gallium used was 7-9's purity, manufactured by Eagle-Picher Industries, Inc. The indium, also 7-9's purity, was produced by Cominco American, Inc., while the β-Ga_2O_3 was 4-9's purity from Research Organic/Inorganic Chemical Company. The vacuum-tight CSZ tubes contained 7.0 w/o (weight per cent) calcia and were manufactured by the Zirconium Corporation of America.

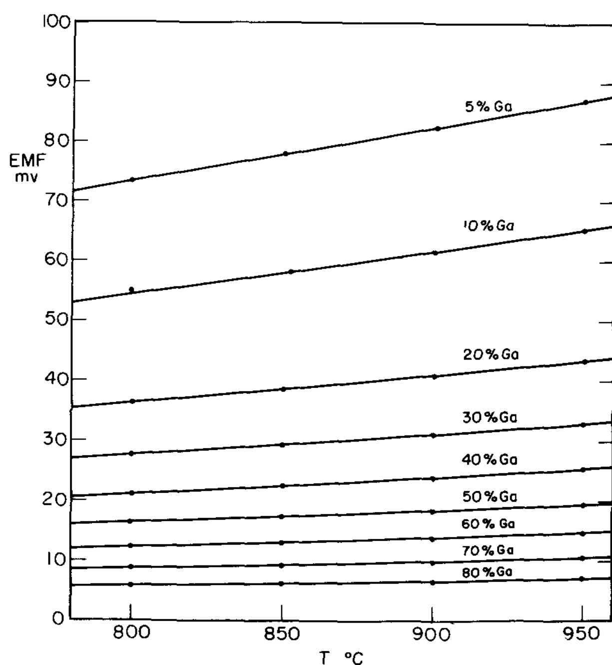

Fig. 2. Experimental emf values vs. temperature

Results and Discussion

The emf *vs.* temperature plots are shown in Fig. 2 for each of the compositions studied. In every case, the three higher temperature points follow linear relationships very closely.

Activities of Ga were calculated using Eq. [5]. The indium activities were calculated using the Gibbs-Duhem equation

$$N_{Ga}\, d \ln \gamma_{Ga} + N_{In}\, d \ln \gamma_{In} = 0 \qquad [6]$$

Both sets of values are listed in Table I, together with the cell voltages. The activities are substantially smaller than those reported by Macur, Edwards, and Wahlbeck (7). They estimated α'_{InGa} (defined by $\log_{10}\gamma_{In}/[1 - N_{In}]^2$) at three temperatures and selected compositions, using a Knudsen effusion technique. The disparity between our data and theirs is not unexpected, since discrepancies between their results and those of previous studies have already been noted (3, 8). Some measure of the inconsistency in the Macur *et al.* data is indicated by the fact that the heats of mixing calculated by them using their measured activities give a value of 2200 cal/mole at $N_{In} = 0.5$, which compares unfavorably with the Bros *et al.* value of 265 cal/mole (5).

* Calculated using Gibbs-Duhem equation.

Rao and Tiller (8) conducted an analysis, using a linear programming optimization technique, in which the liquidus (6, 14) and heat of mixing data (4) were simultaneously analyzed. Using an iterative technique, they obtained a consistent set of α's (in the solid and liquid solutions) and phase equilibrium lines. The experimental activities in this work at all the temperatures are in good agreement with those computed using the Rao and Tiller α-parameters. By way of example, the comparison is shown graphically in Fig. 3 for the 950°C points. The figure also includes our calculated indium activities and all of the experimental values for the activity of In at 950°C reported by Macur *et al.* (7).

Several thermochemical quantities were computed using the experimental information. The parameter α_{GaIn} can, in general, be expected to have the form (15)

$$\alpha_{GaIn} = l + a\,N_{In} + b/T + c\,N_{In}/T \qquad [7]$$

where l, a, b, and c are constant with temperature and composition. This is consistent with the assumption that the heats and excess entropies of mixing are independent of temperature. This is usually a good assumption in metallic systems and has been validated for the heats by Bros (4) and Bros *et al.* (5) for the system In-Ga. They further showed that the heats are symmetrical about the $N_{Ga} = 0.5$ composition point, thus indicating (15) that the parameter c in the equation above is essentially zero. The calculated values of α_{GaIn} are given in Fig. 4 as functions of composition and show only a slight composition dependence of α_{GaIn} at all the temperatures. The fact that the slopes are independent of temperature is consistent with the above deduction that $c \simeq 0$. The α-function is very sensitive to changes in activity, particularly at high Ga concentrations. Therefore, the consistency displayed in Fig. 4 shows the inherent accuracy of the technique. The nature of the scatter is systematic, *i.e.*, the deviation for each composition from the best fit line is essentially the same for each of the temperatures. The extreme sensitivity of the α-function at compositions approaching pure Ga makes the calculation of α at $N_{Ga} = 0.80$ unreliable and, although the points have been plotted, the degree of correspondence with the other points is scarcely significant.

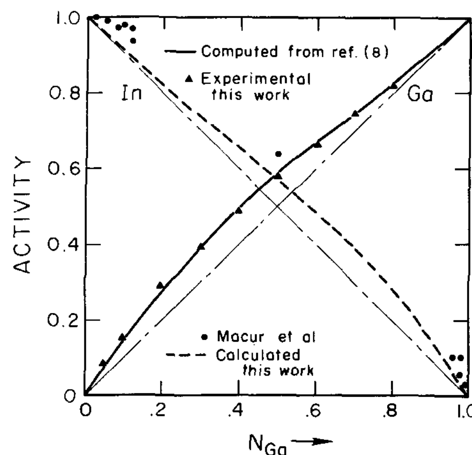

Fig. 3. Activities of Ga and In at 1223°K

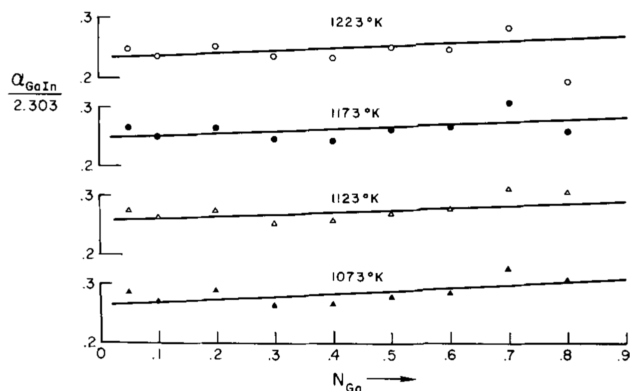

Fig. 4. Dependence of α_{GaIn} on N_{Ga}

This method cannot be expected to give accurate heats and entropies of mixing because of the inherent uncertainties, in general, in the deduction of entropies and enthalpies indirectly from the free energy measurements. Nevertheless, these quantities were calculated in order to show the general consistency in the measurements. The partial molar heats and excess entropies of solution of Ga can be calculated from the slopes and intercepts of the emf *vs.* temperature lines, since

$$\Delta \bar{F}_{Ga} = -nEF = \Delta \bar{H}_{Ga} - T\Delta \bar{S}_{Ga} \quad [8]$$

Figure 5 shows $\Delta \bar{H}_{Ga}$ and ΔH^M, the partial molar heat of solution of Ga and the integral heat of mixing, respectively. The latter was calculated assuming that the ΔH^M was symmetrical about the $N_{Ga} = 0.50$ composition point. Considering the associated uncertainties, the comparison with the points of Bros *et al.* (5) and Predel and Stein (6) is reasonable. The maximum difference in the ΔH^M occurred with the data of Bros *et al.* at 50% Ga and is of the order of 70 cal. The $\Delta \bar{S}_{Ga}$ values calculated from the slopes were scattered on a trajectory slightly more positive than that for an ideal solution. A more meaningful calculation is that of the excess entropies using the free energies measured in this work and the heats of mixing of Bros *et al.* (5), which appear to be very accurate. $\Delta \bar{S}^{xs}_{Ga}$ has been

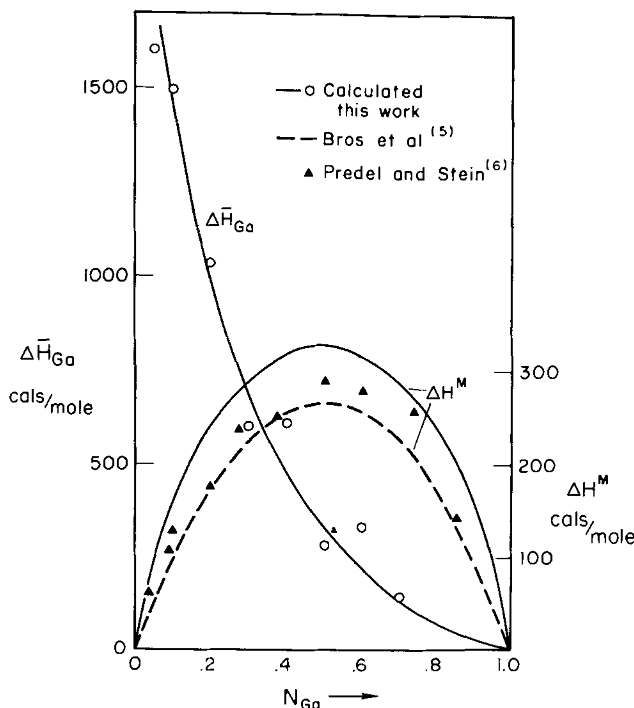

Fig. 5. Heats of mixing in liquid In-Ga alloys

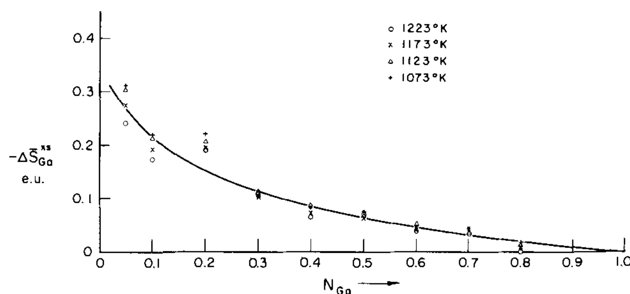

Fig. 6. Dependence of calculated values of $\Delta \bar{S}^{xs}_{Ga}$ on N_{Ga} in In-Ga alloys.

calculated in this fashion at all the four temperatures, and the results plotted in Fig. 6. Considering the sensitivity of the scale upon which the plot is made, the resulting set of points shows good consistency. Table II lists thermochemical quantities of 1223°K obtained using this excess entropy curve and the Bros *et al.* (5) heats of mixing.

Certain aspects of the experimental technique merit discussion. An important consideration is the solubility of oxygen in the In-Ga alloy and the extent of ternary interaction, since the system is in reality the ternary In-Ga-O and is merely being approximated to be the binary In-Ga. The effect, however, is expected to be small in the present system due to low oxygen solubility. The solubility of O in liquid Ga is of the order of 10^{-3} a/o (atomic per cent) at 800°C (16). The component activities are not expected to be influenced by the small oxygen concentration. Another source of error, loss of the constituents by evaporation, is also unimportant in this system since the vapor pressures of Ga and In are of the order of 10^{-5}-10^{-6} atm at 950°C.

Another consideration is the relative stability of the various oxides in the system. The free energy of formation of β-Ga_2O_3 is very much more negative than those of Ga_2O, In_2O, and In_2O_3. Therefore, the stable oxide present at all times can be expected to be β-Ga_2O_3. Separate electrode chambers and argon streams prevented communication between the two electrodes via the gas phase, thus eliminating another possible source of error.

The error limits set on the activity values at each of the temperatures can be ascribed to the ±0.5 mV reproducibility discussed previously, and other sources such as any electronic conductivity present in the calcia-stabilized zirconia. The consistency of the results appears to indicate a very small contribution, if any, from this last source.

The partial pressures of oxygen in equilibrium with Ga and β-Ga_2O_3 may be calculated from the free energy of formation data for β-Ga_2O_3, as obtained by Pankratz and Kelley (17). Several investigators (18, 19) have determined the values of oxygen partial pressure corresponding to an ionic transference number, t_i, equal to 0.99 for the calcia-stabilized zirconia electrolyte. The oxygen partial pressures in equilibrium

with Ga and β-Ga_2O_3 are larger than those reported to correspond to $t_i = 0.99$. Since the oxygen partial pressures in equilibrium with the Ga-In alloys and β-Ga_2O_3 are uniformly larger than those in equilibrium with mixtures of Ga and β-Ga_2O_3, we are justified in expecting that the electrolyte exhibits practically pure ionic conductivity for the range of temperature and oxygen partial pressure encountered in this work.

Conclusions

The galvanic cell technique, utilizing CSZ as the solid electrolyte, was used to measure the activities of Ga in liquid Ga-In alloys. The measured activities are significantly smaller than those reported previously and are in good agreement with activities calculated from heats of mixing and liquidus determinations. The partial molar excess entropies of solution were determined to be negative and small.

Similar measurements on other systems relevant to the III-V binary and ternary semiconducting compounds are desirable in order to provide a sound basis for the processing of these materials. The present technique appears appropriate for determining isothermal activities in systems containing Ga or In as the least noble constituent.

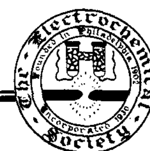
Technical Notes



Growth Via Leakage Paths of Nickel Oxide on Nickel at High Temperatures

M. J. Graham, D. Caplan, and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR9

In the high temperature oxidation of nickel, parabolic kinetics are expected since growth of the oxide layer proceeds by a diffusion process, the outward movement of cations. In experiments with annealed and cold-worked nickel (1) in which cold-worked nickel developed finer-grained oxide and oxidized more rapidly, it was concluded that the faster oxidation resulted from the large number of high-diffusivity paths provided by the fine-grained oxide. The apparent instantaneous parabolic rate constant, $2W \cdot dW/dt$,[1] decreased with oxidation time because the preferred paths for diffusion are progressively eliminated by a combination of annealing and grain growth.

It follows that this apparent parabolic rate constant is made up of two components: the normal lattice diffusion, plus a contribution from so-called leakage paths (1-12). For cold-worked nickel the contribution from leakage paths is greatest at short times and low temperatures; that from lattice diffusion is small at low temperatures, $< 700°C$, but becomes appreciable as the temperature is increased. By correcting oxidation rates on cold-worked nickel for lattice diffusion, and by taking into account leakage path density changes during growth, it is possible to calculate parabolic rate constants and an activation energy for growth via leakage paths only. The paper outlines the evaluation of the rate constants and the activation energy.

Treatment of Data

The contribution from lattice diffusion may be determined from oxidation data on annealed nickel. The thinnest oxides formed on annealed nickel, from 700° to 1270°C, are monocrystalline and are considered to grow exclusively by lattice diffusion. Parabolic rate constants (as W^2/t) were determined by Caplan *et al.* (1) from thickness measurements of the thinnest oxides

* Electrochemical Society Active Member.
Key words: kinetics, leakage-path diffusion.
[1] K_p, as $2W \cdot dW/dt$, is obtained as the product of the measured slope of the weight gain curve at any time and twice the weight gain at that time. Units used are mg² cm⁻⁴ hr⁻¹.

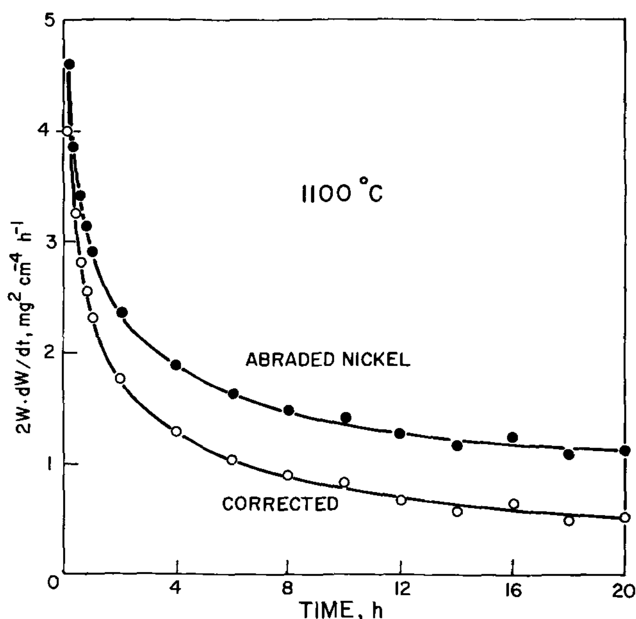


Fig. 1. Values of $2W \cdot dW/dt$ from oxidation at 1100°C of Ni cold-worked by abrasion with 600-grit SiC (1) (filled circles); and values corrected for the contribution from lattice diffusion (K_p = 0.60 $mg^2cm^{-4}hr^{-1}$) to give values of $2W \cdot dW/dt$ for growth via leakage paths (open circles).

and an activation energy of 54 kcal $mole^{-1}$ was found for growth by lattice diffusion (see Fig. 3). Values of W and $2W \cdot dW/dt$ for growth via leakage paths only, are thus obtained by subtracting from data on abraded nickel the weight gain and rate given by the parabolic rate constants for lattice growth. Figure 1 shows the corrected $2W \cdot dW/dt$ values at 1100°C.

The rate of oxygen uptake, dW/dt, is proportional to N, the number of easy diffusion paths per unit area. The rate of uptake also decreases as the oxide thickens, because transport is by diffusion. Thus, for growth via leakage paths

$$\frac{dW}{dt} = K_1 \frac{N}{W} \quad \text{or} \quad 2W \cdot \frac{dW}{dt} = 2K_1N \qquad [1]$$

Since $2W \cdot dW/dt$, the instantaneous parabolic rate constant, diminishes with time as the density of low resistance paths decreases (Fig. 1), the data at different temperatures can best be compared by extrapolating values of $2W \cdot dW/dt$ to zero time. It is necessary to assume that the density of paths at zero time, N_o, does not vary significantly with temperature. Over a limited temperature range this is a reasonable assumption for a given surface preparation, oxidation pressure, etc. As it is not feasible to compare values of $2W \cdot dW/dt$ at the same grain size for different temperatures, the assumption of an invariant N_o with temperature is considered to be the least objectionable compromise. It is difficult to determine values of $2W \cdot dW/dt$ at $t = 0$ by extrapolation because of the very rapid initial decrease (Fig. 1); Eq. [1] will, therefore, be modified to yield these values more readily.

The decrease in the density of easy diffusion paths could be by a first order reaction or by a grain growth process. A first order rate expression was used by Evans *et al.* in a mechanism based on mutual pore blocking (2, 3) and later applied by Smeltzer *et al.* to the oxidation of titanium, zirconium, and hafnium (6). The treatment assumes that the rate of decrease of paths is dependent upon the number of paths remaining, *i.e.*

$$-dN = K_2N\,dW$$

or

$$N = N_oe^{-K_2W} \qquad [2]$$

Substituting for N in Eq. [1] we have

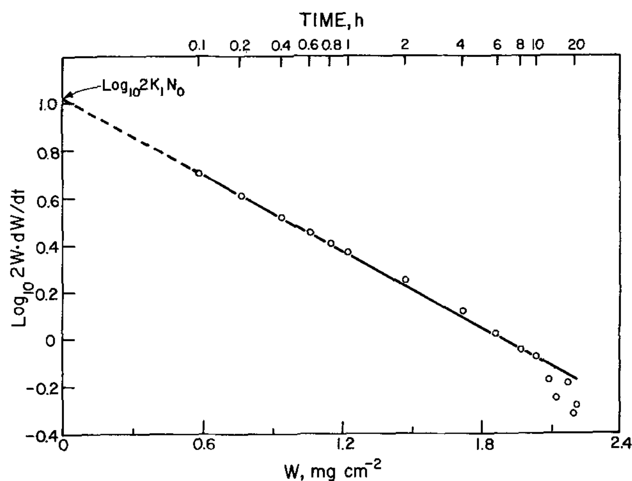

Fig. 2. Plot of $\log_{10}2W \cdot dW/dt$ against W for data on abraded Ni at 1100°C corrected for the contribution from lattice diffusion (corresponding oxidation times are also indicated); $\log_{10}2K_1N_o$ is the initial value of $\log_{10}K_p$ used in determining the activation energy for growth via leakage paths.

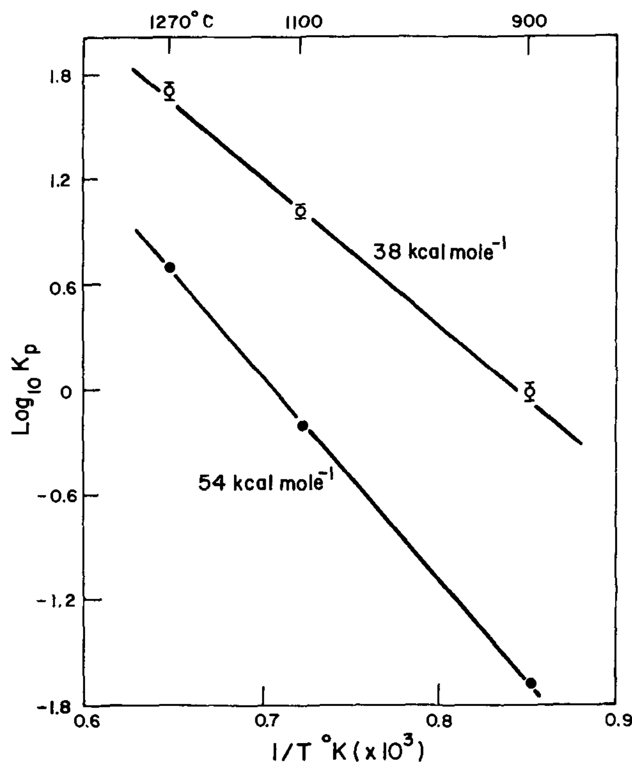

Fig. 3. Arrhenius plot for Ni oxidation from 900° to 1270°C; the activation energies are 38 ± 2 kcal $mole^{-1}$ for growth by leakage path diffusion (this study) and 54 kcal $mole^{-1}$ for growth by lattice diffusion [Ref. (1)] (the error bars indicate the uncertainty in evaluating the intercept, $\log_{10}2K_1N_o$).

$$2W \cdot \frac{dW}{dt} = 2K_1N_oe^{-K_2W} \qquad [3][2]$$

or

$$\log_{10}2W \cdot \frac{dW}{dt} = \log_{10}2K_1N_o - \frac{K_2W}{2.303} \qquad [4]$$

$2K_1N_o$ is the initial value of the instantaneous parabolic rate constant (at $W = 0$, $t = 0$) to be used in determining the activation energy for growth via leak-

[2] Integrating Eq [3] results in the rate expression

$$\frac{e^{K_2W}}{K_2}\left[W - \frac{1}{K_2}\right] + \frac{1}{K_2^2} = K_1N_ot$$

age paths. From Eq. [4] values may be obtained from the intercept of a plot of $\log_{10}2W \cdot dW/dt$ against W. Data on abraded nickel, corrected for lattice diffusion, did yield a straight line when plotted in this form and the intercept value of $\log_{10}2K_1N_0$ was readily determined. The plot for data at 1100°C is shown in Fig. 2. At long times, where the number of leakage paths is approaching a minimum, W tends to a constant value as $2W \cdot dW/dt$ approaches zero.

Although the data comply reasonably well with a first order reduction in leakage paths, other rate expressions are not precluded. An alternative one based on a decrease in leakage paths by a grain growth process (8) did not, however, fit the data as well, nor could good measures of $2K_1N_0$ be obtained. As our primary concern in this treatment is to obtain values of K_p at zero time, in order to provide the activation energy for leakage path growth, the precise manner in which the density of low resistance paths decreases with time is of secondary importance. Hence, values of $2K_1N_0$ readily obtained from plots, as in Fig. 2, have been adopted in determining the activation energy. Figure 3 shows K_p as $2K_1N_0$ plotted in Arrhenius form and the activation energy for growth via leakage paths of NiO on Ni from 900° to 1270°C is found to be 38 ± 2 kcal mole^{-1}. This is in agreement with values of 41 and 37 kcal mole^{-1} determined by Graham *et al.* in nickel oxidation studies from 300° to 700°C where growth was almost exclusively by transport, presumably of cations, via high-diffusivity paths (11, 12). These values are significantly less than 54 kcal mole^{-1} representing growth by lattice diffusion.

The High Temperature Sulfidation Properties of Nickel-Chromium Alloys

G. Romeo*

Research and Development Center, General Electric Company, Schenectady, New York 12301

and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

The reaction between sulfur vapor and nickel-chromium alloys has been the subject of a comprehensive study by Mrowec, Werber, and Zastawnik (1). The sulfidation kinetics and the morphologies of the corrosion products were investigated for the whole range of binary alloy compositions at temperatures from 600° to 900°C and at 1 atm sulfur pressure. With the help of marker studies, a sulfidation model was proposed that accounted for the parabolic growth of the scales as a result of diffusion processes. At very low, as well as at very high alloy chromium contents, homogeneous sulfide scales were found consisting respectively of a solid solution of chromium sulfide in nickel sulfide or *vice-versa.* In the intermediate alloy composition range a duplex scale was reported, the outer layer of which was homogeneous and consisted of nickel sulfide ($Ni_{1-x}S$), while the inner layer was heterogeneous and its morphology varied with the amount of chromium in the alloy. In particular, the inner layer on alloys containing more than 20 weight per cent (w/o) Cr consisted of chromium sulfide (Cr_2S_3) as a dispersing phase for islands and needle-shaped crystals of nickel sulfide. These findings were exemplified by micrographs and x-ray images of the cross section of a Ni-32.6 w/o Cr alloy sulfidized at 900°C. Since the nickel sulfide stringers lay across the inner chromium sulfide layer, linking the metal with the outer nickel sulfide layer, the hypothesis was advanced that these stringers could provide preferential paths for the outward diffusion of nickel ions.

More recently, Romeo, Smeltzer, and Kirkaldy (2) have reported a study of the sulfidation of a Ni-20 w/o Cr alloy at 700°C in hydrogen-hydrogen sulfide atmospheres, the composition of which varied in the range 5-100 volume per cent (v/o) H_2S. The kinetics also conformed, in this case, to the parabolic law and duplex scales were obtained as corrosion products. However, examination with the optical and the scanning electron microscope did not show any evidence of heterogeneity in the inner chromium sulfide layer. Electron microprobe counting indicated nickel solubility in the inner layer of about 2-3 atomic per cent (a/o). They concluded that outward diffusion of nickel ions could take place through the inner chromium sulfide layer, its whole cross section providing a bridge for nickel transport towards the gas phase. Occupation of chromium sites by nickel ions has indeed been suggested (1) to explain the slower sulfidation rate of low nickel content Ni-Cr alloys with respect to pure chromium.

* Electrochemical Society Active Member.
Key words: sulfidation, nickel-chromium alloys, sulfide morphologies, nickel-nickel sulfide eutectic.

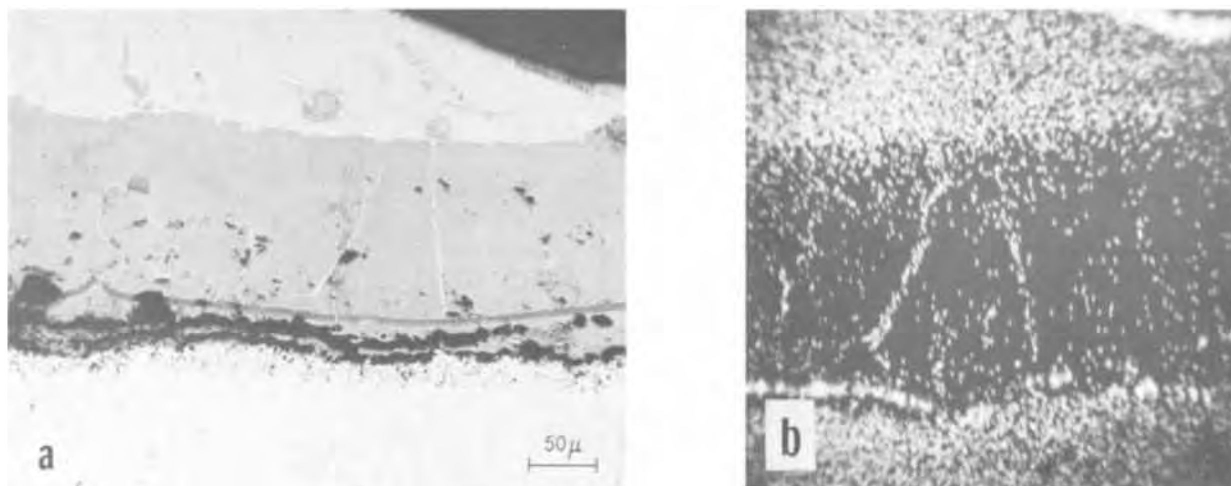

Fig. 1a. Duplex sulfide scale formed on a Ni-35 weight per cent (w/o) Cr alloy in a H_2-10% H_2S atm at 850°C; nickel sulfide stringers can be seen in the inner chromium sulfide layer; the outer nickel sulfide layer was molten at reaction temperature. Fig. 1b. X-ray $Ni_{K\alpha}$ image of the specimen cross section.

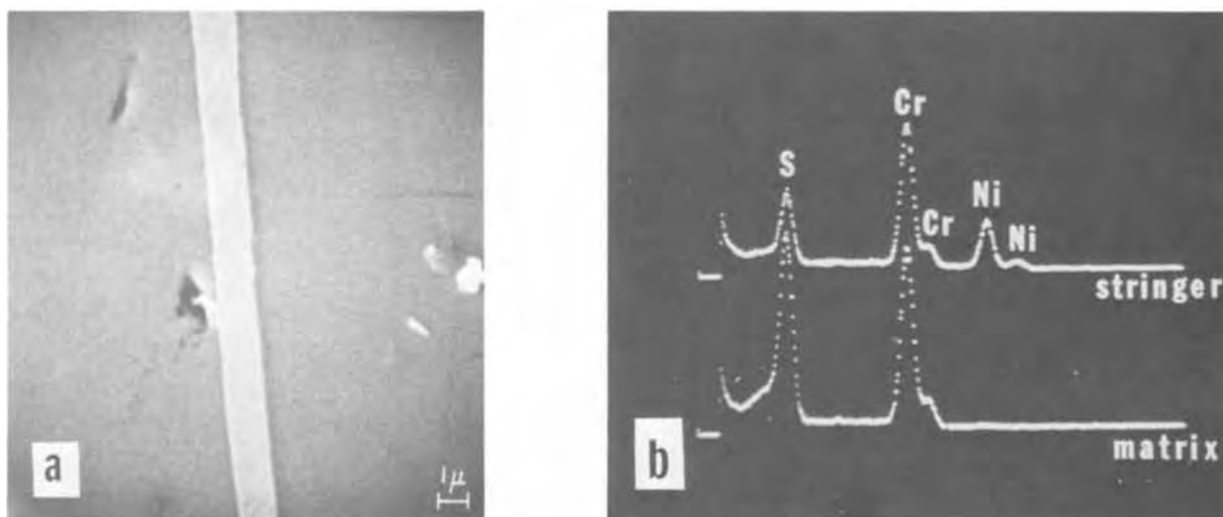

Fig. 2a. Scanning electron microscope image of a nickel sulfide matrix; Fig. 2b, x-ray characteristic peaks of the elements present in the stringer and the matrix.

In the course of the above study (2), the tendency was noticed for the Ni-Cr alloy to form a liquid sulfide phase at relatively low temperature. It is well known that the eutectic, Ni-Ni_3S_2, exhibits a melting point of 645°C. Consequently, sulfidation of Ni-Cr alloys could possibly lead to gas-liquid-solid reactions at temperatures above 800°C. The striking difference in the morphology of scales formed in H_2-H_2S atmospheres on a Ni-20 w/o Cr alloy at 700° and 900°C was reported a decade ago by Hancock (3). While at the lower temperature a duplex uniform sulfide scale was formed, at the higher temperature spheroidal chromium sulfide particles were imbedded in a nickel-nickel sulfide matrix which was liquid at reaction temperature.

We consider, accordingly, the possibility that liquid nickel sulfide formation may cause the needle-shaped heterogeneities in the inner layer reported by other authors (1). For example, Fig. 1a shows the cross-section of a Ni-35 w/o Cr alloy sulfidized at 850°C in a H_2-10% H_2S atm, and the corresponding x-ray $Ni_{K\alpha}$ image as shown in Fig. 1b. A sudden rapid weight gain of the specimen attached to a thermogravimetric balance indicated the formation of liquid nickel sulfide. The presence of nickel sulfide stringers running across the inner chromium sulfide layer is evident in the micrographs. Most probably the liquid has wet the chromium sulfide solid layer, dissolving it preferentially at grain boundaries.

This point of view is supported by analyses run with a solid-state x-ray detector mounted on a scanning electron microscope. This device can detect the presence of elements with atomic number equal or greater than 9 (4). Figure 2a shows a highly magnified micrograph of a nickel sulfide stringer, taken with the scanning electron microscope. The electron beam was then focused on the stringer and on the adjacent chromium sulfide matrix. The resulting x-ray spectra are shown in Fig. 2b. The matrix spectrum shows the K_α and K_β peaks for chromium and the K_α peak for sulfur, while the stringer spectrum shows additional K_α and K_β peaks for nickel. This accounts for some solubility of chromium sulfide in the liquid nickel sulfide.

In conclusion, sulfidation of Ni-Cr alloys at sufficiently low temperature takes place entirely as a gas-solid reaction which may lead to formation of a duplex sulfide scale consisting of homogeneous layers of chromium and nickel sulfides. A likely cause of heterogeneity in the inner layer at higher temperatures is the formation of a liquid nickel sulfide phase which occurs as stringers in the solid chromium sulfide layer.

This occurrence is actually recognized as a feature of accelerated corrosion of Ni-base alloys exposed to sulfur bearing atmospheres.

Ohmic Contacts to Zinc Telluride

W. D. Baker[1] and A. G. Milnes*

Electrical Engineering Department, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

Zinc telluride is a wide-gap (2.25 eV), p-type, II-VI semiconducting compound. One of the important problems in the fabrication of devices from ZnTe is the preparation of suitable ohmic contacts. We report here the results of some quantitative measurements on ohmic contacts to this semiconductor.

Experimental

The ZnTe samples were bars with a 1 mm by 1 mm cross section and a 3 mm length. They had a carrier concentration in the low 10^{16} cm^{-3} range. The bars were first solvent cleaned and chemically etched, and then contacts were made to the ends of the bars by alloying, evaporation, or plating. After the contacts were masked with wax, the bars were given a final light etching. Various etches were investigated and three were used. These etches are: etch in hot, 50% NaOH for a few seconds followed by a rinse in warm, dilute NaOH and then warm water rinses (1); etch in a solution of 40 ml H_2O, 5 ml H_2SO_4, 1g $K_2Cr_2O_7$ at 60°C for about a minute followed by warm water rinses (2); or etch in a 1-5% solution of Br in methanol for 1-2 min followed by methanol rinses. Different etches caused no detectable difference in the ohmic contact quality.

Many of the contacts considered were immediately rejected after a curve-tracer examination because of very high resistance or extreme nonlinearity of the volt-ampere characteristic. Table I summarizes the unsatisfactory contacts. All of these contacts were subjected to various heat cycles without significant improvements in their behavior.

Some successful contacts were found from previous literature, and from our experiments, and four types of contact were studied for linearity and contact resistance quantitatively at 300°K, and qualitatively at 196°K and 77°K. The contacts examined were tin + 1% arsenic alloy, electroless gold, lithium-diffused, and silver-diffused contacts. The tin-arsenic contacts were alloyed at 400°C for 1 min in a hydrogen atmosphere with 1% HCl gas present as a flux. The electroless gold was plated from a water solution of $HAuCl_4$. The lithium diffused contacts were formed using the technique of Aven and Garwacki (1) in which the contact area is coated with a $LiNO_3$ solution and then heated to 350°C for about 1 min in a hydrogen atmosphere. The silver diffused contacts were made by coating the contact area with an $AgNO_3$ solution which was dried and then heated to 400°C for about 1 min in a hydrogen atmosphere. Both the lithium- and silver-diffused contacts were covered with electroless gold.

Contact resistance measurements were made by passing a current through the bar and then probing the potential along the bar. The resulting plot of voltage *vs.* distance was extrapolated to the ends of the bar to infer the contact drop. The contact drop divided by

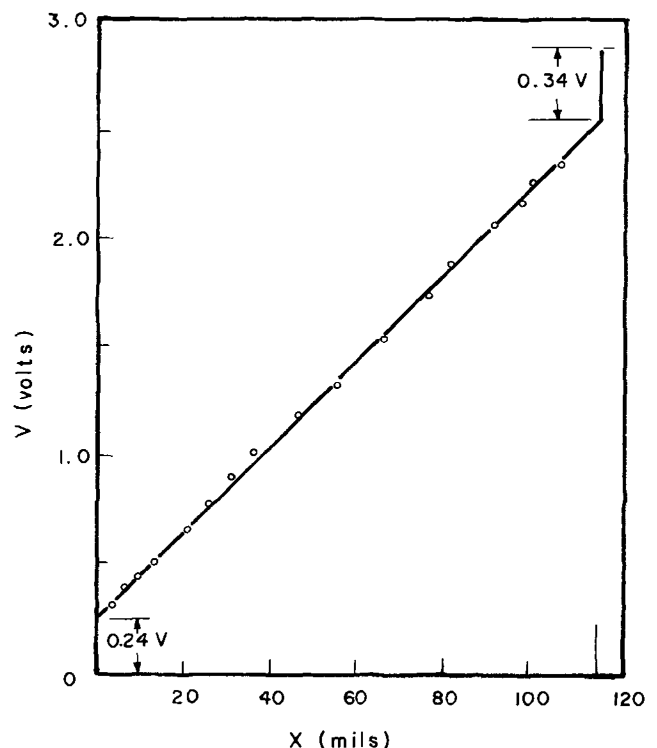

Fig. 1. Voltage *vs.* distance along a ZnTe bar with two lithium-doped contacts at $T = 300°K$ and current density $= 0.7$ A/cm^2.

Table II. Contact measurements on ZnTe ($1 \times 10^{16} cm^{-3}$ free holes)

Contact	Average specific resistance (300°K) (ohm-cm²)	Maximum useful current density (300°K) (A/cm²)	Useful at 77°K
Electroless Au	3.0×10^{-1}	<0.2	No
Sn + 1% As alloy	8.6×10^{-1}	>2	No
Li diffused	2.8×10^{-1}	>2	Yes
Ag diffused	4.0×10^{-2}	>2	Yes

the current density is the specific contact resistance. The potential probe was a tinned phosphor-bronze wire finely pointed. It was necessary to form the probe contact by a capacitor discharge in order to form a reliable contact to the ZnTe surface (3).

Results

A typical plot of voltage *vs.* distance is shown in Fig. 1 for a lithium diffused contact at room temperature with a current density of 0.7 A/cm². The resulting specific contact resistances for the two contacts are 0.34 ohm-cm² and 0.49 ohm-cm². Reversal of the current direction did not change the measured contact resistance. Similar curves were obtained for the other contact materials (4). For the silver-diffused contacts, the voltage *vs.* distance curves tend to flatten out near the ends of the bar, suggesting that the contacts actually penetrate a few mils into the bar. This behavior has been seen previously with silver layers on ZnTe, and the penetration has been attributed to electromigration, which can be observed as filament-like projections of silver into the ZnTe (5).

The results of the contact measurements are given in Table II, from which it can be seen that the lithium-of silver-diffused contacts have the lowest resistance.

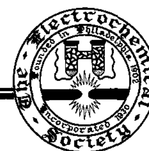
Brief Communication



Identification of Chemical Constituents of Defects in Silicon

Jacques M. Assour

RCA Laboratories, Princeton, New Jersey 08540

Selective chemical etching with Sirtl or Dash etches is commonly used to determine the presence of defects caused by chemical impurities in silicon bulk wafers, epitaxial layers, and diffused regions. Defects in the shape of cones, platelets, protrusions, and various dendritic structures usually appear after etching. In practice, we have found the impurity concentrations in these defects to be below the detection level presently achieved by mass spectrometry and electron-probe microanalysis in agreement with Yanagawa (1) and Green (2). In this note we report new results on the chemical constituents of a number of chemical defects observed in processed silicon devices. The chemical constituents were identified with a secondary ion emission mass spectrometer (3). The sensitivity limit of this spectrometer ranges between 1 ppm to 1 ppb, thus providing a powerful tool to identify the impurity concentrations of the defects. Because of the fine spatial resolution of this instrument (1 to 2 μm), we have been able to identify uniquely several defects and, in some cases, trace their origins.

The samples were first etched to reveal the defects and then thoroughly cleaned to remove surface contamination. The presence of the chemical constituents at a defect was confirmed by analyzing reference silicon areas in the samples which are free of defects. In other words, the impurities reported here were detected only at the defect sites.

Key words: chemical constituents of defects, silicon, identification.

Protrusions from Epitaxial Surfaces

Fast growing protrusions from epitaxial semiconductor surfaces were seen on silicon by Yanagawa (1) and their characteristics were described by Green (2). Typical protrusions observed here on 100 μm thick epitaxial layers, deposited on <111> silicon n-type substrates, are shown in Fig. 1 a and b. Their height is 3-5 times the thickness of the deposited epitaxial layer and their diameter varies from 40-100 μm. The detected chemical constituents of these defects are CO_2, SiO, SiN, hydrides and hydroxyl groups. All of the impurities are present in the protrusions but with varying concentrations. Since the sources of these impurities are many, and critically depend on the conditions of the epitaxial deposition system, no attempt has been made yet to isolate uniquely the source of these contaminants. It has been noted (4), however, that the density of these defects is a strong function of the graphite rf susceptor which supports the wafers during epitaxial deposition; a newly applied SiC coating results in a high density of these protrusions, whereas a coat of pure silicon results in a decreased density.

Impurity Precipitates in Boron Diffused Layers

The properties of boron nitride (BN) wafers as planar diffusion sources for boron have been described by Goldsmith *et al.* (5) and Rupprecht and Stack (6).

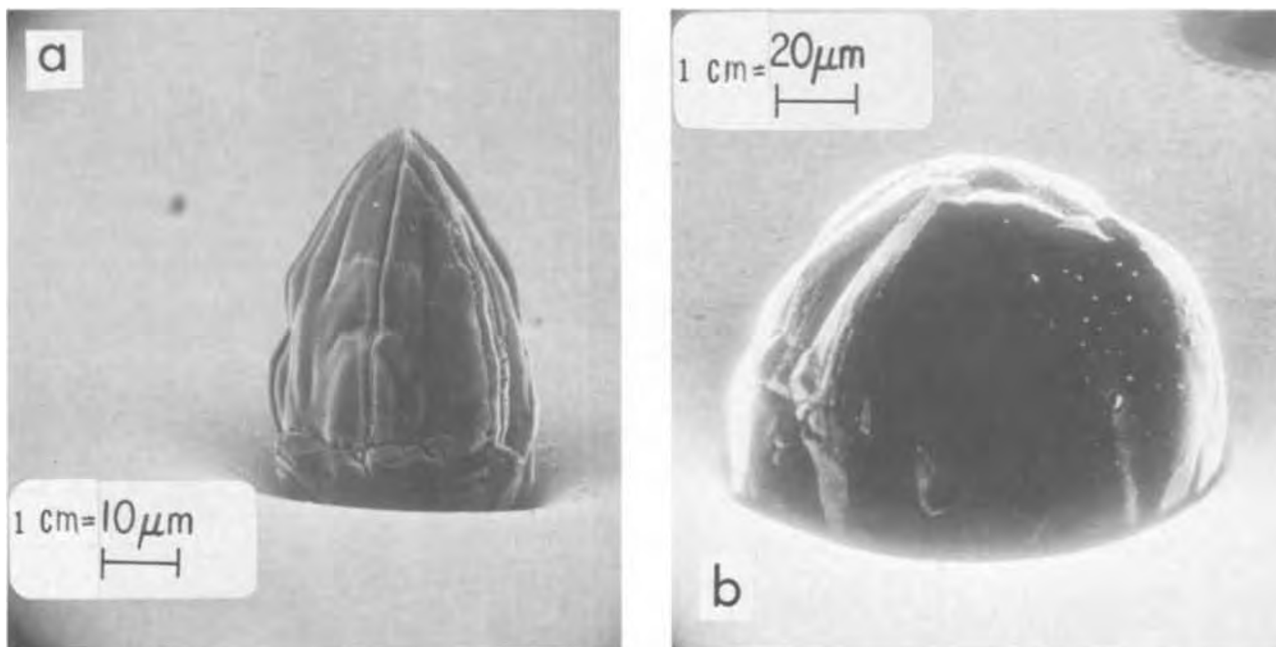


Fig. 1 a and b. Fast growing protrusions from epitaxial silicon surface.

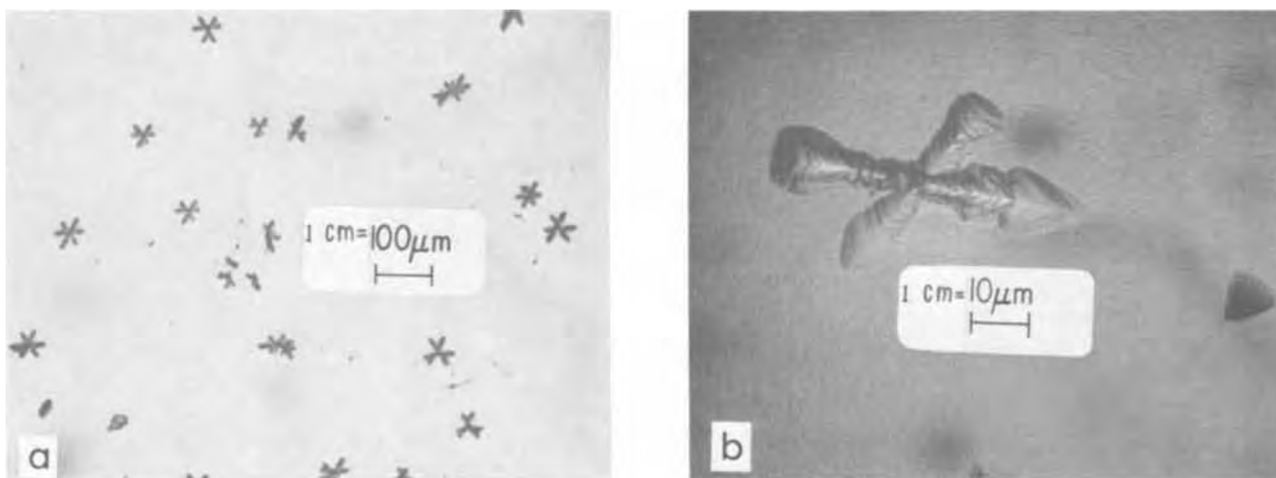

Fig. 2 a and b. Boron and oxygen precipitates after boron diffusion deposited from a grade M, BN diffusion source.

Two grades of BN diffusion sources are available:[1] grade A and grade M. Grade M consists of boron nitride in a silica matrix. The impurity precipitates observed in p-type diffused layers from the above sources are shown in Fig. 2a and b and Fig. 3. The dendritic structure in Fig. 2 is obtained after diffusion from an overly used grade M boron nitride source. The chemical constituents of these defects were boron and oxygen. Based on our observations below, the source of these impurities has been traced to the poor oxidation condition of the BN wafer. Analysis of control wafers, heat-treated in the same furnace but without exposing them to the BN source, has confirmed the clean condition of our gases and furnace. The defects were not present prior to the boron diffusion but were detected after exposure to the BN source. Moreover, the density of these defects markedly decreased with successive chemical etching of the boron-diffused layer and finally disappeared at the n-type substrate. After proper cleaning (5, 6) and reoxidation of the BN wafer, p-type diffused layers deposited from this BN source had no defects.

The defects with a trapezoid geometry, as shown in Fig. 3, were detected in a p-type diffused layer de-

[1] The Carborundum Company, Niagara Falls, New York.

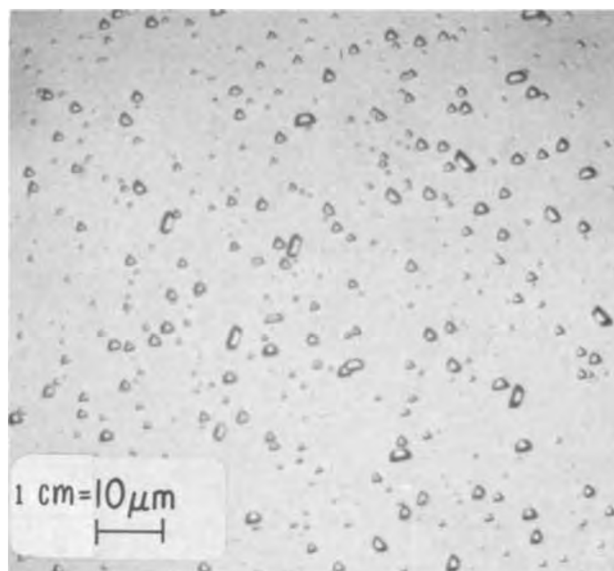

Fig. 3. Aluminum precipitates after boron diffusion deposited from a grade A, BN diffusion source.

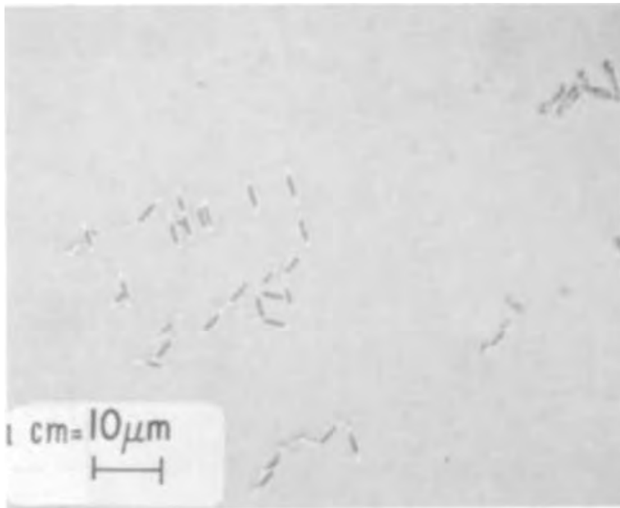

Fig. 4. Copper and silver precipitates in epitaxial silicon after thermal oxidation.

posited from a grade A boron nitride source. Analysis by secondary ion-emission mass spectrometry has revealed that these defects are predominantly Al precipitates, although traces of Na, K, Ca, Mg, Cu, and O_2 were also detected in the sample. We believe that all these impurities originate from the BN diffusion source for the following reasons. The defects are observed only after exposure to the BN source. As mentioned above, the density of these defects decreases with successive etching of the p-type diffused layer and disappear at the n-type substrate. Proper reoxidation of the BN wafer eliminates these defects. Moreover, emission spectrographic analysis of grade A boron nitride wafers[1] has revealed the following metallic impurities in ppm: Al = 600-6000, Cu = 3-30, Ti = 3-30, Ca = 1500-15,000, Ni = 100-1000, Fe = 30-300, Si = 500-5000, Cr = 100-1000, Mn = 10-100, Mg = 150-1500. Analysis by mass spark-source spectrometry of other commercially available BN wafers has also revealed (7) the above metallic impurities.

Metallic Precipitates in Silicon after Thermal Oxidation

This sample consisted of an n-type epitaxial layer, 8 μm thick, grown on a <111> n^+ substrate. The silicon wafer was then thermally oxidized in the presence of H_2O vapor. After Sirtl etching, defects in the shape of elongated cigars, as shown in Fig. 4, were found randomly distributed in the epitaxial layer. The impurity constituents of these defects are Cu and Ag. The source of these metallic impurities has been tentatively identified as contamination introduced with the H_2O vapor during thermal oxidation.

In summary, we have demonstrated that secondary ion emission mass spectrometry is a powerful tool to identify impurity concentrations of defects in silicon. It is hoped that further analysis will uniquely isolate the source of contaminants during processing of semiconductor devices.

Sulfur Trioxide, Oxygen, Platinum Electrode in a Fused Sulfate

F. J. Salzano* and L. Newman

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The behavior of the $O_2,SO_3,Pt/(Na,Li,K)_2SO_4$ electrode was studied at SO_3 concentrations in the parts per million range. The cell studied consists of two similar electrodes isolated from each other by a solid cation permeable membrane. One electrode is a reference electrode through which passes an air or oxygen stream containing a fixed and known concentration of SO_2. Through the other electrode is passed a similar gas stream containing a variable concentration of SO_2. The SO_2 passes into each electrode through a platinum inlet tube which converts a fraction of the SO_2 in the gas stream to SO_3. The emf *vs.* concentration behavior of this cell was studied and shown to exhibit Nernstian behavior. This work shows that the cell has possible applications in continuous monitoring of ambient air for both SO_2 and SO_3, *i.e.*, sulfuric acid aerosols.

A number of gas-metal-fused salt electrodes have been described in the literature. These include: halogen-carbon-halide melts, carbon dioxide-oxygen-platinum-carbonate melts, oxygen-platinum solid oxide, oxygen-platinum-oxide melts, and others (1). These electrodes are widely used in basic electrochemistry studies and in measurements of thermodynamic properties. However, these gas electrodes and others not as well developed can also be the basis for practical monitoring devices useful for measuring the activities of gaseous species. Recently, Boxall and Johnson (2) have described a hitherto undeveloped sulfur trioxide-oxygen-platinum $(Li,Na,K)_2SO_4$ electrode. They studied the emf of this electrode *vs.* a silver, silver ion reference electrode at 550°C when the SO_3 and oxygen concentrations at the electrode were varied from 0.390 to 0.842 atm and 0.036 to 0.577 atm, respectively. This investigation showed that at high concentrations of SO_3 the emf is a linear function of log $P(SO_3)\ P^{1/2}(O_2)$, where $P(SO_3)$ is the partial pressure of SO_3 and $P^{1/2}(O_2)$ is the square root of the partial pressure of oxygen. From the slope of their line we calculate that there are two electrons involved in the electrode reaction.

Flood and Boye (3) have utilized the SO_2,O_2 electrode to obtain thermodynamic information on the systems

$$K_2SO_4 - K_2S_2O_7 - SO_3$$

$$ZnO - ZnSO_4 - SO_3$$

They suggest that the electrode reaction involves the oxidation of SO_2 by oxide ion to SO_3 and that two electrons are involved per mole of SO_2. However, they are careful to point out that the details of the electrode reaction are unknown and the effects they observe may also be attributed to the oxygen electrode. In any case, the performance of the SO_2,O_2 platinum electrode is intimately related to the SO_3,O_2 platinum electrode in a sulfate melt because of the equilibrium reaction between SO_2, O_2, and SO_3.

In this paper we describe work with the SO_3,O_2, platinum electrode in a $(Li,Na,K)_2SO_4$ melt in which we studied the variation in emf *vs.* oxygen and air containing parts per million concentrations of SO_2 in contact with the electrode. In these cells a quartz glass membrane was used to completely isolate each gas electrode. Quartz glass is an effective barrier for SO_3 but is permeable to the cations in the melt (4, 5). Control of the SO_2 concentration at the low levels required in this work was accomplished with sulfur dioxide permeation tubes (6,7). In addition to showing that the results obtained are consistent with the idea that the SO_3,O_2 platinum electrode is basically an oxygen electrode the results obtained suggest that this cell has potential application as a practical monitoring device for SO_2 or SO_3, *i.e.*, $H_2SO_4 \cdot xH_2O$ aerosols, in ambient air.

Theory

The emf *vs.* concentration relation for the cell

O_2, Pt + SO_3 (unknown conc) + Na_2SO_4 K_2SO_4 Li_2SO_4	Cation permeable glass	Na_2SO_4, K_2SO_4, Li_2SO_4	Cation permeable glass	Pt, O_2 + SO_3 (known conc) + Na_2SO_4 K_2SO_4 Li_2SO_4	[I]

can be derived based on the simple assumption that the system behaves as an oxygen electrode. It will be seen that the experimental results obtained in this work and the work of Boxall and Johnson (2) and Flood and Boye (3) are consistent with these assumptions. Cell I consists of two similar $SO_3,O_2,Pt/SO_4^{-2}$

* Electrochemical Society Active Member.

Key words: sulfur trioxide, sulfate melt; SO_3,SO_2,O_2 platinum electrodes; quartz membranes; monitoring SO_3, SO_2 in air.

electrodes. Oxygen gas containing a low, but fixed concentration of SO_3, *i.e.*, 1% or less, is passed through one of the electrodes, designated as the reference electrode (r). The other electrode is called the working electrode (w) and through it is passed oxygen containing a variable or unknown concentration of SO_3. We assume that at each electrode the following equilibria exist

$$\tfrac{1}{2}O_2 + 2e^- = O^{2-} \quad [a]$$

and

$$SO_3 + O^{2-} = SO_4^{2-} \quad [b]$$

We can combine [a] and [b] and write as the over-all reaction

$$SO_3 + \tfrac{1}{2}O_2 + 2e^- = SO_4^{2-} \quad [c]$$

Thus, we assume that the basic electron transfer step is equilibrium [a]. If these are the only reactions to consider then it can be easily shown that the emf of the cell is given by the relation

$$\text{emf} = -\frac{RT}{2\mathbf{F}} \ln \frac{P_r(SO_3)}{P_w(SO_3)} - \frac{RT}{4\mathbf{F}} \ln \frac{P_r(O_2)}{P_w(O_2)} \quad [1]$$

where $P_r(SO_3)$, $P_w(SO_3)$ and $P_r(O_2)$, $P_w(O_2)$ are the partial pressures of SO_3 and O_2 at the reference (r) and working (w) electrode, respectively. Thus, the emf of the cell depends on two terms, the first involves the partial pressures of SO_3 and the second involves the partial pressure of oxygen at the respective electrodes. If we consider that the concentrations of SO_3 and O_2 at the reference electrode are fixed then we can write

$$\text{emf} = E_0(T) - \frac{RT}{2\mathbf{F}} \ln P_w(SO_3)\, P_w(O_2)^{1/2} \quad [2]$$

When the partial pressure of oxygen in each electrode gas stream in cell I is the same we can simplify Eq. [1] to

$$\text{emf} = -\frac{RT}{2\mathbf{F}} \ln \frac{P_r(SO_3)}{P_w(SO_3)} \quad [3]$$

Boxall and Johnson studied the behavior of the SO_3,O_2 platinum/SO_4^{-2} electrode at 550°C, at very high concentrations of SO_3. From their plot of emf *vs.* log $P(SO_3)\,P(O_2)^{1/2}$ we calculate a value of $RT/2\mathbf{F}$ equal to 84 mV. This compares to the theoretical value of 82 mV which shows that their data are consistent with this simple model.

The response of cell I when SO_2 is injected into the oxygen stream rather than SO_3 can be considered by including the effect of the reaction

$$SO_2 + \tfrac{1}{2}O_2 \rightarrow SO_3 \quad [d]$$

The free energy change for reaction [d] is well known (8). High temperatures favor the formation of lower partial pressures of SO_3. When the concentration of SO_2 injected into the oxygen is low we expect the rate of conversion to SO_3 to be first order with respect to the inlet concentration of SO_2, *i.e.*, for a small degree of conversion. This reaction is slow and in the commercial manufacture of SO_3 a platinum or metal oxide catalyst is employed to increase the rate of reaction. Thus, at a high fixed flow rate the fraction of SO_2 converted is expected to be small and approximately independent of the inlet concentration. Thus, we expect at the reference electrode

$$P_r(SO_3) = X_r P_r(SO_2)$$

and at the working electrode

$$P_w(SO_3) = X_w P_w(SO_2)$$

where X is the fraction of SO_2 converted to SO_3 and $P_r(SO_2)$ and $P_w(SO_2)$ are the inlet partial pressures of SO_2 at the respective electrodes. If the electrodes and flow rates are matched then

$$X_r \approx X_w \quad [4]$$

and we expect the relation

$$\text{emf} \approx -\frac{RT}{2\mathbf{F}} \ln \frac{P_r(SO_2)}{P_w(SO_2)} \quad [5]$$

to hold to a fair approximation. In this paper we will show that Eq. [5] holds at SO_2 concentrations at the 1 ppm level by volume. Thus, it follows that Eq. [2] and [3] are valid at SO_3 concentration just below the parts per million range in air and oxygen gas at temperatures in the range of 650°-750°C.

Experimental

Cell and experimental apparatus.—The electrochemical cell studied consisted of two similar but independent electrodes each enclosed in a gas-tight cation permeable quartz membrane. A schematic diagram of the cell assembly is shown in Fig. 1. Each electrode consisted of a 12 mm OD quartz tube having a wall thickness of approximately 1 mm. Each had a closed hemispheric end and was filled with a eutectic mixture of Na_2SO_4, K_2SO_4, and Li_2SO_4 to a level of 12 mm. A 40 mil platinum electrode wire was immersed approximately 5 mm into the salt melt. The platinum wire was threaded through a quartz inlet tube of approximately 3 mm OD. The tube terminated approximately 1 or 2 mm above the salt. We found it was not practical or necessary to bubble the gas directly into the salt melt. In some cases the inlet tube was ⅛ in. OD platinum which had a 5 mm extension immersed in the salt. Both electrodes were immersed in a common salt bath contained in a gold crucible. The gas space over the salt was purged with helium. Dry oxygen is also suitable. The whole cell is contained in a quartz enclosure which is further enclosed in a stainless steel electrical shield. The purpose of the shield is to eliminate inductive pick-up by the wire leads in the cell. The shield is grounded and the working electrode is connected to the shield. The emf developed by the cell was measured with a Keithley Model No. 602 electrometer and measured against a General Resistance digital bucking voltage source Model No. DAV-45D. The output of the electrometer and the temperature were continuously recorded on a two-pen recorder, Honeywell Electronik 19.

Each electrode had an independent gas supply. The gas supply to the reference electrode was commercial oxygen or breathing air. The gas supply to the working electrode was similar but in some experiments room air was pulled through the electrode by means of a vacuum pump and the flow controlled with a throttle valve at the outlet of the cell. The flows through each

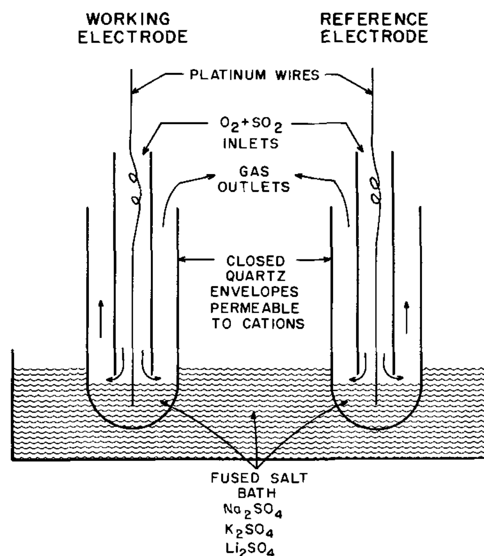

Fig. 1. Schematic diagram of the experimental cell used to study the behavior of the SO_3, O_2, Pt/SO_4^{-2} electrode.

of the electrodes were measured independently with floating ball flowmeters which were continuously checked against the rate of movement of a soap bubble film through a standard volume. In general, the flow rate could be varied from 30 to 300 cm^3/min.

The sulfur dioxide used in these experiments was injected into the respective gas streams in one of two ways. At concentrations in the range of 1% the SO_2 was taken from a cylinder of anhydrous sulfur dioxide (Matheson Company). It was metered into the oxygen stream by means of a small flowmeter. Under these conditions the size of SO_2 flow rate could be held constant, but was not known very accurately. The flow of SO_2 was varied over the range of 0.5-2 cm^3/min.

In the more refined measurements at the parts per million level we employed sulfur dioxide permeation tubes (6, 7) as a source. These are Teflon tubes ¼ in. in diameter which range in length from 3 to 30 cm. These tubes contain liquid sulfur dioxide and are sealed at each end. The tubes leak sulfur dioxide by diffusion at a fixed rate at a given temperature. The concentration of SO_2 was varied by passing the gas stream over different length tubes. Calibration of the SO_2 permeation tubes was accomplished by the standard technique of measuring the loss in weight with time. The smallest tube (SST) the intermediate tube (IST), and the largest tube (LST) lost SO_2 in the ratio of 1:5:8. The initial rate of the SST was 0.7 μg/min at 27°C. This value was not constant during the course of these experiments and decreased to 0.5 μg/min. The IST was obtained from the National Bureau of Standards and used exclusively in the reference electrode gas stream. The other tubes were obtained from Analytic Instrument Development, Inc.

Preparation of the salt.—Standard reagent grade Li_2SO_4, Na_2SO_4, and K_2SO_4 were obtained from the Baker Chemical Company. The reagents were weighed out in the mole proportions 78:13.5:8.5, respectively, thoroughly mixed, and dried at 250°C. The powder was placed in a 2 in. OD × 4 in. high gold crucible and slowly heated while a stream of oxygen containing approximately 1% SO_2 was passed through the apparatus. The salt was heated to 650°C and held overnight. The apparatus was then evacuated at 650°C with a mechanical roughing pump and cooled. The melting point was in the range of 540°-546°C compared to the expected value of 512°C. Small portions of this salt were removed from the crucible and used in the electrode assemblies. The rest of the salt was used in the common salt bath in which the electrodes were immersed. The salt is initially treated with SO_2 in order to overcome its tendency to etch the glass.

Procedure using permeation tubes.—The two electrodes were loaded with the sulfate salt which was melted with a hand torch under a stream of dry oxygen and the platinum wires were positioned in the melt in each electrode. The electrodes were then positioned in the cell in the furnace. Oxygen or air containing from 1 to 10 ppm SO_2 was passed through both electrodes while the cell was brought to temperature. At 650°C the electrodes were positioned in the bath and the cell heated to 700°C and held overnight. The flow in the reference electrode was adjusted to the desired level in general from 100 to 300 cm^3/min. This reference gas was continuously passed over the (IST) National Bureau of Standard's SO_2 permeation tube. After one day, the source of SO_2 in the working electrode gas stream was removed and pure oxygen or air was allowed to pass into this electrode. In general, it took several hours to clear all the SO_2 from the electrode, *i.e.*, for the emf to reach a stable value. In general, the concentration of SO_2 at a given flow rate was changed by putting different size permeation tubes, *i.e.*, SST or LST, in the gas stream of the working electrode.

Results

The emf of the cell at 700°C *vs.* the flow rate of oxygen was measured when SO_2 was injected at a fixed rate into the oxygen stream passing through the working electrode. In these initial experiments pure oxygen was used as the reference electrode gas. In this series of experiments the inlet tube of the reference electrode and working electrode were quartz glass. Results were obtained at oxygen flow rates in the range of 30-300 cm^3/min and SO_2 injection rates of 0.5-2 cm^3/min. When the flow rate or equivalent concentration is plotted on a log scale *vs.* the emf for a fixed rate of SO_2 injection, we obtained a straight line with a slope very close to the expected value of 97 mV/decade of concentration as predicted from Eq. [5]. A typical plot of oxygen flow rate and concentration *vs.* the emf in millivolts is shown in Fig. 2. The concentration range covered is from 0.3 to 2% SO_2. The scatter in the data is due to the difficulty of holding the rate of SO_2 injection at a precisely fixed value.

In another series of experiments the variation in emf of the cell was studied when the concentration of SO_2 passing through the working electrode was varied at a fixed flow rate of oxygen. The sources of SO_2 in these experiments were two Teflon permeation (6, 7) tubes with leak rates in the ratio of 1:8. The concentration range studied was from 1 to 8 ppm with a flow rate in the working electrode equal to 275 cm^3/min. The emf *vs.* SO_2 concentration was studied using commercial oxygen and air stored in steel cylinders. The concentration of SO_2 in the reference electrode was 15 ppm. In all the experiments performed at parts per million levels of SO_2, the inlet tube in each electrode was ⅛ in. platinum. The results obtained in one experiment are shown in Fig. 3, which is a plot of the SO_2 concentration on a log scale *vs.* the emf in millivolts. The results obtained using air and oxygen in both electrodes are similar when the reference electrode concentration is held at a fixed level. Both sets of data points fall very close to the approximate expected line based on Eq. [5]. The slope as predicted is 97 mV/decade. This is based on the assumption that two electrons per mole of SO_2 are involved in the electrode reaction. The highest emf observed was 220 mV ob-

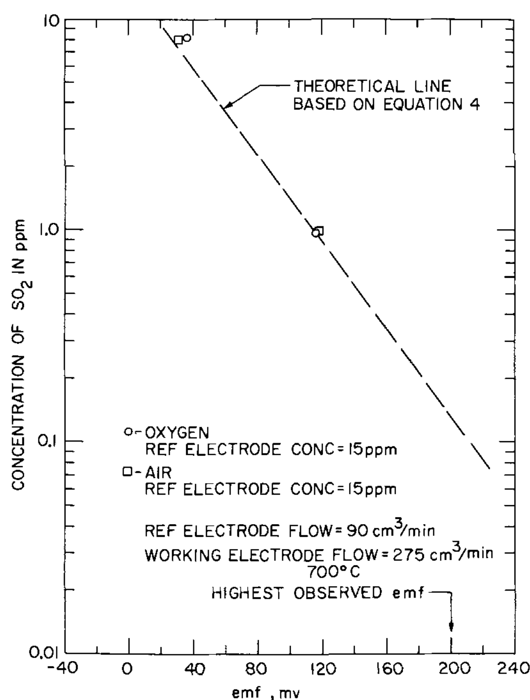

Fig. 3. Variation in emf of the cell as a function of the SO_2 concentration at the parts per million level showing no difference in behavior between air and oxygen.

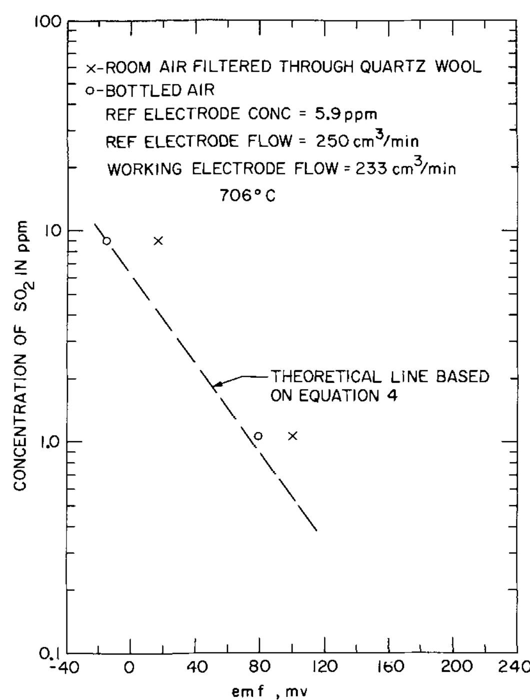

Fig. 4. Calibration of the cell using ambient air as the working electrode gas.

tained when pure bottle air is passed through the reference electrode. This corresponds to 0.08 ppm SO_2, which is high and probably results from residual system contamination introduced into the oxygen stream. Similar results were obtained at oxygen flow rates of 100 cm^3/min which correspond to a factor of three increase in SO_2 concentration.

When gases containing different oxygen activities are passed through each electrode, *e.g.*, air and oxygen, the cell emf responds to changes in the oxygen activity. In fact, the response to changes in oxygen activity was used as a standard test for evaluating the responsiveness of every new cell prior to experiments involving SO_2 injection. When the working electrode gas is changed from air to oxygen (0.2-1.0 atm) in the absence of SO_2, the emf change is within a millivolt of the expected value, *i.e.*, 33.7 mV at 700°C. This is true in the absence or presence of SO_2 in the gas streams and at flow rates in the range of 300-30 cm^3/min. Increasing the oxygen or SO_2 partial pressure causes the emf to change in the same direction as predicted from Eq. [2]. Thus, nitrogen does not affect the performance of the cell even at very low concentrations of SO_2.

In one set of experiments an effort was made to sample and analyze the SO_2 concentration in the working and reference electrode gas streams. The reference electrode concentration was estimated to be 5 ppm and chemical analysis gave a number close to this value. The concentration of SO_2 in the working electrode stream was calculated to be 8 ppm whereas a value of 11 ppm was obtained by chemical analysis. The corresponding emf values at these two levels showed good agreement with the estimated expected value based on Eq. [5]. In some experiments a sample of room air was passed through the working electrode while bottled air containing 5.9 ppm SO_2 was passed through the reference electrode. Typical results are shown in Fig. 4. The data points show good agreement with expected slope but are displaced 28 mV in the direction of higher emf values relative to bottled air. This can be interpreted to mean a lower SO_2 concentration in the working electrode gas stream when room air is used (see Discussion).

An attempt was made to produce SO_3 in the oxygen stream by reacting SO_2 with a platinum filament built into the gas feed line leading to the cell. At a filament temperature of $\approx$500°C a significant amount of SO_3 was produced which reacted with available moisture to form H_2SO_4 which collected on a cold wall ½ in. from the filament. A significant degree of conversion of SO_2 to SO_3 was also evident from the emf of the cell which increased when the filament was turned on suggesting a decrease in the concentration of SO_2 in the gas stream.

Although it was not practical to make a direct addition of SO_3 to the gas stream we did demonstrate in an indirect way that the cell responded to SO_3. This was accomplished by studying the variation in the emf of the cell at different flow velocities through the platinum inlet tube. In this case the concentration of SO_2 in the gas stream was held constant by passing air at a fixed flow rate ($\approx$300 cm^3/min) over one of the permeation tubes. The flow rate through the cell was varied by allowing part of the flow over the permeation tube to bypass the cell, while the rest of the flow was passed into the cell through the ⅛ in. platinum inlet tube which carried the gas into the hot zone and over the surface of the molten salt. Some typical data are shown in Fig. 5 which is a plot of the flow rate through the cell on a log scale, *vs.* the emf in millivolts on a linear scale. In this experiment the oxygen flow through the the cell was varied from 30 to 300 cm^3/min at SO_2 concentration of 0.7 and 5 ppm at 710° and 610°C. We observed that the emf changed by ~55 mV when the flow is varied over this range. We interpret this dependence of emf on the flow rate to be due to a greater degree of conversion of SO_2 to SO_3 at the lower flow rates. This effect was very reproducible and the response kinetics of the cell were measured in minutes when the flow rate was changed from one level to either a higher or lower level.

Furthermore, this effect was independent of concentration in the range studied and gave the same slope of 55 mV/decade at 610°, 710°, and 750°C. When no SO_2 was injected into the working electrode gas stream the emf was independent of flow rate in the range studied.

Discussion

The behavior of the SO_2,O_2, platinum/SO_4^{-2} electrode has been studied in the range of SO_2 concentra-

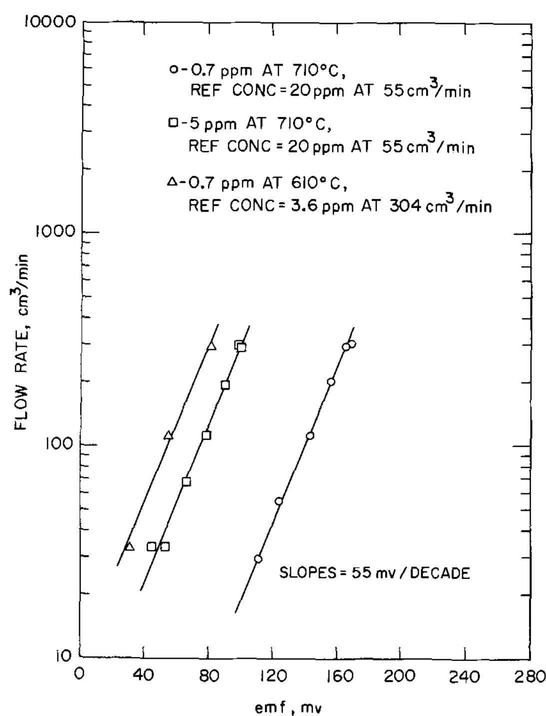

Fig. 5. Effect of flow rate on the emf of the cell when the concentration of SO_2 is held constant at the parts per million level.

tions from 1% to 1 ppm. This electrode is in reality similar to the SO_3,O_2, platinum/SO_4^{-2} electrode studied by Boxall and Johnson (2). Considering their work and the present results, the behavior of this electrode has now been examined in the concentration range of 80% SO_3 to below 1 ppm and it is found to exhibit Nernstian behavior over this range. The performance of this electrode is consistent with equilibria [a] and [b], and Eq. [1], [2], and [3]. This electrochemical system can be regarded as an oxygen electrode which coupled with equilibrium [b] is responsive to SO_3 according to equilibrium [c]. However, if we combine equilibria [a] and [d] we obtain for the overall electrode reaction

$$SO_2 + O^{-2} = SO_3 + 2e \qquad [e]$$

which is the reaction suggested by Flood and Boye (3). Thus, the mechanism of this electrode can be regarded from different points of view, but it is our contention that it is basically an oxygen electrode according to equilibrium [a]. As such, impurities present in the salt which affect equilbrium [b] will affect the SO_3 (SO_2) response of the cell, but may not have any effect on the oxygen response of the cell. Accordingly, we have observed, in one cell, poor response to SO_2, but this cell gave the expected response to changes in oxygen activity.

The agreement of the emf *vs.* SO_2 concentration results obtained from this cell with that expected from Eq. [5] at parts per million concentrations of SO_2 is somewhat fortuitous since Eq. [5] is an approximation. We would expect to get agreement only when the electrodes are perfectly matched, *i.e.*, when they convert the exact same fraction of SO_2 to SO_3. Such good agreement however, was not observed in all cells, but the correct slope of Eq. [5] is always obtained. This type of situation is demonstrated in Fig. 4 where the results are displaced 28 mV higher than the expected line, whereas this cell gave the expected results with bottled air. It is known that the rate of SO_2 emission from the permeation tubes is decreased at humidity levels above 10%. We believe that the higher humidity of the ambient air can account for the unexpected shift of these results from the expected line.

The expected equilibrium ratio of SO_2/SO_3 at 700°C in air is approximately unity. However, the degree of conversion of SO_2 to SO_3 at flow rates around 300 cm³/min was small. This is indicated by the results of chemical analysis of the outlet gas and arises because of the short residence time of the gas in the inlet tube. A more basic question is whether the conversion of SO_2 to SO_3 took place in the inlet line (⅛ in. platinum tube) or at the gas-salt interface in the electrode in the experiments at parts per million levels of SO_2. In one cell in which the surface area of the salt was reduced from 12 to 3 mm and the salt volume reduced to 1/20 the normal value we observed the predicted magnitude of response to changes in the concentration of SO_2 at the parts per million level. Also, the variation in emf with changes in velocity at a fixed concentration of SO_2 at the parts per million level was always 55 mV/decade of flow rate in all the cells studied independent of the surface area or volume of the salt melt in the electrode.

The value of 55 mV/decade of flow rate is interpreted to mean that the SO_3 concentration changes by a factor of 3.7 (Eq. [3]) when the flow rate is varied by a factor of 10. These results indicate that the partial pressure of SO_3 in the gas passing over the salt is approximately proportional to the inverse square root of the flow rate. The exact value observed is 0.57 which is obtained by dividing the slope of Fig. 5, *i.e.*, 55 mV/decade by the value of 97 mV/decade obtained from Eq. [3]. This inverse proportionality between the partial pressure of SO_3 and the square root of the flow rate is expected under laminar flow conditions where the rate of conversion is controlled by diffusion through a gas film at the platinum surface. This result suggests a technique of obtaining controlled or proportioned concentration of SO_3 at low levels for experimental applications connected with atmospheric pollution monitoring.

The results reported in this study demonstrate the performance of the SO_3, O_2, platinum/SO_4^{-2} electrode at sub ppm levels of SO_3 and show that this cell has promise as a practical device for detecting SO_3, SO_2, H_2SO_4, and perhaps decomposable sulfate salts in air. This possibility warrants some brief further discussion. It appears that the basic response of the cell is to SO_3; however, it is clear from this work that the cell can be used to quantitatively measure the concentration of SO_2 in an air stream. Measurement of SO_2 concentrations in air can be accomplished under the following conditions:

1. The air passed through the working electrode initially contains no SO_3.
2. The reference electrode contains a fixed and known concentration of SO_2 at approximately the level being measured in the working electrode.
3. The working and reference electrodes are matched, *i.e.*, the fraction of SO_2 converted to SO_3 in the two electrodes is the same and small. Under these conditions the cell emf is a direct quantitative measure of the concentration of SO_2 in the air stream.

These conditions appear to have been achieved in the experimental cells studied. Further, we have showed that when platinum is inserted into a quartz inlet line of a cell (hot zone) the potential changes to a level which indicates approximately an order of magnitude increase in the concentration of SO_3. The emf returns to the original value when the platinum is removed. Similarly, these cells show a velocity dependence at a fixed concentration of SO_2. This is due to the higher degree of conversion of SO_2 to SO_3 at the lower flow rates. Thus, the gas stream passing through the cell is not at equilibrium with respect to the ratio of SO_2/SO_3 at the flow rates studied. At the operating temperature of the cell (700°C) the equilibrium SO_2/SO_3 ratio calculated from thermodynamic data is approximately unity (8).

Where some uncertainty lies is in adopting this method to quantitatively measure the concentration of SO_3 in an air stream, especially when the stream con-

tains comparable levels of SO_2 and SO_3. However, even in this case, where a significant amount of SO_2 is present, it appears possible to design a cell to limit or minimize the degree of conversion of SO_2 to SO_3. Very preliminary work suggests that the interference ratio of SO_2/SO_3 could be reduced to perhaps 100:1, *i.e.*, a unit amount of SO_2 gives a signal equivalent to 1/100 times the same concentration of SO_3. Assuming this is accomplished one still must solve the problem of supplying the reference electrode with a fixed and known concentration of SO_3. One could resort to calibration of the working electrode *vs.* some standard reference electrode. However, all these questions deal with the development of a practical device for detecting SO_2 or SO_3. We do recognize that this electrochemical system is basically an oxygen electrode which also responds to oxidizing or reducing impurities if they are present at appreciable concentration levels in an air stream. Further, this cell has been tested only under laboratory conditions and all the possible problem areas relating to the development of monitoring devices have not been defined. However, the cell has some very attractive features, foremost being its simplicity and the fact that it can have its own built-in standard, *i.e.*, a reference electrode containing a known level of SO_3.

Acknowledgment

This is to acknowledge the significant contribution of Andrew M. Davis to this work. Mr. Davis did the initial exploratory experimental work which led eventually to the development of the final cell arrangement and gas supply system. Also, our thanks to Dr. H. S. Isaacs for the many useful discussions and suggestions made in the course of this work. This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript submitted Jan. 14, 1972; revised manuscript received May 26, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

ABSTRACT

Corrosion fatigue of copper and alpha-brass of nominal composition Cu:29Zn has been investigated in near neutral aqueous electrolytes using a rotating bend test fatigue machine. The electrolytes employed were pre-oxygenated solutions of ammoniacal copper sulfate for both copper and alpha-brass specimens, and pre-oxygenated solutions of sodium chloride and copper sulfate for copper specimens. All electrolytes reduced the fatigue life relative to a reference environment of preoxygenated double distilled water, and electron diffraction studies of undisturbed fatigue fracture surfaces revealed the presence of cuprous oxide. Accordingly, the mechanism of corrosion fatigue was believed to be generally consistent with a model based on enhanced localized electrochemical dissolution at the tip of the fatigue crack due to the formation and rupture of cuprous oxide films in a manner similar to that proposed for tarnish rupture theories of stress-corrosion cracking. The oxide was considered to form by a deposition process and supplementary studies on concentration cells arising from turbulence effects, differences in oxygen concentration, and differences in pH allowed discussion of the possible anodic and cathodic reactions.

It is well known from the review articles by Gough (1), Gilbert (2), and Evans (3) that the failure lifetime of both pure metals and alloys tested under cyclic loading conditions of fatigue is affected markedly by the environment. Even a test conducted under such apparently innocuous conditions as exposure to the normal atmosphere yields a shorter lifetime than tests conducted under vacuum (4, 5); for example, Wadsworth (6) has shown that an air pressure of 10^{-5} mm Hg may increase the fatigue life of copper by a factor of 20. Furthermore, the fact that both pure metals and alloys are noticeably prone to premature failure under corrosion fatigue conditions in a variety of environments is in marked contrast to the static tensile loading situation of stress-corrosion cracking (SCC) where pure metals are not normally susceptible and environments are usually specific (3, 7). The only reasonably documented situation in which SCC of a pure metal has been reported is contained in the work of Pugh and his colleagues (8, 9) on the SCC of copper in concentrated ammonia solutions containing dissolved copper.

In spite of the considerable published work on corrosion fatigue, most studies have been phenomenological in nature and no well established mechanism incorporating the effect of environment has emerged. It is believed that electrochemistry plays a role during fatigue crack propagation in aqueous environments

Key words: electron diffraction, fatigue, corrosion, tarnish, copper, brass.

because cathodic protection and corrosion inhibitors often reduce damage (3, 10). Furthermore, the damaging species in atmospheric environments appears to be oxygen (1, 2). The oxidation characteristics of the metal appear to have an important bearing on the matter because Wadsworth (6) has shown that oxygen affected the corrosion fatigue life of aluminum, iron and copper but not gold. Also, water was as effective as oxygen on aluminum but without effect on copper. However, when considering the conjoint presence of water and oxygen Gough and Sopwith (11) found they exerted a catalytic effect on fatigue cracking of copper and its alloys. In view of these observations, speculation on the mechanism of corrosion-fatigue cracking has included proposals that failure in atmospheric environments may involve adsorption of oxygen and/or water molecules on the surface of the fatigue crack which may lower the surface energy (10) and/or prevent rewelding of crack surfaces on successive portions of the fatigue cycle (5, 10, 12). Avery and Backofen (13) have proposed a "slip ratchet" mechanism for crack formation based on oxide formation at freshly exposed slip steps preventing slip reversal on the same slip plane. Other proposals, which relate to aqueous environments, include enhanced electrochemical dissolution at the crack tip because of (*i*) "disarrayed metal" at the bare crack tip (3), and (*ii*) as a result of oxygen concentration cells set up at the crack (2,10)—particularly in neutral or near neutral electrolytes (2).

The purpose of the present study was to conduct corrosion fatigue tests on alpha-brass (Cu:29.38Zn) and copper of 99.99% purity in near neutral aqueous ammoniacal environments known to produce SCC in alpha-brass, but not copper, and then to compare corrosion fatigue of the copper in near neutral nonammoniacal environments. In this manner, it was hoped to determine whether or not there are any possible mechanistic similarities between corrosion fatigue and SCC of alpha-brass and then to determine if any such similarities are applicable to corrosion fatigue of copper, bearing in mind that SCC of copper has not been reported in the environments studied.

Experimental Procedure

Materials.—The alpha-brass and copper were received in the form of hard drawn bar of 0.375 in. diameter. The brass was from the same batch as that used in a previous study (14) and chemical analysis established the composition in terms of weight percentages as 70.47% Cu, 29.38% Zn, with total impurities $<0.15\%$. The copper was obtained from Koch Light with a reported purity of 99.99%.

The ammoniacal solutions employed for the experimental studies were of the general type used by Mattsson (15). However, whereas Mattsson's solutions contained 0.05M Cu and a total of 1M NH_3, the present solutions were of the composition used by Johnson and Leja (16) containing 0.04M Cu and 3M NH_3. The preparation procedures of Johnson and Leja were rigidly followed in order to eliminate the aging and precipitation phenomena observed by Mattsson (15). All solutions were made from double distilled water which was subsequently boiled to remove CO_2 and then oxygenated immediately prior to preparation of the solutions. Required Cu and NH_3 values were obtained by preparing solutions containing 0.04M $CuSO_4$ and 1.5M $(NH_4)_2SO_4$. Near neutral *p*H values were investigated ranging from *p*H 4.4 to *p*H 8.0 for Cu and *p*H 5.5 to *p*H 8.0 for the brass. The *p*H values were adjusted by additions of 2*N* NH_4OH and measured to an accuracy of ± 0.05 *p*H units with a Corning Model 10 *p*H meter.

Nonammoniacal solutions employed were 0.04M $CuSO_4$ (*p*H = 4.7) and 2M NaCl (*p*H = 5.0) prepared from double distilled and pre-oxygenated water. The reference environment was double distilled and pre-oxygenated water.

Specimens and testing.—The fatigue specimens were of cylindrical form machined with a reduced, but curved, gauge section as shown in Fig. 1a. The curved gauge section eliminated notch effects and ensured a maximum bending fatigue stress at the midpoint of the gauge section corresponding to a minimum diameter of 0.25 in. The specimens were polycrystalline with a grain size of ~0.001 in. and were tested in the annealed condition (550°C for 1 hr). The surfaces were cleaned in 40% aqueous HNO_3 following the heat-treatment. Fatigue testing was conducted on a rotating beam fatigue machine operating at 1700 rpm. The aqueous environment was contained in a tygon tubing cell surrounding the specimen and was introduced into the cell through a hypodermic needle placed between the specimen and tubing so as to completely fill the cell with liquid and eliminate air. The cell is shown schematically in Fig. 1b. All tests were conducted at 20°C utilizing a maximum bend stress of 30,000 psi for the alpha-brass and 21,000 psi for the copper.

The fatigue life was defined as the number of fatigue cycles to complete fracture and all values reported in the text are based on the mean average of three identical tests for the alpha-brass, and two identical tests for the copper.

Concentration cells.—Supplementary concentration cell experiments were conducted with pairs of copper and pairs of alpha-brass electrodes immersed in the various aqueous environments. Each electrode in a pair was immersed in the environment in one compartment of a two-compartment cell, the compartments being separated by a porous partition similar to the cells described by Evans (3). Potential differences between the two electrodes were measured with a Heathkit potentiometric recorder.

Three types of concentration cell were employed: (*i*) Turbulence-type concentration cell produced simply by bubbling inert nitrogen through one compartment only. The turbulence transported reactant species to, or, product species from the electrode thereby generating a possible moto-electric effect (3). (*ii*) Oxygen concentration cell produced by bubbling oxygen through one compartment while bubbling nitrogen through the second compartment. Equalized conjoint flow rates of oxygen and nitrogen were maintained in order to minimize interference from moto-electric effects. (*iii*) *p*H concentration cell produced by creating a *p*H difference between the two compartments.

Electron diffraction studies.—Corrosion products present on actual undisturbed fatigue-fracture surfaces were identified by electron diffraction studies conducted at 100 kV. The studies were performed in the high

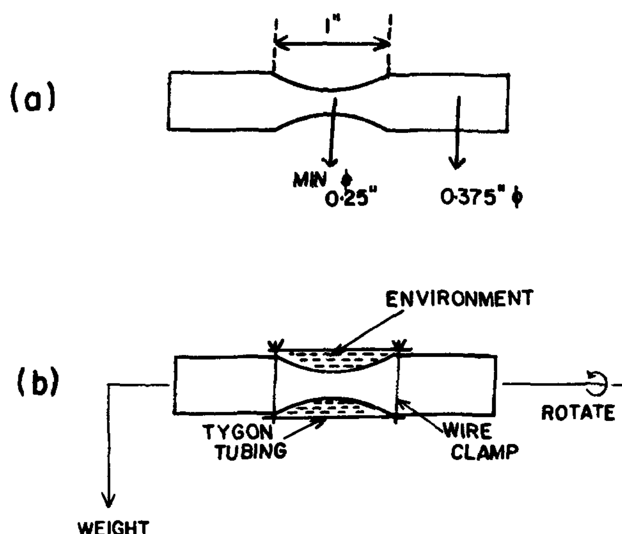

Fig. 1 (a). Dimensions of copper and alpha-brass fatigue specimens. (b). Schematic diagram of corrosion fatigue cell.

resolution diffraction accessory of a Hitachi HU11A electron microscope in which the macroscopic plane of the surface of interest was placed parallel to the incident electron beam and electron diffraction ring patterns obtained by transmission through protuberances on the surface. It was possible to locate the position of the electron beam on the surface of interest by observing the specimen through a port in the diffraction chamber. Wherever the beam was incident upon a protuberance an electron induced light emission effect was visible, the phenomenon being known as cathodoluminescence (17-19). Consequently, it was possible to ensure that diffraction patterns from the fatigue portion of the fracture surface, and not the final overload fracture portion, were studied.

The diameter of the electron beam was maintained at ~0.01 in., which was ten times larger than the grain size of the polycrystalline specimens. This enabled polycrystalline ring patterns to be produced from the copper matrix and alpha-brass matrix adjacent to fracture surfaces when either no corrosion products, or, only traces of corrosion products were present on the fatigue-fracture surfaces.

Phases present on actual surfaces were determined by comparing the observed interplanar spacings with those reported in the literature (20), and by comparing visual estimates of the intensities of electron diffraction rings with theoretical estimates of the integrated intensities (14). The procedural details of the technique have been discussed elsewhere (14).

Fractography.—Conventional two-stage replica electron microscopy was used to observe fractographic detail of fatigue fracture surfaces. It was hoped to quantitatively relate the spacing of fatigue striations on the fracture surface with the effect of environment on fatigue life. Unfortunately, although such striations were observed in all environments and appeared to increase in spacing with decreasing fatigue life, quantitative measurements were obscured by slip lines on the striations due to the magnitude of the fatigue amplitude employed (21).

Observations and Discussion

Fatigue life.—The alpha-brass exhibited a reduced fatigue life in the range of ammoniacal solutions employed as compared to the life in water. The actual relationship between life and pH of ammoniacal environment gave a U-shaped curve whereby the fatigue life was reduced by a maximum factor of ~7.5 at pH 6.8, and by a factor of ~2 at pH values 5.5 and 8.0, as evidenced in Fig. 2. Such a U-shaped type of relationship is commonly observed for SCC lifetimes (*i.e.*, time to fracture) in these types of solutions within the same pH range (15, 16, 22) and, furthermore, the minimum SCC life occurs at the same general value of pH ~6.8 as that for minimum fatigue life.

The copper also exhibited a reduced fatigue life in all of the ammoniacal environments employed, as compared to water, and exhibited a very slight tendency toward minimum lifetimes in the pH range 5.5-6.8, as shown in Fig. 3. However, the dependence of life upon pH was not as pronounced as that of alpha-brass, being reduced by a maximum factor of only ~2.5 within the pH region 5.5-6.8, and by a factor of ~2 in pH regions of 4.4 and 8.0. Furthermore, it appeared that ammoniacal complexes were not specifically necessary for the reduced fatigue life of copper because near neutral solutions of 0.04M $CuSO_4$ (pH 4.7) and 2M NaCl (pH 5.0) gave lifetimes more or less identical to ammoniacal solutions of similar pH, as depicted in Fig. 4.

Fatigue crack path.—Optical studies of fatigue tested and sectioned specimens revealed that the fatigue-crack path was similar in both copper and alpha-brass in all environments employed. There was no specific

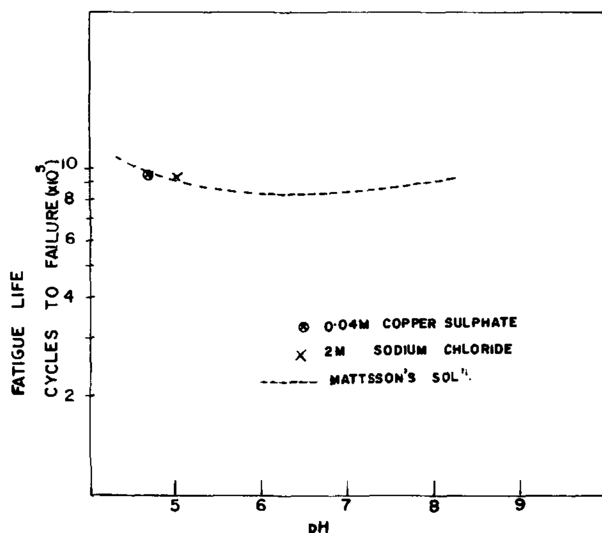

Fig. 4. Comparison of fatigue life of copper in 0.04M $CuSO_4$ and 2M NaCl solutions relative to life of copper in Mattsson's type ammoniacal copper sulfate solution [0.04M $CuSO_4$ + 1.5M $(NH_4)_2$ SO_4]. Fatigue life plotted on log scale.

dependence of crack path upon environment. The crack followed a mixed transgranular and intergranular path approximately normal to the tensile stress components. These observations were important insofar as they precluded the possibility of the marked reduction in fatigue life of alpha-brass in the ammoniacal solution of *p*H 6.8 being associated with preferential intergranular corrosion. Such preferential corrosion has been reported by some workers on unstressed alpha-brass specimens exposed to near neutral ammoniacal environments of different composition from the present studies (8, 23). (It may also be noted that prolonged immersion of annealed and unstressed alpha-brass in the ammoniacal environment of *p*H 6.8 used in the present study failed to reveal any preferential penetration.)

Diffraction studies of fatigue fractures.—In view of the similar dependence of both fatigue life and SCC life of alpha-brass upon the *p*H of the ammoniacal environment it appeared that electron diffraction experiments might reveal other similarities regarding corrosion films on fracture surfaces. Previous electron diffraction work (14) on alpha-brass obtained from the same batch as that used in the present studies has shown that Cu_2O is present on SCC fracture surfaces produced in identical ammoniacal copper sulfate solutions of similar *p*H range (5.9-8.0) to those employed in the present work. Consequently, electron diffraction studies were conducted on fatigue-fracture surfaces of alpha-brass and revealed reflections consistent with the presence of Cu_2O in the *p*H range investigated (5.5-8.0). The details for the specific case of *p*H 6.8, where fatigue cracking is most rapid, are shown in Table I. [*N.B.* At this point it is pertinent to note that Mattsson (15) also observed corrosion films on the original surfaces of alpha-brass specimens subjected to SCC in ammoniacal copper sulfate solutions. However, it is not possible to completely correlate his corrosion films with those observed on fracture surfaces in the present studies due to four basic reasons: (*i*) The majority of his corrosion film analyses were based on visual observations, *e.g.*, "interference colors" in the *p*H range 5.5-5.7 and "a thin grey deposit" at *p*H 7.7, and it is known that the color of Cu_2O is dependent on a number of conditions (14, 24); (*ii*) Mattsson employed an unspecified "microscopic examination" to detect the presence of Cu_2O in the "black coatings" formed in the *p*H range 6.3-7.3; (*iii*) Mattsson's observations were not conducted on the actual fracture surfaces and the environment inside a SCC or fatigue crack may be different from that in the bulk solution; (*iv*) Mattsson's alpha-brass and ammoniacal copper sulfate solutions were of different composition to those employed in the present study and his solutions were subject to aging and precipitation phenomena.]

The electron diffraction techniques were applied to the copper specimens fatigued in the ammoniacal environments and revealed that all fatigue fracture surfaces contained Cu_2O. The details for the specific situation of *p*H 5.5 in the region of minimum fatigue life are given in Table I. Furthermore, electron diffraction studies of fatigue fracture surfaces of copper obtained in 2M NaCl and 0.04M $CuSO_4$ environment were also consistent with the presence of Cu_2O as shown in Table I. In addition, the presence of Cu_2O on fracture surfaces in the copper sulfate environment is reasonably consistent with the observations of Miller and Lawless (25) who used electron diffraction techniques to confirm the formation of Cu_2O films on the surfaces of unstressed copper single crystals immersed in a stronger solution of pre-oxygenated copper sulfate (0.2M $CuSO_4$, *p*H 3.8).

Electron diffraction studies were also conducted on the fatigue-fracture surfaces of copper and alpha-brass produced in the reference environment of pre-oxygenated double distilled water. Comparison of the interplanar spacings of the rings and their visual intensities with data for Cu_2O, copper, and alpha-brass (14, 20, 26) revealed a predominance of the copper matrix and alpha-brass matrix at the fracture surfaces, as shown in Table II. The presence of Cu_2O could be detected only in trace amounts, as evidenced by the weak oxide reflections in Table II.

Thus, two important observations arose from the electron diffraction studies. First, all environments except the reference environment produced well-formed films of Cu_2O on the fatigue-fracture surfaces, whereas the more slowly fatigue-cracking situation in the reference environment produced only traces of Cu_2O on the fracture surface. Second, the studies confirmed a further similarity between SCC of alpha-brass and corrosion fatigue of copper and alpha-brass in that all fracture surfaces contained Cu_2O.

Formation of Cu_2O and electrode reactions.—The detection of Cu_2O on the corrosion-fatigue fracture surfaces necessitated a consideration of its mechanism of formation because of the possible influence of the oxide on the corrosion fatigue behavior. For example, if corrosion fatigue involved electrochemical dissolution of the metal the formation of Cu_2O on the fracture surface would serve three purposes: (*i*) prevent further dissolution of the sides of the crack, (*ii*) localize dissolution to the crack tip which is the only point at which the Cu_2O product is readily parted by the deformation processes to expose fresh metal, and (*iii*) the Cu_2O film is an electronic semiconductor (27, 28) and

would not eliminate the electrochemical dissolution process by electronically insulating the Cu_2O covered cathodic surface. In its general terms, such a role for Cu_2O would be similar to the tarnish rupture models for SCC of alpha-brass in ammoniacal solutions first proposed by Forty and Humble (29) and developed later by McEvily and Bond (30) and the present authors (14).

It is generally believed that formation of Cu_2O in aqueous environments has its origins in electrochemical behavior. However, at the present time the specific reactions involved have not been established, as evidenced by the reviews of Pugh (8, 31). Recent studies by Green *et al.* (32) and the present authors (33) suggest that the oxide is formed by a precipitation process. Consequently, it is probable that Cu_2O precipitation involves a local increase in cuprous ion species and/or hydroxyl ions such that the solubility product of Cu_2O is exceeded. The reaction may be expressed in the general form

$$2Cu^+ + 2OH' \rightarrow Cu_2O + H_2O \quad [1]$$

where Cu^+ may represent a complex ion containing ligands. Such a general reaction has been considered in the literature by previous workers (14, 31, 34).

The local concentration of cuprous ions may be controlled by anodic dissolution of copper atoms to yield cuprous ion species and/or the cathodic reduction of cupric ion species. The hydroxyl ion concentration will be controlled by *p*H and the cathodic reduction of dissolved oxygen. Furthermore, the actual precipitation reaction may occur directly on the electrode surfaces via the interaction of hydroxyl ions with adsorbed cuprous ion species, as suggested by Pugh (31). The concentration cell studies were designed to provide further information on the possible electrode reactions.

Turbulence-type concentration cell.—In all environments turbulence arising from the bubbling of inert nitrogen through one compartment of the two compartment cell, or by stirring the environment in one compartment, always caused the copper or alpha-brass electrode in the turbulent environment to be anodic with respect to the corresponding copper or alpha-brass electrode in the static environment. Potential differences of 5-15 mV were recorded on open circuit. These observations indicated that the electrochemical reactions were under anodic control and governed by removal of product species from the anode (*e.g.*, corrosion films) or diffusion of reactant species to the anode.

The observations were interesting because Bertocci (35) developed an electrochemical model for dissolution of brass in ammoniacal solutions which was under cathodic polarization concentration control. According to this model the anodic process involves dissolution of copper and zinc to form complex ionic species, *e.g.*

$$Cu + 2NH_3 = Cu(NH_3)_2{}^+ + e' \quad [2]$$

$$Zn + 4NH_3 = Zn(NH_3)_4{}^{++} + 2e' \quad [3]$$

The diffusion controlled cathodic process was considered to be the reduction of cupric ion complexes. The general form of the reaction may be written

$$Cu(NH_3)_n{}^{++} + e' = Cu(NH_3)_2{}^+ + (n-2)NH_3 \quad [4]$$

where n = number of NH_3 ligands.

Bertocci's model was developed for dissolution in the absence of corrosion film formation and recent work by Pugh and Green (36) supports the model under these conditions. However, the present electron diffraction studies have shown that Cu_2O films were formed in the specific environments currently employed. Consequently, the availability of anodic sites for dissolution will be governed by the availability of film-free surface whereas the cathodic reaction (Eq. [4]) is able to occur on film-free or Cu_2O-covered surfaces because Cu_2O has electronic conducting properties (27, 28) and may be an effective cathodic surface (37). In addition, the Cu_2O film is believed to be porous (14, 29, 32) and the anodic reaction may be further affected by the necessity for reactant species (*e.g.*, NH_3) to diffuse through the pores in order to interact with the film-free surface. Hence, under conditions where Cu_2O films are formed, it is reasonable to anticipate that cathodic polarization concentration may not be the controlling process even though the anodic and cathodic reactions are the same as in Bertocci's model.

Oxygen concentration cell.—The conjoint equalized flow of nitrogen and oxygen through separate compartments of the two-compartment cell showed that in both the distilled water environment and 2M NaCl solution (*p*H = 5.0) the electrode in the oxygen-rich solution was always cathodic with respect to the electrode in the oxygen-poor solution. The observations held for pairs of copper electrodes and pairs of alpha-brass electrodes, the open-circuit potential differences being 20-30 mV. Thus, in these environments the principal cathodic reaction appeared to be the reduction of dissolved oxygen, *e.g.*

$$O + H_2O + 2e' = 2\,OH' \quad [5]$$

Such a reaction is consistent with the observations that natural corrosion of copper is promoted by differ-

ential aeration cells (10) and that the main cathodic reaction on most metals in near neutral electrolytes containing dissolved oxygen is the oxygen reduction reaction (2, 3).

Closed-circuiting of the electrodes in the 2M NaCl solution yielded a current of ~0.5 mA with a consequent increase in pH of the cathodic compartment after a few hours. The pH change was readily observed visually by adding phenolphthalein indicator to the solution which caused the oxygen-rich electrolyte in the cathodic compartment to turn red as the hydroxyl ion concentration increased.

Closed circuiting of the electrodes in the double distilled water environment yielded a negligible current consistent with the very low electrical conductivity of such water.

Similar oxygen concentration cell experiments in the 0.04M $CuSO_4$ solution (pH 4.7) and the ammoniacal copper sulfate solutions in the pH range 5.5-7.5 for alpha-brass and 4.4-7.5 for the copper showed the electrode in the oxygen-rich solution to be only slightly cathodic. Open-circuit potential differences were ~5 mV suggesting that the reduction of oxygen was not an important cathodic reaction in these solutions. Hence, it is probable that the reduction of cupric ion species is the principal cathodic corrosion reaction in these environments.

Raising the pH of the ammoniacal copper sulfate solutions to 8.0 produced marked cathodic behavior of the copper and brass electrodes in the oxygen-rich compartments. Open-circuit potentials of ~70 mV were recorded. Such behavior is consistent with the studies of Johnson and Leja (16) who observed that SCC of alpha-brass in these solutions was influenced by dissolved oxygen only at pH values >8.0. Thus, oxygen reduction (Eq. [5]) may be a major cathodic reaction in this particular solution.

The preference for oxygen reduction over the cathodic reduction of cupric complexes (Eq. [4]) in copper ammoniacal solutions of pH ~8.0 may be related to the average number of ammonia ligands, n, attached to the cupric complex ion, $Cu(NH_3)_n^{++}$. Johnson and Leja (16) have shown that in these solutions $n = 1$ at pH $\simeq 5.6$, $n = 2$ at pH $\simeq 6.3$, $n = 3$ at pH $\simeq 7.0$, and $n = 4$ at pH $\simeq 8.0$. Thus, at pH 8.0 where $n = 4$, the rate of reduction of $Cu(NH_3)_4^{++}$ may be slow due to the steric effects of four NH_3 ligands at the cathode. For example, the following reduction reaction for $n = 4$

$$Cu(NH_3)_4^{++} + e' = Cu(NH_3)_2^{+} + 2NH_3 \quad [6]$$

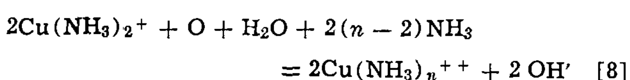
involves a change in the number of NH_3 ligands between cupric and cuprous species. However, when $n = 2$ at pH $\simeq 6.3$ the following reduction reaction

$$Cu(NH_3)_2^{++} + e' = Cu(NH_3)_2^{+} \quad [7]$$

does not involve a change in number of NH_3 ligands and may be a favored reaction (16).

The $Cu(NH_3)_2^+$ complex with two NH_3 ligands was chosen as the product of the reduction reaction because it appears to be the equilibrium complex of dissolved cuprous species in the general pH range studied, as evidenced by published pH-potential diagrams for the homogeneous system with dissolved copper (15, 38).

Alternatively, dissolved oxygen may not be directly involved in the cathodic reduction reaction at pH 8.0 in the ammoniacal copper sulfate solution. Instead, it may act indirectly by oxidizing cuprous species to the cupric state thereby increasing the concentration of cupric ions available for reduction at the cathode. Such a role for oxygen has been considered by Bertocci (35), and Pugh and Green (31, 36) and may be represented in a general form by Eq. [8]



$$2Cu(NH_3)_2^+ + O + H_2O + 2(n-2)NH_3 = 2Cu(NH_3)_n^{++} + 2\,OH' \quad [8]$$

In this situation, the effect of pH would appear to lie in creating sufficient NH_3 to allow favorable conditions for formation of the tetrammine cupric complex, $Cu(NH_3)_4^{++}$, because oxygen concentration effects only became markedly noticeable at pH 8.0 where the number of NH_3 ligands, n, approached 4 (16). The importance of $n = 4$ and the relative rapidity with which the reaction depicted by Eq. [8] is expected to proceed is undoubtedly related to the fact that cupric ions form four strongly bonded unidentate ligands in aqueous solutions (39, 40). In the present solutions these ligands may be H_2O and/or NH_3 groups, although in practice the number of H_2O ligands is usually omitted in equations. However, the NH_3 ligand is more strongly bonded than the H_2O ligand (39, 40) and if the pH is high enough, sufficient NH_3 will be available to allow formation of four very strong NH_3 ligands. Thus, it is postulated that the reaction depicted by Eq. [8] proceeds rapidly only when the number of NH_3 ligands on the cupric ion is increased to $n = 4$.

pH cells. —Studies on pH cells were confined to the ammoniacal copper sulfate solutions in the pH range 5.5-8.0. It was observed that the compartment containing high pH solution was anodic with respect to the electrode in the compartment containing low pH solution. The results are summarized in Table III where open-circuit potentials in excess of 100 mV were observed.

Increasing the pH (*i.e.*, lowering $[H^+]$ concentration) displaces the ammonium dissociation reaction

$$NH_4^+ \rightleftharpoons NH_3 + H^+ \quad [9]$$

to the right and increases the concentration of $[NH_3]$ species. Thus, if the anodic process involves dissolution of metal via the formation of complex ion species with ammonia ligands (*e.g.*, Eq. [2] and [3]), the availability of ammonia molecules may dictate the dissolution rate and render the process under anodic control. Under these conditions, the high pH environment will be anodic with respect to the low pH environment, as observed.

Proposed events within the corrosion-fatigue crack. —The fatigue cycle itself is capable of generating a crack in ductile metals purely by plastic deformation processes (5, 41), each cycle leading to an increment of crack advance during the propagation stage. Thus, in principle, any environment which is able to promote dissolution of the metal should, if given sufficient time depending upon frequency of fatigue cycle (4), contribute an increment of crack advance via dissolution during each cycle and reduce the fatigue life. It is not necessary for the environment to produce a crack under static load conditions (*i.e.*, SCC). Naturally, if factors are present which localize dissolution to the tip of the crack, and not the sides of the crack, the environment will be more effective in reducing the fatigue life. Consequently, the present studies suggest that the basic effect of the aqueous solutions employed for corrosion fatigue of both copper and alpha-brass is to provide an electronically conducting film of Cu_2O which localizes anodic dissolution processes to the tip of the fatigue crack, this being the only point at which the film is readily parted by the localized deformation processes. Such a Cu_2O film was detected by the electron diffraction studies, and its presence also appears to be in reasonable agreement with published thermo-

Table III. pH Concentration cell potentials in aqueous 0.04M $CuSO_4$ + 1.5M $(NH_4)_2SO_4$ solutions

pH of solution		Open-circuit potential difference (mV)	
Anode	Cathode	Alpha-brass electrodes	Copper electrodes
6.8	5.5	37	12
8.0	6.8	150	125
8.0	5.5	185	135

dynamic considerations (15, 38, 42, 43). Thus, the model for corrosion fatigue contains the elements of the tarnish rupture and parting models developed for SCC of alpha-brass (14, 29, 30).

The anodic reaction on copper sites appears to be the dissolution of copper atoms to form dissolved cuprous ionic species. The principal cathodic reaction in the solutions containing dissolved cupric ion species (*i.e.*, Mattsson-type solution and 0.04M $CuSO_4$) appears to be the reduction of cupric species to cuprous species. In the absence of dissolved cupric species (*i.e.*, 2M NaCl and double-distilled water), the cathodic reaction is the reduction of dissolved oxygen. The cuprous oxide forms by deposition when the concentration of cuprous species and hydroxyl ions is such that the solubility product of Cu_2O is exceeded (Eq. [1]). Deposition of Cu_2O is expected to be governed by the availability and mobility of cuprous species because hydroxyl ions have a high mobility due to proton jumps (44) and are readily available from the dissociation of water.

The actual rate of anodic dissolution of fresh exposed metal atoms at breaks in the Cu_2O film at the tip of the fatigue crack is strongly affected by the environment. Thus, in the double-distilled water environment, where the cathodic reaction is reduction of oxygen, the high ohmic resistance of the electrolyte severely restricts the length of crack over which oxygen concentration cells will be effective and this environment should yield the longest lifetimes, as observed in Fig. 2 and 3.

Regarding copper in the ammoniacal copper sulfate solutions, the anodic dissolution of copper to form cuprous species is enhanced by the presence of NH_3 groups which form a cuprous complex with two strongly bonded unidentate NH_3 ligands (40) ($Cu(NH_3)_2{}^+$). Hence, with reference to Fig. 3, increasing the pH from 4.4 to 6.8 increases the concentration of $[NH_3]$ (Eq. [9]) and should produce a tendency for enhanced anodic dissolution of copper and a reduction in fatigue lifetime, as observed. Further increases in pH to 8.0 should continue to yield enhanced anodic dissolution of copper. However, if the physical nature of the Cu_2O film in this pH range is such that it is not fully protective and contains breaks at points other than the tip of the fatigue crack, the enhanced dissolution will not be confined to the tip of the crack and will not fully contribute to a further reduction in fatigue life. If the breaks are sufficiently numerous the fatigue life may actually increase, as observed.

The same general considerations discussed for copper are also expected to apply to corrosion fatigue of the alpha-brass in ammoniacal copper sulfate solutions (Fig. 2). However, the effect of pH may be more dramatic because of the presence of zinc atoms. For example, below pH $\sim$ 6.8 the zinc enters the solutions as Zn^{++} ions with no ammonia ligands (38, 42). Hence, with reference to Fig. 2, increasing the pH from 5.5 to 6.8 increases the concentration of $[NH_3]$ available to enhance the anodic dissolution of copper atoms and, because the alloy contains only $\sim$70% copper, there is effectively more $[NH_3]$ available to assist dissolution than for pure copper at the same pH. This, together with the influence of the high thermodynamic activity of zinc on the dissolution kinetics suggested by Green *et al.* (32) could account for the marked reduction in fatigue life at pH $\sim$ 6.8.

Other factors which undoubtedly complicate the quantitative aspects of the corrosion fatigue lifetimes are variations in environment and alloy composition which affect the semiconducting properties of the Cu_2O film and modify its ability to function as an effective cathode and localize the anodic reaction. It is well known (27, 45) that the conductivity of cuprous oxide depends upon deviations from stoichiometry which affect the cuprous ion, cupric ion, and oxygen ion concentrations in the semiconductor. The effect of oxygen partial pressure on the stoichiometry of Cu_2O has been much studied (27, 45), but apparently there is no information in the literature regarding the effect of aqueous environment variables (*e.g.*, pH) on conductivity of precipitated Cu_2O. Furthermore, there appears to be no published studies on the effect of trace quantities of divalent zinc ions, Zn^{++}, in the Cu_2O lattice on the conductivity of Cu_2O (28). Some preliminary studies on the effect of trace additions of divalent Be^{++} on the conductivity of Cu_2O have been reported (46), but they do not illuminate the present work.

Conclusions

Studies on the corrosion fatigue of copper and alpha-brass in near neutral aqueous solutions of pre-oxygenated ammoniacal copper sulfate (0.04M $CuSO_4$ + 1.5M $(NH_4)_2SO_4$), and of copper in pre-oxygenated aqueous solutions of both sodium chloride (2M NaCl) and copper sulfate (0.04M $CuSO_4$), were consistent with the following conclusions:

1. All environments yielded a reduced fatigue lifetime relative to a reference environment of pre-oxygenated double-distilled water.
2. All fatigue fracture surfaces contained a cuprous oxide corrosion film.
3. The cuprous oxide film localized the anodic dissolution of metal atoms to the tip of the fatigue crack where the film was readily parted by deformation processes. Thus, the general elements of tarnish formation and rupture models developed to explain SCC of alpha-brass were applicable to corrosion fatigue of both copper and alpha-brass.
4. The major cathodic reduction reaction was the reduction of cupric ion species in the environments containing dissolved copper, and reduction of oxygen in the absence of dissolved copper.

Hydrogen Evolution Reaction at Sodium Tungsten Bronzes in Acid Solutions

D. B. Šepa, D. S. Ovcin, and M. V. Vojnović

Institute for Chemistry, Technology and Metallurgy, 11000 Belgrade, Yugoslavia

ABSTRACT

Hydrogen evolution reaction in acid solutions ($-0.7 < pH < 2.0$) at sodium tungsten bronze electrodes of various compositions ($0.45 < x < 0.83$) have been investigated using the galvanostatic steady-state method. The mechanism of the hydrogen evolution reaction has been proposed. A weak electrocatalytic effect dependent on the bronze composition has been found.

Only a few data concerning the hydrogen evolution reaction (HER) in acid solutions at sodium tungsten bronzes, Na_xWO_3, are available in the literature (1-4). The hydrogen dissolution reaction has been studied at some transition metal tungsten bronzes (5), at hydrogen tungsten bronzes (6, 7), and at sodium tungsten bronzes (the term bronze is used to refer to the latter for brevity) (8). The available information, however, is insufficient to present a full picture of the kinetics of the HER in this system.

It is the purpose of this paper to make a contribution to better understanding of the HER at the bronzes in acid solutions.

Experimental

Ten large crystals of the bronzes (approximately 15 × 15 × 15 mm) of compositions $0.45 < x < 0.83$ were grown on gold wire by the electrolytic reduction of a molten mixture of reagent grade sodium tungstate and tungsten trioxide in an alumina crucible (9). Plates about 1 mm thick were cut from these crystals, polished on the finest emery paper, and then washed in 1*N* NaOH solution and hot distilled water. Finally, the plates were mounted in an appropriate Teflon holder.

An all-glass three-compartment cell was used. The HER was studied in sulfuric acid solutions of various pH values ($-0.7 < pH < 2.0$), while purified hydrogen was bubbled through the solution. Measurements of cathodic Tafel lines were carried out using the galvanostatic steady-state method. Potentials were measured against the hydrogen electrode in the same solution.

Results

It was found that the reversible potential of the HER is not established at the bronze electrodes in acid solutions saturated with hydrogen. Rest potentials within the range 0.2-0.5V, and usually about 0.3V, were established.[1]

If a bronze electrode is cathodically polarized and care is taken that steady-state conditions of measurements are strictly applied, a complex V-log *i* relationship is obtained, as presented in Fig. 1 (Down and

Key words: sodium tungsten bronze, hydrogen evolution reaction.

[1] Potentials throughout the paper are referred to the scale of the hydrogen electrode in the same solution, unless otherwise stated.

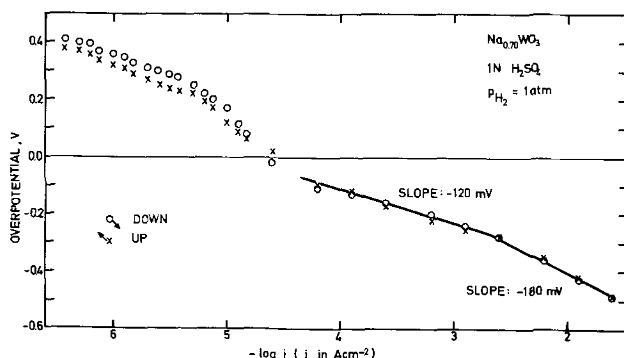

Fig. 1. Typical steady-state cathodic *V*-log *i* relationship

up measurements of this line require about 10 hr.) The following features concerning this *V*-log *i* relationship should be noted:

(*i*) In the range of overpotentials between 0.4 and 0.2V some electrode process occurs, which has been noted also by Vondrak and Balej (3, 4) and by Armstrong *et al.* (8), when they studied the behavior of the bronzes in acid solutions by potential sweep method. It is interesting that Glemser and Neumann (10), who studied hydrogen tungsten bronzes, and Broyde (5), who studied a number of tungsten bronzes of transition metals, also observed an electrode process at overpotentials of about 0.3V.

(*ii*) At lower overpotentials a limiting current, not determined by mass transport from the solution, of approximately (2-5) $\times$ 10^{-5} A-cm^{-2} was observed. The composition of the bronze and the *p*H of the solution showed no effect on the value of this limiting current.

(*iii*) At overpotentials higher than about -0.1V the HER is the predominant electrode process. Two Tafel lines of slopes close to -120 and -180 mV were obtained. At current densities higher than approximately 10^{-3} A-cm^{-2} intensive evolution of hydrogen at the surface of electrodes was observed.

It is interesting to note that quite a different shape of *V*-log *i* relationship is obtained if steady-state measurements are not strictly applied. A typical quasi-steady-state *V*-log *i* relationship, obtained by faster measurements, is presented in Fig. 2. (A line needed about an hour to be measured.) The first down-measured line is rather complex and any linear part cannot be clearly traced. After several repeated up and down measurements in the current density region above approximately (2-5) $\times$ 10^{-5} A-cm^{-2} two linear parts with slopes close to -120 and -180 mV are clearly distinguished, overlapping the line obtained in the steady-state measurements. In the region of lower current densities, however, a qualitatively new picture is obtained. It is possible to get straight lines of slopes varying from -40 to -120 mV, which are usually stretched to more positive potentials than the reversible hydrogen potential. The changes of potential in this region of current densities are very slow. Depending on the speed of recording the potentials, different slopes can be obtained. The quasi-steady-state performance of the electrode in this region of current densities was shown in the following way: after a longer period of time (order of an hour), the potential of an electrode tends to get more positive, approaching slowly the corresponding steady-state value.

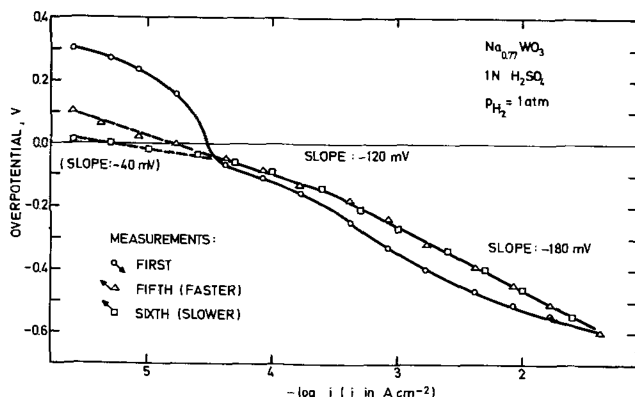

Fig. 2. Various shapes of quasi-steady-state cathodic *V*-log *i* relationships.

The dependence of the kinetics of the HER on the *p*H value of the solution is given in Fig. 3 and 4. Both linear parts of the Tafel lines, with slopes of -120 and -180 mV have the same value of the parameter $\partial V/\partial p$H close to -120 mV per *p*H unit (measured on the *p*H independent scale).

When the Tafel line with the slope of -120 mV is extrapolated to the hydrogen reversible potential, the exchange current density of the HER is obtained. It was found that the rate of the HER, taken as the logarithm of the exchange current density, is slightly dependent on the composition of the bronze electrodes with a maximum value of about 3 $\times$ 10^{-5} A-cm^{-2} in the vicinity of $x = 0.65$, as shown in Fig. 5.

Discussion

A model of the surface of the bronzes in acid solutions has been reported (11, 12) and an explanation of the electrochemical behavior of the surface has been proposed. This model is based on the existence of a nonstoichiometric, hydrated tungsten oxide-like layer at the surface. The rest potential, established at the bronzes in acid solutions, according to this model corresponds to an oxide potential of a metal electrode. Hence, the part of cathodic line in Fig. 1 between the

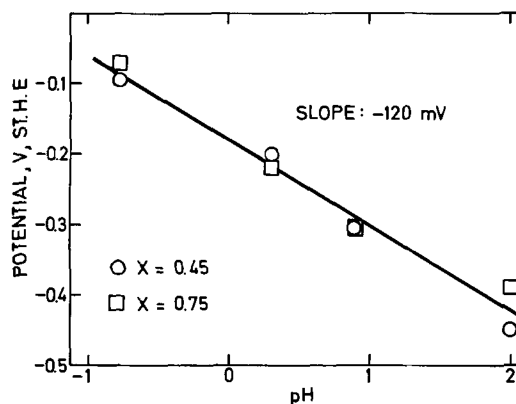

Fig. 3. The *p*H dependence of the HER at Na_xWO_3 in acid solutions. Part of the Tafel line with the slope of -120 mV. Potentials taken at constant current density of 1.5 $\times$ 10^{-4} A-cm^{-2}.

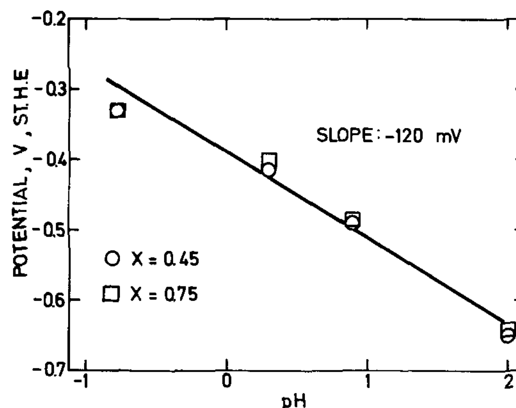

Fig. 4. The *p*H dependence of the HER at Na_xWO_3 in acid solutions. Part of the Tafel line with the slope of -180 mV. Potentials taken at constant current density of 3 $\times$ 10^{-3} A-cm^{-2}.

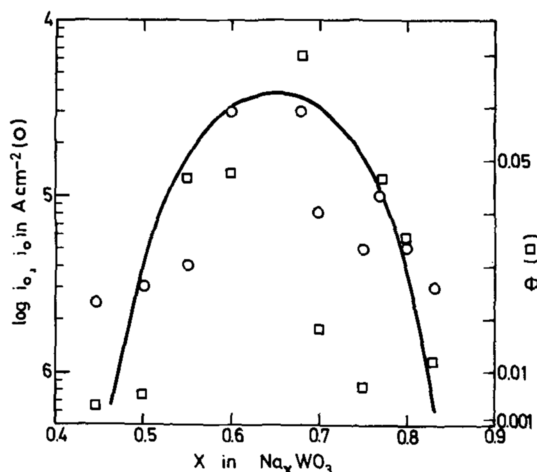

Fig. 5. Electrocatalytic effect for the HER at the bronzes. Solution of 1N H_2SO_4 saturated with hydrogen.

rest potential and the reversible hydrogen potential represents the process of reduction of the hydrated oxide layer of the bronze.

When hydrogen is evolved at the bronze electrode in acid solutions, the oxide layer at the surface is reduced, and a surface with properties close to the bulk-metallic phase is finally obtained. Hence, any kinetic information obtained in the region of current densities lower than about (2-5) $\times 10^{-5}$ A-cm^{-2} does not refer to the HER, but to slow changes in the character of the surface layer of the bronze. Therefore, interpretation of slopes of Tafel lines obtained in this range of current densities attributed by some authors (3, 4) to the HER, is responsible for the considerable discrepancies among data on the kinetics of the HER, as presented in Table I.

Finally, it should be stated that the data concerning the hydrogen evolution and dissolution reactions refer to two substantially different states of the surface of the bronze electrode, and cannot be used together in mechanistic considerations of the reaction kinetics.

The set of kinetic parameters obtained in this paper fits the mechanism of coupled discharge and catalytic steps already theoretically discussed by Thomas (13).

$$H^+ + e \rightarrow H_{ads}$$

$$H_{ads} + H_{ads} \rightarrow H_2$$

Theoretical and experimental kinetic parameters are compared in Table II. The agreement is satisfactory.

In this mechanism the change of the slope of the cathodic Tafel line from -120 to -180 mV is due to the change in the coverage of the atomic hydrogen from Langmuir to Temkin conditions of adsorption (13). When this mechanism is theoretically treated it is possible to calculate the potential dependence of the coverage with atomic hydrogen along the part of Tafel line with the slope of -120 mV. It has been found that $\partial V/\partial \ln \theta = -4RT/\mathbf{F}$. Assuming that the change of the slope always occurred when the threshold of the Temkin region was reached, *i.e.*, when $\theta = 0.2$, and if experimentally found values of potentials of the change of the slope from -120 to -180 mV are taken into account (*cf.* Table III), it is possible to calculate the coverage of the atomic hydrogen the bronzes would have at the reversible hydrogen potential. The values of coverages of atomic hydrogen at the reversible potential calculated in this way appeared to be dependent on the composition of the bronze with a maximum in the vicinity of $x = 0.65$, as presented in Fig. 5. The electrocatalytic effect on the HER at the bronzes is self-explanatory if Fig. 5 is considered, since maxima for both dependencies practically overlap.[2] It is interesting to note that the value of the maximum coverage of atomic hydrogen at the reversible potential, obtained in this way, is about 6%. This value is close to the 3% calculated by Jones and Loebl (15, 16) for adsorption of hydrogen at the bronzes from the gas phase.

Table I. Kinetic parameters of the HER at the sodium tungsten bronze electrodes in acid solutions

Electrolyte	x in Na_xWO_3	$-\partial V/\partial \log i$	$\partial V/\partial$ pH	Electrode pretreatment	Reference
1N H_2SO_4	0.5 0.65 0.8	180 140* 200*		Cathodic polarization 2-20 min at -0.3V	1
(10^1-10^{-2}) N H_2SO_4	0.65	120	-120	Cathodic polarization 5 min at -0.5V	2
1N H_2SO_4	0.74	120**		Cathodic polarization 15 sec at -0.8V	3
1N H_2SO_4	0.71	120**	-65**	—	4

* At these electrodes lower slopes close to -75 and -130 mV, respectively, have been observed in the region of current densities lower than about 1×10^{-4} A cm^{-2}.
** Authors reported the change of slope to the value of -40 mV at lower overpotentials (below -0.2V). The pH dependence for this part of Tafel line is reported to be -35 mV.

Table II. Comparison of theoretical and experimental kinetic parameters for the mechanism proposed

	Kinetic parameter	Theoretical	Experimental

The Corrosion of Zinc Anodes in Aqueous Alkaline Electrolytes

D. P. Gregory,[1] P. C. Jones,[2] and D. P. Redfearn

Research Department, Energy Conversion Limited, Basingstoke, Hampshire, England

ABSTRACT

Rates of self-discharge of porous zinc electrodes in alkaline electrolytes have been measured under a variety of conditions by monitoring the rate of hydrogen evolution. The rate was found to decrease with the addition of lead or mercury to the zinc, the presence of zincate in the electrolyte, and increasing electrolyte concentration up to 5M KOH. Above 5M KOH the rate increased with increasing KOH concentration.

Batteries which provide the highest ratio of power and energy to volume or weight employ negative electrode materials, *e.g.*, zinc or magnesium, which are thermodynamically unstable in most aqueous electrolytes.

For the case of zinc in aqueous alkali, anodic dissolution of the active material and cathodic evolution of hydrogen occur simultaneously, the former resulting in oxide or hydroxide precipitation on the zinc surface and formation of soluble complex anions. Self-discharge of the zinc anode is prejudicial to the battery not only because of the loss of dischargeable capacity with time but, in addition, the need to incorporate a hydrogen venting system makes the battery more prone to deterioration through evaporation of the electrolyte.

The realization that the rate of deterioration of batteries utilizing a zinc electrode is closely related to the rate of hydrogen evolution has led to investigations directed toward the measurement of hydrogen evolved from zinc anodes immersed in battery-type electrolytes. It has long been realized that the rate of hydrogen evolution is minimized by the addition of inhibitors which increase the hydrogen over-potential, *e.g.*, mercury or lead.

Recently, Snyder and Lander (1) have studied the corrosion reaction on commercial, amalgamated zinc anodes complete with separator paper. They found that the rate of hydrogen evolution decreased with increasing electrolyte concentration from 5 w/o (weight per cent) (1M) to 40 w/o (10M) KOH and was also reduced by decreasing the temperature and increasing the mercury content up to 4 w/o HgO. Amalgamation of the silver grid material had little or no effect on the rate of hydrogen evolution. These authors also concluded that the presence of zincate ion in the electrolyte increased the rate at which hydrogen was evolved.

Rüetschi (2) studied the corrosion rate of amalgamated zinc and found, in contrast to Snyder and Lander, that the hydrogen evolution rate increased with KOH concentration above 1M. It was also observed that the rate decreased with the presence of zincate ions above 2M KOH. However, data on the physical properties of the powdered materials used in these experiments were not reported.

Dirkse and Timmer (3) measured the corrosion rate of amalgamated and nonamalgamated zinc wire in KOH electrolytes under a variety of conditions and confirmed Rüetschi's observation that the presence of zincate ions lowers the rate of corrosion for amalgamated zinc. In contrast to Rüetschi, they found that, for amalgamated zinc, increasing the electrolyte concentration above 30-35 w/o (7-8.5M) KOH decreased the corrosion rate.

The present work was undertaken because of these conflicting results and to establish information on the effects of the following variables: choice of inhibitor (lead or mercury), choice of electrolyte (KOH or NaOH), choice of grid material (silver or copper), pretreatment of grid material, presence of zincate, and temperature on the corrosion rate of porous zinc electrodes.

Experimental

Procedure.—Zinc samples were sealed in borosilicate glass cells of ~250 cm^3 capacity as shown in Fig. 1. The cells were filled with electrolyte under

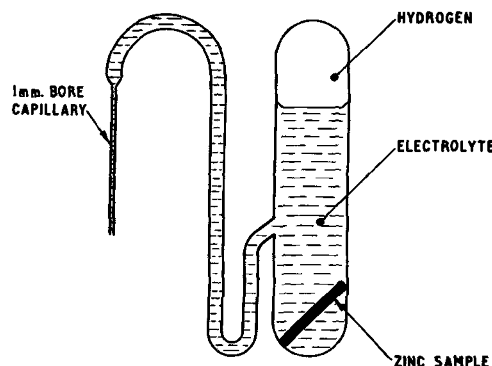

Fig. 1. Electrolytic cell

[1] Present address: Institute of Gas Technology, Chicago, Illinois 60600.
[2] Present address: International Nickel Ltd., Thames House, London S.W.1, England.

Key words: hydrogen evolution, inhibition, self-discharge, porous electrodes.

vacuum and, except for the capillary outlet, were immersed in thermostatically controlled water baths (±1°C). Twenty-four hours were allowed for equilibration before readings were commenced.

Hydrogen, evolved from the reaction of zinc with alkali, accumulated in the cylindrical portion of the cells and displaced an equal volume of electrolyte through the capillary side arm. The volume of hydrogen was measured by the daily titration of the electrolyte displaced from the cell. Average titers were of the order of 25 cm^3 to minimize error and were determined to an accuracy of ±0.1 cm^3. All results were corrected to room temperature. Errors arising from evaporation and carbonation of the displaced electrolyte had no adverse effect because the analysis involved the titration for total alkali (hydroxide ion plus carbonate ion).

All experiments were carried out in triplicate and the duration of the experiments was between twenty and sixty days depending on temperature.

Materials.—All reagents were Analar grade and distilled water was used throughout.

Two types of zinc sample were used. For the initial parts of the investigation zinc battery anodes were prepared by the reduction of zinc oxide compacts, in some cases mixed with lead monoxide or mercuric oxide, on silver mesh grids. All anodes were analyzed for zinc, lead, or mercury and zinc oxide, the content of the latter being ~2 w/o. These were then sectioned to give samples of cross-sectional area ~3 cm^2, thickness ~0.3 cm, and weight ~2.5g. Zinc anodes prepared in this manner had a high surface area (~0.8 m^2g^{-1}) and a porosity of ~72%.

For the examination of grid materials and their pretreatment, electrolytic zinc powder, prepared by electrodeposition from a zincate bath, was pressed on to the grid substrate at pressures up to 5 ton/in.^{2}, giving zinc anode samples of similar dimensions to those above with a surface area of >1.5 m^2g^{-1} and a porosity of ~70%.

The grid substrates were either silver mesh or expanded high conductivity copper, supplied by Expanded Metal Company. Grids were amalgamated by immersion in acidified mercuric acetate solution (0.2M) for 2 min after degreasing in trichloroethylene and etching in hydrochloric acid (1M).

Zincate saturated electrolytes were analyzed and found to contain 102 $g \cdot l^{-1}$ zinc oxide in 10M KOH.

Results and Discussion

The method used by the present investigators was first employed by Craig (4). Modified apparatus have since been used by other investigators (1-3). A sealed system has been used to minimize the possibility of zinc undergoing self-discharge by the reduction of oxygen on the surface of the zinc according to reaction [1]

$$\frac{1}{2}O_2 + Zn + H_2O \rightarrow Zn(OH)_2 \quad [1]$$

Previous experiments (5) have shown that self-discharge by oxygen reduction proceeds at a faster rate than self-discharge by hydrogen evolution. Consequently, it has been suggested (6) that the measure of hydrogen evolution under these circumstances may not represent the behavior of batteries on storage. In the present experiments the back diffusion of oxygen or carbon dioxide was minimized by the use of a fine bore capillary tube (0.1 mm) and the authenticity of the method was confirmed by monitoring the rate of hydrogen evolution from zinc-air batteries sealed in 1 in. thick perspex containers under a nitrogen atmosphere, using a mercury manometer. Excellent agreement was observed between the two rates of hydrogen evolution as shown in Fig. 2 and, as a further check, the remaining dischargeable capacity of the batteries after prolonged storage in these containers agreed with that predicted on the basis of the hydrogen evolution data.

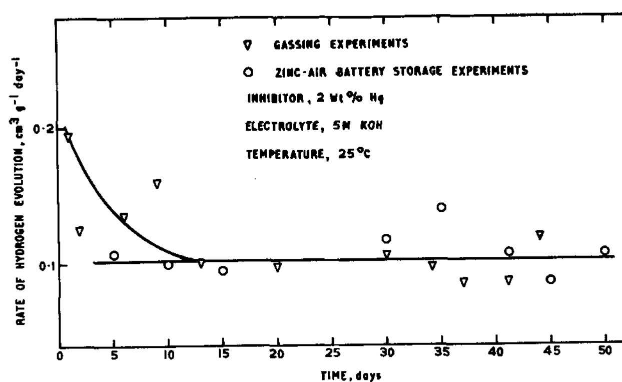

Fig. 2. Comparison between rates of hydrogen evolution from gassing experiments and zinc-air battery storage experiments.

Figure 3 illustrates typical dependences of the rate of hydrogen evolution with time. The measurements were taken over a period of days rather than hours because, first, the time required to achieve saturation of the electrolyte with hydrogen is approximately 24 hr for an evolution rate of 0.1 $cm^3g^{-1}day^{-1}$ (7), and, second, the initial rate of hydrogen evolution is high and steady-state conditions are only maintained after 2-10 days depending on temperature. During this period a surface coating of zinc oxide or hydroxide is formed on the highly active zinc.

Zinc electrodes containing no inhibitor.—The dependence of the rate of hydrogen evolution on KOH concentration for anodes containing no inhibitor is shown in Fig. 4. The rate exhibits a minimum at ~2M KOH. These results are in conflict with those reported by Snyder and Lander (1) and Dirkse and Timmer (3), who both found that the rate of hydrogen evolution decreased with increasing KOH concentration over the range 1-12M.

Rüetschi (2) and Dirkse and Timmer (3), on the basis of the dependence of the rate on activity of water, postulated that the hydrogen evolution reaction [2] is rate controlling, while the dissoluion of the zinc proceeds simultaneously

$$2H_2O + 2e \rightarrow H_2 + 2\,OH^- \quad [2]$$

The dependence of the rate of hydrogen evolution on electrolyte concentration, over the range 0.1-2M, also suggests that the hydrogen evolution reaction is rate controlling.

However, above 2M KOH the direct dependence of the rate on hydroxyl ion concentration suggests a

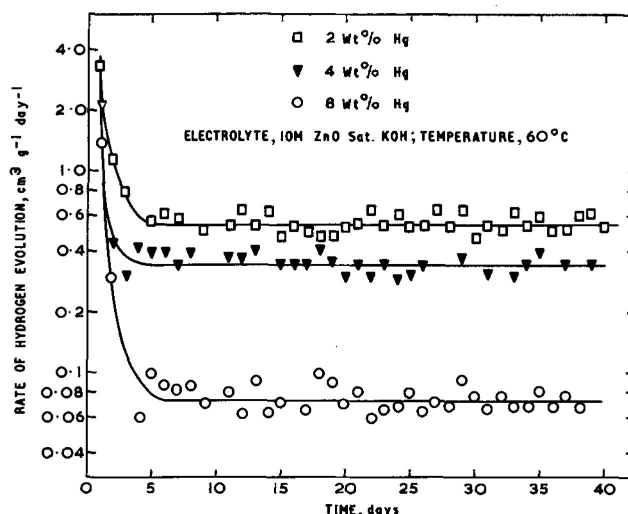

Fig. 3. Time dependence of the rate of hydrogen evolution for zinc anodes containing mercury inhibitor.

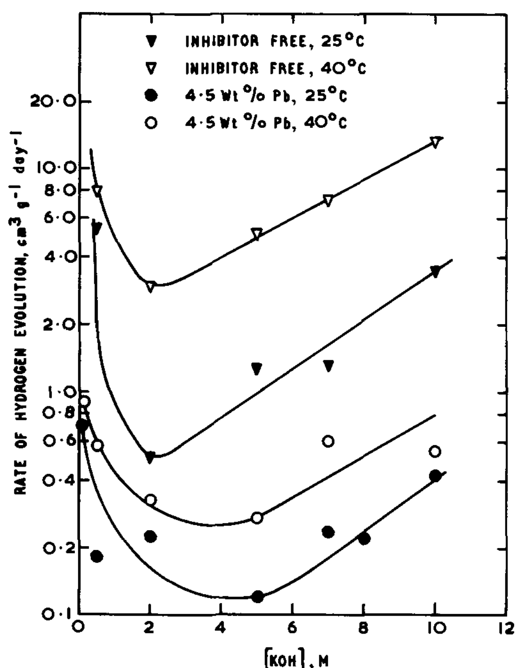

Fig. 4. Dependence of the rate of hydrogen evolution on KOH concentration for inhibitor-free and lead-containing zinc anodes.

change in the rate-controlling reaction from [2] to a reaction involving the anodic oxidation of the zinc. This may be explained if the anodic dissolution of the zinc proceeds via a different mechanism at high KOH concentration. The slope $d\ \log_{10}$ (rate)/$d\ \log_{10}C_{OH^-}$ approximates to one, suggesting that one hydroxyl ion is involved in the rate-determining process, assuming the OH^- concentration at the interphase approximates to that in the bulk. The rate-determining process may be represented by either Reaction [3] or [4]

$$Zn(OH)_2 + OH^- \rightarrow Zn(OH)_3^- \quad [3]$$

$$Zn(OH)_3^- + OH^- \rightarrow Zn(OH)_4^{--} \quad [4]$$

The species $Zn(OH)_3^-$ has been postulated by both Dirkse (8) and Gerischer (9).

An alternative explanation to a change in reaction mechanism is that the rate of dissolution of the charge transfer product, ZnO or $Zn(OH)_2$, becomes limiting. McBreen (10) and Dirkse (11) have found that the diffusion coefficient for zincate ion decreases with increasing KOH concentration. The anodic process is unlikely to be solely controlled by diffusion; convection, particularly within a porous structure, also plays an important role and may explain why the results are at variance with those reported by Dirkse and Timmer for nonporous electrodes.

Zinc electrodes containing lead inhibitor.—The addition of lead to zinc electrodes reduces the rate of hydrogen evolution which is in agreement with the observations of Mansfeld and Gilman (12) and Borchers and Krug (13).

Figure 5 shows that the rate of hydrogen evolution is more or less independent of lead content from 1 to 9 w/o over the temperature range investigated.

The dependence of the rate of hydrogen evolution on KOH concentration for zinc electrodes containing lead inhibitor (Fig. 4) is similar to that exhibited by inhibitor-free electrodes but the minimum occurs at a higher KOH concentration, ~5M. Below 5M KOH the rate-controlling reaction is likely to be hydrogen evolution. The change in gradient once again suggests a change in the rate-controlling reaction to one of the steps in the anodic oxidation of zinc. The rate in electrolytes of concentration >5M is lower than that reported for inhibitor-free anodes and this can be explained if the dissolution process is retarded by the

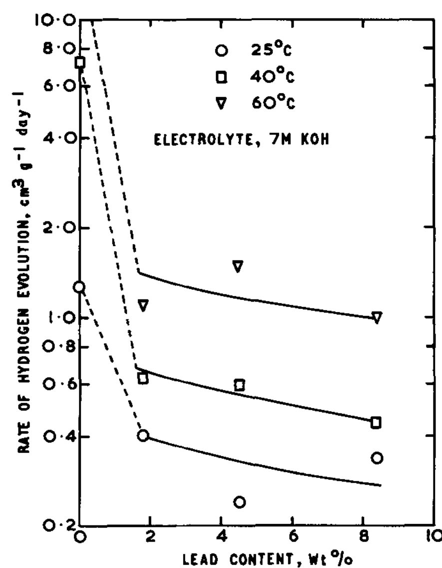

Fig. 5. Dependence of the rate of hydrogen evolution on lead content.

presence of lead at the active sites of the zinc surface which act as a barrier to the passage of zinc species from the electrode as suggested by Mansfeld and Gilman (14).

Zinc electrodes containing mercury inhibitor.—Mercury content.—Figure 6 shows the rate dependence as a function of mercury content at various temperatures. Increasing mercury content decreases the rate of hydrogen evolution which is in line with the prediction that the presence of mercury increases the hydrogen over-potential and agrees with the findings of Snyder *et al.* (1) and Yardney (15). The mercury content required to reduce the rate of hydrogen evolution to an acceptable level increases with increasing temperature and corresponds to 2-3 w/o Hg at 25°C, 3-4 w/o at 40°C, and 6-8 w/o at 60°C.

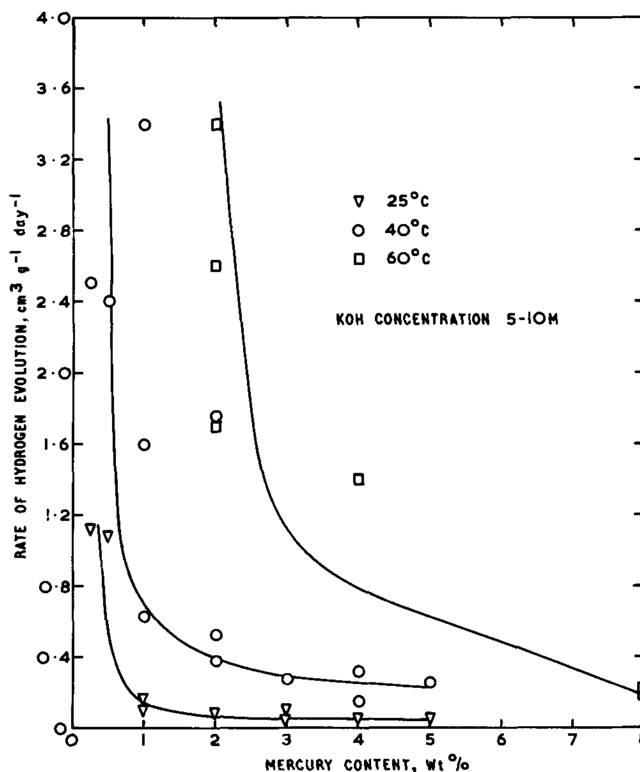

Fig. 6. Dependence of the rate of hydrogen evolution on mercury content.

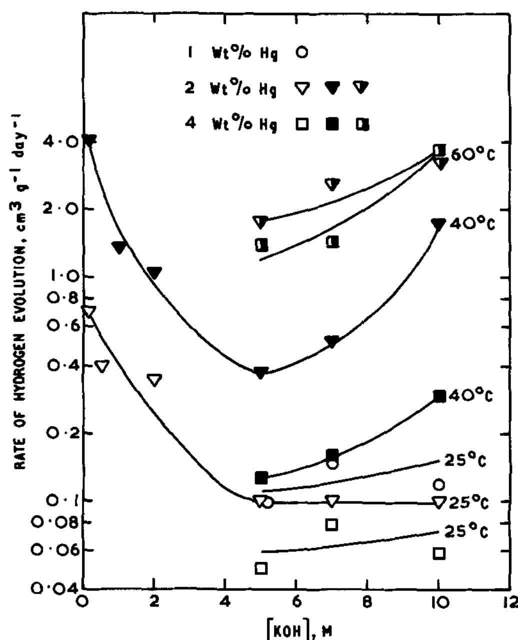

Fig. 7. Dependence of the rate of hydrogen evolution on KOH concentration for zinc anodes containing mercury inhibitor.

KOH electrolyte.—The effect of KOH concentration on the rate of hydrogen evolution for constant mercury content at 25°, 40°, and 60°C is shown in Fig. 7. A minimum in the rate curve is observed at ~5M KOH. Rüetschi (2) found that the rate increased with increasing temperature. In addition, this worker observed that, in the case of zincate-containing electrolytes, the rate decreased initially then increased with a minimum occurring at ~5M KOH. Snyder *et al.* (1) observed a linear relationship for the plot of log (rate) *vs.* [KOH] whereas Dirkse *et al.* (3) observed an irregular dependence of the rate on KOH concentration at 25°C but found an increase in the rate from ~5 to 8.5M KOH, followed by a rapid decrease to ~12M KOH.

Zincate-saturated electrolytes.—The presence of zincate significantly reduces the rate of self-discharge (see Table I). This observation is in agreement with the results reported by Dirkse *et al* (3) and Rüetschi (2) but is at variance with those reported by Snyder *et al.* (1).

NaOH electrolyte.—The use of NaOH electrolyte results in a lower rate of hydrogen evolution than that observed for KOH (Table II). This may be a result of the lower activity of water in NaOH compared with KOH electrolyte, or a change in the nature of the solution species involved in the reaction. The rate of hydrogen evolution as a function of the NaOH concentration was not investigated and consequently it is not possible to differentiate between these alternatives.

Table III. Enthalpies of activation (kcal mole^{-1}) for hydrogen evolution from zinc anodes with different inhibitor contents

	5M KOH	7M KOH	10M KOH	10M ZnO sat. KOH
Inhibitor free	18.4	22.0	17.5	—
Lead inhibitor				
4.5 w/o	9.4	9.1	11.2	—
Mercury inhibitor				
1 w/o	—	17.4	—	—
2 w/o	15.4	19.0	24.0	8.2
4 w/o	17.6	15.0	22.5	16.2

Table IV. Rate of hydrogen evolution (cm^3 g^{-1} day^{-1}) from zinc anodes containing different grid materials in 10M KOH electrolyte

Grid material	25°C	40°C	50°C	60°C
Copper	0.23 ± 0.05	0.75 ± 0.06	2.3 ± 0.2	3.0 ± 0.4
Amalgamated copper	0.19 ± 0.04	0.57 ± 0.05	1.6 ± 0.2	3.8 ± 0.4
Silver	0.30 ± 0.04	0.63 ± 0.05	1.6 ± 0.1	3.0 ± 0.5
Amalgamated silver	0.31 ± 0.03	—	—	4.3 ± 0.5

Temperature dependence of the rate of hydrogen evolution.—The apparent enthalpies of activation for different electrolyte concentrations and inhibitor contents are summarized in Table III. The average enthalpies of activation for the hydrogen evolution reaction are 19.3 kcal mole^{-1} for inhibitor-free, 9.9 kcal mole^{-1} for lead, and 17.3 kcal mole^{-1} for mercury-containing anodes. These are in broad agreement with enthalpy values reported in the literature (16).

Grid materials.—Table IV shows the rate of hydrogen evolution for anodes fabricated using copper, amalgamated copper, silver, and amalgamated silver current collector screens in 10M KOH at different temperatures. Copper and silver current collectors give similar rates and amalgamation of the silver screen has little effect on the rate of self-discharge. Amalgamation of the copper screen, however, gives a reduction in the rate of hydrogen evolution at temperatures <50°C.

Examination of the mercury-coated grid materials by optical microscopy has shown that whereas the copper grid has a surface deposit of mercury, the silver has not. The brittle nature of the latter suggests that amalgamation has occurred and has resulted in alloy formation. However, conflicting evidence is found in the phase diagrams (17) for Ag-Hg and Cu-Hg which show equally steep liquidi, indicating that the rate of solubility of mercury is similar in both substrates.

Conclusions

Self-discharge of the zinc anode is inhibited by the addition of lead or mercury to the zinc. The rate is independent of lead content over the range 1.8-8.4 w/o, whereas increasing the mercury content is found to decrease the rate in agreement with the results of Snyder and Lander (1) and Rüetschi (2).

The dependence of the rate on KOH concentration shows a minimum between 2 and 5M KOH. Similar behavior was observed for inhibitor-free, lead and mercury containing anodes. These results agree, over part of the concentration range, with those reported by Rüetschi (2) and Dirkse and Timmer (3). The discrepancies between the results obtained by the latter authors and those reported may be attributed to the different type of zinc anode used in the experiments.

The self-discharge rate in NaOH is lower than in KOH. The effect of saturating the electrolyte with zincate is to reduce the rate of self-discharge, agreeing with the observations of Rüetschi and Dirkse *et al.* but differing from the results reported by Snyder *et al.*

Amalgamation of the silver grid material has little or no effect on the rate of self-discharge agreeing with the findings of Snyder *et al.* (1). The use of an amalgamated copper grid, however, significantly reduces the rate of self-discharge.

Radiotracer Studies of Metal-Metal Ion Exchange Inhibition Using Organic Inhibitors

Sally Shinew Twining and David S. Newman*

Department of Chemistry, Bowling Green State University, Bowling Green, Ohio 43403

ABSTRACT

The metal-metal ion exchange rate in silver and cadmium systems has been studied using radiotracers in solutions containing organic inhibitors. The inhibitors were *endo-cis*-2,3-dimethylolnorbornane(I) and *endo-cis*-5,6-dimethylol-2-norbornene(II). In the silver system, inhibitor(I) showed an inhibition efficiency of 53% and inhibitor(II) showed an inhibition efficiency of 56%. In the cadmium system, inhibitor(I) showed $<3\%$ inhibition and inhibitor(II) showed 16% inhibition. These data and the arguments given suggest the inhibitor molecules in the silver system are being adsorbed through the unpaired electrons of the oxygen while in the cadmium system the inhibitor molecules are being adsorbed through the unpaired electrons of the oxygen and the double bond electrons of inhibitor(II). A model for the metal-solution interface is given.

In a previous metal-metal ion exchange study (1) it was shown that a judiciously chosen series of organic molecules could be employed to yield information about the structure of the metal-solution interfacial region and the electrochemical processes taking place therein. The molecular "probes" used were butane-1,4-diol, *cis*-2-butene-1,4-diol, and 2-butyne-1,4-diol. In the present investigation the molecules *endo-cis*-2,3-dimethylolnorbornane, (I), and *endo-cis*-5,6-dimethylol-2-norbornene, (II), were used to further probe the interfacial region in the Cd-Cd^{++} and Ag-Ag^{+} systems. The structures of these two organic molecules are shown in Fig. 1.

* Electrochemical Society Active Member.

Key words: corrosion inhibition, adsorption, metal-metal ion exchange.

It is easily seen that compounds (I) and (II) are similar to the straight chain diols but with a bulky cyclopentyl group attached to the middle of the chain. All five inhibitors are, in fact, 1,4 diols. However, the

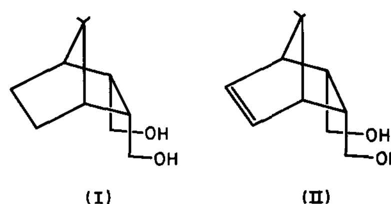

Fig. 1. Inhibitor(I), *endo-cis*-2,3-dimethylolnorbornane and inhibitor(II), *endo-cis*-5,6-dimethylol-2-norbornene

bulky cyclopentyl group is hydrophobic and should therefore cause an increase in the "structuring " of the water in its immediate vicinity. This structuring should increase the water's surface tension and tend to push the norbornane compounds from the metal surface. As a result the inhibition efficiencies, given by the equation

$$I = [(R_o - R_i)/R_o]\,100 \qquad [1]$$

where R_0 is the rate of exchange with no inhibitor and R_i is the rate with inhibitors, should be lower in the norbornane systems than in the butane diol systems.

The interpretation of any differences in the mode of interaction between metal and norbornane molecules should be easier than with the butane diols because the two norbornane molecules have, but for the double bond, nearly the same structures. Moreover, the entropy of adsorption of (I) and (II) should be less than the entropy of adsorption of the butane diols. The microscopic imperfections in the surface layer of the metal crystal are relatively insignificant because re-exchange is taking place at a rapid rate. Therefore after a very short time, probably less than a few seconds, the original outermost layer of metal has been completely replaced. This means that the surface does not have to be absolutely clean for results to be significant. In addition, the increase in radioactivity of the disk as a function of time is determined by the slow self-diffusion process which further reduces transient errors introduced by minor surface imperfections.

Experimental Details

General.—The experimental apparatus and techniques used in this study are similar to those used in previous studies (1, 2).

The radioactivity was measured with a Beckman liquid scintillation counter (Model LS 133) using a standard PPO-POPOP-Toluene scintillation cocktail. All experiments were performed at 25°C. The solutions were deoxygenated and stirred with nitrogen. The inhibitor concentration was 0.001M and the metal ion concentration was 0.1M. All crystal surfaces were polished to a mirror finish. Reagent grade salts were used in each case. The edges of the Cd disks and the edges and one face of the silver disks were coated with paraffin. The exposed faces were then cleaned with chloroform to remove excess paraffin and other organic material present.

Preparation of (I) and (II).—Inhibitor (II) was synthesized by a method first described by Alder and Roth (3). This compound was then hydrogenated using Birch's technique (4) to obtain (I). After each exchange experiment the inhibitor was isolated and identified by means of its IR spectrum to assure that no structural change had occurred.

