N-type Conductivity in Stabilized Zirconia Solid Electrolytes

T. H. Etsell* and S. N. Flengas**

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The n-type conductivity in commercially available stabilized zirconia electrolyte tubes was studied from 600° to 1400°C using three independent techniques: emf measurements on H_2-H_2O mixtures, coulometric titration of oxygen out of liquid silver or copper, and electrolyte breakdown in gas mixtures with low oxygen activities. From the coulometric titration results

$$\log P_\theta = -\frac{54.5 \times 10^3}{T} + 14.0$$

where P_θ is the oxygen pressure at which the ionic and n-type conductivities are equal. Determinations of the electrolyte breakdown voltage permit reasonable estimates of P_θ to be made. Disagreement between the first two techniques was found which enabled discrepancies in the literature to be resolved.

Recent emf measurements on oxide electrolyte cells to determine thermodynamic properties have indicated that accuracies exceeding ±1 mV (±100 cal/mole O_2) can be realized (1, 2). In addition, accuracies exceeding ±2 mV are often reported. Consequently, even small electronic transport numbers in the electrolyte can prove significant, emphasizing the importance of a knowledge of electronic conductivity in oxide electrolytes.

An increasing number of thermodynamic and kinetic studies using oxide electrolytes as well as almost all the investigations concerning either the determination of oxygen in metals or gases or the electrochemical control of oxygen in gas mixtures with oxide electrolyte cells (3) involve the use of commercially available calcia- or yttria-stabilized zirconia tubes (generally from the Zirconium Corporation of America). They are impervious and enable the electrode compartments to function independently. Nevertheless, electronic conductivity data are very limited for such tubes.

Previous work on electronic conductivity in stabilized zirconia samples exhibits marked disagreement. Since, from oxygen permeability measurements, $t_h \leq 10^{-3}$ at 600°-1200°C and $P_{O_2} = 1$ atm where t_h is the transport number of electron holes (4-6), p-type conductivity can be neglected. Nonetheless, it could become significant at higher temperatures since, for ZrO_2-CaO electrolytes, the activation energy for p-type conduction, 43.8 kcal/mole (6), is considerably higher than that for ionic conduction, 25-30 kcal/mole (3). However, n-type conductivity is appreciable at low oxygen pressures on account of the reaction

$$O_O = \frac{1}{2} O_{2(g)} + V_O^{\cdot\cdot} + 2e' \quad [1]$$

where O_O is an oxygen ion on a normal lattice site, $V_O^{\cdot\cdot}$ is a doubly ionized oxygen vacancy, and e' is an excess electron. The usual parameter to describe n-type conductivity is P_θ, the oxygen pressure at which $t_e = 0.5$ where t_e is the transport number of excess electrons (7). The widespread values of $\log P_\theta$ at 1000° and 1600°C which have been reported are listed in Table I. In this table, $\underline{O}$ symbolizes dissolved oxygen.

Regarding the techniques used to obtain these data, the measured emf, E_m, of an oxygen concentration cell having a stabilized zirconia electrolyte and oxygen pressures of P_{O_2}' and P_{O_2}'' at the anode and cathode, respectively, ($P_{O_2}'' > P_{O_2}'$) is given by

$$E_m = \frac{RT}{\mathbf{F}} \ln \frac{P_{O_2}''^{1/4}}{P_{O_2}'^{1/4} + P_\theta^{1/4}} \quad [2]$$

providing that $P_{O_2}'' >> P_\theta$ (7). It is assumed that the n-type conductivity, σ_n, follows the theoretical $P_{O_2}^{-1/4}$ dependence, predictable from Eq. [1]. If the oxygen activity at the anode is very low such that $P_{O_2}' << P_\theta$, a maximum emf, E_{max}, given by

$$E_{max} = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}''}{P_\theta} \quad [3]$$

will be observed and P_θ can be calculated. In the maximum emf method, the low oxygen activity at the anode is achieved thermodynamically whereas, in the coulometric titration method, it is achieved by electrochemically removing oxygen from the anode chamber. In the latter case, if the applied potential is high enough and concentration overpotential only arises at the low oxygen-pressure side, E_{max} can be measured upon opening the circuit.

The thermodynamic emf, E_t, of the cell is

$$E_t = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}''}{P_{O_2}'} \quad [4]$$

An average ionic transport number, $\bar{t}_i$, between the oxygen pressures imposed at the electrodes is defined as

$$\bar{t}_i = \frac{E_m}{E_t} \quad [5]$$

[a] Extrapolated from 1227°C.
[b] 1627°C.
[c] Extrapolated from 1200°C.
[d] Extrapolated from 727°C.
[e] Log P_θ = −28 for ZrO_2 + 16% CaO.

The emf comparison method involves determining E_m for a cell which satisfies the requirement $P_{O_2}'' >> P_{O_2}' \sim P_\theta$ and then calculating P_θ via Eq. [2], *i.e.*, in effect, comparing E_m and E_t. Since only $\bar{t}_i$ values were reported in three papers (12-14), P_θ was found using, in turn, Eq. [4], [5], and [2].

In the d-c polarization technique, potentials are applied to a cell with one reversible electrode and one electrode, which is made the cathode, that prohibits the electrolyte from having access to oxygen because it is either irreversible (11, 19) or nonporous (18). Ionic current is blocked and a plot of log electronic current against applied potential can be used to obtain the n-type conductivity at the oxygen pressure defined by the reversible reference electrode (11, 18, 19). By consequence of the proportionality between σ_n and $P_{O_2}^{-1/4}$ and available ionic conductivity data (3), P_θ can be determined.

Lastly, a-c conductivity measurements as a function of oxygen pressure can be used to obtain σ_n and, therefore, P_θ directly if the required low oxygen activities can be reliably established.

The ionic transport number, t_i, can be readily shown to be

$$t_i = \frac{P_{O_2}^{1/4}}{P_{O_2}^{1/4} + P_\theta^{1/4}} \quad [6]$$

Accordingly, a knowledge of P_θ suffices for calculating the ionic transport number at any required oxygen pressure. Combining Eq. [2], [4], and [6] leads to

$$E_m = E_t + \frac{RT}{\mathbf{F}} \ln (t_i)_{P_{O_2}'} \quad [7]$$

Equation [7], in conjunction with Eq. [5], provides an important relationship between $(t_i)_{P_{O_2}'}$ and $\bar{t}_i$.

The purpose of this paper is threefold: first, to report P_θ values for commercially available stabilized zirconia tubes which were measured over a wide temperature range, second, to introduce an approximate electrolyte breakdown technique, and third, to compare the results obtained by several techniques so that reasons for the serious disagreement in Table I can be advanced thereby indicating which data are more reliable.

Experimental

The solid electrolytes were impervious ZrO_2 + 10 m/o CaO closed-end tubes supplied by the Zirconium Corporation of America. They were 24 in. long with an ID of 9.5 mm and OD of 13.5 mm and contained the following impurities in weight per cent (w/o): 0.62 SiO_2, 0.25 MgO, 0.10 Fe_2O_3, 0.18 Al_2O_3, and 0.11 TiO_2.

The tubes exhibited good thermal shock resistance and excellent stability during temperature cycling and were not destabilized after being partially reduced electrochemically.

In all the experiments, the reference electrode consisted of oxygen at 1 atm pressure flowing through a piece of 45-mesh Pt gauze held firmly against the platinized inside surface of the closed end of the electrolyte tube as previously illustrated (20). Either preanalyzed gas mixtures were passed at 1 atm pressure over a similar electrode on the outside surface of the closed end of the tube, which was held inside a quartz tube, or the electrolyte tube was dipped about ¼ in. into liquid silver or copper of known oxygen content, which was controlled by bubbling preanalyzed gas mixtures (Ar-O_2 for silver and CO-CO_2 for copper) through the metal. Electrical contact with the liquid metals was established with Chromel A wire (80% Ni, 20% Cr) for silver and stainless steel wire (Type 314) for copper.

The measuring instruments have already been described (20).

Results and Discussion

The Pt, O_2 reference electrode is nonpolarizable from 700°-1200°C (20, 21) and hence any overpotential can be attributed to the Pt, gas mixture electrode or the liquid metal electrode.

Emf measurements.—The emf comparison technique was studied from 600°-1100°C with the cell

$$(-)\ H_2\text{-}H_2O/ZrO_2\text{-}CaO/O_2\ (+) \quad (I)$$

In an effort to make $P_{O_2}' \sim P_\theta$, ultrapure hydrogen (>99.999% on a helium-free basis) containing 4 ppm H_2O, 0.5 ppm O_2, ~50 ppm He, and <5 ppm N_2 was passed into the anode chamber. The equilibrium oxygen pressures or, more correctly, oxygen activities (22), measured emf's, and calculated P_θ values (Eq. [2] or Eq. [4], [7], and [6]) are given in Table II.

Table II. Results for the emf comparison technique

Temp, °C	$\log P_{O_2}'$, atm	E_m, mV	$\log P_\theta$, atm
635	−33.33	1464	−34.2
800	−28.95	1466	−28.6
900	−26.89	1459	−25.8
1000	−25.14	1464	−23.9
1050	−24.37	1444	−22.5
1100	−23.65	1430	−21.4

Interchanging the gases in the electrode compartments did not affect the results.

High gas flow rates were required to obtain these data. The emf increased markedly as the flow rate at the anode was increased and did not level off until the ultrapure hydrogen impinged on the electrode with room-temperature linear speeds of 80-100 cm/sec. On an average, flow rates of 2.2, 10, and 30 cm/sec at 25°C yielded emf's that were about 100, 50, and 10 mV lower than those listed in Table II. Because of electronic conductivity and, perhaps, slight porosity in the electrolyte, oxygen is continuously transferred (as ions and atoms or molecules, respectively) from the cathode to the anode chamber where it reacts with hydrogen. The resulting diffusion overpotential lowers the cell emf. High flow rates are needed so that the unwanted water molecules can be flushed away.

Unfortunately, experimental evidence indicates that the complete elimination of diffusion overpotential was impossible making the E_m values in Table II too low and the log P_θ values too high. This was suggested *a priori* by the severe flow rate dependence. The P_θ values are several orders of magnitude higher than those derived from the coulometric titration technique. Drying the H_2-H_2O mixture did not lead to any increase in E_m and its presence in the anode chamber did not produce any detectable changes in the conductivity of the electrolyte.

Oxygen permeability through the electrolyte arising from either electronic conductivity or porosity increases with temperature. From the results for cell (I) in Table II and Eq. [4] and [5], $\bar{t}_i = 0.98$ at 635°C and 0.89 at 1100°C. Interestingly, P_θ was not significantly affected by replacing oxygen in the reference compartment with a CO-CO_2 mixture containing 1.08% CO_2 [$P_{O_2}'' = 10^{-18}$ atm at 1000°C (22)] during the measurements at 1000°-1100°C. Although the driving force for open-circuit oxygen transfer is reduced, n-type conductivity in the electrolyte increases.

Less reducing H_2-H_2O mixtures were also passed into the anode chamber of cell (I). At 1000°C, measured emf's for mixtures containing 0.1% and 0.06% H_2O [$P_{O_2}' = 10^{-20.5}$ and $10^{-21.0}$ atm, respectively (22)] were about 10 and 15 mV too low, respectively. However, when $\bar{t}_i \sim 1$, calculation of P_θ using Eq. [2] is impractical which could, in part, account for the high P_θ values in Table II at the lower temperatures. Previously in H_2-H_2O mixtures, emf deviations from ideality were observed below oxygen pressures of only $10^{-18} - 10^{-19}$ atm at 1000°C (23, 24) and $10^{-8} - 10^{-9}$ atm at 1600°C (12, 23, 25) and have been attributed to both electronic conductivity (12) and porosity (24-26) in the ceramic electrolytes.

Coulometric titration.—Oxygen was electrochemically removed from liquid silver or copper containing 5 x 10^{-4} to 5 x 10^{-3} atomic per cent (a/o) O in the cell

$$(-)\ \mathrm{O(in\ Ag\ or\ Cu)/ZrO_2\text{-}CaO/O_2}\ (+) \qquad \text{(II)}$$

Experiments were carried out from 1000°-1200°C for silver and from 1100°-1400°C for copper.

To appreciably lower the oxygen activity at the metal-electrolyte interface, the applied potential was held constant for 2 min prior to opening the circuit and immediately measuring the cell potential. Repeating this procedure at increasing applied potential (0.2V increments) led to maximum open-circuit cell potentials when the applied potential reached 2-3V. Subsequent increases served only to further reduce the cathode side of the electrolyte. Substoichiometric ZrO_2, but never zirconium metal, was allowed to form. If reoxidation due to oxygen diffusion from the bulk of the liquid metal and oxygen migration through the electrolyte was prevented, the cathode side was observed to be a whitish-gray color, rather than white. If reoxidation was permitted, the original resistance of the electrolyte was generally restored within a few minutes indicating no detrimental structural changes had occurred.

In Fig. 1, E_{max} is plotted against temperature. Comparable values were obtained by coulometrically titrating oxygen out of H_2-H_2O mixtures dilute in H_2O using cell (I). During current passage through cell (II), the only overpotential which appears is diffusion overpotential at the liquid metal electrode (21). Hence, equilibrium exists at the electrode-electrolyte interfaces and P_θ can be calculated from Eq. [3]. The results are presented in Fig. 2 and can be expressed as

$$\log P_\theta = -\frac{54.5 \times 10^3}{T} + 14.0 \qquad [8]$$

The P_θ values are 5-6 orders of magnitude higher than the decomposition pressures of tetragonal ZrO_2 (22).

Such a dependence for P_θ can be predicted by noting that, for an oxide electrolyte

$$\sigma_i = A_i \exp(-\Delta H_i/RT) \qquad [9]$$

$$\sigma_n = A_n P_{O_2}^{-1/4} \exp(-\Delta H_n/RT) \qquad [10]$$

where σ_i and σ_n are the ionic and n-type conductivities, respectively, A_i and A_n are approximately constant, and ΔH_i and ΔH_n are apparent activation enthalpies for ionic and n-type conduction, respectively. When $\sigma_i = \sigma_n$, $P_{O_2} = P_\theta$ and, thus

$$P_\theta = (A_n/A_i)^4 \exp[-4(\Delta H_n - \Delta H_i)/RT] \qquad [11]$$

meaning that

$$\log P_\theta = -\frac{A}{T} + B \qquad [12]$$

where

$$A = \frac{1.7372(\Delta H_n - \Delta H_i)}{R} \qquad [13]$$

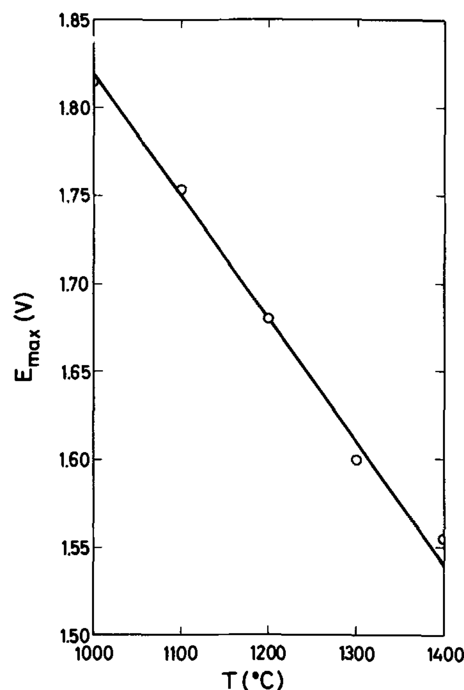

Fig. 1. Maximum cell potential resulting from coulometric titration of oxygen out of liquid silver or copper. Reference electrode was Pt, O_2 (1 atm).

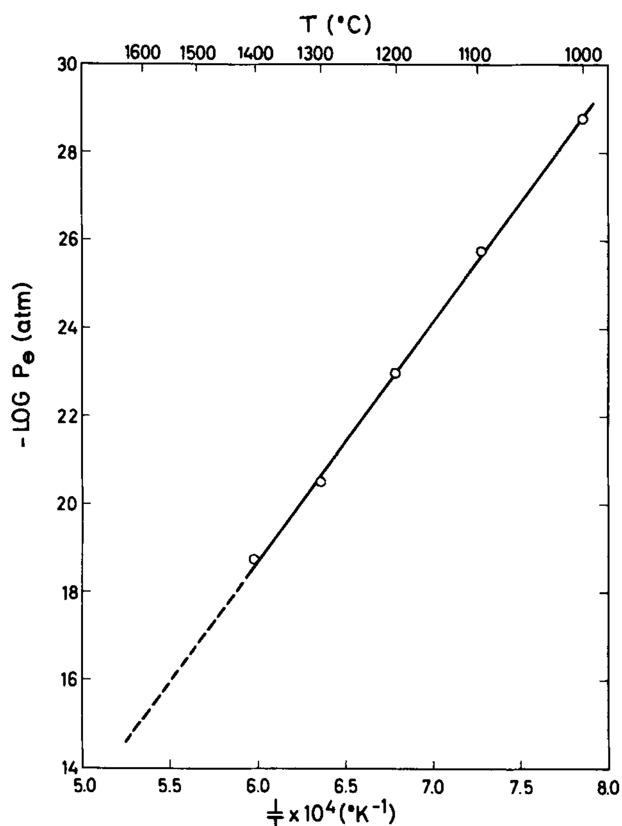

Fig. 2. Temperature dependence of P_θ for commercially available stabilized zirconia electrolytes.

and

$$B = 4 \log (A_n/A_i) \qquad [14]$$

Possible changes in A_i or ΔH_i with temperature (3, 27) make lengthy extrapolations of Eq. [12] uncertain. Comparing Eq. [8], [12], and [13] gives $\Delta H_n - \Delta H_i =$ 62.3 kcal/mole. Since ΔH_i was determined to be 25.3 kcal/mole, $\Delta H_n = 87.6$ kcal/mole. It will be associated with one half the enthalpy of reaction [1] and any enthalpy needed to release excess electrons from electron traps such as ionized oxygen vacancies, Zr^{4+} ions, and interstitial or easily reducible impurity cations.

Electrolyte breakdown.—In the electrolyte breakdown technique, a potential, E, is applied to the cell

$$(-)\ P_{O_2}'/ZrO_2\text{-}CaO/P_{O_2}''\ (+) \qquad (III)$$

as shown, making P_{O_2}' and P_{O_2}'' the oxygen pressures at the cathode and anode, respectively. The equilibrium concentration of electroactive species at the cathode (O, O_2, CO_2, H_2O, etc.) is kept low to essentially suppress ionic current and the anode is a nonpolarizable reference electrode. As the ionic IR drop and any transition overpotential will be negligible, concentration overpotential at the cathode accounts for the entire applied potential. Therefore

$$E = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}''}{P_{O_2}'} \qquad [15]$$

where P_{O_2}' is the oxygen pressure imposed at the cathode surface of the electrolyte by the applied potential (E is considered positive for convenience).

The n-type current density, i_n, obeys the equation

$$i_n = -\sigma_n \frac{dE}{dx} = \bar{\sigma}_n \frac{E}{l} \qquad [16]$$

where x is the distance across the electrolyte from the reference electrode, $\bar{\sigma}_n$ is the apparent average n-type conductivity, and l is the thickness of the electrolyte. At any point inside the electrolyte under steady-state conditions

$$E = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}}{P_{O_2}'} \qquad [17]$$

where P_{O_2} is the oxygen pressure corresponding to the local chemical potential. Differentiating Eq. [17] with respect to x, substituting into Eq. [16], and integrating across the electrolyte gives

$$i_n = \frac{RT}{4\mathbf{F}l} \int_{\ln P_{O_2}'}^{\ln P_{O_2}''} \sigma_n \, d \ln P_{O_2} \qquad [18]$$

Equations of this type have been derived and discussed by Wagner (28).

Alternatively, at any point inside the electrolyte

$$i_n = \frac{\sigma_n}{\mathbf{F}} \text{grad } \eta_{e'} \qquad [19]$$

where $\eta_{e'}$ is the electrochemical potential of excess electrons and the absolute value of the vector grad $\eta_{e'}$ $= d\eta_{e'}/dx$ (4). For reaction [1] in equilibrium

$$\text{grad } \mu_{O_O} = \tfrac{1}{2} \text{ grad } \mu_{O_2} + \text{grad } \eta_{V_O^{\cdot\cdot}} + 2 \text{ grad } \eta_{e'} \qquad [20]$$

where μ is chemical potential. Since the ionic current is virtually zero, at steady state grad $\eta_{V_O^{\cdot\cdot}} = 0$. Also grad $\mu_{O_O} \sim 0$ meaning that

$$\text{grad } \eta_{e'} = -\tfrac{1}{4} \text{ grad } \mu_{O_2} \qquad [21]$$

Substitution of Eq. [21] into Eq. [19] followed again by integration across the electrolyte from $x = 0$ at the anode to $x = l$ at the cathode produces Eq. [18].

From Eq. [10]

$$\sigma_n = \sigma_i \left(\frac{P_{O_2}}{P_\theta} \right)^{-1/4} \qquad [22]$$

Inserting Eq. [22] and $d \ln P_{O_2} = dP_{O_2}/P_{O_2}$ into Eq. [18] yields

$$i_n = \frac{RT}{\mathbf{F}l} \sigma_i P_\theta^{1/4} \left(-P_{O_2}''^{-1/4} + P_{O_2}'^{-1/4} \right) \qquad [23]$$

Substitution of Eq. [15] into Eq. [23] leads to the final expression

$$i_n = \frac{RT}{\mathbf{F}l} \sigma_i P_\theta^{1/4} P_{O_2}''^{-1/4} [\exp(E\mathbf{F}/RT) - 1] \qquad [24]$$

This equation will only apply when E is low enough so that $\sigma_n \propto P_{O_2}'^{-1/4}$, *i.e.*, at reasonably small deviations from stoichiometry in the electrolyte near the cathode.

In the case of significant ionic current

$$E = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}''}{P_{O_2}'} + IR + \eta_t \qquad [25]$$

where I is the ionic current, R is the ionic resistance of the electrolyte, η_t is transition overpotential, and, again, P_{O_2}' is the oxygen pressure at the cathode surface of the electrolyte. If $\eta_t \sim 0$ and P_{O_2}' is determined, i_n could be evaluated using Eq. [7] and [8] in a recent paper (29). For almost complete ion blocking, an approximate expression for i_n has been derived (18).

For the ZrO_2 + 10 m/o CaO electrolytes studied here

$$\sigma_i = 837 \exp(-25{,}300/RT) \qquad [26]$$

and $l = 0.2$ cm. Theoretical electronic current density curves at 1000° and 1100°C for $P_{O_2}'' = 1$ atm, calculated from Eq. [24], are shown in Fig. 3. The P_θ data were obtained from Fig. 2. Applied potentials making $P_{O_2}' =$ P_θ (Eq. [15]) cause considerable electrolyte breakdown, *e.g.*, from Fig. 3, $i_n = 21$ and 47 mA/cm^2 at 1000° and 1100°C, respectively. According to Eq. [24], when exp $(E\mathbf{F}/RT) >> 1$, P_θ could be quantitatively determined by extrapolating plots of ln i_n *vs.* E to $E = 0$.

To effect ion-blocking conditions, low oxygen activities at the cathode in cell (III) were established with either Ar-O_2 mixtures dilute in O_2, CO-CO_2 mixtures dilute in CO_2, or a H_2-H_2O mixture dilute in H_2O. High flow rates were required to eliminate or minimize open-circuit diffusion overpotential which

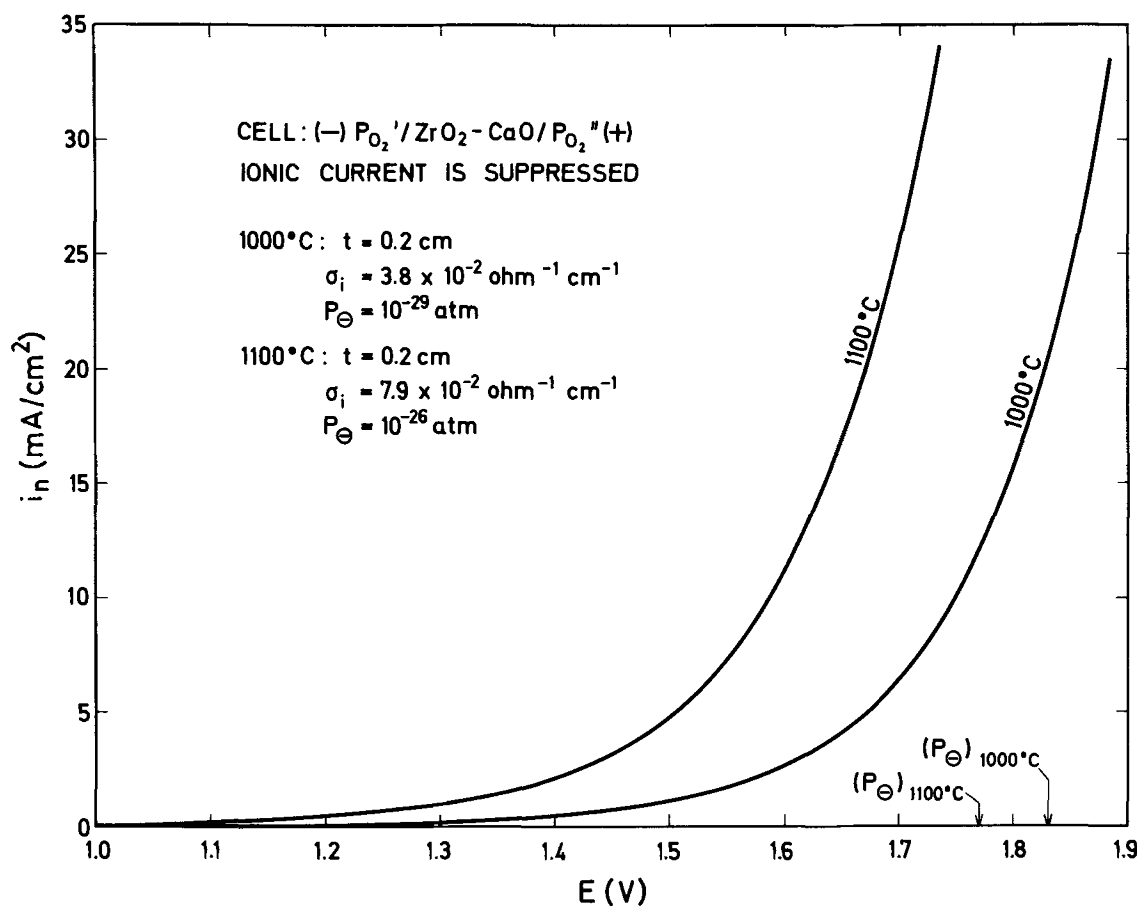

Fig. 3. Theoretical curves of n-type current density against applied potential at 1000° and 1100°C when ionic current is suppressed (P_{O_2}'' = 1 atm).

was discussed in the section on emf measurements. Prior to breakdown, the a-c resistance of the electrolyte measured at 3000 Hz was about 35 and 15 ohms at 1000° and 1100°C, respectively. Potential was applied to the cell allowing 20-30 min per 0.1V increment. Total current density *vs.* applied potential plots are shown for Ar-O_2 mixtures and for CO-CO_2 and H_2-H_2O mixtures in Fig. 4 and 5, respectively. The composition given for the H_2-H_2O mixture was calculated from the cell emf. Between 5 and 60 min were required to reoxidize the electrolyte by interrupting the current.

Comparing Fig. 4 and 5 with Fig. 3, it is evident that ionic current was not totally suppressed although ionic resistance polarization and transition overpotential, which is important in CO-CO_2 mixtures (20), are low. In addition, the surprisingly slow current increase at high applied potentials at 1000°C indicates that, at this temperature, the loading rate was too rapid for steady-state electronic currents to be fully realized. Lastly, the current densities are somewhat low since they are based on the geometric area of the cathode-electrolyte interface (1.0 cm^2) rather than the actual area of contact between the Pt gauze and the electrolyte which was somewhat smaller. Nevertheless, currents were observed to increase significantly at potentials near those corresponding to P_θ (Fig. 1). Extrapolation of the steep portions of the curves to i = 0 gives breakdown voltages of 1.74 and 1.70V at 1000° and 1100°C, respectively, corresponding to oxygen

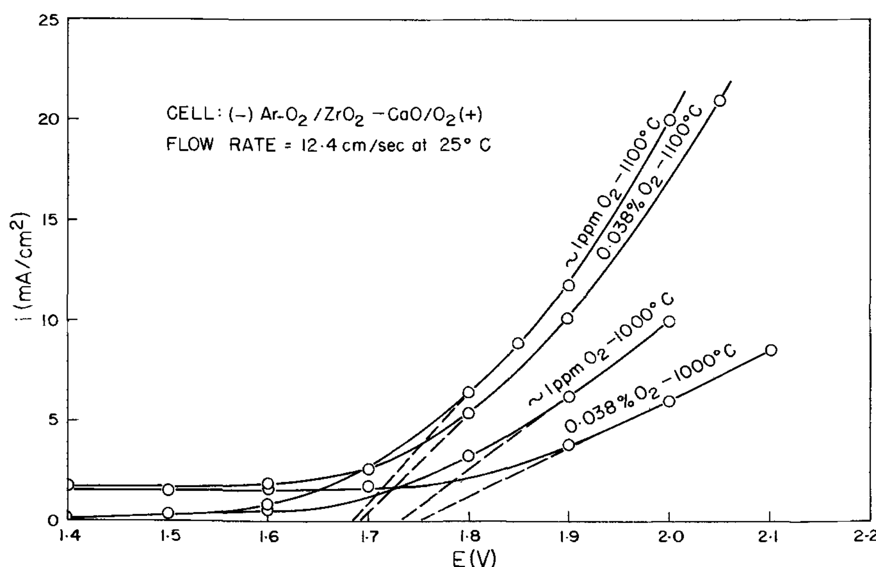

Fig. 4. Breakdown voltages in Ar-O_2 mixtures dilute in O_2.

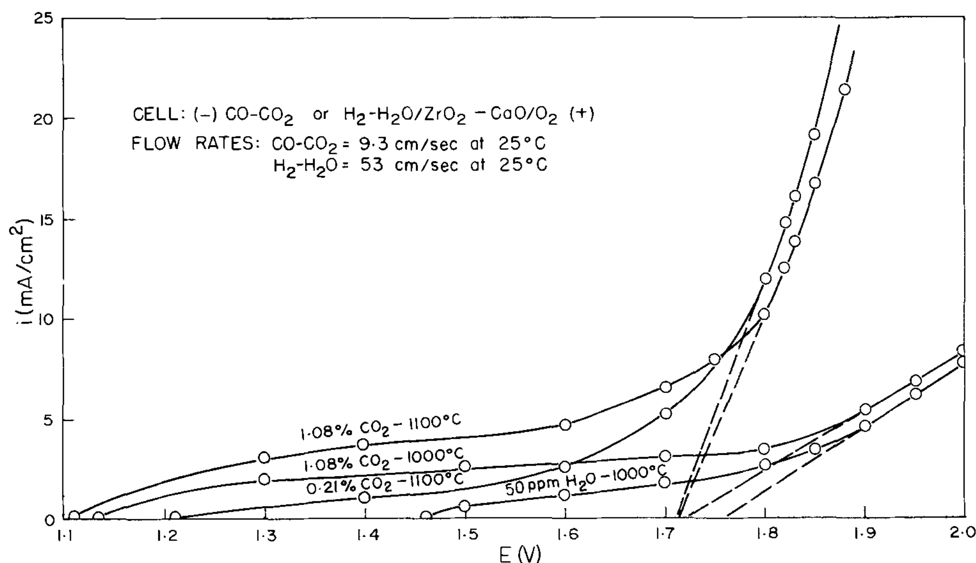

Fig. 5. Breakdown voltages in CO-CO_2 mixtures dilute in CO_2 and a H_2-H_2O mixture dilute in H_2O.

pressures about one order of magnitude higher than P_θ (Fig. 2).

Physically, electrolyte breakdown proceeds as follows. At applied potentials sufficiently high to make the oxygen activity at the cathode very low, the cathode surface of the electrolyte becomes electronically conducting via reaction [1]. The current increases since electrons can now be transferred directly from the cathode to the electrolyte forming **F**-centers (if they are trapped by oxygen vacancies) or Zr^{3+} ions and, as a consequence, more $O^{=}$ ions initially migrate from the cathode side to the anode side of the electrolyte than are produced from oxygen-bearing species in the gas phase. Accordingly, the reduced zone spreads slowly towards the anode at a rate controlled by the electronic resistance of the electrolyte; this reduction causes large hysteresis in current-potential curves. Simultaneously, electronic current continues to increase since the electronic conductivity of the electrolyte increases. Eventually, the equilibrium composition of the electrolyte, dictated by the oxygen activities at the anode and cathode, is reached and the current becomes constant. If the cathode region is markedly reduced ($t_i \sim 0$), oxygen-bearing species attempting to maintain the ionic current are obliged to diffuse through the reduced zone prior to electrochemical reaction. Severe reduction will result in the formation of either tetragonal ZrO_2 or α-zirconium (which may react with the electrode) in conjunction with a CaO-enriched cubic phase and simultaneous or subsequent cracking of the electrolyte (30, 31).

In general, care must be taken to ensure that oxygen-bearing species have limited access to the cathode surface of the electrolyte. The ionic current may increase at high applied potentials because, when the electrolyte can conduct electronically, direct oxygen transfer from the gas phase to the electrolyte does not necessitate the nearby presence of the electrode (18, 20, 32). Secondly, it may be impossible to decrease the oxygen activity in gas mixtures to very low levels because of either their buffer capacity or slow decomposition (15).

Comparison of the different techniques.—The P_θ results at 1000°-1100°C for the emf comparison technique, given in Table II, are 4-5 orders of magnitude higher than those shown for the coulometric titration technique in Fig. 2. Interestingly, using the 1000°C data in Table I, a parallel comparison can be drawn between previous studies involving emf measurements (7, 9, 15) and coulometric titration (8, 10, 14, 17).

In this work, a strong dependence of emf on flow rate for H_2-H_2O mixtures dilute in H_2O was found, which indicates that open-circuit oxygen transfer through the electrolyte leading to diffusion overpotential can seriously limit the accuracy of emf measurements at very low oxygen activities. Not surprisingly, as mentioned earlier, its influence was not eliminated. Its detrimental effect can be further appreciated by noting that P_θ calculated from available $\bar{t}_i$ data (12) for cell (I) depends on the value of $\bar{t}_i$ chosen, *e.g.*, at 1600°C, $P_\theta = 10^{-15}, 10^{-14}$, and 10^{-13} atm using $\bar{t}_i = 0.99$, 0.98, and 0.95, respectively. Although oxygen transfer can be minimized by keeping $P_{O_2}' > P_\theta$ such that $t_i \sim 1$, the required calculation of P_θ from Eq. [2] becomes very sensitive to small errors in the measured emf. In some previous work, emf measurements were taken on cells having, as anodes, two-phase mixtures which only provide an invariant oxygen activity as long as both phases can be retained at the electrode-electrolyte interface. High P_θ values would be calculated if the anode were appreciably oxidized. However, to attribute the high values in Table I solely to concentration overpotential effects may be an oversimplification. For instance, Schmalzried (7) mentioned that his cell emf could be kept constant for hours. Other factors such as impurities in the electrolytes will be partly responsible.

The coulometric titration technique is rapid and should be accurate if very low oxygen activities can be established at the cathode. Failure to achieve this in N_2-O_2 mixtures at 600°-800°C might account for the inconsistently high coulometric titration P_θ data that has been reported (15). Disagreement can, at least in part, be traced to different electrolyte purities. In the electrolyte tubes used here, the ease of reduction of the Fe^{3+} and Ti^{4+} impurity ions could aid the onset of n-type conduction. The low P_θ values recently reported by Swinkels (17) are for high-purity electrolytes.

The d-c polarization technique is often inaccurate, especially when electronic transport numbers are low. Results achieved by this technique for ZrO_2-CaO electrolytes at low oxygen pressures and for ThO_2-Y_2O_3 electrolytes at high oxygen pressures disagreed markedly with a-c conductivity measurements (11). More recent values are entirely unrealistic since ionic current was insufficiently blocked. They are 2-3 orders of magnitude lower than the decomposition pressures of tetragonal ZrO_2 (22).

In summary, the coulometric titration results are preferable. Thermodynamic property measurements with stabilized zirconia cells support the P_θ data obtained by this technique (3).

Critical oxygen pressures for oxide electrolytes.—The results of this investigation are summarized in Table III. Results for the more stable ThO_2-Y_2O_3 electrolytes are included for comparison. The 1600°C values are based on the fact that ThO_2-Y_2O_3 electrolytes have been used

Table III. Critical oxygen pressures (activities) for solid oxide electrolytes

Electrolyte	Temp, °C	log P_{O_2}, atm				Ref
		t_i = 0.50[a]	t_i = 0.99	$\overline{t_i}$ = 0.99[b]	$\overline{t_i}$ = 0.99[c]	
ZrO_2-CaO	1000	−29	−21	−26	−24	This work
	1600	−15[d]	−7	−10		This work
ThO_2-Y_2O_3	1000	−33	−25	−30	−29	(9, 33)
	1600	−19	−11	−15	−13	(34, 35)

[a] Log P_{O_2} = log P_θ.
[b] In a cell with O_2 at 1 atm at the reference electrode (neglecting p-type conductivity in the case of ThO_2-Y_2O_3).
[c] In a cell with an Fe-Fe_xO reference electrode, *i.e.*, oxygen pressures at the cathode of 10^{-15} and 10^{-8} atm at 1000° and 1600°C, respectively (22), neglecting mutual solubility of the liquid phases at 1600°C.
[d] Extrapolated from 1400°C.

to obtain reliable free energy data for the Mn-MnO system at 1550°C (34) and the Si-SiO_2 system at 1600°C (35). The $t_i = 0.99$ data were calculated from Eq. [6] and the $\overline{t_i} = 0.99$ data were obtained by trial and error in Eq. [7] in conjunction with Eq. [6].

For ZrO_2-CaO electrolytes, the critical oxygen pressures are consistent with thermodynamic property measurements using stabilized zirconia cells. Results for the free energy of formation of Cr_2O_3, determined from emf measurements on the cell

$$Cr\text{-}Cr_2O_3/ZrO_2\text{-}CaO/air \qquad (IV)$$

at 700°-1200°C (10, 36, 37), are in excellent agreement with the literature (22). The Cr-Cr_2O_3 electrode exerts an oxygen pressure of $10^{-21.6}$ atm at 1000°C (22) and, from Table III and Eq. [2], [4], and [5], $\overline{t_i} = 0.999$ for cell (IV). Lower oxygen pressures at the anode generally introduce sufficient n-type conductivity to render accurate emf measurements impossible (3).

Evidence has been advanced to suggest that electronic conductivity is quite low at an oxygen pressure of 10^{-12} atm at 1600°C (3). For cell (IV) at 1600°C, the anode oxygen pressure is $10^{-11.8}$ atm (22) and, from this work, $\overline{t_i} = 0.98$. The Cr-Cr_2O_3 electrode has been successfully used as a reference electrode in several recent studies at 1500°-1600°C (35, 38, 39).

Conclusions

Determination of n-type conductivity in oxide electrolytes via emf measurements at low oxygen activities is generally inaccurate on account of oxygen transfer through the electrolyte, an unavoidable consequence of electronic conductivity and porosity. Low oxygen activities are more reliably realized by coulometric titration. Following the breakdown of an oxide electrolyte can lead to reasonable estimates of the magnitude of n-type conductivity.

The oxygen activities imposed by the Cr-Cr_2O_3 system approximately define the lower limit of practical applicability of commercially available stabilized zirconia electrolytes.

Transport number determinations can only serve as a guide to the use of oxide electrolytes. Variables such as electrolyte purity and porosity, possible electrode-electrolyte interactions, and the cell arrangement render individual checks advisable whenever possible.

Mechanism of the Processes of Formation of Lead-Acid Battery Positive Plates

D. Pavlov, G. Papazov, and V. Iliev

Institute of Physical Chemistry, Central Electrochemical Power Sources Division, Bulgarian Academy of Sciences, Sofia 13, Bulgaria

ABSTRACT

The processes involved in the formation of the positive lead-acid battery plate in H_2SO_4 with sp gr 1.15 and 1.05 and in 0.7M Na_2SO_4 were studied by x-ray diffraction, wet chemical analysis, and microscopic observations. It was found that formation takes place in two stages. During the first one, H_2SO_4 and H_2O penetrate from the bulk of the solution into the plate. As a result of chemical and electrochemical reactions tet-PbO and basic sulfates of lead are converted to $PbSO_4$ and α-PbO_2. These compounds form zones which advance into the paste. Part of the hydrogen ions evolved during the reaction of formation of PbO_2 migrate from the plate in order for the latter to remain electroneutral. During the second period H_2O is consumed in the plate. Lead sulfate is oxidized to β-PbO_2. Sulfuric acid originates and diffuses in a direction opposed to that in the first period. Taking into account specific conditions of the chemical and electrochemical reactions in porous electrodes a mechanism is suggested for the formation processes of the positive plate. Ion diffusion and migration are considered to be the rate-limiting steps of the processes. The direction of advance of the PbO_2 and $PbSO_4$ zones is explained in terms of this mechanism as well as the α/β-PbO_2 ratio during formation in the three solutions. The parameters which control the phase composition of the active material of the lead-acid battery positive plate are listed.

Formation is one stage of the technological process of lead-acid battery production. By mixing oxidized lead powder with sulfuric acid a paste is obtained which consists of lead monoxide and basic sulfates of lead. After pasting on a grid and curing, the paste is subjected to formation. During formation lead monoxide and the basic sulfates are converted by electrochemical reactions to active material, *i.e.* to lead at the negative plate and to lead dioxide at the positive one. Formation takes place in a sulfuric acid solution. Lead monoxide and basic sulfates of lead are unstable in sulfuric acid, and therefore the electrochemical reactions are accompanied by chemical sulfation processes. All this imparts a great complexity to the formation process. Until now attention has been mainly focused on the influence of paste, electrolyte and current density, of temperature, etc. on the processes at the positive plate (1-15). This interest may be explained by the fact that formed plates contain both the acidic β and the alkaline α polymorph of PbO_2. On the other hand, the capacity and the life of the positive plate is determined by the ratio between the polymorphs in it. With the increase in the content of the beta polymorph in the active mass, the capacity increases but the life of the plate decreases.

Attempts at elucidating the formation processes of the positive plate were mainly concerned with determination of the mechanism of formation of α-PbO_2. Two schools of thought are to be found in the literature. According to the first one, the solution in the pores is locally alkalinized which leads to the formation of α-PbO_2 (1, 5). According to the second one, α-PbO_2 is a result of solid-state reactions within the basic lead sulfate crystals (2, 4). In order to elucidate the mechanism of the processes which take place upon formation of the positive plate, however, it is not enough to determine the causes which lead to the formation of α-PbO_2.

In the present work the changes in phase and chemical composition occurring during formation of the positive plate in solutions of different pH were followed by x-ray diffraction and chemical analysis. This makes it possible to determine the electrochemical and chemical processes of formation. In order to establish the chemical reactions between the solution and paste, the changes in phase composition upon leaving the plate in the solution at open circuit were followed by x-ray diffraction and chemical analysis. Since the products obtained contrast in color, it proved possible to determine the distribution of the processes within the plate by microscopic observations at low magnification. The suggested mechanisms of the processes of formation and of their dependence on the pH of the solution in which forming was carried out is based on these results.

Key words: lead acid battery, lead acid battery technology, PbO_2 electrode, electrochemical reactions in a porous mass, electrochemical oxidation of lead oxide and basic sulfates.

Experimental

Plates of dimensions 143 × 125 × 1.8 mm (14 A-hr) were formed. The paste was prepared by mixing lead powder with sulfuric acid [4.5 weight per cent (w/o) with respect to the lead powder]. The paste density was 3.60 g/cm^3. The electroformation density current was 5 mA/cm^2 and the temperature 25°C. Formation was carried out in three kinds of solutions: H_2SO_4 sp gr 1.05 (pH = 0.25), and 1.15 (pH = −0.20) and 0.7M Na_2SO_4 (pH = 7). The phases in the dry paste were identified. Samples were taken close to the four corners and from the middle portion of the plate. The material was homogenized in a mortar and transferred to the sample holder of a TuR-M 61 x-ray diffractometer (filtered copper radiation).

Cells constituted by two positive and three negative plates were used in the investigation of the processes. The following parameters were measured every two hours during the formation process:

(*i*) Potential of the positive plate under load ϕ_i.

(*ii*) Potential of the positive plates at open circuit ϕ_o.

(*iii*) Phase composition of the paste and of the active mass. One of the positive plates was removed and washed. Samples were taken as already described and x-rayed.

(*iv*) Chemical composition of the paste and active mass. The following components were analytically determined: ($\alpha + \beta$) PbO_2, total PbO (free PbO plus PbO in the basic sulfates), and total $PbSO_4$ (free $PbSO_4$ plus $PbSO_4$ bonded in the basic sulfates).

(*v*) The distribution of the reaction products along the cross section of the plate. Under the binocular mi-

croscope the distribution of the compounds was followed along the cross section of the plate. Color and black-and-white photographs were taken. After sampling the plate was returned into the cell, the current was adjusted, and the formation resumed.

Results

Formation in H_2SO_4 of sp gr 1.15.—Figure 1(a) shows the changes in the intensities of the characteristic diffraction lines of $PbSO_4$ d = 3.00Å, $3PbO \cdot PbSO_4 \cdot H_2O$ d = 3.26Å, $2PbO \cdot PbSO_4$[1] d = 2.95Å, tet-PbO and α-PbO_2 d = 3.12 — 3.13Å; β-PbO_2 d = 2.79Å measured on x-ray diffraction patterns during formation. Figure 1(b) illustrates the chemical analysis results for $PbSO_4$, PbO, and PbO_2.

From Fig. 1(a) it is seen that $3PbO \cdot PbSO_4 \cdot H_2O$ and $2PbO \cdot PbSO_4$ disappear within the first two hours of formation while chemical analysis [Fig. 1(b)] shows that PbO reacts completely up to the sixth hour. Lead sulfate originates as a result of these reactions. This compound constitutes as much as half of all lead compounds in the plate during the first two hours of formation [Fig. 1(b)]. This amount of $PbSO_4$ begins to decrease after the fourth hour and after 18 hr forming only 10% of it remains. In addition Fig. 1(a) and 1(b) show that up to the fourth hour of formation only tet-PbO and the basic sulfates are electrochemically oxi-

[1] The diffraction line with d = 2.95A is common to $PbO \cdot PbSO_4$ (I = 100) (16) and to $2PbO \cdot PbSO_4$ (I = 100) (16). The second strongest line of $PbO \cdot PbSO_4$ has d = 3.33Å (I = 100) while for $2PbO \cdot PbSO_4$ it has d = 2.87A (I = 70). In its x-ray diffraction pattern there is no line with d = 3.33Å whereas one with d = 2.87Å is observed. The intensity of the latter changes in a way similar to that of the 2.95Å line. This leads us to assume that the 2.95Å line belongs to $2PbO \cdot PbSO_4$.

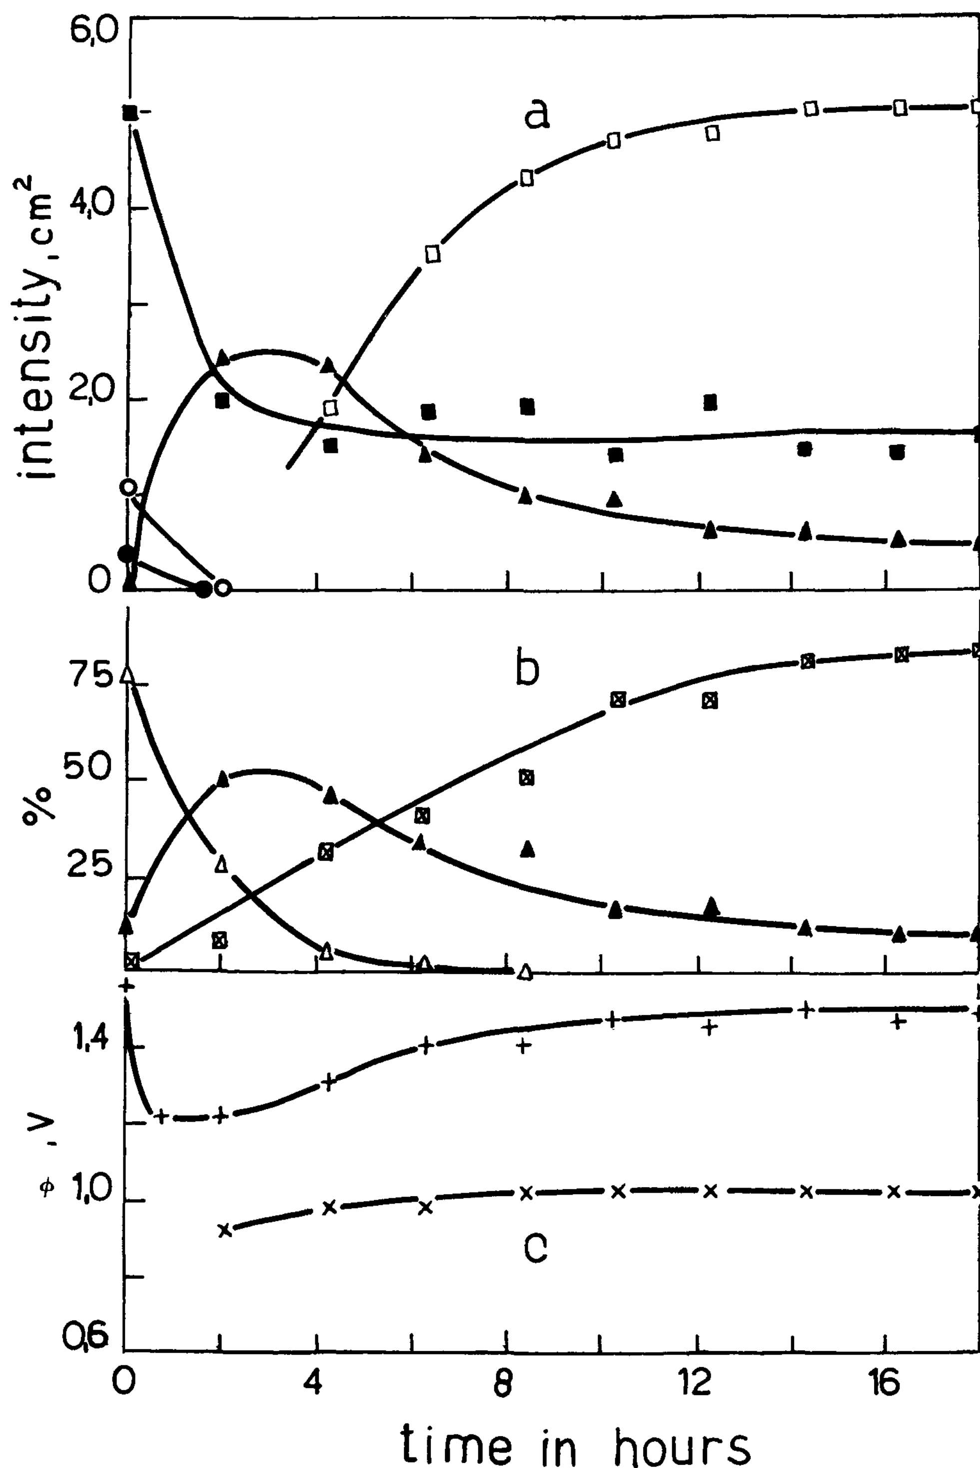

Fig. 1. (a). Intensity changes of the characteristic diffraction lines of $3PbO \cdot PbSO_4 \cdot H_2O$ with d-3.26Å (○), $2PbO \cdot PbSO_4$ with d = 2.95Å (●), $PbSO_4$ with d = 3.00Å (▲), β-PbO_2 with d = 2.79Å (□), tet-PbO + α-PbO_2 with d = 3.12 — 3.13Å (■) during formation in H_2SO_4 of sp gr 1.15. (b). Changes in the amounts of (α + β)-PbO_2 (⊠), $PbSO_4$ (▲) and total PbO (△) in percentages during formation. (c). Change in plate potential (with respect to the Hg/Hg_2SO_4 electrode) under lead ϕ_i (+) and at open circuit ϕ_o (x) during formation.

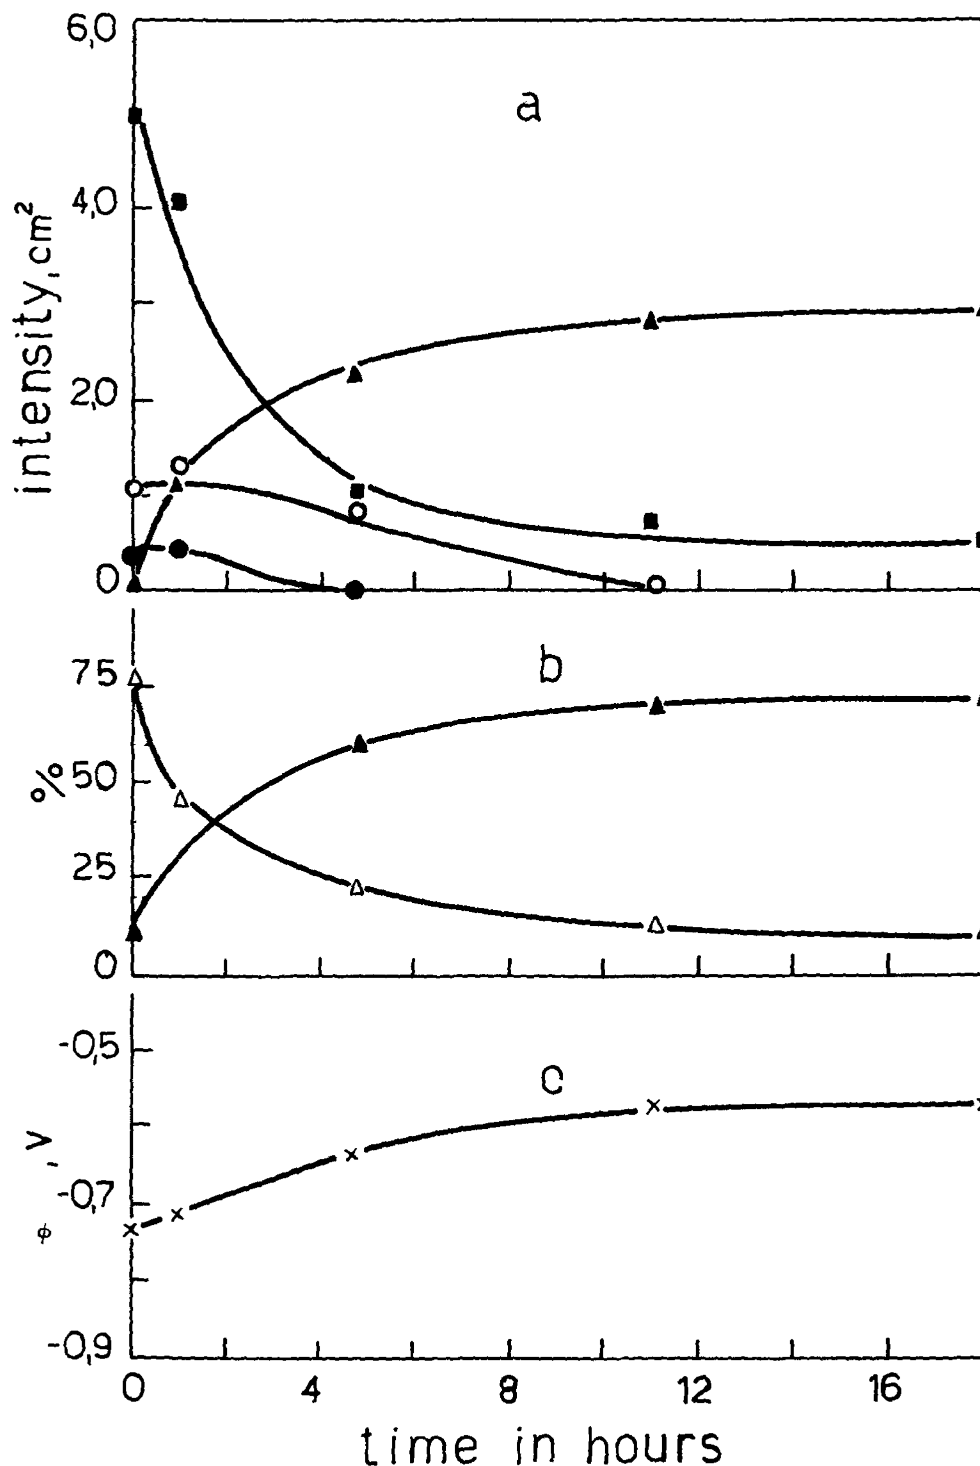

Fig. 2. (a). Intensity changes of the characteristic diffraction lines of $3PbO \cdot PbSO_4 \cdot H_2O$ with d = 3.26Å (○), $2PbO \cdot PbSO_4$ with d = 2.95Å (●), $PbSO_4$ with d = 3.00Å (▲), tet-PbO with 3.12Å (■) upon leaving the plates in H_2SO_4 of sp gr 1.15. (b). Changes in the amounts of the total PbO (△) and $PbSO_4$ (▲) upon leaving the plate in H_2SO_4 of sp gr 1.15. (c). Change in the plate potential (with respect to the Hg/Hg_2SO_4 electrode) ϕ_o (x) upon exposure to H_2SO_4 of sp gr 1.15.

dized to PbO_2. The 3.13Å diffraction line of α-PbO_2 coincides with the 3.12Å line of tet-PbO. The intensity of this diffraction line common to both compounds abruptly decreases during the first four hours of the formation process after which it remains constant. This shows that α-PbO_2 forms only during the first 2-4 hours. Similar results were also reported elsewhere (1, 2). Since during this period only tet-PbO and basic sulfates of lead are oxidized, it follows that α-PbO_2 originates by electrochemical oxidation of these compounds. After 6 hr of formation the 3.13Å diffraction line is diagnostic for α-PbO_2. Beta lead dioxide forms intensively in the plate after the fourth hour. Lead sulfate is oxidized during this time interval. The moment at which the formation of β-PbO_2 begins can be assessed by x-ray diffraction only with great difficulty and uncertainty. This is due to the fact that the 2.79Å line of β-PbO_2 overlaps with the 2.80Å line of tet-PbO, while the remaining strong lines of β-PbO_2 coincide either with those of $PbSO_4$ or of α-PbO_2. At the end of the formation x-ray diffraction data show that the plate contains β-PbO_2 in an amount much larger than that of α-PbO_2.

The values of the plate potential under polarization and at open circuit are plotted on Fig. 1(c). Prior to formation the grid is the only conducting element of the plate. At the beginning of the formation process the current density is large, owing to the small area of the grid. Therefore, the values of ϕ_i are high. With the formation of PbO_2 in the plate, the surface at which an electrochemical process may proceed increases and current density decreases, which leads to the decrease of ϕ_i. This occurs in the first 30 min after the start of formation. Subsequently, up to the fourth

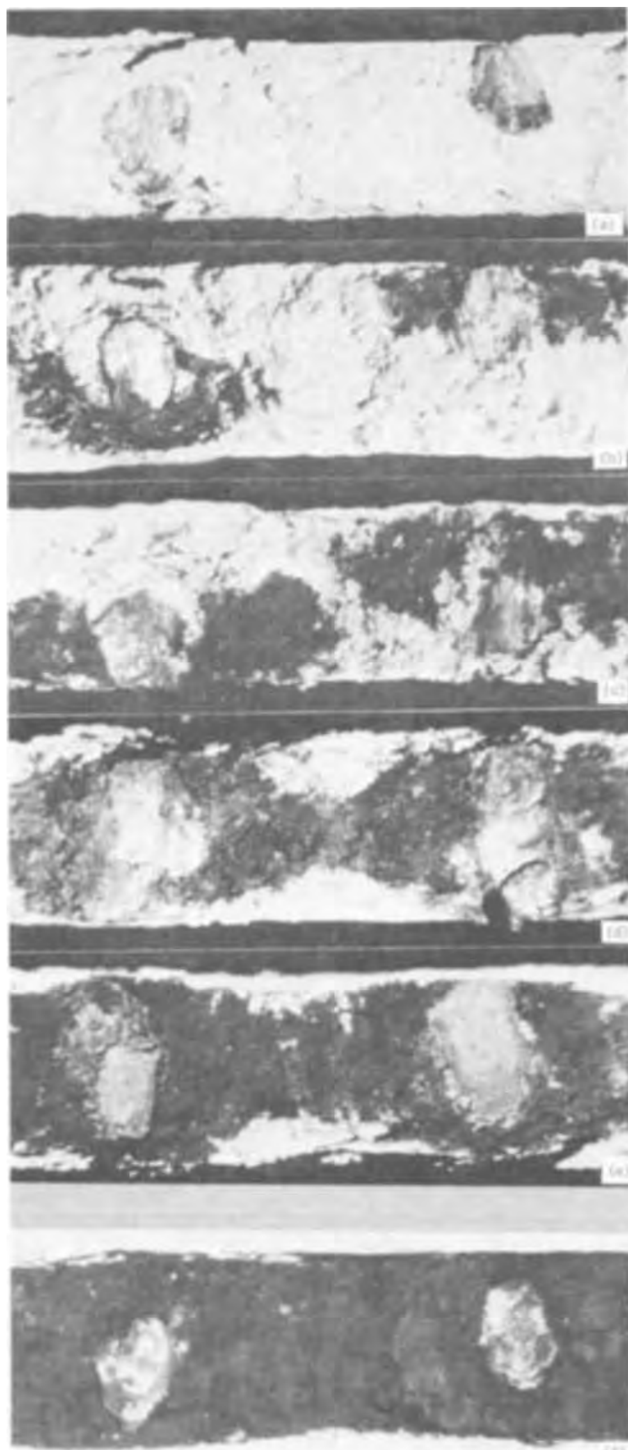

Fig. 3. Photomicrographs of cross sections of a portion of the plate between two grid bars at different stages of formation in H_2SO_4 of sp gr 1.15. (a). Unformed plate. (b-e). The dark portions are PbO_2 zones, while the light ones are zones of unformed divalent lead compounds. (f). Completely formed plate.

hour, the potential retains a comparatively constant value. This period is connected with the oxidation of tet-PbO and basic sulfates of lead to PbO_2. When the amount of PbO becomes small, the potential increases, and $PbSO_4$ begins to oxidize to β-PbO_2. At $\phi_i = 1460$ mV oxygen is evolved at the positive plate. This leads to a decrease in current efficiency for the formation of PbO_2. The curve of PbO_2 in Fig. 1(b) rises more slowly.

Taking into account the changes in the above parameters, the process of formation can be divided into two stages:

First stage (prior to the fourth hour). Chemical reactions between H_2SO_4 and tet-PbO and basic sulfates with $PbSO_4$ as a result; electrochemical reaction during which tet-PbO and basic sulfates are oxidized mainly to α-PbO_2 and partially to β-PbO_2.

Second stage (after the fourth hour). Lead sulfate is oxidized to β-PbO_2. No α-PbO_2 forms. The electrochemical reaction takes place at high positive potentials at which OH^- oxidizes to O_2. During this time interval a considerable part of the current is consumed for the evolution of O_2.

In order to elucidate the reactions occurring between H_2SO_4 and the paste as well as the influence of the electrochemical reaction on the chemical reactions in the plate, the same number of positive and negative plates as in the formation experiment were assembled in a cell and soaked in H_2SO_4 of sp gr 1.15. At open circuit only chemical reactions take place in the paste. The results of phase and analytical investigations and of potential measurements are plotted in Fig. 2. Basic sulfates react completely with H_2SO_4 up to the tenth hour, while 12% tet-PbO remains in the plate even after staying 18 hr in H_2SO_4. By comparing these results with those of Fig. 1, it becomes obvious that the rate of formation of $PbSO_4$ is accelerated by an electrochemical reaction.

The values of the electrode potential in H_2SO_4 of sp gr 1.15 are plotted in Fig. 2(c). These potential changes are due to chemical reactions, which occur in the paste at the surface of the grid. The $Pb/PbSO_4$ equilibrium potential is about 0.5V more negative than that of the Pb/PbO electrode in the same acid. From Fig. 2(a) it is seen that the amount of tet-PbO decreases, whereas that of $PbSO_4$ increases with time. Nevertheless, the plate potential becomes more positive. The electrochemical behavior of the plate is connected with passivation phenomena occurring at the lead grid, which were considered in some detail for the $Pb/PbSO_4$ electrode in a previous work (17).

Figure 3 shows photomicrographs of the plate cross section at the various stages of formation. It is seen that the formation proceeds by zones. The grid bars are alternately arranged with respect to the plate faces. Upon switching on the polarization those portions of the bar which are closest to the solution are covered first by a PbO_2 layer. An electrochemical reaction takes place at the PbO_2 surface as a result of which the paste is oxidized and a PbO_2 zone originates. The latter is located between the bar and the solution [Fig. 3(b)]. This zone grows subsequently inwards in the paste and is preceded by a bleached layer containing $PbSO_4$ crystals (this is seen on the color photographs). The PbO_2 zones from two neighboring bars advance one towards the other in the interior of the paste [Fig. 3(c)]. They include the $PbSO_4$ crystals obtained before them. This lasts until the PbO_2 zones join [Fig. 3(d)]. The chemical sulfation reactions begin with the soaking of the plate in the solution. The paste reacts with H_2SO_4 and $PbSO_4$ layers begin to grow in the paste from the two faces of the plate (color photographs). With the progress of formation a moment is reached in which tet-PbO and the basic sulfates disappear and the $PbSO_4$ zones cover the PbO_2 one [Fig. 3(d)]. Under the action of polarization PbO_2 now grows towards the bulk of the solution at the expense of the oxidation of the $PbSO_4$ zones. Beta lead dioxide is formed [Fig. 1(a), 3(e)]. The lead sulfate crystals included during the first stage in the PbO_2 zones are also oxidized to β-PbO_2. At different heights and breadths the plate shows different stages of this most general course, followed by the motion of the processes throughout its cross section.

From this zonal course of the chemical and electrochemical reactions it follows that the phase composi-

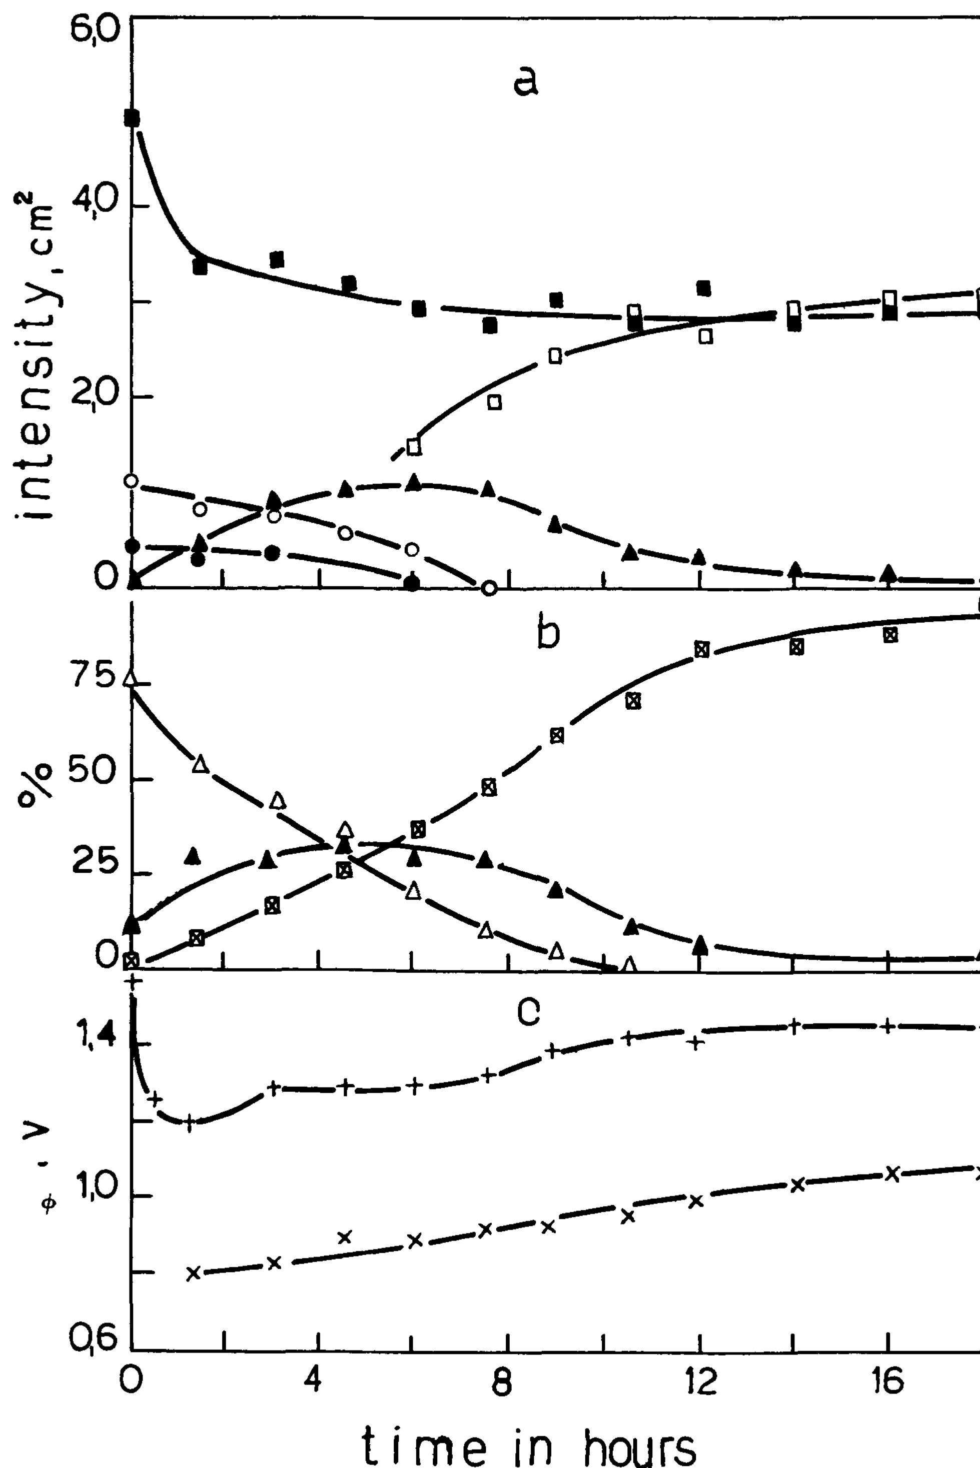

Fig. 4. (a). Intensity changes of the characteristic diffraction lines of $3PbO \cdot PbSO_4 \cdot H_2O$ with d = 3.26Å (○), $2PbO \cdot PbSO_4$ with d = 2.95Å (●), $PbSO_4$ with d = 3.00Å (▲), β-PbO_2 with d = 2.79Å (□), tet-PbO + α-PbO_2 with d = 3.12-3.13Å (■) during formation in H_2SO_4 of sp gr. 1.05. (b). Changes in the amounts of (α + β) PbO_2 (⊠), $PbSO_4$ (▲), and total PbO (△) in percentages during formation. (c). Change in the plate potential (with respect to the Hg/Hg_2SO_4 electrode) under load ϕ_i (+) and at open circuit ϕ_o (x) during formation.

tion of the active material is different in the various portions of any plate segment. Such a difference in the phase composition was also observed by others (3). According to Fig. 1 and 3, around the grids and in a large internal portion of the plate the active material consists mainly of α-PbO_2 while β-PbO_2 is to be found at the surface of the formed plate.

Formation in H_2SO_4 of sp gr 1.05.—Figure 4 gives the values of the parameters during formation. The pattern of the changes in phase and chemical composition is similar to that of Fig. 1. The decrease of H_2SO_4 in the formation solution lessens the role played by chemical sulfation reactions in the formation processes. As a result, the first stage of formation lasts about 8 hr. Basic sulfates react up to the sixth hour [Fig. 4(a)] and PbO up to the tenth hour [Fig. 4(b)]. The $PbSO_4$ content in the plate reaches about 30%. Only after the eighth hour does $PbSO_4$ begin to oxidize to β-PbO_2. An analysis of the strong lines in the x-ray diffraction pattern of β-PbO_2 shows that the 2.79 and 3.51Å lines appear only at the sixth hour of formation. At the same time the plate contains considerable amounts of α-PbO_2. Consequently, the time interval during which the α polymorph of PbO_2 originates upon formation in H_2SO_4 of sp gr 1.05 is longer than upon formation in H_2SO_4 of sp gr 1.15. In a completely formed positive plate the α-PbO_2 content is approximately equal to that of β-PbO_2 [Fig. 4(a)]. The behavior of ϕ_i and ϕ_o follows the changes which take place in the phase composition [Fig. 4(c)] and confirms that the first formation stage lasts longer.

Figure 5 represents the changes in the phase and chemical composition of the plates soaked in H_2SO_4 of sp gr 1.05 at open circuit. At this sulfuric acid con-

centration the rates of sulfation of tet-PbO and basic sulfates strongly decrease.

The microphotographs of the plate cross section at the various stages of formation indicate that the advance of the PbO_2 and $PbSO_4$ zones in the plate is similar to that observed during formation in H_2SO_4 of sp gr 1.15.

Formation in 0.7M Na_2SO_4.—Figure 6 gives the values of the measured parameters during formation. The basic sulfates react up to the eighth hour [Fig. 6(a)] and PbO up to the tenth hour [Fig. 6(b)]. The formation of $PbSO_4$ is slow and its content reaches a maximum value only at the eighth hour [Fig. 6(a), (b)]. At the twelfth hour $PbSO_4$ begins to oxidize. From Fig. 6(a) it is seen that only α-PbO_2 and $PbSO_4$ are formed during the first stage. The intensity of the 3.12Å diffraction line decreases up to the fifth hour owing to the decrease in the amount of tet-PbO. Subsequently the intensity of this particular diffraction line is controlled by α-PbO_2 and therefore increases, reaching a constant value. After 10 hr the 3.12Å line becomes characteristic for α-PbO_2.

Between the eighth and the tenth hour of formation the amount of PbO in the plate is very small. The oxidation of this compound is unable to maintain a constant current. This is why the plate potential increases [Fig. 6(c)] and oxygen evolution begins. Starting from the twelfth hour of formation $PbSO_4$ is oxidized to β-PbO_2. During this time interval oxygen evolution is the second electrochemical reaction. A comparison of the intensities of the diffraction lines of α- and β-PbO_2 [Fig. 6(a)] shows that α-PbO_2 is present in the formed plate in an amount larger than that of β-PbO_2.

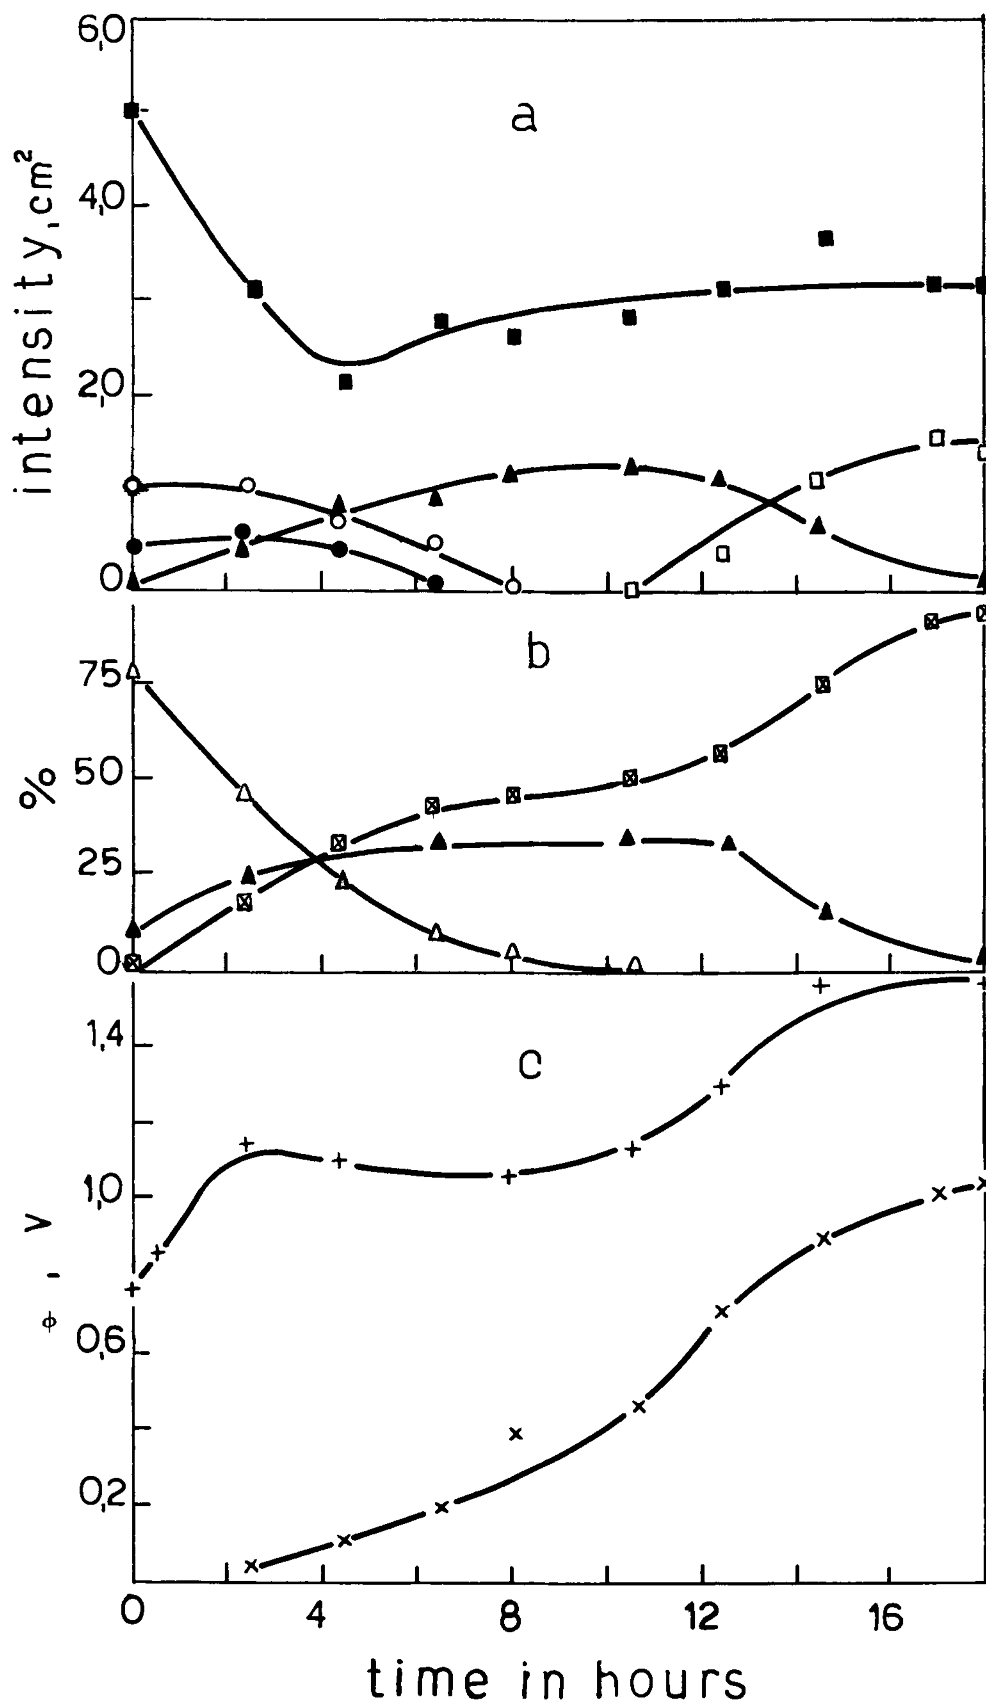

Fig. 6. (a). Intensity changes of the characteristic diffraction lines for $3PbO \cdot PbSO_4 \cdot H_2O$ with d = 3.26Å (○), $2PbO \cdot PbSO_4$ with d = 2.95Å (●), $PbSO_4$ with d = 3.00Å (▲), β-PbO_2 with d = 2.79Å (□), tet-PbO + α-PbO_2 with d = 3.12-3.13Å (■) during formation in 0.7M Na_2SO_4. (b). Changes in the amounts of total PbO (△), $PbSO_4$ (▲) and (α + β) PbO_2 (⊠) in percentages during formation. (c). Potential change in the plate potential (with respect to the Hg/Hg_2SO_4 electrode) under load ϕ_i (+) and open circuit ϕ_o (x) during formation.

Figure 6 indicates that the two formation stages are clearly separated. The first one ends at the eighth-ninth hour, while the second one begins at the eleventh-twelfth hour. During the first stage it was found that the pH of the solution is alkaline. The second stage begins only when the solution is acidified. This occurs after the tenth hour of formation when the pH becomes less than 2. These changes in pH in the bulk of the solution are determined by the total balance of the ions which are consumed and originate at the positive and the negative plates. These phenomena will be studied in another paper.

An experiment was performed in which the pH of the formation solution was maintained between 10 and

Fig. 7. (a). (b). Changes in the amounts of total PbO (△) and total $PbSO_4$ (▲) upon leaving of the plates in a 0.7M Na_2SO_4 solution. (c) Change in the plate potential (with respect to the Hg/Hg_2SO_4 electrode) ϕ_o (x) upon exposure to a 0.7M Na_2SO_4 solution.

11 for 23 hr by means of NaOH. Up to the eighth hour PbO and the basic sulfates were converted to α-PbO_2 and $PbSO_4$. From the eighth to the twenty-third hour x-ray and chemical analyses revealed no change in the amounts of α-PbO_2 and $PbSO_4$. Oxygen was evolved at the positive plate during the period. At the twenty-third hour of formation the solution was acidified with H_2SO_4 and the pH adjusted to 2. For 4 hr the entire amount of $PbSO_4$ in the plate was oxidized to β-PbO_2. Thus the duration of the first stage and the start of the second one may be controlled by means of the pH of the solution.

Figure 7 gives the result of phase and chemical analyses of positive plates soaked in a 0.7M Na_2SO_4 solution as a function of the time of exposure at open circuit. From Fig. 7(a) it is seen that $2PbO \cdot PbSO_4$ disappears after 4 hr from the plate. The amount of tet-PbO decreases to a certain extent while that of $3PbO \cdot PbSO_4 \cdot H_2O$ increases somewhat. This shows a conversion of $2PbO \cdot PbSO_4$ to $3PbO \cdot PbSO_4 \cdot H_2O$. No diffraction lines of $PbSO_4$ were recorded in the x-ray patterns. Figure 7(b) shows that the amounts of total PbO and total $PbSO_4$ in the plate remain unchanged. This means that there are no reactions occurring between the compounds of the plate and Na_2SO_4. If we compare these results with those of Fig. 6 it becomes clear that $PbSO_4$ [Fig. 6(a)] is produced during formation by a process induced by the electrochemical oxidation reaction of the basic sulfates present in the paste.

Figure 8 reproduces photomicrographs at the various stages of formation in 0.7M Na_2SO_4. In this case, too, formation begins at those portions of the grid bars that are close to the plate surface [Fig. 8(b)]. How-

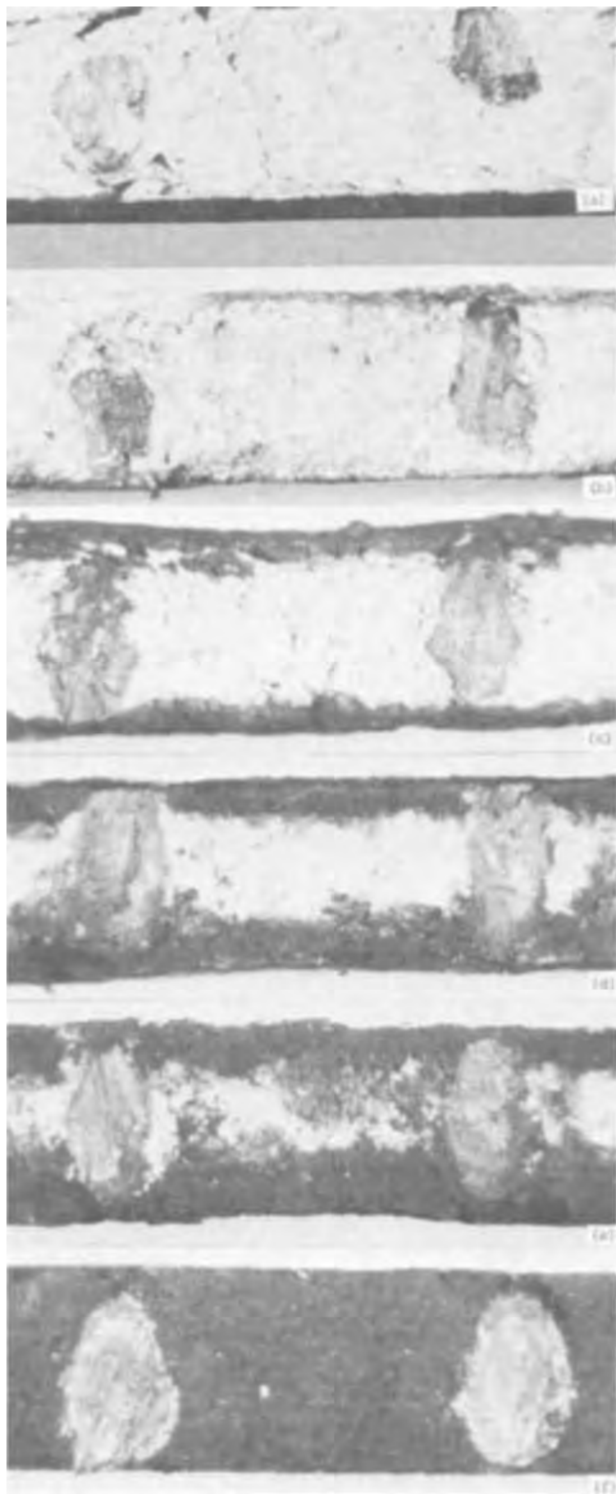

Fig. 8. Microphotograph of cross sections of a plate segment between two grid bars at different stages of formation in 0.7M Na_2SO_4 solution. (a). Unformed plate. (a-e). The dark portions in the section of the plate are PbO_2 zones while the light ones consist of unformed divalent lead compounds. (f). Completely formed plate.

ever, the distribution of the phases upon formation is different from that observed in an acid medium. First the PbO_2 zone grows along the plate surface. Soon the plate is covered with a thin brown layer of α-PbO_2 [Fig. 8(c)]. Subsequently the PbO_2 layer continues to grow from the surface toward the interior of the paste [Fig. 8(d)]. Lead sulfate crystals originate before the PbO_2 zones (seen on color photographs). These crystals are included in the PbO_2 zones [Fig. 8(c), (d), (e)]. Thus the internal portions of the plate formed during the first stage consist of α-PbO_2 and $PbSO_4$ whereas the plate surface is constituted only by α-PbO_2. After full conversion of PbO and basic sulfates to the above compounds and acidification of the solution, $PbSO_4$ oxidizes to β-PbO_2. The fully formed plate consists of α-PbO_2 in which β-PbO_2 is precipitated [Fig. 8(f)].

Discussion of Results

Specific properties of electrochemical and chemical reactions in porous electrodes.—The electrochemical and chemical formation processes take place in a porous medium consisting of the starting and reaction end products. Therefore the number of occurring elementary processes (hydration, dissociation, dissolution, ion diffusion and migration, neutralization, charge transfer, nucleation, crystal growth, etc.) is considerable. Which one of these elementary processes plays a limiting role on electrochemical and chemical reaction rates depends on the specific conditions created by the porous electrode, which may be outlined in the following way.

First, the surface of the crystals is in contact with the solution in the pores. The volume of the solution in the pores is small compared to the surface of the crystals which inclose the pores. This is why under- and supersaturation of the solution in the pores is easily and rapidly achieved. This strongly favors the crystallization and dissolution processes of the crystals, as well as hydration and neutralization within the plate. These processes take place at very high rates.

Second, the pores in the unformed material electrically connect the grid or the PbO_2 zone with the bulk of the electrolyte. An equivalent electrical circuit of the plate would include parallel resistances, each corresponding to one pore. The formation process begins first at those locations in the plate where the length of the pores which connect the electrode surface with the bulk of the solution is smallest. There, the electrical resistance of the paste is smallest. Indeed, the formation begins at those portions of the grid bars which are closest to the bulk of the solution. The PbO_2 zone originates there [Fig. 3(b) and 8(b)]. With its appearance the current density decreases and the importance of other parameters which control the direction of motion of the PbO_2 zone in the paste increases. On the other hand, the pores have widely different electrical resistances. The large pores have a small resistance and favor ion transport between the bulk of the solution and the internal portions of the paste and active material. The small pores hinder this motion of ions. But, since the sum of the surfaces of the small pores is usually several times larger than that of the large pores it follows that the chemical and electrochemical processes are determined by the conditions prevailing in the small pores. The ratio between these two types of pores controls the limiting influence of diffusion and migration of ions on electrochemical and chemical reaction rates in the various portions of the plate.

Third, during the electrochemical process the positive charges of the lead ions increase from 2 to 4. In order for the solution in the pores to become electroneutral, the excess positive charges must migrate from the interior of the plate into the bulk of the solution. The migration of the positive ions, if slowed down, hinders the electrochemical reaction at the given location in the plate. There, the growth of the PbO_2 zone is also slowed down. The participation of a given ionic species in the migration is controlled by its mobility and concentration. The H^+ ions possess a mobility several times higher than that of the remaining ones. Therefore, their participation in the migration process will be overriding. This imparts a considerable role to the pH of the solution on the processes occurring in the plate.

Mechanism of the formation processes.—The over-all chemical and electrochemical reactions which take place during formation of positive plate may be deter-

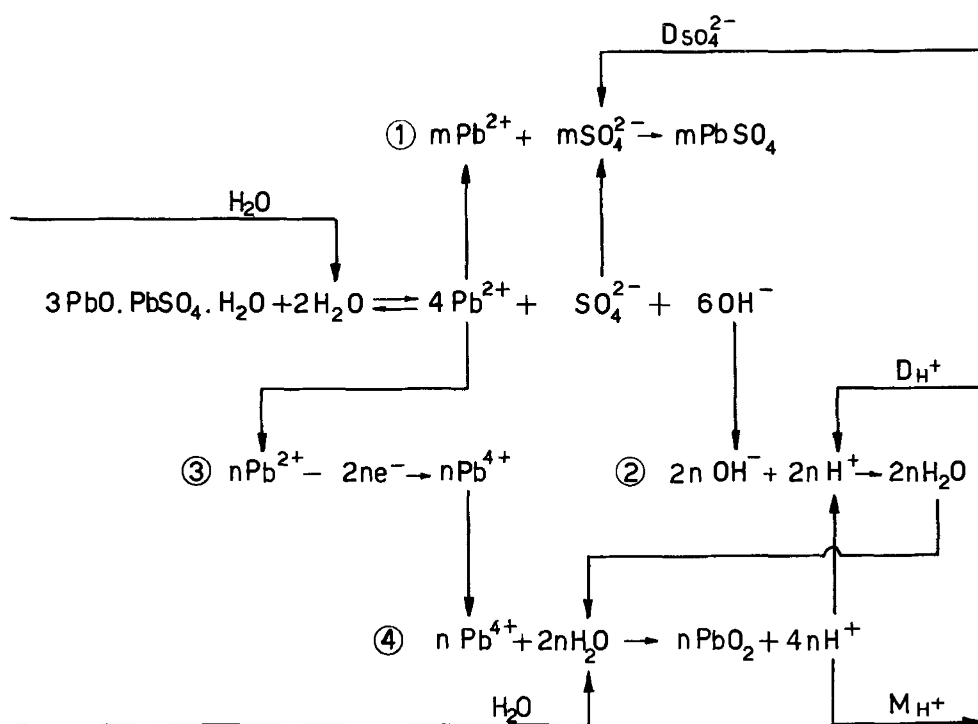

Fig. 9. Diagram of the elementary chemical and electrochemical processes during the first stage of formation.

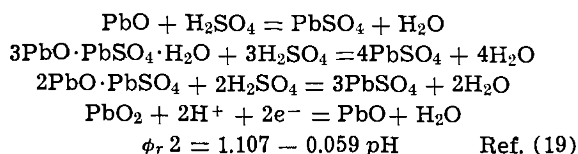
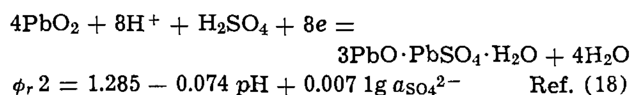
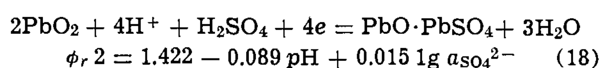
mined from the E/pH diagram of the lead-sulfuric acid-base system. A sufficiently complete E/pH diagram was given by Ruetschi and Angstadt (18) from which it is seen that the following chemical and electrochemical reactions may take place during formation



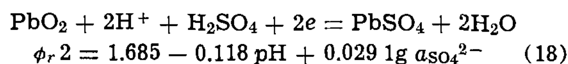
$$PbO + H_2SO_4 = PbSO_4 + H_2O$$
$$3PbO \cdot PbSO_4 \cdot H_2O + 3H_2SO_4 = 4PbSO_4 + 4H_2O$$
$$2PbO \cdot PbSO_4 + 2H_2SO_4 = 3PbSO_4 + 2H_2O$$
$$PbO_2 + 2H^+ + 2e^- = PbO + H_2O$$
$$\phi_r 2 = 1.107 - 0.059\,pH \qquad \text{Ref. (19)}$$



$$4PbO_2 + 8H^+ + H_2SO_4 + 8e = 3PbO \cdot PbSO_4 \cdot H_2O + 4H_2O$$
$$\phi_r 2 = 1.285 - 0.074\,pH + 0.007\,\lg a_{SO_4{}^{2-}} \qquad \text{Ref. (18)}$$



$$2PbO_2 + 4H^+ + H_2SO_4 + 4e = PbO \cdot PbSO_4 + 3H_2O$$
$$\phi_r 2 = 1.422 - 0.089\,pH + 0.015\,\lg a_{SO_4{}^{2-}} \qquad (18)$$



$$PbO_2 + 2H^+ + H_2SO_4 + 2e = PbSO_4 + 2H_2O$$
$$\phi_r 2 = 1.685 - 0.118\,pH + 0.029\,\lg a_{SO_4{}^{2-}} \qquad (18)$$

The equations show that the reactions which occur during formation of the plate depend on the pH of the solution. In addition, the same starting compounds of the paste participate in two competing reactions: chemical and electrochemical. The chemical sulfation reaction is controlled by the concentrations of the ions in the solution in the pores. The electrochemical reactions of formation of PbO_2 depend not only on the ionic composition of the solution but also on the electrode surface potential.

In order to define the processes of formation two questions should be answered: First, what is the mechanism by which the alkaline α polymorph originates during formation in an acid medium and which factors affect the α/β-PbO_2 ratio. Second, what determines the direction of advance of the PbO_2 zone during formation. To this effect the over-all chemical and electrochemical reactions should be decomposed into elementary reactions. The relationships among the latter within the pores should be established. On Fig. 9 this is done for the first stage of formation, $3PbO \cdot PbSO_4 \cdot H_2O$ being taken as example. After water has penetrated in the plate this compound is first hydrated, as a result of which certain Pb^{2+}, $SO_4{}^{2-}$, and OH^- concentrations are maintained in the pores. Besides water, H_2SO_4 diffuses in the plate ($D_{SO_4{}^{2-}}$ and D_{H^+}). After moving toward the interior of the paste it reacts according to reactions 1 and 2 and disappears. Generally speaking, as a result of these reactions tet-PbO and basic sulfate crystals contained in the paste are dissolved and yield $PbSO_4$ and H_2O. The reaction rates and the depth at which H_2SO_4 penetrates in the plate depend on the acid concentration in the formation solution. Our experiments showed that in H_2SO_4 of sp gr 1.15 the rate of formation of $PbSO_4$ is higher (Fig. 2) than that of H_2SO_4 of sp gr 1.05 (Fig. 5). In neutral solutions no $PbSO_4$ is formed, according to the E/pH diagram. This is why reactions 1 and 2 do not take place when the plates are soaked at open circuit in a Na_2SO_4 solution (Fig. 7).

Microscopic examinations of the chemical reactions between the paste and H_2SO_4 showed that during a considerable time interval the internal portions of the plate remain unattacked by H_2SO_4. Tribasic lead sulfate of such internal portions is in equilibrium with Pb^{2+}, $SO_4{}^{2-}$, and OH^- ions of the pore solution. When these pores contact with the PbO_2 surface, electrochemical reaction 3 and chemical reaction 4 will occur. In reaction 4, four H^+ ions are evolved for every lead ion. Two of these hydrogen ions must migrate out of the plate (M_{H^+}) in order to maintain the electroneutrality of the solution in the pores. The remaining two participate in the neutralization reaction 2. This reaction decreases the pH of the solution in the pores. The stability field of $PbSO_4$ is reached and $PbSO_4$ crystals are deposited in the pores before the PbO_2 zone. This may be observed on color photographs (which correspond to Fig. 3, 8). The changes in pH of the pore solution occur in the weakly alkaline, neutral, and weakly acidic pH range and yield the α polymorph of PbO_2. Figures 1, 4, and 6 show that α-PbO_2 forms when the plate contains lead monoxide and basic sulfates. Therefore, the increase of $PbSO_4$ in the basic sulfates leads to a decrease in the OH^- ions in the pore solution. This diminishes the role of reaction 2 in the oxidation mechanism. The formation of α-PbO_2 decreases.

[2] The values are given with respect to the normal hydrogen electrode. The calculations do not take into account the two different polymorphs of PbO_2. No equation is given in the quoted work for the equilibrium potential of $PbO_2/2PbO \cdot PbSO_4$.

Conversely, when the PbO content in the paste and in the basic sulfates is larger the role of reaction 2 is larger, and the amount of α-PbO_2 is larger. Consequently, the amount of α-PbO_2 in the active material is controlled by the $PbO/PbSO_4$ ratio in the paste, irrespective of whether these components are present as discrete phases or combined in basic sulfates. The $PbO/PbSO_4$ ratio changes in the paste when the amount of H_2SO_4 with respect to the lead powder during preparation of the paste is changed. In addition, this ratio changes during formation in H_2SO_4 as a consequence of chemical reactions 1 and 2 between the paste and the solution. Therefore, the α-PbO_2 amount in the active material depends on the concentration of sulfuric acid in the solution. In the case of sulfuric acid of sp gr 1.15 the active material contains less α-PbO_2 [Fig. 1(a)] than the active material obtained by formation in H_2SO_4 of sp gr 1.05 [Fig. 4(a)], since at this latter acid concentration less $PbSO_4$ has been produced during formation [Fig. 1(b), 4(b)].

The direction of motion of the PbO_2 zone in the paste constitutes the second important aspect of the mechanism of the processes taking place during formation. From the equations of the equilibrium potentials of the PbO_2/PbO, $PbO_2/3PbO \cdot PbSO_4 \cdot H_2O$, $PbO_2/PbO \cdot PbSO_4$, and $PbO_2/PbSO_4$ electrodes it is seen that at a given pH, the values of these potentials become more positive with the increase in the $PbSO_4$ content of divalent lead compounds. Therefore, by increasing the plate potential, the equilibrium potentials of PbO_2/PbO and of the basic sulfates are successively reached. The current density 5 mA/cm² is maintained constant by oxidation of these compounds. This explains why during the first stage the potential is low [Fig. 1(c), 4(c), 6(c)]. During formation in H_2SO_4 the surface of the plates is sulfated. Lead monoxide and basic sulfates of lead from the internal portions of the plate remain for a long time unattacked by the acid. This is why the PbO_2 zones advance in the plate, oxidizing the monoxide and the basic sulfates. Lead sulfate crystals formed as a result of the electrochemical reaction are included in the PbO_2 zone since the electrode potential is lower than that required for its oxidation. Figures 3(b), (c) show the advance of the PbO_2 zone at those locations of the paste where the PbO and basic sulfates content is largest. When the amount in the paste of these compounds reaches a small value, the potential increases, reaching values at which $PbSO_4$ is oxidized [Fig. 1(c), 4(c)]. The PbO_2 zone advances from the interior toward the surface of the plate [Fig. 3(d), (e)]. During formation in Na_2SO_4 the solution at the plate surface has a higher pH than that in the pores of the internal portion. This is why the PbO_2 zone advances first along the plate surface [Fig. 8(b), (c)].

The direction of motion of the PbO_2 zone is determined not only by these thermodynamic causes, but also by kinetic factors. Thus, the migration rate of the H^+ ions obtained by reaction 4 may also control the direction of motion of the PbO_2 zone. If the migration is hindered the pore solution will be charged positively. This decreases the rate of electrochemical oxidation of Pb^{2+} since, as a result of this process the number of positive charges in the pore solution increases. Thus the rate of formation of PbO_2 decreases in those portions of the PbO_2 zone, where transport of H^+ ions is hindered. The migration of H^+ ions is favorized in those pores which contain solution with the highest pH. In them the direction of diffusion of H^+ coincides with the direction of their migration. During formation in H_2SO_4 the pores of the internal portions of the plate retain for the longest time the solution with the highest pH. The PbO_2 zone advances during the first stage toward the interior of the plate [Fig. 3(b), (c), (d)]. During formation in Na_2SO_4 or weakly alkaline solutions the migration of H^+ ions is most favorable at the surface of the plate. This explains why the PbO_2 zone

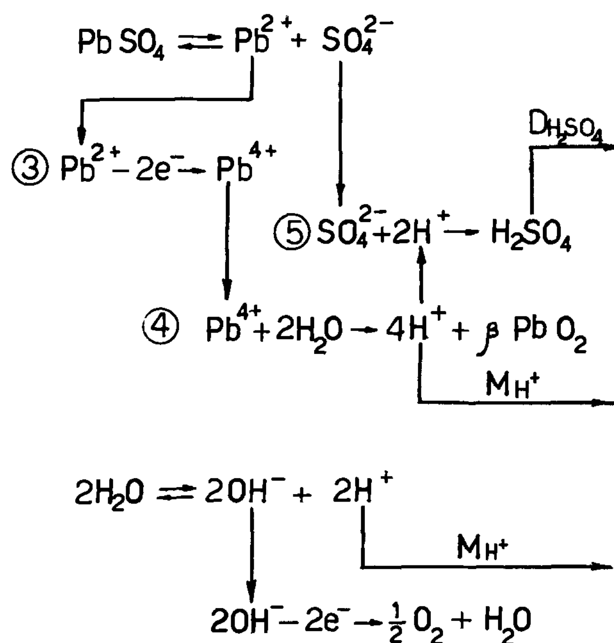


Fig. 10. Diagram of the elementary chemical and electrochemical processes during the second stage of formation.

first covers the plate surface and then advances within the plate [Fig. 8(b), (c)].

The x-ray data on the initial phase composition of the paste did not show the presence of unoxidized lead in it. In practice, however, the unformed paste frequently contains several per cent unoxidized lead. According to Ness (15) and Ruetschi and Cahan (14) upon formation lead powder is oxidized to α-PbO_2. The difference between the plate potential ϕ_i and the equilibrium potential of the Pb/PbO_2 electrode is largest, and, therefore, lead will be thermodynamically most unstable upon formation and the lead particles will be oxidized at the first stage of formation in which α-PbO_2 is obtained.

During the second period of formation $PbSO_4$ oxidizes to PbO_2 and OH^- to O_2. These processes are indicated in the diagram of Fig. 10. Oxidation of $PbSO_4$ takes place entirely in an acidic medium. Therefore, only β-PbO_2 is formed [Fig. 1(a), 4(a), 6(a)]. Sulfuric acid obtained as a result of reaction 5 diffuses from the plate into the bulk of the solution, as opposed to the first stage.

During the second period the electrode potential is more positive than the evolution potential of oxygen and oxygen is evolved at the PbO_2 surface.

At the end of the formation the H_2SO_4 concentration in the formation solution increases with respect to the initial one. The formation processes free the whole amount of H_2SO_4, used for producing basic sulfates during paste preparation.

Parameters which control the processes of formation of positive plates.—Starting from the mechanisms already outlined for the first and second formation stages it becomes possible to determine the parameters controlling the phase composition of the active material. According to them the ratio between α- and β-PbO_2 is determined by the equation

$$\alpha/\beta\ PbO_2 = \frac{q^o_{PbO} - q'_{PbSO_4} - q'_{PbO}}{q^o_{PbSO_4} + q'_{PbSO_4} + q'_{PbO}}$$

q^o_{PbO} is the total starting amount of PbO occurring in the paste as a discrete phase or bonded in basic sulfates. Its value is determined by the ratio between the weight of the oxidized lead powder and that of the H_2SO_4 used in the preparation of the paste.

q'_{PbO} is the amount of PbO converted to β-PbO_2. This process occurs between the first and the second stage oxidation. During this intermediate period the amount of unreacted PbO is relatively small. It is unable to maintain constant the formation current and the plate potential increases while $PbSO_4$ and OH^- begin to oxidize, thus acidifying the pore solution and leading to the formation of β-PbO_2 from PbO.

$q^o_{PbSO_4}$ is the initial amount of $PbSO_4$ combined in the basic sulfates. It is controlled by the amount of H_2SO_4 added to the lead powder during paste preparation.

q'_{PbSO_4} is the amount of $PbSO_4$ produced during the first stage of formation. It depends on the following parameters:

(*i*) Amount of H_2SO_4 in the formation solution (H_2SO_4 concentration and its volume per plate). At equal volumes the larger the concentration of H_2SO_4, the more β-PbO_2 will form. This is confirmed both by Dodson's experiments (1) and by the results obtained in the present work. During formation in diluted H_2SO_4 one should also take into account processes occurring at the negative plate. The products formed or consumed at this plate change the ionic composition of the formation solution.

(*ii*) Formation current density. This parameter determines the velocity of advance of the PbO_2 zones in the paste as well as the potential under current.

(*iii*) Paste density.

(*iv*) Exposure of the plates at open circuit to H_2SO_4 prior to formation. The longer this period, the larger the amount of $PbSO_4$ formed in the paste.

(*v*) Grid design. In thicker plates and in the case of smaller intergrid distances the amount of $PbSO_4$ during the first stage of formation should be less.

(*vi*) Temperature.

If the paste contains unoxidized lead an additional term, which takes into account the oxidation of Pb to α-PbO_2, should be added to the above equation.

This considerable variety of parameters, which influence the formation processes, introduces serious difficulties in the production of plates having strictly defined characteristics. Determining the influence of each of the indicated parameters on the phase composition (α/β-PbO_2) and also on the initial characteristics of the plate (capacity and start) will be the aim of our future investigations.

Mechanism of the Formation of Blisters on the Lead Electrode of the Lead-Acid Battery

C. F. Yarnell*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

A constant current study of the reduction of tetrabasic lead sulfate to lead coupled with microscopic examination of the lead electrode showed that a solid layer of lead sulfate developed on the surface during formation. A fissure develops between the lead formed from the surface layer of lead sulfate and the lead in the center of the electrode. Hyrogen trapped in this fissure pushes the surface layer out to form a blister. A microscopic study of electrodes formed in decreasing concentrations of sulfuric acid showed that blistering is eliminated at lower concentrations.

The spongy-lead negative electrode of the lead-acid cell is made by electrochemical reduction in dilute sulfuric acid of a lead or lead alloy grid filled with a dried paste material. This paste material may be made in the conventional manner by mixing a leady oxide with water and sulfuric acid or by mixing tetrabasic lead sulfate with water (1). The reduction, which is known as formation, may take place either in a completely assembled cell containing unformed positive and negative plates or the plates may be formed individually and subsequently assembled into cells. In the latter method, known as tank formation, the completely formed negative plates often have blistered surfaces. Since negative plates formed in assembled cells are rigidly held in place by the separators, the spongy lead is not free to expand and consequently blisters are not seen. Perhaps because most automobile batteries are made by this method, little attention has been given in the literature to the phenomenon of blistering during tank formation.

* Electrochemical Society Active Member.

Key words: lead sulfate, tetrabasic lead sulfate, negative lead electrode, hydrogen evolution.

Using optical microscopy, Simon and Jones have examined (2) plates that were tank formed in sulfuric acid of different specific gravities ranging from 1.05 to 1.45. They did not report the formation of blistered surfaces on their plates. It has been reported (2, 3) that the formation of lead started at the grid members and then a coating of lead rapidly formed on the outside of the plate which advanced inward toward the center of the plate. More recently Simon has reported (4) that in some plates the formation of lead started below the surface of the plate.

The modification of the lead crystals produced on formation of negative plates containing lignin and $BaSO_4$ in varying amounts was recently reported (5). Blisters were not observed since these negative plates were not tank formed, but formed in assembled cells containing 1.050 sp gr sulfuric acid. The surface layer of these negative plates was different and some plates contained large voids just below the surfaces. It was postulated (5) that the differences in crystal structure at the surface may be the result of surface sulfation.

The exact chemical composition of the unformed, cured plates used in the previous studies is not clear. The chemical composition of the plates undoubtedly affects their behavior during formation, and in fact we have observed that on tank formation, some commercial plates will form blistered surfaces, although others with a different formulation will not. In order to determine the mechanism of formation of the blisters, a study was undertaken using a pure compound, tetrabasic lead sulfate, as the negative paste material. Its performance in the negative plate has been previously reported (1).

Experimental Procedure

Lead-calcium alloy (0.05% Ca) negative grids (7.6 × 6.3 × 0.4 cm) were hand pasted with a water paste of tetrabasic lead sulfate plus 2% of an expander.[1] After air drying, each negative was placed in a Teflon holder between two formed positive (PbO_2) plates of the same size. The positive and unformed negative plates were 0.6 cm apart and microporous rubber separators were placed between them. Each three-plate cell was placed in a glass jar containing 2000 ml of sulfuric acid and allowed to soak for one-half hour. The specific gravity of the sulfuric acid was varied from cell to cell over a range of 1.005 to 1.210. The cells were then formed at a constant current of 0.35A for approximately 70 hr. This corresponds to a negative plate current density of about 0.35 A/dm^2 which is within the range recommended by Vinal (6).

During formation, the negative potential *vs.* a mercury/mercurous sulfate electrode and cell potential were recorded. In order to minimize the junction potential, mercury/mercurous sulfate reference electrodes were made with the same concentration of sulfuric acid as that used in the formation of the negative plate.

After formation, the negative plate was immediately washed in distilled water and dried in a heated vacuum desiccator. The dried negative plates were encapsulated in epoxy and examined under the microscope.

[1] National Lead Companies' KX expander.

Results and Discussion

The number of blisters on a given plate varied from paste batch to batch and was probably dependent to some extent on the paste density. A negative plate which was severely blistered is shown in Fig. 1a. This negative plate was formed in 1.050 sp gr sulfuric acid. A cross-sectional view of a blister is shown at a magnification of 25× in Fig. 1b. Only a part of the blister is visible at this magnification. Porous lead has been lifted from the surface to form a dome-shaped blister.

Areas of the plate which did not contain blisters did contain a fissure which was at exactly the same depth as the thickness of the blister. This fissure is shown in Fig. 2 at a magnification of 25×. The porous lead on either side of the fissure had a different crystalline structure as shown at a magnification of 250× in Fig. 3 and 4. The lead in the center of the plate appeared to be made up of long dendritic crystals. The lead on the surface of the plate was in the form of many small needles radiating from a larger piece of lead. Only porous lead was found throughout the plate which indicates that the tetrabasic lead sulfate had been completely reduced to lead.

Figure 5 shows a typical plot of negative and positive plate potentials *vs.* Hg/Hg_2SO_4 as a function of time on formation at a constant current in 1.050 sp gr sulfuric acid. The positive potential remains constant throughout the formation since the positive plates were completely formed prior to use. Since the negative plate contains pure tetrabasic lead sulfate plus a known amount of expander, the time required to completely convert the plate to spongy lead may be calculated from Faraday's law. This time is plotted as the vertical line on the graph. The formation process is 100% efficient since the complete reduction to lead, as shown by the sudden increase of negative potential, occurs at the calculated theoretical end of formation time. To the right of the vertical line, hydrogen is being evolved at a potential which levels off at −1.55V.

In Fig. 5, three different potential steps or changes in slope are evident during the formation. They occur at 7-17 hr with a potential of −0.99V, at 20-26 hr with a potential of −1.02V, and at 32-37 hr with a potential of −1.105V.These steps could be due to reduction of lead compounds formed when tetrabasic lead sulfate is immersed in sulfuric acid.

Tetrabasic lead sulfate ($4PbO \cdot PbSO_4$) can react with sulfuric acid to yield $3PbO \cdot PbSO_4$,$PbO \cdot PbSO_4$, and $PbSO_4$. $2PbO \cdot PbSO_4$ probably would not be formed since it is reported (7) to be unstable at

25°C. The extent and rate of the reactions that produce these compounds will of course depend upon the acid concentration. Calculations of the free energy of the reduction of each compound indicate that the order of reduction should be, in decreasing potential: $4PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4$, $PbO \cdot PbSO_4$, and $PbSO_4$. Since $PbSO_4$ would be the last compound to be reduced, one might expect the most prominent step occurring at −1.1V to be lead sulfate.

In order to determine whether or not lead sulfate was being reduced at −1.1V, a negative plate was removed from the formation jar after its negative potential *vs.* Hg/Hg_2SO_4 had reached −1.10V. A cross section of the surface of this incompletely formed negative plate is shown at a magnification of 25× in Fig. 6. The negative plate contained only spongy lead in the center, as in Fig. 4, and a layer of unformed material on the surface of the plate approximately the same thickness as the blisters. This unformed material contained no lead, but only a crystalline material surrounding very small pieces of tetrabasic lead sulfate. Some of this crystalline material was scraped off and analyzed. Chemical and x-ray diffraction analyses showed it to be lead sulfate. This suggests that the potential step occurring at −1.1V is due to reduction of lead sulfate to lead.

The thickness of this surface layer of lead sulfate corresponds exactly to the depth of the fissure (see Fig. 2) and the thickness of the blister (see Fig. 1b). As can be seen by comparing Fig. 3 with Fig. 4, the reduction of the lead sulfate in this surface layer produces spongy lead with a different structure from

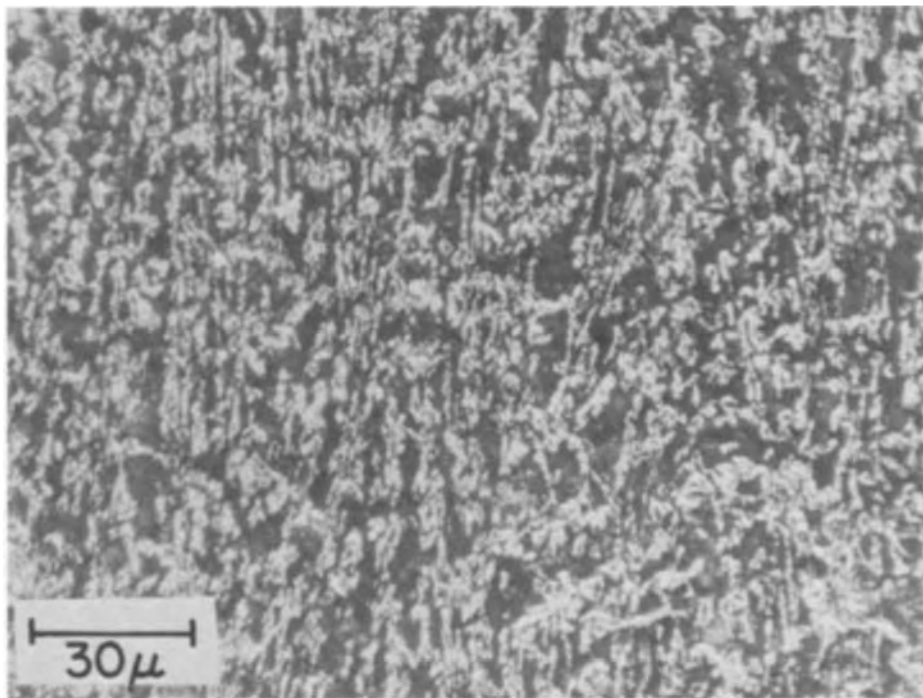

Fig. 4. Same as Fig. 2, cross-sectional view of lead below the fissure, in the middle of the plate. Magnification 250X.

that in the center of the negative. The lead formed from the lead sulfate is more finely divided and consequently less porous than that formed in the center of the plate. The presence of spongy lead with a different structure on cycling on the surface of the negative plate has been previously reported (1).

The above observations suggest a plausible mechanism for blister formation. When a negative plate containing tetrabasic lead sulfate is immersed in 1.050 sp gr sulfuric acid, the surface of the plate reacts with the acid to form a layer of lead sulfate. Fissures develop between the lead sulfate and the material in the plate interior. The fissure is probably caused by the 50% increase in material volume associated with the conversion of tetrabasic lead sulfate to lead sulfate.

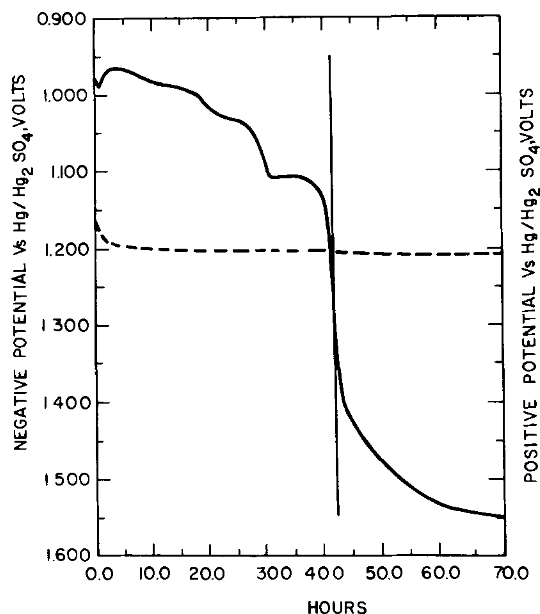

Fig. 5. Positive (dashed line) and negative (solid line) plate potentials *vs.* Hg/Hg_2SO_4 reference electrode as a function of time on formation in 1.050 sp gr sulfuric acid. The solid vertical line is the calculated end of formation time based on the weight of $4PbO \cdot PbSO_4$ contained in the plate.

This surface layer of lead sulfate is the last area of the negative plate to be reduced to lead. The lead formed from it has a different crystal morphology and is perhaps less porous than that in the center of the plate. Near the end of formation hydrogen gas is generated and becomes trapped in the fissure between the two differently structured spongy lead layers. Enough pressure is exerted to push the surface layer out to form a blister.

If the spongy lead contained trace metal impurities, the blistering could be disastrous. In this case, a metal impurity could lower the hydrogen overpotential causing generation of hydrogen before the plate is completely formed. This gas would very effectively be trapped behind the lead sulfate which forms a very nonporous (see Fig. 6) coating on the surface of the plate. Much of the gas generated would be trapped, causing the formation of many severe blisters. This latter phenomenon has been observed in paste batches that contained relatively high levels of metallic impurities.

The observations described previously were obtained with negative plates that were allowed to soak for one-half hour prior to the start of formation. However, a plate not soaked and one soaked for 20 hr prior to formation gave results which were identical to those for plates soaked for one-half hour. Therefore the length of the soak time does not appear to be a significant parameter in relation to the blistering phenomenon. The implications of this observation are being investigated as part of a more detailed study of the formation process.

The thickness of the blisters is directly related to the thickness of the solid layer of lead sulfate which develops on the surface of the plate. If the concentration of sulfuric acid available for reaction with tetra-

basic lead sulfate is reduced, the thickness of the lead sulfate layer and lead formed from it should decrease. This is indeed what is observed as shown in Fig. 7 and Table I. The surface layer of lead due to surface sulfation on negatives formed in 1.005 sp gr acid is so thin that no blisters are observed. For negatives formed in 1.015 sp gr acid only tiny blisters were observed (Fig. 7b). As the specific gravity of the acid is increased, the blisters become larger and thicker until in 1.210 sp gr acid the blisters are so thick (see Table I) that they appear only as a humping of the pellets.

Formation plots of negatives in sulfuric acid of different specific gravities are shown in Fig. 8. For a specific gravity of 1.005, the step due to reduction of lead sulfate is not seen. At specific gravities greater than 1.015, the step increases in width until in 1.210 sp gr sulfuric acid it is the dominant feature of the plot.

The width of the lead sulfate step occurring in the formation plot is a measure of the thickness of the lead sulfate layer and consequently of the thickness of the lead resulting from its reduction. The thickness of the lead layer was estimated from the formation plots by taking the ratio of the width of the step to the theoretical end of formation time, multiplying by the thickness of the negative, and dividing by two. The results are given in Table I and it can be seen that the calculated results agree reasonably well with the measured results.

Conclusion

Blistering of negative plates has been shown to result from the reduction of a surface coating of lead sulfate which is produced by chemical reaction between the paste material and the forming acid. This phenomenon may be eliminated altogether by reducing the

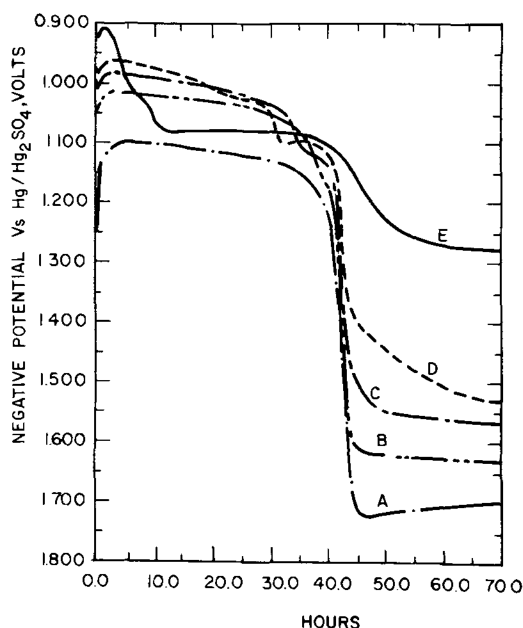

Fig. 8. Negative plate potentials vs. Hg/Hg_2SO_4 reference electrodes as a function of time on formation in (A) 1.005, (B) 1.015, (C) 1.030, (D) 1.050, and (E) 1.210 sp gr sulfuric acid.

concentration of the forming acid. In fact, negative plates without blisters have been formed in distilled water. However, by eliminating the blisters completely, one sacrifices initial plate capacity. Blistering does increase the initial surface area of the plate as well as the amount of acid immediately available for discharge within the plate. However, after cycling a number of times, the capacity of plates without blisters does increase to that of the blistered plates. By choosing the proper concentration of forming acid, a balance may be obtained between the degree of blistering which can be tolerated and the initial capacity desired. Depending on the intended use for a particular battery, one may be willing to accept some blistering in order to obtain a higher initial capacity.

Manuscript received Aug. 25, 1971. This was Paper 20 presented at the Cleveland Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Impurity Distributions in Anodic Films on Tantalum

R. E. Pawel,*[,1] J. P. Pemsler,*[,2] and C. A. Evans, Jr.[3]

ABSTRACT

Anodization of tantalum in electrolytes containing phosphorus or fluorine ions resulted in the incorporation of a quantity of these elements into the anodic film. While phosphorus was concentrated in the outer portions of such films, fluorine was attracted to the oxide/metal interface. We employed an ion microprobe mass spectrometer to examine the concentration profiles of these elements in films formed by a variety of anodization procedures. These experiments demonstrated the usefulness of the IMMS as a tool for such work and, in addition, furnished information on the characteristics of both film growth and the distribution and movement of these impurities. The influence of fluorine-rich layers at the oxide/metal interface on the adherence of the anodic films was also shown.

During the anodization of tantalum (as well as several other valve metals), the inclusion in the product film of impurity atoms from the electrolyte is a common occurrence and impurity effects on both the characteristics of film formation and various film properties have been reported (1). In addition, it has been observed experimentally that the impurity distribution may not be uniform throughout the film and may, in fact, have an unusual variation with depth caused by the particular manner in which the anodization was accomplished. For example, the "two-layer" structure associated with films on tantalum anodized in sulfuric or phosphoric acid has been well documented (1-8). One can argue that important properties of these films may be determined by both the amount and the distribution of the impurities within them.

Since the thickness of barrier-type anodic films on tantalum is generally limited to only a fraction of a micron, special techniques are required for their analysis. Most previous experiments concerning the direct determination of the impurity distribution within these films have involved radio-tracer methods combined with chemical sectioning. Chemical sectioning provides a surprisingly uniform removal of layers of the anodic oxide, although very careful experimental procedures are necessary to assure reproducible sectioning rates (1, 2, 4, 13).

We are examining the applicability of the Ion Microprobe Mass Spectrometer (GCA Technology Division, Bedford, Massachusetts) for the determination of impurity distributions in thin anodic oxide films. The details of the design and general operation of the IMMS have been described in detail previously (9). Basically, the instrument is a sputtering device in which the

sputtered material is sampled by a mass spectrometer. Thus, for a constant sputtering rate, the output of the spectrometer furnishes a measure of the ion yield or concentration of a given material as a function of depth. Although, in principle, comparison of these ion intensities with appropriate standards would permit the determination of absolute concentrations, we have not yet attempted to use the IMMS as a tool for quantitative analysis. All of the profiles presented in this work are based on arbitrary ion intensity units, which may vary from experiment to experiment, and must be considered with this in mind.

In this paper we present results which test the sensitivity of the apparatus for various types of work with ultra-thin oxide films. These results concern the behavior of phosphorus and fluorine impurities incorporated during the anodization of tantalum and, in particular, the use of thin phosphorus-rich layers as "markers."

Experimental Procedure

Tantalum specimens[4] were prepared from 1 × 2 × 0.05 cm coupons. These were annealed in vacuum (10^{-6} Torr) for 2 hr at 1600°C, mechanically polished through 0.3 μ-alumina, and electropolished in a 90% H_2SO_4-10% HF solution. A short length of tantalum wire was spot-welded to each specimen to facilitate handling and to serve as electrical contact during anodization. The polished specimens were then washed carefully and boiled in distilled water for 1 hr to remove or counteract the effect of the residual fluoride from the electropolishing bath.

The specimens were anodized at room temperature to a given voltage in a simple cell in which the initially high currents were limited to about 10 mA/cm^2 by a variable series resistor. The resistance was reduced to zero and the specimen held at full voltage for a "standard" time of 2 min in order to be able to apply previously determined thickness calibrations (10) to the films: 16.5 Å/V in dilute Na_2SO_4 and KF; 13.2 Å/V in concentrated (14.7M) H_3PO_4. The "duplex" and "sandwich" type films dealt with in this paper were produced by sequential anodization in the various electrolytes. It was assumed that the increment of thickness produced by an additional anodization depended only upon the voltage increment and the particular electrolyte.

Results and Discussion

Anodization in 0.035M (0.5%) Na_2SO_4.—The anodization of tantalum in dilute sulfate solutions produces amorphous, essentially stoichiometric tantalum pentoxide films which have uniform properties over a range of formation conditions. We utilized such films in the preliminary stages of this study to observe the effect of instrument variables, particularly those which controlled the size, intensity, stability, and uniformity of the argon ion-beam used for sectioning.

As reported previously (9), some modifications in the ion lenses and ion current measuring devices proved very useful in increasing the reliability of the instrument for our purposes. With these changes, the uniformity of the beam was improved, resulting in a sectioning (crater) geometry which produced a depth resolution useful for work with anodic films. The geometry of material removal was checked by observing intermittently the uniformity of the interference color of the remaining film at the bottom of the 3 mm × 4 mm elliptical crater produced by the beam. At a depth of 1000Å, variations of the order of ±50Å across the crater were generally observed. Calibrations of the sputtering rates of these films as a function of the beam parameters were obtained by means of side-by-side color comparisons with a standard set of anodized specimens. Sputtering rates of 0.5-1Å/sec used in this investigation could be reproduced from run-to-run to within ±10%. By monitoring either the Ta or O ion intensities during sputtering of the films, the position and effective "width" of the oxide/metal interface could be determined. Generally, a sigmoidal decrease of these intensities over a distance of about 200Å was associated with the interface. This was viewed as a reasonable value, particularly since the surface of electropolished tantalum is not precisely planar on a fine scale (11).

Anodization in H_3PO_4.—Anodic films formed on tantalum in H_3PO_4 solutions are known to contain significant quantities of phosphorus. Not unexpectedly, most of the properties of these films are significantly altered as a direct result of such incorporation. While a number of investigators have presented results which have been interpreted in terms of a nonuniform distribution of phosphorus, Randall *et al.* (4) were the first to include a quantitative description. These investigators found that all the phosphorus was concentrated in the outer half to two-thirds of the oxide, and that its concentration within this layer was uniform. Both the absolute concentration of phosphorus and the relative depth of the enriched layer depended upon the concentration of the electrolyte.

Typical phosphorus concentration profiles determined in the present investigation by the IMMS for films formed in concentrated (14.7M) H_3PO_4 are shown in Fig. 1. The phosphorus concentration drops off rapidly to a plateau which extends about two-thirds of the way through the film. The high apparent concentration at the electrolyte/film interface was also observed in earlier measurements (9) on films formed in both 14.7M and 0.9M H_3PO_4. While the extent of the surface enrichment is reduced somewhat by ultrasonic cleaning of the specimens in detergent solution (used on the present specimens), its persistence suggests that more than simply a surface artifact or occlusion is involved. For the case of films formed in 0.9M H_3PO_4, the phosphorus plateau extended about half way through the films; the high surface concentration was also observed. Thus, with the exception of our observation of phosphorus enrichment at the surface of the film, our profiles are in excellent agreement with those of Randall. Subject to the limitations discussed below, the phosphorus profile indicated that there is an apparent transport fraction for tantalum ions of about 0.65 for anodization in 14.7M H_3PO_4.

"Sandwich" films and marker experiments.—The results that two distinct layers are formed when tantalum is anodized in H_3PO_4 solutions implies that both O and Ta ions are mobile. If additional oxide can only be formed at the electrolyte/oxide and oxide/metal interfaces and if the phosphorus itself is essentially immobile, it follows that sequential or multiple anodizations in concentrated and dilute electrolytes could establish zones rich in phosphorus entirely buried within

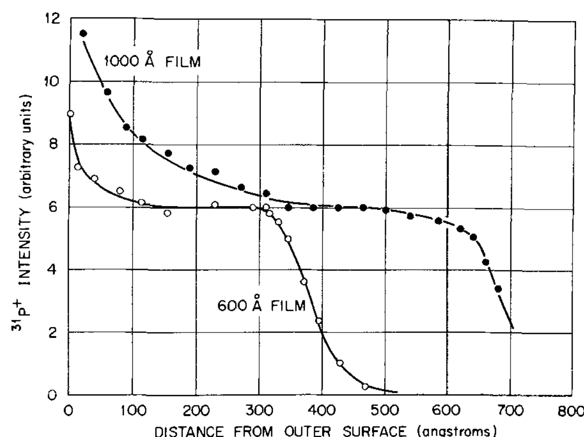

Fig. 1. Phosphorus concentration profiles in anodic films formed in concentrated (14.7M) H_3PO_4 to thickness of 600Å, ○, (45.5V) and 1000Å, ●, (75.8V).

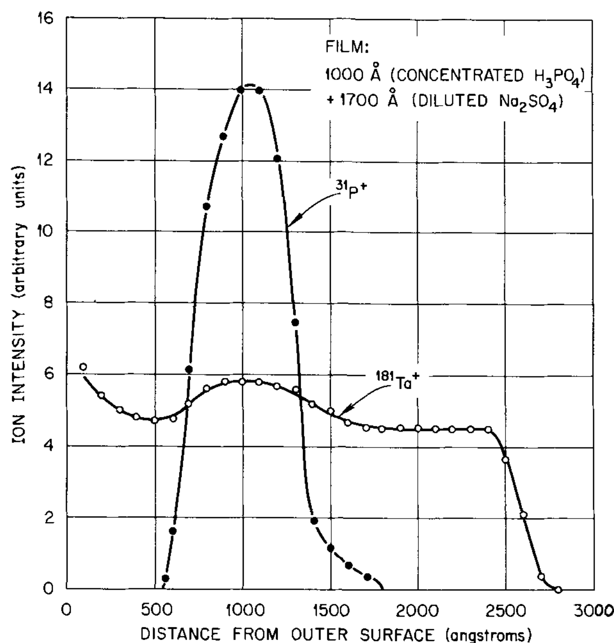

Fig. 2. Concentration profiles for tantalum and phosphorus across "sandwich" specimen formed by sequential anodization of tantalum in 14.7M H_3PO_4 (1000Å) and 0.035M Na_2SO_4 (+1700Å), ● phosphorus profile; ○ tantalum profile.

the layer. The existence of such zones would present interesting implications regarding the properties of these films.

The results of a duplex anodization are illustrated in Fig. 2. In this experiment, a 1000Å film was formed in concentrated (14.7M) H_3PO_4; the specimen was carefully washed and then reanodized in 0.035M Na_2SO_4 to a total film thickness of 2700Å. The Ta and P ion profiles shown in the figure confirm the fact that the phosphorus existed in an isolated region within the film. The thickness of the phosphorus-rich zone is consistent with its thickness prior to the second anodization, except that it does not exhibit the expected asymmetric distribution favoring the side toward the electrolyte. The variations in the Ta ion intensities are thought to be primarily the result of drifts in the sputtering beam currents.

A test of the resolving power of the IMMS for locating and describing thin, embedded layers in oxide films is shown in Fig. 3. In this set of specimens, phosphorus-rich layers having thicknesses of about 17, 35, and 65Å were sandwiched between layers of plain oxide by a three-step anodization in 0.035M Na_2SO_4, 14.7M H_3PO_4, and again in 0.035M Na_2SO_4. All three layers were easily resolved by the IMMS, resulting in the Gaussian-type curves for relative phosphorus concentration shown. The measured widths at half-maximum intensity were 85, 115, and 150Å, respectively, for the three phosphorus layers. Even if we ignore the possibility that the final anodization step caused a slight spreading of the phosphorus layer, these values indicate that the technique is capable of locating an internal interface of this sort to within about 40Å. (Note that an infinitesimally thin layer would exhibit an apparent thickness of 60-80Å.) It therefore appears that the resolution of the instrument is entirely satisfactory for defining impurity distributions on this fine scale.

This method was used to study the systematic movement and broadening of a thin phosphorus-rich layer during subsequent anodization in dilute electrolytes. If the phosphorus is indeed immobile, as suggested by Randall (4), it would serve as an ideal "marker" and information relating to the mechanism of film formation could be obtained. We anodized a group of specimens in 14.7M H_3PO_4 to an apparent film thickness of

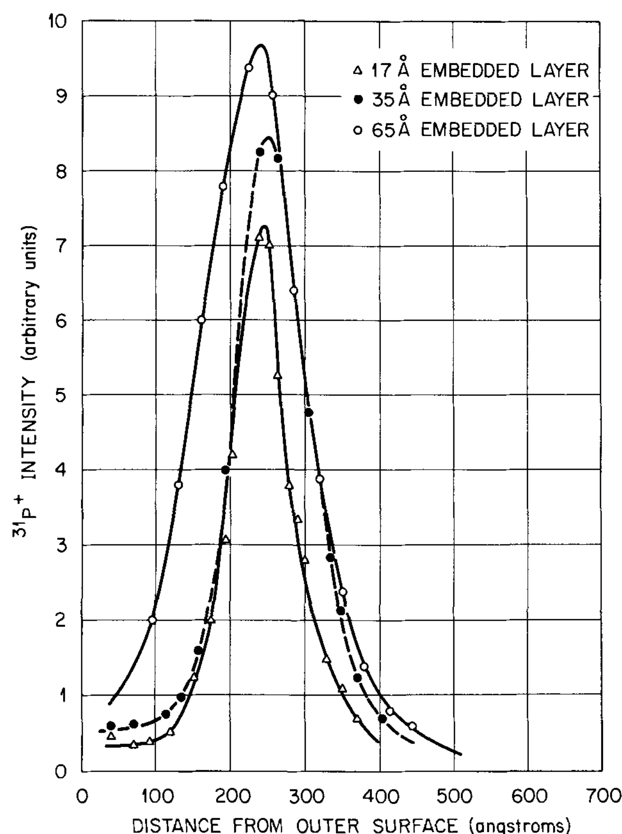

Fig. 3. Concentration profiles for thin phosphorus-rich layers embedded in anodic tantalum oxide film. The three specimens were prepared by *(a)* anodizing each to a film thickness of 500Å in 0.035M Na_2SO_4, *(b)* reanodizing in 14.7M H_3PO_4 to add 25Å △, 50Å ●, and 100Å ○ of film, two thirds of which is phosphorus-rich, and finally, *(c)* anodizing again in 0.035M Na_2SO_4 to add 500Å more to the total film thickness.

25Å. If we neglect the effect of the pre-existing film and assume that the same phosphorus distribution exists here as in the thicker films of Fig. 1, the phosphorus-rich layer will be slightly less than 20Å thick, and its center will be located about 10Å from the outer surface. We then reanodized these specimens in 0.035M Na_2SO_4 to add increments of phosphorus-free oxide from 500-4000Å in thickness. The phosphorus profiles, determined by the IMMS and normalized to a constant peak intensity, are presented in Fig. 4. The final position of the marker layer is approximately in the center of the film for all specimens. Note also that the apparent thickness of the layer (defined as the width of

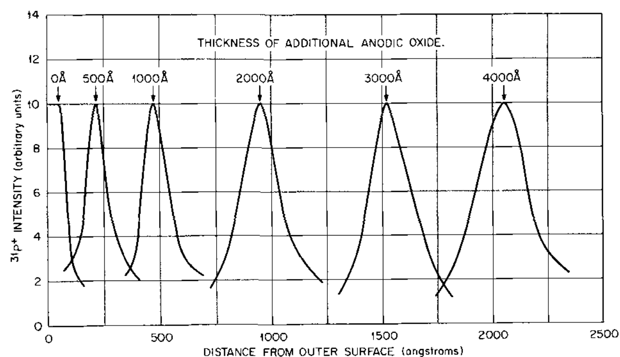

***Fig. 4.* "Marker" experiments with thin, phosphorus-rich layers. Concentration profiles exhibited by 17Å marker layer (25Å film formed directly on tantalum surface) after subsequent anodization in 0.035M Na_2SO_4 to 500, 1000, 2000, 3000, and 4000Å.**

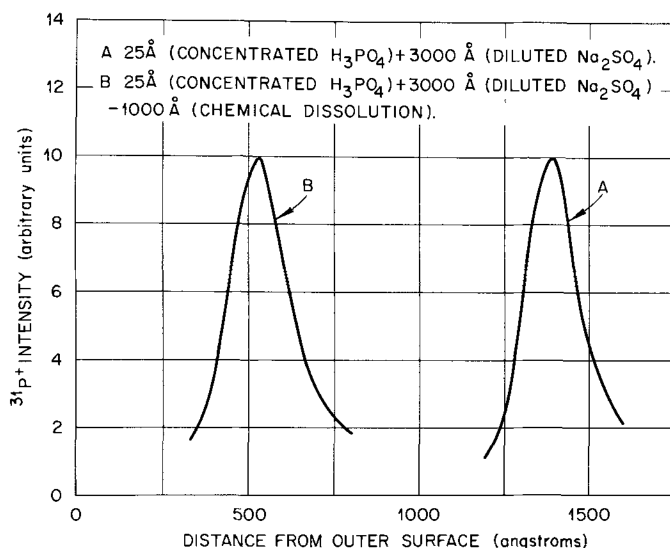

Fig. 5. Effect of marker layer depth on profile determination. Film 'A' contains a 17Å layer buried by subsequent anodization (3000Å) in 0.035M Na_2SO_4. Film 'B' is identical, except that approximately 1000Å of the outer film has been removed by chemical dissolution in NH_4F-HF solution.

the profile at half-maximum intensity), increases with the thickness of added oxide.

The final position of the marker is determined by the relative transport fractions of the ions across the film and also by the extent of its movement induced by the electric field and/or the ion flux. If the degree of the latter type of migration is directly proportional to the amount of anodization after the marker is placed, the transport fractions obtained from the data of Fig. 4 and similar experiments will be in error by a constant factor which relates this movement to the total amount of new oxide formed. The extent of this error cannot be determined from these experiments. However, the apparent spreading of the marker as a function of continued anodization implies at least some small degree of interaction with the ion flux or that some oxide is forming internally.

An apparent spreading of the marker layer would also be observed if the crater formed by the IMMS beam changed in shape or became roughened in proportion to the depth eroded. In order to check this possibility, we repeated the 3000Å film experiment employing chemical means to remove a portion of the outer oxide. Approximately 1000Å of oxide was removed from this specimen by partially dissolving the film in a solution of 25g NH_4F in 100 cc HF. Figure 5 indicates that the marker profiles obtained "before and after" are virtually identical. Thus, unless the chemical removal of the oxide produces an identical roughening of the surface, it appears reasonable to conclude that the marker spreading is a real, albeit a comparatively small effect.

The results of our experiments which bear directly upon the mechanism of anodic oxidation of tantalum in the manner previously described in dilute aqueous solutions are listed in Table I. If it is assumed that the phosphorus-rich layer serves as an inert, immobile marker (*i.e.* that its changes in position are solely a result of the motion of the Ta and O ions), then the fractional burying of the marker, $\Delta X/\Delta W$, is a measure of the tantalum ion transport fraction. In this expression, ΔX is the observed change in marker depth relative to the oxide/electrolyte interface during the period in which the total thickness of the film is changing by ΔW. The tantalum ion transport fractions are listed in the last column of the table and are sensibly constant with a value of 0.46 ± 0.05. Their constancy points out that if the phosphorus marker is indeed mobile, contrary to our above assumption, it moves in virtually direct proportion to the extent of subsequent anodization.

In excellent agreement with the above results, perhaps because phosphorus was also used as a marker, Randall (4) obtained a value of 0.48 for the corresponding transport fraction. However, Davies *et al.* (12) utilizing injected Xe^{125} atoms as markers, and Whitton (14), using Kr^{85}, obtained values of about 0.3. In order to rationalize the two results on the basis of their face value, a difference in mobility of approximately 0.2 Å/Å must exist for the phosphorus and the inert gas markers during anodization. It may be pertinent to note that the mass of the marker species (13), as well as the charge (14), will determine its relative mobility and final position in the film. Obviously, marker behavior is complex and the categoric interpretation of such results is dangerous.

Anodization in 0.09M (0.5%) KF.—It is well known that anodization of tantalum specimens prepared by polishing in reagents containing HF produces anodic films that are poorly adherent. It has also been shown (15) that anodization even in dilute fluorine-containing electrolytes permits large numbers of such films to be stripped in sequence from a single specimen. This is the basis of a sensitive microsectioning technique which is applicable to both tantalum and niobium, as well as their alloys. A reasonable explanation for this behavior is that a fluorine-containing film—perhaps an oxyfluoride—is formed at the oxide/metal interface and serves as an efficient parting agent between the metal and the film. The fact that this parting layer remains in position at the interface during anodizing has been used as evidence to support the idea that cation migration is the primary mechanism of anodic film formation (1).

Our application of the IMMS to the examination of fluorine profiles in anodic films furnishes an explanation for the effect which is consistent with the fact that both tantalum and oxygen ions are mobile. A fluorine concentration profile for a 2000Å anodic film formed in

[a] "P" indicates a phosphorus-rich layer. For example, 500/100P/1000 means the first anodization was carried out in dilute Na_2SO_4 to 500A; next, 100A was formed in 14.7M H_3PO_4 (outer two-thirds is P-rich); finally, 1000A were added by anodizing again in dilute Na_2SO_4.

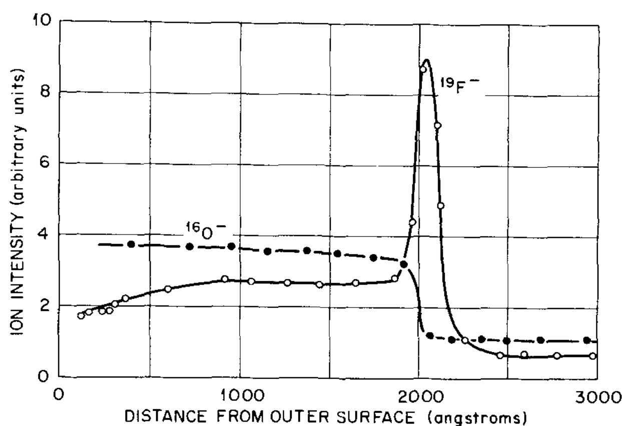

Fig. 6. Fluorine and oxygen concentration profiles in anodic film formed on tantalum in 0.09M (0.5%) KF. ○ Fluorine profile, ● oxygen profile.

a dilute KF solution is illustrated in Fig. 6. The concentration is essentially constant throughout the film, but rises abruptly at the oxide/metal interface. The oxygen profile, shown on a less sensitive scale, shows no such peak, but behaves in normal fashion through the interface. The presence of a fluorine-rich layer of some sort at the interface is evident. Furthermore, the width of the F peak at half-maximum intensity is only about 100Å and, taking into account the resolution limits of the IMMS for such interfaces, we estimate the thickness of this layer to be less than 50Å—perhaps much less.

In order to test the hypothesis that fluorine itself is mobile during anodization and may be driven through the film to the oxide/metal interface, we measured the fluorine profiles on a series of specimens which had been pre-anodized in a dilute sulfate solution to produce 500Å adherent layers of fluorine-free oxide and then reanodized in 0.09M KF to produce increments of fluorine-containing oxide with thicknesses of 250, 500, and 1000Å, respectively. If fluoride were immobile, none should be found within 500Å of the oxide/metal interface. The results of these experiments are presented in Fig. 7. Reanodization to add 250 and 500Å thickness to the oxide layer caused measurable amounts of fluorine to migrate into the formerly "plain" oxide layer as manifested by the considerable broadening of the F-distribution curves into this region. Reanodization to add 1000Å of film, however, resulted in the

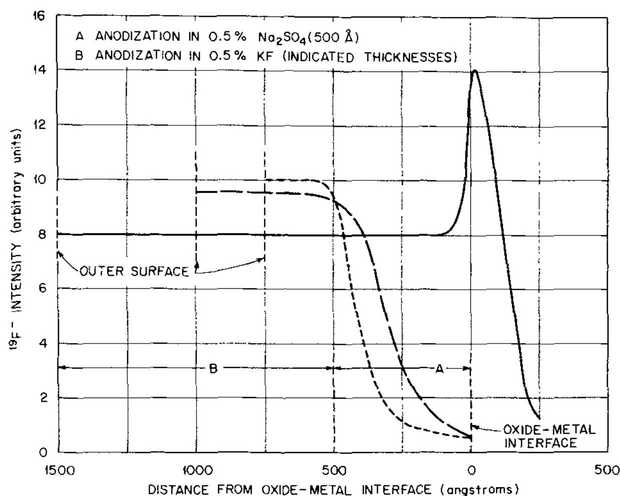

Fig. 7. Fluorine concentration profiles in anodic films formed stepwise on tantalum in dilute Na_2SO_4 and KF solutions. All three specimens were first anodized in 0.035M Na_2SO_4 to form 500Å of fluorine-free oxide. They were then reanodized in 0.09M KF to the indicated total thicknesses.

fluorine finally reaching and apparently being concentrated at the oxide/metal interface. This behavior is similar to that for anodization wholly in KF, and the eventual formation of a discrete F-rich layer shows that the fluorine migrated toward the oxide/metal interface to an extent which depended upon the amount of anodization. Thus, if a fluoride-rich layer does not already exist at the interface, sufficient fluorine can migrate to cause its formation and perhaps continued growth.

It is pertinent to point out that the films which have the fluoride layer at the interface easily strip from the specimen; the others do not. These results are useful in understanding the action of fluorine in determining the relative adherence of anodic films on tantalum. Only very small amounts of fluorine at the interface are required to decrease markedly the adherence of the film. For example, we have found that the fluorine in a 50Å film formed in dilute KF, when driven through an adherent anodic film to the interface, is sufficient to cause complete loss of adherence. Probably less than a monolayer of fluorine atoms is involved.

An estimate of the mobility of the fluorine was also obtained in these experiments. In order to drive fluorine from a "sandwich" through a given thickness of adherent film, it was necessary for additional oxide between two and three times this thickness to be formed. Holding the composite for extended periods of time under conditions where the electric field in the oxide was sufficient to maintain only very slow over-all growth rates did not cause appreciable fluorine movement. Apparently, gross ion movement, or the added field strength associated with it, was necessary to promote this effect.

Conclusions

The ion microprobe mass spectrometer has been shown to be a useful instrument for describing the distribution of impurities in thin anodic oxide films. The sputtering rates and crater shapes were controlled such that they varied very little with time and penetration depth (at least for several thousand angstroms). The effective resolution, in terms of the apparent thickness of a plane interface, was about 50Å. The inclusion and movement of phosphorus and fluorine in anodic tantalum oxide films during a variety of anodization procedures were studied. The specific conclusion are:

(*i*) When films are formed in concentrated H_3PO_4, the phosphorus concentrates in the outer two-thirds of the film implying, if the phosphorus is immobile, a value of the tantalum ion transport fraction of about 0.65. This is different from the value of 0.46 found for anodization in the dilute sulfate solution. It may be significant in this respect to point out that the high-temperature oxygen permeation rates through anodic films containing phosphorus have been observed to be much less than those through the plain anodic oxide (10).

(*ii*) Thin, phosphorus-rich layers of known thickness may be positioned in otherwise normal anodic films.

(*iii*) Phosphorus-rich layers spread only slightly during continued anodization.

(*iv*) If phosphorus is itself mobile during anodization, it moves in virtually direct proportion to the amount of anodization and, thus no direct values could be determined concerning the extent of this movement. Assuming the phosphorus marker layer to be immobile, the apparent tantalum ion transport fraction is about 0.46 for anodization in dilute sulfate solutions. The corresponding transport fraction determined by previous investigators using inert gas atoms as markers is about 0.3. Thus, if these markers are immobile, phosphorus is drawn to the oxide/metal interface by approximately 0.2 Å/Å during anodization.

(*v*) During anodization, fluorine-rich marker layers or fluorine ions from the electrolyte may be driven comparatively large distances through the film toward the oxide/metal interface. Thus, fluorine cannot be

used effectively as a marker for ion transport studies.

(*vi*) The loss of adherence of the anodic films on tantalum occurs when a fluorine-rich layer forms at the oxide/metal interface. This "parting agent" can be produced by (*a*) anodizing specimens polished in fluoride-containing reagents, (*b*) anodizing specimens in fluoride solutions, or (*c*) driving a fluoride-rich layer through the anodic film by continued anodization.

The Effect of Fluoride Ion on the Anodic Behavior of Titanium in Sulfuric Acid

M. J. Mandry[1] and G. Rosenblatt*[,2]

Department of Metallurgical Engineering, Queen's University, Kingston, Ontario, Canada

ABSTRACT

The anodic behavior of titanium in the presence of fluoride ion and sulfuric acid has been studied. Fluoride ion accelerates active corrosion and results in more active, time-dependent corrosion potentials and greatly increased current requirements for passivation. The critical current density is found to be first order with respect to fluoride ion at low concentration and less than unity at higher fluoride levels. Corrosion in the passive region is also increased although to a lesser extent than in the active state.

Titanium offers many advantages over other materials when used in acid media, displaying excellent corrosion resistance. Recent literature (1-4) has been largely concerned with the anodic behavior of titanium in acid solutions. The effect of chloride ion on the corrosion resistance of titanium and its alloys has been recently outlined by Thomas and Nobe (2) for sulfuric acid solutions and by Levy (5) and Takamura (6) for concentrated chloride solutions. However, very little work (7-9) exists on the effect of fluoride ion on titanium corrosion, particularly in the small amounts encountered in industrial environments, despite the fact that fluoride ion has been found to be an extremely pernicious impurity with regard to titanium corrosion. The purpose of the following investigation was to determine the anodic behavior of titanium in the presence of fluoride ions.

Experimental Procedure

Titanium used in this study was commercially pure Ti75A (max % 0.08C, 0.05N, 0.015H, 0.20Fe) in the annealed condition. Samples cut from the slab of the as-received titanium were mounted in epoxy resin (Armstrong Activator W and C-4 resin) so that only one face was exposed to the test solution. Care was taken to avoid crevices between the sample and the epoxy mount. Some titanium samples were machined into cylindrical electrodes and mounted using Teflon compression gaskets (10). Both methods gave the same results in the sulfuric acid-fluoride solutions used in the work. Samples were polished on metallographic abrasive paper, washed in detergent solution, mounted in an electrode holder (10), and degreased with acetone. They were finally rinsed with distilled water before immediate insertion into the cell. The cell and auxiliary platinized platinum electrodes were similar in design to those described earlier in the literature (4, 10), except that a Luggin probe-reference electrode assembly was employed which contained an isolating stopcock to avoid contamination by the chloride solution of the reference electrode. The stopcock was closed during the course of the experiment and ionic contact was maintained through a film of electrolyte on the stopcock. In all cases electrode potentials are reported *vs.* SCE, uncorrected for liquid junction potentials.

Anodic polarization was achieved by using an Anotrol potentiostat (Model 4100). Electrode potentials were measured with a high impedance electrometer (Wenking PPT-19) to an accuracy of 1 mV. The electrode potentials were set in steps of 25 mV into the passive region, after which 50 or 100 mV steps were taken in order to result in an over-all transfer rate of 0.3 V/hr. Solutions of 1*N* sulfuric acid were prepared from reagent-grade sulfuric acid and double-distilled water. Fluoride additions were made to the sulfuric

Key words: anodic polarization, titanium corrosion, fluoride ion.

acid in the form of a concentrated solution of reagent-grade sodium fluoride. Purified hydrogen was bubbled through the solution during the test.

Titanium electrodes were self-activated (2) by immersion in 1*N* sulfuric acid solution through which purified hydrogen was passed for a period of 18 hr. Reproducible corrosion potentials were readily obtained using this procedure which was preferred to the activation treatment using HF (2) or cathodic prepolarization (3). Anodic polarization was initiated only after a steady corrosion potential was attained (no change in potential of more than 2 mV for 30 min). Solutions containing fluoride required a further waiting period before this steady state was reached. The corrosion potential was found to be depressed by about 50 to 75 mV after immersion in the sulfuric acid-fluoride solution, but drifted in a positive direction to a steady potential after a 3-hr period.

Results

Anodic polarization of titanium.—The effect of fluoride ion on the anodic polarization characteristics of titanium are shown in Fig. 1. As can be seen from the data collected from these curves and summarized in Table I, small increases in fluoride ion concentration produce large increases in the critical current needed for passivation. The smallest NaF concentration examined (0.59×10^{-3} M) increased the current density for passivation by a factor of three over that of titanium in the absence of fluoride. Quantitative comparisons were difficult to make because earlier work studying the effect of fluoride ion on the corrosion of titanium involved larger fluoride concentrations and employed HF and various media with added NH_4F and HF. However, the trend observed previously (7-9) of increasing critical current densities with fluoride is in general agreement with our data. Although both the critical current and the passive current density (at 0.6V) show a rapid initial increase with increasing fluoride concentration, the form of the curves is different in each case (Fig. 2). At high fluoride concentrations (greater than 15×10^{-3} M), the passive current density is largely independent of fluoride concentration, while the critical current density required for passivation is found to continuously increase. A more active corrosion potential is also produced when NaF was added (greater than 1.2×10^{-3} M) (Table I) and the potential at which passivation is initiated (primary passivation potential) is also shifted to more active potentials. However, the primary passivation potential remains constant (−0.575V) between fluoride concentrations of 2.5×10^{-3} and 36×10^{-3}M.

At this point it is interesting to compare the effects of fluoride ion with respect to chloride ion on titanium. Thomas and Nobe (2) reported that active titanium corrosion in H_2SO_4 was largely unaffected by additions of NaCl (up to 5.8%). A small decrease in the critical current required for passivation was recorded along with a decrease in the passive current density. Chloride ion therefore acts as a mild inhibitor in the passive corrosion of titanium, but fluoride at much smaller concentrations is a very strong activator of both active and passive corrosion. Fluoride additions are extremely effective in preventing passivation by increasing the critical current and also the anodic current in the passive state and, therefore, reducing the effectiveness of the protective titanium oxide film.

120.0	−0.825	4580	259.0	−0.600

Effect of temperature.—Figure 3 shows the polarization behavior of titanium in 1*N* H_2SO_4 at different temperatures and fluoride concentrations. The active corrosion region for titanium is lengthened when the temperature is increased. Although current fluctuations around the corrosion potential and the narrowness of the active region before the onset of passivity prevented any accurate determination, the corrosion current was estimated to increase with temperature. Passivity was more difficult to attain as evidenced by the increased critical current density, but increased passive current density (at 0.6V *vs.* SCE) indicates that the passive state was less protective at higher temperatures. The potential at which passivation was initiated was found to be similar in all cases (−0.550V).

Discussion

Fluoride ion provides a strong activating effect on the corrosion of titanium in both active and passive states. However, corrosion in the active state is more greatly accelerated by fluoride ion which results in the increased critical current densities and therefore increased charge requirements in order to reach the passive state. Taken together with the observation of a more active and time-dependent corrosion potential, this seems to indicate an adsorption process as part of the corrosion mechanism. However, the high hydration energy associated with the fluoride ion (11), as well as previous experimental work of fluoride adsorption on zirconium (12), seems to preclude any explanation requiring specific adsorption during anodic polarization. If the onset of passivity is delayed by the dissolution of existing film or consumption of the precursors for film formation, then a larger critical current density would be required. Previous mechanisms for zirconium dissolution in fluoride solutions proposed by Meyer (13, 14) and more recently by Rettig *et al.* (15) suggest that the passive film is dissolved by HF which diffuses to the electrode surface in the following reactions (14) involving fluoride complex ions

$$Zr_{\text{passive film}}^{+4} + HF \rightarrow ZrF^{+3} + H^{+} \quad [1]$$

$$ZrF^{+3} + HF \rightarrow ZrF_2^{+2} + H^{+} \quad [2]$$

$$(ZrF)_{b-1}^{4-(b-1)+} + HF \rightarrow ZrF_b^{(4-b)+} + H^{+} \quad [3]$$

where $b = 2.5$ to 4.0. A general equation can be formulated for titanium corrosion in the passive state

$$Ti_{\text{passive film}}^{(5-b)+} + bHF \rightarrow TiF_b^{(4-b)+} + bH^{+} \quad [4]$$

where $b = 1$ to 3 with HF being formed in solution

$$(H^{+} + F^{-} \rightleftharpoons HF;\ \log k_1 = 3.62 \text{ at } 25°C) \quad (18)$$

Further reactions are then possible with the fluoride complex ion according to the reaction scheme (Eq. [2] and [3]) proposed by Meyer (13, 14). Anodic dissolution studies on titanium in sulfuric acid (1) have indicated that titanium is oxidized to Ti^{3+}. If the same reaction can occur in the presence of fluoride then the passive film forming reactions

$$Ti \rightarrow Ti^{3+} + 3e \quad [5]$$

$$Ti^{3+} \rightarrow Ti_{\text{passive film}}^{3+} \quad [6]$$

will occur in competition with the film dissolution reaction

$$Ti_{\text{passive film}}^{3+} + 2HF \rightarrow TiF_2^{2+} + 2H^{+} \quad [7]$$

During anodic polarization in the passive region, the film dissolution reaction becomes rate controlling and the increased local concentration of hydrogen ion pro-

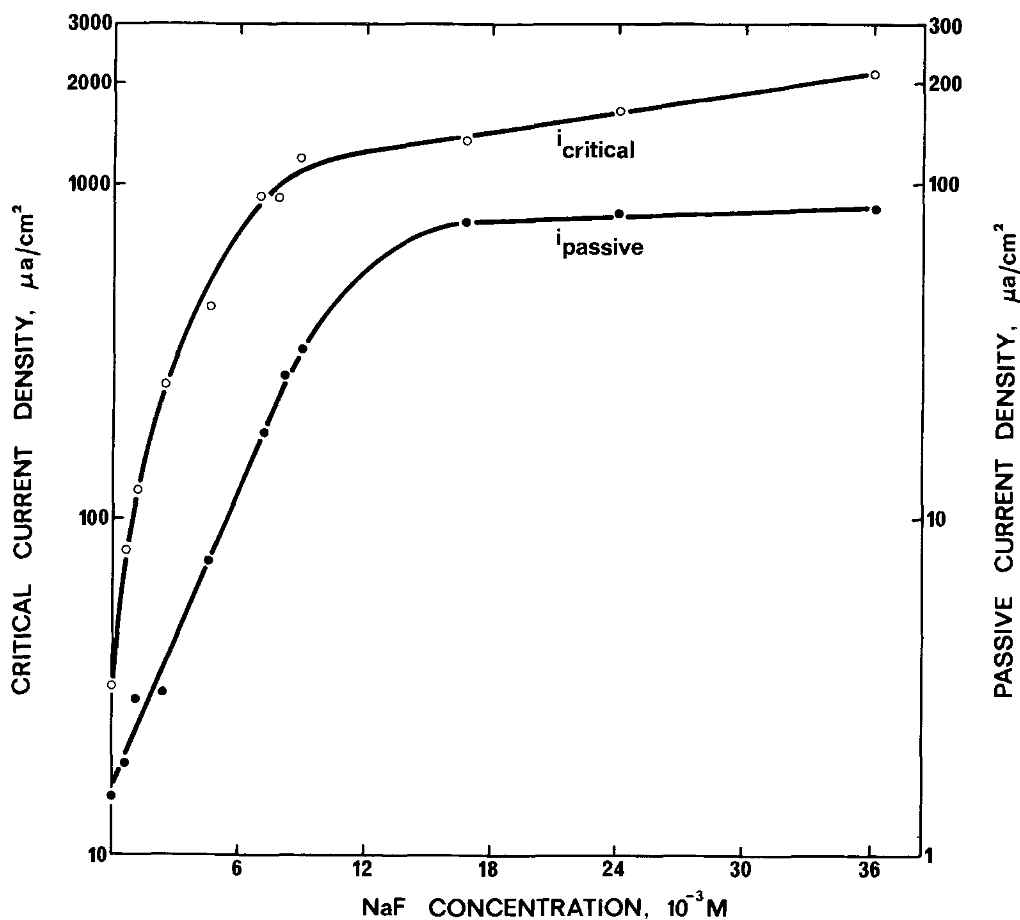

Fig. 2. Variation of critical current density and passive current density with fluoride concentration.

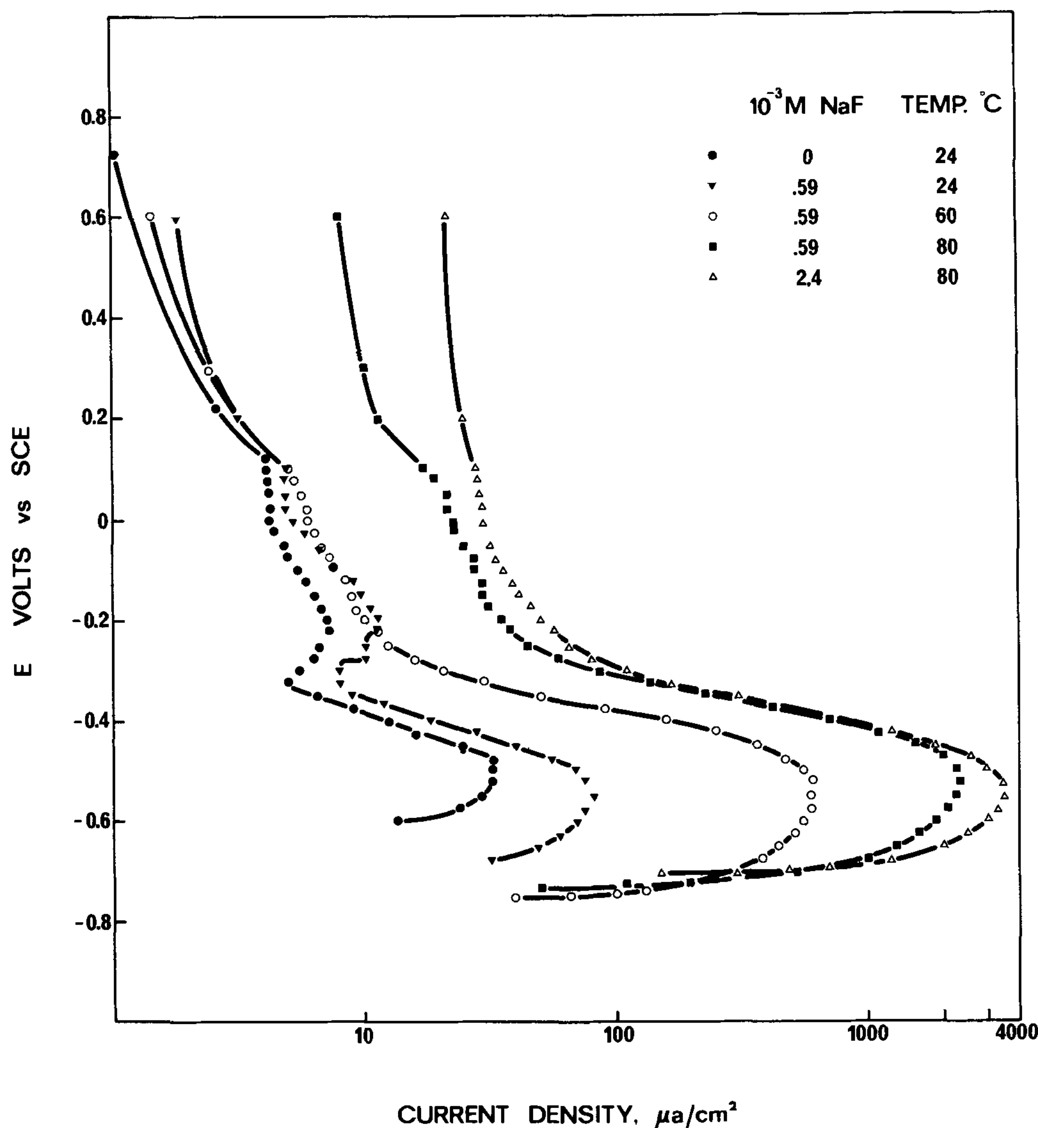

Fig. 3. The effect of temperature on the anodic polarization characteristics of titanium at different fluoride levels.

duced by the film dissolution reaction [7] results in the formation of HF near the titanium surface. The critical current density for passivation then becomes dependent on the local HF concentration. Etching on the tip of the Luggin probe situated near the surface was observed after completion of anodic polarization and confirmed the interfacial formation of HF. Meyer (14) also suggested that the order of the corrosion reaction for such a mechanism would be unity so that the rate would be given by an expression $r = k$ (HF); where k is the rate constant of the reaction sequence. In our case an order slightly larger than unity was obtained for the dependence of critical current density on fluoride concentration (Fig. 4), although a fractional order (0.56) was obtained at higher fluoride concentrations. This change in reaction order indicates a different reaction mechanism from that at lower fluoride concentrations. To obtain an order of unity with respect to HF, a straightforward reaction scheme involving hydrogen ion is assumed. Above a critical concentration, reaction by way of an intermediate fluoride species, either as a surface film or complex ion situated at the surface, may occur and hence a fractional reaction order would then be possible.

In the region of active corrosion, fluoride produces a more active corrosion potential, decreases the anodic and cathodic (hydrogen evolution) Tafel slopes, and results in an increased corrosion current (16). An important factor in the active corrosion of titanium in the presence of fluoride seems to be the increased hydrogen evolution rate brought about by the decreased Tafel slope for hydrogen. The mechanism by which fluoride alters this parameter is the subject of a future paper.

Within the passive region above the primary passivation potential, a fully consolidated oxide film exists, and the action of fluoride ion is difficult to describe without further measurements of oxide film thickness. Increased passive current density (Table I) could result from either the inhibiting action of fluoride ion on the oxide growth, incorporated within the oxide layer with a resultant weakening of the structure, or the increased dissolution of the oxide caused by HF produced within the solution. Potentiostatic pulse measurements (17) performed during the corrosion of titanium in fluoride solutions indicate the existence of a single porous oxide layer. The exact nature of this layer and changes with fluoride concentration remain undefined at present.

Effects of Alkyl Amine Surfactants on Mass Transfer Controlled Corrosion Reactions

G. Kar, I. Cornet,* and D. W. Fuerstenau

College of Engineering, University of California at Berkeley, Berkeley, California 94720

ABSTRACT

The cathodic polarization technique has been used to detect the specific role of concentration and chain length of alkyl amine surfactants on the corrosion reaction in a turbulent-flow system involving a rotating Monel cylinder-saline water interface. The mass transfer limiting current necessary for complete cathodic protection of Monel decreased with increased surfactant concentration and chain length. The phenomenon has been explained in terms of a "resistance barrier" due to the precipitate film of neutral amine molecules on the Monel surface. With the help of a simple "regression" analysis the relative significance of different variables and their interactions have been discussed.

Research on corrosion inhibition by adsorbed surface-active materials in turbulent-flow systems has been largely neglected despite the fact that corrosion and corrosion inhibition in numerous marine applications involve motion of a metal surface relative to a seawater environment. The interfacial region between the metal and the solution is the site for corrosion reaction, and the rate processes may be controlled by mass transfer of the reacting species through the interfacial film. This, in turn, is controlled by the dynamic shear conditions imposed by relative flow of metal and solution. There has been very little work reported on the performance of corrosion inhibitors in such turbulent systems. However, there are several related areas of investigation that are significant to the study of such a system.

Several workers have considered the adsorption of simple organics (1-5) and long chain organic surfactants on polarized copper and nickel (6-8) surfaces and the mercury-water interface (9, 10). Hackerman (7, 8) has summarized the observed relationships between the inhibition process and surfactant molecular structure. Specific effects of organic inhibitors on the corrosion of mild steel in acid solution (11-13), and the effects of organic amine inhibitors on the corrosion of iron in acid solution (14), and in organic solvents (15) have also been reported. The analysis given in two

* Electrochemical Society Active Member.

Key words: Monel, rotating cylinder, cathodic protection, oxygen reduction, mass transfer limiting current, alkyl amines, adsorption, corrosion inhibition.

detailed reviews (7, 16) suggests that the effectiveness of organic and inorganic inhibitors for a given metal depends on the inhibitor concentration, the pH of the system, the velocity of the metal relative to the solution, time, surface preparation, surfactant chain length, temperature, cross-sectional area of the organic molecules, and the nature of the functional group on the inhibitor. Analysis of basic mass transfer-controlled reactions in turbulent systems, at the surface of rotating disks and cylinders and at static surfaces has received considerable attention (17-26). Reviews have also appeared on the suitability of several electrochemical techniques for analysis of the fundamental aspects of the adsorption of organic inhibitors on solid electrodes (27-30).

In the present investigation, the current required to protect a metal cylinder rotating in an aerated 4% NaCl (0.685*M*) solution has been investigated as part of the study of the effect of mass transfer on corrosion and corrosion prevention. In such a system, two major cathodic reactions can occur. At low negative potentials the reaction $O_2 + 2H_2O + 4e^- = 4\ OH^-$ ($E° = -0.40V$) and at a slightly more negative potential the reaction $4H_2O + 4e^- = 4\ OH^- + 2H_{2gas}$ ($E° = -0.828V$) takes place. However, for the purpose of investigating the oxygen mass transfer to and reaction at the surface, the former cathodic reaction is usually considered as the primary one, and all experiments have been done in the potential range of this reaction. Subsequently, the corrosion of the metal can be considered to be governed by the redox reaction

$$O_2 + 2H_2O + 2M \rightleftharpoons 2M^{++} + 4\,OH^- \quad [1]$$

where M is a divalent metal. The metal, however, can be protected by cathodic polarization, whereby the oxygen reaching the metal surface is reduced by the external supply of electrons. The polarizing current necessary to protect the metal completely depends on the rate of convective diffusion and access of dissolved oxygen to the metal surface. This current is often termed "Mass Transfer Limiting Current" (MTLC). The MTLC can be reduced considerably by using cationic surfactants, which, when adsorbed from the solution phase onto the metal cathode, can form a barrier for oxygen diffusion.

The alkyl amine surfactants of various chain length were selected as model corrosion inhibitors in view of the key role of nitrogen centers discussed by Hackerman (7), Nakagawa *et al.* (14, 15), and of increasing chain length (8) in the action of corrosion inhibition. Furthermore, the quantitative hemimicelle model of surfactant adsorption at the solid-liquid interface developed by Fuerstenau *et al.* (31, 32), has been tested in detail for alkyl amines at negatively charged oxide surfaces. The extension to cathodically polarized metal surfaces is therefore well served by this earlier quantitative adsorption work. The results of this investigation have been summarized and discussed in terms of the mechanical and chemical variables affecting the process. An attempt has been made to understand the mechanism of corrosion inhibition and, particularly, its sensitivity to relative motion, inhibitor concentration, and surfactant chain length.

Experimental Method

In order to incorporate into polarization phenomena the effects due to mass transfer between the metal surface and the liquid, an apparatus with a vertically rotating cylindrical cathode was designed and constructed. The cylinder (19.2 cm long × 1.91 cm diam) consisted of a 7.6 cm long test electrode made of Monel (67% Ni, 30% Cu, 1.4% Fe, 1.0% Si, 0.15% C, 0.01% S) alloy in the midsection and acrylic plastic at either end to avoid end effects. The test electrode, operated as a cathode, was rotated at the center of a concentric counterelectrode (7.6 cm long × 14 cm diam) made of platinum strip on titanium. The cell containing the

electrolyte (4% NaCl aqueous solution) was made of Lucite and was partially open to the atmosphere at the top. The speed of the cylinder was varied using a variable-speed motor. Arrangements were made for a galvanostatic polarization study. The potential of the cathode was measured with reference to a saturated calomel reference electrode (SCE). The general layout of the experimental assembly and its electrical circuits is shown schematically in Fig. 1.

The Monel electrode was cleaned mechanically, etched with concentrated hydrochloric acid, and washed repeatedly before immersion in the 4% NaCl solution. This cleaning procedure yields a reproducible surface in that under a given set of solution conditions, the observed rest potential and limiting current are constant.

The alkyl amine surfactants were used as ammonium acetate salts. These were prepared by dissolving high-purity primary amines obtained from Armour Industrial Chemical Company in benzene and adding an equimolar quantity of glacial acetic acid. The acetate salt was recrystallized from benzene by cooling, and excess benzene was removed in a vacuum desiccator.

The oxygen content of the solution, which was analyzed for each run by the standard Winkler method, was varied by controlled exposure of air-saturated NaCl solution to helium gas for various time periods. In most experiments, the oxygen content was maintained reasonably constant by exposing the electrolyte solution to the atmosphere for a day to effect oxygen saturation. During the entire experiment, the electrolyte was left open to the atmosphere.

Considering the complexity arising out of temperature variations, which cause changes in oxygen solubility and its diffusivity, kinematic viscosity of the electrolyte, surfactant solubility, etc., all experiments were conducted at a fixed temperature of 20°C.

Results

Effect of speed of rotation.—In order to delineate the role of the mass transfer controlled process in rotating

Table I. The limiting current densities for a Monel cathode at various rotational speeds

systems, the polarization behavior of Monel was determined as a function of the speed of rotation, in the absence of inhibitors in air-saturated 4% NaCl solution. From the polarization curve, the limiting current was taken as the point at which a slightly further increase in current resulted in a large increase in potential (virtually infinite slope of the polarization curve). The limiting current density values corresponding to particular rotational speed and oxygen concentrations are summarized in Table I. As the speed of rotation increases, the thickness of the diffusion boundary layer decreases, thereby increasing the oxygen concentration gradient and the limiting current density. Thus, in order to achieve protection of the metal surface, larger current density is required at higher rotational speed.

Effect of dissolved oxygen concentration.—Since oxygen is the primary species reduced at the cathode surface, its concentration in solution should control the MTLC. In order to verify this, the oxygen content in solution was varied, keeping the speed of rotation constant at 1400 rpm, and the MTLC values were obtained from polarization measurements on the Monel cathode. These results are given in Table II.

Effect of surfactant concentration and surfactant chain length.—When alkyl amine acetates were added to the system, reduction in MTLC values were observed. A sample polarization curve for Monel in the presence of surfactant is shown in Fig. 2. This figure shows that at low concentrations of amine salt, (10^{-6}, $10^{-5}M$), the effect of surfactant on MTLC is hardly significant, while above $10^{-5}M$ there is a sharp decrease in MTLC. At concentrations exceeding $10^{-4}M$ a thin, white precipitate film appears to be coating the electrode uniformly. The film tends to grow with time. The film appears only towards the latter stages of the polarization experiment, and it dissolves into the electrolyte in a short time if the polarizing current is switched off. The electrode, which is usually hydrophilic before the start of the experiment, becomes hydrophobic after the experiment. The film is clearly a precipitate in that it is easily washable and soluble if the pH is lowered.

The effect of concentration of alkylammonium acetate on MTLC for protection of Monel was investigated at various rpm's of the electrode and various alkyl chain lengths of the surfactant. The results are presented in terms of limiting current density values that have been normalized with respect to oxygen concentration (which usually varied within ±10%). In Fig. 3, the effect of the concentration of dodecylammonium acetate on the limiting current density is presented for several different rotational speeds of the electrode. Figure 4 presents the effect of the concentration of decyl (C_{10}), dodecyl (C_{12}), and tetradecyl (C_{14}) ammonium acetates on the limiting current density at an electrode rotational speed of 1400 rpm.

Effect of pH.—Most experiments were conducted with air-saturated 4% NaCl solution at a pH of about 5.3. Measurement of the pH of the bulk electrolyte during the experiment showed a definite upward trend of pH with the progress of the polarization experiment. When suitable buffers (sodium acetate and acetic acid for pH's below 7 and sodium borate and sodium hydroxide for pH's above 7) were used to fix the pH in both the acid and basic ranges below pH 8, there was no visible precipitate on the Monel surface, and MTLC values in each case coincided with that when no

surfactant was present (Fig. 5).[1] In solutions buffered at pH 3.95, 5.15, 5.85, and 7.86, the limiting current densities were found to be 1.19×10^{-4}, 1.16×10^{-4}, 1.16×10^{-4}, and 1.23×10^{-4} A/cm²/ppm O_2, respectively.

Discussion

MTLC in the absence of surfactants.—Since there is no general exact solution for diffusion of a species to and from a rotating cylinder in an infinite solution medium, the problem has been treated by considering different limiting cases separately. For turbulent flow cases, with a rotating cylinder, the use of dimensional analysis to correlate heat and mass transfer data has been found to be quite convenient. According to Ibl (17) and Eisenberg *et al.* (20, 21), mass transfer data for rotating cylinders can be correlated by the relationship

$$\text{Sh} = 0.079\ \text{Re}^{0.7} \cdot \text{Sc}^{0.356} \qquad [2]$$

where

$$\text{Sh (Sherwood number)} = \frac{i_L d}{n\mathbf{F}D\Delta C}$$

$$\text{Re (Reynolds number)} = \frac{ud}{\nu}$$

$$\text{Sc (Schmidt number)} = \frac{\nu}{D}$$

and

i_L = mass transfer limiting current density (A·cm^{-2})
d = characteristic length of cylinder (cm)
n = number of electrons taking part in the reaction
$\mathbf{F}$ = Faraday constant (A·sec·eqvt.$^{-1}$ mole^{-1})
D = diffusion coefficient for the diffusing species (cm²·sec^{-1})
ΔC = concentration gradient of the reacting species = bulk concentration, since at the MTLC, concentration of the reacting species at the metal surface is assumed to be zero (moles·cm^{-3})
u = radial velocity of the cylinder (cm·sec^{-1})
ν = kinematic viscosity of the solution (cm²·sec^{-1})

The results of our investigation in the absence of any surfactant have been analyzed in terms of the relationship given as Eq. [2] in order to confirm that oxy-

[1] Due to the swamping effect of high concentration of chloride ions in the 4% NaCl solution, the equivalent concentration of alkylammonium ions are largely governed by the chloride ion concentration. Therefore, the amount of acetate ions added for buffering would not affect the alkylammonium ion concentration very much.

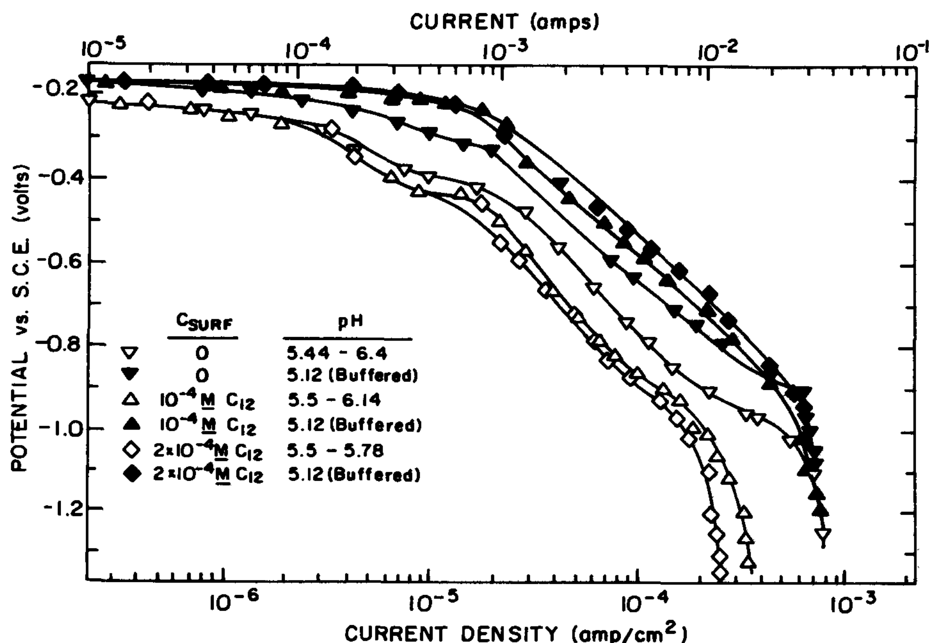

Fig. 5. The effect of buffered electrolyte on the polarization curve for Monel in 4% NaCl (air-saturated) solution with dodecylammonium acetate at 20°C and 1400 rpm.

gen reduction at the metal cathode is a typical mass transfer-limited reaction. In Eq. [2], using the experimental Sc value of 488, and reducing the other dimensionless numbers to measurable parameters, one arrives at the relationship

$$i_L = 7.41 \times 10^{-7} \cdot N^{0.7} [C_{O_2}] \quad [3]$$

where

N = rotational speed of the electrode in rpm

$[C_{O_2}]$ = bulk oxygen concentration at MTLC, in air-saturated 4% NaCl solution at 20°C (ppm)

A linear regression analysis of the experimental data results in an equation of the form

$$i_L = 7.42 \times 10^{-7} \cdot N^{-(0.64 \pm 0.0333)} [C_{O_2}]^{(0.994 \pm 0.088)} \quad [4]$$

with t-values of 43.9 and 23.6 for N and $[C_{O_2}]$, respectively.

If a 95% confidence limit is assigned to the indices of N and $[C_{O_2}]$, Eq. [3] and [4] appear to be in excellent agreement. The results are plotted in Fig. 6 and 7. These results clearly indicate that oxygen reduction at the Monel surface, in a turbulent system, and in the absence of any surfactant, obeys the mass transfer correlation given in Eq. [2].

MTLC in the presence of surfactant.—When the surfactant is added to the electrolyte, various changes may occur. Changes in oxygen solubility, viscosity of the electrolyte, diffusivity of oxygen molecules, etc., in addition to the adsorbed film at the electrode surface, result in over-all reduction in the MTLC. However, it may be assumed that the effect of changes in the solution properties due to the surfactant addition are minor at these low concentrations compared to the effect of the adsorbed film. The nature of the adsorbed film, on the other hand, may very well be a function of the speed of rotation, surfactant concentration and chain length, etc.

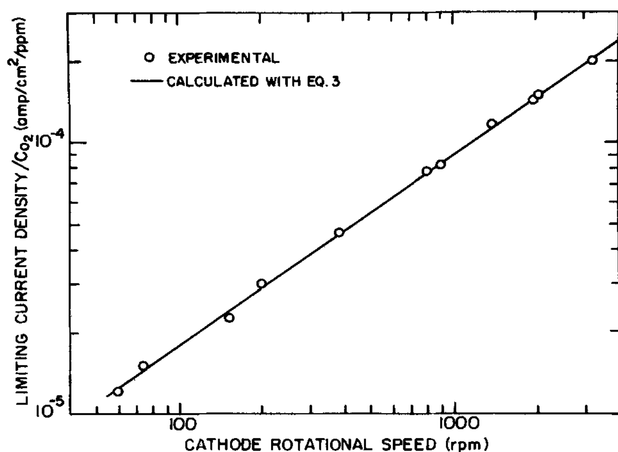

Fig. 6. Rotational speed vs. normalized limiting current density plot for Monel in 4% NaCl (air-saturated) aqueous solution at 20°C.

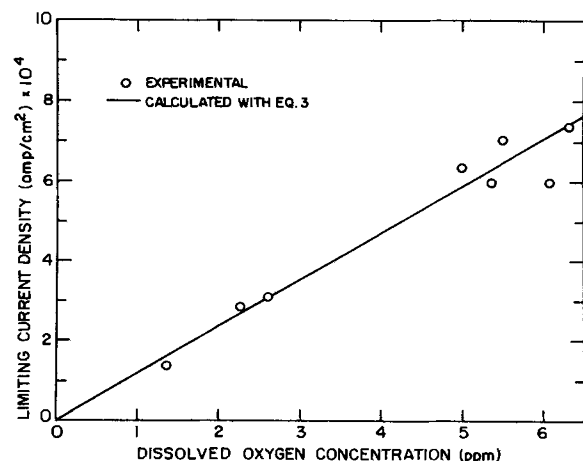

Fig. 7. Dissolved oxygen concentration vs. limiting current density plot for Monel in 4% NaCl (air-saturated) aqueous solution at 20°C and 1400 rpm.

Figure 3, a plot of a logarithmic relation between the normalized limiting current density and concentration of added surfactant, has three clearly distinct regions. Up to a surfactant concentration of $1 \times 10^{-5}M$ there seems to be no effect of surfactant on the limiting current density. Between 1×10^{-5} and $2 \times 10^{-4}M$ concentration there is a rapid decrease of MTLC with increasing surfactant concentration. Above $2 \times 10^{-4}M$ concentration, there is no further reduction of MTLC. Presumably, below $1 \times 10^{-5}M$ concentration, there is very little adsorbed film to offer any resistance to the electron transfer process and thus there is no decrease in MTLC. A concentration of $2 \times 10^{-4}M$ behaves as a "critical concentration," above which there is no further reduction of MTLC. This is explained in the latter part of this section.

In the intermediate range where the surfactant addition causes significant change in MTLC, an attempt has been made with the help of a regression analysis to delineate the effects of different important variables. Based on the results shown in Fig. 3 and 4, the following functional relationship was used for the analysis

$$Y = \alpha X_1 + \beta X_2 + \gamma X_3 + \delta X_1 X_2 + \theta X_2 X_3 \quad [5]$$

where

$Y = (i_L)_0 - (i_L)_{C_{surf}}$ = the reduction in MTLC value due to the addition of surfactant

$(i_L)_0$ = limiting current density in the absence of the surfactant

$(i_L)_{C_{surf}}$ = limiting current density in the presence of a given concentration of the surfactant

$X_1 = \log N$

$X_2 = \log C_{surf}$ (C_{surf} = surfactant concentration)

$X_3 = \log e^m$ (m = number of carbon atoms in each chain; $14 \geq m \geq 8$)

X_1X_2, X_2X_3, X_2X_1 are the first-order interaction terms

A test of the significance of the various terms in Eq. [5] showed that the rotational speed-surfactant interaction was not statistically significant at the 95% level. The reduced form of the regression equation written in terms of the "best fit" parameter values is as follows

$$(i_L)_{C_{surf}} = (i_L)_0 - 1.196 \times 10^{-14} N^{1.089} \cdot C_{surf}^{0.138m - 1.085} \cdot e^{1.784m} \quad [6]$$

The multiple correlation coefficient square was 0.9345, and t-values for α, β, γ, and θ were 10.3, 2.1, 4.1, and 3.2, respectively.

Although this is not a complete model and is limited to a small range, it is significant in the sense that it indicates the important variables which should be considered in case of any later development of a more complete model.

The pH effect on MTLC.—Thus far, the effect of rotational speed, oxygen concentration and alkylammonium acetate concentration and chain length on the MTLC of a Monel cathode has been discussed. However, another important variable such as the pH of the system should be considered here. As indicated

earlier, the pH of the bulk electrolyte continuously increases with the progress of the polarization experiment. A possible explanation for this is given in the following paragraphs.

The rotating cathode has a much thinner diffusion layer around it compared to that of the stationary anode. Although during the passage of the current, OH^- ions produced at the cathode and H^+ ions produced at the anode are of equal quantity, the local amount of OH^- ions per unit volume is much greater than that of H^+ ions because of a much smaller cathodic area compared to the anodic one. This higher concentration per unit volume combined with a thinner diffusion layer creates a higher driving force for OH^- ions than for H^+ ions diffusing into the bulk solution. Since the entire system is a nonequilibrium one, the bulk *p*H increases with time during the polarization experiment. When the polarization is stopped, the bulk *p*H tends to assume the original *p*H value, after sufficient time is allowed for equilibration.

The nonequilibrium *p*H at the cathode surface is conceivably higher than that of the bulk electrolyte at any instant during the polarization measurement. The appearance of a white precipitate film on the Monel electrode is most likely due to the precipitation of neutral amine molecules according to the reaction

$$RNH_3^+ + OH^- \rightarrow RNH_2 + H_2O; \quad pK = -3.4$$

which occurs when the nonequilibrium surface *p*H reaches a value high enough for hydrolysis to become significant. An estimation of solubility constants indicate this reaction is more likely to occur than any other precipitation reaction. Also, infrared spectra of the dried precipitate confirmed that the film material is the amine and not an aminium salt. The bulk *p*H never attains a high enough value for hydrolysis, so the bulk solution remains clear. The reason that the precipitate film disappears shortly after the polarization current is switched off is that there is no further OH^- ion production at the surface and the bulk and surface attain an equilibrium *p*H value.

The above explanation can be justified by supplementing it with the evidence obtained from experiments with addition of a suitable buffer to the system. Figure 5 shows the effect of buffering. The buffering action extends up to the electrode surface and hence there is no local high *p*H with neutral amine molecule precipitation on the cathode. Therefore, no decrease in the MTLC values is observed, even in the presence of high surfactant concentration. Tests with trimethyldodecyl ammonium chloride which does not hydrolyze or precipitate at high *p*H showed no effect on the MTLC.

These results clearly indicate that the effect of alkyl amine surfactants on the reduction of MTLC is mainly due to a precipitate film of neutral amine molecules on the metal surface. The film, which may be formed by direct interaction with the metal surface and by association of these neutral molecules by van der Waals's forces, acts as a "resistance barrier" in addition to the diffusion layer resistance and affects the electron transfer process at the interface. The observation that the metal surface becomes hydrophobic in the presence of the surfactant indicates strong adsorption of alkylammonium ions on the metal surface. However, this initial adsorption alone does not reduce the MTLC. It is the subsequent formation of the precipitate film which affects this mass transfer controlled process.

As seen in Fig. 3 and 4, for all rotational speeds and chain lengths considered, $2 \times 10^{-4}M$ alkylammonium acetate concentration appears to be a critical value above which there is no further increase in the film thickness and reduction of the MTLC. This may result from the films being sufficiently thick when a concentration of $2 \times 10^{-4}M$ is reached so that the O_2 reduction is reduced sufficiently and the *p*H is insufficient to cause any further hydrolysis. Except for the C_{10} chain length case, no experiment could be done above $5 \times 10^{-4}M$ concentration because the surfactant solubility was limited in such concentrated NaCl solution.

Summary

The current requirements for the cathodic protection of a metal-saline water interface in a turbulent-flow system can be considerably reduced by using alkyl amine surfactants. The formation of a film of neutral amine molecules at the metal surface where the local nonequilibrium *p*H is quite high, causes a barrier to the oxygen diffusing to the metal surface. The current requirement is found to be sensitive to the relative velocity of the metal-electrolyte interface, surfactant concentration and chain length, and *p*H of the system. Considering the complex nature of the system, no rigorous physical model can be given at this stage to account for the variation of the film resistance with different variables. However, this study can eventually be applied to the problem of corrosion control by the use of cathodic protection and corrosion inhibitors in a variety of conditions in the marine environment.

Passivation of Chromium-Containing Iron and Nickel-Base Alloys in Aqueous Solutions at 289°C

David A. Vermilyea* and Maurice E. Indig

Corporate Research and Development, General Electric Company, Schenectady, New York 12301

ABSTRACT

A system which allows electrochemical studies to be conducted in relatively uncontaminated aqueous solutions at 289°C, using a reference electrode which permits potentials to be referred to the standard hydrogen electrode scale, is described. Current-potential curves for Type 304 stainless steel, Inconel 600, and other iron and nickel-base alloys containing less than 14% Cr are presented. It is found that passivation in dilute H_2SO_4 is more difficult at 289°C than at 25°C because of the faster attack by the acid at the high temperature.

The advent of nuclear power has resulted in the use of some familiar materials in new environments and, as might be expected, a host of new corrosion problems have been encountered. In order to be able to understand corrosion processes in aqueous solutions at about 300°C it is necessary to have information about the electrochemical phenomena involved. During the last several years a few electrochemical studies under these conditions have been published (1-8). All of these previous studies have been difficult to interpret either because the electrical potential scale was not adequately defined or because the use of static autoclaves resulted in gradual contamination of the solutions with corrosion products.

In this paper we report studies conducted using an internal Ag/AgCl reference electrode, which permits potentials on the standard hydrogen electrode (SHE) scale to be determined. We have also used a refreshed autoclave system for part of our measurements to avoid contamination.

Experimental

The reference electrode used for studies in static autoclaves has already been described (9). That electrode is not suitable for a refreshed autoclave which is always completely full, and so the reference electrode shown in Fig. 1 was designed. The electrode itself is a silver wire onto one end of which a bead of AgCl is melted. The 0.035 in. diam wire passes through a standard high pressure electrical fitting (Conax Company) with a modified insulator. The insulator is made of Rulon for resistance to deformation at the operating temperature, has a hole drilled through it to permit passage of the silver wire, and is threaded at its outer end to accept a retaining nut in which a set screw clamps the silver wire. The retaining nut is required to prevent extrusion of the silver wire by the high internal pressure.

The electrode is insulated from the autoclave solution by means of a Teflon tube which is heat-shrunk onto the electrode. The Teflon tube also forms the salt bridge connecting the electrode to the autoclave solution, and contains an asbestos wick to assure a continuous electrical path. For assembly the Teflon tube containing the asbestos is shrunk onto the silver wire,

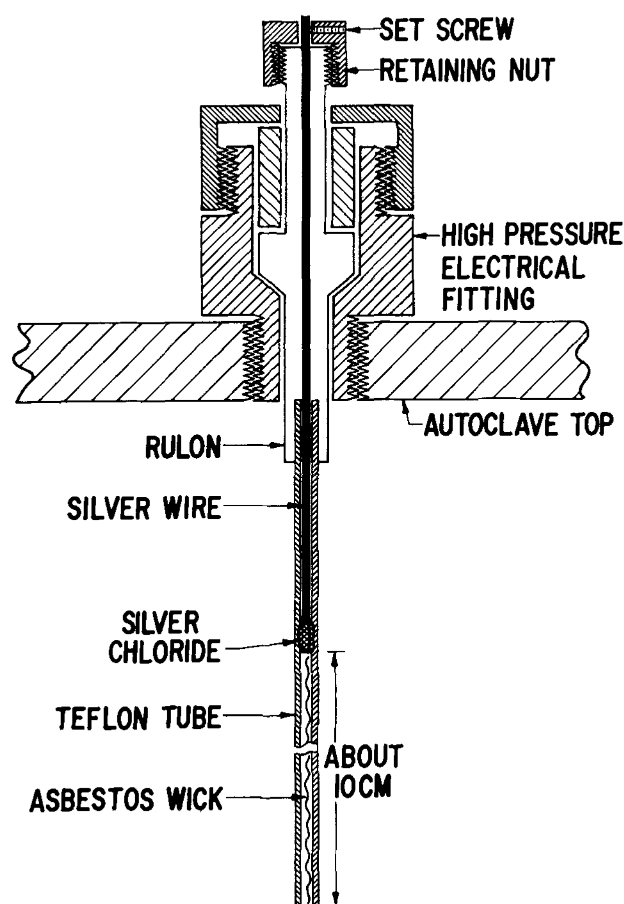

Fig. 1. Ag/AgCl reference electrode for use in refreshed autoclave system.

which is then inserted into the Rulon fitting so that the end of the Teflon tube is about ½ in. inside the Rulon. The salt bridge is filled with 10^{-2}M KCl after evacuation of the air. The salt bridge is long enough (10 cm) so that about 10 days would be required for diffusion to alter the KCl concentration in the vicinity of the

* Electrochemical Society Active Member.

Key words: corrosion, polarization, electrochemical studies.

Ag/AgCl electrode. Contamination of the autoclave solution by the outward diffusion of chloride ions is small because of the small volume of the salt bridge and because of the continual refreshment of the autoclave solution.

We have found that electrodes of this design perform well, provided a pressure of about 200 psi above the vapor pressure of water is maintained on the system. At lower pressures the electrode tends to open circuit, probably because of bubble formation in the salt bridge. We have also found that the potentials developed by this electrode are less reliable than the potential maintained by the electrode used in the static system, and have observed deviations as large as 0.1V from electrode to electrode. We do not know the reason for these variations. Finally, these electrodes are entirely unsuitable for use in solutions containing hydrogen gas, which readily diffuses through the Teflon and reduces the silver chloride.

Specimen electrodes were mostly 0.030 in. wires, and were introduced via Conax fittings in the manner described for the reference electrode. The wires were usually electropolished using standard techniques, and no effort was made to remove the electropolishing residue. We have found that the friction between the wire and the Rulon is very low at 289°C, and that the retaining nut is essential to prevent extrusion of the electrode. The electropolishing residue may have an initial inhibitive action but is probably soon removed or altered by the corrosion process. Such a residue does represent an uncertainty in our experimental data.

Figure 2 shows a schematic diagram of the refreshed autoclave system used in these studies. Ion exchange columns are used to purify the make-up water, which is taken from the laboratory distilled water system. After purification the resistivity of the water is about 5×10^6 ohm-cm. The desired solution composition with respect to acids, salts, and gases is produced in the holding tanks, from which the solution is pumped through a high pressure ion exchange column, to a regenerative heat exchanger and finally to the autoclave. After passing through the autoclave the solution is cooled, again ion exchanged to remove corrosion products in the effluent and depressurized prior to its return to the holding tank or discard. Pumping rates can be as high as 200 cc/min; we normally used 40 cc/min, giving a refreshment time of about 18 min for the 1 liter autoclaves. Autoclaves made from both 316 stainless steel and titanium alloy 6Al-4V were used.

We reported previously (9) that the open-circuit potentials of various electrodes such as stainless steel and Inconel 600 in solutions from pH 3 to pH 10 were close to that for a platinum electrode if the solution contained hydrogen or oxygen. We believe this behavior occurs because of the low corrosion rates of the electrodes and because hydrogen and oxygen react rapidly at 289°C; the electrodes behave as hydrogen or oxygen electrodes. In order to avoid such effects we used an argon atmosphere in all the tests to be reported here.

Potentiostatic polarization curves were obtained using standard equipment and techniques in the static and refreshed systems. The autoclave itself was grounded and used as the counterelectrode; and the potentiostat was connected to the a-c line through an isolation transformer. The resistances between the working electrodes and the autoclave were measured with an a-c bridge, and IR corrections (typically some tens of millivolts at 10^{-3} A/cm^2) were made to the potentials. Since the resistance at a small cylindrical electrode is largely confined to the region very close to the electrode the errors involved in this procedure were small at the moderate current densities used.

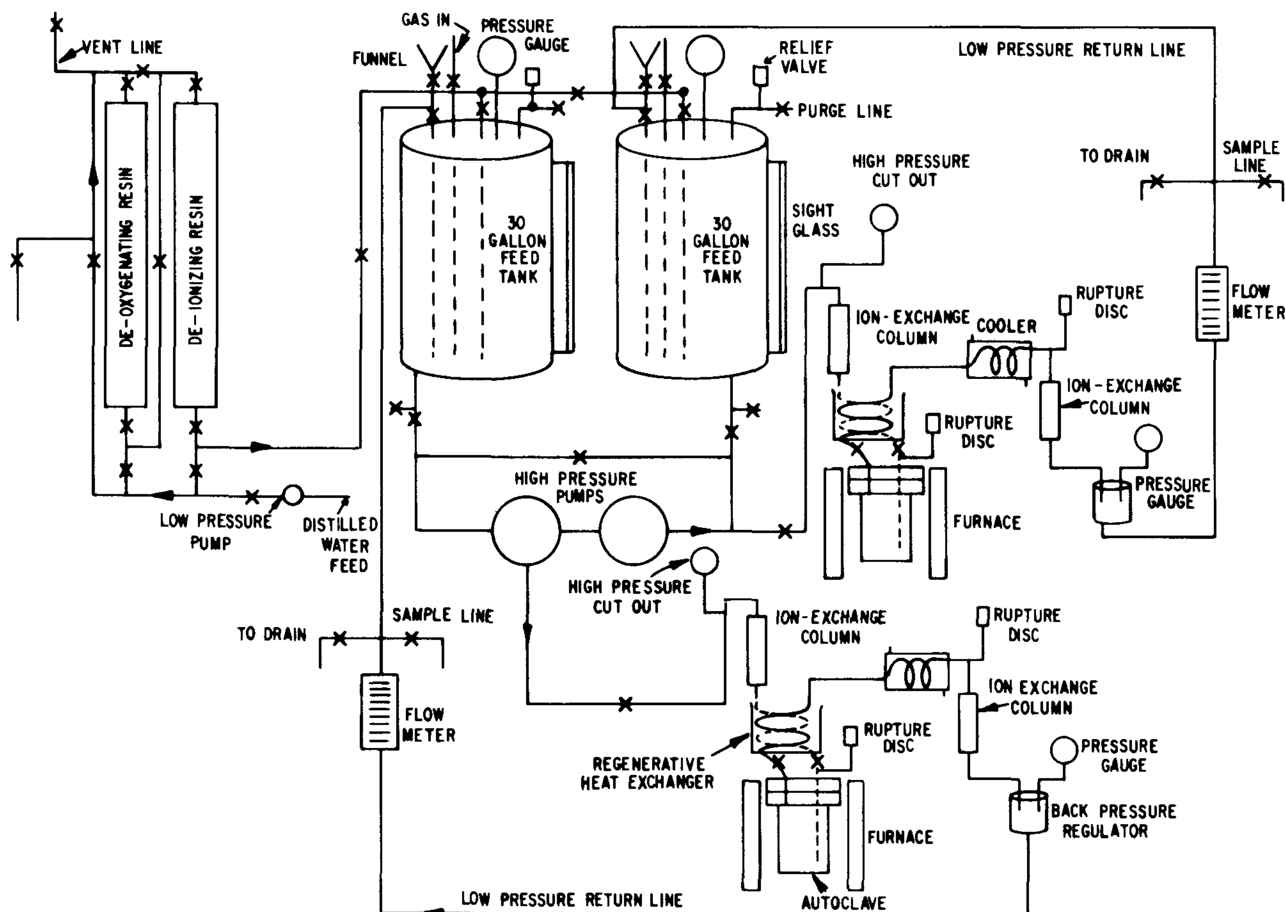

Fig. 2. The refreshed autoclave system

Results

Stainless steel.—A major problem with these passivation studies has been contamination of the solutions with iron dissolved from the specimens or system. The ferrous ions produced are readily oxidized to Fe_2O_3, forming red dendritic deposits and contributing to the observed current. In static autoclaves in solutions of *p*H 3 the iron concentration may easily rise to about 3 x 10^{-4} M/L, and contribute a current of 3 x 10^{-4} A/cm^2. Figure 3 compares typical polarization curves for Type 304 stainless steel in *p*H 3 H_2SO_4 solutions in the static and refreshed autoclaves. It can be seen immediately that the curves do not coincide as far as potentials are concerned, with the curve for the refreshed system about 0.15V more positive than that for the static system. This shift represents an uncertainty in the reference electrode potential which we have not been able to resolve. It may result from poor control of the chloride ion concentration in the reference electrode used in the refreshed autoclave or from differences in the hydrogen or oxygen contents of the electrolytes in the two systems. It is believed that the potentials measured with the electrode used in the static system are more reliable. On that assumption, the oxidation of Fe^{+2} starts at about -0.2V. Even in the refreshed system Fe^{+2} and other impurities are not entirely excluded, and their oxidation contributed about 15 x 10^{-6} A/cm^2 in the passive region. The iron content of the solution after test was 7 x 10^{-6} M/L, which could account for most of the observed current. In the static system iron oxidation almost entirely obscures the passive corrosion of the metal, and causes a current density of about 250 x 10^{-6} A/cm^2 at potentials more positive than $+0.2$V. Contamination with iron and possibly other materials has so far prevented the experimental determination of the true passive corrosion current in these acid solutions.

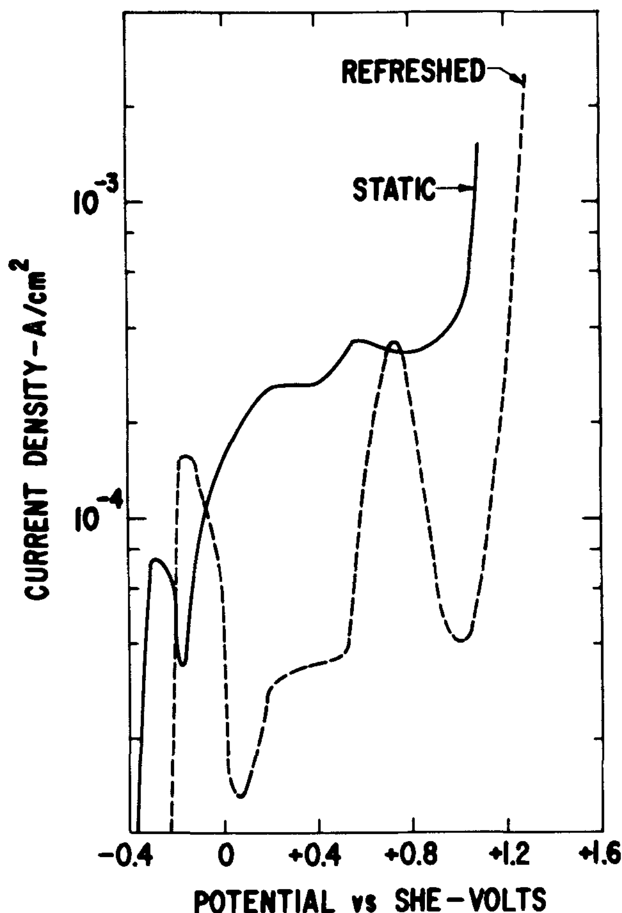

Fig. 3. Polarization curves for Type 304 stainless steel in *p*H 3 H_2SO_4 in static and refreshed autoclaves.

The general features of the passivation of stainless steel are readily visible in Fig. 3. At the open circuit potential stainless steel is "active;" upon polarization it becomes passive; at higher potentials the current increases presumably because of oxidation of Cr_2O_3 to chromate; secondary passivity then occurs; and finally oxygen evolution begins. Note that the current in the region of secondary passivity falls to about the same level as in the passive region, the curent being determined by oxidation of Fe^{+2} and not by corrosion of the metal, which proceeds at a much slower pace.

In the "active" condition the metal is not "clean" but is covered with a corrosion product which reaches interference color thickness after hour-long exposures at *p*H 3-4 and grows to a thickness of about a few microns after a day. We suspect that this film is porous.

When a specimen is polarized into the passive region in dilute acid solutions an extremely thin, light tan film is formed in a day; it is probably less than 500Å thick. In a typical set of experiments a specimen polarized 54 hr in the passive region in an electrolyte containing *p*H 4 H_2SO_4 lost 1.64 x 10^{-4} g/cm^2 while a freely corroding specimen lost 2.34 x 10^{-3} g/cm^2; passivation effected a great decrease in the corrosion rate.

The effect of *p*H on the polarization of stainless steel is shown in Fig. 4. As the *p*H increases the peak active current decreases, and at neutral (not shown) *p*H the material is observed to be passive at open circuit. Also as the *p*H increases the potential at which oxidation of Fe^{+2} starts decreases by *0.330 V/pH* unit, while the potential at which Cr_2O_3 oxidation begins decreases by 0.183 V/*p*H unit. In neutral solutions, in which not much Fe^{+2} is soluble, the current in the passive region is quite low and decreases steadily with time as the passive film grows. In an experiment during which the specimen was polarized into the transpassive region the current fell in one day to about 9 x 10^{-6} A/cm^2, and the specimen remained bright. In other experiments in neutral water currents of about 10^{-6} A/cm^2 have been observed after polarization in the passive region for an hour or so. Probably spurious electrochemical effects contributed importantly to these currents.

Stainless steels depleted of chromium.—Special alloys containing Fe-10Ni-xCr where $x \simeq$ 8, 10, 12.5, and 14% were vacuum arc melted and drawn to 0.030 in.

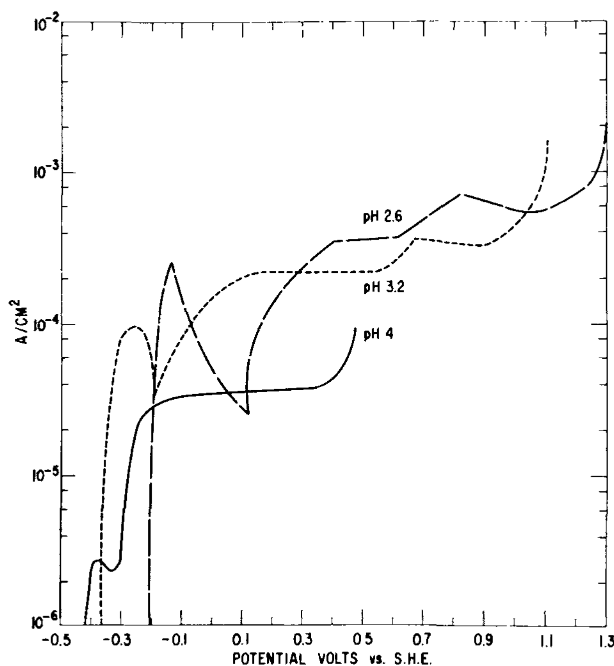

Fig. 4. The effect of *p*H on the polarization of Type 304 stainless steel in static autoclaves.

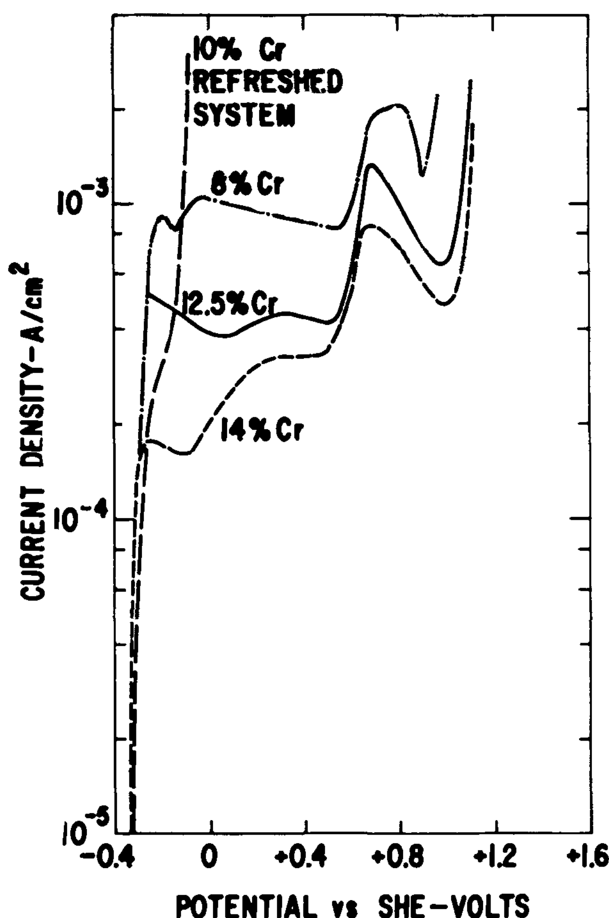

Fig. 5. Polarization curves for Fe-10Ni-xCr alloys in pH 3 H_2SO_4 in static (8%, 12.5%, and 14% Cr) and refreshed (10% Cr) autoclaves.

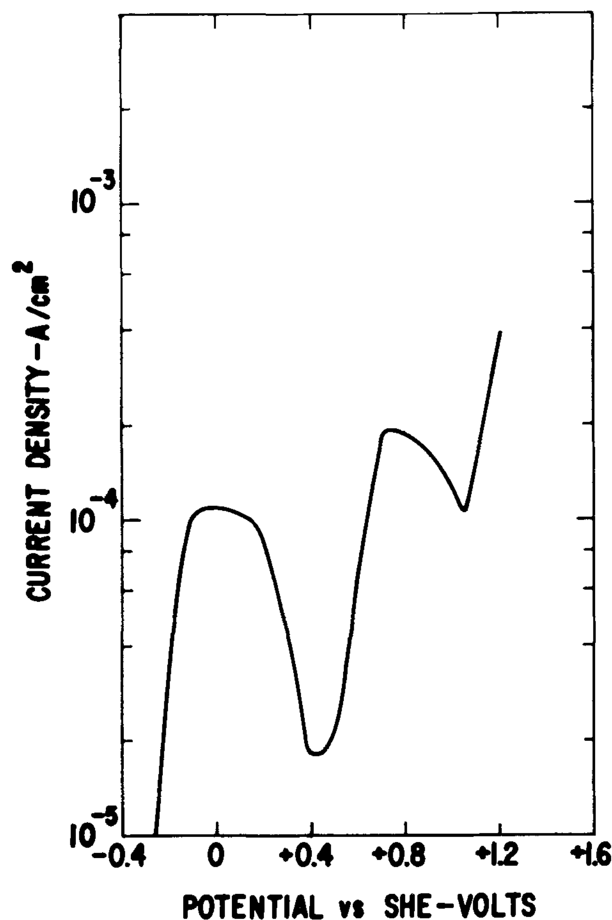

Fig. 6. Polarization curve for a Fe-10Ni-14Cr alloy in a refreshed autoclave.

wires. These wires were annealed in hydrogen to produce a reasonably good surface and to remove cold work. Figure 5 shows several typical curves taken from runs made at *p*H 3 in static and refreshed autoclaves while Fig. 6 shows data obtained at *p*H 4 in a refreshed autoclave. A comparison of data for the 14% Cr alloy in Fig. 5 and 6 again demonstrates the effect of contamination with Fe^{+2} in the static autoclave. The data for the 8, 12.5, and 14% Cr alloys show that as the chromium content is reduced passivation becomes more difficult; the passive current for the 8% alloy is of the order of 10^{-3} A/cm^2 compared to about 10^{-5} A/cm^2 or less for Type 304 stainless steel. Surface condition and/or cold work was very important with these alloys; rough surfaces and heavy cold work greatly inhibited passivation.

The fact that the 10% Cr alloy did not passivate in the refreshed autoclave is an indication of another problem with static autoclaves, namely, that the *p*H increases with time as the protons are reduced in corrosion reactions. The actual *p*H in the static autoclaves for the experiments shown in Fig. 5 was greater than 3, and passivation was easier.

Inconel 600 and related alloys.—With one important exception Inconel 600 behaves in a manner very similar to that of 304 stainless steel. At low *p*H it is active at open circuit; it passivates readily upon polarization; and the current increases rapidly at about the potential at which Cr_2O_3 oxidation occurs. As shown *in* Fig. 7, however, the Inconel does not exhibit secondary passivity but instead corrodes at increasing rates at increasing potentials. Evidently the removal of chromium from the surface of the alloy results in a material which is not readily passivated.

Alloys containing Ni-8Fe-xCr, where $x = 5$ and 10 behave like depleted stainless steels, as shown in Fig. 8. The 5% alloy could not be passivated, while the 10% alloy could be polarized to high potentials but corroded at a high rate. The peculiar irregularities in the current potential curves for the 10% alloy have not yet been interpreted.

Discussion

It is interesting to contrast the behavior of the iron and nickel base alloys at 289°C and at 25°C. The curves for 304 and Inconel 600 in dilute acids at 289°C are similar to those obtained using 1*N* H_2SO_4 at 25°C, except that Inconel 600 does not show secondary passivity at 289°C. Evidently the attack by H_2SO_4 on the passive film is greatly accelerated at the high temperature so that dilute solutions cause high active currents and prevent secondary passivity of Inconel 600. The aggressive behavior of dilute sulfuric acid at 289°C is also shown by the fact that it is not possible to passivate nickel (or iron, for that matter) in such solutions.

A further interesting contrast is the observation of thick films on "active" materials at 289°C and the apparent absence of such films at 25°C. It is commonly thought that active metals are film-free; these experiments show that such is not always the case.

Acknowledgment

We are indebted for helpful advice and discussions to Mr. W. Nelson of General Electric's Atomic Power Equipment Department and to Dr. R. L. Cowan of the General Electric Nucleonics Laboratory.

Manuscript submitted June 7, 1971; revised manuscript received Sept. 9, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

An Experimental Setup for Electroplating of Moving Wire

Aladar Tvarusko*

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

ABSTRACT

A small experimental electroplating line was built to study under controlled laboratory conditions the metal electrodeposition process on wire moving up to 35 m/sec (7000 fpm). This paper describes in detail the wire electroplating line, the process instrumentation, and the computer/electroplating line interface, and briefly, the on-line digital data acquisition system. The electrodeposition of various metals can be studied potentiostatically or galvanostatically in steady-state or transient mode or potentiodynamically. The efficacy of the setup is illustrated by results on copper electrodeposition.

The electrodeposition of various metals has been extensively studied on stationary or rotating electrodes but to much less extent on continuous substrates moving at high speeds.

The electrotinning of rapidly moving steel sheets is widely used for the production of tinplate and has been the subject of numerous investigations (1). The elec-

Fig. 1. View of the electroplating line

trodeposition of metals, especially magnetic alloys, on wire moving at slow speeds (up to 0.02 m/sec) has been studied because of its importance in the production of plated-wire memories (2). Electroplating of wire, especially electrotinning of copper wire moving at high speed (up to 20 m/sec) is done commercially on a large scale. The few publications (3-10) on the electroplating of high-speed wire deal with commercial production lines.

In view of the aforementioned, a small experimental electroplating line was built to study the metal electrodeposition process on moving wire under controlled laboratory conditions. This paper describes in detail the wire electroplating line, associated instrumentation, and briefly, the on-line digital data acquisition system. Results on copper electrodeposition are presented to illustrate the efficacy of this flexible setup.

Electroplating Line

In production, the wire continuously moves through a series of tanks without or with multipassing in the electroplating tank. This arrangement is not suitable

for laboratory investigation because of the need of large amounts of wire and heavy capstans. In the preferred loop arrangement, a kold-welded wire belt is

moved over two wheels, one of which is motor driven. The wire on the bottom level goes through the electroplating line.

The electroplating line, shown in Fig. 1-3, consists of electrocleaning, electroplating, rinsing, and air-wipe cells, wire transport and contact mechanism, solution transfer and storage, support frame with a jig plate, water, gas, and electricity supplies, and drain. The wire can be plated at speeds up to 35 m/sec (7000 fpm) or higher depending on the motor used.

The various parts of the plating line are firmly fastened by stainless steel screws to a 2.5 cm thick aluminum jig plate top. This top is firmly screwed to the supporting frame made of steel square tubing (5 $\times$ 5 cm) which is firmly attached to the concrete floor to prevent its vibration and movement. The plating line rests at a convenient height of 90 cm. The compressed air, water, and drain pipes, and the support for the wire supply reel are firmly attached to the top plate from beneath. The connections to the various cells are made through three long and narrow slits in the top plate. Pumps, filters, flowmeters, and solution containers are located under the plating line. Polypropylene tubing and fittings are used.

Figure 2 shows the flow diagram of the electroplating and electrocleaning solutions which have similar paths. Therefore, only one of them will be described. The solution is stored in a 20 liter Teflon coated glass reaction flask T1 resting in the aluminum heating mantle M1. The magnetic coupled seal-less pump P1 forces the solution through the polypropylene filter. The flow rate is adjusted by the 14-turn stainless steel needle valve V10 and indicated on the flowmeter FM1. These are mounted onto a stainless steel bracket which is firmly screwed to the floor (Fig. 1). The solution enters the bottom of the inner compartment of cell near the wire exit and leaves it over the wall at the wire entrance. The solution flows back from the outer compartments of the cell to the container T1 by gravity and is recirculated by the pump. The solution from the inner compartment of the cell is released by turning off the pump and opening the Teflon solenoid valve.

Figure 3 shows the flow diagram of the water and gas supply lines and the drain. These services are connected to the central service droplines behind the plating line through appropriate, quickly disconnectable filters and shut-off valves (not shown). The temperature of the rinse water is adjusted by the valves in the hot and cold water droplines. Cold and hot water is available at the plating line through valves V1 and V8. The various supplies are turned on by actuating the proper solenoid valves from a central panel.

The compressed air to the air-wipe cells is adjusted by valve V3 to the desired rate of flow. Part of the air is taken from the air chamber of the air-wipe cell to the nozzles located in the electrocleaning and electroplating cells (Fig. 4); the purpose of these nozzles is to blow off most of the adhering solution before the wire enters the rinse cell. Another path from the compressed air dropline goes through solenoid valve V5 to

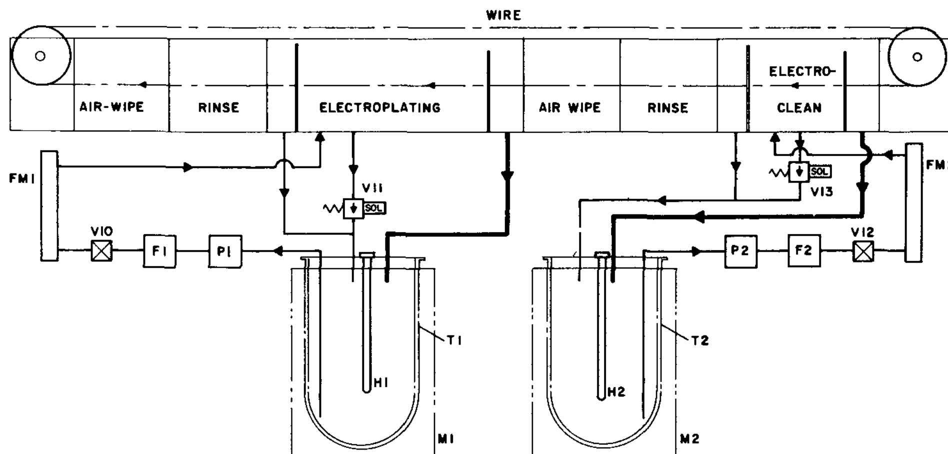

Fig. 2. Flow diagram of electroplating and electrocleaning solutions.

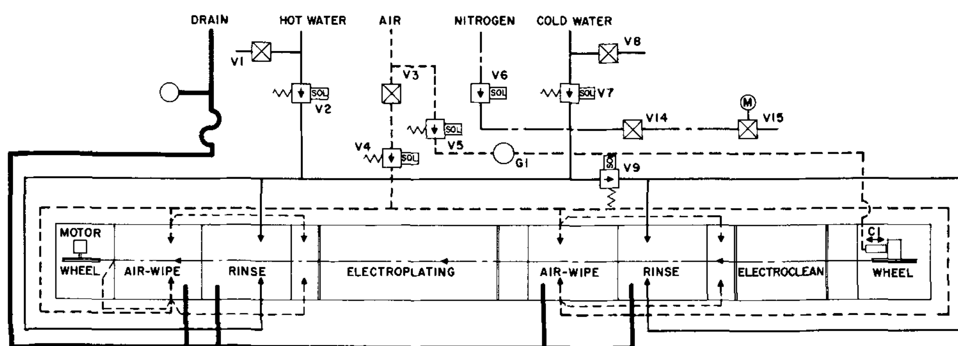

Fig. 3. Flow diagram of water and gas supply lines and drain.

the miniature air cylinder C1 and its rod is connected to the moving contact wheel assembly (Fig. 8). The pressure on the air cylinder is adjusted by regulator G1 to a desired value (0.3 to 1.7 atm) which assures a positive contact between the wire belt and the contact wheel. The tension on the wire, *i.e.*, the pressure on air cylinder should be kept to an optimized minimum to avoid the stretching of the wire. Compressed air is taken from the air chamber of the left air-wipe cell to its last special wire guide (Fig. 5D); this setup significantly decreases the water drag-out by the moving wire.

The nitrogen is used to provide a positive inert atmosphere in the electroplating cell and reaction flask T1 if needed (*e.g.*, in electroplating of tin).

The water from the Plexiglas rinse and air-wipe cells is discharged through PVC pipes into the central drain system without pretreatment.

The electrocleaning and electroplating cells are of similar construction but of various lengths as shown in Fig. 4. The polypropylene cells have three compartments: two outer and a central. The solution is contained in the central, plating compartment by the two inner walls one of which is higher at the wire exit to prevent its escape over this wall. The solution is pumped into the central compartment through the left hole; when the central compartment is filled up, the solution flows over the right, lower inner wall onto the wire even at very high wire speeds and returns to the solution container through the large outlet. The overflowing solution is advantageous because (*a*) the wire is thoroughly wetted by the electrolyte before entering the inner plating compartment, and (*b*) the suction of air bubbles is thus eliminated. The solution is released from the inner compartment through the other hole by opening the solenoid valve. The contoured sheet metal anode is in the central compartment and is contacted through the back wall (not shown).

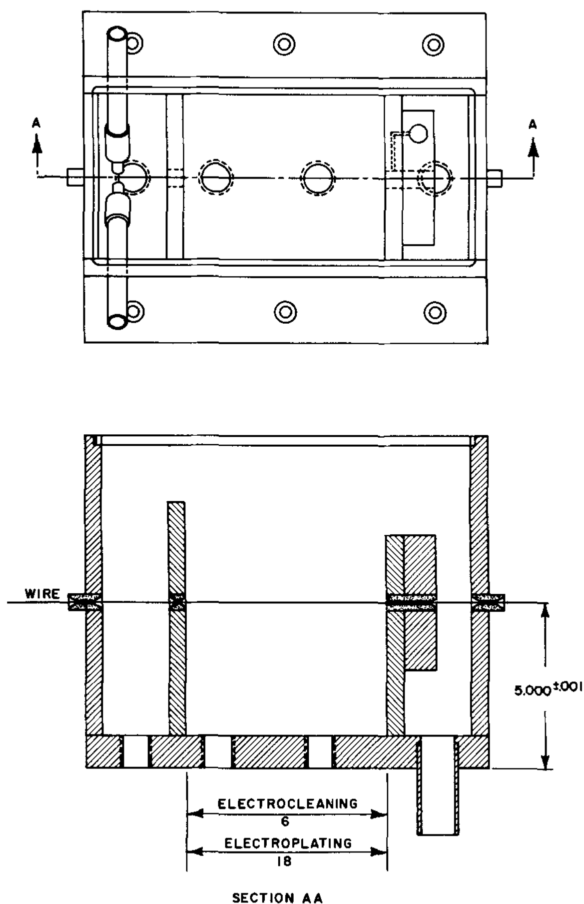

Fig. 4. Top view and cross section of electrocleaning and electroplating cells.

The press-fit Teflon wire guides in the walls (shown in Fig. 5): (*a*) guide the wire through the cells, (*b*) prevent excessive leakage of the solution owing to the small clearance around the wire, and (*c*) are easily replaceable to accommodate wires of various sizes. The ½ in. long Teflon wire guides are used in the inner walls. The 1 in. long guides (Fig. 5B), placed in the outer walls of the neighboring cells, help the alignment of the cells and prevent the dripping of the solution between two neighboring cells.

The electroplating cell has an attachment on the outside of the right inner wall (Fig. 4) for a reference electrode which is inserted through the two-piece Plexiglas cover (Fig. 1). The solution path from the wire to the reference cell is through small drill holes in a special, properly oriented Teflon wire guide (Fig. 5C), inner wall (subsequently plugged up), and the attachment to the inner wall. The overflowing solution and the solution dragged by the wire keeps this path filled. This solution path provides an isolated "capillary" to the wire allowing the measurement of the wire potential at the entrance. A similar arrangement can be added to the other inner wall and thus the potential could be measured at both ends of the wire.

The left outer compartment of both cells (Fig. 4) is equipped with two nozzles (Fig. 6) for high velocity gas which removes a large portion of the solution dragged out by the emerging wire. The solution droplets from this compartment flow back to the solution container through the bottom hole. The entire cell is covered by Plexiglas cover with lifting knobs to prevent the escape of liquid droplets into the air.

The nozzle can be rotated on the nozzle extension to an adequate degree and is tightened in this position by the nozzle clamp as shown in Fig. 6. This nozzle arrangement allows the fluid jet to strike the wire symmetrically. It is preferred to turn the nozzle into the moving wire and thus the fluid stream will hit the wire at less than a 90° angle.

The electroplating line contains two air-wipe and two water rinse cells made of Plexiglas which are similar except for some additional tappings in the air-wipe cells. Figure 7 shows a photo of the last air-wipe cell of the electroplating line. The fluid (air or water) enters

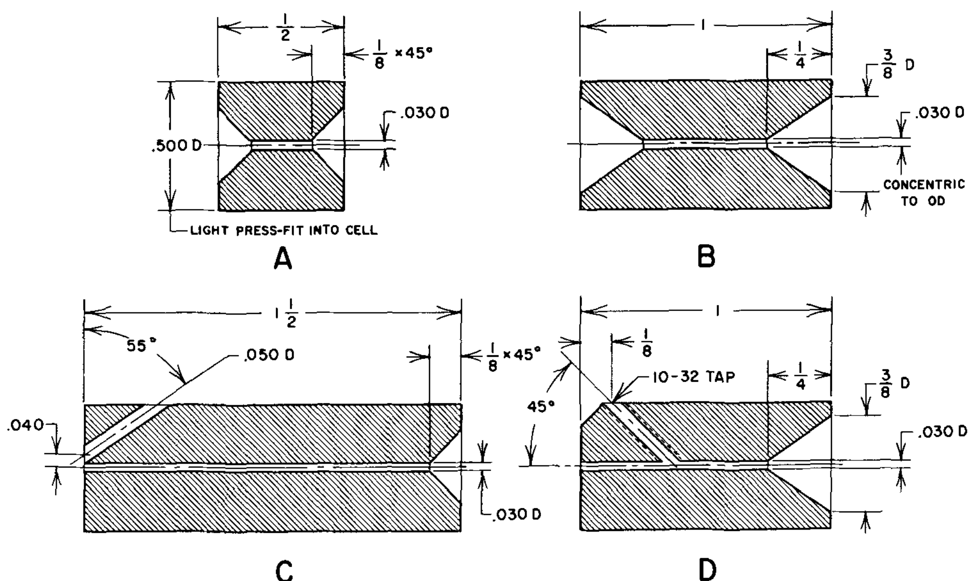

Fig. 5. Wire guides for 24 gauge wire used in inner cell walls (A), to connect outer walls of neighboring cells (B), for the reference electrode (C), and to decrease the water drag-out (D).

symmetrically on both sides of the cell through polypropylene fittings (½ in. NPT). The fluid leaving the chamber through the six nozzles impinges on the wire at six different locations from four different angles at high velocity and exits through the large tube glued into the bottom of the base plate. In order to prevent the escape of liquid droplets from these cells, they have slipfit covers.

Each air-wipe cell has additional polypropylene fittings (¼ in. NPT, only one is shown in Fig. 7) to provide air to the two nozzles located in both electrolysis cells. The last air-wipe cell's right chamber has an additional brass hose fitting leading to the special wire guide (Fig. 5D).

The wire from the spool is threaded through the various cells, and pulled over the driving and contact wheels. The most frequently used copper wire is cut to the required length and the two ends are joined without a foreign material (by a "KOLDWELD" unit, Type KBM3-162, Division of Kelsey-Hayes Company, Utica, New York, shown in Fig. 1 before the plating line). The wire belt is tightened over the two wheels by activating the miniature air cylinder C1 (Fig. 3) to a predetermined pressure. The wire was found to move smoothly in the V-grooves of both wheels at all the speeds investigated.

The driving wheel assembly is located on the left side of the cells (Fig. 1). The phenolic driving wheel (⅜ in. thick) is fastened by two flanges and a key to the shaft of a d-c motor and has six 2-in. diameter equally spaced holes to make it lighter. The motor is firmly screwed to the motor mounting. The vertical alignment of the wire is assured by the close tolerances in the motor mounting and the sideways alignment is made by moving and securing the phenolic wheel by the two flanges.

The sliding contact wheel and rotating contact unit is on the right side of the cells (Fig. 1) and is shown in detail in Fig. 8. The contact wheel assembly is electrically isolated from the metal frame by a thick phenolic base which is firmly screwed to the aluminum jig plate. The aluminum bracket provides a firm support for the sliding contact wheel and rotating contact unit.

The rotating mercury contact (ROTOCON, Model MSD-2, Meridian Laboratory, Inc., Madison, Wisconsin) provides a low resistance (~ 5 mohms) path from its stationary terminal post to the contact wheel for up to 20A continuous direct current; it can be rotated up to 4500 rpm. The stationary part of ROTOCON is electrically isolated from the stainless steel casing by a phenolic split spacer. The flange on ROTOCON's ro-

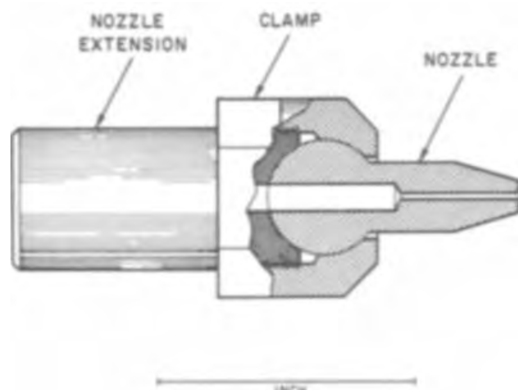

Fig. 6. Nozzle assembly used in rinsing and air-wiping of the wire.

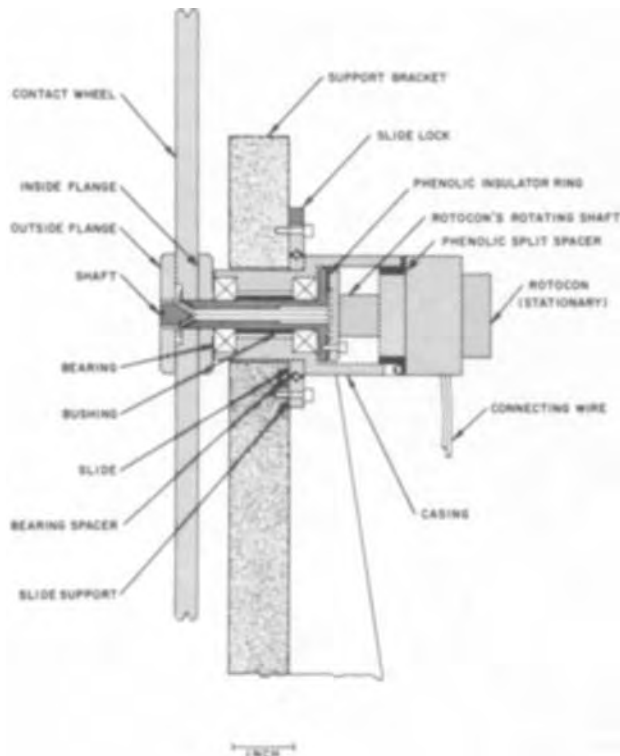

Fig. 8. Cross section of the sliding contact wheel and rotating contact unit.

tating shaft is electrically isolated by a phenolic insulator ring from the flange of the stainless steel shaft; these two flanges are firmly secured to each other by plastic screws. The shaft rotates in two bearings which are inserted into the casing and separated by a stainless steel bushing. The shaft is hollow to bring through the isolated contact wires from the rotating disks of the ROTOCON to the contact wheel. The inside flange and the contact wheel are press-fit onto the shaft and the aforementioned wires are soldered to the hard gold-plated contact wheel. The entire unit is tightened by the threaded outside flange.

The aforedescribed rotating contact unit is firmly housed in the casing which moves on the slide supports. Two V-grooved, hardened tool steel slides are firmly screwed to the top and bottom of the casing. This unit moves on ten stainless steel balls whose equal spacings are ensured by two bearing spacers. These balls are contained by the V-grooved, hardened tool steel slide supports which are firmly screwed to the support bracket. The upper slide support is secured by a slide lock. The rotating contact wheel assembly is pushed away from cells by the air cylinder secured to the casing and thus the wire belt is tightened over the two wheels.

Rotating wheel and wire moving at high speed are potential safety hazards. Therefore, the two wheels are housed under tiltable safety covers. The sides of the cover are 1 in. thick Plexiglas sheets and the top is 1/4 in. thick aluminum plate. The tubular Plexiglas wire guard forms a protective shield around the upper part of the wire belt between the two wheel covers and can be pushed back for easy access to the cells. The two halves of a Plexiglas tube are held together by three hinges on the rear side and can be opened by releasing push button fasteners in the front. These features can be seen in Fig. 1.

In order to eliminate the fumes and/or gases, an exhaust system with tiltable hood was added over the electroplating line and is connected to the ducts on the ceiling by a 10 in. diameter flexible hose (Fig. 10).

Instrumentation

The experimental wire electroplating setup is shown schematically for potentiostatic measurements in Fig. 9 and its view in Fig. 10. The wire is electrocleaned and electroplated on the plating line the process parameters of which are maintained constant by the various controllers. The electroplating of wire may be done potentiostatically or galvanostatically in steady-state or transient mode or potentiodynamically. The measured variable or variables are displayed on the various oscilloscopes and meters and collected by the digital data acquisition system through a suitable interface. The data are recorded on an IBM compatible magnetic tape which is hand-carried to an IBM 360/50 computer and the experimental data are stored on disks. The various experiments can be randomly retrieved from the disk and plotted on the plotter. The experimental data are reduced and correlated with the help of various computer programs.

Process controllers.—The various instruments are housed in standard electric racks and oscilloscope cart on both sides of the electroplating line (Fig. 10). The left rack next to the line contains the relay and solenoid panels for remote activation of the instruments and solenoid valves, motor speed control, heating man-

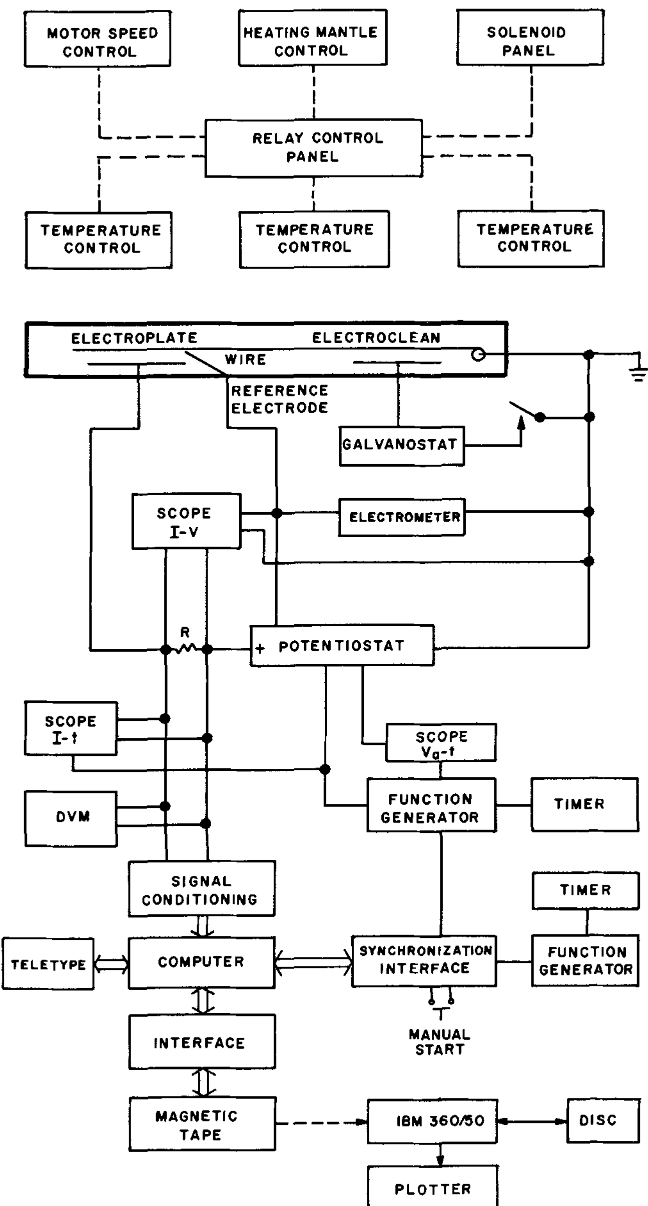

Fig. 9. Schematic of the experimental wire electroplating setup

Fig. 10. View of the experimental wire electroplating setup

tle control, three temperature controllers and temperature indicator for rinse water.

The solution temperatures are maintained at least within 0.2°C by temperature controllers of various ranges through the heating mantles, individual thermistor probes, and 500W immersion heaters.

The speed of the wire is maintained by controlling the speed of the ¼ hp d-c motor through its control unit and is adjusted by a ten-turn potentiometer which is paralleled by a diode for protection. A tachometer is mounted onto the shaft of the motor and its output is converted by a resistor network and displayed on a 4-digit digital voltmeter directly as motor speed in revolutions per minute or wire speed in feet per minute.

Instrumentation for electrochemical studies.—The wire, grounded at one place in the entire setup, is electrocleaned cathodically at constant current for a certain time by the galvanostat (Harrison Laboratories, a Division of Hewlett-Packard, Model 6438A). The lead between the stationary part of the ROTOCON contact and the negative pole of this power supply is opened by a relay after the electrocleaning. The anode is a stainless steel sheet and is connected inside the electrocleaning cell to a stainless steel terminal which is contacted by a tightly secured mechanical lug from the outside.

The potential of the wire in the electroplating solution is measured against the reference electrode (usually saturated calomel electrode) and continuously displayed on a battery-operated, solid-state electrometer with floating inputs (Keithley Instruments, Model 602).

There are two fast response potentiostats ($\sim$10 μsec rise time) (Tacussel, Lyon, France; J. P. Ryaby Associates, Passaic, New Jersey) available on the electroplating line. The first rack on the right of the electroplating line houses the 100A potentiostat (Type PRT20-100XZ), and the 10A potentiostat (Type PRT20-10XZ) is in the second rack. Both potentiostats are equipped with Zerostat and phase shift corrector plug-ins. The lead going to the working electrode receptacle of the potentiostat was interrupted by a relay to allow the correction of the signal's phase shift and set the pulse or sweep length and magnitude to the specified values in the absence of current flow [by a mercury-wetted relay (C. P. Clare & Company, Model HG2A-1007, 5A/pole) and a mercury power relay (C. P. Clare & Company, Model H-1) for the 10 and 100A potentiostat, respectively].

The current flowing through the electroplating cell is measured as a voltage drop on resistor R which is in series with the counterelectrode. The 10A potentiostat has two 0.1 ohm precision four-terminal wire wound current sensing resistors in parallel (5W, "Curristors," General Resistance Inc.) whereas the 100A potentiostat has three shunts mounted on a rear panel (Weston, 100A-100 mV, 50A-50 mV, 25A-50 mV). The voltage drop is fed to the various instruments through a BNC triaxial receptacle.

The potential of the working electrode can be maintained at a constant value for a certain period or varied linearly with the help of the function generator (Tacussel, Type GSTP2B). A single pulse or sweep is usually used and initiated by a manual trigger. There are two manual triggers in the setup. One is in the function generator and the other is connected to the synchronization interface. The manual start in the synchronization interface simultaneously triggers the function generator and associated instruments and the digital data acquisition system. The manual trigger in the function generator initiates the single pulse or sweep to the potentiostat and simultaneously triggers the various oscilloscopes and the timer.

The length of the pulse or sweep is measured by the timer with a microsecond resolution (Beckman Universal Eput® and Timer, Model 7360A). The input to this timer is taken from the synchronization output of the function generator.

The output of the function generator, (V_a − t) is displayed on the oscilloscope (Tektronix Readout, Type 567 with a digital unit, Type 6R1A, dual-trace amplifier plug-in, Type 3A2, and time base plug-in, Type 3B2). The magnitude of the superimposed signal is adjusted to the specified value and read on the digital unit of the readout scope. The shape of the signal taken from the function generator output is compared with the shape of the signal taken from the potentiostat output to the cell on the dual-trace plug-in. It is advantageous to make this visual comparison on repetitive signals. The signal taken from the reference electrode terminal is usually distorted and is corrected by adjusting the RC values of the potentiostat's phase-shift corrector plug-in until the two traces on the scope are closely similar.

The current-voltage curve (I-V) from the potential sweep measurement is displayed on a storage oscilloscope (Tektronix, Type 564 with two dual-trace differential amplifier plug-ins, Type 3A3). The current is displayed also as a function of time (I-t) on another storage oscilloscope (Tektronix, Type 564B with dual-trace differential amplifier plug-in, Type 3A3, and time base plug-in, Type 2B67). Polaroid oscillograms are taken with a trace recording camera and used for immediate qualitative evaluation of the experiment, filing, and comparison with the plots made subsequently by the plotter. The current is also displayed on an integrating digital voltmeter with a floating input (DVM, Weston Instruments, Model 1420). It is used to (*a*) establish the absence of current flow after the open-circuit potential of the cathode was compensated on the function generator, (*b*) display the current used for the frequent testing of the calibration of the signal conditioning amplifiers, and (*c*) display the current in digital form if it is changing slowly.

The experimental setup shown in Fig. 9 for a potentiostatic mode of operation, can be easily and speedily converted for galvanostatic or constant voltage measurements.

Digital Data Acquisition System

The voltage drop on the current measuring resistor R and other variables are available as analog signals. The tedious extraction of numerical data from the analog results for quantitative correlations can be eliminated if the data are collected in digital form in parallel to the analog display of the data.

In view of the aforementioned, a digital data acquisition system (Fig. 9 and 10) was added to the electroplating line which will be described separately in detail. Briefly, the analog signals are conditioned in the signal conditioning unit. The sampling rate of data acquisition, displayed on the timer (Itron, Model 651),

is variable from 36.7 μsec up depending on the computer program, function generator setting (Wavetek, Model 111), and number of channels (up to 5 with the presently available software). The synchronization interface contains a manual start which simultaneously initiates the experiment and the acquisition of data at a predetermined rate after the experimental conditions were entered via Teletype terminal. The maximum 2040 data points are stored in the memory of the computer (Digital Equipment Corporation, DEC, LINC-8) and automatically transferred at the end of the experiment to an IBM compatible 7-track magnetic tape through the magnetic tape interface. An incremental tape recorder (Precision Instrument, Palo Alto, California, Model PI-1167) is used to prepare digital magnetic tapes from low-speed pre-digitized data (coming from LINC-8) in IBM format.

The IBM compatible magnetic tape is carried by hand to an IBM 360/50 computer and the experimental data are transferred to a disk (IBM-2316 disk pack). The various experiments on the disk are randomly accessible and a software has been developed to manipulate, retrieve, and correlate the data and certain, specifically chosen points of the various experiments. The experimental data point and their correlations are plotted by a Cal-Comp plotter.

Signal conditioning.—The magnitudes of the analog signal inputs to the computer are not uniform. The input to the computer, on the other hand, must be ±1.00V or less and one side of the input is near ground potential. In order to provide the optimum 1.00V input to the computer and to avoid ground loops in the entire experimental setup, an interface was built for maximum 10 channels. Its schematic diagram is shown in Fig. 11 for only two channels in view of their similarities.

The signal is fed to the differential input of a d-c operational amplifier which has a single-ended output with a slewing rate of 5 V/μsec. These are commercially available amplifier boards (DEC, Type A201) which are plugged into DEC module sockets. These sockets with the d-c power supply (PS1, DEC, Type 2R1520-.400) are secured to a front panel which houses the fuses, lights, activating switch, and triaxial input signal receptacles. The front panel swings out from the rear of the module sockets so that their wire wrap connectors can be easily reached. The a-c power to this interface is taken from the computer to avoid unnecessary complications.

The feed-back resistors are chosen depending on the magnitude of the input signal. The output of the operational amplifier is fed to a 500 ohm, 15-turn trimpot which is grounded at one end through the computer. This trimpot is adjusted so that the output is 1.00V for the maximum input. The amplifier input is protected by diodes.

Results

Some experimental data will be presented here to illustrate the efficacy of the aforedescribed setup. The experimental results will be discussed in subsequent papers in more detail.

The current-voltage curves are frequently used for the investigation of electrochemical processes and can be obtained in steady-state or transient conditions. Figure 12 shows potentiodynamic *I-V* curves for the electrodeposition of copper from a flowing 0.024M $CuSO_4$-0.24M H_2SO_4 solution onto copper wire (0.5 mm diameter, 24 gauge) at rest and moving at various speeds. It can be seen that the limiting current density, I_L, plateau is present at this slow sweep rate (0.1 V/sec) and I_L increases with increasing wire speed. The *I-V* curves shift toward higher potentials due to the lack of *IR* compensation.

Figure 13 shows the effect of sweep rate on the *I-V* curves for nonmoving copper wire (conditions similar to Fig. 12). The magnitude of *I* increases with increas-

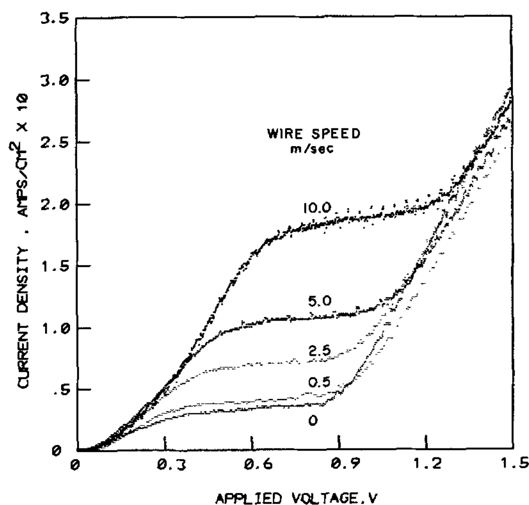

Fig. 12. Potentiodynamic *I-V* curves at various wire speeds and 0.1 V/sec sweep rate for the electrodeposition of copper from 0.024M $CuSO_4$-0.24M H_2SO_4 solution on a 0.5 mm diameter copper wire.

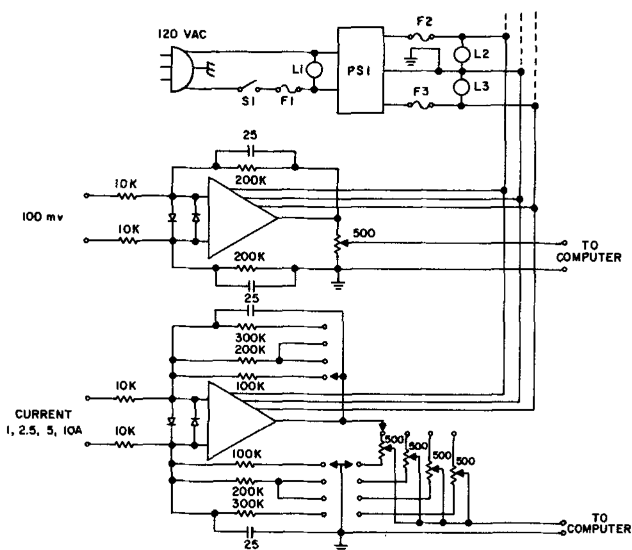

Fig. 11. Schematic diagram of the signal conditioning unit

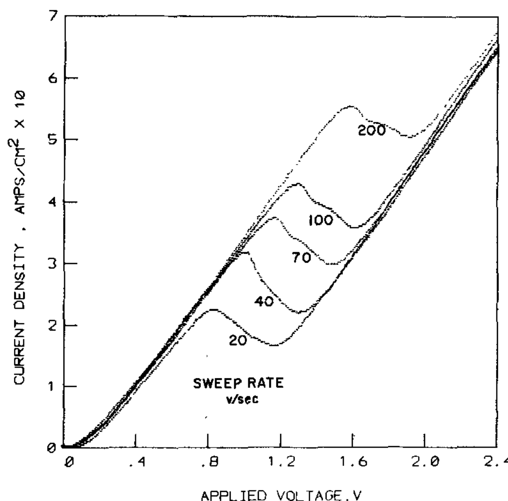

Fig. 13. Potentiodynamic *I-V* curves at various sweep rates for the electrodeposition of copper from 0.024M $CuSO_4$-0.24M H_2SO_4 solution on a 0.5 mm diameter copper wire at rest.

