With a circular target (cathode) 5 in. in diameter, a cathode-substrate distance between 1 and 1½ in. was chosen. A magnetic field of 100 gauss produced by coils around the cathode and anode concentrated the discharge and caused relatively high deposition rates with an rf power of 200W. Substrates of Pyrex glass and tin oxide coated glass (NESA, Corning 9753) with a thin photoconductive film of CdS were placed on the heated anode. The substrate temperature was an important parameter in determining the resistivity of the films; therefore, temperature was measured directly with a fine-wire thermocouple on the surface of the substrate.

Naturally, the metal targets can be sputtered with d-c power; most indium oxide/tin oxide films were deposited with a d-c voltage of around 1.5 kV and a discharge current around 70 mA. However, sputtering with radio-frequency power (13.56 MHz) was preferred, because it allowed the use of lower gas pressures in the development stages of the work. When rf power of 200W was applied, the target assumed a self-bias of typically 1000V.

A pure oxygen atmosphere ranging in pressure from 6 to 200μ was initially used for the sputtering of CdO. Later, an improvement in the optical transparency was obtained when an oxygen/nitrogen mixture was used. As little as 2% oxygen in nitrogen at a total gas pressure of 100μ caused completely reactive sputtering and led to the best results with CdO. However, the In_2O_3/SnO_2 films were finally sputterd only in pure oxygen; 50/50 oxygen/nitrogen and oxygen/argon mixtures caused higher electrical resistances in the films.

CdO and In_2O_3/SnO_2 films differed appreciably in their deposition rates at otherwise equal conditions. CdO showed a rate of about 200 Å/min when sputtered in pure oxygen and 130 Å/min when sputtered in the oxygen/nitrogen mixture. Deposition times of 10 min (pure oxygen sputtering) were required to form films of satisfactory sheet resistances. The deposition rate of the In_2O_3/SnO_2 films was six times lower. Correspondingly, the deposition times were 1 hr.

After the deposition, some films were heat-treated at approximately 340°C on a hot plate for 1 hr in air. Such treatment not only reduced the electrical resistivity but also increased the optical transmission of the oxide films.

Experimental Results

Optical and electrical properties of CdO films.—Table I gives thickness, optical transmission, electrical sheet resistance, resistivity, and estimated electron density of CdO films prepared under various deposition conditions. Curves 1 and 2 in Fig. 1 show transmission as a function of wavelength for two representative films, one sputtered in 100% O_2 atmosphere and the second prepared with 2.5% O_2 in N_2 atmosphere.

These data were measured on a Cary 14 spectrophotometer. As previously reported (15), the films sputtered in 2% O_2 in N_2 have higher transmission for shorter wavelengths. The thickness measurements on these films were made with a Sloan[3] angstrometer which works on the principle of multiple beam interferometry. Sheet resistance measurements were made with a four-point probe. The mobility of electrons is assumed to be 120 cm^2/V-sec (7), and the calculated value of electron concentration is listed in Table I. These values are very close to the values given by Lakshmanan.

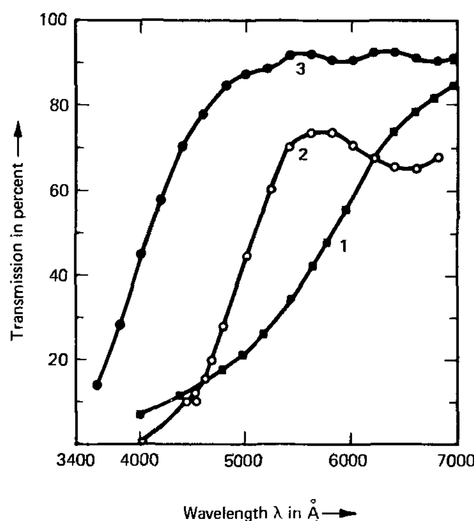

Fig. 1. Spectral transmittance of CdO and In_2O_3/SnO_2 films. Curve 1 is for CdO film No. 91 sputtered in 100% O_2 ambient; curve 2 is for CdO film No. 144 sputtered in 2.5% O_2 in N_2 ambient; curve 3 is for In_2O_3/SnO_2 film No. 214 C-1. Details of preparation are in Tables I and II.

Contact properties of CdO to CdS films.—A cadmium sulfide (CdS) film is deposited by a chemical spray process (16). In this process, a solution of cadmium acetate is mixed with a solution of thiourea to form a soluble complex. This soluble complex is directed in the form of a finely atomized spray to the surface of a heated substrate where it is decomposed to form a film of cadmium sulfide.

The substrate was a tin oxide (NESA) coated glass slide. The conducting coating of tin-oxide acted as a base (or bottom) electrode. CdO spots having an area $\sim 10^{-2}$ cm^2 were deposited on the CdS film. Deposition conditions were the same as for sample 144 listed in Table I, except deposition time was half that for sample 144. Indium metal spots of the same size area were deposited near the CdO spots, so that their contact quality could be compared. The V-I characteristics are always measured between the top electrode (CdO or In) and bottom tin-oxide (NESA) electrode. The measured V-I curves when the sample is illuminated

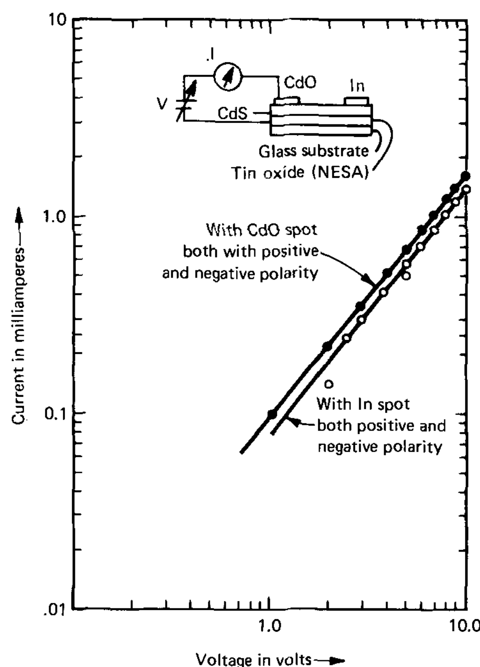

Fig. 2. Current-voltage characteristics under illumination for CdO and In spots on CdS film which is on tin oxide-coated glass substrate (NESA). Sample is illuminated through the glass substrate. Measurement configuration is also indicated.

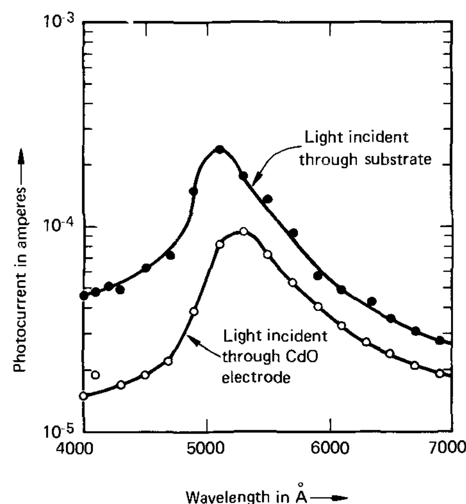

Fig. 3. Photoconductivities (constant intensity) of CdO spots on chemically sprayed CdS film, one with light incident through the contact and the other with light through the glass substrate with NESA coating. The applied voltage is 5V in both cases. Incident photon flux is about 10^{15} photons/cm^2 sec.

through the glass substrate for the CdO and In spots for both polarities are shown in Fig. 2. The slope of these curves is practically constant for both polarities and both CdO and In spots. This suggests that contact quality is equally good for CdO and In, and the linearity of the curves suggests that the contacts are ohmic under the examination conditions.

A further test on this sample was carried out with the measurement of the spectral response of the photoconductor, with light incident through the NESA-coated glass substrate and through the CdO electrode. The results are depicted in Fig. 3. As expected for $\lambda < 5000$Å, the photocurrent is about a factor of 2 smaller for light incident through the CdO spot. For $\lambda > 5000$Å, the photocurrent is smaller by only a factor of 1.7. In this wavelength region, CdO serves as a reasonable contact to the CdS film. In the dark, there does not seem to be any change in the film resistivity as a result of CdO deposition and postdeposition heat-treatment.

Optical and electrical properties of In_2O_3/SnO_2 films.—Table II gives the conditions of film deposition and subsequent heat-treatment, thickness, optical transmission, sheet resistance, and resistivity of In_2O_3/SnO_2 films. From the table it is clear that films deposited at 300°-350°C and subsequently heat-treated at 340°C in air combine low resistivity with high optical transmittance. There does not seem to be a dramatic difference in films produced by either d-c or rf sputtering. In general, higher substrate temperatures favor the lower sheet resistance and higher transmission. Curve 3 in Fig. 1 shows a transmission of film 214 C-1 as a function of wavelength.

Contact properties of In_2O_3/SnO_2 on CdS films.—Again, the contact properties of In_2O_3/SnO_2 films were evaluated in conjunction with the CdS film. Electrodes of 10^{-2} cm^2 area were sputtered through a mask on the same kind of chemically sprayed CdS film mentioned before, which was an a NESA-coated glass substrate; NESA formed the bottom electrode for photoconductivity measurements. On the same films, In metal electrodes of the same area were evaporated between the In_2O_3/SnO_2 electrodes. This electrode arrangement permitted a direct comparison of contact quality of In_2O_3/SnO_2 and In to CdS film. The V-I characteristics are always measured between the top electrode (In_2O_3/SnO_2 or In) and the bottom tin oxide (NESA) electrode.

Figure 4 shows the V-I plot for this film under a photon flux density of 10^{15}/cm^2 sec. Curves 1 and 2 show the current through the sample as a function of voltage with light incident through the In_2O_3/SnO_2 electrode for positive and negative applied voltages, respectively. Curves 3 and 4 show the current through the sample *vs.* voltage when the light is shining through the NESA for both polarities of voltage. The difference in currents for curves 1-2 and 3-4 is due to a difference in light absorption (and reflection) in the indium oxide/tin oxide films on one side and in the tin-oxide coated glass substrate in the other side of the photoconductor. These curves have a constant slope reasonably close to unity, suggesting that current is proportional to voltage. The difference between the current in positive and negative polarities for curves 1-4 is small; the reason for this difference is not understood at the present time. Curve 5 shows current through the CdS film as a function of voltage for an In metal electrode when light is shining through the tin-oxide coated glass substrate. The higher current for curves 3 and 4 compared to 5 can be interpreted

Table II. Details of preparation, optical and electrical properties of indium oxide/tin oxide films

Sample Number	Conditions of film deposition and subsequent heat-treatment	Thickness, A	% Transmission at λ 5000A	% Transmission at λ 7000A	Sheet resistance, ohms per square	Resistivity of films, ohm-cm

possibly in terms of a sensitization effect resulting from doping of the CdS by In during the sputtering and heat-treatment of indium oxide/tin oxide. This effect is similar to that reported by Shivonen and Boyd (12).

This hypothesis of sensitization is further confirmed by measuring the dark current for both In_2O_3/SnO_2 and In electrodes (Fig. 5). For In_2O_3/SnO_2 the dark currents are almost an order of magnitude larger than those obtained for In electrodes, suggesting doping by In and consequently a reduction in resistivity of the film. The In doping for In_2O_3 electrodes results from heat-treatment performed during and after deposition to obtain desired optical transmittance and sheet resistance. However, in the case of In electrodes, no heat-treatment is performed during or after evaporation of In. As a result, the film resistivity is unchanged. The difference between V-I curves for positive and negative polarities in the case of In_2O_3/SnO_2 suggests

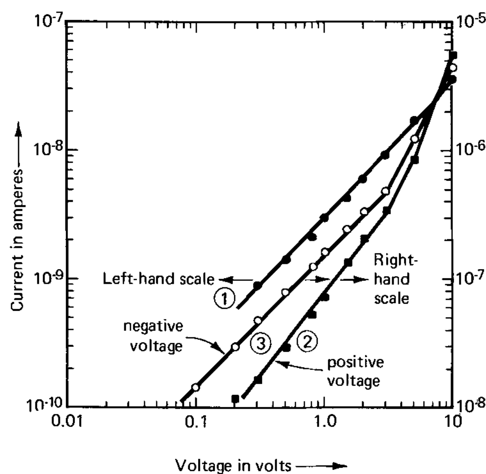

Fig. 5. Current-voltage characteristics in the dark for CdS films having electrodes of both In_2O_3/SnO_2 and In. Curve 1 is for both positive and negative voltages with In electrode. Curve 2 is for In_2O_3/SnO_2 electrode for positive applied voltages and also for In_2O_3/SnO_2 electrode for negative applied voltages. For curve 1 refer to current scale on the left, and for curves 2 and 3 refer to the scale on the right.

a barrier at the interface when no illumination is incident.

To summarize, In_2O_3/SnO_2 gives ohmic contact to CdS under illumination. However, for these 1μ thick CdS films, deposition of the transparent electrodes results in some In doping of the CdS films. This causes the CdS films to have lower dark resistivity.

Discussion—Band Model

From the above-illustrated measurements it is clear that CdO and In_2O_3/SnO_2 produce ohmic contact with CdS under present conditions of measurement. Little is known about the interface between wide bandgap materials like In_2O_3/SnO_2 and CdS. The junction between these two materials is a heterojunction. As a simple extension of the Kroger *et al.* (17) model for ohmic contact of a metal to a semiconductor, we propose a model for ohmic contact of heavily doped, wide bandgap material to an undoped, narrower bandgap material. This model is illustrated in Fig. 6. An ohmic contact is brought about by a rather thin layer (region III) of highly conducting (strongly n-type) material in the photoconductor adjacent to the electrode (region IV). This heavily doped n-type layer in the case of the CdO contact is produced by diffusion of Cd into CdS. For the In_2O_3/SnO_2, the heavily doped n-type layer is produced by the diffusion of In into CdS. Between the highly conducting part of CdS and the electrode, there may exist an exhaustion barrier (layer II) which, due to the presence of such a strongly conducting layer, is so thin that electrons may easily tunnel through it. The region of strongly conducting CdS acts as a supply of electrons for the highly resistive bulk (region IV), and the whole system acts ohmic when an electric field is applied.

Conclusions

The transparent electrode material for an electrooptic device can have a sheet resistance as high as a few hundred ohms per square. From the measurements reported here, it appears that resistances in this range can be readily achieved in sputtered cadmium or indium oxide/tin oxide films. CdO is a better material for making ohmic contact than In_2O_3/SnO_2 because it does not reduce the resistivity of the thin CdS film.

However, the optical transmission properties of CdO on CdS are less desirable compared to those of In_2O_3/SnO_2. Since CdO has an optical transmittance greater than 70% for wavelengths of 6000Å, it may form a better transparent contact to Cd(S, Se) or CdSe, with absorption edges at wavelengths longer than 6000Å. In general, the transparent electrode requirements for an electrooptic device may be met by films of either cadmium oxide or indium oxide/tin oxide.

Acknowledgments

The authors wish to thank D. E. Hill who assisted with the sputtering runs, and J. L. Wolf for making

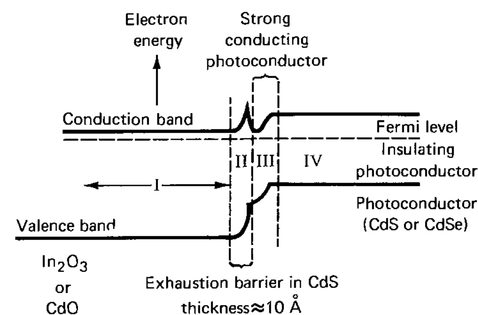

Fig. 6. Proposed band model of an ohmic contact between highly resistive n-type bulk material IV and a highly conducting transparent metal oxide electrode I. Region III is a thin layer of strongly n-type semiconductor, and region II is an exhaustion barrier due to the difference in work function between electrode I and material III.

Coprecipitation of Ga_2O_3 in the Liquid-Phase Epitaxial Growth of GaP

M. Kowalchik, A. S. Jordan, and Mildred H. Read

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Coprecipitation of β-Ga_2O_3 has been observed in O-doped GaP epitaxial films grown by liquid-phase epitaxy under isothermal conditions at an average growth temperature of ~1040°C. The coprecipitation seems to be independent of cooling rate and of the source of O [Ga_2O_3 powder, bulk Ga_2O_3, or glassy $Zn(PO_3)_2$]. The coprecipitation of β-Ga_2O_3 could be prevented either by imposing a temperature gradient over the ampoule (to enhance vapor transport via Ga_2O) or by reducing the amount of O added to the Ga-rich solution in an isothermal system to $\sim 2.5 \times 10^{-2}$ a/o (atom per cent). The latter result is interpreted as giving the solubility at ~1040°C of Ga_2O_3 in Ga saturated with GaP and is used to obtain an estimate of the eutectic valley in the ternary Ga-P-Ga_2O_3 system.

GaP red light-emitting diodes (LED's) have become devices of technological importance in the last decade. The early work of Starkiewicz and Allen (1) demonstrated that the presence of both Zn and O as dopants in the GaP crystals is needed for the generation of red light at room temperature. In the case of solution growth (SG) (2, 3) and sealed-tube liquid-phase epitaxy (LPE) (4, 5), the concentration of Zn added to the Ga-GaP solutions by different investigators to maximize the electroluminescent or photoluminescent efficiency varies from 0.03 (5) to 0.14 a/o (atom per cent (4). Because of vaporization losses the Zn additions in open-tube LPE (6, 7) are higher [0.15 (7) to 0.20 a/o (6)]. At these Zn concentrations in the Ga-GaP solutions the resulting crystals are expected to contain (8) Zn at concentrations less than 10^{18} cm^{-3} (at a typical growth temperature of ~1040°C); hence, the deleterious effect of Auger recombination (9) on efficiency is avoided.

However, the doping requirements for maximizing the efficiency by means of O additions (in the form of Ga_2O_3) are less well understood. In particular, in open-tube LPE "best" devices have been reported for 0.15 (7) and 0.4 a/o O (6). In sealed-tube growth (SG or LPE) maximum efficiencies have been found over a surprisingly wide range of O additions, specifically between 0.03 (2) and 1.05 a/o O (5). The solubility of Ga_2O_3 in liquid Ga (10) is only ~0.03 a/o O at ~1040°C; hence, the reasons for much exceeding this solubility limit in closed-tube LPE systems were not immediately obvious.

Key words: light-emitting diodes, oxygen solubility, crystal growth, compound semiconductors, phase diagrams.

The initial objective of this study is to explain the disparate results on the O-doping of GaP. In the next section it is shown that in a nonisothermal, closed-tube LPE system the loss of O from the tipping solution via the vaporization of Ga_2O is responsible for the high optimum O concentration (5), exceeding the solubility limit (10). Our experiments demonstrate that when more than ~0.025 a/o O is added to the Ga-GaP solution in an isothermal, sealed-tube LPE growth system at ~1040°C, coprecipitation of Ga_2O_3 takes place along with the GaP epitaxial growth. The major objective of this study is to identify, characterize, and explain these precipitates. In particular, the coprecipitation of Ga_2O_3 with GaP (or its absence in a nonisothermal system) is shown to be consistent with thermodynamic information for the Ga-Ga_2O_3 binary system. Moreover, by interpreting the coprecipitation results by means of a ternary phase diagram, the oxygen concentration along the eutectic valley in the Ga-P-Ga_2O_3 system is estimated.

Experimental Procedure and Results

The usual LPE growth of GaP by Nelson's method (11) involves a cooling rate of approximately 10°C/min. To achieve such a relatively large cooling rate many LPE systems utilize furnaces with a small thermal mass which do not possess an isothermal zone

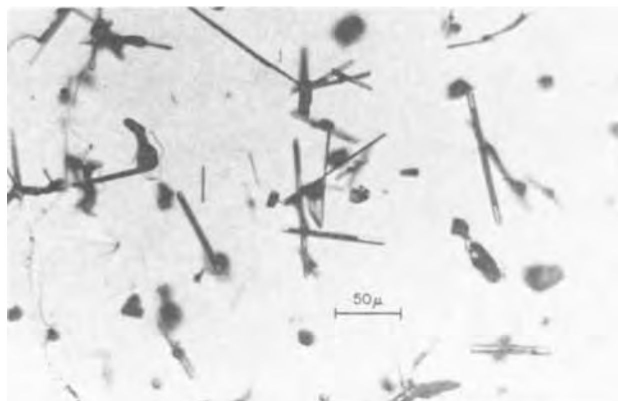

Fig. 1. Transmission photomicrograph of needle-shaped β-Ga_2O_3 precipitates in the GaP matrix grown from a solution containing 1.05 a/o O (added as Ga_2O_3) and 0.05 a/o Zn. The solution was cooled from ~1050° to ~600°C at a rate of ~10°C/min.

over the entire length of the ampoule used for crystal growth. It has been found (12) for a small thermal mass furnace with a viewing port (typical of those used to make efficient LED's) that there may be a decrease in temperature of about 25°C between the Ga-rich melt and the seal-off area (4) at a nominal LPE growth temperature of ~1040°C. Because of the reversible reaction of Ga and Ga_2O_3 to produce $Ga_2O(g)$ according to

$$4Ga(l) + Ga_2O_3(s) = 3Ga_2O(g) \quad [1]$$

a temperature difference causes a drop in the equilibrium partial pressure of $Ga_2O(g)$ (20 Torr for a temperature difference of 25°C at ~1040°C) (13, 14). The reversible nature of this reaction is demonstrated by the observed condensation of Ga_2O_3 and Ga at the cool (seal) end of the capsule during an LPE run.

In order to minimize the loss of Ga_2O_3 via this vapor transport, all the experiments reported herein have been conducted in nearly isothermal furnaces. In the initial phase of this study a furnace (without a viewing port) with a ~4°C difference along the sealed capsule was used. The 10 cm long quartz capsule, similar in construction to capsules described by previous workers (4, 5), enclosed a quartz boat which contained the GaP substrate at one end, near the seal-off plug, and the solution of Ga-GaP-dopants[1] at the other end. The plug serving as the seal was placed tightly against the boat, after evacuation to 10^{-6} Torr, to minimize the capsule volume.

In a typical run the sealed ampoule, containing the substrate and solution doped with 1.05 a/o O added as Ga_2O_3 and 0.05 a/o Zn [serving as a reference dopant concentration in comparison with published values (5)], was heated to 1065°C and held for 30 min to achieve saturation. An LPE layer was then grown by tipping the furnace and capsule assembly at 1050°C and cooling at a rate of ~10°C/min to 600°C. By monitoring thermocouples attached to either end of the capsule, it was determined that the temperature difference was minimal (less than 4°C in this series of experiments) throughout the LPE cycle. After completing a run, excess Ga_2O_3 was found only on the top of the solution, indicating negligible vapor transport. Examination of the typically ~50 μm thick epitaxial layer by optical reflection and transmission microscopy disclosed the presence of a needle-like second phase embedded in the GaP matrix. In Fig. 1 we show a transmission photomicrograph of this second phase in the LPE layer. Note that the thin needles are found at all levels between surface and growth interface and are occasionally as long as 100 μm. That the needles are not an etching artifact due to reaction of the GaP with HNO_3, frequently used to digest the Ga, is shown by the fact that they are also seen without etching. Additional experiments have shown that an undoped or a Zn-doped solution did not result in needles in the LPE layer but a solution doped with Ga_2O_3 alone (1.05 a/o O) did. Moreover, when a sharp temperature gradient was imposed along the capsule, by extending the length of the ampoule with a quartz spacer placed between the end of the boat and the seal and cooling with a stream of N_2, no needles were observed in the LPE layer, even at 1.05 a/o O additions. Not unexpectedly, after this run a mixture of Ga droplets and Ga_2O_3 was found on the seal and no excess Ga_2O_3 appeared on the surface of the Ga solution.

Microscopic examination of the as-received Ga_2O_3 powder at 800X showed a few needles, 5-10 μm long. These needles were similar in shape although not in size to the ones found in the LPE layers. This similarity strongly suggested that precipitation of the monoclinic, high-temperature β form of Ga_2O_3 had occurred in the epitaxial films. The precipitates were conclusively identified by a wide-film, modified, Debye-Scherrer x-ray diffraction method (15). With the flat LPE layer and substrate stationary at 16° to the beam, an x-ray photograph of the epitaxial film was generated. A typical photograph (Fig. 2) for a run with 1.05 a/o O addition shows the curved lines of polycrystalline β-Ga_2O_3 superimposed on the single-crystal GaP pattern. In addition, an examination of the β-Ga_2O_3 precipitate-rich layer by the Direct Image Mass Analyzer (DIMA) (16) exhibits a strong O-signal when sputtered in an oxygen beam. As viewed by the DIMA, a β-Ga_2O_3 needle is represented by a bright elongated image which is much more intense than the background O signal detected from the GaP matrix.

After this positive identification of β-Ga_2O_3 precipitates, a number of changes were made in the experimental apparatus and procedure. In place of the conventional quartz tipping boat, we utilized a slider (17) assembly, fabricated from Al_2O_3 (G.E.-Lucalox). It was anticipated that the use of Al_2O_3 would eliminate the observed reaction between Ga and quartz to form $Ga_2O(g)$ (13). In addition, a new furnace with a variation of only 1°C over the capsule was introduced. Figure 3 is a schematic of the quartz sealed assembly, located in the isothermal zone of the furnace. As in the earlier experiments, the Ga-rich solution, here contained in an opening cut through the moving slider, was tipped onto the GaP substrate. With the slider, however, growth could be terminated at will at any temperature by tipping the slider to its

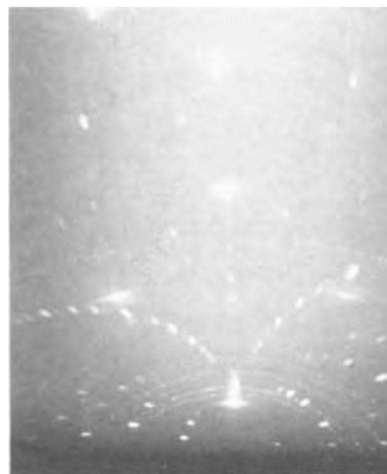

Fig. 2. X-ray photograph of precipitates and matrix. Note the spotty curved lines of polycrystalline β-Ga_2O_3 superimposed on the monocrystalline GaP pattern.

[1] The source materials used for these experiments were phosphine-grown polycrystalline GaP (Monsanto), Ga_2O_3 powder (Alusuisse), and Zn (United Minerals), all with 99.9999% nominal purity. The n-type GaP substrates, cut from liquid encapsulation Czochralski (LEC) grown ingots, were mechanically polished on the phosphorus (B) face.

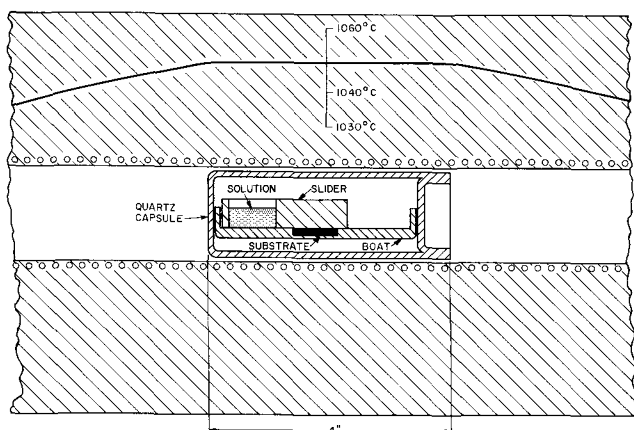

Fig. 3. Slider assembly and its relation to the temperature profile of the furnace (schematic). The slider and boat are made of Al_2O_3 (G.E.-Lucalox).

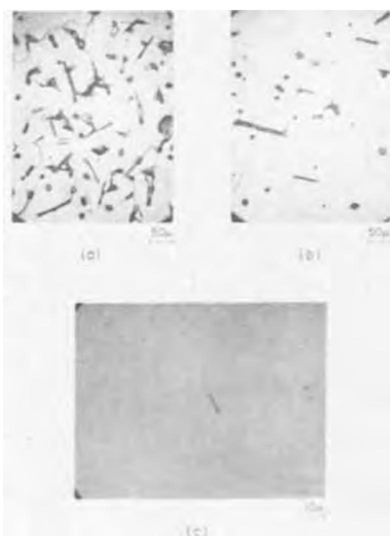

Fig. 4. Effect of decreasing Ga_2O_3 additions to the solution on the density of β-Ga_2O_3 precipitates. The transmission photomicrographs (a), (b), and (c) correspond to 0.45, 0.075, and 0.03 a/o O additions, respectively. All three crystals were grown by cooling the solution from ~1050° to 1035°C at a rate of 1°C/min.

initial position, resulting in the removal of the excess solution from the substrate.

In this manner GaP LPE layers were grown, with 0.45, 0.075, and 0.03 a/o O additions as Ga_2O_3 to the solution, between 1050° and 1035°C at a cooling rate of 1°C/min. Transmission micrographs of these crystals (Fig. 4) show a strong reduction in the concentration of β-Ga_2O_3 precipitates with decreasing Ga_2O_3 additions to the solution. The precipitates completely disappear, as viewed at 800X, between 0.027 and 0.021 a/o O additions to the solution.

Experiments performed by cooling from 1050° to 1020°C at a rate of 2°C/min also resulted in Ga_2O_3 precipitation, demonstrating that the precipitation is apparently unaffected by cooling rate between 1° and 10°C/min. It should be noted that when the solution was cooled to 1020°C even an O addition of only 0.025 a/o gave rise to a few precipitates. Finally, we changed the source of O from Ga_2O_3 powder to bulk Ga_2O_3 [2] or glassy $Zn(PO_3)_2$ (18). Both of these additions to the Ga-GaP solution yielded precipitates.

Discussion

The presence of precipitates in GaP is not unique among III-V compounds. For example, Eckhardt (19) has observed precipitates of α-Ga_2O_3 [the low-temperature form (20)] less than 3 μm in size in Czochralski- and Bridgman-grown GaAs. Recently, Kressel *et al.* (21) have identified by electron diffraction Ga_2Te_3 precipitates in GaAs which they attributed to precipitation from solid solution. However, several observations indicate that the β-Ga_2O_3 second phase in the GaP LPE layers is not the result of solid-state precipitation. First, as seen in Fig. 1, there is no distinct orientation relationship between the precipitates and the matrix. Second, the precipitates are obviously too large to originate from a supersaturated solid solution. Third, precipitates were observed in epitaxial layers grown by relatively slow cooling rates in the narrow temperature range tipping experiments (1°C/min, 1050°-1035°C; 2°C/min, 1050°-1020°C), wherein the excess Ga solution was removed from the film prior to withdrawal from the furnace. It is unlikely that the rate of solid-solution precipitation is rapid enough to account for the formation of precipitates in these experiments, since precipitation would have to take place during the short time required to cool the crystal to room temperature.

Therefore, it is concluded that the β-Ga_2O_3 precipitates are the consequence of the coprecipitation of Ga_2O_3 with GaP from a Ga-rich solution supersaturated with respect to both Ga_2O_3 and GaP. Thus, the tipping experiments conducted between 1050° and 1035°C, showing that the precipitates completely disappear between 0.027 and 0.021 a/o O additions, can be interpreted as giving the solubility of O in liquid Ga also saturated with GaP to be ~0.025 a/o O at ~1040°C. Hence, when O is added to the tipping solution in excess of ~0.025 a/o in a sealed isothermal system at a mean growth temperature of ~1040°C, the presence of precipitates in the epitaxial film results from supersaturation with respect to two solid phases. Conversely, the absence of precipitates in GaP grown in a nonisothermal system indicates that the solution became unsaturated due to the loss of excess oxide via $Ga_2O(g)$ transport according to Eq. [1].

The coprecipitation can be more readily discussed in terms of a schematic ternary liquidus isotherm at ~1040°C for the Ga-P-Ga_2O_3 system, shown in Fig. 5, which was drawn in analogy with the Ga-As-Si system (22, 23). The work of Foster and Scardefield (10) gives the solubility of Ga_2O_3 (or O) in Ga between 1000° and 1200°C. The present tipping experiments show a small (~20%) reduction in the O solubility at

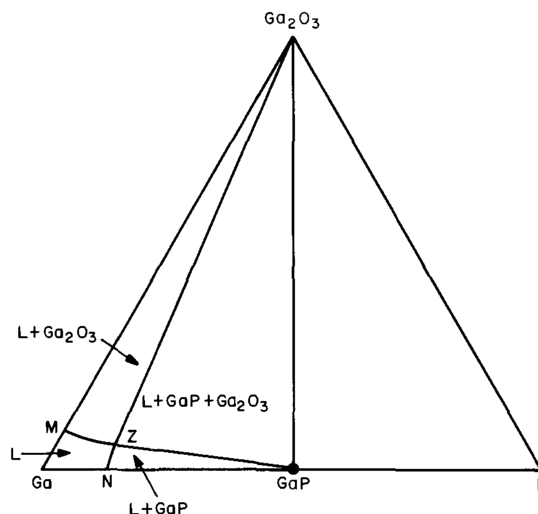

Fig. 5. Schematic 1040°C liquidus isotherm for the Ga-P-Ga_2O_3 system. Points *M*, *N*, and *Z* are the 1040°C solubilities of Ga_2O_3 in Ga (~0.01 m/o) (10), P in Ga (2.5 a/o) (24), and the ternary eutectic point of Ga_2O_3 (~0.008 m/o), respectively. The compositions within the triangle are not drawn to scale; the mole fraction of Ga_2O_3 dissolved in Ga is more than two orders of magnitude smaller than the atom fraction of P saturating Ga.

[2] Bulk polycrystalline Ga_2O_3 was pulled by W. Grodkiewicz of Bell Laboratories by the Czochralski method under ~3 atm of argon pressure.

~1040°C when the solution is also saturated in GaP. In Fig. 5 points M and N, respectively, represent the binary solubilities of Ga_2O_3 (~0.01 m/o) (10) and P (~2.5 a/o) (24) in Ga at ~1040°C, and point Z is the ternary eutectic point at which the solution, saturated with Ga_2O_3 (~0.008 m/o Ga_2O_3 or ~0.025 a/o O) and P, is in equilibrium with GaP and β-Ga_2O_3. According to the schematic liquidus isotherm, as long as the Ga_2O_3 additions to the solution vary along the curve $N - Z$, O-doped GaP but not β-Ga_2O_3 will precipitate. However, over-all solution compositions which are located within the Z-GaP-Ga_2O_3 tie triangle yield a liquid of composition Z in equilibrium with both solid phases, permitting their coprecipitation.

There are two phenomena, consistent with Fig. 5, which may lead to precipitation. The first one is mechanical in nature, due to the closeness in density between Ga and Ga_2O_3 [3] at the tipping temperature. Accordingly, at ~1040°C the Ga_2O_3 powder is either suspended in the liquid solution or it sinks to the vicinity of the substrate. However, the possibility that most of the observed precipitates originate directly from suspended particles which have never dissolved is discounted because only 5% of the as-received powder consists of needles, and even these are about a factor of 10 shorter than the precipitates. Therefore, we suggest that the small excess oxide particles,[4] suspended in the O- and GaP-saturated solution, may serve as nucleation sites for the growth of the observed β-Ga_2O_3 needles during the second phenomenon (coprecipitation) which is of chemical origin. During LPE growth, as the temperature decreases, the ternary eutectic point (point Z in Fig. 5) moves toward the Ga corner of the phase diagram, corresponding to an increasing supersaturation of the liquid with respect to GaP and Ga_2O_3 which results in the coprecipitation of both solid phases.

Since we would expect the number of nucleation sites to be proportional to the amount of excess oxide added to the solution (above point Z), the preceding interpretation is consistent with Fig. 4, showing an increasing amount of precipitates with increasing Ga_2O_3 additions in LPE layers grown under otherwise identical conditions. It should be noted that the presence of oxide nuclei is not a prerequisite for coprecipitation, especially when an LPE layer is grown over a wider temperature range. For example, when a solution of composition Z (0.025 a/o O) was cooled to 1020°C instead of 1035°C, the resulting epitaxial film contained a few precipitates.

Although at ~1040°C the solubility of Ga_2O_3 in Ga saturated with GaP is only a little less than the reported solubility of Ga_2O_3 in liquid Ga alone, it is by no means assured that at higher temperatures, corresponding to larger phosphorus concentrations in the solution, the difference between binary and ternary solubilities will remain small. An approximate thermodynamic calculation can be performed to yield the variation of the O solubility in the ternary system as a function of temperature. Here we consider ternary solubility at the ternary eutectic point Z, illustrated in Fig. 5, which is an invariant point at a set temperature, T. The variation of Z with T gives the ternary eutectic valley.

The dissolution of Ga_2O_3 in Ga or in Ga saturated with P can be represented by the reaction

$$Ga_2O_3(s) = 2Ga(l) + 3\underline{O}(l) \quad [2]$$

where $\underline{O}$ represents the oxygen dissolved in the liquid. Under the conditions of Foster and Scardefield's binary solubility measurements (10), the binary activities, $a_{i,b}$, of the designated species in the liquid are given by $a_{Ga,b} = x_{Ga,b}\gamma_{Ga,b} \approx 1$ and $a_{O,b} = x_{O,b}\gamma_{O,b}$, where $x_{i,b}$ and $\gamma_{i,b}$ are the atom fraction and activity coefficient of species i, and b refers to the binary system. However, a comparison of the Ga-Ga_2O_3 (10) and Ga-P (24) binary data shows that the mole fraction of Ga_2O_3 dissolved in Ga is more than two orders of magnitude smaller than the atom fraction of P saturating Ga, indicating that the activity of Ga in the ternary system cannot be taken as unity. As the activity of Ga_2O_3 is unity, the equilibrium constant, K, for Eq. [2] becomes

$$K = a_{Ga,t}^2 (x_{O,t})^3 (\gamma_{O,t})^3 \approx (x_{O,b})^3 (\gamma_{O,b})^3 \quad [3]$$

where the subscript t refers to the ternary system. Rearranging Eq. [3] gives

$$\ln \frac{x_{O,b}}{x_{O,t}} = \ln\gamma_{O,t} - \ln\gamma_{O,b} + 2/3 \ln(x_{Ga,t}\gamma_{Ga,t}) \quad [4]$$

As there are no thermodynamic data for the liquid phase, we assume regular binary and ternary solution behavior (27). Assuming in addition to $x_{Ga,b} \approx 1$ that $x_{O,t} << x_{P,t}$ and $x_{Ga,t} + x_{P,t} \approx 1$, we find approximate expressions for the activity coefficients[5] which when substituted into Eq. [4] yield

$$\ln \frac{x_{O,b}}{x_{O,t}} \approx \left(\frac{1 - x_{Ga,t}}{RT}\right)\left[-\omega_{Ga\text{-}O} + \omega_{P\text{-}O} + \frac{\omega_{Ga\text{-}P}}{3}(2 - 5x_{Ga,t})\right] + 2/3 \ln x_{Ga,t} \quad [5]$$

where the ω_{ij}'s are the ternary interchange energies.

To evaluate Eq. [5] we take $\omega_{Ga\text{-}P}$ from the work of Thurmond (24) and since $x_{P,t} + x_{Ga,t} \approx 1$, $x_{Ga,t}$ can be approximated by its value along the Ga-P liquidus curve (24). However, $\omega_{Ga\text{-}O}$ and $\omega_{P\text{-}O}$ are both unknown. The simplest assumption is to set $\omega_{P\text{-}O} = 0$ (ideal solution), since at the high temperatures of interest P-O liquids do not exist. By substituting the ratio $x_{O,b}/x_{O,t}$ ($3 \times 10^{-2}/2.5 \times 10^{-2}$) in units of atom per cent at ~1040°C into Eq. [5], we obtain $\omega_{Ga\text{-}O} \approx -25$ kcal/mole. The negative deviation from Raoult's law implied by this value is considered reasonable in comparison, for instance, with the Cu(l)-O system. Recent thermodynamic measurements (28) yield $\omega_{Cu\text{-}O} \approx -6.3$ kcal/mole at 1100°C. By using the estimated value of $\omega_{Ga\text{-}O}$ and keeping $\omega_{P\text{-}O} = 0$, $\ln(x_{O,b}/x_{O,t})$ can be readily calculated from Eq. [5] up to the melting point of GaP. A combination of this ratio with the Ga-Ga_2O_3 solubility curve of Foster and Scardefield (10) gives the variation of $x_{O,t}$ along the Ga-P-Ga_2O_3 eutectic valley, shown in Fig. 6.

Although in Fig. 6 the departure of $x_{O,t}$ from $x_{O,b}$ becomes pronounced at higher temperatures, below about 1100°C only a small error is made by using the binary solubility curve (10) instead of the ternary eutectic valley. Because of the calculated maximum there is only about a factor of 2 increase in the ternary oxygen solubility between ~1100°C and the melting point of GaP. The sections of the eutectic valley at high and low temperatures are shown as dashed lines because they are based on portions of the binary solubility curve which were found by extrapolating the published curve. Moreover, if $\omega_{P\text{-}O} \neq 0$, according to Eq. [5] this would influence $x_{O,t}$ only at high $x_{P,t}$ corresponding to high temperatures.