Cadmium-cadmium ion exchange.—The disks were handled the same as in the previous study (1) except that they were annealed for 12 hr at 175°C. The dimensions of each disk were approximately 1.90 cm in diameter and 2.3 mm thick. The surface of the single crystal was parallel to the $10\bar{1}0$ plane of the crystal. The disks were electropolished to a shiny flat surface by a technique described by King and McKinney (5). Cd^{115m} was used as the radiotracer. Each disk was immersed in solution for 7½ hr.

Silver-silver ion exchange.—Single-crystal silver disks approximately 3 mm thick were cut from a single-crystal rod approximately 2 cm in diameter. The surface of the disk was parallel to the 210 plane. The disks were chemically polished by the method of Levinstein and Robinson (6) to give a flat shiny surface free from strain and pits. The disks were annealed for 18 hr at 850°C to remove the strains and distortions acquired during the polishing process. Ag^{110m} was used as the radiotracer.

The glass cells were covered with dark fabric bags to prevent light from entering. The disks were immersed in the solutions for periods of time ranging from four to sixteen days, removed from solution, washed by various techniques, and counted. In one series of experiments the disks were washed under a stream of water for 15 min per side. In another series they were washed for 30 min per side. A third set of disks was gently rocked in a water bath for 5 min. The washed disks were put back in solution so that the effect of the washing technique on the exchange rate could be studied.

Results

The results of the cadmium-cadmium ion exchange study using inhibitors I and II are shown in Table I. The results of the four-day immersion experiments in the silver-silver ion system are given in Table II. In both tables the efficiencies of the butane diol series are given for reference. Figures 2 and 3 and Table III show the results of the experiments with silver using different washing techniques.

From the information provided by the standards, the total activity, a_t, of the experimental disks, in terms of counts per minute, was converted to gram atoms per square centimeter.

The exchange process is controlled by self-diffusion into the single crystal. This process is analogous to

heat conduction (7). The equation for self-diffusion is Fick's second law

$$\frac{\partial C}{\partial t} = \frac{D \partial^2 C}{\partial x^2} \quad [2]$$

where D, the diffusion coefficient is independent of concentration. In this equation C is the concentration, t is time, and $\partial C/\partial x$ is the concentration gradient. This equation with the appropriate boundary conditions (1) becomes

$$\frac{da_t}{dt} = C_o D^{1/2} (\pi t)^{-1/2} \quad [3]$$

where a_t is the total activity, C_o the surface concentration of cadmium, and D the diffusion coefficient. On integration Eq. 3 gives

$$a_t = 2 C_o \pi^{-1/2} (Dt)^{1/2} \quad [4]$$

From Eq. [4] the surface concentration was calculated. The diffusion coefficient used for cadmium was 3.6×10^{-15} cm²/sec. This value was used by King and McKinney (5) for single-crystal cadmium at 25°C. The diffusion coefficient used for silver was 1.6×10^{-21} cm²/sec. This value was calculated for the 210 plane based on the values determined by Tingley (8) for the 110 and 111 planes.

The values for R were obtained by dividing the total activity in gram atoms per square centimeter by the time of immersion.

The percentage of the disk covered by inhibitor, S_i, was calculated from the equation

$$S_i = 100 \, [1 - (C_{oi}/C_{ou})^{2/3}] \quad [5]$$

where C_{oi} and C_{ou} are the inhibited and uninhibited surface concentrations, respectively.

The surface area covered by each inhibitor molecule was estimated, using Dreiding Molecular Models, from the possible orientations of the inhibitors on the metal surface for the proposed mode of adsorption. Since Dreiding models give bond lengths and bond angles only, the appropriate atomic radius was added to the outermost hydrogen atoms.

The free energy of adsorption was calculated from the equation (1)

$$\Delta G^\circ = -RT \ln \left[\frac{[X_{In}(\text{ads})][X_{M^{++}}(\text{sol})]}{[X_{M^{++}}(\text{ads})][X_{In}(\text{sol})]} \right] \quad [6]$$

where the X_i's are the mole fractions of the various species in the two dimensional cross-sectional area. This equation assumes the chemical reaction for metal-metal ion exchange in the presence of inhibitors is

$$M^+(\text{ads}) + In(\text{sol}) = In(\text{ads}) + M^+(\text{sol}) \quad [7]$$

In calculating the surface concentrations a roughness factor of 1.1 was assumed because this roughness factor gives a C_o very close to the best value for the bulk density of cadmium. The measured geometric area was multiplied by this factor to give a "corrected surface concentration," C_o'. The surface concentration of inhibitor was obtained by multiplying the percentage of the disk covered by inhibitor, S_i, by the correction factor for the area of this disk, 1.1, and then dividing by the surface area of the molecule. The surface concentration of the adsorbed metal ion was obtained from $C_o^{2/3}$. In the cadmium system C_o was calculated from Eq. [4] and found to be equal to the bulk concentration of cadmium metal. In the silver system values calculated from $C_o^{2/3}$ were about six times the average bulk concentration at the silver surface. For this reason the values for C_o used for silver were the number of atoms for the 210 surface. This was multiplied by 1.1, the roughness factor, to obtain the corrected surface concentration C_o'. This assumption is plausible because the holes in the silver surface are too small to seriously affect the inhibitor concentration at the surface but large enough to cause an increase in the rate of $Ag-Ag^+$ exchange.

Table III. Inhibitor efficiencies using different washing methods in the $Ag-Ag^+$

Washing method	I (%), Inhibitor (I)	I (%), Inhibitor (II)
Initial	52.8	55.5
Water bath	41.3	55.6
15 min stream of water	42.4	54.6
30 min stream of water	43.6	53.5

Discussion

In the cadmium system, (I) showed an inhibition efficiency of about 3% while (II) showed an inhibition efficiency of 16% (Table I). Based on the results in the cadmium system using the butane diol series (1) and the structure of the inhibitors used in this study, these results are reasonable. The difference in the inhibitor efficiencies between (I) and (II) suggests that the norbornene molecule is lying flat on the cadmium surface and bonding through its π-electrons and the hydroxyl groups. The attraction for the metal surface by the hydroxyl groups is nearly balanced by the hydrophobic effect of the large cyclopentyl group as can be seen by the $I_{(I)}$ value of ~3%. This conjecture is further borne out when the 21% I value for butane 1,4 diol (1) is compared with the 3% value found for $I_{(I)}$. The increase in inhibitor efficiency with the addition of the double bond is less in the norbornane diol series than in the butane diol series. This is true even though the π-character of the double bond in (II) is greater

due to the ring strain of the molecule. The difference in efficiency can be explained by the hydrophobic nature of the cyclopentyl group and by the fact that the cyclopentyl group cannot lie flat on the metal surface.

Inhibitors (I) and (II) are more efficient in the silver system than in the cadmium system. As shown in Table II, (I) has an average efficiency of 53% while (II) has an average efficiency of 56%. This should be compared with the inhibition efficiencies of butane 1,4 diol, *cis*-2-butene 1,4 diol, and 2-butyne 1,4 diol which are also alike.

There is virtually no chance that the adsorbed inhibitors change the basic mode of self-diffusion within a crystal. To do so, the adsorbed molecule would have to change the migration energy and the energy of vacancy formation or dislocation pipe formation as well as the fluctuation probability. In the absence of any information to the contrary, this sort of change must be considered highly unlikely. The comparison in efficiency between the two series of alcohols in the silver system is valid despite the nearly 30% difference in D_{Ag} for the two crystals used because I reflects the relative difference in exchange rate, rather than the absolute difference. This can be easily proven mathematically. Let

$$R_o = k_o D^a_{Ag} \quad [8]$$

and

$$R_i = k_i D^a_{Ag} \quad [9]$$

where k_i and k_o are constants of proportionality and a is any power. Substituting these expressions into Eq. [1], it is easily seen that the D's cancel. Therefore, when one I is compared with another, the difference in the value for D does not exert a direct influence since the self-diffusion coefficients cancel.

Because each of the norbornane systems exhibits nearly the same inhibition efficiency, it is unlikely that the π-electrons of (II) are contributing to the bonding. This implies that the inhibitors are either perpendicular to the metal surface; adsorption occurring through the unpaired electrons on the oxygen or else they are sticking to the surface for a time that is very long in comparison to the time a silver ion is adsorbed onto the surface. This latter possibility is highly unlikely so we are left with two plausible modes of adsorption. One mode would be with an oxygen bonded to the surface while the second oxygen would be hydrogen bonded to the water. The other mode is with both hydroxyl groups directed toward the metal surface.

The decrease in inhibitor efficiency in the norbornane diol series relative to the butane diol series is again probably due to the hydrophobic cyclopentyl group.

The free energies of adsorption for (I) and (II) (Tables I and II) are lower than in the butane diol series (1). This is to be expected because (I) and (II) cannot bond as strongly to the metal surface. Because of the rigid cage of the cyclopentyl groups, (I) and (II) should have a lower entropy of adsorption than the butane diol series even though (I) and (II) are larger molecules.

In order to further interpret the inhibition efficiencies, the self-diffusion mechanism must be considered. Dislocations in single-crystal silver were shown to exist at room temperature by Levinstein and Robinson (6). These authors used both an etch pit technique and the Lambot x-ray method (9) and found a dislocation density ranging from 1×10^7 to 5×10^7 dislocation pipes per square centimeter.

Models for dislocation pipe diffusion in silver have been postulated by several authors (10-12). Vardiman and Achter (13) demonstrated the plausibility of these models by obtaining excellent agreement between their diffusion data and predictions from the dislocation pipe models over the temperature range 250°-450°C. Moreover, extrapolation of high-temperature diffusion data to low temperatures gave a self-diffusion coefficient that was some twelve orders of magnitude lower than the measured self-diffusion coefficient (14). In other words, dislocations were found by two different experimental techniques. Models based on these dislocation pipes were constructed and predictions on the basis of these models were shown to be in excellent agreement with experimental data. Extrapolation of D *vs.* $1/T$ from high-temperature data based on a vacancy diffusion mechanism gave absurd results.

We therefore assume that self-diffusion in Ag occurs via a diffusion pipe mechanism even though in the previous study this mechanism was suggested only as a possibility. Self-diffusion in cadmium however, occurs via a vacancy mechanism so that the difference in mode of diffusion should greatly affect the measured inhibition efficiencies. In the silver system, when an inhibitor molecule blocks a dislocation pipe there is virtually no other way for a silver atom to enter the crystal. In the cadmium system this is not the case. If it is assumed that the bond strength between oxygen and silver and between oxygen and cadmium are not too different, then a choice between the modes of adsorption of the norbornane diol series can be made. The mode of adsorption which places both hydroxyl groups on the metal surface is the favored orientation.

Because one hydrophobic cyclopentyl group reduces the inhibition efficiency more than 30%, in the cadmium system [comparing the butene diol with (II)] then it would be expected that the same two molecules would differ by roughly 30% in the silver system. However, in the silver system the inhibition efficiency is reduced less than 20%. This implies that butene diol bonds to the surface only through one hydroxyl group while (II) bonds to the surface through both hydroxyl groups; the extra 10% efficiency arising from the additional O . . . M bond.

It is worthwhile pursuing the idea of dislocation pipes further. In this study the rate of increase in activity of a given silver disk was affected by the method of washing. If the disks were slowly rocked in a water bath for 5 min per side the increase in activity was nearly the same as the increase in the activity if the disk was not removed and washed. However, if the disk was washed under a vigorous stream of water an increase in activity occurred roughly proportional to the time of washing.

Using a value of 6.6×10^6 dynes/cm^2 (15) as the pressure necessary to introduce a dislocation into a crystal of silver and assuming the velocity of the water at the surface of the disk to be $V = \sqrt{2gh}$, a value of about 350 cm/sec is obtained for a 60 cm high column of water. The volume of a stream of water with a 1 cm^2 cross section hitting the surface in unit time is $Q = AV = 350$ cm^3/sec. For a 30-min washing this gives a pressure of 6.2×10^8 dynes/cm^2 which means 100 dislocations can be introduced if a constant hydrostatic pressure over a perfectly smooth surface is assumed. One hundred dislocations/square centimeter is an absolute minimum and the actual number introduced will certainly be higher because a turbulent stream is striking an imperfect surface and local pressures will be much higher than 6.2×10^8 dynes/cm^2. Therefore, the force of the stream of water probably introduced more dislocation pipes into the metal surface but whether or not any other factors are involved cannot be determined with any certainty.

It should be pointed out that Tingley (7) found very little increase in activity of single-crystal silver in 0.1M $AgNO_3$ solutions after a four day initial exchange period, even though the silver crystals were taken from the solution, washed, and then put back into solution. The exact washing procedure used is not known.

In the presence of inhibitors, vigorous washing also increased the activity, but the efficiencies remained nearly the same as is shown in Table III. Since it is

hard to duplicate washing conditions, the data are not very precise. These data, however, also tend to confirm the hypothesis that the inhibitors are blocking dislocation pipes. Therefore, we propose the following scheme for evaluating the effect of a dislocation pipe on the apparent inhibition efficiency and for classifying inhibitor efficiencies generally. We define ΔI as representing a unit of efficiency equivalent to a 10% decrease in the exchange rate. An uninhibited system would have a ΔI equal to 0 and a completely inhibited system would have a ΔI equal to 10. Based on the data for cadmium in Table I and the inhibitor efficiencies of the straight chained diols we assigned the values for ΔI shown in Table IV to the various functional groups. The way in which these values were obtained can be shown by using the cyclopentyl group as an example. Comparing $I_{\text{butene diol}}$ with $I_{(II)}$, it can be seen that the former can be taken as 50% or $5\Delta I$ and the latter as 20% or $2\Delta I$. Therefore, the cyclopentyl group must be contributing $-3\Delta I$. $I_{(I)}$ is assumed to be zero. Differences in adsorption of the organic molecules due to differences in exposed crystal face may exist (16) but should exert a second-order effect. The organic compound is competing with water for adsorption sites so that the exposed crystal face affects the difference in the ability of water and the ability of the inhibitor to adsorb. The difference in exposed surface can only manifest itself as a "difference in this difference" and is taken into consideration when the efficiencies are rounded off. Therefore, comparison between adsorption onto the 111 crystal face and the 210 crystal face can be made.

Using the values for I in Table IV, we now calculate the contribution of a hole in the silver system using the equations

$$\Delta I + X = 7\Delta I \text{ (straight chain diols)} \quad [10]$$

$$2\Delta I + X - 3\Delta I = 5\Delta I \text{ (norbornane diols)} \quad [11]$$

In both equations X is $6\Delta I$. It should be noted that in Eq. [11], $2\Delta I$ is used because 2 OH groups are assumed to be bonded to the silver.

We next propose a simple model for the surface of the metal at the metal solution interface based on our data. This model has little real basis but can explain the qualitative differences in behavior of the five inhibitor molecules and does allow predictions to be made for future experiments. We first assume that the metal surface consists of positive holes and negative electrons. To neglect the possible effects of aggregates, we next assume the electron density and the positive hole density are the same.

The configuration of positive holes and negative electrons is shown schematically for both Ag and Cd in Fig. 4. In this figure the 2 butyne, 1,4-diol is shown adsorbed onto the surface in the most appropriate orientation. It is clear from this picture that this diol would lie flat in cadmium but perpendicular in silver.

We further postulate that in the silver system the dislocation pipes are extensions of the positive holes with a diameter approximately that of a silver atom (14). Since there are probably some eight orders of magnitude fewer dislocation pipes than silver atoms (6), even though the norbornane group has two OH groups bonding to the metal surface, the chance of the molecule blocking two dislocation pipes is nearly zero. Moreover, the bulky cyclopentyl group prevents both OH groups from going into a given dislocation pipe, whereas, the straight chained diols can penetrate the pipes quite deeply.

Table IV. Efficiency units

Functional group	Value ΔI
OH	+1
C—C	0
C=C	+3
C≡C	+4
Cyclopentyl group	−3

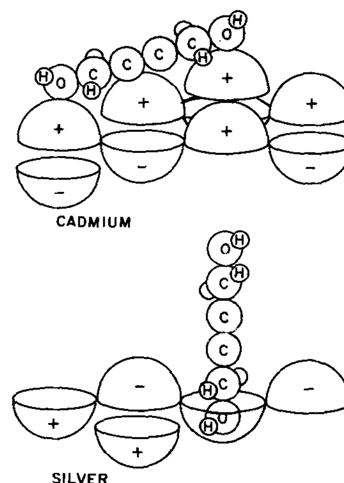

Fig. 4. Model surfaces for cadmium and silver with 2-butyne-1, 4-diol adsorbed on the surfaces.

It is also easily seen how this model accounts for the qualitative differences in the two metal systems as well as the relative I values at the concentrations involved. In the cadmium system the molecules are expected to lie flat while in the silver system they should be perpendicular because the oxygen of the hydroxyl group is sticking down into a positive region.

In addition to arising naturally from our data this model is consistent with the work of other authors. The different distribution of charges in the two metals is reasonable because of the different signs of the Hall effect (17). This model is consistent with Bell and Levine's (18) double layer model when applied to a metal surface rather than a colloidal wall.

Discussion of Errors

The inhibitor efficiencies in both the Ag^{+}-Ag and the Cd^{++}-Cd systems are probably accurate to ±5% while the thermodynamic data are probably only accurate to ±15%. This is because of the uncertainty in the areas of the inhibitors determined by Dreiding models. In the silver system the error is probably slightly greater than these estimates due to the dislocation pipes and the ambiguity in the proper value of the diffusion coefficient. In the cadmium system the error is probably less due to the greater accuracy of the measurement of the surface area.

The data for the silver system in this study is more accurate than in the previous study (1) because the C_o value for silver was only about six times rather than ten times (1) the bulk concentration of silver at the surface which means that the surfaces are probably more uniform.

SYMBOLS

I	inhibition efficiency, %
ΔI	efficiency unit equal to $10\% I$
R	rate of exchange
a_t	total activity acquired by the disk
C_o	surface concentration, atoms/cm^3
D	self-diffusion coefficient
S_i	percentage of surface covered by inhibitor
ΔG°	standard free energy of adsorption

On the Mechanism of Localized Corrosion of Iron and Stainless Steel

I. Electrochemical Studies

H. W. Pickering*,[1] **and R. P. Frankenthal***,[2]

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania 15146

ABSTRACT

During pitting of iron and stainless steels the potential drop across the interface of the dissolving surface within the pit is in the region of active metal dissolution, even when the potential of the specimen surface is controlled at potentials as high at +1.4 (SHE), as well as during natural corrosion. This conclusion is supported by measurements of the potential of the electrolyte within pits and by the observation that hydrogen gas is produced within the pits. From calculations of the concentration and potential gradients within the electrolyte in a pit it is further concluded that existing models of pit growth are inconsistent with these data. A modified model of pit growth is presented which involves growth by active dissolution and includes a high resistance path resulting from a constriction caused by a hydrogen bubble. This model of pit growth is also believed to apply to the propagation of crevices and, in some instances, of intergranular attack.

The concentration of the various ionic species and the potential ϕ of the electrolyte within a pit are different from the values in the bulk electrolyte (1-10). The signs of these gradients are usually known for simple pitting situations, *e.g.*, when the current within the pit is maintained by a single electrochemical reaction. Quantitative descriptions of the concentration and potential gradients, however, are lacking even for simple cases of pitting. Beck and Grens (11) have obtained quantitative results for a complex stress corrosion cracking system, and Vermilyea and Tedmon (12) have obtained results using a simplified approach for crevice attack. Composition changes within growing pits have been most recently emphasized in the experimental investigations of Pourbaix (8), of Brown and co-workers (13, 14), and of Troiano and co-workers (15, 16). Potential variations within pits in iron were measured over a decade ago by Herbsleb and Engell (7) and more recently within crevices in stainless steels and Ti alloy by others (17-19). Variations of one volt or more were measured between the bulk electrolyte and the electrolyte at the bottom of pits and crevices in these investigations. This result is surprising since, as will be shown for pitting and has been shown for other types of localized corrosion (11, 12), only a small fraction of this potential can be accounted for by an IR-drop through an unobstructed column of electrolyte within the pit or crevice. Stolica (20) has observed sharp oscillations of the potential during early stages of pitting on Fe-Cr alloys in 1N H_2SO_4 containing small amounts of Cl^-; their frequency and magnitude depended on the Cl^- concentration.

Only a few investigators have reported the egress of gas bubbles from pits. For ferrous materials Forchhammer and Engell (21) observed the evolution of bubbles from pits during elevated-temperature exposure to neutral chloride solutions. They assumed the gas to be H_2. Masing and Altenpohl (22) and Kaesche (23) observed the egress of bubbles from pits in aluminum.

The purpose of the present paper is to determine the potential $E(X)$ across the interface at the bottom of a dissolving pit, the potential $E(x)$ at any distance x into the pit, the potential $\phi(x)$ in the electrolyte within the pit, and to compare these results with theoretical values.

Theoretical

The concentration of the various ionic species and the potential ϕ in the electrolyte are calculated as a function of distance x into the pit (Fig. 1) for a steady-state current density i_M and the following conditions. A single charge-transfer reaction of the type

$$M(s) = M^+ (aq) + e^- \quad [1]$$

* Electrochemical Society Active Member.

[1] Present address: Department of Materials Sciences, The Pennsylvania State University, University Park, Pennsylvania 16802.

[2] Present address: Bell Telephone Laboratories, Murray Hill, New Jersey 07974.

Key words: active dissolution, crevice corrosion, pitting, potential gradients.

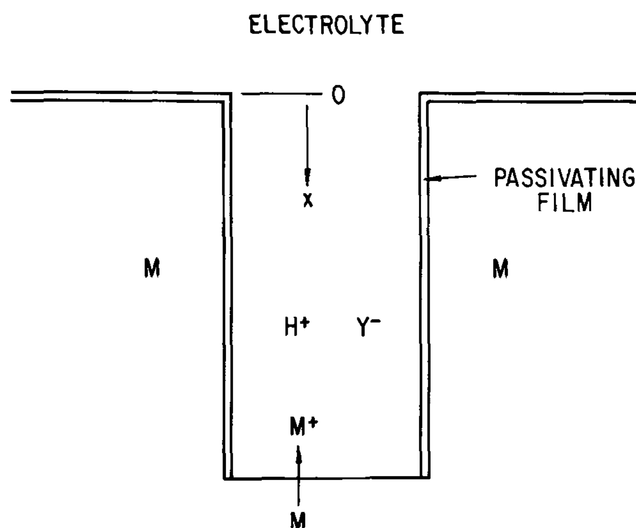

Fig. 1. Schematic of pit in which dissolution occurs only at bottom.

occurs in a moderately concentrated, completely dissociated acid HY; Y^- is a noncomplexing monovalent ion. During growth of a pit, metal dissolution occurs only at the bottom; recession of the metal surface is disregarded.

As an approximation the transport equations for dilute solutions without regard to ionic interaction are used. Then the Nernst-Einstein equation interrelating diffusivity and electrochemical mobility holds. One has for the fluxes j of the various ionic species for (quasi) steady-state conditions

$$j_{H^+} = -D_{H^+}\left(\frac{dc_{H^+}}{dx} + c_{H^+}\frac{\mathbf{F}}{RT}\frac{d\phi}{dx}\right) = 0 \quad [2]$$

$$j_{Y^-} = -D_{Y^-}\left(\frac{dc_{Y^-}}{dx} - c_{Y^-}\frac{\mathbf{F}}{RT}\frac{d\phi}{dx}\right) = 0 \quad [3]$$

$$j_{M^+} = -D_{M^+}\left(\frac{dc_{M^+}}{dx} + c_{M^+}\frac{\mathbf{F}}{RT}\frac{d\phi}{dx}\right) = -\frac{i_M}{\mathbf{F}} \quad [4]$$

in which D is the diffusion coefficient, c the concentration of the indicated species, T the absolute temperature, $\mathbf{F}$ the Faraday constant, and R the gas constant. The fluxes H^+ and Y^- vanish (Eq. [2] and [3]) at steady state since these ions are neither formed nor consumed by the electrode reaction. The right member of Eq. [4] has a negative sign since metal ions move in the negative direction of the x coordinate ($x = 0$ at opening and $x = X$ at bottom of pit).

The boundary conditions are assumed to be

$$c_{H^+} = c^o \text{ at } x = 0 \quad [5]$$

$$c_{Y^-} = c^o \text{ at } x = 0 \quad [6]$$

$$c_M = 0 \text{ at } x = 0 \quad [7]$$

in which c^o is the bulk concentration of HY.

In addition, the electrical potential ϕ at $x = 0$ is defined as zero

$$\phi = 0 \text{ at } x = 0 \quad [8]$$

and since the concentrations of the ionic species must conform to the law of electrical neutrality, one has

$$c_{H^+} + c_{M^+} = c_{Y^-} \quad [9]$$

Equations [2] through [9] are sufficient to calculate c_{H^+}, c_{Y^-}, c_{M^+}, and ϕ as functions of distance x.

Dividing through Eq. [2] and [4] by D_{H^+} and D_{M^+}, respectively, adding corresponding sides and rearranging, and substituting Eq. [9] gives

$$-\frac{dc_{Y^-}}{dx} - c_{Y^-}\frac{\mathbf{F}}{RT}\frac{d\phi}{dx} = -\frac{i_M}{D_{M^+}\mathbf{F}} \quad [10]$$

From Eq [3] and [10] it follows that

$$\frac{dc_{Y^-}}{dx} = \frac{i_M}{2D_{M^+}\mathbf{F}} \quad [11]$$

$$\frac{\mathbf{F}}{RT}\frac{d\phi}{dx} = \frac{i_M}{2c_{Y^-}D_{M^+}\mathbf{F}} \quad [12]$$

Integrating Eq. [11] and using the boundary condition in Eq. [6] one obtains

$$c_{Y^-} = c^o + \frac{i_M x}{2D_{M^+}\mathbf{F}} \quad [13]$$

Substituting Eq. [13] in Eq. [12], integrating, using the boundary condition in Eq. [8] and introducing the symbol $\psi = \mathbf{F}\phi/RT$, one obtains

$$\psi = \frac{\mathbf{F}\phi}{RT} = \ln\left(1 + \frac{i_M x}{2D_{M^+}\mathbf{F}c^o}\right) \quad [14]$$

Integrating Eq. [2] and [4] and using the boundary conditions in Eq. [5] and [7] respectively, one obtains

$$c_{H^+} = c^o e^{-\psi(x)} \quad [15]$$

$$c_{M^+} = \frac{i_M}{\mathbf{F}D_{M^+}} e^{-\psi(x)} \int_0^x e^{\psi(x)}dx \quad [16]$$

in which $\psi = \mathbf{F}\phi/RT$ is given by Eq. [14] as a function of x. Substituting Eq. [14] in Eq. [15] and [16] and integrating Eq. [16] yields

$$c_{H^+} = \frac{2D_{M^+}\mathbf{F}c^{o2}}{2D_{M^+}\mathbf{F}c^o + i_M x} \quad [17]$$

$$c_{M^+} = \frac{4D_{M^+}\mathbf{F}c^o i_M x + (i_M x)^2}{2D_{M^+}\mathbf{F}(2D_{M^+}\mathbf{F}c^o + i_M x)} \quad [18]$$

The results from Eq. [13], [14], [17], and [18] for $D_{M^+} = 10^{-5}$ cm^2-sec^{-1} and $c^o = 1$ mol-liter^{-1} are plotted in Fig. 2, in which the concentrations of the ionic species and the potential ϕ are given in terms of the product of the depth x into the pit and of the current density i_M. The concentration of metal ions, c_{M^+}, increases with increasing x or i_M as expected in as much as metal ions are formed at the bottom of the pit, $x = X$. The concentration of anions (Y^-) increases and that of hydrogen ions (H^+) decreases from the bulk value, c^o, with increasing x or i_M. This is in accord

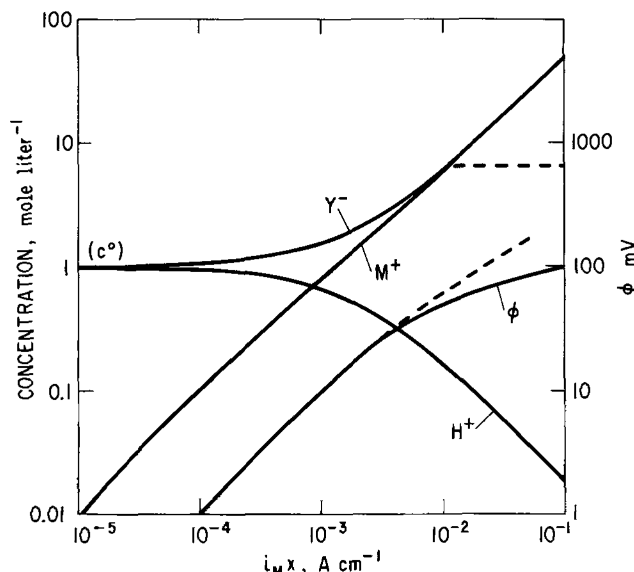

Fig. 2. Concentrations of Y^-, H^+, and M^+ and ϕ as a function of the product of the depth x and the current density i_M calculated from Eq. [13], [17], [18], and [14], respectively. c^o is the bulk concentration of acid HY.

with the tendency for anions to move toward the bottom of the pit and cations to move away from the anode for the prevailing potential gradient, ϕ, increasing toward the anode. At $t > 0$ the total concentration of ionic species within the pit is greater than the bulk concentration.

Departures from the calculated curves, occurring as a result of precipitation of salts and ionic interactions, are schematically indicated by the dashed lines in Fig. 2. The present theory, therefore, applies in an approximate manner to $i_M x$ products less than about 10^{-2} A-cm^{-1} with variations from system to system depending mainly on the solubility product of the metal salt.

The above calculations may be extended to other pit geometries, *e.g.*, hemispherical ones, and to other anodic reactions including those in which complexing, hydrolysis, or other interactions must be considered; the calculations become more complex. Changing geometries do not change the results qualitatively. If other anodic reactions are considered, the concentration gradients of the ionic species will change and may even be of opposite sign, but the magnitude of the potential ϕ is relatively unaffected.

Experimental Procedure

Most of the experiments were performed on Ferrovac E iron; additional experiments were done on three stainless steels: Fe-20Cr (ferritic), Fe-18Cr-8Ni (austenitic), and Type 304 stainless steel. The composition of the iron and the alloys and their thermal treatments are shown in Tables I and II, respectively. The various electrolyte solutions (Table III) were prepared from reagent grade chemicals and doubly distilled water.

A sample was prepared by mounting the specimen, including a lead for electrical connection, in epoxy and polishing it with an aqueous suspension of 1 μm particles of alumina prior to insertion in the cell. The exposed area was 0.42 cm^2.

For some "single-pit" experiments a Lucite plate 0.14 cm thick containing a small hole 0.07 cm in diameter was bonded to the specimen surface with ethylene chloride. This arrangement gave a small, exposed metal area (0.005 cm^2), so that reasonably accurate pitting current densities can be obtained from the measured current. Regular samples were used in the experiments unless indicated otherwise.

A two compartment, three electrode cell was used. The main compartment contained the specimen and a platinum counterelectrode; a saturated calomel reference electrode was connected to the main compartment by a Luggin capillary. The three electrodes were connected to a Wenking potentiostat in the usual manner.

To measure potential variations inside a pit a microprobe reference electrode was used. It consists of a fine glass capillary (0.005 cm outside diameter) connected by means of a salt bridge to a mercury-mercurous sulfate reference electrode. The microprobe is attached to a three-directional micromanipulator with a resolution of 2.5 μm. The specimen and microprobe can be viewed continuously through a stereomicroscope (7-30X).

The microprobe at any depth x into the pit measures the potential across the metal/electrolyte interface plus any potential drops that exist between that interface and the probe tip. The potential difference $\{E(x = 0) - E(x)\}$ is $\phi(x)$. For the single-pit experiments $x = 0$ is defined as the external surface of the Lucite plate.

The procedure for each experiment was as follows: the specimen was introduced into the empty cell, was properly aligned with respect to the microscope and microprobe, electrical connections were made, the potentiostat was set for a potential in the passive region, and the electrolyte solution was introduced. When a pit became sufficiently large, *i.e.*, its diameter was 5-10 times that of the microprobe, the microprobe was introduced into the pit and the potential measured as a function of distance into the pit and as a function of time. The potentials were measured with an Orion Model 801 *p*H meter and recorded on a Honeywell Electronik 19 recorder. The net anodic current supplied by the potentiostat was also measured on a recorder or oscilloscope.

All experiments, unless otherwise noted, were conducted in air-saturated solutions at room temperature, 296°K. All potentials are reported with respect to the standard hydrogen electrode (SHE).

Table II. Thermal history of iron and stainless steels

Iron	Annealed at 1000°K in vacuum and air cooled
Fe-20Cr	Annealed at 1150°K and air cooled Annealed at 1150°K and quenched in brine
Fe-18Cr-8Ni	Annealed at 1400°K and quenched in brine
304 Stainless	Cold-rolled sheet

Table III. Summary of systems studied

Metal		Solution composition
Fe	(a)	0.5M H_2SO_4, 3 mM NaCl (pH 0.3)
	(b)	0.05M H_2SO_4 0.45M K_2SO_4, 3 mM NaCl (pH 1.85)
	(c)	0.5 mM H_2SO_4, 0.5M Na_2SO_4, 3 mM NaCl (pH 3.9)
	(d)	1M $HClO_4$, 3 mM NaCl (pH 0.1)

Results

The most extensive data were obtained for iron in the sulfate solutions. The potential of the specimens was controlled at 0.85, 1.00, or 1.20V. Initially the current density is greater than 1 A-cm^{-2}, but rapidly decreases to its passive value (between 10^{-5} and 10^{-4} A-cm^{-2} for the different electrolytes). Within minutes the current begins to rise, and sometime later the pits are observed as black specks by *in situ* microscopic examination. As the pits grow, they first appear dull, but then, as if going through a transition,[1] become bright and shiny and one could easily recognize the "polished," hemispherical appearance described in the literature (6, 25).

The behavior of iron in 1M $HClO_4$ is somewhat more complex. At low Cl^- concentrations ($\lesssim 10^{-2}$M) pits usually are not observed until after long times (hours),

[1] In Part II (24) the various stages of pit growth are documented by scanning electron microscopy.

Table I. Composition* of iron and stainless steels

Metal	C	Mn	P	S	Si	Cu	Ni	Cr
Iron	0.004	0.001	0.002	0.006	0.0003	0.014	0.002	0.004
Fe-20Cr	0.014	0.068	0.003	0.005	0.014	<0.01	<0.03	20.2
Fe-18Cr-8Ni	0.001	0.052	0.002	0.005	<0.03	<0.01	9.00	17.7
304 Stainless	0.056	1.93	0.033	0.008	0.46	0.21	9.11	18.6

* Weight per cent.

although anodic current bursts (to be described below) begin much earlier. At higher Cl^- concentrations the specimens frequently do not passivate and either rapid pitting or over-all surface dissolution occurs. The pits go through several stages of growth and eventually attain a well-defined polyhedral shape (24).

For all systems studied (Table III) gas bubbles were found within the pits and crevices, under conditions of applied potential and under natural corrosion (open-circuit) conditions. The formation of gas within the pits is thought to be important to the general mechanism of pitting and crevice corrosion; this is described in detail later.

Transient current behavior.—During pitting of iron in the sulfate solutions [(*a*), (*b*), and (*c*) in Table III] the current exhibits a marked transient behavior (Fig. 3). Although observed for both the regular and the single-pit specimens, the transients are more easily resolved in the latter because the area of nonpit surface and, hence, the base current are very small. The magnitude of the base current and of the bursts increases with increasing Cl^- concentration.

In the $HClO_4$ solution (*d*) the current bursts frequently begin before passivation is complete and well before any pits can be observed. After each burst the current immediately declines to the base value, as repassivation of the activated area occurs. The magnitude of the bursts increases with time and eventually rises as high as several milliamperes. If a particular current burst is associated with a pit nucleus, the local current density must be orders of magnitude higher than that calculated for the total sample area.

The average rate of pit growth, determined on the assumption that the largest pit grew from the time of the departure of the current from the passive value until termination of the test, is 0.2-0.3 A-cm^{-2} for iron in the sulfuric acid solution (*a*) in good agreement with literature values (7). Somewhat higher growth rates were obtained for iron in the $HClO_4$ and Na_2SO_4 (pH 3.9) solutions.

In view of the transient behavior it is clear, though, that the average growth rate is comprised of widely differing momentary rates. This was evident in data obtained for single-pit samples; *e.g.*, in Fig. 3 the peak current density at the highest Cl^- ion concentration is $\gtrsim$ 0.3 A-cm^{-2} whereas the current density between bursts is only about 0.04 A-cm^{-2}. With other specimens current densities as high as 0.7 A-cm^{-2} were obtained.[2]

Potential microprobe measurements.—Potential microprobe measurements were made for regular and for single-pit iron samples in the sulfate solutions. Results were the same with both specimen arrangements. The measured potential E with the microprobe placed near the opening of the pit was the same as that set by the potentiostat. As the microprobe was moved into the pit, the measured potential shifted in the less noble (negative) direction. Typical data for a single-pit iron specimen in the H_2SO_4 solution (c) are shown in Fig. 4. For this solution with its low Cl^- ion concentration strong current bursts are not normally observed. Insertion of the probe to within about 0.02 cm of the pit bottom, however, stimulates pit growth; one observes strong current and matching potential bursts (Fig. 5). In this region of transient behavior, *i.e.*, $x \gtrsim 0.13$ cm

[2] If the response time of the recorder (0.5 sec full scale) is slow relative to the rise time of the current or if the area of pitting has been overestimated, the true current densities may be considerably higher than reported here.

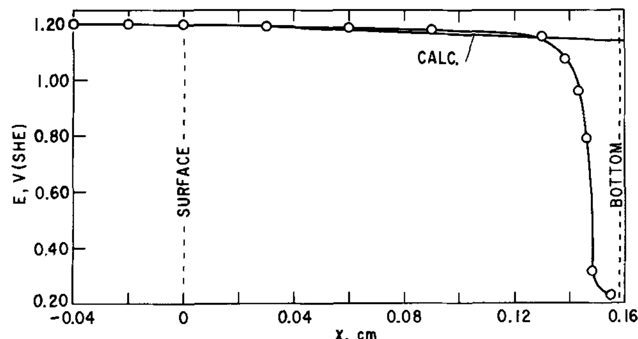

Fig. 4. Plot of measured potential as a function of depth x into the pit for a single-pit iron specimen in solution (c). For $x \gtrsim 0.13$ cm transient behavior is observed; plotted potentials are the least noble ones. Potentials calculated from Eq. [14] and the relation $E(x) = E(x = 0) - \phi(x)$ are given for comparison; i_M is the measured current divided by the area of the hole in the Lucite.

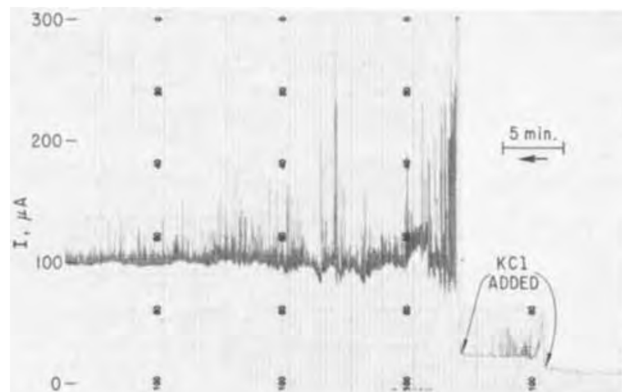

Fig. 3. Segment of the current record for a single-pit iron specimen in solution (c) illustrating transient behavior and the effect of Cl^- on the magnitude of the base current and of the current bursts. Time increases from right to left.

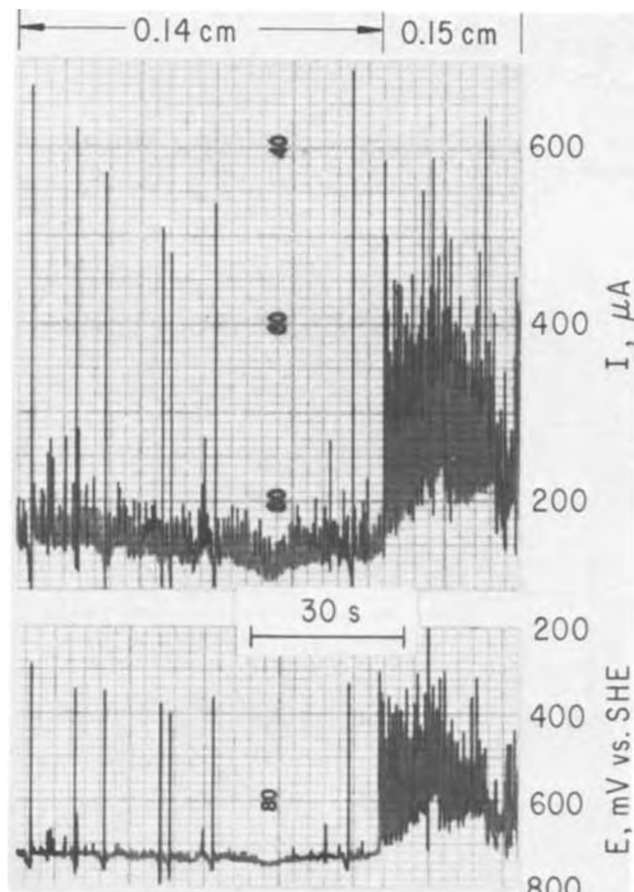

Fig. 5. Segments of the current and potential record for a single-pit iron specimen in solution (c) illustrating that the current and potential transients are in phase.

(Fig. 4), changes in the potential E were observed as great as 0.97V in the less noble direction relative to the potential of the external surface; this corresponds to $\phi = 0.97V$.

In other runs even larger departures of the measured potential from the surface value were observed. The least noble potential measured was $E(x \cong X) = -0.21V$ with the surface held at $E(x = 0) = 0.84V$ in solution (c); this corresponds to $\phi = 1.05V$. Potential variations of this magnitude also were observed with the surface held at 1.20V for the regular and for the single-pit samples in solutions (*a*) and (*c*).

Formation of gas bubbles in the pits.—In situ examination with the optical microscope revealed that for every system studied (Table III) and for both potentiostatic and open-circuit (corrosion) control, gas bubbles formed within the growing pits and crevices (at various interfaces including grain boundaries). For the low *p*H solutions in which visibility was not obscured by corrosion products the bubbles were observed to be in a constant state of rapid motion. For iron in the acidic solutions gas bubbles freely emanated from the pits; this occurred also for the system, Fe20Cr in solution (*g*), which exhibits grain boundary attack. For the other systems the bubbles were observed when the contents of the pit or crevice were disturbed with a glass fiber.

The frequency at which bubbles freely emanated from pits was lower than that of the current and potential bursts (Fig. 5) by about one order of magnitude. The size of an emitted bubble is generally the same as that of the pit from which it comes. In the less acidic solutions corrosion product is sometimes attached to the bubbles as they rise through the electrolyte. This material is left as a residue when the bubbles disappear at the electrolyte surface.

The egress of bubbles occurs over a wide range of applied potential. In one experiment using an Fe20Cr sample in solution (*g*) (*p*H 1.1) the potential E at the external surface was step-changed (with the potentiostat) to less noble values after pitting, grain boundary attack and bubble egress were well established at the initial value of 1.4V. The sample was held at each new potential for a time which was long compared to that of the transient response after switching. The potentials in sequence were 1.4, 0.24, 0.00, −0.10, and −0.20V. At each potential, pit growth and the egress of bubbles were observed. The current and the number of pits from which bubbles emanated decreased as the potential was lowered, indicating that some pits were becoming inactive. However, even at the relatively active potential of −0.20V at least one pit remained active; the current at this potential was 20 μA compared to 3 mA at 0.24V.

A movie of the egress of bubbles from pits was made. A few frames are shown in Fig. 6. Each cluster of white specks (light reflections) represents a pit. In (b) a bubble is just emerging from the (circled) pit. In (c) and (d) it is rising within the electrolyte and is easily recognized by the two, large diffuse spots, one of which is a reflection.

With an iron specimen held at 1.0V in solution (*a*) the emanating gas was collected by placing the flanged end of a Pyrex tube in the electrolyte and over the specimen surface. The gas and some solution were sucked into an evacuated bulb, after which the gas was extracted from the electrolyte and analyzed in a mass spectrometer. A blank (gas extracted from electrolyte which had not been subjected to the corrosion test) was analyzed in an identical manner. The results are given in Table IV. The H_2 content of the test sample greatly exceeds that in the blank. Nitrogen gas is present in essentially the same amount in both samples as it should be for air-saturated solutions. The low O_2 content of the test sample indicates that oxygen is reduced at the specimen surface during the corrosion experiment.

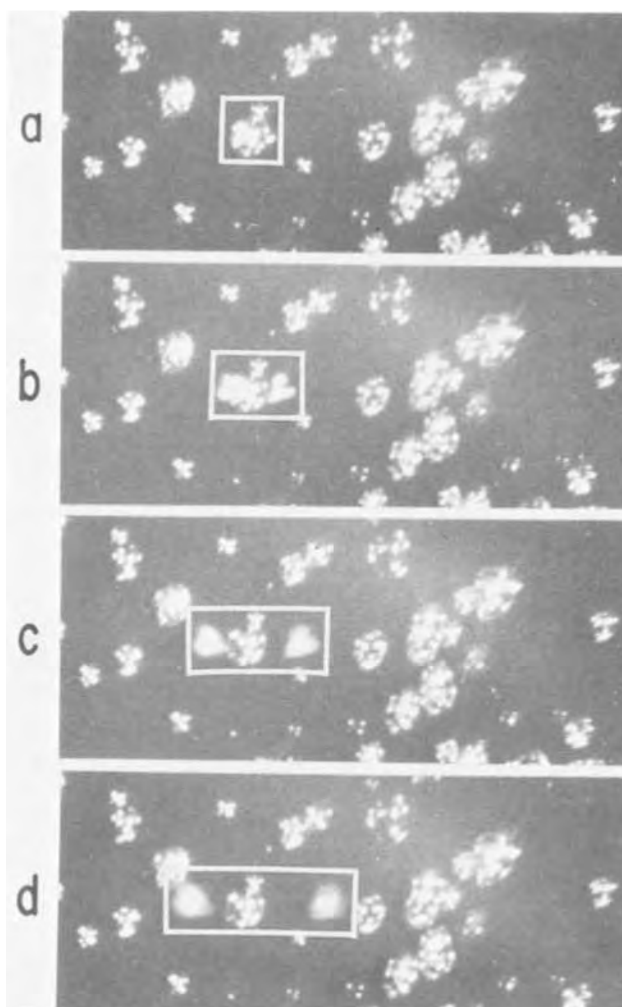

Fig. 6. Four consecutive frames of a movie showing the egress of bubbles from pits in iron in solution (*a*). A bubble (large diffuse spot) and its reflection are shown in rectangular area.

Discussion

In the present experiments, as well as those of Herbsleb and Engell (7), the product $i_M x$ was usually less than 10^{-2} A-cm^{-1}. Under these conditions and in the absence of a solid corrosion product, the variation of the potential ϕ with distance x should be approximately given by Eq. [14] or an analog equation for the particular system under consideration,[3] as depicted in Fig. 2; the maximum ϕ to be expected is of the order of 0.1V, in agreement with other calculations (11, 12). With the single-pit specimens a test of the theory is possible, since the average current density is known. Up to certain values of x the agreement between the measured potential variations and the theory is good, Fig. 4. At pit depths for which the sharp potential bursts were observed, the data do not agree with the theory.

An explanation of the lack of agreement between theory and experiment in the deeper portions of the pit

[3] For semiquantitative purposes Eq. [14] adequately describes the electrical potential behavior for all systems and was used for all calculations in the present paper.

Table IV. Mass spectrometric analysis of gas collected from electrolyte during pitting of Fe, and from fresh (blank) electrolyte (arbitrary units)

	Test	Blank
H_2	110	3.5
N_2	1520	1570
O_2	16	450

seemingly lies in an increased resistance of the electrolyte path, since by the nature of the microprobe experiment the 1V variation in ϕ occurs completely in the electrolyte phase. The resistance, R, of the electrolyte path as a function of distance x may be obtained from experimental data, such as in Fig. 5, using Ohm's law, and is given in Fig. 7 for a single-pit iron specimen in solution (*c*). The resistance in the region $0 < x < 0.14$ cm is at all times in good agreement with calculated values using ϕ from Eq. [14]; the electrolyte resistivity calculated for this region is 8 ohm-cm, whereas that of the bulk solution is 5 ohm-cm. At depths of $x \geqq 0.14$ cm the solution resistance increases sharply. The break in the curve corresponds to the depth at which strong transient behavior began. Over any short period of time, $\lesssim 10^2$ sec, for which the depth X of the pit does not change appreciably $R(x)$ may be obtained from either the peak or the base values of the i and E data; that obtained from the base value is always less than that from the peak value (though still much greater than that extrapolated from $x < 0.14$ cm); the significance of this result is described later. The resistances at $x > 0.14$ cm in Fig. 7 were obtained from the peak values. The source of these high ohmic drops is discussed later.

Active dissolution in pit growth.—The microprobe potential measurements indicate that the potential $E(X)$ at (or near) the bottom of the pit may be as negative as -0.2V, which is in the region of active metal dissolution. The least noble potential possible is the reversible potential of the local metal-electrolyte system plus the overpotential for pit growth by active dissolution. The measurement, however, is complicated by the formation of hydrogen gas, the presence of which leads to possible constriction effects between the pit surface and the gas bubble, and between the bubble and the probe.[4] Since the presence of the bubble prevents insertion of the probe into regions of close approach of the bubble with the pit surface, the least noble electrode potential within the pit may be more negative than the least noble measured value.

The evolution of hydrogen gas from the pits, crevices, and grain boundaries under conditions of applied potential and under natural corrosion conditions indicates that the potential at the bottom of these local cells must be more negative than the reversible hydrogen potential, which is < 0.0V since the pH is > 0.0 for all systems. This is further evidence that the potential of the dissolving surface is in the region of active metal dissolution for all types of local cell corrosion studied. In Part II (24) an analysis of scanning electron micrographs also indicates that localized corrosion processes occur by active dissolution.

[4] The constriction between the bubble and the probe cannot be the source of the large measured ϕ since negligible current flows in this region.

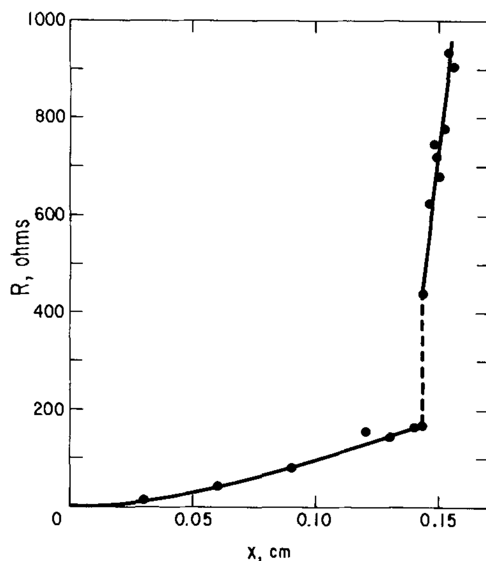

Fig. 7. Plot of the resistance of the electrolyte obtained from the measured current and potential as a function of depth x for a single-pit iron specimen in solution (c).

Role of hydrogen gas in pit and crevice growth.—Although the data strongly support the conclusion that pit and crevice growth occur by active metal dissolution, it remains to be explained how a potential as low as ~ -0.2V is attained at the bottom of the pit or crevice when the potential across the interface at $x = 0$ may be as noble as $+1.4$V; *i.e.*, the cause of IR drops as large as 1.6V. The simple pitting model shown in Fig. 1, as well as any of different geometry or any involving other electrochemical reactions such as hydrolysis of the cations, are inadequate to account for this result. Existing models of pit and crevice growth are also inconsistent with the break in the plot of measured potential and resistance as a function of distance x (Fig. 4 and 7). This includes the pitting model in which a large potential drop across a surface film has been postulated by Franck (6); in the present experiments the measured potential variation is totally within the electrolyte phase, as demonstrated in the data of Fig. 4 and 7, in which the break in the plots occurs well above the bottom of the pit.

The presence of a gas bubble at the bottom of the pit (or crevice) provides an explanation for the large measured ohmic drop. A constriction most likely exists between the bubble and the pit surface, Fig. 8. Since this constriction is a path of current flow, a large *IR* (ϕ) is obtained by virtue of the high current density in this region. In this way a high ϕ is obtained within the electrolyte phase without a significant increase either in the resistivity of the electrolyte or in the local rate of metal dissolution. For somewhat smaller potential variations (< 0.35V) during pitting on aluminum, Masing and Altenpohl (22) proposed that gas bubbles at the mouth of the pit produced a high resistance path. In the present study the high resistance path must clearly be at the bottom of the pit.

The sharp potential fluctuations may be related to the observed continual motion of the bubbles within the pits. Movement of a bubble results in (momentary) relief of the constriction at any particular site which in turn results in a shift of the local electrode potential to more positive values. "Relaxation" of the bubble to its former position restores the constriction allowing again for a more negative potential at this site, followed by relief of the constriction, etc. The lower resistance calculated from the base than from the peak values of the current and potential data is in agreement with a variable constriction effect. Repassivation at a particular site within the pit is unlikely, since the time between occupancies by the bubble is much less than the 10^3-10^4 sec (26, 27) required for complete passivation. Bubble motion may be related to ionic transport in and out of the constricted region, to local

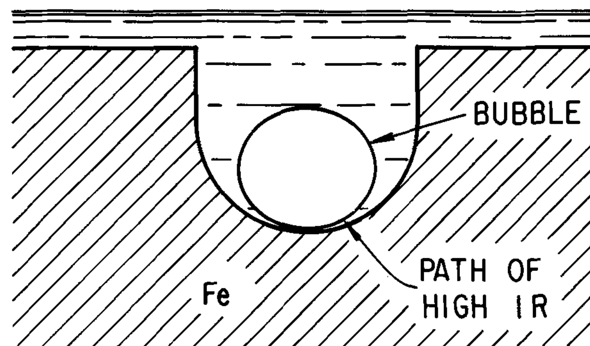

Fig. 8. Schematic of a pit illustrating a high-resistance electrolyte path caused by a bubble.

heating of the electrolyte solution, or to discontinuous growth of the bubble. Discontinuous growth of bubbles has been reported during hydrogen discharge on platinum by Ludwig and Yeager (28).

The formation of a second bubble after egress of the first was always observed to occur with a rather regular frequency and for the duration of the applied potential. This may be an indication that a "tail" of the emitted bubble functions as the nucleus of the next bubble. Such a process has been observed by Green (29) using high-speed photography for the largely different conditions of very high rates of hydrogen discharge on palladium.

The gas has been identified as hydrogen for the pitting of iron. No attempt at identification has been made for the stainless steels since there is no reason to expect a different gas at the measured potentials.

The fact that the gas is hydrogen may be important because its formation causes a decrease in the local H^+ concentration which tends to balance a momentary surge in cation concentration. Hence the maintenance of electroneutrality within the pit is aided by the formation of hydrogen gas. The tendency for the concentration of hydrogen ions within the pit in general to decrease is shown in Eq. [17].

We deduce from the above considerations that pit growth occurs by active dissolution of the metal, and that the electrode potential of the pit surface is controlled by a constriction within the pits which, in the general case, is hydrogen gas. Inclusion of a constriction as a basic element in the pit-growth process is appealing since a high ϕ value can be obtained at relatively low currents.

Other forms of constriction.—It does not necessarily follow, though, that hydrogen bubbles are always the source of the constriction or that a constriction is always necessary. For example, at less noble surface potentials, at which lower ϕ (IR) values are required to shift the potential into the region of active dissolution, pores of a solid reaction product are a potential form of constriction.

For still smaller differences between the potential at the external surface and that at the bottom of the local cell the need for a constriction vanishes. This happens when the resistance of an unobstructed column of electrolyte within a pit or crevice is sufficient (for the given current density) to shift the electrode potential into the active region. Then the concentration and potential profiles given by Eq. [13], [14], [17], and [18] (or their analogs for the particular system under consideration) should approximately apply for not too large $i_M x$ values at all distances x into the pit.

Pit initiation.—The model in Fig. 8 and the above discussion pertain only to propagation of a pit, *i.e.*, the necessary conditions, including the presence of a gas bubble at the bottom of the pit, are presumed to have been established by "nucleation" events. Such events include the "breakdown" of the passivating film, the subsequent surge of current which quickly subsides as a result of polarization effects and the simultaneous or subsequent nucleation of a hydrogen bubble. Bubble nucleation requires that a potential in the region of hydrogen evolution is established at least momentarily by means other than the bubble-constriction effect. One possibility is that the initial (transient) current density at the site of film breakdown is much higher than those measured during pit growth.

The data indicate that very high momentary currents do occur in the form of (*a*) initial current densities of at least 2 $A\text{-cm}^{-2}$ and (*b*) the occurrence of isolated current bursts (ranging up to more than 1 mA) at the initial stage of pitting when the general surface is completely passivated. The peak currents in (*b*) seemingly yield very high current densities since the area associated with film breakdown must surely be very small. In addition Franck (30) has measured transient current densities between 10 and 20 $A\text{-cm}^{-2}$ for iron in 1*N* H_2SO_4. In view of these considerations there appears to be no need at the present time to postulate some other form of constriction for nucleation of a hydrogen bubble within a pit embryo.

Conclusions

By direct measurement with a microprobe of the potential changes within the electrolyte and by the observation of gas, identified as hydrogen, within the pits and crevices, it is established that the potential across the interface of the dissolving surface within pits in Fe is in the active region of iron dissolution. The same is concluded for ferritic and austenitic stainless steels since gas bubbles were also regularly observed within pits and crevices (at various interfaces including grain boundaries) in these steels. Hence for iron and austenitic and ferritic stainless steels in numerous electrolyte solutions ranging in pH from 0.1 to 6 and under conditions of applied potentials as high as +1.4 and as low as −0.2V and under open-circuit (natural corrosion) conditions, pit and crevice growth is believed to occur by active metal dissolution.

The potential, ϕ, in the electrolyte phase within the pit accounts for the difference in measured potential between the pit bottom and the external (passive) surface. The magnitude of ϕ increases to $\phi > 1V$ when the applied potential is about 1V (SHE) or higher; ϕ, however, is not steady at this magnitude but peaks in a rather regular fashion. The pitting current or rate of pit growth peaks in phase with ϕ. As a result, the instantaneous rate of pit growth varies over a wide range.

The presence of hydrogen gas, the large increase in potential in the electrolyte, and the transient behavior are features which are not adequately accounted for in any previously existing model of pit or crevice growth. A model of local cell corrosion is presented which includes a high resistance path to current flow; in many cases this path may be the constricted region between a gas bubble and the pit or crevice surface. The large ϕ can be accounted for by high local current densities in the constricted region. Motion of the gas bubble can account for the transient behavior.

On the Mechanism of Localized Corrosion of Iron and Stainless Steel

II. Morphological Studies

Edgar C. Bain Laboratory For Fundamental Research, United States Steel Corporation Research Center, Monroeville, Pennsylvania 15146

ABSTRACT

The initiation and growth of pits on iron and of crevices and pits on stainless steels in numerous electrolyte solutions, both under potentiostatic and under natural corrosion conditions, have been studied by scanning electron microscopy. The pit morphology on iron is controlled primarily by solution composition: in sulfate-containing solutions the pits are initially crystallographic, but then become polished; in nonsulfate-containing solutions they always remain crystallographic. On stainless steels the pit morphology is determined by solution composition and by the nature of the initiation site; it depends only secondarily on alloy composition. In stainless steels, both austenitic and ferritic, crevice corrosion is the prevalent corrosion form; pitting is initiated only at significantly higher potentials. The results are in agreement with an electrochemical study that showed that the potential across the interface in all local corrosion cells is in the active part of the anodic polarization curve of the metal and that pits and crevices propagate by the same mechanism.

In another paper (1) we discuss the mechanism of pit and crevice propagation on iron and stainless steel as deduced from potential measurements within pits and from the presence of H_2 bubbles in pits and crevices. It is shown that the potential across the interface of the dissolving surface is in the active region of the anodic polarization curve of the metal even when the passivated surface is at a potential more than 1V more positive (noble). The potential difference between the dissolving surface of the local cell and the passive surface of the metal is deduced to be an IR-drop resulting from a high-resistance constriction between the H_2-bubble and the pit bottom. It is concluded that pits and crevices propagate by the same mechanism in all systems studied.

In this paper pits and crevices are examined by scanning electron microscopy (SEM). Observations on their initiation and growth on iron and stainless steels in a variety of electrolyte solutions are related to the mechanistic conclusions in Part I (1). The conditions for pitting and crevice corrosion are discussed for potentiostatically controlled and for natural (open-circuit) corrosion.

Few studies have been conducted on the morphology of corrosion pits and on how the morphology changes with time and corrosion conditions. The subject has been briefly reviewed by Schwenk (2), Hoar (3), and Szklarska-Smialowska (4). Additional studies include those by Ashworth *et al.* (5) on the pitting of mild steel in chloride-containing basic solutions, by Vetter and Strehblow (6) on the pitting of iron in potassium acid phthalate (KHP) buffers containing chloride and a combination of chloride and sulfate, by Bianchi *et al.* (7) on pitting of stainless steel under potentiostatic and under chemically controlled conditions, and by Janik-Czachor (8) on the pitting of iron in a borate buffer containing chloride.

Many studies have been made to determine the nature of sites at which pits are initiated. The subject has been reviewed by Szklarska-Smialowski (4). It appears that the sites are very much a function of the metal (its structure and composition), the composition and distribution of inclusions and other phases, and the corrosion conditions; no generalizations can be made.

Experimental

The systems studied (Table I) are the same as those described in Part I (1), in which the specimen composition, heat-treatment, preparation, experimental arrangement, and procedures are also given.

The specimens were held by means of a potentiostat at a potential which in the absence of Cl^- would be in the passive range. However, all the solutions, with the exception of the 10% $FeCl_3$ and the 3% NaCl, were

sufficiently dilute in Cl^- so that the specimens passivate at least partially before the onset of pitting; even in the $FeCl_3$ and NaCl solutions localized corrosion is observed. The experiments were conducted in air-saturated solutions at room temperature. All potentials are reported relative to the standard hydrogen electrode (SHE).

The natural corrosion experiments were conducted under identical conditions, except that no potential was applied.

The scanning electron micrographs were taken in stereo with a Cambridge Stereoscan microscope. It is essential to examine the micrographs in stereo to understand fully the processes that occur; a monocular examination misses many important factors. An x-ray spectrometer attached to the microscope permits elemental analysis of selected areas of the specimen being viewed, *e.g.*, reaction-product films or inclusions.

Results and Discussion

Two types of localized corrosion (pitting and crevice corrosion) have been studied (Table I). On iron, pitting is the prevalent corrosion form. In the stainless steels crevice and pitting corrosion are observed; the extent of each depends on the potential regardless of how it is applied, *i.e.*, potentiostatically or by a chemical redox couple under natural corrosion conditions.

We will first treat potentiostatically controlled localized corrosion for both iron and the stainless steels and then discuss natural localized corrosion for the stainless steels.

Potentiostatic control.—For iron in all of the solutions pitting only is observed, except when poor contact between the metal and the metallographic mount causes crevice corrosion.[1] On the other hand, for the stainless steels crevice corrosion is the prevalent corrosion form; for example, for Type 304 stainless steel in 0.05M H_2SO_4 + 0.5M NaCl, crevices are observed at potentials below 0.2V, whereas pits are seen only above 0.8V. It is evident that crevice corrosion is easier to initiate and/or propagate than pitting. As may be seen below, the same is true under natural corrosion conditions.

The appearance and the morphology of the pits and crevices depend in a complex manner on the composition of the electrolyte, the presence of inclusions and other phases in the metal, and its composition. We will first discuss pit formation and growth in iron and then in the stainless steels.

Iron.—Pit initiation appears to be random; no attempt has been made to determine pit density as a function of crystallographic orientation.

Initially in all systems (Table I) simple crystallographic pits are formed; *i.e.*, pits bounded by crystallographic planes (Fig. 1). Their growth thereafter is a function of solution composition. In sulfate solutions the pits become hemispherical with the walls of the pits honeycombed by crystallographic planes (Fig. 2); the transition from the initial stage to this one is not understood. As the pits continue to grow, polishing begins at the bottom of each pit and progressively moves up the walls until they are smoother than le derriere d'enfant (Fig. 3). SEM studies of the surfaces of these pits show no visible structure at 10,000X magnification, indicating that any steps must be less than 20 nm (200Å) in height. It is these smooth, bright, hemispherical pits that are generally described in the literature, *e.g.*, Ref. (3 and 9). The reasons for the transition from the faceted structured to the polished one is discussed below.

In perchloric acid solution two different growth paths have been observed (Fig. 4-7); in both paths the pit walls maintain their faceted structure and polishing is never observed. In the first path (Fig. 4 and 5) the simple crystallographic pit continues to grow with the same planes developing continuously; the pit crosses grain boundaries, but maintains its relatively simple structure. The other path (Fig. 6 and 7) results in a spongy, porous structure, the growth of which requires further investigation. In this path, growth also proceeds by the dissolution of crystallographic planes; even the spongy, porous structure is bounded by facets.

In the KHP solution containing no sulfate, pit growth proceeds in a manner similar to the first path

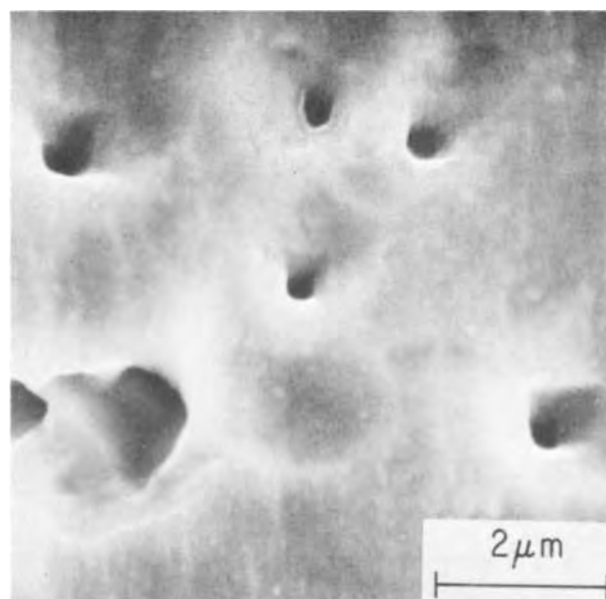

Fig. 1. Crystallographic pits that are typical of initial stage of pitting of iron in all solutions.

[1] In this study the metal/metallographic-mount interface formed a natural crevice.

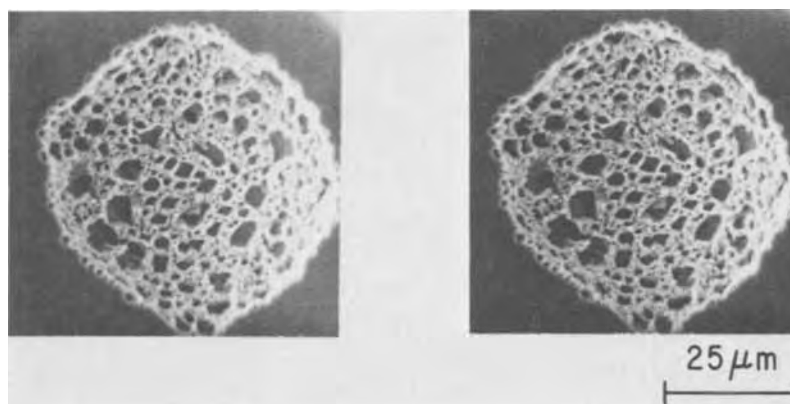

Fig. 2. Stereo pair. Intermediate stage of pitting on iron in sulfate solutions, showing nearly hemispherical pit with honeycomb cells; honeycomb cells are bounded by crystallographic planes. Solution *(a)*; potential held at 0.85V.

in perchloric acid solution. In the KHP solution containing sulfate, the initial, faceted structure vanishes as rounding and some polishing occurs, similar to that described for the sulfate solutions. Vetter and Strehblow (6) have also studied this system and reported similar observations.

It has frequently been stated, *e.g.*, Ref. (3), that pits in iron, stainless steel, and other metals are not crystallographic, but hemispherical and polished. These data show this not to be so. Rather, the shape and morphology depend on the composition of the electrolyte solution.

Crystallographic morphologies are observed at all stages of pitting in sulfate-free solutions (Fig. 4-7) and during the early stages in sulfate-containing solutions (Fig. 1 and 2). This is expected (10, 11) when anodic dissolution of a metal surface occurs under film-free conditions in the active potential range of the anodic polarization curve, *i.e.*, when Tafel behavior is observed. Indeed, faceting occurs under these conditions during the dissolution of Fe in H_2SO_4 and in $HClO_4$ solutions (Fig. 8); similar results are observed in HCl solution. Microprobe potential measurements (1) show that the potential across the interface of the dissolving surface of a pit is in the active region, even when the potential of the specimen surface is maintained in the passive region. Thus crystallographic pits are expected to form if film-free conditions are maintained.

Smoothing and brightening of the surface, as observed for pits at later stages of growth in sulfate solutions (Fig. 3), is not characteristic of Tafel behavior, but is indicative of a mass-transport controlled reaction, *e.g.*, diffusion in the electrolyte (12). Diffusion-limited anodic dissolution of iron in H_2SO_4 is observed in the potential range from -0.1 to $+0.5$V, the current density being about 0.2 A/cm^2 (13-15); the diffusion-limited current density results from the formation of a ferrous sulfate film (14). Our measurements (1) indicate that the potential and current density within pits on iron correspond closely to these values; the polishing of the pits agrees with these facts. The pits initially form with a crystallographic morphology presumably because time is required to form the ferrous sulfate polishing film. The transition from the crystallographic morphology to the polished one begins at the bottom of the pit and moves upward to the rim (Fig. 3), inasmuch as the solution is most concentrated in ferrous and sulfate ions at the bottom (1), and hence film formation is initiated there.

The crystallographic morphology is maintained in the other solutions indicating that a polishing film does not form. This is consistent with the anodic polarization curves for iron in the different solutions and

with the solubility products of the various salts. Although a diffusion-limited current is observed in the active region for iron in H_2SO_4 (9, 14) none is found for iron in the other solutions, *e.g.*, Fig. 9;[2] the solubility products of the various ferrous salts (Table II) indicate that hydrated ferrous sulfate is the least soluble.

Stainless steels.—Within the confines of this study, the various stainless steels behave similarly; hence they are considered as a group. Also the results in the different solutions are essentially the same, unless indicated otherwise. As stated above crevices are the prevalent corrosion form. They start at the interface between the steel and the metallographic mount, propagate under the surface of the steel, and eventually penetrate the surface from underneath (Fig. 10). It is reasonable to conclude that crevices propagate by the same mechanism as pits, since the potential across the interface of a dissolving surface in a crevice is also in the active part of the anodic polarization curve of the metal (1).

Pits are usually not initiated at potentials below 0.7V;[3] most of the pitting studies were conducted at

[2] At low current densities (see insert, Fig. 9) the Tafel relationship is obeyed. At high current densities ohmic control exists, as evidenced by the linear *E-i* relationship. Passivation occurs at 0.55V, the same potential at which it occurs in H_2SO_4.

[3] This is an approximate value, the potential varying with solution composition. No effort was made to determine whether a critical pitting potential exists and, if so, what it is.

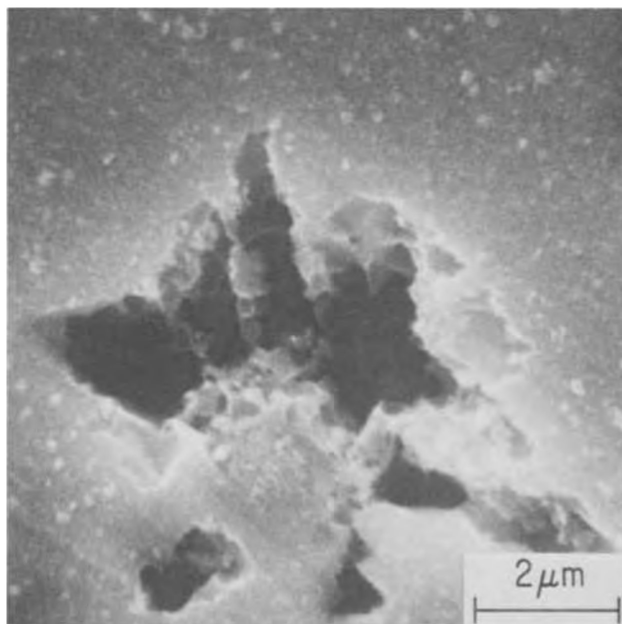

Fig. 6. Intermediate stage of pitting on iron in $HClO_4$ solution (path 2, see text), showing highly complex growth pattern. However, walls of pit are faceted. Solution *(d)*; potential held at 0.84V.

μm in diameter, are similar to those observed on Fe. These pits are not associated with inclusions. The small ones are crystallographic (Fig. 11a) and are observed to form in each solution. The larger ones (Fig. 11b) are observed only in solutions containing sulfate. It appears that, though rounded, these do not undergo polishing, presumably because the $Cl^-:SO_4^{=}$ ratio of 10:1 is too great to permit supersaturation of the solution with ferrous sulfate.

The second type of pit, the most common one and that normally observed in the optical microscope, is initiated at inclusions in the matrix (Fig. 12a)[4] and is not observed to be crystallographic. From the study of stereomicrographs of many pits, it is believed that each pit grows radially under the metal surface away from the inclusion; further surface penetration comes from underneath, giving rise to the lace-like structure that spreads away from the inclusion (Fig. 12b, 13). Stereo examination of these micrographs indicates that the external surface of the lace-like cover is smooth except for the small holes, and that the underside is rough, indicating that this structure is the result of dissolution from within the pit. As the pit grows the cover eventually is completely dissolved, leaving a large open pit, the bottom of which is normally rough with occasional evidence of faceting. Similar observations have been made by Streicher (17) and by Rosenfeld and Danilow (18), but they did not associate the initiation of these pits with inclusions.

The pits associated with inclusions and crevices appear to propagate in a similar manner and presumably by the same mechanism (1); they grow to almost any size, while those pits not associated with inclusions become repassivated early in their history. One explanation of this difference is that enhanced diffusion and convection in the more open, inclusion-free pits prevent the solution from becoming sufficiently concentrated in Cl^- and/or H^+ to sustain pitting; thus repassivation occurs. Conversely repassivation is less likely to occur in the covered pits and crevices. In addition, their highly concentrated solutions could be responsible for the absence of crystallographic structure because a viscous layer or a precipitate that limits the rate of dissolution may form.

[4] X-ray microanalysis indicates that the inclusion seen in Fig. 12a contains Mn, Cr, Ti, and Al.

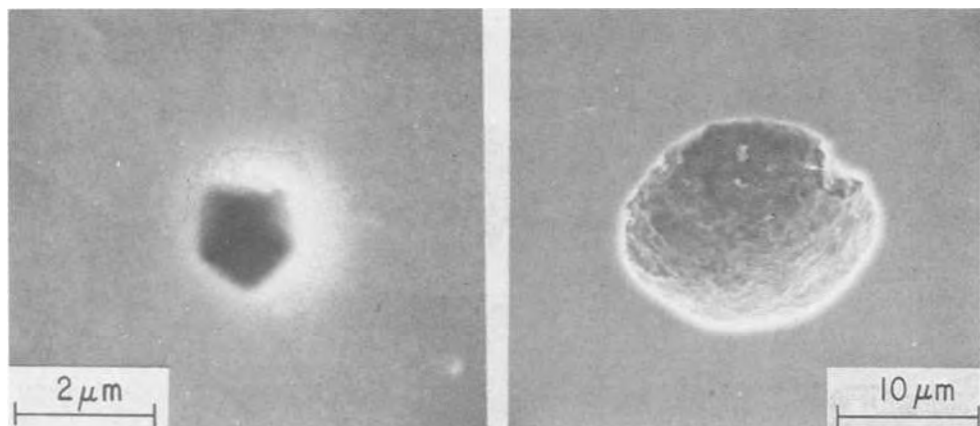

Fig. 11. Examples of pits not associated with inclusions found on stainless steel. (a, left) Crystallographic pit that is typical of initial stage of pitting in all solutions. (b, right) Intermediate stage, showing that pit has grown under the surface and finally penetrated from underneath, producing lace-like cover over pit. Solution *(i)*; natural corrosion.

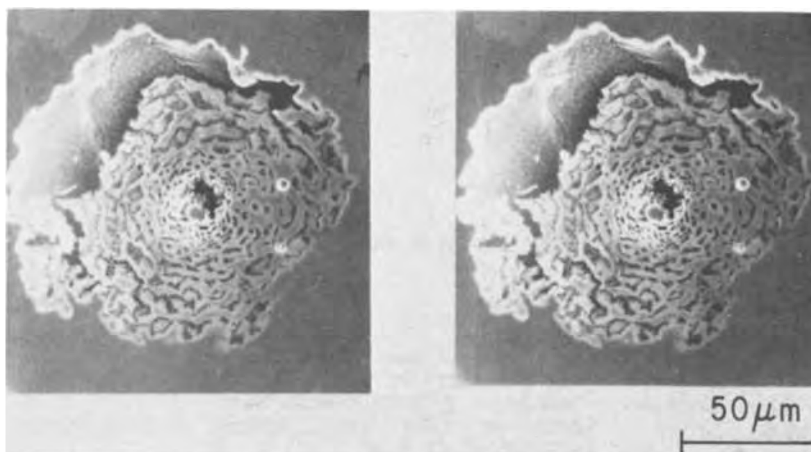

Fig. 13. Stereo pair. More advanced stage of pitting in stainless steel initiated at an inclusion, showing how pit has propagated under and penetrated through the surface from underneath; during last stage of growth lace-like cover dissolves exposing entire pit. Solution *(g)*; potential held at 1.0V.

Natural corrosion.—Iron becomes active when immersed in a solution of $Fe_2(SO_4)_3$ containing a trace of Cl^-, even though this solution has a redox potential of 0.9V (as measured on an inert electrode) which is in the passive region of iron; the reason is that Fe^{+++} reacts with the iron to form Fe^{++}, thereby polarizing the iron to a potential in the active region. Stainless steels, on the other hand, do not activate under these conditions. Thus our studies were confined to the stainless steels, with most experiments conducted on Type 304.

The results indicate that the corrosion potential is the main factor controlling the type of local cell that is initiated, similar to the observations for potentiostatically controlled corrosion. In those solutions in which the corrosion potential is low, only crevice corrosion occurs. For example, when the steel is immersed in a solution of $Fe_2(SO_4)_3$ containing some Cl^- (pH 1; redox potential, 0.9V) the initial[5] corrosion potential is 0.6V and rapidly falls to 0.3V or less; only crevice corrosion is observed. However, when H_2O_2 is added, the corrosion potential jumps to 0.7V and pits develop (Fig. 12b). In a NaCl solution in which the steel exhibits a low corrosion potential, only crevice corrosion is observed. But in acidified $FeCl_3$ solution in which the corrosion potential is initially above 0.7V, both pitting and crevice corrosion occur; the pits generally are bounded by crystallographic facets and remain small, similar to those discussed above and shown in in Fig. 11a. The pits at inclusions were not observed in the $FeCl_3$ solution, the reason for which is not clear. Crevices that form under natural corrosion conditions have the same appearance as those that form under potentiostatic conditions. Thus the propagation mechanism is most likely the same.

[5] Measured about 2 sec after immersion.

Conclusions

The pitting of iron and the pitting and crevice corrosion of stainless steels have been studied under potentiostatically controlled and under natural corrosion conditions. The morphological studies on iron are consistent with the previous conclusion (1) that the potential across the interface of the dissolving surface inside the pit is in the active part of the anodic polarization curve of the metal, even when the potential across the interface of the passivated surface is more than 1V more positive. The surface morphology of the pit is controlled by the composition of the electrolyte solution. If a rate-limiting film can form within the pit, *e.g.*, in sulfate solutions, a pit initially bounded by crystallographic planes will become hemispherical and polished. However, if a film does not form, *e.g.*, in perchlorate solution, the pit will remain bounded by facets, similar to those observed during active anodic dissolution of bulk specimens.

For the stainless steels it has been shown that crevice corrosion is the prevalent form of corrosion and that pitting can be initiated only at relatively high potentials. The results are the same for ferritic and for austenitic alloys, for the numerous electrolyte solutions used, and for potentiostatic and for natural corrosion conditions. The propagation of most pits and crevices appears to be controlled by the same factors. Most pits in stainless steels, but not all, are initiated at inclusions. They grow under the surface away from the inclusion and eventually penetrate the surface from underneath. Pits not associated with inclusions do not grow to an appreciable size, presumably because the entire pit cavity is exposed to the bulk solution and mixing of the solutions facilitates repassivation.

Acknowledgments

We gratefully acknowledge the contributions of Mr. C. E. Brickner and Mr. W. Gundaker who performed the scanning electron microscopy, Mrs. P. J. Byrne who prepared the specimens and assisted with other aspects of the work, and discussions with Dr. J. L. Bomback, all of this laboratory.

Optical Properties of Chromium-Plated Steel

R. F. Hoeckelman*

United States Steel Corporation, Research Laboratory, Monroeville, Pennsylvania 15146

ABSTRACT

The color and the reflectivity of the chromium-plated steel product now being used in the manufacture of containers were examined. A 45-degree Gardner glossmeter was used to determine specular reflectivity and a General Electric Spectrophotometer was used to determine diffuse reflectivity and color in terms of tristimulus numbers and corresponding chromaticity values. Chromium-plated steel with a low level of surface oxides has a blue hue and greater specular and diffuse reflectivity than the unplated steel base. As the chromium oxide level increases, the blue hue decreases and the surface acquires a golden-tan hue. The specular reflectivity decreases with an increase in chromium oxide level and varies with the angle of illumination with respect to the steel rolling direction. The diffuse reflectivity likewise decreases with an increase in the chromium oxide level. There is a linear relationship between the oxide level and the sum of x and y chromaticity values. When chromium-plated steel was coated with a translucent lacquer, the hue of the product still varied in accordance with the hue of the original steel. Heating the chromium-plated steel in air increased the oxide level and the $(x + y)$ chromaticity value. From the data obtained in this study it would appear that the rate of surface oxidation of the chromium metal upon being heated in air at 260°C is 11 mg Cr/m^2 hr (1.0 mg Cr/ft^2 hr).

Chromium-coated steel is being used as an alternative to tin-plate for making cans for beer, beverages, and some foods. Light-gauge steel (0.006 to 0.011 in. or 0.152 to 0.279 mm thick) is electroplated with chromium to a thickness of about 7.6 nm (5 mg Cr/ft^2) and has a surface oxide about 7 to 20 nm thick containing 0.4 to 1.4 mg Cr^{+3}/ft^2. To minimize scratching and to facilitate handling, a light oil film about 5.1 nm thick (0.25g per base box) is applied to the material. This product, known in the industry as tin-free steel chromium-type (TFS-CT), cannot be soldered; but new methods (welding or cementing) of side-seam construction in manufacturing have made the use of chromium-plated steel for containers practical.

A bright, uniform metallic appearance is a desirable feature of chromium-plated steel. The lustrous metal beneath the semitransparent lacquers often used on beer and beverage cans lends eye appeal and enhances product recognition. However, examination of various lots of material shows that chromium-plated steel has a range of color, texture, and luster. Thus, to provide information as to the possible cause of these variations, the reflectance and the color of various TFS materials were determined and the results compared with other properties of the material. When TFS-CT is heated and lacquered, as in the usual can-making operations, the optical properties change; thus, the degree of color change with heating and lacquering was likewise determined.

Materials and Experimental Work

Chromium-plated steel was obtained from various sources: commercial product, experimental material produced on pilot-line equipment, and individual specimens prepared as stationary cathodes in bench-scale plating baths. Some specimens of chromium-plated steel were made by a one-step process; that is, the chromium metal and the surface coating of oxide were deposited simultaneously in one electroplating operation. Other specimens were prepared in two steps; the metallic chromium was deposited in one operation and the chromium oxide in a second operation. For the heating and lacquering experiments, chromium-plated specimens were prepared on bench equipment

Key words: color, tin-free steel, chromium oxide, spectrophotometry.

with the same steel base to ensure uniformity of the steel surface.

To determine the optical properties of the steel base, the specimens were treated to remove the oxide films normally present. The steel surface was cleaned by degreasing, pickling in 10% sulfuric acid solution at room temperature for one minute, rinsing in water, pickling in 5% citric acid at room temperature for one minute, rinsing with an organic solvent such as acetone or methanol, and drying in a hot air stream. For certain measurements, the chromium oxide coating on the TFS-CT was removed by immersion in a 10*N* solution of sodium hydroxide at 195°F (89°C) for 10 min followed by cold-water rinsing and drying in a stream of hot air.

In the experiments concerning the effect of heating on the optical properties of TFS-CT, a laboratory oven was used for room-atmosphere tests, and a tube furnace was used for tests with nitrogen and nitrogen-hydrogen atmospheres. No attempt was made to further purify the bottled gas obtained from a commercial supplier.

The optical properties of lacquered TFS-CT were also determined. The type of lacquer used, the coating weights, and the curing conditions are shown in Table I.

The optical measurements were made with a Gardner Laboratory 45-degree portable glossmeter GG-9020 (P-45), and a General Electric Spectrophotometer, Catalog No. 7015E30G, was used to measure the color of TFS-CT specimens by reflected light in the visible region of the spectrum. The color of the diffuse reflected light was determined after the specular reflection was adsorbed on a black surface. The spectrophotometer gave two outputs, a graph of per cent reflectance *vs.* wavelength of light from 380 to 700 nm, and a computation of the tristimulus values *X*, *Y*, and *Z*. These tristimulus numbers are based on a system chosen by the International Commission on Illumination so that all the spectral colors could be matched by positive amounts of three theoretical primaries (1). The light source used in the spectrophotometer was the standard CIE Source C as described in the ASTM Designation, E308-66 (2).

Results and Discussion

Several factors influence the appearance of chromium-plated steel. Variations in surface roughness can cause changes in the distinctness of image and the ratio of the coefficients of specular to diffuse reflectivity. If the surface becomes covered with oxide, oil, or foreign matter, the over-all luster will be affected. For example, specular gloss of sheet steel varies with the angle of illumination to the rolling direction, and with chromium oxide weight, as shown in Fig. 1. Chromium-coated steel with an oxide coating containing less than 0.16 mg Cr^{+3}/dm^2 (1.5 mg Cr^{+3}/ft^2) is more reflective than the cleaned steel surface; but as oxide coating weight increases, the specular reflectivity decreases.

The diffuse reflectivity of TFS-CT, represented by the *Y* tristimulus value measured by the spectrophotometer, is shown in Fig. 2. The diffuse reflectivity also decreases with an increase in oxide coating weight. The specimens tested for diffuse reflectivity, Fig. 2, are portions of the same samples tested for specular reflectivity and shown in Fig. 1. These samples were prepared by using a single sheet of steel, and measurements of the optical properties of only one surface are shown. Measurements of reflectivity of the obverse surface show quite different results because the surface roughness differs.

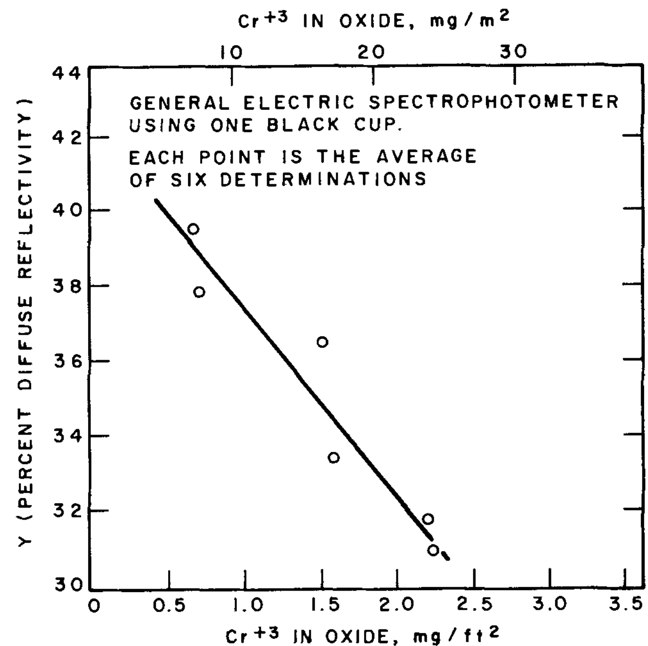

Fig. 2. Diffuse reflectivity of TFS-CT of varying oxide coating weights.

Table I. Lacquer used on TFS-CT

Type of lacquer	Color	Weight of coating,* mg/8 in.^{2} (mg/0.0052m^2)	Curing time, minutes	Curing temperature, °F (°C)
Epoxy amine	Colorless	17.9	8	375° (190°)
Polybutadiene	Gold	37.0	10	400° (205°)
Epoxy	Gold	18.4	10	400° (205°)

* All panels were dip-coated.

Color of TFS-CT and correlation with oxide coating weight.—The diffuse reflectivity varies with the wavelength of visible light, as shown in Fig. 3. The standard white ceramic Vitrolite reflects much more light than the metal surfaces, and, consequently, the metals ap-

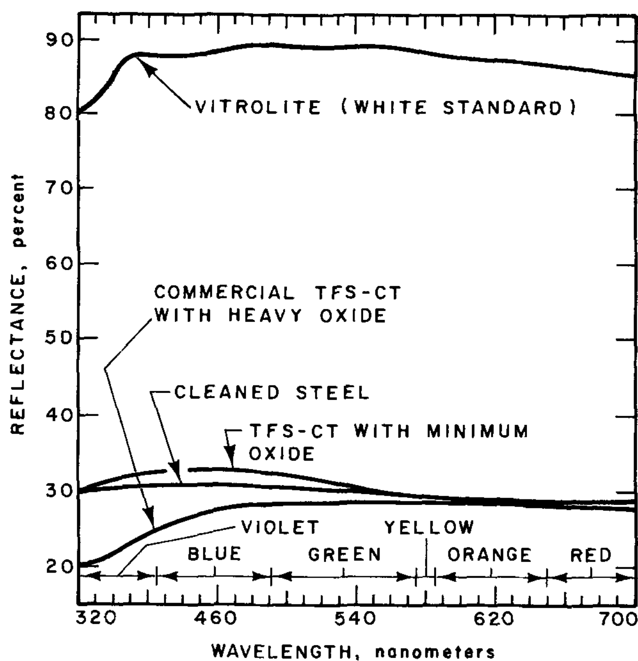

Fig. 3. Diffuse reflectance as a function of wavelength

pear gray rather than white. Steel reflects about the same amount of light at all wavelengths and has the neutral gray color. Metallic chromium has peak reflectivity in the blue region of the spectrum, whereas chromium covered with a heavy oxide coating has depressed reflectivity in the blue region. Metallic chromium, therefore, has a bluish tint, and TFS-CT with heavy oxide on the surface appears golden tan. Gardam (3) has reported on the colors of metals and alloys and has found chromium to be one of the bluest of metals.

The values of the reflectivities can be integrated over the visible spectrum to give the tristimulus numbers as described by Clydesdale and Francis (4). These numbers specify quantities of red, green, and blue primary colors making up the color of the specimen. The tristimulus numbers can be converted into chromaticity values as follows

$$x = \frac{X}{X + Y + Z} \quad y = \frac{Y}{X + Y + Z}$$

where X, Y, and Z are tristimulus numbers and x and y are chromaticity values. A chromaticity diagram, Fig. 4, shows the locus of chromaticity values for the various TFS-CT samples clustered about the illuminant point, an indication of low intensity of color. Figures 5 and 6 show chromaticity diagrams of TFS-CT with various oxide coating weights on four different steel sheets. (Note that only a portion of the chromaticity diagram is shown and the x and y coordinates have been greatly expanded.) Although different plating solutions were used, the locus of chromaticity coordinates for TFS-CT lies along a single line on the chromaticity diagram.

The color of TFS-CT ranges from the blue hue (475 nm) of metallic chromium through neutral or gray and into the yellow region of the spectrum having a dominant wavelength of about 578 nm. Because the blue color is absorbed by the oxide coating, it is reasonable to expect that the oxide coating weight would be related to the seldom-used z chromaticity value. However, to obtain a positive slope on a graph of coating weight *vs.* chromaticity value, coating weight could be plotted against $(1 - z)$ or against $(x + y)$ since $x + y + z = 1$. In Fig. 7 and 8, the Cr^{+3} in the oxide determined analytically is directly proportional to the $(x + y)$ chromaticity. Although there is some spread in the data, as shown by extrapolation to zero oxide coating weight, giving a value of $(x + y)$

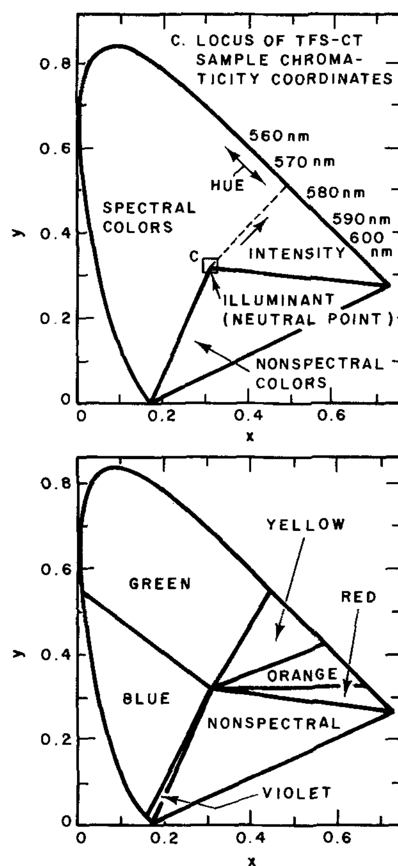

Fig. 4. Chromaticity diagram showing positions of the colors

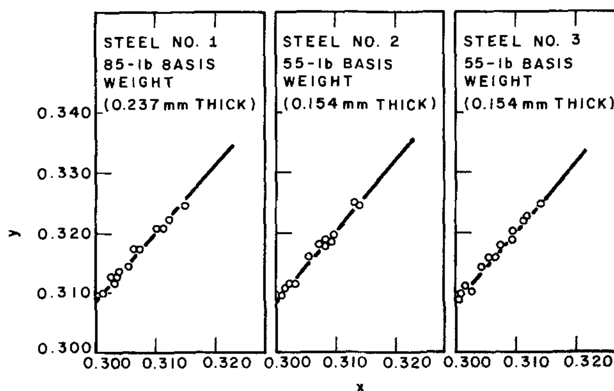

Fig. 5. Chromaticity diagram for TFS-CT with variable oxide coating weights on three different steel substrates.

chromaticity of 0.6064 ± 0.003, an equation can be written to represent the data fairly well. The oxide coating weight, W, expressed as mg Cr^{+3}/ft^2 is related to $(x + y)$ chromaticity as

$$W = 83.41\ (x - y) - 50.58$$

where x and y are chromaticity values determined from tristimulus numbers as described previously. W may be converted to mg Cr^{+3}/m^2 by multiplying by 10.7.

Accuracy of data.—To determine the value of the $(x + y)$ chromaticity at zero oxide coating, the oxide coatings were stripped from 28 samples of TFS-CT according to the method prescribed by Shuto (5). Chromaticity was determined and the $(x + y)$ values had a spread of ±0.0012. The average value, 0.6084, was 0.0020 higher than the average of the extrapolated values discussed previously. This positive deviation seems reasonable because chromium metal in contact with air will always have some oxide on its surface.

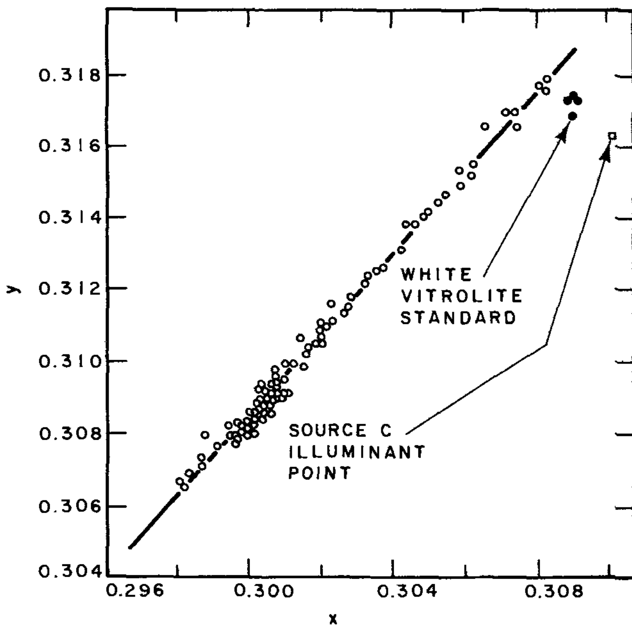

Fig. 6. Chromaticity diagram for a programmed experiment to produce TFS-CT with different oxide coating weights on a single steel substrate.

In another test, the same samples were placed in the sample holder of the spectrophotometer with the rolling direction vertical rather than horizontal. The spread in chromaticity was ±0.0012, but the average value of $(x + y)$ was 0.003 higher than with the same samples held in a horizontal position. The degree of change in color with a change in surface texture was not determined, but some of the point spread in the curves shown in Fig. 7 and 8 may be due to surface irregularity.

The x-ray fluorescence method of chemical analysis for chromium is also sensitive to surface texture, but blank (unplated) panels are used to adjust the zero point and improve the accuracy. The analysis of the chromium in both metallic and oxide coatings is expected to be accurate to ±0.3 mg Cr^1/ft^2 (±3.2 mg Cr^1/m^2). More than 95% of the data fall within the limits of the experimental errors just outlined.

Effect of lacquer coatings on the color of TFS-CT.—Since most TFS-CT is lacquered before being used for beverage or food containers, how is the color of the TFS-CT affected by the lacquer? To answer this question, three lacquers were applied to TFS-CT and the

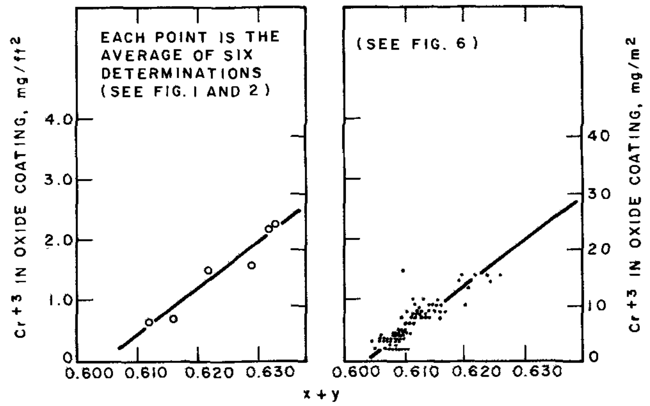

Fig. 8. Oxide coating weight vs. (x+y) chromaticity

colors of the products were measured and compared with the original colors of the TFS-CT. In Fig. 9, 10, and 11, the chromaticity values of both lacquered and unlacquered panels are shown. The color of the TFS-CT affects the color of the lacquered panel. The spread in chromaticity values for the lacquered panels is less than that for the unlacquered panels in all three cases. The difference in color of TFS-CT is made somewhat less apparent by lacquering.

Effect of heating on the color of TFS-CT.—When TFS-CT is used for beer or beverage containers, it is first lacquered and the lacquered material cured. Sometimes the TFS-CT is processed one side at a time so that one side is unlacquered during the first heating cycle. If heating is moderate and the heating cycle is short, relatively little change occurs in the TFS-CT. However, as the temperature increases or the heating cycle lengthens, the oxide coating undergoes chemical and physical changes (6). Briefly, when the temperature is raised above 300°F (149°C), and the baking time goes beyond 30 min, water is driven out and the oxide becomes more crystalline and much less soluble in alkaline solution. Analytical data with respect to Cr^{+3} are questionable for heated TFS-CT, and no accurate determination of the rate of oxidation has been made.

There are unanswered questions about the optical properties of heated TFS-CT. Consider, for example, how does the oxide coating thickness vary with heating when the water is driven off and the coating is becoming more crystalline? Does this chemical change alter the basic color, transparency, or refractive index of the oxide? These questions cannot be answered directly, but tristimulus data can be examined for TFS-

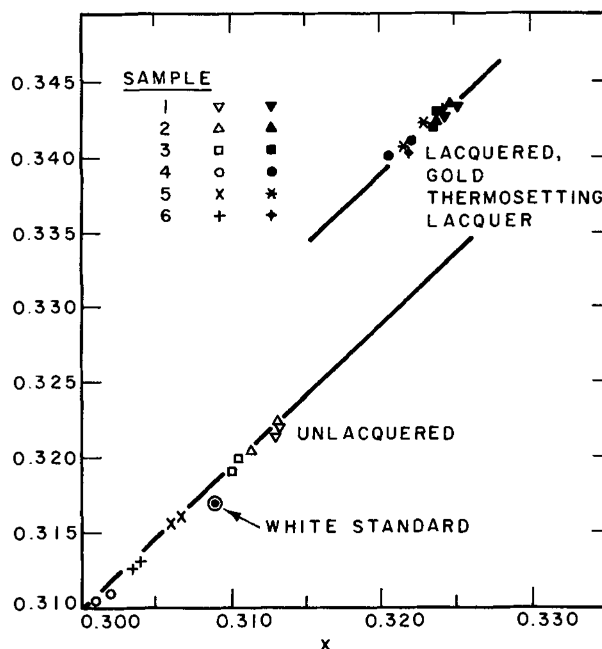

Fig. 11. Chromaticity of lacquered and unlacquered TFS-CT

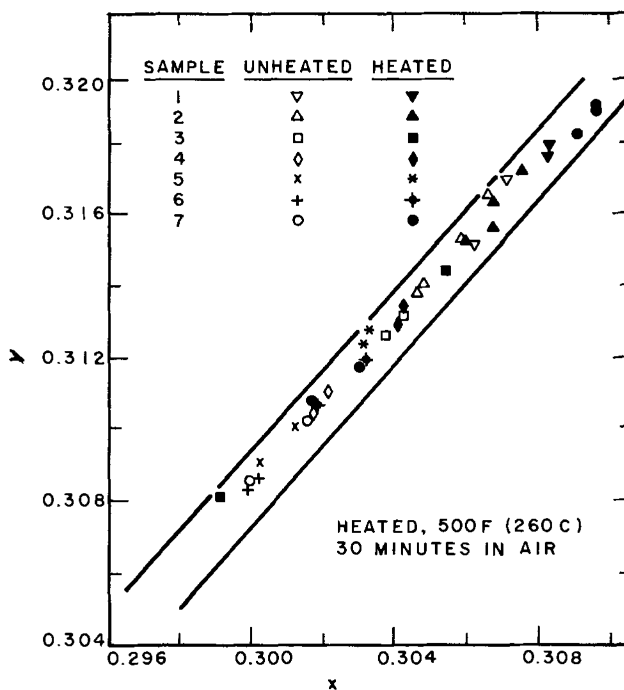

Fig. 12. Chromaticity diagram for TFS-CT before and after heating.

CT before and after heating. The chromaticity diagram of Fig. 12 shows that heating TFS-CT in air for 30 min at 500°F (260°C) moves the chromaticity numbers to the top right of the figure as though each specimen (except one) had been oxidized. TFS-CT heated in an inert atmosphere shows little change in chromaticity numbers, Fig. 13, and thus leads to the conclusion that the optical properties do not change significantly when TFS-CT is heated in an inert atmosphere to 500°F (260°C) for 30 min.

When TFS-CT is heated in air, the increase in the amount of oxide, indicated by the change in chromaticity in Fig. 12, can be calculated for each specimen by using the chromaticity numbers $(x + y)$ and the equation relating $(x + y)$ to oxide coating weight. The calculated increase in coating weight is plotted as a function of the average coating weight in Fig. 14. The scatter in the data is remarkably small and there is some indication that increased oxide coating weight reduces the rate of oxidation, as might be expected intuitively. From Fig. 14 it is apparent that the rate of oxidation of bare electroplated chromium metal in air is about 1.0 mg Cr/ft^2 hr at 500°F (11 mg Cr/m^2 hr at 260°C).

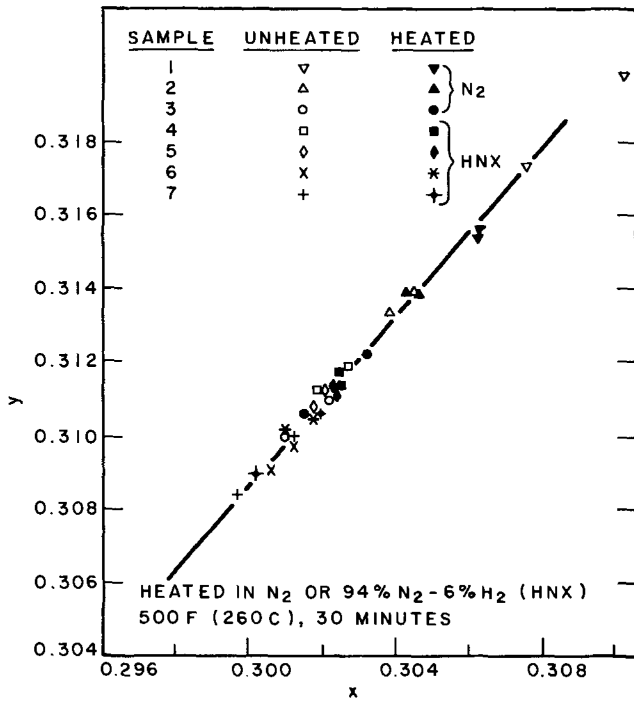

Fig. 13. Chromaticity diagram for TFS-CT before and after heating.

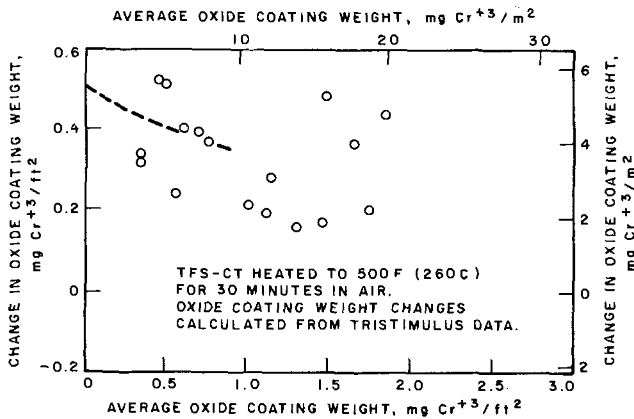

Fig. 14. Apparent increase in oxide coating weight during heating

Summary

TFS-CT has a brighter appearance than steel, and the brightness is related to the amount of chromium oxide present on the TFS-CT surface and the texture of the surface. TFS-CT surfaces with little or no oxide have the brightest appearance. The specular reflectivity of TFS-CT measured with a 45-degree glossmeter was a function of the coating weight of chromium oxide when the same steel base was used to prepare all samples. Likewise, the diffuse reflectivity as measured by a spectrophotometer gave a similar result. When different steel surfaces were involved, however, the amount of light reflected was strongly dependent on surface roughness and the angle of incident light with respect to the rolling direction.

The surface roughness had only a minor effect on the color of TFS-CT. The color of chromium is slightly blue but as the oxide coating on TFS-CT builds up, the blue is absorbed in proportion to the thickness of the oxide. In this way the oxide coating weight (in $mg/Cr^{+3}/ft^2$) has been correlated with the chromaticity values x and y to give the equation $W = 83.41 (x + y) - 50.58$.

The effect of oxide coating weight on the colors of lacquered TFS-CT has been observed for both colorless and gold lacquers. The effect of changes in oxide coating weight on changes in the color of TFS-CT is greatest for the bare product and somewhat less for the lacquered product depending on the type of lacquer used.

Heating TFS-CT in air causes physical, chemical, and color changes in the oxide coating, but the color of that coating remains remarkably stable when TFS-CT is heated in an inert atmosphere. Electrodeposited chromium oxidizes at 500°F (260°C) in air at the rate of 1.0 mg Cr/ft² hr (11 mg Cr/m² hr).

Some Aspects of Electrode Erosion in Arc Heaters

K. Mosley,[1] A. E. Guile, and D. Dring

Department of Electrical and Electronic Engineering, University of Leeds, Leeds LS2 9JT, Yorkshire, England

ABSTRACT

Very little information has been published on the erosion of electrodes occurring when the cathode and anode spots of arcs move over their surfaces for long periods. The results of measurements made during a study of an arc heater are reported herein. Operating an arc at 180A d.c. in argon at pressures between 2 and 73 atm has shown that the cathode erosion rate can vary by at least two orders of magnitude for relatively small changes in arc velocity. Phenomenological observation of electrode surfaces indicates that gas in the electrode material plays a very important role in electrode erosion.

In a number of applications in chemical engineering, aeronautics, and other fields, electric arcs are commonly used to heat gases at atmospheric pressure and above. Particularly where the processes involve operation for very long times, the erosion of the electrodes must be minimized in order to avoid costly shutdown of plant to replace electrodes. It is also frequently necessary to reduce the contamination of the heated gas by electrode material. In attempting to reach these objectives the arc terminations may be moved or rotated by transverse magnetic fields or by gas flow. For example, a recent paper (1) has shown that for a 200A arc in air at atmospheric pressure between water-cooled copper electrodes, a 2:1 reduction in the erosion rate occurred following a 3:1 increase in the strength of the applied transverse magnetic field. Most of the existing data on the erosion of electrode materials comes from the switchgear field, where short-duration arcs are drawn following metal-bridging processes. These arcs, which are in a quasi-stationary condition, may either occur at atmospheric or higher pressures, or may be vapor arcs in an enclosure initially under high vacuum.

The observations reported herein, made during a study (2) of the conditions of energy balance for d-c arcs rotated for several hours in argon at pressures between 2 and 73 atm, suggest that relatively large changes in cathode erosion can be associated with changes in arc velocity.

Experimental Procedure

The equipment used has been described more fully elsewhere (3). Figure 1 shows the basic arrangement in which a high-pressure gas pump circulated gas upward through the annular gap G between the concentric outer anode A and the inner cathode C. After heating by the arc, which was rotated by the axial field of F_1 and F_2, the gas passed into the heat exchanger on its return to the pump. To stabilize the arc at high gas mass flow rates it was necessary to pass a current of up to 1.5 kA through the central conductor M so that the field produced interacted with the arc to give a force in opposition to the aerodynamic force exerted by the gas flow.

Preliminary experiments in argon established that there was no noticeable erosion of the water-cooled copper anode, hence a single anode could be used in all the tests.

Prior to each test a new cathode was weighed to 0.01g and inserted in the arc chamber which was then evacuated to an initial air pressure between 1 and 6 $\times 10^{-3}$ Torr, before filling with argon of 99.995% purity. Experiments (see Table I) with brass cathodes were carried out under steady-state temperature conditions, at several gas flow rates for a given gas, gas pressure,

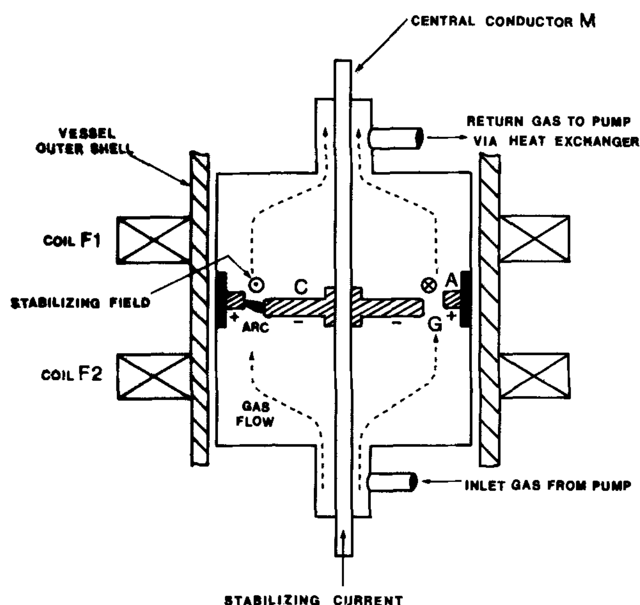

Fig. 1. Simplified diagram of electrode arrangement

and radial electrode gap in an axial magnetic field of 0.071 Tesla (Wb/m^2). This procedure was repeated over the whole range of gas pressures for different electrode gaps. Due to erosion, six cathodes had to be used in these experiments; mainly because with the small radial gaps used, the arc voltage, and hence the energy input to the arc, was very sensitive to even a relatively small increase in the gap.

Cathodes were of brass to specification BS 249, the analysis of which is given in Table I, or of phosphorous-

deoxidized nonarsenical copper to BS 1172 (minimum copper content 99.85%, 0.015-0.08% P).

Experimental Results

In preliminary experiments in argon with the arc chamber initially evacuated to 10^{-2} Torr, the erosion results shown in Table II were obtained for brass and copper cathodes. After the arc had run for 33 min on the brass cathode there was only a fine adherent gray deposit of zinc on the anode surface directly opposite the arcing surface of the cathode, while in the arcing chamber a very fine blue-black powder, identified as cupric oxide, was found. When the copper cathode was used, copper particles were found to be loosely attached to the anode surface opposite the cathode, and particles up to 1 mm long were found in the arc chamber. With the copper cathode the arc was much less stable than with the brass cathode, and this relatively greater stability has also been observed for low-pressure arcs (4). The arc luminosity obtained with the copper cathode was insufficient to make the optical probe record a velocity signal, but from previous experiments (5) using the same electrode material and the same gas it was established that the arc velocity was most probably about 36 m/sec, although a stable low-speed mode at a velocity as low as 20 m/sec was a possibility. The erosion rate for copper given in Table II is plotted against the mid-point of this velocity range in Fig. 2 and a dotted line is drawn joining this point f to the curve c plotted from the data of Harry (1), the justification for which will be discussed later.

It was not practicable to fit a new cathode after arcing under each condition of gas flow rate and gas pressure, because (*i*) the main purpose of the work was not concerned with erosion measurement, (*ii*) a very large number of other measurements were required in a limited time, and (*iii*) replacement of an electrode involved two days work. The erosion results given in Table I, therefore, cover a range of arcing conditions at various argon flow rates and pressures for each cathode.

For each cathode listed in Table I which was tested at a current I (= 180A) for all gas pressures and flow rates, the total weight loss W in grams may be written as

$$W = I \sum_{a=1}^{m} e_a \, t_a \qquad [1]$$

where m is the total number of different gas pressures for which the particular cathode was tested, t_a is the arcing time for any particular pressure, and e_a is the unknown erosion rate for the average arc velocity over the range of gas flow rates explored at the same pressure. (For the highest pressures where maximum erosion occurred, the reduction in arc velocity when the gas flow rate was increased to its greatest value was less than 5%.) Equation [1] assumes that erosion may be expressed in gram/coulomb for these rotating arcs. This assumption is often made for static and for moving arcs although it has been shown (6) for arcs between copper surfaces of contactors in air up to 300A that $dW/dt = KI^{1.6}$. Thus the possibility of an

Table II. Cathode erosion at 2.56 atm with an argon flow of 1.12 to 1.15 m/sec

exponent greater than unity for the current cannot be ruled out. However, since the current was kept constant for all the present tests this difficulty was not encountered.

Equation [1] further assumes that the erosion rate depends on the arc velocity rather than on argon flow rate or pressure, and that where increased erosion has been reported for a magnetically driven arc with increase in gas pressure (7), the increase could be attributed to the reduction in arc velocity at a constant magnetic field. Support for the suggestion that erosion is relatively insensitive to gas pressure variation may be found from tests (8) on copper contacts in air which gave similar erosion rates at pressures between 11 and 23 atm. Also the results were in good agreement with others obtained at atmospheric pressure (6).

Because of the scatter which occurs in erosion rates when similar experiments are repeated (1), Eq. [1] was solved separately for each of the cathodes instead of assuming that e_a is always identical for a given pressure p_a and hence arc velocity. From a number of observations made during the course of this work, such as the large amount of vapor condensed on the molybdenum radiation shields of thermocouples, it was clear that the erosion occurred mainly at the highest pressures. It was found that the results for the erosion of brass in argon could be described by a straight line on Fig. 2, radiating from a point e which represents the measured brass erosion in the preliminary tests (Table II). The line ae gave the exact value of total loss W for cathode B1; line be gave only a discrepancy of 0.5% for cathodes A2 and A4 and 1.8% for C2. The area between lines ae and be is therefore considered to describe the erosion of the brass cathodes used for arc speeds between 7.3 and 31 m/sec running stably in argon over the pressure range 2.5-73 atm. It is interesting to note that the slopes for lines ae and be are almost the same as that of the line fc joining the two points for copper cathodes in air or argon.

Discussion of Results

Figure 2 shows that for a cathode root speed of 30 m/sec, the erosion of the copper cathode was 100 times larger than that of the brass cathode. When the latter was used, the anode surface was covered with a fine deposit of zinc while fine cupric oxide powder was found within the arcing chamber. If the cathode spot

temperature is limited by evaporative processes, then reduction in the zinc content of the brass at the emitting sites may occur since its boiling point (at atmospheric pressure) is less than half that of copper or lead. Experimental evidence of such zinc depletion at the surface of an arc track has been found (9) by means of an electron probe analyzer for arcs moving retrograde in argon at pressures below 1 atm. The fact that zinc was found on the anode suggests that it was carried across the gap by cathode jets, the velocities of which may be 10^3 or 10^2 m/sec when there is little electrode vaporization (10), and which therefore exceed considerably the axial argon velocities of 0.5-6.5 m/sec.

When a copper cathode was used, irregularly shaped pieces of bright copper up to 1 mm long were found in the arcing chamber, together with relatively large globules of copper on the lower parts of the anode, while the downstream parts of the anode surface were covered with a weakly adherent layer of cupric oxide. The copper particles on the anode surface showed evidence of having been molten while traveling in the high-temperature regions of the arc, whereas the irregular particles found in the arcing chamber had clearly not been molten as a consequence of having been ejected clear of the high-temperature regions.

The copper to specification BS 1172 used for the cathode can contain oxygen in solid solution, in pockets, or as copper oxides within the bulk metal, despite the phosphorous used as a deoxidizing agent, whereas the brass is virtually free of oxygen (11). Under the intense heating effects of the cathode root, oxygen present just below the surface may dissociate from oxides or come out of solution to create a void containing high-pressure gas. When the surface adjacent to this highly pressurized void becomes sufficiently weak due to root heating, the gas can escape "explosively," taking with it a relatively large amount of the surface metal. Similarly, microscopic regions of high-pressure gas can be produced by phosphorous which boils at 282°C. Furthermore, oxygen linking with phosphorous to form phosphorous pentoxide may result in zone weakening of the material especially at grain boundaries. It has been observed (12) that a higher erosion rate occurred for a continuously rotating arc on a copper cathode with 0.045% phosphorous than for copper having a 0.034% content. The lack of large eroded particles from a brass cathode may therefore be attributed to the insignificant amounts of oxygen or phosphorous.

Scanning electron microscope photographs (13) of cathode tracks on copper provide further evidence that gas eruptions just below the surface can occur and blast away surface metal. Photomicrographs such as Fig. 3 revealed irregular depressions containing approximately circular holes within which were smaller holes which in turn contained even smaller cavities. Photographs of brass cathodes under similar conditions of arcing did not show such cavities.

In the search for the most suitable materials for vacuum switches, evolution of gas was encountered from ordinary and O.F.H.C. copper and even from the best grade of vacuum-melted copper which was then available (14). Furthermore, whenever electrode material collected on shields was of a coarse globular nature it was accompanied by large bursts of gas from the electrodes. Heating to fusion followed by ejection of material by evolution of occluded gas has sometimes been assumed (15). The presence of fused material on an anode was observed to coincide with a sudden pressure rise caused by gas evolution or vaporization of high vapor pressure materials (16).

At atmospheric pressure or above, this process does not seem to have been discussed previously in connection with cathode erosion, but, in a 4 kA discharge of 10^{-8} sec duration, "flares" photographed coming from a copper anode were tentatively identified as a directed

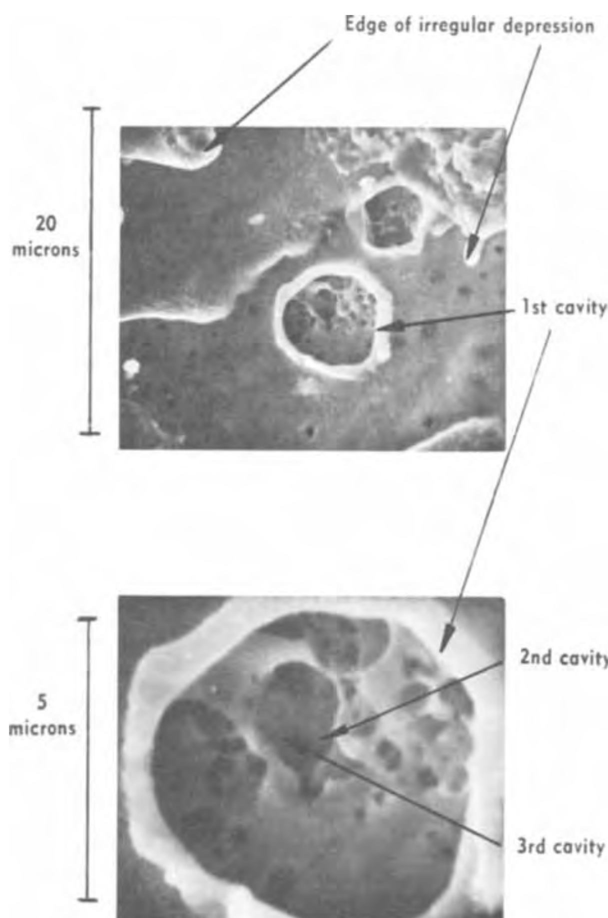

Fig. 3. Stereoscan microphotographs of cavities on copper cathode

"explosive type" of erosion (17). It was implied that a difference in conductivity between the molten surface and base metal was more likely to be responsible than gas in the electrode. No explosive-type erosion of large particles was observed with the copper anode used throughout the present tests, which suggests that the anode current densities being several orders of magnitude below those on the cathode, and the magnetic movement combined to prevent local temperatures at anode roots reaching a level at which sufficient gas pressure developed to tear out metal. Wilson (18) tentatively suggested that a secondary mechanism of the combined cathode and anode erosion of a pair of contacts at atmospheric pressure was vaporizing electrode material blasting out liquid droplets.

It seems likely that the explosive process proposed in this paper explains the reason for recommendations (19) that electrodes used for arc heating in the production of metal oxides should be of essentially void-free material and that they should be tested ultrasonically for number and size of voids. The term essentially void-free is applied to an electrode having less than one part per million by volume of voids in the part liable to consumption by the arc, and with each void being less than 450μ in any dimension.

For a copper cathode, the possibility of almost continuous variation of erosion between Harry's results in air and the results herein for argon, as represented by the dotted line joining c to f, may be due to the

gradual changeover from evaporative erosion of surface layers at low erosion levels, to a larger-scale explosive-type erosion at *f*. The latter would be much less dependent on the ambient gas in which arcing occurs.

Comparison of points *d* and *e* in Fig. 2 appears to indicate that a brass cathode can be eroded far more rapidly in air than in argon. The speed of arc rotation on circular electrodes affects the amount of reoxidation and this, together with the destruction of oxide layers at emitting sites, which depends on the type of gas (4), affects the distribution of these sites relative to their positions at earlier revolutions. When emission consistently recurs at or very near the old sites, the local temperatures and the erosion are likely to be greater than when the search for favorable emission sites causes them to be spread over a large area. There is certainly evidence (4) that in air, arc cathode roots tend to rotate over the same narrow track where evaporation destroys the oxide layers. However, during the time the roots take to complete one revolution, these very hot surfaces form thicker oxide and chemisorbed gas layers on which emission can be established more easily than on surrounding areas. This is supported by localized grooving of a brass cathode in air (1) and of a stainless steel cathode when run in air during the present experiments.

When running an arc on brass cathodes in argon, it was found necessary for arc stability to have a certain minimum amount of air in the system as is well known (20), so that some reoxidation could occur. For a given residual air content in the apparatus on evacuation, the maximum possible gas flow rate at a given pressure which could be attained without arc extinction was found to decrease as the electrode gap was increased, but this maximum flow rate could be increased by allowing more air to remain in the system before arc ignition. For a given flow rate and pressure the instability increased with arc running time, possibly because oxygen in the flowing gas became insufficient to reoxidize to full emission the points on the cathode nearest to the anode root, and the cathode root was forced to wander to more remote points where emission was easier. Table I shows that a few parts per million of oxygen were sufficient for stable operation but the maximum variation in oxygen content was insufficient to have a significant effect on erosion. It should be noted, however, that at least for silver contacts in mixtures of nitrogen and oxygen, it has been found (21) that above or below a certain oxygen content the erosion can rise steeply, and may be related to humidity. The erosion of copper cathodes in a plasma torch at currents up to 600A, was greater in pure oxygen than in air (22). Measurements for copper contacts in air (23) suggest an erosion range between about 7×10^{-6} g/coulomb at 8A and 1.3×10^{-4} g/coulomb at 180A. Earlier results of copper cathodic erosion given by Holm (24) which are about double these values, have been erroneously interpreted (25) as ranging from 1.3×10^{-9} g/coulomb at a current per spot (I/n where there are n spots) of 1A to about 10^{-7} g/coulomb at currents per spot of 10 kA and upward. In fact these currents up to 10 kA for which Holm gave erosion results were total arc currents (I). The currents at individual emitting sites at the cathode surface in air appear from experiments in this laboratory to be of the order of 10A.

The cathode erosion rates measured in the present work are far below those reported for copper contacts in air (23), and Fig. 2 suggests that an increase in velocity may reduce the erosion rate still further. Some results (26, 27) have shown, however, that for homogeneous contact materials operating in air at 1 atm, too great an increase in magnetic field can lead to greater erosion for currents from 100A to 10 kA, and this was attributed to increased spatter of volatile material. At currents below 100A and fields below 0.1 Tesla this spatter did not occur.

Since an arc rotating around a circular track makes a number of revolutions before attaining a steady velocity (5, 28), erosion data (even when obtained from moving arcs) may not necessarily be applicable to continuously rotating arcs. In general the velocity of an arc traveling over linear electrodes is not the same as that of a continuously rotating arc (29), and the method used by Dethlefsen (7) of driving a 6 kA arc over a linear surface in about 1 msec, although yielding data on a wide range of metals, does not necessarily apply directly to continuously operating devices. Furthermore, it does not distinguish between cathode and anode erosion, and introduces transitions between single and double arc which may cause discontinuities in the erosion process which could be very significant in such a short test.

The effect of grain size on erosion has so far been little explored and both increase and decrease in contactor electrode wear has been found to occur as grain size was increased (30, 31).

Porous tungsten electrodes impregnated with barium-calcium-aluminate suffered less erosion than thoriated tungsten, but linear electrode tests showed them to have an erosion rate in air at least an order of magnitude higher than copper (32).

It would appear, therefore, that insufficient information exists to enable an optimum choice of electrode materials and arc parameters that will minimize erosion in equipment using high-power continuously rotating arcs. It seems clear that such data cannot be provided by calculations of the transient temperature distribution at electrode surfaces (1, 33), but only by a systematic investigation attempting to provide data with the widest possible validity over the wide range of arc conditions and environments employed in gas heaters and other continuously operating devices.

Electrochemical Behavior of Nitric Oxide in 4M H_2SO_4 on Platinum

Dilip Dutta* and D. Landolt*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The electrochemical reactivity of different nitrogen oxides or their absorption products in sulfuric acid was investigated by potential scan measurements. Experiments were carried out at 23°C with platinum electrodes. Among the substances studied only HNO_2 and NO exhibited well-defined oxidation and reduction currents. The electrochemical reactions of NO in 4M H_2SO_4 were studied in detail by using a rotating disk electrode. Mass transport limited currents were observed for both oxidation and reduction. From the variation of the limiting current with rotation rate the diffusion coefficient of NO was determined to be 0.9×10^{-5} cm²/sec.

Little work has been reported so far in the literature which deals with the characterization of electrochemical reactions of nitrogen oxides. This is surprising in view of the proposed application of electrochemical current measurements for continuous monitoring of nitrogen oxide air pollutants (1, 2). Electrochemical techniques might also provide useful tools for the investigation of the complicated chemical reaction sequences that take place on absorption of nitrogen oxides in aqueous solutions (3, 4). Furthermore, the mechanism of nitric acid reduction is of interest in corrosion research since HNO_3 is frequently used as a pickling or a polishing agent for metals. Considerable controversy exists at present over whether the charge transfer step involved in HNO_3 reduction involves the reacting species NO_2 or NO (5-11). In the absence of oxygen, NO can be absorbed in aqueous solution without undergoing disproportionation reactions contrary to the behavior of NO_2 (3, 4). The study of its electrochemistry is therefore relatively simple. The thermodynamics of the NO/HNO_2 electrode have been investigated by Schmid and Neumann (12), but no data are available at present about reaction kinetics.

The purpose of this study was twofold. On one hand, because of the absence of such data in the literature, the relative reactivity of different nitrogen oxides or their absorption products was to be characterized by potential scan measurements. Rotating disk experiments were then to be used to study in more detail the electrochemical behavior of NO. The data of this study were to be a first step toward providing a rational basis for a possible development of new electrochemical monitoring methods for nitrogen oxides.

Experimental

Apparatus.—The rotating disk electrode assembly consisted of a variable speed motor (Bodine ⅛ hp d-c motor) driving a rotating shaft by means of pulleys. Constant rotation speeds between 100 and 15,000 rpm could be obtained which were measured by means of a stroboscope. The rotating electrode assembly included a commercial quill (Dumore Company) and a removable disk electrode. Contact to the electrode shaft was made by means of slip rings. A 1.5 liter glass cell was bolted to a fixed PVC cell cover. An "O" ring, placed between the cell and PVC cover, and a water seal arrangement at the shaft prevented any contact of the electrolyte solution with air. Standard Teflon fittings were used to insert thermometer, Luggin capillary, and two glass frits for gas bubbling into the cell. One of the frits used for deaeration prior to experiments was placed into the electrolyte solution. The other frit was located above the solution and served for passing gas during experimental runs. A saturated calomel electrode served as reference. A platinum foil counterelectrode was separated from the working electrode compartment by a glass frit located in the center at the bottom of the cell. The working electrode was a platinum disk 0.79 cm in diameter, silver soldered onto a stainless steel shaft and press fitted into a Teflon insulation.

Initial potential scan experiments with different nitrogen oxides were performed in a conventional sealed-glass cell with a platinum wire electrode. An

Key words: nitrogen oxides, rotating disk electrode, nitric acid, monitoring of air pollutants.

Anotrol 4700 M potentiostat in connection with a function generator (Exact, Type 255) or a multipurpose electrochemistry unit (Princeton Applied Research, Model PAR170) were used as power supply. Potentials were measured by means of a Keithley Electrometer (Model 602) and current voltage curves were recorded on a x-y recorder.

Preparation of solutions.—Solutions were prepared with analytical grade chemicals and doubly distilled water. HNO_2 solutions were prepared by slowly adding required quantities of a 0.1M $NaNO_2$ stock solution from a pipette to a stirred solution of the supporting electrolyte cooled in an ice salt bath. Saturated NO solutions were prepared by first deaerating the system for at least 8 hr with prepurified nitrogen. Then 99.9% pure NO (Air Products Corporation) was bubbled through the solution for approximately 3 hr. Rotating disk measurements indicated that this time was ample to reach saturation of the sulfuric acid solutions with NO. To remove possible NO_2 impurities the NO, prior to bubbling it through the cell, was passed through two wash bottles containing NaOH. Data obtained with the rotating disk electrode (see below) showed that HNO_2 contamination during the experiments, resulting from the possible presence of traces of oxygen during gas saturation, was less than 10% of the NO concentration. When necessary, experimental data were corrected for the presence of this contamination.

Electrode pretreatment.—Pretreatment of the platinum working electrode is critical for insuring reproducible results. The following procedure was adopted. Prior to immersion into the electrolyte solution, the electrode was cleaned with soap and doubly distilled water and dried. It was further cleaned by refluxing benzene for about 1 min. Electrolytic pretreatment in 0.5M H_2SO_4 was then given as follows: cathodic pretreatment at 50 mA/cm^2 for 2 min, anodic treatment at 50 mA/cm^2 for 1 min, and further cathodic pretreatment at the same current density for 2 min.

The electrode was then immersed in the solution. After deaeration, but prior to the experimental run, the electrode was again cathodically polarized and hydrogen was evolved for 2 min. This was followed by anodic polarization of the electrode for 1 min near to the oxygen evolution potential (but not evolving oxygen). Finally, the electrode was once again cathodically treated for 2 min.

For each of the individual solutions and reactants studied, the first experiment carried out was a cathodic scan starting from the open-circuit potential. Prior to this, the electrode had been subjected to a short anodic pretreatment for 15 sec at 300 mV positive of the open-circuit potential. The cathodic experiments were followed by anodic scans between the open-circuit potential and potentials just below the oxygen evolution region. Prior to anodic runs, the electrode had been subjected to a cathodic polarization for 15 sec at 300 mV negative of the open-circuit potential. In some cases a complete scan between the hydrogen and oxygen evolution potentials was also measured. Several experimental runs were always conducted to check for reproducibility.

Determination of NO solubility.—For the quantitative interpretation of limiting current measurements, the saturation concentration of NO in 4M H_2SO_4 had to be known. Because literature values were not available, an experimental titration procedure was developed based on data given by Kolthoff and Elving (13). The airtight apparatus used consisted of a calibrated burette and a titration vessel (Fig. 1). Sulfuric acid solution contained in the 250 ml burette was deaerated with purified nitrogen for approximately 8 hr. Prepurified NO was then bubbled through the solution for 2 hr to reach saturation. Care was taken to exclude any traces of oxygen. A 200 ml flask containing 100 ml of 0.001M $KMnO_4$ was connected to the burette.

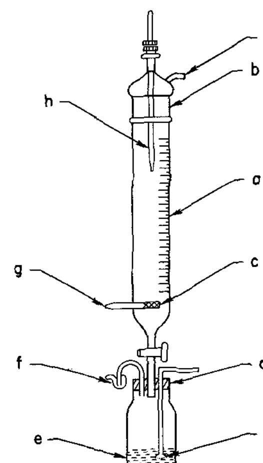

Fig. 1. Apparatus for determining NO concentration in H_2SO_4. a, 250 ml graduated burette containing sulfuric acid; b, ground glass stopper; c, glass frit for gas bubbling; d, rubber stopper; e, potassium permanganate solution; f, gas bubbler; g, gas inlet; h, thermometer; i, gas outlet to wash bottle.

The $KMnO_4$ solution was deaerated with nitrogen for 3 hr. Then 100 ml of the NO-saturated sulfuric acid solution was slowly added to the $KMnO_4$ which oxidizes NO to NO_3^- (13). After completion of the reaction the flask containing the $KMnO_4$ was removed and the excess $KMnO_4$ was titrated with a freshly prepared 0.1M acidified $FeSO_4$ solution. The end point was observed potentiometrically by measuring the potential of a platinum wire electrode *vs.* a saturated calomel electrode with a Keithley electrometer. Two blank experiments carried out in the absence of NO showed the titration procedure to give results to an accuracy of better than 1.4%. In the presence of NO the following data were obtained. Experiment A: $T = 22.4°C$, volume titrated 102.5 ml, $FeSO_4$ used in back titration 0.88 ml, NO concentration 1.34×10^{-3} mole/liter. Experiment B: $T = 23.0°C$, volume titrated 106.5 ml, $FeSO_4$ used in back titration 1.02 ml, NO concentration 1.24×10^{-3} mole/liter. This yields an average value of $1.29 \pm 0.05 \times 10^{-3}$ moles/liter for the saturation concentration of NO in 4M H_2SO_4 at 22.7° ± 0.3°C.

Results

Qualitative information on the cathodic reactivity of different nitrogen oxides is contained in Fig. 2, which gives potential scan measurements on a stationary wire electrode. Deaerated 4M H_2SO_4 was used as an electrolyte to which different nitrogen oxides were added. Before each scan experiment the electrode was subjected to a potential 300 mV anodic to the open-circuit potential for 15 sec. Then repetitive scanning at 1 V/min was initiated starting from the open-circuit potential. The traces shown in Fig. 2 represent the second cycle. The initial cathodic scans frequently differed slightly from those shown but subsequent scans were usually identical. The scan in pure 4M H_2SO_4 (Fig. 2a) showed the usual hydrogen adsorption and desorption peaks on platinum. Addition of 0.01 mole/liter $NaNO_3$ to the sulfuric acid did not measurably affect the behavior, indicating that nitrate ion was not reduced. Addition of approximately 0.01 mole/liter $NaNO_2$ to the sulfuric acid solution led to three well-defined reduction steps (Fig. 2c), in agreement with data reported by Schmid and Lobeck (10). According to these authors, the first two steps of HNO_2 reduction each involve the over-all transfer of one electron per molecule of reactant while the third step involves the over-all transfer of two electrons. The relative magnitude of the observed HNO_2 reduction steps in Fig. 2c is consistent with this view. The cathodic scan measured in NO saturated 4M H_2SO_4 (Fig. 2d) exhibited two well-defined reduction steps at potentials correspond-

ing to the second and third HNO_2 reduction steps. The N_2O voltage scan shown in Fig. 2e was obtained after saturating a 4M H_2SO_4 with 99.99% pure N_2O (Liquid Carbonic Corporation), the literature value of the saturation concentration being 0.018 mole/liter. In spite of this high N_2O concentration in the solution, cathodic currents in the potential region between +200 and −180 mV *vs.* SCE were extremely small, indicating that N_2O reduction on platinum is strongly inhibited. The potential scan of Fig. 2f was obtained in a 4M H_2SO_4 solution to which 0.01M hydroxylamine sulfate had been added. The observed trace was identical to that of the pure H_2SO_4, *i.e.*, hydroxylamine is not reduced cathodically in the potential region between +200 and −180 mV *vs.* SCE. Anodic potential scan measurements performed with the same electrode in 4M H_2SO_4 are given in Fig. 3. After prepolarization at 300 mV negative to the open-circuit potential, several repetitive potential scans were performed. For the experiments in pure H_2SO_4, results for repetitive scans were identical. Platinum oxidation was observed at approximately 800 mV and oxygen evolution set in above 1600 mV. The platinum oxides reduced at potentials between 700 and 200 mV. This behavior of platinum is well known. Addition of 0.01M sodium nitrate did not affect the current trace (Fig. 3b). On the other hand, addition of approximately 0.01M sodium nitrite to the sulfuric acid solution (Fig. 3c), lead to a well-pronounced oxidation current which had already been observed by Schmid and Lobeck (10). According to these authors it corresponds to the oxidation of nitrous acid to nitric acid. Repeating the anodic cycle without intermediate cathodic pretreatment leads to a substantial decrease in the oxidation currents. This fact together with the observed sharpness of the oxidation peaks indicates that the platinum oxidation state affects HNO_2 oxidation kinetics. The same holds true for the oxidation of NO (Fig. 3d). Two peaks were observed here, the second of which corresponded to the oxidation peak of HNO_2. Upon repeating the cycle without intermediate platinum oxide reduction the first NO oxidation peak disappeared while the height of the second peak was strongly reduced.

The cathodic reduction of NO was further investigated by means of the rotating disk electrode. Limiting current plateaus, the height of which increased with rotation rate (Fig. 4), indicated that the first reduction step is diffusion controlled. A plot of limiting current *vs.* the square root of rotation rate yielded a straight line with a slope of 6.7×10^{-5} A $sec^{1/2}/cm^2\ rad^{1/2}$ (Fig. 5). The points in Fig. 5 represent two independent experiments with fresh solution. To compute the limiting current for NO reduction (Fig. 5) a correction had to be made for the unavoidable presence of a small amount of HNO_2 impurity which is evidenced in Fig. 4 by the finite current value in the potential region between 600 and 450 mV. Because HNO_2 is reduced in two steps, twice the value of the residual current was subtracted from the measured limiting current value of Fig. 4.

Figure 6 shows NO oxidation currents measured on a rotating disk electrode. Each current-potential curve was measured after a brief cathodic pretreatment had been given to the electrode. A strong effect of rotation

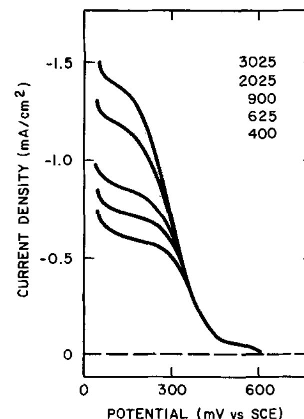

Fig. 4. Cathodic polarization curves measured in 4M H_2SO_4 saturated with NO on rotating disk electrode. Scan rate = 0.5 V/min, $T = 23°C$; numbers indicate rpm.

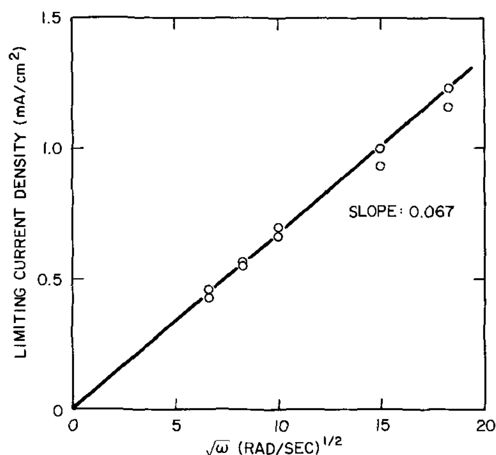

Fig. 5. Limiting current values for NO reduction as a function of rotation rate.

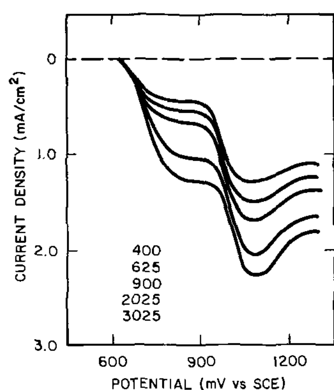

Fig. 6. Anodic polarization curves measured in 4M H_2SO_4 saturated with NO on rotating disk electrode. Scan rate = 0.5 V/min, T = 23°C, numbers indicate rpm.

rate on step height is observed. The second step exhibits a peak rather than a current plateau. In view of the slow scan rates employed, it is concluded that this peak is not due to a nonsteady-state mass transfer situation but to the development of an oxide layer on the platinum anode which slows down the oxidation reaction at higher potentials. The limiting current of the first step and the peak current for the second step are plotted for two independent experiments performed with new solutions in Fig. 7. The straight line obtained when the limiting current is plotted *vs.* the square root of rotation rate indicates that the first step is diffusion controlled. The slope of 6.7×10^{-2} mA $sec^{1/2}/cm^2\ rad^{1/2}$ is identical to that derived from the cathodic reduction data (Fig. 5). The peak height of the second wave does not yield a straight line when plotted *vs.* $\sqrt{\omega}$. At high rotation rates kinetic limitations apparently become important. This is also evidenced by the much poorer reproducibility of these currents compared to those of the first step. Poor reproducibility is typical for reactions which are surface controlled. At low rotation rate the peak currents representing the second NO oxidation step approach a tangent having a slope three times that of the straight line representing the limiting currents of the first oxidation step.

Kinetic parameters of the surface reaction corresponding to the first oxidation step can be determined by a technique described by Jahn and Vielstich (14) employing the rotating disk electrode. For irreversible first-order charge transfer reactions partly controlled by mass transfer, one may set

$$\frac{1}{i} = \frac{1}{i_s} + \frac{B}{\sqrt{\omega}} \qquad [1]$$

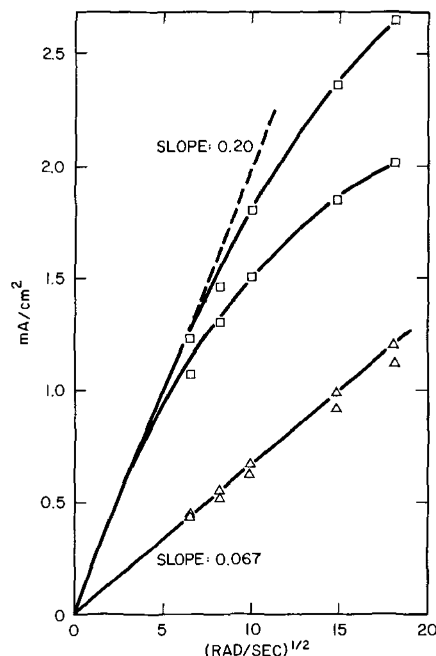

Fig. 7. Limiting current values for NO oxidation as a function of rotation rate; △ first oxidation step, □ peak current of second oxidation step.

where i_s is the charge transfer current corrected for mass transfer effects, B is a constant, and ω is the rotation rate. Figure 8 shows a plot of $1/i$ *vs.* $1/\sqrt{\omega}$ derived from the current voltage curves for NO oxidation on the RDE. According to Eq. [1] the intercepts of the straight line with the $1/i$ axis represent the reciprocal of the charge transfer current i_s at infinite rotation rate. The logarithm of i_s is plotted as a function of potential in Fig. 9. Tafel behavior with a slope of 110 ± 10 mV is exhibited. The data of Fig. 9 represent two independent experiments with new solutions and different disk electrodes.

Potential scan experiments at different scan rates were performed in 4M H_2SO_4 solutions saturated with NO at a stationary disk electrode. Peak currents for both oxidation as well as reduction were found to be a linear function of the square root of scan rate. Peak potentials for both oxidation and reduction waves are plotted *vs.* the logarithm of scan rate in Fig. 10. The

cathodic curve exhibits a straight line of slope 65 mV. The anodic curve is flat at low scan rates but approaches a slope of 60 mV at high scan rates.

Discussion

Oxidation as well as reduction of NO proceeds stepwise. The first oxidation and the first reduction steps involve the same number of electrons transferred because the slopes of Fig. 5 and 7 are the same. Both limiting currents are mass transfer controlled and one electron is transferred per reactant molecule. The latter is concluded from the following observations: (*i*) the Tafel slope for NO oxidation (first step) is 110 $\pm$ 10 mV (Fig. 9), corresponding to a charge transfer coefficient of $\alpha = 0.54$ and an electron transfer number, $n = 1$. (*ii*) The variation of peak potential with scanning rate (Fig. 10) for NO reduction approaches 60 mV/decade consistent with an irreversible one-electron charge transfer process (16). Oxidation of NO at low scan rates proceeds reversibly, but at high scan rates the variation of E_p with log λ also approaches the 60 mV characteristic for an irreversible one-electron charge transfer process. (*iii*) Schmid and Lobeck (10) showed that reduction of the primary reaction intermediate of HNO_2 reduction involves the transfer of one electron per reactant molecule. The data of Fig. 2 confirm that NO is indeed the primary reaction intermediate of HNO_2 reduction, and therefore the observed NO reduction step represents an over-all one-electron transfer process.

Once the number of electrons is established, the limiting current measurements on a rotating disk electrode can be used for determining the diffusion coefficient of NO in 4M H_2SO_4. The limiting current is related to the bulk NO concentration c_b, diffusion coefficient D, kinematic viscosity ν, and rotation rate ω by the Levich equation (15)

$$i_l = 0.62\ n\mathbf{F}c_bD^{2/3}\nu^{-1/6}\sqrt{\omega} \quad [2]$$

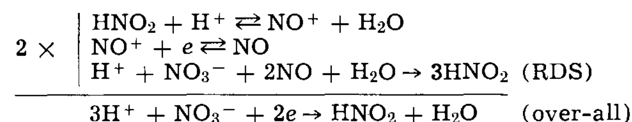
The kinematic viscosity of 4M H_2SO_4 is 1.53×10^{-2} cm²/sec at 25°C (10). With the measured saturation concentration of NO of 1.29×10^{-3} moles/liter and the measured slopes of Fig. 5 and 7 one obtains for the diffusion coefficient $D = 0.90 \times 10^{-5}$ cm²/sec.

It is of interest to take a look into the possible reaction sequences involved in the stepwise oxidation and reduction processes encountered. It is likely that the reduction of NO on platinum proceeds to hydroxylamine as the final product (Fig. 2), the behavior being analogous to that of HNO_2 (10). It may be noted, however, that N_2O does not appear to be a reaction intermediate in spite of the fact that its oxidation state is consistent with that resulting from a one-electron reduction process of NO. This is concluded because Fig. 2 shows that the reaction product generated during the initial NO reduction step (involving the transfer of one electron per reactant molecule) is much more reactive in the potential range between +100 and −180 mV than N_2O is. It is likely that substances of identical oxidation state as N_2O, such as HNO or NO^- are the reaction intermediates in NO reduction.

Oxidation of NO yields HNO_2 which at more anodic potentials is further oxidized to HNO_3. This view is consistent with the relative magnitude of the slopes of Fig. 7 representing the first and second NO oxidation steps. It may be noted that the heterogeneous reaction rates of both reactions strongly decrease with increasing oxidation state of the platinum surface (Fig. 3). Therefore the kinetic data for NO oxidation given in Fig. 9 holds for a cathodically pretreated anode only. The rate of HNO_2 oxidation is maximum in the potential region of beginning oxygen coverage but decreases at higher potentials. It is very possible, therefore, that the HNO_2 oxidation mechanism involves interactions with chemisorbed oxygen on the platinum surface in a similar way as, for example, found during oxidation of methanol (17).

The observed two-step oxidation of NO has implications with respect to proposed reaction sequences for HNO_3 reduction on platinum. According to Schmid (7-10), HNO_3 reduction involves the reaction sequence

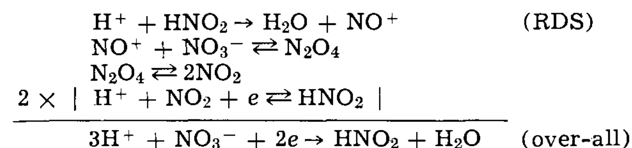
Scheme I



$$2 \times \left| \begin{array}{l} HNO_2 + H^+ \rightleftarrows NO^+ + H_2O \\ NO^+ + e \rightleftarrows NO \end{array} \right.$$
$$H^+ + NO_3^- + 2NO + H_2O \rightarrow 3HNO_2 \quad \text{(RDS)}$$
$$3H^+ + NO_3^- + 2e \rightarrow HNO_2 + H_2O \quad \text{(over-all)}$$

On the other hand, Vetter (5,6) proposed the sequence

Scheme II



$$H^+ + HNO_2 \rightarrow H_2O + NO^+ \quad \text{(RDS)}$$
$$NO^+ + NO_3^- \rightleftarrows N_2O_4$$
$$N_2O_4 \rightleftarrows 2NO_2$$
$$2 \times |\ H^+ + NO_2 + e \rightleftarrows HNO_2\ |$$
$$3H^+ + NO_3^- + 2e \rightarrow HNO_2 + H_2O \quad \text{(over-all)}$$

Both sequences involve a number of chemical and electrochemical steps, but they exhibit significant differences with respect to the charge transfer reaction involved. Scheme I contains only one charge transfer reaction, namely the reduction of NO^+ to NO. If one applies this reaction scheme in reverse order to the present NO oxidation experiments, one expects to find only a single oxidation step the height of which depends on the rate of the slow chemical reaction (RDS). On the other hand, when scheme II is applied to the oxidation of NO, two different charge transfer proc-

esses are required, one involving the oxidation of NO to HNO_2, the other the oxidation of HNO_2 to NO_2. The present experiments clearly exhibit two different NO oxidation steps and therefore they are more consistent with scheme II than with scheme I. Additional kinetic experiments will have to be carried out with NO and HNO_2 solutions before detailed oxidation mechanisms can be established. Particular attention will have to be given to the observed influence of the oxygen coverage of the platinum surface on the reaction kinetics. This has not been included in any of the above reaction schemes.

Conclusions

Nitric oxide absorbed in sulfuric acid solution exhibits well-defined oxidation and reduction reactions on a platinum electrode.

Nitric oxide reduction proceeds in two steps. The first step exhibits a mass transfer controlled limiting current, the magnitude of which corresponds to a charge transfer reaction involving one electron per NO molecule.

Nitric oxide oxidation also proceeds in two steps. The first step leading to HNO_2 exhibits a mass transfer limited current plateau. The second step corresponding to the oxidation of HNO_2 to HNO_3 is only partly governed by mass transfer. Oxidation of the platinum electrode inhibits the reaction.

Rotating disk experiments in 4M H_2SO_4 at 23°C yield a diffusion coefficient of nitric oxide, $D_{NO} = 0.9 \times 10^{-5}$ cm^2/sec.

Polarographic and Coulometric Studies of O-Ethylthioacetothioacetate and O-Ethylthioacetate

A. M. Bond,* A. R. Hendrickson, and R. L. Martin

Department of Inorganic Chemistry, University of Melbourne, Parkville, Victoria, Australia

ABSTRACT

The polarographic and coulometric behavior of O-ethylthioacetothioacetate (OEt-SacSacH) has been characterized in acetone/0.1M Et_4NClO_4 at the DME. Electrolysis of OEt-SacSacH in acetone at a potential of +0.45V relative to Ag|AgCl involves oxidation of the mercury electrode via the consecutive reactions

$$\text{Hg} + \text{OEt-SacSacH} \rightarrow [\text{Hg(OEt-SacSac)}]^+ + \text{H}^+ + 2e \quad [a]$$

$$\text{OEt-SacSacH} + [\text{Hg(OEt-SacSac)}]^+ \rightleftarrows \text{Hg(OEt-SacSac)}_2 + \text{H}^+ \quad [b]$$

On the polarographic time-scale Reaction [b] is slow and the electrode process at the DME is represented by Eq. [a]. The $E_{1/2}$ value is concentration dependent having the value $E_{1/2} = +0.226V$ at infinite dilution. The neutral mercury(II) complex formed under electrolysis conditions enhances oxidation at the mercury electrode ($E_{1/2} = +0.145V$).

$$\text{Hg} + \text{Hg(OEt-SacSac)}_2 \rightarrow 2[\text{Hg(OEt-SacSac)}]^+ + 2e \quad [c]$$

The oxidation electrode process is strongly influenced by adsorption phenomena leading to an additional wave at high concentrations. The characteristics of the adsorption can be followed closely by electrocapillary curves, a-c desorption waves, and d-c current-time curves. An irreversible reduction wave is observed at $E_{1/2} = -1.43V$ for OEt-SacSacH. Comparative studies with the related compound O-ethylthioacetate are reported briefly.

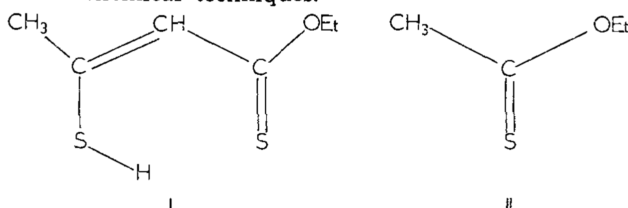
Early speculation on the electrochemical properties of dithioacetylacetonato complexes on the basis of its odd numbered chelate ring suggested these compounds would not undergo reversible electron addition and subtraction reactions (1). However, following the successful synthesis of dithioacetylacetonato (SacSac) complexes of all the Group VIII metals (2-6) it has been shown that most of these compounds are reduced reversibly at the DME in acetone (7-8).

* Electrochemical Society Active Member.

Key words: polarography, coulometry, O-ethylthioacetothioacetate, O-ethylthioacetate.

Unfortunately, with the dithioacetylacetonato series, the parent ligand SacSacH, can only be isolated in the form of a nonco-ordinating adamantane-type dimer $(C_5H_8S_2)_2$. However, the spectral characterization of the closely related O-ethylthioacetothioacetate I (OEt-SacSacH) and its Zn(II), Cd(II), and Hg(II) chelates has been recently reported (9). As part of continuing electrochemical studies of these and related 1,3-dithio ligands and complexes, we report here the polarographic properties of this sulfur-based ligand at the DME. The results of this study have shown that interaction between the compound and the mercury surface is exceedingly complex, although this behavior is not unprecedented for sulfides or sulfur-containing compounds in solvents other than acetone.

The polarographic behavior (oxidation and reduction) of O-ethylthioacetate II as well as that of OEt-SacSacH has been examined in acetone at the DME. The oxidative, reductive, and adsorption behavior of OEt-SacSacH has been examined by alternating and direct current polarography, coulometry, and related electrochemical techniques.



Experimental

Polarography.—Conventional d-c polarography was carried out in May and Baker Analytical Reagent acetone with tetraethylammonium perchlorate (0.1 mole $liter^{-1}$) as supporting electrolyte. A three-electrode, iR compensated system as described in Ref. (7) was employed, the reference electrodes being Metrohm Ag|AgCl EA425 electrodes (0.1 mole $liter^{-1}$ LiCl) in acetone. The glass capillary dropping mercury electrode had the following characteristics in acetone (0.1M Et_4NClO_4) at open circuit and with a mercury column height of 40 cm: flow rate of Hg, m = 1.48 mg sec^{-1}; drop time, t = 4.70 sec; $m^{2/3}t^{1/6}$ = 1.68 $mg^{2/3}$ $sec.^{-1/2}$. Short controlled drop times were achieved with a Metrohm Polarographie stand E354. The a-c polarographic studies utilized a PAR Model 170 Electrochemistry System (Princeton Applied Research Corporation). The major portion of the ohmic iR drop across the solution was compensated for with the three-electrode potentiostat although no positive feedback compensation for the ohmic potential drop of the DME was used in either the a-c or d-c work.

The test solutions, thermostated in a water-jacketed cell at 20°C, were degassed with argon for 20 min before use unless otherwise specified. A slow stream of argon was passed over the test solution while measurements were being taken. Both electrodes (reference and auxiliary) behaved identically although they yielded an $E_{1/2}$ value for $Rh(SacSac)_3$ of −1.09V to be compared with the published result of −1.05V (7). As reported (7), the potential of the electrodes was stable (±2 mV) over a period of three months. The discrepancy of 40 mV for the $Rh(SacSac)_3$ reduction may be attributable to the use of acetone of a different origin from that employed in the previous work. In the present work, the use of May and Baker acetone has allowed the polarographically usable potential range to be extended to −2.2V *vs.* Ag|AgCl. The addition of traces of water lowered this to −2.0V *vs.* Ag|AgCl, the limit previously reported with BDH AnalaR acetone (7). The decrease in the negative potential limit by addition of water to the acetone system has been commented on by Coetzee and Siao (10).