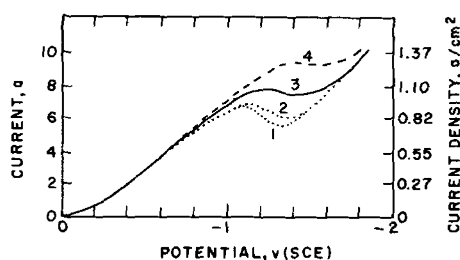

Fig. 14. Potentiodynamic I-V curves at various wire speeds, U and 50 V/sec sweep rate for the electrodeposition of copper from 0.24M $CuSO_4$-2.36M H_2SO_4 flowing solution on a 0.5 mm diameter copper wire. Curve 1, $U = 3.30$ m/sec; curve 2, $U = 6.90$ m/sec; curve 3, $U = 10.52$ m/sec; curve 4, $U = 14.17$ m/sec.

ing sweep rate, as expected. The I_L plateau is absent at these sweep rates and I goes through a maximum and minimum before the start of H_2 evolution. It is to be noted that the sweep rate greatly influences the behavior of I between the maximum and minimum and a plateau appears at high sweep rates.

The instrumentation of this experimental setup provides parallel analog and digital data acquisition systems. Figures 12 and 13 are samples of the latter system and were plotted by the computer plotter. The data were not subjected to any smoothing. The analog signals are recorded as oscillograms on Polaroid films (Fig. 14 and 15). Thus, the experiment can be immediately evaluated and the data, obtained by the two acquisition systems, can be compared.

The wire speed significantly affects the I_L in the potentiodynamic I-V curves at low sweep rates (Fig. 12). At medium sweep rates, the magnitude of I increases also and the minimum in the I-V curves disappears gradually with increasing wire speed, as shown in Fig. 14 for a more concentrated solution (0.24M $CuSO_4$-2.36M H_2SO_4).

Figure 15 shows the time dependence of I during a short potentiostatic pulse at various wire speeds in the aforementioned solution. The individual I-t curves are displaced by 2A (0.275 A/cm²) for clarity. The I-t curves were obtained in flowing solution except as noted. The fluid flow slightly increases the magnitude of I which decreases considerably with time in both cases; this decrease is especially large at longer times. The decrease of I with time becomes smaller with increasing wire speed and I remains nearly constant at the highest wire speeds.

As mentioned earlier, these results are described here to show the usefulness of this flexible wire electroplating setup. The interpretation and correlation of these and other results will be presented in future papers.

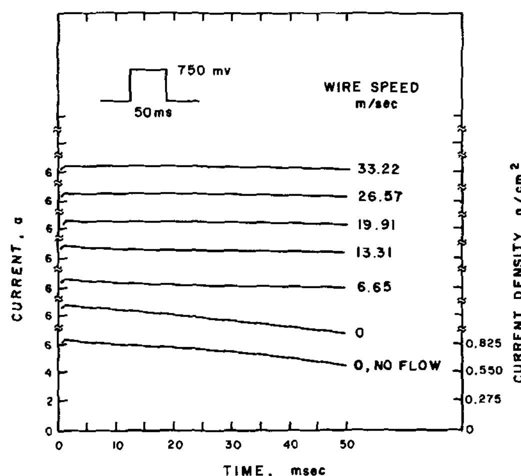

Fig. 15. Time dependence of current density at various wire speeds during potentiostatic pulses of 750 mV for the electrodeposition of copper from 0.24M $CuSO_4$-2.36M H_2SO_4 flowing solution on a 0.5 mm diameter copper wire. The curves are displaced by 2A in the y direction for clarity.

Electrothinning and Electrodeposition of Metals in Magnetic Fields

J. Dash and W. W. King

Physics Department, Portland State University, Portland, Oregon 97207

ABSTRACT

Experiments have shown that metals can be electrothinned and electrodeposited more uniformly if the electrolysis is performed in a magnetic field. In addition, the resistance of electrolytic cells is reduced in a magnetic field. These effects have been characterized for various orientations and strengths of the electric and magnetic fields.

In an earlier, preliminary report, some results were presented to show that the application of magnetic fields during electrolysis increases the uniformity of anodic dissolution of metals (1). These studies have been continued in order to investigate both anode and cathode processes for additional orientations and strengths of the electric fields (E) and magnetic fields (B) and other types of electrodes and electrolytes.

Experimental Methods and Results

Figure 1 shows a diagram of the circuit used for electrolysis. The constant current device was used to compensate automatically for changes in resistance of the electrolytic cell. In this way it was possible to maintain constant current during electrolysis and thus to follow the changes in cell resistance by means of the voltage-time recorder. The cell with the electrode arrangement used for the initial electrothinning experiments is shown in Fig. 2. Later experiments were performed with a plate disk cathode, shown in Fig. 3, which also shows the schematic positioning of the electrolytic cell between the polepieces of the 4 in. electromagnet, used for all experiments. Still other experiments were performed with a 19 mm ID cylindrical cathode surrounding the sample (anode).

Key words: electrothinning, electrodeposition, magnetic fields.

Experiments with the cell of Fig. 2 on Al-3.4 atomic per cent (a/o) Zn were performed at various applied magnetic field strengths in order to determine the minimum B required to produce relatively large electron-transparent films. As previously described (1), the 0.1 mm thick samples used for these experiments were in the solution-treated and air-cooled condition. The electrolyte consisted of 33 volume per cent (v/o) conc HNO_3 and 67 v/o methyl alcohol. This was cooled to $-13°C$ prior to each experiment. Current was maintained at 0.075A during every experiment. Thus, the initial current density was approximately the same for all experiments (about 0.25 A/cm^2). No insulating lacquer was used for edge protection during electrolysis. After electrothining, profiles were obtained by mounting the samples on clear glass in the object plane of a photographic enlarger and recording the patterns of transmitted light on printing paper.

The results obtained with B of increasing strength applied normal to the plane of the sample are shown in Fig. 4. Without an applied B, thinning is concentrated at the air-electrolyte interface, and perforation first occurs here. Application of B during the process lowers the air-electrolyte interface and causes the

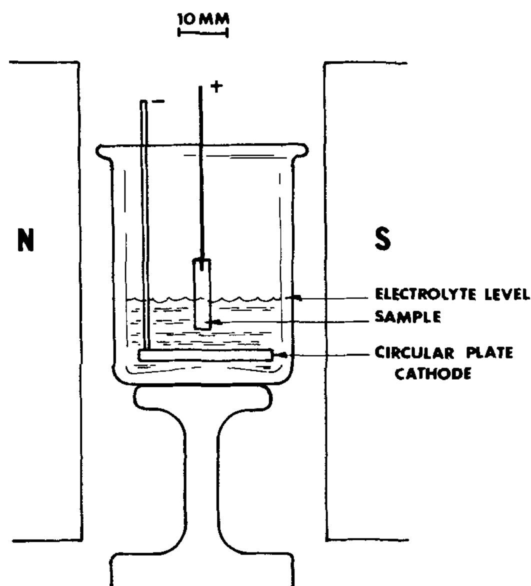

Fig. 3. Schematic arrangement of the electrolytic cell between the polepieces of an electromagnet. The plate-disk cathode, used for some of the experiments, is shown here.

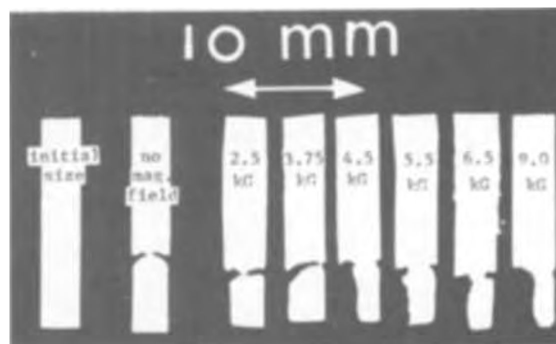

Fig. 4. Profiles of Al-3.4 a/o Zn samples thinned with *B* applied perpendicular to the sample plane in the cell of Fig. 2.

process to occur more uniformly over the entire submerged portion of the sample. With $B = 4.5$ kG, preferential thinning at top of the electrolyte is no longer a limiting factor, and it is possible to continue electrolysis until the sample is fairly uniformly transparent to electrons over the entire remaining area. Electron micrographs taken from a sample thinned with B of 9 kG normal to the sample plane are shown in Fig. 5.

In Fig. 4 it is also apparent that the left edge of each sample thinned in the presence of an applied B has been preferentially dissolved. The stirring pattern established in the electrolyte by this particular orientation of B probably causes enhanced mobility and therefore an increased rate of reaction at this edge.

By periodic reversal of B during the process, it is possible to alternate the preferential attack from the left to the right edge and thus to improve the over-all uniformity of thinning.

With B applied parallel to the sample plane in the horizontal direction (electrode arrangement of Fig. 2), the stirring pattern is altered such that thinning occurs most rapidly at the bottom of the sample (Fig. 6). Again, $B = 4.5$ kG is required to prevent the sample from breaking off prematurely at the air-electrolyte interface. Periodic reversal of B in this orientation is not as effective in increasing the uniformity of thinning as for the case of B normal to the sample plane.

The other electrode arrangements mentioned above helped to establish that it is the orientation of B with respect to the sample that primarily controls the final profile. The results in Fig. 7 and 8, obtained respectively with the cylindrical cathode and with the plate cathode, show that in both cases the profiles obtained with B normal to the sample plane are similar to those obtained for this case with the wire cathodes. This is also true for B parallel to the plane of the sample.

Of all the arrangements described above, perhaps the most practical for uniform thinning with minimum B strength is that shown in Fig. 3. It can be seen in Fig. 8 that B of 3 kG parallel to the sample plane was sufficient to prevent premature break-off at the air-electrolyte interface, whereas approximately 50% higher values of B were required to prevent break-off at this interface in all other arrangements.

Thinning in other metal-electrolyte systems with applied B has not yet been investigated extensively, but the studies which have been conducted indicate that the observations reported above are general. For example, some results of thinning pure, polycrystalline Cu in an electrolyte consisting of water saturated with $CuSO_4$ are shown in Fig. 9. The cell of Fig. 2 was used for these experiments, and the electrolyte temperature at the start of each experiment was 24°C. Constant current of 0.08A was maintained, and the initial current density was about 0.26 A/cm^2. Although electrolytic polishing does not occur under these conditions, the profiles obtained without applied B and with B parallel to the sample plane (Fig. 9) are very similar to those obtained for the Al-Zn alloy under polishing conditions (Fig. 6). An obvious difference is the large number of tiny holes within the thinned regions of the

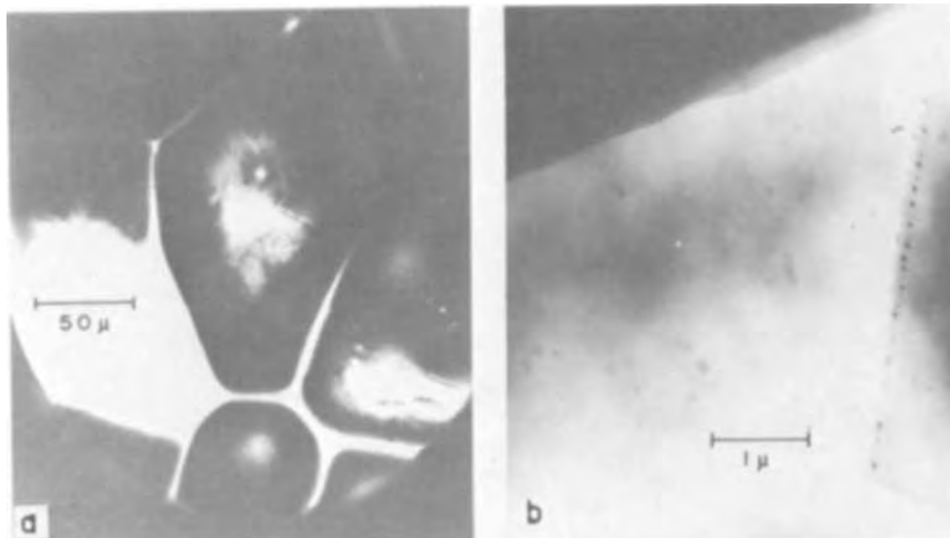

Fig. 5. Electron transmission photographs (50 kV) taken from Al-3.4 a/o Zn sample thinned with $B = 9$ kG normal to the plane of the sample. (a) Low magnification photograph to illustrate qualitatively the manner in which individual crystals dissolve during electrolysis in applied *B*. Though thinning occurs preferentially at grain boundaries and the edges of the grains are rounded, the centers of grains, where chemical composition is more uniform, thin much more uniformly. (b) High magnification photograph to show that relatively large areas are transparent to electrons of moderate energy.

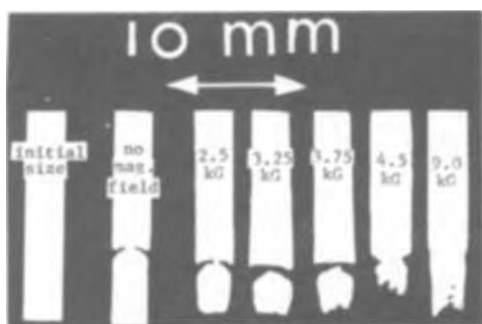

Fig. 6. Profiles of Al-3.4 a/o Zn samples thinned with B applied parallel to the sample plane in the cell of Fig. 2.

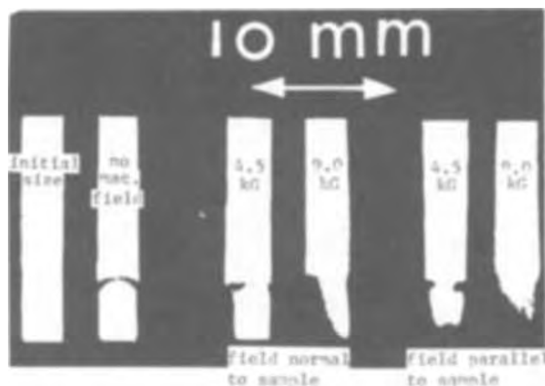

Fig. 7. Profiles obtained with cylindrical stainless steel cathode concentric with the samples (Al-3.4 a/o Zn).

samples to which B was applied. These perforations were caused by preferential dissolution at grain boundaries. It should also be noted that the B strength required to prevent break-off at the air-electrolyte interface is much less in this case than for electrothinning of Al-Zn with the HNO_3-methyl alcohol electrolyte (Fig. 6). This suggests that a given B strength produces a greater degree of stirring in the $CuSO_4$ electrolyte than in the HNO_3 electrolyte. The main reason for this may be due to the greater degree of ionization of the $CuSO_4$ electrolyte and the resulting greater degree of interaction with the applied B.

Stirring effects observed at the cathodes of the cell during the electrothinning experiments with applied B suggested that there might be significant changes in the characteristics of electrodeposits, compared with deposits produced without applied B. This was investigated for the deposition of Cu from $CuSO_4$-saturated H_2O solution with the cell shown in Fig. 10. The substrates used for deposition were double, 3 mm diam Cu grids used to "sandwich" thin specimens for electron microscope examination. These were spot-welded onto Pt wire leads and bent so that the plane of the lower grid was at 90° to the plane of the grid welded to the lead wire. In the electrolytic cell the lower grid was horizontal, as shown in Fig. 10. Profiles of a grid prior to electroplating are shown in Fig. 11(a1) and 11(b). The Cu anode strips were the same size as for the electrothinning experiments (Fig. 9).

Electrodeposition without applied B yielded the profile shown in Fig. 11(a2) [and at higher magnification in Fig. 11(c)] for the horizontal grid. Note that the originally square openings have become distorted to pin-cushion shapes. The corresponding photographs of a horizontal grid plated with the same cell current for the same time, but with B applied normal to the plane of the anode, are shown in Fig. 11(a3) and 11(d). In this case the shapes of the openings remain practically unchanged from the original.

Scanning electron microscope photographs of portions of the grids in Fig. 11(a1) and 11(a2) were taken to show the three-dimensional differences in morphology of the electrodeposits without and with applied B. These are shown in Fig. 12 and 13, respectively. The much greater degree of distortion of the original grid bar shapes resulting from deposition without applied B can be appreciated by comparing Fig. 12a with Fig. 13a. The enhanced uniformity of the electrodeposit with applied B is apparent from the comparison of Fig. 12b and 13b.

In addition to the morphology differences for both electrothinning and electrodeposition which result from the application of B during electrolysis, the electrical resistance of the cell is almost always less with applied

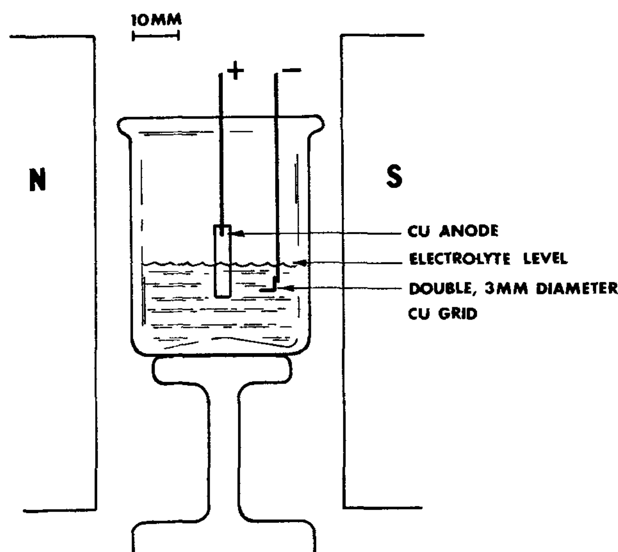

Fig. 10. Electrode arrangement used for deposition of Cu from $CuSO_4$-H_2O electrolyte. The horizontal portion of the cathode was examined after deposition.

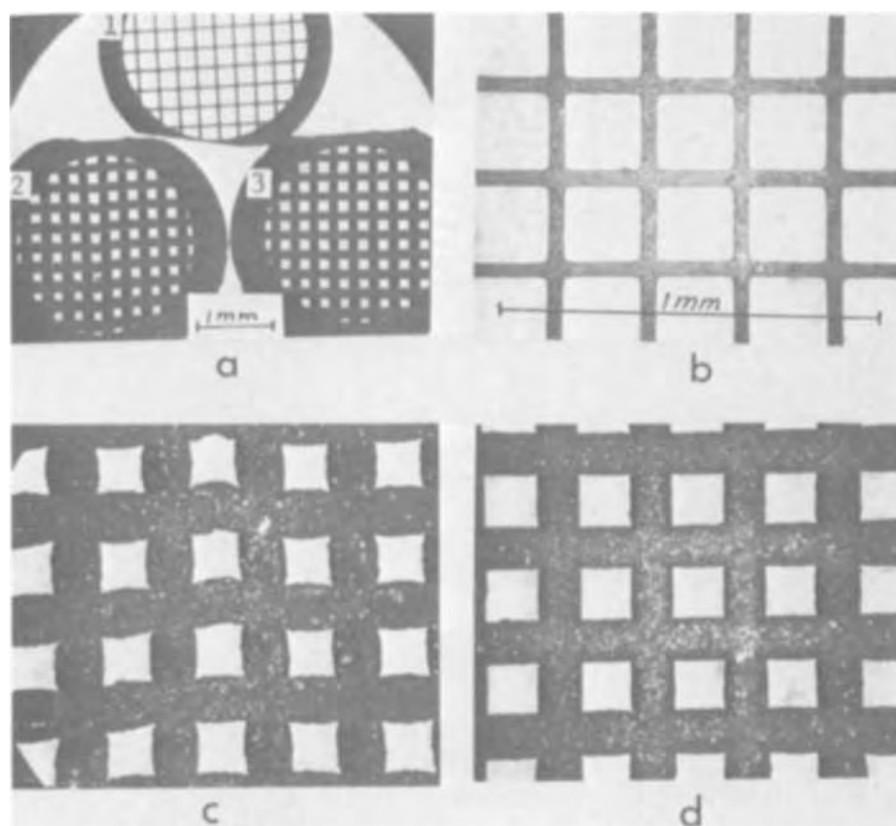

Fig. 11. Profiles of Cu grids electroplated with Cu from $CuSO_4$-H_2O electrolyte: (a1, b) before electroplating; (a2, c) plated without applied B; (a3, d) plated with B = 7.4 kG parallel to plane of the grid. The same deposition current (0.08A) and time (9.4 min) were used for (a2) and (a3).

B. For electrothinning of Al-Zn with the HNO_3 electrolyte, the cell resistance was lowered by about 20% with applied B of 9 kG. The original data for cell voltage at constant current for the electrodeposits of Fig. 11a2 and 11a3 are reproduced in Fig. 14a and 14b, respectively. These data show that the average cell resistance without applied B is at least 20% higher than when B is applied during the process. Furthermore, after about the first minute, deposition proceeds at almost constant cell resistance in the presence of applied B, whereas large fluctuations occur throughout the process without applied B. It is believed that most of this difference is due to changes in the anode processes, but no quantitative information is yet available.

The morphology of the Cu deposit is also dependent on the orientation of B with respect to the plane of the cathode. This is shown by the results of deposition on double, 3 mm diam Cu electron microscope grids with hexagonal openings (Fig. 15). In this case the grids were suspended vertically in the electrolyte, parallel to the plane of the anode. The electrolyte and deposition conditions for these experiments are commonly used in standard plating practice (2). The results in Fig. 15 show that the deposit tends to build up parallel to the direction of B. The extent of closing of the holes is greatest for B parallel to the plane of the grid (Fig. 15d) and least for B normal to the plane of the grid (Fig. 15c). Even in these low magnification photographs, the deposits made with applied B (15c and d) appear more uniform than that made without B (15b). Microhardness tests, taken on comparable portions of the solid border of each grid, appear to confirm this.

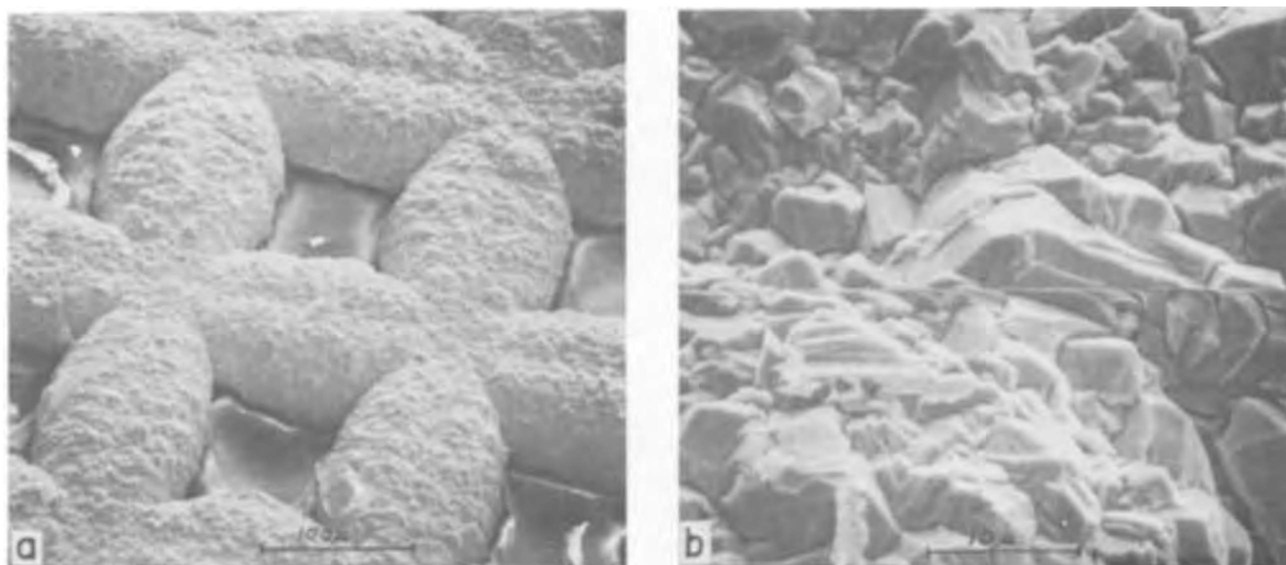

Fig. 12. Scanning electron micrographs of portions of the grid electroplated without applied B, shown in Fig. 11(a2): (a) low magnification; (b) a portion of a grid bar at high magnification.

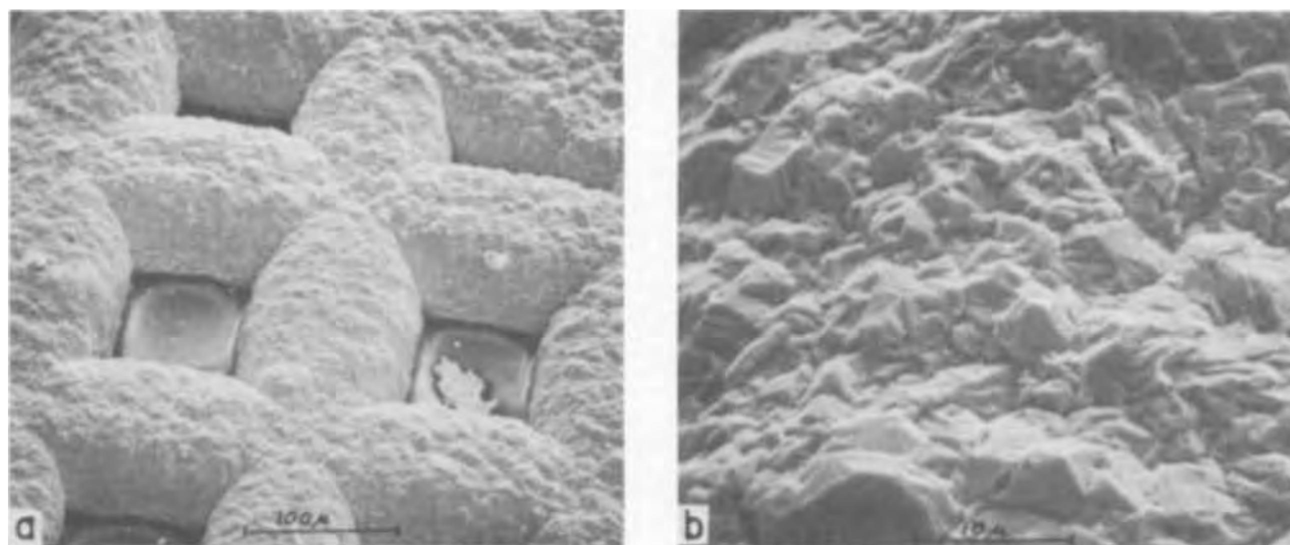

Fig. 13. Scanning electron micrographs of portions of the grid electroplated in the presence of applied *B*, shown in Fig. 11(a3): (a) low magnification; (b) a portion of a grid bar at high magnification.

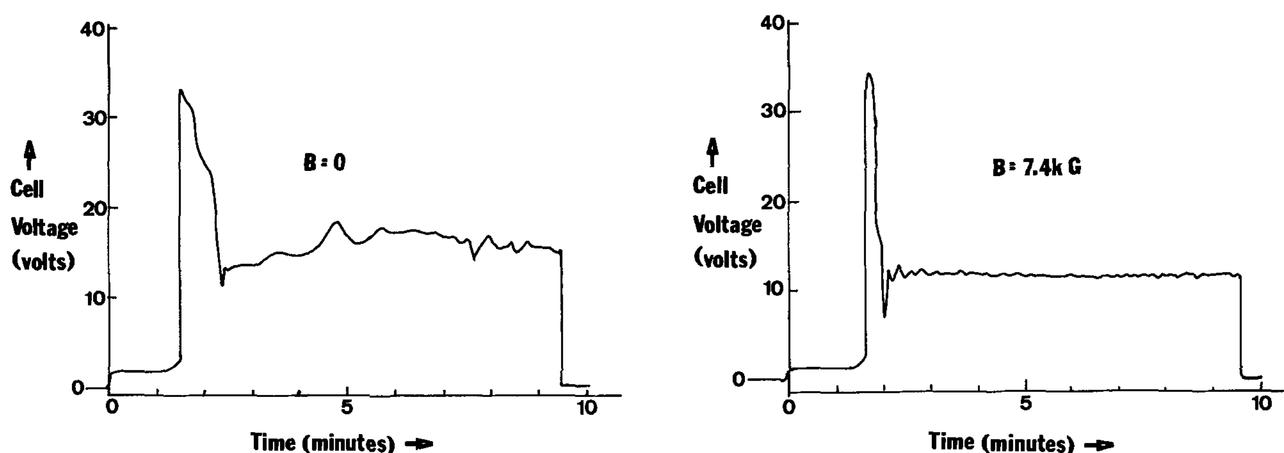

Fig. 14. Variation of cell voltage during deposition of Cu from $CuSO_4$-H_2O electrolyte at constant current (0.08A). (a) Data for deposition on grid shown in Fig. 11(a2) (no applied *B*), (b) data for deposition on grid shown in Fig. 11(a3) (with $B = 7.4$ kG applied parallel to plane of the grid).

Photographs were taken of a group of 4 equally-spaced Knoop indentations on each grid (all made with a 100g load) by focusing on the roots of the indentations. The indentations in the electrodeposit made without applied *B* (Fig. 16b) are less well defined than either group of those made with applied *B* (Fig. 16c and d). The most probable cause of this difference is a rougher surface in the case of the deposit made without applied *B*. Further work is needed to assess the differences in hardness of these deposits.

To determine the effect of applied *B* on the cell resistance during deposition of Cu from the $CuSO_4$-H_2SO_4 electrolyte, *B* was varied both in strength and orientation during deposition on a double Cu grid suspended vertically, parallel to the plane of the Cu anode. The results are given in Table I.

Table I. Electrolytic cell resistance as a function of magnitude and orientation of applied *B*

Applied *B*			Cell current (Amperes ±0.0005)	Resistance lowering due to *B* (% ±1)
Strength (kG)	Orientation	Direction		
0	—	—	0.02	—
5.5	$B \perp$ cathode	Normal	0.02	10
5.5	$B \parallel$ cathode	Normal	0.02	10
3.0	$B \parallel$ cathode	Normal	0.02	7
3.0	$B \parallel$ cathode	Reversed	0.02	7

In this case the cell voltage (0.2-0.3V) is much lower than for the data of Fig. 14, due to the much lower cell current, higher temperature, and greater degree of ionization. The percentage reduction in the cell resistance was less in this case, but the magnitude of *B* was also less. The data of Table I show that a reduction in *B* from 5.5 kG to 3.0 kG increases the cell resistance by about 3%. Change in the orientation or direction of *B* with respect to the electrodes appears not to have any effect on the magnitude of the cell resistance.

Discussion of Results

No previous reports of the effects of applied *B* on electrothinning processes have been found in the literature. Although there have been previous studies of electrodeposition under the influence of applied *B* (3-6), most of this work was concerned with deposition of the ferromagnetic elements, Fe, Co, and Ni. For deposition of Cu and Sb in applied *B*, no effect was observed (3). Yang (3) did observe that *B* applied normal to the cathode caused enhanced deposition of the ferromagnetic elements in this direction, but he reported no difference for the deposits obtained with *B* parallel to the cathode in comparison with those obtained without applied *B*.

Many of the effects of applied *B* on electrolytic processes described above appear to be similar to those

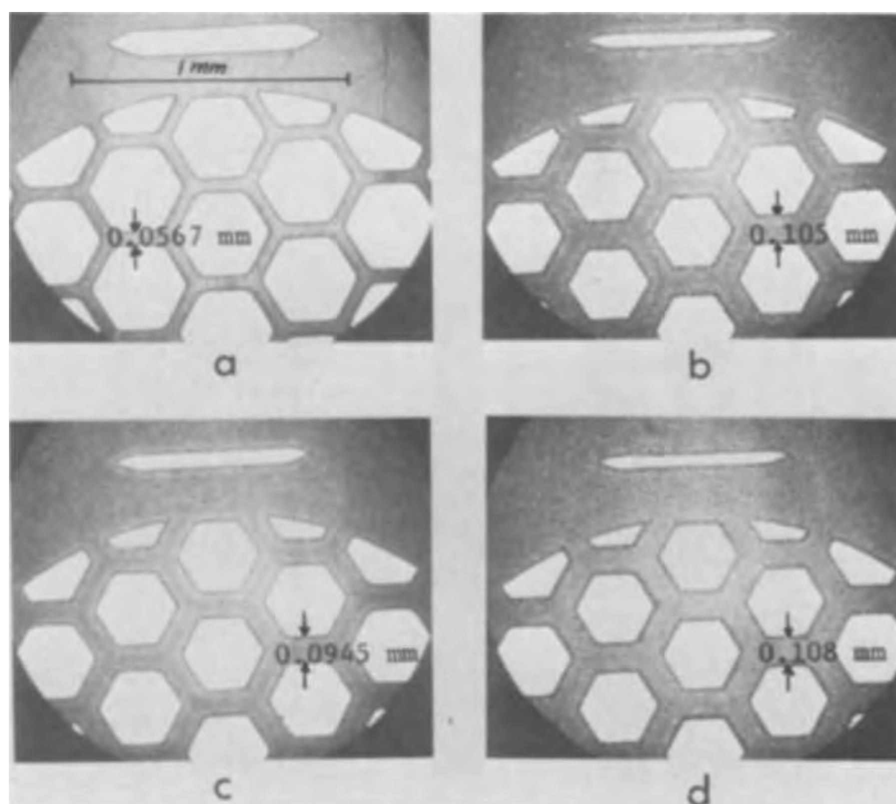

Fig. 15. Electrodeposition of Cu on Cu grids suspended vertically in electrolyte containing 0.22g $CuSO_4$ and 0.04 cc H_2SO_4 per cc H_2O. Electrolyte temperature was maintained at 50° ± 2°C, the current was constant at 0.02A, and the time of deposition was 740 sec for each of these experiments. (a) Profile of grid before deposition, (b) plated without applied B, (c) plated with B = 5.5 kG normal to the plane of the grid, (d) plated with B = 5.5 kG parallel to the plane of the grid. The extent of deposition parallel to the plane of the grid is least for (c) and most for (d).

which occur due to ultrasonic vibration during electrolysis (7). The basic mechanisms by which the two types of field interact with electrolytes are quite different. Ultrasonic fields impart vibratory motion to all particles in the electrolyte, but magnetic fields interact only with moving charged particles. Through the Lorentz force, $\vec{F} = q(\vec{v} \times \vec{B})$, where q is the charge of a particle, $\vec{v}$ its velocity, and $\vec{B}$ the magnetic field strength, a moving charged particle is caused to spiral about its original path. The direction of spiraling is opposite for opposite charges. Other studies, using alternating current during electrolysis, have shown that the magnetic force decreases the mobility of moving charged particles in electrolytes (8). Thus our observation that applied B lowers electrolytic cell resistance in direct-current electrolysis (*i.e.* increases the mobility of charged particles) may be explainable by enhanced mobility at the solid-liquid interfaces due to intense mixing, which more than cancels the reduced mobility in the bulk of the electrolyte. Similarly, the vibratory motion caused by ultrasonic fields may not increase mobility in the bulk of the electrolyte, but the reduction in polarization at the electrodes results in an overall reduction of cell resistance (7).

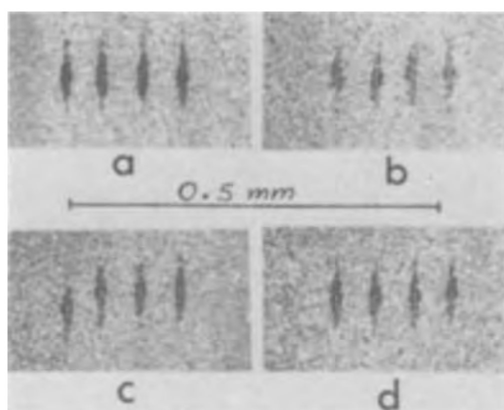

Fig. 16. Impressions from same locations in samples of Fig. 15 made with Knoop indenter under 100g load on Tukon microhardness tester. (a) Sample before deposition, (b) plated without applied B, (c) plated with B = 5.5 kG normal to plane of the grid, (d) plated with B = 5.5 kG parallel to plane of the grid.

A fundamental difference between the ultrasonic and the magnetic interactions is that the former transfers energy to the electrolyte but the latter does not. Thus, if further research proves that magnetic fields are as effective as ultrasonic fields in improving electrodeposition and other important electrolytic processes, it would appear that the former have appreciable economic advantages. This is especially true if the necessary B can be supplied with permanent magnets.

Experimental and theoretical studies to improve the understanding of the results reported above are in progress.

Acknowledgments

Electrophoretic Deposition of Aluminide Coatings from Aqueous Suspensions

H. A. Fisch

TRW Inc., Equipment Group, Materials Technology Department, Cleveland, Ohio 44117

ABSTRACT

A process was developed on a laboratory scale for electrophoretic deposition of metals from aqueous suspensions formed by mixing metal powder or flake with an amine solubilized acrylic resin, glycerol, and a detergent wetting agent in deionized water. Electrophoretic deposition parameters are discussed in terms of deposits formed from aluminum flake on B-1900 alloy. From this basis, the process was extended to the deposition of bisque envelopes for the formation of aluminide coatings modified with additions of Cr, Si, and a Ti coating containing Al_2O_3. Electrophoretically deposited Al, Al-Cr, and Al-Si coatings provided protection against dynamic hot corrosion (sulfidation) for times comparable to those observed for conventionally processed coatings.

Aluminide coatings are widely used in gas turbine power plants of military and commercial aircraft because they provide a reliable deterrent against oxidation, hot corrosion, and thermal fatigue damage of critical and expensive hardware. While much research has been and is currently being conducted to develop improved metallic coating systems, an aluminide coating on nickel- and cobalt-base superalloys has been demonstrated to be the most protective and economical system available for applications up to about 2000°F. Higher operating temperatures of advanced engines may require new substrates and coating alloys; however, in most cases internal cooling of blades and vanes will keep the temperature of some of these components within the protective range of the aluminides. Furthermore, while future turbine inlet temperature requirements may preclude the use of aluminides on first- and possibly second-stage blades and vanes, subsequent cooler stages which at present are uncoated will require protection within the temperature capability of the aluminide coatings.

Aluminide coatings for protecting nickel-base or cobalt-base superalloys against oxidation and hot corrosion are most commonly formed by pack cementation processes, or variations of this process such as pack-diffusion (1) or slurry-diffusion (2) and by slurry-fusion. A typical pack-diffusion process involves placing the article to be coated into a retort containing powdered metallic and nonmetallic coating material and, if required, an activator. This is followed by heating to a temperature sufficient to vaporize the powdered coating material thereby causing a solid-vapor interface reaction to occur between the article and the coating vapor. In a slurry-diffusion process, the analogous solid-vapor interface reaction is ordinarily achieved by applying a sprayed layer or bisque envelope of coating source materials onto the article to be coated, drying to form an adherent deposit, and forming the diffusion coating by heating. Slurry-fusion involves spraying to form a bisque on the surface then heating to melt and diffuse the source materials at the bisque-substrate interface. For each of these processes heating may be done in inert atmosphere, air, hydrogen, or vacuum.

Formation of coatings from a bisque is considered by many to be the most versatile process for producing coatings. In general, any coating formed by pack cementation can also be formed by slurry-diffusion and typical examples of this interchangeability have been described in the literature (1, 2). As modifications of the spray-pack process other means such as dipping, painting, or electrophoretic deposition can be used to form the bisques. Among these methods, electrophoretic deposition has particular advantages. This method provides superior coverage to relatively inaccessible surfaces of the part being coated, better uniformity at edges, and reduced losses from over-spray and drag-out normally associated with spraying and dipping.

Present technology for the electrophoretic deposition of metals is based on using organic solvents as dispersants. Shyne *et al.* (3) discussed the deposition of nickel, nickel-chromium, and nickel-chromium-iron coatings as well as nonmetallic coatings onto base metals using alcohol as the suspending medium. Lamb and Reed (4) investigated the deposition of aluminum, silicon, germanium, GeO_2, WO_3, NiO, $BaTiO_3$ from water as well as organic liquids which were classed as nonpolar, including gasoline and cetane; slightly polar, such as ethers; and strongly polar comprising alcohols, nitroparaffins, and water. They were unable to obtain deposits from water, and the best deposits were obtained from liquids of intermediate polarity; *e.g.*, diethylene glycol dimethyl ether, and pyridine. The use of polar and nonpolar organic liquids for the deposition of aluminum flake on gold-plated Monel rods was investigated by Pearlstein *et al.* (5), who found that the best deposits were obtained from suspensions in butyl amine. Gutierrez *et al.* (6) used isopropanol and nitromethane as suspending media for depositing niobium, other refractory metals, carbides, and oxides on metal and graphite substrates. Ortner (7) deposited metals, oxides, and carbides on various metallic substrates using an isopropanol-nitromethane mixture. Fisch and Kmieciak (8) utilized this solution to deposit tungsten and tungsten-TiH_2 mixtures on a tantalum alloy. Aluminum has been deposited on steel strip and plate from organic suspensions containing water. The British Iron and Steel Institute (9) described the continuous aluminum coating of steel strip from a methanol-water solution containing a small amount of electrolyte and Yamada *et al.* (10, 11) discussed the use of alcohol-20% water, and pure alcohol as suspending media for depositing aluminum on steel plate.

Although electrophoretic deposition of metals from organic media is in an advanced state of development it has not been widely used as a means for applying coating bisques. This may be due in part to potential fire and health hazards associated with deposition from organic solvents. The use of water as the suspending medium would eliminate the fire hazard and to a great extent reduce the health and waste disposal problems associated with high concentrations of volatile organic solvents.

This paper discusses the use of water as the suspending medium for electrophoretic deposition of metals and mixtures of metals and oxides as bisques for the

Key words: aluminide coatings, sulfidation resistant coatings, aerospace coatings, electrophoretic deposition, electrocoating.

formation of aluminide coatings used for protecting aircraft gas turbine engine blades and vanes. Deposition of metallic bisques is analogous to commercial electrocoating processes (12-15) used to deposit resin and pigment mixtures. Each of these deposition processes utilizes suspensions of insoluble phases in water containing a soluble resin complex. Typically, a resin complex consists of a maleinized oil or organic solvent soluble polycarboxylic acid resin and an alkaline (KOH, amine, or ammonia) solubilizing agent. In a very simplified manner an electrocoating process may be described as a combination of three electrokinetic phenomena; electrophoresis, electroosmosis, electrolysis and electrodeposition. The presence of an electrical field produces electrophoretic migration of suspended particles to the anode where they are deposited and the deposit is concentrated and dewatered by electroosmosis. Simultaneously, electrolysis of water results in gas evolution; hydrogen at the cathode, and oxygen and H^+ at the anode. Electrodeposition occurs at the anode (18). At a metallic anode additional reactions may occur. Among these are: electrodissolution of the anode, the formation of organometallic complexes between ions resulting from this dissolution and the resin, and decarboxylation and cross-linking of the resin by reactions such as the Kolbe reaction. The formation of organometallic compounds, cross-linking of the resin and coagulation of the resin as a result of localized decreases in pH in the vicinity of the anode can lead to the deposition of resin on the anode (16-18). These various electrode reactions are schematically shown in Fig. 1 using an amine-solubilized resin as an example.

Procedures

Although electrophoretic deposition parameters were determined using aluminum flake having a particle size 7.5μ or less, deposits were also obtained using 4 to 44μ atomized powders. This flake together with various amounts of an amine-solubilized acrylic resin formulation containing 40% solids (No. 65137 Clear, Glidden-Durkee Division of SCM, Inc.), 4g glycerol, and 0.05g detergent wetting agent (Orvus AB, Procter and Gamble Company) were added to 70g deionized water having an initial resistivity of 1.2-2.0 megohm-cm. The over-all pH of the suspensions varied between 7.8 and 8.3.

The deposition cell was a 100 ml beaker and the aluminum flake was maintained in suspension by agitation with a Teflon-covered magnetic stirrer. The cathode of the deposition cell was a 20 mesh Monel screen having a hollow parallelepiped configuration 25 x 37 x 50 mm. Deposits (bisques) were formed on a centrally located anode which was a cast nickel-base superalloy (B-1900, composition; Ni, 8% Cr, 10% Co, 6% Mo, 6% Al, 1% Ti, 4% Ta, 0.1% C, 0.1% Zr, 0.015% B) coupon approximately 2 x 12 x 18 mm having an area about

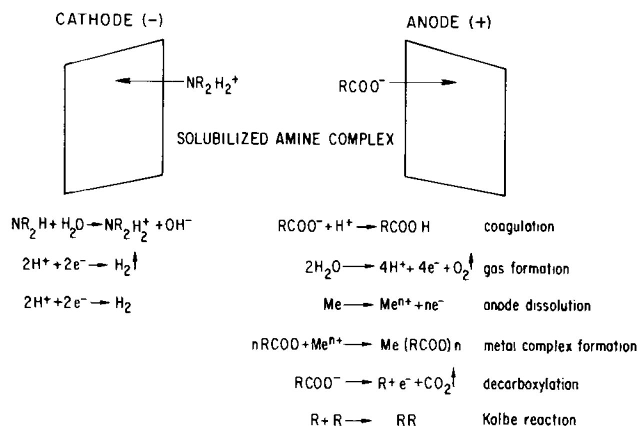

Fig. 1. Electrode reactions during electrocoating

5.3 cm². Before deposition, coupon surfaces were prepared by degreasing in trichlorethylene followed by an acetone rinse. Bisques were formed from freshly prepared suspensions using 40 and 60V d.c. for times from 5 to 30 sec. After coating, the bisques were rinsed in water and air dried at 180°F. Coatings were formed by heating the bisques in a 1 x 10^{-4} Torr vacuum 4 hr at 1975°F.

Other aluminide coatings containing Cr, Si, and Ti plus Al_2O_3 modifiers were formed by substituting different coating source materials for the aluminum flake. In other respects the suspension compositions were essentially the same. However, for these coatings deposition times were as long as 5 min and deposition voltages up to 100V d.c. were used.

The hot corrosion (sulfidation) resistances of the simple aluminide coating and the Cr and Si modified coatings were evaluated using wedge-shaped simulated airfoil specimens in dynamic hot corrosion (sulfidation) rig tests and compared to the resistances of the corresponding conventionally formed coatings.

Electrophoretic Deposition of Aluminum Flake

Electrophoretic deposition of aluminum flake was investigated as a function of deposition voltage, time, and suspension composition.

Effect of suspension liquid composition.—The suspension liquid consisted of deionized water, an organic modifier, a wetting agent, and resin. Varying the composition and amounts of each of these materials had a significant effect on bisque formation.

The deionized water used for the suspensions had a specific resistance of 1.2-2.0 megohm-cm. However, bisque deposits could also be obtained using suspensions in ordinary tap water. Since decorative appearance was not a consideration, the presence of small amounts of impurities such as chloride or sulfate ions and soluble metal compounds[1] was relatively insignificant. However, because of its higher conductivity, the use of tap water may result in more gassing (electrolysis), less electrophoretic transfer of polymer and resin, and excessively pitted deposits.

Control of suspension pH was an important factor in electrophoretic deposition. As the pH increased thinner coatings resulted under equivalent conditions, possibly because an insulating film was formed more rapidly on the substrate as a result of enhanced coagulation of the resin due to the formation of metallic complexes resulting from increased anodic dissolution of the substrate or by cross-linking of the resin. At a bulk pH 10.5-11, the substrate surface under the bisque was etched and the bisque contained hemispherical pits. These observations are indicative of substrate dissolution and gas evolution accompanying bisque deposition. However, etching and gas evolution were not problems at pH 7.9-8.3 where usable bisques were deposited. Local variations in ion concentrations and suspension pH near the anode, and gas evolution at each electrode were not experimentally investigated. The lower usable suspension pH was determined either by the value at which the deposited bisques could not be sufficiently dewatered by electroosmosis, or the resin coagulated in the bulk of the suspension.

The organic modifiers contained one or more hydroxyl groups. Although the addition of glycerol provided the most uniform bisques, other modifiers such as methanol, isopropanol, and cyclohexanol could also be used. The concentration of modifier needed to produce an optimum deposit depended on both the chemical composition of the modifier and the bisque being deposited. In the absence of a modifier or at low concentrations, pitted and/or uneven nodular bisques were formed, while using too much modifier resulted in thin pitted bisques.

Addition of a detergent wetting agent improved bisque adherence and was also found to act as an anti-

[1] Typical analysis: 27 ppm Cl^-, 32 ppm $SO_4^=$, 58 ppm metals, total hardness 125.

pitting agent. Virtually all of the work utilized an alkane sulfonate, "Orvus AB." A household detergent, "Trend," was also usable and other wetting agents compatible with the suspension could probably be substituted.

Effect of deposition temperature and voltage.—The electrophoretic bath was operated at room temperature with the maximum operating temperature being below a temperature (approximately 85°F) which would initiate thermal degradation of the resin-solubilizer complex. The deposition voltage was also critical. Below approximately 25V d.c. the bisque had poor adherence and contained too much water due to an insufficient potential gradient for proper electroosmosis. The upper voltage limit (above approximately 70V d.c.) was determined by a value which produced an unsatisfactory deposit because the bisque was too thin, it was excessively pitted or nodular rather than smooth and uniform or it was excessively thick at edges or corners. With other suspension constituents maintained constant, these limiting voltages varied with resin and aluminum concentrations.

Effect of resin and aluminum concentrations.—Bisques were formed from suspensions containing 0.014-0.086g Al/gram H_2O and solid resin to aluminum ratios 1:1.25, 1:2.5, and 1:5. Figure 2 shows typical variations of deposition current with time at 40V d.c. deposition potential. Similar relationships were observed at 60V d.c. At both voltages, the current decreased with time for all aluminum and resin concentrations. The decrease in current is attributed to progressively increasing resistance of the bisque as deposition progressed. At constant resin to aluminum ratios increasing aluminum concentrations led to a more nearly constant current *vs.* time relationship. The quantity of electricity passed during deposition $\int_0^t Idt$, was computed from these curves and effective currents were obtained by dividing values of this integral by deposition times. The relationship between the effective current at 40 and 60V d.c. and solid resin content of the suspension is shown in Fig. 3 and 4. In each of these figures the line represents the relationship determined in the absence of aluminum at pH 7.9-8.3. Between 0.01 and 0.02g resin/gram H_2O, the effective current changed rapidly and erratically with increasing resin concentration, but became essentially constant at concentrations greater than about 0.02g resin/gram

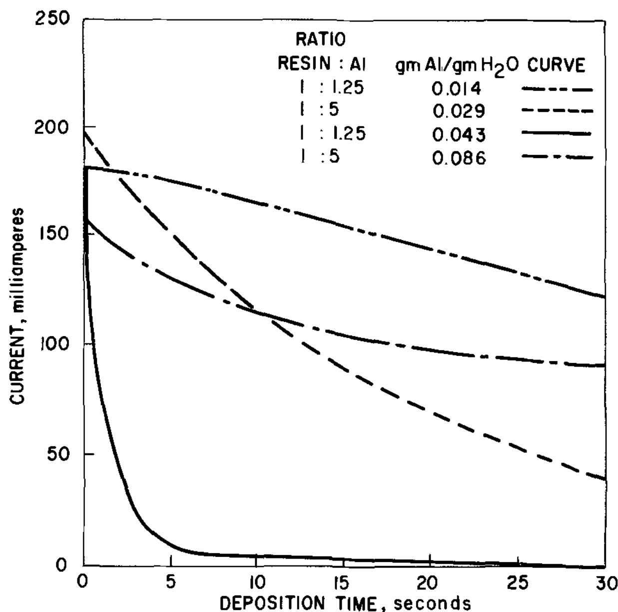

Fig. 2. Typical current-time relationships during electrophoretic deposition of aluminum at 40V.

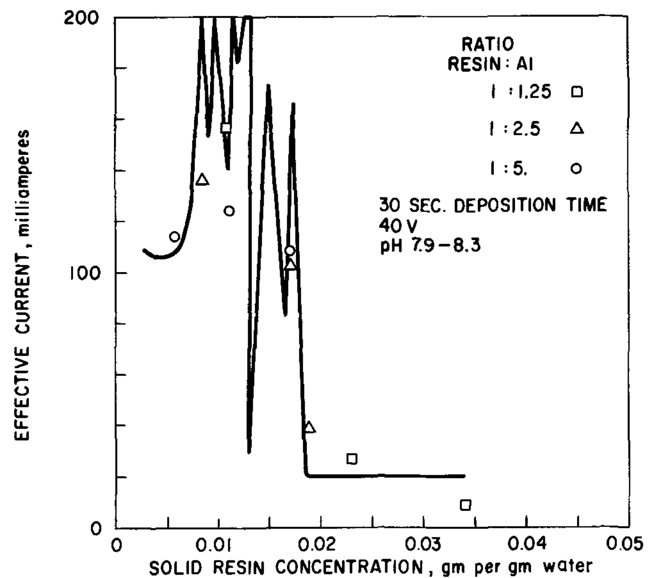

Fig. 3. Effective current at 40V as a function of resin concentration.

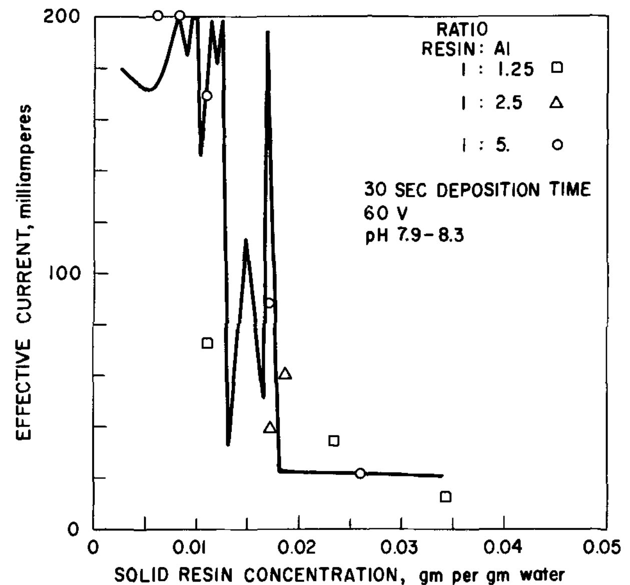

Fig. 4. Effective current at 60V as a function of resin concentration.

H_2O. The approximate correspondence between effective curents measured for suspensions with and without aluminum indicated that effective current depended principally on resin concentration. Similar relationships also were found at pH 7.2-7.6 and pH 8.6-8.8. Since these curves were determined using fresh suspensions, it was suspected that the erratic behavior was caused by incomplete hydrolysis of the resin; however, suspensions aged at room temperature for 4-24 hr provided essentially the same effective current relationships. Figure 5 shows a relationship between unit area bisque weight and coulombs. The slopes of the straight lines represent the coulombic yields of the depositions. Essentially equivalent yields were obtained at 40 and at 60V d.c. and the yields were independent of resin to aluminum ratios and aluminum concentrations up to 0.043 g/gram H_2O. However, at a higher aluminum concentration (0.086 g/gram H_2O) significantly higher yields were obtained.

The relationship between bisque weight and aluminum concentration is given in Fig. 6. Below about

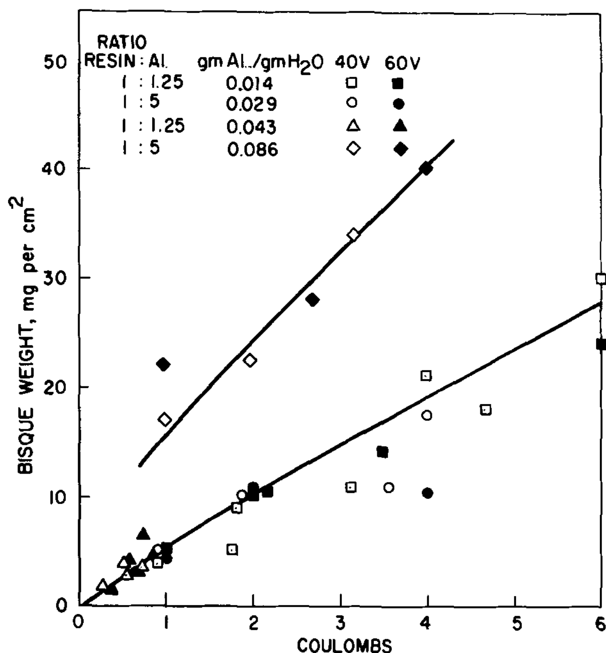

Fig. 5. Relationship between bisque weight and electric current

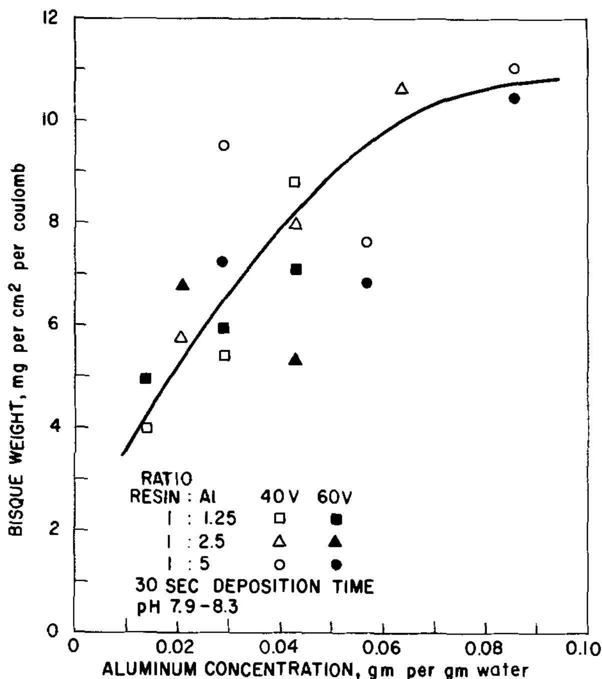

Fig. 6. Effect of aluminum concentration on bisque weight

0.04g Al/gram H_2O, the amount of bisque per coulomb increased in a nearly linear manner with aluminum concentration and appeared to level off above 0.06g Al/gram H_2O.

After vacuum firing to form coatings, the bisques were still intact and easily removed by lightly brushing the coupons. The surface appearances of the bisques and coatings are summarized in Table I. Based on appearance, the best over-all bisques and coatings were obtained from the following four suspensions:

Al conc, gram Al/gram H_2O	Ratio, resin: Al
0.014	1:1.25
0.029	1:5
0.043	1:1.25
0.086	1:5

Coating properties.—In the formation of a coating from a bisque having a specific composition, four physical characteristics are commonly used to evaluate the

Table I. Surface appearance of bisques and coatings

Ratio, resin:Al	Conc Al, g/g H_2O	Surface appearance: Bisque 40V	Bisque 60V	Coating 40V	Coating 60V
1:1.25	0.014	U	Hp	U	S
	0.029	Sp	Hp	S	S
	0.043	Sp	U	U	U
1:2.5	0.021	U	U	U	U
	0.043	U	Hp	U	S
	0.064	Hp	Hp	S	U
1:5	0.029	U	U	U	S
	0.057	U	Sp	U	S
	0.086	U	Sp	U	S

U, uniform; Sp, slight pitting; Hp, heavy pitting; S, spotty.

coating and to control the coating formation process. These are: coating weight per unit area, thickness, build-up, and microstructure. For given bisque compositions and heat-treatment conditions, coating thickness is generally a function of bisque weight per unit area or of bisque thickness, and is essentially constant above a minimum bisque weight. For coating reproducibility, bisques are usually deposited at values above this minimum weight. Figure 7 shows curves for the relationship between coating weight and bisque weight using bisques formed at 40 and 60V d.c. from suspensions having resin to aluminum ratios of 1:1.25 and 1:5 with aluminum concentrations from 0.014 to 0.086g Al/gram H_2O. Essentially constant coating weights were obtained from bisques heavier than 10 mg/cm^2 for all of the conditions investigated up to an aluminum concentration of 0.043g Al/gram H_2O. At a higher aluminum concentration (0.086g Al/8m H_2O) heavier coatings were formed for the same bisque weight indicating an effect of aluminum concentration in the suspension on coating weight. These data illustrate the ranges over which suspension compositions may be varied while still producing an essentially constant coating weight.

As the aluminide coating was formed, the dimensions of the specimen also increased. The amount of this increase is defined as coating build-up, and is measured using a micrometer. Total coating thickness which also includes the aluminide found below the original surface, was determined metallographically on cross sections through the coating and substrate. Figure 8 shows that coating thickness increased linearly with coating weight while the relationship between coating build-up and coating thickness (Fig. 9) was similar to that observed between bisque and coating weight. A photomicrograph of a typical coating is shown in Fig. 10.

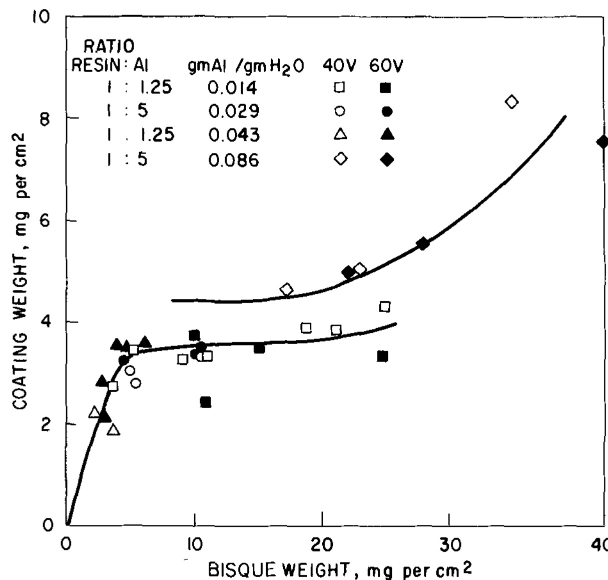

Fig. 7. Relationship between bisque weight and coating weight

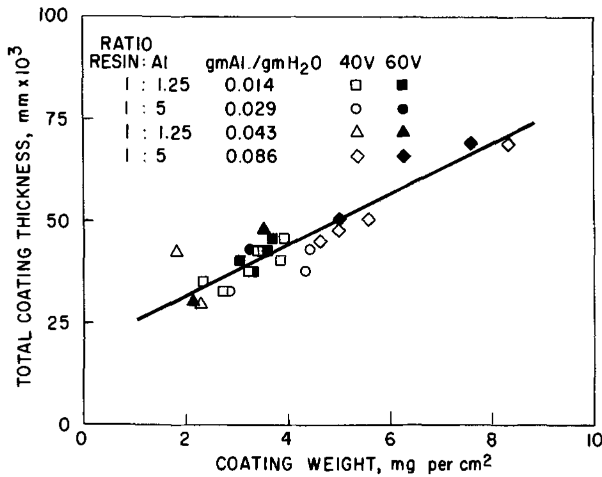

Fig. 8. Relationship between coating weight and coating thickness

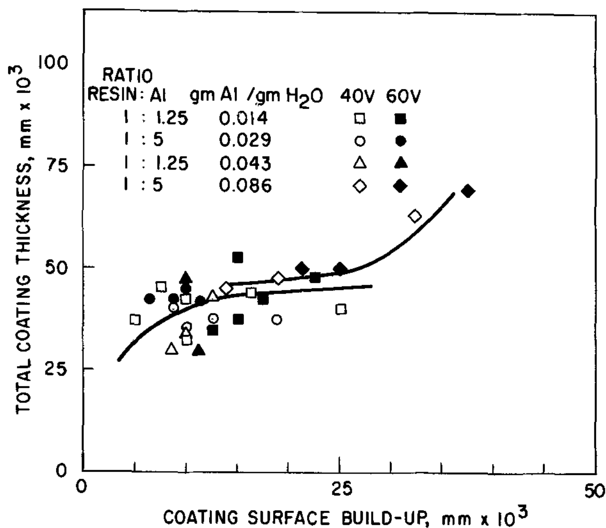

Fig. 9. Relationship between coating build-up and coating thickness.

Other coating properties such as chemical composition and composition gradients from the coating surface into the substrate were not investigated for this coating.

Formation of Other Aluminide Coatings

The electrophoretic deposition technique developed using flake aluminum was used to apply several aluminide coatings to B-1900 alloy coupons. These coatings comprised deposition from suspensions of alloys, mixtures of metals and nonmetals, and mixtures of alloys and oxides. Typical coating formation parameters and coating properties are summarized in Table II.

Deposition parameters such as time, current density, and voltage depended on factors such as the size of the article to be coated and electrode spacing. The relative amounts of resin and coating source material depended on factors such as particle shape (granular or flake), particle size, size distribution, and chemical composition. There was an optimum solids to resin ratio and total solids concentration in the dispersion needed to avoid pitted bisques.

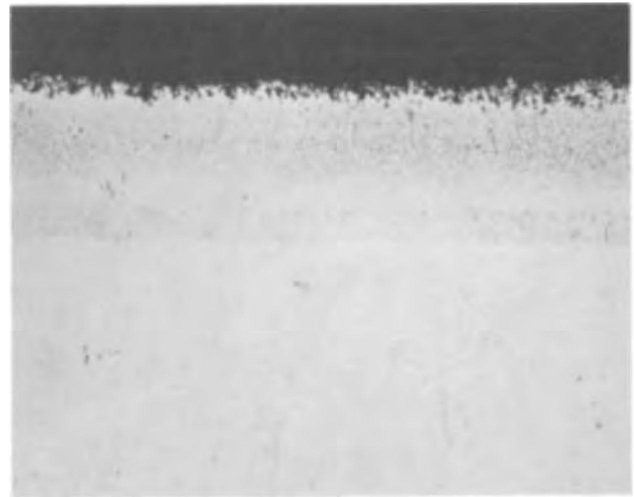

Fig. 10. Microstructure of a coating formed from aluminum flake (190X etched).

Cr modified coating.—In many pack-diffusion or slurry-diffusion processes, Cr-Al alloy powder source activated by inorganic halides is used as the aluminum source. However, these activation materials could not be used in electrophoretic deposition because they coagulated the suspension. Instead, a water insoluble chlorinated hydrocarbon, which did not produce coagulation, was used as an activator. Coating bisques were deposited from suspensions containing chlorinated hydrocarbon activator and -40μ prealloyed 56Cr-44Al powder. In addition, various bisques were deposited containing up to 50 w/o (weight per cent) — 40μ Al_2O_3. Two deposition voltages, 30 and 40V d.c. were used with deposition times up to 30 sec. Diffusion coatings were formed by heating the bisques 4 hr at 1900°F in argon at a pressure of 150 Torr.

The presence of Al_2O_3 in the bisques resulted in more friable bisques after heating but did not affect either the coating microstructure or coating weight gain relationships. The microstructure of a typical Al-Cr coating, Fig. 11, was essentially the same as for a coating formed by either diffusion-pack or spray-pack processes. Figure 12 shows the relationship between coating weight and the weight of 56Cr-44Al powder in the bisque. At the same pH and total solids in the suspension heavier deposits were obtained at 40V d.c. than were obtained at 30V d.c. As shown in Fig. 13, linear relationships were obtained between coating build-up and coating thickness as a function of coating weight.

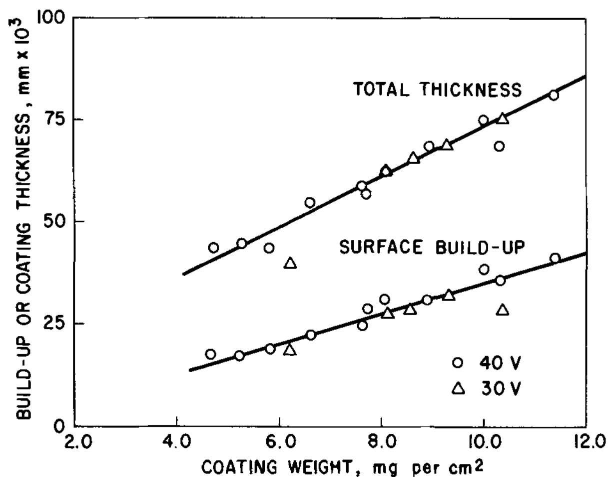

Fig. 13. Relationship between coating weight and coating surface and build-up thickness for Al-Cr coatings.

The relationship between coating build-up and coating thickness is shown in Fig. 14. These relationships are comparable to results obtained for Al-Cr coatings formed on B-1900 by a diffusion-pack process.

Si modified coatings.—Aluminide coatings containing silicon were formed from bisques which were deposited

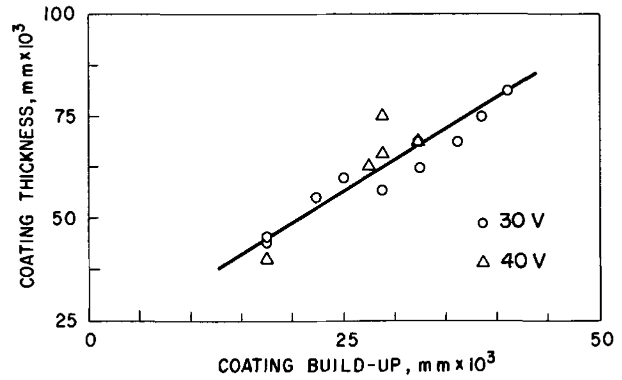

Fig. 14. Relationship between coating build-up and thickness for Al-Cr coatings.

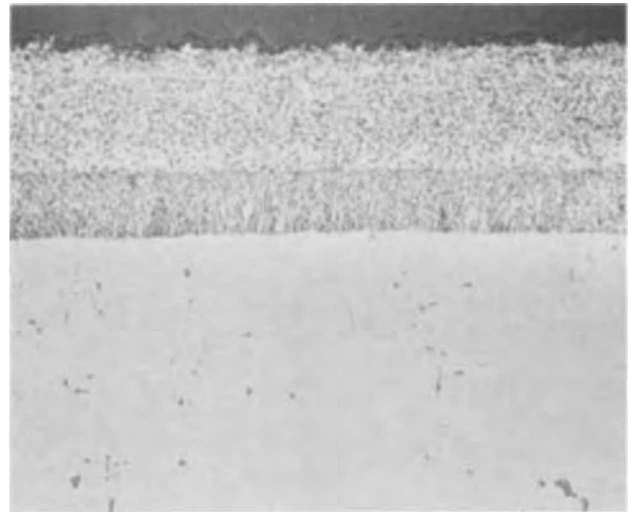

Fig. 15. Microstructure of an Al-Si coating (190X etched)

from suspensions containing either flake aluminum and -40μ powdered silicon or 3.5-6.0 atomized aluminum powder and -40μ silicon. Coatings were formed by heating the bisques at 1975°F for 4 hr in vacuum. Figure 15 shows the microstructure of a coating formed using an atomized powder bisque and comparable microstructures were obtained using bisques of flake aluminum. The presence of silicon in the coating was confirmed by electron microprobe examination.

Al-Ti modified coating containing Al_2O_3 particles.—Aluminide coatings were formed from bisques containing -40μ prealloyed Al-Ti powder, chlorinated hydrocarbon activator, and -40μ Al_2O_3. Coating bisques were applied in two ways: by electrophoretically depositing a layer of Al_2O_3 and subsequently depositing the Al-Ti bisque and by simultaneously depositing a bisque containing Al-Ti and Al_2O_3. Both types of bisques were fired in hydrogen for 6 hr at 1975°F. The microstructure of a coating formed by simultaneous deposition of Al-Ti and Al_2O_3, shown in Fig. 16, was comparable to those produced from sequentially deposited bisques.

SermeTel J coating.—The SermeTel J coating is ordinarily formed by spraying, painting, or dipping a proprietary composition (Teleflex, Incorporated) onto the part to be coated and firing at 1600°F in an inert atmosphere. Since the composition was supplied as a suspension in an organic media, and electrophoretic deposits have been obtained from organic liquids, initial, but unsuccessful, attempts were made to deposit bisques directly from that suspension. Also, it was not possible to form deposits from the as-received suspension either diluted with deionized water or diluted with resin and water.

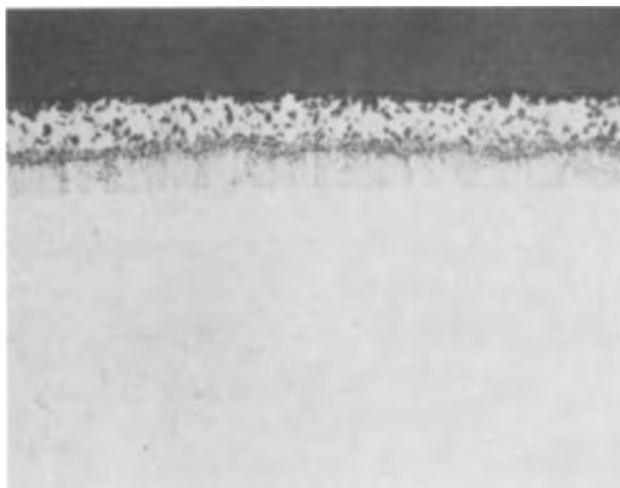

Fig. 16. Microstructure of an Al-Ti coating containing Al_2O_3 particles (190X etched).

Fig. 17. Microstructure of a SermeTel J coating (190X etched)

However, deposits were obtained by suspending the solid constituents of the SermeTel J in water to which resin had been added. The as-received organic suspension was evaporated to dryness, and residue ground and washed with water until the pH of the water increased from 2 to 6.5, then washed with isopropanol, and air dried. The dried powder was made into a suspension, deposits were formed and fired at 1600°F for 2 hr in argon at 150 Torr. A typical microstructure is shown in Fig. 17.

Hot Corrosion Resistance of Coatings

Aluminum, Al-Cr, and Al-Si coatings were formed on wedge-shaped B-1900 test bars approximately 12 mm diameter x 75 mm long (0.5 x 3 in.). These coatings were subjected to a commonly used hot corrosion (sulfidation) test under dynamic conditions which simulate the exposure conditions in an aircraft jet engine. The test bars were rotated at 1750 rpm in a combusted gas stream having a velocity ratio of approximately 0.6 Mach. The apparatus burned Jet A fuel to which 0.4 w/o sulfur was added as ditertiary butyl disulfide and 35 ppm chloride was added as synthetic sea salt (16.6g $MgO_2 \cdot 6H_2O$, 1.9g $CaCl_2$, 6.0g Na_2SO_4, and 37.6g NaCl in 5 gal H_2O). Specimen temperatures were adjusted by varying the fuel/air ratio and temperatures were monitored using an optical pyrometer. The coated bars were exposed under the following temperature cycle:

1 min heat-up + 2 min at 1750°F

1 min heat-up + 1 min at 2050°F

2 min air cool.

The coating characteristics and the protective lives of the coatings are summarized in Table III. This table also gives the protective characteristics of Al-Cr coatings formed by the diffusion-pack process and tested simultaneously with the electrophoretically formed coatings, as well as independently measured protective lives for Al-Si and Al-Cr. These results show that coatings formed by electrophoretic deposition of the coating powders exhibited protective lives comparable to those obtained by the conventional procedures.

Summary and Conclusions

An electrophoretic deposition technique utilizing aqueous suspensions has been developed on a laboratory scale for forming coating bisques used in producing aluminide coatings on nickel-base superalloys. The process which is analogous to commercial electrocoating processes, utilizes a suspension of metallic particles in deionized water containing an amine-stabilized acrylic resin. Electrophoretic deposition parameters (suspension composition, deposition time, and voltage) were determined using aluminum flake. The process was extended to the formation of aluminide coatings modified with additions of Cr, Si, and a mixture of Ti and Al_2O_3 particles.

Chromium modified aluminide coatings were formed from bisques containing chlorinated hydrocarbon activator and prealloyed 56Cr-44Al powder. Silicon modified aluminide coatings were formed from bisques deposited using either aluminum flake or atomized aluminum powder and silicon powder. Titanium-modified aluminide coatings containing particulate Al_2O_3 and the "SermeTel J" coating were also formed from electrophoretically deposited bisques. Microstructures, thickness, and weight gains of these four coatings were comparable to the corresponding properties of coatings produced using vacuum-pack or spray-pack processes.

Simple aluminide, chromium-modified and silicon-modified aluminide coatings were formed on wedge shaped B-1900 test bars and hot-corrosion sulfidation tested under dynamic conditions which simulated conditions in a jet engine. The protective lives of coatings formed by electrophoretic deposition of bisques were comparable to those of the same coatings formed by diffusion-pack or spray-pack processes.

Table III. Hot corrosion resistance of aluminide coatings

Coating type	Bisque wt, mg/cm²	Coating wt, mg/cm²	Coating thickness mm x 10^3	Coating thickness mils	Protective life hr/mil	Protective life Total hr
Electrophoretic						
Al	46	8.2	70	2.8	20	55
Al-Si	47	7.0	63	2.5	22	55
Al-Cr	140	8.0	63	2.5	33	82
Conventional						
Al-Si*	—	—	—	—	13-18	46-64
Al-Cr†	—	10.3	70	2.8	32	90

* Slurry coated.
† Diffusion-pack coated.

Because of its similarity to established electrocoating processes, electrophoretic deposition of metallic coating bisques has excellent potential for use in a continuous automated coating process for applying presently available commercial aluminide coatings to jet engine hardware. These coatings are typically formed using unalloyed metals, mixtures of metals, alloys or mixtures of metals and ceramics, and this work has shown that it is feasible to deposit bisques of these materials by electrophoretic deposition from water.

Cell Design for Potentiostatic Measuring System

B. D. Cahan,[1] Z. Nagy,[†] and M. A. Genshaw[*,2]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Design criteria are examined for an electrochemical measuring system to be used for potentiostatic transient investigation of fast electrode reactions. The importance of codesign of the cell and electronics is emphasized. The cell design is examined in detail in this paper, while that of the potentiostat is treated in a separate paper. To obtain the desired characteristics of stability, good frequency response, accuracy in potential control, and uniform current distribution on the working electrode, the following features are required: small cell resistance, small reference electrode resistance, small interelectrode stray capacitances, small working electrode area, a small but variable solution resistance between the point of potential measurement and the working electrode, and a "symmetrical" electrode arrangement. A cell meeting these requirements was built. The main novel feature of the cell is the complete elimination of the troublesome "classical Luggin capillary."

In a potentiostatic system the cell is in the feedback of the control amplifier. The feedback fraction and phase shift in the feedback loop are determined by the cell, and therefore it can have a strong influence on the response characteristics of the system. When designing such a measuring apparatus it is, therefore, important to view the system as a single unit, to design the cell with the potentiostat in mind, and vice versa. The ideal potentiostatic setup is a physical impossibilty. It would mean that the double layer capacitance is fully charged at $t = 0+$ time, that is, it would require a zero series resistance in the cell, and an infinite current capability of the potentiostat. A real system has finite response characteristics to a step input. These response characteristics can be determined by either the cell or the potentiostat. It is desirable for the experimenter to have control over these response characteristics and, therefore, they should be determined by the potentiostat. The cell characteristics are not under full control by the experimenter, since they depend on the electrode reaction; and even with the same electrode process they are variable, depending on parameters like solution concentration and potential range investigated.[3] It was the aim of the present work to design an apparatus for the investigation of fast electrode reactions with potentiostatic transient technique. The cell and the potentiostat were codesigned, and efforts were made to have the system controlled by the potentiostat at all times and under all experimental conditions. The cell design is described here. A later paper will treat the potentiostat (1).

Key words: low iR drop, low internal resistance, low stray capacitance reference, cell design, uniform current distribution, potentiostatic transients, fast electrochemical reactions.

Criteria of a Good Cell

The following properties of the system are used to establish design criteria for the cell: stability, frequency response, accuracy (including accuracy of potential control and accuracy of the point of potential control), and current distribution over the surface of the working electrode. Figure 1 gives a simplified schematic of a potentiostatic measuring system; both the reference and working electrodes are more complex than indicated, but this simple scheme will be sufficient for the present purpose.

Stability criteria.—The stability criteria of such systems have been treated in detail by Schroeder and

[3] This treatment refers to a completely general case. In specific cases when the electrode reaction is already fairly well known the design problem is simplified.

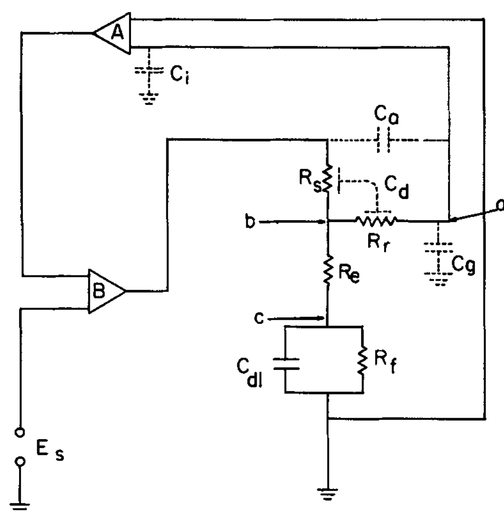

Fig. 1. Schematic for a potentiostatic system. R_s = solution resistance; R_r = resistance of reference electrode; R_e = error resistance; R_f = faradaic resistance; C_{dl} = double layer capacitance; C_g = stray capacitance between reference and ground; C_d = distributive capacitance between the cell solution and the electrolyte in Luggin capillary; C_a = stray capacitance between reference and auxiliary electrode; C_i = input capacitance of potentiostat; E_s = signal voltage; A = input stage of potentiostat; B = control and output stage of potentiostat.

Shain (2). It is required that the cell introduce only a small phase shift in the feedback to keep the system stable. Phase shifts are introduced by variation of the feedback ratio with frequency and by additional delays in the feedback loop, such as the complex impedance presented by the reference electrode capillary, shown as C_d in Fig. 1. The cell acts as a voltage divider and sets the feedback ratio as

$$B = \frac{Z_f + R_e}{Z_f + R_e + R_s}$$

Because Z_f (the electrode impedance)[4] is frequency dependent, the phase shift and the feedback ratio also change with frequency. The worst phase shift occurs at the highest frequencies. Because of this, the stability and frequency response criteria are interconnected since stability can be obtained at a sacrifice in rise time by slowing down the potentiostat (1). This problem was treated in detail by Booman and Holbrook (3), who have shown that for optimum stability-rise time, the total cell impedance should be minimized, and R_e should be set to an optimum (nonzero) value which depends on the characteristics of the cell and the potentiostat. To avoid further signal delays in the feedback loop, the stray capacitance (C_g and C_d) should be kept to a minimum.

Response of system.—The response of the system to a voltage step is determined by the largest *RC* time constant in the system. It is desirable to keep all those associated with the cell [*i.e.*, R_eC_{dl}, R_fC_{dl}, $R_r(C_g + C_i)$, and R_rC_a] at minimum value and set one in the potentiostat to control the rise (1).

It should be remembered here that the potential rise time can be defined at points a, b, and c (Fig. 1). In a practical cell, only that at "a" is measurable; on the other hand, we want to minimize the one at point "c." For example, the effect of R_rC_a is to give a fast rise at "a" but a slow one at "c"; this is because C_a shunts the feedback divider, causing a unity feedback fraction at high frequencies and, therefore, making the potentiostat effectively inoperative at short times (C_d can also have a similar effect). R_fC_{dl} is not directly under the control of the experimenter, since it depends only on the electrode reaction being investigated. R_eC_{dl} can be minimized by keeping R_e small. Decreasing the area of the electrode does not change R_eC_{dl}, since it causes opposite changes in R_e and C_{dl}. There is another reason, however, to keep the electrode small. The rise time of the system (when not controlled by an *RC* time constant in the cell) is determined by either the slew rate of the potentiostat or by i_{max}/C_{dl}, whichever is slower (where i_{max} is the maximum current of the potentiostat). For example, for a 1A potentiostat, the double layer charging takes 1 μsec for every microfarad of double layer capacitance. Also, R_r, C_g, C_a, and C_d should be kept at minimum by cell design.

[4] Z_f in this simple scheme is the parallel combination of R_f and C_{dl}, in reality it can be much more complex.

Accuracy criterion.—The accuracy criterion requires that, after the initial rise, the potential of the working electrode be kept exactly at the signal potential fed to the potentiostat. This criterion of potential control is twofold. The potentiostat controls the potential at point "a" (Fig. 1). Although the feedback fraction affects the gain and so the accuracy (at "a"), this effect is negligible for practical situations. The experimenter, however, wishes to control the potential at point "c"; and the error so introduced is iR_e, where i is the cell current. This can be minimized by keeping R_e small.

Uniform current distribution.—The fourth criterion of cell design is a uniform current distribution over the surface of the working electrode. The experimenter wishes to keep every point of the electrode at the preset potential, which requires that the equipotential lines in the vicinity of the electrode in the solution should run parallel to the electrode surface.

Summing up, then, the requirements: low total cell resistance, low-resistance reference electrode, small-area working electrode, low stray capacitances, and uniform current distribution over the working electrode surface. The requirements for R_e are contradictory: zero is required for precise potential control, but a finite resistance is required for stability; therefore a variable R_e is desired.

Previous Cell Designs

Among the above-listed requirements, those associated with the reference electrode are the most troublesome. The conventional Haber-Luggin capillaries (4) have several drawbacks. Barnartt (5) investigated the errors involved in different positionings of the capillary. When placed perpendicularly in front of the working electrode (the most usual arrangement), it has to be kept at a distance more than twice its outer diameter from the surface to avoid disturbing the equipotential lines; this introduces a considerable R_e. Placing it closer to the electrode will distort the current lines exactly at the point of control, causing most of the electrode surface to be at a potential different from that desired. In addition, the distorted current distribution may affect the nature of the electrode reaction itself. Vertical positioning at the side of the electrode, or backside placement (through a hole from the backside of the working electrode) does not avoid the current distortion problem. The high frequency characteristics of the Luggin capillary are also poor. It usually has a high ohmic resistance, since it is made thin to allow close placement; and it also has large coupling capacitance (C_d) between the cell solution and the electrolyte in the capillary. This question was investigated by Bewick *et al.* (6); they have found its electrical equivalent circuit to be very complex, best approximated by a transmission line. This line (represented by C_d in Fig. 1) cannot be represented by any simple *RC* time constant and can make the problem of correct compensation of potentiostat very difficult; it should therefore be eliminated.

Several efforts were made in the past to correct this situation. Piontelli *et al.* (7, 8) proposed a capillary shown in Fig. 2a. This is a flat-ended glass tube pressed

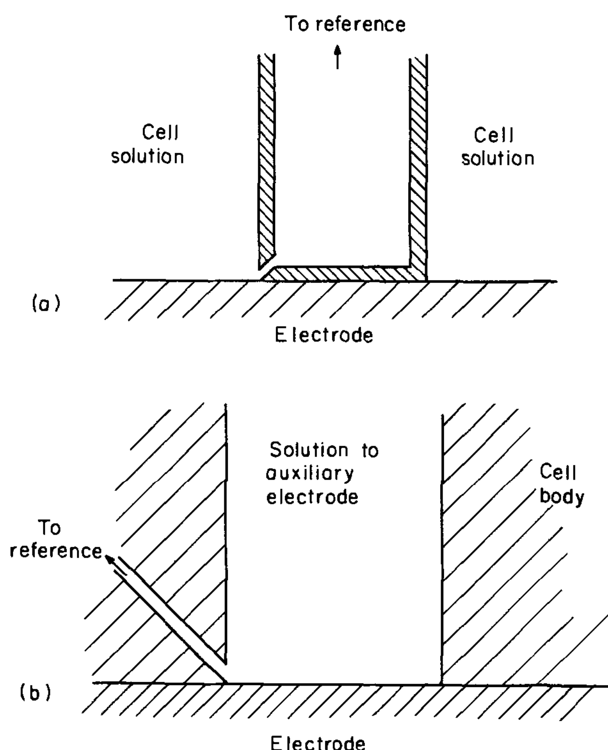

Fig. 2(a). Piontelli electrode; (b) sidehole electrode

against the electrode surface, with the electrical connection made through a small hole near the surface. This can produce low R_e, but the high-frequency characteristics are still poor. Cahan *et al.* (9) used a sidehole electrode, which is an inside-out version of the Piontelli capillary; this is shown in Fig. 2b. A flat working electrode is pressed against a glass or Teflon tube leading to the auxiliary electrode; a small capillary hole is drilled into the wall of this tube, close to the surface of the working electrode, which connects to the reference electrode. This arrangement provides low R_e, and the high-frequency characteristics are also improved. The stray capacitance is small because of the thick walls separating the reference from the other electrodes, and the ohmic resistance can also be made smaller than that of a conventional Luggin, since the capillary hole can be widened after a short distance. Fleischmann and Hiddleston (10) advocated the use of a very thin metal wire coated with organic resin on the sides, in place of the capillary. This also can give low R_e, but the high-frequency characteristics are not good for several reasons. The stray and distributive capacitances are large because of the thin resin coating. The resistance of such a reference electrode can also be high; the resistance of the metallic wire itself is negligible, but the faradaic resistance is high due to the small area exposed to the solution. Assuming that the potential-determining reaction has an exchange current density of 1 mA/cm^2, the faradaic resistance will be over 100 kohms for a 40 s.w.g. wire; if (C_g + C_i) is 50 pf (picofarad), a 5 μsec rise time will result. In selection of such an electrode, therefore, the i_o value of the electrode reaction becomes important, while this resistance term is negligible with usual reference electrodes. This type of reference is also limited to metal electrodes.

The other criteria, namely the low cell resistance and the uniform current distribution (neglecting distortion by the reference electrode), can be more easily met. The impedance of the counterelectrode can be made negligibly small by using a relatively large surface area, and it was completely neglected in the above discussion. The solution resistance can also be made small by using concentrated electrolytes and close electrode spacing; the use of stopcocks between the electrode compartments of the cell should be avoided if possible.

Uniform current distribution can be achieved by a number of geometrical arrangements as given by Kasper (11). A spherical working electrode surrounded by a concentric counterelectrode sphere, or a cylindrical working electrode surrounded by a concentric counterelectrode cylinder with the solution limited to the height of the cylinders, are two possibilities. The counterelectrode does not have to follow exactly the shape of the working electrode if they are sufficiently far removed (12). These two arrangements also have the peculiarity that iR_e can be reduced, for a fixed position of the Luggin tip, by reducing the radius of the working electrode (13, 14). This can be easily shown for the spherical arrangement, with the assumption that the reference electrode distance from the working electrode is large compared to the radius of the working electrode. In this case, R_e will increase with the inverse of the radius, while the area of the electrode will decrease as the square of the radius. Therefore the error, at a given current density, will decrease linearly with the radius. When the reference electrode is closer, and for the cylindrical case, the mathematics is somewhat more complicated, but the effect is in the same direction. An impractically small radius would be needed, however, for fast reactions.

Another way (11) to achieve uniform current distribution is to use parallel plate electrodes with the solution column between them having the same cross section, everywhere along its length, as the shape of the electrodes. Here again the counterelectrode can be of any shape as long as it is far enough removed from the working electrode. For example, if the solution column, having the same cross section as the working electrode, is at least three times as long as the diameter of the working electrode, the shape of the counterelectrode chamber, and the shape and position of the counterelectrode in it, have negligible effect on the current distribution.

Experimental

Cell design.—Among the above designs, the sidehole electrode satisfies best the requirements; but there are some remaining problems. To achieve low R_e, a very fine hole has to be drilled. This still can give considerable R_r, even if the capillary is short; it is not easy to fabricate; and there is possibility of gas bubble blocking, especially with Teflon. Also, it has been pointed out that very low R_e may not be desirable; and with this design, once the cell is assembled, R_e cannot be easily varied.

Extensions of the concept are shown in Fig. 3 and 4. In the first design (Fig. 3) the "sidehole" was extended 360° around to form a conical slot with the two Teflon pieces held apart by suitable spacers. This arrangement would considerably reduce R_r and any blockage problems. It can be used advantageously when a limited area of the large electrode is to be studied. Figure 4 shows the concept of the cell which was actually built. The cell consists of two fluorocarbon plastic pieces. The working electrode is press-fitted into the bottom piece, so as to provide a flush surface with the plastic. The top portion has a cylindrical hole corresponding exactly in position and dimension to the working electrode; this hole leads to the auxiliary electrode chamber. A thin gap between the two pieces, again 360° around, leads to the reference electrode.

A more detailed drawing of the design is shown in Fig. 5, and a photograph is given in Fig. 6. The working electrode (3 mm diameter) is press fitted into a slightly undersized hole to provide a good seal; a backup O-ring seal is also provided. The whole piece can be mechanically polished together to provide a perfectly flush surface, or the electrode can be prepared separately by any desired technique and adjusted flush with the Teflon surface under a microscope, with the adjusting

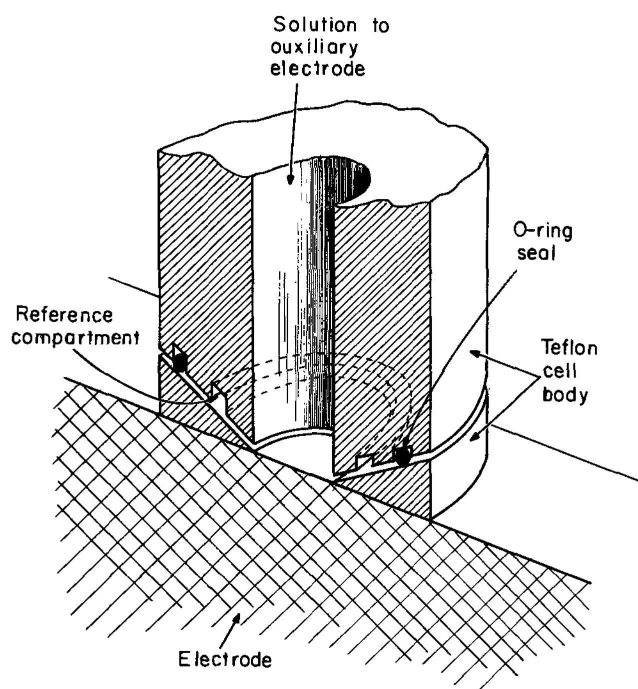

Fig. 3. Extension of the sidehole electrode concept, conical slot reference.

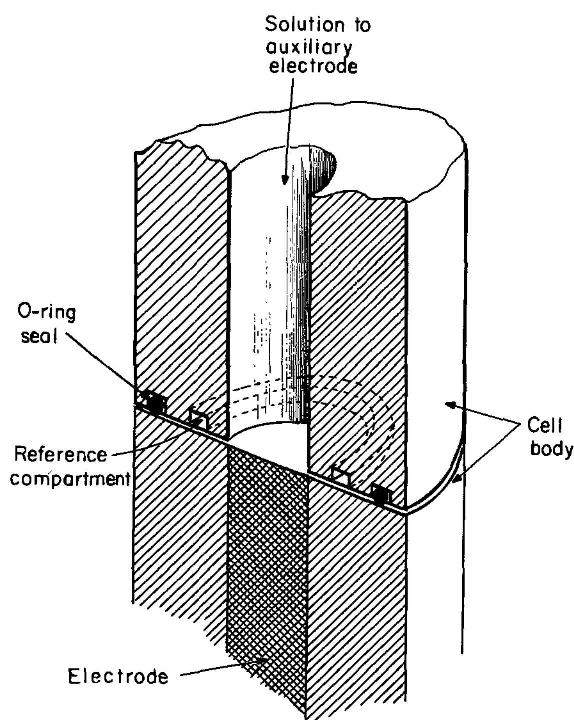

Fig. 4. Extension of the sidehole electrode concept, horizontal slot reference.

screw. Two electrical contacts are provided, one for the current source, the other for potential measurement. This arrangement serves two functions. First, it eliminates the contact resistance which was measured to be about 0.02 ohm, and the resistance of the current lead; these resistances could cause significant iR drop errors. Second, together with the differential input potentiostat (1), it reduces to a minimum the amount of common mode error signal introduced by the inductances of the current leads and by ground loop errors.

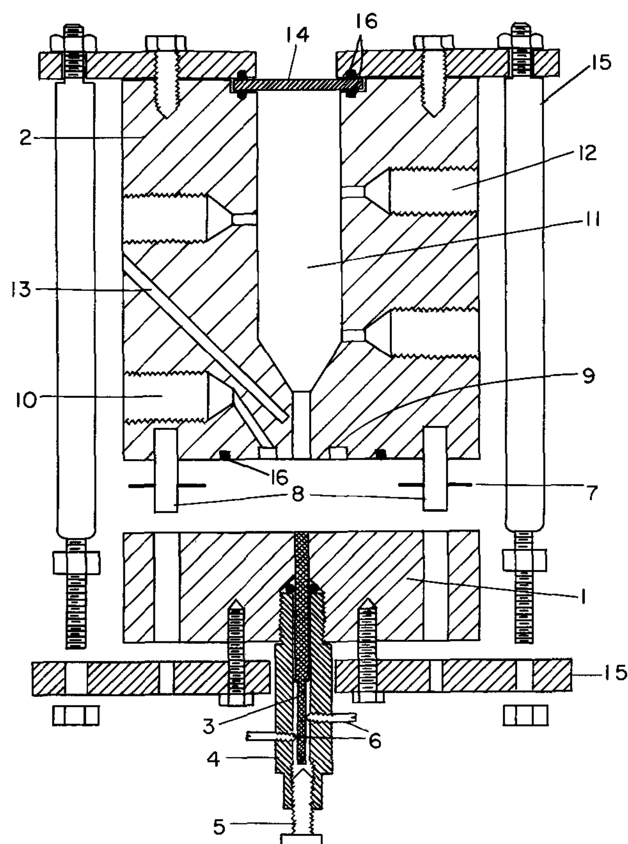

Fig. 5. Exploded cross sectional view of the cell. 1 = Teflon bottom piece; 2 = KEL-F top piece; 3 = working electrode; 4 = nylon bushing; 5 = adjusting screw; 6 = stainless steel contacts; 7 = stainless steel spacer; 8 = stainless steel locating pins; 9 = reference electrode groove; 10 = reference electrode connection, and to vacuum; 11 = auxiliary electrode chamber; 12 = connections for auxiliary electrode, solution inlet, etc.; 13 = hole for illuminating fiber light guide; 14 = observation window; 15 = part of stainless steel frame; 16 = Viton O-rings.

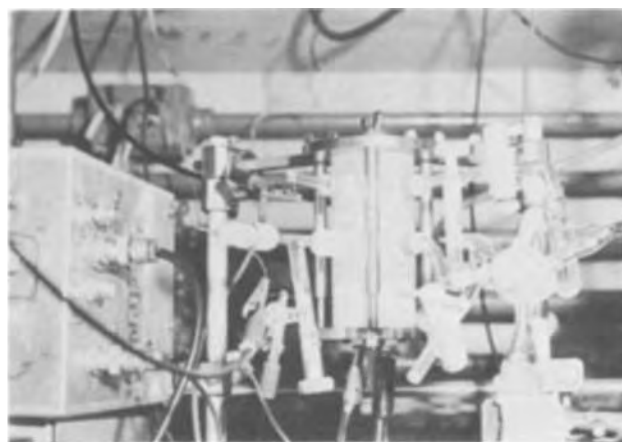

Fig. 6. Photograph of the cell with the potentiostat showing on the left.

The center hole in the top part is three times as long as the diameter of the working electrode. It is surrounded by two concentric grooves. The first one, which contains the reference electrode, is separated by a 1.5 mm wide gap from the center hole. The outside groove contains a Viton O-ring. The gap thickness between the two pieces is controlled by a stainless steel spacer available in thicknesses from 2.5×10^{-3} to 2.5×10^{-2} cm. The gap can also be continuously adjusted slightly

by loosening the nuts on the stainless steel frame holding the two parts together. The exact alignment of the upper and lower parts of the cell is assured by locating pins and by drilling the center hole at the same time in both parts. The auxiliary electrode is a platinum spiral located near the bottom of the auxiliary electrode chamber. The reference electrode in the present work was a metal wire ring in the inner groove. It must be noted here that the reference electrode does not have to form a full ring. As a matter of fact, not only metal wire reference electrodes but any type of reference electrode which can be prepared in micro form can be used (*e.g.*, mercury-coated gold wire for Hg/Hg_2O, Hg/Hg_2Cl_2, or Hg/Hg_2SO_4 electrodes; silver, or silver-coated platinum, for Ag/AgCl electrode; charged palladium, etc.).

The cell can be filled by evacuating it through the reference electrode connection and then sucking solution into the cell. Alternatively, filling with pressure while venting through the reference electrode connection can be used. In either case the solution is forced into the gap. Once the gap is filled, the internal tension will keep the solution in place, in spite of the hydrophobic nature of the surfaces.

Test results.—A set of tests were carried out to check whether the cell achieved the design criteria. The values of R_e, R_s, and R_r were measured and compared to calculated values. A platinum working electrode was polished with the cell bottom to provide a perfectly flush surface. The reference electrode was a zinc wire, and the electrolyte was potassium hydroxide solution. The conductivity of the electrolyte was separately determined. Galvanostatic pulses were applied, and from the resulting potential transient the value of R_e was determined. The values of R_s and R_r were measured with an a-c bridge. Measurements were carried out at a series of solution concentration, gap thickness, and current densities.

The results of R_e measurements are given in Table I. Two examples of the oscillograms are shown in Fig. 7. The value of R_s was measured in 1M KOH giving 70 ohms, the value calculated for the cylindrical channel alone is 60 ohms. The value of R_r was measured also in 1M KOH: 850, 75, and 40 ohms were found for 2.5, 12.5, and 25 $\times$ 10^{-3} cm gaps, respectively. The calculated figures were: 215, 43, and 22 ohms.

Discussion

The data presented above indicate that the design criteria have been met. The R_e value can be reduced to that equivalent to less than 0.0025 cm column of solution. This is much smaller than can be conveniently reached by normal Luggin (about 0.04 cm) (14), and about the same as claimed for the thin wire electrode (10). As can be seen in Table I, R_e is directly proportional to the solution conductivity, increases with gap thickness, and is independent of current density.

Table I. Results of R_e measurements

No.	KOH conc. (M)	d, spacer thickness (cm × 10^3)	Current density (mA/cm²)	R_e (ohm cm²)	d_e, solution height equivalent to R_e (cm × 10^3)	(d_e − ½d) (cm × 10^3)

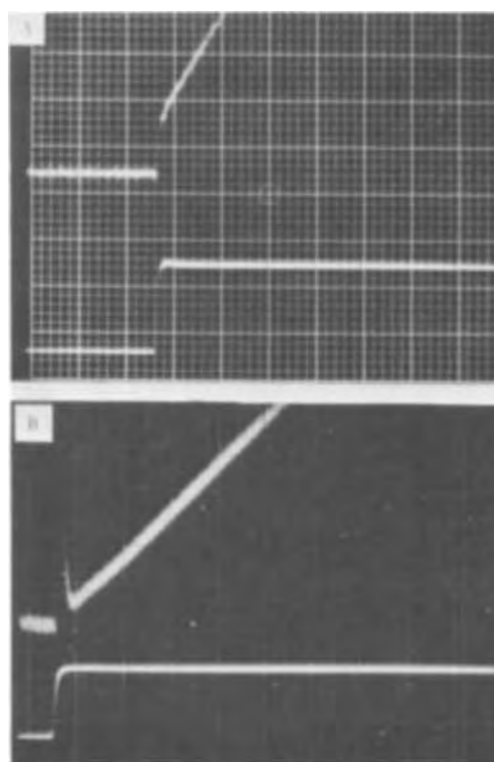

Fig. 7. Examples of R_e measurements. (a) Test No. 1, potential scale = 5 mV/cm; current scale = 2 mA/cm; horizontal = 5 μsec/cm. (b) Test No. 16, potential scale = 10 mV/cm; current scale = 5 mA/cm; horizontal = 5 μsec/cm.

From R_e values an equivalent solution column height was calculated, and compared to the half spacer thickness in Table I. Half of the spacer thickness was used because the reference electrode picks up an average potential over the gap, which should correspond to the midpoint since the current distribution is uniform. At the highest thickness the agreement is good, at the lower values there is an approximately constant error, 2.2 $\times$ 10^{-3} cm in average. This slight error is presumed to be caused by deformation of the plastic cell body under pressure. The frame is exerting a compressing stress on the cell at the edges which might result in a slight expansion of the middle portions, causing the gap to be larger than the spacer. In the examples shown on Fig. 7 a large spike can be seen at the beginning of the potential transient taken with the 0.0025 cm gap. This is due to stray capacitive pickup between the auxiliary and reference electrodes. When the gap is widened to 0.0125 cm this peak completely disappears, because the lowered R_r shunts this capacitive spike to ground.

The value of R_r is also small, in the few hundred ohms range. For a Luggin in the above-quoted (14) minimum thickness, using the same solution, it will be about 4 kohms for every millimeter length of the thinly drawn portion, which could then easily add up to many tens of kilo ohms. The measured gap resistance is about four times that of the calculated for 0.0025 cm gap, and about double for the 0.0125 and 0.025 cm gaps. This discrepancy may be due partially to incomplete filling of the gap by the electrolyte, and partially to the use of less than a full circle of reference wire (the reference wire was forming usually less than a half a circle). The stray capacitances are also reduced as compared to other types of references since heavy plastic blocks separate the electrodes. An important beneficial effect is that C_d is not of a transmission line nature any more but can be represented as a regular (and very small) stray capacitance.

With this cell geometry a compromise has to be reached regarding the requirements of low total cell resistance, and small electrode area. A 3 mm diameter seems reasonable, C_{dl} is then about 2 μf, and since R_e can be lowered to about 0.1 ohm, the R_eC_{dl} time constant is below the microsecond range. At the same time the total cell resistance is reasonably low at 70 ohms for a 1M solution of KOH.

The current distribution over the working electrode surface is uniform, in spite of the nonsymmetrical working-auxiliary arrangement, because of the long channel in front of the working electrode. Note that although the gap will cause some current distortion at the edges of the electrode, this will be very small because of the small thickness of the gap.

Observation of the working electrode is possible with a low power, long working distance, stereomicroscope through the quartz window. Illumination is provided through fiber light guide terminating close to the working electrode in the cell body. The slight transparency of the KEL-F plastic allows the passage of sufficient light.

Further testing of the cell under potentiostatic conditions is to be reported separately (1).

Some further improvements on the cell might be affected. The gap thickness could possibly be further reduced using thinner spacers. This, however, will raise R_r, which could be counteracted by using a less wide gap than the present 1.5 mm. The filling of the gap could be helped by sodium treatments of the gap surfaces to make them less hydrophobic, at the danger of possible introduction of impurities. Placing the reference groove in the lower part of the cell with outlet at the bottom would reduce inductive pickup. The inductive pickup is the function of the area of the loop formed by the reference electrode, working electrode, and connecting leads. When both electrode connections are at the bottom of the cell the loop can be minimized by closely spaced parallel leads. Placing a screen counterelectrode closer to the working electrode, within the channel, would cut down R_s at some sacrifice of current distribution uniformity.

Summary

A cell has been designed and built for potentiostatic transient study of fast electrode reactions which incorporates the following features. Low (and adjustable) error resistance between the point of potential control and the working electrode, a reference electrode having improved high-frequency characteristics, and uniform current distribution over the working electrode surface.

Mass Transfer to a Rotating Sphere at High Schmidt Numbers

John Newman*

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The Lighthill transformation is used to calculate limiting rates of mass transfer to a rotating sphere on the basis of shear-stress calculations found in the literature.

Chin (1) has recently calculated rates of mass transfer to a rotating sphere on the basis of calculated velocity profiles from the literature. Near the poles of the sphere, the situation is essentially identical to a rotating disk. Chin has calculated also the next term in an expansion for small values of θ, the angle from the pole. He takes the Schmidt number to be large, a good approximation for electrolytic solutions.

This is an excellent situation in which to use the Lighthill transformation (2-4) to calculate the mass-transfer rate at angles θ which need not be small. For high Schmidt numbers, the diffusion layer is much thinner than the hydrodynamic boundary layer, and the shear stress or the velocity derivative at the wall

$$\beta = \frac{\partial v_\theta}{\partial r}\bigg|_{r = r_0} \quad [1]$$

provides sufficient information about the velocity profiles to permit the calculation of a first approximation to the mass-transfer rate. For axisymmetric bodies, this result takes the form (4)

$$i_n = \frac{n\mathbf{F}D_i c_\infty \sqrt{\mathcal{R}\beta}}{s_i \Gamma(4/3)} \Bigg/ \left[9D_i \int_0^x \mathcal{R}\sqrt{\mathcal{R}\beta}\, dx \right]^{1/3} \quad [2]$$

* Electrochemical Society Active Member.

Key words: current distribution, limiting current.

where x is the distance along the electrode from its upstream end, $\mathcal{R}(x)$ is the normal distance of the surface from the axis of symmetry, and s_i is the stoichiometric coefficient of the limiting reactant in the electrode reaction

$$\sum_i s_i M_i^{z_i} \rightarrow ne^- \quad [3]$$

This result applies at high Schmidt numbers to the limiting current density i_n when the effect of ionic migration on the limiting reactant can be ignored. Thus, the concentration of the limiting reactant is zero at the electrode surface and equal to c_∞ in the bulk solution outside the diffusion layer.

For a sphere

$$\mathcal{R} = r_0 \sin\theta \text{ and } x = r_0\theta \quad [4]$$

If we define a dimensionless shear-stress distribution $B(\theta)$ according to

$$B(\theta) = \beta\nu^{1/2}/r_0\Omega^{3/2} \quad [5]$$

then Eq. [2] can be written as

$$\mathrm{Nu}(\theta) = \frac{2r_0 s_i i_n}{n\mathbf{F}D_i c_\infty} = \frac{2\sqrt{B\sin\theta}\,\mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3}}{\Gamma\left(\frac{4}{3}\right)\left[9\int_0^\theta \sqrt{B\sin\theta}\,\sin\theta\,d\theta\right]^{1/3}} \quad [6]$$

where $\mathrm{Nu}(\theta)$ is the local Nusselt number, $\mathrm{Re} = r_0^2\,\Omega/\nu$ is the Reynolds number, and $\mathrm{Sc} = \nu/D_i$ is the Schmidt number. For an electrode extending from the pole to the angle θ, we can define the average Nusselt number $\mathrm{Nu}_{\mathrm{avg}}$ analogously in terms of the average current density. Appropriate integration of Eq. [6] yields

$$\mathrm{Nu}_{\mathrm{avg}} = \frac{3^{1/3}\,\mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3}}{\Gamma(4/3)\,(1-\cos\theta)}\left[\int_0^\theta \sqrt{B\sin\theta}\,\sin\theta\,d\theta\right]^{2/3} \quad [7]$$

Banks (5) has solved the boundary-layer equations for a rotating sphere and expresses the shear-stress distribution in an expansion for small θ

$$B(\theta) = 0.51023\,\theta - 0.22129\,\theta^3 + 0.02071\,\theta^5 - 0.00189\,\theta^7 \quad [8]$$

Manohar (6) has solved the boundary-layer equations numerically and gives a graph of the shear-stress distribution. His results should be better than those of Banks when the angle θ is not small.

On the basis of these results, we have expressed B as

$$B(\theta) = 0.51023\,\theta - 0.1808819\,\theta^3 - 0.040408\,\sin^3\theta \quad [9]$$

as shown in Fig. 1. For small values of θ, this reduces to

$$B(\theta) = 0.51023\,\theta - 0.22129\,\theta^3 + 0.020204\,\theta^5 - 0.00438\,\theta^7 + O(\theta^9) \quad [10]$$

and approximates well Bank's expression 8 for the first three terms. Figure 1 can be compared with the graph given by Manohar (6).

The local and average Nusselt numbers are now obtained from Eq. [6] and [7] by carrying out the integration with $B(\theta)$ given by Eq. [9]. The results are shown in Fig. 2 along with Chin's result for the local Nusselt number. Chin obtained correctly the first two terms for the local Nusselt number in an expansion for small values of θ. However, he predicts too high a mass-transfer rate near the equator of the sphere. Thus, his value of 0.474 for $\mathrm{Nu}_{\mathrm{avg}}/2\mathrm{Re}^{1/2}\mathrm{Sc}^{1/3}$ for a sphere or a hemisphere should be replaced by the value of 0.4508.

The boundary-layer results do not predict that the shear stress goes to zero at the equator, as it must. Thus, there must be a small region near the equator

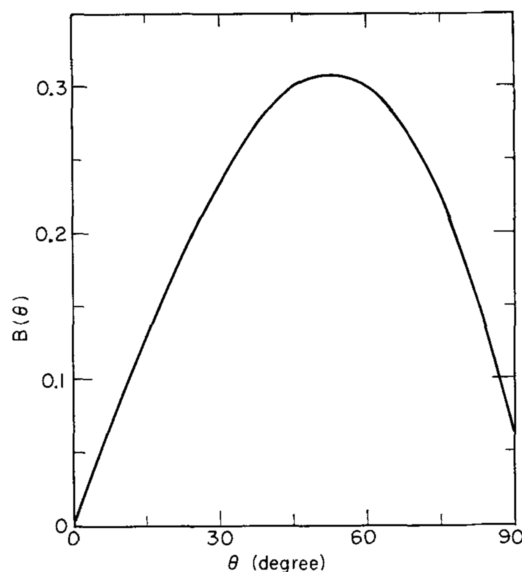

Fig. 1. Dimensionless velocity derivative on the surface of a rotating sphere.

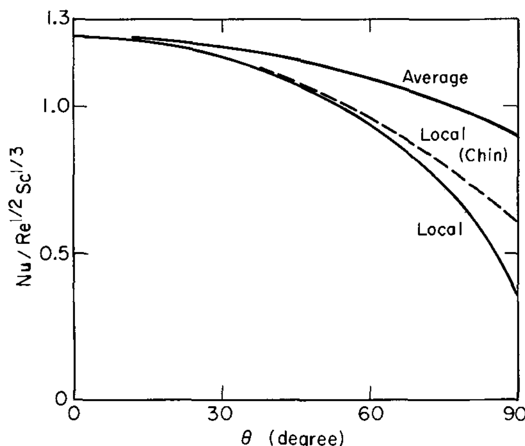

Fig. 2. Local and average Nusselt numbers for a rotating sphere at high Schmidt numbers, calculated from the shear stress results of Manohar. The local Nusselt numbers obtained from Chin's analysis are shown for comparison.

where B goes from the value predicted by boundary-layer theory to zero at the equator itself. This will lower the mass-transfer rates predicted for this region.

These results can be extended to metal deposition on a rotating sphere at the limiting current from a solution of a single electrolyte by redefining the local Nusselt number as

$$\mathrm{Nu}(\theta) = \frac{(1-t_+)\,2r_0 i_n}{z_+\mathbf{F}Dc_\infty} \quad [11]$$

and replacing the Schmidt number by $\mathrm{Sc} = \nu/D$, where D is the diffusion coefficient of the electrolyte and z_+ and t_+ are the charge number and transference number of the reacting cation.

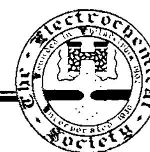
Technical Notes



Interstitial Silver Ions and Standard Potentials

Arnold Hoffman*

Research Laboratories of Polaroid Corporation, Cambridge, Massachusetts 02139

It has been suggested by Awad *et al.* (1) that the potential of a silver electrode is likely to vary with the activity of interstitial silver ions, $Ag^+{}_i$, in an adhering silver halide crystal in a manner analogous to the activity of silver ions, Ag^+, in solution.

Subsequently, we had shown (2) that if it is assumed that the chemical potentials of silver lattice positions in silver halides can be equated and considered as a reference state, a relationship is obtained between the standard Gibbs-Stockholm potentials, E^o, of a silver-silver halide electrode and the $Ag^+{}_i$ composition in the silver halide crystal, *i.e.*

$$E^o = RT/n\mathbf{F} \ln 1/X_i + B + C \qquad [1]$$

where

$RT/N\mathbf{F}$ = 0.059V at room temperature

B = $RT/2n\mathbf{F} \ln \beta$ (β = number of available interstitial sites per silver ion lattice site). The range of values of X_i is relatively large compared to the small differences in the value of B. Therefore, B can be treated as a constant.

C = Constant, assuming the energy of a silver ion lattice position can be taken as the reference state for all silver halides.

X_i = N_i/N_1

N_i = Concentration of $Ag^+{}_i$, (number/cm³)

N_1 = Concentration of silver ions at lattice positions; for all the silver halides $N_1 >> N_i$ and the value of N_1 are approximately equal to each other, therefore X_i can be expressed as N_i.

or

$$E^o = RT/n\mathbf{F} \ln 1/N_i + D \qquad [2]$$

where

D = $B + C + RT/n\mathbf{F} \ln N_1$ = Constant

* Electrochemical Society Active Member.

Key words: silver halides, interstitial silver ions, Frenkel defects, standard potentials.

Equation [2] predicts that a plot of the standard potentials, E^o *vs.* the log of the concentration of interstitials, N_i, should give a straight line with a slope equal to −59 mV (at room temperature).

The standard potentials for the various silver halides are listed relative to NHE (3) in Table I. There exists two modifications of AgI at room temperature, a hexagonal β-phase and a cubic γ-phase (4). Ruby and Tremmel (5) using cathodic cyclic voltammetry with carbon paste silver halide electrodes obtain two current peaks for their AgI results. We have assumed that these two peaks reflect the reduction potential of the two modifications of AgI. These values differ from the value usually tabulated for an unspecified form of AgI [−0.152V (3)].

Also listed in Table I are the concentration of interstitial silver ions obtained by several workers.

The data were obtained in the following ways:

(*A*) The slope of plot of ionic conductivity *vs.* the log $1/T$ which reflects, in part, the free-energy difference of a silver ion in a lattice and interstitial position (6).

(*B*) Applying a model of a diffuse space charge near the crystal surface to measurements of: (*i*) surface charge or zeta-potential of silver halide as a function of pAg using Grimley's theory (4), and (*ii*) dependence of latent-image distribution on an electric field as applied by Trautweiler (7).

A plot of E *vs.* log N_i is shown in Fig. 1. The straight line drawn through the points has a slope

Table I.

AgX	E (*vs.* NHE) volts	N_i	Reference
AgCl	+0.222	6×10^{10}-6×10^{11}	(6)
AgBr	+0.071	5×10^{14}-8×10^{14}	(6-9)
β-AgI	−0.099 ± 5	2.5×10^{16}-2.5×10^{18}	(4)
γ-AgI	−0.189 ± 5	2×10^{10}-3×10^{19}	(4)

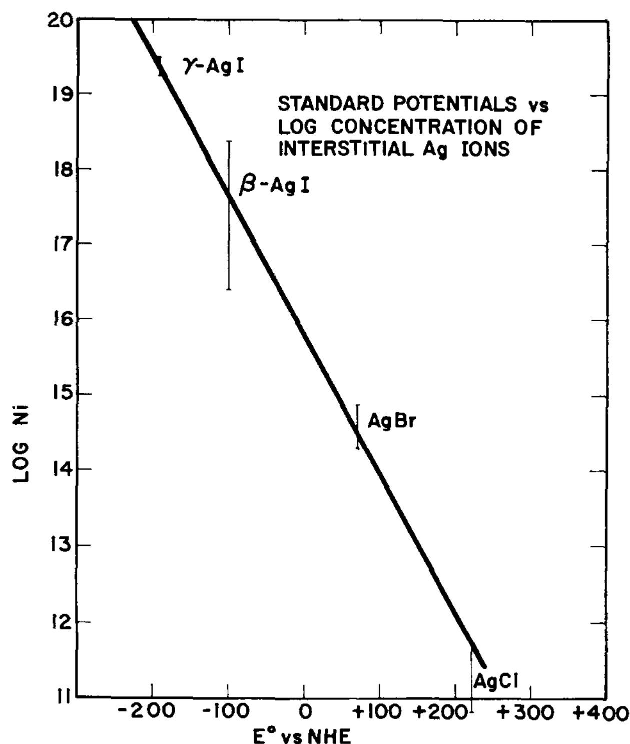


Fig. 1.

equal to about −55 mV, in good agreement with Eq. [2].

Thus, the model proposed by Honig *et al.*, that the silver halide lattice can be treated as a solvent, and the vacancies and interstitial ions as solute anions and cations, respectively, is justified.

The apparent validity of Eq. [2] suggests that any materials incorporated into a silver halide lattice that can change the concentration of interstitials should manifest a potential different from that of an undoped silver halide

Teltow (10) has shown that the incorporation of small amounts of Cd^{++} [<0.01 mole per cent (m/o) $CdBr_2$] into AgBr decreased the ionic conductivity. An extrapolation of his data to room temperature indicates a reduction of Ag^+_i by a factor of three to five at a concentration of 0.01 m/o $CdBr_2$. Since the ionic conductivity of silver halides (in this range of impurity concentration) is proportional to the concentration of interstitial silver ions, it may be concluded that in this range of concentration of Cd^{++}, the concentration of Ag^+_i has been reduced by a factor of three to five.

It has been reported (11) that the cathodic characteristic potential of silver halides, formed in the presence of Cd^{++} (rinsed and reduced in KNO_3) were always more anodic (~30 mV for AgBr) compared to that obtained in the formation of the silver halide in the absence of Cd^{++}. (The actual amount of Cd^{++} incorporated into the silver halides was not measured.) This is equivalent to stating that the E^o is more positive (~30 mV for AgBr) for the silver halide formed in the presence of Cd. The line in Fig. 1 predicts that a change of +30 mV for the E^o of a silver halide (*e.g.* AgBr) should be accompanied by a reduction of the concentration of Ag^+_i by a factor of 3.2. Thus, it would be expected that the level of Cd^{++} incorporated into the silver halide electrochemically is of the order of $\leq$0.01 m/o $CdBr_2$. Quantitative data would be necessary to verify this.

Acknowledgments

The author expresses his grateful appreciation to Dr. P. van Heerden and Dr. L. Cerankowski for helpful discussions and encouragement.

Manuscript received Nov. 4, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Interactions in Mixed Potential Systems

Francis M. Donahue*

Department of Chemical Engineering, The University of Michigan, Ann Arbor, Michigan 48104

Interactions between the anodic and cathodic partial processes in mixed potential systems, *e.g.* corrosion or electroless plating, can be ascertained from extensive studies of the electrodekinetics of the respective partial processes [*e.g.* see Ref. (1)]. During electroless plating studies, the author and co-workers (2, 3) found that the interactions could be deduced without extensive electrodekinetic studies. Because of the general interest in mixed potential systems and a need for a relatively rapid method of deducing the magnitude of interactions among the reactants (if present), the pertinent relationships for this analysis are derived in this paper.

Consider the following generalized mixed potential system

$$\mathrm{Red}_a + \mathrm{Ox}_c \rightarrow \mathrm{Ox}_a + \mathrm{Red}_c \qquad [1]$$

To continue the generality, it will be assumed that both reactants of the mixed potential system interact in both of the partial processes. Thus, the respective rate laws may be written as

$$-r_a = k_a\,[\mathrm{Red}]_a{}^{\gamma}\,[\mathrm{Ox}]_c{}^{\delta_1} \qquad [2]$$

and

$$-r_c = k_c\,[\mathrm{Ox}]_c{}^{\delta}\,[\mathrm{Red}]_a{}^{\gamma_1} \qquad [3]$$

The mixed current density for such a system is

$$i_m = \mathbf{F}n_a\,k^o{}_a\,[\mathrm{Red}]_a{}^{\gamma}\,[\mathrm{Ox}]_c{}^{\delta_1}\exp\left[\frac{\psi_o - \phi^o{}_a}{\beta_a}\right] \qquad [4a]$$

$$i_m = \mathbf{F}n_c\,k^o{}_c\,[\mathrm{Ox}]_c{}^{\delta}\,[\mathrm{Red}]_a{}^{\gamma_1}\exp\left[\frac{\phi^o{}_c - \psi_o}{\beta_c}\right] \qquad [4b]$$

* Electrochemical Society Active Member.

Key words: corrosion, electrochemical reaction orders, electrodekinetics, electroless plating, rate equations.

Equating [4a] and [4b], taking logarithms and rearranging

$$\psi_o = \frac{b_a b_c}{b_a + b_c} \left\{ \frac{\phi^o{}_c}{b_c} + \frac{\phi^o{}_a}{b_a} + \log \left[\frac{(n k^o)_c}{(n k^o)_a} \right] + (\delta - \delta_1) \log [\mathrm{Ox}]_c - (\gamma - \gamma_1) \log [\mathrm{Red}]_a \right\} \quad [5]$$

Partial differentiations of Eq. [5] yield

$$\left[\frac{\partial \psi_o}{\partial \log [\mathrm{Ox}]_c} \right]_{[\mathrm{Red}]_a, T} = (\delta - \delta_1) \frac{b_a b_c}{b_a + b_c} \quad [6]$$

and

$$\left[\frac{\partial \psi_o}{\partial \log [\mathrm{Red}]_a} \right]_{[\mathrm{Ox}]_c, T} = -(\gamma - \gamma_1) \frac{b_a b_c}{b_a + b_c} \quad [7]$$

Further useful relationships may be obtained by taking the logarithms of Eq. [4a] and [4b], solving for ψ_o, equating the results and rearranging to obtain

$$\log i_m = \frac{1}{b_a + b_c} \{\phi^o{}_c - \phi^o{}_a + b_c \log [\mathbf{F}(nk^o)_c] + b_a \log [\mathbf{F}(nk^o)_a] + (b_c\delta + b_a\delta_1) \log [\mathrm{Ox}]_c + (b_a\gamma + b_c\gamma_1) \log [\mathrm{Red}]_a\} \quad [8]$$

Partial differentiations of Eq. [8] yield

$$\left[\frac{\partial \log i_m}{\partial \log [\mathrm{Ox}]_c} \right]_{[\mathrm{Red}]_a, T} = \frac{b_c\delta + b_a\delta_1}{b_a + b_c} \quad [9]$$

and

$$\left[\frac{\partial \log i_m}{\partial \log [\mathrm{Red}]_a} \right]_{[\mathrm{Ox}]_c, T} = \frac{b_a\gamma + b_c\gamma_1}{b_a + b_c} \quad [10]$$

Finally, dividing Eq. [6] by [9] and Eq. [7] by [10] give the following

$$\left[\frac{\partial \psi_o}{\partial \log i_m} \right]_{[\mathrm{Red}]_a, T} = \frac{b_a b_c (\delta - \delta_1)}{b_a\delta_1 + b_c\delta_1} \quad [11]$$

and

$$\left[\frac{\partial \psi_o}{\partial \log i_m} \right]_{[\mathrm{Ox}]_c, T} = -\frac{b_a b_c (\gamma - \gamma_1)}{b_a\gamma + b_c\gamma_1} \quad [12]$$

Equations [6], [7], and [9]-[12] represent diagnostic criteria which can be used to evaluate the properties of mixed potential systems. In particular, these relationships permit the determination of the symbiotic effects of the partial processes.

Mathematically, the six equations noted above represent only four independent relationships. However, they do represent six "independent" combinations of experimental data points. Since there are six "unknowns" in the equations, *viz.* b_a, b_c, γ, γ_1, δ, and δ_1, it is more correct mathematically to evaluate two of the parameters independently of the mixed potential measurements. While the author does not wish to impose his bias on the reader, it is usually simpler to measure the Tafel slopes independently.

In order to demonstrate the utility of the technique two examples will be given. Kelly (1) studied the dissolution of iron in acidic solutions. From a separate study of the anodic partial process, he had ascertained that the rate law for iron dissolution was

$$-r_{\mathrm{Fe}} = k_{\mathrm{Fe}}[\mathrm{H}^+]^{-1} \quad [13]$$

From Eq. [3], one deduces that $\delta_1 = -1$. His Eq. [22] is similar to Eq. [6] of this paper; likewise, Fig. 6 of his paper represents the data required for Eq. [6] of this paper. Solving Eq. [6] using the data in his figure and his observed Tafel slopes, one deduces that $\delta = 1$, which is consistent with all known data for hydrogen evolution on iron.[1]

[1] Kelly clearly saw the potentiality of combining certain rate data with measurements at the mixed potential to deduce "unmeasured" reaction orders. However, his derived relationships, being specific to his system, lacked the appearance of generality.

Experiments in the author's laboratory (2-4) on electroless nickel plating led to the following conclusions: (*i*) nickel ions have no effect on the anodic partial process, and (*ii*) hypophosphite ions interact with the cathodic partial process with a calculated reaction order of 0.7. These conclusions were based upon determinations of the six diagnostic criteria derived above, the Tafel slope for nickel ion reported by Yeager and co-workers (5) and the assumption that $b_a > b_c$ [based on the "polarization curves" of Donahue and Yu (4)].

The foregoing analysis is general for all mixed potential systems. It is predicated upon (*i*) the commonly accepted principle that the rates of all electrochemical reactions at the mixed potential satisfy the requirement of charge conservation first enunciated by Wagner and Traud (6), and (*ii*) the commonly accepted principle that rate laws can be written for postulated chemical reactions in a general form using empirical reaction orders. A final assumption, which cannot be avoided in this analysis, is that the Tafel slopes for the respective partial processes in the mixed potential system are not different from those observed in separate electrodekinetic studies. This assumption can be verified, however, by polarizing the mixed potential system and observing the respective Tafel slopes. More complex mixed potential systems, *e.g.* those involving more than two partial processes, reduce to equations similar in form to the equations derived here (7).

Manuscript received April 12, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

LIST OF SYMBOLS

b_a	anodic Tafel slope ("base 10"), V
b_c	cathodic Tafel slope ("base 10"), V
$\mathbf{F}$	Faraday constant, 96,500 coulombs/g equiv.
$[\mathrm{H}^+]$	concentration of hydrogen ions, M
i_m	mixed current density, $\mathrm{A/cm^2}$
k_a	specific rate constant for the anodic partial process, units dependent upon reaction orders and concentration units
$k^o{}_a$	specific rate constant for anodic partial process at the standard electrode potential, (see k_a for units)
k_c	specific rate constant for the cathodic partial process, (see k_a for units)
$k^o{}_c$	specific rate constant for the cathodic partial process at the standard electrode potential, (see k_a for units)
k_{Fe}	specific rate constant for iron dissolution, g mole iron − g mole $\mathrm{H^+/cm^2}$ 1 − sec
n_a	number of gram equivalents produced/g mole of anodic material reacted
n_c	number of gram equivalents produced/g mole of cathodic material reacted
Ox_a	product of the anodic partial process
Ox_c	reactant of the cathodic partial process
$[\mathrm{Ox}]_c$	concentration of Ox_c, M
Red_a	reactant of the anodic partial process
Red_c	product of the cathodic partial process
$[\mathrm{Red}]_a$	concentration of Red_a, M
$-r_a$	rate of the anodic partial process, g mole/$\mathrm{cm^2}$ sec
$-r_c$	rate of the cathodic partial process, g mole/$\mathrm{cm^2}$ sec
$-r_{\mathrm{Fe}}$	rate of the iron reaction, g moles iron/$\mathrm{cm^2}$ sec
β_a	anodic Tafel slope ("base e"), V
β_c	cathodic Tafel slope ("base e"), V
γ	reaction order with respect to the anodic reactant in the anodic partial process, dimensionless
γ_1	reaction order with respect to the anodic reactant in the cathodic partial process, dimensionless
δ	reaction order with respect to the cathodic reactant in the cathodic partial process, dimensionless
δ_1	reaction order with respect to the cathodic reactant in the anodic partial process, dimensionless

ϕ^o_a standard electrode potential of the anodic partial process, V
ϕ^o_c standard electrode potential of the cathodic partial process, V
ψ_o mixed potential, V

Brief Communications

The Carbon Cloth Electrode

R. Hand, A. K. Carpenter, C. J. O'Brien, and R. F. Nelson[*,1]

Department of Chemistry, Sacramento State College, Sacramento, California 95819

For some time, we have been using carbon cloth electrodes for coulometry and preparative scale electrolytic work. This is a woven graphite material that comes in large rolls from the Carbon Products Division of Union Carbide Corporation.

The carbon cloth appears generally to have the electrochemical properties of other carbon electrodes as far as working ranges in various solvents go. We have used it primarily for anodic work in aqueous and nonaqueous media; however, it functions well for cathodic work in the few systems that we have investigated. The electrochemical area is about 3 cm^2/cm^2 geometrical area and the material stands up well under relatively high current densities. We have passed currents of 100 mA/cm^2 during controlled-potential preparative-scale electrolytic work with no apparent damage to the electrode. Filming does not appear to be any more of a problem with carbon cloth than with other electrodes; in fact, we have had somewhat better luck with it than with platinum with regard to filming by electrolysis products. A striking example of this is in the anodic oxidations of indole and tryptophan in aqueous buffer solution. At a platinum gauze electrode filming ensues from the start of the electrolysis and the currents obtained are very low, thus forcing a prolonged electrolysis. Upon substituting a carbon cloth electrode, however, much higher electrolysis currents were realized and the time of electrolysis was shortened dramatically.

The cloth is relatively inexpensive, so one can simply cut out a piece according to how much is needed and discard it after the electrolysis; alternately, the electrodes can be reused a number of times.

The major drawbacks to the cloth are that it is not readily suited for routine electrochemical work in chronoamperometry, cyclic voltammetry, etc., and it has poor mechanical strength. Because of its configuration, convection begins in acetonitrile after 2-3 sec and rapidly becomes a serious problem. In addition, the electrochemical area is relatively large for a small piece of cloth and this may lead to solution *IR* drop and amplifier limitation problems. In addition, at high cell currents of 5-20A, the resistance of the cloth, normally just a few $ohms/cm^2$, leads to markedly uneven current distribution and poor potential control. However, at "ordinary" current levels, this is no problem at all.

Because it is a woven material, one needs a fairly large piece so that it will hold together. Contact can normally be made through an alligator clip, but it has to be firmly affixed. Because of the poor mechanical strength and the woven nature of the cloth, shredding occurs readily; this would obviously lead to problems in quantitative electrochemical work, since the area is changeable.

For precision coulometric studies the cloth electrode is more than satisfactory; background currents are negligible and the high surface area facilitates electrolysis. We had occasion to carry out low-concentration coulometric n-value studies on oxidations of a large series of substituted carbazoles using first platinum and then carbon cloth working electrodes. The n-value determinations were pretty much the same in both cases, but the pre-electrolysis background currents were considerably lower at the carbon cloth. The major use to which we have put the carbon cloth is for preparative-scale electrolyses. It is ideal for this type of work since one can readily vary the electrode configuration and surface area from one run to the next. Studies in both stirred solutions and flow systems have been very satisfactory.

Since the material is inexpensive (about $35 per pound—and a pound makes a lot of electrodes!) and readily adaptable to a number of electrochemical applications, the carbon cloth electrode may be of considerable use to practical electrochemists.

Acknowledgment

It should be noted that to our knowledge the first use of carbon cloth for electrochemical work was in the laboratory of Dr. R. N. Adams at the University of Kansas. Financial support of this work through NSF grant No. GP-20606 is gratefully acknowledged. Special thanks are also due to Drs. R. N. Adams and D. E. Smith for their support and encouragement.

Manuscript submitted May 21, 1971; revised manuscript received ca. Sept. 24, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Torsion Effusion Determination of Sodium Partial Pressure Over Na_2O

V. Piacente, A. Desideri, and G. Bardi

Laboratorio di Chimica Fisica ed Elettrochimica, Università di Roma, Rome, Italy

The evaporation process of Na_2O has been investigated by several authors (1-5) who have shown that this oxide evaporates according to the scheme

$$Na_2O(l) \rightarrow 2Na(g) + \tfrac{1}{2}O_2(g) \qquad [1]$$

Mass-spectrometric investigation have shown moreover that in the vapor phase NaO and Na_2O molecules are in the ratio $P_{Na}/P_{NaO} \cong P_{Na}/P_{Na_2O} \cong 10^4$. No good agreement was noted between the Na partial vapor pressures from Brewer and Margrave (3) and Hildenbrand and Murad (4) and the ones measured by Kroger and Stratmann (5).

In order to utilize this oxide for a direct mass-spectrometric determination of sodium activity in an alloy utilizing a twin cell (6, 7), we were induced to carry out pressure measurement of the vapor over $Na_2O(l)$ utilizing a torsion-effusion apparatus.

The torsion effusion method was originated by Volmer (8) and the principle of the method has been described elsewhere (9, 10).

Vapor pressures were calculated from the torsion effusion data by means of the equation

$$P = 2k\alpha/(a_1d_1f_1 + a_2d_2f_2) \qquad [2]$$

where P is the pressure, α the deflection, k the torsion constant of the suspension, a_1, a_2, d_1, and d_2 the orifice areas and distances from the axis of rotation and f_1 and f_2 the Freeman and Searcy (11) correction factors for orifice geometry.

In this experiment, cells of MgO, placed in a graphite container, were employed. The temperature was measured with a Pt, Pt-Rh 10% thermocouple inserted in a second container, similar to the one already mentioned and placed beneath it. The details of the effusion cell are given in Table I. Total vapor pressures from 1.2×10^{-5} to 2.0×10^{-4} atm obtained in the temperature range 1144°-1304°K are reported in Table II.

All calculated thermodynamic functions were based on the assumption that no significant number of gaseous oxide molecules were present in the vapor phase. The K_p values of reaction [1] have been calculated from $K_p = 0.286\ P_{tot}^{5/2}$. Calculations of $\Delta H°_{298}$ for reaction [1], reported in Table II, are made from the equation

$$\Delta H°_{298}/T = -R \ln K_p - \Delta[(G°_T - H°_{298})/T] \qquad [3]$$

The free energy function values, $(G°_T - H°_{298})/T$, used for these calculations were taken from the JANAF tables (1967) (12) and are reported in Table II. An average third law value of $\Delta H°_{298} = 149.2 \pm 0.4$ kcal/mole was obtained by this method (Table II).

Key words: vapor pressure, sodium vapor, sodium oxide.

A second law treatment of K_p for reaction [1] yields a $\Delta H°_T$ value at 1224°K of 136.4 ± 3.5 kcal/mole which corresponds to $\Delta H°_{298} = 145.2 \pm 3.5$ kcal/mole calculated utilizing the $(H°_T - H°_{298})$ values reported in the JANAF tables (12).

A weighted average of the second law and third law values gives $\Delta H°_{298} = 149 \pm 2$ kcal/mole, in agreement with the third law value of $\Delta H°_{298} = 151.1 \pm 1.5$ kcal/mole obtained utilizing Hildenbrand and Murad's data (4).

The partial vapor pressure of sodium obtained from our total vapor pressures is somewhat less than the literature data (Fig. 1 open circles and squares), but does not show a very wide difference from Hildenbrand's value (black squares).

Considering the uncertainties associated with the applied measuring methods and with the instrumental sensitivity, for instance, the uncertainties in the Freemen factor or the effusion orifice area and with the relative cross section of Na(g) [about a factor 2 (13)] in Hildenbrand's data, we can conclude that our values are in good agreement with those proposed by this author.

In Fig. 1 a straight line which takes into account Hildenbrand's values and ours, is plotted. We propose this line as representative of the variation of the sodium partial vapor pressure with temperature over liquid Na_2O. The slope, 1.192×10^4, was found by least-squares from our data, and is in good agreement with that obtained from the pressure values of Hildenbrand (1.178×10^4). Differences were found in the absolute values of the partial pressures of Na(g). However, considering the uncertainties of the measurements made by the two methods, the two sets should be considered as being in agreement, all the more so that Hildenbrand used a mass spectrometer which was not very

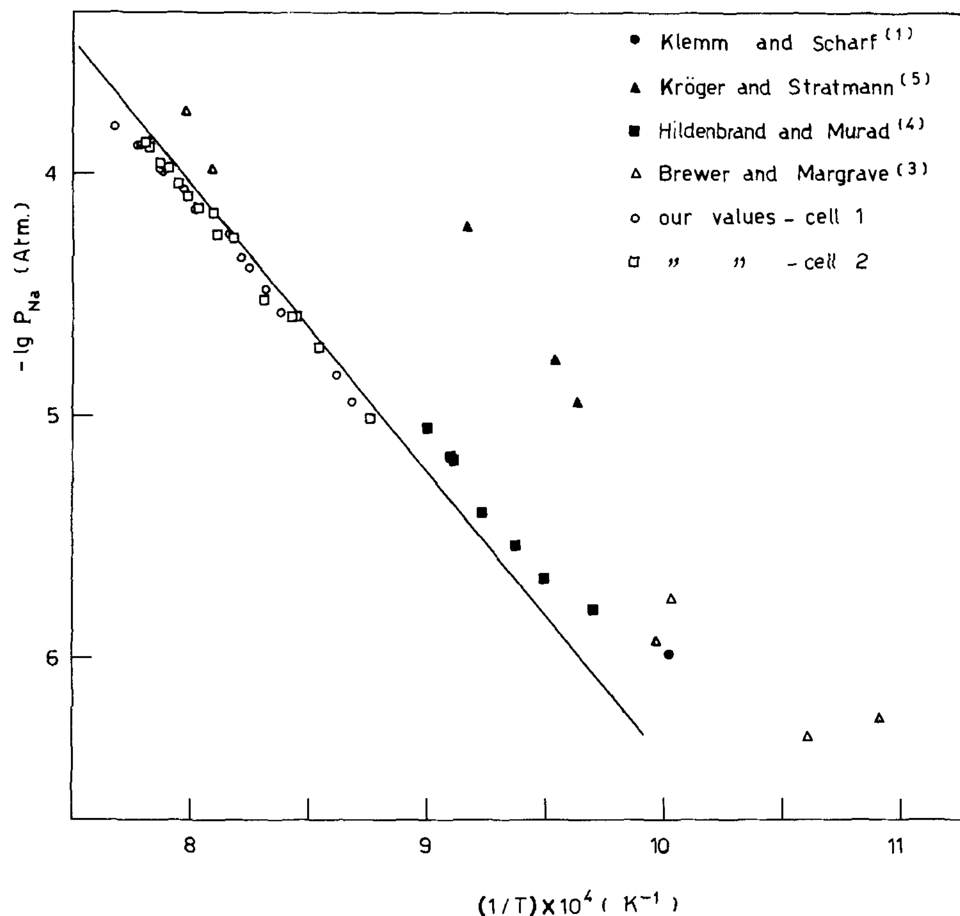

Fig. 1. Na (g) partial pressure over Na_2O(c) between 1150° and 1300°K. The equation of the straight line is log P(atm) = 5.49 — 1.192 x 10^4/T.

sensitive for absolute measurements. Therefore Fig. 1 shows an intermediate line drawn with the same slope as the two experimental lines. The pressure values of the other observers are also shown for comparison; they were not considered in the selection of the line.

LIST OF SYMBOLS

α	Deflection angle, radiant
a	Orifice area, cm^2
d	Distance of the effusion orifice from the axis of rotation, cm
T	Absolute temperature, Kelvin
P	Partial pressure of gaseous species, atm
K_p	Equilibrium constant of reaction
ΔH°_{298}	Standard enthalpy of reaction at 298°K, kcal/mole
$\Delta[(G^\circ_T - H^\circ_{298})/T]$	Free energy function variation for the specified reaction, eu
$(H_T - H^\circ_{298})$	Enthalpy variation between 298°K and T°K, kcal/mole

SUMMARY OF ΔH VALUES

"Second law"	Evaluation of ΔH°_T value of the specified reaction utilizing the van't Hoff equation in the investigated temperature range.
"Third law"	Evaluation of ΔH°_{298} value of the specified reaction utilizing the Gibbs-Helmholtz equation in the form

$$\Delta H^\circ_{298} = \Delta G^\circ_T - T[\Delta(G^\circ_T - H^\circ_{298})/T]$$

together with $[(G^\circ_T - H^\circ_{298})/T]$ values from the JANAF Tables (12).

Ionic Conduction and Oxygen Diffusion in Yellow Lead Oxide

ABSTRACT

Electrical conduction in yellow lead oxide has been studied between 500° and 800°C and ionic and electronic contributions separated by means of transport and EMF techniques. The electronic conductivity depends on oxygen partial pressure and on doping. Its dependence on the oxygen pressure is markedly different for samples doped with bismuth or with potassium. It increases with pressure in K-doped samples; approximately as $P^{1/n}$ with n between 4 and 6. In Bi-doped samples a decrease is found wih n between -4 and -6. Information on ionic conduction stems mainly from transport number determinations with the EMF technique. It was found that the ionic conduction, which is carried by oxygen, is independent of the oxygen pressure and increases on the addition of bismuth. Self-diffusion measurements of oxygen were carried out using the isotope exchange method. It was found that the exchange at the surface is too slow with oxygen gas, but a diffusion-controlled exchange rate could be obtained with a carbon dioxide gas. The results correspond well with those given by Thompson and Strong; the self-diffusion coefficient at 787°K amounts to about 10^{-10} cm²/sec. Doping with bismuth increases this value, whereas an influence of potassium dope is not so evident. No influence of the oxygen pressure could be found. Although doping with bismuth causes similar changes in the ionic conductivity and in the self-diffusion of oxygen, a quantitative comparison suggests that transport of oxygen in neutral form also makes a contribution to the diffusion.

Notwithstanding intensive research, the only good oxygen-ion conductors known are those with fluorite-type lattices like stabilized zirconia. The oxygen mobility in those structures is enhanced by doping with oxygen-vacancy generating ions.

It was suggested many years ago that oxygen is relatively mobile in orthorhombic lead oxide, the yellow, high-temperature modification. Self-diffusion studies by Lindner and Terem (1) showed that the lead mobility is too low to explain the observed oxidation rate of metallic lead and they concluded that fast oxygen diffusion must be possible. This idea was confirmed by measurement of the self-diffusion coefficient of oxygen by Thompson and Strong (2). The value of $7 \cdot 10^{-10}$ cm²/sec extrapolated from their data for 1000°K is comparable with the value of $2 \cdot 10^{-9}$ cm²/sec found for calcia stabilized zirconia at the same temperature (3).

Conductivity studies of orthorhombic lead oxide are scarce (4, 5). The only extensive investigations are those by Grünewald (6) and co-workers and by Ritschel and Schmidt, who summarized the results (7). However, although it was known from the above mentioned diffusion results and from direct observations (8) that ionic conduction must play a role, the conductivity data were interpreted by these authors entirely on the basis of electronic conduction. Moreover, the measurements were carried out at temperatures where the yellow modification is not stable and probably in an atmosphere where oxidation to a higher oxidation state takes place. Therefore, the value of the results and especially of the theoretical discussion seems doubtful.

Key words: *solid electrolyte, semiconductor, isotope exchange, lattice defects.*

With the aim of gaining insight into the defects present in the high-temperature phase of lead oxide a study of the electrical properties and of the oxygen self-diffusion was undertaken. The influence of oxygen partial pressure and of doping was investigated, and the ionic and electronic contributions separated by means of various solid electrolytic techniques. Preliminary results of this investigation were presented orally at a meeting of The Chemical Society (9).

Experimental

Sample preparation.—The starting material was very pure lead oxide, prepared at our laboratory by Kwestroo and Huizing (10). The concentration of most impurities was at the ppm level or lower; no impurities could be detected with spectrographic analysis (10). The material was present in the red tetragonal form, the thermodynamic stable situation, which is also the only form in which high-purity lead monoxide can be kept at room temperature (11).

From this material, 3 mm thick pellets were pressed (compression force 6000 kg, diam 8 mm) in a steel die which was "cleaned" by carrying out several preliminary pressings. For contacting, platinum gauzes were pressed together with the material. The pellets were further densified by hydrostatic pressing at 30 kB. Analytical checks showed that with sufficient care contamination could be largely avoided.

Dopants were introduced in two steps using a 1% mixture obtained by sintering pressed pellets and subsequent powdering as an intermediate step. Bi and K-dopants were introduced as Bi_2O_3 and anhydrous K_2CO_3 of spectroscopic purity. The final compositions were checked analytically.

For the self-diffusion experiments single crystal plates and spheres were also used. Crystals were ob-

tained by pulling from a Pt-crucible or by slowly cooling a melt in a Pt-boat. They contained a variable amount of platinum of up to ½% depending on the oxygen partial pressure during melting, and they were only stable at room temperature if doped with Bi (12, 13). Spherical particles were obtained by melting the lower end of a strongly vibrating rod of sintered PbO and selecting the solidified drops which had sprinkled off according to size and perfection of shape.

Conductivity measurements.—Most electrical conductivity measurements were performed with low frequency a-c techniques. The sample was suspended between lightly pressed Pt-disks contacting the built-in Pt gauzes in such a way that no direct contact between the sample and the quartz glass or alumina sample holder existed. The latter was placed in a quartz glass furnace tube connected to a vacuum system. Stationary or flowing gases in the pressure range of about 10^{-4} to 10^{+3} Torr could be introduced. A special Pirani-type gauge was developed to cover this complete range (14); at a later stage also zirconia-type oxygen gauges (15) were used.

A difficulty arose because of the transformation of the initial low-temperature modification to the high-temperature modification studied. This led to a loss in packing density of the pellet, causing an increased intergrain resistance. If the sample was allowed to cool below the transformation point of about 500°C, often a complete disintegration accompanied the reversed phase transition. Thus the measurement program of a particular sample had to be carried out in one run without cooling. Because of the large intergrain resistances the absolute value of the resistance of the samples was not reproducible between samples. But, taking the precaution of allowing some time for sintering, the values for one sample were reproducible on pressure and temperature cycling in the range of 500°-750°C to within a few per cent and the characteristic pressure and temperature-dependence also reproduced between samples. Samples doped with Bi were stabilized in the yellow modification and consequently did not give rise to the above-mentioned difficulties.

Transport number determination.—Several types of galvanic cells were tried in order to obtain information about the transport numbers. They were of the current as well as of the EMF-type.

$$Pt(O_2,P_1)/PbO\text{-tablets}/Pt(O_2,P_1) \quad [1]$$

$$Pb/PbO/Pt(O_2,P_1) \quad [2]$$

$$A + AO_x/PbO/B + BO_y \quad [3]$$

$$Pt(O_2,P_1)/ZrO_2(0.15\,CaO)/PbO/Pt(O_2,P_1) \quad [4]$$

$$Pt(O_2,P_1)/PbO/Pt(O_2,P_2) \quad [5]$$

Tubandt's method of determining weight changes due to current flow in the tablets of cell [1] allows determination of the Pb-ion transport number (16, 17). The accuracy was found to be severely limited by pellet deformation, sintering together, and evaporation losses. The results suggest that about 1% of the current is transported by Pb-ions (air ambient, 700°C). This value was just above the limit of detectability; hence the influence of temperature, dopant and, oxygen partial pressure could not be studied.

The EMF of cell [2] yields an average ionic transport number, and from the slope of the EMF *vs.* oxygen pressure curve this tranport number can in principle be found as a function of the oxygen pressure (18, 17). The difficulty of localizing the molten lead was solved by the use of a cup-shaped sample obtained by pressing with a suitably shaped die. However, the material to be used for the electrical contact with the lead droplet lying in the PbO-cup was a problem, because of alloying or the formation of an intermediate oxide layer. This, together with problems caused by the geometry and complicated by the poor wetting between Pb and PbO, had the result that no reliable data could be obtained with this cell.

Cells of type [3] are limited by the small choice of metal and metal-oxide mixtures that exhibit an oxygen partial pressure higher than that over Pb-PbO. In this respect $Cu\text{-}Cu_2O$ and $Bi\text{-}Bi_2O_3$ are possible, but it appeared that they could not supply the oxygen current demanded by such a conductive, and at the same time "leaky," electrolyte like PbO without strong modification of the oxygen potential at the electrode-sample interface.

In cells of type [4] the electronic current in the PbO-sample is suppressed by the electrolyte tablet of stabilized zirconia, provided that no oxygen leak between the tablets takes place. At a first sight apparently trustworthy looking values for the ionic conductance of PbO could be derived from the slope of the current-voltage characteristics. A reproducible dependence on oxygen partial pressure, which was different for differently doped samples, was found. However, it appeared that the results were inconsistent with those obtained by means of cell [5]. Further investigation revealed that with the same oxygen partial pressure at both sides the results depended on the pressure of added inert gas, and that also a geometrical influence was present. It could be concluded that oxygen penetration by gas diffusion took place along the interface between the polished pellets; thereby partly removing the blocking action on the electronic current and causing an overestimate of the ionic transport number. Evidently, oxygen migrating between the pellets had occasionally to pass as ions through PbO and so an influence of the dopant concentration and deviation from stoichiometry of the samples was still present in the results. But, of course, a false law of dependence on oxygen pressure was suggested by this complicated and unpredictable mechanism. Attempts to block the gas diffusion, for instance by imbedding the cell in inert powder, were unsuccessful.

These negative results were quoted here primarily because they clearly illustrate the difficulties that may be encountered when applying to oxides the methods of Wagner (18), which were so fruitfully applied to halides.

The results presented below were all obtained by means of cells of type [5], where the sample is used as electrolyte and is arranged to separate two gas compartments. Figure 1 is a schematic drawing of the setup. The PbO-sample, with its platinum gauze contacts, was compressed inside an alumina tube. After inserting the latter in the rest of the equipment it was sintered for a few days and in many cases a reasonably gas-tight cell was obtained. As with the conductivity measurements, the temperature had to be kept above the transition temperature during the complete series of experiments with each sample. Often this took several weeks. Such cells are amenable to two types of measurement. Most direct is the quantitative determination with help of the pressure gauges of the amount of oxygen transported by a known current. In that case P_1 is chosen equal to P_2. Calibration could be done easily by means of a current through the zirconia tube which also separated the two gas compartments. In this way residual leak-through was automatically compensated for. This method was only suitable in a narrow range of oxygen pressures where the differential sensitivity of the Pirani gauges was high.

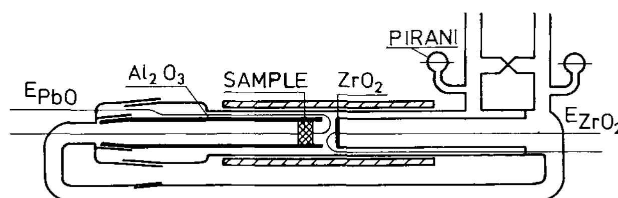

Fig. 1. Electrochemical cell with lead oxide separating two gas compartments. A zirconia cell is used as a reference.

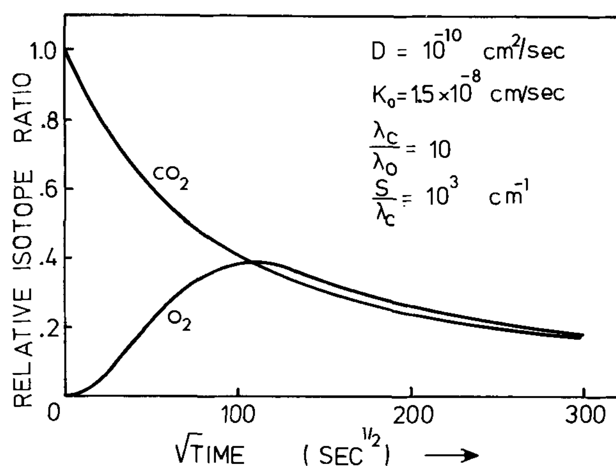

Fig. 2. Theoretical time dependence of the isotope ratio in originally enriched CO_2-gas and initially natural O_2-gas during exchange with natural lead oxide. The symbols used are explained in the appendix.

The method of measuring the EMF developed across the Pt-contacts when a small pressure difference was applied appeared to be applicable over a wider range of oxygen pressures. The ratio of the voltages over the PbO-sample and over the zirconia cell equals the ionic transport number in PbO. Several precautions had to be taken. First, only a relatively small pressure difference had to be used at each pressure in order to obtain a significant transport number, and also to minimize the effect of leak-through. Second, because of the small EMF's encountered, stray thermal EMF's have to be minimized by a very careful construction and positioning of the furnace to avoid thermal gradients. Nevertheless, correction for the residual thermal EMF was necessary. This could not be obtained by simply subtracting the voltage with no pressure difference since the thermoelectric force strongly depended on the average value of the oxygen pressure. However, corrections could be obtained by comparison of the EMF's obtained before and after reverting the high and low pressures. The difference between these voltages amounts to twice the significant EMF.

Oxygen self-diffusion measurements.—Use was made of the method of isotope exchange with a gas phase as introduced by Haul (19). It consists of following the isotope ratio of an O^{18}-enriched gas ambient during the establishment of equilibrium with the sample. For the analysis an Atlas type M86[2] mass spectrometer was used which is specially suited for the accurate determination of isotope concentration ratios because it is equipped with a double ion collector. The ratio of masses 34 and 32 was used. Equilibration of the molecular species in the gas mixture, which was obtained by dilution of heavily enriched oxygen, was ensured by heating with a platinum catalyst before the exchange experiment started. It was found that, in contrast to the experience of Thompson and Strong (2), the exchange rate was limited by a very slow surface reaction so that the self-diffusion coefficient could not be calculated from the results with any accuracy. However, O^{18}-exchange between lead oxide and carbon dioxide was very fast. So diffusion coefficients could be found from experiments with mixtures of carbon dioxide and oxygen, the latter being necessary to be able to control the deviation from stoichiometry.

Due to the very slow exchange rate of oxygen atoms between O_2 and CO_2-molecules in the gas phase a very simple method appeared to be possible for the simultaneous determination of the rate constant for the exchange reaction between O_2 and PbO and the self-diffusion coefficient in the solid. It consisted of the use for instance of natural O_2 mixed with enriched CO_2 and then following the O^{18}-content of both species during the diffusion experiment (masses 34 and 46). A theoretical time dependence of both isotope fractions during such an experiment is shown in Fig. 2.

The rate constant K_O for the exchange reaction can be defined by the equation

$$\frac{dq}{dt} = -\alpha K_O(q - r_s) \quad [6]$$

where q is the O^{18}-isotope fraction in the oxygen gas and r_s that in the solid at the surface (19). If the constant α (dimension cm^{-1}) is defined as the ratio of the total number of O-atoms in a depth of 1 cm in the solid (calculated for the total reacting surface area) to the total number of O-atoms present in the oxygen gas, the proportionality factor K_O attains the dimension of a velocity (dimension cm/sec). Since $r_s = r_{CO_2}$, because the CO_2 exchange reaction is very fast, K_O can be calculated at every moment from the slope of the O_2-curve and the separation between the two curves.

Of course, this holds good only if the exchange in the gas phase and at foreign surfaces is negligible. Blank experiments showed this to be the case provided no metals were present such as Pt or Au in the hot zone of the quartz-glass reactor. Furthermore, the PbO-sample had to be positioned in such a way that the slight amount of PbO that evaporates cannot condense on hot quartz surfaces near the temperature

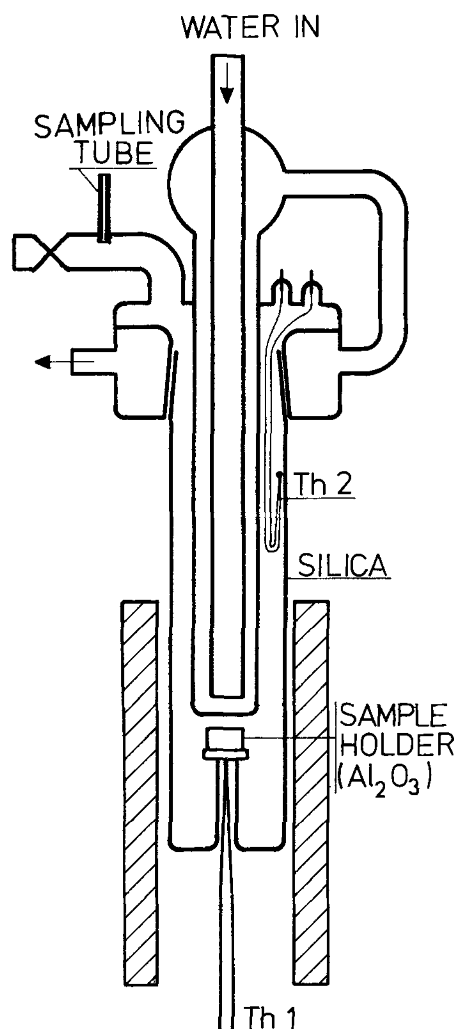

Fig. 3. Reactor vessel used for exchange experiments. A cooled finger screens the hot walls against evaporating lead oxide. The sample is contained in an alumina sample holder with a perforated lid.

[2] Marketed by Varian-MAT G.m.b.H., Bremen, West Germany.

transition zone. These conditions could be met with the setup shown in Fig. 3, in which a cool finger screened the transition zone from the sample holder. The required absence of metals made it necessary to determine the sample temperature in a separate run with the thermocouple Th 2 attached to the sample. It was afterwards bent back into the cool zone. The thermocouple Th 1, positioned in an intrusion of the reactor, served in the furnace-control unit.

Formulas used to calculate D and K_O from experimental time dependence curves of the isotope ratios are given in the appendix. The data were analyzed by means of a digital computer.

Results

Measurement of total conductivity.—Figure 4 gives an impression of the temperature dependence of the total conductivity for different dopants at a fixed oxygen pressure. The slope of the curves for pure and for bismuth containing samples corresponds to an activation energy of 1.2 ± 0.05 eV independent of the dopant concentration and of the oxygen pressure. However, potassium containing samples exhibit a lower value of 0.9 ± 0.05 eV, which is again independent of the oxygen pressure, and which is the same for K-concentrations of 100 ppm and 1000 ppm.

Typical conductivity isotherms for differently doped samples are shown in Fig. 5 in a doubly logarithmic plot. Striking is the positive slope for potassium doped samples and the negative one for those containing bismuth. The slopes of straight line segments correspond to a 1/4 to 1/6 power dependence for K-doping and to the same values but with negative sign for Bi. Undoped samples show a shallow minimum and the curve for 10 ppm Bi illustrates the high sensitivity for contamination.

Isotherms taken at temperatures different from that in Fig. 5 have essentially the same shape; they show merely a shift corresponding to the temperature dependence depicted in Fig. 4. Because of this simple behavior of both the isotherms and the isobars, the information given in the figures is sufficient to derive the conductivity of a certain sample at any temperature and pressure in the ranges 800°-1000°K and 10^{-3} to 760 Torr.

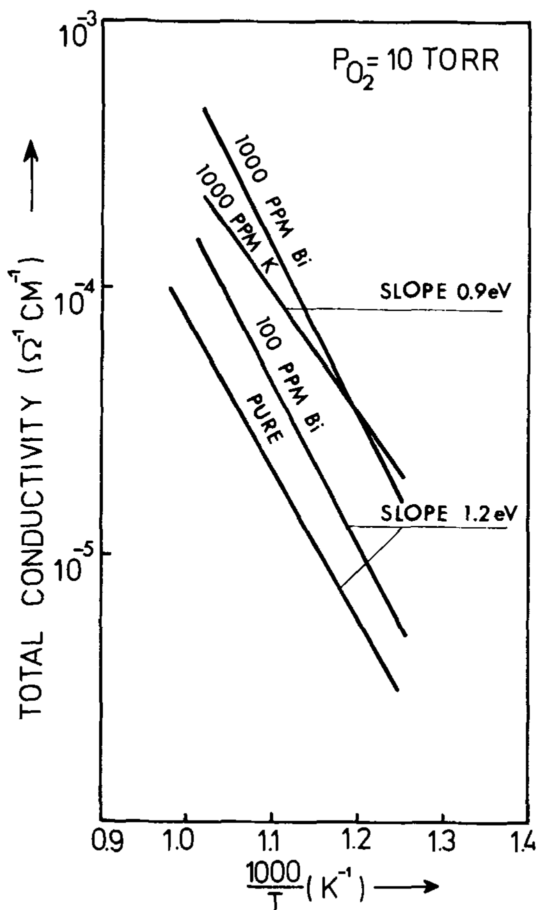

Fig. 4. Conductivity isobars for pure and doped lead oxide

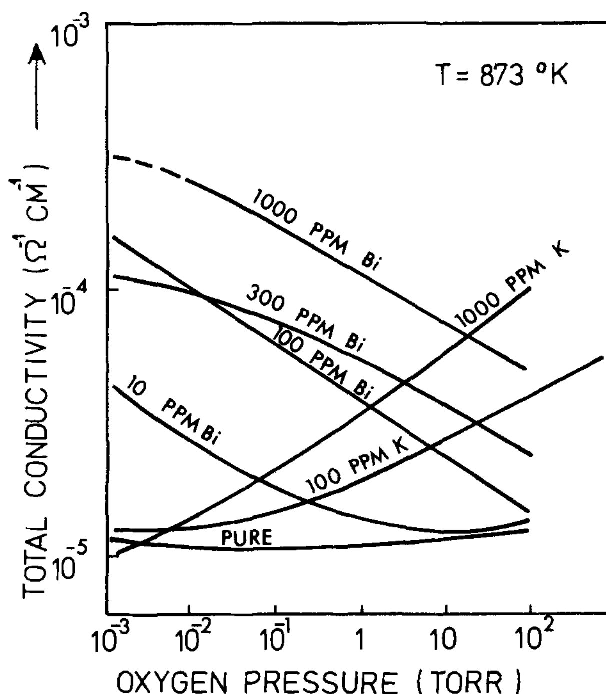

Fig. 5. Conductivity isotherms for pure and doped lead oxide

However, as mentioned before, the magnitude of the conductivity values did not reproduce well in the Bi-free samples. So there is some arbitrariness in the level on which the curves have been drawn corresponding to perhaps a factor of five. For the pure and the K-containing samples the curves represent the more conducting ones encountered. In the plot the minima in the low-doped sample curves fit reasonably well with that of the pure curve as should be expected if they correspond to intrinsic conductivity. But still, it may be possible that the complete set of curves should be shifted somewhat up to higher values. Of course these considerations do not affect the interesting pressure and dopant influences shown.

Ionic transport numbers.—Some typical transport number isotherms are shown in Fig. 6, while a summary of the results is given in Fig. 7. Again we encounter the slopes of Fig. 5, but now in the opposite direction. Because of the logarithmic scales curves representing the ionic conductivity, *i.e.* the product of total conductivity and transport number, can be obtained by simply adding the corresponding curves of Fig. 5 and 7. The opposite slopes then cancel and, to a first approximation, the ionic conductivity is found to be independent of oxygen pressure. For a special case this is shown in Fig. 8.

Since these transport numbers were derived directly from the EMF of cells of type [5], the values obtained were not influenced by intergrain contacts, as were those of the partial conductivities. In accordance with this the values were well reproducible between samples. Moreover, values derived from a direct comparison of the oxygen transported by a current through the PbO and the zirconia standard (see Fig. 1) fitted the curves well, as is illustrated by the triangles in Fig. 6. Only when the observed transport number comes out lower than about 1% are there indications that for some unknown reason the values are underestimated. Therefore, the full lines of Fig. 6 have not been extended to that region.

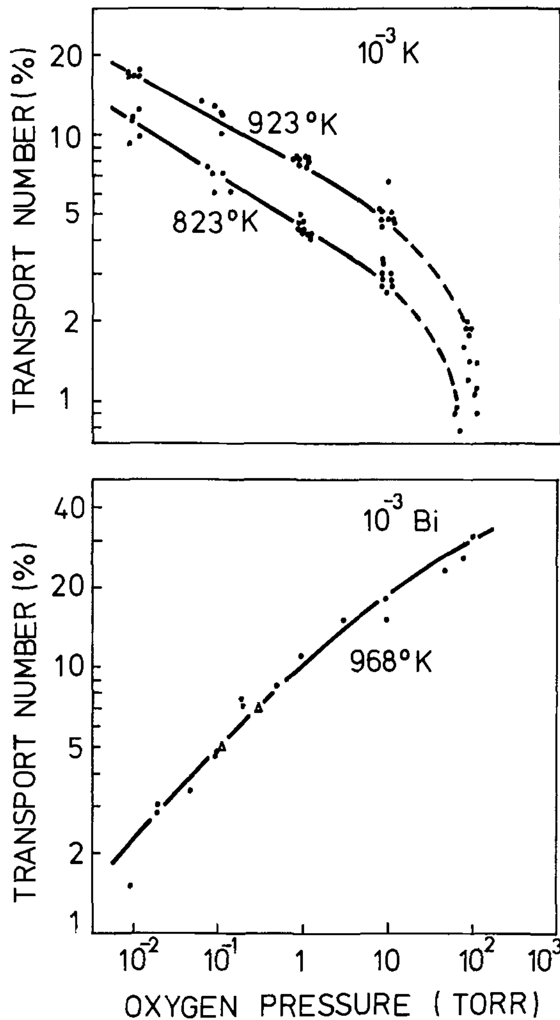

Fig. 6. Typical experimental results of transport number determinations. The triangles in the lower curve represent values obtained by measurement of the gas transported by a current.

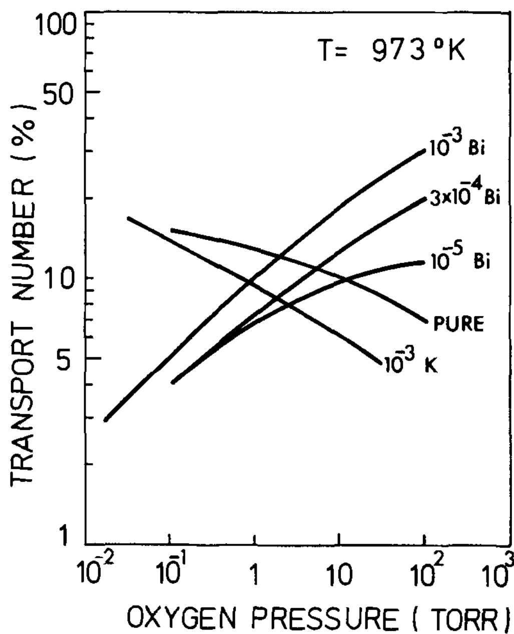

Fig. 7. Summary of transport-number isotherms for pure and doped lead oxide.

The transport numbers generally show a weak temperature dependence. For pure samples some increase is found for a temperature rise from 940° to 1000°K.

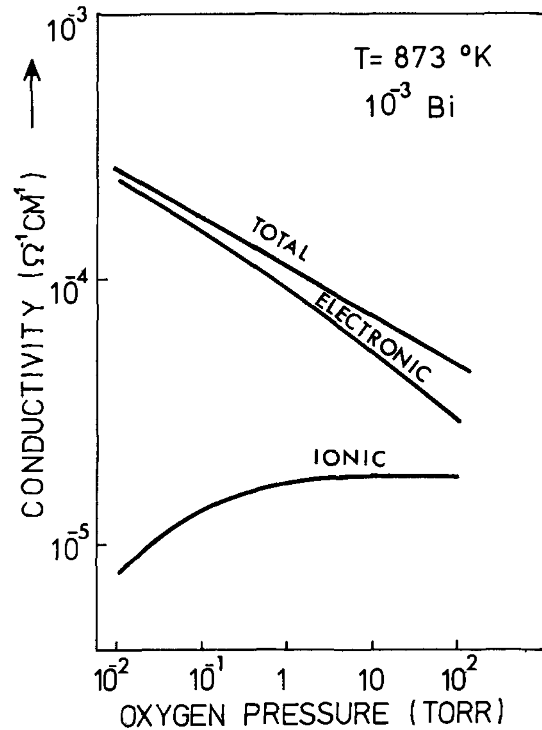

Fig. 8. Partial electronic and ionic conductivity isotherms for Bi-doped lead oxide.

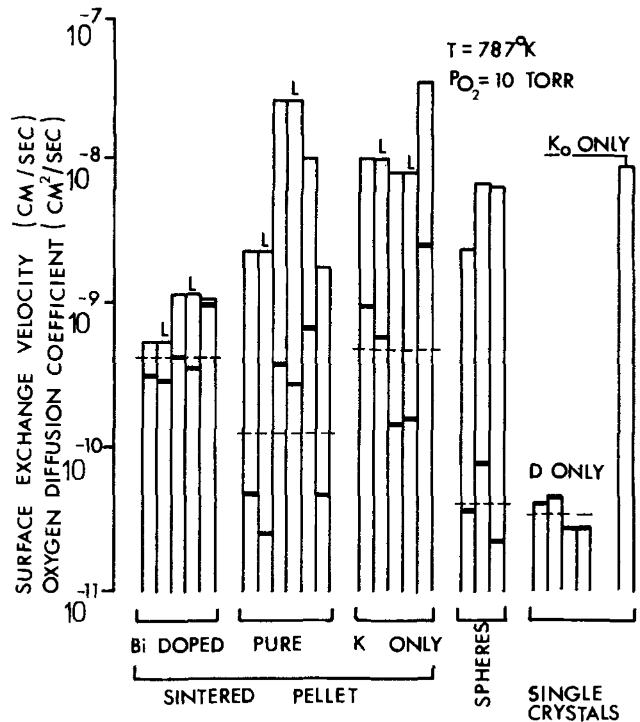

Fig. 9. Survey of results of exchange experiments. The upper levels indicate the rate constant K_0 for oxygen exchange with the surface. The intermediate levels give the self-diffusion coefficients D. The dashed horizontals indicate geometrical averages for D.

The increase with temperature for K-doped samples is apparent from Fig. 6. Moderately Bi-doped samples do not show any temperature dependence, while a very small decrease with temperature is found for the 100 ppm samples.

Self-diffusion coefficient of oxygen.—Since the temperature dependence of the oxygen self-diffusion is known from literature (2), most exchange experiments were performed at a fixed temperature of 787°K. An

influence of sample type, dopant or oxygen pressure was looked for. The results are presented in Fig. 9.

Every column represents an experiment, the upper level corresponds to the value K_O found for the rate constant of the surface reaction with oxygen gas, the lower level gives the diffusion coefficient. The reaction rate constant was defined in Eq. [6].

The oxygen partial pressure was near 10 Torr for all points not marked with an L, and the K_O-values given always correspond to that pressure. The L-marked columns show experiments with the left hand neighboring sample but performed in an oxygen-free CO_2 atmosphere. The doped samples contained 600 ppm Bi or K. The spheres had a radius of about 0.5 mm and were undoped. The single crystals contained up to 0.5% of platinum present as visible aggregates in the cleavage plane. Crystals were selected for absence of these visible defects.

The values show a considerable spread which is least for Bi-doped specimens as was the case in the conductivity experiments. For the pure and K-doped tablets there is a clear correlation between the values of D and K_O. This can be seen in Fig. 9 from the lower spread in the distances between the D and K_O levels, which correspond to the logarithms of their quotients. It seems therefore reasonable to assume that a significant part of the scatter stems from differences in effective surface area of different tablets. Consequently, the value of K_O may be considered as a measure for this area, at least in comparable samples.

If the significantly lower values of K_O for bismuth-doped samples also indicate a lower effective surface area with respect to pure tablets, the higher average D for these samples would be more pronounced than already suggested by the figure. A higher diffusion coefficient is consistent with the higher ionic conductivity found, and also with the better sinterability experienced with these samples leading to better reproducibility and possibly a smoother surface.

The values of the self-diffusion coefficient found for spheres and single crystals average at $4 \cdot 10^{-11}$ cm²/sec, which is in good agreement with the data of Thompson and Strong (2). It is somewhat lower than the average obtained with pure pellets.

Comparison of the diffusion values in L-marked columns, which were obtained at very low oxygen partial pressures with their left hand neighbors, shows that there is no significant pressure dependence on the part of the self-diffusion coefficient of oxygen.

Discussion

Electronic conductivity.—The electronic conductivity, which forms the main component of the total conductivity, shows a dependence on the oxygen pressure that suggests p-type conductivity in potassium and n-type in bismuth containing lead oxide. This is confirmed by the sign of the thermo EMF which was mentioned as a disturbing factor in the discussion of the cell experiments. A sign reversal of this thermo-force also occurred at the minimum of the conductivity isotherms of pure samples as could be expected for a transition from n to p-type. This behavior is consistent with elementary semiconductor theory where Bi is expected to be a donor and K an acceptor assuming them to substitute for Pb.

It is interesting to compare the experimental value for the intrinsic electronic conductivity σ_e obtained from Fig 5 ($\sigma_e = 10^{-5}$ ohm^{-1} cm^{-1} at 873°K) with a theoretical value that can be calculated from the optically determined bandgap value, the carrier mobility, and the effective mass. From the optical absorption spectrum we found indications of an indirect bandgap E at room temperature of 2.66 eV (20). Almost the same value is quoted by Ali Ben Hadj (21), while Iinuma, Seki, and Wada (13) give 2.75 eV at 300°K with a temperature coefficient of -1×10^{-3} eV/deg. Keezer, Bowman, and Becker (22, 23) determine the bandgap as 2.67 eV and find a value for the electron mobility μ_n at room temperature of 50 cm²/V sec. If we assume the same mobility for holes and introduce a $T^{-3/2}$ dependence (24) we find with the formula

$$\sigma_e = 2\left(\frac{2\pi mkT}{h^2}\right)^{3/2} \cdot \exp\left(-\frac{E}{2kT}\right) \cdot q(\mu_n + \mu_p) \quad [7]$$

a value of roughly 10^{-4} ohm^{-1} cm^{-1} for the intrinsic electronic conductivity at 873°K. This must be considered as consistent with the experimental value of 10^{-5} ohm^{-1} cm^{-1} remembering the use of the free electron mass m instead of the effective one and the nature of the sintered samples.

The corresponding free carrier concentration is of the order of magnitude of 10^{13} cm^{-3}. This is several orders of magnitude lower than the dopant concentrations introduced in the doped samples, nevertheless we find only a moderate increase in the electronic conductivity on doping. So we must conclude that the dopant atoms do not act as simple donors or acceptors merely generating equivalent concentrations of free charge carriers but that the main charge compensation of the built-in ions of deviating valency is obtained by the simultaneous formation of charged lattice defects.

Ionic conductivity.—The same lattice defects could also determine the ionic conduction and the self-diffusion. The ionic conductivities as derived from the total conductivity curves (Fig. 5) and the transport numbers (Fig. 7) appear to be independent of the oxygen pressure irrespective of the impurities introduced. However, samples containing 1000 ppm of bismuth show a tenfold higher ionic conductivity than pure ones. Doping with potassium does not seem to give rise to a change in the ionic conductivity.

The activation energy of the ionic conductivity appears to have the same value of 1.2 eV for either bismuth or potassium doped lead oxide. It equals that of the electronic conductivity for Bi-containing samples (constant transport number) but exceeds the activation energy for the p-type conductivity of K-doped material. This results in the positive temperature coefficient of the transport number observed for this material.

The charged lattice defects formed by introduction of bismuth ions on lead ion lattice positions may be either lead vacancies or oxygen interstitials. The observed increase in the oxygen conduction leads us to conclude that interstitial oxygen ions are responsible for the ionic transport. This rather unusual mechanism may be connected with the crystal structure of orthorhombic lead oxide which is made up of sheets containing infinite Pb-O zigzag chains. The outer surfaces of such sheets contain only Pb-atoms, while all oxygen atoms are inside them (25-27). A weak bonding exists between these relatively widely spaced sheets.

Self diffusion.—If the same type of lattice defect is responsible for both ionic conductivity and self-diffusion both phenomena must be related by Einstein's relation, which for lead oxide can be written in the form

$$\sigma_{ion} = 2 \times 10^8\, D/T \quad [8]$$

Here correlation effects are neglected and a charge of 2 is attributed to the mobile oxygen defects. Introducing the value of 10^{-10} cm²/sec for the diffusion coefficient at 787°K in pure samples, we find the value 2.5×10^{-5} ohm^{-1} cm^{-1} for the ionic conductivity carried by oxygen ions. This appears to be about 100 times greater than the value obtained from our experimental data for the ionic conductivity of those samples. For bismuth-doped lead oxide a higher D-value as well as higher ionic conduction was found, but here a large discrepancy factor exists too.

This could mean that some error was made in the interpretation of the experiments. It might be argued that the self-diffusion found is too high because of a fast grain boundary diffusion process. However, the insignificant D-difference found for poly and mono-

crystalline samples rules this out. Moreover, this process would also increase the ionic transport number obtained by both the EMF and the direct transport method.

It must be stated that the diffusion and conductivity measurements, although performed on comparable samples, did not pertain to the same region of the samples. The diffusion data come from experiments where the relevant part of the sample extends to only a few microns below the free surface. In the conductivity determinations the complete sample is involved. So a surface layer of a higher ionic conductivity could explain the results. However, experiments with electrode arrangements using a guard ring did not confirm the presence of such a layer.

Could then perhaps the conductivity measurement have led to much too low values? If grain boundary layers of lower electronic conductivity in the current path had led to underestimation of the conductivity, they would at the same time have caused a higher EMF because the oxygen potential gradient would have concentrated across these electron blocking layers especially. Thus a kind of compensation with regard to the ionic conductivity value would have occurred. Moreover, electronic barriers cannot exist in intrinsic material, since any band bending at the interface would lead to an increased surface conductivity. Furthermore, a nonuniform deviation from stoichiometry was not possible during the experiments, since the time constant for equilibration appeared to be of the order of a second, which value is consistent with the theory of chemical diffusion in a mixed conductor using the data for lead oxide.

There remains the possibility that very small contact areas between the grains are responsible for the loss of a factor of 100 in conductivity. In that case we should expect an impedance drop at higher measuring frequencies due to capacitive bridging of the narrow gaps. However, only a slight decrease in impedance was found at frequencies up to 5 MHz and this stood in no proportion to the factor looked for.

These considerations lead us to consider a fundamental reason for the relatively high diffusion constant, namely that oxygen transport in the neutral form should make the main contribution to it. The proposed predominant covalent character of the bonds in the oxides of lead (28) could be the origin of such behavior. However, the ionic conductivity must still be by oxygen in some charged form since, as we learned from the Tubandt type of transport experiments, the transport number of lead is too low to account for the observed ionic transport.

Defect model.—The relative insensitivity of both the self-diffusion and the ionic conductivity to doping indicates that a fair degree of natural atomic or ionic thermal disorder is present in lead oxide at the temperature of study. The threshold concentration where impurities begin to shift this intrinsic defect equilibrium must be of the order of 100 ppm since at about that concentration the self-diffusion and the ionic conductivity begin to change. As the experiments show, changes of this order of magnitude cannot be induced by pressure variations within our experimental range. Partial confirmation of this may be seen in some potentiometric titration experiments using a zirconia cell, which were not mentioned so far. It was aimed to determine the deviation from stoichiometry, but we could only deduce an upper limit of about 10^{-4}.

When we try to summarize the above-mentioned results in terms of a defect model, we encounter difficulties. The oxygen-pressure dependence of the electronic conductivity of doped samples is consistent with a situation where a concentration of doubly charged defects is fixed by the electroneutrality constraint. They were supposed to be interstitial oxygen ions for the case of Bi-doping. The experience that the ionic conductivity is independent of the oxygen pressure and increases with Bi-content fits well into this picture.

Although the same qualitative behavior of the self-diffusion coefficient of oxygen was found, the quantitative disagreement led us to believe in neutral transport. However, the concentration of neutral interstitial oxygen atoms would certainly depend on the oxygen pressure, probably in proportion to the square root, and this would lead to the same pressure dependence of the coefficient of self-diffusion. This is not found.

This discrepancy is difficult to resolve. The supposition that the isotope diffusion goes by some associate of elementary defects would resolve the problem of the pressure dependence, but leaves the observed dopant dependence to explain. Perhaps more information on the dopant and pressure dependences of the lead-diffusion coefficient could provide a clue to unravel the mechanism in the future.

Conclusion

The conductivity of orthorhombic lead oxide is to an appreciable part ionic and carried by oxygen ions. This oxygen conductivity does not depend on the oxygen pressure. The variations in the ionic transport number with oxygen pressure are due to the changes induced in the electronic conductivity, which in turn depends on the type and concentration of impurities introduced.

Bi-doping results in n-type conductivity with an almost $-1/4$ power dependence on oxygen pressure. At the same time the ionic conductivity is increased; tenfold with 1000 ppm Bi. When in that case the electron conductivity is reduced by a high oxygen pressure, the maximum ionic transport number of about 50% is obtained.

Doping with potassium causes p-type conductivity with a near $+1/4$ power dependence on pressure. Consequently the maximum transport number occurs at the low pressure side with K-doped samples. The resulting electronic and ionic conductivities are somewhat lower than with bismuth as is the maximum transport number obtainable. The ionic conductivity is the same as in pure PbO.

From these results it is concluded that the incorporation of trivalent metal results in the formation of interstitial oxygen ions, which are responsible for the increase in ionic conductivity observed.

The self-diffusion experiments show that oxygen diffusion is also independent of oxygen pressure and increases upon doping with bismuth, just as does the oxygen ion conduction. However, there is a discrepancy because the self-diffusion coefficient appears to be about 100 times higher than would be expected on the basis of the ionic conductivity. It seems therefore that transport of oxygen in neutral form is responsible for the major part of the self-diffusion. However, the observed independence of oxygen diffusivity on oxygen pressure is difficult to understand in this light.

Acknowledgment

This work was started in close cooperation with Dr. Y. Haven who directed the initial self-diffusion studies. His initiatives in this difficult period of the work are gratefully acknowledged. Thanks are also due to Mr. A. T. Vink who built much of the electrical equipment and critically tested various electrochemical cells.

Manuscript submitted June 18, 1971; revised manuscript received Sept. 20, 1971. This was Paper 30 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX

The diffusion results were compared with theoretical curves calculated with the formulas given below. They were derived along lines given by Haul, Dümbgen, and Just (29) for the exchange with one gas species. It is assumed that the surface reaction velocity with CO_2 is very fast, while that with O_2 is described by a rate

constant K_o. Separate formulas are given for a one dimensional geometry and for spherical samples. The error function type of solutions which holds good for relatively small penetration depths are given only. The following notations are used

p	the isotope fraction in CO_2
q	the isotope fraction in O_2
r	the isotope fraction in the solid
index$_t$	means at moment t
index$_0$	means initial value
λ_C	ratio of the total number of O-atoms in the CO_2-gas to that in the solid
λ_O	ratio of the total number of O-atoms in the O_2-gas to that in the solid
S	ratio of the exchanging surface area to the sample volume
D	the self-diffusion coefficient of oxygen
K_O	the surface reaction velocity of oxygen as defined by Eq. [6]
g	the quantity $(\lambda_C K_O)/(SD)$
$F(y)$	a function defined as $F(y) = y^3 + y^2 + (\lambda_C/\lambda_O + 1)gy + g\lambda_C/\lambda_O$
y_i	the three roots of $F(y) = 0$ ($i = 1, 2,$ or 3)
$F'(y)$	the first derivative of $F(y)$
$G(y)$	a function defined as $G(y) = y^4 + y^3 + (g\lambda_C/\lambda_O + g - \lambda_C/3)y^2 + gy\lambda_C/\lambda_O - \lambda^2_C g/(3\lambda_O)$
y_k	the four roots of $G(y) = 0$ ($k = 1, 2, 3,$ or 4)
$G'(y)$	the first derivative of $G(y)$
eerfc(x)	the function $\exp(x^2)$ erfc(x)
erfc(x)	the function 1-erf(x)
t	the time coordinate

For the initial conditions of an experiment starting with the natural isotope ratio in the oxide and in the oxygen gas and with enriched CO_2 we have: $q_0 = r_0$. The solutions for the CO_2 and the O_2 then become for one dimensional geometry

$$\frac{p_t - r_0}{p_0 - r_0} = \sum_{i=1}^{3} \frac{y_i^2 + g\lambda_C/\lambda_O}{F'(y_i)} \text{eerfc}\left(-\frac{S\sqrt{D}}{\lambda_C} y_i\sqrt{t}\right)$$

$$\frac{q_t - r_0}{p_0 - r_0} = \sum_{i=1}^{3} \frac{g\lambda_C/\lambda_O}{F'(y_i)} \text{eerfc}\left(-\frac{S\sqrt{D}}{\lambda_C} y_i\sqrt{t}\right)$$

for spherical geometry

$$\frac{p_t - r_0}{p_0 - r_0} = \sum_{k=1}^{4} \frac{y_k^3 + g\lambda_C/\lambda_O}{G'(y_k)} \text{eerfc}\left(-\frac{S\sqrt{D}}{\lambda_C} y_k\sqrt{t}\right)$$

$$\frac{q_t - r_0}{p_0 - r_0} = \sum_{k=1}^{4} \frac{gy_k\lambda_C/\lambda_O}{G'(y_k)} \text{eerfc}\left(-\frac{S\sqrt{D}}{\lambda_C} y_k\sqrt{t}\right)$$

Optical Investigation of Cathodochromic Sodalite

C. Z. van Doorn, D. J. Schipper, and P. T. Bolwijn

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

The fluorescence and reflection spectra are studied of sodalite doped with S^{--}, S_2^-, O_2^-, Mn^{2+}, Co^{2+}, Ni^{2+}, Cr^{3+}, or Fe^{3+}. New fluorescence emissions reported are an emission consisting of a number of peaks between 4500 and 7000Å ascribed to O_2^-, an emission at 5420Å ascribed to Mn^{2+}, and an emission at 6830Å ascribed to Fe^{3+}. The transition metals appear to be incorporated preferentially at Al or Si sites. Electron irradiation causes irreversible changes in the uv reflection spectrum. These may be connected with the occurrence of a residual coloration after optical bleaching. A residual coloration appears to be connected also with the presence of O_2^- fluorescence under uv excitation.

Sodalite is a material which, because of its photochromic and cathodochromic properties, has been the subject of a number of investigations (1-8).

The chemical composition of the naturally occurring material is $Na_4Al_3Si_3O_{12}Cl$. Synthetic sodalites have been prepared in which the Cl is replaced by OH, Br, I, ClO_3, ClO_4, or BrO_3, the Na by other alkalies, the Al by Ga, and the Si replaced by Ge. The cubic crystal structure (a_o = 8.870Å for Cl-sodalite) was first elucidated by Pauling (9) and refined by Löns and Schulz (10).

Most of the work on the cathodochromism of sodalite concerns sulfur-doped halide sodalite. We found that doping with sulfur is not essential for cathodochromism to occur. This was also noted by Taylor *et al.* (5). Undoped sodalite samples, which are not at all or only slightly photochromic (for 2537 and 3650Å radiation), may even show better cathodochromic properties than sulfur-doped samples. Since the presence of defect centers is essential in the process of coloring, one of the main objects of the present investigation is to try to understand the nature and the role of these defect centers in doped and "undoped" sodalite in order to achieve better control of its cathodochromic properties.

Fluorescence spectra and powder reflection spectra of sodalite samples are described and discussed.

Preparation of Sodalite Samples

Since a full account of the preparation of sodalite will appear in another publication (11), only a short description will be given here. Bromide sodalite is especially dealt with because it seems to show the best compromise between different properties such as sensitivity, bleaching rate, and color. The chloride and iodide sodalites result when sodium bromide in the following methods is replaced by sodium chloride or iodide.

Method 1.—One of the first known preparation methods for sodalite, due to Medved (12), was used by us in the early stages of the investigation. All our sulfur-doped samples were prepared by this method. The method consists in mixing the dry starting materials, *viz.* NaOH, Al_2O_3, SiO_2, NaBr, Na_2SO_4, and Na_2CO_3, and firing at 900°-1060°C in air. The resultant sodalite could be made photochromic by reduction in flowing hydrogen at 900°C. The reduced material often even developed a color in daylight and bleaching was poor. These properties could be improved by partial reoxidation by a short heating at 900°C in air.

Method 2.—This method was developed by Schuil and Holland of our company (13). It is also a "dry" method differing from the previous one in that a gel is first made of the starting materials ($NaAlO_2$, SiO_2, and NaBr) in water and then evaporated to dryness. This material is converted into sodalite by firing at 1100°C in air with extra NaBr.

Method 3.—The preparation of sodalite by low-temperature hydrothermal reaction was first applied by Barrer *et al.* (14), using kaolinite as a starting material. We used pure starting materials instead. An alkaline solution of sodium aluminate, silica, and sodium bromide was agitated for 5 days at 80°C in closed Teflon bottles. The sodalite formed was made cathodochromic by an "activation" consisting in firing for 15 min at 900°C in air. This was sometimes carried out with extra NaBr (75% by weight) added to increase the bromine content. Sodalites containing Ga instead of Al or Ge instead of Si were also made by this method by using the appropriate starting materials.

Method 4.—This is a modification of the previous method, using sodium bromate (or chlorate for Cl-sodalite) in the solution instead of the bromide (chloride). The activation procedure, which is the same as before, converts the halogenate sodalite into the corresponding halide sodalite.

Method 5.—Another modification of method 3 consists in leaving the halide out of the solution. This results in hydroxide sodalite being formed. The same activation procedure, using extra sodium halide, converts the hydroxide sodalite into the halide sodalite.

Measuring Equipment

Optical spectra were measured using a Hilger Monospek 1000 grating monochromator (focal length 1 m, dispersion 8 Å/mm) in conjunction with an 800 Hz chopper, photomultiplier, and lock-in amplifier. The (Philips) photomultipliers used were the 51 UVP (S 13 response) for the uv region and the XP 1002 (S 20 response) and XP 1005 (S 1 response) for the visible and near-infrared regions.

Reflection spectra of powder samples at room temperature were obtained by passing the chopped radiation from a deuterium or tungsten lamp through a monochromator and, after reflection by the sample, detecting it by a photomultiplier. Smoked MgO was used as a standard.

Fluorescence spectra were measured with the samples immersed in liquid nitrogen in a quartz Dewar vessel. Excitation was by radiation from a low-pressure mercury lamp (mainly 2537Å), filtered by a liquid Bäckström filter (15) and a Schott UG 5 filter. In some cases 3650Å radiation from a super-high-pressure mercury lamp (Philips SP 1000), filtered by liquid $CuSO_4$ and UG 1 filters, was used.

Mechanism of Coloring and Bleaching

There is no existing theory concerning defect centers in sodalite, and we will therefore give only a simple and qualitative description of the processes of coloring and bleaching.

Key words: reflection spectra, fluorescence spectra, sulfur, oxygen, transition metals.

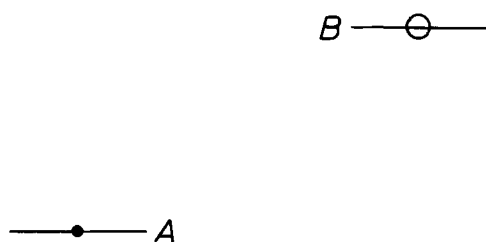

Fig. 1. Energy level diagram for defects in a crystal

We assume the presence in cathodochromic sodalite of two types of defect centers, the acceptor-like type A centers and the donor-like type B centers (see Fig. 1).

The coloration process can be described as the charge transfer from an electron-filled low-lying center A to an empty high-lying center B (see Fig. 1). The visible coloration is connected with the capability of the electron in B of being excited to the conduction band or to an excited state by absorption of a photon. In photochromism the charge transfer from A to B proceeds by photo-excitation of the electron in A to the conduction band and transfer via this band to B. In cathodochromism the final state of affairs is the same, but the primary process is the creation by electron excitation of a large number of free electrons in the conduction band and of free holes in the valence band, these electrons and holes then being captured by centers B and A, respectively.

Bleaching is the transfer of the electron at B back to A, induced by light or by heat. When the bleaching is by heat, the primary process may be the excitation of the electron from B to the conduction band or the excitation of the hole from A to the valence band. It is known from the theory of thermoluminescence (16) that, when a solid containing centers is heated at a constant rate, an approximately linear relation exists between the ionization energy of the centers and the absolute temperature at which the ionization rate reaches a maximum. The value of the proportionality factor for sodalite is not known but values for different materials are found to lie within the range of 1.9×10^{-3} to 2.8×10^{-3} eV/°K (16). It then follows from the temperature at which rapid bleaching occurs ($\approx$ 500°K) that the ionization energy must have a value of 0.95-1.4 eV. As shown by electron spin resonance (1) the B centers in sodalite are halogen vacancies which show an absorption band with a maximum at 2.3 eV. Their thermal ionization energy is not known but the value of 1.8 eV at the long-wavelength tail of the absorption band gives a reasonable estimate of this energy because optical absorption (involving the ground and ionized states) cannot occur for photon energies below the thermal ionization energy. This value is significantly higher than the values of 0.95-1.4 eV obtained from thermal bleaching, so that we conclude that A centers with ionization energies less then 1.4 eV ionize to cause the thermal bleaching rather than B centers.

A residual coloration, *i.e.* a coloration which cannot be bleached optically, can be explained if we assume a second type of A centers which may come into existence as a result of radiation damage and in which trapped holes have a negligible probability to recombine with free electrons. The electrons will then be retrapped by the B centers causing a permanent coloration.

The function of the type A centers can be twofold. In the uncolored state they can serve to compensate for the positive charge of the chlorine ion vacancies. In order to acquire the colored state they must be able to lose electrons to the chlorine vacancies and to bind the remaining holes so that the colored state may persist. Some type A centers may serve only one of these purposes. Type A centers in sodalite which fulfill both these functions can be, for example, S^{--} or O^{--} ions replacing Cl^- ions, Fe^{2+} ions replacing Al^{3+} ions, or sodium-ion vacancies.

Results and Discussion

Band gap of sodalite.—Since the band structure of sodalite is not known and accurate values of the absorption coefficient as a function of the wavelength cannot be obtained from powder reflection spectra, only rough estimates of the value of the bandgap can be made. The powder spectra show a steep drop of the reflection coefficient below a certain wavelength. The straight-line portions of the curve below and above the "knee" were linearly extrapolated and the intersection point was taken as the band edge. Bandgaps thus obtained were 6.1 eV for Cl-sodalite, 5.9 eV for Br-sodalite, and 5.2 eV for I-sodalite. Duncan *et al.* (7) mention a value of 5.2 eV but do not specify the type of sodalite.

Sulfur centers.—The effect of different treatments of sulfate-doped bromide sodalite on its uv reflection spectrum is shown in Fig. 2. The curve for an unreduced sample (curve 1) shows an absorption at 2600Å. This band is probably not characteristic for the SO_4^{--} ion because not all sulfate-doped samples show it. Irradiation by 2537Å uv does not give rise to coloration. These facts, together with the assumed acceptor-like character of the sulfate center, indicate an energy-level position close to the valence band, at a distance greater than 5 eV below the conduction band.

After reduction in hydrogen the uv reflection spectrum shows a strong absorption, with a tail extending up to 4000Å (see curve 2 in Fig. 2). We observed that excitation at 77°K by 3650Å radiation gives rise to a broad fluorescence band with a maximum at 9000Å. This emission was also observed by Taylor *et al.* (5) and was ascribed by them to S^{--} ions. We also ascribe the strong absorption to these ions.

A coloration is observed for radiation with wavelengths up to 4000Å. This fact indicates that the uv absorption must be due to the excitation of electrons from the S^{--} centers to the conduction band. We therefore locate the energy level of the S^{--} ion at a position about 3.1 eV below the conduction band (see Fig. 3), corresponding to the tail of the absorption. The fluorescence may be ascribed to the reverse process, possibly via an excited state.

If the assigned level position is correct, the distance to the valence band will be about 2.8 eV (see Fig. 3). Therefore, if empty S^{--} centers (*i.e.* S^- ions) are present, electrons from the valence band can be excited to the empty levels. Part of the observed uv absorption may be due to this process.

Partial reoxidation of the reduced sodalite samples by short heating to 900°C in air causes most of the strong absorption to disappear and a new absorption with a maximum at 3700Å to appear (see Fig. 2, curve 3). Excitation at 77°K with 3650Å radiation now gives rise to the characteristic fluorescence of the S_2^- molecule ion shown in Fig. 4. This emission is well known in sodalite (1, 5, 17) as well as in the alkali halides (18, 19). The emission peaks of some of our samples showed a fine structure (see Fig. 5) which was also reported by Rolfe (19) in alkali halides and ascribed to coupling with lattice phonons. Radiation of 2537Å wavelength gives rise to photochromism, whereas

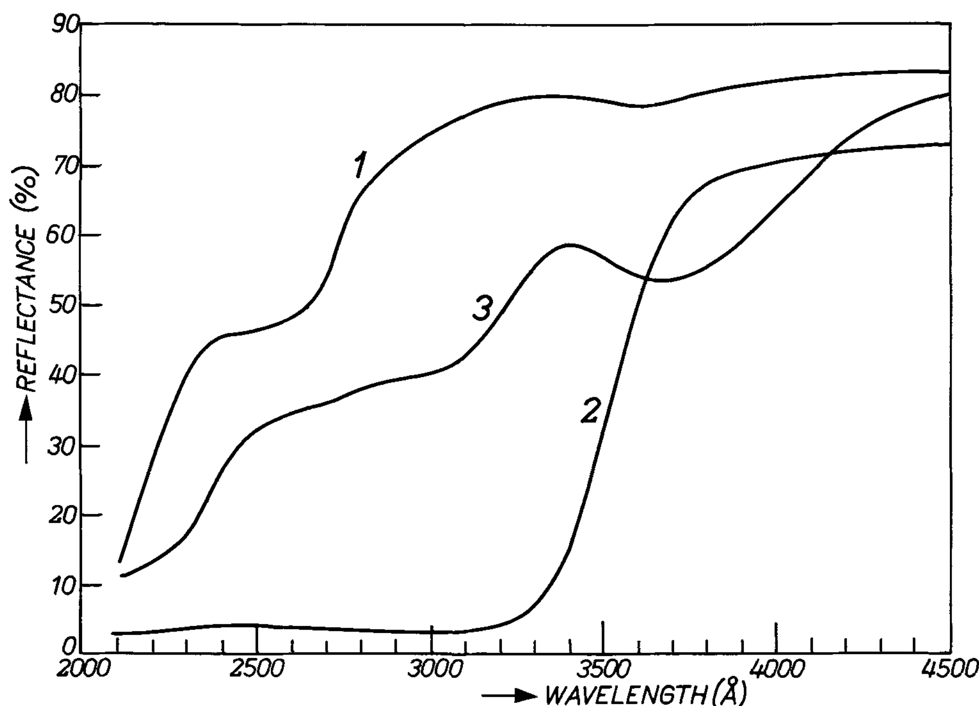

Fig. 2. UV reflection spectrum at 20°C of sulfate-doped bromide sodalite: curve 1, before reduction; curve 2, after reduction in H_2; and curve 3, after partial reoxidation in air.

3650Å radiation does not. These observations suggest an energy level scheme as shown in Fig. 6.

The partly reoxidized samples show a weaker photochromism than the reduced ones, whereas the bleaching properties are better. This may be the result of the different charge of the S^{--} and S_2^- ions. In the uncolored state of the sodalites, S^{--} has an effective negative charge of unity having a large capture cross section for holes, whereas S_2^- is effectively neutral, having a small capture cross section. In the colored state the empty S^{--} center (*i.e.* the S^- ion) is effectively neutral and therefore has a small capture cross section for electrons in contrast to the empty S_2^- center (*i.e.* the S_2 molecule) which is effectively positive, resulting in a large capture cross section for electrons.

The above-mentioned partial reoxidation, converting S^{--} centers into S_2^- centers, may be described by the reaction equation

$$2S'_{Cl} \rightarrow S_{2Cl} + V_{Cl} + 2e \quad [1]$$

In describing this chemical reaction we find it convenient to use the notation of Kröger and Vink (20) for defect centers: S'_{Cl} is a S^{--} ion on a Cl-site, S_{2Cl} is a S_2^- molecule-ion on a Cl-site, V_{Cl} is a chlorine-ion vacancy containing an electron, and e is an electron. The role of the oxidizing agent, *i.e.* the atmospheric oxygen, is to remove the electrons produced by Reaction [1], *e.g.* in the following way

$$\tfrac{1}{2}O_2(g) + V_{Cl} + e \rightarrow O'_{Cl} \quad [2]$$

where O'_{Cl} is an O^{--} ion on a Cl-site.

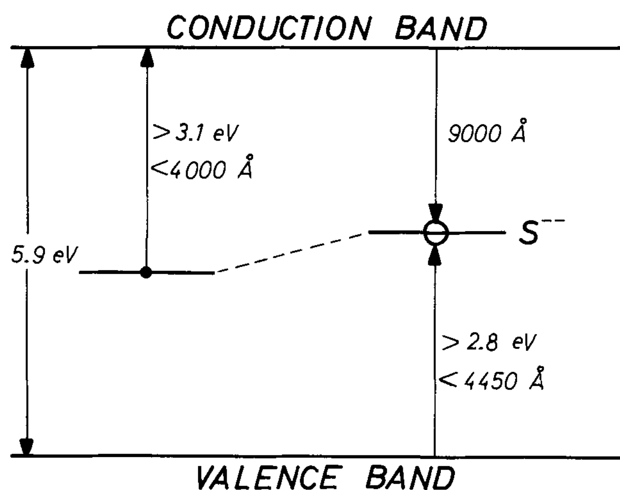

Fig. 3. Schematic energy level diagram of S^{--} in bromide sodalite.

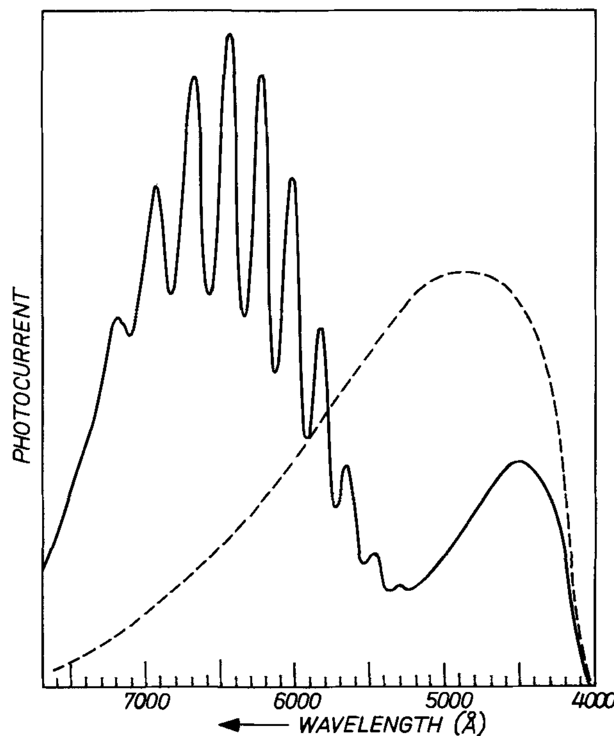

Fig. 4. Fluorescence of S_2^- in bromide sodalite at 77°K (solid curve). The spectral sensitivity of the equipment is shown by the dashed curve; the cutoff near 4000Å is due to a filter (Schott GG 15) used to suppress stray radiation.

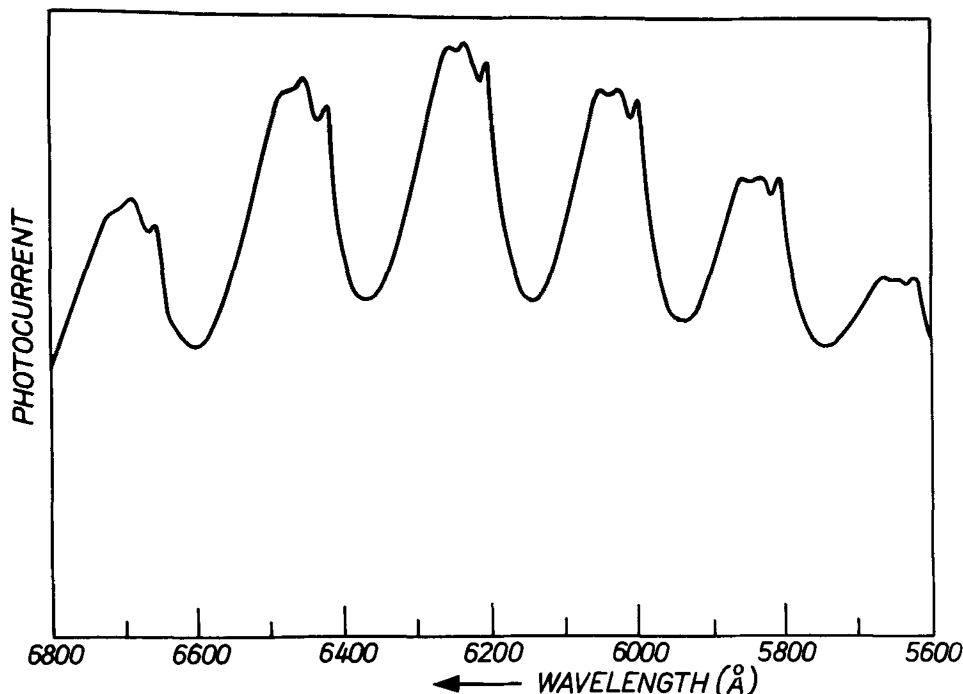

Fig. 5. Fine structure on the S_2^- fluorescence peaks in bromide sodalite at 77°K.

It was found by Taylor *et al.* (5) that chloride sodalite doped with S^{--} showed a residual coloration after prolonged irradiation with electrons, *i.e.* the induced color could not be bleached optically. This was accompanied by the appearance of the S_2^- fluorescence under 3650Å radiation. Though there are probably many reasons for the residual coloration, we propose the following mechanism as a possible one. We assume that the sulfur is incorporated as S^{--} ions which may be excited or ionized by the electron bombardment and then may become mobile and combine with other sulfur ions, forming S_2^- molecule ions. This may again be described by the reaction Eq. [1]. In this case, however, we have no reaction like Eq. [2] to remove the electrons created by Reaction [1]. These electrons will then fill empty chlorine vacancies causing a permanent coloration.

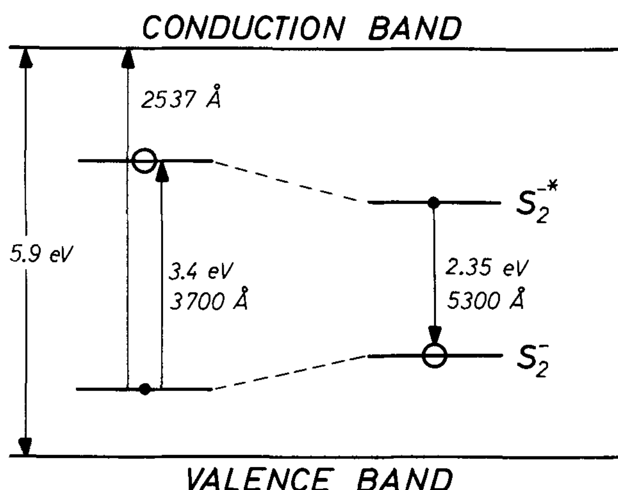

Fig. 6. Schematic energy level diagram of S_2^- in bromide sodalite; 3700Å radiation gives rise to fluorescence (zero-phonon wavelength 5300Å), 2537Å radiation gives rise to photochromism.

Oxygen centers.—Since oxygen is chemically related to sulfur it may be expected that oxygen centers exist that are analogous to the sulfur centers described in the previous section. These centers have been found in alkali halides (21-24) but, until recently, not in sodalite.

Some sodalite samples, when excited at 77°K with 2537Å radiation, show a weak, structured emission superimposed upon a broad background emission (see Fig. 7a) (25). The emission is relatively strong in chloride and bromide sodalite samples made by low-temperature hydrothermal synthesis (method 3) and has also been observed sometimes in samples made by method 4. We ascribe this emission to the O_2^- molecule ion because the general appearance and the peak spacings are similar to those of the O_2^- emission in the alkali halides.

No prominent absorption has been found which can be ascribed to the O_2^- center. Since 2537Å radiation excites the fluorescence while 3650Å radiation does not, the absorption spectrum may be similar to that in KCl with a maximum at 2500Å and almost no absorption at 3650Å (22). Photochromism is observed only for uv with wavelengths shorter than 2100Å. These observations agree with the energy level scheme in Fig. 8.

Sodalite samples exhibiting the O_2^- fluorescence often show a residual coloration. The cause may be the same as that proposed for the S_2^- centers.

We did not observe the O^{--} centers, either in absorption or in luminescence. The centers have been observed in alkali halides (24). We think that they are nevertheless present in sodalite and play an important role as type A centers. This has previously been suggested by Ballentyne and Bye (6).

Transition metals.—Sodalite samples doped with Co, Ni, Mn, Fe, and Cr show some interesting optical prop-

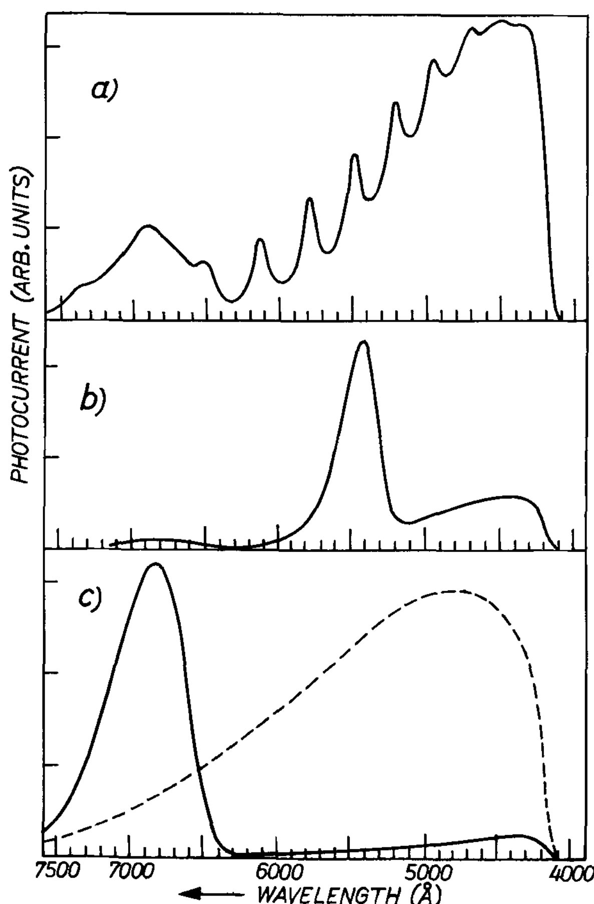

Fig. 7. Fluorescence of bromide sodalite at 77°K due to (a) O_2^- ions, (b) Mn^{2+} ions, and (c) Fe^{3+} ions. The dashed curve in (c) indicates the spectral sensitivity of the equipment (cf. Fig. 4).

erties. These samples were prepared by method 5. The doping was carried out by adding 2% by weight of the transition metal halides to the sodium halide used for the activation. The appearance of the doped powders was "cobalt blue" for Co, light purple for Ni, grayish

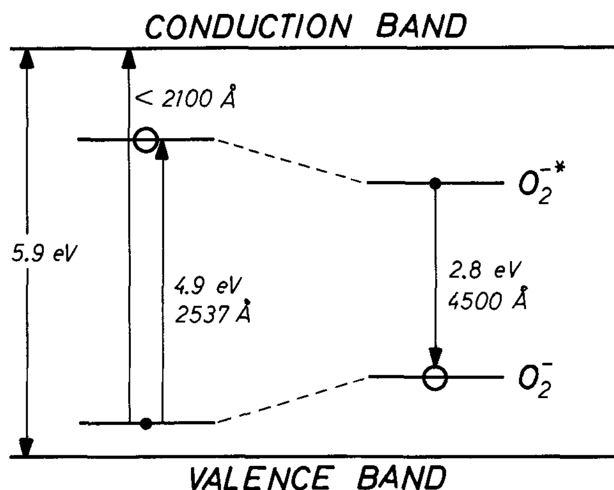

Fig. 8. Schematic energy level diagram of O_2^- in bromide sodalite; 2537Å radiation gives rise to fluorescence (zero-phonon wavelength 4500Å). Photochromism is observed for short-wavelength radiation (< 2100Å) only.

for Mn, and pure white for Fe and Cr. Some of the uv reflection spectra between 2000 and 4500Å are shown in Fig. 9. Fluorescence was observed in the Mn and Fe doped samples only. The green Mn fluorescence was weak, the red Fe fluorescence relatively strong (see Fig. 7b and c).

The incorporation of the transition metals in sodalite has several interesting aspects. First, the question whether the metal ions are incorporated in the aluminosilicate network, at chlorine or sodium sites, or interstitially; second, the coordination number of the ions; and third, their valency.

According to Linwood and Weyl (26), who studied the behavior of Ni, Co, and Mn in glasses, the blue color of the Co-doped samples, the purple color of the Ni-doped samples, and the green luminescence of the Mn-doped samples all point to a fourfold coordination of the divalent ions, which implies incorporation at Al

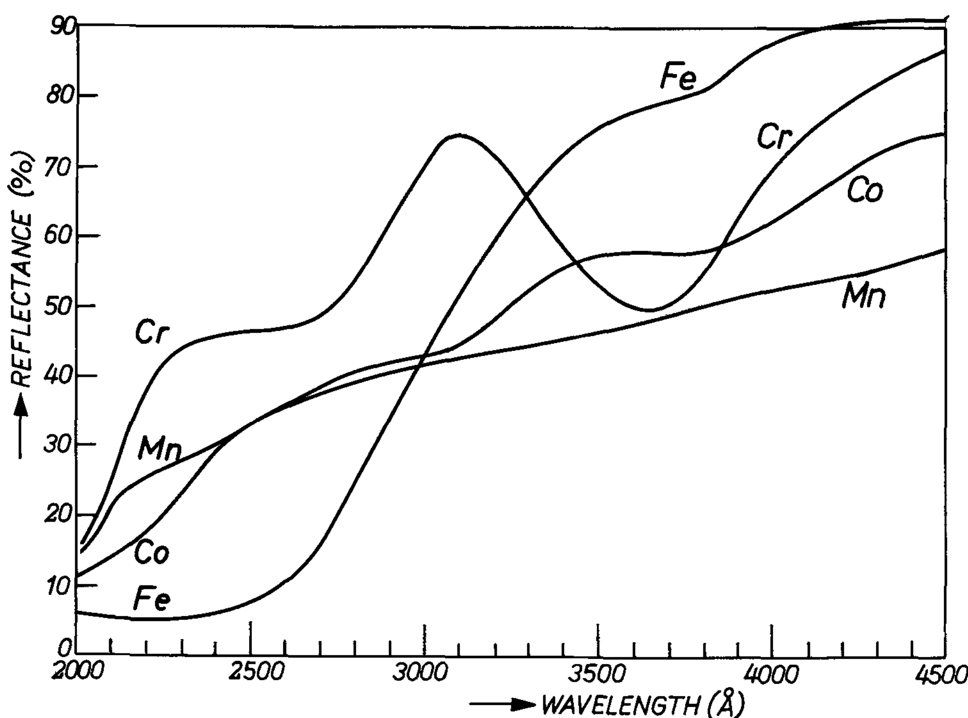

Fig. 9. UV reflection spectra at 20°C of bromide sodalite samples doped with Co, Cr, Fe, or Mn.

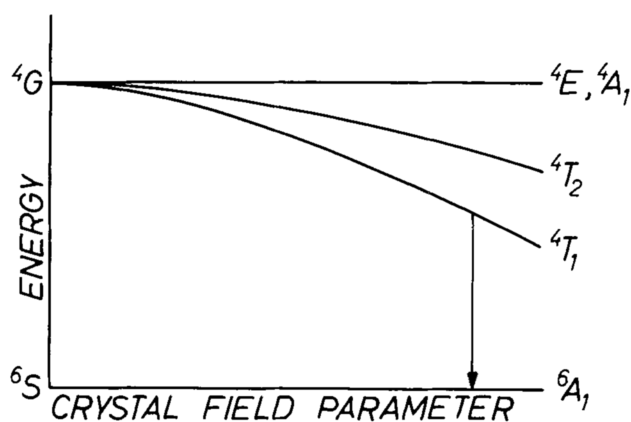

Fig. 10. Crystal-field splitting for the $3d^5$ configuration of Mn^{2+} and Fe^{3+} ions.

or Si sites. The luminescence of Mn^{2+} is connected with a transition from the lowest excited level ($^4T_1$ split off from the ^4G atomic level) to the ground level ($^6A_1$, atomic state ^6S) (see Fig. 10).

Another argument for the fourfold coordination of Mn^{2+} is derived from its e.s.r. signal. An experimental relation between the hyperfine constant and the covalency divided by the coordination number for Mn^{2+} in various host crystals (27) gives a value for the hyperfine constant of 82×10^{-4} cm^{-1} for a sixfold coordination by oxygen and of 75×10^{-4} cm^{-1} for a fourfold coordination. The experimental value of 76×10^{-4} cm^{-1} (28) indicates a fourfold coordination.

For the case of iron we have to consider both the valency (2 or 3) and the coordination number (4 or higher). We can rule out divalent iron for the following reasons. The energy-level splitting of the divalent ion in a fourfold coordination is shown in Fig. 11. For a sixfold coordination the positions of the ^5E and $^5T_2$ levels are reversed. The zero-phonon absorption of Fe^{2+} with a tetrahedral coordination of oxygen has been found at a phonon energy of 3595 cm^{-1} (λ = 3.45μ) (29). The transition energy for an octahedral coordination is not known. In view of its linear crystal field dependence and the crystal field being 9/4 times as strong, it may be estimated to have a value of 8100 cm^{-1} or 1.235μ. Neither of these energies agrees with our experimental value of 15,900 cm^{-1} or 6300Å (the high-energy tail of the fluorescence band). The observation that iron-doped sodalite which has been reduced in flowing hydrogen at 900°C shows neither the fluorescence band at 6800Å nor the absorption band at 2400Å gives additional support to the conclusion that the iron is in the trivalent state.

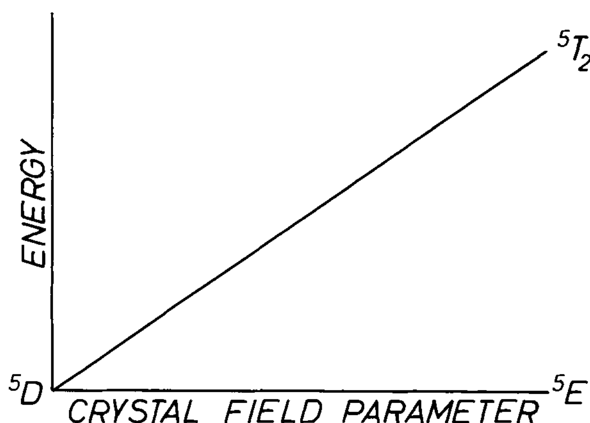

Fig. 11. Crystal-field splitting for the $3d^6$ configuration of Fe^{2+} with tetrahedral coordination.

The question of the coordination of the Fe^{3+} ion is more difficult to answer. Theoretically and experimentally, little is known about the crystal-field-split energy levels of Fe^{3+}. The electron configuration of Fe^{3+} is $3d^5$, the same as that of Mn^{2+}. The variation in the energy levels of Fe^{3+} and Mn^{2+} with the crystal field strength is qualitatively the same (see Fig. 10) but quantitatively different. The first excited level of the free Fe^{3+} ion is 32,000 cm^{-1} above the ground state as compared to 26,859 cm^{-1} in the case of Mn^{2+}. The crystal field splitting parameter is, however, larger for Fe^{3+} than for Mn^{2+} and the lowest transition energy of the Fe^{3+} ion in the crystal may therefore be lower than that of Mn^{2+}. Dvir and Low (30) find a value of 12,300 cm^{-1} for the absorption corresponding to the lowest transition energy of octahedrally coordinated Fe^{3+} in beryl. Comparison of this value with that found above for the fluorescence (15,900 cm^{-1}) indicates a fourfold coordination. Pott and McNicoll (31), however, observed blue and infrared emissions due to Fe^{3+} in γ-alumina which they ascribe to Fe^{3+} in fourfold and sixfold coordination, respectively. Melamed *et al.* (32) observed an emission band with a maximum at 6800Å and a number of absorption bands due to Fe^{3+} in $LiAl_5O_8$. The emission band was ascribed to the $^4T_1$ (^4G) $\rightarrow$ $^6A_1$ (^6S) transition of tetrahedrally coordinated Fe^{3+}. There was, however, some ambiguity in the band assignments, especially those of the absorption bands. We may conclude that the question of the coordination number has not yet been solved.

Doping with Fe, Ni, Mn, Co, or Cu in concentrations of 20-200 ppm causes an increase of the optical bleaching rate of electron-irradiated sodalite (33). This may be connected with the ability of these elements to act as recombination centers. Doping with Cr has little influence on the bleaching rate.

Radiation damage.—The coloring of sodalite by electron bombardment and the optical bleaching will be the subject of another paper (33). Here we will describe the effect of the electron bombardment on the reflection and fluorescence spectra, which was studied in connection with irreversible effects in coloring and bleaching.

The bombardment was carried out in a demountable tube. The duration of bombardment, the effects of bleaching by visible or uv radiation, the temperature, the storage time after the bombardment, and the composition of the material were varied.

A short irradiation (10 kV, 1 μC/cm^2), giving a contrast of about 2:1, causes the appearance of two uv absorption bands at 2600 and 3500Å (see curves 1 and 2 in Fig. 12). These bands are not directly connected with the visible coloration because bleaching of the latter has no effect on the uv bands. Irradiation with uv in one of the bands causes the bands to disappear simultaneously. This experiment has been performed using radiation of 3650Å or 2537Å, situated reasonably well within the absorption range of the bands. The bands always occur simultaneously and with the same intensity ratio. These facts indicate that the bands are associated with the same defect.

Irradiation for longer times (10 kV, 50 μC/cm^2), causing saturation of the visible coloration, does not further increase the uv bands but produces a general absorption in the wavelength range of 2000-4000Å (see curve 3 of Fig. 12). This is often accompanied by the appearance of a permanent color which cannot be bleached optically.

Heating to 200°C causes the complete disappearance of the two absorption bands but only partial disappearance of the diffuse absorption.

The uv absorption spectrum changes when the irradiated sodalite is stored at room temperature. Little change is observed for a couple of hours after irradiation but 24 hr later the absorption bands at 2600 and 3500Å have disappeared and a new band shows up at

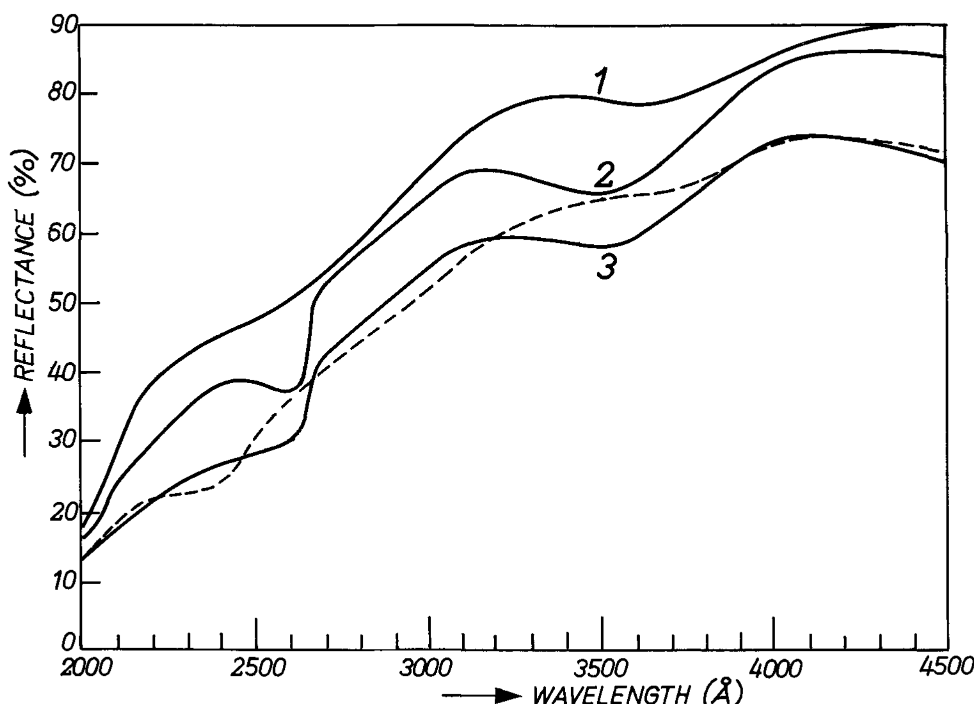

Fig. 12. UV reflection spectrum of bromide sodalite: curve 1, before electron irradiation and after electron irradiation with curve 2, a small dose (1 $\mu C/cm^2$, 10 kV), curve 3, a large dose (50 $\mu C/cm^2$, 10 kV), and dashed curve after 24 hr storage.

2400Å (see dashed curve in Fig. 12). Storage for longer periods does not change the spectrum any further. Preparation method 2 was used for the case illustrated but other methods were found to give similar results.

The effect of the following substitutions in the sodalite were studied: Br by OH, Cl, or I; Na by Li, K, or Rb; Si by Ge; and Al by Ga. In all cases the same absorption bands were observed. The sodalite structure also is not essential since nepheline, which has a different (hexagonal) structure likewise shows these bands.

In view of these observations we tentatively suggest that the defect is an oxygen radical ion, tied with one bond to a silicon or aluminum ion, or an oxygen ion that has been knocked completely free of the silicate network and is occupying some interstitial position.

The nature of the defect corresponding to the continuous absorption between 2000 and 4000Å is not yet known. Since this absorption develops simultaneously with a permanent coloration of the sodalite, there may be a connection between these two effects.

It is not yet certain whether the radiation damage in itself is harmful to the coloring and bleaching properties of sodalite.

The fluorescence spectrum of sodalite (at 77°K) is very sensitive to electron irradiation. A short irradiation (10 kV, 1 $\mu C/cm^2$) causes the development of a broad emission band with a maximum in the near u.v. The origin of this band is not yet known. It vanishes again after prolonged irradiation. All other emissions (due to Fe^{3+}, Mn^{2+}, and O_2^-) are strongly quenched. These effects will be studied further.

Conclusion

Cathodochromic sodalite was prepared by high-temperature solid-state reaction and by low-temperature hydrothermal reaction.

Undoped samples were not photochromic but their cathodochromism was often superior to that of sulfur-doped ones. These "undoped" samples are assumed to contain O^{--} and O_2^-, acting as acceptor centers. Doping with Fe, Ni, Mn, Co, or Cu increases the optical bleaching rate of electron-irradiated sodalite, Cr has little effect, O_2^- causes a residual coloration. Mn^{2+} shows a green luminescence, Fe^{3+} a red luminescence, and O_2^- a luminescence with several peaks between 4500Å and 7000Å. The transition metals are probably incorporated at Al or Si sites of the sodalite. Permanent changes due to electron irradiation were found in the uv reflection spectrum: one, after short irradiation, resulted in two absorption bands at 2600Å and 3500Å; the other, after prolonged irradiation, resulted in a general absorption between 2000Å and 4000Å. The interrelation between these phenomena and irreversible effects in cathodochromism is under study.

Acknowledgment

We wish to thank Th. W. Lathouwers for valuable assistance in the preparation of the sodalite samples and R. A. van Doorn for skillful assitance in the experiments on cathodochromism. We also acknowledge the contribution of J. Goorissen and J. A. M. Smets in the preparation of sodalite during the early stages of this work. Thanks are due to L. C. Bastings for the chemical analysis, to C. Langereis for the x-ray diffraction measurements, and to G. G. P. van Gorkom who kindly performed some e.s.r. experiments. We have further benefited from useful discussions with R. E. Schuil and A. M. B. M. Holland, who also put a number of sodalite samples at our disposal.

Manuscript submitted June 18, 1971; revised manuscript received ca. Sept. 13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Characterization of a Gold-Copper Composite Surface for Plated Wire Memory

F. E. Luborsky, M. W. Breiter,* and B. J. Drummond

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Gold electrodeposited at very low currents onto a coarse-grained copper surface was found to enhance nondestructive read-out (NDRO) memory performance when used as a substrate for the electrodeposition of Permalloy films. The structure of this Au layer is studied. Corrosion potential measurements are used to show that the Au covers about 0.4 of the surface when deposited on the coarse-grain Cu to produce optimum NDRO properties but the same quantity of Au deposited on fine-grain Cu covers ~0.7 of the surface. The average Au thickness, grain size, lattice parameter, and coverage all show a sharp change at the same current. This current occurs just beyond the deposition current used to produce the optimum surface for NDRO memory wire. It appears to correspond to the transition from a Au island structure to a continuous film structure and is close to the point at which the Au deposition efficiency rises sharply. Scanning electron micrographs indicate the presence of Au islands at the low currents but do not have sufficient resolution to show their detailed structure.

Wires plated with a thin film of NiFe are becoming increasingly important as elements for computer memories. The magnetic properties of the NiFe are critically dependent on the nature of the substrate. Copper has typically been used and control of its surface topography to achieve the desired characteristics has been discussed extensively. This area of work has been recently reviewed (1). More recently it has been shown (2, 3) that the presence of gold islands on the copper, particularly on rough coarse-grained Cu, results in greatly improved magnetic properties.

This paper describes the physical and metallurgical structures of these Au films deposited on Cu.

Sample Preparation

Wire samples were all prepared in a continuous plating system briefly described previously (2, 3). The substrate wire was either 2.2 mil diameter electropolished tungsten wire[1] plated with about 1μ of Au or 2.2 mil CuBe wire[2] drawn to a smooth surface finish. A fine-grain smooth Cu layer with an average thickness of 2μ was then deposited from a $CuSO_4$ electrolyte containing UBAC[3] as a leveling agent. Some samples were then given a controlled roughness by depositing another layer of Cu from a $CuSO_4$ electrolyte at higher temperatures without any leveling agents. Finally Au was deposited from an Orosene 999 electrolyte[4] at various currents using 30°C, 4.3 pH, and a constant flow across the wire from four perpendicular directions staggered along the length of the wire. All plating cells were 2 in. long.

Analytical Techniques and Results

Corrosion potential measurements.—Corrosion potentials on specimens consisting of two different metals have been shown (4-6) to be related to the proportion of the exposed areas of the two metals. It can be shown theoretically, assuming that both the anodic reaction of metal dissolution at exposed copper and the cathodic reaction of oxygen reduction at exposed gold are controlled by activation polarization, that

$$V_{corr} = K_1 - K_2 \log (A_{Cu}/A_{Au}) \quad [1]$$

where V_{corr} is the corrosion potential measured against a suitable reference electrode. K_1 and K_2 are constants which depend on the Tafel slopes of the individual electrode reactions, on the corrosion potential of the pure Cu, and on the exchange current densities. A_{Cu} designates the fraction of the total surface which is covered by copper, A_{Au} the fraction covered with gold. Calibration curves obtained on short-circuited Cu and Au electrodes are shown in Fig. 1 for a variety of conditions. As shown by the

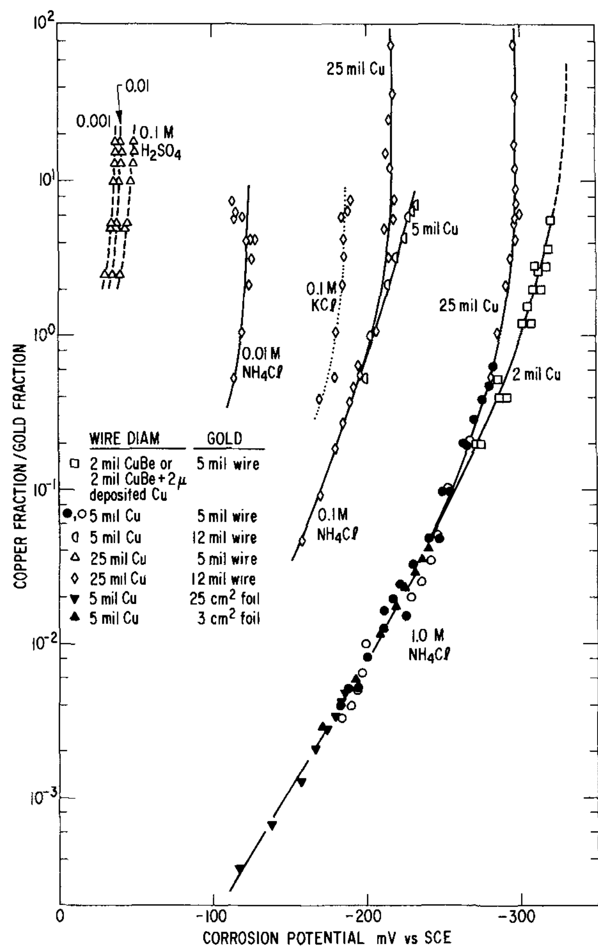

Fig. 1. Calibration for corrosion potentials of Cu-Au coupled samples of various geometries in different electrolytes. Electrolyte was air agitated at 1 ft³/hr for the open symbols or mildly stirred for the solid symbols.

results in 1M NH_4Cl, for A_{Cu}/A_{Au} less than ~0.05 the results follow the functional form of Eq. [1]. This has been demonstrated previously (5). In this range, the results were independent of the size and geometry of the coupled specimen of Cu and Au and independent of the degree of agitation.

For the investigation of small Au islands on Cu substrates in the present work, the region where A_{Cu}/A_{Au} is greater than 0.05 is important. As indicated in Fig. 1, in this range the potentials appear to be sensitive to electrode geometry, and to approach a limiting potential for each electrode geometry and for each of the electrolytes explored. Thus the results no longer follow the form of Eq. [1] at $A_{Cu}/A_{Au} > 0.05$. This suggests that the electrode reactions are at least in part diffusion controlled and that the exchange current for Au is very small compared to the Cu. Thus a steady-state mixed potential cannot be established. Nevertheless, empirical calibration curves can be established for a given set of experimental conditions.

In all cases, when the calibration samples were first immersed, the potentials showed an initial very rapid change with time, before stabilizing to a constant value. In the case of the samples of Au plated on Cu, after the initial rapid change in potential most samples slowly drifted in potential probably indicative of changes in the surface of the samples. Thus the potentials used were obtained by extrapolating this slowly changing portion of the curve back to zero time. Some typical examples of such curves are shown in Fig. 2 for samples prepared at different gold currents onto the rough Cu substrates. Similar curves were

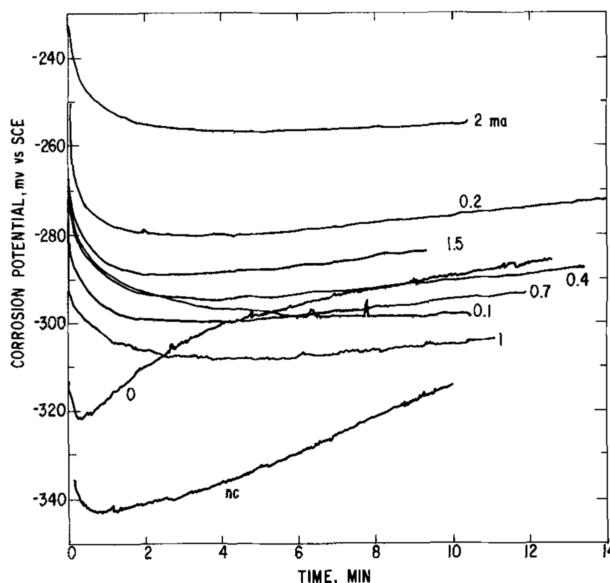

Fig. 2. Typical variation of corrosion potential with time after immersion in 1M NH_4Cl for samples prepared with no Au (nc) and with Au deposited at various currents in a 2 in. long cell onto the 2.2 mil diameter wire. Wire speed 14 in./min; Au electrolyte flow = 1.9 liters/min. Rough coarse-grain Cu substrate.

obtained for samples prepared on the smooth Cu substrates. The corrosion potentials obtained by extrapolation to $t = 0$ are shown in Fig. 3. On the right hand ordinate are the corresponding Cu area fractions obtained from the empirical calibration curve in Fig. 1 using the curve obtained with the 2-mil Cu-plated CuBe wire tested in 1M NH_4Cl. Note that at low Au deposition currents on the smooth Cu, the area fraction of exposed Cu is almost independent of current; $A_{Cu} = 0.3 \pm 0.1$ ($A_{Au} = 0.7 \pm 0.1$). For the rough Cu there is a pronounced minimum at 1.0 mA of the deposition current; $A_{Cu} = 0.55$ ($A_{Au} = 0.45$). For the thick Au films, the scatter indicates the random occurrence of pin holes or other flaws. Under

The corresponding Cu area exposed is shown on the right hand ordinate as obtained from Fig. 1. ○ Smooth fine-grain substrate, □ rough coarse-grain substrate.

Table I. Area fractions of gold determined from corrosion potentials

Au current	On coarse-grained Cu	On fine-grained Cu	
		1st Test	2nd Test
nc	0	0	0
0.05	0.15 ± 0.1	0.6 ± 0.1	0.6 ± 0.1
0.2	0.35 ± 0.1	0.85 ± 0.05	0.80 ± 0.05
10	1.00000	1.00000	1.00000

Notes: Samples prepared at 21 in./min. Electrolyte flow = 0.3 liter/min in Au plating bath. Average value of two samples reported.

the Au plating conditions of Fig. 3, the memory characteristics, specifically the NDRO quality, show a pronounced optimum at a deposition current of 1 mA Au on the rough Cu, but little or no optimum on the smooth Cu. Thus the quality of the memory characteristics may be correlated in an empirical way to the shape of the curves in Fig. 3.

In another set of samples prepared at a lower electrolyte flow rate in the gold plating bath similar results (Table I) were obtained. However, the optimum magnetic properties for the data in Table I occurred at a gold deposition current of ~0.1 mA rather than at 1.0 mA for the data in Fig. 3. The difference is attributed to the different degree of agitation in the gold plating bath.

Cyclic voltammetry, in principle, could also give a quantitative measure of relative surface areas; but it was found in previous work (7) that for these Au-Cu surfaces the results could not be made quantitative because of interference of CuO_2^{--}.

Gold analysis.—Long lengths of CuBe wires plated with gold at various currents were analyzed for Au. A standard wet chemistry Au assay was used, good to ± 2 μg. The results, converted to an average Au thickness, are shown in Fig. 4. The upper points were also obtained by calculation from the weight gain of the sample after the gold plating.

Since gold deposits are formed in the absence of a cathodic current, gold deposition occurs also by either a chemical reaction or a mixed potential process at open circuit. During the deposition process the wires were in the plating bath for the same time (6 sec). Thus the abscissa in Fig. 4 represents also a measure of the number of coulombs consumed during the deposition. The data in Fig. 4 imply that the efficiency of gold plating (= average gold thickness/coulomb) decreases on both the smooth and the rough substrate with increasing current between 0.1 and 1 mA. After passing through a minimum at about 1 mA, the efficiency increases between 1 and about 5 mA; then it decreases again. The latter decrease of the efficiency is understandable. It results from the increase of the contribution of hydrogen evolution to the cathodic current. The decrease of the plating efficiency between 0.1 and 1 mA is more difficult to interpret because the composition of the commercial bath is not known. It is considered likely that the deposition at currents below 1 mA involves a complexed gold ion of a different valency than the deposition above 1 mA. Electrochemical conversion of the complexed ion, involved in the deposition process below 1 mA, to another complexed ion might account for the observed decrease of the plating efficiency between 0.1 and 1 mA.

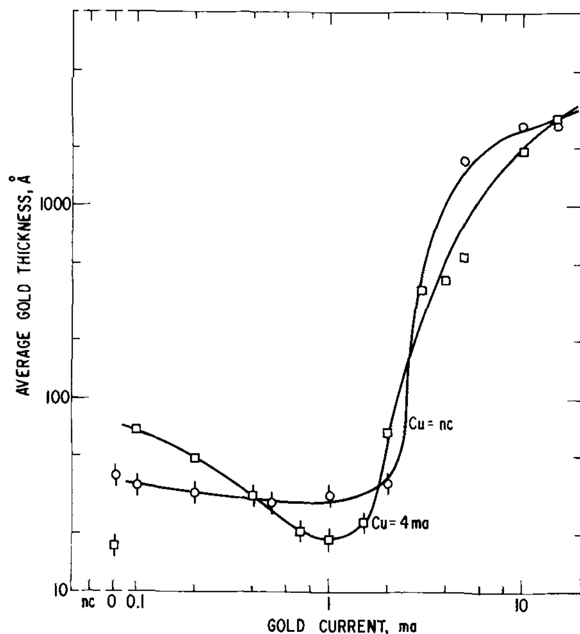

Fig. 4. Average Au thicknesses calculated from weight of Au found by chemical analysis on the same samples as in Fig. 2 and 3. Analytical error possible in the analysis is indicated by the vertical line.

X-ray diffraction.—In order to obtain x-ray diffraction results a thick film of Au was obtained by stopping the line. The lattice parameters and grain sizes obtained are shown in Fig. 5. The lattice parameters at low currents correspond to that of pure Au; at higher currents an alloy is indicated. The grain sizes were determined by line broadening using the average of several reflections. Corrections for strain broadening were not included. Thus the sizes are lower limits. Here also the change in properties occurs at the same Au current as in Fig. 3 and 4.

Scanning electron microscopy.—The same samples as in Fig. 2-5 were examined in a conventional scanning electron microscope using secondary electron detection. Typical pictures, on the smooth Cu substrate, are shown in Fig. 6, originally at 2000 magnification. The first picture (no contact with the plating bath) and the last two (prepared after gold deposition at 5 and 15 mA) show no fine structure. All the other samples show a fine structure which could not be clearly resolved even in pictures taken originally at 10,000 magnification (Fig. 7). The spots, assumed to be the Au islands, appear to be about 1000 ± 500Å in diameter and have a density of about 10^9-10^{10}/cm² at a current of 1 mA.

Scanning micrographs of the Au deposits on the rough Cu substrates all looked alike. A typical example is shown in Fig. 8. The extreme roughness of the Cu masks any effects due to the Au.

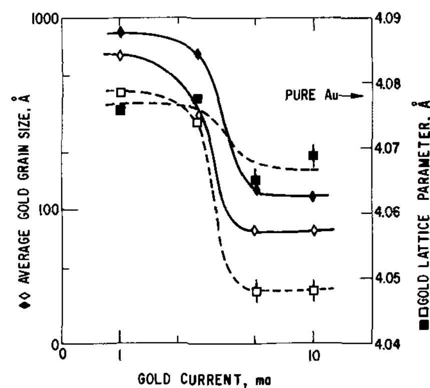

Fig. 5. The grain size and lattice parameter of the gold deposit for samples prepared as in Fig. 4 on a smooth fine-grain Cu surface but with the plating line stopped so as to form a thick enough film for x-ray diffraction. Discussion

The magnetic properties developed in zero magnetostrictive Permalloy films electrodeposited on these substrates are discussed in detail elsewhere (2, 3). The optimum nondestructive read-out characteristics were obtained by deposition of the Permalloy onto a substrate of coarse-grained Cu with Au islands. The gold plating current necessary for the achievement of the optimum characteristics depended on the

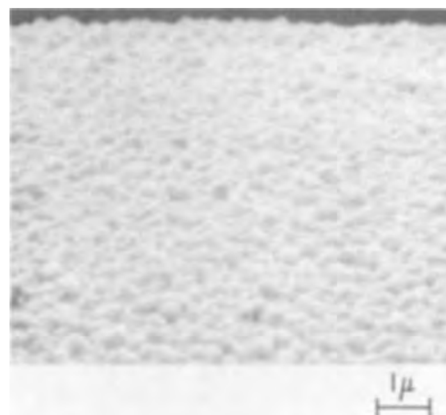

Fig. 8. A typical scanning electron micrograph of the rough Cu surface (Cu = 4 mA).

agitation around the wire as provided by the flow through the plating cell. The optimum current was ~0.1 mA for a flow of 0.3 liter/min and 1.0 mA for a flow of 1.9 liters/min. It was also shown (2, 3) that on fine-grained Cu substrates the presence of Au islands, prepared over the entire range of deposition currents, had little or no effect on the magnetic properties of the Permalloy. All of these results, obtained from the magnetic properties, are consistent with the results found in this work. For example, on the smooth Cu there was almost no change in the amount of Au deposited (Fig. 4) or in its coverage (Fig. 3) below the 1-2 mA range where Au islands form, but on the rough Cu there are significant changes.

One of the features of interest is the geometry of the Au islands. The average height, h, can be calculated assuming that the islands are cylindrical posts, by using the total weight of Au per square centimeter, W_{Au}, obtained from the chemical analysis and the fractional coverage A_{Au} from the corrosion potential measurements where

$$h = W_{Au}/19.3\,A_{Au}$$

For the fine-grained substrates at the optimum plating current, $W_{Au} = 6.4 \times 10^{-6}$ g/cm^2 (=33Å from Fig. 5) and $A_{Au} = 0.7 \pm 0.1$ (Fig. 4) giving

$$h = 48\text{Å}$$

For the coarse-grained substrates, $W_{Au} = 3.7 \times 10^{-6}$ g/cm^2 (=19Å), $A_{Au} = 0.45 \pm 0.1$, and therefore

$$h = 43\text{Å}$$

which is the same as on the fine-grain Cu.

The diameter D and number N of islands/square centimeter, were estimated from the high magnification scanning electron micrographs (Fig. 7) even though the poor resolution limited the accuracy of the measurements. The diameter on fine-grain Cu was estimated to be 1000Å ± 50% and the number of islands as 10^9 to 10^{10}/cm^2 at the optimum plating current of 1 mA. The area fraction of Au, calculated from these estimates

$$A_{Au} = D^2N/4 = 0.08 \text{ to } 0.8 \pm 50\%$$

which is at least in the range of values obtained from the corrosion potential measurements.

It is suggested that the minimum in the curves of Au coverage *vs.* deposition current (Fig. 4) occurs because the quantity of Au deposited also goes through a minimum. The minimum is more pronounced for deposition of Au on the rough surface because of the selective deposition onto the high potential points, *i.e.*, the high points on the surface.

Conclusions and Summary

The deposition of Au at low currents produces islands on the Cu. The production of optimum magnetic properties in a Permalloy film deposited on these substrates corresponds to a specific Au island structure which has been characterized by average thickness measurements, corrosion potential measurements, scanning electron micrographs, and x-ray diffraction results on two types of Cu surfaces. The application of the measurement of corrosion potential to determine the relative surface areas of Cu and Au was found to be especially useful.

Carrier and Zinc Concentrations for Zinc Diffusion in Gallium Arsenide

C. H. Ting

ABSTRACT

The zinc and free carrier concentration profiles for zinc-diffused regions in GaAs were determined by means of radiotracer and Hall coefficient measurements, respectively. The carrier concentration is significantly lower than the total zinc concentration. The difference increases for longer diffusion times. This difference is attributed to zinc precipitaton in the heavily damaged diffused region. The measurements indicate that about 20-35% of the zinc is precipitated in the samples studied. A novel method of making ohmic contacts for Hall measurements is described. These contacts are not destroyed by successive lapping, thus making the incremental Hall measurements possible. The sources of experimental error are discussed briefly.

Zinc is used extensively as an acceptor impurity in GaAs. It was reported that for melt-doped GaAs the free carrier concentration is essentially equal to the zinc concentration, even for heavily doped samples (1). However, for zinc-diffused samples the carrier concentration may be less than the zinc concentration since zinc diffusion is known to induce defects in GaAs (2, 3). Precipitates at these induced defects were revealed by infrared transmission microscopy and x-ray transmission microscopy. The precipitates

Key words: radiotracer profiles, Hall measurement, precipitates, diffusion induced defects.

were found to be zinc rich by electron microprobe analysis (4). Goldstein (5) measured the free carrier concentration in zinc-diffused samples and found it to be approximately equal to the total zinc concentration. However, he did not give any experimental details so it is impossible to tell whether his samples were free of induced defects or to determine how accurately he could have measured a difference between the carrier and total zinc concentrations.

In this study both the carrier and zinc concentration profiles were measured on zinc-diffused GaAs samples. The zinc concentration profiles were determined by measuring the radioactivity of successively removed layers; the carrier concentration profiles were determined by Hall measurements on the same sample before and after the removal of each layer. A significant difference between the zinc and carrier concentrations was observed.

Experimental Procedure

The starting material was single-crystal, p-type GaAs oriented in the <111> direction. Pure Zn^{65} (245-day half-life) was used as a diffusion source. Two diffusion runs were carried out, one at 751°C for 3 hr and another at 755°C for 6 hr. After diffusion the samples were quenched quickly in water. Test samples of 0.200 in. diameter were cut out from the diffused samples with an ultrasonic cutter. The zinc concentration profiles were determined by a conventional radiotracer technique of lapping and counting; it will not be described in detail here. The carrier concentration profiles were determined by measuring sheet conductivity σ_s and sheet Hall coefficient R_{Hs} before and after removal of small layers for radiotracer counting.