The estimate shown in Fig. 6 does not eliminate the need for further experimental work to establish the eutectic valley of the system Ga-P-Ga_2O_3. Such information in conjunction with thermodynamic analysis of the type presented here would greatly aid the understanding of this technologically important ternary system. Unfortunately, even if the Ga-P-Ga_2O_3 eutectic

[3] At ~30°C the density of liquid Ga (25) (6.09 g/cc) is greater than that of β-Ga_2O_3 (20) (5.88 g/cc). However, at 1040°C the measured density of Ga (25) (5.48 g/cc) is smaller than the estimated density of β-Ga_2O_3 (~5.65 g/cc) which is based on an extrapolation of the linear expansion coefficients of Al_2O_3-Ga_2O_3 solid solutions (26) to pure Ga_2O_3.

[4] Because of the brittleness of bulk Ga_2O_3 and the reaction of $Zn(PO_3)_2$ with Ga to form Ga_2O_3, the presence of oxide particles suspended in the melt cannot be excluded even when O was added in one of these forms.

[5] The expressions are: $RT \ln\gamma_{O,b} \approx \omega_{Ga\text{-}O}$, $RT \ln\gamma_{O,t} \approx x_{Ga,t}\omega_{Ga\text{-}O} + (1 - x_{Ga,t})\omega_{P\text{-}O} - x_{Ga,t}(1 - x_{Ga,t})\omega_{Ga\text{-}P}$, and $RT \ln\gamma_{Ga,t} \approx (1 - x_{Ga,t})^2\omega_{Ga\text{-}P}$.

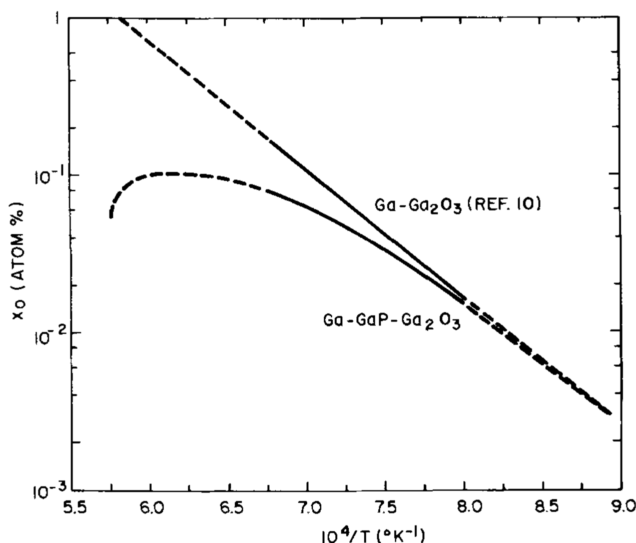

Fig. 6. Estimated eutectic valley for the Ga-P-Ga_2O_3 ternary system and its relation to the solubility of Ga_2O_3 in Ga (10). The plot is given in terms of a/o O vs. reciprocal temperature. Note that Ga_2O_3 can only coprecipitate with GaP at O concentrations above the loop.

valley were known, independent experimental work would be required to give the equilibrium concentration of O dissolved in GaP crystals. However, one can predict on thermodynamic grounds that GaP in equilibrium with liquid compositions along the eutectic valley (Fig. 5, point *Z*; Fig. 6) contains the maximum amount of oxygen which can be dissolved at each temperature. Liquid compositions above Z result in precipitation of a second phase, β-Ga_2O_3, without an increase in the equilibrium oxygen concentration in the GaP crystal.

Of course, GaP epitaxial films which are free of precipitates may be grown in a nonisothermal LPE system even when a large excess of Ga_2O_3 is added to the solution, initially moving the over-all liquid far above Z. The loss of O from the growth solution via the vaporization and transport of Ga_2O according to Eq. [1] explains not only the absence of β-Ga_2O_3 needles in LPE layers grown in a nonisothermal system but also the disparity in reported optimum O additions [0.03 (2) and 1.05 a/o O (5) for SG and LPE, respectively]. Our preliminary experiments demonstrate that efficient diodes can be fabricated in an isothermal LPE system without excessive O additions to the solution. Using the slider (Fig. 3), a nearly precipitate-free p-type layer was grown at ~1040°C onto an n-type LPE and LEC structure from a solution containing 0.03 a/o O in the form of $Zn(PO_3)_2$ and 0.045 a/o Zn. The annealed and encapsulated diodes exhibited red electroluminescent (EL) efficiencies as high as 2.7%, which we consider promising since the dopant concentrations have not yet been optimized. This figure is within about a factor of two of the best reported values of 4.5% (29) and 6% (30) for similar structures which were grown from solutions containing a large excess of Ga_2O_3 but presumably under nonisothermal conditions [tipping in a small thermal mass furnace (29) and dipping, (30) respectively].

The effect of the concentration of β-Ga_2O_3 precipitates on EL efficiency of devices has not been examined in detail. However, point contact EL efficiency measurements were made on mesa diodes taken from a relatively precipitate-free and from a heavily precipitated area (such as shown in Fig. 2) of a p-type LPE film grown on a 2.5 cm long n-type LEC substrate from a solution containing 1.05 a/o O added as Ga_2O_3 and 0.05 a/o Zn. The EL efficiencies were as much as 15 times higher for the diodes prepared from the clean segment than for the ones made from the heavily precipitated area. We think that the reduction in efficiency is very likely due to the difficulty of achieving suitable contact with a heavily precipitated p-type layer. But a small concentration of precipitates may not have any significant effect on the EL efficiency. Indeed, we speculate that such small concentrations of precipitates may be present in the LED's reported in the literature but have been overlooked because of their negligible effect on diode performance. Finally, recent measurements of Gloriozova *et al.* (31) show that the 100°K hole mobility of Zn, O-doped SG GaP drops precipitously when more than 0.03 a/o O is added to the melt as Ga_2O_3. Since we have also seen Ga_2O_3 precipitates in SG platelets, the results of Gloriozova *et al.* (31) may be related to scattering by a second phase.

Acknowledgments

We would like to express our appreciation to F. A. Trumbore for many helpful discussions and suggestions in the course of this work. We are also grateful to C. D. Thurmond for several discussions and advice. Useful discussions with R. H. Saul, M. E. Weiner, and S. Wagner are also acknowledged. We thank L. R. Dawson for the DIMA work.

Manuscript submitted Aug. 9, 1971; revised manuscript received Dec. 13, 1971. This was RNP 250 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Mass Spectrometric Studies of Vapor-Phase Crystal Growth

II. GaN

Vladimir S. Ban

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

A mass spectrometer has been coupled to an open-tube, vapor-phase, crystal growth apparatus in order to study vapor-phase processes leading to the deposition of GaN crystals. Studies of the HCl and Cl_2 reactions with gallium showed that $GaCl_{(g)}$ is the only gallium chloride formed. Studies of NH_3 decomposition showed that very little NH_3 decomposes under given experimental conditions, but this can be changed by the presence of W and Pt. Thermochemical data were collected or calculated for all species detected in the system. The reaction mechanisms leading to the deposition of GaN are discussed. It is concluded that the reaction controlling the deposition of GaN can be written as

$$GaCl_{(g)} + NH_{3(g)} \rightarrow GaN_{(s)} + HCl_{(g)} + H_{2(g)}$$

Comparison of the experimentally determined vapor composition with one predicted from the available thermochemical data showed that important deviations from the thermochemical equilibrium occur in our system.

Gallium nitride has a direct energy bandgap of 3.39 eV (1) and is therefore an interesting material for electronic applications. Recently, single-crystalline epitaxial films of GaN were successfully prepared by means of the open-tube, vapor-transport method (1). The apparatus and technique used were very similar to those used previously in the preparation of other III-V compounds (2).

The chemistry of vapor-phase processes leading to the deposition of GaN was not completely understood. For this reason, we undertook studies of some fundamental aspects of the GaN deposition. In particular, the following processes were studied: (*a*) the transport of Ga with HCl and Cl_2 in the temperature range of 700°-900°C; (*b*) the thermal decomposition of NH_3 in the same temperature range as affected by various catalysts; and (*c*) the reactions leading to the deposition of GaN and the influence of temperature on the rate of this reaction. The influence of the replacement of H_2 by He as a carrier gas was also studied. Furthermore, the thermochemistry of the deposition system is discussed and the experimentally determined composition of the vapor phase is compared with the composition predicted from the chemical equilibrium calculations.

In order to determine the composition of the vapor phase under a variety of experimental conditions, we coupled a time-of-flight mass spectrometer to the vapor-growth tube. With the mass spectrometer, we could directly identify species present in the vapor phase and determine their relative abundances.

Experimental Procedure and Results

The mass spectrometer-vapor growth tube system is shown schematically at the top of Fig. 1. Details of this system and the sampling technique have been described in Part I of this series (3), which reports a study of the $GaAs_xP_{1-x}$ system. The present experiments were done in a similar fashion to those described in Part I. However, the temperature gradients, concentrations of reacting gases, and flow rates were chosen to be similar to those employed (1) in growth of GaN epitaxial layers. GaN was also deposited on the walls of the reactor in the course of our experiments.

Key words: mass spectrometry, vapor-phase deposition, GaN crystals, epitaxial growth, chemical kinetics, thermodynamics.

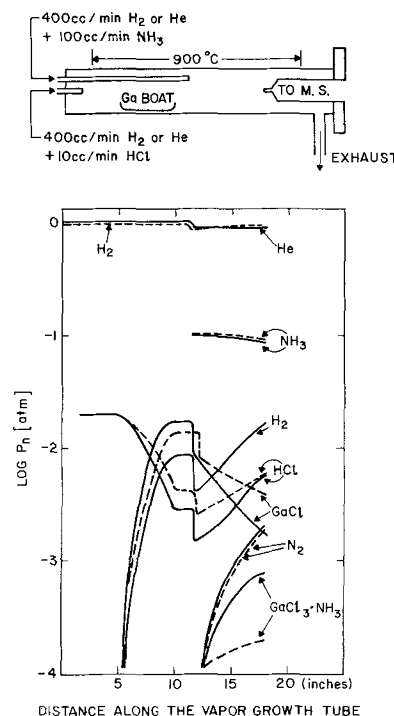

Fig. 1. Mass spectrometric determination of the variation of partial pressures of species along the growth tube during epitaxial growth of GaN. The apparatus and experimental conditions are schematically represented in the upper part of the drawing. (Dotted lines give pressures when H_2 is the carrier, solid lines when He is the carrier. Kinks in the pressure curves at 12 in. are caused by the additional volume of gas introduced at that point by the NH_3 inlet tube. These curves are drawn from the determination of initial and final partial pressures of vapor species.)

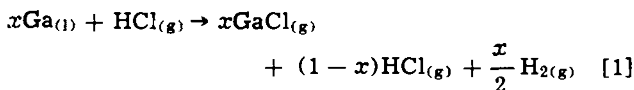
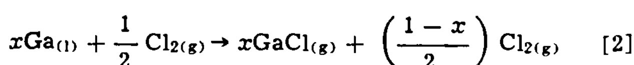
Occasionally, even the sampling capillary became clogged with GaN deposit.

Halogen transport of Ga.—The HCl transport of Ga in the temperature range of 400°-800°C was discussed in Part I (3). This time we also examined the Cl_2 transport of Ga as well as the influence of the carrier gas (H_2 *vs.* He) on the HCl transport efficiency. The boat containing gallium was 12.5 cm long; 25 cm^2 of the liquid gallium surface was exposed to the gas phase. With the chosen flow rates (500 cm^3/min H_2 or He + 10 cm^3/min HCl or Cl_2), the gas stream velocity was about 3.5 cm/sec. It was found that HCl and Cl_2 react with Ga according to the following reactions



$$xGa_{(l)} + HCl_{(g)} \rightarrow xGaCl_{(g)} + (1-x)HCl_{(g)} + \frac{x}{2}H_{2(g)} \quad [1]$$



$$xGa_{(l)} + \frac{1}{2}Cl_{2(g)} \rightarrow xGaCl_{(g)} + \left(\frac{1-x}{2}\right)Cl_{2(g)} \quad [2]$$

where x = mole fraction of HCl or Cl_2 reacting. Values of x for various experimental conditions are given in Table I. These values were obtained by changing the position of the HCl or Cl_2 inlet, which could be placed either upstream or downstream from the boat containing Ga. The mass spectrometer signal due to HCl (or Cl_2) was first measured with the inlet placed downstream, so that the halogen species could not react with Ga. A second measurement was made with the inlet placed upstream, so that a portion of the halogen did react. Since the second signal was due to the unreacted HCl (or Cl_2), its ratio to the first signal was equal to $(1 - x)$. The mass spectra also showed that the monochloride (GaCl) was the only gallium chloride species resulting from the halogen-gallium interaction.

Decomposition of NH_3.—It is important to know to what extent ammonia is decomposed into nitrogen and hydrogen, because GaN cannot be deposited by direct reaction between GaCl and N_2. Ammonia is a thermodynamically unstable gas (4) at temperatures usually employed in the growth of GaN crystals, and over 99.5% of incoming NH_3 would decompose if equilibrium were achieved under our experimental conditions. However, it is known that thermal decomposition of NH_3 is a sluggish reaction. It can be accelerated with various catalysts, *e.g.*, Pt and W (5). Normally, the walls of the growth tube are made of quartz, but sometimes, in order to prevent the deposition of a permanent layer of the insoluble GaN on the reactor wall, a removable tungsten or graphite liner is placed in the tube. This could change the composition of the gaseous phase. We therefore studied the influence of various materials on the decomposition of NH_3, which can be described by the following equation

$$NH_{3(g)} \rightarrow (1-x)NH_{3(g)} + \frac{x}{2}N_{2(g)} + \frac{3}{2}xH_{2(g)} \quad [3]$$

where x = mole fraction of NH_3 decomposing. A foil of Pt, W, or graphite (25 cm^2 in each case) could be placed in and removed from the growth tube. Mass spectrometer signals due to NH_3 and N_2 were measured with and without the foil in the system. The values of

x computed from these measurements in the temperature range of 700°-950°C are given in Table II. In these experiments, a mixture of 100 cm^3/min of NH_3 with 400 cm^3/min of He or H_2 was passed through the tube. The influence of the carrier gas on the extent of decomposition is also depicted in Table II. When no catalyst was present, no more than about 4% of the NH_3 was decomposed at temperatures as high as 950°C. This was estimated from the increase in the N_2 signal at the elevated temperatures in comparison with N_2 background signal at room temperature.

Deposition reactions.—In analogy with the deposition of other III-V compounds, one can postulate two thermodynamically feasible reactions which might lead to the deposition of GaN

$$GaCl_{(g)} + NH_{3(g)} \rightarrow GaN_{(s)} + HCl_{(g)} + H_{2(g)} \quad [4]$$

and

$$3GaCl_{(g)} + 2NH_{3(g)} \rightarrow 2GaN_{(s)} + GaCl_{3(g)} + 3H_{2(g)} \quad [5]$$

In order to test for the occurrence of these reactions, we monitored mass spectrometrically the pressures of GaCl, HCl, and $GaCl_3$ in the system before and after the introduction of NH_3. In these experiments Ga was transported with HCl. A decrease in the GaCl signal and an increase in the HCl signal after the introduction of NH_3 indicated that Reaction [4] does indeed occur. No $GaCl_3$ was detected, but we discovered a $[GaCl_2 \cdot NH_3]^+$ ion in the mass spectra. The most probable parent molecule is $GaCl_3 \cdot NH_3$, whose existence at reasonably high temperatures has been reported (6). It is known that metal trihalides lose a halogen atom when ionized by the electron beam, giving a MX_2^+ ion as the most prominent peak in the mass spectrum (7). From the intensity of the peak we estimate that the partial pressure of $GaCl_3 \cdot NH_3$ was between 1 and 5×10^{-4} atm. From these results we concluded that Reaction [5] also occurs in our system, producing $GaCl_{3(g)}$ which then reacts with NH_3 to form the observed ammonia complex.

The increase in P_{HCl} and the decrease in P_{GaCl} due to the reaction of GaCl with NH_3 at 900°C are listed in Table III. Values of P_{GaCl} and P_{HCl} after the reaction between HCl and gallium were known from the gallium transport experiments, initial P_{NH_3} was 1.0×10^{-1} atm and the total flow in the system was 1.0 l/min. The carrier gas was either H_2 or He. Values of P_{GaCl} and P_{HCl} after the reaction with NH_3 were calculated from the respective changes in mass spectrometric intensities of these species.

We used the same procedure to measure the consumption of GaCl as a function of temperature be-

Table III. Changes in P_{GaCl} and P_{HCl} due to reactions with NH_3

$P_{NH_3} = 1.0 \times 10^{-1}$ atm, total flow rate = 1.0 l/min, T = 900°C

	He carrier	H_2 carrier
Initial P_{GaCl} (atm)	8.5×10^{-3}	7.5×10^{-3}
Final P_{GaCl} (atm)	1.7×10^{-3}	3.8×10^{-3}
Initial P_{HCl} (atm)	1.5×10^{-3}	2.5×10^{-3}
Final P_{HCl} (atm)	5.8×10^{-3}	5.7×10^{-3}

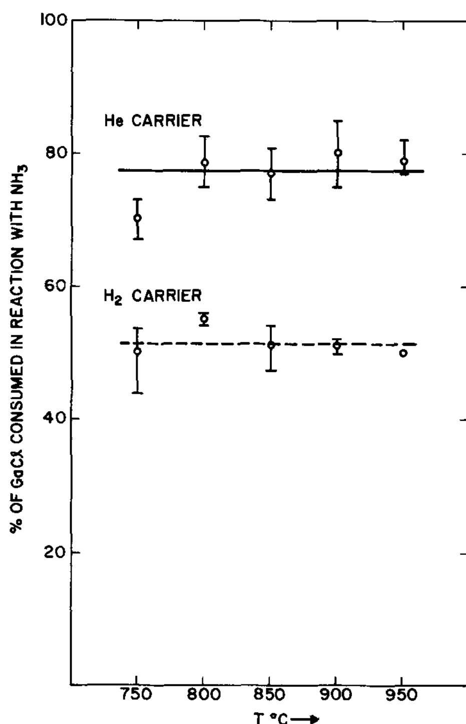

Fig. 2. Percentage of incoming $GaCl_{(g)}$ consumed in reaction with $NH_{3(g)}$ at various temperatures. Initial partial pressures (in atm): P_{H_2} or $P_{He} = 9 \times 10^{-1}$, $P_{NH_3} = 1 \times 10^{-1}$, $P_{GaCl} = 8 \times 10^{-3}$. Total flow = 1 l/min, reaction time = 4 sec.

tween 750° and 950°C. The results are presented in Fig. 2. The extent of GaCl consumption was not markedly temperature dependent, but it was significantly greater for He as the carrier gas than for H_2. In these experiments the reactor walls were graphite lined.

Thermochemical Data

By means of our mass spectrometric measurements, we determined qualitatively and quantitatively the species present in the vapor phase and also specified the reactions occurring in the system. These results combined with reliable thermochemical data for all species in the system make possible a meaningful discussion of the chemistry of the vapor-phase deposition.

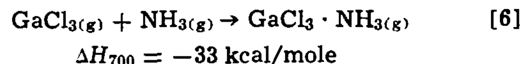
For this purpose the most useful data are the standard free energies of formation $\Delta F°_f$ of all species in the temperature interval of interest. Knowledge of $\Delta F°_f$ permits one to calculate the standard free energies of reaction $\Delta F°_r$ for reactions occurring in the system, and from these to find values of equilibrium constants K_p and values of equilibrium partial pressures for the vapor species.

In Table IV we list values of $\Delta F°_f$ for species in the system at $T = 1173°K$, the temperature at which epitaxial layers of GaN are usually grown. Data for $GaCl_{(g)}$ and $GaCl_{3(g)}$ were taken from a recent paper by Kirwan (8). $GaCl_{3(g)}$ is not present in the system as such, but data for it are necessary to compute the $\Delta F°_f$ for $GaCl_3 \cdot NH_{3(g)}$. Data for $HCl_{(g)}$ and $NH_{3(g)}$ were taken from JANAF Tables (4).

Table IV. Values of $\Delta F°_f$ (free energy of formation) at $T = 1173°K$ for species present in the GaN deposition system

Species	$\Delta F°_f$ (kcal/mole)	Reference
$HCl_{(g)}$	−24.3	(4)
$GaCl_{(g)}$	−28.9	(8)
$GaCl_{3(g)}$	−71.5	(8)
$NH_{3(g)}$	+19.9	(4)
$GaCl_3 \cdot NH_{3(g)}$	−55.6	Calculated from data in (7) and (9)
$GaN_{(s)}$	+6.2	Calculated from data in (10) and (11)

The value for $\Delta F°_f$ of $GaCl_3 \cdot NH_{3(g)}$ was determined from ΔH data given by Friedman and Taube (6)



$$GaCl_{3(g)} + NH_{3(g)} \rightarrow GaCl_3 \cdot NH_{3(g)} \quad [6]$$
$$\Delta H_{700} = -33 \text{ kcal/mole}$$

The ΔS for reactions of this type (*i.e.*, $M_{(g)} + X_{(g)} \rightarrow MX_{(g)}$) is usually around −22 eu (9). Using the expression $\Delta F°_r = \Delta H°_r - T\Delta S°_r$, one finds for the above reaction $\Delta F°_r = -4$ kcal/mole at $T = 1173°K$. Since

$$\Delta F°_r = \Delta F°_f\, GaCl_3 \cdot NH_{3(g)} - (\Delta F°_f\, NH_{3(g)} + \Delta F°_f\, GaCl_{3(g)})$$

one finds $\Delta F°_f\, GaCl_3 \cdot NH_{3(g)} = -55.6$ kcal/mole at $T = 1173°K$.

Marina and Nashel'skii (10) estimate ΔS_f and C_p of $GaN_{(s)}$. Their values are based on the corresponding thermochemical data for the elemental Group IV semiconductors which are well known. The ΔH_f of GaN at 298°K is −26.4 kcal (11). This value is based on experimental work done by Hahn and Juza (12), and applied to the reaction

$$\tfrac{1}{2}N_{2(g)} + Ga_{(l)} \rightarrow GaN_{(s)} \quad [7]$$

The above data permit one to calculate $\Delta F°_f$ for $GaN_{(s)}$; at 1173°K $\Delta F°_f = 6.2$ kcal/mole.

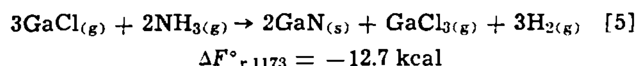
Discussion

Our studies of Ga transport, which are summarized in Table I, showed that between 70 and 80% of the introduced HCl participates in the transport reaction, in good agreement with the values determined in Part I (3). Replacement of H_2 with He as a carrier gas improved the efficiency of the HCl transport, and the HCl/He mixture was more efficient than the Cl_2/He mixture, but the differences in values were not very significant. More important, in all cases chemical equilibrium was not established, since according to the thermochemical data in Ref. (8), practically all the HCl and Cl_2 introduced should have reacted with Ga. It was shown in Part I (3) that the relatively high flow rates employed in our growth systems are responsible for the observed deviations from equilibrium in the transport reaction.

Table II shows the influence of various catalysts on the thermal decomposition of NH_3. The metals tungsten and platinum are significantly more efficient catalysts than the nonmetals graphite and quartz (reactor walls). However, below 700°C very little decomposition occurred, regardless of the catalyst. Furthermore, the influence of the carrier gas was quite pronounced. The decomposition proceeded more readily in the presence of He than in the presence of H_2, particularly in the case of platinum; in the presence of He significant amounts of NH_3 decomposed on platinum, while virtually no decomposition occurred in the presence of H_2. This is possibly due to some interaction of H_2 with platinum which changes the catalytic activity of Pt and therefore inhibits the decomposition of NH_3.

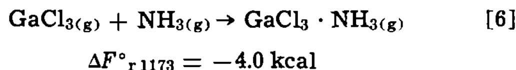
Studies of NH_3 decomposition, as summarized in Table II, indicated that the reactor wall materials and the carrier gas are factors with a significant influence on the composition of the gas phase in the growth system. Frequently, only the vapor species directly participating in the reactions in a system are considered in predicting the vapor-phase composition. Secondary factors, such as those mentioned, are often neglected. Such neglect can lead to serious errors in estimates of the vapor-phase composition.

Combining thermochemical data and the mass spectrometric results one can now discuss the chemistry of the deposition system. Besides the direct reaction of GaCl with NH_3 (Reaction [4]), there are other routes leading to the deposition of GaN. One possible sequence of reactions is



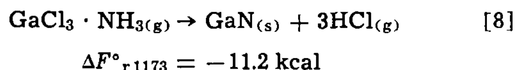
$$3GaCl_{(g)} + 2NH_{3(g)} \rightarrow 2GaN_{(s)} + GaCl_{3(g)} + 3H_{2(g)} \quad [5]$$
$$\Delta F°_{r\,1173} = -12.7 \text{ kcal}$$

The resultant $GaCl_{3(g)}$ then reacts with $NH_{3(g)}$ to form the observed $GaCl_3 \cdot NH_{3(g)}$ complex



$$GaCl_{3(g)} + NH_{3(g)} \rightarrow GaCl_3 \cdot NH_{3(g)} \qquad [6]$$
$$\Delta F^\circ_{r\,1173} = -4.0 \text{ kcal}$$

This complex is thermodynamically unstable with respect to the following reaction

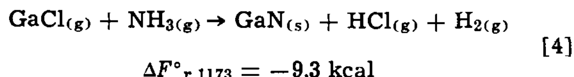


$$GaCl_3 \cdot NH_{3(g)} \rightarrow GaN_{(s)} + 3HCl_{(g)} \qquad [8]$$
$$\Delta F^\circ_{r\,1173} = -11.2 \text{ kcal}$$

Indeed, $AlN_{(s)}$ has been deposited by decomposing the analogous complex $AlCl_3 \cdot NH_{3(g)}$ (13). Recently, the thermal decomposition of a $GaBr_3 \cdot 4NH_3$ complex has been used for the deposition of GaN films (14).

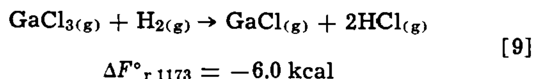
Our results also permit us to say something about the kinetics of the above reactions. Reactions [4] and [5] are fairly fast; *e.g.*, 80% of introduced $GaCl_{(g)}$ reacts with $NH_{3(g)}$ in 4 sec[1] when He is used as the carrier gas, 50% when H_2 is the carrier. Reaction [6] must be fast also, because no unreacted $GaCl_{3(g)}$ was detected. On the other hand, Reaction [8] is slower than [6], because an appreciable amount of $GaCl_3 \cdot NH_{3(g)}$ exists in the vapor phase.

Summation of Eq. [5], [6], and [8] yields the overall controlling equilibrium for the deposition of $GaN_{(s)}$



$$GaCl_{(g)} + NH_{3(g)} \rightarrow GaN_{(s)} + HCl_{(g)} + H_{2(g)} \qquad [4]$$
$$\Delta F^\circ_{r\,1173} = -9.3 \text{ kcal}$$

An alternative reaction path is also thermodynamically feasible. The resultant $GaCl_{3(g)}$ (Reaction [5]) can undergo reduction by $H_{2(g)}$



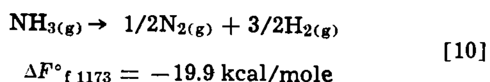
$$GaCl_{3(g)} + H_{2(g)} \rightarrow GaCl_{(g)} + 2HCl_{(g)} \qquad [9]$$
$$\Delta F^\circ_{r\,1173} = -6.0 \text{ kcal}$$

The $GaCl_{(g)}$ then reacts with $NH_{3(g)}$ according to Reaction [5] and contributes to the deposition of $GaN_{(s)}$.

Summation of Reactions [5] and [9] leads again to Eq. [4] which therefore establishes the controlling equilibrium for both complex reaction paths as well as for the direct GaCl-NH_3 reaction. Most likely, the direct Reaction [4] is the biggest contributor to the deposition of GaN, because partial pressures of reactants GaCl and NH_3 are much higher than partial pressures of either $GaCl_3$ or $GaCl_3 \cdot NH_3$.

From the value of $\Delta F^\circ_r = -9.3$ kcal for Reaction [4] the corresponding value of the equilibrium constant $K_{(4)} = 55$. This value of $K_{(4)}$ suggests that in the case of the H_2 carrier the partial pressure $P_{H_2} = 9 \times 10^{-1}$ atm is sufficiently high to prevent all $GaCl_{(g)}$ from reacting with $NH_{3(g)}$ ($P_{NH_3} = 1 \times 10^{-1}$ atm). When He is used as the carrier gas (*i.e.*, $P_{H_2} \approx 10^{-3}$ atm) more $GaCl_{(g)}$ reacts (Fig. 2). However, in neither case was the equilibrium reached.

Figure 1 shows the partial pressures of various gaseous species along the tube for the cases of H_2 and He as the carrier gas. The pressure curves were drawn from the determination of the initial and final partial pressures of vapor species; no experimental data were obtained for the intervening points. It is usually assumed that in vapor-phase deposition apparatus thermochemical equilibrium is established throughout the system. Our results show that this is not the case in the GaN deposition system. From the thermochemical data in Table IV it is obvious that the following reactions would occur readily if equilibrium were achieved under our experimental conditions



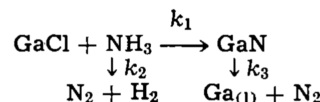
$$NH_{3(g)} \rightarrow 1/2N_{2(g)} + 3/2H_{2(g)} \qquad [10]$$
$$\Delta F^\circ_{f\,1173} = -19.9 \text{ kcal/mole}$$

and

$$GaN_{(s)} \rightarrow Ga_{(l)} + 1/2N_{2(g)} \qquad [11]$$
$$\Delta F^\circ_{f\,1173} = -6.2 \text{ kcal/mole}$$

The decomposition of $NH_{3(g)}$ has already been discussed. Lorenz and Binkowski have shown (16) that while the decomposition of $GaN_{(s)}$ does occur at temperatures over 600°C, the rate of this reaction is very slow. Therefore, due to the kinetic limitations, the above reactions do not proceed in this system and the thermochemical equilibrium is not established. On the other hand, the deposition of $GaN_{(s)}$ is a fast process.

Indeed, the very fact that $GaN_{(s)}$ can be deposited under our experimental conditions is the result of the fortuitous kinetics. The deposition and the deposition-opposing processes can be represented by the following scheme



$$\begin{array}{ccc} GaCl + NH_3 & \xrightarrow{k_1} & GaN \\ \downarrow k_2 & & \downarrow k_3 \\ N_2 + H_2 & & Ga_{(l)} + N_2 \end{array}$$

where k_1, k_2, and k_3 are rate constants of corresponding processes. One succeeds in depositing $GaN_{(s)}$ only because the fact that $k_1 >> k_2, k_3$ leads to the favorable deviations from the thermochemical equilibrium. Due to these deviations the reacting NH_3 is present in sufficiently high concentrations and the decomposition of the deposited $GaN_{(s)}$ is practically negligible.

Significant deviations from the equilibrium situation were also detected in our earlier work on the $GaAs_xP_{1-x}$ system (3).

Conclusions

The main results of mass spectroscopic studies of the GaN deposition system are:

1. Both Cl_2 and HCl react readily with $Ga_{(l)}$ in the temperature interval 700°-900°C. $GaCl_{(g)}$ was the only gallium chloride produced in these reactions.

2. NH_3 does not undergo significant decomposition under the experimental conditions present in our deposition system. The influence of various catalysts and the carrier gas (He *vs.* H_2) on the decomposition of NH_3 was studied and reported.

3. On the basis of mass spectrometric results and collected thermochemical data we discussed the feasibility of various reaction mechanisms which lead to the deposition of GaN. The over-all reaction-controlling equilibrium can be written as

$$GaCl_{(g)} + NH_{3(g)} \rightarrow GaN_{(s)} + HCl_{(g)} + H_{2(g)}$$

4. The ability to deposit GaN under our experimental conditions rests on the fact that reactions of decomposition of NH_3 and GaN are much slower than the GaN deposition reaction. The resulting favorable deviation from the thermochemical equilibrium leads to the net accumulation of GaN, although it is actually a metastable phase at the temperatures employed.

Thermodynamic Analysis of the III-V Alloy Semiconductor Phase Diagrams

III. The Solidus Boundary in the $Ga_{1-x}Al_xAs$ Pseudobinary System

L. M. Foster,* J. E. Scardefield, and J. F. Woods

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The solidus boundary in the $Ga_{1-x}Al_xAs$ pseudobinary system was determined by a technique which employs the electron microprobe to analyze the primary phase of compositions equilibrated in the two-phase field. The solid solutions in this system appear to be essentially ideal over the entire composition range, since the experimental solidus boundary is in good agreement with that calculated with the assumption of ideal solid and liquid solutions. This is consistent with the hypothesis that an alloy whose two components have the same lattice parameter will obey Raoult's law of mixing.

Of all the III-V compound semiconductors, alloys between GaAs and AlAs offer some of the most attractive features. Direct radiative transitions with high quantum efficiencies are permitted up to about 40 m/o (mole per cent) AlAs, corresponding to red (*ca.* 6800Å) light emission. The alloys are particularly amenable to preparation by liquid-phase epitaxy from gallium-rich solutions (1), and high quality, single-crystal GaAs substrates are readily available. A primary consideration in the early choice of $Ga_{1-x}Al_xAs$ for exploitation was the almost perfect lattice parameter match between GaAs and AlAs (a_{GaAs} = 5.653Å; a_{AlAs} = 5.662Å) (2). Because of this lattice match, strain-free layers of $Ga_{1-x}Al_xAs$ of high metallurgical quality could be deposited by epitaxial techniques onto GaAs substrates. Moreover, the lattice parameter match avoids the introduction of carrier trapping states at the interface between the epitaxial layer and the GaAs.

The authors recently suggested (3) that the degree of match between the lattice parameters of the two III-V compounds forming an alloy might also determine in part the homogeneity and general "quality" of bulk crystals of the alloy. This is a consequence of the absence of lattice strain that would otherwise be introduced when alloys are formed from components of different sizes. This strain makes a contribution to the excess free energy of mixing, which causes a departure of the phase boundaries in the $T - x$ phase diagram from their positions for ideal solutions.

In the earlier investigation, Foster and Woods (3) determined the degree of nonideality of the three homologous alloy systems, $Ga_xIn_{1-x}Sb$, $Ga_xIn_{1-x}As$, and $Ga_xIn_{1-x}P$, in which the lattice parameters of the two components differ by 6.10, 6.92, and 7.38%, respectively. The excess free energy of mixing found for the three solid alloys correlated with the lattice parameter mismatch, increasing from the antimonide to the arsenide to the phosphide.

In a separate study (4) it was shown that in the $GaSb_{1-x}As_x$ system, where the lattice mismatch is still greater (7.52%), the excess free energy of mixing is also greater than for the other systems.

Although the relationship between the lattice parameter mismatch and the nonideality of a system is not known in detail, and probably cannot be simply described in terms of elastic strain, it was predicted that a vanishing mismatch would be accompanied by a vanishing excess free energy of mixing. The assumption that the $Ga_{1-x}Al_xAs$ system was ideal, because of the very good parameter match, had been made by others (5, 6), and this was largely supported by calculation of the Ga-Al interaction parameter from solubility data in the gallium-rich corner of the Ga-Al-As ternary. The liquidus data at low temperatures could be fit quite well using an interaction parameter of zero. The fit was poorer at the highest temperature (1100°C), however.

The present investigation to determine the solidus boundary in the $Ga_{1-x}Al_xAs$ system was undertaken in order to test the hypothesis that this pseudobinary system is ideal, with data obtained in the same manner as for the earlier systems (3).

Experimental

The procedure employed to obtain the solidus boundary has been described by Foster and Scardefield (7). In brief, referring to Fig. 1, a finely ground (to pass 200 mesh) mixture of the two components is pressed into a pellet and held at a constant temperature T within the two-phase region of the pseudobinary diagram for a sufficient time to become equilibrated. It will then consist of solid solution particles whose composition is given by the solidus at T, suspended in a liquid whose composition is given by the liquidus at this temperature. After the equilibrated sample is quenched, the solid solution particles can be readily

Table I. Solidus data in the $Ga_{1-x}Al_xAs$ system

Temp, °C	x_{AlAs}, mole fraction
1273	0.200
1313	0.368
1350	0.480
1435	0.680
1490	0.748
1563	0.835
1602	0.879
1653	0.926

identified visually and are analyzed with an electron microprobe. The entire solidus curve is generated by equilibrating a sufficient number of samples in the two-phase region over the temperature range between the melting points of the pure components.

The method of encapsulating the pressed sample pellets for equilibration at high temperatures is shown in Fig. 1 of Ref. (7). For the present experiments, a pyrolytic boron nitride crucible was preferred over the alumina one shown there because of the greater ease of removal of the sintered pellet after quenching. It was determined that 48 hr at temperature was sufficient for equilibration, as indicated by flat plateaus in the composition *vs.* distance plots of the microprobe data [see Ref. (7)].

For samples of high AlAs content it was necessary to maintain a film of kerosene over the polished surface until just before insertion into the microprobe vacuum in order to prevent reaction with air or moisture.

Results and Discussion

Eight experimental points were determined. The data are given in Table I and plotted in Fig. 1. The samples for the four highest temperature points were equilibrated in a different furnace from that used for the lower four. The displacement of one set relative to the other probably reflects a small error in temperature measurement in one of the furnaces and is not considered significant. The melting point of GaAs (1240°C) was taken from Lichter and Sommelet (8). The melting point of AlAs (1770°C) was determined in this laboratory by R. J. Chicotka.

The continuous curves of Fig. 1 are the ideal liquidus and solidus boundaries calculated from [1] and [2] below (Eq. 13 and 14, Ref. 3).

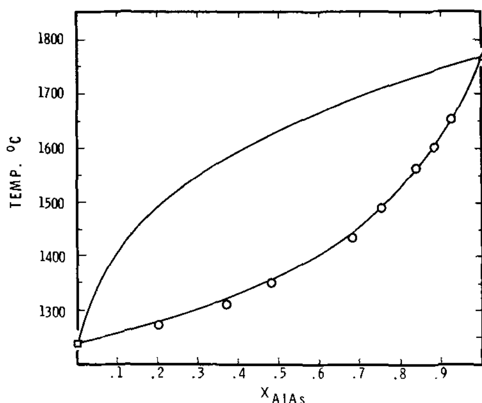

Fig. 1. GaAs-AlAs pseudobinary system. ○ This work; □ Ref. (8); △ R. J. Chicotka, personal communication. ——— Ideal boundaries calculated from [1] and [2] (see text).

$$x_{id}^{l} = \{1 - \exp[-L_1(T - T_1)/RTT_1]\}/\{\exp[-L_2(T - T_2)/RTT_2] - \exp[-L_1(T - T_1)/RTT_1]\} \quad [1]$$

$$x_{id}^{s} = \{1 - \exp[L_1(T - T_1)/RTT_1]\}/\{\exp[L_2(T - T_2)/RTT_2] - \exp[L_1(T - T_1)/RTT_1]\} \quad [2]$$

where the heat of fusion of GaAs, L_1, is taken to be 25.18 kcal/mole, as measured by Lichter and Sommelet (8). There are no experimental heat of fusion data for AlAs. The ideal curves were calculated with the entropy of fusion of AlAs assumed equal to that of GaAs; *i.e.*, $S_f = L_1/T_1 = 16.64$ eu, and $L_2 = 16.64 \times 2043 = 34.0$ kcal/mole. This, of course, is very approximate; however, plots with the entropy of fusion of AlAs taken 0.5 eu higher or lower were essentially indistinguishable from those of Fig. 1. x_{id}^{l} and x_{id}^{s} in [1] and [2] are the mole fractions of AlAs in the liquid and solid, respectively. T_1 and T_2 are the melting temperatures of pure GaAs and AlAs.

It appears from Fig. 1 that the solidus in this system is very nearly ideal. This cannot be established unequivocally in the absence of data for the liquidus, since deviations from Raoult's law in the liquid would affect the solidus curve as well as the liquidus curve. [The liquidus data that are available (5, 6) are not at sufficiently high temperature for extrapolation onto the GaAs-AlAs tie line to give the liquidus in the pseudobinary.] According to our calculations, however, in order for such deviations to shift the solidus for a nonideal solid to the position calculated for an ideal solid, the liquid would have to be even less ideal than the solid. In the four systems studied previously (3, 4) the liquids were all more ideal than the solids. If this character is assumed for the $Ga_{1-x}Al_xAs$ system, it can be concluded that both liquid and solid phases in this system are ideal. This strengthens the hypothesis (3) that, in a III-V semiconductor alloy, departure from Raoult's law of mixing is closely associated with the degree of lattice mismatch between the two components of the alloy.