Coulometry.—The number of electrons involved in the oxidation steps (n) has been determined by coulometry. Electrochemical oxidation of a 0.1M Et_4NClO_4/acetone solution of the ligand (~10^{-3} mole $liter^{-1}$) was achieved with 3.00 ml of solution on a mercury pool electrode having an area of approximately 2 cm^2. The mercury pool replaced the DME in the usual polarographic arrangement, with a Pt wire as the auxiliary electrode thereby reducing the bulk and ohmic resistance of the electrode system and enabling the employment of small volumes for electrolysis. The DME was also positioned in the solution enabling the concentration of unoxidized ligand and other electroactive species to be conveniently monitored.

The solution was thoroughly stirred by magnetic stirrer and concentrations of compounds determined at 5-min intervals. Current (~0.3 mA)-time curves were plotted by the recorder and manually integrated. After 30-min electrolysis n was calculated from plots of "charge consumed" *vs.* concentration of the relevant species. As the oxidation potential of the compound is considerably more positive than the reduction potential of oxygen, degassing was not required. To minimize evaporation the electrolysis vessel was surrounded by a moat of acetone and the apparatus sealed. Blank runs, where no electrolysis occurred showed a slight decrease (<1%) in the concentration of the ligand over 1 hr, presumably due to acetone from the moat "distilling" into the 0.1M Et_4NClO_4 solution.

Materials.—Tetraethyl ammonium perchlorate was prepared by neutralization of a 25% solution of Et_4NOH with 20% $HClO_4$. The precipitated product was recrystallized twice from EtOH (95%) and finally from MeOH (AR). Preparation of Et_4NClO_4 by this method obviates the need for many careful recrystallizations to remove the last traces of the electroactive halide ion, always present in samples of Et_4NClO_4 prepared by the metathesis of tetraethyl ammonium iodide (7) or bromide (10) and $NaClO_4$. Pure Et_4NClO_4 was dried and stored under vacuum over silica gel.

O-Ethylthioacetate and O-ethylthioacetothioacetate were prepared and purified as described previously (9). May and Baker "Pronalys" acetone was used throughout.

Results and Discussion

The polarographic behavior of OEt-SacSacH, being the parent ligand of a series of metal complexes also studied by polarography, is of particular interest and has been examined in detail. Although the electrochemistry of the sulfur-based ligand at a mercury surface is very complex, the present data have enabled the nature of the electrode process and ensuing reaction to be unraveled. The ligand exhibits one reduction and one oxidation wave at the DME (Fig. 1). The oxidation and associated adsorption phenomena are discussed in detail in the first instance.

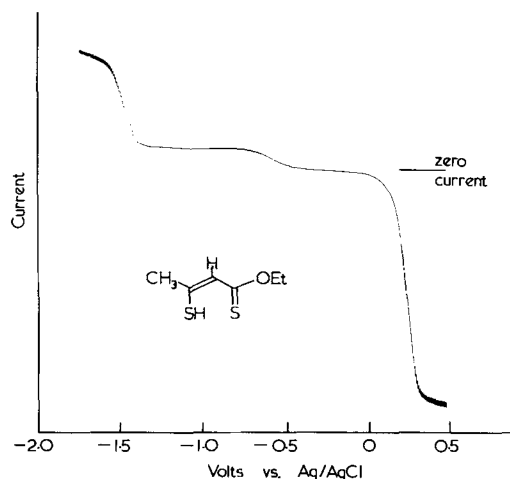


Fig. 1. Complete d-c polarogram of OEt-SacSacH (natural drop time).

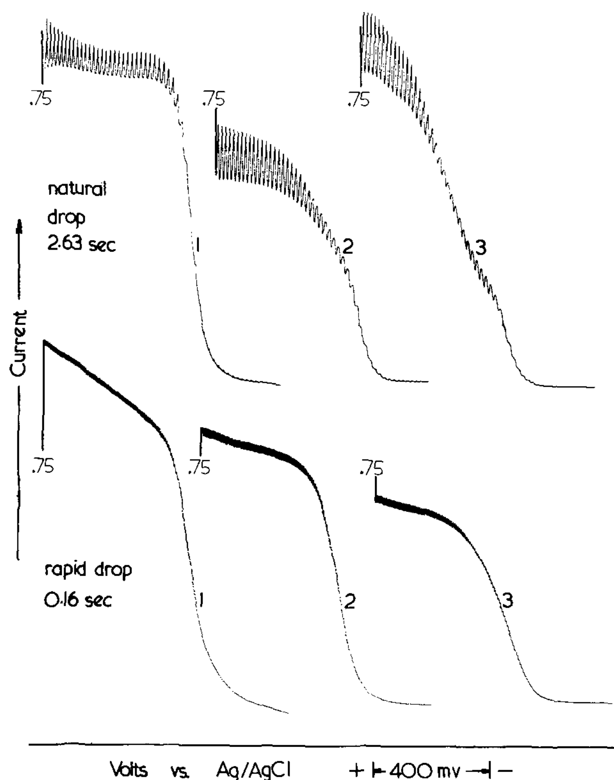

Fig. 2. Natural and rapid polarograms of oxidation process with OEt-SacSacH at approximate concentrations of 1, 5 x 10^{-4}M; 2, 2 x 10^{-3}M; and 3, 2.5 x 10^{-3}M. Current scale has been adjusted for each solution and drop time.

Oxidation.—Both the nature and $E_{1/2}$ value of the oxidation step are concentration dependent. The $E_{1/2}$ values measured over the concentration range 1 × 10^{-4} to 1 × 10^{-3}M extrapolate at infinite dilution to the $E_{1/2}$ value of +0.226 ± 0.004V *vs.* Ag/AgCl.

At concentrations greater than 10^{-3}M it becomes apparent that adsorption and related inhibition of the electrode process are operative at the mercury surface. In this higher concentration region, the oxidation wave splits into two (Fig. 2). However, the total limiting current for the two waves (i_d total) increases linearly with both concentration (Fig. 6), and $\sqrt{h}$ (h = column height of mercury), confirming that the over-all limiting current is diffusion controlled. As NMR studies on OEt-SacSacH in $CDCl_3$ have established that the compound exists in a thio-enol form in this solvent (9) the complex anodic behavior of the compound is not due to a mixture of thio-enol and thione forms.

The electrolysis of OEt-SacSacH solutions at a mercury pool electrode is complicated by the increase in concentration of a species exhibiting an oxidation wave with an $E_{1/2}$ value less positive than that exhibited with OEt-SacSacH (Fig. 3). At the completion of the electrolysis in the presence of the ligand, the polarogram of the remaining species is identical with a polarogram of $Hg(OEt\text{-}SacSac)_2$, even down to the prewave on the reduction step (11). These data have been taken as evidence that the product from the over-all reaction of the oxidation process at a mercury surface is $Hg(OEt\text{-}SacSac)_2$. This is one of the few examples where the mercury complex is both known and soluble, and studies are considerably facilitated because of this.

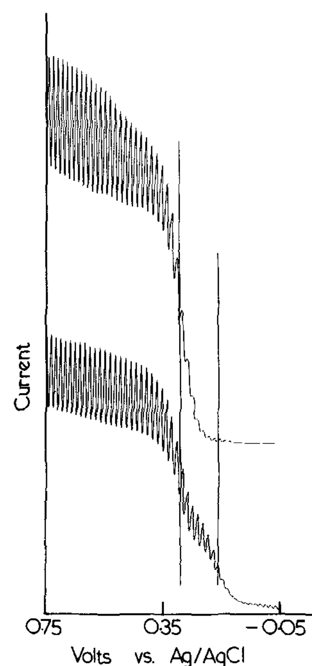

Fig. 3. Oxidation region of solutions of OEt-SacSacH before (upper wave) and after (lower wave) partial electrolysis at a mercury pool electrode, illustrating growth of oxidation wave of $Hg(OEt\text{-}SacSac)_2$ at more negative potentials.

The coulometric experiments of OEt-SacSacH were carried out at +0.45V vs. Ag|AgCl and as can be seen from Table I this potential is sufficiently positive to oxidize mercury in the presence of both OEt-SacSacH and $Hg(OEt\text{-}SacSac)_2$; *i.e.*, the oxidation waves observed are actually due to the oxidation of Hg(0) to Hg(II) in both cases.

The relatively stable $[Hg(OEt\text{-}SacSac)]^+$ moiety is not oxidized at this potential as evidenced by the fact that solutions of $Hg(OEt\text{-}SacSac)_2$ exhibit only a single two-electron oxidation step in the potential range 0.00 to +0.75V *vs.* Ag|AgCl with $[Hg(OEt\text{-}SacSac)]^+$ as the product [1] (11).

$$Hg + Hg(OEt\text{-}SacSac)_2 \rightarrow 2[Hg(OEt\text{-}SacSac)]^+ + 2e \quad [1]$$

Returning to the oxidation of mercury in the presence of the free ligand: the coulometric measurement of n has been determined by monitoring the concentration of free OEt-SacSacH from the oxidation wave.

Table I. Some polarographic parameters of O-ethylthioacetate, OEt-SacSacH, and Hg (OEt-SacSac)$_2$

Compound	$CH_3C(S)OEt$		OEt-SacSacH		$Hg(OEt\text{-}SacSac)_2$

* See text.
** Extrapolated to infinite dilution.
† Markedly drop time dependent.
‡ Reduction step also exhibits a prewave at −0.20V.

The oxidation waves due to OEt-SacSacH and Hg(OEt-SacSac)$_2$ are sufficiently well separated to afford reasonably accurate estimates of their respective concentrations from their diffusion currents. The coulometric value of $n = 1.1 \pm 0.1$ electrons/mole of OEt-SacSacH and the identification of Hg(OEt-SacSac)$_2$ as the product of electrolysis defines the over-all electrode process as

$$\text{Hg} + 2\ \text{OEt-SacSacH} \rightarrow \text{Hg(OEt-SacSac)}_2 + 2\text{H}^+ + 2e \quad [2]$$

The prior isolation of Hg(OEt-SacSac)$_2$ (9) has enabled the increase in absolute concentration of the mercury(II) complex, present at all stages of the electrolysis to be accurately monitored. Figure 4 graphically illustrates the course of the electrolysis. When all free OEt-SacSacH has been consumed, further electrolysis causes the concentration of Hg(OEt-SacSac)$_2$ to decay by Eq. [1]; exactly the same behavior as observed for the electrolysis of solutions of pure Hg(OEt-SacSac)$_2$.

Although the coulometry logically sets the n value at one electron for the over-all oxidation process it can be shown that the actual electron transfer step involves two electrons.

Comparison of the diffusion-controlled limiting current for the oxidation of mercury in the presence of OEt-SacSacH has been made with that of sodium diethyldithiocarbamate. The results were obtained under identical conditions in acetone/0.1M Et_4NClO_4 on 1.00×10^{-3}M solutions of these compounds at a controlled drop time of 0.32 sec. At this concentration, solutions of diethyldithiocarbamate exhibit a one-electron oxidation wave at a DME in acetone (12) in an analogous manner to its behavior in aqueous media (13, 14). The diffusion current for the oxidation of OEt-SacSacH is 2.04 times that for the one-electron process of dithiocarbamate at equal concentrations. Assuming approximately equal diffusion coefficients for these two ligands the electron transfer step with OEt-SacSacH is defined as a two-electron process. To our knowledge, diethyldithiocarbamate is the only ligand with a sufficiently well-characterized electrode process in acetone for this type of comparison.

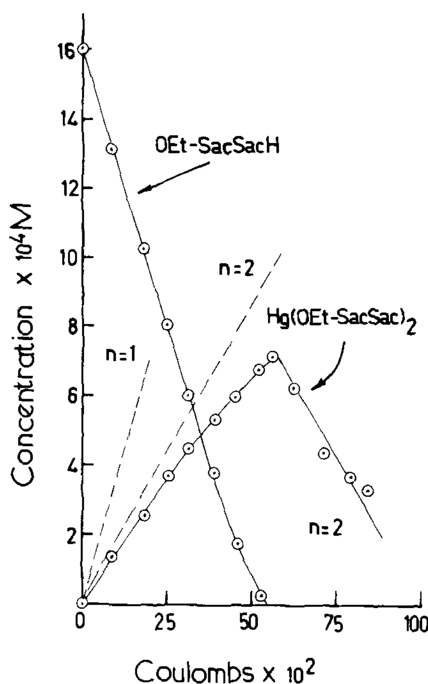

Fig. 4. Complete electrolysis of OEt-SacSacH at a mercury pool electrode. Dashed lines, labeled $n = 1$ and $n = 2$ are calculated lines per mole of compound. Circles represent experimentally determined concentrations of OEt-SacSacH and Hg (OEt-SacSac)$_2$

It must be remembered that the coulometric value of $n = 1$ is obtained for the over-all process of electron transfer and coupled chemical reaction, *i.e.*, Eq. [2]. Furthermore the gradient of the straight line plot of log $[(i_d - i)/i]$ *vs.* $E_{d.e.}$ (63 mV) at a concentration $< 10^{-3}$M and the known polarographic behavior is consistent with an irreversible $2e$ oxidation step.

In view of the two-electron transfer at the electrode, the electrolysis of solutions of OEt-SacSacH presents a very unusual set of reactions. The initial two-electron transfer (Eq. [3])

$$\text{Hg} + \text{OEt-SacSacH} \rightarrow [\text{Hg(OEt-SacSac)}]^+ + \text{H}^+ + 2e \quad [3]$$

produces a cationic product which undergoes a slow reaction with the excess ligand to yield the well-characterized complex Hg(OEt-SacSac)$_2$ (Eq. [4]).

$$[\text{Hg(OEt-SacSac)}]^+ + \text{OEt-SacSacH} \rightleftharpoons \text{Hg(OEt-SacSac)}_2 + \text{H}^+ \quad [4]$$

Obviously Reaction [4] must be slow on the polarographic time scale but is readily observed in the coulometric experiment.

As an examination of the respective $E_{1/2}$ values in Table I indicates, this newly formed, neutral complex enables mercury to be more easily oxidized than does the starting material, OEt-SacSacH. The oxidation via Hg(OEt-SacSac)$_2$ probably accounts for the greater proportion of current flowing toward the completion of the electrolysis. However, as this latter oxidation consumes one mole of electrons per mole of OEt-SacSacH on the coulometric time scale and is regenerative with respect to Hg(OEt-SacSac)$_2$ in the presence of excess ligand, this consecutive process does not perturb the coulometric results.

Burnett *et al.* (13) have obtained a coulometric n value of 0.83 ± 0.03 for the oxidation of mercury in the presence of $[\text{acac}]^-$ and have attributed the low value to the formation of $[\text{Hg(acac)}_3]^-$. Addition of OEt-SacSacH to solutions of Hg(OEt-SacSac)$_2$ does not appreciably alter the oxidation potential of the complex, suggesting that this system is not complicated by increased co-ordination of the Hg(II) ion to give $[\text{Hg(OEt-SacSac)}_3]^-$.

The deviation of the coulometric results from $n = 1$ for the consumption of OEt-SacSacH and $n = 2$ for Hg(OEt-SacSac)$_2$ could be rationalized if Eq. [4] is represented as an equilibrium with an equilibrium constant

$$K_e = \frac{[\text{Hg(OEt-SacSac)}_2][\text{H}^+]}{[\text{OEt-SacSacH}][\text{Hg(OEt-SacSac)}^+]}$$

If this postulated equilibrium step is correct, it follows that the continuing generation of final products and the irreversible electrolytic depletion of starting materials would lead to a slight curvature of the electrolysis plots.

There is no evidence to suggest that any significant quantity of the ligand is oxidized to a disulfide dimer (Eq. [5])

$$2\ \text{OEt-SacSacH} \rightarrow \text{RS} - \text{SR} + 2\text{H}^+ + 2e \quad [5]$$

Indeed, in the early stages of the coulometric oxidation, the increase in concentration of Hg(OEt-SacSac)$_2$ is almost that expected from the decrease in ligand concentration, providing positive evidence against the formation of the dimer. The coulometry is adequately rationalized by the consecutive and concurrent reactions described by Eq. [1], [3], and [4] assuming a slight acid dissociation of Hg(OEt-SacSac)$_2$.

Although the anodic dissolution of mercury is facilitated by the following compounds in the order: Hg(OEt-SacSac)$_2$ > OEt-SacSacH >> acetone, the irreversibility of the electrode process for the first two at least, makes it impossible to draw any conclusions of thermodynamic significance from this fact.

The oxidation process for dithiocarbamate solutions at the DME is summarized as (13, 14)

$$RSH + Hg \rightarrow Hg(SR) + H^+ + e \quad [6]$$

$$2Hg(SR) \rightleftharpoons Hg(SR)_2 + Hg \quad [7]$$

This process differs from that for OEt-SacSacH as the initial transfer step involves only one electron. The electron transfer is followed by a rapid disproportionation with the over-all process being reversible. This oxidation process appears to be operative for a range of thio complexes (16-19). Although Eq. [6] and [7] give the same over-all electrode reactions as OEt-SacSacH, the stability of $[Hg(OEt\text{-}SacSac)]^+$ and the two-electron transfer as elucidated by the diffusion current ratios and electrode characteristics safely dismisses this alternative process in the present work.

Electrocapillary curves.—The electrocapillary curve (drop time *vs.* potential) has been redetermined (20) for the acetone/0.1M Et_4NClO_4 system (Fig. 5). Due to the sensitive nature of these measurements and the high volatility of the solvent, solutions were not deoxygenated. The well-defined curve exhibits an electrocapillary maximum at about 0 volt *vs.* Ag|AgCl. The addition of (1.84×10^{-2}M) the surface active compound, OEt-SacSacH markedly decreases the surface tension, with a substantial reduction in drop time at potentials more positive than -0.5V. The point where this curve joins the curve for acetone/Et_4NClO_4 containing no surface active compound (~ -0.6V), represents the negative adsorption-desorption potential of the ligand. The large shift in the electrocapillary maximum is not unusual for thio compounds, *e.g.*, $NaClO_4/S^=$, -0.37V (21); CH_3COONH_4, KNO_3/diethyldithiocarbamate, -0.3V, estimated from data in Ref. (13).

Not unexpectedly, the positive branch of the curve exhibits complications over the potential region defined by the oxidation process (Fig. 5). Glutathione (22) and diethyldithiocarbamate (13) exhibit similar behavior. The present effect can be attributed to many causes, *e.g.*, a lowering of the concentration of OEt-SacSacH at the electrode surface due to the oxidation process or a different surface activity of the product of oxidation. Unfortunately, the data is insufficiently informative to provide a completely definitive explanation.

Parallel experiments with OEt-SacSacH and $Zn(NO_3)_2 \cdot 6H_2O$ in acetone/0.1M Et_4NClO_4 (11) indicate that the nitrate anion acts as a proton acceptor with the subsequent formation of $Zn(OEt\text{-}SacSac)_2$. With $Zn(ClO_4)_2 \cdot 6H_2O$ however, neither the perchlorate anion nor the acetone accepts the proton, and polarographic studies show the ligand does not chelate to Zn(II) ions in this medium. From this evidence it seems unlikely that the ligand loses its proton on adsorption to the DME unless the adsorbed anionic form of the ligand confers an unexpectedly large stabilization over the adsorbed neutral ligand.

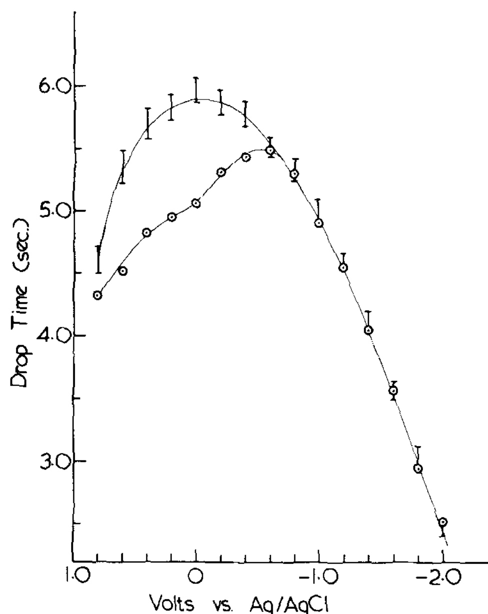

Fig. 5. Electrocapillary curves of (I) acetone/0.1M Et_4NClO_4 and (⊙) acetone/0.1M Et_4NClO_4 + 1.84×10^{-2}M OEt-SacSacH.

A-C polarography and desorption wave.— Preliminary a-c studies on OEt-SacSacH in acetone at concentrations $< 10^{-3}$M show three peaks corresponding to the oxidation process ($E_s = 0.29$V), reduction (-1.28V), and a presumed tensammetric or desorption wave (-0.54V). On increasing concentration of OEt-SacSacH, the a-c oxidation peak becomes quite complex as expected from the adsorption and related inhibition phenomena to be discussed in further detail below.

Extended deoxygenation of solutions of OEt-SacSacH indicates that the small wave present in the d-c polarograph at -0.59V is not due to dissolved oxygen. The wave persists in separate preparations of OEt-SacSacH and is not believed to be an impurity, but is assumed to be the result of the desorption of the ligand on proceeding to more negative potentials. The kink reflects the difference in capacity of the double layer at potentials where the mercury surface is covered by the surface-active ligand and at those where the normal electrical double layer exists (23). The potential of the kink is in agreement with the negative adsorption-desorption potential obtained from the electrocapillary (-0.6V) and a-c (-0.5V) studies.

Further aspects of adsorption.—As well as the adsorption phenomena exhibited by the protonated ligand (or less likely its deprotonated form) a further concentration dependent adsorption is operative at the DME on oxidation of the mercury in the presence of the ligand.

At low concentrations ($< 1 \times 10^{-3}$M) the anodic wave exists as a well-defined, although irreversible, single wave at a drop time of 2.00 sec. The $E_{1/2}$ value of the wave shifts cathodically on decreasing concentration of OEt-SacSacH to yield an extrapolated $E_{1/2}$ value of $+0.226$V *vs.* Ag/AgCl at infinite dilution. On increasing the concentration of OEt-SacSacH the diffusion current increases monotonically up to a concentration of $\sim 1 \times 10^{-3}$M. On further increasing the concentration the limiting current of this first wave (i_d1) remains approximately constant. A second wave with an $E_{1/2}$ slightly more anodic than that of the first wave is generated at concentrations $> 1 \times 10^{-3}$M.

The $E_{1/2}$ of this second wave also moves anodically on increasing the concentration of OEt-SacSacH. Unfortunately, superposition of the mercury oxidation wave on this second wave renders evaluation of its limiting current (i_d2) unreliable at concentrations $> 3 \times 10^{-3}$M. The limiting current for the first oxidation wave is easily monitored to high concentrations and remains relatively constant, cf., 11 μA at 1.3×10^{-2}M. Similar behavior has been observed from the sulfide anion in aqueous media (24-29) and diethyldithiocarbamate (13, 14).

It has been suggested that the oxidative behavior of the sulfide anion may be due to the presence of both $S^=$ and SH^- in solution (24), although an alternative explanation involving adsorption of oxidation product (HgS) at the DME in the form of a monolayer and 3-D crystals on increasing concentration of $S^=$ leading to inhibition of further oxidation accounts for the three waves reported (25-29). The recent observations of a fourth wave for the sulfide system (30) may require both theories for complete understanding.

For OEt-SacSacH, the constancy of the limiting current for the first wave at concentrations $> 10^{-3}$M

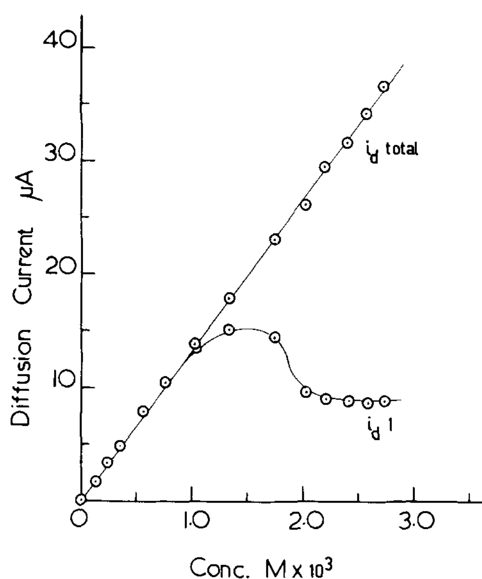

Fig. 6. Concentration dependence of limiting currents for the oxidation wave of Hg in the presence of OEt-SacSacH (drop time 2.00 sec).

(Fig. 6, drop time of 2.00 sec) suggests that the electrode surface is probably covered by adsorbed compound at all concentrations greater than this. It is apparent from the same figure that up to a concentration of 10^{-3}M the limiting current described by the first wave is diffusion controlled. At concentrations $> 10^{-3}$M the sum of i_d1 and i_d2, *i.e.*, i_d total, indicates the total limiting current is diffusion controlled (Fig. 6) although the shift in potential of the second wave indicates that the oxidation is more difficult to accomplish at the covered electrode. Julien and Bernard (29) have attributed the corresponding shift of $E_{1/2}$ to more positive potentials with increasing concentration in the $S^=$ example to the ohmic resistance of the adsorbed film, an explanation which is not inconsistent with the present findings for OEt-SacSacH.

Although this inhibition phenomena has not been reported for the thio compounds; β-mercaptopropionic acid (18), ethylthioglycolate (19), methoxyethylthioglycolate (16), thiolactic acid (17), or glutathione (22), it seems possible to the present authors that this phenomenon may be evident with these compounds at greater concentrations than those reported.

Current-time curves (Fig. 7) on ~ 8 sec drops have been drawn out with the Metrohm recorder at selected potentials across the oxidation waves exhibited by solutions of OEt-SacSacH. Unfortunately limited recorder response has not enabled the point of zero current and zero time to be drawn out. This has resulted in some curves (0.50-0.65V) appearing to present negative currents. The curves dramatically illustrate the adsorption at the DME with the classical initial rise of current at all potentials and the subsequent fall at potentials where adsorption inhibits further oxidation, *i.e.*, 0.40-0.65V. These curves have parallels in the sulfide examples (29).

From these curves it would appear that at shorter drop times (induced by premature mechanical disengagement of slow growing drops) the abbreviated current-time curves should be less influenced by adsorption phenomena and as expected, the resulting over-all polarographic wave shows less perturbation from adsorption (cf., Fig. 2 and 8). However, other considerations are also important here as the limiting current of the first wave (i_d1) actually increases slightly with decreasing drop time.

At concentrations $> 10^{-3}$M the oxidation wave has a marked dependence on drop time; for example, the wave showing clearly 50% contributions from i_d1 and i_d2 at a natural drop time of 2.57 sec becomes a slightly distorted single wave at a rapid drop time of 0.16 sec (Fig. 2). The effect of the rapid drop technique on the recording of the oxidation waves at increasing concentration of OEt-SacSacH is illustrated in Fig. 2.

Undoubtedly the electrode process is less complicated at short drop times and the value of the rapid polarographic techniques in studying electrode processes complicated by adsorption phenomena is clearly illustrated.

Reduction.—The reduction wave ($E_{1/2} = -1.43$V) for the ligand conforms to a linear $\sqrt{h}$ *vs.* i_d plot indicating that the limiting current is diffusion controlled. From the electrocapillary and current-drop time curves it is apparent that the reduction occurs with the ligand in a nonadsorbed state.

The $E_{1/4}$-$E_{3/4}$ value of 68 mV and the a-c polarography indicates the electrode process exhibits kinetic complications. Unlike the product of the oxidation process, the product of reduction has not been isolated or characterized. However, the following observations have enabled constructive suggestions to be made on this process.

As the oxidation step involves a two-electron transfer, the ratio of diffusion currents for the oxidation and reduction waves (2.2:1) at a controlled drop time (0.32 sec) defines the reduction as a one-electron step. This dismisses the possibility of radical dimerization (31, 32) as observed with dibenzoylmethane (33) ($n = 0.5$) and suggests reduction involving the evolution of hydrogen

$$\text{OEt-SacSacH} + e \rightarrow [\text{OEt-SacSac}]^- + \tfrac{1}{2}H_2$$

This is the operative process with acetylacetone (acacH) (34). The complicating keto-enol conversion observed for the reduction of acacH is not relevant for OEt-SacSacH as this compound exists entirely in

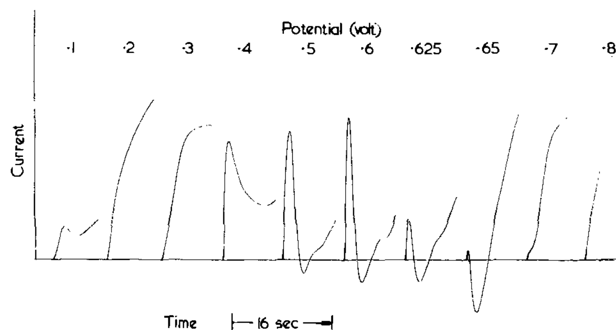

Fig. 7. Current-drop time curves shown at various potentials across the oxidation wave (OEt-SacSacH). Current scale not the same at all potentials.

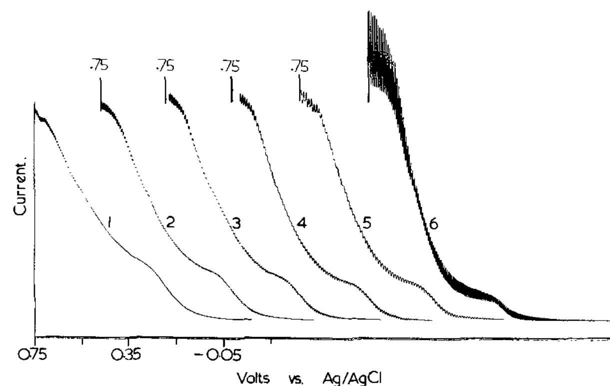

Fig. 8. Drop time dependence of oxidation wave (OEt-SacSacH ~ 10^{-2}M). Drop time: 1, 0.16 sec; 2, 0.20 sec; 3, 0.24 sec; 4, 0.28 sec; 5, 0.32 sec; 6, 0.95 sec. All curves run +0.75 to −0.05V *vs.* Ag|AgCl.

the reactive thio-enol form. Addition of small quantities of 40% tetrabutylammonium hydroxide deprotonates OEt-SacSacH to [OEt-SacSac]$^-$, and as expected from the suggested reduction mechanism, the reduction wave vanishes completely.

The reduction of free H^+ ions in acetone/Et_4NClO_4 has been examined by addition of small quantities of 60% $HClO_4$. The $E_{1/2}$ value of the well-defined reduction wave is very dependent on water content, moving to more negative potentials on increasing concentrations of water. Hence the least negative $E_{1/2}$ obtained, −0.88V can only be regarded as a lower limit for this reduction potential. Molecules containing an X-H unit which can be reduced to X^- and H_2, fall at more negative potentials, *e.g.*, H_2O and acacH are reduced toward the potential limit of the solvent, −2.2V. Although $E_{1/2}$ values for these nonreversible reductions may be misleading, it is pleasing to note that the proposed reduction of the S-H unit falls at a more negative potential than that of free H^+ ions.

O-Ethylthioacetate.—Finally it is of interest to compare the polarographic behavior, in acetone, of OEt-SacSacH (I) with that of O-ethylthioacetate (II) (Table I). The latter compound exhibits both oxidative and reductive activity toward the potential limits of the solvent. The oxidation wave, superimposed on the foot of the mercury oxidation wave, appears to have an $E_{1/2}$ of approximately +0.7V although it is not feasible to accurately evaluate polarographic parameters. The reduction step at $E_{1/2} = -2.08V$ *vs.* Ag|AgCl has an ($E_{1/4}$-$E_{3/4}$) value of 54 mV. A solution of the compound slowly coats the mercury pool with a dark decomposition or reaction product. Although the nature of the reduction product is not completely understood for either compound it is readily apparent that the thiol function of OEt-SacSacH is more amenable to reduction. It is presumed that the resonance stabilized mercury complex formation affords an easier oxidation of the mercury in solutions of OEt-SacSacH than O-ethylthioacetate where the product of oxidation cannot achieve such stabilization.

Protonation of the Anion Radicals of 2,5-Substituted Oxazoles and Oxadiazoles with Hydroquinone in N,N-Dimethylformamide

S. L. Smith, L. D. Cook, and J. W. Rogers

Department of Chemistry, Midwestern University, Wichita Falls, Texas 76308

ABSTRACT

The influence of the proton donor hydroquinone on the polarographic reduction of a series of phenyl and naphthyl-substituted oxazoles and oxadiazoles in DMF has been studied. Cyclic voltammetric data taken at potentials of the first of two polarographic waves at a hanging mercury drop electrode suggest that the oxadiazoles and 2-naphthyl-substituted oxazoles are reduced via a two-electron ECE process at large proton donor to compound ratios. Phenyl-substituted oxazoles are reduced in only one polarographic wave with an n apparent of 4.0 at high proton donor to compound ratios.

The electrode reduction mechanisms of representative 2,5-aromatic-substituted oxazoles and oxadiazoles in N,N-dimethylformamide (DMF) were recently presented (1, 2). The compounds 2,5-diphenyloxazole and 2-(1-naphthyl)-5-phenyloxazole are reduced in N,N-dimethylformamide in two polarographic steps according to the mechanism

First wave:

$$R + e^- \rightleftarrows R^{\cdot-}$$

Second wave:

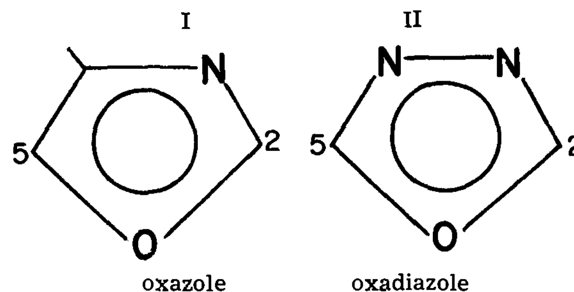
$$R^{\cdot-} + e^- \rightleftarrows R^=$$
$$R^= + HS \rightarrow RH^- + S^-$$

where HS is solvent or other weak proton donor. The anion radical, $R^{\cdot-}$, and protonated dianion, RH^-, are long-lived in the absence of efficient proton donors. Similarly substituted oxadiazoles are reduced accordingly with an additional electrochemical step at potentials near the solvent-supporting electrolyte potential limit (2).

The effects of proton donors on the reduction processes were studied to confirm the postulated mechanisms in DMF (1, 2). The polarographic current plateaus of the 2-phenyl-substituted oxazoles appeared to vary with added proton donors in a manner similar to the polarographic processes of most aromatic hydrocarbons with both plateaus coalescing to one at high proton donor to compound ratios (1, 3, 4). The influence of added proton donors on the polarographic reduction of oxadiazoles is in general uniform, but different from the oxazole behavior and previously reported results of studies on the electrochemical reduction of aromatic hydrocarbons in aprotic media containing controlled quantities of proton donors (2-5). The polarographic data previously presented suggested that the oxadiazole π-radical produced by a reversible one-electron process is either, not readily protonated in the presence of water and hydroquinone (HQ), or protonated but not reduced further at potentials near the first $E_{1/2}$ of the parent compound (2, 3). These observations are not consistent with theory and suggested the need for a more systematic and thorough investigation of the reactions of electrochemically produced intermediates of oxazole and oxadiazole heterocyclics with proton donors in aprotic media. The importance of the role of proton donor species on the electroreduction mechanism of aromatic hydrocarbons has been discussed in detail by Mark and others (6, 7). The controlled protonation of heterocyclic anions has not been treated in detail.

Key words: anion, heterocyclic, protonation.

We wish now to report studies in which polarographic and cyclic voltammetric techniques were employed to investigate the production and protonation of the anion radicals of 2,5-diphenyloxazole, 2-(1-naphthyl)-5-phenyloxazole, 2-(4-fluorophenyl)-5-phenyloxazole, 2-(3-methoxyphenyl)-5-phenyloxazole, 2-(4-methoxyphenyl)-5-(1-naphthyl) oxadiazole, 2-(4-methoxyphenyl)-5-(2-naphthyl) oxadiazole, 2,5-diphenyloxadiazole, 2-(4-fluorophenyl)-5-phenyloxadiazole and 2-(4-fluorophenyl)-5-(2-naphthyl) oxadiazole (note structures I & II) in DMF containing controlled quantities of hydroquinone (HQ). A small portion of the data presented is repetitious, but its inclusion with new data clarifies salient points. The test compounds were chosen to illustrate the influence of 2,5-substituent variations on the reactivity of the anion produced at the first polarographic plateau of each compound.



The complete study included electrochemical measurements in DMF and acetonitrile, both containing controlled quantities of water and HQ. Both substances functioned most effectively as proton donors in acetonitrile. Water functioned as a very weak donor in DMF. These results and the fact that HQ is an effective donor and electroinactive in DMF have been noted previously (5, 6). Although the influence of a set amount of proton donor varied with solvent-donor combinations the general electrochemical behavior (number and type of reactions) of the test materials was not altered. Consequently, we have chosen to report data only from studies in DMF-HQ media.

Polarographic Data

The compound 2,5-diphenyloxazole exhibits two diffusion-controlled, one-electron polarographic waves in dry DMF solvent (Table I, Fig. 1). The currents of both plateaus are enhanced equally by a factor of 40% when the test solution is made 1.75 mM in HQ. The current increase continues with additionally added HQ until at 5.25 mM HQ the first wave exhibits an n

apparent[1] of 2.0 and is kinetically controlled.[2] The second plateau also exhibits an n apparent of 2.0 but is diffusion controlled. The current changes are accompanied by a +20 mV shift in the $E_{1/2}$ of the first wave and a +60 mV shift of the second. Further additions of HQ causes the first wave to grow at the expense of the second with the total current of both waves remaining constant (Fig. 1). Addition of enough HQ to bring the test solution to 50 mM effects limiting behavior with only one diffusion-controlled polarographic wave observed at −2.10V *vs.* SCE with an n apparent of 4.0, (Fig. 1 and 2).

The n apparent of the first wave of 2,5-diphenyloxazole, given as a function of added HQ in Fig. 2, summarizes the electroactivity of the compound in the presence of various amounts of HQ. The behavior is similar to that of alternant aromatic hydrocarbons (3, 5, 6).

Addition of inductively releasing or withdrawing substituents to the phenyl ring at the oxazole 2-position shift $E_{1/2}$ values but effect no significant changes in the electrochemical behavior of the heterocyclic in pure DMF or DMF-HQ mixtures (Table I). Polarographic data given in Fig. 2 show that the n apparent of the first polarographic wave of 2-(3-methoxyphenyl)-5-phenyloxazole and 2-(4-fluorophenyl)-5-phenyloxazole varies with added HQ in the same manner as 2,5-diphenyloxazole. The second polarographic wave of 2-(4-fluorophenyl)-5-phenyloxazole exhibits a diffusion current corresponding to an n apparent of 2.0 in dry DMF. The controlled addition of HQ enhances the diffusion currents of both plateaus. At concentrations of HQ greater than 5.25 mM the first wave grows at the expense of the second with increasing amounts of HQ. One wave corresponding to a 4-electron diffusion-controlled process and observed at −2.06 *vs.* SCE represents limiting behavior. Further additions of HQ do not alter this limiting behavior. As with 2,5-diphenyloxazole and 2-(3-methoxyphenyl)-5-phenyloxazole, addition of HQ influences the extent of reduction at each plateau with the end product of both waves (n apparent of 4.0) not altered by the addition of any quantity of HQ greater than 5.25 mM.

Substitution of a naphthyl group at the heterocyclic 2-position does not significantly alter the electrochemical behavior of the oxazole ring in dry DMF (Fig. 3, Table I). The anodic shift in the $E_{1/2}$ of both plateaus of 2-(1-naphthyl)-5-phenyloxazole relative to those of 2,5-diphenyloxazole in dry DMF is expected (8). The compound does however exhibit a polarographic behavior in the presence of HQ significantly different from that of the other test oxazoles (Fig. 3). The first polarographic wave of the compound does not demonstrate the same reactivity to small quantities of added proton donor as that of the previously discussed oxazoles (Fig. 2). The current of this plateau exhibits kinetic complications and is enhanced slightly by 5.25 mM HQ (Fig. 3). It reaches a limiting value corresponding to a 2-electron diffusion-controlled process at

[1] n apparent = i/id where i is the polarographic limiting current in the DMF-HQ system, and id is the diffusion current of the first wave of the compound in dry DMF.
[2] The plateau current is independent of the corrected mercury head height above the dme.

HQ concentrations greater than 50.0 mM. The wave does not coalesce with those more cathodic at any proton donor to oxazole ratios investigated (Fig. 3). The current of the second wave is enhanced to a greater extent than that of the first by the addition of small quantities of HQ (Fig. 3). At HQ concentrations as low as 1.75 mM a third wave, kinetically controlled, is observed with an $E_{1/2}$ of -2.47V vs. SCE (Fig. 3). The second diffusion plateau along with the kinetic current are greatly enhanced with further additions of HQ (Fig. 3). A significant anodic shift of the kinetic-controlled wave accompanies the current growth with added HQ (Fig. 3). At HQ concentrations near 17.5 mM the second current plateau and the kinetic current coalesce into one diffusion controlled polarographic wave with current corresponding to an n apparent of 4.0 (Fig. 3). The reduction of the naphthyl-substituted oxazole at high proton donor concentrations requires a total of 6 electrons per molecule.

All 2,5-aromatic substituted oxadiazoles exhibited three polarographic waves in dry DMF (Table I, Fig. 4). A reversible electron transfer followed by a rapid protonation of the dianion is the process responsible for the second wave. The most cathodic of the three waves results from a multielectron ring opening reaction (2). The two most cathodic waves are quite sensitive to small quantities of added HQ and in general coalesce to one diffusion-controlled multielectron step at HQ concentrations greater than 5.25 mM (Fig. 4).

An interesting feature of the polarography of the oxadiazoles is the relative insensitivity of the first polarographic wave to added HQ (Fig. 2 and 4). This wave, representing the reversible production of an anion π-radical of each compound in dry DMF, exhibits kinetic complications at HQ concentrations as low as 5.25 mM. However, a maximum n apparent of approximately 2.0 and diffusion-controlled behavior is only approached in experiments conducted in DMF with large concentrations of HQ (Fig. 2). The rate of approach to the limiting behavior, as a function of added HQ, is dependent upon the structure of the 2,5-substituents (Fig. 2). The first wave of the compound 2,5-diphenyloxadiazole exhibits the greatest sensitivity to added HQ, showing kinetic complications at 5.25 mM HQ and approaching a limiting n apparent of 2.1 at HQ concentrations ten times greater (Fig. 2). Substitution of fluorine on the 2-phenyl substituent did not influence the electroactivity of the compounds (Fig. 2). Replacement of the 5-phenyl with a naphthyl function

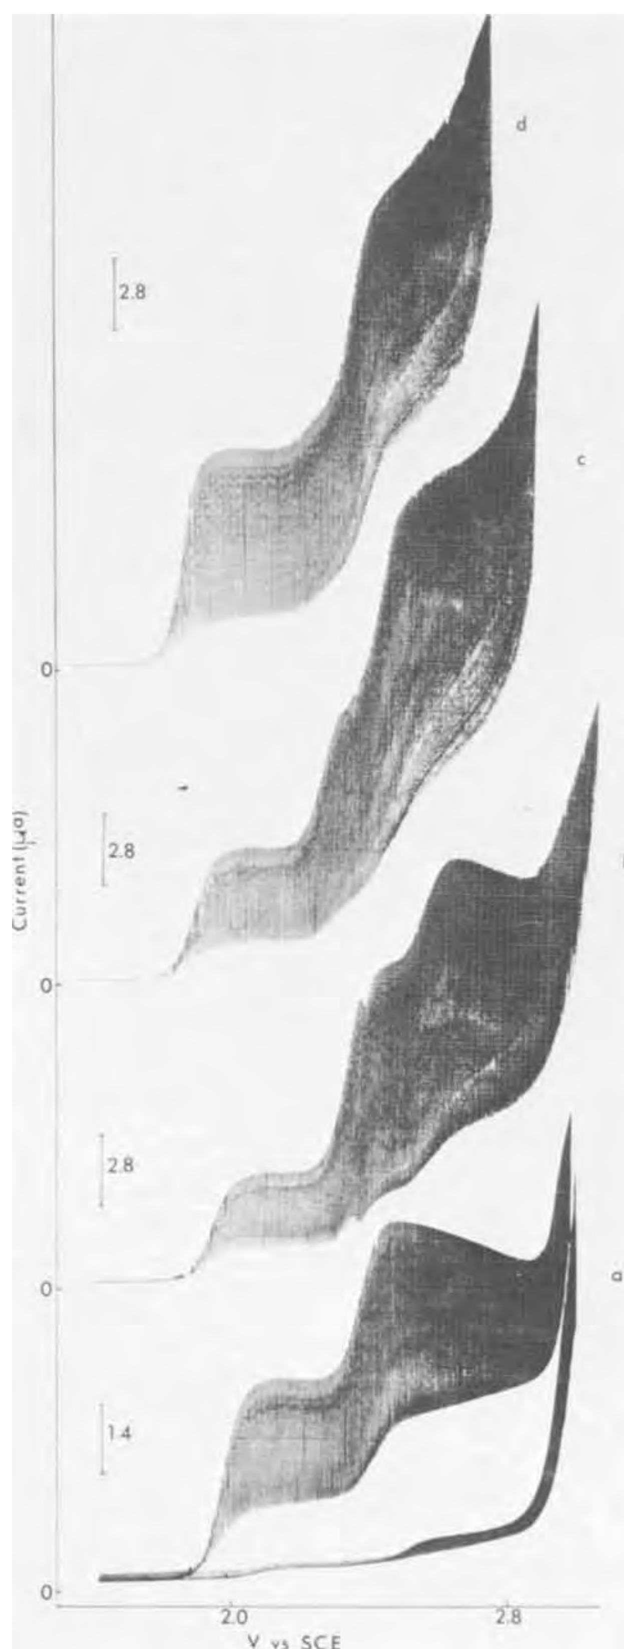

Fig. 3. Polarograms of 2-(1-naphthyl)-5-phenyloxazole in DMF containing (a) no HQ, lower curve is supporting electrolyte polarogram run at current sensitivity 10 times that of polarograms of 2-(1-naphthyl)-5-phenyloxazole; (b) 5.25 mM HQ; (c) 17.5 mM HQ; and (d) 87.5 mM HQ.

(α or β) diminished the sensitivity of the first wave to added proton donor (Fig. 2). The change in behavior is not as dramatic as that resulting from the same substitution at the oxazole 2-position (Fig. 2). The

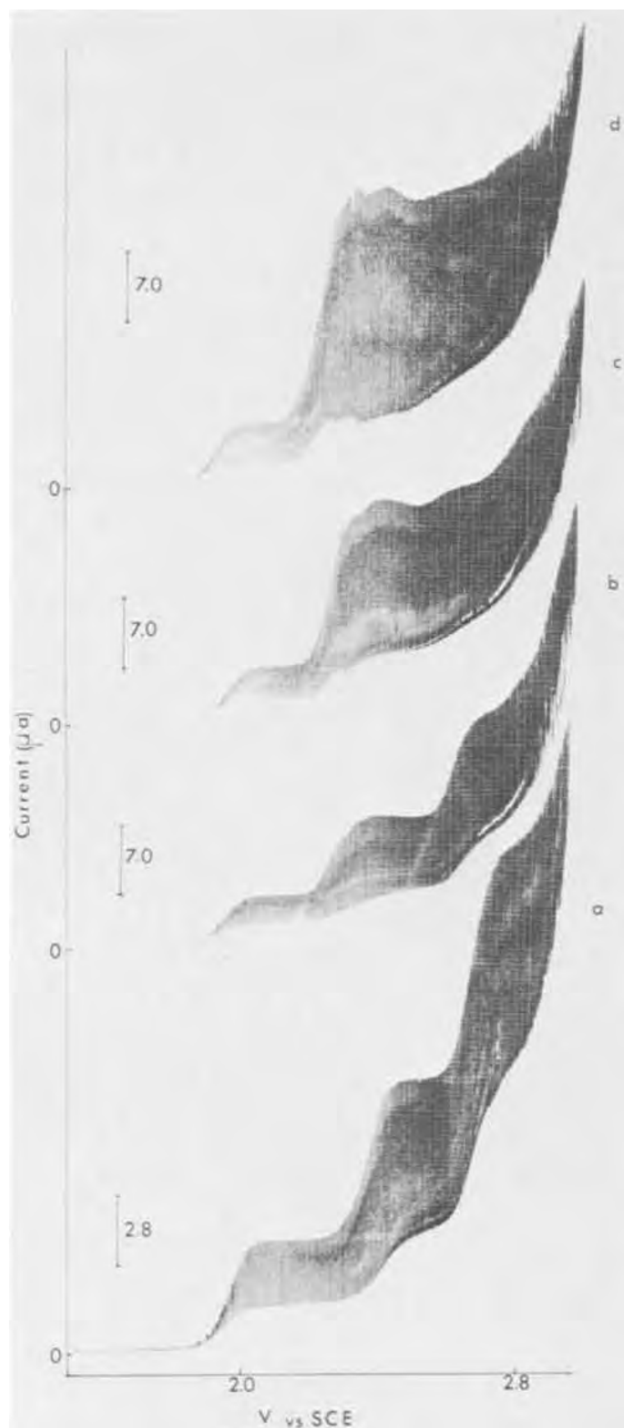

Fig. 4. Polarograms of 2,5-diphenyloxadiazole in DMF containing (a) no HQ, (b) 1.75 mM HQ, (c) 5.25 mM HQ, and (d) 52.5 mM HQ.

first polarographic wave of the compound 2-(4-methoxyphenyl)-5-(2-naphthyl) oxadiazole exhibits the least sensitivity of all compounds to added HQ, approaching a limiting n apparent of 2.0 only at concentrations of HQ near 120 mM (Fig. 2).

Cyclic Voltammetric Data

Cyclic voltammetry provides an excellent means by which the homogenous reactions of radical intermediates may be qualitatively studied and compared. To investigate the nature of the processes responsible for the behavior of the most anodic polarographic wave of each compound, cyclic voltammograms of compounds representative of four of the curves shown in Fig. 2 were recorded at a hanging mercury drop electrode (HMDE). The experiments were conducted at several n apparent values of the first polarographic wave of each compound. Complete cyclic voltammetric data for the first wave of 2,5-diphenyloxazole, 2,5-diphenyloxadiazole, 2-(1-naphthyl)-5-phenyloxazole and 2-(4-methoxyphenyl)-5-(2-naphthyl) oxadiazole are given in Table II as a function of amount of added proton donor.

Cyclic voltammetric data confirm that each of the compounds studied are reversibly reduced to a stable anion radical at potentials cathodic of the first polarographic wave in DMF with no added HQ (Table II). The first cyclic wave of 2,5-diphenyloxazole recorded at 3.5 mM HQ reflects kinetic complications (Fig. 5 and 6). The wave broadens and the ratio of anodic to cathodic current, $(i_p)_a/(i_p)_c$, diminishes with decreas-

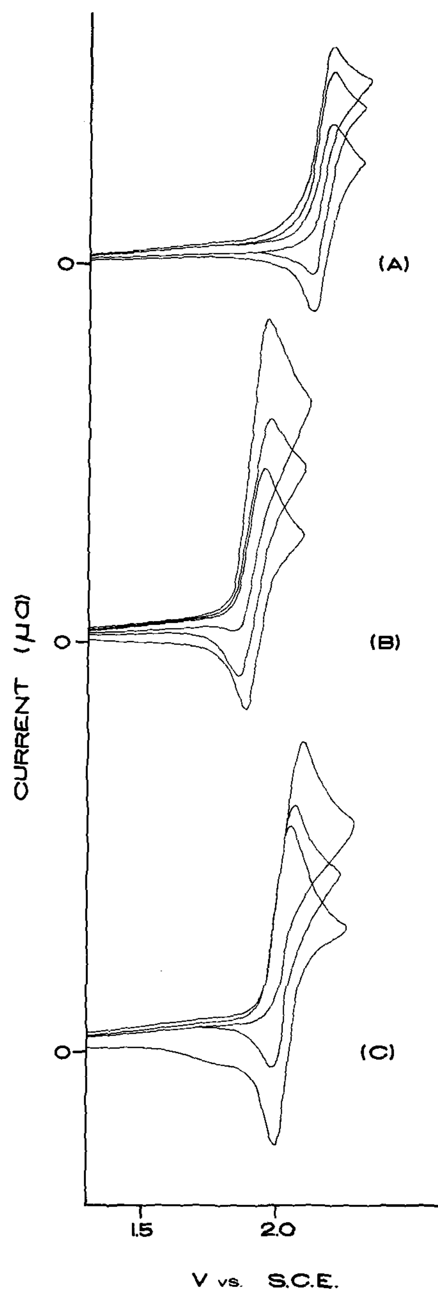

Fig. 5. (a) Cyclic voltammograms of 2,5-diphenyloxazole recorded at 10.56 V/min at a HMDE in DMF containing 0.0, 3.5, and 6.0 mM HQ. (b) Cyclic voltammograms of 2-(1-naphthyl)-5-phenyloxazole recorded at 10.00 V/min at a HMDE in DMF containing 0.0, 32.5, and 105 mM HQ. (c) Cyclic voltammograms of 2,5-diphenyloxadiazole recorded at 10.80 V/min at a HMDE in DMF containing 0.0, 21.5, and 105 mM HQ. The switching potential $E\lambda$ is 200 mV past E_p and the drop size uniform for all voltammograms.

ing potential sweep rate (v) (Table II, Fig. 6). The current function, $(i_p)_c/v^{1/2}$, varies slightly at larger sweep rates and greater at the lower rates, increasing with decreasing v (Table II). A 10 mV anodic shift of the cathodic peak potential is observed for a tenfold increase in the potential sweep rate (Table II, Fig. 6). No anodic current is observed on the reverse going segment of cyclic experiments conducted in 6.0 mM HQ (Table II, Fig. 5). The cathodic current peak sharpens and the potential continues to shift anodically with an increase in v at this HQ concentration (Table II). This particular behavior is contrary to that for a concerted electrochemical step in which a chemical reaction or reactions is coupled to heterogenous electron transfers (9). It is found, however, that the peak potential and current function of voltammograms conducted at HQ concentrations effecting a limiting n apparent of 4.0 behave in a manner consistent with a single, complex electrochemical step (Table II).

[a] n apparent from polarographic data.
[b] $E\lambda$ (switching potential) = 120 mV.
[c] No anodic peak.
[d] Limiting value of n apparent.
[e] Base line for small anodic current could not be determined.

The cyclic voltammograms of 2-(1-naphthyl)-5-phenyloxazole recorded at potentials of the first polarographic wave begin to exhibit definite kinetic effects at HQ concentrations near 17.5 mM (Table II). The effects become much more pronounced at slightly higher HQ concentrations (Table II, Fig. 5 and 6). At concentrations of 50 mM or greater no anodic current is observed at sweep rates up to 10 V/min (Fig. 5, Table II). All parameters of cyclic voltammograms of this compound at all HQ concentrations are consistent with a process in which a chemical reaction is coupled between two reversible electron transfer steps (ECE process) with the product of the reaction more reducible than the parent compound (9). The rate of the coupled reaction is proportional to the ratio of proton donor to parent compound; Fig. 5 and 6 illustrate this assertion (9).

The compound 2,5-diphenyloxadiazole behaves in a manner quite similar to that of 2-(1-naphthyl)-5-phenyloxazole (Table II, Fig. 5 and 6). The kinetic complications become apparent at slightly lower HQ concentrations. The voltammogram parameters of the compound 2-(4-methoxyphenyl)-5-(2-naphthyl) oxadiazole are consistent with an ECE process with kinetic complications and limiting behavior observed at considerably higher HQ concentrations than the other compounds (Table II).

Discussion

A study of the influence of HQ on the reduction of oxazoles and oxadiazoles places the compounds into two basic categories. One category includes compounds exhibiting a limiting behavior of one diffusion-controlled polarographic wave with an n apparent of 4.0 and the other includes compounds exhibiting, as limiting behavior, two diffusion waves with the first approaching an n apparent of 2.0 at high HQ concentrations. The first includes the 2,5-phenyl-substituted

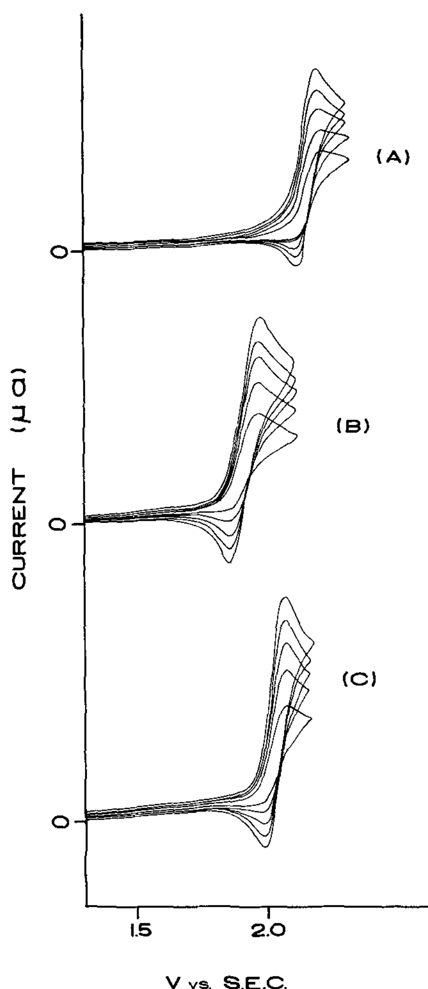

Fig. 6. (a) Cyclic voltammograms of 2,5-diphenyloxazole recorded in DMF containing 3.5 mM HQ at a HMDE at 10.56, 7.91, 5.27, 2.54, and 1.06 V/min. (b) Cyclic voltammograms of 2-(1-naphthyl)-5-phenyloxazole recorded in DMF containing 32.5 mM HQ at a HMDE at 10.00, 7.50, 5.00, 2.50, and 1.00 V/min. (c) Cyclic voltammograms of 2,5-diphenyloxadiazole recorded in DMF containing 21.5 mM HQ at a HMDE at 10.80, 8.10, 5.40, 2.70, and 1.08 V/min. The switching potential $E\lambda$ is 120 mV past E_p and the drop size uniform for all voltammograms.

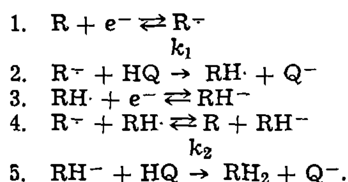
oxazoles and the second the oxadiazoles and 2-(1-naphthyl)-5-phenyloxazole.

Cyclic voltammetric data suggest that the oxadiazoles and 2-(1-naphthyl)-5-phenyloxazole are reduced via a two-electron ECE process to a dihydro species at the first polarographic wave in the presence of HQ. The complete mechanism probably may be represented by the sequence of steps (10)



1. $R + e^- \rightleftarrows R^{\cdot -}$
2. $R^{\cdot -} + HQ \xrightarrow{k_1} RH\cdot + Q^-$
3. $RH\cdot + e^- \rightleftarrows RH^-$
4. $R^{\cdot -} + RH\cdot \rightleftarrows R + RH^-$
5. $RH^- + HQ \xrightarrow{k_2} RH_2 + Q^-$.

Step 5 has been shown to be very fast in the presence of small quantities of proton donor (10). Also, the sensitivity of the second polarographic wave to small quantities of HQ relative to the first wave of each compound confirms that the step is very rapid with respect to step 2. The type equilibrium expressed in step 4 has been shown to lie almost completely to the right for aromatic hydrocarbons. The similar voltammetric behavior of oxazole and oxadiazoles with that of certain aromatic hydrocarbons suggests that this equilibrium also exists to the right for the compounds under study. These facts are consistent with the observed ECE type behavior.

The difference in rate of approach to limiting behavior exhibited by the oxadiazoles and 2-(1-naphthyl)-5-phenyloxazole in Fig. 2 is a result of differences in k_1 of each compound. Mark has pointed out that for an ECE type mechanism the rate of protonation (step 2) relative to the rate of diffusion of $R^{\cdot -}$ away from the electrode surface is an important factor in determining polarographic and voltammetric wave characteristics (6). If the proton donor concentration is high and/or the constant k_1 is large, then step 2 occurs near the electrode surface and behavior as described herein is expected.

Values of the rate constant, k_1, for the reaction of the oxadiazoles and 2-(1-naphthyl)-5-phenyloxazole with HQ were estimated from a plot of the polarographic n apparent *vs.* the product of the pseudo first order rate constant, $k_1[HQ]$, and the drop time, t, after the method of Nicholson *et al.* (11). The values of k_1 appear to be of the same order of magnitude as similar constants for protonation of aromatic hydrocarbon radicals in DMF and acetonitrile (4, 12). The rate constants range from 0.1 liters mM^{-1} sec^{-1} for 2,5-diphenyloxadiazole and 2-(4-fluorophenyl)-5-phenyloxadiazole to 0.05 for 2-(1-naphthyl)-5-phenyloxazole and 2-(4-fluorophenyl)-5-(2-naphthyl) oxadiazole and 0.04 for 2-(4-methoxyphenyl)-5-(2-naphthyl) oxadiazole.

It should be noted that these rate constants obtained assuming pure ECE behavior are possibly in error due to the previously recognized ECE contribution to the total reduction process. However, this possible error is appreciable only at high n apparent values and the rate constants given were measured at an n apparent near 1.4.

Comparison of the k_1 values relative to the curves in Fig. 2 shows that the increased conjugation due to naphthyl for phenyl substitution at the 2 or 5-position carbon has a significant slowing influence upon the rate of protonation of the anion radicals of the oxadiazoles. Electronic effects of substituents on the 2 or 5-position phenyl slightly alter the rate of protonation of the naphthyl substituted oxadiazoles.

Naphthyl substitution at the oxazole 2-position completely alters the electrochemical reduction mechanism of the oxazole ring in the presence of proton donors. At large proton donor to oxazole ratios 2-(1-naphthyl)-5-phenyloxazole is reduced in two polarographic steps with the first appearing to be a two-electron ECE process resulting in a dihydro species (1). The k_1 of this process is comparable to that of the oxadiazoles. At large proton donor to oxazole ratios the phenyl-substituted oxazoles are all reduced in one polarographic step exhibiting an n apparent of 4.0. The unusual cyclic voltammetric data taken of these compounds in DMF in the presence of HQ may be explained in terms of two electrochemical processes occurring at very similar voltages. The first leads to the dihydro compound, RH_2, and the second to saturated-ring or ring-opened products (1, 2). At intermediate HQ concentrations the second step is cathodic enough of the first to cause cathodic current peak broadening and a cathodic shift at the slower sweep rates (Fig. 5). At large proton donor concentrations the two processes coalesce to one concerted step due to an anodic shift of the second process. The resulting voltammetric wave exhibits properties consistent with a complex, but concerted reduction process (Table II).

Bezuglyi *et al.* have studied the polarographic reduction of oxazoles and oxadiazoles in aqueous methanol at various pH values (13). This work and that presented herein provide a description of the electrochemistry of these hetrocyclics in all media ranging from the protic to the closely aprotic. Bezuglyi found that 2-(1-naphthyl)-5-phenyloxazole exhibited a single two-electron wave in aqueous methanol at pH

values ranging from 3.8 to 12.2 (13). The $E_{1/2}$ of this process corresponds to the most anodic of the two waves of this compound observed in solutions containing large concentrations of HQ (Fig. 3). The multielectron process occurring at more cathodic potentials and probably resulting in ring-opened products is not observed in aqueous methanol solutions (13). The limiting behavior of the oxadiazoles in DMF containing HQ corresponds to the behavior of the compounds in aqueous methanol (13).

A major difference is observed in the electrochemical behavior of the phenyl-substituted oxazoles in DMF containing large quantities of HQ and in aqueous methanol (13). These substances are reduced via a single, six-electron wave in aqueous methanol but in a four-electron process in DMF-HQ, suggesting ring-saturation without ring-opening in DMF-HQ.

Experimental

Apparatus.—The electrodes and accessories for electrochemical measurements have been described previously (1). All solutions were 1 mM in electroactive compound unless otherwise stated. The reference electrode, saturated calomel, made contact with the solution through an agar plug behind a Pyrex frit. Water leakage through this tip was found to be negligible in experiments of short time duration. The cyclic voltammetric data were recorded on a Bolt-Barnak-Newman X-Y plotter using a Wenking potentiostat and Exact wave form source for potential control. The polarograms were recorded with a Beckman Electroscan 30 electroanalytical system.

Chemicals.—Spectroquality DMF containing approximately 0.03% water was obtained from Eastman Organic Chemicals. The solvent was vacuum distilled from anhydrous $CuSO_4$ before use. Hydroquinone was obtained from J. T. Baker Chemical Company and was recrystallized from a 50% water ethyl-ether solution. All compounds were purchased from Alfred Bader Chemical Company and were recrystallized from pure methanol before use. The preparation and purification of tetra-N-propylammonium perchlorate has been described previously (1).

Mass Transfer to Point Electrodes on the Surface of a Rotating Disk

Der-Tau Chin*,[1] and Mitchell Litt

School of Chemical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

A zeroth order perturbation solution is presented for the rate of laminar mass transfer to three types of point electrodes embedded in the surface of an insulating rotating disk—those sensitive to radial, tangential, and local velocity components. It is shown that the diffusion current density on the point electrode increases with decreasing geometrical parameter defined as the ratio of the electrode size to the radial location of the electrode on the disk surface. With a properly chosen geometrical parameter, it is possible to obtain a current density ten times greater than that on the disk electrode at a given rotational speed. From the electroanalytical point of view, this offers experimental advantages in the study of fast surface reactions.

An experimental setup for studying the transfer characteristics of such electrodes is described. A diffusion-controlled redox reaction is used for the measurement. The results indicate that the "local" and the "tangential" electrodes give reasonable agreement with the theory prediction. However, data from the "radial" electrode scatter randomly around the predicted values. This failure of the radial electrode to behave properly appears to be consistent with thin-ring experiments reported in the literature.

Study of point electrodes mounted flush on the surface of a rotating disk is of interest to both electrochemists and engineers. Such an electrode, because of its small surface area and high-rate convective transport, offers practical advantages in the study of high rate electrode reactions (1). To the engineers, the electrode may be used to investigate the nature of flow near the disk surface (2-4). While the theory of laminar flow and mass transfer on the rotating disk

* Electrochemical Society Active Member.
[1] Present address: Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090.
Key words: convective diffusion, limiting current.

has been well developed, this is true only for a disk whose surface is completely active, that is, where there is a nonzero axial gradient at every point of the disk surface. Since the point electrode introduces active areas only at small selected points on the disk surface, the previous solutions for mass transfer are inapplicable, and a suitable theory, even for laminar flow, does not exist.

Though there have been a number of studies of heat and mass transfer to partially active rotating disks, these have primarily been disks with some part of the surface, usually the center, blocked off. Gregory and Riddiford (5) found that no significant change occurred in the mean mass transfer coefficient until the central area blocked off exceeded about 10% of the total disk area. This effect presumably occurs because of the radial gradients introduced by the blocked-off area, for in a completely active disk, there are no radial gradients and the surface is "equally accessible" to mass transfer. Levich (6) has obtained a theory for a disk with active rings; however, preliminary measurements by Avdeyeva on thin rings gave results some 20-30% lower than those predicted. Schnurr (7) studied heat transfer with a stepwise discontinuous surface temperature. Albery *et al.* (8) have published extensively on the study of reactions using ring-disk electrodes.

In this work, we are attempting to study the transfer characteristics of the point electrodes on the surface of an insulating rotating disk. A preliminary measurement of the rate of mass transfer on a circular point electrode was made by Serad (9) in a diffusion-controlled redox system. The present authors have extended such measurements to the transition and the turbulent regions with both circular and rectangular point electrodes. A theory has also been derived to correlate data in the laminar region. This paper describes: (*i*) details of the theoretical analysis, and (*ii*) the experimental setup as well as the results of time-averaged measurements in a ferricyanide/ferrocyanide redox system. In the transition and the turbulent regions, the rate of mass transfer is found to be oscillating due to flow fluctuations near the disk surface. The results of these fluctuation measurements and their implications to flow instability has been presented elsewhere (10-11).

Theoretical

The theory of heat and mass transfer to point sources in pipe flow and flat plate has been developed by Mitchell and Hanratty (2), and Ling (12). Here we present an analysis for the point electrodes mounted on the surface of an insulating rotating disk. Three types of the electrodes are considered: (*i*) the "tangential electrode," which is a long, narrow mass sink mounted parallel to the radial direction, so that it responds only to convective transfer due to the tangential velocity component; (*ii*) the "radial electrode," which is also a long, narrow mass sink mounted parallel to the tangential direction, so that it responds only to the radial velocity component; (*iii*) the "local electrode," which is a small circular mass sink, and responds to the local velocity relative to the disk surface (3). Since the development for each of these electrodes is similar, we shall give details of the analysis only for the tangential electrode, and list only results for the other two.

Let us consider a mass sink having an average distance of $r = \overline{oo'}$ from the disk center (Fig. 1). The sink is rectangular in shape, and its small dimension is on the order of the thickness of the momentum boundary layer. Its area is so small compared with the disk surface that a separate Cartesian coordinate system may be taken for the space concerned. We choose such a system with its origin at point o'. Since the disk is rotating with a constant speed, ω, about its axis, the coordinates fixed on the disk surface are traveling with a constant velocity, $r\omega$. The coordinate z is normal to the disk surface, and y is along the radial direction. The coordinate x is parallel to the circumferential direction of the disk, and points towards the opposite direction of rotation. This assumption leads to $V_z = 0$ in accordance with the equation of continuity for fluid flow. Also, for the case of the tangential electrode, we have $L << W$; thus, the equation of convective diffusion may be reduced to

$$V_x^* \frac{\partial \Phi}{\partial x^*} = \frac{1}{\mathrm{R\,Sc}} \frac{\partial^2 \Phi}{\partial x^{*2}} + \frac{\epsilon}{\mathrm{Sc}} \frac{\partial^2 \Phi}{\partial z^{*2}} \quad [1]$$

where $x^* = x/L$; $z^* = z\sqrt{\omega/\nu}$; $\Phi = (C - C_\infty)/(C_0 - C_\infty)$; $V_x^* = V_x/r\omega$; $\epsilon = L/r$; $R = Lr\omega/\nu$; $\mathrm{Sc} = \nu/D$.

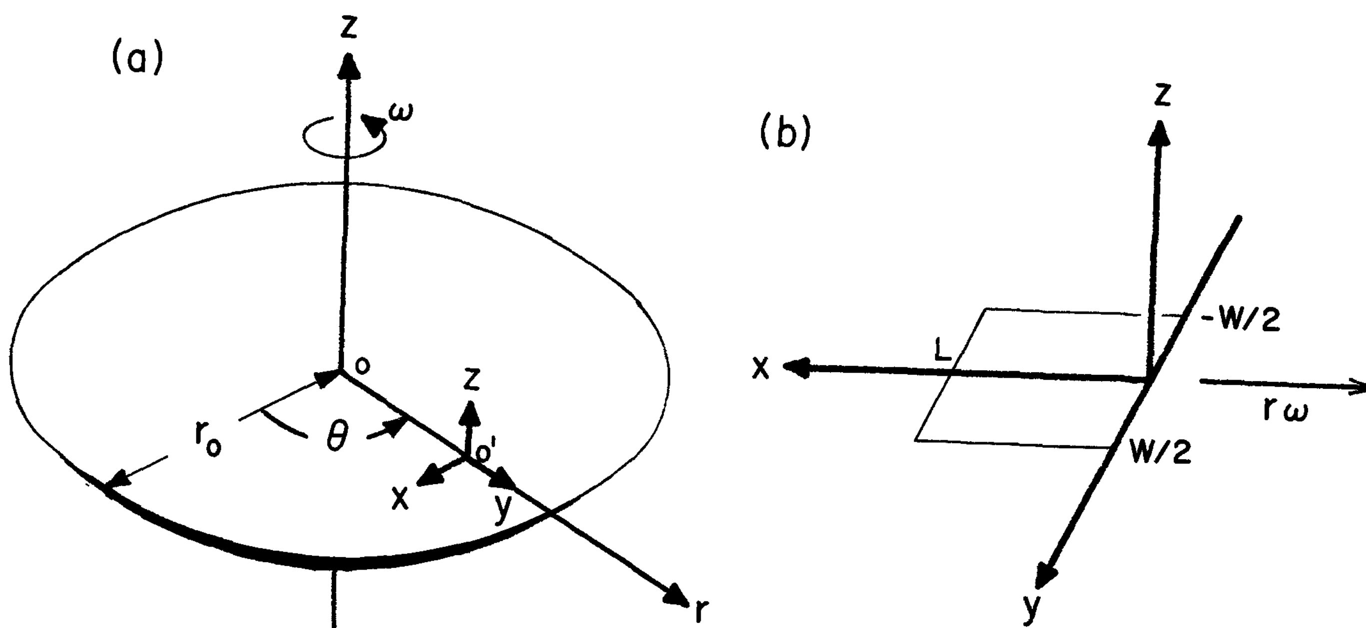

Fig. 1. Cartesian coordinate system for point electrodes on the surface of a rotating disk. (a), Location of the electrode; (b), close view of the electrode surface.

The boundary conditions are

$$\left.\begin{array}{ll} \Phi = 1 & \text{at the electrode surface;} \\ \partial\Phi/\partial z^* = 0 & \text{at the surface of the insulating rotating disk;} \\ \Phi = 0 & \text{at } x^* \to \pm\infty \text{ and } z^* \to \infty \end{array}\right\} \quad [2]$$

Mathematically this is a multi-singularity problem resulting from the nonuniformity of the boundary conditions around the electrode surface. The singular regions can be classified into: (*i*) the leading edge, $x^* \to 0$, $z^* \to 0$; (*ii*) the trailing edge, $x^* \to 1$, $z^* \to 0$; (*iii*) the main region over the electrode surface, $0 < x^* < 1$, $z^* \to 0$; and (*iv*) the wake region, $x^* > 1$, $z^* \to 0$. Only the main region solution is of principal interest to practical applications. It has been shown by Chin (13) that the contribution of mass flux at the electrode surface from the other regions is negligibly small for $Sc > 100$, and $R > 10$. Thus we shall only present the method of solution for the main region. The development of equations for the other singular regions is given in Chin (13), and will not be repeated here.

Following the standard procedure of a singular perturbation method, we introduce a stretched coordinate

$$Z = Sc^{1/3} z^* \quad [3]$$

for the coordinate z^* in the main region, and assume that the dimensionless concentration, Φ, can be expanded in an asymptotic series of Sc

$$\Phi = \Phi_0(x^*,Z) + Sc^{-2/3}\Phi_1(x^*,Z) + \ldots \quad [4]$$

To solve Eq. [1], one also requires an expression for the velocity component V_x^*. For the rotating coordinates considered here, the velocity V_x^* is related to the tangential velocity component, V_θ, of the rotating disk by

$$V_x^* = 1 - V_\theta/r\omega \quad [5]$$

Using Cochran's series solution (14) in the vicinity of the disk surface, we have

$$V_x^* = -G_1 z^* - (F_1/3)z^{*3} + \ldots \quad [5a]$$

For laminar flow, the dimensionless gradients, F_1 and G_1, are constant (0.510 and -0.616, respectively). Substituting Eq. [3]-[5a] into Eq. [1] and equating the terms having the same order in Sc lead to the following zeroth order perturbation equation

$$-G_1 Z \frac{\partial \Phi_0}{\partial x^*} = \epsilon \frac{\partial^2 \Phi_0}{\partial Z^2} \quad [6]$$

with the boundary conditions

$$\left.\begin{array}{lll} \Phi_0 = 1 & \text{at } Z = 0 & \text{for } 0 < x^* < 1 \\ \Phi_0 = 0 & \text{at } Z \to \infty & \end{array}\right. \quad [7]$$

The above equation and boundary conditions are seen to be identical to the Leveque problem (15) of heat transfer in the entrance region of pipe flow. The same result was also obtained by Hanratty (2) and Ling (12) for their geometries. In those instances, this results from a prior assumption of a linear velocity profile near the surface. In this instance, the zeroth order solution becomes equivalent to such an assumption; however, this method of formulating the problem is more general and provides the basis for correcting the approximate solution by numerical integration of the first order equation.

If we define a mass transfer coefficient K as

$$N_z|_{z=0} = K(C_0 - C_\infty) = -\frac{D}{WL}\int_{-W/2}^{W/2} dy \int_0^L dx \left(\frac{\partial C}{\partial z}\right)_{z=0} \quad [8]$$

then, using the results of the Leveque solution, it can be shown that the Sh for the main region becomes

$$Sh = (KL/D) = -0.807 G_1^{1/3} \epsilon^{1/6} R^{1/2} Sc^{1/3} [1 + 0(Sc^{-2/3})] \quad [9]$$

For laminar flow, $G_1 = -0.616$, so that

$$Sh = 0.687\, \epsilon^{1/6} R^{1/2} Sc^{1/3} [1 + 0(Sc^{-2/3})] \quad [9a]$$

In the presence of an excess supporting electrolyte, the average diffusion current density on the electrode surface is related to K by

$$i = nFK(C_\infty - C_0) \quad [10]$$

and Eq. [9a] can be rearranged in dimensional form as

$$i = 0.687 nF(C_\infty - C_0)(r/L)^{1/3} D^{2/3} \nu^{-1/6} \omega^{1/2} \quad [11]$$

Note that this equation differs from the Levich solution of the rotating disk electrode (6) by only a numerical factor and a geometrical ratio, $r/L = \epsilon^{-1}$; thus, dividing Eq. [11] by the Levich solution, we have

$$i/i_D = K/K_D = 1.11\, \epsilon^{-1/3} \quad [12]$$

Here the subscript, D, denotes the process occurring at the disk electrode whose entire surface is subject to mass transfer. Equation [12] implies that the diffusion current density on the point electrode increases with decreasing geometrical parameter, ϵ. For a typical value of $\epsilon = 0.001$ used in this study, the current density on the point electrode would be 10 times greater than that on the disk electrode. In electrokinetic studies, the upper limit that the rotating disk electrode can be used to determine the first-order surface rate constant, is 0.1 cm/sec (1). The point electrode technique is therefore capable of extending this limit to 1.0 cm/sec without difficulty.

Like most electrode geometries, however, the point electrode suffers from a nonuniform current distribution across the surface; the limiting current density near the leading edge tends to be greater than in the main region. This may introduce some errors for the study of irreversible reactions. For reversible electrochemical systems, lack of uniform accessibility does not present a serious problem, for it does not change the current-potential relations obtained from the Nernst diffusion layer concept (8).

Results for the radial and the local electrode are given in Table I. It should be noted that the radial electrode has dimensions, $W << L$, and the definition of ϵ and R has been changed to

$$\epsilon = W/r, \quad R = Wr\omega/\nu \quad \text{(for radial electrode)}$$

Also in deriving the equations for the local electrode, the circular sink has been approximated as a square mass sink having the same surface area as the circular

Table I. Summary of theoretical results

Type of electrode	Zeroth order correlation for laminar flow	Comparison with disk electrode	Estimated fractional error for K
Local	$\sqrt{\pi}Kd/2D = 0.749\, \epsilon^{1/6} R^{1/2} Sc^{1/3}$	$K/K_D = 1.21\, \epsilon^{-1/3}$	$Sc^{-1/3}$
Radial	$KW/D = 0.645\, \epsilon^{1/6} R^{1/2} Sc^{1/3}$	$K/K_D = 1.04\, \epsilon^{-1/3}$	$Sc^{-1/3}$
Tangential	$KL/D = 0.687\, \epsilon^{1/6} R^{1/2} Sc^{1/3}$	$K/K_D = 1.11\, \epsilon^{-1/3}$	$Sc^{-2/3}$

d is the diameter of the local electrode, L and W are the width (short dimension) of the tangential and the radial electrodes, respectively. K_D is the mass transfer coefficient of a rotating disk electrode whose entire surface is subject to mass transfer.

one. Thus to use the results for the local electrode, ϵ and R should be

$$\epsilon = (\sqrt{\pi}/2)\ d/r, \quad R = (\sqrt{\pi}/2)\ dr\omega/\nu$$
(for local electrode)

where d is the diameter of the local electrode. Mass transfer to a ring electrode has been treated by Levich (6), and our result for the radial electrode agrees with his result for a narrow ring on the disk surface.

Experimental

The diffusion controlled reaction used is the oxidation-reduction of potassium ferricyanide and ferrocyanide in aqueous solution. Details of the reaction and its application to mass transfer studies can be found elsewhere (2, 9, 13, 16-17). In the present study, a solution containing 0.01M potassium ferricyanide, 0.01M potassium ferrocyanide, and 1.0M potassium chloride is used for the experiments. Small platinum electrodes mounted flush with the surface of a Lucite rotating disk are used as cathodes. The anode is a platinum foil with a very large surface area, so that the cell current is controlled by the cathode reaction.

The complete system consists of a cell tank containing the anode, a Lucite spinning disk, and a drive assembly equipped with slip-ring contacts. The cell container is a cylindrical Lucite tank, 53 cm ID and 32 cm deep. Six Lucite baffles are evenly spaced along the container wall. The anode is located on the cell bottom; it is a sheet of platinum foil, 0.3 mm thick, 15 cm diameter, cemented to a Lucite plate and has a surface area of 176 cm^2 exposed to the electrolyte.

The Lucite spinning disk is composed of three separate sections. Figure 2 illustrates the details of construction. The upper section is made from a 10 cm Lucite rod. The upper end of this section is threaded to fit a glass-epoxy shaft of the slip-ring contact; the other end, with an Amphenol 12-contact polarized receptacle on its center, is designed to accommodate either a 10 cm diameter disk, or an adapter for fitting on a 15 cm disk. The 15 cm disk is made from a 0.6 cm Lucite sheet, and is machined to fit the adapter to form a bell-shaped rotating disk. A Lucite nose cemented on the center of the inner face of the disk serves as a base for an Amphenol 12-contact polarized plug. The plug matches with the Amphenol receptacle of the upper section when the disk is fastened to the adapter.

Two 15 cm Lucite disks having flush-mounted surface electrodes have been constructed. The types and location of platinum electrodes on each disk are as follows:

(*i*) The first disk has 12 circular platinum local electrodes on the outer surface. The electrodes are made from platinum wires, 0.0127-0.0381 cm in diameter. The radial location of the electrodes ranges from 4 to 6 cm. Holes to accommodate these electrodes are drilled first, and the platinum wires are inserted through the holes. The space between the hole walls and the platinum is filled with epoxy cement, and

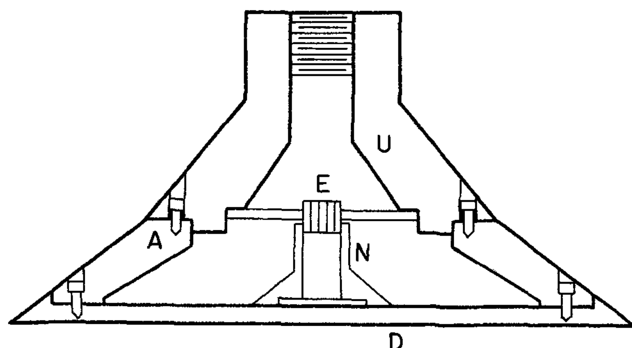

Fig. 2. Rotating disk. A, adapter; D, 15 cm Lucite disk; E, electric connector; N, Lucite nose; U, upper section.

the outer face is then smoothed and polished. The platinum leads on the inner face are connected electrically to the Amphenol plug.

(*ii*) The second disk contains 12 radial and 12 tangential electrodes made from a platinum foil. The dimensions of these surface mounted electrodes are 0.03 mm wide by 0.254 cm long. They are evenly located on the disk surface with radial positions varying from 2.5 to 6.2 cm (13).

The slip-ring contacts, the drive assembly, an electric motor, and a tachometer generator combine to make an integral drive unit. The slip-ring assembly is the same as reported by Serad (9) and will not be discussed further. The lower end of the slip-ring shaft screws into the upper section of the rotating disk; the upper end of the shaft is attached to a coupling connecting with the drive assembly. A Reliance 1 hp d-c motor is used to drive the rotating assembly. A Minarik SH 293 motor control is used in conjunction with the motor. The motor is mounted with a 48XL timing pulley which gives a pulley ratio of 2:1 and allows a speed range of 250-2000 rpm for the rotating disk.

A 6V battery is used as the power supply to the electrochemical cell. The applied potential drop across the anode and the cathodes is controlled by a 350 ohm potentiometer. The cell current is determined by passing the current through a 1000 ohm standard resistor. Since the current fluctuates when flow becomes turbulent, a 10,000 MF capacitor in conjunction with a microvoltmeter (Keithley 151) is used to measure the time-averaged component of the current. For each electrode, the current/potential curves are first measured to determine the limiting current plateau. A proper potential setting is then chosen for the potentiometer, and the limiting currents are measured at various rotational speeds. To avoid interference from the nearby electrodes, this measurement is made for only one electrode at a time, while all the other electrodes on the disk surface are at open circuit.

Results and Discussion

In a diffusion-limited electrode reaction, the mass transfer coefficient, K, is related to the measured current density by Eq. [10]. At the limiting current density, the surface concentration of the diffusing ion goes to zero, giving

$$K = i_{\rm lim}/n\mathbf{F}C_\infty \qquad [13]$$

For the ferricyanide/ferrocyanide reaction, $n = 1$, and all the other quantities are known or measured, so that K may be calculated. For turbulent flow, the mass transfer coefficient will have a time-averaged and a fluctuating component. In this paper we shall present results only of the time-averaged component measurement. Results of the fluctuating component measurement have been reported elsewhere (10-11).

Figure 3 is a plot of the time-averaged mass transfer coefficient *vs.* rotational speed for a 0.0381 cm diameter local electrode located at various positions on the disk surface. These curves are typical of the data obtained, so the raw data with the other electrodes and other positions are not shown. The measurements with smaller size local electrodes gave very poor reproducibility because of small area and very low currents being measured, and these data will not be reported. The main features of the curves are: (*i*) a linear region with a slope of ½ for low rotational speeds, which presumably represents the laminar region; (*ii*) a break-point signifying the beginning of flow instability which occurs at different speeds for different radial positions; (*iii*) a second break-point, again at different speeds, presumably signifying transition to fully developed turbulence. In this final region, the curves again are linear with a slope slightly greater than ½. As would be expected, the break-point speed

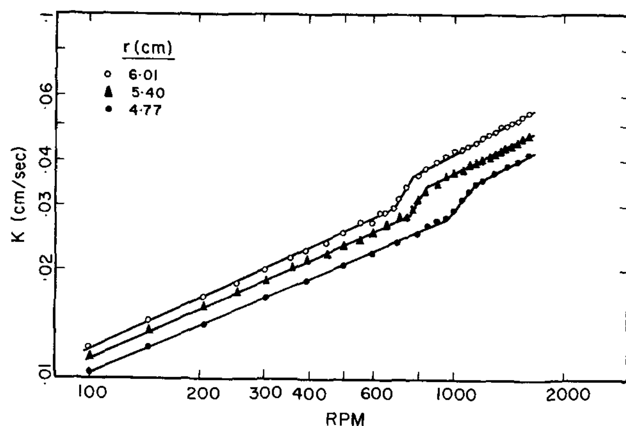

Fig. 3. Time-averaged mass transfer coefficient vs. rotational speed for a 0.0381 cm diameter local electrode. The measurement is carried out at a room temperature of 22°C.

for an electrode located at a smaller radius, is higher than that for an electrode located at a larger radius. This demonstrates that on a given disk, the laminar, transition, and turbulent regimes exist simultaneously at different radii.

As seen from the results shown in Table I, one would expect that a log-log plot of $Sh/\epsilon^{1/6}Sc^{1/3}$ *vs.* R would be linear with a slope of ½ for laminar flow. Figures 4-6 show the results for the local, the radial, and the tangential electrodes.

There is considerable variation in the degree with which the theory appears to correlate the experimental results. From Fig. 4, we see that all the data for the 0.0381 cm diameter local electrode seem to be well correlated. Not only is the slope of the line predicted, but the theoretical coefficient seems to agree well except at the very end of small R, where edge effects may start to become important. Figure 6 indicates that while the data points for different radii are not brought together as well, the theory still gives relatively good agreement for the tangential electrode. Again, there seems to be deviation at the lower Reynolds numbers based upon the electrode width.

Figure 5 shows that agreement between the theory and the data is not quite satisfactory for the radial electrode. While each of the individual electrodes seems to follow a line of proper slope, it is apparent that the theory does not take the ϵ factor into account properly. The failure of the radial electrode to behave properly is consistent with Avdeyeva's (6) mass transfer measurement on thin-ring electrodes. His

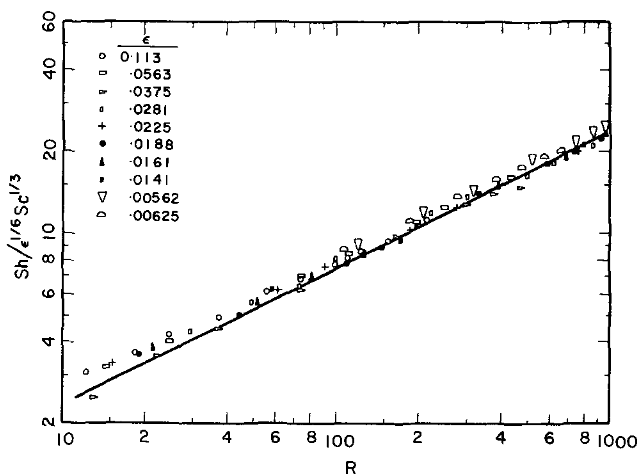

Fig. 4. Laminar mass flux to a 0.0381 cm diameter local electrode. The measurement is carried out over the range of Re from 108 to 167,000, and Sc between 1030 and 1470. The solid line is the theoretical prediction. Some of the data are taken from Ref. (9).

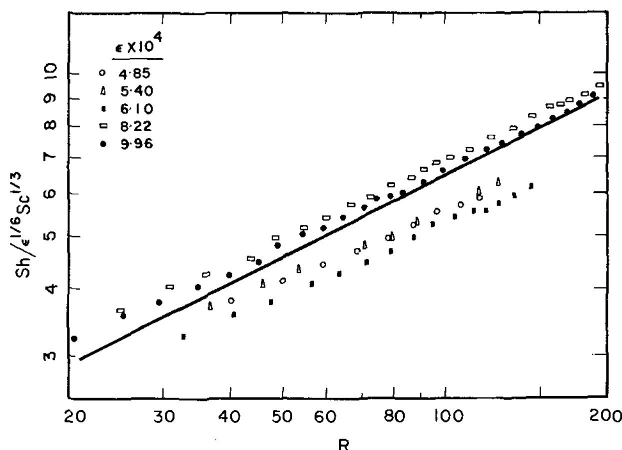

Fig. 5. Laminar mass flux to the radial electrode. The measurement is carried out over the range of Re from 20,500 to 240,000, and Sc between 1300 and 1420. The solid line is the theoretical prediction.

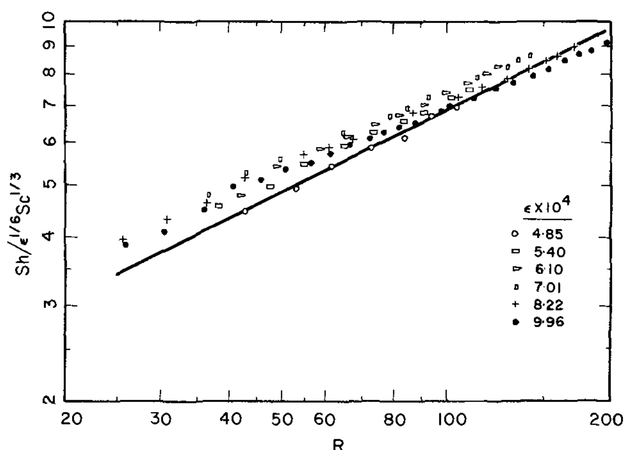

Fig. 6. Laminar mass flux to the tangential electrode. The data cover the range of Re from 21,400 to 204,000, and Sc between 1200 and 1270. The solid line is the theoretical prediction.

results gave 20-30% lower than those predicted from Levich's ring theory. At present there is no reasonable explanation for the discrepancy. However, we may conclude that for any given radial electrode, the theory correctly predicts variation with the Reynolds number.

In order to determine the Schmidt number variation, experiments were made using a 0.3% carboxymethylcellulose (CMC) solution, which has Schmidt numbers on the order of 4000. The results indicate that while some greater scatter is produced because of the slightly non-newtonian character (the shear stress is proportional to the shear rate raised to a power of 0.9) of the solution, in general the 1/3 power Schmidt number dependency is confirmed (Fig. 7).

One additional result which is easily obtained from the curves shown in Fig. 3 is information on the transition Reynolds numbers for the rotating disk flow. The break-points at different radii can be brought together, if one replots Fig. 3 in the form of *K vs.* $Re = r^2\omega/\nu$. Based upon these data, we have found that the initial instability begins at $Re = 2.3 \times 10^5$, and the transition to turbulence takes place at $Re = 3.0 \times 10^5$. These values compare favorably with Gregory and Walker's result of 1.9×10^5 and 2.9×10^5 obtained with a china clay method (18). The transitional Reynolds number also agrees with the results of a recent study of turbulent mass transfer to the disk electrode (19). More detailed pictures concerning the transition of flow near the rotating disk are discussed in Ref. (11).

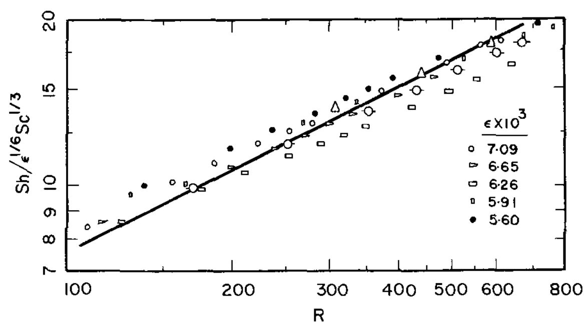

Fig. 7. Laminar mass flux to the local electrode in a solution containing 0.3% CMC7LP. The Schmidt number of the system is 3930. For comparison, some of the data obtained at Sc∼1000 are also plotted as △ and –○–. Again, the solid line is the theory prediction.

Conclusions

Based upon the above discussions, we may conclude that the theoretical results listed in Table I appear to give a reasonable correlation with the experimental data in laminar flow, particularly for the local and the tangential electrodes. For a given rotational speed, the diffusion current density on the point electrode can be made 10 times greater than that on the disk electrode; this offers experimental advantages in the study of fast surface reactions.

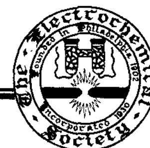
Technical Notes



An Electrochemical Technique for Microsectioning Copper

Nghi Q. Lam, Steven J. Rothman, and L. J. Nowicki

Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

In recent years, various techniques for removing thin uniform sections from a metallic sample have been investigated. These techniques have important applications in measuring depth distributions of implanted ions and radiation damage, and are also useful in determining the diffusion coefficient in solids. These techniques include electrochemical (1-7), vibratory polishing (8), ordinary chemical dissolution (9-10), formation and dissolution of films other than oxides (11), bombardment-induced dissolution of surface layers (12-13), and low-energy sputtering (14-16).

The electrochemical technique consists of forming an anodic oxide layer that can be either mechanically stripped or chemically dissolved without attacking the metal substrate. Although this method has proved reliable for microsectioning metallic samples, it has not been applied to copper. To date, the technique used to section copper has been based on the formation and dissolution of corrosion films of copper iodide (11). In this communication, we report the development of an electrochemical technique for the removal of thin sections of copper to determine small diffusion coefficients.

Experimental Methods and Results

Surface preparation.—Monocrystalline copper rods 0.97 cm in diameter were grown from copper (99.999% pure) by the Bridgman method and spark-cut into disks a few millimeters thick. After polishing through 0.3μ Al_2O_3, the samples were chemically polished with a solution composed of 15 ml of saturated chromic acid and 6 ml of 10% HCl. The chemical polishing was performed by swabbing the copper surface with a wet cotton-tipped applicator saturated with the solution. Chemical polishing in this manner for 20 min removed a layer $\sim 150\mu$ thick, which was far greater than the depth of the region deformed in mechanical polishing. At the end of this polishing step, the sample was washed with a solution of 1% HCl in ethanol, then with alcohol, and dried in warm air. The entire surface obtained was optically flat and free of pits.

Sectioning.—Most of the anodizing experiments were made on a copper single crystal of random orientation that had been irradiated for 25 min in a flux of 10^{12} thermal neutrons/cm^2-sec. Counts/min were converted to micrograms of copper using the specific activity of the crystal (^{64}Cu), which was 6.30×10^3 cpm/μg.

A copper wire was fastened to the back of the specimen with silver paint for the electrical connection. The sample was masked with Tygon protective paint so that only the polished surface was exposed to the electrolyte, which consisted of 0.1g Na_2SO_4 per liter of water. The cathode was a thin strip of platinum. A counting bottle was used as an anodizing cell so that after each sectioning the electrolyte and the cathode could be counted for ^{64}Cu activity. This was important because the copper oxide formed was strongly dissolved during anodizing. After anodizing, the remaining copper oxide films, which, if thick enough, showed uniform interference colors, were dissolved in a solution of 0.1% HCl in ethanol.

To determine whether this solvent attacks the copper, oxide layers of different thicknesses were formed on the irradiated copper crystal by anodizing with current densities of 0.5 and 1.0 mA/cm^2 for 30 sec. The sample was then immersed in the 0.1% HCl-ethanol solution, and the activity of the solution was counted as a function of time. As shown in Fig. 1, the 0.1% HCl-ethanol solution dissolved the oxide quickly and attacked the copper to a negligible extent. About 10 sec were sufficient to dissolve an oxide layer $\sim$500Å thick.

The thickness of copper removed is plotted as a function of anodizing time in Fig. 2 for various current densities. The lines do not go through zero because of the formation of natural oxide before anodizing, a phenomenon also observed on Al (1), Mo (6), Si (3), and W (2). The thickness removed in each anodizing-dissolution step was determined by counting both the anodizing cell and the solvent for ^{64}Cu content and by using the corrected-for-decay value of specific activity to convert to micrograms of copper.

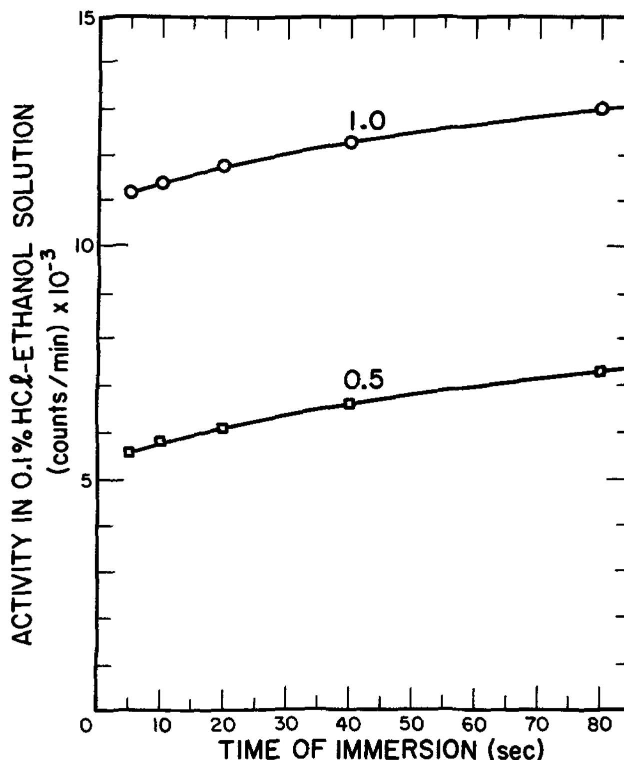


Fig. 1. Plot of ^{64}Cu activity of 0.1% HCl-ethanol solution after immersion of an anodized copper sample in solvent for various times. The different thicknesses of copper oxide were formed by anodizing for 30 sec with current densities of (□) 0.5 and (○) 1.0 mA/cm^2.

Key words: copper, anodization, sectioning, thin films.

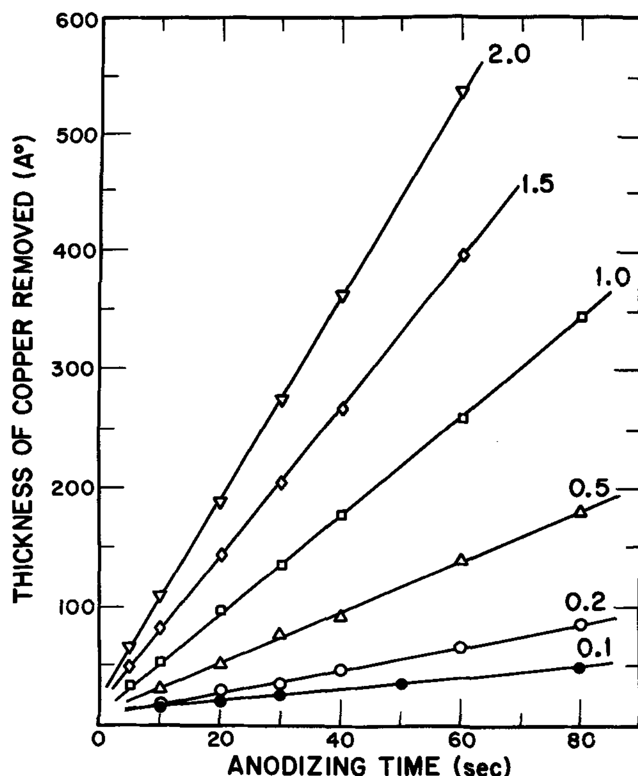

Fig. 2. Calibration of anodizing of monocrystalline copper in aqueous electrolyte that contained 0.01% Na_2SO_4. The numbers on the curves indicate the anodic current densities in units of mA/cm^2.

The relative amounts of activity in the electrolyte and stripping solution depended on the current density and anodizing time. The amount of material removed per anodizing step under identical conditions was reproducible to ± 3%. The sample was also weighed on a microbalance before and after removal of 20 sections. The difference between amounts of material removed, as measured by the two techniques was less than 9%, which is within experimental error. The step height on a nonradioactive copper crystal, part of which was masked by a spot of Tygon paint, was measured on an interference microscope after anodizing and removing 45 sections under the same current-density and time conditions. The step height agreed, within experimental error, with the thickness removed from the radioactive sample. Interference microscopy showed that the copper surface remained clean and flat after sectioning.

The thickness of copper that was anodically oxidized in 1 sec, deduced from the slopes of the curves in Fig. 2, is plotted in Fig. 3 as a function of current density. The anodizing rate x' in Å/sec is related to the current density i in mA/cm^2 by the equation $x' = 4.2i$.

The same anodizing treatments on a (100) face of a copper single crystal yielded the same anodic film thickness, which indicated that the anodizing rate is orientation independent. The same observation was made in anodizing gold (4) and silver (7).

Summary

The anodic oxidation technique can be used to remove thin uniform sections from copper. An aqueous solution of 0.01% Na_2SO_4 was used as the electrolyte. A solution of 0.1% HCl in ethanol appears to be the best solvent for removing the copper oxide. The rate of anodizing increases linearly with the current density, according to the relation $x' = 4.2i$.

Multinuclear Growth of Dislocation-Free Planes in Electrocrystallization

V. Bostanov, R. Roussinova, and E. Budevski

Division of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia, Bulgaria

The importance of two-dimensional nucleation for the electrodeposition of metals was recognized as early as 1931 by Volmer and Erdey-Gruz (1). This mechanism was confirmed experimentally in recent years only using dislocation-free crystal planes (2). The kinetics of the process were closely investigated and a number of kinetic parameters were also obtained. A short account of some of the latest results attained with dislocation-free planes of silver single crystals will be given in this paper. The preparation technique and the experimental conditions are the same as described in Ref. (2) and more detailed in Ref. (3).

The growth of dislocation-free planes is governed by two-dimensional nucleation. At low current densities the overpotential oscillates around a value which is the critical value where the rate of two-dimensional nucleation becomes noticeable. This wavering of the potential (Fig. 1) is evidently connected with the reiterating nucleation process. In the initial stage the plane is completely intact and does not expose sites of growth. When the current is switched on, the overpotential rises rapidly, thus increasing the probability for the nucleation process. A nucleus can be formed only after the critical value of the overvoltage is exceeded. Once a nucleus is formed, the electrode begins to offer an increasing number of growth sites proportional to the periphery of the growing monolayer, the deposition of the metal becomes easier, and the overvoltage drops. Propagating over the surface, the step surrounding the new layer reaches the bounds of the plane and begins to dissolve. With this, the number of growth sites diminishes and the overvoltage rises again, making possible the nucleation of a second layer. The period of this reiterating process is determined by the electric charge required for the formation of a monolayer and is inversely proportional to current density.

Using a potentiostatic pulse technique, the kinetics of nucleus formation were investigated and Volmer's equation

$$I = k_1 \exp(-k_2'/\eta) \quad [1]$$

was verified. Here I denotes the nucleation rate ($sec^{-1} cm^{-2}$), η is the overpotential (V), and k_2' contains the specific edge energy, ϵ, of a monatomic layer. For the cubic plane of silver in 6N silver nitrate solution a value of $2.1 \cdot 10^{-6}$ $erg \cdot cm^{-1}$ was found for ϵ.

It should be stressed again that the growth process at low current densities is a periodic one and a steady state cannot be reached. This is due to the fact that, once a nucleus is formed, the overpotential drops rapidly below the critical nucleation value according to the increasing periphery of the spreading monolayer. A new nucleus can be formed only after the completion of the previous monolayer.

In contrast, at high current densities, a wavering of the potential is observed only in the initial stage. The initial oscillations are very similar to those obtained at low current densities but they die away gradually and a steady state is reached (Fig. 2). The picture is very characteristic for the case and highly reproducible. The period of the oscillations is inversely proportional to the current density; and the product of these two quantities gives an amount of electricity equivalent to the deposition of one monatomic layer of silver. The number of oscillations in the transition period is nearly constant and slightly decreases with increasing current density. The microscopic observation of the crystal plane in the steady-state condition reveals a slightly visible surface profile.

Key words: crystal growth, electrocrystallization, silver single crystals, two-dimensional nucleation.

The explanation of the described effect is obviously connected with a multinuclear type of growth. At high current densities the overpotential remains for a relatively longer period at a high value, and more than one nucleus can be formed. When this period becomes longer, the probability for nucleus formation on the already formed first layer of nuclei increases; and a multilayer structure is obtained. The process is wavering only in the initial stage, but the multilayer surface structure determines a dying away of the initial oscillations and a steady state is reached.

The first theoretical approach to the problem of multinuclear growth at constant supersaturation (corresponding to constant overvoltage) was made by Hillig (4), who derived an expression for the rate of growth in terms of the two-dimensional nucleation rate and the rate of propagation of monatomic steps. A more precise calculation was made later by Borovinskii and Zindergosen (5) and by Armstrong and Harrison (6). Using mathematical simulation the same problem was treated also by Bertocci (7). Nonsteady-

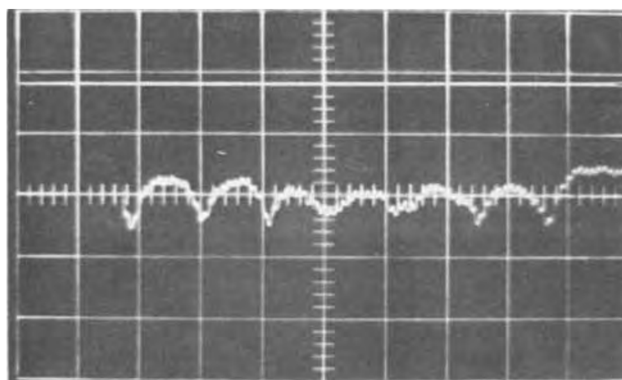

Fig. 1. Fluctuations of the overpotential at constant current growth of a dislocation-free cubic plane: current density, 5.8 · 10^{-4} A · cm^{-2}; vertical sensitivity, 5.2 mV/cm, time base 0.2 sec/cm.

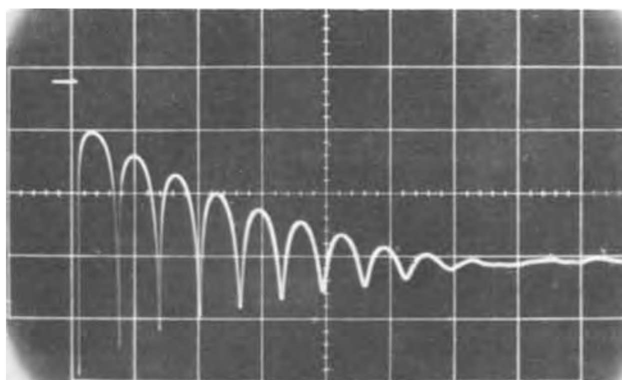

Fig. 2. Damped oscillations at high current densities: current density 2.5 · 10^{-2} A · cm^{-2}; vertical sensitivity, 5 mV/cm, time base 10 msec/cm.

state corrections of the nucleation process were introduced recently by Stoyanov (8). The first to adapt the problem to the case of electrodeposition were Armstrong and Harrison. They used Kolmogorov's equation (9), adapted to the case of electrolytic growth by Fleischman and Thirsk (10), and arrived at an expression of the form in Eq. [2] given below. They showed, in addition, that, in the initial stage, oscillation of the current should be observed which must die away when a steady-state multilayer structure of the surface is attained.

The theory obviously describes, very well, the experimentally obtained facts. Moreover, according to Borovinskii and Zindergosen the number of monolayers for which a steady state is reached should be about eight, which seems to be experimentally verified (Fig. 2). In all treatments for the steady-state current density an expression of the form

$$i = q_{mon} \alpha I^{1/3} v^{2/3} \quad [2]$$

is obtained, where I is the rate of nucleation ($sec^{-1} cm^{-2}$), v the propagation rate ($cm \cdot sec^{-1}$) of monatomic steps, and q_{mon} the amount of electricity required for the formation of a monatomic layer ($coulombs \cdot cm^{-2}$). The constant, α, varies in narrow limits from theory to theory.

It was already shown that the two-dimensional nucleation rate can be expressed by Volmer's Eq. [1] and is dependent on the overvoltage. For the second term in Eq. [2], the rate of propagation of monosteps v, we can assume a linear dependence on overvoltage (small values of the overvoltage are understood)

$$v = k\eta \quad [3]$$

This relation was found to be consistent with experiment (11) in the explanation of the current-square overvoltage law found on planes with screw dislocations following Frank's spiral growth theory. It was recently confirmed by Bostanov and Roussinova (12) in a very close investigation of the propagation rate of monatomic steps on dislocation-free crystal planes.

Having in mind Eq. [1] and [3], Eq. [2] can be transformed to

$$\log i\eta^{-2/3} = \log q_{mon} \alpha k_1^{1/3} k^{2/3} - k_2/3\eta$$

Plotting $\log i/\eta^{2/3}$ *vs.* $1/\eta$, an easy verification of the theory can be obtained (Fig. 3). The slope of the curve contains the specific edge energy ϵ [see for instance Ref. (2)], for which a value of $2.2 \cdot 10^{-6}$ $erg \cdot cm^{-1}$ was found. This value is in excellent agreement with the value obtained from the experiments with single nuclei described above (2).

A discrepancy of more than four to six orders of magnitude of the frequency factor k_1 obtained from both experiments was found. This discrepancy can hardly be ascribed to defects of the theories. So, for instance, the consideration of nonstationary effects as made by Stoyanov (8) cannot explain this large deviation of k_1 in both cases. Remembering that the only difference in the process of nucleation is the fact that nucleation at high current densities proceeds on a fresh surface, adsorption effect could also be taken into account. The larger value of k_1 found in this case seems to be consistent with this idea.

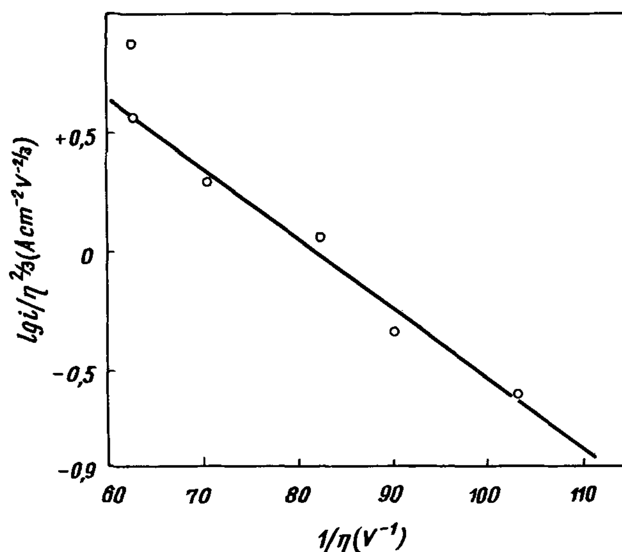

Fig. 3. Experimental plot of log $i \cdot \eta^{-2/3}$ *vs.* η^{-1} (the overvoltage, η, is corrected for the ohmic potential drop in the electrolyte).

Chemical Analysis of Electrodeposited Ni-Ni Bonds by Auger Electron Spectroscopy

H. L. Marcus, J. R. Waldrop, F. T. Schuler, and E. F. C. Cain

North American Rockwell Science Center and North American Rockwell Rocketdyne Division, Thousand Oaks, California 91360

Successfully obtaining a mechanically strong, reliable metal-metal bond in an electrodeposition process is not always a straightforward, well-understood procedure. Thin electrodeposits, for example, will exhibit poor peel resistance unless plating bath conditions are carefully optimized, traditionally through experience, trial, and, perhaps, luck. It is not surprising, then, that diagnosis and correction of poor results is often difficult, especially if the problem is due to contamination on the surface where electrodeposition is to occur. However, as Harris (1) has suggested, Auger electron spectroscopy (AES) is a method of surface chemical analysis particularly well suited for determining electrodeposition surface contaminants. Even so, not much work has been done in this application of AES.

The principal strengths of AES lie in an ability to detect elements in the first few atomic layers of a surface (typically ~10Å) and a sensitivity to elements throughout the periodic table (2). Briefly, in AES a sample is excited by a beam of kilovolt electrons (the primary beam) and the resulting secondary electrons are energy analyzed with an electron spectrometer. In the energy range between 0-1000 eV especially, the secondary electron spectrum contains peaks arising from the emission of Auger electrons by elements at the sample surface (hence, Auger electron spectrum), the position of a given peak in energy is characteristic of a particular element. For a fuller description of AES and further references see the recent reviews by Chang (3), and Sickafus and Bonzel (4).

In this paper we report experiments using AES to determine the chemical composition at electrodeposited Ni-Ni interfaces so as to diagnose and solve a vexing fabrication problem in a relatively direct manner. Specifically, thick nickel laminates were formed from a series of individual electrodeposits, each finished piece of material thereby having several metal-metal bonds. The resulting bulk material showed in tensile testing no degradation of mechanical properties (yield or ultimate strength) over pure Ni. On the other hand, samples of the material sometimes showed minimal resistance to crack formation and propagation along a bond surface. By using AES techniques the chemical effects causing the Ni-Ni bond embrittlement were determined.

Experimental Procedure

The nickel laminate used in these experiments was electrodeposited from a nickel-sulfamate bath. After a thickness of about 0.2 in. was deposited, the material was removed from the deposition bath and the surface smoothed mechanically. The electrodeposit was then chemically polished followed by cathodic activation in a sulfuric acid bath. Next it was placed back into the sulfamate bath for continued nickel deposition. This was continued for several cycles until a deposit about 1 in. thick was formed. Samples 0.10 × 0.14 × 1.0 in. were cut from the deposit, the 1.0 in. direction being parallel to the growth direction. The samples were evaluated for tensile properties along the growth direction and resistance to impact loading transverse to the growth direction. Samples from material with low-impact strength were used for the AES studies.

Two kinds of AES experiments were performed, each in a different type system. The apparatus for the first type of experiment was an ultrahigh vacuum (10^{-10} Torr) bakable system equipped with a sensitive cylindrical mirror electron spectrometer (5) and an electron gun producing a primary electron beam ~0.4 mm in diameter for sample excitation. With this system, the experimental procedure is to first bake the system at 200°C to reduce active gases, then to fracture a nickel laminate *in situ* for immediate AES chemical analysis. The resulting spectra are recorded as $dN(E)/dE$ *vs.* E curves, where $N(E)$ is the relative number of electrons at energy E. After the initial AES analysis, the chamber is backfilled with high-purity argon and the sample argon ion sputtered in the manner of Marcus and Palmberg (6, 7). This technique allows the determination of a chemical profile into the fracture surface, with the underlying assumption that the 400 eV argon ions used have unity-sputtering efficiency.

The second AES experiments involved AES performed in a scanning electron microscope (SEM) (8). This technique offers high spatial resolution (~0.3μ) point-by-point surface chemical analysis, albeit with a loss in sensitivity compared to the apparatus described above. For our experiments the newly developed MacDonald and Waldrop (9) method of Auger electron images was employed to determine the spatial homogeneity of any bond surface impurity found. An Auger electron image for a particular element is a two-dimensional array of points, with each image point denoting the presence or absence of the element at a corresponding sample surface point. If a conventional SEM micrograph is obtained of the same area over which an Auger image is taken, a direct two-dimensional comparison of surface topography and surface elemental distribution is made.

Results and Discussion

Figure 1a shows the Auger electron spectrum from a nickel-nickel laminate that fractured in vacuum at room temperature along the bond surface. The spectrum is dominated by the presence of peaks characteristic of silver. In addition, copper, which normally will coplate with nickel, is present in abundant amounts. To determine the extent of high silver concentration, the surface was sputtered with argon ions. Figure 1b is an Auger electron spectrum with approximately 20Å of surface removed. It is immediately apparent that the silver is virtually absent and that the spectrum is basically that of nickel. Copper is still present at a level significantly higher than that shown in a spectrum taken away from the bond line, indicating excess copper electrodeposition close to the bond surface.

The source of the silver at the bond line was determined by analyzing the bond surface immediately after the various stages of the electrodeposition process. During the cathodic activation process, thin layers of silver appeared that were as thick as 50Å, depending upon the activation parameters used. Metallic silver used at an earlier processing stage dissolved into the activation solution; this was the source of the silver in solution. No quantitative measurement of the silver concentration was made.

To determine the homogeneity of the silver over the bond surface, samples of the nickel-nickel laminate were fractured in an SEM equipped for AES. The SEM micrograph of the surface is shown in Fig. 2a. The

Key words: surface chemistry, fracture, transient deposition.

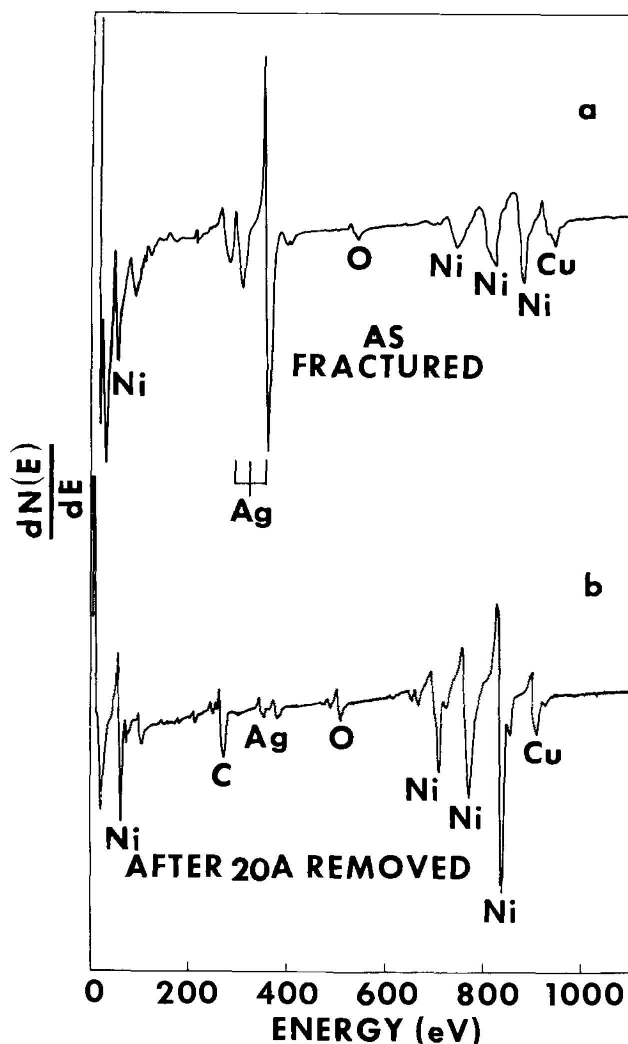

Fig. 1. Auger electron spectra from bond surface. (a) Initial, as fractured, (b) after 20Å removed from surface.

flat surface of the bond surface dominates, but small regions that apparently plastically deformed during fracture are also observed. Figure 2b shows the two-dimensional Auger electron image of silver over the fracture surface. An image point is white if a silver peak is present with a height greater than a predetermined minimum value. It is immediately apparent that the surface is totally covered except where some plastic tearing had apparently taken place. This is consistent with the minimal thickness of the silver described previously.

When the small amounts of silver present were removed from the activation baths the metal-metal bonds were no longer fracture sensitive. The fact that the silver alone was the primary cause of the embrittlement while the copper was not is consistent with the formation of brittle nickel-silver intermetallic interfaces. Since the copper-nickel system does not contain any intermetallics, it is not surprising that it does not behave as an interface embrittler.

The main emphasis in this paper has been on the determination of fracture surface chemistry of electrodeposited material using AES. It is clear that AES serves as a means of determining the chemistry associated with the interface layer in plating, electroforming, or any other deposition process where transient behavior can be expected.

Conclusions

1. Auger electron spectroscopy was used to identify the chemical composition of brittle electrodeposited nickel-nickel interfaces. Both silver and copper were found to be present at higher than the bulk concentration.

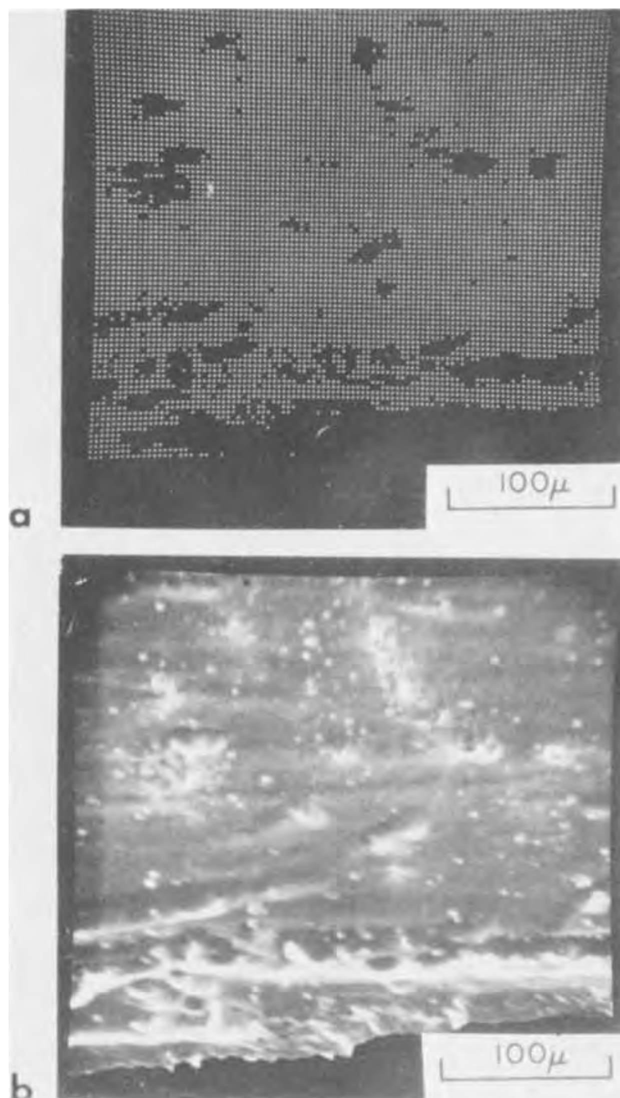

Fig. 2. (a) Auger electron image for Ag over bond surface. (b) SEM secondary electron micrograph of bond surface.

2. Using argon ion sputtering profiles, the extent of the excess silver was determined to be less than 20Å but the copper was present after removal of about 100Å.

3. AES in the SEM of the fractured nickel-nickel shows a uniform profile distribution of silver, except where limited amount of plastic deformation took place.

4. Removal of the silver from the electrochemical activation baths stops the embrittlement.

Electrolytic Preparation of Azobenzenes

S. Wawzonek* and T. W. McIntyre

Department of Chemistry, University of Iowa, Iowa City, Iowa 52240

The macroscale electrolytic oxidation of aromatic amines to azobenzenes in acetonitrile is complicated in some examples by the formation of azophenines (1). The objective of the present work was to determine whether such side reactions could be minimized by using aqueous media for the oxidation. The electrode reactions were assumed to be similar to those in acetonitrile since anodic waves are reported for aromatic amines in aqueous media (2).

Experimental

Electrochemical oxidations were carried out in a 600 ml dye beaker using a Coor's porous cup (7.5 cm × 2.6 cm) for the cathode compartment. The cathode was a coil of No. 16 copper wire and the anode was a rotating platinum screen cylinder. The cell was cooled with ice water during the electrolysis. In the oxidation of dispersions or solutions of aniline, the anolyte was steam distilled and the distillate was extracted with pentane. The pentane solution was washed with dilute hydrochloric acid and upon removal of the solvent gave azobenzene. The hydrochloric acid solution upon neutralization gave aniline. A portion of the residue from the steam distillation was dissolved in acetonitrile and examined polarographically for nitrobenzene.

In the oxidation of substituted anilines the anolyte was evaporated to dryness and the residue was washed with water, dried and extracted with either ethyl acetate or chloroform, and the solution was chromatographed on alumina. Identification of products was made by infrared spectra and comparison with authentic samples.

Electrolytic oxidation of p-anisidine.—*p*-Anisidine (1.0g) was oxidized in an aqueous dimethylformamide (1:4) solution (90 ml) containing 0.5*M* sodium nitrate and pyridine (10 ml) at 10V under nitrogen. The initial current of 0.1A dropped to 0.02A after 9 hr. The anolyte was added to ice (100g) and the resulting solution was extracted with ether. Removal of the ether gave a solid which was dissolved in benzene and chromatographed on alumina. The first fraction obtained was 4,4′-dimethoxyazobenzene (0.033g); mp 162°-163°. The second fraction was an oil which upon crystallization from ethanol gave a dark red powder which was rechromatographed on alumina using benzene. The first fraction was tetra-*p*-methoxyazophenine (0.157g); mp 236°-237°. The second fraction gave 2-amino-5-(*p*-methoxyanilino)-*p*-benzoquinone-*bis*-(*p*-methoxyanil) (0.056g); mp 161°-163° [Ref. (3) 164°]. The acetyl derivative melted at 213° [Ref. (3) 213°]. Heating the 161°-163° compound with *p*-anisidine and concentrated hydrochloric acid gave tetra-*p*-methoxyazophenine (3).

Results and Discussion

The results obtained in the electrolytic oxidation of aromatic amines are summarized in Table I and indicate that the best yields of azobenzene were obtained from the oxidation of aniline dispersions. Passing air through the solution during the electrolysis did not affect the yields of azo compound and did not convert the intermediate radicals into nitrobenzene. The main by-product was aniline black.

Use of dispersions of substituted anilines in a mixture of acetonitrile and water did not increase the yield materially over that from solutions using mixtures of dimethylformamide and water.

The oxidation of *p*-anisidine in a mixture of dimethylformamide and water differed from the behavior observed in acetonitrile(1); 2-amino-5-*p*-methoxyanilino-*p*-benquinone-bis(*p*-methoxyanil) was isolated in addition to the azo compound and azophenine. The isolation of these products indicates that the presence of water does not materially affect the course of the oxidation of aromatic amines. The yield of azophenine was greater (15.7%) however than that obtained in acetonitrile(1) (8.6%).

Periodic Phenomena During the Anodic Dissolution of Iron in Sodium Chloride Solutions

J. Postlethwaite[1] and A. Kell

University of Manchester, Institute of Science and Technology, Manchester 1, England

Periodic phenomena related to unstable surface films have been previously observed for a wide variety of metal electrode systems. These films may be the prepassive salt films formed prior to true passivation by an oxide film (1) or may be the thicker films present during electropolishing (2) or other high-rate dissolution processes similar to these encountered in electrochemical machining (3). This note describes the periodic potential oscillations that have been observed during the galvanostatic anodic dissolution or iron in 20 weight per cent (w/o) NaCl solution. This work was part of a study aimed at a better understanding of the factors controlling the electrode processes associated with "wild-cutting," which occurs in NaCl solutions during electrochemical machining at the low CD region at the edge of the machining zone.

The iron electrodes, nominal composition, Si trace, Sn 0.007, P 0.016, Ni 0.020, Cd 0.03, Cd 0.06, Mn 0.36 w/o, were at the bottom of a 3.8 cm square flow duct (Fig. 1), which was proceeded by an entry length of 30 equivalent diameters. The anode was stopped off with lacquer to give a working surface 0.5×2 cm long; excessive undercutting and major changes in the electrode geometry were found with smaller working surfaces. The anode potentials were measured with respect to an Ag/AgCl reference electrode with a probe terminating 2 mm above the downstream end of the anode. An interrupter technique which has been described previously (4, 5) was used to determine the ohmic contribution to the overpotentials. The total anode overpotential was measured after 5 min at each current setting following which the IR drop was determined. Separate experiments were done with the electrolyte stagnant and flowing with Reynolds numbers in the range 4000 to 30,000.

Tafel behavior was observed (Fig. 2) up to around 200 mA/cm^2 following which there was an increase in the resistance to the dissolution process shown by the increased slope of the electrolysis curves. These curves are corrected for ohmic overpotential as described later. The latter part of the electrolysis curves corresponds to the start of the ECM regime and especially to the low CD "wild-cutting" processes, and it was in this region of the electrolysis curves that the potential oscillations were observed. A typical potential-time trace is shown in Fig. 3a. Following the initial rapid rise in the potential there was a slow secondary rise followed by a steady potential region and then after 17 sec the potential started to oscillate with an approximately constant amplitude. The individual fluctuations are discerned in Fig. 3b, where the frequency is seen to be around 50 Hz. The oscillations which occurred in both the stagnant and flowing solutions had a maximum amplitude at intermediate CD's; decreasing in amplitude and increasing in frequency at the higher CD's.

The interrupter measurements showed the fluctuations to be largely ohmic in nature. The ohmic overpotentials were determined from the blank section on the waveform on an oscilloscope screen when a continuous series of constant current pulses, with equal on and off times, was applied to the cell. As discussed elsewhere (5) the maximum potential attained during each pulse, after some number of pulses has been passed, corresponds to the steady-state potential for the appropriate CD. At the higher CD's, the oscillograms initially took the characteristic shape (Fig. 4a) observed at CD $<$ 200 mA/cm^2; but after some time had elapsed both the amplitude and shape of the transients started to change, as shown in Fig. 4b, and the waveform started to cycle between the two forms as shown in Fig. 4c. During this behavior a secondary potential growth occurred and the resulting higher overpotential was seen to be mainly ohmic in nature. The maximum value of these oscillations were the same as those obtained during the "steady-state" experiments described above, and it seems that these former oscillations were in fact due to factors which changed the ohmic resistance but had little effect on the activation overpotential.

The electrolysis curves shown in Fig. 2, were constructed on the basis of the minimum value of the overpotential, after the onset of the potential oscillations. The *IR* drop in this condition was taken as the value given when the waveform had the form shown in Fig. 4a.

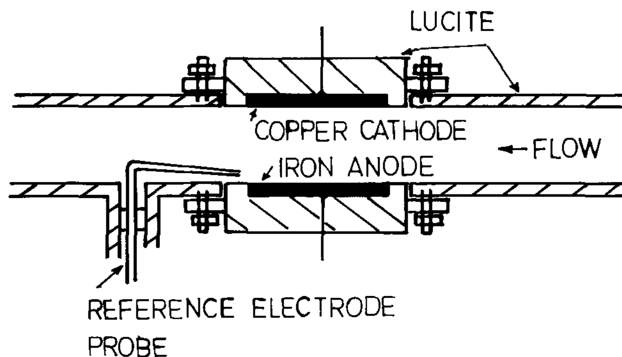

Fig. 1. The electrochemical flow cell. The flow duct was 3.8 cm square, with the working surface of the anode 0.5 x 2 cm longitudinal to the direction of the flow.

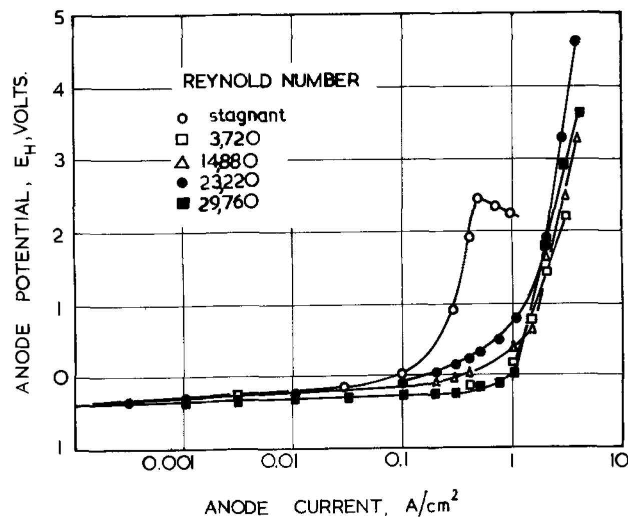

Fig. 2. Electrolysis curves, corrected for ohmic overpotential, for anodic dissolution of iron in 20 w/o NaCl solution at 25°C.

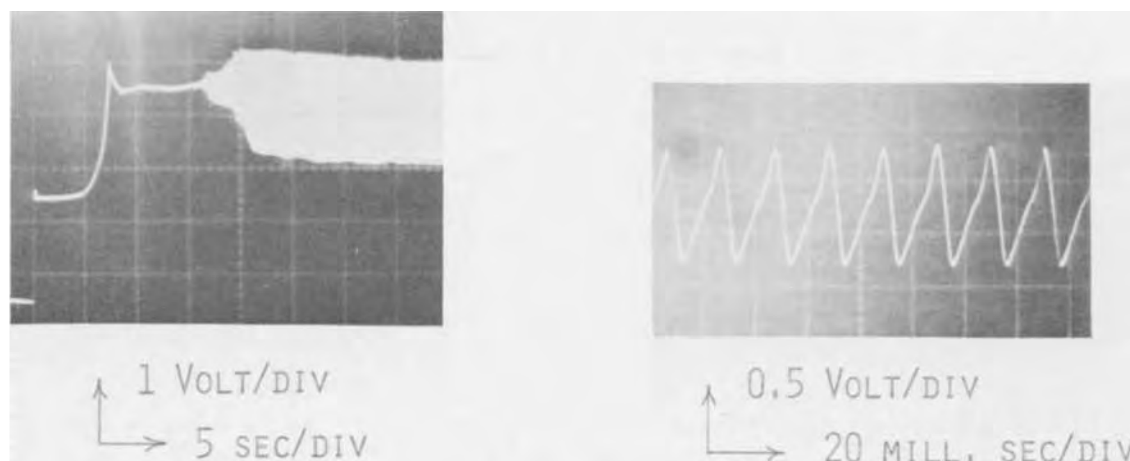

Fig. 3. Periodic fluctuations of the potential during the "steady-state" galvanostatic analysis of the anodic dissolution of iron at 2 A/cm², 20 w/o NaCl solution, Reynolds number, 4000.

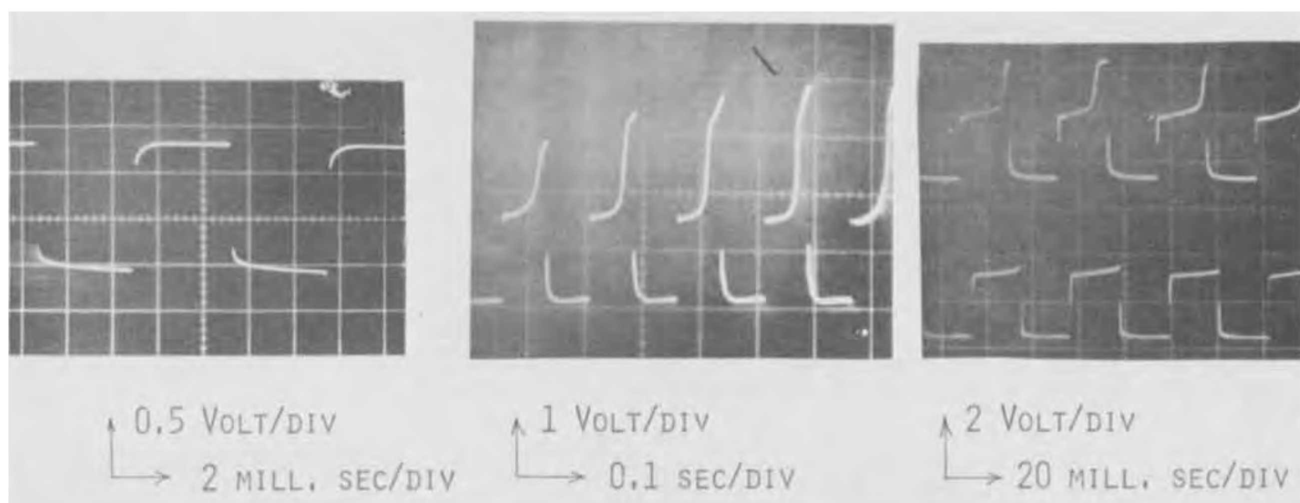

Fig. 4. Potential-time behavior during pulsed current analysis of iron in 20 w/o NaCl solution; (a), 2 A/cm², oscillogram in absence of secondary growth; (b), 2 A/cm², secondary potential growth with increased IR drop; (c) 4 A/cm² the two extreme forms of the waveform in the presence of the cyclic secondary growth. Reynolds number, 4000.

The most likely reason for the potential oscillations is the presence of an unstable porous nonprotective film. Hoare (6) and Chin (7) have reported the presence of nonprotective films on Fe in NaCl solutions and other workers (3) have used motion photography to demonstrate the relation between potential oscillations and the formation and disruption of such films during the high-rate dissolution of copper.

The electron microprobe analysis of a film formed at 2 A/cm² during this work showed the film to contain 70% Fe. The sample was prepared in a beaker cell and withdrawn with the current still switched on. Line analysis gave many spots of 100% Fe, which indicates an extremely porous film, although the film may have been disturbed after the electrolysis. However, whatever the nature of this film, it seems that such films and the related periodic phenomena may play an important part in the "wild-cutting" processes and require further investigation.

Brief Communication

Electrolytic Reduction of Titanium Chlorides in Fused Alkali-Chloride Eutectics

F. Quemper, D. Deroo,* and M. Rigaud*

Department of Metallurgical Engineering, Ecole Polytechnique de Montréal, Montreal, P. Q., Canada

There is great interest today in the problem of an electrolytic method for producing titanium metal. One of the procedures involves the reduction of titanium halides in the fused LiCl-KCl eutectic.

Many authors (1-10) have studied the reduction mechanism of titanium chlorides. Bockris and coworkers (3) have concluded from polarographic measurements that the deposition of titanium in fused alkali-chlorides occurs by a secondary electrode process. This mechanism, which is also proposed by Dean (4) involves the primary reduction of an alkali-metal ion.

The secondary process has been contested by Reid (9) and later by Baboian *et al.* (10). These authors propose a direct mechanism for reduction of Ti(III) and Ti(II).

In this paper data are presented for the reduction of titanium tetra-, tri- and dichloride in fused LiCl-KCl and LiCl-NaCl eutectics. The influence of impurities in commercial titanium tetrachloride has also been investigated.

Experimental

The LiCl-KCl and LiCl-KCl-NaCl eutectic mixtures were prepared from Fisher Scientific chemical products, first dried and kept in a vacuum oven. Just before introducing titanium halides, the eutectics were electrolyzed with graphite electrodes at 1.5V for 24-48 hr.

Electrochemical measurements were carried out in a cylindrical furnace with a constant temperature zone 8 in. high. Temperature was controlled to $\pm$ 0.5°C by a Chromel-Alumel thermocouple, which was enclosed in an alumina sheath in the melt, and controlled by a Lindberg Hevi-Duty furnace regulator.

Current potential curves were plotted by use of a potentiostat Tacussel PRT 20-10 Z coupled with a triangular wave generator GSTP-2 Tacussel and a Hewlett Packard XY recorder.

The electrochemical cell was a graphite crucible in a Pyrex glass cylinder. Anode and cathode were graphite cylinders (1/4 in. diameter). The anodic compartment was isolated by a sintered glass diaphragm. The reference electrode was described by Littlewood and was used in the Ag/Ag(I) system (11).

Titanium tetrachloride (Fisher Scientific) was a commercial product containing impurities. Pure titanium trichloride and dichloride were prepared by reaction of $TiCl_4$ vapor on Ti chips at high temperature (12).

Results and Discussion

The current-potential curves for $TiCl_4$, $TiCl_3$, $TiCl_2$ reduction at 450°C in LiCl-KCl eutectic are shown in Fig. 1. We obtained the same results in LiCl-KCl-NaCl eutectic at the same temperature. The range of concentration is limited by the solubility of titanium tetrachloride at this temperature.

* Electrochemical Society Active Member.
Key words: electrolytic reduction, titanium, titanium chlorides, alkali-chloride eutectics.

In the case of $TiCl_4$, we observed four waves. The last wave, which appears just before alkali-metal ion discharge, corresponds exactly with the wave obtained by reduction of $TiCl_2$. By comparison with the results of Baboian and the equilibrium potentials given in the literature, it is possible to attribute to this wave the reaction

$$Ti^{II} + 2e \rightarrow TiCl$$

The same argument used for respectively the first and the second wave leads to the total mechanism.

$$Ti^{IV} + e \rightarrow Ti^{III} + e \rightarrow Ti^{II} + 2e \rightarrow Ti$$

The third wave is the most significant. It was first observed by Russian workers (13) and does not appear with pure $TiCl_3$. The $Ti(Cl_6)^{3-}$ complex identified in the melt by some authors (14, 15), will give a wave in the case of $TiCl_4$ but also with pure $TiCl_3$. So, the hypothesis of kinetic wave of complex reduction is not applicable.

The impurity discharge is more probable. The most important impurities in titanium tetrachloride are: vanadium chloride, stannous chloride, and titanium oxychloride produced by hydrolysis.

Although the discharge potential of V^{II} corresponds exactly with this wave (Fig. 2), the limiting current is too large for the amount of vanadium chloride in the melt. The concentration of stannous chloride is also negligible and may be neglected. Hence it is thought oxychloride reduction is responsible for the additional wave.

In conclusion, the primary mechanism of titanium halides reduction was confirmed. It is noted that pure titanium production from these melts will be in delicate balance due to hydrolysis of $TiCl_4$ and probable

Ion Implantation Effects of Nitrogen, Boron, and Aluminum in Hexagonal Silicon Carbide

Arrigo Addamiano,* Gordon Wood Anderson, James Comas, Harold L. Hughes, and William Lucke

Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

The effects of the implantation of $^{14}N^+$, $^{11}B^+$, and $^{27}Al^+$ ions in hexagonal 6H SiC crystals were studied through optical and microanalytical methods. The optical data taken for 60 keV $^{14}N^+$ implants indicate that little damage occurs up to a fluence of 10^{14} cm^{-2}. For fluences between 10^{14} cm^{-2} and 1.3×10^{15} cm^{-2}, there is a rapid increase of the optical absorption below ~3 eV with a broad absorption tail extending into the near infrared. For larger fluences, the optical absorption close to the band edge actually decreases. The band edge shifts to lower energies with increasing fluence. The radiation damage begins to anneal at low temperatures but is not completely removed until annealing at 1400°C. Boron and aluminum behave similarly to nitrogen as far as the general behavior of the damage in the implanted regions is concerned. Boron implanted crystals with peak concentrations in the 10^{20} cm^{-3} range show weak yellow "boron" luminescence in the implanted areas after annealing. Qualitative thermoelectric power measurements indicate that boron implants up to this level do not result in conversion of n-type layers to p-type layers. For the aluminum implants conversion from n-type to p-type was observed for the highest fluence used, 5×10^{15} cm^{-2}. The impurity profiles measured before and after annealing for crystals irradiated with different fluences show that the distribution of the impurities is broader than predicted by the LSS theory and changes with fluence. Upon annealing the impurities migrate toward the surface.

Silicon carbide lies between silicon and diamond in its physical and chemical properties. Like silicon and diamond it is chemically very stable. Its dissociation temperature (1), 2830°C, compares favorably to the melting point of silicon, 1412°C, and to the graphitization temperature of diamond (*ca.* 1100°C). In common with silicon and at variance with diamond, silicon carbide can be routinely doped p- and n-type. An additional interesting feature of silicon carbide is the fact that it exists in a large number, over 150, of closely related polymorphic modifications, usually referred to as polytypes. The bandgaps of some of the common polytypes are known to range from 2.3 to 3.3 eV (2-7). Thus, silicon carbide has an enormous potential for device fabrication. Unfortunately, techniques for growing and doping silicon carbide crystals have been restricted to high temperature, vapor phase, or silicon solvent methods (8). Recently ion implantation techniques have been added to the possible approaches for semiconductor doping, and new work on silicon carbide has been reported (9-11). Ion implantation looks very attractive *a priori* because it permits room temperature control of both impurity levels and impurity profiles. Usually removal of the radiation damage calls for annealing at moderately high temperatures, too low for ordinary diffusion of the impurities to occur. With this in mind, we decided to investigate the effects of the implantation of nitrogen, boron, and aluminum into hexagonal 6H SiC crystals. We report in this paper some of the results of our investigation.

Experimental

The apparatus used for the boron and nitrogen implantations is similar to other low energy (100 keV or less) accelerators already described in the literature (12) and is capable of producing resolved beams from 5 to 60 keV. The beams are produced by extracting ions from a radio frequency excited source into which a gas containing the desired species is leaked. The extracted beam is accelerated and focused by a series of lenses before entering an analyzing magnet. The beam passes through an in-line liquid nitrogen trap before entering the target chamber. Resolved beams in the 100 nA range for $^{11}B^+$ at 60 keV are routinely obtained.

The aluminum implantations were done at the Langley Research Center of NASA and at the Hughes Research Laboratories, Malibu, California. The implanted 6H SiC crystals were sublimation-grown platelets of hexagonal contour. Colorless "undoped" crystals, and green, n-type, nitrogen-doped crystals with net donor concentrations in the $1 \times 10^{18} - 5 \times 10^{18}$/cm^3 range were used. The undoped crystals were usually high resistivity p-type plates. For the implantations the crystals were mounted with their c-axes approximately parallel to the ion beams except the Al implanted crystals which were offset by 12° and 7°. In some experiments selected areas of the crystals were shielded from the incident beam. By so doing the effect

Key words: ion implantation, silicon carbide impurity profiles, optical absorption, nitrogen, boron, aluminum doping.

of the ion bombardment and of the annealing treatments could be more conveniently observed.

For the removal of the radiation damage the implanted crystals were annealed in silicon carbide crucibles in neutral atmospheres at temperatures of 400°-1400°C.

The analyses of the impurity profiles in the crystals, before and after annealing, were made at the Battelle Memorial Institute, Columbus, Ohio, using a Cameca Ion Analzyer IMS 300. In this instrument the composition of a microvolume of a sample is obtained by ion etching the sample surface and performing a mass analysis of the ions sputtered from the surface (31). In our work a 10 keV $^{16}O^-$ beam was used to ion etch the surface of the SiC crystals, and the etching rate in the implanted region was measured using an interference microscope. The analysis was repeated several times for each sample focusing the sputtering beam on different regions of the implanted area. Good reproducibility was observed in all cases.

The optical transmission measurements were performed with a Cary 14 spectrophotometer on samples at room temperature.

Nitrogen Implantations

A green body color and absorption at about 0.62 and 0.42 μm are typically observed at room temperature in 6H SiC crystals containing nitrogen impurities at carbon lattice sites (13, 14). Optical measurements on colorless plates irradiated with 60 keV $^{14}N^+$ ions thus seemed particularly suitable to study the effects of this donor type impurity. The implantation schedule for a colorless, high resistivity p-type crystal, SiC No. 15, is shown in Table I.

Following each $^{14}N^+$ implantation, transmission measurements were made from 0.35 to 2.6 μm. Figure 1 shows some of the optical density variations as the fluence is increased from zero to 2.5×10^{17} cm^{-2}. Originally the spectrum is flat through the near infrared and the visible to the band edge. A broad, structureless tail extending from the absorption edge to 8000 cm^{-1}, analogous to that observed in some amorphous semiconductors (16-18), develops as the fluence is increased to about 1.2×10^{16} cm^{-2}. A shoulder is observed at about 10,000 cm^{-1} with a further increase in fluence. A small shift of the band edge to lower energies is also noticeable.

Figure 2 shows the variation of optical density with fluence at 4300, 5000, and 10,000Å. It is seen that a very rapid increase of the optical density occurs near the band edge for fluences of 10^{14} to 1.3×10^{15} cm^{-2}. For very high fluences the optical density actually decreases with increasing fluence. At these fluence levels, however, the absorption shoulder at 10,000Å increases markedly with increasing fluences.

Annealing experiments.—After the implantation run No. 10 (cf. Table I), the sample SiC No. 15 was annealed according to the schedule presented in Table II. After each annealing period, the optical spectra of the heavily (2.5×10^{17} cm^{-2}) and lightly (6.6×10^{14} cm^{-2})

irradiated zones of crystal SiC No. 15 were measured and compared. Selected data are shown in Fig. 3 and 4. After annealing at 550°C, much of the radiation damage is removed from the lightly implanted region, SiC No. 151. Practically no radiation damage can be detected in SiC No. 151 after annealing above 1000°C. The heavily implanted region, SiC No. 15h, still exhibits damage effects after annealing at 1400°C. Neither the implantation alone nor the annealing treatments introduced

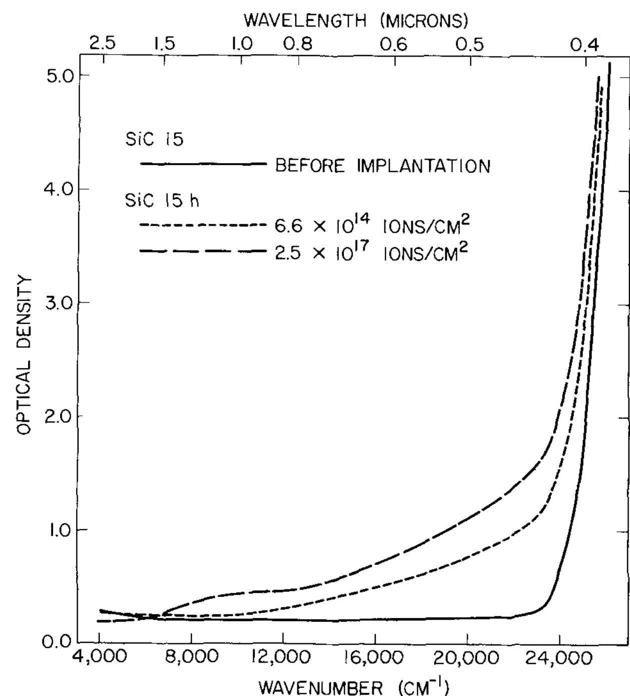

Fig. 1. Typical room temperature optical absorption spectra of hexagonal SiC, sample SiC No. 15, with increasing ion implanted nitrogen dose (fluence). At a dose of 6.6 x 10^{14} cm^{-2} half the sample, called SiC No. 151, was masked to prevent further implantation. The other half of the sample, SiC No. 15h, was subjected to further increases in dose.

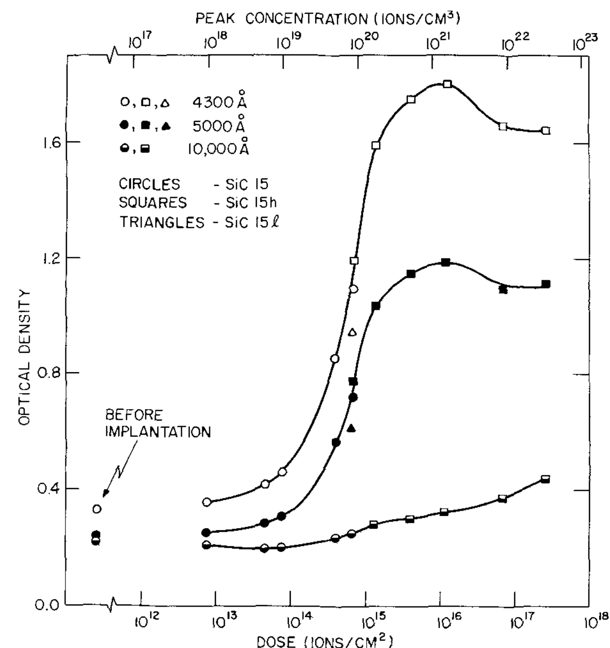

Fig. 2. Room temperature optical density as a function of implanted nitrogen dose (fluence) for sample SiC No. 15 at 4300, 5000, and 10,000Å. At a dose of 6.6 x 10^{14} cm^{-2} half the sample, called SiC No. 151, was masked to prevent further implantation. The other half, SiC No. 15h, was subjected to further increases in dose.

Table II. Annealing schedule for SiC No. 15

°C	Time (hr)	Atmosphere
450	24	Nitrogen
550	40	Nitrogen
680	26	Nitrogen
810	24	Nitrogen
930	24	Nitrogen
1040	24	Nitrogen
1250	0.5	Argon
1400	0.25	Argon

the absorption typical of nitrogen at carbon sites. The crystal was visibly brown for $^{14}N^+$ fluences in excess of 10^{14} cm^{-2}. After 1400°C annealing, SiC No. 151 had recovered the original color, and SiC No. 15h showed light brown islands, separated by transparent areas. Figures 5 and 6, which are low magnification photographs of the area of SiC No. 15 where SiC No. 15h and SiC No. 151 meet, show the effect of annealing at different temperatures.

Thermoprobe measurements indicate that after annealing at 1040°C the irradiated crystal surface changed from high resistivity p-type to weakly n-type. After annealing at 1400°C the thermoprobe response for SiC No. 15h was markedly n-type.

Nitrogen profiles.—Because of the interference of the N^+ and CO^{++} ions, the nitrogen analyses were made using $(^{14}N^{16}O)^-$ and $(^{28}Si^{14}N)^-$ ions as the measured ion species. Figure 7 shows the measured unannealed and annealed profiles of a 60 keV $^{14}N^+$ implant (SiC No. 34) at a fluence of 6.6×10^{16} cm^{-2} and the theoretical profile as derived from the LSS theory (15). The ^{14}N data are plotted as detector current ratio, I/I_0, where I_0 is the main peak current in the distribution, *vs.* depth in Å. The $(^{28}Si^{14}N)^-$ ion current was measured for these analyses, and a $(^{29}Si^{12}C)^-$ signal was monitored during each run for signal normalization.

Since the nitrogen profile for very high doses might be significantly affected by sputtering during implantation, we have tried to measure the step height, if any, between implanted and adjacent nonimplanted areas of the crystals. A Zeiss interferometer was used for the measurements. No sputtering step was detected for any of the high dose 60 keV ^{14}N implanted samples. Estimated from the resolution of the interferometer we find that for our implantation conditions the sputtering yield is less than ~0.1.

We have no explanation at present for the relatively high surface concentration which falls to a minimum

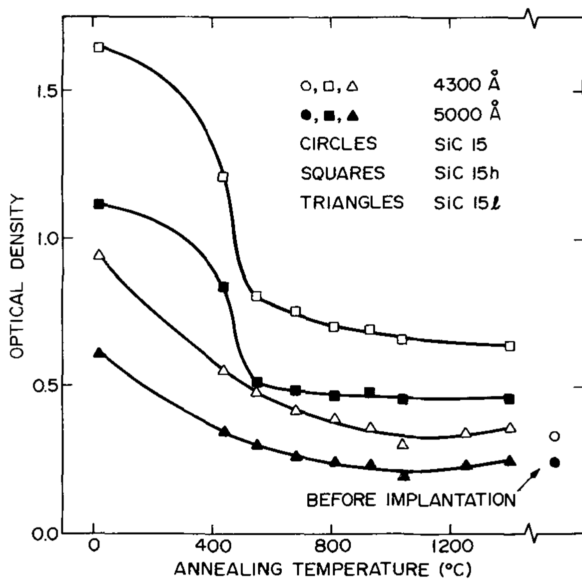

Fig. 3. Room temperature optical density as a function of annealing temperature for sample SiC No. 15 at 4300 and 5000Å. One half of the sample, SiC No. 15h, was subjected to a maximum nitrogen fluence of 2.5 x 10^{17} cm^{-2} and the other half, SiC No. 151, to a maximum fluence of 6.6 x 10^{14} cm^{-2}. The data before implantation were measured on the full sample SiC No. 15.

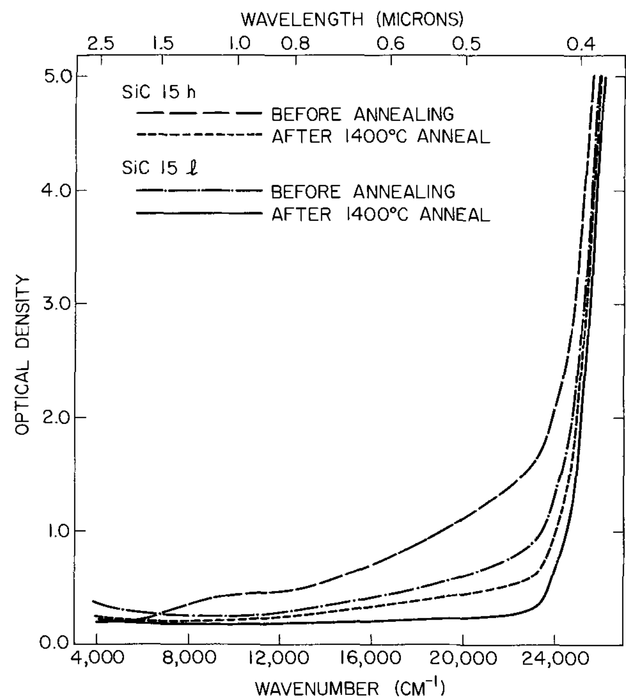

Fig. 4. Room temperature optical absorption spectra of sample SiC No. 15 before annealing and after the final anneal at 1400°C. One half of the sample, SiC No. 15h, was subjected to a maximum nitrogen fluence of 2.5 x 10^{17} cm^{-2} and the other half, SiC No. 151, to a maximum nitrogen fluence of 6.6 x 10^{14} cm^{-2}.