The experimental setup for Hall and conductivity measurements is similar to the four-point probe developed by Buehler and Pearson (6). This method requires a centered, square array of ohmic contacts on a circular sample, and is identical to the van der Pauw method (7) if the contacts are located on the periphery of the sample. Because edge contacts are difficult to make, the spacing of the square array, s, is usually smaller than the sample diameter, d, as illustrated in Fig. 1. The correction factors for nonperipheral contacts can be calculated for this case because of the simple symmetry of the square array centered on a circular sample; the values are given by Buehler (6).

Unlike point contacts on InAs (6), point contacts on GaAs generally do not yield good electrical contacts because an insulating layer always exists on the GaAs surface. Good ohmic contacts are necessary for the measurements. These contacts should be made to the entire depth of the diffused layer instead of just on the surface so they will not be destroyed by each lapping. This is accomplished by drilling ultrasonically a square array of small holes in the diffused sample; then alloy contacts are made inside these holes. The four-point probe can be used on these alloy contacts after successive lappings. The contact holes are 0.006 in. diameter and are spaced about 0.100 in. apart; the sample diameter is 0.200 in. Because the size of the drilled holes is very small compared to the sample size, these alloy contacts can be treated as point contacts. To carry out Hall measurements on the entire diffused p layer, the holes for alloy contacts must be deeper than the diffused layer. In this case a hole depth of 0.005 in. was used.

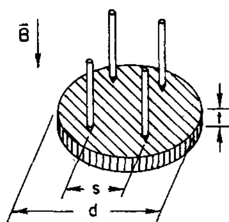

Fig. 1. Four-point Hall probe

The experimental results described here were obtained by diffusing zinc into p-type bulk with low carrier concentrations (2×10^{17} cm^{-3}), to avoid complicating the Hall measurements due to the p-n junction. With n-type bulk, meaningful measurements can be obtained only if the alloy makes good rectifying contacts to the n-type bulk so current flow is limited to the p layer. Good rectifying contacts cannot be obtained readily in the ultrasonically drilled holes and the resulting Hall measurements on n-type samples were unsatisfactory.

Experimental Results

The sheet conductivity σ_s and the sheet Hall coefficient R_{Hs} obtained by successive measurements after removal of incremental layers parallel to the surface are shown in Fig. 2 for the 3-hr diffusion and in Fig. 3 for the 6-hr diffusion. The conductivity $\sigma(x)$ and carrier concentration $p(x)$ can be determined from the measured sheet coefficients by using the following relations (8, 9)

$$\sigma(x) = \frac{d}{dx}\sigma_s \quad [1]$$

$$p(x) = \frac{\left(\dfrac{d}{dx}\sigma_s\right)^2}{q\dfrac{d}{dx}(R_{Hs}\cdot\sigma_s^2)} \quad [2]$$

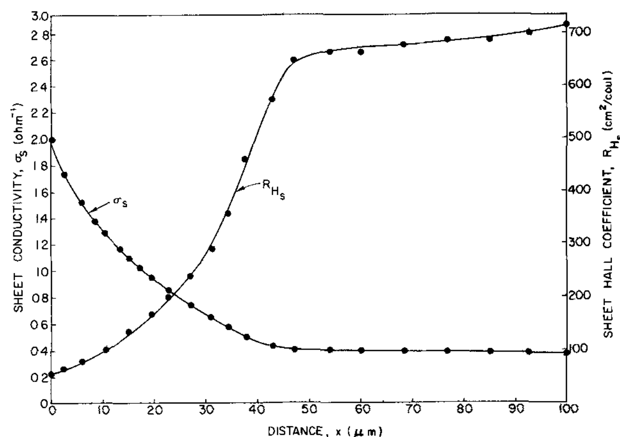

Fig. 2. Sheet conductivity and sheet Hall coefficient vs. distance from the surface for sample No. 1. Diffusion data: T = 751°C, t = 3 hr.

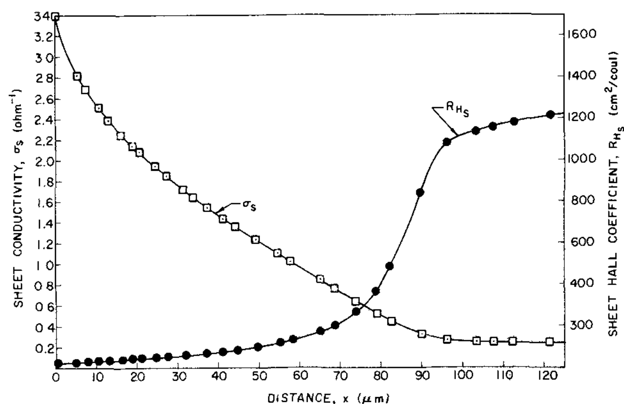

Fig. 3. σ_s and R_{Hs} vs. distance from the surface for sample No. 2. Diffusion data: T = 755°C, t = 6 hr.

These equations and the data given in Fig. 2 were used to determine the conductivity $\sigma(x)$ and the hole concentration $p(x)$ for the 3-hr run, as shown in Fig. 4 and 5, respectively. The total zinc concentration obtained from radioactivity measurements is also shown in Fig. 5 for comparison. Two sets of data points, one obtained for the Hall measurement side and the other for the opposite side, were used to increase accuracy in constructing the zinc concentration profile. The conductivity and carrier concentration of the 6-hr run, obtained from the data given in Fig. 3, are shown in Fig. 6 and 7, respectively. The total zinc concentration profile obtained from the Hall measurement side is also given in Fig. 7 for comparison.

It should be pointed out that some precautions were taken to obtain reasonable accuracy. There are three major sources of experimental error.

1. *Noise*: The Hall voltage measured is rather small (a few microvolts) because of high carrier concentration and relatively low mobility; therefore, fluctuations caused by unavoidable external noise are important. To improve accuracy, the average of four readings obtained by reversing the current and magnetic field is taken, in the usual manner.

2. *Nonohmic contacts*: These will give superfluous voltages that will result in very large errors. Although alloyed ohmic contacts can be made on the diffused

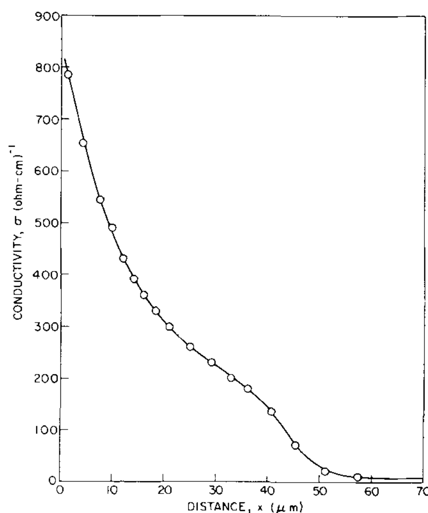

Fig. 4. Conductivity *vs.* distance from the surface for sample No. 1.

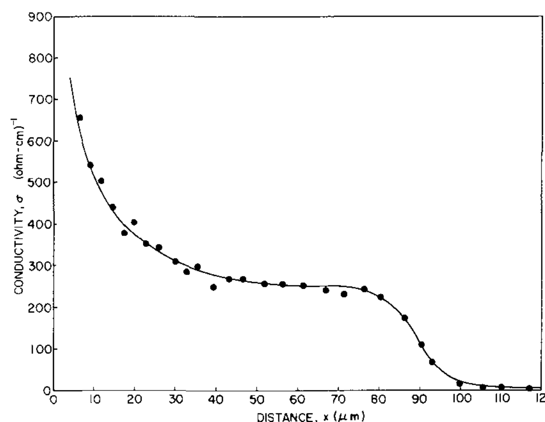

Fig. 6. Conductivity *vs.* distance from the surface for sample No. 2.

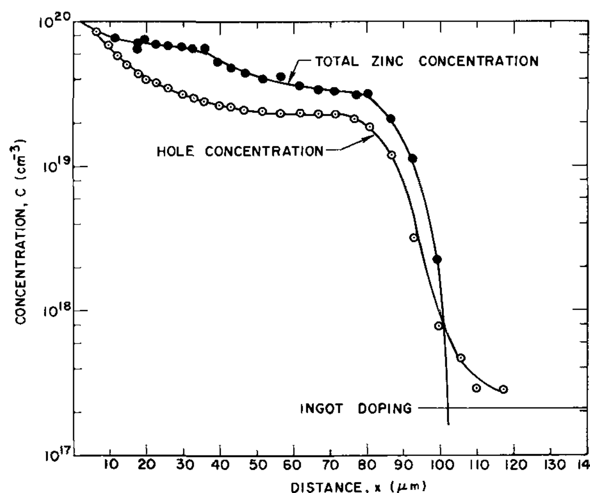

Fig. 7. Total zinc and hole concentration profiles for sample No. 2.

layer, their quality deteriorates as successive layers are removed, because it is more difficult to obtain ohmic contacts in the interior of the sample where carrier concentration is lower. This becomes a serious problem near the diffusion front where the concentration drops sharply.

3. *Nonparallel lapping*: The accuracy in determining diffusion depth is limited by the degree to which lapping is not parallel to the surface. This is particularly important for the first few layers.

Meaningful results can be obtained only when sufficient care is taken with the experiment. That this has been accomplished is evidenced by the small scatter in the experimental values of σ_s and R_{Hs}, as shown in Fig. 2 and 3. However, the final values of $\sigma(x)$ and $p(x)$ are not as accurate as the measured values of σ_s and R_{Hs}. This is because derivatives and the square of derivatives of the measured quantities are involved in the calculation of $\sigma(x)$ and $p(x)$; these derivatives tend to accentuate any experimental error. To increase accuracy, all derivatives obtained from experimental data are first plotted against distance to eliminate any dubious points, and only the smoothed values are used in subsequent calculations.

Discussion

It is clearly shown in Fig. 5 and 7 that the carrier concentration is less than the total zinc concentration in the diffused region. This difference can be attributed to zinc precipitation, since precipitates in the heavily damaged diffused layer have been identified as zinc rich

(4). Therefore, the results presented here verify quantitatively the existence of zinc precipitation in the diffused layer. This result should be compared with the measurements obtained from melt-doped samples, where a one-to-one correspondence between zinc and carrier concentration was reported for zinc at approximately 10^{19} cm^{-3} in the grown crystals (1). The difference could be due to the fact that the melt-doped samples have relatively small defect concentrations as compared to the diffused region.

It should be pointed out that in using Eq. [2] to calculate the carrier concentrations shown in Fig. 5 and 7, the Hall coefficient factor (10) has been taken as unity. It is well known in semiconductor theory that this factor is unity only for degenerate materials; in general its value lies between 1 and 2, depending on the scattering mechanism. In the case of p-type gallium arsenide, the material is degenerate for $p \gtrsim 10^{19}$ cm^{-3} at room temperature (11). Therefore, in Fig. 5 and 7, the calculated carrier concentrations are correct throughout the diffused region except at the sharp diffusion front where carrier concentration falls off rather sharply.

An estimate of the amount of zinc precipitation can be obtained from Fig. 5 and 7. The total zinc present in the diffused sample per unit surface area is given by the area under the concentration-distance curve; similarly, the total number of carriers is given by the area under the carrier-distance curve. Results obtained from Fig. 5 indicate that the number of free carriers is equal to approximately 78% of the total number of zinc atoms present; thus precipitation accounts for approximately 22% of the total zinc in the first sample. The results shown in Fig. 7 indicate that precipitation accounts for approximately 34% of the total zinc in the second sample.

It has been shown that for very shallow diffusions there are no significant induced defects (3). The shallow diffusion corresponds to the thin layer near the surface where defect concentrations should be small; therefore, zinc precipitation should also be small. This is indeed the case since it is shown in Fig. 5 that the agreement between the carrier and zinc concentrations is quite good near the surface. The results presented here, therefore, are consistent with the observations made by Black (3). As diffusion time increases, induced defects will eventually propagate into the region near the surface and zinc precipitates will increase. This is illustrated by the significant difference between carrier and zinc concentrations in the region close to the surface shown in Fig. 7.

Heteroepitaxial GaAs on Aluminum Oxide

The Formation and Electrical Properties of Zn- and Cd-Doped Films

H. M. Manasevit and A. C. Thorsen

Autonetics Division of North American Rockwell Corporation, Anaheim, California 92803

ABSTRACT

An all metalorganic-hydride chemical vapor deposition process has been used to produce p-type GaAs films on sapphire. Dimethylcadmium or diethylzinc have been combined with trimethylgallium and arsine to produce films with net acceptor concentrations as high as 5×10^{17} and 8×10^{19} cm^{-3}, respectively. The doping concentrations are found to be an exponential function of growth temperature when other parameters remain fixed. The electrical properties of thick films are found to be equivalent to good quality bulk GaAs. Hole mobilities approximately 80-90% of the best thick-film values have been obtained for acceptor concentrations $\sim 10^{19}$ cm^{-3} in thin (~ 1 μm) films on sapphire and spinel.

In 1968 the first successful use of metalorganics in the preparation of epitaxial GaAs on sapphire (Al_2O_3) and other substrates was reported by our laboratories (1). Since that time, extensive studies of the properties of undoped GaAs/Al_2O_3 films formed by the reaction of trimethylgallium (TMG) and arsine (AsH_3) have been carried out (2, 3). The process for producing p-type films by the addition of diethylzinc (DEZ) to the reaction mixture containing TMG and AsH_3 (1) has been explored in more detail and has been extended to include dimethylcadmium (DMCd) as the dopant source. The electrical characteristics of these films have been investigated and related to the growth conditions.

Key words: chemical vapor deposition, metalorganics, trimethylgallium, arsine, spinel.

Experimental

The apparatus, chemicals (except for DMCd), and experimental techniques used for the present work

have been described previously (1-3). The DMCd was obtained from Orgmet, Inc., Hampstead, New Hampshire, and handled in a fashion similar to the DEZ.

The TMG was carried into the reactor by passing H_2 gas through the liquid, equilibrated at 0°C. AsH_3 diluted to 10% in H_2 was normally used as the source of As. The dopant gases were added by passing the carrier gas over the liquid (either DEZ or DMCd) maintained at 0°C, unless otherwise stated. In the data discussed in the following sections, a notation X-Y-Z describing a particular set of experimental conditions refers to X cm^3/min of the AsH_3-H_2 mixture passing into the reactor along with Y cm^3/min bubbled through TMG and Z cm^3/min of H_2 passed over the dopant liquid. These were mixed with the carrier gas flowing at 1-3 liters/min.

The dopant vapors were introduced into the reactor in three different ways in order to determine a preferred doping process: (*i*) with the TMG vapor after the introduction of AsH_3 into the reactor (pre-AsH_3 process); (*ii*) with the AsH_3, prior to the introduction of the TMG (pre-AsH_3-DEZ process); and (*iii*) with all gases simultaneously introduced into the reactor.

Mechanically polished (0001) Al_2O_3 substrates were used exclusively for the studies reported.

Results and Discussion

Previous studies (1, 3) on the growth of undoped $GaAs/Al_2O_3$ have led to considerable insight into the deposition conditions (such as gas flow rates and growth temperatures) necessary to produce good quality undoped epitaxial layers. The present work has extended this study with the objective of producing heavily doped 1 μm-thick p-type GaAs with acceptor concentrations greater than 10^{19} cm^{-3} for photocathode applications. Some results of photoemission measurements on these films have been described by Liu *et al.* (4). The over-all deposition conditions used for these doping studies have been those which yield good quality undoped films (3).

Doping Studies with Diethylzinc

Most of the studies of p^+ GaAs growth on Al_2O_3 involved the use of DEZ as the source of dopant. The results are discussed in detail in the following sections.

Effect of deposition conditions on carrier concentrations.—There are a number of growth parameters which can be varied in order to change the acceptor concentration in the GaAs films. An obvious one is the adjustment of the amount of dopant introduced into the reactor per unit time. This control has been achieved by two different means: (*i*) by adjusting the carrier gas flow over the dopant source; (*ii*) by controlling the bath temperature of the dopant source.

In Fig. 1, the effects are illustrated for Zn-doped GaAs films grown on Al_2O_3 for three different DEZ bath temperatures. For the DEZ bath at room temperature, the growth temperature was 725°C with AsH_3-TMG flows of 90-10; at the lower DEZ bath temperatures, a growth temperature of 700°C was employed with AsH_3-TMG settings of 175-65. The semilog plots indicate that higher flow rates produce increases in acceptor concentrations up to a point of saturation, after which the carrier concentration remains essentially constant. The higher carrier concentration obtained by increasing the DEZ bath temperature (and hence vapor pressure) indicate that the saturation in carrier concentrations at a given bath temperature is a consequence of the limited vaporization rate of the DEZ at the temperature of the bath and the depletion of the vapor over the DEZ caused by the high H_2 flow rates. The higher flows are believed to decrease the amount of DEZ vapor over the liquid below that which is expected for equilibrium conditions.

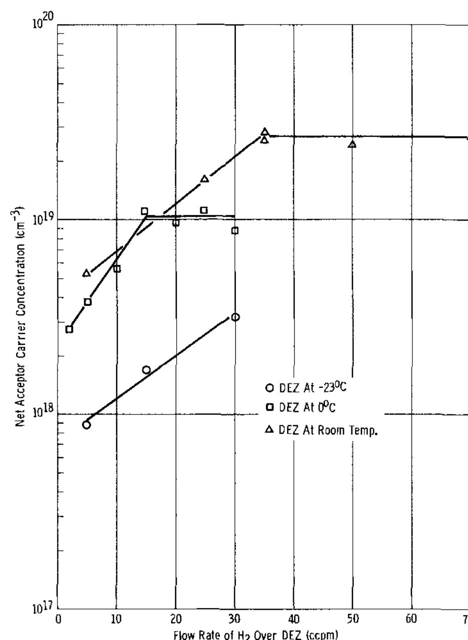

Fig. 1. Net acceptor concentration of Zn-doped $GaAs/Al_2O_3$ films vs. flow rate of H_2 over DEZ. For DEZ at 0°C and −23°C: growth temperature = 700°C, film thickness ≈ 1 μm, AsH_3-TMG setting 175-65-Z; for DEZ at room temperature: growth temperature = 725°C, film thickness ≈ 7-10 μm, AsH_3-TMG setting 90-10-Z.

For a given set of growth conditions, the net acceptor concentration is also found to increase by lowering the growth temperature. A maximum net carrier concentration of ~8 × 10^{19} cm^{-3} was obtained in thick films at 650°C for a DEZ bath temperature of 0°C. Films grown at temperatures of 625°C did not appear, either electrically or visually, to be as good as those grown at higher temperatures.

A plot of the measured variation of acceptor concentration with reciprocal growth temperature is given in Fig. 2 for a series of thin (~1 μm-thick) Zn-doped samples grown under essentially identical conditions. It shows that an exponential relationship exists between the two variables. From the slope of the experimental line an activation energy of 2.1 eV can be

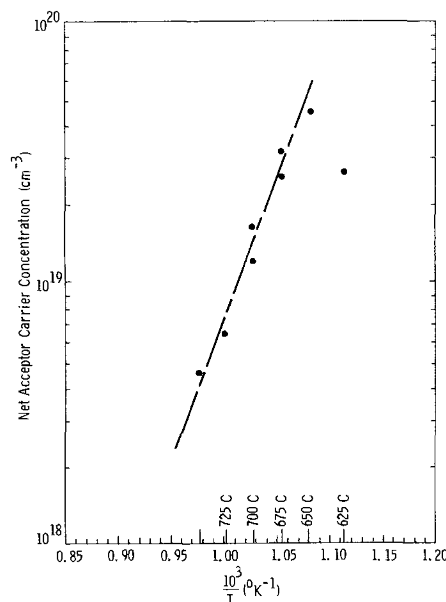

Fig. 2. Net acceptor concentration of ~ 1 μm-thick Zn-doped $GaAs/Al_2O_3$ film vs. reciprocal growth temperature.

Table I. Variation of mobility with film thickness for Zn-doped $GaAs/Al_2O_3$ films grown at 700°C

Thickness (μm)	Carrier concentration (10^{19} cm^{-3})	Hole mobility (cm^2/V-sec)
0.4	2.5	59
0.6	2.3	63
1.0	2.5	66
4.1	2.4	72
5.7	2.5	75
7.9	2.6	77
17.3	2.4	77
21.1	2.4	75

deduced; however, the present data are insufficient to determine the mechanism responsible for this dependence.

Variation of electrical properties with film thickness.—As in the case of undoped $GaAs/Al_2O_3$ (3), there appears to be an improvement in film quality with film thickness. Table I illustrates the changes in hole mobility with thickness for the best films grown with a hole concentration of ~2.5×10^{19} cm^{-3}. These films were grown either by the pre-AsH_3 process (with the DEZ mixed with the TMG) or by the pre-AsH_3-DEZ process (see Experimental section). The average mobilities increase with thickness and appear to reach a maximum at a thickness of about 4 μm. Thin films grown by the technique of premixing all gases were found to have consistently lower mobilities than those grown by the other two methods. Very little change was found in carrier concentration for films of different thicknesses grown under otherwise identical conditions. This indicates that a nearly uniform doping concentration profile exists in these heavily doped layers.

Hole mobility as a function of carrier concentration.—The electrical properties of many of the Zn-doped GaAs films on Al_2O_3 grown using the pre-AsH_3 and pre-AsH_3-DEZ processes are summarized in Fig. 3 and 4, where Hall mobility is plotted *vs.* acceptor concentration for thick and thin films, respectively. Growth rates of 0.6-1.0 μm/min and AsH_3-TMG flow rates which normally lead to good quality undoped films were used. The average hole mobilities characteristic of bulk GaAs (5) are shown for comparison (solid line), although the mobilities of many of the films are greater than these bulk values. For this reason a curve (dashed line) depicting the best mobilities in the thicker films is also plotted in both figures. It can be seen that the mobilities in the best thin films are typically from 80 to 90% of the best thick-film values where comparable data are available.

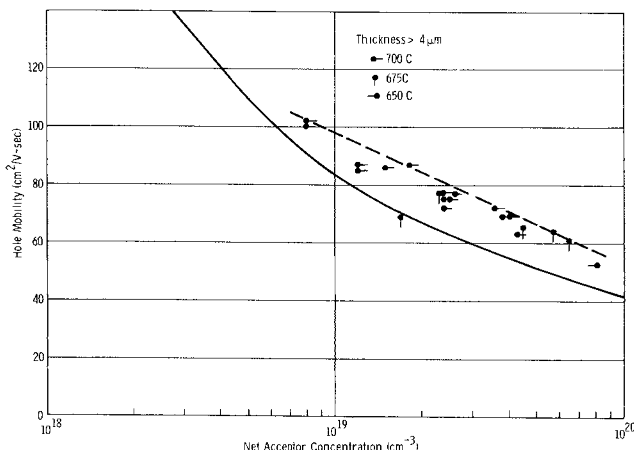

Fig. 3. Hole mobility *vs.* net acceptor concentration for thick (> 4 μm) Zn-doped $GaAs/Al_2O_3$ films grown at various temperatures. The solid line is an average bulk mobility from ref. (5).

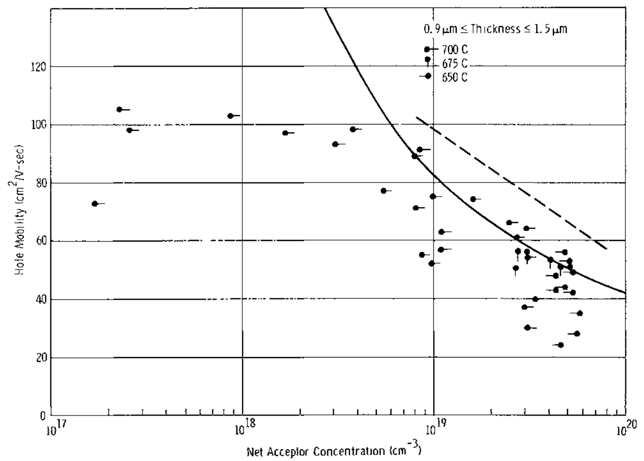

Fig. 4. Hole mobility *vs.* net acceptor concentration for thin (between 0.9 and 1.5 μm) Zn-doped $GaAs/Al_2O_3$ films grown at various temperatures. The solid line is an average bulk mobility from ref. (5), and the dashed line denotes the best thick-film mobilities from Fig. 3.

The mobilities in the thin films at carrier concentrations less than ~5×10^{18} cm^{-3} appear to saturate at a maximum value of about 100 cm^2/V-sec. This behavior is probably due to the comparatively high defect structure found in thin layers (2).

Simultaneous growth studies of Zn-doped P^+ GaAs on spinel and Al_2O_3.—Stoichiometric spinel ($MgAl_2O_4$) was also examined as a substrate for p^+ GaAs epitaxy, with emphasis placed on the (110) orientation of $MgAl_2O_4$. A comparison of data compiled on a number of p^+ Zn-doped GaAs films prepared simultaneously on (0001)Al_2O_3 and (110)$MgAl_2O_4$ substrates utilizing the pre-AsH_3-DEZ method and different doping levels is given in Table II for films grown at 625°-700°C. It would appear that p^+ films grown on (110)$MgAl_2O_4$ [(100)-oriented growth of GaAs] are essentially equivalent electrically to those grown on (0001)Al_2O_3 [(111)-oriented growth of GaAs]. For both types of substrates, growth at 625°C (and to a lesser extent at 650°C) has not appeared to be as good as that obtained at higher temperatures.

When Al_2O_3 is used as a substrate, the growth and subsequent removal of a GaAs film is often found to condition the surface in such a way as to yield superior quality GaAs films on reuse. This behavior was not observed for (110)$MgAl_2O_4$ substrates. In all cases, GaAs films grown on reused but not repolished $MgAl_2O_4$ substrates have been found to be electrically inferior to those grown simultaneously on reused Al_2O_3 substrates.

Doping Studies with Dimethylcadmium

Dimethylcadmium (DMCd) was also examined as a possible dopant for the formation of p-type GaAs

Table II. Comparison of the electrical properties of p^+ Zn-doped (111)GaAs/(0001)Al_2O_3 and (100)GaAs/(110)$MgAl_2O_4$ grown simultaneously by the pre-AsH_3-DEZ method at 625°-700°C

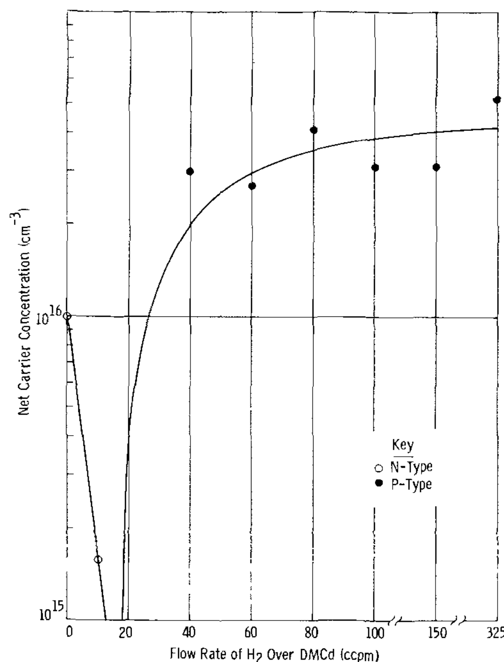

Fig. 5. Net carrier concentration vs. flow rate of H_2 over DMCd for thick (~20 μm) Cd-doped $GaAs/Al_2O_3$ films grown at settings of 175-65-Z.

films on (0001)Al_2O_3. The DMCd was maintained at a temperature of 0°C; gas flow conditions were used which had been satisfactory for Zn doping. The variation of net carrier concentration for a series of thick films grown at 700°C as a function of the flow rate of carrier gas over DMCd is shown in Fig. 5. When using gases which yield undoped films with net electron concentrations of $\sim 10^{16}$ cm^{-3}, the addition of a small amount of Cd results in a decrease in net electron concentration. With increases in Cd, the films become p-type, with the net hole concentration rising rapidly to $\sim 3 \times 10^{16}$ cm^{-3} and saturating at $\sim$ 4-5 $\times 10^{16}$ cm^{-3}. By changing the DMCd bath temperature to room temperature (from 0°C), and hence increasing the DMCd vapor pressure, the acceptor concentration in films grown at 700°C saturated at $\sim 1 \times 10^{17}$ cm^{-3} at a film growth rate of 1.2 μm/min. At a growth rate of 2 μm/min, the hole concentration increased to 1.6×10^{17} cm^{-3}. This last effect, a slight increase in hole concentration with increasing growth rate, was also observed in the Zn-doping studies. The limiting value of carrier concentration appears to be determined by the temperature of the Cd source, as was found with Zn doping.

The net hole concentration in the Cd-doped films also increased exponentially with decreasing deposition temperature when other deposition conditions remain fixed. At 675°C the acceptor concentration increased to 2.2×10^{17} cm^{-3} at growth rates of 1.2 μm/min and to 5.2×10^{17} cm^{-3} at growth rates of 2 μm/min. At 725°C, a hole concentration of 4×10^{16} cm^{-3} was obtained. A plot of the acceptor concentration obtained for Cd doping (for a growth rate of ~1 μm/min) as a function of reciprocal growth temperature is shown in Fig. 6. The limited data available support an exponential relationship with an activation energy of ~2.8 eV, slightly larger than was found in the case of Zn-doped films.

The mobility carrier concentration data for Cd-doped GaAs films are shown in Fig. 7. The highest Hall mobilities for the thick films are slightly larger for a given hole concentration than those reported by Conrad and Haisty (6) for homoepitaxial GaAs films doped with Zn from DEZ, and compare favorably with the average hole mobilities of bulk GaAs taken

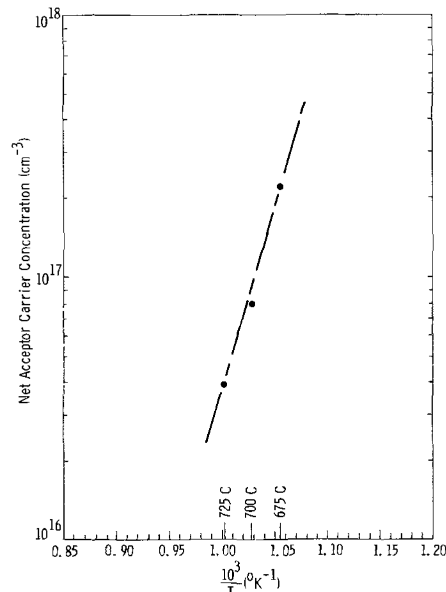

Fig. 6. Net acceptor concentration of thick (24-34 μm) Cd-doped $GaAs/Al_2O_3$ films vs. reciprocal growth temperature.

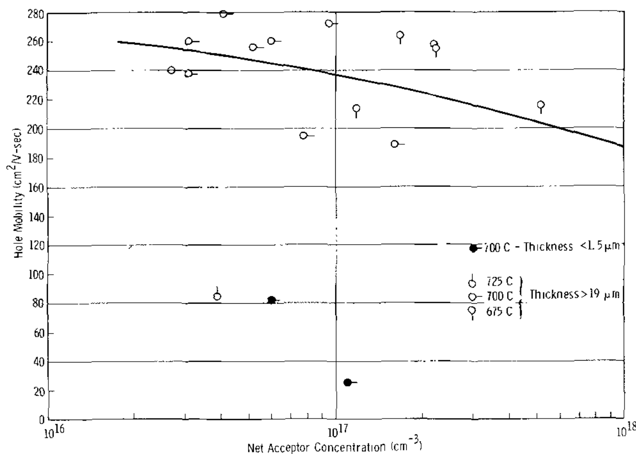

Fig. 7. Hole mobility vs. net acceptor concentration for Cd-doped $GaAs/Al_2O_3$ films grown at various temperatures. The solid line is an average bulk mobility from ref. (5).

from the data of Sze and Irvin (5)[1] (solid curve). The few thin Cd-doped samples that were measured, indicated by the solid circles in Fig. 7, exhibited much lower mobilities.

Conclusions

Diethylzinc and dimethylcadmium have been shown to be effective sources of dopant for the growth of p-type GaAs on insulating substrates by chemical vapor deposition techniques. It has been found that the acceptor concentrations obtained are an exponential function of growth temperature for a given set of growth conditions. The mechanism for this type of dependence cannot be deduced from the experimental data available. The maximum concentrations of Zn and Cd incorporated in the GaAs films in these experiments appear to be limited by the transport of sufficient dopant gas from the source.

Electrical measurements of the films grown in this study have shown that good quality GaAs may be grown over a wide range of acceptor concentration. Thick films are found to have hole mobilities typical

[1] The mobility (μ) *vs.* carrier concentration (n) data were calculated from Fig. 1 of (5) assuming $\mu = 1/ne\rho$. There are some differences between these data and that in Fig. 2 of (5) at low carrier concentrations.

of the best bulk material for acceptor concentrations from $\sim 3 \times 10^{16}$ to $\sim 10^{19}$ cm^{-3}. At the highest doping concentrations the better Zn-doped thin (~ 1 μm) films exhibited hole mobilities nearly as high as the best thick films. At concentrations less than 10^{19} cm^{-3} the thin film mobilities appear to level off at values ~ 100 cm^2/V-sec, although data are limited for these carrier concentrations. The fact that thick films can be grown with bulk mobilities indicates that lower-than-bulk mobilities in thin layers are probably due to a comparatively high defect structure in these films, rather than compensation from donor impurities in the gas sources.

Acknowledgments

The authors wish to acknowledge the assistance of W. I. Simpson in the preparation of the films used in this study, R. E. Johnson for the photolithographic processing of the bridge samples, and J. P. Wendt for carrying out many of the electrical measurements. We thank Dr. R. P. Ruth, Dr. A. J. Hughes, and Dr. J. L. Kenty for most helpful discussions of the subject matter.

Experiments and Calculation of the Ga-GaAs-GaP Ternary Phase Diagram

Kozo Osamura, Jun Inoue, and Yotaro Murakami

Department of Metallurgy, Faculty of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT

A large part of the gallium rich side of the Ga-GaAs-GaP phase diagram has been determined using the DTA method and the powder x-ray method. The ternary phase diagram of Ga-GaAs-GaP has been calculated using two approaches, *i.e.* the quasi-chemical equilibrium model and the regular solution model. Both of these calculated ternary phase diagrams are found to agree with the experimental data.

Interest has increased recently in the semiconducting materials which are obtained when solid solution occurs between two compounds of the type $A^{III}B^{V}$. A number of the III-V ternary phase diagrams have been studied previously, because an understanding of the phase chemistry of these systems is particularly useful for the development of solution growth techniques. A considerable amount of work has been devoted to the study of the Ga-As-P ternary system. The liquidus curves in the parent Ga-As and Ga-P systems have been studied py many authors (1-4) and their thermodynamic properties have been discussed by Thurmond (5) and Arthur (6). The solidus line of the GaAs-GaP quasi-binary phase diagram has been determined by Osamura and Murakami (7). Panish (8) has determined the liquidus-solidus isotherms of the Ga-GaAs-GaP ternary system using the differential thermal analysis and an optical technique.

A method of calculating the ternary phase diagrams for III-V systems from the available thermodynamic data is extremely desirable because the experimental determination of the phase diagrams including liquidus curves and tie lines is a prohibitive task. Ternary phase diagrams of III-V compounds can be calculated using both the quasi-chemical equilibrium (QCE) and regular solution (RS) models which are based upon Ilegems and Pearson's (9) modifications of Vieland's equations (10) to ternary III-V systems. The QCE model has been applied by Stringfellow and Greene to several III-V systems, *i.e.* the In-Ga-As (11), In-As-Sb (11), and Ga-In-P (12) systems. On the other hand, Antypas has used the RS model for the calculation of the In-Ga-As (13), Ga-As-Sb (14), and Ga-GaAs-GaP (15) ternary phase diagrams. However the QCE approach has not been applied to the Ga-GaAs-GaP system until now.

In the present paper, the determination of the liquidus-solidus isotherms in the Ga-GaAs-GaP ternary phase diagram has been performed in detail, especially in the region of the gallium-rich corner using the differential thermal analysis and the powder x-ray method. The ternary phase diagram of Ga-GaAs-GaP system is calculated using two approaches, *i.e.* the QCE and RS models. And both these calculated ternary phase diagrams are compared with the experimental data of this work and Panish's data.

Key words: gallium arsenide, gallium phosphide.

Experimental Results

Differential thermal analysis was used for the determination of the liquidus-solidus isotherms. In this work, the materials used were semiconductor grade Ga, GaAs, and GaP. The DTA method used here is similar to that which was described earlier for the study (13) of the phase diagram of GaAs-GaSb compounds. In order to melt the constituents together completely, the DTA cell, placed in a large block inside a resistance furnace as shown in Fig. 1, was heated to 50°C above the expected temperature for the first appearance of solid. After holding at that temperature for 1 hr, the cell was slowly cooled with a constant cooling rate of 1.5°C/min. Thermal effects were noted by continuously

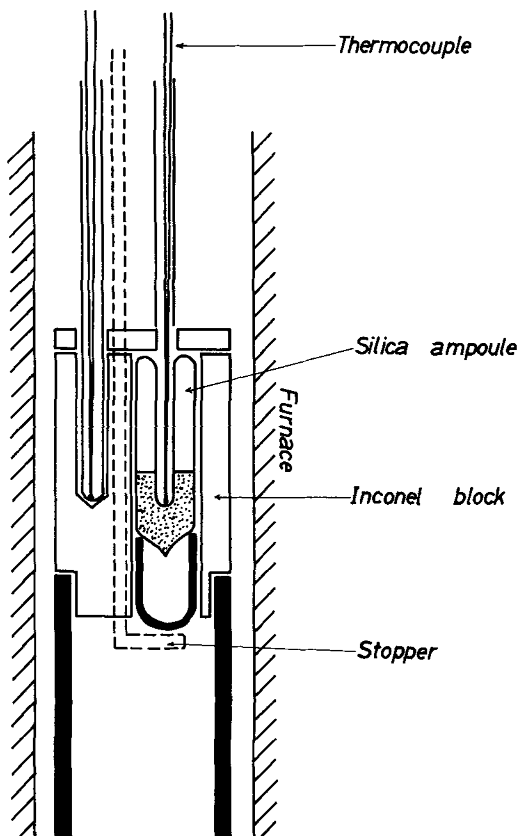

Fig. 1. Apparatus for differential thermal analysis

recording the emf of Pt-PtRh thermocouples. The determination of the transformation temperature seems to be reasonably accurate since the temperature difference between a specimen and the Inconel block was as small as several degrees centigrade. After the cell had been cooled to 50°C under the inflection point observed in the cooling curve, the cell was again heated with a constant heating rate of 1.5°C per minute; Fig. 2 shows a typical example of DTA curves. In both the cooling and heating curves the inflection point could be de-

tected, where it is suggested that a primary crystal appears in the melt at the temperature, T_c, and the last solid completely dissolves at the temperature, T_h; these temperatures are listed in Table I. It was found that T_c is about 20°-30°C lower than T_h. Panish (8) has pointed out that the supercooling effect leads to some discrepancy in DTA (cooling) and optical (heating) data. T_h may be higher than the correct transition temperature because the melting point of the solid which does not contact the equilibrated liquid is higher than the liquidus temperature, and therefore the complete dissolution will lag in the heating process. Therefore, in the present analysis, it seems that an average of T_c and T_h is a more reliable indication of the correct transition temperature.

The primary crystals were collected by the following technique. The same specimen used in the DTA was heated until it was completely liquid and then cooled slowly below its liquidus temperature (T_c) determined previously. After the inflection point was observed in a cooling curve, the ampul was quenched in water by removing the stopper shown in Fig. 1. After removal of the Ga by dissolution in hot HCl solution, the larger crystals were separated, and ground down to an average size of 10μ.

Lattice parameters of the specimens were determined by the powder x-ray method, where the diffraction angle was calibrated by using the standard angles of Si powder. The average value of lattice parameter was calculated from the peaks corresponding to (440), (531), (620), (533), (444), and (511). Figure 3 shows typical x-ray diffraction patterns of (531), of which peaks for GaAs and GaP were measured at $2\theta = 107.42°$ and 113.54°, respectively. Assuming that the change of lattice parameter in the solid solution with composition obeys Vegard's law (17), the alloy composition of specimens was estimated from the lattice parameter and listed in Table I.

Calculation of Phase Diagrams

The RS model assumes a completely random distribution of the constituent atoms and then a temperature independent interaction parameter. However, the interaction parameters in III-V binary solutions show a linear temperature dependence as pointed out by some authors (5, 6). It should be recognized that the RS model with $\Omega^R = a - bT$ is only an approximation for the QCE model as discussed by Stringfellow and Greene (18) for Ge-M, Si-M, and III-V systems. Therefore, the QCE calculation of the ternary phase diagram is mainly carried out and discussed, and the RS calculation is also performed in order to find the validity of the RS model as an approximate treatment of the QCE model in the Ga-As-P system.

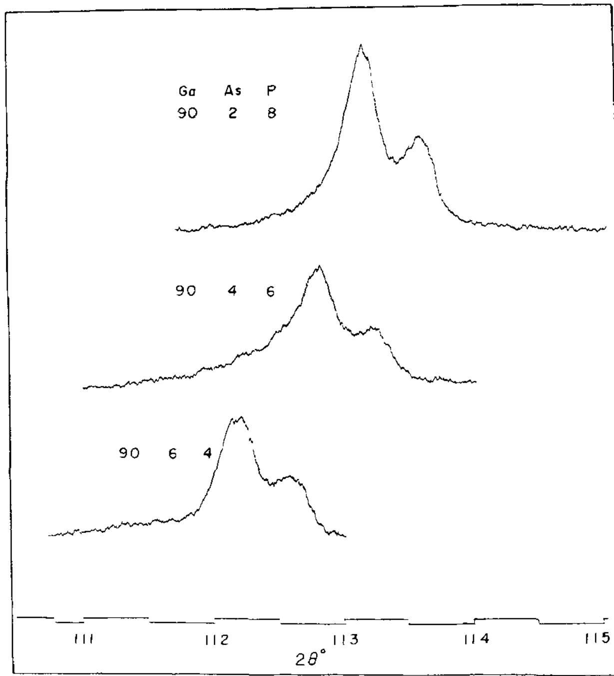

Fig. 3. Powder x-ray patterns of (531) plane for some $GaAs_{1-x}P_x$ solid solutions.

The binary liquidus line on the T-X phase diagram can be calculated using Vieland's expression (10) for the III-V compound-liquid equilibrium

$$\ln\left[\frac{1}{4X(1-X)}\right] + \ln\left[\frac{\gamma_A^{\text{s.l.}}\gamma_B^{\text{s.l.}}}{\gamma_A\gamma_B}\right] = \frac{\Delta S^F}{R}\left[\frac{T^F}{T} - 1\right] \quad [1]$$

where A and B show the III group and V group component, respectively, and T^F is the melting point of AB compound and ΔS^F is the entropy of fusion per mole of compound and X is the atom fraction of A component in the liquid phase in equilibrium with solid AB at a temperature T, and γ_A and γ_B are activity coefficients, and $\gamma_A^{\text{s.l.}}$ and $\gamma_B^{\text{s.l.}}$ correspond to those of the stoichiometric liquid. These values may be expressed in terms of the interaction parameter by the two approaches, *i.e.* the QCE and RS models. The Ga-As and Ga-P interaction parameters were obtained by making a least squares fit of the calculated binary phase diagrams to the experimental data. In the present work, only the data of Köster and Thoma (3) for the Ga-As system and the data of Rubenstein (2) for the Ga-P system have been selected in order to link the ternary experimental data smoothly to the binary data in the region of temperatures where the experiments have been carried out. The temperatures of fusion of GaAs and GaP were extracted from the literature (5). An estimate of the entropy of fusion was obtained by a comparison with entropies of IV-group elements after Thurmond (5), but the values were employed from the table of Kubaschewski *et al.* (19). The interaction parameters in both of the QCE and RS models determined by fitting Eq. [1] to the experimental data are listed in Table II where it was found that the interaction parameters for the Ga-As and Ga-P liquid system are constant from the QCE model and on the other hand are proportional to temperature from the RS model.

Table II. List of thermodynamic parameters used in calculating the Ga-GaAs-GaP phase diagram

$T^F_{GaP} = 1465°C$	$T^F_{GaAs} = 1238°C$
$\Delta S^F_{GaP} = 16.25$ e.u.	$\Delta S^F_{GaAs} = 15.45$ e.u.
$\Omega^Q_{Ga\text{-}P} = -4170$ cal/mole	$\Omega^Q_{Ga\text{-}As} = -6470$ cal/mole
$\Omega^R_{Ga\text{-}P} = -3.0\ T$ cal/mole	$\Omega^R_{Ga\text{-}As} = -5.2\ T$ cal/mole
$\Omega^Q_{As\text{-}P} = \Omega^R_{As\text{-}P} = 0$ cal/mole	
$\Omega^Q_{GaAs\text{-}GaP} = \Omega^R_{GaAs\text{-}GaP} = 0$ cal/mole	

Ternary phase diagrams of III-V compounds have been calculated using the QCE and RS models. In both cases, as activity coefficients in the ternary system can be represented in terms of the interaction parameters in binary systems, ternary phase diagrams can be calculated without the aid of experiments. In computing the conditions for equilibrium between a ternary liquid solution A, B, C (Ga, As, P) and a quasi-binary solid solution AB-AC (GaAs-GaP), Stringfellow and Greene (11) derived the following equations

$$\ln \gamma_{AB}X = \ln\left[\frac{4\gamma_A\gamma_B N_A N_B}{\gamma_A^{\text{s.l.}}\gamma_B^{\text{s.l.}}}\right] + \frac{\Delta S^F{}_{AB}}{R}\left[\frac{T^F{}_{AB}}{T} - 1\right] \quad [2a]$$

$$\ln \gamma_{AC}(1-X) = \ln\left[\frac{4\gamma_A\gamma_C N_A N_C}{\gamma_A^{\text{s.l.}}\gamma_C^{\text{s.l.}}}\right] + \frac{\Delta S^F{}_{AC}}{R}\left[\frac{T^F{}_{AC}}{T} - 1\right] \quad [2b]$$

where γ_{AB} and γ_{AC} are the activity coefficients of AB and AC in the solid solution, X is the mole fraction of AB, N_i and γ_i ($i = A, B, C$) are the atom fractions and activity coefficients of i in the liquid solution, respectively. Equation [2] can be solved numerically on a computer to yield two sets of curves, one describing the liquidus isotherms and the other describing the solidus isoconcentration curves of the system.

First, the calculation of activity coefficients in the ternary system is based on the QCE model. The major assumptions necessary to calculate activity coefficients are:

(*i*) The distribution of constituent atoms is calculated using a mass action-like expression

$$N_{ii}N_{jj}/(N_{ij})^2 = \tfrac{1}{4}\exp\,[2\Omega_{ij}{}^Q/ZRT] \quad [3]$$

where i and j each represent either A, B, or C.

(*ii*) The molar heat of mixing is expressed as

$$\Delta H_m = [N_{AB}\Omega_{AB}{}^Q + N_{BC}\Omega_{BC}{}^Q + N_{AC}\Omega_{AC}{}^Q]/Z \quad [4]$$

and the excess free energy of mixing, ΔF^{XS}, is obtained from ΔH_m by integrating the Gibbs-Helmholtz equation. Therefore, the activity coefficients are derived from ΔF^{XS} using the general thermodynamic relation as follows

$$\ln \gamma_i = \Delta F^{XS}/RT + (1 - N_i)\left[\frac{\partial(\Delta F^{XS}/RT)}{\partial N_i}\right]_{N_j/N_k} \quad [5]$$

In the QCE model, the activity coefficient cannot be expressed analytically, but is computed numerically in terms of temperature and composition.

Second, using the RS model, activity coefficients in the ternary system can be analytically expressed in terms of the interaction parameters of the various binary systems as shown in the following

$$\ln \gamma_A = [\Omega_{AB}{}^R N_B(1 - N_A) - \Omega_{BC}{}^R N_B N_C + \Omega_{AC}{}^R N_C(1 - N_A)]/RT \quad [6a]$$

$$\ln \gamma_B = [\Omega_{AB}{}^R N_A(1 - N_B) + \Omega_{BC}{}^R N_C(1 - N_B) - \Omega_{AC}{}^R N_A N_C]/RT \quad [6b]$$

$$\ln \gamma_C = [-\Omega_{AB}{}^R N_A N_B + \Omega_{BC}{}^R N_B(1 - N_C) + \Omega_{AC}{}^R N_A(1 - N_C)]/RT \quad [6c]$$

This expression of ternary activity coefficients has been reported by Furukawa and Thurmond (20) and is consistent with Darken's quadratic representation (21) only in the case of the regular solution, where the parameter $\Omega_{ij}{}^R$ differs only by a factor of RT from α_{ij} of Darken.

The quasi-binary solid solution in equilibrium with the ternary liquid was assumed to be constituted of AB and AC chemical units (11). For the zincblende lattice, where AB-AC interactions are considered,

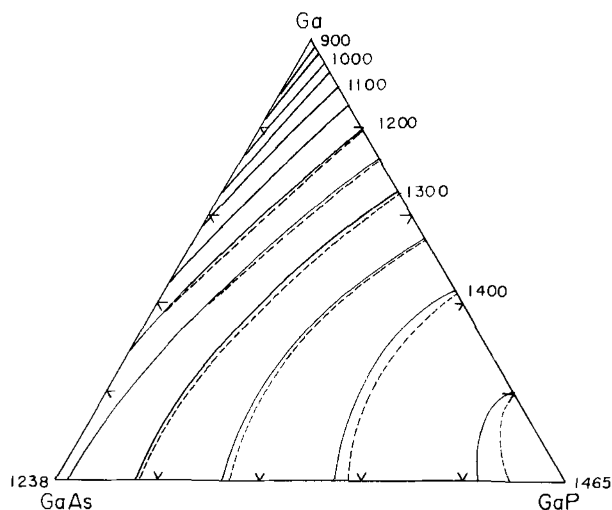

Fig. 4. Ga-GaAs-GaP liquidus isotherms. ——— QCE calculation; - - - - RS calculation.

the appropriate value of Z is 12. The activity coefficients can be calculated similar to the case of the binary system based on the QCE and RS models. Therefore, substituting Eq. [5] or [6] in Eq. [2] the ternary phase diagram can be calculated numerically to yield the liquidus and solid distribution curves. Here the interaction parameter of the GaAs-GaP system was determined by fitting the solidus to experimental data (7) using the QCE model and the RS model. Both calculations were in good agreement for $\Omega_{GaAs\text{-}GaP} = 0$ cal/mole. The interaction parameter of the As-P system was also assumed to be zero cal/mole.

Figure 4 represents the calculated isothermal liquidus lines from 900° to 1450°C by 50°C increments. It is found that the solid lines obtained from the QCE model bend more steeply than the dotted lines from the RS model.

In Fig. 5-8, the experimental results reported by Thurmond for the Ga-As and Ga-P systems, and by Panish for the Ga-GaP-GaAs system from solution growth and solution epitaxy and our experimental results are compared with the computed diagrams. Figure 5 is a portion of Fig. 4, plotted in Cartesian coordinates, showing the equilibrium solubility of P as a function of the As concentration in the melt from 900° to 1300°C isotherms where the experimental points at each temperature are obtained by interpolation and extrapolation from Panish's data and from the data of this work. Figure 6 also shows a portion of the ternary phase diagram in greater detail, on which the solubility of As is plotted as a function of temperature at isophosphorous concentrations. Excellent agreement is obtained between calculated and experimental results. At the same time the liquidus curves calculated using the interaction parameters of the Ga-As and Ga-P binary systems presented in Ref. (15), are shown, where these parameters have been corrected with respect to the values of entropy and temperature of fusion. These liquidus curves are found to be higher than the experimental data on the side of the Ga-P binary system.

In Fig. 7, calculated GaP isoconcentration lines are plotted along with the experimental data, where each curve and point are labeled with X_{GaP}. Figure 8 shows a portion of the GaP isoconcentration lines as a function of As concentrations at isophosphorous concentrations. Although the primary crystals were obtained from the supercooled melts, the experimental results show generally good agreement with the calculated results. At low GaP concentration, experimental data deviate from the calculated isoconcentration lines. It should be pointed out that the liquidus in equilibrium with the quasi-binary solid solution falls rapidly over the binary liquidus and therefore the experimental inaccuracy with temperature is large.

Discussions and Conclusions

The liquidus isotherms of the $GaAs_{1-x}P_x$ primary phase field of the Ga-GaAs-GaP system have been determined in detail over the Ga-rich part of the system using the DTA method, where the liquidus temperatures have been determined from the average of inflection points in heating and cooling curves. The liquidus isotherms were used to determine the liquidus compositions for the growth of $GaAs_{1-x}P_x$ crystals from the liquid. The primary crystals were obtained from supercooled melts and these compositions were determined using the powder x-ray method. Our experimental liquidus temperatures and solidus concentrations are generally in agreement with Panish's optical data.

The interaction parameters of Ga-As and Ga-P binary systems necessary to calculate the ternary phase diagram have been determined in the condition of a smooth linkage from the ternary liquidus curves to the binary data in the region of temperatures where experiments were carried out. It has also been shown that the calculated ternary phase diagram of the system Ga-GaAs-GaP based on the QCE model is in excellent agreement with experimental data. In addition, the ternary phase diagram obtained from the RS treatment is similar to that calculated by the QCE model and ex-

plains fairly the experimental results in the present region where experiments have been carried out. The interaction parameter Ω^{q} in the QCE model is taken to be constant in the present work. In practice the temperature dependent interaction parameter should be chosen in order to fit the binary data in the wide range of composition up to $N_{Ga} = 1$, using both sets of data reported by Hall (1) and Köster and Thoma (3) for the Ga-As system

$$\Omega^{q}_{Ga\text{-}As} = 5120 - 8.00T$$

and the data of Hall (1) and Rubenstein (2)

$$\Omega^{q}_{Ga\text{-}P} = 5360 - 6.42T$$

for the Ga-P binary system. As pointed out by Stringfellow (12), it is, however, doubtful whether bending the model to fit the binary data improves the phase diagram calculation. The appropriate method of improving the calculation is to use a more sophisticated model which includes the physical processes which take into account that the interatomic interactions are temperature and composition dependent.

Acknowledgments

The authors wish to express their hearty thanks to the Research Laboratory of Sumitomo Electric Industries, Ltd. for a supply of the experimental materials. The works of Mr. Kazuo Nakajima in sample preparation and measurements are greatly appreciated.

Nondestructive Thickness Determination of Polycrystalline Silicon Deposited on Oxidized Silicon

Conrad J. Dell'Oca*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

Infrared interferometry is used to determine the thickness of polycrystalline silicon (polysilicon) deposited on oxidized silicon by the thermal decomposition of silane. The thickness is obtained by comparing the measured wavelength positions of the reflectivity extremes with those predicted theoretically and plotted against polysilicon thickness for a given underlying SiO_2 thickness. The infrared optical properties of polysilicon are found to be essentially the same as those of single-crystal silicon.

An accurate method is required for determining the thickness of polycrystalline silicon (polysilicon) films deposited on oxidized silicon substrates. Several nondestructive optical methods were considered because of their apparent advantages over destructive methods which have been used. Although the optical properties of polysilicon appear to depend on deposition and postdeposition conditions (1), it was assumed for the initial survey that these properties are essentially the same as those of single-crystal silicon.

Calculations and measurements indicate that ellipsometry would not be a convenient method except for very thin and smooth films. This is because (*a*) the ellipsometry curves cycle rapidly with polysilicon thickness, and thus this thickness must be known in advance within rather narrow limits.[1]; (*b*) the oxide thickness must be accurately known; and (*c*) the roughness of the polysilicon can be such that very large errors are introduced. Reflectance interferometry in the visible and near infrared has been used by several authors in measuring two dielectrics on silicon (2-4), but it has several drawbacks when applied to polysilicon. One is that the optical properties of the polysilicon and the substrate change rapidly over this spectral range. Another is that the polysilicon becomes absorbing, limiting the lower wavelength at which interference is observed. Conceivably a method (2) wherein the interference response is calibrated by an independent thickness measurement could be used

* Electrochemical Society Active Member.
Key words: infrared, interferometry, thin films, refractive index.

[1] For example, the polysilicon thickness must be known to within about 800Å when using a wavelength of 6328Å at an angle of incidence of 70°.

to overcome the first objection. Reflectance interferometry in the infrared suffers less than the other two methods in that: (a) above 1.5 μm wavelength both silicon and polysilicon can be considered to be nonabsorbing and nondispersive, and (b) the results are less affected by oxide thickness and surface roughness of the layer. There is, however, an increase in the minimum polysilicon thickness which can be measured. This paper describes the application of the last method to the measurement of polysilicon films.

Experimental Procedure

Silicon wafers [$\rho > 1.5$ ohm-cm, n- or p-type, and (111) orientation] which had their front sides mechanically-chemically polished were oxidized in dry oxygen at about 1200°C. The oxide thickness was measured with an ellipsometer. Polysilicon was then deposited on the front side of the oxidized wafer by the thermal decomposition of silane in a hydrogen carrier gas in a horizontal epitaxial reactor.[2]

The spectrophotometer used was a Beckman Model IR5A which has a wavelength range from 2 to 16 μm. Reflectivity measurements were made at an angle of incidence of 30° using a specular reflection attachment. Where computed and experimental reflectivity curves were compared, the spectrophotometer was calibrated by measuring the response of a bare silicon surface prior to and after measuring the response of the polysilicon film. The before and after calibration curves agreed in all cases within 1% intensity.

Calculations

The optical properties of the various materials considered (Fig. 1) are such that interference conditions are in error if calculated from approximations involving single reflection at the interfaces. The exact reflectivity equation must be used and for the reflection of unpolarized light, this equation is

$$\rho = (|R_p|^2 + |R_s|^2)/2 \quad [1]$$

R_p and R_s are the amplitude reflectivity coefficients for light polarized respectively parallel and perpendicular to the plane of incidence, and for two layers on an infinite substrate each has the form (5)

$$R = \frac{r_1 + r_2 e^{-2j\delta_1} + r_3 e^{-2j(\delta_1+\delta_2)} + r_1 r_2 r_3 e^{-2j\delta_2}}{1 + r_1 r_2 e^{-2j\delta_1} + r_1 r_3 e^{-2j(\delta_1+\delta_2)} + r_2 r_3 e^{-2j\delta_2}} \quad [2]$$

where r_i is the Fresnel reflection coefficient of the ith interface, $\delta_i = 2\pi N_i d_i \cos \phi_i/\lambda$ is the phase retardation suffered by light of wavelength λ on crossing the ith film of refractive index $N_i = n_i - jk_i$ and thickness d_i, and ϕ_i is the refractive angle in the ith layer.

Fringe charts for determining polysilicon thickness were constructed by calculating from Eq. [1] the wavelength ($1.5 < \lambda < 12$ μm) at which the reflectivity reaches a maximum or minimum for various polysilicon and silicon dioxide thicknesses. In the calculation, the materials were assumed nondispersive and nonabsorbing. The index of refraction of polysilicon was assumed to be the same as that of the silicon substrate, which was taken to be 3.42 (6), and that of silicon dioxide was 1.46, the value found in the visible light range. Four charts were necessary to span the polysilicon thickness range of interest, which extended from less than 1 to 7.5 μm. A typical fringe chart, in this case for polysilicon on 100 nm of oxide, is shown in Fig. 2. Each line on this chart shows polysilicon thickness *vs.* wavelength position of a particular interference extreme. For the purpose of discussion, the lines are numbered in the order in which the extremes are observed with decreasing wavelength. Calculations indicate that extremes corresponding to lines 1 and 2 are too broad for their position to be determined accurately and are not useful in determining polysilicon thickness. Thus for the wavelengths considered, polysilicon thicknesses above 0.3 μm can be determined by using this chart.

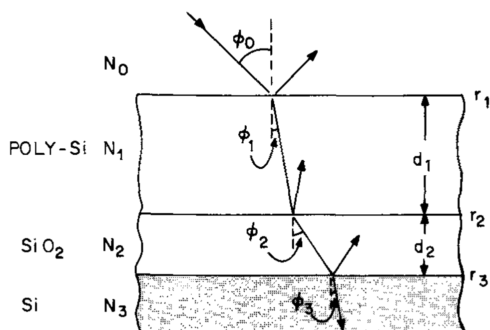

Fig. 1. Reflection of light from polysilicon on oxidized silicon

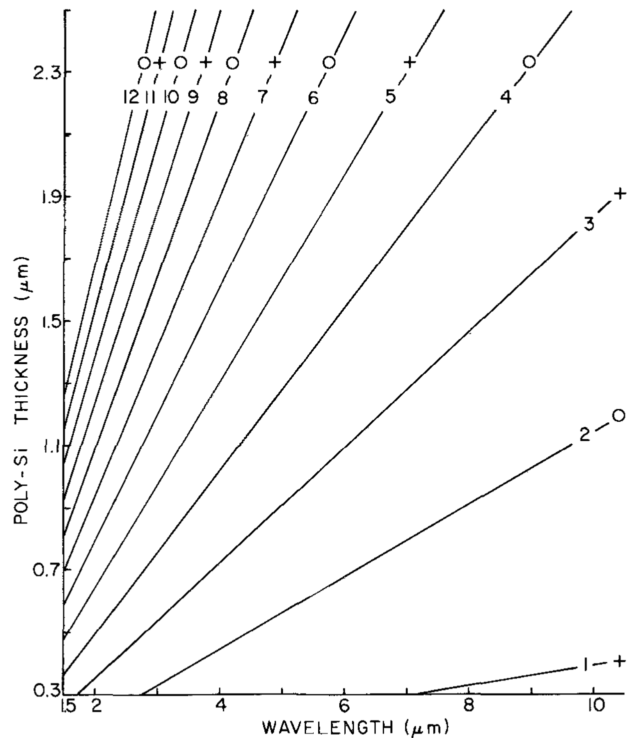

Fig. 2. Polysilicon thickness vs. wavelength position of extremes in intensity for 100 nm of SiO_2 on silicon (+, O, and numbers on lines denote, respectively, lines of minimum intensity, lines of maximum intensity, and the order in which they are encountered with decreasing wavelength).

The effect of oxide thickness on the fringe chart is as follows. Below 100Å, the variations in intensity diminish to a point where it becomes difficult to determine accurately the position of the extremes. Below about 600 nm, the fringe lines are linearly dependent on polysilicon thickness. A change in oxide thickness in this region displaces a given intensity extreme by an amount almost independent of polysilicon thickness. This is seen in Fig. 3, where fringe charts corresponding to 100, 300, and 500 nm of oxide are superimposed. Each interference order is represented by a set of three lines corresponding to the three oxide thicknesses. It is also evident from this figure that the wavelength of an extreme shifts much less (by about four times) for a change in oxide thickness than for the same change in polysilicon thickness. Oxides of 600 nm or more cause some of the fringe lines to become noticeably nonlinear. This is because conditions are being approached for interference at the polysilicon oxide interface. In this region, it is still possible

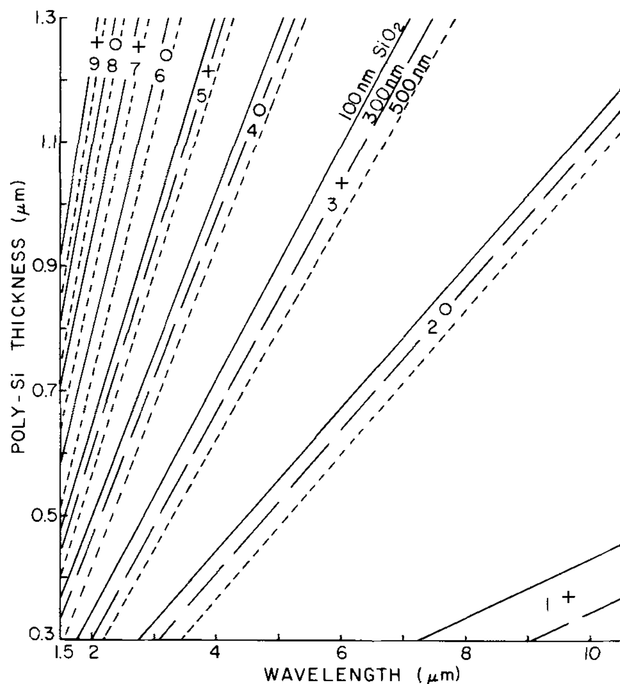

Fig. 3. Superposition of fringe charts for SiO_2 thicknesses of 100 nm (full line), 300 nm (dashed line), and 500 nm (dotted line). The 500 and 300 nm lines are, respectively, omitted from fringe 1 and 6 to 9. (Notation as in Fig. 2.)

to determine polysilicon thickness, but more expertise is required in interpreting the interference response.

Results

Test of assumptions.—Experimental and computed reflectivity curves were compared in order to test the assumptions made in the calculation of the charts. For the case of silicon covered only by thick silicon dioxide films, an index of refraction value of 1.46 for the silicon dioxide was found to hold out to 6 μm wavelength. Beyond this wavelength, deviation between calculated and experimental occurs, and eventually the SiO_2 structural response is observed. With thin polysilicon films (1 μm or less) or films deposited at low temperatures (~650°C) on oxidized silicon, agreement (within 2%) between calculated and experimental reflectivity curves is found out to 8 μm wavelengths (Fig. 4). Above this point, the SiO_2 structural response causes deviations. As the polysilicon thickness increases with respect to the oxide thickness, the effect of this response diminishes. With the thicker films, however, agreement between calculated and experimental results

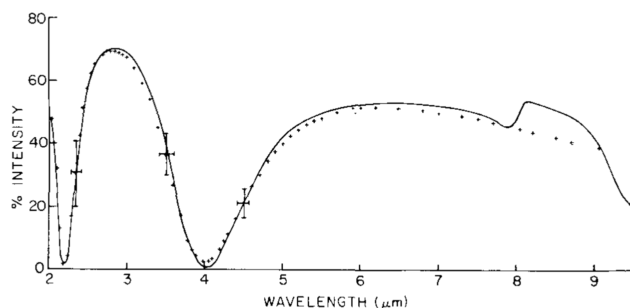

Fig. 4. Comparison of experimental reflectivity (solid line) response for polysilicon film on 240 nm of SiO_2 with the calculated reflectivity (points) using $N_1 = N_3 = 3.42$, $N_2 = 1.46$, and $\phi_0 = 30°$ (cross bars indicate the calculated effect of ±2% variation in polysilicon thickness which is 680 nm, polysilicon deposited at 650°C).

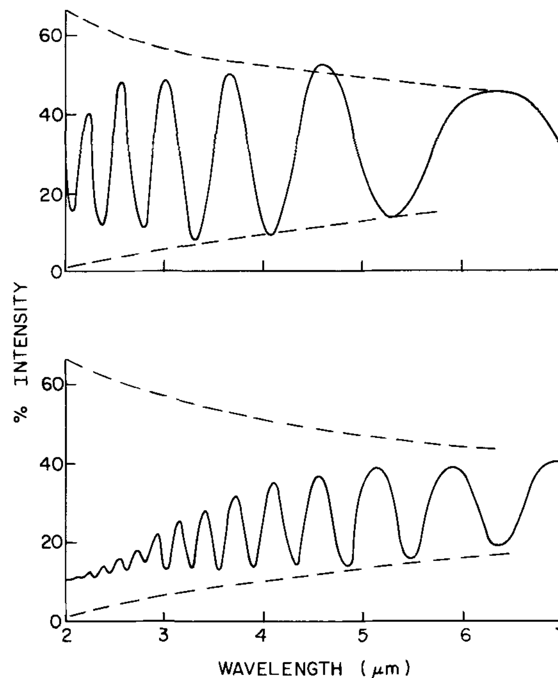

Fig. 5. Experimental reflectivity results yielding 2.45 μm (upper curve) and 5.86 μm (lower curve) of polysilicon on 140 nm of SiO_2. The dashed lines indicate the expected calculated interference envelope. (Polysilicon deposited at 850°C.)

is no longer obtained as shown by the examples in Fig. 5 where the dashed lines represent the calculated reflectivity envelope. The diminished reflectivity response is caused by surface roughness of the polysilicon and not by absorption in the film. Infrared transmission studies of thick (175 μm), unsupported, polished polysilicon films indicate that although the polysilicon is more absorbing than silicon, the imaginary part of its index of refraction, which is about 0.001 at 2.5 μm and decreases with wavelength, is at least several orders too small to produce the observed decrease in the reflectivity.

Even more critical than the assumptions made about the optical properties is the assumption made in Eq. [2] that the silicon substrate is infinite when, in fact, it is transparent at these wavelengths. Nevertheless, the assumption may be used because it can be shown that interference occurring within the silicon substrate and the oxide layer covering its back side has little effect on the reflectivity response measured from the polysilicon. First, the thickness of the silicon substrate is such that interference within it will not be resolved by the IR-5A. This was confirmed by measurements made on unoxidized substrates. Second, any effect that interference in the substrate has on absolute intensity is eliminated by the spectrophotometer calibration. Finally, calculations indicate that the intensity reflected from the back side oxide-air interface is small, and interference occurring in this layer can be neglected. It was found that the wavelengths of the extremes remain, within experimental error, the same after the oxide is removed from the back of the substrate even in the case of thick oxides (~1 μm).

Limitations and accuracy.—The polysilicon thickness was obtained by matching measured wavelengths of reflectivity extremes to those shown in the calculated fringe chart. Extremes occurring below 6 μm wavelength were used because the best agreement between experimental and calculated reflectivity occurs here. As the optical thickness of the polysilicon increases with respect to that of the oxide, the effect of the SiO_2 structural response on the interference response

diminishes, and the 6 μm upper wavelength limit can be relaxed. However, the 2 to 6 μm wavelength range is sufficient to measure polysilicon films from 0.3 to above 5 μm.

The accuracy is the sum of the theoretical and experimental accuracies. On the basis of the foregoing justification of assumptions, the theoretical accuracy is estimated to be 2% in determining polysilicon thickness using wavelengths from 2 to 6 μm. Experimentally, the wavelength of the reflectivity extremes obtained from thin polysilicon films can be measured to 1000Å or less except for extremes No. 1 and No. 2 which are not used. The position of the extremes can be determined more accurately as they get sharper; but the sharper extremes correspond to fringe lines of higher order which have steeper slopes. This results in an uncertainty of about 150Å in the polysilicon thickness determined from any of the extremes. For thicker polysilicon films this may be somewhat larger; for example, in the lower part of Fig. 5, the polysilicon thickness determined from each individual extreme is within 200Å of the mean thickness. Error in determining oxide thickness as was seen in the fringe chart contributes about one quarter of its value to the uncertainty, and this contribution can usually be neglected. Thus in the wavelength range from 2 to 6 μm, it is estimated that the over-all accuracy of the *IR* interference method is 2% + 150Å. The accuracy of relative measurements is less dependent on the correctness of the assumptions, and thickness variations corresponding to roughly twice the instrumental precision or about 75Å should be detectable for thin polysilicon films.

In comparing the *IR* interference technique with other methods of measuring film thickness, it must be kept in mind that this method gives an average thickness over the area covered by the *IR* beam (about 2 cm by 1 to 3 mm) while other methods measure local thickness. Table I presents a comparison of the thickness values for 15 polysilicon films determined from *IR* interference in the wavelength range from 2 to 6 μm with the values obtained by averaging two or more local measurements. The local measurements were made by either Nomarski or Tolanski interference techniques, or with a mechanical stylus (DEKTAC[3]). The nominal accuracy of these methods is estimated to be 0.25 and 0.1 fringes, or 750 and 300Å for the Nomarski and Tolanski techniques, respectively, and 4% for the DEKTAC. Within these accuracies agreement between *IR* and local measurements is found for all except three specimens of Table I. The discrepancy for these three specimens (DP2-1, C1, and C2) arises because they were much less uniform in thickness, as was indicated by local measurements.

Summary

An interference method is described for the thickness measurement of polycrystalline silicon deposited on thermally oxidized silicon. It provides a rapid nondestructive measurement of polysilicon thicknesses greater than 0.3 μm with an estimated accuracy of 2% + 150Å and a sensitivity of 75Å when the interference measurements are made in the 2 to 6 μm wavelength region. The method is developed for SiO_2 thicknesses of 0.5 μm or less but could be extended to larger thicknesses. The sensitivity to variation in thickness is four times greater for polysilicon than for silicon dioxide; thus, the method is particularly suitable for production control.

In-Process Thickness Monitor for Polycrystalline Silicon Deposition

T. I. Kamins* and C. J. Dell'Oca*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

An infrared interference method for monitoring the thickness of a film of polycrystalline silicon during its deposition on oxidized silicon is described. With this method, deposition can be terminated when the desired film thickness is obtained. Qualitative agreement has been found between the calculated and observed variations of the emitted intensity measured during deposition.

This paper describes an infrared interference method for monitoring the thickness of a layer of polycrystalline silicon during its deposition by the thermal decomposition of silane. A theoretical basis for the method is also given. The method is similar to one previously reported in the literature for the silicon-on-sapphire system (1), but in the present case the technique is applied to deposition on a two-layer substrate, such as is currently used in silicon technology.

Since the deposition rate is a strong function of the deposition temperature and the silane flow rate under normal operating conditions, accurate control of these two parameters is necessary. In general, poor control is detected only after the wafers are removed from the reactor and the thickness of the deposited layer is measured. The use of an in-line monitor allows the deposition to be terminated when the desired thickness is obtained. Since only one test wafer is monitored, however, good temperature and flow uniformity are still necessary in order to avoid wafer-to-wafer variations.

With this method of in-line monitoring, an infrared detector is used to observe the radiation emitted from an oxide-covered silicon wafer during the deposition of a polysilicon film on the oxide. As the thickness of the film increases, the intensity of the emitted radiation is modulated and passes through successive maxima and minima. The emitted intensity is also dependent on the optical properties of the materials and the thickness of the oxide layer.

The calculations involved in the preceding paper (2) and in the present paper are formally similar, but the variable monitored by the two methods differs. In the previous case, the intensity was observed as a function of wavelength after the deposition was completed, while the present method considers the intensity as a function of thickness during the deposition process.

Calculations

We show that, as the thickness of the polysilicon changes, interference effects modulate the emissivity and, hence, the radiation emitted from the wafer surface at a given angle.

The emissivity[1] of the wafer surface can be calculated indirectly by using the fundamental relationship that at a given temperature the emissivity and the absorptivity of a body are equal. The absorptivity, and hence the emissivity, can be calculated by considering the reflection of light from the polysilicon surface at an angle ϕ_0 from the normal. If we assume that the silicon substrate appears infinitely thick, then the incident intensity equals the absorbed intensity plus the reflected intensity; *i.e.*, the absorptivity plus the reflectivity equals unity. Thus, the emissivity, ϵ, is related to the reflectivity, ρ, by the equation

$$\epsilon = 1 - \rho \quad [1]$$

where the reflectivity can be calculated for the polysilicon-oxide-silicon system as in the preceding paper (2).

Figure 2 shows the dependence of the emissivity on the polysilicon thickness for three oxide thicknesses as calculated using Eq. [1] for $\lambda = 2.4$ μm and $\phi_0 = 36.4°$ (Fig. 1). Since the optical properties of these materials are not well known at the temperatures and wavelengths under consideration, the room-temperature values of refractive index were used in this calculation. [At least for single-crystal silicon, there is some indication that the optical properties are not strongly dependent on temperature (3,4).] It was further assumed that the polysilicon was not absorbing and had the same refractive index as single-crystal silicon [3.42]. The refractive index of SiO_2 was taken to be 1.46. Figure 2 indicates that interference effects modulate the emissivity and the radiated intensity[2] as the thickness of the polysilicon layer changes.

According to the calculations, successive maxima or minima in the intensity are separated by a change in the polysilicon thickness, Δd, which causes a 180° change in the phase of the light traversing Δd; that is

$$\Delta d = \lambda(2n_1 \cos \phi_1)^{-1} = (\lambda/2)\,(n_1^2 - n_0^2 \sin^2 \phi_0)^{-1/2} \quad [2]$$

where n is the refractive index and the subscripts 0 and 1 refer to the ambient and polysilicon, respectively. This equation indicates that Δd is independent of the oxide thickness and properties. Furthermore, since $n_1^2 >> n_0^2$, Δd is also insensitive to the angle at which

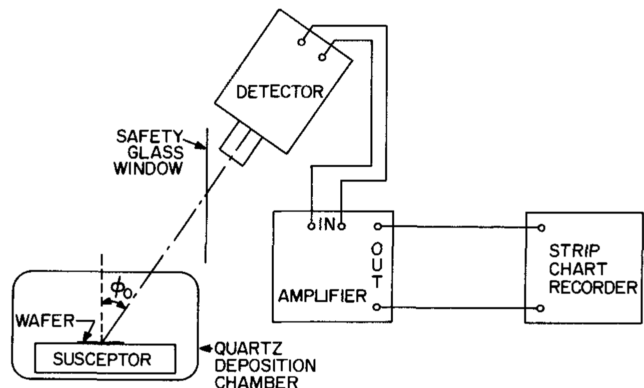

Fig. 1. Schematic representation of experimental arrangement

* Electrochemical Society Active Member.

Key words: infrared, interferometry, thin films.

[1] The emissivity is the ratio of the intensity radiated by a body to that radiated by a perfectly emitting body (a black body) at the same temperature.

[2] The total power radiated by the surface is the integral of the power radiated at all angles and wavelengths and should remain constant as the film thickness increases. Thus, the temperature of the surface will not reflect this modulation in emissivity.

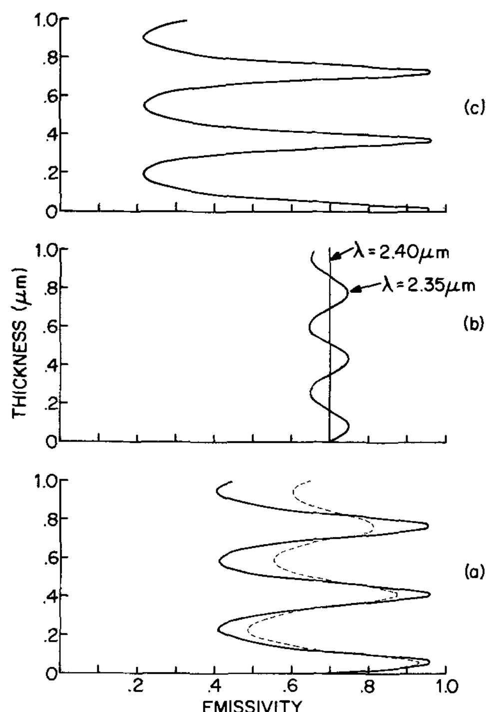

Fig. 2. Calculated dependence of the emissivity on the thickness of the polysilicon for three oxide thicknesses: (a) 0.13 μm, (b) 0.90 μm, and (c) 1.25 μm. The dashed curve in (a) indicates the emissivity for a slightly absorbing polysilicon layer.

the radiation is intercepted so that some error in measuring the angle can be tolerated.

Figure 2 shows, however, that both the starting point and the amount of modulation of the emitted intensity during deposition will be functions of the oxide thickness. If the oxide thickness is such that the phase change, δ_2, of the radiation crossing it is equal to $m\pi$, then the reflectivity and hence the emissivity will remain constant as the polysilicon thickness changes. For this condition, we obtain complete destructive interference between light reflected at the upper and lower surfaces of the oxide layer. Figure 2(b) shows the calculated emissivity for a 0.90 μm oxide film at two wavelengths; the curve for $\lambda = 2.40$ μm represents destructive interference with $\delta_2 = \pi$.

If the polysilicon were to absorb some of the radiation, the amplitude of the emissivity modulation would decrease with increasing polysilicon thickness, so that the emissivity would eventually reach a constant value. This decrease in amplitude would set an upper limit on the polysilicon thickness which could be monitored. The dashed curve in Fig. 2(a) shows the emissivity calculated with the imaginary part of the refractive index of the polysilicon, k_1, equal to 0.2.

Experimental Procedure

The thickness monitor has been used to observe the deposition of submicron films of polysilicon in an RF-heated, horizontal epitaxial reactor.[3] An infrared pyrometer,[4] which is sensitive in the wavelength range from 2.0 to 2.6 μm, was used to detect the radiation being emitted from the growing film. Although only part of the radiation emitted from the wafer surface will reach the infrared detector, the wafer is expected to be the principal source of the radiation striking the detector. Once operating conditions are attained, the temperatures of the various surfaces in the reactor should remain essentially constant. Then, the intensity reaching the detector will be affected only by the changing thickness of the polysilicon film.

[3] Applied Materials Technology, Model AMH-620.
[4] IRCON, Model 300 T5C.

The experimental arrangement is shown in Fig. 1. The pyrometer was focused on the oxide-covered silicon wafer through the wall of the quartz deposition tube and a safety glass window; the light path between the heated wafer and the detector made an angle $\phi_0 \cong 37°$ with the vertical. Radiation sensed by the detector originated from a spot less than 5 mm in diameter. The signal from the pyrometer was recorded on a strip-chart recorder. After the wafer was removed from the reactor, the polysilicon thickness was measured by infrared interferometry (2).

Experimental Results and Discussion

In order to study the usefulness of the method, the effects of deposit thickness, deposition temperature, and oxide thickness were considered.

In the first experiment polysilicon was deposited at 850°C on a silicon wafer covered by 0.13 μm of thermally grown SiO_2. Figure 3(a) shows the recorder trace for an 8.18-min deposition with a flow consisting of 0.05% silane in a hydrogen carrier gas. The trace starts from a point determined by the thickness of the underlying oxide, increases to a maximum, and then goes through successive minima and maxima, in qualitative agreement with the calculated behavior shown in Fig. 2(a). The final film thickness was subsequently measured to be 0.90 μm.

The decrease in amplitude as the film thickness increases can be attributed to three effects. These are dispersion, surface roughness, and absorption of radiation by the film. The first is perhaps the most important since the detector has a fairly large bandwidth. If the effect is solely one of absorption, which is unlikely, a k_1 of 0.2 would be required for the decrease. This value is roughly two orders of magnitude larger than that found at room temperature (2). Surface roughness is not a significant factor at these thicknesses as indicated by *IR* measurements (2). Five complete cycles have been observed during some depositions, at least four of which were useful for thickness monitoring. Therefore accurate control should be possible for films over 1 μm thick. The use of a narrower bandpass filter is expected to extend the use of this method to thicker films. Significantly longer wavelengths cannot easily be used because of the rapid decrease in the transmittance of quartz above 4 μm.

Thickness corresponding to one cycle.—In order to find the thickness corresponding to one complete cycle, a series of films was deposited at 850°C on 0.13 μm of thermally grown SiO_2. Each deposition was terminated at a maximum or minimum in the emitted inten-

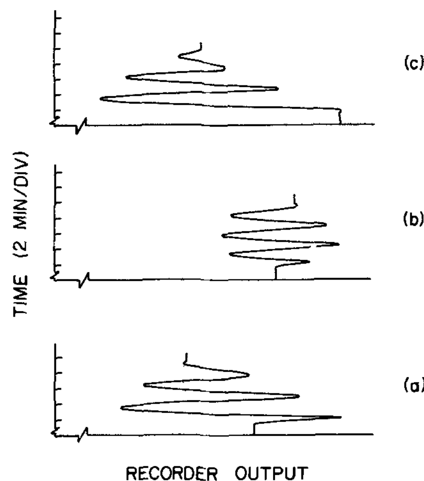

Fig. 3. Recorder traces observed during the deposition of polysilicon films on SiO_2. The three parts of the figure correspond to oxide thicknesses of (a) 0.13 μm, (b) 0.90 μm, and (c) 1.2 μm and may be compared to the calculated curves shown in Fig. 2.

Table I. Deposition parameters for films deposited at 850°C with deposition terminated at an intensity extreme

Deposition time (min)	Cycles	Thickness (μm)	Thickness difference for half cycle (μm)
3.75	1.15	0.39	
			0.16
5.28	1.65	0.55	
			0.18
6.78	2.15	0.73	
			0.17
8.18	2.65	0.90	

sity. Table I shows the time and thickness of each deposit. The fractional part of the cycle corresponds to the trace from the starting point to the first peak and cannot be accurately determined. Therefore, the thickness per cycle was determined from the thickness differences between the successive depositions. We find one complete cycle for each 0.34 μm of deposited silicon. From Eq. [2], the equivalent wavelength is 2.4 μm when the room temperature value of the refractive index of silicon is used; this wavelength is near the center of the region of sensitivity of the detector. The trace [Fig. 2(a)] calculated by using this wavelength is in qualitative agreement with the experiment [Fig. 3(a)]. The agreement indicates that this method of compensating for the temperature variation of the refractive index by using the wavelength found from Eq. [2] leads to a self-consistent set of calculations.

Effect of temperature.—Films were deposited at 750°, 850°, and 950°C on 0.13 μm of thermally grown SiO_2. Each deposition was terminated at the second minimum in the trace, and the thickness of the resulting deposit was measured after the wafer was removed from the reactor. The thickness of the three films was the same within experimental error (0.56 $\pm$ 0.01 μm); the shape of the recorder trace was also the same for the three temperatures, confirming that the relation between emissivity and thickness is not a strong function of the deposition temperature. Therefore, slight errors in the temperature setting during the deposition will not be critically important. Of course, the absolute magnitude of the emitted radiation changes with temperature.

Effect of oxide thickness.—In order to determine the effect of oxide thickness, films were also deposited on oxide layers 0.90 and 1.2 μm thick. Figures 3(b) and 3(c) show the experimental results, which may be qualitatively compared to the calculated behavior shown in Fig. 2(b) and 2(c). The thickness corresponding to one cycle is the same for the different oxide thicknesses, but the starting point and the magnitude of the intensity modulation vary. The trace for the deposit on the 1.2 μm oxide starts near a maximum and shows substantial intensity change, in agreement with the calculations [Fig. 2(c)]. The magnitude of the signal from the deposit on the 0.90 μm oxide is much weaker, as expected [Fig. 2(b)]. Successful use of the method requires avoiding oxide thicknesses close to those corresponding to $\delta_2 = m\pi$ since small experimental variations would lead to large errors in thickness. It should also be noted that the oxide thickness can be chosen so that the deposition of a given thickness of polysilicon will be terminated at a maximum or minimum for the best process control. In addition, best control will be achieved with an oxide thickness less than $\lambda/2n_2$ so that a given percentage uncertainty in oxide thickness will correspond to a small uncertainty in the phase.

Polymethonium-Silver Iodide Compounds as High-Conductivity Solid Electrolytes

M. L. Berardelli, C. Biondi, M. De Rossi,* G. Fonseca, and M. Giomini

Istituto di Elettrotecnica and Istituto di Chimica Generale, Università di Roma, Rome, Italy

ABSTRACT

Polyquaternaryalkylammonium iodide-silver iodide compounds with high ionic conductivity in the solid state have been prepared. The systems $(R_3N\text{-}(CH_2)_n\text{-}NR_3)I_2$ — AgI, at 1:12 ratio, give specific conductivities of the order of 10^{-2} (ohm $\times$ cm)$^{-1}$. For the system octamethyldiethylentriammonium iodide-silver iodide in the ratio 1:22, the specific conductivity reaches, at room temperature, a value of 5.8×10^{-2} (ohm $\times$ cm)$^{-1}$.

Solid-state electrochemical generators are known to present some advantages over traditional ones widely employed in many fields of technique. Considerable further advantages could be attained, provided that the conductivity of a solid electrolyte becomes comparable with that of a strong electrolyte in aqueous solution. These reasons justify the interest in this field and the researches carried out, especially in recent years, on substances which may constitute high-conductivity solid electrolytes.

* Electrochemical Society Active Member.

Key words: electrical conductivity, silver iodide, solid-state electrochemistry.

Several promising results have recently been achieved, mainly as a consequence of work conducted by Takahashi and Yamamoto, Owens and Argue, Bradley and Greene, etc., as summarized in Table I.

So far, the highest specific conductivity at room temperature has been measured with $RbAg_4I_5$ (10), which, in the best conditions, gives a value $\chi = 2.70 \times 10^{-1}$ (ohm $\times$ cm)$^{-1}$. However, rubidium-containing compounds are quite expensive, so that it is of interest to look for other conducting materials of lower cost; moreover, still higher conductivities would be welcomed. Such compounds should also be thermodynami-

Table I.

Authors	Compound	Conductivity $(ohm \times cm)^{-1}$	Reference
Ives and Janz	AgCl	1×10^{-7}	(1)
Miller and Maurer	AgBr	3×10^{-7}	(2)
Lieser	β AgI	2×10^{-6}	(3)
Mrgudich	AgI (amalg. el.)	1.5×10^{-4}	(4)
Takahashi and Yamamoto	Ag_3SI	1×10^{-2}	(5)
Bradley and Greene	$RbAg_4I_5$	1.24×10^{-1}	(6)
Owens and Argue	$RbAg_4I_5$	2.10×10^{-1}	(7)
De Rossi, Pistoia, and Scrosati	$RbAg_4I_5$	2.50×10^{-1}	(8)
Takahashi and Yamamoto	$RbAg_4I_5$	1.70×10^{-1}	(9)
Raleigh	$RbAg_4I_5$	2.70×10^{-1}	(10)
Owens	$Me_4NAg_6I_7$	4.0×10^{-2}	(11, 12)
Owens	$Me_2Et_2NAg_7I_9$	6.4×10^{-2}	(11, 12)

cally stable at low temperatures, while $RbAg_4I_5$ is not. These reasons have furthered studies on other compounds.

In recent papers, Owens (11, 12) extensively examined the behavior of a new series of solid electrolytes still based on AgI, in which rubidium iodide was replaced by a tetraalkylammonium iodide. Since promising results were so obtained (see Table I), the present study was carried out for a new series of compounds in which silver iodide is associated with alkylated polyammonium iodides of the general formula

$$R_3N^+\text{-}(CH_2)_n[N^+R_2\text{-}(CH_2)_n]_m\text{-}N^+R_3\ (2 + m)I^-$$

where R is an alkylic radical: in particular, compounds in which $m = 0$ and $1 \leq n \leq 10$ have been examined.

Most of the experiments reported in this paper were carried out on hexamethonium iodide-silver iodide compounds, because the hexamethonium iodide is a low-cost, readily available material. It yields the intermediate value of $n = 6$. The chemical formula may be written as

$$(CH_3)_3N\text{-}(CH_2)_6\text{-}N(CH_3)_3I_2 \text{ (HexI}_2\text{, see Table III)}$$

Experimental

Among the products of the series under study, only three pentane-1,5-bis-trimethylammonium iodide (pentamethonium iodide), hexane-1,6-bis-trimethylammonium iodide (hexamethonium iodide) and decane-1,10-bis-trimethylammonium iodide (decamethonium iodide) could be found commercially as salts.

The other compounds were transformed into salts through two procedures (examples are reported below), method A for methyl derivatives of amines (1,1-bis-diethylamino-methane, 1,2-bis-dimethylamino-ethane, 1,3-bis-dimethylamino-propane, 1,4-bis-dimethylamino-butane), and method B for the free amine 1,9-diamino-nonane.

All the starting products employed were Fluka or Carlo Erba (analytical grade) and were used without further purification.

Method A.—5g (0.043 moles) of 1,2-bis-dimethylamino-ethane are dissolved in 50 ml of cyclohexane at a temperature of 0° to 5°C; 13g (0.091 moles—slight excess) of CH_3I, dissolved in 15 ml of cyclohexane, are slowly added to the solution, which is stirred for 2 hr, at 0° to 5°C. After filtering, the solid is dried at 140°C for 15 min: 15.5g of product (90% yield) are obtained.

Analysis $I_{th} = 63.5\%$ $I_{ex} = 63.1\%$

Method B (13).—4.74g (0.030 moles) of 1,9-diaminononane are slowly dissolved in 16.5g of 90% formic acid solution (0.320 moles—1:11 ratio) at a temperature not exceeding 5°C; then 13.5g of 35% formaldehyde solution (0.150 moles—1:5 ratio) are added. The mixture is first heated, until carbon dioxide evolution ceases and then is refluxed for 5 hr. After cooling, the solution is saturated with KOH whereupon, the resulting upper layer is extracted three times with ether; after washing with water, the ether is dried over Na_2SO_4.

A solution of 9g (0.063 moles—slight excess) of CH_3I, dissolved in 15 ml of ether, is slowly added (0°-5°C outside temperature—see method A) to the ethereal solution with stirring and then method A is followed through; 13.1g of product are obtained (88% yield).

Analysis $I_{th} = 51.0\%$ $I_{ex} = 50.9\%$

Octamethyldiethylentriammonium iodide $(CH_3)_3N\text{-}(CH_2)_2\text{-}N(CH_3)_2\text{-}(CH_2)_2\text{-}N(CH_3)_3I_3$ was prepared by method A from 10.9g of pentamethyldiethylentriamine and 28.4g of CH_3I: 34.2g of product were obtained (91% yield).

Analysis $I_{th} = 65.1\%$ $I_{ex} = 64.9\%$

The materials used for the conductance tests were prepared by melting the polymethonium iodides with silver iodide. Appropriate quantities of AgI and polymethonium iodide, powdered and intimately mixed, were heated under vacuum to a temperature approaching 250°C. The resulting compound, rapidly cooled to room temperature, was pelletized and annealed for approximately 20 hr at a temperature of 165°C.

The analytical composition of the samples was checked by the following method. A known quantity of the solid electrolyte, suspended in a known volume of a standard silver nitrate solution, was boiled for several hours to obtain the decomposition of the compound and the precipitation of I^- ions as AgI. After cooling, the excess of silver nitrate was titrated with a sodium chloride standard solution. The results of the above analysis show that the error on the indicated equivalent per cent of AgI (calculated as: $100 \times$ AgI moles/AgI moles $+ 2 \times$ polymethonium moles) does not exceed $\pm 0.2\%$.

In order to try to achieve better conductivity results, a radiation test was carried out with some of the products under examination ($HexI_2$-AgI 1:12 and $OdtI_3$-AgI 1:22—see Table IV) and with $RbAg_4I_5$ and $(CH_3)_4NAg_6I_7$. A series of samples were exposed at room temperature to a 0.14 megarad/hr source of γ rays (^{60}Co) with an Atomic Canada Ltd. γ-cell. The radiation doses used ranged from a minimum of 7 megarad to a maximum of about 70 megarad. In no case were variations in electrical conductivity observed. However the color of the samples became reddish-brown, suggesting that, at least within the superficial layers, a decomposition of the iodides to elementary iodine should have occurred.

Differential thermal analyses (DTA) were operated with a 419-Type Netzsh instrument having the following characteristics: low-temperature apparatus, steel block, iron-constantan thermocouple protected against direct contact with the material under examination by suitably shaped platinum plates, calcined kaolin as reference material, heating rate 5° C/min.

X-ray diffraction experiments were performed with a PW 1050/25 Type Philips diffractometer, using nickel-filtered $Cu_{K\alpha}$ radiation.

The specific conductivity of the samples was determined by using a cell (8) in which the electrolyte, pelletized under vacuum at 1100 kg/cm² pressure, was placed between two amalgamated silver electrodes. The measurements were carried out with a 4896 Type Tinsley conductivity bridge with oscillographic resetting (545 B Type Tektronix). The pressure of 1100 kg/cm² was selected since it gives the highest specific conductivity values for the examined electrolytes (see, for example, Table II).

Results and Discussion

DTA and x-rays.—DTA was carried out at temperatures ranging between room temperature and 230°C, *i.e.* up to a temperature just below melting, for different ratios of the $HexI_2$-AgI system (1:10, 1:11, 1:12, 1:13, 1:14). The results showed that each composition presents an endothermic peak at approx. 150°C, *i.e.* close to the $AgI_\beta \rightleftharpoons AgI_\alpha$ transformation temperature.

Table II. Specific conductivity of $HexAg_{12}I_{14}$ pellets as a function of applied pressure at room temperature (average value from 4 or 5 measurements)

Applied pressure (kg/cm^2)	Specific conductivity χ (ohm × cm)$^{-1}$
400	0.025 ± 0.001
800	0.027 ± 0.001
1100	0.029 ± 0.001
1500	0.027 ± 0.001
2000	0.026 ± 0.001

The quantity of heat involved in the transformation, per formula weight of compound, is a minimum for the 1:12 ratio. This seems to indicate that the thermal preparation, described in the experimental section, provides a substantially complete but not quantitative formation of the desired compounds (approx. 95% for the 1:12 ratio). This conclusion is supported by the x-ray diffraction spectra of the same materials.

The AgI reflexes are always present, and their intensities as a function of composition follow the pattern of the areas under the DTA peaks, the 1:12 ratio giving the least AgI intensities.

Figure 1 shows the area of the DTA peaks obtained for the various ratios. The broken curve indicates the values corrected for excess of AgI added over the 1:12 ratio, on the basis of the area of the peak measured with pure AgI samples (average 88 mm^2/mM AgI).

For ratios 1:12 and lower, it is observed that the corrected area (approx. 50 mm^2/mM of the compound) is equivalent to 0.5-0.6 moles of AgI per formula weight, which may correspond to partial decomposition, or to incomplete formation of $HexAg_{12}I_{14}$. For compositions to the left of 1:12, *i.e.* an excess of $HexI_2$, the relative amount of free AgI is even higher, thus justifying the assumption that an excess of $HexI_2$ may decompose some of the conducting compound. The following may be a possible reaction

$$HexI_2 + HexAg_{12}I_{14} \rightarrow 2\,HexAg_4I_6 + 4\,AgI \quad [1]$$

On the other hand, in the absence of $HexI_2$ in excess, the $HexAg_{12}I_{14}$ decomposition reaction could result

$$HexAg_{12}I_{14} \rightarrow HexAg_4I_6 + 8\,AgI \quad [2]$$

Both of these reactions could be responsible for the presence of free AgI in the range of compositions at the left of 1:12 in Fig. 1, while for other ratios only reaction [2] would apply. There is nothing, however, in the literature, to justify reactions [1] and [2], except the analogy with the $RbAg_4I_5$ decomposition reactions. As a matter of fact, the conductivity values calculated on these assumptions (taking into account the partial decomposition of $HexAg_{12}I_{14}$ to $HexAg_4I_6$ and AgI, which are both considered nonconducting compounds, and the relative dilution effects) give values that are substantially greater than the observed values above and below the 1:12 composition.

Conductivity.—The conductivity values obtained for the various compounds and compositions studied, are reported in Tables III and IV.

Figure 2 shows the specific conductivity as a function of the equivalent per cent of AgI for some of the systems studied. For comparison, the curves obtained by

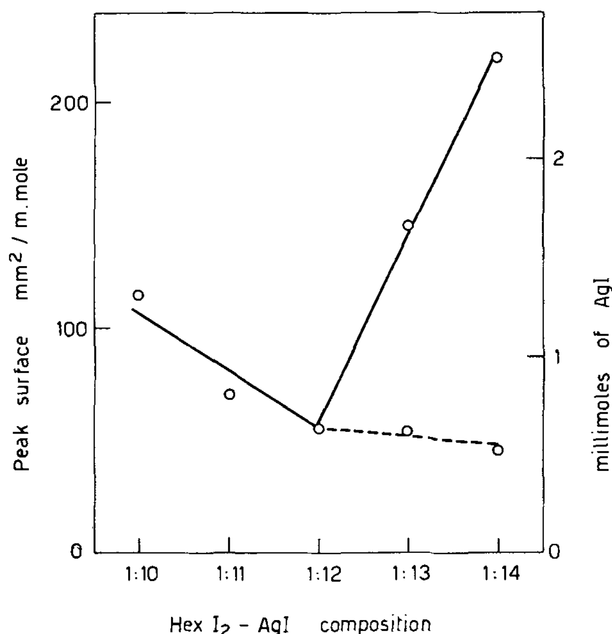

Fig. 1. DTA peak area as a function of molar composition for $HexI_2$-AgI system.

Owens for tetramethylammonium iodide-silver iodide and diethyldimethylammonium iodide-silver iodide systems are also shown. The maximum conductivity values indicate that, according to DTA and x-ray experiments, the formula of conducting polymethonium compounds is $QAg_{12}I_{14}$ (Q is the polymethonium cation).

For $OdtI_3$-AgI system the maximum conductivity value is obtained with a 1:22 ratio.

Table V reports the specific conductivity of $HexAg_{12}I_{14}$ at different temperatures. From these values, an Arrhenius activation energy of 2730 cal/mole can be calculated: the corresponding value for $RbAg_4I_5$ is about 2300 cal/mole, and for $(CH_3)_4NAg_6I_7$ about 4000 cal/mole.

It has been concluded, particularly on the basis of x-ray diffraction evidence, that the reason for the high ionic conductivity of crystals of silver iodide compounds with rubidium or tetraalkylammonium iodides may be ascribed to the high mobility of silver ions through channels made up of iodide ion tetrahedra (14, 15).

While there is the need for additional confirmatory studies, such as transference number measurements, d-c polarization measurements, and Hall effect, it may be assumed at this stage, on account of the similarity between the conductivity values reported in this work and those reported by Owens, and the analogy in the composition of these species that the cause for the high conductivity of our compounds is due to a similar mechanism.

The specific conductivity of AgI (α) at room temperature, obtained by extrapolating data at higher temperatures, is about 7×10^{-1} (ohm × cm)$^{-1}$ (16). This value cannot be obtained directly because the

alpha modification, AgI (α), is unstable below 146°C. The reaction of silver iodide with suitable salts, stabilizes a crystal lattice which possesses the high conductivity channels even at comparatively low temperatures. In a way, it can be thought as a perturbation, induced by the species introduced into the lattice, which, by hindering the close packing of the iodide

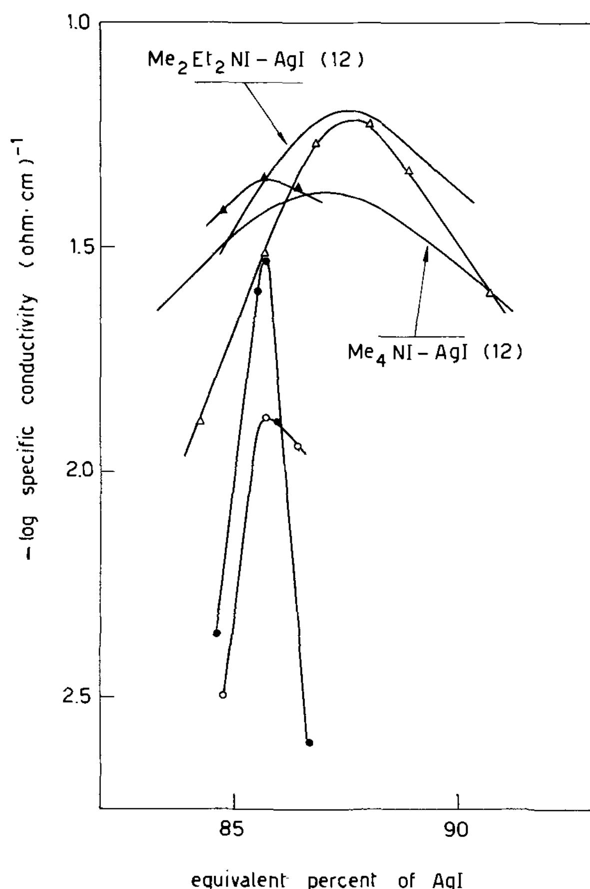

Fig. 2. Composition dependence of the specific conductivity of some binary solid electrolyte systems at room temperature. △, $OdtI_3$-AgI (see Table IV); ■, No. 6 (see Table III); □, No. 8 (see Table III); ▲, No. 1 (see Table III).

ions, characteristic of the nonconducting AgI (β), makes it possible for a more open structure to persist at lower temperatures. Among the salts which stabilize such a structure (see Table I), silver sulfide can be mentioned. In a 1:1 molar ratio with silver iodide, Ag_2S induces a specific conductivity value of approx. 10^{-2} (ohm × cm)$^{-1}$, and rubidium iodide which shows a specific conductivity of approx. 10^{-1} (ohm × cm)$^{-1}$ in a 1:4 molar ratio.

Many quaternary ammonium compounds (Owens and this study) are also capable of modifying the AgI lattice, producing results approaching those obtained with RbI. The greater conductivity of $RbAg_4I_5$ with respect to the R_4NI-AgI compounds is attributed (15) to the higher lattice symmetry of the former, to its higher holes—Ag^+ ratio, and to the lower volume of Rb^+ compared with organic cations.

Similar considerations can be made about the compounds studied in this work. In particular, it is possible to compare conductivities with respect to the size of the organic cations introduced in the lattice.

With reference to Owens' conclusion (11) that it is necessary to use alkylammonic cations of volumes ranging between 30 and 85 A^3 to obtain satisfactory results, it should be observed that in the case of the compounds reported in this study, it appears that it is not the total volume of each individual cationic particle present in the lattice that should be considered, but rather the volume of each stabilization cation, a term referring, in our case, to each individual alkylammonic group present in the organic cation introduced.

A sizable portion of the high conductivity channels are obstructed by the large organic cations. In this respect, perhaps better results would be obtained if a species could block a large number of AgI units in an open-structure lattice, while itself possessing a minimum molecular volume.

It appears that octamethyldiethylentriammonium iodide, whose compound with AgI presents the highest conductivity value among the species examined here, seems to follow this logical order, since in this case each alkyled nitrogen unit stabilizes slightly more than seven units of AgI, although its volume is less than half the volume of the polymethones. (This conclusion is also supported by the tendency of specific conductivity to decrease as the number of carbon atoms per stabilization cation.—See Table III).

In the case of methane-1,1-bis-methyldiethylenammonium iodide, the conductivity is greater than for other polymethones: a similar effect is reported by Owens, who finds the highest values in dimethyl-diethylammonium iodide. Further, a certain tendency for higher conductivity can be observed in polymethones containing an even number of intermediate —CH_2— groups when compared to those with an odd number: this could be justified by the observation that the odd or even number of carbon atoms in normal saturated hydrocarbons determines conformational changes, which considerably affect their melting temperature and the relative enthalpy changes.

It appears then that the polymethonium cations with an even number of —CH_2— intermediate groups tend to hinder less than the ones with an odd number the mobility of Ag^+, as if they might be present in the lattice in a more "streamlined" position, thus obstructing a lower number of conduction channels.

From the above, it can be assumed that, at least for the compounds of the series mentioned here, the maximum specific conductivity limit which can be aimed at would be only slightly lower than the value that silver iodide would reach if it could be present at room temperature in a form with many holes available for each Ag^+. This value, however, would be reasonably high, and could be considered as sufficient for many practical applications, once its ionic character is def-

initely verified. Such studies are in progress and will be reported later. Cells of the type: $Ag/HexAg_{12}I_{14}/HexI_2,I_2,C$ have been already put together and discharged for many hours with an initial emf of about 0.64V. Efforts in this direction should, therefore, be considered with interest.

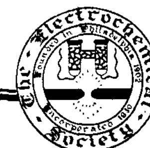
Technical Notes



Washing Calcium Halophosphate Phosphors with Diethylenetriamine Pentaacetic Acid

E. A. Graff*

Westinghouse Electric Corporation, Bloomfield, New Jersey 07003

The calcium halophosphate phosphor having the formula $3Ca_3(PO_4)_2 \cdot Ca(F, Cl)_2$ activated with antimony and manganese is generally prepared by firing a raw mix of the constituents required to satisfy the formulation. An inherent deficiency of the solid-state reaction is that the firing gives rise to local concentration excesses of constituents which are not entirely incorporated into the phosphor matrix. These unincorporated constituents, especially manganese and antimony, tend to absorb both ultraviolet and visible light thus reducing the phosphors response (1). In addition, if the antimony appears on the surface in a reduced state the phosphor may take on a gray body color which leads to an undesirable increase in absorption of visible light (2). Also the probability of mercury attachment to the phosphor arises if there are a number of free metal atoms present (3). This results in a grayish phosphor that yields poor performance in a fluorescent lamp.

Due to lamp output losses associated with the presence of the previously noted undesirable materials, it has long been the practice in the preparation of calcium halophosphate phosphors to employ inorganic and organic acids as washing aids (4, 5).

Martyny (6) showed that employing a sequestering agent, ethylenediamine tetraacetic acid (EDTA) as a washing agent would remove portions of those deleterious materials not previously removable with the organic and inorganic acids.

Though EDTA is an efficient sequestering agent, an even more efficient agent is diethylenetriamine pentaacetic acid (DTPA).

* Electrochemical Society Active Member.

Key words: phosphors, sequestering agents, ball milling, lumen output.

The DTPA is structurally similar to EDTA but it has the advantage of forming more stable complexes and of being able to complex two metal ions per mole. EDTA can only form 1:1 complexes. The structures of the two sequestering agents and the types of complexes formed are illustrated in Fig. 1.

Table I shows the significantly higher stability of the chelates formed with DTPA as compared with those formed employing EDTA.

Another factor in the greater stability of chelates formed with DTPA is its *p*H dependence in comparison to that of EDTA (7). The plots shown in Fig. 2 illustrate the difference between DTPA and EDTA where *p*M is a function of *p*H. *p*M is defined as the negative logarithm of the metal ion concentration (M^+). The data shown are typical of that obtained for many of the cations encountered in calcium halophosphate phosphors. From these data it is evident that DTPA is in many instances a better chelating agent than EDTA at both lower and higher *p*H values.

One last but quite important advantage in the use of DTPA is that it is more soluble than EDTA. At

Table I. Stability of DTPA and EDTA chelates

Magnesium	9.02	8.69

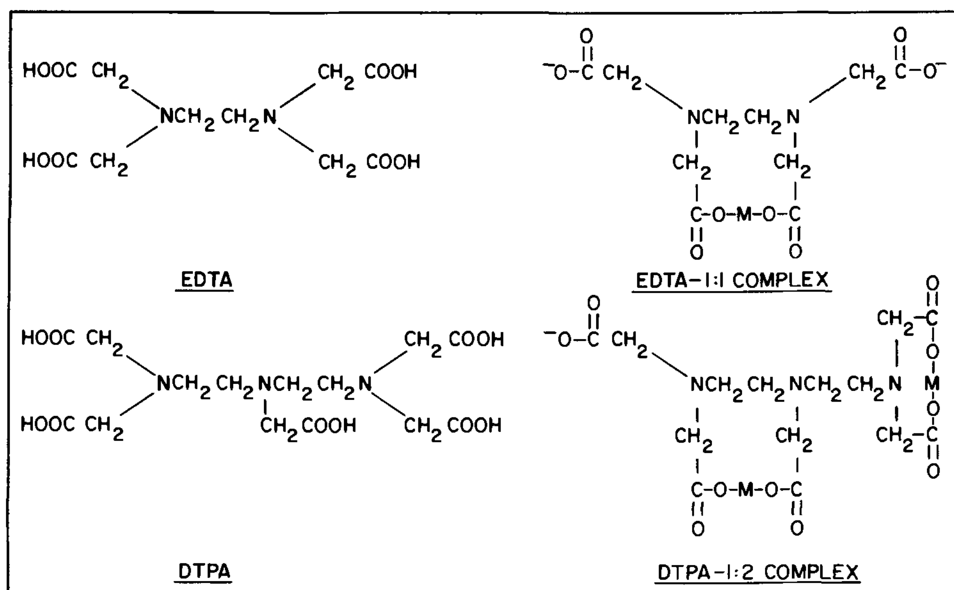

Fig. 1. EDTA and DTPA metal ion complexes.

room temperature the DTPA is 2½ times more soluble than EDTA, and at elevated temperatures the difference in the solubility of the two sequestering agents increases.

In this study I tried to determine if the apparent advantages of DTPA over EDTA could be translated into an improved treating or washing process for calcium halophosphate phosphors.

Initially, tests were run on standard Cool White halophosphate phosphor. This material was ball milled with different quantities of the sequestering agent. After milling, the slurry was washed several times by decantation and then subjected to the normal lamp processing stages for this phosphor. All lamp results were obtained in 40W fluorescent lamps.

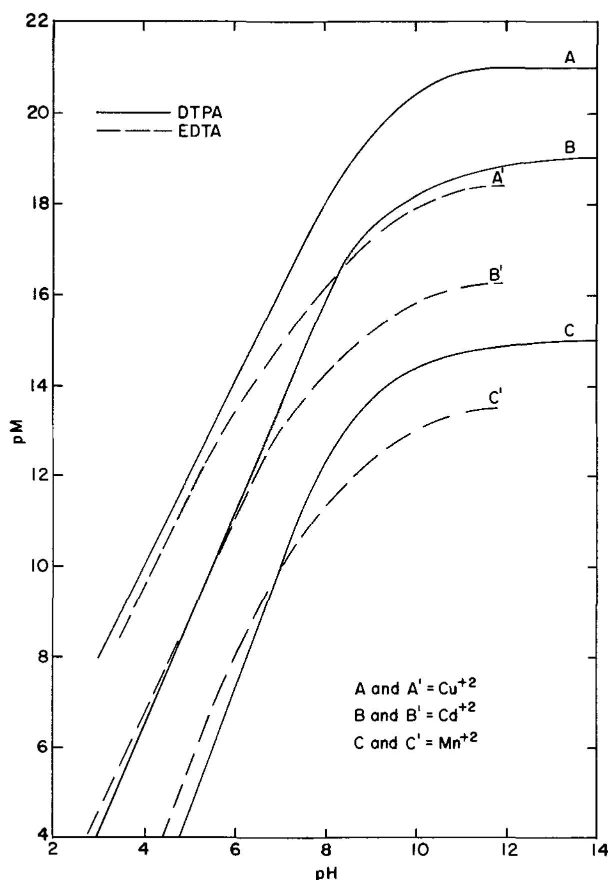

Fig. 2. Effect of pH on chelate formation

Figure 3 is a plot of lumen gain *vs.* weight per cent sequestering agent. As can be seen from the curves, for the weight per cents employed, the lumen improvement is significantly larger for the phosphors treated with DTPA than for those treated with EDTA. The improved output for the DTPA treated phosphors was only partially related to improved maintenance. Figure 4 is a plot of the 0-100 hr lumen drop *vs.* the weight per cent DTPA used. Data is only plotted for the apparently optimum range of 0.05-0.15 weight per cent (w/o) DTPA. As the quantity of the DTPA employed increased, the lamp maintenance degenerated. However, even at 0.15 w/o DTPA the lamp maintenance was somewhat better than for control lamps prepared with untreated phosphors. Figure 4 does show that maintenance improvements represent between 25 and 50% of the improvement obtained with the use of DTPA. The rest of the improvement is related to improved initial output. The data in Fig. 4 indicate the optimum DTPA content from the standpoint of maintenance to be at 0.05 w/o, however, the results plotted in Fig. 3 indicate that 100 hr output peaks at 0.10 w/o DTPA.

Figure 5 shows the effect of sequestering agents on the output of 40W fluorescent lamps over an extended burning period. The treated phosphors shown in the figure were processed with 0.10 w/o DTPA and EDTA based on the total weight of phosphor. After 2500 hr of burning, the lamps containing the DTPA treated phosphor have dropped 2% less in relation to their 100 hr output than the lamps containing the untreated phosphor. The maintenance of the DTPA treated phosphor is slightly better than that of the EDTA treated phosphor.

Analyses of wash water residues from phosphor slurries treated and not treated with DTPA show some marked differences. The level of impurities detected in the DTPA generated residue is generally greater than the level detected in the residue from the untreated phosphors. For some impurities such as manganese and cadmium the level of impurities differs by a factor of 10.

X-ray fluorescence measurements performed on phosphors treated and not treated with the DTPA show striking differences in the quantities of antimony and manganese present. Treated phosphors record 5-8% lower antimony and manganese levels than their untreated controls.

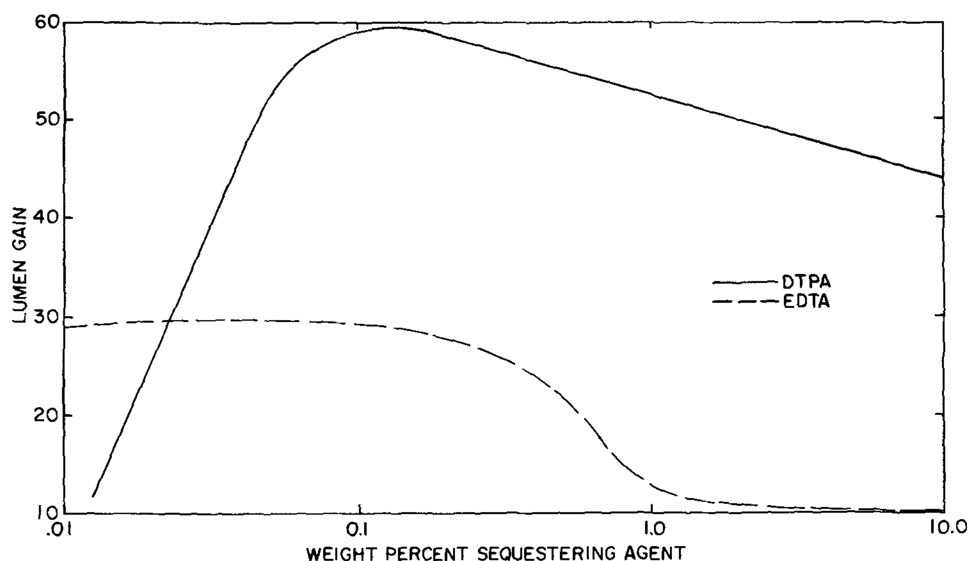

Fig. 3. Lumen gain at 100 hr vs. weight per cent sequestering agent.

From the work performed to date, several conclusions can be drawn.

(*i*) Diethylenetriamine pentaacetic acid is an effective aid in the processing of calcium halophosphate phosphors. Its use reduces the level of certain apparently unreacted phosphor constituents. This reduction in turn is related to both improved initial lamp performance and improved maintenance characteristics for the treated phosphors.

(*ii*) The intrinsic characteristics of diethylenetriamine pentaacetic acid make it a more suitable and effective sequestering agent than ethylanediamine tetraacetic acid for use in processing calcium halophosphate phosphors.

Acknowledgment

The author wishes to thank Mr. John F. Hall, Mr. John Chwan, and Mr. Matthew Wheelan for sample preparation and Mr. Eugene A. Wesley and Mr. Theodore A. Ellis for analytical measurements.

Dielectric Loss, Electrode Deterioration, and the Sodium Problem in MOS Structures

D. J. Silversmith

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Two reports of the high-temperature and low-frequency dielectric loss in MOS structures have purported to study ionic transport and space charge polarization effects. Using this data, the present note correlates the dielectric relaxation results to elevated temperature measurements of capacitance. The comparison indicates that above 300°C the metal electrode reacts with silicon dioxide to give a displacement current component similar to that associated with the "slow trapping instability." The solid-state electrolytic reactions indicated here make the precise ionic contribution to the displacement uncertain: therefore, voltage ramp measurements of ionic impurities above 350°C are problematic. Further evidence for a high-temperature solid-state electrolytic reaction is obtained from measurements performed alternately in N_2 and O_2 ambients.

Dielectric Loss Experiments

Using 3500Å thick steam oxides grown on 4-7 ohm-cm n-type silicon, Burkhardt (1) measured the frequency dependence of the dielectric loss in the oxide as a function of temperature (400°-525°C). From a plot of the frequency at which the dissipation factor, tan δ, peaked (at zero d-c bias) *vs.* the corresponding temperature, an activation energy of 0.438 eV was determined for the relaxation process. Burkhardt related the peak in tan δ to an ionic space charge polarization; his inference is that a solid-state reaction between the aluminum electrode and the SiO_2 produces positively charged oxygen vacancies which can diffuse within the oxide under the influence of an electric field. Burkhardt eliminated the possibility that sodium ions were the source of space charge polarization by observing no change in the experimental results for intentionally contaminated devices. Measurements were also made on MOS devices with chrome field plates instead of aluminum, but these devices showed no structure in the dissipation factor at all.

Kriegler and Bartnikas (2) have reported on measurements of dielectric loss and capacitance as a function of temperature (300° to 425°C) and frequency (1.5 to 1000 Hz) in MOS structures. Gold-protected chrome was used for the field plate, and gold, for a back contact. Figure 1 gives the real and imaginary parts of the dielectric constant of a typical device at 400°C and is taken from the measured parallel capacitance and conductance data of Kriegler and Bartnikas. From the peak of the dissipation factor, tan $\delta = \epsilon''/\epsilon'$, *vs.* measurement temperature, Kriegler and Bartnikas find activation energies ranging from 1.21 to 1.43 eV, depending on the extent of annealing. The relaxation phenomenon is ascribed to sodium contamination. Because the activation energy is close to the value of 1.39 eV found by Snow *et al.* (3) for sodium transport, Kriegler and Bartnikas inferred an indirect confirmation of an ionic model for dielectric loss.

Discussion of Dielectric Loss Data

Burkhardt's temperature range is significantly higher than that of Kriegler and Bartnikas, and different field plate metals were used. All Burkhardt's measurements were preceded by a 1-hr anneal at 490°C. Kriegler and Bartnikas have observed that the peak in the dissipation factor and the structure of the real part of the dielectric constant decrease with time at elevated temperature. In fact, at 490°C a device with gold-protected chrome electrodes has all structure completely annealed out after 1 hr. Therefore, it is not surprising that Burkhardt found no discernable structure for chrome-metallized devices.

The case for Kriegler and Bartnikas' (2) determination of sodium as the source of structure in the frequency dependence of the dielectric constant is, however, tenuous. The apparent "annealing out" of sodium with time necessitates the inclusion of a deep trapping mechanism with a very high activation energy in the model. The work of Kuhn and Silversmith (4) suggests that at temperatures above 300°C the re-emission time for sodium traps is extremely small; no annealing out of ionic transport was observed. Experiments by Kuhn and Silversmith (4) on field-induced transport of alkali ions in MOS structures indicate that the analysis of diffusion of sodium ions in SiO_2 by Snow *et al.* (3) is, in fact, related to trap emission mechanisms at the metal-silica interface rather than to bulk diffusion.

Simultaneously and in substantial agreement with Kuhn and Silversmith (4), Chou (5) has made a study of the MOS current dependence as a function of temperature in terms of an electrochemical cell. He found it necessary to make mobile ion transport measurements in the range of 200° to 250°C to assure equilibrium conditions needed for consistent quasi-static or triangular voltage sweep measurements. Chou could not find any significant ionic current below 145°C; above 310°C there was evidence of a current contribution due to an electrolytic reaction at the electrode-

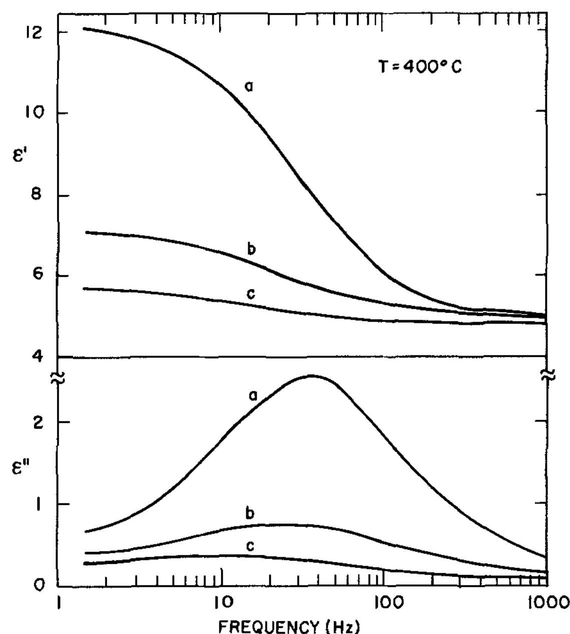

Fig. 1. Dielectric relaxation of a thermally grown SiO_2 film at 400°C from the work of Kriegler and Bartnikas (2). Time dependence of the relaxation spectrum: *(a)* initial measurement, *(b)* after 12 hr, and *(c)* after 6 days.

Key words: metal gate electrodes, ionic impurities, electrical instability in MOS devices, solid-state electrolytic reactions.

oxide interface. In addition, Chou and Eldridge (6) have observed that protracted, postmetallization annealing treatments (*viz.* 30 min at 500°C) can promote extensive low-field breakdown in MOS devices. Hofstein (7) and Yamin (8) have noted solid-state reactions between metal electrodes and silica at elevated temperatures of about 400°C. These reactions modify the apparent nature of the ionic drift instability. Kuhn and Silversmith (4) observed a temperature limit around 370°C, above which gross instabilities were evident. These instabilities appeared to be related to the deterioration of the aluminum or chrome field plate. These observations suggest that reactive metal electrodes can interact with silica to cause devitrification and growth of structural defects under the edge of the metal electrode.

Slow Trapping Instability

Negative bias aging of MOS devices at temperatures in excess of 200°C has been observed to shift the flatband voltage negatively, as if positive charge drifted to the metal-oxide interface (9-11). This effect, which saturates in several hours at 300°C and within minutes at 400°C, has not been considered to be attributable to ionic transport. Deal *et al.* (10) suggested that silicon is injected from the bulk into the silica film under the influence of the negative electric field and that the excess silicon in silica is positively charged. Hofstein (11) has proposed that the effect is related to the trapping of holes by a level of donor-like states in the oxide close to the Si-SiO_2 interface with an energy level close to the Si valence band.

Although such discussions of the slow trapping instability have generally excluded electrode-insulator reactions, this note indicates that electrochemical effects are a likely source for this instability.

Electrolytic Dependence on Gaseous Ambient

In a recent piece of work, Chou (12) has observed displacement currents for triangular voltage sweep measurements on MOS devices at 390°C that were higher in a 10^{-3} Torr oxygen ambient than in 760 Torr oxygen. The present author has performed high-temperature quasistatic measurements alternatively in one atmosphere nitrogen and oxygen ambients. The oxides were prepared by the dry thermal process and were 2000Å thick. For oxides containing less than 10^{12} mobile ions/cm² no significant differences in apparent ion current were observed below 300°C for measurements performed in nitrogen and oxygen. For either higher temperatures or much higher ion surface densities, a higher displacement current was seen for measurements in a nitrogen ambient than in an oxygen ambient.

A typical quasistatic I-V curve is given in Fig. 2 where nitrogen is denoted in solid line and oxygen in dashes. The measurements were made at 319°C on an oxide 2000Å thick. The peaks corresponding to the nitrogen ambient can be taken as a measure of alkali ion contamination if electrode reactions are disregarded. The peak corresponding to the decreasing voltage sweep is more sharply defined because there is, apparently, no trapping-release mechanism associated with the Si-SiO_2 interface; Kuhn and Silversmith (4) have noted, however, an ionic trapping mechanism at the metal-oxide interface. For the device analyzed in Fig. 2, the surface density of alkali (sodium) ions is $4.2 \times 10^{12}/cm^2$. The same measurement in an oxygen ambient indicates a slightly smaller displacement current. At temperatures somewhat higher than 319°C the differences between currents measured in nitrogen and oxygen can be as much as 20%. The problem with very high temperature measurements of the quasistatic I-V curve is that the repeatability is not good. Obviously the devices degrade with voltage cycling at high temperatures. The partial pressure dependences of ion current in MOS devices at temperatures above 300°C is explicable in terms of an electrochemical polarization process at the edge of the electrode-insulator interface, into which the ambient gas can diffuse This dependence is *prima facie* evidence for the occurrence of a reaction at the electrode-insulator interface.

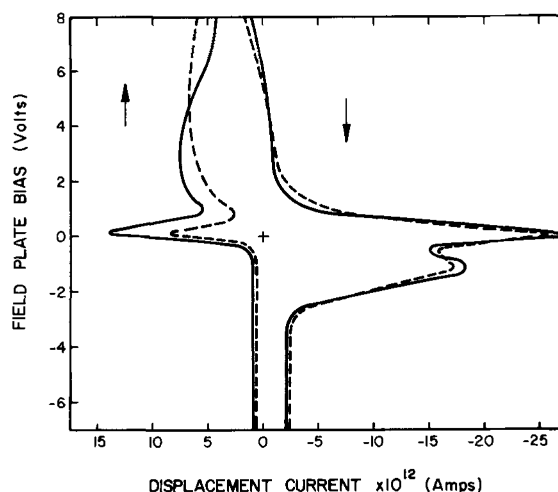

Fig. 2. Displacement current response of an MOS capacitor at 319°C. The substrate consisted of a P-type 10 ohm-cm (100) wafer. The oxide was 2000Å thick and was grown in a dry oxidation furnace at 1150°C. Fifteen-mil dots of 200Å Cr and 2000Å Au were deposited for field plates. The sweep rate of the d-c ramp was 44.8 mV/sec. The solid line measurement was made in a 760 Torr nitrogen ambient, and the dashed line measurement was made in 760 Torr oxygen.

Activity Coefficients for a Regular Multicomponent Solution

A. S. Jordan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

The concept of a regular liquid or solid solution was first introduced by Hildebrand (1) and subsequently placed on a firm theoretical foundation by Guggenheim (2). Many applications of regular solution theory have been made in the field of semiconductor phase equilibria. In particular, in early work, Thurmond (3) and Thurmond and Kowalchik (4) analyzed the liquidus data for a large number of Si- and Ge-based binary systems by means of regular solution activity coefficients (2). More recently, the activity coefficients derived for regular binary (2) and ternary (5) solutions have been successfuly applied to calculations of the binary liquidus curves and ternary liquidus isotherms in the Ga-As, Ga-P (6), Ga-As-Cu (7), Ga-As-Zn (8, 9), Ga-P-Zn (9, 10), and Ga-Al-As (11) systems.

Several semiconductor systems of current interest, such as the quaternary Ga-P-Zn-O and Ga-As-P-Zn systems, contain more than three components. Very recently, a schematic discussion of the main features of the Al-Ga-In-P, Ga-Sb-In-As, and Al-Ga-As-Sn quaternary systems have been presented by Panish and Ilegems (12). The eventual thermodynamic analysis of such complex systems would benefit from a knowledge of the activity coefficients for regular quaternary solutions. However, to the best of this author's knowledge, explicit formulas for the activity coefficients of regular solutions that contain more than three components are not available. It is the objective of this note to derive the activity coefficients for regular multicomponent solutions in a convenient form from the Gibbs free energy of mixing and to provide detailed expressions for the activity coefficients of quaternary mixtures.

The Gibbs free energy of mixing, G^M, of a regular binary solution containing n moles is given according to the statistical treatments of Guggenheim (2) and Prigogine (13) by

$$G^M = \frac{\alpha_{12} n_1 n_2}{n} + R(n_1 \ln x_1 + n_2 \ln x_2) \qquad [1]$$

where n_i and x_i, respectively, are the number of moles and mole fraction of component $i (i = 1 \text{ or } 2)$ and α_{12} is the so-called interchange energy related to the nearest neighbor pairwise interaction energies, u_{ij}, Avogadro's number, N_0, and coordination number, Z, by $\alpha_{12} = N_0 Z[u_{12} - (u_{11} + u_{22})/2]$. Phenomenologically, Eq. [1] states that the entropy of mixing of a regular solution is that of an ideal solution (second term) and that the heat of mixing is parabolic in n_1 and n_2 (first term).

It can be shown in a straightforward manner either by the generalization of the phenomenological definition or by an extension of the statistical work (2, 13) on binary solutions that for multicomponent systems Eq. [1] takes the form

$$G^M = \frac{1}{2} \sum_{\substack{k=1 \\ k\neq j}}^{m} \sum_{j=1}^{m} \frac{\alpha_{kj} n_k n_j}{n} + RT \sum_{k=1}^{m} n_k \ln x_k \qquad [2]$$

where the summation extends to all of the m components and α_{kj} is the appropriate generalization of the interchange energy.

By an application of the well-known thermodynamic relationship

$$\frac{\partial G^M}{\partial n_i} = RT \ln a_i = RT \ln \gamma_i x_i \qquad [3]$$

to Eq. [2],[1] where a_i and γ_i denote the activity and activity coefficient of component i, respectively, one finds

$$RT \ln a_i = RT \ln x_i + \frac{1}{2} \sum_{\substack{k=1 \\ k\neq j}}^{m} \sum_{j=1}^{m} \alpha_{kj} \frac{\partial}{\partial n_i} \left(\frac{n_k n_j}{n} \right) \qquad [4]$$

Performing the indicated partial differentiation, the double sum in Eq. [4] separates into three sums. Then, after rearrangement, one can express $\ln \gamma_i$ as

$$RT \ln \gamma_i = \frac{1}{2} \sum_{\substack{j=1 \\ i\neq j}}^{m} \alpha_{ij} x_j + \frac{1}{2} \sum_{\substack{k=1 \\ i\neq k}}^{m} \alpha_{ki} x_k - \frac{1}{2} \sum_{\substack{k=1 \\ k\neq j}}^{m} \sum_{j=1}^{m} \alpha_{kj} x_k x_j \qquad [5]$$

Since the indices k and j have identical limits and also $\alpha_{ki} = \alpha_{ik}$, the second single sum in Eq. [5] can be combined with the first one, so that $\ln \gamma_i$ reduces to

$$RT \ln \gamma_i = \sum_{\substack{j=1 \\ i\neq j}}^{m} \alpha_{ij} x_j - \frac{1}{2} \sum_{\substack{k=1 \\ k\neq j}}^{m} \sum_{j=1}^{m} \alpha_{kj} x_k x_j \qquad [6]$$

By separating the quadratic terms present in Eq. [6] a more convenient expression for $\ln \gamma_i$ can be derived. Let us exclude the terms from the double sum in Eq. [6] for which $k = i$ and $j = i$ and absorb the resulting single sum

$$-\frac{1}{2} \sum_{\substack{j=1 \\ i\neq j}}^{m} \alpha_{ij} x_i x_j - \frac{1}{2} \sum_{\substack{k=1 \\ i\neq k}}^{m} \alpha_{ki} x_k x_i = - \sum_{\substack{j=1 \\ i\neq j}}^{m} \alpha_{ij} x_i x_j$$

in the single sum in Eq. [6]. Then, the single sum contains the term $1 - x_i$ which can be replaced by

$$1 - x_i = \sum_{\substack{k=1 \\ k\neq j,\ i\neq k}}^{m} x_k + x_j$$

to yield for $\ln \gamma_i$

$$RT \ln \gamma_i = \sum_{\substack{j=1 \\ i\neq j}}^{m} \alpha_{ij} x_j^2 + \sum_{\substack{k=1 \\ k\neq j,\ i\neq k,\ i\neq j}}^{m} \sum_{j=1}^{m} \alpha_{ij} x_k x_j - \frac{1}{2} \sum_{\substack{k=1 \\ k\neq j,\ i\neq k,\ i\neq j}}^{m} \sum_{j=1}^{m} \alpha_{kj} x_k x_j \qquad [7]$$

Contracting the double sums in Eq. [7] and restricting the values of k and j to $k < j$ gives the desired expression for the activity coefficient of component i in a regular multicomponent solution in the form

$$RT \ln \gamma_i = \sum_{\substack{j=1 \\ i\neq j}}^{m} \alpha_{ij} x_j^2 + \sum_{\substack{k=1 \\ k< j,\ i\neq k,\ i\neq j}}^{m} \sum_{j=1}^{m} x_k x_j (\alpha_{ij} + \alpha_{ik} - \alpha_{kj}) \qquad [8]$$

[1] Note that to perform the partial differentiation with respect to n_i, one must rewrite x_k in Eq. [2] in terms of the number of moles as $n_k / \sum_{k=1}^{m} n_k$.

Key words: thermodynamics, phase diagrams, solution theory, compound semiconductors, liquidus surface calculations.

One can readily show that the set of Eq. [8] for $i = 1, 2, \ldots m$ satisfies the multicomponent Gibbs-Duhem equation.

It follows from Eq. [8] for $\ln \gamma_i$ that for an m-component system there are $(m - 1)$ quadratic terms and $[(m - 1)(m - 2)]/2$ cross-terms in the mole fractions x_j. In particular, taking $m = 2$ and $m = 3$, respectively, one has 1 and 2 quadratic terms and 0 and 1 cross-terms, in agreement with the well-known expressions for the activity coefficients of regular binary (2) and ternary solutions (5).

As an example, applying Eq. [8] to a quaternary regular solution (3 quadratic and 3 cross-terms) yields

$$\begin{aligned}
RT \ln \gamma_1 &= \alpha_{12}x_2^2 + \alpha_{13}x_3^2 + \alpha_{14}x_4^2 + x_2x_3(\alpha_{12} + \alpha_{13} - \alpha_{23}) \\
&\quad + x_2x_4(\alpha_{12} + \alpha_{14} - \alpha_{24}) + x_3x_4(\alpha_{13} + \alpha_{14} - \alpha_{34}) \\
RT \ln \gamma_2 &= \alpha_{12}x_1^2 + \alpha_{23}x_3^2 + \alpha_{24}x_4^2 + x_1x_3(\alpha_{12} + \alpha_{23} - \alpha_{13}) \\
&\quad + x_3x_4(\alpha_{23} + \alpha_{24} - \alpha_{34}) + x_1x_4(\alpha_{12} + \alpha_{24} - \alpha_{14}) \\
RT \ln \gamma_3 &= \alpha_{13}x_1^2 + \alpha_{23}x_2^2 + \alpha_{34}x_4^2 + x_1x_2(\alpha_{13} + \alpha_{23} - \alpha_{12}) \\
&\quad + x_2x_4(\alpha_{23} + \alpha_{34} - \alpha_{24}) + x_1x_4(\alpha_{13} + \alpha_{34} - \alpha_{14}) \\
RT \ln \gamma_4 &= \alpha_{14}x_1^2 + \alpha_{24}x_2^2 + \alpha_{34}x_3^2 + x_1x_2(\alpha_{14} + \alpha_{24} - \alpha_{12}) \\
&\quad + x_1x_3(\alpha_{14} + \alpha_{34} - \alpha_{13}) + x_2x_3(\alpha_{24} + \alpha_{34} - \alpha_{23})
\end{aligned} \quad [9]$$

Obviously, if x_4 or x_3 and x_4 are equal to zero, the activity coefficients for ternary (5) or binary (2) regular solutions result from Eq. [9].

Lanthanum Trifluoride as a Membrane in a Reference Electrode for Use in Certain Molten Fluorides

H. R. Bronstein and D. L. Manning

Chemistry Division and Analytical Chemistry Division,
Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

A reference electrode system which utilizes the unique properties of a single crystal lanthanum trifluoride membrane, namely, negligible solubility and virtually 100% current transport by fluoride ions, was successfully used both for electroanalytical measurements and for obtaining thermodynamic data in certain fluoride melts of interest to the Molten Salt Breeder Reactor.

A knowledge of the chemical and thermodynamic properties of molten fluoride salt mixtures used or contemplated for use as fuel solvents or coolants in the Molten Salt Breeder Reactor (1) is necessary not only from the standpoint of operational suitability but also for the fuel reprocessing technology.

The measurement of equilibrium potentials of galvanic cells is in principle one of the most attractive and direct means of obtaining much of this information. As in all galvanic cells the half-cell of interest is coupled with a suitable reference electrode. However, difficulties are encountered in selecting a reference electrode for use in these fluoride melts. Of the few known reference electrodes each has certain inherent disadvantages. Our particular effort was to develop a simple, convenient, and stable reference electrode system useful for thermodynamic as well as electroanalytical measurements in fluoride melts of interest in connection with the Molten Salt Breeder Reactor.

The Ni/Ni(II) couple in fluoride salts shows Nernstian behavior (2). A nickel-nickel fluoride reference electrode contained in a thin-walled (1/32 in.) boron nitride (BN) thimble was previously developed for potential measurements in molten LiF-NaF-KF [42-11.5-46.5 mole per cent (m/o)] and LiF-BeF_2-ZrF_4 (65.6-29.0-5.4 m/o) at a working temperature of about 500°-550°C (2, 3). Boron nitride, normally an insulator in fluoride melts, is slowly impregnated by the melt to provide ionic contact. This wetting occurs in about 24 hr in molten LiF-NaF-KF while a longer period, 10-14 days, is usually required in LiF-BeF_2-ZrF_4 at 500°-550°C. At higher temperatures, however, the BN barrier appears to deteriorate permitting mixing of the melts.

Our modification of this electrode system was suggested by the successful use of single crystal membranes of CaF_2 at elevated temperatures in solid-state electrochemical cells such as Ni, $NiF_2/CaF_2/MgF_2$, Mg to obtain Gibbs energy data from measured emf values (4-6) and the fluoride ion electrode in aqueous media using a LaF_3 membrane (7)

$$F^-/LaF_{3(c)} \,\Big|\, \begin{matrix} NaF(0.1M) \\ NaCl(0.1M) \end{matrix} \, AgCl,Ag$$

The successful operation of each system is basically due to the relatively "open" crystal structures of CaF_2 and LaF_3 which favor a mechanism of conduction virtually 100% by the mobile F^- ion (8, 9).

Experimental

Figure 1 illustrates the

$$Ni \,\Big/\, \begin{matrix} LiF & 67 \\ BeF_2 & 33 \end{matrix} \, m/o, \, \begin{matrix} NiF_{2(c)} \\ sat'd \end{matrix} \,\Big|\, LaF_{3(c)} \,\Big|$$

reference electrode system. A CaF_2 crystal could not be used since its solubility is much too great in the fluoride melts of interest. Although no solubility data are available for LaF_3 in the fluoride melts used or contemplated for use in the Molten Salt Reactor Program, it was expected by analogy to CeF_3 (10) to be approximately 1 m/o at temperatures of interest 500°-600°C. The single crystals of LaF_3 ⅜ in. diam by 1 in. lengths were obtained from Optovac, Incorporated. The cup portion, ⅛ in. diam by ½ in. depth, was formed by drilling with a hollow diamond drill to the proper depth and then carefully breaking the center core loose from the main body. The cup contained the same fluoride salt mixture as the test melt except for the small quantity of NiF_2 necessary to saturate the melt, 10^{-3} mole fraction. Contact to the melt in the cup is achieved with the small nickel electrode. The LaF_3 crystal is contained inside the nickel sheath (some were of copper) but separated from the sheath by a form machined from solid boron nitride. The whole assembly is held firmly in place by the nickel nut. The purpose of the fine porosity nickel frit is to protect the crystal, as much as possible, from undue etching by the molten fluoride. Once the melt inside the frit and at the frit-crystal interface becomes saturated with LaF_3, further attack on the crystal is minimized due to the slow rate of diffusion of the melt in the pores of the frit.

Generally, electrical contact through the reference electrode was achieved within 5 min after dipping into the melt. A depth of ¼ in. to ½ in. was usually main-

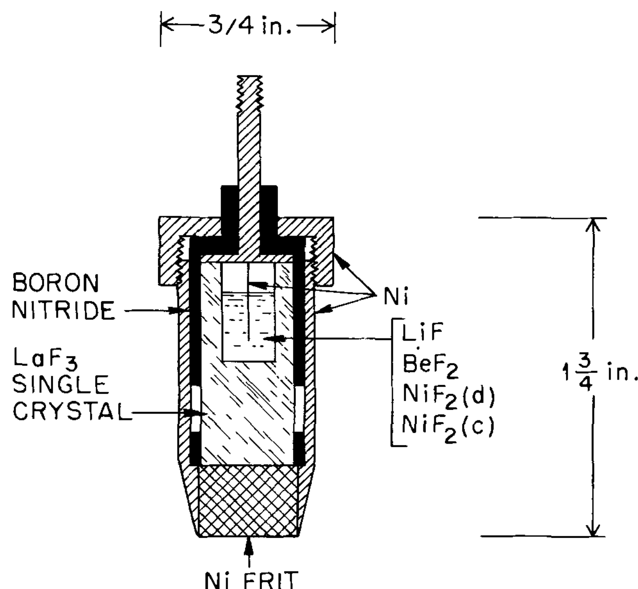

Fig. 1. Construction of the lanthanum trifluoride membrane reference electrode.

tained. Typical resistance of an electrode is of the order of 500 K ohms over the range 500°-600°C as indicated by a Keithley electrometer. The LaF_3 crystal showed insignificant attack from the molten fluorides when wetted through a fine porosity frit, approximately 10μ pore size. One crystal remained in excellent condition after contacting the melt approximately 50 days at 500°C. If care is exercised to heat and cool the crystals slowly to avoid cracking, they can be cleaned with water and reused. A model of an electrode system where a Ni-NiF_2 solid pellet (4) is press-fitted against one face of the solid LaF_3 crystal, the other face of the crystal against the nickel frit, was abandoned because of difficulties in maintaining good contact between the Ni-NiF_2 pellet and the LaF_3 crystal surface.

The experimental arrangement for voltammetric studies in molten fluorides has been described previously (11). The solvent used was LiF-BeF_2 (67-33 m/o). Uranium was added as LiF-UF_4 (73-27 m/o). Handling of the fluoride salts was carried out in a dry box. The controlled potential-controlled current cyclic voltammeter is described elsewhere (12). The voltammograms were displayed on a Moseley Model 2D-2A X-Y recorder or a Tektronix Type 549 storage oscilloscope. A dip-type platinum indicator electrode (area ~0.1 cm^2) was used. The rate of voltage scan was 0.1 V/sec unless otherwise specified.

The LiF-BeF_2 (67-33 m/o) was prepared from optical grade single crystal LiF and doubly distilled BeF_2. For the galvanic cell measurements the melt was contained in a nickel cup, 2½ in. diam by 3 in. high. The nickel cup was positioned within a stainless steel cylinder which in turn was set into a 3 in. diam × 16 in. high Marshall furnace. The header closing the cylinder had provisions for raising and lowering the electrodes and the nickel thermocouple tube through Teflon vacuum-pressure seals. In addition, entry tubes in the header permitted evacuation and pressurization of the apparatus. The salt mixture was pretreated by slowly heating under vacuum. At the melting temperature the apparatus was pressurized with mass-spectrographically pure argon with an overpressure maintained at 3 psi greater than atmospheric as controlled by a nullmatic type of valve. The temperature of the melt was measured with a Chromel-Alumel thermocouple inserted into the nickel tube. Constant temperature 600° ± 2°C, was maintained by conventional control devices. At temperature the electrodes were lowered into the melt to the required depths. The voltage of the cell was measured using a Potentiometric-Voltmeter bridge in conjunction with a Hewlett Packard Model 426 d-c micro voltammeter and recorder.

Results and Discussion

The LaF_3 membrane reference electrode was used to follow voltammetrically the half-wave potential of the U(IV)-U(III) reduction wave (11) in molten LiF-BeF_2-ZrF_4 (67-33 m/o) at 500°C. The melt contained approximately 0.2 m/o UF_4. The concentration of U(III) was varied by controlled reduction of U(IV) with zirconium metal (13). Of interest here was to observe if an increase in the concentration of U(III) (melt more reducing) would adversely affect the performance of the reference electrode which would be reflected in erratic half-wave potentials. The U(IV)/U(III) ratio was varied from ~10:1 to > 10,000:1. The $E_{1/2}$ of the U(IV) → U(III) reduction wave *vs.* the reference electrode remained constant at −1.352 ± 0.024V over a period of 20 days and 62 determinations. The half-wave potential is the voltammetric equivalent of the standard electrode potential (E^o), *i.e.* the potential at which the U(IV)/U(III) ratio is unity at the electrode surface. This potential occurs at 85% of the peak current (14). Since $NiF_{2(c)}$ in the reference electrode is at unit activity, the measured potential is the standard potential of the cell (Ni,$NiF_{2(c)}$//$U^{+3}U^{+4}$). The value of E^o was calculated to be −1.343V from the equation $\Delta G^o = -nFE^o$ and the free energy of formation of NiF_2 (15), and of UF_4, and UF_3 (15) in the solvent LiF-BeF_2 (67-33 m/o). The calculated E^o is in good agreement with the voltammetric value.

Since the activity coefficients are known for BeF_2 in LiF-BeF_2 melts (16) the galvanic cell

$$\mathrm{Be} \Big/ \begin{matrix}\mathrm{LiF}\ 67\\ \mathrm{BeF_2}\ 33\end{matrix}\ \mathrm{m/o} \Big/ \mathrm{LaF_3} \Big/ \begin{matrix}\mathrm{LiF}\ 67\\ \mathrm{BeF_2}\ 33\end{matrix}\ \mathrm{m/o} \begin{pmatrix}\mathrm{NiF_{2(c)}}\\ \mathrm{sat'd}\end{pmatrix} \Big/ \mathrm{Ni}$$

provides a means of ascertaining any deviation from ideal thermodynamic behavior of the reference electrode system.

With the fluoride activities in the melts on both sides of the LaF_3 crystal being essentially the same, and with the LaF_3 membrane conducting 100% by means of its mobile F^- ion, junction potentials should be virtually eliminated.

The measured voltage of this galvanic cell at 600°C should correspond to the voltage calculated by combining the data of the cell Be/LiF-BeF_2 (67-33 m/o)/Pt,$H_{2(g)}$,$HF_{(g)}$ (16) and of the reaction $NiF_{2(c)} + H_{2(g)} = 2HF_{(g)} + Ni$ (17) if asymmetry and junction potentials are negligible or nonexistent. The initial steady-state voltage was 2.045 ± 0.003V in very good agreement with 2.041 ± 0.003V obtained from combining data from Ref. (16, 17). Apparently asymmetry potentials at the LaF_3 crystal interfaces and liquid-solid junction potentials are negligible. However, after a period of initial stability, the potential began a slow decline. At the termination of the experiment it was found that the NiF_2 content of the reference cell had been converted to an equivalent amount of finely dispersed nickel metal. An impurity in the static atmosphere of purified argon or helium gas maintained in the quite limited volume of the apparatus could not be responsible for the consumption of NiF_2. Loss of NiF_2 due to beryllium metal transport in the vapor phase was ruled out since beryllium has no measurable vapor pressure at 600°C. Since this phenomenon did not occur in the U^{4+}/U^{3+} experiment, some small intrinsic electronic conduction in the LaF_3 crystal was also ruled out. However, the possibility of the equilibrium reaction

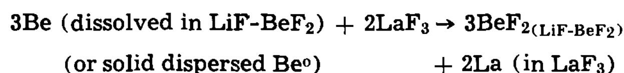
$$\mathrm{Be^o} + 2\mathrm{LiF_{(LiF\text{-}BeF_2)}} \rightleftarrows \mathrm{BeF_{2(LiF\text{-}BeF_2)}} + 2\mathrm{Li^o}$$

providing the source of reducing power via the gas phase must be considered. Pure Li at 600°C has a vapor pressure of approximately 10^{-4} atm. Since the activity of Li at equilibrium is approximately 10^{-10} from thermodynamic calculations (15, 18) and if the lithium is presumed to be soluble in the melt to that extent (19), it is safe to assume that its vapor pressure would be negligible. This assumption was proven valid by later experiments.

This almost negligible concentration of lithium would, however, provide the conditions under which certain ionic solids will start to conduct via electrons (20).

$$3Li_{(LiF\text{-}BeF_2)} + LaF_3 \rightarrow La_{(LaF_3)} + 3LiF_{(LiF\text{-}BeF_2)}$$

The lanthanum metal dissolving, or in other words, electrons substituting for fluoride ions, in the LaF_3 crystal would impart n-type conduction to the crystal (20). Alternatively, the same mechanism would occur if beryllium metal in some manner either by solution, perhaps as a subvalent ion Be^+ or Be_2^{2+} (21) or by the "chunking effect" (22, 23) reached the LaF_3 crystal.



$$3Be \text{ (dissolved in LiF-BeF}_2) + 2LaF_3 \rightarrow 3BeF_{2(LiF\text{-}BeF_2)}$$
$$\text{(or solid dispersed Be}^{o}) \qquad + 2La \text{ (in LaF}_3)$$

From the equation $t_e = \dfrac{n^o \times \mu \times e}{\sigma \text{ ion}} a_{La}^{1/3}$, derived by Wagner (20), one may readily calculate a value for the electronic transference number. Using the values $n^o = 10^{18}$, the number of electrons substituted for fluoride ions per cm^3 with the assumption that this value for Ca in CaF_2 at 600°C is a fair approximation of La in LaF_3, $\mu = 10^{-4}$ cm^2/V-sec, the mobility of the electron in the crystal (20), $e = 1.6 \times 10^{19}$ coulombs, the charge on the electron, $\sigma = 10^{-5}$ ohm^{-1} cm^{-1} (9), the ionic conductivity of LaF_3 at 600°C, and $a = 10^{-9}$, the activity of the La obtained from the free energies of formation of LaF_3 (18) and of BeF_2 in LiF-BeF_2 (67-33 m/o) (15), an electronic transference number, $t_e = 10^{-3}$ is obtained from the above equation. An electronic transference number of this magnitude is much too small to affect the initial measured voltage. However, the internal "short circuiting" resulting from this electronic conductivity (24), *i.e.* $NiF_2 + 2e^- \rightarrow Ni^o + 2F^-$, leads to the depletion of NiF_2 in the LaF_3 cup and ultimate failure of the electrode system as shown by the eventual decline in the voltage. This phenomenon does not occur with the U^{4+}/U^{3+} melt as the formation of lanthanum by this couple is virtually nonexistent, $a_{La} = 10^{-29}$, as would be expected since the free energy per equivalent is much less negative than the Be/BeF_2 couple (15).

To differentiate between the "chunking effect" and solution of beryllium or of formation of dissolved Li the following experiments were performed. The beryllium electrode was immersed in a LiF-BeF_2 (67-33 m/o) melt contained and separated from the main melt of LiF-BeF_2 (67-33 m/o) by a BeO crucible whose porosity allowed ion migration. Since solid beryllium metal is less dense than the melt (25), any solid metal detached from the electrode by "chunking" would rise to, and be trapped at, the melt surface within the crucible. Dissolved metal, on the other hand, would still reach the LaF_3 crystal. The observation was that under these conditions the NiF_2 in the LaF_3 cup was still transformed into Ni metal. In another experiment, NiF_2 was added to the main melt as a "getter" for dissolved metal. The beryllium electrode was again encapsulated within the BeO crucible containing the pure LiF-BeF_2 (67-33 m/o) melt. Any dissolved metal entering the main melt is immediately oxidized by the Ni^{++} ions. By this means the cell potential of 2.045 ± 0.003V was maintained for a period of three days. Termination of the experiment was caused by the loss of ion migration through the porous BeO crucible walls which had become plugged by the deposition of nickel. No metallic nickel was found in the cup, eliminating the vapor tranport mechansm.[1].

This value of 2.045 ± 0.003V when combined with the data of Baes (16) and Blood (17) gives an $E^o_{600°C}$ for NiF_2, our standard, of 2.692 ± 0.010V. This value is in excellent agreement with 2.700 ± 0.015V obtained from the following solid-state cells at 600°C

	emf (V) [2]
Ni,NiF_2/CaF_2/AlF_3,Al	−1.720 ± 0.003 (5, 6)
Ni,NiF_2/CaF_2/MgF_2,Mg	−2.343 ± 0.003 (5, 6)
Mg,MgF_2/CaF_2/ThF_4,Th	+0.310 ± 0.005 (4)
Th,ThF_4/CaF_2/AlF_3,Al	−0.310 ± 0.003 (4)

and the free energies of formation of MgF_2 ($\Delta G^o_{600°C}$ = −232.4 ± 0.6 kg-cal) and AlF_3 ($\Delta G^o_{600°C}$ = −306.5 ± 0.7 kg-cal) calculated from calorimetric data (27).

We have demonstrated the practicality of using single crystal LaF_3 with proper precautions as a bridging ionic conductor with certain high-temperature fluoride melts. Reference electrodes so constructed appear compatible with these molten fluorides for appreciable periods of time and afford a means of obtaining emf data of thermodynamic significance. Such a reference electrode is also useful for electroanalytical measurements, *i.e.* in a three-electrode configuration for voltammetry, chronopotentiometry, etc. The reference electrode couple, of course, is not restricted to nickel. We chose the Ni/Ni(II) couple in light of previous experience (2) which indicated its suitability as a reference electrode couple in molten fluorides.

[1] In cooperation with Dr. J. P. Young of this Laboratory attempts were made to detect spectrally the presence of dissolved Li or Be present possibly as Be^+ or Be_2^{2+}, in molten LiF-BeF_2 (67-33 m/o). The experiments were performed with the melt in a molybdenum windowless cell (26). Both chemical, *i.e.* reaction of beryllium metal with the melt, and electrochemical, *i.e.* anodic dissolution of the beryllium, failed to show any evidence of the above species. It appears from these experiments that the concentrations of these species are too low to be seen spectrally.

Electrochemical Properties of $RbAg_4I_5$ Solid Electrolyte

II. Study of Silver Electrode Reversibility

Bruno Scrosati*

Universita' di Roma, Rome, Italy

and A. Duane Butherus*

ABSTRACT

The reversible behavior of silver electrodes in $RbAg_4I_5$ solid electrolyte has been tested by micropolarization studies. It has been found that while planar silver electrodes are reversible, the mixed silver-electrolyte electrodes most commonly used in solid-state batteries are not. The different behavior of the two electrodes has been related to the different physical aspects of their surfaces. In the case of the mixed electrolyte-silver electrodes, there are preferential points of silver deposition and depletion corresponding to areas of low *IR* drop through the electrolyte. This explanation has been confirmed by the observed dendritic growth of silver along the preferential deposition points on the $Ag(RbAg_4I_5)$ electrodes. Finally, it has been shown that even though planar silver electrodes behave reversibly at low current levels, they may also form dendritic growths at the current levels required for practical batteries. It appears that a practical rechargeable cell which uses $RbAg_4I_5$ electrolyte will require planar silver electrodes of very high surface area and the cell assembly will require a container which allows cell thickness change during cycling.

In recent years a considerable amount of research work has been reported on solid electrolytes, due to the technological advantages promised by solid-state batteries, such as long shelf life, extreme miniaturization, and a wide operating temperature range.

In particular, three types of batteries utilizing $RbAg_4I_5$ as solid electrolyte have been described in detail (1-3). Since the ionic conductivity of this electrolyte is solely due to Ag^+ ions, the above-mentioned three cells have silver as the main anodic material but use different cathodes as shown in Table I.

In both the cells described by Argue, Owens, and Groce (1) and by Takahashi and Yamamoto (3), an attempt to lower the polarization effects between the anodes and electrolyte (which must be minimized if practicable battery drain rates are to be achieved) was made by mixing silver electrode material with the electrolyte itself, a procedure that enlarges the electrolyte/electrode interfacial area. The mixed electrolyte-silver electrode concept is analogous to the porous electrodes used in liquid electrolyte cells to increase the interfacial area and thus decrease the current density for a given discharge rate. A similar result has been obtained by DeRossi, Pistoia, and Scrosati (3) by amalgamation of the silver electrode according to the procedure recommended by Mrgudich (4). Amalgamated silver electrodes, however, are not usable as long-life anodes in solid-state batteries, since mercury slowly reacts with $RbAg_4I_5$ electrolyte, as was pointed out by Scrosati, Germano, and Pistoia (5).

The objective of these studies is an understanding of the $Ag/RbAg_4I_5$ electrode process on discharge and recharge. It is felt that such knowledge is needed before a practical secondary battery based on this elec-

Key words: solid electrolyte, silver electrode reversibilty.

Table I. $RbAg_4I_5$ solid electrolyte cells

Anode composition	Cathode composition	OCV(V)	Reference
Mixture of powdered carbon, silver and electrolyte	Mixture of carbon, RbI_3 and electrolyte	0.66	Argue, Owens, and Groce (1)
Amalgamated silver	Mixture of graphite, I_2, and tetrabutyl ammonium iodide	0.58	DeRossi, Pistoia, and Scrosati (2)
Mixture of powdered silver and electrolyte	Mixture of Te, Ag_2Te, graphite, and electrolyte	0.22	Takahashi and Yamamoto (3)

trolyte can be developed, since the rechargeability of test cells has appeared to be limited by silver dendrites which are deposited at the silver electrode on recharge and which rapidly short the cell (2, 6). An understanding of the electrochemical reversibility of the silver electrode and the factors which influence the reversible behavior of the electrode are basic for the development of a rechargeable cell.

Experimental

The electrolyte was prepared by melting a stoichiometric mixture of AgI and RbI under a dry nitrogen atmosphere. The melt was quenched, crushed, and annealed for at least 24 hr at 160°C. Powder diffraction x-ray analysis showed the product identical to that reported by Bradley and Greene (7). The cells studied in this work were prepared by pressing the electrode materials and electrolyte into a single pellet. Pressures of about 2000 kg/cm^2 were used. The cell diameter was 1.27 cm and the electrolyte thickness of the order of 1-2 mm.

Micropolarization measurements have been shown to be useful tests for determination of electrode reversibility (8) and this technique, which is particularly suitable for the study of solid electrolyte systems, has been applied to the study of both silver and silver-electrolyte mixture electrodes.

Micropolarization behavior was examined by two different methods.

(*i*) *Dynamic.*—Small ($\leq \pm 1$ mV) voltage excursions around zero cell potential were made by use of a Tacussel GSATP multifunction generator coupled to a Tacussel PRT 20-10x potentiostat, and the corresponding current-voltage curves were plotted on a Honeywell Model 560 XY recorder. Times required for a complete voltage scan were varied from 10 sec to 3 hr. The potential was also monitored at the cell by a Cimron Model 6753 DVM. The DVM readings were used for the reported data.

(*ii*) *Static.*—Point by point voltage excursions were effected by use of a Kepco precision voltage source, and the currents monitored by use of the Cimron DVM and a precision resistor. After each new voltage setting, the current fell to a constant value after a few minutes, and these I-V points defined the micropolarization curves.

It was found that the results of both methods were identical for a given cell.

Results and Discussion

The micropolarization behavior of the cell

$$Ag \mid RbAg_4I_5 \mid Ag \qquad [1]$$

is shown in Fig. 1A. There is no evidence of hysteresis, and the anodic and cathodic lines being coincident, thus show that the electrodes prepared by pressing silver powder on the electrolyte so as to form a planar interface may be considered reversible. This is not the case for the electrodes usually used as anodes in solid-state batteries, *i.e.* the silver-electrolyte mixture. This is shown by the micropolarization behavior of the cell

$$Ag(RbAg_4I_5) \mid RbAg_4I_5 \mid Ag(RbAg_4I_5) \qquad [2]$$

reported in Fig. 1B. Gross hysteresis effects are present, and the lines related to the anodic and cathodic current are not coincident. The hysteresis effects were independent of whether the micropolarization measurements were made via voltage sweep methods or

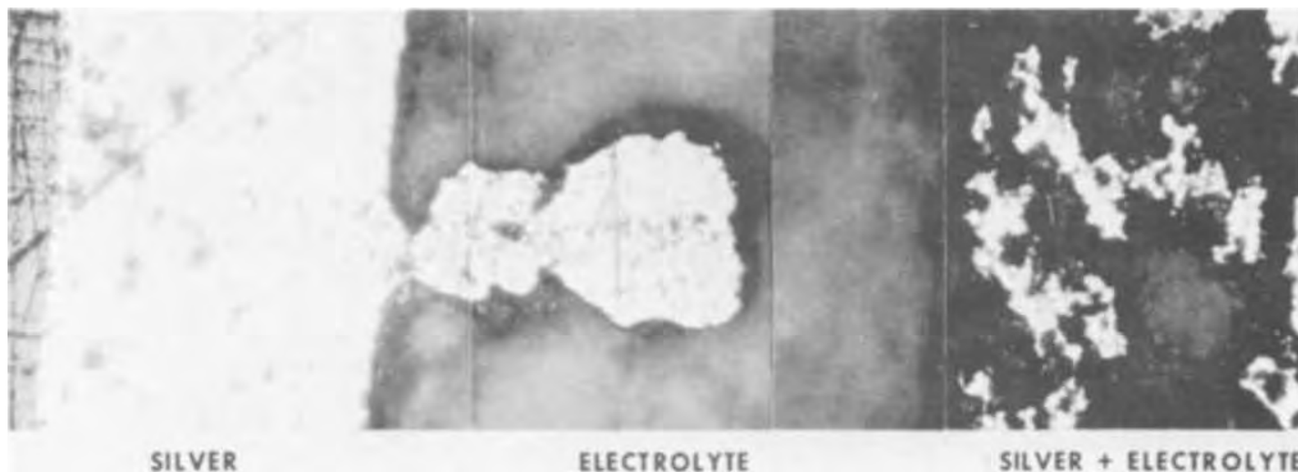

Fig. 4. Cross section of cell showing silver dendrite growth through the electrolyte (×100)

via point-by-point methods. Since polarization is proportional to current density, the micropolarization tests are compared on a current basis, even though for a given current the real current density for the high surface area mixed $Ag\text{-}RbAg_4I_5$ anode will be much lower than the corresponding planar cell. If the comparisons are made on a voltage basis, the hysteretic behavior of the mixed electrode is even more apparent, as shown in Fig. 2A. This increase in irreversibility with decreasing real current density (due to the increased surface area of the mixed electrode) is certainly an unexpected result.

The addition of graphite to the mixed $Ag\text{-}RbAg_4I_5$ anode has been done to prevent the electronic isolation of the silver particles in the electrode (9). Such an electrode shows the same type of hysteresis as the mixed electrode without the graphite, as shown in Fig. 2B. The explanation of the different behavior of the various electrodes may be related to the different physical aspects of their surfaces, as shown in the microphotographs reported in Fig. 3, which shows cross sections of the electrodes.

In the case of the mixed electrolyte-silver electrodes, the surfaces are strictly nonplanar, and thus there are

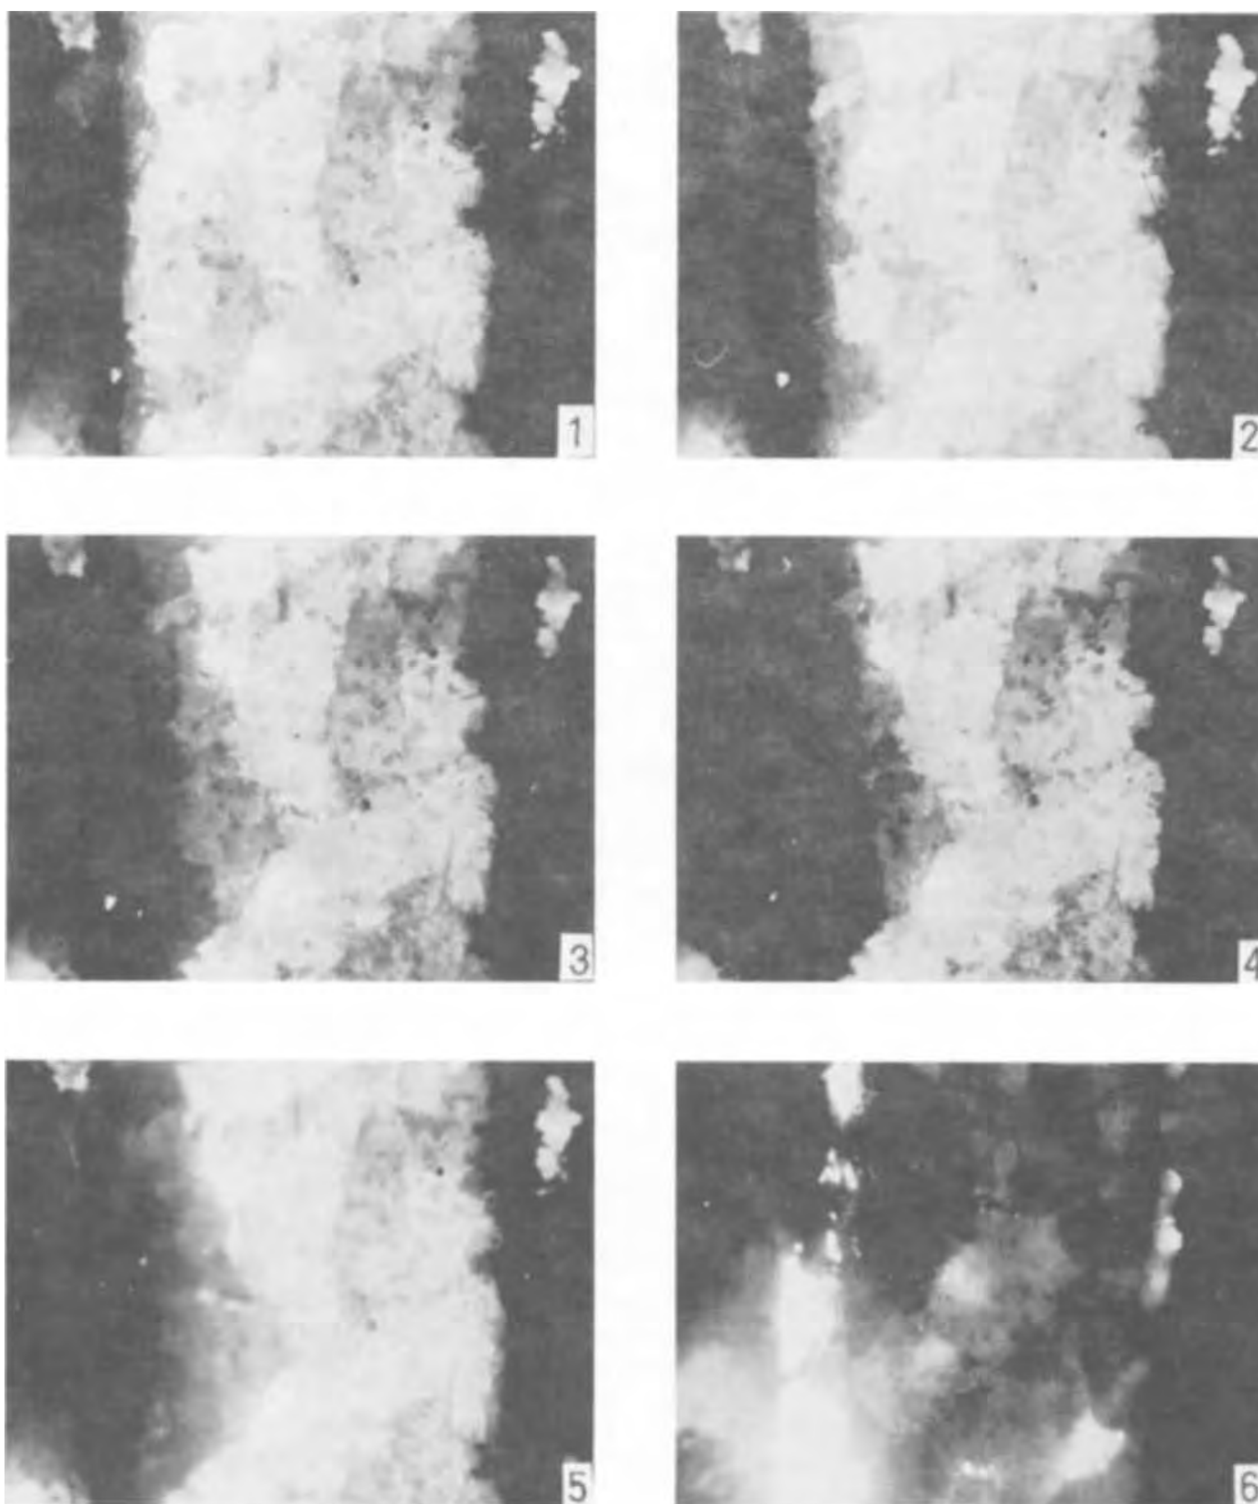

Fig. 5. Progressive dendrite growth and eventual electrolyte fracture. Pictures taken at 5 min intervals (×30).

preferential points of silver deposition and depletion corresponding to areas of low resistance through the electrolyte. At these points, the current density is very high, with consequent high polarization. On discharge (silver oxidation), a "leveling" process occurs; *i.e.* the silver at the projecting points is "dissolved" into the electrolyte, decreasing the height of the projection, with consequent increase of the resistance through the electrolyte at that point and thus a decreased current density.

On charge, however, there is no such "self-regulating" process, and the projections grow with preferential silver deposits. This lowers the resistance through the electrolyte at that point, increasing the current density there with consequent shorting. Since the electrode surfaces continually change on charge and discharge, the current density across the "rough" electrode is therefore not only nonuniform but changes in a random, nonuniform manner. Additionally, the silver and electrolyte phases are noncontiguous, and many electronically isolated masses of electrolyte and silver exist in the electrode. These areas contribute further to the nonuniformity of the electrode and lack of reversibility found.

In an attempt to increase the surface area of the electrode and yet retain the reversible properties of the planar electrode, a silver mesh was pressed on the electrolyte. This electrode showed better micropolar-

0	0.50
26	0.40
80	0.23
100	0.19

ization behavior than the mixed electrode, but some hysteresis was apparent. An analysis of the effect of the dimensions of the roughness on the electrode reversibility may shed some light on this phenomenon. The concepts of micro- and macro-current distribution developed by Cheh (10) for deposition of gold on rough surfaces may be applicable here, and such a study is presently underway. A cross section of this electrode is shown in Fig. 3D.

The reversibility of the planar electrode is apparently due to the following:

i. Lower, more evenly distributed current density. No "Hot Spots."

ii. Minimized sites of preferential silver deposition.

If the explanation above is correct, there are strong possibilities of obtaining a dendritic growth of silver along the preferential deposition points on the Ag($RbAg_4I_5$) electrodes. To test this possibility, a certain amount of charge (about 500 coulombs) has been passed through a Ag | $RbAg_4I_5$ | Ag($RbAg_4I_5$) encapsulated cell. A cross section of the cell, reported in Fig. 4, shows gross dendritic growth through the electrolyte.

To test this further, a 2 mm thick cross section was cut from a test cell similar to [2]. Current was passed between the two electrodes at a current density of $\approx$20 mA/cm^2, and microphotographs were taken at 5-min intervals using light transmitted through the electrolyte. Figure 5 shows the cross section of the cell, with the cathode on the left in each microphotograph. The deposition of Ag shows as the shaded triangular area growing from the cathode into the electrolyte. Under the stated conditions a layer of about 1.8 mm of Ag was deposited during the electrolysis, a sufficient amount to cause the electrolyte fracture exhibited. The current decreased precipitously, of course, when the electrolyte fractured.

Though the planar electrodes showed reversible behavior at low current levels, they may also form dendritic growths at current levels required for practical batteries. About 150 coulombs were passed through the cell

$$Ag \mid RbAg_4I_5 \mid Ag \quad [3]$$

at constant potential. The current remained steady for a time, then progressively fell off to lower values as shown in Table II. When removed from the cell holder, the anode was found disconnected from the cell, and gross silver deposits had separated the cathode from the electrolyte as shown in Fig. 6A. A cross section of the cell, Fig. 6B, shows that the anode surface had been eroded deeply, accounting for its detachment, and the cathode-electrolyte interface was opened up by the deposited silver. This behavior was also seen in a cell which used mixed silver-electrolyte electrodes.

The dendrite growth through the electrolyte always occurred when the cell was absolutely immobilized (*i.e.* encapsulated) and could not accommodate the thickness change due to the silver deposition on charge. In these latter two experiments, the cell was lightly loaded and accommodated the expansion.

Conclusion

The micropolarization results indicate that while mixing silver powder with electrolyte to increase the anode/electrolyte interfacial area may improve the discharge rate of a given cell, it certainly inhibits the reversibility of the silver anode in this system. The electrolysis study shows that there is probably an upper limit of the amount of charge which can be passed either to or from a silver electrode in contact with $RbAg_4I_5$ without seriously breaking the interfacial contact, and that a flexible rather than rigid packaging will prevent dendrite penetration of the electrolyte.

It thus appears that a practical rechargeable cell which uses $RbAg_4I_5$ electrolyte will require the following:

i. Planar Ag | $RbAg_4I_5$ interfaces of high surface area/electrode capacity. A thin-film multilayer sandwich construction appears suitable.

ii. Container which follows slight thickness change during cycling.

Cells which test these proposals are now under examination and the preliminary results appear to support these proposals. The fabrication, testing, and performance of these cells will be reported subsequently.

Manuscript submitted April 14, 1971; revised manuscript received Sept. 24, 1971.

Cathodic Discharge Controlled by Dissolution Kinetics

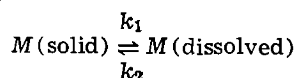
M. M. Nicholson* and M. L. Iverson

Atomics International, A Division of North American Rockwell Corporation, Canoga Park, California 91304

ABSTRACT

A theoretical analysis is presented for the constant-current discharge of a thin-layer cathode with control by dissolution and diffusion of the electroactive material. The treatment involves the solution of Fick's second law of diffusion for an electrolyte layer which is bounded on *one* side by a planar electrode of a metal to be electrodeposited and on the opposite side by a planar surface of a partially soluble compound of that metal. It is shown that the potential at the metal surface may reach a steady state within a few minutes after the current is applied in an initially saturated solution. There is a critical current density, however, at which a transition occurs and the potential approaches infinity. The dissolution rate constant and other parameters of the system may be determined by several procedures involving the use of transient data. This electrode configuration also provides a model of the inner structure of a porous battery cathode. Experimental results on cadmium fluoride in aqueous 4M KF indicated a dissolution rate constant of 8 x 10^{-9} mole/cm^2-sec.

For a material M, with a surface area A, dissolving by the process



$$M(\text{solid}) \underset{k_2}{\overset{k_1}{\rightleftharpoons}} M(\text{dissolved})$$

the rates of dissolution and crystallization may be expressed as

$$\text{Rate}_1 = k_1 A \quad [1]$$

and

$$\text{Rate}_2 = k_2 A C \quad [2]$$

where k_1 and k_2 are the respective rate constants on a unit area basis and C is the concentration of the dissolved material at the surface. At equilibrium, the dissolution and crystallization rates are equal. The exchange rate is then

$$k_1 = k_2 C^o \quad [3]$$

where C^o is the solubility of M in the liquid. At a surface concentration C, less than C^o, the net dissolution rate is

$$\frac{dN}{dt} = k_1 A - k_2 A C \quad [4]$$

or

$$\frac{dN}{dt} = k_2 A (C^o - C) \quad [5]$$

An equation in the form of [5] was given by Shchukarev in 1896 (1) and by Noyes and Whitney in 1897 (2), but k_2 was interpreted as a diffusion parameter. In 1904, Nernst introduced the diffusion boundary layer concept, taking into account the concentration gradient near a dissolving surface by the relationship (3)

$$\frac{dN}{dt} = AD(C - C_\infty)/\delta \quad [6]$$

In Eq. [6], which approximates Fick's first law, D is the diffusion coefficient of the dissolved species, C is its concentration at the surface, C_∞ is the concentration in the bulk of the solution, and δ is the effective thickness of the diffusion layer. For mixed kinetic and diffusion control, Eq. [5], as well as Fick's laws, must be satisfied. Most theoretical treatments of nonfaradaic dissolution rates since the time of Noyes and Nernst have emphasized mass transfer in the solution. Exceptions are the work of Jaenicke (4) and Vermilyea (5) on the potential-dependence of solution rates of salts.

Recent concern with battery electrode mechanisms has prompted further interest in this area. For example, the discharge of an insoluble cathode material will be very slow unless the process is assisted by electronic or ionic conductivity in the solid oxidizer phase (6). If the active material is sufficiently soluble in the electrolyte, however, it can be discharged by a solution mechanism involving dissolution of the solid, transport of the active species through the electrolyte, and subsequent electron transfer at the surface of an inert current collector. The dissolution rate of the oxidizer may then control the discharge process. A theoretical analysis of the solution mechanism is presented in the ensuing discussion, with the condition of constant current density. The results are applicable to battery electrode studies and to more general investigations of dissolution kinetics.

Key words: battery electrodes, critical current density, rate constant, thin-layer.

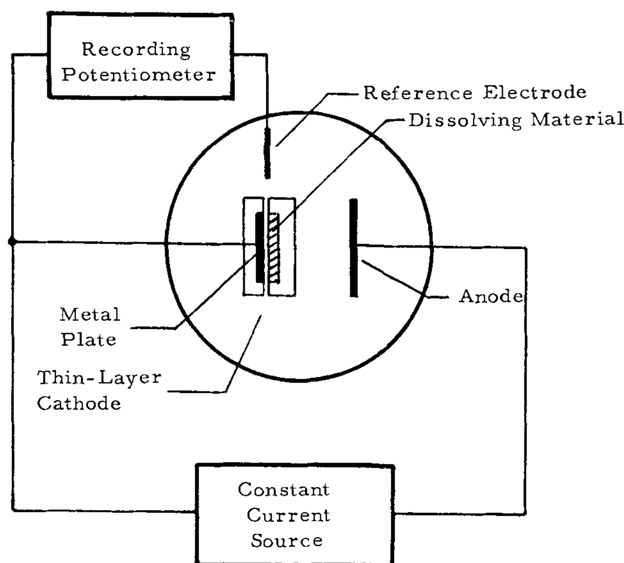

Fig. 1. Arrangement for galvanostatic measurements on thin-layer electrode.

Thin-Layer Electrode with Dissolving Reactant

The arrangement shown schematically in Fig. 1 includes a thin-layer cathode assembly with a smooth current-collector plate as one wall and a smooth nonporous plate of a reducible salt or oxide with significant solubility as the opposite wall. To simplify the analysis for metal ion reduction, the current collector is assumed to consist of the metal that is formed on cathodic discharge of the salt or oxide. The intervening space, of a small thickness l, is filled with an inert electrolyte of high concentration compared to that of the dissolved reactant. The influence of ohmic drop is therefore considered negligible. Discharge of the active material occurs when the metal plate is cathodically polarized. Connection through the electrolyte to the anode is established through the opening around the periphery of the parallel-plate structure. This arrangement is somewhat similar to the thin-layer electrode of Anson and co-workers (8), but the plate opposite the metal electrode now consists of the electroactive material, rather than an insulator.

It will be assumed in this discussion that Eq. [1] through [5] are valid. Generally, this will be true when the electrolyte and the dissolved reactant have a common anion; although k_2 may then depend on the electrolyte concentration, it will be essentially constant during an individual experiment. Variations of activity coefficients and diffusion coefficients with concentration are neglected in this analysis, as are changes in the layer thickness l due to dissolution and electrodeposition.

Analysis for Constant-Current Electrolysis

When a constant cathodic current density is applied to the metal plate, as shown in Fig. 1, the reactive cation will be depleted within the solution layer as the corresponding metal deposits on the electrode surface. Additional salt will dissolve to counteract this loss, and eventually, if the current is not too high, a steady state will be attained. Accordingly, the potential of the metal plate with respect to the reference electrode will change upon application of the current and finally reach a constant value which is a measure of the steady-state metal ion concentration at the plate surface. It will be shown that the rate constant k_1 may be determined from the steady-state potential or from the transient response of the electrode. Conversely, if k_1 and the solubility of the active material are known, the current-potential and potential-time curves may be estimated for a battery cathode with a given inner spacing and a solution-controlled discharge mechanism.

To develop these relationships, it is necessary to solve Fick's second law of diffusion

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \qquad [7]$$

for the appropriate initial and boundary conditions. In this problem, C represents the concentration of the active metal ion at any time t and distance x from the metal surface, and D is its diffusion coefficient in the supporting electrolyte. If the space between the electrode and the dissolving surface is saturated with the active material at the beginning of the experiment, the initial concentration is given by

$$C^o = k_1/k_2 \quad (t = 0) \quad (0 \leq x \leq l) \qquad [8]$$

Under a constant current density I, the concentration gradient at the electrode surface ($x = 0$) is given by

$$\left(\frac{\partial C}{\partial x}\right)_{x=0} = \frac{I}{n\mathbf{F}D} \qquad [9]$$

The flux of metal ion at the dissolving surface ($x = l$) is equal to the net dissolution rate

$$D\left(\frac{\partial C}{\partial x}\right)_{x=l} = k_1 - k_2 C_{x=l} \qquad [10]$$

The corresponding heat transfer problem was solved by Newman and Green in 1934, using the principle of the heat balance integral (7). From their results, the metal ion concentration at any distance and time may be computed for both steady-state and transient conditions. The required transformations are facilitated by the following definitions of dimensionless quantities:

Concentration:	$n\mathbf{F}D(C^o - C)/(Il)$
Distance:	x/l
Time:	Dt/l^2
Dissolution rate parameter:	$k_1 l/(DC^o)$
Current density:	$Il/(n\mathbf{F}DC^o)$

The data for concentration at the electrode surface are available as Table IV in Ref. (7), with the following changes of notation:

$$E = (C^o - C_{x=0}) n\mathbf{F}D/Il \qquad [11]$$

$$P = Dt/l^2 \qquad [12]$$

$$Nu = k_1 l/(DC^o) \qquad [13]$$

The steady state.—Although the transient solution requires a numerical presentation, conditions in the thin-layer electrode structure are quite simple at the steady state. It is apparent from Table IV of Ref. (7) that the dimensionless concentration variable at the metal electrode reaches a limiting value given by

$$\frac{n\mathbf{F}D(C^o - C_{x=0})}{Il} = \frac{1 + k_1 l/(DC^o)}{k_1 l/(DC^o)} \quad (t \to \infty) \qquad [14]$$

Furthermore, at the dissolving surface

$$\frac{n\mathbf{F}D(C^o - C_{x=l})}{Il} = \frac{1}{k_1 l/(DC^o)} \quad (t \to \infty) \qquad [15]$$

Since the concentration gradient at the steady state is uniform throughout the thickness of the electrolyte layer, Eq. [14] and [15] lead to the simple situation represented by Fig. 2.

Steady-state potential.—The concentration at the electrode surface is readily given in terms of the measured potential change ΔE if the metal/metal ion couple is assumed to be reversible

$$C_{x=0} = C^o \exp(n\mathbf{F}\Delta E/RT) \qquad [16]$$

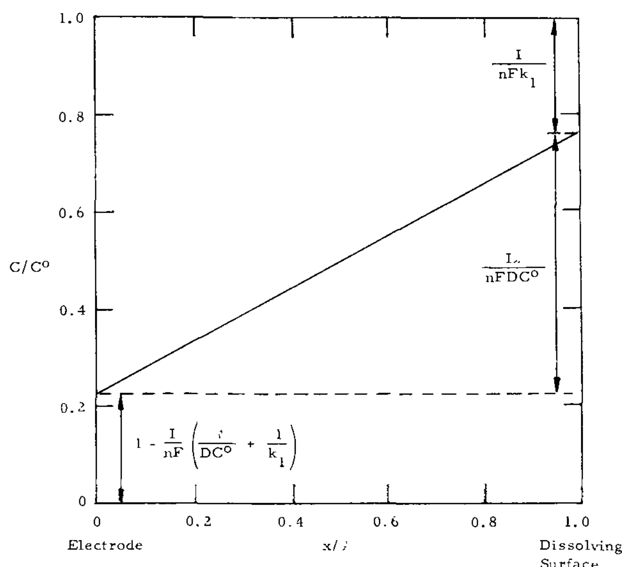

Fig. 2. Concentration profile at the steady state

The combination of Eq. [14] with Eq. [16] yields

$$1 - \exp\,(n\mathbf{F}\Delta E_\infty/RT) = \frac{I}{n\mathbf{F}}\left(\frac{l}{DC^o} + \frac{1}{k_1}\right) \quad [17]$$

from which the steady-state potential change ΔE_∞ may be calculated.

Critical current density.—It follows from Eq. [17] that $-\Delta E_\infty$ becomes infinite when

$$I = \frac{n\mathbf{F}}{\left(\frac{l}{DC^o} + \frac{1}{k_1}\right)} \equiv I_c \quad [18]$$

The metal deposition process cannot sustain, indefinitely, a current density as high as the critical value I_c, defined by Eq. [18]. When the applied current meets or exceeds this condition, a transition is expected in the potential-time curve. The time at which this occurs is predictable as discussed below.

The transient response.—Figure 3 shows a set of potential-time curves calculated at several fractions of the critical current density. These transients were obtained from Table IV of Ref. (7), with Eq. [16], taking $l = 0.01$ cm, $D = 1 \times 10^{-5}$ cm²/sec, $T = 298°$K, and $k_1l/(DC^o) = 1$. A rate parameter of unity corresponds to the condition

$$\frac{l}{DC^o} = \frac{1}{k_1} \quad [19]$$

in which the diffusion and dissolution terms contribute equally to the right side of Eq. [17]. The critical current density is then given by

$$\frac{I_c l}{n\mathbf{F}DC^o} = \frac{1}{2} \qquad \left(\frac{k_1 l}{DC^o} = 1\right) \quad [20]$$

and the critical transient is the upper curve in Fig. 3. It is apparent from this group of curves that the transition occurs quite sharply at I_c. At a current density only 0.2% lower, for example, the potential shift reaches a steady-state value of 0.160V and, theoretically, will not exceed this limit.

Critical transition time.—The transition time $D\tau_c/l^2$ at the critical current density was determined by graphical interpolation of the data in Table I of Ref. (7). That table gives a function $F(O,P)$, which takes the form

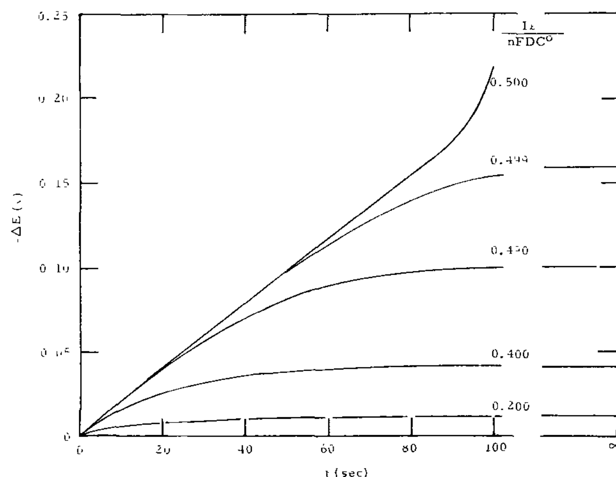

Fig. 3. Potential-time curves for dissolution-controlled electrode. $n = 1$; $k_1l/DC^o = 1$; $l = 0.01$ cm; $D = 1 \times 10^{-5}$ cm²/sec; $T = 298°$K.

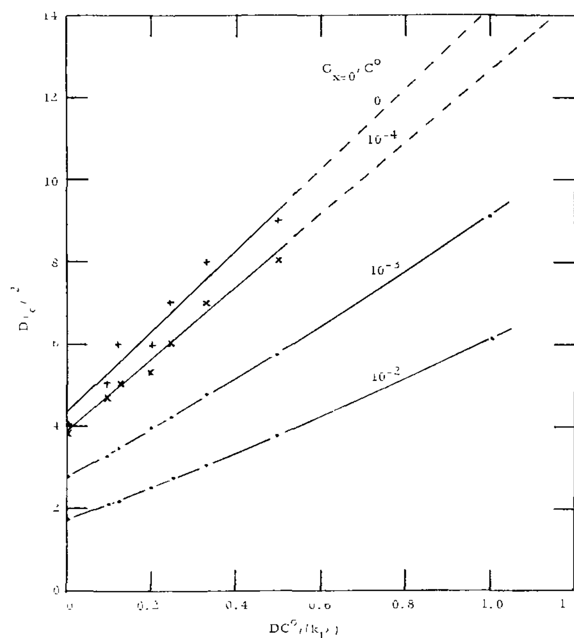

Fig. 4. Transition time function with different criteria for $C_{x=0}/C^o$.

$$F(O,P) = \left(1 + \frac{DC^o}{k_1 l}\right)\frac{C_{x=0}}{C^o} \qquad (I = I_c) \quad [21]$$
$$(P = Dt/l^2)$$

for the critical condition in the electrochemical problem. Ideally, τ_c would correspond to the value of P, or Dt/l^2, at which $C_{x=0}/C^o = 0$ and $-\Delta E = \infty$. Since an infinite potential will not be reached experimentally, Dt/l^2 was evaluated for $C_{x=0}/C^o$ ratios of 10^{-2}, 10^{-3}, 10^{-4}, and $0 (<5 \times 10^{-5})$. The respective values of $-n\Delta E$, in volts at 25°C, are 0.118, 0.177, 0.236, and ∞ (>0.254). These results are shown in Fig. 4, where $D\tau_c/l^2$ is plotted against the reciprocal of the rate parameter. The scattering of calculated points at the two lowest concentration ratios is due to loss of significant figures. It is clear from this analysis that the experimental transition time is better evaluated with reference to a selected $C_{x=0}/C^o$ ratio than by visual estimation on the shoulder of the potential-time curve. The condition $-n\Delta E = 0.118$V occurs before the transition (see Fig. 3), but the corresponding time is correlatable with k_1l/DC^o. The plots in Fig. 4 are almost linear. In

the limiting case, the dimensionless transition time is given by

$$\frac{D\tau_c}{l^2} = 9.8\left(\frac{DC^o}{k_1 l}\right) + 4.4 \qquad \left(\frac{k_1 l}{DC^o} \geq 2\right)^1 \qquad [22]$$

$$(C_{x=0}/C^o = 0)$$

over the indicated range of the rate parameter.

It is of interest to compare the critical transition time τ_c in the dissolving system with the chronopotentiometric transition time for a thin-layer electrode without dissolution (8) and for an unconfined planar electrode (9). The latter times are given by Eq. [23] and [24].

$$\tau = \frac{nFlC^o}{I} - \frac{l^2}{D} \qquad \text{Thin-layer electrode without dissolution } (l^2 < \tau D) \qquad [23]$$

$$\tau = \frac{\pi n^2 F^2 D C^o}{4I^2} \qquad \text{Unconfined electrode; semi-infinite linear diffusion} \qquad [24]$$

Table I gives transition times calculated for the three electrode configurations at equal current densities. As expected, the transition is postponed in the dissolving system by the presence of a nearby source of reactive material. A small rate constant leads to a long critical transition time but corresponds to a small critical current density, according to Eq. [18]. When $k_1 = 0$, the problem of the dissolution-controlled electrode reduces to that of the earlier thin-layer electrode (8), and $I_c = 0$, *i.e.*, a transition is no longer avoidable. In the opposite situation ($k_1 \to \infty$), the discharge is diffusion-controlled; $C_{x=l} = C^o$ at all times, and the dimensionless transition time reaches the limiting value

$$D\tau_c/l^2 = 4.4 \qquad (k_1 = \infty) \qquad [25]$$

$$(C_{x=0}/C^o = 0)$$

[1] This equation may be suitable for extrapolation to lower values of $k_1 l/DC^o$, but the direct numerical calculations have not been extended to that region.

[a] Reversible detector electrode.

Slope of the critical transient.—The critical transient for $k_1 l/(DC^o) = 1$ is seen in Fig. 3 to have a long linear section. The slope

$$\frac{-\partial(nF\Delta E/RT)}{\partial(Dt/l^2)}$$

was determined numerically from Table I of Ref. (7) for this and other values of the dissolution rate parameter. In each case, a region of constant slope was found for $Dt/l^2 > 0.5$, as shown in Fig. 5. Numerical values of the slope in the linear-transient region are given in Table II.

Evaluation of parameters.—The foregoing analysis provides several methods for the evaluation of k_1 if l, D, and C^o are known. Internal checks can thus be made on the interpretation of the data. The rate constant k_1 is available (i) from the steady-state potential, through Eq. [17], although this method is not very precise; (ii) from the critical current density, through Eq. [18]; (iii) from the critical transition time, according to Fig. 4 and Eq. [22]; and (iv) from the slope of the linear part of the critical transient, by means of Table II.

The kinetic and diffusion terms are conveniently resolved by the use of a variable-thickness cell. Equation [18] may be rearranged to the form

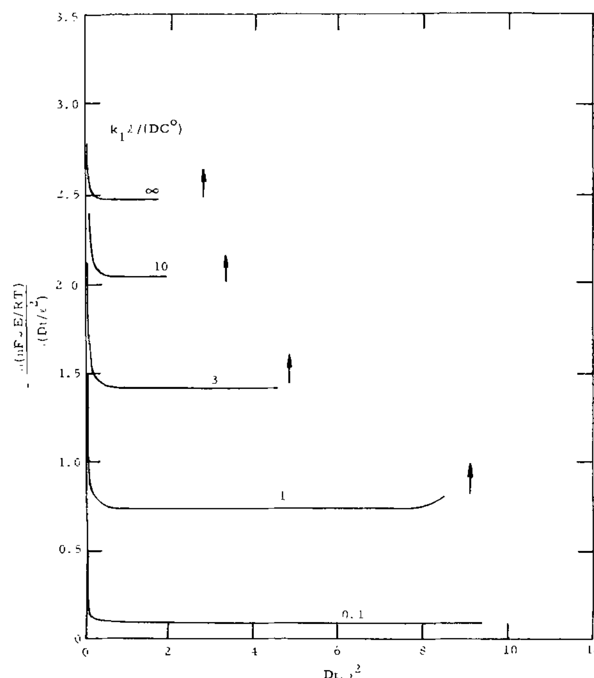

Fig. 5. Slope of the critical transient. Arrows indicate the times for $C_{x=0}/C^o = 10^{-3}$.

$$\frac{n\mathbf{F}}{I_c} = \frac{l}{DC^o} + \frac{1}{k_1} \quad [26]$$

which is linear in l. Then if I_c is determined for several thicknesses of the electrolyte layer, and its reciprocal plotted as a function of l, the constant k_1 is found from the intercept at $l = 0$, and the product DC^o is available from the slope. This is probably the most reliable procedure for determination of k_1. The highest rate constant that can be measured in this way will depend on the relative magnitudes of k_1 and DC^o/l. In a typical situation, $D \simeq 10^{-5}$ cm²/sec and $l \geqq 10^{-3}$ cm. Then if C^o is large, say 10^{-4} mole/cm³, the measurable k_1 might be as high as 5×10^{-6} mole/cm²-sec. When the dissolution is very slow, the critical current is independent of the electrode spacing, and k_1 is given simply by

$$k_1 = \frac{I_c}{n\mathbf{F}} \qquad \left(\frac{DC^o}{l} >> k_1 > 0\right) \quad (27)$$

The smallest measurable k_1 will tend to be limited by extraneous faradaic current.

It is also possible, under favorable conditions, to determine D and C^o separately from the dependence of τ_c on l. For this purpose, Eq. [22] may be written as

$$\frac{\tau_c}{l} = 9.8\left(\frac{C^o}{k_1}\right) + 4.4\left(\frac{l}{D}\right) \qquad \left(\frac{k_1 l}{DC^o} \geqq 2\right) \quad [28]$$

$$(C_{x=0}/C^o = 0)$$

and the value of k_1 taken from the plot of $1/I_c$ *vs.* l. Present experience indicates that the critical transition time is more difficult to determine experimentally with satisfactory precision than is the critical current. It is significant, nevertheless, that all three parameters —k_1, D, and C^o—are obtainable, in principle, from thin-layer cell measurements.

Implications for Battery Electrode Processes

The thin-layer electrode discussed herein may be considered a model for the inner structure of a battery cathode containing a partially soluble reactant which is nonconductive in the solid state. Similarly, it may represent a discharged secondary anode with a slowly dissolving nonconductive solid reaction product. A more general application of this model to include dissolving materials with solid-state ionic or electronic conductivity would require external control of the potential at the dissolving interface. The potential dependence of k_1, as discussed by Vermilyea, could then be taken into account (5). The thin-layer model is expected to find applications in organic-electrolyte batteries, where the solution-controlled cathode process may be a common occurrence (*e.g.*, CuF_2). Some implications of the theory for battery electrode performance are as follows:

(i) The current density within the microstructure of a porous electrode must be less than that given by Eq. [18] if the discharge is to continue without extreme polarization.

(ii) As long as the critical current density region is avoided, a dissolution-controlled electrode will operate with a relatively low overvoltage ($\lesssim 0.2$V), attributable to concentration polarization, unless the faradaic process is irreversible.

(iii) With complete control by dissolution kinetics ($k_1 << DC^o/l$), the critical current density is proportional to the dissolution rate constant and independent of the spacing between the dissolving solid material and the current collector. With complete control by mass transport, the critical current density is inversely proportional to the spacing.

(iv) The number of coulombs obtainable per unit area of the current collector surface, at the critical current density, is given by

$$Q_c = I_c \tau_c \quad [29]$$

With I_c from Eq. [18] and τ_c from Eq. [22], this charge is found to be

$$Q_c = n\mathbf{F}C^o l \left[\frac{9.8 + 4.4\left(\frac{k_1 l}{DC^o}\right)}{1 + \left(\frac{k_1 l}{DC^o}\right)}\right] \left(\frac{k_1 l}{DC^o} \geqq 2\right) \quad [30]$$

For very rapid dissolution, then

$$Q_c = 4.4\, n\mathbf{F}C^o l \qquad \left(\frac{k_1 l}{DC^o} >> 2\right) \quad [31]$$
$$= 4.4\, Q_l$$

where Q_l is the electrical equivalet of the active material initially present in the solution layer at saturation. This limitation on the high-rate discharge depth may be avoided by keeping the current density below its critical value.

Dissolution Rate of CdF_2 in 4M KF

A brief investigation of cadmium fluoride dissolving in aqueous 4M KF was made to verify the thin-layer method for dissolution kinetics measurements. The procedures and results are reported below.

Experimental.—The thin-layer cell assembly, illustrated in Fig. 6, was mounted on a Starrett Model 2MARL micrometer caliper, readable to $\sim \pm 0.0001$ cm. The cadmium fluoride was a slice of a single crystal prepared in an earlier study (10). This material contained 0.01 mole per cent (m/o) Y(III) but was not cadmium-treated. The parallel plate, counter, and reference electrodes were all of cadmium metal. The area of the cadmium plate on which deposition occurred was 0.280 cm². The potential-time curves at constant currents were recorded at room temperature on a Princeton Applied Research Model 170 Electrochemistry System. The solubility of cadmium fluoride in 4M KF was estimated by a colorimetric method involving the comparison of cadmium sulfide suspensions (11).

Results and discussion.—The critical current effect predicted theoretically was observed for cadmium

fluoride, as in Fig. 7. Generally, it was possible to determine I_c within $\sim \pm 10\%$, but an accurate τ_c proved somewhat more difficult to evaluate. The central curve in Fig. 7, for 7.9×10^{-4} A/cm², represented a close approach to the critical condition. The expected linear plot of $1/I_c$ *vs.* l was also obtained, as shown in Fig. 8. The dissolution rate constant k_1, determined by several

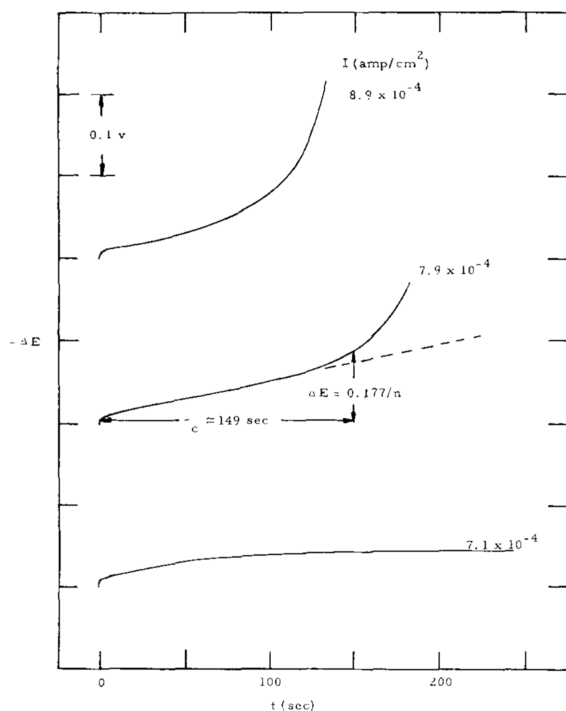

Fig. 7. Potential-time curves for CdF_2 dissolving in aqueous 4M KF. $l = 0.01$ cm.

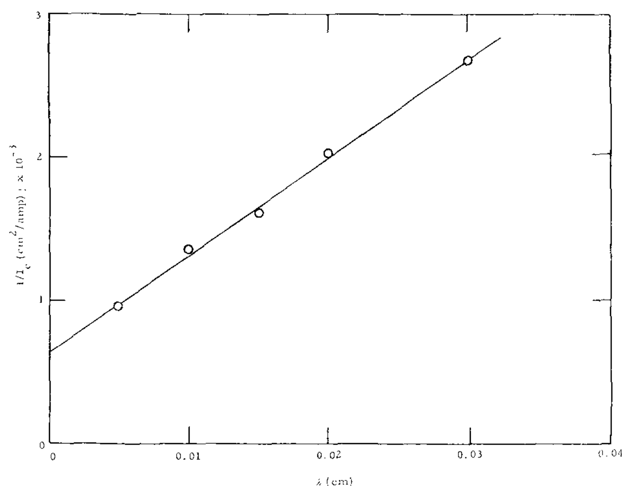

Fig. 8. Determination of k_1 for CdF_2 from critical current density in variable-thickness cell.

different procedures, is reported in Table III. The value of 8.1×10^{-9} mole/cm²-sec, from the intercept in Fig. 8, probably is the most accurate. A value of 7.6×10^{-11} mole/cm-sec was calculated for DC^o from the slope of the same line. With the experimental C^o of 8×10^{-7} mole/cm³, this result indicated a rather high diffusion coefficient of 9×10^{-5} cm²/sec for the cadmium-containing species in 4M KF. A solubility of 2.8×10^{-5} mole/cm³ is reported in the literature for CdF_2 in 4M KF at 20°C (12). However, this amount of CdF_2 did not dissolve, even on standing, in the present room-temperature experiments. The k_1 values for the *E vs. t* curves are therefore given on two bases in Table III: with $D = 9 \times 10^{-5}$, as calculated, and with $D = 1.0 \times 10^{-5}$, which is typical of metal ions in aqueous solutions. The smaller D yielded a more consistent result for k_1 from the linear slope.

These results show that the cadmium deposition process in the electrode system $Cd/CdF_2(s)/4M$ KF was one of mixed control by dissolution kinetics and diffusion. The rate constant of 8×10^{-9} mole/cm²-sec corresponds to an equilibrium exchange rate of approximately 6 atomic layers/sec on the cadmium fluoride surface. Vermilyea (5) has estimated the maximum rate r_e for such an exchange from the relationship

$$r_e = DC^o/d \qquad [32]$$

where d, the "jump distance," is of the order of 3×10^{-8} cm. With $DC^o = 7.6 \times 10^{-11}$ mole/cm-sec, as found from the thin-layer measurements, the maximum exchange rate would be 2.5×10^{-3} mole/cm²-sec, or $\sim 10^5$ times as great as the observed k_1.

The Anodic Oxide of Iron: Its Component Layers and Their Properties

F. C. Ho* and J. L. Ord**

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT

The anodic oxidation of an iron electrode in a neutral borate electrolyte is studied using a following ellipsometer. The oxide film is found to consist of two layers with different refractive indices: an outer layer of Fe_2O_3 and a thicker inner layer of Fe_3O_4. A thin layer of Fe_3O_4 is grown on the electrode in the active state, and the electrode passivates when a partial monolayer of Fe_2O_3 is grown at the Fe_3O_4-electrolyte interface. Passive state anodic oxidation causes simultaneous growth of the two layers, the inner layer growing approximately 80% faster than the outer layer. We conclude that the Fe_2O_3 layer inhibits anodic dissolution of the electrode, and that both the Fe_2O_3 layer and the portion of the Fe_3O_4 layer grown in the passive state act as the electrically limiting barrier across which the overpotential appears. The possibility that the two layers grow in a proportion dictated by the transport numbers of mobile defects (as has been proposed for the anodic oxide of tantalum) is discussed.

Iron has received considerable study as a passive electrode in acid electrolyte and as a battery electrode in basic electrolyte, but many recent studies (1-6) have been carried out in the neutral borate buffer made popular by Cohen and co-workers (7-10). This electrolyte offers many advantages for both electrochemical and ellipsometric measurements. At pH 8.4 iron has an active state which enables passivation to be studied, but the current density required to passivate the electrode (10^{-4} A/cm^2) enables the electrode to be passivated readily without appreciable damage to the optical surface. In the passive state, there is negligible dissolution of the oxide, and the subsidiary layer of dissolution products which complicates optical measurements in acid electrolyte (3) is not present. In addition, the oxide layer can be removed from the surface at a controlled rate by cathodic reduction in the borate buffer, and the optical constants of the surface return to their initial values after reduction is complete.

There have been a number of optical studies of the anodic oxidation of iron in borate buffer (1, 3, 6), and although these studies have generally agreed on the thickness of the anodic oxide, they have disagreed on whether the anodic oxide consists of a single layer or two layers with different composition. The studies which favored two-layer models (1, 3) were unable to present optical evidence of the existence of more than one layer on the surface. The aim of this paper is to present direct optical evidence showing that the anodic oxide consists of two component layers.

Experimental

The following ellipsometer built in our laboratory, described in detail elsewhere (11), uses a helium-neon gas laser as a light source, and all of our measurements are carried out at a wavelength of 6328Å. The ellipsometer is driven by stepping motors geared to give the instrument a resolution of 0.01° and an average nulling time of 0.7 sec under the experimental conditions used in this study. In a typical experiment we record over 1000 data points with a range of 2° in polarizer reading, P, and 0.2° in analyzer reading, A, and a standard deviation of 0.005° as determined by least squares analysis. To simplify handling and displaying the data, we generally divide the points into groups at 0.1° increments in P and calculate an average value of A for the 15 to 30 points in each group. These averaged points are then plotted in figures with the scale on the A-axis expanded fivefold over the scale on the P-axis. The averaged points generally exhibit a 0.003° standard deviation when fitted to straight lines using least squares. All of the measurements reported in this paper were made on a sample whose alignment was not disturbed throughout the series of experiments, and hence the data do not show the offset from experiment to experiment that generally characterizes ellipsometric data.

The cell used with the ellipsometer in this work is a hollow equilateral prism of 75 ml capacity into which a platinum counterelectrode, mercurous sulfate reference electrode with 0.1N K_2SO_4 salt bridge, gas dispersion tube, and sample holder can be inserted through standard-taper joints. The geometry of the cell requires that the ellipsometer be set for an angle of incidence of 60°. The cell has inlet and outlet connections enabling deaerated electrolyte to be added from a 2-liter reservoir, and electrolyte contaminated with ferrous ions to be flushed from the cell. The electrolyte used in all measurements is an equivolume mixture of 0.15N sodium borate and 0.15N boric acid of pH 8.4. All the experiments were carried out at room temperature (23°C).

The iron sample is a cylindrical single crystal 0.3 in. long by 0.2 in. in diam which is clamped between Teflon washers in the holder to expose a vertical surface of 1.2 cm^2 area to the electrolyte. The optical measurements are made on a flat on one side of the cylinder. Since variations in surface roughness can affect the optical data, the experiments were performed in a carefully chosen sequence. Several preliminary oxidation-reduction cycles were performed to smoothen the surface which had been chemically polished just prior to insertion in the cell. When the bare surface polarizer reading increased by no more than 0.01° after an oxidation-reduction cycle, the experiments were started, and no further change in surface roughness was detected until the final experiment in the series was performed. The linear potential sweep experiment was performed last because we expected the slow passivation to roughen the surface (which it did, introducing an offset of 0.06° in P).

The analog circuitry consists of three operational amplifiers which are used to supply the cell with constant currents, constant potentials, or linear potential sweeps, and two operational amplifiers which follow the potential and the current. The current source can provide an a-c current superimposed on the d-c en-

abling a lock-in amplifier to detect the potential component 90° out of phase with the a-c current in order to monitor the capacitance of the electrode. All potentials quoted in this paper are measured relative to the mercurous sulfate reference electrode.

Results

When designing experiments for the following ellipsometer, we try to keep the layer growth rates reasonably slow and approximately constant so that the ellipsometer can achieve its optimum performance. Galvanostatic experiments usually provide the best conditions, and most of the experiments described here were performed at a constant 10 $\mu A/cm^2$. This current density is not adequate to passivate the electrode, but a special passivation technique is required in any event in order to avoid the deposition of FeO·OH from ferrous ions in the electrolyte. Since our experiments are designed to look for a "fine structure" in the optical data, it is important to avoid deposition of even traces of FeO·OH.

The effects of trace FeO.OH deposition show up clearly in a linear potential sweep experiment. This type of experiment provides good experimental conditions for the ellipsometer when the potential is swept in the anodic direction, and is better than a galvanostatic experiment for following passivation. Cathodic potential sweeps provide poor conditions for following layer removal because of the narrowness of the potential regions over which reduction takes place.

The data plotted in Fig. 1 were obtained from an experiment in which an anodic sweep at 10.8 mV/sec was followed by galvanostatic reduction at 10 $\mu A/cm^2$. The sweep begins at point A with the electrode under cathodic reduction in an unstirred electrolyte free of ferrous ions. (The argon flow was shut off for this experiment to provide reproducible conditions for an experiment in which diffusion plays a significant role.) The current density and polarizer null reading are plotted *vs.* potential in the lower part of the figure for the anodic sweep, and the optical data are displayed in a polarizer-analyzer plot in the upper portion of the figure.

The nature of the passivation process shows up clearly from the data in Fig. 1. The change in polarizer null position plotted in the figure is proportional to film thickness for thin films, and estimates of film thickness during passivation can be made using the approximate calibration factor of 15 Å/deg (see Appendix). Little film buildup is indicated until the current density approaches its peak value of 120 $\mu A/cm^2$ at −0.990V, at which point about 4Å of film cover the surface. The layer thickens to 10Å as the current falls from its peak value to 35 $\mu Å/cm^2$ at −0.772V (point B in the figure).

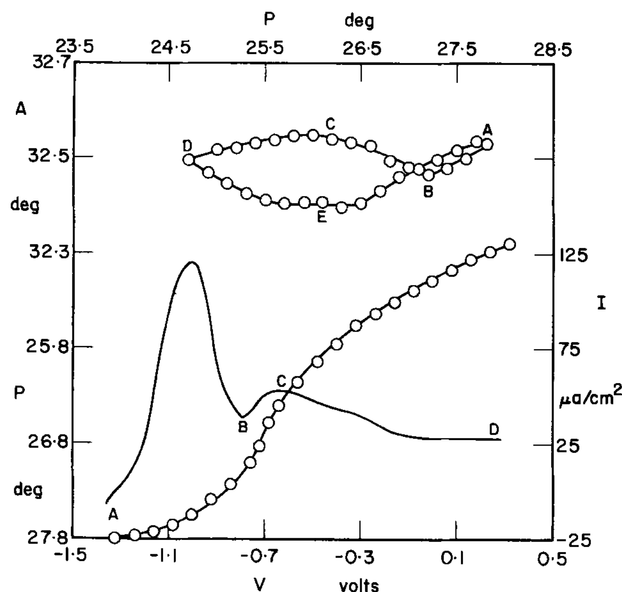

Fig. 1. Anodic potential sweep at 10.8 mV/sec followed by cathodic reduction at 10 $\mu A/cm^2$ for an iron electrode in borate buffer. The current density (solid curve, right scale) and polarizer readings (open circles, lower left scale) are plotted vs. potential in the lower portion of the figure for the anodic sweep ABCD. The optical data are plotted in the upper portion of the figure.

As the linear sweep continues beyond point B, there are three experimental results which detect the deposition of FeO·OH: the current density rises, the *P-A* plot inflects sharply upward, and the *P-t* slope increases. The deposition process has been studied in detail in this electrolyte by Markovac and Cohen (12, 13), and the optical properties of the deposited layer have been studied in our laboratory (14). The reason that even a small deposition partial current has a significant effect on optical measurements is twofold: the deposited FeO·OH has a real refractive index of 1.7 which differs significantly from the index of the anodic oxide, and deposition of one molecule of FeO·OH requires the transfer of only a single electron. Even though the concentration of ferrous ions in the electrolyte does not reach a significant level in this experiment, the critical factor determining the extent of deposition is the concentration of ferrous ions adjacent to the electrode as the potential crosses the value above which deposition takes place. The results presented in Fig. 1 are valid only for a verticial electrode in an unstirred electrolyte swept at 10.8 mV/sec, but any passivation process which takes the electrode through the active state directly to a potential above the deposition potential will show some of the effects of FeO·OH deposition. One very simple way to lessen the deposition effect is simply to pause at point B in Fig. 1 and increase the argon flow for a short time to allow the ferrous ions to diffuse into the bulk of the electrolyte. In the passivation technique we use, the electrode is passivated by connection to a potentiostat set at −0.825V, then, after the current density drops below 2 $\mu A/cm^2$, the cell is drained and refilled with electrolyte three times before the electrode is taken to higher potentials in the passive region. This technique minimizes the total number of ferrous ions produced, and, after three changes of electrolyte, no traces of FeO·OH deposition can be detected optically.

Data obtained from a galvanostatic experiment performed in electrolyte free of ferrous ions are presented in Fig. 2. The electrode was first passivated by the technique described above, then the electrode was held at −0.825V until the current density reached 1.0 $\mu A/cm^2$. At this point (point A in the figure) an anodic current of density 10 $\mu A/cm^2$ was applied, and the growth of the film was followed to a potential of 0.3V (point B). The current was then reversed, and the reduction of the film proceeded through two potential plateaus with distinct optical data segments, BC and CD. At point D the optical data return to their initial values prior to passivation.

The plots of potential and polarizer null reading *vs.* time in the lower part of the figure show that a film builds up at a constant rate under anodic conditions, and is removed at a faster rate under cathodic conditions. In the upper part of the figure the optical data are shown on a polarizer *vs.* analyzer plot. The structure in the data is accentuated in the figure by the fivefold expansion of the analyzer scale over the polarizer scale. The oxidation data trace out a straight line from A to B, and on reduction the data fall on two distinct lines, BC and CD, both with slopes different from the slope of AB. The structure in this figure could not be resolved in the earlier work carried out in this laboratory with a manual ellipsometer (3).

As is always the case when very thin films are studied, unique refractive index and thickness values can-

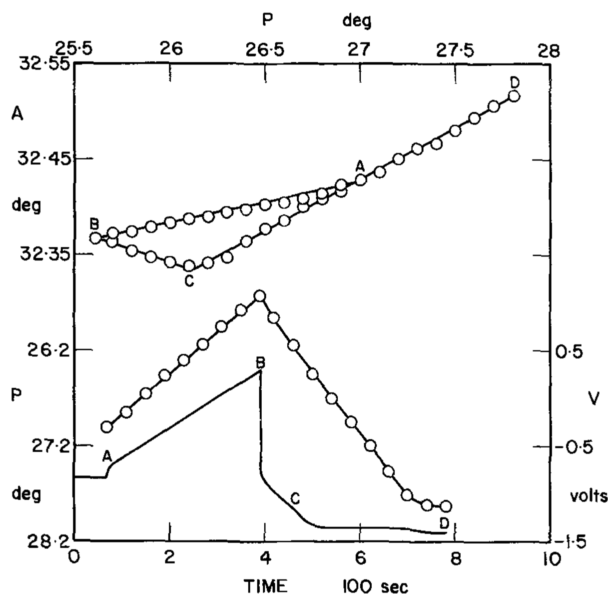

Fig. 2. Galvanostatic oxidation (AB) and reduction (BCD) at 10 $\mu A/cm^2$ of an iron electrode in borate buffer. The optical data are displayed on a *P-A* plot in the upper portion of the figure (top and upper left scales), and potential (solid curve, right scale) and *P* (open circles, lower left scale) are plotted vs. time in the lower portion of the figure.

not be determined from the optical data. Calculations of possible refractive index values are given in the appendix, as are values for the thickness calibration factor (the number of angstroms of film which shift the polarizer null reading one degree).

It is possible, however, to interpret the structure in the optical data without detailed analysis. When a very thin film of constant refractive index builds up uniformly on a substrate, the optical data obtained with an ellipsometer during the growth of the film trace out a straight line on a *P-A* plot. The line starts at the bare substrate point and has a slope which depends on the value of the film refractive index. Of the three linear segments, AB, BC, and CD of the optical data in Fig. 2, only CD is a straight line passing through the bare substrate point, and hence only in this region can the surface be covered with a simple film of constant index and changing thickness. Both the passive growth segment, AB, and the first reduction segment, BC are linear, but neither extrapolates to the bare surface point, point D.

The two-plateau potential transient observed on cathodic reduction was interpreted by Nagayama and Cohen (7) as resulting from sequential removal of layers of γ-Fe_2O_3 and Fe_3O_4 from the surface. This interpretation of the process has met with wide, but not unanimous (6) agreement among workers in the field. It is the simplest interpretation which can be given the data presented in Fig. 2, and it is the only interpretation of the reduction process which is directly consistent with all our experimental results. We therefore conclude that segment BC of the optical data is generated as a constant-index layer of Fe_2O_3 is reduced in thickness until at point C the underlying layer of Fe_3O_4 is exposed to the electrolyte. Segment CD is then generated as this inner constant-index layer is reduced in thickness until at point D the bare substrate is exposed to the electrolyte. The difference between the slopes of segments BC and CD is due to the difference between the refractive indices of Fe_2O_3 and Fe_3O_4. The sets of possible refractive indices for the two layers which fit the data in Fig. 2 are given in the appendix.

If the reduction process is identified as the sequential removal of layers of Fe_2O_3 and Fe_3O_4, the passive-state anodic oxidation process must result in the simultaneous growth of these two layers. (The active state oxidation data run parallel to CD indicating growth of Fe_3O_4 only.) The linearity of optical data segment AB shows that the two layers grow at rates whose ratio is a constant independent of potential. One can think of AB as a vector whose components along BC and CD are proportional to the thicknesses of the component layers grown during passive-state oxidation.

The constancy of the ratio of the layer growth rates and the linearity of the growth as a function of potential can be demonstrated by a series of experiments in which cathodic reduction is initiated at intermediate points along AB. In Fig. 3 the ABC data from Fig. 2 (for which the peak anodic potential was 0.3V) is replotted as A3-B3-C3, and data from experiments with peak potentials of 0.0 and −0.3V are plotted as A2-B2-C2 and A1-B1-C1, offset in the analyzer direction by 0.08° and 0.16° respectively. The offsets enable the data to be plotted without overlap, and construction lines are drawn through the triangle vertices to show the similarity of the triangles and the linear dependence of the lengths of their sides on the peak anodic potential. The lengths of the sides of the optical data triangles are directly proportional to the difference between the peak anodic potential and −0.97V.

The inflection at C in a *P-A* plot of the optical data can also be detected in plots of *P* or *A* *vs.* time. Since *A* has its minimum value at C, the detection of the inflection in an *A-t* plot is just as direct as it is in a *P-A* plot. The inflection in a *P-t* plot is less apparent, but even on the scale used for the *P-t* plot in Fig. 2 the inflection at C can be seen. The slope of the cathodic portion of the *P-t* plot is steeper than it is in the anodic portion.

If we were to choose specific values for the layer indices, we could, from the data presented to this point, calculate growth rates and thicknesses for the two component layers as a function of potential under anodic and cathodic conditions. In order to determine the electrochemical properties of the individual layers, however, we require additional data on the electrical behavior of the electrode. In galvanostatic experiments, the potential of the electrode is its most prominent electrical parameter. When a-c currents are super-

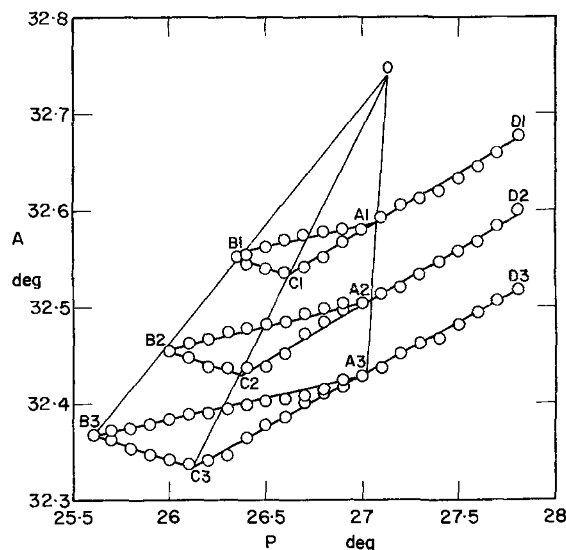

Fig. 3. *P-A* plot of the optical data obtained in galvanostatic experiments at 10 $\mu A/cm^2$ with peak potentials of −0.3V (1), 0.0V (2), and 0.3V (3). The data from the 0.0V and −0.3V experiments are offset 0.08° and 0.16° respectively in the A direction to enable the construction lines to show the proportionality between the lengths of the triangle sides and the difference between the peak potential and −0.97V.

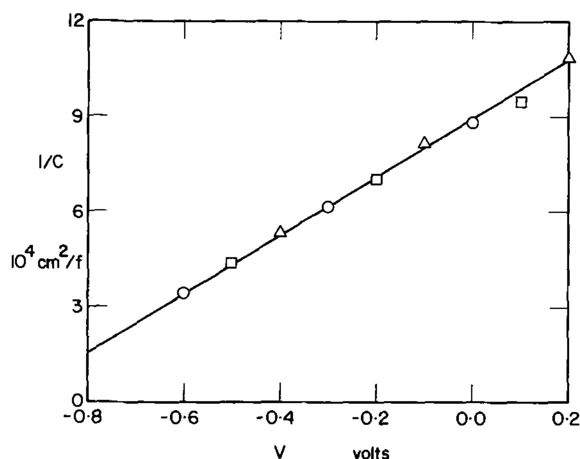

Fig. 4. Reciprocal capacitance as a function of potential during galvanostatic oxidation at 10 $\mu A/cm^2$ with superimposed a-c currents of frequency 50 Hz (circles), 100 Hz (squares), and 200 Hz (triangles).

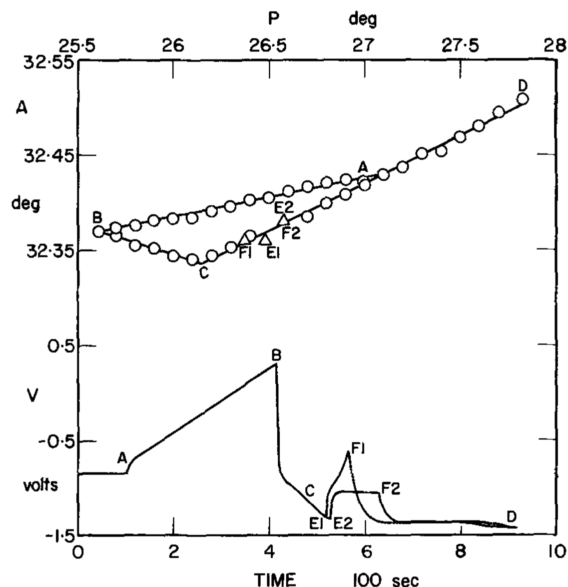

Fig. 5. Galvanostatic oxidation (AB), reduction (BCE), reoxidation (EF), and final cathodic reduction (FD) at 10 $\mu A/cm^2$ of an iron electrode in borate buffer. The results of two experiments in which the initial reduction is taken to slightly different points are superimposed in the figure. The optical data are displayed in a P-A plot in the upper portion of the figure, and potential is plotted vs. time in the lower portion. The time required to change the electrolyte at point E is not shown in the figure.

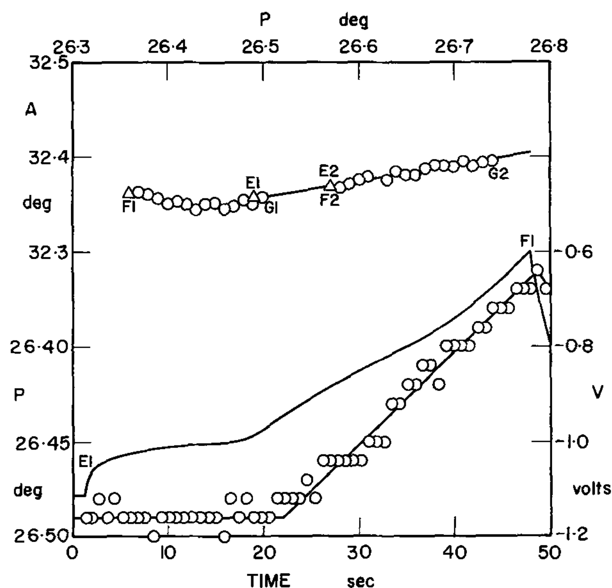

Fig. 6. Data from Fig. 5 plotted on expanded scales. Potential and polarizer reading are plotted vs. time in the lower portion of the figure for segment E1-F1, and the initial portions of the optical data obtained on reduction from F1 and F2 are plotted in the upper portion.

imposed in galvanostatic experiments, the a-c potential can be recorded along with the d-c potential. The capacitance of the electrode can be calculated from the component of the a-c potential 90° out of phase with the current, and conditions can be found for which this capacitance shows the reciprocal dependence on film thickness expected of the capacitance of an oxide film. In Fig. 4, values of reciprocal capacitance measured at frequencies of 50, 100, and 200 Hz are plotted *vs.* formation potential for galvanostatic oxidation at 10 $\mu A/cm^2$. (We use the term formation potential to designate the potential of the electrode under galvanostatic oxidation at a specified formation current density.) The three sets of data all fall on a line which intersects the potential axis at $-0.97V$, the potential at which the optical data triangle extrapolates to zero. This is also the potential which was identified as the zero of overpotential of the passive iron electrode in this electrolyte in an earlier paper (3), in which open-circuit transients were used to determine both the Tafel slope and the reciprocal capacitance of the electrode. Hence the thickness of the passive layer, the electrically limiting layer across which the overpotential appears, has the same dependence on formation potential as have the lengths of the sides of the optical data triangle. The passive layer may correspond to any of the sides of the triangle, and thus it may consist of the outer layer of Fe_2O_3, the inner Fe_3O_4 formed in the passive state, or both. The experiments described below are designed to enable us to decide among these three possibilities.

The key to the determination of the properties of the individual component layers is provided by the fact that they grow simultaneously but are removed sequentially. In principle, we can use cathodic reduction to "plane away" as much of the film as we wish from the side exposed to the electrolyte, then we can make the electrode anodic to determine the electrical properties of the portion of the film which remains. This experiment is complicated in practice by the necessity of sweeping ferrous ions produced on reduction from the electrolyte before the electrode is made anodic. We do this by opening the circuit and changing the electrolyte three times before reapplying the anodic current.

The first cycling experiments show the anodic behavior of the inner layer with the outer layer removed completely by cathodic reduction. The results of two such experiments are plotted in Fig. 5 with some of the finer detail plotted on an expanded scale in Fig. 6. The initial anodic cycles are the same as the one for the data plotted in Fig. 2. At point B the current is reversed and the electrode is reduced until all of the outer layer and about half of the inner layer formed in the passive state are removed from the electrode. The two experiments whose data are superimposed in the figure have the anodic current reapplied at slightly different points along the cathodic reduction transient. At point E1 in the first experiment and E2 in the second, the circuit is opened while the electrolyte is changed. The inner layer dissolves slowly during the minute or so required to change the electrolyte (not shown in the time plot in Fig. 5), and points E1 and

E2 are actually the optical readings recorded just prior to reapplying the anodic current. The anodic transients E1-F1 and E2-F2 differ considerably although their starting points are close together. E2-F2 is a typical active-state transient with the potential remaining in the active region and the optical data showing no change for a period of 100 sec at an anodic current density of 10 $\mu A/cm^2$. E1-F1, plotted on an expanded scale in the lower part of Fig. 6, is a typical passivation transient with the potential staying in the active region for 20 sec before inflecting into the passive region. The polarizer reading shows no change until the potential reaches the passive region, then changes linearly with time at a rate similar to its rate during oxidation from A to B. The electrode is active at both E1 and E2, but at E1 it can be passivated at an anodic current density of 10 $\mu A/cm^2$, whereas at E2 it cannot.

The final cathodic reductions from F1 and F2 to D are included in Fig. 5 and their initial portions are shown in an expanded *P-A* plot in the upper part of Fig. 6. Points E1 and F1 appear in the plot but the optical data obtained during oxidation from E1 to F1 are omitted in order not to obscure the structure in the reduction data. On reduction from F1 the data show the inflection characteristic of the presence of an outer layer, whereas on reduction from F2 the data all fall on the line characteristic of the inner layer.

The cycling data presented in Fig. 5 and Fig. 6 provide more information about the passivation process than they do about the potential profile in the passive state. They show that the inner layer is subject to anodic dissolution when exposed to the electrolyte, but they provide no information concerning the anodic behavior of the inner layer when covered by an outer layer which blocks the anodic dissolution reaction. In order to determine the electrical characteristics of the individual layers, we perform a cycling experiment in which we reapply the anodic current after reducing the outer layer until just sufficient of it to keep the electrode passive (less than one monolayer) remains covering the inner layer. The results of this experiment are plotted in Fig. 7.

The initial anodic cycle in Fig. 7 is the same as it is in Fig. 2 and Fig. 5. The reduction cycle is stopped at E by opening the circuit, and the electrolyte is changed before reapplying the anodic current. As in Fig. 5, the time required to change the electrolyte is not shown in the time plot in the lower part of the figure. The open-circuit potential just before reapplying the 10 $\mu A/cm^2$ anodic current is $-0.92V$, and hence the electrode is still passive. When the circuit is closed, the potential initially rises rapidly to point F, then takes on a slope more like the usual oxidation slope, until at point G the potential returns to 0.3V, its value at point B. The optical data show an inflection at point F, and when 0.3V is reached at point G the polarizer reading is significantly larger than it is at point B. The final cathodic reduction, GHD, enables the thicknesses of the component layers at G to be determined. The lengths of the optical data segments obtained on reduction indicate that point G the outer layer thickness is only 53% of its value at B, and that the inner layer grown in the passive state has increased its thickness by 12% at G over its thickness at B. The slope of the optical data segment GH is significantly greater than the slope of BE, hence the composition of the outer layer must be changed somewhat by the cycling process.

The reciprocal capacitance of the electrode was monitored during the cycling experiment, and the a-c potential recorded during segments AB and EFG of the experiment are plotted in Fig. 8. Along AB it is reasonable to take the a-c potential as a measure of the reciprocal capacitance of the oxide film (except in the region of point B where the curvature in the data is characteristic of the onset of oxygen evolution). On reoxidation, the a-c potential cannot be assumed proportional to the reciprocal capacitance of the film during the rapid rise in potential from E to F, but this assumption appears reasonable along FG. The data in Fig. 8 show that the reciprocal capacitance has lower values during reoxidation than it has at the same potential during oxidation.

Discussion

The difference between the indices of the component layers of the anodic oxide makes their direct experimental detection possible, and the proportionalities between layer thickness and formation potential follow directly from experimental results. The resulting conclusion that the passive-state overpotential must appear either across the outer layer, the inner layer formed in the passive state, or both, is not a definitive statement, but it is based directly on experimental results. In order to decide among these three possibilities we must use the cycling experiment data and draw conclusions concerning the electrochemical pro-

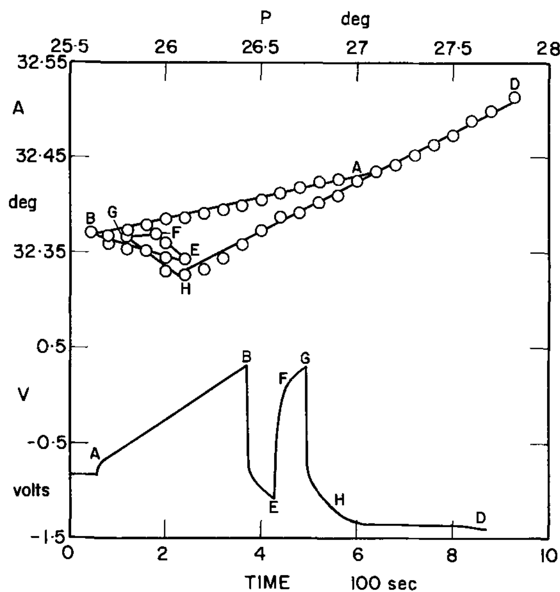

Fig. 7. Galvanostatic oxidation (AB), reduction (BE), reoxidation (EFG), and final reduction (GHD) at 10 $\mu A/cm^2$ of an iron electrode in borate buffer. The optical data are displayed on a *P-A* plot in the upper portion of the figure, and potential is plotted vs. time in the lower portion. The time required to change the electrolyte at point E is not shown in the figure.

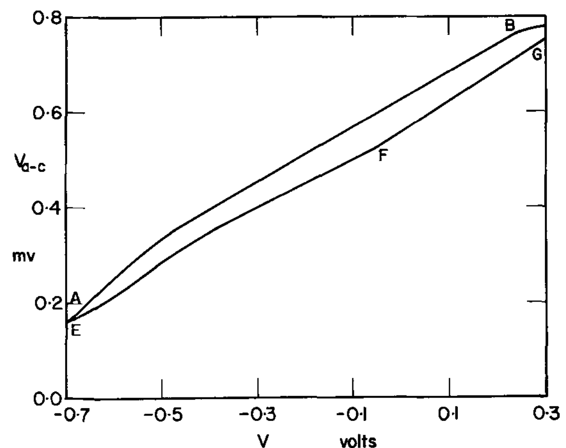

Fig. 8. The a-c potential 90° out of phase with a 10 $\mu A/cm^2$ a-c current superimposed on a d-c current of 10 $\mu A/cm^2$, plotted as a function of potential for segments AB and EFG of the cycling experiment plotted in Fig. 7.

perties of the individual layers. The way in which these conclusions are drawn requires some discussion.

The first cycling experiments show that the electrode is no longer passive once the outer layer is removed. This result can be interpreted in two ways: either the inner layer plays no role in passivity, or it can play a role only when it is protected from the electrolyte by the outer layer.

The final cycling experiment provides results which enable us to decide between these two possibilities. When the electrode is reoxidized with only a thin outer layer covering the lower layer, the potential rises rapidly to within 0.2V of its value at the end of the initial oxidation cycle, and when it does return to this peak potential, the outer layer has regained only 53% of its former thickness. If the overpotential appeared across the outer layer only, the reduction in its thickness would have resulted in a potential of −0.30V rather than the observed 0.30V at point G. Hence the overpotential cannot appear across the outer layer alone; it must appear either across both it and the passive portion of the inner layer, or across the latter only.

Two results from the final cycling experiment show that the overpotential must appear across both the outer layer and the inner passive layer. When 0.3V is reached for the second time, the passive portion of the inner layer has increased in thickness by 12%, and if the potential appeared across this layer alone the potential at point G would have been 0.45V rather than the observed 0.3V. In addition, the decrease in the reciprocal capacitance on cycling suggests that the two layers act as capacitors in series. A decrease in the thickness of the outer layer and an increase in the thickness of the inner layer can return the electrode to the same overpotential and lower reciprocal capacitance only if the overpotential appears across both the outer layer and the passive portion of the inner layer.

If we assume that a simple model of capacitors in series is valid, we can calculate the potentials across the component layers and their reciprocal capacitances at point B. The total potential and total capacitance can be expressed in terms of the individual layer capacitances and potentials at point B and G, yielding four equations. The proportionality between the thicknesses of the component layers at B and G is known from the optical data, and since all simple models have both reciprocal capacitance and potential proportional to thickness, the four equations can be written in terms of the four variables consisting of the component layer potentials and capacitances at point B. These equations can be solved to give $V_1 = 1.01$V and $1/C_1 = 6.78 \times 10^4$ cm²/fd for the passive inner layer, and $V_2 = 0.256$V and $1/C_2 = 3.40 \times 10^4$ cm²/fd for the outer layer.

With an additional assumption concerning the refractive indices of the layers, the fields in the component layers and their low frequency dielectric constants can be calculated. If we assume that the two layers differ little in index, and we take 2.0 for the real components of their indices, we calculate fields of 7.7 and 3.0 $\times 10^6$ V/cm (at 10 μA/cm²), and dielectric constants of 22 and 27 for the inner and outer layers respectively. We present these values as typical of the numbers resulting from this line of reasoning, not as results following directly from experimental data. The optical evidence for a difference in the composition of the outer layer after cycling shows that these calculations are no more than a guess at quantitative values for the electrical parameters of the individual layers.

Although it is difficult to determine the individual layer parameters accurately, it is clear that both layers play important roles in passivity. The outer Fe_2O_3 layer inhibits the anodic dissolution process and drops some of the overpotential, but the bulk of the overpotential appears across the Fe_3O_4 formed in the passive state, and hence it is the growth of this layer which is primarily responsible for the low currents characteristic of passivity. At the present time we can offer no explanation for the difference between the properties of the portions of the Fe_3O_4 layer formed in the active and passive states. We suspect that a slightly different layer is grown when Fe_3O_4 is exposed to the electrolyte, its growth competing with anodic dissolution, than when Fe_3O_4 is grown under a layer of Fe_2O_3 in the passive state. We could fit our optical data on reduction of Fe_3O_4 to two linear segments, but we doubt that this would be significant because the fit to a single line has a standard deviation of less than the resolution of the instrument.

Throughout this paper we have referred to the outer layer as Fe_2O_3, and we have taken pains to point out that its refractive index differs from that of the FeOOH layer which can be deposited if ferrous ions are not removed from the electrolyte. We have taken care to remove ferrous ions from the electrolyte so that deposition of FeOOH does not take place except in the linear sweep experiment, but careful study of the structure in our data leads us to conclude that FeOOH can also be produced by direct anodic oxidation when Fe_3O_4 is exposed to the electrolyte. The buildup or removal of FeOOH can be detected by the slope of the data in a *P-A* plot, and we can distinguish between the two methods of its formation from a *P-t* plot because the deposition process involves only 1/3 as much charge transfer as does direct oxidation, and begins at a higher potential. If we are correct in our conclusion that the hydrated ferric oxide (FeOOH or $Fe_2O_3 \cdot H_2O$) can be formed anodically when Fe_3O_4 is exposed to the electrolyte, whereas Fe_2O_3 is formed by anodic oxidation in the passive state, then passivation of the electrode must result from formation of a partial monolayer of FeOOH rather than Fe_2O_3 at the Fe_3O_4 surface. The rate of FeOOH formation indicates that the process is anodic oxidation in competition with anodic dissolution rather than dissolution-precipitation.

In most of our experiments the proportion of FeOOH in the outer layer is not significant. The most important exception occurs in the reoxidation segment of the final cycling experiment which was used to calculate the electrical parameters of the Fe_3O_4 and Fe_2O_3 layers. If we attempt to correct these calculations to take account of the presence of FeOOH, we obtain values of 8.8 and 2.2 $\times 10^6$ V/cm for the fields at 10 μA/cm², and 28 and 20 for the dielectric constants of the Fe_3O_4 and Fe_2O_3 layers respectively. The numbers should still be considered only rough estimates for the values of the parameters. The other experiment in which a significant proportion (if not all) of the outer layer is composed of FeOOH is the repassivation segment of the first cycling experiment. This is not readily apparent from inspection of Fig. 6 because an expanded polarizer scale is used in the figure.

The simultaneous growth of two layers requires that oxygen incorporated in the inner layer must be transported through the outer layer, and iron incorporated in the outer layer must be transported through the inner layer. With the possibility of iron being transported as ferrous and ferric vacancies or interstitials, and of oxygen perhaps being mobile in the form of vacancies, the problem is not so much one of proposing a model, but of finding sufficient experimental evidence to limit the number of models which can account for the data. The situation at the interface between the two layers is very complex, and no clear distinction can be drawn between growth and conversion processes. It is not surprising that our calculation of the layer parameters indicates that the electric displacement is not the same in the two layers, and hence the interface between them has a charge of density 1.6 $\times 10^{-5}$ coulomb/cm² on it.

In this paper we have presented only the results of galvanostatic oxidation experiments carried out at a current density of 10 μA/cm². Our aim in so doing has

been to present the results of measurements on this system under the simplest set of experimental conditions which show the important features of its behavior. We are currently involved in a more detailed study of this system under a wide variety of experimental conditions, and we will present our attempt at constructing a detailed model for the film growth process when the study is complete.

APPENDIX

The optical data-analysis program is written in Hewlett-Packard's version of BASIC, and consists of approximately 110 statements. The program makes use of the matrix routines and is written to handle multiple-layer calculations. The substrate index calculated for iron at a wavelength of 6328Å is 3.44-3.97i. Values of the layer index, n-ik, giving theoretical curves which fit the data, are obtained by plotting the locus traced out in the P-A plane as k is varied for a layer of fixed n and thickness. This curve generally intersects the experimental data line at two points, one at a low value of k and one at a high value. These intersections give the values of k for which n-ik is a possible value of the layer index, and enable thickness calibration factors, expressed as angstroms per degree change in P, to be calculated for each index value.

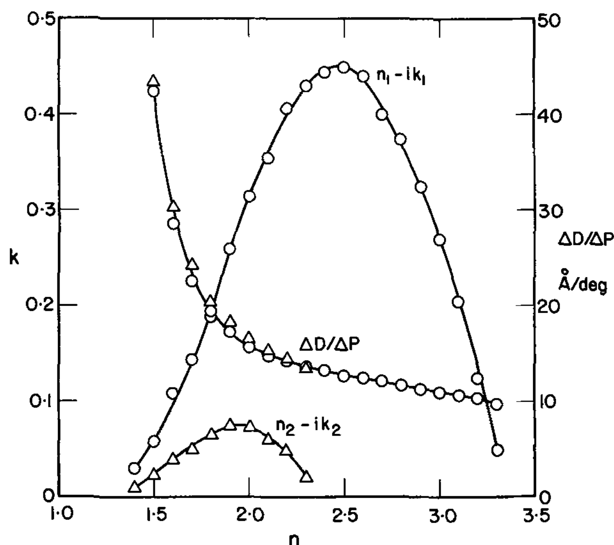

Fig. 9. The low k-value sets of possible refractive indices, plotted as curves in n-k space, for the inner ($n1$, $k1$) and outer ($n2$, $k2$) layers, and the corresponding thickness calibration factors, $\Delta D/\Delta P$, plotted as a function of n.

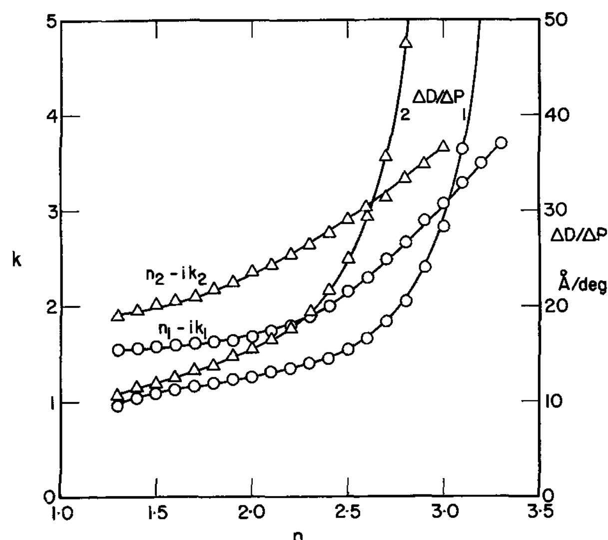

Fig. 10. The high k-value sets of possible refractive indices, plotted as curves in n-k space, for the inner ($n1$, $k1$) and outer ($n2$, $k2$) layers, and the corresponding thickness calibration factors $\Delta D/\Delta P$, plotted as a function of n.

We display the results of these calculations as curves in n-k space in Fig. 9 for low k values and in Fig. 10 for high k values. The values plotted for the outer layer index were calculated for an inner layer index of 2.5-0.45i, but the outer layer index calculation is not overly sensitive to the value chosen for the inner layer index. Each point on these curves gives a possible value of a layer index.

The thickness calibration factor corresponding to each index is plotted in the figures as a function of n. For low k values, the optical thickness calibration factor is not overly sensitive to k, and one curve is drawn for the two layers. If the low k indices plotted in Fig. 9 are taken as more reasonable on physical grounds, and if a value for n of 2 or a little greater is taken as reasonable for an oxide film, a "reasonable guess" at the thickness calibration factor of 15 Å/deg P is obtained.

Double Layer Capacitance of Iron and Corrosion Inhibition with Polymethylene Diamines

E. McCafferty[1] and Norman Hackerman*,[2]

Department of Chemistry, The University of Texas, Austin, Texas 78712

ABSTRACT

The effect of α,ω-polymethylenediamines NH_2-$(CH_2)_n$-NH_2 ($n = 2$-12) on the corrosion of iron in deaerated 6*N* HCl at 25° was investigated by polarization measurements and colorimetric analysis of solution. The adsorption of these inhibitors at the metal/solution interface was monitored by measurement of the double layer capacitance using the single pulse method. 1,3-propanediamine was found to be a better inhibitor than ethylenediamine, but no further improvement in per cent inhibition resulted upon increasing the chain length from $n = 3$ to $n = 8$. Increased inhibitor efficiency for hydrocarbon chains longer than eight carbon atoms was attributed to the concomitant decreased solubility. On a relative solubility basis, the C_6-diamine was more efficient than the C_{12}-diamine, although both inhibitors produced 90% inhibition at a reduced concentration of 0.1. The double layer capacitance was approximately constant at 21 $\mu F/cm^2$ for the C_2- through C_8-diamines, and alternated between 6 and 14 $\mu F/cm^2$ for the C_9- through C_{12}-diamines. The constancy at 21 $\mu F/cm^2$ suggets that diamines with up to 8 carbon atoms are adsorbed in the same configuration, probably the flat position. The subsequent reduction and alternation in capacitance is believed due to a structuring of the adsorbate similar to that in the bulk where certain physical properties oscillate with carbon number. Colorimetric analysis of solutions with and without NH_2-$(CH_2)_4$-NH_2 additions showed the dissolution rates to be higher than those measured by the polarization technique, possibly due to the "chunk" effect, in which dislodged grains of metal contribute to the total but not faradaic corrosion.

Organic amines function as corrosion inhibitors in aqueous solutions by adsorption at the metal/solution interface so as to reduce the metal reactivity (1-3). The adsorption theory of corrosion inhibition (4, 5) postulating that adsorption is general over the entire surface was first proposed by Hackerman and Makrides (6). The first evidence for chemisorption of organic inhibitors was obtained in this laboratory (2, 7, 8), although the adsorption measurements were made separately in parallel noncorrosive environments, such as cyclohexane solutions. More recently, measurement of the double layer capacitance has proved promising in monitoring adsorption directly in the electrolyte of interest (9).

It has been clearly established that the molecular structure of the inhibitor has a major influence on corrosion inhibition (10, 11). Previous work by Annand, Hurd, and Hackerman (12) has shown that short repetitive chains -NH-$(CH_2)_2$-NH- of polyethylene polyamines greatly improved inhibitor effectiveness on a per nitrogen basis compared to the monomeric species NH_2-$(CH_2)_2$-NH_2.

The present communication reports on the effect of increasing the hydrocarbon chain length between the end groups of α,ω-diamines of the homologous series NH_2-$(CH_2)_n$-NH_2, for $n = 2$-12.

These diamines were of interest due to the flexible hydrocarbon chains of the higher carbon numbers in the series. It was expected that the longer units would allow adsorption of both polar end groups connected by a buckled polymethylene chain so as to present hydrophobic "humps" to the corrodent solution. However, the shorter diamines proved to be the more efficient inhibitors on a relative concentration basis.

Corrosion rate measurements of iron in 6*N* HCl at 25°C were made by the polarization technique for several concentrations of each of the inhibitors. Adsorption of the inhibitors was studied by measurement of the double layer capacitance using the single pulse technique developed in this laboratory (13). In separate experiments, the open-circuit corrosion rates with NH_2-$(CH_2)_4$-NH_2 as inhibitor were also determined colorimetrically by the mercaptoacetic acid method.

Experimental

Corrosion inhibitors.—Reagent grade ethylenediamine was used without purification. 1,12-dodecanediamine was analyzed by acidimetric titration with standard hydrochloric acid to be 99.4% pure and was also used without further purification. 1,6-hexanediamine was recrystallized from benzene at 10°C, and was titrated to be 99.1% pure. All other diamines were purified by distillation in air or under reduced pressure.

Inhibitor solutions were made by dissolving a known weight of inhibitor in 6*N* HCl, which was obtained by diluting the reagent grade acid with double distilled water prepared in a Barnstead still. All the inhibitors were completely soluble in the concentrations used; no suspensions were employed. Diamines with more than 12 methylene groups were not studied due to solubility problems. 6*N* HCl was used as the corrosion medium to minimize pH changes upon addition of the inhibitor.

Electrodes for corrosion studies.—Polarization measurements and colorimetric analyses of solutions of freely corroding iron utilized Mallinkrodt analytical grade iron wire (99.5% Fe, 0.01% C, 0.03% Mn, 0.001% P, $<$0.001% Si, 0.01% S). The wire was inserted through a close-fitting hole in a Teflon holder. The holder, in turn, was machined to fit into a standard tapered glass joint at the end of the electrode assembly. Electrical contact was made by means of mercury inside the tubing.