Acknowledgment

The authors wish to thank R. J. Chicotka for supplying the AlAs and J. D. Kupsis for performing the electron microprobe analyses.

The Effect of Mask Edges on Dopant Diffusion into Semiconductors

C. F. Gibbon, E. I. Povilonis, and D. R. Ketchow

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

A series of masked diffusions of Sn into GaAs and B into Si has been made through masks having stripe openings ranging in width from 20 mils (508 μm) down to 0.1 mils (2.5 μm). For Sn diffusion into GaAs from a pyrolytically deposited, doped SiO_2 source the junction depth depends strongly on mask opening width. It increases with decreasing mask opening size, passes through a maximum as large as 3 times the unmasked value and then decreases slightly at the smallest opening widths. These results are shown to be consistent with the presence of an accelerated diffusion at the mask edge. This "pull-down" of the junction at the mask edge overlaps at narrow mask openings and produces the increase in junction depth. Diffusion of boron through an SiO_2 mask opening also results sporadically in the production of a junction profile which suggests that diffusion is accelerated at the mask edge with an accompanying change in junction depth with mask opening size. It is shown that the effect appears in a variety of diffusion source systems. Three possible mechanisms by which mask edges could affect diffusion of dopants into semiconductor substrates are described. Some tentative explanations of the observed effects have been made on the basis of these mechanisms.

Although diffusion into semiconductors is often studied on unmasked slices, in practice most diffusions for device applications are masked to produce a planar pattern. In carrying out diffusions of Sn into GaAs the authors have observed that the junction depth obtained with a diffusion done through a mask opening is frequently much deeper than that obtained under identical circumstances in an unmasked slice. It is clear, therefore, that diffusions through mask openings are not necessarily identical to diffusions into unmasked slices done under the same conditions. At least three factors could cause enhanced penetration in the case of the masked diffusions; they are strain effects, source film edge effects, and indiffusion of impurities from the mask. These three factors are discussed below.

Strain effects.—In many cases, as for instance when using SiO_2 masks on Si, the mask has a significantly different coefficient of expansion than the substrate. Stresses are then present at the mask/substrate interface at any temperature different from the temperature of formation or deposition of the mask. When a strip of the mask is removed for diffusion, it is conceivable that the elastic strain in the vicinity of the mask edge could be relieved by the generation of a dislocation network along the mask edge. This generation might not occur until later when the slice is heated for diffusion and the yield stress diminished by the increase in temperature. It has been shown (1) that mechanical deformation can accelerate or retard diffusion in silicon depending on the dopant type. Thus one might expect to find some enhancement or retardation of diffusion along the mask edge in a semiconductor substrate due to thermal strain effects.

Source film edge effects.—If the diffusion is done by driving the dopant into the substrate from a finite, predeposited, thin film source, then the effective source film thickness can change considerably near the mask edge. (See Fig. 1; the walls of the mask opening are shown as vertical in this illustration although they are generally at some angle to the surface due to undercutting.) At the mask edge the thickness of the film will increase due to the deposition of the film source on the side walls of the mask opening and also due to filleting of the corner if the source viscosity is low enough that it will flow under the influence of the source film surface tension. This effect will be important only in those cases where the source film is sufficiently thin or the diffusivity of dopant in the film sufficiently high that the finite thickness of the source becomes important in the diffusion kinetics.

In-diffusion from mask.—The mask itself can operate as a source of impurities during diffusion. This is particularly true for diffusions of certain dopants into compound semiconductors such as GaAs where pyrolytically deposited SiO_2 films intentionally doped with phosphorus are used as masks (2). The phosphorus is needed to decrease the diffusivity of dopants in the mask medium but, of course, it could diffuse into the substrate itself. Therefore, along the mask edge the diffusion of the dopant could be altered by the presence of the in-diffusing impurity which has the mask as its source. If the impurity is electrically active it can produce a field which may either retard or accelerate the dopant depending on the relative charge and the difference in size of the diffusion coefficients of the two species (3). If the ions are substitutional and of considerably different size then strain effects might also produce an interaction between them, and an alteration of their diffusion coefficients. Thus again some variation in diffusion properties near the mask edge might be expected.

In this work it is shown that the differences in diffused junction depths between masked and unmasked substrates is related to an apparent dopant diffusion acceleration effect associated with mask edges. Several features of this mask enhanced diffusion effect make it of interest. First as noted below, in the case of boron diffusion into silicon from certain sources it is sporadic,

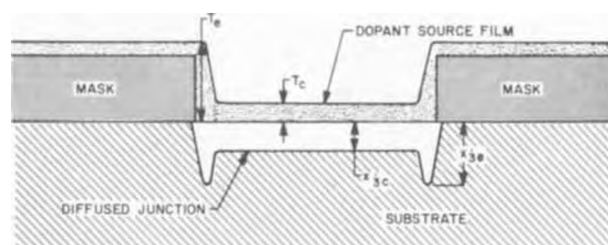

Fig. 1. Hypothetical diagram of diffusion source distribution around a mask opening and resulting junction profile; T_c and T_e are the center and edge thicknesses of the source film; and x_{jc} and x_{je} are the center and edge junction depths.

* Key words: diffusion, silicon, gallium arsenide, masking.

occurring unpredictably for silicon substrates processed with nominally identical procedures in the same or different facilities. It thus represents a possible source of diminished control over diffused elements. Second, the effect gives a variation in the junction depth with mask opening size which makes monitoring diffused layer properties with separate test chips difficult. And third, the mask edge effect, when present, creates a junction profile with a point under the mask edge (see Fig. 1) which could be a source of altered reverse bias breakdown in diodes. [The overlapping effects of the mask edges for small ($\leq$ 10 μm) mask openings produces what appears to be simply a deeper junction than would be produced on an unmasked slice without the edge-associated pull-down.]

Experimental

In order to investigate the existence and magnitude of mask opening effects on diffusion, a mask having openings from 20 mils (508 μm) to 0.1 mil (2.5 μm) wide was made and a series of diffusions was done into slices having this configuration etched into their masks. Diffusions were done with Sn through phosphorus-doped SiO_2 masks into GaAs and with B through thermally grown SiO_2 into Si.

The gallium arsenide substrates into which Sn diffusions were done were p-type boat-grown ingots having a base doping $p = 5 \times 10^{16}/cm^3$. The polished and etched slices were cleaned and phosphorus-doped SiO_2 masks deposited on them. After application of photoresist, exposure through the mask and etching, approximately 3000Å of tin-doped SiO_2 was deposited as a diffusion source from a forming gas stream passed through a solution of ethylorthosilicate plus 2 volume per cent (v/o) tetramethyl tin. The dopant was then driven-in for 1 hr in forming gas at 1050°C. This tin diffusion system has been discussed in detail by Gibbon and Ketchow (4). The specimens were angle lapped, stained, and photographed after diffusion.

The boron diffusions were done into silicon wafers, 8 mils thick, cut from a 10-12 ohm-cm, n-type, phosphorus-doped, <111> oriented silicon ingots, 0.850 in. in diameter. Three of these were float zone ingots and one Czochralski. These wafers had one side silica-sol polished, and it is into this side that the diffusions were performed.

Both sides of the substrate were either wet or dry oxidized to 10,000Å (the oxide on the back side is retained throughout processing). The dry oxidations were done at 1200°C and the wet oxygen oxidations at 1050°C. A boron diffusion is then performed into the substrate wafer through the mask openings. Diffusion sources utilized included boron nitride, boron tribromide, boron-doped oxide films, and low energy boron ion implantations.

Several different BN source systems were used, but in each case a 10-20 min predeposition in an inert gas ambient at 870°-900°C was followed by a 60-70 min drive-in in 10% O_2 in N_2 at 1135°-1150°C. (These parameters were constant for each system, the ranges refer to all systems utilized.) The BBr_3 source diffusion included a predeposition in 0.2% O_2 in N_2 at 875° or 1140°C and a drive-in in 10% O_2 in N_2 at 1135°-1140°C. A control wafer, without any oxide mask, was usually diffused simultaneously with the oxide-masked substrate wafer. The sheet resistance of the diffused layer on the control wafer was measured with a 4-point-probe. Both the control wafer and the substrate wafer were angle-lapped, stained, and the junction depths of the diffusion measured and photographed with an interferometer. In studying the photomicrographs of the angle laps one should keep in mind that the diffused region is distorted by the magnification of distances perpendicular to the surface by a factor of 20 over those parallel to the surface. Surface concentrations were determined from sheet resistance and junction depth data using Irvin's curves (5).

Tin Diffusion into GaAs

Results

Figures 2 and 3 show the junction depths obtained after diffusion of Sn in GaAs as a function of mask opening size. The data are given for two different mask thicknesses: 1600 and 4800Å. The junction depth in an unmasked slice given the same treatment was 0.9 μm. The diffusion depth starts near this value for the center of the widest mask opening and increases with decreasing mask opening. It reaches a maximum of nearly three times the unmasked depth in the neighborhood of 20-50 μm mask opening width. It then decreases slightly. The thickness of the mask seems to have little effect. Near the edge of the phosphorus-doped SiO_2 mask the junction depths are deeper than at the center when the mask opening is larger than 50 μm. This mask edge "pull-down" effect is clearly visible in Fig. 4, which shows photomicrographs of four diffused stripes of various widths in a specimen with a 1600Å phosphorus-doped SiO_2 mask. The junction outline is given a peculiar dished out appearance by this mask edge effect. It can be seen that the apparent increase in center junction depth with decreasing opening width is due to the overlapping of the two-edge effects.

Discussion

The first of the mechanisms postulated in the beginning of this paper by which diffusion might be altered by the presence of the mask edge is the presence of a deformed region due to the difference in the thermal expansion coefficient of the oxide and GaAs substrate.

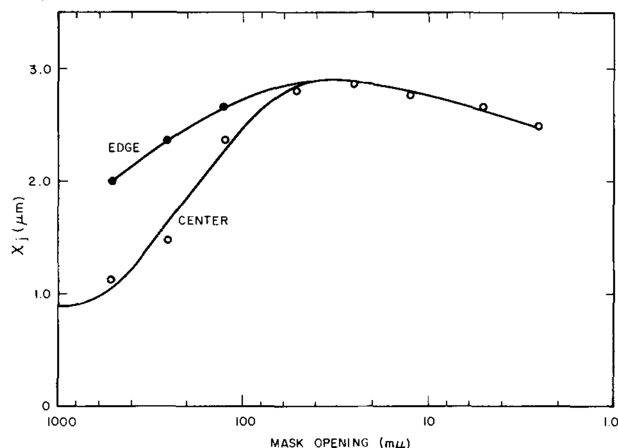

Fig. 2. The junction depth as a function of mask opening size for tin diffusion into GaAs with a 1600Å P-doped SiO_2 mask. Measurements from both the center and near the mask edge are shown.

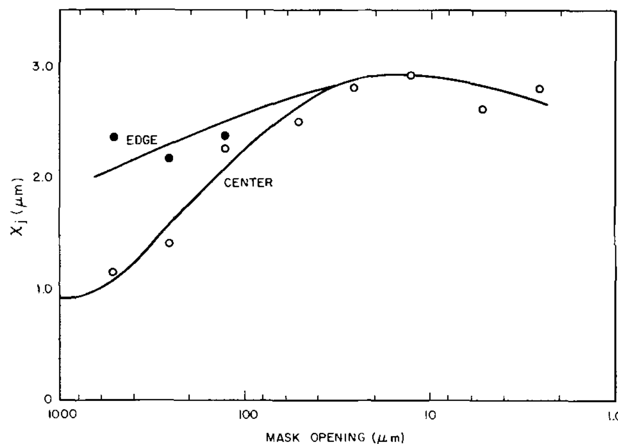

Fig. 3. The junction depth as a function of mask opening size for a 4800Å mask.

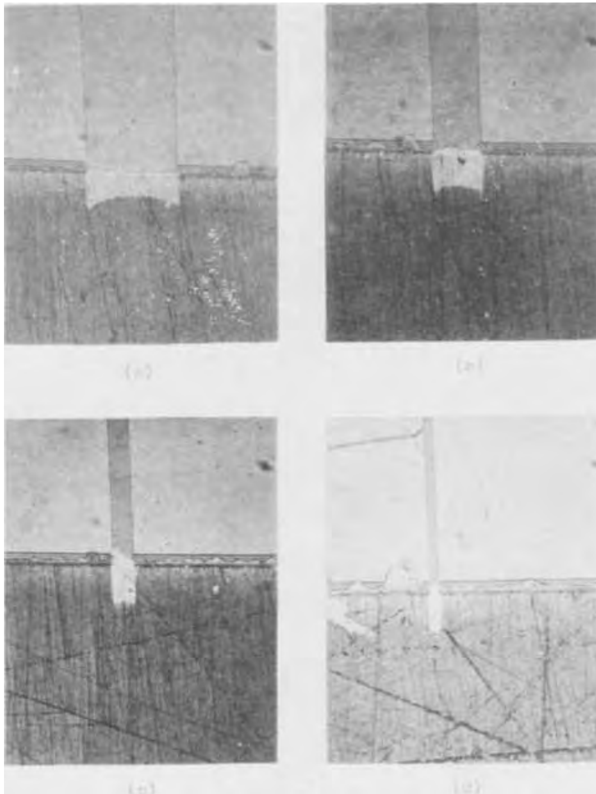

Fig. 4. Photomicrographs of angle-lapped slices of GaAs showing pull-down of diffusion near the phosphorus-doped SiO_2 mask edge; mask opening width (a) 10 mils, (b) 5 mils, (c) 1 mil, and (d) 0.5 mils.

The thermal expansion coefficient of the phosphorus-doped SiO_2 mask is not known; however, the expansivity of pure SiO_2 is low, about $6 \times 10^{-7}/°C$, while that of GaAs is nearly $60 \times 10^{-7}/°C$. The general tendency is for a marked increase, up to an order of magnitude, in the thermal coefficient of expansion of silicate glasses as other compounds are added to SiO_2. For instance, borosilicate glasses have an expansivity around $40 \times 10^{-7}/°C$. Thus the expansion coefficient of the mask is probably, but not certainly, less than GaAs, and interface stresses may develop when the masked substrate is heated above the deposition temperature. This stress could conceivably alter the diffusivity of the tin in the substrate and produce the observed pull-down at the mask edge.

The second effect postulated was variations in the source film thickness due to the presence of the mask walls (see Fig. 1). The possible extent of this effect can be estimated from Eq. [A4], which is developed in the Appendix, that is

$$R^2 = \left(\frac{x_{je}}{x_{jc}}\right)^2 = \frac{4Dt}{(x_{jc})^2} \ln \frac{T_e}{T_c} + 1 \qquad \text{[A-4]}$$

In this case x_{jc} for a wide mask opening is about 1.0×10^{-4} cm, D is approximately 5×10^{-13} cm²/sec (4), t is 3.6×10^3 sec and it seems reasonable to assume that the largest difference one could postulate between T_e and T_c is about the thickness of the mask, so T_c is 3×10^{-5} cm and T_e is about 8×10^{-5} cm. If these values are used to find R from Eq. [A4], one finds

$$R = 1.2$$

This is less than the value of 2.0-2.5 which can be seen from Fig. 2 and 3 to hold for R at large mask openings. The difference of about 0.2 μm between center and edge junction depth predicted is one-fifth the observed difference of 1.0-1.5 μm. Thus source thickness variations appear unlikely to be the major source of the mask edge junction pull-down.

The third possibility for the origin of this effect is the coupling of the Sn diffusion flux to a flux of some impurity which diffuses in from the mask. In these experiments, the mask is doped with phosphorus, and thus it is possible that there is some in-diffusion of P. Very little is published on the subject of phosphorus diffusion in GaAs, but it is known from the work of Stone (6) that a surface concentration of P around $10^{20}/cm^3$ can be produced from 1 atm of phosphorus pressure at 1000°C. Stone estimates the diffusion coefficient of phosphorus in GaAs to be 10^{-12} to 10^{-13} cm²/sec at 700°-800°C. Thus phosphorus may be present in the GaAs under the mask at 1050°C, the drive-in temperature utilized in the present work. The mechanism by which the phosphorus might couple with the tin diffusion to accelerate it is not clear. The phosphorus probably substitutes isoelectronically for arsenic on the arsenic sublattice, and thus it appears that the electronic effects would be small. Phosphorus with a tetrahedral covalent radius of 1.10Å (7) is smaller than the arsenic it replaces which has a corresponding value of 1.18Å. Since the covalent radius of Sn is larger than Ga, 1.40Å as compared to 1.26Å, if tin diffuses substitutionally it could be accelerated by a gradient in strain energy since the strain field associated with it would be opposite in sign to that associated with the phosphorus impurity.

In summary the junction depth variation with mask opening size is a result of junction pull-down along the mask edge. It appears that this acceleration of diffusion at the mask edge is due either to strain effects related to differences in the thermal coefficient of expansion of the substrate (GaAs) and the mask (P-doped SiO_2), or to in-diffusion of phosphorus. A more definitive understanding of this effect will require further investigation.

Boron Diffusion into Silicon

Results

Figure 5 shows the variation in junction depth with mask opening size for a silicon slice diffused with the BN system (note the suppressed zero in this figure). Assuming the diffusion to be approximately Gaussian, calculation of the surface concentration from the sheet resistance and junction depth of an unmasked test slice gives $C_s = 3 \times 10^{19}/cm^3$.

Here, as in the case of Sn diffusion into GaAs, the junction depth varies with mask opening size and this effect is seen in the inset angle lap photographs in Fig. 5 to be associated with a junction pull-down at the mask edge. The enhancement in junction depth

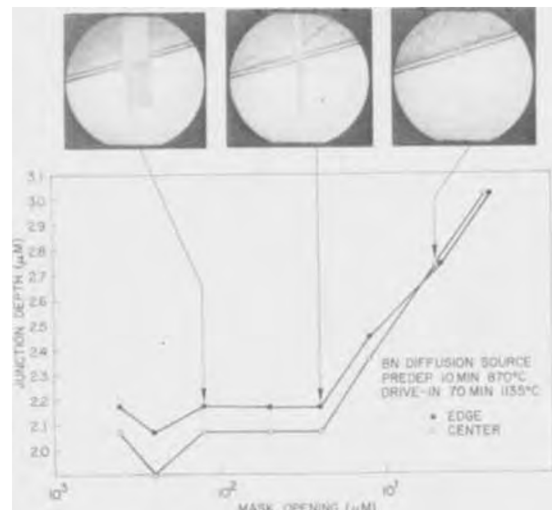

Fig. 5. Typical enhancement in junction depth vs. mask opening size for boron diffused into silicon using a source layer predeposited from oxidized BN disks.

for the smallest mask opening size is considerably greater than the individual enhancement along either edge which suggests that the effect combines super-linearly when the mask edges come in close proximity. It might be suggested that the general increase in junction depth is due to a nonuniform diffusion across the slice, however no such effect was seen on accompanying unmasked test slices, and it recurred in the same way on a number of identical masked slices.

It should be noted though that silicon slices were diffused which had none of the mask edge effect or junction depth dependence on mask opening size seen here. The occurrence, or nonoccurrence, was always uniform across a slice: the slice either showed the mask-edge pull-down or it did not. Identical slices were diffused in similar BN source systems by different operators with similar results: very roughly half the time the mask edge acceleration was seen in four different systems.

A number of variables were examined in detail to try to locate the origin of the sporadic appearance of the mask-edge effect. These included the orientation of the mask opening channels on the (111) slice surface, and the growth ambient and temperature of oxidation of the mask oxide. These variables were selected because it was felt they might influence the strain distribution around the mask edge. None of these variables detectably influenced occurrence of the mask-edge effect.

Another variable examined was the ingot source of the substrate. The slices utilized in this work were cut from four nominally identical ingots. Most of the experiments (86 slices) were carried out on slices from two ingots, one float zone and one Czochralski, in which the mask-edge effect occurred; in the other two (float-zone ingots from which 17 wafers were processed) no mask-edge pull-down was observed. Thus the occurrence of the effect may be contingent on the value of some property in the substrate; however, it was not possible to determine what this feature was. There was no clear relationship, for instance, between ingot growth type and the presence of the enhanced mask-edge diffusion.

For a single system, slices were diffused with a series of predeposition times in order to vary the final surface concentration. Table I lists the results of this experiment. The mask-edge acceleration appears to occur more frequently at higher concentrations. The sporadic nature of the mask-edge effect thus appears to be related to variations in the surface concentration between individual diffusions and to some differences in substrate properties. Although the list of variables examined seems reasonably exhaustive, other undefined variations from slice to slice may influence the appearance of this effect.

The effect appeared much less frequently and with a much smaller influence on junction depth in the case of diffusions from a source glass deposited from BBr_3. Figure 6 shows a typical case where some mask-edge effect was apparent. In this system, the mask-edge effect did not appear uniformly across the slice, also other irregularities away from the mask edge occasionally appeared. Table II lists results of a series of diffusions done with different conditions to produce different surface concentrations. There is in this case little evidence of dependence on surface concentration.

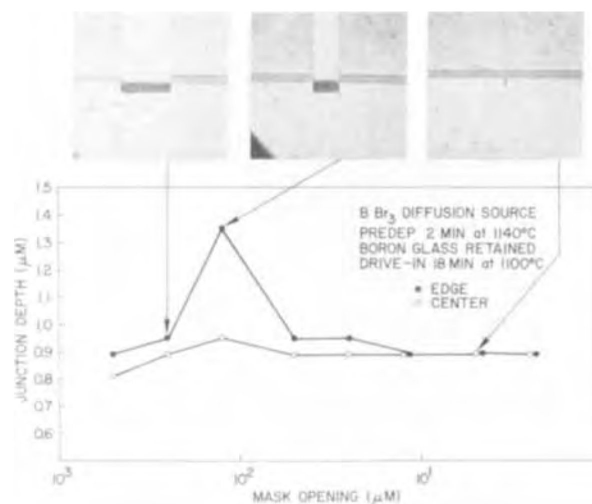

Fig. 6. Junction depth vs. mask opening size for diffusion source predeposited from BBr_3.

Several other sources of boron were used for boron diffusion in this study. Diffusions from these sources also show the mask-edge acceleration effect. It was called to the authors' attention that an apparent mask-edge acceleration of diffusion is occasionally observed in integrated circuits in which a p-layer is diffused from a boron ion-implantation (8). In an effort to independently reproduce this effect, $5 \times 10^{12}/cm^2$ and $5 \times 10^{13}/cm^2$ implantations of boron were made at room temperature at 30 keV. The boron was then diffused in a 10% O_2 in N_2 ambient for 1 hr and 5 hr at 1150°C. Evidence of mask-edge acceleration could be detected in the 5 hr but not the 1 hr diffusions (see Fig. 7). The fact that such an effect is observed in these diffusions strongly suggests that filleting of a chemical source film is not the origin of the mask-edge effect.

Another experiment performed which indicated that the influence of mask-edge filleting is not the source of mask-edge acceleration was the diffusion of boron from channels of boron-doped SiO_2 pyrolytically deposited from silane, diborane, and oxygen at 350°C. No oxide mask, as such, is present in this case. Boron-doped SiO_2 was deposited uniformly over the slice and then all of it was removed except for stripes which were parallel bars forming a pattern just the negative of the mask pattern previously used. The slice was driven-in in N_2 at 1100°C. As seen in Fig. 8 a channel edge acceleration appeared among these slices. (Some lateral diffusion along the unprotected surface also occurred.) Again, this result points away from source

accumulation at the mask edge as the origin of the apparent acceleration.

In summary, this study reveals the presence of a sporadic mask-edge diffusion phenomenon for boron diffusion into silicon. It does not depend on the type or thickness of the masking silica film used nor does it appear to be related to the facility in which the oxide film is formed. No consistent pattern has occurred regarding the mask-edge effect with any of the variations of the many parameters of predeposition and drive-in of the boron impurity which were studied, although there is some suggestion that the pull-down occurs more frequently for higher surface concentrations in the BN system. The possibility of a dependence on silicon ingot source from which the various substrate wafers were cut was found. No influence of the orientation of the channel patterns on the slice surfaces was discerned.

Discussion

The mask-edge effect as has just been seen has a very elusive origin. Its presence in slices diffused from ion implanted sources and B-doped SiO_2 channels eliminates source filleting as a primary cause of it. As noted before some diffusion masks used on compound semiconductors are heavily doped to decrease the permeability of the mask material to the dopant and this may influence in-diffusion near the mask edge. However, the diffusion masks used on silicon are thermally grown SiO_2 which is generally very lightly doped (by accumulation of base doping from the substrate), and, therefore, the influence of impurities in-diffusing from the mask seems unlikely to have a strong influence on subsequent diffusion through openings made in the mask. (The fact that oxidation conditions do not have a critical influence on the appearance of the mask-edge effect supports this conclusion.)

Thus the presence of strain at the mask edge, due to the thermal expansivity mismatch seems the most prominent potential cause of the mask-edge effect. It should be pointed out, however, that x-ray topography has failed to reveal dislocations associated with mask edges in any of the boron diffused slices studied (9). (Dislocations have been observed to be generated at a mask edge (10); however, this appears to be associated with diffusions in which the surface is nearly saturated with the dopant, a condition not generally fulfilled in the present work.) This indicates that any strain effects which are active must be related to elastic strain fields with no influence of plastic deformation. This is a rather surprising observation since mechanical strain effects on diffusion in silicon are generally associated with the generation of dislocations (1). The random appearance of the pull-down strongly suggests that the conjunction of several factors may be required to precipitate its occurrence. The magnitude of the strain field surrounding the mask edge could be a very sensitive function of a number of factors (oxidation temperature, orientation, oxidation ambient, diffusion ambient, and substrate preparation); thus a strain field of appropriate sign and magnitude may be present only in a limited number of cases even where the procedure is nominally the same.

Elastic strain effects if present at the mask edge can influence diffusion in two ways. First there can be the direct influence of the strain field on the diffusion flux itself (11). Second the strain field can alter the equilibrium concentration of point defects and thus potentially influence the diffusion coefficient. Other somewhat more subtle effects of the presence of the mask may be the source of the diffusion acceleration, however. Perhaps, for instance, the transient flow of vacancies of the slice during cooling of the slice from the diffusion furnace may be influential.

Summary and Conclusions

1. An effect of mask opening size on diffusion into semiconductor substrates could arise from a number of sources: (*i*) strain effects at the mask edge; (*ii*) source film filleting at the mask edge; and (*iii*) in-diffusion of impurities from the mask.

2. It has been found that, in the diffusion of GaAs with Sn from Sn-doped SiO_2 through openings in P-doped SiO_2 masks, the junction depth depends strongly on the mask opening size. Examination of the photomicrographs of angle laps of the junctions suggests that the observed variation was due to a diffusion acceleration associated with the mask edge. An approximate calculation shows that this pull-down is probably not due to the presence of a thicker source film along the mask edge. Thus enhancement in the diffusion flux at the mask edge due either to mask-edge strain effects or to the simultaneous in-diffusion of phosphorus from the mask appears to be the origin of the effect.

3. In diffusions of boron into silicon the apparent mask edge associated diffusion acceleration is not associated exclusively with any particular diffusion source system; it appears sporadically in all systems examined including BN, BBr_3, B-doped predeposited SiO_2 channels, and ion-implanted sources.

4. The effect appears in diffusion systems where mask-edge source filleting could not be its origin. Thus mask-edge strain is indicated as a likely source of the apparent diffusion acceleration.

5. Since no dislocations can be associated with the mask edges in x-ray topographic studies of these slices it appears that the effect might be related to elastic strain. However exact delineation of the mechanism of enhanced diffusion will require further study.

Acknowledgments

J. V. Dalton, T. E. Saunders, P. N. Pappas, and K. R. Gardener each prepared several diffused slices for us. The ion-implanted diffusion sources were produced for us under the supervision of R. A. Moline. G. R. Weber deposited the B-doped oxide films.

We are grateful to G. A. Rozgonyi who took and interpreted several x-ray topographs for us.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX

The only case considered is that where the diffusion is sufficiently long that the source film has begun to deplete. In that case we will approximate the source film as an instantaneous source having a surface concentration of C_oT(atoms/cm^2) where C_o is the dopant concentration in the source film and T its thickness. For an instantaneous source

$$C = \frac{Q}{\sqrt{\pi Dt}} e^{-\frac{x^2}{4Dt}} \quad [A-1]$$

where C is the concentration at position x and time t. Q is the source surface concentration and D is the dopant diffusion coefficient. Then, if Q is associated with C_oT, the junction depth, x_j, is related to T by

$$\ln\left(\frac{C_s\sqrt{\pi Dt}}{C_o}\right) = \ln T - \frac{(x_j)^2}{4Dt} \quad [A-2]$$

where C_s is the concentration of dopant in the substrate. If the film thickness at the mask edge is T_e, and at the mask center is T_c, then the junction depth at the edge (x_{je}) and center (x_{jc}) should be related by

$$(x_{je})^2 - (x_{jc})^2 = 4Dt \ln \frac{T_e}{T_c} \quad [A-3]$$

or, dividing by $(x_{jc})^2$

$$(R)^2 - 1 = \frac{4Dt}{(x_{jc})^2} \ln \frac{T_e}{T_c} \quad [A-4]$$

where R is the ratio between the junction depth at the edge and the center. Since

$$(x_{jc})^2 = 4Dt \ln \frac{C_oT_c}{C_s\sqrt{\pi Dt}} \quad [A-5]$$

we have

$$(R)^2 - 1 = \frac{1}{\ln (C_oT_c/C_s\sqrt{\pi Dt})} \ln \frac{T_e}{T_c} \quad [A-6]$$

Thus the center to edge ratio should increase with increasing background doping in the substrate, diffusion coefficient, and time. It should decrease with increasing doping concentration in the source film and increasing source film thickness.

Silicon Cleaning with Hydrogen Peroxide Solutions: A High Energy Electron Diffraction and Auger Electron Spectroscopy Study

R. C. Henderson*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

HEED and Auger electron spectroscopy have been used to evaluate silicon cleaning by sequential immersions in basic and acidic peroxide solutions. It was determined that an oxide film 13-15Å thick was left after the cleaning. This film contained boron at a surface concentration estimated at 10^{13}-10^{14} B/cm^2. The carbide contamination that results upon heating to 800°C in ultrahigh vacuum was dramatically reduced when compared to wafers cleaned with other techniques. Wafers cleaned with the same process except for a final HF etch had no detectable boron in the surface oxide, formed relatively large amounts of surface silicon carbide at 800°C, and suffered extensive surface roughening with 1100°C heating in vacuum. The protective mechanism of the peroxide cleaning is thought to be due to formation of a thin nearly carbon free oxide layer that volatilizes when the wafers are heated in ultrahigh vacuum. It is recommended that experiments requiring a solvent type cleaning and the heating of Si in ultrahigh vacuum should use this cleaning method.

When a silicon wafer is heated to 800°C in ultrahigh vacuum, the silicon decomposes carbon-containing adsorbates to form β-SiC particle protuberances (1-2). These particles can play a significant role as evident by their effect on silicon epitaxy experiments (3, 4). A thorough chemical precleaning is desirable since it is thought that this step is the dominating source of the carbon contamination (2).

A recent study has appeared evaluating the use of basic and acidic peroxide solutions in sequential steps

* Electrochemical Society Active Member.

Key words: silicon cleaning, Auger electron spectroscopy, HEED.

for silicon cleaning (5). The work to be reported here presents the results of high-energy electron diffraction (HEED) and Auger electron spectroscopy experiments on wafers cleaned by this method and heated in ultrahigh vacuum. Particular emphasis in this study has been placed on the desirability of HF as a final processing step. This emphasis was motivated by results indicating HF (*i*) enhances the carbon contamination (6), (*ii*) is a source of metal contamination (5), and (*iii*) is associated with the creation of stacking faults on (100) surfaces following oxidation (7).

The wafers used in these experiments were "Syton" polished (111) samples. The HEED optics and vacuum apparatus have been described previously (2). The Auger electron spectra were obtained using a coaxial cylindrical analyzer manufactured by the PHI Electronics Company. The detailed wafer processing, referred to here as peroxide cleaning, is presented in the Appendix. After loading, pump-down, and bakeout wafers were subjected to various heat-treatments in pressures not greater than 1×10^{-9} Torr. HEED diffraction patterns and Auger electron spectra were recorded after the samples had cooled to room temperature.

Some samples were examined by ellipsometry before being loaded in the vacuum station. In all cases the surface film found after cleaning was 13-15Å thick. A 1 min etch in concentrated HF reduced this thickness to 8-9Å.

Auger electron spectra obtained from a boron-doped wafer ($10^{15}/cm^3$) cleaned with the peroxide method and before any heat-treatment are presented in Fig. 1. In addition to the carbon, SiO, and O peaks, there is a peak at 180 eV. According to tabulated values this peak could be due to the chlorine $L_3M_{23}M_{23}$ or the boron KL_2L_2 Auger transitions (8). No peaks were observed in the region 2200-2400 eV where the KLL chlorine peaks would be expected. Accordingly, the 180 eV peak is ascribed to boron. (From the peak size one would estimate the surface concentration to be 10^{13}-$10^{14}/cm^2$.)

Figure 2 shows the data obtained from the same wafer described above after heating at 500°C for 10^3 sec, heating at 900°C for 10^3 sec, and then rapid cooling to room temperature. No significant data changes were observed after the 500°C heat-treatment. However, it is evident that after the 900°C treatment the peaks due to Si have changed dramatically in a manner described before (8) and that the O and B have been reduced to values below their detection limits (which is expected to be 10^{12}-$10^{13}/cm^2$). A small quantity of carbon remains. Confirming these observations, it is easy to calculate from SiO vapor pressure data (9) and the density of SiO_2 that at 900°C in vacuum the observed 15Å of oxide would have evaporated in less than 10^3 sec.

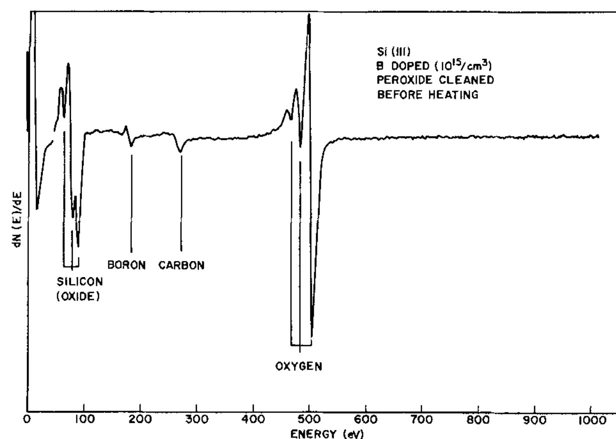

Fig. 1. Auger electron spectra from a wafer cleaned as detailed in Appendix and before any heat-treatment of the sample.

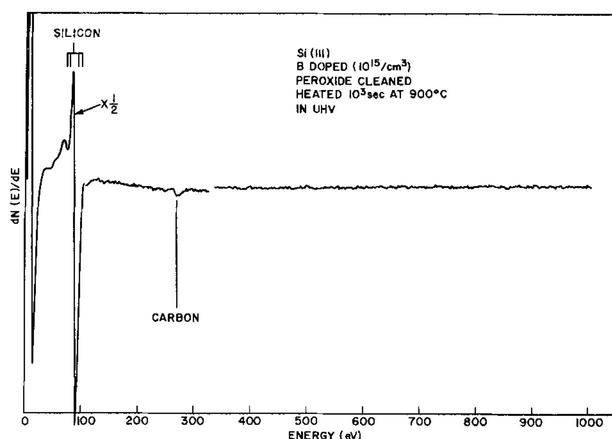

Fig. 2. Auger electron spectra from the wafer in Fig. 1, but after heating at 500°C for 10^3 sec, heating at 900°C for 10^3 sec and then cooling to room temperature.

The HEED diffraction pattern obtained from the same wafer after heating to 900°C is shown in Fig. 3A. The notable feature here is the extremely weak diffraction spots due to β-SiC. (The small streaks distributed on semicircular arcs are the Si(111)-7 surface structure described previously) (2). By way of contrast, note the plentiful amount of carbide evident in the pattern in Fig. 3B. The sample had been treated

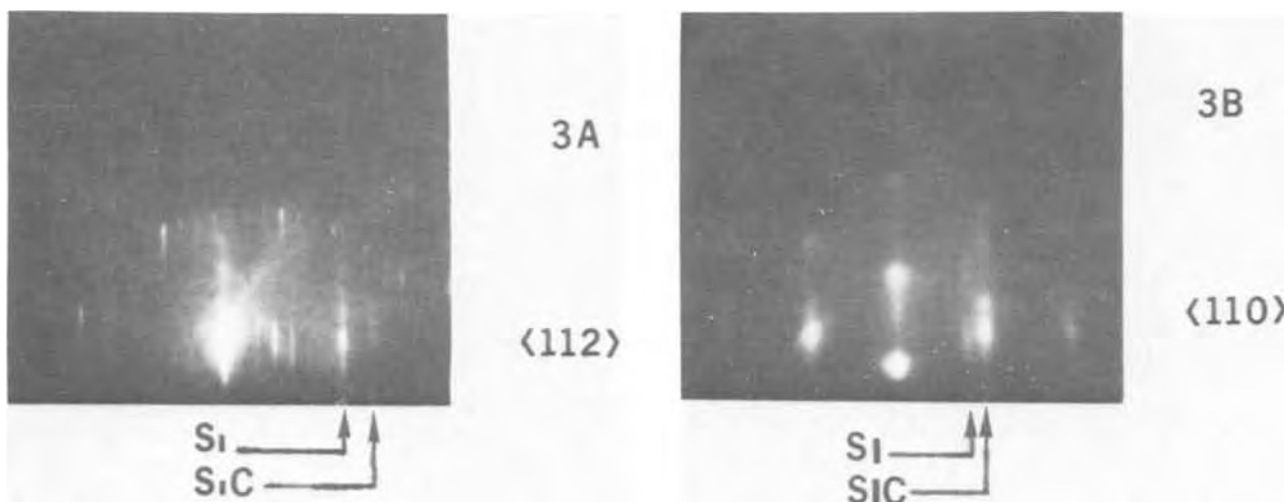

Fig. 3. A. HEED diffraction pattern from the wafer described in Fig. 2. B. HEED diffraction pattern from a wafer cleaned and heated as in Fig. 2 except for a final HF etch.

in the same manner as that of Fig. 3A, except that after the peroxide cleaning the wafer was dipped for 1 min in concentrated HF.

The experiments described above were repeated with phosphorus-doped ($\sim 10^{16}/cm^3$) and antimony-doped ($\sim 10^{15}/cm^3$) wafers. The results were identical.

In all these experiments there was no observable difference in the HEED or Auger data if the final wafer heating was in the range 900°-1100°C. Lower temperatures, however, did not rid the surface of oxide within the 10^3 sec. Higher temperatures ($\gtrsim$ 1150°C) leave no observable carbide (2).

To confirm that the 180 eV peak was indeed boron, a peroxide cleaned wafer was heated to 1100°C for 1×10^3 sec. Subsequently, the surface concentration was obtained by a capacitance inverse doping technique (10). The data showed 3×10^{17} B atoms/cm^3 within 0.1μ of the surface. This number is to be expected based on the diffusion solution from a thin film source using the diffusion constant of boron at 1000°C (4×10^{-13} cm^2/sec) and a surface concentration of 1×10^{13} B atoms/cm^2. The excellent agreement supports the conclusion of boron contamination.

The boron concentration was the one particular uncontrolled variable noted with this cleaning technique. With some wafers no boron was detected at all. On the other hand, consistency was observed for a given batch of samples, all cleaned at the same time although of varying dopant types or crystal faces. This fact implies that the contamination arises from the Pyrex glassware utilized or possibly the cleaning solutions themselves.

Wafers given a final HF etch after being peroxide cleaned differed in several respects from the data presented above. In the first place, no boron Auger peak was detected with these samples. Secondly, as evident from Fig. 3B, significantly greater amounts of carbide were formed when the wafer was heated. Finally, HF-etched wafers unaccountably often exhibit a matte-type finish due to surface roughening after being heated to ~1100°C. For the most part, this effect does not occur with the peroxide cleaned wafers.

These latter results confirm earlier HEED experiments that demonstrate HF enhanced carbon contamination (6). In the early work wafers were cleaned by heating to 1200°C in vacuum until the surface was carbide free (presumably by solid-state diffusion of the carbon). A comparison was made between those wafers that were subsequently exposed to atmosphere and etched in HF and those that were just exposed to atmosphere. After heating to 800°C in vacuum the resulting diffraction patterns were quite similar to Fig. 3B and 3A, respectively.