Fig. 5. SiC No. 15 showing the heavily implanted area (SiC No. 15h; dark area) and the lightly implanted area (SiC No. 151) after annealing 24 hr at 450°C in nitrogen. Note that the lightly implanted area has already recovered substantially from the damage. The heavily implanted area is no longer optically homogeneous. The region between SiC No. 15h and SiC No. 151 is the transition in fluence between the areas. Magnification 20×.

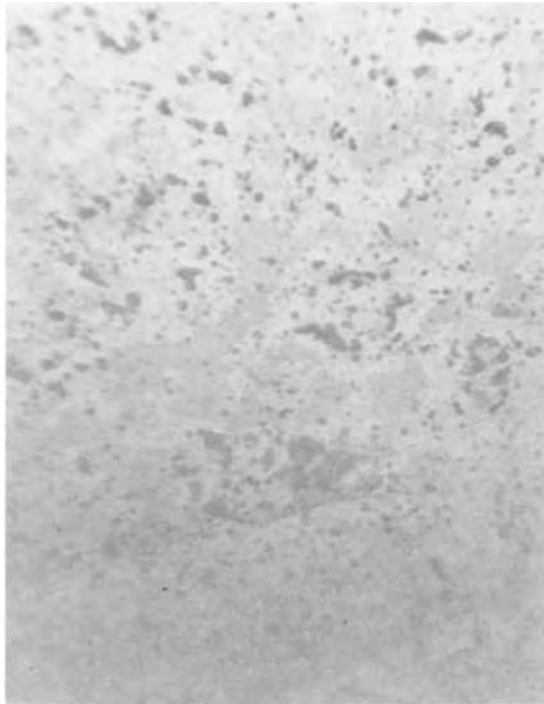

Fig. 6. SiC No. 15h after 24 hr annealing at 1040°C in nitrogen. Brownish amorphous islands alternate with regions of greater transparency. Magnification 200×.

at about 300 and 200Å for the unannealed and for the annealed profiles, respectively, but do not believe that it has a significant effect on the remainder of the profiles. Comparison of the unannealed profile with the theoretical curve shows that the predicted peak depth is about 15% less than that measured for the unannealed sample, while the predicted straggling is about 28% less. As can be seen the effect of the annealing is to shift the main peak towards the surface by approximately 250Å from the unannealed profile.

The effect of increasing the fluence five-fold plus the thermal treatments listed in Table II is shown in Fig. 8, which shows the $(^{14}N^{16}O)^-$ ion current for crystal SiC No. 15h. Comparison with the theoretical profile clearly shows that the combined effect of the increase of fluence and of the thermal treatments on the profile is to shift the peak significantly towards the surface and to increase the full width at half maximum (FWHM) by 20%.

Boron Implantations

Since 6H SiC crystals containing boron and nitrogen have a yellow room temperature fluorescence (19) when excited by 3650Å radiation, the boron implantations were made preferentially in nitrogen doped crystals. Such crystals do not have any room temperature fluorescence, but show a strong blue luminescence when cooled to 77°K (14). Different crystals were implanted with 30 and 60 keV $^{11}B^+$ ions to get peak concentrations from 1.0×10^{17} to 4.8×10^{20} cm^{-3}. For a fluence of 10^{14} cm^{-2}, corresponding to peak concentrations of $\sim 10^{19}$ cm^{-3}, or more, a brownish surface layer developed as a consequence of the implantations.

A gradual clearing of the damaged surfaces occurred after annealing the crystals at 100°C intervals from 550° to 1050°C. After annealing at 1050°C, by visual inspection the crystals appeared to have completely recovered from the damage. The implanted surfaces, however, did not show the yellow "boron" luminescence at room temperature or the original blue luminescence at 77°K. Further annealing in silicon carbide crucibles in argon at 1250° and 1400°C resulted in the reappearance of the blue low temperature luminescence. Moreover, a weak room temperature "boron" luminescence appeared in the irradiated areas of some of the nitrogen doped, green colored crystals irradiated to boron peak concentrations in the range of 10^{20} cm^{-3}. Thermoprobe measurements indicate that even for this implantation level, the yellow fluorescing layers retained n-type conductivity. Colorless crystals or crystals implanted to low boron fluence did not show any room temperature fluorescence after annealing at 1400°C. Coating of the implanted crystals with a 2000Å thick layer of sputtered SiO_2 before annealing did not lead to different results.

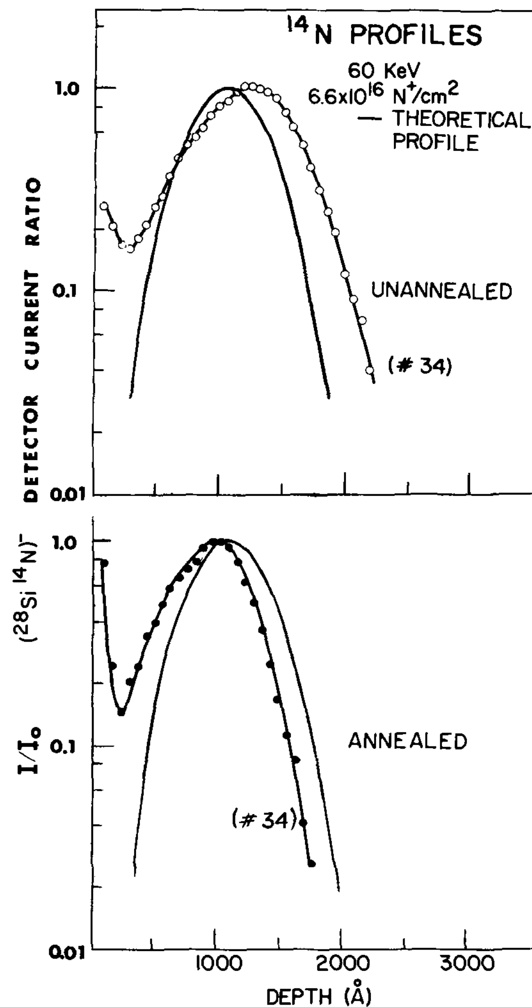

Fig. 7. Unannealed and annealed profiles from crystal No. 34 implanted with 60 keV $^{14}N^+$ ions to a fluence of 6.6 x 10^{16} ions/cm^2. The crystal was annealed in argon at 1400°C for 15 min in a silicon carbide crucible. The data are plotted as $(^{28}Si^{14}N)^-$ detector current ratio, I/I_0, where I_0 is the peak current in the distribution, vs. depth in Å. A $(^{29}Si^{12}C)^-$ signal was monitored during each profile run for $(^{28}Si^{14}N)^-$ signal normalization. A 60 keV ^{14}N theoretical distribution is plotted on the graph in atomic per cent vs. depth.

Boron profiles.—Figure 9 shows the measured unannealed profiles of crystals irradiated with 30 and 60 keV $^{11}B^+$ ions. The data are plotted as $^{11}B^+$ detector current ratio, I/I_0, where I_0 is the peak current in the distribution, *vs.* depth in Å. A $^{12}C^+$ signal was monitored during each profile run for signal normalization. The agreement with the profiles predicted by the LSS theory (15) is only qualitative. The theoretical peak depths are about 20% less than those measured, and the straggling, as measured by the FWHM, is about 40% less. Some of these differences may be due to the large relative atomic number and mass differences of the constituent atoms (^{28}Si and ^{12}C). The tails extending on the deep side of the peaks are typical of implants

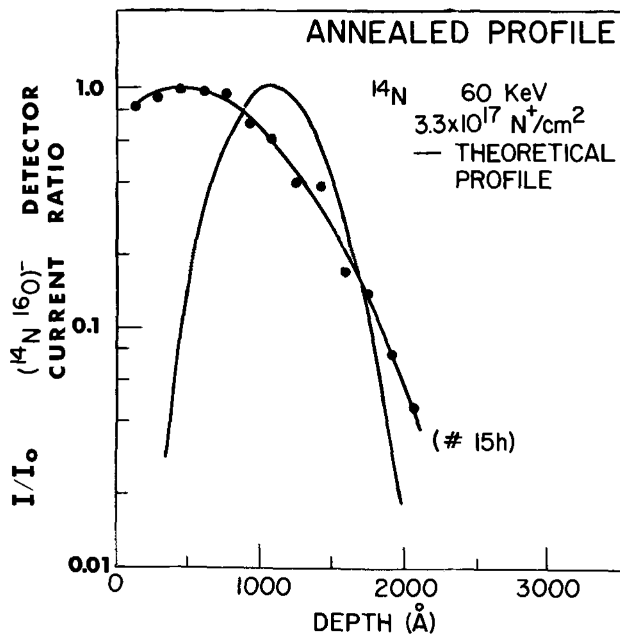

Fig. 8. Profile of ^{14}N distribution in sample No. 15h after annealing in argon at 1400°C for 15 min in a silicon carbide crucible. The crystal was implanted with 60 keV $^{14}N^+$ ions to a fluence of 3.3 x 10^{17} ions/cm^2, which is a fivefold increase in fluence of the annealed sample (No. 34) shown in Fig. 7. The data are plotted as ($^{14}N^{16}O$)$^-$ detector current ratio, I/I_o, where I_o is the peak current in the distribution, vs. depth in Å. A ($^{29}Si^{12}C$)$^-$ signal was monitored during the run for ($^{14}N^{16}O$)$^-$ signal normalization. A 60 keV ^{14}N theoretical distribution is plotted on the graph in atomic per cent vs. depth.

where, as in this case, no attempts were made to suppress channeling. They also may be due, in part, to a radiation enhanced diffusion mechanism, similar to that observed in silicon (20, 12).

After annealing at 1400°C, no boron was detected by the microanalyzer in crystals implanted with 30 and 60 keV $^{11}B^+$ to peak concentrations $\lesssim 10^{19}$ cm^{-3}. A weak yellow boron luminescence was seen, however, when the crystals were excited by 3650Å uv. It is estimated that after annealing there is less than 1×10^{11} boron atoms cm^{-2} in the implanted areas of these crystals.

Aluminum Implantations

Four n-type plates were implanted to fluences of 2×10^{11} cm^{-2}, 4×10^{11} cm^{-2}, 4×10^{12} cm^{-2}, and 4×10^{13} cm^{-2}, respectively, with 60 keV $^{27}Al^+$ ions impinging at an angle of 12° to the c-axis direction. Three additional crystals (No. 30, 31, and 32) were implanted to fluences of 5×10^{13} cm^{-2}, 5×10^{14} cm^{-2}, and 5×10^{15} cm^{-2}, respectively, with $^{27}Al^+$ ions impinging at a 7° angle to the c-axis direction. For a fluence of 5×10^{13} cm^{-2} or more, the implanted areas acquired a dark brown discoloration similar to that of boron and nitrogen implanted crystals. The discoloration disappeared after annealing for 15 min in argon at 1400°C. Thermoprobe measurements indicated that for a fluence of 5×10^{15} cm^{-2} (crystal SiC No. 32) the implanted crystal surface converted from n-type to p-type. For the 5×10^{14} cm^{-2} (SiC No. 31) and the 5×10^{13} cm^{-2} (SiC No. 30) implants a marked decrease of the original n-type signal resulted as a consequence of the implants.

Aluminum profiles.—Figure 10 shows the profiles for the unannealed crystals No. 30, 31, and 32. The data are plotted as $^{27}Al^+$ detector current ratio I/I_o, where I_o is the peak current in the distribution, *vs.* depth in Å. A $^{24}C_2{}^+$ signal was monitored during each profile determination for signal normalization. Crystal No. 30 had a nonuniform aluminum background and

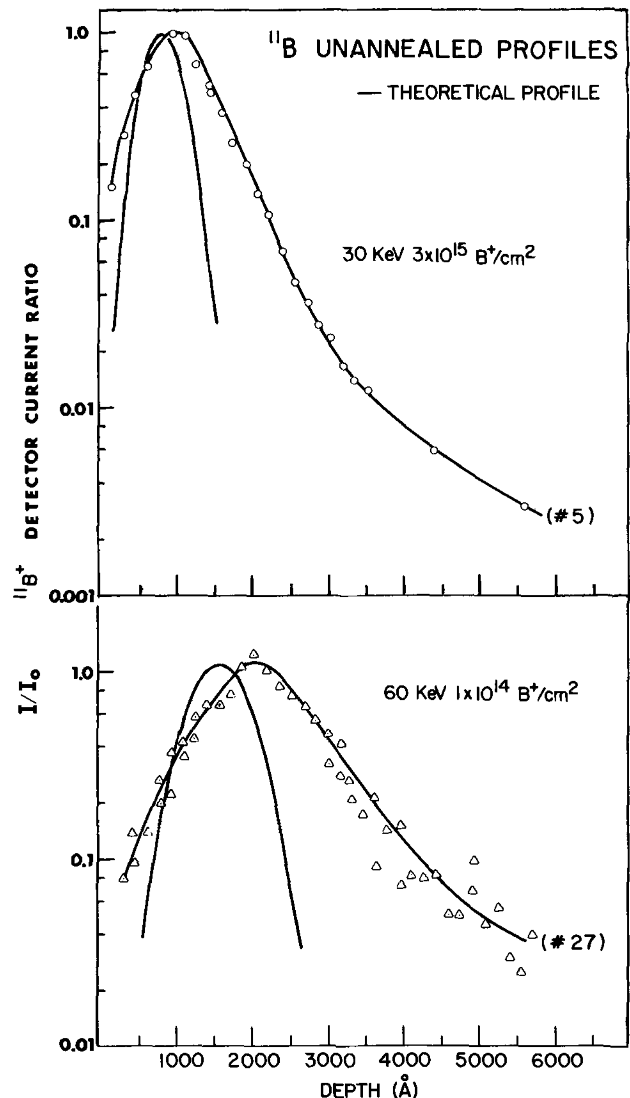

Fig. 9. Unannealed profiles from crystals No. 15 and No. 27 implanted with 30 and 60 keV $^{11}B^+$ ions to a fluence of 3 x 10^{15} and 1 x 10^{14} ions/cm^2, respectively. A $^{12}C^+$ signal was monitored during each profile run for $^{11}B^+$ signal normalization. Theoretical 30 and 60 keV ^{11}B profiles are plotted on the same graph in atomic per cent vs. depth.

the implant concentration lies near the aluminum detectability limit of the ion analyzer. Therefore, only the region near the surface is presented. The aluminum profile calculated from the LSS theory (15) is also shown.

The agreement with the theory is only qualitative. For example, the predicted peak for the 5×10^{14} implant is about 35% less deep than the measured one, and the predicted straggling is about 57% less. Moreover, these differences increase for the heavier implant to 51% and 71%, respectively. At the moment we can only suggest the presence of a radiation-enhanced diffusion mechanism. An analogous effect has been observed in MgO implanted with 3.0 MeV Ne^+ ions (21). The MgO damage profile curves obtained by monitoring the damage as the bombarded surface is chemically removed show that as the fluence increases the FWHM increases and the damage peak increases in depth.

Figure 11 shows the profiles after annealing at 1400°C for 15 min. For SiC No. 30 the distribution shows a sharp gradient up to the surface. For SiC No. 31 and SiC No. 32 two regions are now present: a sharp gradient peaking at the surface and a broad distribution extending deeper into the crystal with relatively flat maxima at about 1300Å. The considerable increase in

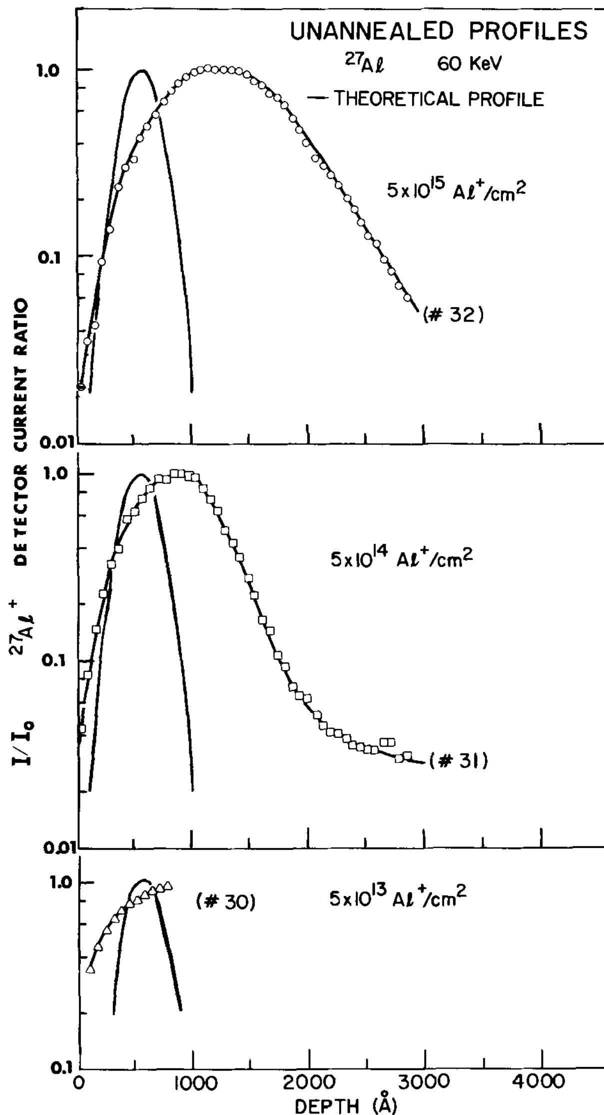

Fig. 10. Profiles from crystals No. 30, 31, and 32 implanted with 60 keV $^{27}Al^+$ ions to a fluence of 5×10^{13}, 5×10^{14}, and 5×10^{15} ions/cm^2, respectively. The data are plotted as ^{27}Al detector current ratio, I/I_0, where I_0 is the peak current in the distribution, vs. depth in Å. A $^{24}C_2^+$ signal was monitored during each profile run for $^{27}Al^+$ signal normalization. Crystal No. 30 had a nonuniform Al background and the Al concentration was near the Al^+ detectability limit of the ion microprobe; therefore only the surface region is presented. A 60 keV Al theoretical profile is plotted on the same graph in atomic per cent vs. depth.

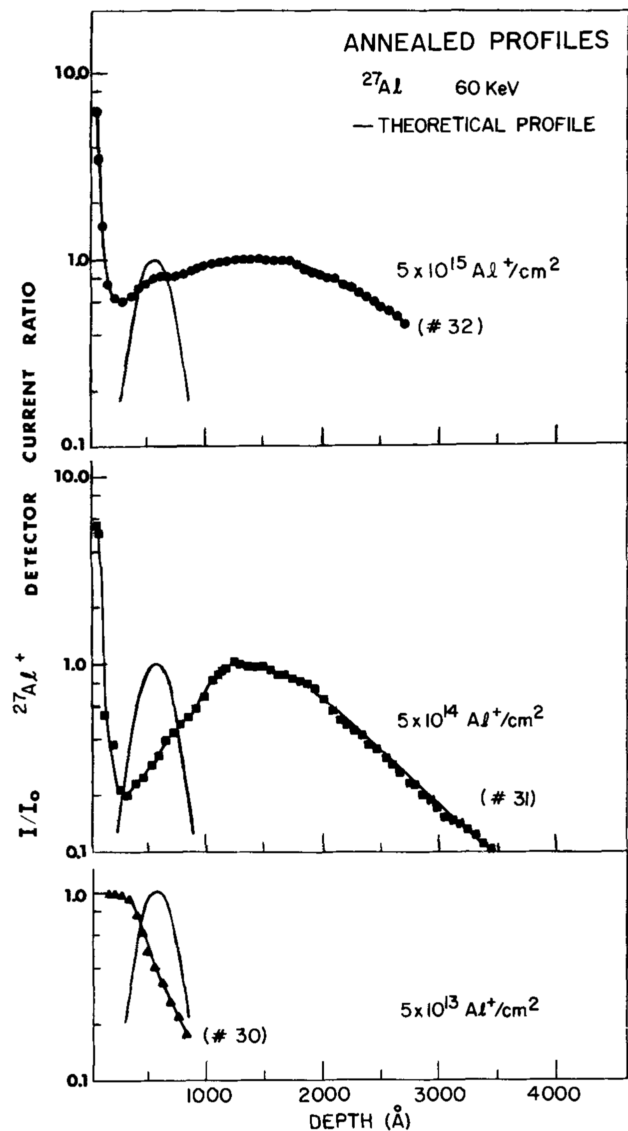

Fig. 11. Al profiles from crystals No. 30, 31, and 32 after annealing in argon at 1400°C for 15 min in silicon carbide crucibles. The data are plotted as $^{27}Al^+$ detector current ratio, I/I_0, where I_0 is the peak current in the distribution, vs. depth in Å. A $^{24}C_2^+$ signal was monitored during each run for $^{27}Al^+$ signal normalization. A 60 keV Al theoretical profile is plotted in atomic per cent vs. depth.

the concentration of the surface aluminum is probably responsible for the appearance of p-type conductivity in SiC No. 32 and the related effects in SiC No. 31 and SiC No. 30.

Discussion

In all cases the primary effect of the ion implantation was the formation of a brownish disordered surface layer. Except for cases of extreme fluences, (for example, SiC No. 15h), annealing at 1400°C eliminated the radiation damage and restored the original 77°K luminescence of the crystals. Moreover, in crystals containing a suitable amount of nitrogen donors, the typical boron room temperature luminescence in the yellow region appeared after implantation to high boron levels and annealing at 1400°C. Obviously, annealing regenerated the original crystal structure, and conversion to polytypes stable at low temperatures, such as the 2H and the 3C polytypes, did not occur. This observation is important because, in the event of a change in crystal structure, only heterojunctions could, in general, be prepared by ion implantation in SiC. Homojunctions would be restricted to one or two polytypes.

Nitrogen implantation and annealing produced n-type conductivity in the implanted areas of originally p-type crystals. This behavior has been attributed by Dunlop and Marsh (11) to the existence of a substantial fraction, ~1/3, of nitrogen atoms at donor sites in the SiC lattice after annealing. It must be remembered, however, that n-type conductivity in 6H SiC was observed also after bombardment with alpha particles, neutrons, and electrons (22-24). Thus donor type defects may contribute to the observed conductivity.

Reflection electron diffraction observations indicate that an amorphous layer is formed as a result of the ion implantation at high fluences. Localized electronic states may occur in the electronic bandgap due to the disorder (16-18) of this amorphous semiconductor layer. The absorption tail extending from the band edge to lower energies thus may be due to electronic excitations at these localized states.

With increasing fluence the shoulder at 10,000 cm^{-1} in SiC No. 15h (Fig. 1 and 4) increases markedly after

the band tail absorption near the fundamental edge begins to decrease (Fig. 2). Subsequently, this shoulder anneals out completely (Fig. 4). It is thought that the shoulder may result from the development of aggregate defect centers at high fluences. Thus localized electronic states of lower energy may occur at the aggregate centers, and the absorption at 10,000 cm^{-1} may be due to electronic excitations at these aggregates. The optical data indicate that a small reversible shift of the band edge of SiC occurs as a result of $^{14}N^+$ implantation (Fig. 1 and 3). This behavior is quite different from that of GaAs and GaP, where large reversible shifts of the optical absorption edge were observed after implantation with argon ions and neutrons (25-27), and is in line with the well-known ability of SiC to withstand radiation damage better than silicon and germanium.

The profiles of the implanted impurities, before annealing, show that qualitative agreement exists with the LSS theory (15), but the impurity distributions are characterized by the presence of a tail extending deeply into the crystals. Similar observations have been reported for silicon (28) and for other materials (12). Apparently channeling and/or enhanced diffusion effects cannot be neglected. Moreover, for aluminum, as shown by the profiles in Fig. 10, the peak position and FWHM change with the fluence.

The profiles of the annealed samples are difficult to interpret in detail. In all cases the impurities diffuse to the surface during annealing. The rate of diffusion may depend on the impurity, on the depth below the surface, on the fluence level, and on the associated damage. If diffusion is particularly fast for the layers immediately below the surface, the impurities in that region migrate to the surface rapidly and, if trapped there, create the surface maxima observed in some of the nitrogen and aluminum implants (crystals No. 31, 32, and 34, Fig. 11 and 7). Outdiffusion during the implantation might be invoked to explain the ^{24}N profile observed for crystal No. 34 before annealing (Fig. 7).

The presence of large Al peaks at the surface of the ^{27}Al implanted crystals after annealing and the conversion from n- to p-type conductivity in the case of SiC No. 32, is particularly interesting. Marsh *et al.* (9, 10) have reported the possible presence of a p-type layer in n-type β SiC as a consequence of low energy aluminum implantations. Significantly, none of the other impurities implanted by them at room temperature (Be, B, Ga, In, Te, N, P, As, Sb) resulted in p-type conversion. Thus, Al may be in a special position compared to other Group III dopants. It is known that aluminum substitutes for silicon in the SiC lattice (29), as might be expected upon consideration of the similarity of the tetrahedral covalent radii of aluminum (1.26Å) and silicon (1.17Å) (30). At the annealing temperature of 1400°C, silicon slowly evaporates from the surface of the SiC crystals, and leaves behind a carbon rich layer. Under these conditions it is possible that the aluminum atoms close to the surface migrate and replace, fully or in part, the missing silicon atoms with consequent formation of a steep gradient in the concentration of the surface aluminum.

We may conclude this discussion by stating that ion implantation looks very promising as a means to make SiC devices. In particular, the appearance of room temperature boron luminescence and the presence of surface aluminum and nitrogen after annealing clearly indicate that the possibility of preparing doped layers by room temperature ion implantation in silicon carbide does exist. Additional work is in progress to learn how to prepare active devices by this technique.

Acknowledgments

We wish to thank R. M. Potter, General Electric Company, Cleveland, Ohio, for some of the crystals used in this research. We are obliged to Herbert Hendrickson's ion implantation group at NASA, Langley, Virginia, and to the Hughes Research Laboratories, Malibu, California, for some of the aluminum implantations. We wish to thank R. Baxter and B. Phillips, Battelle Memorial Institute, Columbus, Ohio, for their cooperation in getting the microanalytical data. We are obliged to J. E. Davey for electron diffraction patterns and to K. R. Gleason for preparing SiO_2 coated crystals. Also, we wish to thank and gratefully acknowledge R. D. Kirk for making available to us the high-temperature furnace used for annealing the crystals.

Manuscript submitted Jan. 31, 1972; revised manuscript received June 9, 1972. This was Paper 196RNP presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Oxygen and Metal Activities of the Iron-Nickel-Oxygen System at 1000°C

Haydn Davies* and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The equilibrium oxygen pressures for Fe-Ni alloys coexisting with their oxides have been determined at 1000°C using an electrochemical cell with a calcia-zirconia electrolyte. These pressures were related to compositional determinations of the solid phases and the Fe-Ni-O isotherm at 1000°C. Oxygen pressure over the wustite-alloy phase field increases from 1.32×10^{-15} atm for Fe-FeO equilibrium to 5.5×10^{-14} atm for the invariant three-phase field of wustite containing 0.51 a/o (atom per cent) Ni, spinel containing 0.6 a/o Ni, and an alloy containing 79.6 a/o Ni. The oxygen pressure subsequently increased through the spinel-alloy phase field to 2.5×10^{-11} atm, that of the invariant phase field composed of spinel containing a calculated composition of 11.4 a/o Ni, nickel oxide containing 42.5 a/o Ni, and an alloy containing 99.6 a/o Ni. Iron behaved ideally up to the alloy content of 40 a/o Ni, but then exhibited small negative deviations, whereas nickel deviated negatively at alloy compositions greater than 10 a/o Fe. The spinel-alloy equilibria have been described by a Gibbs-Duhem calculation and by a structural model for the spinel based on a lattice point defect model.

The thermodynamics of the Fe-Ni-O system containing solid phases at high temperatures has been investigated by several workers (1-12). Measurements based on gas equilibration and electromotive force techniques have been chiefly utilized to determine partial and integral thermodynamic properties of the alloys. In several investigations (6, 9, 11, 12), measurements of oxygen activities have been combined with determinations of compositions and structures of the solids to define the fields within the ternary phase diagram, the results for the isotherm at 1000°C being most extensive (11). The purpose of this work, accordingly, was to obtain additional information concerning the dissociation pressures of wustite and spinel equilibrated with the alloys and to collate the information from the various sources into a complete description of the ternary system at 1000°C.

Experimental

A solid-state electrochemical technique using calcia-stabilized zirconia as the electrolyte was used to determine the dissociation pressures of the oxides. The cell, which was similar to that of Charette and Flengas (13), is illustrated in Fig. 1. The inner reference electrode compartment consisted of a 12 in. long tube of calcia-stabilized zirconia (B grade) supplied by the Zirconium Corporation of America. The outer electrode compartment consisted of the exterior Mullite tube containing an alumina crucible. The arrangement of the electrodes and platinum leads, with respect to the electrolyte, was that shown by Roeder and Smeltzer (6). These components were placed inside a grounded Nionel tube to shield the platinum electrode leads from any inductive field produced by the furnace windings. The cell temperature was determined by a Chromel-Alumel thermocouple calibrated *in situ*, and all emf's were measured with a high impedance potentiometer. Temperatures were controlled to ±1°C and cell voltages measured to 10^{-4}V.

* Electrochemical Society Active Member.

Key words: thermodynamics, Fe-Ni-O system, metal and oxygen activities.

There are several references to the need for "closed cell design" involving two hermetically sealed half-cell compartments to prevent oxygen transfer, via the gas phase, between the electrode compartments. Initially, both compartments were sealed under vacuum, but later experiments used a common vacuum of 10^{-6} Torr. No difference in results was obtained. The present design involving electrodes of metal/oxide compacts together with protective amounts of metal-metal oxide powders was satisfactory for both of the above conditions, and maintained equilibrium cell potentials. Fe/FeO was used as the reference electrode for all experiments.

The electrode materials were fabricated as tablets 0.25 in. diameter by 0.10 in. thick by compressing, at

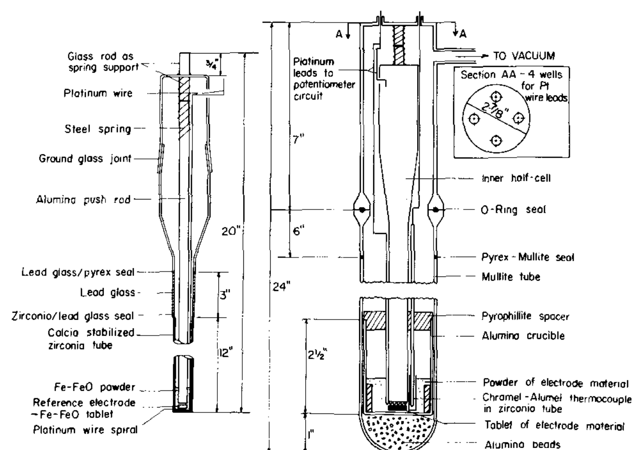

Fig. 1. Electrochemical cell assembly containing a solid calcia-stabilized zirconia electrolyte tube.

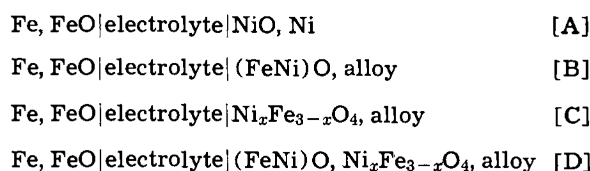
15,000 psi, powders of iron and nickel [99.99 w/o (weight per cent) pure] in predetermined proportions with one, or more, of the oxides (99.6 w/o pure) consisting of nickel oxide, magnetite, and nickel ferrite. The tablets were sealed in quartz tubes containing argon (oxygen content less than 2 ppm) and then annealed at 1000°C for 28 days. They were subsequently cooled to room temperature within 1 min by quenching. Both these tablets and those subjected to emf measurements exhibited identical compositional and structural properties. Techniques for metallographic preparation of the specimens and their chemical analyses using a Cameca electron-probe microanalyzer have been described (11). Fe-Ni alloys, FeO, Fe_3O_4, and $NiFe_2O_4$ were used as standards for preparing compositional calibration curves for this instrument.

Electromotive force measurements were made for the following cells.



Fe, FeO|electrolyte|NiO, Ni [A]

Fe, FeO|electrolyte|(FeNi)O, alloy [B]

Fe, FeO|electrolyte|$Ni_xFe_{3-x}O_4$, alloy [C]

Fe, FeO|electrolyte|(FeNi)O, $Ni_xFe_{3-x}O_4$, alloy [D]

Since the reaction is transfer of oxygen from the cathode to anode compartment, the emf is (14)

$$E = \frac{RT}{4F} \ln P_{O_2}''/P_{O_2}' \quad [1]$$

Here P_{O_2}'' and P_{O_2}' are the dissociation pressures of the oxides in the cathode and anode compartments, respectively. For reversible potentials, the compositions of the solid phases must remain unchanged. The factors which affect the accuracy and reliability of this technique have been described by Steele and Alcock (15, 16) and Sellars and Maak (17). In this investigation, the cell was alternately evacuated and flushed with purified argon, which had been freed of O_2, CO, and H_2 by passage over activated copper and unreduced copper oxide catalysts held at 150°C, and then freed of H_2O and CO_2 by passage through Ascarite and a liquid nitrogen trap. The cell was then evacuated to 10^{-6} Torr and continually pumped throughout the equilibration period at 1000°C and the subsequent measurement period at temperatures over the range 800°-1060°C. For cells A and B, the equilibrium time was initially 20 days but subsequent work showed that two days were sufficient. The equilibration time for cell C was 20 days but the cell emf remained unchanged after 10 days at temperature. Cell D was equilibrated for 26 days, but the emf did not change after 20 days.

The method of Diaz and Richardson (18) was used to measure the emf. At any supposed equilibrium state, the cell was disturbed by passing a small current equivalent to 0.01-0.1 coulombs and the emf value subsequently determined from the plateau in the cell emf *vs.* time curves. The most extensive measurements were made on the cells operating at 1000°C. Measurements were also made at temperatures within the range 800°-1100°C by cycling the temperature to values below and above 1000°C and allowing the cell to stabilize for a period of 1 hr.

Cells B and C correspond to the fields containing a metal phase in the Fe-Ni-O phase diagram. Cell D corresponds to the invariant equilibrium between alloy, nickel oxide containing iron in solid solution, and an iron-nickel spinel. Attempts were also made to prepare electrodes describing the invariant equilibrium between alloy, wustite-containing nickel in solid solution, and an iron-nickel spinel. However, we were unsuccessful because this latter three-phase field is of very narrow compositional extent (11) and the compositions of the fabricated tablets adjusted to two-phase regions during the annealing periods.

Table I. Least squares analyses of emf

Sample	E (mV) = A + BT(°K) A (mV)	B (mV/°K)	Standard deviation (mV)
WA1	8.38	0.038	0.9
WA2	4.90	0.048	0.9
WA3	−13.96	0.073	0.4
WA4	12.54	0.058	0.6
WA5	14.38	0.059	0.5
SA1	−68.06	0.135	0.4
SA2	23.31	0.096	0.9
SA3	−44.76	0.153	0.7
SA4	−18.01	0.141	0.7
SA5	45.26	0.108	0.8
SA6	45.61	0.133	0.6

Results

Cell A.—Emf values over the range 600°-1050°C could be correlated by the linear equation

$$E(\text{mV}) = 157.1 + 0.101T(°\text{K}) \ (\pm 0.9 \text{ mV}) \quad [2]$$

These values were in good agreement with published values and the least square representation of these results (16)

$$E(\text{mV}) = 157.6 + 0.10T \ (°\text{K}) \ (\pm 0.9 \text{ mV}) \quad [3]$$

Cell B.—The emf values at temperatures in the range 800°-1060°C and the linear relationships for the cell temperature coefficients obtained by the method of least squares are given in Fig. 2 and Table I, respectively. The alloys investigated contained up to 75.9 a/o Ni.

Cell C.—The results are also represented in Fig. 2 and Table I. In this case, the alloy compositions ranged from 91.6 to 98.7 a/o Ni.

Cell D.—The emf was determined only at 1000°C. Its value was 270 ± 1 mV.

The compositions determined by the electron microprobe technique for the coexisting oxide and alloy phases at 1000°C are recorded in Table II. The mass concentrations obtained experimentally have been converted to atomic concentrations which are also given.

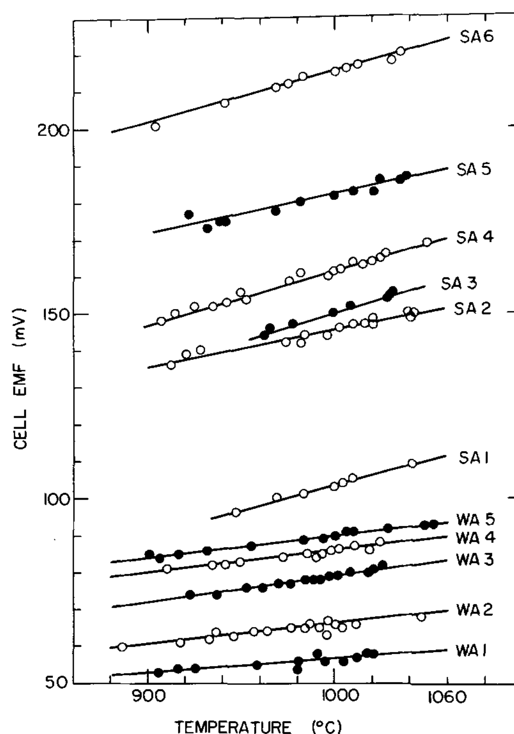


Fig. 2. Electrical potentials vs. temperature for cells B and C. The composition designations for the plots correspond to those in Table II.

Table II. Electron microprobe analyses of coexisting alloy and oxide phases at 1000°C

* For samples WA1-SA2, the nickel contents of the oxide phases were calculated from the measured iron compositions assuming that the metal to oxygen ratio was that of pure wustite at the same oxygen pressure.

Discussion

The Fe/FeO electrode was used as reference in the galvanic cells. Steele (16) has assessed the available calorimetric and high-temperature equilibrium values and described the dissociation pressure of wustite by

$$\log(P_{O_2}\ \text{atm})_w = \frac{-27643.7}{T} + 6.833\left(\pm\frac{54.64}{T(°K)}\right),\ [873°\text{-}1600°K] \quad [4]$$

The dissociation pressures of the investigated oxides were calculated by means of Eq. [1] and [4]. These values could be used with the corresponding compositional determinations of the coexisting oxide and alloy phases to describe the variation of the oxygen activity over the Fe-Ni-O isotherm at 1000°C. Further thermodynamic information concerning the various phase equilibria can also be calculated for particular approximations and assumptions. This is outlined as each phase field is discussed in detail.

Variation of equilibrium oxygen pressure with alloy composition.—Figure 3 shows the values of oxygen pressures calculated from the emf determinations as a function of atom fraction nickel in alloy, N_{Ni}^A, at 900°, 1000°, and 1050°C. Results from this and other investigations (6, 9, 10-12) are included. The results of this investigation are in good agreement with reported values except for those of Ono *et al.* (12) at 1050°C. The invariant oxygen pressure and alloy composition reported by Kushko *et al.* (9) for the wustite-spinel-alloy equilibrium is also included. The ideal curve shown for wustite-alloy equilibria was computed assuming ideal behavior of iron in the alloy. At 1000°C, the terminal composition of the alloy for wustite stability has been reported as 0.803 (8), 0.775 (9), 0.796 (11), and this study has used the latter value consistent with the corresponding compositions of wustite and spinel phases. The only reported terminal alloy composition at 900°C is 0.76 (8). At 1050°C, there are two reported values: 0.82 (8) and 0.88 (12). All of these terminal compositions are shown as vertical lines in Fig. 3.

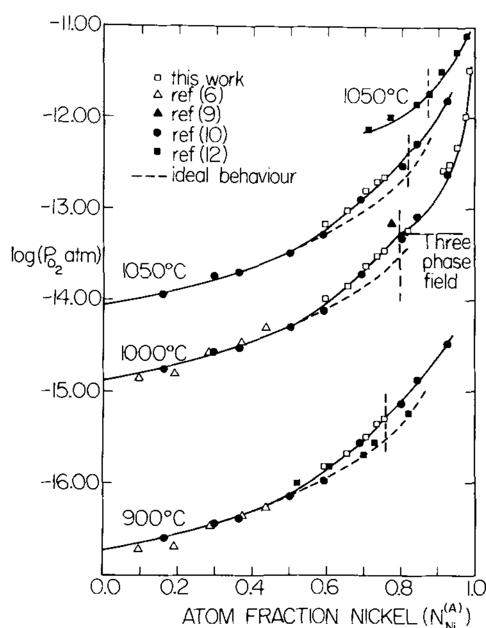

Fig. 3. Dissociation pressures of the oxides coexisting with Fe-Ni alloys at 900°, 1000°, and 1050°C. The dashed curves represent the ideal pressures for wustite-alloy equilibria assuming ideal behavior of iron in the alloy.

Wustite-alloy phase field.—Dalvi and Smeltzer (11) have described the Fe-Ni-O isotherm at 1000°C and reported that wustite can coexist with alloys containing up to 79.6 a/o Ni. The corresponding terminal composition of wustite was 0.51 a/o Ni. The equilibrium oxygen pressure over this phase field increases, with increasing values of N_{Ni}^A, from that corresponding to the iron-wustite equilibrium to the invariant oxygen pressure associated with the three-phase field, wustite-spinel-alloy. Accordingly, the experimental curve of P_{O_2} *vs.* N_{Ni}^A in Fig. 3 was extrapolated to the above limiting alloy composition to obtain an invariant pressure of 5.5 (±0.2) × 10^{-14} atm. These values are to be compared to limiting values of $N_{Ni}^A \simeq 0.775$ and an oxygen pressure of 7.1 × 10^{-14} atm determined by Kushko *et al.* (9) using a gas equilibration method.

Wustite composition as a function of oxygen pressure.—The effect of nickel content in wustite on its dissociation pressure is shown in Fig. 4. The parameter representing the nickel content is the metal atom fraction based on the total metallic content of the wustite phase. Note that the invariant oxygen pressure for wustite-spinel-alloy equilibrium is less than the magnetite-wustite dissociation pressure. Therefore the nickel metal atom fraction in the spinel must be greater than that in the wustite.

Thermodynamic properties of alloy.—The dissociation pressure of wustite equilibrated with the alloy is given by the relationship

$$P_{O_2} = \frac{(a_{FeO}{}^w)^2}{(a_{Fe}{}^A)^2} \cdot P_{O_2}{}^w \quad [5]$$

where $P_{O_2}{}^w$ is the dissociation pressure of wustite equilibrated with pure iron. For $a_{FeO} \sim 1$ and $a_{Fe}{}^A = N_{Fe}{}^A$, this reduces to the ideal relationship which produced the ideal behavior curves in Fig. 3. The experimental

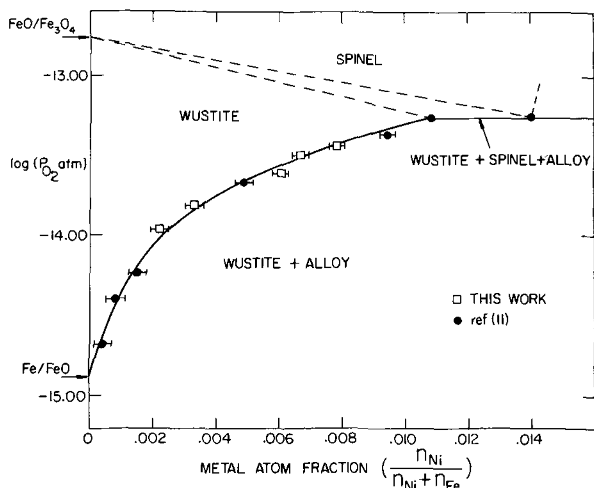

Fig. 4. Dissociation pressure of wustite equilibrated with Fe-Ni alloys at 1000°C vs. the nickel atom metal fraction in the oxide.

values of oxygen pressure, however, become greater than the calculated values, with increasing N_{Ni}^A, due to negative deviations of iron from ideality.

Activities of iron in the alloys may be obtained by considering the virtual reaction for cell B, assuming pseudobinary behavior. The virtual cell reaction is

$$Fe + FeO^w = Fe^A + FeO \qquad [6]$$

where FeO^w represents wustite equilibrated with an alloy. From the Nernst equation

$$E = \frac{RT}{2F} \ln a_{FeO^w}/a_{Fe}^A \qquad [7]$$

The wustite phase contained small amounts of nickel, less than 0.5 a/o, but its effect on the wustite activity is unknown. The data of Swaroop and Wagner (19) provided values for wustite activity at each measured oxygen pressure assuming that negligible error is introduced by neglecting the effect of nickel. The values of the iron activities were then calculated over the compositional range of wustite stability using Eq. [7]. The values of nickel activities were then obtained by numerically integrating the Gibbs-Duhem relationship, following the method of Darken and Gurry (20). Activity data reported by Kushko *et al.* (9) and Gatellier *et al.* (10) were used for the composition range $0.8 \leq N_{Ni}^A < 1$. The variations of the iron and nickel activities are shown in Fig. 5. Values of activities previously determined by the electrochemical (6, 10) and gas equilibration (2, 9) methods are included. The results illustrate that iron behaves ideally up to approximately 40 a/o Ni and shows negative deviations at larger nickel concentrations. Nickel, on the other hand, behaves ideally only up to an alloy iron content of 10 a/o. The nickel activity coefficient over its range of Henrian behavior, 0-40 a/o Ni, was calculated to be 0.82.

The deviations from ideality nevertheless are relatively small. This behavior is illustrated in more detail by the plots in Fig. 6 showing the ideal and actual free energy of mixing curves. Since the activities have been determined, the excess free energy of mixing may be expressed as

$$\Delta G(\text{excess}) = RT(N_{Fe}^A \ln \gamma_{Fe} + N_{Ni}^A \ln \gamma_{Ni}) \qquad [8]$$

where γ represents an alloy activity coefficient. The maximum excess, which occurs at an alloy nickel atom fraction of 0.53, is only -240 cal/g-atom. This small degree of nonideality corresponds to previous findings (1, 2).

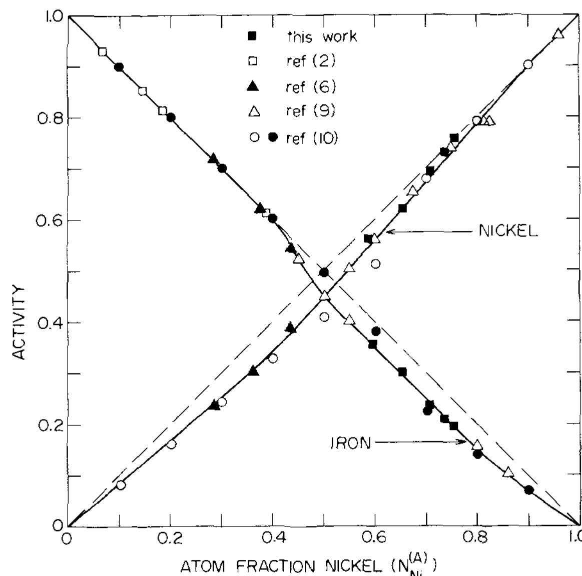

Fig. 5. Activities of iron and nickel in Fe-Ni alloys at 1000°C

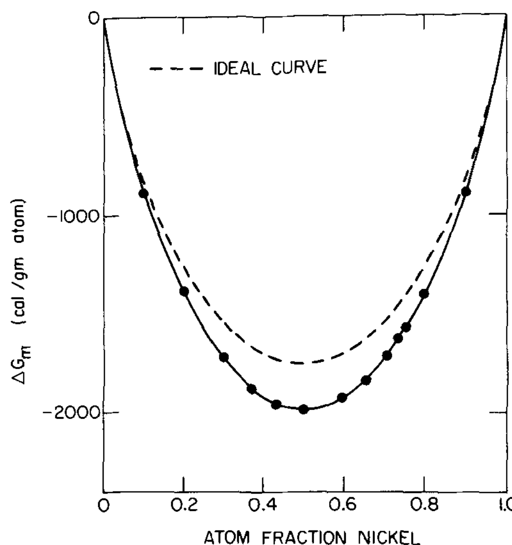

Fig. 6. Ideal and actual free energy of mixing curves for the Fe-Ni alloy system at 1000°C.

Spinel-alloy phase field.—It has been shown previously (11), and confirmed in this investigation, that a spinel, represented by the formula $Ni_xFe_{3-x}O_4$ where $0.04 \leq x < 1$, can coexist with alloys ranging in composition from 79.6 to 99.6 a/o Ni. The equilibrium oxygen pressures over this phase field are shown in Fig. 7. This plot consists of oxygen pressures determined directly by the electrochemical cell technique and of pressures calculated by applying the Gibbs-Duhem relationship to the experimentally determined values of the equilibrium compositions of the coexisting spinel and alloy phases.

The isothermal, isobaric Gibbs-Duhem relationship applied to the alloy and spinel phases gives

$$N_O^A\, d \ln a_O^A + N_{Ni}^A\, d \ln a_{Ni}^A + N_{Fe}^A\, d \ln a_{Fe}^A = 0 \qquad [9]$$

$$N_O^S\, d \ln a_O^S + N_{Ni}^S\, d \ln a_{Ni}^S + N_{Fe}^S\, d \ln a_{Fe}^S = 0 \qquad [10]$$

where N_i is the atom fraction and a_i is the activity of a species i in the alloy (A) and spinel (S) phase. The variation of oxygen activity with respect to nickel activity will then be

$$\frac{d \ln a_O}{d \ln a_{Ni}} = \frac{N_{Ni}^S N_{Fe}^A - N_{Ni}^A N_{Fe}^S}{N_O^A N_{Fe}^S - N_{Fe}^A N_O^S} \qquad [11]$$

Since the oxygen solubility in the alloy is very small, <0.015 w/o (21), the term $N_O^A N_{Fe}^S \approx 0$. The spinel

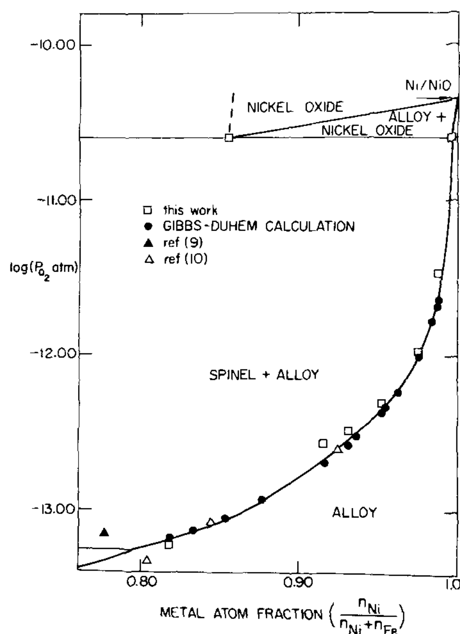

Fig. 7. Dissociation pressure of spinel equilibrated with Fe-Ni alloys at 1000°C vs. the nickel atom fraction in the alloy.

may be written as $Ni_xFe_{3-x}O_4$ assuming stoichiometry of the oxygen sublattice. Accordingly

$$N_{Ni}{}^{S} = \frac{x}{7};\ N_{Fe}{}^{S} = \frac{3-x}{7};\ N_{O}{}^{S} = \frac{4}{7} \quad [12]$$

Therefore

$$\frac{d \ln a_O}{d \ln a_{Ni}} = \frac{3N_{Ni}{}^{A} - x}{4(1 - N_{Ni}{}^{S})} \quad [13]$$

For $N_{Ni}{}^{A} > 0.796$, $0.98 < \gamma_{Ni}{}^{A} \leq 1.0$ (9, 10), and with $a_O = (P_{O_2})^{1/2}$, Eq. [13] becomes

$$\log \frac{P_{O_2}}{P_{O_2}{}^{*}} = 1.50 \log \frac{1 - N_{Ni}{}^{A*}}{1 - N_{Ni}{}^{A}} - 0.217 \int_{N_{Ni}{}^{A*}}^{N_{Ni}{}^{A}} \frac{x}{N_{Ni}{}^{A}(1 - N_{Ni}{}^{A})} dN_{Ni}{}^{A} \quad [14]$$

In this equation, $N_{Ni}{}^{A*} = 0.796$ and $P_{O_2}{}^{*} = 5.5 \times 10^{-14}$ atm are the alloy composition and the invariant oxygen pressure for the wustite-spinel-alloy phase field. Thus the oxygen pressure across the spinel-alloy phase field can be computed for each of the alloy compositions given in this investigation and for those reported previously (11).

Figure 7 shows that the oxygen pressure increases very rapidly for $N_{Ni}{}^{A} > 0.985$ terminating at the horizontal line representing the pressure for the spinel-nickel oxide-alloy phase field. This invariant oxygen pressure was determined from cell D to be $2.5(\pm 0.1) \times 10^{-11}$ atm which should be compared with a value of 1×10^{-11} atm determined by a gas equilibration method (9).

The spinel-nickel oxide-alloy phase field is the lower bound, with respect to oxygen pressure, of the nickel oxide-alloy phase field, which can be described by the pseudobinary reaction

$$Ni^{A} + \tfrac{1}{2} O_2 = NiO \quad [15]$$

At 1000°C, the dissociation pressure of pure nickel oxide is 4.4×10^{-11} atm (16). Since the measured value of the equilibrium oxygen pressure was 2.5×10^{-11} atm over the alloy with nickel activity equal to 0.996, the calculated value of the activity for nickel oxide was 0.75. A value of 0.73 has been reported for this activity at 1050°C (12). However, the measured value for the mole fraction of nickel oxide in this investigation was 0.85 which is larger than the previously reported value of 0.74 at 1050°C.

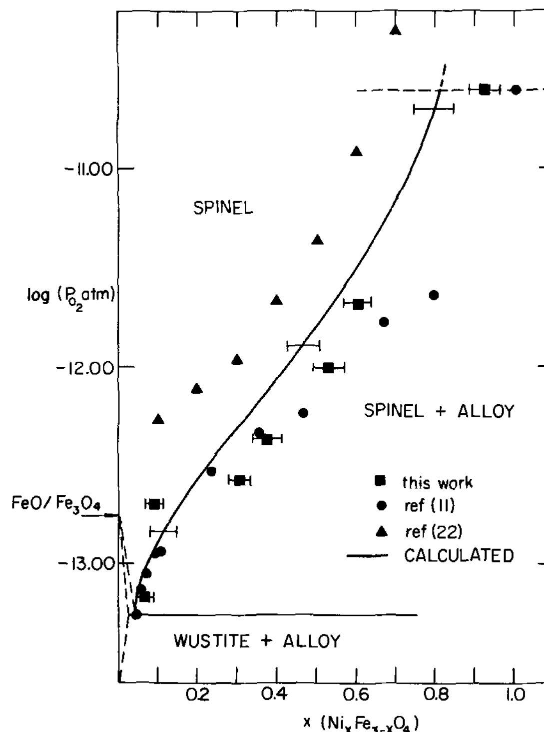

Fig. 8. Dissociation pressure of spinel equilibrated with Fe-Ni alloys at 1000°C vs. the nickel metal atom fraction in the oxide.

Spinel composition as a function of oxygen pressure.—Figure 8 illustrates the increasing equilibrium oxygen pressure of the spinel as its nickel content is increased. Three sets of values are given: those based on the oxygen pressure and composition determinations of this investigation, experimental values reported by Tretjakow and Schmalzried (22), and pressures calculated from the Gibbs-Duhem relationship, Eq. [14], using reported compositional determinations of the spinel and alloy phases (11).

A curve may be calculated to represent these results from a lattice defect model for this spinel proposed by Schmalzried (23). Consider the spinel phase as $Ni_xFe_{3-x}O_4$ and denote the tetrahedral cation sites as the A sublattice and the octahedral sites as the B sublattice. Assume, as with Schmalzried, that the concentration of ferric ions on tetrahedral sites in this inverse spinel is unaffected by nickel substitution into octahedral sites, *i.e.*, $Fe^{+3}|A| = 1$. Since the anionic sublattice is stoichiometric, the divalent and trivalent cations on B sites may be expressed as

$$Ni^{+3}|B| = z;\ Ni^{+2}|B| = x - z;\ Fe^{+3}|B| = 1 - z;\ Fe^{+2}|B| = 1 - x + z \quad [16]$$

The following reactions may be considered. The oxidation and reduction of cations on octahedral sites may be represented as

$$Ni^{+2}|B| + Fe^{+3}|B| = Ni^{+3}|B| + Fe^{+2}|B| \quad [17]$$

and

$$K_1 = \frac{z(1 - x + z)}{(x - z)(1 - z)} \quad [18]$$

where ideal behavior of the ions has been assumed. The transfer of oxygen to form stoichiometric spinel may be represented by

$$Fe^{+3}|A| + Fe^{+2}|B| + Fe^{+3}|B| + 4O^{-2}|O| = Fe_3O_4 \quad [19]$$

Therefore

$$(1 - z)(1 - x + z) = a_{Fe_3O_4} \quad [20]$$

To obtain Eq. [20], it has been implicitly assumed that the magnetite constituent of the spinel behaves ideally, and that the spinel may be considered as a solid solu-

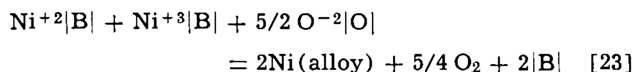
tion of the terminal compounds, *i.e.*, x moles of $NiFe_2O_4$ with $(1 - x)$ moles of Fe_3O_4. Uptake of oxygen by the spinel leads to formation of uncharged vacancies in the octahedral sublattice by the following reaction

$$2/3\,O_2 + 3Fe^{+2}|B| = 2Fe^{+3}|B| + |B| + 1/3\,Fe_3O_4 \quad [21]$$

Accordingly

$$K_2 = \frac{(1 - z)^2(|B|)(a_{Fe_3O_4})^{1/3}}{(P_{O_2})^{2/3}(1 - x + z)^3} \quad [22]$$

Finally, a defect equation may be used to represent equilibrium of the alloy with spinel



$$Ni^{+2}|B| + Ni^{+3}|B| + 5/2\,O^{-2}|O| = 2Ni(\text{alloy}) + 5/4\,O_2 + 2|B| \quad [23]$$

yielding

$$K_3 = \frac{(a_{Ni})^2(P_{O_2})^{5/4}(|B|)^2}{(x - z)z} \quad [24]$$

Equations [18], [20], [22], and [24] may be combined to give

$$\log x - 3.1667 \log(1 - x) = \log a_{Ni} + 1.292 \log P_{O_2} - \log K \quad [25]$$

where $K = (K_1^2/K_2K_3)^{1/2}$ under the restriction that $z << x$ (the ionization energy of divalent to trivalent nickel is about 6 eV). The constant K can be calculated from the experimental determinations associated with the wustite-spinel-alloy which serves as the lower bound, with respect to oxygen pressure, for the spinel-alloy phase field. The value of $\log K$ is -15.92 (± 0.13), the uncertainty arising from the uncertainties attributed to the parameters of the three-phase field, *i.e.*, $x = 0.042$ (± 0.008), $a_{Ni} = 0.78$ (± 0.01), $\log P_{O_2} = -13.26$ (± 0.05). Values of oxygen pressures *vs.* atom fractions of nickel were obtained from Fig. 7 and Eq. [25] solved for the corresponding values of nickel contents in the spinel. This predicted variation of spinel composition with oxygen pressure is shown by the curve in Fig. 8. The error bars on the curve denote uncertainties arising from the computation using uncertainties in the values of a_{Ni} and $\log K$, and are not a measure of the accuracy of the assumptions in the model.

The computed curve, despite the arbitrary assumption of ideality for the ionic species in the spinel, is close to a best-fit curve through the experimental results. The compositions of the spinel based on electron microprobe determinations of nickel contents lie on the nickel-rich side of the computed curve. The error bars on the experimental results are from standard deviations of the counts from spinel phases. The two major problems in analyzing spinel phases by the electron-microprobe technique were the polishing

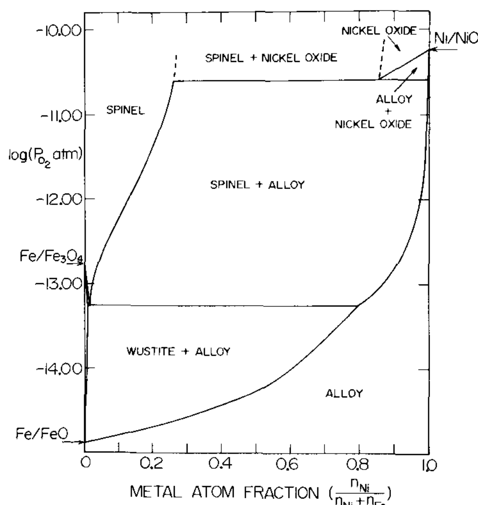


Fig. 9. Oxygen pressure as a function of the nickel atom metal fraction for each solid phase in the Fe-Ni-O isotherm at 1000°C.

of these phases, and the standards required. In this work, Fe_3O_4 and $NiFe_2O_4$ were used as standards, and intermediate compositions were obtained by a linear interpolation between these two compositions. The discrepancies between the sets of experimental results for the spinel compositions cannot be explained.

Oxygen pressure variation over the Fe-Ni-O isotherm at 1000°C.—Figure 9 shows the oxygen pressure as a function of the nickel content of each phase over the portion of the isotherm for which a metal phase exists. It has been compiled from Fig. 3, 4, 7, and 8 and the curves represent the best fit to available results.

Over the wustite-alloy phase field, the oxygen pressure increases, with increasing nickel content, from 1.32×10^{-15} atm corresponding to iron-wustite equilibrium, to 5.5×10^{-14} atm which is the invariant oxygen pressure associated with the wustite-spinel-alloy phase field. The nickel contents of the phases in this field are 0.5 a/o for wustite, 0.6 a/o for spinel, and 79.6 a/o for the alloy. Over the spinel-alloy phase field, the oxygen pressure increases to the invariant value of 2.5×10^{-11} atm for spinel-nickel oxide-alloy equilibrium. The spinel and nickel oxide are represented as $Ni_{0.8}Fe_{2.2}O_4$ and $Ni_{0.85}Fe_{0.15}O$, respectively, but the compositional determinations of spinel vary from $Ni_{0.65}Fe_{2.35}O_4$ to $NiFe_2O_4$ (11, 12, 22) and of nickel oxide from $Ni_{0.74}Fe_{0.26}O$ to $Ni_{0.87}Fe_{0.13}O$ (11, 12). The alloy contains 99.6 a/o Ni. Nickel oxide subsequently exists in equilibrium with metal up to the dissociation pressure of pure nickel oxide, 4.4×10^{-11} atm.

Highly Conductive, Transparent Films of Sputtered $In_{2-x}Sn_xO_{3-y}$

D. B. Fraser and H. D. Cook

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Highly conductive, transparent films of $In_{2-x}Sn_xO_{3-y}$ have been deposited by d-c diode sputtering with Ar, O_2, N_2, Xe, and O_2-Ar mixtures. Sputtering targets with different In_2O_3/SnO_2 ratios were utilized and the best results were obtained with pure Ar or Xe gas and targets containing 9-13 mole per cent (m/o) SnO_2. The lowest film resistivity achieved was 1.77×10^{-4} ohm-cm, but routine films had resistivity values of about 3×10^{-4} ohm-cm. The use of a very low sputtering gas throughput (10^{-2}-10^{-1} Torr liter/sec) was found to be necessary to develop films with a slight oxygen deficiency. Targets differing in density (porosity) differ in their susceptibility to reduction so that sputtering conditions depend on target density. The films have excellent adherence and will tolerate cleaning, heating, polishing, and bonding without failure. They may be etched in heated acids with standard photoresist techniques used to define electrode geometry. Exposure of the films to temperatures of 500°C in air will cause an approximate factor of 3 increase in resistance at room temperature. Sputtered films with sheet resistance of 1.6 ohms/square, 73% light transmission, and 14% reflection at 500 nm have been obtained. Suitable antireflection coated films of 5-7 ohms/square possessing over 97% light transmission appear feasible.

We wish to describe deposition techniques for and film properties of $In_{2-x}Sn_xO_{3-y}$ (ITO), a substitutional alloy oxide system with oxygen vacancies. Because of their low visible light attenuation, high electrical conductivity, stability, and good adherence sputter deposited films of ITO are expected to find wide application in electrooptic device technology.

Transparent, conductive films have generally been obtained by vapor deposition of thin metal films or by use of vapor reacted films of Sb-doped SnO_2 (1). Recently, characteristics of films of In_2O_3 (2, 3), Sn incorporated in In_2O_3 (4, 5), SnO_2 (3, 6), and Sb incorporated in SnO_2 (7), deposited by sputtering have been described.

In the sputtered pure oxides the reported resistivity at room temperature is approximately 10^{-2} ohm-cm after vacuum or other reducing, annealing treatment. Unless severe reduction has taken place, the oxide films display a high light transmission in the visible. Incorporation of donors such as Sb in SnO_2 and Sn in In_2O_3 yields higher conductivity without the optical absorption caused by excessive reduction. Vossen (5) has recently reported the deposition of films of ITO by rf sputtering using targets of 20 m/o SnO_2:In_2O_3. Resistivity values of 6.25×10^{-4} ohm-cm and optical properties similar to those reported here were obtained.

The films described here have been utilized in display devices such as ferroelectric ceramic light valves (8), liquid crystal light valves (9), and electrooptic polarization switches (10).

Sputtering Procedure

Some attempts were made to deposit In_2O_3 films by d-c diode, reactive sputtering of In and In-Sn alloys with mixtures of Ar-O_2. However, these films were deposited at very low rates with excessive substrate heating and the films had to be reduced by subsequent heat-treatment in nitrogen. Much more satisfactory films were achieved directly by d-c sputtering from In_2O_3 and In_2O_3-SnO_2, hot-pressed ceramic targets.[1] Three target sizes were utilized, 4.45 cm, 12.7 cm, and 22.8 cm diameters with most of the films described here sputtered from the 12.7 cm targets. A potential difference of 4-5 kV was used with an approximate current density of 1 mA/cm^2 for the small targets and 0.5 mA/cm^2 for the large targets. The target-to-substrate spacing varied from 5 to 7.5 cm. A thermocouple gauge was used to indicate chamber pressure and 20×10^{-3} Torr was the average pressure indicated during film deposition. Both the target and substrate holder were water-cooled. The substrates were borosilicate glass slides, Corning 7059 glass slides or vitreous silica slides. No attempt was made to thermally lock the substrates to the water-cooled holder.

The best films of ITO are obtained with a controlled throughput of gas. A 4 in. oil diffusion pump equipped with a liquid nitrogen trap was used to pump on the chamber, an 18 in. glass cylinder of either 20 or 50 liter volume. Most of the films to be discussed here were deposited without liquid N_2 in the trap since early in the investigation film properties did not appear to be dependent on cooling the trap. The chamber was equipped with an aluminum shutter that was placed between the target and substrate during pumpdown and predeposition sputtering. Initially, the chamber was pumped to 10^{-6} Torr and then the pumping system was throttled to maintain the admitted sputtering gas at approximately 20×10^{-3} Torr. This usually corresponded to a very low gas throughput

Key words: transparent electrode indium-tin oxide, sputtered sheet conductors.

[1] Targets were obtained from two sources: (i) Haselden Company, San Jose, California (this company supplied the In_2O_3 target and the high density 9 m/o SnO_2:In_2O_3 targets), and (ii) Materials Research Corporation, Orangeburg, New York (this company supplied all other targets).

rate of ~10^{-2} Torr liter/sec but many films were deposited at throughput rates of ~10^{-1} Torr liter/sec.

The sputtering gases used were O_2, N_2, Ar, Xe, and gas mixtures such as Ar-O_2, and O_2-N_2. No purification of the gases was attempted. Generally, the best film properties were obtained with pure Ar or pure Xe, however, the cost of using Xe may outweigh its advantage of higher deposition rate than Ar. Details of the influence of the sputtering gas will be considered in the discussion of film properties.

Initially in the investigation only porous targets were used and a target conditioning procedure was followed when pure inert gases were to be used to deposit test films. The procedure consisted of sputtering with a gas mixture of 80% O_2 and 20% Ar for as long as 1.5 hr, subsequently, sputtering could be carried out using Ar or Xe. After such an oxidizing treatment the porous target could be operated for more than 6 hr of accumulated sputtering time with pure Ar at low throughput rates with no apparent film deterioration. Prolonged sputtering in a pure inert gas resulted in films with a dark appearance showing that excessive reduction had occurred. With Ar or Xe the porous target would slowly acquire a dark appearance which was ascribed to a reduction of the surface. The darkening disappeared after sputtering with the O_2-Ar mixture.

Later in the investigation deposition procedures were modified so that porous targets could be used, without the O_2-Ar preoxidation. The procedure consisted of sputtering with Ar only and to begin film deposition on the substrates after only 4-10 min of sputtering with the shutter between target and substrate. Without the O_2-Ar oxidation apparently sufficient O_2 was adsorbed from the laboratory atmosphere when the system was open, to permit film deposition for 30 min.

The dense targets were used in a similar manner with pure Ar except that predeposition sputtering with the shutter in place was of 3-5 min duration and actual single deposition times could exceed 2 hr duration.

Deposition rates of ~1 μm/hr were routinely obtained with Ar. The highest rates (2.5 μm/hr) were obtained with Xe and the lowest rates (~0.5 μm/hr) with O_2 and the O_2-N_2 mixtures.

Physical Properties of the Films

Film structure.—The structure of bulk In_2O_3 is bcc (11). X-ray diffraction by the ITO films deposited during this investigation revealed a similar structure. A strong fiber texture was also detected with the [111] direction normal to the substrate. This preferred alignment of the [111] direction has been reported for pure In_2O_3 films (3) deposited by sputtering. However, Vossen (5) has reported a [100] direction normal to the substrate for ITO. The different orientation may be due to differences in deposition parameters such as substrate temperature.

The preferred orientation of these films may be better appreciated by studying the scanning electron micrographs made of two representative samples. In Fig. 1, a film approximately 2 μm thick deposited by sputtering with an Ar-O_2 mixture is shown at two magnifications, the apparent viewing angle is 45°. The lower magnification shows a uniform crystallite size for the sputtered layer but considerable surface roughness. At higher magnification, the projections appear as high as 0.5 μm and are about 0.3 μm wide. It should be noted that a film such as described here will scatter light and can supply enough friction that the film side of the substrate plate can be discerned by light rubbing with a finger.

A film approximately 1.3 μm thick deposited by sputtering with Ar is shown in Fig. 2 at the same magnifications as in Fig. 1. In the micrograph obtained at the lower magnification a uniform crystallite size is also observed for this film. At higher magnification, however, the crystallites of this film appeared to project only as high as 0.25 μm and are about 0.15 μm wide. The two films depicted in Fig. 1 and 2 also differed strongly in their light scattering properties with the film of Fig. 1 scattering more. In the visible region of the spectrum these films behave as dielectrics, and the increased light scattering is related to crystallite size and the height of projection.

Where necessary, adequate polishing has been effected by the use of either 0.05 or 0.3 μm grain size alumina and a soft cloth. To remove all scratches produced by the alumina grit the films have then been polished with a combination chemical-mechanical polish.[2] Films polished with this two-step process have appeared smooth when viewed in a scanning electron microscope.

One general observation should be noted: smaller crystallites with lower projections are obtained if higher power is used in the plasma (*e.g.*, 0.7 mA or greater per cm^2 of target at 5 kV). The ITO films described here have been deposited on thermally stable substrates which tolerate high plasma powers. However, more delicate substrates such as single-crystal, single-domain $BaTiO_3$ and thin ferroelectric ceramic plates have also been used. Slower deposition on these substrates results in slightly larger ITO crystallites with some increase in light scattering evident, especially when porous targets are used.

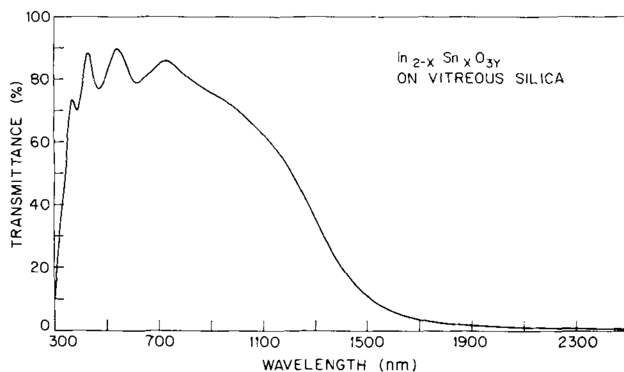

Fig. 3. Transmission characteristics from 300 to 2500 nm of an $In_{2-x}Sn_xO_{3-y}$ film on vitreous silica sputtered from an In_2O_3-9 m/o SnO_2 target.

Optical properties.—Films of ITO sputtered with Ar are highly transparent in the visible as may be seen in the plot of per cent transmission *vs.* wavelength shown in Fig. 3. The data plotted in Fig. 3 were obtained from a 0.5 μm thick film sputterd with Ar from an In_2O_3-9 m/o SnO_2 target. A vitreous silica substrate 0.5 mm thick was used. The structure of this film is similar to that depicted in Fig. 2. The reflection data for this film obtained at an angle of incidence of 14°, are shown for a similar spectral range in Fig. 4. Both the transmission and reflection data are accurate to within 1% and show channel spectrum fringes. Assuming negligible light absorption the reflectance maxima occurring near 480 and 620 nm yield refractive index values of 2.03 and 1.95, respectively, which are in good agreement with the index values measured by Müller (2) for pure In_2O_3 films. Transmission fringes have been used to obtain the values of film thickness, *d*, shown in Table I. Fringes near 500 nm in wavelength have been used with a refractive index of 2.0. From the data presented in Fig. 3 and 4, it is evident that the light absorbed or scattered by the ITO film is about 2% of the incident near 500 nm and that the major cause of transmission loss is reflection. It is clear that suitable antireflection coatings and substrates would permit in excess of 97% of the light to be transmitted within a given spectral region near 500 nm wavelength for such ITO films. The film described here has a sheet resistance of approximately 7 ohms/square. Films with similar optical characteristics have been deposited with even lower sheet resistances (approximately 5 ohms/square).

The achievement of the lowest possible resistivity is of practical significance in that it provides some freedom in selecting the film thickness while still maintaining satisfactorily low sheet resistance. For example, thin films have very broad interference transmission maxima and the use of low resistivity films permits useful sheet resistance to be obtained with maximum transmission (~90%) over a band of wavelengths.

A potentially useful characteristic of these sputtered films is their high reflectivity in the infrared. Transmission data obtained through film and substrate and reflection data are shown out to 15 μm in Fig. 5. The sample used for these measurements was the same as that used for obtaining the data of Fig. 3 and 4. For comparison the reflection data obtained for the vitreous silica substrate are also included in Fig. 5. The transmission is essentially zero over the entire infrared spectrum scanned. The infrared mirror properties are evident in the reflection data from the film surface since none of the characteristics of underlying vitreous silica reflection was detected.

Carrier concentration can be related by a simple theory to the wavelength corresponding to minimum reflectivity which occurs before the onset of constant high reflectivity at longer wavelengths (12). Calcula-

Table I.

Nominal target composition	Sputtering gas, conditions	R (ohm/square)	d (μm)	% T (at 500 nm)	ρ (10^{-4} ohm-cm)	Figure of merit (% T/R)

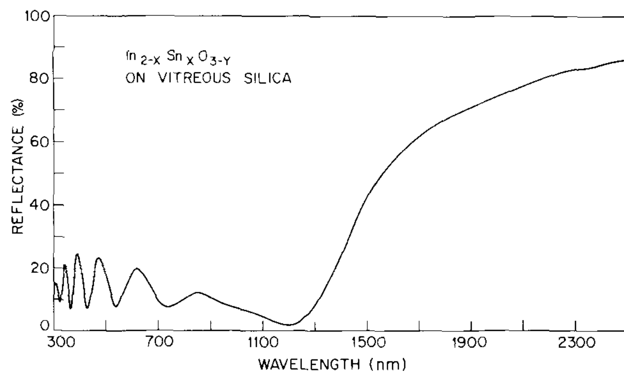

Fig. 4. Reflection characteristics from 300 to 2500 nm of an ITO film on vitreous silica sputtered from an In_2O_3-9 m/o SnO_2 target. The angle of incidence is 14°.

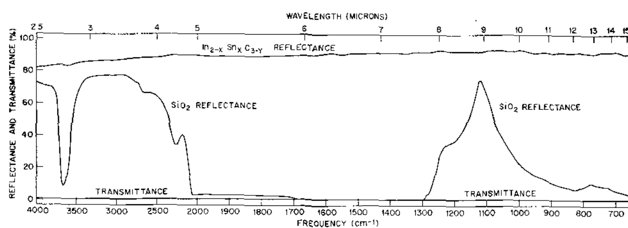

Fig. 5. Transmission and reflection for wavelengths from 2.5 to 15 μm of an ITO film on vitreous silica sputtered from an In_2O_3-9 m/o SnO_2 target. For comparison, a trace of the vitreous silica reflectance is also shown. The reflectance data were obtained at an angle of incidence of 14°.

tions based on the wavelength for this minimum reflectivity of an ITO film have yielded a carrier concentration that agreed well with a value based on Hall measurements. Since not all the ITO films of this investigation have been measured for both reflectance and transmittance, the transmission at 1.5 μm was chosen arbitrarily as a rough indication of carrier concentration. For empirical purposes of film evaluation, a roughly linear relation over a limited range of film resistivity and transmission at $\lambda = 1.5$ μm was found; 10% transmission for $\rho = 3.5 \times 10^{-4}$ ohm-cm and 77% transmission for $\rho = 13 \times 10^{-4}$ ohm-cm. The ITO films compared were sputter deposited from a single 9 m/o SnO_2:In_2O_3 target.

It was found that films deposited using gas mixtures, such as O_2-N_2, O_2-Ar, or O_2-N_2-Ar, scattered light much more than films deposited using a single gas. This scattering could be observed even in films less than 1 μm thick by placing the coated substrate plate edge-on in an intense light beam. The path of the light beam was clearly revealed by scattering. The scattering is related to the larger more protrudant crystallites formed more readily at the lower film deposition rates obtained with the gas mixtures.

Electrical properties.—The properties of a number of representative films are listed in Table I. The resistivity values were obtained from bridge measurements of sheet resistance and thickness values obtained from transmission channel spectra. These results are representative of resistivity values obtained directly from the sputtering process and involve no post-deposition annealing except where specifically indicated. A film approximately 1.5 μm thick deposited by sputtering with Ar and a 9 m/o SnO_2:In_2O_3 target was measured by the van der Pauw technique (13) and the parameters obtained were: resistivity, $\rho = 3 \times 10^{-4}$ ohm-cm; carrier density, $n = 8.6 \times 10^{20}$ cm^{-3}; Hall mobility, $\mu_H = 24$ cm^2/V-sec.

Since the goal is to obtain stable films with the lowest sheet resistance and highest optical transparency, a figure of merit for the films has been obtained by dividing per cent light transmitted at 500 nm (obtained from an average transmission curve drawn through the fringes over the range 450-550 nm) by the sheet resistance of the film. The figure of merit has units of [(per cent transmission)·(square/ohm)]. For brevity, these units will be dropped and the figure of merit will be cited as a number.

Factors Determining Film Characteristics

Target composition.—Incorporation of substitutional Sn into the In_2O_3 crystal structure yields donor centers; consequently, the Sn content of the target influences the resistivity of the sputtered films. Targets were obtained which ranged in composition from In_2O_3 to SnO_2 with a series of the mixed oxides varying from 2 to 23 m/o SnO_2 in In_2O_3.

In order to evaluate the influence of target composition on film properties, a standard procedure was developed for putting a target into service. The target to be tested was first oxidized in Ar-O_2 by sputtering for 30 min. Three distinct sputter depositions were then made using Ar only and resistivity values were obtained from the third deposition. Argon throughout was maintained at approximately 0.01 Torr liter/sec and all other parameters were maintained constant during the series of depositions.

Comparison of the film resistivities on the basis of nominal target composition yielded a discrepancy for films deposited using a target containing 7 m/o SnO_2. As a result, a count ratio of Sn/In obtained from x-ray fluorescence of the actual films was used for a relative Sn content value. Since all films were about 0.4 μm thick it was assumed that this analysis would be valid for a relative comparison. Some of the targets had a speckled appearance and some segregation of the oxides during the target fabrication could have occurred which would cause a discrepancy between the nominal target composition and actual film composition. Incorporation of impurities such as Sb, Pb, Ti, or Bi in a target could also increase the film resistivity (5) and cause some of the scatter in Fig. 6.

A plot of sputter deposited film resistivity *vs.* the x-ray measured Sn/In ratio is shown in Fig. 6 for targets containing from 0 to 23 m/o SnO_2. Small variations in oxygen vacancy content could account for the scatter of the points. Lowest resistivity films occur for Sn/In ratios from 0.18 to 0.28. These low resistivity films were deposited using targets containing 9, 11, and 13 m/o SnO_2. Vossen (5) obtained minimum resistivity from targets containing 20 m/o SnO_2 while the present investigation yielded minimum resistivity in films obtained from targets containing about 10 m/o SnO_2. The discrepancy in optimal target composition may be ascribed to differences in film deposition conditions.

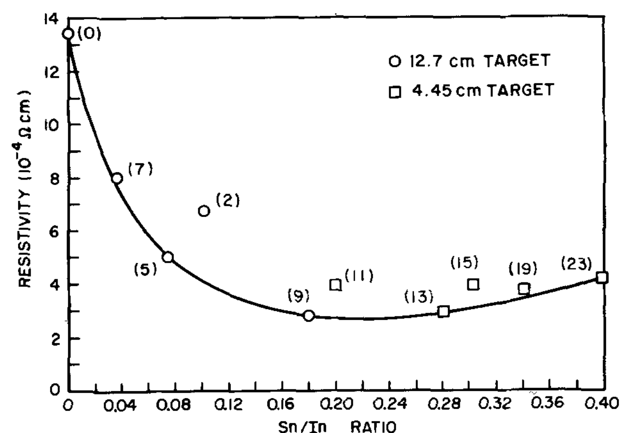

Fig. 6. Resistivity of In_2O_3 films containing varying amounts of SnO_2 plotted as a function of the Sn/In ratio measured by x-ray fluorescence. The numbers in parentheses indicate nominal SnO_2 m/o content of the targets used.

For the films, no significant light absorption was measured and only the reflection loss limited transmission. Not shown in Fig. 6 is the resistivity representative of the SnO_2 target. Under similar sputtering conditions, the SnO_2 target yielded films with ρ values of 0.1 ohm-cm to more than 10 ohm-cm.

One point concerning the data in Fig. 6 should also be made. Note that the effect of adding even an optimal amount of Sn to the In_2O_3 film is only to decrease the resistivity by an approximate factor of 4 from that obtained from a target containing only In_2O_3. The data shown in Table I and Fig. 6 indicate that film resistivity is more sensitive to the oxygen vacancy content than it is to the Sn content. For example, the ITO film deposited by sputtering with O_2 gas and a 9 m/o SnO_2: In_2O_3 target yielded a resistivity more than a factor of 5 greater than that of the film obtained by sputtering Ar and the In_2O_3 target. Further, sputtering with O_2 gas and a 9 m/o SnO_2:In_2O_3 target and then reducing the film in N_2 at 300°C yielded a resistivity only a factor of 2 greater than that obtained for films deposited from the same target using Ar. These results indicate that the same target may yield vastly different resistivities depending on the extent to which oxygen vacancies are incorporated into the deposited films.

For comparison, in addition to the films of SnO_{2-y}, films of $Sn_{1-x}Sb_xO_{2-y}$ were also deposited using the same sputtering parameters as this series of ITO films. The results for two representative films are included in Table I. The Sn-based films show higher resistivity and lower light transmission when deposited by the same methods as the ITO films. As in the case of ITO films, the resistivity of the Sn-based films was primarily dependent on oxygen deficiency. Further oxygen deficiency would have to be incorporated to lower the Sn-based film resistivity to values comparable to those for the In-based films.

Target density.—Most of the sputter deposition of ITO was carried but using targets with 70-80% of solid density. However, two targets with over 90% solid density were acquired and the films deposited with these targets differed from those obtained from the less dense targets. All the targets used in a comparison of films from porous and dense sources were nominal 9 m/o SnO_2:In_2O_3. Generally, less light scattering was observed in ITO films obtained from the dense targets. Also, single long duration sputter depositions resulted in dark (more reduced) films when porous targets were used and much lighter films when dense targets were used.

Porous targets.—A series of films was deposited using a 12.5 cm diameter target. Prior to each deposition the target was conditioned by sputtering with an Ar-O_2 mixture for 10 min. The duration of the film deposition for each test film was 30 min. Only Ar gas was admitted during each deposition period. Power was kept at 275W and spacing fixed at approximately 7 cm. The variable for the deposition series was Ar throughout.

The results of varying the Ar throughput and sputtering from a porous target are shown in Fig. 7-10. In Fig. 7, sheet resistance is plotted *vs.* throughput, and it may be seen that sheet resistance varied by more than a factor of 6 over the series. Film thickness varied by more than a factor of 6 over the series. Film thickness varied by more than a factor of 2 (Fig. 8) with higher rates of deposition occurring at greater throughput of Ar. Resistivity *vs.* throughput is shown in Fig. 9 where an approximate factor of 4 decrease is shown over the range of throughput. From Fig. 9, it may be seen that increasing the throughput of the Ar should yield lower film resistivity. For the sputtering conditions used in this series of depositions such increases of Ar throughput would also yield more light absorption. A figure of merit was calculated for each film but because transmission was limited only by reflection for this series of films, the figure of merit was simply the inverse of the sheet resistance values of Fig. 7.

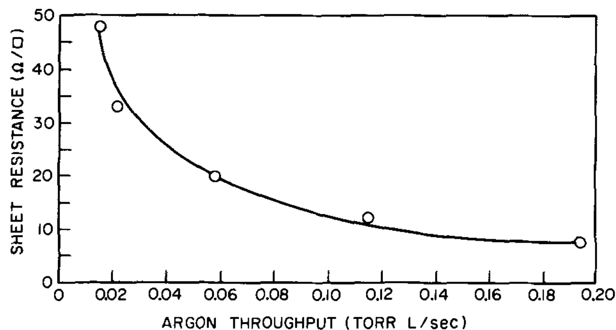

Fig. 7. Sheet resistance obtained after 30 min of sputtering vs. Ar throughput.

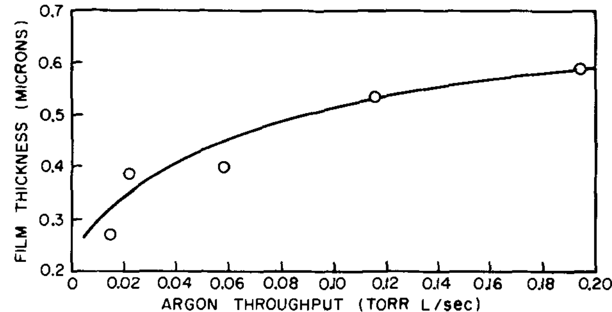

Fig. 8. Film thickness for a 30 min deposition vs. Ar throughput

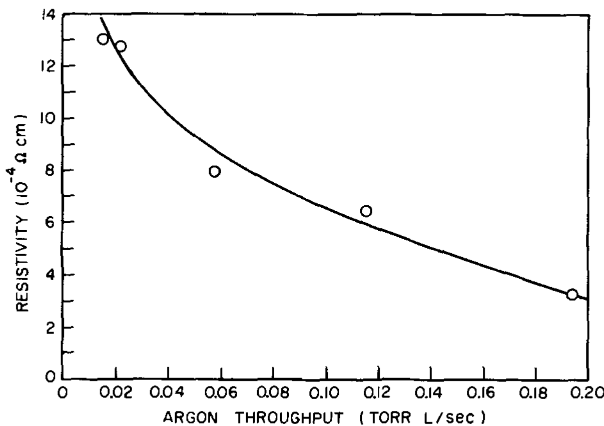

Fig. 9. Film resistivity obtained for a 30 min deposition as a function of Ar throughput.

The results obtained with a porous target and Ar throughput variation can be interpreted in terms of oxygen removal by an increasing flow of Ar through the sputtering chamber. At high throughput, the increased Ar flow may scatter more O_2 from the region between the target and substrate, thus contributing to lower resistivity in the deposited film. Similarly, with more Ar present between the target and substrate, the sputtering is more efficient and the rate of deposition will be increased. In the case of porous targets additional oxygen loss is attributed to poor heat transfer through the target which causes the surface of the porous target to operate at a higher effective temperature than a dense target. Some of these hypotheses have been investigated in experiments with porous and dense targets.

A 7059 slide with Au-Cr electrodes defining a clear square in the center of the slide was used to show that continual reduction occurs during deposition. Leads were attached to the metal electrodes and sheet resistance was measured at intervals during the deposition. A 22.5 cm diameter target was used and the throughput of Ar was 0.01 Torr liter/sec. The target was not conditioned by sputtering with Ar-O_2. Predeposition sputtering against a shutter was performed

for 10 min. Resistance was measured after approximately 8 min of sputtering. From previous results the deposition rate of the film was assumed to be approximately constant. Resistance of the square film area was measured directly and the product of resistance times elapsed deposition time (Rt) was assumed to be proportional to the bulk resistivity of the film. A plot of Rt *vs.* t is shown in Fig. 10 where a decrease of over 75% in the value of the product occurs for the total deposition period. This is interpreted in terms of continuous outgassing of the target and an increase in the state of reduction of the film as sputtering proceeds. A break in the curve is due to readsorption of air when the system was vented to the atmosphere and operated for 30 sec with the shutter masking the substrate. The film layer deposited after the brief exposure to the atmosphere shows a different rate of change of resistivity as the target outgasses. For sputter depositions of 1 hr with this particular target the films were strongly reduced and darker in appearance than films deposited for the same total time with a brief interruption to introduce oxygen after 20 min of sputtering.

Dense targets.—Two dense targets 12.5 cm in diameter were acquired and similar ITO films were obtained from them.

A series of films was deposited using one of the dense targets. Argon throughput was approximately 0.1 Torr liter/sec and power in the discharge was 275W. Predeposition sputtering was performed for 10 min with the shutter in place, and $Ar\text{-}O_2$ sputtering was not used to condition the target. The films were deposited by continuous sputtering without interruption for readmission of air. From the linear relation of film thickness and deposition time (Fig. 11) the deposition rate appears to be constant. Sheet resistance *vs.* time is plotted in Fig. 12 and figure of merit *vs.* time in Fig. 13. From a plot of ln I/I_0 *vs.* thickness, a value for the absorption constant at 500 nm was obtained, $\alpha \sim 10^3$ cm^{-1} (0.4 dB/μm).

The resistivity of these films varied from 4.3×10^{-4} to 2.9×10^{-4} ohm-cm for the shortest and longest sputtering times respectively. This change in resistivity

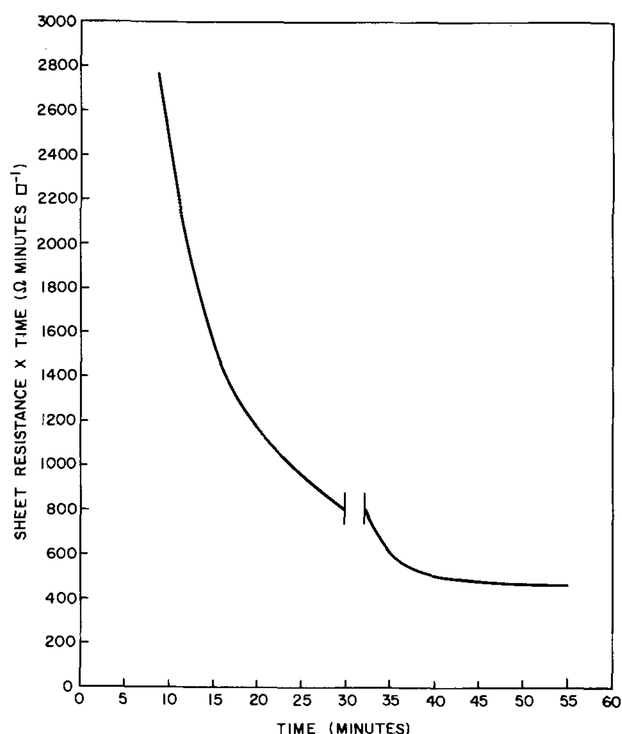

Fig. 10. Product of film sheet resistance times elapsed time vs. elapsed time. The break in the curve shows where sputtering was stopped, system vented, and 30 sec was spent sputtering against the shutter.

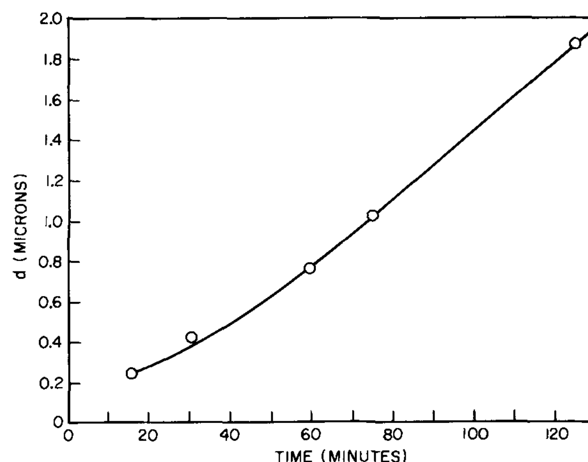

Fig. 11. Film thickness vs. sputtering time

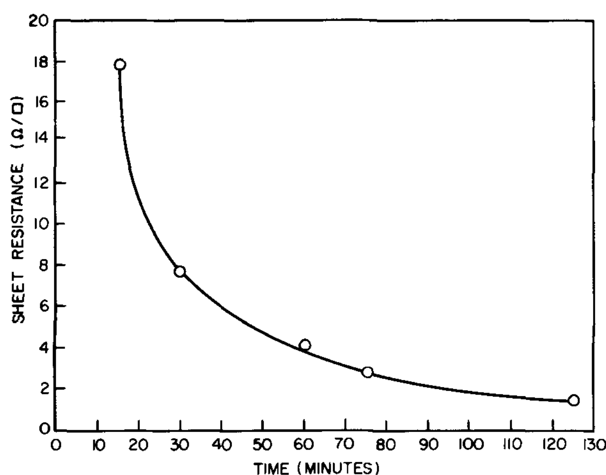

Fig. 12. Film sheet resistance vs. sputtering time

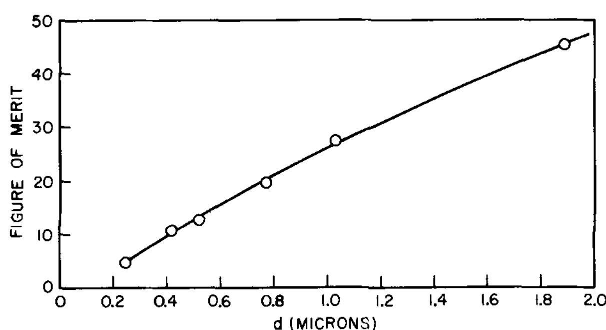

Fig. 13. Figure of merit of films vs. sputtering time

is considerably less than the change in Rt (Fig. 10) displayed by the film obtained from a porous target and is attributed to a lower rate of oxygen loss by the dense target. From the assumption of constant resistivity of 3×10^{-4} ohm-cm and optical absorption of 10^3 cm^{-1}, a maximum figure of merit of 84 should be obtained in a film 7 μm thick from the dense target.

In summary, the differences that are observed between ITO films obtained by sputtering with Ar from dense or porous targets are: (*i*) Dense targets yield a smaller gradient in the state of reduction through the film thickness and hence a smaller gradient in resistivity. (*ii*) Dense targets do not appear to be as sensitive to Ar throughput. (*iii*) Single depositions resulting in thick ITO films without excessive light absorption are more easily performed with dense targets. (*iv*) ITO films obtained from porous targets tend to scatter light more than films obtained from dense targets.

The gradient in resistivity through the film thickness may be minimized by increasing the predeposition sputtering with a shutter in place. However, the characteristics of a given target may require that different sputtering procedures be followed than those described for the porous and dense targets of this investigation.

Thermal effects (target and substrate).—Thermal effects are evident at both the substrate and the target. Preliminary results have shown that bonding a substrate to the water-cooled holder increases the film resistivity by more than a factor of 10^2. This higher resistance is attributed to a lower concentration of oxygen vacancies. Generally, the higher the substrate temperature, the lower the film resistivity. An example of a film deposited on a substrate above 500°C is given in Table I. A film resistivity of 1.77×10^{-4} ohm-cm was obtained. Normal substrate temperature was about 420°C during film deposition.

Target surface temperature effects have been varied by operating a porous target at the same power continuously and intermittently with a 50% duty cycle and an on time of 30 sec. The modulation was accomplished by on-off switching the d-c potential applied to the target. For the same total elapsed sputtering times the films deposited continuously had approximately half the resistivity of films deposited with the intermittent plasma. Both target and substrate temperatures are lower in intermittent operation of the plasma, and more oxygen will be retained by the target surface and more will be accepted by the growing film.

Applications

Films of ITO deposited by sputtering from 9 m/o $SnO_2:In_2O_3$ targets have been used for a variety of applications. The majority of films deposited on 7059 slides have been used as conductive substrates for sputter-deposited CdS films (14), allowing the CdS films to be tested through the ITO layer which acts as an ohmic contact. The ITO-CdS interface has exhibited excellent adherence and CdS films over 20 μm have been deposited without adherence failure. Many films have been deposited on light valve devices, such as the strain-biased ferroelectric ceramic (ferpic) (8), and the ITO has not suffered adherence failure even though strained to more than 10^{-3} in tension. In the same device, a layer of photoconductive CdS is coated with ITO and adherence failures at this surface have occurred only when the surface of the CdS has been contaminated with diffusion pump vapor. Some films have also been utilized in liquid crystal light valve devices. A variety of heater requirements have been satisfied, such as a hot stage for a microscope and a substrate heater for CdS film deposition. The substrate heaters have operated at temperatures as high as 350°C in a sputtering chamber with less than 5% change in the room temperature resistance. Substrate heaters of 3 ohm/square sheet resistance have operated at 250°C for over 300 hr in a sputtering chamber without change or failure. At room temperature, no measurable changes in sheet resistance have occurred in specimens exposed to the laboratory ambient for 2 years.

The ITO films described here would appear to be ideally suited to longitudinal electrooptic devices such as optical polarization switches used in digital light deflector systems. Low optical loss and a low resistivity for high switching speeds and minimal thermally induced refractive index gradients are obvious advantages.

For electrooptic device applications where transparent electrodes of a specific geometry are required, the difficulties associated with sputter-deposition through a mask may be avoided by etching. Various heated acids such as sulfuric, chromic, phosphoric, or mixtures of hydrochloric and acetic acids have been used. A most satisfactory etchant has been oxalic acid in 0.1 molar concentration, which at 50°C, etched ITO films through photoresist defined patterns (15). Pattern definition below 10 μm has been achieved.

Conclusions

Directly usable, highly conductive transparent films of ITO have been deposited by a d-c diode sputtering process. Use of pure Ar or Xe as the sputtering gas yields low resistivity material, but the use of only inert gas requires low throughput rates to avoid excessive reduction of the film and target. Lowest resistivity films have been obtained for In_2O_3 targets containing from 9 to 13 m/o of SnO_2. Target density is important in that more reduced films are obtained from a porous target under a given set of sputtering conditions and conditions must be optimized for an individual target. Generally, high density targets are superior. With suitable antireflection coatings, it is feasible to obtain films with sheet resistances of only a few ohms per square and optical transmission in excess of 95% in regions of the visible spectrum. Due to the excellent adherence and to the desirable optical and electrical properties of the ITO films, application has been found in the strain-biased ferpic, liquid crystal light valves, and as substrates for testing photoconductive films.

Rectification by Anodic Oxide Films on Zirconium

N. Ramasubramanian* and T. Trottier

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

The electrical conduction characteristics of anodic oxide films on zirconium were studied using evaporated metal and aqueous electrolyte contacts. All the films tested showed electrolytic rectification. In the dry systems rectification was not observed, but asymmetry in conduction was pronounced in the case of films grown in the nitric acid solution. Capacitance measurements under an applied d-c bias provided no positive evidence for the presence of a p-n junction either in the bulk oxide or at the oxide-electrolyte boundary. The conduction characteristics were influenced by the anodizing electrolyte used: (*i*) the relatively flaw-free films grown in KOH gave nonohmic but nearly symmetrical *I-V* curves; (*ii*) a porous and hydrated oxide film, essentially monoclinic zirconia, grown in HNO_3 resulted in asymmetric conduction; and (*iii*) phosphate ion incorporation in oxides grown in a solution containing phosphoric acid led to space charge limited current flow characteristics.

Rectification of the electric current by anodic oxide films on zirconium is known to occur when contacted by aqueous electrolyte solutions (1). In the dry system the only reported case of rectification is by films grown in nitric acid and carrying evaporated aluminum electrodes (2). The oxide films grown in nitric acid have been shown to be unique, however. Unlike the oxides grown in a number of other electrolytes, the nitrate grown films are porous and consist of small crystallites, mostly of monoclinic ZrO_2 (3, 4). Electrical conductivity measurements using evaporated metal contacts have been reported by a number of workers. In the case of anodic oxide films grown in KOH on Van Arkel zirconium, Harrop and Wanklyn reported p-type conductivity from thermo emf measurements; whereas Dawson and Creamer assumed n-type conductivity (5, 6). Thus, electrolytic and dry rectification by anodic zirconia films remains unexplained. Moreover, the effect of impurities already present in the starting material and defects introduced during growth on the conduction characteristics has been disregarded. In the present study we have chosen three different anodizing solutions known to result in relatively flaw-free, anion incorporated and porous oxide films and used electrolyte and evaporated metal contacts to investigate whether rectification is a bulk property of anodic zirconia films. A study of the electrical conduction in zirconia films is a part of our research program on understanding the oxide growth and corrosion of zirconium and its alloys.

Experimental

Crystal bar zirconium, supplied by Wah Chang Corporation was mechanically polished, pickled in a $HF\text{-}HNO_3$ mixture, washed, and anodized by the fixed voltage method to various voltages from 10 to 100V in each of the following solutions: 0.1% KOH, 1% HNO_3, and a complex organic solution containing phosphoric acid (7). Diode structures were formed by evaporating counterelectrodes, 3 and 6 mm in diameter, of Al, Au, and Pd or by contacting with a saturated solution of NH_4NO_3. In the latter case the contact area was defined by the opening in a rubber gasket pressed down on to the oxide surface. Each specimen ($2 \times 2 \times 0.1$ cm) carried 6 diode units of a counterelectrode material and a total of ~300 diodes were tested. The sample tube was evacuated to 10^{-5} Torr and filled with helium to atmospheric pressure. The *I-V* curves were recorded at a sweep rate of 1 V/min using conventional electronic equipment; a 10^4 ohm series resistance and a Keithley differential voltmeter 662 were used to measure the currents. In some cases the curves were traced at different polarization rates; occasionally the diode was left in the biased condition for a fixed period of time at the end of a polarization step. An a-c impedance bridge (GR-1650A) was used for capacitance measurements at 1 kHz under an applied d-c bias.

Key words: zirconium, anodic oxide, electrolytic rectification, dry conduction.

Results

Shorting to the base zirconium was a common occurrence in thin films (10-25V) carrying evaporated metal contacts; most of these diodes were found in the shorted state immediately after the evaporation step and a few of them became highly conducting during testing, with applied potentials of only a few volts. A majority of the *I-V* data was therefore collected for films formed from 40 to 100V when evaporated metal contacts were used. Gold and palladium electrodes were often associated with a switching to a high-conductivity state during the measurements. All the *I-V* tracings showed some hysteresis effects; this was more pronounced in the case of nitric acid grown films. The results are presented under the headings of the counterelectrode material concerned.

Heating the diode to temperatures > 298°K (the forming temperature) always resulted in irreversible changes in the conduction characteristics. The measurements were therefore made first at room temperature and then at lower and higher temperatures, respectively and the room temperature characteristics were checked subsequent to each temperature change. The oxide films grown in the KOH and organic solution showed surface features similar to those of the original pickled surfaces when examined on the scanning electron microscope. The HNO_3 grown films were different in this respect. A few areas where the cracking of the oxide film extended to 10 μm or more were present (Fig. 1a); a number of areas of localized cracking (the density of such spots averaging to about $10^4/cm^2$) similar to that in Fig. 1(b) were evident.

Aluminum contacts.—The asymmetric conduction was observed mainly with the films grown in the nitric acid solution. In Fig. 2 the results obtained when testing a 40V film grown in that solution are shown in the log *I vs. V* plots. The anodic direction was not effectively blocking in the sense of rectification; currents comparable to those in the cathodic direction began to flow at 4 to 5V of applied potential. The effect of varying the temperature was also seen to be distinctly different for the anodic and cathodic portions. In the temperature range of 273°-333°K, the slope of the cathodic portions increased by nearly four times, whereas the anodic portion of the curves remained very nearly parallel to each other. Similar results were obtained with films grown up to 75V in the solution.

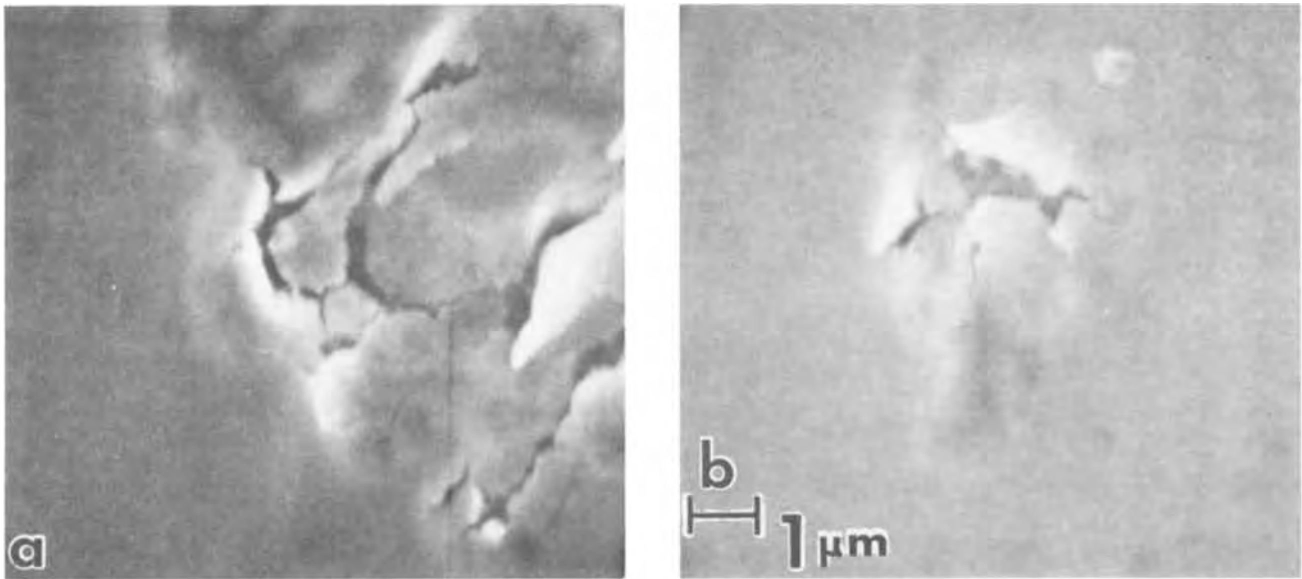

Fig. 1. Scanning electron micrographs of a 62V anodic oxide film grown in 1% HNO_3 solution

An important observation was that varying the forming voltage did not result in any systematic changes in the *I-V* characteristics. They were more or less the same for the various film thicknesses studied. A set of curves showing the anodic and cathodic current flow at room temperature in these films is given in Fig. 3. The data obtained in the case of a 20V film, which became highly conducting during the measurements, is also included for the sake of comparison. The hysteresis effects are described later in the palladium section.

The films grown in 0.1% KOH passed currents under anodic and cathodic bias with much less asymmetry than the HNO_3 grown films. The difference in the applied voltage required for a minimum measurable current flow was about 1V higher when the zirconium was anodic than when cathodic. A set of curves showing the effect of temperature on the current flow through a 40V film grown in the KOH solution is plotted in Fig. 4. The anodic current flow did not fit the exponential voltage dependence relation. Attempts to fit the data to other commonly observed relations such as Schottky emission and SCLC (space charge limited current) were equally unsuccessful; however the data up to ~6V gave reasonable linear fits when

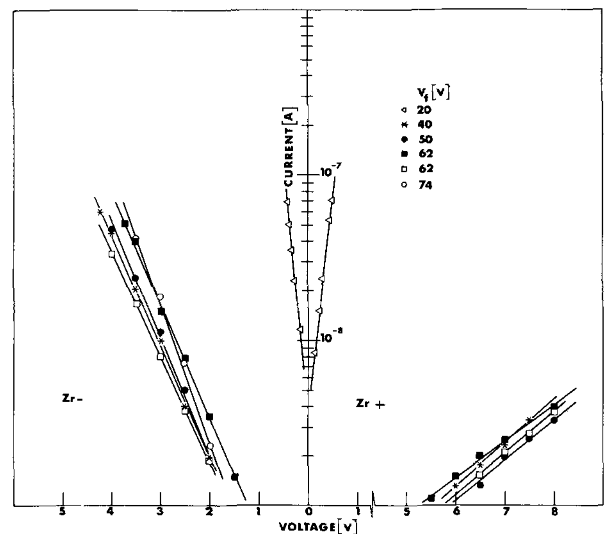

Fig. 3. Influence of forming voltage on the current flow at room temperature through zirconia films grown in nitric acid solution; aluminum counterelectrode area 0.0675 cm^2.

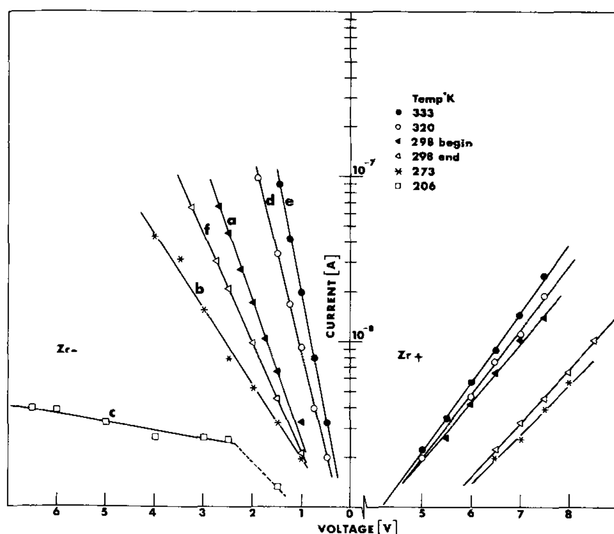

Fig. 2. Current-voltage characteristics at different temperatures of a 40V anodic oxide film grown in 1% HNO_3; area of the aluminum counterelectrode 0.27 cm^2.

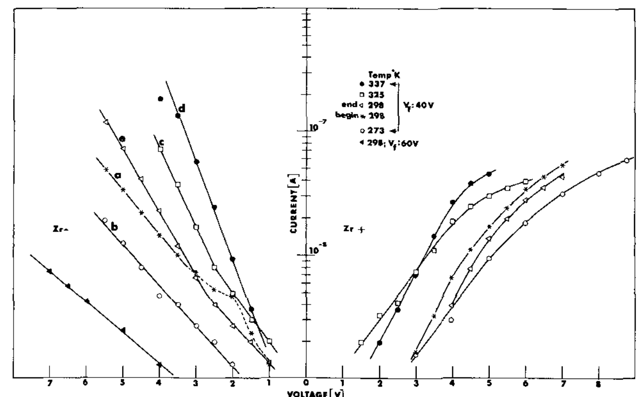

Fig. 4. Zirconium-anodic oxide grown in 0.1% KOH solution—aluminum 0.27 cm^2; effect of temperature on the conduction characteristics for a 40V film and comparison at room temperature with a 60V film.

plotted as log I vs. $V^{1/2}$ or log V. With increase in the forming voltage the KOH grown films became more resistive; under comparable temperature and applied voltage conditions the current flow and the slope of the log I vs. V plots decreased with increase in film thickness.

When the current flow through the films grown in the three solutions was compared the films grown in the complex organic solution were found to be the most resistive. It is known that phosphate ion is incorporated in the oxide during growth in the organic solution and as a result the growth constant (oxide thickness/forming voltage) is lower than for KOH grown films (7). However, with films grown to the same forming voltage and under comparable testing conditions, the diodes carrying the oxide grown in the organic solution passed currents an order of magnitude less than those carrying the KOH grown films. Unlike the HNO_3 and KOH grown films the oxide grown in the organic solution showed large variations in the current density when different areas of a specimen were tested and often exhibited self-healing type current bursts (rapid rise and fall in current) during the I-V measurements. When such current transients were absent the data obtained fitted an $I \propto V^n$ relation. A set of such plots for a 100V film is shown in Fig. 5. The linearity of the plots and their 'n' values strongly suggest a space charge limited current flow. The asymmetry between the cathodic and anodic portions was similar to that observed with the KOH grown films but less distinct than that found in the case of HNO_3 grown films.

Gold contacts.—The films grown in the three solutions had one common characteristic. A majority of the diodes switched to a high conductivity state at room temperature under an applied bias of $\sim \pm 6$V. When such bistable switching did not occur the I-V characteristics were similar to those described for the Al counterelectrode, except that the currents passed were slightly lower. The oxide grown in the organic solution was the most resistive and the data for these diodes gave linear plots on log I vs. log V scales.

Palladium contacts.—The results were essentially similar to those described for the gold counterelectrodes. The influence of the polarization rate and a holding time at the end of polarization on the I-V characteristics is shown in Fig. 6 for a diode carrying a 62V film grown in the nitric acid solution. At sweep rates $>$ 1 V/min much hysteresis was observed in the tracings. However, no systematic change was observed in the successive I-V tracings due to varying the holding time at the end of each cathodic polarization step. In tracing these curves the diode was polarized in the usual manner to 3.5V and held at that potential for a time Δt. Then the applied voltage was reduced to zero and a set of such curves traced for various Δt values. In another set of experiments a negative potential of 4V was applied to anodized zirconium at room temperature and while under the applied bias the temperature was lowered to 205°K. The I-V tracings then obtained at this lower temperature were identical to those traced at this temperature in the normal manner.

NH_4NO_3 solution contacts.—All the oxide films, grown to various voltages from 10 to 100V in the three solutions rectified the current. In the cathodic direction gas bubbles could be seen on the oxide surface when the bias exceeded $\sim$2V. The blocking in the anodic direction improved with increasing oxide thickness in general; the films grown in nitric acid were poorer in this respect. In Fig. 7 a typical set of curves is shown for films of various thicknesses grown in the KOH solution; data for the other two types of films are also plotted for the sake of comparison.

Impedance Measurements under an Applied D-C Bias

In Fig. 8 the change in capacitance against applied d-c bias is plotted for a few diodes. With the NH_4NO_3 solution contacts, for films grown in all three solutions to the various forming voltages, the capacitance showed a gradual increase with bias in the cathodic direction. At 3-4V the readings were unsteady and increased to large values rather suddenly; gas bubbles collected on

the oxide surface. Under anodic bias conditions the capacitance readings either were steady or increased much less rapidly than during cathodic bias. None of the specimens tested showed a decrease in capacitance. Only a few diodes carrying thin anodic oxide films and evaporated metal contacts were tested because of the inherent shorting problem; in all such cases the capacitance increased with the bias voltage in both the directions. When thick films carrying metal contacts were tested the capacitance increased rapidly at a bias of 1.5-3V in the anodic direction; under cathodic bias the curves were similar to that shown in Fig. 8.

Impurities in Zirconium

The purity of the crystal bar material used in the present investigation is comparable to that used by a number of other workers. The major metallic impurities were Fe (82 ppm) and Hf (72 ppm); other elements such as Al, Cr, Cu, Ni, and Ti were present in quantities $\leq$ 20 ppm. After the mechanical and chemical polishing steps microscopic examination of the surface showed no singularities. The scanning electron micrograph (SEM) of such a surface is shown in Fig. 9(a). A variety of aqueous electrolyte solutions was tried for anodizing; when a dilute (0.001*N*) $KMnO_4$ solution was used some peculiarities were noticed. In the $KMnO_4$ solution zirconium could be anodized, as in other electrolytes, up to ~100V. At the end of the first anodizing step, generally around 5-10V, examination of the surface showed a thick porous oxide growth at selected areas and this surface structure persisted throughout the rest of the anodizing steps. In Fig. 9(d) is shown the electron micrograph (EM) of a two-stage replica of such an anodized sample. When a zirconium sample was made cathodic to ~5V in the same solution, preferential reduction of MnO_4^- at selected spots was noticed. The SEM and EM of the replica of this deposit are shown in Fig. 9(b) and (c). By carrying out the reduction step first, washing off the deposit in a solution of oxalic acid and then anodizing, it can be shown that the areas where preferential reduction and thick porous oxide growth occur are the same. Thus it would seem that the impurities are present in areas of extremely minute size whose presence can be revealed by their specificity towards reagents such as $KMnO_4$.

Discussion

From the data published in the literature the information relevant to the present study regarding anodic oxide growth on zirconium can be summarized as follows: (*i*) oxide films grown in nitric acid solution are porous (3), (*ii*) phosphate ion is incorporated during growth in the complex organic solution (7), (*iii*) KOH grown films are free of occluded ions and less porous (3, 7), and (*iv*) transmission electron optical studies of the stripped films have shown them to consist of microcrystallites distributed in a matrix that is probably amorphous; the nitrate grown films are unique in being essentially all monoclinic ZrO_2, whereas films grown in most other electrolytes have $\gtrsim$ 75% of cubic ZrO_2 (3, 4).

The presence of a p-n or p-i-n junction, resulting from nonstoichiometry induced by the oxide growth process, is often proposed in explaining mechanisms of thermal oxidation and rectification. The decrease in capacitance to be expected with applied d-c bias in the anodic (reverse) direction is a means of checking for the existence of such junctions in the oxide or at the oxide-counterelectrode boundary (8, 9). It is also believed that transition from homogeneous conduction by bulk oxide to the heterogeneous or local response at flaws occurs with increase in oxide thickness (10). In the present study, on thin zirconia films the capacitance showed an increase with anodic bias for both metal and electrolyte solution contacts. Of the three types of films tested, the ones grown in KOH should be relatively flaw free; if a homogeneous conduction process was responsible for rectification then one would expect these films to rectify. But the asymmetry in conduction (dry conditions) was pronounced in the nitric acid grown films which showed extensive cracking of the oxide and the work function of the electrode material was without influence on the *I-V* characteristics. These observations inevitably lead to the conclusion that if a junction is grown in during anodization or formed by the contacting electrode then it is not the dominant factor in determining the electrical conduction under the testing conditions employed here.

The conduction characteristics of the oxide grown in KOH might be expected to represent those of the pure oxide (7). It is evident from the results presented here, that contrary to the assumptions made by Dawson and Creamer (6), the conduction in these films is not ohmic. The current flow under negative bias is more of a field-activated type transport (reference to Charlesby's work in this respect is made later) whereas that under positive bias is more complicated involving probably more than one type of process.

The films grown in the organic solution were the most resistive and their *I-V* data are seen to fit a SCLC relation. This finding is in agreement with Banter's observation and would support his model of a stationary negative space charge, created by the immobile phosphate ions in the outer oxide layers, controlling the anodic growth and the electrical conductivity (7). Because of the bistable switching and large

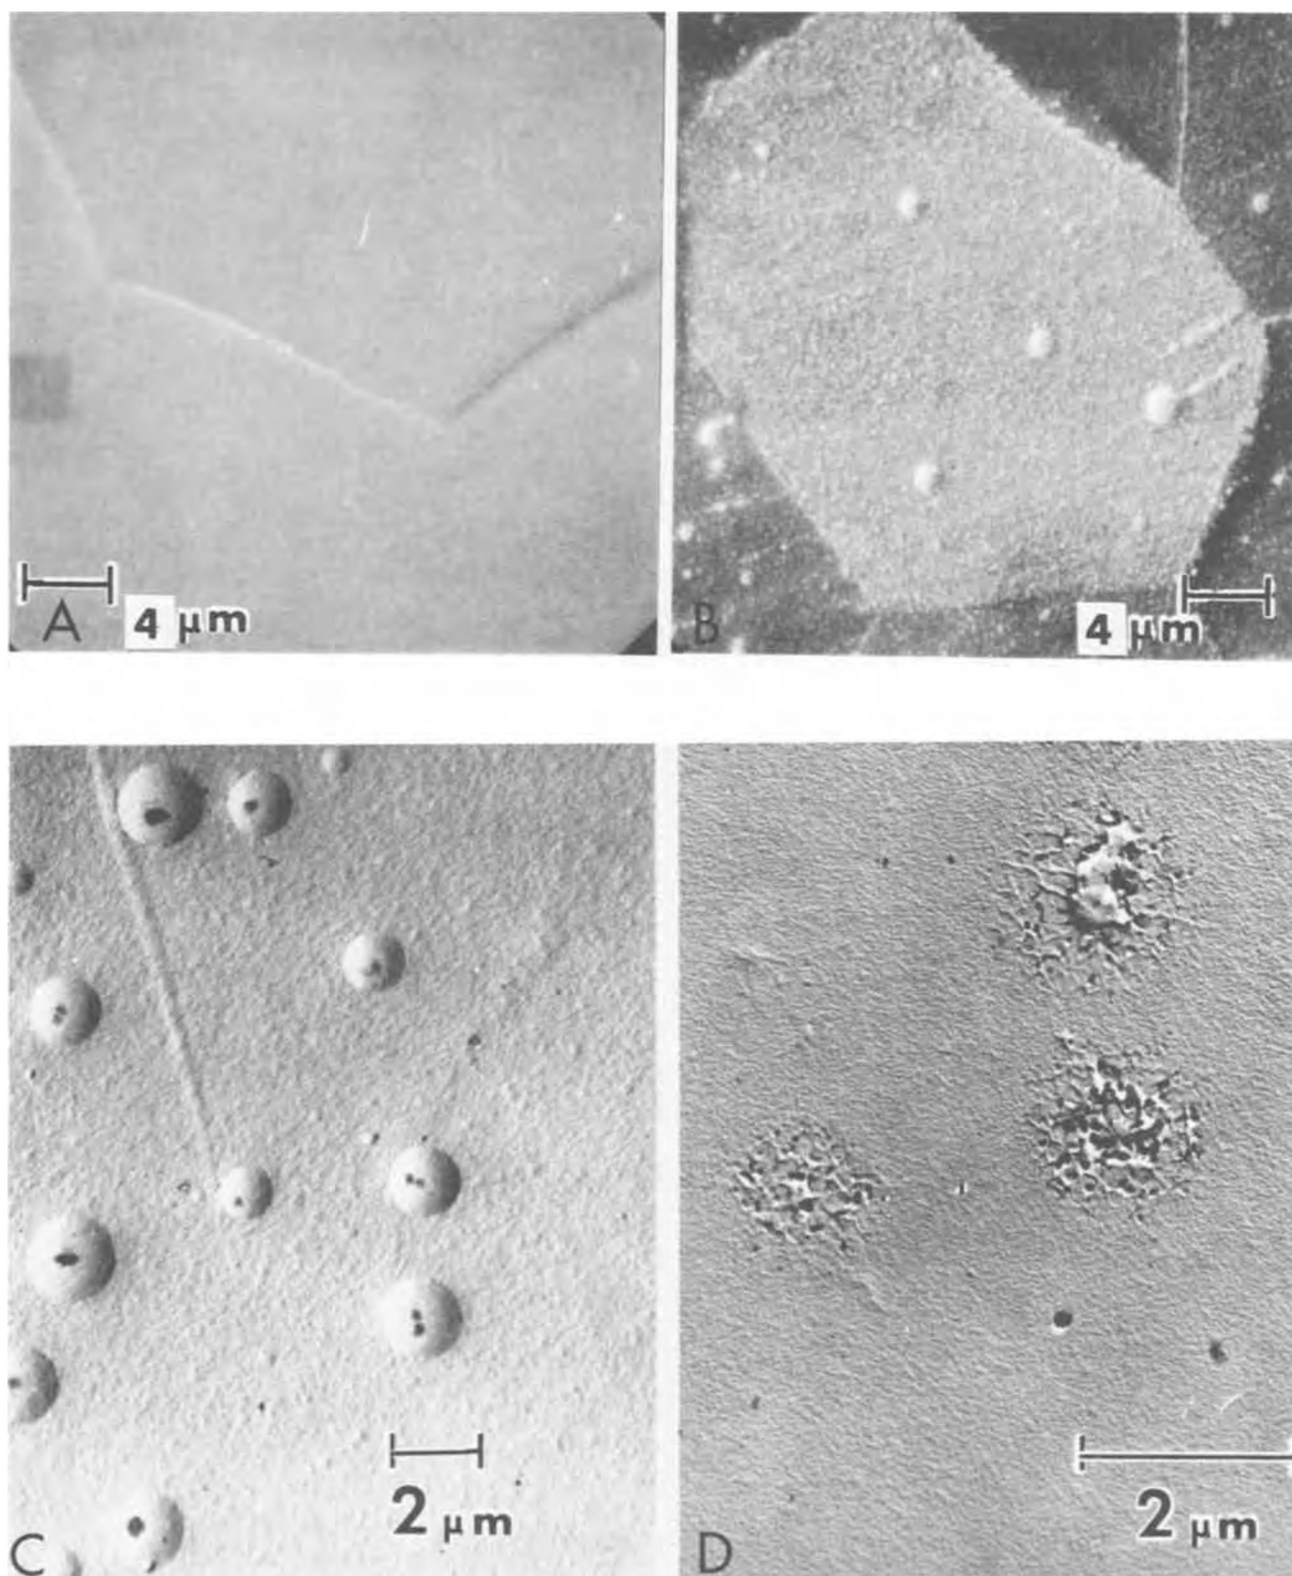

Fig. 9. Scanning electron micrographs: (a) pickled zirconium surface and (b) cathodic reduction of MnO_4- on zirconium. Electron micrographs of two-stage replicas: (c) cathodic reduction of MnO_4- and (d) another specimen anodized in $KMnO_4$ solution to 25V.

variations in current density over different areas of a specimen the thickness dependence of the current could not be checked.

Asymmetry in conduction, pronounced hysteresis effects and independence of the current flow on the forming voltage (40-75V) were observed only with the nitric acid grown films and must therefore be the properties of a porous film of monoclinic zirconia. According to Banter the nitrate grown films are hydrated as well (7); the porosity of these films would imply that much of this hydration water is that locked inside the pores. Based on these facts and the observation that the polarization rate had a marked influence on the current flow and no systematic changes resulted in the *I-V* characteristics when the diodes were left in the biased state (repeatedly) for long periods of

time, it is suggested that protonic migration (from the bound water) along the cracks and pores leads to a high field region in the oxide and results in an easy forward electronic current having characteristics similar to that observed in the case of KOH grown films. Information on the permeability to protons of monoclinic and cubic zirconia would be helpful in this connection.

The electrical conduction of anodic zirconia films when using dry contacts is thus seen to be influenced by the anodizing electrolyte used and could be correlated with the anion incorporation, hydration, and porosity. It might therefore be inferred that in the case of oxide films grown in the three solutions employed here the current flow is mainly through the oxide. However, the possibility exists that the properties of the oxide grown on and around the impurities are also influenced by the anodizing electrolyte and might be the areas of major electronic conduction in these anodic films. These impurity centers have been shown to be the preferred sites of electron flow and reaction in the reduction of cuprous iodide to copper (11). Though the presence of the impurity centers was not detected on microscopic examination of the surface, stress-corrosion cracking experiments in methanol/iodine solutions have revealed the presence of small lenticular second phase precipitates (probably a Zr-Fe phase) in the grain boundaries of crystal bar zirconium (12). Therefore contributions to the conduction by the impurities present in the material cannot be ignored and as is evident from Fig. 9 a contact area $\leq 1.2 \times 10^{-7}$ cm^2 would be required to eliminate such contributions.

Charlesby interpreted the anodic leakage current through zirconia films in terms of a field assisted (in surmounting an energy barrier) transport because the I-V data fitted a "sinh law" (13). This proposal was rejected by Vermilyea (14), and Young has commented on both these suggestions and pointed out that the conduction is likely to be through cracks in the oxide (15). The cathodic current flow through KOH and HNO_3 grown films when evaporated metal contacts were used is seen to fit a log $I \propto V$ relation (high field approximation of the "sinh law") in the present study. However, the slope of such plots showed an increase with temperature; whereas a decrease is expected if the current flow was of the field assisted type obeying the "sinh law." The physical significance of the observed log $I \propto V$ relation is thus not clear.

Electrolytic rectification was observed on all the films tested the common source of which could be traced to one or more of the following: microfissures (impenetrable by evaporated metal contacts) present in anodic films in general, existing impurities, or the property of the ZrO_2/electrolyte interface.

Conclusions

Rectification by anodic oxide films on zirconium was not observed when evaporated metal counterelectrodes were used. Electrolytic rectification was observed. Capacitance-voltage measurements gave no positive evidence for the presence of a p-n or p-i-n junction in the diodes. The conduction characteristics were influenced by the anodizing electrolyte used; the asymmetry in conduction observed in the case of nitric acid grown films is ascribed to the porous and hydrated oxide grown in these solutions; the incorporation of phosphate ions during growth is related to the space-charge limited current flow in films grown in a complex organic solution containing phosphoric acid. The electrical conduction in anodic oxide films on crystal-bar zirconium (the material generally accepted as being of high purity) is not simple as has been assumed previously; the impurities present are likely to be the main contributing factors and work on pure zirconium single crystals might elucidate the situation.

Epitaxial Substrate Carrier Concentration Measurement by the Infrared Interference Envelope (IRIE) Technique

Alvin H. Tong,* Paul A. Schumann, Jr.,* and William A. Keenan*

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Infrared interference measurement of epitaxial thickness requires knowledge of the substrate carrier concentration to correct for the phase shift at the epitaxial layer-substrate interface. A nondestructive technique which measures the epitaxial substrate carrier concentration is described. It uses the information contained in the infrared interference envelope (IRIE) which is the same reflection spectrum used in the epitaxial thickness measurement. A model and experimental results are presented for silicon with a substrate carrier concentration ranging from 1×10^{19} cm^{-3} to 1×10^{21} cm^{-3}.

Optical measurement techniques are becoming increasingly important and popular because they offer the advantages of being nondestructive and contactless. One of the most important optical measurement techniques in the semiconductor industry is the infrared interference technique for the measurement of epitaxial layer thickness introduced by Spitzer and Tanenbaum (1) in 1961. At the suggestion of W. Pliskin, extended work was carried out by Schumann *et al.* (2) which showed that the phase shift on reflection at the epitaxial layer-substrate interface was a function of the wavelength and the substrate carrier concentration, and therefore must be accounted for in calculating the thickness. Since then, the substrate carrier concentration was assumed from prior knowledge, measured before deposition of the epitaxial layer, or obtained by a subsequent independent measurement such as the spreading resistance profile with correction factors (3). However, the substrate carrier concentration changes during deposition of the epitaxial layer due to out-diffusion of substrate dopant, thus making the prior measurement inaccurate. Unfortunately, the spreading resistance profile technique is destructive.

This paper discusses a nondestructive and contactless technique to measure the epitaxial substrate carrier concentration. It uses the information contained in the infrared interference envelope (IRIE) which is the same reflection spectrum used for the epitaxial thickness measurement.

Theory

For normal incidence, the reflection coefficient for a homogeneous sample can be expressed in terms of the refractive indexes of the sample and of the medium adjacent to its reflecting surface

$$R = \left| \frac{n_0 - \bar{n}_1}{n_0 + \bar{n}_1} \right|^2 \qquad [1]$$

For an air to semiconductor interface where $n_0 = 1$, Eq. [1] becomes

$$R = \left| \frac{1 - \bar{n}_1}{1 + \bar{n}_1} \right|^2 \qquad [2]$$

or

$$R = \frac{(1 - n_1)^2 + k_1^2}{(1 + n_1)^2 + k_1^2} \qquad [3]$$

where $\bar{n}_1 = n_1 - ik_1$, the complex refractive index, n_1 = the real part of the index of refraction, and k_1 = the extinction coefficient.

When the reflection coefficient is measured as a function of wavelength in the infrared, a minimum occurs near the plasma resonance frequency. The wavelength at which this minimum occurs, $\lambda_{min.}$, is a function of the carrier concentration of the sample through the optical constants as expressed in Eq. [3]. This technique for measuring the carrier concentration is called plasma resonance (4). This technique uses a set of calibration curves, $\lambda_{min.}$ *vs.* N (free carrier concentration), as shown in Fig. 1 for silicon. Plasma resonance provides a nondestructive and contactless measurement of the surface carrier concentration of a semiconductor sample.

The optical constants (n_1, k_1) have been measured (5) for n- and p-type silicon in the infrared from 2.5 to 50 μm with carrier concentrations ranging from 10^{15} cm^{-3} to 10^{19} cm^{-3}. The results show $n_1 \geq 2.5$ and $k_1 \leq 0.1$ throughout the range. For higher carrier concentrations ($> 10^{20}$ cm^{-3}), k_1 has been reported to be ~0.4 (6). Thus, throughout the range of carrier concentration 10^{15} cm^{-3} to 10^{20} cm^{-3}, $k_1^2 << 1$. From these results, the condition $(n_1 + 1)^2 > (n_1 - 1)^2 >> k_1^2$ is satisfied throughout the range of interest and Eq. [3] can be simplified to

$$R = \left(\frac{1 - n_1}{1 + n_1} \right)^2 \qquad [4]$$

In the case of an epitaxial layer with thickness d_1 over a substrate as shown in Fig. 2, the reflection coefficient for normal incidence (7) can be expressed as

$$R = \frac{r_1^2 + 2r_1r_2 \cos(2\,\delta_1 - \phi) + r_2^2}{1 + 2r_1r_2 \cos(2\,\delta_1 - \phi) + r_1^2r_2^2} \qquad [5]$$

where

$$r_1 = \left| \frac{n_0 - \bar{n}_1}{n_0 + \bar{n}_1} \right| \qquad [6]$$

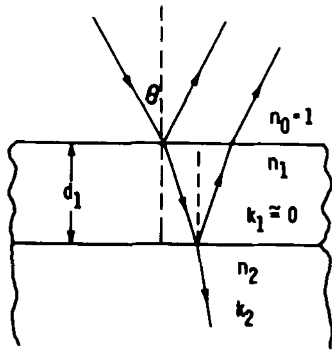

Fig. 2. Light incident at angle θ on sample with epitaxial layer

is the magnitude of the Fresnel coefficient at the air-layer interface

$$r_2 = \left| \frac{\bar{n}_1 - \bar{n}_2}{\bar{n}_1 + \bar{n}_2} \right| \quad [7]$$

is the magnitude of the Fresnel coefficient at the layer-substrate interface

$$\delta = \frac{2\pi}{\lambda} n_1 d_1 \quad [8]$$

is the change in phase of the beam on traversing the epitaxial layer (where λ is the vacuum wavelength of the incident light)

$$\bar{n}_1 = n_1 - ik_1$$

is the complex refractive index of the epitaxial layer

$$\bar{n}_2 = n_2 - ik_2$$

is the complex refractive index of the substrate, and

$$\phi = \tan^{-1} \left(\frac{2n_1k_2}{n_1^2 - n_2^2 - k_2^2} \right) \quad [9]$$

is the phase shift at the layer-substrate interface.

In the high resistivity epitaxial layer, the extinction coefficient k_1 is usually assumed to be zero.

From Eq. [5], it can be shown that minima of the reflectance curve occur at values of n_1d_1 given by

$$n_1 d_1 = \frac{\lambda}{4} \left[(2m + 1) + \frac{\phi}{\pi} \right] \quad [10]$$

where $m = 0, 1, 2, 3, \ldots$. Once the phase shift at the interface is accounted for, the thickness of the epitaxial layer d_1 can be determined, since n_1 is known, λ is observed, and m can be determined from two successive minima. The values of the reflectance at these points are

$$(R)_{\text{min.}} = \left(\frac{r_1 - r_2}{1 - r_1 r_2} \right)^2 \quad [11]$$

Using $n_0 = 1$ for air, and $n_1 = 3.42$, and $k_1 \sim 0$ for the epitaxial layer, the magnitudes of the Fresnel coefficients become

$$r_1 = \frac{n_1 - n_0}{n_1 + n_0} = \frac{3.42 - 1}{3.42 + 1}$$

and

$$r_2 = \left(\frac{(n_2 - n_1)^2 + k_2^2}{(n_2 + n_1)^2 + k_2^2} \right)^{1/2}$$

For the exceptional case where $n_2 = n_1 = 3.42$ at very short wavelength

$$r_2 = \frac{k_2}{\sqrt{(n_2 + n_1)^2 + k_2^2}} << r_1 < 1$$

and Eq. [11] becomes

$$(R)_{\text{min.}} = r_1^2 = \left(\frac{n_1 - 1}{n_1 + 1} \right)^2$$

In most situations, however, $(n_2 - n_1)^2 >> k_2^2$, so

$$r_2 = \frac{n_2 - n_1}{n_2 + n_1}$$

Equation [11] then becomes

$$(R)_{\text{min.}} = \left(\frac{n_1^2 - n_0 n_2}{n_1^2 + n_0 n_2} \right)^2 = \left(\frac{11.7 - n_2}{11.7 + n_2} \right)^2 \quad [12]$$

for

$$n_0 = 1, \quad n_1 = 3.42$$

Equations [12] and [4] are identical in form, the only difference being the numerical constants. Equation [12] thus demonstrates that, similar to the plasma resonance technique, a minimum of the $(R)_{\text{min.}}$'s occurs, and it is a function of the substrate carrier concentration through the optical constant n_2. A comparison between the IRIE and the plasma resonance technique in Fig. 3 shows the reflectivity *vs.* wavelength for the two techniques. The IRIE technique relates the wavelength at which the envelope of the minima or valleys exhibits a minimum to the substrate carrier concentration. Plasma resonance can be considered the limit of this IRIE reflectance curve as the epitaxial thickness goes to zero.

Calibration Curves

A step junction was assumed at the layer-substrate interface and the reflectance was calculated both for N on N^+ and P on P^+ silicon epitaxial layers for the wavelength range 2.5 to 150 μm.

Figure 4 is a typical plot of the $(R)_{\text{min.}}$'s *vs.* wavelength (*i.e.*, the lower envelope of the reflectance curve) for N-type Si. Note that the minimum is very sharp and its magnitude is close if not equal to zero. The data points show the various thicknesses of the epitaxial layer. The resulting smooth curve indicates that the IRIE minimum is independent of the epitaxial layer thickness.

The theoretical calibration curves of λ (envelope)$_{\text{min.}}$ *vs.* the substrate carrier concentration are shown in Fig. 5 for N- and P-type silicon.

Experimental Results

A typical infrared interference reflectance curve is shown in Fig. 6 for an N^+ on N epitaxial layer. From this trace, the lower envelope is drawn and the minimum of this envelope is located. Then the substrate carrier concentration is determined from the calibration curves in Fig. 5. Results shown in Fig. 7 are compared to those obtained from the spreading resistance profile with correction factors and the plasma resonance technique. Plasma resonance was performed on the substrate after the epitaxial layer had been removed. The correlation coefficient of 0.95 attests to the validity of this technique. The discrepancy between the values of substrate carrier concentration determined by IRIE and the other techniques is due to the fact that the calibration curve was constructed from theo-

retical calculations. In actual practice the calibration curve would be calculated from measured results.

Discussion

Schumann and Schneider (8) have reported a technique which gives the epitaxial layer thickness as well as the substrate carrier concentration. It requires the magnitude of the reflectance extremum (maximum or minimum) to be measured as well as the wavelength at which the extremum occurs. Therefore, the spectrophotometer must be calibrated to give an accurate measurement of the magnitude of the absolute reflectivity.

However, the IRIE technique does not require an "absolute" magnitude measurement but instead requires locating the minimum of the interference envelope. To locate this minimum accurately, it is desirable to have as many interference fringes as possible. Therefore, a thick epitaxial layer, for instance 5 μm, gives good results. When the epitaxial layer thickness is less than 3 μm, the number of interference minima is not adequate to locate accurately the minimum of the envelope and this thickness represents the lower limit for this technique. The carrier concentration range of application is also limited by the spectrophotometer available. For a spectrophotometer having a 2.5-50 μm range in wavelength, the range of application for silicon is approximately 1×10^{19} cm^{-3} to 1×10^{21} cm^{-3}.

Acknowledgment

The authors wish to thank Mr. C. P. Schneider and Miss L. Pietrogallo for their respective contributions in the measurements of the infrared reflectance and spreading resistance profile.

Capacitance-Voltage Measurements with a Mercury-Silicon Diode

P. J. Severin and G. J. Poodt

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

The capacitance of a Schottky barrier diode measured as a function of reverse voltage yields the dope concentration and eventually the thickness of an epitaxially grown silicon layer. It is shown that mercury can be used as the metal contact to the silicon. This allows for a rapid and nondestructive *C-V* measurement, particularly when combined with an automated instrument. The results obtained with different surface treatments are discussed. For reliable and reproducible results N-type silicon should be covered with a thin oxide layer about 50Å thick, which can easily be made wet chemically. The precision which can be attained with this system in actual practice amounts to ±2% or better and the accuracy depends on the definition of thickness used. This technique with the mercury contacting accessory works equally well on GaAs and GaP.

In many semiconductor applications the impurity density N as a function of depth x below the surface is an important parameter.

The most appropriate method to date to measure this function is to form a Schottky barrier diode and to use the well-known relationships between the capacitance C of the diode, the applied reverse voltage V, and the depletion layer boundary depth x. For a metal-semiconductor diode the equations

$$C = \frac{dQ}{dV} = \left[\frac{e\epsilon O^2 N}{2(V + V_d)} \right]^{1/2} \quad [1a]$$

and

$$C = \frac{\epsilon O}{x} \quad [1b]$$

yield

$$N = \frac{2}{\epsilon e O^2} \left[\frac{dC^{-2}}{dV} \right]^{-1} \quad [1c]$$

where $O = \pi A^2$ is the diode surface area, V_d is the diffusion potential, and ϵ and e have their usual meaning. Hence, on measuring C as a function of V, $N(x)$ is found.

Hilibrand and Gold (1) showed experimental results with the C-V method and Thomas, Kahng, and Manz (2) demonstrated the validity by experiments on epitaxially grown silicon layers.

Usually with the *C-V* method the change in capacitance C per small increment in reverse voltage V is measured on a capacitance bridge. This technique is rather time consuming and the profile is found after some tedious calculations. Amron (3) produced a simple slide rule facilitating this procedure. Recently, a number of proposals (4-14) have been made to overcome this difficulty electronically and some instruments have become commercially available. They are all based on clever use of the nonlinear circuit properties incorporated in Eq. [1a] to [1c], as discussed originally by Meyer and Guldbrandsen (15). The authors also use an automated instrument designed and built some years ago by Rusche (16). It operates at a 2 MHz carrier wave modulated with a 2 kHz signal modulation using a constant current unit like Copeland's instrument (4, 5).

Key words: epitaxial layer thickness, diode capacitance, mercury, silicon.

All these instruments have in common that they greatly facilitate the capacitance-voltage measurement, but the speed-determining step remains the production of a diode either by evaporation of a metal dot which is eventually alloyed in, or by shallow diffusion of an opposite type impurity. At the very earliest stage of silicon device processing a metal probe is required which can be used locally and instantaneously to nondestructively form a diode. This paper deals with a mercury probe-silicon diode which satisfies these requirements and which can be used for reliable *C-V* measurements. The difficulties encountered are not specific to the Rusche instrument and are equally valid when the mercury probe is coupled to another automated instrument or to an ordinary *C-V* bridge.

Mercury Probe

From the very beginning of the study of MOS structures mercury, in particular as a drop, has been used as an electrode for ease in measuring the oxide and silicon capacitance as a function of d-c voltages (17, 18). Hammer (19) positioned the sample on a rubber O-ring in which the mercury is pressed from below. He obtained in this way a precision of contact surface area of 5% and with a Teflon probe instead of an O-ring he claims even an order better. As far as the authors are aware, no description has been given in the literature of mercury as a contact material to silicon for the purpose discussed in this paper.

The experiments described in this paper were performed with a mercury probe in an accessory as shown in Fig. 1. In a perspex block (*1*) a channel (*2*), 2 mm across is bored which at one end is connected to an air pressure valve and at the top end is narrowed to a diameter of about 0.5 mm over a length of 13 mm and closed by the slice (*3*) under investigation. The channel is partially filled with mercury. The silicon slice is pressed onto the perspex by two steel pins (*4* and *5*) connected to a lever (*6*), with a spring as schematically presented in Fig. 1. After letting into the channel (*2*) air with an excess pressure amounting to about 0.3 atm the mercury contacts the silicon and forms a diode. The electrical contact to the mercury is made with screw (*7*) which penetrates into the channel and to the silicon with the probes (*4*) and (*5*), which can be used separately as current and voltage probes. The

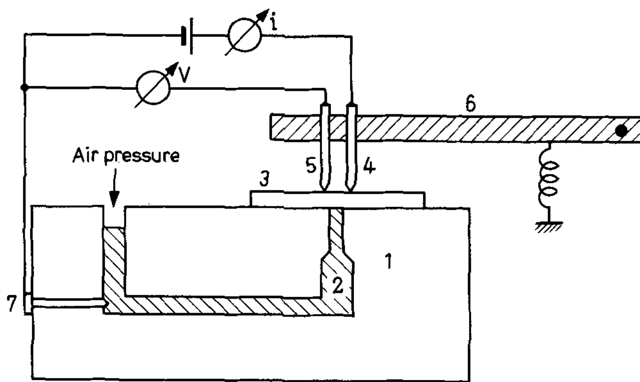

Fig. 1. Schematic drawing of the mercury-silicon contacting accessory: perspex block (1), mercury column (2), silicon slice (3), contact probes (4,5), lever (6), contact to mercury (7). The d-c circuit is also shown, in case there is no back side contact barrier, probes 4 and 5 can be connected.

perspex mercury-silicon contact accessory is shielded in an earthed metal box.

Mercury-Silicon Capacitance Compensation Procedures

Assuming now that the contact of the mercury probe to the silicon has been made, in principle a C-V curve could be measured.

However, it is clear that parasitic capacitances in parallel may invalidate any pertinent conclusions on the impurity density if they are not properly compensated for. The parasitic capacitance can be divided formally into an edge, a stray, and an encapsulation capacitance; they are indistinguishable in actual practice. The edge capacitance C_V is due to the nonhorizontal boundary of the depleted region, which Goodman (20) estimated $C_V = \pi^2 \epsilon A$ and Copeland (21) computed to be remarkably smaller, viz. $C_V = 1.5\pi\epsilon A$. The effect of the edge on the measured capacitance can be evaluated by doing the same experiment with various contact diameters. It is important to note that both in the elementary estimate and in the more detailed calculations it is found that C_V is independent of x and N. By the stray capacitance, C_s, is meant the capacitance between the mercury column and the slice. By the encapsulation capacitance, C_e, is meant the capacitance between the mercury column and the enclosure including the slice.

A second impediment to the sufficiently reliable use of the C-V technique is due to a reverse current which may be too high for the instrument. A phase sensitive detector should therefore be incorporated.

Finally, because the squared diode surface area figures in Eq. [1], the diameter $2A$ should be reproducible and accurately known: it has been found from microscopic inspection of the contact made against a microscope slide that $A = 249 \pm 1\ \mu$m.

The mercury-silicon capacitance cannot be adequately discussed without a brief description of the method by which the difficulties arising from parasitic capacitance can be overcome. Two ordinary capacitors C_1 and C_2 are measured and the instrument produces formally depth readings x_1 and x_2. The slope $(C_1 - C_2)/(x_1^{-1} - x_2^{-1})$ corresponding to a value of the parameter ϵO generally does not agree with the value found microscopically. The instrument is then calibrated for the appropriate area so that these values coincide to yield Cd = 20 pF · μm. The intercept in the C *vs.* x^{-1} plot is reduced to zero by compensating with a built-in opposite-phase current. Then the mercury contact to a silicon slice with plated reverse side is connected to the instrument and assuming that the impurity density N is uniform, the undesired capacitances are eliminated by measuring the dope profile over a certain depth, say from 3 to 4 μm, and adjusting the compensating facilities such that N is a constant over that range. A more refined technique which needs a shorter range of virtually constant N, uses the formal identity between the fundamental equation

$$N = \frac{2\epsilon}{e} \frac{V}{x^2} \qquad [1d]$$

and the equation on which the instrument is based and which is merely a property of the electronic circuitry

$$N = 10^{14} \frac{V_2}{x^2} \qquad [1e]$$

where N is expressed in cm^{-3}, x in μm, and V_2 is the 2 kHz output voltage in mV. The instrument is properly calibrated when V_2 and V reduced by the appropriate constants are read equal. After correct adjustment and calibration the impurity density can be measured.

In general, parasitic capacitances are quite unaccessible, but in order to get a feel for their effects the following experiments have been done. First the equipment is properly compensated with the mercury column at some distance from the slice and subsequently in the measurement situation, making N constant, as described above. The difference between the two readings turns out to be independent of slice resistivity and of depth: with a 3 and 18 ohm-cm N-type slice between 1 and 10 μm the compensation capacitance amounts to about 0.80 pF. In a second experiment the equipment is again properly compensated with the mercury column at some distance from the slice and subsequently with a thin sheet of Polythene, of thickness $\delta = 30\ \mu$m, between the mercury and the slice. The difference between the two readings amounts to about 0.70 pF. In both experiments part of the compensation capacitance is due to a change ΔC_e in encapsulation capacitance. Assuming these to be equal the compensation capacitance in the first experiment equals $\Delta C_e + C_v$ and in the second experiment $\Delta C_e + C_p$, where C_p is the capacitance due to the Polythene sheet with $\epsilon = \epsilon_p \epsilon_o$.

A more precise measurement is done when the equipment is properly compensated in the measurement situation and subsequently with the Polythene sheet of thickness δ between the mercury and the slice. The difference between the two readings is 0.10 pF. When the experiment is repeated with thickness 2δ, the difference is 0.175 pF. From the equations $C_v - C_p = 0.10$ pF and $C_v - C_p/2 = 0.175$ pF it follows that $C_p = 0.15$ pF and $C_v = 0.25$ pF. This value of C_p suggests that $\epsilon = 3.8\ \epsilon_o$ which has been found to hold by varying the thickness. The stray capacitance associated with C_p can be neglected. In the experimental arrangement with $A = 249\ \mu$m and $\epsilon = 11.8\ \epsilon_o$ Goodman's formula yields $C_v = 0.29$ pF, which shows better agreement than Copeland's formula.

Similar effects were reported by Copeland (4) who found with a given diode diameter $C_v = 0.15$ pF whereas $C_v = 0.09$ pF was expected. His suggestion that the additional capacitance is probably due to a slight change in probe stray capacitance as the probe is moved into position can be in agreement with the observation reported above, though it may refer to part of the effect.

Mercury-Silicon Capacitance Measurement

In actual practice, the Rusche instrument with the mercury probe is used continuously to evaluate N-type Si layers epitaxially grown on an N$^+$ substrate. The range of applicability is limited at the lowly doped side by the very small capacitance at high voltage and at the highly doped side by the relatively high voltage necessary to reach a given depth, whereas the maximum voltage is increasingly limited by breakdown. In Fig. 2, V is plotted *vs.* N with d as a parameter from Eq. [1d] and the N-scale is shown converted to the

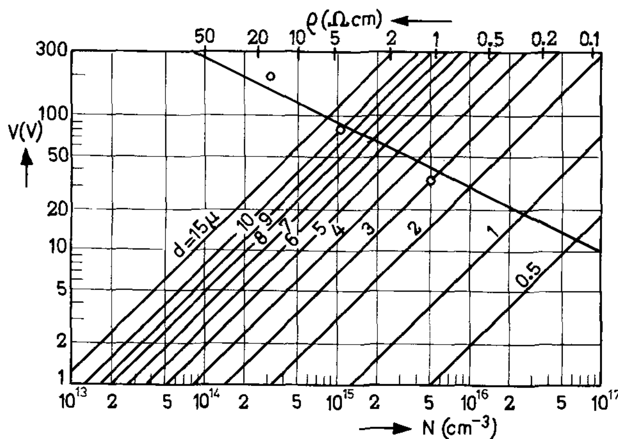

Fig. 2. Range of applicability of the C-V method for measuring a layer of thickness d and charge carrier density N or resistivity ρ is limited by breakdown. The parallel straight lines are obtained from Eq. [1] with $\epsilon = 11.8$, ϵ_0 and $O = 196.10^{-9}$ m^2 and the breakdown characteristic is drawn with slope 0.5 through some measured points.

resistivity ρ from Sze and Irvin's (22) curves. The breakdown voltage as a function of N is drawn with slope 0.5 through some experimental points, roughly according to Schumann's (23) theory.

When the depletion layer reaches the epitaxial layer-substrate interface this is very clearly manifested on the instrument. In this way not only can the resistivity ρ be determined but also, with some established criterion, the thickness d of an epitaxial layer. This is particularly important for layers which are too thin to be accurately measured with the conventional infrared multiple interference (IMI) technique, say for, $d \leqq 3$ μm. The thickness d_i as measured by the IMI technique is uniquely determined and is further operationally defined by the formalism used for the interpretation (24). However, the definition of thickness as measured with the C-V method should be agreed on before the measurement: in general terms d_α, where $N(d_\alpha) = \alpha N_{epi}$. In fact mainly the thickness definition d_x where $N(d_x) = N_{substr} = \infty$, is used. Because the thickness is not uniquely defined, Mantena and Barrera's (25) suggestion to use the IMI measured thickness value d_i and compensate at punch-through where C is known to be $\epsilon\pi A^2/d_i$, does not eliminate the ignorance of parasitic capacitances to the extent required, especially in the case of thick layers. For thin layers, where the parasitic capacitance is relatively unimportant, this method could work, but the IMI technique cannot be used then. In fact, the C-V method is the only method available to date for direct thickness measurement of thin layers.

The precision obtainable depends on the instrument used: taking into account all sources of error the precision should amount to $\pm 10\%$, but in actual practice the reproducibility is found to be $\pm 2\%$. The accuracy of the method is tentatively demonstrated in Table I. The four-point probe (fpp) measured resistivity is compared to the C-V measured dope concentration N converted to ρ with Sze and Irvin's (22) curves and satisfactory agreement is found. It should be realized in interpreting these results that a slice is essentially nonuniform in resistivity, as convincingly demonstrated with the spreading resistance technique (26). The four-point probe method itself is capable of measuring with a precision of about 0.5% but because the result represents a weighted average over several square millimeters it is subjected to larger errors (27). The nonuniformity also affects the capacitance-voltage measurement results. The same mercury contacting accessory has also been used successfully on bulk GaAs and GaP where the reverse sides should be properly contacted and on epitaxially grown N on N^+ GaAs layers (28) where this difficulty does not arise to such extent.

Mercury-Silicon Diode

In the preceding section the instrument has been described as far as relevant and its application to the precise, accurate, nondestructive and rapid determination of thickness and resistivity of epitaxially grown layers has been explained. The much more complicated question as to why the mercury probe works so well is semiquantitatively discussed in this section.

It has been found experimentally that the slice should be polished and that before mercury contact to the silicon is actually made, the slice should be thoroughly cleaned and chemically oxidized by boiling it for about 1 min in HNO_3 or $H_2O_2 + H_2SO_4$. This preparation process produces an oxide layer between 20 and 50Å thick, as do all room-temperature wet oxidizing agents (29-32). It has been found that without such thin oxide interfacial layer no reliable C-V measurements can be made on N-type silicon.

Experiments on mercury-silicon surface barriers have, as far as the authors are aware, only been reported by Donald (33).

Neither the very thin nor the thick oxide layer theories are applicable to the type of mercury contact which this paper deals with. With the intermediate insulating layer thickness, between 10 and 100Å, quantum-mechanical tunneling is the dominant mechanism (34-38). Because the voltage drop is entirely across the oxide layer, the applied bias sweeps the Fermi level in the metal along the different semiconductor levels. Between coincidence with the top of the valence band and the bottom of the conduction band, conductance in this system is very low and this conductance well is typically from 1 to 2V wide. This depends on the energy gap and interface state density. At the edges the d-c current rises steeply and the I-V plot is fairly symmetric. If the doping level of the semiconductor is low or the oxide film is very thin, most of the voltage drop occurs across the semiconductor, which then forms a depletion region, and the metal Fermi level is not free to move, but is pinned to the semiconductor Fermi level. Dahlke and Sze (35) published two I-V characteristics, which under these conditions show a roughly exponential rise in the forward direction and a slowly varying current in the reverse direction. Strong dependence on the ambient temperature proved that emission exceeded tunneling as the current controlling process.

Similar I-V characteristics have been measured with the mercury-thin oxide-covered silicon diode. An example is shown in Fig. 3. The conductance well typical of tunneling is not observed because the voltage drop is mainly across the depletion layer in this lowly doped material and the conventional diode equations are not satisfied because of the presence of the oxide interface.