The wires were cut to a length of 2.0 cm to give a projected surface area of 0.227 cm^2. Before use, an electrode was degreased with spectroscopic grade pentane and then electropolished at 85 mA/cm^2 for 2 min in a 4/1 mixture of $HClO_4$:CH_3COOH, a modification of the etch developed by Sewell, Stockbridge, and

Cohen (14). The electrode was then washed with double-distilled water and inserted into the polarization cell.

Polarization measurements.—Polarization measurements were made at 25°C using small glass cells (40 or 75 ml working volumes) in which anode and cathode compartments were separated by a fritted glass disk. Platinum foil of approximately 1 cm^2 area was used as the auxiliary electrode. Solutions were deaerated for at least 8 hr with helium gas which passed through charcoal at liquid nitrogen temperature and then through a solution identical to that being studied to minimize vapor loss of solution in the polarization cell. The potential of the test electrode was measured *vs.* a saturated calomel electrode using a Keithley electrometer. A Luggin capillary was not necessary due to the high conductance of the solutions used. Steady open-circuit corrosion potentials were established in 1-8 hr, the longer times being required for the more concentrated inhibitor solutions. Polarization measurements were then made galvanostatically using a 90V battery with a series of variable resistors ($R_{external} >> R_{cell}$). A second Keithley electrometer was used to measure the current. The cathodic branch was always determined first; the open-circuit potential was then re-established and the anodic curve determined. Potential values at a given current were generally steady within 1-5 min.

Colorimetric analysis.—Iron dissolution rates were also measured in separate experiments by colorimetric analysis of solution containing a freely corroding iron electrode. One milliliter samples were withrawn periodically and analyzed for iron by the mercaptoacetic acid method (15). Absorbances were read at 526 mμ with a Beckman DU Spectrophotometer and were compared to a standard Lambert-Beer curve. The calibration factor for 1 ml of solution was either 3.29 μmoles Fe^{++}/adsorbance unit or 6.50 μmole/absorbance unit, depending on the final dilution. The experimental conditions for these colorimetric runs were identical to the electrochemical polarization measurements in terms of electrode area, electrode preparation, solution volume (60-80 ml), and time of solution degassing.

Differential capacitance.—Electrical double layer capacitances were measured by the single current pulse technique using the pulse generator developed in this laboratory (13). The pulse duration was 10 μsec with a ½ μsec rise time. Pulse amplitude and repetition rate were variable, but generally 800 μA and 3 pulses/sec, respectively, were used. The double layer charging curves were displayed on a Tetronix 531A oscilloscope with Type D plug-in unit and were photographed.

The double layer capacitance cell was similar to that used in previous work (16). It is essentially a 200 ml Pyrex glass cell which houses the working electrode and an auxiliary platinum electrode of *ca.* 400 cm^2 area. A side limb separated by fritted glass acted as an inlet port for the reference electrode. The solutions were deaerated with helium as in the polarization measurements. No greases or lubricants were used to minimize solution contamination.

More reproducible capacitance data were obtained if a 99.99% iron rod was used in place of the 99.5% iron wire. The rod was enclosed in polyethylene to expose only the bottom face of 0.0108 cm^2 geometrical area. The electrode holder was fashioned so that the exposed portion of the electrode was vertical in the solution. Hydrogen bubbles tended to collect on horizontal electrodes initially used and lead to spurious data. Most capacitance data were taken in 6*N* HCl solutions, but a limited number of experiments were also made for 3*N* HCl.

Solubility determinations.—Because of the decreased inhibitor solubility with longer carbon chains, it was desired to compare the inhibitor efficiencies of the C_6- and C_{12}-diamines at the same relative concentrations, C/C_{sat}, where C_{sat} is the saturation concentration. Saturated solutions of these two compounds were prepared by stirring excess diamine in 6*N* HCl for two months. The mixtures were filtered (or centrifuged) and the filtrate analyzed for diamine concentration.

The saturation concentration of the C_{12}-diamine was determined colorimetrically by the 2,4-dinitrofluorobenzene (DFB) method developed by Dubin (17). The main feature of this method is that colored side products of the DFB reagent are removed by dioxane prior to colorimetry. A standard Lambert-Beer plot was prepared from known solutions of NH_2-$(CH_2)_{12}$-NH_2 in 6*N* HCl. The method of Dubin was followed quite closely, except that all volumes were doubled, *i.e.,* 0.1 ml of diamine solution was used. Absorbances were read at 350 mμ using a Cary 14 recording spectrophotometer. The saturated solution was treated in the same manner after dilution to a known appropriate volume so that the absorbance reading was within the region of the standard Lambert-Beer plot.

The saturated solution of NH_2-$(CH_2)_6$-NH_2 in 6*N* HCl was analyzed for amine concentration by back titration with standard hydrochloric acid. The amine concentration was given by the total number of equivalents titrated plus the equivalents required to neutralize the original 6*N* HCl.

Results

Polarization measurements.—Figure 1 shows polarization curves for iron in 6*N* HCl with and without additions of NH_2-$(CH_2)_3$-NH_2. These curves are representative of plots obtained for all inhibitors used in this study. The anodic Tafel region for both uninhibited and inhibited systems generally spanned less than a decade in current, but intersected with the cathodic Tafel line at the open-circuit corrosion potential. Anodic Tafel slopes were 70 ± 10 mV/decade, in nominal agreement with the value of 60 mV/decade reported by Lorenz (18). Cathodic Tafel slopes were 130 ± 20 mV/decade, in agreement with the usual value of 120 mV/decade (19).

Open-circuit corrosion rates determined from the polarization curves are shown in Fig. 2 as a function of inhibitor concentration for NH_2-$(CH_2)_3$-NH_2. The general decline in corrosion current density from the uninhibited rate of 1982 μA/cm^2 to a limiting value of 150-200 μA/cm^2 was observed for all inhibitors studied.

The various inhibitors in the series NH_2-$(CH_2)_n$-NH_2 are compared in Fig. 3. The inhibitor effectiveness is

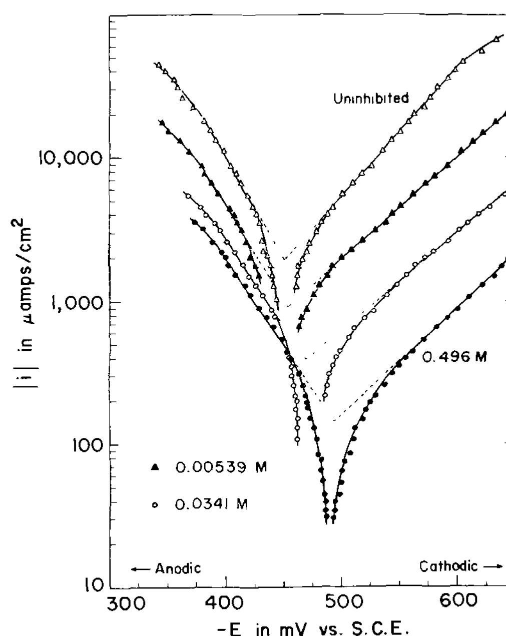

Fig. 1. Polarization curves for iron in deaerated 6*N* HCl at 25°C with NH_2-$(CH_2)_3$-NH_2 as inhibitor. (Molar concentrations of inhibitor are indicated).

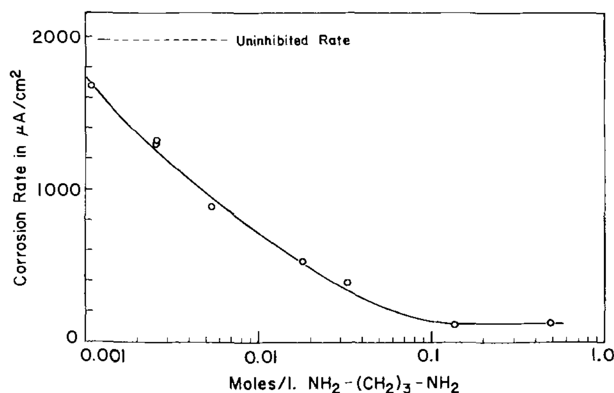

Fig. 2. Corrosion current densities for iron in deaerated 6*N* HCl with NH_2-$(CH_2)_3$-NH_2 inhibitor.

represented as the per cent inhibition, defined in the usual manner

$$\%I = \frac{i_o - i}{i_o} \times 100 \quad [1]$$

where i_o and i are the uninhibited and inhibited corrosion current densities, respectively. According to Fig. 3, NH_2-$(CH_2)_3$-NH_2 is a better inhibitor than ethylenediamine, in the sense that a lower concentration of amine is required to yield a given per cent inhibition. Increases in chain length up to C_8 have no further effect on the inhibitor efficiency. However, for longer carbon chains, the curves again shift to the left. Thus, the concentration of diamine needed to produce a given per cent inhibition follows the order: $C_{12} < C_{11} < (C_8 \text{ to } C_3) < C_2$.

From a practical standpoint, the C_{12}-diamine is the best inhibitor in terms of material requirement, but it also has the lowest solubility and dissolves with difficulty. In fact, the increase in per cent inhibition upon increasing the chain length from 6 to 12 carbon atoms is largely a solubility effect, as will be seen below. On a relative concentration basis, the C_6-diamine is more efficient than the C_{12}-diamine.

Figure 4 shows the calibration curve developed to determine the solubility of NH_2-$(CH_2)_{12}$-NH_2 in 6*N* HCl by the 2,4-dinitrofluorobenzene (DFB) method. This Lambert-Beer plot was made by treating 0.1 ml samples of known concentration of NH_2-$(CH_2)_{12}$-NH_2 in 6*N* HCl. A 5 ml aliquot of the saturated solution, prepared as described earlier, was diluted to a known volume; and a 0.1 ml portion was analyzed by the DFB method. For two different dilution schemes, the results were: $C_{sat} = 9.3 \times 10^{-3}$ M/liter, and 8.6×10^{-3} M/liter, respectively. Analysis of the saturated solution of NH_2-$(CH_2)_6$-NH_2 in 6*N* HCl by acid titration gave the result: $C_{sat} = 6.79$ M/liter.

Figure 5 shows per cent inhibition for the C_6- and C_{12}-diamines as a function of reduced concentration C/C_{sat}. The C_6-diamine is seen to be the more efficient inhibitor.

Double layer capacitance.—Figure 6 shows double layer capacitance curves for iron rod (99.99% purity) in 6*N* HCl with NH_2-$(CH_2)_{11}$-NH_2 as inhibitor. The effect of increased amine concentration is to decrease the double layer capacitance, due to adsorption of the surface active organic molecule (20, 21). In Fig. 6, as well as in all capacitance curves observed in this study, the double layer capacitance was a smooth function of electrode potential. No capacitance humps (9) were observed.

Figure 7 shows the double layer capacitance at open circuit potential as a function of NH_2-$(CH_2)_{11}$-NH_2 concentration. The values tend toward a limiting capacitance of 7 $\mu F/cm^2$. Results for the C_{11}-diamine in 3*N* HCl are also shown in Fig. 7. The set of capacitance-potential curves for 3*N* HCl are very similar to the 6*N* curves, except that the initial uninhibited capacitance is somewhat lower for 3*N* HCl. However, the limiting capacitance is about the same.

Double layer capacitance curves for iron in 6*N* HCl with NH_2-$(CH_2)_{12}$-NH_2 are shown in Fig. 8. The limiting capacitance at open circuit potential is 15 $\mu F/cm^2$.

As seen in Fig. 7, the double layer capacitance of the C_{12}-system attains its minimum at 5×10^{-4} moles NH_2-$(CH_2)_{12}$-NH_2/liter: C_{dl} is then constant with further increases in inhibitor concentration. This value of 5×10^{-4} mole /liter is also that minimum concentration at which the system attains its maximum inhibition. Figure 3 shows the per cent inhibition to be essentially constant at 90% for $C \geqq 5 \times 10^{-4}$ moles/liter. Similarly, comparison of Fig. 3 and 7 shows the C_{11}-system first exhibits minimum C_{dl} and 90% I at $C \cong 0.02$ moles/liter. Limiting double layer capacitances were thus measured for the various diamines at concentrations which yielded the maximum per cent inhibition (*i.e.*, 90%). In the cases of the C_9- and C_{10}-diamines, saturated solutions were used prepared by stirring excess diamine in 6*N* HCl for several days and then filtering. Several C-E curves are shown in Fig. 9 for various carbon numbers. Data for the limiting capacitances are summarized in Table I, and the trend is shown in Fig. 10.

The limiting values of the double layer capacitance are essentially constant at *ca.* 21 $\mu F/cm^2$ for $n = 2$-8. The sharp drop at $n = 9$ is believed due to a change in inhibitor configuration at the metal/solution interface. The subsequent alternation in capacitance is thought to be another manifestation of the "even-odd effect" (22). These aspects will be discussed later.

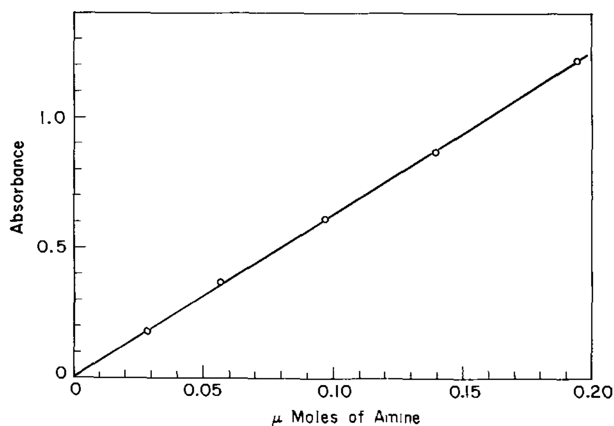

Fig. 4. Calibration curve for the determination of NH_2-$(CH_2)_{12}$-NH_2 by the 2,4-dinitrofluorobenzene method at 350 mμ.

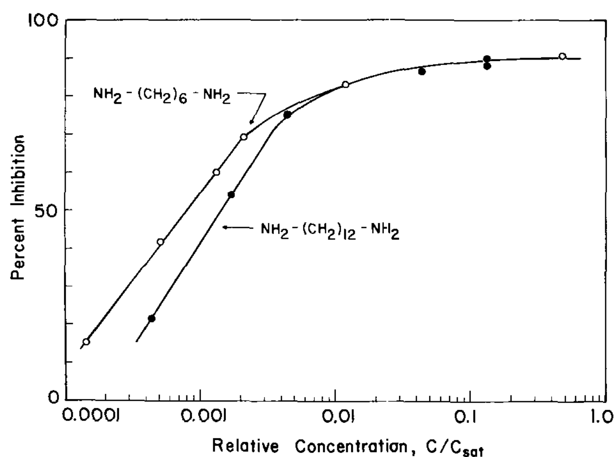

Fig. 5. Comparison of NH_2-$(CH_2)_6$-NH_2 and NH_2-$(CH_2)_{12}$-NH_2 inhibitors on a relative concentration basis.

Colorimetric analysis.—Figure 11 shows corrosion-time curves for iron wire (99.5% purity) at open-circuit potential in 6*N* HCl with NH_2-$(CH_2)_4$-NH_2 as inhibitor. The concentration of Fe^{++} ions in solution was determined by the mercaptoacetic acid method. Equivalent corrosion current densities (based on $Fe \rightarrow Fe^{++} + 2e$) are compared with corrosion current densities determined from the polarization curves in Fig. 12. The two sets of rates do not agree, presumably due to the "chunk" effect (23), as will be discussed later.

Table I. Limiting double layer capacitances of iron in NH_2-$(CH_2)_n$-NH_2 inhibited solutions of 6*N* HCl

Carbon number	Conc. (M/liter)	C in μF/cm²

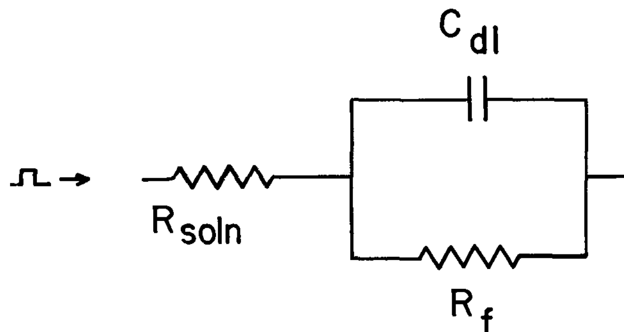
12	0.00137	14.2

* Data not taken for the C_5- diamine.

Discussion

Double layer capacitance.—As is well known, the single pulse technique can separate double layer capacitance from coexistent faradaic effects by charging the double layer quickly relative to the duration of the chemical reaction. Using the Grahame model of the interface



the potential across the analog interface due to a cur-

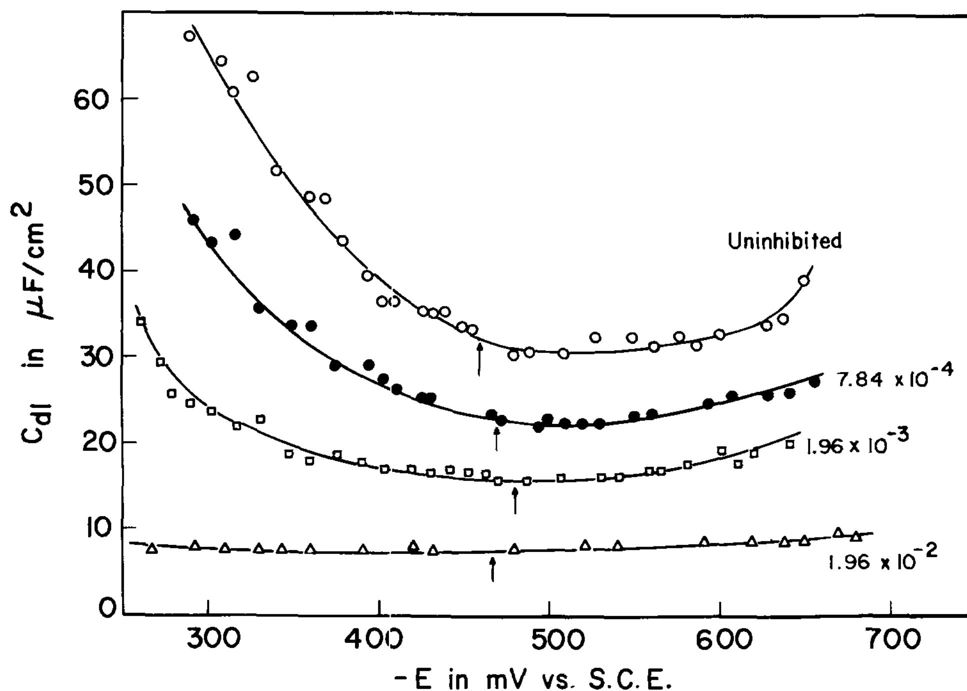


Fig. 6. Double layer capacitance for iron (99.99% purity) in 6*N* HCl with NH_2-$(CH_2)_{11}$-NH_2 inhibitor. (Inhibitor concentrations in mole/liter are given on the figure. Arrows indicate open-circuit potentials.)

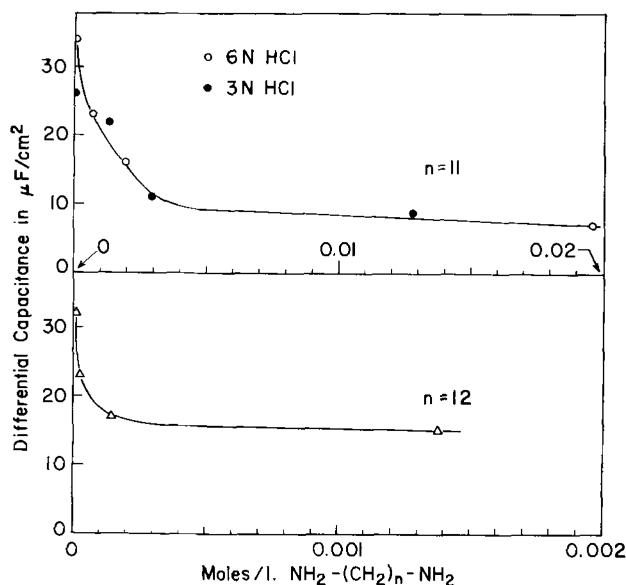

Fig. 7. Effect of inhibitor concentration on the open-circuit double layer capacitance of iron in 6N HCl at 25°.

rent pulse i is (24)

$$V = iR_f \left\{ 1 - \exp\left[-\frac{t}{C_{dl}} \left(\frac{1}{R_{std} + R_{soln}} + \frac{1}{R_f} \right) \right] \right\} \quad [2]$$

where C_{dl} is the double layer capacitance, R_f and R_{soln} the faradaic impedance and solution resistance, respectively, and R_{std} a standard resistance in the circuit used to fix the current pulse. For $(R_{std} + R_{soln}) >> R_f$ (R_{std} = 100 K in this study) and for small t Eq. [2] reduces to

$$C_{dl} = i \frac{dt}{dV} \quad [3]$$

where dt/dV is the reciprocal slope of the charging curve. A typical trace is shown in Fig. 13.

As Lorenz and Fischer (25) have pointed out, minima in C-E curves for certain systems cannot properly be identified with the zero-point of charge of the metal due to specific adsorption of ions from solution. Thus, the minima in Fig. 6, 8, and 9 correspond to the potentials of the noncharged halide ion-covered surfaces (9). In most cases reported herein, the null point of the halide-covered surface is nearly identical with the open-circuit corrosion potential. In the cathodic direction, the double layer capacitance rises due to H^+ adsorption. In the anodic direction, the increase is due to adsorption of halide ions or possibly hydroxyl ions formed during the dissolution process (18, 19).

As seen in Fig. 6, 8, and 9, the addition of inhibitor leads to a general decrease in double layer capacitance over the entire C-E curve. This general decrease shows that the inhibitors are adsorbed on both anodic and cathodic sites, as was first proposed by Hackerman and Makrides in their adsorption theory of corrosion inhibition (6).

As mentioned earlier, double layer capacitances were measured using 99.99% iron instead of the 99.5% wire used in the polarization studies. The purer iron tended to give more reproducible capacitance data, presumably because of the diminished faradaic reaction. The hydrogen evolution reaction proved to be troublesome. Collection of bubbles on the iron electrode was initially a problem and resulted in spurious data until a vertical electrode was adopted.

Configuration of diamines.—The constant double layer capacitance at maximum coverage for $n = 2$ to $n = 8$ (Fig. 10) suggests that those diamines all adsorb at the Fe/HCl interface in the same configuration. The organic molecules are believed to lie flat with both end groups adsorbed. Reasons for this interpretation follow.

At the air/water interface, the surface tensions of short chain difunctional acids, alcohols, and amines are lower than the corresponding monofunctional compounds (26, 27) due to interaction of both polar end groups with the surface. At the metal/solution interface, the flat difunctional molecules exhibit the higher double layer capacitances due to a decreased distance between the "capacitor plates" (26, 27). In 1N Na_2SO_4 with 1N addition of ethylenediamine, double layer capacitances of 11.2 $\mu F/cm^2$ have been reported for mercury (26) and *ca.* 15 $\mu F/cm^2$ for lead (28). These values are of the same order reported herein, allowing for the differences in base solutions.

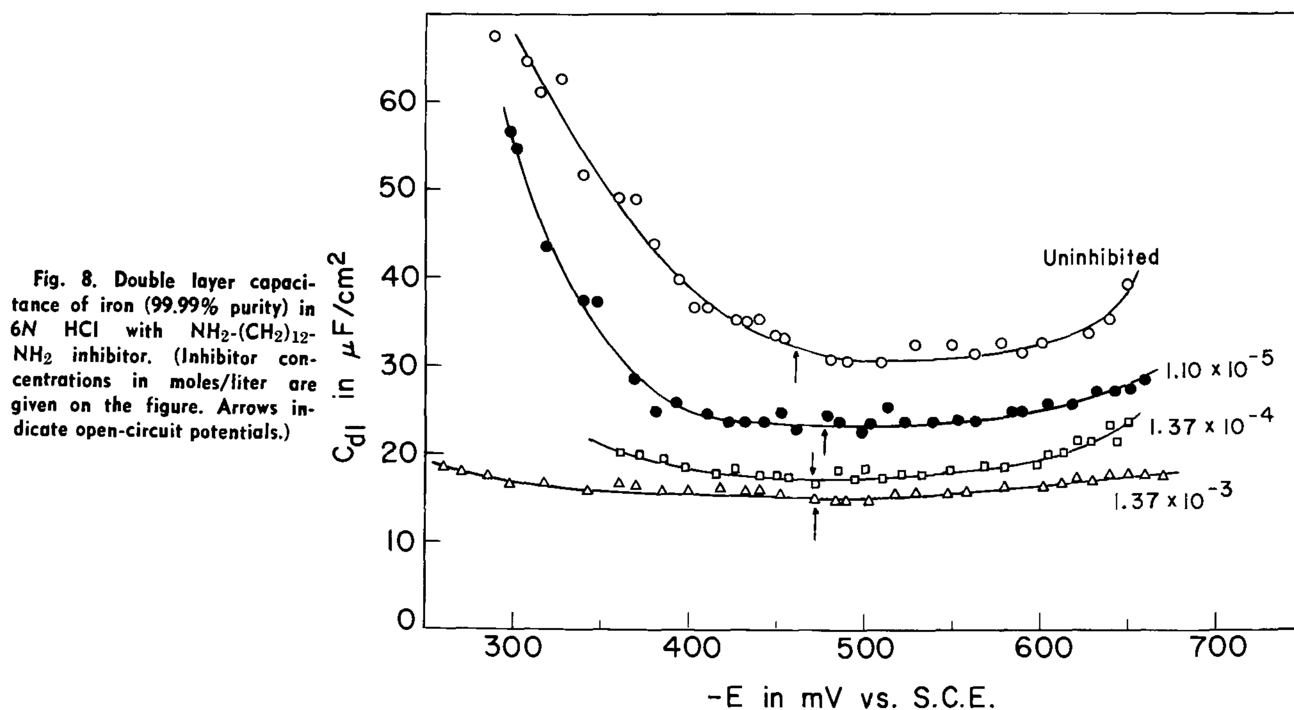

Fig. 8. Double layer capacitance of iron (99.99% purity) in 6N HCl with NH_2-$(CH_2)_{12}$-NH_2 inhibitor. (Inhibitor concentrations in moles/liter are given on the figure. Arrows indicate open-circuit potentials.)

Fig. 9. Differential capacitance curves for several NH_2-$(CH_2)_n$-NH_2 inhibitors at concentrations of optimum corrosion inhibition. (Arrows indicate open-circuit potentials.)

Evidence that short linkages lie flat on the active iron electrode is provided in work by Annand, Hurd, and Hackerman (12), who found that short repetitive chains -NH-$(CH_2)_2$-NH- of polyethylene polyamines increased inhibitor effectiveness by orders of magnitude on a per nitrogen basis compared to the monomeric species. This effect was interpreted in terms

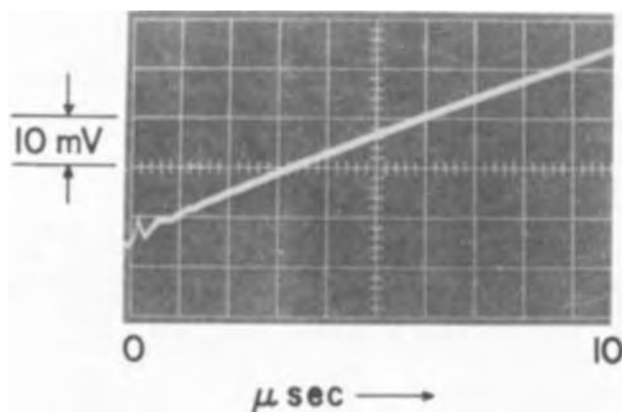

Fig. 13. Double layer charging curve for iron (99.99%) in 6N HCl with 0.0196 moles/liter NH_2-$(CH_2)_{11}$-NH_2 at open-circuit potential (−0.480V vs. SCE).

of increased adsorption, implying that the polymer units must adsorb at repeated distances along the surface.

The abrupt decrease in limiting differential capacitance in passing from NH_2-$(CH_2)_8$-NH_2 to NH_2-$(CH_2)_9$-NH_2 (Fig. 10) reflects a change in configuration and/or dielectric constant. With long enough polymethylene chains, repulsive interactions between amine end groups of adjacent flat molecules cause some of the molecules to reorient to the upright position. When additional metal surface is exposed due to this reorientation to the upright position, additional diamine molecules in solution adsorb end-on between vertical neighbors. The resulting capacitance is thus lower than for the C_2- to C_8-diamines which are adsorbed in the flat position.

This change in conformation is probably a gradual one with coverage, passing through an intermediate stage in which the hydrocarbon chains are "buckled" between the adsorbed amine end groups. Direct determination of end-to-end distances in α,ω-dibromoalkanes has shown that folding of hydrocarbon chains becomes appreciable with 10 or more carbon atoms (29). Film balance studies at the air/water interface with dicarboxylic acids of 12 or more methylene groups have shown considerable buckling of the hydrocarbon chain between the two hydrophilic end groups (30). In addition, based on interfacial tension data for NH_2-$(CH_2)_4$-NH_2 and NH_2-$(CH_2)_{10}$-NH_2 at the water/chloroform interface (31), the limiting cross-sectional molecular areas can be calculated from the Gibbs adsorption equation to be 151 and 58 square angstroms, respectively. The smaller area of the C_{10}-diamine must mean that the hydrocarbon chain is buckled in the organic phase, whereas the C_4-diamine lies flat at the interface.

The reduction and ensuing alternation in differential capacitance for the C_9- to C_{12}-diamines suggests that these adsorbates are structured similar to the bulk, where certain physical properties oscillate with carbon number. It is well known that the physical properties of α,ω-dicarboxylic acids in the solid state, *e.g.*, melting point, refractive index, and solubility, show pronounced alternation with carbon number (32). These fluctuations in physical properties are caused by alternations in the crystal structures. In the zigzag arrangement of the methylene groups, the carbon chains of "even" acids lie in one plane; but the "odd" acids are twisted. This torsional effect imparts higher energies, and lower melting points for instance (33), to the odd acids.

Less is known about the physical properties of the corresponding α,ω-diamines. However, fluctuations in melting points (see Table II.) suggest that the homologous series of diamines also displays the "even-odd" bulk property effect. With regard to the surface, then, the regular oscillation in differential capacitance at saturation coverages can be attributed to alternations in the local dielectric constant, which in turn result from alternations in positioning of the polar end groups in the adsorbed monolayer. That is to say, the C_9- through C_{12}-diamines are structured at the metal/solution interface with hydrocarbon chains in the vertical position. Structuring of polar adsorbates at the gas/solid and solid/liquid interfaces is well known in simpler systems (34, 35).

Comparison of inhibitors.—In comparing the relative efficiency of a homologous series of adsorption type corrosion inhibitors, account must be taken of the following molecular parameters (2-6, 10, 11): (i) the electron donating ability of the adsorbing inhibitor, (ii) molecular area, and (iii) inhibitor solubility.

The electron donating ability of the amines can be estimated from their base strengths (6). Table II lists acid dissociation constants pK_a taken from published literature (36, 37). Larger pK_a's imply stronger bases and hence better electron donors. Table II shows ethylenediamine to be the weakest base. This fact explains the lower inhibition with ethylenediamine compared to propylenediamine (Fig. 3). The two inhibitors have comparable solubilities, and the differences in cross-sectional areas are too small to account for the differences in corrosion current densities. Based on liquid density calculations (38), these cross-sectional areas are 25.3Å^2 for NH_2-$(CH_2)_2$-NH_2 and 29.4Å^2 for NH_2-$(CH_2)_3$-NH_2. The former area is in agreement with the

Table II. Some properties of the diamines NH_2-$(CH_2)_n$-NH_2

values 25.5-29.0Å^2 observed for vapor phase adsorption of ethylenediamine on Al_2O_3 catalysts (39).

The agreement in the per cent inhibition *vs.* concentration curves for the C_3- to C_8-diamines (Fig. 3) was surprising in view of the increased basicity and molecular area (flat configuration) with increasing carbon number. Diamines with up to eight carbon atoms are readily soluble, so that solubility differences were minimal.

Two reasons can be given that the per cent inhibition curves coincide for the C_3-C_8 diamines. First, it is possible that the higher members within the C_3- to C_8-range do not stretch completely flat on the surface. X-ray determination of end-to-end distances in C_6- to C_{18}-polymethylene dihalides has shown that even the shorter chains display some buckling (29). This effect could reduce the differences between the effective cross-sectional areas of the C_3- to C_8-diamines. In addition, a given coverage of any of these inhibitors below the monolayer volume could serve to ennoble a much larger area of metal surface. Previous work, for instance, has shown that an absolute coverage of less than 0.1 monolayer of polypyridine produced 80% inhibition (12). Absolute adsorption isotherms were not determined in the present work, but Fig. 5 shows that a relative concentration of only 0.01 produced 80% inhibition for NH_2-$(CH_2)_6$-NH_2 or NH_2-$(CH_2)_{12}$-NH_2.

With increased chain length, the diamines become notedly more insoluble, with lower concentrations required for protection. Here, the inhibitors must be compared on the basis of reduced concentration C/C_{sat}, in that the free energy of adsorption of the inhibitor is comprised in part of the term $RT \ln C/C_{sat}$ (40, 41).

At reduced concentrations of $C/C_{sat} \geqq 0.01$, the C_6- and C_{12}-diamines yielded the same per cent inhibition, *i.e.*, 80% inhibition at $C/C_{sat} = 0.01$ and tending toward 90% at higher concentrations (see Fig. 5). For such efficiencies, the uptake of inhibitor is no doubt the maximum for each case, although the inhibitor configurations are different. As inferred from the double layer capacitances, the C_6-diamine lies flat but the C_{12}-diamine is vertical. Thus, at concentrations below maximum coverage, the C_6-diamine should cover more metal surface than the vertical C_{12}- and would be expected to be the more efficient inhibitor. Figure 5 shows that 1,6-hexanediamine is more efficient than 1,12-dodecanediane at the lower reduced concentrations.

Other factors being equal, medium-sized hydrocarbon chains of NH_2-$(CH_2)_n$-NH_2 diamines are thus more efficient corrosion inhibitors than the longer hydrocarbon linkages.

Possibility of localized corrosion.—As shown in Fig. 12, open-circuit dissolution rates determined by polarization measurements are not in agreement with rates determined by colorimetric analysis of corrodent solutions. The dissolution rate of uninhibited iron in 6*N* HCl was only half the rate determined by colorimetric analysis of the solution. This observation was reported a few years ago in this laboratory (10) and more recently by Oakes and West (42).

Oakes and West (42) following Florianovich, Kolotyrkin, and Sokolova (43) attribute this disagreement between electrochemically and chemically determined rates to the operation of a separate, potential-independent "chemical dissolution" process (44), which is co-existent with the electrochemical process but not measured by the polarization curve.

Alternately, the observed effect could be due to localized corrosion. Before the appearance of the term "chemical dissolution," Marsh and Schaschl (23) had suggested that such effects could be explained by dissolution of metals in "chunks" or blocks of atoms. That is, preferential attack along grain boundaries can cause grains of metal to be dislodged from the metal surface. These dislodged grains would continue to produce Fe^{++} ions, but would be disconnected from the electrochemical circuit, so that the electrochemically measured rate would be too low.

Loose metallic particles collected from the surfaces of steel dissolving in HCl and H_2SO_4 have been identified by the optical microscope (45). Mechanical disintegration and spalling of various nonferrous metals is well known (46).

A limited number of experiments were also done with 3*N* HCl. Agreement was found between corrosion rates determined by the polarization method and by colorimetric analysis. For uninhibited iron, the two rates were 238 and 241 $\mu A/cm^2$ respectively. With 0.0105 M/liter of added NH_2-$(CH_2)_4$-NH_2, the rates were 101 $\mu A/cm^2$ by polarization and 119 $\mu A/cm^2$ by colorimetric analysis. Agreement between the two methods has also been reported for 1*N* HCl (1).

Figure 14 compares polarization data for NH_2-$(CH_2)_4$-NH_2 in 6*N* and 3*N* HCl. It is seen that the 3*N* data (where no "chunk" effect occurs) lie on the 6*N* curve (where there is an accompanying chemicomechanical effect). Thus, the electrochemically determined per cent inhibition curves for 6*N* HCl accurately reflect the behavior of the inhibitor at lower acid concentrations. If the extent of localized corrosion is the same from diamine to diamine, the electrochemical rates also accurately evaluate the relative performances of the diamines in 6*N* HCl.

Conclusions

1. The double layer capacitance at the Fe/HCl interface decreases at all electrode potentials with additions of NH_2-$(CH_2)_n$-NH_2, for $n = 2$-12. This general decrease indicates that the inhibitors are adsorbed on the surface at both anodic and cathodic sites.

2. The limiting double layer capacitance at saturation coverage is approximately constant at 21 $\mu F/cm^2$ for $n = 2$-8. This constancy is interpreted on the basis that these diamines all assume flat configurations at the interface.

3. The limiting double layer capacitance for NH_2-$(CH_2)_9$-NH_2 drops to 6 $\mu F/cm^2$ and alternates with increasing carbon number between 6 and 14 $\mu F/cm^2$ for $n = 9 \rightarrow 12$. The decrease in capacitance relative to $n = 3 \rightarrow 8$ and subsequent alternation in value suggests that these monolayers are structured like the bulk solids with hydrocarbon chains outward.

4. 1,3-propanediamine is a better corrosion inhibitor than ethylenediamine, but no further increase in efficiency is obtained if up to eight methylene linkages are used.

5. On a relative solubility basis, NH_2-$(CH_2)_6$-NH_2 is more efficient inhibitor than NH_2-$(CH_2)_{12}$-NH_2, although both compounds produce 90% inhibition at $C/C_{sat} = 0.1$.

Pitting and Deposits with an Organic Fluid by Electrolysis and by Fluid Flow

T. R. Beck,* D. W. Mahaffey, and J. H. Olsen

Boeing Scientific Research Laboratories, Seattle, Washington 98124

ABSTRACT

Electrolysis experiments were performed with iron electrodes in phosphate ester fluids. Pitting corrosion occurred and films were deposited on the electrodes. The effect of various additives was investigated and a model involving a threshold current density for pitting was formulated. The relationship of the results to corrosion by electrokinetic currents is studied. The occurrence of electrokinetically produced corrosion is discussed.

This paper describes some electrochemical experiments which were performed in phosphate-ester based hydraulic fluids. The experiments were associated with the discovery of a new wear mechanism in steel hydraulic-control valves. The wear mechanism is a corrosion reaction driven by electrokinetic currents associated with the flowing fluid and has been described in detail elsewhere (1). The present paper is concerned primarily with the associated electrochemistry of the phosphate ester fluids and its relationship to the wear mechanism.

Electrolysis Experiments

A primary objective of the experiments was to determine if corrosion could be produced by purely electrochemical means, without the fluid flow present in the hydraulic valves. The experiments were performed using phosphate ester fluids (2), whose properties are listed in Table I.

Parallel-Electrode Cells

An experiment was conducted with 2 × 12 cm parallel pure-iron sheet electrodes, separated by 0.3 cm, and immersed in 850 cc of continuously stirred phosphate ester fluid in a Pyrex beaker.

For an applied potential of 500V the initial current was 2 mA and decayed over the 313 hr of the test to 0.8 mA. This represented a range of current densities of 0.3-0.8 mA/cm^2 based on the facing areas. No corrosion of the electrodes was observed but deposited films were observed.

The electrodes were washed with acetone and films that had formed were scraped off. Upon returning the electrodes to the cell, the current was about 11% greater for a given potential than the current at the beginning of the run. In this and other experiments the anode film had the high resistance. Fluid conductivity, measured in a conductivity cell, was found to have increased slightly in this experiment although it decreased in other experiments.

* Electrochemical Society Active Member.

Key words: electrokinetics, streaming current, corrosion, phosphate ester, electrode films.

Table I. Properties of phosphate ester hydraulic fluid

Composition:

Basestock—approximately 90%—a mixture of phosphate esters with general formula $RO-\overset{\overset{R}{|}{O}}{\underset{\underset{O}{\|}}{P}}-OR$ where R's may be alkyl or aryl groups.

Viscosity improver—approximately 10%—polymethyl methacrylate

Corrosion inhibitors, dye, etc.—minor constituents

Density—1.05 g/cc

Viscosity—12 centipoise

Vapor pressure at 25°C—2-7 mm Hg

Electrical conductivity—approx. 10^{-7} ohm^{-1} cm^{-1}

Dielectric constant—approx. 8

Current-potential curves both for clean and film-covered electrodes in the parallel-electrode cell are shown in Fig. 1. The slope of the curve for clean electrodes is consistent with the fluid conductivity and cell geometry. Extrapolation of the current-potential curve to zero current indicates a rather large polarization for the film-covered electrodes compared to the clean electrodes.

The light tan colored anode film cracked after washing with acetone and was easily removed with a Teflon scraper. The total weight was 0.135g and accounted for about 90% recovery of the anode film. The amount of the cathode film was only about 1-10% by volume of the anode film, and was very firmly adhering requiring a steel scalpel to remove it. Results of instrumental analyses of the films are presented in Table II. The anode film was amorphous and appeared to have a composition similar to the phosphate ester, although high in iron. Mass spectrographic analysis of the cathode film showed sodium, carbon, and oxygen as major components, suggesting that it was sodium carbonate.

An approximate current efficiency for formation of the anode film can be calculated assuming that the film is a polymer of phosphate ester formed by a one-electron/molecule process. This would be akin to

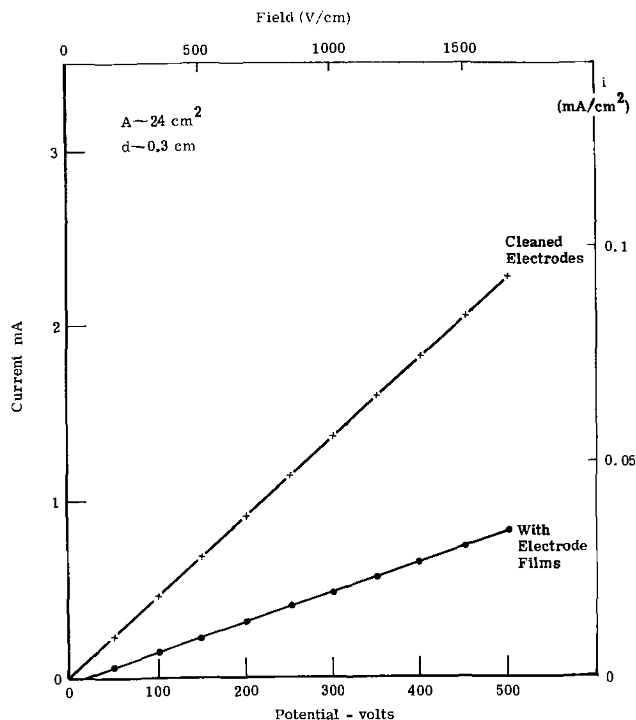

Fig. 1. Current-potential curves before and after electrolysis

a Kolbe-type reaction in which free radicals are formed and subsequently polymerize. The calculation is based on tributyl phosphate with molecular weight 218, which was the dominant species in the fluid. The total charge passed in this experiment was 1100 coulombs which would give 2.5g of material for a one-electron reaction. Only 5.5% of this amount of material was collected. The reaction product was thus either quite soluble or other reactions giving soluble products occurred.

The conductivity of the anode film can be estimated from its thickness and the current-potential data of Fig. 1, to be about 10^{-9} $ohm^{-1}cm^{-1}$ which is about a factor of 100 less than that of the fluid.

Because of the absence of corrosion in the cell, a second parallel-electrode cell with much smaller, 0.025 cm, interelectrode spacing, illustrated in Fig. 2, was used to obtain higher current densities. The current-potential curves for it are given in Fig. 3. The current very rapidly decayed with time (in seconds) to a lower plateau when a constant potential was applied. The initial peak current was consistent with the conductivity of the fluid and the cell geometry. Replacement of the electrolyte in the cell, without cleaning the electrodes, gave the same current *vs.* time profile. Thus the limiting current was due to decreased electrolyte conductivity rather than the anode film which presumably could not form in the short time. At a potential of 400V or more across the thin cell, sparking occurred resulting in arc craters in the metal. The arc craters could be readily distinguished from corrosion by their contour and shiny appearance. A brownish or bluish coloration appeared on the electrodes but the film thickness was insignificant in these short runs as compared to the experiments in the beaker cell. No electrode corrosion was observed with either parallel-electrode cell.

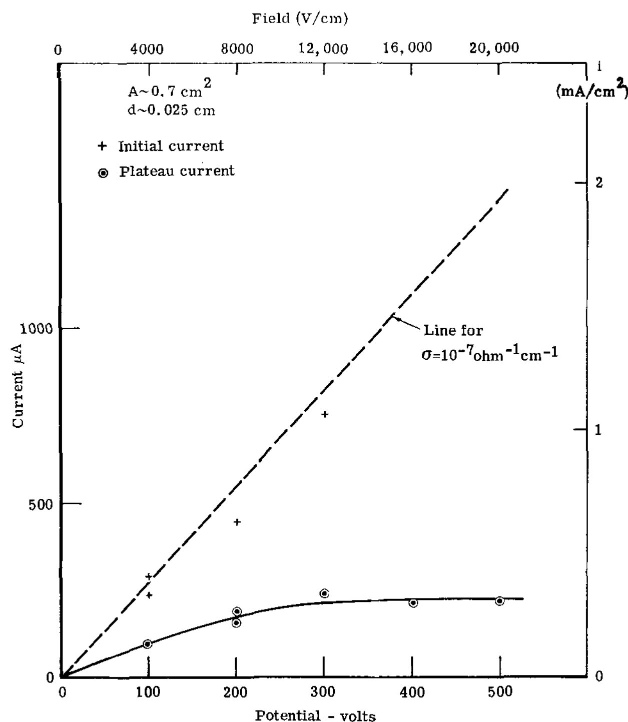

Fig. 3. Initial current and plateau current for thin electrolyte cell.

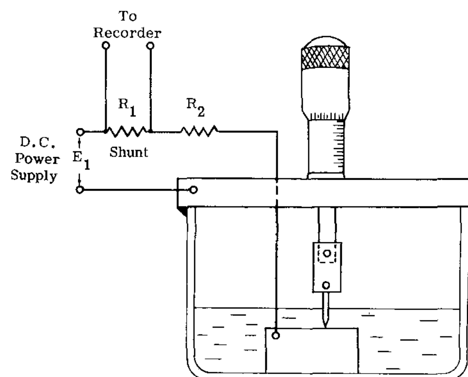

Fig. 4. Needle-to-plane cell

Needle-to-Plane Cell

A small interelectrode distance was needed to obtain high current density to study pitting corrosion and a relatively large volume of electrolyte was required to avoid a decrease in conductivity. These requirements were met with the needle-to-plane cell illustrated in Fig. 4. One electrode was a steel phonograph needle with approximately a 25μ tip radius and the opposing electrode was a polished steel block. Interelectrode spacing could be adjusted with a micrometer head holding the needle. With a potential of about 1V across the cell, the needle was carefully moved until it touched the block as indicated by a sharp increase in current. It was then backed off to a suitable spacing, usually about 25μ.

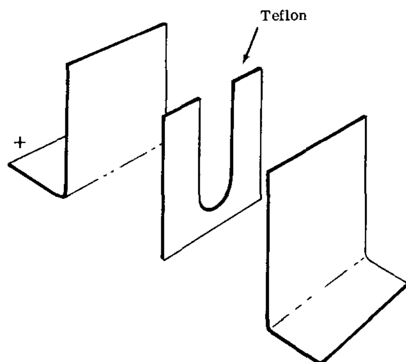

Fig. 2. Exploded view of thin cell

Pitting corrosion was observed; it occurred only on the anodic electrode although deposits were formed on both. The polished block was anodic in most of the runs and photomicrographs were made of its surface. The effect of current density and various additives on the anodic pitting corrosion is summarized in Table III. Only relative measurements of the amount of pitting corrosion based on depth and areas of pitting corrosion were obtained.

A significant amount of pitting occurred in run 6. The maximum depth of the pitted area was about 4μ. The diameter of the continuously pitted area was about 150μ. The continuously pitted area was surrounded by a zone of individual pits.

Table III. Conditions and observations for needle-to-plane electrolysis experiments

Run	Electrolyte	ϕ (V)	I (μA)	τ (min)	q (coulombs)	Cell conductance × 10^6 (ohm^{-1})	Relative amount of pitting (Scale of 10)
6	Phosphate ester	250	40	55	0.131	0.16	5
7	Phosphate ester	170	26	70	0.109	0.15	2
8	Phosphate ester + 1% CCl_4	170	26	60	0.094	0.15	5
9	Phosphate ester + 2% H_2O	82	27	60	0.097	0.33	4
10	Phosphate ester + 1% CH_3NO_2	170	15	95	0.085	0.09	Spark
11	Phosphate ester + 0.1% CH_3NO_2	215	24	60	0.086	0.11	1
12	Phosphate ester	260	40	10	0.036	0.15	1

18	Phosphate ester + 1% CCl_4	80	70	60	0.25	0.9*	10

Interelectrode spacing $d = 2.5 \times 10^{-3}$ cm in all runs.
* Solution had been in open beaker in laboratory atmosphere for several weeks.

Current efficiency of pitting corrosion in the center of the pitted area can be estimated by comparing the measured depth to the calculated depth based on maximum current density. The maximum current density in the center of the corroded area can be estimated from

$$i = \sigma \frac{\Delta\phi}{g} \quad [1]$$

A conductivity, $\sigma = 10^{-7}$ ohm^{-1} cm^{-1}, an applied potential, $\Delta\phi = 250$V, and a gap of 25μ gives a maximum current density of 1×10^{-2} A/cm^2. The thickness of metal removed by this current density in 55 min, assuming the iron corrodes to valence 2, is 11μ from Faraday's law. Only 4μ were measured. The minimum current efficiency for corrosion in the center of the pitted area was therefore about 36%. The average current efficiency for corrosion for the whole surface based on the total volume of metal removed and the total charge was about 2%. Thus, most of the current passed was consumed in the film-forming and other oxidation reactions surrounding the pitted area. There appears to be a threshold current density for corrosion below which only the film-forming reaction or other oxidations occur.

Decreasing the current slightly, as in run 7, significantly decreased the amount of pitting. The deposit and the pitted area, before and after cleaning, is illustrated in Fig. 5 for run 7. The thickness of the deposit decreases with distance from the needle electrode. The center area was opaque while interference fringes are observed on the periphery (Fig. 5a).

Addition of carbon tetrachloride in run 8 markedly increased the amount of pitting as can be seen by comparing Fig. 6 to Fig. 5 for runs having otherwise identical conditions. Addition of the 1% carbon tetrachloride did not change the conductivity of the electrolyte as can be seen by comparing the cell conductance of runs 6, 7, and 8 in Table III. In a second run with 1% carbon tetrachloride added, number 18, much higher conductance was observed. This solution was in an open beaker exposed to laboratory atmosphere for several weeks. Hydrolysis of CCl_4 or absorption of HCl from the laboratory atmosphere may have occurred. The current density was high in run 18, resulting in a relatively large amount of pitting.

Distillation-purified tributyl phosphate, reportedly containing 2 ppm chloride,[1] gave no measurable pitting with a needle-to-plane cell as compared to significant pitting with the unpurified fluid containing 21 ppm chloride for the same current and time. This behavior appears analogous to pitting of iron in aqueous solutions for which pitting is promoted by presence of halide ions. The hydraulic fluids used in the electrolysis experiments of Table III had residual chloride concentrations from the manufacturing process of 50-500 ppm.

Addition of 2% water in run 9 apparently doubled the conductivity and significantly increased the relative amount of pitting compared to run 7 for the same current. Addition of nitromethane, a possible corrosion inhibitor, in runs 10 and 11 caused a decrease in conductivity. Sparking occurred when it was attempted to run at the same current as in run 7. It is, therefore, not certain whether nitromethane acted as a corrosion inhibitor.

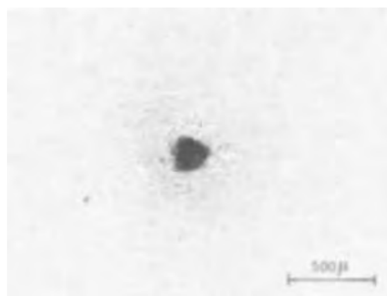

Fig. 6. Pitted area in run 8 with 1% CCl_4 after removal of the solid film.

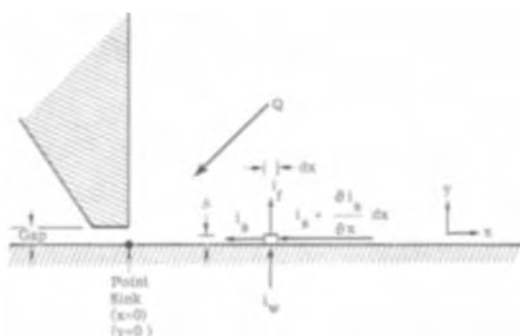

Fig. 7. Relation between streaming current and wall and fluid current densities in two-dimensional, unit-thickness converging channel.

Additions of hydroquinone were made in runs 16 and 17 to determine if an easily oxidizable material would consume current in preference to pitting corrosion. At the 11% level (approximately 1 mole/liter) in run 17, pitting was virtually eliminated for a condition of current density and time which would have otherwise produced a large amount of pitting. Addition of hydroquinone also increased the conductivity.

Flow Induced Pitting Corrosion

To understand the relationship of the electrochemistry of the phosphate esters to the flow induced wear mechanism, a brief description of that mechanism is given here. A detailed description has been published elsewhere (1).

The wear occurs upstream of small gaps at the end of 90° converging channels as shown in Fig. 7. The fluid is accelerated towards the gap and the streaming current i_s, produced by the flow, is a function of fluid velocity and must change with distance from the gap. Consideration of a differential volume element, δ by dx, and conservation of charge, requires the presence of the wall current density, i_w, and a fluid current density i_f, both normal to the wall. Using the assumptions listed in Table IV it has been shown (1) that

$$i_w + i_f = \frac{1.17\epsilon\zeta\nu}{x^3}\left(\frac{Q}{\nu}\right)^{3/2} \quad [2]$$

Table IV. Assumptions used in derivation of Eq. [2]

1. Equilibrium electrical double layer at walls of orifice, *i.e.*, ζ does not change with velocity.
2. No local changes in fluid permittivity and viscosity.
3. Two-dimensional approximation for flow in orifice, *i.e.*, radius of orifice, $R >> $ gap (Fig. 8).
4. Diffuse double layer is thin compared to hydrodynamic boundary layer, therefore velocity is linear in y within double layer.
5. Jeffrey-Hamel solution of Navier-Stokes equations for flow into 90—degree converging channel is applicable for $x \geqq$ gap.
6. Reynolds number, $Q/\nu > 100$.
7. The wall current, i_w, is supplied by electrochemical reactions, *e.g.*, oxidation of a fluid component or corrosion.

As a first approximation with phosphate ester fluids, i_f may be neglected with respect to i_w because resistance to current flow through the fluid is much greater than through the metal-fluid interface. Also, i_w is positive for phosphate ester fluids and results in anodic pitting corrosion of the upstream wall.

Many experiments were performed in tests of the above model. The experiment which is of most interest in connection with the electrochemistry used the apparatus shown diagramatically in Fig. 8. All dimensions of the system were large compared with the gap width, so that the two-dimensional analysis represented by Fig. 7 and Eq. [2] is applicable. After fluid flow for a period of 28.5 hr both film deposits and pitting corrosion were found. The pitting looked identical in appearance to that produced in the needle-to-plane cell.

A photograph of the cleaned surface after the 28.5 hr experiment is shown in Fig. 9. The outer portion furthest from the center had no deposit and retained the polished appearance of the original surface. A worn ring located by the 0.25 cm marker averaged 6.35μ maximum depth directly under the inner edge of the orifice, *i.e.*, at $x = 0$ in Fig. 7. An average profile of the corroded ring was determined from sixteen radial traverses using a Talysurf Model 3 instrument (1). The depth tapered off to zero at about 0.020 cm upstream from the inner edge of the orifice and about 0.005 cm downstream. A light-colored film covered the light-stained area both upstream and downstream of the worn ring. There was no measurable metal removal except within the worn ring. It

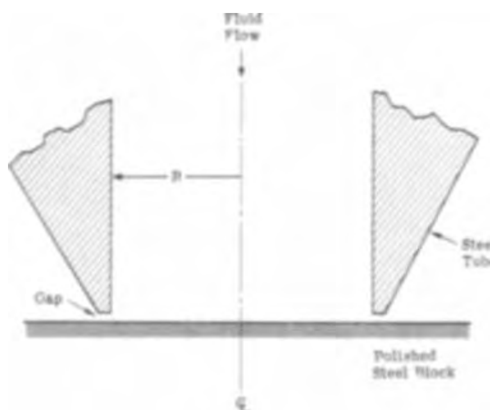

Fig. 8. Wear test apparatus

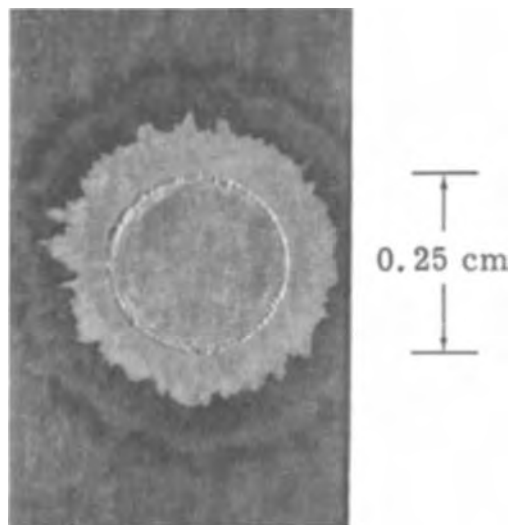

Fig. 9. Photograph of worn and stained areas on polished block

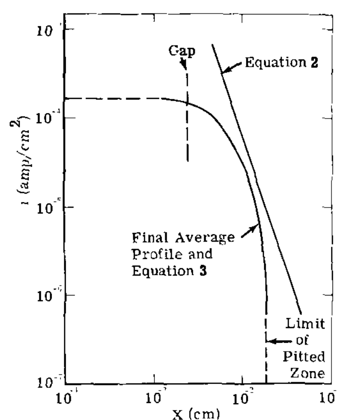

Fig. 10. Comparison of corrosion current density and model equation.

might be added that laminar flow obtains on the upstream side of the orifice so the wear and deposits there are not related to turbulence.

Corrosion current density was calculated from the average measured profile from Faraday's law

$$i_c = \frac{z\mathbf{F}\rho_m t}{M\tau} \quad [3]$$

and is plotted as a function of position, x, upstream from the orifice in Fig. 10. Wall current density calculated from Eq. [2] is also plotted in Fig. 10. Values of the parameters used in Eq. [2] and [3] are given in Table V. There is a range of distance, x, for which there is a correlation between the model and the experiment. For values of x less than the gap width, Eq. [2] is not valid because the point-sink approximation used is invalid. No corrosion was observed for values of $x > 2 \times 10^{-2}$ cm.

Discussion

Relationship of Electrochemistry and Wear Mechanism

Formation of films on the electrodes at low current densities and corrosion plus film formation at high current densities observed in the electrolysis experiments with the needle-to-plane cell appears to have a direct analogy to the results obtained with the flow system. In Fig. 10 a sharp cut-off of the corroded zone at about 2×10^{-2} cm from the orifice was noted, and a film deposit on the surface at larger distances from the orifice is indicated by the light stained areas in Fig. 9. In Fig. 5 for the needle-to-plane cell it is seen that the anode film extends well beyond the pitted area. There is apparently a threshold potential or current density below which pitting does not occur. In both the electrolysis experiments and the flow experiments, the corrosion began as small discrete pits which grew in time and merged in the high-current-density zone.

Formation of a low-conductivity anode film may have a beneficial effect in decreasing corrosion by decreasing the wall current. Ohmic polarization of the anodic film can be calculated from Eq. [1]; a corrosion current density of 2×10^{-4} A/cm^2 under the film (Fig. 10), a film conductivity of 10^{-9} ohm^{-1} cm^{-1} and a film thickness of 2.5×10^{-4} cm (assuming 1/10 of the gap width) gives an ohmic polarization

of the film of 50V. A corresponding potential drop would also occur in the fluid in the direction of flow. This is the same magnitude as the open-circuit potential measured with a stationary ring-disk electrode in the flow system (1). Conduction from the fluid may therefore explain the large deviations from theory in Fig. 10 at distances greater than the gap distance.

A proposed relationship between corrosion and oxidation of other species in phosphate ester fluids, illustrated in Fig. 11, is based on observations in the electrolysis experiments and flow experiments. It is perhaps an oversimplification but provides a basis for further experimentation. Direct experimental measurements of anodic overpotential in phosphate ester fluids have thus far been thwarted by the low conductivity. If there are several different species in the fluid that can be oxidized, the total current for oxidation of these species may be stepped as in a polarographic wave. It is proposed that there is a pitting potential, ϕ_p, as in aqueous solutions and that the current density for pitting rises steeply with potential above ϕ_p. For a wall current i_w, as shown in Fig. 11, pitting corrosion and oxidation of electrolyte species could occur simultaneously.

The amount of corrosion occurring at an orifice could be decreased in three ways according to Fig. 11.

Decrease i_w, *e.g.*: by decreasing zeta potential through control of surfactants present; by decreasing flow rate; by increasing conduction from fluid, with higher conductivity fluid or with high-resistance surface films on surface; by using a very-low conductivity (hydrocarbon) fluid.[2]

Increase i_{ox}, *e.g.*: by adding easily oxidized species.

Increase ϕ_p, *e.g.*: by removing species that promote pitting such as Cl^-; by adding inhibitor.

Some of these techniques have been verified in practice, others remain to be tested.

Other Possible Occurrences of Wear Mechanism

At the completion of the work relating to the wear in the hydraulic valves, other possible technological applications of the theory were explored. A review of the literature and approximate calculations of wall current densities indicate conditions favorable to this mechanism may occur in cavitation, drop impingement and in ball and roller bearings. For example, collapse of a cavitation bubble adjacent to a wall according to the Rayleigh equation (4) can produce high current densities. Alternating currents would be generated at surfaces in these cases but corrosion may still occur, although at less than 100% current efficiency (5).

The review of bearing technology by Bisson and Anderson (6) in 1964, describes unexplained pitting and formation of films and sludges which should be examined in light of the new mechanism. Salomon

[2] Streaming current is observed to go through a maximum as a function of conductivity for hydrocarbons with added conducting species (3). It follows that wall current should exhibit similar behavior.

(7) found electrostatic effects in lubricated machinery and related these to wear but no adequate theory was presented. Furey (8) found interesting patterns of deposits in a rotating ball experiment suggestive of electrostatic fields being present. He also found voltage developed in these experiments although he did not have an explanation. Zaslavsky and Shor (9) observed that wear rate was related to the potential applied between two rubbing lubricated surfaces.

Investigations into relation of wear and deposit formation to wall currents generated during rolling and sliding contact could provide a new approach to understanding some old lubrication problems.

Conclusions

Electrolysis experiments were carried out with iron electrodes in phosphate ester hydraulic fluids having conductivities of 10^{-7} ohm^{-1} cm^{-1}. It was found that:

a. Film deposits with composition similar to the fluid formed on the anodes. The conductivity of these films was significantly lower than the parent fluid.

b. Thinner deposits with composition approximating sodium carbonate formed on the cathodes.

c. Pitting corrosion occurred on the anode at high current density. Pitting was promoted by addition of carbon tetrachloride and inhibited in low chloride fluids, analogous to effect of halide ions on pitting of iron in aqueous solutions.

d. The electrode films and corrosion were similar to films and corrosion observed in high velocity fluid flow systems in which electrokinetic currents are generated.

Sealing Studies of Anodic Oxides by Wide-Line NMR Spectroscopy

Bernard R. Baker and Robert M. Pearson

Kaiser Aluminum & Chemical Corporation, Center for Technology, Pleasanton, California 94566

ABSTRACT

Wide-line nmr measurements show that anodic coatings formed in 15% H_2SO_4 at 25°C and 12 A/ft² for 1 hr and sealed for 30 min in boiling water at pH 6 contain 11-13% H_2O as OH groups plus 1-4% physically adsorbed water. Nitrogen adsorption measurements show a surface area of about 20 m^2/g for unsealed coatings and about 5 m^2/g for sealed coatings. The unsealed coatings contain about 1.2×10^{11} pores/cm² of mean radius of 60Å. About 46% of the water contained in a sealed coating is on a surface. From this, and from nmr line widths, a surface area of 260 m^2/g is estimated. The difference between the gas adsorption and nmr estimates of surface areas is explained by the model proposed for the coating structure, one consisting of an array of microcrystallites estimated to be about 25Å in radius. Gas adsorption analyzes only the major pore surfaces, but nmr analyzes the crystallite surfaces as well. Sealing is regarded to be primarily a surface reaction on the crystallites.

The porous anodic oxide films formed on aluminum by anodizing in sulfuric acid or other strongly acidic electrolytes are commonly sealed, usually by immersion in boiling water or dilute buffer solutions. The oxide becomes hydrated to a certain extent, the porosity decreases and susceptibility to staining or corrosive attack is minimized.

Because sealing is important in commercial anodizing, many investigators have expended considerable effort on studies of the mechanism of the reaction. Some of the more common techniques include electron microscopy, gas adsorption, x-ray and electron diffraction, x-ray emission spectroscopy, and infrared spectroscopy. Unfortunately, none of the techniques has yet produced a definitive answer to the fundamental problems of sealing, in particular, the mechanism by which the oxide adsorbs and binds water.

Key words: anodizing, aluminum, adsorption, hydration.

Several more or less plausible theories have arisen. We make no attempt here to correctly attribute all of these theories to their originators, partly because some of the ideas have almost assumed the status of folklore.

One of the more widely accepted concepts is that Al_2O_3 becomes hydrated to form boehmite (AlOOH) which, because of its greater specific volume, plugs the pores to a certain extent. Spooner and Forsyth (1) found boehmite patterns by x-ray diffraction, but nevertheless minimized the importance of boehmite as a sealing factor. They attempted to explain the apparent pore plugging by a dissolution and reprecipitation of an oxide hydrate. It is as difficult to argue with this concept as it is to prove it.

Another theory which may have considerable merit, at least in part, is the concept put forward by Murphy (2). He regards sealing as a surface effect rather than a pore plugging effect. Murphy postulated that re-

placement of surface sulfate ions by hydroxyl ions changes the surface from an active one that is receptive to dyes (and to stains or corrosive agents) to one that is more inert. This type of ion exchange must certainly occur to some extent, but it is not clear how it would affect coating properties.

O'Sullivan, Hockey, and Wood (3) proposed a model for unsealed coatings consisting of a relatively open array of alumina crystallites. During sealing, these crystallites agglomerate to some extent, forming hydroxylated surfaces and trapping molecular water in the intercrystallite voids.

Few workers have done more than to speculate on the nature of the water in sealed coatings although O'Sullivan, Hockey, and Wood made some reasonable estimates based on infrared spectra of ambient, evacuated, and deuterated films, both sealed and unsealed. They estimated that about 5-20% of the total hydroxylic species in sealed coatings is molecular water. The precise amount was indeterminant because of uncertainty in the extinction coefficient ratio necessary for the calculation. They were able to determine, however, that the relative amount of molecular water increased with an increase in sealing time.

In a preliminary report we discussed the adsorption of water vapor by dry, unsealed coatings formed at 25°C in 15% sulfuric acid on 99.99% aluminum anodized 1 hr at 12 amperes per square foot and 15V (4). We postulated a model similar to that of O'Sullivan, Hockey, and Wood in which the oxide was inferred to consist of submicrocrystallites of nearly anhydrous alumina. On exposure to water vapor, the crystallite surfaces adsorbed water converting it to surface hydroxyl groups which then physically adsorbed molecular water. In this paper, we present a method for analyzing anodic oxides for crystalline hydroxyl, surface hydroxyl, and physically adsorbed water by wide-line nmr. From these results and parallel gas adsorption studies we infer (*i*) a detailed model for unsealed as well as sealed coatings and (*ii*) a mechanism for the sealing reaction which contains several of the best features of previous models.

The analysis we use is based on techniques developed for the study of catalytic and desiccant aluminas (5). General references to the technique include a review by O'Reilly (6) and a paper by Saito and Hagewara (7).

Experimental

All coatings were formed on 99.99% aluminum foil, 3 mil thickness. The foil was partially slit prior to anodizing into 2 in. × 0.4 in. strips for nmr samples or 1 in. × 0.1 in. strips for gas adsorption samples. The end of each strip was left attached to a central bus strip for anodizing. The foil was mounted in a Lucite and aluminum rack, cleaned in Oakite inhibited alkaline cleaning solution, given a 1 min caustic etch (45-57 g/liter sodium hydroxide, 1.5 g/liter sodium gluconate, 5-25 g/liter aluminum at 55°C), then desmutted in 35% nitric acid followed by a thorough distilled water rinse.

Coatings were made by anodizing at 14V, 12 A/ft^2, for 60 min in 15% H_2SO_4 at 25°C. After anodizing, the samples were rinsed thoroughly in distilled water and cut from the bus strip. They were then either sealed immediately for 30 min in boiling distilled water or blown dry in a stream of filtered air depending upon their purpose. The seal bath was prepared fresh for each sample by bringing boiling distilled water to pH 3 with acetic acid then adjusting to pH 6 with sodium hydroxide. They were then placed either in tared 0.5 × 5 in. Pyrex nmr sample tubes sealed with rubber serum stoppers or in tared gas adsorption sample tubes. Oxide weights were obtained finally by stripping the oxide film from the substrate in a boiling solution containing 20 g/liter chromic acid and 35 ml/liter of 1.75 g/ml phosphoric acid leaving the "bare" metal.

Nitrogen adsorption and desorption isotherms were obtained on an Aminco Adsorptomat. Surface areas and pore radii distributions were obtained using the method of Barrett, Joyner, and Halenda (8). The nmr spectra were obtained as described earlier (4) except that data collection and reduction was performed using a Fabri-TEK Model 1074 instrument computer.

The spectra are a composite of a narrow line (*ca.* 0.2G) due to physically adsorbed water and a broad line (*ca.* 5.5-7.0G) due to chemisorbed water (hydroxyl or water coordinated to aluminum ions). If a narrow (0.125G) modulation is used the wide signal is minimized and the narrow signal is dominant. This allows quantitative determination of physically adsorbed water. To obtain a useful spectrum of the broad line species the physically adsorbed water must first be removed. This was accomplished either by heating to 90°C in a vacuum oven for several hours or by evacuating the sample at room temperature to about 10^{-4} mm Hg for several days. The two methods gave comparable results, however, each method also removes some broad line species as well, as shown by comparison of gravimetric and nmr results for the water loss. This difference was added to the nmr value for chemisorbed water as a correction.

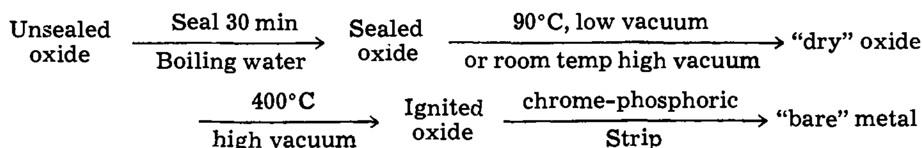
A sample of KA-201 (R) desiccant alumina (a Kaiser Aluminum & Chemical Corporation commercial transition alumina) containing a known concentration of physically adsorbed water was used as a standard for the narrow signal and a sample of gibbsite was used as a standard for the wide signal. The water content was calculated from the double integral of the spectrum using the relation

$$\% \text{ water} = \% \text{ water (std)} \times \frac{\text{curve area (sample)}}{\text{curve area (std.)}} \times \frac{\text{oxide bulk density (std.)}}{\text{oxide bulk density (sample)}}$$

The curve areas were corrected to a common instrument gain setting. The oxide densities were expressed as gram oxide/centimeter of sample tube.

Results

Water content of sealed coatings.—The analysis of the water content and distribution in sealed oxides is based on the following flow sheet



Weights were recorded at each stage. The nmr spectra were recorded for sealed oxide, dry oxide, and ignited oxide. Thus the water losses were observed by weight loss and by nmr. The spectra and water contents of unsealed oxides were discussed previously (4).

We assumed, initially, that gentle heating or strong evacuation would remove just the physically adsorbed water leaving the chemisorbed water intact. This assumption is not valid. The weight loss on heating to 90°C in a low vacuum or at room temperature in a high vacuum is always higher than the physically adsorbed water as determined from nmr (Table I). This is in accord with the thermogravimetric curve of Fig. 1 which shows a continuous water loss over the whole temperature range.

Table I. Comparison of gravimetric and nmr water determinations[a,b]

	Physically adsorbed water		Chemisorbed water		Total water loss		Residual water
Sample	wt. loss 90°C	nmr narrow signal	wt. loss 400°C	nmr (broad signal)	Gravimetric	nmr (corrected)	(nmr signal after 400°C ignition)
1	6.3[c]	3.6	5.5	7.1	12.1	13.4	1.7
2	4.8	1.1	6.1	6.0	10.9	10.8	1.3
3	4.6	2.4	6.4	8.7	11.0	13.3	1.6
4	3.8	1.8	6.7	7.6	10.5	11.4	1.8
5	5.3[c]	3.3	9.3	9.4	14.6	14.7	0.93
6	4.4	2.3	7.2	9.1	11.6	13.5	1.7
7	5.3[d]	3.0	10.0[e]	9.1	15.3	14.4	0

[a] All values are weight per cent based on sealed weights.
[b] All samples sealed 30 min in boiling water at pH 6.0.
[c] Weight loss in high vacuum at room temperature, all other losses in this column by heating to 90°C in low vacuum.
[d] This coating was dried at 90°C before sealing. The residual water content after drying was 0.5%.
[e] This sample ignited at 600°C.

We regard the nmr value for physically adsorbed water to be accurate to about ±10%. The difference between the weight loss and the nmr value thus represents water, held as Al-OH_2 or Al-OH, which is lost easily, therefore not available for analysis as chemisorbed water in the next step. The difference is added to the nmr value for total water loss as a correction (column 7, Table I). It is, of course, not added to the gravimetric value since the total weight loss (column 6) already includes it. The values for chemisorbed water in columns 4 and 5 are the apparent water contents of the "dried" oxide.

The total water determined by nmr is always equal to or higher than the value obtained gravimetrically except for the sample ignited to 600°C. This difference appears also in columns 4 and 5 for chemisorbed water and probably results from reaction of water released from the oxide on the substrate, $2Al + 3H_2O \xrightarrow{400°C} Al_2O_3 + 6H_2$. This reaction would result in a loss of protons without an appreciable accompanying weight loss.

We therefore regard the nmr values to be a better measure of water content and distribution than the gravimetric values but the nmr value for chemisorbed water must be corrected by gravimetric measurement in the first step of the analysis. The results are summarized in Table II which include the residual water content after ignition at 400°C. Table II also shows the line-widths of the chemisorbed water spectra which give information, discussed below, on the structure of the surface.

The relative water contents of about 1-4% physically adsorbed and 11-12% chemisorbed water are in

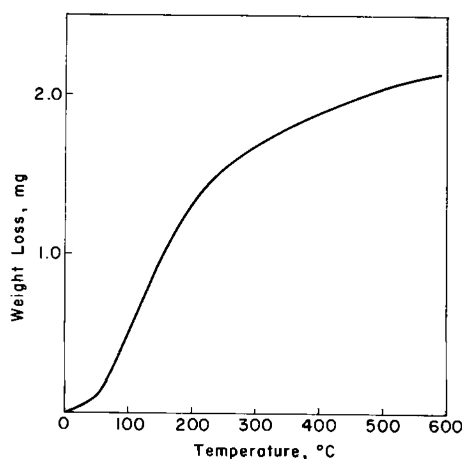


Fig. 1. Thermogravimetric analysis of 18.5 mg of sealed oxide heated at 10°C/min in a 30 cc/min H_2 purge.

Table II. Water contents of sealed anodic oxides[a] (% of sealed weight)

Sample	Weight gain on sealing (% of sealed wt.)	Physically adsorbed water	Chemisorbed water	Total water	Line-width of signal of chemisorbed water (gauss)
1	10.8	3.6	11.5	15.1	7.0
2	8.8	1.1	11.0	12.1	7.0
3	—	2.4	12.5	14.9	7.0

agreement with the estimates of O'Sullivan, Hockey, and Wood (3) on the relative amounts of free and bound water.

Gas adsorption.—Our analysis of the gas adsorption data follows standard procedures discussed by Barrett, Joyner, and Halenda (8); Lippens (9); and Brunauer, Emmett, and Teller (11). The adsorption isotherms permit two independent calculations of the surface area, S_{cum} and S_{BET}. Values of S_{cum} were determined by the Barrett, Joyner, and Halenda method. In principle, the mean pore radius is given by

$$\bar{r} = \frac{2V_P}{S}$$

where V_P is total pore volume and S is the surface area presented by the pores. This assumes uniform, cylindrical, nonintersecting pores. Such a pore will fill by capillary condensation when the pressure of the gas above the capillary reaches a pressure given by the Kelvin equation

$$\text{Ln}\,\frac{P}{P_o} = \frac{2\sigma V \cos\theta}{RTr_k}$$

where P/P_o is the relative vapor pressure of the condensed gas, σ is the surface tension, θ is contact angle, V is the molar volume of the condensed gas, and r_k is the kelvin radius of the pore. In practice the pores are not all the same size and condensation will occur over a range of relative pressures. Thus r_k is obtained over each increment of pressure and

$$S = \frac{2V_P}{r_k}$$

is calculated for that increment.

Also in practice, as gas adsorbs on the pore walls the effective pore radius changes with each monolayer of gas adsorbed. This effect is accounted for in the Barrett, Joyner, and Halenda method by measuring the amount adsorbed at 64 standard values of the relative pressure, P/P_o, for which corrections for the adsorbed thickness have been tabulated.

The value of S_{BET} is obtained from an analysis of the isotherm data using the BET equation

$$\frac{P}{X(P_o - P)} = \frac{1}{X_mC} + \frac{(C-1)P}{X_mCP_o}$$

where X is the weight (g) of adsorbant per gram of sample at pressure, P, and X_m is the weight of adsorbant per gram of sample at full monolayer coverage. C is a constant for a given gas and surface, containing, among other parameters, the energy of activation of adsorption and the vibration frequencies of the adsorbed molecules. If $P/X(P_o - P)$ is plotted *vs.* P/P_o a straight line of slope $S = C - 1/X_mC$ and intercept $i = 1/X_mC$ is obtained. Solving the two equations simultaneously gives the values of the two unknowns, X_m and C. The value of S_{BET} is obtainable from X_m using a value of 16.2Å^2 as the area occupied by one adsorbed nitrogen molecule. Since the value of S_{cum}

Table III. Nitrogen absorption on anodic oxides

[c] From desorption data.

arises from specific assumptions concerning the shape of the pores and S_{BET} makes no assumptions of pore shapes, an agreement between S_{cum} and S_{BET} implies that the assumptions implicit in the value of S_{cum} (cylindrical, uniform, nonintersecting pores) are valid. It is seen from Table III that they are not equal. This implies, that in the equation

$$S = \frac{2V_P}{\bar{r}}$$

$\bar{r}$ is too small, one interpretation of which is that the pores are bottle shaped or that each pore has a variable radius.

This interpretation would account for the hysteresis observed in the isotherm of Fig. 2 and in the different radius distribution curves for adsorption and desorption of Fig. 3. We choose not to belabor this interpretation, however. An equally plausible mechanism, described by Cohan (12), considers cylindrical pores to fill by adsorption on the pore walls presenting a cylindrical meniscus and to desorb by the Kelvin mechanism from a hemispherical meniscus.

In view of the rather poor reproducibility of the pore volumes (0.085-0.20 cm³/g) and surface areas (32.8-60.5 m²/g) for unsealed coatings it does not appear enlightening to pursue further the question of pore shapes. The poor reproducibility probably arises from (*i*) necessarily small oxide sample weights, (*ii*) relatively

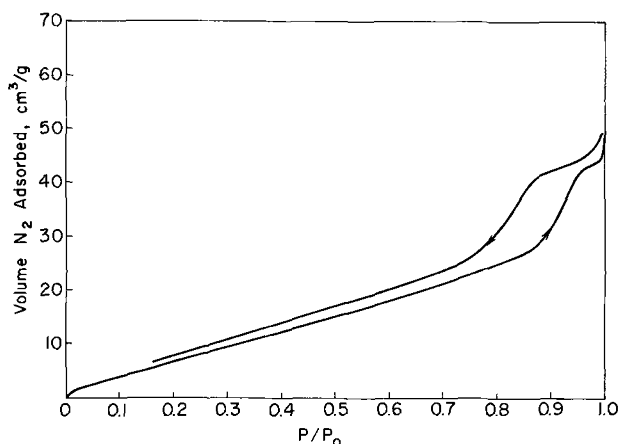

Fig. 2. Typical nitrogen adsorption-desorption isotherm of an unsealed oxide.

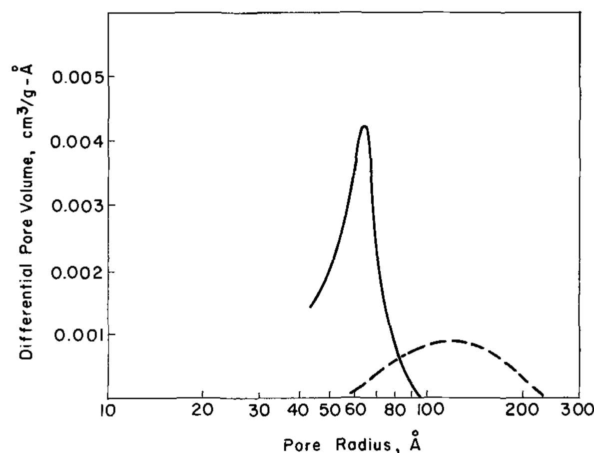

Fig. 3. Typical pore radius distribution curve for an unsealed oxide. The larger radius curve is from the adsorption leg, the smaller one from the desorption leg.

low porosity of the sample, and (*iii*) relatively poor reproducibility of the surface character. The results are good enough, however, to make comparisons to other results in the literature and to compare to current models of the coating structure.

The surface areas we obtain are roughly the same as those obtained by Burwell, Smudski, and May (13); Cosgrove (14); and Paolini, Masoero, Sacchi, and Paganelli (15), although direct comparison is difficult. Burwell *et al.* report 600 cm² real surface per cm² geometrical surface on coatings formed at about 14 A/ft² and 17V in 15% H_2SO_4 at 21°C. If we make a reasonable assumption of coating density, this converts to about 19 m²/g (for an apparent density of 2.5 g/cm³ and the density may be somewhat higher). They estimated a pore radius of 53Å and 1.55×10^{11} pores/cm². Cosgrove finds 81Å radii pores by n-butane adsorption and a surface area of 680 cm² per cm² of geometrical surface. This also converts to about 19 m²/g if the density is taken as 2.5 g/cm². Cosgrove and Paolini *et al.* report isotherms that are somewhat steeper than ours in the capillary condensation region and they do not observe hysteresis.

Based on unpublished pore counts (9.5×10^{10}) from electron micrographs observed earlier in this laboratory for comparable coatings (16) and assuming 100Å radius cylindrical pores, we calculate a surface area of 26.0 m²/g for coatings having our experimental density (2.3 g/cm³). For 60Å radius pores, the calculated area is about 16 m²/g. Alternatively, using our experimental values of the radius (60Å) and surface area (20 m²/g), the calculated pore density is 1.2×10^{11} pores/cm².

In any event, the gas adsorption data is consistent with a pore model with pore counts and pore dimensions about the same as found by other workers from both gas adsorption and electron microscopy. The pore radii, volumes, and surface areas of sealed coatings are interesting. Sealing, either by boiling water or by vapor does not close the pores entirely (note radii of 15 to about 30Å, discounting the one value of 64.4Å). Boiling water seals result in a lower pore volume and surface area than vapor aging although there is not much difference in pore radii between vapor aged and boiling water sealed samples.

The nmr spectra also provide information on surface areas in two ways (5). The first method is an estimate of surface hydroxyl content from the width of the broad hydroxyl signal. It is based on the fact that motional narrowing of the signal occurs for surface protons to a greater extent than for protons bound to oxides on a crystallite interior. A silica gel having only surface hydroxyl groups has a width of 0.310G (6). Gibbsite with only interior hydroxyl groups has

a width of 12.75G. Using these two standards and assuming a linear relation between line width and relative surface concentration gives the equation $F = (12.75 - \Delta H)/12.44$ where F is the fraction of total protons residing on the surface.

The width of the hydroxyl signal on an unsealed coating containing 3% OH is 5.5G. The value of F is thus 0.58. The area covered by OH in the unsealed coating is $S = CFNS_o$ where C is moles of OH per gram of oxide, N is Avogadro's number, and S_o is the area (in square meters) occupied by one OH group. Peri (17) gives a value of S_o of 8Å^2. The value of S is thus 49 m^2/g which is about twice that obtained from nitrogen absorption. We conclude that the major pore surface is nearly completely covered by OH with the remainder of the hydroxyl groups distributed over crystallite surfaces in the pore walls and on the interior of crystallites.

A related empirical relation was developed from a comparison of aluminum-27 spectra with proton spectra for a series of nonanodic aluminas. This showed that the average line-width of hydroxyls in the first two layers of a crystallite is 2.5G. Comparison of this and gibbsite gives the relation $F_2 = (12.75 - \Delta H)/10.25$ where F_2 is the fraction of hydroxyl protons in the first two layers (5). For the unsealed coatings F_2 is 0.71.

The second estimate of surface area is based on an empirical inverse linear relationship observed between BET surface areas and line-widths for OH on the surface of desiccant aluminas (5). This relation, expressed as $\Delta H = 13.20 - 0.0243\ S_{BET}$ gives a value of the surface area of the unsealed coatings of 317 m^2/g. The obvious discrepancy between this value and the gas adsorption results can be rationalized easily by a model which assumes the coating to consist of submicrocrystallites penetrated by pores in the classical sense. Apparently, only the major pore surfaces are accessible to nitrogen in the times allowed for establishment of equilibrium in the isotherm experiments, but in the course of their formation or on long exposure to water vapor or shorter exposure to higher temperature water, water can penetrate into the pore walls. A possible mechanism of water penetration would be a hydroxyl migration from site to site across an oxide crystallite.

This model is supported by the water contents of sealed coatings. The line width of the hydroxyl signal is 7.0G which corresponds to 260 m^2/g where $F = 0.46$ as the fraction of total OH on the surface. Using 8Å^2 surface per OH we calculate a surface capacity of 4.9% H_2O (as OH). If this represents 46% of the total, the total combined water content is 10.7%, in reasonable agreement with the experimental values of Table II.

Further support comes from an analysis of the water contents of coatings formed in an electrolyte of 5-sulfosalicylic acid and sulfuric acid. A preliminary analysis of two of these sealed films showed a hydroxyl line width of about 12G and a total water content of about 3%. The 12G line width corresponds to a surface area of 50 m^2/g which, compared to the sulfuric acid film, should have a capacity of $50/260 \times 11 = 2.1\%$.

We wish to compare the specific volume of the pore wall oxide to an oxide having no intercrystallite void volume in order to estimate the intercrystallite void volume of the pore wall oxide. Since we assume the crystallites in the pore wall to have a close-packed oxide structure, the best comparison is probably with αAl_2O_3. The apparent coating density is 2.3 g/cm^3 and the specific volume is 0.44 cm^3/g. If the major pore volume of about 0.1 cm^3/g is subtracted from this the specific volume of pore wall oxide is 0.34 cm^3/g. The single crystal density of αAl_2O_3 is 3.97 g/cm^3 and the specific volume is 0.252 cm^3/g. The ratio $0.252/0.34 = 0.75$ gives an intercrystallite void volume of pore wall oxide of 25%.

It can be shown that each sphere in a collection of spheres in cubic close packing occupies a volume of about $5.6\ r^3$ where r is the sphere radius. This volume includes the intercrystallite void volume associated with each sphere. The actual volume of the sphere is $4/3\ \pi r^3$ or $4.2r^3$. The ratio of actual volume to apparent volume is 0.75 in agreement with the experimental value. Thus, the oxide structure can be described in terms of a model consisting of close-packed oxide crystallites. If the volume of a model crystallite is $5.6r^3$, n crystallites has a volume, $V(n) = 5.6r^3n = 0.34$ cm^3/g. If the total crystallite area is 317 m^2/g, the area of one crystallite is $3.17 \times 10^6/n = 4\pi r^2$ cm^3/g. From these two equations, the radius of the crystallite is calculated to be 24Å, which is reasonable in view of the weak electron diffraction patterns obtained from anodic oxides (18).

Conclusions

Over half of the combined water in a sealed oxide resides within the first two oxide ion layers of a surface. In order to account for a surface area of this magnitude, capable of accommodating as much surface water as is observed, we postulate a sumicrocrystallite material penetrated by classical pores. The surface area and oxide density is consistent with a close-packed spherical crystallite model in which the crystallite diameter is about 40Å. Only the major pore surfaces are accessible to nitrogen or other gaseous adsorbants but the crystallite surfaces are accessible to water in a reaction that is slow at room temperature. Coatings exposed to boiling water for 30 min absorb about the same quantity of water as similar coatings exposed to saturated water vapor at room temperature for two weeks (4). Furthermore, the relative amounts of physically and chemically adsorbed water are about the same; whether sealed in boiling water or by water vapor adsorption.

There is a difference, however, in porosity between films sealed by boiling water and by room temperature vapor. Boiling water sealing results in smaller pores, smaller pore volumes, and lower surface areas, even though the water contents of the films sealed by the two methods are the same. The partial pore closure observed for the vapor sealed films is probably the result of a swelling that must occur when the crystallite surfaces adsorb water. The additional pore closure for boiling water sealing may be the result of a dissolution and reprecipitation of oxide near the pore mouth as suggested by Spooner and Forsyth (1).

One of the somewhat surprising results of this study was the observation that some proton containing species other than physically adsorbed molecular water can be removed from the oxide relatively easily by gentle heating (90°C) or room temperature evacuation. Water (or, at least the elements of water) probably occur on the surface as Al—OH$^{(I)}$, Al—OH$_2^{(II)}$, and Al—O - - - H-OH$^{(III)}$. The first two structures are responsible for the broad line (about 3-13G, depending on the relative concentration of surface to interior species). The last structure, physically adsorbed water is responsible for the narrow line (about 0.2G). Peri has described a model Al_2O_3 surface to account for differences in ease of dehydration of the oxide surface (17). According to his model adjacent hydroxyl groups combine to lose water randomly subject to the restriction that either adjacent O^{2-} pairs or adjacent exposed Al^{3+} pairs constitute higher energy sites, making H_2O removal from such sites more difficult. We postulate that coordinated water (structure II) should be removed more easily than water condensed from adjacent hydroxyl pairs and it is this form of water that is removed most easily, along with the physically adsorbed water.

One important practical consequence of the relative ease of removal of structural water is the possibility that a water loss-gain cycle is set up on anodized aluminum articles exposed to temperature and humidity changes. Such a cycle could have the effect over a period of time of loosening some of the oxide to form the powdery deposit called bloom or blush. This possibility is now under investigation.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Note added in proof: The broad-line species lost easily at low temperatures may result from condensation reactions occurring in gelatinous, hydrated alumina deposited in the pores and near the oxide surface, —Al—OH + HO—Al— → —Al—O—Al— + H_2O. This type of reaction would break one Al—O bond but would establish another Al—O bond. On the other hand, a condensation of OH groups from two neighboring sites on a surface, Al(OH) Al(OH) → Al(O) Al + H_2O or (OH)Al (OH)Al → Al(O)Al + H_2O, would break one Al—O bond and either leave a Lewis acid site or result in a change in Al coordination number. The condensation occurring in a gelatinous alumina should be more favorable energetically and could account for the easily lost broad-line species.

A Negative-Ion Type Instability in MOS Devices

Earl S. Schlegel*[,1] and George L. Schnable*[,2]

Philco-Ford Corporation, Blue Bell, Pennsylvania 19422

ABSTRACT

A hot-bias instability capable of shifting threshold voltages to positive values has been observed in the field oxide of MOS devices that have stable gate oxides. The instability is attributed to a contaminant that is introduced during thermal oxidation or other high-temperature processes, and is believed to be due to an immobile negative ion coexistent with a mobile positive ion. The activation energy and mobility of the mobile charge are similar to that of sodium in SiO_2. The effects of differences in processing are discussed.

The electrical properties of thermally grown SiO_2 and of its interface with silicon have been the subject of extensive studies designed to create and improve the technology for building planar diodes, transistors, and integrated circuits. These properties, to a large extent, control the performance, yield, and reliability of both bipolar and MOS devices.

A number of papers have been published that describe the electrical properties of thermally grown SiO_2 in detail (1, 2). This literature contains little information on negative charge in thermally grown SiO_2 layers. Kerr (3) found that net negative charge can be built up in lead-alumino-borosilicate or zinc-alumino-borosilicate that has been deposited by sedimentation techniques, if the structure is heated with an applied negative bias. Snow and Dumesnil (4) have shown that net negative charge can be developed in lead glass due to a combination of positive mobile lead ions and immobile negative ions. Snow and Deal (5) showed that net negative charge densities could be created in P_2O_5 (15 mole per cent) containing SiO_2 layers, due to dipolar polarization under negative bias at an elevated temperature. Kuper *et al.* (6, 7) reported that Br from NaBr partially neutralizes the effects of positive ions in SiO_2 and that this Br diffuses much more slowly than sodium at 800°C. Gold is reported to be negatively ionized in SiO_2 (8-10). Chang and Tsao (11) reported that zinc behaves as a negative charge in SiO_2, but they did not show a net negative charge per unit area. Brotherton (12) has shown that platinum can create a large negative charge density in SiO_2 layers. Dunbar and Hauser (13) found a mobile negative ion that builds up large net negative charge densities in unannealed pyrolytic SiO_2 layers. Iwauchi and Tanaka (14) reported on a negative-ion type of instability in Si-SiO_2 structures that were formed by d-c reactive sputtering. They interpreted their observations in terms of a mobile negative ion and reported that it could be immobilized by phosphorus in a manner similar to that used widely in the industry to immobilize positive mobile ions such as sodium.

Many studies of thermally grown SiO_2 layers have shown that the as-formed condition (or the condition after the sample has been heated to 300°C with the metal electrode on the oxide shorted to the substrate) for mobile charge in the oxide is such that the flatband voltage is near its least negative point. Radiochemical studies (6, 7) have shown that the mobile charge species in this case are alkali ions—most frequently sodium.

Two recent papers have described the existence of a negative-ion type of instability in thermally grown oxides. Reynolds *et al.* (15) showed a decrease in the

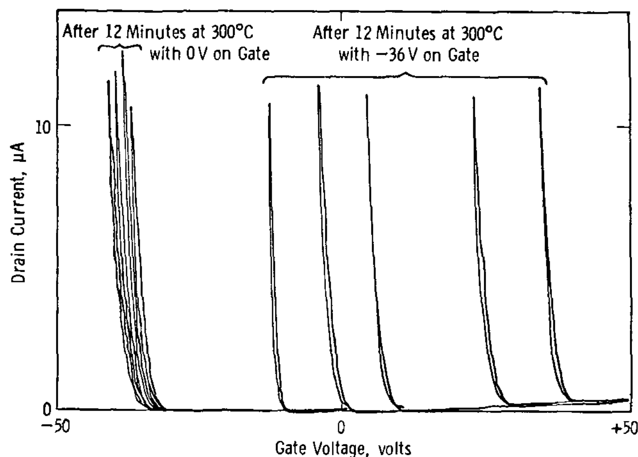

Fig. 1. Effect of Q_{neg} on the characteristics of p-channel MOS transistors located in different areas of a single wafer.

threshold voltage of thick oxide transistors designed for use as MOS test vehicles, due to step-stressing involving a negative bias. Deal (16) reported that negative ions, that are not mobile at 300°C, can contaminate oxides at temperatures of about 900°C and make silicon surfaces p-type.

In this paper, we report on the results of experimental studies of negative charge in thermally grown SiO_2 layers of the type used widely in the industry for field oxides in MOS microcircuits. The results of a study of the characteristics of this type of charge are reviewed and a model is proposed.

Experimental Findings

General.—The charge that is the subject of this paper is set apart from other mobile ion instabilities by a distinctive characteristic. This is that after the device has been fabricated or after it has been baked under shorted conditions, a bake with negative applied bias causes the capacitance-voltage characteristics of an MOS capacitor or the current-voltage characteristics of an MOS transistor to shift in the positive voltage direction. This shift sometimes changes the flat-band or inversion voltage to positive values; that is, the net effective charge density takes on negative values. Changes of this magnitude are shown in Fig. 1 for p-channel MOS transistors designed for use as test structures and fabricated in our laboratory. The oxide in the gate region was 15,000Å thick, and it was formed by the processes being used to form the field oxides in MOS microcircuits (thermal oxidation by a dry-wet-dry process, at 1200°C). The silicon was <111> orientation, phosphorus doped, with a resistivity of 5 ohm-cm. The metallization was e-gun evaporated aluminum.

In this paper we define Q_{neg} as the difference between the effective charge densities after a drift at 300°C under negative applied voltage and an anneal at 300°C under short-circuit conditions.

We have found significant amounts of Q_{neg} in samples from three other manufacturers, and we have found little to indicate that any manufacturer is free of this instability. (The problem is more readily uncovered in the samples from some manufacturers than from others because some microcircuit chips are made with discrete test structures and others are not.) Table I shows typical data taken from devices from three other manufacturers.

Spatial distribution.—This negative-ion type instability is almost never observed in the gate oxide, even in samples in which it occurs to a strong degree in the field oxide.

When Q_{neg} is found on a wafer, its distribution over the area of the wafer is nonuniform, as shown in Fig. 1. The data in Fig. 1 were taken from randomly chosen regions over the area of a single wafer. Each curve represents the current-voltage characteristics of a single transistor.

* Drifting was performed at 300°C for 12 min with either 0 or −30V applied.

Table II. Data from etching experiment to determine location of negative charge

	Effective charge density calculated from the flatband voltage (10^{11} charges/cm^2)	
	After −36V drift	After 0V drift
Unetched layers (2μ thick)	−7.7 to +3.3	+3.4 to +4.0
Etched layers (1μ thick)	+1.7 to +2.6	+3.1 to +3.7

An etching experiment on an oxide sample that contained Q_{neg} showed both a reduction in the mobile and in the net negative charge when 1μ of the 2-μ thick oxide was etched away. The data in Table II show that most of the mobile charge and most of the negative charge were located in the outer half of the oxide.

Metallization effects.—The negative-ion type instability has been found in unmetallized samples that were drifted with a gold ball probe and under electrodes formed with a conductive paste.

Differences in the temperature or ambient composition during the alloying of the aluminum metal do not affect Q_{neg}. Experiments in which the aluminum was removed from metallized samples that were subsequently remetallized showed no significant change in the level of Q_{neg}.

High-temperature process effects.—The differences between the processes used to grow the gate and the field oxides that cause the difference in Q_{neg} in these oxides are believed to be the temperature and humidity levels used to grow the oxides. The field oxide is grown at 1200°C in oxygen bubbled through water at 95°C. The gate oxide, grown in regions from which

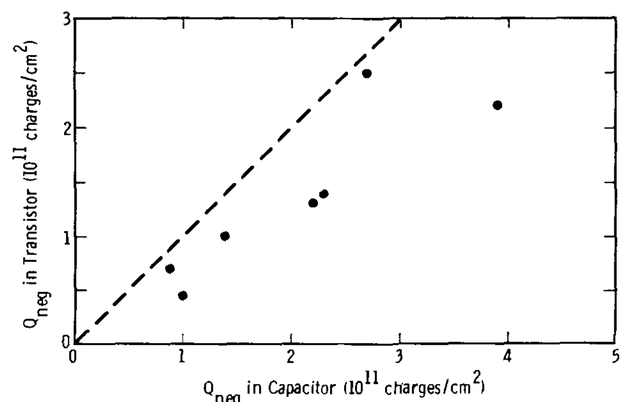

Fig. 2. Comparison of Q_{neg} in MOS capacitors and MOS transistors on the same wafer.

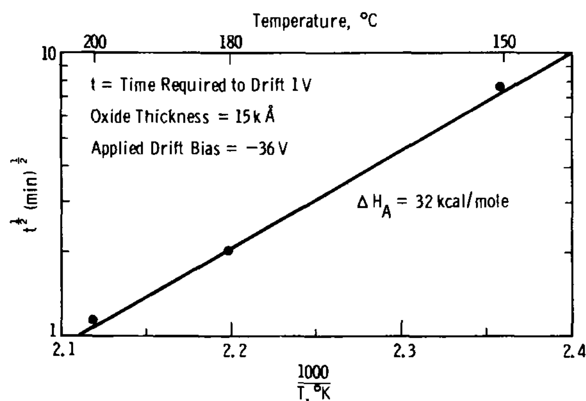

Fig. 3. Temperature dependence of the time required to drift Q_{neg}.

the field oxide was removed, is grown at 1000°C in dry oxygen.

Extensive studies lead to the conclusion that Q_{neg} is always dependent on conditions involved in processes performed above 600°C.

Gettering.—We find that Q_{neg} densities of 5×10^{11} cm^{-2} can be decreased to less than 1×10^{10} cm^{-2} by phosphorus or HCl treatments of the type known to immobilize sodium ions (17-20). The phosphorus was deposited from a $POCl_3$ source onto wafers at 1000°C for 5 min. The phosphorus glass was not stripped, and the phosphorus was driven in for 10 min at 1000°C. In the case of HCl, the sample was heated in 2% HCl in N_2 at 1000°C for 30 min.

We find that Q_{neg} is affected by the proximity of a pn junction, as shown in Fig. 2. This is similar to the effect of a pn junction on positive mobile ion densities (Q_o) reported in Ref. (21).

Kinetics of the instability.—There appears to be no difference between the drift rates for the initial drift and a subsequent recovery drift of Q_{neg} such as that usually found for positive mobile ions (22).

The Q_{neg} ions are nearly immobile at room temperature both before and after they have been drifted at 300°C, although shifts into the positive quadrant have been found after a bias of 10^5 V/cm was applied for 425 hr at room temperature. At 300°C a similar shift occurs in less than 12 min.

Measurements of the drift rate of Q_{neg} have been taken as a function of temperature, and an activation energy of 32 kcal/mole has been calculated. This value agrees very closely with that reported by Hofstein (22) and by Snow *et al.* (23) for sodium ions. Our data are shown in Fig. 3.

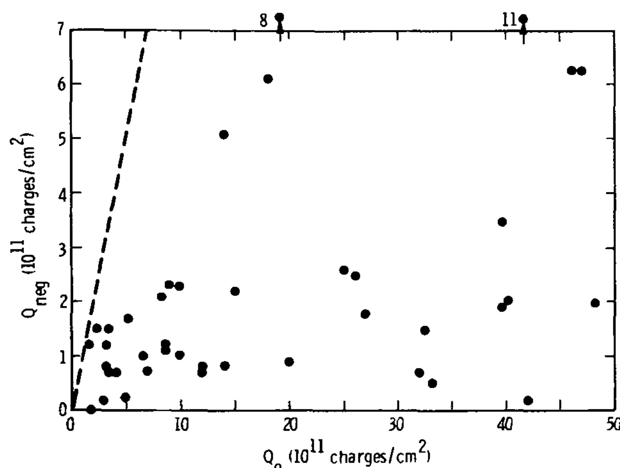

Fig. 4. Comparison between Q_{neg} and Q_o (300°C) in MOS capacitors.

Comparison of Q_{neg} and Q_o.—An effort to determine whether there is a correlation between Q_{neg} and the density of positive mobile ions (Q_o) in individual MOS capacitors yielded the results given in Fig. 4. The broken line shows the locus of points where the densities of the two types of charge would be equal. These data show that Q_{neg} is always less than Q_o and that there is no clear correlation between these two types of charge.

Model

The negative-ion type instability must involve a mobile ion species rather than dipole polarization because the shift along the voltage axis is frequently found to be greater than the voltage that was used to induce the shift. Two possibilities exist: there could be (*a*) negative mobile ions or (*b*) negative immobile ions in combination with positive mobile ions.

Based on previously reported information (7) that anions are only mobile at temperatures of about 800°C or higher and on our observation that the instability appears to be introduced only during processes that involve temperatures above 600°C, we infer (24) that the instability is due to an immobile anion contaminant that is introduced during a high temperature process, in combination with a mobile cation believed to be sodium. The anion contaminant appears to be related to sodium, and sodium ions are typically found in samples that have the negative ion contamination. Apparently, the presence of the anion causes the sodium to be distributed to some extent through the thickness of the oxide layer, in contrast to the usual tendency for the sodium to lie near the metal-oxide interface.

Conclusions

An instability has been observed in the field oxide of MOS microcircuits that has been attributed to a combination of positive mobile ions, probably sodium, and negative immobile ions that are due to a contaminant that is introduced during a high-temperature processing step such as oxidation.

The inversion voltage under metal lines over field oxide of commercially available MOS-integrated circuits can be degraded to the point where the operating voltage causes channeling between two isolated p-regions and degrades or fails the circuit (25).

The instability is found only in field oxides and therefore a test of stability of only the gate oxide is an insufficient test for the prediction of microcircuit reliability.

The manufacture of reliable MOS microcircuits requires (*a*) an understanding of the possible effects of negative-ion type instability, (*b*) the use of fabrication techniques which avoid ionic contamination in field oxides or include gettering techniques, and (*c*) routine quality control techniques to insure the stability of field oxides in completed devices.

ABSTRACT

Noncrystalline electrodeposits of Co-25 atomic per cent (a/o) W prepared from ammoniacal alkaline tartrate electrolyte were studied by x-ray diffraction. A model for the structure of this alloy was developed. The principal assumptions involved in constructing the model are based mainly on requirements for the electrodeposition. The model requires that the alloy consist of distinct basic structural units in the form of tetrahedra, each composed of three cobalt atoms and one tungsten atom. The dimensions of this structural unit correspond to those of the intermetallic compound Co_3W. Certain criteria govern the bonding of the tetrahedra to form larger aggregates. The scattering function calculated from the model agrees quite well with the diffraction data. The model also accounts for differences in the composition of amorphous deposits prepared at different current densities. The electrochemical requirements for the formation of this structure by electrodeposition are discussed. The operation of similar processes in the electro- or chemical deposition of other alloys having stoichiometric composition is considered.

Solid amorphous binary and ternary alloys of various compositions (1-4) can be prepared by several different techniques (1, 2, 5, 6). Many of these alloys have x-ray diffraction patterns which are very similar to one another. This implies similarities in the atomic distributions of the respective alloys. A number of structural models have been considered to describe these distributions (2, 7). In a rather exhaustive study (7) it has been shown that these models generally do not give satisfactory agreement with x-ray diffraction data or that they conflict with physical parameters of the material.

Recently it has been shown (8) that for Ni-P amorphous deposit a model consisting of a dense random packing of hard spheres (9, 10) yields an atomic distribution function (11) which agrees quite well with the pair distribution function deduced from x-ray diffraction data. It is believed (8) that similar agreement should be found for other amorphous alloys possessing similar diffraction patterns.

The dense random packing model in its present form is monatomic and treats all the atoms in the alloy as identical. Its usefulness in the case of Ni-P appears to be related to the following properties of the Ni-P alloy examined: (i) the difference in Goldschmidt atomic radii of Ni and P is small; (ii) the contribution of P to the scattered x-ray intensity is relatively small. Thus, in so far as atomic arrangement and x-ray diffraction are concerned, the phosphorus may be considered as a perturbation in a pure nickel amorphous structure.

The present paper deals with the structure of Co-25 a/o W alloy which has a diffraction pattern similar to that of the Ni-P. This Co-W alloy does not appear to satisfy the conditions required for the usefulness of the monatomic model approximation. Furthermore, from electrochemical and crystallographic considerations to be described, Co-25 a/o W amorphous deposit is expected to possess a distinctive short range order. The dense random packing model, even in a binary form which explicitly recognizes the existence of the two atomic species, would not adequately treat this crucial feature of short range order. Instead, a model for the structure of this alloy is developed entirely from electrochemical and crystallographic considerations. The scattering function of this model is then calculated and is compared with the experimental results from x-ray diffraction measurement.

In a previous paper (12) the relationship between cathode potential and structure of deposits in the electrodeposition of Co-W alloys was reported. Since that paper was published in Japanese, the pertinent results will be summarized here.

Electrodeposition of Co-W alloy from the ammoniacal alkaline tartrate electrolyte has two main electrode reactions. One reaction produces a cathode deposit which is a close-packed hexagonal solid solution containing up to 17.9 a/o W. The second reaction produces a noncrystalline deposit having the stoichiometric composition of Co_3W. The occurrence of these two reactions is a function of the cathode potential. Within a certain range of cathode potential both reactions may be operative and the deposit will consist of a mixture

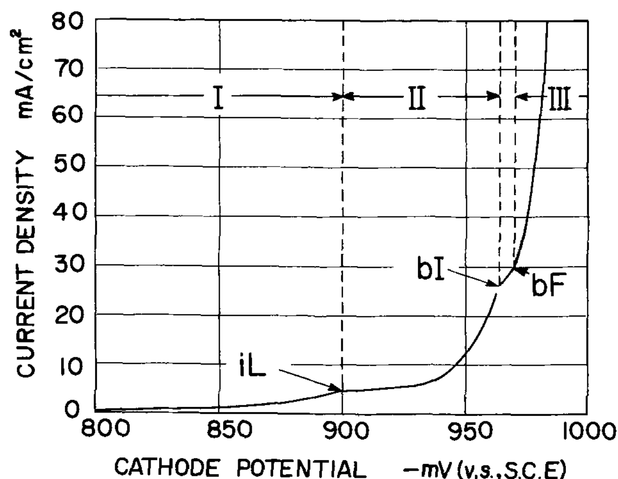

Fig. 1. *Initial current density vs. cathode potential curve for deposition of Co-W alloy from ammoniacal alkaline tartrate electrolyte.* [$(NH_4)_2C_4O_6H_4$, 0.260 M/L; Na_2WO_4, 0.247 M/L; $CoSO_4$, 0.013 M/L; at 80°C, pH 8.7]

of the two phases, *viz.*, noncrystalline phase and cph phase.

Figure 1 is the cathodic current density *vs.* potential curve for this system. There are three important ranges. In range I the cathode potential is less negative than at iL and the deposit consists only of the cph solid solution phase. In range II, from iL to bI, the deposit is a mixture of the cph and noncrystalline phases. Within range II the composition of the cph phase, as determined by gravimetric chemical analysis, remains constant at 17.9 a/o W. However, in going from iL to bI the fraction of noncrystalline phase in the deposit increases so that the total tungsten content of the deposit also increases; from 17.9 a/o W at iL to 22.2 a/o W at bI.

In ranges I and II the deposits are dense and can be electropolished to make thin foils for transmission electron microscopy. In deposits prepared at bI no crystalline phase is detectable by electron microscopy at higher magnifications or by selected area electron diffraction. (As will be explained in the Discussion, the deviation of the composition from that of Co_3W is probably due to excess cobalt rather than to the presence of cph phase.)

Deposits obtained in range III, where the cathode potential is more negative than bF, consist only of the noncrystalline phase having the stoichiometric composition of Co_3W. These deposits contain considerable amounts of hydrogen and, unlike the deposits of ranges I an II, are loose and cannot be prepared as thin foils.

It should be remarked that Fig. 1 is drawn for the particular case in which tungsten ions constitute 95% of the total metal ions in the solution, *i.e.*, W/(W + Co) = 0.95. The following deposition parameters were fixed in the experiment: ammonium tartrate 0.26 M/L; total metal concentration (sodium tungstate + cobalt sulfate) 0.26 M/L; *p*H = 8.7 as adjusted with ammonium hydroxide (all reagents were special grade); bath temperature 80.0° ± 0.2°C; no agitation. If the tungsten concentration is changed while keeping the total metal concentration fixed, the curve of Fig. 1 is displaced vertically; the current densities at iL, bI, and bF increase proportionally as the cobalt concentration increases. However, the values of cathode potential which define the boundaries of the three ranges are invariant. The three ranges with their respective deposit structures were observed to occur throughout a continuum of values of electrolyte tungsten concentration from 70-95%. Thus, the structure of the deposit depends chiefly on the cathode potential.

Deposits of various thicknesses ranging from about 10-50μ were prepared. Neither the composition nor x-ray scattering patterns showed any thickness dependence. Transmission electron diffraction patterns of deposits prepared at bI showed an essentially isotropic halo pattern characteristic of amorphous materials.

X-Ray Measurement and Results

For the present investigation noncrystalline deposits of about 20μ thickness were electrodeposited onto mild steel substrates. The electrolyte had a molar metal ratio of W/(W + Co) = 0.80. The deposition parameters were the same as in the previous work (12). Specimens were prepared potentiostatically at bI in region II and galvanostatically at a current density far above bF in region III. The thickness of 20μ was chosen so that the deposits would appear nearly infinite in thickness for the MoK_α radiation employed in the x-ray scattering measurements.

X-ray scattering data were measured at room temperature in air using a Rigaku Denki counter diffractometer equipped with the Type CN4133L generator. A rotating Mo target operated at a high output of 60 kV and 100 mA, a bent LiF monochromator in the diffracted beam, and a scintillation counter were used. Data were taken by a scanning at 1° of 2θ per min and reading the chart oscillations in steps of 0.2° 2θ. The amplitude of random oscillations for all the scattering angles was less than 85 electron units before damping correction. Fixed time counts were made at 20° 2θ (near the position of the first maximum) and at 90° 2θ. The ratio of these values compared well with the corresponding ratio taken from the chart.

Figure 2 shows experimental interference functions for two specimens; one prepared in region III (curve a) and the other prepared at bI in region II (curve b). These interference functions were extracted from the measured x-ray scattering data by the procedure described in the Appendix. The interference functions for the two specimens are very nearly the same in spite of the differences in over-all composition and occluded hydrogen. Therefore, all the deposits, those obtained at bI as well as those obtained in region III, may be considered to have essentially the same structure, *viz.*, amorphous Co_3W. Since the deposits have been found to be homogeneous and isotropic (12), the usual

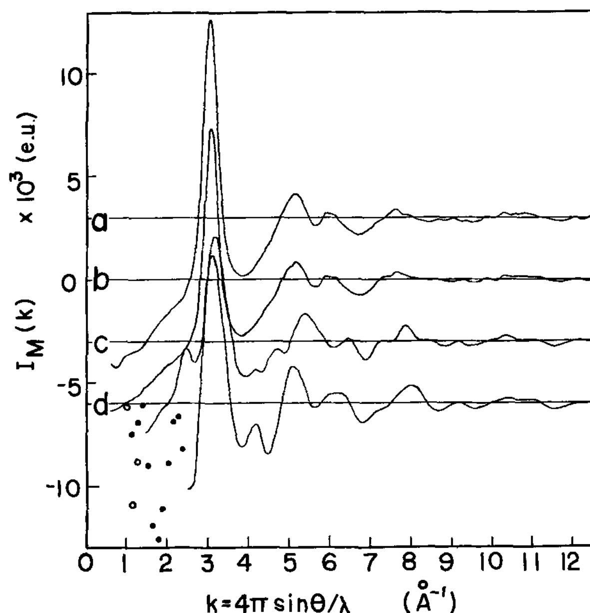

Fig. 2. *Comparison of calculated model interference functions (curves c, d) with experimental interference functions (curves a, b). Zeros of intensity are displaced. a, Specimen prepared in region III; b, specimen prepared at bI; c, 276 atom model aggregate; d, 104 atom model aggregate. techniques for analysis of diffraction patterns of amorphous materials are applicable.

It should be noted that the loose nature of deposits prepared in region III prevents accurate correction for x-ray absorption. Thus, curve b is to be preferred for comparison between experimental and theoretical interference functions.

Theoretical Calculations and Results

Model: Basic Unit

The calculation of the interference function, the double summation term in Eq. [A1], begins with the selection of a model. As indicated above, the noncrystalline phase may be considered to consist only of Co-25 a/o W alloy. A simple model will have as its basic structural unit a group of four atoms; 3 Co and 1 W. These may be arranged in the form of a tetrahedron with interatomic distances 2.560Å for Co-Co and 2.545Å for Co-W. These are the interatomic distances in the Co_3W ordered cph alloy (19) and they should be a good approximation for the amorphous alloy. Pauling (20) or Goldschmidt (21) atomic sizes are not used since transition elements have marked electronic uncertainty, especially on alloying (22). This tetrahedral model is consistent with the observed homogeneity of the deposit (12) and with the location of the first maximum in the x-ray scattered intensity distribution.

An additional reason for the choice of a clustered arrangement comes from the fact that tungsten does not electrodeposit by itself from aqueous solutions (23) although cobalt and cobalt-tungsten alloys do. The tetrahedral basic unit permits each tungsten atom to be surrounded by cobalt atoms in the deposit.

Model: Aggregate

Having assumed a basic structural unit, the tetrahedron formed by three cobalt atoms and one tungsten atom, it is necessary to consider the conditions which govern the bonding of basic units to form larger aggregates. One condition, which shall be called Criterion I, is that for a given number of basic units the most stable of all possible aggregates will be the one having the maximum number of first nearest neighbor bonds. (If two or more possible aggregates have the maximum number of first nearest neighbor bonds, then the one with the maximum number of second nearest neighbor bonds will be the most stable.) Differences in atomic species are neglected. Criterion I has been shown to be valid for pairwise interactions involving Morse or Lennard-Jones potentials (24). Criterion I was implicitly applied in the choice of a tetrahedron as the basic unit.

According to Criterion I, when an additional basic unit is added to a pre-existing aggregate (which may consist only of one basic unit and which may include substrate atoms), one atom of the unit must bond to a tetrahedral site on the aggregate. Such tetrahedral sites are formed when three atoms on the aggregate surface are bonded in the form of a triangle. Keeping in mind the facts that tungsten cannot electrodeposit by itself from aqueous solutions and that the aggregate has the stoichiometric composition of Co_3W, Criterion II is introduced: deposition of a tungsten atom is preceded by the deposition of three cobalt atoms which form a triangular array to provide a tetrahedral site for the tungsten atom. Criterion II perimits tungsten atoms to deposit only on tetrahedral sites formed by three cobalt atoms. Cobalt atoms, however, can deposit on any tetrahedral site. Although Criterion II is reasonable for small aggregates, it may be somewhat too restrictive when large aggregates are considered. Nevertheless, the criterion is expected to be satisfied most of the time and departures from the criterion in large aggregates should not greatly alter the scattered intensity distribution.

Figure 3 illustrates the way in which an additional basic unit may bond to a pre-existing aggregate. First one atom of the unit bonds to a tetrahedral site. Then

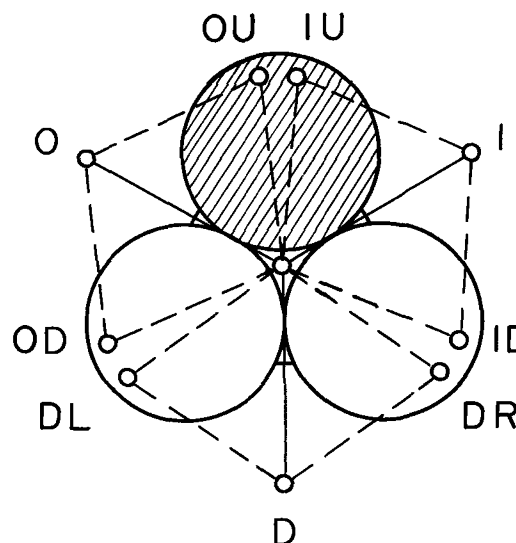

Fig. 3. Illustration of possible bonding sites on tetrahedron

the additional atoms of the unit take up positions so as to maximize the number of first nearest neighbor bonds. Thus, Criterion I is satisfied. In Fig. 3 the three large circles represent atoms on the aggregate surface which form a tetrahedral site. The shaded circle is a tungsten atom. The assumed growth sequence is that three cobalt atoms bond to the aggregate to form a new tetrahedral site which can be occupied by a tungsten atom (Criterion II). The first cobalt atom bonds to the tetrahedral site on the aggregate (center of figure). The second cobalt atom may bond to any of three possible sites; I, O, or D. Once the second atom is bound to one of these three sites, the third atom can bond to either of two sites. For example, if the second atom bonds to site I, the third atom can bond to site IU or to site ID. Although the order in which the three cobalt atoms bond is immaterial, a new tetrahedral site for the tungsten atom can be formed only if the three cobalt atoms take up one of six possible configurations indicated in Fig. 3.

Construction of model aggregate and the calculation of model interference function.—The assumed bond lengths in the basic structural unit were 2.560Å for Co-Co and 2.545Å for Co-W. The difference in these bond lengths, less than 1%, was neglected and a normalized bond length of 2.550Å was chosen for construction of model aggregates as well as for the calculation of model interference functions. This value for the bond length is an average arrived at by assigning the Co-W bond length twice the weight of the Co-Co. This weighing factor approximates the relative frequencies and relative scattering power of Co-W and Co-Co pairs.

The calculation of a model interference function $I_M(k)$ should be done using measured r_{ij} data obtained by selecting each atom in turn as an origin and measuring the distances to all the other atoms in the model. r_{ij} data thus obtained directly give the radial distribution function (RDF) if the model is large enough compared to the atomic size. The size of the model aggregate to be constructed is, however, limited. A significant distinction between small and large aggregates is that in the former the number of atoms lying at or near the surface of the aggregate is a large fraction of the total number of atoms. Therefore, the over-all shape of the model should be nearly spherical so that the environment of an interior atom of a very large aggregate can be represented with a minimum number of spheres.

To compute the model interference function, the atomic pair distribution function (PDF) of the model was measured. This was done by selecting one of the

interior spheres as an origin and measuring the distances to all the other spheres. These distances were normalized to give the actual interatomic dimensions. This procedure was repeated to obtain the PDF's with respect to four different interior atoms, three cobalt atoms, and one tungsten atom. The sum of the four PDF's, which should be approximately proportional to the RDF of a very large aggregate, was used to compute the model interference functions.

Two different model aggregates were constructed according to the prescription described in the preceding section and the model interference functions were computed. The calculations were performed with the aid of a TOSBAC 3400/41 computer.

The first model was built using 276 rigid spheres representing 207 cobalt atoms and 69 tungsten atoms. In constructing this model, the configurations between the pre-existing aggregate and additional basic units were chosen in a random manner within the restrictions of Criterion II. This procedure simulated the obstructive effects of the codepositing hydrogen on surface diffusion and choice of stable deposition sites for cobalts. Particular attention was paid to make the aggregate as dense as possible. Nevertheless, it was found to be impossible to prevent the formation of clearances or voids that could accommodate several atoms. In this model, Criterion II was strictly adhered to. Criterion I, however, was not rigidly maintained.

The second model was built using 104 rigid spheres representing 78 cobalt atoms and 26 tungsten atoms. It was intended to satisfy Criterion I. Certain restrictions were imposed in construction of this model. Three additional units were added to a unit (designated as the base) with the relation OU and satisfying Criterion II. To each of those three units further addition of three units was made with the same relation OU. Thirteen more units were added to make the aggregate as dense as possible and spherical. Criterion II was strictly adhered to. Though the occurrence of clearances was unavoidable, the resultant aggregate is believed to be the densest of numerous configurations examined.

The calculated model interference functions for the 276 and 104 atom aggregates are shown in Fig. 2 as curves c and d, respectively. In computing these functions, the measured PDFs were arbitrarily terminated at 12Å for the 276 atom model and at 9Å for the 104 atom model.

Discussion

The curves a and b in Fig. 2 are the experimental interference functions of specimens prepared in region III and at bI, respectively. As previously explained, absorption corrections for specimens prepared in region III are subject to some inaccuracy. Therefore, curve b is to be preferred for comparison with the calculated interference functions c and d. Such comparison shows that the 276 atom curve gives poor agreement with the experimental curve at lower scattering angles. At higher angles, however, the agreement is better and there is complete consistency of phase. The 104 atom curve gives quite good agreement over the entire angular range. The sharpness of the first maximum ($k = 3.1$) is reproduced quite well in both calculated curves. This serves to justify the choice of PDF used in the calculation. The additional small bumps at low angles in the calculated curves, where the contributions from the longer interatomic distances are significant, are probably termination effects.

For purposes of calculation it was assumed that the RDF of a very large aggregate could be represented by the sum of the PDF's with respect to four different interior atoms in the model aggregate. It should be mentioned that there were noticeable differences between those four PDF's. Thus, the sum may differ somewhat from the RDF of a very large aggregate. This may be responsible for some of the disagreement between the experimental and calculated interference functions.

The fundamental features of the model may be summarized as follows: (i) the alloy consists of basic structural units in the form of tetrahedra, each composed of one tungsten and three cobalt atoms; (ii) the deposition of a tungsten atom is preceded by the deposition of three cobalt atoms which form a triangular array to provide a tetrahedral site for the tungsten atom (Criterion II); (iii) the bonding energy of an aggregate should be minimized by maximizing the number of first nearest neighbor bonds (Criterion I) or by some other dense packing of the tetrahedra subject to the limitations imposed by (i) and (ii). These three assumptions seem reasonable in view of the justifying evidence already presented.

It should be noted that the aggregates constructed using the above rules exhibit neither crystal symmetry nor translational invariance. They do not correspond to the model of randomly stacked close-packed planes (ii).

As indicated above, the model was deduced from the existence of tetrahedra and from the rules that dominate the geometry during the coagulation of atoms of different species. These features of the model result in certain similarities to the model of dense random packing of hard spheres (11). The dense random packing model is the structure that rigid balls assume when they are poured into a vessel and vibrated to attain dense packing. This model was initially developed independently by Scott (10) and Bernal (11) for the structure of liquids.

The principal difference between the present model and the dense random packing model is that the present model deals explicitly with the existence of two atomic species with a distinct short-range order. The consequence of this is the existence in the present model of clearances and voids that can accommodate several atoms. This is impossible in Bernal's model. In contrast to the procedure of the present paper, Bernal extracted a statistical geometry describing the atomic arrangement in dense random packing. This statistical geometry consists of five polyhedral, arrays of atoms. Of these five Bernal polyhedra, the tetrahedron has the highest frequency of occurrence, 73%. In the present model the choice of basic structural unit (tetrahedron) and bonding rules (Criteria I and II) result in a preponderance of tetrahedrally arranged atoms. Some other polyhedra also form, such as at clearances and voids.

In view of the points that were mentioned here, the present model is new and different from the model of dense random packing. A short range order should also be considered in the case of the Ni-P system since evidence suggesting short-range order in Ni-P noncrystalline deposits has already been found (25, 26).

As previously mentioned, large aggregates will contain voids. These occur even when a conscientious effort is made to keep the aggregate as dense as possible. The voids are believed to contribute to the loose nature of deposits formed in region III (Fig. 1). Codepositing hydrogen is also expected to play a role in producing looseness at these higher current densities. The noncrystalline deposits formed at bI in region II are dense rather than loose. They also have an overall composition which is richer in cobalt, containing only 22.2 a/o W. These differences are attributed to excess cobalt filling in the voids of the deposits made in region II. Since individual voids are not expected to be large enough to accommodate more than a small number of cobalt atoms, the presence of the excess cobalt would not effect the observed scattered intensity distributions.

One must consider the character of the electrochemical processes for the formation of the homogeneous deposit at the stoichiometric composition Co_3W. Obviously, the basic unit composed of three cobalt atoms and one tungsten atom arranged in a tetrahedron is formed by the preferred deposition of tungsten on the tetrahedral site formed by the cobalt triangle. It should be noted that two features, (i) the deposition

sequence deduced from the empirical fact that cobalt can deposit by itself from aqueous solutions but tungsten cannot, and (ii) the specific site at which tungsten bonds, should both be strictly adhered to otherwise the tetrahedral structure and stoichiometric composition cannot exist.

The triangular array of three cobalts can form anywhere on the surface of the electrode by the diffusion of three deposited cobalts. Thus, for the formation of Co_3W, there must be a high probability that a tungsten bonds to the site formed by the cobalts regardless of where on the surface the triangle forms. This implies that everywhere near the surface the concentration of cobalt is nearly zero while the concentration of tungsten is finite. Such a situation will prevail if deposition of cobalt is a diffusion controlled process and if tungsten forms an adsorbed layer over the entire electrode surface. Since the basis supporting this electrochemical process (a diffusion controlled process and an adsorbed surface layer) is only geometrical, it should be independent of the following factors: (*a*) whether the process is electro- or chemical deposition; (*b*) whether the deposit is crystalline or noncrystalline; (*c*) what atomic species are involved; and (*d*) what the stoichiometric composition is. Thus an analysis of an electrochemical process will have a simplification if the deposit is found to have any fixed stoichiometric composition in the as-plated conditions.

It should be noted that the unquestionable existence of cobalt triangles to provide sites for the deposition of tungsten is in accordance with the recent (27) but classical (28) assumption that chemisorption, which should be required for catalytic action, involves more than one transitional metal-ion. Thus, the existence of the cobalt triangle is believed to give support for the catalytic interpretation of the deposition process of reluctant metals (29-31). There is no final agreement as to the mechanism by which the deposition of reluctant metals occurs, and the catalytic hypothesis is merely a restatement of the phenomenon with the unknown factors termed catalytic (32, 33). Though there is a basic problem of why the triangular array (34) of cobalt is stable in the electrodeposition of Co-W alloy, the explanation given here supports the concepts of catalytic action of freshly deposited iron group metals. Furthermore, the existence of an adsorbed layer, which was deduced here, is in accordance with considerations described elsewhere (29, 31, 35-37). The idea of cobalt deposition being diffusion controlled is not inconsistent with the formation of intermetallic compounds by electrodeposition at high current densities (38).

APPENDIX

Treatment of X-ray Scattering Data

As indicated, the samples are considered to be noncrystalline alloys formed by the units of three Co atoms and one W atom. The x-ray scattered intensity at T = 0°K is

$$I(k) = I_e \left\{ \sum_i f_i^2 + \sum_{i \neq j} \sum f_i f_j \frac{\sin (kr_{ij})}{kr_{ij}} + \sum_i S_i \right\} \quad \text{[A1]}$$

where $k = 4\pi \sin \theta/\lambda$; r_{ij} is the distance between atoms i and j; f_i and S_i are, respectively, the scattering factor and inelastic scattering intensity of atom i; and I_e is the intensity scattered by an isolated electron. The summations are carried out over all atoms in the diffracting volume. The first two terms on the right side of Eq. [A1] are the Debye formula (13).

Due to thermal agitation, the double summation term in [A1], which shall be called the model interference function $I_M(k)$, suffers Debye-Waller damping (14). At a temperature T(°K), $I_M(k)$ may be expressed as $[I_M(k)]_T$

$$[I_M(k)]_T = \sum_i f_i^2 [1 - \exp(-2M)] + I_M(k) \exp(-2M) \quad \text{[A2]}$$

The value of B (15) involved in the Debye factor, $\exp(-2M) = \exp[-2B(\sin \theta/\lambda)^2]$, is a calculated mean value weighted by the alloy composition. At 300°K the value of B equals 0.44 for the alloy prepared at bI and 0.43 for the alloy prepared in region III.

The single summation terms in [A1] and the summation term in [A2] are the independent coherent, incoherent, and thermal diffuse scattering, respectively. These are determined by the alloy composition and are independent of the structure. The only term which is determined by the structure is the double summation term $I_M(k)$. The value of this term is determined by the atomic arrangement in the material, *i.e.*, the values of r_{ij} which occur and their frequency of occurrence as well as the distribution of atomic species.

In this paper the interference functions $I_M(k)$ for two differently prepared samples are experimentally obtained by the procedure described below. The experimental interference functions are compared with the calculated model interference functions. No attempt is made to obtain an experimental radial distribution function (RDF).

The measured intensity data were corrected for air scattering, polarization, and absorption. The corrected intensities are proportional to $I(k)$ of [A1] in which $[I_M(k)]_T$ is involved in the double summation term. The intensity was normalized to electron units by assuming that at high scattering angles ($k > 10 Å^{-1}$)

$$I(k)/I_e \approx \sum_i \{f_i^2 + S_i + f_i^2 [1 - \exp(-2M)]\} \quad \text{[A3]}$$

Monochromator attenuation of Compton scattering at higher angles (16) was neglected. $I_M(k) \exp(-2M)$ was obtained from the normalized intensity by subtraction of all the single summation terms, *viz.*, right side of [A3]. Multiplication by the inverse of the damping, exp (2*M*), gave the experimental interference function, $I_M(k)$.

In the treatment of the intensity data, linearly interpolated literature values were used for f_i (17) and S_i (18). The same values of f_i were used in the calculation of the model interference functions.

On the Uniformity of Phosphorus Emitter Concentration for Shallow Diffused Transistors

P. C. Parekh[1]

Sylvania Electric Company, Woburn, Massachusetts 01801

ABSTRACT

The variables affecting the uniformity of sheet resistance for a two-step shallow phosphorus emitter diffusion were examined. The source used was $POCl_3$. The uniformity of sheet resistance (and hence surface concentration) was predominantly dependent on the variables during the deposition process. These were oxygen and nitrogen flow, wet nitrogen flow and temperature of deposition. The latter ranged from 700° to 860°C. A comparison was made of the variables that affect phosphorus, boron, and arsenic depositions. The behavior of oxygen on the sheet resistance profile during phosphorus deposition was different from that observed for boron and arsenic depositions.

Recently considerable attention has been devoted to the fabrication of shallow diffused high-speed integrated circuits. Here the use of small components coupled with submicron diffusions places a considerable demand on the fabrication technology. In some recent work it has been shown that the uniformity of boron (1) and arsenic (2) diffusions is governed by the deposition variables. By optimizing these variables a desired control of surface concentration can be achieved. In this paper the variables controlling the uniformity of phosphorus emitter diffusion (using $POCl_3$ as a source) for shallow diffused transistors are investigated.

Experimental Conditions

The temperature of deposition was varied from 700° to 860°C. Drive-in was performed in dry oxygen at 1040°C. In all cases the time of deposition was 30 min while the time of drive-in was 10 min. The final junction depth was 0.8μ.

Figure 1 shows the arrangement of the source bottle and the deposition furnace tube used in this experiment. A major portion of the nitrogen and oxygen gases (designated here as carrier gases) was introduced into the furnace tube at room temperature. In some cases wet nitrogen gas (designated at N_2/H_2O) was introduced by bubbling nitrogen gas through a water container maintained at 20°C. A fixed quantity of nitrogen gas (designated as N_2/source, flow rate = 200 cm³/min) flowing parallel to the surface of the $POCl_3$ liquid was used to introduce the $POCl_3$ vapor into the furnace tube at point A as shown in the figure. The temperature at position A varied from 500° to 680°C, the precise value was dependent on the temperature of the constant zone. The source bottle was maintained at 20°C.

The starting material was 2-in. diam n-type substrates of resistivity 0.2 ohm-cm and (111) orientation.

The wafers were diffused with a uniform shallow boron base diffusion with a surface sheet resistance of 300 ohm/sq. A flat boat 16 in. in length was loaded

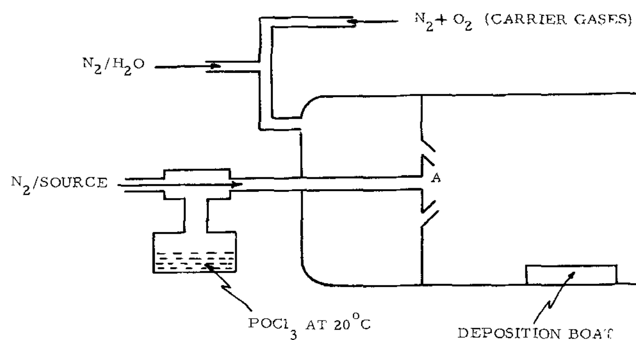

Fig. 1. Geometry of the source bottle and the deposition furnace tube.

[1] Present address: Raytheon Company, Microwave Transistor Group, Spencer Laboratory, Burlington, Massachusetts 01803.

Key words: silicon, sheet resistance, $POCl_3$.

with these wafers and placed into a furnace tube for phosphorus deposition. The wafers were labeled to identify their position in the furnace tube. After 30 min of deposition, the wafers were driven at 1040°C for 10 min.

Some recent work has shown that the uniformity of diffusion is predominantly dependent on the variables during the deposition process (1, 2). Thus anomalous behavior during deposition can be detected after the drive-in diffusion by measuring sheet resistance, r_d, and junction depth, X_j. This was accomplished by the four-point probe method. The junction depth was measured using angle-lapping techniques and an interference microscope. From these measurements surface concentration, C_0, (for a gaussian distribution) was obtained using Irvin's curves (3).

The uniformity of the diffusion is indicated by variations in surface concentration, C_0, within a slice and from slice to slice. For a specific drive-in diffusion, the surface sheet resistance, r_d, is a good indication of the surface concentration involved. However, slight discrepancies may be observed for the following cases: (I) A nonuniform diffusion results in large variations in the concentration gradient within a slice and from slice to slice. This in turn causes variable junction depths, X_j. If a fixed value of X_j is chosen to evaluate C_0, erroneous results are obtained. (II) When concentrations exceed the solid solubility limit in silicon at the diffusion temperature, sheet resistance measurements in general indicate a lower value of concentration than is actually present. This is due to the formation of phosphorus and silicon-phosphide precipitates. From the above cases uncertainty may exist in obtaining correct values of surface concentration in some instances. For most cases, however, the variation of r_d (after the drive-in diffusion) can be taken as a good indication of the surface concentration involved.

Results and Discussion

Factors Affecting the Uniformity of Diffusion

Recently, several workers (4-6) have considered the variables affecting the uniformity of phosphorus diffusion. Heynes and Wilkerson (4) used $POCl_3$ as a source and observed that the oxygen concentration was a critical parameter for deposition temperatures $\leq$1000°C. They also observed that in the absence of oxygen, etching of silicon occurred due to by-products formed by disassociation of $POCl_3$. In addition, this was accompanied by high sheet resistance values. Heynes and Van Loon (5) and Kesperis (6) observed that in a phosphine system, the presence of oxygen was essential in achieving good diffusion characteristics. In addition, increasing the oxygen concentration increased sheet resistance indicating that an increasing amount of SiO_2 was formed.

Also recently, in a two-step investigation of boron (1) for base diffusion (using BBr_3 as a source) and arsenic (2) for buried layer diffusion (using $AsCl_3$ and tetraethyl orthosilicate as the sources) three points were observed: (*I*) Increasing the oxygen concentration during deposition increased the rate of formation of B_2O_3 or As_2O_3. This shifted the position of the zone of uniform sheet resistance toward the source end of the deposition tube. The "zone of uniform sheet resistance" is defined as that part of the furnace tube in which the rate of deposition of B_2O_3 or As_2O_3 on the wafers is maximum. This is indicated by the maximum glass thickness after deposition and the lowest value of r_d after the drive-in diffusion. (*II*) Increasing the deposition temperature increased the rate of formation of B_2O_3 or As_2O_3, thus shifting the position of the zone of uniform sheet resistance toward the source end of the tube. (*III*) Increasing the nitrogen carrier flow shifted the position of the zone of uniform sheet resistance toward the open end of the tube.

From the above observations, the basic role of oxygen in the two systems is to change the rate of formation of B_2O_3 or As_2O_3. No appreciable oxidation of silicon, which could lead to high sheet resistance, was observed. In the subsequent discussion, it will be shown that oxygen did not influence the rate of formation of a phosphorus species in the furnace atmosphere. However, the presence of wet nitrogen considerably increased the rate of formation of such a species leading to lower sheet resistance.

The influence of oxygen flow on sheet resistance profile across the deposition boat.—Figure 2 shows the r_d profile across the deposition boat for a deposition temperature of 860°C. In one set of curves, the carrier gas was only oxygen with a flow rate of 1800 cm³/min, while in the second set of curves, the carrier gas was only nitrogen with a similar flow rate. As indicated earlier, in both cases the N_2/source flow rate was 200 cm³/min. In the figure the zero reference of the boat is taken as that end nearest the gas inlet of the furnace tube (source end) while the numbers on the horizontal axis indicate the distance in inches from the zero reference to the center of a slice. From the figure, the following points may be observed: (*I*) Stripping glass prior to drive-in diffusion increases sheet resistance as expected. (II) Heynes and Wilkerson (4) observed that in the absence of O_2 and using $POCl_3$ as a source, a considerable amount of damage due to etching during deposition was observed. This was accompanied by shallow penetration of junctions and high sheet resistance. In this investigation, in the absence of O_2, no surface damage such as etching of wafers was observed after deposition. In addition, the lowest value of r_d and the highest value of X_j were observed. The degradation of diffusion observed by Heynes and Wilkerson (4) may have been due to excessive $POCl_3$ present in the furnace atmosphere. From Fig. 1 it can be seen that N_2 gas carries vapor of $POCl_3$ into the furnace tube. This is unlike most $POCl_3$ systems used where N_2 gas is bubbled through $POCl_3$ liquid. This causes an excessive amount of $POCl_3$ to enter the furnace, resulting in the formation of large amounts of chlorine which leads to surface damage. The surface concentration (after the drive-in diffusion) in Fig. 2 in the absence of O_2 was 7×10^{20} atoms/cm³ when glass was not stripped (thickness <500Å) prior to the drive-in diffusion. (*III*) $POCl_3$ partially disassociates into its constituents. The disassociation products are

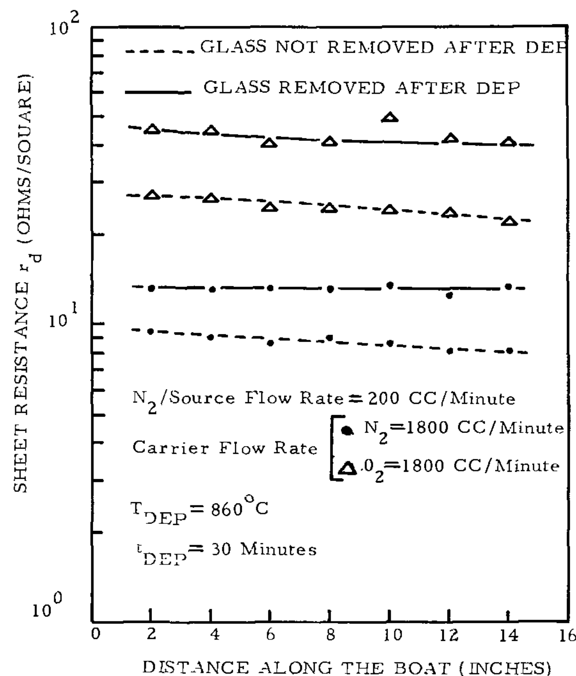

Fig. 2. Sheet resistance, r_d, profiles along the deposition boat with nitrogen and oxygen as the carrier gases. The drive-in temperature and time are 1040°C and 10 min, respectively.

P_4O_6, PCl_3, and Cl_2. P_4O_6 in turn disassociates into P_2O_4 and red phosphorus by the following reaction (7)

$$2P_4O_6 \rightarrow 3P_2O_4 + 2P \text{ (red)}$$

The above compounds react with O_2 to form phosphorus pentoxide. Note that the point of contact between the phosphorus species and O_2 is at point A (temperature 680°C) as shown in Fig. 1.

The rate of formation of phosphorus pentoxide should be dependent on the O_2 concentration. Varying the O_2 flow rate should shift the position of the zone of uniform sheet resistance as in boron (1) and arsenic (2) diffusions. In the present work increasing the O_2 concentration increased sheet resistance uniformly on all slices across the boat while the position of the zone of uniform sheet resistance was insensitive to O_2 variations. In addition, the glass thickness on wafers after deposition remained constant (as observed visually, thickness <500Å) for different O_2 concentrations.

The influence of deposition temperature on sheet resistance profile across the deposition boat.—The rate of formation of phosphorus species (P_4O_6, P_2O_4, red phosphorus) in the furnace atmosphere is dependent on the temperature of deposition. This in turn profoundly affects the sheet resistance profile across the deposition boat, which was previously illustrated for boron (1) and arsenic (2) diffusions. Figure 3 shows the variation in sheet resistance profile across the deposition boat for phosphorus at deposition temperatures of 700°, 760°, and 860°C. Here no oxygen was used. From the figure, the following points can be observed: (*I*) toward the source end of the tube, sheet resistance is high for a deposition temperature of 700°C. As the gases proceed toward the open end of the tube, increasing amounts of phosphorus species are formed causing a reduction in sheet resistance. (*II*) For a deposition temperature of 860°C, the rate of formation of phosphorus species is enhanced, resulting in a low sheet resistance value across the deposition boat. The surface concentration here was calculated to be $\sim 10^{21}$ atoms/cm^3 indicating that the solid solubility limit of phosphorus in silicon was reached. (*III*) In the boron (1) and arsenic (2) depositions, the sheet resistance after the drive-in diffusion was correlated with the glass deposited after deposition. In Fig. 3, no glass was visually observed for a deposition temperature of 700°C, but for 860°C the thickness was approximately 500Å.

The influence of carrier gas velocity on sheet resistance profile across the deposition boat.—In the boron base system (1) increasing the carrier gas velocity shifted the position of the zone of uniform sheet resistance toward the open end of the tube. However, no increase in sheet resistance was observed due to dilution of B_2O_3 in the furnace atmosphere. This is a result of having a sufficient amount of B_2O_3 present even at the higher gas velocity. In the case of the arsenic deposition (2), the position of the zone of uniform sheet resistance shifted toward the open end of the tube upon increasing the N_2 carrier gas velocity. However, a decrease in surface concentration was obtained. This is thought to be due to an insufficient amount of As_2O_3 present when the gas velocity is increased. Similar behavior was observed here for the phosphorus system. Increasing the gas velocity shifted the position of the zone of uniform sheet resistance toward the open end of the tube. However, considerable dilution of phosphorus species in the furnace atmosphere was observed, thus increasing the sheet resistance. This is shown in Fig. 4 where r_d after the drive-in diffusion is plotted *vs.* nitrogen carrier flow rate for deposition temperatures of 760° and 860°C. For these two cases, approximately similar sheet resistances (solid solubility range) were observed for a nitrogen carrier flow rate of 300 cm^3/min when no glass was removed prior to drive-in diffusion. This indicates that the glass deposited at the lower deposition temperature was sufficiently doped for the surface concentration to attain the solid solubility limit. The decrease in the formation of the phosphorus species at the lower deposition temperature and at the higher nitrogen gas flow is apparent from the figure. When glass was stripped, prior to the drive-in diffusion, a higher sheet resistance was observed for both deposition temperatures as expected.

The influence of wet nitrogen flow on sheet resistance profile.—In the presence of a wet N_2 flow (with no

O_2 present) the phosphorus specie formed by the dissassociation of $POCl_3$ reacts with H_2O (7)

$$P_2O_4 + 2H_2O \rightarrow H_3PO_3 + HPO_3$$

to form phosphorus and metaphosphoric acid. The former is immediately converted into orthophosphoric acid by the reaction

$$4H_3PO_3 \rightarrow 3H_3PO_4 + Ph_3$$

In general, the reaction of wet N_2 with P_2O_4 produces a series of mixtures such as orthophosphoric acid, present over the entire range of $P_4O_{10} \cdot 6H_2O$ to $P_4O_{10} \cdot 2H_2O$; triphosphoric acid, $H_5P_3O_{10}$, likewise present over the entire range; phyrophosphoric acid, $H_4P_2O_7$, present up to 85% weight per cent (w/o) P_4O_{10}, and one or more polymers of metaphosphoric acid, $(HPO_3)_n$, present at P_4O_{10} compositions above 83%.

Figure 5 shows the distribution of sheet resistance across the deposition boat in the presence and absence of wet nitrogen flow. In the former case, 150 cm^3/min of nitrogen gas was bubbled through a water bath maintained at room temperature. The deposition temperature was 700°C and no oxygen was used. In the absence of wet nitrogen, no glass was visually observed after deposition. In the presence of wet nitrogen, the wafers toward the source end of the tube had a coating of 1300Å of glass, while on those toward the open end of the tube the coating was 600-700Å. The wafers were processed through the drive-in diffusion without stripping the glass. The effect of adding the wet nitrogen was to shift the position of the zone of uniform sheet resistance, r_d, toward the source end of the tube. Here, the glass formed consisted of complex compounds of the P_2O_5-H_2O system as described before. The concentration of these compounds deposited on the surface of the wafer was determined by their partial pressure in the gas. The partial pressure of the phosphorus specie formed in the presence of wet nitrogen far exceeds that formed when no wet nitrogen was added to the system.

Similar results, as indicated, were obtained when oxygen replaced nitrogen as the carrier gas. This is illustrated in Fig. 6 for a deposition temperature of 760°C. The adddition of wet nitrogen decreased the

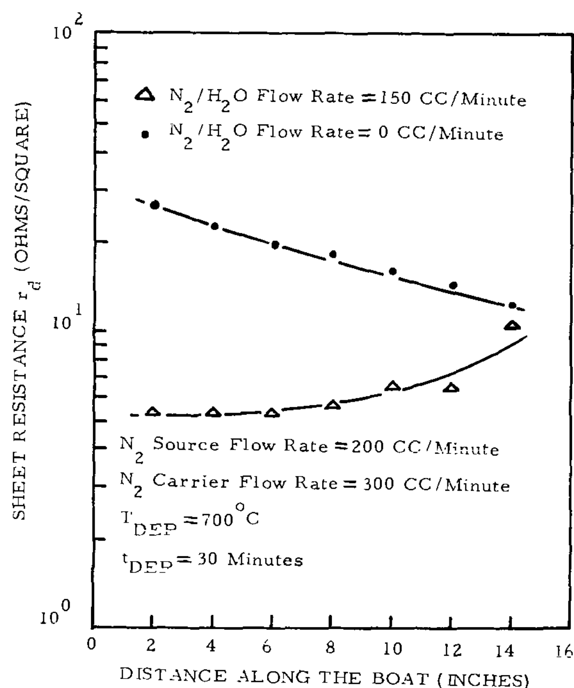

Fig. 5. Sheet resistance, r_d, profiles along the deposition boat with the presence and absence of N_2/H_2O flow using N_2 as the carrier gas. The drive-in temperature and time are 1040°C and 10 min, respectively.

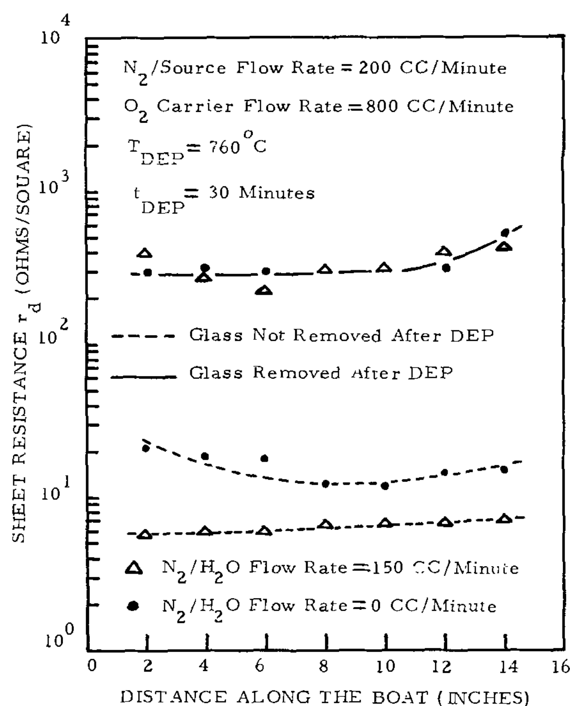

Fig. 6. Sheet resistance, r_d, profiles along the deposition boat with the presence and absence of N_2/H_2O flow using O_2 as the carrier gas. The drive-in temperature and time are 1040°C and 10 min, respectively.

sheet resistance considerably. No glass was detected in the absence of wet nitrogen; however, in the presence of wet nitrogen, the thickness of the deposited glass was approximately 1400Å. The dotted line in the figure shows the sheet resistance profile when glass was not removed prior to the drive-in diffusion. The solid line shows the case when glass was removed prior to drive-in diffusion. It can be seen that no difference in sheet resistance was recorded for the latter case between the absence and the presence of wet nitrogen. This indicates that at the temperature of deposition additional penetration of phosphorus into silicon did not occur when wet nitrogen was used. These results appear to contradict the predictions of Heynes and Van Loon (5) who indicated that phosphorus pentoxide and phosphoric acids are expected to be equally reactive with a silicon surface. However, a parallel analogy exists in the present work and Heynes' work on boron diffusion (8). The presence of water assisted in the distribution of doping through the formation of boric acids which are much more volatile than the B_2O_3 formed by the reaction of BBr_3 and O_2. The result was that higher surface concentrations were achieved when water was present.

Formation of Phosphorus Skin

The formation of arsenic (2) and boron (9) skins have been reported in the literature. Their occurrence is a result of the formation of a high rate of B_2O_3 or As_2O_3. In the present experiment under certain conditions the presence of a phosphorus skin (insoluble in HF) was observed. These conditions were low temperature of deposition, low carrier flow rate, and the presence of wet nitrogen.

Degradation of Device Parameter

The need for phosphorus emitter surface concentrations $\leqq$ the solid solubility has been emphasized by several workers. Lawrence (10) observed that the enhanced diffusion of base impurities (emitter dip effect) was attributed to excess vacancies in the base region generated by dislocations formed during the emitter diffusion. Recently, it was observed (11, 12) that degradation in Δh_{FE} [$\Delta h_{FE} = h_{FE}(T_2)/h_{FE}(T_1)$, $T_2 > T_1$] occurred as the phosphorus emitter concen-

tration increased. This has been attributed to a decrease in energy band gap in the emitter region upon increasing the phosphorus concentration. The formation of emitter edge dislocations due to high concentration phosphorus diffusion has been recently discussed (12-14). The increase in junction leakage current in the presence of these dislocations and the degradation of several transistor parameters clearly indicate the need for a well-controlled low concentration phosphorus emitter diffusion. The system presented in Fig. 1 is clearly capable of achieving a wide range of concentrations at and below the solid solubility limit.

Conclusion

For deposition temperature ranging from 700° to 860°C, the presence of O_2 increased sheet resistance while the deposited glass thickness was generally less than 500Å. In the presence of wet N_2, high surface concentrations resulted with a deposited glass thickness of 1300-1400Å. The position of the zone of uniform sheet resistance was affected by the introduction of moisture; however, it was insensitive to the presence of O_2. The position was also affected by varying the phosphorus deposition temperature when no O_2 or moisture were present.

It can be concluded that any reaction of O_2 with $POCl_3$ or its constituents appears to have no affect on surface concentration. The influence of O_2 is in masking the diffusion of phosphorus into silicon.

Electrochemical Reduction of Benzofuroxan

I. Aqueous Solutions

C. D. Thompson* and R. T. Foley**

Chemistry Department, The American University, Washington, D.C. 20016

ABSTRACT

Constant potential reductions of benzofuroxan in acidic, neutral, and basic solutions over a stirred mercury pool electrode were followed by analysis of the products. The primary product was o-benzoquinone dioxime which was further reduced to 2,3-diaminophenazine and o-phenylenediamine in proportions which vary with the pH. Fast sweep voltammograms and data of other investigators suggest that the reduction of the dioxime proceeds through an o-benzoquinone diimine intermediate which further reduces or couples to yield the observed products.

Previous studies of the electrochemical reduction of benzofuroxan (BFO) include polarographic work at a dropping mercury electrode (DME) by Schindler (1) and Levin (2) and battery depolarizer work by Hardy (3) and Shaw (4). Schindler found that BFO reduced in two waves throughout the *p*H range from 1.24 to 9.90. The first wave corresponds to a two-electron reduction which was ascribed to formation of o-benzoquinone dioxime (ODI) on the basis of the spectrum and electrochemical behavior of the reduced solution. However, the height of the second wave was *p*H dependent. At *p*H's below about 4.5 or above 7.8, the height of the second wave indicated a further six-electron reduction, presumably to o-phenylenediamine (OPD). Between *p*H 4.5 and *p*H 7.8 the wave height indicated only a four-electron reduction, for which no explanation was given. The top line in Fig. 1 shows this relationship between polarographic current and *p*H from data extracted from Schindler's paper (1).

This paper presents data for constant potential reductions of aqueous BFO solutions over a stirred mercury pool electrode at various *p*H values. Reductions performed at voltages more negative than the crest of the second polarographic wave resulted in an insoluble precipitate which was isolated and identified as 2,3-diaminophenazine (2,3-DAP). Analytical procedures were developed to measure quantitatively the concentrations of the various species in the reduced solutions and these are described in the experimental section.

The objective of this work has been to identify and measure quantitatively the major products resulting from the electrochemical reduction of benzofuroxan. The isolation of these products, fast sweep voltammograms, and the work of other researchers make possible a reasonable understanding of the pathway of the reduction.

Experimental

Reagents and Solutions

Electrolyte solutions at pH 2.12, 6.50, and 9.90 were made which contained 0.10N KCl as electrolyte. The pH 2.12 electrolyte was made by adding 7.5 ml H_3PO_4 to 1.0 liter water. KCl, 7.45g, was then added and the solution titrated to pH 2.12 by dropwise addition of 30% KOH. The pH 6.50 electrolyte was made by adding 403 ml 0.1N KOH to 900 ml 0.1M KH_2PO_4 containing 9.693g KCl. The pH 9.90 electrolyte was made by titrating a 1.0 liter solution containing 16.34g K_3PO_4 and 7.455g KCl to pH 9.90 with 6N HCl. Solutions of 1.0×10^{-3}M BFO were made by dissolving 0.0681g BFO (Eastman No. 10204) in 500 ml of the desired electrolyte.

o-Benzoquinone dioxime (ODI) was synthesized by the method of Pesin *et al.* (5) in which BFO is reacted with $H_2NOH \cdot HCl$. The product was recrystallized from ethanol and water two times and dried in a vacuum desiccator mp: 144.5°-145.0°C (uncorr.), literature 144° (5) and 149° (6).

2,3-DAP was synthesized by a method similar to that of Ullman and Mauthner (7) and Sawicki *et al.* (8) wherein OPD is reacted with $FeCl_3$ in acidic medium. After purification the product yielded yellow plates of 2,3-DAP mp: >320°. The visible and ultraviolet spectra showed peaks at 263, 280 (shoulder), 454, and 432 mμ (shoulder) which are in good agreement with those reported by Matsumura (9) of 265-285 and 454 mμ. The *IR* spectrum was identical to that reported by Stammer and Taurins (10).

Analytical Procedures

ODI may be determined spectrophotometrically in the presence of BFO and OPD. In neutral solutions BFO absorbs at 356 mμ and interferes with the ODI absorption at 397 mμ. In 6N HCl or in dilute ammonia solution the ODI absorption is split into two peaks at 321 and 425 mμ. The 425 mμ value is sufficiently high to prevent interference by BFO. Under these conditions, plots of ODI concentration *vs.* absorbance were made from which the ODI concentration in reduced solutions could be measured. 2,3-DAP interferes and the test cannot be used on solutions reduced at voltages more negative than the first polarographic wave.

2,3-DAP was also determined by a spectrophotometric procedure. Dechary *et al.* (11) determined glyoxal by condensing it with 2,3-DAP and measuring the blue color produced at 600 mμ. For this work the determination was reversed: glyoxal was used to determine 2,3-DAP. For reasons of solubility, 2,3-DAP standard solutions were prepared in a 1:1 mixture of electrolyte solution and glacial acetic acid. Reduced solutions of BFO or ODI were also diluted with an equal volume of acetic acid and the test was then performed simultaneously on the standard and reduced solutions. Appropriate aliquots of samples and standards (0.5-3.0 ml) were diluted to 3.0 ml with a 1:1 mixture of electrolyte solution and acetic acid. To each of these solutions was added 1.0 ml conc H_2SO_4 and 50 μl glyoxal. The tubes were placed in a boiling water bath and 50 μl additional glyoxal was added. After 10-min heating, the tubes were removed, chilled in an ice bath until cold, and 1.0 ml KNO_2 solution (48 mg/200 ml H_2O) was added followed by 1.0 ml H_3PO_2 (50% aqueous Fisher A-154) and reheating for 30 min. On cooling, the tubes were diluted to 7.0 ml with 10N H_2SO_4 and absorbance of standards and samples read at 600 mμ.

It was shown that BFO, ODI, and ODP do not interfere. The test performs less well in acidic electrolyte solutions where green rather than clear blue solutions are sometimes observed. In nonaqueous electrolyte solutions, *e.g.*, γ-butyrolactone-0.5M $LiClO_4$, the color fades on prolonged heating and the azo-forming step must be omitted.

OPD was determined by conversion of the OPD to 2,3-DAP followed by a second running of the 2,3-DAP test. Since the $FeCl_3$ oxidation does not go to completion, standard OPD solutions in the same electrolyte-acetic acid mixture were run concurrently with the reduced solutions and it was assumed that the same percentage oxidation was obtained in both cases. To 3.0 ml samples of reduced solutions or standards was added 1 drop 40% $FeCl_3 \cdot 6H_2O$ and 1 drop 10N H_2SO_4. The solutions were heated in a boiling water bath for 10 min, cooled to room temperature, and diluted to 7.0 ml with distilled water. At this point, a white precipitate was sometimes observed due to formation of ferric phosphate from the phosphate buffer system in the electrolyte. If so, the tubes were centrifuged and aliquots used in the phenazine test. The normal conversion of OPD to 2,3-DAP was 70-80%.

Reductions

The polarograms and constant potential reductions were performed with a Beckman Electroscan-30 in a large H-cell constructed of two 100 ml beakers separated by a tube containing a glass frit. The working compartment contained a dropping mercury electrode, saturated calomel reference, mercury pool working electrode with an estimated area of 16.0 cm^2, nitrogen bubbler, and a motor-driven glass rod which stirred the mercury pool. Electronic connection to the mercury pool was made through a platinum wire encased in a glass tube sealed at the lower end. The counterelectrode in the other cell compartment was a large platinum gauze. The stirred mercury pool arrangement was adopted as a result of preliminary studies at a stationary platinum electrode which resulted in insoluble film formation which made reductions difficult to perform.

An initial polarogram was made and the solution was reduced at the desired voltage. The coulombic data could be calculated from a chart of the current *vs.*

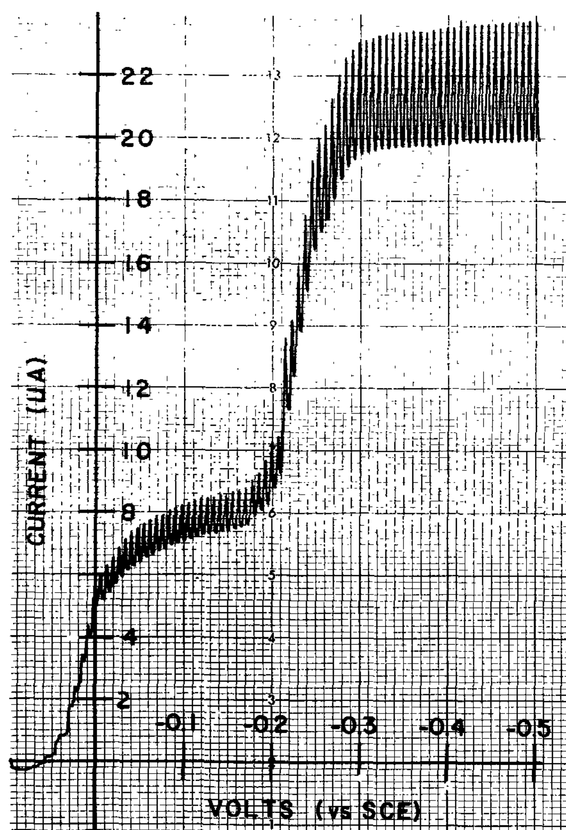

Fig. 2. Polarogram of 1.0 x 10^{-3}M benzofuroxan at pH 6.5

time. The reduction was interrupted periodically to run additional polarograms from which the BFO and ODI concentrations could be estimated. Figure 2 is a polarogram of 1.0 × 10^{-3}M BFO in pH 6.5 electrolyte. Two distinct waves can be seen that have $E_{1/2}$ values of −0.005 and −0.25V, in substantial agreement with those reported by Schindler (1) of −0.00 and −0.26V (SCE). The average diffusion currents measured at −0.10 and −0.40V were 7.8 and 22.7 μA, thus, the height of the second wave is 22.7 − 7.8 μA, or 14.9 μA. The ratio of the first and second waves at pH 6.5 is 7.8/14.9, or very nearly one to two. Polarograms of ODI show only a single wave at the same $E_{1/2}$ value as the second reduction wave of BFO.

The polarographic current values for the various concentrations of BFO and ODI were measured in the three electrolyte solutions. Figure 3 shows a plot of average diffusion currents measured at −0.10 and −0.40V *vs.* BFO and ODI concentration in pH 6.5 electrolyte from which the BFO and ODI concentrations in a reduced solution may be estimated. Similar plots were constructed at pH 2.12 and 9.90.

Fast sweep voltammograms at the DME were made with a Hewlett Packard Model 202-A triangle generator coupled with the Electroscan. The recorder of the Electroscan was disconnected and the cell current measured on a Tektronix Type 564B storage oscilloscope through terminals provided in the Electroscan. This arrangement results in the cell current being superimposed on the voltage sweep which makes absolute quantitative measurements of the current impossible. For this reason, current scales have been omitted from Fig. 5, 6, and 7. Since the sweep rate was fairly fast, 1 sec to 40 msec per cycle, compared to the drop time, 3.6 sec, it was felt that the growth of the drop during a single cycle would have a minimal effect.

Results

First reduction wave.—85.0 ml 1.0 × 10^{-3}M BFO in pH 6.5 electrolyte was reduced at −0.10V. The concentration of ODI after the passage of 3.86 coulombs was

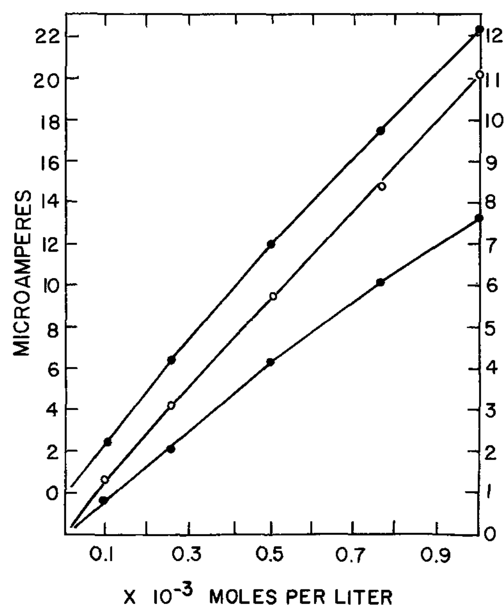

Fig. 3. Top curve, left scale: average polarographic current measured at −0.40V (SCE) *vs.* concentration of benzofuroxan at pH 6.5. Bottom curve, right scale: average polarographic current measured at −0.10V *vs.* concentration of benzofuroxan at pH 6.5. Middle curve, right scale: average polarographic current measured at −0.40V *vs.* concentration of o-benzoquinone dioxime at pH 6.5.

measured as 0.26 × 10^{-3}M (acidic spectrophotometric test) and 0.30 × 10^{-3}M (basic spectrophotometric test). The theoretical coulombs necessary to produce the 0.26 × 10^{-3}M solution is 4.26. Another reduction of 80.0 ml of the same solution at the same voltage yielded the results shown in Table I. In this case, the BFO and ODI concentrations were determined from the polarographic wave heights.

These results support the contention of Schindler (1) and Levin (2) that the product of the first wave is ODI resulting from a two-electron reduction of benzofuroxan.

Second reduction wave.—Reduction of 80.0 ml 1.0 × 10^{-3}M BFO in pH 6.5 electrolyte at −0.40V, approximately −0.10V beyond the crest of the second wave as seen in Fig. 2, resulted in the polarographic currents shown in Table II. After the passage of 12.8 coulombs, the BFO and ODI concentrations were 0.13 × 10^{-3}M and 0.90 × 10^{-3}M, respectively. The calculated coulombs necessary to reduce this much BFO to ODI is 13.4. The implication is that reduction of BFO at potentials slightly more negative than the second wave does

* 2,3-DAP values in ( ) are as monomer.

not proceed directly to the fully reduced products but rather yields the dioxime which, after the BFO in solution is depleted, is then further reduced. The appearance of the solution during a reduction also supports this conclusion. Initially the solution is colorless. During the reduction, the solution becomes reddish-brown (the color of the dioxime at pH 6.5) until sufficient coulombs for a two-electron reduction have passed. Upon further reduction the solution clears to a yellowish color.

A small amount of brown precipitate was observed in the cell at the end of the reduction. The amount of this precipitate seemed to increase upon standing, even though the electrolytic reduction had been completed. Experiments were undertaken to determine the structure of this precipitate and the products remaining in solution.

Nine 80 ml solutions of 1.0 × 10^{-3}M BFO in pH 6.5 electrolyte were reduced at −0.40V. The total coulombs passed were estimated at 600. After standing 4 to 6 hr, each solution was filtered, and the precipitate thoroughly rinsed with water. The total weight of this precipitate, referred to as "A," was 39.8 mg. The product remaining in solution was isolated by evaporation of the combined supernatent solutions and extraction with ethanol which was evaporated to yield "B."

The NMR, uv, *IR*, and visible spectra of B were identical with the spectra of synthetic 2,3-DAP. 2,3-DAP forms a green solution with concentrated H_2SO_4 which becomes brown upon dilution (12). Synthetic 2,3-DAP and product B gave positive results with this test.

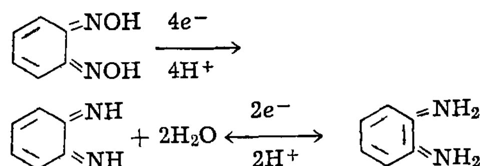
The uv and visible spectra of A indicated that the product was, in part, also 2,3-DAP. However, the *IR* spectrum of A showed strong adsorptions at 1340, 2850, and 2900 cm^{-1} which are not due to 2,3-DAP. A did not give nearly as strong a qualitative test with sulfuric acid as did synthetic 2,3-DAP or B. Because so little product was available, 40 mg, of which most had been used in qualitative tests and for *IR*, uv, and visible spectra, no further characterization was attempted.

Since it was known that OPD air oxidizes to 2,3-DAP (13) and product B was isolated from evaporation of the reduced solutions, the 2,3-DAP and OPD determinations were developed which could be run directly on the solutions immediately following the reduction. Constant potential reductions at voltages slightly above the crest of the second wave were performed on BFO and ODI solutions at the three pH values. The coulombic, polarographic, and analytical data collected from these reduced solutions are given in Table III.

Discussion

The first two-electron polarographic wave in neutral and basic solutions results in the dioxime product. In acidic solutions the two waves cannot be distinguished as seen in Fig. 4, the polarogram of BFO in pH 2.12 electrolyte.

A satisfactory explanation of the processes involved with the second reduction wave, the two-electron "dip" in the second reduction wave in the middle pH range as shown in Fig. 1 and the formation of the phenazine and diamine products can be made by assuming an o-benzoquinone diimine intermediate resulting from a four-electron reduction of the dioxime. This diimine may be further reduced to OPD or couple to produce 2,3-DAP. The over-all reaction for the formation of the imine and further reduction to OPD is shown in reaction I.



[I]

The argument in support of the diimine intermediate is summarized here followed by a more complete description of each line of evidence.

(*a*) Chemical and electrochemical oxidations of OPD in aqueous solutions are known to proceed through the diimine intermediate which couples to yield 2,3-DAP.

(*b*) The transition in the polarographic reduction wave of BFO and ODI from four to six electrons occurs at the same pH value, 7.8, as does the change in slope of the $E_{1/2}$ *vs.* pH curve for the oxidation of OPD. It has been shown that this pH is the same as the pK_a value for the diimine intermediate.

(*c*) The formation of the diimine intermediate, resulting from a four-electron reduction of ODI, ac-

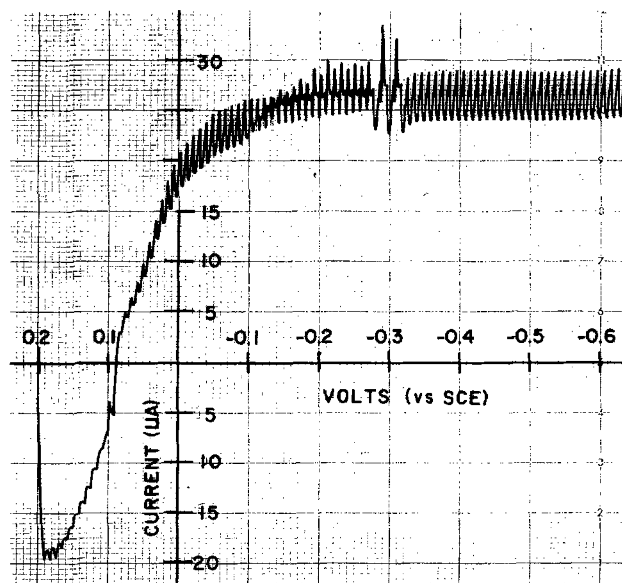


Fig. 4. Reduction polarogram of 1.0 x 10^{-3}M benzofuroxan at pH 2.12.

counts for the four-electron polarographic wave observed in the middle pH range.

(*d*) Fast sweep voltammograms show a new peak for the reduction of BFO and ODI at pH 9.9. This is the expected result for an intermediate species in the reduction pathway between ODI and OPD.

The electrochemical oxidation of OPD has been studied in considerable detail in aqueous solutions throughout a wide range of pH values and at a variety of electrode surfaces (13-17). The unanimous consensus of these investigators is that the reaction proceeds through a two-electron oxidation of the diamine to diimine, and in middle or slightly acidic pH ranges the diimine couples with unreacted OPD to yield 2,3-DAP which is the observed product. This latter coupling reaction involves a further four-electron oxidation. Parker and Adams (14), who describe the initial two-electron wave as a redox couple, plotted $E_{1/2}$ values for the oxidation of OPD at a rotating platinum electrode and found sharp changes in the slope of the curve at pH 4.5 and 7.8. These data are shown in Fig. 1 along with a plot of the polarographic current of the second reduction wave from Schindler's data.

The correlation between the break in the $E_{1/2}$ curve at pH 7.8 and the transition between a four- and a six-electron reduction wave for BFO at the same pH is very striking. Parker and Adams (14) showed that this break is the pK_a value of the diimine intermediate. The other change in slope at pH 4.5 occurs at the pK_a value for OPD. Elving and Krivis (16, 17) found that at pH 5, in the region of the four-electron wave for the reduction of ODI, the oxidation of OPD gave two waves. The first wave is a two-electron oxidation to the diimine which then couples with unreacted OPD to form 2,3-DAP. This is followed by a second one-electron wave due to a free-radical reaction resulting in a polymeric film coating of the electrode. At pH 11 a single two-electron oxidation occurs but no further oxidation wave is seen, and the electrode is not fouled. Evidently, in solutions above pH 7.8 where the diimine is not protonated, it does not easily couple to form the phenazine. Consequently, when this intermediate is formed by the reduction of BFO or ODI above pH 7.8, the coupling does not occur, but rather the imine is further reduced to OPD. As a result a single six-electron wave is seen for the reduction of ODI above pH 7.8. This conclusion is supported by the data in Table III which show that OPD is the major reduction product at pH 9.9 and that very little phenazine is formed.

At pH values between about 4.5 and 7.8, where the imine is known to couple to form the phenazine, the reduction of ODI proceeds in only a four-electron process to the intermediate followed by coupling. Table III shows that the major reduction product in this pH range is 2,3-DAP.

Fast sweep voltammograms provide further evidence for the diimine intermediate. Figure 5 shows voltammograms of 1.0×10^{-3}M BFO in pH 9.9 electrolyte solution at sweep rates of 1, 5, and 10 Hz. The initial voltage was 0.0 (SCE) and the sweep amplitude was -1.05V. At 1 Hz, peaks can be seen at -0.15 and -0.52V, with a very small peak at -0.41V which is not present in the dropping mercury polarograms. As the frequency of the sweep is increased to 10 Hz the peak at -0.41V becomes larger than the peak at -0.52V. This is the expected behavior if the reduction is proceeding through the diimine intermediate at this pH.

Voltammograms at pH 6.5 are shown in Fig. 6. The first wave is difficult to see. However, at 1 Hz there is a large wave at -0.25V with a very small wave at -0.73V. At 10 and 25 Hz no change is seen which agrees with the polarographic behavior indicating only a four-electron reduction to the diimine in the middle pH ranges. It might be added that similar results are obtained from fast sweep voltammograms of ODI. This is expected since the initial BFO reduction yields the dioxime.

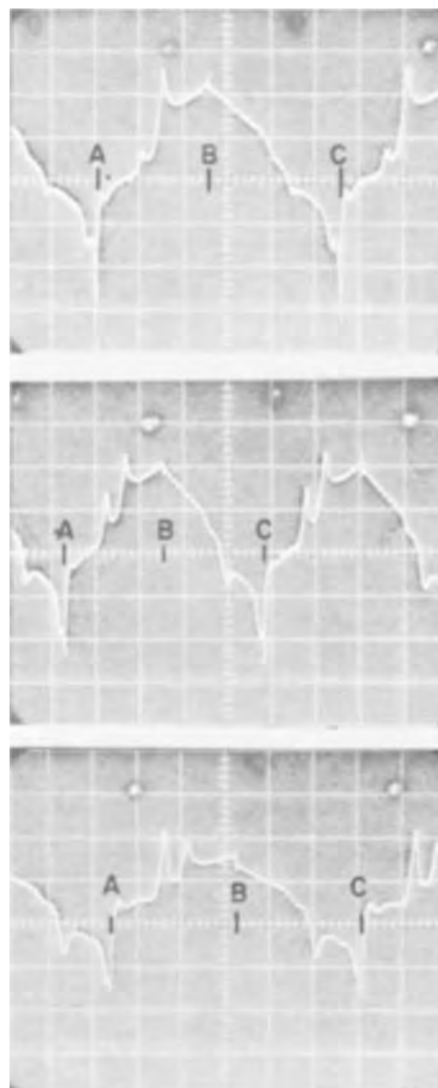

Fig. 5. Fast sweep voltammogram of 1.0×10^{-3}M BFO at pH 9.9. For all three sweeps, point A marks the beginning of the cathodic sweep at 0.00V (SCE). Point B marks the end of the cathodic sweep and the beginning of the anodic sweep at -1.05V. Point C is the end of the anodic sweep, 0.00V. Upper sweep: 1 Hz, oscilloscope trace rate 0.2 sec and 0.41V/large division. Middle sweep: 5 Hz, 50 msec and 0.46V/large division. Lower sweep: 10 Hz, 20 msec and 0.37V/large division.

In acidic solutions below about pH 4.5 the situation is less clear. The polarographic wave for the reduction of BFO shifts from four to six electrons quite gradually as can be seen in Fig. 1. It is hard to correlate this shift with the change in the slope of $E_{1/2}$ *vs.* pH for the oxidation of OPD. However, one explanation seems possible. The papers of Elving and Krivis (17) and Parker and Adams (14) reported only a single two-electron oxidation wave for OPD to the diimine at pH's below 4.6. Nonetheless, an electrode coating or film was observed, which was attributed to a post-electrolytic reaction of the diimine in acidic solutions. There is evidence of such a process in the reduction of BFO. Figure 7 shows fast sweep voltammograms from $+0.20$ to -0.88V for the reduction of BFO in pH 2.12 electrolyte. It was observed that there is an initial peak at -0.04V followed by a large wave whose maxima is at -0.55V. Then, as the voltage decreases, another reduction wave is seen; an unusual occurrence. This may be interpreted as an electrochemical reduction followed by a chemical reaction which yields a product that may be further reduced. At 10 Hz the scan shows no second wave, perhaps because the scan is faster than

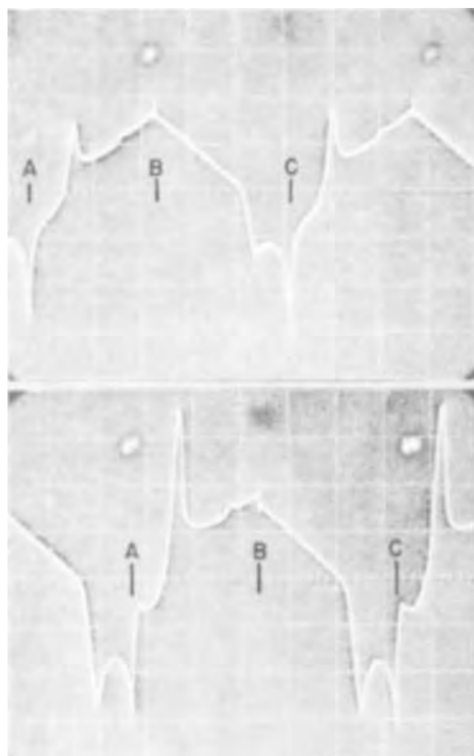

Fig. 6. Fast sweep voltammogram of 1.0 x 10^{-3}M BFO at pH 6.5. Cathodic sweep from A (+0.10V) to B (−0.98V). Anodic sweep from B to C (+0.10V). Upper sweep: 1 Hz, 0.2 sec and 0.40V/large division. Lower sweep: 10 Hz, 20 msec and 0.40V/large division.

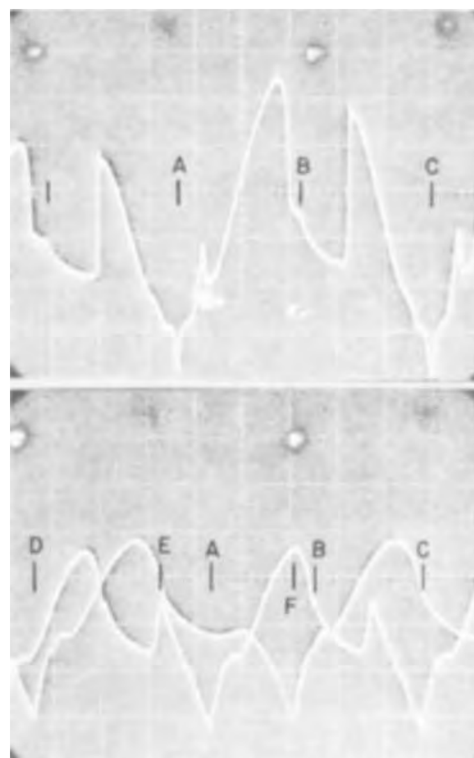

Fig. 7. Fast sweep voltammogram of 1.0 x 10^{-3}M BFO at pH 2.12. Cathodic sweeps from A (+0.20V) to B (−0.88V). Anodic sweep from B to C (+0.20V). Upper sweep: 1 Hz, 0.2 sec and 0.41V/large division. The lower sweep shows two traces. The sweep which includes the first major peak is at 5 Hz, 50 msec and 0.49V/large division. This sweep is marked by points A, B, and C. The trace of slightly larger amplitude is at 10 Hz and 0.40V/large division. The cathodic sweep is from D (+0.20V) to E(−0.88), and the anodic sweep is from E to F (+0.20V).

the chemical reaction. Other explanations such as the production of an insoluble film on the electrode are also plausible.

The reduction of two molecules of ODI to 2,3-DAP requires six electrons over-all. This would account for the over-all six-electron reduction wave in acidic solutions. However, this explanation fails to account for the "missing" product noted in Table III for the reduction of ODI at pH 2.12. The fact that a film forms on the electrode during the oxidation of OPD and the same phenomenon is observed in the reduction of BFO (the odd behavior of the mercury electrode in Fig. 4 between −0.1 and −0.3V) indicates a polymer formation, perhaps due to successive coupling of diimine with phenazine molecules. The complexity of the reaction in acidic solutions is increased by the fact that BFO reacts with the mercury electrodes in acidic solutions. If a solution of BFO is allowed to stand over a mercury pool for several hours the solution darkens to reddish-brown. The uv and visible spectra indicate that this product is not the dioxime.

Conclusions

The general course of the reduction of benzofuroxan in aqueous solutions is clear. The BFO undergoes a two-electron reduction to o-benzoquinone dioxime which is further reduced to o-benzoquinone diimine by a four-electron process, reaction [II], below. The diimine is then reduced to o-phenylenediamine, reaction [III], or couples to form 2,3-diaminophenazine.

The details of the phenazine formation are not clear, but a number of possibilities must be considered. Condensation of ODI and OPD with loss of two molecules of water could lead to 2,3-DAP. However, in neutral or basic solutions, analysis of the reduction products showed that a considerable amount of these products can exist together without reaction, or with only very slow reaction. The more likely explanation is that the phenazine formation is electrochemical in nature and involves the imine intermediate. Reaction with BFO and subsequent reduction is ruled out because the first product of the reduction of BFO, even at voltages more negative than the second polarographic wave is ODI. That is, nearly all the BFO in solution is reduced to ODI before the ODI is further reduced to the imine. It is also possible that the phenazine formation results from a coupling of the diimine with ODI involving a two-electron reduction. This pathway is attractive except for the fact that no polarographic wave is seen to indicate this process. Also this would require six electrons over-all from the dioxime to the phenazine, whereas only a four-electron wave is observed in the middle pH range where the phenazine product is most abundant. This leaves coupling of the imine with itself or with OPD, there being precedent for the latter alternative (16, 17).

Interdependence of Parameters in Reactive Sputtering of Manganese in Oxygen

L. D. Locker,* R. W. Landorf, C. L. Naegele,[1] and F. Vratny*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Manganese oxide thin films deposited over the Ta_2O_5 layer in tantalum capacitors are known to improve yield and reliability. In this investigation reactive sputtering is used to prepare manganese oxides. The results show that films with resistivities below 1 ohm-cm can be produced, but the interdependence of oxygen partial pressure, power input, and substrate temperature limits the deposition rates that can be obtained without producing oxide phases with higher resistivities.

With d-c sputtering at 4.0 kV, Mn_2O_3 is produced as the oxygen pressure increases from 3×10^{-2} to 4×10^{-2} Torr. This corresponds to a substrate temperature increase from 275° to 360°C and a 50% increase in deposition rate. The complexity of the interactions in both d-c and rf reactive sputtering is further illustrated by the maximum in substrate temperature obtained with argon-oxygen mixtures containing 0.5% O_2. For reactive sputtering of materials similar to Mn-O, where several phases and variable stoichiometry are possible, it is therefore necessary to determine experimentally the conditions of power density, pressure, and substrate temperature that give the maximum deposition rate for each phase.

Independent investigations (1-3) confirm the improvement in the yield and the reliability of tantalum thin-film capacitors obtained by adding a thin layer of MnO_2 over the Ta_2O_5 dielectric (*e.g.*, Ta-Ta_2O_5-MnO_2-Au). The manganese dioxide films can be deposited by pyrolysis of $Mn(NO_3)_2$ sprayed onto the tantalum pentoxide, by reactive evaporation of manganese, or by reactive sputtering of manganese (4). Favorable capacitor performance has been obtained with d-c diode reactive sputtering in pure oxygen or in oxygen-argon mixtures when low resistivity (1-15 ohm-cm) MnO_2 is produced (2). RF sputtering of Mn in oxygen has produced manganese oxide films with resistivities as low as 5×10^{-3} ohm-cm (5). By using the technique of rf + d-c sputtering (6), deposition rates can be increased compared with the more conventional methods of diode sputtering. The plasma density is increased, and an insulating oxide layer that forms on the cathode can be sputtered. However, in reactive sputtering there is a complex interdependence among power input, substrate temperature, total pressure, and oxygen partial pressure, and the resultant deposition rate, composition, and electrical properties of the films. Especially for the Mn-O system, where several phases and variable stoichiometry can occur, it is not usually possible to obtain the optimum electrical properties at high deposition rate.

Key words: dielectric films, manganese oxides, sputtering, thin films.

Experimental

Sputtering was done in an oil-diffusion-pumped bell jar system with a liquid nitrogen baffle, capable of an ultimate pressure of 1×10^{-6} Torr. Corning 7059 glass substrates were mounted on a water-cooled support 3 in. above the cathode. The sputtering source consisted of electroplated manganese on stainless steel. The reactive gas was pure oxygen at pressures of 5×10^{-2}, 3×10^{-2}, 2×10^{-2}, 1×10^{-2}, and 5×10^{-3} Torr and oxygen-argon mixtures with different oxygen partial pressures between 2×10^{-5} and 2×10^{-2} Torr. In the oxygen-argon mixtures the total pressure was constant at 2×10^{-2} Torr. Cathode voltages with pure oxygen were either 1.5, 2.5, or 4.0 kV d.c., and 4.0 kV d.c. with the oxygen-argon mixtures. In separate experiments approximately 200W of rf power was combined with either 2.5 or 4.0 kV d.c. Film thicknesses were measured with the Talysurf, and resistivities were measured from the current-voltage characteristic between metal contacts evaporated on the sample surface. The substrate temperature was measured with a thermocouple imbedded in the substrate holder. Although this is a low estimate of the surface temperature, the heat flow conditions, and more recent measurements with thin film thermocouples that are cited below, indicate that the observed variations in tem-

perature are valid for the growing film. Crystallographic phase identification was done by x-ray diffraction.

Results

All of the phases Mn, MnO, Mn_3O_4, Mn_2O_3, and MnO_2 have been obtained in the course of the experiments, although the x-ray diffraction patterns are often difficult to interpret. The resistivities of the films cover the range from 10^{-2} ohm-cm to 10^7 ohm-cm. Deposition rates cover the range from 2.5 Å/min to 85 Å/min. The results are summarized in Fig. 1 and 2. In Fig. 1 the resistivity values in ohm-cm are marked next to the corresponding data points. The substrate temperature maximum with approximately 0.5% O_2-95.5% A has been confirmed in an independent investigation (7), using a Pt/Pt-10% Rh thin film thermocouple on a glass substrate.

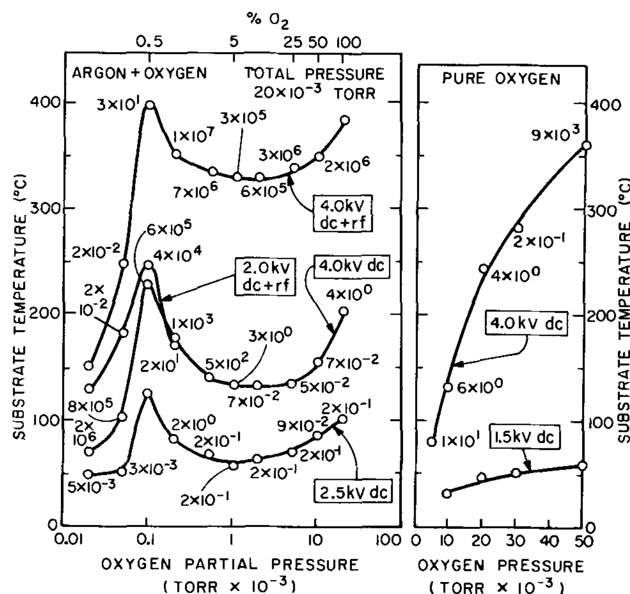

Fig. 1. Substrate temperature vs. oxygen pressure for different d.c. or d.c. and rf power levels. Numbers adjacent to data points are resistivity values (ohm-cm) for the manganese oxide films.

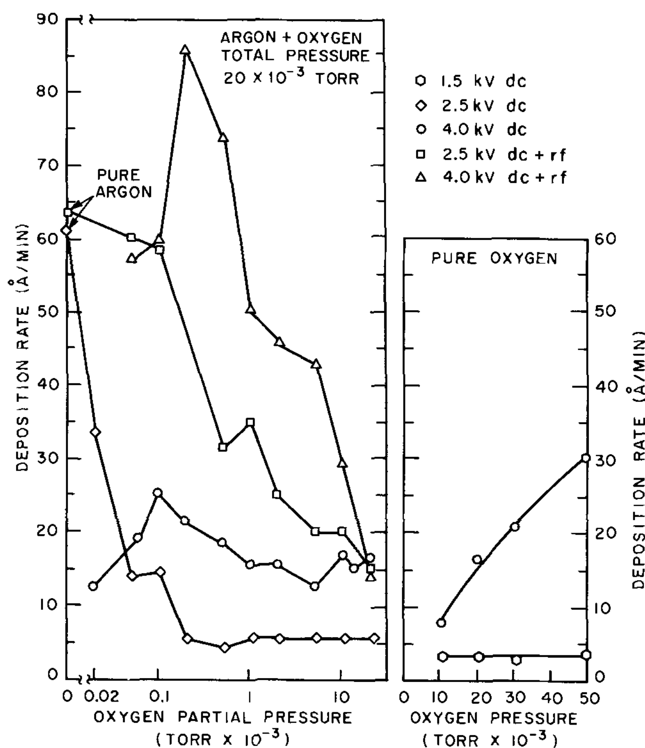

Fig. 2. Deposition rate vs. oxygen pressure for different d.c. or d.c. and rf power levels.

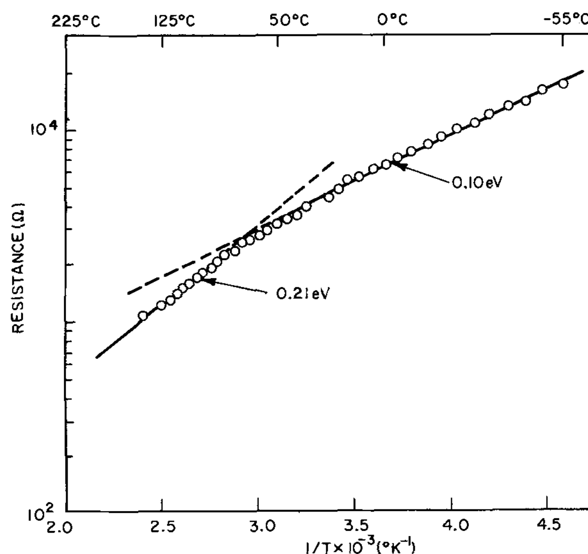

Fig. 3. Resistance vs. temperature typical of manganese oxides with resistivities between 0.1 and 10 ohm-cm.

Films with resistivities between 0.1 and 10 ohm-cm are probably close in structure and composition to the MnO_2 prepared by pyrolysis of $Mn(NO_3)_2$ (8, 9). Only a few diffuse lines appear in the x-ray diffraction patterns of the sputtered films, so that a specific phase identification is not possible. However, for all the films in this resistivity range the temperature coefficient of resistance ($d \ln R/d\ (1/T)$) is approximately constant and is close to the values found with films produced by $Mn(NO_3)_2$ pyrolysis. The activation energy for the n-type conduction is indicated in Fig. 3. The apparent nonlinearity in the plot may be due to oxygen of water vapor evolution during heating. Upon recycling the sample temperature between $-55°$ and 125°C, the 0.21 eV activation energy is removed and only the 0.10 eV value is obtained.

For d-c sputtering at 2.5 kV, the lowest oxygen partial pressure producing a resistivity in the 0.1 to 10 ohm-cm range is 2×10^{-4} Torr. In comparison, at 4.0 kV d.c. the lowest pressure is 1×10^{-3} Torr. The higher substrate temperatures in the latter case would favor transformation to Mn_2O_3 at a higher pressure than at 2.5 kV d.c. At 4.0 kV d.c. and an oxygen partial pressure of 5×10^{-4} Torr the x-ray diffraction pattern is clearly α-Mn_2O_3. Similarly, in pure oxygen at 4.0 kV d.c. there is a change to Mn_2O_3 between 3×10^{-2} and 5×10^{-2} Torr, when the substrate temperature increases from 275° to 360°C. In this case, the $MnO_2 \rightarrow Mn_2O_3$ transition, which decreases the O:Mn ratio, occurs even as the oxygen pressure is increased. This is further evidence that the increase in substrate temperature and possibly the change in manganese sputtering rate from the cathode as the pressure is increased, are important in determining the phase that forms. The substrate temperature is also important in regard to the rate of film growth. When the substrate temperature is increased independently of power input and oxygen pressure (4.0 kV d.c., 5×10^{-2} Torr pure O_2), by resistance heating of the substrate holder, the film growth rate increases. The thermal activation energy is 4 ± 2 kcal/mole Mn_2O_3.

When rf power is added to the argon-oxygen discharge, the growth rates (A/min), at corresponding pressures, increase in almost all cases. (An accurate comparison of rates in terms of mass/time must account for changes in film density.) The resistivity of the films also increases, and the x-ray diffraction pat-

terns show that a lower oxide than MnO_2 is produced. The results therefore indicate that the interdependence of the sputtering variables restricts the flexibility to obtain given film properties at high deposition rates.

Discussion

Valletta and Pliskin (10) have used the infrared spectra to characterize manganese oxides prepared by d-c reactive sputtering in oxygen at 5×10^{-2} Torr. They conclude that manganese dioxide is formed only when the substrate temperature is below 350°C. This is in agreement with the x-ray diffraction results presented above, where a definite transformation to Mn_2O_3 is observed between 275° and 360°C. The resistivity changes also indicate the phase transformation.

The metastable products formed in the thermal oxidation of manganese can be explained in terms of the rate-limiting transport reaction, producing concentration gradients and an electric field across the growing oxide film (11, 12). For example, thermal oxidation in 1 atm air at 350°-450°C produces Mn_3O_4, and at pressures down to 10^{-4} Torr produces MnO and Mn_3O_4 (11). The situation is analogous in the oxidation of iron and copper. For copper, results on reactive sputtering have been obtained by Perny and Laville-St. Martin (13, 14). The Cu_2O phase is formed under conditions where equilibrium calculations predict CuO. Although the mechanism of reactive sputtering is unlikely to be the same as thermal oxidation, nonequilibrium conditions also exist during reactive sputtering since the oxide is deposited from species in an electric discharge.

Figures 1 and 2 suggest that the interactions in an argon-oxygen discharge are sensitive to the composition of the mixture. This is best illustrated by the maximum in substrate temperature observed with 0.5% O_2. A complete explanation of the observed changes in substrate temperature and deposition rate require information on the concentrations of positively charged ions, secondary electrons, and reactive species in the discharge. The species in an argon rf glow discharge are A, A^+, A^*, and e^-, where A^* denotes an excited argon atom. Lounsbury (15) has recently studied the effects of 1% O_2 added to the argon discharge at a total pressure of 4×10^{-2} Torr. The oxygen addition increases the A^+ concentration, decreases the A^* concentration, and probably causes a change in the electron energy distribution in the plasma. The increased ion concentration will cause an increase in secondary electron emission from the cathode. Secondary electron emission will also be affected if an oxide layer is present on the cathode. These secondary electrons are responsible for the substrate heating (16, 17). Therefore, a combination of factors will have an effect on the substrate temperature and the sputtering rate from the cathode. Although the species in oxygen-argon mixtures have not been examined for compositions other than A-1% O_2, this type of information is very important in general. When this is combined with information about the reaction processes on the substrate surface, a detailed mechanism of the reactive sputtering process can be proposed.

Acknowledgment

The authors wish to thank Mrs. M. H. Read for the x-ray diffraction studies.

ABSTRACT

The precipitation of ions generated at an electrode, operating at a constant current, with ions of the adjacent electrolytic solution has been modeled as a growing porous layer. The thickness of the layer as a function of time for short times is given by a power series expansion of time. The long-time solution was determined by a numerical calculation on a digital computer. A criterion for linear growth rate as a function of time is given.

Moving boundary problems, such as melting-freezing, evaporation-condensation, and purification of materials, involving heat and mass transfer have been treated in depth (1-7). A moving boundary problem is encountered in the field of electrochemistry when ions being generated at an electrode, operating at a constant current, form a precipitate with ions of the adjacent electrolytic solution. The resulting precipitate forms a growing porous layer on the electrode. Studies of anodic dissolution of various metals which form porous coatings (8) can be considered examples of growing porous layers. In the case of silver, a porous layer occurs only after a nonporous layer has been formed or when large currents are employed (9, 10). Jackson and Blomgren (11) studied the anodic dissolution of lithium in a 1M solution of $AlCl_3$ in propylene carbonate and observed a growing porous layer of LiCl. Other examples of growing porous layers are the oxidation of tungsten (12) and the scaling of metals (13). In the following analysis, the thickness of a growing porous layer as a function of time is determined, and a criterion for linear growth rate as a function of time is given.

Description of Model

The system under consideration consists of an electrode in contact with a binary electrolytic solution. The current density is assumed uniform over the surface of the electrode. Variation in concentration occurs only in the direction perpendicular to the electrode surface, and convection is assumed to be negligible. At time $t = 0$, a constant current is applied to the electrode. The metal ion which is being generated at the electrode surface combines with the anion of the binary electrolyte and precipitates at the electrode surface (the solution being initially at the saturation concentration, c_s). Further precipitation occurs at the interface between the advancing front of the porous layer and the electrolytic solution. The porous layer is assumed to have a homogeneous porosity. The saturation concentration inside the porous layer will be allowed to increase above the initial saturation value due to local resistance heating (10, 14). Dilute-solution theory (15) will be used to relate the derivative of the concentration at the electrode surface to the current density.

Mathematical Formulation

The equations necessary to describe the growing porous layer are (where c refers to the concentration inside the porous layer)

$$\frac{\partial c}{\partial t} = \overline{D}\frac{\partial^2 c}{\partial X^2} \qquad 0 < X < \delta(t) \qquad [1]$$

$$c|_{t=0} = c_s \qquad [2]$$

$$c|_{X=\delta(t)} = c_s \qquad [3]$$

$$\left.\frac{\partial c}{\partial X}\right|_{X=0} = -\frac{it_-}{nF\overline{D}\epsilon} = -\frac{K}{\epsilon} \qquad [4]$$

$$\frac{d\delta(t)}{dt} = -\frac{\overline{D}\epsilon}{(1-\epsilon)\rho_m}\left.\frac{\partial c}{\partial X}\right|_{X=\delta(t)} \qquad [5]$$

Equation [1] is the species continuity equation with the rate of production in the porous layer equal to zero. Equations [2] and [3] give the initial and boundary value concentrations. Equation [4] relates the derivative of the concentration at the electrode surface to the applied current, transference number of anion, diffusion coefficient of the binary electrolyte in the porous layer, and porosity of the layer. Equation [5] is obtained from an over-all material balance and relates the rate of growth of the porous layer to the flux of precipitate in solution at $X = \delta$ (thickness of porous layer). The diffusion coefficients in these equations are assumed independent of concentration and equal to each other. The quantity $(1 - \epsilon)\rho_m$, indicates the amount of precipitate present in the solid portion of the porous layer.

The following change of variables is made in order to immobilize the boundary (7)

Let $x = X/\delta(t)$, $\tau = \overline{D}t(K/(1-\epsilon)\rho_m)^2$
$\theta = (c - c_s)\epsilon/K\delta(t)$, $\Delta = \delta(t)K/(1-\epsilon)\rho_m$ [6]

Equations [1-6] are now expressed as

$$\frac{\Delta^2\partial\theta}{\partial\tau} + \frac{1}{2}\left(\theta - x\frac{\partial\theta}{\partial x}\right)\frac{d\Delta^2}{d\tau} = \frac{\partial^2\theta}{\partial x^2} \qquad 0 < x < 1 \qquad [7]$$

$$\theta|_{\tau=0} = 1 - x \qquad [8]$$

$$\theta|_{x=1} = 0 \qquad [9]$$

$$\left.\frac{\partial\theta}{\partial x}\right|_{x=0} = -1 \qquad [10]$$

$$\frac{d\Delta}{d\tau} = -\left.\frac{\partial\theta}{\partial x}\right|_{x=1} \qquad [11]$$

$$\Delta|_{\tau=0} = 0 \qquad [12]$$

The x domain has now been reduced to $0 < x < 1$. Equation [7] is slightly more complex than its counter part (Eq. [1]), however, the dependence of Eq. [3] and [5] on $\delta(t)$ has been removed. The solution to Eq. [7-12] will first be examined for small τ by expressing Δ and θ as a power series in τ.

$$\Delta = \tau - a\tau^2 + b\tau^3 + c\tau^4 + d\tau^5 + 0(\tau^6) \qquad [13]$$

Key words: porous layers, precipitation, growth rate.

$$\theta = 1 - x - A(x)\tau + B(x)\tau^2 - C(x)\tau^3 + D(x)\tau^4 + 0(\tau^5) \quad [14]$$

By substituting the above series into Eq. [7-12], the unknown coefficients can be determined. The result is given by

$$\Delta = \tau - \tau^2/2 + 5\tau^3/6 - 17\tau^4/8 + 827\tau^5/120 + 0(\tau^6) \quad [15]$$

$$\theta = (1-x) - (1-x^2)\tau/2 + 5(1-x^2)\tau^2/4 + [53(1-x^2)/12 - (1-x^4)/2]\tau^3 + [895(1-x^2)/48 - 17(1-x4)/24]\tau^4 + 0(\tau^5) \quad [16]$$

Let us digress a moment and determine what a reasonable value for τ might be. For $i = 10^{-3}$ A/cm^2, $\epsilon = 0.1$, $D = 10^{-5}$ cm^2/sec, $\rho_m = 4 \cdot 10^{-2}$ moles/cm^3, $t = 5.4 \cdot 10^3$ sec one obtains $\tau \cong 0.001$. Therefore, as can be seen, the short-time solution can be used to describe the behavior of the porous layer for relatively long real times.

Let us now determine if $\Delta \sim \tau^{1/2}$ at long times, which would be characteristic of unrestricted semi-infinite diffusion from an electrode. The change of variables used to obtain Eq. [7-12] was useful in obtaining the short-time solution. For the development of the long-time solution, the following change of variables will be used in Eq. [1-6]

$$f(\eta,\tau) = \frac{(c - c_s)}{(1-\epsilon)\rho_m} \frac{\epsilon}{2\sqrt{\tau}}$$

$$\eta = XK/2(1-\epsilon)\rho_m\sqrt{\tau}$$

$$\Delta_1 = \delta(t)K/2(1-\epsilon)\rho_m\sqrt{\tau}$$

$$\tau = \bar{D}t[K/(1-\epsilon)\rho_m]^2$$

Equations [1-6] then become

$$4\tau\frac{\partial f}{\partial \tau} = \frac{\partial^2 f}{\partial \eta^2} + \eta\frac{\partial f}{\partial \eta} - 2f \quad [17]$$

$$f|_{\eta=\Delta_1} = 0 \quad [18]$$

$$\left.\frac{\partial f}{\partial \eta}\right|_{\eta=0} = -1 \quad [19]$$

$$\frac{d\Delta_1}{d\sqrt{\tau}} + \frac{\Delta_1}{\sqrt{\tau}} = -\left.\frac{\partial f}{\partial \eta}\right|_{\eta=\Delta_1} \quad [20]$$

$$\Delta_1|_{\tau=0} = 0 \quad [21]$$

Equations [14-19] can be transformed into the following to facilitate the computer computation

$$\frac{\Delta_1}{\sqrt{\tau}} + \frac{d\Delta_1}{d\sqrt{\tau}}\left[1 + \frac{\sqrt{\pi\tau}\,e^{\Delta_1^2}}{[\sqrt{\pi}\,\Delta_1 e^{\Delta_1^2}\,\mathrm{erf}\,\Delta_1 + 1]^3}\left[(\sqrt{\pi}\,\Delta_1\,e^{\Delta_1^2}\,\mathrm{erf}\,\Delta_1 + 1)\,\mathrm{erf}\,\Delta_1 - \sqrt{\pi}\int_0^{\Delta_1} e^{\eta^2}(\mathrm{erf}\eta)^2 d\eta\right]\right] = \frac{1}{[\sqrt{\pi}\,\Delta_1 e^{\Delta_1^2}\,\mathrm{erf}\,\Delta_1 + 1]} \quad [22]$$

$$f = \eta + \frac{2\Delta_1 e^{\Delta_1^2}\left[\eta\int_0^\eta e^{-\eta^2}d\eta + e^{-\eta^2}/2\right]}{[\Delta_1\sqrt{\pi}\,e^{\Delta_1^2}\,\mathrm{erf}\Delta_1 + 1]} + \epsilon(\tau)\left[[e^{-\eta^2} - \sqrt{\pi}\,\eta\,\mathrm{erfc}\eta]\int_0^\eta e^{\eta^2}\mathrm{erf}\eta d\eta + \sqrt{\pi}\,\eta\int_0^\eta e^{\eta^2}\mathrm{erfc}\eta\,\mathrm{erf}\eta d\eta\right] + B[\eta\mathrm{erf}\eta + e^{-\eta^2}/\sqrt{\pi}] \quad [23]$$

where

$$\epsilon(\tau) = \frac{2\sqrt{\tau}}{\sqrt{\pi}} \frac{e^{-\Delta_1^2}}{\left[\Delta_1\mathrm{erf}\Delta_1 + \frac{e^{\Delta_1^2}}{\sqrt{\pi}}\right]^2} \frac{d\Delta_1}{d\sqrt{\tau}}$$

$$B = \frac{\epsilon(\tau)/2}{\left[\Delta_1\mathrm{erf}\Delta_1 + \frac{e^{-\Delta_1^2}}{\sqrt{\pi}}\right]}\left[[\sqrt{\pi}\,\Delta_1 e^{\Delta_1^2}\,\mathrm{erfc}\Delta_1 - 1]e^{-\Delta_1^2}\int_0^{\Delta_1} e^{\eta^2}d\eta - [\sqrt{\pi}\,\Delta_1\mathrm{erfc}\Delta_1 + \sqrt{\pi}\,\Delta_1\,\eta\,e^{-\Delta_1^2}]\int_0^{\Delta_1} e^{\eta^2}\,\mathrm{erfc}\eta d\eta + \sqrt{\pi}\,\Delta_1\int_0^{\Delta_1} e^{\eta^2}\,(\mathrm{erfc}\eta)^2 d\eta\right]$$

Equations [22] and [23] were solved on the IBM 360 computer using a standard Runge-Kutta program. The short- and long-time solutions for Δ as a function of τ are given in Fig. 1.

Discussion

One can see from Fig. 1 that for $\tau < 0.01$ we have $\Delta \cong \tau$. As was shown earlier, this linear dependence can be used to characterize a growing porous layer for relatively long real times ($\sim 10^3$-10^4 sec). If for this region, $\Delta \cong \tau$, the resistance of the porous layer (small porosity) is the main factor in determining the potential difference between the metal electrode and a reference electrode located just outside the porous layer (at constant current), then one should observe a linear dependence of potential *vs.* time. Jackson and Blomgren (11) studied the anodic dissolution of lithium in a $AlCl_3$– propylene carbonate electrolyte solution and observed a growing porous layer of LiCl. Their model assumes a linear growth rate of the porous layer. Using the parameters suggested for their system, τ was found to be ~ 0.01 which justifies the use of the linear growth rate assumption. Using similar parameters for systems studied by Webb, Norton, and Wagner and Haycock, one obtains a value of $\tau < 0.01$ thus justifying their assumption of a linear growth rate of the porous layer.

As shown in Fig. 1, Δ does not become proportional to $\tau^{1/2}$ even for $\tau \sim 100$. Increasing the value of i in the previous example from 10^{-3} to 10^{-1} A/cm^2 gives $\tau = 10$. This value of τ corresponds to a concentration ~ 0.5 moles/cm^3 at the electrode surface, a highly unrealistic number. We may therefore say that the physical properties of the solution are violated long before Δ becomes proportional to $\tau^{1/2}$.

In summary, while there are questions concerning the validity of some of the assumptions made in posing the growing porous model, it is believed that the qualitative description of the phenomena is correct and is in agreement with experimental results. Also a criterion for assuming a linear rate of growth of a porous layer is given by $\tau < 0.01$. The maximum value of τ for which Eq. [15] and [16] remain valid is ~ 0.1.

Liquid Ammonia as a Nonaqueous Solvent: The Kinetics of the Pb/Pb^{2+} Exchange

D. Larkin,[1] N. Hackerman,*[,2] A. E. Buck,*[,3] and L. K. Thompson[4]

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The exchange reaction at polycrystalline lead electrodes in liquid ammonia at $-45° \pm 1°C$ has been investigated. At low overpotentials the reaction appears charge transfer controlled. At high overpotentials the reaction is more complex. It is suggested that this is due to the surface being blocked by $Pb(NH_3)_2(NO_3)_2$.

Liquid ammonia has considerable attraction for use as a nonaqueous solvent. It has a sizable temperature range in the liquid phase $-33.3°$ to $-77.7°C$. It is interesting for electrochemists since its properties are analogous to those of water. Liquid ammonia dissociates in a similar manner to that of water

$$2NH_3 \rightleftharpoons NH_4^+ + NH_2^- \quad [1]$$

$$2H_2O \rightleftharpoons H_3O^+ + OH^- \quad [2]$$

although its dissociation constant (1,2) $10^{-30\pm1}$ is considerably less than that of water 10^{-14}. Ammonium salts act as an equivalent to acids in water and amides as an equivalent to alkalis in water. Also, many common inorganic salts are soluble in liquid ammonia so that the problems of high electrolyte resistance and diffusion resistance are not frequently encountered in electrochemical studies as they frequently are in other nonaqueous solvents.

Liquid ammonia has been used extensively for the preparation of compounds which are either unstable at ambient temperatures or sensitive to water. These preparations have been carried out either electrochemically (3, 4) or chemically (5-7). We became interested in using an electrochemical technique to produce deprotonated species of the type $[M(L - H)_X(L)_{Y-X}]X_Z$ (where M = transition metal, L − H = deprotonated ligand, L = ligand, X = halide) which have previously been prepared by chemical methods (5-7).

Initial studies by us on the deprotonation of compounds of the above type were complicated by the lack of a suitable reference electrode for use in liquid ammonia. A literature search showed that few electrochemical studies have been made in this solvent. Pleskov and Monossohn (8) first described a $Pb/Pb(NO_3)_2$ half cell for use as a reference electrode in liquid ammonia. This has reportedly been used successfully by Laitinen and Shoemaker (9) and by Miles and Kellet (10). An electron reference electrode has been used by Hammer and Lagowski (11) while Watt and Sowards (12) describe the use of a $Hg/HgCl_2$ half cell as a reference electrode for potentiometric titrations. A hydrogen reference electrode has been described by Baldwin and Gill (13) though Herlem (1) indicated that such an electrode was not practical.

We have investigated all these reference electrodes with the exception of the electron electrode. We agree with the findings of Herlem (1) that the hydrogen electrode is not a practical reference electrode in liquid ammonia (the exchange current is too small) while investigations of the $Hg/HgCl_2$ electrode were inconclusive in that it appeared to operate for only a few minutes at a time. The $Pb/Pb(NO_3)_2$ electrode, however, appears to work well. Therefore it seemed useful to investigate it further and a kinetic study of this electrode is recorded in this paper.

Experimental

Vacuum line.—The vacuum line was evacuated using a rotary vacuum pump. Provision was made on the vacuum line for attaching an electrolytic cell and a cylinder of ammonia. A mercury manometer was used to monitor the pressure in the line. The electrolytic cell, cylinder of ammonia, and the vacuum pump could all be isolated individually from the vacuum line.

The cell.—The electrolytic cell consisted of a single compartment into which could be introduced, test, auxillary, and reference electrodes. The cell was provided with a means to attach it to the vacuum line and a manometer for monitoring the pressure in the cell.

The electrodes.—The test, auxillary, and reference electrodes were constructed from polycrystalline lead rod (99.999% supplied by Materials Research Corporation) sheathed in polyethylene. Electrical connections to the electrodes were via platinum wires fused to the lead rod.

The electrical circuit.—The experimental technique used in this study was that of linear sweep voltammetry. This was carried out using a potentiostat based on Philbrick Research K2W Operational amplifiers which were chopper stabilized by Philbrick Research K2PA amplifiers and used in a modified Philbrick Research Operational Manifold 6009. The sweep generator, current follower, and adder were of conventional chopper stabilized design. A Keithley 601B electrometer was used as a voltage follower. Current potential curves were recorded on a Mosley Autograf Model 2DR-2 X-Y recorder.

Experimental procedures.—A known quantity (analytical reagent grade) of lead nitrate and sodium nitrate [a constant concentration ($2.0M$ NO_3^-) in nitrate being maintained] were placed in the electrolytic cell together with a magnetic stirrer. The test electrodes were prepared by cutting a thin slice from the electrode, so exposing a new surface for every run. The cell and the electrodes were assembled together, connected to the vacuum line and then evacuated for a number of hours before use. During this time the cell was gently heated so as to drive off any water which may have been present. The cell and the vacuum line were then isolated from the vacuum pump and the combined system monitored for any leaks. This was accomplished by observing if there was any fall in the manometer attached to the vacuum line over a period of half an hour. The cell was then immersed in an isoproponyl/CO_2 bath at $-70°C$ and allowed to cool. Ammonia gas was then introduced into the vacuum line from the cylinder of ammonia. The ammonia was twice distilled over potassium before use and condensed in the cell at a pressure of a few centi-

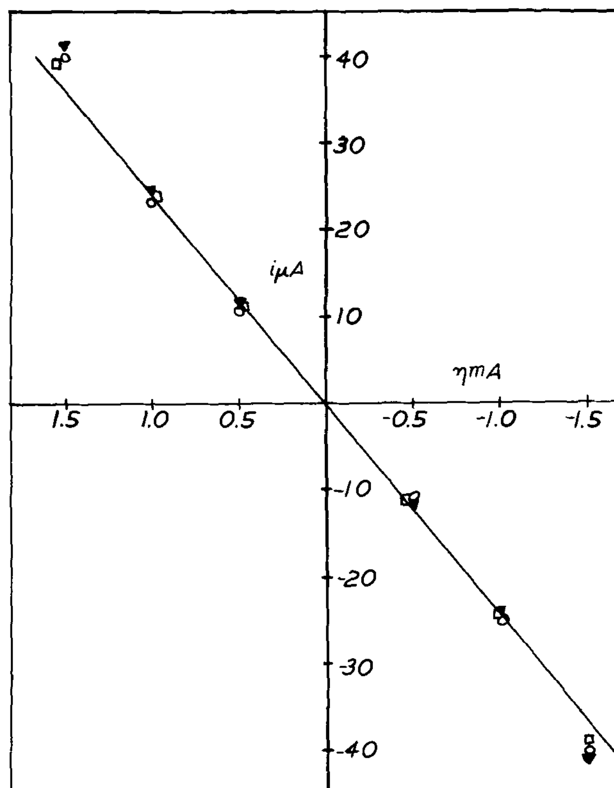

Fig. 2. Current density against overpotential curves at different sweep rates; ○ 0.02 V/min, ▼ 0.16 V/min, □ 0.8 V/min, 2.0M NO_3^-, 0.7M Pb^{2+}, $-45° \pm 1°C$.

meters less than atmospheric. The liquid ammonia was stirred continuously in the cell during condensation by means of the magnetic stirrer to help the dissolution of the salts. When the required volume of liquid ammonia had been condensed, the ammonia cylinder and the electrolytic cell were isolated from the vacuum system. The vacuum line was then evacuated, the small amount of ammonia left in the system being expelled into the atmosphere. The electrolytic cell was then removed from the vacuum line.

Ohmic resistance.—The contribution of R_E (the ohmic resistance) to the total resistive component of the electrode impedance was made negligible by the cell electrode geometry and could be neglected. Typical values of a few ohms were obtained from impedance measurements.

It was noticed that when the liquid ammonia reached its boiling point, −33.3°C, a white precipitate was obtained from the solution; this was collected and later analyzed.

Results

Figure 1 shows a typical current/voltage curve obtained at a polycrystalline lead electrode in sodium nitrate/lead nitrate/liquid ammonia electrolytes. A study was made of the kinetics of the exchange reaction at low and high overpotentials.

Low overpotentials.—Figure 2 shows a number of scans at different sweep rates. In Fig. 3 are shown a number of current/potential curves at varying lead ion concentrations. In Fig. 4 log Pb^{2+} has been plotted against i_o,[5] the slope of the curve gives $\alpha = 0.50$.

High overpotentials.—Figure 5 shows typical anodic Tafel plots obtained at high overpotentials for two different lead concentrations. The slopes of the curves give $\alpha = 0.51 \pm 1$ assuming a two electron transfer. In general at lower lead ion concentrations the Tafel region became less distinct. Cathodic plots at high overpotentials did not show a distinct Tafel region. The electrode behaved as if the exchange reaction was slowly being blocked off.

Analysis of the white precipitate.—The white solid precipitated from solution when the temperature of the liquid ammonia reached its boiling point, −33.3°C, was analyzed and found to have the chemical formula $Pb(NH_3)_2(NO_3)_2$.

Discussion

At low overpotentials the rate-controlling step appears to be the charge transfer reaction

$$Pb \rightleftharpoons Pb^{2+} + 2e \qquad [3]$$

The value of $\alpha = 0.5$ indicates that at low overpotentials the reaction is not complicated by kinetically active adsorbed species (14). At high anodic overpotentials the reaction appears also to be charge transfer controlled. At high cathodic overpotentials (>40 mV from equilibrium) the current appeared to decrease with increasing cathodic potentials. If the electrode was maintained at a constant cathodic potential the current still decreased with time but did not become constant even after many hours. This behavior seems consistent with the electrode reaction being inhibited by some cathodic product blocking the electrode surface [tentatively identified as $Pb(NH_3)_2(NO_3)_2$, see later].

The exchange reaction at a polycrystalline lead electrode in aqueous solutions has been studied by a number of workers (15-17). They found that at low overpotentials the reaction was charge transfer controlled with an apparent exchange current of 100 mA cm^{-2} (0.5M Pb^{2+}), an activation energy of 12.6 ± 2 kJ $mole^{-1}$ and $\alpha = 0.68$. The high α value was attributed to the adsorption of Pb^{2+} ions on the electrode surface. As stated above, the value of $\alpha = 0.5$ obtained in liquid ammonia indicates that in this solvent such adsorption does not occur. If the apparent exchange cur-

[5] i_o is obtained from the reduced form of the Erdey-Gruz and Volmer equation which at low overpotentials reduces to $i = -i_o \frac{zF\eta}{RT}$.

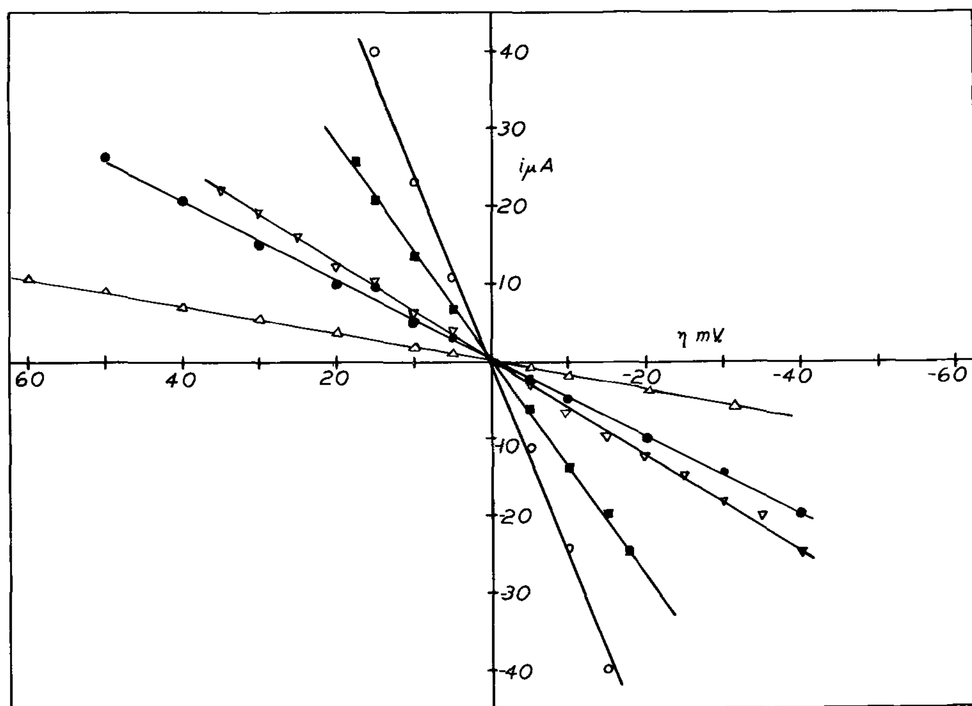

Fig. 3. Current density against overpotential curves at different Pb^{2+} concentrations; ○ 0.7M Pb^{2+}, ■ 0.5M Pb^{2+}, ▽ 0.1M Pb^{2+}, ● 0.05M Pb^{2+}, △ 0.001M Pb^{2+}, 2.0M NO_3^-, −45° ± 1°C.

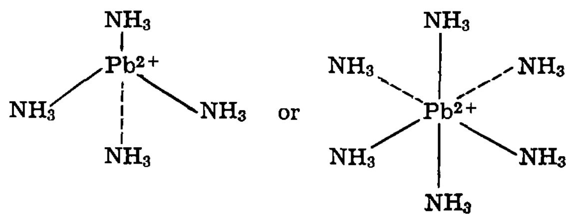
rent in both solvents is calculated for the same temperature, a value of 31.0 mA cm^{-2} is obtained at −45°C for the exchange current in the aqueous system and 20.0 mA cm^{-2} for the exchange current in liquid ammonia. This seems to indicate that at low overpotentials the mechanism of the exchange reaction at a polycrystalline lead electrode is not primarily controlled by the solvent but by the surface of the electrode itself.

The white precipitate obtained from solution when the liquid ammonia is allowed to boil has been identified as $Pb(NH_3)_2(NO_3)_2$, showing that the species $Pb(NH_3)^{2+}$ leads to the production of this insoluble salt in liquid ammonia. As divalent lead tends to be either four or six coordinated, we can assume that in solution we have species of the type



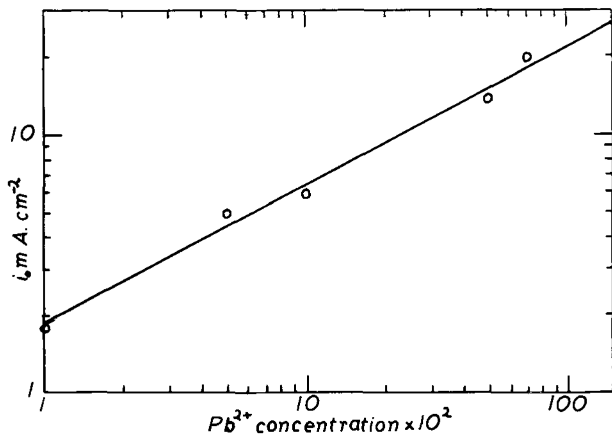


Fig. 4. The variation of exchange current with Pb^{2+} concentration; 2.0M NO_3^-, −45° ± 1°C.

It is suggested that at low overpotentials the lead loses its ammonias of solvation simultaneously so that no species of the type $Pb(NH_3)^{2+}$ are produced while at high cathodic overpotentials the reduction goes via the $Pb(NH_3)^{2+}$ species, causing a solid to form on the electrode and so inhibiting the reaction. Therefore we can write

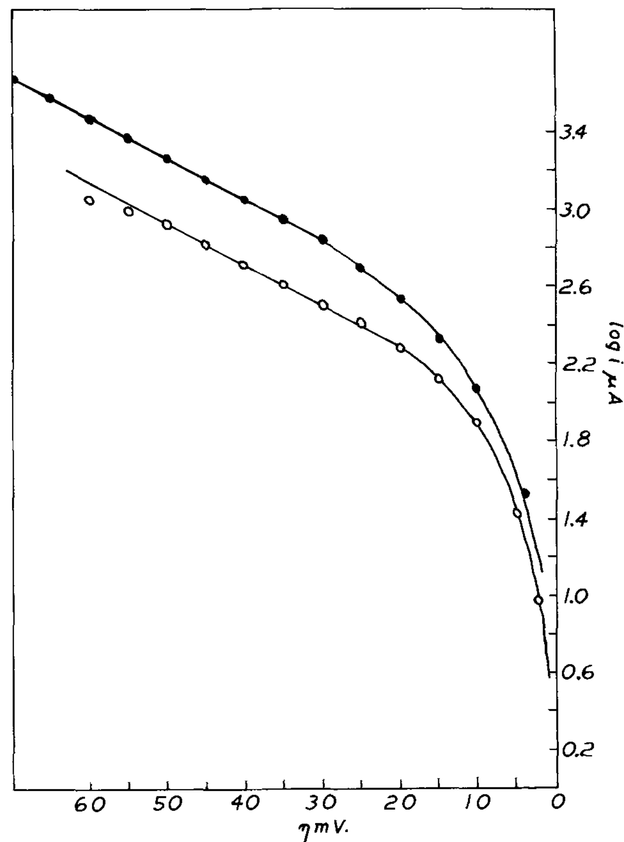

Fig. 5. Anodic Tafel plots obtained at different Pb^{2+} concentrations; ● 0.5M Pb^{2+}, ○ 0.05M Pb^{2+}, 2.0M NO_3^-, −45° ± 1°C.

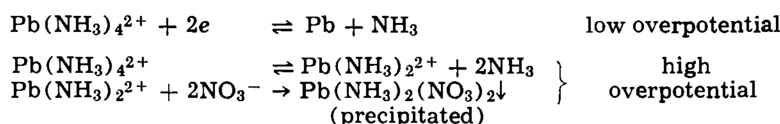

$Pb(NH_3)_4^{2+} + 2e \rightleftharpoons Pb + NH_3$ low overpotential

$Pb(NH_3)_4^{2+} \rightleftharpoons Pb(NH_3)_2^{2+} + 2NH_3$
$Pb(NH_3)_2^{2+} + 2NO_3^- \rightarrow Pb(NH_3)_2(NO_3)_2\downarrow$ (precipitated) } high overpotential

ABSTRACT

Shear viscosities have been measured as a function of temperature for aqueous calcium nitrate solutions in the composition range $R = 4\text{-}10$ ($R =$ moles water/mole salt) over a temperature range from 25°C to as low as −83°C and over a viscosity range from 10^{-1} *P* to as high as 5×10^7 *P*. Conductivity measurements are also reported for the solution of composition $R = 8$ over the range 30° to −83°C. As is the case for a wide variety of other liquids, the Fulcher equation is found to give an inadequate description of the temperature dependence of the transport properties of these solutions when applied to data extending over many orders of magnitude, and the transport properties exhibit a tendency to return to Arrhenius behavior at high viscosities. Comparison of the conductivity and viscosity data for the $R = 8$ composition indicates that it is similar to other ionic liquids in that at low viscosities the time scales for viscous flow and for ionic conduction are comparable in magnitude, but that at high viscosities, in the vicinity of the glass transition temperature, the time scale for viscous flow is very much longer than that for conduction.

A characteristic feature of concentrated aqueous electrolyte solutions is their glass-forming ability. Angell and Sare (1) have recently reported glass-forming concentration ranges for a large number of these solutions, along with the corresponding glass transition temperatures, T_g, at which the solution viscosity approaches a value of around 10^{13} *P*. In some cases these solutions cannot only be quenched to the glassy state, but held in the supercooled state long enough to make physical measurements in the largely unexplored range between the thermodynamic liquidus temperature and the glass transition temperature. Reports of measurements of transport properties of concentrated electrolyte solutions at temperatures well below room temperature are not uncommon [Garrett and co-workers (2) have carried out measurements as low as −75°C]. However, except for two recent reports (3, 4) on electrical relaxation phenomena near T_g, none of these studies have been carried to sufficiently low temperatures to allow observation of a significant fraction of the huge change in transport properties (as much as fifteen orders of magnitude for viscosity) which occurs between the temperature region of "normal" fluidities and the glass transition region.

As an initial effort in this direction, we report in this paper a study of the temperature dependence of the viscosity of concentrated aqueous calcium nitrate solutions in the glass-forming composition region over a viscosity range from 10^{-1} *P* to as high as 5×10^7 *P*. For purposes of comparison, the temperature depen-

* Data from Ref. (1).

dence of the conductivity has also been studied at one composition. Our choice of the calcium nitrate-water system for study was motivated by the relative ease with which these solutions can be supercooled and by their high glass transition temperatures, which lead to the development of high viscosities at temperatures not too greatly removed from ambient. In addition, considerable interest has been exhibited in the transport properties of this system over the past several years (1, 3, 5-13).

Experimental

Sample preparation.—Solutions were prepared from reagent grade calcium nitrate tetrahydrate (Mallinckrodt AR). To remove any insoluble matter capable of acting as nucleation centers for crystallization, the solutions were filtered in a recirculating system containing a Teflon filter of 5 μm pore size (Millipore Corporation). Water content was determined from the weight loss of samples dehydrated at 115°C and then dried to constant weight at 190°C. Density measurements (see below) were used to cross check the composition of all samples. We will express solution compositions in terms of the molar water to salt ratio, R.

$$R = \text{moles water/mole salt}$$

The actual R values for the solutions studied are given in Table I along with the corresponding molalities. Since the R values are so close to integers, we will subsequently specify solution compositions by R values rounded off to the nearest integer (R = 4, 6, 8, or 10). T_g values for these solutions taken from the paper of Angell and Sare (1) are also given in Table I.

Temperature control and measurement.—Samples were thermostated in a 4 liter Dewar flask containing either methanol or an ethanol-methanol mixture stirred with a mechanical stirrer. Temperature was controlled to within ±0.01° above −60°C and to within ±0.05° below −60°C by periodically adding small amounts of dry ice or liquid nitrogen to the bath. Temperatures were measured to an accuracy of ±0.10°C with a calibrated copper-constantan thermocouple whose measuring junction was situated in the bath just outside the sample container. Sufficient time for thermal equilibration was allowed at each temperature before measurements were started. The reproducibility of the data taken over a period of time at the same temperature was considered proof that thermal equilibrium with the bath had been reached.

Density measurements.—Densities of the solutions at 25°C were measured in a pycnometer and agreed within 0.01% with the density data of Ewing and Mikovsky (14). Densities as a function of temperature were measured over the range −25°-25°C by means of a calibrated dilatometer and agreed within 0.03% with densities extrapolated linearly from the Ewing and Mikovsky data (14) (measured over the range 25°-60°C). Subsequently the density data were used both to check sample compositions and to calculate densities at temperatures below −25°C by linear extrapolation. Linear density *vs.* temperature equations for our solutions are given in Table I.

Viscosity measurements.—Viscosities below 200 P were determined with factory-calibrated Cannon-Fenske capillary viscometers with an inherent accuracy of about ±0.5%. Above 10^2 P viscosities were measured with a Brookfield Model RVT rotating cylinder viscometer using a 2.2 cm ID cylindrical glass sample container and a 0.32 cm OD stainless steel spindle immersed in the solution to a depth of 5.1 cm. The Brookfield viscometer was calibrated with NBS standard viscosity oils. In the range 10^2-10^4 P viscosities were measured with the Brookfield viscometer using the rotational method (inherent accuracy ±1%). In the range 10^4 to $5 \times 10^7 P$ the decay method was used (inherent accuracy ±2%). Weiler *et al.* (15) have described both methods in detail. The principal problem encountered in viscosity measurements at low temperatures was the limited amount of time the solutions could be kept in the supercooled state without crystallizing. With the R = 8 solution this problem necessitated frequent remelting of the sample, while with the R = 4 and R = 10 solutions the tendency of the solutions to crystallize prevented viscosity determinations above 10^4 and 10^1 P, respectively.

Conductivity measurements.—Conductivities in the range 10^{-1} to 10^{-4} ohm^{-1} cm^{-1} were measured in the frequency region 1-30 kHz with a three-terminal transformer arm ratio bridge (inherent accuracy ±0.5%) similar in design to that described by Cole and Gross (16). The conductivity cell used in this range was similar to one described previously (6, 17) and had a cell constant of $214._5$ cm^{-1}. The conductivity cell, admittance bridges, and procedure used for measurements in the range 10^{-5} to 10^{-9} ohm^{-1} cm^{-1} have been described elsewhere (3). As is shown in Fig. 1, at the lower end of this range the measured conductivity of the sample exhibits a marked frequency dependence

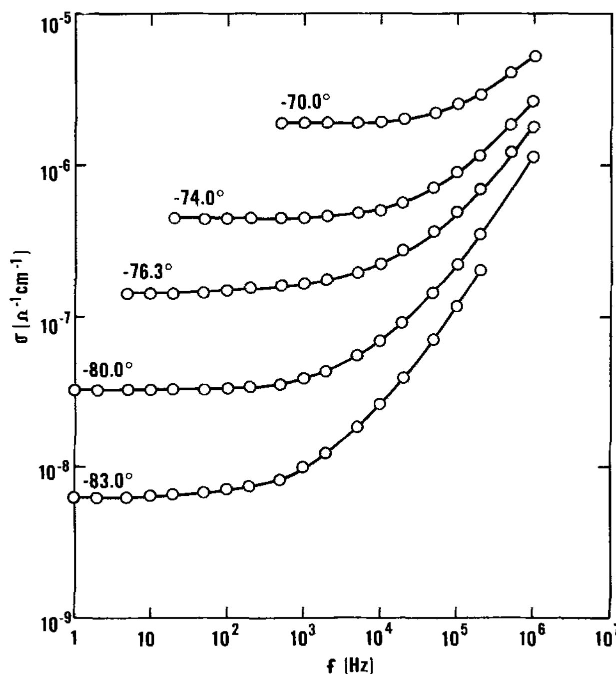

Fig. 1. Frequency dependence of measured conductivity of $Ca(NO_3)_2$-H_2O solution, R = 8, at low temperatures.

in the audio region due to relaxation processes in the solution (3, 4), so that determination of the limiting low frequency conductivity at the lowest temperatures required measurements at frequencies as low as 1 Hz.

At all temperatures the over-all accuracy which may be claimed for our viscosity and conductivity measurements is primarily determined by the temperature dependence of the transport properties and the accuracy of the temperature determination (±0.10). In the vicinity of room temperature, this temperature-induced uncertainty is in the range of 0.3-0.6%, but it rises to 5-8% in the vicinity of the lowest temperatures (around −80°C) at which measurements were performed.

Results and Discussion

Our experimental values for the shear viscosities, η, of solutions of composition R = 4, 6, 8, and 10 and specific conductances, σ, for the R = 8 composition are given in Table II.

In Fig. 2 and 3, Arrhenius plots are shown for the shear viscosities and the conductivity. As is the usual case for liquids in this viscosity range, these plots are curved in a direction corresponding to an increase in the apparent activation energy with decreasing temperature, where apparent activation energy, E, is defined by

$$E/\mathcal{R} = \partial \ln w/\partial(1/T) \qquad [1]$$

where w is a transport property such as η or $1/\sigma$, and $\mathcal{R}$ is the ideal gas constant. We have calculated apparent activation energies as a function of temperature for viscosity and conductivity from the slopes of least-squares fits of the data to equations cubic in $(1/T)$. These are plotted in Fig. 4. (The E *vs.* T plot for η at R = 10, which lies atop the E *vs.* T plot for $(1/\sigma)$

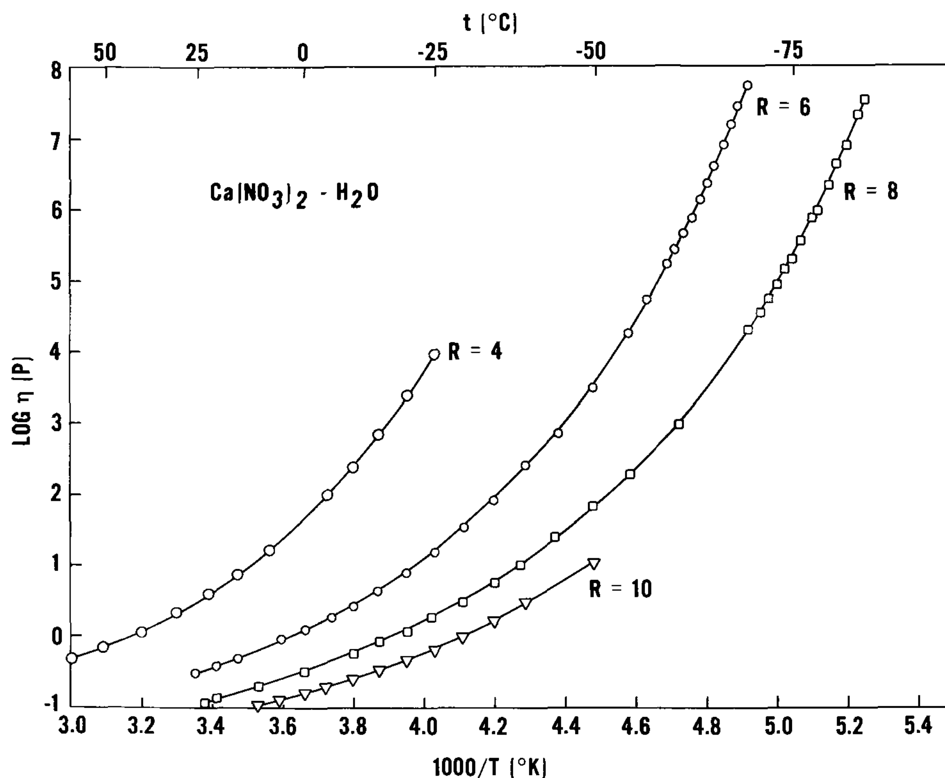

Fig. 2. Arrhenius plots of shear viscosity for aqueous calcium nitrate solutions.

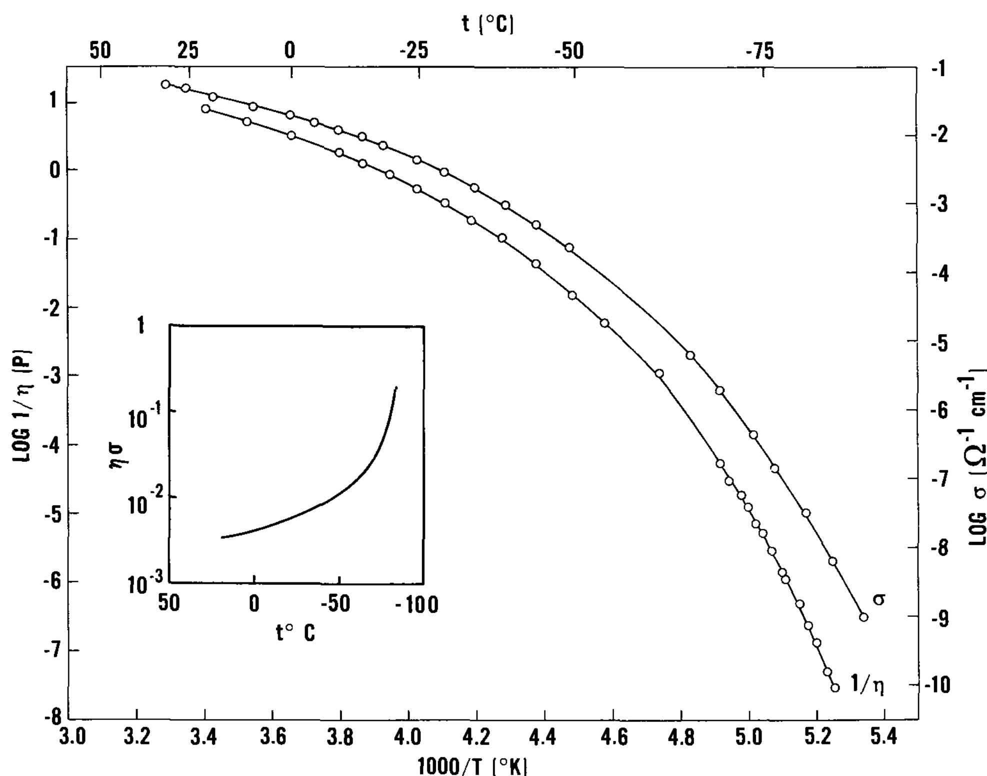

Fig. 3. Arrhenius plots of shear viscosity and conductivity for $Ca(NO_3)_2$-H_2O solution, $R = 8$. Inset: Viscosity-conductivity product as a function of temperature.

at $R = 8$ has been omitted for clarity.) As may be seen from Fig. 2-4, the transport properties of these solutions become extremely temperature dependent at high viscosities so that at the highest viscosities for which measurements were performed the viscosity changes by an order of magnitude in only three to four degrees.

During the past several years the non-Arrhenius temperature dependence of concentrated aqueous electrolyte solutions in the viscosity range 10^{-1} to 10^{1} P has frequently been accounted for in terms of the Fulcher equation (5-13)

$$\ln w = A + B/(T - T_o) \quad [2]$$

where A, B, and T_o are empirical parameters. The T_o has been interpreted as a zero-mobility temperature at which the free volume (18) or configurational entropy (19) of the liquid would vanish at equilibrium. In Table III are shown the Fulcher equation parameters obtained from least-squares fits of the viscosity or conductance data for each solution over the entire temperature range available. In the cases in which the data cover an extensive range (η for $R = 6$ and 8 and $1/\sigma$ for $R = 8$), the standard deviations of $\ln w$ from the best-fit Fulcher equations lie outside the estimated uncertainties in the precision of our measurements. (Note that standard deviation $\ln w \approx |\Delta w/w|$ avg $\approx$ (1/100) avg % error in w.) Hence the Fulcher equation does not give a good description of the transport properties of concentrated aqueous electrolyte solutions over extended ranges. To confirm this, we divided the data for each solution into subsets corresponding roughly to the viscosity ranges 10^{-1} to 10^{1}, 10^{1} to 10^{4}, and 10^{4} to 10^{8} P and fit each subset to the Fulcher equation. These results are also shown in Table III and in all cases the standard deviations are consistent with the estimated precision of our data. Thus the Fulcher equation, as a smoothing function for transport property-temperature data, should not be applied over ranges covering more than about three orders of magnitude in the transport property.

It is noteworthy that for each solution, as one proceeds to higher and higher viscosity ranges, the T_o value obtained from the Fulcher equation-fit in that range progressively decreases. The apparent activation

* Data from Ref. (6).

energy in terms of the Fulcher equation parameters is

$$E/\mathcal{R} = BT^2/(T - T_o)^2$$

so that a decrease in T_o indicates a reversion to Arrhenius behavior (constant E, corresponding to T_o = 0) of the transport property in question. Hence these concentrated electrolyte solutions exhibit the same tendency to revert to Arrhenius behavior at very high viscosities that has been noted for a wide variety of other glass-forming liquids (20). In this respect it is also noteworthy that the rate of decrease of the apparent T_o value with increasing viscosity is smaller for the less concentrated solutions, so that the more dilute solutions tend to revert to Arrhenius behavior at higher viscosities than do the more concentrated solutions.

Recently Tweer *et al.* (20) have proposed a theory (the "environmental relaxation model") for the temperature dependence of liquid transport properties over extensive viscosity ranges. The theory successfully predicts the occurrence of Arrhenius behavior at the high and low temperature viscosity extremes, along with an intermediate region of varying activation energy, by relating the temperature dependence of the apparent activation energy to the temperature dependence of the range of the local liquid microstructure. Tweer *et al.* (20) have also derived from the environmental relaxation model a semiempirical equation containing five adjustable parameters for the temperature dependence of liquid transport properties. Our present data do not cover a sufficient range to allow an unambiguous determination of these five parameters, which are highly interdependent. Hence we will not attempt at present any quantitative expression of our results in terms of the environmental relaxation model, but rather merely point out their qualitative accord with this theory.

Figure 5 shows isothermal logarithmic plots of viscosity *vs.* mole per cent salt. The large composition dependence of transport properties of these solutions and the increase in composition dependence with decreasing temperature has been noted previously by Angell (7, 8). Angell also noted that the isothermal composition dependence of the transport properties at temperatures above 0°C may be expressed simply in terms of the apparent composition dependence of the Fulcher equation T_o parameter. In support of this correlation Angell and co-workers (9, 12) have noted that the measured T_g and the Fulcher equation T_o derived from data in the 10^{-1} to 10^{1} P viscosity range show identical composition dependences. Our present measurements are in accord with this finding, the T_g/T_o ratio being constant at 1.05 ± 0.01 over the composition range R = 4-10 for T_o values extracted from data in the lowest viscosity region. For the higher viscosity ranges, however, the T_g/T_o ratio is no longer composition independent, so that it seems unlikely that Angell's treatment of the composition dependence of the transport properties of these solutions will be valid in these regions.

In the inset of Fig. 3 the $\eta\sigma$ product for the R = 8 solution has been plotted *vs.* temperature. The remarkable feature of this plot is the sharp upward bend in the $\eta\sigma$ curve at the lowest temperatures. This feature is also revealed in Fig. 4 in terms of the large differences in the viscosity and conductivity apparent activation energies at the lowest temperatures and in Table III in the more rapid decrease (with increasing viscosity) of the apparent T_o value for conductivity relative to that for viscosity. In this respect, the R = 8 calcium nitrate-water solution is strikingly similar to the fused nitrate system 0.4 $Ca(NO_3)_2$-0.6 KNO_3 (20, 21), in which the viscosity to conductivity apparent activation energy ratio, E_η/E_σ, was constant at about 1.29 up to a viscosity of about 10^4 P, then rose gradually with decreasing temperature, finally leveling off at a value of about 1.85 near T_g. In the present case of the R = 8 calcium nitrate solution, E_η/E_σ is roughly constant at about 1.18 at higher temperatures, but, like the fused salt, begins to increase with decreasing temperature at a viscosity of about 10^4 P. Tweer *et al.* (20) have shown that in terms of the environmental relaxation model the observed temperature dependence of the E_η/E_σ ratio for the above mentioned nitrate melt (and hence also for the $Ca(NO_3)_2$

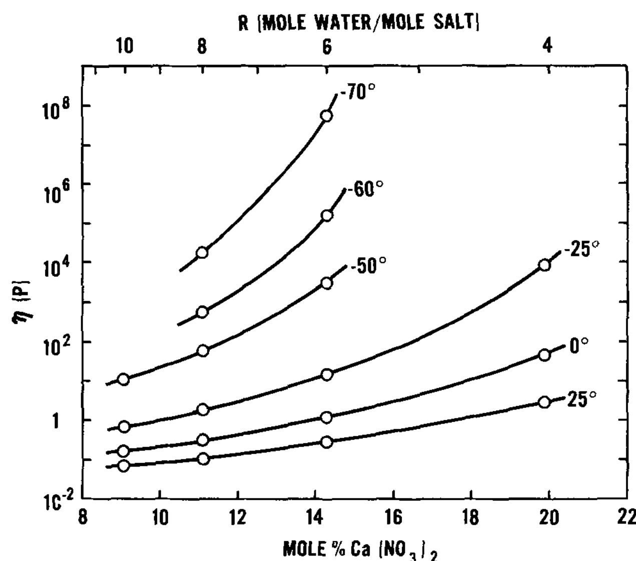

Fig. 5. Composition dependence of shear viscosity of $Ca(NO_3)_2$-H_2O solutions.

$R = 8$ solution) may be interpreted in terms of differences in the ranges or distances over which the ionic conductivity and viscous flow processes are affected by the local liquid microstructure.