Another comparison may be made to wafers cleaned by vapor etching in HCl gas at a substrate temperature of 1100°C until 10 μm of Si has been removed. After loading the wafer into the vacuum station no carbon is detectable with the Auger electron spectrometer and only a faint trace of carbide is detectable with HEED after heating to 900°C (11). This latter technique is the most successful approach observed to date with respect to carbon. However, as a method the elevated temperature and the relatively large amount of Si removal required for successful cleaning, limit its applicability.

It is thought that the peroxide cleaning process produces a relatively small amount of carbide contamination by the following mechanism: After processing the 15Å of film remaining is silicon oxide that is relatively free of carbon-containing compounds. The oxide acts as a passivating and protective layer with respect to carbon adsorbates. At 900°C the oxide becomes relatively volatile. Since the majority of the adsorbates are physisorbed to the oxide, they are carried away during the sublimation process when the wafer is heated.

In contrast the surface that emerges from HF etch is particularly reactive. In addition to oxygen, the surface will also take up carbon compounds either from the HF directly or from the atmosphere. The resulting oxide film has relatively large amounts of carbon in contact with native silicon. When heated, the silicon attacks these compounds and yields copious amounts of SiC. Moreover, it is seen that carbon codeposited within this oxide phase is the major source of contamination rather than from the background gases of the vacuum station as had been previously supposed (1).

Previous HEED experiments have examined wafers cleaned by iodine passivation (12) or other etchants. Judging the amount of carbide from the intensity of the SiC diffraction spots, these experiments all show that the peroxide method is the most successful solvent type precleaning approach observed to date with respect to carbon. On the other hand, based on the discussion above, any method that would leave ~15Å of carbon-free oxide should serve equally as well.

Preferential local thermal etching is thought to be the mechanism that causes the surface roughening with high-temperature vacuum heating. The results obtained above suggest that this roughening is associated with the amount of silicon carbide contamination.

The boron incorporation is not surprising due to the known strong affinity of boron for the oxide phase (13). As noted above, this surface boron acts as a thin film diffusion source when these wafers are heated, and the Pyrex cleaning glassware is suspected to be the boron source. Although the boron can be eliminated by HF etching, this has undesirable effects with regard to carbon or metallic contamination. Consequently, it is recommended that the peroxide method described here be used, but modified by using quartz ware for the cleaning solutions.

It is also evident that the peroxide method does not completely eliminate the carbide resulting from heating the wafers. Moreover, vacuum ambient exposures of 10^{-4} Torr · sec are sufficient that heat-treated "clean" silicon surfaces became carbon contaminated (2). Hence, some sort of *in situ* cleaning (*e.g.*, argon sputtering) is desirable to obtain a rigorously clean surface or to rejuvenate one that has been treated in vacuum. In any case, since it is difficult to get rid of the carbide, the relatively small amount formed with the peroxide cleaning is advantageous.

A summary of the HEED and Auger electron spectroscopy results regarding the peroxide process are:

1. An oxide film 15Å thick is left after the cleaning. This film can contain appreciable amounts of boron presumably due to the use of Pyrex glassware.
2. Wafers heated in vacuum after this processing are considerably reduced in the carbide contamination when compared to other cleaning methods.
3. Etching with HF as a final processing step enhances the carbon contamination.
4. Surface roughening that occurs with 1100°C vacuum heating is largely reduced.
5. The protective mechanism of the cleaning process is thought to be due to the formation of a thin carbon-free oxide layer that volatilizes when the wafers are heated in ultrahigh vacuum.

In light of the desirability of reducing the carbide contamination, the peroxide cleaning method is recommended for experiments that require heating of Si in vacuum and where the high temperature and large amount of surface removal by the HCl vapor etching method cannot be tolerated. Etching with HF as a final step should be avoided. Quartz ware for containing the cleaning solutions should be used to avoid the boron contamination. Although these recommendations are particularly directed to Si vacuum experiments the information contained in this report should be useful for IC processing as well.

Acknowledgments

The author wishes to thank Rohe Helm who assisted in setting up the Auger electron spectrometer and obtaining some of the data. Thanks are also due to R. Kaiser who obtained the ellipsometry data and M. Hanes who obtained the doping profile. Miss B. Kerns provided the detailed peroxide cleaning specifications.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX

Peroxide Cleaning Specifications

1. Scrub polished wafer with acetone and then with 0.2% Triton X-100 solution. Rinse with filtered deionized water. Flush wet surface with absolute ethyl alcohol. Keeping slice surfaces wet transfer to a quartz holder in methyl alcohol.
2. Place holder and slices in a solution of NH_4OH-H_2O_2-H_2O maintained at 80°C for 10 min, insuring that the holder is beneath the liquid surface at all times. Agitate during this period. (The solution is to be made up fresh prior to use and is to have the following composition:
   1 part NH_4OH—reagent grade
   1 part H_2O_2—Superoxol, unstabilized
   4 parts H_2O—18 megohm, 0.2 μm filtered
   Mix NH_4OH and H_2O and bring to temperature. Three minutes prior to use add H_2O_2.)
3. Overflow rinse with grade O or better deionized water for 2 min.
4. Rinse in cascade, 30 sec in each compartment. Agitate.
5. Place holder in a suitable container of fresh 49% HF for 2 min with agitation.
6. Rinse as in steps 3 and 4.
7. Place holder in a beaker of freshly prepared 4 to 1 to 1 HCl-H_2O_2-H_2O at 80°C for 10 min. Agitate by hand. (Mix HCl and H_2O and bring to temperature. Three minutes before use add H_2O_2.)
8. Rinse as in steps 3 and 4.
9. Blow dry with filtered N_2.

Thermodynamic Calculations of the Ge-H-Cl System

V. J. Silvestri*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The partial pressures of the gas species $GeCl_4$, $GeCl_2$, $GeHCl_3$, HCl, and H_2 in equilibrium with Ge solid have been calculated in the temperature range 400°-1223°K at chlorine to hydrogen ratios ranging from 10^{-4} to 10. The theoretical efficiency for the deposition of germanium as applied to an open tube epitaxial system is discussed. Comparisons are made to the Si-H-Cl system.

In conjunction with growth rate and surface morphology studies in the $GeCl_4$-H_2 system, thermodynamic calculations giving theoretical maximum Ge deposition rates were made and compared with specific experimental Ge growth rate data (1). The purpose of this report is to separately, but more extensively describe the calculations and to display the pertinent features of the Ge-H-Cl equilibrium in a more general way. Comparable calculations have been reported by Lever (2) for the analogous Si-H-Cl system.

Equilibrium considerations in an open tube vapor growth system are useful (*i*) to determine a maximum yield for the system, (*ii*) for certain mass transport limited systems (3, 1) to predict deposition rates, and (*iii*) as a general guide for optimizing a process.

Assumptions.—The present analysis considered the gas species $GeCl_4$, $GeCl_2$, $GeHCl_3$, HCl, and H_2 in equilibrium with Ge solid.[1] The important assumptions which were made for the calculations were:

1. The above gas species are the pertinent species.
2. All chlorine containing species are confined to the gas phase in equilibrium with solid Ge.
3. It was assumed that all gas species obey ideally Dalton's and the Ideal gas law.
4. Certain assumptions were also made with regard to the constancy of $\Delta H°_T$ and $\Delta S°_T$ for specific equilibria and these shall be cited appropriately below.

Variables.—The phase rule requires that a system having three components (Ge, H, and Cl), and consisting of two phases will have three degrees of freedom. Since these calculations were made specifically with reference to an open tube epitaxial deposition system, practical considerations lead to the following choice of independent variables: (*i*) total pressure, where for these calculations $P_T = 1$ atm, since in most open tube systems this approximation is valid, (*ii*) temperature T, and (*iii*) the chlorine to hydrogen ratio, Cl/H, which is a conserved quantity in the gas phase.

Equilibrium.—For a given temperature the reaction chamber would contain the five gas species in equilib-

* Electrochemical Society Active Member.
Key words: thermodynamics, germanium-hydrogen-chlorine system.

[1] Gas species such as GeH_2Cl_2, GeH_3Cl, GeH_4 and GeCl were not considered in the calculations, since it has been shown by Lever (2) that in the analogous Si-H-Cl system that the corresponding Si species were minor constituents.

rium with Ge solid. Among the five species considered to be present in the system, three independent equilibria may be written with their associated equilibrium constants, K, where P_x is the partial pressure of the species x.

$$Ge(s) + 4HCl(g) = GeCl_4(g) + 2H_2(g) \quad [A\text{-}1]$$

$$K_1 = \frac{(P_{GeCl_4})(P_{H_2})^2}{(P_{HCl})^4} \quad [1]$$

$$Ge(s) + 2HCl(g) = GeCl_2(g) + H_2(g) \quad [A\text{-}2]$$

$$K_2 = \frac{(P_{GeCl_2})(P_{H_2})}{(P_{HCl})^2} \quad [2]$$

$$Ge(s) + 3HCl(g) = GeHCl_3(g) + H_2(g) \quad [A\text{-}3]$$

$$K_3 = \frac{(P_{GeHCl_3})(P_{H_2})}{(P_{HCl})^3} \quad [3]$$

Thermodynamic data.—The calculations made use of the above equations along with the appropriate van't Hoff expressions of the form

$$\log K = -\frac{\Delta H}{2.303\,RT} + \frac{\Delta S}{2.303\,R} \quad (R \text{ is the gas constant})$$

relating the equilibrium constant with temperature T written below

$$\log K_1 = \frac{6730}{T} - 8.02 \quad [1a]$$

$$\log K_2 = \frac{-465}{T} + 1.12 \quad [2a]$$

$$\log K_3 = \frac{7580}{T} - 7.45 \quad [3a]$$

The linear relationship for $\log K_1$ (Eq. [1a]) is the best fit of K_1 values for a number of temperatures in the temperature interval 400°-1100°K. The K_1 values were calculated from room temperature enthalpy and entropy of formation data for Ge(s), H_2(g), HCl(g) (4), and $GeCl_4$(g) (5) corrected for higher temperatures using the tables of Kelley (6).

Sedgwick's (7) equilibrium data, Eq. [4a], for the reaction

$$GeCl_4(g) + Ge(s) = 2GeCl_2(g) \quad [A\text{-}4]$$

$$\log K_4 = \frac{-7660}{T} + 10.25 \quad [4a]$$

was used along with Eq. [1a] to obtain Eq. [2a]. The reported K_4 data for reaction, Eq. [A-4], was extrapolated to include the entire range of the calculations.

Thermodynamic data for $GeHCl_3$ is not known, and the room temperature enthalpy and entropy of formation were estimated by linear interpolation for the series GeH_4, GeH_3Cl, GeH_2Cl_2, $GeHCl_3$, and $GeCl_4$. This procedure is based on the assumption that bond energies are additive in generating the above series. Approximations of this type have been found to be valid in the analogous carbon series, and were used in estimating heats for the Si series (2). Using this method, $\Delta H°_{298}$ for $GeHCl_3$ was estimated at −90 kcal ± 10 kcal from the room temperature enthalpy of $GeCl_4$ and the reported enthalpy of 21.6 kcal for GeH_4 (8). An interpolated room temperature entropy of 75.6 eu was used for $GeHCl_3$, since the linear assumption was found to hold well for the above series for calculated values of GeH_4, $GeHCl_3$, and $GeCl_4$ as reported by Kelley (9). Equation [3a] was obtained assuming that $\Delta H°_{298}$ and $\Delta S°_{298}$ for reaction, [A-3], is constant over the temperature range of the calculations.

Because of the large uncertainty in the thermodynamic constants for $GeHCl_3$ the enthalpy of formation was varied in the calculations using values of −100 and −85 kcal. The effect of these enthalpy value changes on the calculations shall be discussed later. Equation [3a] has been written using a −100 kcal enthalpy value for $GeHCl_3$(g). Dalton's law and Ideal gas law—from Dalton's law we have that the total pressure

$$P_T = P_{GeCl_4} + P_{GeCl_2} + P_{GeHCl_3} + P_H + P_{HCl} = 1 \text{ atm} \quad [5]$$

Conservation of Cl, H, Ge in the system.—The following conservation equations have been written in terms of partial pressures which are convenient to the calculations, since it has been assumed that the partial pressures of each species is related to its molar density in the system by the Ideal gas law $PV = nRT$. The following summations may be written

$$P_{Cl} = 4P_{GeCl_4} + 2P_{GeCl_2} + 3P_{GeHCl_3} + P_{HCl} \quad [6]$$

$$P_H = 2P_{H_2} + P_{GeHCl_3} + P_{HCl} \quad [7]$$

$$P_{Ge} = P_{GeCl_4} + P_{GeCl_2} + P_{GeHCl_3} \quad [8]$$

From Eq. [6-8] we can readily evaluate the various component ratios, such as

$$Cl/H = \frac{P_{Cl}}{P_H},\ \frac{Ge}{Cl} = \frac{P_{Ge}}{P_{Cl}},\ \text{and}\ \frac{Ge}{H} = \frac{P_{Ge}}{P_H}$$

A convenient ratio to consider in this case is the Cl/H ratio. This ratio is an independent variable controlled experimentally, and is conserved in the gas phase. Thus the chlorine to hydrogen ratio at equilibrium, Cl(e)/H(e), is equal to the chlorine to hydrogen ratio at input, Cl(i)/H(i), and

$$\frac{4P_{GeCl_4}}{2(1\text{ atm} - P_{GeCl_4})} = \frac{Cl(i)}{H(i)} = \frac{Cl(e)}{H(e)} \quad [9]$$

where P_{GeCl_4} is the partial pressure of the $GeCl_4$ in the gas stream, and $(1\text{ atm} - P_{GeCl_4}) = P_{H_2}$.

Since we are interested in evaluating an efficiency for the system which describes the amount of dissolution of Ge in the gas phase or deposition of Ge from the gas at equilibrium, the Ge(e)/Cl(e), the Ge to chlorine ratio at equilibrium corresponding to a particular Cl(i)/H(i) must also be evaluated. The change in the Ge/Cl ratio from the input value can then be written in terms of an efficiency factor, α, as defined by Sedgwick (9) where

$$\alpha = \frac{\dfrac{Ge(i)}{Cl(i)} - \dfrac{Ge(e)}{Cl(e)}}{\dfrac{Ge(i)}{Cl(i)}} \quad [10]$$

The $\dfrac{Ge(i)}{Cl(i)}$ at input refers to the input gas consisting of $GeCl_4$ and hydrogen, and is therefore 0.25.

The factor, α, which is a function of T, and Cl/H, where total pressure is assumed constant may change from 1 through 0 to negative values. Thus a positive value of α predicts germanium deposition ($\alpha = 1$ indicating 100% Ge deposition from the gas phase); $\alpha = 0$ to no net deposition, since $\dfrac{Ge(i)}{Cl(i)} = \dfrac{Ge(e)}{Cl(e)}$; and negative values of α to various degrees of etching.

Method of calculation.—The calculations described below for the Ge-H-Cl employed a parametric approach which has been described in detail by Darken (10) and Lever (2). In such an approach one specifies a partial pressure ratio at equilibrium which allows one to calculate many sets of numerical values of the equilibrium partial pressures which are consistent with the values of the equilibrium constants and the total pressure. By evaluating $\dfrac{Cl(e)}{H(e)}$ and using Eq. [9] one can relate these solutions to a particular $\dfrac{Cl(i)}{H(i)}$.

For these calculations the quantity $P_{HCl}/P_{H_2} = X$ was chosen.

By substituting for the partial pressures in Eq. [5] in terms of the appropriate K, X, and P_{HCl} from Eq. [1-3] one obtains

$$(P_{HCl})^2 [K_1X^2 + K_3X] + P_{HCl} \left[K_2X + 1 + \frac{1}{X} \right] - 1 = 0$$

This quadratic equation can be readily solved for P_{HCl} by specifying a value for X for a given temperature, and employing Eq. [1a-3a]. The other partial pressures and component ratios of interest may then be readily evaluated.

Results and Discussion

Calculations of partial pressures of all species, the Ge(e)/Cl(e) and Cl/H ratios, and α were made in the temperature range 400°-1223°K for a total pressure of 1 atm. The computer calculations were made using an APL program on IBM System 360.

The results are graphically displayed in Fig. 1-9. In Fig. 1-4, the partial pressures of the different species together with the Ge(e)/Cl(e) ratio have been plotted as a function of temperature for specific Cl/H ratios. For increasing Cl/H it is noted that in general the formation of $GeHCl_3$, $GeCl_2$, and $GeCl_4$ is favored, hence we note an increase in the equilibrium Ge(e)/Cl(e) ratio. Exclusive of H_2 which is nearly always at an atmosphere, HCl is consistently the major vapor species. Normal operating conditions for epitaxial deposition systems are generally at inputs using Cl/H ratios in the 0.001 range and at temperatures of 759°C or higher (Fig. 2). It will be noted that the major chlorine containing species under these conditions are HCl and $GeCl_2$. For any given Cl/H condition (Fig. 1-4) we note that increasing temperature causes

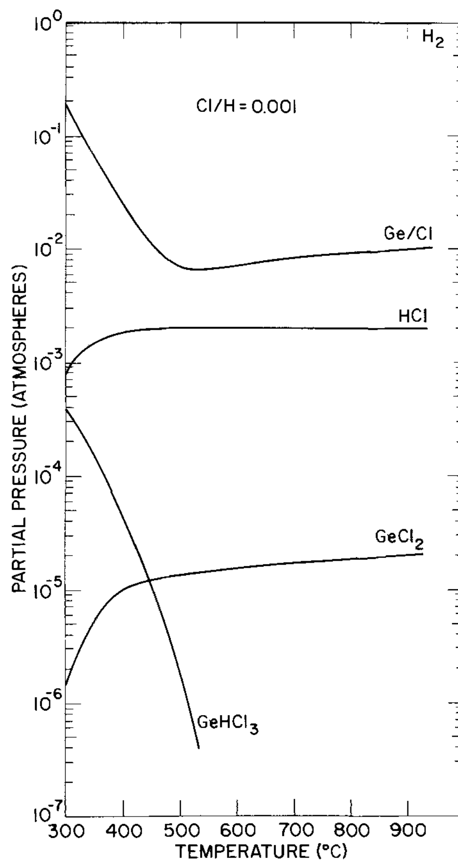

Fig. 2. Partial pressures of the various gas species vs. temperature at a total pressure of 1 atm at a chlorine/hydrogen ratio of 0.001.

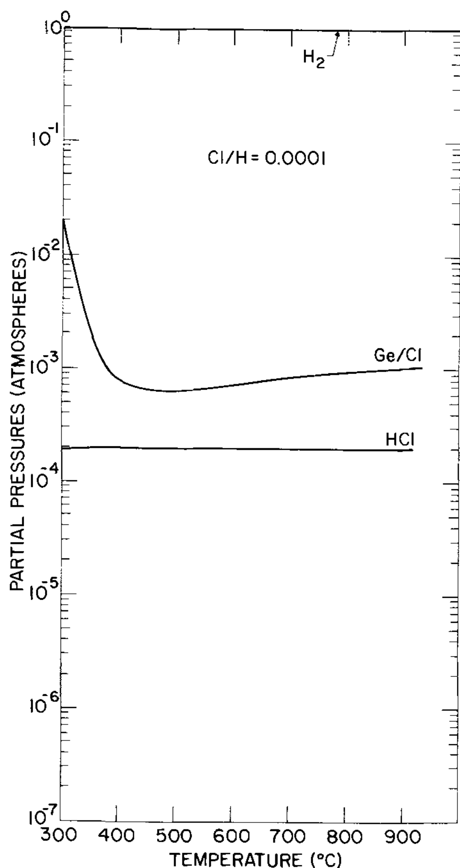

Fig. 1. Partial pressures of the various gas species vs. temperature at a total pressure of 1 atm at a chlorine/hydrogen ratio of 0.0001.

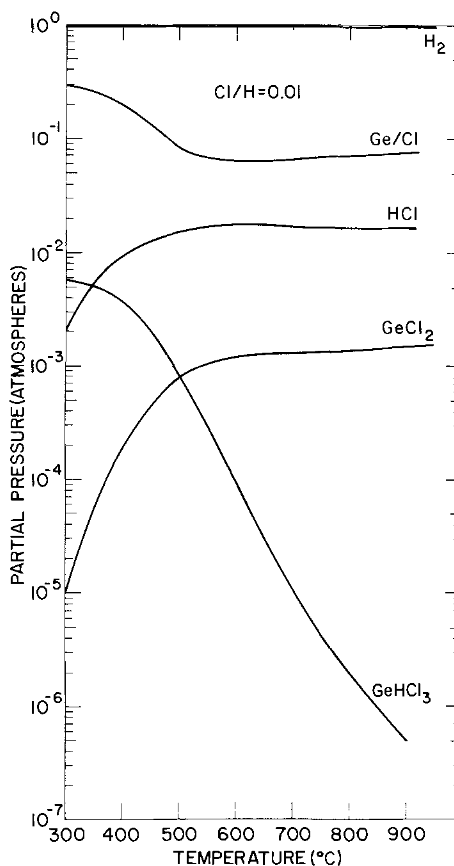

Fig. 3. Partial pressures of the various gas species vs. temperature at a total pressure of 1 atm at a chlorine/hydrogen ratio of 0.01.

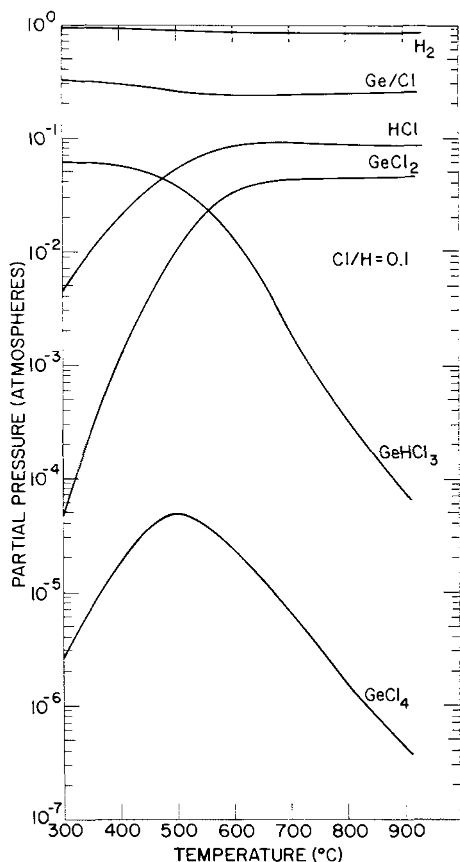

Fig. 4. Partial pressures of the various gas species vs. temperature at a total pressure of 1 atm at a chlorine/hydrogen ratio of 0.1.

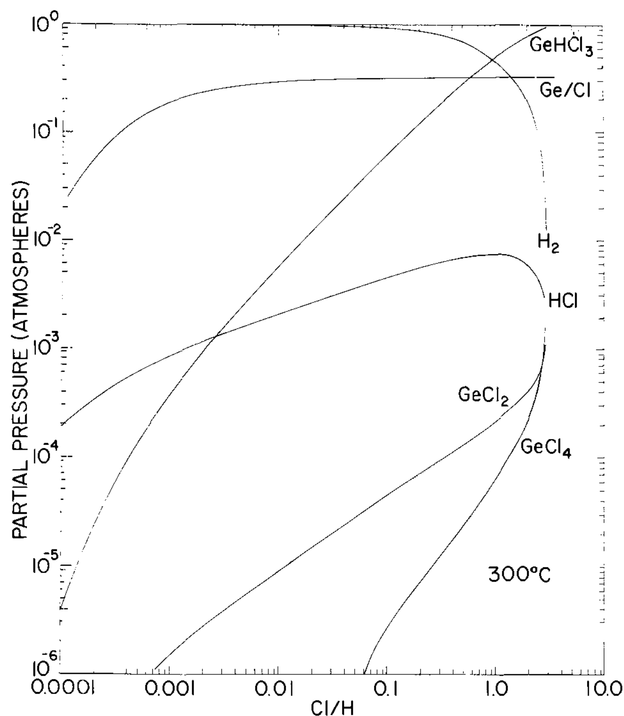

Fig. 5. Partial pressures of the various gas species vs. Cl/H ratio at a temperature of 300°C. Total pressure = 1 atm.

a reduction of $GeHCl_3$ pressure and an increase in $GeCl_2$ and HCl pressure.

In Fig. 5 and 6 the composition of the gas phase, in terms of partial pressure, is plotted for two temperatures, 300° and 800°C, respectively as a function of Cl/H ratio. For the lower temperature (Fig. 5) it can

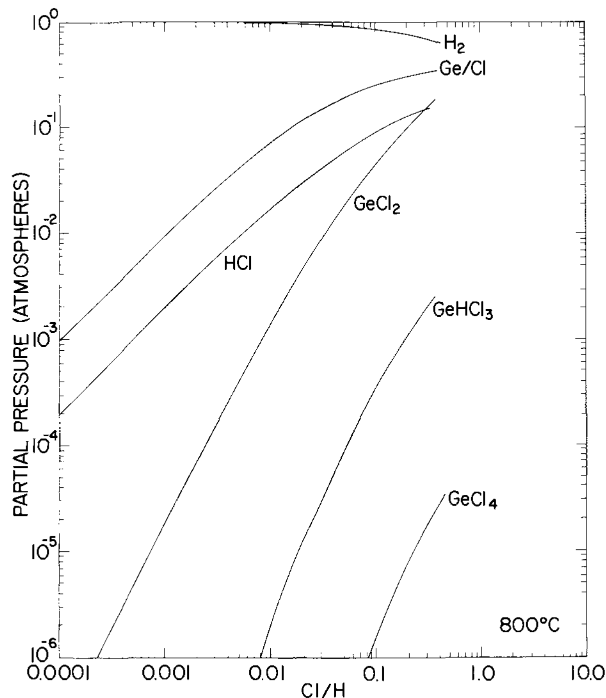

Fig. 6. Partial pressures of the various gas species vs. Cl/H ratio at a temperature of 800°C. Total pressure = 1 atm.

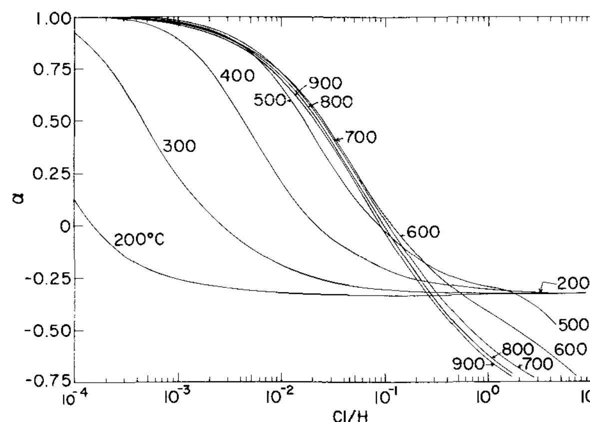

Fig. 7. Efficiency factor, α vs. Cl/H ratio for different temperatures at a total pressure of 1 atm.

be clearly seen that $GeHCl_3$ dominates the system as the major Ge bearing gas species, while at the higher temperature (Fig. 6) $GeCl_2$ is dominant. Since the formation of any Ge bearing species leads to etching, one can consider the etching to be primarily due to the formation of $GeHCl_3$ at lower temperatures and at higher temperatures to the formation of $GeCl_2$.

In Fig. 7 the efficiency factor, α, has been plotted *vs.* the Cl/H ratio for specific temperatures. As might be expected from the previous figures, etching is favored ($\alpha < 0$) for all temperatures at high Cl/H input ratios. The trend of all curves toward 100% efficiency, $\alpha = 1.0$, at low Cl/H ratios correspond to a complete reduction of all Ge bearing species (Ge(e)/Cl(e) = 0), to form HCl and H_2. For Cl/H values < 0.1 one observes that for the temperature interval 500°-900°C there is little change in α resulting from temperature variation. This is more clearly seen in Fig. 8 where α is plotted as a function of temperature for specific Cl/H inputs. The convergence of curves to a value of -0.33 is the result of the dominant trend for $GeHCl_3$ to form at low temperatures and high Cl/H ratios.

The effect of varying the enthalpy value of $GeHCl_3$ from -100 kcal to -85 kcal in the calculation as discussed earlier, are summarized in Fig. 9. In Fig. 9 the

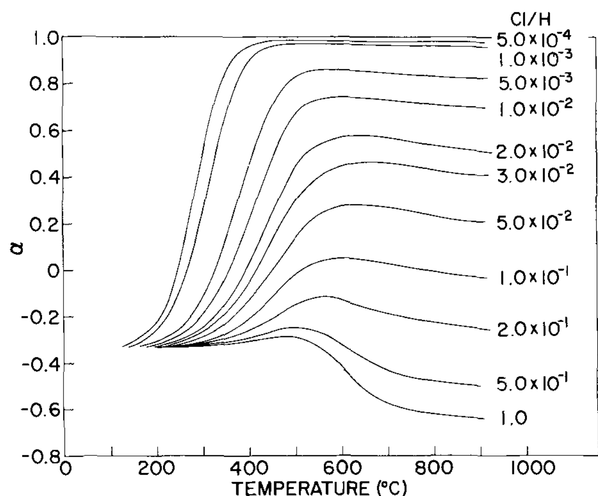

Fig. 8. Efficiency factor, α vs. temperature at different Cl/H ratios at a total pressure of 1 atm.

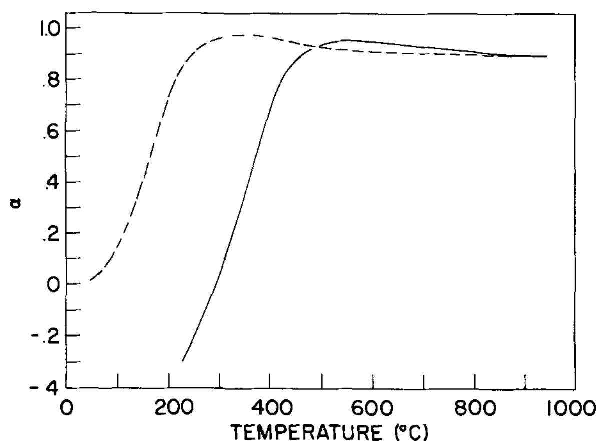

Fig. 9. Efficiency factor, α vs. temperature calculated using two room temperature enthalpy values for $GeHCl_3$. Cl/H = 2.2 x 10^{-3}; - - -, (−85 kcal); ———, (−100 kcal).

efficiency factor, α, is plotted *vs.* temperature for a Cl/H ratio of 2.2×10^{-3} using the indicated enthalpy values for $GeHCl_3$. It will be noted that at temperatures $< 500°C$, α becomes highly sensitive to the enthalpy value chosen. For the general calculations the more negative enthalpy value was used.

The Ge-H-Cl system is analogous to the Si-H-Cl system (2) with respect to the role that the corresponding gas species $SiHCl_3$ and $GeHCl_3$, and $SiCl_2$ and $GeCl_2$ have on the dissolution or deposition rate. The general trends in both systems are:

1. That increased concentration of Ge or Si bearing vapor species reduces efficiency.
2. That in certain temperature intervals there is little variation of the Ge/Cl or Si/Cl ratios and hence efficiency. This results from increased formation of $(M)Cl_2$ vapor species being balanced by the reduction of $(M)HCl_3$ species where M can be either Ge or Si.
3. In the temperature intervals where significant variations of Ge/Cl or Si/Cl ratios occur, they are associated with the increased concentration of either $(M)HCl_3$ or $(M)Cl_2$.

Some Properties of Vapor Deposited Ge_3N_4 Films and the Ge_3N_4-Ge Interface

Takehisa Yashiro

Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan

ABSTRACT

Germanium nitride films were deposited on germanium substrates heated to 400°-600°C by vapor phase reactions of germanium tetrachloride and ammonia. The properties of these films, such as the dissolution rate and the dielectric constant, were determined as a function of deposition temperature. The masking against Sb and As was also investigated. The films exhibited an instability related to trapping at room temperature but Na^+ ion migration was not observed under bias-temperature stress. A hysteresis of the C-V curves for metal-nitride-semiconductor structures was noted. The amount of the hysteresis depended on deposition temperatures; a deposition temperature of 550°C resulted in the smallest hysteresis. By heat-treatment in NH_3, the magnitude of the hysteresis of the samples deposited at low temperature could be diminished while the interface state densities increased.

A method for depositing Ge_3N_4 films by vapor phase reaction of germanium tetrachloride and ammonia has been reported by Nagai and Niimi (1). They investigated the physical and chemical properties of the films formed at temperatures between 400° and 600°C and reported that the films deposited at these temperatures were amorphous. When the films were kept at or above 600°C in H_2, Ar, or N_2, they were reduced or decomposed. They were crystallized by heat-treatment above 700°C in NH_3 (2).

In this study, the physical properties of the nitride films and the electrical properties of the Ge_3N_4-Ge interface were investigated as a function of deposition temperature of the nitride films. It has been found that the electrical characteristics of the Ge_3N_4-Ge interface vary with deposition temperature. It became clear that germanium nitride can be utilized as a diffusion mask for Sb and As into germanium.

Experimental

Germanium wafers used for these studies were (111) surface oriented, p-type, in the range of 0.2-3 ohm·cm. The wafers were etched in an acid containing 25 parts by volume of HF, 25 of HNO_3, and 0.75 of acetic acid with 0.2 Br_2 dissolved, and washed in distilled water. Germanium nitride was formed by reacting germanium tetrachloride and ammonia in a horizontal quartz tube with an inside diameter of 4.5 cm. The germanium tetrachloride vapor was transported to the rf-heated substrates by bubbling hydrogen through the saturator at 0°C. This gas was mixed with pure hydrogen and then with ammonia near the rf-heated substrates, as reported by Nagai and Niimi (1). Ammonia was dried by passing it through a cold trap kept at −30°C. The relative flow rates were as follows: H_2 600 mliter/min; NH_3 200 mliter/min; H_2 through germanium tetrachloride 200 mliter/min. Depositions were carried out at 400°-600°C.

Metal-nitride-germanium (MNS) capacitor structures for electrical measurements were formed by vacuum evaporation of either aluminum or gold on the surface of the nitride film through the mask. The area of the electrodes ranged from 3.0×10^{-4} to 4.5×10^{-4} cm².

Results and Discussion

Physical Properties

Dielectric constant and etch rate.—The thickness of the nitride films used for this experiment was 1540-1620Å and was measured by multiple beam interferometry on mechanically polished test slices. The field plates of circular dots 200μ in diameter were formed by photolithography. The capacitance of germanium nitride films was measured at 1 MHz by applying a large negative d-c bias to the field plates so that the p-type germanium surface was accumulated. From these values, the dielectric constant of germanium nitride films was calculated. The results, shown in Table I, indicate that the dielectric constant is almost independent of deposition temperature.

Since the etch rate is sensitive to the structural properties of the films, the value in H_3PO_4 at 110°C was measured as a function of deposition temperatures. The results are also shown in Table I. It is noted that at lower substrate temperatures the etch rate increases. The increase in the etch rate for the lower deposition temperatures is thought to be due to the increase of unsaturated bonds of germanium in the germanium nitride (3-5).

Diffusion masking.—When the germanium nitride film was kept at or above 600°C in H_2, Ar, or N_2, the film was reduced or decomposed (1). However, since the film was stable to 650°C in NH_3, the masking properties of the germanium nitride film on germanium were investigated in NH_3. The diffusion was carried out in an open tube system. The source material was metallic Sb kept at 525°C or As at 350°C. Because of the low diffusion constant of acceptor elements (Ga, In, B) in germanium, they were excluded from this experiment.

Nitride films 1200Å thick were deposited at 500°-550°C on the surface of chemically etched 0.2-3 ohm·cm p-type wafers in which circular dots 100μ in diameter or rings 160μ in outside diameter and 80μ in inside diameter were opened for diodes. During the diffusion process, the germanium wafers were kept at 600°C for 1-5 hr.

The results were determined by two methods: (*i*) the diode characteristic measurement and (*ii*) the hot probe method after removing the nitride film. A typical diode curve obtained by As diffusion is shown in Fig. 1. From these results, it is concluded that ger-

Table I. Dielectric constant and etch rate of Ge_3N_4

Deposition temperature (°C)	Dielectric constant	Etch rate in H_3PO_4 at 110°C (Å/sec)
600	7.8	23
550	8.0	38

manium nitride films 1200Å thick can be used as masks against the diffusion of Sb and As into germanium.

Electrical Properties

Interface properties.—The C-V curves of as-deposited Ge_3N_4-Ge structures were obtained at room temperature and 1 MHz. Typical examples are shown in Fig. 2. The scanning speed of the bias was 4 V/sec. The theoretical curve in the absence of surface charge and interface state (6) is also shown in the figure. Hysteresis was observed for all samples investigated and its extent depended on the deposition temperature. The deposition below 500°C resulted in large hysteresis. The smallest hysteresis was obtained on the sample deposited at 550°C. The shape of the C-V curves deposited below 500°C depended on the scanning speed of the bias. The low scanning speed showed that the curve becomes flatter. On the other hand, the deposition at 600°C showed a distortion as compared to the theoretical curve, *i.e.*, the very gradual decrease of capacitance with the bias voltages. This phenomenon would indicate a continuous distribution of states in the forbidden gap of germanium (7). The "knee" (8) or "plateau" (9) observed in the SiO_2-Ge systems were not observed on as-deposited samples.

The direction of the hysteresis in this experiment is opposite to that which is caused by the polarization of insulators in metal-insulator-semiconductor structures (10, 11). Such a phenomenon can be explained if charges move across the Ge_3N_4-Ge interface and are trapped (12). Since the hysteresis is thought to be related to the bulk properties of the nitride film near the Ge_3N_4-Ge interface, the nitride film deposited at lower temperatures may be incompletely nitrified (13-15), *i.e.*, there will be unsaturated bonds or vacancies in germanium nitride as suggested by the fast etching rates in H_3PO_4. On the other hand, as the origin of the interface states could be due to unsaturated bonds very near the semiconductor-insulator interface (16, 17), the high-temperature deposition is thought to make unsaturated bonds at the interface.

Heat-treatment.—It was observed that heat-treatment in NH_3 affects the shape of C-V curves, *i.e.*, the magnitude of the hysteresis and slope variation. In this investigation, three wafers on which germanium nitride was deposited at 400° or 450°C showing the large hysteresis and two wafers on which germanium nitride was deposited at 550°C showing the smallest hysteresis, were divided into many pieces and each piece was treated at a given temperature in NH_3. Then, gold electrodes were evaporated through the metal mask.

Typical C-V curves measured at room temperature are shown in Fig. 3. The samples were cut from the same wafer deposited at 450°C and then heat-treated at various temperatures for 30 min. The measuring frequency of 1 MHz was affected slightly by the frequency response of the interface states, so that the curves were obtained at 50 MHz to prevent the interface states from following the a-c signal. The voltages were applied from left to right. A feature of the Ge_3N_4-Ge interface after annealing is that increasing the treatment temperature causes the curves to become flatter because the interface states continuously distribute energy throughout the bandgap (7). Sedgwick (8) and Sedgwick *et al.* (18, 19) reported the appearance of a "plateau" or "knee" in the C-V curves in the SiO_2-Ge systems after annealing in H_2 or N_2 containing H_2 above 600°C due to monoenergetic acceptor states at the interface. They reported that the acceptor states are located at the center of the Ge energy gap. However, since the samples of Fig. 3 were heat-treated in NH_3 between 500° and 650°C, the plateau related to hydrogen was not observed. The other feature of the shape of C-V curves after annealing is the decrease in the extent of hysteresis. The polarization-type hysteresis observed by Iwauchi *et al.* (20) in the Al_2O_3-Ge structure after annealing in N_2 was not observed in the Ge_3N_4-Ge structure.

In Fig. 4, the interface state density N_{SS} at zero surface potential and the extent of hysteresis $\Delta N_{FB}'$ are shown. The samples in the figure were obtained from the same wafer deposited at 450° or 550°C and heat-treated at various temperatures. N_{SS} was calculated

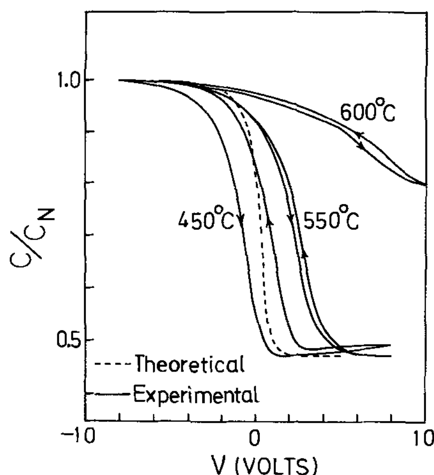

Fig. 2. C-V curves for MNS structures measured at 1 MHz showing the effect of deposition temperatures of the nitride. (p-type, 0.45 ohm·cm; film thickness 1300Å; electrode Al.)