The influence of the oxide layer and the silicon-doping type and level is more clearly illustrated in Fig. 4. Both low- and high-conductivity N-type silicon, mercury contacted just after HF-etching (labeled lNe and hNe, respectively) show low-resistance ohmic

Table I. Some measurement data obtained with the four-point probe and C-V methods on five N-type and three P-type Si slices

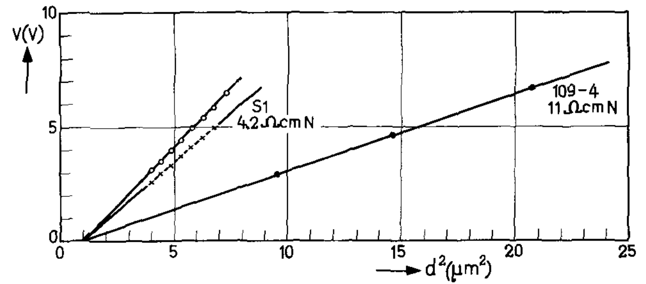

Fig. 3c. Some *C-V* curves of thin-oxide covered, N-type Si slices

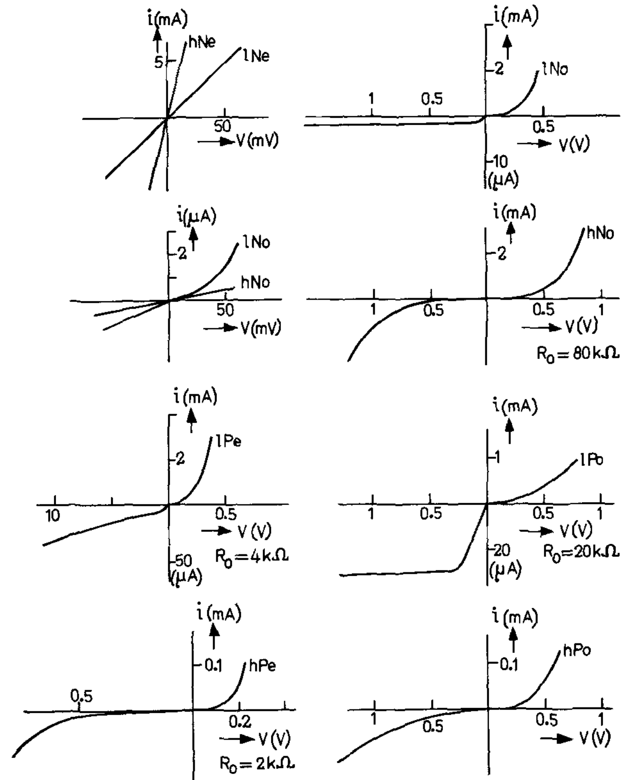

Fig. 4. *I-V* characteristics of eight essentially different diodes on silicon: highly and lowly doped (h and l), N and P-type (N and P), thin oxide layer-covered or etched (o or e). Note that the forward and reverse currents have different scales. The following materials are used: 1 ohm-cm, 10 μm thick, N-type epitaxial layer on 10^{-2} ohm-cm N^+-type substrate (lN), 0.008 ohm-cm N-type (hN), 2.8 ohm-cm, 9 μm thick P-type epitaxial layer on 10^{-2} ohm-cm P^+-type substrate (lN) and 10^{-2} ohm-cm P-type (hP).

characteristics. When oxidized before the mercury contact is applied, the highly doped material (labeled hNo) shows the conductance well discussed above, whereas under reverse bias the lowly doped material (labeled lNo) develops a depletion layer, which presents the dominant barrier to current flow. The forward biased parts of the lNo and hNo materials are about equal, in both charge transport is controlled by the tunneling process because the main voltage drop is across the oxide. The ratio of forward to reverse current in lNo material is about 10^4 and in hNo material the conductance well is centered at about 0.2V reverse bias. From the low-voltage *I-V* characteristic the zero-bias barrier resistance R_0 is found for both lNo and hNo material to be equal to about 10^5 ohms and apparently the leakage current density J_s is determined by the oxide layer.

The considerations and evidence discussed above can be summarized by stating that in lowly doped material the oxide layer is thick enough to present a barrier to current flow and thin enough to allow the reverse bias voltage drop to exist across the semiconductor depletion layer. This enables a capacitance voltage measurement to be made. The thin oxide series capacitance is completely negligible with respect to the depletion layer capacitance and conductance via small holes in the oxide layer must be excluded because of the ensuing high spreading resistance which is not measured.

To P-type material, HF-etched before mercury is applied, no ohmic contact can be made. This is to be expected because for a particular metal the barrier heights to N- and P-type material add to about the semiconductor energy gap (39, 40). Therefore, hPe material produces about the same *I-V* characteristic as hPo material and lPo material does not produce a more pronounced diode characteristic than lPe material.

Summarizing it can be said that lowly doped P-type material can be *C-V* measured with the mercury probe equally well with or without oxide layer.

Some examples of plots of V *vs.* $d^2 \sim 1/C^2$ are given in Fig. 3c. The presentation is not typical, because with the automated instrument reading the d-c reverse voltage is not needed; it is merely shown in order to exemplify the validity of the method. The diffusion voltage as read from the intercept is typically between 0.5 and 1.5V. It cannot be used simply to characterize the material probably because surface charge and the interfacial layer are important for the actual value. Such effects have been discussed by Cowley (41) and Sze (42) for Si, GaAs, and GaP.

Discussion of Epitaxial Layer Measurements

In the procedure outlined above it is assumed that over a small depth the impurity density is uniform. Epitaxially grown layers satisfy this requirement and home-grown N on N^+ layers with resistivities between 0.1 and 20 ohm-cm are currently measured with the mercury probe and automated equipment as far as the impurity density and thickness ranges plotted in Fig. 2 allow. The breakdown voltage boundary should not be considered as accurate and sharp because it depends to some extent on surface damage and preparation and cleanliness of the epitaxial layer surface. It is evident that for an N on N^+ layer in the thickness range which can be measured with IMI this *C-V* method obviates the N on P check slice procedure and for very thin N on N^+ layers it presents a new, rapid and nondestructive technique. In Fig. 5 the results of evaluation of a batch of rather thin epitaxially grown N on N^+ layers are shown. It would have been very difficult to obtain these results in any other way, and they cannot be checked easily. Similar results on a batch of thicker layers are presented in Fig. 6 and the thickness is compared to the data obtained with IMI. It is clear that a discrepancy must exist between the two sets of results due to the incompatibility of the definitions used.[1] Because a fairly constant difference between both sets exists it is reasonable to assume that the precision obtained with the *C-V* method is well within the limit indicated above, ±5%. A typical epitaxial layer measurement is shown in Fig. 7.

Acknowledgment

The authors wish to express their thanks to Dr. Hagen and Dr. van Opdorp for discussions on the nature of the mercury-silicon diode.

[1] The same argument can be put forward against introducing the IMI measured thickness for spreading resistance data interpretation.

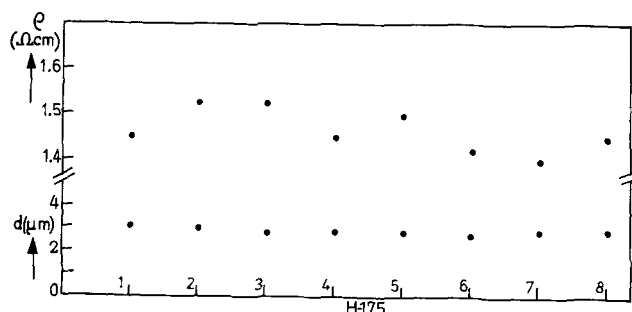

Fig. 5. Resistivity ρ and the thickness d, *C-V* measured with d_∞ criterion on a batch of eight epitaxially grown N on N^+ layers (H175). The numbers correspond to the centers of the eight slices, positioned in a row on the susceptor.

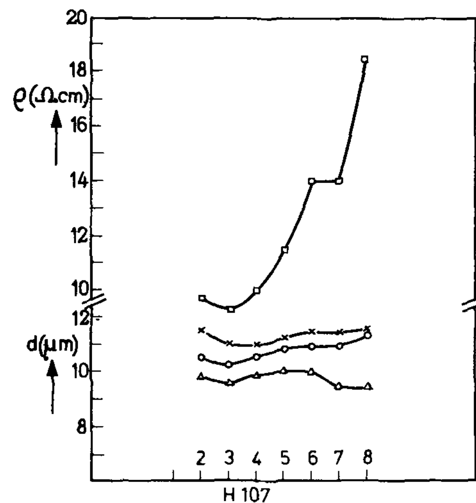

Fig. 6. Resistivity ρ, and the thickness d, *C-V* measured with the $d_{1,1}$ criterion (Δ), the d_∞ criterion (o), and IMI measured (x) on a batch of eight epitaxially grown N on N^+ layers (H107). No gas dope was added to the silane, and the resistivity increases along the susceptor propably due to autodoping. The numbers correspond to the centers of the eight slices, positioned in a row on the susceptor.

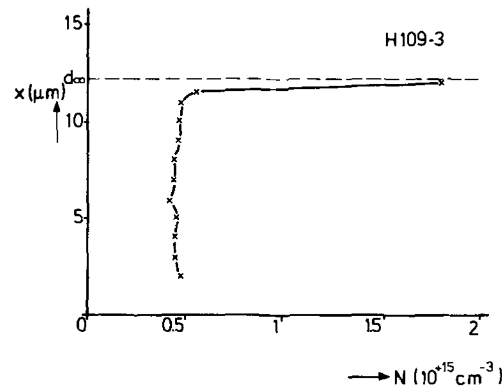

Fig. 7. Dope concentration as a function of depth in an epitaxially grown N on N^+ layer (H109-3). The uncorrected (24) IMI measured thickness $d_i = 12.9$ μm, whereas $d_\infty = 12.25$ μm.

High Concentration Arsenic Diffusion in Silicon from a Doped Oxide Source

Richard B. Fair

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania 19603

ABSTRACT

The properties of As-doped SiO_2 and As-doped Ge/SiO_2 diffusion sources as a function of the O_2 concentration in a horizontal, open-tube deposition chamber are examined. The effect of the Ge doping in the oxide is to enhance the etch rate and to reduce As_2O_3 incorporated during the oxidation of AsH_3. The elemental As thus formed diffuses more rapidly than As_2O_3 in the oxide, thus enhancing the transport of As across the Si-oxide interface. A prediffusion H_2 anneal of the oxide is shown to produce a similar effect. Control of the source doping by varying the O_2 concentration in the deposition chamber, C_{O_2}, is shown to result in diffusions where the sheet resistance, R_S, varies as $(C_{O_2})^{-1}$. In terms of the molecular fraction of As in the oxide, $C_{As}^{SiO_2}$, $R_S \propto (C_{As}^{SiO_2})^{-2}$. R_S is shown to decrease with time as $t^{-1/2}$ for $t \gtrsim 40$ min. For shorter times the diffusion of As is complicated by the changing surface concentration of the electrically active fraction of As. Singly diffused As profiles in Si are shown to be described by the solutions to the diffusion equation with a concentration-dependent diffusion coefficient. However, the preanneal in H_2 is shown to cause the subsequently diffused As to have an anomalous electrical profile.

The use of arsenic-doped oxides has been reported for several years (1-6). Recently, these oxides have shown much promise as emitter diffusion sources in planar transistor processing (7). In general, the advantages of using doped oxide diffusion sources have been well reviewed (8, 9). However, little is known about the relationships that exist between the properties of arsenic-doped oxides and the characteristics of diffusions from them. It is the purpose of this paper to present the results of a study of shallow, high concentration arsenic diffusions in silicon from doped oxides whose chemical compositions have been experimentally determined. Two general types of doped oxides were deposited in a horizontal, open-tube reactor: As-doped SiO_2 and As-doped Ge/SiO_2. These films were deposited on silicon substrates by the oxidation reactions of AsH_3, SiH_4, and GeH_4 or $GeCl_4$ with O_2. The following sections describe the dependence of As doping in the oxides on the O_2 concentration in the reaction chamber. As a diffusion source, the effects of oxide composition and prediffusion annealing are discussed.

Key words: arsenic, diffusion, doped oxides.

Experimental

The horizontal open-tube deposition furnace that was used in this study is shown schematically in Fig. 1. This unit has the capability of depositing doped and undoped SiO_2 films from the oxidations of silane

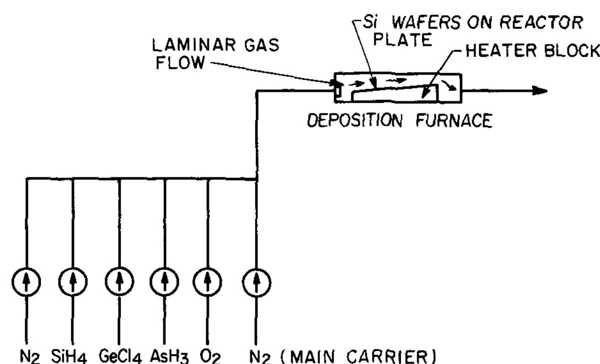

Fig. 1. Schematic diagram of the arsenic-doped germano silicate oxide deposition system.

(SiH_4), and the gaseous compounds of the doping species. Doping gases were controlled by mass flowmeters. The reactor plate was heated by a 4 kW resistive-type heater block. For a typical deposition, wafers were placed on a vitreous carbon reactor plate. The reactor plate was placed on the heater block, and then the gases were introduced into the chamber (rectangular cross section, volume $\cong$ 300 in.^{3}). Using a N_2 carrier gas flow rate of 92 l/min, the 5% SiH_4, 10% AsH_3, and O_2 flow rates were typically 0.7, 0.08, and 5 l/min, respectively. Deposition occurred in excess AsH_3 at $\approx$ 500 Å/min for a heater temperature of 470°C. For a total oxide thickness of 3000Å, slice-to-slice uniformity was ± 200Å over ten, 1½ in. wafers.

All diffusions were performed in <100>, 1 ohm-cm p-type Si wafers, 1½ in. in diameter. These wafers were cut from Czochralski-grown crystals. They were then chemically lapped, Syton polished, and cleaned. Prior to oxide deposition the wafers were rinsed in a buffered HF solution.

Properties of the Source Oxide

The dependence of As doping in the deposited oxide upon O_2 concentration in the reaction chamber was investigated by varying the O_2 flow rate with all other gas flows held constant. Room temperature infrared spectra were obtained of as-deposited oxides so that the As_2O_3 content could be determined, and neutron activation measurements were made in order to determine the total As doping in the oxides. The infrared spectra of As-doped SiO_2 and As-doped Ge/SiO_2 films deposited with $C_{O_2} = 0.073$ (mole fraction of O_2 computed with respect to the total gas mixture) are compared in Fig. 2. These kinds of spectra have been thoroughly analyzed by Arai and Terunuma (10) and by Abe *et al.* (7). From the 10.7μ absorption lines [due to symmetric stretching vibrations of As_2O_3 (11)] it was estimated that the amount of As_2O_3 incorporated into the As-doped SiO_2 films increases superlinearly with C_{O_2} over the range $0.045 \leq C_{O_2} \leq 0.073$. However, over the same range the As_2O_3 density increases as $C_{O_2}{}^{1/2}$ for the Ge/SiO_2 system. Also for the case $C_{O_2} = 0.073$ the As_2O_3 density in the SiO_2 film is approximately 40% larger than the As_2O_3 density in the Ge/SiO_2 film. At $C_{O_2} = 0.053$ the As_2O_3 concentration in the SiO_2 film is larger by 13%. In order to determine if the increased As_2O_3 doping in the SiO_2 films is due to a difference in the oxidation kinetics of the AsH_3-SiH_4 system as compared with the AsH_3-SiH_4-$GeCl_4$ system, neutron activation of these same oxides was performed in order to determine total arsenic concentrations. The results of some of these measurements are summarized in Table I for 3000Å thick films. The total As concentration, [As], increases approximately as $C_{O_2}{}^{1/2}$ for both the As-SiO_2 and the As-Ge/SiO_2 systems, which agrees with the independent observations of Weber (12). However, the [As] in the As-doped SiO_2 films is larger for a given O_2 concentration than in the As-doped Ge/SiO_2 films. A possible explanation for this is that the $GeCl_4$ or GeH_4 molecules in the gas phase "tie-up" O_2 molecules for oxidation, leaving a lower concentration of O_2 available for the oxidation of AsH_3 and SiH_4.

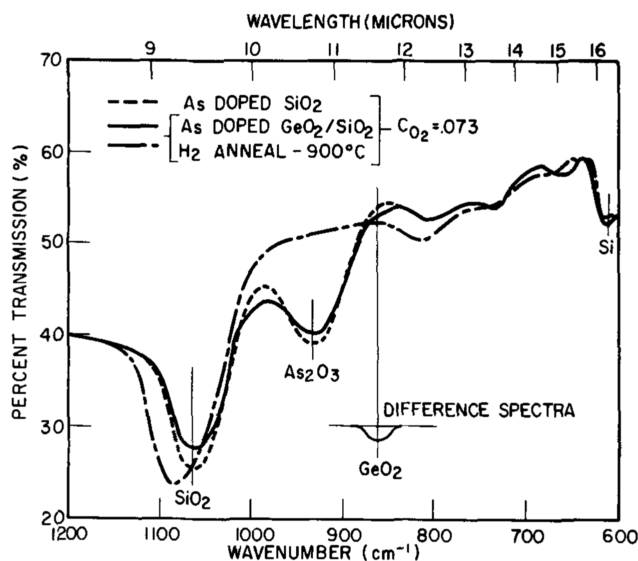

Fig. 2. Infrared spectra of as-deposited As-SiO_2 and As-Ge/SiO_2 oxides for the O_2 concentration of 0.073. The spectrum of an H_2 annealed film is shown for comparison (900°C for 20 min).

In order to try to understand the effect that the addition of Ge has on the incorporation of As_2O_3 into the deposited oxides, it is necessary to study the kinetics of the various reactions. However, some insight can be obtained if the following thermodynamically favorable reactions are considered at 470°C (13, 14)

$$GeO_2 + Si = Ge + SiO_2, \quad \Delta G^\circ = -78 \text{ kcal} \quad [1]$$

$$\tfrac{3}{4}Ge + \tfrac{1}{2}As_2O_3 = \tfrac{3}{4}GeO_2 + As, \quad \Delta G^\circ = -16.5 \text{ kcal} \quad [2]$$

$$\tfrac{3}{4}Si + \tfrac{1}{2}As_2O_3 = \tfrac{3}{4}SiO_2 + As, \quad \Delta G^\circ = -75 \text{ kcal} \quad [3]$$

where ΔG° is the standard free energy of the reaction. Regarding reaction [1] the presence of GeO_2 in the Ge/SiO_2 films can be seen from the spectra of Fig. 2. At 11.5μ the weak GeO_2 absorption band is visible when the As-Ge/SiO_2 spectrum is subtracted from the As-SiO_2 spectrum. However etch rate measurements indicate that the total Ge doping density in these films is 1.5-2 $\times$ 10^{21} atoms/cm^3 (4, 12) [approximately 8 a/o (atom per cent) in SiO_2]. If all of this 8 a/o of Ge were in the form of GeO_2, it is expected that a more pronounced absorption band would have been detected (4). The presence of other Ge compounds could not be detected in full-spectrum measurments. Consequently, it is probable that elemental Ge dominates in the As-doped Ge/SiO_2 oxides. The Si in Reactions [1] and [3] is the Si wafers and that Si which is formed by the pyrolysis of SiH_4. Consequently, the presence of Ge appears to enhance the [As] over the [As_2O_3] directly through Reaction [2], although Reaction [3] may contribute significantly to the [As]:[As_2O_3] ratio.

Diffusion Studies

In this section the characteristics of As-doped oxide diffusion sources are discussed in light of the information presented above.

Prediffusion annealing.—In order to investigate the effects of prediffusion annealing on the doped oxide characteristics, six silicon samples were simultaneously deposited with 1500Å of As-doped SiO_2. These films were then capped with 1500Å of SiO_2. Three slices were annealed in H_2 and three in O_2, all at 900°C for 20 min. Film quality of the H_2 and O_2 annealed slices was excellent. All six slices were then placed in a 1000°C, O_2 furnace for 30 min. The average sheet resistances, R_S, the R_S ranges, and the diffused layer junction depths in the silicon were as follows

$$R_S{}^{H_2} = 34.4 \pm 2.5\% \text{ ohms/square}, \quad x_J = 0.18\mu$$

$$R_S{}^{O_2} = 38.3 \pm 1.5\% \text{ ohms/square}, \quad x_J = 0.22\mu$$

Table I. Oxide* arsenic doping as a function of O_2 concentration

Oxide composition	C_{O_2}	As_2O_3 doping (area of absorption) curve		Total As doping, [As] (atoms/cm^2)	
As-SiO_2	0.073	70	$\propto C_{O_2}{}^{>1}$	8.35 $\times$ 10^{16}	$C_{O_2}{}^{1/2}$
	0.053	45		7.24 $\times$ 10^{16}	
As-Ge/SiO_2	0.073	51	$\propto C_{O_2}{}^{1/2}$	7.45 $\times$ 10^{16}	$C_{O_2}{}^{1/2}$
	0.053	40		6.22 $\times$ 10^{16}	

* All oxide films were 3000A thick.

The room temperature infrared spectrum of the H_2 annealed doped oxide is shown in Fig. 2. It can be seen that the H_2 anneal has completely reduced the As_2O_3 in the film. Diffusions that were performed at 1000°C for 30 min in H_2 yielded diffused layers of $R_S \simeq 300$ ohms/square. These observations are in agreement with the results of Arai and Terunuma (10). It can, therefore, be concluded that diffusion in O_2 is important for the efficient transport of As from the oxide to the Si. Such transport may depend on the presence of As_2O_3 according to Reaction [3]. The effect of the H_2 anneal appears to be similar to the effect of incorporating Ge into the source oxide, *i.e.*, to form elemental As which apparently can diffuse through SiO_2 more rapidly than As_2O_3. The increased diffusivity of "As" in Ge/SiO_2 was verified at 1270°C where $D_{As\ Ge/SiO_2}/D_{As|SiO_2} \cong 1.5$ was measured. Enhanced As diffusivity in $GeSiO_2$ also was suggested by Abe *et al.* (7) as the cause of enhanced As doping in Si.

Effect of O_2 concentration on the diffusion of As in Si.—The dependence of sheet resistance and junction depth on the As concentration in the oxide source was investigated. Arsenic diffusions into silicon were performed from doped oxides that were deposited with O_2 concentrations between 0.025 and 0.073 mole fraction. The AsH_3 and SiH_4 concentrations were held constant at 0.00008 and 0.00043, respectively. The deposition temperature was 470°C measured in the heater block. After each deposition the individual wafers were scribed, and groups of four pieces were then diffused for 15, 25, 30, 40, and 60 min, respectively. Sheet resistances and junction depths (angle-lap and HNO_3-HF stain) were measured on each piece, and the results for each diffusion time were averaged. The experiments were repeated with Ge doping in the oxides (mole fraction of $GeH_4 = 0.00003$).

The results of these measurements for 1000°C, 30-min diffusions in O_2 are shown in Fig. 3. The sheet resistance is seen to vary approximately as $(C_{O_2})^{-1}$. Resistivity profiles of these diffusions were then obtained by a differential four-point probe technique, and Irvin's (15) curves were used to obtain the resulting electrically active As-doping profiles. Integration over these profiles yielded the total number of electrically active As atoms/cm^2, Q. In Fig. 4 Q is shown plotted against the molecular fraction of As in the source oxide. For two diffusions, the Q of the As in the Si was determined by neutron activation analysis as well as by resistivity measurements. These data are indicated in Fig. 4 by a superscript, n.

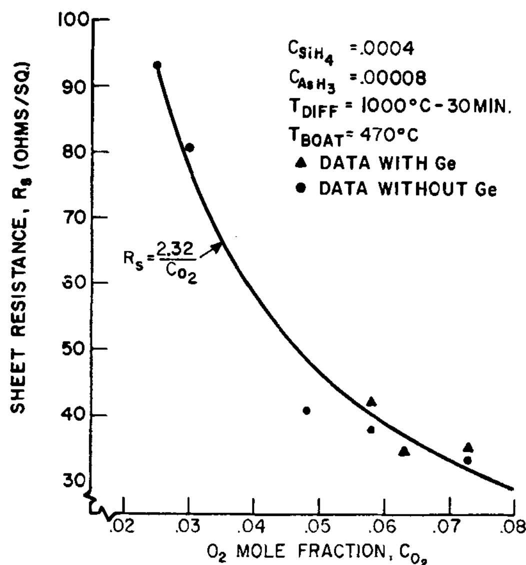

Fig. 3. Variation of the sheet resistance of diffused As layers in Si with O_2 concentration in the deposition chamber.

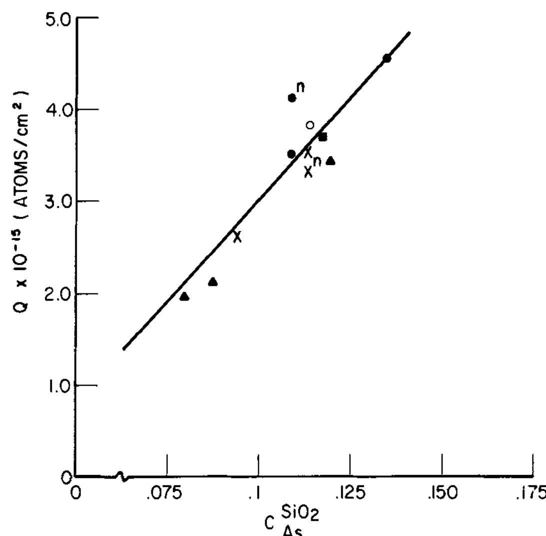

Fig. 4. Total arsenic concentration in silicon vs. molecular fraction of arsenic in the doped oxide source following 1000°C diffusion in O_2. As-SiO_2 source: ▲ 30 min; ● 60 min. As-Ge/SiO_2 source: 0 20 min; x 60 min. H_2-As-Ge/SiO_2 source: ■ 30 min. n: neutron activation data.

In order to determine the dependence of R_S on $C_{As}^{SiO_2}$, the molecular fraction of As in SiO_2, the empirical equations

$$R_S = \frac{2.32}{C_{O_2}} \quad [4]$$

$$C_{As}^{SiO_2} = 0.45\, C_{O_2}^{1/2} \quad [5]$$

can be combined to give

$$R_S = \frac{0.47}{(C_{As}^{SiO_2})^2} \quad [6]$$

This result is plotted in Fig. 5 along with experimental data (from 1000°C, 30-min diffusions only).

The variation of the sheet resistance with diffusion time is shown in Fig. 6. It can be seen that there is approximately a 13% dip in the curves at $t = 30$ min. For times greater than 40 min, the sheet resistance decreases as $(t)^{-1/2}$. From $t = 25$ min to $t = 30$ min, R_S decreases approximately as t^{-1}. The theoretical dependence of R_S on t can be approximated if it is assumed that the electron mobility of the As-doped Si remains constant for concentrations $\gtrsim 10^{19}$ atoms/cm^3. It has been shown that for a constant C_s diffusion (16)

$$R_S = \frac{1.56 \times 10^{17}}{x_J C_S} \quad [7]$$

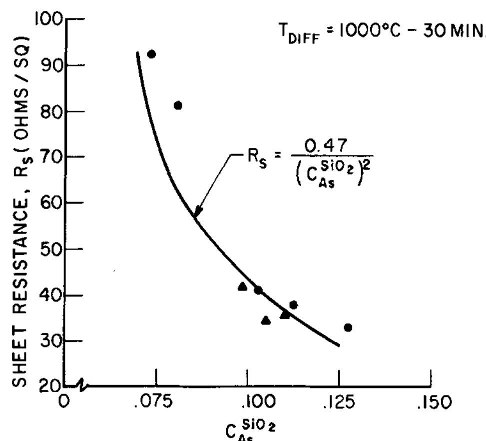

Fig. 5. Variation of the sheet resistance with molecular fraction of As in the source oxide.

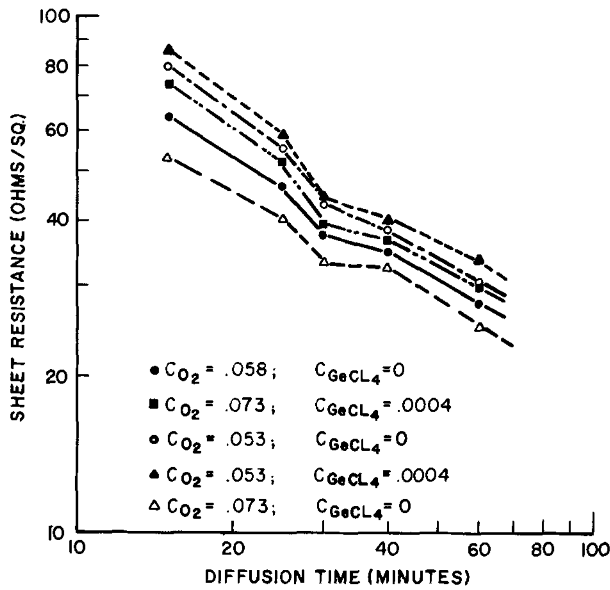

Fig. 6. Variation of sheet resistance with diffusion time

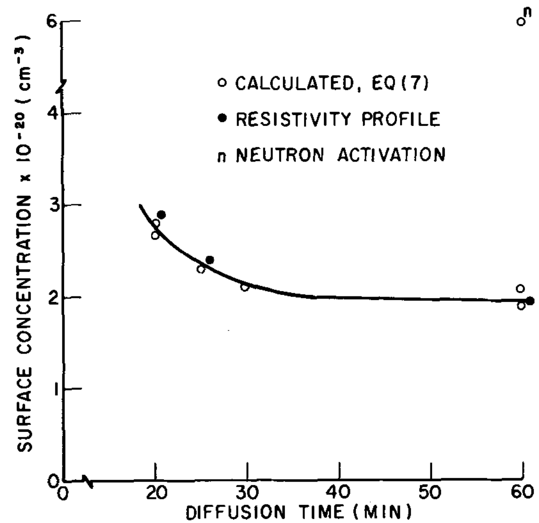

Fig. 8. Variation of surface concentration with diffusion time (diffusion from an As-doped SiO_2 source, $C_{O2} = 0.073$, $T = 1000°C$).

where C_S is the electrically active surface concentration (atoms/cm^3). The validity of Eq. [7] is not dependent on the type of As diffusion source. From Fig. 7, x_J can be seen to increase approximately as $t^{1/2}$ for As diffusions into 1 ohm-cm p-Si at 1000°C. Under such conditions, x_J can be written as (16)

$$x_J = 2.3 \sqrt{\frac{C_S D_i t}{n_i}} \quad [8]$$

where D_i is the intrinsic diffusivity of As, and n_i is the intrinsic electron density. Substitution of Eq. [8] into Eq. [7] yields

$$R_S = \frac{6.8 \times 10^{16}}{C_S^{3/2}} \sqrt{\frac{n_i}{D_i t}} \quad [9]$$

It can be seen that R_S is a sensitive function of surface doping concentration, C_S. If C_S is constant, then R_S decreases as $t^{-1/2}$. However, the C_S *vs.* t data collected from As diffusions performed with the same source oxides ($C_{O_2} = 0.058$, $GeCl_4 = 0$) are shown in Fig. 8. It can be seen that C_S becomes approximately constant for $t \gtrsim 35$ min, near the beginning of the $t^{-1/2}$ decrease of R_S. For $t < 35$ min it is felt that the dominant effect on C_S is the establishment of equilibrium between monatomic As^+ ions and inactive As complexes. According to the annealing studies of Schwenker *et al.* (17), considerable time is required for equilibrium to obtain (15-30 min at 1000°C). Also, the fact that the doped oxide source is finite will cause an eventual decrease in C_S.

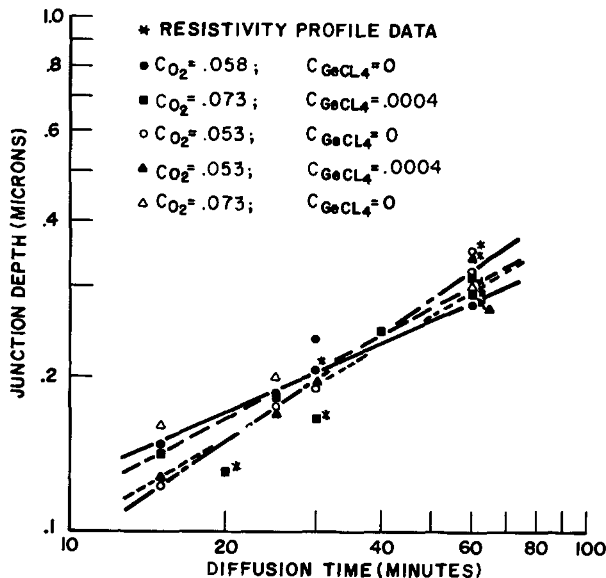

Fig. 7. Variation of As-diffused layer junction depths in Si with diffusion time (1000°C in O_2).

Diffusion profiles.—Shallow arsenic diffusion profiles in silicon were obtained experimentally by a step anodization process in which the sheet resistance was measured as a function of depth. Irvin's curves were then used to deduce the concentration profiles. These profiles are shown in Fig. 9, 10, and 11. The sources for these diffusions were As-doped SiO_2, As-doped Ge/SiO_2, and H_2-annealed As-doped Ge/SiO_2, respectively. The theoretical profiles were obtained by numerically solving the diffusion equation

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D_{Si}\frac{\partial C}{\partial x}\right) \quad [10]$$

where D_{Si} is given by the expression (18)

$$D_{Si} = \frac{D_i C}{n_i}$$

It can be seen that C_S is higher for the profile shown in Fig. 10 than for the profile shown in Fig. 9 (an addi-

tional 10-min diffusion would bring C_S shown in Fig. 10 down by only 15%). Thus, the effect of Ge doping in the oxide has been to increase C_S, in agreement with previous results (7). The H_2 prediffusion anneal has been shown to lower the sheet resistance of the subsequently diffused As layer. However, it can be seen in Fig. 11 that the expected increase in C_S does not occur. The experimental profile deviates from the theoretical profile in the first 600Å of the Si. The reason for this is not clear at this time, nor is it certain that this effect is real. If there exists a large concentration of nonelectrically active As (clusters, complexes, etc.) in the surface region, the electron mobility could be significantly lowered. The lower mobility would yield lower inferred values of As doping from Irvin's curve.

The transistor profile that resulted when As was diffused into Si with an initially predeposited B layer (no oxidation) is shown in Fig. 12. A comparison is indicated between the total As doping profile (obtained by neutron activation analysis) and the profile obtained by conductivity measurements and Irvin's curves. The total doping in the surface is consistently three to five times greater than the measured electrical doping (for As diffusion into initially p-type Si). This may be due to vacancy undersaturation in the crystal as a result of the very high concentrations of As. Thus, in order for equilibrium conditions to exist, As atoms would jump into interstitial sites and then condense into clusters or vacancy-As complexes (19, 20). Near the emitter-base junction it can be seen that the inferred electrically active As exceeds the measured total As. This might be due to the enhanced carrier mobility as a result of ion pairing (21). The collector-base junction was retarded by 65% during the As diffusion. Similar results were obtained when the As was diffused from an As-doped Ge/SiO_2 source except that the electrical surface concentration was only 8×10^{19} cm^{-3}.

Microwave transistors that have been fabricated with the doped oxide emitter diffusion have exhibited low leakage currents ($I_{CEO} < 2$ nA), low noise figure (3.5 db at 1.3 GHz) and high cutoff frequency ($f_T = 7.5$ GHz). Direct-current gains have been in the range of 50 to 100.

Summary and Conclusions

The properties of As-doped oxides that were deposited in a horizontal open-tube reactor have been investigated. Neutron activation measurements indicate that the total As density is greater in the As-SiO_2 oxides than in the As-Ge/SiO_2 oxides when the deposition conditions are similar. However, the total As doping was observed to increase as $C_{O_2}{}^{1/2}$ for both types of oxides.

In the deposition chamber, GeO_2 is formed by the oxidation of GeH_4 (or $GeCl_4$). The Si substrate and the Si which is formed by the pyrolysis of SiH_4 appear to reduce most of the GeO_2 to Ge. The existence of unpaired Ge probably contributes to the enhanced etching of the doped oxides (5:1 differential etch rate over thermally grown SiO_2). Elemental Ge also acts to reduce As_2O_3 that is formed during the oxidation of AsH_3. The elemental As thus formed in the doped film probably diffuses more rapidly than As_2O_3. However, the presence of As_2O_3 is necessary for the efficient transport of As across the Si-oxide interface. These effects can account for, (*i*) the higher As surface concentrations in Si after diffusions in O_2 from Ge-doped oxides, and (*ii*) the lower As surface concentrations in Si after diffusions in an H_2 ambient.

For 1000°C, 30-min diffusions in Si from As-doped oxide sources, the sheet resistance, R_S, decreases approximately as $(C_{O_2})^{-1}$. In terms of the molecular

fraction of As in SiO_2, $R_S \propto (C_{As}^{SiO_2})^{-2}$. As a function of time, R_S decreases as $t^{-1/2}$ for $t > 40$ min at 1000°C. For shorter times the diffusion of As is complicated by the changing surface concentration of the electrically active fraction of As.

A decrease in the concentration of electrically active As in the surface is observed for diffusions performed in O_2 with a preanneal in H_2. An increase in the concentration of electrically active As is observed when As diffuses into highly doped p-type Si. These variations can probably be explained by the influences of complexes and ion pairing or carrier mobility. Such effects were not included in the establishment of Irvin's curve.

Liquid Phase Epitaxial Growth of Silicon in Selected Areas

H. J. Kim

Bayside Research Center, GTE Laboratories Incorporated, Bayside, New York 11360

ABSTRACT

A liquid phase epitaxial technique has been used for growing thin Si-contact pedestals selectively on planar diffused diodes. Best results were obtained using a solution of 80 w/o (weight per cent) Sn and 20 w/o Pb with additions of 0.46 w/o Si and 0.1 w/o Ga and cooling at a rate of 0.8°C/min from 750° to 700°C. The amount of Si added was determined from a calculation based on the regular solution method. The various growth parameters used and their effect on morphology, doping level, nucleation, and growth, and the electrical characteristics of the contact pedestals are discussed.

The growth of various III-V compound-semiconductors by liquid-phase epitaxial techniques has been widely practiced (1-4). Recently, this technique was used also to grow low-defect-density silicon layers on {111} and {100} substrates (5). One of the advantages of the liquid phase epitaxial growth technique over the vapor phase epitaxial technique is that the growth can occur at a much lower temperature, making it possible to be below the polymorphic or plastic transformation temperature.

In this paper a liquid phase epitaxial technique is described for selectively growing highly doped epitaxial silicon pedestals for use as ohmic contacts on planar diffused diodes. The Si contact is believed superior to conventional metallic contacts, particularly for severe thermal environments where the temperature may fluctuate considerably creating openings in these whiskerless diodes. This selective growth technique could also be extended to produce elevated electrodes for a silicon photodiode array.

Key words: epitaxial, silicon, diode, ohmic contact, thermodynamics, phase diagram, gallium, tin, lead.

The basic mechanism of the LPE growth, and various parameters which affect the growth morphology, doping level, nucleation, and growth, are discussed. Also, thermodynamic calculations of Si-solubility limits for Sn-Pb alloys are given. Growth conditions found most suitable for the formation of silicon diode contact pedestals are described.

Experimental

A vertical solution-growth system similar to systems used for the growth of GaAs (6, 7) was adopted for this study. A horizontal growth-system (1) was also tried with less successful results. The system was operated using an H_2 atmosphere to prevent oxidation of the melt. However, there was always a thin layer of slag on the surface of the melt which attached to the substrate during dipping, resulting in nonuniform nucleation. To avoid such a slag-contact during dipping, a special substrate holder was devised. The specimen holder, shown in Fig. 1, facilitated isolating slag in one compartment created by the holder and allowed

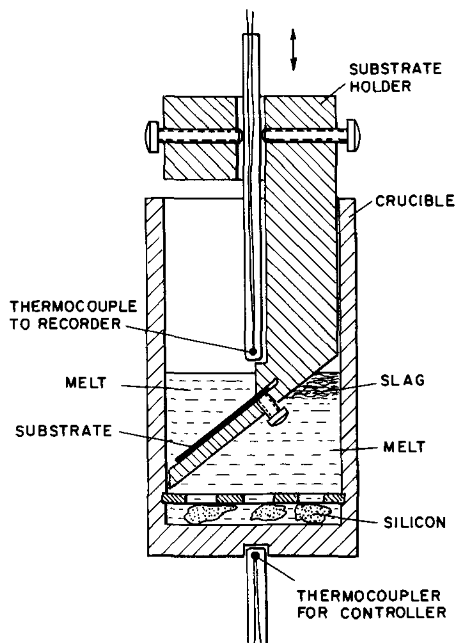

Fig. 1. Crucible and substrate holder

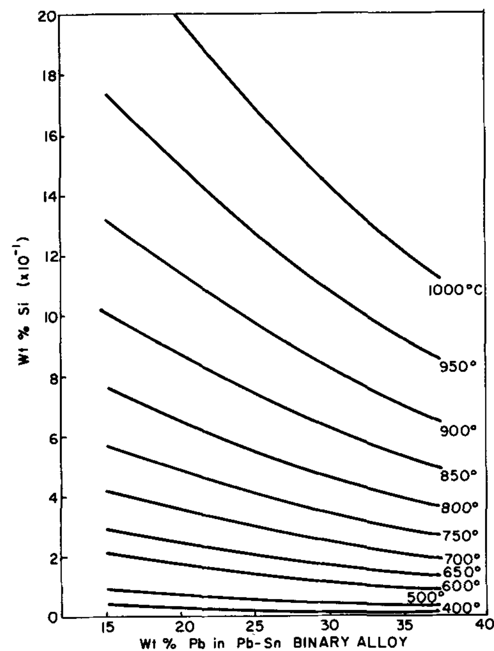

Fig. 2. Solubility of Si in Sn-Pb melts

fresh melt to wet the substrate. The holder and the crucible were made of either quartz or graphite.

A silicon planar diode slice having 127 μm (5 mil) diameter diffusion windows was chemically cleaned to remove thin oxide films in the diode windows. The cleaned surfaces were protected by immediately depositing a thin layer of Ni (or Au) nonelectrolytically. This wafer was then placed in the cold zone of the furnace, and after a hydrogen flow was established, the wafer was introduced into the melt. The Sn-Pb-Si melt composition used was determined from thermodynamic calculations based on the data from respective binaries as shown below. The amount of Ga added to the melt as a dopant was determined from several experimental runs. In general, the melt was maintained at an equilibration temperature about 200°C higher than the dipping temperature for several hours to homogenize the melt. The temperature was then reduced prior to insertion of the substrate.

After introducing the substrate into the melt, it was necessary to raise the melt temperature about 5°C above the initial dipping temperature to solution-etch the diode surface for improved wetting. A slow cooling rate of 0.8°C/min was initiated to permit uniform growth of silicon inside the windows. After the growth of epitaxial Si layers, the substrate was gradually withdrawn from the melt to the cold zone of the furnace to minimize thermal stress in the wafer.

Calculation of Si Solubility in Sn-Pb Melts

The solubilities of Si in Sn-Pb alloy melts can be calculated with emphasis on Sn-rich alloys using a regular solution approach originally used for the In-Sb-Ge system by Lehovec and Slobodskoy (8). Although a quasi-chemical approach has been used for similar systems (In-Ga-As, In-As-Sb, Ge-Si-Sn, and Ge-Si-Pb) by others (9), the assumption of a regular solution for the present system can be justified. This is based on the fact that all three elements are in the same column in the Periodic Table, indicating the least chemical interaction.

The activity coefficient of Si in Si-Sn-Pb ternary melts can be written as

$$\gamma_1 = \exp\left\{\frac{[(1-X_1)^2/RT]\cdot[A_{12}+A_{13}r-A_{23}r/(1+r)-T(B_{12}+B_{13}r)]}{1+r}\right\}$$

where X is the mole fraction, r the ratio of the mole fraction of Sn to that of Pb, and A and B are the interaction parameters. The numbers 1, 2, and 3 designate Si, Sn, and Pb, respectively. The plots of Si solubility in various Sn-Pb melts at various temperatures are shown in Fig. 2. The interaction parameters for Sn-Si and Pb-Si were obtained from Thurmond and Kowalchik (10). The interaction parameter A_{23} for Sn-Pb alloy was obtained by plotting T *vs.* X_{Sn} taken from the phase diagram since

$$A_{23} - B_{23}T = \frac{T\,\Delta S^f_{Sn} - \Delta H^f_{Sn} - RT\ln X_{Sn}}{(1-X_{Sn})^2}$$

The following are values of the constants used:

A_{12}	= 8,145 cal/mol	B_{12}	= 1.5 cal/mol
A_{13}	= 19,830 cal/mol	B_{13}	= 4.58 cal/mol
ΔS^f_{Sn}	= 3.3 cal/mol deg.	ΔH^f_{Sn}	= 1,665 cal/mol
A_{23}	= 1,790 cal/mol	B_{23}	= 0

Results and Discussion

Growth of undoped silicon pedestals.—The regular solution approach provided a guide to determine the amount of Si required to saturate an 80-20 Sn-Pb melt, and a relatively wide temperature range was studied for silicon LPE growth using these melts. The best results were obtained when the growth was initiated at a temperature of 750°C. According to the calculation, 0.46 w/o (weight per cent) Si is the solubility limit in an 80-20 Sn-Pb melt at 750°C.

Figure 3 shows the growth of Si pedestals having hexagonal morphology on (111) substrate. Figure 4 is a similar growth on (100) silicon substrate. The facet formation, terminating at the apex of the pedestal, is a most pronounced feature. The criteria used to judge the quality of undoped silicon pedestals were uniformity in height and size, restricted lateral growth, flatness of the top of the growth, and cleanliness of the slice surface after growth.

There was one major difficulty in choosing an optimum melt composition and growth temperature. As shown in the hypothetical ternary phase diagram (Fig. 5) which was deduced from the three binaries, there exists an immiscible two-liquid zone. The extent of this zone has not been determined. If the two-liquid

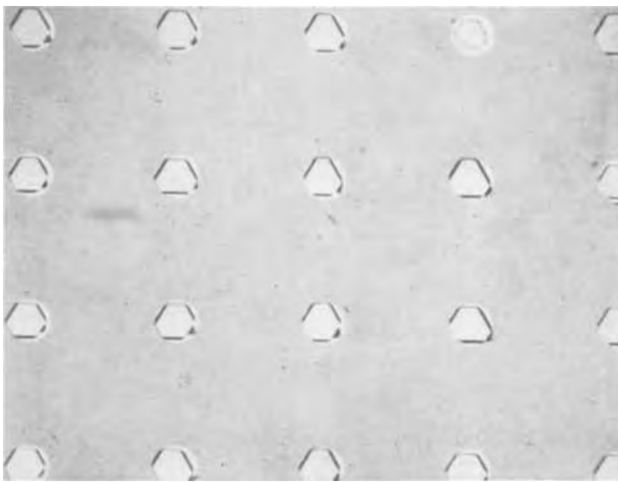

Fig. 3. Growth temperature 750°-700°C. Undoped silicon growth on (111) substrate.

Fig. 4. Growth of undoped silicon pedestals in oxide windows on (110) substrate.

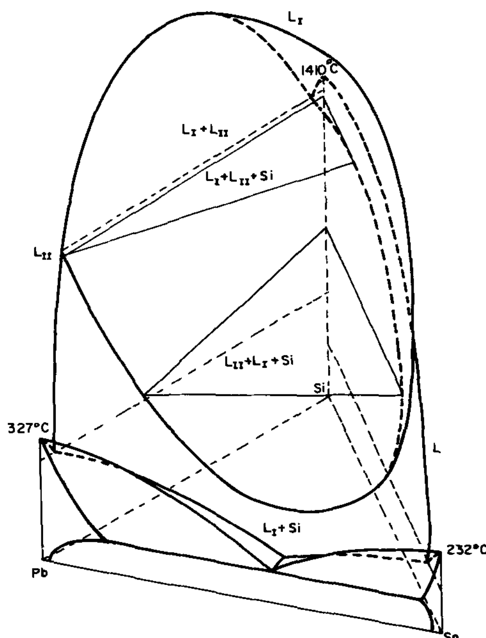

Fig. 5. Hypothetical ternary diagram of Sn-Pb-Si showing an immiscible two-liquid zone.

zone extends down to the growth temperatures used (750°-700°C), the epitaxial growth must occur by the monotectic reaction where only Liquid I is responsible for the formation of solid silicon and the heavier Liquid II remains at the bottom of the crucible. In a few cases, it was observed that the lower part of the substrate did not have any growth but was solution-etched. It is not possible to determine whether such results indicate the passage through the two-liquid zone during cooling or the existence of nonequilibrium Liquid II which occurred at the higher homogenization temperature (900°C) employed before the growth.

The optimum cooling rate for the growth should be dictated by the speed with which silicon atoms diffuse to the growth interface since the total amount of silicon dissolved in the solution is small. Because the present LPE growth process occurs under a transient condition without ever reaching a steady-state condition, and the thickness of the growth is small, it is highly unlikely that constitutional supercooling will occur during growth. According to Tiller *et al.* (11), there must be an incubation distance for the occurrence of the constitutional supercooling and the distance is of the order of 1 mm for a typical experimental case. The observed flat growth interface further verifies the absence of such supercooling. Thus, the energetics associated with impurity and Si incorporation at the growth interface are more important aspects to be considered.

Doped Silicon Growth

Several solutions (Al, Ga, Pb, Sn, and Pb + Sn) containing silicon were used in attempts to grow highly doped p-type Si-contact pedestals on diodes. The main problem associated with incorporating a p-type doping impurity in the growth was the resulting change of nucleation and growth energetics. This change appears to be delicately balanced with respect to the dopant concentration, the cooling rate, and the growth temperature. For example, various Ga additions ranging from 0.001 to 1.0 w/o in Sn solutions were tried to grow p^+ pedestals at 850°C. There was, for a given cooling rate, a critical dopant concentration, below which no appreciable growth was observed. Such a critical concentration was also affected by the type of protective metal film used (either Ni or Au). Apparently, the combined effect of Ni or Au and Ga atoms alters the surface energy state of the substrate.

The best results were obtained using the same growth temperature (750°-700°C) and the same Pb-Sn melt composition (20-80 w/o) as used in the undoped Si growth plus ~0.1 w/o Ga. A cooling rate of 0.8°C/min was also the optimum value for high yield and uniform growth as seen in Fig. 6a. This growth condition produced well-defined silicon contacts as shown in the cross-sectional view of the growth (Fig. 6b). Little change was produced in electrical characteristics of the junctions, as illustrated in Fig. 7.

Neither Ni nor Au protecting films affected the growth for Pb-Sn melts. However, both higher dopant concentration (0.2 w/o) and faster cooling rate (1.6°C/min) produced a poor yield and nonuniformity in growth. Although slower cooling rates or lower dopant concentrations yielded a good morphological result, the amount of dopant incorporated in the growth was not high enough for good forward characteristics of diodes. Lower doping concentrations confirm the theoretical prediction as shown in the following equations (12, 13).

$$C_s = k_e C_o (1 - g)^{k_o - 1}$$

and

$$k_e = \frac{k_o}{k_o + (1 - k_o) \exp\left(\frac{-Rd}{D}\right)}$$

where C_s is the concentration of dopant in the epitaxial growth, C_o the average concentration of dopant in the liquid, k_o the ratio of concentrations of the dopant in the solid and the liquid in equilibrium with it, g the fraction of the liquid that has solidified in the system, and d the thickness of the boundary layer through

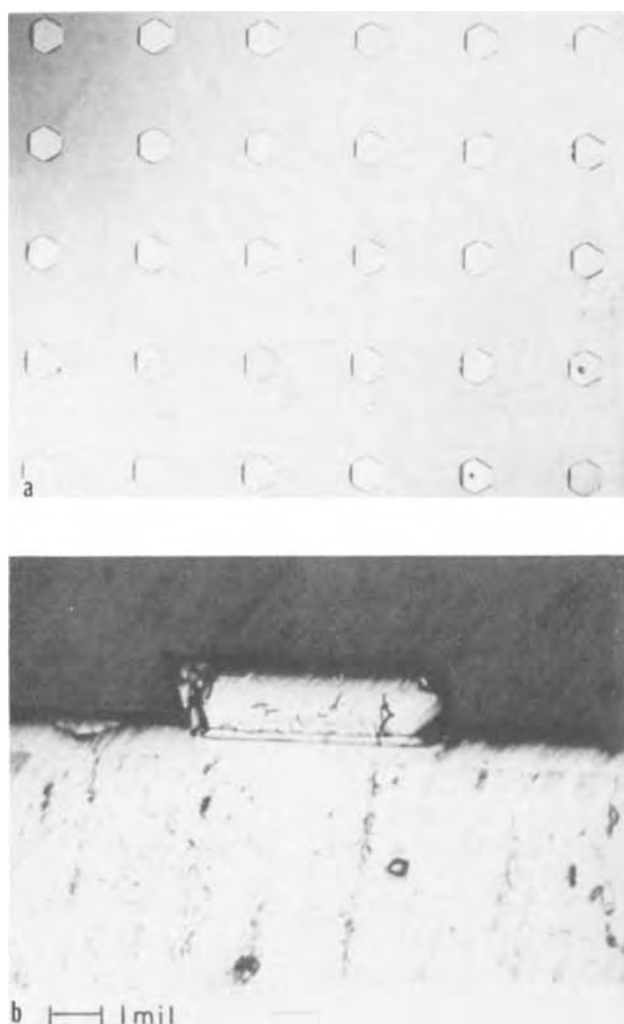

Fig. 6. Growth of Ga-doped Si contact pedestals on (111) substrate. (a) Top view; (b) cross-sectional view. Vertical lines may be dislocation loops.

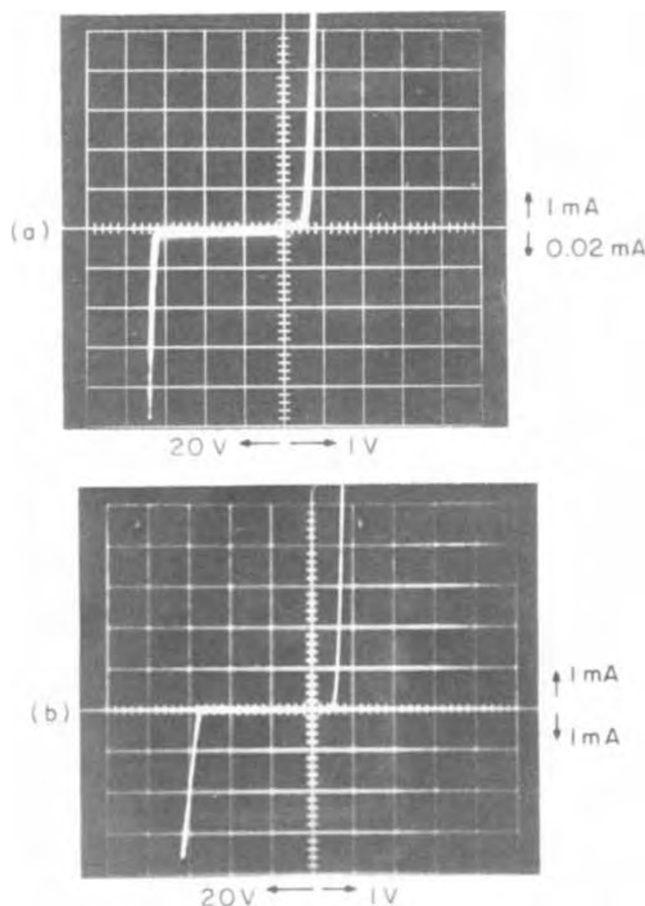

Fig. 7. Forward and reverse bias characteristics of silicon diodes. (a) Through Si-contact pedestal, (b) without the pedestal.

which the solute must diffuse (10^{-1}-10^{-3} cm). The effective distribution coefficient k_e, which is defined as the ratio of the concentrations of solute in the solid that is formed to the average value for the liquid, approaches the maximum value of one as the growth rate (R) increases and $k_e = k_o < 1$ at very low growth rates. Also, in view of the above equation, no stirring or agitation was employed in the present experiment. This permits the incorporation of as much dopant as possible, since the mixing of the liquid decreases d and effectively increases the diffusion coefficient D of the dopant.

In addition to the effect of dopant concentration and cooling rate on nucleation of Si layers, impurity atoms and solvent atoms are known to greatly influence the growth morphology. In growing pure Si from a Si melt, (111) planes are the slowest growing and most stable faces. The epitaxial growth of Si on a (111) substrate can be treated as the growth of a twin having the substrate plane as a twin plane. According to Wagner (14), in the twin plate having a hexagonal morphology bounded by (111) planes, the re-entrant twin edge is a nucleation site for new layers on the edges of the plate, and growth occurs in a <112> direction. However, impurity or dopant atoms and solvent atoms can alter the surface energy of the substrate stabilizing other crystallographic planes, and this change in turn affects the size-to-thickness ratio of the growth pedestals. Faust *et al.* (15) examined platelets of Si grown from several metal solutions and ranked them in order of increasing size to thickness ratio as follows

$$\mathrm{Au} \approx \mathrm{Au} + \mathrm{Sb} \approx \mathrm{Au} + \mathrm{Ga} < \mathrm{Sn} \approx \mathrm{Ga} < \mathrm{Zn} < \mathrm{Ag} < \mathrm{Al}$$

It was impossible to deduce from the above findings how the combination of Ni (or Au used for substrate protection), Sn, Pb, and Ga would affect the growth morphology. Only an empirical determination of the optimum concentration of the various elements plus the optimum cooling rate and growth temperature was possible in obtaining a desirable size-to-thickness ratio of the growth.

Summary

The liquid-phase epitaxial technique for growing thin Si-contact pedestals on 127 μm (5 mil) diameter diodes was demonstrated. This process was found to be very sensitive to melt composition, cooling rate, and growth temperature. The critical parameters which give an optimum growth with respect to yield, size, and substrate cleanliness were obtained. A solution of 80 w/o Sn and 20 w/o Pb with 0.46 w/o Si and 0.1 w/o Ga additions produced the most favorable growth. The optimum cooling rate and growth temperature range were 0.8°C/min and 750°-700°C, respectively. The solubility limits of Si in Sn-Pb solutions were calculated assuming regular solutions and used as a guide to prepare a saturated solution at a given growth temperature. The Au or Ni film used as a protective coating prior to growth did not affect the growth of Si from Sn-Pb melts. For the maximum incorporation of Ga into the pedestal, it was necessary to keep the solution from being agitated during growth.

Chlorine Adsorption at a Titanium Surface

Segregation from the Bulk Crystal

Interaction with Chlorine Gas

Tennyson Smith

Science Center, North American Rockwell, Thousand Oaks, California 91360

ABSTRACT

Experiments have been conducted with a single crystal of Ti [exposing the (0001) face] in an ultrahigh vacuum system ($\sim 10^{-10}$ Torr) using Auger spectroscopy, ellipsometry, and surface potential difference measurements to monitor adsorbed chlorine on the surface. It was discovered that although the impurity level of chlorine and sulfur in the bulk crystal are < 1 ppm, these elements segregate from the bulk to the crystal surface at elevated temperatures with a segregation coefficient $\sim 10^5$ to 10^6. Above 600°C sulfur displaces the chlorine from the surface. Segregation coefficients and diffusion coefficients are measured for chlorine as a function of temperature. Adsorption of chlorine gas on a clean Ti surface occurs as a nonactivated process with a sticking coefficient ~ 0.05. The adsorption isotherms are consistent with dissociation of molecular chlorine to atomic chlorine. The change in work function of the Ti surface with a monolayer of Cl with respect to a clean surface is +1.2V. The index of refraction of the film is about 2.4 and the thickness of a monolayer is approximately 4.5Å. Ellipsometer data show that more than a monolayer of chlorine will form at room temperature and a chlorine pressure of $\sim 10^{-7}$ Torr. It is concluded that at room temperature the diffusion coefficient and segregation coefficient are much too low to allow chlorine to segregate to the surface at a crack tip during stress corrosion cracking unless the stress and increased local temperature are sufficient to lower the diffusion activation energy.

The stress corrosion cracking (SCC) of Ti alloys in aqueous solutions has been related to the chloride ion concentration in solution (1-3). However, as the chloride ion concentration is decreased the rate of crack propagation asymptotically approaches a limiting value.

The question arises as to the possibility that chlorine impurity within the Ti metal may segregate from the bulk to the crack tip surface, thus providing the chlorine atoms. It has been shown (4, 5) and is shown in this paper that indeed chlorine atoms of very small concentration in the Ti bulk (~ 0.2 ppm) segregate to the Ti surface with a very large segregation coefficient (~ 1 Cl atom per 3 Ti atoms) if the temperature is high enough. However, it is concluded that the rate of segregation is much too slow and the segregation coefficient too small to account for an appreciably Cl segregation at a crack surface at room temperature. The possibility that the stress in the crack tip region lowers the activation energy for diffusion sufficiently to allow rapid diffusion to the crack tip region at room temperature needs further investigation.

Key words: ellipsometry, Auger spectroscopy, surface potential measurements.

Experimental

The ultrahigh vacuum system was a Varian low energy electron diffraction unit (Model 981) with special windows in side flanges for ellipsometry.

Ellipsometry.—A good description of ellipsometry can be found in Ref. (6). In brief, when plane polarized light is reflected from a surface the light becomes elliptically polarized. That is, the surface renders a phase shift (Δ) in the normal and parallel components of the polarized light as well as a change in the ratio of the amplitudes ($\tan \psi$) of these components. The experimental parameters measured with the ellipsometer are the polarizer angle p and the analyzer angle a, which are directly related to Δ and ψ; $\Delta = 2p + \pi/2$ and $\psi = a$ (in zone 1). There are four quadrants (zones) related to the polarizer, analyzer, and compensator angles. It has been shown (6) that averaging

the readings in all four zones minimizes the alignment errors. Unless otherwise stated, the ellipsometric results were obtained by averaging the data in the four zones. A compensator (quarter wave plate) is used to compensate for the ellipticity such that the reflected beam is plane polarized and thus can be nulled with the analyzer.

If the surface is clean, Δ and ψ are directly related to its complex index of refraction $\hat{n}_s(\equiv n_s(1 - i\kappa_s))$. The subscripts of the real part n_s and imaginary part κ_s, refer to the substrate the subscript f will refer to the film. κ_s is sometimes referred to as the attenuation index or extinction coefficient. If the surface has a film of different index ($\hat{n}_f \neq \hat{n}_s$), Δ and ψ (and therefore p and a) are directly related to $\hat{n}_s$, $\hat{n}_f$, and the film thickness.

Components of a Rudolph ellipsometer (sensitivity 0.01°) were mounted such that the beam from a mercury arc passed through a filter (removed 99% of the light except in the range 5100-5650Å) to isolate the 5461Å spectral line. The polarizer and compensator were placed before the reflecting surface, with the analyzer and detector after the reflecting surface.

Angle of incidence.—To obtain a very accurate value for the angle of incidence, a quartz prism was mounted directly above the sample. The prism was designed (7) such that, when the beam which was reflected from its base surface and the beam which was reflected from the internal prism surfaces were in coincidence, the base surface was aligned with an angle of incidence 79.81°. The sample could then be aligned to within 0.01° of this angle.

Windows.—It is imperative to minimize the birefringence of windows in order to obtain accurate values for the optical constants by ellipsometry. Fused silica windows, selected for very low birefringence were obtained[1] and sealed on to quartz to Pyrex to stainless steel (⅞ in. OD) tubes. These window assemblies were then welded to Conflat flanges to match the UHV system. To test the windows, two of the steel tubes were connected to a rubber hose with a tee connection for attaching to a vacuum pump. The windows were then placed in the ellipsometer in the straight through configuration. The windows were rotated with and without vacuum while observing the photometer indicator in its most sensitive mode. Movement of the photometer needle of less than the smallest division, when the windows were placed in the beam, indicated the birefringence of the windows was negligible ($\sim$0.01°) with or without vacuum. After welding the steel tubes to the flanges, ellipsometric readings were made on the polished Ti sample in the UHV system. Changes of the p and a values were $\sim$0.01°. It was concluded that window effects are negligible.

Auger electron spectroscopy.—The Auger electron spectrometer was constructed as a four grid system according to Palmberg and Rhodin (8). The grid system was made of 1 mil 100 $\times$ 100, Type 304 stainless steel wire mesh ($\sim$81% transparent) that was formed with the technique described by Todd (9). The electron gun was a Model SE-3K 15μ obtained from Superior Electronics,[2] modified with a 1 $\times$ 5 mil W ribbon filament and operated at 3 kV. The electron beam had an angle of incidence of 80° with respect to the sample. The Auger measurement yields the derivative of the energy distribution function ($dN(E)/dE$) *vs.* the voltage applied to the retarding grid (E).

Work function measurements.—The surface potential difference (SPD) between the sample and a W reference electrode was measured by the Kelvin vibrating capacitor technique and was automatically recorded by the servo-mechanism of Palevsky (10). The W reference electrode was mounted on a flange with a bellows such that it could be vibrated from outside the vacuum system and positioned adjacent to the sample as desired. The reference electrode could be cleaned by resistive heating.

Sample manipulation.—The sample was mounted on a Varian multipurpose feed-through (954-5031) and could be rotated into position for simultaneous SPD and ellipsometer measurements or rotated 180° from this position for Auger measurements. The sample holder was made of Mo. Immediately behind the sample was a W filament heating element. Two thermocouples touched the sample surface at different points. The temperature could be maintained constant to ±3°C by a temperature controller connected to a third thermocouple.

Ion guns.—A Cs ion gun was constructed by melting a few milligrams of Cs impregnated zeolite on a platinum ribbon. The ribbon was connected to W leads that were electrically insulated from the stainless steel cylinder surrounding the ribbon. The ribbon could be heated to drive off Cs^+ which was accelerated to the crystal by giving the ribbon a positive potential with respect to ground. A grid a few millimeters in front of the ribbon could be given a negative potential with respect to the ribbon in case the ion current became limited by saturation of the ion vapor at the ribbon surface. The ion current was monitored by placing a high impedance electrometer between the sample and ground. The ion current, I, only indicates the flux of Cs^+ that is adsorbed and neutralized by an electron in the crystal or receives an electron from the crystal and desorbs as an atom. If ions are reflected from the crystal surface as ions and become neutralized at the walls of the UHV system they are not monitored by the electrometer. The advantages of the Cs ion gun are: (*i*) it can be operated in the system with ultrahigh vacuum; (*ii*) it can be used to sputter clean and etch at high voltage or for Cs adsorption at low voltage; and (*iii*) currents up to 50 μA can be obtained, depending on the crystal substrate. For example, good conducting surfaces (metals) give high currents, poor conducting surfaces such as Si_3N_4/Si charge up and currents of the order of 1 μA or less are obtained. With titanium specimens the Cs^+ gun is undesirable because both Cs and Ti have an Auger peak at about 47 eV, which is the most indicative of the Ti surface cleanliness. However, if no peaks were observed at 560 and 580 eV for Cs, the 47 eV peak was interpreted to be due to Ti.

The Ar ion gun was a Varian Model 922-0013. Argon bombardment is advantageous with titanium specimens since the Auger peaks do not coincide. However, Ar must be let into the system and only low currents can be obtained in the pressure range necessary to keep the Vac Ion pumps working ($< 10^{-5}$ Torr).

Samples.—The Ti sample was 1 $\times$ 11/32 $\times$ 1/16 in. single crystal cut to expose the (0001) basal plane. The surface was polished to a mirror finish with 600 silicon carbide paper and etched to remove surface damage. The final chemical polish consisted of 1μ alumina in a solution, 1 part ammonium hydroxide, 1 part distilled water, and 1 part 30% hydrogen peroxide. The hydrogen peroxide was added last and was fresh. A Microlon "D" pad was mounted on the chemical lap and the sample was held down with heavy pressure for approximately 5 min. The surface was specular but not optically flat. The sample and manipulator were ultrasonically cleaned in acetone before placing in the UHV system.

Chlorine pressure.—A Varian dual range ionization gauge (Model No. 971-0014) was used to measure the gas pressure. A table of ionization probability values was supplied with the ionization gauge, for various gases. These values are used to calculate the correct pressure from the meter reading with the meter calibrated for N_2. No ionization probability for Cl_2 was

[1] Dynasil Corporation, Berlin, New Jersey.
[2] 208 Peagent Ave., Clifton, New Jersey 07015.

available. A fairly smooth correlation exists between the ionization probabilities (compared to N_2) and the mass spectroscopic sensitivities compared to N_2, for various gases (see Table I). From the mass spectroscopic sensitivity of 2 for Cl_2 (as compared to N_2) the ionization probability was estimated to be 2. The meter readings were therefore multiplied by 2 to obtain the Cl_2 pressure.

Results

Chlorine and Sulfur Segregation

Auger spectrograms.—For comparison with the Auger spectrograms reported here, Table II gives the electron energy values for which Auger peaks have been observed for various elements. Figure 1 shows the Auger spectrogram for the Ti sample immediately after placing it in the UHV system. The major peak at 272V indicates heavy carbon contamination which remained after cleaning the sample in acetone. Aside from the Ti peaks and the C peak, small peaks are observed for O, S, and Cl. Figure 2 is the Auger spectrogram for the Ti sample after heating to 600°C for about 2 min. The instrument sensitivity was 2.5 times greater for Fig. 2 than for Fig. 1, therefore, for comparison with Fig. 2, the peak heights in Fig. 1 should be multiplied by 2.5. Heating the sample has removed much of the carbon contamination but has caused Cl and S to segregate from inside the Ti crystal to the surface. The possibility that Cl and S are degassed from the adjacent sample holder and heater does not seem likely because these contaminants did not appear on heating freshly deposited Al films on Al samples in the same holder. Study (11) of the interaction of chlorine gas with Al films showed that stable chloride films are formed at room temperature and Cl_2 pressure $\sim 10^{-7}$ Torr. No Cl or S was detected on the Ti sample after heating the adjacent W reference electrode to 1200°C.

The Auger peak to peak heights, defined as the distance between the top and bottom of a peak (see the arrows in Fig. 2), will be designated APPH. The units of $dN(E)/dE$ and APPH are arbitrary, so that, only the relative magnitudes have significance.

Figure 3 shows, as a function of the time of heating, the Auger peak to peak heights for Cl and S, and the 47 eV peak (interpreted as Ti, since no peaks at 560 and

580 were observed for Cs). At 500°C for the first 90 min the Cl APPH increased rapidly then leveled off at about 130. Since the 47 eV electrons for Ti relate primarily to the outermost layer of Ti, the Ti (47) APPH is complimentary to the Cl APPH and decreases from 195 to 28. At 90 min the surface was bombarded with Cs^+ at 500V, 5 μA, 500°C for 5 min. The Cs^+ sputtering removed Cl (lowered Cl APPH from 130 to 25) and increased the Ti (47) APPH. Further heating of the sam-

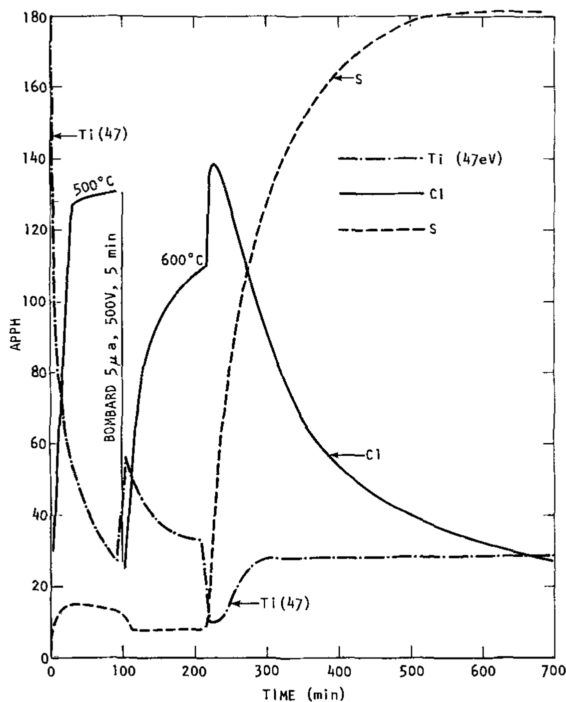

Fig. 3. Auger peak to peak heights (APPH) for Ti (47 eV), Ti (380 eV), Cl, S, C, and O as a function of time and temperature.

ple at 500°C caused the Cl to segregate again but at a slower rate. The S APPH increased from about 2 to 15 during the first 90 min and decreased to 8 by the Cs^+ bombardment. Although the C APPH only changed slightly (APPH ~ 22), the O APPH decreased from ~15 to zero in 20 min, then increased to 2 during the first 200 min. At 210 min the temperature was increased to 600°C. The C and O peaks were not observed on the spectrogram after about 10 min at 600°C. The S APPH increased rapidly and leveled off at about 180 at 700 min. The Cl APPH increased sharply during the first 10-15 min at 600°C, then decreased as the Cl was displaced by S. The high energy 380 eV Ti peak (APPH ~ 35) was only slightly affected during the entire treatment, indicating that the heat-treatment has little effect on Ti two or three atom layers beneath the surface.

Cs^+ bombardment.—In Fig. 4 a plot is given of the ratio of the APPH of Ti (47 eV peak) Cl and S to that

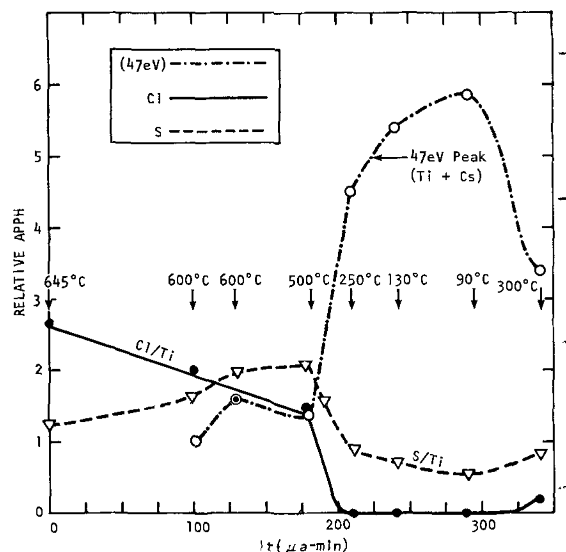

Fig. 4. APPH for Cl, S, and the 47 eV peak (Ti or Cs) as a function of Cs^+ bombardment at 500V. The temperature was changed, during the bombardment, to those indicated across the plot.

of Ti (380 eV) as a function of ion bombardment exposure at various temperatures. Since the APPH for Ti (380 eV) is only slightly affected by adsorption at the surface for low coverage, the ratio of the APPH values to that for Ti (380 eV) at low coverage is used in order to avoid the necessity of calibrating the Auger spectrometer for each measurement. In the temperature range from 645° to 500°C, and integrated ion current (It = 0 to 180 μA-min), the Cl peak decreased and the S and Ti (47 eV) peaks increased. Lowering the temperature to 250°C caused the Cl peak to rapidly approach zero and the S peak to decrease. The peak at 47 eV is drastically increased (due to the Cs and Ti 47 eV peaks) on removal of Cl and S from the surface. Increasing the temperature from 90° to 300°C caused a reappearance of the Cl peak and corresponding decrease in the Ti (47 eV) peak. The Ti surface can be cleaned of Cl and S if the temperature is low enough that the rate of segregation is slower than the sputter cleaning process. However, one cannot be sure that the surface is not contaminated with Cs. Other experiments have shown that bombardment with Ar ions also cleans the surface of Cl and S but leaves Ar if the temperature is too low. The cleanest Ti surface (very small Ar, Cl, and S peaks) was obtained by bombarding with Ar ions at about 550°C.

Figure 5 shows Auger results for the APPH of chlorine relative to the Ti 380 eV peak (designated Cl/Ti), as a function of time, temperature, and Cs^+ bombardment. From Fig. 5 an estimate of the diffusion coefficient and concentration of chlorine on the surface and in the bulk can be made.

Diffusion coefficient.—The diffusion equations are developed in the Appendix for the following model. It is assumed that the process controlling the rate of Cl segregation at the Ti surface (as in Fig. 5) is diffusion of Cl in the bulk crystal to the interface. Thus, each time the crystal is annealed the surface concentration ($C_s(t)$) approaches equilibrium with respect to the bulk concentration ($C(l,t)$ and each time the surface is cleaned a concentration gradient forms within the crystal, causing the Cl to diffuse to the surface. It is assumed that the process of atom transfer from within the crystal (adjacent to the surface) is rapid with respect to diffusion to the interface so that equilibrium is maintained between the bulk and the surface at the interface. This boundary condition is expressed

$$C_s(t) = KC(l,t) \quad [1]$$

where K is the equilibrium constant. K has the same dimensions as the crystal thickness l (*i.e.*, centimeters) since $C(l,t)$ has the dimension atoms/cubic centimeter and $C_s(t)$ has the dimension atoms/square centimeter.

Plots of $C_s(\infty)$-$C_s(t)$ *vs.* t are given on semilog paper in Fig. 6, which corresponds to the data between $t = 0$ and $t = 100$ min (524°C), and $t = 107$ to 120 min (670°C) in Fig. 5. From analysis of the theoretical equation

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial x^2} \quad [2]$$

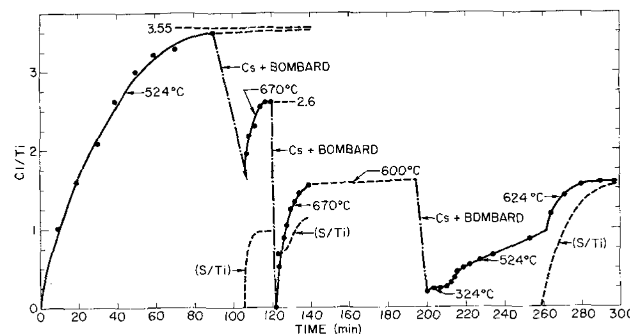

Fig. 5. Plot of chlorine segregation vs. time at various temperatures. The dashed line marked S/Ti represents sulfur segregation.

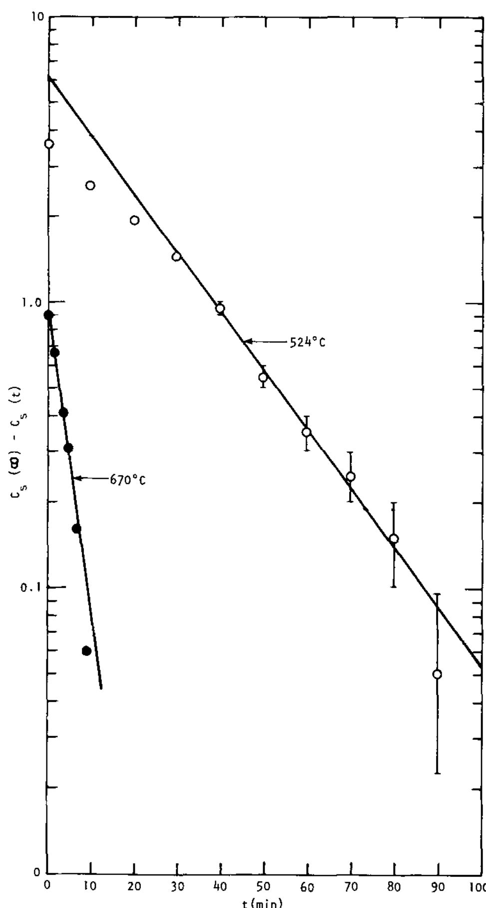

Fig. 6. Plot of $C_s(\infty) - C_s(t)$ vs. time

(see the Appendix), the plots in Fig. 6 should be linear at large t, as observed. As $C_s(t) \rightarrow C_s(\infty)$ at 100 and 120 min, the relative experimental error becomes very large. Extrapolation of the upper line of Fig. 6 (524°C data) to $t = 0$ gives an intercept of 6.2. As shown in the Appendix, this intercept is equal to

$$2l^2KC_o/[l(l + K) + K^2\kappa_1^2] \approx 6.2 \quad [3]$$

where $C_o = C(x,0)$ is the homogeneous concentration after an anneal and κ_1 is the first root of the transcendental equation. At $t \rightarrow \infty$

$$lKC_o/(l + K) \sim 3.55 \quad [4]$$

where 3.55 is estimated to be the equilibrium value in Fig. 5. One of the roots of the transcendental equation (Appendix, Eq. [A-12]) is

$$\kappa_1 K/l = -\tan \kappa_1 \quad [5]$$

Solving Eq. [3], [4], and [5] yields

$$\kappa_1 = 2.87 \quad [6]$$

$$K/l = -0.097 \quad [7]$$

$$K = 0.0154 \quad [8]$$

since the thickness of the crystal was $l = 0.159$ cm. The slope of the line (524°C) in Fig. 6 (see Eq. [A-15], [A-16], and [A-17], Appendix) yields

$$\tau_1 = l^2/\kappa_1^2 D \approx 1250 \text{ sec} \quad [9]$$

where τ_1 is a time constant and D is the diffusion coefficient. The diffusion coefficient for Cl in Ti at 524°C proves to be

$$D \approx 2.4 \times 10^{-6} \text{ cm}^2/\text{sec} \quad [10]$$

Similar calculations for the 670°C line yields

$$\kappa_1 = 2.0 \quad [11]$$

$$K/l = 1.1 \quad [12]$$

$$K = 0.175 \quad [13]$$

$$D = 2.6 \times 10^{-5} \text{ cm}^2/\text{sec} \quad [14]$$

From values of D at the two temperatures the following equation for the diffusion of chlorine in Ti is obtained

$$D \approx 9 \exp(-24{,}100/RT) \text{ cm}^2/\text{sec} \quad [15]$$

and

$$K \approx 10^5 \exp(-25{,}000/RT) \text{ cm} \quad [16]$$

Chlorine concentrations.—As will be shown, adsorption of a monolayer of chlorine from the gas phase yields a value of (Cl/Ti) ≈ 9.1. Based on the ionic and atomic diameters (*i.e.*, Cl^- 3.6Å, Ti 2.6Å), Anderson and Gani (12) show that for a regular array of Cl^- on a Ti (0001) face, $C_s \sim 4.5 \times 10^{14}$ ions/cm² and for a random array $C_s \sim 3 \times 10^{14}$ ions/cm². The average, $C_{s,avg} \approx 3.7 \times 10^{14}$ ions/cm², is in close agreement with the measured (10) value ($C_s \approx 3.6 \times 10^{14}$ ions/cm²). Therefore the surface concentration can be calculated from the Auger values of (Cl/Ti) as

$$C_s(t) \approx [(\text{Cl/Ti})/9.1] \times 3.6 \times 10^{14} \text{ atoms/cm}^2 \quad [17]$$

The value of the bulk concentration, $C_{o,o}$, at $t = 0$ in Fig. 5, can be obtained from the kinetic data (Eq. [4] and [8]); if the value $C_s(\infty) \approx 3.55$ is multiplied by $3.6 \times 10^{14}/9.1$ (Eq. [17]) to obtain units of atoms/square centimeter, *i.e.*

$$C_{o,o} \approx 10 \times 10^{15} \text{ atoms/cm}^3 \quad [18]$$

A similar calculation for $C_{o,100}$ from $C_s(\infty) \approx 2.6$ at 120 min yields

$$C_{o,100} \approx 1.2 \times 10^{15} \text{ atoms/cm}^3 \quad [19]$$

A check on the values from the kinetic data can be made with the equilibrium data as follows: since at equilibrium the concentration in the bulk will be directly proportional to that on the surface, $C_{o,100}/C_{o,120} \approx 3.55/2.6 = 1.36$. Also a mass balance gives $(C_{o,100} - C_{o,120}) = 0.9 \times 3.6 \times 10^{14}/9.1 = 3.6 \times 10^{13}$ atoms/cm², where 3.6×10^{13} corresponds to the amount of Cl transferred from the bulk to the surface between $t = 107$ and 120 min (Fig. 5). Solving for $C_{o,100}$ and $C_{o,120}$ yields

$$C_{o,100} \approx 0.8 \times 10^{15} \text{ atoms/cm}^3 \quad [20]$$

$$C_{o,120} \approx 0.6 \times 10^{15} \text{ atoms/cm}^3 \quad [21]$$

The correlation between the kinetic result in Eq. [19] and the equilibrium result in Eq. [20] for $C_{o,100}$ is considered to be good, lending support to the proposed segregation model.

Prior to the experiment represented in Fig. 5, about 5×10^{14} atoms/cm² had been removed by ion bombardment. Therefore the initial impurity concentration in the Ti crystal was $\sim 1.3 \times 10^{16}$ atoms/cm³, or 0.2 ppm, since there are $\sim 5.68 \times 10^{22}$ atoms Ti/cm³. If the concentration on the surface is expressed in volume units rather than surface units, using 4.5Å as the thickness of a chlorine monolayer, a segregation coefficient can be defined as (see Eq. [2])

$$K_s = K/4.5 \times 10^{-8} = 2.2 \times 10^7 K \quad [22]$$

From Eq. [8] and [22], at 524°C

$$K_s \approx 3.4 \times 10^5 \quad [23]$$

and at room temperature (using Eq. [16])

$$K_s \approx 1.3 \times 10^{-6} \quad [24]$$

Chlorine Adsorption From the Gas Phase

Ellipsometric and SPD results.—Ellipsometric values for p and a were measured before and after exposure to chlorine gas. From these values of p and a the refractive index of Cl adsorbed on Ti was calculated to be approximately 2.4 (if it is assumed that the film is

transparent to 5461Å light). Plots of the calculated change in film thickness as a function of time (for $P_{Cl} \approx 2 \times 10^{-7}$ and $P_{Cl} \approx 10^{-7}$ Torr, and room temperature) are given in Fig. 7(a). The experimental values of the change in Δ (*i.e.*, $-\delta\Delta$) are given on the right ordinate in Fig. 7(a). The change in film thickness per degree change in $-\Delta$ proves to be ~4.25Å. The change in film thickness per degree change in ψ is ~14.7Å.

The SPD results, which correspond to the ellipsometer results, are given in Fig. 7(b), with an additional curve for $P_{Cl} \approx 2 \times 10^{-8}$ Torr. ΔV is the surface potential difference between the Ti surface and the polycrystalline W reference electrode. $\delta(\Delta V)$ is the change in ΔV from the value for the clean Ti surface. Values of $\delta(\Delta V)$ are positive and level to approximately constant values with time. This indicates that the chlorine concentration on the surface approaches its equilibrium value at a particular chlorine pressure (P_{Cl}) and temperature (24°C). However, the ellipsometric results show that the Cl film thickness does not level off in the time of the experiment. This indicates that a second layer is forming. Apparently the SPD and Auger measurements are only sensitive to the outer layer, whereas the ellipsometer detects further film growth at room temperature. For comparison with our SPD measurements note that Anderson and Gani (10) observed $\delta(\Delta V) \approx 2.1$V for a film, 5 atom layers of Cl on Ti (presumably at $P_{Cl} \sim 10^{-3}$ Torr). They found that exposing the Ti sample to $P_{Cl} = 10^{-3}$ Torr at 600°K for 10 min, followed by pumping then cooling to room temperature removed some Cl and reduced $\delta(\Delta V)$ from 2.1 to 1.1. The value of 1.1V corresponds with the result in Fig. 7(b) for $P_{Cl} \sim 10^{-7}$ Torr, with about 1.5 atom layers of chlorine.

There is a slight change in slope of the thickness and $\delta(\Delta V)$ *vs.* t curves ($P_{Cl} \approx 2 \times 10^{-7}$ Torr) at about 600 sec (Fig. 7). This effect has been observed (9) for Cs adsorption on Ti and W, and is interpreted to indicate the beginning of a second layer. If this is the case [from Fig. 7(a)] the thickness of the first monolayer of Cl on Ti is about 4.5Å. This corresponds with the average of the Cl^- diameter (3.6Å) and the TiCl diameter (5.4Å).

Auger results.—Figure 8 shows the ratio of the APPH for chlorine to that for Ti (380 eV), referred to as (Cl/Ti), as a function of time and chlorine pressure. The curve at 2×10^{-8} Torr chlorine pressure (Fig. 8) increases with time but levels to a constant

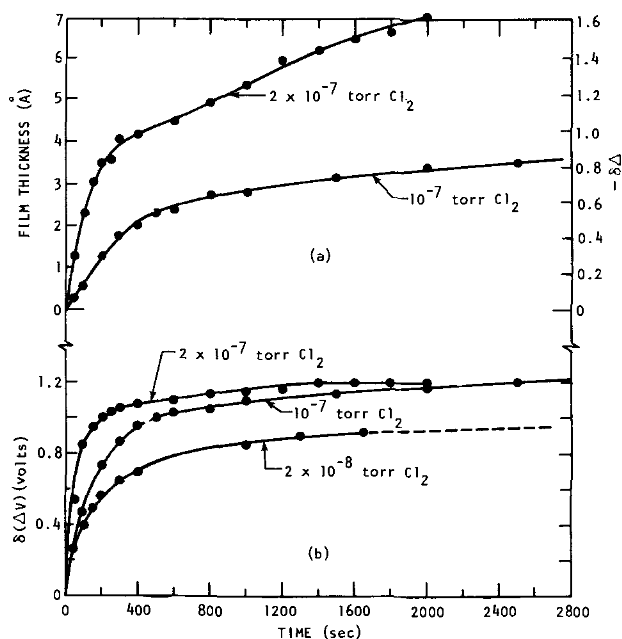

Fig. 7. Plot of calculated film thickness, $-\delta\Delta$, and $\delta(\Delta V)$ vs. time for chlorine adsorption from the gas phase at 24°C.

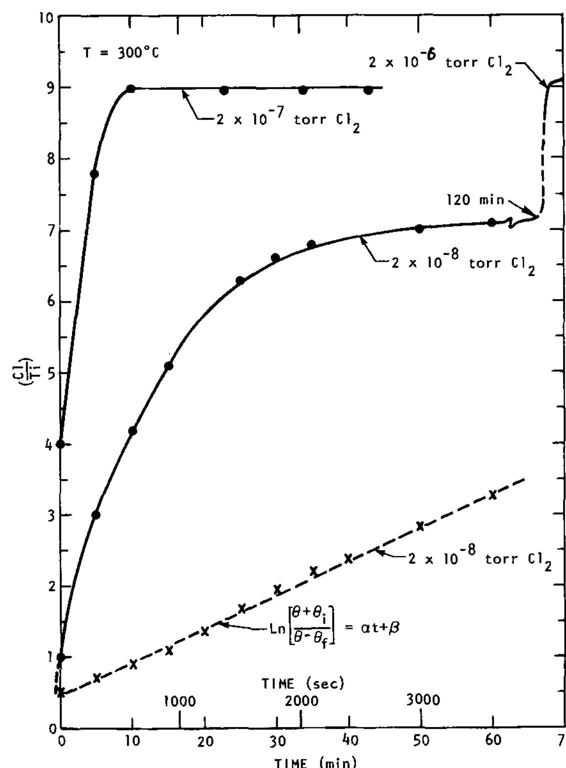

Fig. 8. Plot of chlorine adsorption (with Auger spectroscopy) as a function of time and chlorine pressure with the Ti sample at 300°C. The dashed straight line is the average of the values of Ln[$(\theta + \theta_i)/(\theta - \theta_f)$] calculated from the curve at 2x10^{-18} Torr Cl_2.

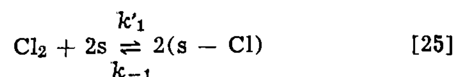
value (7.4) between 60 and 120 min. At 120 min the chlorine pressure was increased to 2×10^{-6} Torr; the (Cl/Ti) value increased and leveled off at 9.1. After removing the chlorine from the surface (to (Cl/Ti) = 4) by Cs^+ bombardment ($P_{Cl_2} \sim 5 \times 10^{-10}$ Torr) the chlorine pressure was increased to 2×10^{-7} Torr, yielding the curve labeled as such in Fig. 8. At the higher pressure, chlorine adsorption was much more rapid and leveled off at (Cl/Ti) = 9. It was concluded that the saturation value for Cl on Ti corresponds to a value of (Cl/Ti) $\approx$ 9.1 so that θ can be obtained from $\theta \approx$ (Cl/Ti)/9.1.

Kinetic equations.—If chlorine gas adsorbs on Ti with dissociation, the reaction can be represented



$$Cl_2 + 2s \underset{k_{-1}}{\overset{k'_1}{\rightleftharpoons}} 2(s - Cl) \quad [25]$$

where s represents a surface site and s − Cl represents a chlorine atom adsorbed on a site. The forward rate constant is k'_1 and the reverse (desorption) rate constant is k_{-1}. Let N_s be the number of sites available and n_{Cl} the number occupied, so that the fraction occupied is $\theta = n_{Cl}/N_s$. The rate of adsorption can be expressed

$$d\theta/dt = k'_1 P_{Cl}(1 - \theta)^2 - k_{-1}\theta^2 \quad [26]$$

At equilibrium $d\theta/dt = 0$, yielding

$$\theta_f = (1 - \sqrt{k_{-1}/k_1})/(1 - k_{-1}/k_1) \quad [27]$$

where $k_1 = k'_1 P_{Cl}$. Integration of Eq. [26] yields the relation between θ and t

$$\mathrm{Ln}[(\theta + \theta_i)/(\theta - \theta_f)] = \alpha t + \beta \quad [28]$$

where

$$\theta_i = -[(1 + \sqrt{k_{-1}/k_1})/(1 - k_{-1}/k_1)] \quad [29]$$

$$\alpha = 2\sqrt{k_{-1}k_1} \equiv 2k_1(1 - \theta_f)/\theta_f \quad [30]$$

$$\beta = \mathrm{Ln}[(\theta_o + \theta_i)/(\theta_o - \theta_f)] \quad [31]$$

$$\theta_0 = \theta \text{ at } t = 0 \quad [32]$$

For the curve at $P_{Cl} \approx 2 \times 10^{-8}$ Torr, $\theta_f \approx 7.4/9.1 = 0.81$ and from Eq. [27], $k_{-1}/k_1 \approx 0.055$, yielding $\theta_i \approx -1.30$ from Eq. [29]. Values of (Cl/Ti) from Fig. 8 were used to calculate θ *vs.* t. The X's in Fig. 8 are the calculated values of $\text{Ln}[(\theta + \theta_i)/(\theta - \theta_f)]$ *vs.* t, using the experimental values 0.81, −1.30, and 0.11 for θ_f, θ_i, and θ_0, respectively. The linearity of the curve between 0 and 60 min is very sensitive to θ_f; for example, the curve becomes concave to the time axis for $\theta_f > 0.81$ and convex to the time axis for $\theta_f < 0.81$. The slope of the dashed line in Fig. 8 yields the approximate value $\alpha \approx 0.047$ and from Eq. [30], $k_1 \approx 0.1$ (min^{-1}) and $k_{-1} \approx 0.0055$ (min^{-1}).

A check on the value of k_1 (and therefore the adsorption model), obtained from the dashed curve in Fig. 8 (*i.e.*, from α), was made by measuring the initial rate of chlorine adsorption as a function of P_{Cl} and temperature with Auger spectroscopy. The initial rates $d(\text{Cl/Ti})/dt$ are shown in Fig. 9. The pressure values along the abscissa in Fig. 9 are ion gauge readings. These readings must be multiplied by 2 to make the ionization probability correction for chlorine as mentioned in the experimental section. Although the scatter of the experimental data in Fig. 9 is rather large, they can be used to estimate the relationship between the initial rates and Cl_2 pressure. From the line drawn through the data

$$d(\text{Cl/Ti})/dt|_{\theta\to 0} \approx 0.6 \times 10^6 P \text{ sec}^{-1} \quad [33]$$

yielding

$$d\theta/dt|_{\theta\to 0} \approx 0.7 \times 10^5 P \text{ sec}^{-1} \quad [34]$$

At $P_{Cl} = 2 \times 10^{-8}$ Torr (as for the dashed curve in Fig. 8), $k_1 \approx 0.09$ min^{-1}; within experimental error of the value from Fig. 8 (*i.e.*, $k_1 \approx 0.1$ min^{-1}). Calculation of the initial rate at $P_{Cl} = 2 \times 10^{-8}$ Torr with the value of $k_1 = 0.1$ min^{-1} is indicated by the symbol ⊗ in Fig. 9. A second check on k_1 is obtained by calculating values of $d\theta/dt|_{\theta\to 0}$ and therefore $d(\text{Cl/Ti})/dt|_{\theta\to 0}$, from the SPD measurements in Fig. 7(b). The values of $d(\text{Cl/Ti})/dt|_{\theta\to 0}$ from Fig. 7(b) are represented by the symbol △ in Fig. 9 and are within experimental scatter of the other values.

It is observed from Fig. 9 that, within experimental error, the initial rate of chlorine adsorption is independent of the sample temperature, indicating the reaction to be a nonactivated process.

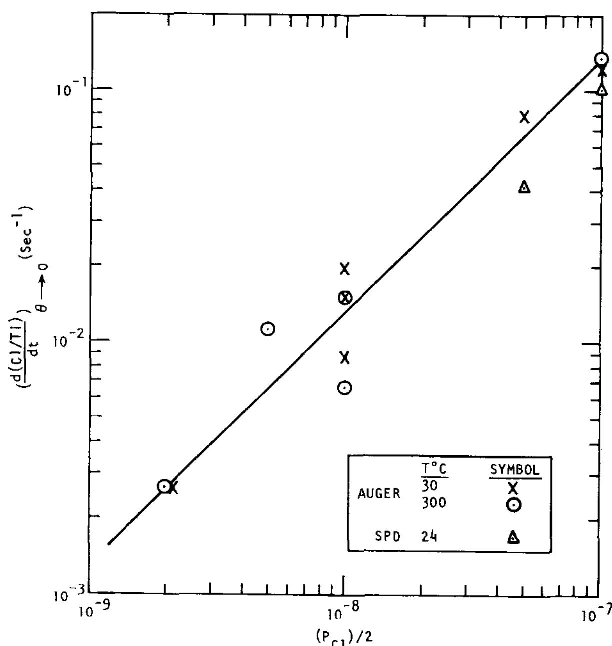


Fig. 9. Log-log plot of initial Cl adsorption rates as a function of chlorine pressure.

Sticking coefficient.—It is of interest to calculate the probability (sticking coefficient) that a chlorine molecule will stick once it has struck the Ti surface. The forward rate constant can be expressed in terms of the sticking coefficient (designated S), the rate of gas impingement ν, and the pressure P_{Cl} by

$$k'_1 = 2S\nu/N_s P_{Cl} \quad [35]$$

since $dn_{Cl}/dt|_{\theta\to 0} = 2S\nu \equiv N_s(d\theta/dt|_{\theta\to 0})$. The rate of chlorine gas impingement per unit area at P_{Cl} and at gas temperature T, is

$$\nu = P_{Cl}/\sqrt{2\pi m_{Cl}kT} \quad [36]$$

where m_{Cl} is the mass of a chlorine molecule and k is the Boltzmann constant. The equation for the sticking coefficient becomes

$$S = (k'_1 N_s \sqrt{2\pi m_{Cl}kT})/2 \quad [37]$$

The slope of the line in Fig. 9 is 0.6×10^6, yielding $d\theta/dt|_{\theta\to 0} \approx 0.7 \times 10^5 P \text{ sec}^{-1}$ and

$$k'_1 \approx 0.7 \times 10^5 \text{ (Torr-sec)}^{-1}$$

However, in order to calculate S, k'_1 must be in units of square centimeter/dyne-second, so that

$$k'_1 \approx 0.7 \times 10^5/1.31 \times 10^3 \simeq 50 \text{(cm}^2\text{/dyne-sec)}$$

From Eq. [37]

$$S \sim 0.05$$

for chlorine on Ti.

Other possibilities exist. For example, chlorine may adsorb in a precursor state as a molecule, which then dissociates. If equilibrium is rapid with respect to the precursor state, the concentration of molecular chlorine on the surface can be expressed by a Langmuir isotherm

$$\theta_p = K_p P/(1 + K_p P)$$

where θ_p is the fraction of the surface covered with molecular chlorine and K_p is the equilibrium constant. For very small values of P ($K_p P << 1$), $\theta_p \approx K_p P$. The equilibrium constant can be expressed in terms of the rate of adsorption into the precursor state, $S\nu_1$, and the rate of desorption, ν_{-1}, by

$$K_p = S\nu_1/\nu_{-1}$$

where $\nu_1 = \nu/P$. If chlorine does equilibrate in a precursor state, the experimental value 0.6×10^6 in Eq. [33] relates to $k'_1 K_p$ rather than k'_1 and S cannot be determined until K_p and ν_{-1} are known. In this case the experimental slope taken as k'_1 is $k'_1 K_p$ and the rest of the analysis remains unchanged.

Summary and Conclusions

Although elements such as hydrogen and oxygen dissolve in Ti at high temperature, it has been demonstrated that chlorine and sulfur segregate from within the Ti crystal to the surface if the temperature is high enough. The fact that the Ti (380 eV) Auger peak is only slightly affected by the segregation process while the APPH for Ti (47 eV) is complimentary to the APPH for Cl, indicates that only the outer layer has the high concentration of Cl. The segregation coefficient (ratio of Cl concentration at the surface to that in the bulk) is of the order of 10^5 at 525°C, but is reduced to $\sim 10^{-6}$ at room temperature due to the large positive enthalpy change ($\sim$25 kcal/mole) for the segregation process. Although it appears that these facts contradict the mechanism for SCC mentioned in the introduction, these tests were not conducted with the sample under stress. The large stresses and local heating that exist in the crack tip region may lower the diffusion activation energy and the segregation enthalpy,

in which case it is conceivable that segregation could occur rapidly enough at room temperature. If the SCC requires ~1 Cl atom per 3 Ti atoms at the surface, and the bulk concentration is ~0.1 ppm, the stress zone at the crack tip must extend at least 10^6 atom layers deep in order to supply sufficient Cl to the surface. Further experiments are needed to investigate the effect of stress on the segregation process.

It has been demonstrated that chlorine segregates at a lower temperature and a faster rate than sulfur. At higher temperatures sulfur displaces chlorine at the surface.

Adsorption of chlorine from the gas phase is postulated to be a nonactivated process, the rate of initial adsorption being independent of the temperature of the sample. The adsorption rate on a bare Ti surface is directly proportional to the gas pressure, with a sticking coefficient of ~0.05.

Ellipsometric data indicate that more than a monolayer of chloride will form on Ti at room temperature and at a chlorine pressure in the 10^{-7} Torr range. However, the SPD and Auger measurements seem to be sensitive to the outermost layer only. The index of refraction of the chloride layer is ~2.4 and the effective thickness of the layer at monolayer coverage proves to be about the average between a chlorine ion (3.6Å) and the sum of the Ti^{+2} and Cl^- diameters (5.4Å), *i.e.*, ~4.5Å. Table III gives a summary of the fundamental constants that have been determined for the segregation process for the Cl-Ti system.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

APPENDIX

Solution of the Diffusion Equations

Assume that the physical system can be represented by the following mathematical model

1. The diffusion equation is

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial x^2} \quad \text{[A-1]}$$

2. Initial concentration constant throughout a region $o < x < l$, surface concentration initially zero

$$C(x,o) = C_o,\ C_s(o) = 0 \quad \text{[A-2]}$$

3. Impermeable boundary at $x = o$

$$\frac{\partial C}{\partial x}(o,t) = 0 \quad \text{[A-3]}$$

4. Fixed segregation constant between impurity concentration in the medium and on the surface

$$C_s(t) = KC(l,t) \quad \text{[A-4]}$$

so that K is the equivalent thickness of the boundary layer required to contain the same amount of impurity, at the concentration level in the medium, as is present in the surface layer.

5. Conservation of matter: impurities which diffuse from the medium must be accounted for at the surface

$$\int_o^l [C_o - C(x,t)]dx = \int_o^t -D\frac{\partial C}{\partial x}(l,t')dt' = C_s(t) \quad \text{[A-5]}$$

To solve the set of equations [A-1]-[A-5] the most convenient procedure is to use the method of Laplace transforms; let $f(x,s)$ be the transform of $C(x,t)$. Then

$$sf(x,s) = C_o + D\frac{d^2f}{dx^2}(x,s) \quad \text{[A-6]}$$

$$\frac{df}{dx}(o,s) = 0 \quad \text{[A-7]}$$

$$\int_o^l \left[\frac{C_o}{s} - f(x,s)\right]dx = -\frac{D}{s}\frac{\partial f}{\partial x}(l,s) = kf(l,s) \quad \text{[A-8]}$$

The solution of the differential equation, [A-6], including the boundary condition, [A-7], is immediately

$$f(x,s) = \frac{C_o}{s} + A(s)\cosh\sqrt{\frac{s}{D}}x \quad \text{[A-9]}$$

and when this is introduced into Eq. [A-8] one obtains

$$-A(s)\sqrt{\frac{D}{s}}\sinh\sqrt{\frac{s}{D}}l = \frac{KC_o}{s} + KA(s)\cosh\sqrt{\frac{s}{D}}l$$

or

$$A(s) = -\frac{KC_o}{\sqrt{Ds}\sinh\sqrt{\frac{s}{D}}l + Ks\cosh\frac{s}{D}l} \quad \text{[A-10]}$$

The transform is therefore

$$f(x,s) = \frac{C_o}{s} - \frac{KC_o\cosh\sqrt{\frac{s}{D}}x}{\sqrt{Ds}\sinh\sqrt{\frac{s}{D}}l + Ks\cosh\sqrt{\frac{s}{D}}l} \quad \text{[A-11]}$$

This function has a simple pole at $s = 0$ with a residue $lC_o/(l + K)$ as well as poles given by the roots of the transcendental equation

$$\frac{\tan\kappa_n}{\kappa_n} = -\frac{K}{l},\ s_n = -D\kappa_n^2/l^2 \quad \text{[A-12]}$$

For large n the roots are approximately

$$\kappa_n \approx \left(n - \frac{1}{2}\right)\pi + \frac{l}{\left(n - \frac{1}{2}\right)\pi K} + \ldots \quad \text{[A-13]}$$

The residue at $s = s_n$ is

Table III. Some fundamental constants for the segregation process, of chlorine-titanium system

	Temperature, °C			Equation
	Room	524	670	
Sticking coefficient	0.05			
Segregation coefficient	$\sim 10^{-6}$	3×10^5	4×10^6	$K_s \approx 2.2 \times 10^{12}\exp(-25{,}000/RT)$
Diffusion coefficient	$\sim 10^{-17}$	2.4×10^{-6}	2.6×10^{-5}	$D \approx 9\exp(-24{,}100/RT)$

$$= \frac{2KC_0 \cosh\sqrt{\frac{s_n}{D}}\,x}{\sqrt{\frac{D}{s_n}}\sinh\sqrt{\frac{s_n}{D}}\,l + l\cosh\sqrt{\frac{s_n}{D}}\,l + 2K\cosh\sqrt{\frac{s_n}{D}}\,l + Kl\sqrt{\frac{s_n}{D}}\sinh\sqrt{\frac{s_n}{D}}\,l}$$

$$= -\frac{2KlC_0\cos(\kappa_n x/l)}{[(k+l)l + K^2\kappa_n^2]\cos\kappa_n}$$

and the complete solution becomes

$$\frac{C(x,t)}{C_0} = \frac{l}{l+K}\left[1 - 2\sum_{n=1}^{\infty}\frac{\cos(\kappa_n x/l)\exp(-\kappa_n^2 Dt/l^2)}{\left[1+\frac{K^2\kappa_n^2}{l(l+K)}\right]\cos\kappa_n}\right] \quad \text{[A-14]}$$

For $t > 4l^2/\pi^2 D$, the concentration reaches its equilibrium value, $C(x,\infty) = lC_0/(l+K)$, asymptotically with an exponential relaxation; for very small values of $t(t << 4l^2/\pi^2 D)$ the series is slowly convergent but the successive terms alternate in sign.
Then

$$C_s(t) = KC(l,t) = (lKC_0/l+K)\left[1 - 2\sum_{n=1}^{\infty} e^{-\kappa_n^2 Dt/l^2}/(1 + K^2\kappa_n^2/l(l+K))\right] \quad \text{[A-15]}$$

Let

$$\tau_1 = l^2/\kappa_1^2 D$$

$$C_s(\infty) = lKC_0/(l+K)$$

$$C_s(\infty) - C_s(t) = 2lKC_0/(l+K)\{[e^{-t/\tau_1}/(1+K^2\kappa_1^2\,l(l+K)] - \ldots\} \quad [16]$$

$$= C_0\,2\,l^2K\,e^{-t/\tau_1}/[l(l+K) + K^2\kappa_1^2] - \ldots \quad [17]$$

Gas Flow Pattern and Mass Transfer Analysis in a Horizontal Flow Reactor for Chemical Vapor Deposition

R. Takahashi and Y. Koga

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

and K. Sugawara*

Semiconductor and Integrated Circuit Division, Hitachi Ltd., Kodaira, Tokyo, Japan

ABSTRACT

To study mass transfer characteristics in a vapor deposition reactor, gas flow patterns in a horizontal tube were investigated. Combined free and forced convection spiral flow and pure forced convection laminar flow were observed depending on experimental conditions of various flow rates and pressures. Further, local deposition rates under two flow behaviors were numerically obtained by solving a three-dimensional mass conservation equation. It was estimated on the basis of calculated results that forced convection laminar flow in a rectangular reactor produced better uniformity on the deposition rate distribution across the width than did combined convection spiral flow.

The chemical vapor deposition process has been widely used in the field of crystal growth and dielectric film formation. For instance, the following deposition reactions can be cited as examples

silicon epitaxy $SiCl_4 + 2H_2 \rightarrow Si + 4HCl$ [1]

dielectric film $SiH_4 + 2\,O_2 \rightarrow SiO_2 + 2H_2O$ [2]

(in N_2 carrier gas)

Since the deposited layer must be of uniform thickness, it is necessary to study the distribution of deposition rates in a flow reactor. It is well known that the deposition rate is frequently controlled by mass transfer of reactant in the gas phase (1). In such a case, the gas flow pattern is an important factor affecting thickness distribution of the deposited layer.

When the susceptor in a deposition reactor tube is locally heated by usual high-frequency induction, a temperature difference appears between the susceptor and the tube wall. Under such circumstances, the flow in the reactor is subject to the influence of free convection induced by the buoyancy force. The flow in which free convection modulates on forced convection is called the combined flow or mixed flow.

* Electrochemical Society Active Member.

Key words: combined convection, low pressure operation, concentration profile, layer thickness distribution.

In the case of horizontal tubes, free convection acts perpendicularly to the direction of forced convection flow. In situations where the forces of free and forced convection are nearly equal to one another, the gas flow pattern becomes the spiral form (2, 3).

However, it can be predicted that the combined flow converts to a pure forced flow under an operating condition such as a large Reynolds number, Re, or a small Grashof number, Gr, where Re is the controlling parameter for forced convection flow and Gr is the controlling parameter for free convection flow.

This work was conducted to ascertain the transition region between pure forced flow and combined flow by observing gas flow patterns, and to theoretically study the relationship between the two flow behaviors and corresponding deposition characteristics.

Experimental

Figure 1 shows the schematic diagram of the experimental apparatus for observing the gas flow patterns. Four kinds of reactors were used: namely, two circular quartz tubes (60 and 113 mm ID) and two rectangular quartz tubes (40×70 mm and 70×118 mm), all four tubes 1200 mm long. Silicon carbide heaters were placed at the bottom of each tube, on which a flat iron plate was set in order to obtain a uniform temperature distribution by sandwiching a quartz insulator plate in between. The flow gases used were nitrogen and helium. The fluid characteristics of helium gas resemble those of hydrogen gas which is commonly used in vapor deposition. Titanium tetrachloride ($TiCl_4$) vapor was mixed through the capillary with the flowing gas in the tube. $TiCl_4$ was converted into titanium dioxide by reaction with the water moisture contained in the flow gas. The fine particles of TiO_2 formed were utilized to trace the gas flow. Velocity disturbance by the $TiCl_4$ vapor was negligible compared with main flow velocity because of a small quantity of titanium tetrachloride vapor.

A movie camera was used to photograph the gas flow patterns from the side as well as from the end of the tube. Sectional photography of the gas flow pattern was made by focusing on the specified section illuminated by spotlights.

Gas flow rates were from 0 to 60 liters/min, and pressure varied from 160 to 760 Torr. The temperature of the flat plate and the reactor wall were measured by a Pt-Pt · Rh thermocouple. In measuring temperature of a gas phase, radiation from a heated plate may cause an error. Consequently, three thermocouples with 0.2, 0.5, and 1.0 mm diameters were used. When the temperature is plotted graphically against the diameter, the point extrapolated to the zero diameter should give the true gas temperature (4).

Experimental Results

Gas flow patterns in horizontal tubes were photographed by a 16 mm movie camera under conditions producing various flow rates and pressures. In this paper, the patterns shown by photographs were selected from the 16 mm movie films.

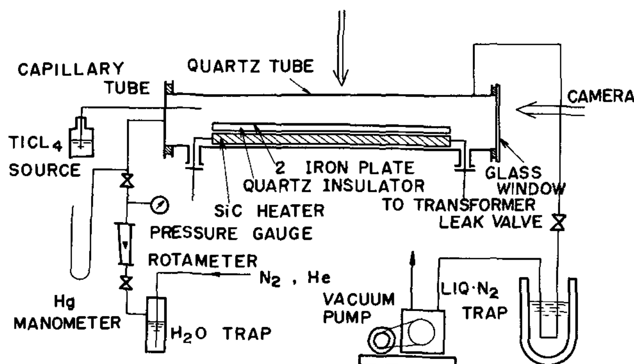

Fig. 1. Schematic diagram of experimental apparatus

It is known that fluid in an enclosed region heated from below forms a two-dimensional vortex pattern by free convection (5-7). In the case of combined flow, fluid motion is three-dimensional. However, we can observe a sectional pattern similar to the free convection pattern by projecting a three-dimensional streamline at a cross section of a tube. Figure 2 shows the flow pattern in a cross section at a very small flow rate. Although dynamical flow behavior is not visible in the photograph, the heated gas moved upward, starting from the center portion of the iron plate, then downward along the tube wall. This motion is designated as positive motion and its reverse motion as negative. Generally, motion by free convection starts from the point where viscosity is lowest (8). In most of this experiment, two vortex patterns with positive motion were observed independently from tube geometries, which implies that the temperature distribution across the tube width had the highest point at the center of the plate due to heat loss toward the tube wall.

Since the vortexes by free convection were modulated by forced convection directed to the outlet, the flow streamline actually became a spiral pattern. In the situation where two vortexes exist in a cross section of the tube, two spiral flow patterns were generated in the tube.

With an increase of the flow rate, pitch of the spiral streamline was gradually extended in the axial direction of the tube; however, on the sectional pattern, the following behaviors were observed.

In the nitrogen flow system, the positive vortex motion observed at a low flow rate converted to a negative one. To examine this behavior, temperature distribution in the cross section was measured corresponding to the vortex pattern, as shown in Fig. 3; that is, horizontal temperature distribution near the heated plate over the width had the lowest point at the width center when the flow rate was high. It appears that this difference between temperature distribution is related to whether or not the thermal boundary layer was fully developed.

Under a fully developed state, temperature of the gas stream did not vary in the flow direction, and horizontal temperature distribution over the width

Fig. 2. Vortex patterns produced in a rectangular tube

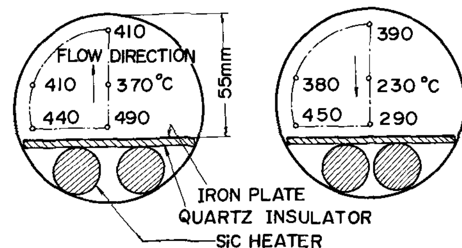

Fig. 3. Temperature profiles varying with flow rates

Fig. 4. Vortex patterns varying with flow rates: (a, left) He 1 liter/min; (b, center) He 5 liters/min; (c, right) He 10 liters/min

was governed by heat loss as stated previously. In the region where the thermal boundary layer was not fully developed, on the other hand, horizontal temperature distribution depended on the velocity distribution of forced convection over the width, so that temperature of the gas stream in the center part of the tube became lower than that in the outer part, and consequently, the vortex motion was negative.

Length of the thermal entrance region for laminar flow is well known by the relation

$$L/De = 0.05 \text{ Re} \cdot \text{Pr} \quad [3]$$

where L is thermal entrance length and De is hydraulic diameter of a tube. Although the entrance length for combined flow somewhat differs from that for laminar flow, from the above relation it is still estimated that the position of observing the flow pattern, when it is 150 mm apart from the inlet edge of the heated plate, lies in the thermal entrance region when the reverse of the vortex motion is observed.

In the helium flow system, vortex patterns were shifted to the corners of the cross section with increasing flow rates, as shown in Fig. 4. According to the above estimation thermal boundary layers were fully developed in all experiments. If the vortex was induced locally at a position where forced convection velocity is small, pattern variation occurred under circumstances that the small velocity zone was reduced to the corner with increasing flow rates. However, detailed analysis remains to be conducted on the hydrodynamic problem.

Under further increased flow rates, the forced convection became predominant, although there was complex behavior induced by expansion of both the thermal and hydrodynamic entrance regions.

A decrease in the Grashof number, which consists of factors such as temperature difference and gas density, imparts to the flow pattern the same effect as an increase in flow rate. McComas and Eckert (9) have conducted operations at low pressure in order to obtain negligible free convection heat transfer data. In the present study, pressure dependence on a fully developed spiral flow was examined. Figure 5 shows the effect of pressure at a constant flow rate. At low pressure the pure forced convection streamline was observed in contrast with the vortex motion at atmospheric pressure. The low-pressure operation was effective in producing laminar flow in a CVD reactor.

Summary of Observation Results

As described previously, two modes of flow can exist in a horizontal CVD reactor. The problem is to determine the transition region between the two flow patterns.

Sparrow (10) has studied combined convection heat transfer on a vertical surface, in which he theoretically classified the flow criteria by using a parameter, Gr/Re^2, introduced from the momentum conservation equation as follows

$$Gr/Re^2 > 16 \quad \text{free convection flow} \quad [4]$$

$$16 > Gr/Re^2 > 0.3 \quad \text{combined flow} \quad [5]$$

$$0.3 > Gr/Re^2 \quad \text{forced convection flow} \quad [6]$$

Additionally, from the heat transfer data, Metais and Eckert (11) have reported regimes for flow through vertical and horizontal circular tubes. These criteria are defined by deviation between the actual heat flux and the heat flux caused by pure convection. The transition region for a semicircular or rectangular tube may differ from the above criteria.

Conditions for the transition region obtained from observation results in the present experiment are described in Table I. Values in the table are for the flow parameters at which vortex motion disappears in the tube cross section.

Regarding combined flow on a horizontal flat plate, a parameter of $Gr/Re^{2.5}$ has been theoretically derived by Mori (12). For simplicity, however, a parameter of

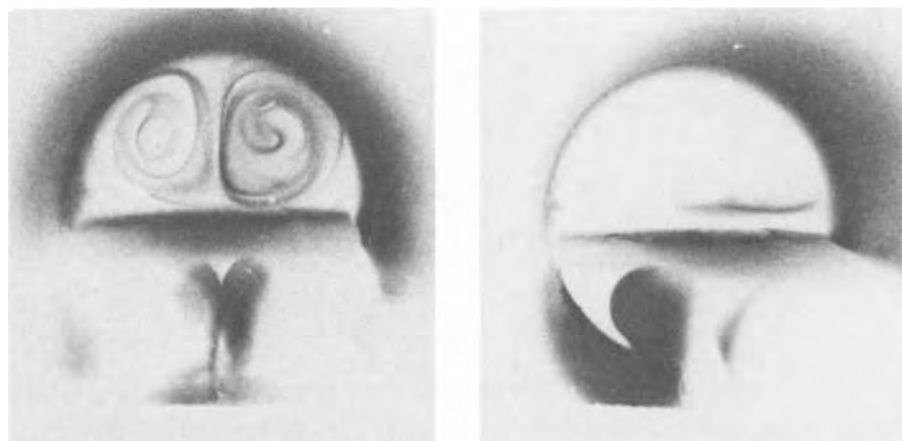

Fig. 5. Effect of pressures on flow patterns: (a, left) 760 Torr 1 liter/min; (b, right) 160 Torr 1 liter/min.

Table I. Fluid parameters representing the disappearance of vortexes

Tube type	Maximum distance between hot plate tube wall (mm)	Equivalent diameter *De* (mm)	Flow rate (l/min)	Re	Gr	Gr/Re^2
		Nitrogen gas				
64 mm circular	55	43	5	45	8,200	4.1
113 mm circular	45	55	60	228	23,000	0.4
70 × 40 rectangular	19	26	5	35	1,600	1.4
70 × 118 rectangular	57	62	20	140	46,000	2.3
118 × 70 rectangular	49	82	20	100	30,000	3.0
118 × 70 rectangular	39	66	20	80	9,800	3.0
118 × 70 rectangular	29	52	20	80	4,800	1.5
		Helium gas				
64 mm circular	55	43	14	14	153	0.8
64 mm (160 Torr)	55	43	1	1.3	4	2.2
70 × 40 rectangular	19	26	5	4.3	22	1.2
70 × 40 rectangular	9	18	No vortex	—	—	—
118 × 70 rectangular	39	66	20	13	600	3.5
118 × 70 rectangular	29	52	10	5	90	3.5

Gr/Re^2 was employed because $Gr^{1/2}/Re$ corresponds to a dimensionless velocity ratio of free convection velocity to forced convection velocity.

As shown in the table, the disappearance of vortex occurred under the transition condition of $Gr/Re^2 = 0.4$ to 4.1, although it is difficult to give precise values since transitions are gradual in observing flow patterns.

Moreover, note that vortex by free convection was observed at small Grashof numbers in the helium flow system. In general, free convection vortex in the horizontal space bounded by two plane surfaces appears under the conditions of $Gr \cdot Pr > 1700$ (8). Although the limiting condition for producing free convection depends on reactor geometry (13, 14), the values described in the table are very small. This may be due to heat loss, effects based on the entrance regions, the gravity force of titanium dioxide particles, and so forth; however, such details will be left to advance study.

Theoretical Consideration on the Relation between Flow Behaviors and Deposition Characteristics

Deposition under forced convection laminar flow.— Thickness distribution of the deposited layer makes a difference between pure forced convection laminar flow and combined convection spiral flow. The problem can be examined theoretically by solving a mass conservation equation of the diffusing species, of which the general form is

$$\nabla v \cdot c = D_m \nabla^2 c \quad [7]$$

where ∇ denotes the operator, $\partial/\partial x + \partial/\partial y + \partial/\partial z$, ∇^2 is the Laplace operator, v the velocity vector of the gas flow, c the concentration of the reactant, and D_m the effective diffusion coefficient.

Solutions of this equation under different boundary conditions have been obtained from the analogous relation between mass and heat transfer. For example, the mass transfer correlation in isothermal laminar flow over a flat plate is given by

$$Sh = 0.332\, Re^{1/2} Sc^{1/3} \quad [8]$$

where Sh represents the local Sherwood number defined by kz/D_m with k the mass transfer coefficient, z the distance along the gas flow; Re is defined by wz/ν with w the flow velocity, ν the kinematic viscosity; and Sc represents the Schmidt number defined ν/D_m. In detail, the above is a solution obtained from the following equation under a situation of the variable hydrodynamic boundary layer thickness

$$w\, \partial c/\partial z + v\, \partial c/\partial y = D_m\, \partial^2 c/\partial y^2 \quad [9]$$

where w is a gas velocity component in the flow direction, z, and v is a y-direction velocity component perpendicular to z.

If the hydrodynamic boundary layer is fully developed, the term (including the velocity component, v) can be neglected. Regarding a special condition of the linear velocity profile, $w = \alpha y$, there is Leveque's solution on heat transfer (8). The equivalent mass transfer rate equation can be written as

$$N = D_m (\partial c/\partial y)_{y=0} = \frac{c_0 D_m}{0.893} \left(\frac{\alpha}{9 D_m z} \right)^{1/3} \quad [10]$$

On the other hand, a solution to the parabolic velocity profile has been solved by Pigford (15). Further, Rundle (16) has reported an analytical solution of the following two-dimensional diffusion equation in the same velocity field

$$w(y)\, \partial c/\partial z = D_m (\partial^2 c/\partial z^2 + \partial^2 c/\partial y^2) \quad [11]$$

In an actual reactor, moreover, velocity is also distributed over the width. Fully developed velocity profiles in a rectangular and a semicircular section, used frequently for chemical vapor deposition, have been calculated by Andrew (17), who suggested important information that deposition in a rectangular reactor gave better thickness distribution than that in a semicircular reactor.

In this study, deposited layer thickness distributions in a rectangular reactor in which velocity is distributed on both the axial and the width direction were examined in a three-dimensional diffusion system as follows

$$w(x,y)\, \partial c/\partial z = D_m (\partial^2 c/\partial x^2 + \partial^2 c/\partial y^2 + \partial^2 c/\partial z^2) \quad [12]$$

Consideration was given, in particular, to the dependence of diffusion along the width on thickness distributions. Also, the axial diffusion effect was considered in the equation since vapor deposition is usually conducted at small Reynolds numbers, although it may be neglected in the ranges of $Re \cdot Sc > 10$ (18).

Generally, the velocity profile under laminar flow fully developing in a rectangular reactor is expressed by the complex formula (17, 19); however, a convenient simple expression (19) is given by

$$w/w_{max} = (1 - |\xi|^m)(1 - |\zeta|^2) \quad [13]$$

where $\xi = 1 - (2x/B)$, $\zeta = 1 - (2y/H)$, B and H are the respective width and height of the reactor, and m is a constant which is determined by the aspect ratio of the reactor section.

By using dimensionless variables, the mass conservation equation can be written as

$$W\, \partial C/\partial Z = \frac{1}{Sc} (\partial^2 C/\partial X^2 + \partial^2 C/\partial Y^2 + \partial^2 C/\partial Z^2) \quad [14]$$

where $C = c/c_0$, $X = x/H$, $Y = y/H$, $Z = z/H$, and $W = wH/\nu$.

Boundary conditions are $C = 0$ at $Y = 0$ when the reaction rate is very large at the deposition surface; consequently, the deposition rate is controlled by diffusion, $C = 1$ at $Z = 0$, $\partial C/\partial Z = 0$ at $Z = L/H$ (L = reactor length), $\partial C/\partial X = 0$ at $X = 0$ and B/H, and $\partial C/\partial Y = 0$ at $Y = 1$.

Concentrations distributed three-dimensionally in a reactor were numerically calculated by using a finite

difference approximation method. The finite difference representation can be expressed by approximated concentrations on six grid points around a selected point as follows

$$W(i,j)\frac{C(i,j,k+1)-C(i,j,k-1)}{2\Delta Z} = \frac{1}{\mathrm{Sc}}\left[\frac{C(i+1,j,k)-2C(i,j,k)+C(i-1,j,k)}{\Delta X^2} + \frac{C(i,j+1,k)-2C(i,j,k)+C(i,j-1,k)}{\Delta Y^2} + \frac{C(i,j,k+1)-2C(i,j,k)+c(i,j,k-1)}{\Delta Z^2}\right] \quad [15]$$

where i, j, and k are grid numbers spacing in the X, Y, and Z direction, respectively. Calculation was effected with a digital computer, HITAC 5020F.

From the concentration gradient at the deposition surface, the mass transfer rate N is

$$N(x,z) = D_m(\partial c/\partial y) = \frac{c_0 D_m}{H}(\partial C/\partial Y) = k_m \Delta c \quad [16]$$

If the diffusion boundary layer consists of the original concentration c_0, that is $\Delta c = c_0$, and if there is a successive concentration gradient, the dimensionless concentration gradient is equivalent to the Sherwood number as

$$R = (\partial C/\partial Y)_{Y=0} = k_m H/D_m = \mathrm{Sh} \quad [17]$$

The deposition rate is

$$G = \frac{m}{M\rho}\left(\frac{\partial C}{\partial Y}\right)_{Y=0} \quad [18]$$

For the values of $D_m = 5$ cm²/sec, $c = 0.005$ mol, and $H = 3$ cm, a unit dimensionless concentration gradient $R = 1$, corresponds to a deposition rate of $G = 0.5$ μ/min. Therefore, $(\partial C/\partial Y)_{y=0}$ implies a dimensionless deposition rate.

Figure 6 shows calculated rate distributions across the width of a rectangular reactor of the aspect ratio, $B/H = 1$. Distributions in a case where diffusion along the width is not considered in the mass conservation equation are also given for reference by the hyphenated lines. It is obvious that the diffusion effect along the width cannot be neglected.

However, this consideration is still insufficient. At the shallow position of a reactor the deposition rate may be controlled by the chemical reaction rate because of the thin diffusion boundary layer thickness. In addition, existence of a hydrodynamic and thermal entrance region will effect a complex rate distribution

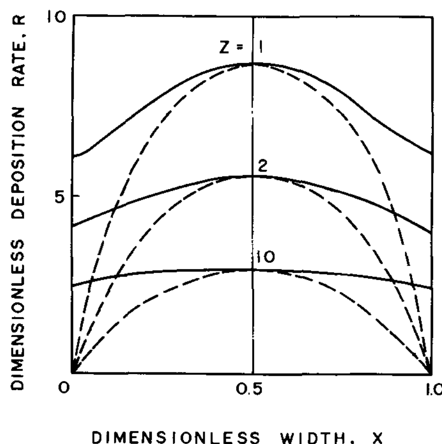

Fig. 6. Theoretical deposition characteristics for forced convection laminar flow inside a rectangular tube.

such as the deposition characteristics reported by Sutton (20). These behaviors will be analyzed by more detailed study, considering the above mechanisms.

Deposition under combined free and forced convection spiral flow.—The problems of combined flow have been studied by a number of investigators in the field of heat transfer. On the other hand, regarding studies of combined convection mass transfer, for instance, investigations are found such as mass transfer from gas phase to horizontal cylinder during chemical vapor deposition (21, 22) or diffusion in a semipermeable plate associated with free convection (23).

In a flow system in which free convection acts perpendicular to forced convection, the flow is three-dimensional; thus, the theoretical expression on fluid dynamics is complex. Recently, combined flow with a spiraling character in a circular tube was studied by Newell *et al.* (24), and also the behavior of vortexes under combined flow was reported by Uchida and Mori (25).

In this work, mass transfer under combined convection spiral flow is studied to evaluate the deposited layer thickness distribution in a vapor deposition reactor. Consideration is given to the rectangular reactor to make a comparison with the deposition characteristics under forced convection laminar flow.

We now assume an incompressible and Newtonian fluid with constant physical properties, except for a fluid density in the buoyancy term. When combined flow is fully developed

$$\partial u/\partial z = 0,\ \partial v/\partial z = 0,\ \text{and}\ \partial w/\partial z = 0 \quad [19]$$

dimensionless conservation equations can be stated as follows:

Momentum

$$U\frac{\partial U}{\partial X} + V\frac{\partial U}{\partial Y} = -\frac{\partial P}{\partial X} + \frac{\partial^2 U}{\partial X^2} + \frac{\partial^2 U}{\partial Y^2} \quad [20]$$

$$U\frac{\partial V}{\partial X} + V\frac{\partial V}{\partial Y} = -\frac{\partial P}{\partial Y} + \frac{\partial^2 V}{\partial X^2} + \frac{\partial^2 V}{\partial Y^2} + Gr'\cdot T \quad [21]$$

$$U\frac{\partial W}{\partial X} + V\frac{\partial W}{\partial Y} = -\frac{\partial P}{\partial Z} + \frac{\partial^2 W}{\partial X^2} + \frac{\partial^2 W}{\partial Y^2} \quad [22]$$

Continuity

$$\frac{\partial U}{\partial X} + \frac{\partial V}{\partial Y} = 0,\ \frac{\partial W}{\partial Z} = 0 \quad [23]$$

Energy

$$U\frac{\partial T}{\partial X} + V\frac{\partial T}{\partial Y} = \frac{1}{\mathrm{Pr}}\left(\frac{\partial^2 T}{\partial X^2} + \frac{\partial^2 T}{\partial Y^2}\right) \quad [24]$$

Diffusion

$$U\frac{\partial C}{\partial X} + V\frac{\partial C}{\partial Y} + W\frac{\partial C}{\partial Z} = \frac{1}{\mathrm{Sc}}\left(\frac{\partial^2 C}{\partial X^2} + \frac{\partial^2 C}{\partial Y^2} + \frac{\partial^2 C}{\partial Z^2}\right) \quad [25]$$

where $U = uH/\nu$, $V = vH/\nu$, $W = wH/\nu$, and $T = 2(\theta - \theta_0)/(\theta_h - \theta_l)$ in which θ_h is the upper surface temperature θ_l the lower surface temperature, and θ_0 the average temperatures $(\theta_h - \theta_l)/2$.

The boundary conditions given for this system are

$U = V = W = 0$ at all surfaces
$T = 1$ at $Y = 0$, $T = -1$ at $Y = 1$
$\partial T/\partial X = 0$ at $X = 0$ and $X = B/H$
$C = 1$ at $Z = 0$, $C = 0$ at $Y = 0$, $\partial C/\partial Y = 0$ at $Y = 1$
$\partial C/\partial X = 0$ at $X = 0$ and $X = B/H$, $\partial C/\partial Z = 0$ at $Z = L/H$

The derived equation by combining Eq. [20] and [21] is known as the vorticity equation, that is

$$U\frac{\partial Q}{\partial X} + V\frac{\partial Q}{\partial Y} = \mathrm{Gr}'\frac{\partial T}{\partial X} + \frac{\partial^2 Q}{\partial X^2} + \frac{\partial^2 Q}{\partial Y^2} \quad [26]$$

where $Q = (\partial V/\partial X) - (\partial U/\partial Y) = -\nabla^2\varphi$ and φ is the stream function defined by $U = \partial\varphi/\partial Y$ and $V = \partial\varphi/\partial X$. This equation has been solved numerically by Fromm (5), Samuels and Churchill (6), and others (7, 26-28) on the problem of two-dimensional free convection.

The present calculation for three-dimensional combined flow was conducted by utilizing the numerical solution of unsteady-state free convection using a central finite difference approximation, the details described in Ref. (6, 29, 30). When free convection velocity is obtained from the vorticity and energy equations, a momentum equation with respect to the axial velocity can be solved by the successive approximation method. The axial velocities in laminar flow, expressed according to Eq. [13], were used as initially approximated values. Also, this equation was solved under a constant condition of pressure drop. From the determined velocity components, the mass conservation equation was solved and the mass transfer rate was finally evaluated. Computation required about 1 to 5 min for values of certain Gr, Pr, Re, and Sc on the digital computer, HITAC 5020F.

Figure 7 shows the vortex streamlines of a combined flow projected on the cross section of a rectangular reactor. The calculation result refers to a rectangular reactor with an aspect ratio of $B/H = 2$, which theoretically produces two vortex motions (5), because two vortexes were frequently found in the present observation of flow patterns. The referenced streamlines represent positive vortex motion; if the stream functions have opposite signs, vortex motion becomes negative.

Under the same reactor geometry, axial velocity distributions over the width are shown in Fig. 8. It is evident from the figure that axial velocity is largest at the center of each projected vortex pattern on the cross section of a reactor (hyphenated lines indicate laminar flow).

Figure 9 reveals contour maps of computed isoconcentration profiles. By the positive motion of free convection vortexes, gas of the dilute concentration moves upward at the width center so that the mass transfer rate at this position becomes minimum at the width center.

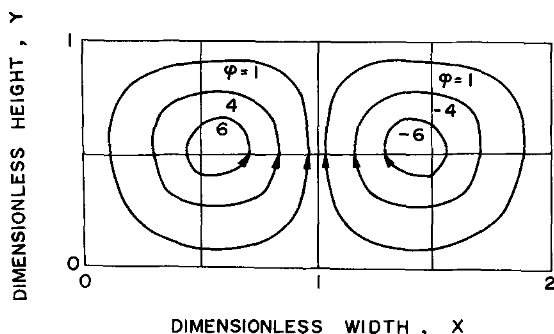

Fig. 7. Streamlines of combined flow projected on a cross section ($Gr' = 3000$, $Pr = 1$, and $B/H = 2$).

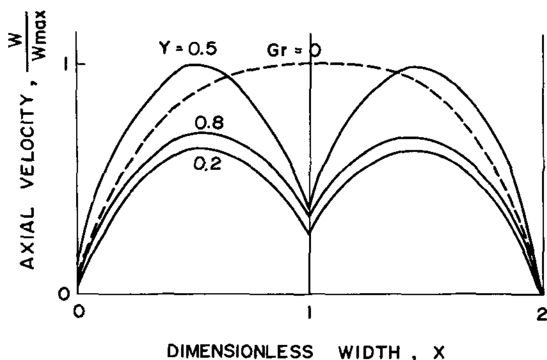

Fig. 8. Axial velocity profiles across the width ($Gr' = 3000$, $Pr = 1$, and $B/H = 2$).

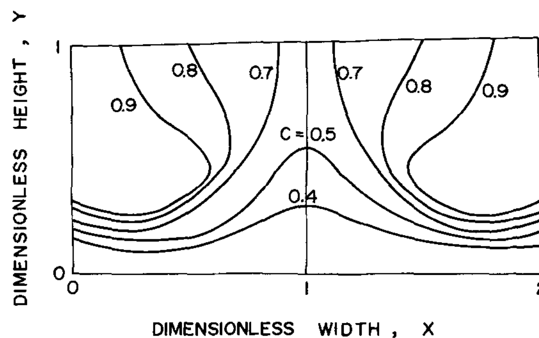

Fig. 9. Concentration contour lines in a cross section for $Gr' = 3000$, $Pr = 1$, $Re = 200$, $Sc = 1$, $Z = 5$, and $B/H = 2$.

For three types of gas flow (forced convection laminar flow, and combined convection spiral flows with positive and negative vortex motions) the deposition characteristics represented by the dimensionless mass transfer rate are shown in Fig. 10.

Deposition characteristics under combined flow are generally wavy compared with those under forced convection laminar flow. Although a uniform rate distribution exists under the properly selected Grashof number, predictable from deposition characteristics between forced convection laminar flow and combined convection spiral flow with positive vortex motion, control to attain an optimum operating condition may be difficult. In the case of forced convection laminar flow, deposition characteristics can be further improved by using a rectangular reactor with large aspect ratios because of flatness velocity distribution over the width. The formation of forced convection laminar flow in a chemical vapor deposition reactor can be effectively realized by low-pressure operation.

Conclusions

1. In horizontal tubes simulating a vapor deposition reactor, two modes of flow (combined free and forced convection spiral flow, and pure forced convection laminar flow) were observed, depending on experimental conditions of various flow rates and pressures. In particular, straight streamlines were found at low pressure.
2. With increasing flow rates, reverse vortex motion and eccentricity of the vortex center were observed.
3. Transition between the two flow modes occurred in the range of $Gr/Re^2 = 0.4$ to 4.1.
4. The three-dimensional diffusion equation was solved numerically under two conditions. Concentration and deposition rate distributions across and along the tube were calculated on the basis of a rectangular reactor.
5. It was estimated from calculation results that forced laminar flow in the rectangular reactor revealed

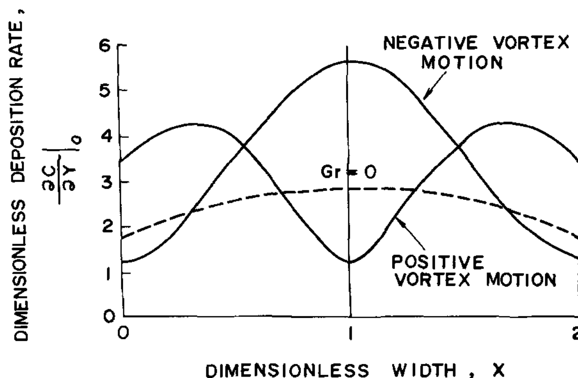

Fig. 10. Deposition characteristics corresponding to flow behaviors

an excellent uniformity of deposition rate across the width in contrast to combined flow.

Arsenic Diffusion in Silicon Using Low As_2O_3-Content Binary Arsenosilicate Glass Sources

J. Wong and M. Ghezzo*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Arsenic diffusion from a low-As_2O_3 content arsenosilicate glass film into silicon has been measured in the range 1000°-1200°C. The activation energy is found to be 4.1 ± 0.1 eV in good agreement with previous work. Concentration dependence of the diffusion coefficient of arsenic in silicon has been evaluated from the diffusion profiles using the Boltzmann-Matano analysis. In addition, the masking ability of SiO_2 toward arsenic diffusion and some diffusion parameters of arsenic in SiO_2 have been estimated.

Most of the diffusion studies performed on arsenic in silicon have been based on a gas-to-solid diffusion technique (1-8). The use of doped oxides such as binary arsenosilicate glasses in the process of solid-to-solid state diffusion of arsenic into silicon has only been recently realized since the work of Lee (9). Subsequent investigations by various authors (10-13) showed that glasses prepared from the reaction system suggested by Lee suffer severe "glass damage" when heated to 1000°C and up.

A more recent study (14, 15) shows that CVD arsenosilicate films on silicon in the range 2-20 m/o (mol per cent) As_2O_3 exhibit film detachment upon heat-treatments at 800°C and up. Thermal stresses generated in the film, arising from a mismatch of expansion coefficient with the silicon substrate are largely responsible for the observed film detachment from the substrate. However, when the amount of As_2O_3 in the film is reduced to 1.0 m/o As_2O_3 and below, film detachment and consequent glass damage can be eliminated altogether even at temperatures as high as 1100°C.

In this paper, the diffusion characteristics of arsenic in silicon from these low As_2O_3-content arsenosilicate glass films are reported. The advantages of using doped oxides in the technique of solid-to-solid state diffusion for device fabrication are well known (16-19). In the case of arsenic diffusion, one distinct advantage of using arsenosilicate glass sources is that the quantity of total arsenic involved is very small (0.1 mg or less) compared with a source of the order of grams, which must be vaporized in the technique of gas-to-solid diffusion using either open or sealed tubes. Thus, health hazards due to arsenic poisoning may be reduced considerably. The junction depths and sheet resistivities of diffused layers have been measured systematically as a function of time and temperature of diffusion. Effects of source concentration and diffusion ambient on these two parameters were also studied wherever possible. Moreover, in view of the current recognition of concentration dependence of impurity diffusion in silicon at high impurity concentration (from 10^{19} cm^{-3} and up), diffusion profiles in silicon at various temperatures have been determined experimentally so as to enable a more meaningful evaluation of arsenic diffusivities and surface concentrations in silicon.

Finally, by diffusing arsenic through a barrier layer of SiO_2 into silicon, the masking ability of SiO_2 toward arsenic diffusion has been studied as a function of SiO_2 thickness, temperature, and As_2O_3 concentration in the glass. In addition, some useful diffusion parameters of arsenic in SiO_2 can be estimated using a simple model.

Experimental

Glass deposition.—The silicon substrates used for glass deposition and subsequent diffusion of arsenic were 1 ohm-cm p-type (100)-surface oriented wafers 2.5 cm in diameter and 0.05 cm thick. These were heavily etched in a conc HNO_3-conc HF solution (3:1 by volume) and rinsed thoroughly in distilled water prior to deposition. Arsenosilicate films were deposited by a CVD technique using argon-diluted reaction mixtures of SiH_4, $AsCl_3$, and O_2. The materials and deposition apparatus have been described elsewhere (14, 15). All films were deposited at 450°C. Compositions of the as-deposited films were determined nondestructively by infrared absorption spectroscopy using a published calibration for the IR absorbance ratio *vs.* mol per cent As_2O_3 obtained by chemical analysis (14). All arsenosilicate films had a thickness of about 7000Å, which is greater than the largest diffusion length of arsenic in the glass in these experiments.

In order to study the masking effect of a barrier layer of SiO_2 on arsenic diffusion into silicon, a layer of SiO_2 was grown thermally on the bare silicon at 1000°C. The thickness of this thermal SiO_2 was determined ellipsometrically prior to arsenosilicate deposition and arsenic diffusion.

Diffusion.—A conventional horizontal diffusion furnace consisting of an electrically heated fused quartz tube having a projecting side arm for sample loading was used. The temperature of the constant temperature zone (1½ in. long) was controlled to within 2°C at 1100°C. Diffusions were performed in either argon or oxygen.

Sample preparation.—Two modes of sample preparations were used prior to the diffusion experiments. For initial determinations of junction depth x_j and electrical resistivity V/I of diffused layers as a function of temperature and time of diffusion, and thickness of the sandwiched thermal SiO_2 layer, the wafer was divided into four quarters after glass deposition. Each of these quartered wafers was then diffused individually at the preset conditions. For profile determinations, after the glass source had been deposited the wafer was halved, each piece was then diffused at the desired conditions.

After diffusion in Ar and glass removal, a thin grayish brown film was found to remain on the silicon substrate. This film, which is insoluble in the buffered HF etching solution, renders the silicon surface hydrophilic and can be removed simply by mechanical wiping. When the diffusion is performed in O_2, however, the resultant silicon surface is hydrophobic. Formation of this so-called "brown skin" has recently been reported (13) but its chemical nature is still uncertain.

Junction depth and sheet resistivity.—The junction depth and sheet resistivity of diffused layers were determined by the standard methods of angle lapping and staining, and the four-point probe technique, respectively. The former was calculated from the width of the white band in the micrograph of the

* Electrochemical Society Active Member.
Key words: arsenic diffusion in silicon, η-type glass source.

junction after staining using the appropriate magnification factor and beveling ratio. An accuracy of $\pm$ 0.035μ has been estimated with the present procedure. By switching the probe orientation on the wafer three times and reverting the current polarity, six V/I measurements were made on each sample. The arithmetic average of these V/I values was then converted to sheet resistivity using Smits' table (20).

Profile determination.—Arsenic-diffusion profiles were determined using the technique of anodization-sectioning in conjunction with the four-point probe differential sheet resistivity measurements (1, 21). The theory underlying this technique has recently been reviewed by Donovan and Evans (22). The procedure of profiling consisted of successively measuring the sheet resistivity of the diffused layer followed by removal of a silicon layer of controlled thickness, and was repeated until a sheet resistivity of ~2000 ohm/square was reached.

All anodizations were performed in a diluted aqueous HNO_3 solution at a constant voltage of 25V for 30 min. Under these conditions it was found that the thickness of the resultant anodized layer decreases with increase in sheet resistivity of the diffused layer due to a lower impurity surface concentration and/or junction depth. Ten reference anodized oxides of thickness varying in the range 200-1200Å were prepared and their thickness measured by ellipsometry. The thickness of each individual anodized layer on the diffused samples was then determined to within 50Å by comparing with the color of the reference samples. From the refractive index of the anodized SiO_2 (1.415-1.420 at λ = 5460Å) the thickness of silicon removed at each anodization was estimated to correspond to 0.40 times the thickness of the anodized oxide. The oxide was subsequently removed by etching in a buffered HF solution. The depth at any point is then the sum of the silicon increments already removed.

Results

Junction depth and sheet resistivity of diffused layers.—Two experimental parameters are of importance in the characterization of diffused layers in semiconductor technology. These are the junction depth x_j and sheet resistivity ρ_s of the diffused layer. In the present investigation these parameters were studied systematically as a function of temperature and time of diffusion and thickness of a sandwiched SiO_2 layer. Variation in As_2O_3 concentration in the diffusion source was somewhat limited due to the occurrence of glass damage on bare silicon when films containing more than 1 m/o As_2O_3 are heat-treated at 1000°C and up (15).

In Fig. 1, the junction depth x_j and sheet conductivity ρ_s^{-1} of the diffused layers are plotted as a function of the square root of diffusion time, $\sqrt{t}$. Diffusions were performed in an Ar ambient using a 0.8 m/o As_2O_3 arsenosilicate glass, 7000Å thick in each case. Linearity is obtained in the x_j *vs.* $\sqrt{t}$ plots while a monotonic increase in ρ_s^{-1} with $\sqrt{t}$ is observed at all temperatures. The diffusion is enhanced in the presence of O_2 as shown by the higher junction depths and higher sheet conductivities at 1100°C.

The junction depth and sheet resistivity of diffused layers have also been studied as a function of thickness of the sandwiched SiO_2 layer for a constant diffusion time of 4 hr at 1100° and 1150°C in Ar. The results are plotted in Fig. 2 and 3 for a 0.8 m/o As_2O_3 source and a 2.5 m/o As_2O_3 source, respectively. It can be seen that x_j decreases and ρ_s increases monotonically with thickness of the SiO_2 layer, demonstrating a positive masking effect of the thermal oxide toward arsenic diffusion. The masking ability of a given SiO_2 layer decreases with increase in As_2O_3 content in the diffusion source.

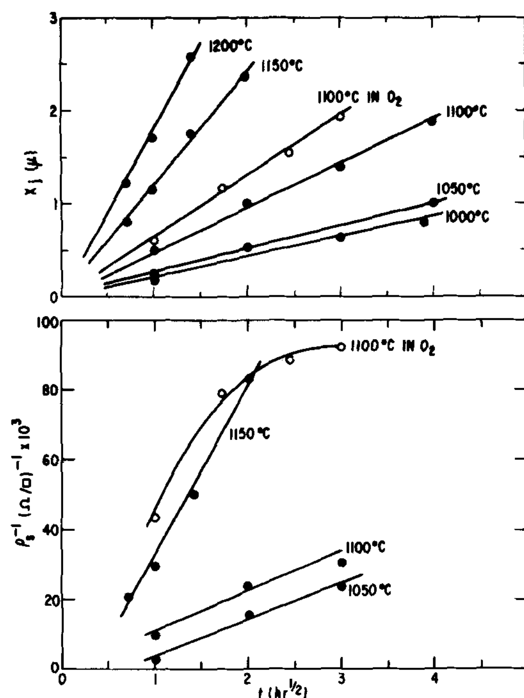

Fig. 1. Plots of (a, top) x_j and (b, bottom) ρ_s^{-1} of arsenic diffused layers in silicon *vs.* square root of diffusion time at various temperatures of diffusion in Ar (closed circles) and in O_2 (open circles). The diffusion source in each case was a film of 7000Å arsenosilicate glass containing 0.8 m/o As_2O_3.

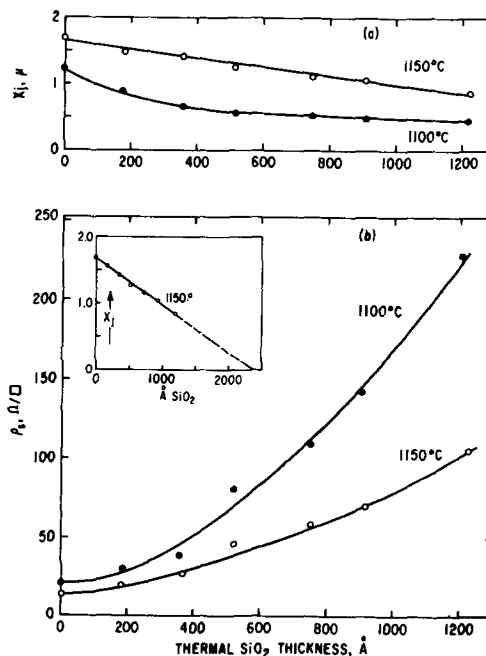

Fig. 2. Plots of (a) x_j and (b) ρ_s of arsenic-diffused layers in silicon *vs.* thickness of barrier SiO_2 at 1100° and 1150°C. All diffusions were performed in Ar for 4 hr using glass sources containing 0.8 m/o As_2O_3. Inset in Fig. 2(b) is an extrapolation to the masking thickness of SiO_2.

An attempt to evaluate the dependence of x_j and ρ_s at higher As_2O_3 concentration in the glass source proved to be unsuccessful due to the onset of severe glass damage from 5 m/o As_2O_3 and up. Nevertheless, the x_j and ρ_s data obtained by diffusing As from various As_2O_3-content glasses up to 16 m/o As_2O_3 through a 519Å SiO_2 layer at 1100° and 1150°C for 4 hr in Ar are given in Fig. 4. Monotonicity is lost in the composition region of glass damage.

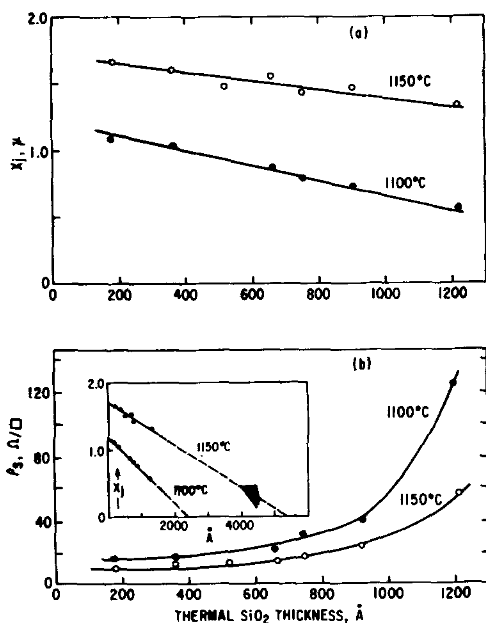

Fig. 3. Plots of (a) x_j and (b) ρ_s vs. thickness of barrier SiO_2. Diffusion conditions were identical to those shown in Fig. 2, except a 2.4 m/o As_2O_3 arsenosilicate source was used. Inset in Fig. 3(b) shows extrapolation to the masking thickness of SiO_2.

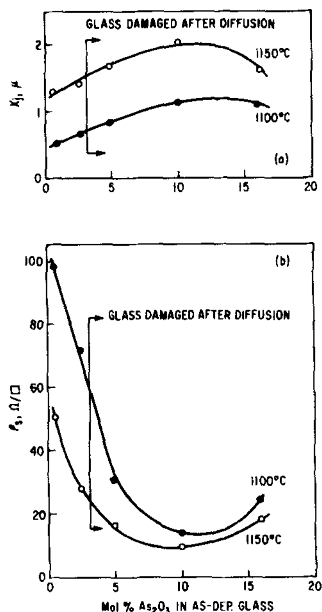

Fig. 4. Plots of (a) x_j and (b) ρ_s vs. glass composition at 1100° and 1150°C. All diffusions were performed through a 520Å barrier SiO_2 in Ar. Note glass damage beyond 2.5 m/o As_2O_3.

Arsenic-diffusion profiles.—In Fig. 5, the sheet conductivity is plotted as a function of depth into the diffusion layer at various temperatures of diffusion in Ar for 4 hr from a 0.8 m/o As_2O_3 glass source on bare silicon. The data for a similar diffusion in an oxygen atmosphere are also given in Fig. 5. The conductivity data were then statistically regressed and the differential conductivity as well as the differential carrier concentration at each point were obtained with a computer routine. The latter quantity is calculated using the effective mobility values compiled by Irvin (23). The profiles are given in Fig. 6 and represent the ionized arsenic distributions at various diffusion temperatures. It is of interest to note that the flat regions in the initial portion of the concentration profiles at 1000°, 1050°, and 1100°C are merely a manifestation of the linearity in the initial portions of the

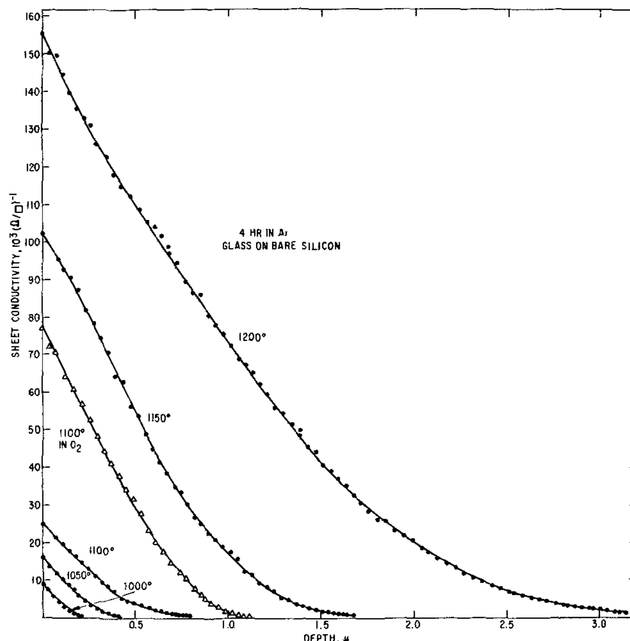

Fig. 5. Sheet conductivity profiles of diffused layers at various temperatures. The diffusion source in each case consisted of a 0.7 m/o As_2O_3 arsenosilicate film, 7000Å thick. Note the open triangles for diffusion in O_2.

respective sheet conductivity profiles (see Fig. 5). Similarly, the upward convexity and concavity in the initial portions of the conductivity profiles at 1150° and 1200°C in Fig. 5 are accordingly reflected in the respective concentration profiles in Fig. 6.

The carrier concentration profiles resulted from a 4-hr diffusion of arsenic from various As_2O_3-content arsenosilicate glasses through a layer of thermal SiO_2 of various thickness have also been studied at 1150°C. The sheet conductivity profiles in these diffused layers are given in Fig. 7, from which the carrier concentrations were determined and are shown in Fig. 8. The masking effect of the sandwiched SiO_2 layer in reducing both the carrier concentration in silicon at a given depth and the over-all junction depth can easily be seen from the profiles. For example, in going from a diffusion through bare silicon (Fig. 8 curve a) to a diffusion through a 519Å SiO_2 (Fig. 8 curve d) the carrier concentration at the surface drops from 6×10^{19} to 2.4×10^{19} cm^{-3}. Furthermore, increasing the thickness of the SiO_2 layer will lower the surface carrier concentration as well as the junction depth (cf. Fig. 8 curve c and e). Enhanced diffusion in the presence of O_2 was again observed (cf. curves b and c in Fig. 8).

Discussion

Junction depth and sheet resistivity.—It can be seen from Fig. 1 that the junction depth, x_j, of the diffused layer varies linearly with the square root of diffusion time, $\sqrt{t}$, in either an argon or oxygen ambient at all the temperatures investigated. This linear relationship holds if the arsenic concentration $N(x,t)$ in the neighborhood of the background concentration, N_B, is given by

$$N(x,t) = F(x/\sqrt{t}) \quad [1]$$

where x is the distance from the silicon surface, t is the diffusion time, and F is a function of diffusion temperature, impurity concentration in the glass, and impurity diffusivity in silicon. When x is equal to the junction depth, x_j, Eq. [1] becomes

$$N_B = F(x_j/\sqrt{t}) \quad [2]$$

As all the experiments were conducted on silicon wafers of equal resistivity with doped glasses of the

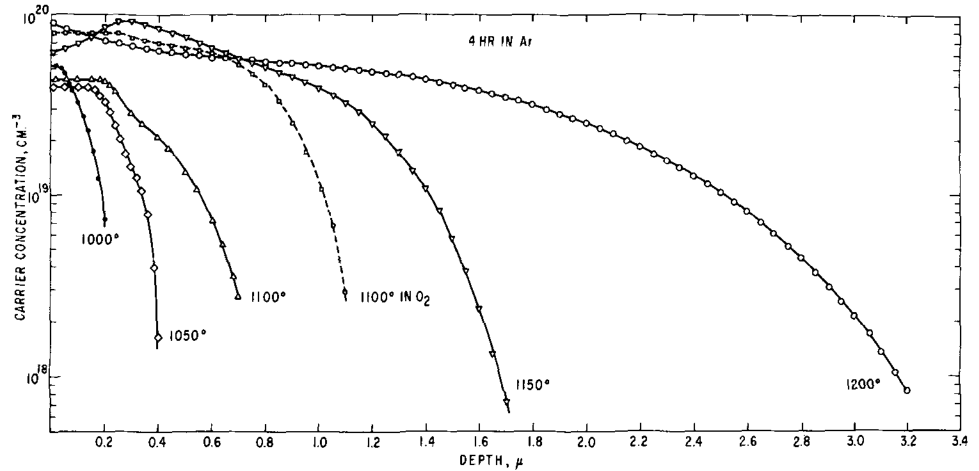

Fig. 6. Carrier concentration profiles in silicon calculated from the corresponding conductivity profiles shown in Fig. 5. The points are computer generated at regular depth intervals.

same composition, Eq. [2] is equivalent to

$$x_j = [F^{-1}(N_B)]\sqrt{t} \qquad [3]$$

where F^{-1} is the inverse of F and $F^{-1}(N_B)$ is a constant at a given temperature.