Both viscous flow and ionic conduction may be described in terms of characteristic relaxation times. For viscous flow the appropriate relation is (22)

$$\eta = G_\infty \langle\tau_s\rangle$$

where $\langle\tau_s\rangle$ is the average shear relaxation time and G_∞ the limiting high frequency or "solid-like" shear modulus of the liquid. For ionic conductivity the relation is (3, 4, 23)

$$\sigma = \epsilon_o\epsilon_s/\langle\tau_\sigma\rangle$$

where $\langle\tau_\sigma\rangle$ is the average conductivity relaxation time, ϵ_o is the permittivity of free space ($8.854 \times 10^{-14}F$ cm^{-1}), and ϵ_s is the relative permittivity or dielectric "constant" of the liquid arising from polarization processes not involved in long range charge transport. While G_∞ and ϵ_s are in general temperature dependent, their variations with temperature are expected to be negligible compared to the order-of-magnitude changes encountered in σ and η. Reasonable "figure-of-merit" values for G_∞ and ϵ_s are

$$G_\infty \sim 2 \times 10^{10}\ \text{dyne cm}^{-2}$$

$$\epsilon_s \sim 10$$

so that to estimate the shear to conductivity relaxation time ratio we may use

$$\langle\tau_s\rangle/\langle\tau_\sigma\rangle = \eta\sigma/(G_\infty\epsilon_o\epsilon_s) \sim 5 \times 10^1\,\eta\sigma$$

In the temperature interval 25° to -60°C for the $Ca(NO_3)_2$ $R = 8$ solution, the $\eta\sigma$ product is (within a factor of two about 1×10^{-2}, which gives a $\langle\tau_s\rangle/\langle\tau_\sigma\rangle$ ratio of 0.5, *i.e.*, approximately unity. Hence at high temperatures and low viscosities the time scales for the ionic conduction process and for the structural rearrangements involved in the viscous flow process are of similar magnitude, which is in turn the basis for the approximate validity of the Stokes-Einstein and the Nernst-Einstein relations in the highly fluid region of the liquid. As indicated in the inset of Fig. 3, however, the $\eta\sigma$ product begins to increase rapidly with decreasing temperature at viscosities above 10^4 *P*, leading to a similar marked rise in the $\langle\tau_s\rangle/\langle\tau_\sigma\rangle$ ratio. At the lowest temperature for which data are available for the $Ca(NO_3)_2$ $R = 8$ solution the estimated $\langle\tau_s\rangle/\langle\tau_\sigma\rangle$ ratio has risen to about 15 and, judging from the temperature dependences of η and σ in this region, probably attains a value of at least 10^4 at T_g. The $\langle\tau_s\rangle/\langle\tau_\sigma\rangle$ ratio at T_g for the fused calcium-potassium nitrate mixture (21) is also around 10^4. Hence near T_g ionic conduction in these liquids does not require simultaneous structural rearrangements of the liquid quasi-lattice. Such a phenomenon could be explained if the cations were considerably more mobile than the anions or *vice versa*, since viscous flow would require motion of both types of ions, while conduction would presumably involve primarily displacement of the more mobile ionic species. Thus a $\langle\tau_s\rangle/\langle\tau_\sigma\rangle$ ratio much greater than unity would be expected for alkali silicate melts, where charge would be transported by the alkali ion moving through a network formed by the large, multiply charged silicate ions. It is somewhat surprising, however, to find this in simpler ionic liquids, such as $Ca(NO_3)_2$-H_2O solutions or $Ca(NO_3)_2$-KNO_3 melts, where neither the cation nor the anion is incorporated into a covalently bonded network. Nonetheless on the basis of the two systems which have been investigated so far, we speculate that the occurrence of a $\langle\tau_s\rangle/\langle\tau_\sigma\rangle$ ratio near T_g which is substantially greater than unity is probably a general feature of all highly concentrated ionic conductors.

Previous interpretation of the Fulcher equation T_o parameter as an equilibrium property of a liquid had led Moynihan, Angell, and their co-workers (6, 12, 13, 24) to suggest that the T_o parameter should be the same for all transport properties of the same liquid. As may be seen from the T_o parameters for η and $(1/\sigma)$ for the $R = 4$ and 8 solutions in Table III, this is true within experimental uncertainty for the viscosity range 10^{-1} to 10^1 *P*, but, as is shown for the $R = 8$ solution, ceases to hold true at higher viscosities. Results of the same sort were obtained from a comparison of viscosity and conductance for the nitrate melt 0.4 $Ca(NO_3)_2$-0.6 KNO_3 (21).

Conclusion

The present results for transport properties of concentrated aqueous $Ca(NO_3)_2$ solutions indicate the failure of the Fulcher equation to adequately account for the data over extensive ranges in viscosity, as has recently been found to be the case for a wide variety of other liquids (15, 20, 21, 25). These solutions also exhibit the general tendency to revert to Arrhenius behavior at high viscosities. At temperatures near T_g the large differences in the temperature dependences of the viscosity and conductivity lead to the conclusion that in the glass transition region there must be a large difference between the time scales for ionic conduction and for viscous flow. In the future we hope to report extensive results of ultrasonic and electrical relaxation experiments for these solutions to provide a quantitative comparison of the structural and electrical relaxation times.

Acknowledgments

The authors wish to thank Mr. K. Strom for assistance with the viscosity measurements and Mr. J. Costa and Mr. V. Provenzano for assistance with the conductivity measurements. This research was supported by the Naval Ordnance Laboratory's Independent Research Program and by a Themis Grant from the Office of Naval Research.

Voltammetric Determination of Oxygen in Liquid Metals Using Solid Oxide Electrolytes

T. H. Etsell* and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

Dissolved oxygen was electrochemically reduced in cells of the type

$$(-)\ O(\text{in M})/ZrO_2\text{-}CaO/O_2\ (+)$$

where M was either silver or copper. Impervious ZrO_2 + 10 m/o (mole per cent) CaO electrolyte tubes were immersed in the liquid metal. The dependence of current on immersion depth, applied potential, time, dissolved oxygen concentration, temperature, and the amplitude and frequency of vibration of the electrolyte was studied. The electrode reactions are reversible. At sufficiently high applied potentials, diffusion overpotential appears at the liquid metal electrode and, for small depths of immersion, limiting currents are eventually realized. They are directly proportional to the concentration of dissolved oxygen meaning that voltammetric measurements could be used to determine the dissolved oxygen content of liquid metals. This proportionality was verified from 0.002 to 0.15 a/o (atomic per cent) O in silver between 1000° and 1200°C and from 0.005 to 0.13 a/o O in copper between 1100° and 1300°C. Effective diffusion layer thicknesses are about 0.05 cm.

Electromotive force measurements on oxygen concentration cells with solid oxide electrolytes have been used for the *in situ* determination of dissolved oxygen in many liquid metals and alloys. For instance, results have been reported on the activity of oxygen in liquid silver (1-3) and copper (3-21). In several investigations, values for the solubility limit of oxygen in liquid copper were concurrently determined (6, 7, 10).

An earlier paper concerning the behavior of the liquid silver electrode during current flow (22) indicated the feasibility of analyzing liquid metals for dissolved oxygen using a voltammetric technique. This method depends upon the establishment of limiting currents at the metal-electrolyte interface during the electrochemical removal of oxygen from the liquid metal. The conditions necessary to observe limiting currents were defined in this investigation. The influence of the depth of immersion of the electrolyte tube is discussed in detail, and current-potential and current-time characteristics are shown. Results are given which relate the dissolved oxygen concentration to the limiting current density over a wide range of oxygen contents for both silver and copper.

The principle of the oxygen concentration cell when current is passed with the liquid metal electrode as the cathode is illustrated in Fig. 1 (*O* symbolizes dissolved oxygen in the figures). At the metal-electrolyte interface, dissolved oxygen (existing in solution as atoms or anions) is reduced according to

$$O\ (\text{in M}) + 2e \rightarrow O^{=} \quad [1]$$

Hence, liquid metals can be electrolytically deoxidized, *e.g.*, copper (23, 24). When the applied potential is high enough to lower the dissolved oxygen concentration at the interface below the bulk concentraton, oxygen passes through a diffusion layer, which appears in the liquid metal, in order to reach the interface. If the interfacial concentration becomes negligible with respect to the bulk concentration, limiting currents, controlled by diffusion and convection, will be observed. Forced convection in the metal results from vibrating the electrolyte, as indicated. As a consequence, the diffusion layer is set up more quickly and is more stable. Oxygen ions are transported through the solid electrolyte and are oxidized at the Pt, O_2 anode via the reaction

$$O^{=} \rightarrow \tfrac{1}{2} O_2 + 2e \quad [2]$$

Experimental

The cell design used for the reported measurements is shown in Fig. 2. The electrolyte was an impervious tube of ZrO_2 + 10 m/o CaO, closed flat at one end. The inner surface of the closed end had been platinized by applying drops of a 5-10% chloroplatinic acid solution and decomposing the solution at 600°-700°C. The electrolyte tube was 24 in. long with a nominal ID of ⅜ in. and OD of ½ in.

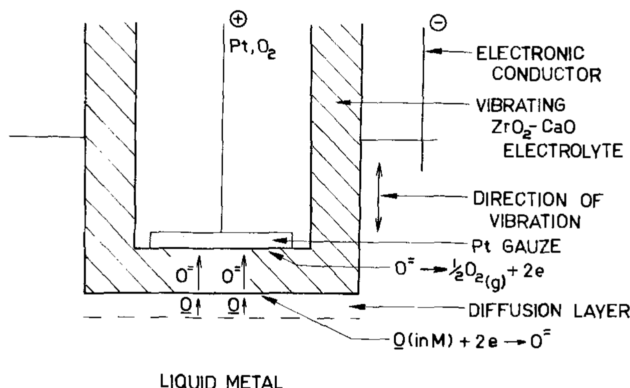

Fig. 1. Principle of the voltammetric determination of oxygen in liquid metals.

Key words: solid electrolytes, zirconia, oxygen determination, voltammetry, limiting currents, diffusion overpotential, liquid metals, silver, copper.

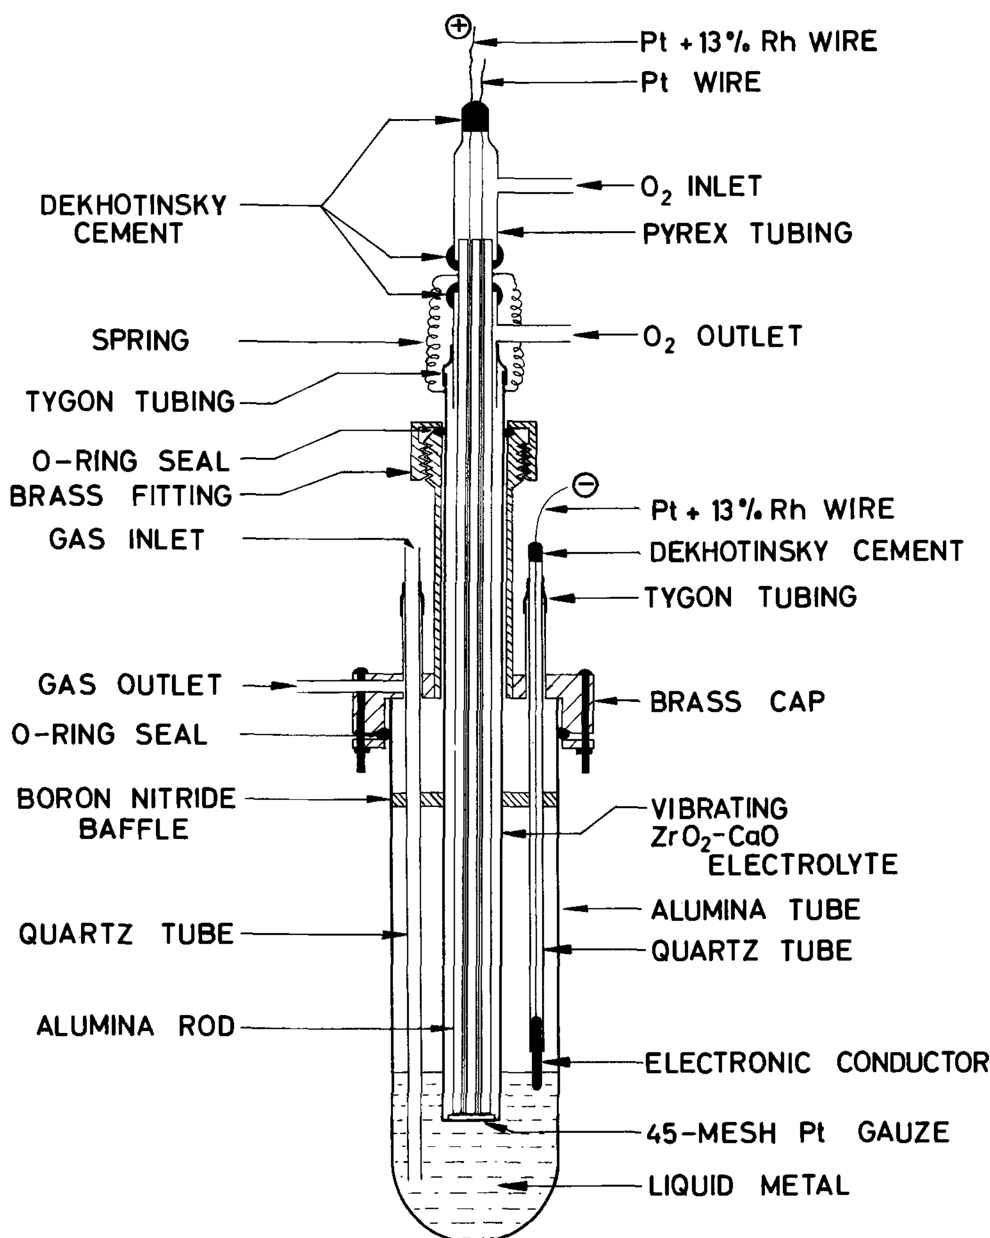

Fig. 2. Oxygen concentration cell.

The liquid metal was contained inside an alumina tube having a hemispherical closure which was 18 in. long with an ID of 1-1/16 in. and OD of 1-5/16 in. Enough 99.999+% metal shot was initially added so that the liquid would have a height of 1½ in.—175g of silver or 150g of copper.

To serve as a conducting lead for establishing electrical contact with the liquid metal, a 2 in. length of 0.057 in. Chromel A wire (80% Ni, 20% Cr) for the silver experiments and of 0.105 in. stainless steel wire (Type 314) for copper were used. The lead was spot-welded to a piece of 0.020 in. Pt + 13% Rh wire. Since the joint was in the hot zone, thermoelectric forces were virtually eliminated. The lead wire was held in a 4 mm OD quartz tube. (For copper, this tube was joined to a piece of 6 mm OD quartz tubing to accommodate the stainless steel.) The lead protruded 1 in. below the quartz tube and dipped about ¼ in. into the metal. The space between it and the quartz tube was small enough to prevent attack of the Pt-Rh wire by metal vapor.

To control the concentration of dissolved oxygen, gas mixtures of known oxygen content (Ar-O_2 for silver and CO-CO_2 for copper) were bubbled through the liquid metal. They entered the cell via a quartz tube with an ID of 2.5 mm and OD of 4 mm which was generally inserted about 1¼ in. into the metal. Both quartz tubes could be easily raised or lowered through the Tygon tubing seals.

The boron nitride radiation baffle, held 10 in. above the surface of the liquid metal by a piece of wire wound on the electrolyte tube, had been machined to fit tightly against the ceramic tubes to help achieve proper alignment. In order to prevent its reaction with quartz, the baffle was kept in the cold zone. Further alignment of the electrolyte tube was achieved because a 3 in. long brass tube with an ID of ½ in. was soldered to the brass cap. The brass fitting was adjusted so that the O-ring seal pressed very gently against the electrolyte which was coated with a thin layer of grease in this region. In this manner, a gas-tight seal could be maintained while the electrolyte tube was vibrated freely. A motor-driven steel rod was clamped to the tube immediately above the brass fitting (not shown).

A ¼ in. alumina rod, which had two 1/16 in. holes and was 28 in. long, held a ⅜ in. diam circle of 45-mesh Pt gauze firmly against the inside of the electrolyte tube. Three springs located at 120° intervals around the cell ensured satisfactory electrical contact. Oxygen at a pressure of 1 atm was passed over the Pt gauze to

form the reference electrode. To facilitate the gas flow, slits had been cut into the bottom of the alumina rod. A Pt-Pt + 13% Rh thermocouple was welded to the Pt gauze. The Pt-Rh wire also served as the positive lead to the cell.

The cell was heated in a Pt resistance furnace with a 2 in. long constant temperature zone (±2°C). For electrical shielding, a grounded 0.025 in. thick Inconel tube lined the furnace walls. The rubber and cement connections were protected by a cooling coil soldered to the brass cap and a fan.

Before measurements were begun, the cell was heated to 1200°C to reduce contact resistance between the Pt gauze and the electrolyte. Suitable gas mixtures were bubbled, in turn, through the metal until the cell emf reached the theoretical value. Equilibrium was approached very slowly (several hours were often inadequate) for Ar-O_2 mixtures dilute in O_2 (<100 ppm) and CO-CO_2 mixtures dilute in CO (< 1%), probably due to slow CO_2 decomposition in the latter case (8). It was usually achieved coulometrically for these mixtures. Prior to the voltammetric measurements, the gas flow was stopped. The experiments were not conducted above 1200°C for silver because of excessive evaporation, nor above 1300°C for copper because of excessive oxidation of the stainless steel lead wire. In the latter case, the oxide severely attacked the quartz sheath at 1300°C. Three independent runs for both silver and copper were made.

Results and Discussion

As inert conducting leads, Chromel A and Type 314 stainless steel functioned very well for silver and copper, respectively. They were not chemically attacked and the oxide films protecting them had a negligible resistance.

For liquid copper, 6 in. lengths of ⅛ in. SiC rod, mechanically joined to either Chromel A or gold wire, were also tried. The rods had a density of 92% of the theoretical value. They were found to be quite satisfactory for emf measurements but unreliable for voltammetric measurements, probably due to the formation of a surface layer of SiO_2 which often caused a large increase in their resistance. A SiC lead could be useful for emf readings in liquid copper containing impurities such as sulfur and phosphorus which would restrict the use of stainless steel. In earlier work, a cermet of 72% Cr and 28% Al_2O_3 was successfully used (3, 8, 13, 14, 20, 21).

Initially, the resistance of the electrolyte varied somewhat with time due to a changing contact area with the Pt gauze electrode upon the evolution of oxygen during current flow. However, it soon became approximately constant (±5%). On an average, the a-c resistance of the cell (electrolyte and lead wires), measured at 3000 Hz, for an electrolyte immersion of ⅛ in. into the liquid metal was 17.5, 8.2, 5.2, and 4.0 ohms at 1000°, 1100°, 1200°, and 1300°C, respectively.

Emf measurements.—The emf or reversible potential of the cell illustrated in Fig. 2 can be expressed as

$$E_{\text{rev}} = -\frac{RT}{4F} \ln P_{O_2} \qquad [3]$$

where P_{O_2} is the oxygen pressure imposed by the gas mixture in equilibrium with the liquid metal. When the electrolyte was submerged even slightly in the metal, the emf responded slowly to changes in the oxygen pressure above the metal relative to the virtually instantaneous response recorded for a Pt,gas electrode. Therefore, the emf is mainly dependent on the oxygen activity at the bottom of the electrolyte tube. Agreement between measured and theoretical values to within ± 1 mV for Ar-O_2 mixtures and ± 3 mV for CO-CO_2 mixtures was generally achieved. Thermoelectric forces were found to be no greater than 0.5 mV (the liquid metal electrode was positive).

After the gas flow was interrupted, emf's of 250 and 700 mV for silver and copper, respectively, remained essentially constant for 12 hr. These results indicated that the cells were gastight and verified the expected low electronic conductivity and porosity of the ZrO_2-CaO tubes.

Dissolved oxygen concentrations.—In the case of silver, the oxygen pressures calculated from Eq. [3] were converted into dissolved oxygen concentrations using available solubility data at an oxygen pressure of 1 atm and Sievert's law which has been verified for the Ag-O system (1, 25). At 1 atm, silver will dissolve 1.969, 1.793, and 1.649 a/o O at temperatures of 1000°, 1100°, and 1200°C, respectively (1, 25, 26).

For copper, the dissolved oxygen concentrations were determined from data recently reported by Fruehan and Richardson (14). The reaction

$$\tfrac{1}{2} O_2 \text{ (g, 1 atm)} \rightarrow \text{O (in Cu, 1 a/o)} \qquad [4]$$

has partial free energies of solution of −18,300, −18,130, and −18,020 cal/g-atom at 1100°, 1200°, and 1300°C, respectively, whereby dissolved oxygen has the properties corresponding to infinite dilution. The former two values are in excellent agreement with the earlier results of Wilder (7) although the most recent data (21) indicate free energies about 130 cal/g-atom less negative. The equilibrium constant for reaction [4] is given by

$$K = \frac{\text{a/o O}}{P_{O_2}^{1/2}} \qquad [5]$$

assuming Henry's law is obeyed—a reasonable assumption for the Cu-O system below 1 a/o O from 1100° to 1400°C (4-6, 7, 11, 12, 14, 17). At 1100°, 1200°, and 1300°C, $K \times 10^{-2}$ = 8.18, 4.90, and 3.19 atm$^{-1/2}$, respectively. Using Eq. [5], the dissolved oxygen concentration can be readily calculated for any given oxygen pressure in equilibrium with liquid copper.

Cell reversibility.—The plot of cell potential *vs.* current in Fig. 3 for an electrolyte immersion depth of ⅛ in. indicates that the oxygen concentration cell discharges reversibly. In agreement with earlier work on liquid silver (22), only resistance polarization is present since, within experimental error, the slopes of the lines approximate the corresponding a-c resistance of the cell. At lower oxygen concentrations, some diffusion overpotential caused by a buildup of dissolved oxygen at the metal-electrolyte interface was unavoidable, especially at high currents. The Pt, O_2 reference electrode was nonpolarizable, even at 200 mA and 1000°C.

Influence of the depth of immersion of the electrolyte tube.—During electrochemical removal of oxygen from

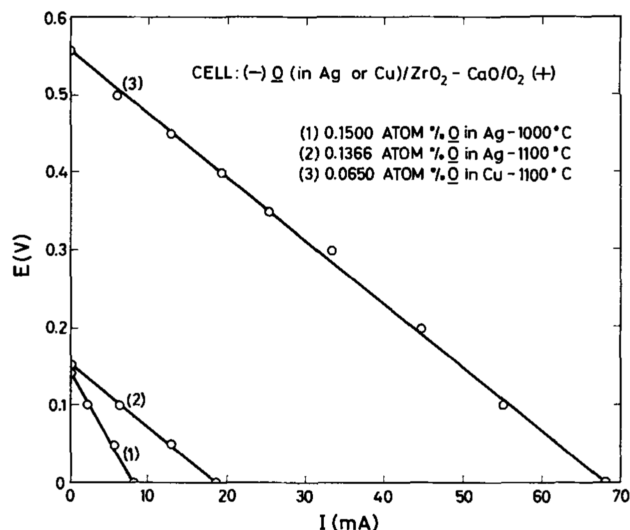

Fig. 3. Discharge curves. Cell potential is plotted against current.

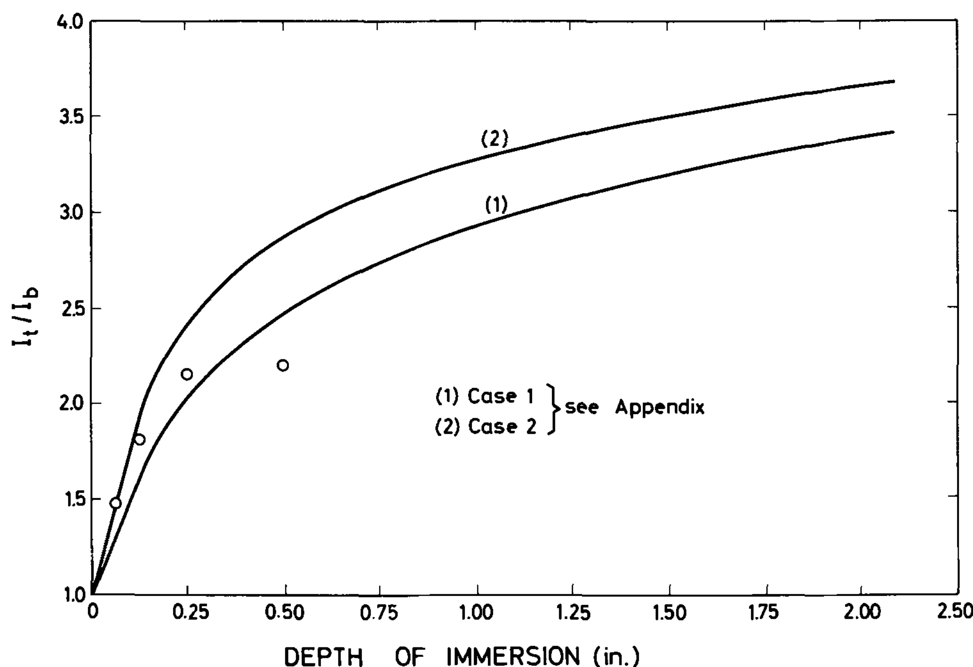

Fig. 4. Ratio of the total current to the current crossing the outside surface of the bottom of the electrolyte tube as a function of the depth of immersion of the electrolyte in the absence of diffusion overpotential. Both theoretical curves and experimental points are shown. The Pt gauze electrode has a diameter of ¼ in. for case 1 and ⅜ in. for case 2.

the liquid metal, reaction [1] will occur over the entire metal-electrolyte interface, *i.e.*, some of the $O^=$ ions will be formed on the side of the electrolyte tube. Theoretical curves for the ratio of the total current, I_t, to the current carried across the bottom of the electrolyte tube, I_b, as a function of the depth of immersion are presented in Fig. 4. These curves were derived by dividing the tube into a number of parallel conductors; their derivation is given in the Appendix. It should be emphasized that the curves are applicable only when the current is controlled by the resistance of the electrolyte, *i.e.*, in the absence of diffusion overpotential.

Case 1 and case 2 refer to two different sizes of the circular Pt gauze electrode. Case 1 (diam = ¼ in.) would apply if only that portion of the Pt gauze directly under the alumina rod (Fig. 2) were making suitable contact with the electrolyte, whereas case 2 (diam = ⅜ in.) would apply if the entire Pt gauze were making suitable contact. Although the currents are higher in case 2 (see Appendix), it results in a greater percentage of the current crossing the side of the electrolyte for a given depth of immersion. The experimental points, representing an average of several determinations of either the a-c resistance of the electrolyte or the d-c resistance at low currents and high oxygen concentrations at various depths of immersion, support the correctness of the model proposed in the Appendix and favor case 2 up to a depth of immersion of ⅛ in. The agreement with case 2 is consistent with the observation made after the runs that both the Pt gauze electrode and Pt black deposit covered the entire inside of the bottom of the electrolyte tubes. At greater depths of immersion, the currents became more insensitive to changes in the depth than predicted from Fig. 4 indicating, undoubtedly, some interference among the competing currents in the various segments of the tube.

The effects presented in Fig. 4 would be less severe if the thickness of the bottom of the electrolyte tube were reduced. However, grinding the electrolyte with SiC powder led to a serious risk of cracking the ceramic tube. When diffusion overpotential appears, the influence of the depth of immersion becomes more pronounced since the longer resistance paths through the electrolyte for $O^=$ ions formed at the side of the tube (see Appendix) become less important. In the limit, when the oxygen concentration is very low along the entire metal-electrolyte interface, the current will be proportional to the submerged outside area of the electrolyte tube (assuming a constant diffusion layer thickness). As the electrolyte tubes had an actual OD of 1.25 cm, the area of the metal-electrolyte interface was 1.23, 2.47, and 3.72 cm^2 for depths of immersion of 0, ⅛, and ¼ in., respectively.

Establishment of limiting currents.—Most of the measurements were taken while the electrolyte tube was vibrated with an amplitude of 1/16 in. and a frequency of 84 cycles/min. These conditions produced current fluctuations near the limiting currents of 2-3% and <0.5% of the readings for depths of immersion of ⅛ and ½ in., respectively. These percentages increased markedly at higher amplitudes and increased by a factor of about 1.5 at a frequency of 42 cycles/min.

Several important features of the preceding section are illustrated by the current-potential curves for 0.0622 a/o O in silver at 1000°C shown in Fig. 5. The potential was applied at a rate of 0.8 V/min to avoid lowering the bulk oxygen concentration significantly. A rate of 0.4 V/min was satisfactory if the initial reading was taken near the onset of appreciable diffusion overpotential.

At low currents, the d-c resistances, calculated from the slopes of the curves, were generally somewhat higher than the corresponding a-c resistance, *e.g.*, 17% higher for ⅛ in. immersion in Fig. 5. The percentage increased when either the oxygen concentration or the a-c resistance was decreased. For instance, it was about 50% at 1000°C and 75% at 1200°C for 0.01 a/o O in silver. However, this disagreement was determined to be solely caused by diffusion overpotential at the liquid metal electrode and, consequently, reactions [1] and [2] proceed reversibly. Diffusion overpotential, η_d, in the absence of other types of overpotential, can be expressed as

$$\eta_d = E - E_{rev} - IR_{a\text{-}c} \quad [6]$$

where E is the applied potential, E_{rev} is the reversible potential ($I = 0$), and $R_{a\text{-}c}$ is the a-c resistance of the cell. Close agreement was found between the diffusion overpotential, measured immediately after the current was interrupted, and the total overpotential, given by the right-hand side of Eq. [6]. Further evidence of diffusion overpotential was derived from the fact that, at low oxygen concentrations, the a-c resistance measured at 1000 Hz was often about 5% higher than that

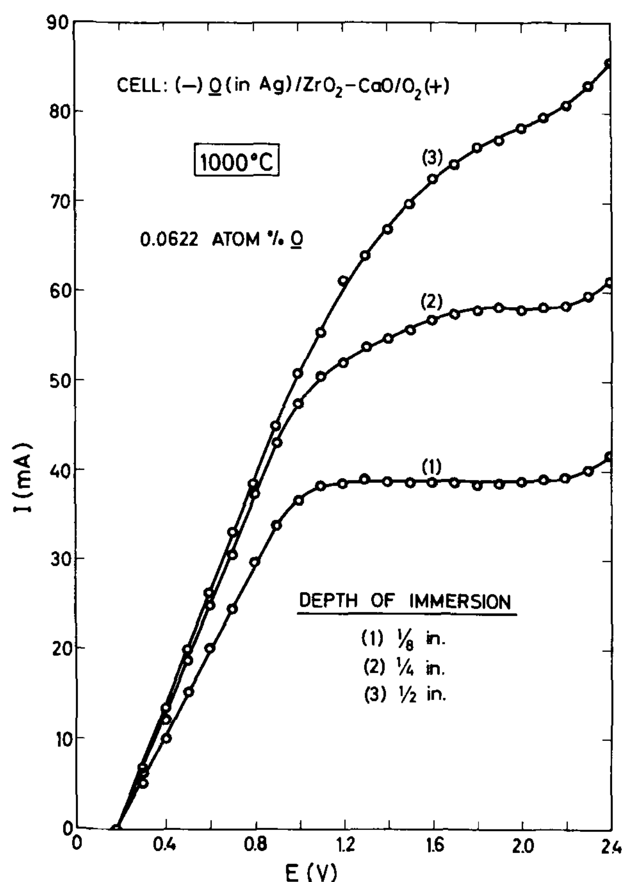

Fig. 5. Current vs. applied potential curves for 0.0622 a/o O in silver at 1000°C. The potential was applied at a rate of 0.8 V/min. Results are shown for three depths of immersion of the electrolyte tube. The amplitude of vibration of the electrolyte was 1/16 in. and the frequency of vibration was 84 cycles/min.

measured at 3000 Hz. It should be noted that the low-current points for ¼ and ½ in. immersion are almost coincident as would be predicted from Fig. 4.

From the example in Fig. 5, it is evident that limiting currents were readily observed at a depth of immersion of ⅛ in. For this condition, the path lengths for the $O^=$ ions formed at all points on the metal-electrolyte interface were similar (see Fig. 16b). At the higher applied potentials, there was a tendency for the current to drop because of a decrease in the bulk oxygen concentration. At 2.2V ($E - IR_{a\text{-}c} > 1.5$V), reduction of the oxide electrolyte leading to n-type conductivity begins to interfere. For ¼ in. immersion, the curve has an irregular shape since the current is a composite of contributions from competing sections of the electrolyte with varying path lengths. The $O^=$ ions formed on the outside of the electrolyte tube near the surface of the metal must travel a relatively long distance to reach the Pt gauze electrode. Accordingly, higher applied potentials are required to achieve current control by diffusion overpotential, rather than the electrolyte resistance, in this region. Therefore, the limiting current is observed at higher applied potentials than that for ⅛ in. immersion. The ratio of the limiting currents (1.5) is in excellent agreement with the ratio of the areas of the metal-electrolyte interface, *i.e.*, the limiting current densities are equal.

Unfortunately, limiting currents could not be measured at a depth of immersion of ½ in. Even in the flattest region of the curve, the current increases by about 2% per 0.1V increment. N-type conductivity near the bottom of the tube interfered before the oxygen concentration at the metal-electrolyte interface near the surface of the liquid metal could be significantly lowered. The limiting current would be 97 mA if it continued to be proportional to the submerged outside area of the electrolyte.

Necessarily, from Fig. 5, the majority of the results were obtained at small depths of immersion. Accordingly, the depth of immersion had to be accurately controlled since the current is very sensitive to this variable (Fig. 4 and 5). Although limiting currents were observed to be independent of the cell resistance from 17.5 to 40 ohms at 1000°C, the attainment of a low cell resistance was very important for ¼ in. immersion since limiting currents could then be established over a wider potential range. When the resistance was too high, the current-potential curves at ¼ in. immersion took a similar shape to curve 3 in Fig. 5.

Possible interference from the gas phase due to either direct electrochemical reaction near the metal-electrolyte-gas boundary or chemical dissolution of oxygen from the gas phase into the diffusion layer must be considered, particularly at high oxygen pressures. However, limiting currents were not significantly affected by evacuating the system immediately prior to the voltammetric measurements. The large size of the electrolyte relative to the quantity of liquid metal rendered a noticeable drop in the bulk concentration of dissolved oxygen unavoidable. Nevertheless, by applying the potential at 0.8 V/min, it was calculated that this error caused the limiting currents to be low by no more than 1.5% at ⅛ in. immersion and 4% at ¼ in. immersion.

Current-potential curves for two oxygen contents in liquid copper at 1200°C are plotted in Fig. 6. The depth of immersion of the electrolyte was ⅛ in. From the initial slopes of the curves, the d-c resistances are 15 and 50% higher than the a-c resistance (5.2 ohms) for the 0.0500 and 0.0146 a/o O compositions, respectively. Again, limiting currents are well-defined and n-type conductivity interferes at high applied potentials ($E - IR_{a\text{-}c} > 1.4$V).

If the thickness of the diffusion layer (Fig. 1) is independent of the applied potential, then diffusion overpotential obeys the relationship

$$\eta_d = \frac{2.3RT}{n\mathbf{F}} \log \frac{i_l}{i_l - i} \qquad [7]$$

where n is the number of electrons involved in the electrode reaction, i is the current density, and i_l is the limiting current density. The plots of η_d *vs.* log $[i_l/(i_l - i)]$ in Fig. 7 and 8 serve to verify the two-electron process at the cathode given by reaction [1]. Figure 7 is derived from curve 1 in Fig. 5 and Fig. 8 is derived from Fig. 6. Theoretical slopes are 0.126 and 0.146V at 1000° and 1200°C, respectively. The most accurate points were generally obtained in the range $0.1\text{V} < \eta_d < 0.2\text{V}$. Below 0.1V, small errors in i greatly affect η_d and, above 0.2V, small errors in i greatly affect log $[i_l/(i_l - i)]$.

Linear plots only resulted from data obtained at ⅛ in. immersion of the electrolyte tube. For case 2 in Fig. 4 which represents resistance control of the current, $I_t/I_b = 1.93$ at ⅛ in. immersion. This factor becomes 2.01 for diffusion overpotential control (ratio of the appropriate areas). Consequently, the ratio is almost unaffected by the applied potential and theoretical behavior is observed. For greater depths of immersion, similar plots were displaced above the theoretical lines and were convex towards the abscissa.

Limiting currents could also be established by holding the applied potential constant as illustrated by the current-time curves for liquid silver in Fig. 9. Similar chronoamperometric results were obtained for copper. The applied potentials correspond to approximately the middle of the flat portions of the respective current-potential curves ($\eta_d = 0.4$-0.6V). At zero time ($\eta_d = 0$), the currents were equal to $(E - E_{rev})/R_{a\text{-}c}$ in accordance with Eq. [6]. They were within 10% of the limiting values in 15 sec and were fully established in 1 to 1½ min. The time required decreased when either the temperature or applied potential was increased or the depth of immersion of the electrolyte was de-

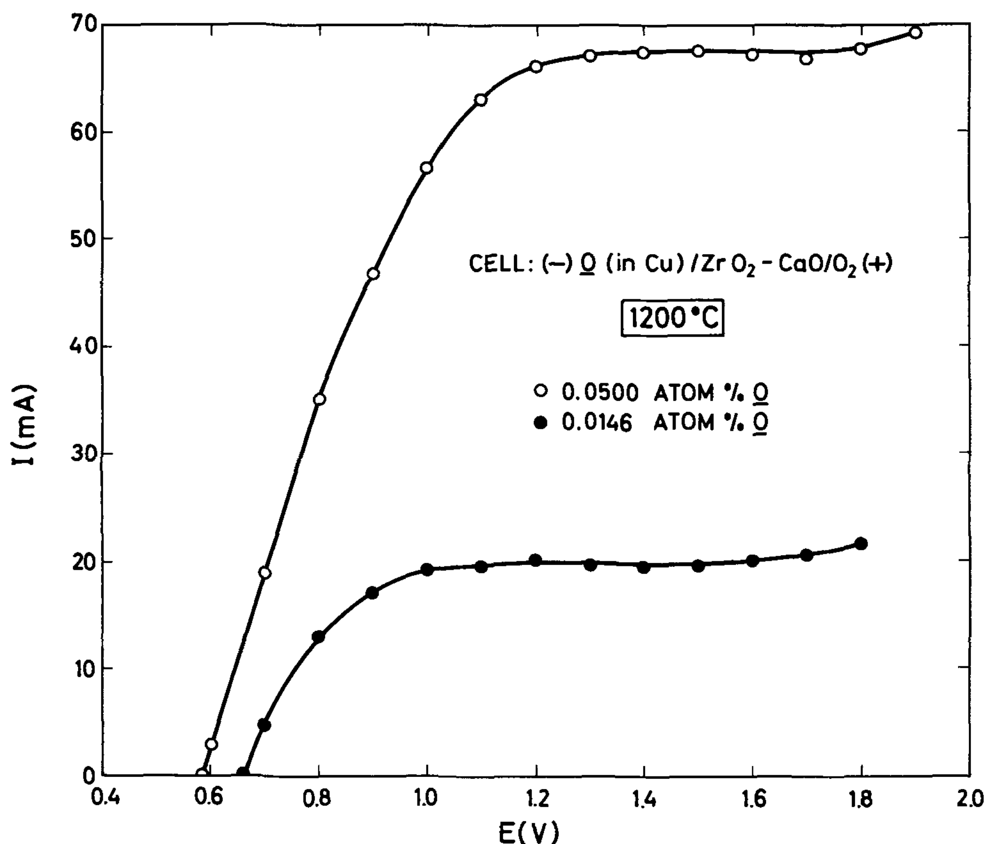

Fig. 6. Current vs. applied potential curves for two oxygen concentrations in liquid copper at 1200°C. The depth of immersion of the electrolyte tube was ⅛ in. The conditions were identical to those given for Fig. 5.

creased. After 1½ to 2 min, the currents dropped because of a decrease in the bulk oxygen concentration. This is more apparent for the lower curve in Fig. 9 since the limiting currents increase notably with temperature (next section). Even after 1 min, it can be calculated that the limiting currents can be up to 3% low on account of the decrease in the bulk oxygen concentration.

Effect of the dissolved oxygen concentration.—The relationship between the limiting current density and the dissolved oxygen concentration is presented for silver in Fig. 10 and 11 and for copper in Fig. 12. The log-log plot has been drawn for silver in Fig. 11 to enable the results for the entire oxygen concentration range which was studied to be seen more clearly. The depth of immersion of the electrolyte was either ⅛ or

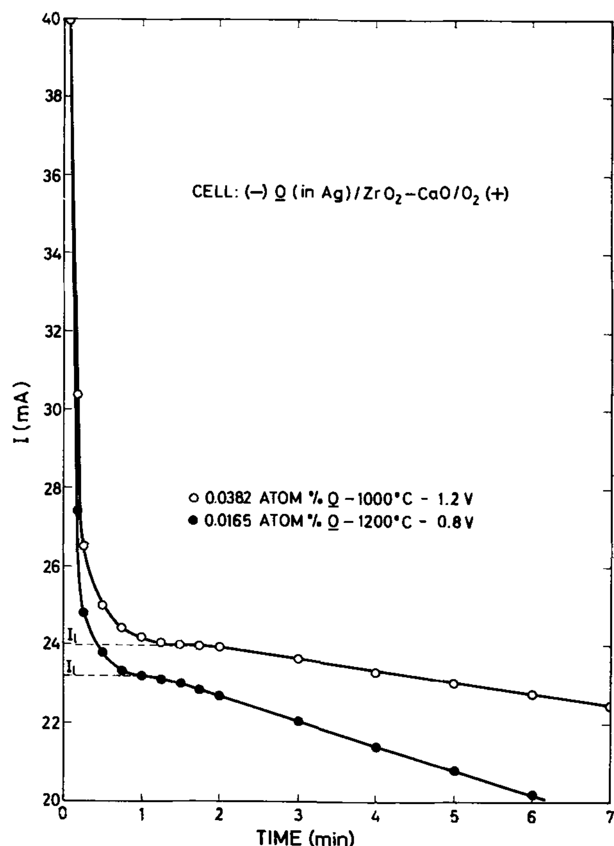

Fig. 9. Current-time curves for two oxygen concentrations in liquid silver. The depth of immersion of the electrolyte tube was ⅛ in. The amplitude of vibration of the electrolyte was 1/16 in. and the frequency of vibration was 84 cycles/min.

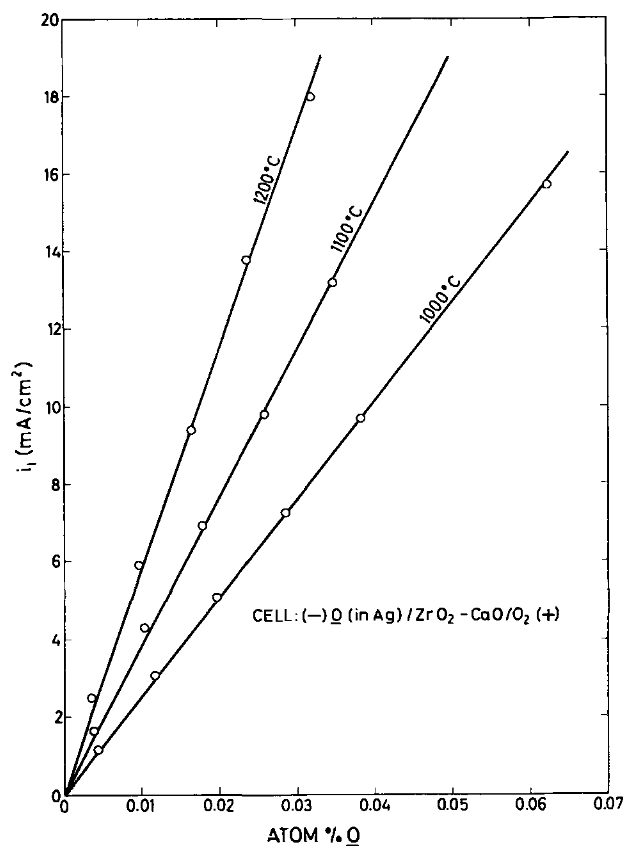

Fig. 10. Limiting current density vs. oxygen concentration at low oxygen concentrations in silver. The depth of immersion of the electrolyte tube was either ⅛ or ¼ in. The amplitude of vibration of the electrolyte was 1/16 in. and the frequency of vibration was 84 cycles/min.

¼ in. Current densities were calculated by dividing the currents by the geometric area of the metal-electrolyte interface, *i.e.*, 2.47 or 3.72 cm^2, respectively. However, these areas are somewhat uncertain because of the surface tension of the liquid metals. Since contact angles generally exceed 90°, the actual areas may be less than the calculated values which would make the current densities higher.

Generally, the data were reproducible to ±3% upon oxygen content or temperature cycling within a given run, but only to about ±10% from run to run. Points below 2 and above 50 mA/cm^2 were usually not as reproducible as those in the intermediate range.

Limiting currents are directly proportional to the dissolved oxygen concentration. They increase significantly with temperature and the lines in Fig. 10 and 12 pass through the origin. Calibration curves such as these could be used to analyze liquid metals for dissolved oxygen.

Using Fick's first law, the limiting current density can be written as

$$i_l = \frac{2FD_O c_O}{\delta} \quad [8]$$

where D_O is the diffusion coefficient of oxygen in the liquid metal, c_O is the bulk concentration of oxygen in the metal, and δ is the effective thickness of the diffusion layer. From the average of three recent independent investigations (27-29), $D_O \times 10^4$ in silver is 0.99, 1.28, and 1.59 cm^2/sec at 1000°, 1100°, and 1200°C, respectively. The diffusion coefficient is independent of oxygen concentration (30). From the average of two recent independent studies (31, 32), $D_O \times 10^4$ in copper is 0.74, 0.98, and 1.27 cm^2/sec at 1100°, 1200°, and 1300°C, respectively. Converting concentrations to g-atoms/cm^3 using the densities of liquid silver (33) and copper (34) enables effective diffusion layer thick-

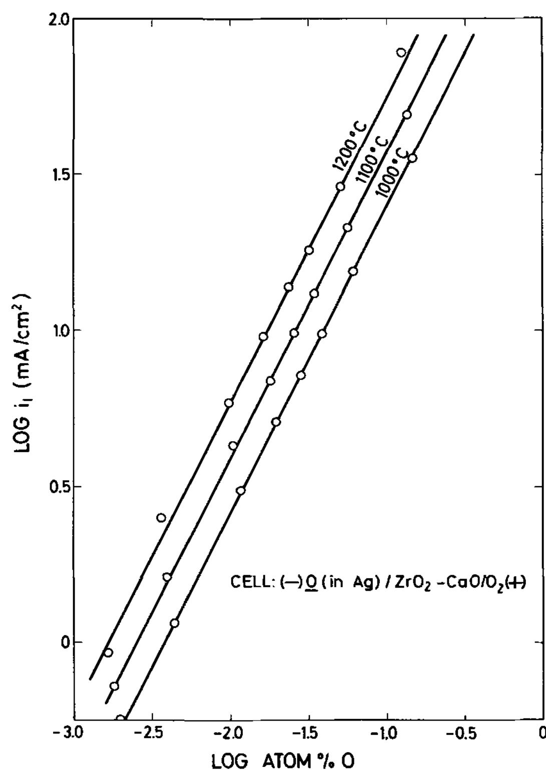

Fig. 11. Log limiting current density vs. log oxygen concentration for silver. The conditions were identical to those given for Fig. 10.

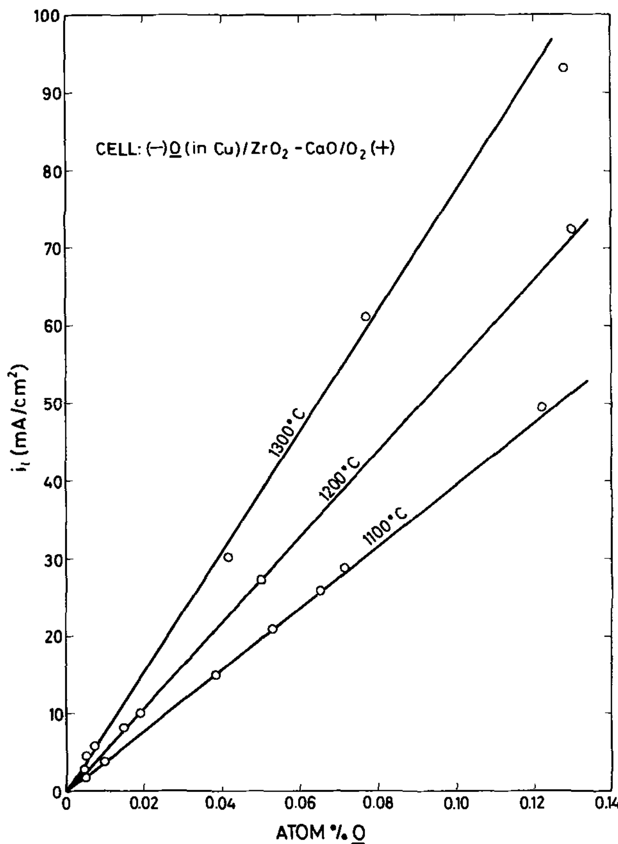

Fig. 12. Limiting current density vs. oxygen concentration for copper. The conditions were identical to those given for Fig. 10.

nesses to be found. For example, at 0.0385 a/o O in copper at 1100°C, since i_l = 15.0 × 10^{-3} A/cm², F = 9.65 × 10^4 coulomb/equiv, D_O = 0.74 × 10^{-4} cm²/sec, and c_O = 4.84 × 10^{-5} g-atoms/cm³, Eq. [8] gives δ = 0.046 cm. At 1100°C, a value of 0.054 cm was calculated for silver. At 1200°C, δ = 0.042 and 0.045 cm for copper and silver, respectively. Consequently, the limiting currents increase with temperature due to both an increase in D_O and a decrease in δ (Eq. [8]). The latter occurs because the viscosity of the liquid metal decreases as the temperature is increased.

The diffusion layer data are comparable for liquid silver and copper since their viscosities are similar (35). Nevertheless, the values are somewhat higher for silver, probably since D_O is higher. Often, δ has been found to vary as D^x $(0 < x < 1)$ in aqueous studies (36).

The effective thicknesses of the diffusion layer are relatively high implying that vibrating the electrolyte was not an efficient method of stirring the metal. However, this served to stabilize the diffusion layer (prevent it from spreading with time) and lower the time required to establish limiting currents. By continuing to bubble the gas mixtures through the metal during the measurements, i_l could be markedly increased and, accordingly, δ could be markedly decreased. However, limiting currents obtained in this manner were not very reproducible.

It should be noted that the results for δ are average values over the entire metal-electrolyte interface. They are not necessarily the same along the side as across the bottom of the electrolyte tube, nor are they probably even constant across the bottom of the tube. By sealing an electrolyte pellet into a quartz tube or pressing a pellet against a polished alumina tube, the diffusion conditions could be better-defined and uncertainties associated with measurements near the surface of the metal could be eliminated. Unfortunately, attempts to do this led to poorer reproducibility of

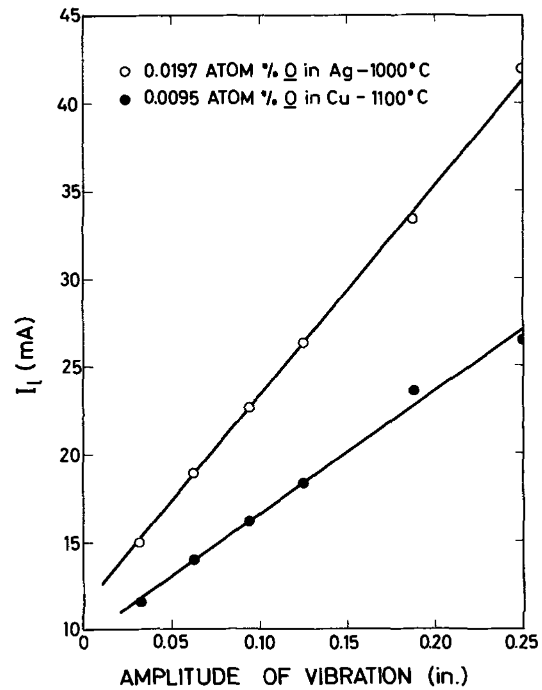

Fig. 13. Limiting current vs. amplitude of vibration of the electrolyte tube for silver and copper. The depth of immersion was ¼ in. and the frequency of vibration was 84 cycles/min.

the voltammetric measurements on account of leakage between the electrode compartments.

Effect of the amplitude and frequency of vibration of the electrolyte.—The effect of the amplitude of vibration of the electrolyte tube on the limiting current for both silver and copper is shown in Fig. 13. At lower temperatures, the dependence appeared somewhat more pronounced. The limiting current was approximately doubled by increasing the amplitude from 1/16 to 1/4 in. The currents at zero vibration were often higher than the extrapolated values, undoubtedly due to natural convection in the metal which arises from density gradients that are, in turn, caused by oxygen concentration and temperature gradients. The density increases as the oxygen concentration decreases.

Limiting current as a function of the frequency of vibration is plotted for both metals in Fig. 14. Again,

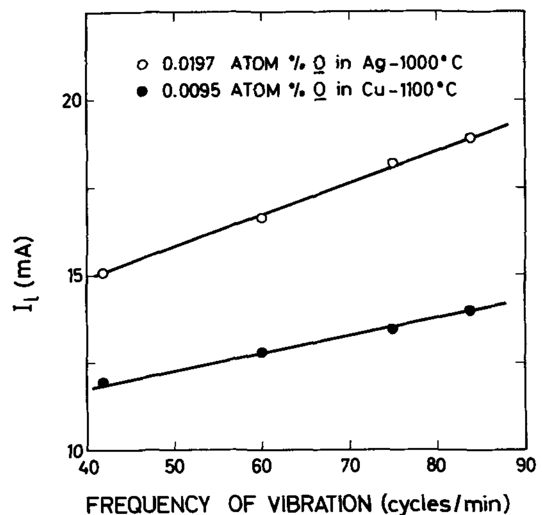

Fig. 14. Limiting current vs. frequency of vibration of the electrolyte tube for silver and copper. The depth of immersion was ¼ in. and the amplitude of vibration was 1/16 in.

a linear dependence was observed which was stronger at lower temperatures.

Conclusions

By electrochemically removing dissolved oxygen from liquid metals in cells with impervious solid oxide electrolytes, limiting currents controlled by oxygen diffusion and convection in the liquid metal can be established. Either the applied potential can be increased at a rate of about 0.8 V/min or a suitable applied potential can be held constant for 1 to 1½ min. To achieve electrical contact, Chromel A wire for silver and Type 314 stainless steel wire for copper are very satisfactory. Using electrolyte tubes, the influence of the depth of immersion must be considered to interpret the results and small immersion depths are necessary to obtain limiting currents. Stability of the diffusion layer is ensured by providing forced convection in the metal, but natural convection may be sufficient.

Limiting currents are directly proportional to the dissolved oxygen concentration at low oxygen contents and increase substantially with temperature. Diffusion layer thicknesses decrease with temperature and are slightly greater for liquid silver than liquid copper. Voltammetric measurements could be used to analyze liquid metals and alloys for dissolved oxygen.

APPENDIX

Calculation of the Influence of the Depth of Immersion of a Solid Electrolyte Tube in a Liquid Metal

The following calculation is applicable to the influence of the depth of immersion on the current through the cell when the current is solely controlled by the resistance of the solid electrolyte, *i.e.*, in the absence of diffusion overpotential. Regarding emf measurements, it could also be used to determine mixed potentials resulting from oxygen activity gradients along the liquid metal-electrolyte interface.

For an electrical conductor with potential-independent conductivity, the current, I, is given by

$$I = \frac{E\sigma A}{y} \quad [9]$$

where E is the applied potential (corrected for the cell emf in the case of an ionic conductor), σ is the specific conductivity, A is the area through which the current passes, and y is the path length for the current. In the case of an electrolyte tube immersed in a liquid metal depicted in Fig. 15, the path length for $O^=$ ions will be dependent upon the position on the liquid metal-electrolyte interface where they are either produced or consumed. Since the liquid metal conducts electronically, the electrochemical reduction of oxygen dissolved in the metal will occur over the entire surface abcde. To be oxidized, the $O^=$ ions which are produced must migrate through the electrolyte to the Pt electrode. Oxygen ions formed at c must only travel a distance ch and those formed at b must travel a distance bg, while those formed at a must travel a distance afg.

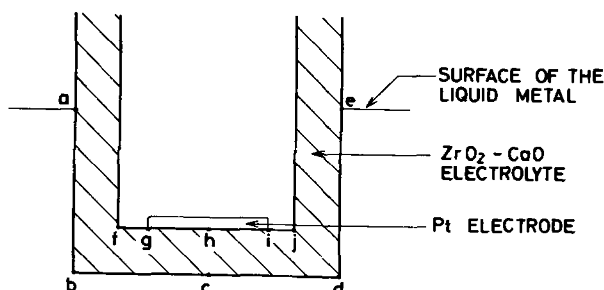

Fig. 15. Solid electrolyte tube immersed in a liquid metal

Since E is constant over the surface abcde and σ is constant throughout the solid electrolyte (electronic conductivity is negligible), Eq. [9] predicts that

$$I \propto \frac{A}{y} \quad [10]$$

When y is not constant for a given area, then

$$A\left(\overline{\frac{1}{y}}\right) = \frac{A}{y^*} = \lim_{n\to\infty}\left(\frac{\Delta_1 A}{y_1} + \frac{\Delta_2 A}{y_2} + \ldots + \frac{\Delta_n A}{y_n}\right)$$

and, therefore

$$\frac{A}{y^*} = \int_{A_1}^{A_2}\left(\frac{1}{y}\right)dA \quad [11]$$

where A is the area on the outer surface of the electrolyte tube $(A_2 - A_1)$, $(\overline{1/y})$ is the average value of $1/y$ for this area, and y^* is the effective path length which is the reciprocal of $(\overline{1/y})$. It is assumed that the current carried by each element $\Delta_i A/y_i$ is independent of the remaining elements since the elements unavoidably overlap, *i.e.*, in Fig. 15, the area defined by abcde (the area of the liquid metal-electrolyte interface) is greater than the area defined by ghi (the area of the Pt-electrolyte interface).

When values of A/y^* for two or more areas are determined, then, if their currents are independent, the total current passing through them will simply be proportional to the sum of their A/y^* values. In effect, the electrolyte is divided into a number of parallel conductors. Calculations for the electrolyte tubes used in the present experiments for two different cases regarding the Pt electrode will now be given.

Cross sections containing the longitudinal axis of the electrolyte tube are drawn in Fig. 16. Each length on the outside surface defines an area—circular on the bottom and curved on the side. Each area involving a different type of calculation will be discussed in turn.

Case 1. The Pt electrode only partly covers the bottom surface of the inside of the electrolyte tube (Fig. 16a).—In Fig. 16a, the circular Pt gauze electrode has a diameter of ¼ in. This represents the smallest area of Pt-electrolyte contact possible in the present investigation since the Pt electrode was held firmly against the electrolyte with a ¼ in. alumina rod (Fig. 2).

Area fg. The path length for all the $O^=$ ions formed in this area is fi. Accordingly,

$$\frac{A}{y} = \frac{\pi(1/8)^2}{1/16} = 0.7854 \text{ in.} = 1.995 \text{ cm}$$

Area df. For a given element of this area at e, the path length y is $\sqrt{x^2 + (1/16)^2}$ where x is the distance fe and 1/16 in. is the thickness of the electrolyte tube. The area represented by fe is

$$A = \pi(x + 1/8)^2 - \pi(1/8)^2 \quad [12]$$

Therefore

$$dA = 2\pi(x + 1/8)dx \quad [13]$$

Substituting for y and dA in Eq. [11] and evaluating the integral gives

$$\frac{A}{y^*} = 2\pi\sqrt{x^2 + (1/16)^2}\Big|_{x_1}^{x_2} + \frac{\pi}{4}\ln\left(x + \sqrt{x^2 + (1/16)^2}\right)\Big|_{x_1}^{x_2} \quad [14]$$

Integration constants will be omitted since definite integrals are being considered. At f, $x = x_1 = 0$ and at d, $x = x_2 = 1/8$ in. Substituting into Eq. [14] yields the result that

$$\frac{A}{y^*} = 4.113 \text{ cm}$$

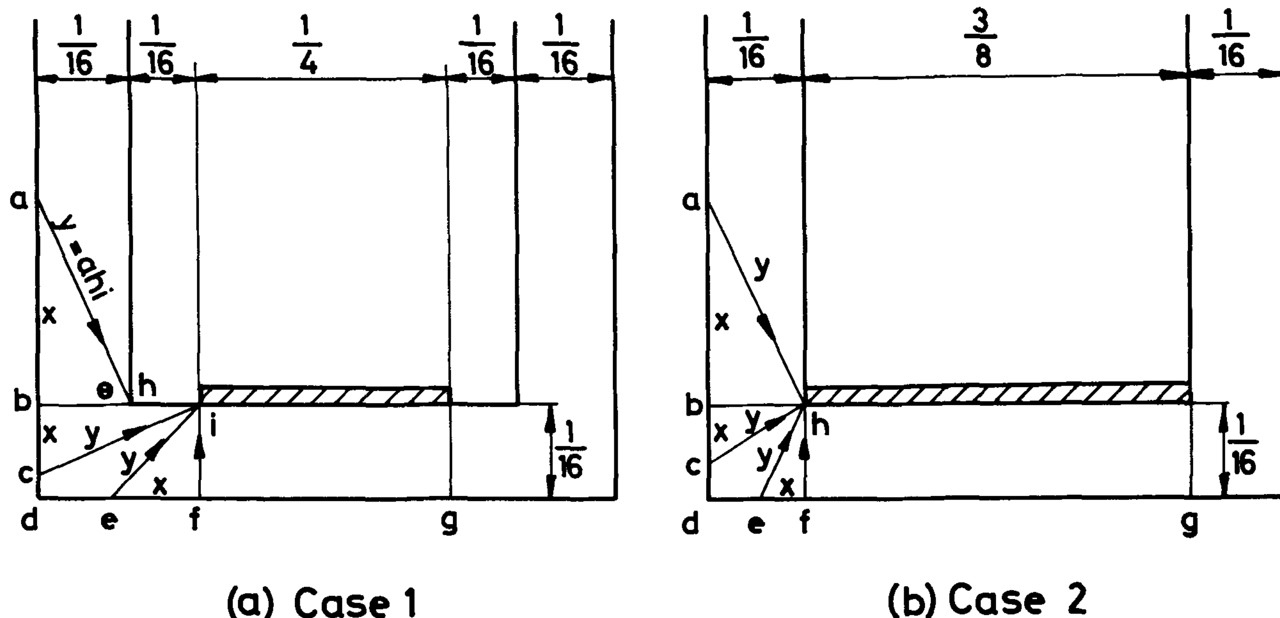

Fig. 16. Illustration of the method used to calculate the effect of the depth of immersion of a solid electrolyte tube on the current. Dimensions are in inches. The Pt electrode is hatched. Arrows are drawn on lines representing current paths through the solid electrolyte which was divided into sections fg, df, bd, and ab.

Area bd. The path length y for $O^{=}$ ions formed at any element c within this area is $\sqrt{x^2 + (1/8)^2}$ where x is the distance bc. The area defined by bc is simply given by

$$A = \frac{\pi}{2} x \quad [15]$$

since the electrolyte tube has an OD of ½ in. Therefore

$$dA = \frac{\pi}{2} dx \quad [16]$$

Again, substituting for y and dA in Eq. [11] and evaluating gives

$$\frac{A}{y^*} = \frac{\pi}{2} \ln \left(x + \sqrt{x^2 + (1/8)^2} \right) \Bigg|_{x_1}^{x_2} \quad [17]$$

Here, $x = x_1 = 0$ at b and $x = x_2 = 1/16$ in. at d. Consequently

$$\frac{A}{y^*} = 1.920 \text{ cm}$$

Area ab. Oxygen ions formed at a must travel along ahi to reach the Pt electrode. Accordingly, the path length y is $\sqrt{x^2 + (1/16)^2} + 1/16$ where x is the length ba. For the area defined by ba, Eq. [15] and [16] apply. Therefore, from Eq. [11]

$$\frac{A}{y^*} = \frac{\pi}{2} \int_{x_1}^{x_2} \frac{dx}{\sqrt{x^2 + (1/16)^2} + 1/16} \quad [18]$$

Evaluating this integral by rationalizing the denominator invalidates the situation where $x = 0$. For the general case, it can be determined by making the substitution $x = 1/16 \tan \theta$ where θ is the angle shown in Fig. 16a. Hence, $dx = 1/16 \sec^2\theta \, d\theta$. The integral in Eq. [18] can now be written as

$$\int \frac{dx}{\sqrt{x^2 + (1/16)^2} + 1/16} = \int \frac{d\theta}{\cos\theta(1 + \cos\theta)} \quad [19]$$

Using the method of partial fractions and integrating yields

$$\int \frac{d\theta}{\cos\theta(1 + \cos\theta)} = \ln(\sec\theta + \tan\theta) - \frac{\sin\theta}{1 + \cos\theta} \quad [20]$$

Recalling that $\tan\theta = \frac{x}{1/16}$ results in an expression for Eq. [18] of the form

$$\frac{A}{y^*} = \frac{\pi}{2} \ln \frac{\sqrt{x^2 + (1/16)^2} + x}{1/16} \Bigg|_{x_1}^{x_2} - \frac{\pi}{2} \frac{x}{\sqrt{x^2 + (1/16)^2} + 1/16} \Bigg|_{x_1}^{x_2} \quad [21]$$

At b, $x = x_1 = 0$ and at a, $x = x_2$. The value of x_2 will depend on the depth of immersion of the electrolyte tube. For example, if the depth of immersion is ½ in., then $x_2 = 7/16$ in. and

$$\frac{A}{y^*} = 7.089 \text{ cm}$$

Case 2. The Pt electrode covers the entire bottom surface of the inside of the electrolyte tube (Fig. 16b).—This case would be experimentally realized in the present work if all of the Pt gauze electrode (diameter = ⅜ in.) were in close contact with the electrolyte.

Area fg. The A/y value can be calculated as for case 1.

Area df. For $O^{=}$ ions formed at e, the path length y is $\sqrt{x^2 + (1/16)^2}$ where x is the distance fe. For the area defined by fe, $dA = 2\pi(x + 3/16)\, dx$. Substituting for y and dA into Eq. [11] produces a solution similar to Eq. [14]. Here, $x_1 = 0$ and $x_2 = 1/16$ in.

Area bd. Inserting $y = \sqrt{x^2 + (1/16)^2}$ and Eq. [16] into Eq. [11] gives a solution similar to Eq. [17]. Again, the limits of integration are 0 and 1/16 in.

Area ab. Oxygen ions formed at a must travel a distance ah through the electrolyte (the Pt electrode is thin). The path length y is $\sqrt{x^2 + (1/16)^2}$ and Eq. [15] and [16] apply. The solution is identical to that for area bd. At b, $x = x_1 = 0$ and x_2 can have any desired value.

Some of the calculated values are recorded in Table I. It is apparent from these data and Eq. [17] and [21] that, if the $O^{=}$ ions migrating through the electrolyte do not interact, then as $x_2 \to \infty$ (area ab), $A/y^* \to \infty$ and the percentage of the current carried across the bottom of the electrolyte tube → 0. Recalling Eq. [10], it is obvious that higher currents will be observed in case 2 than in case 1.

The total current for any depth of immersion, I_t, may now be easily compared to the current crossing the outside of the bottom of the electrolyte tube, I_b, *i.e.*, the

Table I. A/y^* values (cm) for the solid electrolyte tube

Area	Case 1	Case 2
fg	1.995	4.489
df	4.113	3.051
bd	1.920	3.516
ab(x_2 = 1/16 in.)	1.864	3.516
ab(x_2 = 3/16 in.)	4.380	7.255
ab(x_2 = 5/16 in.)	5.955	9.226
ab(x_2 = 7/16 in.)	7.089	10.550

total current at zero depth of immersion. As an example, for case 1 and a depth of immersion of ½ in. (x_2 = 7/16 in.), the ratio is

$$\frac{I_t}{I_b} = \frac{1.995 + 4.113 + 1.920 + 7.089}{1.995 + 4.113} = 2.475$$

Ratios calculated in this manner for nine depths of immersion were used to plot Fig. 4.

ABSTRACT

The relative merits of different methods of detecting a nonuniform current distribution on a disk electrode are discussed. Some implications of such a distribution are presented. Experimental results are reported for collection efficiency measurements on the system of Albery and Ulstrup.

We consider here several aspects of the current and potential distribution on a rotating disk electrode, a problem for which a theoretical analysis has been presented earlier (1-4). Since this electrode is popularly regarded to have a uniform current distribution, it is appropriate to give examples illustrating under what conditions a nonuniform distribution can be expected. We should also like to discuss possible methods of detecting that a nonuniform current distribution prevails. In this connection, new experimental data are given for one of these methods, that involving the rotating ring-disk electrode system as used by Albery and Ulstrup (5).

* Electrochemical Society Active Member.
Key words: ohmic potential drop, collection efficiency.

Current Distribution on a Disk Electrode

The current distribution on a rotating disk electrode is described in detail in Ref. (2). On the basis of mass-transfer considerations alone, Levich (6) has shown that the current distribution should be uniform, and the disk surface is said to be uniformly accessible from a mass-transfer standpoint. This conclusion is valid at the limiting current, where the concentration of the reactant is zero over the entire surface of the disk electrode. [See, however, the paper (7) on the effect of radial diffusion.]

At currents below the limiting current, the ohmic potential drop tends to produce a nonuniform current distribution. The extreme case is the primary current distribution (1)

$$\frac{i}{i_{\text{avg}}} = \frac{0.5}{(1 - r^2/r_o^2)^{1/2}} \qquad [1]$$

which corresponds to the solution of Laplace's equation for the potential when the potential in the solution adjacent to the electrode is uniform. Here, the disk electrode is taken to be embedded in a large, insulating plane with the counterelectrode at infinity. The primary current distribution prevails when the surface overpotential for the electrode reaction is negligible and there are no mass-transfer limitations.

For intermediate cases, the current distribution can be described in terms of seven parameters (2), two of which we consider here

$$J = \frac{ZFr_oi_o}{RT\kappa_\infty} \text{ and } N = -\Gamma\left(\frac{4}{3}\right)\frac{ZFr_oi_{\text{lim}}}{RT\kappa_\infty} \qquad [2]$$

J can be regarded as a dimensionless exchange current density and N as a dimensionless limiting current density. Small values of J lead to a uniform current distribution; large values, to a nonuniform distribution. Even for a small value of J, the distribution can be nonuniform if the current is large. Here one can use as a parameter the average current density made dimensionless in the same manner as J in Eq. [2]. The value of N determines how large the dimensionless average current density can be without exceeding the limiting current. At the limiting current, the current distribution is uniform, but this mass-transfer effect loses force at currents only slightly below the limiting current.

The current density, whether it be the exchange current density, the limiting current density, or the average current density, is made dimensionless with the electrode radius r_o, the solution conductivity κ_∞, and other parameters over which there is little experimental control. Large disks and low conductivities promote a nonuniform current distribution, and *vice versa*. For laboratory work on polarography and electrode kinetics, small disks and small reactant concentrations with an excess of supporting electrolyte can be used to ensure a uniform current distribution. However, in engineering systems involving electroplating, corrosion, *etc.*, a nonuniform current distribution must be expected. Ohmic effects can lead to the following undesirable results: (*a*) nonuniform deposition or dissolution, (*b*) errors in kinetic parameters calculated with neglect of current nonuniformities, (*c*) loss of control in analytical determinations [Harrar and Shain (8) give a lucid account of such an example in large cells], and (*d*) waste of current in cathodic protection in corroding systems.

Some numerical examples may be helpful. For $r_o = 0.25$ cm, $\kappa_\infty = 0.1$ (ohm-cm)$^{-1}$, $i_o = 1$ mA/cm^2, $Z = 1$, and $T = 298$°K, the value of J is about 0.1. For small values of the average current density, this value of J implies a fairly uniform current distribution, but for an average current density of 0.1 A/cm^2, the current distribution will be nonuniform. However, for a value of $i_o = 40$ A/cm^2, the value of J is about 4000, and the current distribution will be nonuniform at all current densities (except very close to the limiting current). For this value of i_o, it is unlikely that a large enough concentration of supporting electrolyte could be used to obtain a uniform current distribution.

As an example of the ohmic effect in corrosion studies, we might ask how large a disk electrode can be protected cathodically by a counterelectrode at infinity, without waste of current. We assume that the disk is rotated, the flow is laminar, and the limiting current for the oxygen reaction is uniform.

The desired current distribution for cathodic protection is determined by the limiting current distribution for oxygen reduction. This results in a potential variation in the solution adjacent to the protected surface. The potential difference $\Delta\Phi_o$ between the solution adjacent to the center of the disk and that adjacent to the outside edge of the disk, for a uniform current distribution, can be obtained from Ref. (2) as

$$\Delta\Phi_o = 0.36338\, r_oi/\kappa_\infty \qquad [3]$$

We want the electrode to have a potential between that necessary to prevent oxidation of the metal (say, -0.1V *vs.* NHE) and that at which hydrogen generation begins (say, -1.0V *vs.* NHE). This means that $\Delta\Phi_o$ should be no larger than 0.9V. For a limiting current density of 10 mA/cm^2 and a conductivity of 0.04 (ohm-cm)$^{-1}$, the largest disk which can be cathodically protected is $r_o = 9.9$ cm.

The above equation can also be used for anodic protection of an electrode with active-passive kinetics. The potential of the electrode should be large enough to ensure that the surface is in the passive region and small enough to ensure that it is not in the transpassive region. Assume that this gives an allowed maximum of $\Delta\Phi_o$ of 0.5V and that the current density in the passive region is 10^{-5} A/cm^2. Then, the largest disk which can be protected anodically corresponds to $r_o = 5500$ cm, again for a conductivity of 0.04 (ohm-cm)$^{-1}$. Equation [3] can also be used to guide the selection of conditions for constant-potential electrolysis.

Detection of the Current Distribution

Various methods are conceivable for detecting a nonuniform current distribution on a rotating disk electrode. Direct measurement of the deposit thickness has been used with success by Marathe and Newman (9). Irene Sun, at Berkeley, has sectioned a radioactive deposit on a disk electrode, and autoradiograms of radioactive deposits have been made by Jordan and Finston (10). Recently, Bruckenstein and Miller (11) have reported additional results of deposit thickness measurements.

Albery and Ulstrup (5) have measured collection efficiencies at the ring electrode of a ring-disk system with a view toward detecting a nonuniform current distribution on the disk electrode. If the current density is higher near the edge of the disk than at the center, then the collection efficiency at the ring should be higher than that calculated with the assumption of a uniform current density on the disk. A quantitative comparison of theory and experiment is made difficult by the fact that a current to the ring will accentuate the nonuniformity on the disk. Nevertheless, the results of Albery and Ulstrup show a lower measured collection efficiency. This conflict led us to repeat the experiments, as described in the next section. After completion of the present work, Bruckenstein and Miller (11) also reported results on this system, with conclusions which generally agree with those described below. Also, it is reported[1] that the results of Albery and Ulstrup have been recanted.

It would be more straightforward to use the ring-disk system as a sectioned electrode for the purpose of measuring the nonuniformity of current distribution. In this application, the ring and the disk would be held at the same potential so as to function as a single electrode to the parts of which the current

[1] Barry Miller, Private communication. See Ref. 8 of the paper by Bruckenstein and Miller (11).

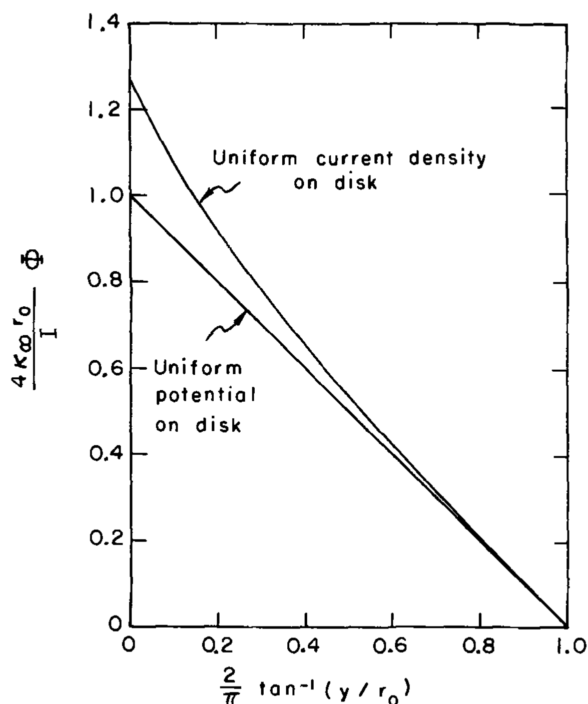

Fig. 1. Potential distribution along the axis of the disk

could be measured separately. Since this is a classical method of measuring current distributions, we have assessed in a separate paper (12) the error which might be introduced by the nonzero gap between the ring and the disk. Experimental measurements are also reported for this technique.

Angell, Dickinson, and Greef (13) have measured the potential distribution near a rotating disk electrode. In order for such measurements to detect a nonuniformity of current distribution on the disk, measurements would have to be made quite close to the electrode itself, as shown by the theoretical potential profiles along the disk axis (see Fig. 1). McIntyre and Peck (14) have developed an interrupter technique and applied it to the measurement of the ohmic potential drop at a rotating disk electrode. Although the ohmic potential drop to the center of the disk can vary by 27% depending on the uniformity of distribution of the same total current (2), an interrupter technique will ideally measure the ohmic potential drop corresponding to the primary current distribution, independent of the actual current distribution prevailing before interruption of the current (15).

Ring Collection Efficiencies for the Bromide-Bromine System

Albery and Ulstrup (5) have reported the results of experiments with a ring-disk assembly to test critically the predictions of current distribution on a disk electrode. The disk was operated at a given current as an anode, oxidizing bromide to bromine, which was then reduced back to bromide at the ring. The nonuniform current distribution on the disk should produce a concentration of bromine at the edge of the disk which is higher than that expected from the average current density.[2] This should result in a higher current on the ring (or a higher collection efficiency) than that predicted by Albery and Bruckenstein (16). In other words, bromine produced near the edge of the disk has less chance to diffuse away and therefore more chance to react at the ring. In contrast, Albery and Ulstrup report a lower current on the ring.

Three effects might complicate the interpretation of these results: (i) Operation of the ring cathodically enhances the nonuniformity of the current distribution on the disk and should lead to a still higher collection efficiency; (ii) the ohmic potential drop may have been large enough in some of the dilute soutions to obviate the limiting-current measurements on the ring, that is, the ring may not have been at limiting current at the potential of its operation; and (iii) kinetic complications on the disk might have resulted in the production of less bromine than was supposed.

For the rotating ring-disk system described below, calculations were made of the ohmic potential drop between the ring and the reference electrode, with the ring operating at limiting current. The results of Newman (2) and of Nanis (17) were used for the calculations. It was found that the ohmic effect was too small, and in the wrong direction, to be of importance for the concentrations and placement of reference electrode used in the measurements reported below.

Since the importance of the last possibility could not be determined from the data reported by Albery and Ulstrup, the measurements were repeated. The solutions were NaBr and $HClO_4$ in water. The ring, disk, and counterelectrodes were made of platinum. The dimensions of the ring-disk assembly (RD1) were $r_o = 0.442$ cm, $r_1 = 0.504$ cm, and $r_2 = 0.621$ cm. The calculated collection efficiency was 0.340. The ring and disk were imbedded in epoxy, and the over-all radius was 1.27 cm. The reference electrode probe (Luggin capillary tip) was placed in the plane of the disk at $r = 2.27$ cm. A Regatron constant-current power supply maintained a constant disk current. A Wenking potentiostat and voltage-ramp generator were used to measure the limiting current curves on the ring. Currents were determined by measuring the potential drop across precision resistors. The vessel containing the solution and electrodes was open to ambient air and was at ambient temperature (23° ± 2°C). The ring-disk assembly was rotated at 1550 rpm.

Since this system has received recent attention (11), we shall describe our results briefly.

At high and moderate concentrations, the ring limiting current for bromine reduction was broad and well defined. At decreased concentrations, especially that of $HClO_4$, the region between attainment of limiting current and onset of reduction of oxide on the platinum was more narrow.

Results of collection efficiency measurements at moderate concentrations are given in Table I. The measured collection efficiency is greater than that calculated for all but three entries in the table. This indication of a nonuniform current distribution is in qualitative agreement with the predictions of Newman (2).

However, the more interesting systems are the dilute solutions in which Albery and Ulstrup found the anomalous collection efficiencies. To investigate the possibility that these results were caused by kinetic complications on the disk, disk polarization curves were

Table I. Collection efficiencies for NaBr-$HClO_4$ systems

Solution composition	Total disk current (mA)	$-I_r/I_d$
0.1M NaBr 0.1M $HClO_4$	0.1 1.0 5.0 10.0	0.350 0.345 0.360 0.350

0.001M NaBr 0.01M $HClO_4$	0.010 0.012 0.050 0.10	0.340 0.360 0.360 0.355
0.0001M NaBr 0.1M $HClO_4$	0.02 0.03	0.350 0.350

[2] Note however that the equation that they propose for predictions of this effect is incorrect (12).

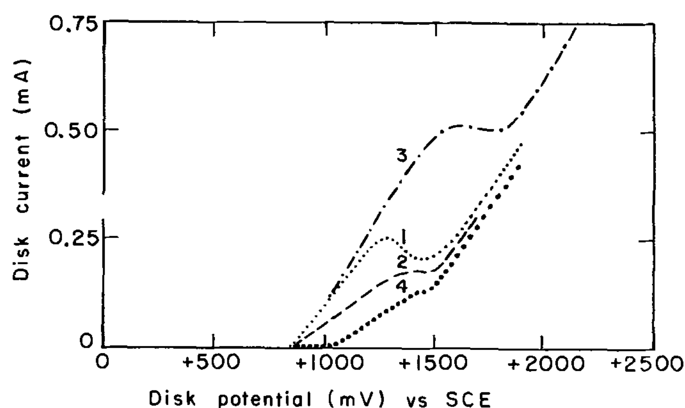

Fig. 2. Disk polarization curves in 0.001M NaBr-0.001M $HClO_4$: curve 1, freshly buffed; curve 2, run immediately after 1; curve 3, prereduced at —100 mV for 1 min; curve 4, preoxidized at +2500 mV for 1 min.

measured for different preparations of the surface. Typical results are shown in Fig. 2.

Curves 1-4 were obtained in a solution of 10^{-3}M $HClO_4$ 10^{-3}M NaBr, with RD1, and in the sequence numbered. Curve 1 was taken after the ring disk had been freshly buffed on a metallographer's wheel—our usual preparation. The run (and each subsequent run) was started at +500 mV (*vs.* SCE) and swept at 156 mV/min to more positive potentials, with simultaneous measurement of the disk current. Immediately after curve 1 was obtained, the potential was returned to +500 mV, another sweep was started, and curve 2 was obtained. The difference in the two was caused by the different state of the platinum surface in the two runs. This was confirmed by (i) prereducing the disk at −100 mV (*vs.* SCE) for 1.5 min before curve 3 was taken and then (ii) preoxidizing the disk at +2500 mV (*vs.* SCE) for 1 min before curve 4 was obtained. Finally, a curve was obtained after the disk had been prereduced at −100 mV (*vs.* SCE) for 5 min, and the results were identical to curve 3.

Similar investigations at concentrations of 10^{-2}M $HClO_4$ and 10^{-3}M NaBr revealed that the inhibition of Br_2 production on a preoxidized surface was much less important than for the above system. With a lower concentration of $HClO_4$ (10^{-4}M, 10^{-3}M NaBr), however, it was not possible to obtain a current due to Br^- oxidation of more than 0.12 mA (total disk current) no matter how much the disk had been prereduced. One may conclude that (i) bromine evolution on the disk is affected by the surface preparation, *i.e.*, inhibited by oxide on the platinum and (ii) a reproducible surface may be obtained by prereduction of the disk. Similar inhibition effects have been obtained recently for the Cl^--Cl_2 system (18).

The influence of the preparation of the disk surface on the collection efficiencies in dilute solutions is demonstrated by the results in Table II. For preoxidized platinum disks, these results are qualitatively in agreement with those of Albery and Ulstrup. Presumably, the extra disk current on a preoxidized surface (above that required to produce the Br_2 detected on the ring) goes to produce oxygen which is not reduced on the ring in the potential region scanned. However, prereduced platinum shows a striking difference, *i.e.*, the collection efficiency is constant up to the disk limiting current. This indicates that all the disk current is going to produce Br_2, which is then detected on the ring. Bruckenstein and Miller (11) also obtained results on prereduced platinum but did not use the same system to obtain results on preoxidized surfaces. In general, their measured collection efficiencies are in agreement with ours but showed larger deviations from the calculated collection efficiencies

Table II. Surface treatment effects on collection efficiency in NaBr-$HClO_4$ systems

Solution composition	Total disk current (mA)	$-I_r/I_d$	Disk treatment
0.001M NaBr 0.001M $HClO_4$	0.01	0.330	Prereduced at −100 mV for 1 min
	0.02	0.330	Prereduced at −100 mV for 1 min
	0.03	0.330	Prereduced at −100 mV for 1 min
	0.05	0.340	Prereduced at −100 mV for 1 min
	0.10	0.340	Prereduced at −100 mV for 1 min
	0.25	0.350	Prereduced at −100 mV for 1 min
	0.30	0.340	Prereduced at −100 mV for 1 min
	0.40	0.330	Prereduced at −100 mV for 1 min
	0.25	0.120	Preoxidized at +2500 mV for 1 min
	0.40	0.075	Preoxidized at +2500 mV for 1 min
0.001M NaBr 0.0001 $HClO_4$	0.01	0.340	Prereduced at −500 mV for 1 min
	0.03	0.330	Prereduced at −500 mV for 1 min
	0.05	0.330	Prereduced at −500 mV for 1 min
	0.10	0.330	Prereduced at −500 mV for 1 min

than ours do. This may be due to a geometrical effect. but it seems premature to discuss such possibilities.

We have two general conclusions about this experimental work. First, the conditions of the platinum surface are important in the kinetics of formation of Br_2 from Br^- in dilute $HClO_4$ solutions. Preoxidized surfaces give collection efficiency results in agreement with those of Albery and Ulstrup; prereduced surfaces give results in qualitative agreement with theoretical predictions. Second, these kinetic complications make the system a poor one for more extensive investigations of this type. Another, more reliable system should be used for more quantitative work on detecting nonuniform current distributions by collection efficiency measurements. On the other hand, it will be extremely difficult to obtain results by collection efficiency measurements which will be more than just qualitative tests of the theoretical predictions. The other methods, herein discussed, seem more suitable for quantitative work [see also Ref. (12)].

Conclusions

Nonuniform current distributions on a disk electrode may be detected in several ways. Of these, the method of measuring the deposit thickness on the disk and the technique of using the ring-disk system as a sectioned electrode are probably the most straightforward. The collection efficiency method, proposed by Albery and Ulstrup (5) is not as simple to interpret, but it may be used to provide qualitative evidence for nonuniform current distributions. Experimental data have been reported here that support the predictions of theory (2) when the platinum surface is properly prepared.

ABSTRACT

Integrals relating surface concentration to surface flux for the diffusion layer on a rotating disk are used to evaluate collection efficiencies for a ring-disk system and to assess the error involved in using this system as a sectioned electrode to measure the current distribution. Experimental results are reported which confirm these predictions at the limiting current. Below the limiting current, a nonuniform current distribution is obtained.

The Diffusion Layer on a Rotating Disk

Equations relating to the diffusion layer on a rotating disk are used to rederive in a new way Albery and Bruckenstein's formula (1) for the collection efficiency of a rotating ring-disk system. The same method is then used to assess the accuracy of using a ring-disk electrode as a sectioned electrode for the direct measurement of the current distribution on a disk electrode.

Steady transfer of a solute species obeys the equation of convective diffusion

$$\underline{v}\cdot\nabla c_i = D_i\nabla^2 c_i \quad [1]$$

if, for one reason or another, electric migration of this species can be ignored. This condition applies to a neutral solute and to a minor ionic solute in a solution with an excess of inert, supporting electrolyte. The equation also applies to a solution of a single electrolyte where the migration terms can be eliminated by means of the electroneutrality condition (2-4). In this case, D_i is replaced by the diffusion coefficient of the electrolyte.

The appropriate form of this equation for the diffusion layer on a rotating disk is

$$ay\Omega(\Omega/\nu)^{1/2}\left(r\frac{\partial c_i}{\partial r} - y\frac{\partial c_i}{\partial y}\right) = D_i\frac{\partial^2 c_i}{\partial y^2} \quad [2]$$

The radial diffusion terms are neglected on the basis of the thinness of the diffusion layer, compared to the radius of the electrode. We treat the neglect of these terms in a separate paper (5). For large values of the Schmidt number $Sc = \nu/D_i$, as encountered in electrolytic solutions, the diffusion layer is also much thinner than the hydrodynamic boundary layer, and it is appropriate to approximate the normal and radial components v_y and v_r of the velocity by the first terms of their power-series expansions in the normal distance y from the disk. This introduces the rotation speed Ω, the kinematic viscosity ν, and the dimensionless constant a from the solution of the hydrodynamic problem (6-8), where it is assumed that the mass-transfer process does not influence the fluid motion.

Equation [2] forms, in essence, the basis of the derivation of the limiting current at a disk electrode (3, 4). It is also the starting point for Newman's analysis of the current distribution on a disk electrode below the limiting current (9) and for Albery and Bruckenstein's analysis of the collection efficiency of a ring-disk system (1). It is convenient to introduce the dimensionless distance from the disk

$$\zeta = y(a\nu/3D_i)^{1/3}\ (\Omega/\nu)^{1/2} \quad [3]$$

so that Eq. [2] becomes

$$3\zeta\left(r\frac{\partial c_i}{\partial r} - \zeta\frac{\partial c_i}{\partial \zeta}\right) = \frac{\partial^2 c_i}{\partial \zeta^2} \quad [4]$$

The boundary conditions for Eq. [4] will normally include

$$c_i = c_\infty \text{ at } \zeta = \infty \text{ and } \partial c_i/\partial r = 0 \text{ at } r = 0 \quad [5]$$

as well as a specification of the concentration c_o or the concentration derivative $\partial c_i/\partial\zeta$ or a combination of these on the surface of the disk at $\zeta = 0$. The problem can be solved formally to yield either the derivative at the surface in terms of the surface concentration (10)

$$\left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} = \frac{-r}{\Gamma(4/3)}\int_o^r \left.\frac{dc_o}{dr}\right|_{r=r'} \frac{dr'}{(r^3 - r'^3)^{1/3}} \quad [6]$$

or *vice versa* (11)

$$c_o(r) - c_\infty = \frac{-1}{\Gamma(2/3)}\int_o^r \left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} \frac{r'\,dr'}{(r^3 - r'^3)^{2/3}} \quad [7]$$

These equations are analogous to those integral equations commonly used to relate the surface concentration and the normal derivative of concentration for problems involving unsteady, linear diffusion in a stagnant medium. Equation [6] should be regarded as a Stieltjes integral.

Rosner (10, 12) has discussed the application of these equations to certain aspects of the ring-disk system

* Electrochemical Society Active Member.

Key words: current distribution, collection efficiency.

and to other geometries [see also Chambré (13) and Chambré and Acrivos (14)]. Analogous expressions have been derived for heat-transfer problem by Tribus and Klein (15). Appendix II treats other geometries at high Schmidt numbers.

At the limiting current, the concentration of the reactant is zero over the entire surface of the disk electrode. In Eq. [6], c_o is regarded in this case to change discontinuously from c_∞ to 0 at $r = 0$, and dc_o/dr is zero over the remainder of the electrode. This equation then yields

$$\left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} = \frac{c_\infty}{\Gamma(4/3)} \tag{8}$$

the result of Levich (3).

Ring and Disk Electrodes

The integrals in Eq. [6] and [7] can be applied to evaluate the collection efficiency of a ring-disk system and to treat the limiting current on a sectioned disk electrode. We wish to treat three cases. It should be emphasized that the application of the mathematical expressions [6] and [7] represents a new treatment of these three cases and completely confirms the older work referenced. On the other hand, Eq. [6] and [7] and their extensions in Appendix II are more widely useful than just for the three cases described here, which illustrate their use for disk and sectioned-disk electrodes.

I. In most applications of rotating ring-disk electrodes, an unstable intermediate is generated on the disk and detected on the ring. The appropriate boundary conditions on the surface are

$$\left.\begin{array}{lll} 0 \le r \le r_o & \text{(on the disk)} & c_o = c_d \\ r_o < r < r_1 & \text{(on the insulating annulus)} & \partial c_i/\partial \zeta = 0 \\ r_1 \le r \le r_2 & \text{(on the ring)} & c_o = 0 \end{array}\right\} \tag{9}$$

Here c_d is the concentration of this species on the disk, where it is produced. Normally the bulk value is $c_\infty = 0$. It should be pointed out that the condition of uniform concentration on the disk surface is, strictly speaking, an assumption, problems of current distribution on the disk having been ignored. Furthermore, Eq. [1] and [2] do not account for any homogeneous decomposition of the species produced on the disk.

II. When both the disk and the ring are at limiting current for the same reaction, the boundary conditions on the surface are

$$\left.\begin{array}{ll} 0 \le r \le r_o, & c_o = 0 \\ r_o < r < r_1, & \partial c_i/\partial \zeta = 0 \\ r_1 \le r \le r_2, & c_o = 0 \end{array}\right\} \tag{10}$$

III. When no current is passed through the disk and the ring is at limiting current, the boundary conditions are

$$\left.\begin{array}{ll} 0 \le r < r_1, & \partial c_i/\partial \zeta = 0 \\ r_1 \le r \le r_2, & c_o = 0 \end{array}\right\} \tag{11}$$

This case, of course, also applies when there is no disk electrode. Obviously, $c_o = c_\infty$ for $0 \le r < r_1$, as shown by Eq. [7].

These three cases will be discussed in detail, and the concentration and current distribution will be derived for each region on the rotating surface. These cases can be treated simultaneously with the appropriate values of c_∞ and c_d given in Table I.

On the disk, the surface flux is given by Eq. [6].

$$\left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} = \frac{c_\infty - c_d}{\Gamma(4/3)} \quad \text{(disk)} \tag{12}$$

On the insulating annulus, the surface flux is zero. Hence, Eq. [7] can be used to determine the surface concentration, the surface flux on the disk being given by Eq. [12].

Table I. Values of c_∞ and c_d for the various cases

Case	c_d	c_∞
I. Collection efficiencies	c_d	0
II. Sectioned disk	0	c_∞
III. Ring only	c_∞	c_∞

$$c_o = c_\infty - \frac{c_\infty - c_d}{\Gamma(2/3)\Gamma(4/3)} \int_0^{r_o} \frac{r'\,dr'}{(r^3 - r'^3)^{2/3}} \quad \text{(annulus)} \tag{13}$$

In Appendix I it is shown how to evaluate this integral. With that result, Eq. [13] can be expressed as

$$c_o = c_d + \frac{c_\infty - c_d}{\Gamma(2/3)\Gamma(4/3)} \left[\frac{\pi}{6\sqrt{3}} + \frac{1}{\sqrt{3}} \tan^{-1}\left(\frac{2\theta - 1}{\sqrt{3}}\right) + \frac{1}{6} \ln \frac{(1+\theta)^3}{1+\theta^3} \right] \tag{14}$$

where

$$\theta^3 = r^3/r_o^3 - 1 \tag{15}$$

On the ring electrode, the surface concentration is zero, and the surface flux can be obtained from Eq. [6], the surface concentration on the disk being given by c_d and the surface concentration on the annulus being given by Eq. [13] or [14].

$$\left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} = \frac{-r}{\Gamma(4/3)} \left\{ \frac{c_d - c_\infty}{r} + \int_{r_o}^{r_1} \left.\frac{dc_o}{dr}\right|_{r=r'} \frac{dr'}{(r^3 - r'^3)^{1/3}} - \frac{c_o(r_1)}{(r^3 - r_1^3)^{1/3}} \right\} \tag{16}$$

From Eq. [14]

$$\frac{dc_o}{dr} = \frac{c_\infty - c_d}{\Gamma(2/3)\Gamma(4/3)} \frac{r_o^2}{r(r^3 - r_o^3)^{2/3}} \quad \text{(annulus)} \tag{17}$$

and Eq. [16] becomes

$$\Gamma\left(\frac{4}{3}\right) \left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} = c_\infty - c_d + \frac{r c_o(r_1)}{(r^3 - r_1^3)^{1/3}} - \frac{c_\infty - c_d}{\Gamma(2/3)\Gamma(4/3)} \int_{r_o}^{r_1} \frac{r r_o^2 dr'}{r'(r'^3 - r_o^3)^{2/3}(r^3 - r'^3)^{1/3}} \tag{18}$$

Let us evaluate a quantity j_r, proportional to the total flow of the species to the ring

$$j_r = \int_{r_1}^{r_2} \left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} r dr \tag{19}$$

Integration of Eq. [18] in this way over r gives

$$j_r = \frac{1}{2\Gamma(4/3)} \left\{ (c_\infty - c_d)(r_2^2 - r_1^2) + c_o(r_1)(r_2^3 - r_1^3)^{2/3} - \frac{(c_\infty - c_d) r_o^2}{\Gamma(2/3)\Gamma(4/3)} \int_{r_o}^{r_1} \frac{(r_2^3 - r'^3)^{2/3} - (r_1^3 - r'^3)^{2/3}}{(r'^3 - r_o^3)^{2/3}} \frac{dr'}{r'} \right\} \tag{20}$$

In Appendix I it is shown how to evaluate integrals of the type involved here. Similarly, let

$$j_d = \int_0^{r_o} \left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} r dr = \frac{c_\infty - c_d}{2\Gamma(4/3)} r_o^2 \tag{21}$$

In order to avoid writing complicated expressions more than once, let us define N as the following function of the geometric ratios r_2/r_o and r_1/r_o

$$N = \frac{(r_2^3 - r_1^3)^{2/3}}{r_o^2\Gamma(2/3)\Gamma(4/3)} \int_0^{r_o} \frac{r'\,dr'}{(r_1^3 - r'^3)^{2/3}} - \frac{r_2^2 - r_1^2}{r_o^2} + \frac{1}{\Gamma(2/3)\Gamma(4/3)} \int_{r_o}^{r_1} \frac{(r_2^3 - r'^3)^{2/3} - (r_1^3 - r'^3)^{2/3}}{(r'^3 - r_o^3)^{2/3}} \frac{dr'}{r'}$$

$$= (A^3 - B^3)^{2/3} \left[\frac{\sqrt{3}}{4\pi} \ln \frac{1+\theta^3}{(1+\theta)^3} - \frac{3}{2\pi} \tan^{-1}\left(\frac{2\theta - 1}{\sqrt{3}}\right) + \frac{3}{4} \right] + \frac{\sqrt{3}}{4\pi} \ln \frac{1 + A^3\psi^3}{(1 + A\psi)^3} + \frac{3}{2\pi} \tan^{-1}\left(\frac{2A\psi - 1}{\sqrt{3}}\right) + \frac{1}{4} - A^2 \left[\frac{\sqrt{3}}{4\pi} \ln \frac{1+\psi^3}{(1+\psi)^3} + \frac{3}{2\pi} \tan^{-1}\left(\frac{2\psi - 1}{\sqrt{3}}\right) + \frac{1}{4} \right] \quad [22]$$

where

$$A = r_2/r_o, \quad B = r_1/r_o, \quad \theta = (B^3 - 1)^{1/3}, \quad \psi = \frac{1}{A}\left(\frac{A^3 - B^3}{B^3 - 1}\right)^{1/3} \quad [23]$$

Then we can write

$$j_r = -\frac{c_\infty - c_d}{2\Gamma(4/3)} r_o^2 N + \frac{c_\infty (r_2^3 - r_1^3)^{2/3}}{2\Gamma(4/3)} = - j_d N + \frac{c_\infty (r_2^3 - r_1^3)^{2/3}}{2\Gamma(4/3)} \quad [24]$$

If no other reactions occur, the ratio of the total ring current to the total disk current for the first case in Table I is found to be

$$- j_r/j_d = N \quad [25]$$

since in this case $c_\infty = 0$ and all the active intermediate which reacts on the ring is produced at the disk. Then, N is called the collection efficiency, and Eq. [22] agrees exactly with the expression derived by Albery and Bruckenstein (1) by another method. These authors have tabulated values of N for given values of r_1/r_o and r_2/r_1. The analytic form of the result makes it easy to evaluate N numerically for values of r_1/r_o and r_2/r_1 outside those tabulated.

For case III, when there is no disk electrode, $c_d = c_\infty$, and the total flow to the ring reduces to

$$j_r = c_\infty \frac{(r_2^3 - r_1^3)^{2/3}}{2\Gamma(4/3)} \quad [26]$$

a result first obtained by Levich (16) and later by Ibl (17) and Rosner (10).

The geometric quantity N can also be measured with a ring-disk system where both electrodes are operated at the limiting current for the same reaction. Equations [21] and [24] then yield for the ratio of the total ring current to the total disk current, since $c_d = 0$ (case II in Table I)

$$\frac{j_r}{j_d} = \frac{(r_2^3 - r_1^3)^{2/3}}{r_o^2} - N \quad [27]$$

in agreement with the result of Bruckenstein (18).

The rotating ring-disk electrode system is usually used as a polarographic instrument; species which are generated at the disk are detected on the ring. The presence of unstable intermediates can be detected in this way, but it is difficult to treat quantitatively the kinetics because of uncertainty in the relative importance of ohmic potential drop and concentration and surface overpotentials. On the ring, the influence of surface overpotential and ohmic potential drop is negligible when it is operated at the limiting current. The kinetics of generation of the active intermediate on the disk is less well known, however, because of the nonuniformity of the current distribution on the disk. The assumption of a uniform surface concentration on the disk surface is questionable for case I of Table I.

When the ring-disk system is used for plating-type applications, the same reaction would occur on both electrodes, and they would normally be operated at the same potential. If both are operated below the limiting current, the nonuniform current distribution on the disk again makes it difficult to analyze the electrochemical kinetics. However, it is just because of the nonuniform current distribution that a ring would be used with the disk. The ring-disk system might be used to determine the current distribution, or the ring might be included to make the current distribution more nearly uniform on the disk. Since the nonuniformities are greatest on the outer edge of a disk, the ring might be viewed as "soaking up" the nonuniformities. The justification for use of the ring for either purpose must come from an analysis of the current on a ring as compared to the current over an equivalent area of a disk electrode.

Since sectioned electrodes are commonly used to measure the current distribution on an electrode, frequently at the limiting current, it would be valuable to assess the error introduced by the nonzero thickness of the insulator. One standard of comparison would be the ring current divided by the current density on the disk and the area of the ring electrode. From Eq. [24], this ratio is given by

$$f_1 = \frac{(r_2^3 - r_1^3)^{2/3} - r_o^2 N}{r_2^2 - r_1^2} \quad [28]$$

and is tabulated in Table II. Departures of this ratio from unity show by how much the average current density on the ring exceeds the current density on the disk. Since limiting currents are being considered, this current density on the disk is the appropriate standard since it would prevail everywhere if the insulating annulus were of zero thickness.

As a second standard of comparison, we take the ring current divided by the current density on the disk and the area of both the ring electrode and the insulating annulus. This ratio is given by

$$f_2 = \frac{(r_2^3 - r_1^3)^{2/3} - r_o^2 N}{r_2^2 - r_o^2} \quad [29]$$

and is tabulated in Table III. Again, departures of this ratio from unity show by how much the average current density on the ring and annulus is less than the current density on the disk.

For thin insulators or wide rings, both of these ratios approach unity. For a ring electrode whose area

is ten times the area of the insulator, the error represented by the ratio f_2 can be expected to be less than 3% while that represented by f_1 can be greater than 7%. These ratios thus provide a basis for the design of ring-disk systems for current-distribution studies. Similar considerations apply to the design of sectioned electrodes for other geometries when mass-transfer limitations determine the current distribution (see Appendix II).

The ratio f_2 depends most strongly on the ratio of the area of the insulator to the area of the ring electrode. Consequently, we have used this for one of the geometric parameters in Tables II and III. With a strong dependence on this parameter, the choice of the other parameter becomes less important; we chose r_2/r_o, the ratio of the outer radius of the ring to the radius of the disk electrode. These geometric parameters replace the ratios r_1/r_o and r_2/r_1.

Experimental Determination of Current Distributions

The experimental investigation of these predictions was divided into two parts. The first objective was to investigate whether or not Eq. [29] was obeyed at limiting current for the solutions used here. The second part was to investigate the departure from this equation below the limiting current, *i.e.*, to determine whether or not a nonuniform current distribution could be observed.

The electrolytic solutions used were composed of KNO_3, $K_4Fe(CN)_6$, and $K_3Fe(CN)_6$. The concentration of KNO_3 was always 1 molar, and the concentrations of the other two components were varied but their ratio was always 1. Fresh, filtered solutions were used for the determinations because it was found that the solutions decompose slowly upon exposure to light and air. The measurements were made at about 23°C.

The rotating ring-disks were constructed of platinum with epoxy insulation. The relevant dimensions of the assemblies were: ring-disk 1 (RD1), $r_o = 0.441$ cm, $r_1 = 0.502$ cm, $r_2 = 0.620$ cm, and over-all radius 1.27 cm; ring-disk 2 (RD2), $r_o = 0.322$ cm, $r_1 = 0.478$ cm, $r_2 = 0.633$ cm, and over-all radius 1.27 cm; ring-disk 3 (RD3), $r_o = 0.441$ cm, $r_1 = 0.498$ cm, $r_2 = 0.616$ cm, and over-all radius 1.27 cm. The ring-disks were polished before each run on a metallographic wheel with 0.05μ alumina.

The ring-disks were operated potentiostatically with a Wenking potentiostat. Both were operated anodically. One output from the potentiostat was taken to a parallel circuit in one leg of which was a precision resistor and the connection to the disk, and in the other leg was a variable resistor and the connection to the ring. For measurements at the limiting current, the potential drop across each resistor was measured, and the current was calculated from this and the measured resistance of each resistor. For measurements below the limiting current, the potential across the resistors was matched to within 0.05 mV. From this and the measured resistance, the current through each resistor was calculated. These potential drops were measured with a Honeywell potentiometric strip chart recorder.

Table IV. Sectioned-electrode measurements at limiting current All solutions were 1M in KNO_3. Solutions I, II, and III were 0.005, 0.01, and 0.05M respectively, in both $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$

Ring-disk assembly	Solution	Rotation speed (rpm)	$\frac{I_r}{I_d}$	$\frac{I_r}{I_d}\frac{r_o^2}{r_2^2 - r_o^2}$	f_2 theory

The reference electrode was a strip of platinum partially immersed in a side arm compartment filled with the solution being investigated. The side compartment was connected through a Luggin capillary to the main solution. The capillary tip was positioned in the plane of the disk surface at 2.27 cm from the center of the ring-disk assembly.

The anodic limiting current was attained with overpotentials between +400 mV and +800 mV. In the limiting current region, both the ring current and disk current were constant with potential. In Table IV is listed the ratio of ring current to disk current, in the limiting current region, for each solution used and at several rotation speeds. The results are the average of several runs, and the per cent of average deviation is also given. Also given is this ratio multiplied by the ratio of disk area to the area of insulating annulus plus ring electrode. This may be compared to the value of f_2, also listed, calculated from Eq. [29].

The experimental results agree with the predictions of Eq. [29] to better than 1%. Also, there is no dependence on concentration or rotation speed, which is also consistent with Eq. [29]. The deviation from f_2 (theory) is considered to be within experimental error. The largest error was probably the measurement of the electrode dimensions.

The second part of the investigation, *i.e.*, sectioned electrode measurements below the limiting current, would be expected to reveal a higher value of f_2 (meas.) than predicted by Eq. [29]. This is the result obtained, as shown in Fig. 1 and 2. Δ is the deviation of the measured results from predictions of Eq. [29], plotted in Fig. 1 as a function of the fraction of limiting current on the disk plus ring. Δ is zero at limiting current, and increases with decreasing importance of the concentration overpotential and the increasing importance of ohmic potential drop as the current is decreased below the limiting current. The ferro-ferricyanide system was not under kinetic control in the concentration and potential ranges used here.

Curves A and B of Fig. 1 were obtained for RD2 and RD3 at the same rotation speed in solutions of the same composition. The difference between the two curves is due to the different gap widths of the two assemblies.

Since the outer radii of RD2 and RD3 are approximately equal, curves A and B were obtained with the same value of the dimensionless rotation speed, N, of Newman's theory (9) (not to be confused with the collection efficiency N). This parameter is defined as

$$N = -\Gamma(4/3)\,\frac{ZFr_2 i_{\text{lim}}}{RT\,\kappa_\infty}$$

The values of N for curves A and B are[1] 5.84 and 5.89, respectively. The parameter is a measure of the relative importance of the ohmic potential drop as com-

[1] The values of N were calculated from the limiting current density and the conductivity of 1M KNO_3, *i.e.*, $\kappa_\infty = 0.1$ ohm^{-1} cm^{-1}.

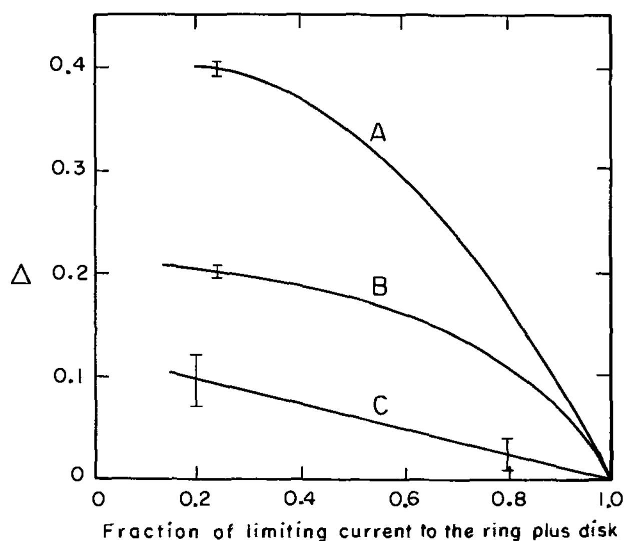

Fig. 1. Δ as a function of the fraction of limiting current. Curve A-RD3, 1550 rpm, 1M KNO_3, 0.05M $K_3Fe(CN)_6$, 0.05M $K_4F_3(CN)_6$. Curve B-RD2, 1550 rpm, 1M KNO_3, 0.05M $K_3Fe(CN)_6$, 0.05M $K_4Fe(CN)_6$. Curve C-RD3, 1550 rpm, 1M KNO_3, 0.005M $K_3Fe(CN)_6$, 0.005M $K_4Fe(CN)_6$. I—indicates standard deviation.

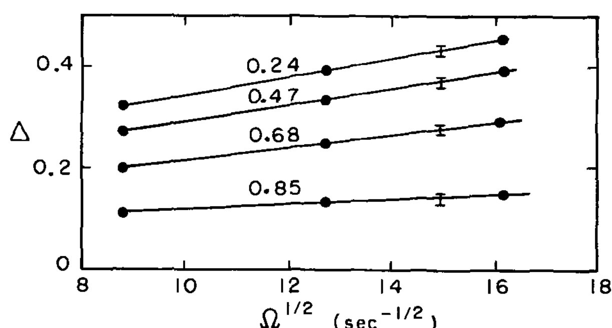

Fig. 2. Δ as a function of rotation speed. Numbers on the curves indicate the fraction of limiting current on ring plus disk. RD3—1M KNO_3, 0.05M $K_3Fe(CN)_6$, 0.05M $K_4Fe(CN)_6$. I—indicates standard deviation.

pared to the concentration overpotential at a particular fraction of limiting current.

The effect of changing N was measured in two ways. First, the composition of the solution was changed from 0.05M in both ferrocyanide and ferricyanide to 0.005M in both ferrocyanide and ferricyanide. With this solution, the value of N is[1] 0.595 for RD3, and curve C of Fig. 1 was obtained. These results may be compared to curve A. Thus, by reducing the concentration of ferro-ferricyanide, one reduces the importance of the ohmic potential drop, at a particular fraction of limiting current, and the current becomes more uniform.

N was also changed by varying the rotation speed, with the results shown in Fig. 2. The increase of rotation speed increases N and thus the importance of the ohmic drop, producing a less uniform current distribution.

Conclusions

It has been possible to determine the error involved in using the ring-disk system as a sectioned electrode. The predictions for operation at limiting current were verified by experiment within 1%. When operated below the limiting current, a nonuniform current distribution is observed. The average current density on the ring is higher than the average current density on the disk—an observation which is consistent with Newman's theory (9).

Bruckenstein and Miller (21) recently reported measurements similar to those here but with a NaBr-$HClO_4$ system. Their measurements also revealed a nonuniform current distribution. They found that an increase in conductivity (thus reducing N) made the current distribution more uniform. They do not report values of the important parameters for their system, nor even the location of the reference electrode, so a more direct comparison with the present results is not possible. It is surprising, however, that the ratio of ring current density to disk current density, which they measure, is constant for various fractions of limiting current (which fractions they do not specify). This should be contrasted with the data reported here, in Fig. 1. The explanation for this behavior is not clear, but it may be related to the kinetic complications of the NaBr-$HClO_4$ system (22).

The diffusion coefficient for the ferrocyanide ion in the systems used here has been calculated from the measured anodic limiting currents, and the equation (3, 9)

$$i_{\lim} = \frac{nFc_\infty}{\Gamma(4/3)} \left(\frac{a}{3}\right)^{1/3} \Omega^{1/2} D_i^{2/3} \nu^{-1/6}$$

In making the calculations, the viscosity of water and the density of 1M KNO_3 were used. The viscosity of 1M KNO_3, 0.05M ferrocyanide, 0.05M ferricyanide was found to be the same as that for water (within 5%) at the same temperature. The results are:

(i) 1M KNO_3, 0.05M $K_3Fe(CN)_6$, 0.05M $K_4Fe(CN)_6$ rotation speeds of 750, 1550, and 2500 rpm $D_i = 0.567 \times 10^{-5}$ cm²/sec with a standard deviation of 0.0166×10^{-5} cm²/sec.

(ii) 1M KNO_3, 0.01M $K_3Fe(CN)_6$, 0.01M $K_4Fe(CN)_6$ rotation speed of 1550 rpm $D_i = 0.599 \times 10^{-5}$ cm²/sec with a standard deviation of 0.007×10^{-5} cm²/sec.

(iii) 1M KNO_3, 0.05M $K_3Fe(CN)_6$, 0.005M $K_4Fe(CN)_6$ rotation speed of 1550 rpm $D_i = 0.577 \times 10^{-5}$ cm²/sec with a standard deviation of 0.013×10^{-5} cm²/sec.

The value of $D_i = 0.606 \times 10^{-5}$ cm²/sec is predicted from the correlation of Gordon, Newman, and Tobias (23). This compares favorably with that reported here.

The theoretical results for sectioned electrodes can be extended to a variety of geometries involving forced, laminar convection, as shown in Appendix II.

Acknowledgment

This work was supported by the United States Atomic Energy Commission and by Boeing Scientific Research Laboratories.

We wish to acknowledge the help of Robert L. Lee of BSRL in making the experimental measurements.

Manuscript submitted March 8, 1971; revised manuscript received ca. Sept. 29, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX I

First let us evaluate the integral

$$\int_0^x \frac{xdx}{(1-x^3)^{2/3}} = \int_0^1 \frac{xdx}{(1-x^3)^{2/3}} - \int_x^1 \frac{xdx}{(1-x^3)^{2/3}} \quad [30]$$

In the first integral, make the substitution $y = x^3$; in the second, make the substitution

$$\theta^3 = 1/x^3 - 1 \quad [31]$$

Then we have

$$\int_0^x \frac{x\,dx}{(1-x^3)^{2/3}} = \frac{1}{3}\int_0^1 \frac{dy}{y^{1/3}(1-y)^{2/3}} - \int_0^\theta \frac{d\theta}{1+\theta^3}$$
$$= \frac{1}{3}\Gamma\left(\frac{2}{3}\right)\Gamma\left(\frac{1}{3}\right) - \frac{1}{3}\int_0^\theta \frac{d\theta}{1+\theta}$$
$$- \frac{1}{3}\int_0^\theta \frac{2-\theta}{\theta^2-\theta+1}\,d\theta = \Gamma\left(\frac{2}{3}\right)\Gamma\left(\frac{4}{3}\right)$$
$$- \frac{1}{3}\ln(1+\theta) + \frac{1}{6}\ln(\theta^2-\theta+1)$$
$$- \frac{1}{\sqrt{3}}\tan^{-1}\frac{2\theta-1}{\sqrt{3}}\Bigg|_0^\theta = \Gamma\left(\frac{2}{3}\right)\Gamma\left(\frac{4}{3}\right)$$
$$+ \frac{1}{6}\ln\frac{1+\theta^3}{(1+\theta)^3} - \frac{1}{\sqrt{3}}\tan^{-1}\frac{2\theta-1}{\sqrt{3}} - \frac{\pi}{6\sqrt{3}} \quad [32]$$

Next we want to evaluate the integral

$$I = \int_1^x \frac{(A^3-x^3)^{2/3}}{(x^3-1)^{2/3}}\frac{dx}{x} \quad [33]$$

where $A \geq x > 1$. Let

$$\omega = x^3/(x^3-1) \quad [34]$$

Then

$$I = \frac{A^2}{3}\int_\omega^\infty \frac{(\beta\omega-1)^{2/3}d\omega}{\omega(\omega-1)} = \frac{A^2}{3}\left[\int_\omega^\infty \frac{d\omega}{\omega(\beta\omega-1)^{1/3}} - (1-\beta)\int_\omega^\infty \frac{d\omega}{(\omega-1)(\beta\omega-1)^{1/3}}\right] \quad [35]$$

where

$$\beta = 1 - 1/A^3 \quad [36]$$

In the first integral, let $y^3 = \beta\omega - 1$; in the second integral, let $y^3 = (\beta\omega-1)/(1-\beta)$. Then we have

$$I = A^2\int_\psi^\infty \frac{y\,dy}{1+y^3} - \int_{A\psi}^\infty \frac{y\,dy}{1+y^3} \quad [37]$$

where

$$\psi = (\beta\omega-1)^{1/3} = \frac{1}{A}\left(\frac{A^3-x^3}{x^3-1}\right)^{1/3} \quad [38]$$

The integrals here can now be evaluated in a manner used above for the first integral

$$I = (A^2-1)\int_0^\infty \frac{y\,dy}{1+y^3} + \int_0^{A\psi}\frac{y\,dy}{1+y^3}$$
$$- A^2\int_0^\psi \frac{y\,dy}{1+y^3} = (A^2-1)\Gamma(4/3)\Gamma(2/3)$$
$$+ \frac{1}{6}\ln\frac{1+A^3\psi^3}{(1+A\psi)^3} + \frac{1}{\sqrt{3}}\tan^{-1}\left(\frac{2A\psi-1}{\sqrt{3}}\right) + \frac{\pi}{6\sqrt{3}}$$
$$- A^2\left[\frac{1}{6}\ln\frac{1+\psi^3}{(1+\psi)^3} + \frac{1}{\sqrt{3}}\tan^{-1}\left(\frac{2\psi-1}{\sqrt{3}}\right) + \frac{\pi}{6\sqrt{3}}\right] \quad [39]$$

Note that

$$\Gamma(2/3)\Gamma(4/3) = 2\pi/3\sqrt{3} \quad [40]$$

and that

$$\tan^{-1}\left(\frac{2\psi-1}{\sqrt{3}}\right) = \frac{\pi}{3} - \tan^{-1}\left(\frac{2/\psi-1}{\sqrt{3}}\right) \quad [41]$$

APPENDIX II

Diffusion Layers in Laminar Forced Convection at High Schmidt Numbers

Because the diffusion coefficient is so small in electrolytic solutions, the diffusion layer generally lies very close to the electrode surface and it is appropriate to approximate the velocity components by the first terms in their power-series expansions in the normal distance from the surface. The Lighthill transformation (19, 20) is useful for treating such diffusion layers. The diffusion-layer form of Eq [1] then is

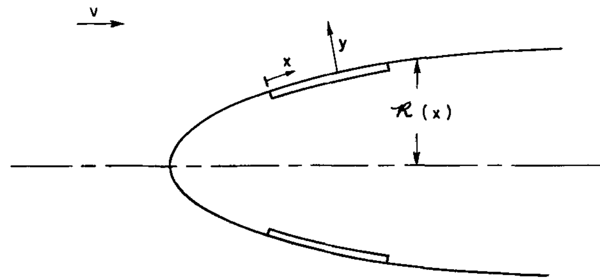

Fig. 3. An electrode on an axisymmetric body with axisymmetric flow.

$$y\beta\frac{\partial c_i}{\partial x} - \frac{1}{2}y^2\frac{(\mathcal{R}\beta)'}{\mathcal{R}}\frac{\partial c_i}{\partial y} = D_i\frac{\partial^2 c_i}{\partial y^2} \quad [42]$$

where the coordinate system is indicated in Fig. 3, $\beta(x)$ is the velocity derivative $\partial v_x/\partial y$ at $y = 0$, and for an axisymmetric body $\mathcal{R}(x)$ is the distance of the surface from the axis of symmetry. For two-dimensional diffusion layers, $\mathcal{R} = 1$. Outside the diffusion layer, at $y = \infty$, the concentration is $c_i = c_\infty$.

We solve the problem first for the boundary conditions on the surface

$$\left.\begin{aligned} c_i &= c_\infty \text{ at } y = 0, x < x_o \\ c_i &= 0 \text{ at } y = 0, x \geq x_o \end{aligned}\right\} \quad [43]$$

In terms of the similarity variable

$$\xi = y\sqrt{\mathcal{R}\beta} \Bigg/ \left[9D_i\int_{x_o}^x \mathcal{R}\sqrt{\mathcal{R}\beta}\,dx\right]^{1/3} \quad [44]$$

the solution is (for $x > x_o$)

$$\frac{c_i}{c_\infty} = \theta(\xi) = \frac{1}{\Gamma(4/3)}\int_0^\xi e^{-x^3}dx \quad [45]$$

which gives for the concentration derivative at the wall

$$\left.\frac{\partial c_i}{\partial y}\right|_{y=0} = \frac{c_\infty\sqrt{\mathcal{R}\beta}}{\Gamma(4/3)} \Bigg/ \left[9D_i\int_{x_o}^x \mathcal{R}\sqrt{\mathcal{R}\beta}\,dx\right]^{1/3} \quad [46]$$

The above solution can be used to treat the case of a varying surface concentration by superposition of results for appropriate changes in the surface concentration at many points x_o along the surface

$$\left.\frac{\partial c_i}{\partial y}\right|_{y=0} = -\frac{\sqrt{\mathcal{R}\beta}}{\Gamma(4/3)}\int_0^x \left.\frac{dc_o}{dx}\right|_{x=x_o} \frac{dx_o}{\left[9D_i\int_{x_o}^x \mathcal{R}\sqrt{\mathcal{R}\beta}\,dx\right]^{1/3}} \quad [47]$$

By means of the coordinate transformation

$$r^3 = \int_0^x \mathcal{R}\sqrt{\mathcal{R}\beta}\,dx \text{ and } \zeta = y\sqrt{\mathcal{R}\beta} \Bigg/ \left[9D_i\int_0^x \mathcal{R}\sqrt{\mathcal{R}\beta}\,dx\right]^{1/3} \quad [48]$$

Eq. [47] becomes

$$\left.\frac{\partial c_i}{\partial \zeta}\right|_{\zeta=0} = \frac{-r}{\Gamma(4/3)}\int_0^r \left.\frac{dc_o}{dr}\right|_{r=r'} \frac{dr'}{(r^3-r'^3)^{1/3}} \quad [49]$$

which is the same as Eq. [6]. The coordinate transformation [48] also reduces Eq. [42] to Eq. [4].

Equation [49] should have the same inverse [7] as Eq. [6]. We can derive this in a more straightforward manner than that used in Ref. (11) by following Tribus and Klein (15), p. 215. Write Eq. [49] as

$$\left.\frac{\partial c_i}{\partial \zeta}\right|_{\substack{\zeta=0\\ r=r'}} = \frac{-r'}{\Gamma(4/3)}\int_0^{r'} \left.\frac{dc_o}{dr}\right|_{r=x} \frac{dx}{(r'^3-x^3)^{1/3}} \quad [50]$$

Multiply by $(r^3 - r'^3)^{-2/3}\, 3r'dr'$ and integrate from 0 to r.

$$3\int_0^r \left.\frac{\partial c_i}{\partial\zeta}\right|_{\zeta=0}\frac{r'dr'}{(r^3-r'^3)^{2/3}} = -\int_0^r \frac{3r'^2}{\Gamma(4/3)}\int_0^{r'}\left.\frac{dc_o}{dr}\right|_{r=x}\frac{dx}{(r'^3-x^3)^{1/3}}\frac{dr'}{(r^3-r'^3)^{2/3}} \quad [51]$$

Interchange the order of integration on the right.

$$3\int_0^r \left.\frac{\partial c_i}{\partial\zeta}\right|_{\zeta=0}\frac{r'dr'}{(r^3-r'^3)^{2/3}} = \frac{-1}{\Gamma(4/3)}\int_0^r \left.\frac{dc_o}{dr}\right|_{r=x}\int_x^r \frac{3r'^2dr'}{(r'^3-x^3)^{1/3}(r^3-r'^3)^{2/3}}dx \quad [52]$$

In the inner integral, let

$$y = (r'^3 - x^3)/(r^3 - x^3)$$

so that

$$\int_x^r \frac{3r'^2dr'}{(r'^3-x^3)^{1/3}(r^3-r'^3)^{2/3}} = \int_0^1 \frac{dy}{y^{1/3}(1-y)^{2/3}} = \Gamma\left(\frac{1}{3}\right)\Gamma\left(\frac{2}{3}\right) = \frac{2\pi}{\sqrt{3}} \quad [53]$$

Then we have

$$\int_0^r \left.\frac{dc_o}{dr}\right|_{r=x} dx = c_o(r) - c_\infty = \frac{-1}{\Gamma(2/3)}\int_0^r \left.\frac{\partial c_i}{\partial\zeta}\right|_{\zeta=0}\frac{r'dr'}{(r^3-r'^3)^{2/3}} \quad [54]$$

in agreement with Eq. [7]. The inverse of Eq. [47] can thus be written, expressing the surface concentration as an integral over the flux

$$c_o(x) - c_\infty = -\frac{(D_i/3)^{1/3}}{\Gamma(2/3)}\int_0^x \left.\frac{\partial c_i}{\partial y}\right|_{\substack{y=0\\ x=x_o}}\frac{\mathcal{R}(x_o)\,dx_o}{\left[\int_{x_o}^x \mathcal{R}\sqrt{\mathcal{R}\beta}\,dx\right]^{2/3}} \quad [55]$$

With these results we can now work, for various geometries, the same problems as outlined in Table I. The collection efficiency problem may then not be realistic since we have no justification for assuming that the surface concentration is uniform on the first electrode (unless the first electrode is at limiting current for the reaction which produces the active intermediate). The third problem is trivial since we worked it out before the superposition (see Eq. [46]).

Let us have two electrodes given by

$$0 \le r \le r_o \text{ and } r_1 \le r \le r_2$$

with an insulator between ($r_o < r < r_1$). On the first electrode, $c_o = c_d$, and Eq. [12] gives the flux. On the insulator, $\partial c_i/\partial\zeta = 0$ at $\zeta = 0$, and the surface concentration is given by Eq. [13] or [14]. On the second electrode, $c_o = 0$, and the flux is given by Eq. [18].

Note that

$$j_r = \int_{r_1}^{r_2} \left.\frac{\partial c_i}{\partial\zeta}\right|_{\zeta=0} r\,dr = \left(\frac{D_i}{3}\right)^{1/3}\int_{x_1}^{x_2}\left.\frac{\partial c_i}{\partial y}\right|_{y=0}\mathcal{R}\,dx \quad [56]$$

and is proportional to the total flow to the second electrode. Similarly, j_d is proportional to the total flow to the first electrode, and Eq. [21] and [24] apply.

Furthermore, for sectioned electrodes at the limiting current, f_1 and f_2 have the meaning originally intended (but not stated explicitly). f_1 is the current to the second electrode divided by the current which would flow to the area of the second electrode if the insulator were an electrode. f_2 is the current to the second electrode divided by the current which would flow to the combined area of the second electrode and the insulator if the insulator were an electrode.

Consider the special case of sectioned electrodes in the wall of a flow channel (or a tube or an annulus). $\beta = \beta_o$, a constant, and $\mathcal{R}$ is a constant. Then, according to Eq. [48]

$$r^3 = x\mathcal{R}\sqrt{\mathcal{R}\beta_o} \quad [57]$$

Tables II and III still apply, but $A = r_2/r_o = (x_2/x_o)^{1/3}$ and $B = r_1/r_o = (x_1/x_o)^{1/3}$, and the parameters on those tables are

$$\frac{r_2}{r_o} = \left(\frac{x_2}{x_o}\right)^{1/3} \text{ and } \frac{r_1^2 - r_o^2}{r_2^2 - r_1^2} = \frac{x_1^{2/3} - x_o^{2/3}}{x_2^{2/3} - x_1^{2/3}} \quad [58]$$

NOMENCLATURE

$a = 0.51023$
$A = r_2/r_o$
$B = r_1/r_o$
c_i concentration of the species of interest (mole/cm^3)
c_o surface concentration of the species of interest (mole/cm^3)
c_∞ concentration of the species of interest outside the diffusion layer (mole/cm^3).
c_d uniform concentration of the species of interest near the surface of the disk electrode (mole/cm^3)
D_i diffusion coefficient of the species of interest (cm^2/sec)
f_1 see Eq. [28]
f_2 see Eq. [29]
i_{lim} limiting current density on disk electrode (A/cm^2)
I see Eq. [33]
j_d proportional to the total mass-transfer rate to disk electrode (mole/cm).
j_r proportional to total mass-transfer rate to ring electrode (mole/cm).
N dimensionless limiting current density for disk electrode [see Ref. (9)]
N collection efficiency for ring-disk system
r radial distance from the axis of the disk
r_o radius of disk electrode (cm)
r_1 inner radius of ring electrode (cm)
r_2 outer radius of ring electrode (cm)
$\mathcal{R}$ distance of axisymmetric surface from axis of symmetry (cm)
$Sc = \nu/D_i$, the Schmidt number
v fluid velocity (cm/sec)
x distance along electrode (cm)
y normal distance from the electrode surface (cm)
β velocity derivative at the wall (sec^{-1})
Γ gamma function
ζ dimensionless normal distance for the diffusion layer (see also Eq. [48])
$\theta = (r^3/r_o^3 - 1)^{1/3}$
$\theta = (B^3 - 1)^{1/3}$
κ_∞ solution conductivity outside the diffusion layer (mho/cm)
ν kinematic viscosity (cm^2/sec)
ξ see Eq. [44]
ψ see Eq. [23]
Ω rotation speed (radian/sec)

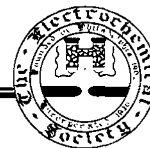
Technical Note



Electrochemical and Chemical Corrosion of Tungsten Carbide (WC)

John D. Voorhies*,[1]

Chemical Engineering Department, Stanford University, Stanford, California 94305

Tungsten carbide (WC) has attracted interest in recent years because of its electrocatalytic properties in anodic reactions of H_2, CO, and other fuels (1-6). Bianchi *et al.* (7) have studied the general electrochemical properties of a low area WC surface and Mazza and Trasatti (8) have used WC as an "inert" electrode material for solution redox measurements.

In the work of Binder *et al.* (4, 5) and Pohl and Böhm (1-3), there is evidence for chemical and electrochemical reactivity of the WC surface in aqueous electrolytes. Binder cites anodic passivation of WC with evolution of CO_2 and speculates that the passivated surface consists of WO_3 which is reducible to a hydrogen tungsten bronze. Böhm (6) finds that preanodization is necessary to achieve moderate levels of hydrogen adsorption on WC. There is also a consensus that oxidation of the WC surface is necessary for electrocatalytic activity in the anodic oxidation of fuels.

The present work is a potentiostatic-coulometric study of the anodic corrosion of WC powder and the cathodic reduction of the surface anode product. Oxidation of WC by the one-electron oxidants, ceric sulfate, and ferricyanide is also described.

Experimental

The sample of WC powder (I) used almost exclusively in this work was gratefully received from Prof. Dr.-Ing. F. A. Pohl and Dr. H. Böhm of AEG-Telefunken, Forschungsinstitut Frankfurt, 6 Frankfurt (Main)-Niederrad, Goldsteinstrasse 235. The BET surface area of this material is 5 m^2/g. X-ray diffraction shows a clean WC pattern with lattice constants for the simple hexagonal structure, $a = 2.9004$Å, $c = 2.8444$Å and an average apparent particle size from x-ray line broadening of about 300Å. Deviation of the lattice constants from the accepted values, $a = 2.906$Å, $c = 2.837$Å (9) may be interpreted as a slight deficiency of carbon, a condition which is claimed (5) to favor electrocatalytic activity of WC. Spectral analysis by uv emission indicates about 10 ppm Cu, 2 ppm Mg, and 20 ppm Si.

* Electrochemical Society Active Member.

[1] 1970-71 Senior Educational Leave from American Cyanamid Company, Stamford, Connecticut 06904.

Key words: tungsten carbide (WC), corrosion, surface oxide.

Sample II was obtained from Norton Company, Worcester, Mass., and also shows a clean diffraction pattern with exact WC stoichiometry. The surface area is 2 m^2/g.

All electrochemical measurements were obtained with the Wenking 61-TR Standard Potentiostat used only in its simple static mode with manual adjustment of the controlled electrode potential in discrete potential steps. The working electrode compartment was a Pyrex glass tube 10 cm long with an I.D. of 11 *mm* and a fine fritted glass closure at one end, the bottom of the electrode compartment in its normal vertical orientation. In the first experiments, the working electrode was contained in this compartment, and the reference electrode was positioned in the electrolyte outside of the frit. As the frit resistance was 15 ohms saturated with 2*N* H_2SO_4 electrolyte, the "controlled potential" was actually the sum of a variable *IR* component and the electrode potential. Nevertheless, useful coulometric information was obtained in 200-300 mV intervals with this setup, and the first two entries in Table I are from measurements of this kind.

In order to obtain more meaningful current-electrode potential values, a glass sidearm was attached to the working electrode compartment and the reference electrode placed therein, thereby contacting the electrolyte within the working electrode compartment and eliminating the variable *IR* component.

Table I. Coulombic ratio—anodic corrosion: cathodic reduction of corrosion product

Sample (AEG WC) (g)	Anodic corrosion[a] (coulombs)	Cathodic reduction[b] (coulombs)	Ratio (A:C)
0.49	15.2	0.806	18.8
0.224	7.61	0.377	20.2
0.125	5.32	0.246	21.6
0.50	32.9	1.65	19.9
0.50	17.6[c]	0.437	40.2[c]

[a] Corrosion at one or more potentials in the range +0.45 to +0.75V *vs.* HE.
[b] Net cathodic reduction of anodic corrosion product on surface of WC.
[c] Experiment in 2*M* H_3PO_4, all others in 2*N* H_2SO_4.

The working electrode itself was a compacted slug of powdered material, WC or tungsten metal powder, contained in the annulus provided by a sleeve of polyethylene tubing (6 mm I.D.) extending 0.5-1 cm beyond the contact end of a spectrographic graphite rod which provided electronic contact to the potentiostat. The counterelectrode was a spectrographic graphite rod positioned in the simple beaker cell far from the working electrode to prevent contamination with gas from the counterelectrode.

The reference electrode was a small, stable Beckman fiber-junction saturated calomel electrode whose potential was checked frequently against several larger SCE's and measured against a platinized platinum wire hydrogen electrode [p_{H_2} = 1 atm, E(SCE-HE) = +249 mV] in the test electrolyte. All values of electrode potential are reported with respect to the hydrogen electrode in the test electrolyte (HE).

Two electrolytes were used, 2*N* H_2SO_4 and 2*M* H_3PO_4, both prepared with doubly distilled water and Baker and Adamson reagent grade acid without further purification. The test electrolyte was not deaerated during or prior to an experiment, and therefore small residual oxygen currents were observed in cathodic measurements. These currents were accounted for in a small cathodic "blank" measured before the anodic corrosion-cathodic reduction measurements and subtracted from the coulombs for cathodic reduction.

Coulometric values for a specific faradaic process were obtained by integrating current-time curves at a given controlled potential or range of potentials. The coulombs required to charge the double layer on these high area powder electrodes were not subtracted from these values. An estimate of this capacitative charge in a potential step of 100 mV for an 0.50g sample of AEG WC (2.5 m² BET area) in 2*N* H_2SO_4 is 0.01-0.02 coulomb from the charging current in a step from +0.2 to +0.1V in the initial potentiostatic measurements before anodic corrosion. This charging error in the coulombic measurements cited in Table I is most significant for the cathodic reduction step. Although the error is partially compensated by the blank correction mentioned previously, it could make the smaller cathodic values in Table I 5-10% high.

Results

Potentiostatic-WC powder.—In the anodic corrosion of WC powder in dilute H_2SO_4, the corrosion reaction forms a passive surface layer, and the current decreases irreversibly over periods up to 45 min as the active surface area is depleted. Even after excursions of several minutes into regions of cathodic reduction, a return to a given anodic corrosion potential produces no faradaic increase in anodic current over the prior level attained. This phenomenon was also cited by Binder *et al.* (4) using the triangular wave potential sweep method on resin-bonded WC powder electrodes.

Potentiostatic current-potential curves are shown in Fig. 1 for AEG WC(I) in 2*N* H_2SO_4 at room temperature, based on current observed after 2 and 5 min at each potential. Corrosion begins at relatively low anode potentials compared with titanium carbide in the same medium (10). At currents above 4 mA for a typical 0.50g test electrode, gas evolution is observed in the anode compartment. The gas contained CO_2, identified by mass spectroscopy and acid titration after absorption in NaOH. Cathodic reduction of the surface oxide and the early part of the hydrogen evolution reaction are also shown in Fig. 1.

The two WC powder samples are surprisingly different in their anodic corrosion behavior. Sample II requires about 300 mV higher anode potential to produce corrosion current densities equivalent to I. Reduction of the surface oxide is similar qualitatively to sample I. Anode currents are so low in the normal corrosion range for I, however, that an accurate coulometric measure of reduction of anode product is impossible.

The extent of anodic corrosion before low currents of about 5% of the maximum faradaic current are

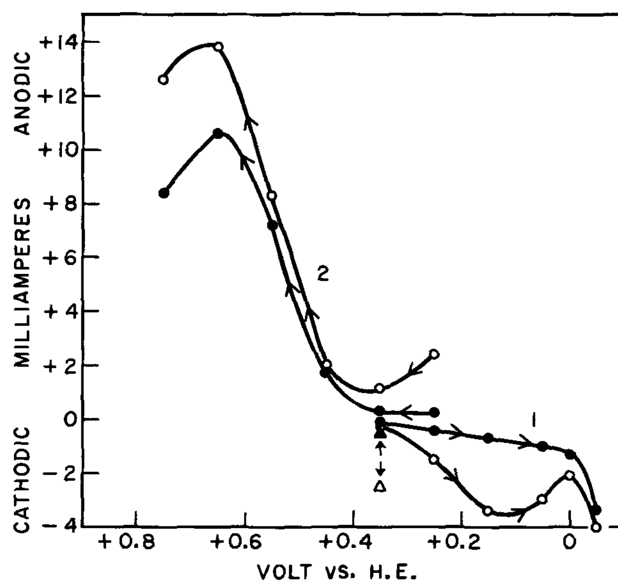


Fig. 1. Potentiostatic $I_{a,c}$ *vs.* *E* curves. 1, First measurements (cathodic direction); 2, second measurements (anodic direction); ○, 2 min points; ●, 5 min points; △, cathodic reduction of surface oxide—2 min; ▲, cathodic reduction of surface oxide—5 min; 0.50g AEG WC.

observed is in the order of 1-5 tungsten atom layers depending on the stoichiometry of the anode process, which could involve from 2-10 electrons per W atom. This assumes that all of the 5 m²/g BET surface area is electroactive and that the average surface tungsten atom density is 1.3×10^{15} W atoms/cm².

Cathodic reduction of anode product.—The cathodic reduction of the surface corrosion product formed anodically occurs very rapidly in a narrow range of potential (+0.35 to +0.25V *vs.* HE, Fig. 1). The coulombic value associated with this process can be separated from the small background cathodic "blank" mentioned previously with reasonable accuracy. As the potential of reduction is about 350 mV anodic to the hydrogen evolution reaction, the electrode process must be the reduction of a tungsten species, possibly WO_3.

The coulombic ratio of anodic corrosion to net cathodic reduction of the corrosion product is remarkably constant for several sample sizes, ranges of anode potential and extents of corrosion (Table I). The value of this ratio in 2*N* H_2SO_4 is about 20.

The experiment with 2*M* H_3PO_4 was prompted by expectation of a solubilizing or complexing effect of phosphate on the anodic tungsten oxide. The very large coulombic ratio of anodic corrosion to cathodic reduction indicates a surface reaction very different from that in sulfuric acid. The anode product does not, however, appear to be soluble in that the surface is still irreversibly passivated by the anode process.

Tungsten metal.—A comparison of the behavior of tungsten metal with WC under identical experimental conditions in 2*N* H_2SO_4 is also striking. Tungsten as a pure high area powder (2 m²/g) or as a polycrystalline foil does not passivate under the current-potential-time conditions of the present study. Also, no easily reducible surface oxide is observed on W. Anode products are either soluble and thereby reducible over a broad and more cathodic range of potentials or insoluble and cathodically inert prior to hydrogen evolution.

Current-time curves.—The current-time curves at a fixed electrode potential were compared with the exponential curves predicted for a simple first order rate process at a two-dimensional surface layer in which the instantaneous current, i_t, is given by

$$i_t = k(N_s^o - \int_o^t i_t \, dt) \quad [1]$$

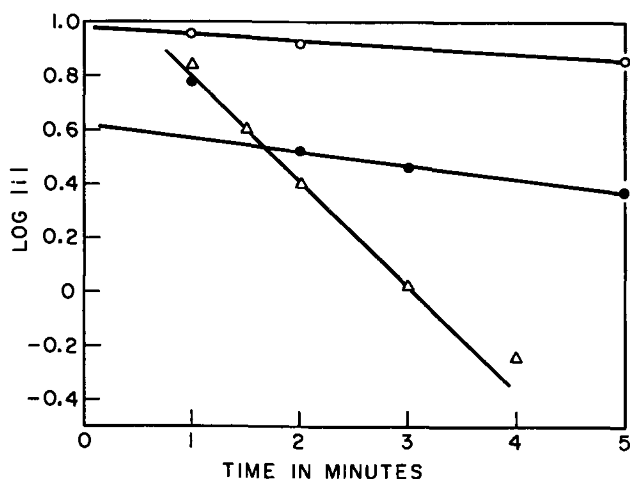

Fig. 2. Kinetic analysis of current-time data. ○, anodic corrosion at +0.55V (sample A); ●, anodic corrosion at +0.60V (sample B); △, cathodic reduction of oxide at +0.35V (sample A).

in which k is a first order rate constant which depends on potential and has the units sec^{-1}, and N_s^o = initial surface sites for the electrode reaction expressed in coulombs. The anodic corrosion and cathodic reduction of WO_x should obey this relationship providing there are no slow diffusional processes in the liquid or solid phases at the electrode surface. For the case of anodic corrosion assuming $n = 10$ electrons per W atom, N_s^o = (grams sample) × (BET surface area, m^2/g) × (20.8) coulombs.

A more convenient integrated form of Eq. [1] is

$$\log i_t = \frac{-kt}{2.303} + \log kN_s^o \quad [2]$$

Figure 2 shows log i_t *vs.* t for several anodic and cathodic experiments. Experimental plots do not follow the expected rate law in the initial portion because of capacitative charging and in the final portion because of subsurface oxidation for the anodic process. Values of N_s^o obtained from an extrapolation of the linear portion of the experimental curves are compared below with the calculated values for a complete BET monolayer corrosion.

WC Sample	N_s^o (slope-intercept)	N_s^o (calc.)
0.125g	2.08	13.0
0.500g	10.4	52.0

The low values of N_s^o from this analysis of the i-t curves may mean that (i) the stoichiometry, $n = 10$ electrons, is too high, (ii) the measured BET area is not the effective corrosion area, or (iii) the total anodic coulombs passed in a given experiment represents several layers of subsurface oxidation on a fraction of the BET area rather than a real monolayer.

The i-t analysis of cathodic reduction of the anode product is also difficult because of small regions of linearity in log i_t *vs.* t. The best estimate of N_s^o for one 0.50g sample of WC was 0.99 coulomb by the slope-intercept method compared with the measured 1.65 coulombs required to reduce the surface oxide.

The very high rate of reduction of oxide is indicated by a rate constant, k, of 0.03 sec^{-1} measured at +0.35V *vs.* HE compared with 0.0009 and 0.002 sec^{-1} at +0.55 and +0.60V respectively for anodic corrosion. The ratio of rate constants is even larger if N_s^o is expressed as number of sites rather than as coulombs.

Hydrogen evolution reaction.—Binder *et al.* (4) and Böhm (6) have suggested that the electrocatalytic activity of WC for fuel cell anode reactions, *e.g.*, hydrogen ionization, is promoted by the formation of an oxygenated surface containing W, C, O, and H. A similar promotion effect might be observed in the hydrogen evolution reaction (h.e.r.) on "as is" WC and surface oxidized WC. The observed current-potential curves for the h.e.r. on these two surfaces (AEG WC) in 2N H_2SO_4 at room temperature were, however, identical.

Chemical oxidation.—A suspension of AEG WC in 0.2N ceric sulfate 2N in H_2SO_4 evolved gas rapidly at room temperature, and the fine particles were completely oxidized to a white material believed to be tungstic acid. An 0.099g sample completely decolorized 2.0 meq. of Ce^{+4} (40% bulk oxidation of WC assuming WO_3, CO_2, $n = 10$) and was about 50% oxidized in bulk by a further increment of Ce^{+4}, which was not fully decolorized. Apparently, the complete bulk oxidation of the sample was precluded by passivation of the large WC particles which settled under the layer of white tungstic acid precipitate.

In order to determine the CO_2 evolved quantitatively, the product gas was absorbed in 0.0924N NaOH and titrated with 0.0987N HCl. An excess of WC (0.101g = 5.1 meq. for bulk oxidation, $n = 10$) was reacted with 1.0 meq. of Ce^{+4} completely decolorizing the solution and evolving about 70% of the expected CO_2. The low result was probably caused by inefficient collection of CO_2.

Ceric sulfate in 2N H_2SO_4 is strongly oxidizing (formal potential, E^{o1} = 1.459V). Oxidation with ferricyanide in 2N H_2SO_4, E^{o1} = +0.69V, represents more closely the range of corrosion potentials in the electrochemical work. In 0.2N ferricyanide, 2N H_2SO_4, AEG WC powder evolved gas very slowly and showed no evidence of bulk oxidation. In fact, the amount of CO_2 collected from 0.4-1.0g samples of WC in excess ferricyanide corresponded to surface monolayer or partial monolayer oxidation.

Discussion

The primary result of this study is the ratio of about 20 between the coulombs required to oxidize a sample of WC anodically and the coulombs for reduction of the anode product. The constancy of this value in 2N H_2SO_4 under varying conditions of sample size, extent and potential of anode corrosion (Table I) suggests that there are single anodic and cathodic reactions rather than a multiplicity of poorly defined reactions. Moreover, for any anodic stoichiometry involving from 2 to 10 electrons per tungsten atom, the cathodic reduction requires only 0.1-0.5 electrons per tungsten atom oxidized. If a W(VI) oxide is the anode surface product, then the cathodic process is either a partial reduction of W(VI) to W(V) or the formation of $H_xW(VI)$ oxide in which $x = 0.1$-0.5.

A possible scheme supported in part by the identification of CO_2 as an anode product, the chemical oxidation work described herein, and chemical and electrochemical reduction of bulk WO_3 to hydrogen tungsten bronzes (11-13) is

Anode

$$WC + 5H_2O \rightarrow WO_3 + CO_2 + 10H^+ + 10\bar{e}$$

Cathode

$$WO_3 + 0.5H^+ + 0.5\bar{e} \rightarrow H_{0.5}WO_3$$

Some evidence against the formation of "surface hydrogen tungsten bronzes" are the citations by Armstrong *et al.* (14) that "sodium tungsten bronzes are completely inactive for anodic hydrogen oxidation" and by Vondrak and Balej (15) that hydrogen on cation vacancies in the lattice of a sodium tungsten bronze is oxidized at −0.1V *vs.* RHE, while in the present study "H_xWO_3" is formed at +0.35V.

The work of Böhm (6) on adsorption and anodic oxidation of hydrogen on WC is interesting and relevant in that the maximum value of hydrogen adsorption, 32.5 microcoulombs/cm^2, represents a coverage of only about 15% of the available surface tungsten atoms and in that an oxidative pretreatment of the

WC, namely several anodic square wave pulses to 1000 mV *vs.* hydrogen electrode, substantially increases hydrogen adsorption. Both facts can be explained by assuming that the hydrogen is "adsorbing" on a complete or partial surface oxide as H_xWO_3, where x is small in the range 0.1-0.5.

The comparison of WC with W metal indicates a strong influence of carbon in the tungsten lattice on the electrochemistry of W. Although WC is an interstitial carbide, its crystal structure is simple hexagonal whereas W is body centered cubic. The shortest W-W distance is 2.86Å in WC and 2.74Å in W: the density of WC is 15.6 g/cc compared with 19.2 g/cc for W. It is difficult to imagine that this moderate expansion of the W lattice in WC is responsible for the differences in electrochemical behavior of W and WC. It is more likely that there is a chemical effect of carbon on the formation and reduction of the surface oxide.

The experiment on the hydrogen evolution reaction on "as is" WC and anodized WC is certainly not definitive in that "as is" WC may be covered with sorbed oxygen. It is noteworthy, however, that the h.e.r. occurs on WC with essentially no overvoltage whereas pure W powder requires an overvoltage of about 0.10V to achieve a given low current density for the h.e.r. in 2*N* H_2SO_4.

The oxidation-reduction properties of WC in aqueous media are novel and interesting in several respects. It is surprising that the surface and bulk corrosion, both anodic and chemical, occur so easily at room temperature in aqueous solutions at "medium to high" anodic potentials. The almost complete bulk oxidation of WC by aqueous ceric sulfate is unexpected in view of the literature (9, 16) on the apparent kinetic stability of WC to oxidation ($WC + O_2 \xrightarrow{>500°C}$ oxidation) and to the dissolving power of strong mineral acids. A thermodynamic estimate of standard free energy at room temperature of the reaction

$$WC + 5H_2O + 10Ce^{+4} \rightarrow \text{"}WO_3\text{"} + CO_2 + 10H^+ + 10\bar{e}$$

$$\text{"}WO_3\text{"} = \text{a } WO_3 \text{ hydrate}, \quad \Delta F°_f = -180 \text{ to } -200 \text{ kcal/mole}$$

is $\Delta F° = -319$ kcal/mole, and it is apparent that one-electron oxidants with a potential as low as +0.1V *vs.* the standard hydrogen electrode are possible oxidants for WC.

Acknowledgment

The author is sincerely grateful to Professor Michel Boudart for his invitation to study in the Chemical Engineering Department of Stanford University and for his encouragement and support of this work. Several of the physical measurements and many useful comments and suggestions were made by Mr. Ricardo Levy of the Chemical Engineering Department.

Oxide Charge Reduction by Chemical Gettering with Trichloroethylene During Thermal Oxidation of Silicon

Mao-Chieh Chen* and John W. Hile*

Electronics and Instrumentation Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48089

ABSTRACT

Silicon dioxide was thermally grown in an oxygen atmosphere containing a small percentage of trichloroethylene (C_2HCl_3) vapor. As a result of this process, it was possible to fabricate metal-oxide-semiconductor (MOS) diodes with greatly reduced oxide space charge. This reduction in oxide charge was accompanied by improved electrical stability under bias-temperature stress. It is believed that the pyrolysis product, chlorine, acts as a getter to continuously remove mobile impurity cations such as Na^+ during the oxidation process. Also described are various charge phenomena under bias-temperature stress conditions.

The performance of MOS devices depends critically on the stability of the insulating oxide between the silicon substrate and the metal counterelectrode. The most significant device instability generally arises from ionic contamination (such as sodium) which is unavoidably included in the oxide during thermal oxidation. These ions act as a positive space charge and are mobile under bias-temperature stresses (1-4). Thus the electrical characteristics of such devices are not predictable and are variant with time.

A number of researchers have developed techniques for eliminating or reducing the positive ion space charge in thermal oxide layers with varying degrees of success. These techniques include the use of phosphosilica layers (5-7) and the production of clean oxides by *in situ* gaseous etching with HCl and subsequent oxidation of the silicon by means of rf induction heating (8). More recently, Heiman and Robinson (9) and Kriegler *et al.* (10) have shown that clean oxides can be produced by the addition of HCl during thermal oxidation. In this paper the method disclosed is a similar technique, but it is much easier to implement since the gettering agent (C_2HCl_3) is noncorrosive and is very easy to handle safely. This process results in the reduction of oxide charges and in the stabilization of the ionic migration instability. Various charge phenomena under bias-temperature stress conditions are described.

Experimental Procedures

Silicon dioxide films were thermally grown in a dry oxygen atmosphere at 1050°C with a small percentage of trichloroethylene (C_2HCl_3) vapor included.

The oxygen flow rate was 1.5 liters per minute. The trichloroethylene vapor was added by bubbling helium (at a slow rate of 0.05 liters per minute) through C_2HCl_3 maintained at room temperature. No special mixing was employed. Epitaxial n/n^+ silicon wafers of 10 and 30 ohm-cm were used. The wafer orientation was (111). No special precautions were used with respect to furnace cleanliness. However, the wafers were degreased in trichloroethylene and acetone and rinsed in ultrasonically agitated, flowing, deionized water for 10 min before being loaded into the modified oxidation furnace. For comparison, wafers with conventionally grown, dry thermal oxide were also prepared.

Following oxidation, aluminum gate electrodes (26 mil diameter dots) were applied to the oxide films by means of vacuum evaporation and photomasking. Individual MOS devices were diced out, die bonded (at 400°C), and ultrasonically lead bonded to TO-5 headers.

Measurements of the MOS capacitance voltage characteristics were performed at 1 MHz and were automatically recorded on an X-Y plotter. The X-Y plotter scheme is a modification of that proposed by Zaininger (11).

Results

The flat-band voltages V_{FB} for a number of MOS devices are plotted in Fig. 1. It is clearly indicated that the effective oxide charge density is greatly reduced in samples exposed to C_2HCl_3 vapor during oxidation. It is also evident that the C_2HCl_3 treated samples have their flat-band voltages constrained to a much narrower range of values. In Fig. 2, the results of bias-temperature stress tests for oxide stability are shown. In these tests positive or negative bias voltages were applied for 30 min at the temperature indicated. The samples were then quenched to room temperature while still under bias. The improvement in stability afforded by the C_2HCl_3 process is obvious. It is, however, noted that at temperatures above 200°C, the flat-band voltage, V_{FB}, increases significantly upon prolonged stress.

Key words: oxide charge, gettering, oxidation, clean oxide.

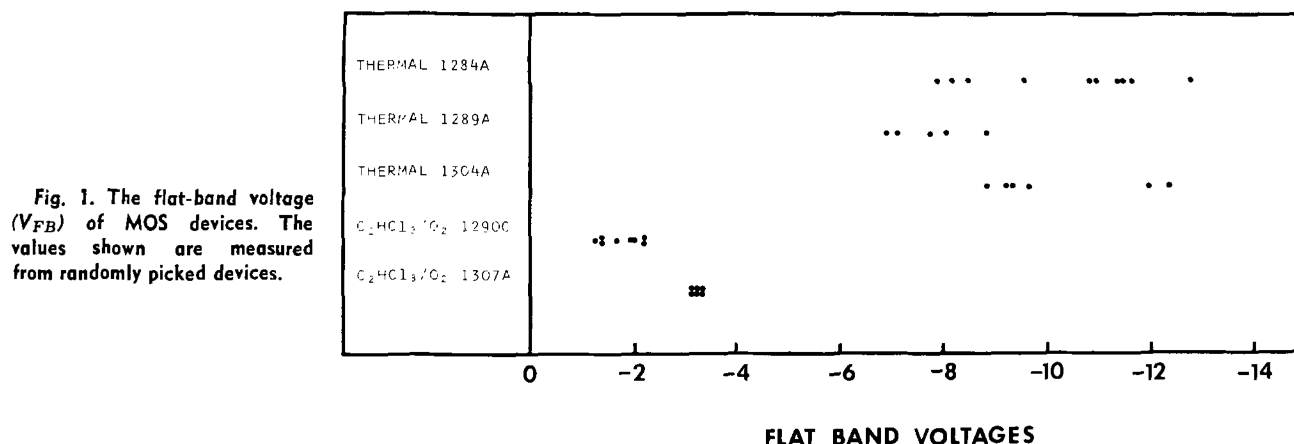

Fig. 1. The flat-band voltage (V_{FB}) of MOS devices. The values shown are measured from randomly picked devices.

It was observed that for C_2HCl_3 grown samples, both positive and negative B-T stress cause the flat-band voltage to shift slightly in the negative bias direction. A slight broadening of the C-V curve is also observed with this small increase in V_{FB}. With a positive bias of 20V applied to a 1500Å thick oxide, the flat-band voltage shift, ΔV_{FB}, was within half a volt after several days of stress at 150°C. At temperatures higher than 200°C, however, V_{FB} shows a large increase and slowly reaches a saturated value in approximately 10 hr. These saturated values are $V_{FB} = 1.6V$ at 200°C and $V_{FB} = 2.7V$ at 250°C. These high-temperature bias-stress shifts in the flat-band voltage cannot be recovered either by short circuiting the device at elevated temperature nor by reverse bias stresses. Since it has been shown that ionic contamination within an SiO_2 layer can be rearranged in minutes at 150°C, the above high-temperature, slow bias-stress phenomenon cannot be attributed purely to ionic migration. The actual mechanism is not yet well understood.

Under negative bias-stress, the flat-band shift is in the negative bias direction even with bias voltages as low as −5V. The saturated values of ΔV_{FB} at 250°C (see Fig. 3) were observed to be proportional to the applied negative bias. This observation is similar to that reported by Deal *et al.* (12) and Miura *et al.* (13). The time to reach a saturated ΔV_{FB} condition is relatively long and requires several hours even at temperatures as high as 400°C. Only partial recovery of the shifted C-V curve can be obtained by a short circuit, high-temperature treatment. Slightly higher values of ΔV_{FB} were observed for higher stress temperatures. These observed phenomena suggest that it is intrinsically connected with the silicon dioxide/silicon interface, and that the dominant drift mechanism is carrier injection-trapping (8, 14, 15) although some ion migration appears to be active.

The exact mechanism by which the C_2HCl_3 vapor acts to reduce the oxide charge is not known. It is believed that the pyrolytic product, chlorine, acts as a gettering agent for sodium and other ionic contaminants during the oxidation process. Presumably the chlorine reacts with the metallic ions to form volatile chlorides which are removed as gases. It is also suggested that the carbon reacts with the oxygen to form carbon dioxide and escapes from the furnace as a gas.

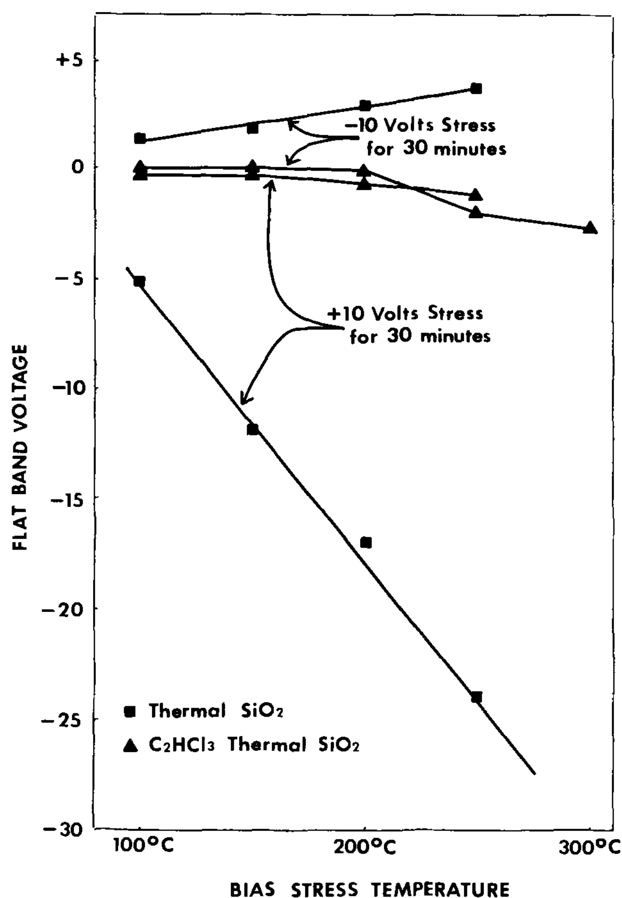

Fig. 2. The shift of flat-band voltage under bias-temperature stress at various temperatures. The stress was ±10V bias for 30 min. The oxide thickness is about 1500Å.

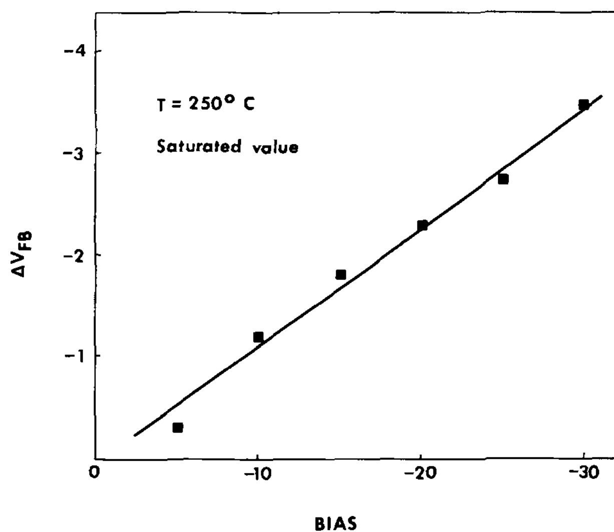

Fig. 3. Saturated values of flat-band voltage as a function of applied negative bias for MOS devices.

In addition to the possible gettering of alkali ions from the oxide, there also appears to be some kind of chemical reaction occurring which modifies the oxide structure. This is evidenced by the observed shifts in the C-V curve at bias-stress temperatures greater than or equal to 200°C. The fact that ΔV_{FB} is temperature dependent very likely reveals the creation of oxide charge (a slow state). Possibly this charge arises from the ionization of metallic chlorides which are formed and are not removed during the oxide growth process. These charged species may have very low mobilities and may be well trapped. It was found that high-temperature annealing of the sample in air without bias causes an increase in V_{FB}. The amount of increase is proportional to the annealing temperature and is in the order of 1V at 400°C. This would support our assumption.

In summary, it has been demonstrated that silicon dioxide grown in a C_2HCl_3/O_2 atmosphere has a much lower oxide charge. However, the exact mechanism controlling the high-temperature ($\geq$200°C) instability is not well understood and additional effort is required.

Acknowledgments

We would like to thank Mrs. C. M. Hoyland and Mr. A. Fritz who assisted in the fabrication of the devices.

Effects of Annealing on Luminescent Properties of (Zn,O)-Doped GaP†

H. D. Pruett and D. L. Hughes[1]

Western Electric Engineering Research Center, Princeton, New Jersey 08540

and M. R. Notis*

Department of Metallurgy and Material Science, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

Annealing studies were performed on (Zn,O)-doped GaP at 400°, 600°, and 900°C. The photoluminescent quantum efficiency and the visible/infrared emission ratio were both found to increase with decreasing annealing temperature. The increase in both quantities is primarily attributed to an increase in the concentration of nearest-neighbor (Zn,O)-pairs. Results are discussed and quantitatively compared to a recent theoretical model which predicts the equilibrium (Zn,O)-pair concentration as a function of temperature.

The purpose of this paper is to present preliminary results of annealing studies that were performed on samples of (Zn,O)-doped GaP. A particular objective of the present work was to evaluate the effects of low annealing temperatures ($\leq$ 600°C) in conjunction with long annealing times (many hours) to increase the equilibrium concentration of red-luminescence recombination centers. The present study differs from earlier work in that the investigation was made on bulk material, rather than on p-n junctions, and it included annealing temperatures lower than previously explored. Our investigation was limited to bulk material because evaluation of electroluminescent emission from a p-n junction would have added another degree of complexity to the problem, as is discussed later.

Numerous fundamental studies have been made on red-luminescence emission of (Zn,O)-doped GaP (1, 2). Low-temperature investigations of Henry, Dean, and Cuthbert (3) and Morgan, Welber, and Bhargava (4) were responsible for clearly establishing the red-luminescence emission process. Basically, red emission is produced by either the decay of excitons bound to (Zn,O)-complexes or from recombination of electrons bound at (Zn,O)-complexes with holes trapped at distant zinc acceptors. At temperatures below approximately 60°K, pair luminescence dominates, but above 60°K, exciton luminescence dominates. However, the actual temperature at which exciton decay becomes predominant depends upon the zinc doping concentration and the excitation intensity (5). Infrared emission is produced by recombination of electrons at

Key words: luminescence, semiconductors, gallium phosphide, annealing, dopants, photoluminescence.

unpaired-oxygen sites with either holes on distant zinc-acceptor sites (donor-acceptor pair recombination), or with free holes (bound-free recombination). Recent work has suggested that the latter is the dominant process at room temperature (6, 7).

Several previous investigations (8-13) have shown that the quantum efficiency, η_E, of GaP diodes can be improved by employing a suitable heat treatment. Part of the change in η_E can be attributed to an increase in the concentration of Zn-O pairs (8) and part can be attributed to a change in the electrical properties of the p-n junction. However, the change in the electrical properties may have an opposite effect to that of an increase in the Zn-O pair concentration. It is, therefore, difficult to quantitatively determine the increase in Zn-O pair concentration by studying electroluminescent emission from GaP diodes. For this reason, the present investigation was confined to an examination of photoluminescent emission from bulk GaP.

Experimental

The p-type GaP crystals used in this study were flux grown from a gallium phosphide saturated gallium solution by a slow cooling method. In addition to the GaP and Ga, the solution included 0.07 mole per cent (m/o) Zn and 0.04 m/o Ga_2O_3. The small Ga samples produced by the growth process were first lapped into 15 mil thick platelets and then polished on one side. Next the samples were cut into a cloverleaf shape about 4 mm in diameter. Carrier concentrations and Hall mobility were determined using the van der Pauw technique (14).

In an attempt to inhibit out-diffusion of dopants, all of the samples (except for those in a control group) were coated with an rf-sputtered film of SiO_2, approximately 3500Å thick.

Samples were annealed in a quartz ampoule which, after being evacuated to 10^{-6} Torr, was filled with argon to atmospheric pressure. To establish an initial reference condition, all samples were first heated to 900°C for 10 min and then quenched by plunging the ampoule into a room-temperature water bath. After this initial heat treatment, but prior to further heat treatment, the samples were said to be in the "time-equal-zero" ($t = 0$) condition. The same quenching procedure was used after each annealing cycle to insure that the equilibrium defect concentration at a given annealing temperature would be fixed in the sample. If samples were cooled slowly, rather than quenched, further annealing would occur during the cool-down period and the defect concentration would generally not correspond to the equilibrium value for the annealing temperature that was used.

There are several approaches that can be used to obtain a time-temperature plot of the effects of annealing on a given parameter. One approach is to start with many groups of samples, one for each annealing time to be investigated. Each group is then annealed only once; the first group is annealed for a certain length of time and each successive group is annealed for a progressively longer time. Unless all of the samples have nearly identical properties, such an approach results in a considerable amount of scatter in the data. An alternative approach, and the one used in the present investigation, is to cycle the same group of samples in cumulative fashion assuming that N successive annealing cycles of duration Δt are equivalent to a single annealing cycle of duration N times Δt.

Two annealing temperatures, 400° and 600°C, were investigated in addition to the initial 900°C temperature. One group of SiO_2 coated samples was annealed at 400°C using 30 min time increments up to a cumulative value of 4 hr, after which the time increment was increased to 4 hr. A second group of coated samples was annealed at 600°C using 4 hr time increments. A third group of samples, not SiO_2 coated, was annealed at 400°C using 15 min increments for the first hour and one hour increments thereafter.

After every heat treatment, each sample's photoluminescent efficiency was measured and its 77°K emission spectra was recorded. Emission spectra measurements were performed at 77°K in order to completely resolve the red and infrared emission bands, the tails of which overlap each other at room temperature. Efficiency measurements were made only at room temperature because it was not possible to make absolute efficiency measurements at 77°K with the existing apparatus.

Results

Conventional x-ray methods were used to identify both the composition and orientation of grown crystals. Debye-Scherrer patterns and Laue photographs confirmed that the samples were gallium-phosphide single crystals with the polished face parallel to a (111) plane. Room temperature resistivity and Hall-effect measurements were made on five representative samples. The average resistivity and Hall coefficients obtained were 0.129 ohm-cm and 8.61 cm^3/coulombs, respectively, from which the corresponding average values of carrier concentration and Hall mobility were calculated to be 8.10×10^{17} cm^{-3} and 70 cm^2/V-sec.

In Fig. 1, the external photoluminescence quantum efficiency, η_p, is plotted as a function of annealing time for two temperatures, 400° and 600°C. The plotted data are for two specific samples, however, the shape of the curves obtained is typical for all samples. That is, there were variations in the initial values of η_p, but a plot of η_p *vs.* time annealed at a given temperature for all samples in a group showed a consistent trend in the data. The significant features of Fig. 1 are: first, the existence of a plateau in the values of η_p after long anneal times; second, a larger percentage increase in the plateau value of η_p for a 400°C anneal temperature than for a 600°C anneal temperature; and third, the observation that the plateau value of η_p for samples annealed at 600°C was reached in less than 4 hr, whereas approximately 16 hr were required to reach the corresponding plateau-value of η_p for samples annealed at 400°C. The short-term peak in η_p after approximately 1 hr of cumulative annealing at 400°C was observed for all samples that had been coated with an SiO_2 film, but was not observed for uncoated samples.

In Fig. 2 the integrated red to infrared emission ratio is shown as a function of annealing time for two representative samples annealed at 400° and 600°C. This ratio is seen to increase by a factor of 14 after 24 hr of cumulative annealing time at 400°C, whereas only a factor of four increase is observed for samples annealed at 600°C. Measurement of the red/infrared ratio for samples annealed at 600°C was discontinued after 12 hr of cumulative anneal time when it ap-

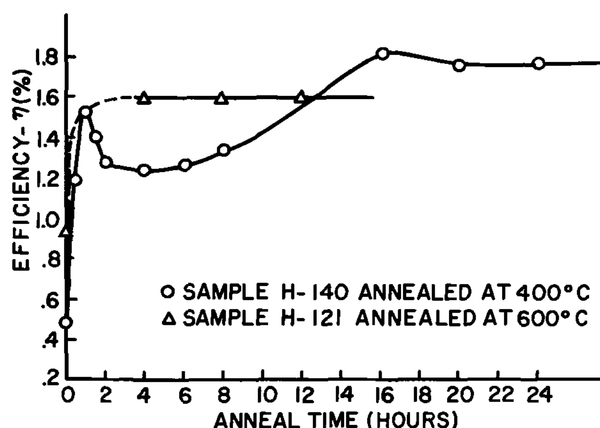

Fig. 1. Total radiative efficiency, using photoexcitation, is shown for two representative SiO_2-coated GaP samples annealed at 400° and 600°C.

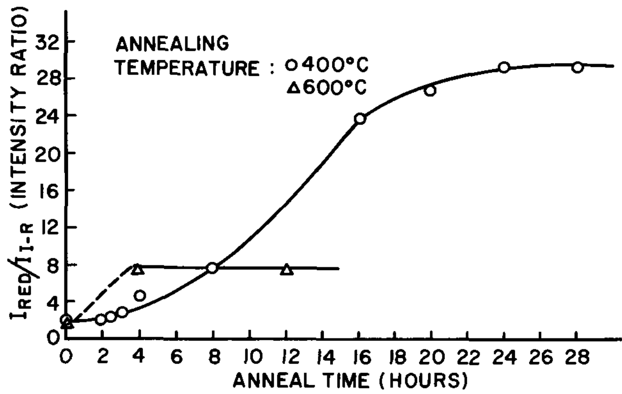

Fig. 2. The integrated red to infrared emission ratio at 77°K is shown for the two samples whose room temperature efficiency is shown in Fig. 1.

peared that this quantity had reached a maximum after less than 4 hr of annealing.

As indicated earlier, SiO_2 films were not deposited on one group of samples annealed at 400°C. The data obtained from measurements on these uncoated samples were not as consistent as the data from coated samples, but the following observations were made. The efficiency of uncoated samples steadily decreased for the first hour and then leveled off, or began to gradually increase with further heat treatment. For those samples whose efficiency did increase, approximately 16 hr of annealing at 400°C were required to reach the original $t = 0$ value (15). The appearance of the surfaces of uncoated samples indicated that some type of surface deposits were being produced. Etching the bulk samples produced only a slight improvement in the photoluminescent efficiency, whereas etching has been reported (13) to improve the efficiency of electroluminescent diodes by 20-30%. The increase in the integrated red-infrared emission ratio was also less for uncoated samples than for coated ones.

A brief experiment was performed to see if the difference between coated and uncoated samples could be explained by zinc out-diffusion from the uncoated samples. An uncoated sample was broken into two pieces, but only one was annealed in the usual manner. Both samples were then examined for zinc concentration by using d-c arc excitation to record optical emission of elemental zinc. Unfortunately, the results were inconclusive because the zinc concentrations were too near the detection limit of the equipment. However, no obvious loss of zinc was observed.

Discussion

The results shown in Fig. 1 and 2 are generally consistent with those obtained by Onton and Lorenz (8) in their annealing studies. It should be noted, however, that OL measured diode electroluminescence efficiency, η_E, rather than bulk photoluminescence efficiency, η_p. Thus, the "permanent" degradation in η_E which they observed after extended annealing at 600°-900°C may have been degradation of the p-n junction itself rather than being related to (Zn, O)-pairing. For example, extended annealing may have merely altered the impurity concentration at the p-n junction and thereby reduced the efficiency of injection of electrons into the (Zn, O)-doped p-side of the diode. By measuring η_p in bulk material, the present study concentrated on basic luminescent efficiency and avoided the complication of possible p-n junction degradation.

In agreement with the observations of Onton and Lorenz, the present results indicated that infrared emission could be shifted to red emission by annealing at temperatures of 400°-600°C. Conversely, red emission could be shifted into the infrared band by annealing at a higher temperature. Onton and Lorenz suggested that such results could be explained in terms of the equilibrium number of Zn-O nearest-neighbor pairs formed at a given temperature. Assuming the total number of zinc and oxygen atoms in a sample to be constant, the number of oxygen atoms that can participate in infrared emission is reduced whenever zinc and oxygen atoms combine to form nearest-neighbor pairs. Thus an increase in red emission via exciton decay at Zn-O complexes is expected to be accompanied by a decrease in infrared emission whenever a sample is annealed at a temperature which favors formation of Zn-O pairs.

The above qualitative arguments were put in quantitative form by Onton and Lorenz and, more recently by Wiley (16). Both calculations are based upon the similarity between formation of Zn-O pairs in GaP and the formation of Coulomb-bonded donor-acceptor pairs in Ge and Si. Using the work of Lidiard (17) as a basis, Wiley has calculated a theoretical curve for the fraction, $F = [P]/[O]$, of oxygen atoms which are paired, where $[P]$ is the equilibrium (Zn, O)-pair concentration at a given temperature and $[O]$ is the total substitutional oxygen concentration, assumed to be temperature independent.

As will be shown, the red/infrared emission ratio obtained experimentally in the present investigation can be compared to Wiley's theoretical pairing fraction. However, it is first necessary to develop a model for minority carrier recombination in GaP using standard semiconductor statistics (18). Referring to Fig. 3, we see that there are three recombination paths labeled S, Q, and Y. The paths labeled S and Q correspond to minority-carrier capture by the (Zn,O) and O-centers, respectively, while the Y-path corresponds to nonradiative band-to-band recombination through some unknown center or centers. Path Y, the "shunt path," is used as a means of quantitatively accounting for all minority carriers which do not recombine through either (Zn, O) or O-centers.

After Dishman and DiDomencio (19), we define a branching ratio as the fraction of minority carriers that recombine through a given path. If R_s, R_q, and R_y denote the capture rates for the three recombination centers, the branching ratio for a given center is just the capture rate for that center divided by the sum of the three capture rates. Thus, the branching ratios s, q and y are

$$s = R_s/(R_s + R_q + R_y) \quad [1]$$

$$q = R_q/(R_s + R_q + R_y) \quad [2]$$

$$y = R_y/(R_s + R_q + R_y) \quad [3]$$

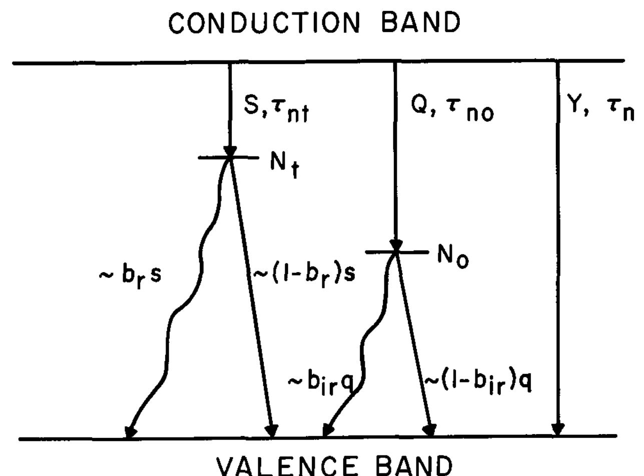

Fig. 3. The three minority-carrier capture paths, denoted S, Q, and Y, applicable to GaP at 77°K are shown along with other notation used in the text. Radiative transitions from the (Zn,O) and O-centers are indicated by wavy-line arrows.

At low excitation levels we can ignore the fraction of (Zn,O) or O-traps that are already electron-occupied (or exciton occupied) and take each capture rate to be simply the minority carrier concentration, n, divided by the appropriate capture lifetime. The capture rates are (19)

$$R_s = n/\tau_{nt} = nv\sigma_{nt} N_t \quad [4]$$

$$R_q = n/\tau_{no} = nv\sigma_{no} N_o \quad [5]$$

$$R_y = n/\tau_n \quad [6]$$

In the above equations, v is the conduction-band-electron thermal velocity, τ is the capture lifetime, σ is the capture cross section, and N is the recombination-center concentration. Quantities subscripted with t refer to (Zn,O)-centers, while those subscripted with o refer to oxygen centers. Using the above expressions, and eliminating the common factor n, we obtain the following equations for the branching ratios

$$s = \frac{v\sigma_{nt} N_t}{v\sigma_{nt} N_t + v\sigma_{no} N_o + 1/\tau_n} \quad [7]$$

$$q = \frac{v\sigma_{no} N_o}{v\sigma_{nt} N_t + v\sigma_{no} N_o + 1/\tau_n} \quad [8]$$

$$y = \frac{1/\tau_n}{v\sigma_{nt} N_t + v\sigma_{no} N_o + 1/\tau_n} \quad [9]$$

It is convenient to define two more branching ratios, b_r and b_{ir}, in the following way (19). We are ultimately interested in radiative quantum efficiency, and, therefore, b_r or b_{ir} is defined as the fraction of the total recombination through (Zn,O) or O-centers, respectively, that is radiative. If, for example, $y = 0$ and $b_r = b_{ir} = 1$, the radiative quantum efficiency would be 100%.

We can now write down expressions for the red and infrared quantum efficiencies η_r and η_{ir}, respectively, for band-to-band excitation.

$$\eta_r = b_r s \quad [10]$$

$$\eta_{ir} = b_{ir} q \quad [11]$$

Denoting the integrated red/infrared emission ratio by α, we see that $\alpha = \eta_r/\eta_{ir}$ can be written as

$$\alpha = \frac{b_r s}{b_{ir} q} \quad [12]$$

$$= \frac{b_r \sigma_{nt} N_t}{b_{ir} \sigma_{no} N_o} \quad [13]$$

The above expression for α can be compared with the theoretical results of Wiley by making a few slight changes in his notation. Wiley calculated the fraction, F, of oxygen atoms that are paired into Zn-O complexes. Denoting the total substitutional oxygen concentration by N_{oo}, the fraction F can be written

$$F = N_t/N_{oo} \quad [14]$$

However, $N_o = N_{oo} - N_t$, and now α can be expressed in terms of F

$$\alpha = \frac{b_r \sigma_{nt}}{b_{ir} \sigma_{no}} \left(\frac{F}{1 - F}\right) \quad [15]$$

The coefficient of $F/(1 - F)$ in Eq. [15] can be considered a scale factor which will be denoted as K

$$K = \frac{b_r \sigma_{nt}}{b_{ir} \sigma_{no}} \quad [16]$$

Although not necessarily true, K will be assumed independent of heat treatment in the present discussion. Solving Eq. [15] for F we have

$$F = \frac{\alpha}{K + \alpha} \quad [17]$$

Thus, through Eq. [17], the present experimental values of α can be related to theoretical values of F in terms of the scale factor, K, given in Eq. [16].

To compare F and α, the scale factor K can either be calculated using Eq. [16], or empirically determined by curve fitting. Experimental work performed elsewhere (20) gave the following estimates for the branching ratios and capture cross sections: $b_r \simeq 0.07$; $b_{ir} \simeq 0.6$-0.7; $\sigma_{nt} \simeq 10^{-16}$ cm^2; and $\sigma_{no} \simeq 1$-2×10^{-18} cm^2. More recent work (21) has indicated σ_{nt} is about a factor of twenty larger than the above value and that σ_{no} depends linearly on the hole concentration. For the present samples where $p \simeq 8 \times 10^{17}$, the estimated value of σ_{no} is 4×10^{-16} cm^2. Using the more recent values of σ_{nt} and σ_{no}, the calculated value of the scale factor is $K \simeq 5$.

When plots of K *vs.* temperature and α *vs.* temperature were made using the value $K = 5$, the two curves were found to have a similar shape but to differ in magnitude. In view of the uncertainties involved in the estimates given above, it was decided to use K as an empirically determined scale factor. This was accomplished by calculating the value of K required to make the curves coincide at 400°C. The empirical value ($K = 32$) was then used in conjunction with experimental values of α at 600° and 900°C to calculate, using Eq. [17], new values of F. The experimentally determined values of F are plotted in Fig. 4 along with the complete theoretically predicted curve of Wiley. As can be seen, the experimental agreement is quite good.

In the above mathematical development, the reason why (Zn-O)-pairing produces an increase in the red/infrared emission ratio can be easily seen. Less obvious is whether an increase in (Zn-O)-pairing can account for the observed increase in photoluminescent efficiency. To answer this question, η_p should be expressed in terms of F, σ, N, etc., and the resulting equation differentiated with respect to F. If $d\eta_p/dF > 0$, this indicates that (Zn-O)-pairing does improve the photoluminescent efficiency as well. The calculation is given here, but it is easy to show that $d\eta_p/dF$ is, in fact, always positive. This result is reasonable because, physically, radiative recombination is being shifted from the unpaired-oxygen center to the (Zn,O)-center which has a larger capture cross section and, hence, a faster minority-carrier capture rate.

Although (Zn,O)-pairing is seen to increase η_p, the amount of this increase could not be quantitatively determined. It was necessary to measure η_p at room temperature where the relationship between η_p and the various fundamental quantities becomes very complicated and involves additional parameters which depend on N_t (19). Thus, it is not practicable to calculate $d\eta_p/dF$ at room temperature. The observation that

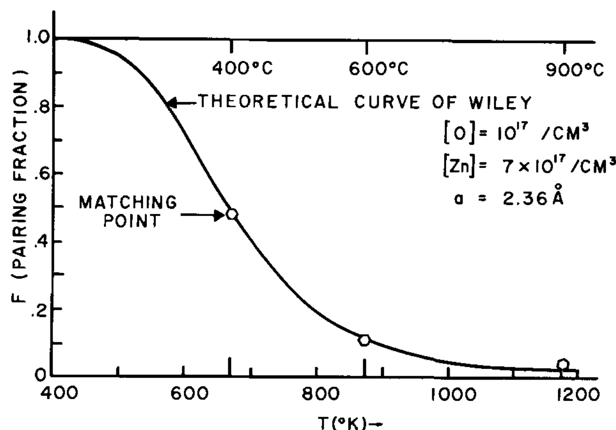

Fig. 4. A plot of the present experimental results is shown together with the theoretical pair-equilibrium curve of Wiley.

the plateau value of η_p was reached in about 16 hr of 400°C annealing, whereas α was still increasing at that time, indicates that η_p does not depend solely on *F*.

There are two other possibilities which can account for part of the increase in η_p with annealing. One possibility is that oxygen is liberated from compounds during annealing and, thereby, the total substitutional oxygen concentration in the lattice is increased. The basis for this suggestion is that Ga_2O_3 precipitates have been observed (22) in GaP crystals and there is the possibility that other compounds which dissociate at a lower temperature might also be present. A second explanation for part of the net increase in η_p is that annealing might produce a reduction in the amount of nonradiative recombination that occurs. If the recombination through shunt path Y were reduced, the photoluminescent efficiency would increase but the red/infrared ratio would not be affected, as shown by Eq. [13].

To investigate the reversibility of pairing, sample H-140 was heated to 900°C for 30 min and quenched after it had undergone an annealing cycle of 24 hr at 400°C. For comparison purposes, the original $t = 0$ values were $\eta_p = 0.47\%$, $\alpha = 2.2$, while the values after the final 30 min-900°C treatment were $\eta_p = 0.81\%$, $\alpha = 2.4$. The reset value of α is, within experimental error, equal to the original $t = 0$ value, thus demonstrating that emission can be shifted between the red and infrared emission bands by appropriate heat treatment and that no permanent degradation was observed in this sample. The reason why the efficiency, η_p, was not reset to its original $t = 0$ value is not clear but at least this result is not inconsistent with the two latter suggestions regarding the over-all increase in η_p with annealing. That is, annealing might have irreversibly increased the substitutional oxygen concentration and/or decreased the amount of nonradiative recombination.

Summary

In the present work we have investigated the effects of annealing on the photoluminescence efficiency of Zn-O doped GaP. Samples that were examined were solution-grown with doping concentrations similar to those used for the p-side of GaP light-emitting diodes. Photoluminescence emission spectra were obtained at 77°K in order to determine how the red and infrared emission bands are separately affected by heat treatment. Samples were cut in a small cloverleaf shape to insure that successive optical measurements would be made at the same position on the sample. A SiO_2 coating was applied to samples in an attempt to reduce factors which might adversely affect the reproducibility of the results.

The results obtained in the present investigation are in substantial agreement with those obtained by Onton and Lorenz (8). We did not observe any permanent degradation in the photoluminescence properties of bulk samples after prolonged heat treatment, and therefore we attribute the permanent degradation of diode efficiency observed by Onton and Lorenz to some adverse change in the electrical properties of their p-n junctions. The present results are consistent with the notion that low-temperature annealing promotes coulomb-bonding of Zn-O acceptor-donor pairs at nearest-neighbor lattice sites (16). Using a scale factor based upon a well-founded model (19), quantitative agreement between the present experimental results and the theoretically predicted (Zn,O)-pair equilibrium curve calculated by Wiley (16) has been obtained. It was shown that the increase in total radiative efficiency could be attributed in part to an increase in the number of (Zn, O)-pairs that results from low-temperature annealing. Other possible mechanisms that are proposed to explain part of the increase in η_p are: (i) an increase in the total amount of substitutional oxygen and (ii) a decrease in nonradiative transitions, particularly through the band-to-band shunt path. The observation that the original efficiency could not be reset after a subsequent 900°C anneal-quench cycle is qualitatively explainable by either of the above arguments.

Conclusions

The results obtained in the present work indicated that annealing temperatures lower than 600°C are desirable in order to increase both the red-luminescence efficiency and the total luminescence efficiency of (Zn, O) doped GaP. Although the present work involved bulk material, similar results are expected for diodes fabricated with p-type material having similar doping concentrations. Inasmuch as luminescence recombination processes are the same for any band-to-band excitation method, the only reason for annealing diodes at temperatures higher than 400°C would be if the p-n junction were adversely affected by a long duration annealing at 400°C.

Although the present study was unable to completely evaluate the efficacy of the SiO_2 films used on the samples, the conclusions are that such films are generally beneficial. A further evaluation of the films should be made using GaP diodes similarly coated and subjected to the same type of heat treatment.

In view of the intentionally limited scope of the present investigation, further work of a similar nature is suggested in order to answer some of the unresolved questions. Additional information about radiative and nonradiative processes in GaP can be obtained by studying the luminescent time decay of the bound exciton emission, as shown recently by Jayson *et al.*[23] Measurements of photoluminescent efficiency and emission spectra, as performed in the present investigation, only determine steady-state luminescent properties, whereas decay measurements yield information about the kinetics of radiative and nonradiative recombination. Through an understanding of GaP recombination processes, obtained in such studies, it should be possible to improve the already-high electroluminescent efficiencies obtainable with GaP light-emitting diodes.

Acknowledgment

We are particularly indebted to J. D. Wiley for making the results of his pairing calculations available prior to publication. We would like to acknowledge many helpful discussions with L. Derick and F. A. Trumbore during the crystal growth portion of this work. Also, we would like to acknowledge the assistance of J. S. Jayson and W. A. Erdman in making their laboratory facilities available to us for electrical measurements and for sputtering the SiO_2 coatings.

Manuscript submitted June 22, 1971; revised manuscript received Sept. 29, 1971. This was Paper 210RNP presented at the Washington, D.C., Meeting of the Society, May 9-13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Luminescence and Structural Properties of Thiogallate Phosphors Ce^{+3} and Eu^{+2}-Activated Phosphors. Part I

T. E. Peters* and J. A. Baglio

The Bayside Research Center of GTE Laboratories, Incorporated, Bayside, New York 11360

ABSTRACT

Thiogallate compounds represented by the formula MGa_2S_4 [where M = Ca^{+2}, Sr^{+2}, Ba^{+2}, Pb^{+2}, Eu^{+2}, ($Na^{+1}La^{+3}$), and ($Na^{+1}Ce^{+3}$)] were prepared by solid-state reaction. Single crystals of the alkaline earth derivatives were also obtained by vapor transport of the corresponding polycrystalline material. X-ray diffraction analyses of the single crystals show that $BaGa_2S_4$ is cubic belonging to space group Th^6-Pa3 while $SrGa_2S_4$ and $CaGa_2S_4$ are isomorphous belonging to the orthorhombic space group D_{2h}^{24}-Fddd. X-ray powder diffraction results on the other derivatives indicate that they are all isostructural with the Sr analogue. The alkaline earth thiogallates are the basis of a new type of sulfide phosphor. Rare earth ions readily substitute for the alkaline earth in the host lattice resulting in phosphors that fluoresce strongly under ultraviolet and cathode rays. The luminescence properties of the host compounds and the Ce^{+3} and Eu^{+2}-activated phosphors are described.

In recent years much of the luminescence research has been concerned with the fluorescence of rare earth ions in oxygen dominated systems. The fluorescence of rare earth ions in sulfur dominated lattices has received considerably less attention. Contemporary research, for example, includes the work of Brown and Shand (1) and Suchow and Stemple (2) who reported on the emission of several of the trivalent rare earth ions in various semiconducting thiospinel host crystals. Anderson (3-4) investigated rare earth emission in zinc and cadmium sulfides and noted that the trivalent rare earth ion can associate with a variety of acceptor defects, and it thereby occupies a number of nonequivalent symmetry sites. This gives rise to complex emission and absorption spectra and consequent difficulty in theoretical interpretation. Additional complications arise as a result of broad band emissions originating from impurity levels within the bandgap of sulfide host. The only efficient sulfide phosphors based on rare earth activators were those described by Urbach (5), Ward (6) and their associates beginning in 1946-1947. These are the infrarad stimulable alkaline earth sulfides doubly activated with Ce^{+3}, Eu^{+2} and Eu^{+2}, Sm^{+3}. Keller and co-workers (7) later reported on the fluorescence of virtually all of the rare earth ions in SrS and recently Lehmann and Ryan (8) presented data on the cathodoluminescence of CaS: Ce^{+3} and CaS:Eu^{+2}. Although the alkaline earth sulfides are efficient hosts for rare earth ions, phosphors of this type have not been widely used because of their susceptibility to hydrolysis. It was decided, therefore, to investigate binary compounds based on the alkaline earth sulfides since these materials should readily accommodate substitutional rare earth ions and might also be more stable toward hydrolysis.

It has been shown (9) that the bandgap of a binary chalcogenide compound can be estimated from the arithmetic mean of the bandgaps of the unary components. The absorption spectra of SrS have been determined (10) and consequently the bandgap is known to be about 4.05 eV. Gallium sulfide (Ga_2S_3) was chosen as the second part of the binary system since it also possesses a relatively large bandgap (3.31 eV) (11). The absorption edge of the binary compound was calculated to be about 3.68 eV and it would therefore be transparent in the visible region of the spectrum. Evidence for the existence of such compounds was given by Bostsarron (12) who prepared $CaGa_2S_4$ and noted that it exhibited a complicated x-ray diffractogram.

Initially, the activators chosen for study included those in which $4f^{n-1}5d \rightarrow 4f^n$ transitions were known to play an important role in the emission process (*i.e.*, Ce^{+3}, Eu^{+2}, Yb^{+2}). Of these only Ce^{+3} and Eu^{+2} were found to exhibit visible emission at 300°K. Subsequently, activators chosen from the remaining rare earth ions in which the fluorescence arises from transitions within the shielded 4f shell were also investigated. In this report the luminescence and structural properties of the host compounds and the Ce^{+3} and Eu^{+2}-activated phosphors are described. Applications of the Ce^{+3} and Eu^{+2} phosphors and the luminescent properties of the remaining rare earth ions will be the subject of subsequent articles.

Experimental

Materials preparation.—The starting materials employed in the preparation of the thiogallate compounds were high purity alkaline earth carbonates PbS,Ga_2O_3

* Electrochemical Society Active Member.

Key words: luminescence, phosphors, structural properties, Eu^{+2} activated, Ce^{+3} activated, thiogallate.

(99.99%) and the appropriate rare earth oxides (99.9%). All reagents except PbS were subsequently converted to their respective sulfides by reaction at 900°-1200°C in a stream of H_2S gas. Stoichiometric quantities of the various sulfides were then thoroughly mixed by grinding in a glass mortar and the resulting blend was subjected to a solid-state reaction at 900°-1000°C in H_2S. Under these conditions the reaction usually resulted in the formation of $M^{+2}Ga_2S_4$ in about 2 hr. The compound was obtained in the form of a sintered cake which was then mortared and sieved prior to evaluation. The phosphors were formulated as: $M_{1-x}Eu_xGa_2S_4$ or $M_{1-2x}Ce_xNa_xGa_2S_4$ (M = Ca, Sr, Ba). Alternate compensation mechanisms for Ce^{+3} such as those expressed by the general formulas $M^{+2}_{1-3x}Ce_{2x}Ga_2S_4$ and $M^{+2}_{1-x}Ce_xZn_xGa_{2-x}S_4$ were also investigated but sodium compensation proved to be the most effective in producing efficient phosphors. The monovalent sodium was usually introduced as NaCl but in some syntheses (*viz.* $Na_{0.5}Ln_{0.5}Ga_2S_4$) Na_2CO_3 was found to be more suitable. The Ce^{3+} and Eu^{2+} activators were generally introduced at a sufficiently high concentration level to assure accurate gravimetry and lower doping levels were achieved by dry dilution.

Alkaline earth thiogallate single crystals were grown from the corresponding polycrystalline compounds by iodine vapor transport. Quartz ampules 2.54 cm I.D. and 20. cm in length were filled with enough iodine so that the pressure was approximately 0.5 atm at the hot zone temperature of 960°C. The ampules were placed in a tube furnace with a 200°C temperature drop over the length of the tube. The reaction time was usually 5 days. The crystals thus obtained were usually in the 1 mm range or less. In one case, however, ($SrGa_2S_4$: Eu), it was possible to obtain a single crystal with dimensions 5 × 5 × 2 mm.

Measurement techniques.—X-ray powder diffraction techniques were employed in the identification of the various sulfide reagents and thiogallate compounds. Single crystal lattice parameters and space group determinations were obtained from Weissenberg photographs. In addition, emission spectroscopy and chemical analysis were employed to monitor the purity and stoichiometry of the starting materials, the sulfide reagents, and the finished phosphors. Emission and excitation spectra are given in terms of relative energy and relative energy efficiency *vs.* wavelength. Radiant efficiencies under cathode ray excitation were determined in a manner analogous to that described by Bril and Klasens (13). Photoluminescence was measured relative to suitable standard phosphors under excitation by a medium or low pressure mercury vapor lamp whose output was filtered by a Wratten No. 7-54 filter. The emission was detected by a Photovolt Photometer equipped with a 1P21 phototube and a Wratten 106 filter.

Results and Discussion

Crystallography.—Optical and crystallographic examination of single crystals of $BaGa_2S_4$ show that it is cubic. The diffraction symmetry and systematic absences correspond to the tetrahedral space group T_h^6-Pa3 (14). Since the general position for this space group is twenty-four fold and because there are 12 formula-weight units per unit cell, the barium ions must be in two different sites; 8 Ba ions lie in the special position c with point symmetry 3, and 4 Ba ions lie in the special position a or b with point symmetry $\bar{3}$. Since it is assumed that activator ions substitute for Ba, these ions also lie in two different sites. The pertinent crystal data are compiled in Table I.

Microscopic examinations of the Sr and Ca analogues indicated that both these compounds are biaxial. Weissenberg patterns confirmed that they are isomorphous and belong to the orthorhombic crystal class. The diffraction symmetry and systematic absence are consistent with space group D_{2h}^{24}-Fddd. As shown, however, in Table I there are additional extinctions that are not accounted for by this space group. Attempts to reindex the patterns so as to be more consistent with other space groups were unsuccessful. An explanation for these anomalous extinctions is the possibility of twinning, although no evidence of this was detected by polarized microscopic studies. Even if Fddd is indeed the correct space group, the point symmetries for Ca and Sr atoms are not determinable from existing data because the general position is thirty-two fold and there are 32 formula-weight units per unit cell. The point symmetries of Ca and Sr would be low, however, since the highest possible site symmetry for this space group is 222 (positions 8a and b). Moreover, only half of the cations could occupy these positions; the remainder would be required to be in sites with either 2 or $\bar{1}$ point symmetry.

X-ray powder diffractograms on all the other related compounds show that they are isomorphous with $SrGa_2S_4$. The lattice parameters and other crystal data are listed in Table I. The observed interplanar spacings are compared in Table II with those obtained from the assumed crystal model.

In a recent article, Eholie and co-workers (15) reported the preparation and crystallographic properties of PbM_2X_4, EuM_2X_4, and SrM_2X_4 (M = Al, Ga and X = S, Se). The unit cell parameters for the supercell of $EuGa_2S_4$ (with their notation a and b interchanged) and density (32 formula units/unit cell) are in good agreement with our results as presented in Table I. (They did not report any lattice parameters for $SrGa_2S_4$.) Their single crystal studies on $PbGa_2Se_4$

showed that this compound is also orthorhombic $a = 21.28$, $b = 21.54$, and $c = 12.72$Å, with 16 formula weight units/unit cell. These authors did not report a space group for this or any of the other compounds since, as in our case, there were more systematic absences observed than are strictly required by any orthorhombic space group. In order to explain the anomalous extinctions these authors also postulated the presence of twinning even though they were unable to interpret the diffraction data with this assumption. Attempts, moreover, to refine a proposed substructure with unit cell parameters $a/2$, $b/2$, and $c/2$ and space group Bbmb were unsuccessful. The absences found for the "superstructure" are, at least, consistent with Fddd and until these anomalies can be resolved by more extensive structure analysis, it appears that in all cases Fddd would be the most consistent tentative space group for all these compounds.

Compound stability.—All of the MGa_2S_4 (M = Ca, Sr, Ba) phosphors appeared to have a satisfactory shelf life but efforts were made to ascertain their stability toward hydrolysis. This was accomplished by measuring the pH change of an aqueous dispersion of several representative samples of each of the alkaline earth phosphors. The results of these measurements indicate that the stability decreases in the order Ba > Sr > Ca.

Experiments employing $SrGa_2S_4$:Eu indicate that the phosphor undergoes limited hydrolysis after synthesis which imparts an alkaline *p*H to its aqueous dispersion. After repeated replacement of the dispersion medium the *p*H of the liquid returns to the neutral range and remains constant. The initial alkaline reaction is probably related to the hydrolysis of free SrS since phosphors prepared with a stoichiometric excess of Ga_2S_3 did not produce this phenomenon. However, chemical analyses indicated the presence of both gallium and strontium ions in the dispersion medium which suggests that the initial hydrolysis of SrS is followed by a much slower hydrolysis of the stoichiometric phosphor.

Luminescence.—The thiogallates exhibit many of the perversities observed in other sulfide phosphor systems with regard to nonreproducibility. This is particularly true with the unactivated thiogallates and is much less so for the activated products. Only the most consistently observed characteristics of the thiogallate phosphors are discussed in the following sections.

Unactivated phosphors.—Unactivated $BaGa_2S_4$ is inert at 300°K but calcium and strontium thiogallates exhibit a broad band luminescence. The intensity of the emission is stronger near the top surface of the reacted phosphor cake and diminishes near the core. Typical excitation and emission spectra, which are similar for both compounds, are presented in Fig. 1.

Initially it was assumed that the luminescent centers responsible for the host emission were cation vacancies introduced by the sulfurizing atmosphere em-

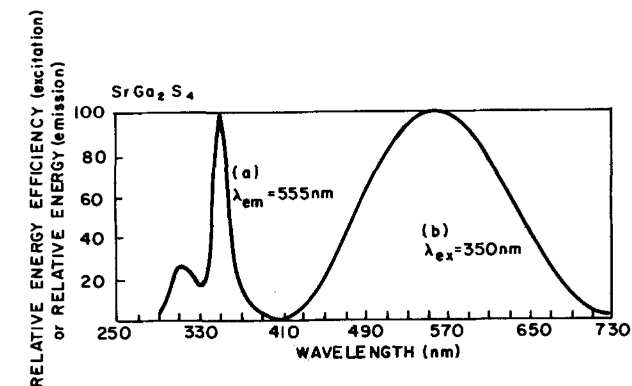

Fig. 1. Relative excitation spectra (a) and spectral energy distribution of fluorescence (b) for $SrGa_2S_4$.

ployed in the synthesis. However, the same emission was observed when syntheses were conducted in N_2 or N_2-H_2 ambients and when a stoichiometric excess of either MS or Ga_2S_3 were provided in the formulation. In a subsequent investigation it was found that $MGa_2S_4:Pb^{+2}$ [M = Ca, Sr; Pb $\leqq$ 0.5 atomic per cent (a/o)] phosphors exhibited excitation and emission spectra similar to those of the unactivated products. However, none of the metallic ions with the ns^2 electronic configuration were detected by a spectrographic analysis of the sulfide starting materials or the unactivated thiogallate phosphors. Thus the luminescent center responsible for the emission of the unactivated thiogallates remains unassigned.

Ce^{+3}-activated phosphors.—The fluorescence in Ce^{+3}-activated phosphors arises from $^2D \rightarrow {}^2F$ electronic transitions of the Ce^{+3} ion. Although visible emission has been reported (16) the fluorescence is usually characterized by broad bands appearing in the near ultraviolet region of the spectrum.

Emission and excitation spectra for the Ce^{+3}-activated thiogallates are presented in Fig. 2. The spectra are for samples containing 2 a/o Ce^{+3}. In the isomorphous calcium and strontium thiogallates significant levels of photoluminescence were observed for concentrations as small as 0.01 a/o and complete concentration quenching did not occur even when all of the alkaline earth cation was replaced, *viz.*, $Na_{0.5}Ce_{0.5}Ga_2S_4$. Solid solutions of $BaGa_2S_4$ with $Na_{0.5}Ce_{0.5}Ga_2S_4$ are limited.

The emission spectra of all three phosphors are similar; two bands are observed and their separation corresponds to that usually found for the ground doublet $^2F_{7/2}$, $^2F_{5/2}$. Furthermore the excitation spectra are identical for both emission bands. The excitation spectra for the isostructural calcium and strontium thiogallates are similar while that of the $BaGa_2S_4$:Ce,Na differs slightly. Diffuse reflectance spectra of the unactivated thiogallate host compounds show no indication of a strong absorption corresponding to the principal excitation bands in the Ce^{+3} phosphors, while the Ce^{+3} activated compounds do absorb in this region. Consequently the principal excitation bands must be due to direct Ce^{+3} absorption. In the 310 nm region, however, both the unactivated and Ce^{+3}-activated compounds absorb strongly, and it is therefore quite likely that the shorter wavelength excitation bands are due to host absorption. The most apparent feature of these spectra is that the excitation and emission bands are located at longer wavelengths than are generally observed for Ce^{+3} in oxidic hosts, but a spectral shift of this type is expected as a consequence of the nephelauxetic effect (17).

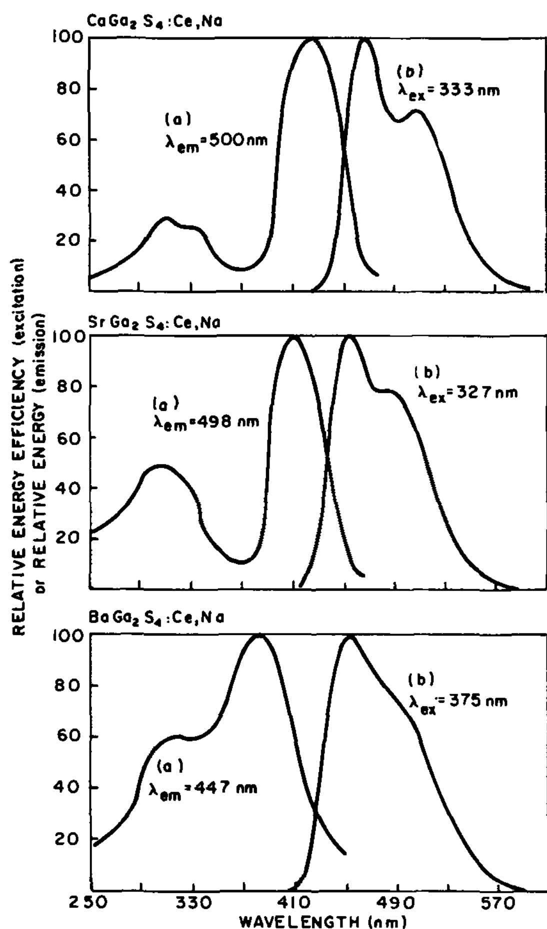

Fig. 2. Relative excitation spectra (a) and spectral distribution of fluorescence (b) for $M^{+2}Ga_2S_4$:Ce,Na phosphors.

The luminescence response of the $M^{+2}Ga_2S_4$:Ce,Na phosphors is compared to that of blue-emitting standard phosphors in Table III. The radiant cathodoluminescence efficiency of the Ce^{+3}-activated calcium and strontium thiogallates are approximately equal to the $Ca_2Al_2SiO_7$:Ce (P-16) phosphor while the barium thiogallate exhibits a slightly lower efficiency. The thiogallate phosphors also exhibit a strong response to the radiation from a medium pressure mercury vapor lamp but are less effectively excited by low pressure mercury vapor lamp radiation.

Eu^{+2} phosphors.—In Eu^{+2}-phosphors the fluorescence arises from transitions between the $4f^65d$ and $4f^7$ configurations. The fluorescence is characterized by broad bands whose peak wavelength is strongly influenced by the chemical nature and symmetry of the host crystal. Blasse *et al.* (18), for example, show that in a number of oxygen-dominated compounds the Eu^{+2} emission peaks in the wavelength interval 390-520 nm and in alkaline-earth sulfides the emission has been observed at even longer wavelengths (*viz.*, CaS:$Eu^{2+}\lambda_{max}$ = 650 nm) (8).

The excitation and emission spectra for the Eu^{+2}-activated thiogallates are shown in Fig. 3. The spectral data are for phosphors activated with 2 a/o Eu^{+2}.

The excitation spectra consist of extremely broad bands which extend well into the visible region and overlap the emission bands to a considerable extent. The excitation bands in the visible are undoubtedly due to Eu^{+2} absorption since the unactivated host compounds do not absorb in this region. As a consequence of this strong visible absorption, the phosphors exhibit a light green to yellow body color.

Blasse *et al.* (18), using an approach similar to that employed by Wood and Kaiser (20) for Sm^{+2}, described an approximate energy level scheme for Eu^{+2}. As in the case of Ce^{+3}, the excitation spectrum was interpreted in terms of the crystal field splitting of the 5d levels. This approach was successful when applied to hosts where the Eu^{+2} ion is located in a lattice site of fairly high symmetry, but for lower symmetry sites such as in the present case the excitation spectrum is too complex for such an analysis.

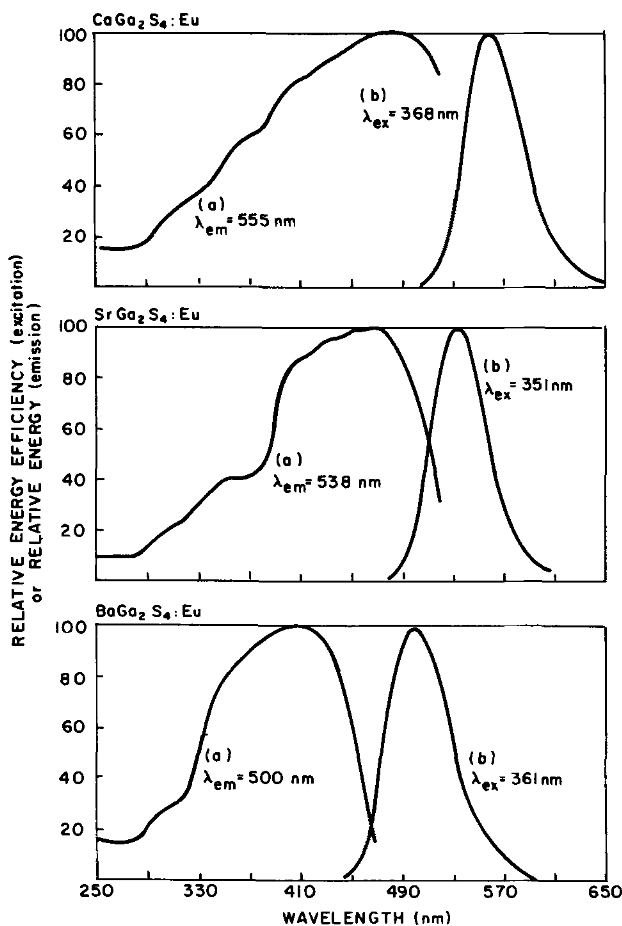

Fig. 3. Relative excitation spectra (a) and spectral energy distribution of fluorescence (b) for $M^{+2}Ga_2S_4$:Eu phosphors.

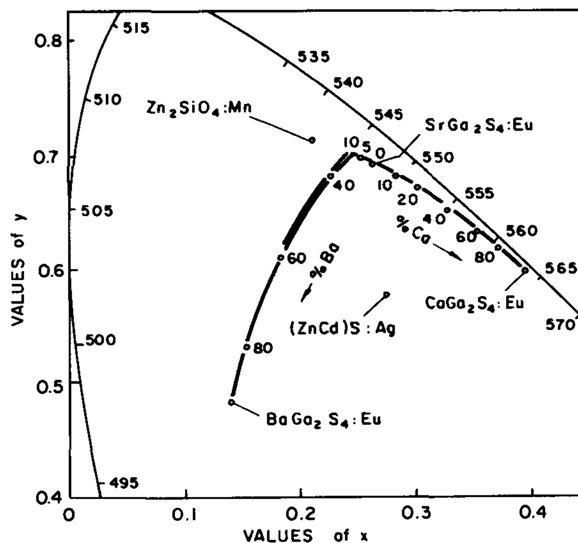

Fig. 4. Trichromatic coefficients of $M^{+2}Ga_2S_4$:Eu and other green-emitting CRT phosphors.

As shown in Fig. 3, the emission bands are relatively narrow and depending on the choice of host cation they peak in the blue-green through yellow regions of the spectrum. The isostructural calcium and strontium thiogallates form a complete series of solid solutions whose spectral energy distribution vary uniformly from the green of $Sr_{1-x}Eu_xGa_2S_4$ (λ = 535 nm) to the yellow of $Ca_{1-x}Eu_xGa_2S_4$ (λ = 555 nm). Solid solutions in the barium-strontium system are limited.

Trichromatic coefficients derived from the cathodoluminescence spectra of the Eu^{+2}-activated $M^{+2}Ga_2S_4$ compounds and some of their binary solid solutions, together with those of several commercial phosphors, are given on the CIE diagram in Fig. 4. In the figure the lines connecting the coordinate points of the $M^{+2}Ga_2S_4$:Eu phosphors indicate the range of chromaticity values that can be obtained from solid solutions of the type $Sr_{0.97-x}Eu_{0.03}M^{+2}{}_xGa_2S_4$ (where M = Ca, Ba and $x = 0 \rightarrow 1.0$). The double lines on the $SrGa_2S_4$:Eu-$BaGa_2S_4$:Eu join indicate a region of mixed phase. Thus from $x = 0 \rightarrow 0.1$ the phosphors exhibit the $SrGa_2S_4$ crystal structure and from $x = 0.6\text{-}1.0$ they possess the $BaGa_2S_4$ structure.

One of the more interesting of these phosphors is $SrGa_2S_4$:Eu whose chromaticity values indicate that it is more saturated in color than most of the commercially available phosphors. Employed in a color TV application as a substitute for the (Zn,Cd)S:Ag green primary the $SrGa_2S_4$:Eu phosphor would increase the gamut of obtainable colors approximately 10%. It is also interesting to note that small (~ 10%) substitutions of Ba for Sr actually improves the color slightly and at the same time improves the stability of the phosphor toward hydrolysis.

The Eu^{+2}-activated thiogallates exhibit an excellent cathodoluminescence response as demonstrated by the data presented in Table IV. The table also presents analogous data for two commercial phosphors which have served as the green primary in color television picture tubes.

The radiant efficiency of the Eu^{+2}-activated thiogallates decreases in the order Ca > Sr >> Ba. In general, the lumen equivalents follow this same progression and as a consequence the differences in the luminous efficiencies are larger.

A comparison of the cathodoluminescence data for the green-emitting phosphors is of particular interest because of the excellent color coordinates of the $SrGa_2S_4:Eu^{+2}$. The radiant efficiency of the $SrGa_2S_4:Eu^{+2}$ is observed to be only 38% that of the (Zn,Cd)S:Ag but its lumen equivalent is approximately 30% higher. Thus it has a luminous efficiency which is 50% that of the green sulfide primary. Similarly, by virtues of its higher lumen equivalent and a slightly higher radiant efficiency the luminance of the $SrGa_2S_4$:Eu exceeds that of Zn_2SiO_4:Mn by about 19%.

At low current densities the emission intensity of a cathodoluminescent phosphor increases linearly with increasing beam current. At high current densities, however, ZnS type phosphors saturate or become nonlinear in their response to current (21). The luminance of a $SrGa_2S_4$:Eu phosphor relative to that of the green (Zn,Cd)S:Ag primary is presented as a function of cathode current in Fig. 5. These measurements were obtained with a 25 kV electron beam scanned at the normal TV rate over a 4 in. × 4 in. raster. The beam spot diameter was 0.010 in. and the dwell time was about 0.1 μsec. The relative luminance is observed to increase linearly with current reaching a value of 85%

Table IV. Luminescence data for $M^{+2}Ga_2S_4$:Eu and related phosphors

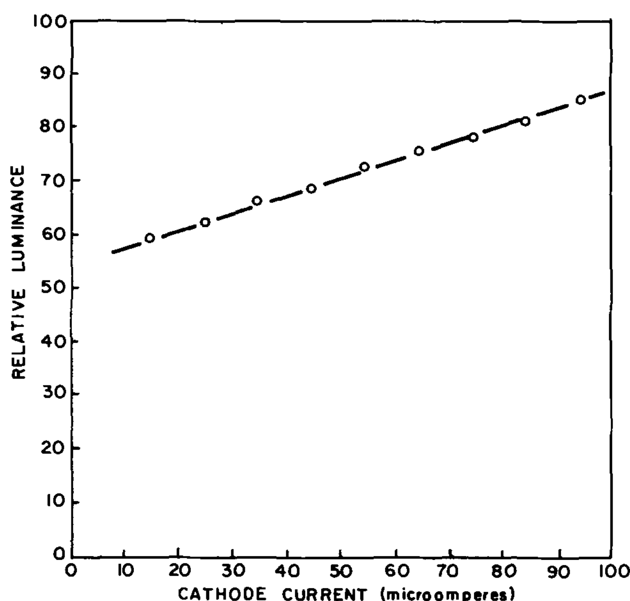

Fig. 5. Relative luminance of $SrGa_2S_4$:Eu vs. cathode current

of the green (Zn,Cd)S:Ag at 95 μA. Phosphors with a linear response are of interest for use in PDF (post deflection focusing) and Trinitron type CR tubes where they are subjected to higher current densities than those encountered in conventional TV picture tubes. Thus the $SrGa_2S_4$:Eu phosphor might find application in one of these tube designs.

The response of the $M^{+2}Ga_2S_4$:Eu phosphors to the radiation from low and medium pressure mercury vapor lamps is also given in Table IV. The Eu^{+2}-activated thiogallates are similar to the $M^{+2}Ga_2S_4$:Ce,Na phosphors in that they have a somewhat higher response to the long uv radiation of the medium pressure mercury lamp. However, the Eu^{+2}-activated phosphors, in contrast to the $M^{+2}Ga_2S_4$:Ce,Na materials, also respond rather well to short uv excitation.

Sulfide phosphors are generally avoided in fluorescent lighting applications because of their poor maintenance. The light output of a 40W lamp containing (Zn,Cd)S:Ag, for example, drops to 73% of its initial value after 100 hr of operation. The $SrGa_2S_4$:Eu phosphor, while it does not compare favorably to standard lamp phosphors for maintenance, is considerably better than the (Zn,Cd)S:Ag losing only 10% of its initial intensity in 100 hr.

Summary

The synthesis and crystallographic properties of thiogallate compounds of the general formula $M^{+2}Ga_2S_4$ [where M = Ca^{+2}, Sr^{+2}, Ba^{+2}, Pb^{+2}, Eu^{+2}, ($Na^{+1}La^{+3}$), and ($Na^{+1}Ce^{+3}$)] have been described. All of these compounds, except $BaGa_2S_4$, are isomorphous and belong to the orthorhombic space group D_{2h}^{24}-Fddd. $BaGa_2S_4$ was found to be cubic and belongs to the space group T_h^6-Pa3.

Unactivated $BaGa_2S_4$ does not fluoresce at 300°K but the calcium and strontium thiogallates exhibit a broad band emission peaking at 560 nm. Thus far the luminescent center responsible for this fluorescence has not been identified.

The Ce^{+3}-activated phosphors exhibit a strong blue fluorescence when excited by the radiation of a medium pressure mercury vapor lamp or cathode rays. The Eu^{+2}-phosphors fluoresce in the blue-green through yellow region of the spectrum depending on the choice of host cation. The Eu^{+2}-activated phosphors are effectively excited by uv radiation from low and medium pressure mercury vapor lamps and by cathode ray.

The CIE coordinates of the $SrGa_2S_4$:Eu phosphor ($x = 0.26$, $y = 0.69$) indicate that it is superior in color to most of the commercially available CRT phosphors. Optimum cathodoluminescence values are about 50% of the green (Zn,Cd)S:Ag primary employed in color CRT's. Relative luminances of 85% are achieved at higher current densities indicating the potential of this material in CRT systems requiring nonsaturable phosphors.

Acknowledgments

The authors wish to acknowledge the technical assistance of A. Alimonda and A. Calvano, who performed a large portion of the experimental work. Thanks are also due to V. D. Meyer for his determination of the absolute radiant efficiencies of the phosphors under cathode ray excitation.

Manuscript submitted Oct. 1, 1970; revised manuscript received ca. Oct. 11, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Measurement of Resistivity of Epitaxial Wafers Using a Voltage Relaxation Technique

Takashi Agatsuma*

Semiconductor & Integrated Circuits Division, Hitachi, Ltd., Kodaira, Tokyo, Japan

ABSTRACT

A voltage relaxation technique has been devised as a means of measuring the resistivity of epitaxial wafers. The principle, the method, and examples of the measurement are presented. In this approach, the steady-state value, V_s, of the voltage relaxation characteristic which is observed when a high-voltage ramp is applied in the reverse direction to a point contact diode, is related to the resistivity of the epitaxial wafer. V_s, measured on silicon slices, showed a power dependence of $k\rho^n$ where ρ is the resistivity of the silicon slice and k is a constant. This dependence was used to obtain calibration curves. It was also found, in the case of epitaxial wafers, that time spent in room air after epitaxial growth, and heat conduction from the back side of the wafers, had to be taken into consideration. V_s could not be measured for approximately 1 hr after epitaxial growth, but after 2 or 3 hr it was possible to take stable measurements; this can be explained in terms of slow surface states which grow with the silicon dioxide film on the surface of the wafers. When heat conduction from the back side of a wafer 200μ thick is considered, it was found that the pulse width of the measuring voltage ramp should be less than 100 μsec. If wafers were treated with hydrofluoric acid, then V_s could be measured immediately after such a treatment. However, when treatments were repeated on the same wafer and V_s was measured after every repetition, it was noted that V_s varied ± 4 to 5V. It is suggested that the variation of V_s would be reduced if the fast surface states at the interface of the SiO_2 film and the silicon bulk could be fully occupied.

The method for evaluating the resistivity of epitaxial wafers by utilizing the turnover breakdown of point contact diodes has been known as the point contact breakdown (PCB), or three-point probe breakdown, technique. This approach uses calibration curves obtained by measuring the turnover voltage as a function of the resistivity.

Three theories have been proposed in connection with the turnover phenomenon associated with point contact diodes. The first theory explains the turnover in terms of an avalanche effect, treating the point contact diode as a step PN junction (1). In the second theory, turnover is considered to be a thermal effect. It implies that turnover occurs when the temperature at the point contact has reached the intrinsic temperature of bulk silicon (2). The third theory states that the turnover phenomenon should not be considered to be a pure thermal effect, but that a field emission effect from surface states may be involved (3).

The PCB method has been explained in terms of the first or the second theory. However, this paper presents a method for measuring the resistivity of epitaxial wafers by the point contact breakdown technique based on the third theory. This method has been called the voltage relaxation technique (4).

Principle of Measurement

Measurement of V_s.—The principle of measurement is based on the relaxation characteristics of the voltage past the turnover point when a silicon point contact diode is biased in the reverse direction. A schematic representation of the measuring circuit and a typical example of the voltage relaxation characteristic for an N-type Si slice are shown in Fig. 1 (a) and (b). The applied voltage consists of a ramp with a constant slope, $\sim 10^7$ V/sec, followed by a constant voltage region. The voltage ramp is applied in the reverse direction through the current limiting resistance, R_L.

As noted in Fig. 1 (b), the diode voltage rises steeply, corresponding to the rising slope of the applied voltage and then shows an exponential decay characterized by the time constant "τ." This is the first stage, Fig. 1 (b). Subsequently, the voltage approaches the steady-state value of V_s. This is the second stage. Initiation of turnover corresponds to the point where the voltage begins an exponential decay from its maximum value, *TO*.

As observed in Fig. 1 (b), the turnover voltage and the time constant in the first stage vary with the amplitude of the applied voltage V_a, but the voltage V_s in the second stage shows almost no variation with amplitude of the applied voltage. V_s, however, as shown in Fig. 2 (a) and (b), was found to show a power dependency on resistivity of the samples. The turnover voltage measured using the PCB method is shown as dotted lines in Fig. 2. The samples were mirror-polished silicon slices obtained from melt-

grown single crystals. Before measurement, specimens were dipped in hydrofluoric acid, followed by a deionized water rinse and a spin dry. A tungsten whisker with a 3 ~ 5μ point diameter was used. The point loading was 4 grams.

The voltage relaxation technique uses the resistivity dependency of V_s to generate calibration curves in order to evaluate the resistivity of epitaxial wafers. Figure 3 is used to show how V_s is determined from the voltage-current and the voltage-time characteristics.

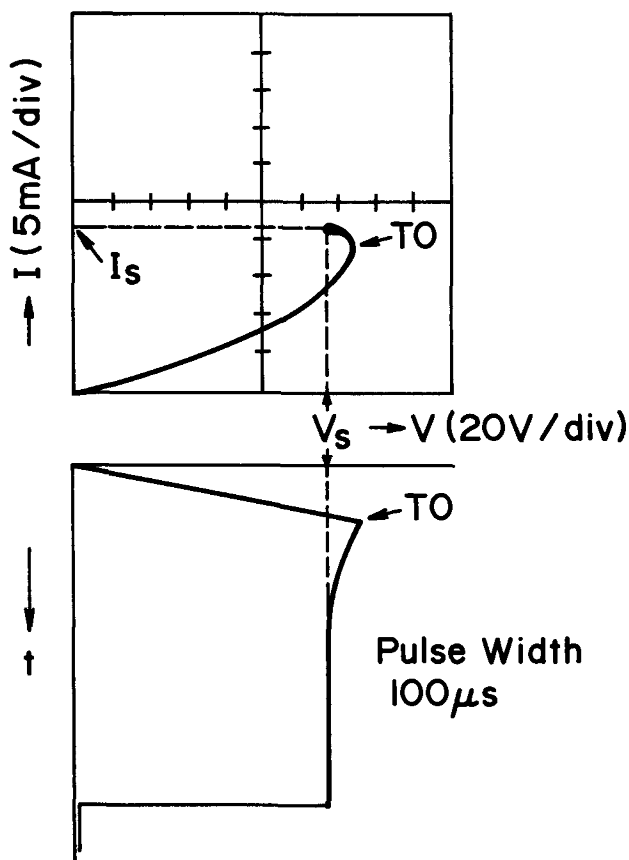

Fig. 3. Determination of V_s from I vs. V and V vs. t plots

It is seen that the dense spot in the V-I characteristic, after turnover, corresponds to the value of V_s.

Physical model of V_s.—The relaxation phenomenon shown in Fig. 1(b) can be understood as a process of charge transfer from a nonequilibrium to an equilibrium state (3). The process may be described in terms of the rate of change in the density of occupied slow surface donor states n_t. The rate, dn_t/dt is proportional to the product of n_t and the tunneling probability of electrons through the forbidden zone of Si, $\exp(-\alpha/F_s)$, where F_s is the electric field strength at the Si-SiO_2 interface and α is a constant depending on the properties of slow states.

The voltage V_s is considered to correspond to the condition $dn_t/dt = 0$, where the process of electron transfer comes to equilibrium such that the current due to emitted electrons from slow states balances the charging current from the metal (tungsten). Under this condition the interface electric field strength F_s reduces to a value (F_{ss}) just large enough to maintain the equilibrium state for the system.

An energy diagram showing nonequilibrium and equilibrium states for a tungsten point contact to N-Si is shown in Fig. 4.

The voltage drop V_s across the depletion layer in the equilibrium state is related to F_{ss} in terms of the depletion layer width *vs.* the resistivity of Si substrates. Therefore, V_s can be correlated with the resistivity of Si if an appropriate form of the junction is assumed at the point contact and F_{ss} is also assumed not to change with resistivity of the Si. However, the resistivity dependence of V_s will not be expressed explicitly, because the junction shape at the point contact is not established, and the dependence of the slow surface states on resistivity is not known. Hence the dependence of V_s on resistivity must be determined experimentally.

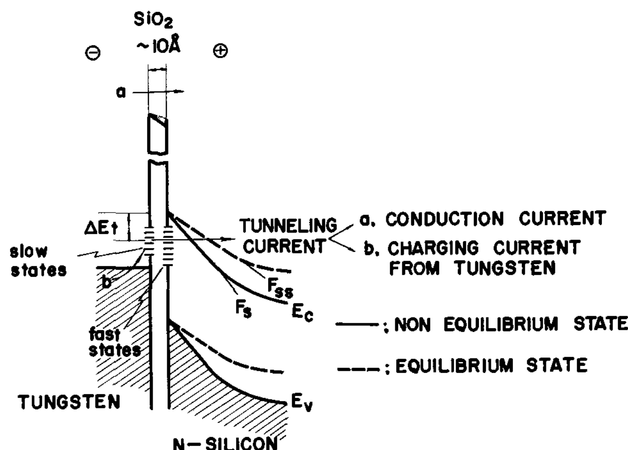

Fig. 4. Energy diagram for the system under the application of the voltage ramp.

Results and Discussion

The value of V_s was found to vary with many factors when using epitaxial wafers.

Variation of V_s with applied voltage.—The value of V_s was found to vary with temperature (3). Therefore, the measurement of V_s must be made by taking into consideration heat conduction from the wafer to the sample holder, since the wafer is of limited thickness and does not make a good thermal contact with the copper plate of the sample holder. The pulse width and the amplitude V_a of the applied voltage are subject to restrictions.

In order to eliminate the effect of heat conduction at the contact between the wafer surface and the copper plate, the pulse width of the applied voltage should be shorter than the time it takes the heat generated at the point contact to reach the back side of wafers; this is given by $t_r \simeq 0.3\ W^2/k$ (7), where W is the wafer thickness and k is the thermal diffusivity of silicon. If 200μ is substituted for W and 0.51 cm^2/sec for k, $t_r \simeq$ 0.24 msec. Figure 5 shows how the values of V_s vary with pulse width of the applied voltage for various wafers. V_s has a tendency to decrease with pulse width beyond 0.1 ~ 0.2 msec, which is of the same order of magnitude as the calculated value of t_r.

V_s for thick silicon slices (5 ~ 6 mm) showed no variation with pulse width, so the decrease of V_s with

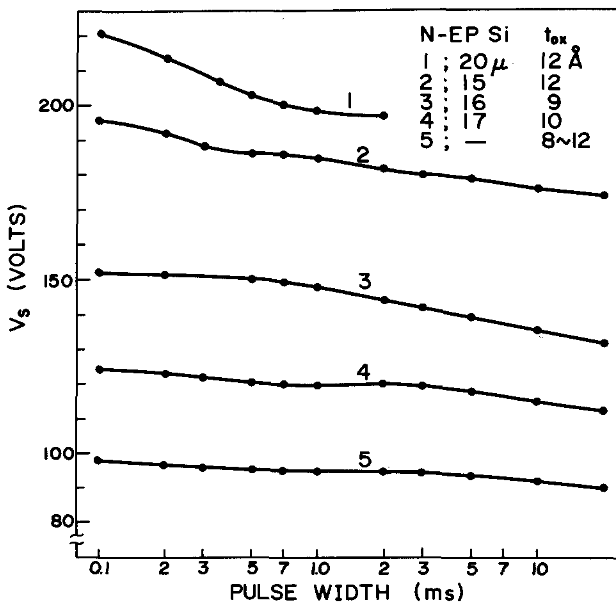

Fig. 5. Variation of V_s with pulse width of the applied voltage

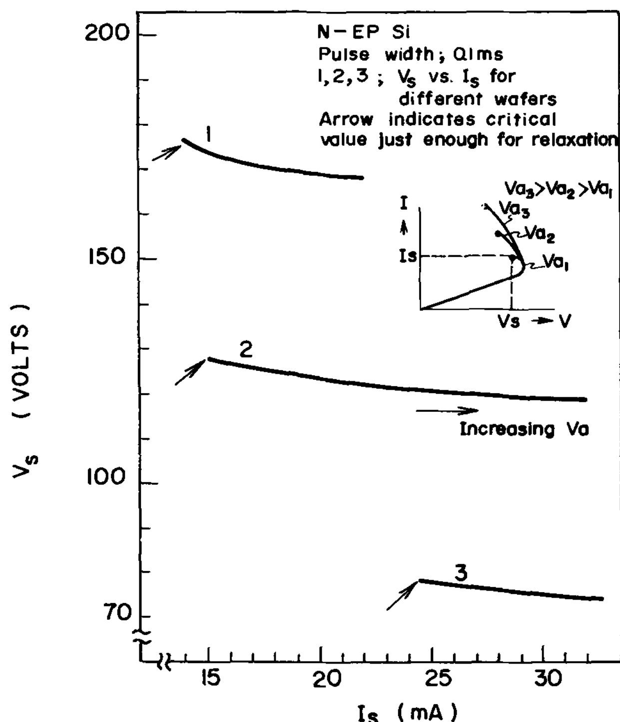

Fig. 6. Variation of V_s with I_s for a pulse width of 0.1 msec

pulse width for the thinner wafers may be explained in terms of the thermal effect mentioned above. Hence, for wafers of practical thickness, pulse width of the applied voltage should be kept below 0.1 ~ 0.2 msec.

When the amplitude of the applied voltage V_a is increased, V_s decreased slowly, but I_s, the current at V_s, increased noticeably. This is shown in Fig. 6 in terms of V_s *vs.* I_s curves, where pulse width was held to 0.1 msec. For thick silicon slices, V_s showed no variations with applied voltage. Therefore, the decrease of V_s with I_s is also considered to originate from a temperature rise at the point contact due to poor thermal conduction at the contact surface of the wafer and copper plate. Thus the amplitude of the applied voltage must be limited to a value just large enough for observing voltage relaxation.

Variation of V_s with time.—Figure 7 illustrates how V_s for N-type epitaxial wafers varies with time after a hydrofluoric acid etch. The width and amplitude of the applied voltage pulse were selected so as to give consistent results as discussed above. V_s showed a very slight increase with time, but for practical purposes, it may be considered as constant. The variation of V_s for N-type epitaxial wafers as a function of time after epitaxial growth is shown in Fig. 8. The sample was a lot consisting of six wafers made in the same epitaxial furnace. As shown in Fig. 8, different values of V_s were measured among the wafers as well as at various points on a given wafer within an hour or two after epitaxial growth. There were also points on wafers through which no current flowed. In this case, an oscillation appeared in the voltage-time characteristics. After 2-4 hr (or longer) V_s reached a uniform value without variation from wafer to wafer or from point to point on a given wafer.

The variations of V_s with time on wafers after hydrofluoric acid etching and after epitaxial growth are considered to be due to the different thicknesses of the insulating thin films on the surfaces of the wafers. These films probably increase in thickness with time after treatment. Thickness of the insulating thin film as a function of time after hydrofluoric acid treatment is shown in Fig. 9. These data were measured by ellipsometry (5). In this case, the extinction coefficient, $k = 0$, and the refractive index, $n = 1.45$ for SiO_2 were used for the insulating thin film. As can be seen in Fig. 9, an SiO_2 film of 8-12Å was formed immediately after the treatment; in a few days it became 17-19Å thick.

The variation of SiO_2 film thickness as a function of time in room air after epitaxial growth is shown in Fig. 10. Immediately after epitaxial growth, the surface is seen to be covered with an SiO_2 film of ~4Å. In a few hours the film gradually grew in thickness to ~14Å. However, it did not grow beyond ~14Å even after several weeks.

As shown in Fig. 8, within 1-2 hr after epitaxial growth V_s had different values from wafer to wafer, and from point to point on a given wafer. This period of 1 to 2 hr is considered to correspond to the time for which the thickness of the SiO_2 film is in the range of 4-8Å. After 3-4 hr, where V_s showed no variation from wafer to wafer, the SiO_2 film was observed to grow to 8-12Å (see Fig. 10). This may indicate that for the measurement of V_s on epitaxial wafers, an SiO_2 film of ~10Å in thickness is required on the surface. For wafers after a hydrofluoric acid treatment, an SiO_2 film of 8-12Å in thickness was formed on the surface immediately after treatment (Fig. 9). Thus, V_s can be measured immediately after a hydrofluoric acid treatment, Fig. 7.

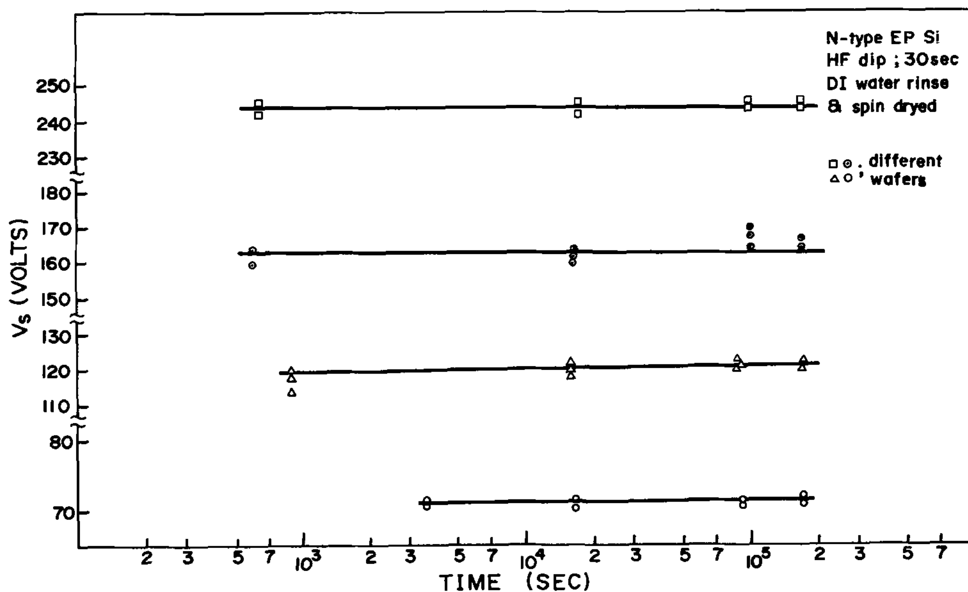

Fig. 7. Variation of V_s with time after hydrofluoric acid treatments

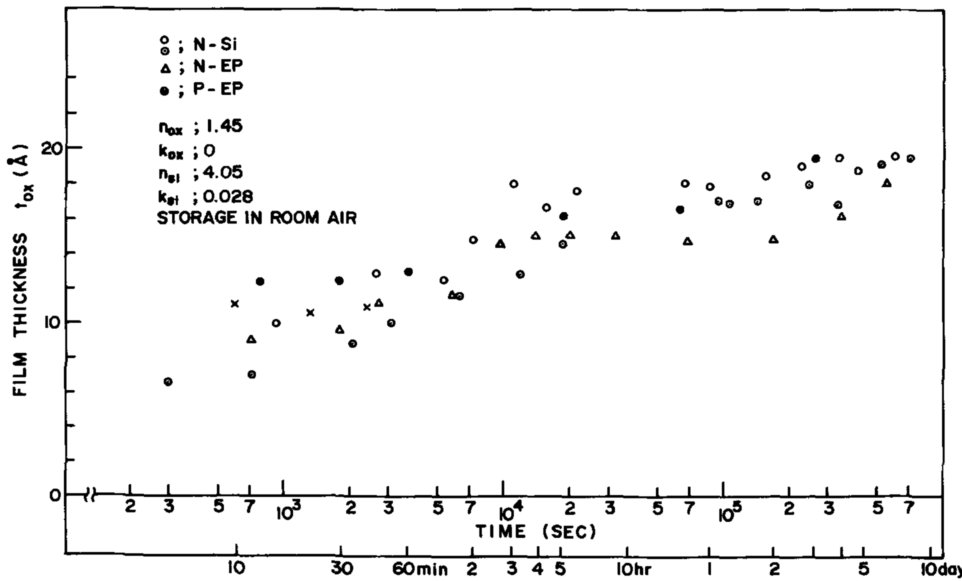

Fig 9. Film thickness of SiO_2 as a function of time after hydrofluoric acid treatment.

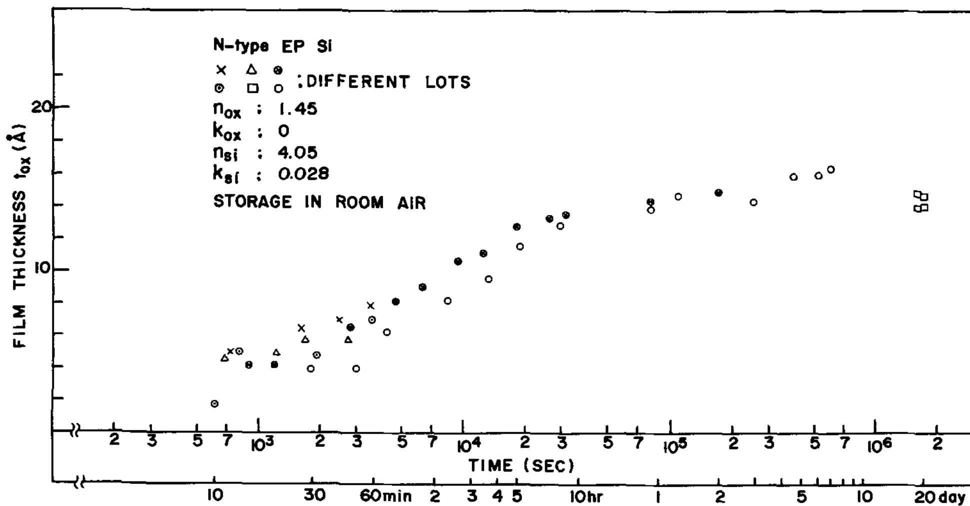

Fig 10. Film thickness of SiO_2 as a function of time after epitaxial growth.

The requirement of an SiO_2 film ~10Å thick on the surface of Si for consistent results shows evidence that the slow surface states responsible for the voltage relaxation are formed after the SiO_2 film becomes ~10Å thick.

Waveform of voltage relaxation.—Figures 11(a) and (b) show the various types of voltage relaxation waveforms for N-EP Si wafers. Figure 11(a)-(1) gives the normal mode of voltage relaxation and Fig. 11(a)-(2) shows the case when secondary breakdown occurs (6).

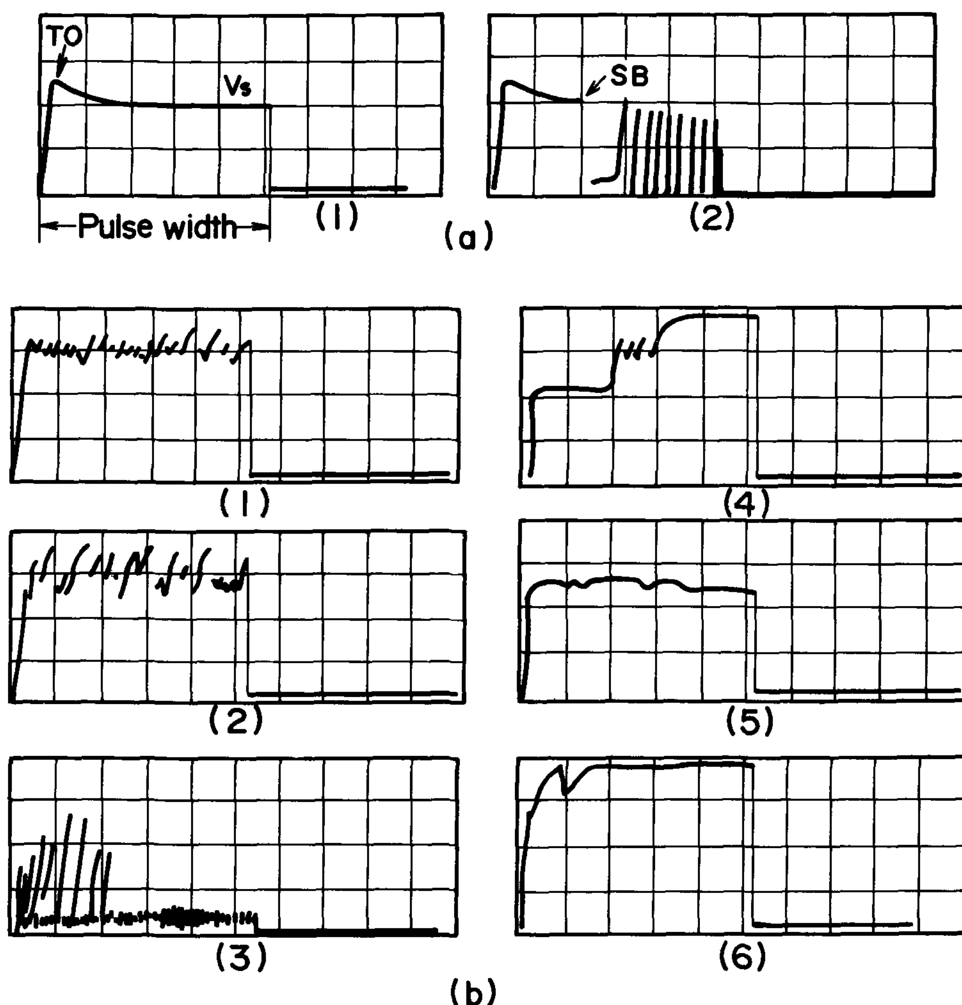

Fig. 11. Various modes of the relaxation voltage waveform.

This is observed in thinner, higher resistivity epitaxial layers. In this case, the initiating voltage of secondary breakdown is measured as V_s.

Figures 11(b)-(1) and (2) are used to show the condition for epitaxial wafers having an SiO_2 film ~26Å thick. No current was observed to flow and thus the measurement was not possible. Also, Figures 11(b)-(3), (4), (5), and (6) show abnormal modes observed during the first 10 min to 1 hr after epitaxial growth. As noted, V_s could not be defined.

Variations of V_s with successive hydrofluoric acid treatments.—The manner in which V_s for the same wafer of N-type EP Si varies as a function of the number of times it is subjected to hydrofluoric acid treatment is shown in Fig. 12. The treatments and the measurements were repeated every hour and repeated 9 times. Also shown in Fig. 12 are different V-I characteristics. For the "O" trace, V_s ~90V and for the "X" trace, V_s ~100V.

When the voltage ramp was applied successively to the same point on a wafer, V_s was observed to increase at every repetition of the voltage pulse. The variation of V_s as a function of the number of times the ramp voltage was applied is shown in Fig. 13. (The sample used was the same as that of Fig. 12.) As shown in Fig. 13, when V_s was ~90V, the change of V_s was small (~2V). For a V_s of ~100V, the variation was as large as 6V.

The change of V_s when city water and deionized water were used alternately for rinsing after hydrofluoric acid treatment is shown in Fig. 14. (The same sample studied in Fig. 12 was used again.) V_s for the deionized water rinse was ~100V, but it became ~90V when city water was used. The magnitude of this variation is consistent with that noted in Fig. 12. Thus, it is possible that the variations observed in Fig. 12 are due to fluctuations in the purity of water used for post rinsing after the hydrofluoric acid treatments.

As illustrated in Fig. 12 and 13, the variation of V_s with successive hydrofluoric acid treatments, as well as with every repetition of applied voltage, was accompanied by a different slope of the ohmic region in the V-I characteristics. Although the V-I characteristics in this region are not understood, it is assumed that fast states at the interface of the SiO_2 film and the silicon bulk are responsible for the current conduction of the region as shown in Fig. 4. Then, the rate equation for the number of electrons in fast states can be given in terms of the change in n_t (8), where n_t is the density of occupied fast states of the donor type capable of emitting electrons into the conduction band of Si.

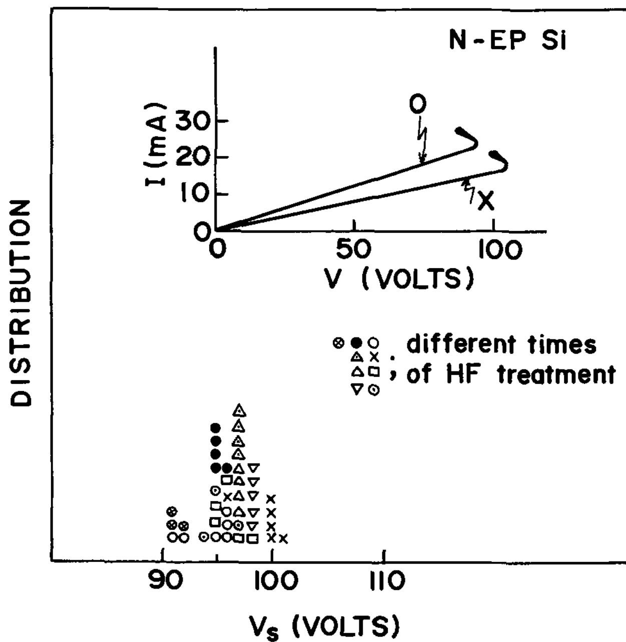

Fig. 12. The variation of V_s as a function of the number of times it is subjected to hydrofluoric acid treatments.

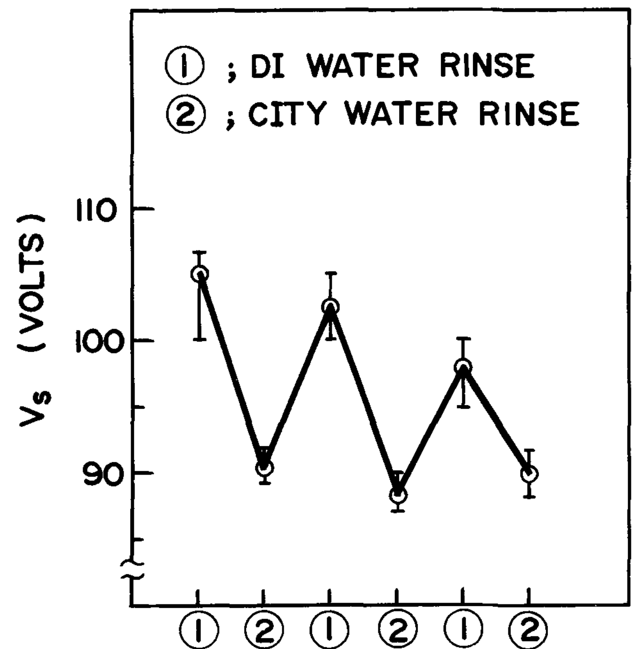

Fig. 14. The variation of V_s with rinsing water after hydrofluoric acid treatments.

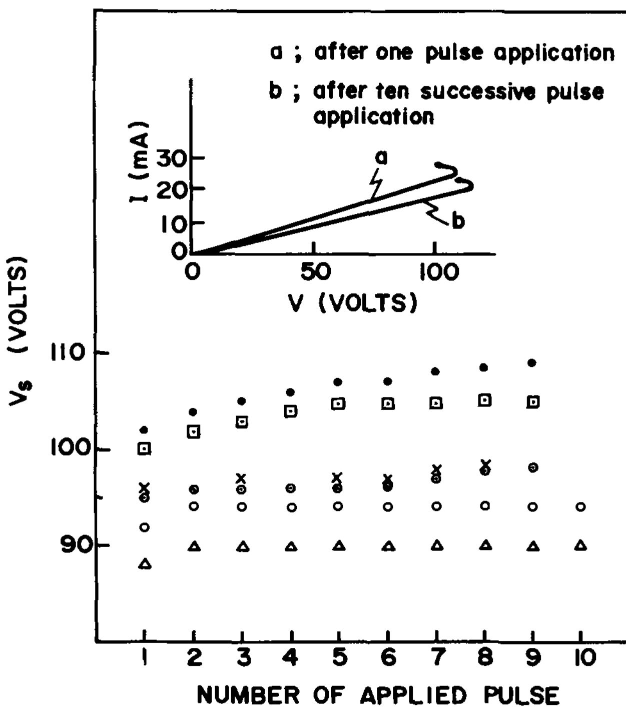

Fig 13. The variation of V_s as a function of the number of times the ramp voltage is applied.

$$\frac{dn_t}{dt} = C_n\,(n_s p_t - n_t n_1) + J_t/q \qquad [1]$$

with

$$n_1 = N_c \exp\,[-\,(E_c - E_t)/kT]$$

$$n_s = N_c \exp\,[-\,(E_c - E_{Fe})/kT]$$

$$p_t = N_t - n_t$$

where N_c is the effective density of states for the conduction band, N_t is the density of fast states, C_n is the capture coefficient of electrons, E_t is the energy level of fast states (assumed to have a single charged center) and E_{Fe} is the quasi-Fermi level of Si to which a negative bias is applied. J_t/q represents the charging current of electrons from tungsten.

In the present case where the rise time of the applied ramp is long enough compared to the time constant of fast states, the system can be regarded as being in a steady-state condition. Then, the current in the ohmic region is given by the first term of Eq. [1] as

$$J_s = qC_nN_c\,[p_t \exp\{-\,(qV + \phi_B)/kT\} - n_t \exp\{-\,(E_c - E_t)/kT\}] \qquad [2]$$

where ϕ_B is the barrier height for a tungsten-silicon contact, and V is the reverse applied voltage. For large bias voltage the first term in Eq. [2] can be neglected, so J_s varies largely with the values of n_t and $E_c - E_t$. Substituting typical values for fast states under large bias voltage (8) ($C_n = 10^{-8}$ cm^3/sec, $N_c = 2 \times 10^{20}$ cm^3, $E_c - E_t = 0.15$ eV, $n_t = 10^{13}$ cm^{-2}, $kT = 0.025$ eV) in Eq. [2], J_s becomes 10^4 A/cm^2, which is found to correspond to the experiments, $\sim 10^4$ A/cm^2 for $I_s = 10$ mA and the radius at the point $= 7.5\mu$.