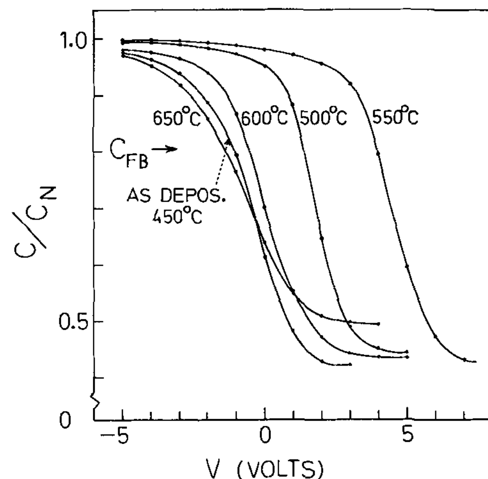

Fig. 3. C-V curves measured point by point and at 50 MHz for the samples after heat-treatment at various temperatures in NH_3 for 30 min. (p-type, 0.45 ohm·cm; film thickness 1150Å; electrode Au.)

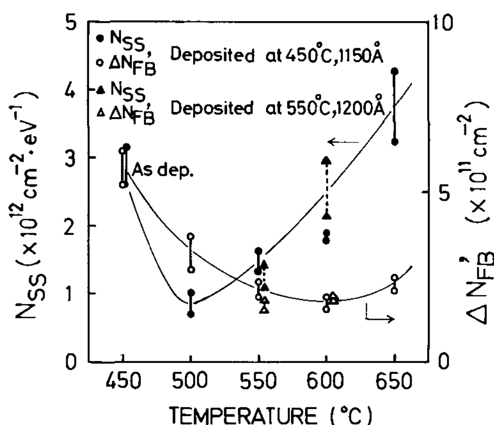

Fig. 4. Change of N_{SS} and $\Delta N_{FB}'$ after annealing at various temperatures for 30 min. The sample deposited at 450°C was the same as that in Fig. 3. The sample deposited at 550°C was 0.7 ohm·cm, 1200Å. N_{SS} and $\Delta N_{FB}'$ after annealing at 550°C for the sample deposited at 550°C were about the same.

from the C-V curves measured at 50 MHz by the following equation (21, 22)

$$N_{SS} = \frac{C_N}{q} \frac{d\Delta V(\psi_S)}{d\ \psi_S}$$

where C_N is the capacitance of the nitride film, $\Delta V(\psi_S)$ is the difference between the measured and ideal C-V curves, and ψ_S is the germanium surface potential. $\Delta N_{FB}'$ was calculated by $\Delta N_{FB}' = C_N \cdot \Delta V_{FB}'/q$ and $\Delta V_{FB}'$ was obtained as the difference of V at the theoretical flat-band capacitance when V was swept from positive to negative and from negative to positive values by a constant applied field swing of about -8×10^5 to $+8 \times 10^5$ V/cm. The C-V curves used to obtain $\Delta N_{FB}'$ were measured at 1 MHz and automatically plotted on an X-Y recorder by the voltage sweep of 4 V/sec. The reason for the primed ΔN_{FB} is that the capacitance does not correspond to a true flat band condition because of the capacitive contribution of the interface state charges as stated above. The experimental results shown by bars are the upper and the lower limits of more than three measurements on the same piece.

As seen in the figure, N_{SS} and $\Delta N_{FB}'$ are reduced by heat-treatment at 500°C for the samples deposited at 450°C. Above 550°C, $\Delta N_{FB}'$ was found to decrease with increasing treatment temperature to 600°C, while N_{SS} increased uniformly. On the other hand, the reduction of $\Delta N_{FB}'$ was not clearly observed on the samples deposited at 550°C in the temperature range investigated. N_{SS} does not change at 550°C but increases at 600°C. The increasing trend of N_{SS} at 600°C is the same as that of 450°C deposited samples. These trends of N_{SS} and $\Delta N_{FB}'$ after annealing were reproducible. Only one of an anomalous curve shape observed is shown in Fig. 5. The C-V curve in this figure is similar to that of the other heat-treated samples with regard to the increase of the interface states and the decrease of the extent of hysteresis, but a "break" appears in the curve. This result was not reproducible. The reason for the appearance of the break is not clear at the present time.

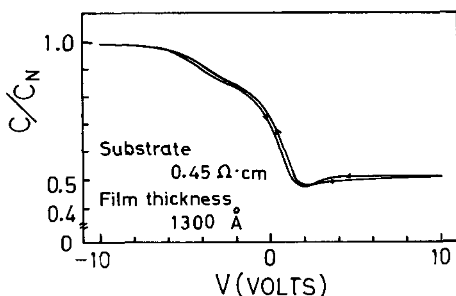

Fig. 5. C-V curve measured at 1 MHz showing a "break" after annealing at 600°C for 1 hr in NH_3. Germanium nitride was deposited at 400°C.

To investigate the reason for the change of N_{SS} or $\Delta N_{FB}'$, the sample deposited at 450°C was annealed at 350°C in H_2 or at 530°C in Ar for 30 min. Annealing in H_2 at high temperature was excluded because of the reduction of germanium nitride. It was found that annealing in H_2 or Ar did not reduce N_{SS} or $\Delta N_{FB}'$ compared to as-deposited structures. Therefore, the effect of annealing in NH_3 appears to be that nitrogen atoms fill unsaturated bonds in germanium nitride and reduce the hysteresis. At the same time, the reaction of germanium and nitrogen proceeds at the interface and the increase of N_{SS} results. This reaction at the interface between germanium nitride and germanium was also observed by Nagai (2).

Ion migration.—An instability related to metal-silicon dioxide-silicon structures is alkali ion migration within silicon dioxide as reported by Snow *et al.* (23). It is observed as a displacement of C-V curves along the voltage axis when the voltages are applied to the metal electrode above 150°C. The direction of the displacement is opposite to the applied voltages and the extent is a function of applied voltage, temperature, and time.

In this investigation, germanium wafers covered with 1300A of germanium nitride were first rinsed in a solution of NaCl (0.1%) and then aluminum electrodes 200μ in diameter were deposited. The contamination of NaCl was confirmed by the microscopic observation prior to the deposition of the electrodes.

Initially, C-V curves were obtained at room temperature. The samples were then treated at 200°C, +2V on the field plate for 10 min and were cooled rapidly to room temperature with the voltage applied. Thereafter, C-V curves were traced again. The applied field during this treatment was smaller than the threshold field required for trapping of electrons (8.5×10^5 V/cm). The result of these bias-temperature treatments is shown in Fig. 6. A displacement of about 0.5V in the positive direction was observed. However, since this displacement is opposite to that of ion migration, we concluded that Na^+ ions do not migrate appreciably within the germanium nitride films.

Trapping.—When positive or negative voltages exceeding some critical values are applied to the field plate at room temperature, the shift of C-V curves in the positive or negative direction, respectively, has been observed by many investigators (12, 14, 24-27). The direction of this displacement is opposite to that caused by ion migration. The reason for this displace-

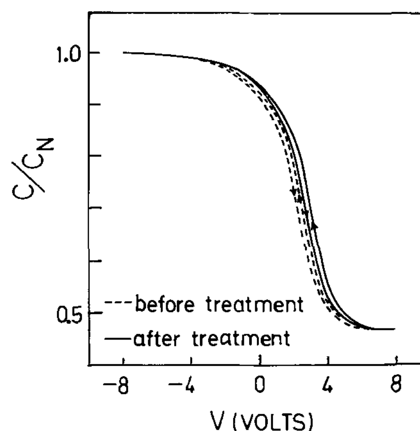

Fig. 6. Bias-temperature treatment for intentionally NaCl-contaminated Al-Ge_3N_4-Ge structures.

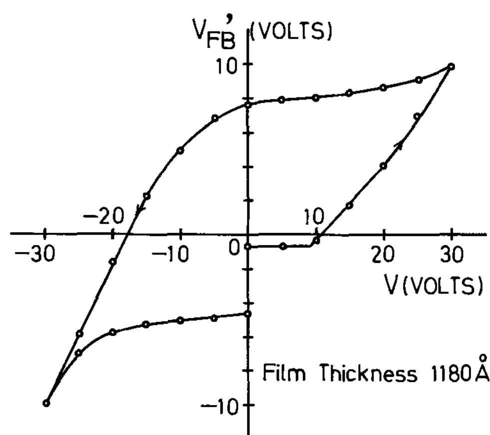

Fig. 7. Shift of V_{FB}' (see text) as a function of applied bias for 30 sec.

ment is thought to be due to trapping or releasing of carriers in the insulator.

It was found that the trapping occurs in the metal-germanium nitride-germanium system. A measurement of V_{FB}' *vs.* applied voltage is shown in Fig. 7. The meaning of the primed V_{FB} is the same as that given in the section on Heat-treatment. From these results, it was determined that the threshold field of the displacement is 8.5×10^5 V/cm for the positive bias.

By a combination of photon radiation and C-V measurement, trap levels in germanium nitride were investigated. It was found that there are deep and shallow electron traps in germanium nitride (28). Therefore, the positive shifts in this investigation would be caused by trapping of electrons.

Conclusion

Physical and electrical properties of germanium nitride and the germanium nitride-germanium interface were investigated. It became clear that germanium nitride can be used as a mask against the diffusion of Sb and As at 600°C in NH_3. Na^+ ion migration was not observed by bias-temperature treatments at 200°C. The dielectric constant of germanium nitride was about 8.0 and was not significantly affected by the deposition temperatures. The etch rate depended on deposition temperature and is in the range of 23-75 Å/sec in H_3PO_4 at 110°C. The hysteresis of C-V curves was observed for all the samples and was a function of the deposition temperature. A small hysteresis in the C-V curves was obtained on samples deposited at 550°C. At lower deposition temperature the hysteresis was larger. The magnitude of the hysteresis could be reduced by heat-treatment in NH_3 while interface state density increased. The extent of the hysteresis and the interface state density for as-deposited samples at 550°C and for samples deposited below 500°C and then heat-treated at 550°C were about the same. An instability in germanium nitride due to trapping of electrons was observed. Germanium nitride is unstable as compared with silicon nitride and is reduced or decomposed above 600°C in H_2, Ar, or N_2. However, the reverse characteristics of the germanium diodes that utilized germanium nitride as a diffusion mask and as passivation film were good.

Acknowledgments

The author wishes to thank Professor T. Niimi of Keio University and Mr. Igarashi for helpful suggestions throughout the work. He is also grateful to Mr. Nagai and Mr. Shibata for their discussions and Mr. Yano for his preparation of germanium nitride films.

Crystal Growth and Isothermal Annealing of $Pb_{1-x}Sn_xTe$ Alloys

G. Dionne

Hydro-Québec Institute of Research, Varennes, Quebec, Canada

and J. C. Woolley

University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Single crystal ingots of $Pb_{1-x}Sn_xTe$ alloys have been grown using the Bridgman technique. A study of the crystal perfection revealed that in most cases the bulk of each ingot consists of a highly perfect single crystal with no detectable grain boundaries. In addition, the "as-grown" material is highly homogeneous in both alloy composition and carrier concentration, and is free from metal precipitates. A simplified isothermal annealing technique has been used to obtain various carrier concentrations in $Pb_{1-x}Sn_xTe$ alloy samples with $x = 0.06$, 0.13, and 0.21. The carrier concentration in these alloys, equilibrated at the liquid + solid/solid solution boundary, has been determined for several annealing temperatures.

The alloys $Pb_{1-x}Sn_xTe$ and several other IV-VI compounds and alloys have much in common in that they have the same cubic rocksalt structure, have similar phase diagrams, can be prepared by similar methods, and their carrier concentrations can be controlled in a similar manner. These systems are often represented by the symbol MN to generalize the discussion (1), M representing the group IV elements and N the group VI elements. The use of the stoichiometric formulas MN (*i.e.*, with the number of M atoms exactly equal to the number of N atoms) to represent these compounds and alloys is only approximate. At finite temperatures, the free energy of the crystal may be lowered by the introduction of atomic point defects, such as vacancies, and in general the compound is stable over a range of composition, called the homogeneity range, which sometimes does not include the stoichiometric composition. In undoped PbTe, SnTe, and their alloys the carrier concentration is a direct measure of the deviation from stoichiometry because the point defects, responsible for this deviation, supply practically all extrinsic carriers. While intrinsic effects and ionized impurities may also contribute to the total carrier concentration, for materials prepared from pure elements and not deliberately doped, these contributions are usually very small at low temperatures (1). In the present work, the lowest carrier concentration investigated was about 10^{17} cm^{-3}. At the temperature of the Hall measurements (77°K), the intrinsic carrier concentration will not exceed 2.2×10^{13} cm^{-3} for any of the three alloy compositions investigated here (2). The alloys were prepared from elements of high semiconductor purity. While the impurity content was not directly determined, as will be shown in Fig. 3 the present alloys had higher mobilities than similar alloys prepared elsewhere (3), and the latter had total p-type impurities of approximately 1×10^{17} cm^{-3} as found by mass spectrometry. Thus in the present work, it is reasonable to assume that the carrier concentration is a direct measure of the nonstoichiometry of the alloy except perhaps at the lowest carrier concentration values. It has been found for SnTe that each tin vacancy produces 2 holes (4-6). Brebrick (6) indicates that the hole to vacancy ratio c varies smoothly with x in these alloys and is closer to unity in the Pb-rich alloys. Thus in the present work, the value of c has been assumed to lie between 1 and 2.

Key words: nonstoichiometry, carrier concentration, IV-VI alloys, single crystals, semiconductors.

Growth and Characterization

The furnace used to grow all the crystals is shown schematically in Fig. 1, together with a typical temperature profile. The furnace consisted of a high and a low temperature section which were independently controlled. The two sections were separated by a water-cooled jacket which permitted the establishment of a steep temperature gradient. The quartz ampoule, containing the melt, was held in a mullite tube which was driven slowly in the direction of the low temperature zone. The driving mechanism was built to provide three speeds: 1.1, 3.4, and 10.4 cm/day. In addition, the furnace could be tilted as shown in Fig. 1. The temperature gradient, at the temperature of freezing, was always greater than 50°C/cm.

The melts were prepared by mixing the elements in stoichiometric proportion. Lead, tin, and tellurium, all six 9's grade, were obtained from Cominco Ltd., Montreal. Lead and tin were available in the form of rods,

Table I. Starting composition, weight, 1st to freeze composition, and carrier concentration of $Pb_{1-x}Sn_xTe$ alloys grown by the step-freeze technique

Ingot No.	Starting x	Weight, g	1st to Freeze x	Hole carrier concentration at 77°K, cm^{-3}
2	0.2	50	0.12	$2\text{-}4 \times 10^{19}$
3	0.4	50	0.27	$7\text{-}15 \times 10^{19}$
4	0.6	50	0.45	$2\text{-}4 \times 10^{20}$
5	0.8	75		5×10^{20}
6	0.1	100	0.05	1.2×10^{19}
7	0	67	0	7×10^{18}
8	0.3	100	0.18	4×10^{19}

approximately 12 mm in diameter, from which sections were cut and the oxide skin removed, with a steel blade, just before use. The elements were sealed under vacuum in a 13 mm inside diameter quartz ampoule, one end of which was made conical. The ampoule was then introduced in the hot zone of the step-freeze furnace and left there, at a temperature higher than 1000°C, for at least 1 day for complete mixing. The melt was driven through the steep temperature gradient at a speed of 3.4 cm/day, the conical tip being the first to freeze.

Table I lists the $Pb_{1-x}Sn_xTe$ ingots grown using the above procedure. Ingots 2 to 4 were grown with the furnace in the horizontal position, while ingots 5 to 8 were grown with a tilt angle of 45° (Fig. 1). The main advantages of the tilted position are the following: (*i*) since the melt completely fills the ampoule, as shown in Fig. 1, large cross sections of crystal are obtained; (*ii*) there is no transport of material, through the vapor phase, over already grown material as there is in the horizontal set-up; (*iii*) there is no need to seal the quartz ampoules close to the material, thus oxidation during the sealing operation can be avoided.

The alloy compositions were determined using the results of Bis and Dixon (7) which showed that the lattice parameter a_0 depends upon both composition x and carrier concentration p (*i.e.*, nonstoichiometry), but that for a fixed value of p, a_0 varies linearly with x. Thus the composition of each sample was found by measuring the carrier concentration and the lattice parameter for the sample and then using the data in Fig. 2 of Bis and Dixon (7). Composition values determined in this way were accurate to better than 1%. The lattice parameters were determined from Debye-Scherrer powder photographs taken with CuK_α radiation and using a standard 114.6 mm diameter camera. The $\left(\frac{\cos^2\theta}{\sin\theta} + \frac{\cos^2\theta}{\theta}\right)$ extrapolation method was used to determine a_0. To remove any internal stress, produced during the grinding operation, the alloy powder samples to be used for the x-ray work were annealed for about 10 hr at a temperature no higher than 250°C. The accuracy of the lattice parameter so determined was ±0.0005Å.

The starting compositions and the first-to-freeze compositions, listed in Table I, are consistent with the phase diagrams for $Pb_{1-x}Sn_xTe$ determined by Wagner and Woolley (8). As expected from this phase diagram, the growing material is always richer in PbTe than the melt. As growth slowly proceeds, the melt becomes more and more depleted of PbTe and hence a composition gradient exists along the length of the ingot. However, the composition gradient is very small in the first quarter to freeze due to the relatively small separation between the liquidus and solidus curves at a given temperature. In ingot No. 2, for example, the composition varied by less than 2% in the first quarter of the ingot to freeze.

Table I also lists the range of carrier concentrations measured in these ingots. The higher the SnTe content of the alloys, the higher are the carrier concentrations. This is due to an increasing deviation from stoichiometry as we go from PbTe to SnTe. When grown from stoichiometric melts, $Pb_{1-x}Sn_xTe$ alloys are always

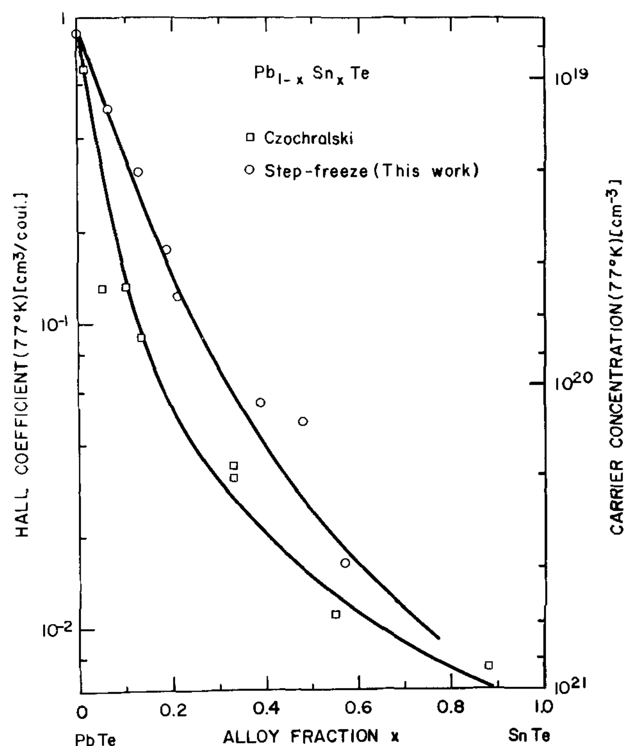

Fig. 2. Hall coefficient as a function of alloy composition in the "as-grown" $Pb_{1-x}Sn_xTe$ alloys.

tellurium rich, and this excess tellurium is accommodated in the lattice by lead and/or tin vacancies, which ionize to produce p-type carriers. That the alloys grown from stoichiometric melt are tellurium rich is clearly seen in SnTe rich ingots, for which the last to freeze is always a small amount of pure tin. Brebrick (4) showed that the point defects in SnTe were tin vacancies and that the carrier-to-vacancy ratio was approximately 3. But Brebrick calculated the carrier concentration using $p = 1/R_0e$, in which R_0 is the low field Hall constant and e is the electronic charge. When using the correct expression for the carrier concentration, $p = r/R_0e$, with the values for r given by Tsu *et al.* (9), the carrier-to-vacancy ratio becomes 2. This agrees with the intuitive notion that an ionized divalent (Sn^{++}) vacancy produces exactly 2 carriers. The increase of carrier concentrations from PbTe to SnTe is almost a hundredfold for ingots grown from stoichiometric melts (see Table I), suggesting that tin vacancies are more easily generated than lead vacancies.

Several circular disks cut from ingots No. 6 and No. 8 were lapped with coarse powder to produce microcleavages over the surface of the disks. By using a distant source of light, any small angle grain boundaries could be detected with a high degree of accuracy by observing the reflection from the numerous {100} microcleavage planes. A detailed examination revealed that the ingots were single crystal over their whole length with small grain boundaries predominantly in a small first-to-freeze region and near the surface of the ingots. With each circular disk so treated, the examination showed that more than 50% of its volume was single crystal with no detectable grain boundary, while the remaining volume had small angle grain boundaries present, the angles varying from about 2° to 5°. With ingots No. 6 and No. 8, x-ray back reflection photographs were taken at 3 mm intervals across a diameter of a face cut parallel to the long axis of the ingot with normal incidence of the x-ray beam. These x-ray photographs confirmed some of the above observations concerning the single crystal character and the crystal perfection of the material.

The "as-grown" material was homogeneous. First, metallographic examination showed no voids, no cracks,

and no sign of metal precipitation. We believe that the small growth rate (3.4 cm/day) and the steep temperature gradient at the freezing interface (> 50°C/cm) were responsible for the absence of metal precipitation and cellular substructure frequently observed in $Pb_{1-x}Sn_xTe$ ingots (10). Second, x-ray diffraction (Debye-Scherrer powder photographs) indicated that the alloys were single phase and of good alloy homogeneity, in all cases the α_1, α_2 doublet being resolved in the high angle lines. Third, resistivity measurements taken at two different positions along the samples, indicated that the "as-grown" material was homogeneous in carrier concentration. Several samples were measured in this way at temperatures between 4.2°K and room, and, in all cases, the two resistivity measurements agreed to better than 1% at every temperature.

Values of Hall coefficient and Hall mobility are plotted in Fig. 3 and 4. For comparison, the results of Czockralski-grown (3) single crystals are also shown. It is seen that the alloys grown by the Bridgman method in this laboratory have fewer carriers and higher mobilities. The higher mobility for a given alloy composition is probably due to the corresponding lower carrier concentration.

Isothermal Annealing

For the heat treatments, a constant temperature furnace was needed. In order to satisfy this requirement for several temperatures, an annealing furnace was constructed with two concentric furnace tubes, each with a particular type of winding. The outer heater consisted of a wire element very closely wound near each end of the furnace, and gradually more spaced towards the center of the furnace. The temperature profile of this outer heater alone thus peaked at each end and showed a minimum at the center. The inner heater was wound with a constant spacing between the turns and hence its temperature profile showed a broad maximum at the center of the furnace. For all temperatures at which the furnace was used, it was possible to find current settings on the two heaters which gave a resultant temperature variation with position of less than ±1°C over at least 15 cm. The

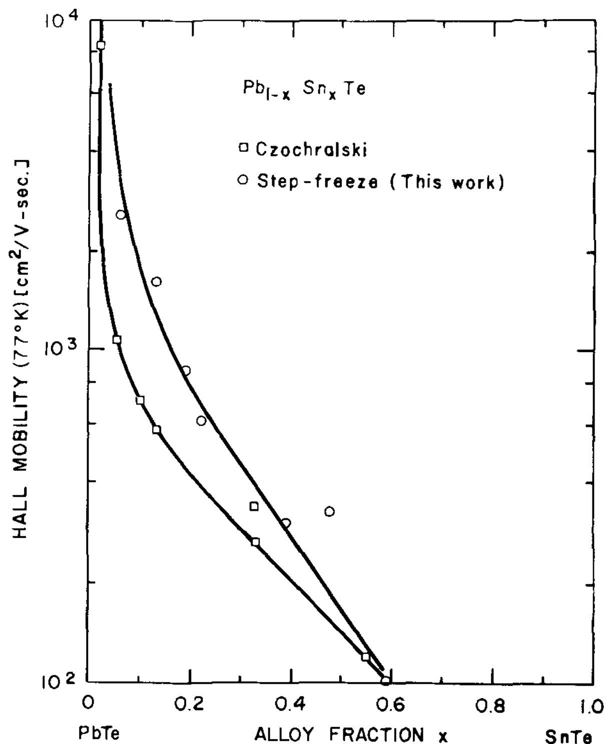

Fig. 3. Hall mobility as a function of alloy composition in the "as-grown" $Pb_{1-x}Sn_xTe$ alloys.

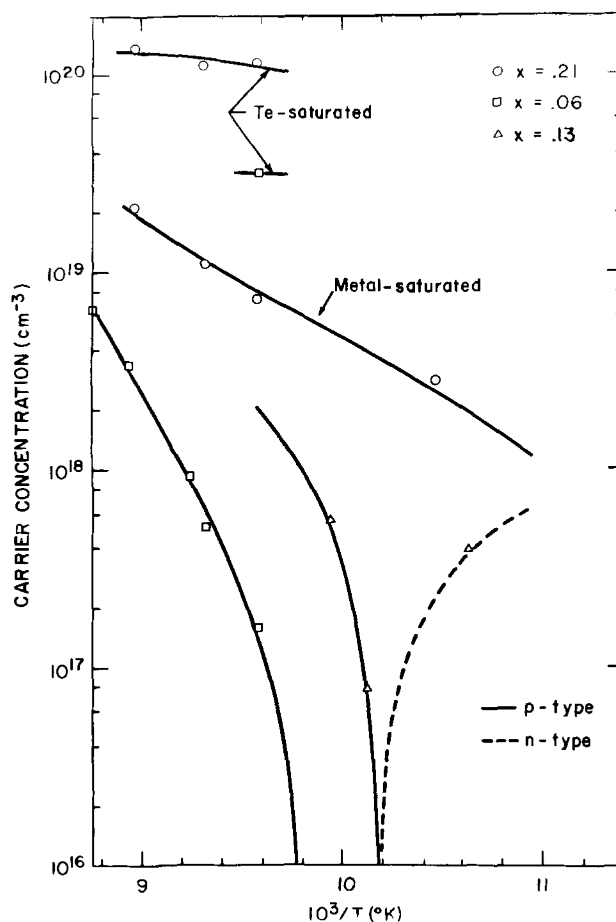

Fig. 4. Carrier concentration ($1/R_0e$) at 77°K as a function of isothermal annealing temperature for $Pb_{1-x}Sn_xTe$ alloys.

furnace temperature was maintained constant with time by a proportional control acting on the outer heater. For each annealing temperature, the appropriate value of the current in the inner heater was found by trial and error. The stability of the temperature over long periods of time was ±2°C.

The explanation of the method used to control the deviation from stoichiometry in $Pb_{1-x}Sn_xTe$ requires a knowledge of the various phase diagrams used to describe nonstoichiometry in MN systems. A general review of this information has been given by Strauss and Brebrick (1). These diagrams suggest several methods by which nonstoichiometry (or carrier concentration) can be controlled. For example, the carrier concentration can be controlled by fixing the temperature and the partial vapor pressure P_{N_2} over solid MN. However, this is a technique that requires special furnaces to control the two variables P_{N_2} and T. Another more practical method was first used by Brebrick and Allgaier in PbTe (11). The technique involved the equilibration under isothermal conditions of a relatively large Pb-rich PbTe charge with a sample of PbTe. The charge and the sample were enclosed in a sealed quartz ampoule, the volume of which was made small enough to prevent any change of composition of the sample by volatilization. When equilibrium is reached, the PbTe sample lies on the Pb-rich solidus line and is made to retain that phase by fast quenching to room temperature. For alloys of the system $Pb_{1-x}Sn_xTe$, this technique would require the preparation of metal rich charges having the same Pb-Sn ratios as those of the samples to be annealed. Here a simplified annealing technique has been used.

This technique is based on the same principle as that of Brebrick and Allgaier (1, 11). If the MN system is closed and contains all three phases (liquid, solid, and vapor), it has only one degree of freedom, and hence fixing the temperature fixes the equilibrium

composition of each phase. Thus, if the composition of the charge and sample combined lies in the liquid-solid region, the solid composition and the liquid composition are fixed by the values of the solidus and liquidus lines at the annealing temperature, and the partial pressure P_{N_2} in equilibrium with the system is fixed by that temperature. When the above condition is satisfied, the composition of the sample changes by solid-state diffusion until, at equilibrium, it reaches the M-saturated or N-saturated solidus line depending on whether the charge is M-rich or N-rich. By varying the annealing temperature, solid specimens can be equilibrated to various nonstoichiometry values, corresponding to various carrier concentrations or compositions.

The simplification of the present annealing technique over those used elsewhere (11, 12) is in the use of minute charges of pure N or pure M only. Since the only requirement is that the composition of the sample and charge combined lie between the solidus and the liquidus curve at the annealing temperature, the amount of M or N needed is given by

$$\text{atoms of M or N} > \{p\ (\text{sample}) - p\ (\text{at the solidus line})\}\ V/c \quad [1]$$

in which p is the carrier concentration, V the volume of the sample, and c is the number of carriers per vacancy, c lying between 1 and 2. For example, consider a PbTe sample, with 2×10^{19} holes cm^{-3} and of dimensions $0.1 \times 0.3 \times 1.0\ \text{cm}^3$, which is to be equilibrated at a temperature for which the Pb-saturated solidus line is at the stoichiometric composition. The number of atoms of pure Pb required is given by Eq. [1] and is $> 6/c \times 10^{17}$. Thus only a little over $0.2/c$ mg of pure lead, introduced in the quartz ampoule with the PbTe sample, is necessary to equilibrate the sample to the stoichiometric composition. The exact amount is not critical and in general more than the amount calculated from Eq. [1] can be used to allow for the uncertainty in the exact value of c and to ensure that the composition of the charge and the sample together is well into the liquid-solid region. At the start of the annealing, the Pb charge is liquid. The excess tellurium in the sample is transferred (*via* vapor phase) to the charge until the charge has collected enough Te to cross the liquidus line. Then, the charge will be partly liquid and partly solid until equilibrium is reached. At equilibrium, the sample is lead saturated and lies on the solidus line. If the amount of pure lead used is so large as to prevent the charge from reaching the liquidus line before the sample reaches the solidus line, then surface melting of the sample will occur to provide the extra Te needed by the charge to reach the liquidus line. Thus, in order to prevent melting of the sample, an upper limit to the amount of pure Pb used as a charge is determined by the position of the liquidus line in the T-x projection [Fig. 1 of Ref. (1)]. This limit is given by

$$\text{atoms of M} < \frac{\Delta pV}{c}\left(\frac{1-x}{x}\right) \quad [2]$$

$$\text{atoms of N} < \frac{\Delta pV}{c}\left(\frac{x}{1-x}\right) \quad [3]$$

in which $\Delta pV/c$ is the right hand side of Eq. [1] and x is the composition of the appropriate liquidus at the annealing temperature. For example, in PbTe $x = 0.1$ at 700°C for the Pb-rich liquidus. From Eq. [2], we find $9(\Delta pV/c)$ as the upper limit to the number of atoms in the Pb charge.

For the $Pb_{1-x}Sn_xTe$ alloy samples, the charges used for N- and M-saturation were pure tellurium and a mixture of lead with tin respectively. The mixtures of lead with tin, at 5 atomic per cent (a/o) intervals, were prepared by melting the elements together at a high temperature and then quenching rapidly. For M-saturation, the mixture having the closest Pb-Sn ratio to that of the $Pb_{1-x}Sn_xTe$ sample to be equilibrated was used. It was not necessary to have exactly the same Pb-Sn ratio in both the charge and the sample because the charge was minute and could not produce an appreciable change in composition x of the much larger $Pb_{1-x}Sn_xTe$ sample. The charges were weighed using a precision balance, and ranged in weight from 0.1 to 1.3 mg. Each sample and its charge were encapsulated in a small quartz ampoule, which was evacuated and backfilled with 1/3 atmosphere of argon to minimize thermal etching of the specimens (12). After the specimens had been equilibrated, the quartz ampoules containing the samples were rapidly quenched in water.

The main advantage of the present annealing technique are: (*i*) the preparation of the charge is simple and the equality of its Pb-Sn ratio to that of the sample is not as critical a requirement as it was in previous techniques (11, 12); (*ii*) the sample and the small charge can easily be separated inside the quartz ampoule and hence no complications such as a "tube within a tube" (12) are necessary to keep them separated; (*iii*) owing to the small size of the quartz ampoules, it is easier to have the whole ampoule in a region of constant temperature in the furnace. This is desirable to prevent transport of the sample, through the vapor phase, to colder regions of the ampoule; (*iv*) the small size of the quartz ampoule permits higher quenching rates. Fast quenching is desirable to prevent internal precipitation (1).

The results of the annealing experiments using the above technique are given in Table II for several compositions of $Pb_{1-x}Sn_xTe$ alloys. The first column gives the sample number. The second column indicates the nature of the charge (M for Pb-Sn mixture, and Te for tellurium), the amount of which was determined using Eq. [1-3] assuming a suitable value for c, and which varied from 0.1 to 1.3 mg for a typical sample volume of $0.15 \times 0.3 \times 1.0\ \text{cm}^3$. The third, fourth, and fifth column give the thickness in mm, the annealing temperature in degrees centigrade, and the annealing time in days, respectively.

The annealing times chosen should be sufficiently long for equilibration. The values of interdiffusion coefficients necessary for the calculation of equilibration times are not available for the various carrier concentrations, alloy compositions, and temperatures used in the present work. However, if the smallest of the two interdiffusion coefficients determined for PbTe

Table II. Results of isothermal saturation annealing experiments obtained from $Pb_{1-x}Sn_xTe$ alloys grown by the step-freeze technique. All carrier concentrations are p-type unless indicated (n) for n-type

Sample No.	Charge	Thickness, mm	Temp. (°C)	Annealing time (days)	Hole carrier concentration at 77°K, cm^{-3}	Carrier mobility at 77°K $\text{cm}^2/\text{V-sec.}$

2-2.1	M	1.0	734	2	5.65×10^{17}	15,000
2-2.4	M	1.0	712	3	7.9×10^{16}	16,000
2-2.3	M	1.0	667	7	3.9×10^{17}(n)	40,600

(13) is assumed to apply for the alloys, the annealing times used here were more than sufficient for equilibrium to be reached in all cases. For example, the interdiffusion coefficient for the annealing temperature of sample 8-8 is 5×10^{-8} so that it would be equilibrated after 1.1 day which is about 25 times less than the annealing time used for that sample.

As with the "as-grown" material, the homogeneity of the annealed samples were checked by measurement of electrical resistivity and Hall effect. Since during the finite quenching time following the annealing, some diffusion may take place near the surface and produce a change in carrier concentration in a thin surface layer, the annealed samples were lapped on all 6 faces to remove about 100μ of material before the Hall and conductivity measurements were made. The homogeneity in carrier concentration, which indicates whether or not equilibration was attained during annealing, was checked by measuring the resistivity at two positions along each specimen. All samples with 21% SnTe and 6% SnTe were measured in this way at temperatures from 77°K to room and in every case the agreement between the two measurements was better than 1%. However at temperatures lower than 77°K, samples No. 6-3 and No. 6-2 showed drastic changes in resistivity and Hall coefficient. It should be pointed out that for these samples with low carrier concentration and high mobility, large surface effects are not unlikely and hence the observed resistivity anomalies need not be due to bulk material inhomogeneities. For all the annealed samples, including No. 6-2, and No. 6-3, metallographic examination revealed no sign of precipitation, supporting the assumption that during quenching either no retrograde solidus line was crossed, or, if such a line were crossed, it was at too low a temperature for precipitation to occur.

Values of carrier concentration ($p = 1/R_oe$) and Hall mobility ($R_o\sigma$) determined at 77°K are given in the sixth and seventh columns of Table II. The variation of p with annealing temperature is also shown in Fig. 4. Similar curves were obtained by Calawa *et al.* (12) in $Pb_{1-x}Sn_xTe$ and the general agreement between the two sets of results is good. However, our 13% SnTe curve shows a crossover temperature (from p-type to n-type) significantly higher than that reported by Calawa *et al.* (12) for the same composition. This difference could be due to the presence of ionized impurities, in addition to ionized vacancies, which would be n-type in our material or p-type in the material of Calawa *et al.*

Technical Notes

Preparation and Properties of Hexaferrite Films

R. C. Taylor* and V. Sadagopan*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Polycrystalline hexaferrite films have been prepared both by RF sputtering and chemical vapor deposition (CVD) techniques for possible semi-transparent photomask (STP) applications. Among the three hexaferrite compositions investigated, the $PbFe_{12}O_{19}$ films prepared by the CVD technique appear particularly interesting for STP applications in view of their satisfactory combination of hardness, optical transmission characteristics, and etchability Hexaferrite films also have a potential application in the area of magnetic bubble domain devices.

The fabrication and utilization of masks is a significant aspect of the manufacture of integrated circuits. It is recognized that the quality of the circuits is largely dependent on the quality of the masks. The lack of transparency of current materials used for contact mask fabrication, such as chromium and photographic emulsions, makes it very difficult to visually align the mask with the structures underneath it, especially when the ratio of opaque to clear area is large. Recently, a number of new materials that are transparent in the visible region and opaque in the ultraviolet around 4000Å have been suggested for STP applications (1, 2, 3). The favorable optical characteristics of these materials permit the accurate visual alignment of the mask and make it possible to use much finer structures for contact printing. The general material requirements for STP applications are: (*a*)

* Electrochemical Society Active Member.

Key words: chemical vapor deposition, magnetoplumbite, optical transmission spectra.

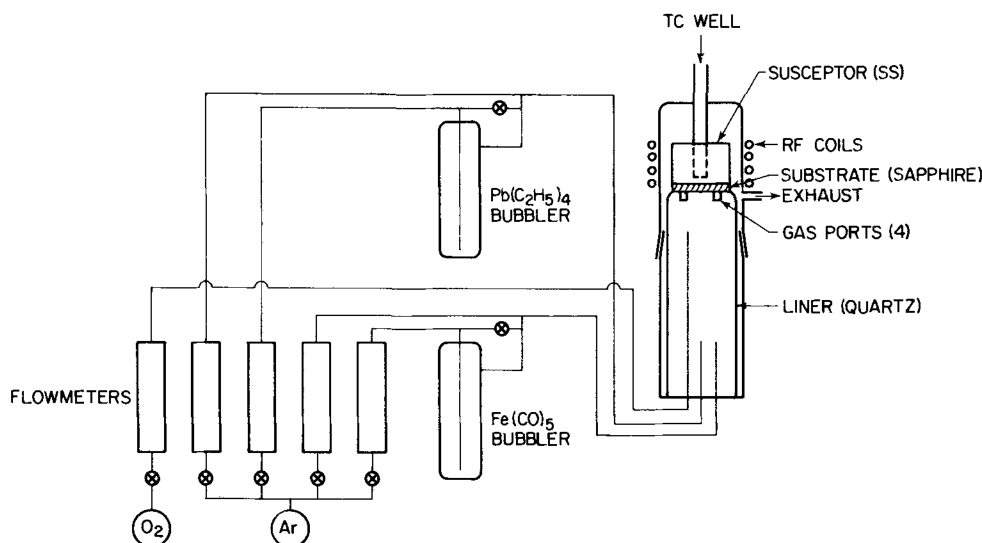

Fig. 1. Apparatus for the deposition of $PbFe_{12}O_{19}$ films by the chemical vapor deposition technique.

zero transmission in the region below 3500A to facilitate masking; (*b*) transmission of greater than 30% at 5890Å to permit visual alignment; (*c*) easy etchability in solvents compatible with photoresist processing; and (*d*) reasonable hardness to provide durability. In the light of the above requirements, we have examined a variety of transition metal oxides in addition to those screened by Sinclair *et al.* (1). Among these, thin films of $GaFeO_3$, prepared by sputtering techniques, and hexaferrite of the composition $PbFe_{12}O_{19}$ (magnetoplumbite), prepared by the CVD method, appear to be promising for STP applications. We present here the details of the CVD method of preparation of $PbFe_{12}O_{19}$ and its optical transmission characteristics and compare the optical properties of the latter with those of other hexaferrite films with compositions such as $BaFe_8Ga_4O_{19}$ and $BaFe_{8.5}Al_{3.5}O_{19}$.