Furthermore, if the concentration profile can be described by Eq. [1], then the surface concentration, N_s, in silicon is invariant with time and equal to $F(0)$. This is the case when the glass layer is thick enough to be regarded as semi-infinite (17). Thus, a new normalized function, $f(x/\sqrt{t})$, can be introduced by the relationship

$$f(x/\sqrt{t}) = F(x/\sqrt{t})/N_s \qquad [4]$$

with

$$f(0) = 1$$
$$f(\infty) = 0 \qquad [5]$$

The second boundary condition is justified by the physical requirement that impurities diffuse into silicon with a finite rate. At low impurity concentrations where the diffusion coefficient D of As in Si is concentration independent a simple erfc distribution results, and

$$f(x/\sqrt{t}) = \text{erfc}\,(x/2\sqrt{Dt}) \qquad [6]$$

which satisfies the boundary conditions of Eq. [5].

The sheet resistivity, ρ_s, of the diffused layer is related to the carrier concentration $n(x)$ by

$$\rho_s^{-1} = \int_0^{x_j} q\,\mu(n)\;n(x)\;dx \qquad [7]$$

where q is the electron charge and μ the carrier mobility which is a function of the total impurity concentration. At high arsenic concentrations, the number of carriers is only a fraction ϕ of the total arsenic impurity concentration N (24, 25). Furthermore, this fraction is a function of N (26), so that Eq. [7] becomes

$$\rho_s^{-1} = q\int_0^{x_j} \mu(N)\;\phi(N)\;N(x)\;dx \qquad [8]$$

Using Eq. [1] and [4] to substitute for N, we have

$$\rho_s^{-1} = qN_s\int_0^{x_j} \mu\left(\frac{x}{\sqrt{t}}\right)\;\phi\left(\frac{x}{\sqrt{t}}\right)\;f\left(\frac{x}{\sqrt{t}}\right)\;dx \qquad [9]$$

Introducing a new variable $\eta = \dfrac{x}{\sqrt{t}}$, Eq. [9] becomes

$$\rho_s^{-1} = q\,N_s\sqrt{t}\int_0^{x_j/\sqrt{t}} \mu(\eta)\;\phi(\eta)\;f(\eta)\;d\eta \qquad [10]$$

The integral in Eq. [10] is not a function of time, as $x_j/\sqrt{t}$ is constant and equal to $F^{-1}(N_B)$ (from Eq.

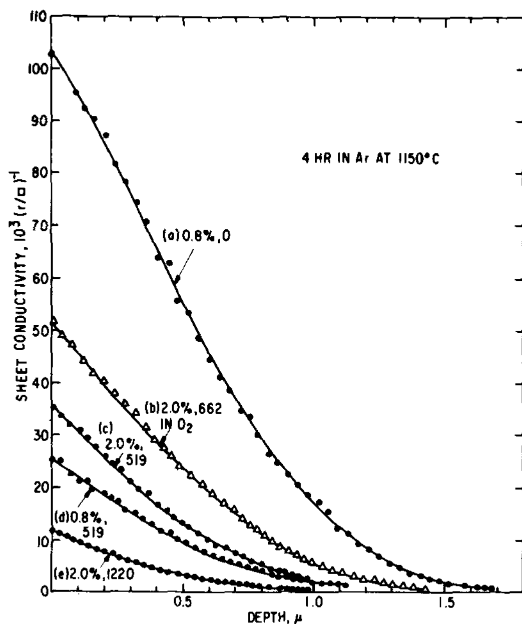

Fig. 7. Sheet conductivity profiles of diffused layers at 1150°C as a function mol per cent As_2O_3 in the diffusion source and barrier SiO_2 thickness. Note the open triangles for diffusion in O_2.

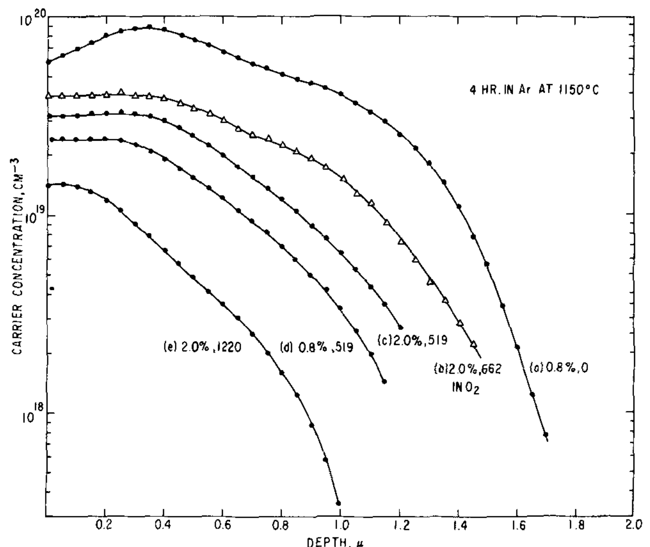

Fig. 8. Carrier concentration profiles in silicon calculated from the corresponding conductivity profiles shown in Fig. 7. The points are computer generated at regular depth intervals.

[3]). This implies that the sheet conductivity varies as the square root of time, as can be seen from the isothermal plots of ρ_s^{-1} *vs.* $\sqrt{t}$ shown in Fig. 1(b).

It must be noted however that any deviation of the concentration profile in the vicinity of the silicon surface from that given by Eq. [1] and [4] would modify the $\sqrt{t}$ dependence of the sheet conductivity. This is because close to the surface, the concentration is highest and provides the largest contribution to the integral in Eq. [10]. On the contrary, the time dependence of x_j is related to the evolution in time of the profile tail and linear plots of x_j *vs.* $\sqrt{t}$ are obtained when $N(x, t)$ can be expressed by Eq. [1] for large values of x. Thus, the linearity of x_j *vs.* $\sqrt{t}$ can be attained independently from the linearity of ρ_s^{-1} *vs.* $\sqrt{t}$, and vice versa.

In the presence of an oxygen ambient, deeper junction depths and higher sheet conductivities are obtained when compared with those of identical wafers diffused in an inert atmosphere of argon under the same conditions (see Fig. 1). This enhancement of arsenic diffusion in silicon is further manifested by the higher surface carrier concentrations observed in the profiles at 1100° and 1150°C as shown respectively in Fig. 6 and 8. Similar enhancements have recently been noted for boron and phosphorus diffusion in silicon in an oxidizing ambient (27).

It has been established that oxygen diffuses as an ionic species in silica in the process of thermal oxidation of silicon (28). If a similar ionic species is present in binary borosilicate, phosphosilicate and arsenosilicate glasses, diffusion of the impurity in the glass in the vicinity of the glass-silicon interface can be field-aided. Thus, it is conceivable that an enhanced impurity flux can be obtained at this interface to give rise to higher surface concentrations in the presence of O_2. Furthermore, a higher surface concentration can also result in higher concentrations of impurity along the profile (compare with those obtained in Ar). This in turn would increase the diffusivity of the impurity and give rise to a deeper junction.

Profiles and arsenic diffusivity in silicon.—The diffusion profiles shown in Fig. 6 and 8 can generally be described by a region of almost constant concentration near the silicon surface, followed by a region where the carrier concentration decays rapidly. Preliminary examination suggests that they do not at all appear to conform to simple complementary error functions which postulate an approximate exponential decrease in concentration in going into the junction. In Fig. 9, a direct comparison is made of the measured profiles at 1000° and 1100°C (from Fig. 6) with the corresponding erfc profiles calculated from the measured junction depths and sheet resistivity of the diffused layers based on Irvin's curves (23). It is clear from Fig. 9 that the erfc predicts a higher than actual concentration at the surface and a lower than actual concentration gradient in the vicinity of the junction. A similar "non-erfc" profile at a higher surface carrier concentration of 1.7×10^{20} cm^{-3} has also been reported (7) for the diffusion of arsenic into silicon at 1200°C using a Si(As) powdered source in an evacuated closed quartz capsule.

Indeed, it is well established experimentally that the actual diffusion profiles of Group III and V impurities in silicon at high doping concentration and deep diffusion cannot be correctly described by a simple erfc function (5, 7, 12, 21, 29-43). The assumed erfc profile bears essentially no relevant relationship with the actual profile except at low concentrations ($\leq 10^{19}$ cm^{-3}), where the diffusivity becomes a constant. In the semiconductor industry and literature, a "fictive diffusivity" is often employed, which is so defined as to make the measured junction depth and sheet resistivity, the two arbitrarily chosen parameters for the

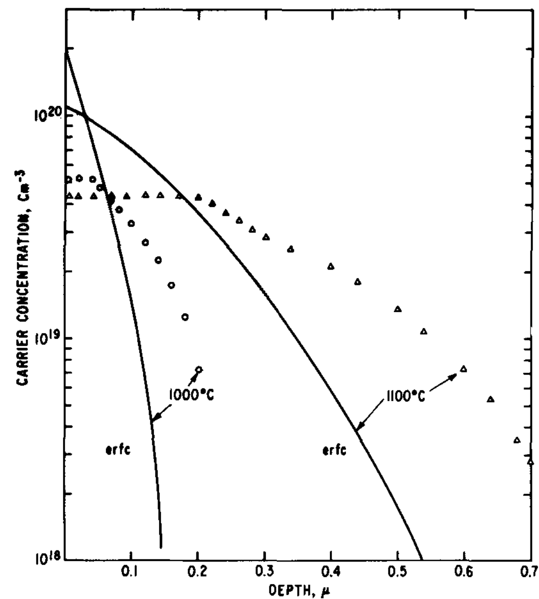

Fig. 9. Comparison of erfc distribution with actual profiles at 1000° and 1100°C from Fig. 6.

characterization of a diffused layer, coincide with a presumed erfc profile. The fictive diffusivity is also made to vary with surface concentration and background concentration (1, 7, 44). Basic inconsistencies such as those illustrated in Fig. 9 often arise as a result of the difference between the nature of an erfc and an actual profile. To avoid these discrepancies, Hu and Schmidt (5) have pointed out that it is necessary to abandon the concept of a constant diffusivity and to consider interaction of first-order importance in the treatment of the diffusion process.

One probable reason for a deviation from the erfc distribution of the carrier concentration profiles resulted in the present diffusion of arsenic from an arsenosilicate glass source into silicon is that the diffusion coefficient of arsenic is not a constant. Using the Boltzmann-Matano method (45, 46) an effective diffusion coefficient $\overline{D}$ of arsenic in silicon as a function of carrier concentration can be calculated. If $\overline{D}$ is only a function of carrier concentration which in turn will change only with $x/\sqrt{t}$ but not with x and t separately, where x is the depth into the junction and t is the diffusion time, then

$$\overline{D}_{cx} = -\frac{1}{2t}\left(\frac{dx}{dc}\right)_{cx}\int_0^{c_x} x\, dc \qquad [11]$$

From the profiles shown in Fig. 6 and using Eq. [11], the value of $\overline{D}$ as a function of carrier concentration is calculated by means of a computer routine. The results are given in Fig. 10 for various diffusion temperatures. At carrier concentration $\geq 10^{19}$ cm^{-3}, $\overline{D}_{As}$ rises sharply with increase in carrier concentrations at all temperatures. Furthermore, at diffusion temperatures of 1100°C and higher, distinct maxima in the $\overline{D}_{As}$ *vs.* carrier concentration plots are evident, which interestingly enough are quite analogous to those calculated recently by the IBM group (47, 48). A somewhat similar maximum in the diffusion coefficient of boron in silicon at 1050°C from a borosilicate glass source has also been reported by Brown and Kennicott (44) who plotted D as a function of surface concentration calculated by assuming erfc distributions.

It must be emphasized, however, that the diffusion coefficient of arsenic calculated from the carrier concentration profiles is valid only (a) if the carrier concentration profiles obtained for various diffusion times coincide with one another when plotted against the

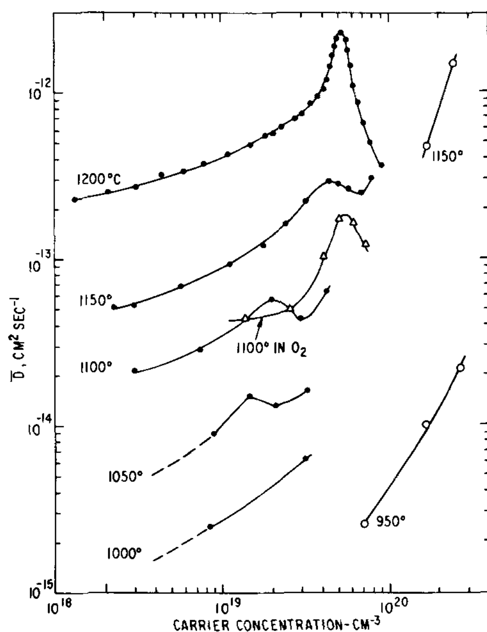

Fig. 10. Plots of D_{As} obtained from the Boltzmann-Matano analysis of the profiles shown in Fig. 6 vs. carrier concentration at various temperatures. Open circles are the data of Masters and Fairfields (6) at 950° and 1150°C.

normalized distance $x/\sqrt{t}$, and (b) if the ratio of the concentration of electrically active arsenic to that of the total arsenic in invariant with depth into silicon. In Fig. 11, the carrier concentration profiles of two identical samples diffused under the same conditions for two different times are plotted against $x/\sqrt{t}$. No exact coincidence of the profiles is obtained. Therefore, the effective diffusion coefficient obtained from the Boltzmann-Matano transformation is only approximate and the results shown in Fig. 10 are at best to be regarded as formal.

Strong concentration dependence of arsenic diffusivity in silicon has recently been observed by Masters and Fairfield (6) in their isoconcentration diffusion experiments at various background doping levels using a neutron activated Si(As) source powder in evacuated quartz capsules. Their isoconcentration results at 950° and 1150°C are also plotted in Fig. 10 for comparison.

The temperature dependence of $\overline{D}_{As}$ can be obtained from Fig. 10 by plotting $\log_{10} \overline{D}_{As}$ as a function of the reciprocal absolute temperature of diffusion at constant carrier concentration. In Fig. 12 the lines (a), (b), and (c) represent the least squares fits of the corresponding data at carrier concentrations of 4 × 10^{19} cm^{-3}, 1 × 10^{19} cm^{-3}, and 4 × 10^{18} cm^{-3}, respectively, using an Arrhenius-type expression of the form

$$\log_{10}D = \log_{10}D_o - \frac{Q}{2.303kT} \quad [12]$$

where D_o is the pre-exponential term in $D = D_o \exp(-Q/kT)$, Q is the activation energy of diffusion, and $k = 0.86 \times 10^{-4}$ eV deg^{-1}, the Boltzmann constant, With a standard deviation of 8% in the corresponding $\log_{10}D$ *vs.* $1/T$ plots, the diffusivity data may be represented by (*a*) $D = 110 \exp(-4.1 \text{ eV}/kT)$, (*b*) $D = 25 \exp(-4.0 \text{ eV}/kT)$, and (*c*) $D = 44 \exp(-4.2 \text{ eV}/kT)$, giving an activation energy of 4.1 ± 0.1 eV for the diffusion of arsenic in silicon. This value appears to be constant in the concentration range[1] of 4 × 10^{18}-4 × 10^{19} cm^{-3} and compares well with an "accepted" value of 3.9 ± 0.3 eV cited by Millea (49). Data on the temperature dependence of arsenic diffusivity in silicon by other workers (1, 3, 6, 8, 50) are also plotted in Fig. 12. Direct comparison is difficult in light of the fact that the previous calculations of D_{As} were based on assumed erfc distribution profiles with surface concentration as the concentration variable. However, the combined results of Armstrong (3) and Masters and Fairfield (6) on intrinsic silicon agree quite well with the present data at carrier concentration of 4 × 10^{18} cm^{-3}. The results of Hsueh (8) obtained from gas-solid diffusions using an AsH_3 source give $D_o = 8.3 \times 10^4$ cm² sec^{-1} and Q = 5.2 eV, and appear unreliable.

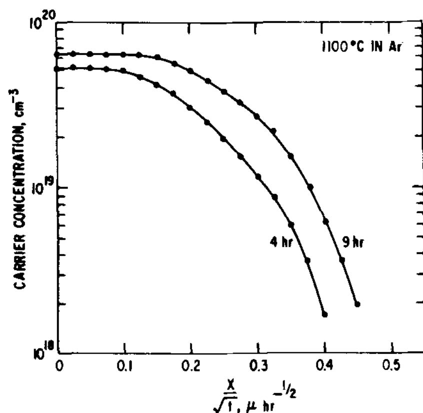

Fig. 11. Carrier concentration in two identical samples vs. normalized distance.

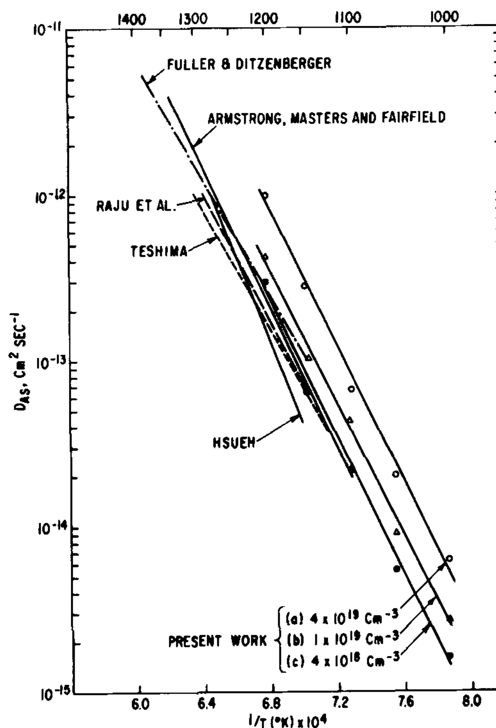

Fig. 12. Temperature dependence of arsenic diffusivity in silicon

Diffusion through a barrier SiO_2 layer.—In a recent systematic study (15) it has been shown that vapor-deposited binary arsenosilicate films on bare silicon exhibit glass detachment and consequent glass damage when glasses containing more than 1 m/o As_2O_3 are heat-treated at 1000°C and up. When glass damage occurs, undesirable characteristics such as irregular diffusion fronts and appearance of deep spikes are introduced into the resultant diffused layers (14). The

[1] Note that only $\overline{D}_{As}$ values in the carrier concentration range of 4 × 10^{19} to 4 × 10^{18} cm^{-3} (i.e., those below the maximum value in Fig. 10) are considered in the temperature dependence plots (Fig. 12). This is because of the fact that a maximum in the $\overline{D}$ *vs.* concentration plot results simply from a change in curvature of the corresponding concentration profile, which may or may not be significant experimentally in the present work.

diffusion of arsenic from these binary arsenosilicate glasses on bare silicon is therefore limited to the use of low As_2O_3-content sources (< 1 m/o As_2O_3). However, by inserting a barrier layer of pure SiO_2 between the silicon substrate and arsenosilicate glass, the concentration of As_2O_3 in the source can be increased to 2.5 m/o As_2O_3 without introducing glass damage when heat-treated to 1150°C. Thus, by diffusing arsenic through a barrier layer of SiO_2 it is possible to obtain an estimate of the effects of source concentration on the diffusion of arsenic in silicon. Furthermore, diffusion parameters of arsenic in SiO_2 and the masking ability of the latter may also be measured.

From the results shown in Fig. 2(a) and 3(a), the junction depth of diffusion layer in silicon decreases linearly with increasing thickness of the barrier SiO_2 layer. The masking thickness of the barrier layer at the given diffusion conditions is obtained by extrapolating to $x_j = 0$ (51) [see insets in Fig. 2(b) and 3(b)]. Thus, diffusing from a 0.8 m/o As_2O_3 glass source at 1150°C for 4 hr, a 2400Å thickness SiO_2 layer is required for complete masking, whereas diffusing from a 2.5 m/o As_2O_3 source at 1100° and 1150°C for 4 hr, masking thicknesses of 2400 and 5300Å are required, respectively. Under the same conditions of temperature and time of diffusion, therefore, a higher As_2O_3 content source requires a thicker SiO_2 layer for complete masking. Alternatively, for a given masking thickness of barrier SiO_2, a lower diffusion temperature is required for diffusion from a higher As_2O_3-content source at constant time.

Of interest too is the lack of upward convexity in all the x_j *vs.* SiO_2 thickness plots shown in Fig. 2(a) and 3(a). This suggests that the segregation coefficient of arsenic in silicon and SiO_2 is equal to or greater than 1 in accordance with the impurity-redistribution model of Grove *et al.* (51, 52).

Furthermore, with increasing thickness of barrier SiO_2 layer the sheet resistivity of the diffused layer increases [see Fig. 2(b) and 3(b)]. This simply implies that there is a progressive reduction of the total amount of arsenic entering the silicon substrate. From the carrier concentration profile shown in Fig. 8, it can be seen with clarity that not only the total amount of arsenic diffusing into silicon was reduced but also its concentration at the surface was substantially lowered.

Arsenic diffusion parameters in SiO_2.—The ratio of the diffusion coefficient of arsenic in SiO_2, D_1, to that in Si, D_2 can be calculated from the x_j *vs.* SiO_2 thickness data shown in Fig. 2(a) and 3(a) by using the relation

$$\sqrt{\frac{D_1}{D_2}} = \frac{x_B}{(x_j)_N - (x_j)_B} \qquad [13]$$

where x_B is the thickness of the barrier SiO_2 layer, and $(x_j)_N$ and $(x_j)_B$ are the measured junction depths obtained by diffusing without and with the barrier layer, respectively. This relation has been developed by Barry and Olofsen (17) for diffusion of a dopant from a glass source through a barrier layer of pure SiO_2 into a semiconductor substrate. The results are summarized in Table I.

Table I. Calculated D_1/D_2 ratios as a function diffusion temperature at two source concentrations

As_2O_3 in glass, m/o	D_1/D_2* 1100°C	D_1/D_2* 1150°C
0.8	0.012	0.018
2.5	0.037	0.102

* Each D_1/D_2 ratio tabulated is the arithmetic average of the set of values calculated from the respective data points in Fig. 2(a) or Fig. 3(a).

It can be seen from Table I that the diffusion coefficient of arsenic in SiO_2 is lower than that in silicon by approximately 2 to 1 order of magnitude depending on source concentration and diffusion temperature. Of more interest is the increase of the D_1/D_2 ratio with both increase in temperature and source concentration. A positive temperature coefficient of this ratio implies a negative slope in the plot of ln D_1/D_2 *vs.* $1/T$, as is evident from the following

$$\ln\left(\frac{D_1}{D_2}\right) = \ln\left(\frac{D^\circ_1}{D^\circ_2}\right) - \frac{Q_1 - Q_2}{kT} \qquad [14]$$

where D°_i are the pre-exponential terms in the Arrhenius expression: $D = D^\circ \exp\left(\frac{-Q}{kT}\right)$, and Q_1 and Q_2 are the activation energies of diffusion for arsenic in SiO_2 and silicon, respectively. This in turn implies that $Q_1 - Q_2$ is positive and that the activation energy of diffusion of arsenic in SiO_2 is greater than that in silicon. Using the combined data of Horiuchi and Yamaguchi (53), Brown and Kennicott (44) on boron diffusivity in SiO_2, and Millea's compilation (49) on boron diffusivity in silicon, a similar trend is found for the activation energies of diffusion for boron in SiO_2 (3.78 eV) and in silicon (3.71-3.69 eV). In the case of phosphorus, however, Sah *et al.* (54) found that the ratio D_1/D_2 is relatively insensitive to temperature, at least in the range 1100°-1150°C. The present data show that $Q_1 - Q_2$ for arsenic is of the order 1 ± 0.5 eV.

The 3- to 5-fold increase in the D_1/D_2 ratio with increase in As_2O_3 concentration in the source is worth noting. In the model of Barry and Olofsen (17), it was assumed that (*i*) the diffusion coefficient D_1 of dopant is the same in both the glass source and pure SiO_2 and (*ii*) D_2 is concentration independent. The fact that D_1/D_2 changes with source concentration implies that the diffusivity of arsenic in the arsenosilicate source varies with concentration and the validity of the first assumption above is therefore questionable. A strong dependence on the phosphorus concentration has also been noted by Thurston *et al.* (55) in studying P-diffusion in SiO_2 with radiotracers. Furthermore, it has been shown in the discussion earlier that the diffusivity of arsenic in silicon is concentration dependent in the range presently studied.

It must be remarked, therefore, that the above diffusion parameters calculated for arsenic in SiO_2 are best to be regarded as qualitative estimates. Further refinements of the model and more experimental data are needed to substantiate quantitative evaluation of these parameters.

Summary and Conclusion

Diffusion of arsenic in silicon from low As_2O_3-content arsenosilicate glass sources was investigated. The glass films were prepared by chemical vapor deposition using argon-diluted mixtures of SiH_4, $AsCl_3$, and O_2 at 450°C. When diffusion experiments were carried out with glass in direct contact with silicon, the film composition was held below 1 m/o As_2O_3 to avoid glass detachment at 1000°C and higher (14, 15). However, with a barrier layer of thermal SiO_2 sandwiched between the glass and silicon, the As_2O_3 content in the glass could be increased to 2.5 m/o As_2O_3 without introducing detachment at diffusion temperatures.

The resultant arsenic-diffused layers in silicon were evaluated (*a*) by measuring the junction depth x_j and sheet conductivity ρ_s^{-1} as a function of time and temperature of diffusion in both argon and oxygen ambients (see Fig. 1); (*b*) by measuring x_j and ρ_s as a function of thickness of the barrier SiO_2 layer at two temperatures and two source concentrations (see Fig. 2-4); and (*c*) by determining the carrier concentration profiles as a function of diffusion temperature (Fig. 6),

and barrier SiO_2 thickness and source concentrations (Fig. 8).

The above experimental data show that:

1. The slopes of Arrhenius plots of log $\overline{D}_{As}$ *vs.* $1/T$ (Fig. 12) at various carrier concentrations in the range 4×10^{18} to 4×10^{19} cm^{-3} correspond to an activation energy of 4.1 ± 0.1 eV in good agreement with an "accepted" value for arsenic in silicon (49).

2. The diffusion of arsenic in silicon is enhanced in the presence of O_2 to yield deeper junctions and higher surface concentrations than those in Ar at constant glass composition.

3. The diffusion profiles of arsenic in silicon are different from those of an erfc distribution.

4. The ratio of the diffusion coefficient of arsenic in SiO_2 to that in silicon increases with increase in temperature. $Q_1 - Q_2$ is estimated to be 1.0 ± 0.5 eV.

Acknowledgments

We are much indebted to L. F. Cordes for his comments and assistance in the profiling technique, and his generous loan of the computer routines for analyzing the diffusion data. We are grateful to D. M. Brown for the use of his equipment and facilities. We thank E. A. Taft and R. J. Connery for the ellipsometric measurements of film thickness and preparation of thermal oxide, respectively. Suggestions and encouragement given by M. Garfinkel in the course of this work are gratefully acknowledged. Helpful discussions with J. W. Mitchell, R. N. Hall, and P. V. Gray are also appreciated.

Manuscript submitted Jan. 14, 1972; revised manuscript received May 23, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

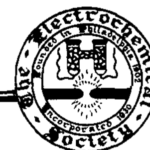
Technical Notes



Effects of Hydrogen Annealing on High Power RF Sputtered Al_2O_3 Films on Silicon

P. K. Ajmera, M. A. Littlejohn, and J. R. Hauser

North Carolina State University, Raleigh, North Carolina 27607

A study of radio-frequency (rf) sputtered Al_2O_3 films has indicated that the density, dielectric constant, and index of refraction of these films increase while the P-etch rate decreases with increasing target-power density (1). In spite of these superior physical properties, Al_2O_3 films obtained by high-power rf sputtering have a serious drawback in that the surface-charge density located at the Al_2O_3-Si interface also increases with increasing power density (1). This high density of positive surface-charge results in large negative values of the flat-band voltages (V_{FB}) of metal-Al_2O_3-Si (MAS) devices fabricated from high-power sputtered films. This makes high-power sputtered Al_2O_3 films unsuitable as insulating layers for field effect metal-insulator semiconductor devices.

In this paper the results of a post-deposition annealing treatment which reduces the value of the effective surface-charge density in MAS devices are described. Metal-Al_2O_3-SiO_2-Si (MAOS) devices are also investigated, and the effects of the annealing treatment on some of the electrical properties of the MAOS devices are reported. The improved properties of high-power rf sputtered Al_2O_3 films offers the possibility for improved performance of MAOS memory elements (2).

Sample Preparation

Al_2O_3 films were deposited on both p- and n-type silicon substrates. The substrates were polished single-crystal Czochralski silicon slices of (111) orientation. The resistivity of the substrates was between 5-10 ohm-cm.

The rf sputtering system used was similar to the one described elsewhere (1) except for the fact that no provision was made for applying a magnetic field in the sputtering chamber. The rf sputtering power density was 500W which corresponded to a power density of 3.95 W/cm^2 at the target. A value of target-power density greater than 2.5 W/cm^2 has been found to yield an effective value of the positive surface-charge density located at the Al_2O_3-Si interface greater than 10^{13} e/cm^2. This value can not be significantly reduced by annealing in nitrogen gas at 300°C (1). For an effective surface charge density of 2×10^{13} e/cm^2 located at the Al_2O_3-Si interface, the magnitude V_{FB} of a MAS device is greater than 40V for a 1000Å sputtered Al_2O_3 film.

Two sets of sputtering runs were made. The first set of runs were made at a pressure of 5×10^{-3} Torr and a target-to-substrate distance of 1.8 in. In this set of runs either only argon or 20% oxygen along with argon was present in the plasma during the film deposition. High-purity argon and oxygen carrier gases were used. For convenience, films obtained from this set of runs will be identified as those obtained by "method 1". The second set of sputtering runs were made at a pressure of 7.5×10^{-3} Torr with a target-to-substrate distance of 1.7 in. The plasma, for all the runs made in this set, contained 20% oxygen-80% argon. For convenience, this second set is referred to as "method 2." For both methods, the target voltage was 3.53 kV (peak value), the plate current was about 0.5A, and the substrate holder was grounded and water-cooled. The target was a 99.98% (or better) pure disk of Al_2O_3. Films were deposited on both p- and n-type substrates simultaneously during each run. The deposition rate of the Al_2O_3 films was 90 Å/min for method 1 when only argon was present in the plasma and was 70 Å/min with 20% oxygen. The rates, along with other physical properties such as dielectric constant and breakdown strength compared favorably with values reported by Salama (1).

MAS devices were fabricated from Al_2O_3 films of thicknesses varying from about 500 to 4400Å and obtained by method 1. In the case of MAOS devices, prior to Al_2O_3 deposition, approximately 200Å of SiO_2 was thermally grown in dry oxygen at 900°C. The MAOS devices were fabricated from Al_2O_3 films of thicknesses varying from about 500 to 3140Å obtained by method 2. Aluminum dots (10 mil diameter) were evaporated on the oxide layers to form the metal contacts for MAS and MAOS structures. Aluminum was also evaporated on the back of the Si substrates. Annealing of the oxide layers was always carried out prior to the metal evaporation. A standard probe was used to test MAS and MAOS devices on which no long-time bias stresses were applied. MAOS devices, on which long-time bias stresses were applied, were mounted on TO-5 headers, bonded, and sealed in an argon atmosphere prior to testing.

Experiment and Results

Standard C-V techniques were used to study the electrical properties of MAS and MAOS structures. A "slow" and a "fast" C-V system was used. The "slow" C-V system required 22-23 sec while the "fast" C-V system, which is described in detail elsewhere (3), required 55 msec for the complete bias sweep. Slow C-V measurements were made on both MAS and MAOS devices while fast C-V measurements were made on MAOS devices.

Slow C-V measurement results on MAS devices.— Slow C-V measurements on MAS devices fabricated from unannealed Al_2O_3 films obtained by method 1 and in argon plasma showed no variation of capacitance with d-c bias voltage between ±40V, or up to the breakdown value. The fact that the capacitances of MAS devices fabricated from films deposited in argon plasma on p-type Si substrates increased on applying external illumination while the capacitances of devices on the corresponding n-type substrates were insensitive to external illumination suggested the presence of a large negative value of the flat-band voltage. This corresponds to the presence of a large density of positive charges either in the oxide or at the Al_2O_3-Si interface, or both. This is in agreement with the results

Key words: aluminum oxide, sputtering, H_2-annealing, films, MIS.

of Salama (1). Also, no changes in capacitance with bias were observed on MAS devices fabricated from films obtained by method 1 or method 2 and deposited in argon and oxygen plasma for d-c bias sweep voltages between ±40V or the breakdown value. This indicated the presence of a high density of charges in the bulk of the Al_2O_3 and/or at the Al_2O_3-Si interface for films sputtered with 20% oxygen in the plasma as well.

Portions of a 950Å, Al_2O_3 film obtained by method 1 in an argon plasma were annealed in either: (*i*) nitrogen gas at 720°C for 20 min; or in (*ii*) oxygen gas at 730°C for 20 min; or in (*iii*) forming gas (95% N_2, 5% H_2) at 425°C for 75 min. The slow C-V curves of the MAS devices fabricated from the above differently annealed portions of the same Al_2O_3 film were similar to the unannealed case in that none of them showed any change in the capacitance value with the applied d-c bias voltage sweeps up to ±40V or the breakdown value. In Salama's studies of rf sputtered Al_2O_3 MAS devices (1), annealing in N_2 at 300°C had little or no effect on the oxide charge for power densities above 2.5 W/cm^2.

In one further attempt to reduce the oxide charge the Al_2O_3 films fabricated in either argon plasma or in argon and oxygen plasma by method 1 were annealed in H_2 gas at 710°C for about 10 min. Slow C-V curves were observed on MAS devices fabricated from the above hydrogen annealed films. The presence of surface states and/or a change in flat-band voltage during the bias sweep time may account for the gradual change in the value of capacitance with the applied d-c bias sweep observed on these H_2-annealed devices. Both positive and negative values of flat-band voltages were observed; however, most of the devices made from films sputtered in argon plasma had large negative flat-band voltages. The devices made from films sputtered with both argon and oxygen in the plasma had smaller negative, zero, or positive flat-band voltages. For this reason MAOS devices reported in this paper were fabricated from films sputtered with both argon and oxygen plasma.

Hysteresis was observed on the slow C-V curves of the hydrogen-annealed MAS devices. This hysteresis was, in general, found to be negligibly small for devices having a positive value of the flat-band voltage. The devices with negative values of flat-band voltages, and especially those with large negative values, showed considerably larger hysteresis. The magnitude and the direction of the hysteresis loop were found to be dependent on the applied bias voltage sweep. At low values of applied bias sweep, the direction of the hysteresis loop corresponded to that observed for ion-migration in the oxide, while at higher values of the applied bias sweep, it corresponded to the direction observed for charge injection occurring at the oxide-semiconductor interface. An instability due to charge injection has also been observed on MAS devices fabricated from low power (<2.5 W/cm^2) sputtered films (1). Ion migration at lower applied electric fields and charge injection at higher applied electric fields were found to be the dominant type of instabilities observed in these MAS devices. A high density of surface states and a probable presence of change in flat-band voltage during the bias sweep time make the high-power sputtered Al_2O_3 films deposited over Si and reported on in this paper unsuitable for solid-state field effect device technology.

Slow C-V measurement results on MAOS devices.—To avoid the undesirable Al_2O_3-Si interface, the properties of MAOS structures were studied. This structure has been reported on by several other authors (4-6). MAOS devices were fabricated from (*i*) unannealed films, (*ii*) films annealed in hydrogen at 710°C for 10 min, and (*iii*) films annealed in nitrogen at 720°C for 10 min following the hydrogen-gas annealing as in step (*ii*) above.

Slow C-V shifts were observed on all MAOS devices including the ones made from unannealed films. The shapes of the C-V curves of MAOS devices indicated a significant reduction of surface states, with unannealed devices having effective surface-charge densities of approximately 5×10^{11} e/cm^2. However, the MAOS devices fabricated from H_2- and N_2-annealed films showed a larger number of surface states than the MAOS devices fabricated from unannealed films or films annealed in hydrogen alone. Nitrogen-gas annealing following the hydrogen-gas annealing seemed to distort the shapes of the C-V curves of the MAOS devices, especially at the higher bias sweep voltages. The flat-band voltages of the MAOS devices made from unannealed films were either slightly positive, zero, or slightly negative (between −0.5-0.5V) while those of devices made from hydrogen-annealed films or hydrogen- and nitrogen-annealed films were always negative (less than −0.5V) indicating the introduction of a net positive charge in the oxide upon annealing.

Ion migration was found to be the dominant type of instability observed on the MAOS devices for small values of applied fields. Charge injection occurring at the SiO_2-Si interface was found to be the dominant type of instability at higher applied bias voltages. Charge injection at the SiO_2-Si interface was observed on annealed MAOS devices for both polarities of the applied bias voltages. Charge injection was observed at smaller magnitudes of applied negative bias voltages as compared to applied positive bias voltages. The positive bias voltages were at least twice the magnitude of the negative bias voltages required to observe charge injection. However, most devices began to conduct excessively before charge injection could be observed for positive bias voltages. Charge injection at the SiO_2-Si interface was observed on unannealed MAOS devices on the application of high-negative bias voltages only. The magnitudes of negative fields necessary to observe the effects of charge injection in unannealed devices were higher than the magnitudes of the negative fields necessary to observe the effects of charge injection in the corresponding annealed devices. No charge injection was observed on MAOS devices made from unannealed films for positive bias voltages as large as the breakdown values.

Fast C-V measurement results on MAOS devices.—The stability of MAOS devices under applied bias stresses was investigated in detail since Al_2O_3-SiO_2 double-layer structures showed a greater promise for practical applications. The fast C-V measurement technique was used to obtain changes in V_{FB} with applied bias time at 40°C. A fast C-V system is not only more accurate, as the error due to changes in V_{FB} during the bias sweep time is reduced, but also makes observation of changes in V_{FB} possible for a small duration of bias time.

Data on MAOS devices fabricated from unannealed, hydrogen-annealed, and hydrogen- and nitrogen-annealed portions of a 930Å sputtered Al_2O_3 film obtained by method 2 are presented. Figures 1 and 2 show changes (ΔV_{FB}) in V_{FB} from the initial value just prior to application of bias plotted against bias-time for two separate bias voltages. A positive value of ΔV_{FB} denotes change in V_{FB} which corresponds to ion migration in the oxides while a negative value of ΔV_{FB} denotes change in V_{FB} due to charge injection at the oxide-semiconductor interface, regardless of the polarity of the applied bias voltage.

Under applied positive bias voltages of magnitudes up to 10V, the hydrogen-annealed devices, in general, were found to have the largest values for ΔV_{FB} while the unannealed devices were found to have the smallest values for ΔV_{FB} for a given bias time (Fig. 1). Under applied negative gate voltages charge injection at the oxide-silicon interface was, in general, found to occur in the hydrogen- and nitrogen-annealed devices for the shortest duration of bias time (Fig. 2).

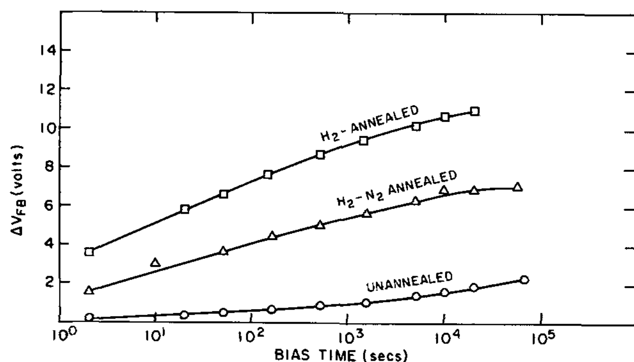


Fig. 1. ΔV_{FB} vs. time for +10V applied bias (930Å Al_2O_3 and 200Å SiO_2 on a n-type Si substrate).

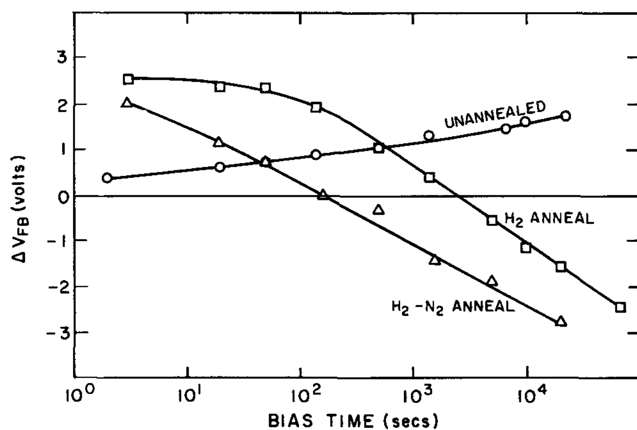

Fig. 2. ΔV_{FB} vs. time for −20V applied bias (930Å Al_2O_3 and 200Å SiO_2 on a n-type Si substrate).

The unannealed devices were again found to be the most stable with no observable charge injection occurring at the SiO_2-Si interface for bias-times in the range of 10^4-10^5 sec for applied negative bias of up to −20V. The values of ΔV_{FB} were considerably greater for positive values of applied bias voltages for all devices considered as compared to the applied negative bias voltages of the same magnitudes as long as the effects due to charge injection were not significant. This is evident from Fig. 3 which shows ΔV_{FB} with bias time for an unannealed device for various values of applied positive and negative biases.

The flat-band voltage of each device was allowed to recover to its initial value by shorting its leads for at least 6 hr after the completion of each bias cycle. The change in V_{FB} of the device from the initial value of V_{FB} before the application of a bias cycle was noted after each recovery period. Significant changes in V_{FB}

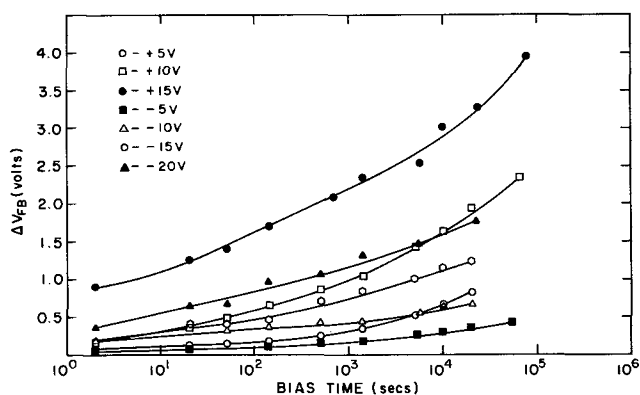

Fig. 3. ΔV_{FB} vs. time for various bias voltages for an unannealed MAOS device (930Å Al_2O_3 and 200Å SiO_2 on a n-type Si substrate).

were obtained after the recovery period for annealed devices. It should be remembered here that the values of ΔV_{FB} were also correspondingly high for the annealed devices. The most significant changes in V_{FB} after the recovery period for annealed devices occurred after the application of a −20V bias cycle. For this value of applied bias the effects of charge injection across the SiO_2-Si interface were also simultaneously significant. Even after shorting the device for 48 hr the initial value of V_{FB} could not be recovered after a −20V bias cycle. This indicated the presence of deep trapping centers in the sputtered film. No significant changes in the values of V_{FB} were obtained for unannealed devices after each recovery period following the completion of the applied-bias cycles. Simultaneously, no significant charge injection was observed on unannealed devices. The values of V_{FB} and consequently the values of ΔV_{FB} for annealed devices were hence found to depend upon the previous bias history.

Discussion of instabilities associated with MAOS devices.—Ion migration was the dominant type of instability observed in MAOS devices at low values of applied electric fields. The hydrogen-annealed MAOS devices showed the largest positive values of ΔV_{FB} corresponding to the largest amount of ion migration in the bulk of oxide layers. Nitrogen annealing following the hydrogen annealing seemed to reduce this ion density somewhat to yield smaller amounts of ion migration in hydrogen- and nitrogen-annealed MAOS devices. Unannealed devices were the most stable, having the least amount of ion migration.

Charge injection across the SiO_2-Si interface was observed in MAOS devices at high values of applied electric fields. Charge injection was also found to be strongly dependent on the applied field. Schottky emission at 40°C is not the likely cause for the observed charge injection as the energy barrier present at the Si-SiO_2 interface is fairly large (7). The SiO_2 thickness of 200Å is small enough to suggest the presence of Fowler-Nordheim tunneling through the reduced barrier width of SiO_2 at fairly high applied fields. A possible mechanism for charge injection under an applied negative field can be Fowler-Nordheim tunneling of holes from the Si into the traps located at the Al_2O_3-SiO_2 interface through the reduced effective barrier width of the SiO_2 layer. An equivalent mechanism can also be injection of electrons from the Al_2O_3 into the Si.

Conclusions

MAS devices fabricated from high-power sputtered films in argon plasma or in argon and oxygen plasma had large values of effective surface-charge densities. High temperature H_2-gas annealing reduced the value of this effective surface-charge density. Ion migration at low values of applied electric field and charge injection at the SiO_2-Si interface at higher applied electric fields were the dominant type of instabilities in MAS and MAOS devices. However, MAOS devices showed fewer surface states than MAS devices. Significant changes in the flat-band voltages were observed with applied bias stresses for both the hydrogen-annealed and hydrogen-nitrogen annealed MAOS devices. Unannealed MAOS devices were found to be the most stable devices under prolonged applied bias stresses. The double-layer Al_2O_3-SiO_2 structure over Si shows a greater promise than the MAS structure for possible use of high-power sputtered Al_2O_3 films in device technology.

An Effect of Organic Electron Donors and Acceptors on a Real Silicon Surface

J. A. Jackson, J. R. Szedon, and T. A. Temofonte

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

Semiconductor surface-state effects have received considerable attention in the past. From a practical point of view, electrical effects of such states can strongly influence and often limit the performance of semiconductor devices, *e.g.*, by the formation of conducting-surface channels, by the limitation of junction-blocking voltage capability due to surface breakdown, by the addition of a surface-generation component to a junction-reverse current, and by other effects. Before the development of silicon-device technology and the use of thermally grown silicon dioxide for device passivation, a great deal of work was done on electrical-surface effects of various chemical species. In general, this work was empirical, establishing the electrical effects of, for example, water vapor on germanium (1), acetone vapor on silicon (2), and etchants and metallic impurities on germanium (3). Some attempts have been made to provide detailed models for the interaction of chemical species with semiconductor surfaces, *e.g.*, water on silicon (4) and amines on germanium (5).

Basic work on treating chemical effects on silicon-surface properties has diminished significantly with the development of silicon dioxide passivation technology. This was probably due to the great difficulty in controlling and modelling surface-defect effects for the case of silicon surfaces coated with thick amorphous dielectric films. However, from a practical point of view, the effect of organic materials used in packaging unpassivated semiconductor devices is of considerable interest. Impurities arising from poorly matched stoichiometry affect the elevated temperature performance of microdiodes (6) and recent work has attempted to characterize the relative effect of different types of impurities (7).

For the present work we return to the case of an unpassivated, real silicon surface, *i.e.*, a silicon surface covered by a thin (~10–40Å) layer of residual oxide. Our aim is to demonstrate that both positive and negative charge can be induced at a silicon surface by the *a priori* selection of an organic material on the basis of its known ability to donate or attract electronic charge.

Work on the adsorption of amines on germanium transistors (5) suggested that the relative effect of this group of compounds is associated with the ease of electron donation to the semiconductor surface. Amines have an unshared pair of electrons which they can donate to suitable molecules which exhibit electron-accepting ability. The ease with which an amine, $NR_1R_2R_3$, can lose an electron is determined by the nature of the group R. If R is electron repelling, then ease of electron donation is increased. One of the strongest electron donors (8) is N,N,N, N-tetramethyl-p-phenylene-diamine (TMPD). In this paper, we have compared the effects of TMPD with a strong electron attractor on the surface conduction behavior of a field-effect transistor. The cyano group has a known electron-withdrawing effect; tetracyanoethylene (TCNE) is one of the strongest electron acceptors (8) known and for this reason was chosen for investigation of this effect. For a comparison of the effects of these two compounds, both were purified[1] then dissolved (approximately 20% by weight) in electronic-grade benzene.

Key words: silicon, surfaces, organic, charge, transfer.

Charge effects of the organic materials on real silicon surfaces were evaluated by noting the change in conductance of surface-controlled field-effect transistors (9) prepared without gate electrodes. Since the chemical species were chosen to produce strong electron donating and extracting effects, transistors were fabricated on both n-type (20 ohm-cm) and p-type (30 ohm-cm) silicon. Shallow diffusions (2-4 μm) of boron and phosphorus, respectively, were made into these materials to provide the source and drain contacts. The silicon surfaces were passivated with thermally grown silicon dioxide (5400Å) except for the channel areas (25 × 350 μm) in which the organic materials were expected to have their effect.

Consider first a structure of the type $n^+/p/n^+$ which is capable of detecting mobile electrons induced in the silicon channel window area. Prior to immersion in the benzene solvent, the drain-source current was less than 10 μA at 4V. After immersion of the device in the undoped solvent, and with application of a 4V peak, full-wave rectified voltage to the device,[2] the conductance had increased as shown by the lower curve of Fig. 1. This current could be reduced to zero

by reverse biasing the substrate with respect to both the source and the drain. Such a result indicated that the conduction was occurring within the silicon near its outer surface and not in the solvent or at the solvent-silicon interface.[3] A similar conduction effect was observed on immersion of the complementary $p^+/n/p^+$ transistor structure into undoped benzene. Since enhanced conduction was noted on both types of structures, we ascribe the effect to creation of a conducting channel within the silicon by electrostatic induction due to potential propagated from the drain electrode. The conductivity value for benzene ($\sim 10^{-7}$ mho cm^{-1}) is large enough to support the propagation of drain potential over the silicon surface, but is too low to be observed directly in terms of source-drain leakage. Such propagation, supported by low conductivity of a solid organic dielectric material at elevated temperatures, is well established (10). This model is also consistent with the observed increase of conduction with drain bias (with a time lag of 1-2 sec).

Addition of TMPD to the benzene solvent increased the electronic channel current in the $n^+/p/n^+$ transistor as shown in Fig. 1. The increase in conductance in the 2-4V range of source-drain voltage was 7×10^{-5} mhos, corresponding to a density of 4×10^{10} sites/cm^2 if an electron surface mobility value of 600 cm^2/V sec is assumed (11). The level of conduction induced by the dopant was not sensitive to drain bias in the range indicated in the figure. For this reason, we attribute the additional conduction to induction of mobile electrons at the silicon surface by the electron-donating action of the organic dopant. To rule out the possibility of enhanced drain-potential propagation by the action of the dopant in benzene, we immersed a complementary ($p^+/n/p^+$) device in benzene with the same dopant and saw no increased channel conduction in that case. When removed from the doped solution and introduced into undoped benzene, the $n^+/p/n^+$ device still exhibited strong channel conduction which did not decay significantly over the period of the test (~ 5 min). This suggests that the electron donor becomes strongly associated with the silicon surface.

Complementary observations were made when a $p^+/n/p^+$ transistor was immersed in benzene doped with TCNE. Hole conduction increased by 3×10^{-5} mhos above the level for the undoped solvent, corresponding to approximately the same charge site density, 4×10^{10} cm^{-2}, as in the case of TMPD, when the lower surface mobility of holes is taken into account (11). A cross-effect experiment, introduction of a structure of the $n^+/p/n^+$ type into benzene doped with TCNE, resulted in no enhanced conduction. This indicated, as in the case of TMPD, that the dopant does not cause enhanced conduction in the solution, which could allow the drain potential to affect the silicon to a greater degree than in the case of the undoped benzene.

We interpret the increased hole conduction for the $p^+/n/p^+$ device immersed in the solution doped with TCNE as being due to the ability of the dopant to accept negative charge. The following is proposed to explain the effect. A molecule of TCNE on the real silicon surface is initially neutral. The electron-deficient region associated with the π bond could provide empty electronic states into which electrons from the silicon surface might tunnel, even with the thin oxide present. The radical anion derived from the TCNE would then represent a static negative charge requiring compensating positive charge within the silicon supplied by ionized donors and mobile holes. We do not exclude the possibility of electron transfer back to the silicon by tunneling, but in our case the effect is not dominant. The observed effect is one of net electron extraction to form a region of negative-charge exterior

[3] This feature of distinguishing between solvent and semiconductor mechanisms makes the ungated FET structure an extremely powerful tool for "wet" surface studies.

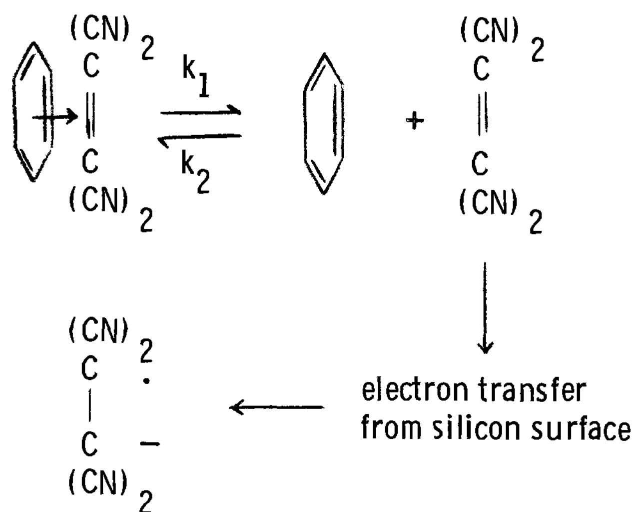

Fig. 2. Formation of cationic intermediate from charge-transfer complex.

to the silicon. The donor effect of TMPD can be explained in a similar manner, if we invoke the formation of a radical anion (or dianion), which gives rise to a sheet of positive charge adsorbed on the surface.

In experiments involving TCNE, ultrasonic agitation resulted in conduction enhancement, about 2.5 times above that observed in the studies with TMPD. The data reported above for both p and n devices were obtained with ultrasonic agitation. We speculate that a concentration gradient of the electron donor or acceptor exists near the silicon surface which limits the rate of formation of the reactive intermediate. Agitation may be viewed as destroying this concentration gradient and hence allowing for higher concentrations of the additives at the surface. The observed effect of agitation suggests that the rate-determining step (for TCNE, k_1 in Fig. 2) is dissociation of the TMPD-benzene or TCNE-benzene complexes, with the relative effect reflecting the difference in their stabilities.

More detailed studies of the electronic interactions are needed to determine if the organic compounds affect the generation-recombination behavior of the real surface or if they result in carrier mobility behavior at the silicon surface significantly different from that inferred from studies on passivated surfaces.

The Solidus Boundary in the GaAs-GaP Pseudobinary Phase Diagram

L. M. Foster,* J. E. Scardefield, and J. F. Woods

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

In previous articles of this series (1-5), phase boundaries of the pseudobinary phase diagrams of a number of III-V compound semiconductor systems were reported and, in cases where the data were sufficiently complete, thermodynamic analyses were carried out. The objective of this continuing investigation is to arrive at a model which will contribute towards a better understanding of the nature of these interesting solids.

In order for similarities and differences between various systems to be apparent, quite precise data for the phase diagrams are required. Although it is now known that, with a few recognized exceptions (4), there is complete miscibility in the solids of the III-V alloy systems, in many cases the phase boundaries are only approximately known. Osamura and Murakami (6) reported data for the solidus of the GaAs-GaP system, but the points are badly scattered, have wide error limits and, in fact, fall on either side of the ideal boundary so that even an approximate calculation of the departure from ideality cannot be made. In the present note, we will report new data for the solidus boundary of this system.

Points on the solidus boundary were obtained by a technique that was developed by two of the authors for determining the boundary of the InP-GaP system (1). In this method, a pellet pressed from intimately mixed powders of the two components (GaAs and GaP) is encapsulated in fused silica and held at a constant temperature within the two-phase region of the phase diagram for sufficient time for equilibration of the liquid and solid phases to be achieved (typically, a few days). The sample is then quenched and the composition of the solid-solution phase is determined by electron-microprobe analysis. This composition corresponds to a point on the solidus boundary at the equilibration temperature.

Seven solidus points were determined for the GaAs-GaP system. These are listed in Table I and are shown in Fig. 1. The crystal lattice parameter of the primary solid-solution phase in each sample was also determined. This phase can readily be distinguished from the quenched liquid in the x-ray powder pattern, since it is present in the largest amount and has a smaller a-parameter than any other composition in the sample. That Vegard's law is strictly followed in this system throughout the entire composition range is seen in Fig. 2.

The excess free energy of mixing in a binary system can be calculated if both solidus and liquidus curves are known (2). There are no liquidus data for the GaAs-GaP system; however, an estimate of this quantity can be made if the liquid is assumed to be ideal. Justification for this assumption lies in the fact that in the systems studied to date, nonideality in the solid solutions has always been substantially greater than in the liquids (1-5), and quite strongly dependent on the difference in lattice parameter between the two components of the alloy. The parameter difference in GaAs-GaP (3.7%) is about midway between that of GaAs-AlAs (0.16%) and InSb-GaSb (6.1%), both of which had essentially ideal liquids.

Following the procedure described in Ref. (2) to determine the excess free energy of mixing, $B^s x(1-x)$, gives $B^s/RT = 0.2 - 0.12x$, where x is the mole fraction of GaP. The solid curves in Fig. 1 show the resulting fit to the solidus data, and the calculated liquidus curve, assuming $B^l = 0$. The significance of the excess free energy in the GaAs-GaP system, and the relation of this system to the other III-V alloy systems will be presented elsewhere (7).

Growth of Silver Crystals in the Meniscus Region

Richard J. Roethlein[*,1]

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts 01247

Recently, it has been observed that at the junction of the three-phase interface of a partially immersed silver foil in an acid solution containing silver ions, there is a tendency for silver crystals to grow under certain conditions. Tests conducted on both polished and etched silver foils indicate that this phenomenon is due to a slight temperature differential between the liquid electrolyte and the vapor immediately above the electrolyte level. A series of tests was run in which the electrolyte and surrounding atmosphere were completely saturated with nitrogen in order to rule out any effects due to differential aeration. The electrolyte used was 20*N* phosphoric acid containing a silver ion concentration ranging from 0.1 to 1.0*N* Ag^+ ions. Tests were conducted in a sealed Pyrex cell containing a partially immersed silver or gold foil. When the cell was placed in an oil bath, so that a slightly lower temperature occurred in the vapor immediately above the electrolyte, silver crystals were observed to grow in the region of the interface on both the gold and silver substrate (Fig. 1). This was observed to take place for electrolyte temperatures above 40°C and became more accentuated with increasing temperature. Temperature measurements immediately above the electrolyte level showed that a 1° or less temperature differential existed. In the absence of any silver ions in solution, no crystal growth or corrosion of the substrate was observed to occur at any temperature up to 85°C.

Visual inspection of the silver foil while immersed in the electrolyte indicated that the region where crystal growth occurred closely coincided with the area of meniscus formation. Measurements of the vertical length of the crystal deposition zone are approximately 0.28 cm, which corresponds to the meniscus height measured previously in phosphoric acid on partially immersed platinum electrodes (1). Above the region of crystal growth the silver foil surface showed evidence of severe corrosion attack. In this region, there is a thin film of electrolyte on the surface of the foil having a thickness of less than 1μ (1). The application of small cathodic currents (5-100 $\mu A/cm^2$) under these conditions only accelerated the rate of crystal growth and corrosion. The accelerated rate of corrosion during current flow is probably due to concentration changes caused by the rapid depletion of silver ions in the upper meniscus thin-film region. Tests conducted on partially immersed gold foils produced similar results in that a silver crystal build-up occurred only in the region of meniscus formation. In the case of a gold substrate, no corrosion was evident in the region of film formation.

Key words: electrodeposition, corrosion, thermal gradient, crystal growth.

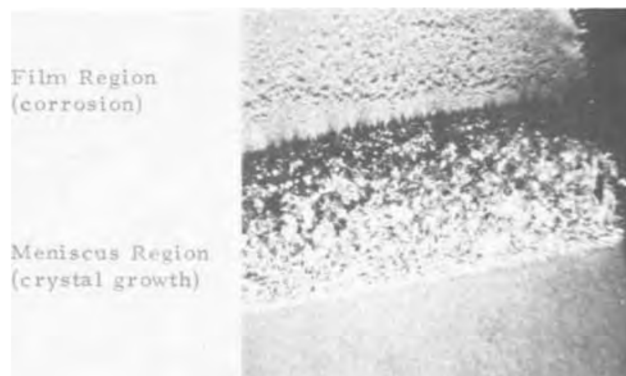

Fig. 1. Ag foil partially immersed, 24 hr 70°C (20X)

The test cell apparatus was then placed in an oven where the whole unit could be kept at a uniform temperature. Tests were conducted on both partially immersed silver and gold foils at various temperatures up to 85°C. In no case did silver crystal growth or corrosion occur either on the submerged portion or in the meniscus region. After one week in an air saturated system at 85°C, no growth occurred; however, when the cell was placed back in an oil bath where a temperature differential occurred, crystal growth was evident after a few hours. In the absence of a thermal gradient, the application of a cathodic current to the partially immersed electrode produced a uniform deposit of silver on the submerged portion of the electrode, which gradually tapered off in the meniscus region.

This investigation indicates that the silver deposition-dissolution reactions occurring in the region of the gas/liquid interface on a substrate are due to a slight temperature differential. The effect of differential aeration for the case under consideration has been shown to be of negligible consequence. With the formation of a temperature gradient at an electrode-electrolyte interface, there is a corresponding potential gradient also formed. The potential gradient is approximately 0.2 mV for each degree-temperature differential. In the case of simple metal-metal ion reaction

$$Me \rightleftharpoons Me^+ + e^-$$

which has a high exchange current, such as silver, a very small potential gradient can cause a considerable amount of dissolution and deposition to occur. Current-potential curves for this system exhibit a large variation in current for slight changes in potential (2). Other metals having lower exchange currents would exhibit a proportionally lower tendency to be affected by this type of phenomenon. Factors such as differen-

Fig. 2. Cross section Ag crystal (700X)

tial aeration could then become a predominant corrosion mechanism.

Figure 2 is a cross section of a silver foil which had been partially immersed and upon which crystal growth had occurred. After polishing and etching with a 1:1 ammonia hydroxide-hydrogen peroxide solution, the presence of twin planes was revealed in the crystal growth structure. The growth of twins has previously been shown to be important in the dendritic growth of face-centered cubic metal crystals (3-5), where the reentrant groove between two facets at the twin plane provides a low-energy site for mobile silver adions to deposit into lattice positions.

Chemical Vapor Deposition of Phosphosilicate Glasses from Mixtures of SiH_4, O_2, and $POCl_3$

M. Ghezzo*

General Electric Corporate Research and Development, Schenectady, New York 12301

In the fabrication of n-channel MOS transistors with the refractory metal gate technology (1), the drain and source regions are obtained by diffusion through a thin thermal oxide from a phosphosilicate layer in an inert ambient. The use of phosphosilicate glass prepared from oxidation of silane and phosphine resulted in a soft reverse breakdown characteristic of the diodes formed by the substrate and the diffused regions. As this high-leakage current was due to heavy-metals contamination in the silicon substrate, it was thought that the gettering action of the phosphosilicate glass was not sufficient and could be enhanced by the substitution of phosphine with phosphorus oxychloride, due to the gettering efficiency of chlorine compounds (2). This led to an experimental investigation of the feasibility of phosphosilicate glass preparation from a mixture of silane, oxygen, and phosphorus oxychloride at low substrate temperature.

1 ohm-cm p-type silicon wafers with a (100) surface orientation sliced from Czochralski-grown crystals were used as substrates. The wafers were lapped and chemically polished on both sides before depositing the glass.

The reactor and gas flow system was similar to that previously described by Wong and Ghezzo (3). The flow rates of the gases in the reactive mixture were: argon, used as a carrier gas, 3200 cc/min; 1% silane in argon, 240 cc/min; oxygen, 20 cc/min; and argon bubbling through phosphorus oxychloride from 10 to 20 cc/min. The deposition temperature varied between 300° and 500°C, while the temperature of the phosphorus oxychloride was 24°C, corresponding to a vapor pressure of 34 mm Hg (4).

The deposition time was adjusted to the deposition rate in order to obtain films of constant thickness (6000Å) as determined by interference colors assuming for the PSG the refractive index of pyrolytic SiO_2 (5). Transmission infrared spectra were taken on the glasses as deposited and from them the molar fraction of P_2O_5 in the glass was determined using a calibration curve, which will be published (6). A summary of the deposition parameters is presented in Table I, which shows that both the film deposition rate and the molar fraction of P_2O_5 in the glass increase with the substrate temperature and the molar fraction of $POCl_3$ in the reactive mixture.

Diffusion experiments were carried out at 1050° and 1100°C in argon for different periods of time. After diffusion, the glass layers appeared damaged in various degrees, due to the presence of Newton interference rings as shown in Fig. 1. From the number of fringes it was estimated that the height of these defects was often several times larger than the film thickness suggesting the possibility of a film detachment from the substrate for relieving compressive stresses. Furthermore it was observed that the damage increased with the heat-treatment temperature and the molar fraction of P_2O_5 in the glass. A comparison between PSG layers of equal composition and exposed to the same heat-treatment, but prepared with phosphine rather than phosphorus oxychloride showed that the phosphine deposition system yielded glasses more resistant to damage, capable of maintaining structural integrity after 1 hr at 1100°C in argon and up to 12 mole per cent (m/o) P_2O_5. The glass structure or its

Table I. Deposition parameters

adhesion characteristics to the substrate might be responsible for this interesting result.

After diffusion, sheet resistivity and junction depth were measured using a four-point probe and by angle lapping and staining. The beveling ratio was 20:1. Figure 2 shows a picture of a beveled sample after staining.[1] The accuracy of the junction depth determination was estimated to be ± 0.1μ. The diffusion data are plotted in Fig. 3, which shows the time dependence

[1] The composition of the staining solution was: 49% HF: 70% HNO_3: 100% CH_3COOH = 1:2:12 by volume. This solution was chosen for its property of not stripping the glass during staining, which allows for a more accurate determination of the junction depth, due to the better definition of the glass-silicon interface.

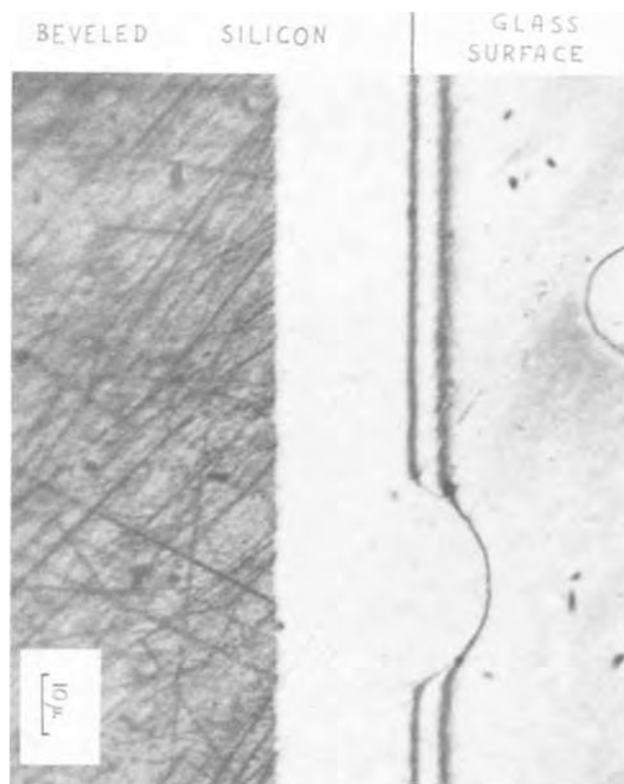

Fig. 2. Micrograph of an angle-lapped section of a p-type (100) surface oriented 1 ohm-cm Si wafer coated with phosphosilicate glass (4.2 m/o P_2O_5) and diffused in argon at 1100°C for 1 hr. Beveling ratio is 20:1. The junction depth is 1.1μ.

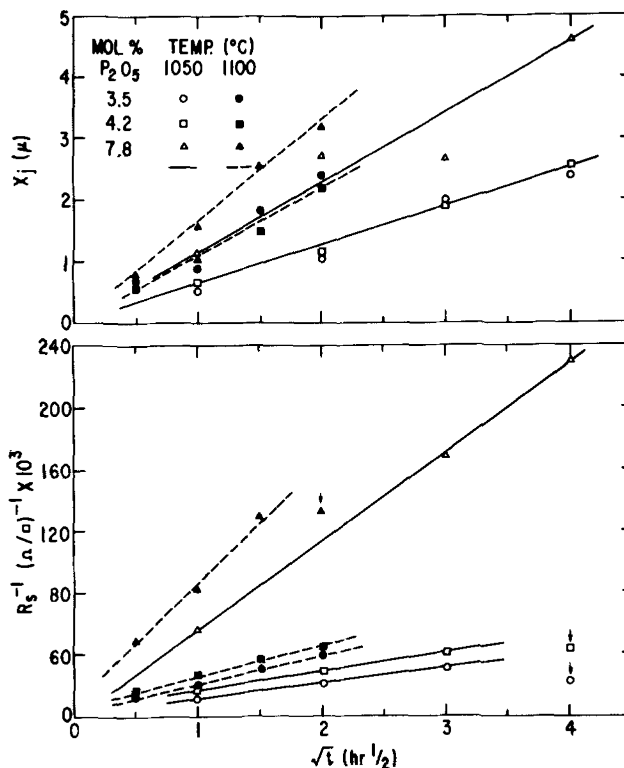

Fig. 3. Plots of junction depth and sheet conductivity of the diffused layers as a function of the square root of diffusion time at two diffusion temperatures (1050°C and 1100°C) and for three phosphosilicate glass compositions (3.5, 4.2, and 7.8 m/o P_2O_5). Points marked with arrows in the bottom plot correspond to badly damaged glass and irregular diffusion front.

of the junction depth and the sheet conductivity for two diffusion temperatures (1050° and 1100°C) and for glasses of different composition (3.5, 4.2, and 7.8 m/o P_2O_5).

Assuming a complementary error function diffusion profile and making use of Irvin curves (7), the surface concentration, C_s, and the diffusion coefficients of P in Si, D, were computed from each set of junction-depth and sheet-resistivity measurements, and the results averaged over different diffusion times before their presentation in Table II. As expected, both C_s and D increased with the molar fraction of P_2O_5 and with the temperature of diffusion, providing a further proof of the concentration dependence of D at high-impurity levels. Moreover the small increase of C_s with temperature was attributed to the temperature dependence of the ratio between the diffusion coefficients of P in Si and SiO_2, due to the difference in the corresponding activation energies [3.7 eV in SiO_2 *vs.* 4.2 eV in Si, as computed from Barry's data (8)].

As the purpose of this investigation was to use phosphorus oxychloride for the deposition of a PSG with enhanced gettering action, this property was tested in the fabrication of planar diodes using a patterned molybdenum layer mask (1) and diffusing through a thin thermal oxide layer. No significant im-

Mole per cent P_2O_5 in the glass	1050°C		1100°C	
	D (cm²/sec)	C_s (cm⁻³)	D (cm²/sec)	C_s (cm⁻³)
3.5	4.2×10^{-14}	4.9×10^{19}	1.2×10^{-13}	6.1×10^{19}
4.2	4.2×10^{-14}	7.3×10^{19}	1.2×10^{-13}	8.2×10^{19}
7.8	1.1×10^{-13}	2.3×10^{20}	2.3×10^{-13}	2.7×10^{20}

provement was observed in the leakage current and the reverse current-voltage characteristics of these diodes still presented a soft breakdown. For obtaining an avalanche breakdown, it was found that the PSG had to be in contact with the silicon substrate, and this result was independent from the phosphorus compound used in the preparation of the PSG.

Summary

Chemical vapor deposition of phosphosilicate glass layers on silicon from an argon diluted mixture of silane, oxygen, and phosphorus oxychloride was investigated in an effort to enhance the gettering action of the PSG for heavy metals during diffusion. Properties of these glasses as diffusion sources of P in Si were studied in terms of glass composition and diffusion temperatures. In parallel experiments with glasses prepared from oxidation of phosphine and silane at low temperature, it was found that the phosphorus oxychloride glasses are more susceptible to glass damage than the phosphine ones. Furthermore the gettering action of the PSG appears unrelated to the deposition system, but strongly dependent on the use or not of a thin thermal-oxide film between the PSG and the Si substrate.

Brief Communication

Selective Growth of Heteroepitaxial GaP on Si Substrates

Osamu Igarashi

Electrotechnical Laboratory, Tanashi, Tokyo, Japan

Selective homoepitaxial depositions of Si and GaAs have long been realized. The method consists of the deposition of an epitaxial layer on selected areas of the substrate which are exposed by windows in a protective film. Using the same technique, we succeeded in depositing heteroepitaxial GaP selectively on Si substrates.

It has been reported that GaP layers deposited on Si substrates have serious cracks (1, 2). The GaP layer is separated into small regions of random sizes by the cracks. This phenomenon is undesirable from the practical viewpoint of device fabrications. By the use of selective-growth technique, this unfavorable cracking can be overcome. In this case, however, a selectively grown GaP layer without the cracks is relatively small in size (less than 0.02 mm^2).

The selective growth of the heteroepitaxial GaP layer was carried out on the (111), (110), (100), and 5° off (111) faces of Si substrates. The Si substrate surfaces were thermally oxidized in wet oxygen to produce an oxide layer of about 10,000Å thickness. Windows or slits were formed in the SiO_2 film by the use of photolithographic techniques and appropriate etchants.

A growth system reported previously by the present author (1) was employed to prepare the heteroepitaxial layer. The growth method is essentially the same as a close-spaced technique described by Nicoll (3). In our system, the GaP source and Si substrate wafers were spaced by about 1 mm in an atmosphere of purified hydrogen gas, and were surrounded by graphite blocks and an alumina ring. These materials were heated to the desired temperatures by the graphite blocks coupled to an external rf coil. During growth periods, the source to substrate temperature difference was about 20°C. The source temperature was up to 1160°C. Prior to deposition process, the Si substrate was slightly gas-etched in an atmosphere of dried 1 HCl/50 H_2 mixture at about 1200°C. After deposition, a number of Ga droplets was observed on the GaP source wafer surface.

In our growth apparatus, any transport agent was not intentionally introduced. We thought that the transport of the GaP source occurs by evaporation of the source material because of the significantly high vapor pressure of Ga metal dissociated from GaP. The equilibrium vapor pressure of Ga is 2×10^{-2} mm Hg at 1100°C (4). However, another possible transport mechanism is the water-vapor transport reaction due to the presence of small amounts of water vapor in the hydrogen ambient. Robinson has deposited GaAs with growth rates of 1-3 mils/hr using a close-spaced technique without intentionally introducing a transport agent. It has been concluded that the transport agent in the growth system is residual water vapor in the system which reacts with the GaAs source to form the volatile species Ga_2O (5). Moreover, it may be pointed out that the transport of GaP in our system takes place by the reaction with residual HCl gas remaining in the reaction chamber after the gas etching. However, it should be added that the GaP source can be transported to the substrate even in a deposition chamber in which any trace of HCl is not used.

Key words: selective growth, heteroepitaxial GaP, Si substrate, SiO_2.

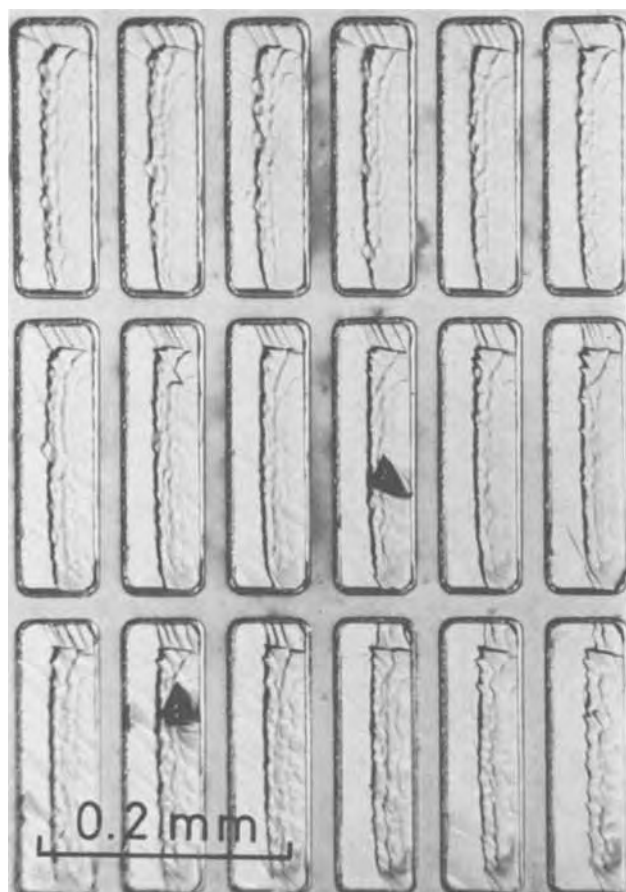

Fig. 1. Photomicrograph of selectively grown GaP (about 5μ thickness) in windows etched through SiO_2 film on 5° off (111) face of a Si substrate.

Figure 1 shows an optical photomicrograph of a GaP layer deposited on 5° off (111) face of a Si substrate at 1100°C. The growth rate of the GaP islands in Fig. 1 was about 1 μ/min. As can be seen from the micrograph, the masked regions are free from GaP deposits. The best surface appearance of deposited GaP heteroepitaxial layers was obtained when 5° off (111) face of the Si substrate was employed. Figure 2 shows an x-ray back-reflection micro-Laue pattern originating from a GaP island in Fig. 1. Cu radiation was used. The diameter of the x-ray beam incident on the sample was between 60 and 80μ. In Fig. 2, a pair of Laue spots is recognized. One set of these Laue spots disappears when the x-ray beam is incident on a region where GaP is not deposited. Thus, one set of the spots is due to the Si substrate and the other due to the GaP deposit. It should be noted that the separation

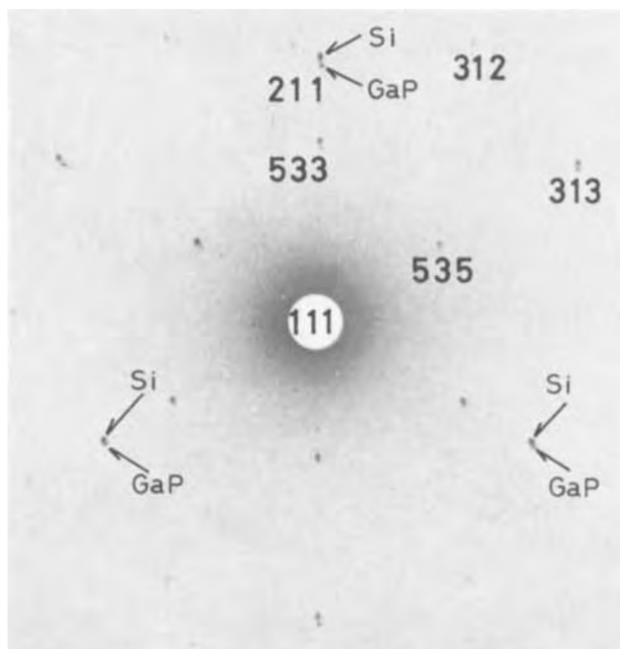

Fig. 2. X-ray back-reflection micro-Laue pattern originated from a GaP island in Fig. 1. A pair of Laue spots is observed. One set of the spots is due to the GaP deposit and the other due to the Si substrate.

of the Laue spots originating from the GaP deposit and the Si substrate indicates the presence of a tilt misorientation between the [111] axes of these two crystals. The angle of the misorientation is probably less than 30′.

Electrical Evaluation of Doped and Undoped Cobalt Chromite as the Interconnection Material for High-Temperature, Zirconia-Electrolyte, Fuel-Cell Batteries

C. C. Sun, E. W. Hawk, and E. F. Sverdrup

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

Cobalt chromite is an electronically conductive oxide stable in both air and mixtures of H_2-H_2O and CO-CO_2 having oxygen partial pressures greater than 10^{-15} atmospheres at 1000°C. It is potentially useful as a material to interconnect cells of a high-temperature, zirconia-electrolyte, fuel-cell battery. The 1000°C resistivities and conductivity-types of cobalt chromite doped with manganese and vanadium were measured over the range of oxygen partial pressures of interest for fuel cell operation. Vanadium-doped cobalt chromite increased in resistivity on exposure to air. Two mole per cent manganese doping resulted in stable 1000°C resistivities of 6 ohm-cm in air and 50 ohm-cm in H_2-H_2O mixtures having an oxygen partial pressure of 10^{-15} atm. These resistivities are sufficiently low to make manganese-doped cobalt chromite useful for the fuel-cell battery application.

The individual cells of a thin-film, high-temperature, fuel-cell battery using zirconia electrolytes are connected in series by a film of an electrically conductive oxide which joins the air and fuel electrodes of adjacent cells, as shown in Fig. 1. Previous work (1) established that cobalt chromite was a possible interconnection material for fuel cells operating at 1000°C. Electrical characteristics were studied by Copp *et al.* (2), Bradburn and Rigby (3), and Schmalzried (4). Resistivity at 1000°C in air varied by two orders of magnitude—2, 70, and 200 ohm-cm were reported respectively by these authors.

Measurements of a 80μ thick film of undoped cobalt chromite separating the air and fuel atmospheres in the fuel-cell battery configuration gave an "effective double-atmosphere resistivity" of approximately 200 ohm-cm. This is four times higher than desired for practical fuel-cell batteries.

In choosing dopants to enhance the electrical conductivity of cobalt chromite, the observation of Bradburn and Rigby (3), that the B cations in the normal spinel structure AB_2O_4 play an important role in determining the conductivity, was considered. Cobalt aluminate displays resistivities several orders of magnitude higher than both cobalt chromite and nickel chromite. Inspection of a model of spinel reveals possible conducting paths by way of 3d electron interchange between adjacent B ions because of their collinearity and small B-B separation. Both manganese, which has a +3 ionic radius of 0.62Å and four 3d orbital electrons, and vanadium, having a +3 ionic radius of 0.66Å and two 3d orbital electrons, should be able to occupy chromium sites as the Cr^{+3} ionic radius is 0.64Å and has three 3d orbital electrons. Either vanadium or manganese might be expected to introduce defects in the normal 3d electronic structure of cobalt chromite and hence enhance the conductivity. Based on these considerations, it was decided to employ manganese sesquioxide and vanadium sesquioxide as dopants to lower the resistivity of cobalt chromite. As discussed later, there is experimental evidence that some manganese actually substituted for cobalt.

This study investigated the feasibility of lowering the resistivity of cobalt chromite by doping with vanadium or manganese. Both resistivity and conductivity-type were measured. Measurements were made in the range of oxygen partial pressures between 0.2 and 10^{-15} atm using air, nitrogen, and nitrogen-hydrogen-water vapor mixtures. The temperature range studied extended from 600° to 1200°C.

Experimental

Starting Materials

Cobalt chromite.—Three types of cobalt chromite varying in stoichiometry and particle size were used to prepare the test specimens. Their properties are summarized below.

Cobalt chromite, Poly Research, −325 mesh.—Cobalt chromite supplied by Poly Research Corporation is slightly rich in its chromium content with chromium/cobalt ratio of 2.29. X-ray diffraction identifies the presence of trace amounts of chromium oxide. The Poly Research cobalt chromite was sieved to obtain −325 mesh powder for preparation of specimens.

Cobalt chromite, Poly Research, air-milled.—The Poly Research cobalt chromite was air-milled by Northern Chemical Company to achieve particles of submicron size. Average particle diameter estimated from an electron micrograph of the air-milled cobalt chromite powder was 0.3μ.

Cobalt chromite, Pfizer.—Cobalt chromite supplied by Chas. Pfizer and Company, Inc. is slightly excess in cobalt. The chromium/cobalt ratio is 1.92 as compared with Cr/Co = 2 for perfect stoichiometry and Cr/Co = 2.29 for the chromium-rich cobalt chromite from Poly Research. The Pfizer cobalt chromite is of submicron particle size, similar to that of the air-milled, Poly Research material.

Vanadium oxide.—Reagent grade of V_2O_3 from Fischer was used. It was kept under nitrogen during handling.

Manganese oxide.—Reagent grade, fine-particle Mn_2O_3 was supplied by Poly Research Corporation.

Preparation of Test Bars

Undoped cobalt chromite bars.—Undoped bars were prepared using the three different types of starting materials in the following manner.

Cobalt chromite of −325 mesh size range, obtained by sieving the Poly Research material, was first cold-pressed at 10 ksi to form bars of approximate dimensions 1 cm × 1 cm × 3 cm. The bars were then sintered in air for 48 hr at 1500°C.

Both the air-milled, Poly Research material and the Pfizer cobalt chromite were prepared by first cold-pressing at 10 ksi. The bars were sintered at 1500°C in air for 24 hr, followed by equilibrating the bars in a hydrogen-water mixture at oxygen partial pressure of 10^{-9} atm for an additional 24 hr at 1500°C. This atmosphere was achieved by saturating a nitrogen-5% hydrogen forming gas with water vapor at 58°C. Figure 2 is a scanning electron micrograph of the fractured surface of an undoped bar after sintering.

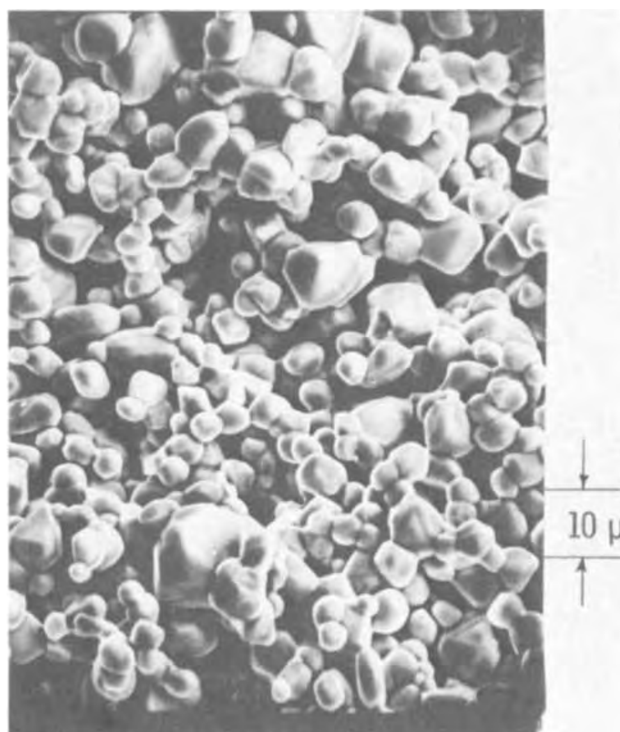

Fig. 2. Electron micrograph of an undoped Co-rich $CoCr_2O_4$ sintered bar (fractured surface).

Vanadium-doped cobalt chromite bars.—Doping was achieved by dry-milling appropriate amounts of vanadium sesquioxide and Poly Research cobalt chromite, cold-pressing and sintering at 1530°C for 48 hr in a hydrogen-water mixture of oxygen partial pressure of 10^{-9} atm. Electron microprobe traces (of 5μ resolution) showed a continuous vanadium distribution throughout the cobalt chromite sample. X-ray diffraction identified the doped bar as having spinel structure. Electron and x-ray scanning microscopy did not detect a second phase. Figure 3 shows typical electron micrograph of the 2 m/o[1] (mole per cent) vanadium-doped cobalt chromite bar.

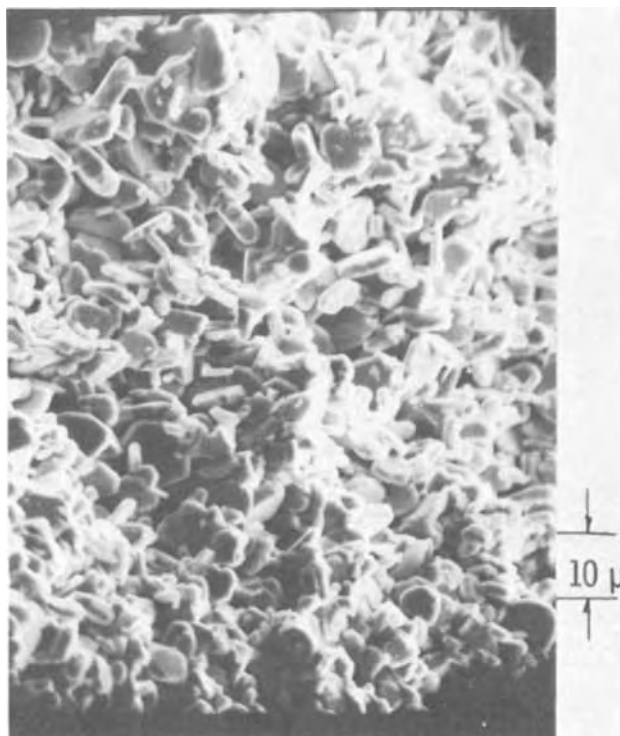

Fig. 3. Electron micrograph of a 2 m/o V-doped $CoCr_2O_4$ sintered bar (fractured surface).

Manganese-doped cobalt chromite bars.—In the case of manganese-doped samples, doping was achieved by ball-milling appropriate amounts of manganese sesquioxide and Pfizer cobalt chromite, cold-pressing, and sintering. Special effort was taken to disperse the fine particles of the mixture to increase the probability of successful doping during sintering. Sintering was carried out in two steps. First, the pressed bars were sintered at 1500°C in air for 24 hr. Under these sintering conditions, Mn_2O_3 is expected to be oxidized to Mn_3O_4, which is a normal spinel (5). Formation of a solid solution between the two normal spinels, Mn_3O_4 and $CoCr_2O_4$, was expected at this stage. During the second step of sintering, the bars were equilibrated

[1] Throughout this paper $X^{m}\%$ of vanadium- or manganese-doped cobalt chromite symbolizes X moles of V_2O_3 (or Mn_2O_3) in (100 − X) moles of $CoCr_2O_4$, *i.e.*, molar per cent of manganese =

$$\frac{[\text{moles of } Mn_2O_3]}{[\text{moles of } Mn_2O_3] + [\text{moles of } CoCr_2O_4]}.$$

with a hydrogen-water mixture at an oxygen partial pressure of 10^{-9} atm at 1500°C for an additional 24 hr.

In all the manganese-doped cobalt chromite bars, the electron and x-ray scanning microscopic analysis revealed the presence of a small percentage of a spherical-shaped second phase which was rich in cobalt. Figure 4 is a typical scanning electron micrograph of the 2 m/o manganese-doped cobalt chromite bars. An x-ray diffraction pattern of the 9 m/o manganese-doped cobalt chromite indicated the presence of traces of metallic cobalt. Since the lower limit of sensitivity was 5%, the absence of cobalt lines on x-ray powder diagrams of the 2 and 4 m/o manganese-doped samples did not exclude the possibility of cobalt presence in these samples.

Lattice parameters of the undoped and manganese-doped cobalt chromite were determined from the x-ray diffraction patterns and they were

a_0 (undoped $CoCr_2O_4$) = 8.320Å
a_0 (2 m/o Mn-doped $CoCr_2O_4$) = 8.341Å
a_0 (4 m/o Mn-doped $CoCr_2O_4$) = 8.344Å
a_0 (9 m/o Mn-doped $CoCr_2O_4$) = 8.360Å

It can be noticed that the lattice parameter increases as a function of manganese doping. As Mn^{+3} cation is smaller than Cr^{+3} (0.62Å for Mn^{+3} *vs.* 0.64Å for Cr^{+3}), a decrease in lattice parameter would be expected had Mn^{+3} substituted in the Cr^{+3} sites of the cobalt chromite lattice. This is the opposite to what we observed.

Comparison of ionic sizes and electronic configuration of Mn^{+2} and Co^{+2} (0.80Å for Mn^{+2} and 0.72Å for Co^{+2}) shows the possibility of Mn^{+2} substituting in Co^{+2} sites in the cobalt chromite lattice. As Mn^{+2} is larger than Co^{+2}, substitution of Co^{+2} by Mn^{+2} would be expected to result in expansion of the lattice parameter of the cobalt chromite spinel. If this had been the doping mechanism, the Co^{+2}, which was freed by Mn^{+2} from the cobalt chromite lattice, would have been reduced to cobalt metal during the second step of the sintering under oxygen partial pressure of 10^{-9} atm at 1500°C. Indeed, x-ray diffraction detected the presence of traces of cobalt metal in the 9 m/o manganese-doped sample.

The undoped specimens sintered to 48-55% of theoretical density, the vanadium-doped specimens reached 64-70% of theoretical density, while the manganese-doped specimens achieved 75-90% of the theoretical density of cobalt chromite. Comparison reveals that vanadium oxide and manganese oxide at low doping levels, especially 2 m/o and 4 m/o of manganese oxide, serve as densification aids to cobalt chromite sintering. These results compare with the results reported by Bron and Diesperova (6), who found that additives, whose cations could replace Cr^{+3} (*e.g.*, Ti^{+4}, Fe^{+2}, Fe^{+3}, Zr^{+4}, Mn^{+2}, Mn^{+3}), considerably accelerated the rate of formation and sintering of magnesium chromite spinel. The fact that the oxide dopants not only improve conductivity but also promote densification of cobalt chromite is worth special notice, because the interconnection of the high-temperature thin-film fuel-cell batteries must be both highly conductive and gas-impermeable.

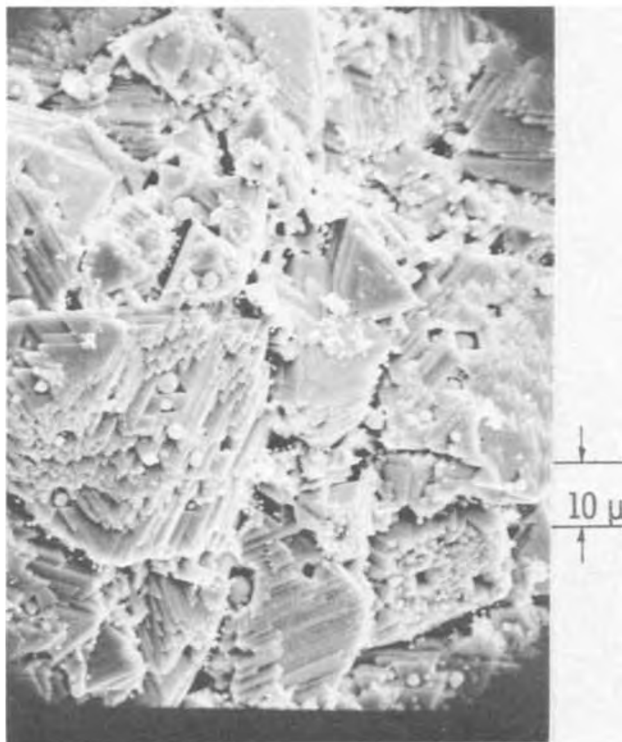

Fig. 4. Electron micrograph of a 2 m/o Mn-doped $CoCr_2O_4$ sintered bar (fractured surface).

Electrical Measurements

Two bars of each composition were tested. One bar was located in the hot zone of the tester furnace for resistance measurement using the d-c, four-probe technique and the other bar placed toward one end of the same furnace where a thermal gradient existed for thermoelectric studies. From the gauge lengths and the dimensions of the specimen bars, the resistance measurements are accurate to ±20%.

Resistivity and Seebeck effect were measured as functions of temperature, in the range of 600°-1200°C, and oxygen partial pressure, in the range P_{O_2} = 0.2 to 10^{-15} atm using air, nitrogen, and nitrogen-hydrogen-water mixtures. The oxygen partial pressures were measured using a stabilized zirconia oxygen gauge operating at 1000°C with air as the reference.

Results

Undoped cobalt chromite.—Figure 5 shows the temperature dependence of resistivity of undoped chromium-excess cobalt bars in air and nitrogen. The thermoelectric measurements indicated that the chromium-rich cobalt chromite displayed p-type conductivity throughout the oxygen partial pressure range of 0.21 to 10^{-15} atm. Figure 6 presents the Seebeck coefficients determined by our experiments as a function of oxygen partial pressure. Schmalzried's results are shown for comparison.

Figure 7 shows the oxygen partial pressure dependence of resistivity at 1000°C of the two types of un-

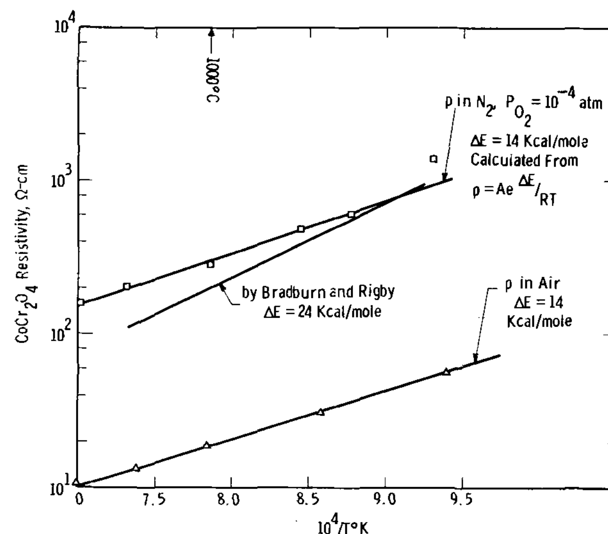

Fig. 5. Measured resistivity of undoped Cr-excess $CoCr_2O_4$ in air and N_2 as a function of the reciprocal of absolute temperature.

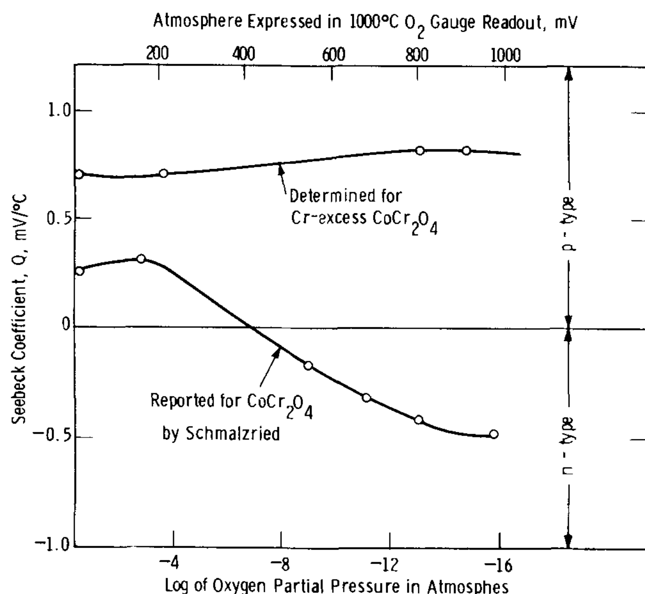

Fig. 6. Seebeck coefficient determined for the Cr-excess cobalt chromite as a function of oxygen partial pressure.

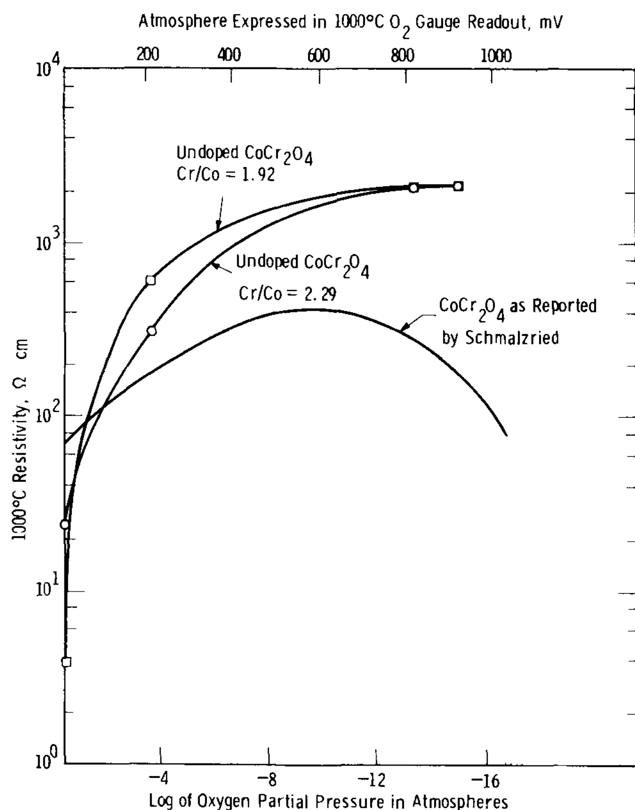

Fig. 7. Comparison of resistivity of two types of cobalt chromite

doped cobalt chromite specimens. They are compared to Schmalzried's data. It can be concluded that both types of cobalt chromite display a 1000°C resistivity of less than 25 ohm-cm in air and a 1000°C resistivity of about 2×10^3 ohm-cm in fuel atmospheres despite the difference in chromium/cobalt ratios.

Vanadium-doped cobalt chromite.—The chromium-rich cobalt chromite with 1 and 2 m/o of vanadium sesquioxide doping were sintered in reducing atmosphere ($P_{O_2} = 10^{-9}$ atm at 1530°C) to preserve vanadium cations in the +3 valence state. Electrical measurements were first performed in the same atmosphere to speed the atmosphere equilibration process and the results are shown in Fig. 8-10. Figures 8 and 9 demonstrate respectively the variations of resistivity and Seebeck coefficient with oxygen partial pressure. Figure 10 shows the temperature dependence of the resistivities. From Fig. 8-10, it can be observed that vanadium doping of cobalt chromite enhances n-type conductivity at low oxygen partial pressures. Resistivity is reduced initially by a factor of 15 with 1 m/o and a factor of 25 with 2 m/o of vanadium doping at an oxygen partial pressure of 10^{-14} atm. Vanadium doping reduced the 1000°C resistivity in air from 22 ohm-cm to 15 ohm-cm by 1 m/o vanadium doping and from 22 ohm-cm to 10 ohm-cm by 2 m/o doping. The improvement of bar density, from 48% theoretical density of

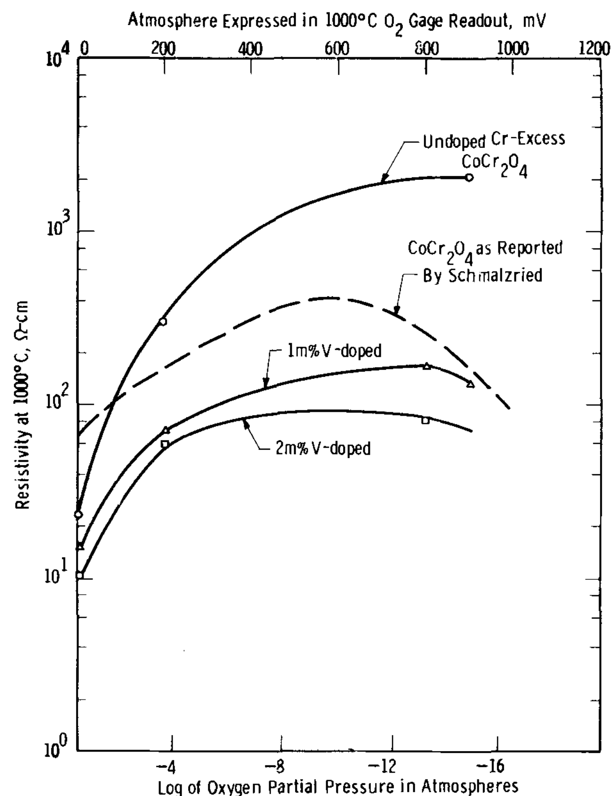

Fig. 8. Effects of V-doping on $CoCr_2O_4$ resistivities as a function of oxygen partial pressure.

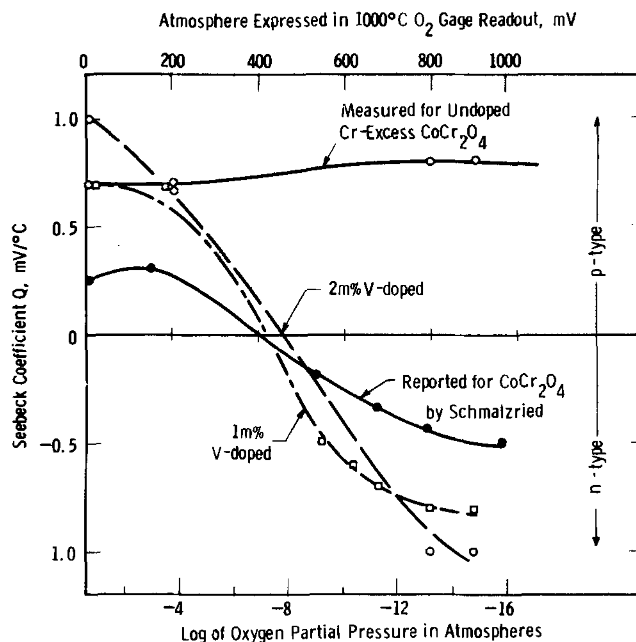

Fig. 9. Effects of V-doping on Seebeck coefficients as a function of oxygen partial pressure.

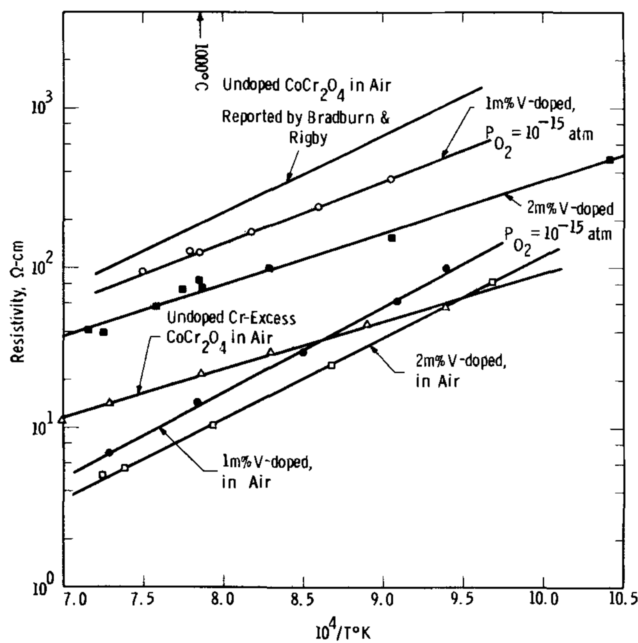

Fig. 10. Effects of V-doping on $CoCr_2O_4$ resistivities in air and fuel atmospheres as functions of $1/T$.

the undoped bars to 64% for 1 m/o and 70% for 2 m/o vanadium-doped bars, must be considered in interpreting the resistivity results.

As the oxygen partial pressure was increased over 10^{-10} atm, gradual loss of vanadium dopant by oxidation and vaporization occurred. This was verified by chemical analysis of the bar before and after electrical tests in the oxidizing atmosphere and by spectrographic analysis of a dark deposit on the upstream portion of the testing apparatus. The loss of vanadium was accompanied by an $n \rightarrow p$ transition in conductivity type and an irreversible increase in resistivity at low oxygen partial pressures. Figure 11 shows the change in resistivity at low oxygen partial pressures of the vanadium-doped cobalt chromite *vs.* time of sample exposure to air. The resistivity of the vanadium-doped cobalt chromite in air remained nearly unchanged apparently being insensitive to vanadium loss to the 30% vanadium losses measured.

Manganese-doped cobalt chromite.—Figure 12 shows a plot of resistivity in air and in fuel atmospheres as a function of molar per cent of manganese doping at 1000°C. Doping with 2 to 4 m/o of manganese oxide reduces the resistivity by almost two orders of magnitude under low oxygen partial pressures. The resistivity of the 2 m/o manganese-doped cobalt chromite in fuel atmosphere is stable over the 26 days of total testing time and is independent of sample cycling to an oxidizing atmosphere. Its resistivity in air also appears to be stable (Fig. 13). The resistivity of 4 m/o manganese-doped cobalt chromite increases steadily on exposure to the fuel atmosphere. It decreases slightly with time in air. The resistivity of 9 m/o manganese-doped cobalt chromite is also unstable. It can be concluded from these tests that the 2 m/o manganese-doped cobalt chromite is close to the optimum doping level. Its resistivity is least sensitive to oxygen partial

pressure change and most stable with respect to testing time and atmosphere cycling.

Conclusions

Undoped-cobalt chromite.—Commercially supplied, undoped-cobalt chromite had a resistivity in air at 1000°C of 20 ohm-cm. At 1000°C in hydrogen-nitrogen-water vapor mixtures, having an oxygen partial pressure of 10^{-14} atm, the resistivity was 2000 ohm-cm. The order of magnitude of the resistivity and the conductivity type was not sensitive to deviations of cobalt and chromium content from the ideal stoichiometric ratio of two parts chromium to one part cobalt between Cr/Co ratio of 1.9 to 2.3. Resistivity in air of undoped cobalt chromite is low enough for the fuel cell application. Resistivity in low oxygen-partial-pressure fuel gas atmospheres is two orders of magnitude too high.

Measurements of thermoelectric power showed that the sample having a chromium to cobalt ratio of 2.3 displayed "p"-type conductivity over the oxygen partial pressure range 10^{-15} to 0.2 atm and at temperatures between 600° and 1200°C.

Vanadium-doped cobalt chromite.—The resistivity of cobalt chromite at low oxygen partial pressure can be reduced by vanadium doping. Two mole per cent of V_2O_3 doping lowered the resistivity of cobalt chromite at 1000°C from 2000 to 80 ohm-cm at an oxygen partial pressure of 10^{-14} atm.

The resistivity of the vanadium-doped cobalt chromite was not stable after the samples were exposed to atmospheres having oxygen partial pressures higher than 10^{-10} atm. The increase in resistivity was associated with a loss of vanadium from the samples when in oxidizing atmospheres. The resistivity in air was not affected by the addition or the loss of the vanadium dopant. Vanadium-doped cobalt chromite was an "n"-type conductor at low oxygen partial pressures and a "p"-type conductor in air. As vanadium was lost, the magnitude of the thermoelectric power in the low oxygen partial pressure atmosphere decreased, changed sign, and approached the values typical of the "p"-type conductivity observed with the undoped material. Only one strategy was used to incorporate the vanadium doping in the spinel and these results are specific to that diffusion-sintering schedule.

Manganese-doped cobalt chromite.—Three levels of manganese doping were tested: 2, 4, and 9 m/o Mn_2O_3. Cobalt chromite containing 2 m/o Mn_2O_3 displayed stable resistivities. Resistivity at an oxygen partial pressure of 10^{-14} atm was lowered from 2000 to 50 ohm-cm at 1000°C. Resistivity in air was 6 ohm-cm. Resistivity at 1000°C was stable over a testing period of 26 days in the low oxygen partial pressure atmosphere. It was not affected by cycling to air.

The resistivity of the 4 and 9 m/o manganese sesquioxide-doped cobalt chromite varied with time.

Manganese-doped cobalt chromite also displayed "p"-type conductivity.

Manganese-doped cobalt chromite is sufficiently conductive to be a satisfactory cell interconnection for zirconia electrolyte fuel cells operating at temperatures near 1000°C. At this temperature level, coal gasification rates are high enough that a practical coal reacting fuel-cell power system can be engineered.

Acknowledgments

The Westinghouse Electric Corporation and the Office of Coal Research—U. S. Department of the Interior jointly sponsored this work directed toward a practical fuel cell power system capable of utilizing coal as a fuel. The authors would like to express their appreciation of the support of Mr. Neal P. Cochran, Chief of Utilization, Office of Coal Research and Mr. Paul Towson, Division of Utilization. The efforts of Mr. Robert L. Eback in preparing chromite dispersions were also appreciated.

Manuscript submitted March 8, 1972; revised manuscript received May 8, 1972. This was Paper 16 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Equilibrium Phases in the Lithium-Sulfur System

Ram A. Sharma*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Equilibrium phases in the lithium-sulfur system on the sulfur side of Li_2S (the only compound observed in this system) were determined using an unusual vapor transport technique. In this method, equilibrium compositions of the melts at various temperatures can be obtained by utilizing the transport of sulfur vapor from one melt to a second one. The lithium-sulfur phase diagram exhibits a large miscibility gap which extends from the monotectic composition, 65.5 mole per cent (m/o) sulfur, to almost pure sulfur (0.035 m/o lithium) at the monotectic temperature, 362° ± 3°C. The melting point of lithium sulfide was found to be 1365° ± 10°C. The results are also presented as the lithium sulfide-sulfur phase diagram, in which the miscibility gap extends from the monotectic composition, 73.7 m/o sulfur, to nearly pure sulfur (0.0175 m/o lithium sulfide). A comparison of the liquidus at the Li_2S-liquid region of the Li_2S-S system with those constructed using Temkin's model indicates the probable existence in these melts of sulfide species such as S_2^{2-}, S_3^{2-}, and S_4^{2-}, in addition to S^{2-}.

Among the systems considered in the development of a high-temperature molten-salt battery for vehicular propulsion, sodium-sulfur and lithium-sulfur appear to be promising, practical, and economical (1). Basic thermodynamic data, which are essential in the development of these batteries, are available to some extent for the sodium-sulfur system (2, 3), but to still lesser extent for the lithium-sulfur system (4-6). This investigation was conducted to determine the equilibrium phase diagram of the lithium-sulfur system. These data were also used to gain some insight into the nature of the lithium-sulfur melts.

The normal techniques used in the determination of phase diagrams cannot be applied to the lithium-sulfur system. Lithium and sulfur are very corrosive and consequently the choice of container materials is limited. The container which cannot be made of metal because of sulfur or sulfide reaction, has to be sealed to avoid the loss of sulfur by vaporization. The phases involved appear to have similar densities and are very fluid; therefore, the quenching technique cannot be used indiscriminately because of the difficulty in obtaining satisfactory phase separation. Differential thermal analysis (DTA) and thermal analysis can only be used in limited regions because the melts undercool, coupled with the fact that the phase boundaries rise very steeply with change in composition.

Therefore, an unusual vapor transport technique was developed in which equilibrium compositions of the melts were obtained through transfer of sulfur vapor from one melt to a second one. This simple and inexpensive technique can also be used to determine the phase diagrams of other systems involving one or more volatile components.

Experimental

Materials.—Sulfur of 99.999% purity was used. Lithium sulfide was used in the form of a white powder; its lithium content was found by chemical analysis to be 29.8 weight per cent (w/o) (30.26 w/o theoretical). Its x-ray powder diffraction pattern data are given in Table I. The stronger diffraction lines agree with those calculated from the data reported by Zintl *et al.* (7). The present pattern also shows more and weaker lines for which these authors might not have bothered to report the data.

* Electrochemical Society Active Member.

Key words: lithium, sulfur, lithium sulfide, equilibrium phases.

Apparatus.—A Kanthal-wound tubular furnace, capable of being rocked through an angle of approximately 90°, was used to heat the mixtures. The furnace, suitable for use up to 1000°C, had external terminals from its heating element every 2.0 in. By manipulating the power supply to two different segments of the furnace element, a constant-temperature zone about 6 in. long was obtained. Two concentric stainless-steel containers (2 in. diam × 6 in. long and 1 in. diam × 6 in. long) were placed inside the uniform temperature zone to provide further uniformity of temperature (Fig. 1). Auxiliary apparatus used with the furnace included a furnace controller and a temperature recorder. Calibrated Chromel-Alumel thermocouples were used for measuring temperatures. A Leeds and Northrup potentiometer was also used to confirm the melt temperatures recorded.

Sealed containers, made of silica (Vycor), were used for lithium-sulfur melts of low lithium content and at lower temperatures. These containers, shown in Fig. 2, were fabricated in uncommon shapes in an effort to obtain clear separation of the phases on quenching. Dense-graphite containers were used for melts of high lithium content and at higher temperatures. The

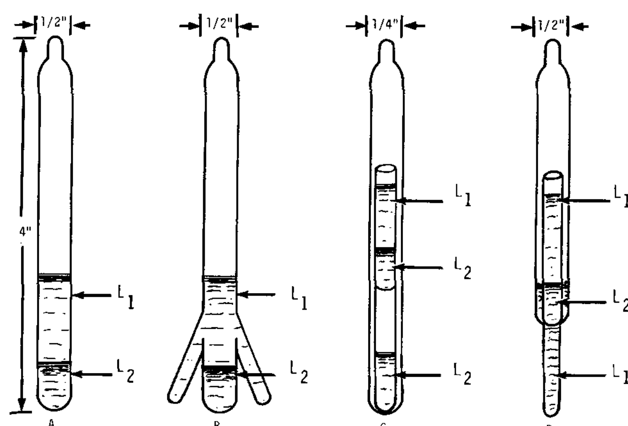

Fig. 2. The melt containers

graphite containers were sealed in silica (Vycor) capsules to avoid sulfur loss by vaporization.

Procedure.—Lithium sulfide and sulfur were used in preparing the lithium-sulfur melt compositions because lithium and sulfur react violently.

Quenching methods.—In the preliminary experiments, the desired amounts of lithium sulfide and sulfur were mixed thoroughly and about 5g of this mixture were placed in a silica capsule (Fig. 2A) inside a helium-atmosphere dry box. The silica capsule was then sealed under vacuum and placed in the uniform temperature zone of the rocking furnace. The furnace, while rocking, was slowly heated to the desired temperature. The silica capsules were kept at this temperature for 24-72 hr for equilibration. After the equilibration period, which was normally about 24 hr, the silica capsule was quenched in 10% LiCl solution at -10°C. On solidifying, two layers were formed. The bottom layer was dark red in color. The top layer was yellow in color and had a lower concentration of lithium than did the bottom layer.

Chemical analyses of samples from the two solidified layers were used to determine the compositions of the respective liquids at the equilibrium temperature. The general pattern of the equilibrium phase diagram, consisting of a miscibility gap and a solid-liquid region on the sulfur side of the lithium-sulfur system, could be obtained from these preliminary experiments. It was also observed from these experiments that the rocking was not necessary for equilibration of melts above 500°C, and that the lighter yellow liquid undercooled and appeared to separate into two layers before solidifying.

To circumvent the undercooling of the lighter yellow liquid, silica capsules with side arms (Fig. 2B) were used in subsequent experiments. In these experiments, sulfur was solidified in the side arms of the capsule, and a lithium-sulfur solidified melt (approximately 37 m/o lithium) prepared separately, was placed in the bottom of the capsule. Additional sulfur was then solidified in the capsule over the lithium-sulfur mixture and in the region extending above the side arms. The capsule was sealed under vacuum. The procedure was then the same as that for capsules without side arms. After equilibration and quenching, chemical analyses of the solidified contents of the side arms were used to determine the composition of the lighter yellow liquid, and analyses of the lower portion for determining the composition of the dark red liquid. The compositions of the equilibrium liquids could be determined by this technique only up to about 600°C. Above this temperature, the silica capsule was observed to react with the lithium-sulfur melt and occasionally to explode. The silica capsule might possibly react with a certain amount of lithium of the melt shifting its composition to a higher concentration of sulfur.

Vapor transport technique.—For determination of the compositions of the liquids in the two-liquid region at higher temperatures (>600°C), and to check the compositions at lower temperatures, an unusual, simple technique was developed—the vapor transport technique. In this method, two graphite crucibles were used (Fig. 2C), one containing a lithium-sulfur melt with a composition slightly different than the expected equilibrium composition, and the other containing a melt composition from within the two-liquid region. The second crucible was placed above the first one in a silica capsule. The capsule was sealed under vacuum and placed in the uniform temperature zone of the furnace. The furnace was slowly heated, without rocking, to the desired temperature and kept at this temperature for 24-72 hr. The contents of the two graphite crucibles were thus equilibrated by transfer of sulfur through the vapor phase. After equilibration, which normally required no more than 24 hr, the capsule was cooled to room temperature in a jet of air. The composition of the melt at the equilibrium temperature was determined from the chemical analyses of the total contents of the bottom graphite crucible. At lower temperatures, and for compositions with higher sulfur concentrations, a slightly modified arrangement was used (Fig. 2D). In this arrangement, the liquid with concentration of lithium less than equilibrium was placed in the bottom extension of the silica capsule, and the two-liquid mixture was contained in a silica tube located in the upper part of the capsule. The silica capsule was sealed under vacuum and quenched in 10% LiCl solution at -10°C. The composition of the melt at the equilibrium temperature was determined from the chemical analysis of the total content of the extension of the silica capsule. The results obtained using this procedure were the same as were obtained from the two-graphite-crucible quenched-in-air method.

The technique of using two graphite crucibles for the container was also used to determine the liquid composition in the solid-liquid region of the phase diagram. In this case, solid lithium sulfide, instead of the two-liquid composition, was contained in one graphite capsule.

The melting points of lithium sulfide and of sulfur, and the monotectic temperature at 6.0, 7.1, 16.3, 21.2, 31.0, and 41.0 m/o Li_2S were determined using both the heating and cooling curves from differential

thermal analyses performed with Mettler Thermo-analyzer. The specially designed sample holders of dense graphite were used to determine the melting point of lithium sulfide, while graphite as well as silica sample holders were used to determine the monotectic temperature. Alumina was mostly used as a reference material.

Chemical analysis.—The melts containing lithium sulfide-sulfur were leached from the weighed graphite crucibles with boiling water. The process was repeated several times. After that, the crucible was dried and then soaked in carbon disulfide for 10 min or so, and then the crucible was again dried and weighed. The crucible was examined with a stereo microscope before melt dissolution and at the end to be sure that all the material was removed. The difference in weights of the graphite crucible with and without the melt was taken as sample weight.

The carbon disulfide solution was evaporated to dryness, and the residue was treated with water. This solution and the water extract were combined in a 100 ml volumetric flask and diluted to the volume. An appropriately measured aliquot of this solution was transferred to a beaker, nitric acid was added, and the solution was evaporated to dryness to remove the sulfide ions. A solution of potassium chloride was added to a water solution of the dried residue in a volumetric flask, the solution diluted to volume, and lithium was determined by flame photometry *vs.* standard solution containing the same concentration of potassium chloride. The analysis method was checked for accuracy by determining lithium in pure lithium sulfide, and sulfur and lithium sulfide mixtures. The analysis was found to be accurate within ±1% of the amount present.

Results and Discussion

The phase equilibrium results obtained by the various techniques are summarized in Table II. The equilibrium phase diagram of the lithium-sulfur system based on these measurements is shown in Fig. 3; sulfur-rich compositions are shown enlarged in the insert in this figure. The measurements represented by the open circles in Fig. 3 were deliberately not included in delineating the liquidus. The measurements indicate slightly high percentages of lithium as a result of incomplete dissolution of the sample in the early developmental stages of the chemical analysis. The liquidus was drawn through the points obtained after the difficulty of dissolving the sample was removed.

The melting point of lithium sulfide was determined to be 1365° ± 10°C, in good agreement with the recently reported value of 1372°C (4). The literature value (5) of 975°C is in considerable disagreement with both of these results. The melting point of sulfur was determined to be 118°C, in good agreement with the literature value (8) of 119°C.

In the range of compositions investigated, only one solid compound, Li_2S [and not the other two, Li_2S_2 and Li_2S_4 reported by Pearson and Robinson(6)], was observed (x-ray analysis of the solidified samples) in the lithium-sulfur system. A monotectic was observed at 34.5 m/o lithium and 362° ± 3°C. The monotectic temperature is in good agreement with the value of 365 determined elsewhere (4). The monotectic composition found in the present work is slightly lower than 37.0 m/o determined by the latter workers. In the present investigation, the monotectic composition was determined by arriving at an equilibrium between lithium sulfide and a Li-S melt on one side, and between a lithium-sulfur melt and a two-liquid-phase melt on the other side. Therefore, the monotectic composition reported here, 34.5 m/o lithium, should not be in error by more than the error involved in the chemical analysis, and is considered to be accurate to ±1 m/o. The solubility of lithium in the sulfur-rich liquid, 0.035 m/o lithium at the monotectic temperature, is also in disagreement with the 0.3 m/o lithium reported by these workers (4). Although it could not be measured precisely by the vapor transport technique, the consolute temperature, or critical solution temperature appears to lie between 838° and 860°C. The data reported by Pearson and Robinson (6) such as the compounds Li_2S_2 and Li_2S_4, a liquidus and melting point of

Li_2S, 900°-975°C for lithium-sulfur system have no agreement with the present data.

The results have also been presented in Fig. 4 as the lithium sulfide-sulfur phase diagram, in which form they may be treated elegantly in terms of Temkin's model of molten salt mixtures (9). The Li_2S-S system has a miscibility gap extending from the monotectic composition, 26.3 m/o Li_2S, to nearly pure sulfur (0.0175 m/o Li_2S), at the monotectic temperature of 362° ± 3°C.

From the equilibrium phase diagram of the lithium sulfide-sulfur system, almost pure liquid sulfur (0.017-0.15 m/o Li_2S) is observed to be in equilibrium with a melt of approximately constant composition (26-22 m/o Li_2S) in the temperature range of 362°-700°C. This small variation with temperature of the sulfur concentration in the lithium-sulfur melt indicates that the heat of solution of sulfur in these melts is nearly zero. This means that the bonding energy of sulfur in the nearly pure sulfur is not much different than the bonding energy of sulfur in the lithium-sulfur melt containing about 24 m/o Li_2S. This also indicates the degree of ease with which sulfur can transfer from one liquid to another.

Temkin's model for molten salt mixtures (9) appears to be appropriate to apply to melts of the lithium sulfide-sulfur system. In this model, the activity, $a_{Y_{iy}Z_{iz}}$, of a given component, $Y_{iy}Z_{iz}$, of a molten salt mixture is given by the product of the ionic fractions of the cations and anions in the mixture

$$a_{Y_{iy}Z_{iz}} = (X_{Y_i})^y \cdot (X_{Z_i})^z \qquad [1]$$

The cationic fraction is given by

$$X_{Y_i} = \frac{n_{Y_i}}{\sum_{i=1}^{s} n_{Y_i}} \qquad [2]$$

where n_{Y_i} is the number of moles of cations, Y_i, in the molten salt mixture, assuming that the salts are completely ionized. An analogous definition applies for the anionic fraction. The term, s, is the number of constituent salts. The Temkin model assumes that the cations (anions) are randomly distributed on sites equal in number to the total number of cations (anions).

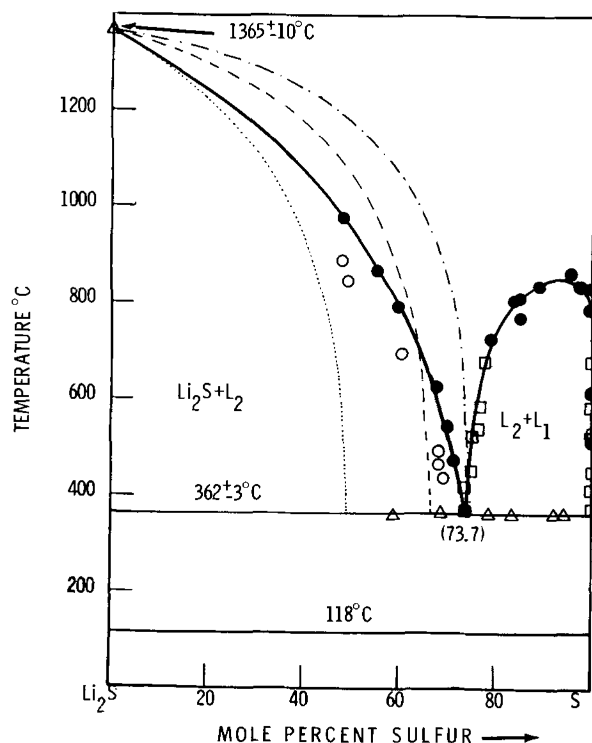

Fig. 4. The equilibrium phase diagram of the lithium sulfide-sulfur system. ● and ○, vapor transport technique; □, quenching technique; △, differential thermal analysis technique ——— through experimental points ·····, - - - - -, and -·-·-·- lines on assuming Temkin's model and reactions [3], [4] and [5], respectively.

Pure molten Li_2S is assumed to ionize completely to Li^+ and S^{2-}. The solution of additional sulfur in the Li_2S-sulfur melt is assumed to proceed by any of the reactions

$$S^{2-} + S = S_2^{2-} \qquad [3]$$

$$S^{2-} + 2S = S_3^{2-} \qquad [4]$$

$$S^{2-} + 3S = S_4^{2-} \qquad [5]$$

These reactions do not appear unreasonable in view of the ease with which sulfur can transfer from one liquid melt to another, as pointed out before. The mole fraction of Li_2S in these Li_2S-S melts would then be

$$\frac{2n_{Li_2S} - 100}{n_{Li_2S}}, \quad \frac{3n_{Li_2S} - 100}{2n_{Li_2S}}, \quad \text{and} \quad \frac{4n_{Li_2S} - 100}{3n_{Li_2S}}$$

for reactions [3], [4], and [5], respectively. The mole fraction of Li_2S is equal to the product of the ionic fractions because of the presence in the melts of lithium as the only cation, consequently, the mole fraction of Li_2S is equal to the activity of Li_2S if the melt obeys Temkin's model.

The activity of lithium sulfide in melts of the Li_2S-S system may be related to the liquidus temperature, T, by the simplified equation

$$\ln a_{Li_2S} = -\frac{\Delta H_m}{RT}\left(1 - \frac{T}{T_m}\right) \qquad [6]$$

where ΔH_m is the heat of fusion and T_m is the melting point of lithium sulfide. In this relation, the difference between the heat capacities of liquid and solid lithium sulfide is assumed to be zero. The melting point of lithium sulfide, 1365°C, was determined in this investigation. ΔH_m, which is not available in the literature, has been calculated to be 10.5 kcal/mole by assuming reaction [3] and applying Temkin's model to the lithium sulfide-sulfur melts at very low concentrations of sulfur using the phase diagram data of this investigation.

Using the activities of Li_2S calculated from Eq. [6], and assuming the Li_2S-S melts obey Temkin's model, the liquiduses corresponding to reactions [3], [4], and [5] have been constructed and are presented in Fig. 4. The constructed liquiduses have shapes similar to those determined experimentally. At higher temperatures and lower sulfur concentrations, the liquidus based on reaction [3] has best agreement with the experimentally determined one, implying that the sulfur exists preponderously as S_2^{2-}. This may be expected since the most likely species to form on the initial addition of sulfur to Li_2S would be the next higher sulfide polymer, S_2^{2-}. At lower temperatures and higher sulfur concentrations, the liquidus based on reaction [4] has the best agreement with the experimental curve. This also is to be expected since species like S_3^{2-} are likely to form with an increase of sulfur concentration in a Li_2S-S melt, and since the tendency is for higher sulfide polymers to exist at lower temperatures. General agreement with the liquidus based on reaction [5] with the experimentally determined curve indicates the possibility that the species S_4^{2-} may form with a further increase in the sulfur concentration.

In the situation where sulfur can transfer without much difficulty from nearly pure sulfur to the Li_2S-S melt, and when a general agreement is observed between the liquiduses constructed on the basis of reactions [3], [4], and [5] and that determined experimentally, a distribution of the different species rather than one particular species is more likely to occur. The

concentration of species such as S_2^{2-} may be predominant at lower concentrations of sulfur, and species such as S_4^{2-} at higher concentrations of sulfur.

In addition to the above, an approximation of the partial pressure of sulfur over Li_2S-S melts can be obtained from these results. For example, at 500°C, sulfur containing 0.1 m/o lithium is in equilibrium with lithium-sulfur containing 32 m/o lithium, so the partial pressure of sulfur over these two melts is the same. At the same temperature, another melt containing 37 m/o lithium is in equilibrium with Li_2S, so the partial pressure of sulfur over this melt is the same as that over Li_2S. The partial pressure of sulfur over Li_2S at 500°C can be approximated as 10^{-2} atm by treating lithium-sulfur melts similar to sodium-sulfur melts (3). If we assume that the partial pressure of sulfur over the 32 m/o lithium melt is approximately the same as that over the 37 m/o lithium melt, then the partial pressure of sulfur over the melt of sulfur containing 0.1 m/o lithium is approximately 10^{-2} atm. This means that the addition of 0.1 m/o lithium has lowered the vapor pressure of sulfur from about 2.0 atm (10) to about 10^{-2} atm. This can also be inferred from experiments where two liquids, one containing higher and the other lower concentrations of sulfur, were sealed in a silica capsule and heated to about 850°C. The fact that the silica capsule did not rupture indicates that the vapor pressure of sulfur is definitely far lower than that of pure sulfur, which is about 60 atm under these conditions (10).

This lowering of the sulfur vapor pressure may not be unexpected if the addition of lithium helps to increase the chain length of sulfur as a result of lithium and sulfur being metallic and nonmetallic in nature, and the lithium ions presumably being located at the ends of these chains. Then the situation becomes similar to that of an ionic melt, where a sulfur chain behaves like a large anion, and the sulfur vapor pressure is comparable to that over any ionic sulfide melt.

A Computer-Operated Facility for Research Testing of Secondary Batteries

R. F. Scarr* and F. W. Meszaros

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

A working computer-operated system for the cyclic testing of up to 192 secondary batteries is described. The computer, operating on-line in a time-sharing mode, may conduct as many as 12 independent tests simultaneously. This approach has several advantages over other automated methods including: greater flexibility in test formating, real-time updating of characteristic quantities for each battery, real-time data reduction, systematic information filing, and a logical capability which facilitates the handling of contingencies. System technique, configuration, and capabilities are discussed as an approach to battery testing.

The testing of experimental cells is an important function in the research and development of battery systems. Until recently, it had been difficult to combine the attributes of quality and quantity into one installation because, for any particular testing device, capacity and complexity appeared to be mutually exclusive properties. With the advent of computer systems, however, it seemed reasonable to apply such technology to the problem of comprehensive testing of large numbers of batteries.

In view of the effort required to develop a computer-operated battery test system, it would be instructive to describe a particular installation as an example of one solution to the problem of battery testing. A computer-operated facility for the cyclic testing of secondary batteries has been in operation at Parma Technical Center since May, 1970. While the nature of any individual battery test system is oriented toward the specific needs of its users, a general description of this system may aid in the planning and design of other installations. It is the purpose of this paper to describe various considerations in conceiving this battery test system, the techniques used, and the results achieved.

* Electrochemical Society Active Member.

Key words: battery:tester, tester:computer-operated, computer-operated battery tester.

The Parma Technical Center system, in its present configuration, has evolved from an earlier version which was first developed about eight years ago (1). Its general function is to cycle batteries continuously through a repeated step-wise sequence of constant current, constant resistance, or open-circuit modes, while test data are continually sensed and stored. Its intended use as a tool in battery research and development, however, called for special flexibilities to be built into the system to satisfy the many potential users.

Maximum freedom was required in such capabilities as the available current range, the resolution of time and voltage, the number of data points per position, and the sequencing of the various test modes. In addition it was necessary to protect the well-being of the test samples; hence the system had to be capable of detecting malfunctions during the progress of the test.

While these functions could have been performed adequately by an electromechanical system, the justification for computer operation was based on four additional capabilities which could be achieved in no other way. With one exception these features are related to the efficiency of the data handling process. First, voltage and current integrals can be computed in real time, that is, at the instant the data are obtained. Second, data reduction can be performed in real time, thus minimizing the storage requirements necessary to describe adequately the battery behavior. Third, data are stored in an organized fashion making the information retrieval problem less cumbersome. Fourth, the computer brings into the system a logical capacity which permits interpretation of contingency situations and the ability to act on them.

Most computer-operated battery test systems, such as those of the Martin-Marietta Corporation (2), Western Electric Company (3), San Francisco Bay Naval Shipyard (4), and Electric Storage Battery Research Center (5), as well as our original version, have utilized computers which are totally dedicated to the test facility. This approach has the advantage of minimizing problems of data transmission over appreciable distances and eliminating logical interference from background (or nonprocess) jobs.

In the present case, however, there were several advantages to be gained with remote operation utilizing the central laboratory computer on a time-shared basis. The larger central computer affords more powerful computing capability, less expensive and more regular maintenance, more complete software support, greater economy and flexibility in equipment options, etc. As a result, it has been possible to exploit more fully than the smaller systems the potentialities of computer operation, particularly with regard to information retrieval and contingency situations.

System Capabilities and Techniques

This battery test system is capable of testing up to 192 secondary batteries in 12 groups (or banks) of 16 positions each. Environmental chambers are available in which tests may be conducted at constant temperatures between −40° and 100°C. Each bank may be operated independently of the others in accordance with a predetermined but variable pattern of unit operations called steps. Each repetition of the pattern is designated one cycle. A cycle may consist of up to six steps selected from a choice of four modes:

1. Constant current charge
2. Constant current discharge
3. Constant resistance discharge
4. Open-circuit rest

Constant current in the range of 50 μA to 5A is generated by a separate power supply for each bank. Up to six different current levels in any mode may be established. The computer does not control the current, but it can select the designated setting and monitor the level. If the current has deviated from the desired level by more than a specified amount, the batteries are placed on standby and an error message is sent.

Battery voltages are checked 100 times an hour at regular intervals. Each battery position also has provision for an auxiliary data point which may be used for a reference electrode voltage, temperature, pressure, or any other input as desired.

At the moment each reading is obtained, certain computational operations are performed which if accomplished at any other stage in the data handling process would be less efficient. First, the voltage of each battery is used to update the accumulated voltage from which the average voltage is later to be calculated. Next, it is determined if the battery voltage has changed significantly from the voltage most recently stored in memory. If so, the new value and the time at which it was measured is added to the file. The incremental voltage which is used to decide whether or not to store the newly acquired data is a variable, subject to user specification. This technique, which has been used in other installations, results in concentrating the most voltage-time data points in the regions of greatest change. The data required to characterize the charge/discharge curves to the desired accuracy are thereby minimized. The final step in the scanning sequence is to determine if the battery voltage remains within a pre-established limit. If not, the battery is temporarily removed from test until the beginning of the next step.

The format of a hypothetical test showing some of the variables and their corresponding accuracy which the user can specify is given in Table I. It will be noted that operation at multiple current levels may be achieved. Step-wise constant current, if properly adjusted, can be used to approximate constant voltage operation. The voltage logging increment is chosen to produce the desired number of data points for each step. If the battery should reach the cutoff voltage before the time limit, it is temporarily placed on open-circuit until the beginning of the next step. Actual current control is much better than the current tolerance would indicate. This specification represents only the maximum deviation which the user will accept before the test is suspended. At the completion of step five, the sequence repeats beginning at step one. The first cycle may be initiated at any step desired.

The test data are stored temporarily in an organized format on a half-million word disk. Once each day, at a designated time, the data accumulated on disk for the previous 24 hr are transferred to magnetic tape. At the earliest opportunity, this tape is used to produce a printed report of the day's results. Thus, the turnaround time for the primary record of the test is nominally 24 hr or less.

The structure of the data file on magnetic tape, shown in Table II, is organized to expedite data proc-

Table I. Battery test format example

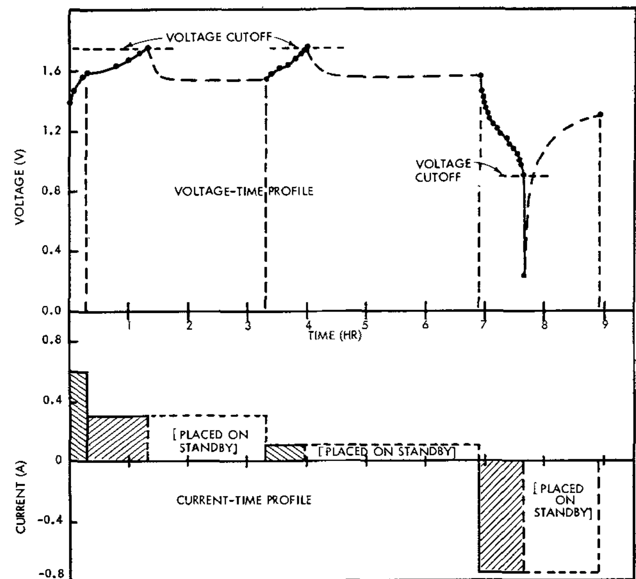

Fig. 2. Reconstruction of voltage-time profile for test format given.

essing. Each daily tape begins with the day number for identification and thereafter is divided into two main sections. The first contains the voltage-time data for all batteries on test in chronological order, that is, without regard to bank or cycle. Since, in practice, voltage-time profiles are required only infrequently by the user, this file is actually sorted only when necessary. The next section contains the step summaries and other information arranged by bank. Sequential arrangement of test data in this fashion facilitates efficient retrieval of results. Each daily tape output contains all the data necessary to reconstruct the test in prescribed detail. Further data processing, including recall of earlier results, may be performed on the raw data as needed.

Primary record reports may be obtained in either abbreviated or complete forms. The abbreviated type, which is most frequently used, presents a summary of characteristic quantities for each test unit in the bank. Summary data consists of the following descriptive quantities evaluated for each complete step:

1. Time to cutoff
2. Charge added or removed
3. Average voltage, or in the case of open-circuit steps, the final voltage
4. Energy content
5. Electrical efficiency

The complete format lists, in addition to the summary data, all the voltages and corresponding elapsed times obtained during cycling, one test position to a page. If a reference electrode is provided in the battery, the anode- and cathode-to-reference voltages will be given as well.

An example of this format is given in Fig. 1 for an actual test performed on so-called "zinc limited cells." These were specially fabricated 0.5 A-hr rechargeable alkaline cells which were being used to study how anode-limited capacity affects cycle life. The cells contained a $Cd/Cd(OH)_2$ reference electrode to permit characterization of single electrode behavior. The cyclic test specified by the investigator consisted of a three-step tapered charge period to bring the cell to a maximum state of charge (with voltage cutoff protection), followed by constant current discharge at a fairly substantial rate to discharge the cell to a preselected limit. The final step was a momentary open-circuit period to record the voltage of a discharged cell at rest. The test format is illustrated in the lower half of Fig. 2. The accuracy with which the system followed the test may be seen in the voltage-time profile of Fig. 2. It will be noted that the cell reached its specified voltage limit in the discharge step as well as two of the charge steps, whereupon it was automatically placed on temporary stand-by.

Occasionally, interruptions in the normal progress of a test may occur from either intentional or accidental causes. The system is capable of automatically detecting, characterizing, and denoting such interruptions on all pertinent reports.

System Configuration and Operation

The configuration of the battery test system hardware is given in Fig. 3. All of the equipment to the left of the dashed line is situated in the computer center, located 400 ft from the battery test room which is shown to the right of the dashed line. The two installations are connected by cable.

The heart of the system is an IBM 1800 Process Control Computer with 24K words of core memory. This computer constitutes the regular data processing facility for an institution of over 500 employees. In addition to operating the battery test facility 24 hr a day,

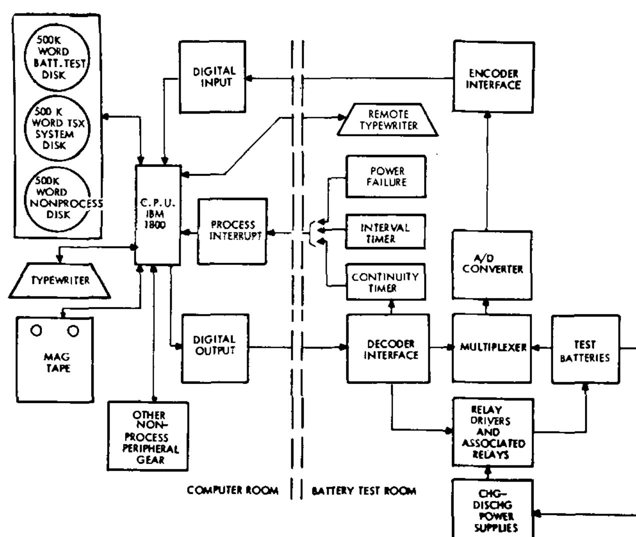

Fig. 3. Block diagram of battery test system

it also runs another data acquisition system and supports a full load of scientific and business programming on a time-shared basis. Of the three 500K word disks installed in the system, one is dedicated to the battery test facility for data and program storage. A magnetic tape unit is used only once a day to record data dumped from the disk. One 16-bit word of digital input is used to receive information from the battery test facility. Instructions to the battery test facility are transmitted through the 16-bit digital output. Other peripheral gear includes those devices not normally used by the battery test facility, such as a printer, typewriter, card reader/punch, and incremental plotter.

The system operates on an interrupt basis through the process interrupt which is a set of inputs used to signal the computer of some event in the battery test room. Thus, the interval timer interrupts the computer from its time-sharing operation once every 36 sec to begin the scan of the battery test positions. The computer determines sequentially which test position is to be read and sends the appropriate instruction to the decoder. The multiplexer, a reed relay scanner, selects the designated data point. The corresponding voltage is then digitized by the A/D converter. After a specified delay, namely 10 msec, the computer picks up the result through the encoder. During this delay, as well as at the conclusion of the scan period, the computer temporarily returns to time-sharing.

The status of each battery and power supply is controlled by relays and their associated drivers. If, due to an error, there should be a loss of communication between computer and battery test facility, the continuity timer will switch the entire system to standby in order to protect the test batteries. The remote typewriter fulfills many functions: it may be used to interrogate the computer memory on the status of a test, to receive error messages, to transmit instructions modifying a test once it is in progress, and to exercise manual control over the system hardware. That portion of the equipment located in the battery test room is shown in Fig. 4 and 5.

It is estimated that over-all the battery test job actually uses the central processing unit (CPU) of the computer only 5% of the time. There is, therefore, little interference with other simultaneous processing the computer may be doing. In cases where the nonprocess job is largely input/output there is no observable effect, while with jobs that are confined to the CPU, running time is slowed by a maximum of 30%.

One of the most useful features of the system to which the computer is particularly adaptable is the ability to modify a test once it is in progress. This may be accomplished in two ways. If the change may be anticipated, it may be programmed to occur automatically at a predetermined point. Using this capability, batteries may be preconditioned in one sequence and tested in another. If, on the other hand, a program change is required immediately, the typewriter is used in a conversational mode to alter specifications contained in computer memory. Certain logical safeguards are incorporated into the typewriter routine to prevent inadvertent program modification.

The main part of the computer program for the battery test facility, written in assembler language, occupies 1056 words of core memory. It contains the basic scan routine and other programs which are used every time a clock interrupt is received. Battery test also uses about 2000 words of "Inskel/Common" a

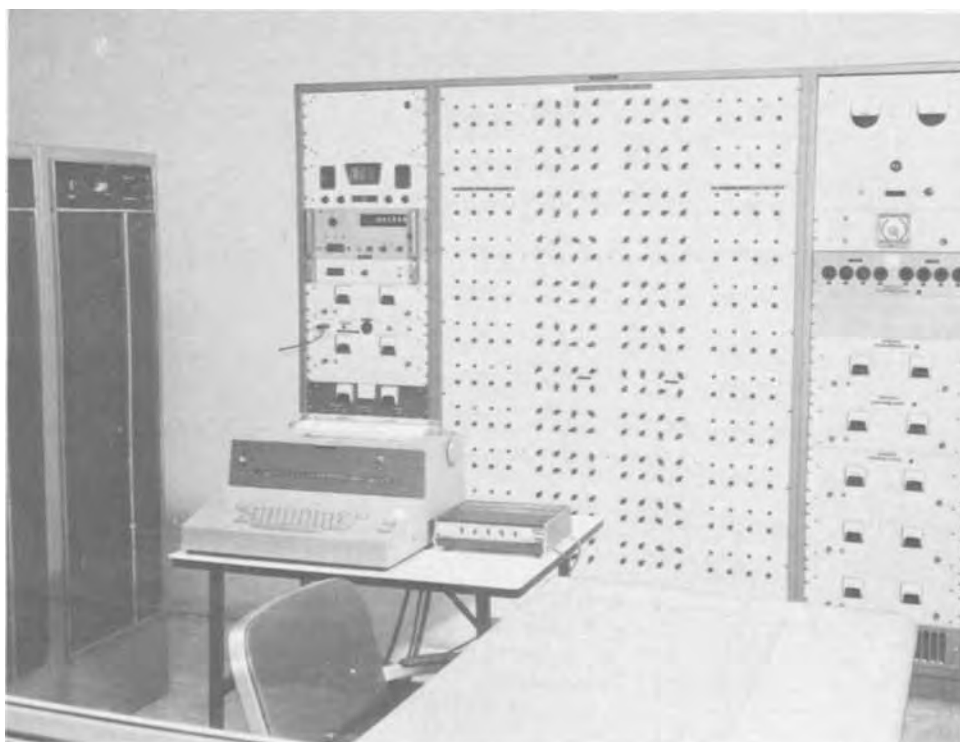

Fig. 4. Battery test room equipment and control panel. In the foreground is the remote typewriter. The equipment bay at the left contains the interface. The control panel at the rear, from the top down, contains: (left)—multiplexer, A/D converter, low-level analog amplifier, and several bank power supplies; (center)—level controls for presettable current channels; (right)—relay power supply, interval timer, and the remaining bank power supplies.

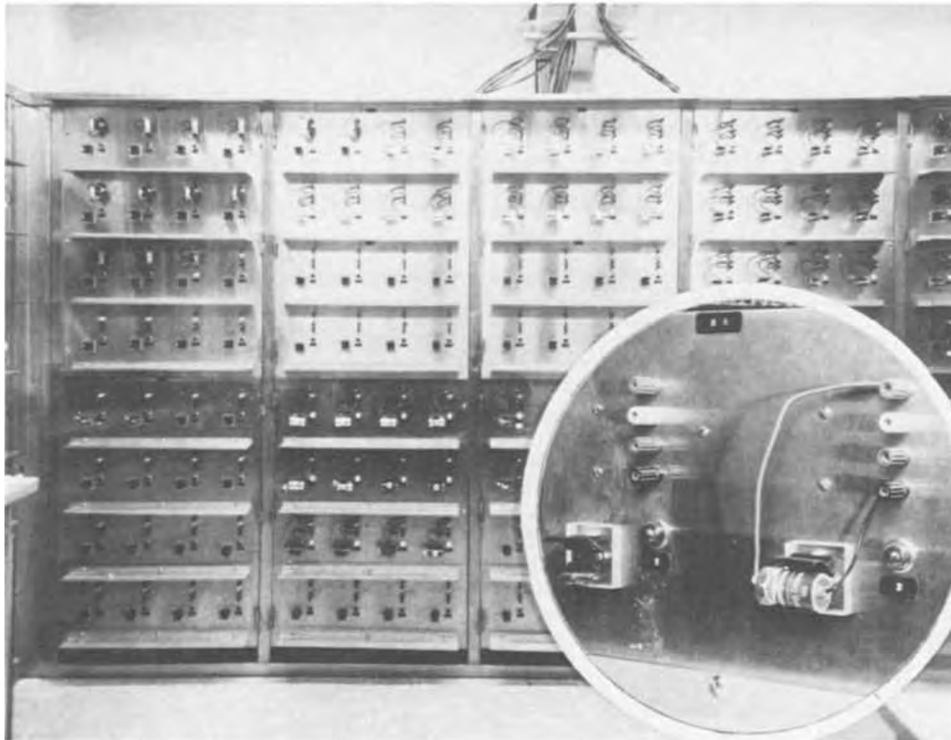

Fig. 5. Battery test stand. Test batteries are mounted on stainless steel panel. Individual test position is pictured in inset showing data point terminals and signal light.

region of core which is reserved only for data storage. This region contains instantaneous test data, test specifications, and other information continually used by the system. Thus, the total core space assigned permanently and specifically to the battery test operation is only just over 3000 words.

The rest of the battery test program consists of auxiliary subprograms which are used less frequently than the main program. They are called from disk only when needed, swapping temporarily with whatever program resides in core at the moment. Subprograms to start a bank, or to change its operating mode, or to dump the disk to tape are in this category. These programs are written largely in Fortran. Furthermore, because they are not an integral part of the operating system but are utilized on a "job" basis, it is not necessary to interrupt battery testing in order to modify these programs when required.

Development of the original programs sufficient to get the system into production required about 2 man-years of effort. Since then, the computer approach to this operation has permitted program modification and improvement to be an on-going process.

System Evaluation and Summary

The reliability of this battery test system has been good. Although it runs 24 hr a day, it is attended by a single operator only during daytime working hours. System interruptions, when they occur, stem from one of three causes with about equal frequency: line power flicker or failure, malfunction of a peripheral device in the computer room which binds up the central processor unit, or logical program errors in a non-process (background) job. As a result of such causes, the system is down less than 4 hr a month.

Preventive maintenance on the computer and peripherals is performed biweekly. Normally this does not require the suspension of battery testing. About once every 2 months, it is necessary to suspend testing for a few hours. At such times shutdown is accomplished under programmed control so as not to influence unduly the test results.

Operating cost for this system varies somewhat with the utilization level. At 100% occupancy of test positions, the daily operating cost exclusive of personnel is about 42 cents per cell. This figure includes equipment rental, allocated computer operating costs, and the cost of final data processing.

In summary, this computer-operated battery test facility has provided a reliable, accurate means of testing a large number of batteries of all types for a varied group of users. Time-sharing of the computer has worked to our advantage. All the data necessary to reconstruct the test are contained on magnetic tape in easily stored and retrievable format. Further data processing, in addition to that normally furnished, is thereby facilitated. Modification of the basic system, when desired, is accommodated by the modular nature of both the hardware and software.

Acknowledgments

The authors are deeply grateful to the following individuals for their contributions to this project: to Mr. T. P. LaFramboise for the original design of the interface; to Mr. A. F. Deckert, Jr., for his part in installing the system; and to Mr. D. L. Wright who has made many important modifications to the hardware and who, at present, is the system operator.

Manuscript submitted April 5, 1972; revised manuscript received July 12, 1972. This was Paper 25 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Phase Equilibria in Lithium-Chalcogen Systems

II. Lithium-Sulfur

P. T. Cunningham, S. A. Johnson, and E. J. Cairns*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The equilibrium phase diagram of the lithium-sulfur system has been investigated. A miscibility gap extends from 0.2 to 37.0 atom per cent (a/o) lithium above a monotectic temperature of 364.8°C; the critical temperature is greater than 600°C. The only intermediate phase found is Li_2S, which melts at 1372°C.

Recent research and development work on high-specific-power, high-specific-energy secondary cells based on alkali metal/chalcogen couples (1) has focused attention on the need for more complete phase equilibrium data for these systems. The work reported here was undertaken as part of a broad program to determine the lithium-chalcogen phase diagrams. Results for lithium-selenium have been published (2).

Previous work on the lithium-sulfur system has not been extensive.[1] Bergstrom (3) reported the preparation of lithium sulfide and polysulfides in liquid ammonia. Pearson and Robinson (4) have reported their preparation in aqueous and alcoholic solution and by direct combination of the elements under boiling napthalene. Pearson and Robinson also reported a portion of the Li-S phase diagram between Li_2S and Li_2S_2, indicating that Li_2S was stable up to its observed melting point (900°-975°C) and that Li_2S_2 was slightly decomposed at its reported melting point of 369.5°C. The compound Li_2S prepared in liquid ammonia has been reported to have an antifluorite structure (5) with a lattice parameter of 5.708Å.

Experimental

Materials.—The sulfur used was a special high-purity (99.999+%) grade obtained from American Smelting and Refining Company, South Plainfield, New Jersey. The lithium, a high-purity reactor grade (99.98%), and lithium sulfide (97+%) were obtained from the Foote Mineral Company, Philadelphia, Pennsylvania. These materials were used without further purification. Li_2S was mixed with the appropriate terminal phase in a purified-helium-atmosphere glove box (6) to obtain the desired composition for the various experiments. The samples were contained in borosilicate glass, quartz, aluminum, vitreous graphite, or niobium depending on the temperature range covered and the sample composition.

Apparatus and procedures.—The experimental techniques used included thermal analysis (heating and cooling curves), differential thermal analysis (DTA), high-temperature centrifugation, chemical analysis, and x-ray diffraction.

Heating and cooling curves were obtained on samples weighing from 10 to 20g using a furnace-well attached to the floor of the helium-atmosphere glove box (7). Sulfur-rich samples for thermal analysis were contained in borosilicate glass, quartz, or aluminum vessels, which were usually sealed to prevent rapid sulfur loss. The necessity of sealing the sample container made cooling curves almost useless because of extreme undercooling of samples that were not vigorously stirred. Some samples were run in open containers with stirring but the compositions of these samples are uncertain. Temperatures were measured with platinum *vs.* platinum-10% rhodium thermocouples fabricated from wire which had been calibrated against NBS pure tin (mp 231.88°C), zinc (mp 419.58°C), and aluminum (mp 660.0°C).

DTA samples, which weighed about 80 mg, were contained in aluminum or niobium capsules with press-fit caps. Data were obtained with a du Pont Model 900 Differential Thermal Analyzer using a 5°C/min rate of temperature change with a powdered alumina reference material and a dynamic helium atmosphere. The thermocouples used were described above and the over-all accuracy of the apparatus was determined to be ±1°C using NBS standard quartz and KNO_3.[2]

The melting point of Li_2S was determined using a molybdenum-wound resistance furnace. The samples were placed in niobium or vitreous graphite crucibles and heated in an argon atmosphere. Temperature was measured with a calibrated optical pyrometer and the occurrence of fusion was visually determined.

Chemical analysis was used to determine the compositions of materials taken from samples in which phase separation occurred. Phase separation under normal gravity was usually slow, and in many cases a high-temperature centrifuge was used to increase the rate of phase separation. A mixture of Li_2S and sulfur having the over-all composition of interest was placed in a quartz ampoule, which was evacuated and sealed. The ampoules were placed in a rocking furnace and mixed for several hours (in some cases several days) at a temperature about 25°C above the planned centrifugation temperature prior to placing them in the centrifuge. After centrifugation for several hours at speeds corresponding to centrifugal forces about 250 times normal gravity, the ampoules were quenched in liquid nitrogen and placed in a helium-atmosphere glove box where they were broken open and the zones of the samples were carefully separated mechanically. The same quenching and separation procedure was used for samples in which phase separation was achieved at normal gravity after 7 to 10 days at temperature. Chemical analysis was carried out on the separated materials using flame photometry to analyze for lithium. The sulfur content was calculated by difference. The accuracy of this procedure (±5% of the lithium weight) was confirmed by analyzing several samples for sulfur as well, using standard gravimetric techniques.