Thus, for the sample that has $V_s \sim 90$V and a steeper slope, the ohmic region is considered to have the higher density of occupied fast states, n_t. On the other hand, the sample that has a $V_s \sim 100V$ shows evidence of fast surface states that are partially occupied and that interact with the unoccupied fast states.

The V_s variations at every repetition of the applied voltage are assumed to result from a decrease in the density of fast states capable of emitting electrons, n_t, due to the trapping of electrons in the unoccupied fast states. If this is the case, it will be understood that for the sample of $V_s \sim 90$V, which showed the lowest value of V_s variations in Fig. 13, the density of unoccupied fast states is considered to be minimum. The sample of $V_s \sim 100$V which showed a large variation of V_s with repetitive pulse application has a large density of unoccupied fast states which act as a trapping center for electrons.

The variations of V_s with water after HF treatment may also be understood in terms of the density of occupied fast states which are able to emit an electron into the conduction band. The sample treated with city water has a higher density of occupied fast states. For the deionized water rinsed sample, the density of occupied fast states is considered to be lower, and is

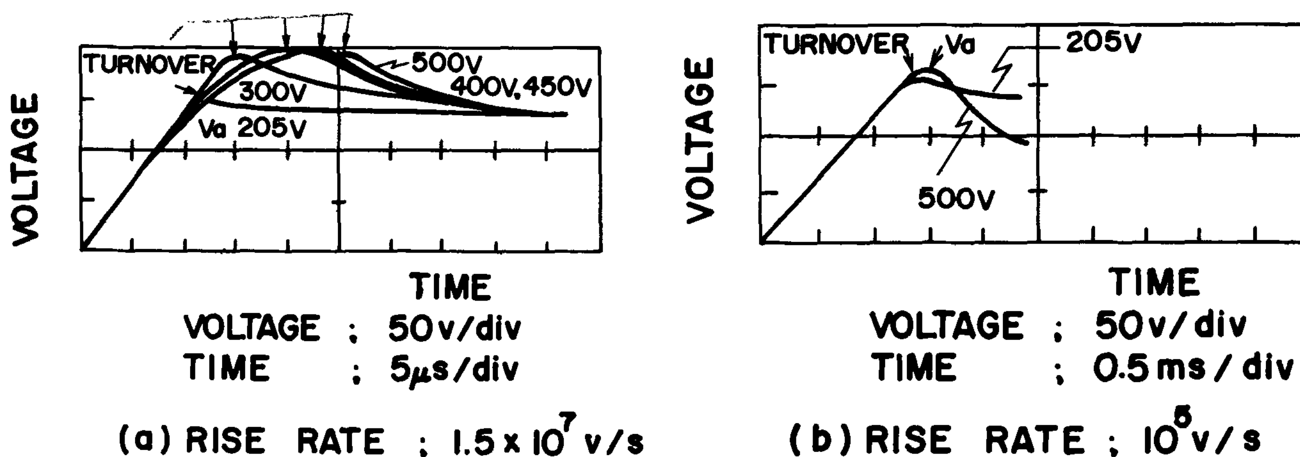

Fig. 15. Voltage relaxation curves for rising slopes of ~10^7 V/S and ~10^5 V/S

also subjected to variations with purity of the deionized water.

From the above experiments and discussions, it is evident that in order to measure V_s, the fast states must be fully occupied (metallic surface). Under this state, the effect of fast states on V_s will be eliminated.

Comparison with usual PCB method.—Figure 15 shows a comparison of the voltage relaxation curves for two cases where the rising slopes of the voltage ramp are 10^7 V/S and 10^5 V/S. A N-Si slice of 3.8 ohm-cm resistivity is used. The rising slope for the latter case corresponds closely to that of the PCB method which uses a 50 Hz half rectified voltage.

For Fig. 15-(a) many values of turnover are seen depending on the amplitude of the voltage ramp, but in each case the voltage relaxed towards its steady-state value, V_s. On the other hand, for Fig. 15-(b), it was not possible to define a steady-state value, V_s, since the turnovers were not characterized in terms of the relaxation process as described in Fig. 1(b). However, the turnovers occurred at nearly the same voltage, irrespective of the amplitude of the voltage ramp. This indicates that the turnover voltage can be correlated with the resistivity, as utilized in the PCB method. The turnover voltages as a function of Si resistivity however, as shown by the dotted lines in Fig. 2, were seen to depart from the V_s *vs.* resistivity curves for both the lower and higher resistivity ranges.

Summary and Conclusions

1. The steady-state value of V_s for voltage relaxation curves, which is observed when a high voltage ramp is applied in the reverse direction to a point contact Si diode, can be related to the resistivity of Si slices.

2. The voltage relaxation is due to the emission of current carriers from slow surface states at the interface of the tungsten point and the silicon dioxide film through the forbidden zone into the conduction band of Si; V_s corresponds to the voltage which gives a critical field strength at the interface of Si and SiO_2 film just large enough to hold a steady state of current flow for the system.

3. The voltage relaxation technique, which is based on V_s *vs.* the resistivity of Si slices, is applied to the evaluation of the resistivity of NN^+ epitaxial wafers. In this case, the effects of heat conduction, slow surface states, and fast surface states on V_s must be taken into consideration.

4. The thermal consideration arising from the limited thickness of silicon wafers requires that the pulse width of the voltage ramp should be below ~100 μsec and the amplitude should be limited to a value just large enough for observing voltage relaxations.

5. For the measurement of V_s, an SiO_2 film ~10Å in thickness is required for growth of the slow surface states necessary for voltage relaxation. Moreover, the fast states must be fully occupied. In this case, a higher slope of the ohmic region of V-I characteristic is obtained, and less variation with repetitive applications of the voltage ramp is seen.

Growth Mechanism for Germanium Deposition near a SiO_2-Ge Boundary

V. J. Silvestri,* R. Ghez, and T. O. Sedgwick*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Enhanced growth (ridge growth) of germanium on germanium near an oxide-germanium boundary has been studied in the Ge-H-Cl system as a function of temperature and oxide pad width. A model is presented assuming that surface diffusion of some germanium-containing species occurs along the SiO_2 pads, thereby feeding additional material to the germanium at the pad edge to form the ridge. It is shown that volume diffusion effects alone cannot explain the data. It appears that the reaction at the oxide-germanium boundary is much faster than surface diffusion and that adsorption of germanium-bearing species on the oxide mask constitutes a rate-limiting step.

A number of investigators (1-14) have studied the selective epitaxial deposition of silicon, germanium, and gallium arsenide through holes in thin SiO_2 masks. In some cases (6, 7, 8, 12) an enhanced growth or "ridge" on the otherwise planar Si epitaxy has been observed immediately adjacent to the edge of the SiO_2 mask. In attempting to prepare such structures for epitaxial depositions by either vapor phase or liquid etching, sometimes an enhanced etching or trough formation has been found in the semiconductor surface just at the edge of the mask (5, 7-9).

The ridge growth has not been studied in detail partly because of the prevalence of Si nucleation on the oxide. It has been reported, however, that the ridge growth could be reduced by using narrow oxide windows (7), or by lowering the temperature or reactant concentration (12). Alexander and Runyan (5) and Schnable *et al.* (7) showed that the reaction of Si and SiO_2 in the presence of H_2 (or H_2O) explains in part the trough formation above 1250°C. Oldham and Holmstrom (8) assumed that both ridge and trough formations are due to enhanced reactant concentrations and hence enhanced growth and etching rates at the edges of the holes. They develop a volume diffusion model and are able to explain qualitatively their observed trough formation. Shaw (10) speculates that in the liquid etching of GaAs there is a surface diffusion of etchant along the mask which leads to enhanced etching at the edge of the hole. Sirtl and Seiter (12) report that the use of silicon nitride masks eliminated both the trough and ridge formation in Si although very little experimental data was presented.

In the epitaxial deposition of Ge from $GeCl_4$ and H_2, we have found that ridge growths occur around the periphery of SiO_2 masking pads on the Ge surface. Trough formation has not been observed. In this system the Ge does not either nucleate on or react with the SiO_2 mask at the relatively low temperatures of 600°-875°C used. For these reasons and because the ridge growth was found to vary significantly over a wide range of growth conditions, this system was investigated in some detail both theoretically and experimentally.

A model has been developed assuming that surface diffusion of some Ge-containing species occurs along the SiO_2 pads, thereby feeding additional material to the Ge at the pad edge to form a ridge. The model is able to explain both the increase of ridge growth with temperature and the saturation of growth with increasing pad width. It is shown in the Appendix that a pure volume diffusion model cannot explain the experimental results.

Key words: ridge growth, selective epitaxial deposition.

Experimental

Oxide pad formation.—Preliminary observations of ridge growth on partially masked substrates indicated that the excess or ridge growth was sensitive to both temperature and oxide pad width. Therefore, ridge growth was investigated systematically as a function of these parameters. First, SiO_2 (2000Å) was deposited on <110> germanium substrates. Then oxide pads were formed on the substrate using conventional photoresist-etch techniques in the pattern shown in Fig. 1. These pads were rectangles in sets of three having a length to width ratio of 5:1. The oxide pad widths, equal to the interpad widths, varied from 40 to 588 μm. The oxide pads covered approximately 16% of the total germanium area. The germanium surrounding the oxide pads was then selectively etched to a depth of 1 μm using an H_2O_2-H_2O solution. During this etching an oxide overhang developed from the etch undercutting the oxide at the SiO_2 boundary. The amount of undercutting was the same as the etch depth of 1 μm thereby forming a 45° angle for the mesa side.

Germanium was deposited from a $GeCl_4$-H_2 mixture in a conventional vertical epitaxial reactor under the following conditions: substrate temperature range, 600°-875°C; Ge/H_2 = 3.6×10^{-4}; linear gas stream velocity, 175 cm/min; growth times were constant at 11 min. Under these conditions the growth rate was constant at 0.099 μm/min (15), and ridge growth immediately adjacent to the oxide was noted for all samples.

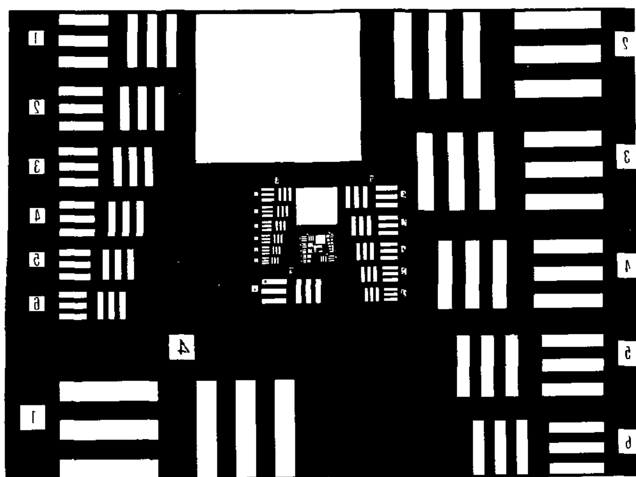

Fig. 1. Mask pattern

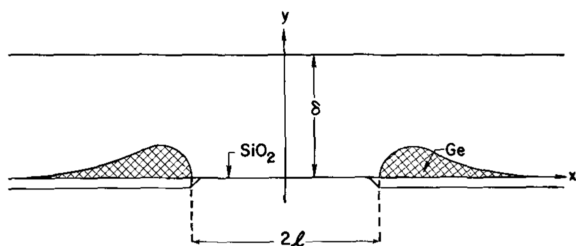

Fig. 2. Schematic of a representation of a section through a ridge showing coordinate system.

Ridge measurement.—Vertical profiles of the ridge were taken across the shorter dimension of the pads employing a stylus gauge. The top of the germanium epitaxy far from the oxide pads, extreme left or right (Fig. 2), was taken as the reference level. The excess growth area, A in square centimeters was calculated from the area under the Talysurf curve above the reference level which corresponded to the cross-hatched area in Fig. 2. Thus A is the growth above that which one would expect on a bare Ge wafer. The figure depicts a case where the epitaxial refill level corresponds exactly with the oxide level. Experimentally we could approach this exact refill case within 15% and in cases where there were deviations, corrections were made to simulate a perfect refill. In addition a small correction was made to the calculated excess area due to the nonplanarity of the germanium surface under the oxide overhang. This correction was no greater than 5% and usually was less than 1%. It was found that the excess growth between pads of a set was the same as that exterior to a set.

Results.—In Fig. 3 a scanning electron microscope photograph of a typical ridge surrounding an oxide pad is shown. Ridges were smooth, nonfaceted, and typically 1-2 μm high. A few ridges were 3 μm high. They could extend to a distance of 200 μm from the oxide. In Fig. 4 we plot the average excess growth area as a function of oxide pad width. The deposition temperatures for the samples range from 600°-875°C. The dashed curves through the experimental points are discussed later. We note that the experimental points for each excess growth curve seem to begin parabolically at the smaller pad widths but then saturate for larger pad widths. We also note that the maximum excess area increases with increasing temperature.

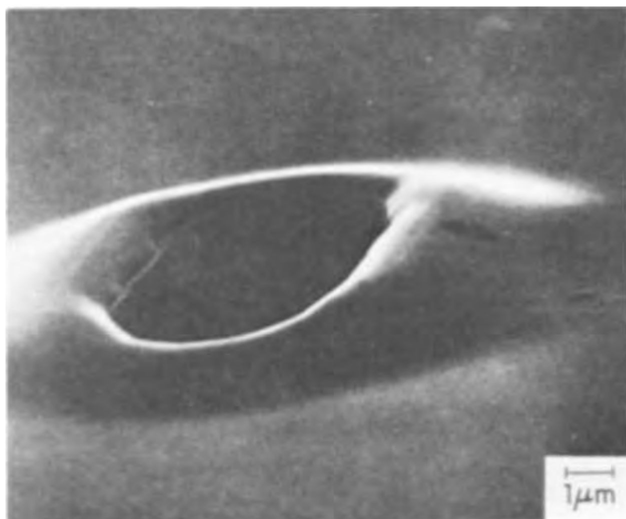

Fig. 3. Scanning electron microscope photograph of "ridge growth" surrounding an oxide pad.

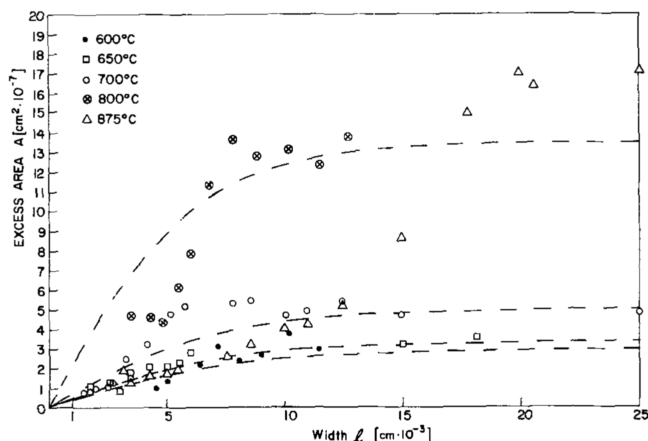

Fig. 4. Excess area of the ridge as a function of pad width. — — — Theoretical.

It was observed from ridge examination with the scanning electron microscope that the Ge-SiO_2 contact angle of the ridge varied markedly during growth as a function of time of growth. It was also noted that the overgrowth of Ge on the SiO_2 was a small fraction of the pad width.

Model

To our knowledge, the only quantitative analysis of excess growth during selective chemical vapor deposition is due to Oldham and Holmstrom (8). In a sense, their system is the "inverse" of ours since in their case the ratio of exposed Si area to that of the oxide mask is small. Their analysis is based on a calculation of an enhanced volume diffusion field. In the Appendix it is shown that this effect cannot explain our observations. However, the results of the preceding section suggest the following model: ridge growth is due to the surface diffusion on the oxide of some Ge-bearing species to the Ge-oxide boundary.

Referring to Fig. 2, a stagnant layer of thickness δ allows volume diffusion. The existence of a stagnant layer has been argued by several authors (16-19) as a convenient means of calculating mass transfer coefficients. The impinging molecules may then be incorporated directly at the Ge-vapor interface or be adsorbed on the oxide of width $2l$ where they will diffuse to the oxide-Ge boundary. In both cases, incorporation into the Ge lattice requires a chemical reaction. In the Ge-H-Cl system, the net reaction is

$$GeCl_4 + 2H_2 \rightleftharpoons Ge + 4HCl \quad [1]$$

and it is assumed that $GeCl_4$ is the major chemically reactive species. A detailed thermodynamic analysis of this system, similar to that carried out by Lever (20) on the Si-H-Cl system, is contained in unpublished work by Silvestri. For low Cl to H ratios and for increasing temperatures, this analysis shows that most of the $GeCl_4$ will first be converted to $GeHCl_3$ and with further increase in temperature to $GeCl_2$. In lieu of any detailed kinetic information we simply point out that if this conversion is sufficiently rapid, then the major chemically reactive species diffusing through the stagnant layer could be $GeHCl_3$ or $GeCl_2$. Investigations by infrared spectroscopy (21-23) indicate that such might be the case, although operating conditions were different from ours. The over-all reaction [1] is assumed to hold also for the adsorbed $GeCl_4$ at the oxide-Ge boundary. Isothermal conditions are assumed since mainly processes at the interface are considered. Also it can be shown that essentially steady-state conditions prevail.

In order to set up the surface diffusion model, let $n(x)$ be the number of adsorbed molecules on the oxide per unit area. The coordinate x refers to the

direction parallel to the wafer in Fig. 2. It has been shown (24-26) that n must obey the mass-balance equation

$$D_s \frac{d^2n}{dx^2} - \frac{n}{\tau} + \phi = 0, |x| < l \quad [2]$$

where D_s is the surface diffusion coefficient, τ the mean lifetime of an adsorbed molecule on the oxide, and ϕ is the flux of impinging molecules. Physically, the first term of [2] is the divergence of the surface flux which must accommodate the net flux from the vapor. This net flux may be viewed as a detailed balancing of two processes: a flux ϕ from the vapor to the oxide which may have to take an adsorption barrier into account and a reverse process $-n/\tau$ due to desorption. The surface flux at the oxide-Ge boundary is prescribed by a first-order chemical reaction

$$-D_s \frac{dn}{dx} = k_s n, x = l \quad [3]$$

where k_s is a reaction rate constant. We assume a first-order reaction since such is the case for growth on a bare Ge wafer (15). Defining a mean diffusion distance (24) $x_s = (D_s \tau)^{1/2}$, a symmetric solution of [2] and [3] is easily obtained

$$n(x) = \tau\phi \left[1 - \frac{\cosh x/x_s}{(D_s/k_s x_s) \sinh l/x_s + \cosh l/x_s} \right] \quad [4]$$

Physically, x_s is a capture distance; the density n varies largely within a distance x_s of the Ge-oxide boundary. The surface flux at the boundary is then

$$j_s = -D_s \frac{dn}{dx} \bigg|_{x=l} = x_s \phi \, [D_s/k_s x_s + \coth l/x_s]^{-1} \quad [5]$$

and the average density is

$$\bar{n} = \frac{1}{l} \int_0^l n(x) \, dx = \tau\phi \left[1 - \frac{1}{(l/x_s)(D_s/k_s x_s + \coth l/x_s)} \right] \quad [6]$$

Turning now to the Ge ridge, the existence of such a smooth (*i.e.* nonfaceted) structure can be explained on the basis of Mullins' analysis (27, 28) of morphological changes due to capillarity. However, contrary to the case of grain boundary grooving, the Ge-oxide contact angle is not maintained, *i.e.*, local edge equilibrium is *not* satisfied. If it is assumed that each adsorbed molecule reacting at the Ge-oxide boundary according to [1] and [3] is then transported by surface diffusion over the ridge (formally, the surface flux is continuous at $x = l$), the excess area A, defined in the last section, is just

$$A = \Omega t j_s = \Omega t x_s \, \phi \, [D_s/k_s x_s + \coth l/x_s]^{-1} \quad [7]$$

where Ω is the atomic volume of Ge (2.21×10^{-23} cm^3), t the time, and where [5] has been used. The argument leading to the first equality of [7] can be made rigorous by using Mullins' equation of motion of the ridge (27). It is seen that, as a function of pad width l, A is linear in l for $l << x_s$. The slope at the origin is

$$\frac{dA}{dl} \bigg|_{l=0} = \Omega t \, \phi \quad [8]$$

and is independent of the surface processes. For $l >> x_s$, A saturates reaching a maximum excess growth A_{max}

$$A_{max} = \Omega t \, x_s \, \phi / (1 + D_s/k_s x_s) \quad [9]$$

Discussion and Conclusions

To summarize, two extreme models are proposed. A surface diffusion model in which volume diffusion through the stagnant layer is unperturbed by the oxide, and a volume diffusion model in which surface diffusion on the oxide is not operative. The calculated excess growth curves for large pad widths saturate for the first model ($l \gtrsim x_s$) and increase linearly for the second ($l \gtrsim \delta$). Since our observations (Fig. 4) show a plateau region for all temperatures, the surface diffusion mechanism is favored. However, this does not rule out some enhanced volume diffusion which is probably negligible at small pad widths, but which might dominate for larger ones. In fact, experimental observation on larger pads should show again a rise above the plateau level that has been observed. This might explain why Oldham and Holmstrom's calculations (8) fit their data. A more accurate description would have to couple the surface and volume diffusion processes.

At this point let us examine another mechanism leading to a saturation of growth curves. The reaction at the Ge-oxide boundary could become surface rate limited (29). Silvestri (15) has established under the same operating conditions that above 600°C the bare Ge wafer system is mass transport limited. However, just at the Ge-oxide boundary where the ridge is highest, the effective growth rate is about three times faster than on the remainder of the bare Ge surface. This enhanced growth rate must be due to an increase in the transport of reactants to (or reaction products from) the ridge. We can conceive that for sufficiently large enhanced transport rates due to large enough pads coupled with very fast surface diffusion or due to very high linear gas stream velocities as was observed by Reisman (29) in a different system, the growth rate will reach a maximum. This will occur when the partial pressures of the reactants at the surface become essentially equal to the input pressures or when the partial pressures of the products become either essentially uniform throughout the system or zero due to the fast effective removal of products from the ridge to the gas phase. Under these conditions the reaction is surface rate limited and further increase in transport rates, however accomplished, will not further increase the growth rate. How close are we to that condition in the present system? For a bare Ge wafer, Silvestri has shown (*i*) that the growth rate can be at least doubled by doubling the linear gas velocity [see Fig. 6, Ref. (15)] without showing any sign of saturation in growth rate which might occur if surface limited operation obtains (29), and alternatively (*ii*) at 800°C the growth rate would have to increase a factor of sixteen before the reaction becomes surface rate limited. In this latter case, we assume that an increase in the net transport of reactants to the ridge by the oxide pads is equivalent to the net increase in growth rate that occurs by increasing the Ge/H_2 ratio from 3.6×10^{-4} to $\sim 5.9 \times 10^{-3}$ as indicated by Fig. 2 and 3 of Ref. (15). Thus, we conclude that a surface rate limitation probably has not been reached in the neighborhood of the ridge, although any increase in transport rates unavoidably shifts the system closer to that condition.

The expression [7] for the excess area A, has been fitted to the experimental data of Fig. 4. To this effect, the observed plateau in A for large pad widths, l, was equated to A_{max}. An initial slope was estimated so that the dashed (calculated) curves would go through most of the experimental points at the "knee." Such an estimate was not carried out for the 875°C data. A_{max} and the slope are recorded as a function of temperature in Table I. In Fig. 5 and 6 of ln A_{max} and ln $dA/dl|_{l=0}$ *vs.* $1/T$, it is seen that the data points fall on straight lines. Since we have not measured a slope for 875°C, two least-squares lines have been calculated for A_{max} corresponding to the case when one does or does not include the 875°C value of A_{max}. These lines are almost coincident so that only the line correspond-

Table I.

	Temperature, °C				
	600	650	700	800	875
$dA/dl \times 10^5$ (cm)	3.3	4.8	8.8	16.7	—
$A_{max} \times 10^7$ (cm²)	2.9	3.3	5	13.5	16.5
$x_s \times 10^3$ (cm) (without 875°C point)	7.529	7.357	7.206	6.953	—
$x_s \times 10^3$ (cm) (with 875°C point)	7.7	7.36	7.07	6.6	6.312

ing to the full data has been represented in Fig. 5. Preliminary numerical analysis has shown that an optimum fit requires that $D_s/k_s x_s << 1$ which means that the surface reaction is much faster than mass transport on the oxide. Equation [7] then reduces to

$$A = \Omega t \phi x_s \tanh l/x_s = A_{max} \tanh l/x_s \quad [10]$$

Then, using Eq. [8], the mean diffusion distance can be expressed as

$$x_s = A_{max} \Big/ \left.\frac{dA}{dl}\right|_{l=0} \quad [11]$$

As a function of temperature, values of x_s are calculated according to Eq. [11] by using the least-squares fit of A_{max} and the slope. Corresponding to the two least-square lines of A_{max}, two sets of values of x_s are calculated and are recorded in Table I. It is seen that x_s decreases slowly with temperature according to the relation $x_s = x_s^\circ \exp E/kT$ which is consistent with the prediction of Burton, Cabrera, and Frank (24). The values of x_s just calculated and the measured values of A_{max} allow the excess growth to be computed according to Eq. [10]. The computed curves are dashed in Fig. 4. Both sets of x_s are used and lead to curves differing at most by 5%. Although our surface diffusion model does predict a plateau, the calculated curves do not fit the initial portions of the experimental data, since these present an inflection point. In particular, the discrepancy between the data at 875°C and our model is so large that no curve representing these data has been shown. Although the reason for this lack of fit is not clear, we speculate that, in addition to reaction [1] there are other competing reactions as yet unaccounted for. For example, it might be postulated that HCl, liberated by the reaction, [1], on the Ge surface flows back over the oxide and is desorbed into the vapor. The inclusion of a second adsorbed species into the model could possibly explain the observed discrep-

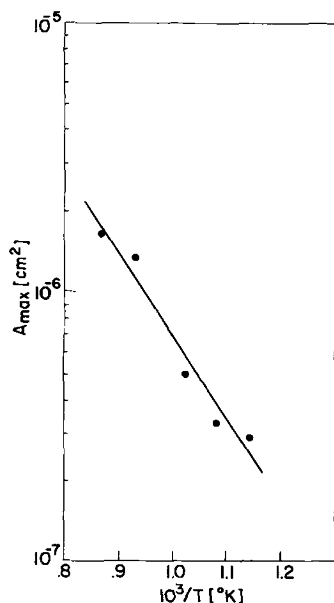

Fig. 5. A_{max} (cm²) as a function of $10^3/T$ (°K)

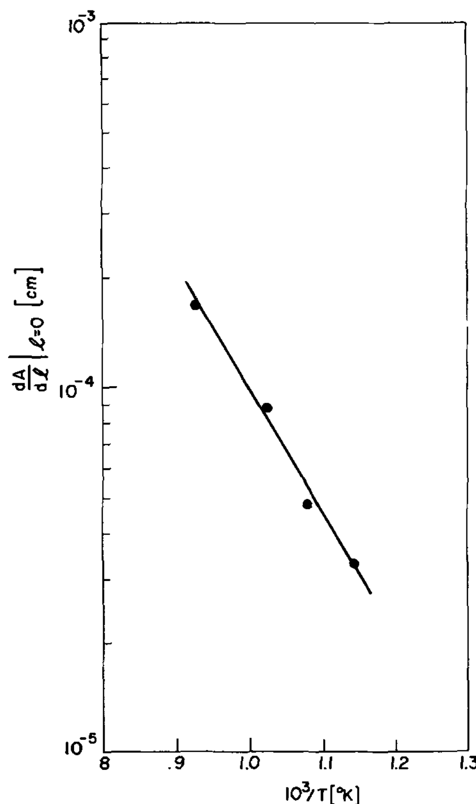

Fig. 6. Initial slope $dA/dl|_{l=0}$ as a function of $10^3/T$ (°K)

ancy. In particular, such an improved model would have to explain the 875°C data where deviations to the present model are largest.

In spite of these limitations we have tried to obtain an understanding of the impingement flux ϕ. Figure 6 and Eq. [8] suggest that an Arrhenius form holds

$$\phi = \phi_o \, e^{-Q/kT} \quad [12]$$

where k is Boltzmann's constant (8.62×10^{-5} eV/°K). Since $\Omega = 2.21 \times 10^{-23}$ cm³ and $t = 660$ sec, we calculate $\phi_o = 1.69 \times 10^{19}$ cm^{-2} sec^{-1}, $Q = 0.67$ eV. This suggests that an adsorption step (which might include a partial reaction with energy barrier Q) is rate limiting and that ϕ_o is a frequency factor. The value of ϕ_o may be compared with the molecular impingement flux Z given by kinetic theory (30)

$$Z = p(2\pi\, mkT)^{-1/2} \quad [13]$$

where p is the partial pressure and m is the mass of a molecule of $GeCl_4$. The $GeCl_4$ to H_2 concentration ratio is 3.6×10^{-4} the mass of a $GeCl_4$ molecule is 3.56×10^{-22}g. Z varies from 2.212×10^{19} cm^{-2} sec^{-1} at 600°C to 1.929×10^{19} cm^{-2} sec^{-1} at 875°C which is very close to the calculated value of ϕ_o.

Finally an estimate of the surface diffusion coefficient (31) can be obtained with Eq. [6] and [10]. Since $A_{max} \cong \Omega t \phi x_s$ and for large pad widths $\overline{n} \cong \tau\phi$

$$D_s = x_s^2/\tau = \left(\frac{A_{max}}{\Omega t}\right)^2 \frac{1}{\overline{n}\,\phi} \quad [14]$$

For large l, when the effects of the oxide-Ge boundary can be neglected, $\overline{n}$ could be estimated by an appropriate adsorption isotherm. This will not be pursued further since experimental data on D_s is unavailable.

In conclusion, we observe Ge ridges at the edges of SiO_2 masks. These growths increase with temperature and oxide pad width. A surface diffusion model is proposed which explains the saturation effect. It appears that the reaction at the oxide-Ge boundary is much faster than surface diffusion and that adsorption of Ge-

bearing species on the oxide mask constitutes a rate-limiting step. It is further shown that volume diffusion cannot explain the observations. However, certain details remain unexplained; in particular the inflection characteristic at higher temperatures indicates some competing process (or processes) not being considered. It should be noted that if the boundary condition [3] is altered to allow half- and second-order reactions, it can be shown that the curves obtained still exhibit the same behavior as [7]. Thus a more complete description will have to introduce more than one reaction and the diffusion paths of the products of the reactions.

APPENDIX

It remains to be investigated whether or not volume diffusion alone can explain the saturation effect. Let $N(x, y)$ be the density of Ge-bearing species (molecules/cubic centimeter) in the gas phase; x, y are the rectangular coordinates of Fig. 2. Under steady-state conditions, N must obey the time-independent diffusion equation (32)

$$\frac{\partial^2 N}{\partial x^2} + \frac{\partial^2 N}{\partial y^2} = 0 \qquad \text{[A-1]}$$

Assume then that surface diffusion is not operative, *i.e.*, n is a constant. Then Eq. [2] implies that the net flux above the oxide is zero

$$\left.\frac{\partial N}{\partial y}\right|_{y=0} = 0, \quad |x| < l \qquad \text{[A-2]}$$

This boundary condition produces a bending of the flux lines toward the Ge, thereby enhancing the volume flux to the ridge. An explicit calculation is possible when the Ge-vapor reaction is much faster than mass transport. The density over the Ge is then constrained to its equilibrium value N_e

$$N(x, o) = N_e, \quad |x| > l \qquad \text{[A-3]}$$

Finally it is assumed that the density is maintained at a constant value N_o (determined by the input) at the top of the stagnant layer

$$N(x, \delta) = N_o \qquad \text{[A-4]}$$

Since excess growth between pads is the same as that exterior to a set of pads, an infinite interpad distance can be assumed. The solution of [A-1] under the conditions [A-2-4] can be obtained by standard methods of conformal mapping (33). A mapping of the $z = x + iy$ plane into the (ω) plane can be found which conserves the boundary conditions and reduces the problem to a simple one-dimensional one. If I_m denotes the imaginary part and $\lambda = \pi l/2\delta$, we get

$$N = N_e + (N_o - N_e)\, I_m\, \omega/\pi$$

$$\omega + \lambda = \cosh^{-1}\left[\frac{\cosh \pi(|x| + iy)/\delta - \sinh^2\lambda}{\cosh \lambda}\right] \qquad \text{[A-5]}$$

with the restriction $0 \leq I_{m}\omega \leq \pi$. Finally, the excess growth is given by

$$A/\Omega Dt = \int_l^\infty dx \left[\left.\frac{\partial N}{\partial y}\right|_{y=o} - \frac{N_o - N_e}{\delta}\right]$$

$$= \frac{N_o - N_e}{\pi}\,[2\lambda - \ln \cosh \lambda] \qquad \text{[A-6]}$$

where in the integral, we have subtracted out the unperturbed flux, *i.e.*, the flux derived from [A-5] for $l \to o$. This function is plotted in Fig. 7. It depends solely on the characteristic ratio l/δ (experimentally always $<< 1$) and does not saturate. The linear rise for $l \gtrsim \delta$ is easily understood because the flux lines over the oxide are then essentially parallel to the x-axis.

Acknowledgments

The authors wish to thank S. A. Sharpe, S. A. Chan, and J. B. Bartivic for their technical assistance throughout the course of the work. Contributions by their colleagues, in particular, M. Berkenblit, M. E. Cowher, J. M. Green, R. A. Laff, R. F. Lever, T. B. Light, and A. Reisman are gratefully acknowledged. O. C. Wells and C. G. Bremer furnished the scanning electron microscope photograph.

High Apparent Mobility in Inhomogeneous Semiconductors

C. M. Wolfe,* G. E. Stillman,* and J. A. Rossi

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

In this paper we discuss in detail a simple model for an inhomogeneous semiconductor which leads to an anomalously high measured mobility. Quantitative results from this model are compared to experimental data from several different measurement configurations with intentionally introduced conducting inhomogeneities. These results cast doubt on the use of a high mobility as an indication of the quality of a semiconductor unless the homogeneity is unambiguously determined. These results may also qualitatively account for the behavior of samples with conducting inhomogeneities such as accumulation layers, metallic inclusions or precipitates, and doping variations due to polycrystalline growth or faceting effects.

The effects of various types of inhomogeneity on the mobility in semiconductors have been examined theoretically in some detail. Juretschke *et al.* (1) have treated the effects of nonconducting cavities in conducting materials. The properties of semiconductors with disordered regions produced by fast neutron irradiation have been discussed by Crawford and Cleland (2) and Gossick (3). A detailed treatment of the effects of random inhomogeneities has been given by Herring (4). Bate and Beer (5) and Bate *et al.* (6) have examined the influence of macroscopic conductivity gradients and discontinuities. Weisberg (7) has treated the scattering of current carriers by the space charge regions surrounding localized inhomogeneities. All of these treatments have shown that the mobility of inhomogeneous samples should be anomalously low either as a result of the averaging inherent in the Hall and resistivity measurements or as a result of carrier scattering.

Although anomalously low mobilities are commonly observed experimentally, anomalously high mobilities have also been observed in several semiconductors, including silicon where an accumulation layer was induced on a high-resistance n-type sample by an HF treatment (8) and GaAs which was grown under gallium-rich conditions (9). Mobilities which appear to be anomalously high have also been observed in other compound semiconductors which were grown under metal-rich conditions and which may have metallic inclusions or precipitates (10). By means of a simple model we have previously shown (11) that high apparent mobilities can be obtained in semiconductors with conducting inhomogeneities. Since this model may qualitatively account for the high measured mobilities in semiconductors with conducting inhomogeneities, we extend these results in the present paper and discuss in more detail the theoretical and experimental effects of conducting inhomogeneities on resistivity and Hall measurements in semiconductors.

Theoretical Model

The model which leads to an anomalously high measured mobility is shown in Fig. 1. This sample consists of a cylindrically symmetric van der Pauw configuration (12) of radius a, conductivity σ, and mobility μ, with a conducting inhomogeneity in the center of radius b, conductivity σ_0, and mobility μ_0. The apparent resistivity of this sample is determined by measuring the voltage induced between contacts 3 and 4 with zero magnetic field while a current is flowing through contacts 1 and 2. The apparent Hall constant is obtained by measuring the voltage induced between contacts 2 and 4 by a magnetic field B while a current is flowing through contacts 1 and 3. (In this model we treat the conductivity and the mobility as fundamental parameters of the semiconductor, whereas we treat the apparent resistivity, the apparent Hall constant, and the apparent mobility as parameters of the measurement sample.) By assuming that the contacts have only one dimension along the sample thickness (t), general expressions are derived in the Appendix for the apparent resistivity (Eq. [A-5]) and the apparent Hall constant (Eq. [A-6]) of the measurement configuration. Although the numerical results to be presented later were calculated for various values of the conductivity ratio (σ_0/σ), for discussion purposes these expressions can be simplified by assuming that the conductivity of the inhomogeneity (σ_0) is much greater than the conductivity of the medium (σ). Thus, in the limit ($\sigma_0/\sigma \rightarrow \infty$) the apparent resistivity is given by

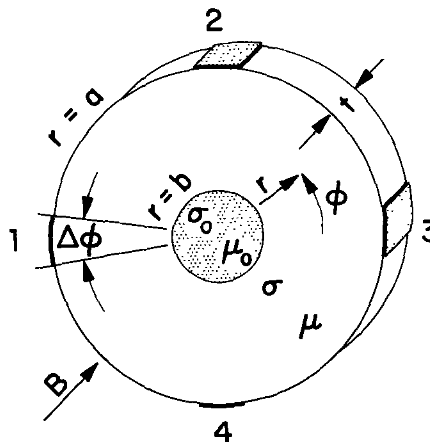

Fig. 1. Cylindrically symmetric van der Pauw configuration of radius $r = a$ with a conducting inhomogeneity of radius $r = b$ which leads to an anomalously high apparent mobility. The contacts are indicated by 1, 2, 3, and 4.

* Electrochemical Society Active Member.

Key words: high mobility, inhomogeneity, metallic inclusion, faceting effect.

$$\rho_{app}(\alpha) = \frac{1}{\sigma \ln 2} \sum_{n=1}^{\infty} \frac{(1-\alpha^{2n})^3}{(1+\alpha^{4n})(1+\alpha^{2n})} \frac{(-1)^{n+1}}{n} \quad [1]$$

and the apparent Hall constant is given by

$$R_{app}(\alpha,\beta) = \frac{4}{\pi}\frac{\mu}{\sigma} \sum_{n=1}^{\infty} \frac{\left(\frac{1-\alpha^{4n-2}}{1+\alpha^{4n-2}}\right)^2 (1+\beta^2)}{1+\left(\frac{1-\alpha^{4n-2}}{1+\alpha^{4n-2}}\right)^2 \beta^2} \frac{(-1)^{n+1}}{(2n-1)} \quad [2]$$

where α is the ratio of the radius of the inhomogeneity (b) to the radius of the sample (a) and β is the product of the real mobility of the semiconductor (μ) and the magnetic field (B).

From these equations we can examine qualitatively the effect of the inhomogeneity on the resistivity and Hall measurements. In the absence of an inhomogeneity ($\alpha = 0$) the series in Eq. [1] reduces to ln 2, so $\rho_{app}(0) = 1/\sigma$. The series in Eq. [2] reduces to $\pi/4$ and $R_{app}(0,\beta) = \mu/\sigma$. The calculated mobility

$$\left[\mu_{app}(0,\beta) = \frac{R_{app}(0,\beta)}{\rho_{app}(0)} \right]$$

is then equal to the real mobility of the sample. (Actually, both the apparent Hall constant and the apparent mobility are independent of β in this case, since the effects of scattering mechanisms are not included in the model. The β arguments are maintained for notation consistency.)

In the low field limit ($\beta^2 << 1$), it can be seen that both the apparent resistivity and the apparent Hall constant decrease as the relative extent of the inhomogeneity is increased ($\alpha > 0$). However, the resistivity decreases faster than the Hall constant, thus resulting in a higher apparent mobility. Physically, this is a geometrical effect where the current lines in the Hall measurement configuration with an applied magnetic field tend to spread around the inhomogeneity more than the current lines in the resistivity measurement configuration. Thus, the Hall voltage is reduced less than the resistivity voltage by the inhomogeneity.

For a given size inhomogeneity as the magnetic field is increased the measured Hall constant increases and, since the resistivity is measured in zero magnetic field, the measured mobility increases. In the high field limit ($\beta^2 >> 1$), the measured Hall constant is equal to μ/σ, which is the Hall constant of the homogeneous part of the sample. Physically, this effect is a result of the current lines being distorted out of the inhomogeneity by the magnetic field, until in the high field limit there is no current flow into the inhomogeneity. As has been pointed out by Herring (4) this is a consequence of the interactions of the boundary conditions between the inhomogeneity and the surrounding medium induced by the magnetic field.

Quantitative results for the dependence of the apparent resistivity, apparent Hall constant, and apparent mobility on the relative extent of the inhomogeneity (α), the normalized magnetic field (β), and the ratio of the conductivity of the inhomogeneity to the conductivity of the surrounding medium (σ_o/σ), have been calculated from the general expressions derived in the Appendix. Since the results are dominated by the discontinuity in conductivity σ_o/σ as opposed to the discontinuity in mobility (μ_o/μ), it was assumed that $\beta_o = \beta$ in the calculations to avoid unnecessary complications. These results are plotted in Fig. 2, 3, and 4.

Figure 2 shows the dependence of the normalized resistivity $[\rho_{app}(\alpha, \sigma_o/\sigma)\sigma]$ on α and σ_o/σ. In addition to the decrease in $\rho_{app}(\alpha)$ with increasing α previously indicated, for small values of α the major decrease in $\rho_{app}(\alpha, \sigma_o/\sigma)$ occurs for σ_o/σ between 1 and about 10. Thus, relatively small values of σ_o/σ can significantly affect the resistivity measurement.

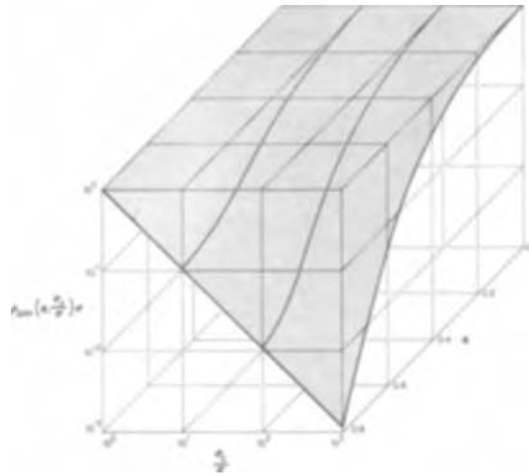

Fig. 2. Theoretical dependence of the normalized apparent resistivity $[\rho_{app}(\alpha, \sigma_o/\sigma)\sigma]$ on the relative extent of the inhomogeneity ($\alpha \equiv b/a$) and the ratio of the conductivity of the inhomogeneity (σ_o) to the conductivity of the medium (σ).

The dependence of the normalized Hall constant

$$\left[\frac{R_{app}\left(\alpha, \beta, \frac{\sigma_o}{\sigma}\right)\sigma}{\mu} \right]$$

on α, β, and σ_o/σ is shown in Fig. 3. Here we see the increase in $R_{app}(\alpha, \beta)$ with β previously indicated. However, these quantitative results for $R_{app}(\alpha, \beta, \sigma_o/\sigma)$ show that for values of β as low as about 10 the measured Hall constant approximates rather closely the Hall constant of a homogeneous sample for all values of α. Also, relatively small values of σ_o/σ have an appreciable effect on the Hall constant measurement (for values of α greater than about 0.2 which corresponds to 4% of the volume) as well as on the resistivity measurement.

Figure 4 shows the dependence of the normalized mobility

$$\left[\frac{\mu_{app}(\alpha, \beta, \sigma_o/\sigma)}{\mu} \right]$$

on α, β, and σ_o/σ. For low values of α and β we see the increase in apparent mobility with increasing α as previously indicated. However, for rather large values of α the apparent mobility begins to decrease. This is because in the low field region the relative shunting

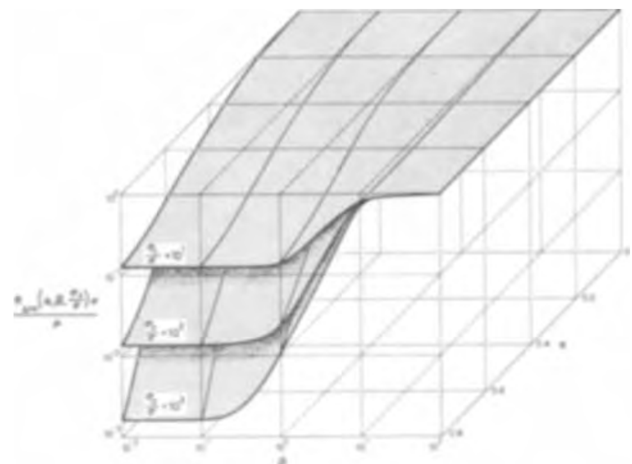

Fig. 3. Theoretical dependence of the normalized apparent Hall constant $[R_{app}(\alpha, \beta, \sigma_o/\sigma)\sigma/\mu]$ on the normalized magnetic field ($\beta \equiv \mu B$) and α for several values of σ_o/σ.

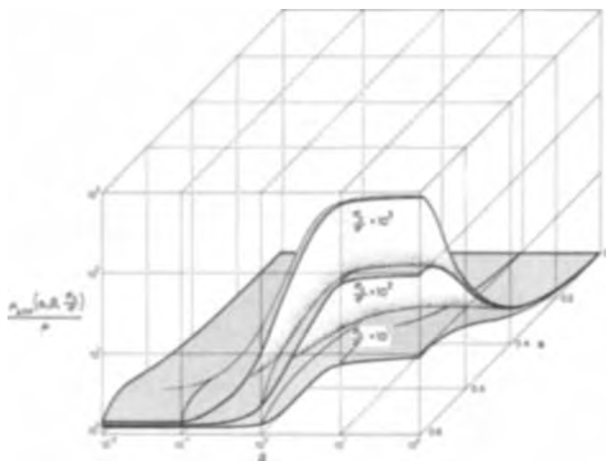

Fig. 4. Theoretical dependence of the normalized apparent mobility [$\mu_{app}(\alpha, \beta, \sigma_0/\sigma/\mu$] on β and α for several values of σ_0/σ.

effect of the inhomogeneity on the Hall voltage compared to the resistivity voltage begins to decrease for relatively large inhomogeneities. In the high field region, however, the apparent mobility continues to increase with α since almost all of the current is in the homogeneous part of the sample regardless of the size of the inhomogeneity. Here also for a given α we see rather sizable increases in apparent mobility with β and σ_0/σ, so that, depending on the various parameters, the apparent mobility can exceed the real mobility by as much as several orders of magnitude.

Experimental Verification

Since the theoretical model represents a rather idealized inhomogeneous measurement sample, a number of the more commonly used measurement configurations were investigated experimentally to test the generality of the model. For this purpose conducting inhomogeneities were intentionally introduced into thin epitaxial layers of GaAs which were grown on semi-insulating substrates. Conducting n^+ regions were obtained by alloying tin, and metallic inclusions were simulated by alloying gallium into the exposed surface of the epitaxial layers. This was expected to be a good representation of the theoretical model since the layers were thin compared to the extent of the inhomogeneity and also because the current flow tends to become two-dimensional with increasing magnetic field (4). In addition to a number of van der Pauw configurations, including cloverleaves, crosses, squares, and circles, the standard rectangular Hall configuration was also investigated. The real mobility (μ) was determined from resistivity and Hall measurements before the inhomogeneities were introduced, and the apparent mobility [$\mu_{app}(\alpha, \beta)$] was determined by measurements after the inhomogeneities were introduced. In each configuration the apparent mobility after introducing inhomogeneities was greater than the real mobility.

Some of these results are shown in Fig. 5 where the ratio of the apparent mobility to the real mobility is plotted *vs.* the relative size of the inhomogeneity (α). Experimentally, the parameter α was estimated from the area of the inhomogeneity and the area of the portion of the sample which was measured. The different symbols indicate different measurement configurations. Experimental values of β were between 0.5 and 1.0 and the corresponding theoretical curves calculated for $\sigma_0 >> \sigma$ are shown. Much of the scatter in the experimental data is caused by uncertainties in estimating area. Also we expect the effect to be quantitatively somewhat different in the various measurement configurations. However, it can be seen that in all configurations an anomalously high apparent mobility could be obtained by introducing a conducting inhomogeneity and that the experimental data are in reasonable agreement with the theoretical model.

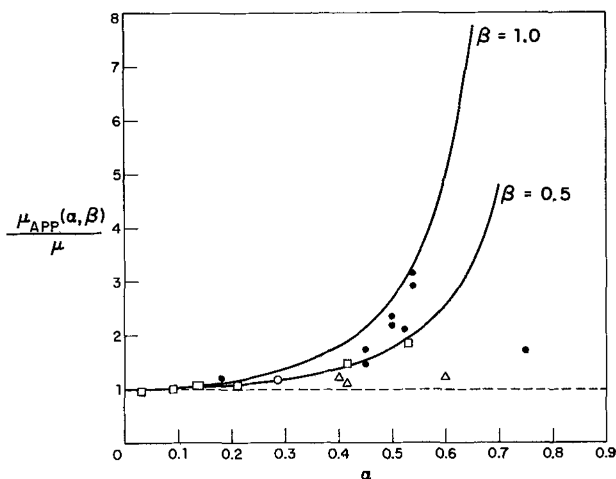

Fig. 5. Experimental dependence of $\mu_{app}(\alpha, \beta)/\mu$ on α. The theoretical curves for $\sigma_0 >> \sigma$ bracket the values of β for the experimental data. Different symbols indicate the different van der Pauw measurement configurations: ○—cross, △—cloverleaf, □—square, and ●—circle. The rectangle indicates the standard Hall configuration.

In Fig. 6 we show the experimental dependence of the apparent mobility on the normalized magnetic field (β). The parameter β was varied either by changing the magnetic field or by changing the measurement temperature and thus the real mobility of the sample. As in the previous figure the different symbols represent the different measurement configurations and theoretical curves calculated for $\sigma_0 >> \sigma$ bracket the estimated values of α for the experimental samples. As can be seen, the apparent mobility increases with β in reasonable agreement with the model.

Applicability

Since it has been shown that anomalously high apparent mobilities can be obtained as a result of conducting inhomogeneities in semiconductors, it is apparent that the homogeneity of the material must be determined before the mobility can be used as a figure of merit for the material. Although there are a number of techniques for detecting inhomogeneities (13), they may not produce definitive results for some types of

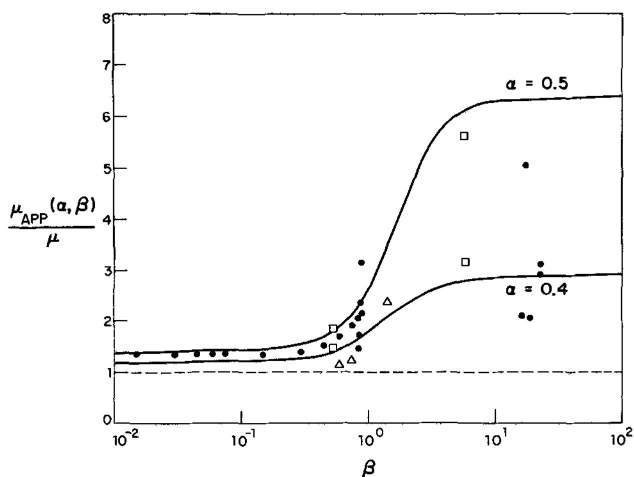

Fig. 6. Experimental dependence of $\mu_{app}(\alpha, \beta)/\mu$ on β. The theoretical curves for $\sigma_0 >> \sigma$ bracket the values of α for the experimental data. The symbols have the same meaning as in Fig. 5.

material inhomogeneity. Unintentionally introduced conducting inhomogeneities which are similar to the model constructed here are expected to have several characteristic features.

First, the observation of anomalously high mobilities is generally not expected to be very reproducible. The effect may be observed in samples prepared under conditions which result in accumulation layers on the surface of the measurement sample, or for compound semiconductors the effect may be most commonly observed in samples which are grown under metal-rich conditions and which may have metallic inclusions or precipitates. Doping variations in a sample may also lead to measurements of anomalously high apparent mobility. Since crystallites of different orientation can incorporate impurities at different rates during growth (14), the effect may be observed in polycrystalline samples. High apparent mobilities due to the so-called "facet effect" may also occur in Czochralski-grown crystals for measurement samples which are cut normal to the growth direction. [Expressions for the apparent resistivity and Hall constant of samples with conductivity gradients which approximate those observed in the "facet effect" (15) are derived in the Appendix.]

For pure samples the measured mobility in samples with conducting inhomogeneities may exceed the theoretical lattice scattering limited values. For example, in GaAs the polar optical phonon scattering limit (16) at 300°K is calculated to be 8000 ± 1000 cm^2/V-sec using the most accurate experimental parameters. At 77°K a lattice limited mobility of about 240,000 cm^2/V-sec has been calculated (17). However, by intentionally introducing conducting inhomogeneities in samples, we have increased the measured 300°K mobility from 7400 to 24,000 and the measured 77°K mobility from 150,000 to 740,000 cm^2/V-sec.

Samples with conducting inhomogeneities may appear to be quite uncompensated. For measurements in low magnetic fields this is because the apparent carrier concentration is higher than the real concentration. However, this is also true for measurements in high magnetic fields, since, even though the apparent carrier concentration approaches the real concentration, the apparent mobility is higher.

One method of determining the presence of conducting inhomogeneities and thus estimating the homogeneity of a material is to examine the magnetic field dependence of the Hall constant. For a homogeneous sample the Hall constant should decrease with increasing magnetic field as expected by the magnetic field dependence of the Hall coefficient factor. This dependence can be estimated or calculated from the Hall coefficient factors for the relevant scattering mechanisms (18, 19). The effect of conducting inhomogeneities however, is to give an increase in Hall constant with magnetic field which may reduce or eliminate the expected variation. Thus, if the magnetic field dependence of the Hall constant is anomalous, then the presence of conducting inhomogeneities is indicated.

For the intentionally introduced inhomogeneities previously described, this effect is quite pronounced. This is shown in Fig. 7 where the magnetic field dependence of the normalized Hall constant is plotted for a GaAs sample before and after an inhomogeneity was introduced. The upper curve shows the variation expected due to the magnetic field dependence of the Hall coefficient factor (19) [$r(\beta) = neR(\beta)$] and the experimental data points for a homogeneous sample (open circles) are in reasonable agreement with the expected dependence. The lower theoretical curves and experimental data points (solid circles) indicate the dependence obtained after an inhomogeneity was introduced in the sample.

Conclusions

Since intentionally introduced conducting inhomogeneities result in anomalously high measured mobilities, similar effects may be observable in samples with other conducting inhomogeneities such as accumulation layers, metallic inclusions and precipitates, and doping variations due to polycrystalline growth or faceting effects. This casts doubt on the use of mobility as a figure-of-merit for a material unless homogeneity can be established.

APPENDIX

Formulation of Model

Consider the cylindrically symmetric van der Pauw configuration with a radial change in conductivity (σ) shown in Fig. 1. The relationship between the current density, $\vec{J}$, and the potential, V, is given by $\vec{J} = \vec{\sigma}$ grad V, where $\vec{\sigma}$ is the magnetoconductivity tensor. With the magnetic field B in the z direction

$$\vec{\sigma} = \begin{bmatrix} \frac{\sigma}{1+\beta^2} & \beta\frac{\sigma}{1+\beta^2} & 0 \\ -\beta\frac{\sigma}{1+\beta^2} & \frac{\sigma}{1+\beta^2} & 0 \\ 0 & 0 & \sigma \end{bmatrix}$$

where $\beta \equiv \mu B$. In the steady state div $\vec{J} = 0$ and the differential equation which determines the transport of charge is

$$\text{div}\ \vec{\sigma}\ \text{grad}\ V = 0 \qquad \text{[A-1]}$$

We next consider a current I through any contact on the perimeter $r = a$. The current density at the contact is

$$J_r(a, \phi) = \frac{I}{ta\Delta\phi}$$

To simplify the problem we obtain one-dimensional contacts by letting $\Delta\phi$ approach zero.

$$\lim_{\Delta\phi \to 0} J_r(a, \phi) = \lim_{\Delta\phi \to 0} \frac{I}{ta\Delta\phi} = \frac{I}{ta}\delta(\phi - \phi_0)$$

where $\delta(\phi - \phi_0)$ is the Dirac delta function, and ϕ_0 is the angular position of the contact. In the resistivity calculation we pass a current through the contacts at $\phi = \pi/2$ and $\phi = 0$, which results in the boundary conditions

$$J_r(a, \phi) = \frac{I}{ta}\left[\delta\left(\phi - \frac{\pi}{2}\right) - \delta(\phi - 0)\right] \quad \text{[A-2]}$$

and determine the voltage induced between the contacts at $\phi = \pi$ and $\phi = 3\pi/2$ with zero magnetic field. In the Hall constant calculation we pass a current through the contacts at $\phi = \pi/2$ and $\phi = 3\pi/2$, which results in the boundary conditions

$$J_r(a, \phi) = \frac{I}{ta}\left[\delta\left(\phi - \frac{\pi}{2}\right) - \delta\left(\phi - \frac{3\pi}{2}\right)\right] \quad \text{[A-3]}$$

and determine the voltage induced between the contacts at $\phi = 0$ and $\phi = \pi$ by a magnetic field B.

Discontinuity in Conductivity

If we assume that the conductivity, σ, and the mobility, μ, are discontinuous at $r = b$, then Eq. [A-1] reduces to Laplace's equation which is separable. At the boundary between the two regions we require that the radial components of the current be equal, $J_r(b, \phi) = J_r^o(b, \phi)$, and that the tangential components of the field be equal, $E_\phi(b, \phi) = E_\phi^o(b, \phi)$. This gives us for the potential at any point (r, ϕ) in the outer region

$$V(r, \phi) = A_0 + \sum_{n=1}^{\infty} \{[A_n r^n - b^{2n} r^{-n}(A_n\gamma + B_n\eta)] \cos n\phi + [B_n r^n - b^{2n} r^{-n}(B_n\gamma - A_n\eta)] \sin n\phi\} \quad \text{[A-4]}$$

where

$$\gamma \equiv \frac{(\omega_0^2 - \omega^2) + (\omega_0\beta_0 - \omega\beta)^2}{(\omega_0 + \omega)^2 + (\omega_0\beta_0 - \omega\beta)^2},$$

$$\eta \equiv \frac{2\omega(\omega_0\beta_0 - \omega\beta)}{(\omega_0 + \omega)^2 + (\omega_0\beta_0 - \omega\beta)^2},$$

$$\omega \equiv \frac{\sigma}{1 + \beta^2} \text{ and } \omega_0 \equiv \frac{\sigma_0}{1 + \beta_0^2}$$

$$\left(\text{Note that } \lim_{\frac{\sigma_0}{\sigma} \to \infty} \gamma = 1, \text{ and } \lim_{\frac{\sigma_0}{\sigma} \to \infty} \eta = 0.\right)$$

A_n and B_n are then determined from the boundary conditions at $r = a$.

For the resistivity determination Eq. [A-4], boundary conditions [A-2], and van der Pauw's expression (12) for the resistivity in zero magnetic field, $\rho = (\pi/\ln 2)(Vt/I)$, yield an apparent resistivity given by

$$\rho_{app}\left(\alpha, \frac{\sigma_0}{\sigma}\right) = \frac{1}{\sigma \ln 2} \sum_{n=1}^{\infty} \left[\frac{2(1 - \gamma\alpha^{2n})}{(1 + \gamma\alpha^{2n})} - \frac{(1 - \gamma\alpha^{4n})}{(1 + \gamma\alpha^{4n})}\right] \frac{1}{n}(-1)^{n+1} \quad \text{[A-5]}$$

where $\alpha \equiv b/a$ and $\gamma = (\sigma_0^2 - \sigma^2)/(\sigma_0 + \sigma)^2$ for $\beta = 0$.

To obtain Eq. [1] $\lim_{\sigma_0/\sigma \to \infty} \rho_{app}(\alpha, \sigma_0/\sigma) \equiv \rho_{app}(\alpha)$.

For the Hall constant determination we use Eq. [A-4], boundary conditions [A-3], and the expression for the Hall constant, $R = Vt/IB$, to find an apparent Hall constant given by

$$R_{app}\left(\alpha, \beta, \frac{\sigma_0}{\sigma}\right) = \frac{\mu}{\omega}\frac{4}{\pi}\sum_{n=1}^{\infty} \frac{\left[(1 - \gamma\alpha^{4n-2})^2 + \eta^2\alpha^{8n-4} + \frac{2}{\beta}\eta\alpha^{4n-2}\right]}{[(1 + \gamma\alpha^{4n-2})^2 + \beta^2(1 - \gamma\alpha^{4n-2})^2 + (1 + \beta^2)\eta^2\alpha^{8n-4} + 4\beta\eta\alpha^{4n-2}]} \times \frac{(-1)^{n+1}}{(2n - 1)} \quad \text{[A-6]}$$

To obtain Eq. [2] $\lim_{\sigma_0/\sigma \to \infty} R_{app}(\alpha, \beta, \sigma_0/\sigma) \equiv R_{app}(\alpha, \beta)$.

The apparent mobility is

$$\mu_{app}\left(\alpha, \beta, \frac{\sigma_0}{\sigma}\right) = \frac{R_{app}\left(\alpha, \beta, \frac{\sigma_0}{\sigma}\right)}{\rho_{app}\left(\alpha, \frac{\sigma_0}{\sigma}\right)}$$

which results in

$$\frac{\mu_{app}\left(\alpha, \beta, \frac{\sigma_0}{\sigma}\right)}{\mu} > 1$$

for $\alpha > 0$ and $\sigma_0/\sigma > 1$.

Gradient in Conductivity

If we assume that the conductivity has a radial dependence of the form $\sigma = \sigma_0(b/r)^{2\zeta}$ so that $(1/\sigma)(d\sigma/dr) = (-2\zeta/r)$, and the mobility is uniform, then Eq. [A-1] is again separable. The potential at any point (r, ϕ) in the outer region is

$$V(r,\phi) = A_0 + r^{\zeta}e^{\zeta\beta\phi}\sum_{n=1}^{\infty} r^{-\zeta(4n^2+1)^{1/2}} [A_n \cos\zeta(4n^2 - \beta^2)^{1/2}\phi + B_n \sin\zeta(4n^2 - \beta^2)^{1/2}\phi] \quad \text{[A-7]}$$

for $2n > \beta$ and ζ positive. To determine A_n and B_n from the boundary conditions at $r = a$, it is necessary to construct a set of orthogonal solutions to Eq. [A-1]. Since this is quite cumbersome to do in general, we make the simplifying assumption that $\beta^2 << 1$ and then use the solutions [A-7] which are orthogonal on the interval 0 to 2π with respect to the weighting function $e^{-\zeta\beta\phi}$. To approximate the radial conductivity dependence observed experimentally for the "facet effect" in Czochralski-grown crystals, we use a value $\zeta = 1/2$ so that $\sigma = \sigma_0(b/r)$.

For the resistivity determination Eq. [A-7], boundary conditions [A-2], and van der Pauw's expression for the resistivity yield an apparent resistivity given by

$$\rho_{app} = \frac{1}{\sigma_0}\left(\frac{a}{b}\right)\frac{4}{\ln 2}\sum_{n=1}^{\infty} \frac{[(16n^2 + 1)^{1/2} - (4n^2 + 1)^{1/2}]}{[(16n^2 + 1)^{1/2} - 1][(4n^2 + 1)^{1/2} - 1]}(-1)^{n+1} \quad \text{[A-8]}$$

For the Hall constant determination we use Eq. [A-7], boundary conditions [A-3], and the expression for the Hall constant to find an apparent Hall constant given by

$$R_{app} = \frac{\mu}{\sigma_0}\left(\frac{a}{b}\right)\frac{16}{\pi}\sum_{n=1}^{\infty} \frac{(2n - 1)}{\{[4(2n - 1)^2 + 1]^{1/2} - 1\}^2}(-1)^{n+1} \quad \text{[A-9]}$$

For $\mu_{app} = \frac{R_{app}}{\rho_{app}}$, Eq. [A-8] and [A-9] give $\frac{\mu_{app}}{\mu} > 1$.

Effects of Grown-In and Process-Induced Defects in Single Crystal Silicon

D. I. Pomerantz*

P. R. Mallory & Co., Inc., Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

Distributions of defects observed in single crystals of silicon grown from the melt are shown to be congruent with two well known growth inhomogeneities characterized either by a spiral ramp pattern or a faceted core pattern in the crystal. The consequences of these defects are traced through the oxidation of the substrate, as required for a subepitaxial diffusion, and (after removal of the oxide) the growth of an epitaxial layer. It will be shown that the defect distributions persist through these processes and, interacting with process induced defects, produce several characteristic distributions of stacking faults in the epitaxial layer.

The two most striking growth inhomogeneities of silicon single crystals grown from the melt are growth spirals and growth cores (1-5). Spiral growth (1-4) is produced when the axis of crystal rotating is not coincident with an axis of thermal symmetry so that the growing interface experiences temperature fluctuations with the period of the rotation. The result is a surface of constant (*e.g.*, maximum or minimum) growth rate which will normally have the shape of a spiral ramp distributed within the growing crystal with its axis parallel to the direction of growth.

Growth cores (4, 5) are characterized by a solid-liquid interface which is extremely flat and close to a (111) plane. This facet, which is usually in the center of the crystal is believed to be produced by rapid lateral growth.

The existence of both types of growth fluctuations described above is largely deduced from the presence of resistivity striations (1, 4) in the crystal which are caused by the variation of effective segregation coefficient with growth rate.

In the light of these results, it is reasonable to expect that the observed fluctuations in growth rate might also produce a defect structure resembling the structure of resistivity striations; and in fact defect structures which are similar to spiral growth patterns have been observed by several workers. In particular Schwuttke (6) and Kaiser and Keck (7) have shown the precipitation of oxygen in this pattern in crystals grown from quartz crucibles. In low dislocation, low oxygen crystals grown by the Dash technique Plaskett (8) and de Kock (9) have described a similar distribution of defects which are attributed to vacancy clusters. Both types of defect were found to be nucleation sites for the precipitation of copper, which by infrared microscopy enabled the distribution to be made visible.

* Electrochemical Society Active Member.
Key words: silicon, single crystals, defects, stacking faults, oxidation, epitaxy, sodium, copper.

It will be the purpose of this work to show that silicon crystals can contain defect distributions which are congruent to both spiral- and core-type growth inhomogeneities. We do not here attempt to identify the nature of these grown-in defects, but their effects will be traced through the processing of silicon slices as typically required for subepitaxial diffusion and the growth of an epitaxial layer. It will be seen that the over-all distribution of defects remains stable throughout these processes although the individual defects undergo characteristic changes. Specifically it will be shown that during thermal oxidation of a slice these grown-in defects can act as nucleation sites for the precipitation of fast diffusing impurities which form clusters characteristic of copper.

It will also be seen that these defect distributions, interacting with surface defects at the oxide-silicon interface, nucleate characteristic patterns of stacking faults in epitaxial layers.

Experimental Procedure

The single-crystal slices used in this study were obtained from several commercial sources and were grown either by the Czochralski method from quartz crucibles or by the Dash "pedestal" method (10-11). All crystals were grown on the <111> axis to a diameter of 1.25 in. and were doped with boron in the range 10^{15}-10^{16} atoms/cm^3. Dislocation density in the crucible-grown crystals was less than 1000/cm^2 and essentially zero in the Dash-grown crystals. Slices from these crystals were cut from 2-5° off the <111> axis along the <110> direction and were supplied with one side polished in such a way as to remove a minimum of two mils from the sawn surface. Final slice thickness was 7.5-9.5 mils. Various polishing methods were used, but to eliminate the possibility that any of the observed structures could be attributed to polishing variables; samples of as-received slices were further

polished to a depth of 1-2 mils using the nonpreferential etch described by Lawrence and Koehler (12). This etch was also used, where specified, to remove saw damage from the back of the slice.

Slices or portions of slices prepared as described above were oxidized under one of the following conditions: (i) wet oxygen, saturated with water vapor at 95°C, for a period of 1-2 hr at 1200°C, (ii) dry oxygen for periods ranging from 1-7 hr at 1200°C, (iii) steam at 1200°C for a period of 1-2 hr. All oxidations were carried out in an externally heated quartz tube with slices held by a quartz boat and the oxidation period was preceded and followed by a 5 min flush with dry oxygen.

In some cases where indicated below the quartz boat was deliberately contaminated with a drop of 0.1M sodium nitrate solution prior to insertion in the oxidation furnace. Oxidation tubes used for this purpose were not used for other types of oxidation.

Portions of slices which were oxidized as described above were etched in HF to remove the oxide and then used as substrates for epitaxial deposition of silicon layers by the hydrogen reduction of silicon tetrachloride. The growth conditions and substrate preparation are described in Ref. (13). In order to observe the effects of the oxidation, control slices which had not been oxidized were also subjected to the HF etch and processed in parallel with the oxidized slices through epitaxial deposition.

The defect structures in as-received, oxidized, and epitaxially deposited slices were revealed by means of the structural etch described by Sirtl and Adler (14) (Solution B). Epitaxial layers were etched 1-2 min to show stacking faults. Other samples were etched 2-5 min. To reveal the stacking fault distributions in the macrophotographs the samples were illuminated at glancing incidence in a direction normal to one of the stacking fault edges. In this way specular reflections are obtained from the etched stacking fault facets which produce the small bright spots in the photographs.

Results

The experimental procedure described above has been used to trace the evolution and effects of grown-in silicon crystal defects through the processes typically used to produce an epitaxial layer over a localized diffused layer as required for many electronic devices. These processes are the oxidation of a substrate as required for a subepitaxial diffusion followed by removal of the oxide and growth of the epitaxial layer.

Grown-in defects.—The defect distributions observed in this work will be seen below to be morphologically congruent to the growth inhomogeneities described in the introduction. In this work the defect pattern corresponding to spiral growth has been seen only in Dash-type crystals (10, 11). Such a "spiral-growth" type of defect distribution in a Dash crystal is seen in Fig. 1 which illustrates the structural etch pattern produced on the polished surface of a slice cut perpendicular to the growth direction. These "swirl patterns" are found on more careful examination to be spirals rather than concentric rings. They cannot be attributed to surface preparation since they penetrate the slice, as can be demonstrated by removing various thicknesses of the sample with a nonpreferential etch (12) followed by application of the structural etch (14). More complex swirl patterns are frequently observed, one of the more common being a double spiral as seen in Fig. 2. (This sample was oxidized to make the swirl pattern more visible, as explained below.)

Although the defect patterns seen in Fig. 1 and 2 appear similar to resistivity striations, the detailed structure is quite different as seen in Fig. 3. This shows the microstructure of the swirl pattern of Fig. 1 which is found to be composed of small, triangular, flat bot-

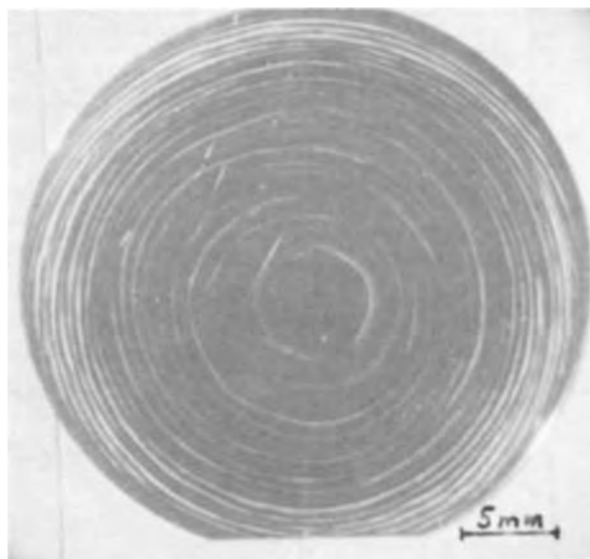

Fig. 1. Swirl pattern seen in low dislocation silicon crystal as grown

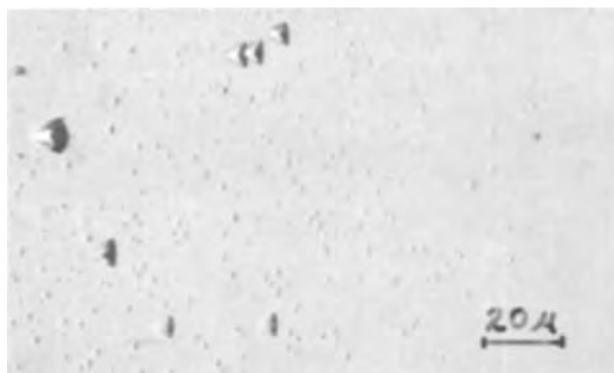

Fig. 3. Microstructure of the swirl pattern shown in Fig. 1 at the edge of a spiral band.

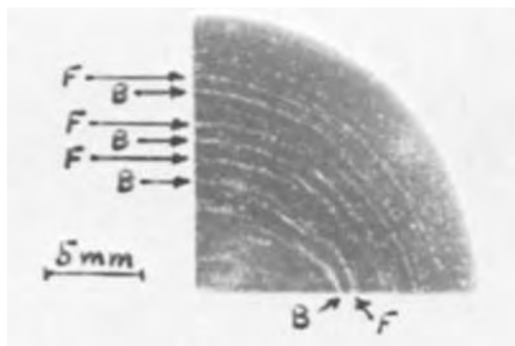

Fig. 4. A montage of the swirl pattern on the front (F) and back (B) surfaces of a slice illustrating the shape of the growth interface. Two mils removed from each side after oxidation by nonpreferential etch.

tomed pits mixed with a much lower density of larger pits having the same geometry. Both types of etch pit can vary considerably in density from crystal to crystal and at high densities the smaller pits merge to form an "orange peel" surface. Crystals from a number of commercial sources grown by the Dash method have been examined and all have shown this structure.

By comparing the spirals produced by etching the front and back surfaces of a slice it can be established that these patterns represent the intersection of the (111) faces of the slice with the spiral growth ramp surface described above. This is shown in Fig. 4 where photographs of the spiral pattern on the front and back surfaces are superimposed. From the spacing between the patterns on the front and back surface the contours of the growth interface can be determined. To enhance the visibility of the swirl pattern on this sample the slice was oxidized prior to structural etching as described below.

Corresponding to the observation of Wang (15) that growth cores are generally observed in crucible-grown crystals, this work has observed the corresponding core-type defect structure only in crystals of this type. The characteristic defect pattern in such a crystal is a core region consisting of a series of lamellar regions parallel to (111) planes with defect density alternating between high and low values in alternate lamellae.

When such a crystal is sliced more than a few degrees off the (111) plane these lamellar regions intersect the slice surface in a series of bands of alternating defect density. These bands are seen in Fig. 5 and the left-hand sample of Fig. 6. Both samples are oriented 4° from the (111) plane. The sample illustrated in Fig. 6 was etched nonpreferentially to a depth of 2 mils prior to the structural etch to eliminate the possibility that the observed structure was due to surface preparation of the slice. The apparent curvature of the core bands is due to slight curvature in the surface after the nonpreferential etch.

The straight core defect bands illustrated in Fig. 5 are characteristic of a flat polished surface. Although these are visible on the polished and etched surface of the as-grown slice, as in Fig. 6, this sample was oxidized prior to structural etching to improve contrast in the photograph.

A typical core-type defect pattern of a slice cut close to a (111) plane is shown in the left-hand sample of Fig. 7. The microstructure of as-grown core defects is similar to that found in growth spirals such as illustrated in Fig. 3.

Effects of oxidation.—Generally speaking all of the oxidation processes described above produce a coarsening of the defect structures observed in slices cut from the as-grown crystal; that is, the etched structures become larger and more distinct. However, the wet oxidation processes (steam or wet oxygen) generally produce a much greater degree of coarsening than dry oxidation. This is true even when the oxides are grown to the same thickness.

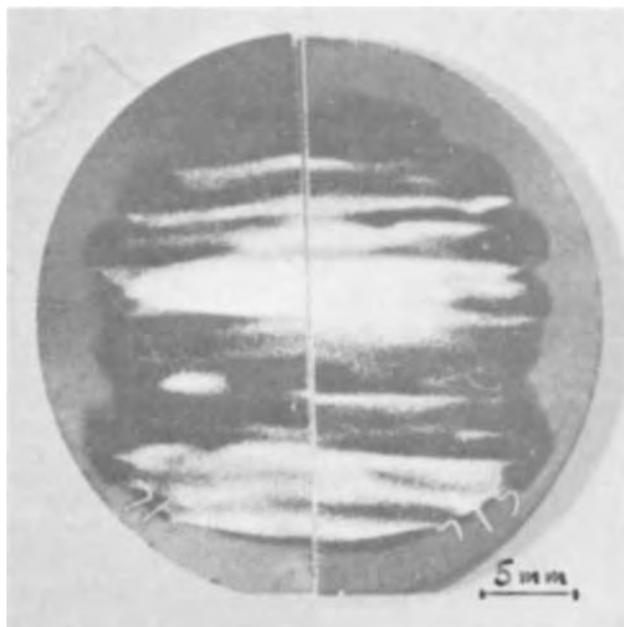

Fig. 5. The bands of structure in the center of this oxidized silicon slice are produced by a lamellar distribution of defects grown into the core of the crystal. The defects around the periphery occur at the oxide-silicon interface and are gettered by the core defects. Slice is from crucible-grown crystal cut 4° off (111) orientation with back surface etched nonpreferentially before oxidation.

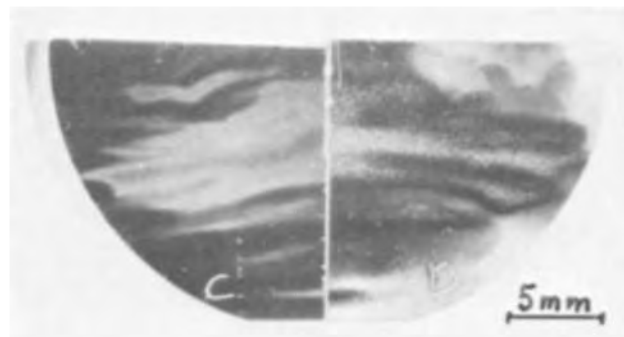

Fig. 6. Core band defects before oxidation (left) and after oxidation (right). Interfacial defects on the right-hand sample (bottom and upper right) are gettered from the surface in the clear areas around the oxidized core bands. Two mils removed from front and back of both samples by nonpreferential etch prior to treatment.

The coarsening of the swirl microstructure after a 2 hr wet oxidation (procedure No. *i*) is illustrated in Fig. 8 and 9. Here it can readily be seen that the small pits present in as-grown crystals develop into large and distinct saucer pits after oxidation. This effect is not due to oxidation of the surface but penetrates through the slice as illustrated in Fig. 4 in which the sample after oxidation was etched nonpreferentially to a depth of 2 mils before structural etching.

When the as-grown crystal has a strongly developed swirl pattern, *i.e.*, one where the pits are numerous and relatively well developed after structural etching, the microstructure produced after oxidation becomes more complex. In increasing order of complexity, the first stage results in increased size and definition of the saucer pits after structural etching. The second stage results in linear arrays of over-lapping saucer pits

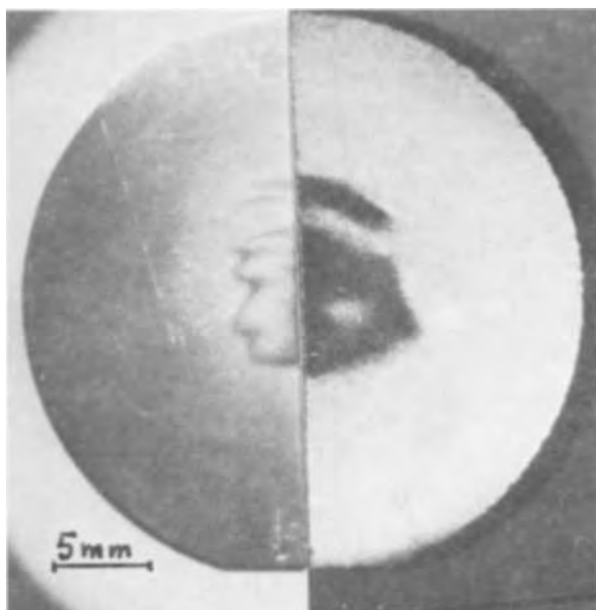

Fig. 7. Defect structure in a core cut close to a (111) plane; after oxidation (left) and core gettering effect on stacking faults in an epitaxial layer (right). Crucible-grown crystal with back surface etched nonpreferentially before oxidation.

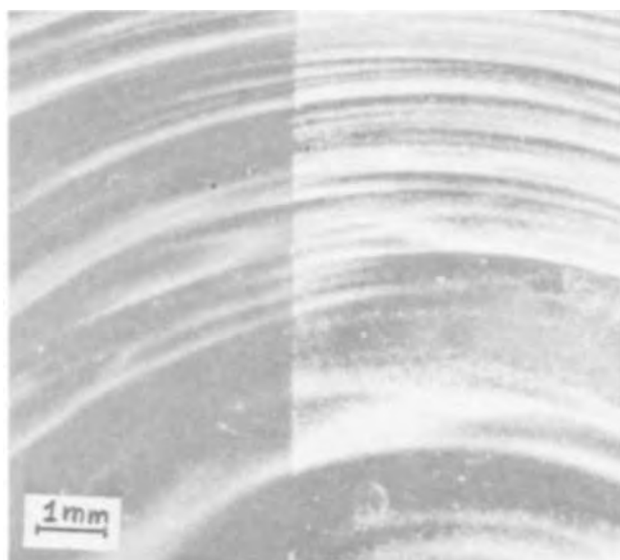

Fig. 8. Swirl structure after oxidation (right) is considerably coarser than before oxidation (left).

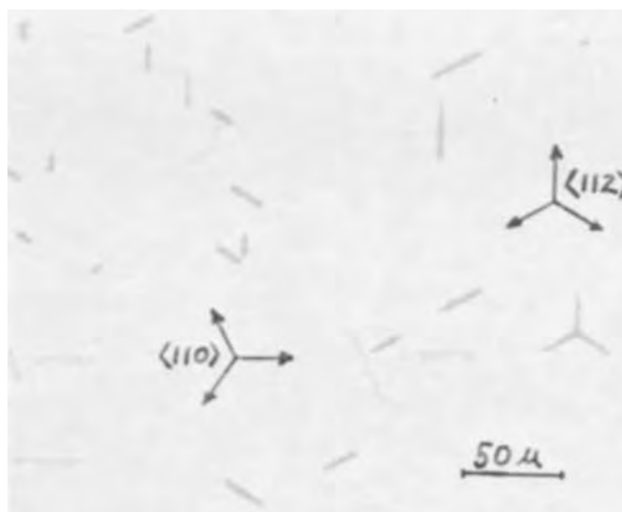

Fig. 10. Detail of a swirl pattern showing copper-like precipitates after oxidation.

aligned in <112> directions. Finally, for very strongly developed swirl patterns in the as-received crystal, oxidation produces structures such as shown in Fig. 10. Here we see the <112> arrays of pits observed in the second stage producing deeply etched, structured grooves. At the same time a number of granular appearing linear structures aligned in the <110> direction appear. These <110> structures are much more superficial than those aligned in the <112> direction. The etch properties of these two types of arrays are evidently due to the fact that the <112> oriented structures are plate-like precipitates penetrating into the crystal whereas the <110> oriented figures are needle-like structures. The result is confirmed by sequential etching of the slice using alternating structural and nonstructural etchants.

The defects observed in crystal cores also exhibit a coarsening effect due to oxidation. The effect of oxidation on core defects is illustrated in Fig. 6. As with defects distributed in the form of growth spirals, this effect also penetrates the slice as seen in Fig. 11. In this figure the front and back surfaces of the sample are shown simultaneously, but offset so as to align corresponding band patterns. The core bands such as illustrated in Fig. 6 (left sample) produce a characteristic defect microstructure after oxidation. As illustrated in Fig. 12, short etching times produce an array of linear grooves oriented in the <110> directions. Further structural etching expands these grooves into trapezoids and finally into large triangular pits.

Considerable variation in the degree of coarsening of as-grown defect structure during oxidation is observed when different oxidation furnaces are used and when different oxidation boats are used. Variations are also observed due to differences in density of defect structure from crystal to crystal in the as-grown condition. A high degree of coarsening is frequently observed when the slices are oxidized in contact with specific "slab" type quartz boats while other boats of the same type produce lesser effects. These results are not altered by conventional techniques of cleaning or etching the quartz. Using a quartz slab which produces a high degree of coarsening, this effect can be

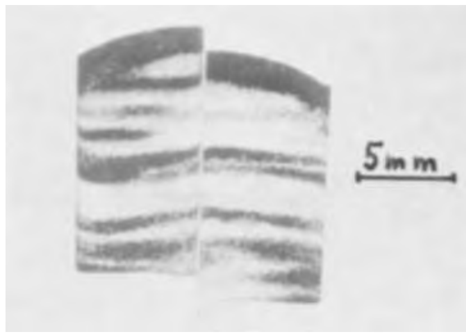

Fig. 11. The front (left) and back (right) surfaces of the same oxidized slice containing core band defects. The shift in core bands over the thickness of the slice is due to the slight misorientation of the slice surface from the (111) planes of the core lamellae. Two mils etch-polished from both sides after oxidation.

significantly reduced by inserting a dummy slice between the oxidized slice and the slab.

In contrast to the bulk defects described above, oxidation also introduces another type of defect which is largely confined to the region of the crystal near the oxide interface and will be referred to as an interfacial defect. The characteristic etch structure of these defects, like some of the bulk defects described above, is a shallow triangular "saucer" pit on (111) surfaces. The defects described in the previous work (13) were found to be of this type which was determined by the disappearance of these structures a few microns below the surface. [Analogous pits are not seen on (100) surfaces.] Unlike the bulk defects however, no evidence has been observed at or near the slice surface of any etch structures prior to oxidation which are precursors of interfacial defects.

It was speculated that the interfacial defect might be due to sodium, a prevalent contaminant and a rapid diffuser in the quartz tubes used for oxidation. To clarify this point some slices were oxidized by the methods described above except that the quartz boat or tube was contaminated with a drop of sodium nitrate solution. The result of such an experiment is shown in Fig. 13. To see the effect of the sodium more clearly the back surface of this slice was etched before oxidation to prevent gettering of the sodium (see below). The upper right-hand quarter which was oxidized in a sodium-contaminated tube clearly *has* a much higher density of defects than the upper left-hand quarter which was oxidized as control in an uncontaminated tube. As seen in Fig. 14 these sodium-induced defects produce the characteristic saucer-shaped etch pit of an interfacial defect. The sodium-induced defects also occur quite close to the oxide interface; although for sufficiently contaminated samples they may penetrate to a depth of 5 to 10μ. As will be seen they behave in other respects exactly like the saucer pits described above and in Ref. (13) which occur adventitiously during oxidation such as those seen in the upper left-hand sample of Fig. 13.

Like the interfacial saucer pits previously described, the sodium-induced defects produced during oxidation also have a strong orientation dependence. This is seen *in Fig.* 15 where a small, roughly hemispherical hole has been etched in the (111) surface prior to oxidation in a sodium-contaminated environment. Figure 15 is a scanning electron micrograph of such a

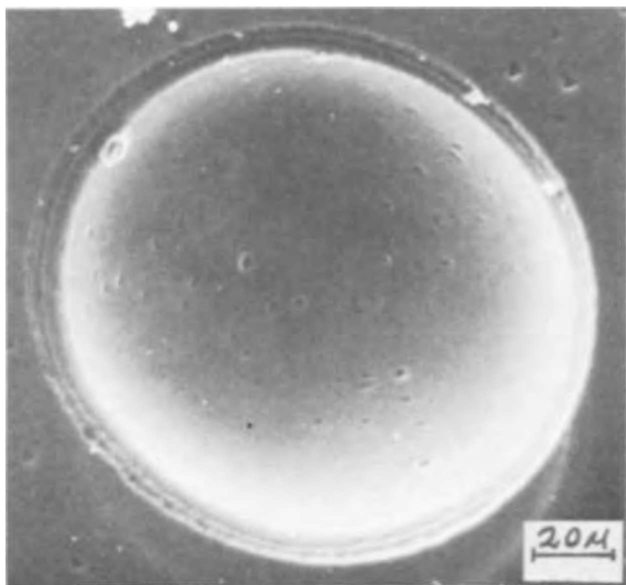

Fig. 15. Scanning electron micrograph of a hemispherical hole in a (111) silicon surface which has been oxidized in a sodium-contaminated environment. Sodium precipitates occur preferentially near the (111) surfaces of the hole.

hole after a structural etch. The sodium defects can be seen to cluster near the regions of the hole surface which are near the (111) orientation.

Gettering effect of bulk defects.—In this section it will be shown that the two types of defects described in the previous section, bulk and interfacial, interact in such a way during the oxidation process that the interfacial defects tend to disappear from regions of the interface which are closely approached by the bulk defect distribution. For reasons given below, this will be referred to as a gettering effect. The result is illustrated in Fig. 16 (upper segments). This slice was oxidized with the back surface etched nonpreferentially to remove saw damage. The left and right halves

Fig. 16. The hazy rings in the upper segments are interfacial defects after oxidation which are gettered by the underlying swirl structure in the clear areas. The bottom segments show the stacking fault distribution produced by the interfacial defects in an epitaxial layer. Back surface nonpreferentially etched before oxidation.

Fig. 17. The interfacial defect structure of Fig. 16 (upper right segment) superimposed on the underlying swirl structure shown in Fig. 4.

were oxidized in two different furnaces but under the same conditions, namely 1200°C for 1 hr in dry oxygen. After removal of the oxide the upper two segments were structurally etched. The ring-like hazy regions, which in microstructure consist of densely packed saucer pits, are readily shown to be interfacial defects of the type described above, since they disappear if a few microns of the silicon surface are removed by a nonpreferential etch and the exposed surface is then re-etched structurally. The clear areas between these rings of structure have been gettered of interfacial defects by the underlying "spiral-growth" defect distribution. This is illustrated in Fig. 4 which depicts the upper right segment of Fig. 16 Sirtl-etched at a depth of 2 mils below the surface. The relationship between the bulk defect distribution of Fig. 4 and the surface defect distribution of Fig. 16 can be visualized by superimposing photographs of the two distributions as in Fig. 17. Here it can be seen that the swirl pattern is located close to the inner edge of the rings of interfacial defects. Interfacial defects produced by sodium contamination during oxidation are also gettered, as seen in Fig. 13, by grown-in bulk defects of the spiral distribution.

Gettering effects due to bulk defects are also observed in crystals having growth cores as seen in Fig. 5, 6, and 18. Figure 18 shows, in the top two quarters, the gettering of interfacial defects by subsurface core defects during oxidation. This slice was cut on the (111) plane and had a nonpreferentially etched back surface during oxidation. Figure 5 and the right-hand segment of Fig. 6 show the disappearance of interfacial defects during oxidation due to the gettering effect of core bands as observed when the slice is cut slightly off the (111) plane. In Fig. 5 the interfacial defect structure consists of a ring of saucer-shaped etch pits around the edge of the slice. This structure disappears due to gettering in the center of the slice inside a scalloped boundary which approximates the perimeter of the core band. A similar effect is seen in the right-hand segment of Fig. 6 where the interfacial defects appear in the lower and upper right areas.

Interfacial defects can be gettered by dislocations induced during oxidation as well as by defects grown into the crystal. One technique which was previously demonstrated to achieve this effect is to leave the back surface in a roughened condition during oxidation (13). The effect of this treatment can be seen by comparing the left-hand half slice shown in Fig. 19 with the slice shown in Fig. 5. The sample shown in Fig. 19 was oxidized with the back surface in a lapped condition while that shown in Fig. 5 was oxidized with the back surface etched nonpreferentially. The absence of interfacial defects around the perimeter of Fig. 19 is due to the gettering effect of the lapped back surface during oxidation. As can be seen in Fig. 19 this condition of the back surface during oxidation does not have any gettering effect on core-type defects. The

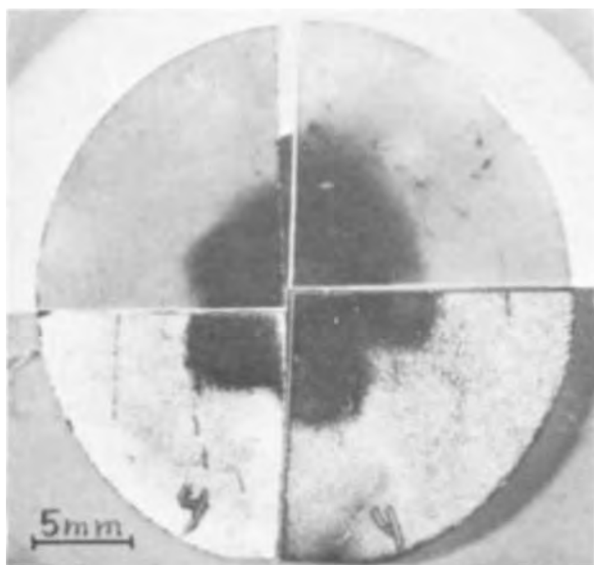

Fig. 18. Gettering of interfacial defects by a core after oxidation (upper segments) and the effect on stacking fault nucleation in a subsequent epitaxial layer (lower segments). Fig. 20. A scribe mark produced before oxidation getters interfacial defects around the rim of this slice but not bulk defects occurring in the core region. Detail from Fig. 5.

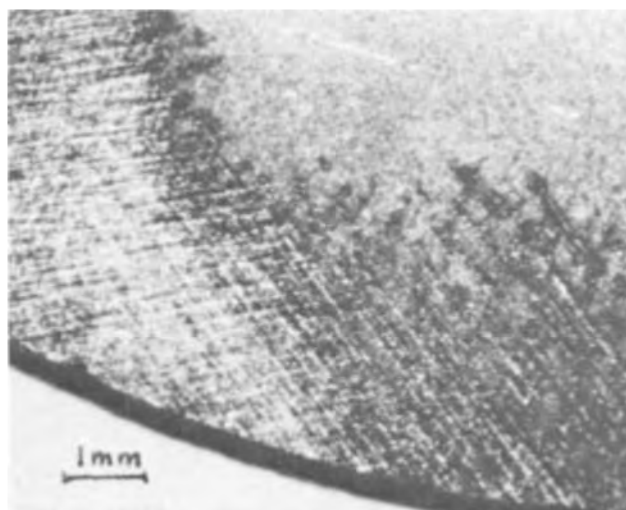

Fig. 21. The gettering of interfacial defects (upper right) by dislocation array (bottom and left) produced by thermal shock during oxidation.

effect of process-induced dislocations is also illustrated in Fig. 20 and 21. In Fig. 20 the dislocations which propagate from the scribe mark during oxidation getter the interfacial defects around the rim of the slice. The same effect is seen in Fig. 21. This slice was oxidized with the central region in contact with a spacer on a quartz slab. The region with a high density of slip in the figure (bottom and left) overhung the spacer and slip is due to the thermal shock produced in this region when the slice was inserted into the oxidation furnace. The thermal shock of the central region was considerably less because it was in good thermal contact, through the silicon spacer, with the underlying quartz boat, a relatively large thermal mass. The hazy regions in this sample consist of interfacial precipitates and, especially at the boundary of the slipped region, one can clearly see the gettering effect of the dislocations introduced by thermal shock during oxidation. It can also be observed from Fig. 20 that the dislocations induced during oxidation do not produce any apparent gettering of the grown-in defects in the crystal core. In fact, it is observed that grown-in bulk defects in general are resistant to gettering by process-induced dislocations.

Nucleation of stacking faults.—Both interfacial defects, and bulk defects which intersect the oxidized surface, are found to nucleate stacking faults in epitaxial layers. Epitaxial growth conditions and the method of observing the stacking faults are given in the section on Experimental Procedure. Substrates from the same lots which had not been oxidized produced epitaxial layers with a uniformly low stacking fault density averaging less than $10/cm^2$.

The nucleating effects of interfacial defects are clearly seen in Fig. 16, 18, and the right-hand segments of Fig. 13. These slices were oxidized and after removal of the oxide the lower segments received an epitaxial deposit. In all three cases there is a clear-cut correlation between interfacial defects seen in the upper segments after oxidation and stacking faults nucleated in the epitaxial layer on the lower segments.

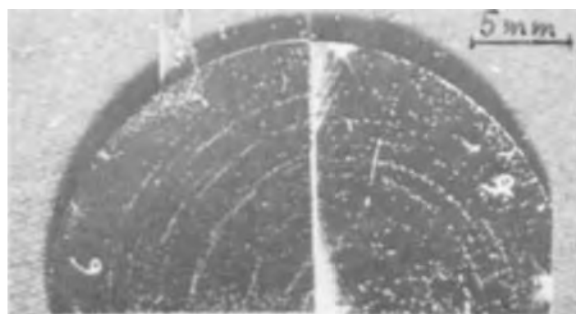

Fig. 22. The swirl pattern defects produced after oxidation (left) nucleate stacking faults (right) in a subsequent epitaxial layer. Back surface lapped before oxidation.

In the case of Fig. 13 the stacking fault density is extremely high due to deliberate sodium contamination. Figures 13, 16, and 18 also illustrate the effect of gettering on stacking fault nucleation. The underlying spiral defect pattern in Fig. 13 and 16 has gettered ring-like regions of the surface which are relatively free of interfacial defects and therefore have a much reduced stacking fault density. In Fig. 18 the same effect is seen in the core region. (Note also in Fig. 18 the gettering effect on stacking faults of the numerals, scribed before oxidation.)

To observe the nucleation of stacking faults by bulk defects it is generally necessary to suppress nucleation by interfacial defects. This can usually be done by oxidation of the slice with the back surface in a lapped or sawed condition. As mentioned above such a procedure has the effect of eliminating interfacial defects, but does not have any observable gettering effect on bulk defects. The result is illustrated in Fig. 22. Both segments of this slice were oxidized together for 2 hr in wet oxygen with back surfaces lapped. After oxide removal the right segment then received an epitaxial deposit. After structural etching the rings of swirl-type defects seen on the left (oxidized) sample can be seen to correlate closely with rings of stacking faults in the right (epitaxial) sample.

It is frequently difficult to distinguish a stacking fault nucleated by a bulk defect from one produced by an interfacial defect when both are present. However, if the bulk defects occur in the well developed form shown in Fig. 10 these linear structures also result in linear arrays of stacking faults as shown in Fig. 23.

Stacking faults are also nucleated by the core type of bulk defects. Again, as with swirl-type defects, it is not always easy to distinguish the stacking faults nu-

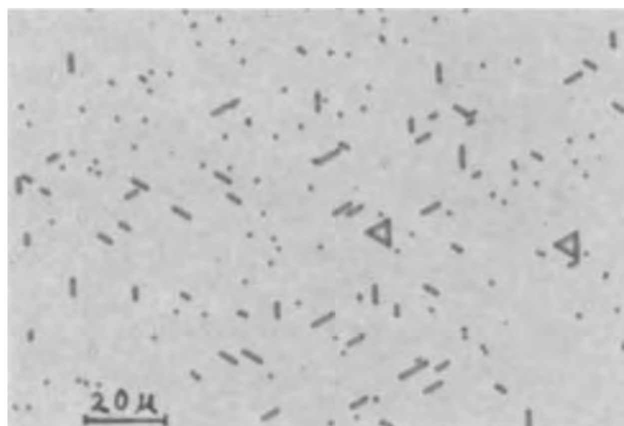

Fig. 24. Microstructure of the epitaxial layer from Fig. 19 (right) showing high density of linear stacking faults produced by core defects of the type shown in Fig. 12.

cleated by core defects unless those nucleated by interfacial defects are suppressed by gettering. An example is seen in Fig. 19 which shows a slice gettered during oxidation by means of a lapped back surface. As seen in the left-hand sample the gettering effect of the back surface does not prevent development of core defects during oxidation. (The same result as for swirl defects seen in Fig. 22.) The right-hand half of the sample shown in Fig. 19 received an epitaxial deposit subsequent to oxidation. The stacking fault distribution in this sample is seen to correlate closely with the distribution of defects in the core bands.

The linear type of defect found in core bands, as illustrated in Fig. 12, invariably produces a very high percentage of linear stacking faults in epitaxial overgrowths as opposed to the triangular stacking faults nucleated by saucer defects such as seen in Fig. 14. Such linear stacking faults are illustrated in Fig. 24. It can also be seen from this figure that the linear faults are equal in length or shorter than a side of a triangular fault. There are also many dislocation pairs separated by distances of this order. In many cases the stacking faults nucleated by linear-type core defects disappear entirely leaving only the dislocation pairs, as seen in Fig. 25.

As described above the incidence of interfacial defects on (100) surfaces after oxidation is much less common than on (111) surfaces. This was illustrated for sodium-induced defects in Fig. 15. The nucleation of stacking faults on oxidized (100) surfaces is similarly rare. Figure 26 illustrates the orientation de-

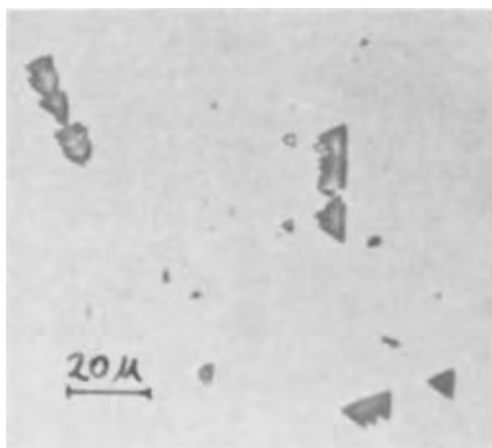

Fig. 23. These oriented lines of stacking faults are nucleated in epitaxial layers grown over substrates containing linear defects such as shown in Fig. 10.

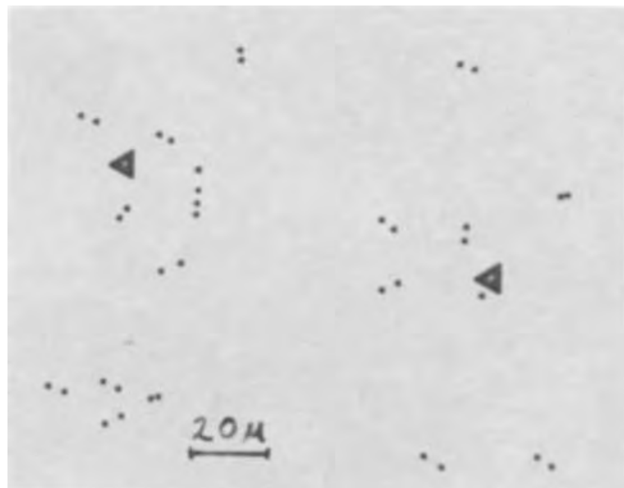

Fig. 25. Dislocation pairs seen in epitaxial layers grown over banded core defects appear to be annealed linear stacking faults.

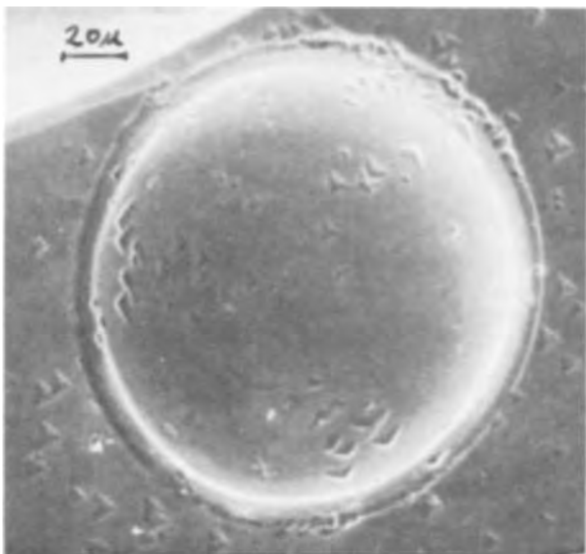

Fig. 26. Scanning electron micrograph of the stacking fault distribution in an epitaxial layer grown in a hemispherical hole on a (111) surface. The surface of the hole was previously oxidized in a sodium-contaminated environment as in Fig. 15.

pendence of stacking fault nucleation in a hemispherical hole previously oxidized in a sodium contaminated environment similarly to the sample shown in Fig. 15. Again, it can be seen that stacking faults nucleate preferentially close to the points of tangency of (111) planes with the hemispherical surface on which the epitaxial layer was deposited.

Interpretation of Results

The defect distributions described above which are observed in as-grown crystals have a striking similarity to the resistivity striations previously described (1-5). This suggests a common origin, namely, growth rate fluctuations. The spiral ramp type of growth inhomogeneity which is congruent with the "swirl"-type defect structures illustrated in Fig. 1 and 4 has been explained as due to a temperature fluctuation of one cycle per rotation of the crystal (1-3). This is produced when the temperature distribution around the circumference of the growth interface has one maximum and one minimum. The double spiral pattern seen in Fig. 2 where both spirals have the same rotational sense can be explained by a temperature distribution with two maxima separated by two minima around the circumference of the growth interface, thus producing two cycles of temperature fluctuation per crystal rotation.

Figures 5, 6, 11, and 19 show that the core defect distributions observed in this work are congruent with the faceted growth inhomogeneities previously reported (4,5); that is, the defects appear in a series of lamellae of alternating defect density which are parallel to (111) planes and located within the core region of the crystal. If the slice cut from the crystal is slightly misoriented from the <111> direction, this results in a series of bands of alternating defect density on the surface of the slice. The shift in the position of these bands from the front to the back surface of the slice as in Fig. 11 can, in fact, be used to estimate the misorientation of the slice surface which is equal (in radians) to the shift in position of the striations divided by the sample thickness. In the case of the sample of Fig. 11, the result is about 4° from the <111> direction toward the <110> direction.

The result of oxidation on the microstructure of grown-in defects implies that the coarsening of as-grown defect structure during oxidation is due to the decoration of the defects by impurities introduced in the oxidation process. The fact that the coarsening effects penetrate the slice indicates that these impurities have high diffusion constants in silicon similar to copper, nickel, iron, manganese, or cobalt. The fact that many of these impurities also diffuse rapidly in quartz at the oxidation temperature probably explains the result obtained with quartz slabs as oxidation boats. It is probable that some degree of contamination also comes from diffusion of such impurities through the wall of the quartz furnace tube. In fact, it appears that the presence of contaminants from this class of impurities cannot be completely eliminated from conventional oxidation systems in spite of precautions taken to purify and clean the components of the system. If grown-in defects are present in the crystal, it is probable that these contaminants will precipitate on such defects.

The bulk defects exhibited by oxidized swirl pattern (Fig. 10) have a form which is very close to the copper precipitates observed by Schwuttke (6) in the form of needles oriented in the <100> direction and platelets which bisect the angles made by the needles when observed in the <111> direction.

The properties of linear defects produced in core bands (Fig. 12) could be explained if these defects existed in the form of triangular plates lying in (111) planes perpendicular to the growth direction. In a slice cut slightly off the (111) orientation only one edge of such a platelet could lie in the plane of the sample and would be the first to etch. On deeper etching the whole platelet would be delineated as in Fig. 12. This mode of etching suggests that these defects are very similar to the stacking faults reported by a number of workers (16-21) to be produced when surfaces damaged by abrasion or vacuum annealing are oxidized. The difference is that the faults observed in this work penetrate the crystal so that their appearance is not due to oxidation as such, but rather to the accompanying processes of annealing and/or the precipitation of fast diffusing impurities. A similar generation of bulk stacking faults is reported by de Kock (9). Thomas (17) and Lawrence (18) showed that linear defects of the type seen in core striations also nucleate the precipitation of copper.

The above results do not throw much light on the nature of the grown-in defects prior to oxidation. It is therefore not possible to decide whether these defects might be produced by oxygen as shown by Schwuttke (16) or by vacancies as proposed by Dash (11), Plaskett (8), and de Kock (9). However, the resemblance to copper-like structures after oxidation suggests a third possibility, namely, that these bulk defects are initially due to copper, which combines a very low equilibrium segregation constant with a very low solid solubility. Because of its small segregation coefficient, fluctuations in growth rate will produce large changes in effective segregation coefficient and therefore large fluctuations in the amount of copper incorporated into the growing crystal. Because of its low and strongly temperature dependent solubility, the copper may be expected to precipitate out readily during cooling from the growth temperature. This idea is supported by the observation that bulk defects tend to be most prominent in crystals grown at high rates.

The interfacial defects described in this work which occur adventitiously during oxidation and those which are introduced deliberately during oxidation, by contamination with sodium, can be identified with the "saucer" defects described in Ref. (13) which produced the same etch structures. This is to say both nucleate stacking faults (see Fig. 13, 16, and 18) and are gettered both by dislocations (see Fig. 21) as well as by regions of surface damage (see Fig. 20 and 22). In addition to these previously described properties of interfacial defects this work has found that they are located within a few microns of the oxidized interface. Unlike the bulk defects described above, however, no evidence has been observed at or near the slice surface of any structures prior to oxidation which are precursors of interfacial defects. That is to say, the inter-

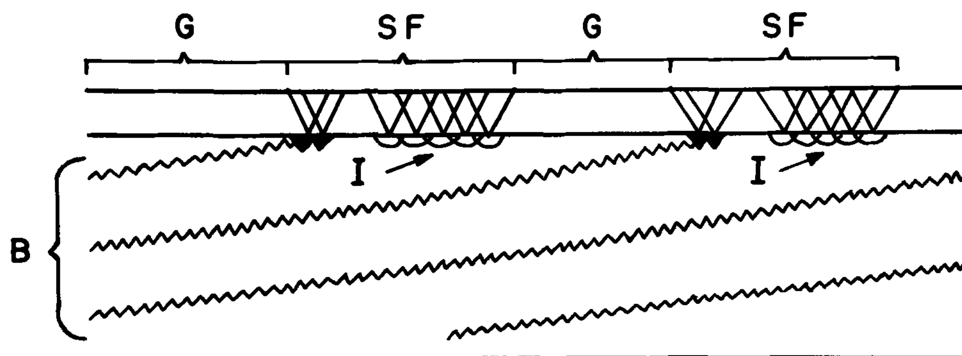

Fig. 27. Cross section through a slice explaining the relationship between bulk and interfacial defect structures seen in Fig. 17. The gettering effect, G, of the bulk defect distribution, B, is most pronounced where the bulk defect distribution approaches the surface of the slice. Both interfacial defects, I, and the bulk defect distribution, where it intersects the surface of the slice, nucleate stacking faults, SF.

facial defect is not due to the heterogeneous nucleation of impurities precipitating on a pre-existing site but rather the homogeneous nucleation of precipitates at the oxidized interface. Another property of interfacial defects which has been demonstrated here is that they are gettered by bulk defects of both the core and spiral patterns. Examples of core gettering are Fig. 5 and the upper segments of Fig. 18. Examples of spiral gettering are the upper segments of Fig. 16.

The variable density of interfacial defects can be explained by the variable gettering due to bulk defects such as those described above. This is understood with reference to Fig. 27 which diagrammatically shows a cross section of a slice such as the one shown in Fig. 4, 16, and 17. The spiral growth pattern is shown as concave toward the upper surface of the slice (as demonstrated in Fig. 4). The result is a periodic variation of spacing between this gettering sink and the surface, the separation being a maximum just at the outside edge of the swirl pattern and a minimum at the inside edge of the swirl pattern. This explains why the gettering effect of the spiral growth surface is greatest inside the swirl contour and least outside the swirl contour as seen in Fig. 17.

The difference between the left and right halves of the slice shown in Fig. 16 is believed to be due to the fact that the furnace used for oxidizing the left half was somewhat more contaminated so that more of the subsurface gettering structure was saturated with impurities during oxidation. In general, it has been found that in the absence of a gettering surface on the back of the slice during oxidation, considerable variations of this type exist. In fact, it is difficult with a tube-type oxidation furnace to maintain a (111) surface free of interfacial precipitates in the absence of some type of gettering sink.

The observations of the sodium-like species responsible for interfacial defects may be explained as follows. If the quantity of sodium contamination is small and the back surface of the slice is lapped or otherwise damaged prior to oxidation, the sodium will be quantitatively removed by this gettering sink. If the quantity of sodium present is large enough to saturate this gettering sink or to saturate the crystal in the absence of such a sink at the oxidation temperature, then, as the crystal is cooled down after oxidation, the sodium will be forced to precipitate either in the bulk or at the surface of the crystal. Since the diffusion constant of sodium is very high (22) it can freely move to either bulk or surface sites. Which site the sodium reaches will depend both on its proximity and affinity for the site. Where the bulk defect distribution approaches closely to the surface it getters sodium from the surface, indicating that it has a greater affinity for this species. Where the bulk defect distribution is further away from the surface, some sodium will precipitate at the oxide interface because of its closer proximity, in spite of the fact that this site has a smaller affinity for sodium.

As illustrated in Fig. 27 it has been shown that epitaxial stacking faults are nucleated both by interfacial defects and also by bulk defects where they intersect the surface of an oxidized slice. In regions where bulk defects below the surface getter interfacial nucleii (*e.g.*, Fig. 16 and 18) the stacking faults also disappear in the overlying epitaxial layer. The stacking faults produced by interfacial defects may also be eliminated if the back surface is left in a lapped or otherwise damaged condition during oxidation. This is probably due to the network of dislocations introduced by such a treatment and is similar to the gettering effect of dislocations seen in Fig. 21. Such a treatment does not however prevent the formation of stacking faults due to bulk defects (*viz.*, Fig. 19 and 22). These can only be eliminated either by preventing the formation of defects during crystal growth or by eliminating the impurities which precipitate on such defects in processing.

The linear stacking faults (Fig. 24) produced by core band defects seem to have a tendency to anneal out of the slice during epitaxial growth leaving as residue a shallow dislocation loop such as shown in Fig. 25.

The observation that stacking faults are relatively rare in epitaxial layers grown on previously oxidized (100) substrates compared with (111) substrates can be interpreted in the light of Fig. 15 and 26. It appears that this result is due to the strong tendency of interfacial precipitates to prefer (111) surfaces.

Conclusions

In summary, a relationship has been established between two types of defects in single-crystal silicon and two types of impurities which have properties similar to sodium and copper. The following properties of the defects have been demonstrated.

Properties of bulk defects:

1. They are present in the crystal, as grown, and distributed congruently with growth rate inhomogeneities either of the spiral or of the core (faceted) type.
2. They produce etch structures after oxidation which are similar to copper precipitates. The formation of these structures is not inhibited by known copper gettering centers such as dislocations or regions of surface damage.
3. Where close to the surface, they act as gettering sites during oxidation for the species responsible for interfacial defects and thus inhibit the nucleation of stacking faults by such defects in epitaxial layers.
4. Where they intersect an oxidized surface, they nucleate stacking faults in epitaxial layers. In particular linear defects nucleate linear stacking faults which tend to anneal out of the epitaxial layer.

Properties of interfacial defects:

1. They occur after oxidation at or near the oxide-silicon interface with a strong preference for (111) surfaces.
2. They are not correlated with observable surface structures prior to oxidation.
3. They are greatly enhanced by deliberate sodium contamination during oxidation.

4. They are gettered during oxidation by damaged regions of the crystal, by dislocations, and by bulk defects while lie close to the oxide interface.
5. They nucleate stacking faults in epitaxial layers.

Manuscript submitted June 12, 1970; revised manuscript received ca. Oct. 25, 1971. This was Paper 98 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

ABSTRACT

Electrolytic effects, crystal coloration, and charge storage observed when an electric field is applied to single crystals of calcium orthovanadate at temperatures above 700°C are shown to be associated with oxygen migration and the creation of V^{4+} centers in the crystal. The oxygen transport number is shown to be constant at 0.9 over the temperature range 650°-900°C with an activation energy for predominantly ionic conduction of 1.05 ± 0.05 eV. The amount of recoverable charge stored in the crystal depends on the sample used and also on the charging current, but is about 15% for an average crystal with a charging current density of several milliamperes/square centimeter. The open-circuit voltage is of the order of several volts. Deterioration of the bulk material during electrolysis and barrier effects appear to be the major limitation on the use of the material as a charge storage medium.

Calcium orthovanadate has been grown as a single crystal and investigated for use as a laser host material (1, 2). Crystals grown from melts having stoichiometric proportions and in an atmosphere of excess oxygen are yellow in color, while growth in an atmosphere deficient in oxygen results in a strong black coloration. It has been found that a similar black coloration can be electrolytically induced into crystals of calcium orthovanadate by the application of an electric field at temperatures above about 700°C (3). On removal of the applied field, colored crystals are found to contain an excess charge which can be released by short-circuiting the crystal through an external circuit. This suggests applications such as current integrating devices.

Electrolytic coloration is well known in the alkali halides (4) and normally requires the migration of an ionic species (and/or its associated vacancy) with the injection and capture of electrons at an appropriate site in the crystal lattice. The main feature of the orthovanadate is the high current density achieved (10^{-3} A/cm^2 at tens of volts/centimeter) compared with the alkali halides where 10^{-8} A/cm^2 at hundreds of volts/centimeter is more usual. In the alkali halides, the characteristic optical and electrical properties arise from electrons captured at halide ion vacancies to form F-centers. In calcium orthovanadate, $Ca_3(VO_4)_2$, the migrating ionic species is likely to be oxygen, while an optical absorption which causes a black coloration is known in other vanadium compounds to be due to V^{4+} ions (5). In this paper we report experiments which confirm these suggestions and describe an investigation of the charge storage process.

Key words: solid-state electrolysis, ionic conductivity, charge storage, oxygen transport, calcium orthovanadate, and electrolytic coloration.

Experimental

Measurements of the oxygen transport number and of electrical conduction were undertaken in the apparatus shown in Fig. 1. The crystal was held between two ceramic tubes by spring pressure with a concentric pair of smaller diameter tubes allowing gases to be circulated near the crystal face. The central tubes also carried platinum wires which made contact to platinum electrodes evaporated on to the surface of the crystal. The crystal and electrode system were mounted within a small muffle furnace and a side window was used to view the crystal during the experiment. The furnace temperature was measured and controlled by means of an internal thermocouple and the gas flow rate and composition were regulated by an external gas mixing system. The crystals were Czochralski-grown and were prepared by cutting with a wire saw

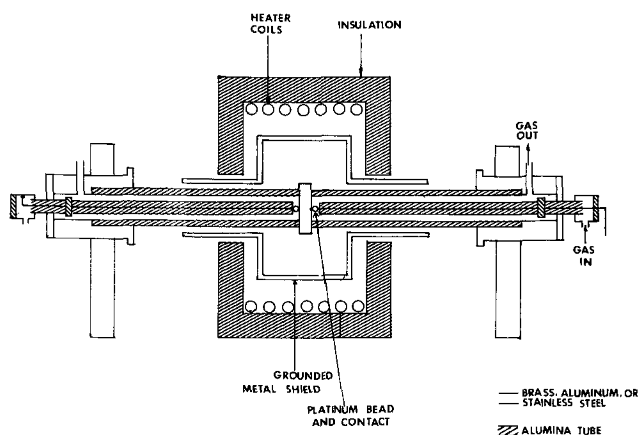

Fig. 1. High-temperature apparatus for conductivity and oxygen transport measurements.

and by subsequent mechanical polishing. A Keithley 610B electrometer having an input impedance of 10^{14} ohms was used to measure open-circuit voltages or emf's, while current was measured by a potentiometric recorder connected across a 100 ohm resistance placed in series with the crystal.

Results

Oxygen Transport

The theory and practice of transport number measurements have been discussed by Mitoff (6). If the partial pressure of a gaseous ion which is involved in transport within a membrane is p_1 and p_2 on either side of the membrane, respectively, an emf is developed across the membrane given by

$$E_{\text{theor}} = \frac{2.3\ RT}{4\mathbf{F}} \log \frac{p_1}{p_2} \quad [1]$$

where R is the gas constant, $\mathbf{F}$ is the Faraday constant, and T is the absolute temperature. However, if conduction within the membrane occurs also by the movement of other ions or by electrons, the observed emf, E_{exp}, is less than that calculated from Eq. [1] and the transport number t_i is defined by

$$t_i = \frac{E_{\text{exp}}}{E_{\text{theor}}} = \frac{\sigma_i}{\sigma_{\text{total}}} \quad [2]$$

The emf measured as a function of temperature between evaporated platinum contacts of an area much less than that exposed to the gas is shown in Fig. 2 for the case of pure oxygen ($p_1 = 1$ atm) maintained at one surface and air ($p_2 \sim 0.2$ atm) maintained at the other. Results for activated zirconia are also shown since it is known (7) that the transport number for this material is very close to unity and this fact was used as a form of calibration for the apparatus. The transport number calculated for calcium orthovanadate is shown as a function of temperature in Fig. 3. The transport number is constant at 0.9 over the temperature range from 650° to 900°C and the conduction process in as-grown crystals is therefore predominantly due to oxygen ion migration.

Measurements were also made of the conductivity of the crystals as a function of temperature, using either a constant current of less than 10^{-8} A/cm² or a small a-c voltage in an attempt to avoid polarization effects. In both cases the conductivity was found to be thermally activated with an activation energy of 1.05 ± 0.05 eV. The magnitude of the d-c conductivity for nearly stoichiometric crystals under these conditions was of the order of 10^{-8} (ohm-cm)$^{-1}$ at $T = 800$°K. The conductivity was larger for crystals grown in an atmosphere deficient in oxygen, although such crystals

were not colored as strongly as those colored electrically. The activation energy for conduction was similar for as-grown crystals of both yellow and black color.

Charge Storage

General.—Crystals were cut in the form of flat slabs 1-2 mm in thickness and 0.5 to 1.0 cm² in area. Platinum contacts were evaporated to completely cover the slab faces and the crystals were then mounted within the furnace. When the crystal was heated above 700°C and a voltage applied corresponding to a field of the order of 30-40 V/cm a black coloration was observed

to enter the crystal from the negative electrode and sweep across the crystal. The magnitude of the threshold voltage was not particularly reproducible suggesting that electrode conditions were of importance. On the assumption that the color was due to the injection and migration of electrons, an effective carrier mobility and concentration could be computed from the transit time for the color and from the calculated conductivity. This assumes a uniform field distribution within the crystal which is probably unwarranted and the calculation can only be regarded as providing an order of magnitude for the quantities. The values obtained for the effective mobility and carrier concentration at 730°C were 1×10^{-4} cm²/V-sec and 3×10^{19} cm^{-3}, respectively. Removal of the external field showed that the blackened crystal retained a potential difference between the electrodes of several volts with a polarity the same as that of the applied voltage. Short-circuiting the electrodes produced a current in the external circuit which decayed with time accompanied by the movement of the black color back toward the negative electrode.

Current and voltage as a function of time.—The crystal current and open-circuit voltage measured as a function of time are shown in Fig. 4. For voltages below 30 V/cm, no color could be observed to enter the crystal and the current decreased with time from an initial value indicating effects due to polarization. At higher voltages, carrier injection was observed and the current in the crystal increased monotonically. The open-circuit voltage measured on removal of the external voltage was found to increase with applied voltage, although no simple relationship could be deduced. The variation of open-circuit voltage with the charging time for fixed applied voltage was also complex as shown in Fig. 5. The longer charging times produced a smaller initial open-circuit voltage, but the time dependence was less pronounced. A similar effect has been observed in polyethylene (8).

Short-circuiting the electrodes caused a discharge current to flow in the external circuit. The discharge current time constant was longer than that for the charging process and integration of the charging and discharging current over time indicated that for an average crystal about 15% of the charge was recoverable. It may be noted that in a previous set of experiments (3) a larger recovery rate was obtained (up to 80%), particularly in crystals grown from a stoichiometric melt. These experiments were carried out with

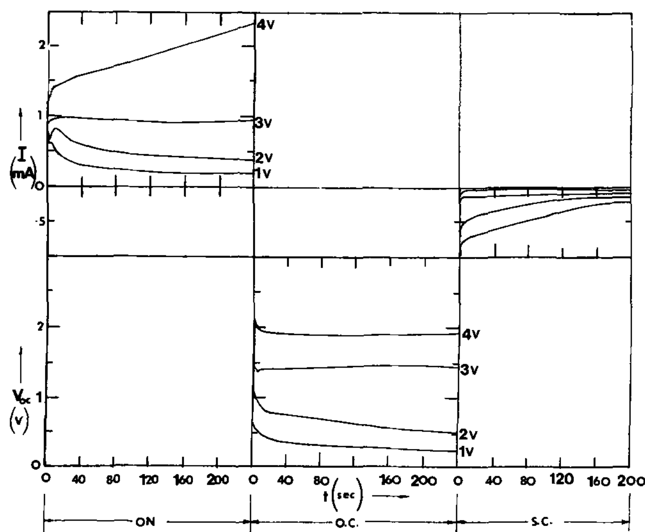

Fig. 4. Time dependence of current (upper) and open-circuit voltage (lower) for a cycle, i.e., applied voltage on, open circuit, short circuit. Voltages marked on diagram are those applied from the external voltage source. Crystal thickness 1.07 mm.

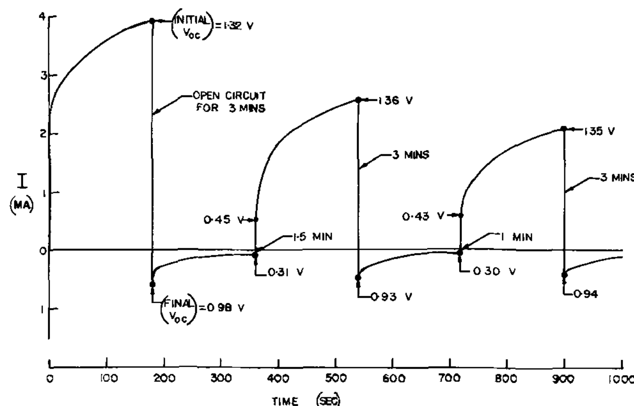

Fig. 6. Successive charging and discharging current cycles for a fixed applied voltage of 4V across 1 mm thick crystal.

charging currents about five or ten times smaller than those used in the present experiments and this could have had some bearing on the difference in results. The effect of repeated charging and discharging cycles is shown in Fig. 6. The current flowing for a given applied voltage becomes smaller on successive cycles, indicating a change in the bulk material or in the electrodes during the course of charge injection.

Potential distribution.—The internal potential distribution during coloration was estimated by wrapping a platinum wire around the center of a crystal of about 1 cm thickness and recording the potential of this electrode with respect to the left-hand electrode using a second Keithley 610B electrometer. As shown in Fig. 7, the electrode potential was roughly one half the applied voltage for the uncolored crystal but became smaller if the color entered from the left-hand side, or larger when the color entered from the right-hand side. The simplest interpretation of this behavior is that the conductivity of the blackened region of the crystal is higher than that of the uncolored material due to the presence of the injected charge.

Crystal decomposition.—On cooling crystals which had had currents of several mA/cm² passed for 10 min or so with the same polarity being maintained, the bulk material was found to become clouded and in some cases to be severely cracked. In addition the negative platinum electrode became blackened with

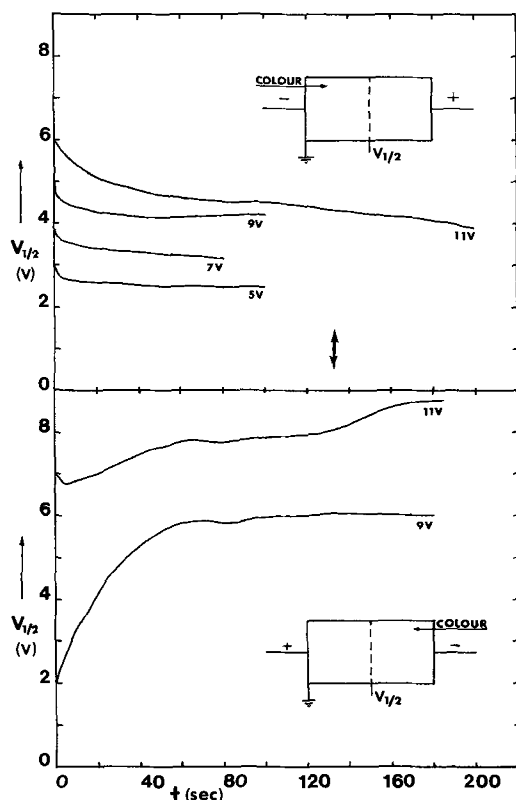

Fig. 7. Voltage measured between a central electrode and ground for various voltages applied across the full crystal; upper diagram, as the color is injected from the grounded electrode; lower diagram, as the color is injected from the ungrounded electrode. Arrows indicate approximate times when cloud is at mid-point and has completely traversed crystal.

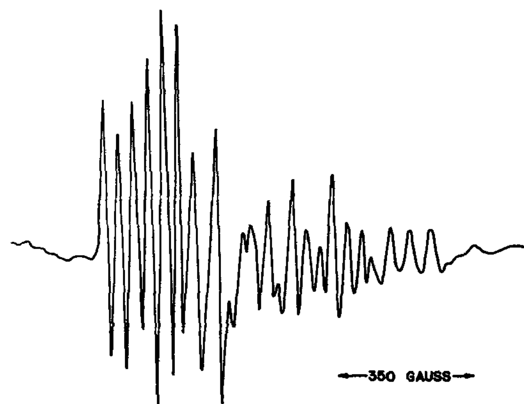

Fig. 9. Electron paramagnetic resonance spectrum of color centers in electrolytically colored calcium orthovanadate.

some visible evidence of diffusion of the electrode material into the crystal. Although the color of the positive electrode was unchanged, microscopic examination showed large depressions had been formed under the electrode indicating that material had been lost from the crystal. These observations are consistent with electrolytic action within the material, with the movement of oxygen vacancies toward the negative electrode and the release of gaseous oxygen from the positive electrode.

Optical effects and electron paramagnetic resonance.—The optical absorption spectrum recorded by a Cary Model 15 spectrophotometer is shown in Fig. 8 for a yellow and blackened crystal, respectively. The black color is seen to arise from a broad absorption band extending the width of the visible spectrum (4). Direct evidence that the electron is associated with a vanadium site is shown by the electron paramagnetic resonance spectrum measured at 21 GHz at 70°K and shown in Fig. 9. A full analysis of this spectrum has not yet been carried out, but the two sets of eight lines could either arise from electrons trapped at two types of vanadium sites or from an electron trapped between a vanadium site and an associated defect such as an oxygen vacancy. Such V^{4+} sites have an electron spin $S = 1/2$ and a nuclear spin $I = 7/2$ leading to a single resonance containing $(2I + 1 = 8)$ lines. The concentration of paramagnetic spins in a colored crystal was found to be of the order of 10^{19} spins/cm³ which is in agreement with the carrier concentration estimated from the electrical data. As far as could be ascertained the resonance signals were similar for electrically colored crystals and for those grown in an oxygen-deficient atmosphere.

Discussion

The transport measurements indicate that conduction in stoichiometric calcium orthovanadate occurs predominantly by the movement of oxygen ions. The transport number of 0.9 implies that an emf may be developed in a cell based on calcium orthovanadate which is close to the thermodynamic maximum. The internal impedance of several such cells was in the range 10^5-10^6 ohms when operated in the temperature range near 1000°C.

The mechanisms of charge injection and crystal coloration in alkali halides and calcium orthovanadate are compared in Fig. 10. In the alkali halides, coloration involves the migration of halide ions toward the positive electrode, the movement of halide ion vacancies toward the negative electrode, and the injection of electrons from the negative electrode to form neutral F-centers at the halide ion vacancy sites. In the orthovanadate, where measurements show that oxygen migration is predominant, the corresponding process is that of oxygen migration to and release from the positive electrode, oxygen vacancy migration to the negative electrode, and electron injection and capture at oxygen vacancy sites. Local neutrality requires two electrons for each vacancy site and the optical and electron paramagnetic resonance results suggest that these electrons are located at vanadium sites adjacent to the vacancy. Electron migration by hopping between

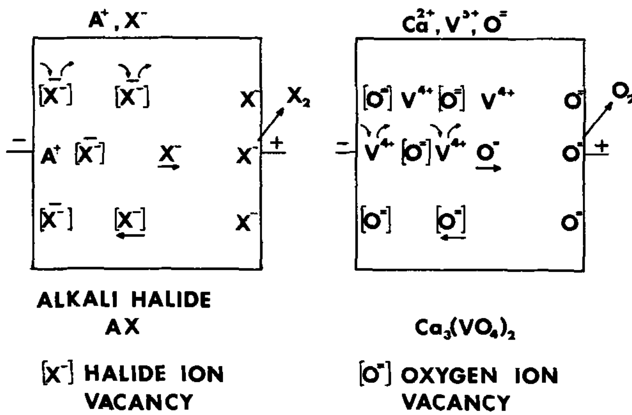

Fig. 10. Comparison of the mechanisms of electrolytic coloration in alkali halides and in calcium orthovanadate.

V^{4+} and V^{5+} sites is well known in vanadium compounds and the large number of available V^{5+} sites may account for the high current densities observed in the orthovanadate compared with alkali halides.

A full analysis of time-dependent space charge injection into insulators is normally difficult. In the present case, the evidence for local neutrality in the colored region, the comparable ionic and electronic contributions to the total conductivity, and the well-defined boundary of the charged region allow a quasi-static approach to be used to interpret the processes involved. This is illustrated in Fig. 11. The crystal is divided into colored and uncolored regions with a boundary at d, the conductivity in the colored region σ_1 being due to an ionic component σ_i and an electronic component σ_e, while that in the uncolored region σ_2 is totally ionic σ_i. The ratio of these conductivities is conveniently written as

$$\frac{\sigma_1}{\sigma_2} = 1 + \frac{\sigma_e}{\sigma_i} = 1 + m \qquad [3]$$

Making an initial assumption of no space charge accumulation within the crystal, the partly colored crystal of area A can be regarded as two resistances in series

$$R_1 + R_2 = \frac{d}{\sigma_1 A} + \frac{(L-d)}{\sigma_2 A} \qquad [4]$$

and the current and voltage distribution calculated as a function of the position of the boundary. Three quantities can be compared with experiment: the values of current when the boundary is at $d = 0$ and at $d = L$, and the voltage measured at an electrode situated at the mid-point of the crystal. The current should rise from an initial value $\sigma_2 AV/L$ to a value of $\sigma_1 AV/L$, an increase of $(1 + m)$ due to the injection of electrons into the sample. It is easily shown that the voltage measured at an electrode placed at $L/2$ is given as a function of $y = d/L$ by the expression

$$V_{L/2} = \frac{V}{2[y + (1-y)(1+m)]} \qquad [5]$$

This expression has a value of $V/2$ when the conductivity is uniform (with the boundary at $d = 0$ and $d = L$, respectively) and has a minimum value of $V/(2 + m)$ when the boundary is at $d = L/2$. A similar analysis can be made for the injection of electrons at $d = L$ with the voltage again being measured between electrodes at $d = 0$ and $d = L/2$. In this case the voltage at $L/2$ is expected to rise as the electron cloud penetrates the crystal.

Comparison of these results with the experimental data shown in Fig. 4 and 7 shows general agreement with this model. The approximate position of the boundary is shown by arrows on the diagram. The rise in current and fall in center electrode potential occur as predicted as the color enters the crystal and leads to a value of the parameter m between 2 and 3. However the rise in center electrode potential as the color crosses the mid-point does not occur and it is therefore necessary to consider other phenomena which may occur during coloration. These are illustrated in Fig. 12 and include the formation of a negative space charge region beneath the positive electrode due to the migration of negatively charged oxygen ions and the release of oxygen through the electrode.

The effect of a negative space charge layer may be evaluated by repeating the above analysis with the inclusion of a distribution of space charge within the crystal. For example, a distribution which can be justified on empirical grounds is a negative space charge density which increases linearly from the edge of the colored region toward the positive electrode. This corresponds to the accumulation of oxygen ions beneath this electrode. The effect of the distribution is included through Poisson's law and it is found that the center electrode potential falls continuously to zero when calculated as a function of increasing boundary parameter $y = d/L$. This polarization effect is not in accord with the experimental behavior shown in Fig. 7.

The experimental observation of a loss of material under the positive electrode is strong evidence that oxygen escapes through the electrode and that the total density of excess negative charge in the boundary

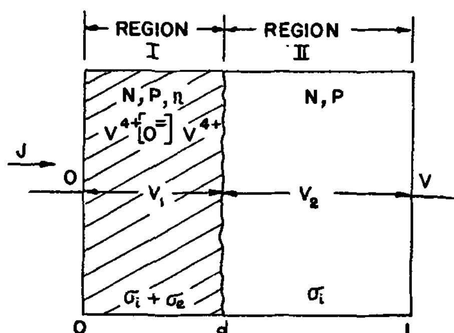

Fig. 11. Model for charging process. Region I is neutral but has conductivity $\sigma_i + \sigma_e$, region II has purely ionic conductivity, σ_i.

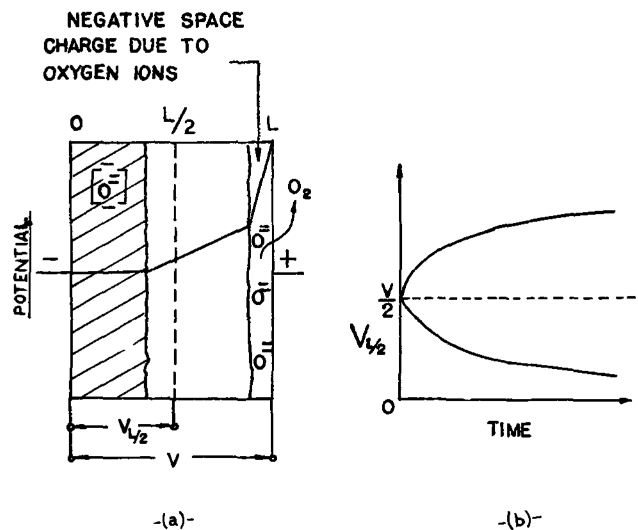

Fig. 12. Model including space charge at the positive electrode and oxygen loss from the crystal. The graph shows the expected change in the potential of the center electrode with the position of the boundary layer.

layer distribution is thereby reduced. Taking this effect into account is difficult to do in a quantitative fashion without further information regarding conditions at the boundary. However, qualitatively, oxygen loss would be expected to lead to a slower decrease in the center electrode potential as the color enters the crystal. This is shown in the graph in Fig. 12 and is in substantial agreement with the experimental behavior. Such a large effect due to electrode conditions would account for the difficulty of obtaining reproducible threshold and open-circuit voltages in repeated experiments on a single sample or between different samples.

The effect of electrolysis may be seen in the decreasing magnitude of the injected current on successive charging cycles shown in Fig. 6. If electrical neutrality is maintained in the colored region during the application of the external field, the injected charge must be located in the neighborhood of an oxygen vacancy. During electrolytic action and subsequent crystal decomposition, such vacancies will be progressively swept out of the crystal leading to a smaller charge injection during subsequent cycles.

Conclusions

Some application of calcium orthovanadate as a high temperature charge storage and oxygen transport medium appear to be possible. The principal limitation is contact and material deterioration due to electrolysis within the bulk. An increase in lifetime and improved charge storage efficiency can be obtained by operating at low specimen currents.

A Radiochemical Technique for Determining Depth Distributions in Mo

M. R. Arora* and Roger Kelly*

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Molybdenum can be anodized at up to 235V in an electrolyte containing glacial acetic acid, $Na_2B_4O_7 \cdot 10\ H_2O$, and water. The resulting oxide films, which must be stabilized by compressed-air drying, show brilliant interference colors, have a linear (or nearly linear) thickness-voltage relation, and can be formed with thicknesses of up to 380 $\mu g/cm^2$ of oxide (~8400Å). When exposed to 1.0 g/liter aqueous KOH, the films dissolve ("strip") within 30 sec, whereas the underlying metal dissolves at a rate of only 20 Å/hr. The film thicknesses formed on Mo which has been subjected to Kr ion bombardment at doses of up to 4×10^{16} ions/cm^2 are similar to those on unbombarded specimens. It follows from these results that the use of an anodizing-stripping sequence for determining depth distributions in Mo should be possible. Examples of depth distributions for 10-keV Kr implanted at doses from 4×10^{13} to 4×10^{16} ions/cm^2 are given and are shown, by comparison both with theory and with previously obtained results for W, to be numerically plausible.

Although a great deal of effort has been devoted in recent years to studying the penetration of energetic charged particles into solids, most of the work has been restricted either to low-mass targets (Al, Si, Al_2O_3, WO_3) or to high-mass targets (W, Au) (1-5). This leaves much to be done in the intermediate mass region, for example, work on maximum ranges (6) and on "supertails" (7). We propose to describe here an electrochemical technique suitable for depth-distribution measurements with Mo, mass 96; in addition, we demonstrate the plausibility of the technique by reporting preliminary depth-distribution measurements for Mo in the little-studied high-dose region.

The technique developed for studying the penetration of ions into Mo is similar in all respects to the anodizing-stripping methods previously developed by Davies and co-workers with Al (1), Si (2), W (3), and Au (4). Thus, with all five materials under suitable anodizing conditions, an extremely uniform oxide layer can be formed, whose thickness is determined mainly by the applied formation voltage. Also with all five materials, solvents exist which will rapidly dissolve the anodic oxide layer but not attack the underlying metal.

We would point out that further possibilities for studying intermediate masses have recently presented themselves. Andersen and Sørensen (8) have demonstrated that well-defined halide films can be formed and stripped from Cu (mass 64) and Ag (mass 108). In addition, vibratory polishing (9) and sputtering (10) are nearly universally applicable. None of these alternatives is, however, as straightforward as might be desired.

Anodizing-Stripping Procedure for Mo

Specimen preparation.—Polycrystalline Mo foils, which were 0.1 mm thick and had purities of 99.8%,

* Electrochemical Society Active Member.
Key words: molybdenum, anodization, thin films, depth distributions.

were used as specimens throughout this work. They were degreased with petroleum ether and etched in dilute nitric acid; they were then anodized at 80-100V several times and the anodic oxide films thus formed were dissolved in dilute KOH solution (to be discussed later). This preanodizing treatment may be assumed by analogy with Al (1) to provide a reproducibly flat surface of constant area for thickness calibration and subsequent depth-distribution measurements.

Anodizing step.—There are at least two examples in the literature where Mo has been anodized under etching or polishing conditions (11, 12), although no examples at all are known to the authors where the anodizing of Mo led [as with the closely related W (3)] to a protective oxide film. For example, negative results were obtained by Wood and Pearson (13). While the initial results obtained here tended to confirm the difficulty of forming films, it was found, after a rather large number of unsuccessful experiments, that films could be readily grown using an electrolyte similar to that proposed by Keil and Salomon (14) for V: glacial acetic acid, 0.02M $Na_2B_4O_7 \cdot 10H_2O$, and either 1.0M or 2.0M water. Higher amounts of water (> 2.0M) resulted in excessively unstable films: specifically, with 5.0M water in the electrolyte, fresh films tended to become nonuniformly thinner in 25 sec when exposed to the surrounding air and could not be stabilized by compressed-air drying. Films formed in the electrolyte with 1.0M water were not affected by 45-sec exposure to air and were found to be particularly stable when dried with compressed air. They could then be preserved in air for more than a day and in a desiccator for more than two weeks. Films formed with 2.0M water showed an intermediate behavior, being closer, however, to those formed with 1.0M water. Water contents of less than 1.0M resulted in stable but nonuniform films, the nonuniformity being presumably due to the low conductivity of the electrolyte [*cf.* Ref. (15)]. These conclusions are all based on the observation of interference colors.

The experiments were carried out at 25° ± 1°C and, on the basis of the above considerations, were confined mainly to the electrolyte with 1.0M water. A planar Pt foil, separated by about 1.0 cm from the Mo specimens, acted as cathode. A calomel reference electrode was occasionally inserted into the bath during anodizing to determine what portion of the applied voltage actually appeared across the oxide film on the Mo and what portion corresponded to the ohmic drop in the electrolyte. Except at the beginning of a run, the voltage across the film was similar (typically 97-98%) to the total applied voltage and corrections have therefore not been applied.

The anodizing was carried out at a constant current of 2.0 mA/cm^2 until the desired voltage had been reached and the current was then allowed to drop for a total anodizing time of 6 min. The current had by this time decreased to an almost limiting value of 0.1 to 0.3 mA/cm^2, most of which is believed to be electronic in nature (16).

Above 10 to 15V, the presence of the oxide films on Mo could be detected visually, and their uniformity verified, by means of the characteristic interference colors that occur. As described above, freshly prepared films were highly unstable, although they could be stabilized by exposing them for about 10 to 15 sec to a jet of compressed air immediately after withdrawal from the anodizing bath. The films were shown by reflection electron diffraction at 60 kV to be amorphous (Fig. 1a), although they were subject to crystallization at temperatures greater than about 400°C (Fig. 1b); they are similar in these respects to anodic WO_3 (17).

Apparently normal anodizing behavior was found up to a voltage of 235V, corresponding to an oxide film thickness of 380 $\mu g/cm^2$ of oxide (~ 8400Å). At that potential, film breakdown occurred as evidenced by discoloration and a tendency for the voltage either to rise reluctantly or to fall.

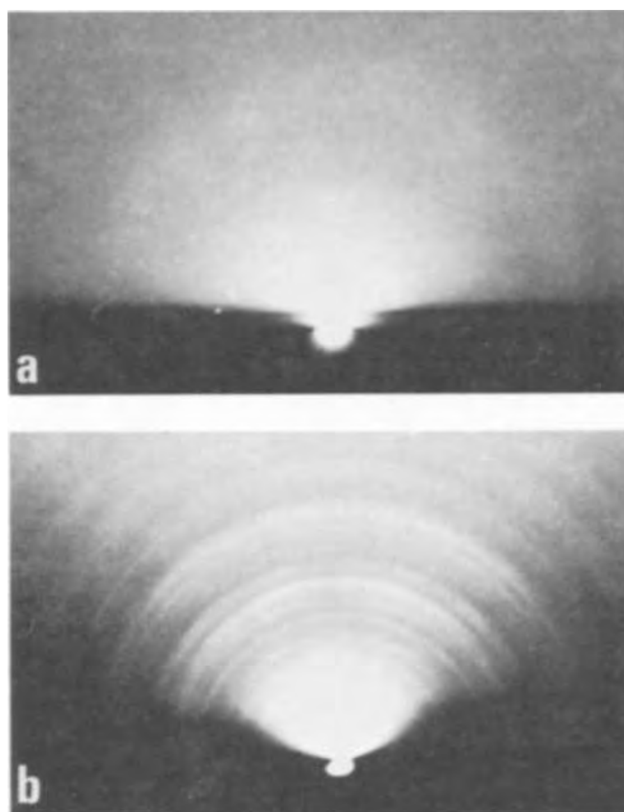

Fig. 1. Electron diffraction patterns taken by reflection in a Philips EM300 electron microscope operated at 60 kV. (a) Mo as anodized at 50V. (b) Mo which has been first anodized at 50V and then heated in air at 450°C for 5 min.

Stripping step.—The only oxide solvent tried was, by analogy with WO_3 (3), 1.0 g/liter KOH. It was observed that the oxide interference colors disappeared within 30 sec. By using specimens first labeled with 35-keV Kr^{85} to a dose of 5×10^{15} $ions/cm^2$ and then anodized at 15, 30, or 60V, it was confirmed that film dissolution was complete within 30 sec and that the attack on the underlying metal occurred at about 20 Å/hr.[1] Partial results are given in Table I.

The existence of a dissolution "end-point" at the oxide-metal interface is perhaps the most crucial consideration in setting up an anodizing-stripping procedure. It was therefore gratifying that the "end point" is so well-defined with Mo.

Thickness Calibration

Calibration for ≥ *10V.*—As a first step in establishing a thickness-voltage calibration for the anodizing-

[1] The ion bombardments used throughout this work were carried out with a high-current, 0-40 kV accelerator located in the Institute for Materials Research at McMaster University.

Table I. Stripping experiments*

10 min	63.8	39.7	17.9
60 min	62.0	39.0	17.6

* The Mo specimens were labeled with 35-keV Kr^{85}, anodized at 15, 30, or 60V, and then exposed to 1.0 g/liter aqueous KOH for various times.

stripping procedure, the extent to which Mo went into solution during the anodizing step was estimated. Eight specimens were labeled with 10-keV Kr^{85} to a dose of 5×10^{15} ions/cm^2 and were then counted three times: before anodizing, after anodizing at 3 to 50V, and after stripping. From 30 to 80% of the activity was found to be lost during anodizing, indicating that significant oxide-film dissolution was occurring. This means that Mo, as distinct from W (3), requires two types of thickness calibration, one for oxide-film thickness due to anodizing alone and the other for total metal removed in a full anodizing-stripping sequence.

In further experiments, it was shown that the oxide thickness and its uniformity, as inferred both from the interference colors and from the time to reach the limiting electronic current, did not depend significantly on whether the anode-cathode spacing was 0.5 or 1.0 cm provided the initial current density was at least 2.0 mA/cm^2 and the total anodizing time at least 6 min. Had the time been increased to 9 min, spacings of up to 2.0 cm could have been tolerated.

The main results, as determined by the conventional weight-loss procedure, are shown in Fig. 2 and can also be represented by the following expressions:

Thickness of oxide film for electrolyte with 1.0M water

$$= 1.4 + 1.58 \times V \quad \mu g/cm^2 \text{ of oxide}$$

Thickness of oxide film for electrolyte with 2.0M water

$$= 1.4 + 1.78 \times V \quad \mu g/cm^2 \text{ of oxide}$$

Total Mo removed for electrolyte with 1.0M water; $\leq 10V$

$$= 1.5 + 1.60 \times V \quad \mu g/cm^2 \text{ of metal}$$

Total Mo removed for electrolyte with 1.0M water; $\geq 10V$

$$= 7.3 + 1.02 \times V \quad \mu g/cm^2 \text{ of metal}$$

Note how the curves for oxide thickness are given in units of micrograms/square centimeter of Mo [deduced by assuming the oxide to be MoO_3 (16)], whereas the corresponding analytical expressions are in terms of micrograms/square centimeter of total oxide (no assumptions necessary as to its nature). Note also that the calibrations are not unique, but apply for an initial current density of 2.0 mA/cm^2, a total anodizing time of 6 min, and an anode-cathode separation of $\leq$ 1.0 cm.

Calibration at low voltages.—Since the precision of depth-distribution measurements depends mainly on the knowledge of small thicknesses (< 10 $\mu g/cm^2$), supplementary calibration experiments (*i.e.*, other than weight-loss measurements) were made in the low-voltage region.

Oxide films on Mo as prepared here were found to be sufficiently stable for the use of ellipsometry to measure their thickness. Six specimens, prepared with the electrolyte having 1.0M water, were therefore examined assuming the following refractive indices (18): $n_{Mo} = 3.14 - i\ 3.60$; $n_{oxide} = 1.55$. It was found that the thickness of a natural film was 31 ± 2Å, of a 4-V film was 127 ± 4Å, and of a 6-V film was 219 ± 5Å. For an oxide density of 4.52 g/cm^3 and an assumed composition MoO_3 (16), these thicknesses correspond to, respectively, 0.93, 3.84, and 6.61 $\mu g/cm^2$ of Mo.

Values for the total metal removed could be obtained using a technique based on comparing depth distributions. Twenty-four specimens were bombarded with 30-keV Kr^{85} under identical conditions of dose (5×10^{15} ions/cm^2). The specimens were then subdivided into eight groups and the Kr depth distributions were determined such that each group was anodized and stripped using only one voltage. By letting the total amounts of metal removed at the lower voltages (1, 2, 3, 6, and 8V) be unknowns, these amounts could be expressed relative to those at the higher voltages (10, 15, and 20V). A typical example, which serves to establish the 2-V amount as being 0.17 of the 10-V amount, is shown in Fig. 3.

Over-all low-voltage results are summarized in Fig. 4 and have been taken into account in the analytical expressions of the preceding section. The depth-distribution procedure, in particular, will be recognized as being related to that used by Whitton (9) for calibrating the vibratory polishing behavior of W and Ta_2O_5.

Effect of radiation damage on thickness calibration.—Andersen and Sørensen (8) were concerned in their work on halide films on Cu with the effect of ion-bombardment damage on the thickness calibration. No effect was observed for doses of up to 10^{16} ions/cm². In the present work we have prepared a series of 12 specimens, bombarded them with 10-keV Kr to various doses, and then anodized them at 40V. The total amount of metal plus implanted Kr removed in a full anodizing-stripping sequence was then determined and from it the estimated weight of the Kr was subtracted. (The sticking probability of the incident ions was taken into account in making this correction.) The results are given in Table II and serve to confirm again the absence of a damage effect except perhaps at the highest dose (4×10^{17} ions/cm²).

Depth Distributions in Mo at High Doses

As a specific application of the anodizing-stripping procedure described here, we have undertaken experiments on Kr depth distributions in Mo in the little studied high-dose region. The results are still preliminary but one series in particular will be included here, since its plausibility serves as a good indication of the effectiveness of the anodizing-stripping procedure.

Figure 5 shows distribution curves of the residual target activity (*i.e.*, integral concentration) for Kr^{85} injected into Mo at a constant energy of 10 keV but at various doses. Each curve is based on at least 12 separate specimens with typically 8 to 15 points per specimen, and we note first of all that the reproducibility, as shown by the vertical bars, is rather good for this type of work [*cf.* Ref. (10)].

The theoretical curve was deduced from a knowledge of the Thomas-Fermi values of the mean projected range, $\langle x \rangle$, and mean projected straggling, $(\langle \Delta x^2 \rangle)^{1/2}$, as calculated by Schiøtt (19) assuming a

Table II. Effect of radiation damage

Kr dose (ions/cm²)	Total metal removed in 40-V step (μg/cm²)
Zero	47.9
5×10^{15}	47.0
4×10^{16}	48.4
4×10^{17}	42.4

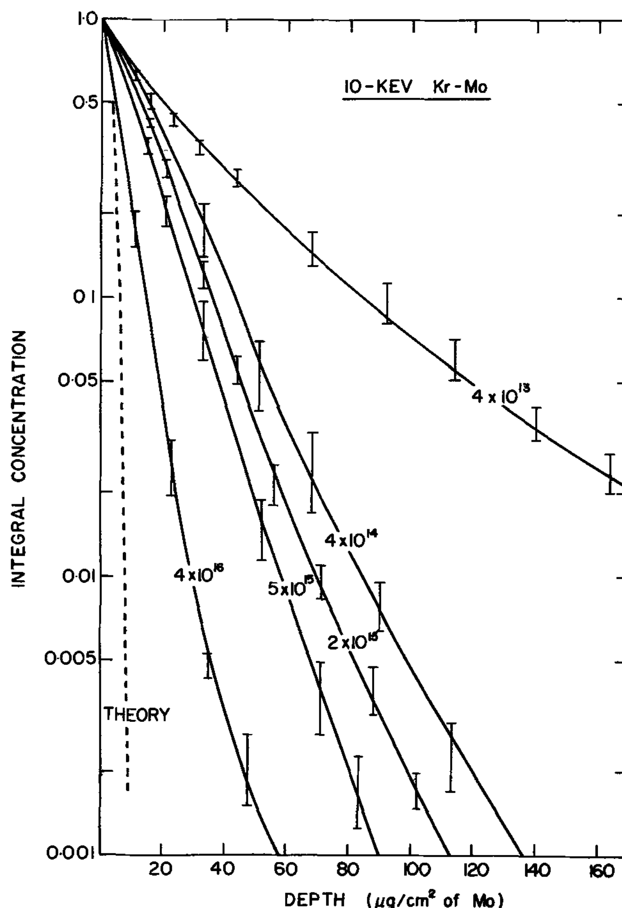

Fig. 5. Integral Kr depth distributions in Mo as a function of dose for a constant energy of 10 keV. Solid: experimental curves, each involving approximately 100 to 180 experimental points which have a scatter as shown by the vertical bars. Numbers such as 4×10^{13} refer to doses in ions/cm². Dashed: theoretical curve corresponding to $\langle x \rangle = 3.7$ μg/cm² and $(\langle \Delta x^2 \rangle)^{1/2} = 1.9$ μg/cm².

random (amorphous) solid

$$\left.\begin{array}{l} \langle x \rangle = 3.7 \ \mu g/cm^2 \\ (\langle \Delta x^2 \rangle)^{1/2} = 1.9 \ \mu g/cm^2 \end{array}\right\} \text{for 10-keV } Kr^{85} \text{ in Mo}$$

These values were substituted into the leading term of an integral Edgeworth expansion (20)

$$\text{integral concentration} \simeq (1/2) \ \text{erfc} \left[\frac{x - \langle x \rangle}{2^{1/2} (\langle \Delta x^2 \rangle)^{1/2}} \right]$$

Table III enables a comparison to be made between the experimental median projected range, R_m, and the expected value $\langle x \rangle = 3.7$ μg/cm².

R_m is seen to be a factor of 5.4 larger than expected at the lowest dose used, 4×10^{13} ions/cm². We do not regard this as a sign of experimental error, but rather a normal result, due to there being mixed random and channeled stopping in nonamorphizable substances

Table III. Median ranges for 10-keV Kr in Mo

Kr dose (ions/cm²)	Median range, R_m (μg/cm² of Mo)	$R_m/\langle x \rangle$*
4×10^{13}	20	5.4
4×10^{14}	15.5	4.2
2×10^{15}	12.5	3.4
5×10^{15}	10	2.7
4×10^{16}	4	1.1

* The expected value of $\langle x \rangle$ is 3.7 μg/cm² of Mo (19).

such as Mo. Consider, for example, the behavior of low doses of Kr in W: for *polycrystalline* W, Davies *et al.* (21) found $R_m/\langle x \rangle$ to have an average value of 2.3, while for single-crystalline W with <111> or <100> orientations Kornelsen *et al.* (22) found values of 10 to 12. The Mo specimens were subsequently shown to have virtually only three orientations present, <100>, <211>, and <111>, and it is thus not surprising that $R_m/\langle x \rangle$ was large.

R_m decreases with increasing dose, such that for a dose of 4×10^{16} ions/cm^2 it is comparable to the theoretical value. This is again an expected result, for in the context of mixed random and channeled stopping, one anticipates a progressive blocking of the channels both by incident ions and by lattice damage. The blocking is evidently complete in the near-surface region at a dose of 4×10^{16} ions/cm^2, although it is clearly incomplete at greater depths. The corresponding results for W include a bombardment to 5×10^{14} ions/cm^2 (22), where R_m was only slightly reduced from the value for 2×10^{13} ions/cm^2, and bombardments at 5×10^{15} ions/cm^2 (16), where $R_m/\langle x \rangle$ was 2.2 to 2.8. In addition, Eriksson (23) has showed that a dose of 3×10^{16} ions/cm^2 still yields a distribution of which the deeper portions are dominated by channeling effects. Reference to Table III or Fig. 5 reveals that these results are very similar to those obtained here for Mo.

One concludes that depth distributions can be obtained in Mo which are numerically plausible. Depending on the dose, R_m either deviates from theory in an expected way or else agrees with theory.

Other series of high-dose depth distributions are in the course of being obtained by the present authors for the metals Mo, Al, and W. One of the conclusions that is emerging is, however, already clear from the present work: Mo behaves, as far as stopping phenomena are concerned, more nearly like W than like Al. This means that Mo will be particularly effective for studying maximum ranges (6) and "supertails" (7).

Summary

A procedure is outlined whereby Mo can be anodized at voltages up to 235V. The resulting oxide films are highly unstable unless dried with a jet of compressed air immediately after withdrawal from the anodizing bath. The films are rapidly soluble in 1.0 g/liter aqueous KOH, whereas the underlying metal dissolves at a rate of only 20 Å/hr.

Oxide thicknesses are determined both by the conventional techniques of weight-loss and ellipsometry, as well as by a procedure based on comparing depth distributions. For example, depth distributions for 30-keV Kr were obtained both from a sequence of 2-V anodizings and from a sequence of 10-V anodizings, and the value of the 2-V thickness increment was deduced as being 0.17 of the 10-V increment.

Sequences of anodizings and strippings enable depth distributions to be obtained only if the amount of metal removed in such a sequence is independent of ion-bombardmennt damage. This condition is shown to be met with Mo for Kr doses up to 4×10^{16} ions/cm^2.

Examples of depth distributions are given for various doses of 10-keV Kr in Mo. The median range exceeded the Thomas-Fermi value by a factor of 5.4 at a dose of 4×10^{13} ions/cm^2 but agreed at a dose of 4×10^{16} ions/cm^2. Since these results are numerically plausible, they indicate that an anodizing-stripping sequence is an effective depth probe with Mo.

Acknowledgments

The authors acknowledge with pleasure various discussions held with Dr. J. A. Davies (Chalk River) during the course of this work. Dr. D. C. Santry (Chalk River) read a preliminary version of this manuscript and made many constructive suggestions. In addition, Dr. J. Shewchun and Mr. E. C. Rowe (McMaster University) provided valuable assistance, as well as use of their equipment, in the ellipsometry measurements. This work was supported by a grant from the National Research Council, Ottawa, Ontario, Canada.

Manuscript submitted July 30, 1971; revised manuscript received Oct. 5, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 issue of the JOURNAL.

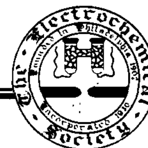
Technical Notes



Fast Cathodoluminescent Calcium Sulfide Phosphors

W. Lehmann* and F. M. Ryan

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

Calcium sulfide phosphors are attractive for use as luminescent materials in cathode ray tubes (1). Their decay of luminescence following excitation by a short electron beam pulse is primarily determined either by the electron transition within the used activator ion, or by carriers temporarily captured in various traps depending on which is slower. Since traps are always present in CaS phosphors, the phosphorescence decay (even of phosphors containing relatively fast activators) is slower than might be desired for some applications. As an example, the recombination time constant corresponding to the luminescent 5d → 4f transition of Ce^{3+} in CaS is less than 10^{-7} sec while the observed decay time of the phosphorescence of normal CaS:Ce^{3+} phosphors is about 10^{-6} sec, somewhat dependent on the particular phosphor and the excitation conditions (1).

We have tried to reduce this afterglow by incorporating a suitable chemical "killer" element in the phosphor, without an excessive reduction in the emission intensity resulting. Killers of luminescence of ZnS-type phosphors are well known to be mainly Fe, Co, and Ni (2, 3), and of these, nickel comes closest to the ideal of affecting mainly the afterglow with a minimum reduction in efficiency (4), and is commercially used in the phosphors P-11, P-36, and P-37. Corresponding actions of various killers in CaS phosphors are less well known. We have observed that, in striking contrast to ZnS, nickel is almost ineffective in CaS[1] which tolerates appreciable amounts of it without much effect. This apparently was noted already by Avinor who proposed instead to reduce the afterglow of CaS phosphors by addition of cadmium (5). Our experience disagrees with this claim as we cannot see a clear action of Cd in CaS in this respect. However, we observe cobalt to perform well in CaS, about equal to the performance of nickel in ZnS.

The technically ideal killer would be one that removes all afterglow without reducing the efficiency of the phosphor. In practice this cannot be achieved as killer centers compete with radiative recombination centers for recombining carriers and thereby introduce energy losses. A more realistic goal is to seek for a killer which associates to some degree with deep traps and, in this way, reduces the long-time afterglow more than the short-time afterglow. One must then vary the killer concentration in order to reach an acceptable compromise between high efficiency and short decay. The following shows how this has been achieved in several CaS phosphors by adding cobalt in varying amounts.

Experimental

The general conditions of CaS phosphor preparations are described elsewhere (1, 7). Cobalt containing phosphors were made in the same way except for the addition of cobalt.

Emission spectra of CaS phosphors considered here are shown in Fig. 1. Neither excitation intensity nor the addition of cobalt measurably altered these spectra. This contrasts with the behavior of nickel in ZnS which, besides its action as a killer, produces an intense optical absorption band in the blue which does change the emission spectrum, probably by selective reabsorption of the emission light. A corresponding strong absorption of cobalt in CaS is not observed.

Decay characteristics were measured under conditions approaching those encountered in flying-spot scanners. The phosphors were excited in a demountable system by an electron beam of 10 kV in pulses of 50 nanoseconds duration with a current density of between 10-100 mA/cm². The light emission was detected with a photomultiplier and displayed on an oscilloscope screen. The decay curves were photographed and evaluated afterwards. The RC-response time of the system was 27 nanoseconds, well below the decay rates of the phosphors. The efficiencies presented in this paper are time-average energy efficiencies determined under the same pulse excitation conditions as mentioned above by comparison of the phosphors to several standard phosphors whose efficiencies were known from other sources (8).

Decay times and efficiencies of various phosphors vary somewhat with variation of the excitation conditions which, in turn, may depend upon the desired application. Hence, we include data on several commercial fast phosphors excited under the same conditions as our CaS phosphors in order to provide a somewhat firmer base of evaluation.

Results

The decay of green emitting CaS:Ce^{3+} containing no cobalt consists of several subsequent t^{-n} branches probably due to thermal emptying of several groups of traps. Details vary somewhat from sample to sample, average times to decay to 1/e or to 1/10 of the original

intensity may be about 0.5 and 2 μsec respectively. A very weak tail of the afterglow may be observed even in the millisecond range.

Decay curves of several CaS:Ce^{3+} phosphors containing different amounts of cobalt are shown in Fig. 2 and compared to those of commercially used P-24 (ZnO) and P-36 (ZnS-type, Ni). All of these phosphors are green emitters. The curves in Fig. 2. are normalized to 100 units at zero time. The time-average efficiencies of these phosphors under the used pulse excitation are listed in Table I. It may be noted that CaS:Ce^{3+} containing properly adjusted amounts of cobalt easily matches P-24 and P-36 in speed of decay but is many times more efficient. Values of the efficiencies of CaS: Ce^{3+}, Co and of the times required to decay to 1/e ($\tau_{1/e}$) and to 1/10 ($\tau_{1/10}$) of the original as functions

Table I. Efficiencies and decay times

Ultraviolet emitters:			
CaS:Pb^{2+},(no Co)	16	0.6	3-4
CaS:Pb^{2+},Co(0.01%)	0.5	0.09	0.25
P-16 (silicate, Ce^{3+})	4	0.15	0.43

of the cobalt concentration are given in Fig. 3. Increasing amounts of cobalt reduce the decay until it finally approaches exponential shape with a time constant, $\tau_{1/e}$, of about 80 n-sec. This appears to be the final speed limit of this phosphor type. Excessively high cobalt concentrations only reduce the efficiencies without further reduction of the decay times.

This general behavior of CaS:Ce^{3+}, Co is observed also in other CaS phosphors containing fast activators, all excited by electron beam pulses at room temperature[2] although minor details depend on the activator. Some performance data of CaS and, for comparison, of several commercial fast phosphors are given in Table I. In every case, cobalt reduces nonexponential decay of CaS until, with increasing amounts of cobalt,

[2] Striking differences are observed at low temperatures, however. For instance, CaS:Ce^{3+}, (no Co) is very efficiently excited to cathodoluminescence also at low temperatures and its decay becomes faster with decreasing temperature and is perfectly exponential ($\tau_{1/e}$ = 77 n-sec) at about 10°K. In contrast, CaS:Eu^{2+}, (no Co) is extremely poorly excited at low temperatures and its decay becomes slower, not faster, with decreasing temperature down to about 10°K.

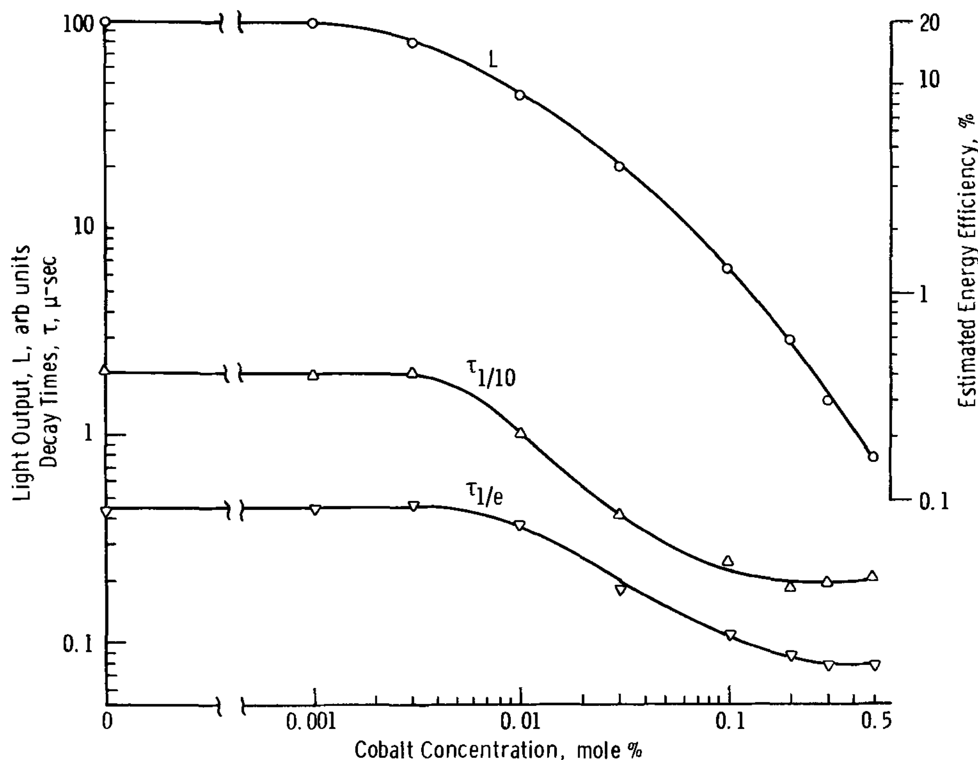

Fig. 3. Energy efficiencies and decay times of CaS:Ce^{3+}, Co.

it approaches exponential shape. The time constants, $\tau_{1/e}$, of decay at this ultimate limit are about 120 n-sec for Eu^{2+} and 80 n-sec for Pb^{2+}. The limits of the activators Bi^{3+} and Cu are still unknown. If the decay of a CaS-phosphor containing a particular activator is exponential already without cobalt, then addition of the latter only reduces the efficiency but not the decay times. An example of this case is CaS: Sb^{3+} whose exponential decay ($\tau_{1/e} = 0.8$ μsec) is not affected by the addition of cobalt.

Discussion

The observed action of cobalt on the luminescence decay of CaS-phosphors may be understood as follows.

The process of excitation and luminescence consists of a chain of events, the length of the afterglow is determined by the slowest link in the chain, and reduction of the afterglow by selective killing is possible only if the killer affects this slowest link. Well shielded 4f-states of trivalent rare earth ions are not affected by a killer in the surrounding lattice, for example, and since 4f → 4f transitions generally are relatively slow, the afterglow of CaS-phosphors containing these ions is also slow and cannot be shortened by addition of cobalt or any other killer. The same holds true for the emission of Mn^{2+} and, more or less, for various other activators. Only activators with intrinsically fast electronic transitions permit a substantial reduction of the afterglow, and the ultimate speed limit attainable with increasing killer action is that of the intrinsic electron transition within the activator ion. Transitions between well-shielded states inside of an activator ion are first-order processes resulting in simple exponential decays but transitions involving states of the surrounding lattice normally are not. The chemical "killer" competes with the latter so that in the limit of high killer concentrations one approaches the simple exponential decay due to the first-order kinetics within the activator ion.

On the basis of this general picture one might describe the observed phenomena by a simplified model involving luminescence centers (activators), nonluminescent recombination centers (killers), traps, and various interactions between them. However, we believe any such model presently to be of little value since there are still too many unknowns, and we prefer not to go into details here.

A practical result of this investigation is the conclusion that some partly cobalt-killed CaS phosphors may advantageously replace conventional phosphors in applications where high speed of response is required. This includes mainly green CaS:Ce^{3+} and, perhaps, red CaS:Eu^{2+}. CaS phosphors containing the activators Pb^{2+}, Bi^{3+}, and Cu perform less well in this respect and are not likely to be competitive to conventional phosphors purely in terms of efficiency and speed.

A New Technique for Terminating Liquid Phase Epitaxial Growth

R. M. Potemski and J. M. Woodall*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

A problem that is encountered with the liquid phase epitaxial growth method is that terminating growth by rapid cooling of the melt while it is still in contact with the substrate produces a gradient in composition along the growth direction (1) which is undesirable for certain device applications. Methods which have been employed to overcome this problem, such as withdrawal (2), tipping (3), and melt wiping (4) or a combination of these, suffer some disadvantages. For instance, gravitational methods such as tipping do not always remove the melt completely and droplets are left on the surface of the epitaxial layer. Wiping insures removal of the melt, but it is suitable only for carefully designed systems and can result in damage to the surface. Also, these methods expose the new surface to the atmosphere of the system at a high temperature with the possibility of contamination. This note describes a new method for terminating growth which can be easily applied to currently used growth systems. In this method the substrate is moved, along with a portion of the growth melt, from the growth melt into a quench melt which has a very low solubility for the solute species of the growth melt. When a small volume of this mixed melt, in contact with the wafer, is cooled to room temperature, an insignificant amount of growth occurs. Thus, the composition of the solid at the growing interface, as well as the surface morphology that existed just prior to termination of the layer growths, are essentially preserved.

Experimental Procedure

The system that was studied was the $Ga_{1-x}Al_xAs$ LPE growth on (100) GaAs substrates. The apparatus shown assembled (top) and exploded (bottom) in Fig. 1 is a modification of that which has been previously described (5). Briefly, a substrate holder B can rotate with respect to melt chamber D, which can accommodate four separate melts. Spacer C fits between D and B to both hold the substrate in place and transfer a fixed volume of melt, depending on the spacer thickness, from one chamber into the other. Part A contains B, C, and D and fixes D in place during the rotation of B and C. The apparatus is such that the substrate can be rotated into a position between two melt chambers and be isolated from the melts.

Experiments were performed where all growth conditions were fixed except for the procedure for growth termination. In one case, the procedure of allowing the wafer to cool in the presence of a small volume of growth melt was followed. In the other, the wafer was brought into a quench melt prior to cooling. The growth melt consisted of 5g of Ga and 0.006g of Al, saturated with As from a bar of GaAs in

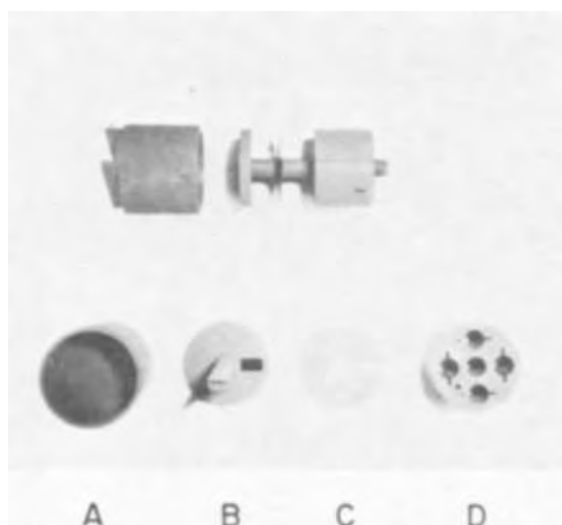

Fig. 1. Apparatus used for growth termination experiments. The diameter of part D is 2 in.

contact with the melt. The quench melt consisted of 2g of Ga, 0.200g of Al, and no GaAs. The growth schedule consisted of a 300°C vacuum bakeout, back filling and continuous flushing with palladium diffused H_2, and heating to 835°C. During this time the substrate was held between two chambers out of contact with any melt. After 55 min of soak time the substrate was moved into the growth melt and allowed to equilibrate for 10 min. Growth was then produced by lowering the temperature 0.1°C/min for 100 min. Next, the substrate was moved to a storage position between melts together with a small volume of growth melt carried along by the spacer. The run was then terminated by either (*a*) removal of the furnace, or (*b*) moving the substrate into the quench melt, holding for 30 sec while the carryover and quench melt mixed and then moving to a storage position followed by removal of the furnace. In both cases the substrate remained in the store position with a small amount of melt covering it until it was cooled to room temperature. Upon removal from the system the substrates were washed with hot water and detergent to remove any melt still present.

Results and Discussion

The wafers from the quench melt rapidly develop a blue film over the epitaxial layer surface when exposed to the air. The surface characteristics of such a layer are shown in Fig. 2a. This film (the dark regions of Fig. 2a), presumably $Ga_{1-x}Al_xAs$, with $x \sim 1$, readily oxidizes in moist air and is easily removed by washing in aqueous HCl (Fig. 2b). The surface structure of layer growth obtained by cooling in the presence of a small volume of growth melt is shown in Fig. 3. This surface does not exhibit oxidation because of its much lower aluminum content.

The wafers were cleaved parallel to the growth direction on (110) planes, etched in H_2O_2:HF:H_2O (1:1:10) to facilitate metallography and composition profiling. The composition profiles were measured with an electron beam microprobe. Figure 4 is a plot of the Al concentrations along the growth direction as a function of distance. Figure 4a shows the profile for growth terminated with a small volume of the growth melt. Figure 4b is the profile of the growth terminated with a quench melt and also etched in HCl. It is readily seen that both layers are initially uniform in composition. However, when growth is terminated by cooling in the presence of the growth melt, additional material is deposited in which the Al concentration decreases toward the surface. A comparison of the photomicrographs in Fig. 5 with the Al concentration

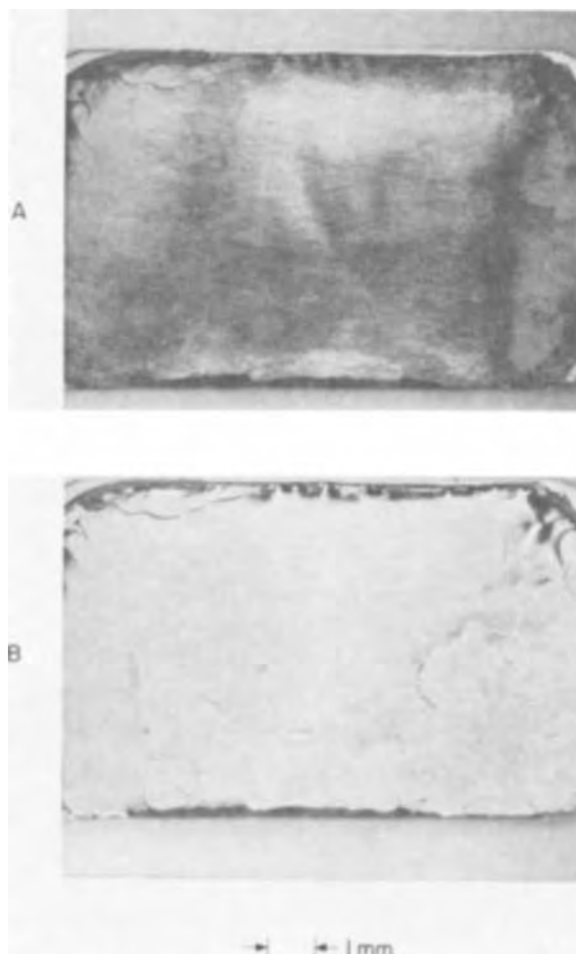

Fig. 2. Surface of a layer the growth of which was terminated by cooling in the presence of a mixed melt: (A) 1 hr exposure to air after growth, and (B) after washing in aqueous HCl.

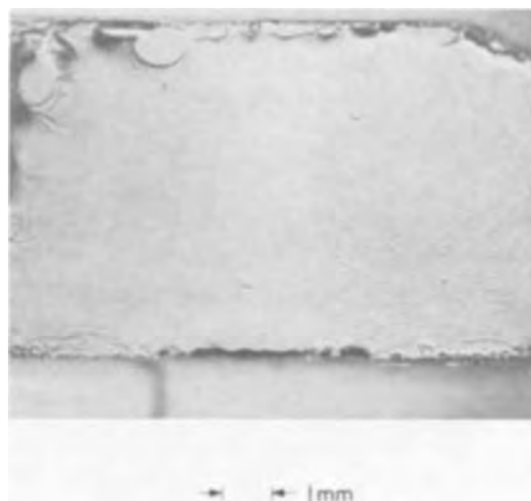

Fig. 3. Surface of a layer the growth of which was terminated by cooling in the presence of a growth melt.

profiles shown in Fig. 4 shows that terminating in contact with even a small volume of growth melt over the surface of a layer leaves behind an additional layer with a steep Al gradient along the growth direction. However, this additional layer growth is nearly eliminated using the growth-quenching technique and the small amount of growth that is present and nondetectable with an optical microscope is readily removed in HCl. Since cooling was done by rapidly

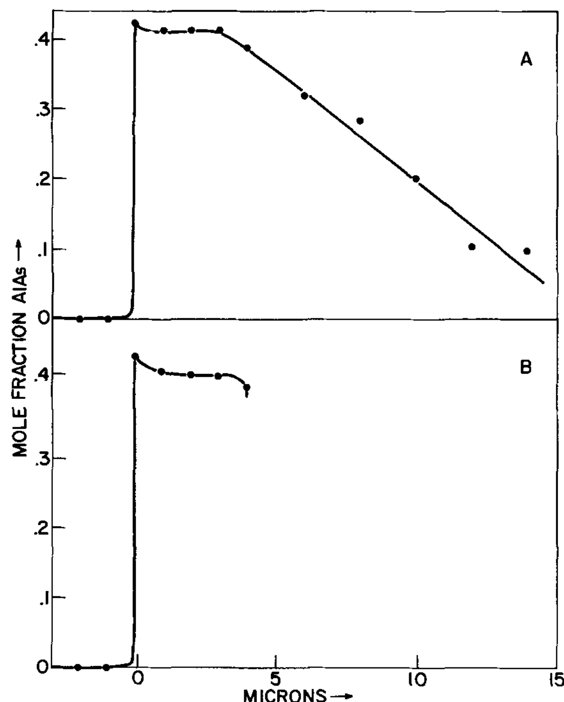

Fig. 4. Composition profile along the growth axis of (A) growth terminated by cooling in the presence of a growth melt and (B) growth terminated by cooling in the presence of a mixed melt.

removing the furnace from the melt and flushing with a large volume of H_2 gas, the amount of material that is deposited during cooling in the presence of a small volume of growth melt (Fig. 5a) represents the minimum amount of growth which will occur. Cooling more slowly produces termination layers even thicker than that shown in Fig. 5a. It is interesting to note that the surface morphology of the growth-melt cooled layer (Fig. 3) does not show constitutional supercooling effects such as deep valley cellular growth normally produced by large cooling rates.

An obvious application of the melt quench technique is the preparation of electroluminescent device structures of $Ga_{1-x}Al_xAs$ having sandwich layers which are optically transparent to light generated in an active region. The composition profile of a structure which should lead to devices with greatly improved external quantum efficiencies, provided the absorbing substrate can be etched away, is shown in Fig. 6. Even with the substrate intact, devices with this profile have had room temperature quantum efficiencies into air of 2% with the peak emission at 7900Å. This structure was grown from three different growth melts and terminated with a quench melt.

Preparation and Semiconducting Properties of $Cu_2In_4Te_7$

A. Congiu, L. Garbato, P. Manca, and S. Serci

Istituto di Fisica dell'Università di Cagliari, Italy, Gruppo Nazionale di Struttura della Materia del C.N.R.

Following the current rules for normal valences and for valence electron concentrations used in the prediction of new semiconducting compounds (1) of tetrahedral structure, one can derive, for $A^IB^{III}C^{VI}$ group elements (A^I = Ag, Cu; B^{III} = Al, Ga, In; C^{VI} = S, Se, Te), the general composition formula $A^I{}_2B^{III}{}_{2n}C^{VI}{}_{3n+1}$. This formula is equivalent to $(A^I{}_2C^{VI})(B^{III}{}_2C^{VI}{}_3)_n$ in the $A^I{}_2C^{VI}$-$B^{III}{}_2C^{VI}{}_3$ pseudobinary system and predicts the possibility of preparing a number of isostructural semiconducting alloys with controlled cation vacancies.

The incorporation of cation vacancies makes it possible to satisfy the valence rules by nonintegral values of n, as well as by integral values of this coefficient. The formation of such an alloy system as n decreases can be regarded as a systematic filling, by atoms of the group A^I element, of the vacant lattice sites of the $B^{III}{}_2 \square C^{VI}{}_3$ defect structure in the range $0 \leq 1 - \frac{2n+2}{3n+1} < 0.33$, eventually reaching the normal tetrahedral phase $A^IB^{III}C^{VI}{}_2$ with $n = 1$.

Recent works (2-4) on the $A^I{}_2Te$-In_2Te_3 pseudobinary phase diagram, where the group A^I element is Ag or Cu, have shown the existence of the defect tetrahedral phases $AgIn_3Te_5$, $AgIn_5Te_8$, and $AgIn_9Te_{14}$, which are cases of the previous general composition formula with n = 3, 5, and 9 respectively.

$AgIn_3Te_5$ (2), $AgIn_5Te_8$, and $CuIn_5Te_8$ (3) were shown to have the sphalerite (B_3) type structure, and $AgIn_9Te_{14}$ (4) seems to be of chalcopyrite (E_1) type.

The tetrahedral short-range order in these compounds is a consequence of the overlapping of sp^3 hybridized orbitals which can be assumed to be the predominant character of the bonding in these intermetallic alloys. All these phases are expected to be semiconductors but semiconducting properties have been investigated only for $AgIn_3Te_5$ (2) and $AgIn_9Te_{14}$ (4).

For the Cu-In-Te system the physical investigations are limited to normal tetrahedral phase $CuInTe_2$ (5, 6, 7). The pseudobinary Cu_2Te-In_2Te_3 diagram recently reported (3) contains a δ-phase region with sphalerite structure, stable at sufficiently high temperatures, which includes the $Cu_2In_4Te_7$ composition. In this note some results of our investigations concerning the synthesis and characterization of the defect phase $Cu_2In_4Te_7$ and its semiconducting properties are presented and briefly discussed.

Preparation and Metallurgical Properties

Polycrystalline ingots of nominal $Cu_2In_4Te_7$ composition were prepared by direct melting of the component elements (Johnson-Matthey quoted purity 99.999+%) sealed in evacuated silica tubes. To prevent surface oxidation, the tubes were first washed with HF + HNO_3 mixture, rinsed with deionized water, outgassed under dynamic vacuum (10^{-5} Torr) at 900°C over a period of 8 hr., and then cooled to room temperature under an argon atmosphere. Using a suitable temperature gradient along the furnace axis to prevent distillation of the volatile component, the samples were heated to 900°C with continuous 50 Hz vibration to assist mixing and left at this temperature for several hours. The ingots were obtained by slow cooling or by quenching in water from a temperature just below the melting point. Metallographic examination of mechanically and chemically polished surfaces showed the sample to be single-phase with a micro-hardness of (220 ± 20) kg/mm². The results of chemical analysis are consistent with the composition $Cu_2In_4Te_7$; the differences between the theoretical and the measured values for the components do not exceed 1%.

Key words: compound semiconductors, ternary compounds, I-III-VI compounds, transport properties.

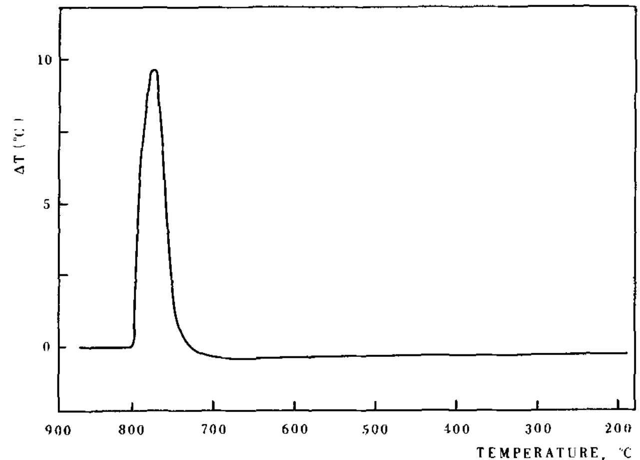

Fig. 1. Differential thermal analysis cooling curve

X-ray analysis on powders reveals the crystal structure to be of sphalerite type. At room temperature the lattice constant was found to be 6.16Å, the calculated density of 6.02 g/cm³ and the observed pycnometric density 5.93 g/cm³. By using the experimental data for the melting point and density, a Debye temperature of about 138°K has been evaluated according to the Lindeman melting formula (8).

The phase behavior has been investigated by DTA performed with a Netzsch differential thermal analyzer. Use of a sample heating rate of 2°C/min and differential thermocouple sensitivity of 0.3°C permits the phase change temperature to be determined within ±5°C.

The thermogram of Fig. 1 shows no solid-state phase change in the temperature range investigated and may be consistent with the small difference in liquidus and solidus temperatures indicated for this composition in Fig. 1 of Ref. (3). From a quantitative analysis of the DTA curves the heat of fusion was found to be approximately ΔQ_F = 168 kcal/mole.

Some characteristic parameters of $Cu_2In_4Te_7$ are summarized in Table I.

Electrical and Thermoelectric Properties

All measurements were carried out on polycrystalline samples. Electrical conductivity measurements were made in the range 200°-570°K by a conventional

d-c method with 4-probe contacts on samples with approximate dimensions 10 × 4 × 1 mm. Both thermal conductivity and thermoelectric power were measured by the absolute method on cylindical samples 2 cm long and 1 cm in diameter by using a slightly modified version of the apparatus reported by Klein and Caldwell (9). To minimize heat transfer by radiation, the sample was surrounded with a thermal shield. Steady-state heat flow conditions were reached at each temperature with a system isolated in vacuum. The temperatures were measured by calibrated copper-constantan thermocouples soldered to the heater and sink. To insure low thermal resistance contacts, the heater, sink, and sample were lapped and then a thin layer of thermosetting silver (Johnson-Matthey) was introduced between the lapped surfaces.

The samples investigated, all of which were prepared by slow freezing, exhibit nondegenerate behavior in the electrical conductivity *vs.* temperature (200°-570°K) curves. The Hall effect (300°-400°K) and thermal emf

(100°-300°K) measurements show that the predominant carriers are holes.

At room temperature the conductivity is about $3 \cdot 10^{-4}$ mho/cm and the hole concentration p = $7 \cdot 10^{15}$/cm^3.

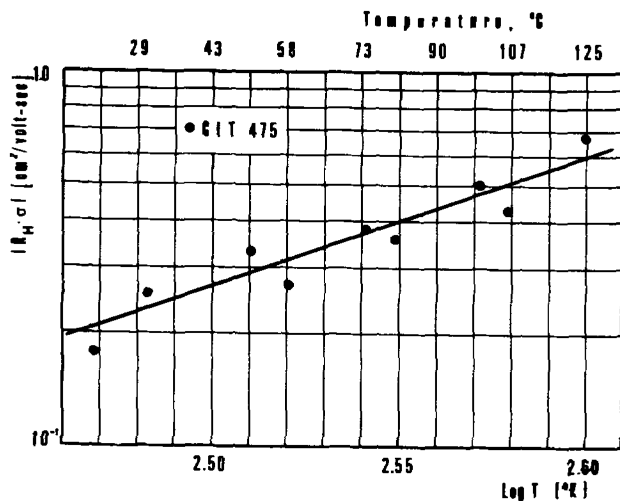

Fig. 3. Logarithm of Hall mobility plotted against logarithm of absolute temperature.

The typical curves of log σ *vs.* $10^3/T$ shown in Fig. 2 indicate that the intrinsic conductivity region begins at 390°K; above this temperature the slope of the line for the samples CIT 475 and 479 gives an energy gap of 1.10 eV.

The hole mobility calculated from the measured values of σ and R in the extrinsic range by using the single carrier approximation is between 0.3 and 1 cm^2/V-sec. The mobility in this range is plotted against temperature on a logarithmic scale in Fig. 3. The value of the scattering parameter, of the order 3/2, calculated from the slope of this graph, indicates that ionized impurity scattering is dominant at these temperatures.

Figure 4 shows the temperature dependence of the thermal conductivity, for $Cu_2In_4Te_7$ ingots CIT 475, 479, 473. Its value varies between 0.017-0.023 W/°C-cm at room temperature.

The electronic contribution at this temperature, calculated according to the Wiedemann-Franz law, is negligible ($3 \cdot 10^{-9}$ W/°C-cm). The thermoelectric power at room temperature, for the same samples of Fig. 4, is of the order 550-900 μV/°C. Its temperature variation is shown in Fig. 5.

From the measured values of thermoelectric power and Hall constant the effective mass of holes was found to be $m^*/m = 0.13$ by assuming ionized impurity scattering. The values of the figure of merit (Z), calcu-

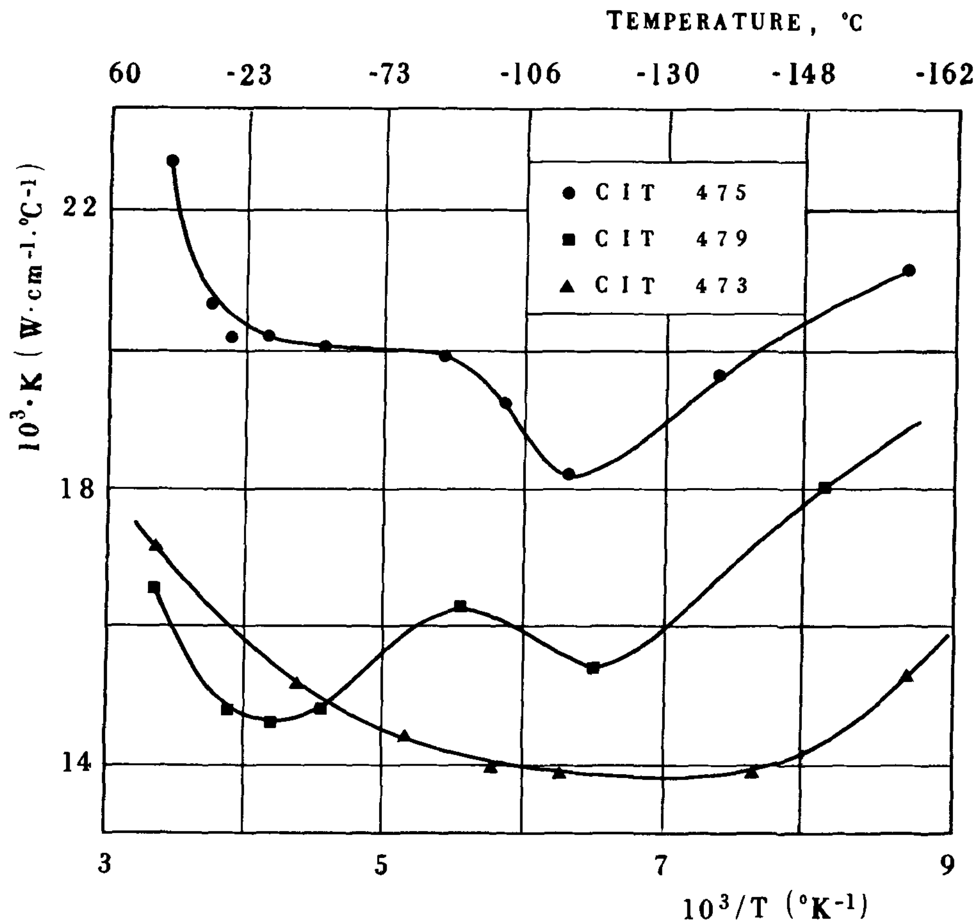

Fig. 4. Thermal conductivity vs. 1/T for three samples.

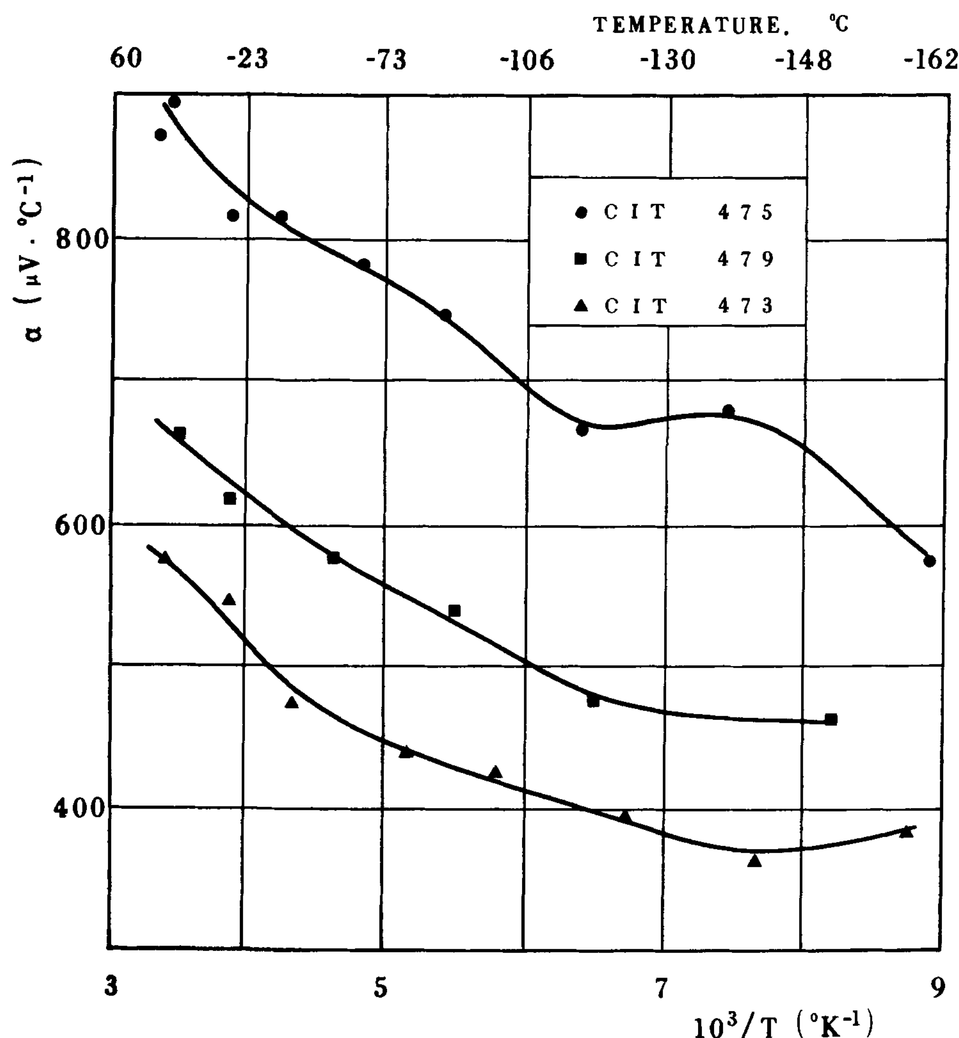

Fig. 5. Thermoelectric power vs. 1/T for three samples.

lated from the data for α, σ, and K is very small, reaching the value of 10^{-8} °K^{-1} at room temperature. Table II lists representative room temperature values of the fundamental electric and thermoelectric properties, based on the results of measurements on several samples.

Conclusion

According to the general composition formula $A^{I}_2B^{III}_{2n}C^{VI}_{3n+1}$ derived for defect tetrahedral phases in $A^{I}B^{III}C^{VI}$ system, a defect tetrahedral phase of $Cu_2In_4Te_7$ composition has been prepared and characterized by metallographic, x-ray structure, and differential thermal analysis, as a single phase of sphalerite-type structure.

$Cu_2In_4Te_7$ is a p-type semiconductor with an energy gap of 1.10 eV. Some of its properties are compared with those of $CuInTe_2$ in Table III.

On the Deposition and Dissolution of Zinc in Alkaline Solutions

J. O'M. Bockris,* Z. Nagy,*[,1] and A. Damjanovic[2]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The zinc/KOH-zincate electrode reaction was investigated under high purity conditions with galvanostatic and potentiostatic transient techniques in the 0.1-3.0M KOH and 0.0001-0.5M zincate concentration range. The exchange current density was found to be between 8 and 370 mA/cm^2, with 40 mV/decade anodic and 120 mV/decade cathodic nominal Tafel slopes; an overpotential range of ± 100 mV was covered. The cathodic reaction orders were 1 for zincate, and −1 for hydroxyl ions. A four-step mechanism, consistent with the kinetic data, is suggested. It consists of four consecutive dissociation reactions of the zincate complex, with two of them incorporating a single electron charge transfer. The rate-determining step is

$$Zn(OH)_3^- + e = Zn(OH)_2^- + OH^-$$

The mechanism of the anodic and cathodic reactions is the same. The transients indicate only double layer charging and charge transfer processes. No surface diffusion effects or intermediate build-up was observed (no pseudocapacitance). A rationalization is given for the mechanism. The effect of zinc surface preparation is discussed.

The electrochemistry of metal deposition and dissolution, in the past, has been mostly an applied science, and only in recent years has some fundamental knowledge been accumulating in this field. These advances are summarized in a recent review (1). These reactions form a special section of electrodics because the electrode material itself is being formed or dissolved during the process. Therefore, in addition to the basic charge transfer step, and the preceding or following chemical steps and solution transfer processes, the crystal building or breaking of the solid and the surface transport of intermediate species must be considered. In certain cases one of these latter steps may be rate determining; *e.g.*, the lattice building step was suggested as the rds in the electrodeposition of silver on carbon electrodes (2), and slow surface diffusion was found to be the rds for silver (3, 4) and copper (5) depositions at low overpotentials. Because of the direct involvement of the substrate in the reaction, any changes in its surface structure can have profound influence; the decrease of dislocation density can cause a shift from charge transfer control to surface diffusion control (6) and in the extreme case, on a dislocation free surface, the process may become controlled by two dimensional nucleation as was shown for silver (7, 8). These characteristics also introduce some experimental limitations, mainly the need for reproducible surface preparations, the necessity of short pulse measurements to avoid any changes in surface structure due to the measuring current, and special precautions to avoid spontaneous surface changes when in contact with the solution.

Key words: zinc/alkaline zincate electrode, reaction kinetics and mechanism, galvanostatic and potentiostatic transients, consecutive single electron transfers, predissociation, charge transfer rate-determining step.

Some fundamental work has been reported recently on the zinc/alkaline zincate system (9-13) but the experimental results and conclusions of the different investigators are contradictory. The lack of more extensive work and the poor agreement among the data are indicative of the complexity of the system; some of the difficulties arise from the possible surface changes by corrosion reaction and oxide formation. A better understanding of this system is desirable not only because of the fundamental interest in the metal deposition-dissolution reactions but also because of its technological importance. The silver-zinc battery is the only one among the presently commercially available electrochemical energy storers which approaches the power and energy density required for an electric car. However, a short cycle life limits its present use to air- and spacecraft applications (14-15). The zinc-air system seems one of the most promising future energy storers. The further improvement of this almost practical system is partly impaired by a lack of fundamental understanding of the electrode processes occurring, both at the angstrom and micron level. In this paper, the first of these levels is the subject.

Experimental

Galvanostatic and potentiostatic pulse techniques were used to examine both the transient and the steady-state current–potential behavior of the system.

Electrode preparation.—Polycrystalline zinc rods (99.999%), machined to 3 mm diameter, were used. The electrodes were first mechanically polished with silicon carbide papers (grits 180, 320, and 600), and then with alumina powders (1.0 and 0.3μ). The surface was then anodically etched for 10 min in 2M KOH solution at a current density of 2.5 mA/cm^2 with a 100 Hz 3.25 mA/cm^2 (peak) a.c. superimposed. This treatment removed a layer more than twice as thick as the

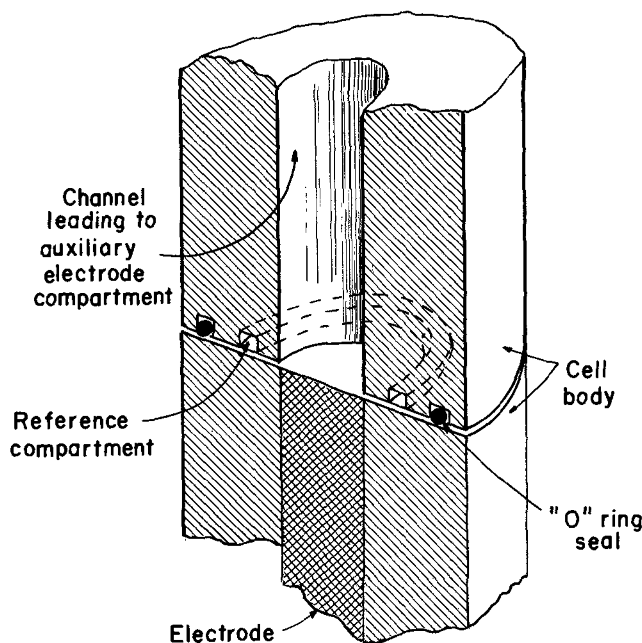

Fig. 2. Concept of cell design

last polishing powder and eliminated imbedded particles. After this treatment the rod was annealed in a purified nitrogen atmosphere at 200°C for 2 hr, followed by slow cooling. The electrode was then stored in a desiccator. A final treatment of the electrode was carried out in the test cell; it was an electrochemical reduction in 0.1M KOH solution at a current density of 50 mA/cm² for 8 min.

Solution preparation.—The solutions ranged from 0.1 to 3M KOH and from 0.0001 to 0.5M zincate. The equipment used for the solution preparation is shown schematically in Fig. 1. The procedure was as follows. Potassium amalgam was first made electrolytically from a solution of AR grade KOH dissolved in double-distilled water. The amalgam was then transferred under N_2 pressure into the decomposition vessel and electrolytically decomposed into triple-distilled water. The third distillation of the water was carried out under a nitrogen atmosphere directly into the decomposition vessel, just before preparation of the solution. This pure KOH solution was then transferred to another vessel (*cf.* D_2, Fig. 1) and left there for an extended time (10-20 hr) over zinc amalgam, prepared electrolytically from zinc sulfate solution, to remove any traces of dissolved mercury which may have been introduced during the preparation of pure KOH. Finally, the required amount of zinc was electrolyzed into the solution from the zinc amalgam. The counterelectrodes in these processes were platinum wires separated by glass frits from the main solutions. This type of purification has been shown to remove all metallic impurities below the 0.1 ppm level (16). The nonmetallic impurities were also removed since there always remained a mercury seal between the amalgam preparation and decomposition vessels and only the amalgam was transferred from one vessel to another.

During every stage of these operations, purified nitrogen was passed through the solutions. The gas was purified by passing it over 400°C copper turnings and then over 13X Molecular Sieve. The solutions were analyzed before being used by acidimetric and EDTA titrations (17). The solutions containing 0.6M KOH or less were supersaturated in zincate to avoid diffusional limitations in the measurements. The stability of the supersaturated solutions has been shown before (27).

Cell.—The measuring cell was designed to give low IR drop between the reference and the working electrode and at the same time provide a uniform current distribution and small interelectrode stray capacitances. These features were necessary to provide a short rise time for the potentiostatic transients (18). This was achieved by a cell construction which completely eliminates the "classical Luggin-capillary." The basic concept of the cell is illustrated in Fig. 2. The working electrode is pressfitted into a Teflon holder comprising the bottom of the cell. The top portion (made of KEL-F) contains the reference electrode compartment and the auxiliary electrode chamber. The latter is connected to the working electrode by a channel exactly matching the size and position of the working electrode to assure uniform current distribution. This channel is surrounded by a concentric groove which serves as the reference compartment. The cell bottom and top are held apart by a suitable spacer providing a gap between them. This circular gap serves as a connector between the working and reference electrodes and provides (*i*) a very low IR drop between the point of potential measurement and the surface of the working electrode, (*ii*) a low internal resistance, and (*iii*) a minimal interference with the current distribution. The gap thicknesses used in the present experiments were 0.0025 and 0.0125 cm. The counterelectrode was a platinum wire spiral; the reference was a zinc wire immersed in the test solution. The potential of the zinc reference was often checked against an outside Hg/HgO electrode with KOH concentration the same as that of the test solution. Purified nitrogen was bubbled continuously through the cell. A detailed description of the cell is given elsewhere (18).

Electronics.—Galvanostat.—The galvanostat was basically a transistor amplifier in the emitter-follower configuration (Fig. 3). A fixed reference voltage is supplied by the Zener diode, which results in a fixed

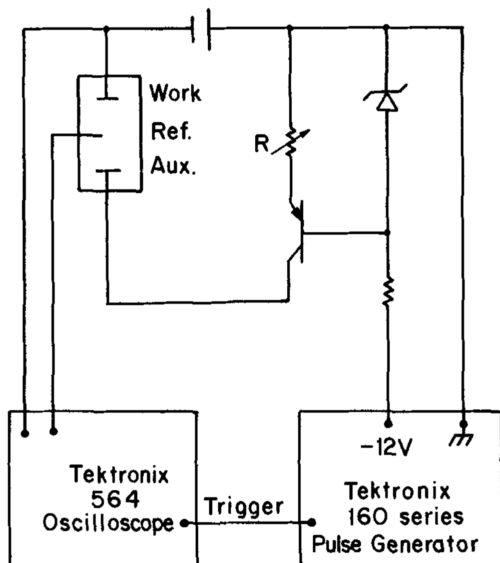

Fig. 3. Schematic of the galvanostatic equipment

voltage drop over the variable resistor, R. The current is set by the reference voltage and the value of R, and will remain constant independently of the resistance of the cell and the supply voltage. A similar type galvanostat, using a common power source for the Zener and the cell circuits, was previously described (19). When a separate pulse generator is used for the Zener it is possible to control precisely the pulse length. This is necessary in order to reduce the total charge passed during the experiments and hence to avoid excessive changes of the electrode surface.[2] In Fig. 3 the cathodic galvanostat is shown: the anodic one was similar, *mutatis mutandis*, using an n-p-n transistor. Two different circuits are needed to provide low noise sources. The potential-time transients were recorded with a Tektronix 564 storage scope connected to the cell through a voltage-follower buffer stage (20) to avoid loading the cell.

Potentiostat.—The potentiostat was a wide-band, differential input unit built of operational amplifiers. It was equipped with variable phase compensator and IR compensation features to allow fast and close control of the potential. It is described in detail elsewhere (20).

Experimental procedures.—The pulses applied were usually of 5 msec duration or shorter. Longer pulses were made only occasionally. All measurements were made at room temperature.

Galvanostatic experiment.—A galvanostatic experiment proceeded as follows. The cell was flushed and filled with 0.1M KOH solution and the working electrode was reduced. The cell then was flushed and filled with the test solution and the measurements were made. During the course of a run an arbitrarily selected current point was often repeated to check reproducibility. Usually a range of ± 100 mV overpotential was covered. Current densities up to 4 A/cm^2 were used. Some examples of the galvanostatic transients are shown in Fig. 4. In spite of the special cell used there still remained a measurable IR drop; a correction for this was applied in the determination of the overpotential. Examples of Tafel and linear plots constructed from the steady-state portion of the transients are shown in Fig. 5 and 6.

Potentiostatic run.—A potentiostatic run was completed in the following way. The electrode was reduced galvanostatically as described above. After the cell was filled with test solution, a galvanostatic pulse was applied to determine the IR drop between the reference and the working electrodes, and the IR

[2] A set-up like this could also be used to supply a galvanostatic pulse train or repetitive pulses.

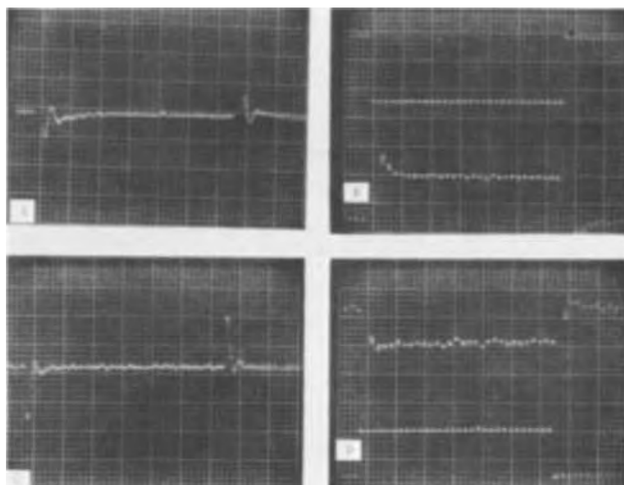

Fig. 7. Examples of potentiostatic oscillograms. Electrolyte: 1M KOH, 0.02M $Zn(OH)_4^=$. A and B cathodic, C and D anodic. A: Error signal; 10 mV/cm, 20 μsec/cm. B: Top. Potential signal to potentiostat 20 mV/cm, 20 μsec/cm. Bottom. Current, 5 mA/cm, 20 μsec/cm. C: Error signal, 5 mV/cm, 20 μsec/cm. D: Bottom. Potential signal to potentiostat, 5 mV/cm, 20 μsec/cm. Top. Current, 2 mA/cm, 20 μsec/cm.

compensation of the potentiostat was adjusted accordingly. The electrode was potentiostated at its rest potential and then a few short pulses of the desired potential were applied in order to allow optimum adjustment of the potentiostat. The error-signal of the potentiostat (the difference between the desired and actual electrode potentials) was displayed on the scope, and the phase compensation of the potentiostat was adjusted to eliminate or minimize ringing and achieve the shortest possible settling time. The measuring pulse was then applied and the current-time transient recorded. The error-signal was checked before each pulse, but the phase compensation needed only occasional readjustments. Examples of oscillograms are shown in Fig. 7.

Although the cell was designed to provide minimal IR drop, and so to avoid the necessity of IR compensation in the potentiostat, the error was still significant at the high exchange current densities, even with the smallest (0.0025 cm) gap distance. (*E.g.*, at 3M KOH concentration the solution resistance was 7 x 10^{-3} ohm cm^2 while the reaction resistance could be as low as 35 x 10^{-3} ohm cm^2, a 20% error). Therefore, a wider gap (0.0125 cm) and IR compensation was used in many of the experiments resulting in settling times of 10-30 μsec. The selection of gap thickness and the choice of operation with or without IR compensation are discussed in detail elsewhere (18, 20).

Determination of reaction orders (galvanostatic method).—Because the exchange current density *vs.* concentration plots (see Fig. 8 and 9) had a considerable spread of points, additional experiments of other types were carried out to confirm the reaction orders by the measurement of $[\partial \log i/\partial \log C_1]_{C_2,E}$. Since the spread of the i_0 was attributed to the day-to-day variations of the surface of the working electrodes, in these additional experiments the electrolyte concentration was changed during the test itself with a single electrode. In this type of experiment, the electrolyte concentration was varied and at each concentration a quick galvanostatic cathodic run was made to establish Tafel lines. The electrode was reduced before each run.

Determination of reaction orders (potentiostatic method).—An even faster way (therefore, affording less chance for surface change) was to measure the change of current at a constant potential (NHE) as a function of solution concentrations. This required tak-

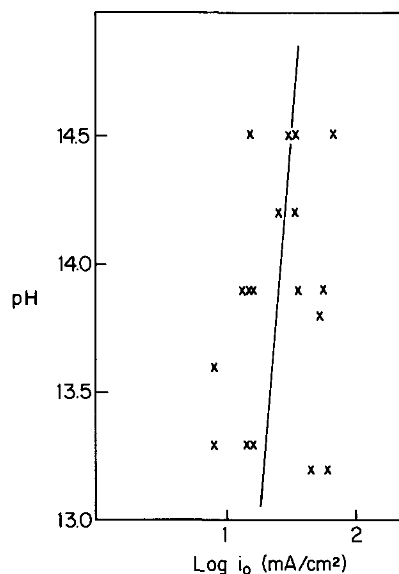

Fig. 8. The *p*H dependence of exchange current density (zincate concentration: 0.019M).

ing only one point at each concentration. It was carried out for varying zincate at constant *p*H and for varying *p*H at constant zincate concentration.

Corrosion rate measurements.—The corrosion rate of zinc in various test solutions was measured by immersing zinc wire in nitrogen stirred solutions for 74 hr; the increase of zincate concentration of the solution was determined by titration (17). The measurements were carried out at room temperature, in duplicates.

Results

Rest potentials.—The rest potential of zinc in different alkaline zincate solutions is compared to the calculated equilibrium potentials in Table I. The equilibrium values were obtained using the equation (21)

$$E = 0.441\text{-}0.1182\, p\text{H} + 0.0295 \log a_{Zn(OH)_4^=}$$

and the potential of the Hg/HgO reference electrode was taken as (22)

Table I. Measured and calculated electrode potentials

Solution composition KOH (mol/l)	$K_2Zn(OH)_4$ (mol/l)	Activity coefficient KOH	$K_2Zn(OH)_4$	Potential (NHE) Calculated (V)	Measured (V)
0.3	0.011	0.74	0.44	−1.205	−1.187
1.0	0.087	0.78	0.30	−1.248	−1.230
1.0	0.022	0.76	0.31	−1.264	−1.249
1.0	0.0065	0.75	0.32	−1.278	−1.257
3.0	0.435	1.39	0.21	−1.318	−1.291
3.0	0.085	1.12	0.22	−1.327	−1.300

$$E = 0.926 - 0.059\,\text{pH}$$

There are no activity data available for alkaline zincate solutions, and the following approximations were made to obtain the activity coefficients. For potassium hydroxide the tables of Harned and Owen (23) were used, taking the values at the appropriate ionic strengths of the test solutions, with the assumption that addition of zincate has no specific effect. Activity coefficients of a number of 1-2 electrolytes are tabulated by Robinson and Stokes (24) and the values of all the salts reported seem to be in fair agreement with each other. Therefore, as a first approximation, the coefficients reported for K_2CrO_4 were used for the zincate, taken at the appropriate ionic strengths.

Transition times.—Since the potential of zinc is negative to the reversible hydrogen potential a possibility of hydrogen evolution interference with the test measurements exists. To investigate this effect transition times of the zincate deposition reaction were measured galvanostically in the milliampere to the ampere per square centimeter current density range, at different zincate concentrations. The calculated and measured transition times agreed within the limit of experimental error [a D value of 0.7×10^{-5} cm^2/sec was used (25) in the Sand's equation].

Corrosion rates.—The corrosion rate of zinc in 1.8M KOH solution was found to be equivalent to a current of 45 $\mu A/cm^2$. Addition of 0.03 and 0.1M zincate to the above solution decreased the corrosion rate below 1 $\mu A/cm^2$ (the sensitivity of the measurement).

Galvanostatic steady-state data.—Tafel slopes.—The steady-state activation overpotentials, taken from the flat portion of the galvanostatic transients, were plotted in the usual manner (Fig. 5) and the Tafel slopes were determined. The cathodic slopes were 113 ± 30 mV/decade, and the anodic ones 49 ± 13 mV/decade. The slopes were found to be independent of solution composition.

Exchange current densities.—These were determined by extrapolation of cathodic and anodic Tafel lines (Fig. 5), and also from the polarization resistance values measured at low overpotentials (Fig. 6). The agreement among these four i_o values was better than ±10% in most cases, in a few instances deviations up to ±30% were observed. For each test, an average value was calculated and these are plotted as a function of solution composition in Fig. 8 and 9. The value of the exchange current density was found to be practically independent of pH, the statistical best line through the points of Fig. 8 gives

$$\left[\frac{\partial \log i_o}{\partial \text{pH}}\right]_{C_{Zn(OH)_4^=}} = 0.14$$

The dependence of the exchange current density on zincate concentration is shown in Fig. 9. The best fitting line has a slope of

$$\left[\frac{\partial \log i_o}{\partial \log C_{Zn(OH)_4^=}}\right] = 0.67$$

The i_o values measured at all pH's fell on the same line, confirming the virtual pH independence of the exchange current density.

Potentiostatic steady-state data.—Only a limited number of potentiostatic experiments were carried out. The resulting Tafel slopes and exchange current densities were within ± 10% of those measured galvanostatically on the same electrode.

Determination of reaction orders.—In the determination of reaction orders, the activity of water was considered constant. Calculations using the Gibbs-Duhem equation have shown that, within the limits of solution concentrations used in these experiments, the maximum change in the activity of water is 12%.

Concentration dependence.—From the concentration dependence of exchange current density, the reaction orders can be obtained by taking into account the concentration dependence of the equilibrium potential (38). By this method reaction orders of 0.94 (cathodic) and 0.06 (anodic) were found for zincate, and −0.92 (cathodic) and 2.59 (anodic) with respect to the hydroxyl ions.

Direct determination of reaction orders.—Two methods were used. The results of the galvanostatic method [*cf.* section on Determination of reaction orders (galvanostatic method)] for zincate are shown in Fig. 10. The current density values taken at a constant potential were then plotted in Fig. 11 against zincate concentration. The resulting cathodic reaction order was

$$\left[\frac{\partial \log i}{\partial \log C_{Zn(OH)_4^=}}\right]_{pH,E} = 0.85$$

With the potentiostatic technique [*cf.* section on Determination of reaction orders (potentiostatic method)] the cathodic reaction order was found to be 0.75 and 1.05 with respect of zincate ions in two separate experiments (Fig. 11).

Three measurements were made with the potentiostatic technique [*cf.* section on Determination of reaction orders (potentiostatic method)] to determine the reaction order with respect of hydroxyl ions, and the value of the cathodic

$$\left[\frac{\partial \log i}{\partial pH}\right]_{E,C_{ZnOH_4^=}}$$

was found to be −0.75, −1.04, and −1.06 (Fig. 12).

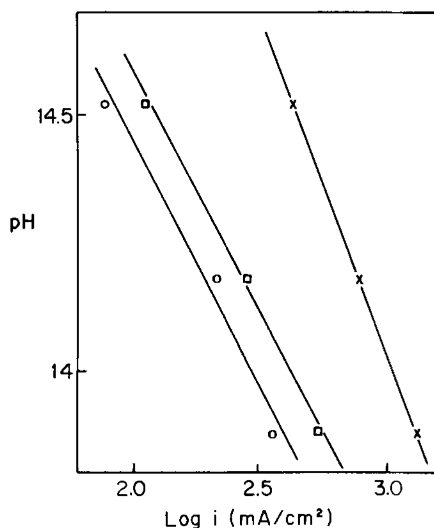

Fig. 12. Determination of cathodic reaction order in hydroxyl ions from potentiostatic (−1.358V, NHE) measurements. Zincate concentration: 0.08M. Results of three separate experiments.

Galvanostatic transient data.—Double layer capacitance.—Double layer capacitance values were obtained from the slope of the tangent drawn to the beginning of the galvanostatic transients. In summary, C was between 40 and 85 $\mu F/cm^2$ in most cases and did not show any dependence on solution composition.

Rise time of galvanostatic transients.—Rise times were measured in the linear current-potential region. Assuming that the only processes taking place are the charging of the double layer, and a charge transfer reaction, a τ value can be calculated as

$$\tau = \frac{RT}{nFi_o} \cdot C_{dl}$$

and the full rise time is expected to be about 4τ. The calculated and measured rise times agreed within 20%.

Potentiostatic transient data.—After the settling time of the system (10-30 μsec) only steady-state currents were observed, and no transient results were obtained.

Effect of cathodic reduction of the electrode.—The final reduction of the electrode in the test cell (*cf.* section on Electrode preparation) was found to be a critical step in the surface preparation. Some preliminary

Table II. Effect of reduction time on i_o and C_{dl}

Total time of reduction (min)	i_o (mA/cm²)	C_{dl} (μF/cm²)
0	8	60
0.05	14	60
5	30	85
8	30	85

data, taken with electrodes subject to a shorter or no reduction treatment, gave irreproducible results which are summarized in the following. The apparent exchange current density was not reproducible, it was strongly dependent on the duration of the reduction, increasing with increasing length of reduction and leveling off after about 5 min, with further reduction having no effect on i_o. The observed changes were of an order of magnitude; an example is given in Table II. The Tafel slopes were independent of the reduction treatment. The C_{dl} values were irreproducible, sometimes very high (several hundred $\mu F/cm^2$) capacitances were observed with unreduced electrodes, but usually the capacitance was normal and increased slightly with reduction (Table II). The transition behavior to hydrogen evolution was also variable: with fully reduced surfaces a long, flat plateau was observed for zincate reduction (*cf.* section on Transition times) with subsequent quick potential rise to hydrogen evolution (Fig. 13A); with nonreduced surfaces no flat potential plateau for zinc deposition was observed but a continuous slow rise of potential to that of hydrogen evolution (Fig. 13B,C); occasionally irreproducible shoulders appeared (Fig. 13D). After a full reduction (8 min) the electrode remains in the "reproducible" state in the solution for about ½-1 hr, then it slowly reverts to its original behavior; with repeated reduction the "reproducible" state can again be obtained.

Discussion

Rest potentials and the effect of hydrogen evolution.—The rest potential of zinc in these solutions is a mixed potential set up by the zinc dissolution-hydrogen evolution corrosion couple. Since the corrosion current is small (*cf.* section on Corrosion rates) and the exchange current density of the zinc dissolution is high (Fig. 8, 9), this rest potential will differ only slightly (less than 1 mV) from the equilibrium zinc potential (37). The rest potentials, therefore, can be directly compared to the calculated thermodynamic equilibrium potentials (Table I). The observed values are 21 ± 6 mV less negative than the calculated poten-

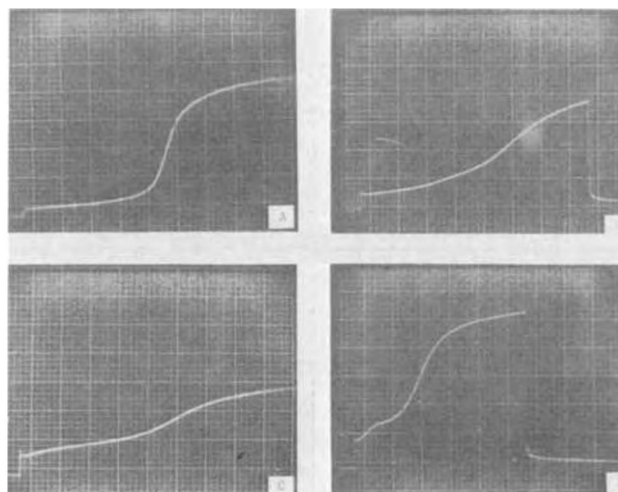

Fig. 13. Examples of zinc-hydrogen transitions. Current density: 50 mA/cm². Scale: 100 mV/cm and 100 msec/cm (A,B,C), and 200 msec/cm (D). A: Fully reduced electrode. B,C,D: Not fully reduced electrodes. Solution: 1M KOH, 0.07M $Zn(OH)_4^=$. Calculated transition time: 440 msec.

tials, a fair agreement considering the approximate nature of the activity coefficients (*cf.* section on Rest potentials). From the measured corrosion rates, and the known 120 mV/decade Tafel slope of h.e.r. on zinc (26), it can be concluded that the contribution of the h.e.r. to the cathodic current will be negligible (less than 3%) within the limits of the experimental conditions. The negligible hydrogen effect is also corroborated by the good agreement of the measured and calculated transition times for the zincate reduction reaction. The hydrogen contribution can also be calculated from h.e.r. kinetic data reported for zinc in KOH solutions (26). The exchange current density is in the range of 10^{-10}-10^{-12} A/cm^2, with a 120 mV Tafel slope. According to these data the h.e.r. current would not exceed 10 μA/cm^2 in the whole potential range investigated in the present work; this is in good order of magnitude agreement with the conclusions reached above.

Surface state of the test electrodes.—It was found that a strong cathodic reduction (*cf.* section on Electrode preparation), carried out shortly before the measurements, was necessary to obtain reasonable reproducibility for the data (less than one order of magnitude spread in the i_o values). It is suggested that the unreproducible behavior of the electrodes not subjected to this treatment (*cf.* section on Effect of cathodic reduction of the electrode) was due to residual oxide (or hydroxide) film on the zinc surface. The electrodes were in contact with air prior to assembly of the cell and therefore were covered by an oxide film; the chemical dissolution of this film by the solution is assumed to be incomplete. Such surface films have been proposed specifically for zinc by previous workers (27-28), and it has been shown in general (29-31), that a monomolecular layer of film can exist below the appropriate thermodynamic reversible potentials if the surface free energy of the electrode-electrolyte interface is reduced by the film formation. The transient behavior of the electrodes with the occasional potential arrests corroborates this suggestion. All the data used in the following mechanism determination were taken on "fully reduced" electrodes.

Selection of the reaction mechanism.—The predominant solution species has been identified as the tetrahedral $Zn(OH)_4^{=}$ ion by potentiometric and solubility studies (32-34), IR and Raman spectra (35), and NMR (36); and the over-all electrode reaction has been shown (27) to be

$$Zn(OH)_4^{=} + 2e = Zn + 4OH^- \quad [1]$$

Therefore, the simplest possible reaction mechanism must consist of at least four steps, the consecutive dissociation of the complex ion, with two steps including a charge transfer each. Different combinations of these four steps give rise to a number of possible paths. Furthermore, the charge transfer need not occur directly to or from a zinc complex, it could involve a charge transfer between the electrode and some other solution species (H_3O^+, OH^-, H_2O), and the intermediate reacting further with a zinc complex. In principle, a very large number of possible reaction paths could be suggested. In reality, the comparison of measured kinetic parameters with those predicted by the different mechanisms will considerably reduce the possibilities. The experimental facts which can be used in this selection process are summarized in Table III.

The first conclusion suggested by the experimental results is that the mechanism of the anodic and the cathodic reactions is the same (*cf.* the agreement between anodic and cathodic exchange current densities, and the fact that $\alpha_a + \alpha_c \approx 2$). In the following discussion the mechanism in the cathodic direction will be examined in detail with the full analysis applicable, *mutatis mutandis,* to the anodic reaction.

Rate-determining step.—Considering the theory of multistep electrode reactions (37-38) the Butler-Volmer equation can be written as

$$i = i_o \left[\exp\left(\frac{\alpha_a F \eta}{RT}\right) - \exp\left(-\frac{\alpha_c F \eta}{RT}\right) \right]$$

where

$$\alpha_c = \frac{\gamma_c}{\nu} + r\beta$$

$$\alpha_a = \frac{n - \gamma_c}{\nu} - r\beta$$

giving

$$\alpha_c + \alpha_a = \frac{n}{\nu}$$

where γ_c is the number of electrons transferred before the rds in the cathodic direction; ν is the stoichiometric number; n is the total number of electrons transferred in the over-all reaction; β is the symmetry factor; and r is the number of electrons transferred in a single occurrence of the rds.

Since

$$n = 2, \text{ and } \alpha_c + \alpha_a \approx 2$$
$$\nu = 1$$

Therefore

$$\alpha_c = \gamma_c + 0.5r$$

$$\alpha_a = 2 - \gamma_c - 0.5r$$

The calculated possible values of transfer coefficients are given in Table IV. Comparison with experimental values reveals that only a type B mechanism could explain the data.

Nature of the rate-determining charge transfer.—Selection among the different charge transfer reaction possibilities can be made on the basis of their predicted reaction orders with respect to zincate and hydroxyl ions. All but the zinc complex would predict a zeroeth order in zincate for the cathodic reaction, furthermore, reactions with H_2O would give a cathodic zeroeth order for hydroxyl, and if OH^- were in the rds one would predict an anodic first order with respect to hydroxyl. These predictions are in contradiction with the experimental facts (Table III) eliminating all but

Table III. Summary of steady-state results

Measured parameter	Value
Cathodic transfer coefficient (α_c)	0.56 ± 0.15
Anodic transfer coefficient (α_a)	1.3 ± 0.35
$\left[\dfrac{\partial \log i_o}{\partial \log C_{Zn(OH)_4^=}}\right]_{pH}$	0.67
$\left[\dfrac{\partial \log i_o}{\partial pH}\right]_{C_{Zn(OH)_4^=}}$	0.14
Cathodic reaction order for zincate	0.72-1.05
Cathodic reaction order for hydroxyl	(−0.75)-(−1.06)
Anodic reaction order for zincate	0.06
Anodic reaction order for hydroxyl	2.59

Table IV. Calculated values of transfer coefficients

	A	B	C	D	E	F
Number of electrons transferred in the rds (r)	2	1	1	0	0	0
Number of electrons transferred before the rds in the cathodic direction (γ_c)	0	0	1	0	1	2
Cathodic transfer coefficient (α_c)	1	0.5	1.5	0	1	2
Anodic transfer coefficients (α_a)	1	1.5	0.5	2	1	0

A represents a two electron transfer rate-determining step (rds).
B represents two consecutive electron transfer steps, with the first one in the cathodic direction being the rds.
C represents two consecutive electron transfer steps, with the second one in the cathodic direction being the rds.
D represents a chemical step rate control, rds occurs before charge transfer in the cathodic direction.
E represents a chemical rds between two single electron transfer steps.
F represents chemical rate control, the rds occurs after two cathodic charge transfer steps.

a zinc-containing species as reactant in the charge transfer step, which can then be written as

$$Zn^{++} + e \rightarrow Zn^{+} \quad [2a]$$

or

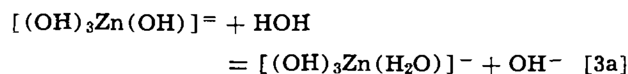
$$Zn(OH)_i^{2-i} + e \rightarrow Zn(OH)_{i-1}^{2-i} + OH^- \quad [2b]$$

This leaves five different possibilities, as reaction [2b] can be written with "*i*" ranging from 1 to 4. A selection is, however, possible comparing the predicted reaction orders in hydroxyl ion of the five reactions with the experimental values (Table III). Agreement is obtained with [2b] if $i = 3$, therefore, the first two steps of the reaction are

$$Zn(OH)_4^{=} \rightleftarrows Zn(OH)_3^- + OH^- \quad [3]$$

$$Zn(OH)_3^- + e \xrightarrow{\text{rds}} Zn(OH)_2^- + OH^- \quad [4]$$

Estimation of the rate of the chemical predissociation step—According to the above mechanism the chemical dissociation step (Eq. [3]) should be faster than the charge transfer step (Eq. [4]). An estimate of the rate of the dissociation can be obtained as follows. There are a number of reasons to suggest that the dissociation step is really a proton transfer reaction



$$[(OH)_3Zn(OH)]^{=} + HOH = [(OH)_3Zn(H_2O)]^- + OH^- \quad [3a]$$

that is the complex species in solution are

$$[Zn(OH)_i(H_2O)_{4-i}]^{2-i}$$

rather than $[Zn(OH)_i]^{2-i}$. (*i*) It is known (39) that $(pK_n - pK_{n-1})$ values remain constant with changing n (cf. Table V) unless there is a change in the symmetry of the complex. (*ii*) There is evidence for a tightly held inner coordination sphere for Zn^{++} by NMR technique (40) of about 4. (*iii*) The existence of tetrahedral $Zn(H_2O)_4^{++}$ ion was shown in nearly neutral aqueous solutions by a temperature-pH transient technique (41).

The proton transfer between OH^- ion and water molecules has been shown (42-44) to proceed by proton tunneling and the rate-determining step was found to be the orientation of the water molecule in the field of the ion to a position required for tunneling. It is suggested that reaction [3a] also proceeds by this path. The pseudo first order rate constant of the reaction

$$H_2O + OH^- = OH^- + H_2O \quad [5]$$

was reported (45) to be 2.1×10^{11} sec^{-1}. For reaction [3] this should be diminished by a Boltzmann factor arising from the fact that the free energy of the reaction [3] is 4.7 kcal (*cf.* Table V). The rate of the reaction [3] can then be calculated to be between 5×10^5 and 5×10^8 mol/liter sec, for the present zincate concentration range. This estimate gives a minimum value for the rates, the real rates are expected to be higher for the following reason. In reaction [5] the proton transfer occurs from a water molecule which is part of the water structure and its rotation is therefore hindered. In the vicinity of large ions, the first layer of water has been shown (46) to consist of free monomers which will rotate more freely than the water of reaction [5]. This minimum rate of reaction [3] can now be compared to rates of reaction [4] which were calculated from the maximum currents applied in the given zincate range as 10^4 to 4×10^5 mole/liter sec.[3]

Table V. Formation constants of zincates

[Gubeli and Ste-Marie (34)]
$pK_4 = -17.7$
$pK_3 = -14.3$
$pK_2 = -11.2$
$pK_1 = -6.3$
$K_i = \dfrac{C_{Zn(OH)_i^{2-i}}}{C_{Zn^{++}}[C_{OH^-}]^i}$

Double layer effects on the rds.—The double layer structure on solid electrodes is much less known than that of mercury, and the literature data are often contradictory and nonreproducible. Such is also the case for zinc. The value of the potential of zero charge (pzc) is not known in alkaline zincate solutions. For sulfate solutions a good agreement exists among different authors and techniques (47) giving a pzc value of -0.64 ± 0.04V. There is some evidence from capacitance minimum determinations that in chloride solutions the pzc is about 0.25V more negative, but there is no firm confirmation of this value (48-51). The potential range of the present investigation therefore, was taken to be 0.5 to 0.9V negative to the pzc of zinc in the following evaluation of double layer effects.

(*i*) At such negative potentials, and in the concentration range covered, the double layer corrections for the Tafel slope, and for reaction order determination, can be considered negligible. These corrections depend on the parameters $(\partial\phi_2/\partial\eta)$ and $(\partial\phi_2/\partial E_{rev})$ (52) which are not known for zinc but in analogy with Hg data (53) can be assumed to be less than 0.1.

(*ii*) Complications from specific adsorption of anions can also be disregarded since at such highly negatively charged electrode the adsorption of anions was found to be negligible (54-56).

(*iii*) The species reacting in the rds are negatively charged and therefore will have a negative surface excess under the prevailing conditions. Numerical values for the zinc/KOH system, again, are not known. By analogy to mercury (57) the concentration at the Helmholtz plane is expected to be 10 to 100 times lower than the bulk concentration, a decrease not large enough to be an objection against the proposed mechanism.

(*iv*) For the discharge of anions at a potential negative to the pzc a further effect should also be considered. It has been suggested (58-59) that under these conditions a limiting current may arise due to the influence of the diffuse double layer (especially at low concentrations and far from the pzc where ϕ_2 is larger). An approximate equation for this limiting current was given (58)

$$i_1 = \frac{FDC\kappa}{2} \exp \frac{F\phi_2}{RT}$$

where κ is the Debye-Hueckel reciprocal length. Limiting currents calculated with this equation for the present reaction [using ϕ_2 values from 30 to 100 mV (52)] gave at least two orders of magnitude larger current densities than the currents used in this study, showing that this effect is also negligible.

Nature of the nonrate-determining charge transfer.—The considerations of the section on the Nature of the rate-determining charge transfer refer only to the rds and give no clues as far as the other charge transfer step is concerned. A selection can, however, be made based on thermodynamic and kinetic considerations of the oxygen and hydrogen evolution reactions since the steps suggested for the charge transfer are part of these reactions. The potential range investigated extended from about -1.3 to -1.6V of the standard oxygen potential in the test solutions, thereby excluding the possibility of any charge transfer step which would be part of the oxygen evolution reaction. The hydrogen evolution reaction has been investigated in KOH solution on zinc electrodes by Iofa and co-workers (26). The exchange current density was measured to be in the order of 10^{-10}-10^{-12} A/cm^2 and the charge transfer step was found to be the rate-determining step. Since the exchange current densities observed for the zincate electrode reaction are about ten orders of magnitude larger, the charge transfer to form H_{ads} cannot be part of the mechanism. It can be concluded there-

[3] In these calculations a 5Å double layer thickness was assumed.

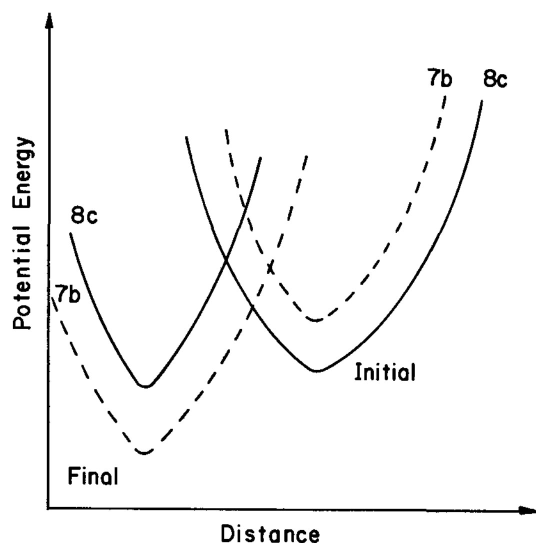


Fig. 14. Potential energy-distance curves for reactions [7b] and [8c].

fore, that the nonrate-determining charge transfer also occurs with a zinc complex reactant.

Steps occurring after the rds.—There remain but three possibilities to write up the steps following the rds

$$Zn(OH)_2^- + e \rightleftarrows Zn(OH)^- + OH^- \quad [6a]$$

$$Zn(OH)^- \rightleftarrows Zn + OH^- \quad [6b]$$

$$Zn(OH)_2^- \rightleftarrows Zn(OH) + OH^- \quad [7a]$$

$$Zn(OH) + e \rightleftarrows Zn + OH^- \quad [7b]$$

$$Zn(OH)_2^- \rightleftarrows Zn(OH) + OH^- \quad [8a]$$

$$Zn(OH) \rightleftarrows Zn^+ + OH^- \quad [8b]$$

$$Zn^+ + e \rightleftarrows Zn \quad [8c]$$

None of the measured kinetic parameters gives help in selecting between these three possibilities and there is little known about the chemistry or stereochemistry of Zn^+ complexes. The single charged Zn^+ ion is very unstable in aqueous solutions, its half-life was measured in the order of 100 μsec (60). Some speculative considerations can be made to suggest the most probable path. Changes in the activation energy of the charge transfer can be estimated using the Bockris-Matthews theory of charge transfer (61-62). Reaction [6a] produces a negatively charged species which will not be adsorbed on the electrode at the prevailing high negative potentials (*cf.* section on Double layer effects on the rds) and therefore is energetically unfavorable compared to [7] and [8] where adsorption stabilizes the charge transfer product. Furthermore, [6a] suggests that an uncharged zinc atom, coordinated by an OH^- ion, exists at the Helmholtz plane and in reaction [6b] this uncharged Zn atom transfers from the Helmholtz plane to the surface of the electrode, a rather unlikely mechanism.

For the selection between paths [7] and [8] a relative potential energy-distance diagram is used (61-62), (Fig. 14).[4] The parameters needed for the calculation of these curves are not all known, but since it is the difference between the activation energies, rather than their absolute values that is needed, only the relative positions of the curves have to be established. The curves for reaction [7b] were, therefore, drawn arbitrarily. The final state of reaction [8c] will differ from that of [7b] only by the heat of hydration of hydroxyl ions which is −110 kcal/mol (63). The initial curves will differ by the difference of heat of hydrations of Zn^+ and ZnOH. The former is estimated to be between −65 and −70 kcal/mole based on its diameter (46), while the latter (being a neutral molecule) will be negligible in comparison. These effects are shown in Fig. 14. There is one further term to be taken into account for the initial curve, and this is the Zn-OH bond energy. This value is not known but it certainly will be less than 175 kcal/mol which would be needed to overcome the above two effects. The activation energy change is therefore in favor of reaction [7].

[4] The implicit assumption is, of course, adiabaticity.

Suggested mechanism.—From the above considerations, the following reaction path is the most probable

$$Zn(OH)_4^= \rightleftarrows Zn(OH)_3^- + OH^-$$

$$Zn(OH)_3^- + e \xrightarrow{\text{rds}} Zn(OH)_2^- + OH^-$$

$$Zn(OH)_2^- \rightleftarrows ZnOH + OH^-$$

$$ZnOH + e \rightleftarrows Zn + OH^-$$

The mechanism is written in the cathodic direction, the anodic reaction proceeds through the exact reverse of the above path. This mechanism is in agreement with all the experimental facts given in Table III.

In this analysis, all data taken with supersaturated solution were included. Exclusion of these points does not alter the conclusions. This indicates that supersaturation of the solution with respect to zincate, has no effect on the mechanism.

Mechanism at low overpotentials.—Surface diffusion, rather than charge transfer, has been suggested for several metal deposition reaction (3-5) as the rate-determining step in the low overpotential region. In the present case this possibility was eliminated by the fact that the exchange current densities obtained from the extrapolation of the Tafel lines and from the slope of linear $i - \eta$ plots at low overpotentials are in complete agreement. This was further substantiated by the fact that the rise times of the galvanostatic transients can be explained by considering only the double layer charging and charge transfer processes.

Concentration of the intermediate species containing Zn^+.—The fact that no pseudocapacitance was observed indicates that the change of concentration of Zn^+-containing species in the Helmholtz plane is very small and so is its equilibrium concentration [*cf.* Ref. (6)]. This is also corroborated by the rise time of the potentiostatic transients which was found to be less than the 10-30 μsec settling time of the potentiostat. With considerable intermediate concentrations a larger rise time would be expected even if the fastest step (which determines the rise time of the potentiostatic transients) in the mechanism has a rate constant 100 times that of the rds (64-65). This low concentration is in agreement with the known reactivity of single charged zinc (60).

Comparison of the results to data of other workers.—A series of papers was published by Hampson and co-workers (10-12) on the electrochemical behavior of solid zinc in alkaline electrolytes. Both the anodic and the cathodic processes were investigated in a wide range of overpotentials and solution compositions. Armstrong and Bulman (13) investigated the anodic dissolution of solid zinc in 1 and 2M sodium hydroxide solutions using a rotating disk electrode. A very brief report is given on zinc dissolution in KOH by Kabanov (9). The experimental data of these workers is summarized in Table VI and compared to the results of this work. A good agreement is found with the results of Armstrong and Bulman and with those of Kabanov; also with some of Hampson's data. There are, however, three areas of disagreement with the data of Hampson and co-workers; (*i*) the dependence of exchange current density on zincate concentration; (*ii*) the value of Tafel slopes; and (*iii*) the value of the double layer capacitance. These are discussed in detail in the following paragraphs.

The dependence of the exchange current density on the concentration of zincate, and the transfer co-

Table VI. Comparison of experimental data

Parameter	Hampson and co-workers (10-12)	Armstrong and Bulman (13)	Kabanov (9)	Present work
i_o (mA/cm^2)	40-250	—	—	8-370
$\left[\frac{\partial \log i_o}{\partial pH}\right]_{C_{Zn(OH)_4^=}}$	0.2	—	—	0.14
$\left[\frac{\partial \log i_{an}}{\partial pH}\right]_E$	—	ca 3.5	3	2.6
$\left[\frac{\partial \log i_o}{\partial \log C_{Zn(OH)_4^=}}\right]_{pH}$	0	—	—	0.67
C_{dl} (μF/cm^2)	30-600	—	—	40-120
Anodic Tafel slope (mV/decade)	65 ± 10 (at low η)* 320 (at high η)*	42 ± 5	30	49 ± 13
Cathodic Tafel slope (mV/decade)	55 ± 8 (at low η)* 280 ± 40 (at high η)*	—	—	113 ± 30

* Calculated from the reported transfer coefficients.

efficients at low overvoltages were determined by galvanostatic double pulse technique in the linear $i - \eta$ range (11). The tacit assumption was made (66) that the solution resistance between the Luggin capillary and the surface of the electrode is small compared to the reaction resistance. [This assumption was also extended to some of their high overvoltage measurements (67), although later the authors themselves (12) realized the ohmic errors thus introduced at the high overpotentials.] The validity of this assumption can be examined by calculating the reaction resistance and the solution resistance for a number of their reported experiments. For the calculation of the solution resistance it will be assumed that the distance between the Luggin and the electrode surface was 0.3 mm (a rather close placing). The values of reaction resistance were calculated from their reported exchange current densities. The resulting values are shown in Table VII. Clearly, although the absolute value of the solution resistance is very small because of the high conductivity of the solution, it is not negligible compared to the reaction resistance due to the large exchange current density of the reaction. It therefore seems probable that the ohmic overpotential was a considerable part of the total overpotential for these workers. The following observations are consistent with this suggestion:

(*i*) The claimed independence of i_o from the zincate concentration is understandable since the addition of zincate causes little change in the conductivity.

(*ii*) The reported slight pH effect on i_o could also be, at least partially, due to the decrease of solution conductivity as NaOH was replaced by $NaClO_4$ ($\kappa_{NaOH} \approx 2.3\kappa_{NaClO_4}$) (68)

(*iii*) The reported $\left(\frac{\partial \log i_o}{\partial 1/T}\right) = 0.65$ in 7M KOH solutions, compares with $\frac{\partial \log \kappa}{\partial 1/T} = 0.72$ (69).

The above suggestion is thus consistent with their observations.

The Tafel slopes reported in a recent paper (12) for the high polarization range are surprisingly high, about 300 mV/decade for both the anodic and the cathodic processes. These measurements were done in 7M KOH solutions and Tafel behavior was reported over the 80-300 mV range. Both the solution concentration and the overpotentials are outside the range of the present work, therefore direct comparison is not possible. In fact, however, a linear η-log i relationship with a slope of about 40 mV (in agreement with the present work) exist below 80 mV polarization on the anodic curves of these workers.

Table VII. Comparison of Farr and Hampson's solution and reaction resistances

Solution	i_o (mA/cm^2)	κ(68) (ohm^{-1} cm^{-1})	R_r (ohm cm^2)	R_s (ohm cm^2)
7M KOH	238	0.54	0.054	0.056
5M LiOH	185	0.33	0.070	0.091
7M NaOH	140	0.30	0.092	0.100

The capacitance values (10) were bridge measurements taken on electrodes "equilibrated" with the solution for many hours; a strong time dependence of the values was reported. A time-dependent electrochemical behavior and some high values of capacitances for nonreduced electrodes were also found in this study (section on Effect of cathodic reduction of the electrode). It seems, therefore, that the capacitances measured with our freshly reduced zinc electrodes cannot be compared directly with those taken under quite different surface conditions.

Acknowledgments

Useful discussions with Dr. M.A. Genshaw and Dr. D. Drazic are gratefully acknowledged. Our thanks are also due to Dr. B. D. Cahan for his advice in the design of the apparatus. Financial assistance for this work was provided by the National Science Foundation under grants NSF-GK-1724, and -16550; and the A.R.P.A. Program in Materials Science (University of Pennsylvania).

Manuscript submitted June 8, 1971; revised manuscript received Oct. 28, 1971. Part of this work was presented as Paper 14 at the Detroit Meeting of the Society, Oct. 5-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Performance of Aluminum-Manganese Dioxide Dry Cells

David Belitskus

Aluminum Company of America, Alcoa Technical Center, Pittsburgh, Pennsylvania 15230

ABSTRACT

Aluminum-manganese dioxide dry cells were constructed and discharged to determine voltages, capacities, corrosion rates, pH changes, and internal resistances. Aluminum cells showed promise for moderate to heavy-duty discharge but had lower capacities than commercial general purpose zinc cells on more intermittent discharge. Anode corrosion during discharge and on open circuit following partial discharge raised cell pH and decreased capacity. The internal resistances of the aluminum cells decreased during initial discharge, indicating dissolution or alteration of the original anode film. Substitution of electrolytic for natural manganese dioxide increased cell capacity, as did certain acid additions to the electrolyte. Use of a high potential anode alloy or addition of lithium chloride to the electrolyte increased cell voltages during initial discharge but did not increase capacity. Amine additions to the electrolyte reduced corrosion but did not increase capacity.

Aluminum is a theoretically attractive anode material for primary cells, from the standpoints of electrochemical equivalence (2.98 A-hr/g, *vs.* 0.82 for Zn) and reversible electrode potential (E_0 acid $= -1.66$V, *vs.* -0.76 for Zn). However, rapid formation of an oxide film on aluminum in air or water prevents the reversible electrode potential from being reached (1). With electrolytes in which the oxide layer is soluble, potentials are higher but corrosion becomes a problem.

Key words: discharge, capacity, voltage, resistance, pH.