Polycrystalline films of magnetoplumbite have been vapor deposited onto single crystal sapphire substrates by pyrolysis of iron pentacarbonyl and tetraethyl lead in the presence of oxygen. The structure of the films was examined by standard x-ray diffraction techniques.

The apparatus for the chemical vapor deposition of magnetoplumbite is shown schematically in Fig. 1. The reactants, tetraethyl lead and iron pentacarbonyl, are contained in two quartz bubblers which are painted black to prevent photodecomposition of the reactants into free organic radicals and $Fe(CO)_9$. Each source bubbler is connected to two flowmeters, one for metering the transport argon flow and one for the argon diluent flow. The reactant and oxygen vapors feed into a vertical quartz reactor. The quartz liner inside of the reactor is tapered at the top to support the substrate and contains four slits below the substrate which serve as gas exhaust ports. A stainless steel susceptor is in contact with the upper surface of the substrate and is RF heated. The thermocouple well goes almost to the bottom of the susceptor to monitor the substrate temperature. The substrate is mounted at the top of the reactor to prevent wall deposits from falling onto it. In a typical deposition of $PbFe_{12}O_{19}$ onto a C-axis sapphire substrate, the reactant bubblers are kept at room temperature and the substrate is heated to 400°C. Argon flow is regulated to 50 cm³/min through the tetraethyl lead bubbler, and 7 cm³/min through the iron pentacarbonyl bubbler, resulting in transport rates of 6×10^{-5} moles/hr $Pb(C_2H_5)_4$ and 7×10^{-4} moles/hr $Fe(CO)_5$. The oxygen flow rate is 50 cm³/min. Under these conditions, a film of approximately 1000Å thickness is deposited in 3-4 hr. The films are polycrystalline with the standard hexaferrite structure. Attempts at film orientation by post-deposition annealing at 1000°C resulted in decomposition with the loss of PbO and a residual deposit of Fe_2O_3 on the substrate.

The effect of substrate temperature on the rate of PbO deposition by the oxidation of $Pb(C_2H_5)_4$ has been studied. The results are shown in Fig. 2. The shape of the curve shows the usual effects of kinetic control at low temperature, diffusion limitation at intermediate temperature, and gas-phase reactant depletion at higher temperature. These results were combined with those of MacChesney (2) and Carlton (4) for $Fe(CO)_5$ to arrive at the approximate deposition conditions.

Thin films of other hexaferrite compositions ($BaFe_8Ga_4O_{19}$ and $BaFe_{8.5}Al_{3.5}O_{19}$) for possible STP applications have been prepared by standard RF sputtering techniques starting from either a powder target or a bulk pressed disk. The films were prepared both in argon and in oxygen atmospheres. The details of the sputtering parameters and their effect on the structure, orientation, deposition rate, and composition of the films will be presented elsewhere.

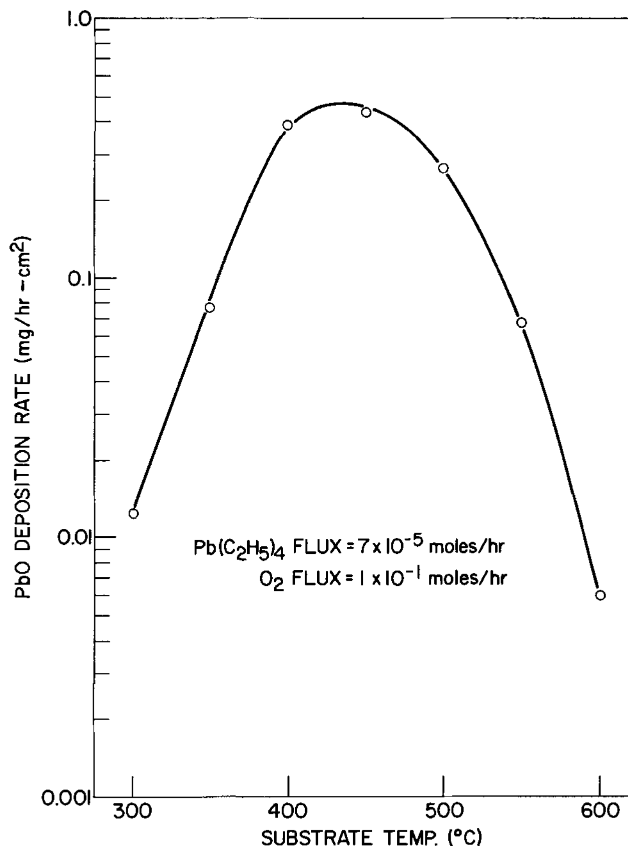

Fig. 2. Deposition rate of PbO vs. substrate temperature (°C)

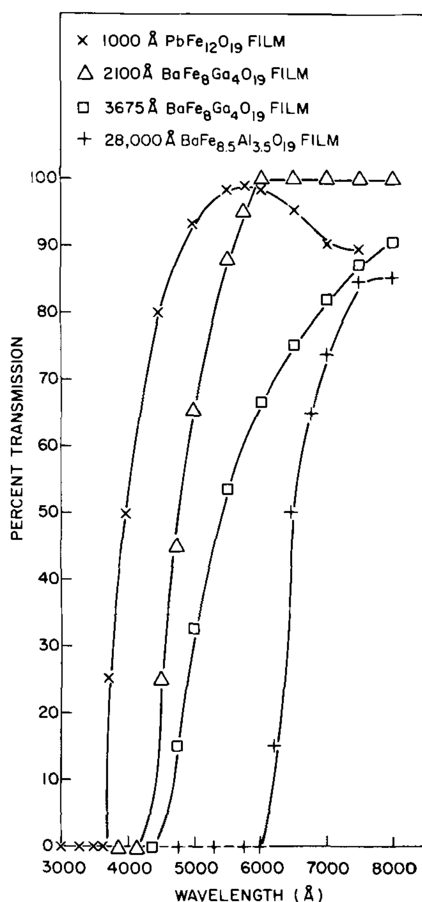

Fig. 3. Optical transmission vs. wave length of selected hexaferrite compositions; 1000Å $PbFe_{12}O_{19}$ film was prepared by CVD method; 3675Å $BaFe_8Ga_4O_{19}$ and 28,000Å $BaFe_{8.5}Al_{3.5}O_{19}$ films were prepared in argon atmosphere in contrast to the 2100Å $BaFe_8Ga_4O_{19}$ film which was prepared in oxygen atmosphere. A 2800Å argon-sputtered $BaFe_{8.5}Al_{3.5}O_{19}$ film had transmission features similar to the data presented in this figure.

All the deposited films adhered well to the substrates and could not be scratched by a stainless steel needle. Their durability is thus satisfactory although no quantitative measurement of their abrasion resistance was made. The films with thickness greater than 2000Å were free from pinholes. The optical transmission characteristics of the different hexaferrite compositions are presented in Fig. 3. The data shows that the hexaferrite films sputtered in argon ambient have a broad absorption edge in contrast to the sharp absorption edge exhibited by films sputtered in oxygen ambient. The broad absorption edge of argon-sputtered films is interpreted to arise from oxygen nonstoichiometry in such films. Among the three hexaferrite compositions investigated, $BaFe_{8.5}Al_{3.5}O_{19}$ films are not transparent in the 5890A (see-through) region (Fig. 3) and, hence, are not considered useful for STP applications. On basis of their favorable optical spectra, the vapor deposited $PbFe_{12}O_{19}$ and sputtered $BaFe_8Ga_4O_{19}$ films qualify for use in STP technology. The sputtered films, however, are remarkably resistant to chemical attack by acids that are compatible with photolithographic processing. On the other hand, vapor deposited $PbFe_{12}O_{19}$ films are readily and uniformly etched by dilute HCl (9%) at room temperature at the rate of 300 Å/min. The observed differences in the etching behavior of sputtered and vapor deposited hexaferrite films are attributed to differences in morphology of the deposits unique to the individual film fabrication techniques (2). The ease with which vapor deposited $PbFe_{12}O_{19}$ films dissolve in dilute HCl is, however, not an adequate criterion for its selection as a STP mask. An etched pattern could still be ragged if the rate of etching were distinctly different in different crystallographic directions. Etched test patterns have been obtained with satisfactory resolution. It is believed that the slow rate of deposition of $PbFe_{12}O_{19}$ is partially responsible for the uniform etching. Thus, slow deposition might be an advantage rather than a handicap for this material.

In summary, on the basis of their adequate hardness, favorable optical absorption characteristics, satisfactory etchability, and ease of fabrication, the vapor deposited films of $PbFe_{12}O_{19}$ are considered to be of particular interest for STP applications in the manufacture of semiconductor integrated circuits. Further, the optical and etching characteristics of $PbFe_{12}O_{19}$ films compare favorably with those of vapor deposited films of Fe_2O_3, the only other material that, so far, has met the stringent criteria for masks capable of real time visual alignment. In addition to their potential usefulness for STP applications, the hexaferrites would be of considerable interest in the area of magnetic bubble domain devices if deposition conditions and substrate materials were modified in order to give single crystal films.

Acknowledgments

The authors are indebted to W. J. Haag for technical assistance in film growth and to E. A. Giess for fabrication of hexaferrite targets used in the sputtering part of the study.

The Detection of Silicon-Oxynitride Layers on the Surfaces of Silicon-Nitride Films by Auger Electron Emission

H. G. Maguire and P. D. Augustus

Allen Clark Research Centre, The Plessey Company Limited, Caswell, Towcester, Northants., England

Considerable attention has been paid recently to the properties of silicon nitride films as the diffusion mask and gate dielectric since the advent of the insulated-gate field-effect transistor, and a great amount of effort directed toward the investigation of these films for semiconductor device applications. There are many purposes for which dielectric films may be used in devices but for most practical device applications it is normally desirable to achieve a single-phase film in order to avoid possible inhomogeneous properties associated with mixtures. In order to possess uniform properties, these films should be amorphous in structure, impervious to contaminants to reduce instability effects, and be compatible with the substrate for acceptable mechanical and electrical characteristics. Previous work (1) concerning films intermediate in composition between silicon nitride and silicon dioxide has not been clear in distinguishing between the solid solution and mixture possibilities. Recent work, however, using electron diffraction (2) indicates that the silicon nitride and silicon dioxide end members form a continuous series of solid solutions rather than mixtures. Generally, a variation in the gas composition during deposition (3, 4) influences the stoichiometry of the nitride layers which will cause the electrical and optical properties to vary.

Apart from the electron diffraction work mentioned above, there does not appear to have been any investigation using microscopic techniques on these films. However, recently, backscattering and channeling effect measurements with MeV ^{4}He ions have been used to analyze the composition as a function of depth of oxide and nitride layers on silicon (5). The composition was determined to be stoichiometric for high ratios of NH_3 to SiH_4 used in the deposition reaction but, for lower ratios, departures from this were found. Previously these techniques had been used to analyze ion implanted layers (6-8) and surface contamination (9), and α-particle backscattering from a radioactive source such as 242 Cm has also been used in chemical analyses of surfaces (10).

In view of the importance of nitride films in MNS and MNOS device fabrication, the present investigation of the surfaces onto which metal electrodes, normally aluminum, are to be deposited was undertaken using the techniques of Auger emission spectroscopy and low-energy electron diffraction. Using Auger electron emission, the surface of the sample to be studied is bombarded by primary electrons of several keV of energy while the energy distribution of the secondary and backscattered electrons is observed. Within this energy distribution, Auger electrons are observed with energies characteristic of the atoms from which they arise (11, 12). The low energies of the Auger electrons (below 1 keV) ensure that the observed effects arise from atoms very near the surface and the Auger method is particularly sensitive for the detection of the lighter elements on solid surfaces.

Experimental

The variables of importance which affect the deposition rate of Si_3N_4 and its subsequent properties are the composition and flow rate of the reactant mixture and the substrate temperature. In this work all depositions were carried out on Si substrates at a temperature of 900°C with ammonia as the major constituent in the reaction mixture. The flow rate of silane was 5 ml/min, while that of ammonia was 500 ml/min. The flow rate of the nitrogen carrier gas was 30 liter/min. Using these mixtures, the reaction kinetics taking place during the pyrolytic formation of Si_3N_4 films is quite complicated and the possible reactions that may occur have already been considered in some detail (1).

Key words: Auger, LEED, plasmon, ellipsometry.

Of the many films of varying thicknesses that were grown under identical conditions, two were selected, one having a growth time of 1.5 min and the other 2.5 min, giving films of thicknesses 610 and 1010Å, and refractive indices of 1.88 and 1.95, respectively. These quantities were determined using ellipsometry.

The Auger spectrometer used, which was modified from a LEED system (13-15), consisted of three-grid electron optics constructed in these laboratories, with the electron gun producing a beam current of about 1 μA at normal incidence to the specimen. The specimens used were typically 1 cm $\times$ 5 mm $\times$ 0.2 mm thick and were resistively heated while held in tantalum clips. A modulating frequency of 2 kHz was used throughout, and detection of the Auger signal was carried out by recording the second harmonic which yielded the derivative of the energy distribution, $dN(E)/dE$. Peak-to-peak modulation varied from 15V for detection in the higher energy range down to 3V in the lower energy range. All the observations described here were made using incident beam energies of not more than 1.5 keV.

After initial pumpdown from atmospheric pressure and overnight bakeout, a working pressure of 5 $\times$ 10^{-10} Torr was achieved which never exceeded 2 $\times$ 10^{-8} Torr during initial outgassing of the specimen. Temperatures were measured using an optical pyrometer with appropriate corrections made for emissivity and transmission through the viewport.

Both sides of the specimen were subjected to examination, and for comparison the first derivative of the energy distribution of secondary electrons from Si_3N_4 and Si is shown in Fig. 1. The peaks at 522 and 495 eV are due to oxygen and are attributed to the $KL_{2,3}L_{2,3}$ and KL_1L_1 transitions, respectively (16). The peaks occurring at 389 and at 362 eV are the $KL_{2,3}L_{2,3}$ transition of nitrogen and its associated plasmon. The peak at 270 eV is the $KL_{2,3}L_{2,3}$ transition of carbon which is found on most samples freshly inserted into the UHV chamber and is increased by contamination from residual hydrocarbons during bakeout.

The remaining peaks below 100 eV from both sides of the specimen are due to silicon and reflect the effect of chemical binding. The spectrum from clean silicon which has been adequately discussed elsewhere (17-19) and will not be considered further, is shown in the upper trace of Fig. 2.

Heating the specimen at 1140°C for 5 min was sufficient to remove the oxygen from the silicon side of the specimen, but only a slight reduction in the oxygen peak was detectable on the nitride side from which practically all the carbon had desorbed. The same heat treatment for a further 20 min followed by argon ion bombardment (1 μA at 500V for 30 min) removed the nitrogen and remaining carbon from the silicon side,

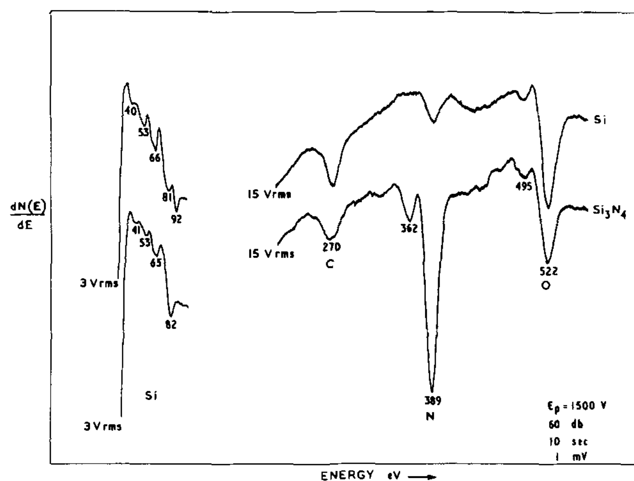

Fig. 1. The first derivative of the energy distribution of secondary electrons from Si (upper trace) and Si_3N_4 (lower trace) for the as-inserted specimen showing the presence of C and O on both sides of the specimen, together with the degraded spectrum of silicon.

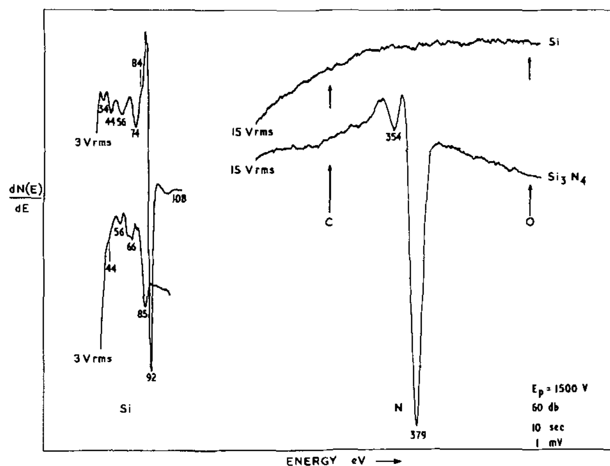

Fig. 2. The same specimen as in Fig. 1 but showing clearly the effect of the desorbtion of C and O from both sides of the specimen.

and was accompanied on the nitride side by an increase in the nitrogen peak.

Further heating for up to 2 hr was necessary in order to dislodge the remaining oxygen with an increase in the magnitude of the nitrogen peak to a final steady value. The silicon spectrum from the silicon side (Fig. 2) now has the character normally associated with "clean" silicon while that from the nitride has changed with the desorption of carbon and oxygen, and reflects the effect of chemical binding in the nitride.

Measurements of the thickness of the layers by ellipsometry after removal from the UHV chamber showed that they had decreased by about 30Å, and that the refractive index had increased to just over 2.0. This may be compared to a value of about 1.99 obtained with a reactant molar ratio $O_2/SiH_4 = 0$ (4).

Both specimens were scanned on a Perkin-Elmer 337 infrared spectrometer at room temperature, before and after the above-mentioned heat-treatment in UHV. No shift was found for either of the samples in the broad absorbtion band characteristic of the stretching of the Si-N bond. However, the absorbtion peaks differed for the two films; that for the thinner film occurring at about 870 cm^{-1} and that of the thicker film at about 840 cm^{-1}. Evidently the small amount of oxygen we are dealing with here limits severely any useful comparison using infrared techniques.

We have at all stages monitored the surfaces for LEED patterns and after the initial heat-treatment obtained a good, clear (7 × 7) pattern on the silicon side. No patterns were obtained at any time from the nitride layer.

Summary and Conclusions

Amorphous layers of silicon nitride of varying thickness have been deposited on silicon substrates by the pyrolysis of silane with ammonia. Care was taken to exclude likely sources of oxygen contamination. Using Auger emission spectroscopy, we have examined the surface of these layers and of silicon on the reverse side for comparison.

Initial heating of the specimen at 1080°C for about 40 sec was sufficient to desorb the oxygen from the silicon surface but only produced a slight reduction in the size of the oxygen peak from the nitride. Further heating at 1140°C did not result in a decrease in the oxygen signal. This then would suggest that on top of the silicon nitride layer is another layer consisting of silicon oxynitride, $Si_xO_yN_z$, and further that it is about 30Å thick, as deduced by ellipsometry. It is possible that this film is more common than had been previously realized in which case one would not have a strictly metal-nitride interface but a metal ($Si_xO_yN_z$-nitride) interface. The effect of this on film characteristics is noticeable. One notices immediately a rise in the refractive index once all the oxynitride layer has been removed by prolonged heating in ultrahigh vacuum. The differing values reported in the literature for the refractive index for zero oxygen to silane ratios may in fact be due to the presence of just such a layer. It is expected that the presence of an oxynitride layer on the nitride will influence the value of the dielectric constant but it would appear that here it is the ratio of ammonia to silane in the formation of the nitride layer that is more important. It would also be of interest to investigate the effect of these films on the I-V and C-V characteristics bearing in mind the stronger polarity dependence of the oxynitride over the nitride.

Though every precaution was taken to ensure an oxygen free system, the only plausible explanation for the presence of oxygen is as an impurity in one of the reactor gases. The fact that oxygen occurs only in the top 30Å would suggest possible contamination of the nitrogen carrier gas with water and/or oxygen, remembering, of course, that after the flow of the silane and ammonia is stopped, the specimen is left to cool with the nitrogen still on, during which time the surface of the layer remains at a sufficiently elevated temperature to react with the oxygen to form an oxynitride. Under these circumstances it would be difficult to avoid formation of such a layer at all.

In conclusion we may consider the mechanism by which the oxygen is desorbed. Assuming that oxygen on the surface from the interior is not an important factor since oxygen exchange between the surface and the bulk at temperatures below 1000°C is an exceedingly slow process (20), then removal of oxygen from the silicon is facilitated by evaporation of silicon monoxide which does not form associated molecules (21). As far as removal of oxygen from the nitride by total depletion of the oxynitride is concerned, we would tentatively suggest that silicon released from the rapid pyrolysis of silane results in a nitride layer containing excess silicon. Formation of the oxynitride then proceeds as suggested above, with the subsequent removal of oxygen by evaporation of silicon monoxide formed by the reaction of this excess silicon with the oxygen in the oxynitride layer. This process would require diffusion of the excess silicon from the nitride to react with oxygen to form volatile silicon monoxide but at a much slower rate than happens on the reverse side where silicon is readily available; hence the extended period of heating necessary to bring about removal of oxygen.

Acknowledgments

Thanks are due to The Plessey Company Limited for permission to publish these findings and to R. Oakley who prepared the specimens and carried out the ellipsometric measurements.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 118, No. 2, 9, and 12; February, September, and December 1971.

Observation of Mixed Thermoelectric Power in ThO_2

N. M. Tallan and I. Bransky (pp. 345-349, Vol. 118, No. 2)

D. S. Tannhauser[1]: In the paper by Tallan and Bransky, and in a previous one by Ruka, Bauerle, and Dykstra,[2] the change of thermoelectric power of an ionically conducting oxide is measured when the atmosphere surrounding the sample is changed. The materials are ThO_2 in the paper being discussed, and $(ZrO_2)_{0.85}(CaO)_{0.15}$ in the paper by Ruka *et al.*[2] The atmosphere varies from pure oxygen through mechanically diluted oxygen to mixtures of CO_2/CO and H_2O/H_2. The change of thermoelectric power, referred to that measured in an arbitrary standard atmosphere, is then plotted against the difference between physical quantities, which are called in these papers the partial molar entropies of oxygen, and which are calculated for the atmospheres involved. Agreement between experiment and theory is good.

It is the purpose of this note to point out that the use of the term "partial molar entropy" in these papers is wrong. This does not affect the validity of the papers but we believe it is worthwhile to point this out since the use of thermodynamic concepts in an incorrect way can be misleading and has often led to the wrong results.

According to Darken and Gurry[3] the definition of the partial molar entropy of component j in a multicomponent mixture is

$$\bar{S}_j = \left(\frac{\partial S'}{\partial n_j}\right)_{T,P,n_{i\neq j}} \quad [1]$$

Here S' is the total entropy of the mixture, n_j is the molar fraction of component j, and T and P are temperature and pressure of the mixture.

Darken and Gurry[3] then derive the following relation (their Eq. [10-23]) between the chemical potential and the partial molar entropy

$$\left(\frac{\partial \mu_j}{\partial T}\right)_{P,n_i} = -\bar{S}_j \quad [2]$$

In Eq. [2] the derivative with respect to temperature is calculated with all n_i as well as P constant. This derivative has a real physical meaning for a mechanical mixture of components, *i.e.*, components which do not react with each other, since there one can actually vary the temperature while keeping P and all n_i constant.

For a chemical mixture in equilibrium this derivative does not have a physical meaning. It implies clamping of the composition of the mixture (*e.g.*, CO_2, CO, and O_2) while the temperature is varied at constant pressure; and this clamping is not compatible with chemical equilibrium. However, the definition of Eq. [1] as well as the relation given in Eq. [2] still holds.

Tallan and Bransky show that the heterogeneous part α_{het} of the thermoelectric power $\alpha = \alpha_{het} + \alpha_{hom}$ of an oxide conducting by $O^=$ ion diffusion can be expressed as

$$\alpha_{het} = -\frac{1}{q}\left[\frac{1}{2}\frac{\partial\mu(O_i^=)_{oxide}}{\partial T} - \frac{1}{4}\frac{\partial\mu(O_2)_{gas}}{\partial T} - \frac{\partial\mu(e^-)_{Pt}}{\partial T}\right] \quad [3]$$

They then calculate the change with oxygen partial pressure of α, after assuming that α_{hom} is independent of oxygen partial pressure and that the only term in α_{het} that depends on oxygen partial pressure is the second term on the right of Eq. [3]. This gives the equation

$$\alpha_{gas\,1} - \alpha_{gas\,2} = \frac{1}{49}\frac{\partial\mu(O_2)_{gas\,1}}{\partial T} - \frac{1}{49}\frac{\partial\mu(O_2)_{gas\,2}}{\partial T} \quad [4]$$

---

[1] Department of Physics, Technion—Israel Institute of Technology, Haifa, Israel.

[2] R. J. Ruka, J. E. Bauerle, and L. Dykstra, *This Journal*, 115, 497 (1968).

[3] L. S. Darken and R. W. Gurry, "Physical Chemistry of Metals," p. 238, McGaw Hill Book Co., New York (1953).

Equation [4] is verified by plotting experimental values for $\Delta\alpha$ against calculated values of $\Delta\partial_{\mu}(O_2)_{gas}/\partial T$. The latter are calculated by the use of the equation

$$-\frac{\partial\mu(O_2)}{\partial T} = 2\left[\bar{S}^\circ(CO_2) - \bar{S}^\circ(CO) - R\ln\frac{P(CO_2)}{P(CO)}\right] \quad [5]$$

which is valid for a chemical gas mixture in which the ratio $P(CO_2)/P(CO)$ is independent of temperature.

Tallan and Bransky as well as Ruka, who apparently did the same calculation, call the derivative in Eq. [5] the partial molar entropy and denote it by $\bar{S}(O_2)_{gas}$. This, as stated above, is not correct, since the derivative is calculated for conditions in which the partial pressure, and, therefore, the molar fraction of oxygen, is a function of temperature.

The original theory of the thermopower of chemical cells was developed by Holtan, Mazur and de Groot.[4] After Eq. [38] of their paper, they introduce ΔS as the change of entropy due to the heterogeneous electrode reaction, but they do not call this term the partial molar entropy. We repeat again that the calculations in the paper discussed here and in the paper by Ruka *et al.*[2] are correct, but the use of the expression "partial molar entropy" is misleading.

Equation [4] can, incidentally, be interpreted in a manner which is more familiar to electrochemists: we can write

$$\alpha_{gas} - \frac{1}{4}\frac{\partial\mu(O_2)_{gas}}{\partial T} = \text{constant}$$

and after multiplying by dT this equation gives

$$V_a - V_b = \frac{1}{4}[\mu(O_2)_a - \mu(O_2)_b] + \text{constant}$$

which, except for the constant term, is the equation of an electrochemical cell with different oxygen activity on its two sides a and b. The constant nonzero term, generated by the temperature gradient, comes from the entropies of transport of ions in the electrolyte and electrons in the platinum electrode which are assumed in Tallan and Bransky's paper and in the paper by Ruka *et al.*,[2] to be independent of oxygen pressure.

Phosphorescence Decay of Calcium Oxide Activated by Yttrium

L. M. Schwarz, J. M. Voutay-Poncet, and J. Janin
(pp. 1512-1514, Vol. 118, No. 9)

W. Lehmann[5]: This paper is misleading as it implies luminescence in calcium oxide due to "activation" by yttrium, *i.e.*, to traces of yttrium dissolved in the CaO lattice. We have looked into this system as well as into many other combinations of CaO with various other impurities. To set the matter clear, neither we nor the authors of this paper[6] have observed any luminescence in CaO clearly attributable to yttrium. Yttrium may possibly have an influence on the trap distribution in CaO and, thus, on the decay characteristic of phosphorescence of CaO activated by whatever else it might be. However, yttrium is no activator of luminescence in calcium oxide in the commonly used sense.

L. M. Schwarz: Dr. Lehmann's comment is right. The choice of the word "activated" is wrong. The system CaO(Y) has no fluorescence. Nevertheless the CaO samples we have examined are very phosphorescent and thermoluminescent at all temperatures. The addition of small quantities of certain elements like Ga, Y, Hf, *etc.*, increases the phosphorescence and then allows the study of its decay during a very long period. That is the only purpose of this paper.

Dielectric Breakdown in Electrolytic Capacitors

F. J. Burger and J. C. Wu (pp. 2039-2042, Vol. 118, No. 12)

S. E. Libby[7]: Determination of the breakdown voltage of tantalum samples, when anodized in simple aqueous electrolytes at room temperature, was carried out. Several series of electrolytes were used. In each electrolyte series, the anion and its concentration was held constant and the cation species was varied, thereby varying the resistivity of the electrolyte solutions.

Tantalum samples were 2 × 2 cm flags with an integral tab 0.5 × 2 cm. The samples were cut from capacitor grade foil 0.001 in. thick. The samples were prepared for anodization by vapor degreasing trichloroethylene, washing in warm detergent solution, and rinsing in deionized water. Anodization was carried out using a constant current of 0.005 A/cm². The electrolyte was controlled at 25° ± 1°C and strongly stirred to avoid local heating effects.

Breakdown voltage was defined as the voltage at which the first observable deviation from linearity occurred in the voltage-time plot as recorded by a chart recorder with 10 V/in. scale factor. A VTVM with 11 megohm input impedance was used as a preamplifier to reduce loading effects. The measured breakdown voltage was corrected for *IR* drop in essentially the same manner as that used by Burger and Wu.

The following summary of an electrolyte series using acetate as the anion (Table I) serves to indicate the nature of the results obtained. Each electrolyte in the series was prepared in such a manner that the concentration of the acetate ion was 0.010M. Seven to ten determinations of breakdown voltage were carried out in each electrolyte.

Other series having different anions (Cl^- and NO_3^-) and different anion concentrations (0.01 to 0.5M) were also used and the results were consistent: for a given anion and anion concentration, the breakdown voltage was constant and not dependent on the electrolyte resistivities.

It is obvious that these results do not remotely resemble those reported by Messrs. Burger and Wu. I can in no way account for the disagreement unless it is due to my use of electrolytes which are simple compared to those which they employed.

F. J. Burger and J. C. Wu: There are major differences in experimental technique which may account for discrepancies between our results and those of S. E. Libby. For example, he uses a current density ten times our own which was 0.5 mA/cm², also his temperature is 25°C, compared to our 85°C, his choice of acetate as the electrolyte bears a likely responsibility. Not all of our electrolytes are complicated, indeed electrolytes K, M, and O, as described in our paper, are quite simply dilute aqueous solutions containing 0.1, 0.03, and 0.01 parts by weight of phosphoric acid, respectively.

The conclusion at this stage must, therefore, be that some anomalies occurred in Mr. Libby's formation experiments which prevented the full potential of breakdown voltages from being attained. His voltages are from about 120 to 160V below what might have

[7] Pownal Center, Vermont 05261.

Table I.

Electrolyte	Resistivity at 25°C	Mean breakdown voltage	Standard deviation
$HC_2H_3O_2$	705 ohm-cm	343V	7.0V
$KC_2H_3O_2$	1020 ohm-cm	350V	4.2V
$Cu(C_2H_3O_2)_2$	1900 ohm-cm	345V	5.5V

been predicted from electrolyte resistivities as supplied by him, in accordance with our experience.

The empirical linear relationship between breakdown voltage and log of electrolyte resistivity, as described by us, should be looked upon as a limiting relationship in the sense that the observed breakdown voltages have been found to be the highest attainable, provided no side reactions occur that interfere with the formation process. In the case of aluminum, we have singled out certain corrosion reactions as examples of the interference mechanisms. Anomalies of a different kind are known to occur in the tantalum system, *e.g.*, characterized by the production of the so called "gray" oxide. Whereas in the case of tantalum it has been found relatively easy to develop electrolyte systems and discover conditions that ensure trouble free anodization, this has been much less successful in the case of metals such as Nb and Zr; this latter point was briefly mentioned in our paper.

ABSTRACT

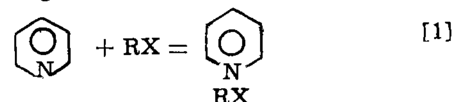
The specific conductance of pyridinium HCl, N-methylpyridinium chloride, N-methylpyridinium bromide, 4-methylpyridinium bromide, and pyridinium bromide, was measured as a function of temperature. The NMR spectra of the first three fused salts were also measured over the same temperature ranges. Correlations between conductance data and spectral data were found to exist. The experimental results indicate that the "friction" between the chloride and pyridinium ion is greater than between the bromide and the pyridinium ion. The positive charge of the pyridinium ion seems to be localized on the nitrogen. In the pyridinium HCl system the labile proton is probably contributing to the conductivity.

The present investigation focuses its attention on a series of fused pyridinium salts with the intention of correlating a transport property, the conductance, with a spectral property. The pyridinium salts were chosen for study for a variety of reasons. They are potentially very important as the conducting media in high-temperature batteries. They are useful solvents for synthetic purposes and for investigations of the structure of complex ions (1). They are low-melting, noncorrosive to Pyrex, stable over a relatively wide temperature range, and easily synthesized. Because of their low melting points, many of the pyridinium salts are accessible to study by NMR techniques as well as by more conventional means. The intriguing possibility of obtaining direct correlations between transport properties and spectral properties, therefore, presents itself.

This kind of correlation between a structural property and a transport property, though very useful, has been made in only a limited number of fused-salt systems and then only fairly crudely. For example, there is a rough correlation between ion size and mobility. The reason why the literature lacks such correlations is that transport properties result from a combination of short and long range forces, but a typical transport property experiment does not give the individual contribution of each kind of force. Spectral measurements predominately elucidate short range forces except when lattice vibrations are being studied so that both kinds of measurement on the same system under similar conditions are thus necessary to remove ambiguity and characterize the melt. The salts studied, and their melting points, are shown in Fig. 1.

Experimental

Synthetic methods.—Each of the salts was synthesized in fundamentally the same way based on the method first described by Rozdhestvenskii and Brode (2). The appropriate anhydrous gas, acting as a Lewis acid, reacted with pyridine [in the case of (IV), 4-methylpicoline] which acted as a Lewis base. The equation describing the neutralization reaction is



[1]

Reagent grade pyridine was dried over BaO and then distilled. The dried distilled pyridine was mixed with anhydrous reagent grade ether to form a 40% pyridine solution. The anhydrous halide gas was then

bubbled through this solution. After about 45 sec, white crystals of salt became visible. The reaction takes place in pure pyridine, but the yields of salt are better and the subsequent purification processes are easier using the pyridine-ether mixture. The reaction is slightly exothermic so the reaction flask was placed in an ice bath.

After the salt had formed, the excess ether and pyridine were removed, first by decantation and then by evaporation from a rotatory solvent evaporator. The resulting salt was identified by its infrared spectrum in a KBr pellet and by its melting point.

All transfer operations were carried out in a dry box or glove bag because the salts are hygroscopic.

Conductance measurements.—The specific conductance, κ, of each salt was measured with an Industrial Instruments bridge at 1000 Hz. The salts were contained in a Pyrex capillary cell. Cylindrical platinum electrodes were used.

The advantages of this type of cell over conventional cells for fused salt conductance measurements are many (3), but the most important advantage is that the cell constant does not vary significantly as function of temperature. The major portion of the salt's resistance occurs in the capillaries which increase in both diameter and length as the temperature is raised. A Teflon stopper, machined to fit the outer half of a 29/42 ground-glass joint, served as the top of the cell. Three holes were drilled in the Teflon stopper. Two of them were for the electrode compartments and the third was for a gas outlet tube. Using a Teflon top, rather than a glass top, made it much easier to remove the salt after an experiment and substantially increased the life span of the cell. A small hole in each of the glass tubes above the capillaries allowed trapped air and other gases to escape, thereby facilitating the rise of the fused salt into the capillary.

Dow-Corning 710 silicone oil was used as the heat transfer medium in the constant temperature bath. This oil has a flash point of 300°C. The temperature was regulated to ± 0.2°C. The cell constants were measured at 25°C using a 1 Demal-KCl solution. They ranged from 150 to 1500 cm^{-1} depending on the diameter of the capillaries used.

A minimum of two series of conductance measurements of each of the salt samples were made. Conductance readings were taken at 10° intervals over a temperature range bounded at one end by the melting point of each salt and at the other by the boiling point or the decomposition point of those salts that showed signs of decomposition. The system was allowed to stabilize at each temperature for 20 min. The readings at the highest temperature were taken first, then the next highest, etc. The process was then repeated. A second sample of the salt was treated in the same fashion.

NMR spectroscopy.—The NMR spectra were obtained using the variable temperature probe of a Varian A56/60A NMR machine. A sample of salt was transferred into an NMR tube in a dry box. Both hexamethyldisilane and hexamethyldisiloxane were tested as reference materials. The disilane was selected because of its higher melting point. In the subsequent discussion all chemical shifts of fused pyridinium salts will refer to this material. To correct to TMS, an addition of 3.83 Hz is required.

The NMR tubes were sealed under a partial vacuum and then removed from the dry box. The filled tubes were next placed in the oil bath. The bath temperature was raised to just over 200°C, the upper temperature limit of the NMR machine, or until the salt began to decompose noticeably. The bath temperature was then lowered to below the melting point of the salt being studied. This thermal cycling was repeated several times to assure the stability of the particular salt sample and to minimize the chance of a tube exploding in the NMR machine. After cycling, the NMR spectrum of each salt was taken, as a function of temperature, from just below 200°C to its melting point. N-methylpyridinium chloride showed signs of decomposition at approximately 180°C so this temperature was set as an upper limit for this salt. The NMR machine was allowed to stabilize for at least 15 min at each selected temperature. In most instances sharp spectra could be obtained well below the normal melting points of the salts which implies they are easily supercooled.

Results

The conductance data measured as a function of temperature are shown in Table I. The complete NMR spectrum of (I), measured with a sweep width of 1000 Hz at 156°C, is shown at the bottom of Fig. 2. The ring protons are emphasized using the slower sweep (250 Hz) at the top of Fig. 2. The entire spectrum is offset 100 Hz.

The chemical shifts of the ring protons as well as the chemical shift of the R group attached to the nitrogen are listed for all three compounds in Table II. The chemical shifts of the α, β, and γ hydrogens of (III), dissolved in DMSO, are also listed, with an asterisk, in the table for comparison (4).

The coupling constant, $J_{\beta\gamma} = \delta_\gamma - \delta_\beta$, was essentially the same for all four systems and had a value of 3.6 Hz with a variation of ± 0.1 Hz. This consistency in $J_{\beta\gamma}$ indicates that the coupling is intramolecular and not affected by the external field.

The NMR spectrum of (V) could not be obtained because of the high melting point of this salt. The NMR spectrum of (IV) will be discussed in a subsequent paper.

Discussion

Conductance.—Focusing attention on the conductance data, several points can be made. The salts are very good conductors. Also, the principal charge carrier is the anion. This can be seen, in the absence of reliable transference numbers, by comparing the conductance of (III) and (IV) in Table I. These data compared the N-methylpyridinium ion with the 4-methylpyridinium ion because Br^- is the anion in both salts. The values of κ are nearly the same, despite differences in both size and electron density of the cations, because the more mobile species is the Br^-. The small difference that does exist in κ is also in the expected direction with (III) being the better conductor. The difference in conductance between compounds (II) and (III) in Table I further substantiates the notion that the anion is the principal charge carrier in these salts. Here, the same cations are being compared so any difference in conductance is most likely due to differences in anion size. The conductance difference is in the right

direction with the Cl^- being a better conductor than the Br^-. The size of this difference is predictably larger than in the previous case because these ions carry most of the current. Since the salts are all somewhat alike, it is probable that they have similar glass transition temperatures. Therefore, comparison of conductances at the same temperatures is reasonable.

The conductance data for (I) as a function of temperature is within approximately 1% of the results published by Easteal and Angell (5). The conductance data for (II) is about 10% higher than that of Wallace and Bruins (6). A partial explanation for this discrepancy is that these authors were not especially interested in quantitative results and so used a dipping type conductivity cell which is ill suited to fused salt work. The electrodes spread apart as the temperature is raised, thereby decreasing the conductance of the salt relative to its true value based on a cell constant measured at room temperature. Their cell constant was also too small (7, 8). This meant that, with the bridge employed, fairly imprecise results were obtained. A combination of these factors can easily account for the difference in the two sets of conductance data. There does not seem to be conductance data for the other fused salts in the literature.

NMR spectroscopy.—All five salts are basically AB_2X_2 systems and their spectra are extremely complex (9). The major features of the spectra are those expected for this system and are shown in Fig. 2. The α hydrogens show a nitrogen broadened doublet, the γ hydrogen appears as a triplet of triplets, and the β hydrogens give a triplet. The fine structure of the spectra will not be discussed further.