X-ray diffraction powder patterns were obtained for a large number of samples having a wide variety of compositions and thermal histories, using a 114.6 mm Debye-Scherrer camera with CuKα radiation.

Results and Discussion

All of the experimental results are summarized in Fig. 1. The thermal analysis and DTA results, which

* Electrochemical Society Active Member.

Key words: lithium, chalcogen, sulfur, sulfide.

[1] During the preparation of this paper, it came to our attention that R. Sharma had also studied this system concurrently and had also prepared a manuscript.

[2] The quartz and KNO_3 are SRM 755 and SRM 756, respectively, available from the Office of Standard Reference Materials, National Bureau of Standards, Washington, D.C. 20234.

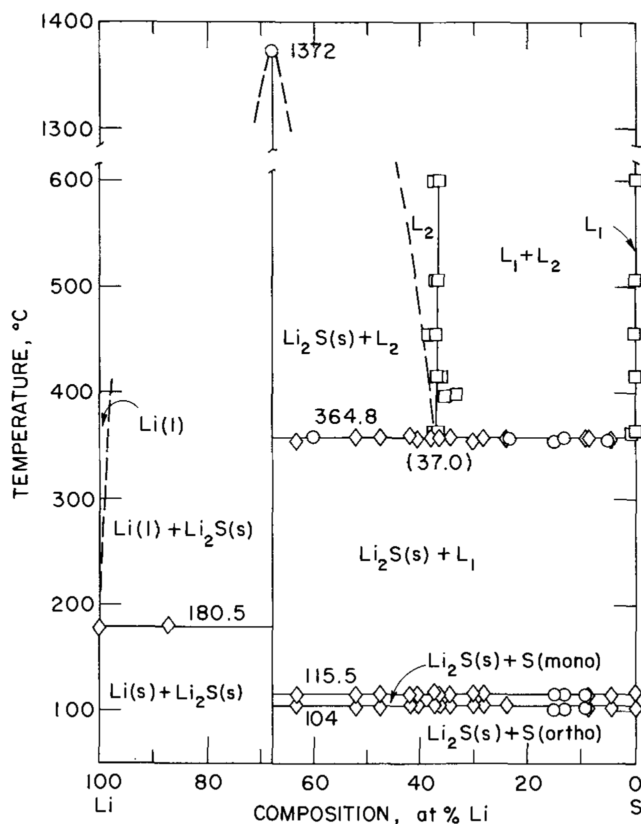

Fig. 1. Partial phase diagram of the lithium-sulfur system. ○, Thermal analysis; ◇, DTA; □, chemical analysis.

are presented in Table I, show that five thermal effects were observed. The few measurements made on the lithium-rich side of Li_2S indicate that Li_2S does not affect the melting point of pure lithium (180.5°C) within the accuracy of these measurements (±1°C) and that there are no other thermal invariants present in this composition range below 860°C. The melting point of Li_2S was observed to be $1372°\,^{+10}_{-5}$ °C in the resistance furnace for samples contained in both niobium and vitreous graphite crucibles. This value is considerably higher than that reported by Pearson and Robinson (4), who indicated that their experiments were vitiated by rapid reaction of the samples with their glass and porcelain containers, a problem which we also encountered.

On the sulfur-rich side of Li_2S, thermal effects were observed at 104.0° ± 3.7°C, 115.5° ± 1.0°C, and 364.8° ± 4.0°C. These temperatures are weighted averages where the weighting is admittedly somewhat subjective. The indicated uncertainties show the variance of the data. The effects observed at 104° and 115.5°C are associated with the transformation from α(orthorhombic) sulfur to β(monoclinic) sulfur and the melting of β sulfur, respectively. The accepted value for the $\alpha \rightarrow \beta$ transition is 95.5°C (8) but in none of our experiments, even with pure sulfur, was the effect observed at this temperature. The fact that the α-β transition is observed about 10° above the equilibrium temperature is typical and in good agreement with the temperature for the appearance of the β form in thin films of α sulfur (9). Pure sulfur was observed to melt at 118.0°C in our experiments, in fair agreement with the accepted value of 118.9°C (8). With lithium present, this transition was observed at 115.5°C, which is significantly lower than 118.9°C and is presumably the temperature of a eutectic reaction [$L_1 \rightarrow Li_2S(s) + \beta$ sulfur].

The thermal effect at 364.8°C is attributed to a monotectic reaction [$L_2 \rightarrow Li_2S(s) + L_1$]. The extent of the miscibility gap (see Fig. 1) was determined by chemical analysis of material taken from two easily distinguishable zones, which were observed in samples quenched from temperatures above 375°C, and of over-all composition from 15 to 30 a/o lithium. The upper zone was very similar to pure sulfur which had the same thermal history, whereas the lower zone was a red, glassy-appearing material which appeared to be homogeneous but which gave a room-temperature x-ray powder pattern clearly showing Li_2S and α sulfur. These zones are associated with the separated liquid phases L_1 and L_2, respectively (see Fig. 1). Separation of the liquid phases under normal gravity was slow; about 6 days were required to achieve clear separation. With centrifugation at 250*g*, separation was achieved in 6 hr. Chemical analyses, the results of which are shown in Table II, were performed on material that was mechanically separated. Considerable care was taken to insure that the samples were homogenous and cross-contamination, which would lead to an apparent narrowing of the miscibility gap, was

Table I. Summary of thermal data on the lithium-sulfur system

avoided. Scatter in the data for the lithium-rich side of the miscibility gap is generally within the experimental uncertainty of the analysis (±5% of the lithium weight present), but there is greater scatter on the sulfur-rich side. Based on these results, the region of immiscibility is taken to be from about 0.2 to 37.0 a/o lithium at the monotectic temperature.

Thermal effects associated with liquidus crossings were not observed. Attempts to establish the location of the upper liquidus by determination of the equilibrium sulfur vapor pressure as a function of temperature for compositions greater than 37 a/o lithium gave very scattered results. The time necessary for equilibration between the vapor and the condensed phase was at least several days. It is significant that the vapor pressure of samples with less than 34 a/o lithium was not significantly different from that for pure sulfur within the experimental uncertainty (±10%).

X-ray powder patterns were taken on a large number of samples of various compositions and thermal histories. In all cases, the observed lines were accounted for by the appropriate terminal phase and Li_2S.

The phase diagram which we have found for the lithium-sulfur system is very much like that for the lithium-selenium system, and previous comments (2) regarding that system and the implications of the phase equilibria in terms of the performance and design of electrochemical cells will not be repeated. Additional investigation of the lithium-sulfur system is needed in the region between Li_2S and lithium and at temperatures greater than 600°C.

Acknowledgments

The authors are indebted to Argonne's Analytical Support Group for assistance in x-ray and chemical analyses and to Dr. R. C. Vogel and Dr. A. D. Tevebaugh for their encouragement and support. This work was performed under the auspices of the United States Atomic Energy Commission.

Electrochemical Behavior of Titanium

Effect of Ti(III) and Ti(IV)

N. T. Thomas* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Anodic polarization of titanium in 1*N* H_2SO_4 containing Ti(IV) showed that Ti(IV) inhibited dissolution and facilitated passivation. Polarization of titanium in 1*N* H_2SO_4 containing both Ti(III) and Ti(IV) indicated that Ti(III) accelerated the anodic dissolution of titanium in both the active and passive region. An empirical expression for anodic dissolution of titanium in 1*N* H_2SO_4 was obtained

$$i_a = k_a[H^+]^{0.53} \exp(0.43\,\mathbf{F}\phi/RT)$$

A dissolution mechanism based on the barrier layer model and Temkin adsorption of an adsorbed intermediate is shown to be consistent with the experimental data. A similar mechanism is used to interpret the accelerated dissolution of titanium with Ti(III).

Not many investigations on the effect of trivalent and tetravalent titanium on the polarization of titanium electrodes have been reported. Andreeva and Kazarin (1) and Weiman (2) reported that tetravalent titanium had an inhibiting effect on the corrosion of titanium in sulfuric acid and in boiling 5% HCl, respectively. Tsvetnova *et al.* (3) found that the presence of trivalent titanium had a depassivation effect on passive titanium. In this study, the effect of tetravalent and trivalent titanium on the electrochemical behavior of titanium is examined.

* Electrochemical Society Active Member.

Key words: anodic dissolution, polarization, corrosion.

Experimental

Details of the experimental apparatus are given elsewhere (4). Tetravalent titanium in sulfuric acid was prepared by a method given by Codell (5) with a slight modification. A solution of 1g of tetravalent titanium in one liter of 1*N* H_2SO_4 was prepared as follows. Two grams of purified titanium (Fisher Scientific Company) was placed in a beaker and 200 ml of distilled water were added followed by 55.6 ml of concentrated sulfuric acid. The mixture was warmed gently on a hot plate until all the titanium dissolved to give a violet-colored solution. Then, quantities of 30% H_2O_2 were added until an orange-colored solution was obtained. The solution was heated until it was colorless. The solution was then cooled and transferred to a 2 liter volumetric flask and diluted to 2 liters. The pH of this solution was 0.25. It should be noted that in the method described by Codell (5) small amounts of HF were used to facilitate the dissolution of titanium. In the present case, HF was not added. The solutions of lower concentrations of tetravalent titanium were prepared by diluting the appropriate quantity of the stock solution with 1*N* H_2SO_4.

Ti(III) was obtained as a stock solution of titanous sulfate (Lamotte Chemical Company, titanous sulfate, 20% standardized solution). The analysis of the stock solution showed that the solution contained 1.35M Ti(III) and, in addition, 0.3M of Ti(IV). Hence, for this study, tetravalent titanium was always present in solutions of trivalent titanium.

When a steady-state corrosion potential of titanium was attained in 1*N* H_2SO_4, the appropriate quantity of tetravalent or the trivalent and tetravalent titanium solution were added. After a steady-state corrosion potential was attained, cathodic and anodic polarization of titanium were performed.

Results and Discussion

Effect of Ti(IV).—The presence of the tetravalent ion increased the corrosion potential of titanium in the noble direction. The corrosion potential of titanium at different concentrations of Ti(IV) is shown in Table I. At a concentration above 5 mM Ti(IV) the electrode self-passivated.

The cathodic polarization of titanium in the presence of Ti(IV) is shown in Fig. 1 and indicates that a reduction reaction, in addition to the hydrogen evolution, occurs between the corrosion potential and −950 mV *vs.* SCE. The reduction of Ti(IV) can be obtained by subtracting the rate of hydrogen evolution from the total cathodic current. The reduction currents of Ti(IV) which is shown in Fig. 2 exhibit limiting currents. The limiting current values obtained are given in Table I. According to Latimer (6) the oxidation-reduction potential of the Ti(III)/Ti(IV) couple is −142 mV *vs.* SCE. Therefore, it is assumed that the limiting diffusion current observed is due to the reduction of Ti(IV) to Ti(III).

Figure 3 shows the anodic polarization of titanium in the presence and the absence of Ti(IV). As shown in this figure, the presence of Ti(IV) decreased the anodic current in the active region. Although there was no change in the primary passivation potential, the presence of Ti(IV) decreased the critical current. During the anodic polarization of titanium in Ti(IV) solutions, a small cathodic current was observed in the

initial part of the passive region between −400 to 200 mV *vs.* SCE, indicating a net reduction reaction in this potential region. The presence of Ti(IV) has apparently no effect on the passive current at more positive potentials.

Figure 4 shows the anodic dissolution current at −580 mV *vs.* SCE and the critical current for titanium corrected for both the h.e.r. and the reduction of Ti(IV). As seen in the Fig. 4, the presence of Ti(IV) decreased the anodic dissolution of titanium and also the critical current. This decrease in anodic dissolution and critical current was found to be proportional to the concentration of Ti(IV). Thus, it is apparent that Ti(IV) inhibits the anodic dissolution of titanium. After anodic polarization, the titanium electrode remained passive.

Effect of Ti(III).—Figure 5 shows the cathodic polarization of titanium in the presence and the absence of the mixture of Ti(III) and Ti(IV). Between the corrosion potential and −950 mV *vs.* SCE a second reduction process in addition to hydrogen evolution was observed. The rate of the second reduction process can be obtained by subtracting the rate of the h.e.r. from the net cathodic current. This reduction current is plotted *vs.* the potential in Fig. 6 and a limiting current was observed. These limiting reduction currents

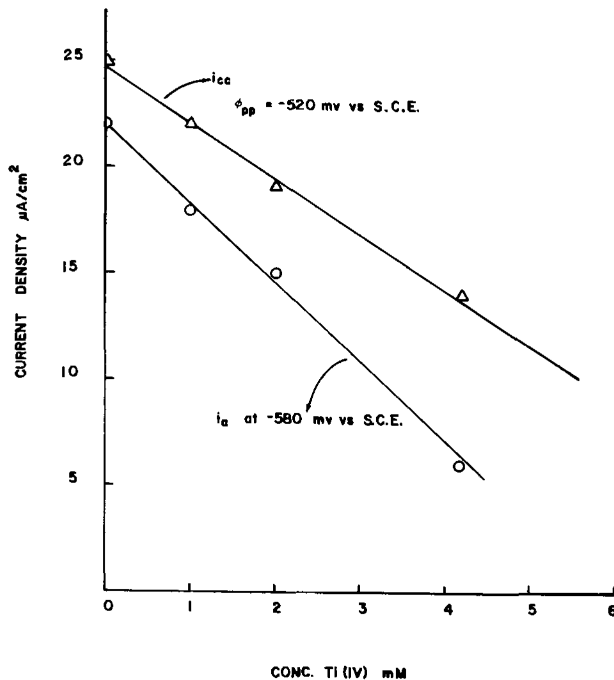

Fig. 4. Anodic current and critical current density of titanium *vs.* Ti(IV) concentration.

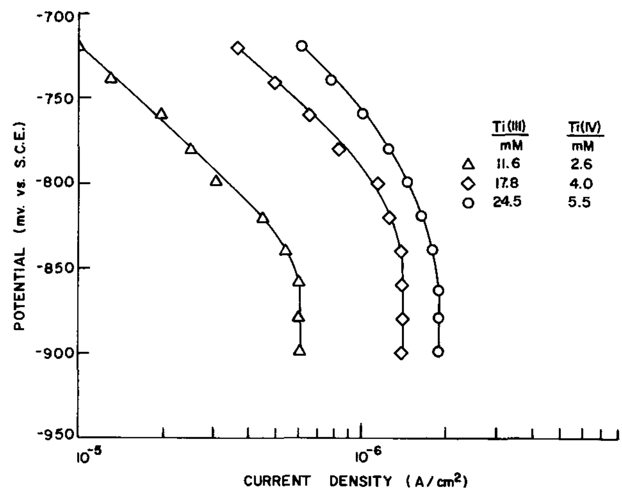

Fig. 6. Electrochemical reduction of Ti(IV) in the presence of Ti(III).

which increased with an increase in concentration of Ti(III) and Ti(IV) is presented in Table I. According to Latimer (6) the redox potential of the Ti(III)/Ti(II) couple is −0.610V *vs.* SCE. On the other hand, the theoretical work of George and McClure (7) indicates that the redox potential of Ti(III)/Ti(II) is −2.54V *vs.* SCE. The experimental data of Oliver and Ross (8) supports the calculations of George and McClure (7) indicating that the reduction process observed during the cathodic polarization of titanium in the presence of Ti(III) and Ti(IV) is the reduction of Ti(IV) to Ti(III) and not Ti(III) to Ti(II).

Figure 7 shows a plot of limiting reduction current *vs.* concentration of Ti(IV). The square symbols represent the limiting current obtained without Ti(III) in the solutions. The circle symbols represent the limiting current obtained for solutions containing both Ti(III) and Ti(IV). As seen in Fig. 7, the two sets of limiting currents are consistent. Therefore, by both thermodynamic considerations and comparison of the two sets of reduction currents, it seems reasonable to assume that the second reduction current on titanium in solution containing both Ti(III) and Ti(IV) is due solely to the reduction of Ti(IV).

Figure 8 shows the results of the anodic polarization of titanium in 1*N* H_2SO_4 in the presence and the absence of the mixture of Ti(III) and Ti(IV). At a concentration of 35 mM Ti(III) and 7.8 mM Ti(IV), titanium was passive. For solutions containing only Ti(IV), as stated above, titanium passivated at concentrations of 5 mM Ti(IV) and above. The passivation of titanium in solution containing 35 mM of Ti(III)

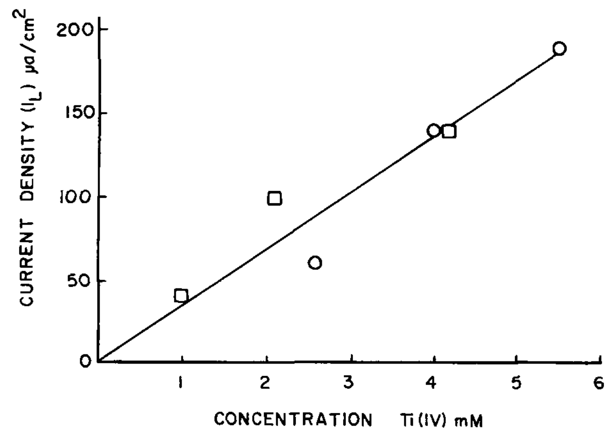

Fig. 7. Limiting diffusion currents of Ti(IV) reduction. Square points represent data for Ti(IV) solutions. Circle points represent data for solutions containing Ti(IV) and Ti(III).

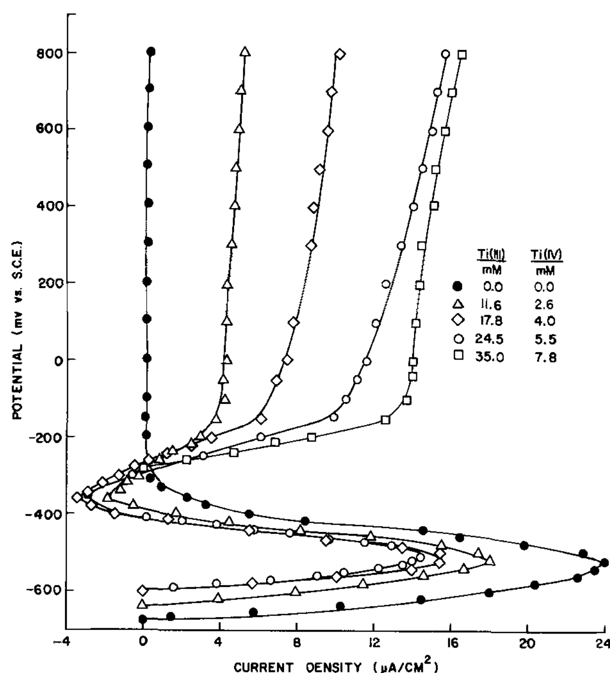

Fig. 8. Anodic potentiostatic polarization of titanium in 1*N* H_2SO_4 containing Ti(III) and Ti(IV).

and 7.8 mM of Ti(IV) can be attributed to the presence of Ti(IV). The passive corrosion potentials observed with the mixture of Ti(IV) and Ti(III) were considerably lower than those of the passive corrosion potential observed with only Ti(IV) indicating a marked activation of titanium in the passive region due to Ti(III).

As seen in Fig. 8, the presence of both Ti(III) and Ti(IV) decreased the anodic current and the critical current density. However, no change in the primary passivation potential of titanium in the mixture of Ti(III) and Ti(IV), -520 mV *vs.* SCE, was observed. At the corrosion potential of titanium in solutions containing both Ti(III) and Ti(IV), the corrosion current of titanium can be calculated by summing the rate of the h.e.r. and the rate of Ti(IV) reduction. These calculated corrosion currents are given in Table I. In the above calculations, the Ti(IV) reduction current was obtained by extrapolating the cathodic curve in Fig. 6 to the corrosion potential of titanium in solution containing both Ti(III) and Ti(IV); the rate of the h.e.r. was obtained by extrapolating the h.e.r. Tafel line to the same potential.

If the anodic dissolution of titanium is independent of Ti(III), the corrosion current of titanium in solutions containing both Ti(III) and Ti(IV) should have been smaller than the values obtained. Comparison of the corrosion current of titanium in solutions containing 17.8 mM Ti(III) and 4.0 mM Ti(IV) with the corrosion current of titanium in 4.2 mM Ti(IV) solution indicates that Ti(III) has an accelerating effect on the dissolution of titanium.

The rates of anodic dissolution of titanium in solutions containing Ti(III) and Ti(IV) at -580 mV *vs.* SCE after correction for the h.e.r. and Ti(IV) reduction are given in Table II. Table II gives some anodic dissolution rates of titanium in the presence of Ti(IV) and Fig. 4 shows that the decrease in anodic current was proportional to the concentration of Ti(IV). As seen in Table II, the anodic current of titanium in the presence of both Ti(III) and Ti(IV) is larger than the value expected when Ti(IV) only was present. Table II also gives the anodic current of titanium in the absence of Ti(IV) and Ti(III) at -580 mV *vs.* SCE. From the above results the anodic current of titanium in the presence of only Ti(III) is estimated and presented in Table II. In the potential range of active

titanium dissolution, the oxidation of Ti(III) to Ti(IV) is not possible thermodynamically. Hence, it seems reasonable to assume that Ti(III) accelerated anodic dissolution of titanium in the active region. It should be noted that the calculated anodic dissolution of titanium in the presence of Ti(III), $i_a(\gamma)$, was based on the assumption that the inhibiting effect of Ti(IV) is independent of Ti(III). A log-log plot of $i_a(\gamma)$ *vs.* concentration of Ti(III) in Fig. 9 shows that

$$\frac{\partial \log i_a(\gamma)}{\partial \log[\mathrm{Ti(III)}]} = 0.5 \qquad [1]$$

The critical currents of titanium in the presence of both Ti(III) and Ti(IV), only Ti(IV) and in the absence of Ti(III) and Ti(IV) after considering h.e.r. and Ti(IV) reduction are given in Table II. The critical current in solutions containing only Ti(III) have been estimated from the above results and are given in Table II. These results show that Ti(III) increased the critical current of titanium.

During potentiostatic anodic polarization of titanium in solutions containing both Ti(IV) and Ti(III), a small cathodic current between -400 and -275 mV *vs.* SCE was observed. This observed net cathodic current is probably due to the reduction of Ti(IV) to Ti(III).

As seen in Fig. 8, Ti(III) increased the apparent passive current. The passive currents were independent of the rotation speed of the electrode indicating the absence of mass transfer effects. The passive current of titanium in solutions containing both Ti(III) and Ti(IV) at $+800$ mV *vs.* SCE is presented in Table I.

After anodic polarization the electrode remained passive at all concentrations of Ti(III) and Ti(IV) studied and the passive corrosion potential was -270 ± 15 *vs.* SCE. This passive corrosion potential was much lower than the passive corrosion potential of titanium in 1*N* H_2SO_4 in the presence and absence of Ti(IV).

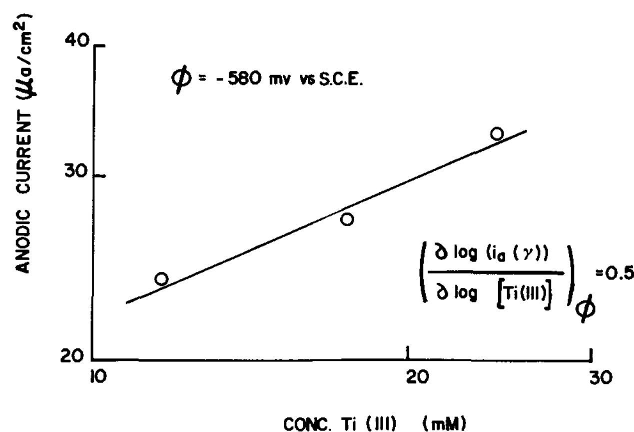

Fig. 9. Anodic current, $i_a(\gamma)$, vs. Ti(III) concentration

The observed depassivation of titanium with Ti(III) is in accord with the results of Tsvetnova (3) who reported that Ti(III) depassivated titanium in 1*N* H_2SO_4 solution containing 4.2 mM Ti(III) at 65°C. According to Tsvetnova the passive current increased by approximately a factor of 20. The present study also showed that the presence of Ti(III) appreciably increased the passive current of titanium in 1*N* H_2SO_4 at 25°C. For example, at a concentration of 24.5 mM Ti(III), the passive current increased by approximately a factor of 40.

Anodic dissolution in the absence of Ti(III) and Ti(IV).—Studies on the mechanism of titanium dissolution in H_2SO_4 have been difficult due to the small active region observed. It has been reported (4) that the anodic polarization of titanium in sulfuric acid at different *p*H showed that anodic dissolution increased with increase in the concentration of hydrogen ions. The increase in anodic dissolution of titanium with acid concentration has also been shown by others (9, 10).

Since the corrosion potential of titanium did not change with rotation of the electrode, the active corrosion potential observed for titanium is due to activation-controlled anodic dissolution of titanium and hydrogen evolution. In the vicinity of the active corrosion potential the net current can be written

$$i = k_a[H^+]^{Z_a} e^{\frac{\alpha_a F}{RT}\phi} - k_H[H^+]^{Z_H} e^{\frac{-\alpha_c F}{RT}\phi} \quad [2]$$

where k_a and k_H are rate constants for anodic dissolution of titanium and hydrogen evolution, respectively. Z_a and Z_H are reaction orders with respect to hydrogen ions for anodic dissolution of titanium and the h.e.r., and α_a and α_c are the over-all transfer coefficients for the anodic and cathodic reactions, respectively.

Equation [2] can be written

$$i = i_{corr}\left(e^{\frac{\alpha_a F}{RT}\Delta\phi} - e^{\frac{-\alpha_c F}{RT}\Delta\phi}\right) \quad [3]$$

where $\Delta\phi = \phi - \phi_{corr}$

For very small $\Delta\phi$ values, Eq. [3] can be written

$$i = i_{corr}(\alpha_a + \alpha_c)\frac{F}{RT}\Delta\phi \quad [4]$$

and

$$R_P = \left(\frac{\partial\Delta\phi}{\partial i}\right)_{\Delta\phi\to 0} = \frac{RT}{i_{corr}(\alpha_a + \alpha_c)F} \quad [5]$$

Figure 10 shows a linear plot of $\Delta\phi$ *vs.* current for potentiostatic anodic and cathodic polarization of titanium at different *p*H. [A similar plot of galvanostatic experiments are given in Fig. 6 of Ref. (11)]. The slope of each curve is the polarization resistance, R_P. From the polarization resistances determined and the corrosion current and the h.e.r. Tafel slope values reported in Ref. (11), Eq. [5] gives the average calculated value of α_a as 0.43. Since the expression for anodic Tafel slope is

$$b_a = \left(\frac{\partial\phi}{\partial \log i_a}\right) = 2.3\frac{RT}{\alpha_a F} \quad [6]$$

b_a is 140 mV.

$$i_{corr} = k_a[H^+]^{Z_a} e^{\frac{\alpha_a F}{RT}\phi_{corr}} - k_H[H^+]^{Z_H} e^{\frac{-\alpha_c F}{RT}\phi_{corr}} \quad [7]$$

Thus

$$\phi_{corr} = \frac{RT}{(\alpha_a + \alpha_c)}\{[\ln k_H - \ln k_a] + \ln[H^+](Z_H - Z_a)\} \quad [8]$$

$$\left(\frac{\partial\phi_{corr}}{\partial pH}\right) = -2.3\frac{RT[Z_H - Z_a]}{(\alpha_a + \alpha_c)F} \quad [9]$$

It has been reported (11) that the corresponding potential of titanium was independent of *p*H in the *p*H range studied. Similar independence of corrosion potential with acid concentration was observed by others (9, 12). Thus, Eq. [9] shows that the anodic reaction order with respect to hydrogen ions is equal to the cathodic reaction order with respect to hydrogen ion concentration. In studies of the h.e.r. on titanium (11) it was found that the hydrogen evolution reaction order was 0.6 with respect to hydrogen ions. Thus, the anodic reaction order with respect to hydrogen should be about 0.6.

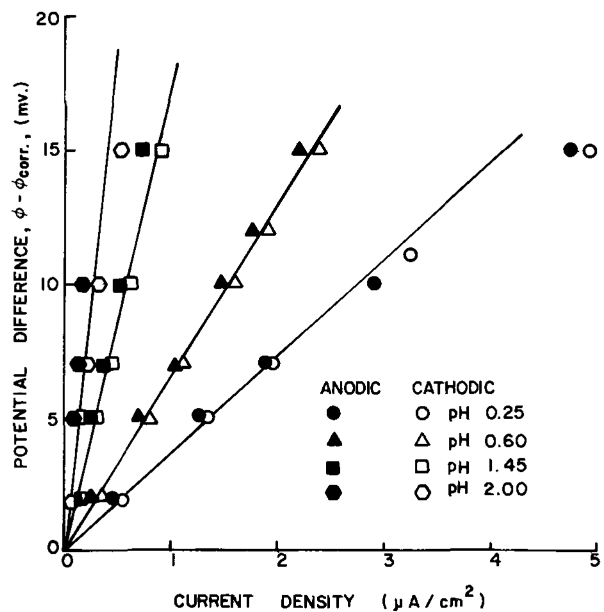

Fig. 10. $(\phi - \phi_{corr})$ *vs.* current density

Anodic polarization Tafel lines for titanium dissolution can be constructed from the corrosion potentials, corrosion currents, and the anodic Tafel slope. From such a plot, the anodic reaction order with respect to hydrogen ion can be determined by plotting log i_a *vs.* *p*H at constant potential. This latter plot is shown in Fig. 11 which shows that

$$\left(\frac{\partial \log i_a}{\partial pH}\right)_\phi = -0.53 \quad [10]$$

Hence, the reaction order for anodic dissolution of titanium with respect to hydrogen ions is shown to be about 0.53.

In the active region, the current due to anodic dissolution of titanium can be obtained at the applied

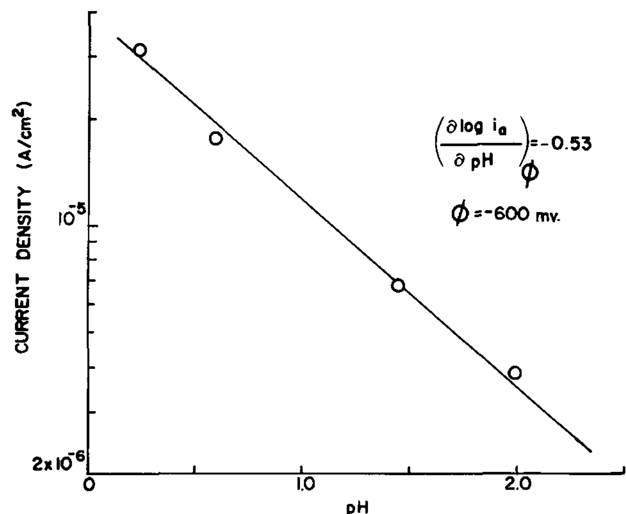

Fig. 11. Anodic dissolution of titanium *vs.* *p*H

potential by adding the hydrogen evolution current (obtained by extrapolating the Tafel line for h.e.r. to the applied potential) with the measured anodic current. Figure 12 shows these results during potentiostatic polarization in the vicinity of corrosion potential. From Fig. 12 the anodic Tafel slopes obtained were 135 mV, and the reaction order for anodic dissolution of titanium with respect to hydrogen ions was 0.57. The above results of the anodic Tafel slope and reaction order are in agreement with the results obtained from an analysis of the polarization resistances, corrosion currents, and cathodic Tafel slope.

In this study it has been shown that in the vicinity of corrosion potential, the anodic dissolution rate of titanium in H_2SO_4 can be expressed by the rate expression

$$i_a = k_a[H^+]^{0.53}\, e^{0.43 \frac{F}{RT}\phi} \quad [11]$$

A mechanism for the dissolution of titanium must be consistent with the pH dependence and the presence of an oxide film on the surface (13, 14). When titanium dissolves in acid solution, the over-all process is (15, 16)

$$Ti \rightarrow Ti(III) + 3e^- \quad [12]$$

This process does not take place in a single step, but rather in a series of individual reaction steps [*e.g.*, see Ref. (17)].

As discussed earlier, the titanium surface is covered with an oxide film at the active corrosion potential. During anodic dissolution, titanium is assumed to pass through this film. The following scheme for titanium dissolution is proposed

$$Ti = Ti(II) + 2e^- \quad [13a]$$

$$Ti(II) + H^+ = \{Ti(III)H\}_{ads} \quad [13b]$$

$$\{Ti(III)H\}_{ads} \rightarrow Ti(III) + H^+ + e^- \quad [13c]$$

In the above sequence, it is assumed that step a takes place at the metal-oxide interface and steps b and c occur at the oxide-solution interface. The reaction rate of step a depends on the potential at the metal-oxide interface, ϕ_f, and the rates of step b and c depend on the potential at the oxide-solution interface, ϕ_s. It can be shown that Eq. [11] for anodic dissolution of titanium can be derived by assuming step c is rate controlling with Temkin behavior of the adsorbed $\{Ti(III)H\}_{ads}$ species. It is also assumed that the film reaction (step a) and step b are both at equilibrium.

The total potential, ϕ, observed can be written as $\phi = \phi_f + \phi_s$ where ϕ_f and ϕ_s are the potential across the metal oxide film and metal-oxide solution interface, respectively. Since step a is the film reaction and is assumed to be in equilibrium, Eq. [14] can be applied to the metal-oxide interface (18)

$$\phi_f = \phi_f^0 + \frac{RT}{2F} \ln [Ti(II)] \quad [14]$$

With Temkin adsorption behavior of the adsorbed

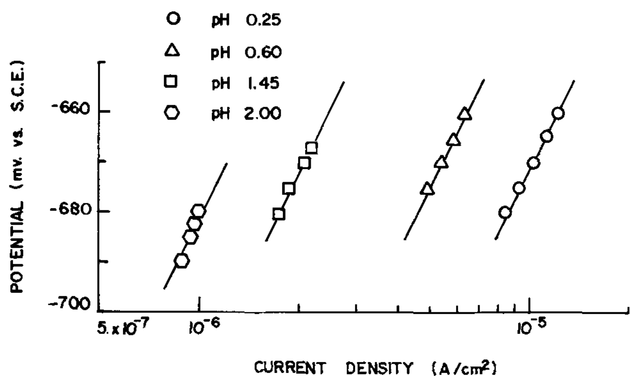

Fig. 12. Anodic dissolution of titanium vs. potential

$\{Ti(III)H\}_{ads}$ species, the rate expression for step b and c can be written as

$$r_2 = k_2[H^+]\, e^{-\beta f\theta} - k_{-2}\, e^{(1-\beta)f\theta} \quad [15]$$

$$r_3 = k_3\, e^{(1-\gamma)f\theta}\, e^{\frac{\alpha F\phi_s}{RT}} \quad [16]$$

where β, γ, and α are symmetry factors and $f\theta$ is the function which accounts for the change of free energy of activation with coverage of $\{Ti(III)H\}_{ads}$. When step b is in equilibrium, the value of $f\theta = \ln k_2 - \ln k_{-2} + \ln[H^+]$. By substituting the value of $f\theta$ in Eq. [16]

$$r_3 = k_3 \left(\frac{k_2}{k_{-2}}\right)^{(1-\gamma)} [H^+]^{(1-\gamma)}\, e^{\frac{\alpha F\phi_s}{RT}} \quad [17]$$

Since $\phi = \phi_s + \phi_f$ and ϕ_f is given by Eq. [14], Eq. [17] can be transformed to Eq. [18]

$$i_a = k[Ti(II)]^{-\alpha/2}\, [H^+]^{(1-\gamma)}\, e^{\frac{\alpha F\phi}{RT}} \quad [18]$$

where k is a rate constant. For constant concentration of Ti(II) in the film, the equation for the anodic current can be written

$$i_a = k[H^+]^{(1-\gamma)}\, e^{\frac{\alpha F\phi}{RT}} \quad [19]$$

With the usual value of the symmetry factor of 0.5, the anodic dissolution rate for titanium can be expressed as

$$i_a = k[H^+]^{0.5}\, e^{\frac{F\phi}{2RT}} \quad [20]$$

which is comparable to the experimental rate expression (Eq. [11]).

By comparing Eq. [19] and [11], the symmetry factors obtained in this investigation for the adsorption of $\{Ti(III)H\}_{ads}$ and the charge transfer reaction at the oxide-solution interface are 0.47 and 0.43, respectively.

Anodic dissolution in the presence of Ti(III).—In the study of anodic dissolution of titanium in the presence of Ti(III), the reaction order for anodic dissolution with respect to Ti(III) was found to be 0.5. To account for the effect of Ti(III) on the anodic dissolution of titanium, the following mechanism for titanium dissolution in the presence of Ti(III) is proposed

$$Ti + Ti(III) \leftrightarrows 2Ti(II) + e \quad [21a]$$

$$Ti(II) + H^+ \leftrightarrows \{Ti(III)H\}_{ads} \quad [21b]$$

$$\{Ti(III)H\}_{ads} \rightarrow Ti(III) + H^+ + e \quad [21c]$$

In the above sequence, it is assumed that step a occurs at the metal-oxide interface and steps b and c occur at the oxide-solution interface. The reaction rate of step a depends upon the potential at the metal-oxide interface, ϕ_f, and the reaction rate of step c depends upon the potential at the oxide-solution interface, ϕ_s. It will be shown below that a rate expression can be derived giving fractional orders with respect to Ti(III) and hydrogen ions for the anodic dissolution of titanium by assuming step c is rate controlling, Temkin behavior of the adsorbed $\{Ti(III)H\}_{ads}$, and step a and b are in quasi-equilibrium.

The total potential, ϕ, is

$$\phi = \phi_f + \phi_s \quad [22]$$

Since step a, the film reaction, is assumed to be in quasi-equilibrium

$$\phi_f = \phi_f^0 + \frac{RT}{F} \ln \frac{[Ti(II)]^2}{[Ti(III)]} \quad [23]$$

By utilizing the Temkin adsorption isotherm for the adsorbed species, the rate expressions for step b and c, respectively, are

$$r_2 = k'_2[H^+]e^{-\beta' f\theta} - k'_{-2}e^{(1-\beta')f\theta} \quad [24]$$

$$r_3 = k'_3 e^{(1-\gamma')f\theta} e^{\frac{\alpha' F \phi_s}{RT}} \quad [25]$$

Since step b is in quasi-equilibrium, $f\theta = \ln k'_2 - \ln k'_{-2} + \ln [H^+]$. By substituting this value of $f\theta$ in Eq. [25]

$$r_3 = k'_3 \left(\frac{k'_2}{k'_{-2}} \right)^{(1-\gamma')} [H^+]^{(1-\gamma')} e^{\frac{\alpha' F \phi_s}{RT}} \quad [26]$$

Equations [26], [22], and [23] give the anodic dissolution current

$$i_a = k' \frac{[Ti(III)]^{\alpha'}}{[Ti(II)]^{2\alpha'}} [H^+]^{(1-\gamma')} e^{\frac{\alpha' F \phi}{RT}} \quad [27]$$

For constant concentration of Ti(II) in the film, Eq. [27] becomes

$$i_a = k'[Ti(III)]^{\alpha'} [H^+]^{(1-\gamma')} e^{\frac{\alpha' F \phi}{RT}} \quad [28]$$

For $\alpha' = \gamma' = 0.5$, the anodic dissolution rate for titanium can be expressed as

$$i_a = k'[Ti(III)]^{0.5} [H^+]^{0.5} e^{\frac{F\phi}{2RT}} \quad [29]$$

Equation [29] predicts a Tafel slope of 120 mV for anodic dissolution of titanium in sulfuric acid and reaction orders of 0.5 with respect to both hydrogen ions and Ti(III). Experiments have shown that for the anodic dissolution of titanium, the reaction order with respect to Ti(III) is 0.5 which agrees with the predicted value. It was shown above that the anodic dissolution of titanium in the absence of Ti(III) was 0.5 order with respect to hydrogen ions. Thus, the proposed mechanism seems to provide a consistent interpretation for the observed acceleration of titanium dissolution by Ti(III).

Conclusions

The electrochemical behavior of titanium in 1N H_2SO_4 indicates that Ti(IV) is readily reduced electrochemically, but Ti(III) is not reduced, at least in the potential range investigated. Above a concentration of 5 mM Ti(IV), titanium self-passivates. At lower concentrations, Ti(IV) is shown to inhibit active anodic dissolution. In contrast, both Ti(III) and hydrogen ions are shown to accelerate anodic dissolution. The apparent electrochemical reaction orders for anodic dissolution are one-half with respect to both Ti(III) and H^+. By postulating an adsorbed intermediate, $\{Ti(III)H\}_{ads}$, and Temkin adsorption behavior, mechanisms for the anodic dissolution of titanium in 1N H_2SO_4 in the presence and absence of Ti(III) consistent with the electrochemical data have been devised.

Electrodissolution Kinetics of Iron in Chloride Solutions

III. Acidic Solutions

Robert J. Chin* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The dissolution kinetics of iron in acidic chloride media has been investigated by potentiostatic polarization. An anodic Tafel slope of approximately 70 mV/decade was obtained. An increase in the chloride ion concentration, at a constant pH, increased the dissolution rate of iron. The following empirical rate expressions for iron dissolution and hydrogen evolution have been determined from the experimental data

$$i_a = k_a [Cl^-]^{0.5} [OH^-]^{0.6} \exp (0.85 \, \mathbf{F}\phi/RT)$$

$$i_c = k_c [H^+] \exp - (\mathbf{F}\phi/2RT)$$

The rate expression for iron dissolution can be developed theoretically by a mechanism which includes the direct participation of chloride ions in the dissolution of iron.

Mechanistic studies on metallic dissolution in aqueous media have been mainly focused on the effect of pH at constant anion concentration. However, there has been some work considering the direct participation of anions in metallic dissolution. The effect of anions on the kinetics of metallic dissolution has been reviewed by Kolotyrkin (1). Foley (2) has reviewed the specific case of the effect of chloride ions on the dissolution of iron.

Lorenz (3) studied the dissolution of iron in $0.5N$ H_2SO_4 in the absence and presence of KCl. He found that below $0.1N$, chloride ions did not affect the anodic polarization behavior of iron. An anodic Tafel slope of 30 mV was obtained. For concentrations greater than $0.1N$, increasing the chloride ion concentration decreased the rate of iron dissolution and changed the anodic Tafel slope to 60 mV. At zero or low chloride ion concentrations, Lorenz (3) interpreted his results for iron dissolution in terms of the Heusler mechanism (4). At high chloride ion concentrations the direct participation of the chloride ions in the dissolution process was surmised and Lorenz proposed the following mechanism to explain the experimental data

$$Fe + Cl^- \rightleftharpoons FeCl^-_{ads} \quad [1]$$

$$FeCl^-_{ads} + Fe \rightleftharpoons FeCl^-_{ads}Fe \quad [2]$$

$$FeCl^-_{ads}Fe + OH^- \rightarrow FeOH^+ + Fe + Cl^- + 2e^- \quad [3]$$

$$FeOH^+ + H^+ \rightarrow Fe^{++} + H_2O \quad [4]$$

By assuming step [3] as rate determining with the surface coverage of $FeCl^-_{ads}$ approaching unity, the above mechanism predicts a Tafel slope of 60 mV and a reaction order with respect to chloride ion concentration of -1.

Heusler and Cartledge (5) studied the adsorption of iodide ions on iron and its effect on the dissolution rate of iron in $1N$ H_2SO_4. At a given potential, increasing the iodide concentration increased the adsorption of iodide and decreased the dissolution rate of iron. It was concluded that the iodide ion participated in the dissolution of iron by providing a second dissolution path for iron and occurred in parallel with the Heusler mechanism.

Kolotyrkin and co-workers (6, 7) investigated the dissolution of iron in H_2SO_4-Na_2SO_4 and HCl-NaCl solutions. In both types of solutions an increase in the anion concentration increased the dissolution rate of iron. This increase in the rate of dissolution could not be attributed solely to a change in the solution pH. It was concluded that both the sulfate and chloride ions participate in the dissolution of iron, and both have an accelerating effect. By addition of KCl to $0.1N$ H_2SO_4, the dissolution rate of iron was found to decrease with increasing KCl concentration up to $0.1N$, similar to the observations of Lorenz (3) and Heusler and Cartledge (5). However, further increase in KCl concentration increased the dissolution rate. Kolotyrkin's interpretation of these results were based on the competitive adsorption of chloride and sulfate ions on the iron surface. The retarding effect observed when chloride ions were added to H_2SO_4 was attributed to the displacement of sulfate ions by chloride ions on the iron surface.

In a subsequent study by Lorenz and co-workers (8), it was concluded that the $SO_4^=$ ions did not participate directly in the dissolution of iron. Experiments were performed in the absence of chloride ions, but the ionic strength of the electrolyte varied with the sulfate ion concentration.

The competitive adsorption of sulfate and chloride ions on iron was studied by Hackerman and Stephens (9) using radiotracer techniques. Their results indicated that small quantities of chloride ions in a sulfate solution increased sulfate ion adsorption. On the other hand, large chloride ion concentrations decreased sulfate ion adsorption. The inverse effect was shown with chromium by Maksimchuk and Rosenfeld (10). Additions of sulfate to chloride solutions lowered the amount of adsorbed chloride ion.

As shown above, it is evident that the effect of chloride ions on the dissolution of iron is complicated by the presence of sulfate ions. Although the sulfate ion may not participate directly in the dissolution mechanism, as suggested by Lorenz *et al.* (8), its effect on the adsorption of chloride ions must be considered. Thus, it is difficult to interpret the data obtained for a $SO_4^=/Cl^-$ system because of the indirect participation of $SO_4^=$ ions.

In this study the effect of chloride ions, at constant pH, on the kinetics of iron dissolution is investigated using steady-state polarization techniques. The pH effect is also examined by using an inert supporting electrolyte to maintain a high and constant ionic strength. The perchlorate ion was chosen because it is not believed to adsorb strongly on iron (11) nor has it very strong tendencies to serve as ligands in complex formations (12).

Experimental

Cylindrical electrodes (1.24 cm in diameter and 0.95 cm in length) were made from Ferrovac E iron rods.

* Electrochemical Society Active Member.

Key words: corrosion, mechanism, polarization.

The test electrodes were used in the form of rotating disks with exposed cross-sectional surface areas of 1.2 cm^2. The exposed surface was polished with increasingly finer grades of aluminum oxide paper, followed by degreasing with boiling benzene in a Soxhlet column for 3 hr. After degreasing, the electrodes were annealed at 700°C for 1 hr in a vacuum. The electrodes were mounted in a Teflon assembly which allowed only the prepared cross-sectional surface to be exposed to the electrolyte.

A three-electrode cell of Teflon and Pyrex glass was used in the experiment. The Teflon top has entry ports for the test electrode, a Luggin probe, a thermometer, and a bubbler for the saturating gas. The Luggin probe connected the reference electrode (saturated calomel electrode) compartment to the test cell, while the auxiliary electrode (platinized platinum) compartment was separated from the test cell by a fritted glass disk. More details of the experimental apparatus can be found elsewhere (13).

Solutions were prepared from reagent grade chemicals and doubly distilled water. Two type of solutions were employed: (*i*) 0.1*N* $HClO_4$ + x *N* NaCl + y *N* $NaClO_4$($x + y = 1.9$); (*ii*) m *N* NaCl + n *N* HCl ($m + n = 1.0$). In the first set of solutions the chloride ion concentration was varied while maintaining both the total ionic strength and the *p*H constant. In the second set of solutions the *p*H was varied while both the total ionic strength and the chloride ion concentration were held constant. The *p*H of the test solutions were measured with a Beckman *p*H meter.

Before immersion of the test electrode, the test electrolyte was deoxygenated for several hours with prepurified nitrogen. Potentiostatic polarization was performed using a Wenking potentiostat. The electrode potential was measured with a Keithley 621 R electrometer and the current was measured with a Simpson 269 ammeter.

Results

Anodic polarization curves for iron in deoxygenated type 1 solutions are shown in Fig. 1. The Cl^- concentration was varied between 0.01 and 1.9*N*. Increasing the Cl^- concentration shifted the polarization curves in the more active direction. This means that the rate of the anodic reaction is increased by the Cl^-. For all the Cl^- concentrations a Tafel slope of approximately 70 mV was obtained in the vicinity of the corrosion potential. Deviation from this Tafel region is observed for low Cl^- concentrations at more noble potentials. The deviation takes the form of a sharp increase in current density with potential, starting at approximately −350 mV *vs.* SCE.

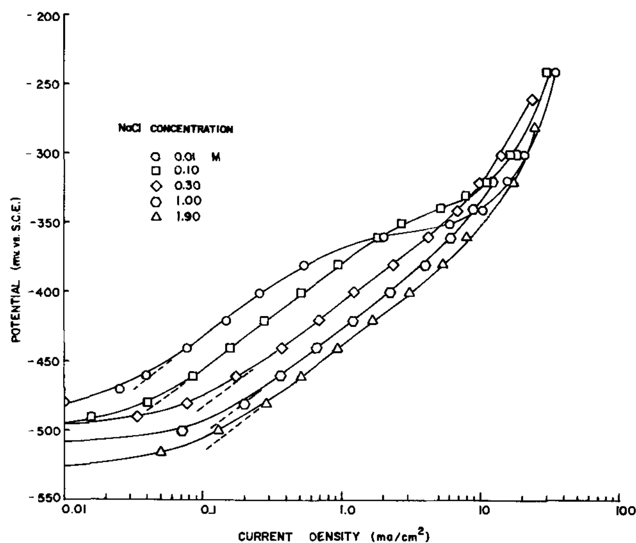

Fig. 1. Anodic polarization of iron in deoxygenated 0.1*N* $HClO_4$. Effect of Cl^- concentration.

An increase in the *p*H shifted the anodic polarization curves of iron towards the more active direction as shown in Fig. 2. Again a Tafel slope of approximately 70 mV was obtained. Atomic Absorption (A.A.) analysis of the electrolyte during polarization for dissolved iron was converted to current density-potential data by using Faraday's law. A comparison of the polarization data and the A.A. data for iron in 1*N* HCl is also shown in Fig. 2. Good agreement is observed between the two methods showing that the polarization curve corresponds to iron dissolution.

Cathodic polarization of iron is shown in Fig. 2 at different *p*H values. Increasing the *p*H decreased the rate of hydrogen evolution at a given potential. A cathodic Tafel slope of approximately 115 mV was obtained.

The corrosion potential was a function of both the *p*H and the Cl^- concentration as shown in Fig. 3. Increasing the *p*H and Cl^- concentrations shifted the corrosion potential in the active direction. The corrosion current density was determined by the intersection of the corrosion potential and the extrapolation of the anodic Tafel lines. The effect of *p*H and Cl^- concentration on the corrosion current density is shown in Fig. 4. The corrosion current increased with increase in the chloride ion concentration and hydrogen ion concentration.

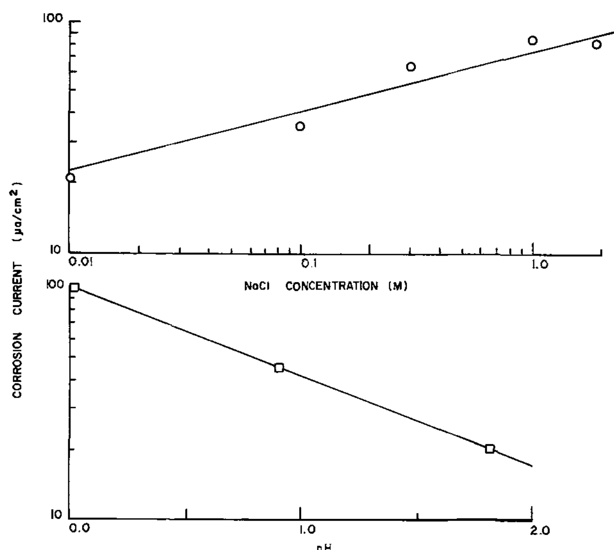

Fig. 4. Effect of Cl^- concentration and *p*H on the corrosion current density of iron.

Discussion

The electrode potential measured *vs.* the saturated calomel electrode can be divided into four components: the potential drop across the double layer; the zeta potential; the *IR* potential drop; a liquid junction potential between the solution and the reference. For electrode kinetic studies, the latter three must be subtracted from the measured potential. The zeta potential is not appreciable for high ionic strength electrolytes and the *IR* drop is negligible for highly conductive solutions. By use of Henderson's equation (14), the liquid junction potential was estimated and found to be only significant for the 1*N* HCl system. In the latter electrolyte, it was determined as 15 mV.

The reaction order with respect to the hydroxyl ion concentration for iron dissolution can be determined from the corrected polarization curves by a plot of log current *vs.* *p*H, at a constant potential, in the Tafel region. This plot is shown in Fig. 5 and shows that

$$\left(\frac{\partial \log i_a}{\partial pH}\right)_{[Cl^-],\ \phi_a} = 0.6 \qquad [5]$$

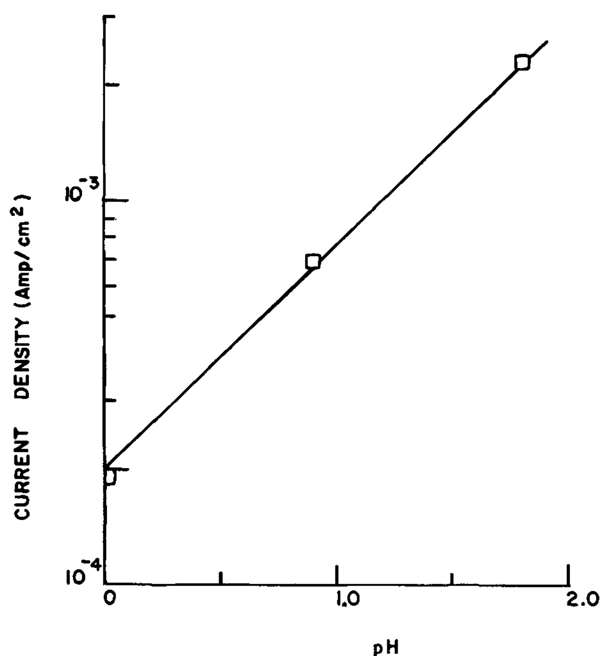

Fig. 5. Reaction order plot with respect to *p*H for iron dissolution. $\phi_a = -450$ mV.

Without correction of the polarization curves, the data would yield a reaction order with respect to the hydroxyl ion concentration of 0.8, which is close to the values reported by other workers for the same system (15, 16).

The reaction order with respect to chloride ion concentrations for iron dissolution can be obtained in a similar manner. The log current *vs.* log chloride ion concentration plot is shown in Fig. 6 and shows that

$$\left(\frac{\partial \log i_a}{\partial \log [Cl^-]}\right)_{pH,\ \phi_a} = 0.5 \qquad [6]$$

Similarly, the reaction order with respect to the hydrogen ions for hydrogen evolution is determined from a plot of log i_c *vs.* *p*H at constant potential in the cathodic Tafel region. Figure 7 shows that

$$\left(\frac{\partial \log i_c}{\partial pH}\right)_{\phi_c} = -1.0 \qquad [7]$$

The experimental results can be summarized by the following expressions

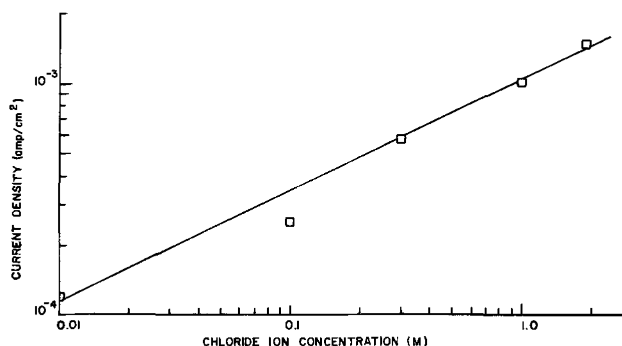

Fig. 6. Reaction order plot with respect to chloride ions for iron dissolution. $\phi_a = -425$ mV.

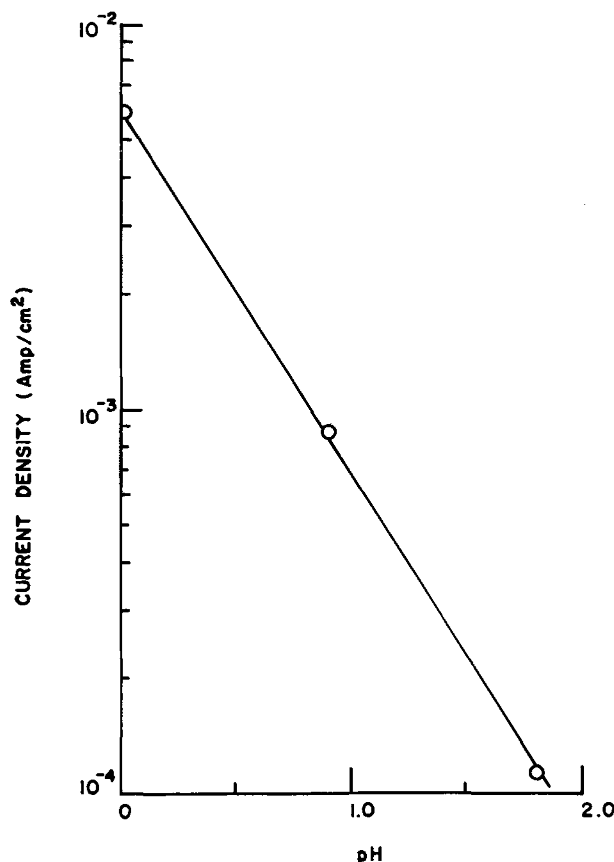

Fig 7. Reaction order plot with respect to *p*H for the hydrogen evolution reaction. $\phi_c = -700$ mV.

$$i_a = k_a\,[OH^-]^{0.6}\,[Cl^-]^{0.5} \exp\,[0.85\,\mathbf{F}\phi/RT] \quad [8]$$

$$i_c = k_c\,[H^+] \exp - [\mathbf{F}\phi/2RT] \quad [9]$$

$$\left(\frac{\partial \phi_{corr}}{\partial pH}\right)_{[Cl^-]} = -70 \text{ mV/pH} \quad [10]$$

$$\left(\frac{\partial \phi_{corr}}{\partial \log [Cl^-]}\right)_{pH} = -20 \text{ mV/decade} \quad [11]$$

$$\left(\frac{\partial \log i_{corr}}{\partial pH}\right)_{[Cl^-]} = -0.4 \quad [12]$$

$$\left(\frac{\partial \log i_{corr}}{\partial \log [Cl^-]}\right)_{pH} = 0.3 \quad [13]$$

The rate expression for the hydrogen evolution reaction (Eq. [9]) is in accord with the work of Bockris (17) and Kelly (18) and is consistent with a mechanism in which the discharge step is rate controlling.

The anodic Tafel slope of 70 mV/decade obtained in this study is comparable to the values reported by Foroulis (19), Stern and Roth (20), and Smialowska and Dus (21) for iron in acidic chloride solutions. On the other hand, Hurlen (22) reported 30 mV/decade for iron in 1*N* HCl, Podesta and Arvia (23) obtained values ranging from 37 to 61 mV/decade for iron in 2*N* NaCl (pH 1.78-2.73) and Felloni (15) reported values ranging from 44 to 70 mV/decade for iron in 1*N* (HCl + NaCl). Foroulis (19) has attributed the difference in anodic Tafel slopes obtained by various workers to the differences in chloride ion concentrations and the experimental techniques used.

The corrosion potential behavior of iron in deoxygenated HCl-NaCl systems in this study are fairly consistent with data in the literature. For deoxygenated 1*N* HCl, Foroulis (19) reported −460 mV, Felloni (15) −466, and Cammarota *et al.* (24) −494 mV. In this study, a corrosion potential of −475 mV was observed for iron in 1*N* HCl.

Felloni (15) reported a −51 mV change in corrosion potential with each unit change in pH. Kelly (18) found −60 mV/pH for iron in H_2SO_4 and Podesta and Arvia (23) found −62 mV/pH in both perchlorate and chloride solutions. The change in corrosion potential with pH observed in this study was −70 mV/pH.

A corrosion current density of 100 $\mu A/cm^2$ was obtained for iron in 1*N* HCl and is lower than the 400 $\mu A/cm^2$ reported by Hurlen (22) but higher than the 45 $\mu A/cm^2$ obtained by Felloni (15). For iron in 4% NaCl (pH 1.5) Stern and Roth (20) reported a corrosion current of 260 $\mu A/cm^2$. Podesta and Arvia (23) found that the corrosion current density was pH dependent in acidic halide media within the pH range of 0-5. They observed that

$$\left(\frac{\partial \log i_{corr}}{\partial pH}\right) = -0.5 \pm 0.1 \quad [14]$$

Bockris and co-workers (17) report approximately the same value for iron corrosion in sulfate media. The value observed by Felloni (15) for iron in acidic chloride media was −0.06. In this study $\left(\frac{\partial \log i_{corr}}{\partial pH}\right) = -0.4$.

The following mechanism is proposed for iron dissolution in deoxygenated chloride media

$$Fe + Cl^- + H_2O \rightleftharpoons [FeClOH]^-_{ads} + H^+ + e^- \quad [15]$$

$$[FeClOH]^-_{ads} \xrightarrow{RDS} FeClOH + e^- \quad [16]$$

$$FeClOH + H^+ \rightarrow Fe^{++} + Cl^- + H_2O \quad [17]$$

where the over-all reaction is

$$Fe \rightarrow Fe^{++} + 2e^- \quad [18]$$

The kinetic parameters predicted by this mechanism are dependent on the adsorption behavior of the intermediate, $[FeClOH]^-_{ads}$. If the adsorbed intermediate follows Temkin adsorption behavior, the rate equations for the reaction in Eq. [15] can be written as (25)

$$r_1 = k_1\,(1-\theta)\,[Cl^-] \exp\,(\beta\mathbf{F}\phi/RT) \exp\,(-\gamma f\theta) \quad [19a]$$

$$r_{-1} = k_{-1}\,\theta\,[H^+] \exp\,[-(1-\beta)\mathbf{F}\phi/RT] \exp\,[(1-\gamma)f\theta] \quad [19b]$$

where r_1 and r_{-1} are the rates of the forward and backward reactions, respectively; θ is the surface coverage of the adsorbed intermediate; $[H^+][Cl^-]$ are the bulk concentrations of hydrogen and chloride ions; γ,β are the symmetry factors; f is the Temkin parameter; and k_1 and k_{-1} are the rate constants for the forward and backward reaction, respectively.

For Temkin adsorption, $0.2 < \theta < 0.8$. Therefore, in comparison with the exponential terms in θ (Eq. [19a] and [19b]), the variations in the $(1-\theta)$ and θ pre-exponential terms are negligible and can be combined with the constants k_1 and k_{-1}, respectively (26). Equations [19a] and [19b] become

$$r_1 = k'_1\,[Cl^-] \exp\,(\beta\mathbf{F}\phi/RT) \exp\,(-\gamma f\theta) \quad [20a]$$

and

$$r_{-1} = k'_{-1}\,[H^+] \exp\,[-(1-\beta)\mathbf{F}\phi/RT] \exp\,[(1-\gamma)f\theta] \quad [20b]$$

Within the reaction in Eq. [15] in quasi-equilibrium

$$r_1 = r_{-1} \quad [21]$$

and

$$f\theta = \ln\left\{\frac{k'_1}{k'_{-1}}\,\frac{[Cl^-]}{[H^+]} \exp\,(\mathbf{F}\phi/RT)\right\} \quad [22]$$

The rate of the reaction in Eq. [16] can be written as

$$r_2 = k_2\,\theta \exp\,(\alpha\mathbf{F}\phi/RT) \exp\,(\epsilon f\theta) \quad [23]$$

Since the pre-exponential term in θ is negligible in comparison to the exponential term (26), the rate equation can be written as

$$r_2 = k'_2 \exp\,(\alpha\mathbf{F}\phi/RT) \exp\,(\epsilon f\theta) \quad [24]$$

where α and ϵ are symmetry factors. Substituting Eq. [22] for $f\theta$ in Eq. [24] yields

$$r_2 = k'_2 \left(\frac{[Cl^-]}{[H^+]}\right)^{\epsilon} \exp\left[(\epsilon + \alpha)\frac{\mathbf{F}\phi}{RT}\right] \quad [25]$$

By assuming values of ½ for the symmetry factors, Eq. [25] can be expressed as

$$i_2 = k''_2\,[Cl^-]^{0.5}\,[OH^-]^{0.5} \exp\,[\mathbf{F}\phi/RT] \quad [26]$$

Thus, the proposed mechanism predicts values of 60 mV, 0.5, and 0.5 for the anodic Tafel slope, the reaction order with respect to the chloride ion concentration, and the reaction order with respect to the hydroxyl ion concentration, respectively. These calculated values are in good agreement with the experimental data.

By setting $\phi = \phi_{corr}$ and $i_a = i_c = i_{corr}$ in the theoretical expressions for iron dissolution and hydrogen evolution the following expressions are obtained

$$\left(\frac{\partial \phi_{corr}}{\partial pH}\right)_{[Cl^-]} = -60 \text{ mV/pH}$$

$$\left(\frac{\partial \phi_{corr}}{\partial \log [Cl^-]}\right)_{pH} = -20 \text{ mV/decade}$$

$$\left(\frac{\partial \log i_{corr}}{\partial pH}\right)_{[Cl^-]} = -0.5$$

$$\left(\frac{\partial \log i_{corr}}{\partial \log [Cl^-]}\right)_{pH} = 0.2$$

These relationships agree reasonably well with the experimental results (Eq. [10] to [13]).

As shown in Fig. 1, the abrupt change in the polarization of iron in low concentrations of chloride ions at the higher potentials suggest a change in the dissolution mechanism. It should be noted that at these higher potentials the dissolution rates are sufficiently large that the measured potential must be corrected for the *IR* potential drop. It is surmised that two dissolution mechanisms occur simultaneously. One involves the direct participation of the chloride ions in the dissolution of iron, and the second is independent of chloride ions. At low polarization the former mechanism is dominant, but at higher polarization a dissolution mechanism such as the one proposed by Bockris (17) may be dominant.

The Morphological Changes of Low Index Planes of Copper Single-Crystal Electrodes near Equilibrium

V. Markovac*

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The behavior of low index planes of copper single-crystal electrodes, simultaneously exposed to deaerated and pre-equilibrated acidic copper sulfate solution, has been studied. The surface topographies indicated that a small net dissolution reaction occurred, due to traces of oxygen present in the experimental system, in spite of all the purification steps applied. Potential differences between electrodes were within 1 mV. A low rate dissolution reaction occurred everywhere on the exposed surfaces of all specimens, but the extent of dissolution varied over the surface of the same specimen, indicating considerable heterogeneity of the metal crystal surfaces. The surface features formed during dissolution on all electrodes, like grooves, pyramidal pits, macro ledges, hillocks, etc., are consistently bounded by the {210}, {111}, and {100} planes. The application of Batterman's stability conditions indicates that these planes are slow dissolving and stable, under present experimental conditions. The crystallographic characteristics of these planes, in relation to the process of dissolution, are discussed. Mechanisms of formation of these surface features are proposed utilizing the terrace-ledge-kink model for metal crystal dissolution, and considering the effects of crystallographic structure, surface imperfections, and adsorbed inhibiting species on the step motion over the surface, for the given rate of dissolution.

The work of Jenkins and Bertocci showed that under conditions of "true equilibrium," in acidic copper sulfate solution, no copper single crystal orientation spontaneously changed with time (1). Also, no differences in equilibrium potentials could be measured between different orientations, within their limits of experimental accuracy of less than 1 mV (2). When air was permitted to leak into the system, the existing equilibrium was destroyed and dissolution of copper occurred (3). This resulted in potential differences arising between differently oriented copper single-crystal electrodes and produced morphological changes on the electrode surfaces.

Under the experimental conditions employed in this work, true equilibrium was not attained. Very prob-

ably due to some last trace of oxygen, net dissolution currents of about 1 $\mu A/cm^2$ or less were present. Since the exchange current densities for copper single crystals in the corresponding solution are of the order of magnitude of mA/cm^2 (4), it seems reasonable to conclude that the electrodes were very near to the equilibrium state.

In this work it has been demonstrated that a low rate dissolution of copper occurred everywhere on the exposed surfaces of all three low index planes of copper single-crystal electrodes, even though the system was only slightly displaced from equilibrium, exhibiting potential differences of less than 1 mV between low index orientations. The very interesting morphological changes on the surfaces of all three electrodes, developed during dissolution, will be discussed. It has been recognized that a study of morphological changes can be very helpful in the understanding of mechanisms of metal crystal dissolution. The experimental results show that the {210}, {111}, and {100} planes limit the surface features formed during dissolution on the low index copper single-crystal electrodes. The application of the Batterman-Irving stability conditions (5, 6) indicates that these planes are slow dissolving and stable. The mechanisms of formation of these surface features can be explained using the terrace-ledge-kink model for a crystal surface of Kossel (7) and Stranski (8) in which the nearest-neighbor atomic interaction is assumed. The effects of crystallographic structure, surface imperfections, and adsorbed inhibiting species on the motion of dissolution steps are also considered.

Experimental

Materials.—The high purity MARZ grade[1] single-crystal electrodes, used in these studies, were disk shaped, diameter 20 mm and thickness 10 mm, and cut parallel to the (111), (100), and (110) planes. The crystals were first mechanically polished with emery papers through to 600, and then with 0.3 and 0.05μ alumina. Finally, the crystals were electropolished in a copper-containing phosphoric acid electrolyte [60 weight per cent (w/o) H_3PO_4]. Electropolishing was carried out at a constant voltage of 1.75V, and a high-purity copper sheet served as the cathode. After $\sim$ 60 min, the upper layer of the specimen surface, damaged by mechanical polishing, was removed and a smooth, very bright finish was obtained. In order to remove traces of phosphate film, immediately after electropolishing the crystal was rinsed with distilled water, immersed in 10% solution of phosphoric acid, washed in a stream of distilled water, rinsed successively in ethyl alcohol, and dried with a jet of pure oxygen (9, 10). The general orientation of the electropolished copper single-crystal electrodes was determined by Laue back-reflection x-ray diffraction. The misorientation was determined with a Picker Diffractometer, and the average deviation was found to be $\pm$ 0.5° from the exact low index planes. The average dislocation density, in the crystals prepared in this manner, was $\sim 5 \times 10^6$ cm^{-2}. The dislocation density of copper single crystals was determined by etching in Livingston's etchant (11).

The acidic 0.25M $CuSO_4$ solution, used in these studies, was prepared by dissolving the twice-recrystallized copper sulfate in triply distilled water, and the analytical reagent grade sulfuric acid was added in order to obtain a 0.1M solution with respect to H_2SO_4. The solution was pre-equilibrated in the storage vessel by immersion of MARZ grade spectrographically pure copper wire, and deaerated by passing ultra high purity hydrogen through it for at least 1 month (12).

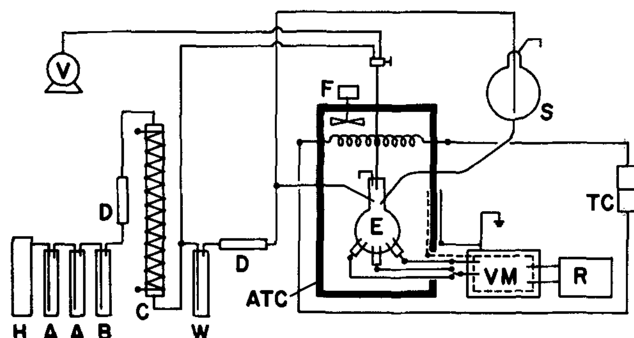

Fig. 1. Schematic diagram of apparatus: H, hydrogen tank; A, washing bottle with Fieser's solution; B, washing bottle with H_2SO_4; D, drop collector; C, column with active copper; W, washing bottle with H_2O; ATC, air thermostat and Faraday cage; F, fan; TC, thermostatic circulator; E, electrochemical cell; S, storage vessel; V, vacuum system; VM, voltmeter; R, chart recorder.

Apparatus.—The experimental apparatus, shown in Fig. 1, consisted of an electrochemical cell with storage vessel, hydrogen purification unit, and electrical equipment.

The modified[2] tripod-type electrochemical cell was similar to the one used by Jenkins and Bertocci (1). The cell was placed in an air thermostat, supplied with an outside thermostatic circulator, surrounded by a Faraday cage, and maintained at 23° $\pm$ 0.1°C. The electropolished copper single-crystal electrodes were mounted in the "legs" of the tripod cell, so that in each leg only one low index surface of disk-shaped electrode was exposed to the solution. The legs of the tripod cell were symmetrically positioned. The storage vessel of 5 liters capacity was connected with the cell via a glass tube provided with 2 three-way solution lubricated stopcocks. The system was made of Pyrex glass. All taper joints and stopcocks were precision high vacuum grade, and those which were not in contact with solution, were greased with Apiezon N vacuum stopcock grease. The system was provided with a vacuum pump for the evacuation of the cell.

The solutions in the cell and the storage vessel were kept under a stream of moist highly purified hydrogen. The UHP tank hydrogen, with an oxygen content of less than 1 ppm, was further purified by passing through two washing bottles filled with Fieser's solution (13) and a column filled with active copper spread on infusorial earth maintained at 205°C (14).

The potential differences between electrodes were measured by a high input impedance differential voltmeter, Hewlett-Packard Model 740B, and recorded by the Clevite Brush Mark 250 chart recorder. The accuracy of voltage measurements was $\pm$ 5 μV.

Procedure.—The three freshly electropolished low index copper single-crystal electrodes were mounted in the cell, and the assembly was connected to the lines of solution, hydrogen, and vacuum as shown in Fig. 1. Before the introduction of solution, the cell was repeatedly evacuated and flushed with dry hydrogen at least 20 times. The first amount of solution ($\sim$ 200 ml), which was passed through the connecting tube between the storage vessel and the cell, was discarded via the three-way stopcock on the cell. After that, the solution was admitted into the cell, and the potential differences between the electrodes were continuously measured during 500 hr, which was the duration of a typical experimental run.

After the experiment, the surfaces of all specimens were investigated microscopically. In all cases where

[1] The MARZ grade, 99.999%, copper single crystals were obtained from the Materials Research Corporation, Orangeburg, New York. Typical mass spectrographic analysis for this material shows the following main impurities: Zn = 5, Al = 2, O = 1.3, S = 1, Mo <5, K <1, Ni <1, P <1, Pd <1, Sn <1, V <1, H <0.6, Ca <0.7, Fe <0.7, Mg <0.5, Mn <0.5, Na <0.5, Ta <0.5, Rare Earths <1 ppm by weight.

[2] In order to reduce the number of possible leaks (faulty seals), the glass electrode and the side port with the sealed platinum wire (1) were omitted from this cell.

surface features were large enough, the surface morphology was studied by optical microscopy. Orientations of revealed surface facets were determined with the Unitron two-circle microgoniometer Model GM-5. Details of these surface features were studied by electron microscopy using parlodion replicas and a carbon film substrate shadowed with platinum at an angle of 45% to the plane of the surface. In some instances, where additional information about the inclination of fine facets was desired, the replicas were platinum shadowed at angles of 10°, 15°, 20°, and 30°. Occasionally, inclinations were also calculated from the variations in emulsion density of the shadowed replica micrograph plates. Densitometry was performed by a double-beam recording microdensitometer Model MK IIIC, Joyce, Loebl and Company, Limited. The ledge heights were determined by measurement of the shadowed replicas, using the shadows cast by polystyrene spheres of 0.250μ as reference. The dissolution rates were calculated on the basis of all material removed from the electrode surfaces.

Results

After the experiment, the surfaces of all specimens were slightly etched, indicating that the small net dissolution of copper occurred, and suggesting that the true equilibrium was not attained. The potential differences between low index copper single-crystal electrodes, measured in these studies, were within 1 mV. The potential of the (100) electrode was always positive or anodic in relation to those of the (110) and (111) electrodes, and this is in agreement with the observations of other authors, for nonequilibrium conditions (1). The slight dissolution of copper was attributed to traces of oxygen present in the experimental system (1), in spite of all purification steps applied and efforts made to isolate the system from the air. The dissolution of copper can be described by a general corrosion reaction (3)

$$Cu + \frac{1}{2} O_2 + 2 H^+ \rightleftarrows Cu^{++} + H_2O \quad [1]$$

The rate of dissolution depends on the diffusion of oxidizing species, through the solution to the metal surface (3, 12). Therefore, the rate of dissolution on all electrodes should be the same (15). Although dissolution of copper occurred everywhere on the exposed surfaces of all electrodes, the extent of dissolution was different on different areas of the same electrode, indicating considerable heterogeneity of the metal crystal surfaces. However, different surface features characteristic for the particular crystal planes were formed during dissolution, indicating that the process of dissolution is also crystallographically affected. Obviously, measured potential differences are indicative of dissolution processes taking place on the low index planes of copper single-crystal electrodes.

The possible sources of oxygen present in these experiments are considered to be: the bulk copper crystal, copper sulfate solution, hydrogen gas, adsorption on the walls of the cell, and leakage of air into the system. Since it was not possible to avoid this problem by improved experimental conditions, it seems that the oxygen adsorbed on the walls of the cell is the most probable cause of dissolution (system was not bakeable). However, small contributions from the other possible sources cannot be entirely excluded.

The effect of adsorbed contaminants on the formation of pits on the (111) plane.—Under the corrosion conditions at the highest rate encountered, calculated to be about 1 $\mu A/cm^2$, randomly distributed macro pits were observed on the (111) specimen surface. The shape of the pits was an inverse triangular pyramid with the edges of the base parallel to the <112> directions (Fig. 2a). The pit density was $\sim 10^2 \ cm^{-2}$, about four orders of magnitude less than the measured dislocation density for this specimen, indicating that only a fraction of the existing dislocations were revealed during dissolution under these experimental conditions (16-18). In this experiment a liquid nitrogen trap was used in order to prevent appreciable back-streaming of oil vapor from the vacuum pump to the cell, during repeated evacuation and hydrogen flushing, before the introduction of solution into the cell.

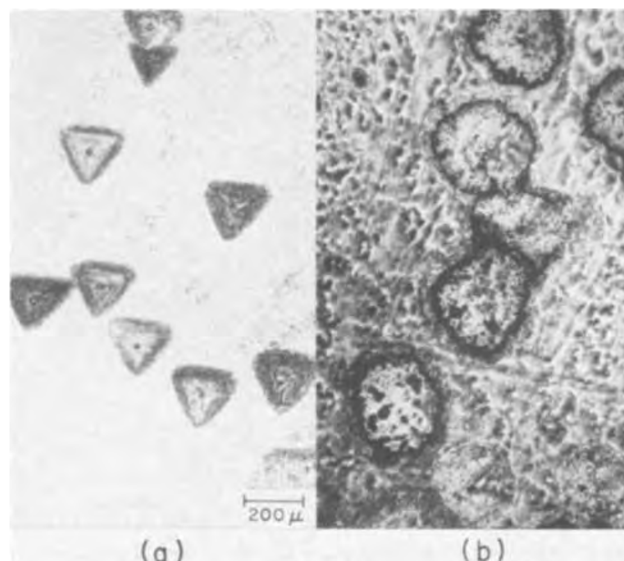

Fig. 2. Effect of surface adsorbed contaminants on pit formation on the (111) plane: (a) decreased amount of surface adsorbed contaminants; (b) increased surface contamination.

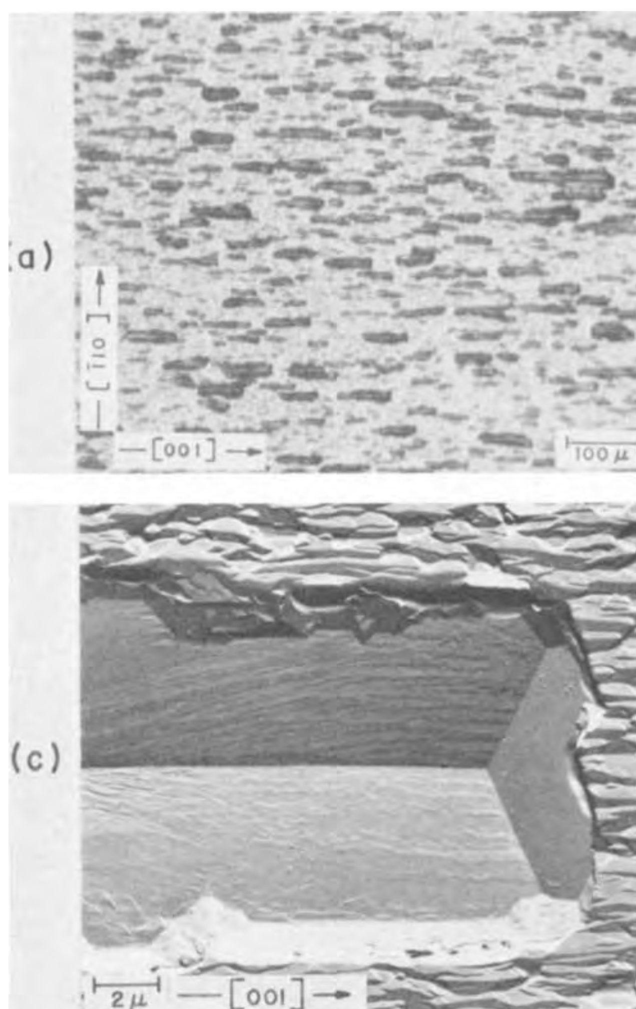
To demonstrate the effect of surface adsorbed contaminants, another experiment was performed on the freshly prepared surface of the same crystal. The same experimental conditions were employed, but without the liquid nitrogen trap, allowing the hydrocarbon molecules, from the back-streaming oil vapor, to enter the cell and adsorb on the specimen surface (19). As a vacuum source a Welch pump Model 1400 with a Duo-Seal pump oil, supplied by the Welch Scientific Company, Skokie, Illinois, was used.

After the experiment, only rounded pits were observed, as shown in Fig. 2b. The formation of triangular pits, under the conditions of decreased amount of surface adsorbed contaminants, and rounded pits with increased surface contamination, indicate that in the presence of a greater amount of contaminants the anisotropic motion of dissolution steps become isotropic (20-22). The rounding of pyramidal pits, at increased inhibitor concentration, was studied extensively by Ives *et al.* (21, 23) in the system lithium fluoride-aqueous solution of ferric chloride. After giving up the diffusion-control hypothesis, Ives postulated that increased concentration of adsorbed inhibitors stabilizes the large number of monatomic steps (23). Based on the works of Burton *et al.* (24) and Keller (23), Ives concluded that for monatomic steps the stable configuration is rounded. Hence, pyramidal pits become rounded and finally attain conical shape. To the author's knowledge, the mechanism of rounding of triangular pits on copper single crystals has not been discussed hitherto. Although Ives' explanation for lithium fluoride seems suitable, it is believed that more experimental evidence for copper single crystals would be desirable.

In these experiments a large number of hillocks were observed on the specimen surface (Fig. 2). The surface between pits and hillocks was generally smooth and covered with a large number of more or less resolvable steps (ledges). Under the conditions of decreased surface contamination, both hillocks and ledges appear to be more crystallographic than in the



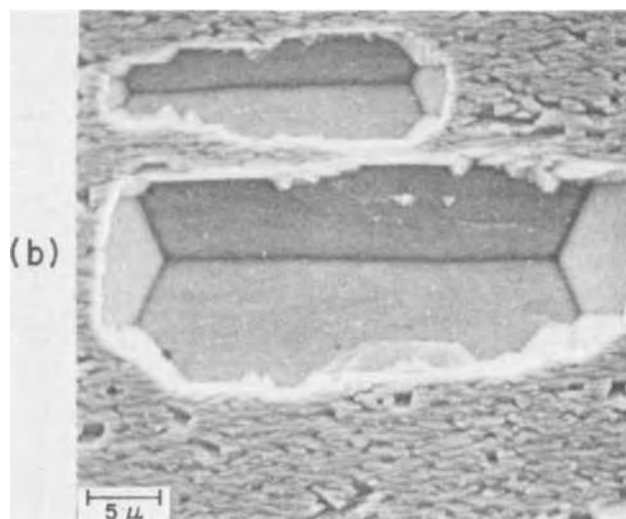


Fig. 3. (a) Photomicrograph of grooves formed during dissolution on the (110) plane; (b) scanning electron micrograph of a groove showing two side faces and two "closing" facets; (c) electron micrograph showing the details of the groove facets and the "ridge and valley" structure on the rest of the surface.

case of greater contamination (19). The characteristics of these surface features will be discussed later.

In all subsequent experiments the oil pump was replaced by other vacuum sources, not containing oil (*e.g.*, water aspirator). Nevertheless, experimental results still indicate the presence of some surface adsorbed species, although in much smaller quantities, suggesting other possible sources of inhibiting particles, like the copper sulfate solution, and the bulk crystals.

The formation of grooves on the (110) electrode.— In all subsequent experiments the three low index copper single-crystal electrodes were simultaneously exposed to the solution, at corrosion rates calculated to be ~ 0.5 $\mu A/cm^2$ or less. After the experiment, the surface of the (110) electrode was partially covered by big grooves which were all aligned parallel to the <100> direction (Fig. 3a). The grooves were bounded by two large side faces parallel to the same <100> direction (Fig. 3b). On the groove side faces arrays of fine ledges parallel approximately to the <100> direction were always observed (Fig. 3c). In contrast, the groove's closing facets were always ledge free and very smooth. Between the big grooves a large number of smaller, less well-developed grooves or a "ridge and valley" structure were observed, which were also aligned parallel to the <100> direction.

Since some of the grooves were reasonably regular, the crystallographic information on side faces and facets could be obtained utilizing simple geometric analysis (Fig. 4). The side faces of 24 measured grooves show a mean slope of 18.1°, toward the original (110) plane, and a mean deviation of −0.3° from the theoretical (210) plane, which is at an angle of 18.4°. The width of the grooves was in the range of 8-26μ. Although the side faces of experimentally obtained grooves are slightly terraced, it may be concluded that their mean slopes still indicate that they correspond to the {210} planes (26). The measured mean inclination of the smooth facets at the ends of grooves was 35.1°, with a deviation of only −0.2° from the theoretical (111) plane, which should be at 35.3°. Hence, it seems reasonable to assume that the smooth "closing" facets of grooves correspond to the low index {111} planes.

The "ridge and valley" structure between big grooves (Fig. 3c) appears to be composed of facets similar to those of the big grooves, but they do not attain sufficient size very probably due to lack of a constant dissolution source (27).

The formation of pyramidal pits on the (100) electrode.—Under the same conditions, under which the

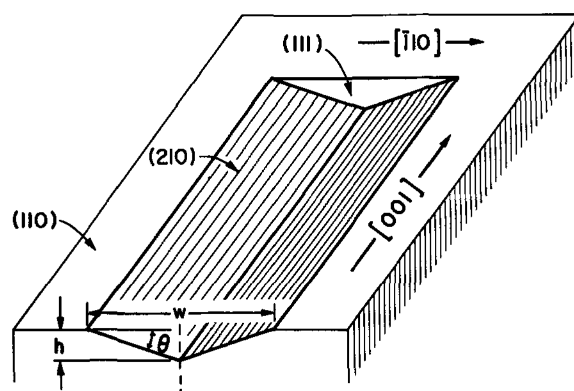

Fig. 4. Schematic presentation of profile and perspective view of a groove developed on the (110) plane.

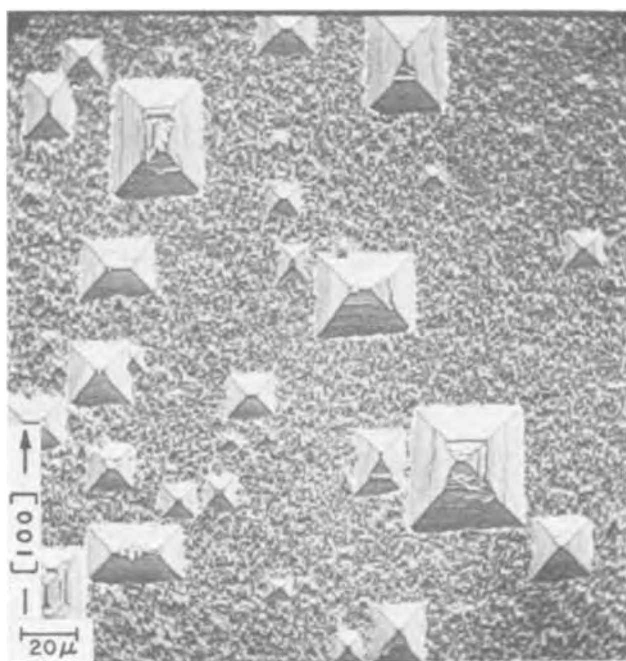

Fig. 5. Scanning electron micrograph of pits developed on the (100) plane.

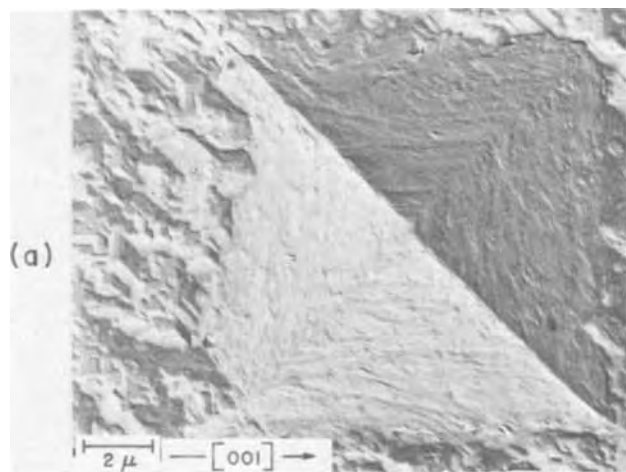
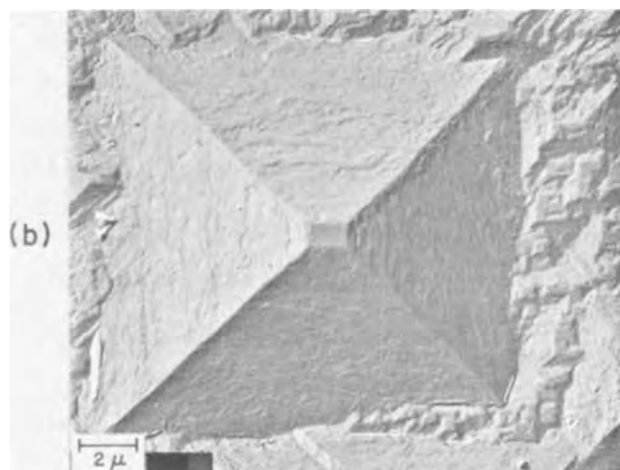
big grooves were formed on the (110) electrode, on the surface of the (100) electrode randomly distributed, crystallographically well-defined etch pits were observed. The pits have the shape of an inverse rectangular pyramid with the base edges always parallel to one of the <100> directions (Fig. 5). The density of pyramidal pits was $\sim 10^3$ cm^{-2}, *i.e.*, about 3-4 orders of magnitude less than the average dislocation density for these crystals. Besides regular square pyramids, pits with the shape of truncated and extended pyramids were also observed. Details of these pyramidal pits are shown in Fig. 6. On the side faces of these pyramidal pits, arrays of fine ledges parallel approximately to the <100> direction were always observed. Truncated pyramidal pits observed in these studies are sometimes very shallow, with large flat bottoms; but sometimes they are almost complete pyramids, lacking only the apex. The rest of the surface, between pyramidal pits, is covered with tiny facets (Fig. 6), which look similar to those of the pyramidal pits; but they do not attain macro size, again probably due to the lack of constant dissolution source. At the bottom of these facets, a horizontal plane parallel to the original {100} surface is frequently revealed.

A schematic presentation of pyramidal pits developed on the (100) electrode during dissolution is shown in Fig. 7. The regular shape of these pits offers crystallographic information about the pit side faces. The measurement of 75 experimentally obtained pyramidal pits (regular, truncated, and extended) shows the mean inclination of their side faces to be 27.4°. The range of widths of these pits was 8-28μ. Since the theoretical (210) plane forms an angle of 26.6° with the original (100) plane, it may be concluded that the sides of pyramidal pits correspond to the {210} planes. Accordingly, they are the same planes which were noted after dissolution of the (110) electrode (Fig. 4). The ball model of a square-based pyramidal pit developed on the (100) plane is shown in Fig. 8.

The formation of macro steps and hillocks on the (111) electrode.—Although all three electrodes, the (110), (100), and (111), were simultaneously exposed





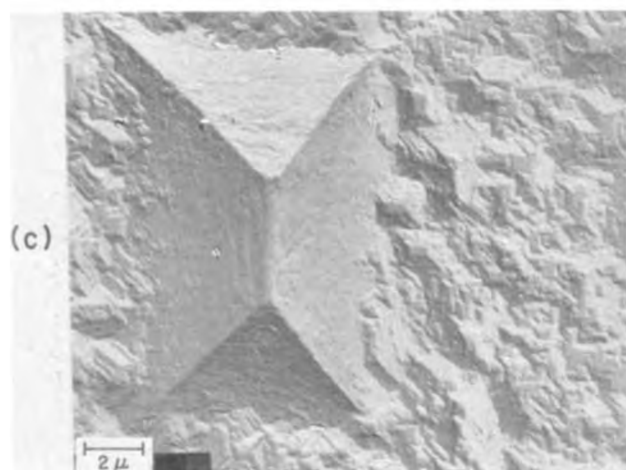


Fig. 6. Electron micrographs of pyramidal pits formed during dissolution on the (100) plane: (a) simple pyramidal pit; (b) truncated pyramidal pit; (c) extended pyramidal pit. Arrow indicates the crystallographic direction for all three micrographs.

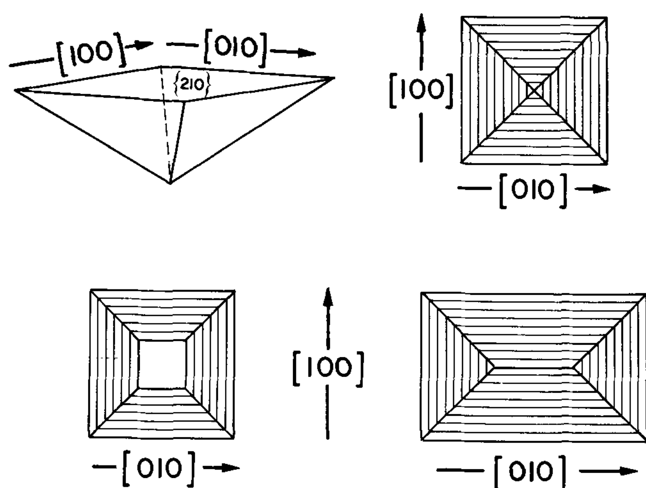

Fig. 7. Schematic presentation of pyramidal pits formed during dissolution on the (100) plane.

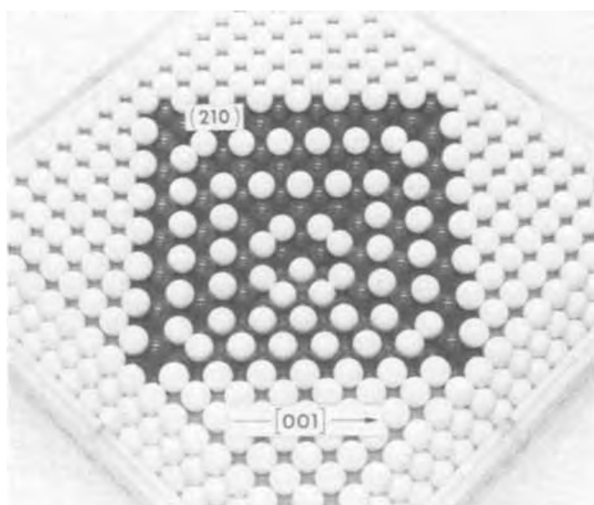

Fig. 8. Ball model of a square-based pyramidal pit developed on the (100) plane. The light balls in the {210} planes represent kink atoms.

to solution, no grooves or pits were observed on the (111) electrode; only macro steps (ledges) and hillocks were found on this surface. The dissolution steps visible on the electron micrograph, shown in Fig. 9a, have the fronts rather irregularly shaped with the height ranging from 200Å up. Frequently, the hillock concentration is larger in the vicinity of the step fronts than on the terraces. The size of hillocks is in the range from several hundred angstroms up to a few microns. A detailed picture of hillocks is shown in Fig. 9b. Very often, hillocks have the shape of hexagonal pyramids, but some of them clearly resemble their triangular origin and look like triangular pyramids with three small additional facets developed on the corners at the pyramid base (Fig. 9b). The edges at the base of pyramidal hillocks are parallel to one of the <112> directions which lie in the (111) plane. A few hillocks have the shape of extended pyramids (Fig. 9b) which consist of two half pyramids with their apexes connected by a line parallel to one of the <112> directions. Between hillocks and large macro steps (Fig. 9b and c), a smooth ledge-free surface, parallel to the original surface, and corresponding to the low index (111) plane, is revealed during dissolution.

On some parts of the specimen surface the steps were very large, up to several microns (Fig. 9b and c). These steps look quite crystallographic and clearly present threefold symmetry. The fronts of macro steps or macro ledges look like high index planes having fine ledges similar to those already observed at the sides of grooves and pyramidal pits on the (110) and (100) electrodes, respectively. The mean inclination of 10 experimentally obtained macro ledges was 39.0°, which is in good agreement with the theoretical (210) plane, which should be at 39.2°. The straight edges at the base of macro ledges were nearly parallel to the <112> directions, and the measured angles between them were in the range of 115°-125°. On the ground of these experimental results, it was possible to construct the model which may correspond to the planes revealed during dissolution. On the ball model shown in Fig. 10, the (210) and (120) planes are presented as a possible set of planes developed during dissolution. The angle between edges at the base is 120°, in agreement with the values found experimentally. The base is, of course, the low index (111) plane. The appearance of the {210} planes as limiting planes of surface features formed during dissolution of copper single-crystal electrodes is in agreement with Jenkins' observation of "extensive faceting with near {012} orientations," under similar experimental conditions (3).

Discussion

The stability of planes revealed by dissolution.—The stabilization of planes revealed during dissolution can be demonstrated utilizing the conditions for the occurrence and stability of etch hillocks and pits developed by Batterman (5) and extended by Irving (6). Detailed atomic dissolution mechanisms are not considered in this approach, and the dissolution rate is regarded as a vector property of a macroscopic surface. In general, the Batterman stability conditions show that, upon dissolution, convex surfaces are limited by fast dissolving planes, while concave surfaces are limited by slow dissolving planes.

The application of these conditions to the grooves, pyramidal pits, and macro ledges observed on the (110), (100), and (111) electrodes respectively (Fig. 3c, 6a, 9c) shows that all orientations between limiting {210} planes are faster dissolving planes. The same applies for the range of orientations between the low index {111} planes and the groove side faces (Fig. 3c and 4), and between macro ledges and revealed basic {111} planes (Fig. 9c and 10). All these planes should be the faster dissolving ones. Accordingly, the {210} and {111} planes are slowly dissolving planes.

For the application of the stability conditions on the pyramidal pits formed on the (100) electrode (Fig. 5 and 6), it has to be emphasized that the formation of pyramidal pits has been related to active sites[3] on the electrode surface. These active sites are characterized by an increase in the local dissolution rate. At the apex of a pit a high dissolution rate is predicted, and this is the direction of the enhanced dissolution rate, say, due to a dislocation. If, for any reason, pyramidal pits lose their dislocations (28) or the other causes of enhancement of dissolution rate (29), they will become truncated, revealing the {100} plane (Fig. 6b). The tendency of newly revealed bottoms of truncated pyramidal pits toward widening, and the appearance of the {100} flats on the faceted rest of the surface (Fig. 6) suggest that the actual dissolution rate of the {100} plane is probably slower than the rate for contiguous facets.

The extended pyramidal pits observed on the (100) electrode (Fig. 6c) consist of two half pyramids with their apexes connected by a line which is always parallel to the one of the <100> directions. The stable square-based pyramidal pit should have the same dissolution rate on all faces. The appearance of extended pyramidal pits suggests a slight difference in

[3] In order to form observable macro pits, the active sites should have some continuity into the bulk crystal, e.g., dislocations or rod-shaped impurity zones (26).

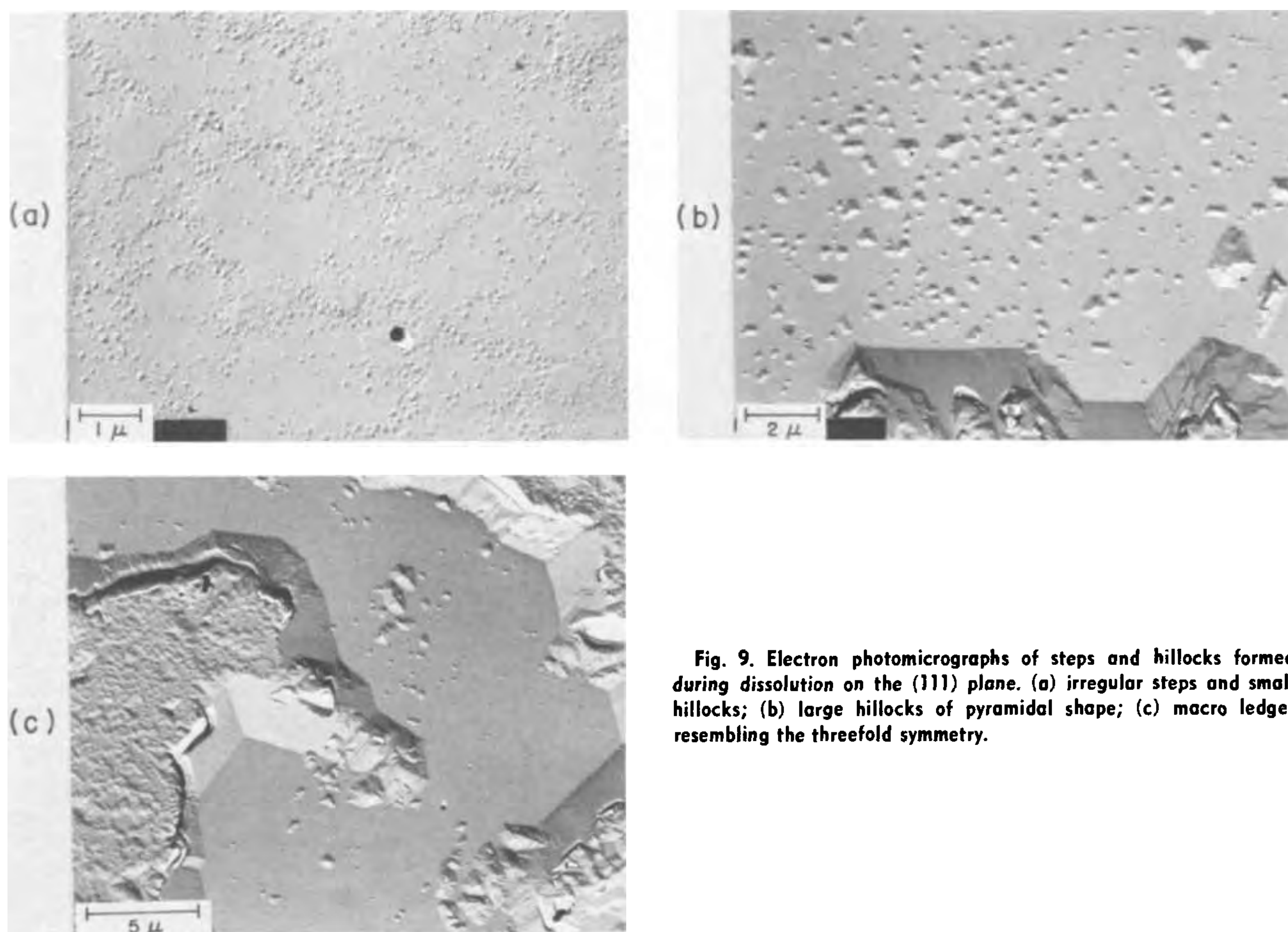

Fig. 9. Electron photomicrographs of steps and hillocks formed during dissolution on the (111) plane. (a) irregular steps and small hillocks; (b) large hillocks of pyramidal shape; (c) macro ledges resembling the threefold symmetry.

dissolution rate between two pairs of side faces on the same pit, exhibiting the extension line between the faster dissolving planes. The mechanism by which one pair of planes dissolves faster than the other, crystallographically equivalent pair of planes is not yet understood.

The application of the stability conditions to the hillocks formed on the (111) electrode indicates that all orientations between the hillock's faces and the basic (111) plane are faster dissolving ones (Fig. 9b). At the same time the orientations between neighboring hillock faces should be the slowly dissolving planes. The trend toward widening and revealing of large areas of smooth, close-packed, low index (111) planes (Fig. 9b and 9c) suggests that these planes dissolve slower than the bounding macro ledges and hillock faces. This observation looks contradictory, because the Batterman stability conditions predict that the hillock planes should dissolve slower than the surrounding crystal surface. In order to explain this phenomenon, one may assume that on the original electropolished surface of the (111) electrode there are a large number of active sites (see later), where locally enhanced dissolution takes place, very probably in a step-wise manner. This process shall continue until the real (111) flats are revealed, and the macro ledges are formed (Fig. 9b and 9c). At this stage, it seems likely that most of the dissolution reaction takes place at the macro ledges (38) which may "grow together," forming the hillocks, as a transient form in the process of dissolution. These ideas are supported by the fact that hillocks are observed only on the (111) electrode, they cover a wide range of sizes, their side faces look the same or similar to macro ledges, and their apexes are fairly sharp. The occurrence of extended hillocks indicates that a pair of slightly faster dissolving planes exist, forming a ridge between them (6).

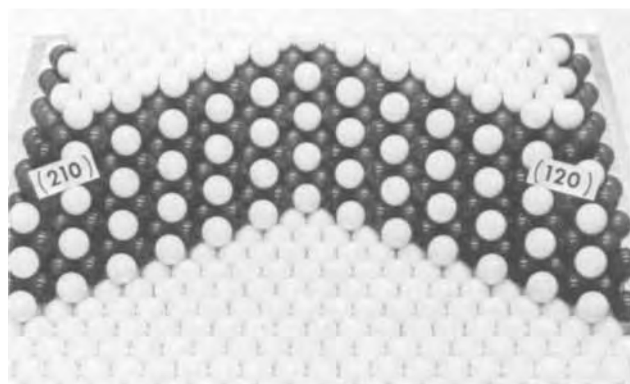

Fig. 10. Ball model of a set of two {210} planes formed on the (111) plane. The light balls in the {210} planes represent kink atoms.

The experimental results presented here show that the {210}, {111}, and {100} planes consistently limit the surface features formed during dissolution on the low index copper single-crystal electrodes. The application of Batterman's stability conditions to these surface features indicates that the {111}, {100}, and {210} planes are slowly dissolving and stable planes, under present experimental conditions.

The atomistic characteristics of planes revealed by dissolution.—In the previous paragraph, the dissolution rate of a crystal surface was regarded as a function of orientation. Here, an attempt is made to elucidate the characteristics of revealed planes, utilizing the well-known terrace-ledge-kink model for a crystal surface of Kossel (7) and Stranski (8), in which the nearest-neighbor atomic interaction is assumed.

It was experimentally established that surface features like grooves and pyramidal pits formed during dissolution on the surfaces of the (110) and (100)

electrodes, respectively, have the edges parallel to the <100> directions (Fig. 3 and 5). Due to the fact that the steps parallel to the <100> directions, in fcc crystals, are not parallel to the close-packed directions, they necessarily must be kinked. Actually, the <100> oriented steps are so heavily kinked that every second atom in the step is a kink atom, as can be seen in Fig. 8 and 11. The same applies for the macro ledges, parallel to the <112> directions, formed on the surface of the (111) electrode (Fig. 9c and 10). Here, the kink motion as a concept is not applicable (there is no length of step between kinks, along which they can move), and the only process for dissolution is the "step motion" by the successive removal of atoms at the salient corners of the kinked step (30). The {210} plane consists of a large number of kinked steps with a small step spacing, *i.e.*, it necessarily contains a high concentration of kinks, and therefore is a highly roughened orientation (31).

The appearance of the {210} planes as relatively stable planes observed on the surfaces of all three low index copper single-crystal electrodes suggests a preferential adsorption of inhibiting species,[4] from the solution, on the surfaces of this orientation (26). The preferential adsorption may be attributed to some special structural attraction between the {210} planes and adsorbed species, *e.g.*, the "hole" arrangement between kink atoms (32), which can be seen on ball models in Fig. 8, 10, 11. In addition, the occurrence and stabilization of the kinked edges parallel to the <100> direction[5] was explained by Keller (25), postulating that the velocity of a step is given by a balance between the number of atoms removed from the step and the number of atoms "trapped" into it. It was assumed that the trapping processes take place preferentially at the kinked <100>-step with its "reentrant corners" rather than at the close-packed <110>-step. In this way, the motion of the <100>-step should be slowed down more than that of the close-packed <110>-step, and the edges parallel to the <100> direction could appear.

The sides of experimentally obtained grooves, pyramidal pits, and macro ledges on the (110), (100), and (111) electrodes, respectively, were covered with arrays of fine ledges (Fig. 3c, 6, and 9c); and the measured inclinations of these faces, corresponding to the {210} planes, are considered the average values. Although the real surfaces of these features are not identical to those of the ideal ball model, it is likely that, on the average, they represent kink stepped arrangements similar to those on the ball models, seen in Fig. 8, 10, and 11. The formation of arrays of ledges or terracing has been related to the kinetics of monatomic step motion which under certain conditions, like adsorption of inhibiting species and/or impurities, may lead to step bunching and formation of visible surface ledges (26, 33-35). This experimental fact also supports the idea of adsorption of inhibiting species on the electrode surface.

[4] Inhibiting species adsorbed on the electrode surface can be impurities and/or components from the solution.

[5] K. W. Keller (25) studied the evaporation of ionic crystals of sodium chloride, where the <100> direction is the close-packed direction, and the <110> is the kinked one. In metallic fcc crystals the situation is reversed.

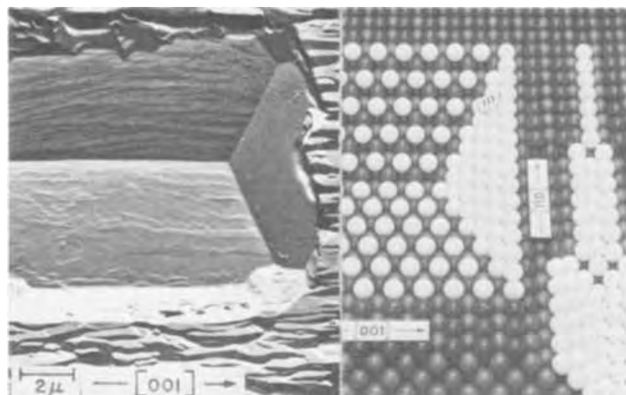

Fig. 11. Left: Electron micrograph of part of a groove formed on the (110) plane. Right: The same feature is presented on a ball model.

It is interesting to note that the (111) planes revealed during dissolution on the (110) and (111) electrodes (Fig. 3c, 4, 9), as well as the (100) planes at the bottom of truncated pyramidal pits and the faceted rest of the surface, revealed on the (100) electrode (Fig. 6), were always ledge free and smooth. This experimental fact suggests that on the really low index surfaces the bunching of steps, due to the adsorption of inhibiting species, is less effective than on the {210} planes. It is likely that the dissolution process at these low index planes proceeds via monatomic steps and/or bunched steps, but of such diminished height that they are unresolvable by electron microscopy. This is in agreement with the Cabrera and Vermilyea postulation, that the morphological changes are a result of changes in the step motion on different crystal faces, due to differences in the amount of impurities adsorbed on different faces (36).

The mechanism of the formation of surface features revealed by dissolution.—An attempt has been made to describe a possible mechanism for the formation of grooves on the surface of the (110) electrode, as shown in Fig. 11. On the left side an electron micrograph of part of a groove is shown, and on the right side the same feature is represented by a ball model with the (110) plane as the base plane. Let us assume that dissolution starts at some active sites, and on the basis of the pair-wise interaction model it is expected that it will continue along the rows of close-packed atoms, parallel to the <110> direction, as shown on the right side of Fig. 11. It is likely that dissolution will continue in this direction until the propagation is slowed down and eventually blocked by the accumulated contaminants or other inhibiting species at the front of dissolution steps (20, 36). This depends, of course, on the rate of dissolution for the given degree of surface contamination. In order to sustain a given dissolution rate, the process should continue in the areas of lowest adsorption density; and that is, according to Frank (33) the area where the previous step passed, "sweeping" the adsorbed impurities. Accordingly, dissolution may proceed deeper into the substrate and laterally (parallel to the {111} plane, and also parallel to the <100> direction) forming the grooves and revealing the {111} planes at their ends.

The step-wise model of metal crystal dissolution takes into consideration two aspects of formation of visible surface features (*e.g.*, pits, etc.), outlined by Gilman *et al.* (28), Cabrera (37), and Ives *et al.* (26): first, nucleation of monatomic steps at a source; and second, the step motion away from this source. Sources of dissolution steps are mainly surface defects (*e.g.*, dislocations) and misorientations of the actual surfaces from the low index planes. Measured dislocation densities for copper single-crystal electrodes, used in these studies, were of the order of magnitude of $\sim 10^6$ cm^{-2}. In addition, it can be shown that for a misorientation of 0.5° from the low index planes, about 10^5 monatomic steps per the length of 1 cm result on a copper crystal surface (38, 39). Also, it is very probable that the electropolishing used in this work introduces a moderate undulation of the surface, which results in an increased number of monatomic steps on the specimen surface. Consequently, it is very likely that the total number of steps, or potential dissolution sites, existing on all electrodes is large enough to sustain the low dissolution rates used in this work, and the nucleation of new steps does not

appear necessary (15). Accordingly, it seems reasonable to assume that the motion of dissolution steps (monatomic and bunched) away from their origin, rather than the step origins themselves, affect the formation of different surface features, during the dissolution of low index copper single-crystal electrodes.

The large smooth areas, corresponding to the (111) plane, revealed during dissolution on the (111) electrodes (Fig. 9) are indicative of a step-wise ledge mechanism of dissolution and suggest that the step motion across the (111) plane was able to remove material required by the given rate of dissolution. In contrast, the appearance of etch pits and fine facets on the (100) electrode (Fig. 6) suggests that the motion of steps over the (100) plane was more impeded and was not able to sustain the given dissolution rate; and therefore dissolution proceeded around more active sites (dislocations) forming the pits.

The idea of a very slow or impeded motion of dissolution steps across the surface of the (100) electrode is supported by the behavior of potential differences measured between different low index copper single-crystal electrodes, during dissolution. A typical set of potential differences between the (111) electrode and the other two low index electrodes as a function of time are presented in Fig. 12. In this case, the (111) electrode may be considered as a reference electrode. Although the absolute value of the equilibrium electrode potential was not obtained, the relations between these potential differences indicate the relations between corresponding overpotentials. Accordingly, the dissolution, or more precisely the motion of dissolution steps, on the (100) electrode proceeds at higher, more anodic, overpotentials than on the other electrodes,[6] indicating an impeded and very slow step motion. The same pattern of higher overpotentials and "very slow and difficult" step motion, for the (100) surface was found by others, at anodic dissolution of copper single crystals in various electrolytes: chloride solution, Bertocci (40); perchlorate solution, Jenkins (38); and sulfate solution, Jenkins and Durham (39).

In the last part of the experiment an overpotential decay to a lower value was observed for the (100) electrode (Fig. 12). It seems possible that during dissolution the electrode surface and/or the adsorption on the surface change to the extent that the effect of the original structure of the (100) electrode on the process of dissolution disappears. This explanation is in accordance with the conclusion made by Jenkins (38) that once facets are developed on the surface, little reaction takes place on the areas covered by low index facets, and the surface no longer acts in a uniform manner.

[6] It is presumed that possible differences in the active surface areas on different electrodes do not cause these differences in the measured overpotentials.

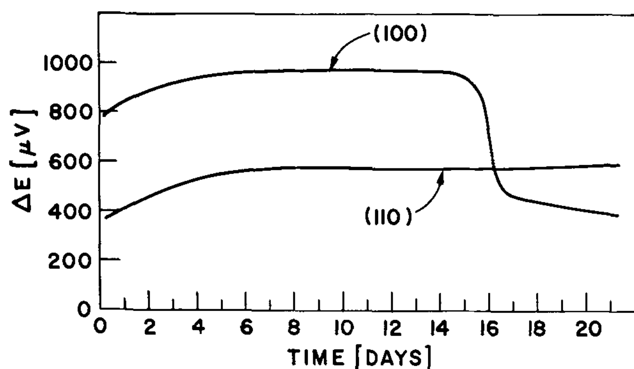

Fig. 12. Typical set of potential differences between the (111) electrode and the other two low index copper single-crystal electrodes, measured during dissolution in acidic copper sulfate solution.

The formation of pits on the (100) electrode and macro ledges on the (111) surface, when both electrodes are simultaneously exposed to dissolution, may be explained by the interaction of surface adsorbed species on the structures of the respective planes. In Fig. 13 the ball models of the monatomic dissolution steps are presented in both the (100) and the (111) planes. In both cases, the inhibiting species or contaminants of different sizes are randomly distributed. Following the very simple "nearest-neighbor" approximation, it is obvious that each species on the (100) plane is bound to 4 nearest neighbors, and on the (111) plane, to 3 nearest neighbors. Based on this, one may assume that the adsorption is stronger on the (100) plane than on the (111) surface. When a dissolution step starts at some active site and moves across the surface "sweeping" (41) and "pushing" the contaminants ahead of its front (20, 36) it is likely that it will be impeded and slowed down more on the (100) plane than on the (111). In order to sustain a given dissolution rate, the removal of material on the (100) plane continues in the areas of high activity and lowest adsorption density; and those are, according to Frank (33), the areas where the previous steps have just passed, forming the pits around active sites, forming dislocation pits. On the (111) surface the retardation of dissolution steps (monatomic and bunched) is less severe, and the step motion may remove the material required by the given rate of dissolution. Under these conditions, of course, there are no reasons for the formation of classical types of pyramidal pits on the (111) plane.

It seems likely that the dissolution step motion across crystallographically different surfaces, and the corresponding overpotentials, are affected by the adsorption of inhibiting species on these surfaces. This idea is in general agreement with the findings of Jenkins *et al.* (38, 39) that the measured overpotentials show pronounced orientation effects, but no influence of step density. According to proposed interpretations, for the given experimental conditions, it does not seem decisive for the process of dissolution how many steps are present on the surface, but rather how they are "pinned" by the adsorbed species. The observation that overpotentials for the (100) plane are higher than for other orientations, as found in various solutions (38-40), also supports this interpretation. However, the complexity of the time-dependent adsorption and its effect on dissolution processes permit, at the present time, only a qualitative treatment of these phenomena.

Conclusions

1. Under present experimental conditions the true equilibrium for copper single-crystal electrodes was not attained; instead a slight net dissolution reaction occurred, caused very probably by traces of oxygen present in the system.

2. Dissolution reaction occurred everywhere on the exposed surfaces of all specimens. The extent of dis-

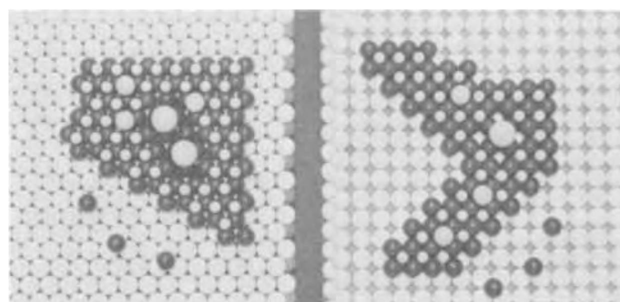

Fig. 13. Ball models of monatomic dissolution steps (dark balls) presented on the (111) plane (left), and on the (100) plane (right). Light balls on the upper layers represent adsorbed inhibiting species.

solution was different on different areas of the same specimen, indicating clearly considerable heterogeneity of the metal crystal surfaces.

3. The {210}, {111}, and {100} planes consistently limit the surface features, like grooves, pyramidal pits, macro ledges, etc., formed during dissolution on the low index planes of copper single-crystal electrodes. According to Batterman's stability conditions, these are slowly dissolving and stable planes, under present experimental conditions.

4. The mechanisms of formation of these surface features can be explained utilizing the step-wise ledge model for metal crystal dissolution, and considering the effects of crystallographic structure, surface imperfections, and adsorbed inhibiting species on the step motion across the surface, for the given rate of dissolution.

Acknowledgment

The author wishes to express his gratitude to Dr. J. V. Petrocelli, Dr. W. L. Winterbottom, and Dr. R. P. Tischer for valuable suggestions and critical review of the manuscript. He would also like to thank Dr. N. A. Gjostein and Dr. E. N. Sickafus for helpful discussions. The technical assistance of Mrs. C. Kelly in x-ray measurements, and Messrs. J. W. Sprys and G. M. Greene in electron metallography, are gratefully acknowledged.

Manuscript submitted March 23, 1972; revised manuscript received June 6, 1972. This was Paper 131 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Insoluble Polybromides of Quaternary Ammonium Salts and Their Phase-Transitions in the Presence of Aqueous Bromine-Bromide Solution

Francesco Rallo and Paolo Silvestroni

Istituto di Chimica della Facoltà di Ingegneria, Rome, Italy

ABSTRACT

By progressive addition of bromine to aqueous 1.0F NaBr solutions containing quaternary ammonium bromides, the precipitation and phase transitions of tetramethylammonium-, tetrabuthylammonium-, and phenyltrimethylammonium polybromides have been potentiometrically detected at constant temperature. The results show existence of solid $TMABr_{3,9}$, $TBABr_{3,7,8,9,11}$, and $PhTMABr_{3,5,7}$. Addition of bromine to a saturated $TMAClO_4$ solution leads to the precipitation of only $TMABr_9$.

Polyhalide salts of inorganic and organic cations have been well known for a long time, and have recently been reviewed by Popov (1, 2); the most common examples of polyhalide anions are univalent groups formed by an odd number of the same or mixed halogen atoms. Among the organic polyhalides, quaternary ammonium salts are the most representative class: many of these are quite stable, probably because the large size of such cations adapts well to the dimensions of polyhalide anions. This geometrical stability seems to be of importance also in inorganic polyhalides (2).

Since the publication of the first extensive synthesis report (3), most of the experimental work on quaternary ammonium polyhalides has been done with polyiodides or mixed iodide-halide compounds. Polybromides have been rather neglected, chiefly because their large bromine vapor pressure prevents studies on crystalline compounds at room temperature. To our knowledge, only tetramethylammonium bromide-bromine (4) and tetrabuthylammonium bromide-bromine (5) phase diagrams have been reported. It has been shown that tetramethylammonium bromide (TMABr) is able to form the tribromide $TMABr_3$ and the enneabromide $TMABr_9$, both solid at room temperature, and probably also another adduct containing 16 bromine molecules, with an incongruent melting point at 5.2°C. For the tetrabuthylammonium bromide (TBABr)-bromine system the phase diagram shows the existence of the tribromide $TBABr_3$ and the heptabromide $TBABr_7$. The stability constant of $TBABr_3$ in organic solvents has also been evaluated (6).

Our work on organic polybromides is connected with their potential practical use in improving the performances of zinc-bromine secondary cells. Several patents (7) claim that quaternary ammonium salts are suitable for retaining a large amount of bromine, as polybromides, in the pores of the positive electrode. This reduces the diffusion of bromine toward the negative zinc electrode, raising the self-discharge time and the electrical capacity of the cell in comparison with simple zinc-bromine cell (8), in which the elemental bromine is adsorbed on the active carbon paste of the anode.

For the practical use of a quaternary ammonium salt in zinc-bromine secondary cells, three major requirements must be fulfilled:

(*i*) The polybromide formation must be reversible. Oxidative bromination of the salt would, of course, drastically reduce the number of charge-discharge cycles. The formation of a polybromide with low bromine vapor pressure would give an emf too low for practical purposes.

(*ii*) The salt should give polybromides containing a large number of bromine molecules per mole of salt, otherwise the increase in weight over the simple zinc-bromine cell could not be compensated for by the increased electrical capacity of the cell.

(*iii*) The polybromides should be solid in order to prevent liquid bromine-rich compounds from percolating from the positive electrode.

On the basis of these considerations, we studied the formation of insoluble polybromides by progressive additions of elemental bromine to a NaBr solution containing quaternary ammonium salts. The precipitation of polybromides and their phase-transitions in bromine-richer solid or liquid compounds has been followed potentiometrically, at constant temperature, by measuring after each bromine addition, the emf between a saturated calomel electrode and a Pt electrode immersed in the solutions. Following this procedure in experiments with TMABr and TBABr, we obtained quite quickly results agreeing with conventional phase diagrams, and we extended our research to other quaternary ammonium salts. In this paper we report the results related to tetramethylammonium, tetrabuthylammonium, phenyltrimethylammonium bromides and perchlorates; other measurements relating to the behavior of penta-, hexa- and decamethylen-bis-trimethylammonium bromides ("methonium" salts, containing a two-valent cation) are being carried out at present in our laboratory.

Experimental

Bromine (Carlo Erba RP), NaBr (BDH Lab. Reag.), $NaClO_4$ (BDH Analar) were used as received. TMABr (Fluka), TBABr (Fluka or Carlo Erba RP), and phenyltrimethylammonium bromide (PhTMABr, Fluka) were crystallized twice from ethanol or water-ethanol mixtures, and kept in a desiccator over P_2O_5. The respective perchlorates were prepared by precipitation from aqueous concentrated solutions of bromides and $NaClO_4$, crystallized twice from water and dried at room temperature over P_2O_5.

The reaction cell was a cylindrical Pyrex vessel, about 200 cc capacity, thermostated by a water jacket, and fitted with a ground glass cover with four holes; two of these were used for the introduction of the two electrodes (a Pt wire electrode and a saturated calomel electrode, with a procelain plug). One of the other two holes was used for the introduction of a microburette with a Teflon-glass stopcock for bromine delivery. Using the fourth hole, a small glass-spoon electrically heated, was introduced inside the cell just below the

Key words: polybromides, potentiometry, zinc-bromine secondary cells.

burette tip (about 3 cm above the solution level). Additions of the progressive aliquots of bromine to the solution were made by dropping a known amount of liquid bromine from the microburette to the glass-spoon inside the cell, then heating the spoon until all the bromine had evaporated, leaving the vapors to be absorbed by the solution which was kept constantly and rapidly stirred. In this way the polybromides separate in the form of fine particles, and their subsequent phase transitions are reasonably rapid. If the bromine is added to the solution directly as liquid drops, the formation of some mixed polybromide-bromine lumps is unavoidable, and this requires a much longer time for reaching the solution-precipitate equilibrium.

The emf between platinum and calomel electrodes was measured by a Leeds & Northrup Model 8687 potentiometer; the cell temperature was controlled within ±0.05°C.

As an example of a typical experiment, 10.0 mmoles of TMABr were dissolved in 50.0 ml of 1.0F NaBr solution in the reaction cell. Then bromine was gradually added to the solution, usually in 0.1 ml aliquots. After each addition, a time of 5-20 min was required for the equilibrium, and the emf was recorded. The bromine was added until the solution was saturated with liquid bromine. The plot emf *vs.* amount of added bromine shows several steps, indicating the initial precipitation of $TMABr_3$ and its subsequent transformation into $TMABr_9$.

A part of the added bromine is of course bound to the insoluble polybromides and the rest remains in solution as Br_3^-, Br_5^- etc. To allow for this amount of bromine which does not enter into the insoluble polybromides composition, a blank potentiometric curve was previously recorded by adding successive amounts of bromine to 50.0 ml of 1.0F NaBr solution. The total amount of bromine in the solution for each emf value, is determined by this curve. In the experiments with ammonium salts, the amount of bromine fixed as insoluble polybromides (indicated as "bromine uptake" in the curves reported in this paper) has been calculated, for each emf value, as the difference between the amount of the added bromine and the amount of bromine in solution (from the blank curve).

After this correction, the resulting plot emf *vs.* bromine uptake has the same meaning as a plot made by measuring the bromine vapor pressure during the addition of bromine to pure TMABr. In fact, the measured emf is a function of the activity ratio $a_{Br_2}/a^2_{Br^-}$ but after the precipitation of the tribromide, which is quite insoluble, the a_{Br^-} in the solution is practically equal both in the polybromide and blank solution. For all the subsequent phase transformations the blank curve corrections are operative.

Results and Discussion

In Fig. 1, curve 1 shows the compositions and the physical states of the insoluble polybromides formed during the bromine uptake by TMABr dissolved in 1.0F NaBr solution at $t = 25°C$. At point f the solution becomes saturated with liquid bromine, which gradually dissolves the enneabromide previously formed. No other solid adducts appear on subsequent bromine additions.

This behavior agrees with the phase diagram of the $TMABr-Br_2$ system (4) which shows the existence of a eutectic between $TMABr_3$ and $TMABr_9$ of composition $TMABr_{4.65}$ and a melting temperature of 15.8°C. At $t = 25°C$, according to the phase diagram, polybromides are completely liquid in the composition range $TMABr_{4.4}$-$TMABr_{4.95}$. In our experiments the corresponding composition range (c-d tract) was larger, very likely due to the presence of a small amount of water in the nonaqueous phase. A similar enlargement of the liquidity range in presence of aqueous solution has already been noted also by Bloch *et al.* (4).

In experiments at a temperature lower than eutectic, no liquid adducts are formed in the range TMABr-$TMABr_9$ as shown in Fig. 1, curve 2.

After the end of the experiment, by bubbling N_2 in the solution for 12 hr, all the bromine fixed by TMABr is eliminated. A subsequent curve of bromine uptake is superimposable on the previous one. We repeated the experiment three times on the same TMABr solution, always obtaining the same results, and thus demonstrating in our experimental conditions, the absence of irreversible appreciable brominations between TMABr and bromine.

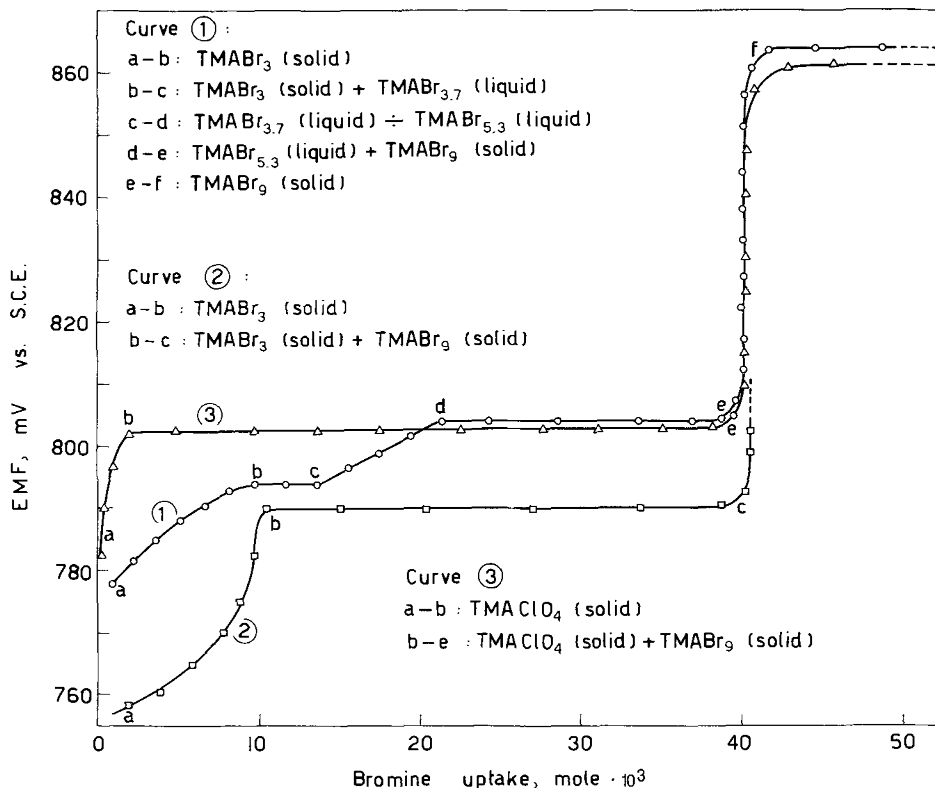

Fig. 1. EMF values for bromine uptake by: Curve (1) (circles), $10.0 \cdot 10^{-3}$ mole of TMABr in 50.0 ml of 1.0F NaBr solution; $t = 25°C$. Curve (2) (squares), as in curve (1); $t = 0°C$. Curve (3) (triangles), $10.0 \cdot 10^{-3}$ moles of $TMAClO_4$ in 50.0 ml of 1.0F NaBr and 1.0F $NaClO_4$ solution; $t = 25°C$.

Figure 1, curve 3 shows the emf variations during the bromine uptake by $TMAClO_4$ which is only slightly soluble in water. Our measurements at $t = 25°C$ made by comparing the conductivity of the saturated solution diluted twenty times and the conductivities of $TMAClO_4$ solutions of known concentrations, gave, for the saturation concentration, the value $(7.50 \pm 0.05) \cdot 10^{-2}F$, agreeing with previous findings (9). In the experiment related to curve 3 in Fig. 1, the solubility is made even lower by the presence of $NaClO_4$ in the solution, and at the beginning of the experiment the 10.0 mmoles of $TMAClO_4$ are almost completely insoluble.

The value of emf measured in the invariant tract b-e of Fig. 1, curve 3 (802 mV) is very near to that measured during the d-e tract of Fig. 1, curve 1 (804 mV). Moreover, in experiments made with TMABr in 1.0F NaBr and 1.0F $NaNO_3$ solution, at a similar ionic strength of the solution used for $TMAClO_4$ experiments, emf value of d-e tract of Fig. 1, curve 1 is practically coincident with that of b-e tract of Fig. 1, curve 3. It is therefore evident that for the addition of bromine to a saturated $TMAClO_4$, 1.0F NaBr and 1.0F $NaClO_4$ solution at $t = 25°C$, the only insoluble polybromide formed is the enneabromide $TMABr_9$, without any formation of tribromide and liquid mixtures TMABr-Br_2 of various composition. This indicates that if the TMA^+ concentration in the solution is rather low, on adding bromine the $TMABr_9$ precipitates earlier than the activity product $a_{TMA^+} \cdot a_{Br_3^-}$ reaches the value corresponding to the tribromide precipitation.

For the equilibrium

$$TMA^+ + Br_3^- \rightleftarrows TMABr_3 \downarrow$$

it is possible to calculate the activity product because the value of the equilibrium constant for the reaction

$$Br_2 + Br^- \rightleftarrows Br_3^-$$

is known (10), but for the enneabromide precipitation equilibrium the analogous calculation is not feasible because the value of the Br_9^- ion formation constant is not known, even should this ion exist in solution. Therefore, a numerical quantitative verification of our opinion about the relative solubilities of tribromide and enneabromide does not seem possible at the present time.

Nevertheless our observation of the precipitation of enneabromide starting from the sparingly soluble $TMAClO_4$ is in agreement with the results of Bloch *et al.* (4), who also observed separation of enneabromide only, by adding bromine to dilute solutions (less than 0.115F) of TMABr.

Figure 2, curve 1 shows the compositions of the insoluble polybromides formed during the bromine uptake by TBABr dissolved in 1.0F NaBr solution at $t = 15°C$. This temperature was chosen to avoid the formation of liquid polybromides since the existence of a eutectic between $TBABr_3$ and $TBABr_7$ with melting temperature at $t = 28°C$ is known (5). In fact, at $t = 15°C$, all the polybromides formed until the salt fixed 5 moles of bromine per mole are solid. The solution becomes saturated by liquid bromine at point 1.

The phase diagram (5) does not show the existence of $TBABr_8$, $TBABr_9$, and $TBABr_{11}$ compounds. They are probably compounds with an incongruent melting point, undetectable with the technique used by the authors of the above-mentioned paper in the determination of the phase diagram.

The low emf value measured during the precipitation of $TBABr_3$ indicates a very low solubility in water of this polybromide. Unlike the behavior of $TMAClO_4$, the tribromide $TBABr_3$ precipitates even by addition of bromine to a saturated $TBAClO_4$, 1.0F NaBr and 1.0F $NaClO_4$ solution.

Also for the polybromides formed by TBABr, we found no oxidations and good reversibility of the bromine uptake by repeated bromine additions and eliminations with N_2 bubbling.

The compositions of the insoluble polybromides formed during the bromine uptake by PhTMABr in 1.0F NaBr solution at $t = 25°C$ are shown in Fig. 2, curve 2. The solution becomes saturated by liquid bromine at point f. The curve is practically identical

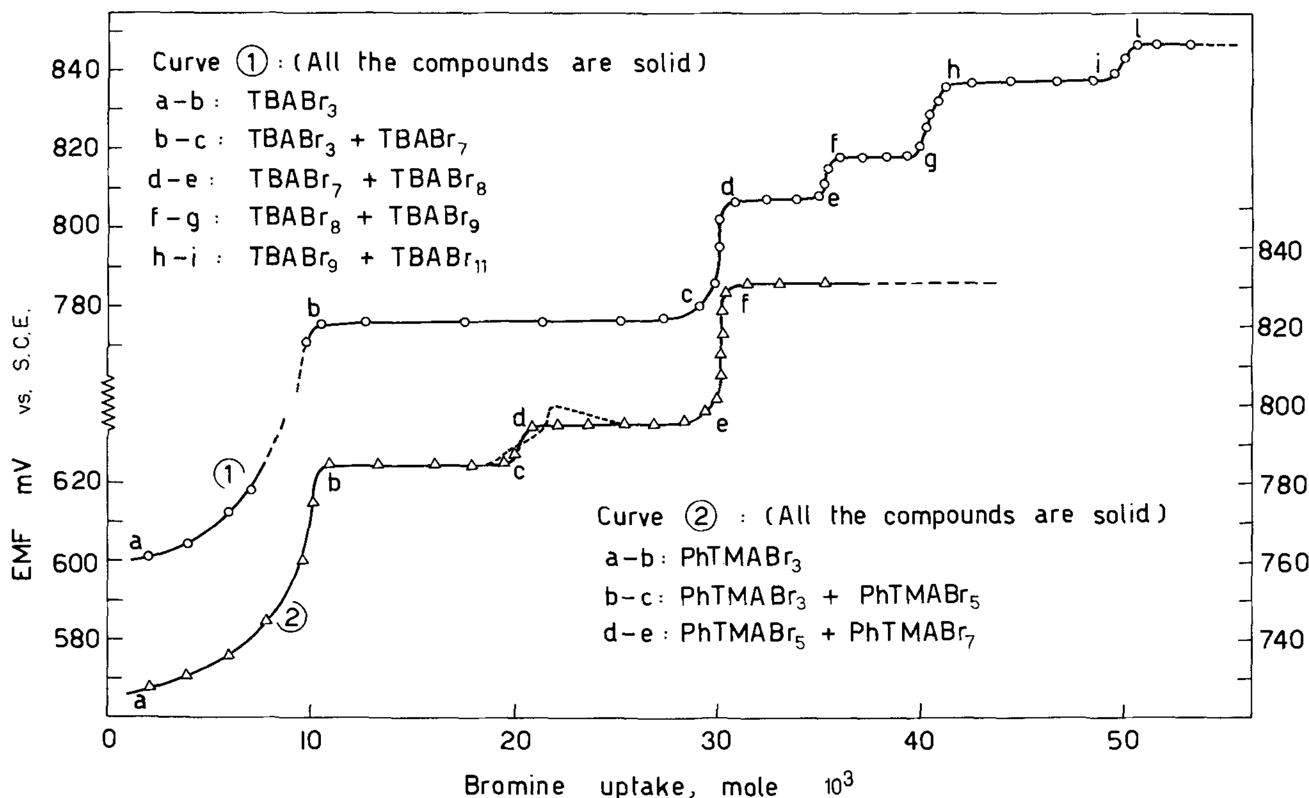

Fig. 2. EMF values for bromine uptake by: Curve (1) (circles), 10.0×10^{-3} moles of TBABr in 50.0 ml of 1.0F NaBr solution; $t = 15°C$. Curve (2) (triangles), 10.0×10^{-3} moles of PhTMABr in 50.0 ml of 1.0F NaBr solution; $t = 25°C$.

for 10.0 mmoles of solid $PhTMAClO_4$ in the presence of 50.0 ml of 1.0F NaBr and 1.0F $NaClO_4$ solution. Therefore in this case, as with $TBAClO_4$, the presence of the perchlorate does not prevent the tribromide precipitation.

The $PhTMABr_5$-$PhTMABr_7$ transition is particularly slow. Only with very slow additions of bromine vapors and rapid stirring, is it possible to avoid supersaturation phenomena, indicated with a dotted line near the c-d tract in Fig. 2, curve 2.

The existence of $PhTMABr_3$ is known. (This compound is commercially available and is used for organic brominations in nonaqueous solvents.) The compounds $PhTMABr_5$ and $PhTMABr_7$ have not been reported to date.

Conclusions

The potentiometric titrations we made represent a convenient screening method for detecting the formation of quaternary ammonium polybromides in a condensed phase. The results obtained with TMABr at $t = 25°C$ and at $t = 0°C$ confirmed the existence of the solid compounds $TMABr_3$ and $TMABr_9$, and the possibility of a eutectic between them. With TBABr we confirmed, at $t = 15°C$, the existence of the solid tribromide and heptabromide, and we obtained experimental evidence about the formation of solid $TBABr_8$, $TBABr_9$, and $TBABr_{11}$. PhTMABr, at 25°C, is able to form the solid $PhTMABr_3$, $PhTMABr_5$, and $PhTMABr_7$. All the polybromides we studied release all the added fixed bromine by N_2 sweeping at room temperature.

We consider of interest the results obtained with $TMAClO_4$; its direct transformation in solid $TMABr_9$ at 25°C makes this salt particularly suitable for practical use in zinc-bromine secondary cells because it avoids the formation of liquid polybromides (obtained, on the contrary, with TMABr) and because the four bromine molecules are fixed at the same emf value.

Acknowledgment

We would like to thank Mr. M. Lecci for his valuable help during the longest bromine uptake experiments.

Manuscript submitted Nov. 24, 1971; revised manuscript received May 24, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Cathodic Synthesis of Tetraalkyltin Compounds

Harris E. Ulery

Organic Chemicals Department, E. I. du Pont de Nemours & Company, Wilmington, Delaware 19899

ABSTRACT

Methyl bromide and allyl bromide are efficiently reduced at a tin electrode to form tetramethyl and tetraallyl tin. A variety of other bromides with appreciably more negative reduction potentials also produce tetra-substituted tin compounds but the yields are lower. At higher potentials, cathode disintegration is a consequence of the competitive reduction of the carrier electrolyte ($Et_4N^+Br^-$).

The present manufacture (1) of organotin compounds (chiefly dibutyl derivatives) uses the following Grignard process

$$BuCl + Mg \rightarrow BuMgCl \quad [1]$$

$$4BuMgCl + SnCl_4 \rightarrow Bu_4Sn + 4MgCl_2 \quad [2]$$

$$Bu_4Sn + SnCl_4 \rightarrow 2Bu_2SnCl_2 \quad [3]$$

Of lesser importance is the Wurtz-Fittig synthesis which employs finely dispersed sodium

$$Bu_2SnCl_2 + 2BuCl + 4Na \rightarrow Bu_4Sn + 4NaCl \quad [4]$$

↑ Recycle

$$Bu_4Sn + SnCl_4 \rightarrow Bu_2SnCl_2 + Bu_2SnCl_2 \quad [5]$$

A sodium-tin alloy process is also known analogous to that used in tetraethyl lead (TEL) manufacture

$$Na_4Sn + 4BuCl \rightarrow Bu_4Sn + 4NaCl \quad [6]$$

Key words: tin cathode, tetraalkyl tin, tetramethyl tin, tetraallyl tin, electrolysis, cathode disintegration, alkyl bromides, reduction.

In recent years a number of related anodic syntheses of organometallics have been devised (2). Typical of these are Ziegler's electrolytic aluminum alkyl process (2b) and the Grignard process (2c). While these are currently applied to the manufacture of lead tetraalkyls (*e.g.* Eq. [7] and [8]) (3) they represent potential routes to tin compounds if the tendency of this metal toward anodic passivation can be overcome (4).

$$\text{Anode: } 4RMgCl + Pb \rightarrow R_4Pb + 4MgCl^+ + 4e^- \quad [7]$$

$$\text{Cathode: } 4MgCl^+ + 4e^- \rightarrow 2Mg + 2MgCl_2 \quad [8]$$

Formally these electrochemical syntheses are analogous to the chemical methods described above where the anode may be viewed as providing the required oxidized form of the recipient metal. Fundamentally, each of these schemes depends on a reactive metal (Na, Mg, etc.) to provide the substantial energy required to initially reduce a carbon-halogen bond to a carbanionoid species

$$RX + 2M^{\circ} \rightarrow R^{\ominus}M^{\oplus} + M^{\oplus} + X^{\ominus} \quad [9]$$

The principal variations in these anodic schemes relate to how the fate of R^- is controlled.

Each of these processes has been criticized (1a) because the use of the reactive metals, which are not in all cases reclaimed, lead to inflated raw material costs. Also, the methods are hazardous to operate. A procedure for the direct addition of alkyl groups to tin, therefore, would be a matter of considerable technical merit.

One obvious solution is to circumvent the use of a reactive metal by supplying all the energy for alkyl halide reduction electrochemically. In 1963 Silversmith and Sloan (5) reported that a number of soft metals could be sacrificed cathodically by an alkyl halide with the consequent formation of the polyalkyl metal. This work was both a refinement and generalization of the earlier finding by Calingaert (6) that Et_4Pb was formed during the electrolysis of an EtI solution between lead electrodes. Our purpose at this time is to report on some initial studies of the application of this reaction to the synthesis of organotins.

Experimental

Apparatus.—Electrolyses were conducted in a 100 cm^2 discoid cell operated at 10A. Cathode and anode were separated by an Amfion® C-310 ion exchange membrane. Catholyte and anolyte were independently circulated through external reservoirs and heat exchangers, and vented through wet test flowmeters. The cathode was fabricated from ¼ in. cast tin plate which analyzed at 99.85%. The anode was constructed from oil impregnated electrolytic grade graphite.

Procedure.—For the batch electrolyses the anolyte consisted of 570g of an acetonitrile solution containing 35 weight per cent (w/o) tetraethylammonium bromide (TEAB) and 10 w/o water. The TEAB was present in *ca.* 27% excess over the amount needed to form the tribromide. The concentration of MeBr was set initially at 1 molar: the total amount of catholyte, therefore, varied as indicated in Table II. Both catholyte and anolyte were circulated at 500 ml/min. The temperature stabilized near 50°C. The total current passed was 0.5 Faraday.

The continuous electrolyses utilized additional feed reservoirs. Electrolysis was allowed to proceed with recirculation only for the first 10 min, at which time the soluble tin concentration was about 2.5%. A feed/bleed rate of about 7 g/min was then established to maintain an approximately constant concentration of tin in the circulating stream. The temperature was maintained at 35°C.

The amount of tetramethyl tin found was determined by vapor phase chromatography. The total soluble tin was obtained by polarographic analysis.

Electrolyte densities.—Densities of the three component systems $R_4N^+Br^-$-H_2O-MeCN were obtained to allow the conversion between weight per cent compositions and fundamental concentration units. These data were fitted to the following regression equation

$$d_4^{25} = 0.7768 + 0.002202P_w + \alpha P_s + \beta P_w P_s$$

where P_w and P_s are the true weight per cent of water and tetraalkyl ammonium bromide. The regression coefficients and standard errors of estimate are given in Table I.

Results and Discussion

The general reaction under study is

$$\text{Cathode: } nRX + M + ne^- \rightarrow R_nM + nX^- \quad [10]$$

$$\text{Anode: } nX^- \rightarrow \frac{n}{2}X_2 + ne^- \quad [11]$$

$$\text{Over-all: } nRX + M + n\text{Faraday} \rightarrow R_nM + \frac{n}{2}X_2 \quad [12]$$

The case where RX = an alkyl bromide and M = Pb has been studied previously (7, 8). It was found that with methyl bromide the reaction is exceedingly efficient and essentially quantitative yields of tetramethyl lead based on both electricity and lead consumed are possible. With ethyl bromide, n is between 3 and 4 and lower yields of both Et_4Pb and Et_6Pb_2 are formed.

Table I. Regression coefficients and standard errors of estimates for densities of the three-component system R_4N^+Br - H_2O - MeCN

R=	$\alpha \times 10^2$	$\beta \times 10^4$	σ
Me—[a]	0.7747	−0.6222	0.015

n-Bu	0.2264	+0.3134	0.009

[a] $Me_4N^+Br^-$ forms two liquid phases at some compositions. These data refer to the monophase liquid compositions only.

General scope of the reaction.—The versatility of the sacrificial tin cathode is suggested by the data in Table II. The yields assume the stoichiometry of Eq. [12] with $n = 4$; they are based on the conversion of cathode material to a soluble organic form and are referred to the consumption of current (% el) and of tin (%Sn). Electrical yield losses were found to be due largely to three competing processes: (*i*) reduction of RX to RH, (*ii*) dimerization of RX to R-R, and (*iii*) reduction of the tetraethylammonium bromide (TEAB) electrolyte to triethylamine. Tin yield losses were due primarily to cathode sloughing and to a lesser extent the formation of insoluble organic and inorganic tin salts. The tetra-substituted tin product was identified in several cases by using known standards with gas chromatography and/or mass spectrometry.

Since the results indicate that the electrolyses of methyl and allyl bromide are both qualitatively and quantitatively superior to the other examples, these were examined in some detail.

$(CH_3)_4Sn$ yield vs. catholyte compositions.—Previous work with lead cathodes (7, 8) had shown that the reduction process was sensitive to catholyte composition. The results of Table II, therefore, do not correspond necessarily to optimum values. The results of a systematic variation in the concentrations of H_2O, TEAB, and MeBr are shown in Table III for a series of batch electrolyses. The minimum values for the water and MeBr concentrations were set to avoid excessive sloughing of Sn. The TEAB concentration is constrained by its solubility and by the power requirements of the cell. In order that the MeBr and tin concentration changes be about the same for each run, the total amount of catholyte was different for each level of MeBr. The reproducibility of the data was limited by minute membrane damage and lack of temperature control; high temperatures developed during reduction led to outgassing of MeBr.

A series of continuous electrolyses provided better control of composition variables and temperature

Table II. Reduction of organic bromides (RBr) at a tin cathode

[a] Electrical basis assuming a 4-electron process.
[b] Electrical basis assuming a 2-electron process. Figures include entrained MeBr and, therefore, may exceed 100%.

(Table IV). The concentration of tin in the catholyte reached 1.5-2.5 w/o. Water permeation from the anolyte increased the average level in catholyte by 0.8-1.8% over the initial value. Under the conditions of these experiments all the consumed tin present in the product catholyte was as a soluble material. Furthermore, gas chromatographic analysis indicated that TMT is indeed the major reaction product initially.[1] Consequently cathode weight loss in the absence of sloughing may be taken as a crude measure of TMT formation. All the data at present indicate that current efficiencies must be based on a 4-electron process (Eq. [10]).

Product yields.—Regression analysis of the results in Table III indicates that most of the variations in yields based on cathode weight loss is accommodated simply by the differences in water and TEAB content; changes in the initial concentration of MeBr did not significantly influence tin consumption. That decreased water concentrations promote higher yields of the organometallic product is to be expected on the basis of competition, and is a familiar fact in the cathodic synthesis of tetramethyl lead (8). By comparison, the influence of water is about 3 times larger in the case of TMT than for TML. This agrees favorably with the factor of 5-6 predicted solely on the basis of polarographic studies of the hydrogen overvoltage on tin and lead cathodes in related electrolytes.

Increasing the carrier electrolyte increases the consumption of tin. While regression analysis attributes a much smaller role to TEAB than to water, it is by no means insignificant. Discussion of this point will be deferred to a later section, but it should be pointed out that when the TEAB concentration is set above about 5% in relatively dry systems, sloughing of tin is observed; the current efficiency with respect to solubilized tin is not as high. Increasing the water content raises the level of TEAB required to cause sloughing.

Gassing.—The evolution of gas is a 2-electron process. It appears to be the major side reaction under optimal conditions. Accordingly, gas production and tin consumption are inversely related and display opposite dependencies on water and TEAB concentrations. This was not true with alkyl bromides with much higher reduction potentials than MeBr. In these cases some triethyl amine is obtained from the reduction of tetraethyl ammonium ion.

Tetraallyltin.—The reduction of allyl bromide under conditions similar to those used with MeBr results in an efficient sacrifice of the tin cathode. The results parallel those obtained by a strictly chemical method (9), for the preparation of tetraallyl tin. About 75% of the tin consumed appears in a soluble form, which at least initially seems to be mostly tetraallyl tin (g.c. analysis). The remaining 25% is accounted for as an amorphous, MeCN insoluble product containing 37-46% Sn corresponding to the probable composition $(R_3SnOH)_x \cdot (R_3SnBr)$. When water is replaced by MeOH and allyl chloride is used, no solid complex was formed.

Less than 4 electrons/atom of consumed tin were required on the average in spite of a nominal loss of electrical efficiency as a consequence of the formation of gas.[2] It is quite probable that a 3-electron process is competing with the "normal" 4-electron reaction

$$3RX + Sn + 3e^- \rightarrow \tfrac{1}{2}R_6Sn_2 + 3X^- \quad [13]$$

The formation of hexaallylditin would be consonant with the earlier observation (7) that hexaalkyldilead compounds are favored when the alkyl groups are so large as to inhibit the formation of four carbon bonds to one central metal atom. Table V shows that under similar conditions the reaction at a lead electrode (which also produces some insoluble complex) is comparatively less efficient. With neither metal was sloughing of the cathode material itself observed. This is reasonable, since the reduction potential of allyl bromide is similar to that of MeBr.

Sludge formation.—At low water concentrations, the extent of sludging increases very rapidly with catholyte TEAB content. The sludge is composed primarily of metal fines together with some salts. An interesting trend can be discerned: sludge rates increase rapidly as the catholyte approaches saturation with respect to TEAB. Table VI shows that the per cent of saturation is rather constant for a given level of sludge

[1] The catholytes are unstable and some alkyl tin bromides and insoluble tin compounds form due to the presence of air and traces of Br_3^- and HBr. The cathodic formation of lower alkyltin products will be discussed in a later paper.

[2] Propene was identified among the off-gases.

formation during MeBr reduction in spite of the overall change in solution composition.

Other data also implicate the carrier electrolyte as a responsible factor in the formation of sludge: (*i*) Poorer solvents for TEAB (eq. propionitrile, benzonitrile) produce more sludge for a given concentration of electrolyte. (*ii*) Co-solvents with reduction potentials lower than TEAB in particular hydroxylic solvents, inhibit sludging; by contrast, relatively nonpolar unreactive solvents such as benzene, diglyme, and tetramethyl tin increase sludge rates. A lead cathode behaves in much the same way (8). (*iii*) Qualitatively, less cathode sloughing is observed with tetrapropyl ammonium and tetrabutyl ammonium salts than with the corresponding tetraethyl ammonium salts. (*iv*) High current densities and poor catholyte circulation both promote sludge formation suggesting that high local potentials are responsible for nonfaradaic metal removal (see below).

In the absence of extensive cathode disintegration the reduction of MeBr at a tin or lead electrode is unique. This is the only alkyl bromide that yields a specularly etched cathode in which the crystalline detail of the metal is preserved down to the submicron level (Fig. 1 and 2). All other depolarizers studied have decidedly more negative reduction potentials (7) and these remove metal in an apparently random fashion such that no microscopic evidence of cathode crystallinity is preserved (Fig. 3 and 4). When trace metal fines are produced with MeBr, cratering is observed along microcrystalline edges and corners (Fig. 2b), but not on faces—in other words, pitting appears where the local potential is the highest (10).

It is suggested that reduction of the tetraethyl ammonium cation and subsequent implantation of the product ($Et_4N\cdot$) is responsible for the formation of cathode sludges. Implantation of alkali metals is frequently observed at soft metal cathodes (11) including Pb and Sn. Often it results in cathode disintegration. Seebeck's remarkable and still curious ammonium amalgam (12) is an analogous phenomenon. In fact, both Me_4N^+ and Et_4N^+ yield amalgams (13), although that of the latter is appreciably less stable owing to the greater ease of fragmentation expected when the ethyl group is present.

While the details of the implantation process *per se* remain obscure, it is clear that the first step—reduction of the cation—readily explains many of our observations. The relatively high potential required to reduce Et_4N^+ is not accessible as long as other reducibles are present. It is not surprising, then, that the following order for sludge inhibition is observed for a given weight per cent of additive: $H_2O > MeOH >$ glycerol $>$ polyethylene glycol. The reverse might be expected if adsorption of the inhibitor was responsible instead of the hydroxyl group activity. Finally, we note that when a 0.5% H_2O/10% TEAB/acetonitrile solution is subjected to electrolysis at (0.1 A/cm^2), the electronmicrographs of the surface (Fig. 5) resembled those obtained from cathodes sacrificed to higher alkyl bromides (cf. Fig. 4). The principal off-gas was ethane, while triethylamine was a major product in solution. That reduction proceeds through the intermediate $Et_4N\cdot$ is reasonable, since the cathode fines were found to possess a residual reactivity toward water.

Acknowledgments

I am indebted to M. R. Kegelman who designed the electrolytic cell used in this work and who shared with me much of his experience in the electrolytic synthesis of tetramethyl lead. The electronmicrographs were obtained by W. S. Kay. Chromatographic, mass spectrographic, and elemental analyses were conducted by the staff of Jackson Laboratory's Analytical Division. Finally, I wish to mention particularly T. Tessmer, whose manipulative skills and general laboratory as-

Electron Microscope Study of Breakdown and Repair of Anodic Films on Aluminum

J. Zahavi* and M. Metzger*

Department of Metallurgy and Mining Engineering and Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

In films forming in 2.4M H_2SO_4 at 5 mA/cm^2, many breakdown events including pit initiation were found to occur continually but to be followed by almost immediate repair, so that the stability of film growth was due not to the absence of breakdown but to the efficacy of repair. A relation between the sites of breakdown and substrate structure was not indicated. Film growth was interpreted as occurring through a compact film at pore bases, as in the classical mechanism, and also through breakdown—extension of a pore near to the metal interface—and repair by reanodization to form a hemisphere of compact film extending into the substrate. An interpretation of the geometrical structure of the film is proposed.