Table I. Dry cell electrolytes for use with aluminum anodes (14)

	A	B	C	D
$AlCl_3 \cdot 6H_2O$ (aluminum chloride hexahydrate)	8.1%	13.6%	—	6.9%
$CrCl_3 \cdot 6H_2O$ (chromic chloride hexahydrate)	3.4%	5.7%	6.1%	3.5%
NH_4Cl (ammonium chloride)	—	—	6.1%	6.9%
$(NH_4)_2CrO_4$ (ammonium chromate)	4.5%	9.1%	4.5%	—
HCl (hydrochloric acid)	2.9%	—	—	—
$KHC_8H_4O_4$ (potassium acid phthalate)	4.8%	—	—	—
MnO_2 (manganese dioxide)	63.6%	62.6%	69.4%	68.9%
C (Shawinigan black)	12.7%	9.0%	13.9%	13.8%
H_2O (water [cc/100g dry mix])	43	30	43	42

Factors associated with use of aluminum, magnesium (whose chemistry also is largely dominated by its oxide film), and zinc primary cell anodes have been reviewed by Glicksman (2).

Although the subject of numerous patents (3-13), primary cells containing aluminum anodes are not in commercial production. The present work was undertaken to further characterize and improve the aluminum cells described by Stokes (14).

Cell Construction

Size D cells were constructed from the duplex alloy aluminum cans (0.010 in. thick 99% Al, 99.8% pure-1% Zn inner layer, 0.004 in. thick 3003 alloy outer layer) previously found to reduce pitting perforation (6, 14). Separators made from 0.16 mm thick, medium weight chromatography paper were employed along with paper washers and paraffin-impregnated carbon rods identical to those in zinc dry cells. Cells were constructed using the electrolyte formulations listed by Stokes (14) and repeated here as Table I. Water contents were adjusted to give consistencies comparable to those of commercial zinc cells. The black mix, including natural (African) MnO_2 ore, 50% compressed Shawinigan black, and the electrolyte, was compacted at 200 psi in cans lined with dry paper, with the electrolyte exuding from the mix to wet the paper. Cells were sealed with either pitch of the type used in zinc cells or with a 1:1 mixture (by weight) of beeswax and rosin.

Capacity

Testing was concentrated on "B" formulation aluminum cells, found to have the greatest capacity, and "C" formulation cells, reported to have a long shelf life (8). Six different brands of general purpose zinc cells purchased through normal sources and aluminum cells aged for one week or more after assembly were discharged in 4- and 2.25-ohm continuous and intermittent tests. The intermittent testing employed automated apparaus.

Each curve in Fig. 1 represents an average from 2-6 zinc or "B" formulation aluminum cells in 4-ohm tests. Capacities of aluminum cells increased as testing became more intermittent, from continuous discharge, to the heavy industrial flashlight test (4 min discharge per 15 min period, 8 hr per day), to the light industrial flashlight test (4 min discharge per hour, 8 hr per day), but dropped off on the general purpose test (5 min discharge per day).[1] Increase in performance with intermittent testing was much greater for zinc cells. Some 2.25-ohm tests, continuous and general purpose,[2] were also performed with the following results: continuous discharge, 255 min for Al cell and 200 min for Zn cell; general purpose test, 225 min for Al cell and 490 min for Zn cell. Some of the discharge times to cut-off in Table II of the original report on these cells (14) are believed to be high because of contact resistances that developed in the automatic intermittent discharging apparatus.

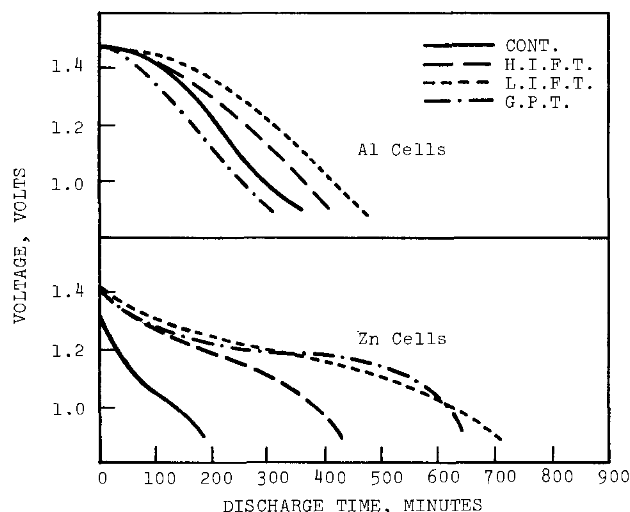

Fig. 1. Discharge curves for "B" formulation aluminum dry cells and commercial general purpose zinc dry cells: 4-ohm discharges. [Cont. = Continuous Discharge; H.I.F.T. = Heavy Industrial Flashlight Test; L.I.F.T. = Light Industrial Flashlight Test; G.P.T. = General Purpose Test.]

The ratios of "B" formulation aluminum cell capacity to zinc cell capacity (in terms of minutes of service to cut-off voltage for each of the various tests performed, *i.e.*, 0.90V for the 4-ohm tests, 0.65V for the 2.25-ohm tests) are plotted against minutes of discharge per day in Fig. 2. For comparison of cells under continuous discharge, minutes-per-day was arbitrarily taken as the average of aluminum and zinc cell service to the cut-off voltage. On this basis. formulation "B" aluminum cells outperform general purpose zinc cells in discharges where the cell is under load for more than about 2 hr per day. From the discharge curves from both the 4- and 2.25-ohm tests, energy (watt-hours) extracted from the cells (to the cut-off voltage) was also determined and the ratios are included in Fig. 2. Because of initially higher voltages under load (about 0.07V higher under either 4- or 2.25-ohm load), the aluminum cells performed even better on this basis, yielding greater watt-hour capacities than zinc cells when discharged for more than about 1.25 hr per day. Considering that the commercial zinc cells undoubtedly contained some electrolytic ore, which increased capacity, these aluminum cells show promise for moderate to heavy-duty discharges.

Aluminum cells with the "C" formulation had lower capacities, yielding 270 min of service to 0.90V

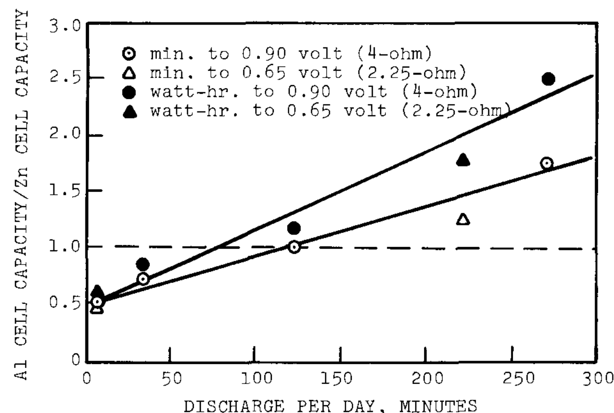

Fig. 2. Comparison of capacities of "B" formulation aluminum dry cells and commercial general purpose zinc cells. [Time for continuous discharge is average for Al and Zn cell to cut-off voltage; intermediate times are for standard discharge tests.]

[1] The heavy industrial flashlight test (4-ohm) and light industrial flashlight test (4-ohm) are standard tests (National Bureau of Standards Annual Qualifications Tests) for D-size cells. The general purpose test (4-ohm) has been discontinued for D-size cells.

[2] The general purpose test (2.25-ohm) is a standard test for D-size cells.

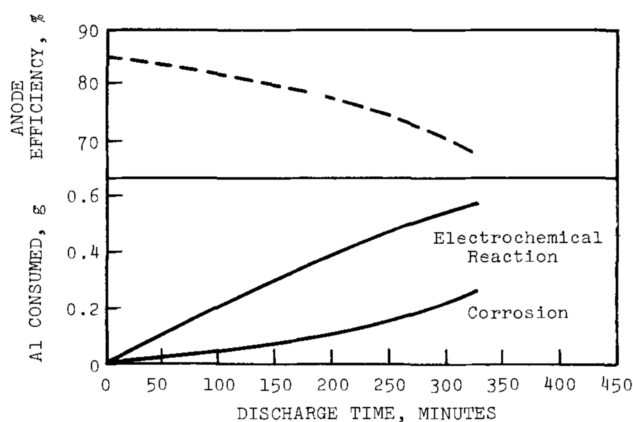

Fig. 3. Anode consumption and efficiency of a "B" formulation aluminum dry cell during a 4-ohm continuous discharge.

when discharged continuously under 4-ohm load and 350 min on the heavy industrial flashlight test (4-ohm), for example. Cells having the "A" and "D" formulations had intermediate capacities.

Corrosion

Corrosion of aluminum, with the evolution of hydrogen, was significant under all discharge conditions as in Fig. 3 for 4-phm continuous discharge of a "B" formulation cell. Over-all anode ampere-hour efficiency to a 0.90V cut-off was 71%, calculated from the discharge curve in Fig. 1 and simultaneous gas evolution data (not shown). Total gas evolution was 300 ml (NTP). During intermittent discharge gassing continued during periods on open circuit, but at a reduced rate. The ammonium chromate in the black mix inhibits corrosion of unused cells but apparently is of less value after a cell has been partially discharged. The corrosion on open circuit decreased anode efficiencies as discharge became more intermittent. During the heavy industrial flashlight test (4-ohm), gas evolution to a 0.90V cut-off increased to 550 ml, corresponding to an anode efficiency of 65%; during the light industrial flashlight test (4-ohm), gas evolution and anode efficiency were 800 ml and 57%, respectively. During the general purpose test (4-ohm), gassing was not recorded during an entire discharge, but efficiency extrapolated from gas evolution during one week was 33%. Cells which had undergone the general purpose test for one week continued to evolve gas for at least two weeks after discharging. The low capacity of aluminum cells on the general purpose test was probably due to this extensive corrosion.

Gas evolution invariably caused seal rupture and leakage of cells during continuous discharge, and usually during the heavy industrial flashlight test. Paraffin-impregnated carbon rods sufficiently porous to permit escape of gas can undoubtedly be developed. A few cells vented through dimethyl silicone membranes did not leak during continuous discharge.

Acidity of Electrolyte

Numerous studies on zinc dry cells have indicated that during intermittent discharge the MnO_2 is reduced according to the reaction

$$MnO_2 + H^+ + e \rightarrow MnOOH \quad [1]$$

so that cell voltage is a function of pH [-0.059 V/pH at 25°C theoretically, although this value is seldom observed (15)]. Hydrogen ions are replenished by hydrolysis of zinc ions added in the original formulation and generated during the cell reaction. During continuous discharge hydrolysis and diffusion are apparently not rapid enough to maintain acidity, and cell capacity is low.

The change in acidity of the cathode-electrolyte mix of aluminum cells with extent and type of discharge was measured and compared with zinc cells. To prevent any effect from differences in cathode-electrolyte mix, comparisons were made between aluminum and zinc anode cells having the identical mix. This consisted of: 15% NH_4Cl, 5% $ZnCl_2$, 1% $(NH_4)_2CrO_4$, 70% natural MnO_2, 9% Shawinigan black, and ~25 ml H_2O/100g black mix.

The mix is similar to that used in zinc cells, except for the $(NH_4)_2CrO_4$ added to reduce aluminum corrosion. These zinc cells had lower capacities than the commercially available cells but showed the same large increase in capacity during the heavy industrial flashlight test (relative to continuous discharge) as commercial cells.

The change in pH during discharge was measured by a glass electrode pressed into finely ground black mix removed from cells subjected to continuous discharge (4-ohm), the heavy industrial flashlight test (4-ohm), and the light industrial flashlight test (4-ohm) for various predetermined times.

The initial cell pH of 5.2 for zinc cells in Fig. 4 increased during continuous discharge and cell capacity was correspondingly low. During the heavy industrial flashlight test, pH leveled off near 6 and cell capacity was correspondingly much greater. A small additional increase in capacity (and a marginally flatter pH curve) was obtained during the light industrial flashlight test.

As with the aluminum cells described previously, the capacities in Fig. 5 for cells with aluminum anodes increased slightly as discharge became more intermittent. The pH increased most rapidly during continuous discharge and less rapidly as discharge became more intermittent, but did not level off even during the light industrial flashlight test. The pH increased in the same way during discharge of cells having the formulations in Table I, even though initial pH was lower. For example, pH of a "C" formulation aluminum cell was 3.5 before discharge and 7.8 after a 4-ohm continuous discharge to 0.90V.

Thus, capacity of an aluminum anode cell, like capacity of a zinc cell, is related to changes in pH of the cathode-electrolyte mix during discharge. The present formulations for aluminum cells probably do not maintain a low pH during either continuous or intermittent discharge because of the extensive corrosion that consumes hydrogen ions both during discharge and, to a lesser extent, on open circuit, as represented below

$$2Al + 6H^+ \rightarrow 2Al^{3+} + 3H_2 \quad [2]$$

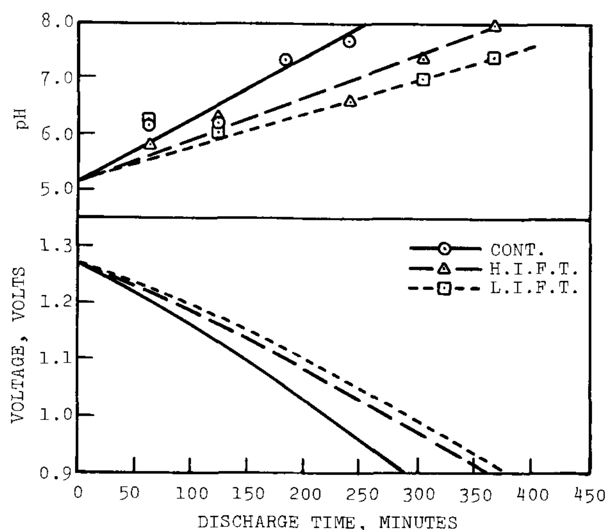

Fig. 5. Discharge curves and pH changes of the electrolyte of aluminum dry cells (having the same electrolyte as zinc cells shown in Fig. 4): 4-ohm discharges. [Cont. = Continuous Discharge; H.I.F.T. = Heavy Industrial Flashlight Test; L.I.F.T. = Light Industrial Flashlight Test.]

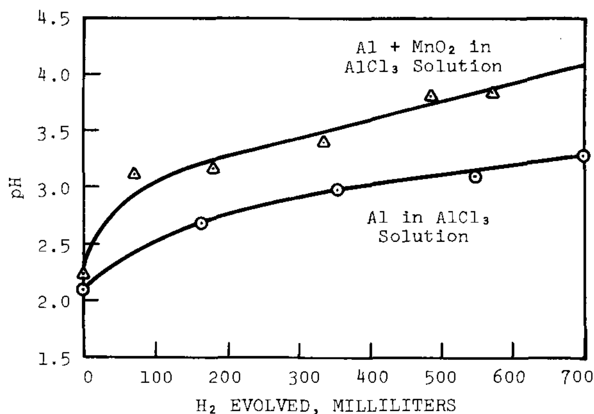

Fig. 6. Change in pH of an electrolyte caused by aluminum corrosion and by reduction of manganese dioxide: 6g $AlCl_3 \cdot 6H_2O$/20 ml H_2O + 2g Al powder, with or without 3g MnO_2.

Although hydrogen ions can be regenerated by hydrolysis of the aluminum ions formed, they are consumed more rapidly and pH increases. This was demonstrated by hydrogen evolution and pH changes in Fig. 6 for mixtures prepared by adding 2g of atomized aluminum powder (0.85 m^2/g surface area) to a solution of 6g $AlCl_3 \cdot 6H_2O$ dissolved in 20 ml of water and the same mixture with 3g of natural manganese dioxide added. The latter test simulates hydrogen ion consumption by cell discharge (Reaction [1]) and the accompanying aluminum corrosion (Reaction [2]). These tests were, of course, only qualitative since the electrolyte composition and aluminum surface area differed from those in an actual cell.

Internal Resistance

Another possible cause of relatively low capacity of the present aluminum cells was high internal resistance from an anode film or reaction products such as $Al(OH)_3$. Comparative internal resistances of zinc and formulation "B" and "C" aluminum cells were measured with an oscilloscope, milliammeter, and a mercury switch by interrupting the current momentarily during discharge across a 3-ohm resistance.

As for magnesium dry cells (16) the instantaneous voltage changed more for aluminum cells than for commercial zinc cells. An oscillographic trace for the "B" formulation aluminum cell one minute after the start of discharge is shown in Fig. 7(a). While the

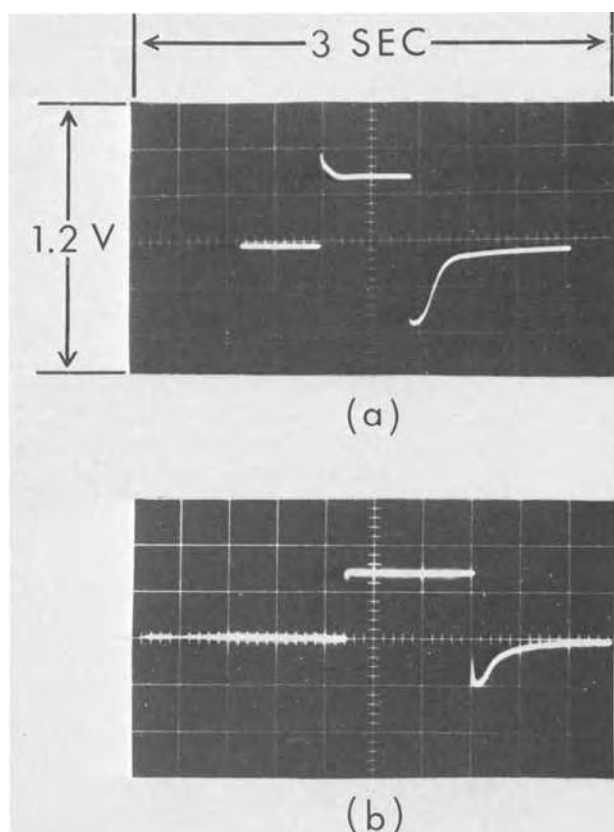

Fig. 7. Voltage of an Al dry cell (formulation "B") for a 3-ohm discharge, with (from left to right) the circuit closed, opened, and reclosed: (a) 1 min after start of discharge; (b) 2 hr after start of discharge.

circuit was closed, the aluminum anode was either film free or the film was readily penetrated by electrolyte species, probably chloride ions. When the circuit was opened, the anode was in an active condition, but passivated in about 0.1 sec to attain a steady voltage. Reclosing the circuit decreased the voltage below the steady closed-circuit voltage until the oxide film could be fully penetrated, which required over 0.5 sec. The difference between the instantaneous and steady closed-circuit voltage early in the discharge was about 0.34V for "B" formulation cells and 0.52V for "C" formulation cells. Zinc anode chemistry is not dominated by the presence of a surface oxide film, and the voltage changed only 0.05V instantaneously in opening or closing the circuit.

As discharge proceeded, two changes in aluminum cell ("B" formulation) behavior took place in Fig. 7(b). The voltage instantaneously attained a constant value on opening the circuit, and the difference between the instantaneous and steady closed-circuit voltage decreased. Both of these changes indicate a trend toward decreased film formation, possibly because the chromate inhibitor was losing effectiveness. This correlates with the increase in corrosion rate during discharge (*cf.* Fig. 3).

The internal cell resistances obtained by dividing the instantaneous change in voltage produced by opening the circuit[3] by the current at each of several stages of discharge are plotted against discharge time in Fig. 8. The zinc cell resistance was essentially constant during discharge, while resistances of both types of aluminum cells were about constant for 30 min, decreased sharply, then gradually increased. The large increase

[3] The rapidity of this measurement should minimize any polarization effects. During the subsequent period on open circuit (~0.5-1 sec), the voltage of the zinc cell gradually increased, indicating polarization. This effect increased with extent of discharge. There was no change in the open-circuit voltage of the aluminum cells in the same time span except for the passivation phenomenon mentioned above.

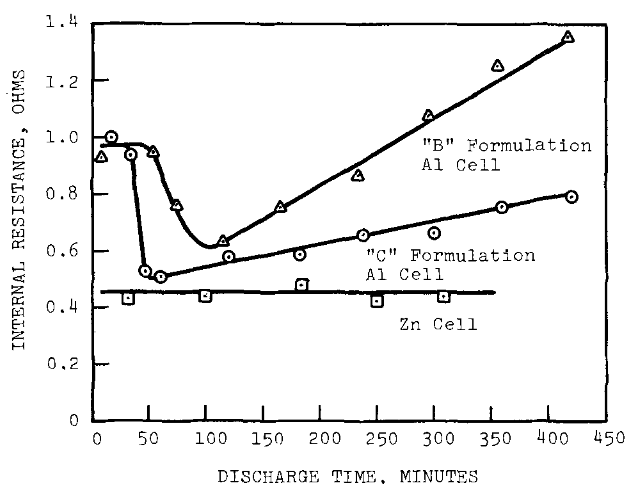

Fig. 8. Internal resistances of two aluminum dry cells and a commercial general purpose zinc dry cell: 3-ohm discharges. [Continuous discharge, except for momentary interruptions.]

in internal resistance of the "B" formulation aluminum cell correlates with the voltage drop in the discharge curve for this cell. During continuous discharge, the voltage for a "B" formulation cell decreases slowly initially but then drops rapidly [*cf.* Fig. 1(a)], whereas the voltages of a zinc cell [*cf.* Fig. 1(b)] and "C" formulation aluminum cell drop rapidly at first, then more slowly. The large increase in resistance of the "B" formulation cell could be the result of a build-up of amorphous $Al(OH)_3$ [4] produced from the large amount of $AlCl_3 \cdot 6H_2O$ in the cell formulation and the added aluminum ions formed by the discharge and corrosion reactions. The "C" formulation cell does not include $AlCl_3 \cdot 6H_2O$ in the electrolyte formulation so might be expected to show less of a resistance increase, as is the case.

The high internal resistance of the undischarged aluminum cells appears to be an anode phenomenon. A cell with "B" formulation electrolyte but a zinc anode had an initial resistance similar to that of a commercial zinc cell and an increase in resistance with discharge time. Also, the minima in resistance of the aluminum cells in Fig. 8 correspond closely to a noticeable decrease in the difference in instantaneous closed-circuit voltage and the steady closed-circuit voltage, as shown in Fig. 7. The aluminum anode of an undischarged cell is probably covered with a resistant oxide or chromate film which decreases working cell voltage during the early part of the discharge. During continued discharge, this film is dissolved or modified and cell resistance decreases. The straight line portions of both aluminum cell curves in Fig. 8 extrapolate to about 0.4 ohm. The difference between actual initial resistance and this value, about 0.5 ohm, could be attributed to the initial resistance of the anode film. While reducing cell capacity by increasing internal resistance, this film undoubtedly improves the storage capabilities of new or slightly discharged cells.

Aluminum Cell Modifications

Use of electrolytic manganese dioxide.—Substitution of electrolytic (Mitsui) manganese dioxide for natural ore improved aluminum cell capacity significantly: a "B" formulation aluminum cell containing electrolytic manganese dioxide had a capacity of 580 min (to 0.90V) on the heavy industrial flashlight test (4-ohm), 35% greater than a cell with natural ore. Initial voltage under load was 1.50V, 0.03V higher than a cell with natural ore.

Anode alloy change.—While the potentials of binary aluminum-zinc alloys are higher than aluminum, they are lower than zinc. A ternary galvanic anode alloy, CB75[5] (Al-7.2% Zn-0.12% Sn), with a potential of −0.85V (*vs.* H_2 electrode) in 0.5M $AlCl_3$ + 0.2M $(NH_4)_2CrO_4$, compared with −0.66V for Al-1% Zn, and −0.77V for zinc, was tried as a dry cell anode in "B" formulation cells. The initial cell voltage was 1.65V on the heavy industrial flashlight test (4-ohm) but capacity was not improved over a cell with Al-1% Zn. A black coating which may have increased cell resistance formed on the anode.

Electrolyte changes.—"B" formulation cells containing 1 ml of various corrosion inhibiting amines and amino alcohols (triethanolamine, triethylenetetramine, n-isopropylethylenediamine, or 2-(isoamylamino)-ethanol) were tested under the heavy industrial flashlight test (4-ohm). Although gassing in some cases was only 70% that of cells without the additions, capacity was not correspondingly increased. A film which decreased corrosion but increased cell resistance may have formed.

Two acids which are solids at room temperature, citric and oxalic, were mixed into the black mix of "C" formulation aluminum cells (1.5 g/cell) in an attempt to maintain a low pH during discharge without overly lowering initial pH (which would increase corrosion on shelf stand). It was hoped that solid acid would slowly dissolve during discharge. While the cells had higher capacities than cells without the additions (50% greater for the cell with oxalic acid) on the heavy industrial flashlight test (4-ohm), an initial gas-producing reaction of the acids with manganese dioxide made sealing of the cells difficult. A buffer system, included in "A" formulation cells, did not produce a high capacity.

Substitution of lithium chloride for chromic chloride in "B" formulation aluminum cells, to reduce internal resistance, increased closed circuit (4-ohm resistance) voltage 0.10V, but reduced capacity during the heavy industrial flashlight test. The lithium chloride perforated the aluminum anode cans during discharge, reducing capacity.

Discussion

Capacities of some D-size aluminum dry cells containing natural manganese dioxide exceeded those of commercial general purpose zinc cells on heavy-duty discharge, and capacity was increased substantially by use of electrolytic manganese dioxide. Because of higher initial potentials under load, the aluminum cells performed even more favorably on a watt-hour basis.

On continuous 4-ohm discharge, an aluminum anode yielded 71% of its theoretical ampere-hour capacity, or 2.1 A-hr/g, comparable to the theoretical capacity of a magnesium anode, and about 2.5 times the theoretical capacity of a zinc anode. Even under the most unfavorable discharge condition (general purpose test), an aluminum anode yielded 1.0 A-hr/g.

The ammonium chromate added to aluminum cell electrolytes to reduce corrosion of undischarged cells loses effectiveness during discharge until the anode of a partially discharged cell corrodes even on open circuit. In addition to decreasing anode efficiency and producing hydrogen, the corrosive reaction raises cell pH, decreasing manganese dioxide capacity. Although a certain amount of corrosion may be inevitable while the cell is under load and the anode surface is relatively film free, an alloy-electrolyte-inhibitor combination which would effectively inhibit corrosion of a partially discharged cell on open circuit, should increase capacity on intermittent discharge as with zinc cells. An alternate, although less satisfactory, method of increasing capacity on intermittent discharge may be adding materials which can help maintain a low pH. Additions of this type present a trade-off by re-

[4] X-ray diffraction examination of the black mix, material in the separator, and material adhering to the anode surface revealed no crystalline alumina.

[5] Patented, Aluminum Company of America.

ducing the amount of manganese dioxide which can be included in the cell.

After remaining fairly constant for a short time, the internal resistance of an aluminum dry cell decreases during discharge because of dissolution or modification of the anode film, then increases. A cell formulation high in aluminum chloride produces the largest increase, possibly due to $Al(OH)_3$ formation. However, since a cell with this formulation has a high capacity, other factors such as pH control must be more important.

Hydrogen Ion (Proton) Conduction in Thoria-Base Solid Electrolytes

David A. Shores* and Robert A. Rapp*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The total conductivities of a series of ThO_2-base electrolytes have been determined over a wide range of oxygen activity in atmospheres of $H_2/H_2O/Ar$ mixtures. At 1200° and 1400°C and low oxygen activities, a significant conductivity contribution corresponding to hydrogen ion (proton) conduction was found for electrolytes with high dopant contents. The experiments are interpreted in terms of a defect model involving two dopants.

When high temperature equilibration with a gas phase containing H_2-H_2O, CO-CO_2, etc. is used to establish the oxygen activity of a compound, it is important to know the extent to which the second components of the gas mixtures are soluble and mobile in the compound, particularly in experiments concerned with the nature, concentrations, and mobilities of charged point defects. Stotz and Wagner (1) have analyzed several defect reactions whereby hydrogen or water vapor may dissolve into oxides as protons or hydride ions at high temperatures. If a substantial solubility for these dopant ions exists, the defect-dependent properties of the oxide will be altered.

Hydrogen dissolved in crystalline oxide can be treated as a dopant whose concentration is established by equilibration with an atmosphere containing hydrogen. In the following discussion, the dissolved hydrogen is considered to be fully ionized either as H^+ or H^-, and thus the concentration of dissolved neutral hydrogen atoms is assumed to be negligibly small. To maintain electrical neutrality in the presence of dissolved hydrogen ions, compensating changes in the concentration of the predominant defects in the host crystal will occur according to the arguments of Koch and Wagner (2) and Kröger and Vink (3). In the present work, with the dissolution of hydrogen into doped oxide electrolytes, the base oxide, ThO_2, is actually doped with two components, i.e., hydrogen ions and aliovalent metal ions. In the absence of hydrogen and over a range of relatively low oxygen activities, the predominant ionic defect is the oxygen vacancy whose concentration is essentially established by the metal dopant content, *eg.*, Y_2O_3, La_2O_3, or Sm_2O_3 in ThO_2 (4-6). Within this P_{O_2}-range, and with the presence of hydrogen, electrical compensation of dissolved hydrogen ions is assumed to occur by changes in the concentration of oxygen vacancies. At oxygen activities above and below the P_{O_2}-range of predominant ionic conduction, the effect of dissolved hydrogen on the positive hole and excess electron concentrations might become observable.

Wagner (7, 8) and Kröger (9, 10) have shown that each dopant affects the solubility of the other dopant. The interaction is such that the solubility of each is increased if the dissolved ions have relative charges of opposite sign and is decreased in the case of relative charges of the same sign. The interaction between dopants arises from the electrical neutrality condition, which in the present study is

$$n + 2[O_i''] + [F_{Th}'] = p + 2[V_O^{\cdot\cdot}] + [H^{\cdot}] \quad [1]$$

where according to the defect notation of Kröger and Vink (3), n and p are the concentrations of electrons and positive holes respectively, $V_O^{\cdot\cdot}$ is an oxygen vacancy, O_i'' is an interstitial oxygen ion, $H^{\cdot}$ is a dissolved hydrogen ion (proton), F_{Th}' denotes La_{Th}', Sm_{Th}' or Y_{Th}', etc., and the brackets denote concentrations. There are numerous examples of controlled doping with two or more components in both elemental semiconductors and in simple ionic compounds (9) in which the description by an algebraic summation was adequate. On the other hand, in a discussion of the effects of multicomponent doping in calcia-stabilized zirconia, Kröger (10) found it useful to postulate the

* Electrochemical Society Active Member.

Key words: ionic conductivity, proton conduction, ThO_2-base electrolytes.

existence of uncharged associates, $(Ca_{Zr}V_O)^x$, which in effect, reduced the concentration of dopant calcium ions $[Ca_{Zr}'']$ that entered the electrical neutrality condition. In the present study, it is assumed that interactions between defects, such as the formation of associates, do not occur.

Stotz and Wagner (1) have proposed some defect reactions whereby hydrogen can dissolve into an oxide which contains oxygen vacancies as the predominant defect. Two possibilities involve either interstitial protons $(H_i^\cdot)$ or hydride ions (H^-) located on oxygen lattice sites $(H_O^\cdot)$. Both defects have a net electrical charge of +1 relative to the host crystal.

For the case of interstitial protons, an oxide crystal containing anion vacancies as the predominant ionic defect could equilibrate with an atmosphere containing $H_2(g)$ and $O_2(g)$ by

$$H_2(g) + \tfrac{1}{2} O_2(g) + V_O^{\cdot\cdot} \rightleftharpoons 2H_i^\cdot + O_O \quad [3]$$

where O_O denotes an oxygen ion on a normal lattice site. From the law of mass action corresponding to the assumption of a dilute solution of defects

$$K_3 = \frac{[H_i^\cdot]^2}{[V_O^{\cdot\cdot}]\, P_{H_2}\, P_{O_2}^{1/2}} \quad [4]$$

Further, for equilibrium in the gas phase

$$H_2(g) + \tfrac{1}{2} O_2(g) \rightleftharpoons H_2O(g) \quad [5]$$

so that

$$[H_i^\cdot] = K_3^{1/2} K_5^{-1/2} [V_O^{\cdot\cdot}]^{1/2} P_{H_2O}^{1/2} \quad [6]$$

The partial electrical conductivity of a charged species is given by

$$\sigma_i = c_i q_i u_i \quad [7]$$

where σ_i is the partial conductivity (ohm^{-1}-cm^{-1}), c_i is the carrier concentration (number/cm^3), q_i is the charge on the species (coulombs), and u_i is the electrochemical mobility $\left(\frac{\text{cm/sec}}{\text{V/cm}}\right)$. Thus it follows from Eq. [6] and [7] that at constant temperature

$$\sigma_{H_i^\cdot} \propto [V_O^{\cdot\cdot}]^{1/2} P_{H_2O}^{1/2} \quad [8]$$

Alternatively, if negatively charged hydride ions are situated on oxygen lattice sites, then

$$2H_2(g) + V_O^{\cdot\cdot} + O_O \rightleftharpoons 2H_O^\cdot + H_2O(g) \quad [9]$$

From the law of mass action

$$K_9 = \frac{[H_O^\cdot]^2 P_{H_2O}}{P_{H_2}^2 [V_O^{\cdot\cdot}]} \quad [10]$$

From Eq. [5] and [10]

$$[H_O^\cdot] = K_9^{1/2} K_5^{-1} [V_O^{\cdot\cdot}]^{1/2} P_{H_2O}^{1/2} P_{O_2}^{-1/2} \quad [11]$$

From Eq. [7] and [11]

$$\sigma_{H_O^\cdot} \propto [V_O^{\cdot\cdot}]^{1/2} P_{H_2O}^{1/2} P_{O_2}^{-1/2} \quad [12]$$

A comparison of Eq. [6] with [11] and [8] with [12] shows that the solubility and partial conductivity of interstitial protons are independent of P_{O_2}, whereas the solubility and partial conductivity of hydride ions are proportional to $P_{O_2}^{-1/2}$. Measurements of the partial hydrogen ion conductivity as a function of P_{O_2} at constant P_{H_2O} may be used to distinguish between the two defect models. Equations [6] and [11] show explicitly that the solubility of hydrogen depends on the concentration of the other dopant, *viz.*, with $2[V_O^{\cdot\cdot}] \approx [F_{Th}']$ (when $[H^\cdot]$ is small)

$$[H^\cdot] \propto [F_{Th}']^{1/2} \quad [13]$$

If an oxide solid electrolyte dissolves a significant concentration of hydrogen ions, then the use of H_2-H_2O mixtures as an oxygen electrode in a galvanic cell could lead to mixed electrode reactions and hence to an ambiguous cell voltage with an unreliable determination of oxygen activities. Further, the doping effect of hydrogen ions could conceivably affect the partial electronic conductivities (to be discussed) and thereby change the range of oxygen activities over which the electrolyte exhibits predominant ionic conduction $(t_{ion} \geqq 0.99)$. For other applications (11) a significant solubility and partial conductivity of hydrogen ions in a solid electrolyte might affect the experiment or process in other ways.

Only one measurement of the solubility of hydrogen or water vapor in solid oxide electrolytes has been reported. Wagner (12) found that the solubility of water vapor in ZrO_2 containing 8 or 17 weight per cent (w/o) Y_2O_3 at relatively low temperature (near 900°-1000°C) was rather low, about 13-30 parts per million. However, the activities of hydrogen and oxygen in the gas phase were not fixed and known, but rather were established through the dissociation of water molecules. In another paper, Primas *et al.* (6) reported electrical conductivities in thoria-base solid solutions which appear to have a significant hydrogen ion component under certain conditions. The present study was an extension of that aspect of Primas' work, and its purpose was to test the proposals of Stotz and Wagner (1) which concerned the dissolution of hydrogen or water vapor in solid oxides containing oxygen vacancies as the predominant ionic defect.

Experimental Procedure

Electrical (a-c) conductivity measurements were made on thoria-base solid solutions at 800°, 1000°, 1200°, and 1400°C with equilibration in H_2-H_2O-Ar or H_2O-O_2-Ar atmospheres. Specimens in the shape of "pills" (5/16 in. diameter by 1/16 in. thick) were prepared from high-purity oxide powders (99.9% purity) obtained from the Rare Earth Division of American Potash and Chemical Corporation. The following compositions in cation per cent (c/o) were prepared:

ThO_2—1 c/o, 8 c/o, and 15 c/o $SmO_{1.5}$

ThO_2—1 c/o, 8 c/o, and 15 c/o $LaO_{1.5}$

ThO_2—1 c/o, 8 c/o, and 15 c/o $YO_{1.5}$

The components were blended for one or more days, calcined overnight, ground, screened, blended again, and cold pressed into pills. The pills were prefired overnight at 1100°C and then sintered at 1950°C or higher for 3-4 hr in air to obtain dense samples.

Several pills of differing compositions were platinized on their faces and were assembled and held in an alumina cell holder with spring pressure. The pills were separated from each other by 5-mil thick platinum sheets which also served as electrodes. The alumina cell holder was placed in an impervious alumina combustion tube in a noninductively wound furnace which was controlled to ±½°C while conductance measurements were being made. The design of the cell holder, as well as general procedures and precautions for conductivity measurements, have been described in detail elsewhere (13). Previous measurements (6) had established that the conductances were independent of frequency over a broad range; a Wayne-Kerr conductivity bridge with 1592 Hz was used in the present study. As is usual with sintered specimens, duplicate runs on different pills of the same composition yielded conductivities which differed slightly in absolute magnitude; however, such specimens exhibited the same conductivity increments with respect to changes in P_{H_2}. Since, for the most part, only changes in conductivity were important in the present study, the agreement between duplicate runs was quite satisfactory.

Electrical conductivities were determined in separate runs at both low and relatively high oxygen activities. For low oxygen activities, H_2-H_2O-Ar atmospheres were prepared by passing accurately metered flows of argon and hydrogen through a water saturator which was maintained at carefully controlled tem-

peratures. A P_{H_2}/P_{H_2O} ratio of 0.40 was chosen and held constant throughout this experiment, and hence an unvarying oxygen activity was established over the samples by the equilibrium between H_2 and H_2O at each temperature, *i.e.*, at 800°C, $P_{O_2} = 10^{-17.55}$ atm; at 1000°C, $P_{O_2} = 10^{-13.74}$ atm; at 1200°C, $P_{O_2} = 10^{-10.95}$ atm; at 1400°C, $P_{O_2} = 10^{-8.84}$ atm. The oxygen partial pressure can be expressed in terms of the experimental variables as

$$P_{O_2} = \left(\frac{P_{H_2O}}{P_T - P_{H_2O}}\right)^2 \left(\frac{N_{Ar} + N_{H_2}}{N_{H_2}}\right)^2 \exp\left(\frac{2\Delta G°_{H_2O}}{RT}\right) \quad [14]$$

where P_{H_2O} is the vapor pressure of water at the temperature of the water saturation unit, P_T is the total pressure, N_{Ar} and N_{H_2} are the flow rates of argon and hydrogen, $\Delta G°_{H_2O}$ is the standard free energy of formation of H_2O at the furnace temperature T. The partial pressure of hydrogen (and necessarily that of water) was varied by the simultaneous adjustment of the flow rates of hydrogen and argon and the temperature of the water saturation unit.

In another experiment, conductances were measured as a function of P_{O_2} in H_2-H_2O-Ar atmospheres at constant P_{H_2O}. A few conductance measurements were made in CO-CO_2 atmospheres having the same low oxygen pressure at a given temperature as the H_2-H_2O-Ar mixtures, but these values appeared to be inconsistently low (perhaps because of electrode polarization by adsorbed CO_2) and were not used in subsequent calculations.

Atmospheres with high oxygen activity were achieved by passing mixtures of oxygen and argon through the water saturation unit held at various temperatures. With this procedure, the oxygen partial pressure was maintained at approximately 0.263 atm at all furnace temperatures. The resulting hydrogen partial pressures are listed in Table I.

Results and Discussion

The conductivity measurements at low P_{O_2}, where ionic conduction predominates, and at high P_{O_2}, where mixed ionic and positive hole conduction occurs, will be discussed separately. The results for the fixed relatively low P_{O_2}, where P_{H_2}/P_{H_2O} was held constant, are presented in Fig. 1-3 as plots of log total conductivity as a function of log P_{H_2} (or equivalently log P_{H_2O}) at constant P_{O_2}. Those lines with slopes significantly greater than zero indicate a contribution of mobile hydrogen ions to the total conductivity; one possible exception is the data for 1 c/o dopant samples at 800°C, which will be discussed subsequently. Thus, significant hydrogen ion conduction occurs at high temperatures (1200° and 1400°C) and in samples with high metal ion dopant contents (8 and 15 c/o). No appreciable difference in behavior was noted between equivalent compositions with differing metal ion dopants.

In Fig. 4 is shown a plot of log hydrogen ion conductivity *vs.* log P_{H_2} (or log P_{H_2O}) for samples with high dopant contents and at high temperatures. This hydrogen ion component was computed as the total conductivity minus the oxygen vacancy partial conductivity which is essentially independent of P_{H_2} for a small solubility of hydrogen. The oxygen vacancy partial conductivity was obtained as the intercept at $P_{H_2} = 0$ of a plot of the total conductivity *vs.* $P_{H_2}^{1/2}$. A slope of ½ on a plot of log $\sigma_{H^\cdot}$ *vs.* log P_{H_2O} is predicted for both the interstitial hydrogen ion model (Eq. [8]) and the hydride ion model (Eq. [12]). With consideration of the inherent uncertainty for a small difference between two large quantities, the agreement of the experimental curves with the predicted slope is satisfactory.

The effect of the concentration of metal ion dopant on the partial conductivity of hydrogen ions is shown in Fig. 5. The rather considerable scatter of the data in this plot is not unusual when comparing the behavior of different sintered pills. However, from Fig. 5, the

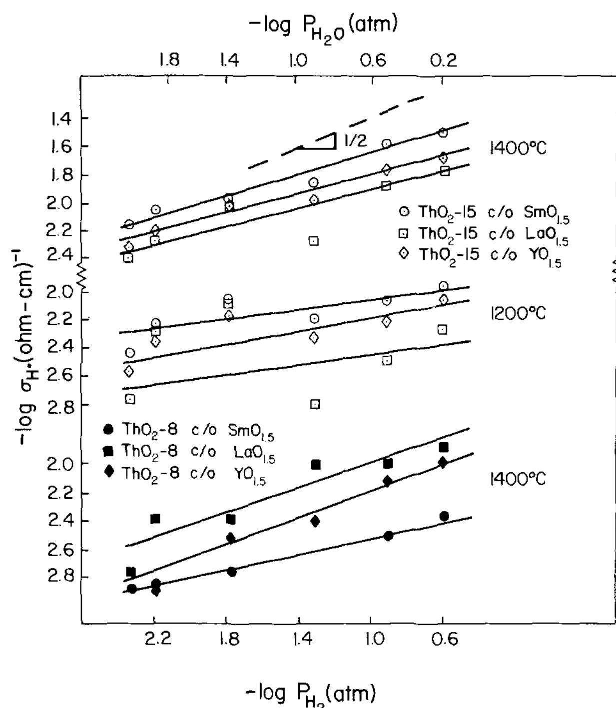

Fig. 4. Hydrogen ion conductivity of thoria-base solid solutions at 1400°C (P_{O_2} = $10^{-8.8}$ atm) and at 1200°C (P_{O_2} = $10^{-10.9}$) as a function of partial pressure of hydrogen. A slope of ½ is predicted by the interstitial proton model.

hydrogen ion partial conductivity increases with increasing dopant content in qualitative agreement with Eq. [8] or [12]. Recent conductivity measurements on pure ThO_2 in H_2-H_2O mixtures at 1000° and 1200°C by Bransky and Tallan (14) show no indication of a proton conductivity contribution.

In Fig. 6 are shown the results of a separate set of conductivity measurements in which P_{H_2O} was held constant while P_{O_2} was varied. These conductivities

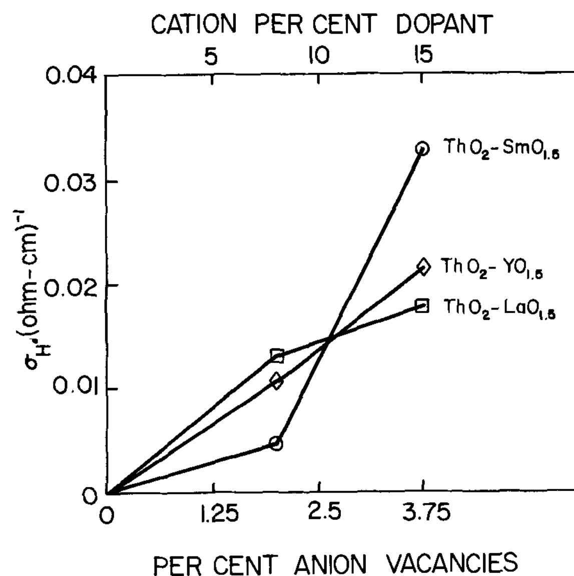

Fig. 5. Hydrogen ion conductivity of thoria-base solid solutions at 1400°C and at a hydrogen activity of $10^{-0.59}$ atm as a function of dopant content.

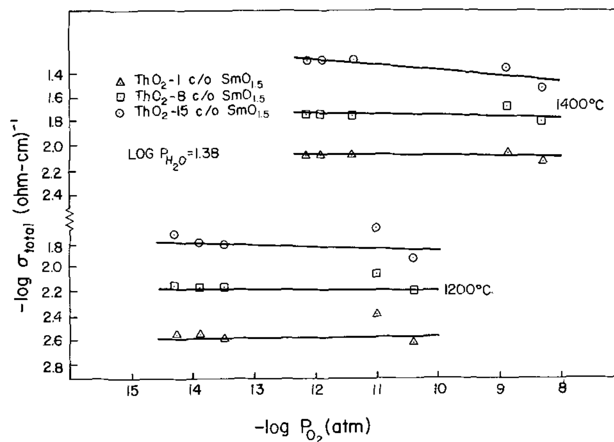

Fig. 6. Total conductivity of thoria-base solid solutions at a constant water vapor pressure of $10^{-1.38}$ atm as a function of oxygen activity. A slope of −½ is predicted by the hydride ion model; a slope of zero is predicted by the interstitial proton model.

were found to be independent of P_{O_2} which is consistent only with the interstitial hydrogen ion model; a $P_{O_2}^{-1/2}$ dependence is predicted from the hydride ion model. Thus, it is concluded that the interstitial hydrogen ion model is appropriate for the dissolution of hydrogen into thoria-base electrolytes in the P_{O_2}-range of predominant ionic conduction. According to the model, electrical compensation of the dopant protons is accomplished by an equivalent (small) reduction in the concentration of oxygen vacancies.

The increasing total conductivity with increasing P_{H_2} for samples containing 1 c/o dopant at 800°C (Fig. 1-3) probably does not represent hydrogen ion conduction. This conclusion is based on the observations that (*i*) the conductivities of samples containing 8 and 15 c/o dopant at 800°C indicated no partial hydrogen ion conductivity (see Eq. [6]), and (*ii*) the conductivities of 1 c/o doped samples at higher temperatures, where a greater solubility and hence a larger partial hydrogen ion conductivity would be expected, indicated no hydrogen ion conduction. The results of Primas *et al.* (6) for some dilute ThO_2-Sm_2O_3 electrolytes at 800°C showed similar behavior. In their work, the conductivities in H_2-H_2O-O_2 atmospheres were significantly higher than the value extrapolated from data obtained in higher oxygen activity atmospheres containing no hydrogen.

The apparently anomalous behavior for the 1 c/o dopant specimens at 800°C at a fixed low oxygen activity may represent a significant contribution from excess electron conduction. Lasker and Rapp (4) have shown for doped oxide electrolytes that in the absence of proton doping, $\sigma_\theta \alpha [F_{Th}']^{-1/2}$ is expected. Thus, it is unlikely that a σ_θ conductivity contribution could be detected in the 8 and 15 c/o specimens, particularly in view of the higher σ_{ion}. A tentative explanation of the anomalous behavior is proposed as follows.

The reduced electrical neutrality condition for the 1 c/o dopant specimens at 800°C and low P_{O_2} would be

$$n + [F_{Th}'] = 2[V_O^{\cdot\cdot}] + [H_i^{\cdot}] \quad [15]$$

With consideration of the expected relative mobilities of the species and the observed conductivity behavior, one could conclude that the terms $[F_{Th}']$ and $[V_O^{\cdot\cdot}]$ greatly exceed $[H_i^{\cdot}]$ which, in turn, greatly exceeds n.

For equilibrium of the specimen with the gas phase

$$\tfrac{1}{2}\, O_2(g) + V_O^{\cdot\cdot} + 2e' \rightleftharpoons O_O \quad [16]$$

and at constant P_{O_2}, as in Fig. 1-3

$$[V_O^{\cdot\cdot}]\, n^2 = K_{16}' \quad [17]$$

From Eq. [15]

$$[V_O^{\cdot\cdot}] = \tfrac{1}{2}\,(n + [F_{Th}'] - [H_i^{\cdot}]) \quad [18]$$

Solving Eq. [17] for $[V_O^{\cdot\cdot}]$ with substitution into Eq. [18]

$$n^3 + [F_{Th}']\, n^2 - [H_i^{\cdot}]\, n^2 = \text{constant} \quad [19]$$

Upon differentiation, the fractional change in n with increasing $[H_i^{\cdot}]$ is given by

$$\frac{1}{n}\frac{dn}{d[H_i^{\cdot}]} = \frac{1}{2}\,\frac{1}{[F_M'] - [H_i^{\cdot}]} \quad [20]$$

Integration between a hydrogen-free state with excess electron concentration n^* to a hydrogen-containing state with excess electron concentration n_H yields

$$n_H = n^* \left(\frac{[F_M']}{[F_M'] - [H_i^{\cdot}]}\right)^{+1/2} \quad [21]$$

considering that $n^* \alpha [F_M']^{-1/2}$ gives

$$n_H\, \alpha ([F_M'] - [H_i^{\cdot}])^{-1/2} \quad [22]$$

Thus, an excess electron conductivity contribution might become observable in a hydrogen-containing atmosphere when $[H_i^{\cdot}]$ approaches $[F_M']$ (at low $[F_M']$), and at a low temperature where σ_{ion} is sufficiently low to allow the detection of σ_θ by a measurement of σ_{total}.

The above development has described the effect on an electronic concentration n_H caused by compensation of a dopant $H_i^{\cdot}$ by the change in the concentration of an ionic defect $V_O^{\cdot\cdot}$. This interpretation may describe the conductivity behavior of the 1 c/o dopant specimens at 800°C in Fig. 1-3, as well as the behavior of the 0.5, 1, and 3 c/o $SmO_{1.5}$ specimens at 800°C from the work of Primas *et al.* (6). Unexplained, and apparently inconsistent, is the fact that the "pure" ThO_2, 0.1 c/o $SmO_{1.5}$, and the dilute $LaO_{1.5}$-doped specimens of Primas *et al.* (6) did not exhibit analogous behavior.

The results of conductivity measurements as a function of P_{H_2} at a constant, relatively high P_{O_2} (0.263 atm) are shown in Fig. 7-9. The calculated hydrogen activities for these conditions are presented in Table I. The total conductivity of such compositions at this P_{O_2} in H_2O-free atmospheres is composed of ionic and positive hole contributions of comparable magnitudes (4, 6). From Eq. [8] and [12], conduction by both protons and hydride ions should be proportional to $P_{H_2O}^{1/2}$. However, conduction by hydride ions is otherwise excluded because of its $P_{O_2}^{-1/2}$ dependence in Eq. [12]. On the other hand, because the same range of P_{H_2O} was used in the high P_{O_2} measurements as in the low P_{O_2} measurements, proton conduction according to Eq. [8] would be expected at high P_{O_2} in a magnitude equal to that found at low P_{O_2} and plotted in Fig. 4.

Except for 1 c/o doped samples at low temperatures, the total conductivities at high P_{O_2} were independent of P_{H_2O} or P_{H_2} and therefore proton conduction was not detected. However, this result is not unexpected because the magnitudes of σ_{proton} of Fig. 4 are sufficiently lower than the corresponding total conductivities of Fig. 7-9.

Interestingly, the dissolution of protons from H_2O at high P_{O_2} caused no detectable change in σ_θ, except possibly for the 1 c/o dopant specimens at 800°C. Considerations of intrinsic electronic equilibrium in the crystal with

$$n \cdot p = K_i \quad [23]$$

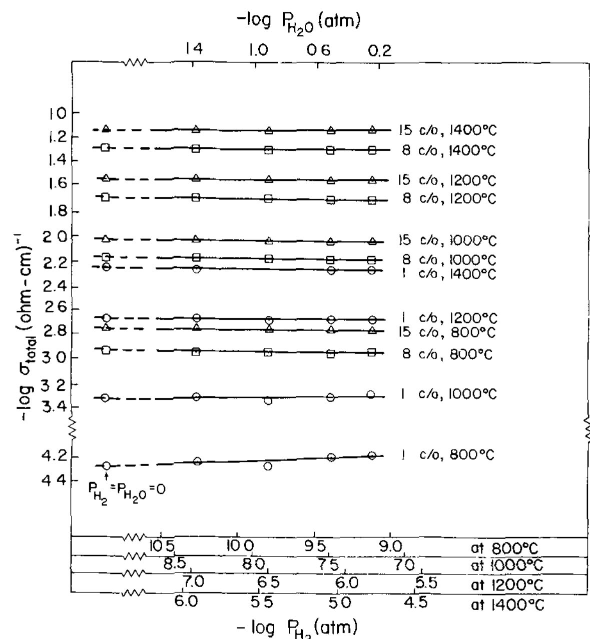

Fig. 7. Total conductivity of thoria-yttria electrolytes at a constant oxygen activity of 0.263 atm as a function of partial pressure of hydrogen and water vapor.

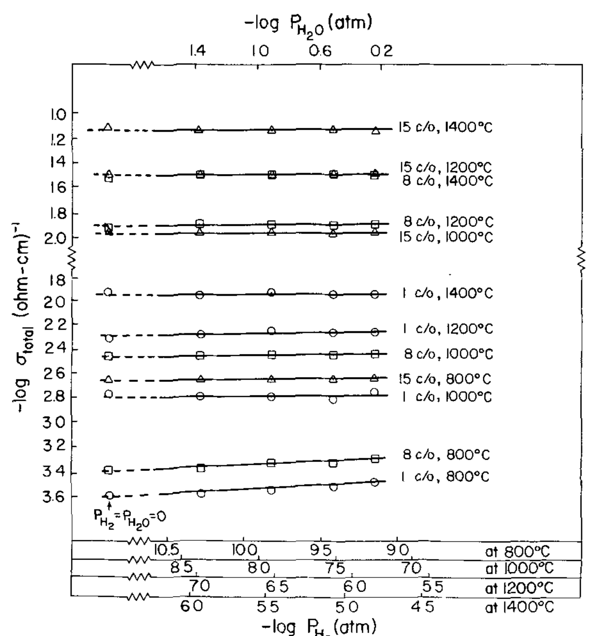

Fig. 8. Total conductivity of thoria-samaria electrolytes at a constant oxygen activity of 0.263 atm as a function of partial pressure of hydrogen and water vapor.

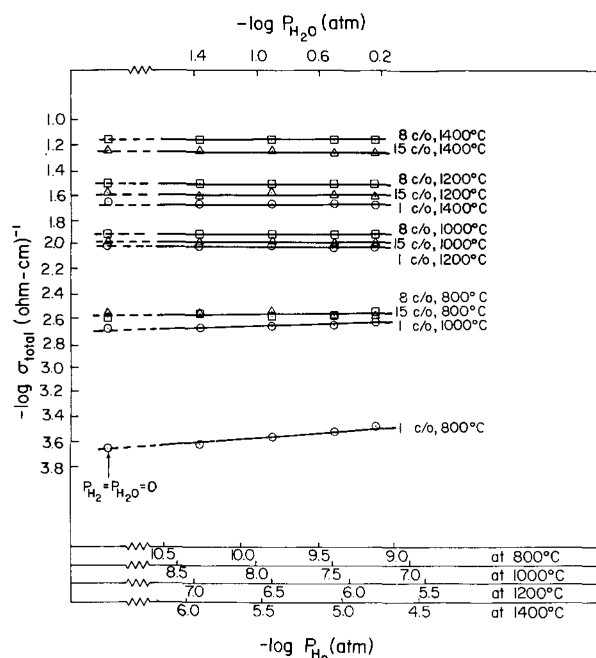

Fig. 9. Total conductivity of thoria-lanthana electrolytes at a constant oxygen activity of 0.263 atm as a function of partial pressure of hydrogen and water vapor.

and use of Eq. [21] with $p\alpha[F_{Th}']^{1/2}$ gives

$$p_H\,\alpha([F_M'] - [H_i^{\cdot}])^{1/2} \quad [24]$$

where p_H is the concentration of positive holes in the H_2O (or H_2) containing environment. The observed low slopes of the lines for 1 c/o dopant specimens are of the opposite sign compared to the expected effect of dissolved protons on positive hole conduction. Further interpretation of these results is not obvious.

Summary and Conclusions

A-C conductivities of nine thoria-base solid electrolytes have been measured at high temperatures as a function of the partial pressure of hydrogen at fixed oxygen partial pressures. The present study encompassed oxygen activities in both the ionic (low P_{O_2}) and the mixed (high P_{O_2}) conduction ranges. The results have shown that appreciable hydrogen ion conduction by protons occurs at 1200° and 1400°C at low P_{O_2} in samples with high aliovalent metal dopant contents. At high P_{O_2} (low P_{H_2}) significant hydrogen ion conduction was not detected and the dissolved protons did not affect the positive hole conductivity contribution. The results were consistent with the interstitial proton model of Stotz and Wagner (1). Seemingly anomalous behavior for 1 c/o dopant specimens at low P_{O_2} at 800°C was interpreted as excess electronic conduction.

Sputtered Fe_2O_3 Films for Use in "See Through" Masks

F. G. Peters, W. Robert Sinclair,* and M. V. Sullivan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

A sputtering technique has been devised for preparing Fe_2O_3 films with rates of solubility in 6M HCl and with transmission spectra appropriate for use as "see-through" photomasks (*i.e.*, photomasks sufficiently transparent at 589 nm for viewing purposes and opaque in the spectral region 360-400 nm). This method involves rf or d-c sputtering of Fe electrodes in CO-CO_2 mixtures or rf sputtering of Fe_2O_3 electrodes in CO-CO_2 mixtures. To achieve films with acceptable transmission spectra the CO content must not exceed 82% with the metal electrode and must not exceed 87% with the oxide electrode. The fastest deposition rate obtained was 120 Å/min for 350W input rf power using an Fe electrode and an 80% CO/20% CO_2 ambient. Measurements of scratch resistance, defect density, and film morphology are presented.

The requirements for a "see through" mask for use in integrated circuit technology have been stated recently (1). These are primarily: (*a*) sufficient absorption (<*ca.* 1% transmission) of light in the spectral region near 360-400 nm, (*b*) sufficient transmission (*ca.* 30%) at the sodium D line for viewing purposes, (*c*) a rate of solubility in selected solvents (in our case 6M HCl) appropriate to photoresist technology, and (*d*) a hard, abrasion resistant film. MacChesney *et al.* (2) have shown that Fe_2O_3 films prepared by

* Electrochemical Society Active Member.
Key words: semitransparent photomasks, thin films, sputtering.

chemical vapor decomposition (CVD) of $Fe(CO)_5$ on a glass surface in the presence of oxygen can have these properties if prepared in the proper temperature range (*ca.* 100°-160°C). Reid and Cukor (3) have also described a process for preparing iron oxide films for "see through" masks by decomposition of iron organics (4) at about 500°C.

Attempts to prepare iron oxide films by reactive d-c sputtering of Fe in O_2 (1) have led at best to highly strained films which dissolve with removal of curled chunks of film and are, therefore, useless for preparing precision masks. In this paper we explore the possibilities of preparing Fe_2O_3 films suitable for mask use by sputtering. Initially, our interest was solely in the rf sputtering of Fe_2O_3. However, this interest was broadened to reactive rf sputtering of Fe and reactive d-c sputtering when the essentials of the solution were perceived.

There are three main reasons why a sputtering process for preparing Fe_2O_3 films suitable for masks could be of interest. First, toxicity problems for personnel are not usually encountered in sputtering as they can be in the CVD method. Second, the process of sputtering onto large numbers of substrates has already been automated (5) so that for large scale production of masks commercially available equipment can be used. Third, if at some later date masks of dimensions greater than the present 2 × 2 in. size are desired, scaling up the procedure to larger areas may be more straightforward than for MacChesney's CVD process (2) or Reid and Cukor's spun film process (3).

Apparatus and Experimental Procedure

The rf sputtering apparatus used in these studies is shown schematically in Fig. 1. The sputtering electrodes consisted of 6 in. disks of hot pressed Fe_2O_3 and cold-rolled steel. Some work was done with Fe_3O_4 electrodes also but these results will not be included as no significantly different results were obtained. These targets were placed on the bottom electrode assembly and sputtering was upwards to minimize pinholes caused by dust. The iron oxide films were deposited onto cleaned 2 × 2 in. soda-lime glass substrates. Because the strain in the films was found to be a function of the efficiency of the water cooling of the electrodes a special electrode was fabricated of copper for holding substrates. Etching studies indicate that films deposited onto substrates attached to the more efficiently cooled copper holder were usually less strained than those prepared using the usual stainless steel assembly. Films were deposited onto substrates that were either electrically floating or attached to a grounded electrode. However, when sputtering in CO-CO_2 mixtures, the preferred ambient, the electrical condition (*i.e.*, floating or grounded) was not important and the water cooling not as critical.

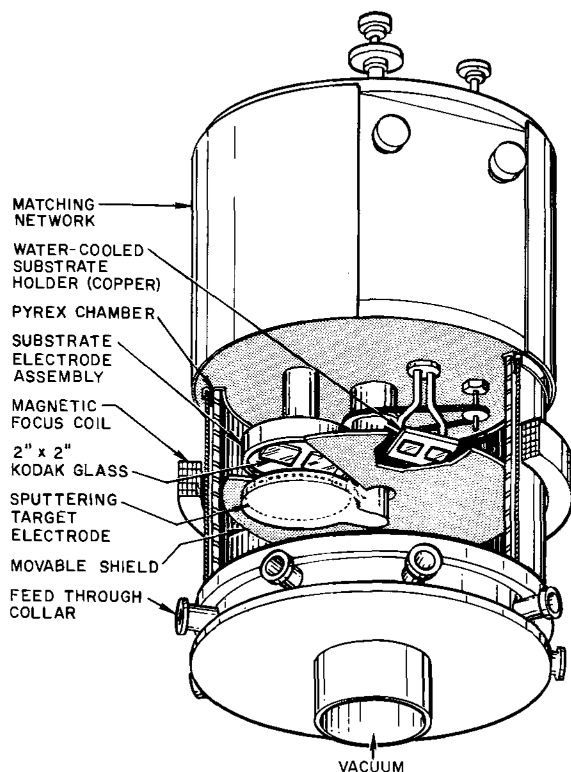

Fig. 1. RF sputtering apparatus

The Pyrex chamber was evacuated by a turbomolecular pump to 1×10^{-5} Torr prior to establishing the sputtering gas pressure range of 20 to 40 mTorr through needle and throttle valve adjustments. Various compositions (0 to 100%) of Ar-CO_2, CO-CO_2, and Ar-O_2 were used directly from commercial grade tanks (Matheson Company Inc.) without further purification. Some compositions were obtained from cylinders containing known gas mixtures. In other cases the preparation of known mixtures was achieved in the deposition chamber by admitting the gases successively and measuring the pressure after the addition of each gas. When sputtering in an atmosphere containing CO, a heated nichrome screen was situated over the exit port of the vacuum chamber to decompose any iron carbonyl being pumped from the system. However, no evidence of any decomposition to Fe_2O_3 was found on this screen. As another safety precaution, the mechanical pump was exhausted through a line to a fume hood. A focus coil located around the electrodes and outside the chamber was used to obtain a concentrated plasma between the sputtering target and the substrate. A presputtering period of 30 min was employed with the substrates shielded from the depositing material. In some experiments the substrates were also sputter etched just before film deposition. This was done by interchanging the cathode and anode leads. After sputter etching the leads were switched back and film deposition started without breaking vacuum.

Typical sputtering conditions involved the use of a net power of 270W at a gas pressure of 28 mTorr with a target-to-substrate distance of 1.5 in. The operating frequency was 13.56 MHz. The deposition rate varied considerably as shown in Fig. 2 and was dependent on the gas composition, sputtering target, and power. Sputtering of the cold-rolled steel in 50% CO-50% CO_2 at 270W resulted in iron oxide being deposited at a rate of 52 Å/min. The deposition rate of iron oxide was increased to 110 Å/min by sputtering the same steel electrode in 80% CO-20% CO_2 at 350W.

After the successful rf sputtering in CO-CO_2 mixtures, the d-c reactive sputtering technique was employed using the cold-rolled steel electrode in 80% CO-20% CO_2. The apparatus was the same as that used in the rf studies except that a d-c power supply was substituted for the rf supply. The d-c sputtering was conducted at a 3.5 kV cathode potential, a current of 62 mA, and a gas pressure of 60 mTorr. Under these conditions the deposition rate of iron oxide was 55 Å/min onto electrically floating substrates.

Experiments and Discussion

Ar-O_2 and Ar-CO_2 ambients.—Presumably the main reason that sputtered Fe_2O_3 films prepared by reactive sputtering in O_2 dissolve more slowly in dilute HCl, our selected etchant, than the low-temperature CVD films is that they are produced at a higher surface temperature and, therefore, have larger crystallites. Since the reactively sputtered films studied previously were in some cases prepared on water-cooled substrate holders whose temperatures did not exceed 25°C and since the CVD films were deposited at 100°-160°C, this may seem inaccurate. However, it has long been recognized that the temperature on a thermally insulating substrate where a film is being formed can differ con-

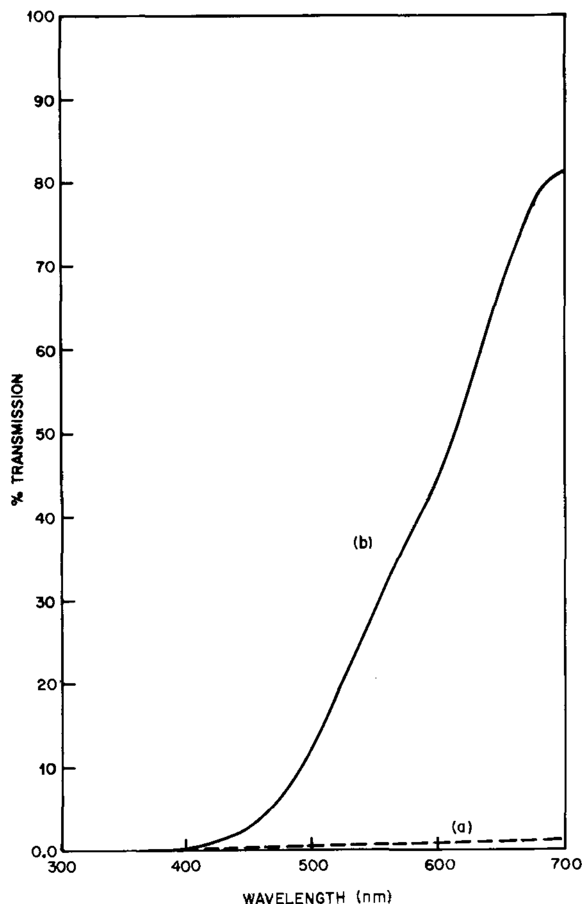

Fig. 3. Transmission spectra of films sputtered from Fe_2O_3 electrode; (a) Film sputtered in 100% Ar (black color) (2500Å). (b) Film sputtered in 100% O_2 (orange or rust color) (2100Å).

siderably from the temperature as measured by a nearby thermocouple. For instance, Pliskin and Lehman (6) using refractive index and etch rates as analytic tools found that reactively sputtered SiO_2 prepared at 25°C resembled SiO_2 grown thermally at 950°C more closely than SiO_2 films prepared by CVD at 675°C.

The three main causes of this local heating during film formation by sputtering are chemical heats of reaction (*e.g.*, $2Fe + 3/2\,O_2 \rightarrow Fe_2O_3$), electron and ion bombardment of the substrate surface during deposition, and bombardment by energetic neutrals. In our first study (1), the heat of reaction where the film was grown was unknown because for reactive sputtering of iron we did not know what molecular species were hitting the substrate. In rf sputtering of Fe_2O_3 we likewise do not know what the sputtered species are and oxidation of Fe neutrals at the substrate could still be the dominant reaction, but presumably there is a greater possibility of depositing an already oxidized iron atom. Reduction of heating effects from ion and electron bombardment can be accomplished by electrically isolating or biasing the substrate holder. The effects of bombardment of the substrate by energetic neutrals can be lessened by working at higher pressures and keeping the input rf power reasonably low. Thus, our initial approach in this study was aimed at lowering the deposition temperature by sputtering from an oxide cathode using rf excitation, by electrically isolating the substrate, and by working at somewhat higher pressures than usual.

The first gas discharge system studied for sputtering was Ar-O_2. The film which was sputtered in pure argon dissolved in 6M HCl in a few seconds at 25°C. However, the spectrum was unsatisfactory being too strongly absorbent at 590 nm as indicated in Fig. 3a. Visually the film was black. If O_2 was added to the sputtering gas in concentrations ranging from about 1 to 100% O_2, absorption spectra similar to that shown in Fig. 3b were obtained. These films were orange or rust colored. Unfortunately, although the spectra for films obtained using these Ar-O_2 mixtures were acceptable the solubility of these films in 6M HCl was much too slow to be useful (> 1 hr at 25°C). It is evident, we believe, that neither reactive sputtering in O_2-Ar mixtures, nor rf sputtering of Fe_2O_3 electrodes in O_2-Ar mixtures, will lead to films having the desired rate of solubility in 6M HCl along with an acceptable spectrum.

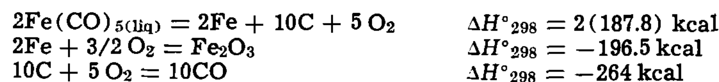
In an effort to come up with some solution to this problem we decided to substitute CO_2 for O_2 in the discharge gas. The reasons for this approach were more speculative than solid. One hope was that the effects of bombardment by ions and neutrals might be lessened by having a heavier gas molecule, but there was no firm basis for this hope. Another possibility was that ferric carbonate might be formed which presumably would be quite acid soluble. The existence of ferric carbonate has not been shown, however (7), nor have we found a spectrum attributed to it in the chemical literature. Despite the flimsy basis of these speculations we found on sputtering in 100% CO_2 that a film with an acceptable spectrum very similar to that of Fig. 3b was obtained. [In this paper we discuss the transmission spectra as being either of type a or type b of Fig. 3. This oversimplifies, of course, because there are thickness effects on the transmission curves and there are intermediate situations in going between the two types. The thickness effects (*i.e.*, deviations from Beer's law behavior) are comparatively small and the change from one type of spectrum to the other occurs over a very small change in gas composition and is not of interest to us. Another important optical property of the films that will not be discussed is the

reflectivity. Kerwin (8) has found the reflectivity of Fe_2O_3 films to be low.]

The film also dissolved in 6M HCl at room temperature in about 2 min analogous to the rate of solubility obtained using Fe_2O_3 films formed at 110°C by the CVD method. Films sputtered in Ar-CO_2 mixtures in the range of 4-100% CO_2 have absorption spectra similar to Fig. 3b. The solubility of the rust-colored films becomes progressively slower as the CO_2 percentage decreases. With CO_2 contents lower than 4%, black films are obtained.

CO-CO_2 mixtures.—Having obtained films with both transmission spectra and solubility in 6M HCl appropriate for making "see through" photomasks by sputtering in Ar-CO_2 ambients, plasmas of CO-CO_2 compositions were tested. All gas compositions in this system yielded films easily soluble in 6M HCl and acceptable spectra were obtained with a CO_2 composition above 18% using an Fe electrode or with a CO_2 composition above 13% using an Fe_2O_3 electrode. D-C reactive sputtering of Fe in CO-CO_2 mixtures also can give acceptable films.

At this time it is perhaps appropriate to inquire as to the reason for our choice of a CO-CO_2 ambient and to propose some explanation for the successful use of this mixture, unusual in sputtering. We first discuss the CVD method, the reaction of $Fe(CO)_5$ and O_2 to form Fe_2O_3. Following MacChesney *et al.* (2) we say that the solubility is inversely related to the crystallite size which is presumably directly related to the temperature where the reaction occurs. We have previously commented that the heat of reaction is of importance here. The thermodynamics is suggestive (9).



$$2Fe(CO)_{5(liq)} = 2Fe + 10C + 5\,O_2 \qquad \Delta H^\circ_{298} = 2(187.8)\ \text{kcal}$$
$$2Fe + 3/2\,O_2 = Fe_2O_3 \qquad \Delta H^\circ_{298} = -196.5\ \text{kcal}$$
$$10C + 5\,O_2 = 10CO \qquad \Delta H^\circ_{298} = -264\ \text{kcal}$$

$$2Fe(CO)_{5(liq)} + 3/2\,O_2 = Fe_2O_3 + 10CO \quad \Delta H^\circ_{298} = -84.9\ \text{kcal}$$

It is seen that the standard heat of formation of a mole of Fe_2O_3 at 25°C is more than a factor of 2 smaller starting with $Fe(CO)_5$ rather than Fe which may be the reactant in our sputtering experiments thus far. However, this alone is not sufficient to explain the easy formation of acid-soluble Fe_2O_3 at a low temperature. In addition to the lower heat of reaction we must assume a very low activation energy as was pointed out by MacChesney *et al.* (2). The known ease with which $Fe(CO)_5$ decomposes to give an active iron is probably the significant feature here (10). It is, therefore, this combination of having a reaction which cuts down the heat of reaction where the film is formed and use of a molecule with a low activation energy for decomposition which is probably at the root of the explanation for the success of the pentacarbonyl method. This almost unique property of the iron carbonyls makes it doubtful that a better system can be found with commonly available iron compounds to make Fe_2O_3 films of high rate of acid solubility at a low temperature.

Returning now to sputtering in CO_2, a possibility for explaining the easy solubility in acids (and, therefore, lower formation temperature) of the Fe_2O_3 films obtained is suggested by a reaction which is known to occur in CO_2 discharges (11).

$$CO_2 = CO + \tfrac{1}{2}\,O_2$$

The reactive sputtering of metal carbides has been studied previously (12). The discharge gas in such a system rapidly becomes a mixture of CO and CO_2. It was noted at the time that Cr_2O_3 was formed at a much faster rate (from 5 to 15 times faster) from the carbide than Al_2O_3 from Al_4C_3 and SiO_2 from SiC (sputtering of iron carbide was not studied). No explanation of this fact was offered at the time but later the possibility that $Cr(CO)_6$ was being formed and evaporating from the cathode was pointed out (13). Because of the chemical similarities between $Cr(CO)_6$ and $Fe(CO)_5$ it is natural to consider the possibility that we are forming $Fe(CO)_5$[1] at the cathode during the discharge and this is evaporating from the cathode. If, indeed, this is occurring one should be able to increase the rate of film formation by using CO-CO_2 mixtures rather than pure CO_2 without adversely affecting the acid solubility of the films.

Thus far we have not considered deposition rates in any detail. In Fig. 2 deposition rates are presented graphically as a function of gas composition and target material. It is seen that the highest deposition rates are obtained with the Fe electrode and the highest CO/CO_2 ratios. Rates above 100 A/min can be obtained using 350W input power to give films with good spectra as in Fig. 3b and good solubility (complete solution in less than 2 min in 6M HCl at 25°C with no evidence of strain). It is noted that the sputtering rate in CO_2-Ar mixtures is relatively low unless one is sputtering in pure or almost pure Ar. The same type of results are obtained in Ar-O_2 mixtures. The deleterious effects of oxygen in plasmas on the deposition rate of oxides is known (15). It is seen that the deposition rate in the CO-CO_2 ambients is different in behavior increasing strongly throughout as one increases the CO/CO_2 ratio. This is consistent with our suggestion that an iron carbonyl is evaporating. However, we hasten to add that the evidence is by no means conclusive. Also to be considered is the fact that the concentration of oxygen species (*e.g.*, O, O^+, etc.) is kept at a very low level by the presence of scavenging CO molecules.

Physical properties of films.—Approximate measurements have been made on the scratch resistance of these films and of the CVD films. The measurement technique involves weighting a diamond stylus until the film is scratched on dragging the stylus over the film surface. The test is similar to that of Benjamin and Weaver (16). The results are shown in Table I. The films sputtered in CO-CO_2 mixtures are identical to those of the CVD method. The films formed in pure CO_2 are considerably more scratch resistant. All of the oxide films are more scratch resistant than a chromium film.

Some pictures of film texture have been obtained using the scanning electron microscope (SEM). Figure 4a shows a film obtained by rf sputtering from an Fe_2O_3 target in pure CO_2. The large particles are about 1500Å in diameter. That some control of the concentration of these large particles is possible is indicated by the significantly smaller number of large particles obtained by sputtering from an Fe target in 80% CO-20% CO_2 as shown in Fig. 4b. The desired result, total elimination of these large particles, is obtained by sputter etching about 600Å of glass substrate in 80% CO-20% CO_2 before depositing Fe_2O_3 using the

[1] We recognize that the system is much more complex than sketched here [cf. Ref (14)] but the picture presented here suffices for our purpose.

Table I. Results of approximate measurements of scratch resistance of some films

Sample description	Force in grams needed to scratch film
Fe_2O_3, CVD deposited	350-400
Fe_2O_3, sputtered in 80% CO-20%CO_2	350-400
Fe_2O_3, sputtered in 100% CO_2	750-800
Cr, evaporated	<250

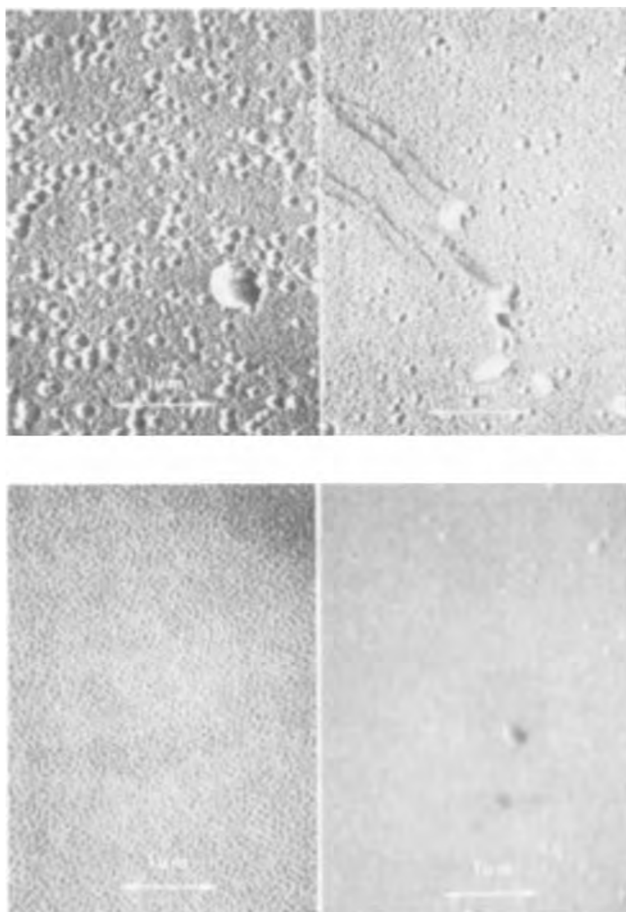


Fig. 4. Scanning electron microscope pictures of Fe_2O_3 film textures. (a, upper left), Sputtered Fe_2O_3 film from Fe_2O_3 electrode and a 100% CO_2 atmosphere. (b, upper right), Sputtered Fe_2O_3 film from an Fe electrode and a 80% CO-20% CO_2 atmosphere. (c, lower left), Sputtered Fe_2O_3 film formed in same way as (b) film but with the substrate sputter etched before deposition. (d, lower right), Fe_2O_3 film prepared by CVD.

same ambient. Evidently surface structure and/or surface impurities cause these large particles but no detailed investigations have been made. The particle size of the sputtered film (Fig. 4c) is about 500Å which is comparable with the low-temperature CVD films (Fig. 4d). This particle size is much smaller than can be taken advantage of in present photoresist technology. It is possible that the process by which the film is generated is not the limiting determinant of the film particle size but rather the chemistry and topography of the substrate is limiting.

The defect density and defect size for Fe_2O_3 films prepared in various ways were estimated after studying the SEM photographs and are shown in Table II. They are essentially equal in the various films considering the poor statistics one gets with such small numbers. This suggests that the defects may be in the glass substrate and that the number of actual film defects may be considerably fewer in number. Partial support for this hypothesis was found in an optical examination of the films at 500X by transmitted light. Pinhole densities were $\sim 1/cm^2$ whereas the SEM examination had indicated defects $\sim 1/mm^2$. It should also be pointed out that defects smaller than 1 μm will probably be insignificant for most present day device fabrication.

Table II. Results of defect density measurements made on Fe_2O_3 films using scanning electron microscope

Film	Total area scanned by SEM, mm^2	Total No. defects found	Defect diameter, μm
Fe_2O_3 by CVD	3.0	6	1
RF sput. Fe_2O_3 (80% CO-20% CO_2)	0.6	3	0.5
RF sput. Fe_2O_3 with pre dep. sputter etch (600A glass removed, 80% CO-20% CO_2)	0.6	2	0.5

Conclusions

RF sputtering of Fe_2O_3 electrodes and rf or d-c sputtering of Fe electrodes in CO-CO_2 plasmas can give Fe_2O_3 films with a sufficiently high dissolution rate in 6M HCl and transmission spectra appropriate for use in making "see-through" photomasks if the CO_2 content is above 13% with the Fe_2O_3 electrode and above 18% with the Fe electrode. Somewhat similar results are obtained with Ar-CO_2 plasmas but deposition rates are smaller. RF sputtering of Fe_2O_3 in Ar-O_2 mixtures yields films which have either a poor rate of solution or an unacceptable transmission spectrum. The scratch resistance of the films sputtered in CO-CO_2 are essentially equivalent to Fe_2O_3 films prepared by CVD and both are superior to evaporated Cr films. The defect density for both the sputtered films and for the CVD films is low. Film particle size in the sputtered films is affected by plasma composition and surface conditions on the substrate. Best results were found using a gas composition of 80% CO-20% CO_2 and sputter etching the substrate before deposition. In this case particle size was about 500Å.

Acknowledgments

We are pleased to acknowledge the assistance we have received from colleagues in various portions of this work. G. W. Kammlott performed the SEM measurements. Spectra were obtained by Mrs. G. A. Pasteur. Miss B. E. Prescott also helped in interpretation of some spectra. E. E. Francois made the scratch tests.

Manuscript submitted June 14, 1971; revised manuscript received Oct. 29, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Jet Polishing of Semiconductors

I. Automatic Jet Thinning of GaP for Transmission Electron Microscopy

B. D. Chase, D. B. Holt, and B. A. Unvala

Metallurgy Department, Imperial College of Science and Technology, London S.W.7, England

ABSTRACT

A method has been developed for thinning localized regions in GaP for examination by means of transmission electron microscopy. A jet of chlorine in methanol was used to chemically polish slices from the P($\bar{1}\bar{1}\bar{1}$) face. To thin specimens from the Ga(111) face the same reagent and apparatus were used, but a voltage was applied so that the specimen was anodic with respect to an electrode inserted in the jet. In this case the surface was free from etch pits, but yellowish surface films were formed which could be removed by a short chemical polish. GaP is optically transparent, but if it is illuminated only with wavelengths for which it has a sufficiently large absorption coefficient, it can be arranged that significant transmission of light begins only when the material is thin enough for electron transmission. This light can be detected by a photomultiplier and the resultant signal used to automatically terminate the thinning. The principles of this method are discussed, and the equipment required for its utilization is described. Large transparent areas were produced in material of various dopings and defect contents with a 100% success rate.

Chemical etching and polishing reagents have been developed to produce required types of attack on a great variety of crystallographic faces of many semiconducting compounds in numerous conditions of doping (1-3). It was reported in an earlier paper that several of the reagents described in the literature could be used to thin samples of a number of the more important III-V and II-VI compounds for transmission electron microscopy (4). The area to be examined in an electron microscope must be uniformly thin. In general it must be less than 1 μm thick and in the case of the more electron-opaque materials, only a few thousand angstroms thick. The thin area should preferably be produced by localized attack, so that the remainder of the specimen, shaped to fit the electron microscope holder, is left in the form of a relatively thick and sturdy rim of a disk. This type of localized attack can be achieved by several techniques falling into two classes. Either the specimen disk is immersed in a bath of the reagent but has the edges masked in some way or a jet of the reagent is used to bring about contact only with the chosen central area of one face (4). The latter techniques are referred to as jet polishing or thinning and have been long and widely used, generally with an electropolishing action. Chemical polishing has important advantages however. Chemical polishes have been developed for many important compounds (1-3) for which electropolishing reagents are not known. Moreover, the turbulent conditions involved in jet polishing in our experience tend to produce a smoother surface than is otherwise obtained with the same chemical reagent. Thus the published reagents generally work well in jets without modification. Chemical polishing rates are often less dependent on the doping of the semiconductor than are electropolishing rates. That is because the current flowing for a given applied voltage varies directly with the conductivity which varies rapidly in magnitude and in charge carrier sign at the doping levels used in semiconductor technology. Uniform electropolishing of nonuniformly doped microcircuit slices is therefore not possible.

Later development (5) showed that in the thinning of GaAs, which is an opaque material, a microscope and photomultiplier could be used to detect the moment at which a selected level of light transmission occurred. The photomultiplier signal was then used to trigger a solenoid which removed the specimen from the chemical polishing jet to a nearby washing jet. With this equipment large (80 μm diam) areas could be produced in areas on GaAs laser diodes, preselected by optical microscopy (6), with a 100% success rate (5). The use of a microscope and photomultiplier to produce a signal which turned off a jet electropolishing current when the specimen was thin enough was first introduced for Ge, another opaque material, by Riesz and Bjorling (7).

In the present paper a development of this technique is described that is applicable to an optically transparent material such as GaP. The most suitable reagent was found to be chlorine in methanol (8), and this was used for both chemical and electrochemical polishing. The electrochemical polishing of the Ga (111) face of GaP was found to produce a yellowish surface film. Transmission electron microscope studies established that this surface film was actually a region of tunnel etching, and this work is described in part II of this paper (9).

Recently equipment was developed for scanning the point of impingement of a jet of a chemical polishing reagent over the face of a rapidly spinning slice of germanium. It was found that this technique produced smooth, flat surfaces (10). Further work has shown that an improved version of this equipment will not only polish slices of Si, GaAs, and GaP as well as Ge, but it can be used to shape silicon slices that have been masked. This work is reported in the third paper in this series (11).

Experimental Methods

The Thinning Apparatus

The thinning apparatus, shown in Fig. 1, was similar to that described previously (5), but was modified as follows. To prevent the escape of gases to the atmosphere the reagent and washing jets were enclosed in a PVC box. This made it unnecessary to operate the apparatus in a fume cupboard. The specimens, mounted as discussed below, were fitted into a PTFE disk, which acted as the lid of the box. Once a solenoid had been actuated the lid rotated, so moving the specimen from a position above the polishing jet to one above the washing jet. A weight connected to the lid by a nylon cord provided the rotational force. Optical filters were added to the light detection system so that the thinning of a transparent material like GaP could be controlled. This will be discussed below. Arrangements were also

Key words: polishing, thinning, semiconductors, electron microscopy.

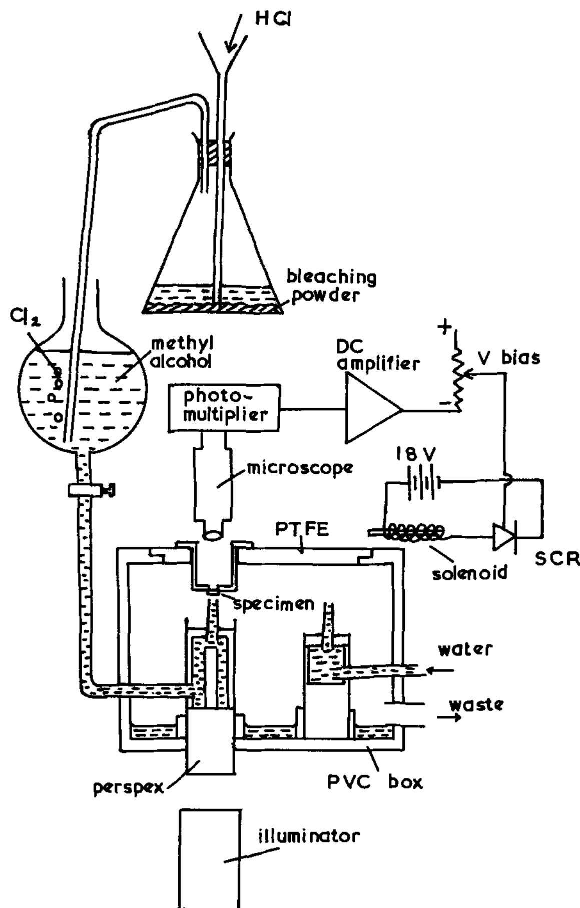

Fig. 1. Jet thinning apparatus. The polishing jet (chlorine in methanol) and the washing jet of water were enclosed in a PVC box with a rotating lid of PTFE which carried the specimen. For electropolishing, a short tungsten wire cathode (not shown) was introduced into the polishing jet.

made so that either chemical or electrochemical thinning could be employed.

The jet nozzles were drawn from glass tubing. A perspex (or lucite, *i.e.* PMMA) light guide was built into the polishing jet to make it possible to illuminate the specimen through the jet. This guide was sealed into the PVC box with an O-ring. A microscope was used to position the specimen over the center of the polishing jet nozzle, and to observe light transmitted through the specimen during thinning. A photomultiplier (E.M.I. Type 9664B) with an S10 photocathode could be substituted for the eyepiece. The output from the photomultiplier was fed into a stabilized d-c amplifier and on reaching a selected level triggered an SCR, which activated the solenoid. As a result, when the intensity of the light reaching the photomultiplier through the specimen had increased by a predetermined amount, the specimen was automatically repositioned over the washing jet and thinning ceased.

The photomultiplier was sensitive to wavelengths of light which were transmitted by GaP with little absorption. To obtain adequate variation of photomultiplier signal with specimen thickness, it was necessary to selectively remove these wavelengths by the use of filters. It was found that Kodak Wratten filter No. 47B used together with a Chance Pilkington OB 10 metal oxide filter to remove infrared gave satisfactory results. The principles of the control process will be discussed below. The two filters were positioned inside the photomultiplier case rather than at the source of illumination to reduce the influence of extraneous light. As a result it was found possible to operate the system under conditions of normal room lighting.

The Thinning Process

This work was undertaken with a view to analyzing defects in electroluminescent GaP diodes in relation to their performance as light sources. Results obtained in this way will be reported elsewhere (12, 13). Initially interest was centered on material grown by vapor phase epitaxy on GaAs substrates. Thinning was done from the GaAs surface which presented the $P(\bar{1}\bar{1}\bar{1})$ or B face. This ensured that the final thin area contained material distant from the GaP/GaAs interface. Since it is relatively simple to obtain a good polish on the $P(\bar{1}\bar{1}\bar{1})$ face of GaP, smooth well-shaped dimples with large thin areas were formed.

The chemical polishes generally used for GaAs had much lower polishing rates when applied to GaP. Three of the more rapidly acting reagents were considered. Boiling aqua regia although commonly used as a polish for GaP was not suitable for jet thinning. Br in methanol, although suitable as a polish, was unusable because of the effect of the Br in absorbing light passing through the jet. With the filters in place no light could be detected by the photomultiplier even without a specimen in position. The third alternative, Cl in methanol (8), was found to be satisfactory. This was produced in the equipment illustrated in Fig. 1, by feeding concentrated HCl into a conical flask containing bleaching powder. The chlorine gas that was evolved was bubbled through a flask containing methanol, which could then be fed directly to the jet.

Later in the work it became necessary to examine GaP grown by liquid phase epitaxy on the $P(\bar{1}\bar{1}\bar{1})$ faces of GaP substrates. In order to thin the material from the substrate side it was necessary to find means to polish the Ga(111) or A faces of these specimens. Cl in methanol would not form satisfactory dimples by chemical polishing. Preferential edge attack left a raised pitted portion in the center of the specimen. An electrochemical technique for dimpling of Ga(111) faces was developed using the same apparatus and reagent. The specimen was connected to the positive terminal of a battery. The negative electrode consisted of a short length of tungsten wire inserted into the jet nozzle from below. With an applied potential difference of 120V the current flow was about 20 mA and a smooth-sided dimple could be produced on Ga(111) faces.

The surfaces of electrochemically jet-polished dimples in Ga(111) faces were covered by an orange film which could be removed by chemical action when the current was switched off for a few seconds. Unfortunately this surface film had a very high optical absorption coefficient in the relevant range of wavelengths, so that the automatic detection system was triggered only when a hole appeared in the thin area. This was unsatisfactory and better results could be obtained in two alternative ways. The first successful method developed was to use visual control. By repeatedly turning off the current to disperse the surface film the true appearance of the thin area could be observed. The specimen thickness was correct when light which appeared nearly white to the eye was transmitted. The second successful method was to use electrochemical polishing to produce an initial dimple on the Ga(111) face of the specimen. The specimen was then reversed in the mount and finally thinned chemically from the $P(\bar{1}\bar{1}\bar{1})$ face. In this way the automatic mechanism could be used in the final stage of the process. This also had the advantage of removing any possible surface damage and meant that no special surface polishing was required prior to thinning. Some specimens were examined in the transmission electron microscope with the orange surface film remaining in order to try to establish its nature. The results are reported in a later paper (9). In the majority of specimens it was removed by a short chemical polish. It was found that the films could be removed from the

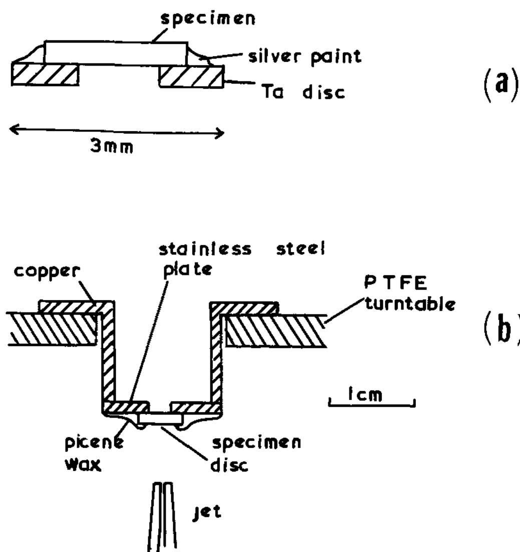

Fig. 2. Techniques for mounting specimens for thinning: (a) Small, fragile specimens were first mounted over holes in Ta disks, 2.3 mm diam. Larger samples were ultrasonically cut to form 2.3 mm diam disks of GaP. (b) The specimens were then affixed to a metal holder and mounted in the rotating lid of the apparatus shown in Fig. 1.

Ga(111) faces in this way without causing any detectable etching of the surfaces.

Mounting Specimens for Thinning

The vapor-grown GaP was received in the form of very thin layers. To facilitate handling, small pieces were cleaved off and mounted, using silver paint over small holes drilled in 2.3 mm diam Ta disks as illustrated in Fig. 2(a). The liquid phase epitaxy and pulled samples were large and disks of 2.3 mm diam were cut ultrasonically from this material.

The specimen holder for the jet thinner is illustrated in Fig. 2(b). The specimens were positioned beneath a 1.5 mm hole in a stainless steel plate. Silver paint was used to ensure electrical contact for the electrochemical process. When this had dried, the metal plate and the edges of the specimen were coated with a layer of picene wax so that just the area to be thinned was exposed. After thinning, the picene wax was dissolved in trichlorethylene and the silver paint was peeled off with tweezers. The specimens were then washed in hot trichlorethylene followed by rinsing in ethyl alcohol and deionized water.

Automatic Control of Thinning

When opaque semiconductors such as Ge, Si, or GaAs are thinned for electron microscopy they become transparent to visible light, appearing orange to the eye when a suitable thickness is reached. When an automatic thinning system is used it is this light which is detected by the photomultiplier (5, 7). GaP, however, is transparent to certain regions of the spectrum to which both the photomultiplier and the human eye are sensitive. The absorption edges of intrinsic GaAs (14) and GaP (15) are shown in Fig. 3, together with the spectral response curve of the S10 type photocathode used in the photomultiplier. It is apparent that the photomultiplier is completely insensitive to wavelengths of light transmitted by a thick specimen of GaAs. However, a specimen of thickness near 5000Å (0.5 μm) will transmit sufficient light to be detected.

For an order of magnitude calculation of the conditions required to automatically detect the desired thickness in the case of GaP, suppose that the photomultiplier triggers the solenoid when 1% of the intensity of the light incident on the specimen in the relevant wavelength range is transmitted. Assuming reflection to be negligible the transmitted intensity is given by

$$I = I_0 \exp\ (-\alpha t)$$

where I_0 is the intensity of the incident light, α is the linear absorption coefficient, and t is the specimen thickness. On the assumption therefore that $I/I_0 = 0.01$ for the SCR to be triggered

$$\alpha t = 4.6$$

And for

$$t = 0.5\ \mu\text{m}$$

$$\alpha = 9.2 \times 10^6\ \text{m}^{-1}$$

Thus a wavelength of light with a linear absorption coefficient near 10^7 per meter will be transmitted through a specimen, thin enough to be electron transparent, with sufficient intensity to trigger the detection system. In practice a range of wavelengths and absorption coefficients are involved, but the simple calculation serves to illustrate the principle.

The same principles apply in the case of GaAs. Extrapolation of the absorption data for n-type with a

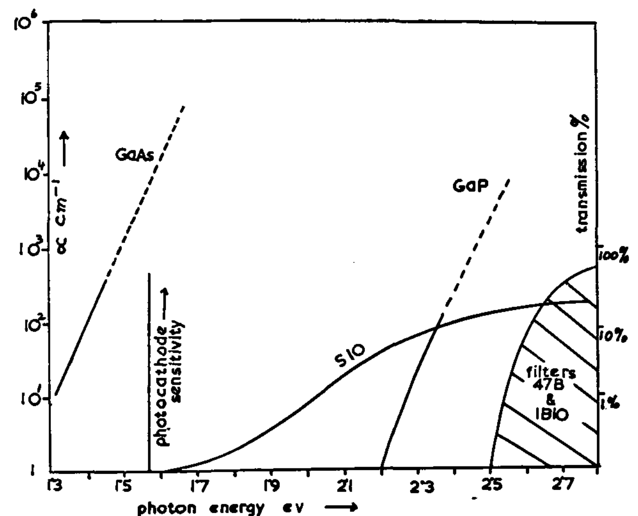

Fig. 3. Comparison of the linear absorption coefficients for light of GaAs and GaP with the spectral sensitivity range of the photomultiplier photocathode and the wavelength range passed by the two filters.

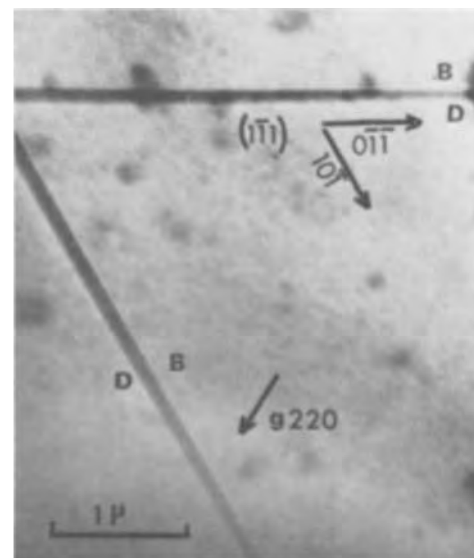

Fig. 4. Transmission electron micrograph of a tetrahedral stacking fault in Te-doped GaP grown from the vapor phase on a GaAs substrate. B and D indicate the bright and dark bounding fringes of the stacking faults. It can be deduced that the faults are intrinsic (12).

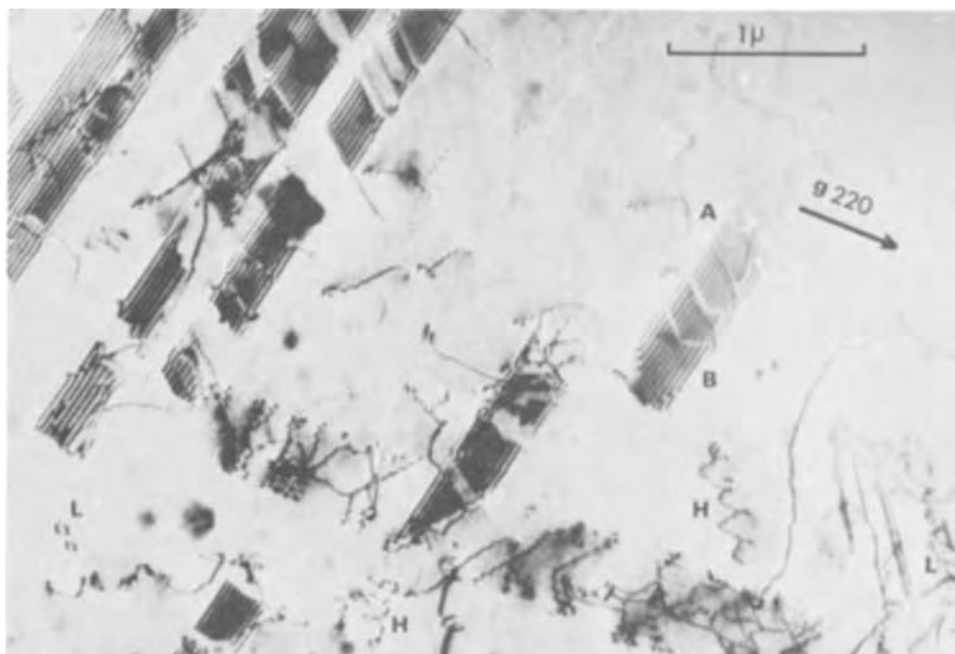

Fig. 5. Dark field micrographs showing defects in Te-doped vapor phase grown GaP. Helices are marked H and loops are marked L. At A-B there is a set of overlapping stacking faults.

free carrier concentration of 2×10^{18} cm^{-3} indicates (14) that a wavelength of about 0.75 μm (with a photon energy of hv $\simeq$ 1.8 eV in Fig. 3) corresponds to a value of α of 10^7 per meter. This corresponds to light of a reddish orange color which is just detectable by both the photomultiplier and the human eye.

The absorption edge of GaP lies at a much lower wavelength than that of GaAs. Even a thick specimen will transmit visible (yellow-orange) light with very little absorption. For automatic thinning it was necessary to use optical filters to cut out the portion of the transmitted spectrum to which the photomultiplier was sensitive. Ideally an interference filter would provide a suitable narrow band width for which α has a value near 10^7 m^{-1}. A satisfactory and cheaper alternative was found using a Kodak Wratten filter No. 47B in conjunction with a Chance Pilkington OB 10 filter to remove the infrared component. The combined region of transmission is illustrated by the shaded area in Fig. 3.

Results

In those cases in which it was possible to thin from the P($\overline{111}$) faces of the specimens the automatic system for terminating thinning could be used. It was found that the technique worked less well than in the case of GaAs which could be reduced to a reproducible thickness with a 100% success rate (5). Drift in the electronics made it impossible to obtain reproducible thicknesses by adjusting the brightness of the light source and the voltage applied to the photomultiplier. It was found best to set the system to cut off at too great a specimen thickness and to give a final manually controlled thinning. Thinning was then terminated when the transmitted light appeared white. Specimens of different dopings have slightly different absorption edges. Therefore it was necessary to obtain settings for each batch of material by trial and error. Nevertheless the technique was a great convenience since visual control was not required except during the brief and crucial final stage of thinning.

Large (40-50 μm diam) electron transparent areas were produced in thinning from both the Ga(111) side and from the P($\overline{111}$) side. It was found that GaP was transparent to the beam in a conventional 100 kV transmission electron microscope up to a thickness greater than 0.8 μm (8000 Å). This is the thickness of the specimen shown in Fig. 4 as determined from the projected widths of the tetrahedral stacking fault.

The present thinning technique was used successfully on heavily doped material as shown in Fig. 4 and on material containing a profusion of stacking faults as shown in Fig. 5.

Jet Polishing of Semiconductors

II. Electrochemically Formed Tunnels in GaP

B. D. Chase and D. B. Holt

Metallurgy Department, Imperial College of Science and Technology, London S.W.7, England

ABSTRACT

Transmission electron microscopy showed that high density networks of tunnels about 300Å in diameter were formed in {111} foils of GaP thinned by jet electropolishing using a chlorine in methanol solution. These tunnels ran in <111> directions, in the polar sense from the gallium to the phosphorus atom along a chemical bond. They were unrelated to any of the pre-existing defects in the material that could be seen by transmission electron microscopy.

Deep, narrow, optically resolvable tunnels produced in crystalline materials by dissolution processes have long been known to mineralogists as "anomalous solution phenomena" (1). Later such a process described as tunnel etching producing "negative whiskers" was studied in LiF (2). A similar phenomenon of tunnel corrosion has recently been observed on a transmission electron microscope scale in Cu_3Au alloys (3).

We observed that narrow crystallographic channels were produced in GaP in the course of electrochemical thinning of this material for transmission electron microscopy (4). The results of a microscopic study of these etch tunnels are presented in this paper.

Experimental Methods

The method of thinning the specimens was described in the previous paper (4). It involved directing a jet of chlorine in methanol on the GaP specimens. This worked well when the P$(\bar{1}\bar{1}\bar{1})$ face was to be attacked. When the Ga(111) side had to be attacked however, it was found necessary to employ electropolishing. The specimen was made. The anode and a potential difference of 120V was applied between it and a tungsten electrode inside the jet nozzle. A current of about 20 mA then flowed, and rapid localized attack on the GaP occurred. An orange surface film was formed during electrochemical thinning from the Ga(111) face. This surface film could be removed by a final 15 sec chemical attack in the chlorine in methanol jet with no voltage applied. The evidence to be discussed below showed a dense network of tunnels to be present in the orange films. The scattering of light from these networks of tunnels caused the translucence of the films and the diffuse nature of light reflected from them when observed in the optical microscope.

Results

In GaP specimens which were prepared by electrochemical polishing alone, dense networks of linear features were visible in transmission electron microscopy. Examination using the stereo pair technique, in which two micrographs like those in Fig. 1 were taken with a difference in specimen tilt of about 10°, showed that the features formed a three-dimensional array with each one penetrating the foil from top to bottom.

Selected area diffraction patterns from regions of high tunnel concentrations showed no additional diffraction spots or rings. This ruled out the possibility of the presence of a second phase or of extensive precipitation.

All the specimens examined were close to a {111} orientation and the tunnels projected onto the three <211> directions in this plane. Examination of the (111) stereogram shows that this condition is met if the tunnels lie either in the <111> or in the <110> direction. To decide between these two possible directions a series of micrographs was taken at widely differing angles of tilt, using a high tilt goniometer stage in the electron microscope. The angles between the projected tunnel directions were measured on each micrograph, and the beam directions were determined by analysis of the diffraction pattern relative to a foil normal of [111]. The results established that the tunnels lay along the $[11\bar{1}]$, $[1\bar{1}1]$, and $[\bar{1}11]$ directions at 70.5° to the [111] foil normal (7).

At extinction contours the absence of material in the tunnels gave rise to characteristic contrast. In Fig. 2 it can be seen that the contours are displaced where they are crossed by a tunnel. Also given in Fig. 2 is a cross-sectional diagram showing the relation of the tunnel at A to the top and bottom surfaces of the foil. By counting extinction contours on the micrograph it was established that the bottom of the etch pit was the equivalent of 1.5 extinction distances ξg from the unetched base of the foil. In each such case the projected length of the tunnel was in proportion to the depth of material below the pit.

The displacement of the extinction contours where they crossed the tunnels was measured as about two-thirds of the contour separation ξg for a tunnel diameter of 0.4 cm on the micrograph. Thus the effective thickness of the tunnel as seen by the electron beam can be written

$$t = \frac{0.4}{\sin \theta} = \frac{2}{3} \xi g \qquad [1]$$

where θ is the angle between the tunnel and the normal to the foil. Moreover, a tunnel of measured length 3 cm on the micrograph penetrated a thickness of material

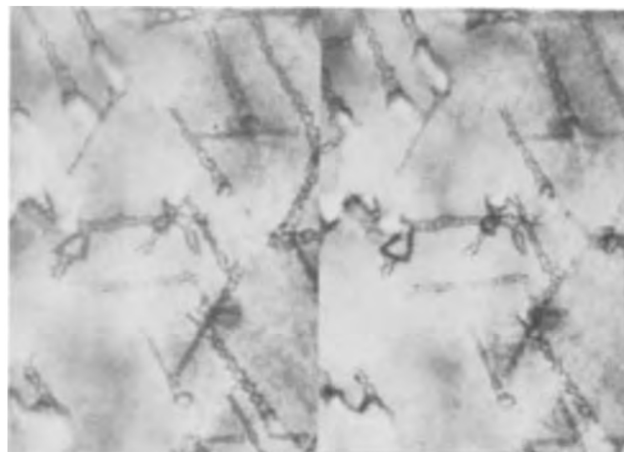

Fig. 1. Stereo pair of transmission electron micrographs of an area of an electrochemically polished GaP specimen showing crystallographic etch tunnels. The micrographs were taken at specimen tilts differing by about 10°.

Key words: localized attack, polarity, tunnels, GaP.

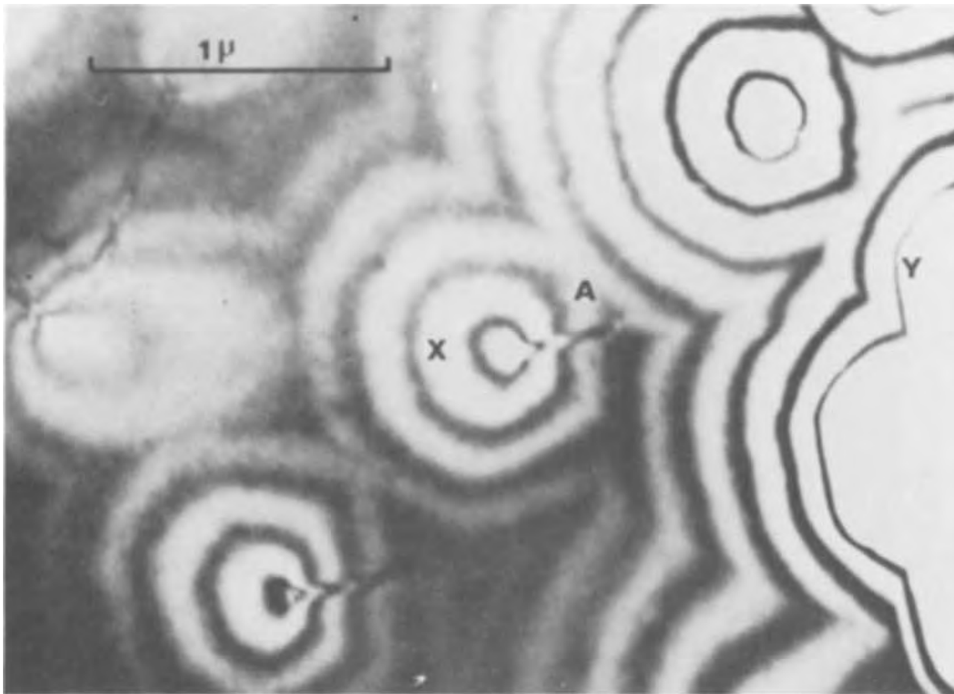

Fig. 2. Contrast effect obtained when an etch tunnel crosses an extinction contour: *(left)* micrograph showing displacements of the contours and *(below)* cross-sectional diagram of the tunnel orientation through the foil.

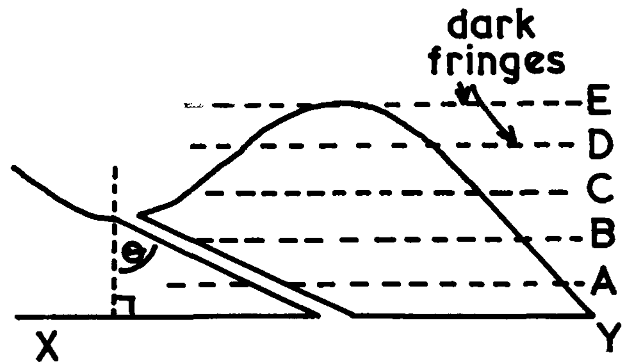
equal to 1.5 ξg. Therefore

$$\tan \theta = \frac{3}{1.5\ \xi g} \qquad [2]$$

Combining Eq. [1] and [2] to eliminate ξg gives a value for θ of 72.5° which is close to the value of 70.5° of the angle between <111> directions. This therefore supports the finding that the tunnels lay in the <111> directions. The mechanism of extinction is that of the scattering of the electrons by the specimen material. The observed displacements of the extinction contours therefore also suport the supposition that the linear features were empty tunnels.

The opposite contrast effects shown by the linear features in Fig. 3(a) and (b) can also be understood on the basis that they are tunnels. Both these micrographs were taken in a two-beam condition with a



single extinction contour operating over the whole area of the micrograph. Extinction contours arise because as the thickness of the material changes, the extinction

Fig. 3. Opposite contrast conditions exhibited by tunnels: (a) dark contrast *(left)* and (b) bright contrast *(right)*.

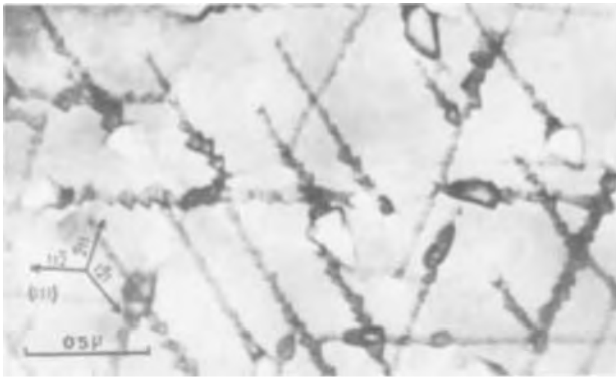


Fig. 4. Etch tunnels of crystallographic internal form, produced by low voltage polishing (less than 120V). At the points marked A tunnels terminate inside the material but are continued by much narrower channels.

conditions change cyclically, so that the effective transmission of electrons changes. This gives rise to a variation of intensity in the form of successive bright and dark fringes. The reduction in the thickness of the material traversed by the beam, due to the presence of etch tunnels, can change the extinction conditions so as to increase, or reduce, the brightness depending on the point in the cyclic variation of the extinction representing the situation in the specimen in the absence of any tunnel. In the case shown in Fig. 3(a) the reduction in thickness due to the tunnels shifts the extinction to a more absorbing condition and the tunnels appear in dark contrast. In case 3(b) the tunnels alter the extinction conditions so that a greater beam intensity is transmitted and they appear bright.

Thus the linear features were tunnels about 300Å in diameter.

Tunnels were observed apparently in various stages of formation. In some cases the main tunnel was found to penetrate only part of the foil while the continuation of the line of the tunnel was marked by a narrow trace. Examples of this type can be seen in Fig. 4 at the points marked **A**.

Tunnels of cystallographic shape like those in Fig. 4 were only observed in specimens electrochemically polished at low voltages of less than 120V. Specimens that were thinned at high applied voltages (near 240V) contained tunnels with rounder shapes like those in Fig. 3(b). It appears, therefore, that only at lower voltages were the conditions such that some degree of crystallographic etching within the tunnels themselves could occur.

In some specimens it was found that the tunnels lay mainly in one preferred <111> direction as in Fig. 3(b). In some cases this was limited to one portion of a thin foil while other regions contained tunnels equally distributed among the three available directions.

These electrochemical etch tunnels were first discovered due to the fact that it was found necessary to use electrochemical polishing to thin {111} GaP specimens from the Ga(111) face. Most observations were made on tunnels produced by electrochemical attack on this side of the specimens. This resulted, as reported above, in the formation of tunnels lying only along the three <111> directions at 70.5° to the specimen surface. In cases of electrochemical action on the $P(\bar{1}\bar{1}\bar{1})$ surface tunnels were also formed. However, in this case most of them ran in the <111> direction normal to the surface as shown in Fig. 5. This evidence indicates that the tunnels were etched in specific polar directions.

Discussion

Figure 6 indicates that these observations are consistent with the tunnels preferentially propagating in the Ga-to-P directions along the bonds as indicated by the arrows. The other tunnels occurring in films thinned from the $P(\bar{1}\bar{1}\bar{1})$ side may be spurious. The mounting of some of the specimens was not leakproof and the reagent was observed to creep around and attack the Ga(111) faces of these specimens. The tunnels inclined at 70° to the normal in the specimens thinned from the $P(\bar{1}\bar{1}\bar{1})$ side may have resulted from this unintended Ga(111) attack.

The presence of etch tunnels on a transmission electron microscope scale has not previously been reported in GaP or any other semiconducting material. This also appears to be the first report of an example of electrochemical tunnel etching. Tunnels have, however, been observed in certain other materials under particular conditions.

Westwood and Rubin (2) investigated the growth and dissolution of LiF crystals in aqueous solutions containing long-chain fatty acids. Both "positive and negative whiskers," that is, both growth whiskers and dissolution tunnels of similar form, could be formed

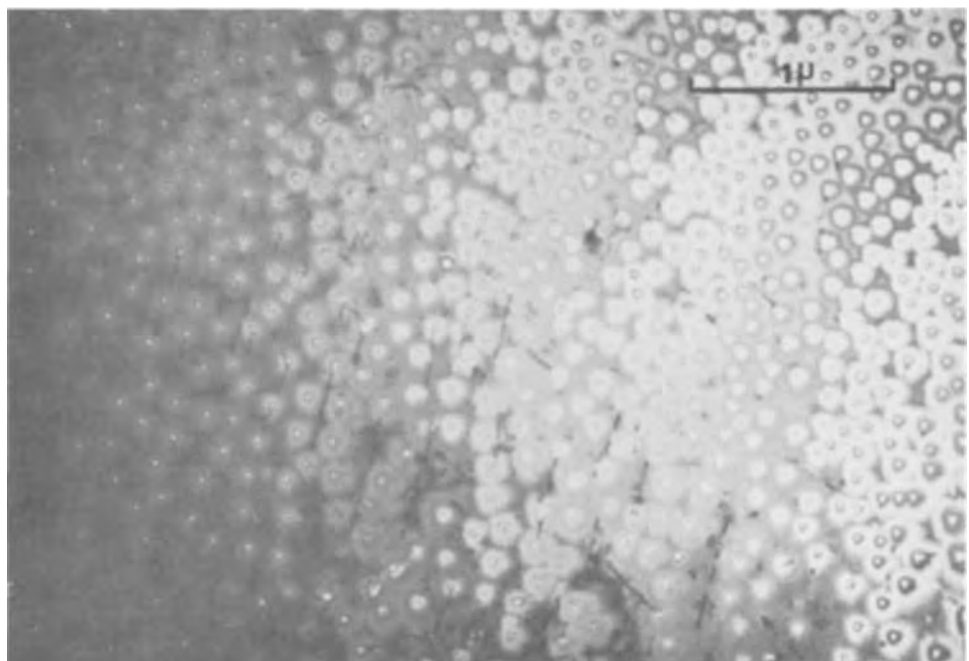

Fig. 5. GaP specimen electrochemically attacked from the $P(\bar{1}\bar{1}\bar{1})$ surface. About half of the etch tunnels lie along the <111> direction normal to the specimen surface. No tunnels were formed in this direction when the specimens were attacked from the Ga(111) side as in all the previous figures.

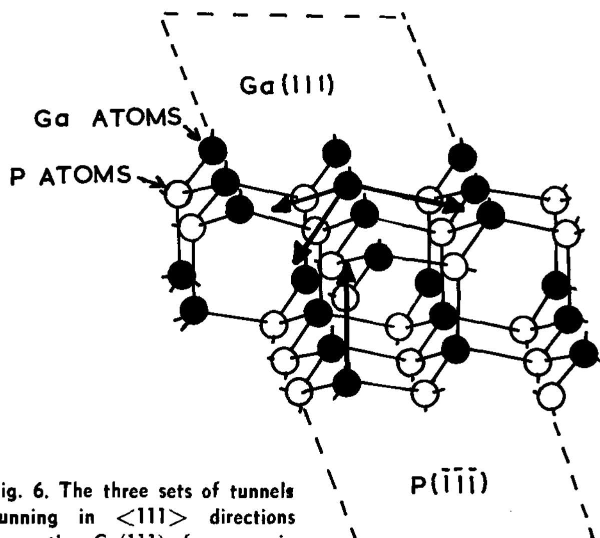

Fig. 6. The three sets of tunnels running in <111> directions from the Ga(111) face, as in Fig. 1, 3(a) and 4, are consistent with preferential propagation in the polar Ga-to-P directions along the bonds as indicated by the three arrows. The tunnels running vertically through the foils from the P(1̄1̄1̄) faces as in Fig. 5 are also consistent with preferential propagation in the Ga-to-P polar direction as indicated by the single vertical arrow.

using supersaturated and undersaturated solutions, respectively, containing identical concentrations of stearic acid. It was thus possible to equate the formation of tunnels with a reversal of crystal growth. It was suggested that the fatty acids acted as step poisons and were less concentrated at the base of the tunnels than at the surface. The maximum depth of the tunnels in LiF was 200 μm and their diameter was between 1 and 2 μm. Thus they were orders of magnitude larger than those reported above.

Swann (3) observed corrosion tunneling in the dissolution of Cu_3Au in ferric chloride solution. Electron microscope studies showed that a passive layer of gold was formed on the tunnel walls. A theory was developed to explain the longitudinal rather than lateral growth of the tunnels. According to this, passivation of the tunnel walls would occur at a critical radius found by equating the number of gold atoms in the tunnel with the number of copper surface sites on the tunnel walls. This radius was found to be two-thirds of the maximum radius of the hemispherical pit at the base of the tunnel. Thus the tunnel walls become passivated before the base and the tunnels grow longitudinally.

The formation of tunnels in GaP, however, appears to be purely an electrochemical phenomenon and there is no evidence that passivation is involved. No electron diffraction effects attributable to surface layers of a different structure or composition than the bulk material were ever seen.

Electrochemically formed tunnels similar to those reported here have been observed by transmission electron microscopy in GaAs and Si.[1] Theunissen *et al.* (5) in a study of the electropolishing of Si in hydrofluoric acid reported that a thin dark brown layer formed on n^+ material. Sirtl etching of cross sections of these specimens "revealed a high density of etch channels (about 10^8 cm^{-1}) extending a few microns (0-5 μm)" into the specimen. It seems probable that the dark brown layers observed by Theunissen *et al.*, like those reported above, contained a high density of tunnels on an electron microscopic scale and the Sirtl etch enlarged some or all of the deeper ones to produce the optically visible etch channels. Subsequently Theunissen (6) reported scanning electron microscope (SEM) observations of channels in these electropolished slices. The intermediate resolution of the SEM means that those channels were probably on a rather larger scale than those reported here.

No relation was found between the formation of tunnels and any defects originally present in the materials examined in this paper. It is certain that the tunnels in GaP do not follow lines of dislocations as they formed in material in which the dislocation density was too small by several orders of magnitude to account for all the tunnels. The observed density of tunnels varied from about 10^6 to 10^8 cm^{-2}, and this density was found to increase with the electropolishing voltage used. The density of dislocations in this material was 10^4 to 10^5 cm^{-2}. Furthermore, dislocations in GaP tend to lie along <110> directions (7, 8), whereas the tunnels were invariably formed along <111> directions. It therefore seems certain that the tunnels are formed by localized electrochemical reaction occurring at the semiconductor-electrolyte interface. It is possible, however, that the tunnels initiate at some form of minor surface defect.

An hypothesis that appears to be consistent with our observations is that localized electrochemical attack is the result of avalanche breakdown of the surface depletion layer of the semiconductor due to the large applied field in this layer. Avalanche breakdown produces a localized microplasma. This contains a high density of the electron holes that are required for electrochemical attack. A similar idea was put forward by Theunissen (6). However, he appeared to suggest that the phenomenon was unique to n^+n epitaxial slices of Si and reported that in some cases the channel networks could be related to dislocation networks. The present work, however, as just discussed, shows that in GaP the tunnels are not related to dislocations.

Jet Polishing of Semiconductors

III. Polishing and Shaping of Si, Ge, GaAs, and GaP Slices

B. A. Unvala, D. B. Holt, and Aung San

Metallurgy Department, Imperial College of Science and Technology, London S.W.7, England

ABSTRACT

Clean, flat, strain-free surfaces of Si, Ge, GaAs, and of the $P(\bar{1}\bar{1}\bar{1})$ faces of GaP were prepared by scanning jets of chemical polishing reagents across one side of the rotating slices. The Ga(111) faces of GaP were electrochemically polished in the same apparatus. It was found possible to reduce the central areas of large diameter Si slices to thicknesses of tens of microns while retaining thick, mechanically strong rims with this technique by masking the edges of the slices. Whole slices of Si were also reduced to uniform thicknesses of under 20 μm by this technique.

Chemical polishing reagents are available for the more important semiconductors. [Tabulations of these reagents were listed in the first paper in this series (1).] By using jets of these reagents improved polishing action in our experience is generally obtained. Techniques for thinning small areas for transmission electron microscopy in several semiconducting materials by chemical jet polishing were successfully developed (1-3). It was also shown that by rotating germanium slices under a chemically polishing jet which scanned over one side it was possible to produce clean, flat, and strain-free surfaces for use as epitaxial substrates (4). This method has been improved and applied to the polishing of silicon, germanium, GaAs, and GaP slices in this present work.

For the production of certain semiconductor devices and for optical transmission studies, it is desirable to produce large areas that are uniformly thin but have thick, mechanically strong rims. A method for doing this has been developed for silicon and is reported here.

Some evidence is also reported which indicates that the very thin slices required for certain types of integrated circuits can be produced by the technique described here.

Equipment

The apparatus used to scan the jet across an arc under which the rapidly rotating slices passed is shown in Fig. 1(a). The slices were given a planetary motion, that is a rotating platform was used which carried the slice mounts, each rotating about an axis parallel to and moving round the axis of rotation of the platform as indicated in Fig. 1(b). This prevented the formation of raised central spikes that were occasionally produced when slices were rotated on a stationary axis beneath a scanning jet (4). Electrical contacts for electropolishing were made to the stainless steel jet nozzle and to the rotating platform.

The planetary gear ratio was approximately four to one. The central spindle was rotated at speeds of about 300 rpm and the reciprocator carrying the jet nozzle was driven at about 950 cycles per minute in all the experiments.

Before chemical polishing the slices were mounted on the spinner disks and mechanically polished in a special jig as described previously (4).

Slices were successfully polished using standard reagents. For polishing silicon a mixture of $HF:HNO_3:HAc$ in the volume ratio 5:15:3 at room temperature was used. With a flow rate of about 4 $cm^3\ sec^{-1}$ for all the polishing experiments, the rate of removal of Si was about 0.5 $\mu m\ sec^{-1}$ for both n- and p-type materials. Ge was polished using CP-4 at 47°C. The rate of removal was again about 0.5 $\mu m\ sec^{-1}$. Heavily Cr-doped GaAs was polished using 2% of Br in methanol at room temperature. The rate of attack was about 8 $\mu m\ min^{-1}$.

Key words: polishing, shaping, semiconductor slices.

A solution of $H_2O:NaOCl:HCl$ in the volume ratio 16:2:2 was employed to polish the $P(\bar{1}\bar{1}\bar{1})$ sides of GaP{111} slices. The slices were attached to the stainless steel platform with silver paint. The Ga(111) sides of the slices were polished with the same reagent but a current of 35 mA was passed between the slice and the nozzle. (The Ga(111) and $P(\bar{1}\bar{1}\bar{1})$ sides of the slices were identified by etching in hot aqua regia. The Ga faces were etched and the P faces were polished.)

Results and Discussion

Polishing

The polished Si slices were flat as was shown by the straightness of optical interference fringes. That they were microscopically smooth was demonstrated by the absence of any detail due to asperities on dark field optical microscope observations of these surfaces. The use of planetary motion eliminated the central spikes which sometimes resulted when slices were rotated about a stationary central axis during jet polishing (4).

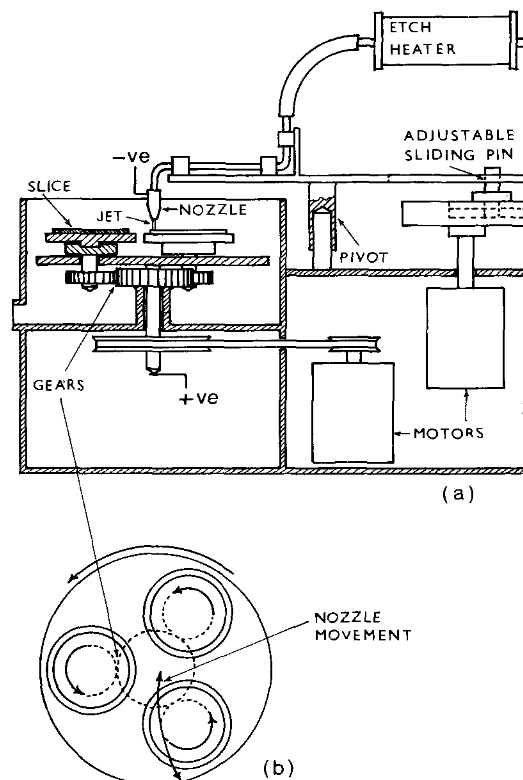

Fig. 1. Modified apparatus for the jet polishing of rotating slices

Germanium slices were polished to a similar standard.

The polish achieved on the GaAs slices, despite their being heavily Cr-doped, was of the same quality as that on Si and Ge. That is, chemical polishing produced surfaces that were optically smooth and flat on both Ga(111) and As($\overline{111}$) faces. Attempts were also made to electropolish GaAs. H_2O:HCl:NaOCl (about 10% available chlorine) in the volume ratio 170:10:20 was used. At 200-240V applied, 30 to 40 mA flowed and the rate of attack was about 150 μm/min. The surfaces so produced were, however, found to be tunnel-etched similarly to GaP as described previously (5).

The P($\overline{111}$) faces of GaP slices were also chemically polished, flat, and smooth to optical standards. Smooth, flat Ga(111) surfaces could, however, only be produced electrochemically as described above. These faces had a thin yellow surface film. All semiconductor slices polished by this method were rounded at the edges.

Shaping and Thinning Silicon

For a certain device application large thin areas of silicon were required with a thick strong rim. The ability of this method to produce silicon slices with this shape was tested. Regions about 2 mm wide around the edge of Si slices 2.54 cm in diameter and 125 μm thick were masked with a gold-chromium alloy. The slices were then hollowed by chemical polishing as described above. A central area about 1.9 cm in diameter was found to be uniformly thick. Figure 2 is a Tallysurf trace showing the shape of the rim produced by polishing a masked slice. No undercutting or formation of stress-concentrating sharp corners occurred. Thicknesses of the central area less than 20 μm could be achieved. The thicknesses were determined by an infrared interference method (6).

There is also currently a growing interest in uniformly thin slices of Si for the production of integrated circuits involving only p-n junctions oriented normal to the slice. Recently it has been pointed out that electropolishing can be used to preferentially attack a substrate leaving only the thin, differently doped epitaxial layer in the cases both of Si (7) and of GaAs (8). Mash *et al.* (9) have reported a mechanical polishing technique for thinning Si slices to 10 μm. This process must however introduce some degree of mechanical damage.

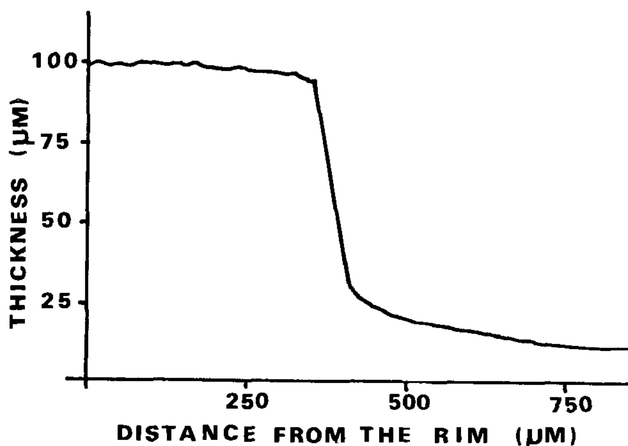

Fig. 2. Tallysurf trace of the rim of a hollowed Si slice

Using the method described above Si slices were successfully reduced to less than 20 μm in thickness at which value they were beginning to be optically transparent. Without special apparatus to prepare slices with faces that were initially accurately parallel and to monitor thickness continuously during final thinning it was not practical to reduce thicknesses much below about 20 μm. However there is no reason in principle why the technique should not be used for this purpose. The present technique can be used for uniformly doped slices and not only for removing substrates from differently doped layers. Moreover, due to the insensitivity of chemical polishing rates to semiconductor levels of doping, this technique, using chemical polishing reagents, should be capable of thinning slices containing n- and p-type areas.

Acknowledgments

One of us (AS) would like to thank the S.R.C. for financial support. It is a pleasure to thank C. Marsh for the construction of the polishing device, P. Steigman of Marconi Ltd., Witham, Essex, for supplying the masked silicon slices and determining their final thicknesses, Dr. M. J. Hill for determining the polishing conditions for GaP, and Prof. J. G. Ball for the provision of research facilities.

ABSTRACT

Equations previously formulated for a model electrolyzer-reactor system for production of sodium chlorate are tested with experimental pilot-plant data. The reactor volume and circulation rate between the electrolyzer and reactor were systematically varied in the pilot-plant tests. Mass-transfer coefficients for hypochlorite discharge and the Foerster rate constant for formation of chlorate in solution determined from these data were compared to laboratory data from the literature. Literature rate constants were put in the model equations and calculated efficiencies were found to vary with reactor volume and circulation rate in a similar way as pilot-plant efficiency data.

An equation relating current efficiency to the significant parameters of a model electrolyzer-reactor system for producing chlorate was presented in a prior paper (1). The model was based on the Foerster mechanism (2) of homogeneous formation of chlorate from hypochlorite in solution and of mass-transport-limited anodic discharge of hypochlorite. Only beaker-scale laboratory data from the literature were available to the author at the time of development of the model so it did not receive a critical test.

Pilot-plant studies were made with a separate electrolyzer-reactor system providing data with which to test the applicability of the model. The pilot plant was installed at the Domsjo chlorine plant in Sweden where studies were made on the effect of circulation rate and reactor volume on current efficiency. Fortuitous circumstances brought the two authors together for collaboration on this paper.

Pilot Plant Description

The arrangement of the pilot plant is illustrated in Fig. 1. The pilot plant consisted of a rectifier, an electrolytic cell with a plastic cover, two reaction tanks, a circulation pump of rubber lined iron, a tube cooler of titanium, and a salt dissolver. The tubing, reactors, and dissolver were made of polyvinyl chloride plastic (PVC).

Rectifier.—An air-cooled rectifier made by ASEA, Type RPI G, equipped with germanium cells was used. The rated output was 2400A at 2.5-8.0V d.c.

Cell.—The electrolytic cell was made of mild steel and had the internal dimensions; length 63 cm, height 67 cm, and width 47 cm. The anodes consisted of impregnated graphite plates with length 62.5 cm, width 15.0 cm, and thickness 5.0 cm. Twenty plates of this size were arranged in four rows with five in each row. An anode immersion depth of 48 cm gave a total anode area of 4.0×10^4 cm^2 and an area directly facing the cathodes of 3.05×10^4 cm^2. From the main busbar four copper bars conducted the current to the electrodes as shown in Fig. 2. The cathodes consisted of 1.0 cm thick mild steel plates welded between the anodes, forming five compartments in the cell. The distance between two plates was 7.0 cm, and the distance between anode

Fig. 2. Top view of electrolytic cell

and cathode thus 1.0 cm. The cathode busbar was bolted to the bottom of the cell.

In order to keep the graphite anodes in place there was a set of plastic spacers in the bottom and on the top of the cathode plates. The electrolyte was introduced through five perforated pipes, one in each compartment with eight 0.4 cm holes evenly distributed along each. These tubes were introduced through the end at the bottom of the cell.

The electrolyte left the cell through an overflow placed in the upper part of the cell at the same side as the inlet tubes. In the end box the gas was separated from the solution and was removed through a plastic pipe with a fan.

In the middle of the cell cover, which was divided in five parts, a plastic tube was arranged and submerged into the electrolyte. From this tube gas samples were taken for analysis. The cover was sealed with asphalt.

Reactors.—From the cell the solution flowed by gravity to the bottom of reactor No. 1 through a 3.0 cm plastic hose, and then from the upper part of this reactor to the upper part of reactor No. 2. From the covers of the reactors any chlorine-containing vapors were removed with plastic hoses which were connected to the gas pipe from the cell. The two reactors had the same volume, about 450 liters, but reactor No. 2 was only partly filled during the main part of the experiments. In the cover of reactor No. 1 two quartz heaters were arranged for heating the solution. They were not in use during normal operation, since the cell then developed enough heat for keeping the temperature at the desired level.

Pump.—The solution flowed from the bottom of reactor No. 2 through the pump to the titanium cooler. The cast-iron, rubber-lined pump was of centrifugal type with a Teflon-stuffed packing gland. The circulation rate was controlled with a valve placed on the pressure side of the pump. The pump was operated with a 3 HP motor at 1450 rpm.

Cooler.—From the pump the solution flowed through a 2.5 cm plastic tube to the titanium cooler which consisted of an outer steel tube (4.5 cm diameter and 520 cm length) and an inner 2.5 cm titanium tube. Between the inner and outer tube the water was fed concurrently to the electrolyte in the inner tube.

Salt dissolver.—The electrolyte flowed from the cooler through a 2.5 cm pipe to the salt dissolver. This consisted of a plastic vessel with 50 cm diameter and 100 cm length. At the inlet were two 2.5 cm tubes placed 6.0 cm above the bottom. Just above the inlet tubes there was a bubble cap plate with seven caps. Salt was dissolved as the electrolyte passed through the caps. The solution left the vessel through an overflow about 60 cm above the bottom. The required amount of salt was added hourly. In the outlet the solution passed a perforated plastic disk, and thereby solid particles were separated.

Deaeration tube and distribution tube.—The electrolyte flowed by gravity from the saturator through a 5.0 cm tube to a deaerator in which the air was removed which had been taken up by the solution in the dissolver. With respect to the gas analyses air was not desired in the cell. The deaerating tube had a diameter of 16 cm and a length of 160 cm.

The solution then passed through a distribution tube, which distributed the solution to five channels connected to the five compartments of the cell. Above the outlet channels pitot tubes were placed, indicating the flow to each compartment. Both the deaeration and the distribution tube were made of PVC.

Experimental

The pertinent experimental conditions used are summarized in Table I. A constant current of 2250A was used in all tests reported here. The total immersed anode area is listed and was used in the calculations. The total immersed area is accessible to diffusion and discharge of hypochlorite. The total current density would not be uniform, however, and this could cause some departure from the model equations.

Table I. Experimental conditions

Current	2250A	
Cell voltage	3.0-3.4V	
Anode area	4.0×10^4 cm^2	
Volume of electrolyte in cell	9.0×10^4 cm^3	
Volume of electrolyte in reactors and circulation loop exclusive of cell	80×10^4 cm^3 in circulation rate experiments (where q = 170-1010 cm^3/sec	
Circulation rate	830 cm^3/sec in reactor volume experiments (where $V_r = 30 \times 10^4$ to 100×10^4 cm^3)	
Temperature	40 ± 2°C	
Electrolyte composition:	Set I	Set II
NaCl	200 g/ liter	100 g/liter
$NaClO_3$	0-400 g/liter	600 g/liter
$Na_2Cr_2O_7$	2 g/liter	2 g/liter
*p*H in reactor	6.7-6.9	6.75

The volume of electrolyte in the cell was calculated by deducting the volume of the anodes, cathodes, and spacers from the internal cell volume. The volume of electrolyte in the reactors was controlled by measuring the height of the liquid. The value of V_r is the volume of liquid in the reactors and recirculation loop exclusive of the cell. The circulation rate was controlled by measurement of pressure drop in a calibrated section of pipe in the rising part of the circulation loop.

The electrolyte composition was maintained by salt additions to the dissolver. The concentration of $NaClO_3$ was allowed to build up during the experiments to the levels indicated in Table I. The *p*H was maintained in the reactor at 6.75 by addition of dilute HCl under the liquid surface in the second reactor at hourly intervals. Chemical analyses were made at intervals during the runs for total hypochlorite, chlorate, chloride, and chromate. Orsat analyses of the cell gas for oxygen and CO_2 were made for the determination of current efficiency.

Experimental results for the reactor volume experiments are given in Table II and results for the circulation-rate experiments are given in Table III.

Current efficiency of hypochlorite discharge was calculated from the gas analysis by

$$\epsilon_2 = \frac{2(\%O_2 + \%CO_2)}{100 - (\%O_2 + \%CO_2)} \quad [1]$$

Equation [1] is based on the assumptions that all of the O_2 and CO_2 are produced from discharge of hypochlorite and that hydrogen is produced at 100% current efficiency at the cathode.

The mass-transfer coefficient for hypochlorite discharge was calculated (1) from

$$K_L = \frac{I\epsilon_2}{ACF} \quad [2]$$

The gas evolution rate was calculated from (1)

$$v = \frac{IRT\epsilon_2}{4AP\,\mathbf{F}} \quad [3]$$

The rate constant for auto-oxidation of hypochlorite in solution by the Foerster mechanism to form chlorate was calculated (1) for perfect mixing in the reactor by material balance from

$$kf_r = \frac{q(C_e - C_r)}{V_r C_r^3} \quad [4]$$

and for plug flow in the reactor from

$$kf_r = \frac{q}{2V_r}\left(\frac{1}{C_r^2} - \frac{1}{C_e^2}\right) \quad [5]$$ [1]

[1] Obtained by integration of $dC/d\tau = -kf_rC^3$ in reactor with residence time $\Delta\tau = V_r/q$.

Discussion

Mass-transfer coefficient.—A plot of the mass-transfer coefficient for hypochlorite discharge *vs.* anodic gas evolution rate from Tables II and III is shown in Fig. 3. On the basis of theory (1), a line for the one-half-power law expressed by

$$K_L = 2.4 \times 10^{-2} v^{1/2} \quad [6]$$

was drawn through the data. The value of the coefficient on the right hand side is smaller than that calculated from laboratory data on hypochlorite discharge (1) as indicated in Fig. 4, in which the ratio of coefficients for hypochlorite discharge (B) to the coefficient in the one-half-power law for the Ibl-Venczel data (3) for Fe^{+3} reduction in 1M H_2SO_4 ($B_o = 2.2 \times 10^{-2}$) is shown. The expected effect of temperature on diffusivity (4) and thus B/B_o (3) is indicated by the function $a(T/\mu)$, which was adjusted to pass through the Foerster data. Viscosity data for NaCl and $NaClO_3$

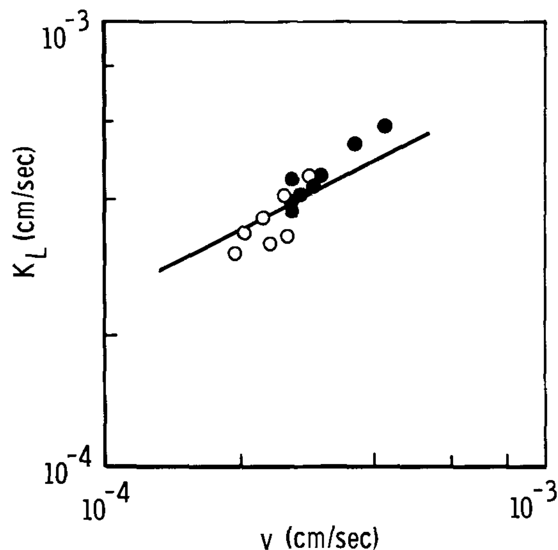

Fig. 3. Relation of mass transfer coefficient for hypochlorate discharge to anodic gas evolution rate.

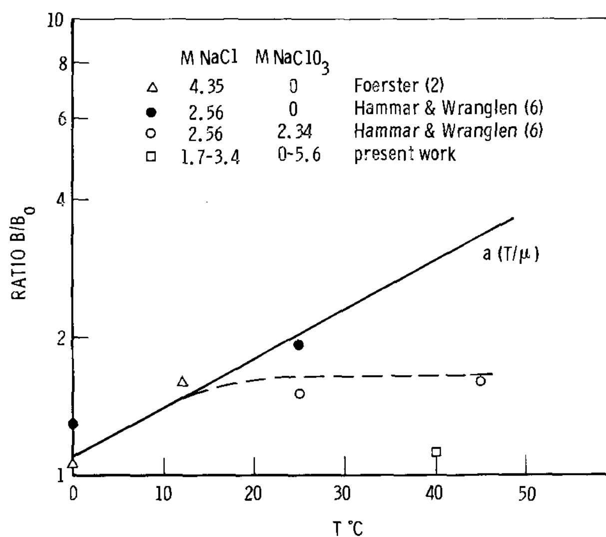

Fig. 4. Extrapolation of B/B_o to higher temperature

solutions were from International Critical Tables (5). The Foerster data (2) and the Hammar and Wranglen data (6) for NaCl solutions were reasonably close to the line in Fig. 4. The Hammar and Wranglen data and the present pilot plant data for solutions containing $NaClO_3$ were below the line.

There are at least two important factors affecting the prediction of mass transfer coefficients for hypochlorite discharge from the Ibl-Venczel data (3) for cathodic reduction at a hydrogen evolving electrode. First, Janssen and Hoogland (7) observed that mass transfer coefficients for oxidation of Ce^{3+} at an oxygen evolving electrode was about a factor of two larger than for reduction of Ce^{4+} at a hydrogen evolving electrode at the same volumetric gas rate per unit area at 25°C. The value of the correlation line at 25°C in Fig. 4 is consistent with this observation. Second, Landolt and Ibl (8) found with 4M NaCl solutions containing hypochlorite in forced convection experiments, for which the hydrodynamics were well characterized, that the anodic chlorate formation rate was smaller than predicted by a purely diffusional process. This may account in part for the negative deviations from the correlation line in Fig. 4 for the more concentrated solutions. Janssen and Hoogland further found that their mass transfer rates were a function of electrode height. This perhaps is related to effects of convection currents established by the gas bubbles.

The dashed line in Fig. 4 through the Hammar and Wranglen data give

$$K_L = 3.7 \times 10^{-2} v^{1/2} \quad [7]$$

at 40°C which is used in predicting pilot-plant performance.

Rate constant for chemical chlorate formation.—Values of kf_r determined in the experiments (Tables II and III) and from the literature are compared in Table IV. Values from the pilot plant varied by more than an order of magnitude between Set I and Set II and fell on either side of the value calculated from literature data. Values of kf_r were calculated for the limiting conditions of perfect mixing and plug flow in the reactors as it was expected that the actual condition would be between these two limits. The value calculated for perfect mixing is larger because this is a less efficient condition and a higher rate constant is required to achieve the same amount of reaction. The high values of the rate constant for Set II are discussed in the next section.

In obtaining a calculated value of kf_r from literature data the Knibbs and Palfreeman (9) value of the Foerster rate constant, k, was used. Their value was determined at 40°C in a concentrated NaCl solution.

Table IV. Comparison of values of kf_r calculated from pilot plant data and from literature data

	$kf_r \times 10^{-3}$ (mole/cm^3)$^{-2}$ sec^{-1} Perfect mixing	Plug flow
Pilot plant values (from Tables II and III)		
Set I		
Reactor volume experiments	9.0	8.0
Circulation rate experiments	16.2	13.8
Set II		
Reactor volume experiments	116	70
Circulation rate experiments	90	48
Calculation from literature data		
k Knibbs and Palfreeman (9) (concentrated NaCl solution at 40°C) 9.6 (mole/liter)$^{-2}$ min^{-1} = 1.60×10^5 (mole/cm^3)$^{-2}$ sec^{-1}		
C_{H^+} (for pH = 6.75 in reactor) = 1.8×10^{-7} mole/liter		
$K_i^{40°}$ [calculated from $K_i^{25°} = 3.2 \times 10^{-8}$ (10) and $\frac{d \ln K}{dT} = \frac{\Delta H°}{RT^2}$ where $\Delta H° = +3.95$ kcal (10)] = 4.5×10^{-8} mole/liter		
$f_r = \left(\frac{1}{1 + K_i/C_{H^+}}\right)^2 \left(1 - \frac{1}{1 + K_i/C_{H^+}}\right)$ (1) = 0.128		
$kf_r = (1.60 \times 10^5)(0.128) =$	20.5	

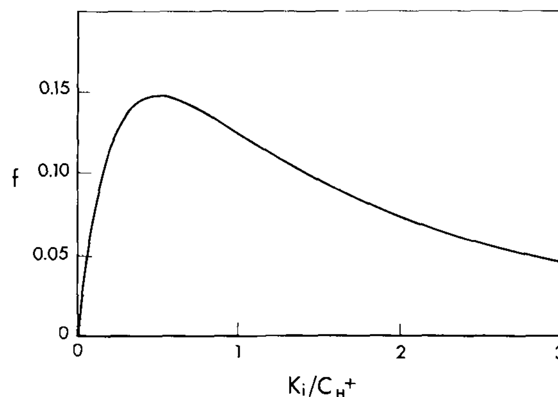

Fig. 5. Plot of $f = \left(\frac{1}{1 + K_i/C_{H^+}}\right)^2 \left(1 - \frac{1}{1 + K_i/C_{H^+}}\right)$

The dimensionless concentration factor, f_r, was calculated from an expression previously derived (1). A plot of f_r *vs.* K_i/C_{H^+} shown in Fig. 5 indicates that conditions in the electrolyzer were nearly optimum for maximum conversion rate.

Correlation of efficiency data.—Pilot-plant current efficiency data are now compared to predictions of the model equations for efficiency of a separate electrolyzer-reactor system (1) using values of K_L and k_f based on laboratory data from literature cited above. The parameters used in the model equations are given in Table V. No data were available on the pH in the electrolyzer but it was assumed to be less acidic than in the reactor. Therefore $kf_e = kf_r$ (curve A) and $kf_e = 0$ (curve B) were considered as limiting conditions based on Fig. 5.

The parameters of Table V substituted in the model equation [Eq. [11-14], ref. (1)] give

(Curve A)

$$V_r = \frac{[3.40\epsilon_2^{3/2} - 10.2\epsilon_2^{5/2} - 9.0\epsilon_2^3] \times 10^4}{[0.141\epsilon_2^2 + 0.163\epsilon_2^{3/2} + \epsilon_2 - 0.0542\epsilon_2^{1/2}]^3} \quad [8a]$$

(Curve B)

$$V_r = \frac{[3.40\epsilon_2^{3/2} - 10.2\epsilon_2^{5/2}] \times 10^4}{[0.163\epsilon_2^{3/2} + \epsilon_2 - 0.0542\epsilon_2^{1/2}]^3} \quad [8b]$$

for the reactor volume experiments, and

(Curve A)

$$q = \frac{[119\epsilon_2^2 + 135\epsilon_2^{3/2} - 45\epsilon_2^{1/2}]}{[0.0427\epsilon_2^{3/2} - 0.128\epsilon_2^{5/2} - 0.113\epsilon_2^3]^{1/3} - \epsilon_2} \quad [9a]$$

(Curve B)

$$q = \frac{[135\epsilon_2^{3/2} - 45\epsilon_2^{1/2}]}{[0.0427\epsilon_2^{3/2} - 0.128\epsilon_2^{5/2}]^{1/3} - \epsilon_2} \quad [9b]$$

for the circulation rate experiments. Equations [8] and [9] are plotted in Fig. 6 and 7 in terms of ϵ_1 (where $\epsilon_1 = 1 - \epsilon_2$) and compared to Set I and Set II data.

Several important observations can be made in Fig. 6 and 7:

(*i*) Current efficiencies based on gas analyses and on the model equations followed the same trends in respect to reactor volume and to circulation rate.

(*ii*) Set I data are closer to the model equations than Set II data.

Table V. Values of parameters used in model equations

I = 2250A
A = 4.0×10^4 cm^2
V_e = 9.0×10^4 cm^3
V_r = 80×10^4 cm^3 in circulation rate experiments
q = 830 cm^3/sec in reactor volume experiments
K_L = $3.7 \times 10^{-2} v^{1/2}$ cm/sec
kf_r = 20×10^3 (mole/cm^3)$^{-2}$ sec^{-1}
kf_e = 20×10^3 (mole/cm^3)$^{-2}$ sec^{-1} (Curve A)
kf_e = 0 (Curve B)

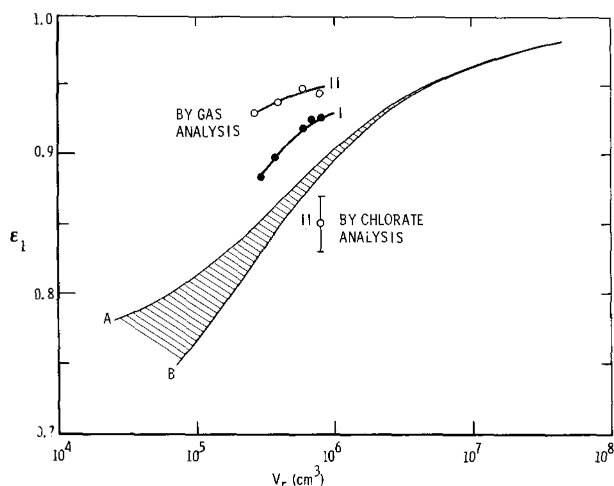

Fig. 6. Comparison of model equation to Set I and Set II data for reactor volume experiments.

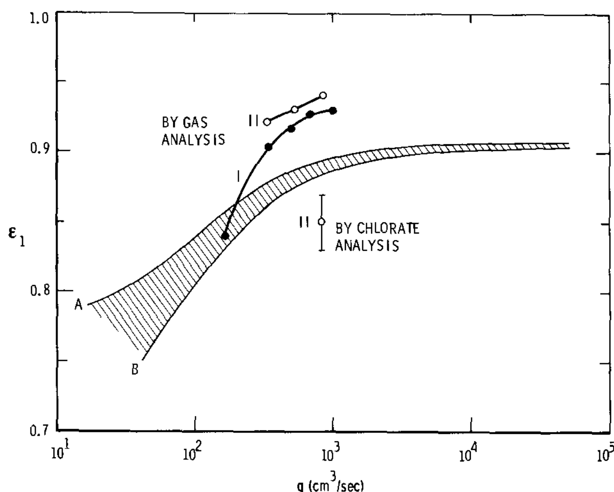

Fig. 7. Comparison of model equation to Set I and Set II data for circulation rate experiments.

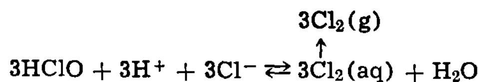
(*iii*) The experimental current efficiency had a stronger dependence on circulation rate than that of the model equations.

(*iv*) Set II current efficiencies based on gas analyses were above, and current efficiencies based on chlorate analyses were below, the values for the model equations.

It would appear that there were some systematic errors in the experimental data. Possible systematic errors of differences in the experimental data are:

(*i*) Loss of chlorine from cell and reactors by



$$3HClO + 3H^+ + 3Cl^- \rightleftarrows 3Cl_2(aq) + H_2O \quad (3Cl_2(g) \uparrow)$$

(*ii*) Decomposition of hypochlorite by

$$HClO \xrightarrow{\text{catalysis}} 1/2\ O_2 + H^+ + Cl^-$$

(*iii*) Cathodic reduction of hypochlorite.

(*iv*) Effect of high salt and chlorate concentrations on kf and K_L.

(*v*) Flow conditions not exactly defined.

(*vi*) Nonuniform anode current density.

(*vii*) Catalysis of Foerster reaction.

The difference between current efficiency determined by gas analyses and by chlorate analyses indicates a loss of hypochlorite as by items (*i*), (*ii*), or (*iii*), although cathodic reduction would not be expected to be significant with sufficient chromate present. The difference between Set II and Set I current efficiencies indicates an abrupt change such as through solution contamination affecting catalysis in items (*ii*) and (*vii*). The steep dependence of current efficiency on circulation rate and the apparent increase in kf_r with q noted in Table II suggest a loss of chlorine due to agitation. On balance it appears that chlorine losses and catalytic decomposition may both have occurred in the pilot plant. It also appears that the model equations predicted current efficiently more accurately than the calculation from gas analyses.

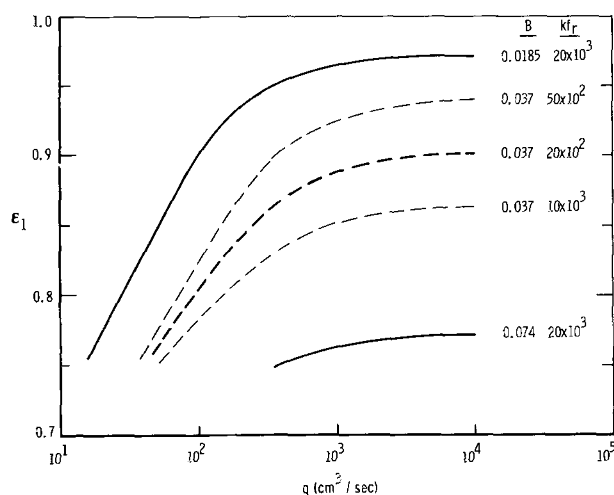


Fig. 8. Relative effect of mass transport and kinetic parameters on predicted current efficiency.

The relative effect of values of the two rate parameters, B and kf on current efficiency (Curve B) is indicated in Fig. 8. It is seen that current efficiency is more sensitive to B than to kf. This is because an increase in the value of B increases hypochlorite discharge and increases gas evolution giving a greater effect on K_L and current inefficiency, ϵ_2, whereas an increase in kf causes a decrease in concentration of hypochlorite diminishing the increase in rate of formation of chlorate. Thus it appears to be more important to get accurate mass-transport data than reaction kinetics data for this system.

Perhaps the greatest utility of the model equations is that they permit extrapolation of the system performance from experimental data. Thus Fig. 6 indicates that current efficiency could be further increased by increasing reactor volume, whereas Fig. 7 indicates that efficiency is near the plateau for circulation rate. Furthermore the model equations would allow interpolations of the data for combinations of reactor volume and circulation rate different than used in the experiments. The interpolations and extrapolations could be used in determining the economic optimum combination of pump and reactor.

Conclusions

Calculations performed on pilot plant data for a separate electrolyzer-reactor system for production of sodium chlorate showed:

1. Mass-transfer coefficients for anodic hypochlorite discharge and the Foerster rate constant for formation of chlorate were consistent in respect to order of magnitude with laboratory data in the literature.

2. Previously derived equations expressing current efficiency as a function of system parameters using mass transfer coefficients and Foerster rate constant from laboratory data in the literature gave trends of current efficiency *vs.* reactor volume and circulation rate consistent with pilot plant data.

Manuscript received April 30, 1969; revised manuscript received Nov. 11, 1971. This was Paper 253 presented at the Boston Meeting of the Society, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

The Differential Capacitance of Polycrystalline Gold in Aqueous Solutions

J. P. Carr and N. A. Hampson

Chemistry Department, Loughborough University of Technology, Loughborough, Leicestershire, England

ABSTRACT

The impedance of polycrystalline gold in aqueous NaOH and H_2SO_4 solutions has been studied as a function of bias potential. The pzc is estimated to be 0.33 ± 0.02V in H_2SO_4 solutions. Evidence is found for the adsorption of oxygen species. Addition of n-butylamine to the electrolyte solutions inhibits adsorption of oxygen species from NaOH solutions. In H_2SO_4 solutions n-butylamine is apparently absorbed as the quaternary ammonium ion and is adsorbed only at negative rational potentials.

The gold/aqueous solution interphase has been studied by a number of workers (1-14, 16, 17) however there is considerable disagreement regarding the position of the potential of zero charge, E_z. Reported values of E_z range from −0.47 to 0.5V.[1] Table I summarizes the previous work and the wide range of E_z values indicates that the double layer structure on gold electrodes in aqueous solutions may be complicated by oxide films and adsorption of solution species.

Studies concerning oxide formation and the anodic dissolution of gold in aqueous solutions have been reported (18-34) however most of the work has been performed under acid conditions. In alkaline and neutral solutions there is a limited amount of data (26, 27, 31). Thermodynamically Au_2O_3 can exist on gold electrodes under alkaline conditions (35) and the possibility of adsorption of hydroxyl species from the solution giving rise to adsorbed OH and O species at the electrode has been discussed by a number of workers (30, 32-34), however the absence of hydrogen adsorption was shown by Bauman and Shain (28).

In this paper we present the results of a study of the differential capacitance of polycrystalline gold in aqueous NaOH solutions from which inferences concerning oxide formation or adsorption at the electrode within the polarizable region could be made. The results obtained under alkaline conditions are compared with complementary results in acid solutions.

Experimental

The experimental procedure has been described previously (36, 37). The test electrode (3.48×10^{-2} cm^2 superficial surface area) was prepared from 99.999% pure gold wire supplied by Johnson Matthey and Company and sheathed in polythene (38). The adhesion of the polythene to gold was found to be excellent (liquid-tight junctions were invariably obtained) and was found to be the most satisfactory way of mounting the gold micro electrodes. The counterelectrode was of platinum gauze of high surface area[2] and contained in a compartment separated from the test electrode compartment by a glass frit. Electrolyte solutions were prepared from AR quality reagents and twice distilled water from deionized stock and subjected to continuous purification over cleaned activated charcoal (the electrolyte from the counterelectrode compartment being passed through the charcoal and the purified solution passing into the test electrode com-

Key words: gold, differential capacitance, adsorption, n-butylamine.

[1] All potentials are reported with respect to the normal hydrogen electrode.

[2] The use of platinum counterelectrodes was shown to be satisfactory since the magnitude and the time stability of the impedance measurements was the same irrespective of whether a platinum or "glassy carbon" counterelectrode was used.

partment). When adding the n-butylamine the purification procedure was stopped and the solution left to equilibrate for 12 hr before taking any readings. At all times the test solutions were kept under an atmosphere of N_2.

The electrode impedance was matched as a series combination of resistance and capacitance using a modified Schering bridge. Before each experimental run the test electrode was mechanically polished on roughened glass using bidistilled water as a lubricant, immersed in nitric acid (50%) for 3 sec followed by a bidistilled water wash and placed in the test solution. The electrode was held on open circuit until stable impedance readings were obtained.

Results

Figure 1 shows typical faradaic current *vs.* bias potential curves for the electrolytes investigated. The gold electrode is nowhere ideally polarizable however there exists an experimental region in which faradaic current is negligible. The extent of this region is ~0.9- −0.7V for H_2SO_4 and ~0.6- −0.8V for NaOH solutions. The negative extreme of this region is determined by H_2 evolution and the rise at the positive limit can possibly be related to the compression of the solvent monolayer at the electrode by the electric field across the electrical double layer; however, the situation is complicated by OH^- adsorption from solution.

The electrode/electrolyte contact times required for electrode stability were ~30 min for both electrolytes, thereafter the electrodes remained reasonably stable for ~24 hr. Electrodes forced to potentials outside the extremes of the polarizable region showed only slight hysteresis in both electrolytes being more predominant at the negative extremity. Stable impedance measurements were rapidly established after small potential changes of the test electrode within the polarizable region, however longer times were required when large capacitance changes occurred for small potential changes.

Figure 2 shows a series of differential capacitance *vs.* bias potential curves for polycrystalline gold in aqueous NaOH electrolytes. The direction of the potential sweep had no significant effect on the shape and magnitude of the capacitance curves. Impedance readings were reproducible to ± 3% about a mean. The capacitance curves showed a capacitance peak at ~0.4V and a capacitance minimum at −0.26V. Also in Fig. 2 is shown a typical electrode resistance, R_E,[3] *vs.* bias potential curve which shows a rapid rise at the positive extremity of the polarizable region, a peak at ~ −0.25V complementary to the capacitance peak observed and a decrease in resistance at the negative extremity. Figure 3 shows a typical frequency dispersion of the capacitance curves in aqueous NaOH solution. With decreasing frequency the peak observed in

[3] It was not possible in the present experiments to correct R_E for electrolyte resistance. Thus values of R_E are only of qualitative significance.

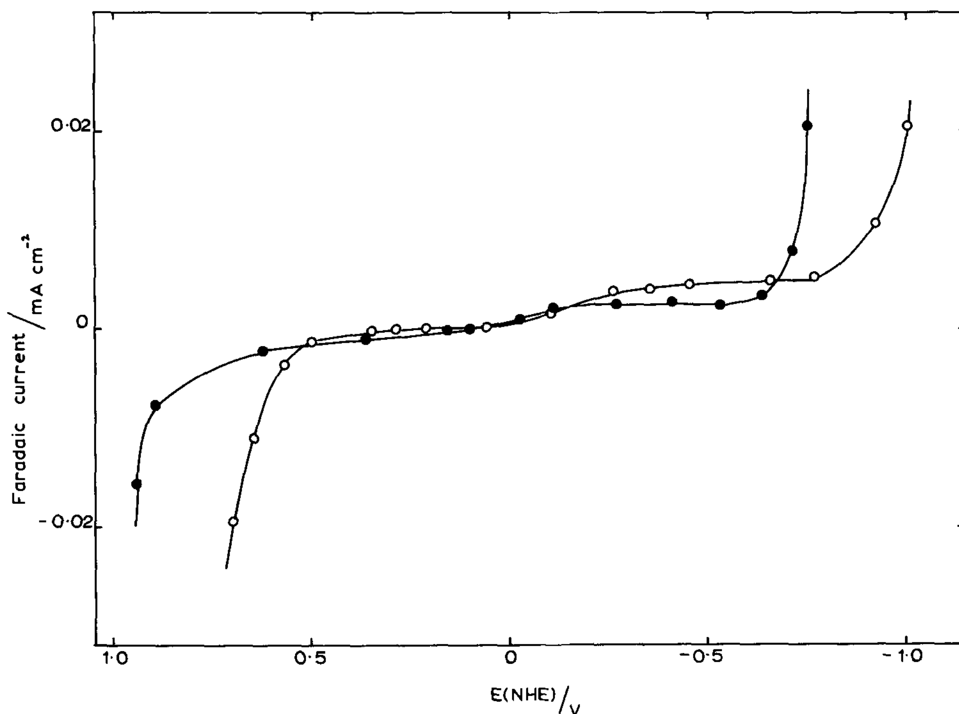

Fig. 1. Typical faradaic current vs. bias potential curves for polycrystalline gold at 23°C. (○) 0.194 mol l^{-1} NaOH; (●) 0.06 mol l^{-1} H_2SO_4.

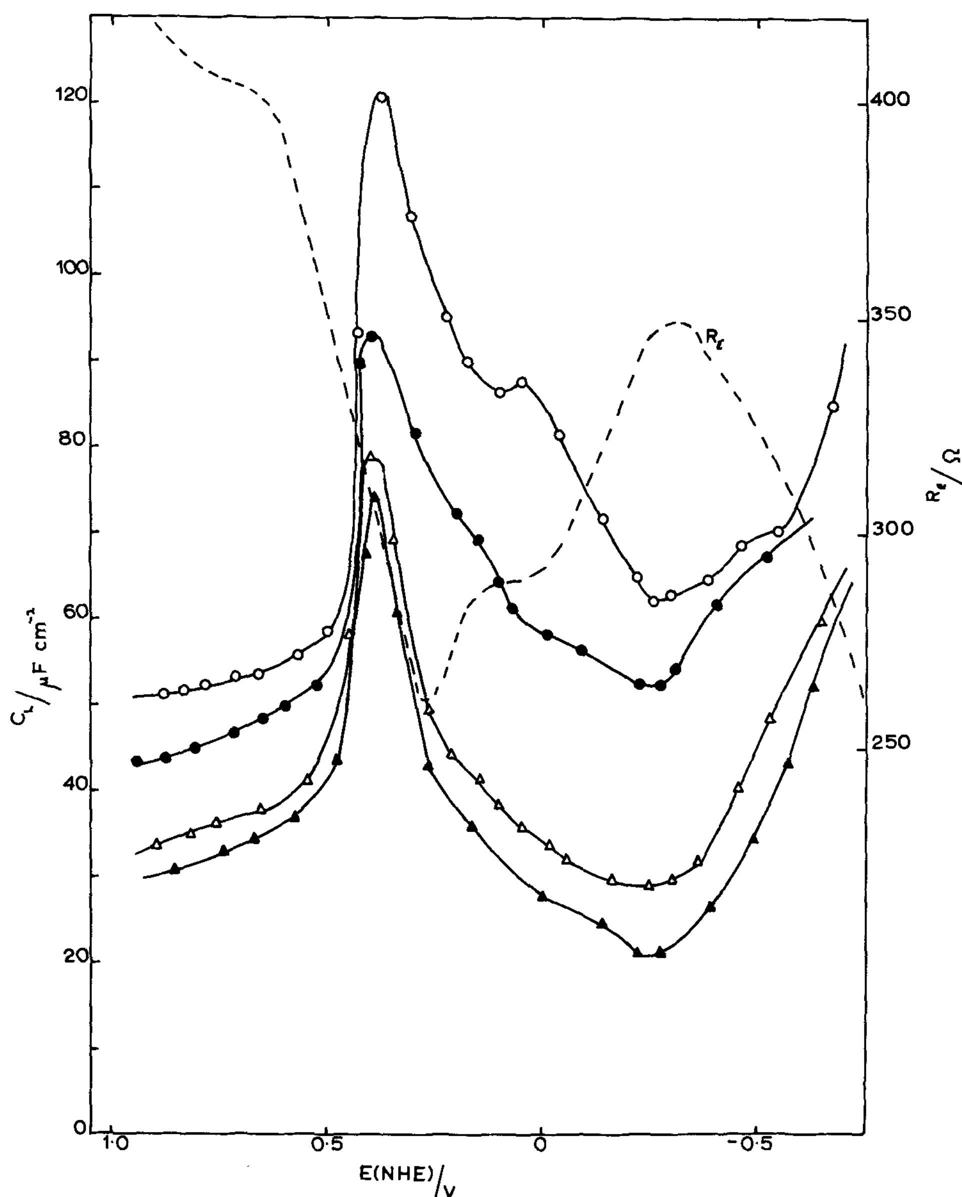

Fig. 2. Differential capacitance curves for polycrystalline gold in aqueous NaOH solutions at 23°C, 1000 Hz; (○) 0.81 mol l^{-1}; (●) 0.194 mol l^{-1} (△) 0.0635 mol l^{-1}; (▲) 0.0091 mol l^{-1}. Broken line shows electrode resistance, R_E, vs. bias potential at 23°C, 1000 Hz, electrode area 3.48×10^{-2} cm^2; 0.81 mol l^{-1} NaOH.

the capacitance curves at ~0.4V increases in magnitude, however for all frequencies a capacitance minimum was observed at −0.26V at which potential the frequency dispersion tended to be minimal.

Figure 4 shows the influence on the differential capacitance curves of small additions of n-butylamine. The magnitude of the resulting capacitance was reduced by these additions at all potentials within the polarizable region, however at the extremities of the experimental polarizable region the values obtained resembled those in organic free NaOH solutions. The capacitance curves obtained when the potential was varied cathodically showed a capacitance peak at ~0.4V and a capacitance minimum as in organic free NaOH solution, however the capacitance minimum observed was much broader than that observed in organic free NaOH solutions. Anodic potential sweeps gave capacitance curves showing a broad capacitance minimum and an absence of a peak at ~0.4V. For concentrations of n-butylamine greater than 0.03 mol l^{-1} little further effect on the capacitance curves was observed. The starting potential of both anodic and cathodic potential sweeps were varied and in the case of cathodic sweeps seemed to have little effect on the shape and magnitude of the curves, however for the anodic sweeps with starting potentials > 0.3V the capacitance peak could be observed whereas for starting potentials < 0.0V no peak appeared.

Figure 5 shows a series of differential capacitance *vs.* bias potential curves for polycrystalline gold in aqueous H_2SO_4 solution. The direction of potential sweeping had little effect on the shape and magnitude of the capacitance curves except that the small peak observed at ~+0.15V in the more concentrated solutions was more pronounced for cathodic sweeps. The capacitance curves were reproducible to ± 5% about a mean. All the curves showed a characteristic capacitance peak at ~0.8-0.85V and a minimum at 0.33V. Also on Fig. 5 is shown the electrode resistance, R_E, as a function of bias potential characterized by a rapid rise at both extremities of the polarizable region and a resistance peak at ~0.3V complementary to the capacitance minimum.

Figure 6 shows the influence of additions of low concentrations of n-butylamine on the differential capacitance curves in H_2SO_4 solutions. At the more negative potentials the curves show a progressive lowering of the capacitance values in the concentration range up to 0.03 mol l^{-1} n-butylamine thereafter further additions having no significant effect on the capacitance curves. At more positive potentials a capacitance peak was observed at a potential corresponding to that of the capacitance peak observed in organic free H_2SO_4 solutions. The direction of the potential sweep and the initial potential had no effect on the curves.

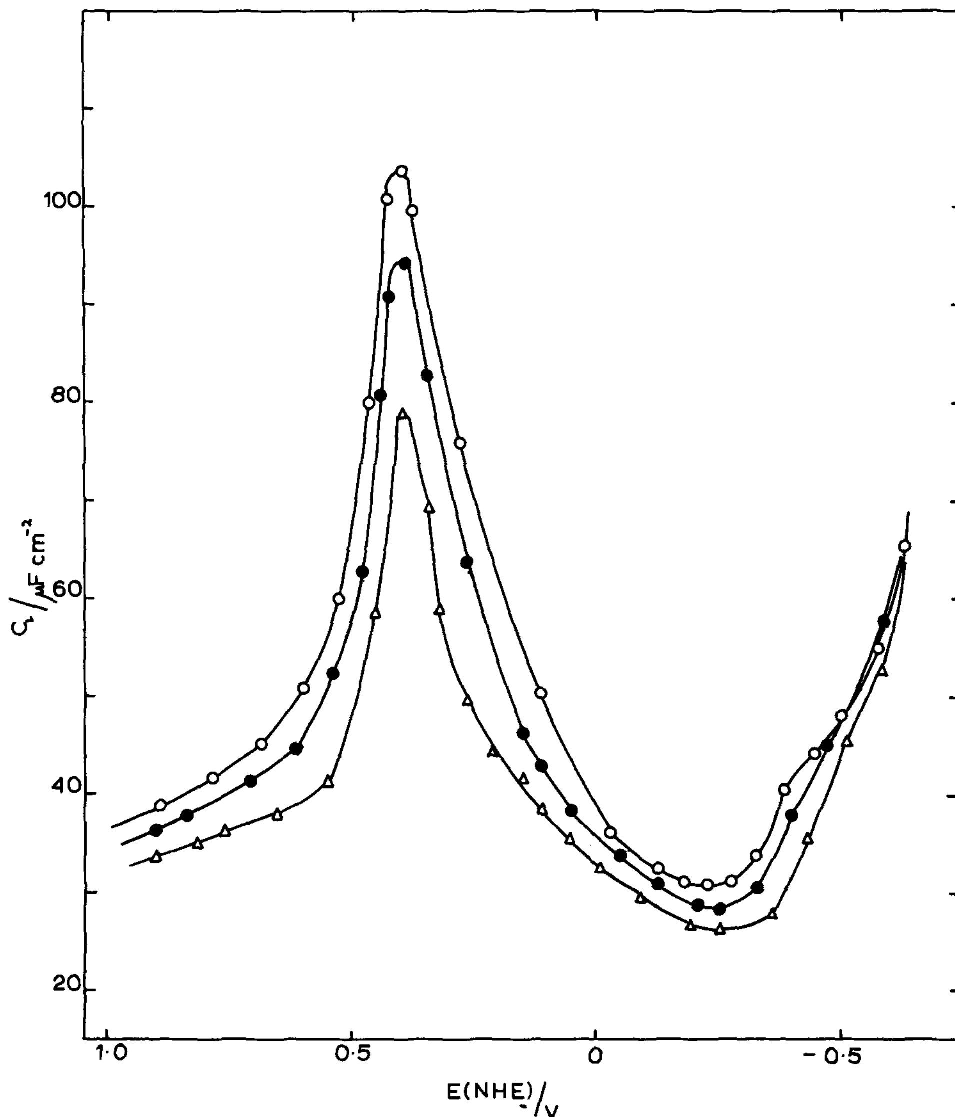

Fig. 3. Typical frequency dispersion of the differential capacitance curves for polycrystalline gold in aqueous NaOH solution (0.0635 mol l^{-1}), 23°C, (○) 120 Hz; (●) 500 Hz; (△) 1000 Hz.

Discussion

The time stability of the electrode impedance, in all the electrolytes investigated indicates that no irreversible chemical or structural changes occur at the electrode surface for potentials within the experimental polarizable region. The magnitude of the differential capacitance is similar to that observed for lead electrodes (39) which have a low roughness factor. This, taken with the small degree of frequency dispersion, indicates that the gold electrode has a relatively smooth surface.

The capacitance minimum in dilute NaOH solutions at −0.26V is well removed from the value of E_z, 0.23V, which has been estimated from work function data. It is suggested that for the potentials studied (∼+0.6-−0.6V) adsorption of OH^- from solution occurs. This is evidenced by a slight shift in the capacitance minimum (Fig. 2) observed with increasing concentration of NaOH and also by the rise in R_E values at potentials of ∼0.2-−0.2V. At the negative extremity the adsorbed species is expelled from the electrode, as would be expected at high negative rational potentials, and results in a decrease in R_E and rise in capacitance values. The fall in R_E and the capacitance peak at ∼0.4V could indicate a possible valency change of the adsorbed species at this potential.

In H_2SO_4 solutions the capacitance minimum at 0.33V is in agreement with previous work in which pzc values of Au were reported (Table I), and it appears that the gold electrode interphase is relatively uncomplicated by adsorbed species.

The capacitance peaks, ∼0.4V and ∼0.8V in Fig. 2 and 5 respectively are associated with adsorption of hydroxyl species from the solutions giving rise to adsorbed OH and O species (30, 32-34) prior to formation of an insoluble gold compound.[4] The increased frequency dispersion of the capacitance at potentials in the region of the capacitance peak (Fig. 3) indicates that the adsorbed compounds are able to undergo redox reactions at the electrode which can follow changes in the electrode potential.

The adsorption of n-butylamine from NaOH solutions shows differing behavior depending on the direction of the potential sweeps. For cathodic sweeps the capacitance peak, associated with hydroxyl adsorption, is unaltered in potential by adsorption of n-butylamine; however for anodic sweeps such a peak is absent indicating inhibition of hydroxyl adsorption by an adsorbed organic layer. By starting potential sweeps at more positive potentials the gold electrode is initially covered with a layer of an insoluble gold compound and on moving to more negative potentials this layer is reduced. Starting the sweep from potentials negative with respect to the polarizable region excludes O and OH adsorption leaving the gold electrode free for adsorption of n-butylamine and on proceeding to more positive potentials the adsorbed organic layer prevents any adsorption of oxygen species at potentials where the adsorption pseudocapacitance peak is observed for organic free NaOH solutions.

[4] The exact constitution of the insoluble gold film could not be determined by these experiments.

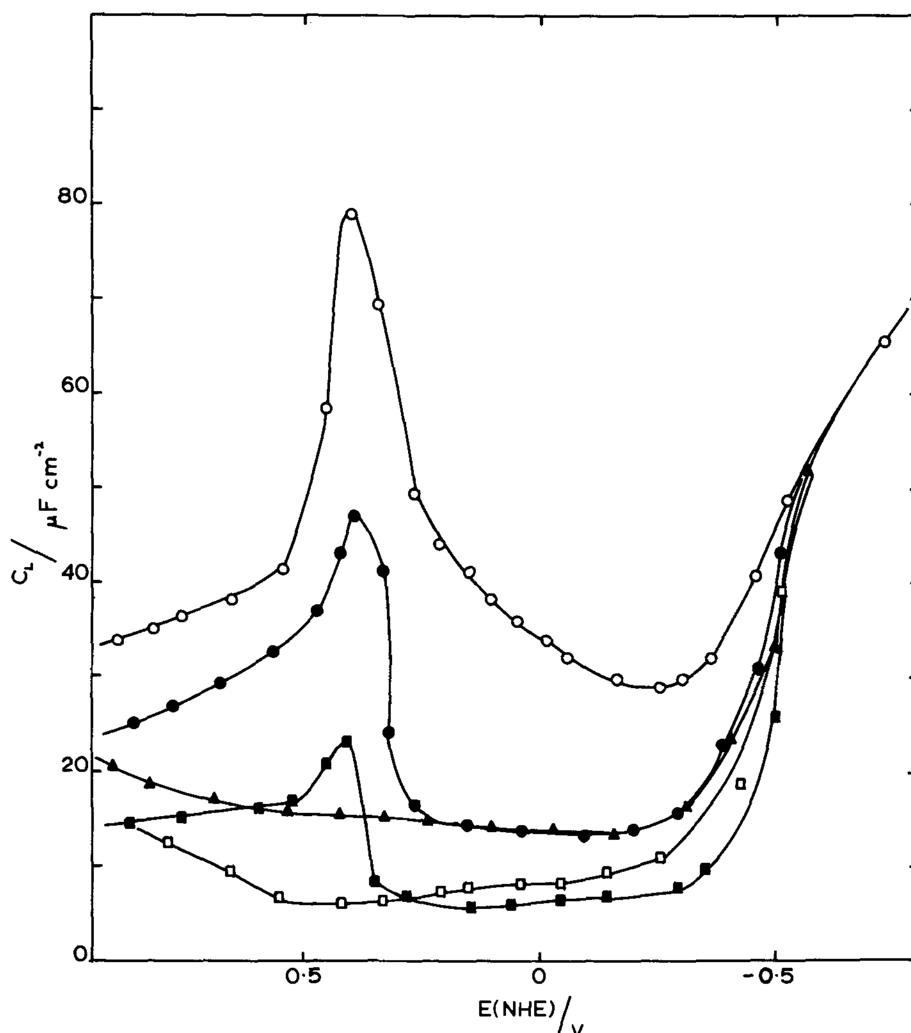

Fig. 4. Effect of addition of n-butylamine on the differential capacitance of polycrystalline gold in aqueous NaOH solution (0.0635 mol l^{-1}) at 23°C, 1000 Hz. (○) no n-butylamine; (●) 0.003 mol l^{-1} n-butylamine, cathodic potential sweep; (△) 0.003 mol l^{-1} n-butylamine, anodic potential sweep; (■) 0.03 mol l^{-1} n-butylamine, cathodic potential sweep; (□) 0.03 mol l^{-1} n-butylamine, anodic potential sweep.

It is expected that organic molecules which have a lower polarizability than water would be adsorbed at low rational and desorbed at high rational potentials. This type of agreement has been very useful in estimating potential regions where adsorption of an organic substrate is to be expected and the fall of the differential capacitance values in the presence of amine, observed in the present case (Fig. 4 and 6) is fairly typical of the adsorption of aliphatic compounds on Hg from aqueous solution. In the case of NaOH solutions adsorption of n-butylamine causes the largest capacitance reduction (compared with organic free solutions) at potentials neighboring −0.26V indicating that at this potential the gold interphase, although complicated by adsorption, has zero net charge. For acid solutions it is suggested that n-butylamine forms the quaternary ammonium ions which would be expected to be adsorbed at negative rational potentials and desorbed at positive rational potentials. In the present capacitance curves (Fig. 6), it appears that little adsorption occurs at potentials positive of 0.33V but at potentials negative of this value the capacitance magnitude is significantly reduced indicating adsorption and suggests that the pzc of Au is at 0.33 ± 0.02V in H_2SO_4 solutions.

Conclusions

(*i*) The pzc of polycrystalline gold in H_2SO_4 solutions is estimated at 0.33 ± 0.02V.

(*ii*) There is evidence for adsorption of oxygen species at gold electrodes and in the case of NaOH solutions adsorption seems to occur throughout the polarizable region.

(*iii*) In acid solutions n-butylamine is adsorbed as the quaternary ammonium ion, adsorption only occurring at potentials negative of the pzc. At positive rational potentials n-butylamine does not appear to be adsorbed to any great extent.

A Study of the Adsorption and Desorption of Iodine and Iodide at Platinum Electrodes in 1.0M Sulfuric Acid

Dennis C. Johnson*

Department of Chemistry, Iowa State University, Ames, Iowa 50010

ABSTRACT

Various reactions involving adsorption and desorption of I_2 and I^- at platinum electrodes in 1.0*M* H_2SO_4 were studied using a rotating, ring-disk electrode. Reversibly adsorbed I_2 was found to be desorbed in the potential region of the limiting current for the oxidation of I^- to I_2. Iodine was found to coexist with I^- in an irreversible state of adsorption. The irreversibly adsorbed I_2 is electrochemically reduced to I^- at $E < 0.1V$ *vs.* SCE. The presence of irreversibly adsorbed I_2 was determined to result in a positive shift of the potential for desorption of I_2 from the reversible state of adsorption. Also found was evidence that I_2 will slowly pass from the reversible to the irreversible state of adsorption at an electrode surface covered with irreversibly adsorbed I^-.

The adsorption and desorption of I_2 and I^- at platinum electrodes in acidic media have been studied using radiochemical (1-10) and electrochemical (8, 11-17) methods. Iodide ions are rapidly adsorbed on a platinum surface which previously has been electrochemically reduced. The adsorption process is irreversible and the adsorbed I^- is not removed if the electrode is taken from the solution and the surface rinsed with an I^--free solution of electrolyte (17). Nor is the adsorbed I^- oxidized if the potential of the electrode is adjusted to a value at which I^- from the bulk solution is oxidized to I_2 at the electrode surface (17). This absence of any apparent electroactivity for adsorbed I^- led some investigators to conclude that I^- is not adsorbed at platinum surfaces (15). The maximum coverage of a platinum electrode by irreversibly adsorbed I^- was reported as 1.5×10^{-9} g ion/cm^2 (5) on the basis of radiochemical data and 1.6×10^{-9} g ion/cm^2 (17) on the basis of electrochemical data. Irreversibly adsorbed I^- is removed from the electrode surface when the potential of the electrode is adjusted to a value at which I^- is oxidized to IO_3^- (5, 10, 17), *e.g.*, $E > 1.1V$ *vs.* SCE for 1.0*M* H_2SO_4. Oxidation of the platinum surface occurs simultaneously. There is no adsorption of I^- at a platinum surface covered with platinum oxide (7, 9, 10, 17).

Studies using electrochemical techniques (8, 13-17) resulted in conclusions that I_2 is adsorbed at platinum surfaces. Hubbard, Osteryoung, and Anson (17), using thin-layer cells and radiochemical tracers, differentiated between reversible and irreversible adsorption of I_2. They determined that I_2 is adsorbed by an irreversible process at a platinum surface bearing no adsorbed I^-. They reported a surface coverage by irreversibly adsorbed I_2 equal to 1.6×10^{-9} mol/cm^2 at an electrode in $1.00 \times 10^{-3}M$ I_2. These authors showed that I_2 is adsorbed by a reversible process at a platinum surface covered with I^- or I_2 adsorbed in irreversible states. They reported that the coverage by reversibly adsorbed I_2 is 0.9×10^{-9} mol/cm^2 at such an electrode in $1.14 \times 10^{-3}M$ I_2 (17). Iodine adsorbed in both reversible and irreversible states is reportedly removed electrochemically from the electrode surface during anodization, being oxidized to IO_3^- (17).

Key words: rotating ring-disk electrode, iodide adsorption, iodine adsorption, platinum electrode.

The purpose of this research was the correlation of the various adsorption and desorption processes for I^- and I_2 with the observed current-potential behavior of platinum electrodes in 1.0*M* H_2SO_4 containing NaI. This study was made using a rotating ring-disk electrode (RRDE) for which both the ring and the disk electrodes were platinum. Use of a RRDE for investigating mechanisms of electrode reactions has been described (18-23). Johnson and Bruckenstein (24) reported use of a RRDE for study of the adsorption and desorption of Br^- at a platinum electrode in 1.0*M* H_2SO_4. Bromide is adsorbed by an irreversible process and is oxidized to HOBr at $E > 1.25V$ *vs.* SCE. Bromine is not adsorbed in observable quantities in this media.

Experimental

Instrumentation.—The RRDE used in this study was constructed by Pine Instrument Company of Grove City, Pennsylvania. The electrode dimensions are given in Table I of Ref. (23) where the electrode is designated as B. For this electrode $\alpha = 0.089$, $\beta^{2/3} = 0.151$, and $N = 0.090$. The geometric area of the disk electrode equals 0.470 cm^2. The bipotentiostat used is described in Ref. (22). Signal voltages were obtained from the circuit described in Ref. (25). Current-potential (*I-E*) curves were recorded on an Electronic Associates Inc., Model 1131, XYY' Recorder. The electrolysis cell is described in Ref. (24). Experimental work was performed at 25° ± 2°C. Integration of *I-E* data was performed on the original *I-E* recordings using a Keuffel and Esser Compensating Polar Planimeter.

Chemicals.—1.0*M* H_2SO_4 and solutions of NaI were prepared using Mallinckrodt Analytical Reagents. All water was triply distilled with a deionization following the first distillation and the second distillation being from alkaline permanganate. Due to the heat resulting from addition of concentrated H_2SO_4 to water, the 1.0*M* H_2SO_4 was cooled to room temperature before stock solution of NaI was added. At room temperature, oxidation of I^- to I_2 by O_2 in 1.0*M* H_2SO_4 was found to be negligible. Solutions were deaerated prior to the electrochemical experiments using Air Products Prepurified N_2 (99.9995%) saturated with H_2O. During experimentation, an N_2 atmosphere was maintained over the solution.

Notation.—Notation used is that described in Ref. (24). All potentials were measured and are reported in V *vs.* SCE.

Current-potential curves.—The surface of the RRDE was polished with 0.3μ Buehler alumina on Buehler microcloth using water as lubricant and then thoroughly rinsed with triply distilled water. Following insertion of the electrode into a solution, E_d was scanned approximately 100 times between the limits $E_d^a = 1.6V$ and $E_d^c = -0.2V$. Except as stated otherwise, electrical treatment prior to recording *I-E* data consisted of scanning E_d between the limits specified by that experiment until the *I-E* curves produced on subsequent scans were reproducible. The *I-E* curves for the second and third scans were invariably identical. All scans of E_d had a triangular wave form.

To determine *I-E* behavior of soluble and electroactive species produced by reactions at the surface of the disk electrode, I_r was recorded *vs.* E_d, during the triangular potential scan, for fixed values of E_r. Values of E_r were varied by 50 mV increments between the potential limits set by solvent decomposition. The shapes of I_r-E_d curves is determined by: (*i*) convective-diffusional transport of electroactive species present in the bulk of the solution to the ring electrode, (*ii*) collection of a fraction of any electroactive species produced at the disk electrode, and (*iii*) decrease of the flux of an electroactive species at the surface of the ring electrode due to reactions at the disk surface (22).

Variations of the I_d-E_d and I_r-E_d curves obtained for particular values of E_r, while scanning E_d, which resulted from changes in the bulk concentration of I^-, scan rate of E_d, or rotation velocity of the electrode were diagnostically used to differentiate processes limited by the surface area of the disk electrode from those limited by the rate of convective-diffusional mass transport. Electrical currents from electrochemical processes limited by the rate of mass transport show linear dependences on bulk concentration and the square root of rotation velocity and no dependence on the rate of potential scan after correcting for charging current. Electrical currents from electrochemical processes limited by the surface area of the electrode are proportional to the scan rate of applied potential. Because the scan of E_d was a linear function of time, the I_r-E_d curves were also I_r-t curves. The quantity of an electroactive species involved in a reaction controlled by the surface area of the disk electrode was estimated from the difference in the time integrals of the I_r-E_d curves obtained at rates of E_d scan equal to 6.0 V/min and 0.0 V/min over the potential region where the reaction occurred. The I_r-E_d curve for an effective scan rate of 0.0 V/min was determined as the best smooth curve fitting steady-state values of I_r measured at fixed values of E_d. At a scan rate of 6.0 V/min and the rotation speed used (2500 RPM), the average time required for transit of electroactive species from the disk electrode to the ring electrode was negligible (80 msec). Evidence is presented that this procedure may be in error for surface processes occurring in the vicinity of the $E_{1/2}$ of the *I-E* curve for the species involved in the surface process.

Results and Discussion

I_d-E_d curves for NaI.—A I_d-E_d curve obtained for 1.0*M* H_2SO_4 containing $3.0 \times 10^{-4}M$ NaI is shown in Fig. 1. The solid and dashed lines correspond to the anodic and cathodic portions, respectively, of the triangular scan of E_d at 6.0 V/min. The dotted line between 0.4 and 0.7V corresponds to the curve obtained under steady-state conditions, *i.e.*, an effective scan rate of 0.0 V/min. This was included to assist in distinguishing surface-controlled processes from those limited by the rate of convective-diffusional mass transport.

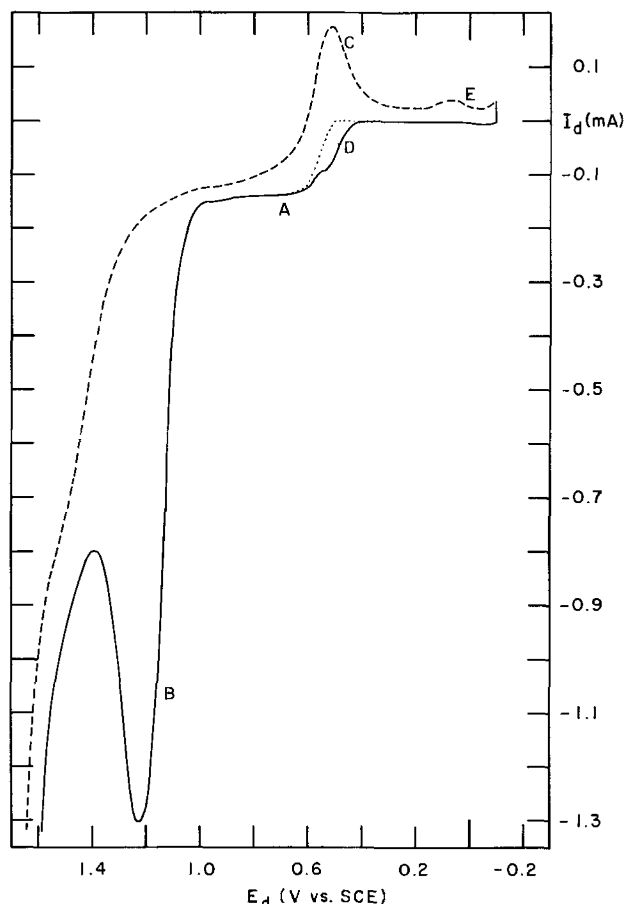

Fig. 1. I_d-E_d curve for $3.0 \times 10^{-4}M$ NaI in 1.0*M* H_2SO_4; 1600 rev/min, 6.0 V/min. $E_d^a = 1.6V$, $E_d^c = -0.2V$, ——— is anodic scan, – – – – is cathodic scan, ... is steady-state curve.

Wave A in Fig. 1, with a limiting-current plateau between 0.6 and 1.0V, results from the oxidation of I^- to I_2. The anodic peak, B, obtained for $E_d > 1.0V$ results from oxidation of I^- to IO_3^- at the electrode surface (17). The production of IO_3^- does not result in a limiting-current plateau and is apparently inhibited by the formation of platinum oxide on the electrode surface. The cathodic peak at 0.6V, C, observed during the cathodic E_d scan is the result of reduction of the platinum oxide formed during the anodic potential scan for $E_d > 1.1V$.

The prewave to wave A, designated D in Fig. 1, results from the oxidation of I^- at the electrode surface and adsorption of the I_2 produced. This process occurs at potentials less than those predicted by the Nernst equation when calculated for a soluble product because of the stabilization of I_2 by adsorption. The height of the prewave was found to be a linear function of the scan rate of E_d as is expected for a surface-controlled process such as adsorption.

Oxygen is evolved at the disk electrode for $E_d > 1.4V$ and H_2 is evolved for $E_d < -0.2V$.

I_r-E_d curves for NaI.—I_r-E_d curves were obtained at various values of E_r under the conditions of Fig. 1. Figure 2 contains curves for selected values of E_r. The I_d-E_d curves recorded simultaneously were identical to that of Fig. 1. Wave P in Fig. 2 obtained at $E_r = 0.0$ and 0.2V results from the reduction of soluble I_2 produced at the disk electrode by oxidation of I^-, wave A of Fig. 1, which is transported to the ring electrode by connective-diffusional processes. The ratio of ring-to-disk currents at $E_d = 0.7V$ is -0.094 which compares favorably with the value of $-N$ for this electrode. From I_r-E_r curves obtained in 1.0*M* H_2SO_4 containing $NaIO_3$ and O_2 it was determined that IO_3^-

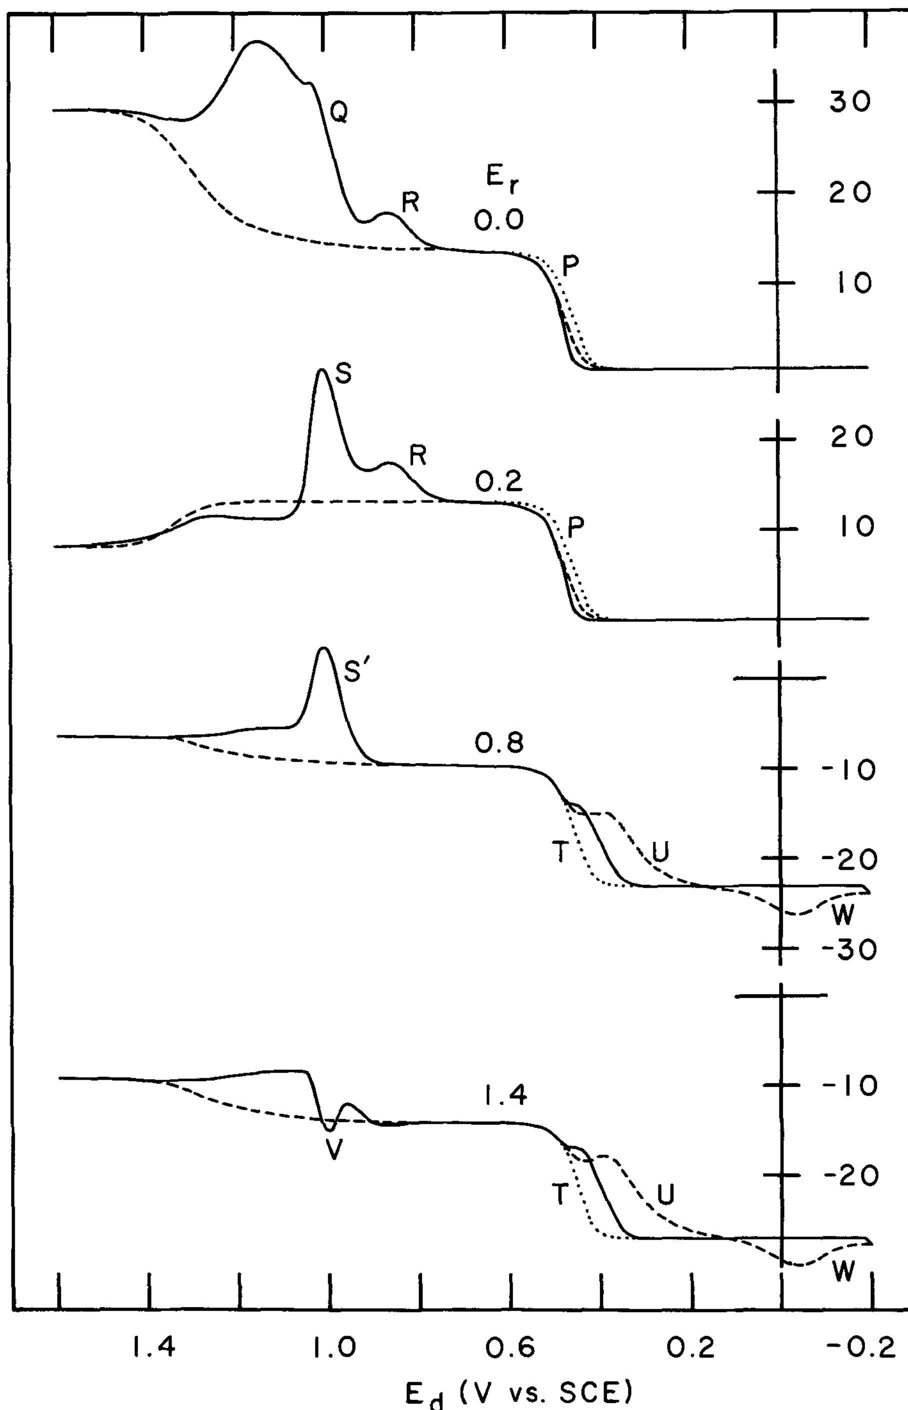

Fig. 2. I_r-E_d curves for $3.0 \times 10^{-4}M$ NaI in $1.0M$ H_2SO_4; 1600 rev/min, 6.0 V/min, $E_d^a = 1.6V$, $E_d^c = -0.2V$ ——— is anodic scan, — — — — is cathodic scan, ... is steady-state curve.

and O_2 are reduced at a platinum-ring electrode at $E_r < 0.1V$. Iodate ions produced at the disk electrode during the anodic E_d scan in the region of wave B are reduced at the ring electrode when $E_r = 0.0V$ with the resultant appearance of wave Q.

No I_2 reaches the ring electrode when E_d is in the region of wave D during the anodic potential scan. This is consistent with the interpretation of wave D wherein I^- is oxidized to I_2 which is adsorbed at the surface of the disk electrode.

Peak R observed during the anodic scan of E_d results from a species which was found to have the electrochemical properties of I_2. Because of the absence of a significant peak on the I_d-E_d curve of Fig. 1 in this region of the I_d-E_d curve, it is my conclusion that this I_2 is produced at the disk electrode by a desorption process.

Iodate and O_2 are not reduced at the ring electrode in $1.0M$ H_2SO_4 for $E_r \geqq 0.2V$. The I_r-E_d curve shown for $E_r = 0.2V$ is identical to those obtained for $0.2V < E_r \leqq 0.4V$. Again, a peak is observed for the reduction of the I_2 desorbed at the disk surface during the anodic scan at $E_d = 0.8V$. Peak S observed at $E_d = 1.0V$ cannot be the result of reduction of IO_3^- or I_2 at the ring electrode. The height of peak S was found to be nearly independent of the scan rate of E_d contrary to the behavior expected for a surface-controlled process. The peak height is a linear function of $C_{I^-}{}^b$ and $\omega^{1/2}$. Apparently, the species whose reduction produces peak S is an intermediate in the production of IO_3^- at the disk electrode, possibly I(+1).

For $E_r = 0.8V$, I^- is oxidized quantitatively to I_2 at the ring electrode. The I_r-E_d curve shown for $E_r = 0.8V$ is identical to those obtained for $0.6V \leqq E_r \leqq 0.9V$. The ratio of I_r measured at $E_d = 0.2V$ to I_d measured at $E_d = 0.6V$ is 0.164 in fair agreement with the value of $\beta^{2/3}$ for this electrode. A cathodic ring current, peak S′, was obtained at $E_d = 1.05V$ for the spe-

cies concluded to be an intermediate in the production of IO_3^- at the disk electrode. This is evidence sufficient to prove that species is not I_2.

The difference between the I_r-E_d curve for E_r = 0.8V obtained during the anodic scan of E_d at 6.0 V/min and the steady-state curve in the region designated T is the result of consumption of I^- at the disk electrode. Wave D is obtained simultaneously on the I_d-E_d curve. This result is consistent with the conclusion that I^- is oxidized to I_2, in the region of wave D, which is subsequently adsorbed at the disk surface.

The interpretation of the portion of the I_d-E_d curve of Fig. 1 obtained during the cathodic scan of E_d is complicated by the large cathodic current resulting from reduction of platinum oxide. On the basis of radiochemical studies it has been concluded that I^- is not adsorbed at a platinum surface covered with oxide (7, 9, 10). The reduction of platinum oxide in this study during the cathodic scan of E_d for $E_d < 0.5V$ results in electrochemical preparation of the disk surface for I^- adsorption. The adsorption of I^- at the disk electrode results in the shielding of the flux of I^- at the ring electrode and wave U results on the I_r-E_d curve obtained at E_r = 0.80V. Inspection of the I_r-E_d curve for E_r = 0.2V reveals that no I_2 is collected at the ring in this region of the I-E curve.

Some IO_3^- is produced at the ring electrode by oxidation of I^- for E_r = 1.4V. As a result the anodic currents observed when $E_d < 0.5V$ for E_r = 1.4V are greater than for E_r = 0.8V. The intermediate from the production of IO_3^- at the disk electrode, detected at the ring electrode during the anodic scan of E_d, is oxidized at the ring electrode for E_r = 1.4V, peak V. The oxidation product presumably is IO_3^-.

Intermediate from the production of IO_3^-.—Figure 3 is of the approximate I_r-E_r curve constructed for the electroactive species which was detected at the ring electrode during the anodic scan of E_d at E_d = 1.05V and concluded to be an intermediate in the electrochemical production of IO_3^-. The curve is of the difference between I_r measured at E_d = 1.05V and that measured at E_d = 0.8V plotted *vs.* E_r. The curve reflects the fact that the intermediate species can be oxidized and reduced at the ring electrode. The anodic process at the ring electrode for $E_r > 1.1V$ is quite irreversible which may be the result of platinum oxide present on the ring surface.

In an earlier study of the adsorption of Br^- at a platinum electrode (24), it was determined that the adsorbed Br^- is oxidized and desorbed as HOBr during the anodic potential scan. It might appear consistent in this study that adsorbed I^- is the precurser of the species concluded to be the intermediate. This is not the case, however. As stated earlier, the height of peak S is a linear function of $\omega^{1/2}$ and $C_{I^-}{}^b$ and independent of the scan rate of E_d. These evidences are not characteristic of a desorption process. Further support for the conclusion that the species which produces peak S does not originate as irreversibly adsorbed I^- is given below. Essentially it is that no adsorbed I^- was determined to be desorbed from an electrode during the anodic scan of E_d until $E_d^a > 1.1V$. The species in question is produced at the disk electrode during the anodic scan of E_d in the region of the I_d-E_d curve corresponding to onset of the oxidation of I^- to IO_3^-. No experimental evidence was obtained which is inconsistent with the conclusion that the species is an intermediate in the electrochemical oxidation of I^- to IO_3^- at the disk electrode.

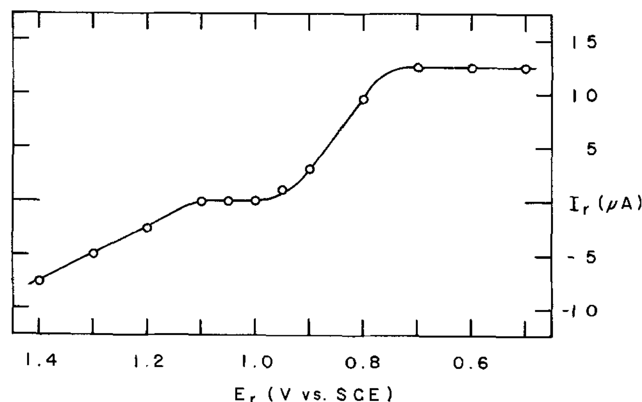

Fig. 3. I_r-E_d curve for intermediate detected at onset of oxidation of I^- to IO_3^-; 3.0 × $10^{-4}M$ NaI, 1.0M H_2SO_4, 1600 rev/min, 6.0 V/min.

No intermediate was detected during a cathodic scan of E_d originating at $E_d^a > 1.2V$. Figure 1 reflects the inhibition of the production of IO_3^- at the disk electrode due to the formation of platinum oxide. As reported in a later section, formation of platinum oxide was found to occur with the concurrent loss of irreversibly adsorbed I^-. This change in the surface composition of the disk electrode probably results in a change of the mechanism for IO_3^- production to one in which this intermediate is not involved.

Attempts to prepare solutions of HIO and obtain its I-E characteristics failed. HIO rapidly decomposes to IO_3^- and I_2 in acidic media.

Irreversible adsorption of I_2.—Hubbard, Osteryoung, and Anson (17) determined that both I^- and I_2 are adsorbed at a reduced platinum surface in solutions of I^- or I_2, respectively. The adsorption processes are irreversible and both species are removed from the electrode by oxidation to IO_3^- at $E > 1.1V$. These authors found that 1.6 × 10^{-9} mol/cm² of I_2 is adsorbed in an irreversible state at a platinum electrode in 1.00 × $10^{-3}M$ I_2.

The reduction of platinum oxide at the disk surface in 1.0M H_2SO_4 occurs on the cathodic scan of E_d at a value where both I_2 and I^- are present at the electrode surface (see Fig. 1 and 2). These two species are probably simultaneously adsorbed at the disk surface and may coexist in their respective irreversible states of adsorption. The I_d-E_d curve of Fig. 1 obtained at 6.0 V/min has a cathodic peak, E, on the cathodic half of the potential scan at E_d = 0.0V. The I_r-E_d curve of Fig. 2 obtained for E_r = 0.8V has an anodic peak, W, which was obtained simultaneously with the appearance of peak E. The species produced at the disk electrode was found to have the electrochemical properties of I^-. It is my conclusion that peak E results from the electrochemical reduction of I_2 present at the disk surface in an irreversible state of adsorption. Further experimental evidence supporting this conclusion is that if, during the cathodic scan of E_d, the value of E_d is stepped rather than scanned over the region from 0.6 to 0.3V, peaks E and W are not obtained. In this experiment the I_2 produced at the disk surface of the rotating electrode when $E_d > 0.6V$ is transported away from the electrode surface before the platinum oxide is electrochemically removed from the disk electrode and only I^- is adsorbed. The ratio of the height of peak W to peak E, correcting for charging current at the disk electrode, equals −0.09 approximately the value of −N for this electrode.

Isotherm for irreversible adsorption of I^-.—The adsorption isotherm for I^- at the platinum disk electrode in 1.0M H_2SO_4 was determined using the RRDE according to a procedure described by Bruckenstein and Napp (26). Advantage was taken of the fact that I^- cannot remain adsorbed at the disk electrode when E_d = 1.6V (17) and that adsorption proceeds after E_d is stepped to a value at which the surface oxide is reduced. The surface coverage by irreversibly adsorbed I^- was calculated as a function of $C_{I^-}{}^b$ from I_r-t curves obtained for E_r = 0.8V when E_d was stepped from 1.6 to 0.2V and to −0.1V. It was concluded earlier that no I_2 is adsorbed by an irreversible process under these conditions. The adsorption isotherms calculated

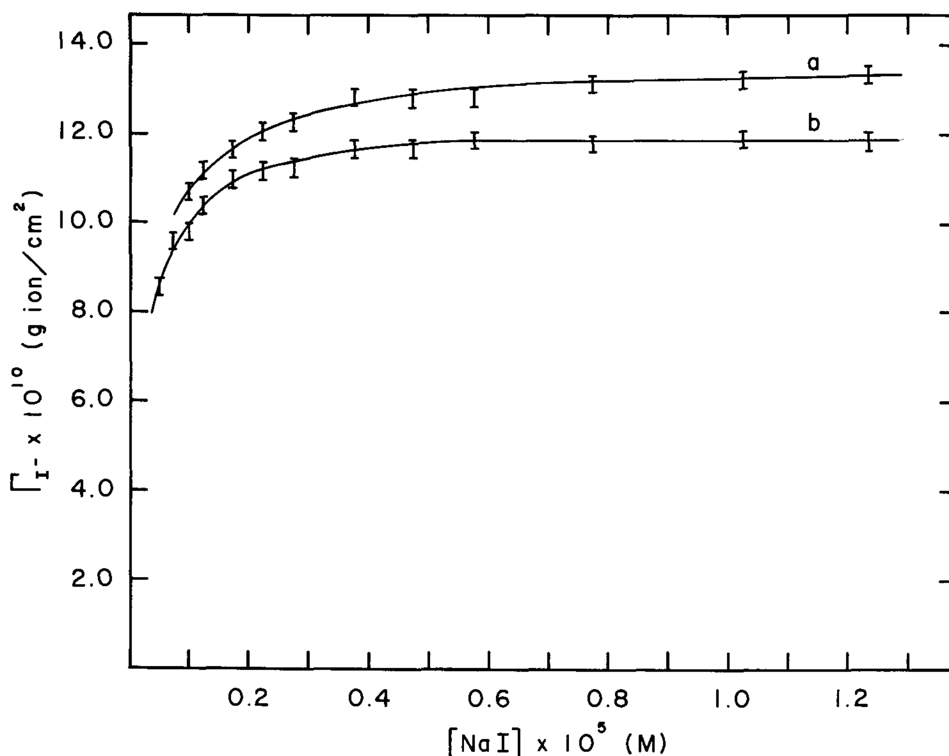

Fig. 4. Isotherm for I^- adsorbed in irreversible state at platinum disk electrode; 1.0M H_2SO_4; a, results for E_d step to 0.2V vs. SCE, b, results for E_d step to −0.1V vs. SCE.

are given in Fig. 4. The maximum surface coverage observed at 0.2V is 1.3×10^{-9} g ion/cm² and at −0.1V is 1.2×10^{-9} g ion/cm². These values are in fair agreement with those obtained by electrochemical (17) and radiochemical (10) techniques in view of the possible differences in surface roughness of the electrodes used in the various studies.

The value of E_d for which desorption of I^- commences on an anodic potential scan was determined by measuring the quantity of I^- adsorbed following a step of E_d from various anodic values to 0.2V. From this study it was found that no I^- is desorbed for $E \leq 1.1V$ and that the desorption is complete for $E \geq 1.4V$.

Reversible adsorption of I_2.—Figure 5 is of I_d-E_d and I_r-E_d curves obtained for 1.0*M* H_2SO_4 containing NaI. For these curves $E_d{}^a = 1.0V$ and $E_d{}^c = -0.2V$. Within these scan limits the disk surface is not oxidized and I^- adsorbed in an irreversible state is not oxidized or desorbed. As a result there is no irreversibly adsorbed I_2 at the electrode surface as evidenced by the absence of peaks E and W. Production and adsorption of I_2 at the disk electrode by oxidation of I^- results in wave D on the I_d-E_d curve obtained during the anodic scan of E_d. This adsorption occurs at an electrode surface covered by irreversibly adsorbed I^- and is a reversible process (17). For $E_d < 0.4V$ on the cathodic scan, the reversible adsorbed I_2 is reduced to I^- resulting in peak F on the I_d-E_d curve. The I^- produced is soluble and the resulting increase in the flux of I^- at the ring electrode in excess of the steady-state value results in peak Y for $E_r = 0.8V$. The surface coverage of the disk electrode by reversibly adsorbed I_2 was calculated from the difference between the time integrals of the I_r-E_d curves, for $E_r = 0.8V$, obtained on the cathodic scan of E_d at scan rates equal to 6.0 V/min. and 0.0 V/min. The isotherms are shown in Fig. 6. Curves a and b correspond to those obtained by integration from 0.60 to 0.35V and to 0.15V, respectively. The isotherms in Fig. 6 do not show a limiting surface coverage as $C_I{}^{-b}$ is increased. Hubbard, Osteryoung, and Anson found that 9×10^{-10} mol/cm² of I_2 is adsorbed in the reversible state at a platinum electrode in 1.14×10^{-3}*M* I_2.

Peak R is observed on the I_r-E_d curve of Fig. 5 for $E_r = 0.2V$. The presence of this peak is concluded to result from the reduction at the ring electrode of I_2 produced at the disk surface by desorption of I_2 from the reversible state of adsorption. Following reversal of the E_d scan at 1.0V, I_2 is readsorbed at the disk surface, when $E_d < 0.9V$, resulting in peak X on the I_r-E_d curve in Fig. 5. Cycling E_d between the limits $E_d{}^a =$

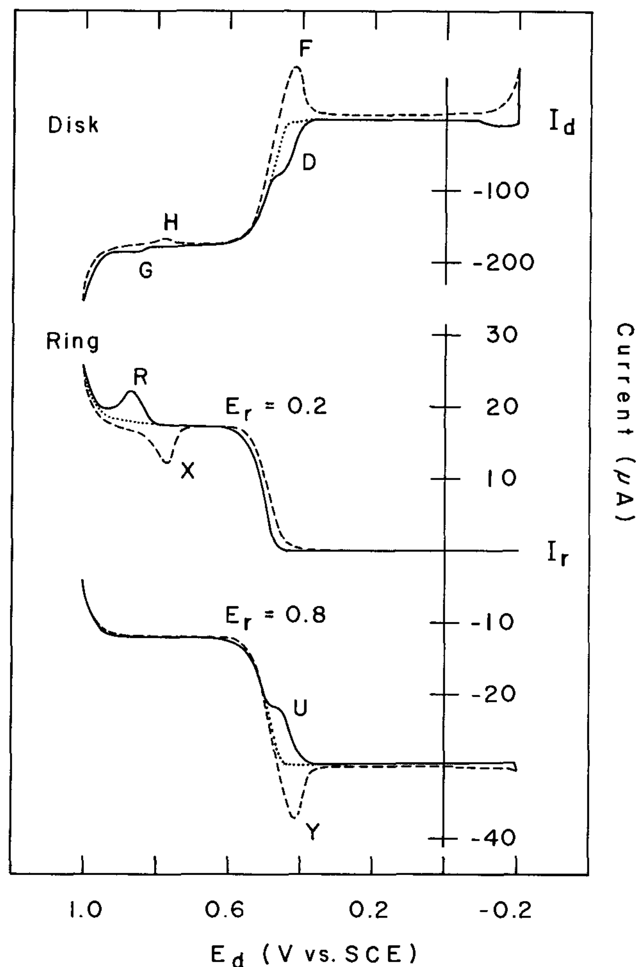

Fig. 5. I_d-E_d and I_r-E_d curves for 3.0×10^{-4}M NaI in 1.0M H_2SO_4; 2500 rev/min, 6.0 V/min, ———— is anodic scan, — — — — is cathodic scan, ... is steady-state curve.

Fig. 7. I_r-E_d curves for NaI in 1.0M H_2SO_4; 2500 rev/min, 6.0 V/min, ——— is anodic scan, - - - - is cathodic scan.

1.0V and $E_d^c = 0.6$V produced I_r-E_d curves reflecting repeated adsorption and desorption of I_2 at the disk surface.

Very small peak currents G and H can be observed on the I_r-E_d curve of Fig. 5. The magnitude of these peaks is much less than would be obtained if the phenomena at the disk surface resulting in peaks R and X were only Faradaic in nature. Apparently, desorption of I_2 from the disk surface is accompanied by the loss of a very small quantity of I^- which is subsequently oxidized. During the cathodic E_d scan, I_2 is readsorbed and a small quantity of I^- is reincorporated into the adsorption layer.

I_r-E_d curves for $E_r = 0.2$ and 0.8V were obtained for various values of $C_{I^-}{}^b$ and are shown in Fig. 7. Peak R observed for $E_r = 0.2$V is shifted to more positive values of E_d as $C_{I^-}{}^b$ increases. This is expected since the surface process at the disk electrode is reversible and increasing $C_{I^-}{}^b$ results in increasing surface concentrations of I_2 at the disk electrode in the potential region 0.6V $< E_d <$ 1.0V. The position of peak R does not shift when $C_{I^-}{}^b$ is constant and ω is varied. This is expected since increasing ω, while increasing the flux of I^- to the disk electrode, does not result in a change of surface concentration of I_2.

Wave U, obtained during the cathodic E_d scan for $E_r = 0.8$V, becomes less evident as $C_{I^-}{}^b$ is increased. This results since the time required to obtain the equilibrium surface coverage by adsorbed species decreases as bulk concentration of adsorbing species is increased.

Effect of irreversibly adsorbed I_2 on the desorption of reversibly adsorbed I_2.—The presence of I_2 adsorbed in an irreversible state at the disk surface prevents the desorption of I_2 during an anodic scan at $E_d = 0.8$V and, therefore, the appearance of peak R on the I_r-E_d curve. This is demonstrated by the I_r-E_d curves in Fig. 8. The program for the scan of E_d for obtaining the curves in Fig. 8 is given in Fig. 9. The recording of the I_r-E_d curves was begun at point a of the E_d program. Peaks R and X were obtained only during the scans following the cathodic scan for which $E_d^c = -0.20$V. It should be noted that electrochemical reduction of irreversibly adsorbed I_2 occurs at $E_d <$ 0.1V.

In a separate experiment, I_r-E_d curves were obtained at $E_r = -0.2$V using $E_d^a = 1.60$V and a value of E_d^c varied by 50 mV increments from -0.20 to 0.20V. As E_d^c increased such that successively greater amounts of irreversibly adsorbed I_2 remained at the disk surface, peak R was observed to be shifted to more positive potentials and to finally converge with peak S. As a result, the height of peak S increased. Repeating the experiment using $E_r = 0.8$V yielded $I_r - E_d$ curves on which the height of peak S' did not vary. Apparently, the reversibly adsorbed I_2, even though desorbed in a region of the I_d-E_d curve corresponding to the onset of IO_3^- production, is not oxidized to IO_3^-. Nor is it oxidized to the oxidation state of the intermediate species detected on the anodic scan of E_d during the onset of IO_3^- production.

The dotted line in Fig. 8 represents the I_r-E_d curve obtained under steady-state conditions. The quantities of material produced or consumed by the various surface-controlled processes at the disk electrode were estimated from the area between the steady-state curve and those curves obtained at an E_d scan of 6.0 V/min. The results are tabulated in Table I for waves T, U, W, and Y.

The calculated quantity of I_2 adsorbed into a reversible state (from curve 2 of Fig. 8) during the anodic half of a scan of E_d for which $E_d^c = 0.15$V is 4.0×10^{-10} mol/cm². However, the calculated amount of I_2 desorbed at the disk surface on the subsequent

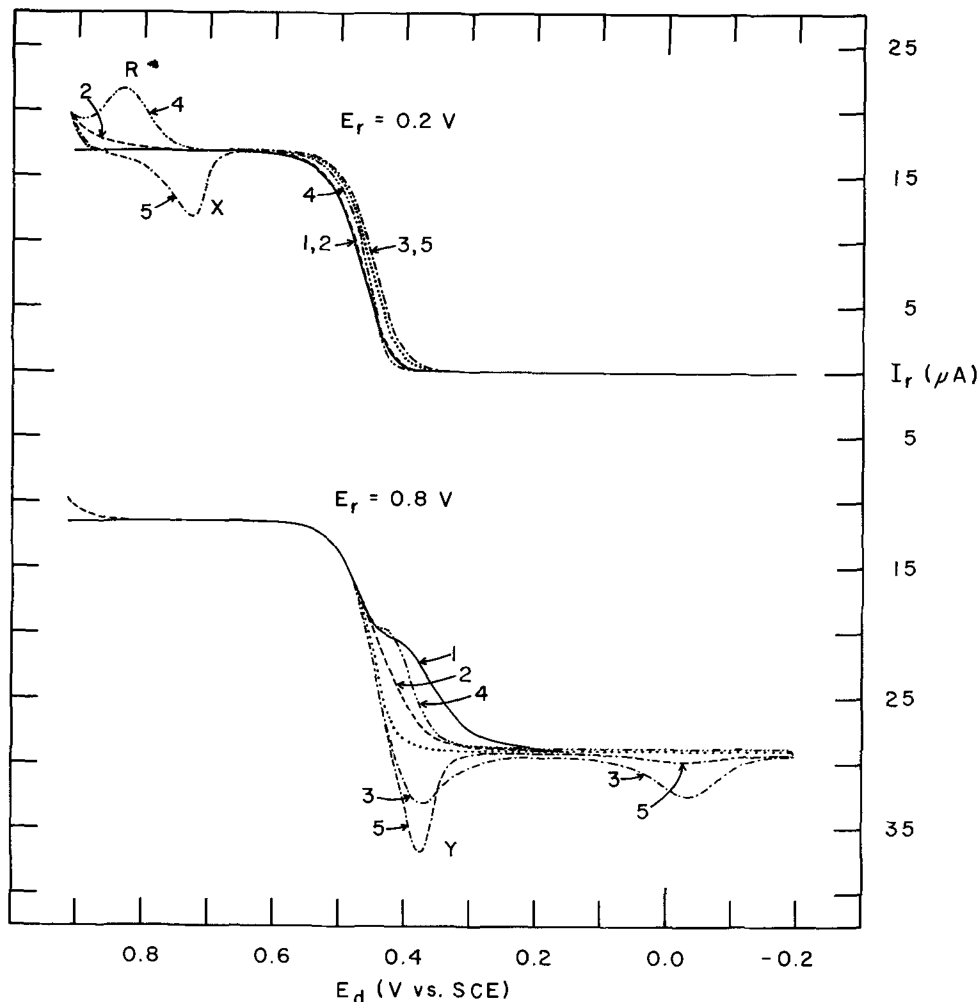

Fig. 8. I_r-E_d curves for $3.0 \times 10^{-4}M$ NaI in 1.0M H_2SO_4; 2500 rev/min, 6.0 V/min, program for scan of E_d given in Fig. 9.

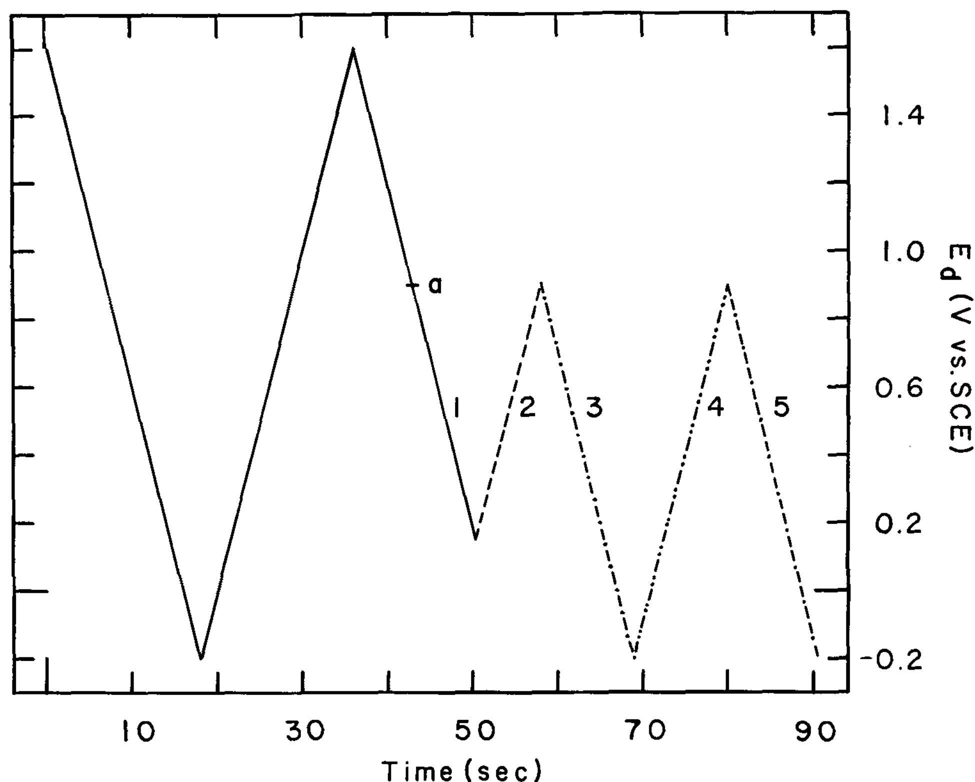

Fig. 9. Program for scan of E_d used in Fig. 8; 6.0 V/min, recording of I_r-E_d curves started at a.

cathodic scan (from curve 3 of Fig. 8) is 6.0×10^{-10} mol/cm^2. I_r-E_d curves obtained during repeated cyclic E_d scans between the limits $E_d{}^c = 0.15$V and $E_d{}^c = 0.90$V were identical to those in Fig. 8. Since more I_2 cannot be desorbed than is previously adsorbed, it is apparent the use of the steady-state curve as a reference for the calculation of values in Table I is not correct. This would be the case if the $E_{1/2}$ for the oxidation of I^- to I_2 on the steady-state curve differs from the $E_{1/2}$ on curves obtained during cathodic and/or anodic scans of E_d at 6.0 V/min.

The surface coverage by reversibly adsorbed I_2 at a disk surface bearing only I^- in an irreversible state of adsorption (from curve 5 of Fig. 8) was found to be approximately the same as that adsorbed at a surface bearing both I^- and I_2 in irreversible states of adsorption (from curve 3 of Fig. 8). This is in agreement with the findings of Hubbard, Osteryoung, and Anson (17).

An accurate calculation of the quantity of I_2 adsorbed in a reversible state at a surface covered with I^- is based on the areas under peak R and X. On that basis 5.5×10^{-10} mol/cm^2 of I_2 is adsorbed at an electrode in $3.0 \times 10^{-4}M$ NaI. This result is consistent with results given in Fig. 6.

The quantity of species adsorbed at the disk electrode in the region of wave T (curve 1 in Fig. 8) was calculated as 2.1×10^{-9} g eq/cm^2. The isotherm for adsorption of I^- in an irreversible state (Fig. 4) shows a maximum surface coverage of 1.3×10^{-9} g ion/cm^2. It does not seem possible that this large difference can be accounted on the basis of the possible incorrect use of the steady-state curve. Hubbard, Osteryoung, and Anson (17) found that 3.2×10^{-9} g eq/cm^2 of I_2 may be adsorbed in an irreversible state at a platinum electrode. The value calculated here is intermediate the values for surface coverage by I^- and by I_2.

As stated earlier, the height of peak W is equal to $-$N times the height of peak E after correcting for charging current. On the basis of this evidence, it is my conclusion that the quantity of I^- removed from the disk surface during reduction of the irreversibly adsorbed I_2 is equal to the quantity of I^- produced at the disk surface by the reduction. It is clear that the inclusion of I_2 as an irreversibly adsorbed species does not prevent the value of surface coverage by irreversibly adsorbed I^- from being equal to the maximum value, 1.3×10^{-9} g ion/cm^2.

Rate of exchange between reversible and irreversible states of I_2 adsorption.—The knowledge that I_2 and I^- can be adsorbed simultaneously at the electrode surface and that the quantity of I^- adsorbed is equal to that adsorbed if no I_2 were present leads immediately to a question. Will I_2 which is adsorbed in a reversible state at a platinum surface covered with irreversibly adsorbed I^- enter a state of irreversible adsorption? To obtain an experimental answer, I_r-E_d curves were obtained as follows: E_d was adjusted to 1.6V, then stepped to -0.20V, and then to 0.70V. E_d was maintained at 0.70V for time, t, from 0 to 360 sec. After the desired time period, the I_r-E_d curve was recorded while scanning E_d from 0.7 to -0.20V at 6.0 V/min. The I_r-E_d curves are shown in Fig. 10 for $t = 5$, 60, and 360 sec. It is clear that I_2 is slowly adsorbed into the irreversible state at a surface covered with ir-

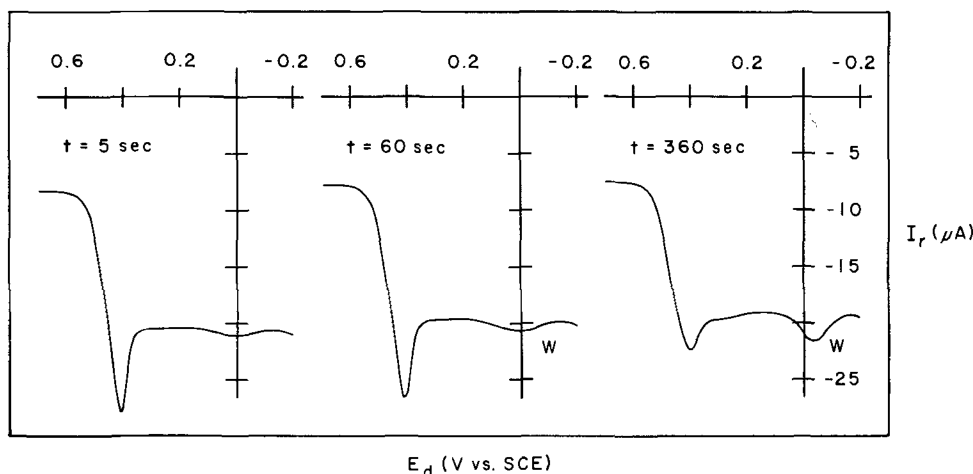

Fig. 10. I_r-E_d curves illustrating exchange of I_2 between reversible and irreversible states of adsorption; $2.0 \times 10^{-4}M$ NaI, $1.0M$ H_2SO_4, 2500 rev/min, 6.0 V/min.

reversibly adsorbed I^- as evidenced by the increase in the size of wave W for longer t values.

In a similar experiment, E_d was stepped from 1.6 to -0.20V and then to 0.90V at which it was maintained for values of t ranging from 0 to 360 sec. The I_r-E_d curves were then recorded while scanning E_d from 0.90 to -0.20V at 6.0 V/min. It is shown above that in this experiment no I_2 was present at the disk surface in a reversible state of adsorption even though a potential of 0.90V is in the limiting-current region of the wave for oxidation of I^- to I_2. The size of wave W was no larger after $t = 360$ sec than when $t = 0$ sec. Thus, the mechanism whereby I_2 is slowly adsorbed into an irreversible state at a surface covered with irreversibly adsorbed I^- requires preliminary adsorption to the reversible state.

Summary

New conclusions about the processes of adsorption and desorption of I^- and I_2 at platinum electrodes in $1.0M$ H_2SO_4 have resulted from this study. Iodine was determined to rapidly and simultaneously adsorb with I^- by an irreversible process following electrochemical reduction of an anodized platinum electrode. The irreversible adsorption of I_2 does not result in a decrease of the surface coverage by I^- from that determined in the absence of I_2. Iodine was found to adsorb equally to a surface covered with irreversibly adsorbed I^- or a mixture of I^- and I_2. This is in agreement with the findings of Hubbard, Osteryoung, and Anson (17) who determined that I_2 adsorbs by a reversible process to the same extent at a surface covered by irreversibly adsorbed I^- or irreversibly adsorbed I_2. Iodine is desorbed from the reversible state of adsorption by a potential-dependent mechanism at a surface covered with irreversibly adsorbed I^- at $E = 0.8$V. The presence of I_2 in an irreversible state causes the desorption to shift to more positive values. Irreversibly adsorbed I_2 is electrochemically reduced and the I^- produced is desorbed at $E < 0.1$V. It was also found that I_2 undergoes slow adsorption to the irreversible state at an electrode surface covered by irreversibly adsorbed I^- and this proceeds by a mechanism involving preliminary adsorption of I_2 to the reversible state.

Current Distribution Along an Electrode of High Resistance During Unsteady-State Diffusion

Richard C. Alkire*,[1] **and Aladar Tvarusko***

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

ABSTRACT

Current-time behavior is predicted following a step-change in applied potential for electrolysis at a straight wire electrode of high resistance in unstirred solution. Transport equations are integrated by finite difference techniques on a digital computer. Six classes of electrode behavior are described in accord with the relative importance of diffusion, charge-transfer, and ohmic resistance effects. A high electrode resistance leads to nonuniform current distribution along the wire whereas diffusion resistance in the electrolyte causes appreciable transient current decay.

The surface on which an electrochemical reaction takes place may not be equipotential if the resistance of the electrode phase is large. Accordingly, the electrochemical reaction may proceed at different rates along the electrode surface. The variation of the reaction rate along the electrode depends upon the kinetic, geometric, and transport characteristics of the specific electrochemical system involved. The over-all behavior of such a distributed reaction system can be quite complicated since it is the result of several competing factors such as ohmic resistance of the wire and solution, mass transport by diffusion and migration in the electrolytic solution, hydrodynamic motion of the solution, charge-transfer overpotential, and geometry of the electrolysis cell.

In the past, several studies have been conducted on straight wire electrodes of small diameter immersed in electrolytic solution and surrounded by cylindrical counterelectrodes. These analyses have shown how the current and potential distributions along a wire electrode depend upon ohmic electrolyte resistance and upon the rate of sluggish electrode reaction (1-8). Calculations were carried out by treating the electrode as a one-dimensional region along which electrochemical reaction takes place.

To date, no theoretical analyses are known to be reported which take into consideration mass transfer effects during electrolysis at electrodes of high resistance. Such mass transfer effects may be complicated when there is convective motion of solution as, for example, encountered in axial flow during the electroplating of moving wires, transverse forced flow through a wire grid or porous electrode, and natural convection at stationary electrodes.

In the present study, an analysis of potentiostatic electrolysis is conducted on a wire electrode immersed simply in stationary electrolyte and surrounded by a cylindrical counterelectrode. If the applied potential is sufficiently cathodic, the concentration of reacting species at the electrode surface would be quickly reduced to nearly zero along the entire electrode surface. In such cases the current density distribution would be uniform, the total current would decrease according to unsteady-state radial diffusion (9), and electrode operation would be under pure mass transfer control. On the other hand, if the mass transport process proceeds with ease, the concentration of reacting species at the electrode surface may not be appreciably reduced below the value in the bulk electrolyte so that diffusion-controlled transient behavior would not be anticipated. Instead, a steady-state condition would be obtained immediately following the double-layer charging process. If the resistance of the wire electrode is sufficiently high, then ohmic losses in the metal phase may consume much of the applied potential so that the current distribution along the electrode would not be uniform. At intermediate conditions, ohmic resistance of the wire electrode may lead to a nonuniform current distribution while, at the same time, the concentration of reacting species at the electrode surface is reduced to a value between the bulk value and zero. The transient current response may then be expected to deviate significantly from that predicted on the basis of simple radial diffusion at the limiting current. Establishment of a constant applied potential does not fix the surface concentration on the wire surface since there is more than one series resistance in the distributed reaction circuit. In the present study, conditions are ascertained under which mass-transfer transient behavior and/or a nonuniform current distribution may be anticipated. The theoretical model predicts the current and potential distributions along the electrode as a function of time during electrolysis. The investigation of this simple case can illuminate how the reaction distribution depends upon mass transport, ohmic, and charge-transfer effects, and can serve as a basis for extension of model studies to more complex conditions such as continuous electrodeposition on moving wire.

Model Formulation

The model for the resistive wire electrode is based on consideration of a single straight metal wire which extends the entire length of an electrolysis cell as shown in Fig. 1. The cylindrical counterelectrode surrounds the wire and the primary current distribution is supposed to be uniform. Electrical contact is made at one end of the wire. The other end of the wire is insulated and no current passes through it; alternatively a plane of symmetry may exist. There is no motion of fluid relative to the solid surface. The potential of the wire electrode is maintained at a desired value with respect to a reference electrode placed in the solution near the wire at the end of the cell closest to the electrical contact point.

The theoretical model presented below may be employed for predicting either anodic or cathodic behavior. For convenience of presentation, however, only cathodic electrodeposition of metal onto a wire electrode is chosen for discussion.

Prior to the application of potential, the electrode is supposed to be at its rest potential so that no current passes and the metal-ion concentration is uniform throughout the electrolyte. Following the sudden application of cathodic potential, current flows through the electrode at a rate which is limited "initially" by charge-transfer overpotential and/or ohmic resistance.[2]

Key words: current distribution, electrodeposition on wire, nonequipotential surface, potentiostatic transients.

[2] In a metallic conductor, electrons attain their steady-state velocity within approximately 10^{-14} sec. The establishment of an electrical double layer at the metal-solution interface is typically completed within approximately 10^{-4} sec, depending upon the resistance of the metal, the capacity of the double layer, and the charging current. The theoretical model presented here does not apply to behavior during these processes.

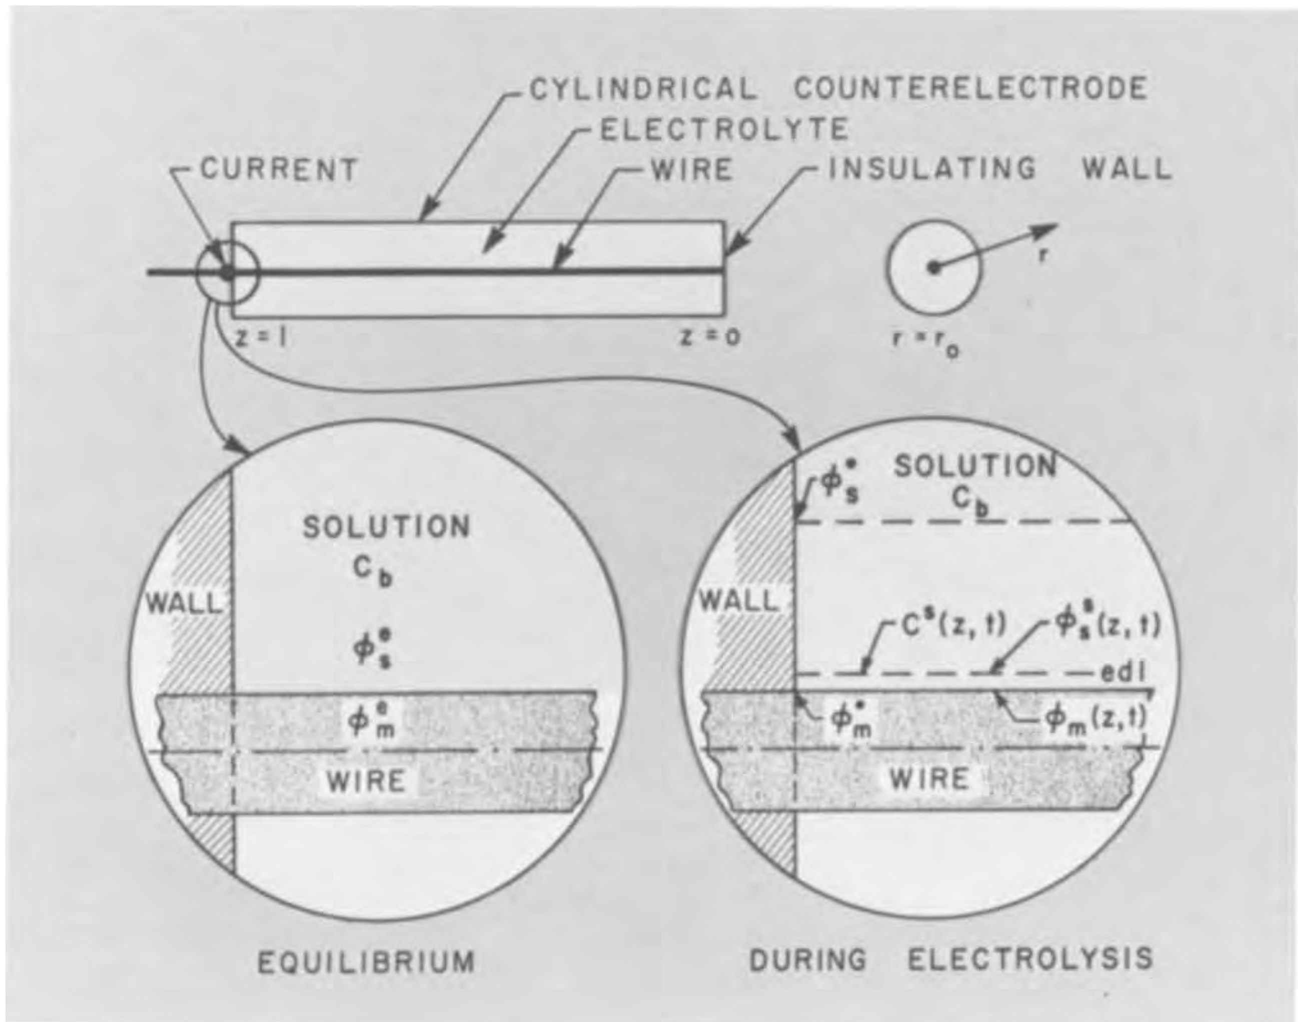

Fig. 1. Electrolysis cell and schematic diagram of the model for stationary wire electrode

If the transference number of the reacting ion is less than one, a concentration gradient is caused to form in the solution. The concentration of reacting species at the surface of the cathode thus decreases below the bulk value to an extent which depends upon the applied potential and upon the competing series resistance: ohmic and charge-transfer.

The current in the metal is carried by the electrons and in the solution by the ions. The local concentrations and potentials may be obtained by solving the transport equations in each phase. If these concentration and potential distributions are known throughout both phases, the local reaction rate may be calculated, in principle, by a relation which suitably describes the kinetics of the electrode process. Thus the local current distribution may be determined along the wire.

Because rigorous calculations are cumbersome, several simplifying assumptions have been introduced. Although these assumptions restrict somewhat the range of validity of the model, they do not obviate the essential features of behavior which are of interest.

(*i*) The wire is a straight circular cylinder, and the counterelectrode configuration is such that the primary current distribution along the wire is uniform. The wire diameter is not appreciably altered by conduct of electrolysis.

(*ii*) The rate of establishment of the electrical double layer is rapid with respect to any transient electrode behavior under consideration.

(*iii*) The wire diameter is small with respect to distances over which significant potential variation takes place in the metal phase so that the one-dimensional macroscopic method is applicable for calculation of the potential field in the metal electrode.

(*iv*) There is negligible ohmic resistance in the contact wires external to the electrolysis cell.

(*v*) Only one electrochemical reaction takes place and the overpotential of the reaction sequence is adequately characterized by a Volmer-type expression (Eq. [3]).

(*vi*) The metal ions are present in small concentration in an electrolytic solution containing a large excess of nonreactive charged species. Thus motion of the metal ions is not appreciably affected by the presence of the potential field in the electrolyte.

(*vii*) The resistance of the electrolytic solution is negligible with respect to other resistances in the cell and thus does not tend to alter the current distribution along the wire.

(*viii*) There is no hydrodynamic motion in the electrolyte.

(*ix*) The ratio of wire length/diameter is sufficiently large that, in the electrolyte, axial diffusion along the wire is everywhere negligible in comparison with radial diffusion away from the wire.

(*x*) The system is isothermal.

(*xi*) Nonelectrochemical reactions do not occur.

The spatial coordinate along the wire, z, extends from the insulated end ($z = 0$) to the current feeder side ($z = l$). The radial coordinate, r, has the value r_0 at the wire surface. The electronic current and potential along the wire are related by Ohm's law.

$$i(z,t) = -\sigma \frac{d\phi_m(z,t)}{dz} \quad [1]$$

The electronic current in the wire, $i(z,t)$, varies with position owing to the electrochemical reaction taking place at the wire surface

$$\frac{di(z,t)}{dz} = -\frac{2}{r_o} j(z,t) \quad [2]$$

The local reaction rate along the wire, $j(z,t)$, is related to the local metal ion concentration at the surface, $c^s(z,t)$ and to the potentials in both phases by the kinetic expression associated with the metal deposition process. The Volmer equation (10) has found particularly widespread use and will be used in this study. For application to electrodeposition systems, this equation is written

$$j(z,t) = i_o \left\{ \exp\left[\frac{\alpha n\mathbf{F}}{\Re T}\eta(z,t)\right] - \frac{c^s(z,t)}{c_b}\exp\left[\frac{(\alpha-1)n\mathbf{F}}{\Re T}\eta(z,t)\right]\right\} \quad [3]$$

The exchange current density, i_o, has the value which corresponds to the reactant concentration in the bulk of the electrolyte, c_b. The quantity $\eta(z,t)$ is defined as the potential difference between metal and solution, outside the diffusion layer, during passage of current minus the potential difference existing under equilibrium conditions. This quantity thus includes both charge-transfer overpotential and concentration overpotential. It is convenient to introduce two additional potentials, $\phi_m^\bullet$ and $\phi_s^\bullet$, which are defined as the potentials during electrolysis at the current feeder side of the electrolysis cell in the metal and in the bulk solution, respectively. Thus

$$\eta(z,t) = [\phi_m(z,t) - \phi_s^\bullet] - [\phi_m^e - \phi_s^e] \quad [4]$$

By denoting the potential in the electrolyte "at the surface of the wire" as $\phi_s^s(z,t)$, the right-hand side of Eq. [4] may be rearranged to

$$[(\phi_m^\bullet - \phi_s^\bullet) - (\phi_m^e - \phi_s^e)] = [\phi_m^\bullet - \phi_m(z,t)] + [\phi_s^s(z,t) - \phi_s^\bullet] + \{[\phi_m(z,t) - \phi_s^s(z,t)] - [\phi_m^e - \phi_s^e]\} \quad [5]$$

If a reference electrode is placed outside the diffusion layer at the current-feeder side of the electrolysis cell, then the quantity on the left side of Eq. [5] is the applied or control potential. Equation [5] indicates that the applied potential is consumed within the cell by (*i*) ohmic losses in the metal electrode, $[\phi_m^\bullet - \phi_m(z,t)]$, (*ii*) concentration overpotential in the electrolyte, $[\phi_s^s(z,t) - \phi_s^\bullet]$, and (*iii*) charge-transfer overpotential at the electrode surface, $\{[\phi_m(z,t) - \phi_s^s(z,t)] - [\phi_m^e - \phi_s^e]\}$. The concentration overpotential is related to the concentration difference across the diffusion layer in accord with the formula

$$\phi_s^s(z,t) - \phi_s^\bullet = \frac{\Re T}{n\mathbf{F}} \ln \frac{c^s(z,t)}{c_b} \quad [6]$$

The relative magnitude of the three overpotentials vary in distance along the electrode and in time during electrolysis, but their sum remains constant. The sum of potential losses (*ii*) and (*iii*) constitute the quantity $\eta(z,t)$, as already indicated by Eq. [4].

Combination of Eq. [1] to [5] gives

$$\frac{d^2\phi_m}{dz^2} = \frac{2i_o}{r_o\sigma}\left[\exp\left\{\frac{\alpha n\mathbf{F}}{\Re T}[(\phi_m - \phi_m^\bullet) + (\phi_m^\bullet - \phi_s^\bullet) - (\phi_m^e - \phi_s^e)]\right\} - \left(\frac{c^s}{c_b}\right)\exp\left\{-\frac{(1-\alpha)n\mathbf{F}}{\Re T}[(\phi_m - \phi_m^\bullet) + (\phi_m^\bullet - \phi_s^\bullet) - (\phi_m^e - \phi_s^e)]\right\}\right] \quad [7]$$

where, for compactness, the functional dependence upon the z-coordinate and upon time has been deleted from the variable notation. Equation [7] is to be integrated subject to two boundary conditions:

1. Current does not pass through the insulated end of the wire

$$\frac{d\phi_m}{dz} = 0 \qquad \text{at } z = 0 \quad [8]$$

2. During electrolysis the potential at the current-feeder end of the wire is constant

$$\phi_m - \phi_m^\bullet = 0 \qquad \text{at } z = l \quad [9]$$

Equation [7] has two unknown variables: the potential in the metal, $\phi_m(z,t)$, and the concentration of reacting metal ion along the surface of the electrode, $c^s(z,t)$. In order to determine the distribution of surface concentration along the nonequipotential surface of the wire, diffusion in the solution must be taken into consideration. Thus, in accord with the conditions listed above, the radial diffusion equation is applied locally along the wire with neglect of axial terms

$$\left[\frac{\partial c(r,t)}{\partial t}\right]_z = D\left[\frac{\partial^2 c(r,t)}{\partial r^2} + \frac{1}{r}\frac{\partial c(r,t)}{\partial r}\right]_z \quad [10]$$

At the onset of electrolysis, the concentration of reactant species in the electrolyte is everywhere uniform

$$c(r,t) = c_b \qquad (t = 0, \text{ all } r > r_o) \quad [11]$$

During electrolysis, the concentration far from the electrode remains constant

$$c(r,t) = c_b \qquad (r = \infty, \text{ all } t) \quad [12]$$

At the surface of the wire, the local current density is related to the local concentration gradient in the solution

$$\left[D\frac{\partial c(r,t)}{\partial r}\right]_z = -\frac{j(z,t)}{n\mathbf{F}} \qquad (r = r_o, \text{all } t) \quad [13]$$

Equation [13] states Fick's first law which is valid in the absence of migration effects. The time dependence of the local current density, $j(z,t)$, indicates that Eq. [13] does not correspond to a constant current boundary condition. Since neither the concentration c^s nor the current j are constant in time or in distance, both need to be calculated during the transient period; the calculation is performed such that Eq. [13] is obeyed.