The positions of the α, β, and γ peaks were virtually independent of temperature. That is, the spectra of a given salt, taken at 10° intervals, were superimposable. This indicates no substantial change in molecular structure or aggregation as a function of temperature and probably indicates that these salts are completely dissociated in the melt even at the lowest molten temperatures.

The sharp downfield spike in the pyridinium HCl spectrum indicates a rapid exchange of protons between equivalent nitrogen sites. A similar sharp, upfield spike appeared in the spectra of (II) and (III) indicating that the methyl group is also exchanging rapidly. The position of the methyl peak seemed to be independent of the anion.

The most important differences in the spectra of the ring protons become apparent when salts (II) and (III) are compared. The three sets of protons in the chloride are all further downfield than the equivalent protons in the bromide. This indicates the interaction between the chloride and the N-methylpyridinium ion is stronger than the interaction between the bromide and the same ion. This is certainly reasonable because the chloride has a higher charge to volume ratio than does the bromide.

Correlations between NMR spectra and conductance.—In the chloride melt the α protons are 0.13 ppm down field, relative to the protons of the bromide, whereas the β and γ protons are only 0.07 ppm down field. This implies that, as the halide ion passes by the N-methylpyridinium ion, it spends, on the average, more time in the vicinity of the nitrogen than at the opposite end of the ion. This concept leads to the likelihood that the positive charge is localized on the nitrogen atom rather than spread over the entire ion. If the charge were delocalized, the chemical shifts of the three sets of protons in the chloride salt would be about equal, relative to the same protons in the bromide salt, because the halide would pass by the center of the ion.

At this point it is useful to discuss the interaction between the halide ions and the pyridinium ion in terms of "interionic friction." The concept of friction originated in the works of Onsager and Kirkwood but the particular form of the idea that is meaningful here arose from equations of the form (10, 11)

$$\vec{F_i} = \sum_k^N \Gamma_{ik} X_k (\vec{v_i} - \vec{v_k}) \qquad [2]$$

where $\vec{F_i}$ is the force on component i, X_k the mole fraction of component k, the $\vec{v_i}$ are the average velocities

Table III. Per cent difference in κ between chlorides and bromides in several "anion conductors"

Salts	Ω^{-1} cm^{-1} at M.P.	Per cent difference	Best estimate for anion transference numbers
$PbCl_2$	1.43	65	(0.75)
$PbBr_2$	0.58		
CsCl	1.12	34	(0.60)
CsBr	0.84		
$BaCl_2$	2.03	36	(0.75)
$BaBr_2$	1.18		
(II)	0.115	28	$>$(0.75)
(III)	0.090		

of the components, and the Γ_{ik} are the friction coefficients. The Γ_{ik} are called friction coefficients because they encompass the proportionality between i relative to species k and $\vec{F}_i$ when species i is in the environment of species k. For a particular value of $\vec{F}_i$ and X_k, in Eq. 2, $(\vec{v}_i - \vec{v}_k)_1$ can only be less than $(\vec{v}_i - \vec{v}_k)_2$ if $(\Gamma_{ik})_1$ is greater than $(\Gamma_{ik})_2$. In other words, there must be more friction between species i and k in system 1 than in system 2. In the absence of detailed information about changes in the wave functions of the species as they pass one another, this phenomenological description is necessary.

The friction between the chloride or the bromide and the cation probably causes an unusually small percentage difference in the conductance of (II) and (III) relative to inorganic salts with the same two anions. The average drift velocity of the halides is reduced because of this interionic "friction" but the velocity of the chloride is reduced more than the velocity of the bromide. Stating it somewhat differently, there is more friction between anion and cation in the organic chloride melt than in the organic bromide melt but there is more friction in both of them than in "hard" salts. Presumably, the greater polarizability of the N-methylpyridinium ion relative to a metal ion causes the excess friction.

The plausibility of these conjectures can be further substantiated by observing the data shown in Table III. In this table the percentage difference in conductances for hard salts, in which the anion is the principal carrier, are compared (12). The number in parenthesis is the best estimate of the transference numbers (13). The data have not been corrected for this factor making them minimum per cent differences. Even so, the per cent difference between chloride and bromide is smallest in the pyridinium salts.

Another interesting correlation can be made. The conductance of (I) and (II) compares the N-methylpyridinium ion with the pyridinium ion, the Cl^- being common to both. These conductances should be closer together. The same anion is carrying the major share of the current which implies that the salts should show nearly the same per cent difference in κ as (III) and (IV) where the N-methylpyridinium ion is being compared with the 4-methyl N-methylpyridinium ion, the bromide ion being common to both. A reasonable explanation is that the pyridinium HCl is an abnormally good conductor because the labile proton, which appears in the spectrum of fused pyridinium HCl and in aqueous solutions of pyridinium salts (14), is contributing to the conductance.

Errors.—The conductance data is accurate to nearly $\pm 1\%$. This figure takes into account the precision and accuracy of the bridge, $\pm 0.2\%$, the ability to regulate temperature, $\pm 0.2°$, impurities in the salts $\sim 0.5\%$, and a small amount of decomposition and hydrolysis. The NMR data have about the same accuracy. The chemical shifts seem accurate to ± 0.02 ppm. The variable temperature probe of the NMR machine can regulate temperature to $\pm 2°$ which is not nearly as good as the temperature regulation of the bath. However, the peak positions are not very temperature sensitive. While impurities have less effect on the spectra than on κ, there are more "noise" and machine "stability" problems at elevated temperatures.

Acknowledgments

Chloroaluminate Equilibria in $AlCl_3$-NaCl Melts

Armand A. Fannin, Jr., Lowell A. King, and David W. Seegmiller

Frank J. Seiler Research Laboratory (AFSC) and Department of Chemistry, United States Air Force Academy, Colorado 80840

ABSTRACT

Equilibrium constants were calculated for reactions governing the species present at 175°C in molten mixtures of aluminum chloride and sodium chloride. The equilibria postulated pertain to formation of the complex ions $AlCl_4^-$, $Al_2Cl_7^-$, and $Al_3Cl_{10}^-$ from Cl^-, $AlCl_3$, and Al_2Cl_6. The constants were derived from potentials exhibited by concentration cells of the type Al/$AlCl_3$(N), NaCl//$AlCl_3$(N'), NaCl/Al, and from vapor pressures over pure $AlCl_3$ and molten $AlCl_3$-NaCl mixtures. Measurements were made throughout the concentration range N = 0.498-0.71. The possibilities of using these concentration cells as high energy density batteries are considered.

Aluminum-chlorine formation cells utilizing molten mixtures of $AlCl_3$ and NaCl as the electrolyte are being investigated in this laboratory for use as high energy density batteries. An essential part of the program has been the determination of the activities of the aluminum species in the electrolyte. Several investigators have presumed the aluminum to be distributed among various chloroaluminate species in such melts, and have made calculations based on this presumption. Øye and Gruen (1) calculated equilibrium constants governing the formation of chloroaluminate ions in $AlCl_3$-NaCl melts at 190°C in the composition region 0.536 $\leqq N \leqq$ 0.658. They used the vapor pressure data of Dewing (2) as the basis of their calculation. Trémillon and Letisse (3) introduced the solvent system definitions of acid and base (chloride ion acceptor and donor, respectively) for $NaAlCl_4$ melts, and determined the value of the solvent dissociation constant at 175°C. They performed a potentiometric titration of Cl^- over the composition range of 0.498 $\leqq N \leqq$ 0.502 by the strong acid $Al_2Cl_7^-$, which was produced coulometrically. A similar technique was employed to measure equilibrium constants by Boxall, Jones, and Osteryoung (4) over the composition range 0.50 $\leqq N \leqq$ 0.70 and the temperature range 175°-355°C. Torsi and Mamantov (5) potentiometrically measured the same dissociation constant in the temperature range 175°-400°C and the composition range 0.498 $\leqq N \leqq$ 0.503. They varied the composition of their melt by adding known weights of $AlCl_3$ to the salt mixture. Morrey and Moore (6) calculated equilibrium constants governing the formation of chloroaluminate ions in $AlCl_3$-KCl melts at 725°C by measuring the distribution of uranium(III) between the two phases UCl_3(l) and $AlCl_3$-KCl(l).

A wide variety of additional properties of aluminum halide-Group I metal halides melts has been investigated. Boston (7) recently reviewed these studies.

A convenient way to measure activities is to use a concentration cell of the type Al/$AlCl_3$(N), NaCl//$AlCl_3$(N'), NaCl/Al where the activities of aluminum in solution and the observed cell voltage are related by the equation

$$E = \sum_i \frac{RT}{z_i \mathbf{F}} \ln \left(\frac{a_i}{a_i'} \right) + E_J \qquad [1]$$

Experimental

Concentration cells.—A variety of concentration cells was built. All had in common an aluminum wire immersed in each of two different electrolytes contained in compartments connected by a porous barrier. Glass frits, asbestos wicks, Fiberglas mats, and thin Pyrex membranes were used as barriers in the several cells. Electrolytes were molten mixtures of aluminum chloride and sodium chloride, with the aluminum chloride content ranging from N = 0.498 to 0.71. These compositions correspond, respectively, to a saturated solution of NaCl and to a point where the vapor pressure of $AlCl_3$ over the electrolyte was too difficult to contain with our cell design.

Most of the cells were made of Pyrex glass in two basic designs. One version was a typical H-cell, with the porous barrier in the connecting arm. Some of the electrolyte compartments were simply closed with cork stoppers through which the aluminum wire electrodes passed. However, because of the extreme reactivity of aluminum chloride with moisture and because of the relatively high vapor pressures over $AlCl_3$-rich electrolytes, the H-cells usually were completely sealed with tungsten wire lead-throughs for electrical connections. Tungsten did not touch the melts; the aluminum wire electrodes were mechanically bound to the tungsten in the vapor phase region of the cells.

In experiments where the aluminum chloride content of either of the electrolytes exceeded approximately N = 0.55, the vapor pressure of the electrolytes tended to force the melt through the barrier (Pyrex membranes were not used with the H-cell design). To eliminate this problem, a second capillary was used to connect the vapor phase regions of the two arms of the H-cell. Electrolyte composition changes due to vapor transfer were extremely slow and did not present a problem.

The other basic cell design was comprised of a small tube, one end of which terminated in a Pyrex bubble. This tube was ring-sealed into a larger closed-ended tube equipped with a side arm. The side arm and the remaining end of the small tube were sealed, with tungsten lead-throughs provided as in the first design.

All cells were loaded with powdered electrolyte at room temperature in a glove box. The glove box atmosphere was nitrogen recirculated through a molecular sieve. The dew point was below −60° (less than 15 ppm H_2O). All of the sealed cells were equipped with side arms connected to each electrolyte compartment. Weighed amounts of powdered electrolyte were added to the compartments, the cells evacuated, and the side arms sealed off. The composition of an electrolyte could be changed by breaking the side arm, adding the required salt, and resealing the cell. Loading and changing the compositions of electrolytes in cells which were closed with cork stoppers were simpler.

Chemicals.—"Baker Analyzed" reagent grade 0.032 in. aluminum wire was used as electrodes. The reported impurities totaled less than 0.2%. The principal impurities were silicon and iron. "Baker Analyzed" reagent grade sodium chloride was heated in air to just below its melting point for 24 hr, then ground to a powder inside a glove box immediately before use. "Baker Analyzed" aluminum chloride was purified by a crystal growth method described elsewhere (8). The

Key words: aluminum chloride, concentration cell, battery, molten salt.

crystals were ground to a powder immediately before use by means of a Chemical Rubber Company Micro-Mill which was located inside the glove box.

Apparatus.—The concentration cells were immersed in a well-stirred bath of the ternary eutectic $NaNO_3$-$NaNO_2$-KNO_3. Bath temperature was measured with a Chromel-Alumel thermocouple calibrated at the melting point of Sn-Pb euctectic (9) and was maintained by a temperature controller. Voltages of the cells which utilized Pyrex membranes were measured with a Data Technology Corporation Model 370 digital voltmeter and the voltages of the remaining cells were measured with a L&N Type K-3 potentiometer and Type 9834 electronic d-c null detector.

Results and Discussion

The ratio of activities of aluminum in the two electrolytes of a concentration cell can be calculated by Eq. [1] and the observed cell voltage. Many binary molten halide systems are approximately ideal mixtures if the species are correctly identified (10). The aluminum chloride-alkali metal chloride system appears to be no exception (11). If the aluminum system were to behave ideally and the activity of Al^{III} were proportional to N, the expected cell voltages from Eq. [1] would reach a maximum of 0.03V with electrolyte compositions corresponding to the extreme maximum and minimum values which we used. This value includes in E_J the term involving the two sodium ion activities, but no other junction effects.

[a] Listed in the order in which data were taken.

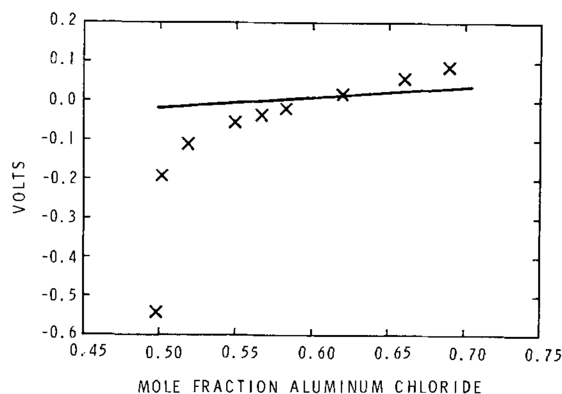

Fig. 1. Concentration cell voltages, cell No. 6. ———, Predicted for ideal mixing; X, observed.

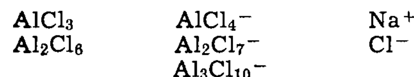
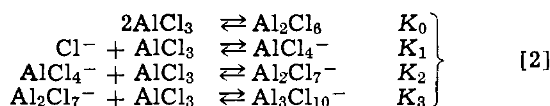
The voltages observed on nine cells in which electrolyte composition was varied are given in Table I. The results for a typical cell, No. 6, are shown in Fig. 1 and are compared with the results expected for ideal mixing. Two significant features are apparent. The experimental points on the upper half of the figure span over 0.3V and are an order of magnitude larger than the ideal values. This behavior was reproducibly observed on all cells, as long as the aluminum chloride mole fraction in both electrolytes exceeded $N = 0.500$. The other notable feature of these cells is a sharp increment of approximately 0.4V obtained whenever the composition of aluminum chloride in one of the electrolytes was reduced to below $N = 0.500$. This behavior also was reproducibly obtained in a number of cells, including some cited in Table I.

The following species have been reported (1, 11, 12) to exist in aluminum chloride-sodium chloride melts



$AlCl_3$ $\quad AlCl_4^-$ $\quad Na^+$
Al_2Cl_6 $\quad Al_2Cl_7^-$ $\quad Cl^-$
$Al_3Cl_{10}^-$

A reasonable set of reactions linking these anions and molecular species follows



$$\left.\begin{array}{lll} 2AlCl_3 & \rightleftarrows Al_2Cl_6 & K_0 \\ Cl^- + AlCl_3 & \rightleftarrows AlCl_4^- & K_1 \\ AlCl_4^- + AlCl_3 & \rightleftarrows Al_2Cl_7^- & K_2 \\ Al_2Cl_7^- + AlCl_3 & \rightleftarrows Al_3Cl_{10}^- & K_3 \end{array}\right\} \quad [2]$$

Aluminum chloride in the vapor phase exists almost exclusively as the dimer Al_2Cl_6 at temperatures below 400°C (13). From the JANAF Tables (14) one may calculate the vapor dimerization constant. Using that value and the vapor pressure of pure aluminum chloride (15) it is possible to calculate K_0. At 175°C, $K_0 = 2.9 \times 10^7$. (See Appendix I for the method of calculation.)

Equation [2] is written in terms of $AlCl_3$, even though Al_2Cl_6 is the dominant neutral species in solution over virtually the entire composition range studied. That choice was made primarily because it led to simpler algebra, and because measurements in the literature customarily are expressed in terms of the apparent mole fraction of monomer, which is our N. As may be seen in the Appendixes, the actual calculations were made in terms of Al_2Cl_6. In any case, the equilibrium constants of Eq. [2] are related by the factor K_0 to an equivalent set of equilibria written in terms of Al_2Cl_6.

If it is assumed that Na^+ is the only current-carrying species, and that the concentration of the electrochemically active aluminum species is in equilibrium with the aluminum-containing species cited above, the Nernst equation can be written for this type of con-

centration cell. For convenience, the equilibrium chosen was

$$Al^{III} + 4Cl^- \rightleftarrows AlCl_4^-$$

The term E_J in Eq. [1] becomes $-(RT/\mathbf{F})\ln(a_{Na^+}/a_{Na^+(ref.)})$, since other contributions to E_J were small enough compared to experimental errors to be neglected. Within experimental error, the cells with Pyrex membranes yielded the same potentials as did cells of the other designs when the same concentration of electrolyte was employed in the two different cells.

The activity coefficients of Na^+, $AlCl_4^-$, and Cl^- are not known precisely. The most important term in the Nernst equation is the one involving the activity of Cl^-. The concentration of Cl^- remained very small over the entire composition range which was studied. Boxall and Johnson (16) showed that the activity coefficients of dilute solutes remain constant as their concentrations change. The concentrations of Na^+ and of $AlCl_4^-$ were too large to make this assumption; however, the concentrations of these species did not vary greatly over the composition region studied, and unless relatively enormous changes in activity coefficients occurred, little error was introduced by replacing activity ratios by mole fraction ratios.

Accordingly, the Nernst equation for a concentration cell with transference then becomes

$$E = \frac{-RT}{3\mathbf{F}}\left[4\ln\left(\frac{X_{Cl^-}}{X_{Cl^-(ref.)}}\right) - \ln\left(\frac{X_{AlCl_4^-}}{X_{AlCl_4^-(ref.)}}\right) + 3\ln\left(\frac{X_{Na^+}}{X_{Na^+(ref.)}}\right)\right] \quad [3]$$

If the model of Eq. [2] is correct, and if the concentration of any one of the participating species (except Na^+) can be determined precisely as a function of over-all melt composition, the constants K_1, K_2, and K_3 can be determined. A composition range in which concentrations are relatively easy to determine lies in the immediate vicinity of the $N = 0.500$ point, since E changes rapidly and $X_{AlCl_4^-}$ and X_{Na^+} remain nearly constant.

Suitable experimental data for this composition range are those of Torsi and Mamantov (5). Their experiment was performed by adding very small increments of aluminum chloride to one arm of a concentration cell. The composition of the variable arm of the cell was thus increased in small steps from an initial composition of $N = 0.498$ to a final composition of $N = 0.503$. Their experimental cell voltages, when plotted *vs.* composition, displayed typical titration curve behavior. The titration data was treated by means of the equilibrium expression

$$K = \frac{K_2}{K_1} = \frac{X_{Cl^-}X_{Al_2Cl_7^-}}{(X_{AlCl_4^-})^2} \quad [4]$$

and the simplified Nernst equation

$$E = \frac{-4RT}{3\mathbf{F}}\ln\left(\frac{X_{Cl^-}}{X_{Cl^-(ref.)}}\right) \quad [5]$$

At the equivalence point

$$\frac{K_2}{K_1} = \frac{(X_{Cl^-})^2}{(X_{AlCl_4^-})^2} \quad [6]$$

Equation [5] can be expanded to a theoretical equation of the form (see Appendix II for derivation)

$$E = \frac{-4RT}{3\mathbf{F}}\ln A + B \quad [7]$$

where

$$A = (0.5)(-C + [C^2 + 0.0245\,K_2/K_1]^{1/2}) = n_{Cl^-}$$

$$C = \frac{w - x}{133.34}$$

$$B = 0.05149\ln m_{Cl^-(ref.)} - 0.2162$$

The Torsi and Mamantov data were fit to Eq. [7] by a grid technique. Trial values of the ratio K_2/K_1 were substituted into Eq. [7] and least squares fit values of x and C were computed. The equilibrium constant ratio was varied until an apparent minimum occurred in the standard deviation of the fit. The best fit values of the three parameters, K_2/K_1, x, and m_{Cl^-} are given in Table II, and are compared with the results calculated by Torsi and Mamantov, who used a graphical procedure. The ratio K_2/K_1 at 175°C was calculated to be $(7.8 \pm 0.6) \times 10^{-8}$.

The composition range where K_2 most conveniently may be evaluated extends approximately from $N = 0.55$ to 0.70. The majority of the data given in Table I were taken in this composition range. Some of the remaining data were taken with one arm of the cell saturated with NaCl. This common reference point allowed the data from this laboratory to be combined with those of Torsi and Mamantov. The voltage-composition data for each cell appeared to fall on individual curves generated by cubic polynomials, as long as the composition of the electrolyte to which $AlCl_3$ or NaCl increments were added remained above $N = 0.51$. Therefore, these concentration cell data (excluding the saturated NaCl points) were least squares fit to Eq. [8], which is mathematically equivalent to transforming each of the least squares cubic polynomials for individual concentration cells to a (arbitrary) common reference

$$E = b_1(N - N') + b_2(N^2 - N'^2) + b_3(N^3 - N'^3) \quad [8]$$

The resulting values of b_1, b_2, and b_3 are listed below, immediately following Eq. [12].

The value of K_2 was obtained in the following manner: The concentrations of the various species required in Eq. [3] were calculated by an iterative technique from Eq. [2]. The value of K_2 was obtained by curve matching Eq. [8] with Eq. [3], the latter obtained by substituting the known values of K_0, K_2/K_1, and various trial values of K_2 and K_3 into Eq. [2]. Unfortunately, it was not possible to match directly the experimental data with the calculated curve from Eq. [3] in lieu of using Eq. [8]. That was because the individual cells

[d] G. Mamantov, private communication; graphical method used, not explicitly calculated in Ref. (5).
[e] $N = \frac{1 + 0.095885\,(w - x)}{2 + 0.095885\,(w - x)}$; $N = 0.5$ at equivalence point since $w = x$.

all employed different reference concentrations. It therefore was necessary to resort to some mathematical treatment such as represented by Eq. [8], which converted the cell data to a common reference concentration.

The experimental data did not lie in the composition range which would be well suited for evaluation of K_3. However, an upper limit of approximately 10^3 may be placed on K_3, since trial values of K_3 appreciably larger than that produce significant deviations from experimental results even in the composition range which was explored.

An alternate evaluation of K_2 is possible using measurements of vapor pressures over $AlCl_3$-NaCl melts. Several studies of vapor pressure have been reported (2, 17-21). Of these, the most reliable data appeared to be those reported by Narita, Ishikawa, and Midorakawa (20), since no residual gases were present during the measurements, and melt analyses were made after the pressure measurements. Their pressure values, taken at seven melt compositions between $N = 0.54$ and 0.75, yield a value of K_2 similar to the value obtained by the electrochemical measurements. In the composition range $N = 0.591$ to 0.657, the pressure-derived $K_2 = (5.5 \pm 0.5) \times 10^4$ at 175°C. The method of calculation is given elsewhere (22).

Davey, Floyd, and Marcantonio (21) examined vapor pressure measurements of several other workers (2, 17, 18). They resolved the inconsistencies between the data of Rogers (18) and those of Dewing (2) by correcting the heat capacity term in the equations reported by Dewing. From these data, Davey, Floyd, and Marcantonio (21) derived empirical equations from which vapor pressures over $AlCl_3$-NaCl melts can be calculated. These pressures in the composition range $N = 0.52$ to 0.60 yield a K_2 of $(1.5 \pm 0.3) \times 10^4$.

Øye and Gruen (1) derived an equilibrium constant from Dewing's vapor pressures (2). The constant calculated by Øye and Gruen is equivalent to K_0/K_2^2 in the present work. At 175°C, $K_0/K_2^2 = 0.05$, which is in good agreement with the value at 190°C of 10^{-2} obtained by Øye and Gruen.

It also is possible to predict the correct voltages of concentration cells with transference from the vapor pressure data of Narita, Ishikawa, and Midorakawa (20). From theoretical free energy calculations and the Gibbs-Duhem relationship one can derive the expression

$$E = \frac{-RT}{3\mathbf{F}} \int_N^{N'} t_{Na^+} \left(\frac{2N+1}{1-N} \right) \left(\frac{1}{N} + \frac{d \ln \gamma_N}{dN} \right) dN \quad [9]$$

where t_{Na^+} is the transport number of Na^+ and γ_N is the apparent activity coefficient of $AlCl_3$, and is defined by

$$\gamma_N = \frac{X_{AlCl_3}}{N} = \frac{(X_{Al_2Cl_6}/K_0)^{1/2}}{N} \quad [10]$$

A least squares empirical polynomial for $d \ln(\gamma_N)/dN$ was obtained from Eq. [10] and the vapor pressures (15, 20). The only current carrying species was assumed to be Na^+. Voltages obtained on integration of Eq. [9] are compared with the measured values on Fig. 2.

The derivation of Eq. [9], and a description of the calculations made from vapor pressures may be found elsewhere (22).

The experimentally determined values of the equilibrium constants are summarized in Table III. The cell voltage data of the present work and that of Torsi and Mamantov (5) are given by the empirical Eq. [11] and the theoretical Eq. [12]

$$E = b_0 + b_1 N + b_2 N^2 + b_3 N^3 \quad [11]$$

$$0.51 \leq N \leq 0.71$$

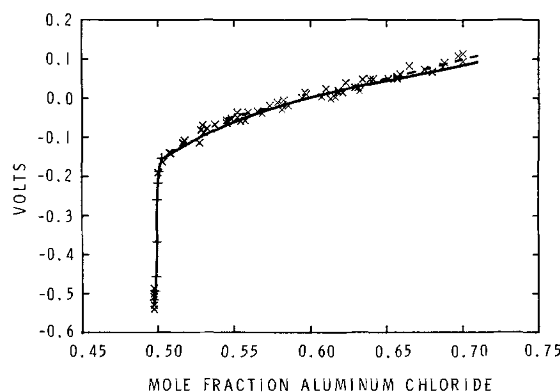

Fig. 2. Comparison of concentration cell voltages with calculated values. ———, Calculated from empirical Eq. [11] and [12]; - - - -, calculated from vapor pressure measurements. Observed values: X, present work; +, Torsi and Mamantov (5).

$$E = \frac{-4RT}{3\mathbf{F}} \ln \left\{ \frac{1-2N}{1-N} + \left[\left(\frac{1-2N}{1-N} \right)^2 + \frac{4K_2}{K_1} \right]^{1/2} \right\} + D \quad [12]$$

$$0.498 \leq N \leq 0.504$$

where $b_0 = -6.9028536$, $b_1 = 30.0446$, $b_2 = -44.3122$, $b_3 = 22.3541$, and $D = -0.7454$, and the reference electrode composition $N' = 0.600$.

The derivation of Eq. [12] is described in Appendix II. Figure 2 compares the experimental data and the results obtained from empirical equations. The curve calculated from Eq. [11] begins to move away slightly from the experimental voltages at $N > 0.65$. It is not clear whether this divergence, if real, was due to failure to take activity coefficients properly into account, or whether it reflected the increased participation of $Al_3Cl_{10}^-$ as an aluminum-containing species at high N.

The values of K_1 and K_2 imply a very tightly bound Al^{III}, and therefore sharply enhanced electrochemical oxidation at aluminum anodes in the sense that the free energy change at the anode is much more negative in $AlCl_3$-NaCl melts than in the presence of pure aluminum chloride. Moreover, the effect of the equilibria is to complex the aluminum to a degree markedly dependent on melt composition. This, in turn, gives rise to the unusually large concentration cell voltages. The composition range in which this behavior was observed is quite broad; although to achieve the 0.4V increment, the composition of the two arms of a cell must lie on opposite sides of the $N = 0.500$ point. These effects can be seen more clearly in Fig. 3, which illustrates the distribution of the various species in melts. The concentrations were obtained from calculations analogous to those used for concentration distributions in polyprotic acid equilibria. According to the model, the principal aluminum-containing species is $AlCl_4^-$ when $N < 0.63$, and is $Al_2Cl_7^-$ beyond that composition. The reaction involving K_3, *i.e.* the formation of $Al_3Cl_{10}^-$, was not included in the calculations.

The calculations were straight forward but rather complicated, and involved an iterative solution of an

equation in $X_{Al_2Cl_6}$ raised to integral and half-integral powers The calculations are given in detail in Appendix III. Table IV gives the calculated values of $X_{Al_2Cl_6}$ and X_{Cl^-} at selected N. From these, all other concentrations at composition N may be calculated easily. The concentrations shown in Fig. 3 assume activity coefficients of unity. Even if the activity coefficients are not unity, the indicated concentrations are very nearly correct, the error being in the reported values of K_1 and K_2.

Concentration cell behavior similar to that obtained in the aluminum chloride systems should be observable whenever there is a series of very stable complex ions to consume the anode metal. Whether or not any such cells would display voltages as high as those encountered with aluminum remains to be seen. There is at least one possibility already in the literature; beryllium concentration cells utilizing molten BeF_2-LiF electrolytes have been reported to yield potentials greater than 0.22V (23).

Curve matching was done by overlaying curves plotted by a Hewlett-Packard 9100B programmable calculator and plotter. All other data reduction was done with the aid of a Wang 720B programmable calculator.

APPENDIX I

The value of K_0 was calculated as follows

Let

$$y^\circ_{AlCl_3} = p^\circ_{AlCl_3}/P^\circ \quad \text{and} \quad y^\circ_{Al_2Cl_6} = p^\circ_{Al_2Cl_6}/P^\circ$$

$$X_{AlCl_3} = p^\circ_{AlCl_3}/P^T_{AlCl_3} \quad \text{and} \quad X_{Al_2Cl_6} = p^\circ_{Al_2Cl_6}/P^T_{Al_2Cl_6}$$

Then

$$K_0 = \frac{X_{Al_2Cl_6}}{(X_{AlCl_3})^2} = \frac{y^\circ_{Al_2Cl_6} P^\circ/P^T_{Al_2Cl_6}}{(y^\circ_{AlCl_3} P^\circ/P^T_{AlCl_3})^2} \quad \text{[AI-1]}$$

$$P^T_{AlCl_3} = p^\circ_{AlCl_3} + 2p^\circ_{Al_2Cl_6} = P^\circ + p^\circ_{Al_2Cl_6}$$

$$P^T_{Al_2Cl_6} = p^\circ_{Al_2Cl_6} + (P^\circ - p^\circ_{Al_2Cl_6})/2 = (P^\circ + p^\circ_{Al_2Cl_6})/2$$

By definition

$$K_pP^\circ = \frac{y^\circ_{Al_2Cl_6}}{(1 - y^\circ_{Al_2Cl_6})^2} \quad \text{[AI-2]}$$

Upon substitution into Eq. [AI-1], one obtains

$$K_0 = 2K_pP^\circ(1 + y^\circ_{Al_2Cl_6}) \quad \text{[AI-3]}$$

Equation [AI-2] then is solved for the physically realizable value of $y^\circ_{Al_2Cl_6}$, and that value substituted into Eq. [AI-3] yields K_0. For all practical purposes $y^\circ_{Al_2Cl_6}$ = unity at 175°C.

The vapor pressure equation of Smits and Meijering (15) yields $P^\circ = 1145.5$ Torr. This value is high enough that the nonideality of the gas should be taken into account. The Dieterici equation (24) was used in the form

$$(P^\circ \exp[a/\tilde{V}RT])(\tilde{V} - b) = RT \quad \text{[AI-4]}$$

Equation [AI-4] was solved for the ideal $\tilde{V}$, using

$$a = 4bRT_{critical}$$

$$b = \tilde{V}_{critical}/2$$

where $T_{critical}$ and $\tilde{V}_{critical}$ are from Denisova and Baskova (25).

An ideal pressure, $P^\circ_{ideal} = 1206.3$ Torr, calculated from $P^\circ_{ideal} = RT/\tilde{V}$, was the value used in Eq. [AI-2] and [AI-3] to calculate K_0.

0.7000	0.8317	8.1797

APPENDIX II

The theoretical Eq. [7] was derived as follows: From Eq. [2] one can derive the equations

$$n_{AlCl_3} = \left(\frac{n_t}{K_1 n_{Cl^-}}\right) n_{AlCl_4^-}$$

$$n_{Al_2Cl_6} = \left(\frac{K_0 n_t}{K_1^2 (n_{Cl^-})^2}\right) (n_{AlCl_4^-})^2$$

$$n_{Al_2Cl_7^-} = \left(\frac{K_2}{K_1 n_{Cl^-}}\right) (n_{AlCl_4^-})^2 \quad \text{[AII-1]}$$

The amount of $AlCl_3$ added by Torsi and Mamantov (5) is related to the species present in the electrolyte by the equation

$$\frac{w}{133.34} = n_{AlCl_3} - n^\circ_{AlCl_3} + 2n_{Al_2Cl_6} - 2n^\circ_{Al_2Cl_6} + n_{AlCl_4^-} - n^\circ_{AlCl_4^-} + 2n_{Al_2Cl_7^-} - 2n^\circ_{Al_2Cl_7^-} \quad \text{[AII-2]}$$

where

$$n_{AlCl_4^-} - n^\circ_{AlCl_4^-} + n_{Al_2Cl_7^-} - n^\circ_{Al_2Cl_7^-} = n^\circ_{Cl^-} - n_{Cl^-} \quad \text{[AII-3]}$$

and $n^\circ_{AlCl_3}$, $n^\circ_{Al_2Cl_6}$, and $n^\circ_{Al_2Cl_7^-}$ are near enough to zero to be neglected. By substituting Eq. [AII-1] and [AII-3] into Eq. [AII-2], neglecting the vanishingly small terms, and rearranging, one obtains the cubic polynomial

$$(n_{Cl^-})^3 + \left(\frac{w}{133.34} - n^\circ_{Cl^-}\right)(n_{Cl^-})^2 - \left(\frac{K_2(n_{AlCl_4^-})^2}{K_1} + \frac{n_t n_{AlCl_4^-}}{K_1}\right) n_{Cl^-} - \frac{2K_0 n_t (n_{AlCl_4^-})^2}{K_1^2} = 0 \quad \text{[AII-4]}$$

The term immediately preceding the equality sign in Eq. [AII-4] is small enough that it may be neglected without introducing any significant error. Equation [AII-4] then will reduce to a quadratic in n_{Cl^-}. The equation will further simplify if $K_2 >> 1$ by noting that

$$\frac{K_2(n_{AlCl_4^-})^2}{K_1} >> \frac{n_t \cdot n_{AlCl_4^-}}{K_1}$$

Therefore

$$(n_{Cl^-})^2 + \left(\frac{w}{133.34} - n^\circ_{Cl^-}\right) n_{Cl^-} - \frac{K_2(n_{AlCl_4^-})^2}{K_1} = 0 \quad \text{[AII-5]}$$

Equation [AII-5] may be derived more directly by neglecting the term $2n_{Al_2Cl_6}$ in Eq. [AII-2].

On substitution of Eq. [AII-6] into Eq. [AII-5] and reducing the latter into the standard form for finding the roots of a quadratic equation we obtained Eq. [AII-7]

$$n^\circ_{Cl^-} = \frac{x}{133.34} \quad \text{[AII-6]}$$

$$n_{Cl^-} = (0.5)\left(-\frac{w-x}{133.34} + \left[\left(\frac{w-x}{133.34}\right)^2 + \frac{4K_2(n_{AlCl_4^-})^2}{K_1}\right]^{1/2}\right) \quad \text{[AII-7]}$$

From Eq. [5]

$$B = \frac{4RT}{3F} \ln n_{Cl^-(\text{ref.})} \quad \text{[AII-8]}$$

Torsi and Mamantov (5) added aluminum chloride to 0.0782 moles of $NaAlCl_4$. On converting from moles to molality units, Eq. [AII-8] becomes

$$B = \frac{4RT}{3F} \ln [0.015\, m_{Cl^-(\text{ref.})}] \quad \text{[AII-9]}$$

Equations [AII-7] and [AII-9] together yield Eq. [7].

From the definition of N

$$\frac{w-x}{133.34} = \left(\frac{2N-1}{1-N}\right) n^\circ_{AlCl_4^-} \quad \text{[AII-10]}$$

Since $n^\circ_{AlCl_4^-}$ is very nearly equal to $n_{AlCl_4^-}$ in the immediate vicinity of $N = 0.5$, Eq. [AII-7] reduces to

$$n_{Cl^-} = \frac{n^\circ_{AlCl_4^-}}{2}\left(\frac{1-2N}{1-N} + \left[\left(\frac{1-2N}{1-N}\right)^2 + \frac{4K_2}{K_1}\right]^{1/2}\right) \quad \text{[AII-11]}$$

From Eq. [5], [AII-9], and [AII-11], one may derive Eq. [12], an expression analogous to Eq. [7], but written in terms of N. Changing N', the reference arm of the cell, corresponds to changing the value of D in Eq. [12]. The term, D, for $N' = 0.6$ was obtained in the following manner: For each of the cells No. 5, 6, 7, and 9, the voltage was calculated which would exist between the actual reference composition used and 0.6. This increment was added to the measured voltage between the reference used and saturation. The average of these sums, -0.5294V, was used to obtain the constant term, D, in Eq. [12].

APPENDIX III

From Eq. [2] one can derive the equations

$$X_{AlCl_3} = (X_{Al_2Cl_6}/K_0)^{1/2}$$
$$n_{AlCl_4^-} = K_1\, n_{Cl^-}\, (X_{Al_2Cl_6}/K_0)^{1/2}$$
$$n_{Al_2Cl_7^-} = K_2\, n_{AlCl_4^-}\, (X_{Al_2Cl_6}/K_0)^{1/2} \quad \text{[AIII-1]}$$

These quantities were substituted into the equations for aluminum mass balance and for charge balance

$$N = 2n_{Al_2Cl_7^-} + n_{AlCl_4^-} + n_{AlCl_3} + 2n_{Al_2Cl_6} \quad \text{[AIII-2]}$$

$$n_{Na^+} = n_{Al_2Cl_7^-} + n_{AlCl_4^-} + n_{Cl^-} \quad \text{[AIII-3]}$$

On expressing the quantities $n_{Al_2Cl_7^-}$ and $n_{AlCl_4^-}$ in Eq. [AIII-2] and [AIII-3] in terms of $X_{Al_2Cl_6}$ and n_{Cl^-} from Eq. [AIII-1], one obtains

$$N = [2K_2(X_{Al_2Cl_6}/K_0)^{1/2} + 1]\, K_1 n_{Cl^-}\, (X_{Al_2Cl_6}/K_0)^{1/2} + n_{AlCl_3} + 2n_{Al_2Cl_6} \quad \text{[AIII-4]}$$

$$n_{Na^+} = \{[K_2(X_{Al_2Cl_6}/K_0)^{1/2} + 1]\, K_1(X_{Al_2Cl_6}/K_0)^{1/2} + 1\}\, n_{Cl^-} \quad \text{[AIII-5]}$$

On eliminating n_{Cl^-} in a simultaneous solution of Eq. [AIII-4] and [AIII-5], one can derive the equation

$$(Y-2)K_1K_2X_{Al_2Cl_6}/K_0 + (Y-1)K_1(X_{Al_2Cl_6}/K_0)^{1/2} + Y = 0 \quad \text{[AIII-6]}$$

where

$$Y = \frac{N - n_{AlCl_3} - 2n_{Al_2Cl_6}}{n_{Na^+}} \quad \text{[AIII-7]}$$

The total number of moles in solution is defined by

$$n_t = 2n_{Na^+} + n_{AlCl_3} + n_{Al_2Cl_6}$$
$$n_t = \frac{2n_{Na^+}}{1 - X_{AlCl_3} - X_{Al_2Cl_6}} \quad \text{[AIII-8]}$$

By substitution of Eq. [AIII-8] into Eq. [AIII-7], and rearrangement, one obtains

$$Y = \frac{N}{1-N} - \frac{2(X_{Al_2Cl_6}/K_0)^{1/2} + 4X_{Al_2Cl_6}}{1 - (X_{Al_2Cl_6}/K_0)^{1/2} - X_{Al_2Cl_6}} \quad \text{[AIII-9]}$$

Equation [AIII-6] was solved for $X_{Al_2Cl_6}$ at various values of N, and then n_{Cl^-} could be obtained from Eq. [AIII-5]. From these two values and Eq. [AIII-8] and [AIII-1] all of the species compositions could be expressed as mole fractions. Figure 3 was constructed from these calculations.