Considerable investigation of the stability of surface films in electrolytes has been done through the macroscopic electrochemistry of anodic behavior in passivation and pitting, electrolytic polishing and formation of protective or dielectric films by anodizing. Since film breakdown is usually localized in cases of interest, insight into the mechanisms of failure may be sought through direct observations of the microtopography of the initial failure events by electron microscopy. For application to corrosion of aluminum, the initial work was based on films formed in sulfuric acid, so that the extensive anodizing literature [the subject of a recent review (1)] could be used as partial guide and reference, but at a low current density yielding thinner slowly growing films.

In constant-current anodizing of aluminum in sulfuric acid (typically 15% or 1.5M at C.D. between 10 and 100 mA/cm^2), the cell voltage (referred to a Pt cathode) first rises rapidly with growth of a film and then, usually after passing through a maximum, levels off at a steady-state value (2, 3). At least by the early part of the voltage plateau, pores are initiated by preferential film dissolution along channels from the external surface and the film then develops the classical more or less hexagonal array of pores with a scalloped barrier layer at the base (4) and maintains this structure during thickening by growth through the barrier layer and dissolution of film at pore bases (3, 4). The rate of purely chemical dissolution as measured by several methods is only $\lesssim$1 Å/min (5-7) and is responsible only for some tapering of the pore walls toward their mouths and some external film surface dissolution, and the rapid pore-base dissolution which keeps pace with the imposed C.D. is attributed to a field-assisted process (8), the details of which are not known. A discussion of classical pore growth has been given recently by O'Sullivan and Wood in connection with studies in phosphoric acid, where steady-state voltage was high ($\sim$ 100V) and where films many microns thick could be studied in section as well as on their surfaces and the relations between forming voltage and the dimensions of the pore structure determined (9). For sulfuric acid anodizing, the relation found for pore diameter was 9-10 Å/V and for cell diameter 25-28 Å/V (3); the value for barrier layer thickness was not determined [this was 10 Å/V in phosphoric acid (9)]. The details of the pore initiation process are not established. A useful relation has been derived from constant-voltage anodizing studies in which pore formation in various electrolytes was found to accompany protracted current decay (10-13) and thus could be associated with the condition, according to high-field film growth theory, that the forming field had fallen to a sufficiently low value (11). The concept that film dissolution is inhibited at high fields has also received support from constant C.D. studies in sulfuric acid (2).

This paper is sometimes concerned with deviations from the classical pore structure, and it is helpful to refer in general to the conducting columns of electrolyte in the film as "channels" and reserve the term "pores" for those approximating the classical model in character and dimensions. The term "breakdown" is used here not in the electrochemical sense of a fall in film resistance but only in a broad geometrical sense of creation of a film-free zone or highly conductive path (*e.g.*, by dissolution or cracking) which extends to or almost to the film-substrate interface. Since this may be merely creation of an advance channel through the barrier-layer film at the base of an existing channel or pore, porous film growth and breakdown are likely to be related phenomena. The initial breakdown event within a thin film would not normally be observable directly but its incidence and character would be inferred from the microtopography of the resulting pit in the substrate or zone of repaired film. The present observations necessarily lead to geometrical models and do not deal directly with questions discussed elsewhere concerning the chemical structure of the film and the state of hydration at various levels (14).

Experimental

99.999% aluminum sheet containing in ppm wt. 2.4 Fe, 1.5 Si, 1.0 Cu, and 0.6 Mg as major impurities (Lot III-A) was milled into blanks 20x10x1 mm with a narrow tab and these were annealed in air 24 hr at 650°C and cooled in an air stream. They were etched in 10% HF and electropolished in 20 volume per cent (v/o) 70% perchloric acid in ethanol at $-10°$ to $-15°$C for 10 min at 100 mA/cm^2, then rinsed in a jet of ethanol and dried. The intention was to standardize the procedure and the initial state of the surface while holding close to the conditions found previously (15) to yield surfaces without grain boundary grooves or level differences between grains; longer polishing times are normally required to yield a featureless surface. Anodic films were formed in a stirred bath of 2.4M H_2SO_4 at 25.0° $\pm$ 0.2°C at 5 mA/cm^2 from a constant-current source with a 50 cm^2 platinum cathode for times up to 30 min. The acid concentration (and the

* Electrochemical Society Active Member.
Key words: film-breakdown, film-repair, pitting, aluminum.

batch itself) was the same as used previously to study the structure-related free corrosion behavior of Lot III-A (16).

Surfaces were examined by optical microscopy and by scanning electron microscopy after applying a thin carbon layer to prevent charging in the beam. Films stripped in mercuric chloride solution were examined in transmission [flakes of MoO_3 smoke (17) being used for focusing], and carbon replicas preshadowed at 35° with platinum were taken of outer and inner film surfaces, the film being removed in 10% HF without attack of the platinum. Film thickness estimated from the transparency to 100 kV electrons showed the formation efficiency was low; the 30 min film, opaque to the beam, was checked by an interferometric method and found to be near ½ μm thick.

Results and Discussion

Kinetics.—Galvanostatic anodizing at C.D. of 25-100 mA/cm^2 gave cell voltage-time curves, as for 50 mA/cm^2 in Fig. 1a, similar to those reported previously for slightly lower acid concentrations (2, 3). At lower C.D. the maximum was broader and the plateau lower and 5 mA/cm^2 (Fig. 1b) was chosen as yielding suitable conditions for this work. The curve displayed on a millivolt recorder was smooth with only weak voltage fluctuations in the region of the maximum; recording the curve on an oscilloscope with much higher frequency response did not reveal substantially larger fluctuations. Instead of the initial linear rise of voltage seen at higher C.D., the 5 mA/cm^2 curves showed a change in slope near ½V. If before anodizing the specimen were either etched 2 min in 10% HF or treated with the hot chromic-phosphoric acid film stripping solution to remove the residual electropolishing film (about 200Å) and leave only the much thinner film remaining after a water rinse, the curve was altered somewhat below 1V, but the remainder of the curve was unchanged.

Optical and scanning microscopy.—Examination of anodized surfaces by bright-field optical microscopy or by scanning electron microscopy revealed small repaired pits of micron size with densities of $\sim 10^2$ per cm^2. Many of these pits formed early in the anodizing process but they soon ceased to grow. Figure 2a shows the secondary-electron image of the surface of the film over a pit after 25 sec anodizing; the anodic film over the pit had been lifted and cracked. The specimen-current image gives a "radiograph" reflecting the thickness of film overlying the substrate and so could be used to give some information in depth. This image (Fig. 2b) was everywhere darker over the pit, *i.e.*, the total film thickness was greater there indicating that a repair film had already formed. It was deduced

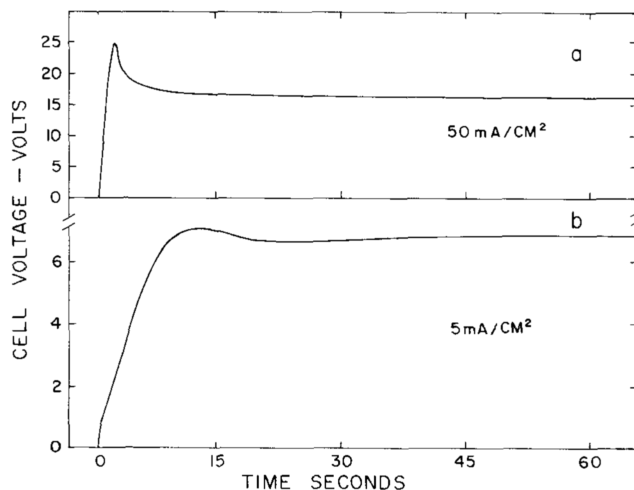

Fig. 1. Cell voltage-time in 2.4M H_2SO_4

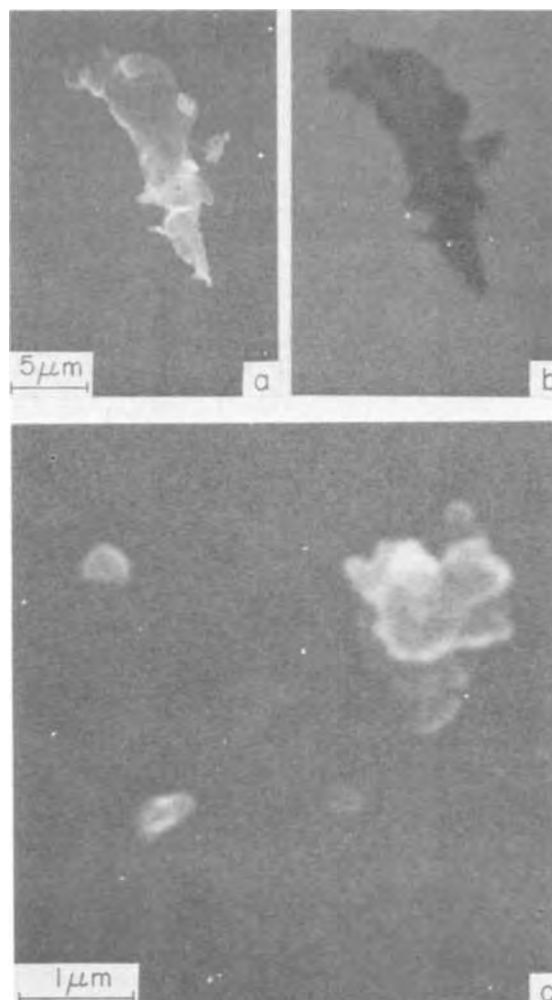

Fig. 2. Scanning electron micrographs at small pits in anodized specimens. (a) after 25 sec, secondary-electron image; (b) same field, specimen-current image; (c) after 15 min, cluster of pits of typical size, secondary-electron image.

that pitting began by undermining the original film (3) and the repair process was a rapid reanodization of the exposed metal at high local C.D. This repair was effective; in specimens examined after longer anodizing times, pits such as those in Fig. 2a were no larger and most of the scattered pits present were smaller and associated with very little perturbation of the external surface of the film, as illustrated by the group shown at higher magnification in Fig. 2c. Wood and O'Sullivan had found that at 10 mA/cm^2 pits formed in sulfate solutions only above pH 1.1 (3). In the present experiments, the absence of distinct pitting was due not to the absence of a tendency for pit formation but to the capacity for rapid repair.

A more sensitive method for detecting the presence of geometrical features beneath the film is dark-field optical microscopy, which is sensitive to minor irregularities in the metal surface. In the original electropolished surface, this revealed some bright spots (Fig. 3a) attributed to shallow depressions remaining from pits produced in the course of electropolishing and now almost removed by the subsequent electropolishing. In specimens anodized 84 sec or more, there were many more spots ($\sim 10^5$ per cm^2) in the dark-field view (Fig. 3b) (many of these were too faint to survive reproduction). Only a small fraction of these could be identified by optical or scanning microscopy and most are thought to have represented some of the many small depressions in the metal-film interface revealed in the replica studies described in the following section.

The spots in anodized specimens showed no apparent preference for grain boundaries nor was the appearance of individual boundaries altered greatly from that observed in the electropolished state where grain boundary grooves were usually visible as faint lines (arrows in Fig. 3a), their appearance varying somewhat with the short polishing times employed. The distribution of spots within the grains of anodized specimens was not strongly associated with subgrain boundaries, as determined in specimens for which the substructure had been previously established by etching. It was conceivable that the spots might be associated with segregations of iron or other impurities, which under free corrosion conditions at much lower C.D. ($\sim 10^{-2}$ mA/cm^2) lead to the formation of small pits in sulfuric and other acids (16). This was checked by subjecting zone-refined aluminum containing only about 0.1 ppm Fe and Cu to the same treatment, and the dark-field micrographs (Fig. 3c) were found to be essentially the same. The events giving rise to the bright spots were thus not strongly structure- or impurity-sensitive.

Transmission and replica studies.—Transmission studies, made on the plateau of the cell voltage-time curve, were limited mainly to anodizing times up to 150 sec because of the fogged background and obscuring of detail in thicker films. These studies (Fig. 4) revealed structures which were nonclassical in several respects. For one, instead of the classical pore structure appearing as rounded 60-70Å light spots on a uniform darker ground, the channels observed were usually elongated or streaked and there was considerable detail in the background. Also, the film showed numerous dark zones indicative of breakdown and repair events, these being prominent at low magnifications (Fig. 4f).

With regard to the dark zones, it was determined by varying the focus that these represented locally greater mass thickness. The presence of the zones was reflected in the external surface replicas (Fig. 5a and b) only in minor ways. It was on the film underside (Fig. 6) that the events were manifest. The larger ones appear in Fig. 6c and d as rounded projections extending out from the film and thus representing the locally thicker regions of film giving rise to the dark zones in the transmission image. For shorter anodizing times, the zones were smaller and less prominently reflected in the film underside topography (Fig. 6a and b). In general, it appeared that in the course of anodizing breakdown-repair events occurred continually in one form or another at the base of the film and the underside replicas revealed those that had taken place shortly before the time of observation before the projections were obscured by continuous uniform film growth.

Extensive selected-area diffraction of these zones revealed no evidence of the crystallinity shown by Zahavi and Yahalom to be associated with breakdown zones at higher C.D. and higher plateau voltages (18, 19). This could be checked even for the 900 sec film by using a defocused (phase contrast) image to locate the zones.

The events visible on the film underside replicas corresponded to depressions in the substrate-film interface which could serve as light scattering centers in dark-field optical microscopy. Most of the events observed were too small to provide sufficient intensity for detection in the present optical studies. However, the events covered a wide size range and the underside replicas did reveal a number of breakdown-repair events or repaired pits larger than those shown in Fig. 6c and d, and it was deduced that the weak light spots in the dark-field optical micrographs originated at these (> 0.1 μm across). The electron-microscope studies indicated that the breakdown could occur at any point on the surface and thus supported the conclusion of the optical studies that these events were not limited to boundaries or impurity segregations in the substrate.

A case of local growth of repair film in to the substrate had been described by Renshaw (20) who studied the anodizing of aluminum (in chromic acid) through a substantial pre-existing compact film and found large hemispheres of porous film growing from the base of the compact film. This was a different situation, its point of interest being not an anomaly in the character of the porous film itself but the fact that it started to grow only from discrete locations where the compact layer had been penetrated.

Consideration is now given to the nonclassical aspects of the pore structure. In transmission, the structure that developed (Fig. 4d) appeared to consist of major channels or pores of somewhat irregular shape and between them some finer ones usually of lower contrast and sometimes running in strings. The appearance of the channels changed somewhat on tilting in a manner which suggested many were inclined to the normal or jogged [they were not sloped uniformly in one grain as has been reported (21)] and their apparent shapes were related to this. The diameters and spacings of the

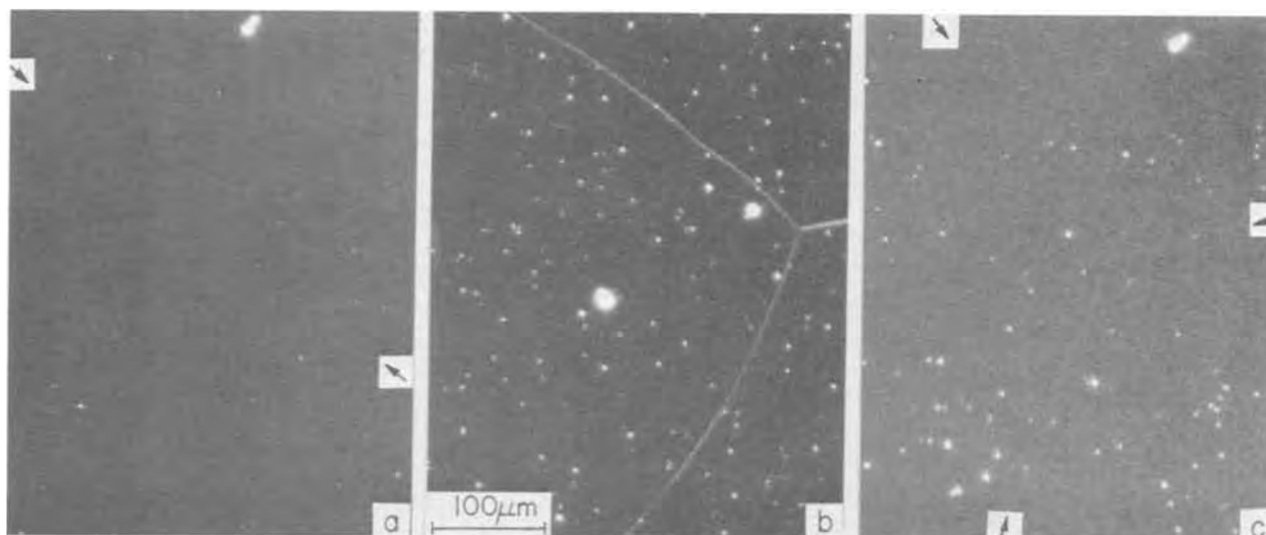

Fig. 3. Dark field optical micrographs of specimens: (a) as electropolished, (b) after anodizing 30 min, (c) zone-refined aluminum after anodizing 84 sec. Arrows indicate positions of faintly visible grain boundaries.

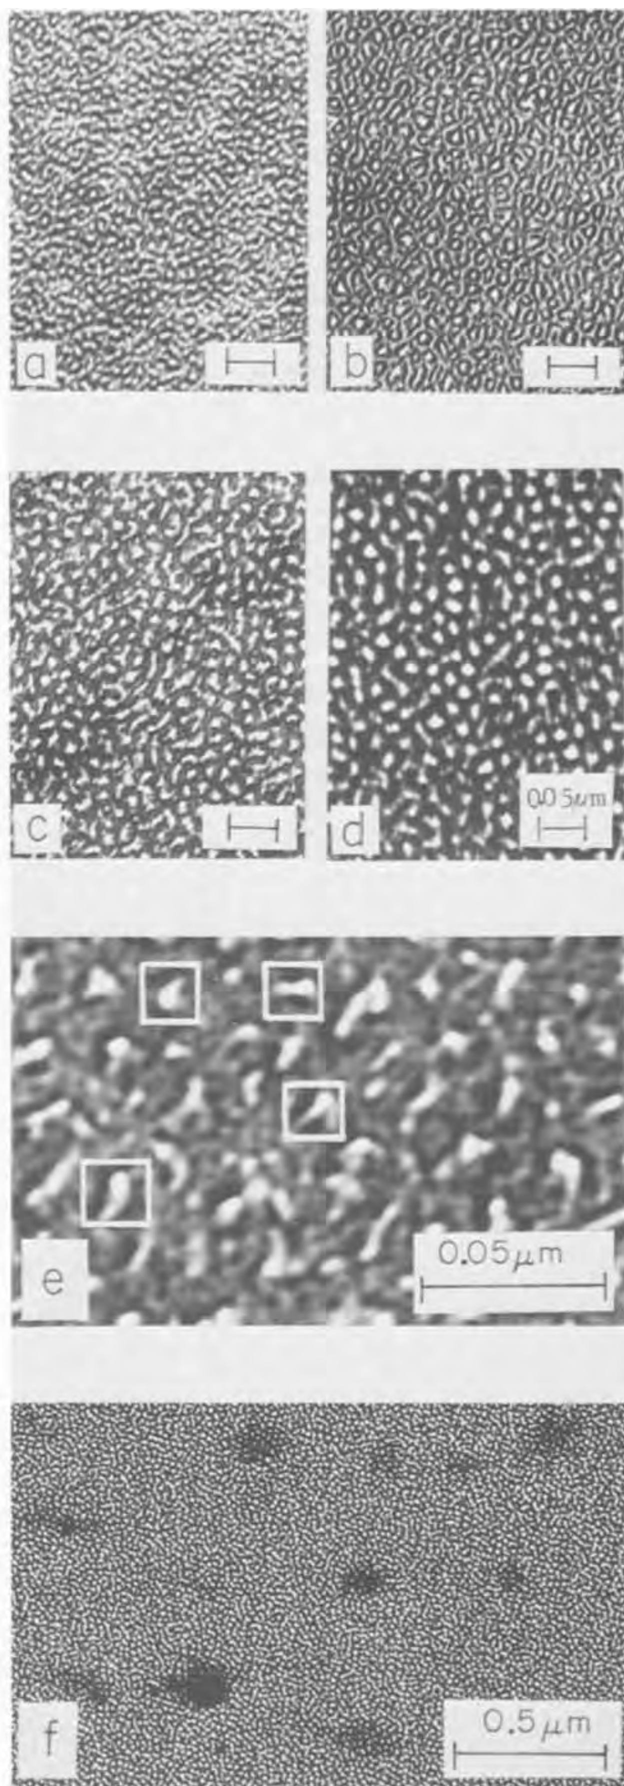

Fig. 4. Transmission electron micrographs at 100 kV of films formed for various times. (a) 15 sec, (b) 25 sec, (c) 84 sec, (d) 150 sec, (e) 25 sec at higher magnification showing the details of the channels in the film, (f) 84 sec at lower magnification showing breakdown-repair events.

major channels after 150 sec were approximately those expected from Wood and O'Sullivan's figures (3, 9) for the classical pore structure at the present cell voltage. The channel density was about half the value observed at 15 sec (just after reaching the voltage plateau) (Fig. 4a). The density at 15 sec was approximately 7×10^{11} cm^{-2} both in transmission (Fig. 4a) and in the channel mouths visible on the external surface replica (Fig. 6a); this density was retained at the external surface, as seen in the 900 sec film (Fig. 6b) where the only substantial change from Fig. 6a was that a few of the channel mouths were enlarged. These observations indicated that the origin of the change in channel density seen in transmission was that certain channels ceased to grow and thus yielded insufficient contrast to be visible after the film thickened. The density of active channels could not be determined from the dimensions of the pattern in the film-underside replicas (Fig. 6c and d) because it was not possible to make a clear distinction between the bases of active cells and residual breakdown-repair events.

The over-all view given by these observations is that film structure evolved toward the classical model but was perturbed and modified as a result of the breakdown-repair events. It appeared that in the early part of the cell voltage plateau ($t < 25$ sec) many small events were occurring more or less simultaneously all over the film but later (84-1800 sec) the events were multiple or clustered and occurred intermittently at various locations.

Elementary breakdown-repair process.—The interpretation of the basic processes occurring in the present work makes use of the ideas derived from previous porous-film studies cited in the introduction. It is supposed that a system of channels (not necessarily straight) is present and the film is growing continuously through a 10 Å/V barrier layer at the bases of these, as in "normal" growth of a porous film. In breakdown, certain channels become extended near to the metal interface (Fig. 7a) (usually at some angle to the normal), and this breakdown is followed by rapid repair in one of the ways indicated in Fig. 7b. In event 1, the repair current is supposed limited by channel resistance. In event 2, there is no such limitation and hemisphere growth proceeds as rapid formation of a barrier layer film at constant voltage to a limiting thickness h_c of 13-14 Å/V determined by the instantaneous cell voltage. The hemisphere as formed, before protracted current decay, is tentatively viewed as compact. If the passage of the high local repair-current density initiates a subsequent breakdown, the result will be a multiple event consisting of overlapping hemispheres. Figure 7b, event 3, shows a double event. The topography of the larger ($\sim$ 0.1 µm) events in the film underside, as in Fig. 6c and d, is consistent with the interpretation that they are clusters of smaller units.

If the cell voltage remains constant as on the plateau of Fig. 1, the film at hemispheres 2 and 3 can suffer no immediate further growth but must await decay of the current at their channels and extension of these by some field-assisted dissolution process to reduce barrier-layer thickness to 10 Å/V. During this short period before normal film growth at the repair hemispheres resumes there is normal continuous film growth at the bases of the other channels, as in Fig. 7c. There is thus a leveling effect on the film underside profile tending to keep film growth relatively uniform.

A special mechanism for the breakdown event depicted in Fig. 7a is not required. This event may be viewed as a condition where the film-dissolution rate at the channel base has jumped ahead of the film-growth rate instead of keeping pace with it as in continuous film growth, *i.e.*, the film thickness at the channel base has undergone a large fluctuation from

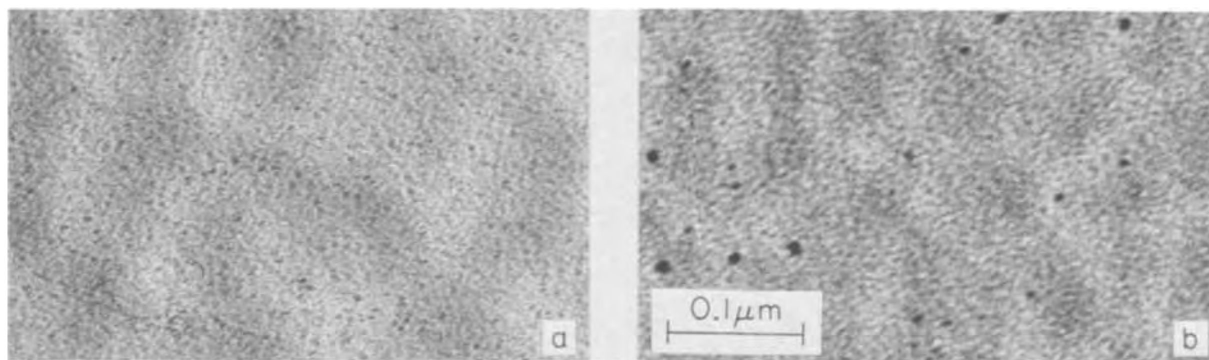

Fig. 5. Single-stage Pt-shadowed carbon replicas of external film surface after (a) 25 sec and (b) 15 min anodizing.

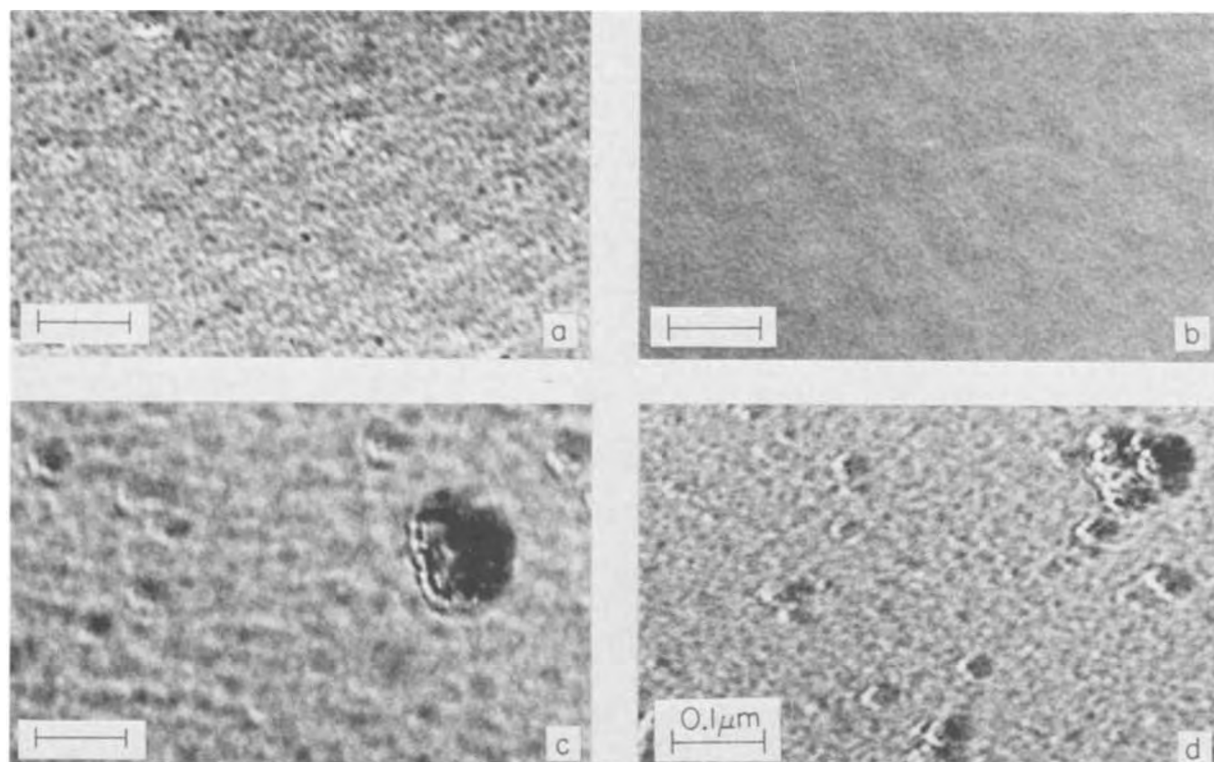

Fig. 6. Replicas of film at metal interface after (a) 15 sec, (b) 25 sec, (c) 300 sec, and (d) 900 sec.

the normally self-regulated value h_p, so that breakdown is not seen as representing a basically new or different process. The breakdown event itself was not observed directly in this work, but micrographs of such a process (the formation of channels extending from the base of a large pore) have been shown by O'Sullivan and Wood in sections of a film formed at 115V in phosphoric acid when the voltage was reduced to 85V (9). Since channel-base dissolution is viewed as field-assisted or associated with the passage of current, the schematic of breakdown in Fig. 7a assumes a small ion current in the film.

The nature of the breakdown process which initiated the observed pits is not clear. It is to be noted that in addition to the relatively few repaired pits detected by scanning microscopy the presence of an undetermined number of much smaller size was indicated in the replicas. This was deduced from the distinctly angular outlines of some of the repair events (several are visible in Fig. 6d). The angularity could have arisen if there had been a brief period of metal dissolution beneath the film yielding a small geometric pit which was then repaired, as indicated schematically in Fig. 8. Some nonangular events may also have involved pitting before repair. In experiments in progress in which Cl^- is added to the acid, a breakdown-pitting-repair process is readily identified and the film formation efficiency is found to be lower, as required if part of the impressed current is used for metal dissolution. Even for the sulfuric acid without additions, metal dissolution is thought to have consumed a significant fraction of the impressed current. Recent studies by the oxygen nuclear microanalysis technique have indicated that in sulfuric acid anodizing there is a substantial direct dissolution current (22).

Breakdown and film structure.—A schematic view of how breakdown is related to the appearance of pores and channels in transmission is given in Fig. 9. The occurrence of individual breakdown-repair events at pores B, D, C is represented by the segments running at an angle to the normal, the straight segments at the bases of these pores representing the resumption of continuous growth. The breakdown at C had caused it to advance ahead of B which then became inactive. As viewed in transmission normal to the film (*e.g.*, Fig. 4d), A and E would appear as rounded pores and C and D as elongated ones and B would be elongated with somewhat lower contrast. The nonuniform spacing of these is implied in Fig. 9. The channels F-K which

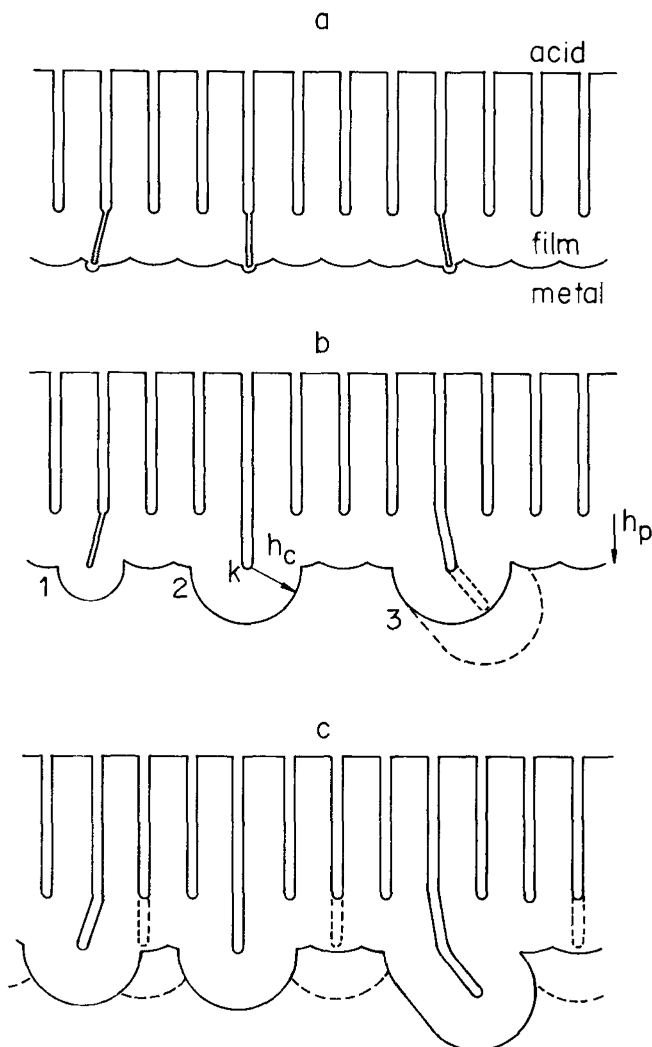

Fig. 7. Schematic of breakdown-repair. (a) Breakdown at three channels. (b) Three forms of repair event (the volume change associated with hemisphere formation is not represented). (c) Normal film growth continuing at the bases of some of the other channels; the repair hemispheres, having reached limiting thickness, h_c, have temporarily stopped growing.

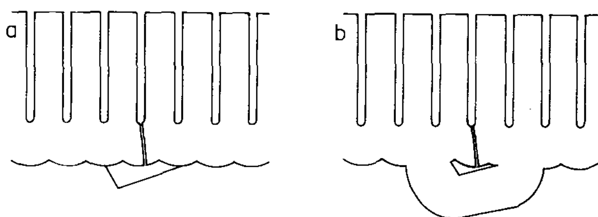

Fig. 8. Schematic of pitting-repair. (a) Small geometric pit growing beneath the film. (b) Film just after reanodization of the surface of the pit.

became inactive at an earlier stage would appear as small spots of low contrast if visible above the background. The distribution of pores and channels in the transmission image for anodizing times ≧ 84 sec was apparently often related to the processes occurring in multiple not individual breakdown repair events and is not interpreted in Fig. 9. The microscopic evidence for jogging or sloping of pores indicative of the individual breakdown-repair processes visualized is best seen in the 25 sec film, a high magnification transmission view of which is given in Fig. 4e. In this, a number of pores (boxed) can be seen with rounded central regions plus lower contrast tails (sometimes terminating in a small low contrast satellite spot) as expected for a pore consisting of a long straight section and a short inclined one. The tails are usually associated with a distinct dark border indicative of the extra thickness provided by the repair hemisphere.

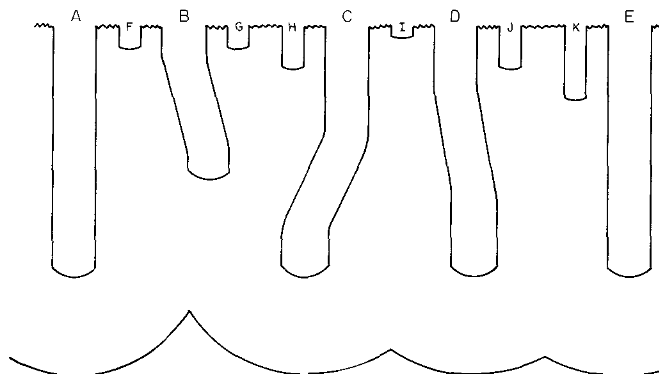

Fig. 9. Schematic of the structure at the base of the film illustrating the interpretation of the appearance of the pores in the transmission micrographs.

Remarks on mechanisms.—The high incidence of breakdown was not unique to the surface preparation used here as shown by observations, to be described subsequently, of films formed after preparing the surface by several different methods. In view of this and of the result that breakdown sites were not necessarily associated with defects in the substrate, the incidence of breakdown is regarded as the consequence of a tendency inherent in the film growth process itself. Given the present limited knowledge of the mechanisms of film dissolution, only rather general notions and plausibility arguments can be dealt with.

It seems useful to view breakdown as related to the phenomenon of pore initiation (*i.e.*, channel formation) in a compact film on aluminum when the forming field falls to a sufficiently low value, as in constant voltage anodizing with protracted current decay (11). The breakdown process in a film containing channels, as represented in Fig. 7a, may be viewed as initiation of "pores" in the compact film at the channel bases. Now in constant current anodizing, use of a low forming C.D. yields a lower average forming field throughout the anodizing and thus is according to the view presented more favorable for film dissolution. It is necessary to postulate that the tendency to form and extend channels is always present from the start of anodizing in sulfuric acid and that it is strong enough at the lower C.D. used here to produce breakdown of the type shown in Fig. 7a. One factor conceivably significant at low plateau voltages where channels are narrow is the formation of constrictions in certain channels by mechanical readjustments to volume changes associated with the formation of new film at the base of the old; this could cause channel resistance, normally negligible, to rise and the forming field at the base to fall.

In considering any effects produced by the repair event, it appears that despite the possibly high local C.D. associated with it local heating was not a major factor in this work. In forming at higher C.D. and higher cell voltages, it is known that there is significant bulk heating, recently measured for compact films on aluminum (23, 24), and that breakdown-repair can be accompanied by local heat input rapid enough to produce local crystallization of the amorphous film, which requires a temperature >600°C (24). The nature of the heat flow problem, pointed out by Young (25), is that the heat flow path to the substrate is so short that there is rapid heat transfer and little temperature difference across the film and normally

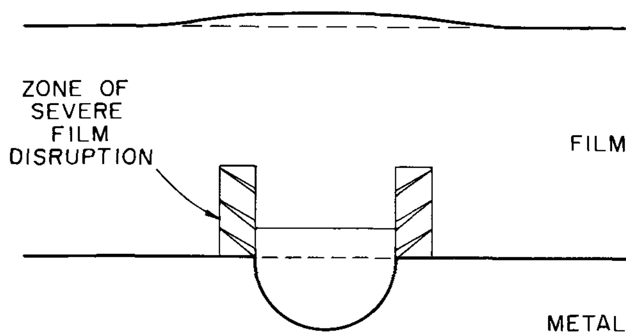

Fig. 10. Schematic of film disruption produced by punching action of repair hemisphere.

film and substrate heat up together, as recently verified by detailed calculations for tantalum (26). The creation of a hot spot requires unusually fast local heat input. For a rough estimate of local temperature rise in the present work, heat input was considered localized at point K in Fig. 7b and the Joule heating idealized in terms of a continuous point source (in an infinite medium) (27) operating long enough to form the repair hemisphere. The hemisphere is so small that even with the choice of a high rate of charge input and a short pulse, *e.g.*, 1 msec, the local temperature rise estimated was negligible.

If local heating is eliminated, any perturbation of the film by the repair event is to be sought in a mechanical process. This is likely to originate in the volume change involved in converting the hemisphere of Al to Al_2O_3, which is 50-60% depending on the value used for oxide density. This volume change must be taken up by forming a thickness of oxide greater than that of the metal from which it formed. The repair hemisphere at the base of a pre-existing film thus tends to force the overlying film outward. To the extent the hemisphere can be idealized as a punch acting on the overlying cylinder of film, it will disrupt the film along the boundary of this cylinder, as represented schematically in Fig. 10. The film above the hemisphere is a low-density solid containing channels and the nature of its response under these circumstances is not clear. However, one can visualize not only consolidation processes (closing of channels) occurring but also something like formation of a conical crack within the film near its base or of short oblique cracks in the shear zone. It is assumed a crack would not persist as such but be converted into a string of discrete channels by chemical and mechanical processes in the course of film growth. A mechanical disturbance of the film could account for (*i*) the tendency of the repair event to trigger additional breakdowns at its periphery and so produce the multiple events observed; (*ii*) the initiation of a pit. The scheme of Fig. 7a does not predict breakdown extending to the metal-film interface and initiating a pit, but these would be accomplished by the formation of a crack, as in Fig. 10, which intersects an existing channel and creates a continuous path of electrolyte extending to the metal. Note that the mechanical effect is seen not as the cause of the original breakdown but as a product of its repair. Recent studies on silicon crystals have made use of x-ray topography to show that tensile stress gradients were not the cause but the result of film "breakdown" (28).

In addition to calling attention to the role breakdown-repair can play in the evolution of film structure and to certain features worthy of close study, the thrust of the present work is that breakdown of an anodic film (including pit initiation) may occur continually at lower C.D. even when there are no gross manifestations of film failure or pitting, and film stability depends on the efficacy of repair. This notion is likely to be applicable to other anodic processes.

Some Aspects of the Chemistry of Tin Sensitizing Solutions

N. Feldstein,* J. A. Weiner, and G. L. Schnable*

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

In the electroless plating of dielectric substrates, sensitization and activation pretreatments are used to provide catalytic sites. The presence of the catalytic sites provides a path for the initiation of the electroless plating process. Based upon findings in this laboratory, a new sensitizing composition containing tin(II) and tin(IV) compounds was developed. This sensitizer was found to be particularly useful in the case of hydrophobic surfaces, and has resulted in good uniformity of metallic coverage on hydrophobic surfaces. In preparing the final sensitizer composition, the use of aged stannic chloride solution was responsible for the improved performance. The present investigation reveals the various chemical changes taking place during the aging of stannic chloride solution. Based upon the current findings, it is believed that during the aging process, a slow formation of a β-stannic acid takes place. This material is a polymeric form, which causes a light scattering effect to take place. It is the presence of β-stannic acid and its interaction with tin(II) that accounts for the improvement in sensitizer performance.

It has been demonstrated (1-3) that contact angle measurements can be an effective technique by which sensitizer solutions may be evaluated. It was also demonstrated (1, 2) that the addition of stannic compounds to tin-type sensitizers can have a major influence on the effectiveness of such solutions, especially when hydrophobic substrates are employed. The results obtained (1, 2) employed sensitizers prepared by aging the stannic chloride stock solution prior to mixing with $SnCl_2$ solution. Specially prepared and aged (4-6) stannic chloride solutions are most effective when added in low concentrations to solutions for the sensitization of dielectric substrates. By contrast, the stannic chloride normally present in typical stannous chloride does not result in improved wetting in spite of the fact that it is present in the same approximate concentration range as the added aged stannic chloride concentrations.

However, according to Cohen *et al.* (7, 8) the presence of stannic ions in conventional sensitizers ($SnCl_2$/HCl) constitutes the basis for a proposed mechanism of sensitization. Employing the Mossbauer spectroscopy of tin, a model based upon colloidal stannic hydroxide (hydrated oxide) with bound stannous ions on the colloid surface was proposed. This colloid is present in bulk solution as well as on the sensitized surface. Sard (9), using electron diffraction had shown that sensitized films derived from conventional $SnCl_2$ sensitizers are adsorbed clumps of material several hundred angstroms in diameter. Luce *et al.* (10) and Drotar *et al.* (11) also described sensitizers in which excess stannic chloride was added to conventional sensitizer media ($SnCl_2$/HCl). However, in all cases, no attempt was made to precondition the stannic solution while in the present work, the stannic halide solutions are first prepared, allowed to age, and then mixed with the stannous chloride solution. Bernhardt (12) described a sensitizer in which stannic chloride was incorporated into a sensitizer media, and the final solution was permitted to age for about 2 weeks before use. While this procedure provided improvement in performance, the approach was reported to be limited to solutions in which the acidity content is relatively low. More recently, Kenney *et al.* (13) have indicated that colloidal suspensions of tin oxides or iron oxides can wet hydrophobic surfaces; however, details related to solution preparation are not at present available. In this paper, the aging phenomenon of the stannic chloride solution has been examined in greater depth as related to the sensitization process. Based upon these findings, a model accounting for the effect(s) of stannic ions (1, 2) in tin sensitizers is proposed.

Key words: sensitizer, aging of stannic solutions, electroless plating.

Experimental Procedures

Chemicals and solutions.—Most of the common chemicals used throughout this investigation were Baker reagent grade. The less common chemicals were c.p. grade. The acids used were Mallinckrodt electronic grade. The water used was deionized and then distilled.

Contact angle measurements and substrate preparation.—The procedure adopted was to measure the contact angle following the sensitization step. Details for the preparation of substrates, and for substrate treatment have been described in detail previously (2).

Spectral absorbance.—The spectral absorbance measurements in the visible range were made using a Beckman DB-G spectrophotometer. In all cases, air was the reference.

Conductance measurements.—Conductance measurements were made using a Beckman Type RC 16B2 conductivity bridge. The conductivity cell used had a cell constant of 1.0 cm^{-1}, and all measurements were taken at 23° ± 1°C.

pH measurements.—These measurements were made using a Corning pH/Controller, Model 10-C.

Nephelometric measurements.—Nephelometric measurements were made using a Coleman Model 9 Nepho-Colorimeter. The reference standard used was Coleman Nephelos Standard 21. A 25-mm diameter immersion well and 19-mm diameter cells were used. The null reading method for total nephelos was employed, as suggested in Coleman Manual D-202D.

Results and Discussion

In the course of this investigation, it became apparent that the aging of stannic chloride solutions plays a major role in the sensitization process. Although the chemistry of aging stannic solutions was a subject of research at the beginning of the 20th century (14), some of the available references are vague. In the following section, certain aspects of the aging process and of the interaction of stannic-stannous components are reviewed as an introduction to the model proposed.

On the Aging of Stannic Chloride Solution

It was previously demonstrated (1, 2) that the extent of lowering of the contact angle after sensitization (for solutions having stannic and stannous together) is greater than either of the corresponding values resulting from immersion of hydrophobic substrates in stannic or stannous solutions, respectively. This observation suggests that some interaction may exist between the stannic and the stannous components. To test whether this interaction is unique to the tin(II)/tin(IV) system, the results of Tables I and II are submitted. In Table I, the contact angle was examined upon replacement of the stannous ion by an equivalent concentration of other divalent ions while holding the concentrations of aged stannic chloride, sodium chloride, and hydrochloric acid at fixed values. As seen from Table I, in all cases except for the incorporation of stannous chloride, the resulting contact angle is either the same as the control solution (7.5×10^{-3}M $SnCl_4$, 2M NaCl, and 4.7×10^{-1}M conc. HCl) or greater. In view of these results, it appears that the interaction between the stannous and stannic ions is of specific chemical nature rather than a coulombic type interaction between the stannic ions and the divalent ions added. Further examination of these results shows that the divalent salts added may be divided into two categories. In the first category ($MnCl_2$ $NiCl_2$,$Co(NO_3)_2$, and $CuCl_2$) the resulting contact angle is either the same or slightly greater than that of the control stannic solution, while in the second category ($MgCl_2$, $ZnCl_2$, and $PdCl_2$) the resulting contact angle values are considerably greater than the control value (48 degrees). Poor wetting has resulted when employing these solutions. The reasons for this behavior are not apparent. However, a combination of stannous chloride and zinc chloride with added aged stannic component provided good wetting and good plating uniformity of subsequently applied electroless deposits. It would thus seem that the interaction of stannous/stannic is very strong in comparison to the zinc/stannic interaction.

In Table II the resulting contact angle is shown as varying with the addition of tetravalent ionic salts to a fixed conventional-type sensitizer solution ($SnCl_2$/HCl). As seen from Table II, there is a significant lowering of the contact angle (55° *vs.* 67° for the control solution) only in the case of $SnCl_4$. These results further support the previous conclusion that a unique chemical interaction between the stannic and stannous ions probably accounts for the improved effectiveness of the tin sensitizer solutions.

Table I. Contact angle[a] variations vs. divalent salts used

Salt	Contact angle (degrees)
None	48
$MnCl_2$	50
$NiCl_2$	53
$Co(NO_3)_2$	55
$CuCl_2$	49
$MgCl_2$	62
$ZnCl_2$	72
$PdCl_2$	71
$SnCl_2$	27

[a] All solutions composed of: 7.5×10^{-3}M $SnCl_4$, 2M NaCl, and 4.7×10^{-1}M HCl to which 1.3×10^{-1}M of divalent salts were added. Measurements were made on AZ-1350 resist.

Table II. Contact angle[a] vs. tetravalent salt[b] in sensitizer[c]

Salt	Contact angle (degrees)
None	67
ZrF_4	68
$Th(NO_3)_4$	66
$Ce(NH_4)_2(NO_3)_6$	69
$SnCl_4$	55

[a] Measurements were made on AZ-1350 photoresist.
[b] Solutions of 10^{-2}M Zr, Th, and Ce were aged 24 hr. The $SnCl_4$ solution (0.5M) was aged about 1 week.
[c] Final composition used composed of 1.3×10^{-1}M $SnCl_2$, 4.7×10^{-1}M HCl, and 1.0×10^{-2}M of tetravalent salt.

From the initial discovery of the improved sensitizer composition, it has been apparent that aging of the stannic chloride solution is an essential factor responsible for the improvement. In order to gain a better insight into the aging phenomenon and its role in the sensitization process, the data of Fig. 1-3 and Table III are submitted.

Figure 1 shows the variations in contact angle as aging (at room temperature) of the stannic chloride stock solutions takes place. In all cases, it is apparent that the contact angle decreases as the stannic chloride stock solution is allowed to age. Moreover, decreasing the concentration of the stannic chloride stock solution provides a more rapid and effective aging process.

In Fig. 2 the absorbance spectra of the tin solutions in the near ultraviolet range are shown. As seen, the

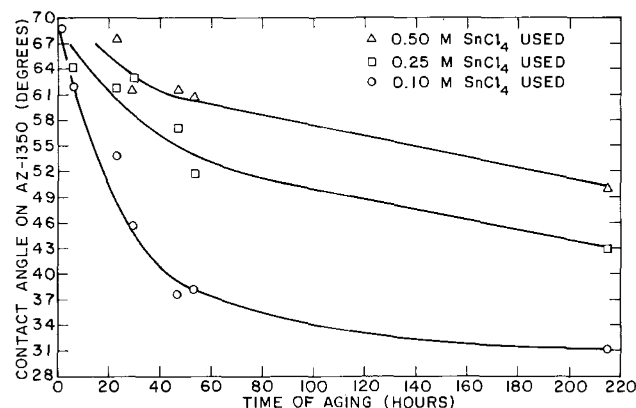

Fig. 1. Contact angle variations vs. aging time on AZ-1350 resist. Solutions prepared composed of 0.47M HCl, 0.13M $SnCl_2$, and $7/5 \times 10^{-3}$M $SnCl_4$.

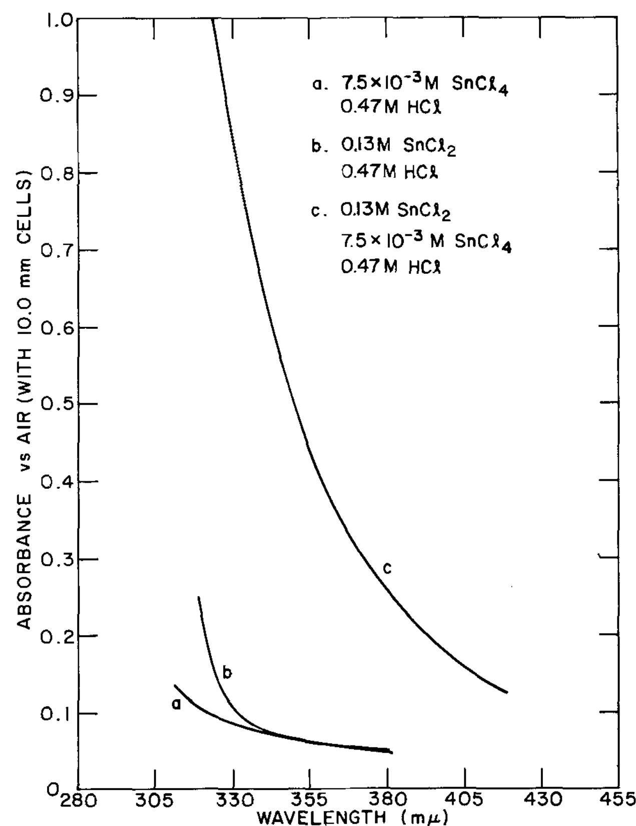

Fig. 2. Absorbance vs. wavelength for stannous, stannic, and mixed tin solutions.

resulting absorbance values of the combined solution of stannous and stannic components is nonadditive in comparison to the absorbance curves for the two components individually. This behavior is consistent with the previous observation by Browne *et al.* (15) on the optical interaction of stannous and stannic ions.

Craig *et al.* (16) suggested that the intense nonadditive adsorption of light by systems containing an element in two different oxidation states may be regarded as being due to the vibration of electrons between the atoms in the two different oxidation states. Other systems reported (17, 18) to exhibit this effect are: Fe(II)/Fe(III), Cu(I)/Cu(II), Ti(III)/Ti(IV), Tl(I)/Tl(III), Sb(III)/Sb(IV), and others. More recently, an extensive review related to this broad phenomenon was made by Allen and Hush (18). Hush designated the above systems as "homonuclear intervalence-transfer systems." It should be noted that the optical interaction (Fig. 2, curve C) takes place only under specific conditions. The mixed complex which forms may be completely dissociated upon the addition of complexing agents for either the stannous or stannic ions. A typical complexing agent is the chloride ion. Complementary to the results of Fig. 1, Fig. 3 is provided in which the absorbance of sensitizer solutions was monitored as the continuous aging of the stannic chloride stock solutions was taking place. As the aging process for the stannic solution proceeds, the absorbance of the sensitizer solutions is increased, but eventually levels off. The results of Fig. 3 further support the advantages of using aged dilute stannic chloride stock solutions, as this provides a more rapid aging, and a more effective sensitizer solution. From the results of Fig. 1 and 3, it is believed that a colloidal specie(s) (whose predecessor is stannic chloride) is formed during the aging process. The presence of such specie(s) can provide the improvement in the wetting process, and also in the formation of a colored stannous-stannic complex. The formation of such complex may be inhibited in bulk solution if excess sodium chloride is added (17); however, the improvement in the sensitization process is retained. Further examination of the results of Fig. 1 and 3 suggests that a reciprocal relation exists between the measured contact angle and solution absorbance (for the conditions examined without excess sodium chloride) during the different stages of the aging process. Specifically, as the contact angle values decreased, the solution absorbance values increased. The existence of this correlation (in the absence of excess chloride) justified further investigation in which only spectral absorbance measurements were taken. From the reciprocal relationship, the trend in spectral absorbance may be used in estimating the contact angle and hence the effectiveness of the sensitizer solution(s). Figure 4 shows the spectral absorbance of sensitizer solutions made from stock stannic

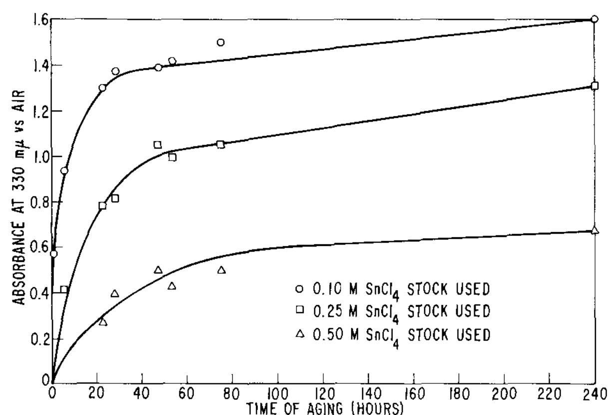

Fig. 3. Absorbance vs. aging of stannic solutions. Solutions prepared composed of 0.47M HCl, 0.13M $SnCl_2$, and 7.5×10^{-3}M $SnCl_4$. Cell length = 10 mm.

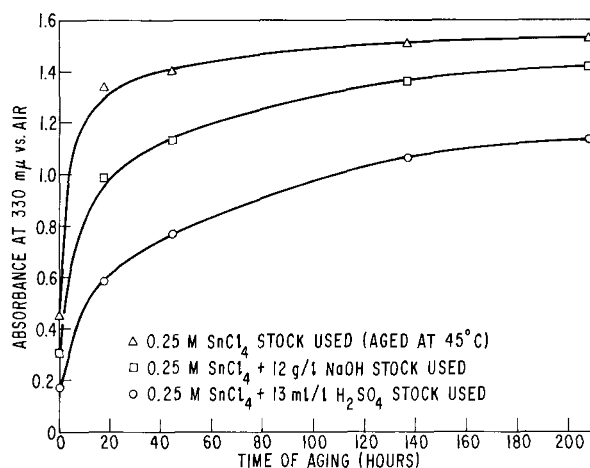

Fig. 4. Absorbance vs. aging condition of stannic solutions. Solutions prepared composed of 0.47M HCl, 0.13M $SnCl_2$, and 7.5×10^{-3}M $SnCl_4$ Cell length = 10mm.

chloride which has been aged under varied conditions. As seen, aging of stock solution (0.25M $SnCl_4$) at 45°C provides an improvement in comparison to aging the same solution with added alkali or acids, or to aging at room temperature (see Fig. 3). Furthermore, the addition of alkali provides a slight accelerating effect of the aging in comparison to the case in which acid was added. Attempts to age the stannic chloride (0.25M) in aqueous media having a higher acid content (*e.g.,* 10*N* HCl, H_2SO_4, or HNO_3) showed that the aging process is totally inhibited. Sensitizer solutions made by this approach did not provide the improved wetting characteristics.

In Table III, the effectiveness of aging condition and concentrations is demonstrated. In order to determine the effectiveness of the aging condition, the concentration of aged stannic chloride necessary to give a fixed absorbance value (0.72 absorbance) was determined.

From these results, it is apparent that more effective aging is carried out at higher temperatures and at lower stannic concentrations. Under such optimized conditions, less of the aged stannic chloride solution is required in order to yield a given absorbance level or a specific wetting characteristic. This observation seems to be consistent with prior reports on the hydrolysis of stannic solutions. Collins *et al.* (19, 20) have demonstrated that the extent of hydrolysis for stannic chloride solutions is decreased as the concentration of the tin is increased. Specifically, the authors (20) reported 94 and 72% hydrolysis for 0.197*N* and 0.396*N* stannic solution which were allowed to age at 25°C. Mellor (14) reported that heating of stannic solution does accelerate the hydrolysis. However, caution should be exercised as prolonged heating of such solution(s) produces a heavy precipitation which is probably due to the formation of stannic hydroxide (hydrated stannic oxide). This same precipitation was also found during the aging (at room temperature) of stock solutions having a stannic chloride content below about 0.1M.

Table III. Effect of temperature and concentration on rate of aging of stannic chloride solutions

Molar concentration of $SnCl_4$	Aging temperature, °C	Concentration used,[a] molar
0.50	80	6.0×10^{-3}
0.50	45	25×10^{-3}
0.25	80	2.8×10^{-3}
0.25	45	5.2×10^{-3}
0.10	45	3.6×10^{-3}

[a] Concentration required to give absorbance of 0.72 ± 0.01 *vs.* air at 330 mμ. In all cases $[Sn^{+2}]$ = 0.13M and [HCl] = 0.47M. Cell length = 10.0 mm.

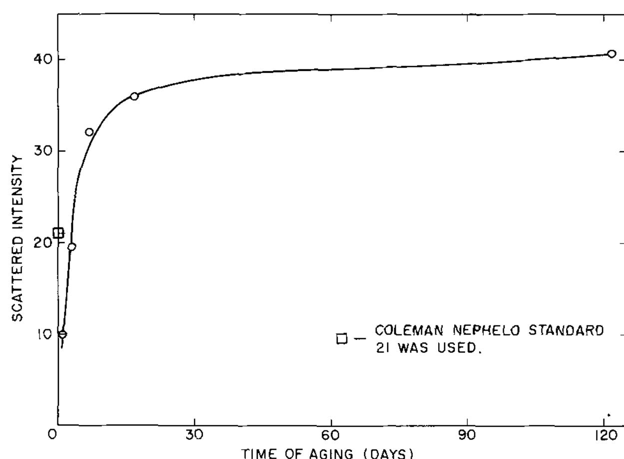

Fig. 5. Scattered intensity vs. aging time of 0.50M $SnCl_4$ solution.

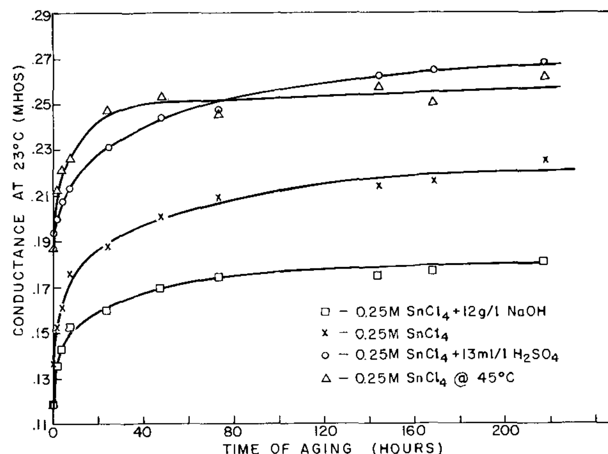

Fig. 6. Conductance variations vs. aging of stannic chloride solutions.

In Fig. 5, the variation in turbidity taking place during the aging process for a stannic chloride stock solution is shown. The results of Fig. 5 closely resemble the general characteristics of Fig. 3 and 4. With the increased turbidity taking place during the aging process, there must be an increase in the number and/or size of colloidal particles which cause the Tyndall effect. The colloidal particles are a polymerized specie(s) containing tin(IV). In a recent publication, Cohen *et al.* (7, 8) proposed a model for the mechanism of conventional sensitizers. In their proposed model, the presence of stannic hydroxide (or hydrated stannic oxide) colloids in bulk solution was invoked as being primarily responsible for the sensitization process. The stannous ions were reported bound onto these colloids in a compositional ratio of 1-tin(II) to 2-tin(IV).

Although the current report and the published work of Cohen (7, 8) both describe the presence of colloidal particles containing tin(IV), it should be apparent that these are different colloids. These two colloids, although their formulas are not known, result in different chemical and physical characteristics of the final sensitizer solutions. Moreover, the colloidal particles [polymerized specie(s) containing tin(IV)] present in the current system may be physically included with conventional sensitizer solution or be used prior to the immerison in the conventional sensitizers (2). In both cases good plating uniformity has resulted on hydrophobic surfaces. By contrast, the colloids present in conventional sensitizers proposed by Cohen *et al.* (7, 8) are not effective when used with hydrophobic substrates, and they are an integral part of the sensitizing media and cannot be separated from the stannous component.

In order to ascertain the nature of ionic reaction(s) taking place during the aging process, conductance measurements were made. Figure 6 shows the manner by which solution conductance varies with aging time. In all cases, independent of aging condition, solution conductance is increased in a manner which resembles the characteristics results of Fig. 3. In Table IV, the pH changes during the aging process are summarized for typical stannic chloride stock solutions. In all cases, there is an actual decrease in solution pH. The trend is in good agreement with the results of Gueron (21). Based upon the increase in hydrogen ion concentration taking place (Table IV), an estimate of change in solution conductance was made. Specifically, for a 0.25M $SnCl_4$ aged at room temperature, a 0.11 mho increase in conductance was anticipated. The experimentally found value (Fig. 6) was a change of approximately 0.09 mho. The difference between the experimental and anticipated values is probably due to the net effect of the hydrolysis reaction and the polymerization of the stannic ions. The latter effect decreased solution conductance. Furthermore, based upon the results of Table IV, it would appear that the number of hydrogen ions liberated, relative to the initial stannic ion concentration, is increased as the concentration of stannic ion is decreased. This observation further supports the optimized condition for aging stannic solutions. This relative ratio (last column of Table IV) is probably an average value, with individual aged stannic species having a greater or lower ratio than the average value.

The Proposed Mechanism of Sensitization

Before proposing a physical model that accounts for the improvements associated with the stannous-stannic sensitizer solution, a brief review of pertinent literature references and findings from this laboratory will be made.

1. As has been demonstrated in Fig. 2 and 3 of this paper, and in the reports by Browne (15), Craig (16), and Paul (17), there is an apparent chemical interaction between the stannous and aged stannic components resulting in a mixed complex. The mixed complex formed has been reported to have a fixed stoichiometric ratio of stannous to stannic ions. Specifically, Paul *et al.* (17) reported a 1:4 Sn(II)-Sn(IV) complex while Browne *et al.* (15) reported a 1:1 Sn(II)-Sn(IV) complex.

2. In a previous publication (2), it has been demonstrated that the aged stannic chloride may be either incorporated along with conventional type sensitizers ($SnCl_2$/HCl), or may be used as a separate immersion step prior to the immersion in conventional sensitizers. In both cases, equivalent results were obtained following the plating step.

3. As the concentration of aged stannic component (β-stannic acid) is increased to or above the approximate level of the stannous concentration, the uniformity of metal deposition is decreased. Although this type of composition is not used, it does reflect an interesting aspect of the mechanism of the sensitization process.

Based upon the findings of this investigation and previous reports on the subject of stannic chloride hydrolysis, the following key steps are proposed to ac-

Table IV. Effect of aging on the pH[a] of stannic solutions

[$SnCl_4$]	pH as prepared	Final pH	$\Delta[H^+]/Sn^{+4}$
0.10	0.94	0.52[b]	2.0
0.25	0.50	0.19[b]	1.3
0.50	0.38	0.06[c]	0.9
2.00	−0.05	−0.12[c]	0.08

[b] Aged for 30 days.
[c] Aged for 10 days.

count for the mechanism taking place during the sensitization process.

Case A: Immersion in aged stannic solution prior to immersion in stannous solution.—(*i*) Upon immersion in aged stannic solution, a retention, by adsorption or other mechanism, of the aged stannic component takes place on the dielectric surface. This adsorption step is an equilibrium reaction with some specie(s) existing in bulk solution. The active specie(s) is probably a β-stannic acid which is slowly formed during the aging process.

(*ii*) Upon immersion in stannous solution, the stannous ion is adsorbed at the interface. In fact, it is the presence of the β-stannic component at the interface that provides new boundary conditions which result in a new kinetic path for the adsorption of the stannous component on the surface. This path is probably the same chemical reaction which leads to the formation of the mixed tin(II)/tin(IV) complex. This reaction probably provides the driving force for the formation of a final stabilized surface layer consisting of both stannic and stannous components. In the formation of such a layer, the stannous component may have also replaced a fraction of sites previously occupied by the stannic component and/or be adsorbed in sites which were vacant at the conclusion of step (*i*).

Case B: Immersion in sensitizer solution composed of stannous and aged stannic components.—Under this condition, it is possible that the mechanism described in Case A takes place. It is also possible to postulate that the existing mixed complex tin(II)/tin(IV) is directly adsorbed onto the surface. This alternative, however, is unlikely in view of the fact that if the concentration of aged stannic component is made larger than the stannous component (approximately 1.5×), there is a deterioration in the uniformity of plating. This behavior is due to the fact that most of the stannous ions are tightly held in the mixed complex present in the solution phase and are not available for adsorption at the interface. This condition can be rectified by the addition of sodium chloride which causes a dissociation of the mixed complex, hence liberating "free" stannous capable of adsorbing at the interface. Alternatively, using the stannic component prior to the stannous immersion step also rectifies this trend. In subsequent studies (22), the results of surface characterization of sensitized layers using radiochemical tin-113 have been found to support the proposed mechanism. The results of the surface characterization also further distinguish between the current colloid and that proposed by Cohen (7, 8).

Conclusions

Aged stannic chloride solution has been shown to have a significant role in improving the performance of conventional sensitizer solutions. The aging process in the stannic halide solution is believed to be a slow transformation of an α-stannic acid to a β-stannic acid form (14, 19, 21). Such transformation is probably due to a water elimination reaction resulting in a general structure of the type (21)

$$(HO)_3\text{-Sn-}[OSn(OH)_2]_n\text{-OH}$$

where n may have values of 1, 2, 3, etc. reflecting the extent of polymerization. In the above structure some further water condensation may take place. The increasing β-stannic acid character of such solutions results in a Tyndall effect, probably due to the colloidal nature of the β-stannic acid. Furthermore, as the concentration of β-stannic component is increased, improvements in the sensitizer solution's wetting performance have resulted.

Conditions which optimize the formation of the β-stannic acid were found to be consistent with earlier reports on this subject. Specifically, acceleration in the aging process was found with increased temperature and/or decreased stannic concentrations. High acid content as well as high concentrations of sodium chloride were found to inhibit the α to β transformation. The transformation of the α-stannic acid to the β-stannic acid is generally irreversible under normal conditions. However, under those conditions in which the aging process is inhibited, some degree of reversibility of the β-stannic to α-stannic does take place.

Although the current work was focused upon the improvement of sensitizers on hydrophobic surfaces, it should be apparent that the current finding may be used for other processes in which it is necessary to convert hydrophobic surfaces to hydrophilic type. Hydrophobic surfaces immersed in aged stannic solution only were converted to hydrophilic type and this property was retained for at least several days.

The Use of Organic Additives to Stabilize and Enhance the Deposition Rate of Electroless Copper Plating

Leonard N. Schoenberg*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A persistent problem in the use of electroless copper baths has been their tendency to decompose spontaneously. Materials previously proposed as stabilizers have, in general, the undesirable effect of decreasing the plating rate of the bath. It has been found in the present work that the organic additive 8-hydroxy-7-iodo-5-quinoline sulfonic acid (HIQSA) not only stabilizes electroless copper baths but also enhances the plating rate by as much as 50%. The additive 2-iodo-3-pyridinol stabilizes the solutions but has little effect on the plating rates. An explanation for this behavior is set forth and is supported by the stabilizing effect, if any, of other organic additives with structures similar to HIQSA.

Interest in electroless copper plating has increased recently because of its use in the manufacture of printed circuits and its potential application to many other processes. A persistent problem in the use of these baths has been their tendency to decompose spontaneously. Many materials have been proposed to serve as stabilizers (1) but in general these have the undesirable effect of decreasing the plating rate of the bath. Okinaka and Blom (2) found that a large amount of methanol could stabilize electroless copper baths with only a minimal decrease in the plating rate. Another approach involves stabilizing a copper bath by the incorporation of less frequently used complexing agents (3). This paper discusses organic additives which stabilize electroless copper solutions not only without adversely affecting the plating rate but in some cases actually enhancing it. The use of thiourea and other compounds both to stabilize and increase the plating rate of electroless nickel baths has been reported by deMinjer and Brenner (4).

The organic additives chosen for study are shown in Fig. 1. All were obtained from Aldrich Chemical Company, Inc. and used without further purification. Most of the experimental work was carried out with 8-hydroxy-7-iodo-5-quinoline sulfonic acid (HIQSA). The other additives shown were surveyed because of their partial resemblance to HIQSA and their potential to support the proposed mechanism of stabilization-acceleration discussed in a subsequent section.

Determination of Bath Stability

Electroless baths often spontaneously decompose (*i.e.*, deposit metal) after a certain time whether or not they are in active use. Small metallic nuclei may form and initiate plating or decomposition may be started by random variables such as dust particles or other impurities. Thus decomposition time is variable and solutions prepared in identical fashion may have nonidentical lifetimes. It was decided that the best way to achieve consistent behavior and to determine the effect, if any, of an additive was to run stability tests at an elevated temperature with the addition of controlled amounts of impurities.

The composition of the electroless copper bath selected for study was 0.02M cupric sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$), 0.1M disodium ethylenediaminetetraacetate dihydrate ($Na_2EDTA \cdot 2H_2O$), 0.4M formaldehyde (added as paraformaldehyde), and sufficient sodium hydroxide to obtain a pH value of 12.8. Forty-five milliliter aliquots of the solution were placed in a 75°C constant temperature water bath.

To evaluate stabilizing additives, bath decomposition was accelerated by the following method. [A similar means of inducing decomposition of electroless nickel baths was used by Ramirez (5).] After a 5-min interval to allow the solutions to reach 75°, three small drops of an activating solution containing palladium were added. The activating solution is used in metalizing nonconductors. It is made by dissolving 1g of palladium chloride in 10 ml of concentrated hydrochloric acid and diluting to one liter. (Palladium activator can be carried over into an electroless copper bath during actual printed circuit processing.) At 75°C, an additive free bath decomposes instantaneously. However, with the addition of various organic additives bath life can be extended significantly as shown in Table I. The time to decomposition reported in Table I may vary depending on the time between bath preparation and testing, the exact bath composition (which fluctuates due to normal experimental error), and random variables such as dust particles, etc. The importance of Table I is to show that certain organic

Potassium iodide (KI)	0	2	2.5	2.5	—	—

additives markedly improve bath stability under accelerated decomposition conditions and therefore would be expected to improve stability under normal operating conditions as well.

It can be seen that two additives are highly effective in stabilizing the bath, namely, HIQSA and 2-iodo-3-pyridinol (IP). These were selected for further study. It can also be noted that iodide ion alone, in equivalent quantities, while it has some stabilizing influence cannot be considered an effective bath stabilizer.

Plating Rate Studies

Plating rate measurements were carried out on 0.002 in. thick copper rectangles of approximate dimension 1 × ½ in. The substrates were etched for 15 sec in 20% nitric acid, rinsed, activated for 1 min in the 0.1% palladium chloride solution, and rinsed again. This resulted in a reproducible metallic palladium surface for plating rather than a possibly variable surface of cuprous oxide. The substrates were held in a vertical position by Teflon holders. Plating was usually done from 90 ml aliquots of the various electroless copper solutions at room temperature. Plating times varied from 1 to 7 hr. The 7-hr plating experiments were done from 180 ml of solution to ensure a large excess of copper ions. The thicknesses of the copper deposits were determined by weight gain measurements making the usual assumptions that the deposit thickness is uniform over the entire surface and that the deposit density is that of bulk copper. The appearance of the copper is the same as that deposited from an additive free bath. No measurements of ductility or other physical properties were made.

The results with various amounts of HIQSA are shown in Fig. 2. The plating rates are plotted as the differences (in μM/hr) between an additive free bath and a bath containing a given amount of HIQSA. This is done to eliminate effects due to random variables such as the solution composition and age, exact room temperature, etc. Each point on the curve is an average of at least two determinations. The plating rate of an additive free bath is in the vicinity of 1 μM/hr so that the maximum of the curve represents an increase in plating rate of about 50%.

Less extensive data of the same sort for additions of IP are presented in Fig. 3. It can be seen that IP has much less accelerative effect on the bath.

Discussion of Results

To understand the action of HIQSA on an electroless copper bath, the effects of stabilization and acceleration must be discussed separately.

For an additive to be an effective bath stabilizer it must interact with at least two different kinds of impurities. The first type is ionic impurities such as Pd^{2+} which if reduced by formaldehyde to the metallic state could initiate electroless plating in the bulk of the solution. The second type is small metallic nuclei or cuprous oxide particles which may be formed in the solution as electroless plating proceeds.

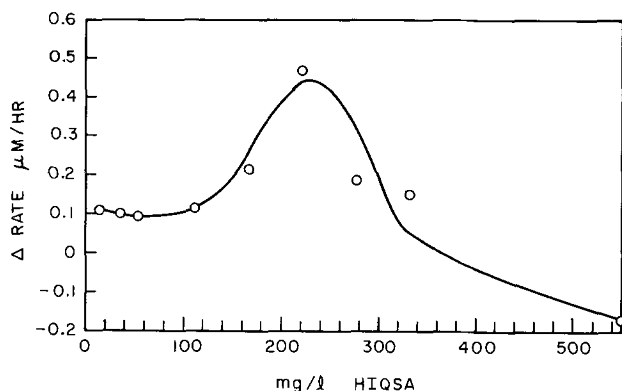

Fig. 2. Change in plating rate of an electroless copper solution (0.02M $CuSO_4 \cdot 5H_2O$, 0.1M $Na_2EDTA \cdot 2H_2O$, 0.4M HCHO, pH 12.8) with varying amounts of HIQSA.

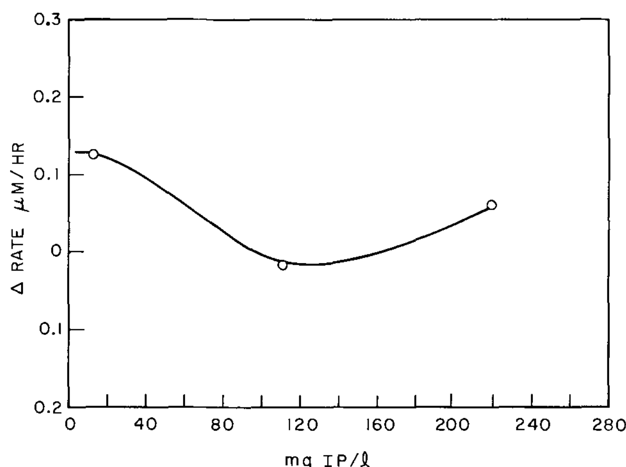

Fig. 3. Change in plating rate of an electroless copper solution (0.02M $CuSO_4 \cdot 5H_2O$, 0.1M $Na_2EDTA \cdot 2H_2O$, 0.4M HCHO, pH 12.8) as a function of added IP.

HIQSA may inhibit decomposition by the first type of impurity by using its nitrogen and hydroxide functions to form a chelate. This chelate contains the same type of linkage as those formed by metal ions and 8-hydroxy quinoline (HQ), a well-known sequestering agent and the parent compound of HIQSA (Fig. 4). The sulfonic acid group of HIQSA is responsible for HIQSA complexes being more water soluble than HQ complexes.

HIQSA may prevent decomposition of the bath by metal nuclei or cuprous oxide particles by being adsorbed through the iodide portion of the molecule (Fig. 5). We have previously shown that iodide ions in sufficient quantity can poison electroless copper baths (7). These strongly adsorbed species are thought to inhibit the kinetics of the electroless deposition.

Plating is not completely inhibited by adding the proper amount of HIQSA because it is not present in large enough quantities to poison the surface on which it is desired that plating occur, although larger amounts of additive do decrease the rate as expected. This is in agreement with the observations of Gutzeit (8), who in a discussion of electroless nickel plating states that the adsorption density of stabilizing ions is a direct function of the radius of curvature of the catalytic body so that small particles are more rapidly and com-

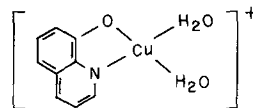

Fig. 4. Structural formula of diaquo 8-hydroxy quinoline (4)

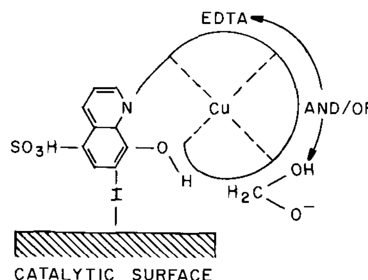

Fig. 5. Speculative schematic representation of the adsorption of HIQSA on a catalytic surface and subsequent bond formation to a chelated copper ion in the solution. The copper ion in solution is bonded to EDTA and/or methylene glycolate.

pletely poisoned. This observation is not elucidated further by Gutzeit. It is clear, however, that after plating has begun, the behavior cannot be explained by an area effect alone since if a large surface and a small particle are present in the same solution at the same time, they will be covered with the same number of adsorbed particles per unit area. The difference in poisoning of small and large surfaces must be due in some way therefore to the difference in their surface to volume ratios which can be expressed in terms of radius of curvature. Their surface energies or electrical potentials may be different, for example.

The accelerative effect of HIQSA in proper quantity may be explained by visualizing it adsorbed through the iodide atom on portions of the catalytic surface. The complexing part of the molecule is then extending into the bulk of the solution where it is able to form a bond to nearby chelated copper ions (Fig. 5). This would tend to accelerate plating by making it easier for the Cu^{2+}-ligand bond to be broken. When HIQSA is present in large quantities, however, it is able to poison the entire catalytic surface and electroless plating is slowed and finally stopped. (In practice, the addition of very large quantities of HIQSA results in the formation of a precipitate, presumably containing copper and HIQSA.)

The hypothesis discussed above is supported by the results with additives other than HIQSA. The additives that do not contain an iodide atom have not nearly as much stabilizing effect. The most striking example of this difference is HQSA, a molecule identical to HIQSA except for the absence of the iodine atom in the former.

The other molecule which has a large stabilizing effect is IP. This molecule, however, has much less accelerative effect (Fig. 3). This is consistent with the proposed explanation for acceleration since IP contains no adjacent nitrogen and hydroxide functions to enable it to chelate with a copper ion.

A more definitive explanation of the unique behavior of HIQSA could be obtained by a study of its effect on the current-voltage curves of the two half reactions. Information of this nature for an additive-free electroless copper solution of this type has already been obtained by Okinaka (9). The effect of various additives on the electrochemical potential of nickel and cobalt baths has been discussed by Feldstein and Lancsek (10).

Faster Plating Bath

Although electroless copper plating baths which plate at 1.0-1.5 μM/hr are fast enough for most applications which involve a subsequent electrolytic metalization, there are certain advantages to be gained in using a bath with a faster plating rate. Consequently some baths with higher copper concentrations than those described previously were investigated.

The most promising formulation consisted of 0.06M $CuSO_4 \cdot 5H_2O$, 0.3M $Na_2EDTA \cdot 2H_2O$, 0.4M HCHO, and NaOH sufficient to obtain a pH of 12.8. The change in plating rate of this bath as a function of HIQSA added is depicted in Fig. 6. It can be seen that the curve is of the same general shape as that of the less concentrated bath (Fig. 2). The maximum is at about 170 mg/liter of HIQSA and represents a plating rate of about 3.1 μM/hr. This bath was able to withstand 45 sec at 75° after the addition of $PdCl_2$. While not a long time, this is still better than the performance of a comparable additive-free bath. It is apparent that an electroless copper solution containing HIQSA could be tailored for speed or stability depending on the application for which it would be used.

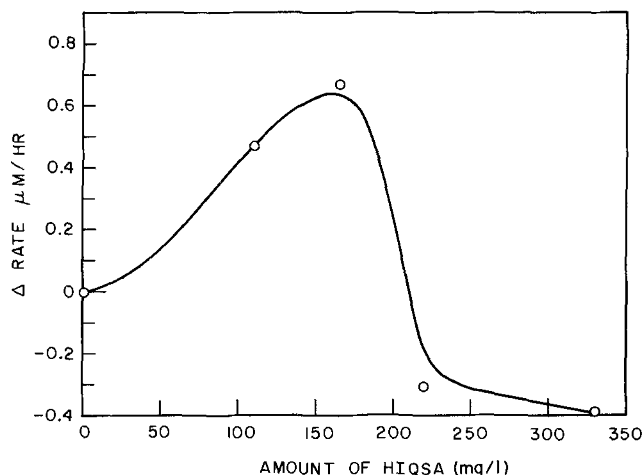

Fig. 6. Change in plating rate of a more concentrated electroless copper solution (0.06M $CuSO_4 \cdot 5H_2O$, 0.3M $Na_2EDTA \cdot 2H_2O$, 0.4M HCHO, pH 12.8) as a function of added HIQSA.

The Electroreduction of Beta-Aminoethyl Mercurials

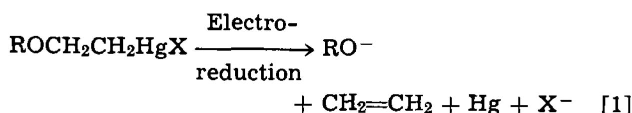
John H. Wagenknecht*

Central Research Department, Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

2-(Piperidino)-ethylmercuric chloride (I) and 2-(diethylamino)ethylmercuric chloride (II) are each reduced by two separate one-electron reductions in DMF or 50% ethanol. The products formed are the corresponding bis-2-aminoethylmercury compound and/or the secondary amine (piperidine or diethylamine) depending on the solvent and reduction potential. Only traces of tertiary amine were detected. Bis[2-(piperidino)-ethyl] mercury (III) is reduced to piperidine in 50% ethanol, but no reduction occurs in DMF.

Studies of the electroreduction of mercuric salt-olefin addition products have been reported by several groups (1, 2). Alkoxy- and hydroxymercuration products show electroreduction behavior similar to simple alkylmercuric halides (3) except that reduction leads to regeneration of olefin (reaction [1])



$$ROCH_2CH_2HgX \xrightarrow[\text{reduction}]{\text{Electro-}} RO^- + CH_2{=}CH_2 + Hg + X^- \quad [1]$$

under acidic conditions (2). The alkoxy- and hydroxymercuration products undergo two separate one-electron reductions just as the simple alkylmercuric halides. Aminomercuration products ($>N—CH_2CH_2HgX$), however, are reported to undergo only a single two-electron reduction (2). The products of that reduction were not reported.

Studies at this laboratory have shown that 2-(piperidino)-ethylmercuric chloride (I) and 2-(diethylamino-)ethylmercuric chloride (II) in fact do exhibit two one-electron polarographic reduction waves in aqueous alcohol, and the reduction products are similar to those obtained from oxymercuration products. The basic electroanalytical data and the results of macroelectrolyses of I, II, and bis[2-(piperidino)-ethyl] mercury (III) are reported in this paper.

Experimental

Literature preparations were used for the synthesis of 2-(piperidino)-ethylmercuric chloride (4), 2-(diethylamino)ethylmercuric chloride (4), and 1,4-dipiperidinobutane (5). Piperidine, diethylamine, ethylene, mercuric chloride, and N-ethylpiperidine were obtained commercially and used as received. Tetraethylammonium tetrafluoroborate was prepared from aqueous tetraethylammonium hydroxide and aqueous tetrafluoroboric acid. The water was stripped from the salt and it was then recrystallized from methanol. EtOH-water mixtures were made up from 200-proof EtOH and distilled water. The DMF (dimethylformamide, Fisher D-119) was distilled at reduced pressure from anhydrous $CuSO_4$ and then passed through a column of Linde 3A molecular sieves.

Polarograms were obtained with a Sargent Model XXI polarograph. A simple H-shaped two-electrode cell was used with the secondary electrode (and reference) being a saturated calomel electrode. The capillary constants were $M = 1.19$ mg/sec and $t = 9.0$ sec (open circuit, distilled water), and the mercury column height was 50 cm. Depolarizer concentrations were 1.0 mM with 0.1M $Et_4N^+BF_4^-$ as the supporting electrolyte.

Cyclic voltammetry was obtained at a hanging mercury drop electrode with a SCE reference electrode and platinum wire secondary electrode. The instruments used were a Wenking Model 66TS10 potentiostat, an Exact Electronics Inc. Model 505 function generator, and a Tektronix Type 502 oscilloscope.

Coulometry was carried out in a fine-glass frit divided three-compartment cell with a Pt foil anode, mercury pool cathode, and SCE reference electrode. The substrate concentration was 10 mM with 0.1M $Et_4N^+BF_4^-$ as the supporting electrolyte. A Wenking Model 66TA1 potentiostat was used to carry out the coulometry.

Macroelectrolyses were performed in a medium glass frit divided H cell with Hg pool cathode (7 cm diam) and Pt foil anode. The cell was cooled in a tap water bath at approximately 20°C. The cathode potential was controlled *vs.* a SCE reference electrode which contacted the cathode via a Luggin capillary. The cathode compartment volume was 200 ml and the anode compartment volume was 50 ml. The supporting electrolyte was a 1M $Et_4N^+BF_4^-$. The catholyte was stirred with a magnetic stirrer or overhead mechanical stirrer. Electrolyses were carried out with either a Chemical Electronics Corporation (1.6A model) or a Wenking (Model 60HU1/90) potentiostat.

The nmr spectra were obtained using a Varian T-60 nmr spectrometer and the gas chromatography was carried out with a F&M Model 720 gas chromatograph with a Model 1609 flame-ionization attachment.

Electrolysis of I in DMF.—Ten grams of I were added to the cathode compartment and the electrolysis was carried out at −0.9V *vs.* SCE. After 20 hr, the current was less than 10 mA and the electrolysis was stopped. A total of 0.0304 Faraday of electricity had been passed or 1.055 Faradays per mole of I. No N-ethylpiperidine or 1,4-dipiperidinobutane and only a trace of piperidine were detected in the catholyte by g.c. analysis. The DMF was distilled from the catholyte at reduced pressure and the residue was extracted with ether. The ether was stripped from the ether extract and the residue was stirred at reduced pressure (0.001 mm) to remove residual DMF. The residue was 5.0g (82%) of crude (nmr analysis) bis[2-(piperidino)-ethyl] mercury (III). This oil was distilled at reduced pressure (0.04 mm) boiling at 123°C with a slight amount of decomposition at the beginning of the distillation.

Anal. Calcd. for $C_{14}H_{28}N_2Hg$: C, 39.56; H, 6.64; N, 6.59. Found: C, 39.83; H, 6.89; N, 6.66.

The nmr spectrum (Fig. 4) consists of multiplets centered at $\delta = 1.15$ (4H, $—CH_2—Hg$), 1.45 (12H, methylenes not adjacent to N in the piperidine ring), 2.35 (8H, methylenes adjacent to N in the piperidine ring) and 2.75 (4H, $>N—CH_2—CH_2—Hg$). The satellites formed by splitting due to Hg^{199} are faintly visible in the spectrum.

A similar electrolysis in DMF carried out at −2.5V *vs.* SCE gave identical results with 1.04 Faradays of electricity passed per mole of I and a 91% crude yield

* Electrochemical Society Active Member.

Key words: β-aminoethyl mercurials, polarography, coulometry, cyclic voltammetry, macroelectrolyses.

of III. Again, only a trace of piperidine[1] was detected by g.c. analysis and no N-ethylpiperidine or 1,4-dipiperidinobutane were detected.

Electrolysis of I in 50% EtOH.—Five grams of I were added to the catholyte and the electrolysis was carried out at −0.5V *vs.* SCE. After 0.0144 Faraday of current (1.01 Faradays/mole of I) had passed, the current was negligible. Gas chromatographic analysis showed the presence of 0.14g of piperidine. The solvent was stripped from the catholyte and the residue was extracted with ether. Evaporation of the ether left a residue of 1.8g (59%) of crude III (nmr analysis).

A similar electrolysis was carried out at −0.5V *vs.* SCE for 1.02 Faradays/mole of I and then the potential was increased to −1.8V *vs.* SCE and an additional 1.08 Faradays/mole of I was passed. Analysis as above showed 0.55g (78%) of piperidine and no III.

An electrolysis of I in 50% EtOH was carried out as above except the potential was set at −1.3V *vs.* SCE and 5 ml concentrated HCl was added to the catholyte. Then 1.25 Faradays/mole of I was passed and analysis as above showed 0.241g (20%) of piperidine and 2.07g (67%) of III.

Electrolysis of II.—The reduction of 8g of II was carried out in DMF containing 0.1M $Et_4N^+BF_4^-$. The potential was set at −0.8V *vs.* SCE and a total of 1.05 Faradays of electricity/mole of II was passed. The DMF was stripped from the catholyte at reduced pressure and the residue was extracted with ether. Evaporation of the ether left a dark oily mixture. This was treated with petroleum ether and decolorizing carbon. The solution was filtered and the filtrate was stripped of solvent to give a clear oil which was distilled in a short-path distillation apparatus at reduced pressure (0.05 mm). The product distilled as a relatively unstable clear liquid boiling at approximately 130°. The nmr spectrum ($DCCl_3$) was consistent with bis(2-diethylaminoethyl) mercury having overlapping signals at δ = 1.08 (16H, CH_3^-, and —CH_2—Hg), a multiplet at δ = 2.87 (4H, N—CH_2—CH_2—Hg)[2] and a quartet at δ = 2.51 (8H, CH_3CH_2—N<).

Anal. Calcd. for $C_{12}H_{28}N_2Hg$: C, 35.93; H, 7.04; N, 6.99. Found: C, 37.23; H, 6.97; N, 6.65.

Results

The results of polarography, coulometry, and macroelectrolyses of I, II, and III are shown in Table I. The polarographic waves in 50% EtOH were normally shaped and only the waves indicated were present. Polarograms obtained with I or II that had been stored for a few days and had apparently partially decomposed showed maxima on the second waves. Polarograms of I and II obtained in DMF were abnormally shaped, and that for I is shown in Fig. 1. Note that the maximum at around −2.2V precedes a wave with the diffusion current less than twice the first wave value. The polarogram for II in DMF is similarly shaped. Compound III is not reduced in DMF.

Cyclic voltammetry of I and II at a hanging Hg drop in DMF were unusual and scans of I at different sweep rates are shown in Fig. 2. Compound II gave similar cyclic voltammograms. Compound I in 50% EtOH shows two irreversible broad peaks at −0.82 and −1.65V *vs.* SCE (Fig. 3). Compound II shows two irreversible broad peaks at −0.69 and −1.50V *vs.* SCE. The reverse trace showed a negative current peak (*i.e.*, the same direction as the forward trace) similar to those in Fig. 2 at slow sweeps. The macroelectrolyses

[1] It is important to note that pyrolysis of III leads to formation of piperidine requiring that a correction be made for g.c. analysis of any solution containing III since piperidine was always formed by pyrolysis of III in the injection port. The piperidine peak area was related to III concentration in known samples so that a fairly accurate correction could be made.

[2] These sharp peaks are spaced like the ones in Fig. 4 at a comparable chemical shift.

were generally carried out with approximately 0.1M substrate. Since all of the electroanalytical results were similar, the only macroelectrolysis for II was carried out to obtain a sample of $(Et_2NCH_2CH_2)_2Hg$. No 1,4-dipiperidinobutane was detected in any of the electrolysis products. Only traces of N-ethylpiperidine were ever detected in the electrolysis products.

In addition to the coulometric data in Table I, it was found that for I in 50% ethanol after complete electrolysis at $-0.5V$ *vs.* SCE approximately 1 Faraday of current/mole of I was passed and no extra current would pass at $-1.2V$, but at $-1.8V$ an additional 1 Faraday of current/mole of I was passed. II behaved similarly. A macroelectrolysis of I carried out similarly yielded 0.14g (20%) of piperidine on complete reduction at $-0.5V$ (1.02 Faradays/mole I). The potential was then increased to $-1.8V$ *vs.* SCE, an additional 1.08 Faradays of electricity per mole of I was passed and the yield of piperidine increased to 0.55g (78%).

Discussion

The results of coulometry and cyclic voltammetry of I and II indicate an initial reversible one-electron reduction (reaction [2]), contrary to the previous report (2). It is also evident that the intermediate IV is consumed by

$$R_2NCH_2CH_2Hg^+ + 1e^- \rightleftarrows \underset{(IV)}{R_2NCH_2CH_2Hg^\cdot} \quad [2]$$

some fairly fast reactions since no reverse is obtained with slow-sweep cyclic voltammetry. Apparently, two reaction pathways are required to explain the two products observed in macroelectrolyses. Reaction [3] is shown as simple

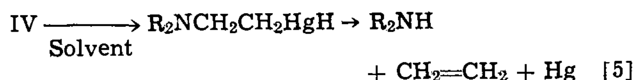
$$2IV \rightarrow \underset{(V)}{(R_2NCH_2CH_2Hg)_2} \rightarrow Hg + \underset{(VI)}{(R_2NCH_2CH_2)_2Hg} \quad [3]$$

dimerization of the radical IV to form an intermediate (V) which would be likely to disproportionate to free mercury and VI at room temperature, as has been observed in the reduction of simple alkylmercuric salts (6).

An additional reaction route for IV must occur, however, to account for the formation of piperidine at the first wave. The simplest reaction to write is reaction [4]

$$IV \rightarrow Hg + CH_2{=}CH_2 + R_2N^\cdot \xrightarrow[\text{Solv.}]{} R_2NH \quad [4]$$

It is not apparent from reaction [4] why one might get different rates[3] in different solvents (as we observe in DMF and 50% ethanol). The addition of amino radicals to olefins is a well-known reaction (7) and the opposite of the first part of reaction [4]. Reaction [5] allows for a solvent effect and bypasses the step of elimination



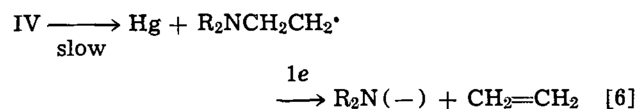
$$IV \xrightarrow[\text{Solvent}]{} R_2NCH_2CH_2HgH \rightarrow R_2NH + CH_2{=}CH_2 + Hg \quad [5]$$

of an aminoradical from ethylene. One can envisage a concerted reaction of the hydride involving a 5-member cyclic intermediate. There is evidence, however, that a simple alkylmercuric hydride decomposes to form the alkyl-free radical (8).

The absence of the intermediate $R_2NCH_2CH_2^\cdot$ (expected in reaction [4]) is further indicated by the absence of 1,4-dipiperidinobutane in the electrolysis products.

The cyclic voltammograms obtained in DMF are interesting in that at fast sweeps a reversible $1e^-$ reduction is indicated (Fig. 2), as has been reported for the reduction of mercuric salts by others (9). However, at slow sweeps an inverse peak occurs on the reverse sweep, indicating a radical intermediate presumably reacting with the mercury drop (10). In this case, the addition of mercury to the surface (reaction [3]) may be responsible for the unusual behavior. The first and second reductions were indistinguishable in the cyclic voltammograms in 50% ethanol (Fig. 3). However, a second peak occurred at a potential at which no polarographic reduction wave appears. This second peak was found to correspond to that for the reduction of III in 50% ethanol. The III is formed at the first reduction by reactions [3], [10], or [11] (see below) and remains at the drop surface long enough to be reduced when its reduction potential is reached. During polarographic reduction a two-electron reduction not leading to III (see below) is already occurring when the potential of the reduction of III is reached and, therefore, no wave is obtained. The III formed at the first polarographic wave is, of course, dissipated because of the fresh drops being formed every few seconds.

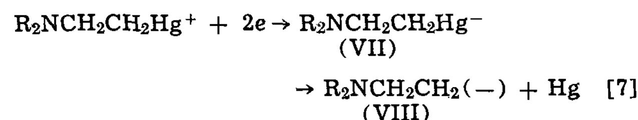
The I_d values shown in Table I for the first waves of I and II in DMF seem too high for a one-electron reduction. Rapid-scan cyclic voltammetry indicates a $1e$ reduction, coulometry and macroelectrolysis at higher concentration indicate a one-electron reduction, and polarography in 50% ethanol indicates a one-electron reduction. Therefore, to obtain a greater than one-electron reduction in DMF requires a relatively slow solvent dependent reaction of the one-electron reduction product leading to a reducible product. A possible pathway is shown in reaction [6]. A simple alkyl radical would probably not be reduced (11-12) or reduced only very slowly (13)



$$IV \xrightarrow[\text{slow}]{} Hg + R_2NCH_2CH_2^\cdot \xrightarrow{1e} R_2N(-) + CH_2{=}CH_2 \quad [6]$$

at this potential, but the beta-amino group may allow the reduction to occur rapidly. At higher concentrations (coulometry and macroelectrolysis) reaction [3] predominates. In 50% ethanol the rate of reaction [5] may be faster than that of reaction [6]. Reaction [5] does not form a reducible species and, therefore, only a one-electron reduction occurs.

The total I_d value beyond the second polarographic wave corresponds to a two-electron reduction (reaction [7])

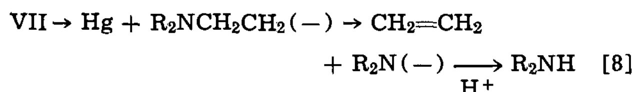


$$R_2NCH_2CH_2Hg^+ + 2e \rightarrow \underset{(VII)}{R_2NCH_2CH_2Hg^-} \rightarrow \underset{(VIII)}{R_2NCH_2CH_2(-)} + Hg \quad [7]$$

Under dilute conditions (polarography) the intermediate VII undergoes reactions like [8] or [9]. The second

[3] One of the referees suggested the different rates in reaction [4] may be due to the equilibrium in reaction [2].

wave



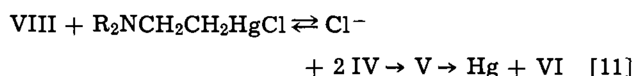
$$\text{VII} \rightarrow \text{Hg} + R_2NCH_2CH_2(-) \rightarrow CH_2{=}CH_2 + R_2N(-) \xrightarrow[H^+]{} R_2NH \quad [8]$$

$$\text{VII} \xrightarrow[H^+]{} R_2NCH_2CH_2HgH \rightarrow R_2NH + CH_2{=}CH_2 + \text{Hg} \quad [9]$$

shows a large (1.3V) potential shift between DMF and 50% ethanol. This same effect is observed in the reduction of III for, whereas the reduction begins at -1.5V in 50% ethanol, no polarographic wave occurs in DMF. Addition of 1.3V to the value in 50% ethanol gives -2.8V or reduction in the region of electrolyte discharge. Reduction of dialkylmercurials has been reported to occur in this region (14); however, we were unable to reproduce those results.

Under macroelectrolysis conditions at the potential of the second wave the products appear to be those of a one-electron reduction. However, routes to the bismercurial (VI) are straightforward via two-electron reduction products (reactions [10] and [11])

$$\text{VIII} + R_2NCH_2CH_2HgCl \rightarrow Cl^- + \text{V} \rightarrow \text{Hg} + \text{VI} \quad [10]$$

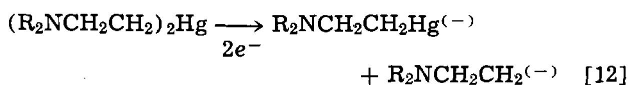


$$\text{VIII} + R_2NCH_2CH_2HgCl \rightleftarrows Cl^- + 2\,\text{IV} \rightarrow \text{V} \rightarrow \text{Hg} + \text{VI} \quad [11]$$

Reaction [10] is a nucleophilic-displacement reaction, similar to a variety of known replacement reactions at mercury (15). Reaction [11] is an electron-transfer disproportionation reaction, common in cases in which 1- and 2-electron reduction products are formed (16). Both are second-order resulting in the same product and, thus, are indistinguishable.

These reactions do not explain the other products obtained or the apparent two-electron reduction in 50% ethanol by coulometry and polarography. Reactions [8] and [9] are possible routes to the observed product, piperidine. Reaction [8] does not seem likely, however, in view of the fact that only traces of N-ethylpiperidine were detected, even when the reduction was carried out in the presence of hydrochloric acid. Under conditions of polarography and coulometry in 50% ethanol, reaction [9] appears to occur more rapidly than [10] or [11]. However, under macroelectrolysis conditions the concentration of $R_2NCH_2CH_2HgCl$ is much higher and the region near the cathode is probably quite basic (17) even though the bulk solution is acidic, thus, allowing reactions [10] or [11] to compete favorably with [9].

The reduction of III (initially formed by reduction of I) in 50% ethanol leads only to piperidine and no N-ethylpiperidine. It would seem that the reduction would proceed as in reaction [12]



$$(R_2NCH_2CH_2)_2Hg \xrightarrow[2e^-]{} R_2NCH_2CH_2Hg^{(-)} + R_2NCH_2CH_2^{(-)} \quad [12]$$

The intermediate $R_2NCH_2CH_2^{(-)}$ would be expected to lead to at least some N-ethylpiperidine. It may be possible that the reduction is a concerted process with $R_2N^{(-)}$ and ethylene leaving as the first electron is added so that there is never any free $R_2NCH_2CH_2^{(-)}$ formed.

Although electroreduction of I apparently does not lead to N-ethylpiperidine, the chemical reduction of I to N-ethylpiperidine may be accomplished with sodium amalgam and various metal hydrides (18). Reduction of I with sodium borohydride is reported to yield some III in addition to N-ethylpiperidine; however, their product is reported as a solid (mp 128°), whereas the product (III) obtained here is a distillable colorless liquid. The nmr spectrum of III is included (Fig. 4) as further evidence for the structure.

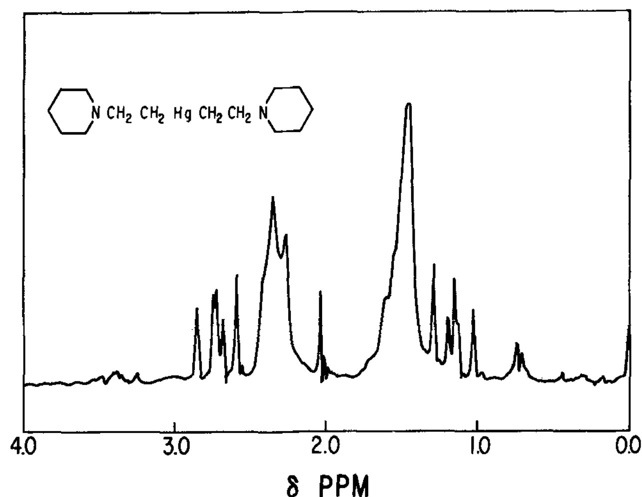


Fig. 4. Proton nmr spectrum of bis [2-(piperidino)-ethyl] mercury

Electrode Reactions on Demetalized Surfaces

Ashok K. Vijh*

Hydro-Quebec Institute of Research, Varennes, P. Q., Canada

ABSTRACT

Many electrode reactions occurring nominally on metals proceed in fact on a demetalized surface produced by formation of a semiconducting surface reaction film on the electrode. A viewpoint is presented that in these cases of electrode reactions, the electrode kinetic behavior should be interpreted in terms of solid-state surface properties (especially the bandgap and thence semiconductivity and solid-state cohesion) of the surface film rather than the electronic properties of the underlying metal. Equations are formulated to take this into account and the considerations developed provide a basis to interpret a large amount of literature data on the following subjects: oxygen reduction reaction; oxygen evolution reaction; anodic dissolution of metals in anhydrous hydrogen fluoride and in sulfamic acid-formamide solutions; $Fe(CN)_6{}^{4-}$/$Fe(CN)_6{}^{3-}$ reaction on platinum, oxide films, and oxides; and possibly the open-circuit corrosion potentials of some common metals.

A vast majority of common electrode reactions occurring on metals proceed, in fact, on surfaces that have been demetalized to some extent, by formation of either a chemisorbed layer or a thicker film approaching a phase compound. This is particularly true of anodic reactions, although several cathodic reactions (*e.g.*, hydrogen evolution, oxygen reduction, some electroorganic reductions, etc.) also involve reaction intermediates which can impart a demetalized character to the electrode surface.

In some cases of anodic reactions in which the metallic electrode is clearly covered by a multilayer (>>10Å) surface film, one would expect the properties of the latter to affect the rate of the electrode reaction. The film properties of interest in this connection are such as the estimated semiconductivity, solid-state cohesion (*i.e.*, lattice energies, bond energies, heats of formation, melting points, boiling points, etc), and the defect structure.

The object of the present paper is to attempt an interpretation of some electrode reactions involving surface films in terms of semiconductivity and related properties of the latter.

Theory

To formulate the argument, consider reduction of oxygen on an oxide-covered metal surface denoted by *S*. In acidic solutions, the over-all reaction may proceed either by participation of electrons of the conduction band, e_c, of *S* as

$$S + O_2 + 2H_2O + 4e_c \rightarrow 4\,OH^- + S \qquad [1]$$

or by involvement of holes of the valence band as

$$S + O_2 + 2H_2O \rightarrow 4\,OH^- + 4p_+ + S \qquad [2]$$

Here it is assumed that the oxygen reduction occurs by the four-electron process. Parenthetically, the following argument will not be affected even when one assumes a two-electron reduction. It also is assumed that the oxide substrate, *S*, on the metal is sufficiently thick (>>10Å) and hence may be treated as a bulk semiconducting surface. For the oxide reduction reaction, which proceeds at high anodic potentials (with respect to the hydrogen electrode), this assumption clearly would be fulfilled for metals such as Cu, Cr, Pd, Cd, Ni, Fe, Co, Zn, Mg, and even Ag and Au on which anodization can result in quite thick oxides. For the case of Pt and other "noble" metals, however, this assumption perhaps is fulfilled only marginally since phase oxide growth generally is not observed, although three to four layers (*ca.* 10Å) can be formed easily even on platinum. In any case there is direct evidence (1) to support that the oxide on platinum, although relatively thin, sustains a potential drop of about 0.7V (at 100 μA-cm^{-2}) across it under conditions of anodization; hence it may be treated approximately as a semiconducting surface.

A possible rate-determining step (rds) for oxygen reduction (on oxide-covered platinum) in acidic solutions may be as (2)

$$S + O_2 + H^+ + e^- \rightarrow SO_2H \qquad [3]$$

which may be written in two alternative forms involving either e_c or p_+ as

$$S + O_2 + H^+ + e_c \rightarrow SO_2H \qquad [4]$$

or

$$S + O_2 + H^+ \rightarrow SO_2H + p_+ \qquad [5]$$

The rates of these two alternative mechanisms may be represented as (3)

$$i_4 = Z\mathbf{F}\, k_4\, [O_2]\, [H^+] \exp\left(-E^*{}_4/RT\right) \qquad [6]$$

and

$$i_5 = Z\mathbf{F}\, k_5\, [O_2]\, [H^+] \exp\left(-E^*{}_5/RT\right) \qquad [7]$$

where i_4 and i_5 are the rates (current densities); *Z* is the number of electrons (or holes) transferred in the rds (one in the present example); k_4 and k_5 are constants; **F** is the Faraday constant; $[O_2]$ and $[H^+]$ are the concentration of oxygen and protons (hydrated of course) on the surface *S*; $E^*{}_4$ and $E^*{}_5$ are the effective activation energies for the steps [4] and [5], respectively, under conditions of a given applied potential. Concentrated solutions have been assumed so that there is virtually no potential drop in the diffuse double layer of the solution. In any case, for the wide bandgap semiconductors, potential drops across the Helmholtz and the diffuse double layers may be neglected.

Following Gerischer (3), we note that the presence of a hole, used in reaction [5], in the valence band signifies that an electron has been excited from a bonding state in the valence band to an antibonding state in the conduction band. The energy difference between the initial states for reactions [4] and [5] would thus be equal to the bandgap value, *Eg*. Since the transition states for reactions [4] and [5] are relatively closer to their final states, as argued by Gerischer (3), the difference in the activation energies for the two steps, namely, $(E^*{}_4 - E^*{}_5)$ will be close to the *Eg*; *i.e.*, one has

$$E^*{}_4 - E^*{}_5 = \gamma\, Eg; \quad 0.5 < \gamma < 1 \qquad [8]$$

By adding rate equations [6] and [7], one gets the total rate of oxygen reduction, i_t as

* Electrochemical Society Active Member.

Key words: oxygen reaction, anodic dissolution, corrosion films, electrode reactions, semiconductor electrochemistry.

$$i_t = k' \exp(-E^*_4/RT) + k'' \exp(-E^*_5/RT) \quad [9]$$

where

$$k' = ZF k_4 [O_2] [H^+]$$

and

$$k'' = ZF k_5 [O_2] [H^+]$$

Dividing Eq. [9] by $k'' \exp(-E^*_5/RT)$, one obtains

$$\frac{i_t}{k'' \exp(-E^*_5/RT)} = \frac{k' \exp(-E^*_4/RT)}{k'' \exp(-E^*_5/RT)} + 1 \quad [10]$$

or

$$i_t = K \left\{ K' \exp - \left(\frac{E^*_4 - E^*_5}{RT} \right) + 1 \right\} \quad [11]$$

where

$$K = k'' \exp(-E^*_5/RT)$$

and

$$K' = \frac{k'}{k''}$$

Combination of Eq [8] and [11] gives

$$i_t = K \left\{ K' \exp - \left(\frac{\gamma Eg}{RT} \right) + 1 \right\} \quad [12]$$

In Eq. [12], for a given oxide substrate, S, all the quantities in the right-hand side are constant provided that one works at a constant temperature T. If now one assumes that for a number of oxide substrates, S, constants K, K', and γ change in a relatively minor way as compared to the bandgap value, Eg, one would expect a rough correlation between i_t and Eg values. That the effect of Eg in Eq. [12], for a large number of oxide substrates, is indeed paramount as compared to any possible variations of K, K', and γ, as assumed, appears to be borne out by some experimental evidence presented below where the overpotential (at constant i_t) increases with increasing Eg values for a number of oxide substrates; this, of course, is the same thing as the increasing i_t with decreasing Eg values at a given overpotential (*i.e.*, Eq. [12]). It may be added that although Eq. [12] has been formulated for the reduction of oxygen on an oxide-covered electrode, the considerations developed should apply to any electrode reaction proceeding on a film-covered metal by means of reactions such as [1] and [2] in which an exchange of electrons or holes is involved.

Electrocatalysis of the Oxygen Reaction on Oxide-Covered Metals

In Fig. 1, results of Kozawa *et al.* (4) for the reduction of oxygen on metals (presumably covered by oxide films) are plotted against the corresponding Eg values of the oxides. At a given current density, higher electrode potentials, E, are associated with higher bandgap values, as predicted above. In order to extend this plot to some more metals for which the Eg values are not available, one may examine the graph of $-\Delta He$, the heat of formation per equivalent for the highest valent oxide, against the E values since (5)

$$Eg \simeq 2(-\Delta He) \quad [13]$$

This has been done in Fig. 2 where increasing $-\Delta He$ ($\simeq$ ½ Eg) values are associated with higher electrode potentials for oxygen reduction at a given current density as reported by Kozawa *et al.* (4); Fig. 2 thus extends to some other metals the conclusions drawn from Fig. 1.

In order to make sure that these correlations are not merely fortuitous because of the particular set of oxygen reduction data chosen, it is necessary to examine them in relation to data reported by other workers. Figure 3 gives the E (at a given i_t) *vs.* Eg plot for several oxide-covered metals on which oxygen reduction data have been reported by Khumotov (6), after Tomashov (7). These E values are plotted against the corresponding $-\Delta He$ (= ½ Eg) values in Fig. 4. It is clear that the data of Kozawa *et al.* (4) and Tomashov (7) sustain the theoretical prediction, *i.e.*, at a given rate, higher electrode potentials are observed on oxide-covered metals whose oxides have high Eg values (Fig. 1-4).

The $-\Delta He$ values not only signify half the bandgaps (5), but they are also related to the enthalpy (in its

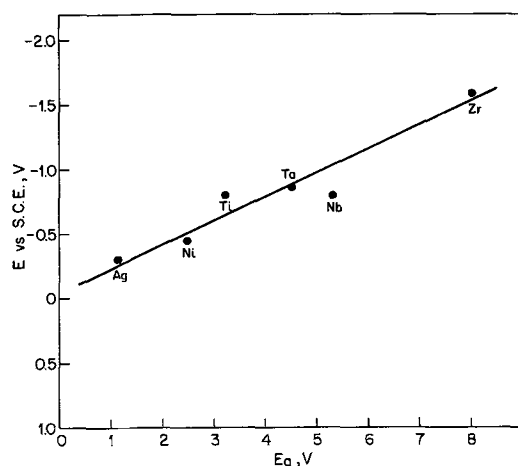

Fig. 1. Plot of electrode potential E (vs. SHE) for oxygen reduction at 20 μA-cm^{-2} in 0.15M NaCl solution (phosphate buffer, pH 7.22) on the (oxide-covered) shown metals vs. the bandgap, Eg, values for the corresponding oxides. E and Eg values are from Ref. (4) and (18), respectively.

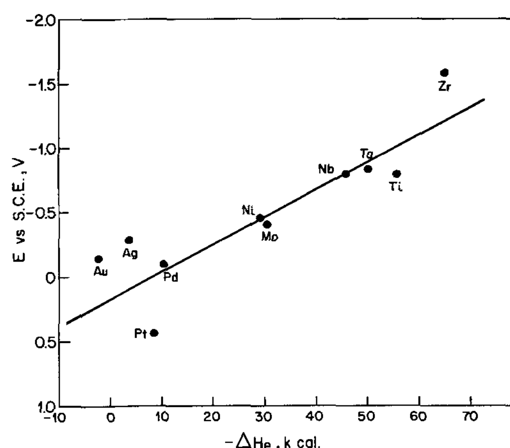

Fig. 2. E values for oxygen reduction (same data as in Fig. 1) now plotted against $-\Delta He$ ($\simeq$ ½ Eg) values of the oxides of the shown metals. The $-\Delta He$ values are taken from Ref. (18) and (21) and the references cited therein.

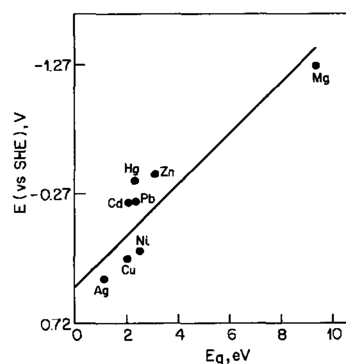

Fig. 3. Plot of electrode potential E (vs. SHE, in 0.5M NaCl + 0.005M Na_2CO_3 + 0.005M $NaHCO_3$, at 1 mA-cm^{-2}) for oxygen reduction (6, 7) on the (oxide-covered) shown metals vs. the Eg values (21, 22) for the corresponding oxides.

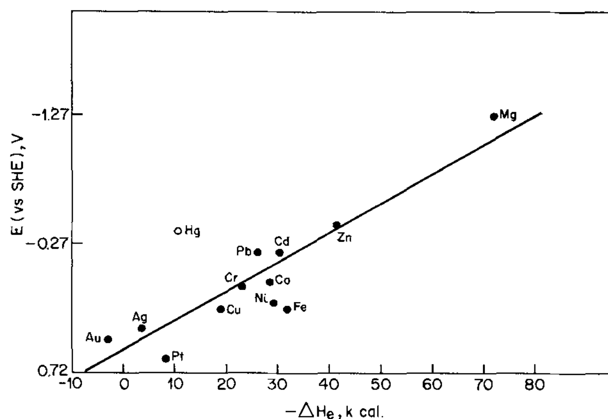

Fig. 4. Plot of E for oxygen reduction (same data as in Fig. 3) vs. the $-\Delta He (= \frac{1}{2} Eg)$ values (18, 21) of the highest valent oxides of the shown metals.

nomalized form, *i.e.*, as per equivalent (8) of the reaction

$$MO(s) \rightarrow M(s) + O(g) \quad [13]$$

where s and g denote solid and gas, respectively; MO is the metal oxide, i.e., the substrate S in the kinetic equations above. The enthalpy change in reaction [13], $(\Delta H)_{13}$, is

$$(\Delta H)_{13} = -\Delta He + \frac{1}{4}\Delta H_D \quad [14]$$

where $\frac{1}{4}\Delta H_D$ is the heat of dissociation, per equivalent, of the oxygen molecule (note: ΔH_D is heat of dissociation per mole, $\frac{1}{2}\Delta H_D$ per atom, and $\frac{1}{4}\Delta H_D$ per equivalent). For all the oxides, $\frac{1}{4}\Delta H_D$ is of course the same so that the bond rupture in Eq. [13], *i.e.*, the enthalpy per equivalent of reaction [14], may be represented by the heat of formation per equivalent, ΔHe. It may be added that usually the bond energy (9) is represented by the heat of atomization per equivalent, *i.e.*, the enthalpy of the bond rupture

$$MO(s) \rightarrow M(g) + O(g) \quad [15]$$

For our considerations, however, the bond energy of Eq. [15] is not relevant since bond breaking or formation involved in various electrochemical steps never converts the metal to its gaseous form. Since the metal in the MO bond always stays as a solid, the bond energy corresponding to the rupture in Eq. [14] is appropriate. One thus concludes that $-\Delta He$ values not only represent $\frac{1}{2}Eg$ but are also an index of the average energy of a bond likely to be involved in an electrochemical step on the oxide-covered electrodes.

With the preceding comments in mind, we proceed to examine a third set of data, due to Appleby (2), on oxygen reduction. The correlation between electroactivity and the $-\Delta He$ values for the metals examined by Appleby does not follow the predictions made in the section on theory here. Instead, one obtains a volcano plot. This probably would emphasize that for these metals, the semiconductivity (and thence Eg or $-2\Delta He$) is perhaps not the paramount factor (cf. Eq. [11]) and that the overriding consideration is probably the energy of the MO bonds as represented by $-\Delta He$. This is not at all unexpected for these "noble" metals (Fig. 5) on which the Eg values are small and the effect of oxide mainly shows up in terms of the strength of the MO bonds involved as predicted in the theories, *e.g.*, of Parsons (10) and Gerischer (11). A similar volcanic relation also results for the oxygen evolution reaction (oer) when the data taken from Reutschi and Delahay (12), supplemented by the data given by Hoare (13), are plotted against the $-\Delta He$ value (Fig. 6). The significance and interpretation of Fig. 6 is, of course, quite similar to that of Fig. 5.

It may be mentioned that any attempts to estimate bond energy values from the Pauling-type equations

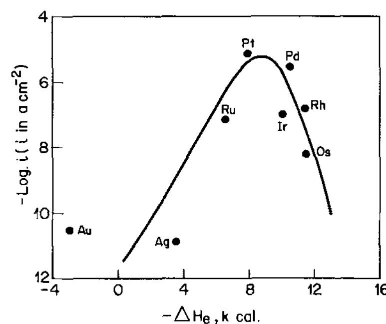

Fig. 5. Oxygen reduction rate at 800 mV (SHE) in 85% orthophosphoric acid (2) on the shown (oxide-covered) metals plotted against the $-\Delta He$ values (18, 21) of the corresponding oxides.

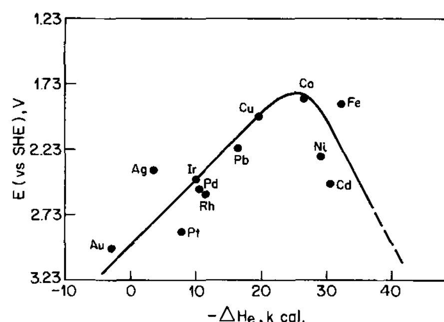

Fig. 6. Electrode potential E (vs. SHE) for the oxygen evolution reaction, at 1 A-cm^{-2} in 1M KOH solution, as given in Ref. (12) plotted against the $-\Delta He$ values (18, 21) of the oxides of the shown metals. The oxygen evolution data for Rh and Ir taken from Hoare (13); although the data on Ir is for acidic solutions, it may be used in the present plot (by adjusting the potential scales to the alkaline solutions) since the mechanism of oxygen evolution on Ir is the same both in acidic and alkaline solutions.

(12) are not relevant for the present case since these equations give estimates of isolated MO molecules in the gas phase. Similar comments also apply to the spectroscopic values of the MO bond strengths.

Anodic Dissolution of Film-Covered Metals

It was shown previously (14, 15), on the basis of data of Hackerman *et al.* (16) that in the anodic dissolution of a large number of metals in anhydrous hydrogen fluoride (AHF), the dissolution proceeds via relatively thick fluoride corrosion films. Further, it was noted that the solid-state properties of the fluoride films determine the anodic dissolution rates of the underlying metals. Since the dissolution of the semiconducting surface film must proceed by reactions involving electron-hole exchange between the fluoride film and the electrolyte (similar to reactions [1] and [2]), the data (16) may now be examined in terms of Eq. [12]. In Fig. 7, the normalized anodic dissolution rates of metals are plotted against the corresponding $-\Delta He$ $(= \frac{1}{2} Eg)$ values. The log dissolution rate roughly increases with decreasing $-\Delta He$ values as required by Eq. [12].

The theoretical ideas developed here may also be applied to the case of anodic dissolution of metals in sulfamic acid-formamide solutions (17, 18). The anodic dissolution in this case proceeds via electrode films bound to the metal by M-S bonds. It is of interest, therefore, to plot the $-\Delta He$ $(= \frac{1}{2} Eg)$ values of metal sulfides against the anodic dissolution rates of metals (Fig. 8). Log (anodic dissolution rate) increases with decreasing bandgap values in agreement with Eq. [12].

Redox Reactions

One may now examine the behavior of redox reactions such as $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ in relation to the

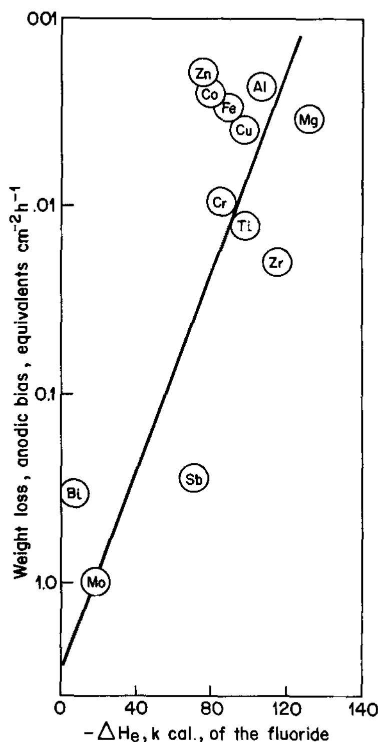

Fig. 7. Plot of normalized (*i.e.* equivalents cm^{-2}-hr^{-1}) anodic dissolution rates (16) of the shown (fluoride-covered) metals *vs.* the $-\Delta He$ ($= \frac{1}{2} Eg$) values (14, 15) of the corresponding highest valent fluorides. The anodic dissolution data on Cd is not included since the fluoride film on Cd is nonadherent and nonprotective, a case not relevant to the theory of film-covered electrodes developed here. It may be mentioned that, perhaps for the foregoing reason, the anodic dissolution data on Cd does not follow the rough trend shown in Fig. 7.

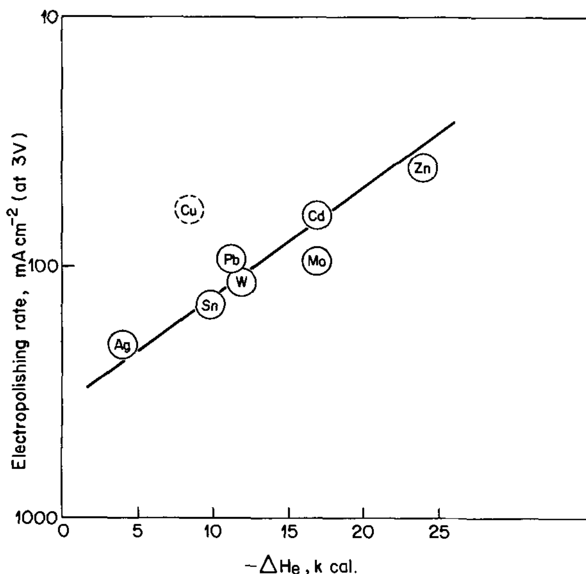

Fig. 8. Electropolishing (*i.e.*, the anodic dissolution) rates at a typical (3V *vs.* $Cd/CdCl_2$ in KCl-saturated formamide) anodic potential of the shown (film-covered) metals, in sulfamic acid-formamide solutions (17, 18), *vs.* the $-\Delta He$ ($= \frac{1}{2} Eg$) values of the corresponding highest valent metal sulfides (18).

viewpoint developed here. Moshtev (19) has recently reported standard exchange current densities of this reaction on oxide-free platinum (hence $Eg = 0$), some oxide films (SnO, γ-Fe_2O_3, TiO_2) and some bulk oxides (NiO, ZnO). Since primary electrocatalytic effects of the substrate on redox reactions are zero, it is valid to use the exchange current density on Pt as the reference point ($Eg = 0$), for the electron exchange involved in the reaction. A plot of exchange current densities *vs.* the Eg values again shows that higher rates in general are associated with low Eg values (Fig. 9), which is qualitatively consistent with Eq. [12].

Open-Circuit Corrosion Potentials

For open-circuit potentials of common metals under certain experimental conditons, it is possible to show that the estimated semiconductivity of the corrosion reaction films is related to the mixed corrosion potentials. The arguments involved are substantially different from those formulated here, although the crucial role of the semiconductivity of reaction films on the demetalized electrodes is again indicated. The treatment has been presented previously (20) and need not be elaborated here.

Comments on the Scope and Limitations of the Theory

An assumption in the present theoretical treatment is that the thickness of the solid semiconducting films is greater than the Debye length L_D, which may be taken as the effective width of the space charge region. This assumption would appear to be contestable at first sight since the L_D is usually regarded as in the region *ca.* 10^3-10^4Å (23) which would be greater than the thickness of electrodic films observed in some of the cases discussed. The Debye length is given by the formula (24)

$$L_D = \left(\frac{\epsilon kT}{4\pi ne^2} \right)^{1/2} \quad [16]$$

where ϵ is the dielectric constant of the film, k is the Boltzmann constant, T is the absolute temperature, n is the density of the electronic charge carriers, and e is the electronic charge. It is observed that for high density of charge carriers (*ca.* $\gtrsim 10^{18}$-10^{20} carriers cm^{-3}) and reasonable values of dielectric constant (*ca.* 50), one can, in fact, observe values of L_D substantially less than 10Å and even approaching the width of the Helmholtz layer. Although application of the semiconductor space charge theory to such cases would appear debatable, considerable success has been achieved in fitting the experimental data to theory for several cases of this kind; *e.g.*, electrode reactions on bulk graphite (25), NiO (26), PbO_2 (27), and sodium-tungsten bronzes (28). On the basis of this evidence, it is concluded that the theory developed here is applicable even to quite thin films, provided that the n values are quite high, an assumption likely to be valid for the electrodic films by virtue of their nonstoichiometry and "doping" resulting from their intrinsically composite nature. It should be mentioned, however, that for thin films there exists the very real possibility of tunneling from the metal Fermi level to the reactants in the Helmholtz double layer. This latter situation would not be easy to reconcile with the theory and the correlations presented here. If the tunneling barrier is assumed to lie within the film, however, as

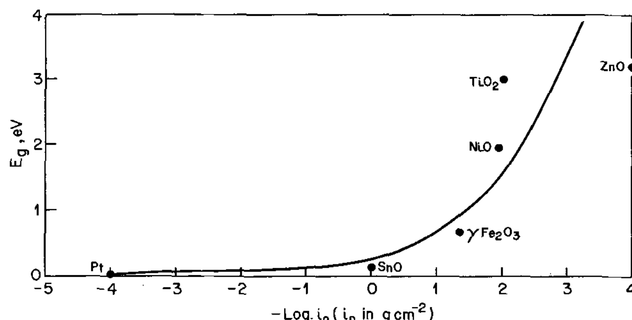

Fig. 9. Plot of exchange current densities of the $Fe(CN)_6^{4-}$/$Fe(CN)_6^{3-}$ reaction on Pt, SnO, γ-Fe_2O_3, NiO, TiO_2, and ZnO (19) against the corresponding Eg values (Eg for Pt $= 0$).

previously considered (29, 30), the bandgap of the film would again be the crucial factor in the rate equations since it would determine the width of the tunnel barrier.

A point that merits some further comment here is the definition of terms in the rate equations [6] and [7]. In these equations, the activation energies E^*_4 and E^*_5 have been written as under conditions of a given applied overpotential. One may in fact separate the "chemical" free energy of activation (corresponding to the overpotential, η, approaching zero) and its potential-dependence in these equations and write

$$i_4 = ZF\, k_4\, [O_2]\, [H^+] \exp(-E^{**}_4/RT) \exp^{-\eta F/RT} \quad [6a]$$

and

$$i_5 = ZF\, k_5\, [O_2]\, [H^+] \exp(-E^{**}_5/RT) \quad [7a]$$

where E^{**}_4 and E^{**}_5 refer to the activation energies at equilibrium (no overpotential) for the steps 4 and 5, respectively; η would, of course, operate almost entirely in the space charge region of the semiconducting film. In other words, one is now writing Eq. [6] and [7] as Eq. [6a] and [7a] in order to show explicitly the potential-dependence of rate. It should be noted that these equations have been written for a cathodic reaction (oxygen reduction) in which the potential-dependence of rate is $\exp^{-\eta F/RT}$ for the electron current and unity for the hole current assuming a wide gap semiconductor; for an anodic reaction, of course, the reverse situation holds true. By combining Eq. [6a] and [7a] one gets

$$i_t = \text{const} \exp^{-\eta F/RT} \quad [9a]$$

The Tafel slope then would be *ca.* 60 mV/decade at room temperature. The experimental slope for the oxygen reduction reaction and oxygen evolution reaction (at low current densities) on platinum in alkaline solutions is indeed about 60 mV (31). In most of the other cases of electrode reactions on film-covered electrodes Tafel slopes equal to 120 mV or, frequently, higher than 200 mV are observed. These values of slopes, although not easily reconciled with the treatment presented here, can be interpreted in different ways, all of which assume a part of the potential drop as operating across the semiconducting film (32, 33). When the high Tafel slopes indicate that only a fraction of the potential drop operates across the film with the rest available across the Helmholtz double layer, one is led to conclude the possible influence of surface states, arising from adsorption of reactants, intermediates, or products, on the reaction kinetics. Although the present theory does not take into account the surface states explicitly, an obvious extension on these lines may be mentioned. Let us suppose that a radical reaction intermediate gets chemisorbed on the film and creates a surface state with the energy term of its unpaired electron as E_R and lying, of course, within the bandgap. In this case, the Eg of Eq. [12] would be replaced by the energy difference between the energy term E_R and the energy at the bottom of the conduction band, E_C. Now if, $(E_C - E_R/Eg)$ is roughly constant for a given electrodic film (*e.g.*, oxide) on a series of metals, the present theory would stay valid. Alternatively, if E_R is close to the valence band edge for every metal, the theory would remain unchanged, notwithstanding the surface states. However, if the ratio $(E_C - E_R/Eg)$ is not constant, not even roughly, for a series of metals, the theory would be inapplicable in its present form and would need some very complicated modifications, the nature of which is not completely clear at this time.

One should probably mention that factors k_4 and k_5 in the rate equations are frequency factors and would be expected to be of similar magnitude; one could thus have used only one symbol for both of them except that the present notation helps point out their different origins in different rate equations.

Conclusions

A case is presented that for electrode processes proceeding *via* formation of solid electrode films, attention should primarily be focused on the role of these films in the electrode reactions. A possible way of taking into account the semiconductivity of these films is outlined and the ideas stated appear to provide interpretation of literature data on: oxygen evolution and reduction reactions; anodic dissolution of metals in some systems; redox reactions; and open-circuit potentials of metals.

Acknowledgments

Thanks are due to Dr. J. P. Randin and Dr. P. Lenfant for numerous discussions in which the possibilities of the interpretations given in this paper were developed.

Manuscript submitted April 27, 1972; revised manuscript received June 26, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Speculation on Some Effects of Complexation and Anion-Induced Adsorption on the Polarography of Indium in Acidic Halide and Thiocyanate Media

A. M. Bond*

Department of Inorganic Chemistry, University of Melbourne, Parkville, Victoria, 3052, Australia

ABSTRACT

Some phenomena found in the polarographic reduction of indium(III) in acidic halide and thiocyanate media have been studied by a-c polarography. Speculation on the role of complex formation and anion-induced adsorption on the polarographic reduction at potentials near the half-wave potential are given. At low ligand concentrations the a-c peak potential is believed to be influenced by anion-induced adsorption while at high ligand concentrations the value is the thermodynamic value predicted from bulk complexation equilibria. The unusual d-c minimum found at more negative potentials and the above phenomena are discussed in terms of the coupled occurrence of electroinactive $[In(H_2O)_x]^{3+}$ ions at potentials where the complexed ion is electroactive and anion-induced adsorption. The reduction mechanism at the half-wave potential and at more negative potentials are concluded to be similar. The irreversible reduction of the uncomplexed indium ion is attributed to the slow rate of exchange of co-ordinated water, in agreement with other workers.

A number of recent publications have dealt with the adsorption of metal complexes on mercury electrodes from solutions containing anions that also adsorb on mercury (1-12). Several different experimental techniques have been used in these studies including such methods as chronocoulometry and chronopotentiometry. From these studies, two mechanisms have been proposed to account for the experimental findings.

The first mechanism, suggested by O'Dom and Murray (4), assumed that one particular complex species present in the solution, ML_N, adsorbed on the mercury surface to produce an adsorbed species with the same chemical composition

$$ML_N + Hg \rightarrow L_{N-1}M - L - Hg \qquad [1]$$

An alternative proposal by Anson and Barclay (5) differs from the above in that interaction with anions already adsorbed on the mercury occurs according to scheme [2]

$$ML_N + L - Hg \rightarrow L_NM - L - Hg \qquad [2]$$

Data supporting the second scheme as being the predominant one have been obtained for a number of metals and cations (11), although in several studies (9, 10), authors have been unable to choose between reactions [1] and [2]. The bulk of evidence therefore indicates at least that the second scheme is the more usual one.

The influence of anion-induced adsorption in some areas of polarography has previously been considered. In particular, Barker and Bolzan (13) looked at the influence on maxima in d-c polarography and other areas of a-c, rf, square wave, and pulse polarography. Other workers (14-17) have also examined the analytical implications of anion-induced adsorption on a wide variety of polarographic techniques.

From these studies on anion-induced adsorption it is apparent that complexation of metal ions both in the bulk of the solution and at the electrode surface can be extremely important in determining the nature of the observed electrode reaction. Reduction of the metal ion complex could occur in the adsorbed state. The adsorbed complex can be quite different from the complex existing in the bulk solution and this could profoundly influence the observed electrode process, compared with that based on calculations of bulk equilibria. Speculation on the polarographic reduction of indium(III) in halide and thiocyanate media is now considered in terms of complexation and anion-induced adsorption. In particular possible influences of anion-induced adsorption at the half-wave potential are considered and then these ideas extended to more negative potential regions where a minimum is frequently observed in the d-c polarography of indium.

* Electrochemical Society Active Member.

Key words: anion-induced adsorption, polarography, indium complexes.

Experimental

An indium stock solution was prepared by dissolving indium(III) perchlorate in concentrated perchloric acid. Appropriate aliquots of this stock solution were taken to give solutions for polarography, 4.6×10^{-4}M in indium and 0.8M in perchloric acid.

The thiocyanate solution was prepared from laboratory grade NaSCN, analyzed by titration against standard silver nitrate (the Volhard method). The halides fluoride, chloride, bromide, and iodide were added as the sodium salt.

The ionic strength of 3.0 was maintained by addition of sodium perchlorate. The concentrations of chloride, bromide, iodide, and thiocyanate used are shown in the tables.

All solutions were degassed with oxygen-free nitrogen.

The temperature was maintained at 30° ± 0.1°C.

All potentials measured in this work are relative to an Ag|AgCl reference electrode (5M NaCl), separated from the indium solutions with a salt bridge containing 5M $NaClO_4$.

Polarograms were obtained using a Metrohm Polarecord E261. The a-c polarography was carried out using the Metrohm AC Modulator E 393 with an a-c voltage of 10 mV, rms at 50 Hz.

To minimize cell impedance, a-c polarography was carried out with a three-electrode system, tungsten being used as the auxiliary electrode. Rapid polarographic techniques with controlled drop times of 0.16 sec were achieved with the Metrohm Polarographic Stand E 354.

Results and Discussion

Indium(III) electrode process at the DME.—In noncomplexing acid media, such as perchloric or nitric acid, one drawn out irreversible indium(III) wave is

observed (18). The addition of a low concentration of certain ligands can accelerate the normally slow and irreversible polarographic reduction of the aquated ion $In(H_2O)_x^{3+}$ and in several aqueous electrolyte solutions such as the halides (18, 23-25) and the pseudohalide, thiocyanate (26-28), a reversible three-electron reduction wave is observed. However at potentials considerably more negative than the half-wave potential, a curious minimum appears on the d-c polarogram. On the a-c polarogram a negative admittance is observed over the potential region where the minimum appears on the d-c polarogram (27). The nature of the three-electron reduction wave and the minimum have been the subject of a large number of papers [see Ref. (25-32) for instance].

The nonreversible reduction of indium in perchloric acid was confirmed in this work with no polarographic wave being observed prior to reduction of the hydrogen ion. In 0.8M $HClO_4$ available evidence (33) shows that hydrolysis of indium is suppressed and $[In(H_2O)_x]^{3+}$ is the major species present. Data by Eigen (34) shows that the characteristic half-life for H_2O substitution in the inner co-ordination sphere is of the order of 10^{-3} sec. This is a relatively slow rate of exchange of water and an irreversible electrode process for reduction to the metal could be expected, as the solvated water molecules have to be eliminated (35)

$$[In(H_2O)_x]^{3+} + 3e \rightarrow In\ (amalgam) + xH_2O$$

This conclusion is essentially in agreement with that reached by Aikens and co-workers (23, 36).

In accordance with previous studies on bismuth (37), it is suggested that if a covalently bonded ligand displaces the co-ordinated water and this ligand has a fast and close to diffusion-controlled rate of exchange, then the rate of the electrode process can be accelerated to the reversible value. Whether the complex is formed in the bulk solution or at the electrode surface via anion-induced adsorption as in Eq. [2] should be irrelevant.

In high concentrations of chloride, bromide, iodide, and thiocyanate plots of E_{de} *vs.* log $i/(i_d - i)$ were linear, with slopes very close to the theoretically expected value of 20 mV for a reversible three-electron reduction. $E_{1/2}$ was independent of indium(III) concentration and drop time.

The a-c polarograms were highly symmetrical with half-widths of 34 ± 2 mV. Theoretically, the half-widths for a reversible electrode reaction should be approximately 90/n mV (at 25°C and for an applied a-c voltage of ≤ 8/n mV). The value of 34 mV (uncompensated for iR drop) obtained with an applied a-c voltage of 10 mV and at 30°C is thus in satisfactory agreement with the theoretically expected value. Good agreement was obtained between $E_{1/2}$ from d-c polarography and the summit potential E_s from the a-c polarograms. E_s was independent of indium(III) concentration and drop time.

With high halide or thiocyanate concentrations, d-c and a-c polarograms are well defined and easily interpreted, and the parameters $E_{1/2}$, E_s, i_d, or I_s are easily evaluated, where $E_{1/2}$ = d-c half-wave potential, E_s = a-c summit potential, i_d = d-c limiting current, and I_s = a-c summit current.

At low halide or thiocyanate concentrations d-c polarograms are somewhat difficult to analyze. The heights of the waves are very much lower than for high halide concentrations and the limiting height (i_l or i_d) of the wave is ill-defined because of the minimum. Thus the value of i_d to be used in plots of E_{de} *vs.* log $i/(i_d - i)$ is difficult to ascertain and the reversibility of the electrode reaction is uncertain. The a-c polarograms at low concentrations (Fig. 1) are still easily evaluated for E_s, from the potential of the wave at maximum alternating current. $E_{1/2}$ values, however, require a knowledge of the limiting current, which in the presence of the minimum is not readily known,

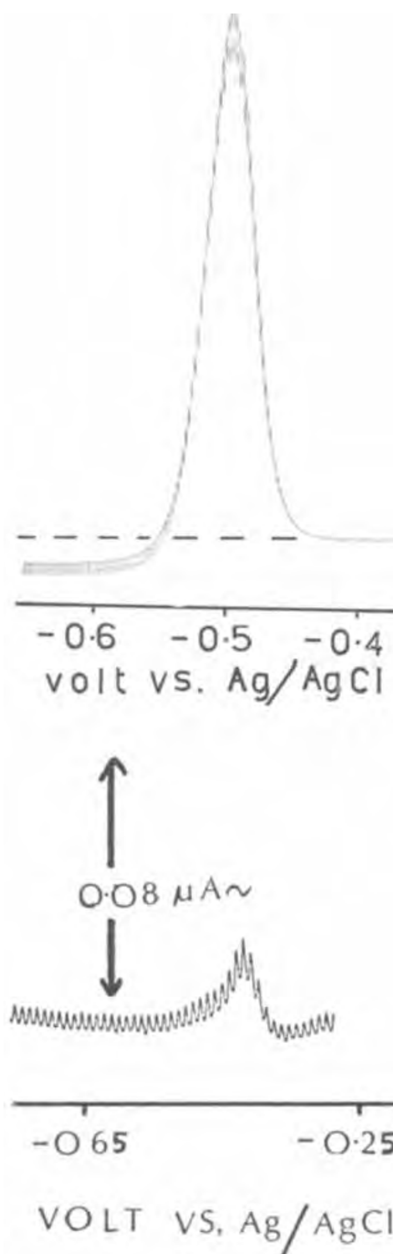

Fig. 1. Typical rapid a-c polarograms of In(III) at low halide or thiocyanate concentrations for which the minimum occurs [NaCl]. (a, upper) 6 × 10^{-2} M, (b, lower) 10^{-3} M.

so that accurate $E_{1/2}$ values at low halide levels cannot be determined.

It was observed that E_s values become more positive with decreasing halide concentration. For the four systems, chloride, bromide, iodide, and thiocyanate, an extrapolation of E_s *vs.* ligand concentration to zero ligand concentration, gave a value of −0.44V *vs.* Ag|AgCl (Fig. 2). This value of E_s could represent the thermodynamic value for the uncomplexed ion, *i.e.*, for the electrode process

$$In(H_2O)_x + 3e \rightleftarrows In\ (amalgam) + xH_2O$$

but this point is considered further at a later stage as complications introduced by adsorption could effect this value.

For the lower concentrations of halide reported in the tables, the height of the a-c and d-c waves are functions of ligand concentration.

The a-c electrode process, despite the decrease in height with decreasing halide concentration, does not appear to alter from being highly reversible from the point of view of both shape and peak potential at least

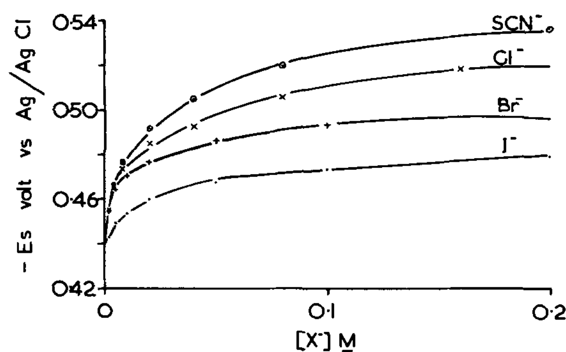

Fig. 2. Extrapolation of E_s to zero ligand concentration to obtain an apparent $(E_s)_f$.

down to 10^{-3}M in ligand concentration. With decreasing ligand concentration the E_s value always becomes more positive as stated above. This is consistent with the electrode reaction being reversible, the changes in E_s being predominantly thermodynamic ones due to complex formation. If the charge transfer had become less reversible, say quasi reversible, then it would be expected that considerable broadening of the a-c wave would occur and that the E_s values would eventually become more negative, rather than positive, with decreasing halide concentration, because of increasing kinetic control.

Although many other systems undergo anion-induced adsorption, and presumably with increased co-ordination, the peculiarities of the indium(III) electrode process appear to be manifestations of the $In^{3+}(aq)$ species being electroinactive at d-c potentials where $[InX_n]^{(3-n)x}$ complexes are electroactive.

The height of the reversible wave would appear to be dependent on the concentration of In(III)-ligand complex present, which in turn appears to be influenced by adsorption phenomena and kinetics of adsorption at the DME.

Thus it can be postulated that the over-all electrode process at potentials near the half-wave potential is as follows:

Indium(III) species in the bulk of the solution are transferred toward the electrode by diffusion. Any uncomplexed In^{3+} is irreversibly reduced, and complexed In(III) reversibly reduced at the DME. The indium(III) complex species are in rapid equilibrium with each other and near or at the DME, interaction can occur with adsorbed ligand, prior to reduction of indium(III) to indium (amalgam).

The height of the resultant a-c or d-c polarographic waves therefore reflects the concentration of indium(III) complex present near the electrode, rather than in the bulk of the solution: that is, a form of the mechanism Pospisil and De Levie derived for low concentrations of thiocyanate [at potentials where the minimum is observed (32)] is believed to be operative at all d-c potentials. More generally, it is concluded that scheme [2] is operative and at low halide concentrations this step is rate determining and is followed by reversible charge transfer: that is, despite the fact that at low ligand concentrations the bulk solution consists almost entirely of uncomplexed In^{3+}, anion induced adsorption permits reduction of indium(III) complexes to occur in the adsorbed state.

Chloride, which forms a strong indium(III) complex, but is not strongly adsorbed (relative to other ligands) is influenced mainly by complex formation in the bulk of the solution. The electrode reaction therefore remains diffusion controlled and the height of the reversible wave increases with increasing chloride concentration because of the increase in concentration of indium complex.

Iodide, which is strongly adsorbed at the DME and forms only a weak complex, is much more influenced by complex formation of indium near the electrode surface with adsorbed iodide.

The adsorption ⇄ desorption equilibrium of halide must also be taken into account (12) and probably explains in part the presence of the minimum. Around the potential of the indium complex wave, which is near the electrocapillary maximum, the adsorbed ligand concentration would be expected to change substantially with potential as desorption occurs. The concentration of the absorbed ligand at potentials beyond the electrocapillary maximum would decrease especially sharply at more negative potentials. The concentration of indium complexes formed near or at the electrode would thus also decrease as the potential becomes more negative and if this was a significant source of complexation then the height of the d-c wave beyond $E_{1/2}$ value, in the normally diffusion-controlled potential range, would also decrease. The decrease in the adsorbed ligand at the electrode surface can in this way give rise to the minima.

Limiting current at very high chloride concentrations.—If the increase in direct or alternating current for indium(III) arises from the combined effects of electroinactive $In(aq)^{3+}$ and anion-induced adsorption, it follows that under conditions where all the In(III) is complexed, that the limiting current should be almost independent of ligand concentration. For bromide, iodide, and thiocyanate it has been suggested that much of the complexation occurs in the double layer via anion-induced adsorption. However, for chloride considerable complexation probably exists in the bulk solution. Calculations of the percentage of each In(III) species present in the bulk solution can be made quite readily by appropriate computational techniques (38), using reported stability constants from the literature. Results for chloride are given in Table I. As stability constant data are notoriously variable, calculations based on three sets of data which cover the range of answers present in the literature, are

Table I. Percentage distribution of the various indium(III) species in the indium(III)-chloride system as a function of chloride concentration

% In^{3+} A*	B**	C†	% $InCl^{2+}$ A*	B**	C†	% $InCl_2^+$ A*	B**	C†	% $InCl_3$ A*	B**	C†	−log[Cl−]

* Column A was calculated assuming Log $\beta_1 = 2.4$, Log $\beta_2 = 3.6$, Log $\beta_3 = 5$.

** Column B was calculated assuming Log $\beta_1 = 2.3$, Log $\beta_2 = 3.4$, Log $\beta_3 = 4$.

† Column C was calculated from data given in Ref. (52), *i.e.*, Log $\beta_1 = 1.4$, Log $\beta_2 = 2.2$, Log $\beta_3 = 3.2$.

All percentages are calculated as mole percentages.

given. From the three sets of data it can be seen that the percentage of $In(aq)^{3+}$ becomes less than 1 when log $[Cl^-]$ lies in the range -0.9 to -0.3, *i.e.*, for chloride concentrations between about 0.1 and 0.5M. From Table II it can be seen that for chloride, I_s ceases to become strongly dependent on chloride concentration over this same concentration range. Similarly, the d-c i_d value is almost independent of chloride concentration above about 0.1M, and the minimum for indium(III) reduction disappears at this high chloride concentration.

With the other systems, similar calculations on the percentage distribution of each species as a function of ligand concentration can be made and it is most evident that the limiting, direct, or alternating currents, which are essentially independent of ligand concentration, are obtained long before all of the In(III) has been complexed in the bulk solution, in accordance with the theories put forward in this work.

Influence of fluoride.—In previous work, the other common halide, fluoride, has not been considered. Fluoride, being very small and virtually nonpolarizable, is one of the least adsorbable ligands available (39) and its behavior might therefore be different from the other halides and thiocyanate. With fluoride being nonadsorbable, but forming quite strong complexes, it would, in fact, be expected that complexation should occur only in the bulk solution, and that complexation via anion-induced adsorption should not be possible. In view of this difference expected for fluoride it would obviously be advantageous to study the influence of fluoride on the polarographic behavior of indium(III). However, to study fluoride, several difficulties are encountered, and it is not surprising that the influence of fluoride is unknown to date. First, fluoride exists in acid media as hydrofluoric acid, which rapidly etches the glass dropping mercury electrode capillary, thus prohibiting measurements with conventional polarographic apparatus. Second, hydrofluoric acid is a weak acid, and under the acid conditions used to study indium(III) reduction, it cannot be assumed that the analytical and free fluoride concentrations are identical. In fact, there will be very little free fluoride available. Third, the insolubility of $Na_3[InF_6]$ could lead to problems (40, 41).

Elsewhere it has been reported that rapid polarographic measurements can be used to overcome problems of etching the glass capillary (42, 43) under the conditions of this work. The other two difficulties do, however, limit the amount of work that can be done with fluoride, to the following:

(*i*) With the same conditions used for the other halides no reversible polarographic wave was observed around -0.4V *vs.* Ag|AgCl on addition of fluoride.

(*ii*) Addition of weighed quantities of fluoride to solutions containing 4.6×10^{-4}M indium and about 10^{-2}M chloride, bromide, iodide, or thiocyanate did not cause any alteration to the reversible indium(III) wave outside of those changes attributable to changes in ionic environment.

While the conclusions that can be made from the work on fluoride are limited, it has at least been shown that traces of fluoride do not give rise to phenomena consistent with anion-induced adsorption and this is in accord with ideas presented in this paper.

A-C summit potential.—Importantly, the reversibility of the electrode process for high ligand concentrations has been established in the above discussion in at least one sense. Work by Moussa *et al.* (44), who measured standard rate constants, k_s, for the exchange

$$In(III) + 3e \rightleftarrows In(Hg)$$

by faradaic impedance methods however, is probably even more convincing.

In 1M NaCl they calculated k_s to be 3.4×10^{-2} cm-sec^{-1} and in 1M NaBr, k_s was 6.5×10^{-1} cm-sec^{-1}. These rate constants are certainly sufficiently fast, particularly in bromide media, to define the d-c electrode process as being reversible. Furthermore, in the a-c sense, they are fast enough, so that provided low frequency a-c polarography is used, as in this work, E_s should equal the reversible half-wave potential $E_{1/2}{}^r$ (45, 46) if normal conditions are operative: that is, provided anion-induced adsorption of some other phenomenon does not alter the E_s value substantially (47).

If the a-c summit potential is equivalent to the "normal" thermodynamic half-wave potential, then the use of this value as a function of ligand concentration in standard polarographic equations could be expected to lead to stability constants in excellent agreement with those obtained by potentiometry, ion exchange, solvent extraction, etc.

In a-c polarography the a-c summit potential, E_s, is used instead of the d-c $E_{1/2}$ value and the equation to be solved is a modified form of the DeFord-Hume relationship (48)

$$F_0(X) = \text{antilog}\left\{0.4343\frac{n\mathbf{F}}{RT}[(E_s)_f - (E_s)_c] + \log\frac{(I_f)}{(I_c)}\right\} = \sum_{j=0}^{j}\beta_j C_x{}^j$$

where $F_0(X)$ is introduced for convenience to represent the experimentally measurable quantity on the left-hand side of the equation. β_j is the formation constant of the jth complex, C_x the concentration of the complex-forming substance, and the subscripts f and c refer to the free ion and complex ion, respectively. Other symbols are those conventionally used in polarography.

The DeFord-Hume equation can be solved for the various β_j values by a considerable number of computational procedures. In this work the graphical method described in detail in the original paper was used with the appropriate $F_j(X)$ functions, where for example

$$F_1(X) = \frac{F_0(X) - 1}{[C_x]},\quad F_2(X) = \frac{F_1(X) - \beta_1}{[C_x]},\quad \text{etc.}$$

The reduction wave for indium(III) in the absence of halide is irreversible so that the $(E_s)_f$ value cannot be determined directly. Thus the value of E_s extrapolated to zero ligand concentration or described previously was used in the first instance.

The term $\log(I_f)/(I_c)$ in the DeFord-Hume equation, which is normally measured by d-c polarography as $\log\ (i_d)_f/(i_d)_c$ cannot be calculated for indium(III) because of the nature of the electrode process. The term therefore had to be neglected. The ratio would be expected to be small in any case so that this approximation should be a good one.

Results, assuming the DeFord-Hume (48) or the simpler Lingane (49) equations to apply, are given below.

DeFord-Hume method.—Indium(III)-chloride system.—Figures 3, 4, and 5 and Table II show the graphical method of calculation of the indium(III)-chloride system. Three complexes were observed with $\beta_1 = 3 \times 10^3$ ($InCl^{2+}$), $\beta_2 = 1.5 \times 10^5$ ($InCl_2{}^+$), and $\beta_3 = 1.3 \times 10^6$ ($InCl_3$).

Indium(III)-bromide system.—Table III and Fig. 3, 4, and 6 show the graphical method of calculation of the indium(III)-bromide system. Three complexes were observed with $\beta_1 = 2.5 \times 10^4$ ($InBr^{2+}$), $\beta_2 = 2.0 \times 10^4$ ($InBr_2{}^+$), and $\beta_3 = 7.7 \times 10^4$ ($InBr_3$).

Indium(III)-iodide system.—Table IV and Fig. 3 and 7 show the graphical method of calculation of the indium(III)-iodide system. One iodide complex was observed with $\beta_1 = 3.5 \times 10^2$ (InI^{2+}).

Indium(III)-thiocyanate system.—Table V and Fig. 3, 4, and 8 show the graphical method of calculation of

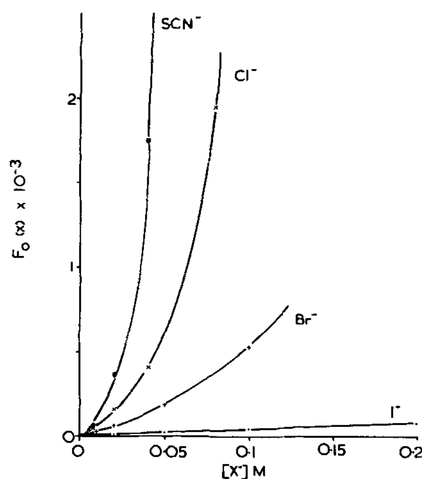

Fig. 3. Graphical analysis of the $F_0(X)$ functions for the various complex systems as shown.

the indium(III)-thiocyanate system. Three complexes of thiocyanate were observed with $\beta_1 = 3 \times 10^3$ ($In(SCN)^{2+}$), $\beta_2 = 9 \times 10^5$ ($In(SCN)_2^+$), $\beta_3 = 3.3 \times 10^6$ ($In(SCN)_3$).

Lingane method.—Figure 9 shows the Lingane (49) method of evaluation of complex ion systems. Plots of E_s ($=E_{1/2}$) *vs.* log concentration of halide or thiocyanate are given. This clearly shows, as do the β_n values, that the order of stability is $SCN^- > Cl^- > Br^- > I^-$. These plots also show the existence of three complexes of thiocyanate, chloride, and bromide. The plots may conveniently be described by three straight lines of slopes 20, 40, and 60 mV, respectively, corresponding to the complexes InX^{2+}, InX_2^+, and InX_2. For the iodide, however, only InI^{2+} is indicated over most of the concentration range studied. The last two points on the graph at very high iodide concentration depart from the straight line and provide evidence for a second weak complex.

Comparison with other data.—Table VI shows a comparison of results obtained in this work with some other studies at similar ionic strength and temperatures. The order of stability established in this work of $SCN^- > Cl^- > Br^- > I^-$ appears to be consistent with most other results.