In accord with the assumptions of the model, the potential and current distributions during transient operation may be determined from the solution of the coupled equations, [7] and [10], subject to the boundary conditions [8], [9], [11], [12], and [13]. Before proceeding with the analysis of these equations, it is worthwhile to reformulate the variables into dimensionless form. For this purpose the following relations seem convenient

$$Z = \frac{z}{l} \qquad R = \frac{r}{r_o}$$

$$\tau = \frac{Dt}{r_o^2} \qquad C(R,\tau) = \frac{c(r,t)}{c_b}$$

$$\Phi_m(Z,\tau) = \frac{n\mathbf{F}}{\Re T}[\phi_m(z,t) - \phi_m^{\bullet}]$$

$$\Phi_a = \frac{n\mathbf{F}}{\Re T}[(\phi_m^{\bullet} - \phi_s^{\bullet}) - (\phi_m^e - \phi_s^e)]$$

When the above variables are introduced into Eq. [7]-[13], the following dimensionless groupings of the system parameters arise

$$\xi = \frac{2n\mathbf{F}l^2 i_o}{\sigma r_o \Re T} \qquad \chi = \frac{\sigma r_o^2 \Re T}{2n^2 l^2 \mathbf{F}^2 c_b D}$$

$$\beta(\tau) = \frac{n\mathbf{F}l i^{\bullet}(t)}{\sigma \Re T} \qquad J(Z,\tau) = \frac{2lj(z,t)}{r_o i^{\bullet}(t)}$$

$$\theta(Z,\tau) = \beta J \chi \qquad [14]$$

The parameter ξ is seen to be proportional to the ratio of exchange current density to metal conductivity and thereby is a measure of charge-transfer *vs.* ohmic effects. In a similar manner, the parameter χ is a measure of the relative importance of ohmic *vs.* diffusion resistances.

Equations [7]-[13] which describe the model used in this study may now be written in dimensionless form

$$\frac{d^2\Phi_m}{dZ^2} = \xi\{\exp[\alpha(\Phi_m + \Phi_a)] - C^s \exp[(\alpha - 1)(\Phi_m + \Phi_a)]\} \qquad [15]$$

$$\frac{d\Phi_m}{dZ} = 0 \qquad (Z = 0, \text{all } \tau) \qquad [16]$$

$$\Phi_m = 0 \qquad (Z = 1, \text{all } \tau) \qquad [17]$$

$$\frac{\partial C}{\partial \tau} = \frac{\partial^2 C}{\partial R^2} + \frac{1}{R}\frac{\partial C}{\partial R} \qquad [18]$$

$$C = 1 \qquad (\tau = 0, R > 1) \qquad [19]$$

$$C = 1 \qquad (R = \infty, \text{all } \tau) \qquad [20]$$

$$\frac{\partial C}{\partial R} = -\theta \qquad (R = 1, \tau > 0) \qquad [21]$$

Once the potential and concentration distributions along the wire surface are known, the current distribution may be calculated by

$$J(Z,\tau) = \frac{\xi}{\beta}\{\exp[\alpha(\Phi_m + \Phi_a)] - C^s \exp[(\alpha - 1)(\Phi_m + \Phi_a)]\} \qquad [22]$$

It is interesting to observe that the current distribution in porous electrodes obeys Eq. [15] in the absence of concentration gradients in the pores (11, 12). The above model also characterizes certain transient processes which may occur during electrocrystallization (13).

Method of Solution

The solution of the set of equations and boundary conditions which describe the wire electrode model, Eq. [15]-[21], was carried out by a computer-implemented numerical procedure. In principle the transient calculation was accomplished by uncoupling Eq. [15] and [18] and solving each equation alternately in a stepwise manner with use of finite difference representations to the differential equations at each time step. First, Eq. [15] was solved with the surface concentration set equal to the bulk value ($C^s = 1$), and the current distribution was determined with Eq. [22]. These results correspond to the potential and current distributions prevailing before depletion of metal ions commences. Calculations were then carried out at specified time intervals during the ensuing mass-transfer transient period. Equation [18] was applied at each spatial incremental element along the wire, with the surface flux (θ) set equal to the local current density in accord with its definition, Eq. [14]. The initial time increment was chosen so that the surface concentration at the current-feeder end of the wire decreased by 3%; the numerical results were not appreciably improved with use of smaller time increments. After a specified incremental period of radial diffusion under a given current distribution, the concentration distribution was re-evaluated. With the values thus determined for the surface concentration distribution along the wire, Eq. [15] was again solved for a new current distribution and the sequence repeated for as many time intervals as required.

The central problem of these calculations is the solution of two second-order differential equations. Equation [15] was first linearized about an approximate solution and then put into finite difference form. The tridiagonal matrix was solved in accord with the method of Newman (14). The solution of the nonlinear problem was obtained by iteration with successive correction of the approximate solution. The transient diffusion equation, Eq. [18] was placed into finite difference representation in accord with the Crank-Nicolson symmetric form, and the tridiagonal matrix was inverted at each time step with use of an algorithm attributed to Thomas (15). Quarter-point representation of the finite difference equations was employed for the boundary conditions at the wire surface in accord with the discussion of Beck and Dhanak (16).

Results presented in this work were determined with use of 100 Z-increments in the axial direction and 40 R-increments in the radial direction ($\Delta R = 0.05$). For the range of parameters under study, this choice gave numerical results which were not appreciably improved by use of smaller mesh sizes. Between successive time steps, the time increment was increased by a factor of 1.1 in order to conserve computer time. A typical single time-step calculation involving 100 Z-increments with 40 R-increments at each Z-increment was found to take approximately 0.8 sec on an IBM 360 computer when the program is compiled in FORTRAN G.

Results and Discussion

The simple theoretical model developed above was used to predict several essential features of wire electrode behavior. The dimensionless quantities used in presentation permit evaluation of a wide variety of actual systems. All calculations were carried out for cathodic deposition (negative applied potentials) with use of the values $n = 2.0$ and $\alpha = 0.5$.

First consider the state which exists in the absence of significant concentration overpotential. As shown in Fig. 2, the current density distribution depends upon the value of the parameter ξ. For highly resistive wires, or reversible reactions (large values of ξ), electrochemical reaction takes place mainly near the current feeder end of the wire. For sluggish reactions on good conductors, charge-transfer overpotential near the current feeder end of the wire forces the electronic current to pass further along the wire so that for a given current density the reaction is more uniformly distributed at the expense of higher overpotential. Figure 3 illustrates how the total current passing to the wire electrode increases with applied potential. For small values of ξ, the total current β increases in direct proportion to an increase in ξ; that is, since the current distribution is uniform for small ξ, the total current is proportional to the exchange current density, as may be seen in Eq. [3] and [22]. For large values of ξ, Fig. 3 indicates that the total current increases with approximately the square root of ξ for a given potential. For large ξ, the potential in the electrode varies with position, Eq. [1], so that the exponential terms in Eq. [22] become dependent upon the value of ξ.

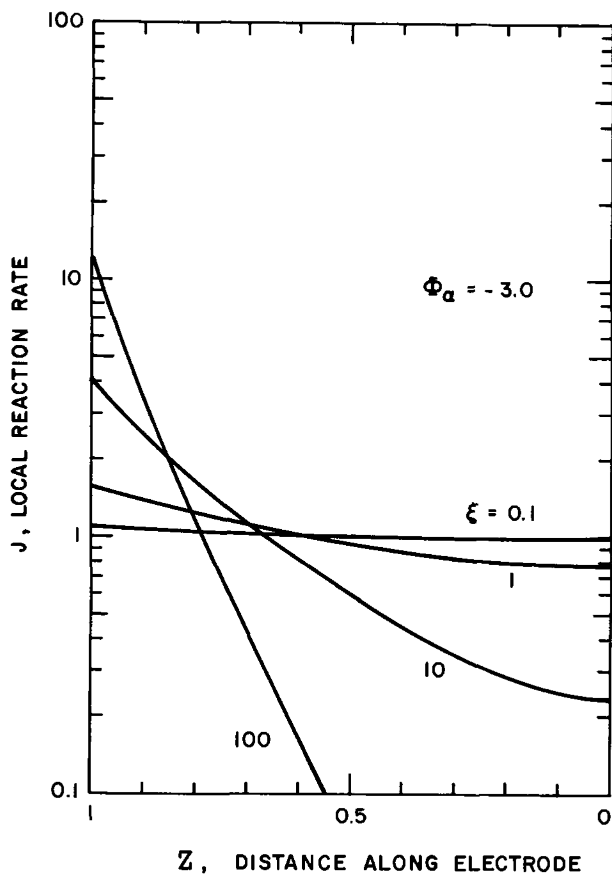

Fig. 2. Current density distribution along a wire electrode of high resistance in the absence of mass transport effects.

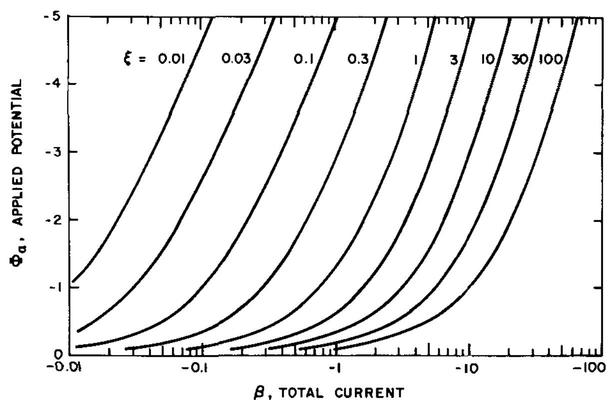

Fig. 3. Current-potential curves in the absence of concentration overpotential for high resistance wire electrodes at several values of the parameter ξ.

Let us now consider the effect of diffusional resistance on electrode behavior. The applied cathodic potential will be partitioned into ohmic, charge-transfer, and concentration overpotentials (Eq. [5]) according to the system parameters ξ and χ. The surface concentration at any point along the electrode may have a value between that in the bulk electrolyte and the minimum value

$$C^s_{\min} = \exp(\Phi_a) \quad [23]$$

given by the Nernst equation. If the ohmic resistance of the electrode is important, the reaction distribution will be nonuniform; if the mass transport resistance is important, diffusion-controlled transient behavior will be observed. "Initially," the concentration overpotential will be zero since the concentration distribution is uniform at the onset of electrolysis. The applied potential is thus initially partitioned between charge-transfer overpotential and ohmic losses in the wire according to the parameter ξ. With subsequent passage of current, concentration overpotential will eventually become significant if the parameter χ has a large value. As shown in Fig. 4, the concentration of metal ions at the cathode surface decreases during electrolysis at a rate which is in accord with the prevailing current density distribution. Eventually, for large χ, concentration overpotential can become the predominant resistance to current flow in the cell.[3] The current density distributions which correspond to the results depicted in Fig. 4 are nonuniform (large ξ) and, indeed, the concentration decreases most rapidly near the current-feeder, where the local reaction rate is highest. As electrolysis proceeds, the region depleted in reacting species propagates along the wire. The minimum possible surface concentration, attained when ohmic and charge-transfer resistances are essentially negligible, has the value given by Eq. [23]. This lower limiting value is shown as the dashed line for the applied potential employed in Fig. 4.

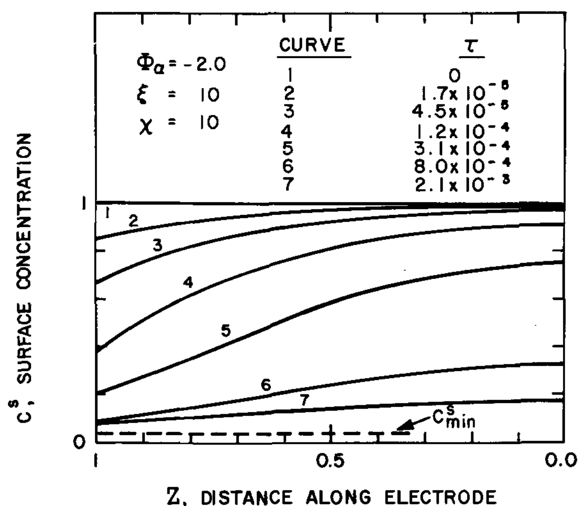

Fig. 4. Concentration variation at the surface of wire electrode of high resistance during unsteady-state potentiostatic electrodeposition at various dimensionless times.

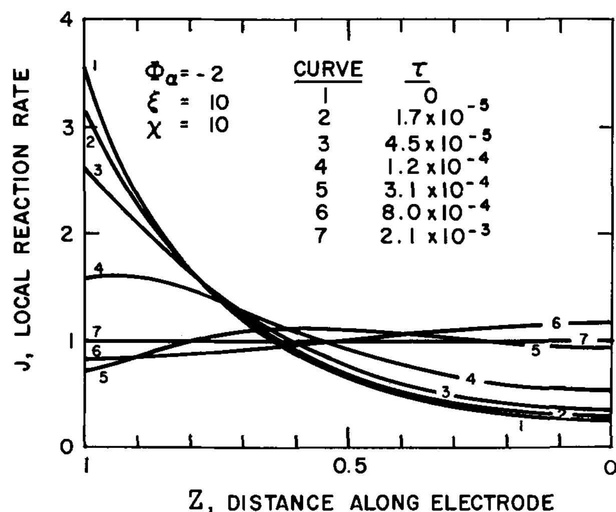

Fig. 5. Current density distribution on a wire cathode of high resistance during unsteady-state potentiostatic electrodeposition.

Naturally, the variation of concentration during electrolysis has a dramatic effect on the current density distribution along the wire. Figure 5 shows the current distributions on the wire during electrolysis under the same conditions as in Fig. 4. Initially, the local reaction rate varies along the length of wire in a nearly exponential fashion as was already indicated

[3] Because the diffusion field is unbounded, the transient process does not attain a steady state and the diffusion layer grows indefinitely.

in Fig. 2. As concentration overpotential sets in near the current feeder end of the wire, however, reaction takes place further along the wire. At sufficiently long times, the mass transfer restriction near the current feeder becomes so severe that the most favorable reaction zone shifts away from the end of the wire. This most favorable reaction zone is sufficiently far from the current feeder end of the wire that concentration overpotential does not dominate, but yet not so far down the wire that ohmic losses in the electrode consume the applied potential. In this intermediate zone, the parameter ξ will influence the value of the maximum in the local current density. As electrolysis proceeds further, the most favorable reaction zone propagates down the wire owing to further depletion of metal ions near the current feeder side of the zone. Eventually, the most favorable zone reaches the far end of the wire, in which case the current distribution becomes nearly uniform along the entire electrode.

During the transient behavior depicted in Fig. 4 and 5, the individual overpotentials (ohmic, charge-transfer, and concentration) all vary with position and time in such a way that the applied potential remains constant throughout electrolysis.

The preceding discussion of events occurring locally along the wire surface during electrolysis has emphasized the interplay between diffusion, ohmic and charge-transfer overpotentials. Now, consider how such local behavior influences the total current flowing to the electrode, an easily accessible experimental quantity. For a given applied potential, two independent parameters, ξ and χ, are necessary to characterize the relative importance of the three effects. As shown in Table I, six possible combinations for the order of relative importance of diffusional, ohmic, and charge-transfer resistances can be ascertained according to the values of ξ and χ. It has already been mentioned that, generally speaking, a large value of ξ corresponds to a nonuniform current distribution owing to large ohmic resistance losses. In addition, a large value of χ corresponds to the predominance of diffusional resistance in comparison to ohmic resistance. Therefore, a large value of the product $\xi\chi$ indicates that concentration overpotential will eventually surpass the charge-transfer overpotential.

At the onset of electrolysis the total current, β, is determined by the applied potential, Φ_a, and by the parameter ξ. The subsequent timewise variations of β depend upon whether or not concentration gradients form near the electrode, *i.e.*, upon the value of χ. In Fig. 6, ξ has a low value which corresponds to nearly uniform current distribution at the onset of electrolysis as already indicated in Fig. 2. For small values of χ, concentration overpotential does not set in since the over-all process is primarily limited by change-transfer overpotential. For increased values of χ, however, transient behavior becomes more pronounced since the diffusional process becomes rate limiting. In Fig. 7, ξ has a large value which corresponds to a nonuniform current distribution at the onset of electrolysis. Once again it may be seen that transient behavior sets in to an extent which depends upon the value of the parameter χ.

Table I. Interpretation of the parameters ξ and χ

Case	ξ	χ	$\xi\chi$	Order of importance of competing effects
1	small	large	large	$C > S > O$
2	large	large	large	$C > O > S$
3	small	small	small	$S > O > C$
4	small	large	small	$S > C > O$
5	large	small	small	$O > S > C$
6	large	small	large	$O > C > S$

C—concentration overpotential.
S—surface overpotential.
O—ohmic loss in wire electrode.

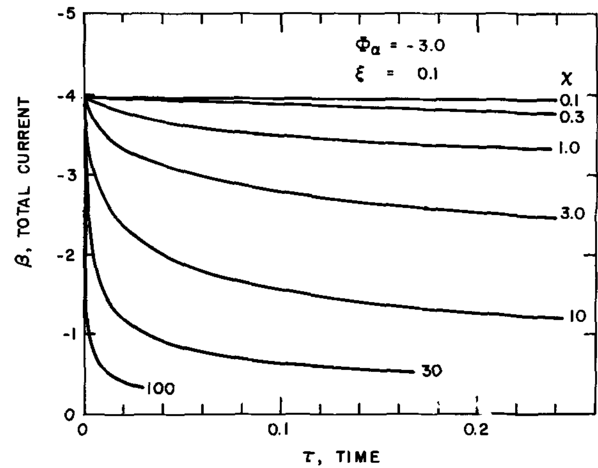

Fig. 6. Importance of mass transfer resistance (χ) at low ξ value on variation of total current during unsteady-state potentiostatic deposition at a wire electrode of high resistance.

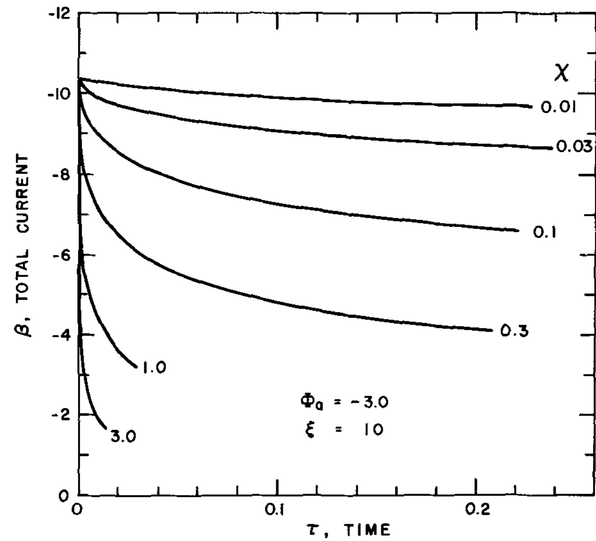

Fig. 7. Importance of mass transfer resistance (χ) at high ξ value on variation of total current during unsteady-state potentiostatic deposition at a wire electrode of high resistance.

It is illustrative to compare the above predictions with the "ideal" situation of pure radial diffusion under which both the current distribution is uniform and the concentration overpotential predominates at all times. Such a situation corresponds to one-dimensional unsteady-state radial diffusion from a circular cylinder with (constant) surface concentration equal to the value $c^s_{\min}$. The analytical solution (9) is

$$\frac{jr_o}{nFD(c^s_{\min} - c_b)} = f\left(\frac{Dt}{r_o^2}\right) \qquad [24]$$

The quantity on the left is a dimensionless ratio of the mass flux to the mass transfer driving force, that is, a Nusselt number for pure mass transport in an electrochemical system. In dimensionless form, Eq. [24] is

$$\frac{\beta\chi}{e^{\Phi_a} - 1} = f(\tau) \qquad [25]$$

where

$$f(\tau) = (\pi\tau)^{-1/2} + \frac{1}{2} - \frac{1}{4}\left(\frac{\tau}{\pi}\right)^{1/2} + \frac{1}{8}\ldots \qquad [26]$$

for short times and

$$f(\tau) = \frac{1}{\ln(4\tau) - 2\gamma} - \frac{\gamma}{[\ln(4\tau) - 2\gamma]^2} \qquad [27]$$

for long times. The quantity γ is Euler's constant

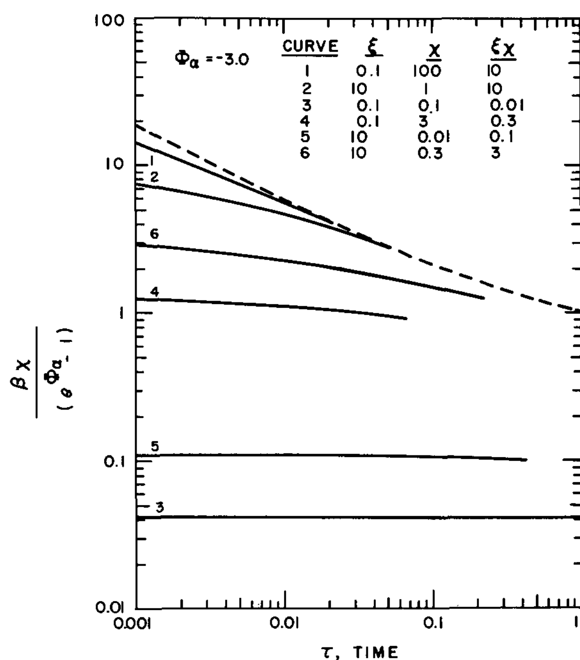

Fig. 8. Comparison of transient current response of resistive wire electrodes with idealized situation of pure diffusion control.

(0.57722). Notice from Eq. [26] that at time zero the current density would be infinitely large since competing resistances were not accounted for. The transient current response which corresponds to this limiting situation is shown by the dashed line in Fig. 8.

The limiting case of Eq. [25]-[27] may be compared with predictions based on the foregoing theoretical model. Deviations from the dashed line in Fig. 8 will always be observed for sufficiently small times, when ohmic or change-transfer resistance prevail. The predicted results, of course, are invalid for extremely small times since the model does not include effects associated with the double layer charging process. Sample calculations for each of the six cases of behavior (Table I) are reported in Fig. 8 for an applied potential of $\Phi_a = -3.0$. Curve 1 corresponds very nearly to the limiting situation of Eq. [25] except that an infinitely large current is not passed at short times; the current density distribution is uniform at all times owing to the small value of ξ. For curve 2, the initial current distribution is nonuniform and, as previously illustrated in Fig. 4 and 5, concentration overpotential propagates down the wire; eventually diffusion resistances predominate along the entire length, and the current distribution is forced to become uniform. In curve 3, charge-transfer overpotential predominates at all times so that the current distribution is uniform and no transient diffusion behavior is observed. In curve 4, although charge-transfer predominates, a weak transient response is predicted since diffusional restrictions are not completely negligible owing to the large value of χ. In curves 5 and 6, ohmic effects predominate at all times so that the current distribution is highly nonuniform; in the former case, appreciable concentration gradients are not formed in the solution ($\chi = 0.01$) whereas, in the latter case, concentration overpotential develops to a moderate extent ($\chi = 0.3$). The various example curves shown in Fig. 8 will depend upon the value chosen for the applied potential. In general, more cathodic applied potentials will shift all curves upward and to the left, will tend to enhance the formation of concentration gradients, and will result in more nonuniform current disrtibutions along the wire.

Conclusions

The behavior of resistive wire electrodes as illustrated by the preceding calculated results is consistent in pattern with what should be expected on the basis of qualitative reasoning. The predicted behavior is subject to the limitations imposed by the assumptions which define the model.

By assumption (*ix*), axial diffusion along the wire is considered negligible in comparison with radial diffusion away from the wire. The appropriatenes of this assumption may be tested by examination of the computed results. For the most nonuniform concentration distribution reported above, the axial diffusion flux attains only 1% of the value of the radial diffusion flux if the wire length/diameter ratio has the value 80. A smaller length/diameter ratio would also satisfy the assumption at smaller values of ξ and χ.

The conductivity of electrolytic solutions is less than the conductivity of common metallic electrode materials. Thus assumption (*vii*), that the ohmic resistance of the solution is negligible with respect to other resistances, may be expected to be good when the total current density in the wire is large with respect to the reaction rate at the wire surface. The ohmic overpotential in the solution phase will be less than 5% of the applied potential when the inequality

$$11 \frac{\sigma r_o^2}{kl^2} \frac{J\beta}{\Phi_a} \leq 1$$

is satisfied, where k is the conductivity of the electrolytic solution.

In the absence of concentration polarization, the uniformity of the current density distribution at a given applied potential depends solely upon the parameter ξ. Consequently, experimental methods which require uniform current density distribution for proper methodology or analysis of results should be designed such that ξ has a small value. Alternatively, the foregoing model may be employed to analyze the experimental data.

The effect of transport restrictions on electrode behavior is determined in accord with the value of χ. A value greater than unity indicates that transient response will be observed whether the current distribution is uniform or not. In the case of a nonuniform distribution, the most favorable region for reaction propagates along the wire as transport restrictions develop at the current feeder end of the electrode. For large values of χ, the current distribution will eventually be forced to become uniform regardless of the value of ξ.

Manuscript submitted July 30, 1971; revised manuscript received *ca.* Oct. 28, 1971. This was Paper 110 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

LIST OF SYMBOLS

English Characters

- c Concentration of reacting species, g mol/cm^3
- c_b Concentration of reacting species in bulk electrolyte, g mol/cm^3
- C c/c_b, concentration of reacting species, dimensionless
- D Diffusion coefficient, cm^2/sec
- **F** Faraday's constant, 96,500 coulombs/g-equiv
- i Current density in the wire, A/cm^2
- $i^\bullet$ Current density in the wire at the current-feeder side, A/cm^2
- i_o Apparent exchange current density of the electrode reaction, evaluated at the bulk concentration, A/cm^2
- j Local reaction rate (current density) along wire surface, A/cm^2
- J $2lj/i^\bullet r_o$, local reaction rate along wire, dimensionless
- l Length of wire, cm
- n Number of electrons taking part in electrode reaction, g-equiv/g mol
- r Spatial variable in radial direction, cm
- r_o Radius of wire electrode, cm

R — r/r_o, spatial variable in radial direction, dimensionless
$\mathcal{R}$ — Gas constant, 8.31 joules/g mol °K
t — Time, sec
T — Temperature, °K
z — Spatial variable along wire, cm
Z — z/l, spatial variable along wire, dimensionless

Greek Characters

α — Transfer coefficient in reaction rate expression, Eq. [3]
β — $nFli^{\bullet}/\sigma\mathcal{R}T$, current density in the wire at the current-feeder side, dimensionless
κ — Electrolytic conductivity of solution, $ohm^{-1} cm^{-1}$
η — Electrode overpotential as defined by Eq. [4], V
θ — jr_o/nFc_bD, local reaction rate along wire, dimensionless
ξ — $2nFi_ol^2/\sigma r_o\mathcal{R}T$, kinetic parameter, dimensionless
σ — Electrical conductivity of wire electrode, $ohm^{-1} cm^{-1}$
τ — Dt/r_o^2, time, dimensionless
ϕ — Potential, V
Φ — Potential, dimensionless
Φ_a — Potential applied by potentiostatic power supply, dimensionless
χ — $\frac{\sigma r_o^2\mathcal{R}T}{2n^2l^2F^2c_bD}$, mass transfer resistance parameter, dimensionless

Subscripts

b — Denotes value in bulk of electrolytic solution
s — Pertains to electrolytic solution phase
m — Pertains to metallic electrode phase

Superscripts

e — Pertains to equilibrium conditions
s — Pertains to values prevailing at the electrode surface outside the double layer region but at the inner edge of the diffusion layer
$\bullet$ — Pertains to reference position at $Z = 1$

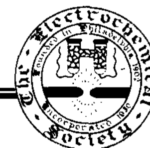
Technical Note



Transient Pressure Considerations in Charge Control of Sealed Batteries

Sidney Gross*

The Boeing Company, Seattle, Washington 98124

When sealed batteries with imperfect charge efficiency approach full charge, gas often evolves and increases pressure. In addition to the problems caused by increased heat and pressure, gassing causes mechanical forces within pores that contribute to structural breakdown; mechanical breakage causes loss in capacity and promotes shorting, and thus should be minimized (1). In this Technical Note it is shown that cell structural damage, when it occurs, can be greatest at the start of gassing due to transient pressure effects. An analysis is developed to compare the relative severity of this effect by the use of cell transient pressure data.

Analysis

The physical model postulated consists of a small pore of gas volume V_1 within a plate connected by a flow restriction to the larger gas volume V outside the plate. The pressures inside and outside the pore are P_1 and P, respectively. Gas of mass W leaving the pore either recombines on another electrode or causes a pressure increase in the sealed cell. The gas recombination rate may be approximated by

$$\frac{dW'}{dt} = KP \quad [1]$$

where W' is the unit mass of recombining gas, t is the unit time, and K is the gas recombination coefficient, determined experimentally.

The gas flow associated with cell pressurization is derived by differentiating the gas equation

$$W'' = C_1 \frac{PV}{T} \quad [2]$$

where W'' is the unit mass of pressurizing gas, T is temperature absolute, and C_1 is a gas constant.
Hence

$$\frac{dW''}{dt} = \frac{C_1 V}{T}\left(\frac{dP}{dt}\right) \quad [3]$$

* Electrochemical Society Active Member.

Key words: charge control, batteries, electrode gassing, gassing, pressure transients, sealed batteries.

Thus, the total gas flow from the pore is

$$\frac{dW}{dt} = \frac{dW'}{dt} + \frac{dW''}{dt} \quad [4]$$

$$\frac{dW}{dt} = KP + \frac{C_1 V}{T} \frac{dP}{dt} \quad [5]$$

The gas flow results from a pressure difference between P_1 and P. If this pressure difference is small relative to P, then the gas flow rate may be defined by the conventional orifice flow equation [Ref. (2), Eq. VIII.71, or Ref. (3), Eq. D] as follows

$$\frac{dW}{dt} = C_2 \left[\frac{P (P_1 - P)}{T} \right]^{1/2} \quad [6]$$

where C_2 is a constant related to geometry and gas composition.

Equation [6] and the subsequent Eq. [7], [8], and [9] describe incompressible flow conditions in which density change is negligibly small. Nevertheless, these incompressible relationships may be used for many compressible flow conditions with acceptable error. For example, when $P_1 - P$ is less than 10% of P, the error does not exceed 2%; when it is less than 25% of P, the error does not exceed 15% (4). A more precise form of Eq. [6], not used in this analysis, is

$$\frac{dW}{dt} = C_2 Y \left[\frac{P (P_1 - P)}{T} \right]^{1/2} \quad [6a]$$

which includes the expansion factor Y, derived and tabulated in Ref. (4). Combining Eq. [5] and [6]

$$P_1 - P = \frac{T}{C_2{}^2 P} \left[KP + \frac{C_1 V}{T} \frac{dP}{dt} \right]^2 \quad [7]$$

The pressure difference $P_1 - P$ is directly related to stresses on the plate structure due to gassing.

When the pressure is stabilized, Eq. [7] reduces to

$$P_1 - P = \frac{K^2 PT}{C_2{}^2} \quad [8]$$

When the gas recombination is small relative to the rate of gas generation, Eq. [7] reduces to

$$P_1 - P = \frac{1}{T} \left[\frac{C_1 V}{C_2} \right]^2 \left\{ \frac{\left(\frac{dP}{dt} \right)^2}{P} \right\} \quad [9]$$

where the first bracketed term shows the influence of the configuration and the second bracketed term shows the influence of the cell charge control method.

A useful application of these results is in the evaluation of charge control designs for sealed cells, especially those types for which overcharge is known to cause structural damage to positive plates. The forces in plates resulting from gassing are proportional to the pressure change parameter $(dP/dt)^2/P$ of Eq. [9], which can be calculated from the transient pressure curve during charging.

The significance of this can be illustrated using two typical pressure rise curves (Fig. 1) for charging with relatively slow gas recombination rate. Both cases start and end with equal pressures and rise with equal slopes; they differ only in the initial transient at the start of gassing. Calculation of the pressure change parameter (Fig. 2) shows that it is highest toward the start of gassing. Since this is directly related to stresses on the plate structure due to gassing, the highest stresses in plates can occur long before maximum pressure is reached, and occurs at the start of gassing if the initial pressure rise is linear. Charging that results in a transition pressure rise phase (curve A) develops smaller stresses than when the initial pressure change is abrupt (curve B).

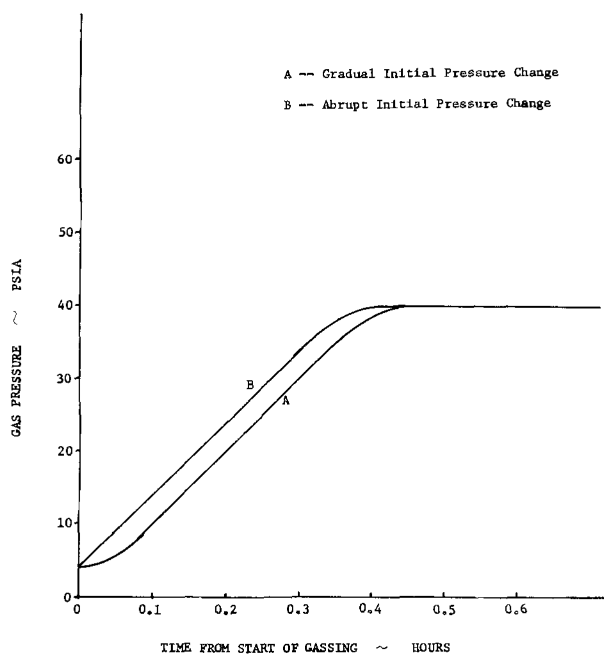


Fig. 1. Typical pressure rise in sealed cells

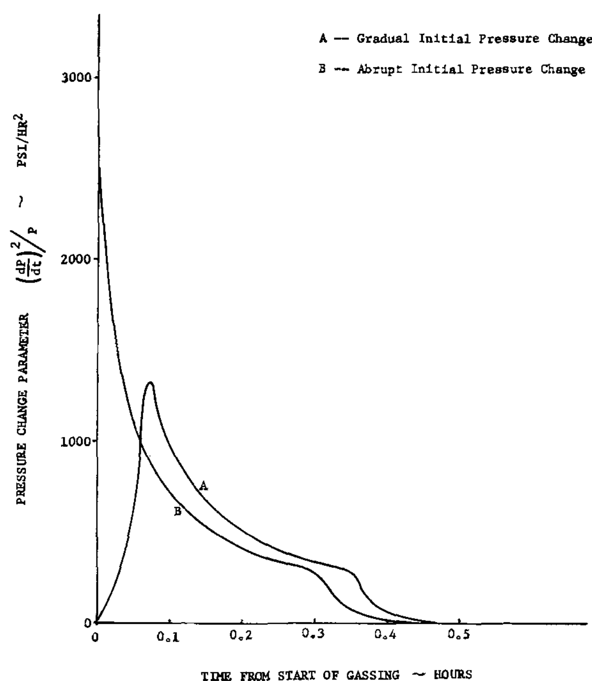

Fig. 2. Pressure change parameter for typical pressure rise

Discussion

The greatest stresses in plates due to gassing in sealed cells can often occur before maximum pressure is obtained. Thus, current tapering should start early enough to influence the initial gassing behavior, when stresses can be highest. Reliance entirely on methods that provide a charge termination signal is not sufficient, for this gives no consideration to transient pressure effects.

An order-of-magnitude estimate can be made of structural stress caused by gas evolution. Assume a cell pressure of one atmosphere, with an instantaneous pressure difference across a pore of 0.1 atm, and assume the pressure difference is developed across a particle 0.1 mil $\times$ 0.1 mil $\times$ 0.6 mil which is cantilevered from one end. With uniform loading across one face, the moment is 2.64×10^{-11} inch-lb, and the stress on the attached end is 160 psi. If the particle dimensions are

reduced by a factor of 100, the stress increases to 16,000 psi. Thus, gas evolution can develop substantial stresses on some particles, especially those that are small and poorly attached. As a point of comparison, lead and carbon have yield strengths of approximately 1200 and 900 psi, respectively, which could be much less at particle attachment points.

Experimental evidence for structural change caused by gas evolution has been obtained for the PbO_2 electrode (5, 6). These studies showed that gas generation within the structure formed channels through which gas escaped to the surface of the plate. Apparently the gas evolution dislodged many of the more loosely attached PbO_2 particles and carried them to the surface. Gas evolution is a common problem also with dry cells, resulting in movement of the electrolyte paste and bobbin (7). Even the sintered nickel positive electrode, though relatively strong, can also be damaged by gas evolution, especially plates weakened by cycling and corrosion; a common commercial manufacturing test to screen for weak plate structures is to overcharge for several days and observe structural damage caused by gassing.

Designing cells for maximum gas recombination rate can sometimes be questioned, based on this analysis; gas recombination electrodes can maintain low cell pressure during overcharge and give the illusion of safely controlling charge. Also, this causes pressure to be very low at the commencement of gassing, which is seen to be detrimental (Eq. [7]). Even for applications where continuous overcharge must be endured, low cell pressures could be harmful for a given gassing rate. Inert gas in sealed cells could be beneficial by providing at least a known minimum pressure, though there are disadvantages in other respects, such as decreased gas diffusion rates.

Brief Communication

A Method for the Stripping of Anodic Titanium Oxide Films from Metal by Using A-C Current

Masaki Yamazaki and Hiroshi Nozaki

Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo, Japan

Stripping of anodic oxide films from metals is of importance in connection with investigation on a structure of the oxide films, which would be provided for x-ray analysis or for electron diffraction analysis. Isolation of the films has been usually carried out by dipping the oxide films in a suitable solution which selectively attacks the film/metal interface without dissolution of the oxide films (1). However, it often happens that the films are not stripped completely from a metal substrate by employing this method.

Recently, it has been found that the pretreatment of titanium by using a-c current in a H_2SO_4 solution is effective in producing good insulating oxide films (2), and in fact the a-c pretreatment has been used in the formation of electrolytic titanium oxide films (3, 4). It is also found that this a-c procedure has an effect on stripping of the titanium oxide films from the titanium substrate. Thus, in this work we report the stripping of the anodic oxide films, using the a-c procedure.

Titanium electrodes, 50 mm × 20 mm × 1 mm, were prepared from ST-40 titanium (H_2, < 0.02%; O_2, < 0.20%; N_2, < 0.05%; Fe, < 0.20%). The electrodes have very thin films of unknown composition, and it is necessary to remove these films from the electrodes to do analyses. In order to make the surface clean, the

Key words: stripping, titanium oxide, oxide films, a-c current.

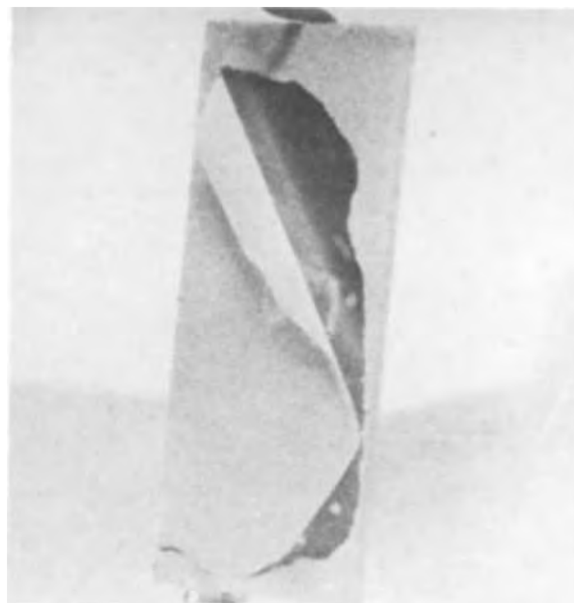

Fig. 1. Photograph of the stripping of an anodic film from titanium by using a-c current in H_2SO_4 solution.

electrodes were first treated in a 16 weight per cent (w/o) H_2SO_4 aqueous solution at 25°C, using a-c current (50 Hz) at 50 ~ 70 mA/cm^2 for 2 hr. After the pretreatment, the electrodes were anodized in a 8 w/o H_3PO_4 aqueous solution at 25°C with a current density of 3 mA/cm^2. The oxide films of controlled thickness from 500 to 3500Å were formed in this anodization.

The electrodes with the oxide films obtained were then electrolyzed by using a-c current in the same H_2SO_4 solution with the same current density mentioned above. After 10 ~ 20 min, the oxide films were beautifully stripped from the titanium substrate. A photograph of the stripping of a film (*ca.* 3500Å) is shown in Fig. 1.

Of course, the above method is applicable to the stripping of other titanium oxide films which are produced by other anodizations. It is considered that the stripping effect is based on a process in which the metal surface is dissolved without dissolution of the oxide films by applying a-c current in the H_2SO_4 solution. However, a detailed mechanism of the process is not clear at present.

Etch Channel Formation during Anodic Dissolution of N-Type Silicon in Aqueous Hydrofluoric Acid

M. J. J. Theunissen*,[1]

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven, The Netherlands

ABSTRACT

Anodic dissolution of n^+-, n-, and n^--type silicon in 5% aqueous hydrofluoric acid at moderate current densities results in the formation of etch channels which propagate in crystal-oriented directions in the monocrystal. Density and depth of the channels are a function of the applied voltage, the donor concentration, and the exposure time of the electrolyte under anodic bias conditions. It is assumed that the channel formation originates at spots with a lower breakdown voltage of the depletion layer which exists on the surface of the crystal under reverse bias conditions. Channel formation in epitaxial n layers can occur during preferential electrochemical etching of the n^+ substrate of n^+n^- structures. This is the case when the n^+ to n^- interface profile is not abrupt and when defects in the epitaxial layer are present. Some methods of restricting the influence of channels occurring during device processing are mentioned.

Several phenomena have been reported occurring during the anodic dissolution of n-type silicon in fluoride-containing solutions. In general terms the experimental conditions determine whether dissolution is complete, partial, or absent. One set of conditions of practical importance is that which leads to the complete dissolution of n^+ material but not n^-. In this case it is possible, for example, to remove by electrochemical etching the n^+ substrate from an n^+n^- structure while the very thin epilayer remains unattacked. This etching process was originally presented by van Dijk and de Jonge (1) and was more recently described (2-4).

Partial dissolution of n-type silicon was observed, and it was reported that preferential electrochemical etching of n^+n^- structures can lead to the formation of etch channels in the remaining thin n-type layer (2). Etch channel formation was also observed in homogeneously doped n-type silicon (2). During etching channels form and extend in crystallographical directions, leading to a complex network of caverns beneath the silicon surface.

In anodization experiments with n-type germanium and silicon, Uhlir (5) observed etch pits growing in crystallographically well-defined directions into the monocrystal.

Turner *et al.* (6) observed thick film formation on n-type silicon anodized in HF solutions. To explain the presence of the elemental silicon found in this film they suggested that after a primary dissolution reaction

$$Si + 2HF + 2e^+ (\text{holes}) \rightarrow SiF_2 + 2H^+$$

the SiF_2 rapidly disproportionates into Si and SiF_4 according to

$$2SiF_2 \rightarrow Si\downarrow + SiF_4$$

$$SiF_4 + 2HF \rightarrow H_2SiF_6$$

A brown layer was also observed on the etched side of the n^- layer after the selective removal of the n^+ substrate (1, 2).

In a recent paper by Meek (7) connection was made between the current density and the appearance of the silicon surface. For highly doped silicon three types of etching behavior were distinguished. Below a critical current density, J_{crit} (which depends on resistivity and orientation), a brown layer was found to be formed on the etched surface. In an intermediate range of current densities (from J_{crit} to J_{max}), dissolution occurred without film formation, but the surface was rough and pitted. Beyond J_{max} bright electropolishing occurred. For low doped n-type silicon Meek observed etch pit formation at all current densities, even at current densities below the saturation current.

In this paper a systematic experimental study of the occurrence of channels in silicon as a function of donor concentration and silicon voltage or current density is reported. The formation of channels during etching and the dependence of their density, length, and propagation direction upon conditions used are demonstrated. It is further shown that the published reports of brown layers, etch pits, and channels in n-type silicon refer essentially to the same phenomenon of partial dissolution and that these apparently different features are all attributable to various degrees of attack of the monocrystal.

Experimental

N-type, Czochralski-grown, antimony-doped silicon was used. After the sawing and lapping procedures, the slices were etched for 3 min in 1 vol HF (48%), 2 vol HAc (98%), and 3 vol HNO_3 (fuming). The etch rate of this mixture is about 15 μm/min. The surface orientations used were (111), (110), and (100).

Key words: anodic dissolution, etch channels, silicon, brown layers, crystal-oriented attack, monocrystal.

The donor concentration, deduced from resistivities, ranged from $4 \cdot 10^{18}$ to $5 \cdot 10^{14}$ cm^{-3}. The three concentration ranges n^+ ($N_D > 2 \cdot 10^{18}$), n ($2 \cdot 10^{18} > N_D > 2 \cdot 10^{16}$), and n^- ($N_D < 2 \cdot 10^{16}$) differ from each other in electrochemical etch behavior at 10V as mentioned in (2).

The epitaxial slices used were n^+n^- structures with a highly doped substrate ($N_D > 2 \cdot 10^{18}$ cm^{-3}) and epitaxial layers phosphorus-doped to about $5 \cdot 10^{15}$ cm^{-3}. The epitaxial growth was by either a $SiCl_4$ process at 1220°C as described in (2) or a SiH_4 process. The latter was carried out at 1050°C in a water-cooled horizontal reactor (8), using a SiH_4 and H_2 gas mixture. The growth rate was about 0.25 μm/min.

The procedure for the electrochemical etching of the slices has been described (2). Most of the experiments were carried out at a potential difference of 10V between anode and cathode in a 5% aqueous HF solution. If necessary, ohmic contact between the platinum contact strip and silicon was made by an additional n^+ diffusion.

Measurements of the current density J against the silicon potential V were carried out using an arrangement as sketched in Fig. 1(a) and 1(b). The potential difference between anode and cathode was increased manually. The potential of the silicon working electrode was measured against a calomel reference electrode (saturated KCl). As can be seen in Fig. 1(b) the silicon slice is contacted at the rear by an outer and an inner contact. The outer contact was used for the application of the potential difference between the silicon and a platinum mesh electrode. The inner contact was used to measure the silicon electrode potential against the calomel electrode for very low current densities at the silicon-metal contact.

Etch channels, formed during the electrochemical dissolution process were studied with a microscope at surfaces or cross sections of the slices. The cross sections were mostly {111} planes obtained by cleavage. A 3-5 sec treatment in Sirtl etchant (9) was used to reveal the channels.

Laue diffraction patterns were used to determine the degree of crystallinity of brown, channel-rich layers and infrared absorption measurements for determining the composition.

Experimental Results and Discussion

Anodic Dissolution of N-Type Silicon

The charge distribution at an n-type silicon anode in an aqueous HF solution is shown in Fig. 2(a). Because of the positive bias of the silicon, a positively charged depletion layer forms at its surface. A thin layer containing a high concentration of negatively charged ions is formed in the electrolyte. As shown by Myamlin and Pleskov (10), the potential drop in the electrolyte and the Helmholtz layer in sufficiently concentrated solutions (relative to the free charge concentration in the semiconductor) can be neglected. The voltage drop in the system is almost completely supported by the depletion layer in the semiconductor. The depletion thickness and the corresponding electric field are functions of the donor concentration of the n-type silicon. Anodic dissolution is governed by the supply of holes at the surface of the semiconductor (6). Taking the dissolution as divalent (6), then the following reaction may be assumed to occur

$$Si + 2HF + 2e^+ \rightarrow SiF_2 + 2H^+$$

Without an additional generation or injection mechanism there will be essentially very few holes at the surface of the n-type material. Hole concentration at the silicon surface can be increased in several ways (6), one of which is the application of a sufficiently high reverse bias voltage. Excess holes are generated by impact ionization or Zener breakdown at the depletion layer and silicon can dissolve. The evidence of a breakdown mechanism has been demonstrated by Uhlir (5). The selective electrochemical etching of n^+n^- slices can be explained on the basis of the difference in breakdown voltage between n^+ and n^- silicon.

In order to predict whether or not breakdown occurs, the maximum electric field of the depletion layer, E_{max}, will be calculated and compared with the critical field, E_{crit}. The situation as sketched in Fig. 2(a) can be treated as a metal-n silicon or an abrupt p^+n junction under reverse bias. The following simplifying assumptions must be made: (*i*) The semiconductor-electrolyte interface is planar and infinitely extended (width >> depl. depth). (*ii*) The semiconductor is homogeneously doped and no defects are present which lower the breakdown voltage. (*iii*) The electrolyte n-type Si system has a charge distribution

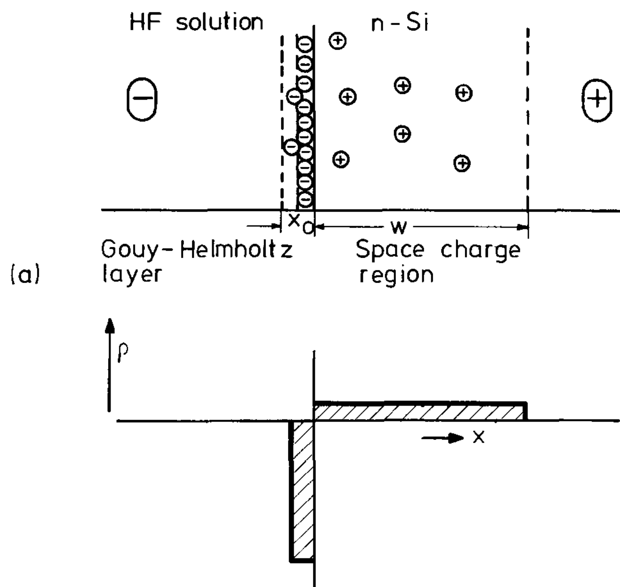

Fig. 2. (a) The HF electrolyte-n-type Si interface under anodic bias conditions and (b) schematic representation of the charge distribution.

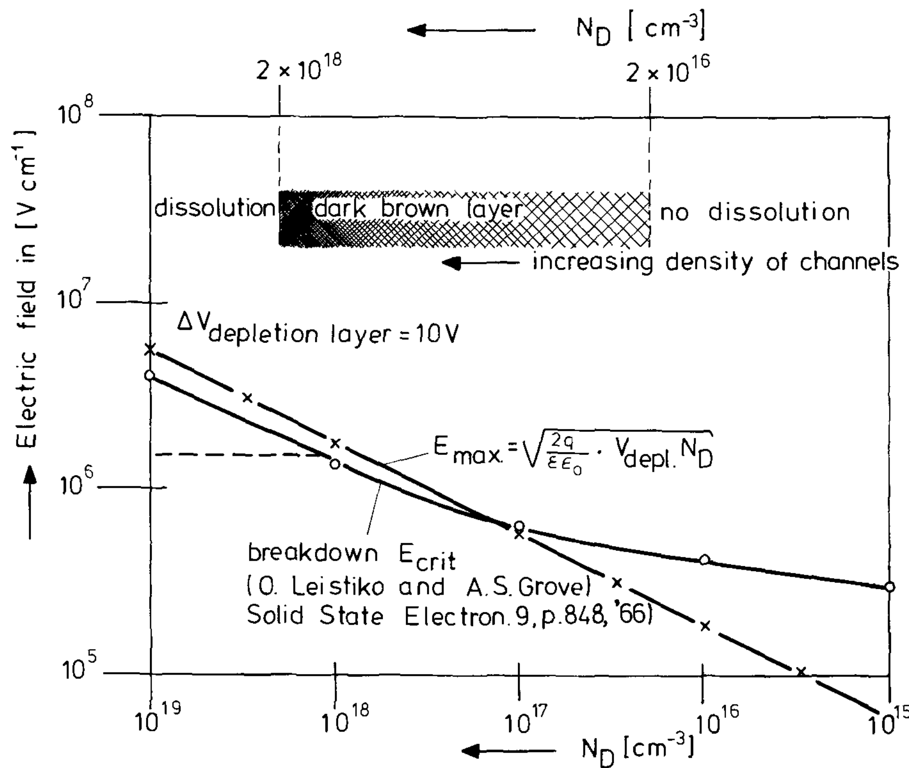

Fig. 3. The calculated maximum electric field, E_{max}, and the value of the breakdown field, E_{crit}, as a function of the donor concentration N_D. The upper part of the graph schematically indicates the three ranges of different etch character found in practice after 30 min etching.

as sketched in Fig. 2(b); the maximum field, E_{max}, exists at the silicon-electrolyte interface.

The value of E_{crit} as a function of the donor concentration is given in (11). Figure 3 gives the values of E_{crit} and E_{max} for a 10V drop across the depletion layer. In the upper part of the same graph, an indication is given of what has happened in practice during 30 min etching of dislocation-free material. It can be seen that the E_{max} value exceeds the value of E_{crit} at donor concentrations above 2×10^{17} donors/cm^3 and dissolution due to breakdown of the depletion layer may be expected. Above 10^{18} donor/cm^3 tunneling is the most probable breakdown mechanism. The field at which tunneling may occur is indicated by the broken line. In the donor concentration range below 2×10^{17} cm^{-3}, E_{max} is lower than E_{crit}. It is expected that no holes are generated by impact ionization and no dissolution should occur.

The influence on the etching behavior of the donor concentration and defects.—In practice the situation is much more complicated as some of the approximations made are not valid. In fact three ranges of different etch character were found after a 30 min etch of dislocation-free, homogeneously doped n-type material (2). Anodic dissolution occurred (at 10V) when the donor concentration was higher than about 2×10^{18} cm^{-3}. For impurity concentrations between 2×10^{18} and 2×10^{16} cm^{-3} a brownish-black, pitted surface was formed. Sections of the slices showed higher density of channels at the higher donor concentrations. In the range below about 2×10^{16} cm^{-3} no measurable dissolution occurred and no channels were detected.

Figure 4 shows the current density *vs.* time plot for dislocation-free, float zone silicon of various donor concentrations at a potential difference of 10V between anode and cathode. Pre-etched samples were used. The increase of the current density for the samples of $(1.3\text{-}3.7) \times 10^{16}$ and $(2.5\text{-}13) \times 10^{15}$ cm^{-3} coincides with the formation of etch channels which were found in these samples. The observed higher current density may be explained as an increase in real etching surface, which means that the real current density does not necessarily change. The other samples exhibited no channels; uniform etching was observed with the highly doped sample ($N_D = 4 \times 10^{18}$ cm^{-3}); the low-doped samples did not show a visible attack. However when silicon material with dislocations,

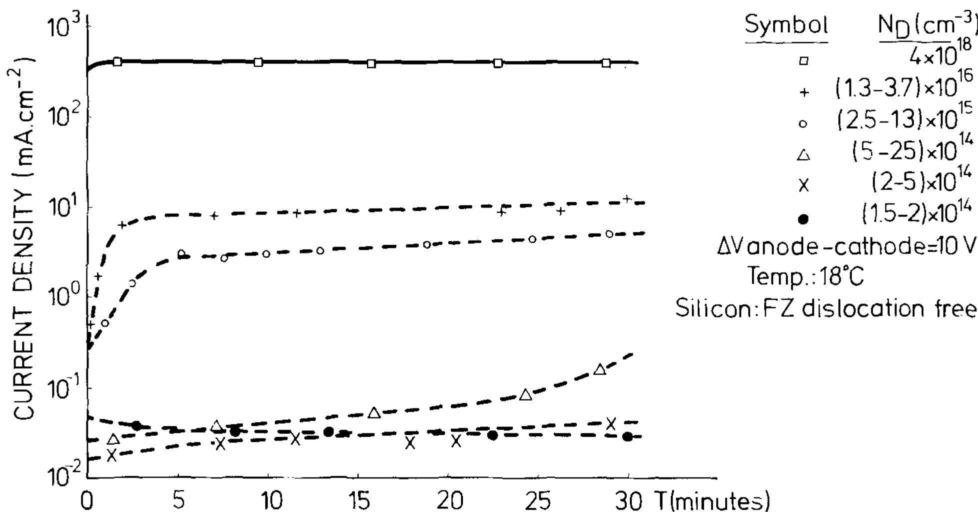

Fig. 4. Current density *vs.* time for silicon of various donor concentrations for an etching time of 30 min at 10V.

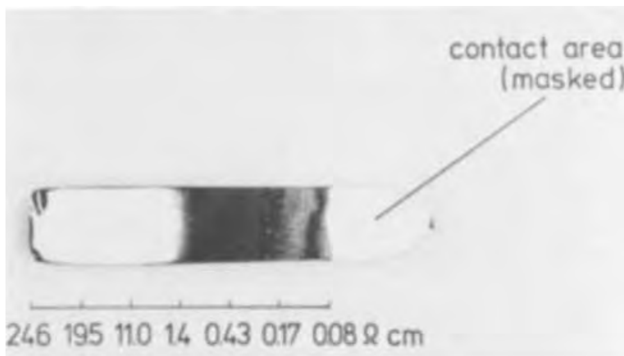

Fig. 5. Longitudinal section of a silicon bar (float zone, dislocation free) with varying resistivity. The surface of the section has been subjected to the electrochemical etching process for 60 min.

scratches or other kinds of mechanical damage was used, etch pits surrounded by a pattern of fine lines were found in low-doped samples. Cross sections of these slices revealed networks of etch channels around these pits. Bellin and Zwicker (12) did anodization experiments on n^- silicon in hydrofluoric acid and copper sulfate. They found a remarkable agreement between the channel and dislocation networks which are often observed around defects.

Figure 5 shows the etched side of a longitudinal section of a float zone, dislocation-free silicon bar of varying resistivity. This bar had been subjected to the electrochemical etching process with an anode-cathode voltage of 10V. The dark area of the n-zone and the bright unattacked n^- zone are clearly visible; the transition between the two zones shifts to higher resistivity material when the etching time increases.

Figure 6, shows *J-V* curves for some silicon samples of various donor concentrations. The dislocation density of these samples was low. The potential difference between anode and cathode was increased stepwise. Current and voltage were measured within 30 sec after the application of the potential. The total measuring time was less than 30 min. Because the high resistivity samples exhibited *J-V* curves that were very sensitive to surface damage such as scratches, lapping, polishing processes, or surface contamination, pre-etched samples were used. As can be seen the low-doped samples exhibited breakdown-like characteristics. The breakdown voltage seems to be inversely proportional to the donor concentration, but it is still much lower than that expected theoretically. The explanation may be that during the measurement of the *J-V* curves channels are etched which influence the shape of these curves. Meek (7), for example, observed etch pits even at current densities below the saturation current. The influence of the channel formation on the *J-V* measurement can easily be demonstrated by repeating a *J-V* curve of the same slice. This is shown in Fig. 7. *J-V* curves for the n^+ (and p)-type silicon appeared to be much more reproducible (7).

Channel Etching in n-Type and n^+-Type Silicon

At silicon electrode voltages of 10V etch channels were always formed in moderately doped n-type silicon ($2 \times 10^{18} > N_D > 2 \times 10^{16}$ cm^{-3}), but the attack did not seem to be related to crystal defects. The density of the channels increased with the donor concentration. With N_D about 10^{18} cm^{-3} cross sections showed a brownish layer in which the channel density was so high that the individual channels were hardly visible. Figure 8(a) and 8(b) show cross sections of two n-type samples with donor concentrations $N_D = 2 \times 10^{18}$ cm^{-3} and $N_D = 2 \times 10^{16}$ cm^{-3}. As can be seen the channel density in the highly doped sample is much higher than in the lower doped sample. Moreover the highly doped sample shows a straight line between the brown, channel-rich structure and unattacked silicon substrate whereas the low-doped sample shows fluctuations of the channel depth along the section. The fluctuations could be attributed to fluctuations of the donor concentration (resistivity striations) along the section. For the low-doped samples the local etch rate seems to be a function of the local donor concentration. This is not the case with the highly doped samples although striations were found to be present.

For n^+ silicon ($N_D > 2 \cdot 10^{18}$ cm^{-3}) it was found that etching at 10V resulted in a bright electropolished surface. The corresponding current density was about 130 mA·cm^{-2}, but this value could be considerably

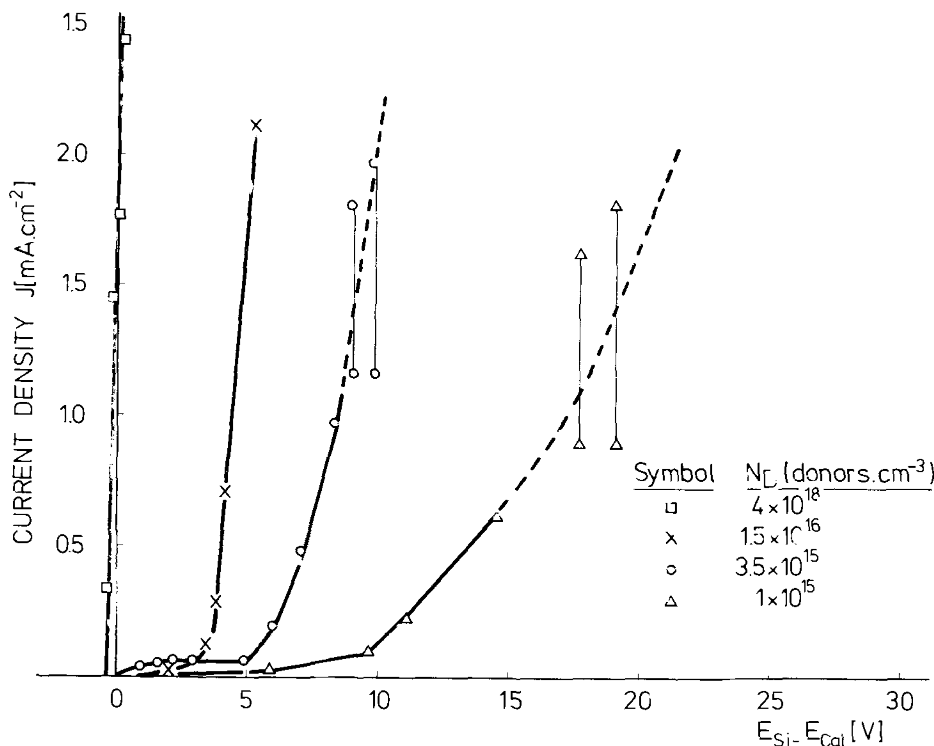

Fig. 6. Current density vs. electrode potential for various donor concentrations.

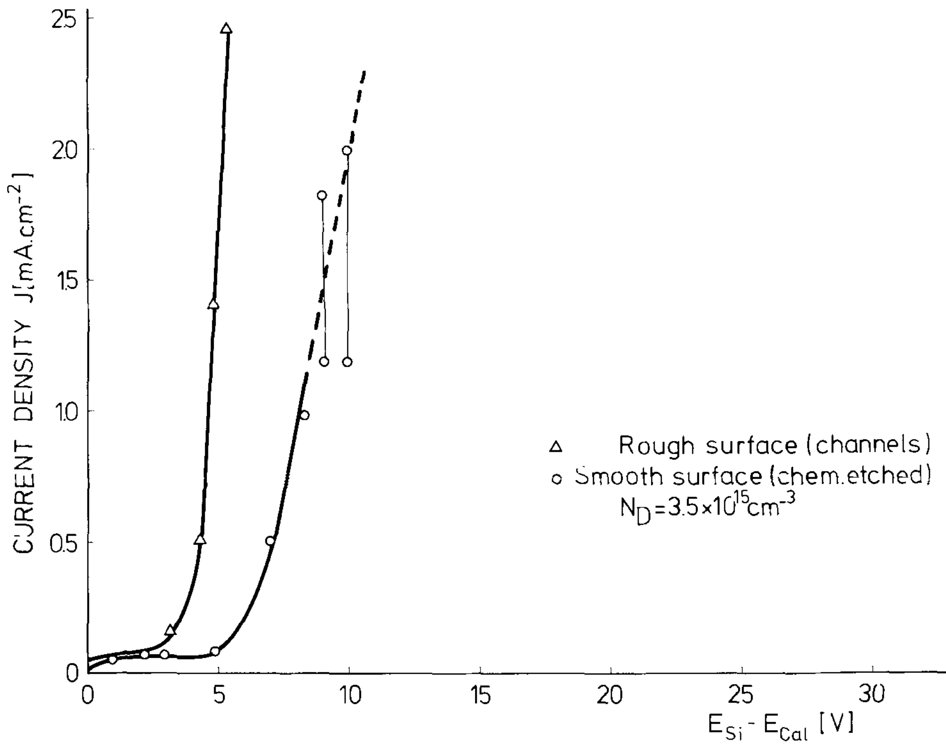

Fig. 7. Current density vs. electrode potential for a smooth and a rough surface.

increased by stirring, which implies that the etch rate is controlled by diffusion. This is in agreement with Turner's observation (6). At lower voltages (or current densities), depending on the donor concentration, the formation of a brownish layer was observed. In order to determine the crystallinity of the brown layers, n^+- and n-type silicon samples were totally converted to channel-rich structures. X-ray diffraction patterns [Fig. 9(a) and 9(b)] showed that except for minor differences, the monocrystalline character was unchanged. Infrared transmission spectra confirmed that the brown layer samples were almost pure silicon. These observations are consistent with the idea that the brown layers consist of a framework of the monocrystal, which is left after the channel etching.

As reported by Meek (7) the brownish layer formation on n^+ samples is typical for current densities below J_{crit}. J_{crit} is the current density at which the brown layer starts to be detached. Above J_{crit} it is not likely that the etch rate is determined by the availability of holes, but rather by the supply of F^- ions to the etching surface. At current densities lower than J_{crit} it is difficult to say which step determines the etch rate. Meek's measurements (13) suggest that a trap to band transition mechanism supplies holes to the etching interface. The dissolution process itself seems to be divalent (7).

As indicated by the short time needed to reveal the channels in Sirtl etchant, inside these channels there is probably some fast etching material. Amorphous

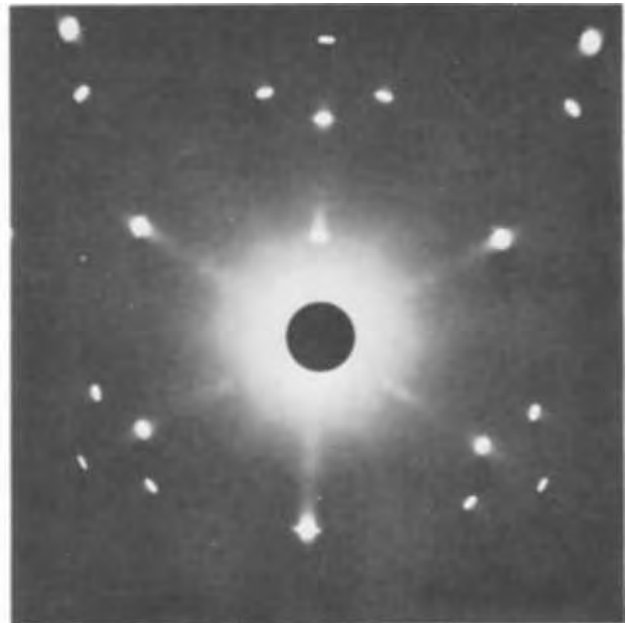

Fig. 9(b). X-ray pattern of the same slice electrochemically converted into "brown layer" structures.

silicon or silicon hydride compounds have been reported elsewhere (14) The presence of the amorphous silicon had been explained by Turner (6) by the disproportionation of SiF_2. The presence of SiH_4-like compounds may be due to hydrogen passivation of the surface. At current densities lower than J_{crit} hydrogen evolution was observed. As described by Memming and Schwandt (15), hydrogen may be evolved with the reactions

$$SiF_2 + 2HF \rightarrow SiF_4 + H_2\nearrow \quad \text{or}$$

$$2SiF_2 \rightarrow Si + SiF_4$$

$$Si + 2H_2O \rightarrow SiO_2 + 2H_2\nearrow$$

However, more information will be needed to support this hypothesis, because most of the relevant interface processes are still unknown.

The Direction of the Channels in the Monocrystal

Figure 10 shows the surface and (111) cleaved sections of (111), (100), and (110) oriented silicon slices. The channels or the points of intersection of the channels with the surface or cleavage planes were made visible after 3 sec Sirtl etching. Slices with a (111) surface orientation were found to give channels lying in {111} planes and in the [110] directions. The fact that the channels grow out in well-defined directions can point to either a bulk property of the silicon lattice (open directions where impurities prefer to collect) or to a surface mechanism (influence of the

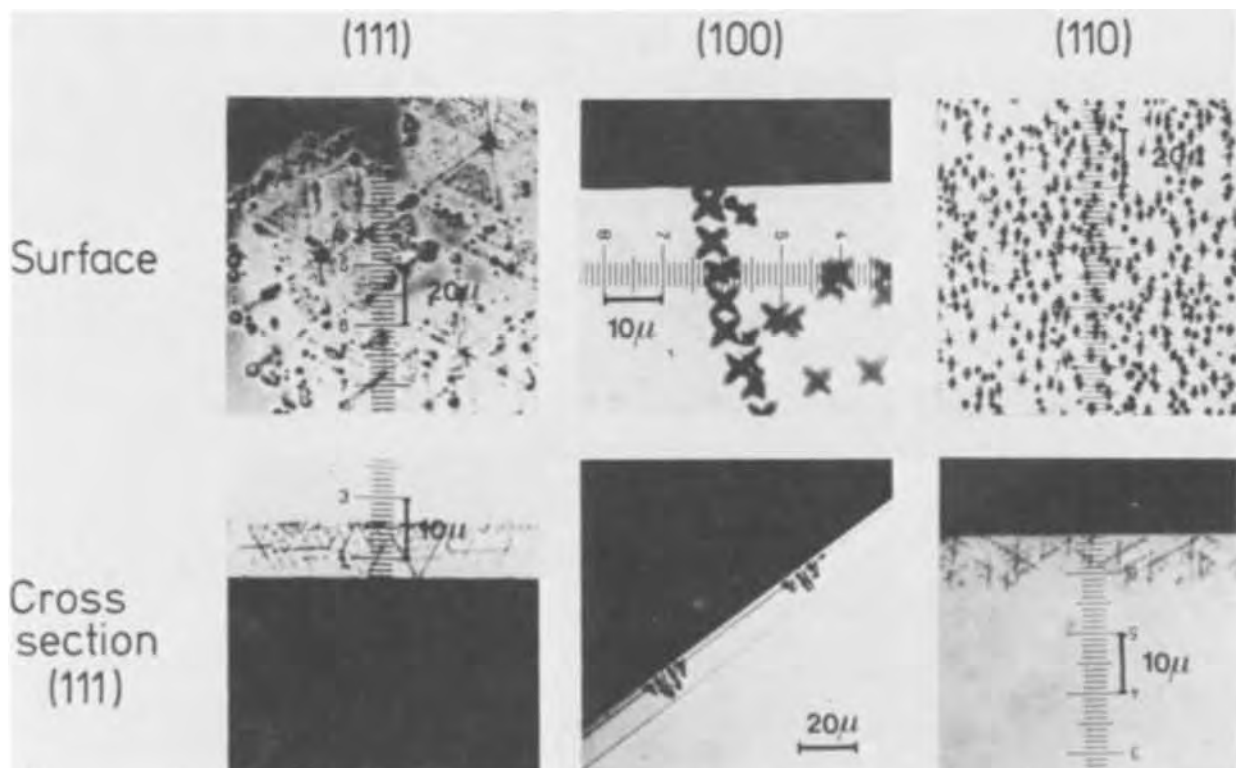

Fig. 10. Surface and (111) cleavage sections of slices of the (111), (100), and (110) orientations

adsorbed or chemisorbed ions at the surface). As mentioned before, it is reported elsewhere (14) that brown layers contain, in addition to silicon, SiH_4-like compounds. Hydrogen passivation of the interior surfaces other than in the channel propagation directions might explain the anisotropic etching behavior.

Etching of Epitaxially Grown Structures

Preferential etching of $n^+ n^-$ structures was carried out at 10V (2). The thin n^- layer was always covered by a brown layer. In practice the $n^+ n^-$ interface profile is not abrupt; its slope depends on the time and temperature of growth, autodoping, and subsequent heat treatment. In fact it is a $n^+n\ n^-$ structure, in which the thickness of the intermediate n layer depends on the processing. During the electrochemical treatment the n-type layer is converted into a brown, channel-rich layer. Moreover it was observed that the high resistivity epitaxial n^- layer, which is not expected to etch, sometimes contains channels (Fig. 11). From the n layer a minor part of the channels grows out into the n^- layer. Because the channel formation is a time-dependent process, the channel depth across the n^- layer (2) will follow a distribution schematically indicated in the figure (Fig. 12). In this figure diffused areas in the epitaxial layer are indicated. The areas which are farthest from the contact are attacked because the electrolyte can communicate

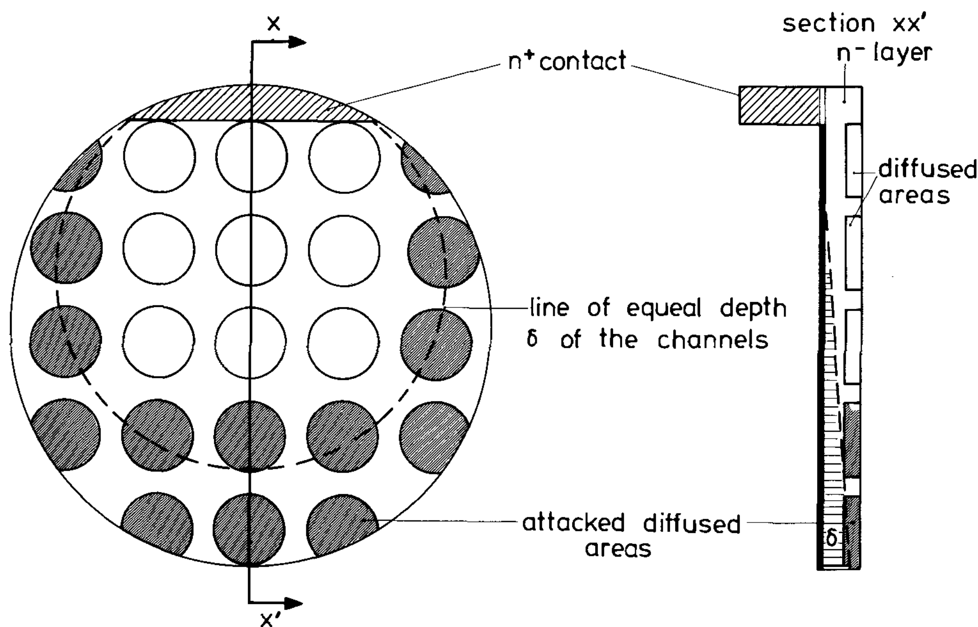

Fig. 12. Schematic representation of the attack of diffused areas through channels.

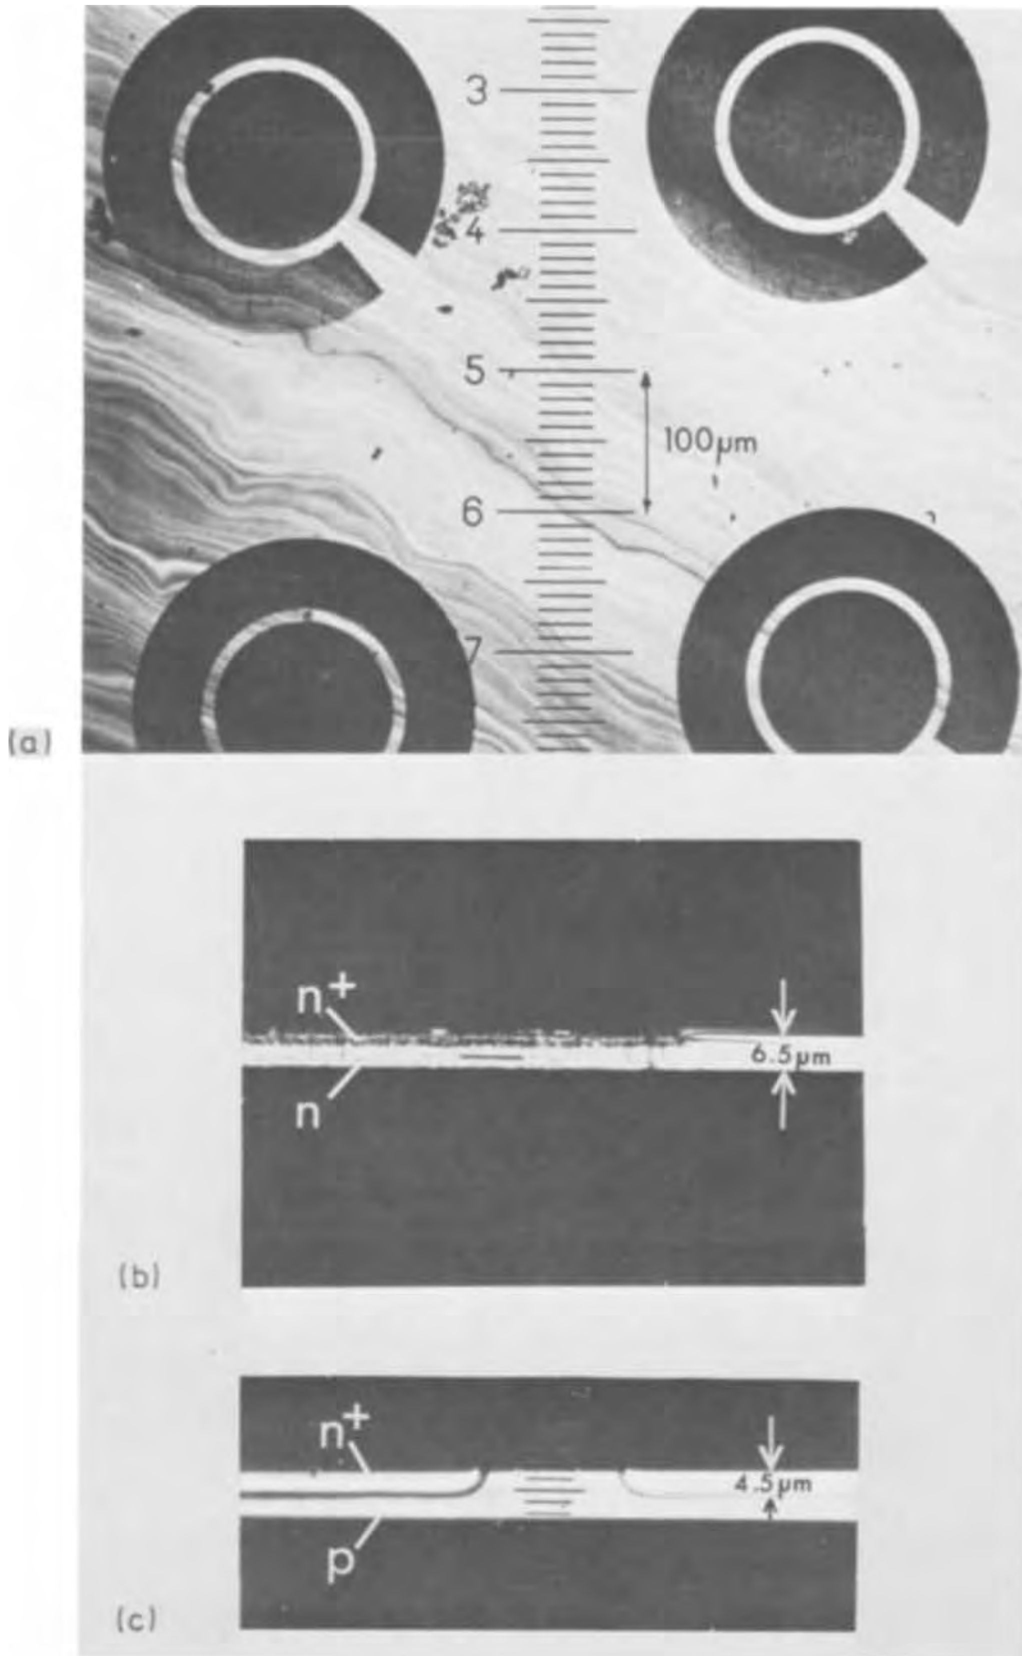

Fig. 13. Photograph of the attack of n$^+$ diffused areas: (a) the etched side of the n$^-$ layer, (b) detail of a cross section, which shows that the n$^+$ areas are attacked through the thin intermediate n$^-$ layer, and (c) cross section of a thin p-type layer, in which n$^+$ areas have been made by diffusion. The n$^+$ areas and the p-type layer are not attacked.

here with the highly doped regions. This distribution of the attacked diffused areas was often observed. Moreover n$^+$ diffused areas were found to be readily attacked with respect to p$^+$ diffused areas, as demonstrated in Fig. (13(a) and 13(b). This is probably due to the increased hole generation at defects (dislocations, precipitates) at the n$^+$ diffused regions. Meek (4) points to the field-aided diffusion of minority carriers (holes) toward the etching interface. This may also be the case with n$^+$ diffusions in p layers, but no influence on the etching behavior would be expected because holes are already the majority carriers. That n$^+$ diffusions in p-type layers are not attacked is demonstrated in Fig. 13(c).

One means of preventing attack of the diffused areas is to take a relatively thick intermediate n$^-$ layer between the n$^+$ diffusion area and the n$^+$ substrate. A second method employs an additional p-type layer which can be made between the n$^+$ substrate and an n-type epitaxial layer. P-type silicon exhibits no etch channels. Some other methods are suggested in Ref. (4).

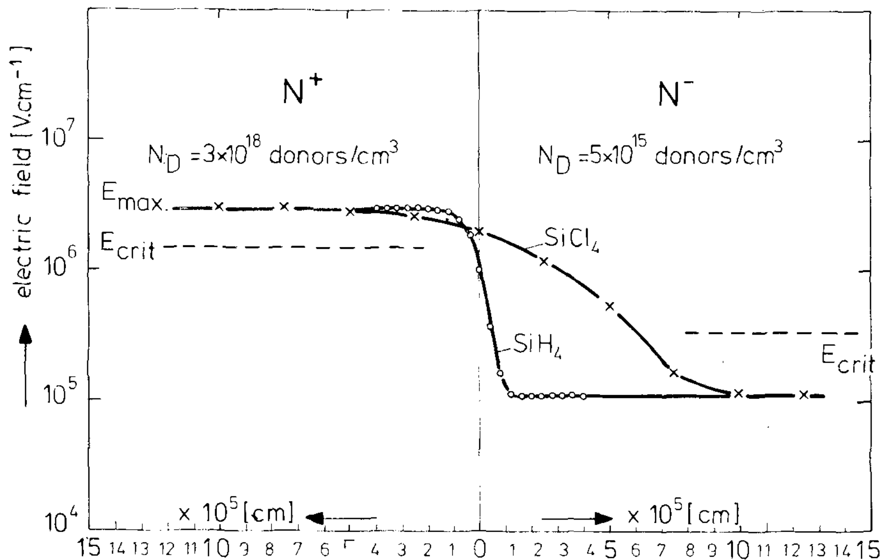

Fig. 14. The calculated electric field, E_{max}, near the epitaxial interface during etching, assuming $V_{\text{depletion layer}} = 10V$; the distribution of donor atoms is given by $N(x) = N_o/2 \text{ erfc} \left(\frac{x}{2\sqrt{DT}}\right)$ Heat-treatment during epitaxy gives $\sqrt{DT} = 4 \cdot 10^{-6}$ cm for SiH_4 and $25 \cdot 10^{-6}$ cm for $SiCl_4$. The breakdown field, E_{crit}, has been indicated by the broken line.

In order to reduce the thickness of the outdiffused layer between the n^+ substrate and the n^- epilayer, epitaxial structures were made at relatively low temperatures (1050°C) using SiH_4 epitaxy. The donor concentration of the n^- layer did not exceed 5×10^{15} cm^{-3}. It was found that when such structures were etched preferentially at 10V, no channels were detected in the n^- layer. This contrasts with a silane-grown n^+n^- slice that has been subjected to an additional high-temperature treatment and with an n^+n^- slice made by $SiCl_4$ epitaxy at 1220°C. Typical etch times were about half an hour in both cases. The difference in etching behavior might be explained by the difference in outdiffusion profile of the donor concentration. Assuming that the interface profile of n^+ to n is determined only by outdiffusion and not by autodoping (16) during epitaxy, we can calculate E_{max} from the Poisson equation, using $\mathbf{V}_{\text{depl.}} = 10V$, and $N(x)$ should be given by

$$N(x) = \frac{N_o}{2} \text{erfc}\left(\frac{x}{2\sqrt{DT}}\right)$$

$N(x)$ is the donor concentration at a distance x from the interface, N_o the concentration of the n^+ silicon, D the diffusion coefficient, and T the diffusion time. Figure 14 shows the variation of the E_{max} value across the interface for epitaxial slices made by the SiH_4 and $SiCl_4$ process. The value of E_{crit} has been indicated for the n^+ and n^- silicon. The intermediate layer, which is converted into a brown, channel-rich zone, is much thinner in the SiH_4 slices. Moreover, E_{max}, drops sharply for SiH_4, whereas the corresponding change in E_{crit} is more gradual.

N-type layers made by SiH_4 and $SiCl_4$ epitaxy having equal resistivities and thicknesses were compared by four-point-probe resistivity measurements after etching of the n^+ substrate. It was found that SiH_4-made layers systematically showed higher resistivities. Apparently for the $SiCl_4$-made layers the tail of the outdiffusion profile and the monocrystalline framework of the brown layer contribute to the conductance. This means that in the case of SiH_4 the potential drop alongside the slice is greater. Areas farthest from the contact place have such a low electrode voltage that the channel etching process probably does not occur.

Conclusion

During the anodic dissolution process of n^--, n-, or n^+-type silicon, etched channels can be formed, which grow out in crystallographically well-defined directions in the monocrystal. The origin of these etch channels is ascribed to the local breakdown of a barrier at the surface of the silicon. This provides holes which are necessary for the etching process. For high resistivity silicon a depletion layer model can be used. The maximum electric field E_{max} at an electrolyte-silicon interface is a function of the voltage across the layer and the donor concentration. Breakdown will occur when $E_{max} > E_{crit}$. In practice local breakdown will occur, dependent on crystal defects, impurities, fluctuations of the donor concentration, *etc.* Highly doped silicon exhibits a high channel density only at low values of the silicon electrode potential.

J-V curves for low-doped silicon are dependent on the growing process of the channels. This means the shape of the curves is time dependent.

The occurrence of etch channels in the n^- layer during preferential electrochemical etching of n^+n^- can be easily explained with the results of the homogeneously doped samples. The anode voltage, the donor concentration of the n^+- and n^--type silicon, the steepness of the n^+n^- interface profile, the presence of defects in the n^- layer (often introduced by diffusions), and the total exposure time of the n^- layer to the electrolyte must be taken into account. Using standard etching conditions (10V) it was found that etch-through effects between the diffused areas and the n^+ substrate can be eliminated in the following ways: (*i*) Take a relatively thick intermediate n^--type layer between the n^+ substrate and the diffused areas. (*ii*) Use an additional p layer between the n^+ substrate and the n^- layer. (*iii*) Reduce the total amount of heat-treatment which precedes the electrochemical process. Good results were obtained with SiH_4 epitaxy carried out at 1050°C and $N_D = 5 \times 10^{15}$ cm^{-3} for the n^- layer. Typical etch times were half an hour.

Acknowledgments

The author wishes to thank Mrs. E. Olijdam, who carried out much of the experimental work, W. J. Schouten for the scanning electron microscopy, C. Langereis for the x-ray diffraction techniques, and C. Albrecht for mathematical assistance.

Comments by T. L. Tansley, E. Kooi, J. de Jonge, and G. Schwandt were very helpful.

The Chromium-Glass Interface

R. G. Frieser

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Using a combination of etch and contact angle techniques, three regions were identified in the thin chromium films deposited on glass substrates. It appears that the thin native oxide surfaces do not usually etch homogeneously. The glass/chromium interface, approximately 50-100Å thick, is formed by modifying the original glass due to the penetration of the chromium during the oxidation process. The interface seems to become a chrome-glass with the chromium concentration decreasing as a function of the depth of penetration.

The prevalence of the use of thin chromium films on oxides and glass substrates in the present technology makes the study of the chromium-glass interface particularly relevant.

Chromium was chosen for many applications because of its good adhesion to glass, its hardness, and the relative inertness which is protected by a supposedly uniform layer of oxide. Attempts to peel chromium films ~1000Å or less from glass substrates invariably resulted in a layer of glass coming off with the chromium. This indicates that rupture occurs below the "interface," since apparently the cohesive forces in the glass adjacent to the interface are smaller than the adhesive forces of the chromium to the glass. Furthermore, the original glass surface may have become modified during the chromium deposition process, in which case one would expect an interfacial region rather than a sharp interface. The properties in this interfacial region would change gradually from the properties of pure chromium to that of the glass.

By etching off successive layers of the chromium films below the "interface" and measuring the contact angles that drops of water form with the respective surfaces, it appears that an interfacial region was located.

Experimental Procedure

Contact angles were measured using a Ramé-Hart Contact Angle Goniometer. Uniform water drops were dispensed from a precision liquid dispenser with 0.1% accuracy of the dispensed volume through a 0.1 ml range. The actual volume of the drops used was 2×10^{-4} ml. Only water distilled in a quartz still from a potassium permanganate solution was used. Photographs of three drops on each respective surfaces were taken and the contact angles were determined using a geometric technique. Thus, the contact angles could be measured to $\pm$ 1°. An acidic ceric sulfate solution (20g $Ce(SO_4)_2$, 164 ml HNO_3 conc, 6 ml H_2SO_4 conc, and 330 ml D.I. water) was used to etch the chromium films.

Surface Cleaning

Meaningful contact angle measurements can only be made on homogeneous surfaces. However, highly nonuniform etch rates on large area chromium films were noted in spite of the fact that the optical density of these films was uniform prior to etching. Similar results were obtained with conventional standard alkaline etchants. Ordinarily this effect may escape attention, because the chromium is completely removed between patterns etched into the chromium films. It was further noted that this phenomenon is highly surface sensitive. Various schemes of cleaning the chromium surface followed by an annealing procedure at different temperatures in a nitrogen furnace resulted in even more irregular etch rates across the treated films. The etch rates were particularly irregular when organic solvents such as acetone, trichloroethylene, methanol, or freon were part of the cleaning cycle. This was true even when either was preceded or followed by an oxidant.

However, it was possible to obtain sufficiently homogeneous surfaces by the following technique: One-half hour boiling of the chromium-coated substrate in an ammonia-hydrogen peroxide solution (80 ml 30% hydrogen peroxide, 35 ml 58% ammonium hydroxide, and 885 ml water) at 80°C, rinsing in deionized water at R.T., boiling for 15 min in deionized water, rinsing again in deionized water (R.T.), and inserting into the etching solution while still covered with a uniform film of water.

Presumably, this procedure not only cleaned the surface but hydrated the thin native oxide on top of the chromium film.

Further verification for the inhomogeneity of the surface was obtained from ellipsometric studies of the surfaces of thin chromium films on glass substrates prior to cleaning.

Because neither the type of oxide, much less the optical constants, were known, the delta and psi values which are complex functions of the refractive index, the wavelength, and the angle of incident light could only be compared (1). Employing an immersion technique, data on the chromium-glass interface were obtained in the same study. The following conclusions support the observations noted during the etching experiments: (*i*) The free chromium surface is very nonuniform; data were highly ambiguous. (*ii*) The chromium/glass interface data were extremely uniform.

Key words: chromium-glass, etching, contact angle, penetration, oxidation, interface.

Table I. Freshly cleaned vs. aged chromium surface

Position of contact angle on surface	Top	Center	Bottom
Freshly cleaned	16°	24°	21°
24 hr aging in air	45°	46°	43°
Optical densities	2.89	2.81	2.80
Recleaned	18°	18°	21°
24 hr aging in air	52°	42°	40°
Optical densities	2.86	2.81	2.78

Table II. Chromium-glass interface

Position of contact angle on the surface	Chromium glass Original chromium	Chromium glass Etched 14'30"	Bare glass Original glass	Bare glass Etched 14'30"
Fresh				
Top	17	90	6	13
Center	19	91	7	17
Bottom	20	83	5	9
Aged for 24 hr				
Top	38	86	12	14
Center	37	81	6	14
Bottom	41	88	9	19

(*iii*) No obvious correlation was observed between the optical density of the films and delta values.

Contact Angle Study

After obtaining homogeneous surfaces by the above technique, contact angles were measured before etching the chromium films, on freshly etched, as well as aged chromium and glass surfaces.

Table I is a summary of representative data of contact angles of water on cleaned and air-aged chromium surfaces. Three drops on each sample were measured. Top, center and bottom refers to the location of the drop on the surface to be measured.

These data indicate that the increase in the contact angle on aging were repeatable and probably a function of the degree of hydration of the surface. The constancy of the optical densities shows that the observed surface changes should be attributed to a reversible transformation of the surface and that no loss of chromium metal seems to be involved. The effect of overetching on the chromium and bare glass side is shown in Table II. The samples were exposed to the etchant approximately twice as long as required to completely remove the chromium film.

Only the original chromium surface exhibits an increase in the contact angle. However, a dramatic increase in the contact angle after etching on the chromium side is observed—indicating that the glass adjacent to the chromium has different etch characteristics. Replica electron micrographs showed that the high contact angle was not due to surface roughness. Figure 1 shows that, on the scale 24,800X, the surface with the lower contact angle (16°) appears rougher than the high angle surface (85°). It appears that the noted roughness is much too small to have an effect on the contact angle.

The same observation can be made in Fig. 2 (176X). Again, little, if any, surface roughness can be noted which could account for the difference in contact angles. Table III shows the variation of the contact angles on one and the same plate as a function of depth from the surface after repeated etchings. The optical density shows the thinning of the chromium film. At an optical density of 0.40, a very thin

Table III. Contact angles of water

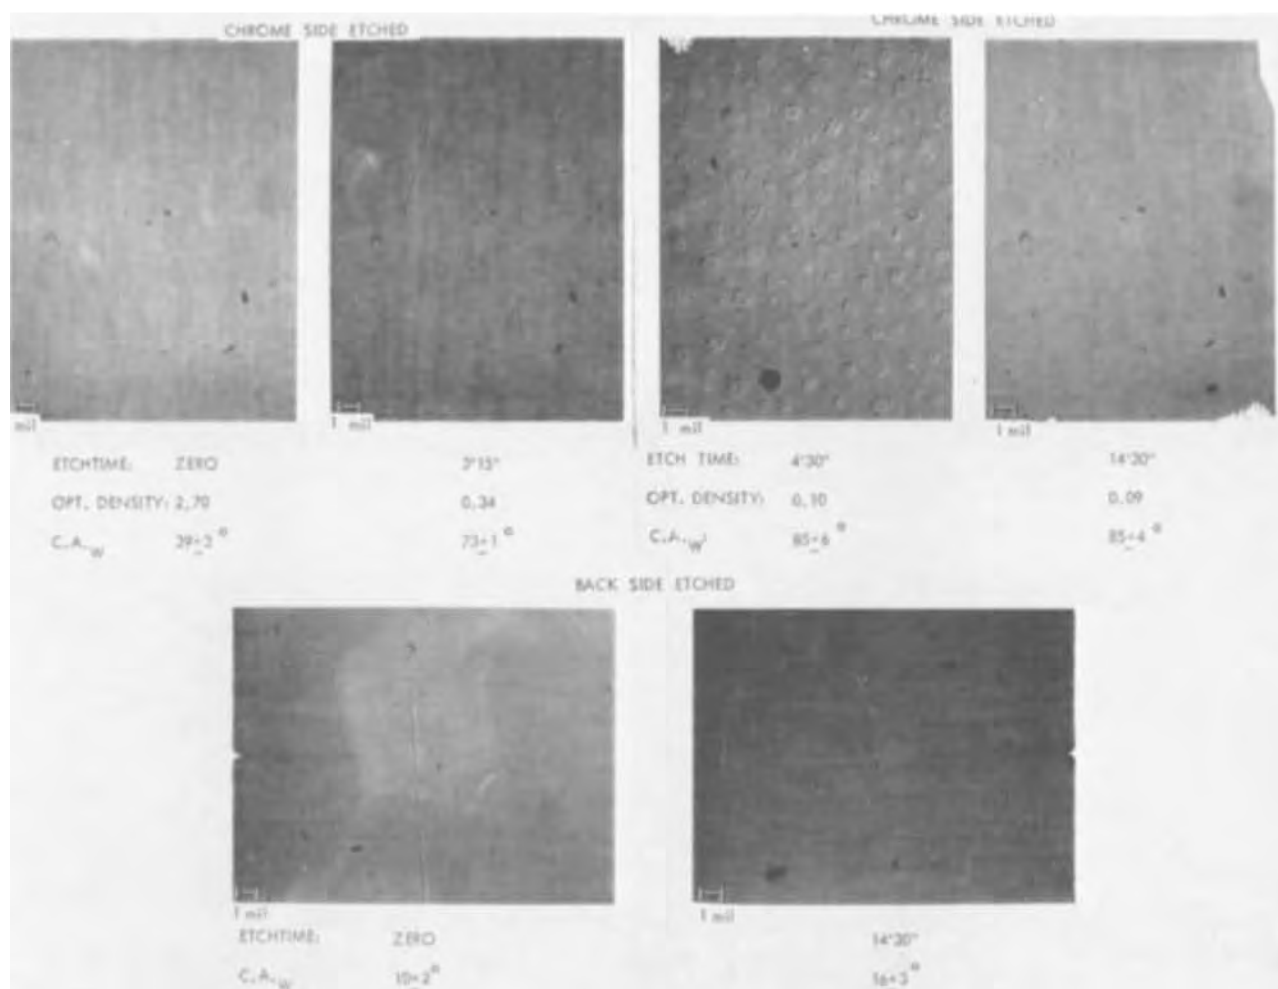

Fig. 2. Chrome and back-side etched

film of chromium was present—indeed a faint gray haze was still visible with the unaided eye. The contact angle is low (as might be expected) on a freshly hydrated chromium surface. At optical densities between 0.22 and 0.13, no chromium was visible to the unaided eye and the contact angles increased to what was previously observed on an overetched plate.

Figure 2 is a summary of the above experiment: A chromium-coated substrate was cut into six pieces. Each piece was etched in ceric sulfate etchant at room temperature as indicated below the respective pictures. After all the samples had been prepared, water contact angles were measured. Results were essentially similar to those observed in the previous experiment. The first etched sample (3′15″) still had some chromium on the surface, but showed a higher contact angle than the respective sample in the previous experiment because of aging.

An electron microprobe analysis showed that the chrome side etched for 4′30″ and 14′30″ showed the presence of Cr on both sides. The significance of this test is qualitative, although the electron microprobe showed the presence of 0.07 and 0.02 weight per cent (w/o) Cr of the volume as compared to the standard. The Cr was in the glass below the original surface and none could be detected on the back-side, etched nor unetched. The electron beam was 10 Kv with a 25 diameter spot and an approximate penetration of 9000Å. In a subsequent experiment, 0.02% Cr was noted on a substrate which was etched for 7 min (optical density was 0.02) until all chromium has disappeared, but not in a second substrate. The inference from these experiments is that chromium, on sputtered as well as evaporated glass substrates, can be found in layers below the original surface—though in some instances, it is readily leached-out by the etchant.

Discussion

The deposition of a chromium film on top of a glass substrate appears to modify the glass immediately beneath the chromium films. This interfacial region seems to be rather shallow, probably in the order of 50-100Å. These figures are based on etch-rate studies of the chromium-glass system. It appears that chromium penetrates the glass surface and is oxidized in the process since on etching much of it is readily leached-out. In some experiments performed under the same conditions, some chromium was detected after etching below the original glass surface indicating the presence of chromium ions loosely held by the glass. Further evidence for the penetration of chromium comes from carbon replicas on angle lapped surfaces. In Fig. 3, a region of cracks appears at the interface. Such cracks are attributed to the penetration of metal atoms and/or have been reported previously in the literature (2).

This study indicates then that three distinct regions can be identified in thin chromium films on glass on the basis of contact angle studies. This is further supported in etch studies by this laboratory and elsewhere (3). Figure 4 shows that the optical density is a linear function of the thickness of the films in Å. Thus optical density was used to determine film thickness in the etch studies. Figure 5 is an anticipated generalized etching curve. Regardless of the etchant employed or the type of chromium film, the character and the slopes of the "bulk" portion of the films of the curves obtained are similar, thus indicating three distinct regions or phases but not the slope which must be found experimentally.

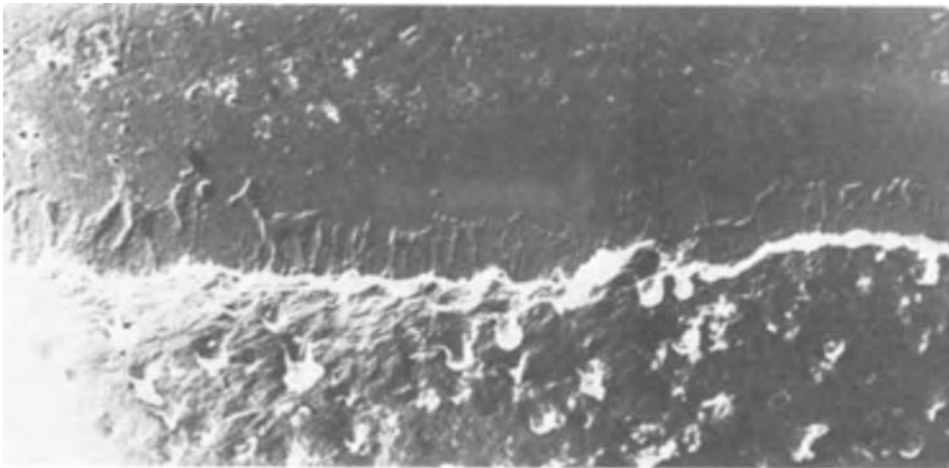

Fig. 3. Polished section of Cr/glass interface (unetched showing fissures), 13,400×.

These three regions are as follows:

(*i*) The surface of the chromium film which may be, but more likely is not homogeneous, due to organic or other contamination. This effect is aggravated on heating in air or nitrogen because it can modify the oxide, and in turn the etch rate. This could account for the observation that the slope of the section A of the curve in Fig. 5 varies more widely than the slopes of the "bulk" portions of this curve.

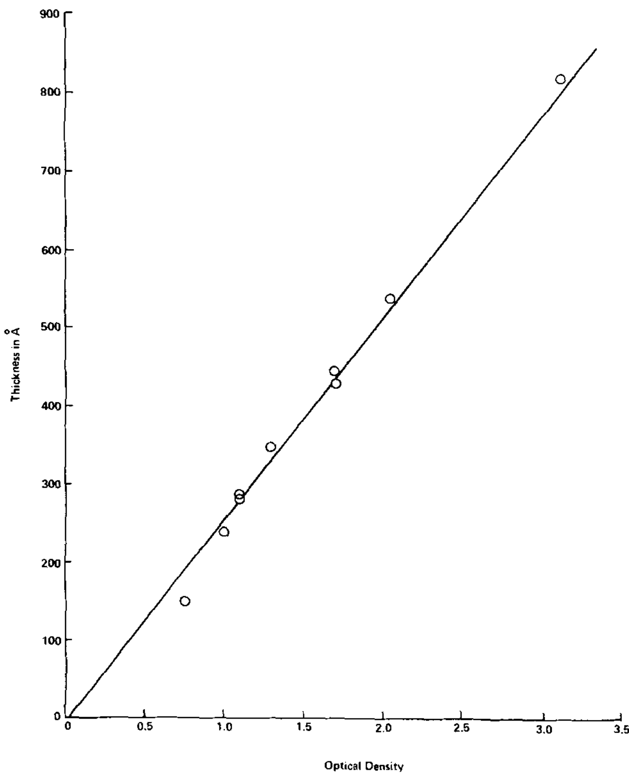

Fig. 4. Optical density *vs.* thickness of thin chromium films on glass substrates.

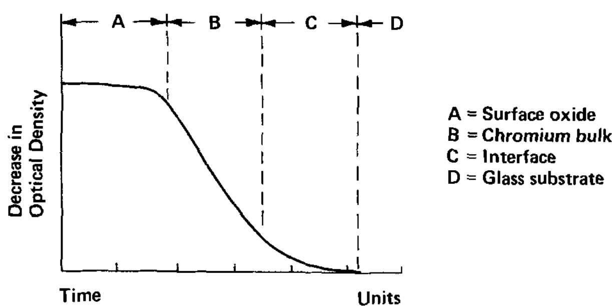

Fig. 5. Anticipated generalized etch curve

(*ii*) The bulk of the chromium film (section B in Fig. 5) has a relatively constant etch rate of ~100 Å/min for acidic ceric sulfate etchant regardless of the manner in which the chromium film was deposited. Figure 6 represents experimental etch curves of chromium film deposited by three different techniques.

(*iii*) The interface proper which constitutes the modified original glass surface has again a much lower etch rate than the chrome but presumably faster than the glass itself. This is assumed because the etch rate of glass is ~1 Å/min, but the permanent steps can be etched into the glass when etching off the chromium on a partially coated glass substrate. It is impossible to avoid such steps even if etching is stopped as soon as the chromium film has disappeared by visual inspection.

Thus, this interfacial layer is formed by chromium ions penetrating into the original glass surface forming presumably a chromium-glass, with the chromium concentration decreasing as a function of depth into the glass.

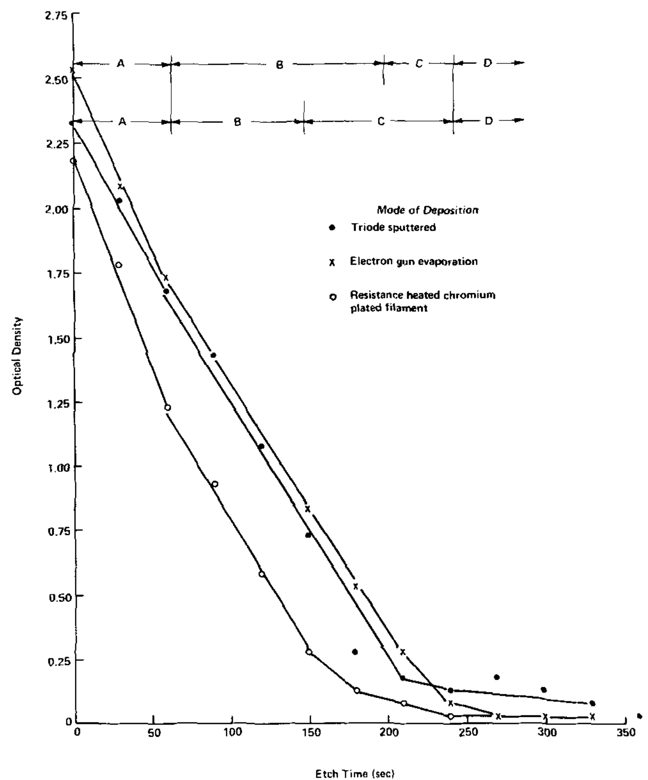

Fig. 6. Optical density vs. etch time of chromium films deposited on glass by three different techniques.

Selective Deposition of Silver on Silicon by Reaction with Silver Fluoride Vapor

R. J. H. Voorhoeve and J. W. Merewether

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

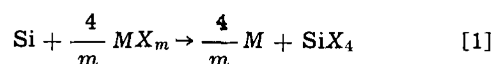
ABSTRACT

Reaction of silver fluoride vapor with a silicon surface has been shown to produce a smooth silver film at temperatures from 80° to nearly 600°C. The silicon surface is etched in the beginning of the deposition process, and silicon is continuously removed from the silicon-silver interface, leading to improved adherence of the film. Films of up to 1 μm have been obtained. On surfaces which are partly covered by an oxide pattern, selective deposition on bare silicon occurs in the range of 80°-600°C. This method is, in principle, applicable to the deposition of a wide variety of metals on elemental and compound semiconductors.

For the manufacture of electronic devices, *e.g.*, of silicon integrated circuits, depositions of metals and semiconductors onto selected areas of the substrate have been of interest to reduce the number of diffusion, photolithography, and masking steps. In particular for microminiaturization, where definition of fine lines is essential, selective depositions appear to be attractive, especially in combination with electron beam delineation techniques.

The deposition of semiconductors on selected areas has been successfully accomplished by those deposition processes which are surface-reaction limited. Disproportionation of GeI_2 at 350°C has been used for selective germanium deposition onto Ge and GaAs (1). Selective epitaxy using silane and germane has been done under high-temperature conditions ($>$ 1175°C for Si, $>$ 800°C for Ge), where the mobility of the Si and Ge atoms over the oxide parts of the substrate, in conjunction with a low sticking coefficient on the oxide, produce preferential growth on the bare semiconductor (2-4).

Selective depositions of metals are possible also and seem widely applicable in the deposition of metal films on silicon, germanium, and compound semiconductors such as GaAs or ZnS. For convenience, the discussion will be limited to silicon. A necessary condition is that the reaction



$$\mathrm{Si} + \frac{4}{m} MX_m \rightarrow \frac{4}{m} M + \mathrm{Si}X_4 \quad [1]$$

will go to completion. M is here a metal of valency m, X is a halogen. A further condition is that diffusion of the metal or of silicon in the deposited layer must be sufficiently fast to allow a film of practical thickness to form. The metal halide must have enough stability and volatility to yield a reasonable evaporation rate. The halide produced in the plating reaction should be volatile at the temperatures and pressures employed. The process may be carried out in a flow system for metal halides with high volatility, such as WF_6 and PtF_6, or in a vacuum evaporator for many metal halides with low vapor pressure.

Selective depositions are possible if reaction [1] is sufficiently faster than the reaction of metal halide with the silicon dioxide or silicon nitride mask. Reaction with the mask seems likely only for metal fluorides.

The expected advantages of this metallization process over physical vapor plating (5) are the selectivity of the deposition and the inherent etching of the semiconductor surface, leading to well-adherent films. Possible disadvantages include the limited film thickness and the possibility of halogen incorporation in the films.

Examples of metals which have been deposited through their halides are tungsten and copper (6-10).

Some metals which judged on the basis of thermodynamic data could be deposited this way are, in addition to copper and tungsten, silver, tin, lead, vanadium, tantalum, chromium, molybdenum, iron, cobalt, nickel, and platinum. These metals have one or more halides of sufficient volatility, and for which reaction [1] is favorable ($\Delta F° << 0$). Available diffusion data for these systems are not sufficient to predict the thickness limits for such films, since diffusion in these thin films, with halogen present, is generally appreciably faster than volume diffusion.

In the present paper, the deposition of silver on silicon through the reaction

$$\mathrm{Si} + 4\mathrm{AgF} \rightarrow 4\mathrm{Ag} + \mathrm{SiF_4} \quad [2]$$

is described.

With an oxide layer the following reaction is possible

Key words: metallization, chemical vapor deposition, integrated circuits, PICTUREPHONE®, surface chemistry.

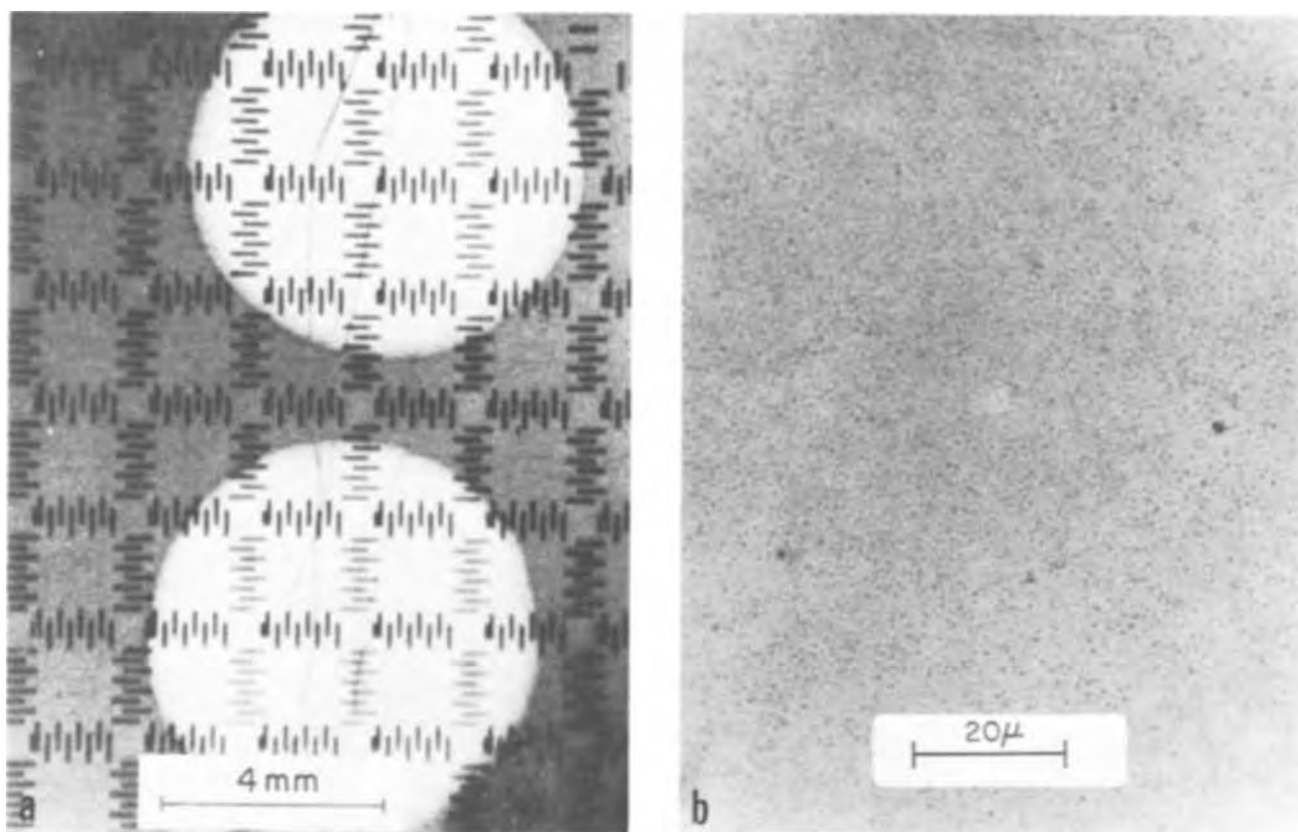


Fig. 1. Silver (2000Å thick) deposited at 100°C; (a) on a rectangular oxide island pattern; oxide is black, silicon gray, and silver white (b) on "plain" silicon.

$$SiO_2 + 4AgF \rightarrow SiF_4 + 4Ag + O_2 \qquad [3]$$

but this is much less favorable thermodynamically than reaction [2].

Experimental

The depositions were carried out in an ion-pumped 12 in. Viton-sealed bell jar evaporator with a base pressure of 6×10^{-8} Torr. During depositions the pressure was about 10^{-6} Torr.

A (111) silicon wafer, 0.010 in. thick, is mounted against a molybdenum heater plate, which is heated by electron bombardment or by passage of a current. The silicon temperature is measured with a thermocouple spot-welded to the molybdenum plate or, at high temperature, by pyrometry. Temperatures indicated in the following are therefore only approximate.

Three types of silicon slices were used: (*i*) unoxidized ("plain"), (*ii*) with a pattern of rectangular oxide islands of 1600Å thickness, and (*iii*) with a PICTUREPHONE® pattern of bare silicon windows in an oxide mask. Before use, each slice was degreased, washed with HF, and rinsed with deionized water. Slices with oxide patterns were washed with a 1:3 HF solution to thin the oxide to 1000Å. Before depositions were made, the silicon wafers were cleaned by heating in $<10^{-6}$ Torr for a few minutes, to 1100°C for "plain" wafers, or to 750°C for wafers with an oxide pattern.

Silver fluoride was evaporated from a graphite crucible mounted in a strip-heater. The powder (Ventron, Alfa Inorganics) was thoroughly outgassed by melting in the graphite crucible at 10^{-6} Torr.

A shutter with a 0.125 in. hole was placed between the source and the silicon wafer. This allowed several consecutive depositions to be made on a single wafer.

After deposition of the metal layer, the wafers were immediately rinsed in deionized water to remove any unreacted silver fluoride from the surface. This is necessary because unreacted fluoride causes rapid de-

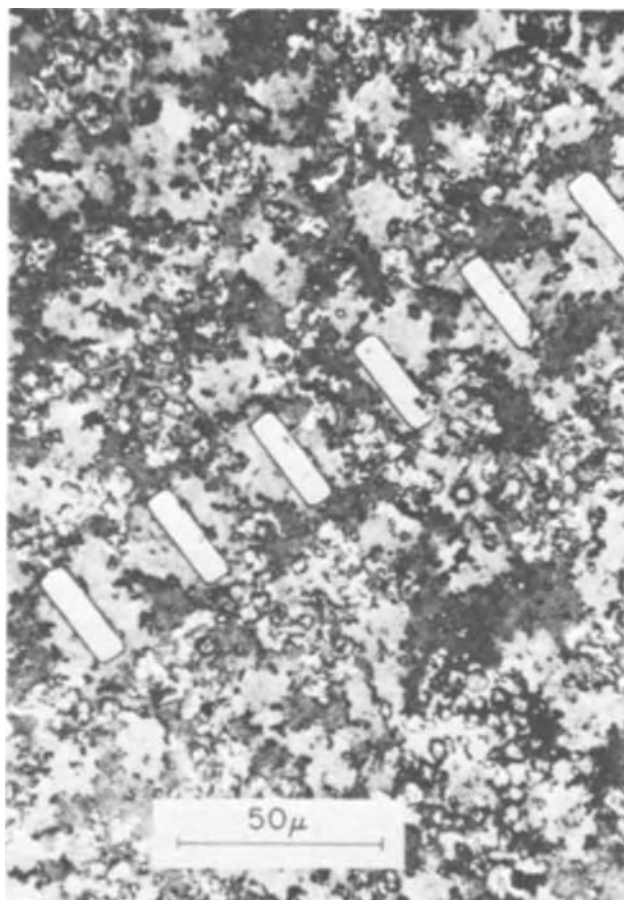

Fig 2. Silver deposited at 60°C. The irregularly shaped smooth and bright areas are silver, the grainy deposit is AgF, the rectangles are oxide islands.

terioration of the silver and silicon oxide surfaces in air.

Results

General characteristics of the deposition process.— Deposits of silver on silicon could be readily distinguished because of the higher reflectivity of silver, compared to silicon and silicon dioxide (Fig. 1a). The optimal deposition temperature and the structure of the silver deposit were studied on "plain" silicon substrates (p-type, 4-15 ohm-cm), at AgF impingement rates of about 2×10^{16} cm^{-2} sec^{-1}, equivalent to 50Å of silver per second if the reaction is complete. The substrate temperature was varied from 900°C to room temperature.

A smooth silver deposit was obtained with the substrate between 80° and 600°C. A typical example of a deposit in that range is shown in Fig. 1b. The structure of the deposit was determined by x-ray to be polycrystalline, but with the Ag (111) preferentially parallel to the substrate, Si (111).

The thickness of these films is limited by the temperature-dependent rate of diffusion of silver and/or silicon. At 400°C, a film of 1 μm could be obtained in 2-5 min, at lower temperatures (100°-200°C) the limit was about 1000-2000Å. Even at 80°C films of about 1000Å were obtained in a few minutes. This indicates rather fast diffusion, which may be enhanced by the presence of the halide (11).

The silver films showed better adherence to the substrate than evaporated films and were not removed with the "scotch tape method." This is probably due to etching of the interface during the deposition process.

Two phenomena interfere with the formation of smooth films. At room temperature, reaction of AgF with silicon is very slow. At 40°-60°C, only a patchy silver deposit is formed, with codeposition of AgF (Fig. 2). Grain growth becomes evident at 600°C, especially in thicker films (Fig. 3). At 700°C, the mobility of the silver under deposition conditions becomes excessive, leading to agglomeration and formation of large crystals, up to 5 μm in size (Fig. 4). Some of these form on top of the oxide, where nucleation is presumably facilitated by etching, which becomes especially prominent beyond 700°C.

The structure of the interface between silver and silicon was observed by etching off silver with HNO_3/HCl and removing any oxide pattern with HF. Difficulty was experienced in dissolving silver deposits in HNO_3 alone. This may be due to the presence of silicon in solid solution or at the grain boundaries (12). The silicon surface remaining presented a hazy appearance at spots where silver had been deposited. The haze is due to the presence of a roughness with a "grain" of 0.3 μm or less resulting from the reaction with AgF (Fig. 5). A few larger pits were observed. Etching of the interface is most noticeable at the borderline of the oxide pattern. The resulting depression lining the islands is less pronounced at higher temperatures (compare Fig. 5a and 5b.). It may be due to stress-enhanced etching.

Selectivity on SiO_2/Si patterns.—Between 80°-600°C silver deposition occurs exclusively on the bare silicon. The selectivity indicated in Fig. 1a is further illustrated by scanning electron micrographs of the small rectangular features in the rectangular pattern (Fig. 6). The secondary electron pattern shows the definition of the features to be quite good (Fig. 6a). The scanning electron microscope was also used to scan the surface specifically for silver, using an x-ray detector and a multi-channel analyzer tuned to the Ag $L\alpha + L\beta$ x-ray fluorescence. It was shown that very little, if any, silver is deposited on the oxide (Fig. 6b). The difference in appearance of silicon

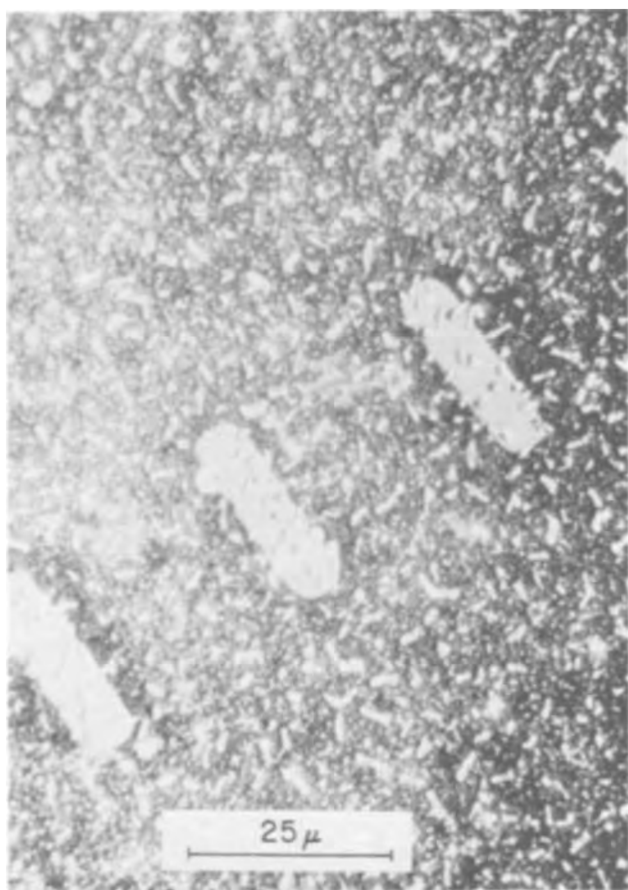

Fig. 4. Silver deposited at 700°C. Except for the light rectangular oxide islands, the whole surface is covered by silver. Bright Ag crystals cover part of the oxide.

underlying oxide islands and silicon on which silver had been deposited (Fig. 5) also shows the good selectivity of the method.

The rectangular pattern consists of oxide islands on a silicon substrate. Selective deposition was also tested for an array of circular windows in an oxide mask on silicon (PICTUREPHONE® array). The objective was to deposit silver in the windows only. Figure 7 shows that selective deposition is possible for such configurations, even at 100°C. Some spurious growth of silver adjacent to the windows does occur, however. No effort has been made to find the optimal conditions for this deposition.

A feature of some of the deposits is the collection of a somewhat heavier silver deposit on the silicon near the edges of the oxide. This may give rise to the formation of rings, rather than solid dots, in the PICTUREPHONE® pattern. This may be due to AgF molecules landing on the oxide surface and migrating to the edge of the oxide film. Similar effects have been shown for the Ge deposition from GeI_2 (Ref. 1).

Discussion and Conclusions

In this largely exploratory study, it has been shown that the deposition of silver on silicon through the reaction of AgF with the silicon surface is a feasible process. The reaction is sufficiently fast to allow depositions of films at substrate temperatures of 80°C and higher. In the range from 80°C to nearly 600°C, the films are smooth, with small grains (<0.3 μm). Thicknesses from 1000Å to 1 μm are obtained in a few minutes. Thicker films could be built up, *e.g.*, by electroplating, electroless plating, or both.

The films adhere well to the silicon surface. The silicon-silver interface is etched by the deposition process, and this may contribute to the good adherence and the preferred orientation of silver crystallites.

Selective deposition of silver has been obtained through windows on an oxide-masked silicon substrate, and also on a silicon surface partly covered with oxide islands. The oxide surface remains free of silver between 80° and 600°C, and pattern details are well preserved. Deposited films can probably be heated to 700°C long enough to allow deposition of Si_3N_4 protective coatings or to anneal out ion implantation damage in silicon [see *e.g.*, Ref. (13)].

Two subjects not covered in the present study are the possible incorporation of fluorine in the metal film, and the specific resistivity of the films in comparison with bulk silver.

The method may be applicable for the deposition of several other metals mentioned in the introductory remarks of this paper allowing selective depositions at conveniently low temperatures.

Acknowledgments

We would like to thank K. E. Benson for supplying silicon slices, and R. E. Caffrey and A. C. Dumbri for the oxide-patterned silicon wafers. We also thank H. J. Leamy and S. D. Ferris for the scanning electron microscope results, and Mrs. Mildred H. Read for determining the preferred orientation of the deposits.

ABSTRACT

A method based on photoluminescence measurements is described to determine the suitability of GaAsP wafers for red-light emitting devices. Using a focused laser beam as an excitation source, testing was carried out in the open at room temperature, assuring simplicity and speed of wafer evaluation. It is shown that one can readily determine whether a wafer is uniform in composition and/or uniform in external quantum efficiency and determine what the spectral characteristics of diodes fabricated from a given wafer will be. It is also shown that one can study the effects of wafer processing on the radiative recombination of electron-hole pairs, which will allow one to rapidly develop optimum device fabrication procedures.

This paper describes one phase of a continuing study of optical methods for nondestructive evaluation and characterization of semiconductors (1). Nondestructive testing of semiconductor wafers for light-emitting diodes (LEDs) allows one to reject unsatisfactory material before a valuable effort is wasted in fabricating it into diodes. It also provides a check on device fabrication procedures, *i.e.,* if a material checks out as high quality before processing and then yields LEDs of low performance, it is evidence of faulty fabrication procedures. Such a test, besides being nondestructive in nature, should be sensitive, accurate, simply and rapidly executed, capable of high spatial resolution and, of particular importance for LEDs, possess high spectral resolution. In addition, the test should be a direct reflection of the performance of an LED made from the material under examination, and it should be capable of examining, as nearly as possible, the same region (both in area and in depth) that is to be effective in producing light in the finished device.

The end result of electro-excitation, *i.e.,* as in a forward biased p-n junction, and photo-excitation is the same, namely, radiative recombination of electron-hole pairs to produce electroluminescence (EL) and photoluminescence (PL), respectively. Thus a PL test should provide a direct means for evaluation of many of the materials parameters of importance for LEDs.

The use of a laser as an excitation source offers significant advantages in screening out scattered exciting radiation during PL measurements and in achieving sufficiently intense levels of excitation via focusing optics to produce strong PL spectra (2). Recent work has shown that measurements of photoluminescence, especially when generated by lasers can be extremely useful for fundamental studies of semiconductor properties (3). Less attention has been paid to laser-induced photoluminescence for materials evaluation purposes. This paper describes a method, based on photoluminescence (PL) measurements and using a laser as an excitation source, which meets all of the requirements noted above. The method is applied to determine the suitability of GaAsP wafers for red-light-emitting devices. The measurement is carried out with the wafer in the open and at room temperature, assuring simplicity and speed of evaluation.

Apparatus and Experimental Techniques

The PL apparatus consists of the following arrangement: a 6328Å He-Ne laser, designed and built at the Bayside Research Center, operating in a single (TEM_{00}) mode with a nominal power output of 15 milliwatts; a 50Å bandwidth filter peaked at 6328Å with peak transmission of 47%, and with long wavelength and short wavelength rejection of $> 10^4$ at $\pm$ 150Å of peak transmission (to remove extraneous He-Ne emissions). This arrangement is followed by a selection of neutral density filters capable of reducing the beam power incident on the sample by a factor of 10^3; a beam power meter for monitoring the laser power incident on the sample; an objective lens system for focusing the laser beam down to a fine spot; an x-y-z micrometer stage which carries the sample mounting assembly for holding and positioning the GaAsP water; a highly absorbing beam trap for the reflected laser beam, and a high-pass filter to absorb scattered laser radiation. A schematic of the apparatus is shown in Fig. 1.

The PL signal was collected and focused onto the entrance slit of a Perkin-Elmer 112C Recording Spectrometer by the standard front-end optical system supplied with this instrument. The half angle of the cone of acceptance, dictated by the size and tilt of the plane mirror and its distance from the GaAsP wafer, was 6°.

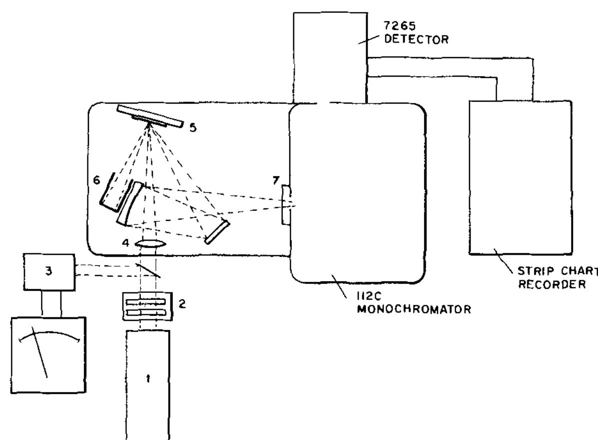

Fig. 1. Schematic of the apparatus used for photoluminescence measurements of GaP_xAs_{1-x} (x $\leq$ 0.4 epitaxial wafers: 1, 6328Å He-Ne laser; 2, filter rack for 50Å bandwidth filter and for neutral-density filters; 3, beam power meter; 4, objective lens system for focusing the laser beam; 5, x-y-z sample mount; 6, trap for reflected laser beam; 7, filter for absorbing scattered laser radiation.

Key words: photoluminescence, electroluminescence, semiconductors, light-emitting diodes, gallium arsenide-phosphide.

Laser radiation scattered from the sample was absorbed by a CS2-58 or, in a few instances, by a CS2-64 Corning glass filter placed over the entrance slit of the monochromator. Photoluminescence spectra were measured using a DF-2 prism in the monochromator generally working at a slit opening yielding a bandwidth of 40Å, and using an RCA 7265 photomultiplier (PM) tube as a detector. Provision was made for cooling the PM tube to improve signal-to-noise ratio. All photoluminescence measurements were conducted with the GaAsP wafer at room temperature, in the open. The diffraction-limited spot size calculated from the optical parameters of the system was 5.6×10^{-3} cm. Experiments using thin metal masks with various hole sizes showed that the actual diameter of the focused laser spot was not more than 10^{-2} cm. Laser-stimulated PL was restricted to GaAsP wafers with compositions $\leq$40 mole per cent (m/o) GaP (emission energy $\leq$1.91 eV), largely because of limitations imposed by the photon energy (1.96 eV) of the He-Ne laser radiation, but also because of limitations imposed by the absorption edge of the CS2-58 and CS2-64 filters.

Because the two parameters of most importance in LEDs, the radiative quantum efficiency and the ratio of near-band-edge to impurity emission, are sensitive to the concentration of electron-hole pairs produced per unit time (4), it was important that our PL test apparatus be capable of exciting electron-hole pairs in GaAsP wafers comparable in density to those generated in the average LED. Typically, LEDs operate at a current density from 1 A/cm^2 to 50 A/cm^2 (d.c.). All of the electron-hole pairs in an LED are injected into a layer about one micrometer thick near the p-n junction. Corresponding electron-hole pair production is 6.3×10^{22}/cm^3 sec and 3.1×10^{24}/cm^3 sec. A well-focused laser beam of moderate power can excite an electron-hole pair population equal to or greater than that typical of LEDs operated at room temperature, as shown in the following calculation.

The laser output of 15 mW was focused to a circular spot of minimum area 2.47×10^{-5} cm^2, maximum area 7.85×10^{-5} cm^2. Taking into account losses due to the narrow-pass laser filter ($T = 47\%$) and reflection from the sample ($R = 35\%$), the laser power available for creating electron-hole pairs in the sample provided a minimum of 50 W/cm^2 and a maximum of 235 W/cm^2. One watt of 6328Å radiation is equivalent to 3.3×10^{18} photons/sec. If it is assumed that every photon absorbed creates one electron-hole pair, then the electron-hole pair flux produced by the He-Ne laser was not less than 1.65×10^{20}/cm^2/sec nor more than 7.75×10^{20}/cm^2/sec. The absorption coefficient (α) for 6328Å radiation in the GaAsP epitaxial layers used for this investigation ranged from about 2000 cm^{-1} to 10,000 cm^{-1}, depending on exact composition (5). Thus we calculate that 9/10 or $[1 - (1/e^2)]$ of the optical power absorbed in generating PL was absorbed in a layer from 2.0 to 10.0 micrometers thick at the surface of the wafer. The corresponding lower and upper limit for electron-hole pairs excited is accordingly 1.65×10^{23}/cm^3 sec and 3.9×10^{24}/cm^3 sec, respectively. Thus ample laser power density is available to effect good correlation between PL and EL. Photoluminescence signals were produced which were strong enough to allow detection of shifts of peak wavelength of 5Å, corresponding to differences in GaAsP composition—in the composition range of interest—of about 0.1 m/o (6).

The angle of incidence of the focused laser beam on the GaAsP wafer was made as near normal as possible (never greater than 10° from the normal), commensurate with keeping scattered laser light to a minimum, to insure an essentially symmetrical (nearly circular) focused laser spot. At the same time the take-off angle between the optical axis of the cone of acceptance and the surface of the sample was kept as near normal as possible to take advantage of the fact that for a given solid angle there is more PL power at near normal incidence in this type of PL source. A take-off angle of 30° was found to be optimum for all samples measured. GaAsP wafers or wafer sections with area ranging from 1 to 2 cm^2 were mounted on thin metal plates with a low-melting-point wax. Photographs of each sample were taken and either imperfections on the surface of the wafer or the corners of the metal plate or wafer were used as fiducial marks. The mounted sample was placed on the x-y-z stage and the fiducial marks were referenced to an x-y position coordinate. The sample was then divided into a reference grid array of 2×2 mm squares and PL measurements were made in the center of each square. Anywhere from 20 to 100 measurements were made on a sample.

The GaAsP LEDs, which were fabricated from epitaxial wafers by zinc diffusion, generally contained an emitting region 0.38 mm in diameter, but diodes with an emitting region as small as 0.1 mm in diameter were also made. The p-n junctions in all of these diodes ranged from 3 to 5 micrometers below the surface. Thus the region in which most of the PL test signals were generated included the region in which the EL was subsequently generated.

A random sample of several dozen diodes was taken from the four or five hundred diodes that were usually produced from each wafer section. This was considered adequate to expect reasonably good correlation between photoluminescence and electroluminescence.

Experimental Results and Discussion

Since the total PL power emitted from the GaAsP samples under the action of the focused laser beam is of some importance, several experiments were devoted to obtaining this information. In a well-polished or highly reflecting semiconductor wafer, internally generated emission (for either PL or EL) exits from the surface with a Lambertian-like distribution (7). Therefore it is important to define the take-off angle of the PL as well as the angle of the cone of acceptance of the front end of the spectrometer to arrive at an accurate determination of the "total" PL power output. With a take-off angle 30° from the normal and a cone of acceptance of 12°, the fraction of the PL power entering the spectrometer is calculated to be slightly less than 1%.

A convenient optical power reference for calculating PL output in our system is the laser beam itself. The slit opening of the monochromator was set to produce a spectral bandwidth of about 40Å over the spectral range of interest. This was more than adequate to allow all of the 6328Å laser output to pass through the monochromator to the detector, but it only allowed 20% of the PL output to pass through. An appropriate multiplication factor was applied to arrive at a correct total PL output. The focused laser beam was reflected onto the entrance slit of the monochromator from a front surface aluminized mirror substituted in place of the GaAsP sample. By comparison of PL output with laser output, it was determined that the "total" PL power emitted from a good GaAsP wafer was 1.5×10^{-6} watts.

Figure 2a shows a 5×6 PL scan of a GaAsP epitaxial layer with variations in peak emission wavelength that indicate compositional homogeneity within 0.3 m/o. It was noted that there is a slight but definite trend to longer PL wavelength (lower phosphorus content) toward the upper-right-hand corner of the scanned area. In Fig. 2b is shown a nearly complete 6×8 scan of another epitaxial layer. The variation of the PL emission peaks in this sample suggest random compositional inhomogeneity of 1.0 m/o.

There was no significant heating of the GaAsP area illuminated. This was established by measurments of PL spectra at successively lower laser power using neutral density filters to attenuate the laser beam. The PL wavelength showed no shift (within 5Å) to shorter

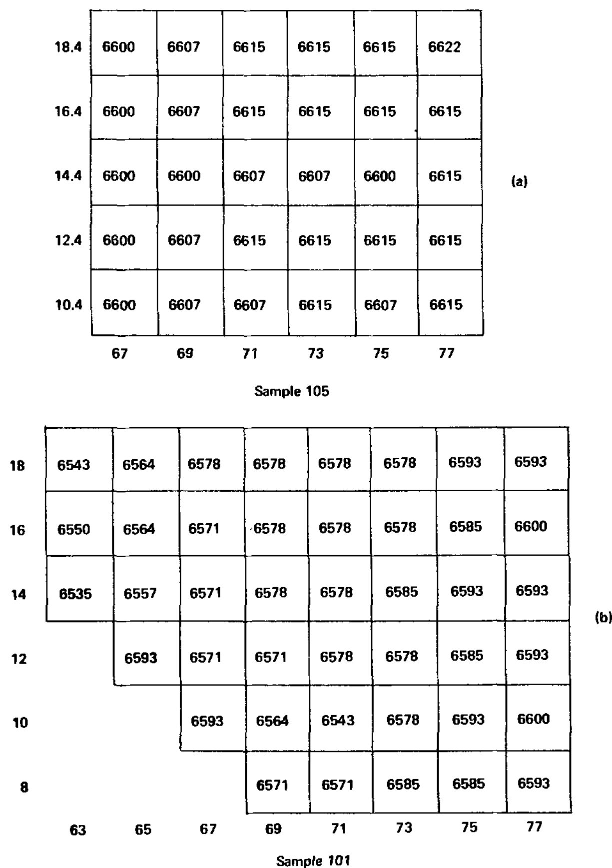

Fig. 2. (a) Map of photoluminescence measurements which show the variation of peak wavelength in reasonably homogeneous epitaxial wafer of GaAsP. The numbers outside of the 5 × 6 array represent position coordinates in units of millimeters. The number within each box is the peak wavelength of photoluminescence (expressed in Å) measured for an illuminated area between 0.01 cm and 0.005 cm in diometer, located in the center of the box. (b) Map of photoluminescence measurements which suggest compositional inhomogeneity of 1 m/o in a GaAsP epitaxy. The regions in the lower left hand corner were not measured because they were close to the edge of the wafer.

wavelength such as would have occurred had there been even moderate heating at the maximum laser power. (A rise of 1°C would cause an increase of 2.4Å in peak emission wavelength.)

The average peak emission wavelength observed for PL of a given wafer usually agreed within 10Å with the average peak emission wavelength for diodes made from that wafer. Table I compares PL and EL for four different samples of GaAsP. Care was taken in our diode measurements to keep the current low enough (generally less than 10 A/cm^2) to preclude wavelength shifts due to self-heating of the diode. Photoluminescence and electroluminescence measurements involving near-bandgap emissions from a III-V semiconductor wafer do not usually show peak wavelengths that agree as closely as those shown in Table I. There are several reasons for this; first, the energy of a conventional excitation source for PL is usually high compared to the energy gap of the semiconductor

Table I. Comparison of PL measurements with LED measurements

Sample number	Photoluminescence peak wavelength (A) Average	Range	Diode luminescence peak wavelength (A) Average	Range
101	6576	6535-6600	6578	6571-6586
105	6609	6600-6622	6597	6585-6607
112	6580	6557-6585	6581	6578-6593
114	6572	6557-6593	6573	6564-6578

and, typically, generates electron-hole pairs within a region only a few tenths of a micrometer below the surface. The region where most of the recombination occurs may be much deeper than this, but it is not likely to be more than a few micrometers from the surface in the GaAsP which was the subject of this investigation. Diode emissions, on the other hand, are generated many micrometers below the surface and self-absorption causes strong attenuation of the high energy portion of the electroluminescence resulting in a shift of the peak wavelength to lower energy. The good agreement between EL and PL peaks shown in Table I may be explained in part by the close correspondence of p-n junction depth and the thickness of the layer sampled by the He-Ne laser.

Second, and more important, EL in III-V diodes is usually dominated by recombination on the p-side of the junction through acceptor centers that lie several hundredths of an electron volt above the edge of the valence band (8). One must account for the apparent absence of a strong shift in peak emission to longer wavelength between original (n-type) and p-diffused wafers that would be consistent with the generally observed situation. The results in Table I are most simply explained if the emission in these diodes is dominated by recombination on the n-side of the junction, through donor impurities, which in direct band gap III-V's lie only a few thousandths of an electron volt from the edge of the conduction band.

In two instances the emission wavelength (both PL and EL) was at variance with that expected from the composition of the GaAsP epitaxial layer stated by the supplier. An emission wavelength of energy lower than that expected from the stated composition can be explained in terms of impurity recombinations or near-band-edge recombinations. However, in the two cases cited here the emission wavelength was at higher energy than could be ascribed to the wafer composition, a practical impossibility. In each case, precision lattice parameter measurements confirmed the composition, within 0.2 m/o, deduced from PL and EL (LED) measurements. Table II compares the stated composition of five epitaxial wafers with composition deduced by means of PL or EL measurements and by x-ray techniques.

Photoluminescence measurements were also used to investigate changes in the quantum efficiency of the epitaxial material after chemical processing of the surface. Table III shows the results of measurements of PL in a GaAsP layer as received, and after treatment with Br_2-CH_3OH solution to remove about

Table II. Comparison of GaAsP wafer composition determined by different measurement techniques

18-71	6578	155	6578	308
18-67	6578	122	6571	245
18-63	6543	120	6543	185

5 μm from the surface. Note that the peak wavelength at each point is practically identical, but the peak intensity, which is a measure of the quantum efficiency, has increased markedly at each point sampled. The precision with which a particular point on a sample could be located on successive measurements was 0.1 mm, or about 0.004 in., equal to the maximum diameter of the focused laser beam.

Since the area that is sampled in each PL measurement is no more than 10^{-2} cm in diameter, a highly detailed map of the photoluminescence response of a wafer can be constructed. If we could generate PL maps or images with high spatial resolution in a reasonably short space of time, similar to the way in which infrared maps or images are produced by scanned laser techniques (1), we would have a valuable new technique for evaluating LED wafers.

Conclusions

This investigation has provided strong evidence that PL testing can be employed as a process control and process development tool as well as a tool for rapid, accurate evaluation of the results of semiconductor materials synthesis and purification procedures. The effects of wafer processing on quantum efficiency (including steps such as SiO_2 masking) that are involved in fabricating a wafer into LEDs can be studied. Peak emission wavelength and variations thereof can be determined with an accuracy of 10Å, relative quantum efficiency and variation within a given wafer can be determined within 10%.

PL measurements have been used to establish the beneficial effects of chemical treatments on GaAsP wafers prior to the formation of diffused light-emitting junctions. Photoluminescence testing of wafers has also been used to check the phosphorus content stated by the supplier and to check for the presence of undesired impurity radiations. In addition, this nondestructive test technique has been employed to determine whether point-to-point variations in wafer composition exist that would cause serious variations in LED emission wavelength. Finally, it is clear that the extension of these PL techniques to the evaluation of other higher energy-gap semiconductors is largely a matter of substituting another laser, for example an argon-ion laser (ΔE = 2.41-3.35 eV), for the He-Ne laser.

Acknowledgments

Control of the Deposition of Silicon Nitride Layers by 2537Å Radiation

C. H. J. v. d. Brekel and P. J. Severin

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Thin Si_3N_4 films were deposited on polished Si crystals at low temperatures using the Hg-photosensitized reaction of N_2H_4 and SiH_4. The deposition rate increases linearly with the light intensity. The experiments showed that destructive interference between multiply reflected beams has a pronounced effect in limiting film thickness to a well-defined value with a high degree of uniformity over the slice.

The formation of silicon nitride films by a number of methods has been reported including the reaction of ammonia and silane under an rf discharge (1), the pyrolitic reaction of the silane-ammonia system (2, 3), the silane-hydrazine system (3) or the silicon tetrachloride-ammonia system (4), and reactive sputtering of silicon in nitrogen (5, 6). These are chemically activated processes which are effected at a relatively high temperature. The Hg-photosensitized decomposition of hydrazine and of silane has been described by Mitchell and Zemansky (7). Collet (8) has used the Hg-photosensitized decomposition of hydrazine and silane for

Key words: Si_3N_4-deposition, destructive interference, stepwise growth, Hg-photosensitized, uniform thickness layers.

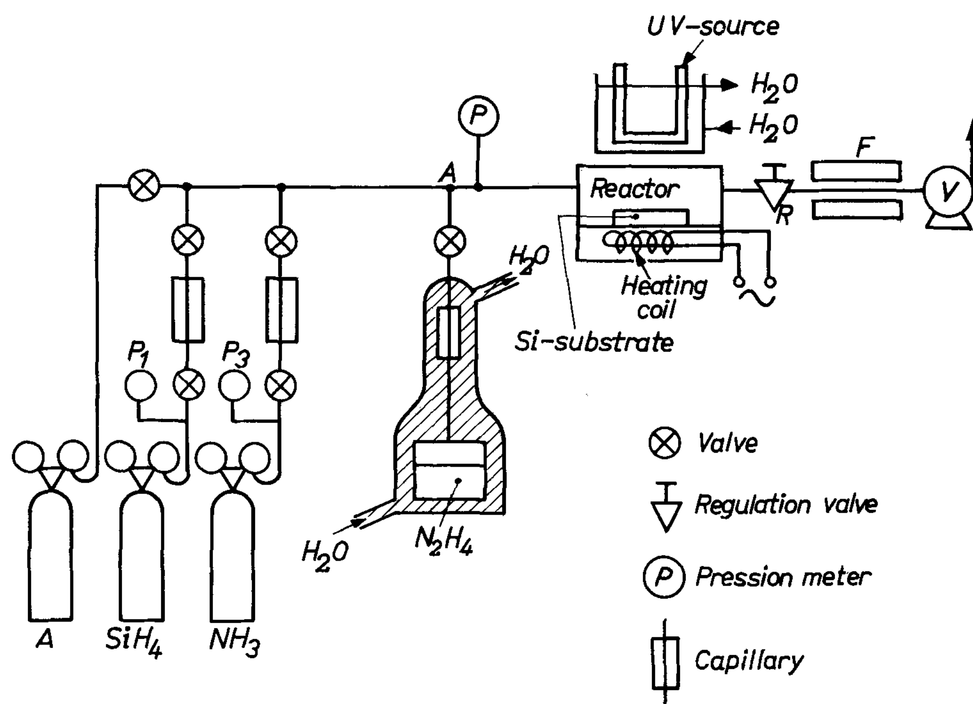

Fig. 1. Apparatus for depositing Si_3N_4.

the deposition of silicon nitride films at low temperatures. This technique works with a closed system, which results in a varying deposition rate, due to a gradual consumption of the reactants from the gaseous phase and an increase in total gas pressure. In order to maintain a reasonable growth rate the system has to be refilled after a certain exposure time with a fresh N_2H_4/SiH_4 mixture. To eliminate this effect we used a fast-flow system with a constant input of the reactive species. At a constant intensity of uv radiation, the growth rate of silicon nitride was expected to have a constant value. A second advantage is the additional possibility of using ammonia instead of hydrazine as the nitrogen delivering compound, because in a fast-flow system ammonia is photochemically converted into hydrazine (9). In practice it is much easier to remove traces of water from gaseous ammonia than from liquid hydrazine.

Apparatus

The apparatus is shown schematically in Fig. 1. It consists of a gas supply, the reactor and a vacuum system. The pump (V) maintains a constant pressure P in the system. The silane, ammonia, and hydrazine vapor are forced into the system through capillaries by the difference in pressure $(P_1 - P)$, $(P_3 - P)$, and $(P_2 - P)$, respectively.

The vapor pressure P_2 of hydrazine is fixed by the temperature of the thermostated water bath which surrounds the bottle containing the liquid hydrazine. By adjusting the needle valve (R) a constant total pressure range within the reactor can be reached. Variation of P_1 with respect to P_2 or P_3 permits variable ratios of silane to hydrazine or ammonia flow.

The quartz reactor is 10 cm long, 3.5 cm wide, and 4 mm high. A heating coil under the bottom of the reactor keeps the sample at a constant deposition temperature (maximum, 500°C). A low-pressure mercury discharge tube (40W) acts as the radiation source situated just above the reactor. To avoid Doppler-broadening of the resonance line, the tube is cooled in a quartz tank with running water.

A drop of mercury at the inlet of the reactor dopes the gas mixture with mercury vapor.

The exhaust gases are decomposed into hydrogen, nitrogen, and solid products in the furnace (F) at 900°C and the gases are pumped off.

By repeated pumping and filling of the system with argon, the apparatus can be emptied of the highly reactive silane before the reactor is opened.

Experimental

Water-free hydrazine, distilled from sodium hydroxide (10), and silane (Matheson) were used to deposit silicon nitride layers on 10 ohm-cm n-type polished silicon substrates of about 3 cm diameter.

In the experiments the hydrazine or ammonia flow was set to at least 2/3 times that of the silane being the stoichiometric ratio to prevent the deposition of a white-yellow film of polymerized silicon hydrides by the decomposition of silane (11, 12). In general this ratio was set to unity.

At constant total pressure P, flow rates, and temperature, the influence of the intensity of the uv radiation on the growth rate was investigated. The light intensity was varied by changing the distance between the substrate and uv source. The thickness of the deposited layers were estimated from their interference colors (6). Figure 2 shows that the growth rate G increases with decreasing distance x as x^{-2}.

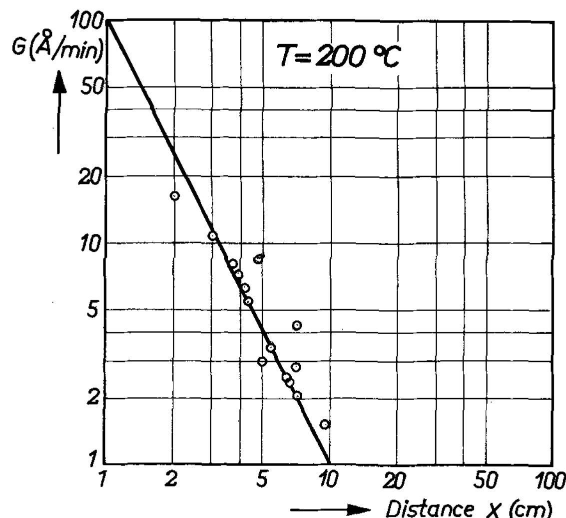

Fig. 2 Growth rate G of Si_3N_4 vs. distance x between the sample and light source.

Considering the mercury tube as a point source, Fig. 2 indicates a direct proportionality of the growth rate to the uv intensity.

The growth rate of the Si_3N_4 film was roughly constant. A closer examination, however, revealed that the precise growth rate depends on the layer thickness. In fact, at some thickness the growth rate turns out to be greatly reduced. This phenomenon will be explained in detail in the next section by taking into account the interference between multiply reflected beams close to the nitride-gas interface. The same effect in photoresist films has been described recently by Middelhoek (14) and Fried *et al.* (15).

Theory

Figure 3 shows schematically the experimental situation. A silicon wafer is covered by a silicon nitride layer. Only the mercury line $\lambda = 2537$Å is used for the experiments as has been substantiated by filtering the different wavelengths. It has been experimentally verified that the layers discussed in this paper actually have within 2% the value for the index of refraction for 5860Å as published by Reizmann and van Gelder (6). Therefore we assume the index of refraction for Si_3N_4 at 2537Å to be also as measured by those workers, *viz.*, 2.18. The index of refraction for Si at 2537Å has been found (17) to be 1.65. As Fig. 2 suggests the radiation may be considered as normally incident. Absorption in the Si_3N_4 layer is neglected and light reflects at the Si surface with a phase change π. The light intensity at the silicon nitride-vacuum interface if the relevant values of the refractive indices are substituted in (A1) can, as shown in Appendix A, be represented by

$$R = \frac{I_R}{I_O} = \frac{0.05 + 0.20 \sin^2 \phi/2}{0.90 + 0.20 \sin^2 \phi/2} \quad [1]$$

where I_R and I_O are the intensities of incident and reflected beams, and

$$\phi = 2hn\pi/\lambda \quad [1a]$$

where h = layer thickness and n = refractive index of Si_3N_4, which is asumed to be independent of both growth rate and layer thickness.

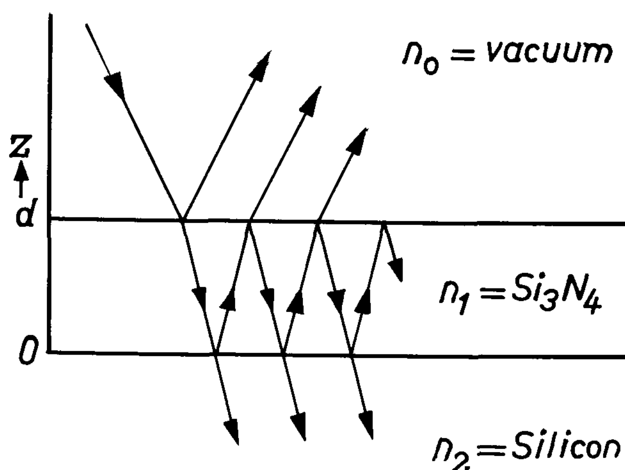

Fig. 3. Schematic representation of the optical system. For clarity the incoming beam is shown at an angle of incidence θ.

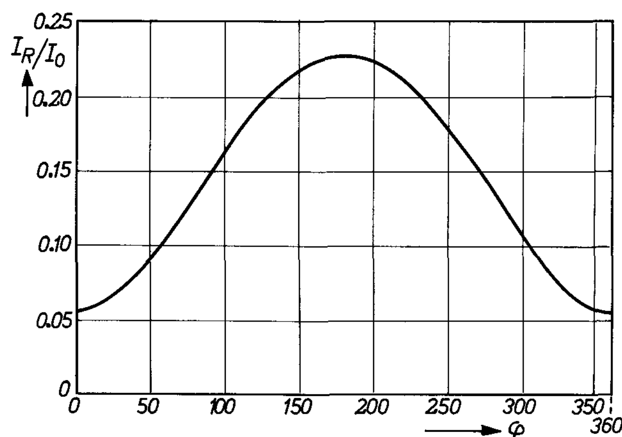

Fig. 4. Relative surface light intensity vs. layer thickness

The deposition rate G is found to be directly proportional to the intensity I_O of the radiation (Fig. 2)

$$G = C \cdot I_O \quad [2]$$

The intensity at the surface I_R depends on the thickness, and shows maxima and minima, and it has experimentally been observed that G also depends on the thickness. Therefore we assume that in fact $G \sim I_R$. Figure 4 shows the intensity I_R at the interface as a function of the reduced layer thickness, in fact a plot of Eq. [1]. From the definition of the growth rate

$$G(h) = \frac{d}{dt} h(t) \quad [3]$$

The time t required to grow in thickness from 0 to $h(t)$ is found to be equal to

$$t = \int_0^{h(t)} \frac{dh}{G(h)}$$

or with Eq. [1], [1a], and [2]

$$AI_O t = \int_0^{\phi(t)} \frac{0.90 + 0.20 \sin^2 \phi/2}{0.05 + 0.20 \sin^2 \phi/2} d\phi \quad [4]$$

This integral is evaluated in Appendix B.

The constant $A = 2n\pi C/\lambda$, which is a function of the quantum efficiency of the process, the pressure in the reactor and partial pressures of the reactive species, can be calculated by substituting the experimental values of t at which the growth retardation occurs. When A is known, the thickness *vs.* time curve can be plotted from Eq. [4].

Figure 5 shows the result of a calculation for one experiment. As shown, a good agreement between theory and experiment is obtained. The critical thickness is defined as the value at which a minimum in growth rate occurs.

Discussion

The deposition of Si_3N_4 was carried out in a temperature range of 100°-400°C, therefore thermal degradation of the compounds was negligible.

As neither gaseous hydrazine nor silane shows absorption of 2537Å radiation, the process must be initiated by excited mercury. Thus the reaction is Hg-photosensitized. It was noticed that across the wafer the growth rate decreased strongly in the downstream direction, owing to depletion of the reactants in the gaseous phase. Thus a nonuniform Si_3N_4 film resulted, even up to a decline of 500Å over 2 cm. The film, however, was always uniform across the slice at about the critical values of the Si_3N_4 thickness. This phenomenon can be explained by the model. When the film at the gas inlet edge of the wafer ($x = 0$) approaches a critical thickness, the growth rate is retarded drastically since $G \sim I_O$ and I_R decreases as $\phi \rightarrow 2\pi$. At other points

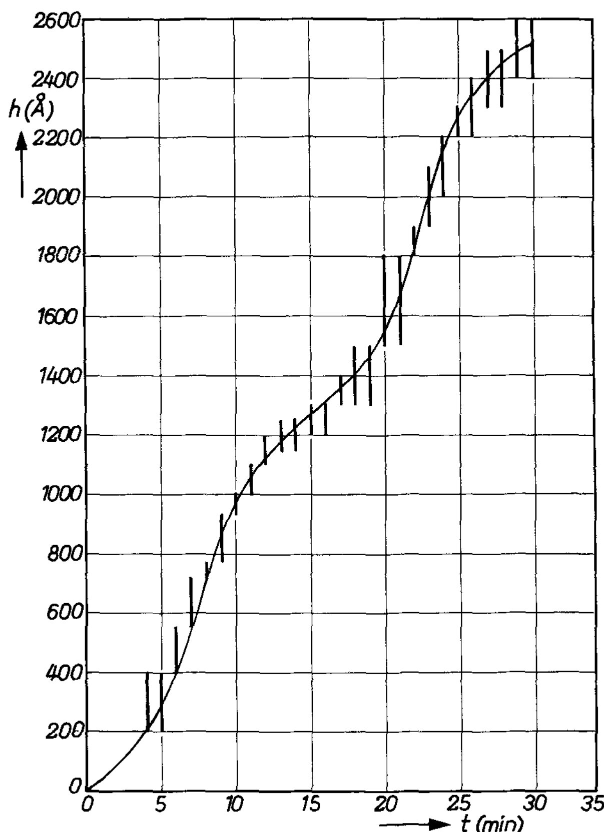

Fig. 5. Thickness increase vs. exposure time curve according to the model. Vertical lines represent the experimental precision. The film was deposited at 200°C, at a reactor pressure of 1.5 Torr and $P_{N2H4}/P_{SiH4} = 1$. The light source was at 20 mm distance.

($x > 0$) the growth rate has a higher value, because $h_x < h_{crit}$ or $\phi < 2\pi$. The thickness increase in t seconds at $x > 0$ will be larger than at $x = 0$. The film consequently changes from wedge-shaped into a layer of uniform thickness. By stopping the process at the appropriate moment, we were able to deposit Si_3N_4 films in integer times 1268Å thick with a thickness variation of less than 20Å over 3 cm (see Appendix A).

The experiment confirms that the intensity at the interface is the major factor which controls the decomposition of the compounds, and that accordingly the contribution of both in the gas phase excited mercury atoms, and obliquely incident light can be neglected. Both these factors would make the growth rate thickness independent. As a consequence it may be concluded that the mercury atoms adsorbed on to the surface catalyze the decomposition only if these are activated *in situ* by the radiation. In other words the sensitized decomposition shows itself as a heterogeneous process. A relatively high surface concentration of hydrazine and mercury due to specific adsorption may be present on the sample surface, increasing the chance for a collision between an excited mercury atom and a hydrazine molecule.

The above theory and experiments apply more generally to any chemical surface reaction which is rate controlled by any photosensitive process step and which produces or destroys a layer transparent to the radiation.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX A

Application of Multiple Reflection (18-20)

It can be shown that the rays directly reflected at the (0,1) interface (Fig. 3) interfere with the rays transmitted through layer (1) and reflected at the (1,2) interface producing effective reflection coefficient R. In the case of normal incidence and refractive indices with no imaginary part, the pertinent equation becomes (20)

$$R = 1 - \frac{(1 - r_{01}^2)(1 - r_{12}^2)}{(1 - r_{01}r_{12})^2 + 4r_{01}r_{12}\sin(-\phi/2)} \quad \text{[A-1]}$$

where $R = I_R/I_O$: ratio of the reflected and incident light.

The amplitude reflection coefficients r_{01} and r_{12} are given by Fresnel's equations

$$r_{01} = \left|\frac{n_0 - n_1}{n_0 + n_1}\right| \quad ; \; r_{12} = \left|\frac{n_1 - n_2}{n_1 + n_2}\right| \quad \text{[A-2]}$$

At the (0,1) interface a phase shift equal to π occurs. Maxima and minima occur at certain optical path differences yielding

$$\text{for } \phi = l \cdot 2\pi \quad \text{minima with } R = \frac{(r_{01} - r_{12})^2}{(1 - r_{01}r_{12})^2} \quad \text{[A-3a]}$$

and

$$\text{for } \phi = (l + \tfrac{1}{2})2\pi \quad \text{maxima with } R = \frac{(r_{01} + r_{12})^2}{(1 + r_{01}r_{12})^2} \quad \text{[A-3b]}$$

with l being an integer.

Insertion of the numerical values mentioned in the text leads to Eq. [1]. Eq. [A-3a] and [A-3b] give

$$I_{min} = 0.05\, I_O \text{ for } h = 1268\text{Å}, \ldots \quad \text{[A-4a]}$$

$$I_{max} = 0.23\, I_O \text{ for } h = 634\text{Å}, \ldots \quad \text{[A-4b]}$$

APPENDIX B

The integral in Eq. [4]

$$AI_Ot = \int_0^{\phi(t)} \frac{0.90 + 0.20\sin^2\phi/2}{0.05 + 0.20\sin^2\phi/2}\, d\phi \quad \text{[B-1]}$$

can be evaluated to be equal to

$$AI_Ot = B \cdot \phi(t) + D \arctan(E \tan\phi/2) \quad \text{[B-2]}$$

B and C being constants

The shape of the t *vs.* ϕ curve is controlled by the value of the parameter E. It can be seen that for $E = 1$ a straight line and for $E \neq 1$ a set of S-shaped curves is found (Fig. 6). The role of the parameter E can be demonstrated when the integrand in Eq. [B-1] is rewritten also in terms of E by differentiating [B-2]

$$\frac{1}{G} = \frac{1}{2}\frac{ED}{E^2\sin^2\phi/2\,\cos^2\phi/2} \quad \text{[B-3]}$$

The curves start at $\phi = 0$ with a slope equal to $\frac{1}{2}E$. All curves cross at $\phi = l \cdot \pi$. For values of E exceeding

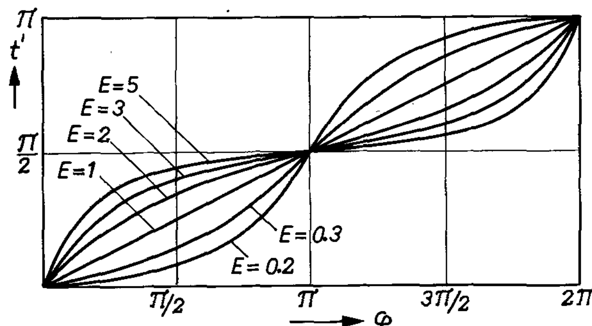

Fig. 6. Plot of the reduced time $t' = \frac{AI_O}{D}t$ vs. ϕ curves according to Eq. [B-2] for a number of E values. For clarity the term $B \cdot \phi(t)$ is omitted.

unity this point of inflection corresponds to a maximum in growth rate. The maximum value increases with E. For values of E smaller than unity this point corresponds to a minimum growth rate. For any particular combination of optical parameters of a layered system E should be calculated.

Electron Trapping in Single Crystal Cuprous Oxide

Jerome D. Schick*,[1] and Dan Trivich*

Department of Chemistry, Wayne State University, Detroit, Michigan 48202

ABSTRACT

Samples of Cu_2O after illumination at low temperatures possess a higher electrical conductance than the same samples without preillumination. The excess conductance is removed by heating above 100°C. The possibility that this "photomemory" effect is due to electron trapping was investigated by methods analogous to thermally stimulated conductivity. When the preilluminated samples are heated at a constant rate with time, $\beta = dT/dt =$ constant, the plots of excess conductance *vs.* temperature are characterized by two maxima lying at about 25° and 100°C. Under different heating rates, the temperatures of the maxima, T_m, are shifted according to the function $\ln(T_m^2/\beta) = E_t/kT_m +$ constant. The values of E_t obtained are interpreted as indicating traps lying 1.03 and 1.34 eV below the conduction band, with a precision of ±15%.

The semiconducting properties of cuprous oxide have been of interest for many years and recently developed methods (1, 2) for reliable preparation of single-crystal Cu_2O have allowed new measurements of properties which had previously been performed only on polycrystalline material. The considerable variation found in the previous data could be due to impure materials, variations in sample preparation, and the effects of grain size and grain boundaries in the polycrystalline cuprous oxide samples. New data have been obtained in our laboratory using these single crystals.

Electrical conductivity measurements have been performed (3) on single-crystal samples of cuprous oxide which had been quenched from high temperatures and controlled oxygen pressures. Optical transmission measurements (4) have been carried out on similarly prepared samples. In particular we have observed that the electrical conductivity of quenched samples decreases irreversibly when the sample is heated to somewhat above room temperature. This phenomenon, which is called "aging," may be similar to the aging in cuprous oxide rectifiers (5) and in polycrystalline cuprous oxide (6). The aging effect may be simulated by first preilluminating the aged sample and then measuring the conductivity in the dark. The increase in conductivity due to preillumination has been called a "photomemory effect" and has been studied by several investigators (7), especially by Kužel (8). In order to gain information which might explain these results, in particular the photomemory effect, we have been led to a consideration of electron trapping as a possible explanation for the variations in the conductivity results and a possible correlation between the conductivity and optical data.

Methods for studying electron trapping in solids include the method of thermally stimulated conductivity. In this method, the sample is illuminated at low temperatures and then, in the dark, the temperature is increased, *e.g.*, at a constant rate with time, while the conductivity is measured. The difference between the conductivity of a preilluminated sample as a function of temperature and the normal dark conductivity as a function of temperature is called the thermally stimulated conductivity (TSC). In an attempt to better understand the electron trapping phenomenon as it pertains to cuprous oxide, a study of single-crystal cuprous oxide was undertaken using methods related to thermally stimulated conductivity.

Much of the work done on investigating trapping levels by thermally stimulated current measurements has been done on CdS (9) and other similar materials (10). There are a number of studies in the literature that compare various methods of analyzing TSC data

* Electrochemical Society Active Member.
[1] Present address: IBM Corporation, East Fishkill Facility, Hopewell Junction, New York 12533.
Key words: cuprous oxide, electron trapping, photomemory, thermally stimulated conductivity.

(9). In general, the temperature of the TSC maximum gives information regarding the magnitude of the trap depth (E_t), the area under the TSC curve gives information about the density of traps, and in some cases, the detailed shape of the TSC curve may give information about the capture cross section of the trap (11). The methods used for analyzing TSC data are generally applicable to all the materials studied, since they are primarily n-type materials with similar properties. In these cases, the thermally stimulated conductivity, σ^*, is due to a transient increase in the number of free electrons during trap emptying. For cuprous oxide, the interpretation of the data may be complicated by interdependent electronic processes. In fact, we have shown that σ^* for Cu_2O increases significantly before trapped electrons are released, making the application of TSC-like measurements to cuprous oxide considerably different from that for n-type materials in general. Thus we have chosen to call the difference between the preilluminated conductivity and the dark conductivity, that is σ^* for cuprous oxide, the excess conductivity (EC).

A center may be considered a trapping center or a recombination center (12) depending on the relative magnitudes of (*a*) the probability of thermal freeing of the carrier from the center and (*b*) the probability of recombination of the carrier at the center occurring with a free carrier of opposite sign. Imperfection levels lying E_t below the conduction band will behave as trapping centers if

$$n_t p v S_p << n_t S_n v N_c \exp(-E_t/kT) \quad [1]$$

where n_t is the density of centers occupied by electrons, p is the density of free holes, and S_n and S_p are the capture cross sections for a free electron (and hole) by a center occupied by a hole (electron), N_c is the effective density of states in the conduction band, and v is the thermal velocity of an electron.

Figure 1 shows a model for a material with N_A acceptors, N'_{A^-} of which are ionized, N_t trapping states, and N_{dt} deep trapping states. The trapping level lies E_t below the conduction band and is occupied by n_t trapped electrons. The electronic transitions for thermal freeing and retrapping are labeled with their respective probabilities, γ and α.

Let us consider the situation where $n_t = 0$, and let us also neglect the deep trapping level. With these restrictions we may plot ln σ against $1/T$ and the slope of this plot may be used to calculate the energy for ionization of an acceptor. This information is obtained from what may be called dark conductivity curves, that is, no illumination reaches the sample insuring that the conductivity is due to the thermal interaction of the valence electrons with the acceptor level.

Now suppose that, due to preillumination, $n_t \neq 0$, that is, there are n_t trapped electrons at E_t below the conduction band. Suppose also that the preilluminated conductivity, $\sigma'(T)$, is greater than $\sigma(T)$, at some temperature far below trap emptying temperatures.

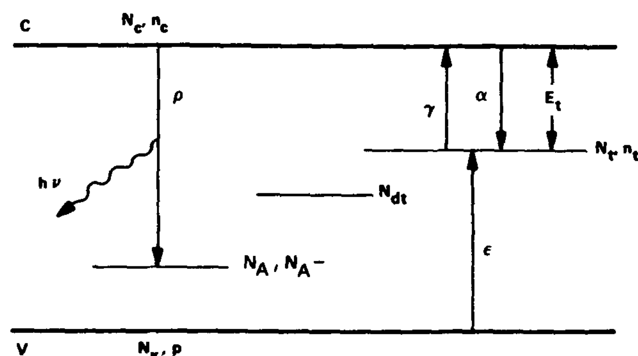

Fig. 1. Energy level diagram for a p-type material with trapping levels.

This greater conductivity could be attributed to an increase in the hole concentration as a result of removing electrons from the valence band/acceptor level equilibrium. These effects are complicated and interdependent; however, under no circumstances should $\sigma'(T) < \sigma(T)$.

Let us consider the variation of σ^* with increasing temperature. In the low-temperature region, the p-type conductivity, $\sigma'(T)$ is larger than the dark conductivity, $\sigma(T)$, due to the previous removal of n_t electrons from the valence band/acceptor equilibrium system. This leads to an increase in σ^* with increasing temperature. As the temperature approaches the region where n_t is affected, electrons are liberated from the traps by being excited to the conduction band from which, by recombination, they re-enter the valence band/acceptor equilibrium system leading to a reduction in $\sigma^*(T)$. Since the free carrier lifetime should be relatively constant over the small temperature range of trap emptying, a maximum in the number of excess free electrons, available for recombination, should occur where the rate of trap emptying is a maximum. These effects will eventually die out as $n_t \to 0$ and $\sigma^*(T) \to 0$. This will produce a maximum in the σ^* *vs.* T curve and the maximum will occur in the temperature region where the rate of change of n_t becomes significant.

In thermally stimulated conductivity of n-type materials, the TSC curves are explained in terms of an increased conductivity as a result of an increase in the number of electrons in the conduction band. In this case, the rate of change in the concentration of free carriers is

$$dn_c/dt = -(n_c/\tau) - (dn_t/dt) \quad [2]$$

where τ is the recombination lifetime for the excess free electrons. Beginning with this expression and using definitions for γ and α, one may arrive at expressions which relate the trap depth E_t to the temperature T_m at which the maximum excess conductivity occurs. For the case of a constant heating rate, $\beta = dT/dt =$ constant, with no retrapping, Bube (13) obtained the relation

$$\ln(T_m^2/\beta) = (E_t/kT_m) - \ln(N_c S_n v k/E_t) \quad [3]$$

We found that a similar analysis could be applied to cuprous oxide to interpret the maxima in the EC curves, and that an expression similar to Eq. [3] could be applied. In the application of the heating-rate method to cuprous oxide, T_m was determined for several values of the heating rate, β, and the first term of Eq. [3], ln (T_m^2/β), was plotted against $1/T_m$ resulting in a straight line whose slope taken as E_t/k gave a value for the trap depth E_t. The justification for this treatment is given in the discussion.

Experimental

The single-crystal cuprous oxide samples were prepared using the method developed in this laboratory by Toth, Kilkson, and Trivich (1) and modified by Kellogg (14). In this method, high-purity copper sheets were oxidized at 1000°C to polycrystalline cuprous oxide and subsequently annealed at higher temperatures to form large area single crystals in the plate. The single-crystal samples cut from this plate were polished to a thickness of 0.02 cm and then equilibrated. Equilibration was accomplished at 1020° or 750°C in an atmosphere of known and controlled oxygen partial pressure. The purpose of the equilibration procedure was to fix the departure from stoichiometry. The concentration of defect species, *e.g.*, copper atom vacancies, presumably varies according to the oxygen pressure used in the equilibration. Oxygen partial pressures used were in the range of 112 to 8.9×10^{-2} Torr for 1020°C and 1.48 to 7.5×10^{-4} Torr for 750°C, thus covering a wide region of conditions in which Cu_2O is stable.

The single-crystal samples were quenched to liquid nitrogen temperatures from equilibration temperatures. This technique was presumed to "freeze-in" the departure from stoichiometry determined during equilibration. After gold ohmic contacts were evaporated on the sample, it was placed in the measuring system. This system allowed measurements of conductivity, photoconductivity, minority carrier lifetime, and excess conductivity. Measurements could be performed under illuminated conditions or total darkness and at a pressure less than 5×10^{-7} Torr.

The samples were mounted on a holder in the system which allowed cooling to liquid nitrogen temperatures and heating to 300°C. A control thermocouple was connected from the sample holder to a modified Fisher DTA programmer/controller. Two additional Chromel/Alumel thermocouples were attached to the sample holder and connected to a recorder for time/temperature curves and a plotter for current/temperature plots. The sample current was plotted on the vertical axis of the plotter.

Illumination of the sample was performed by using either a tungsten filament source, a pulsed light source, or a monochromatic source. Each of these could be positioned adjacent to the quartz window of the vacuum system.

After the sample was placed in the system it was initially heated to above 100°C after which it was cooled to −160°C in the dark. The temperature was then linearly increased and sample current plotted as a function of temperature on the X-Y plotter. This gave the dark conductivity curve. The sample was again cooled to −160°C and illuminated, *e.g.*, for precisely 4 min with white light. Then in total darkness, it was again heated at a linear rate producing the preilluminated curve. The difference in conductivity between the two curves is called the excess conductivity curve.

Results

Figure 2 gives a typical recorder plot of conductance curves for cuprous oxide, showing the dark conductance, σ, the conductance after preillumination, σ', and the difference or excess conductance, σ^*. In this plot, the difference is doubled in conductance to accentuate the shape of the EC curve. Since only relative values of the conductivity are required, the directly recorded values of the conductance in ohm^{-1} are given in the plots, but in the discussion the term, conductivity, is used.

The dark conductivity curves were very nearly identical for all the samples run which had been equilibrated at oxygen pressures of 14.2 to 7.4×10^{-4} Torr and quenched from 1020° and 750°C. These curves were used to obtain plots of log σ *vs.* $1/T$ which were straight lines whose slopes of $-E/2.303\ kT$ gave $E = 0.4$ eV in all cases. The dark curve was repeated through as many as thirty cooling-heating cycles for a given sample.

The curves for conductance after preillumination all showed two maxima producing two peaks in the EC curves near 298° and 373°K. As indicated by Eq. [3], a change in the heating rate, β, causes a shift in the temperature at which the EC peak occurs. This then provided a method of determining the trap depth, E_t. In this work, heating rates of 0.09 to 0.4°C/sec were used to produce the shifts in the EC maximum temperatures as shown in Fig. 3. From these curves, the maxima were determined, T_{m1}, for 298°K peak and T_{m2} for the 373°K peak, and plots were made of log (T_m^2/β) *vs.* $1/T_m$. Figure 4 shows these two plots which can be used to determine the electron trap depths associated with the two peaks in the EC curves. Thus an average value of 1.03 eV for the trap depth was obtained from the 298°K peak and 1.34 eV for the trap depth associated with the 373°K peak. Values for the trap depths from the EC curves of all the samples varied by as much as 15%, but this was judged to be the limit of the precision of reading and treating the data, rather than being due to significant variations among the samples.

In order to determine the minimum photon energy for trap filling, an experiment using monochromatic light was performed. Monochromatic light of controlled intensity was directed on the sample at low temperatures for 1 hr, and then the curves for the conductance of the sample after preillumination and for the dark conductance were run in the normal manner. The heights of the EC curves at the maxima were then plotted against the photon energies of monochromatic light. Figure 5 shows the results of these measurements. For measurement of the higher temperature peak, the preillumination was done at room tempera-

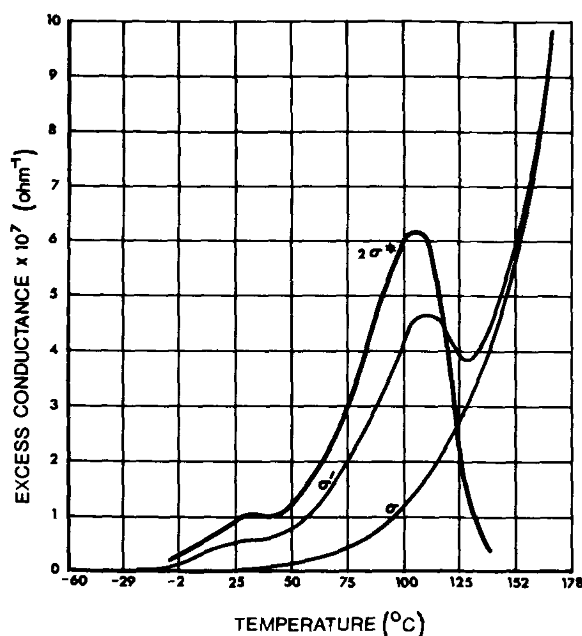

Fig. 2. Typical excess conductance curve, showing the dark conductance, σ, the conductance after preillumination, σ', and the difference, σ^*, the last on a doubled scale.

ture since this resulted in elimination of the lower temperature peak. In fact, separation of the two peaks was frequently used, *e.g.*, by warming a preilluminated sample to room temperature, cooling the sample again, and then making a normal programmed run with only the higher temperature peak present.

No significance is attached to the detailed shape of the curves in Fig. 5 except to the tendency to approach a threshold. The threshold energy for filling of the 1.03 eV trapping level was found to be about 1.3 eV and the threshold energy for filling of the 1.34 eV trapping level was about 1.1 eV. A discussion of the consequences of these results appears later.

The proposed energy level diagram for cuprous oxide as determined from this work is shown in Fig. 6. Level 1 is the 0.4 eV acceptor level, and levels 2 and 3 are the two electron trapping levels whose depths and threshold energies were determined independently in this work.

Discussion

To explain these results one must make some assumptions concerning a model for cuprous oxide. A widely accepted model is that by Wagner (15), which describes cuprous oxide as a defect compound in which an excess of oxygen gives rise to copper atom vacancies. These vacancies act as acceptors thus explaining the observed p-type character. Since this model, while moderately successful in explaining high-temperature

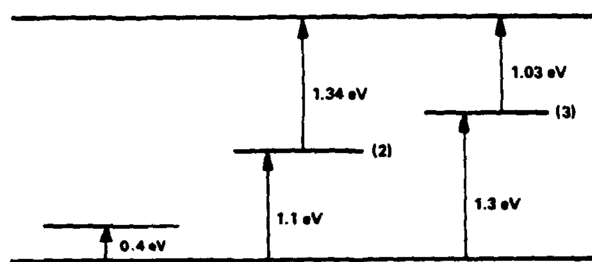

Fig. 6. Proposed energy level diagram for Cu_2O. The lowest level is an acceptor level; the higher levels are trap levels. The values associated with the trap levels are approximate, with an estimated precision of ±15%.

properties, is inadequate for low temperatures, more elaborate models have been proposed, largely based on Bloem's (16) work and more recently treated by the Strasbourg group (7, 17). The principal species postulated are copper atom vacancies, oxygen vacancies, which can be singly and doubly ionized, and also complexes among these various species. While these postulates are plausible, very little concrete evidence is yet available to assign the various species to the energy levels that are invoked to explain the experimental results.

The dark conductivity and the conductivity after preillumination at temperatures below the maximum can be described by the functions $\sigma = K \exp(-E/kT)$ and $\sigma' = K' \exp(-E'/kT)$, respectively, in which $E \approx E' \approx 0.4$ eV within the precision of measurements, and $K' > K$. In this region, which has been called the "photomemory" region, the problem is to explain the increase in the pre-exponential factor, K, due to preillumination. Kužel (8) has proposed that K is dependent on the concentration of isolated copper atom vacancies which act as acceptors. Heating in the dark removes some of these by forming associates, *e.g.*, copper atom divacancies, and preillumination causes a dissociation of these complexes, enlarging the concentration of single atom vacancies. While Kužel's model is a possible one, our results are better explained by a model which is based on a changed concentration of un-ionized acceptors due to preillumination. A similar model is apparently preferred by the Strasbourg group.

Let K be proportional to the concentration of un-ionized acceptors, $K = BN_{A_0}$. It is possible that even at absolute zero some of the acceptors are ionized, thus implying a partially compensated model, so that $N_{A_0} = N_A - (N_{A^-})$ at $T = 0$°K. Here N_A is the total concentration of acceptors and N_{A^-} is the concentration of ionized acceptors at 0°K.

As the temperature is increased, electrons are excited from the valence band to the acceptor levels, giving rise to more ionized acceptors and p-type conductivity, so that $N_{A_0} = N_A - [(N_{A^-}) + p]$, where p is the hole concentration. We assume $p << [N_A - (N_{A^-})]$.

The effect of preillumination is to remove some electrons from the ionized acceptors and place them in higher, trapping states. The details of this process need not be specified since the equilibrium between the valence band and the acceptor states allows the removal to occur from both of these. The net effect is to increase the concentration of un-ionized acceptors so that after illumination $N_{A_0} = N_A - [(N_{A^-}) - n_t]$ where n_t is the concentration of trapped electrons. Thus K is increased to K' giving rise to a greater conductivity due to preillumination.

The above discussion applies to the temperature region below the maximum in the EC curve. The effect of further increase in temperature is to excite electrons out of the traps to the conduction band from which they re-enter the valence band/acceptor equilibrium system by way of recombination centers. The net effect

is to regenerate the ionized acceptors which had been bared by preillumination. This tendency toward a decrease superimposed on a rising EC curve then gives rise to a maximum in the curve. The temperature at which this occurs, T_m, can be used to locate the depth of the trap level by methods analogous to those used for the TSC case.

Neglecting the contribution to the conductivity by the electrons in the conduction band, the excess conductivity $\sigma^* = (K' - K) \exp(-E_A/kT) \propto (p' - p)$ and $(K' - K) = Bn_t$. We modify Bube's treatment of the heating rate method for locating trap depth by postulating that the rate of trap emptying determines the rate of regenerating ionized acceptors, *i.e.*, the lifetime of the excess electrons in the conduction band is very small.

Thus at the maximum, $d\sigma^*/dT = 0$ and also $d\Delta p/dT = 0$ if one neglects the temperature variation of the hole mobility, μ_p. At a constant heating rate, $\beta = dT/dt$ = constant, we have $d\Delta p/dT = \beta^{-1}d\Delta p/dt$. Now setting $d(\ln \Delta p)/dt = 0$, and noting that $\sigma^* = q\mu_p\Delta p$, we obtain

$$\frac{d}{dt}[\ln(B/q\mu_p) + \ln n_t - E_A/kT] = 0 \quad \text{at } T = T_m \qquad [4]$$

so that

$$\frac{\beta E_A}{kT_m^2} = -\frac{1}{n_t}\frac{dn_t}{dt} \qquad [5]$$

The factor on the right of Eq. [5] represents the probability of escape from traps and this is given by Bube (18) as

$$-n_t^{-1}(dn_t/dt) = P = N_c v S_t \exp(-E_t/kT) \qquad [6]$$

where S_t is the capture cross-section of the traps. Then for $T = T_m$, we obtain

$$\beta E_A/kT_m^2 = -n_t^{-1}(dn_t/dt) = P = N_c v S_t \exp(-E_t/kT_m) \qquad [7]$$

so that

$$\ln(T_m^2/\beta) = (E_t/kT_m) - \ln(N_c S_t v k/E_A) \qquad [8]$$

Equation [8] is analogous to Eq. [3] previously derived for the treatment of the TSC curves. Thus by the present model, plots of $\ln(T_m^2/\beta)$ *vs.* $1/T_m$ can be used to evaluate the trap depth by setting the slope equal to E_t/k, as was done in the Results section.

The model proposed is also in accord with the results of Zouaghi *et al.* (17) who showed by Hall measurements that the effect of the preillumination is primarily to increase the density of holes. Further support may be found in the work of Fortin *et al.* (20) who related the photomemory effect to high-temperature photoconductivity for which the time constants vary from minutes to fractions of a second over temperature ranges from room temperature to 250°C.

While the above is apparently the most economical model that could be used to explain the present data, it is possible to make a more detailed model by making further postulates which are quite plausible. In the model thus far we have not identified the source of the ionization of the originally ionized acceptors of concentration, N_{A-}. It is conceivable that both donors and acceptors exist in cuprous oxide with a predominance of acceptors. The neutral donors would lose electrons to the acceptors (not necessarily rapidly), thus leading to partial compensation. As shown by Brattain (19) for partially compensated cuprous oxide, the hole concentration would be given by

$$p = \frac{N_A - (N_{D+} + p)}{N_{D+} + p} N_v \exp(-E_A/kT) \qquad [9]$$

where N_{D+} is the concentration of ionized donors.[2] For the condition $p << N_{D+} < N_A$

$$p = \frac{(N_A - N_{D+})}{N_{D+}} N_v \exp(-E_A/kT) \qquad [10]$$

which is identical to our previous treatment with $N_{D+} = N_{A-}$ and $B/q\mu_p = N_v/N_{D+}$. Further the effect of preillumination may be to move the electrons from the ionized acceptors to the ionized (empty) donor states so that

$$N_{A^0} = N_A - N_{D+} \text{ and } N_{D+} = N_D - n_t$$

A further elaboration of the model could proceed by attempting an identification of the species responsible for the various levels. Following Bloem, one could assign the two trap levels to oxygen vacancies which can be singly and doubly ionized. The acceptor levels could be assigned to copper atom vacancies or some complex arising from them. Still further levels are presumably necessary to explain other results. However the identification of the species responsible for these levels must await more definitive experiments.

Manuscript submitted May 20, 1971; revised manuscript received Nov. 3, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Vapor-Phase Epitaxial Growth and Some Properties of ZnSe, ZnS, and CdS

W. M. Yim and E. J. Stofko

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Single-crystal layers of ZnSe, ZnS, and CdS have been grown epitaxially on GaAs, GaP, and sapphire substrates in an open-tube system by reaction of the metal vapors with the nonmetal hydride gases. Various factors are discussed which were found to affect the epitaxial growth. These include the role of vapor compositions and growth temperatures in controlling stoichiometry and polymorphism, and the choice of substrate materials with particular emphasis on the effects of lattice and thermal expansion match between the substrate and the epitaxial layer. High crystalline quality of the epitaxially grown layers was evidenced by the Kikuchi lines present in their electron diffraction patterns. As-grown layers of ZnSe and ZnS, both undoped and doped, were high resistivity, while CdS was readily grown n-type. These epitaxial layers showed at room temperature a bright, visible cathodoluminescence, and for each compound different emission colors were observed with specimens grown at different temperatures.

Although published literature abounds with reports describing crystal growth of II-VI compounds, relatively little information is available on vapor-phase epitaxial growth of these compounds. The lack of information is particularly true for epitaxial growth using gaseous starting sources of the component elements, since in nearly all of previous work (1-3) the starting materials used were presynthesized bulk compounds.

In this paper, we report the heteroepitaxial growth of single-crystal ZnSe, ZnS, and CdS layers on GaAs, GaP, and sapphire substrates in an open-tube system by reaction of the metal vapors with the nonmetal hydride gases. The results presented include growth morphology, crystalline perfection, and some of the electrical and luminescent properties of these epitaxially grown layers.

Experimental

The epitaxial growth of ZnSe, ZnS, and CdS on various substrates was investigated with the apparatus (4) shown schematically in Fig. 1.[1] In this apparatus the Group II element (Zn or Cd) was transported as the vapor by passing H_2 over the molten metal located in the source zone at a temperature T_1. The Group VI element (Se or S) was introduced as gaseous hydride (H_2Se or H_2S) diluted in H_2. The Groups II and VI gases were brought together in the reaction zone at a temperature T_3, and growth of the II-VI compound occurred on a substrate in the deposition zone maintained at a temperature T_5.

The substrate material most extensively used was GaAs of (100) and (111)[2] orientations, but we also used (100)- and (111)[2]-oriented GaP and (0001)-oriented sapphire, while the use of other substrate materials such as Si and Ge was limited to only a few experiments. The GaAs and GaP substrates were first mechanically polished to a mirror-smooth finish, followed by chemical polish in a dilute bromine-methanol solution with or without H_3PO_4. The sapphire substrates (which were furnished with a smooth surface finish by the supplier[3]) were annealed *in situ*, prior to epitaxial growth, in flowing H_2 for about 15 min at 1300°C. This simple treatment was found satisfactory for single-crystal epitaxy. Although we have explored other methods of sapphire surface preparation, which included chemical etch in hot H_3PO_4 followed by Caro's acid etch, as well as gas-phase etch in flowing HCl-H_2 at temperatures from between 1000° and 1250°C, the substrates thus treated did not provide single-crystal epitaxy within the experimental conditions investigated.

Virtually all of the present II-VI compound epitaxial layers were deposited directly onto the substrates prepared as above. However, as is discussed later, for ZnS we also used GaAs substrates coated with thin layers of single-crystal GaP.

A comprehensive series of experiments with various reactant gas compositions, flow rates, and zone temperatures led to the selection of the optimum growth conditions, the discussion of which follows.

Results and Discussion

Effect of Growth Conditions

Of various growth parameters investigated, the reactant gas compositions and particularly the substrate temperatures had the most significant effects upon stoichiometry, growth rate, and crystallinity. In addition, the choice of substrate materials had an important bearing on the crystallinity of the deposited layer, as is discussed in a later section.

Reactant gas compositions.—The effect of reactant gas compositions on epitaxial synthesis was investigated primarily with the growth of ZnSe on GaAs substrates near 700°C; the most significant data are given in Table I.

The gaseous flow rates (200 cm³/min H_2 over molten Zn and 15 cm³/min H_2Se) listed first in Table I were

calculated to give an approximately equal number of moles (10^{-5} moles/min) of Zn and Se for deposition of stoichiometric ZnSe. This, however, resulted in polycrystalline, multiphased material. The major phase consisted of a Ga_2Se_3-ZnSe alloy[4] and the minor phase was ZnSe of zincblende form mixed with a small amount of wurtzite form. The Ga_2Se_3-ZnSe alloy apparently resulted from the reaction between excess H_2Se and the GaAs substrate, since no Ga_2Se_3 alloy formed when sapphire substrates were used. By reducing the H_2Se flow to 10 cm^3/min, the Ga_2Se_3 alloy formation was substantially suppressed, and by further reducing the H_2Se flow to 3 cm^3/min the single-crystal epitaxy of ZnSe was achieved. On the other hand, the Zn vapor concentration had relatively little effect on formation of ZnSe within the Zn concentration range investigated of 10^{-6}-10^{-5} moles/min, as shown in Table I.

For ZnS and CdS deposition, we used approximately the same gas flow rates as that found to be optimum for the growth of ZnSe.

Substrate temperatures.—The growth rate of ZnSe epitaxial layers was found to increase with increasing substrate temperature, as shown in Table II. At deposition temperatures below 700°C, the growth rates were small (1-5 μ/hr). Faster growth occurred in the temperature range of 700°-800°C, but with mixtures of zincblende (cubic) and wurtzite (hexagonal) polymorphs. The wurtzite polymorph generally disappeared at temperatures higher than 830°C, leading to return of the single-phase cubic form with a growth rate as high as 36 μ/hr at 890°C.

[4] Our unpublished results indicated that Ga_2Se_3, with a defect zincblende structure having a lattice constant of 5.42A, forms continuous solid-solution alloys with ZnSe.

For ZnS the growth rate increased also with increasing temperature to more than 15 μ/hr at 830°C, but it decreased with further increase in temperature. The zincblende-wurtzite polymorphism was also observed for ZnS, but we defer general discussion of the observed phenomenon to a later section.

In contrast to relatively high temperatures found for optimum growth of ZnSe and ZnS, 890°C and 830°C, respectively, the optimum growth temperature for CdS was found to be near 700°C with a growth rate of 50 μ/hr. Above 700°C the growth rate decreased, and no CdS deposit formed beyond 800°C.

The observed dependence on substrate temperature of the growth rate could not be predicted on the basis of equilibrium thermodynamics. The free energy changes ($\Delta F°_T$) in chemical reactions postulated for the vapor deposition of ZnSe, ZnS, and CdS (see Appendix) are all negative in the range of substrate temperatures investigated, as shown in Fig. 2. Further, the $\Delta F°_T$ values become more negative with decreasing temperature. Therefore, the deposition rate would probably increase monotonically with substrate temperature, contrary to the present experimental data, if equilibrium thermodynamics is the only factor that affects the vapor deposition process. The assumption, however, is not valid as amply demonstrated in recent studies, which showed that considerable deviations from thermochemical equilibrium exist (5) in an open-tube growth system such as the present one, and

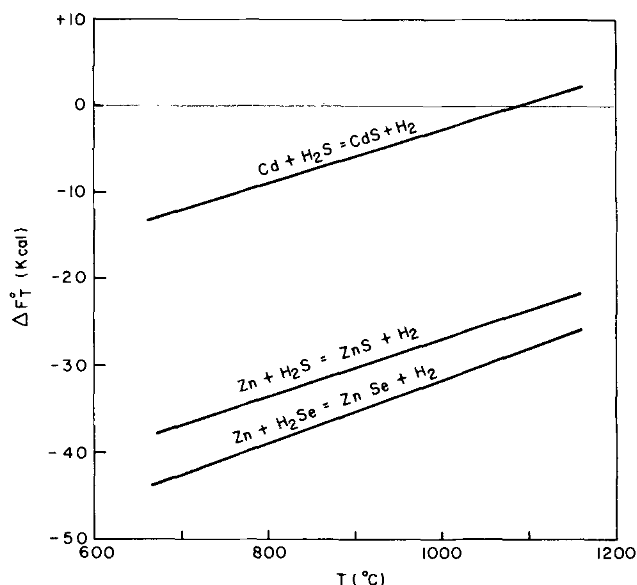

Fig. 2. Free energy of reaction ($\Delta F^0{}_T$) for vapor deposition of ZnSe, ZnS, and CdS.

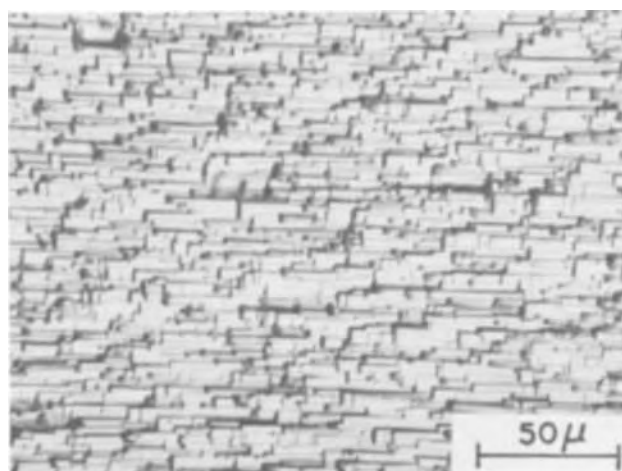
that kinetic factors significantly influence the deposition process (6).

While simple arguments based on equilibrium are inadequate to describe the present vapor growth process, it is, nonetheless, noteworthy that the experimental optimum growth temperatures are lower for materials of smaller calculated $\Delta F^\circ{}_T$ values than for materials of larger $\Delta F^\circ{}_T$. Namely, the optimum growth temperature listed in Table III for CdS of 700°C is lower than that for ZnS of 830°C which is yet lower than that for ZnSe of 890°C, and this is to be correlated with the trend shown in Fig. 2 of $|\Delta F^\circ{}_T|_{CdS} < |\Delta F^\circ{}_T|_{ZnS} < |\Delta F^\circ{}_T|_{ZnSe}$ below about 1100°C. The above observation is not limited to the case of II-VI compound vapor deposition. Previously, in an open-tube vapor growth of III-V compounds, we also observed (7) the similar relationship between experimental optimum growth temperature (T_{opt}) and $\Delta F^\circ{}_T$; for example, $(T_{opt} = 700°C)_{InP} < (T_{opt} = 750°C)_{GaAs} < (T_{opt} = 800°C)_{GaP}$ and $|\Delta F^\circ{}_T|_{InP} < |\Delta F^\circ{}_T|_{GaAs} < |\Delta F^\circ{}_T|_{GaP}$. It is certain that any attempt to explain the above relationship must include considerations not only of equilibrium thermochemistry but also of kinetics, for which experimental data are lacking at the present time.

Structure and Crystallinity

ZnSe epitaxial layers.—Typical microstructure of a single-crystalline cubic ZnSe layer grown epitaxially on a (100)-GaAs substrate is shown in Fig. 3a. The layer was grown at 890°C and, as shown, it is well oriented. The reflection electron diffraction pattern in Fig. 3b confirms the (100) epitaxy. In addition to the well-defined diffraction spots, Kikuchi lines are present, which indicate high crystalline perfection. Similarly, epitaxial layers on (111)-GaAs substrates (not shown) revealed well-oriented triangular growth patterns, characteristic of the (111) epitaxy. The cubic (111) ZnSe was also found to grow on (0001)-sapphire substrates; a microstructure of the (111)-oriented ZnSe single-crystal layer is shown in Fig 4a.



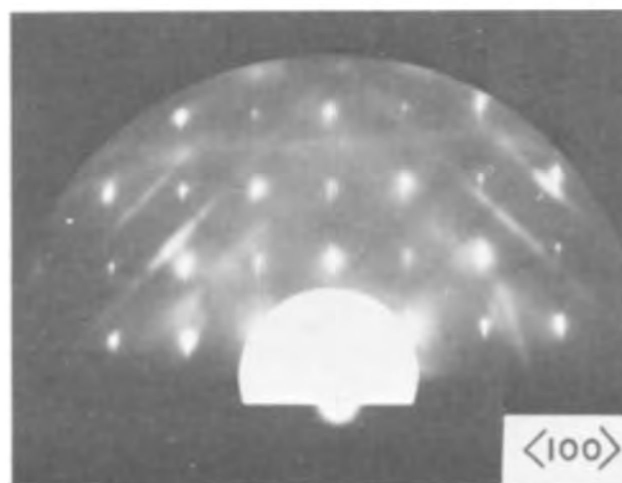


Fig. 3. (a, top) Photomicrograph, and (b, bottom) reflection electron diffraction pattern, of (100) ZnSe grown epitaxially on (100) GaAs.

The excellent epitaxy of ZnSe on GaAs can be understood in the light of complete solid-solution alloying (4), and good match both in the lattice constant and in the thermal expansion coefficient, between ZnSe and GaAs; and this makes possible a smooth transition between the substrate and the grown layer with minimal strains involved. As shown in Table IV, the difference is their lattice constants at room temperature is only 0.3%, and it increases slightly to about 0.6% at 800°C. Even with this good lattice match, rapid cooling sometimes caused the epitaxial layers to crack. However, cracking was com-

pletely eliminated by slowly cooling the specimens from the growth temperature.

ZnS epitaxial layers.—The room-temperature lattice constant of GaP matches that of cubic ZnS to within 0.7%, and their thermal expansion coefficients are not appreciably different from each other (see, Table IV). Furthermore, GaP and ZnS form complete solid solutions (4), and therefore GaP appears to be a good substrate material for epitaxial growth of ZnS. The thermal expansion match is one of the most important factors to be considered in selecting suitable substrate materials. Silicon, in spite of its good lattice match to within 0.4% of ZnS at room temperature, is not a good substrate material, since ZnS layers grown on Si substrates were frequently found to crack. This is probably due to a relatively large difference in the thermal expansion between ZnS and Si. Since high-quality GaP single crystals of large dimensions were not readily available when the present study was undertaken, we initially used GaAs substrates after slowly varying the composition through graded regions of Ga(As, P) alloys from GaAs to GaP, using a vapor-phase growth technique previously developed by Tietjen and Amick (8). Subsequently, however, we used (100)-GaP as well as (100)-GaAs substrates for direct deposition of (100)-oriented cubic ZnS.

Typical microstructure of a cubic (111)-ZnS layer epitaxially grown on (111) GaP on a (111)-oriented GaAs substrate is shown in Fig. 5a, and the reflection electron diffraction pattern of Fig. 5b confirms the epitaxy. The pyramid-shaped growth patterns were formed during the epitaxial growth of GaP, with the

result that they also appeared in the ZnS epitaxial layer. By contrast, the single-crystal ZnS layers deposited directly on (100)-GaP or on (100)-GaAs substrates showed less well-defined microstructure, *e.g.*, Fig. 6a; but, as shown in Fig. 6b, the Laue picture proved the deposited layers to be single-crystal cubic ZnS of the (100) orientation.

CdS epitaxial layers.—Epitaxial layers of (0001) CdS grown on (111)-GaAs substrates show a distinct growth feature consisting of many flat-topped and some pointed hexagonal pyramids. The surface microstructure of one such layer is shown in Fig. 7a and the epitaxial relation was determined to be (0001) CdS // (111) GaAs from the reflection electron diffraction pattern shown in Fig. 7b. The hexagonal patterns are apparently a common growth morphology for the (0001)-oriented CdS epitaxial layer, found not only in the layers grown on (111) GaAs and (0001) sapphire (Fig. 4b), but also in the films deposited on many other substrate materials such as ZnS, Ge, SrF_2, mica, CaF_2, and CdS itself (9). These morphological patterns are believed to indicate the characteristic growth mechanism (surface nucleation) of the epitaxial CdS layers (9).

There is a relatively large difference (3.2%) in the room temperature lattice constant between CdS and GaAs, although the difference in their thermal expansion coefficients is small. Since the present CdS layers were directly deposited on GaAs substrates, a considerable strain would be present in the CdS layers, particularly if the grown layers were thin. The strain arising from the lattice mismatch would, however, diminish with increasing distance away from the CdS-GaAs interface. In fact, for specimens with CdS layers thicker than about 50μ, Kikuchi lines were sometimes observed in the electron diffraction patterns.

Polymorphism.—It is well known (2) that many II-VI compounds exhibit zincblende-wurtzite polymorphism, as well as polytypism in the wurtzite form. The zincblende form is closely related to the wurtzite form by a simple lattice stacking difference, and the free energy difference between the two phases is prob-

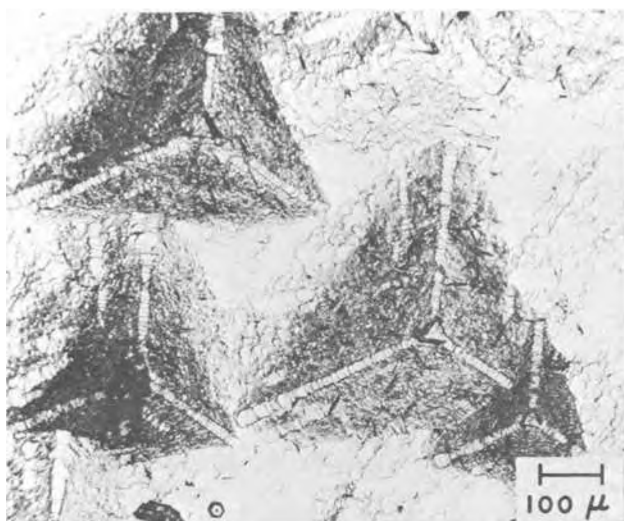

Fig. 5. (a, top) Photomicrograph, and (b, bottom) reflection electron diffraction pattern, of (111) ZnS grown epitaxially on (111) GaP on (111) GaAs.

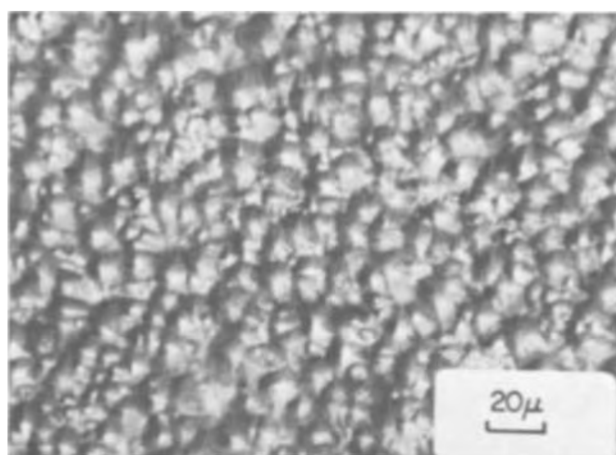
ably small since they frequently coexist in one sample, as mentioned in a previous section. Although the zincblende phase is generally thought to occur at low temperatures and the wurtzite phase at high temperatures, previous results on this are widely conflicting. For instance, in the case of ZnSe, the wurtzite polymorph was reported (10) to appear in vacuum-sputtered films at substrate temperatures above 210°C. On the other hand, we did not observe (11) the hexagonal phase either in flash-evaporated ZnSe films deposited at temperatures up to 600°C, or in closed-tube chemically transported ZnSe grown at temperatures up to 950°C. A much higher temperature, $\gtrsim$ 1000°C, was reported (12) for the occurrence of the wurtzite phase in vapor-transported ZnSe using Ar as a carrier gas.

In the present study with an open-tube chemical vapor deposition process, the temperature range where the wurtzite form of ZnSe appeared most frequently was between 700° and 830°C, as shown in Table II. The ZnSe layers grown outside of this temperature range were entirely in the cubic form, except when the vapor deposition was carried out in large excess H_2Se (see, Table I); and under this condition the hexagonal polymorph appeared, mixed with the cubic form in varying proportions, at all deposition temperatures investigated.

For bulk ZnS, it is also generally accepted that wurtzite is the stable form at high temperature, and that the hexagonal to cubic transition takes place at a temperature between 1020° and 1150°C (2, 13). In the present vapor-deposited ZnS, the wurtzite modification was obtained at growth temperatures as low as 650°C, and this was the only form that grew on (0001)-sapphire substrates throughout the entire range of



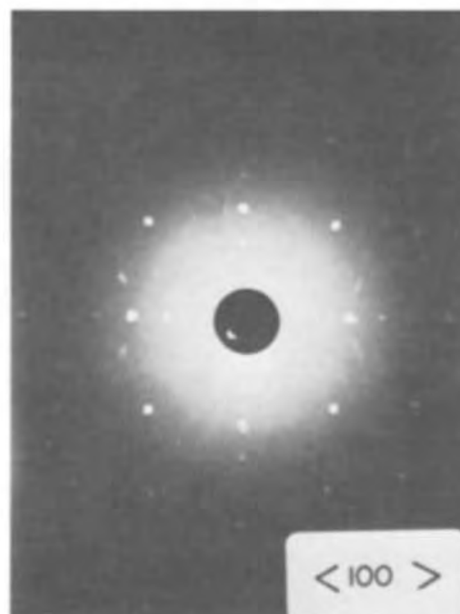


Fig. 6. (a, top) Photomicrograph, and (b, bottom) Laue back reflection pattern, of (100) ZnS grown directly on (100) GaAs.

deposition temperatures investigated up to 900°C. The crystal structure of substrate materials had a very significant effect on the type of polymorph to be obtained, since the ZnS epitaxial layers deposited near 800°C on GaAs and GaP consisted entirely of the cubic form, as opposed to the hexagonal form that grew on sapphire under otherwise identical growth conditions (see, Table II).

In contrast to the epitaxially grown ZnSe and ZnS, no polymorphism was observed in the present CdS epitaxial layers, which were all in the wurtzite form. This is in agreement with general observations that the zincblende form of CdS occurs only rarely in nature or in synthesized bulk material.

It is clear from the above discussion that the occurrence of polymorphism is a sensitive function of such variables as preparative techniques, growth temperatures, substrate materials, and reactant gas compositions. In addition to the aforementioned variables, previous investigations (2, 13) on the polymorphism in II-VI compounds, particularly in ZnS, list such factors as impurity effects, cooling rates, pressure, and mechanical strain that significantly affect the structure, and thus emphasize even more the complexity of the problem involved. The frequently quoted hexagonal to cubic transition temperature for ZnS, 1020°-1150°C, is for the bulk crystal probably under equilibrium conditions. Accordingly, it is not too surprising that the data are at variance in the present case, where the epitaxial layers were grown under

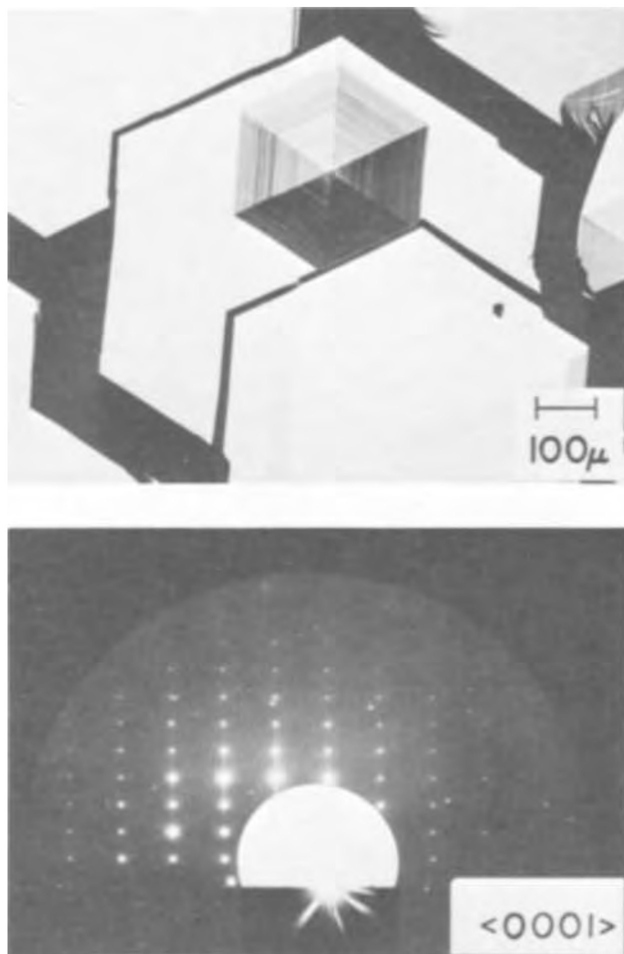

Fig. 7. (a, top) Photomicrograph, and (b, bottom) reflection electron diffraction pattern, of (0001) CdS grown on (111) GaAs.

conditions deviating appreciably from equilibrium and where the structure of the grown layers was dictated largely by that of the substrate.

Electrical Properties

Epitaxial layers of ZnSe grown without intentional doping were high resistivity, $\gtrsim 10^8$ ohm·cm. N-type specimens were obtained by doping during growth with 300-3000 ppm Al, but the resistivity still remained high, $\sim 10^5$ ohm·cm. The difficulty of obtaining low-resistivity wide-bandgap II-VI compounds is well known, and it is attributed to the process whereby added doping impurities are compensated by native lattice defects (14). The most effective method to induce a high n-type conductivity in ZnSe involves annealing the specimen submerged in molten Zn containing the desired donor impurities such as Al (15). The zinc liquid suppresses the formation of Zn vacancies and, at the same time, helps the electrically active donor element to be incorporated into the lattice. The liquid anneal also helps to extract any acceptor impurities that may be present in the specimen.

Our preliminary experiments showed that high-resistivity melt-grown ZnSe can indeed be converted to n-type (*e. g.*, to a resistivity of 5×10^{-2} ohm·cm, with corresponding carrier concentration of 4×10^{17}/cm^3 and Hall mobility of 313 cm^2/V·sec) after about 70-hr annealing in $Zn_{0.97}Al_{0.03}$ liquid at 1000°C. Although successful for bulk crystals, this annealing condition was found unsuitable for epitaxially grown ZnSe layers on GaAs substrates, since both the ZnSe and the GaAs dissolved completely in the zinc liquid after annealing treatment. In fact, even for the bulk crystals, it was subsequently determined that the zinc melt dissolved more than 20% of ZnSe upon annealing as above. Shorter periods of anneal, however, were ineffective in rendering ZnSe high conductivity.

Since the liquid annealing procedure thus involved drastic conditions, annealing of Al-doped ZnSe epitaxial layers was carried out in approximately 1-atm Zn vapor in the temperature range 800°-1000°C for periods of 1-100 hr; however, all specimens remained high resistivity. The vapor anneal was motivated by previous reports (15) that a highly conducting ZnSe:Al (obtained by zinc-liquid anneal similar to that described above) can be rendered insulating by a brief annealing in vacuum at 850°C, but that it can be completely restored to the original conductivity by reannealing in about 0.5-atm Zn vapor at the same temperature. However, our experience with melt-grown bulk ZnSe showed that the zinc-vapor anneal can effect only a partial restoration of the original conductivity (*e. g.*, to a resistivity of 7×10^{-1} ohm·cm from the original value of 5×10^{-2} ohm·cm), and this indicated that the vapor anneal is not as effective as the liquid anneal. With ZnSe:Al epitaxial layers on GaAs substrates, a further complication is that GaAs dissociates during high-temperature anneal to dope ZnSe:Al with As (acceptor), thus resulting in compensation and high resistivity, as observed in the above vapor anneal of the ZnSe:Al epitaxial layers.

The ZnS layers grown without intentional doping, much like ZnSe, were high resistivity, and neither Al-doping nor postgrowth anneal in Zn-Al liquid or in Zn vapor rendered them low-resistivity n-type. It is worth mentioning in this connection that melt-grown bulk crystals of ZnS, when annealed for a long time ($\sim$ 10 days) in $Zn_{0.97}Al_{0.03}$ liquid at 1000°C, became multiphased showing a dark metallic color, and x-ray powder patterns revealed the presence of a cubic material of the form $ZnAl_2S_4$ in the annealed specimens. The present data indicate that it is difficult to obtain high-conductivity ZnSe and ZnS epitaxial layers by vapor-phase synthesis, and this is true even by using postgrowth annealing techniques.

In comparison, the majority of the epitaxially grown CdS was conducting n-type with resistivities in the 10^{-2} ohm·cm range. A relatively high resistivity of 10^2 ohm·cm (n-type) was obtained for the layers grown at higher substrate temperatures than the optimum shown in Table III, or by intentionally doping them with acceptor impurities such as As and Li.

Observations on Cathodoluminescence

We have described earlier the occurrence of polymorphism in ZnSe. Associated with the dependence of polymorph type on deposition temperature, a variation was observed in the color of cathodoluminescence in ZnSe specimens grown at different temperatures. The colors observed at room temperature were bright yellow, orange, and red for the specimens grown in the temperature ranges 890°-830°C, 800°-700°C, and 700°-600°C, respectively. Although quantitative information is lacking at present, this could be due to small variations with temperature in the stoichiometry, or impurity concentration, of the epitaxially deposited ZnSe. The ZnSe samples prepared at 890°C were of sufficient purity to permit an observation of near-bandgap cathodoluminescence, 2.76 eV, at 77°K (16).

The epitaxially grown ZnS showed a bright blue cathodoluminescence at room temperature, and this might have emanated from the self-activated emission process (2) involving Zn vacancies and some unknown ionized donors.

As for the epitaxial layers of CdS, a green cathodoluminescence was observed at room temperature for the majority of conducting n-type specimens. A red cathodoluminescence was also observed, but with specimens showing relatively high resistivities ($\sim 10^2$ ohm·cm) due probably to the compensation by acceptor impurities. Similar observations of luminescence

in CdS of different electrical resistivities have been reported previously by Aven and Garwacki (3), but detailed studies of the exact nature of the luminescent centers have not been made.

Conclusions

Single-crystal layers of ZnSe, ZnS, and CdS have been epitaxially grown on GaAs, GaP, and sapphire substrates in a flow system by reaction of the metal vapors with the nonmetal hydride gases. The growth morphology, crystalline perfection, and some of the electrical and luminescent properties of these epitaxially grown materials have been studied. Although the present paper is concerned with the above three compounds, the results obtained suggest that other II-VI compounds may also be grown with equal success using the present vapor-phase epitaxial growth technique. HgTe is one such compound recently reported (17) to have been grown by a growth technique similar to that used in the present study.

Acknowledgments

The authors are grateful to D. Richman and J. J. Tietjen for valuable discussions, and to W. C. Roth and R, T. Smith for electron diffraction and x-ray work. The research herein reported was made possible by the support of the Advanced Research Projects Agency under Order No. 1034, through the United States Army Electronics Command, Fort Monmouth, New Jersey, under Contract No. DAAB07-68-C-0129 and DAAB07-69-C-0145.

Manuscript submitted March 11, 1971; revised manuscript received Oct. 27, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX

In the absence of direct determination such as by mass spectrometry (5) of the chemical species present in the vapor phase we cannot unambiguously identify the chemical reactions responsible for the present II-VI compound vapor deposition. However, the most reasonable chemical reactions, consistent with the initial reactant gases used and the final solid products formed, are of the type either

$$\text{II (g)} + \text{H}_2\text{-VI (g)} = \text{II-VI (s)} + \text{H}_2\text{ (g)} \quad [1]$$

or

$$\text{II (g)} + ½\text{VI}_2\text{ (g)} = \text{II-VI (s)} \quad [2]$$

where II = Zn or Cd and VI = Se or S. The free energies of the appropriate reactions are calculated from the known sources (Table V) and are tabulated in Table VI. It should be noted that the calculated values of the free energy change (Table VI) are all negative in the temperature range of interest, and that the values are roughly similar whether they are calculated for reaction [1] or [2].

The Effect of HCl and Cl_2 on the Thermal Oxidation of Silicon

R. J. Kriegler, Y. C. Cheng, and D. R. Colton*

Bell-Northern Research, Ottawa, Ontario, Canada

ABSTRACT

The addition of a few mole per cent of HCl or Cl_2 to the oxidizing atmosphere has been found to significantly improve the electrical stability of dry-grown SiO_2 films. The results reported here were obtained with 30 min oxidation at 1150°C. The process not only decreases the mobile ion contamination originating from the furnace tube, but to a large extent also passivates the films against ionic instabilities caused by contaminated metallization. The use of HCl or Cl_2 apparently also reduces the number of surface states at the Si-SiO_2 interface. No significant change between standard and HCl or Cl_2 oxides was observed in oxide charge, dielectric strength, dielectric constant and index of refraction, but the oxidation rate of Si is considerably increased in the presence of HCl or Cl_2. The mixture of HCl and dry O_2 was also found to be very effective for the "cleaning" of quartz furnace tubes.

A major cause of electrical instabilities in MOS devices is the migration of positive ions [see, *e.g.*, Ref. (1)], particularly of sodium in the oxide, although not all of the sodium incorporated into the oxide is electrically active. Most of the effort to produce highly stable MOS structures using SiO_2 has been concentrated on avoiding sodium contamination as much as possible during the various stages of processing, rather than on the immobilization of easily ionizable or ionic species already incorporated into the structures. The only exception was perhaps the use of a phosphosilicate glass layer on top of the oxide, but the instability introduced by the polarizability of the phosphorus glass itself (2) has prevented this technique from being universally accepted. The purpose of this paper is to report preliminary experimental results on the apparent immobilization of ionic contaminants in SiO_2 films by the use of HCl or Cl_2 during dry oxidation.

The development of this process was instigated by our accidental observation that SiO_2 films grown in a furnace tube containing NaCl were found to contain a much smaller concentration of mobile ions than those grown in the presence of Na_2CO_3. These results lead to the speculation that, in the presence of chlorine, at least some of the sodium being incorporated into the oxide may have entered in an electrically inactive form, such that it remained immobile even under the influence of high electric fields at elevated temperatures. Based upon this premise, we investigated the electrical stability of SiO_2 samples grown in the presence of HCl or Cl_2 and found (3) that these "HCl oxides" and "Cl_2 oxides" were indeed more stable than their counterparts grown in pure oxygen ("standard oxides"). We have since extended our work particularly for the HCl oxides to assess their immobilizing effects on contaminations introduced from various sources during processing, and have also observed various other properties of these oxides.

Experimental Details

To evaluate the "resistance" of HCl oxides to different sources of contamination, first a systematic study was undertaken in which the amount of contamination originating from our various laboratory processing steps was determined. In agreement with previous investigators (4) we found that by far the most significant contribution to the mobile ion content in the final MOS structures came from contaminated metallization. The only other detectable amount of contamination was introduced from the high temperature furnace tube during oxidation and *in situ* annealing. The elimination of the cleaning of the silicon slices before oxidation did not result in a measurable increase in the mobile ion contamination of our oxides. To separate the above two contributions of contamination, various methods were developed in which the amount of contamination could at least partially be controlled. As the experimental results to be given below will demonstrate, the contamination originating from the furnace tube could be completely eliminated by the prolonged exposure of the tube to a mixture of HCl and dry O_2. The mobile ion contamination originating from the metallization could be reduced at most to the 10^9 ions/cm^2 level, and even then, only by a special process, not applicable for routine evaporation. Our routine processes produced ion concentrations in the range of 10^{10} to 10^{12} ions/cm^2 for both aluminum and gold metallization. Aluminum was evaporated both by an electron beam and from a resistance-heated tungsten basket, the latter method resulting in considerably higher values of contamination. To avoid any considerable degree of radiation damage, gold was always evaporated from a resistance-heated molybdenum boat and in this case the level of contamination was controlled by the length of the vacuum prefiring of the molybdenum. Our study confirmed that oxidized slices could be stored in room air under cover for at least several days without picking up any measurable amount of contamination from the surroundings. It was also found that, at least for lower levels of contamination, samples processed in an identical way and metallized simultaneously, exhibited approximately the same level of mobile ion concentrations; this observation allowed the comparison of slices processed in various ways, *i.e.*, grown with various HCl or Cl_2 concentrations. Based upon the previous results and somewhat

* Electrochemical Society Active Member.
Key words: SiO_2, MOS structure, electrical stability.

arbitrarily chosen parameters the following procedure was adopted for sample preparation:

(*i*) N-type 10 ohm-cm (100) Si slices were used, as received from Monsanto without any cleaning process before oxidation.

(*ii*) Slices were oxidized for 30 min at 1150°C in various mixtures of HCl or Cl_2 and dry O_2. The flow rate of O_2 was always maintained at 800 cc/min.

(*iii*) *In situ* annealing in a He ambient was carried out at 1050°C for a period of 15-30 min. The oxidation and annealing steps were carried out in a double walled quartz tube in which the space between the tubes was also flushed with the oxidizing or annealing gas. No liner of any kind was used.

(*iv*) Oxidized slices were kept in the laboratory under cover until metallization.

(*v*) Front oxide surfaces were metallized first; all oxides grown for a given experiment were metallized simultaneously.

(*vi*) Back oxides were removed with HF, the bare Si surface was metallized with Al, and finished samples were sintered at 470°C for 10 min in N_2.

Electrical testing of the samples mainly consisted of the determination of their C-V characteristics measured at 1 mHz. The oxide charge, Q_{ox}, was directly calculated from the initial room temperature flat-band voltage taking account of the metal-semiconductor work function difference (5). The number of fast interface states, N_{ss}, obtained according to the Gray and Brown technique (6), was calculated from the shift of the flat-band voltage between room and liquid nitrogen temperatures, taking into account the change of silicon depletion layer capacitance and the change of the metal-semiconductor work function difference between the two temperatures. The mobile ion concentration was directly calculated from the shift of the flat-band voltage after a 5 min positive bias-temperature stress at 250°C with a field of 10^6 V/cm, provided that the flat-band shift after negative bias-temperature stressing was negligible, which was found to be the case for most samples tested. Only in special instances, when the ultraclean metallization technique was used, was the ion concentration determined from current-voltage measurements using a constant rate voltage ramp (7, 8). Such a voltage ramp was also used to determine the approximate breakdown field in the oxide. The thickness of the samples and their index of refraction at a wavelength of 5461Å was determined by ellipsometry with an average accuracy of ±5Å and 0.005, respectively. The dielectric constant was determined at room temperature at 10 kHz on samples having aluminum electrodes of 0.02 cm^2 area. The amount of HCl added to the oxygen flow was measured by dissolving the HCl in water and titrating it with NaOH, while Cl_2 was allowed to react with a solution of KI and the precipitated iodine was titrated with $Na_2S_2O_3$. The maximum concentration of Cl_2 used in these experiments corresponded to a Cl_2/O_2 mole ratio of 0.035, and was limited by the tendency of chlorine to cause peeling of the oxide, presumably due to the etching of the silicon substrate by chlorine penetrating through the pinholes in the oxide. No similar effect was observed with HCl at least up to a 0.2 HCl/O_2 mole ratio, which was the highest employed. For the sake of brevity, HCl/O_2 and Cl_2/O_2 mole ratios will subsequently be referred to as percentage HCl and Cl_2 content, respectively.

Results and Discussion

Basic observations.—The results presented here are representative of a large number of experiments and were chosen to demonstrate some important characteristics of the HCl and Cl_2 oxides. Table I shows the effect of HCl on the electrical stability of SiO_2 samples grown in a furnace tube which became contaminated from a methanol rinse, and for comparison, includes data on samples grown in a steam-cleaned furnace tube. Two sets of samples were prepared and metallized in separate evaporations. The cleanliness of the metallization was different in the two instances; significantly however, the difference between the mobile ion concentrations of the standard oxides grown in the steam-cleaned tube and in the ethanol-rinsed tube is about the same for the two evaporations, and therefore this difference, approximately 1.5 × $10^{10}/cm^2$, can be attributed to contamination introduced from the furnace tube. Oxides grown with increasing HCl concentrations show decreasing mobile ion content, which at 6% HCl content reduces to the $10^9/cm^2$ region, well below the figure that would be expected to result from contamination introduced by either of the metallizations. In addition, standard oxides grown in the contaminated tube after the preparation of the HCl oxides, *i.e.*, after the tube had been exposed to an HCl-O_2 flow for some time, are considerably cleaner than the first ones grown in the same tube, and have mobile ion concentrations just slightly below those samples grown in the steam-cleaned tube. These results suggest that: (*i*) the presence of HCl during the oxidation can render electrically inactive ionic impurities resulting from both a contaminated furnace tube and contaminated metallization, and (*ii*) the oxidation furnace tube itself can be cleaned with a prolonged exposure to an HCl-O_2 atmosphere at a high temperature. The following experiments were designed to confirm these two observations separately.

Furnace tube cleaning.—Table II shows two examples of the cleaning effect of HCl on the furnace tube. In one case a methanol-contaminated furnace tube is cleaned by steam and a subsequent HCl process. The cleanliness of the tube was measured by the mobile ion contamination detected in standard oxides, which were grown before and after each cleaning step and metallized together with our ultraclean evaporation process. Dry oxides grown after contamination contained an average of 1.9 × $10^{10}/cm^2$ mobile ions (which figure here is attributable to the oxidation furnace tube only). After 6 hr of steam cleaning (1800 cc/min H_2 burned in approximately stoichiometric O_2)

Table I. The effect of HCl on the electrical stability of SiO_2 grown in a contaminated furnace tube

Sample description	HCl/O_2 mole ratio (%)	Thickness (A)	Metallization I		Metallization II	
			ΔV^{+}_{FB} (V)	N_{ion} ($10^{10}/cm^2$)	ΔV^{+}_{FB} (V)	N_{ion} ($10^{10}/cm^2$)
Standard oxide grown in steam-cleaned furnace tube	0	1100	0.35	6.6	0.16	3.6
Standard oxide grown in tube contaminated with ethanol rinse	0	1100	0.43	8.1	0.23	5.2
HCl oxides grown in contaminated tube	2	1210	0.42	7.2	0.15	2.8
	4	1340	0.40	6.2	0.12	2.0
	6	1380	0.05	0.8	0.0	<0.8
Standard oxide grown after HCl oxides in contaminated tube	0	1100	0.34	6.4	0.14	3.1

All oxidations were carried out for a period of 30 min at ~1150°C. ΔV^{-}_{FB} was negligible on all samples and N_{ion} was calculated from ΔV^{+}_{FB}. Q_{ox} for all samples was in the region of 10^{10} charges/cm^2, apparently uneffected by the HCl concentration.

Table II. The cleaning effect of HCl on the oxidation furnace tube

Time of oxide growth (all standard oxides)		N_{ion} (from I-V measurements) (10^{10}/cm^2)
	A) Steam and HCl cleaning of methanol contaminated furnace tube	
Immediately after contamination	Dry oxides (avg.)	1.9
After 6 hr of steam	Dry oxides (avg.)	1.75
	Wet oxides (avg.)	1.31
After 6 hr with 10% HCl/O_2	Dry oxides (avg.)	0.1
	Wet oxides (avg.)	0.1
After additional 2 hr of steam	Dry oxides (avg.)	0.3
	Wet oxides (avg.)	0.1
	B) Pure O_2 and HCl cleaning of tube contaminated with 0.01*N* NaOH solution. (All tests done on dry oxides)	
One hr after contamination	without any previous gas-flow	170
After 6 hr of gas-flow	O_2 cleaning	5.0
After 24 hr of gas-flow	O_2 cleaning	4.8
After 2 hr of $HCl\text{-}O_2$ flow	5% HCl cleaning	1.0
After 6 hr of $HCl\text{-}O_2$ flow	5% HCl cleaning	0.47
Arter 12 hr of $HCl\text{-}O_2$ flow	5% HCl cleaning	0.15
After 6 additional hr of 25%	HCl cleaning	0.25

at 1150°C the mobile ion contamination measured in 1700Å thick dry and wet oxides only reduced to 1.75 and 1.3×10^{10} ions/cm^2, respectively. On the other hand, a subsequent 6 hr period of cleaning with an $HCl\text{-}O_2$ mixture of 10% HCl content at 1150°C reduced the mobile ion contamination in both dry and wet oxides to the low 10^9 ions/cm^2 region, which is just on the limit of detectability even with the I-V measurements. A further 2 hr period of steam cleaning did not introduce any statistically significant change in the cleanliness of the oxide. The second example compares the effect of pure O_2 cleaning with HCl cleaning of a tube that was contaminated with 0.01*N* NaOH solution. 1100Å thick oxides grown 1 hr after the NaOH rinse exhibited levels of contamination in the 1.3×10^{12} ions/cm^2 range. As a result of O_2 flushing (800 cc/min) at the normal oxidation temperature, in a matter of 6 hr the contamination was reduced to 5×10^{10} ions/cm^2, without any appreciable further reduction in the subsequent 18 hr. By contrast, HCl cleaning of an initially identically contaminated tube, employing as low as 5% HCl content, eliminated even the last trace of contamination in a matter of half a day. Beyond this no further improvement could be obtained, and the small variation observed may be attributed to fluctuations in the cleanliness of the metallization.

Passivating effect.—Samples prepared to establish the behavior of HCl oxides after metallization from contaminated sources were always grown in an HCl cleaned furnace tube, so that the metallization gave the only detectable contribution to the contamination. Table III compares the flat-band shift on standard and HCl oxides measured after a negative and positive bias-temperature stress, respectively, for two aluminum and one gold metallization process. Taking the appropriate thickness into account, N_{ion} was calculated from ΔV^+_{FB}, except where ΔV^+_{FB} became so low as to be comparable with the generally small ΔV^-_{FB} shift, in which case the $\Delta V^+_{FB} - \Delta V^-_{FB}$ difference was used for the calculation. The possible percentage error in the ion concentration, of course, increased with diminishing N_{ion} value. The results indicate that oxides grown with higher concentration of HCl have decreasing concentrations of mobile ions for all three levels of metallization contamination resulting from the three different metallizations. Comparison of samples metallized with aluminum shows that a higher amount of initial contamination requires higher HCl concentrations to reach comparable electrical stability, while the comparison between the resistance-heated aluminum and the resistance-heated gold evaporations suggests that the immobilization of contaminating ions may be easier for gold-metallized than for aluminum-metallized MOS samples. This latter observation was also borne out by experiments in which the mobile ion contamination was measured in oxides grown with identical HCl concentrations and metallized with gold and aluminum electrodes that introduced approximately the same level of contamination in standard oxides. It is interesting to observe that even though the use of a small amount of HCl results in an increased electrical instability, a certain HCl concentration, somewhere between 6-8% HCl content for these experiments, brings about a sudden large reduction in the mobile ion concentration for the two more heavily contaminated metallizations. This threshold-like effect has been frequently observed but the HCl concentration at which it occurs has varied somewhat and its origin is not yet understood.

Other properties.—Various other HCl oxide properties of interest are summarized in Table IV, where

again samples having both gold and aluminum electrodes are listed. As is well known, because of the sintering of slices as a last step in their preparation, samples metallized with aluminum show properties attributable to hydrogen annealing (9). It is seen that for neither metal is there any systematic change in the room temperature flat-band voltage between the standard and HCl oxides, and consequently no fixed charge appears to be introduced into the oxide by the HCl process. V_{FB} was not converted to oxide charge figures for the case of aluminum metallization, because even for the standard oxide, a small negative rather than positive charge would have resulted; this apparently unusual behavior however, is most likely due to an error in the metal semiconductor work function difference assumed for the samples. The number of fast interface states are seen to be generally lower for HCl oxides than for standard oxides, and of course, samples metallized with aluminum all exhibit lower values than the corresponding gold-metallized samples. The breakdown field, which was determined from the point where the first rapid increase in current across the samples occurred, and therefore would probably be best described as a self-healing breakdown (10), shows little systematic change between standard and HCl oxides, although a small improvement with increasing HCl concentrations is suggested from the data. While the dielectric constant shows no variation with HCl concentration within experimental error, the index of refraction displays a slight increase with increasing HCl concentration. It is not certain whether the apparent increase in the index of refraction for HCl oxides is a real one, or whether it is caused by a small absorption in the oxides, the net effect of which on the ellipsometric data is the same as if the index of refraction had changed in the absence of absorption.

Effect on Si oxidation rate.—As the data from Tables I and III imply, the oxidation rate of silicon is increased in the presence of HCl. This is shown in somewhat more detail on a log-log scale in Fig. 1, where the ratio of the cycle lengths of the ordinate and abscissa scales are 2:1. In the thickness range indicated, oxidation in pure oxygen results in an approximately parabolic time dependence; the solid lines for other oxides were obtained by fitting the experimental points with lines parallel to that for the standard oxide. Apart

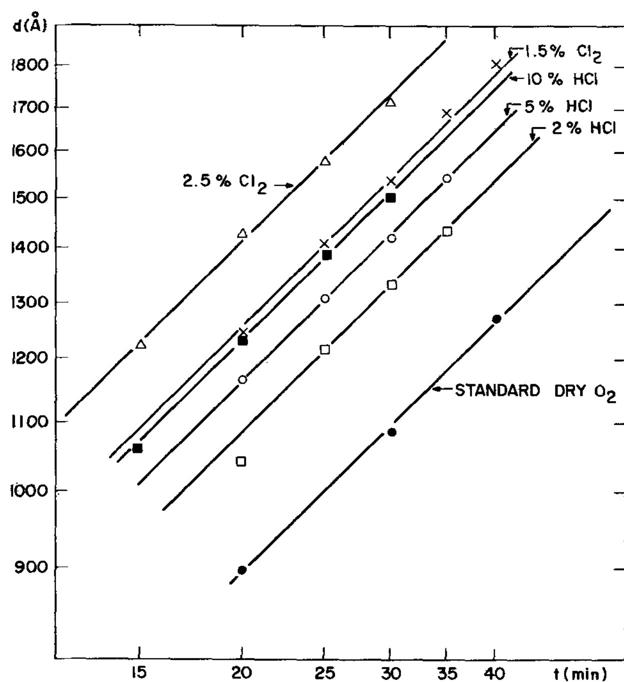

Fig. 1. Oxidation rate of (100) Si at 1150°C in the presence of HCl and Cl_2.

from one experimental point, the rather good fit suggests that at least for the limited range of thickness covered here, the effect of HCl can be described as an increase in the parabolic coefficient (11), which depends linearly on the effective diffusion rate of the oxidizing species in the bulk of the silicon dioxide. Based upon the extrapolation of data obtained for the oxidation rate of silicon in the mixture of O_2 and H_2O (12), it is easy to conclude that the formation of water vapor in the HCl-O_2 mixture is insufficient to account for the observed degree of enhancement of the parabolic rate constant. At equilibrium, the reaction, $2HCl + \frac{1}{2}O_2 \rightleftarrows H_2O + Cl_2$, for a 1:10 mixture of HCl and O_2 results in a H_2O/O_2 ratio of 0.0142 at 1150°C, which amount of water would cause less than half of the observed effect. On the other hand, the fact that a 1.5% dry Cl_2 content results in a growth rate somewhat higher than a 10% HCl content could indicate that chlorine may be mainly responsible for the higher oxidation rate.

Cl_2 oxides.—As previously mentioned, we have found that the use of Cl_2 during oxidation also has beneficial effects on the electrical properties of the oxides. A comparison between the properties of the HCl and Cl_2 oxides is given in Table V. Since it was obvious even from the preliminary experiments that the passivation effect of HCl is not due to Cl_2 "molecules" alone, the samples listed in the table were prepared with HCl and Cl_2 concentrations such that the effect of the same total number of chlorine "atoms" could be compared. All the samples were oxidized for 30 min at 1150°C and metallized with aluminum. The data indeed show that the two forms of chlorine, HCl and Cl_2, are about equally effective in the reduction of the mobile ion concentration in the oxides. The surface state density at the silicon-oxide interface is approximately the same for Cl_2 as for HCl oxides. This effect however, may be due to minute amounts of water vapor present in our Cl_2 source.

Related experiments.—It is noteworthy that other effects of HCl, of somewhat similar nature to those described here, were reported recently. MacKenna *et al.* (13), observed that the introduction of mobile ion impurities into thermally grown silicon dioxide during a subsequent pyrolytic deposition of silicon nitride was much reduced when $SiCl_4$ was used instead of SiH_4. Robinson and Heiman (14), found an increased minority carrier lifetime in silicon under an oxide layer when the oxide was grown with an HCl concentration as low as 0.5 to 1%, presumably due to a gettering effect of heavy metal ions. This latter paper, published during the course of our work, and referring to a private communication by A. Mayer, has also alluded to the gettering effect of HCl for sodium when an HCl solution was used as a source for steam oxidation, but no experimental facts in this regard were given.

Conclusions

The results presented here have all been derived from experiments carried out with dry oxygen at 1150°C using (100) Si, and all samples were oxidized for a period of 30 min. Within these limitations it has been demonstrated that the addition of HCl or Cl_2 to

Slices were oxidized for approximately 30 min at 1150°C and metallized with Al.

O_2 during the thermal growth of SiO_2 has beneficial effects on the oxide properties: the main effect is the increased electrical stability, observable in oxides grown in a contaminated furnace tube as well as in oxides metallized by a contaminated metallization; in addition, at least the use of HCl, also reduces the surface state density at the silicon-oxide interface. It has been established furthermore that a mixture of HCl and O_2 can "clean" a quartz furnace tube so effectively that, even in the absence of chlorine in any form, no contamination can be detected to enter into the silicon dioxide during its thermal growth or high temperature anneal.

All the results, and in particular, the fact that contamination introduced into MOS structures after oxidation is rendered, at least partially electrically inactive, strongly suggest that chlorine becomes incorporated into the oxide during growth. However, neither the nature of this chlorine species, nor the mechanism leading to the increased electrical stability has been established so far. Further work now in progress is directed towards the understanding of the mechanisms involved, along with the extension of the present experimental data to include a wider range of time and temperature.

Chemical Etch Rate Studies on Sputtered Chromium Films

Alan R. Janus*

Roanoke College, Salem, Virginia 24153

ABSTRACT

An etch rate measurement technique is proposed for the study of compositional variants through the thickness of sputtered chromium thin films. Verification of the technique is given by a correlation of chemical etch rate measurements with variations in deposition conditions. These included deposition rate, substrate potential, reactive sputtering in oxygen, and postdeposition air bake.

While the practice of sputtering chromium has been generally adopted by the major razor blade manufacturers throughout the world as a means of prolonging razor blade life, very little effort has been given to understanding the mechanism by which this improvement is operative or to the optimization of deposition parameters with regard to a maximum improvement. Both areas have suffered for lack of a convenient analytical technique pertinent to compositional variants through the thickness of a thin film; that is, the oxide layer formation necessary for corrosion passivation. Until recently, resistivity measurements have offered the only means of determining the effect on thin films of variations in deposition and postdeposition conditions (1). These, however, relate to gross effects.

Within the past year, ion probe measurements (2) have yielded infinitely more detailed information on compositional variants in thin films. Since this method requires the use of expensive equipment and detailed interpretive effort, it is not yet in wide use.

[1] Present address: Electronic Materials Division, Bell & Howell Company, 360 Sierra Madre Villa, Pasadena, California 91109.
Key words: sputtering, chromium thin films, etch rate measurement, multiple beam interferometry.

The subject of this effort was, therefore, to develop a simple technique to detect compositional variants in thin films and to monitor these variations relative to deposition and postdeposition procedures related to the sputtering technique.

Initial verification of a chemical etch rate technique involved the use of a chromium film deposited in an rf tubular cathode sputtering system. Subsequent experiments were directed to a variation in chromium deposition conditions in a d-c triode system. In particular, the latter effort was directed to the effect of deposition rate in inert atmospheres on oxidative compositional variants through the thickness of the thin film. The etch rate relationship was observed at different substrate bias potentials. Etch characteristics were also measured on films intentionally subjected to oxidizing conditions. These included a postdeposition air bake as well as reactive sputtering in a range of partial pressures of oxygen.

Experimental

The etch rate measurement technique has previously been utilized in the study of thermally grown silicon dioxide films (3) as well as reactively sputtered silicon

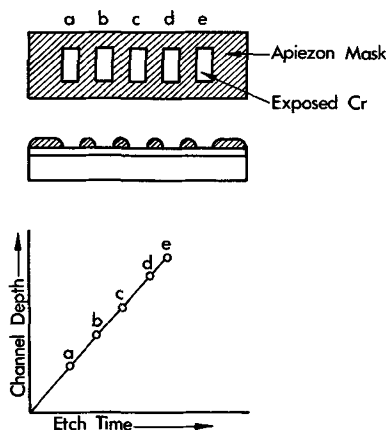

Fig. 1. Chemical etch technique used

nitride films (4). The method is described in Fig. 1. Apiezon Q wax is dissolved in trichloroethylene to form a viscous solution. This solution is used to define the mask pattern on the film as illustrated.

The masked slide is immersed in an appropriate etchant for a timed period. On withdrawal from the etch solution, the slide is dipped into deionized water to stop the etching action. It is then blown dry and one of the exposed areas masked over with the masking solution. This operation is repeated until all exposed portions of the film have been utilized in a progressive fashion. The slide is then immersed in the trichloroethylene solvent to remove the masking material. The operation results in a series of progressively deepening channels in the film, extending to the film substrate interface. The etched film is next coated with evaporated aluminum for thickness measurement by multiple beam interferometry. The depth of the individual channels is measured and plotted *vs.* corresponding etch time. The slope of the curve is the etch rate.

In this particular study a Varian Å Scope was utilized as a means of thickness measurement. The etchant, at a temperature of 28° ± 2°C was a variant of a commercially available chromium etch: $Ce(SO_4)_2 \cdot 2(NH_4)_2SO_4 \cdot 2H_2O$, 2g; HNO_3 (conc), 10 ml; and H_2O, 50 ml. The triode investigation utilized a more dilute solution containing twice the amount of water.

Sputtering systems were the MRC 30-in. Tubular Cathode Unit and the Bendix AST-100 Triode apparatus. In both cases MARZ grade chromium targets were used. Similarly, both systems were evacuated by 6-in. oil diffusion pumps to less than 5×10^{-6} Torr prior to deposition. In the former case a Freon refrigerated chevron baffle was employed; in the latter system, a combination of ambient and an uncooled liquid nitrogen chevron baffle were utilized.

With regard to the metallic depositions, AIRCO welding grade argon was employed. In the reactive sputtering experiments, partial pressures of oxygen and argon were read by an ion gauge located in base plate throat calibrated to chamber pressure. Gauge pressures rather than nitrogen equivalent calibrations were employed. Utilization of the ion gauge in this manner was accomplished by interposition of a variable restricted orifice at the base plate. This method was found to be an effective means of controlling relative reactive gas compositions in the micron range. Pirani gauge and flowmeter techniques were found to be inadequate for this purpose.

Bias variation in the triode system was accomplished by grounding and floating the substrate holder. It has been observed that a minimum of a 50V differential exists in the triode configuration for an applied anode voltage of 75V. In the presence of a 5.0A magnet current, a 3.0A plasma current is obtained between filament and anode. The self-bias condition satisfies levels of voltage both above (~60V) and below (~10V) the sputtering threshold of chromium.

Substrate holder geometry was such in the tubular rf unit that neither target presputtering nor substrate glow discharge cleaning could be accomplished prior to deposition. The target-to-substrate distance was 7-in. The pressure of argon in the sputtering chamber was 2.6×10^{-3} Torr.

In the triode system, at a total gas pressure of 1.5×10^{-3} Torr, a rotating substrate holder allowed for a 10-min glow discharge cleaning of the substrates as well as a 10-min target preconditioning period prior to the actual deposition. The target-substrate distance was 2 in.

Substrates in all cases were 1 × 3 in. Bioloid brand microscope slides (Will Corporation) used as supplied without further cleaning other than a compressed air blowoff.

Postdeposition baking conditions for the tubular films were 179°C for 3 hr. The triode films were baked at 350° ±25°C for 30 min.

Results

Ideally it is expected that an invariant slope in the etch rate plot would be obtained for a unicompositional film on the basis of Fig. 1. Further, one would expect that on the cessation of etching activity, a plateau would be established in the curve. In Fig. 2, relating to the rf deposition, this plateau is seen to occur at 1340Å and yields a deposition rate of 89 Å/min. However, the data through the thickness of the film do not hold for a single composition, but indicate three distinct regions. These regions are designated as surface layer (A), inner layer (B), and interfacial layer (C).

The surface layer, 100-200Å in thickness represents 8-15% of the film thickness. This value is slightly greater than the 80-100Å value reported in the literature for the ambient oxide. The increase could be a consequence of exposure of the film to atmosphere while still hot. The etch rate of this layer is a minimum 3.3 Å/min.

The inner layer, probably chromium, etches at a slower rate of 1.4 Å/sec, and at 520-620Å, represents 39-46% of the total film thickness.

The layer at the film substrate interface is of the same thickness as the inner layer, but according to an etch rate of 3.4 Å/sec, could represent a composition similar to that of the ambient oxide.

Postdeposition baking under the conditions listed does not alter this compositional variation.

Deposition rate variation with target voltage is plotted in Fig. 3 for the triode system. Under otherwise constant conditions, the target current was found to vary between 0.68 and 0.46 mA/cm². It can be seen that little difference exists between the floating and grounded substrate condition at a given voltage.

Figures 4 and 5 detail etch rate measurements on films prepared at varying deposition rates on both floating and grounded substrate holders. The expected

increase in film purity with increase in deposition rate is observed in both cases (5-7). However, a comparison of Fig. 4 and 5 shows that the grounded substrate favors a generally lower etch rate and a more homogeneous film than does the floating substrate under the same deposition conditions. Here, homogeneity is defined as a relatively lower degree of etch rate variation through the thickness of the film. Independent of deposition rate, films prepared on grounded substrate undergo a lower degree of oxidation during deposition. The data are in general agreement with previous resistivity data and detail more precisely the distribution of oxide layers in the film for various deposition conditions. In addition, it is seen that less variation in etch rate with regard to deposition rate is observed in the grounded condition over the range of deposition rates. That is, ion bombardment during deposition can be a stronger influence in determining film purity than deposition rate under certain conditions. This factor

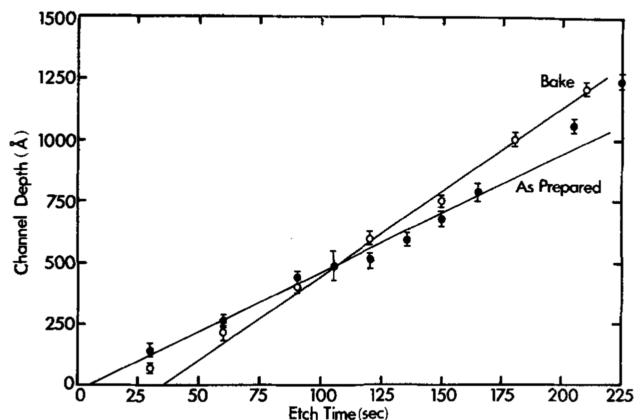

Fig. 7. Effect of postdeposition bake on etch rate of films prepared at 600V, floating potential.

is stronger at lower deposition rates. At higher deposition rates, the effect is minimized.

The assumption that oxidation will cause an increase in etch rate is verified by the results of a postdeposition air bake. Figures 6 and 7 are typical of films prepared below 900V and compare the etch rate characteristic of baked and nonbaked films prepared under identical conditions. For the 900V films, however, an apparent reversal of this trend is observed in Fig. 8 and 9 in that the baked films etch at a lower rate for both the floating and grounded cases. An explanation of this anomaly cannot be given. It is apparent that other factors become operative at the higher deposition rates. However, Fig. 10 reveals that the homogenizing effect of the higher substrate bias observed previously is still evident.

Figures 11 and 12 compare etch rate data on films sputtered in the presence of varying partial pressures of oxygen. The increase in etch rate with increase in the amount of oxygen in the sputtering gas pro-

vides independent confirmation of the hypothesis that the etching mechanism proceeds by an attack of the oxide. Again, the grounded substrate provides a more homogeneous film. The fact that these films etch at a higher rate under otherwise identical conditions can be explained if one postulates the existence of O_2^+ species in the plasma. Enhanced bombardment of the growing film with this specie as favored by a grounded substrate condition would be expected to increase the oxygen content of the film. Direct evidence of this reaction lies in the fact that while both the grounded 5 and 10 gauge per cent oxygen films were transparent, only the 10% floating film was not opaque. Measurements have confirmed that differences observed between the floating and grounded situations were not due to differences in deposition rate as indicated in Fig. 13.

Summary

It is shown that the proposed etch rate measurement technique is sensitive to compositional variants in thin films produced by variations in deposition conditions.

The method indicates that deposition rate has a strong influence on film composition and homogeneity. Further, the method reveals that a d-c substrate bias in excess of sputtering threshold is a profoundly influential variable even on nonconducting substrates. It enhances film reproducibility and homogeneity under a variety of deposition conditions. In inert atmospheres, film purity is increased, while compound formation is furthered in the presence of reactive gases.

The effect of postdeposition baking of sputtered films depends in large measure on deposition conditions.

Acknowledgment

I would like to express my thanks to J. W. Downing and Susan M. Janus for experimental work and to Dr. C. G. Dodd for his encouragement and support. This work was supported by the American Safety Razor Division of the Philip Morris Corporation.

Manuscript submitted Aug. 18, 1971; revised manuscript received Oct. 19, 1971. This was Paper 109 presented at the Washington, D. C., Meeting of the Society, May 9-13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.