SYMBOLS

- a_i thermodynamic activity of the ith species
- Al^{III} electrochemically active species of aluminum in $^{3+}$ oxidation state
- E electromotive force
- E_J any voltage difference in a concentration cell associated with the junction between the two cell compartments
- F the faraday constant
- K_i equilibrium constant for the ith chemical reaction
- K_p vapor phase dimerization constant
- ln natural logarithm
- m_{Cl^-} molality of chloride ion
- n_i number of moles of ith species
- n_t total number of moles in system
- n°_i initial number of moles of ith species
- N apparent mole fraction $AlCl_3$ (the over-all mole fraction of aluminum chloride in the $AlCl_3$-NaCl electrolyte)
- P vapor pressure of $AlCl_3$-NaCl melts
- $p^\circ_{AlCl_3}$ partial pressure of monomeric $AlCl_3$ in vapor over pure aluminum chloride
- $p^\circ_{Al_2Cl_6}$ partial pressure of dimeric Al_2Cl_6 in vapor over pure aluminum chloride
- P° vapor pressure of pure aluminum chloride
- $P^T_{AlCl_3}$ hypothetical vapor pressure of pure aluminum chloride if vapor existed solely as monomeric $AlCl_3$
- $P^T_{Al_2Cl_6}$ hypothetical vapor pressure of pure aluminum chloride if vapor existed solely as dimeric Al_2Cl_6
- R universal gas constant
- T temperature in degrees Kelvin
- $\tilde{V}$ ideal molar volume of aluminum chloride vapor
- w weight of aluminum chloride added to melt
- x weight of aluminum chloride added to melt to just reach the equivalence point
- X_i mole fraction of ith species in melt
- $y^\circ_{AlCl_3}$ mole fraction of monomeric $AlCl_3$ in vapor over pure aluminum chloride
- $y_{Al_2Cl_6}$ mole fraction of dimeric Al_2Cl_6 in vapor over $AlCl_3$-NaCl melts

$y°_{Al_2Cl_6}$ mole fraction of dimeric Al_2Cl_6 in vapor over pure aluminum chloride

z_i number of equivalents per mole of the ith species

A Description of the Discharge Mode of Porous Ag/Ag_2O Electrodes at Low Temperatures in KOH

E. G. Gagnon*,[1] and L. G. Austin*

Department of Material Sciences, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Further results are presented on the anodic discharge of electroformed and pressed powder electrodes of Ag/Ag_2O in eutectic KOH (aq) solution at low temperatures. It is concluded that the results are consistent with a mechanism $Ag_2O(s) + H_2O \rightarrow [Ag_2O(aq)] \rightarrow 2Ag^+ + 2\,OH^-$, $Ag(s) + Ag^+ + e^- \xrightarrow{slow} 2Ag(s)$. Loss of capacity at low porosity, high current density, and low temperature may be due to deposition of solid phases in the electrolyte.

In a previous publication (1), the loss of performance of Zn/KOH/silver oxide cells at low temperatures was found to be predominantly due to increased polarization on the silver-silver oxide cathode. The discharge of porous Ag/Ag_2O electrodes in 31 w/o (weight per cent) aqueous KOH at temperatures down to $-60°F$ was studied by galvanostatic techniques; the general pattern of results is illustrated in Fig. 1 and shows five distinct regions of discharge, a, b, c, d, e, and f. It was suggested that the results are generally consistent with a mechanism

$$Ag_2O(s) + H_2O \rightarrow [Ag_2O(aq)] \rightarrow 2Ag^+ + 2\,OH^- \quad [1]$$

$$Ag(s) + Ag^+ + e^- \rightarrow 2Ag(s) \quad [2]$$

This paper gives additional data and discussion on this system.

Experimental

The experimental arrangement and methods for fabricating porous Ag/Ag_2O electrodes have been described elsewhere (1-3). Some of the electrodes were electroformed and were provided by Harry Diamond Laboratories; others were fabricated from Ag and Ag_2O powder using pressed powder techniques. The physical characteristics of some of these electrodes are shown in Table I.

Key words: polarization, surface area, mass transport.

Table I. Description of electrodes

Designation	Weight per cent Ag	Ag_2O	Thickness (mm)	Porosity (%)
PP 18	9.95	90.05	0.34	14
PP 17	9.95	90.05	0.28	14
PP 28	9.95	90.05	0.35	62
PP 85	49.9	50.1	0.41	63
PP 73	49.8	50.2	0.34	19
PP 114	75.0	25.0	0.38	66
HDL	50.0	50.0	0.25	70
F 19	50.0	50.0	0.34	19
F 63	50.0	50.0	0.44	63

An electrode was mounted in a Teflon holder, with one face of about 1/3 cm^2 exposed to the electrolyte and a current collector press-fitted against the sealed back of the electrode. A Hg/HgO/KOH reference electrode with Luggin capillary was used. Ohmic polarization at various stages of discharge were obtained using a Hg-wetted relay for rapid make-and-break of the circuit and an oscilloscope, and hereafter will be referred to as IR polarization.

Results

In previous work (1) it was suggested that the length of the discharge plateau at c was due to a layer of abnormally active surface Ag_2O, corresponding to roughly a monolayer over the silver surface. This material discharges at lower polarizations (region c) than the bulk Ag_2O used in electrode preparation (region e). To test this hypothesis, electrodes PP 28, 85, 114 were prepared with approximately the same porosity and thickness but varying amounts of silver powder of specific surface 0.4 m^2/g. These electrodes were allowed to equilibrate with electrolyte and then were galvanostatically discharged. The discharge time of plateau c *vs.* the amount of silver is shown in Fig. 2; the length of the step at c was roughly proportional to the weight of Ag present in the electrode at the beginning of the experiment. The slope of the line is about 4 sec/0.04g of Ag, which is equivalent to 0.24 m-coulomb/cm^2 Ag. These results indicate that whatever was stripped off the surface of the electrode was present on a Ag surface and had a thickness of about one monolayer.

As mentioned in an earlier paper (1), the length of plateau c is increased by anodic preforming, if the electrode is then immediately discharged after anodizing. The result is shown in Fig. 3. As might be expected, the amount of abnormally active Ag_2O formed (as indicated by the length of plateau c) is roughly proportional to the coulombs of anodization. Note that the anodization potential does not reach the Ag_2O/AgO potential, and the material cannot therefore be AgO. Figure 4 shows the result if the Ag_2O/AgO potential is exceeded; a peak b' is introduced between region b and c on the cathodic discharge curve. This is most likely a nucleation polarization effect associated with the transformation of AgO $\rightarrow$ Ag_2O. If, on the other hand, the anodized electrode is allowed to stand for 20 min and then discharged, the peak b' disappears. This indicates that the AgO which was formed during anodic charge had been removed on stand at open circuit. Presumably, after the brief charging period, the electrode was made up of Ag, the bulk Ag_2O used in the electrode preparation, and recently formed AgO and [Ag_2O], where the brackets indicate that the actual structure is not known. Since the electrode cannot be at both the Ag/Ag_2O and the Ag_2O/AgO potentials simultaneously, it is likely that at open-circuit conditions, the following reaction occurred, Ag + AgO $\rightarrow$ Ag_2O, so that when the cathodic current was switched back on, only Ag and Ag_2O were present in the electrode. Finally, anodized electrodes allowed to stand in electrolyte for 12 hr reverted to a length of plateau c the same as that without anodization, showing the unstable nature of the abnormally active material.

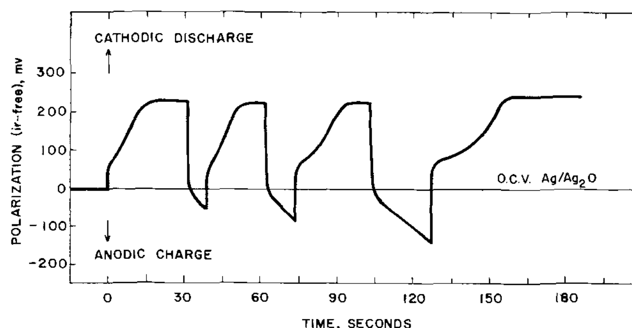

Fig. 3. Effect of anodic charging on the galvanostatic discharge of HDL electrodes at low temperature; anodic charging stopped and reversed before the electrode passed through the Ag_2O/AgO potential.

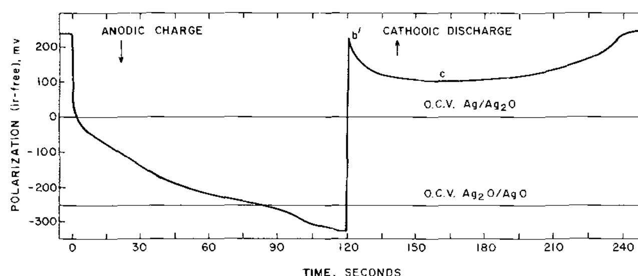

Fig. 4. Effect of anodic charging on the galvonstatic discharge of electrodes at low temperature; anodic charge stopped and current reversed after the electrode passed through the Ag_2O/AgO potential.

Considering the peak voltage ΔV at d, Fig. 5 shows the value of ΔV as a function of the amount of silver in the pressed-powder electrodes (top curve). The amount of silver in electroformed electrodes was also varied by partially discharging electrodes to different degrees at a low current density of 6 mA/cm^2; they were then discharged at 30 mA/cm^2 and $-52°F$, ΔV measured, and the results plotted in Fig. 5 (bottom curve). The correspondence between ΔV and amount of

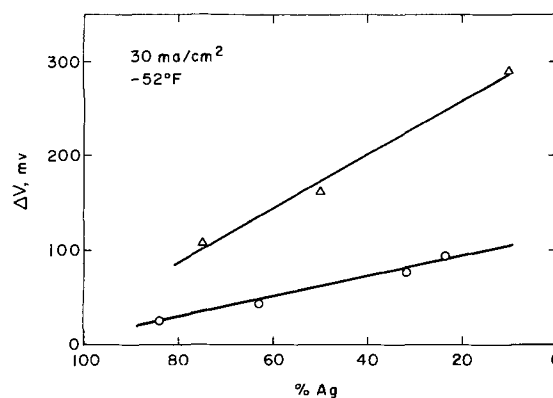

Fig. 5. Plot of ΔV vs. % Ag in the electrode: △ pressed powder electrodes; ○ electroformed electrodes.

silver indicates that high silver area reduces the peak voltage difference ΔV; it was also shown that the peak voltage is not primarily due to ohmic polarization. This eliminates the possibility that the polarization overshoot is caused (1) by a slow rate of solution of $Ag_2O(s)$, and implies that it is due in some way to the $Ag(s) + Ag^+ + e^- \rightarrow 2Ag(s)$ step in the mechanism.

The peak overshoot at d occurs regardless of whether the test electrode is an electroformed (HDL) or a pressed powder electrode. When the current was shut off after the peak region at d and then suddenly reapplied within seconds, the voltage returned to the same value without going through a peak. This behavior is evident in Fig. 3. However, if the electrodes were allowed to stand at open-circuit conditions for some time before the current was switched back on, a peak formed which was much more pronounced than the initial peak. This type of behavior has been noted with other oxide electrode systems, such as β-PbO_2 in H_2SO_4, MnO_2 in H_2SO_4, and Tl_2O_3 in alkaline media (4), at room temperature conditions.

Results from our previous studies (1, 5) indicated that the process occurring in the major discharge plateau e was due to a simple, one-electron charge-transfer process, probably $Ag(s) + Ag^+(aq) + e^- \rightarrow 2Ag(s)$. It was reasoned that if the area of the Ag was reduced significantly by fabricating electrodes with large particles of Ag, the performance of the electrode would be drastically reduced. Pressed powder electrodes were fabricated using a standard Ag_2O powder (approximately 1μ) and silver powders of different particle sizes (Handy and Harmon). The electrodes fabricated with silver powders of approximately 1μ in diameter were found to be strong and could be handled easily without the electrode crumbling. Electrodes made up with silver powders $\geqq 20\mu$ were fragile and difficult to handle. Polarization curves for these electrodes had the same characteristic shape as described earlier. Figure 6 shows oscilloscopic traces for the a, b, c, d, e portions of discharge. In general, electrodes made with 1μ Ag powder gave about the same type of results as the HDL electrodes, and performed much better than the electrode fabricated with the larger 149μ Ag powder (see Table II).

Electrodes made with the larger particles of Ag displayed higher polarization peaks and larger IR polarization than did electrodes fabricated with 1μ size Ag. After about 40 sec of discharge, the IR polarization had decreased to $\sim$70 mV, of the same order as the HDL and pressed electrodes made up with 1μ size Ag particles.

At low temperatures, there is a region f, after the plateau region, where the polarization increases rapidly as the electrode approaches complete discharge. To test whether the discharged electrode builds up a relatively impermeable (product) layer which gives rise to IR or mass transport effects, experiments were carried out using HDL electrodes that had been completely discharged at 200 mA/cm^2 (A) or 10 mA/cm^2 (B) and then placed as the outer-face in a 20-mil stack, giving a total stack thickness of 30 mil. In another arrangement (C), the outside electrode in the stack was a porous Ag electrode of the type used in the electroformation (1) of the HDL electrodes. Each stack was discharged at 30 mA/cm^2 and the results compared to a 20-mil stack of HDL electrodes having no discharged electrode at its face (D). The results of these tests are shown in Fig. 7 plotted as polarization (corrected for IR loss between test and Luggin tip) *vs.* discharge time. Initially, the polarization difference between electrodes D and C is that expected from the outer layer acting as a barrier to ion flow (ohmic effect). As discharge progresses and when discharge is nearly completed (in region f), the presence of the outer layers in A, B, C causes a large deviation from D, and the effect is not solely an ohmic effect. The higher the rate of discharge prior to using as an outer layer, the higher the polarization; *e.g.*, A is worse than B is worse than C.

Earlier work showed that an electrode of 0.25 mm thickness and 70% porosity discharged at $-52°F$ does not show marked effects of distributed reaction until currents in excess of 30 mA/cm^2 are used. However, lower porosity forces the electrode into the distributed reaction region, since the effective conductance of electrolyte in the porous system is approximately proportional to porosity squared (6). Low porosity ($\sim$14%) electrodes (PP 17 and 18) made up with 90% Ag_2O:10% Ag gave large initial peaks d at room temperature (130 mV) and at $-52°F$ (850 mV). The peak for the 14% porosity electrode was about 350 mV greater, at $-52°F$, than that obtained for the 60% porosity electrode (PP 28). A low porosity (19%) pressed powder electrode (PP 73, Table I) was discharged at 30 mA/cm^2, than placed as the outside electrode in a two-electrode stack where the inside electrode had the same physical characteristics as PP 73. This two-electrode stack was then discharged at 30

Table II. Effect of particle size of Ag on discharge of pressed powder electrodes at 30 mA/cm^2 and $-52°F$

Particle size of Ag (μ)	d Peak height (mV)	ΔV (mV)	IR polarization (mV)	
			Initial	Steady

149	560	310	170	70

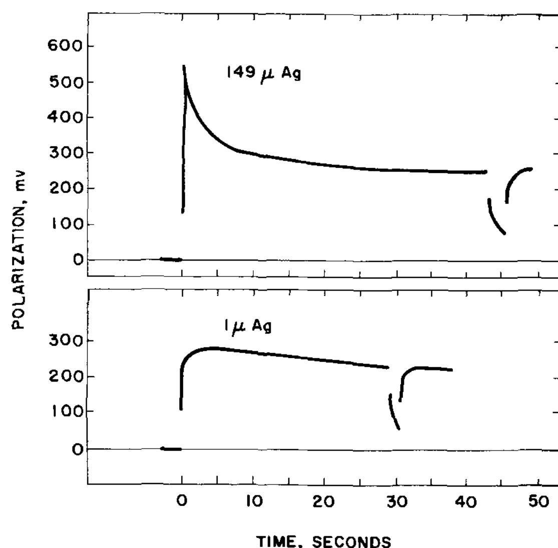

Fig. 6. Initial portions of the oscilloscopic traces of polarization vs. time of pressed powder electrodes varying in Ag particle size.

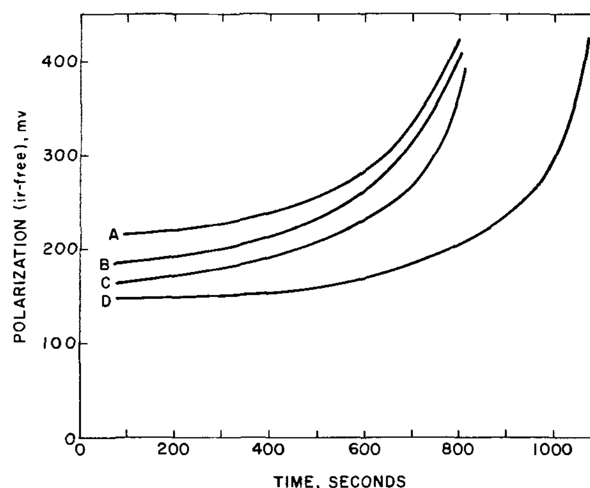

Fig. 7. Effect on polarization vs. time for stacks of HDL electrodes with an outer layer that had been previously discharged.

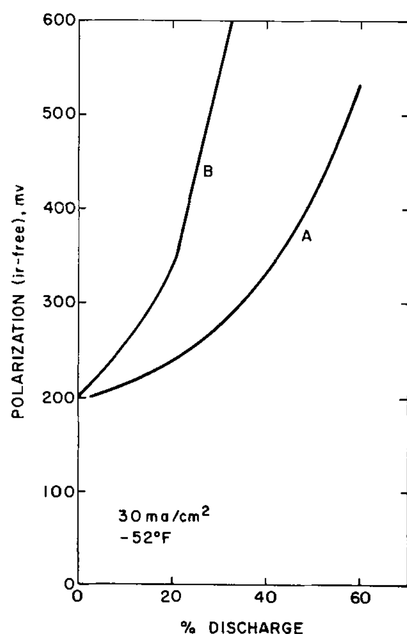

Fig. 8. Polarization vs. per cent discharge for low porosity electrodes.

mA/cm². Figure 8 shows the results for the discharge of a single PP 73 electrode (B, top curve) compared to the stack containing the discharged outer electrode (A, bottom curve). It can be seen that these low porosity electrodes give high polarization even at low states of discharge. Further, the results show that the use of a discharged electrode as the outer layer in a stack causes the polarization to increase much more rapidly than the electrode without the outer layer of discharged material.

At room temperature, discharge of 19 and 63% porosity, pressed powder, electrodes (F19 and F63, Table I) occurred with little polarization over most of the discharge (see Fig. 9); there was no difference in polarization up to 50% of discharge, at which time the polarization of the 19% porosity electrode started to increase faster than the 63% porosity electrode. As the electrodes approached 80% discharge, both gave rapidly increasing polarization (region f). At −52°F, the low porosity electrode gave high polarization and

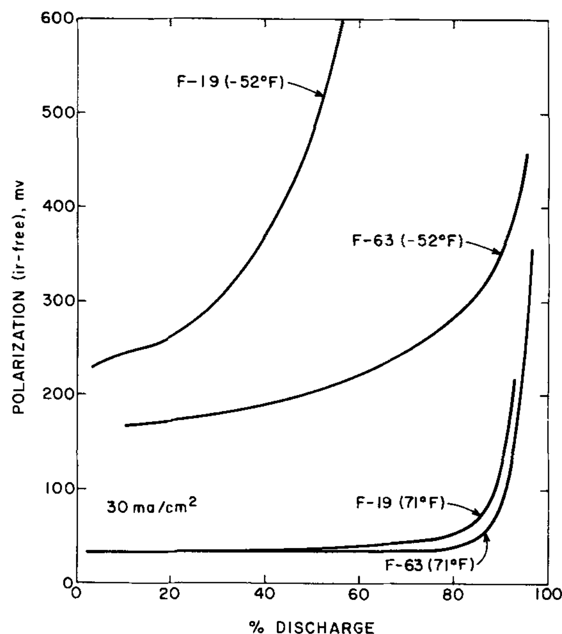

Fig. 9. Polarization vs. per cent discharged for different porosity electrodes at different temperatures.

the electrode reached 600 mV before the electrode was 60% discharged.

Discussion of Results

Explanation of discharge regions.—Region a.—For the electroformed HDL electrodes, this region represents the IR polarization which is due primarily to the electrolyte path between the surface of the test electrode and the tip of the Luggin capillary (1). For the pressed powder electrodes, however, this region varied with the physical properties of the pressed powder electrode. For example, electrodes made up with 90% Ag_2O and 10% Ag were found to have high initial IR polarization, which decreased to normal values before the electrode was 5% discharged. This effect was also noticed with high porosity (>80%) pressed powder electrodes (1). On the other hand, when pressed powder electrodes of 60% porosity were made with equal amounts of Ag and Ag_2O of about 1μ size, the initial IR observed was the normal value. It is concluded that in this case there is intimate contact of particles in the matrix leading to negligible electronic resistance, whereas smaller proportions of Ag to Ag_2O, or larger silver particles, or very high porosity, give significant contact resistance. As silver is deposited during charge, it grows as crystallites on existing silver, and these form conductivity bridges between the silver particles in the matrix. Thus, contact resistance becomes negligible after some discharge, or is initially negligible for an electroformed electrode. The formation of Ag crystallites on existing Ag is consistent with the kinetic model which proposes that the Ag_2O forms Ag^+, which is then deposited in new locations where it can receive an electron, thus growing from pre-existing conductive Ag matrix.

Region b.—When the time scale in this region is expanded using faster sweep times (millisecond) on the oscilloscope, the voltage-time trace can then be used to estimate the double layer capacity of the electrode from $C = i/(dV/dt)$, providing faradaic current is small compared to the applied current. For a porous system, it is possible to get spurious results due to distributed capacity, but the mathematical treatment by Austin (3) gives a method of calculating the operating conditions for which correct results may be obtained. He concludes that the apparent capacity approaches the true capacity when $t \geq (1/3)\rho CL$, where ρ is the effective specific resistance of the electrolyte in the porous system (ohm-cm); C is the capacitance per plane area of electrode (farads/cm²), and L is the electrode thickness (cm). Distributed reaction produces a curvature in the initial portion of the potential-time trace (typically for about 7 msec for the HDL electrodes). Using the subsequent straight line portion gave an average capacity of 6300 μF for HDL electrodes containing 0.14g Ag. Taking the true capacity of Ag to be about 50 μ/cm² (7), this gives a double-layer capacity area of 0.4 m²/g, compared to the BET area of 0.7 m²/g. The double-layer capacity of bulk Ag_2O is much less than that of Ag, and if all of the silver surface were covered by a thick film of Ag_2O, the electroformed electrode would show a very small double layer capacity. If, however, electroforming of fine Ag powder produces discrete, fresh crystallites of Ag_2O which do not block the remaining silver surface, then the double-layer capacity of a 50% Ag:50% Ag_2O electrode would be that of the remaining silver, which is less than the total BET area. This is in accordance with the data.

Region c.—This region is the discharge of abnormally reactive material, which discharges at lower polarization than the bulk Ag_2O. The quantity of abnormal material at equilibrium with electrolyte (at open circuit) is proportional to the silver area and corresponds to roughly 0.24 mcoulombs/cm² of internal area. Electroforming increases the quantity of abnormally reactive material [Ag_2O], but the quantity reverts to the equiv-

alent of a few millicoulombs per square centimeter on standing in contact with electrolyte. Presumably this material is surface Ag_2O or AgOH in an amorphous form which is less stable than an ordered Ag_2O crystallite.

Region d.—The polarization decrease, ΔV, between the peak at d and the plateau at e is greater for a lower proportion of silver area, for lower temperature, for lower porosity, and for higher current density. In some cases, part of this decrease was directly due to lowered IR loss as a conducting network of silver was formed during discharge. It should be noted that a decreasing resistance not only reduces IR polarization but also indicates that silver area not previously in contact with the general matrix [and, therefore, not taking part in the reaction $Ag^+ + e^- \rightarrow Ag(s)$] may be brought into play, thus lowering activation polarization. However, significant ΔV was found where the resistance did not change before and after the peak at d, and the peak at d is re-established when the electrode is allowed to stand at open circuit in contact with electrolyte. It is concluded that ΔV contains a major component of nucleation polarization from the nucleation of silver deposition sites.

Region e.—In addition to the discussion of this region given before (1, 5) the additional work shows that polarization in this region is less for higher specific silver areas, indicating that the rate-determining step is the reaction $Ag(s) + Ag^+ + e^- \rightarrow 2Ag(s)$.

Region f.—At lower currents and higher temperatures, an extended plateau region at e is seen, followed by sudden development of region f. As current is increased, or temperature decreased and/or the porosity of the electrode is decreased, region f starts at a lower per cent of discharge and is more spread out. Also, the use of discharged outer layers (Fig. 7 and 8) forces the polarization to reach higher values (in region f) than with electrodes not having the discharged outer layers. It does not seem possible to explain these effects solely on the basis of decreased reaction surface area, or increased hindrance to ionic and diffusional transfer due to reaction products blocking the pores. Gomis *et al.* (8) have shown that NiOOH/KOH/Cd cells discharged at $-60°C$ gave only 10-20% of their rated capacity; the discharge behavior of the positive nickel electrode has similarities to that presented here for Ag/Ag_2O. The loss in capacity was attributed to the formation of ice and/or hydrates such as $KOH \cdot 2H_2O$, etc., blocking the pores of the electrodes. On discharge of Ag_2O, water is consumed and OH^- ions are formed; hence, water is the reactant which must be transported from the bulk of the electrolyte through the pores of the electrode to the interior, and hydroxyl ions must be transported from the interior of the electrode to the bulk electrolyte. The effect of discharge is thus to increase the concentration of the electrolyte in the interior of the electrode, which may lead to sufficient deviation from the eutectic composition to give crystal deposition.

Some idea of the magnitude of possible concentration changes occurring in the electrode can be obtained as follows. The diffusion coefficient of water at room temperature is about (2) (10^{-5}) cm^2/sec; assuming that the diffusion coefficient decreases with temperature in approximately the same ratio as the specific resistance of the electrolyte increases, the diffusion coefficient of water at $-52°F$ is roughly 0.2×10^{-5} cm^2/sec. The concentration changes occurring across a 10-mil HDL electrode at 30 mA/cm^2 at $-52°F$ can be crudely approximated using "'rate per unit area" $\simeq (D\Delta C/L)$, giving $\Delta C = 2.2M$. Lower porosity, lower temperature, increased depth of discharge, and the presence of added outer layers would all aggravate the concentration change. Thus, the concentration of the electrolyte at the back interior of the electrode at almost complete discharge should be about 9.4M (38 w/o KOH). From the phase diagram of the H_2O/KOH system (9) it follows that one or more hydrates might be deposited within the pores of the electrode under these conditions.

Such deposition may cause radical increases in polarization by (*i*) slowing the rate of dissolution of Ag_2O, (*ii*) slowing mass transport of dissolved silver to the conductive matrix, and (*iii*) causing electrolyte IR polarization effects due to pore blockage.

Corrosion Kinetics of Iron in Acid Sulfate Solutions

Effects of Impurities in the Metal

Sidney Barnartt*[,1]

ABSTRACT

The kinetics of anodic iron dissolution and cathodic hydrogen evolution have been studied during the corrosion of four grades of iron: zone-refined, iron with 0.5 Mn (a/o) or 0.15 Ti added, and Ferrovac E. The titanium, which caused second-phase particles to accumulate on the surface, and manganese had little effect on iron-dissolution rates, but both additions inhibited hydrogen evolution significantly. Zone-refined iron yielded constant Tafel slopes: $b_a = 0.067 \pm 0.002$, $b_c = -0.11$ to 0.12V. Impurities caused b_a and b_c to drift to more positive values during corrosion. A new method of analyzing anodic transients is recommended, and this analysis shows that the usual steady-state polarization curve is an unreliable indicator of reaction mechanism.

When iron corrodes in acid solutions at low pH, the corrosion rate is the same as the rate of anodic iron dissolution

$$Fe = Fe^{2+} + 2e^- \qquad [1]$$

and is also the same as the rate of cathodic hydrogen evolution

$$2H^+ + 2e^- = H_2 \qquad [2]$$

The reverse reaction of either [1] or [2] occurs at an insignificant rate at low pH. The rate of reaction [1], expressed as current I_1 at potential ϵ, is known to follow the Tafel equation which may be written as $\epsilon - \epsilon^\ddagger = b_a \log (I_1/I^\ddagger)$, where b_a is the anodic Tafel slope and $\epsilon^\ddagger$ is a reference potential. Since it is convenient to refer polarized potentials to the corrosion potential ϵ^*, the rate equation for reaction [1] takes the form

$$\epsilon - \epsilon^* = b_a \log (I_1/I^*), \quad \text{or } I_1/I^* = \exp\left[\frac{2.303}{b_a}(\epsilon - \epsilon^*)\right] \qquad [3]$$

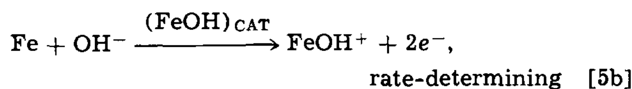
A similar relation may be written for reaction [2], which is also known to follow the Tafel equation. When current is applied to change the potential of a corroding electrode, the measured current I is just $\pm(I_1 - I_2)$, and is given by

$$I/I^* = \pm\left\{\exp\left[\frac{2.303}{b_a}(\epsilon - \epsilon^*)\right] - \exp\left[\frac{2.303}{b_c}(\epsilon - \epsilon^*)\right]\right\} \qquad [4]$$

Here the cathodic Tafel slope b_c is always a negative number, b_a always positive, and the negative sign in front of the braces applies only when $(\epsilon - \epsilon^*)$ is negative.

Experimental determinations of the cathodic Tafel slope for purified iron have given values close to $b_c = -2.303\ RT/0.5\mathbf{F}$ (or -0.118V), which is in accord with (but does not itself establish) a slow H^+-discharge mechanism for the hydrogen evolution reaction (1). Experimental determinations of b_a, however, have varied significantly. There are two theoretical values which are most frequently found experimentally. One of these is $b_a = 2.303\ RT/2\mathbf{F}$ (or 0.030V), predicted by the Heusler mechanism (4-6) for reaction [1]

$$Fe + OH^- = (FeOH)_{CAT} + e^- \qquad [5a]$$



$$Fe + OH^- \xrightarrow{(FeOH)_{CAT}} FeOH^+ + 2e^-, \quad \text{rate-determining} \qquad [5b]$$

$$FeOH^+ = Fe^{2+} + OH^- \qquad [5c]$$

This mechanism, involving adsorbed FeOH as a catalyst, has found independent support (7, 8). The other theoretical value is $b_a = 2.303\ RT/1.5\mathbf{F}$ (or 0.039V), predicted by the mechanism of Bockris, Drazic, and Despic (1-3)

$$Fe + OH^- = FeOH + e^- \qquad [6a]$$

$$FeOH \rightarrow FeOH^+ + e^-, \text{ rate-determining} \qquad [6b]$$

$$FeOH^+ = Fe^{2+} + OH^- \qquad [6c]$$

This mechanism also has independent experimental support (9-11). The experimental methods of various authors who obtained the results $b_a = 0.03$ or 0.04V were all based on steady-state polarization data. The discrepancies in the steady-state data may have been caused by impurities in the electrolyte (1, 9), by impurities or high dislocation densities in the metal (11-13), and by rather large differences in the electrolysis time required to reach steady state [*e.g.*, 5 sec for zone-refined iron *vs.* 20 min for Armco iron (11)].

In the present work, some effects of impurities in annealed iron on the kinetics of both iron dissolution and hydrogen evolution are investigated. Also, the validity of steady-state galvanostatic measurements is studied. The results lead to new recommendations for obtaining charge-transfer polarization data from galvanostatic potential-time curves. Minor impurities in the iron are found to inhibit the hydrogen-evolution reaction significantly. Impurities can also cause the Tafel slopes to change slowly as corrosion proceeds.

Experimental

Metals.—Four relatively pure grades of iron were studied: a high-purity zone-refined iron,[2] a zone-refined iron to which 0.5 Mn [atomic per cent (a/o)] was added (14), an "interstitial-free" iron gettered with 0.15 Ti,[1] and commercial Ferrovac E iron. Each material, obtained as rod, was cleaned by a standardized procedure consisting of chemical polishing in concentrated H_3PO_4: 50% H_2O_2 (2:1 parts by volume) for 8 min, lightly etching in 6M H_2SO_4 for 3 min, then thorough rinsing in redistilled water and pure acetone. The metal was first reduced to 8 mm diameter by swaging with carefully cleaned dies. It was then recleaned and wire-drawn with molybdenum disulfide lubricant to 2.7 mm diameter, followed by centerless

grinding and honing to obtain straight rods 2.4 mm in diameter. From these rods electrodes were cut to a length of 5 cm with one end hemispherical and the other end threaded. After recleaning the electrodes were annealed in very dry purified hydrogen, as shown in Table I which also lists the metal analysis. No second phase was seen microscopically in annealed specimens of the zone-refined iron and Fe (z-r, 0.5 Mn). Small particles of a second phase were present in the Ferrovac E, presumably iron oxide, and in the Fe (0.15 Ti), presumably a Ti(C,N) phase.

Solutions.—The solutions studied were 1M $NaHSO_4$ and 1M H_2SO_4 at 25°C. They were made from reagent grade chemicals and redistilled water and were purified by passage through acid-washed activated charcoal (15). The reversible hydrogen electrode potentials, on the standard hydrogen electrode (SHE) scale, were −0.028V in the sodium bisulfate ($pH = 0.48$) and −0.003V in the sulfuric acid solution ($pH = 0.05$).

Cell.—The cell, shown schematically in Fig. 1, was designed so that only the three metal electrodes and Pyrex glass contacted the electrolyte. The test electrode t (also the similar auxiliary electrode a) was threaded tightly into a bare Ferrovac E holding rod which fit snugly into the Teflon stem T of a sealable Teflon-glass valve v (Lab Crest valve, Fischer and Porter Company). The bottom edges of the two valves, and the top edges of the three Teflon sleeves used to seal the standard-taper joints, were the only Teflon areas exposed to the vapor phase. It was found in preliminary experiments that contact of the iron electrodes in the liquid phase with Teflon or glass insulators must be completely avoided, for this induced trenching attack along the metal-insulator-solution contact line and affected the corrosion kinetics. The simple electrode arrangement of Fig. 1 always yielded uniform corrosion with no evidence of localized pitting or trenching.

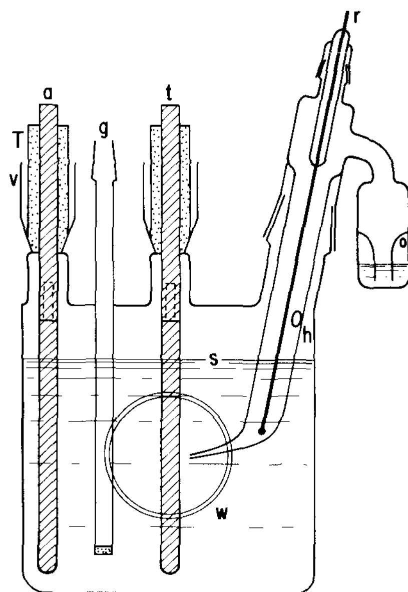

Fig. 1. Schematic diagram of cell

The two cylindrical iron electrodes were 2 cm (17 × electrode radius) apart and were immersed to a depth 3.5 cm below solution level s (total solution depth 3.8 cm). With this geometry, the difference between the current density at the center of the test electrode and the mean current density was expected to be acceptably small. The capillary tip (diameter d) of the reference compartment was positioned about 3d from the test electrode; measurement of the tip to electrode distance, facilitated by the optical window w, permitted accurate IR drop corrections. The hydrogen reference electrode r was a platinized platinum wire in the same electrolyte. A hydrogen atmosphere was maintained in the cell. Purified hydrogen entered the cell at g and passed through hole h into the reference compartment before exiting through a bubbler. Hydrogen flow was turned off 3 min before a potential-time curve was recorded; preliminary measurements showed no change in reference potential during this 3-min period.

Just before being inserted in the cell, the iron test specimen was first chemically polished by a 3-min immersion in H_3PO_4-H_2O_2, and then etched 3 min in 6M H_2SO_4 followed by 1 min in 0.5M HNO_3. This precleaning procedure yielded reproducible corrosion behavior.

Electrode polarization measurements.—Galvanostatic pulses were applied from a constant-current source (Model 225, Keithley Instruments, Inc.), which was switched rapidly from a dummy load to the cell by use of a mercury-wetted contact relay (Type HG 3A1008, C. P. Clare Company). Potential-time curves were recorded on a storage oscilloscope (Tektronix 564 with 3A9 vertical amplifier and 3B3 time base) and photographed. Corrosion potentials were measured with a high-impedance millivoltmeter (Orion Model 801) standardized from a K3 potentiometer (L&N).

Polarization curves at a specified corrosion time t^* (corresponding to corrosion current density i^* and potential ϵ^*) were obtained by applying a series of anodic and cathodic constant-current pulses, each of duration 0.5-2 sec, with sufficient time between pulses to permit the potential to return to the same value of ϵ^* within $\pm 10^{-3}$V. By limiting the magnitude of the applied current so that the polarized electrode potential remained within the range $\epsilon^* \pm 0.06$V, reproducible and hystere-

sis-free polarization curves were obtained, as described in detail in a preliminary report of the present work (16). These polarization curves were analyzed by a three-point method developed for the pre-Tafel region (17), a method which yields i^*, b_a, and b_c with good precision (16).

Results and Discussion

Potential-time curves.—The four grades of iron studied all had regular cathodic behavior: during a short constant-current pulse the potential rose smoothly from the corrosion potential to a steady value, and on opening the circuit it decayed smoothly back to ϵ^*.

Anodic galvanostatic behavior was more complex, and here proper interpretation of the ϵ-t curves was crucial for obtaining consistent values of i^* and b_a. In the first 30 hr or so of corrosion each of the four metals yielded anodic ϵ-t curves similar to those in Fig. 2A and B. These curves exhibit the characteristic $\Delta\epsilon$ maximum ($\Delta\epsilon_m$) reported by Heusler (4) and later authors. However, the curves are not in accord with Heusler's finding that the total potential change on opening the circuit ($\Delta\epsilon_{oc}$) is equal to $\Delta\epsilon_m$. For the four grades of iron studied here $\Delta\epsilon_{oc}$ was always smaller than $\Delta\epsilon_m$ if the curve contained an appreciable peak.

As corrosion proceeds, the rise to a maximum $\Delta\epsilon$ becomes sharper (compare Fig. 2A and 2B), an effect associated with a large increase in the current required to produce a given change in potential. The existence of the anodic peak persisted through 75 hr of corrosion with Fe(z-r), Fe(z-r, 0.5 Mn), and Fe(0.15 Ti). With Ferrovac E, however, the sharp peak disappeared after 40 hr of corrosion, Fig. 2D, within the restricted range $\Delta\epsilon \leq 0.06$V of this study (but peaks still appeared at higher applied currents).

The anodic curves, whether the usual peaked ones or the peakless Ferrovac E curves, exhibited a drop in potential to a value less than ϵ^* at the end of the anodic pulse. In the case of peakless curves (Fig. 2D) the value of $\Delta\epsilon_{oc}$ was independent of pulse time over a wide range, 0.5-5 sec, and was the same as the extrapolated value $\Delta\epsilon_{t=0}$. In the case of peaked curves where $\Delta\epsilon_{oc} < \Delta\epsilon_m$, the value of $\Delta\epsilon_{oc}$ was again essentially constant as illustrated in Fig. 2C, which shows consecutive pulses of 1 and 8 sec. The examples of ϵ-t curves given in Fig. 2 all refer to 1M $NaHSO_4$ solution, but the same general behavior was found in 1M H_2SO_4.

These facts led to the interpretation depicted in Fig. 3, in which the general transient is considered to be the

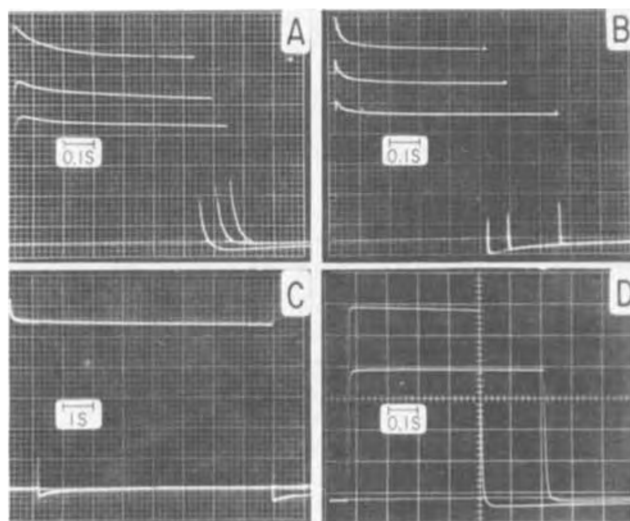

Fig. 2. Constant-current anodic pulses, iron in 1M $NaHSO_4$, vertical scale 10 mV per major division, horizontal trace $\epsilon = \epsilon^*$. A: Fe(z-r) at $t^* = 5.5$ hr; 1.5, 2.5, and 5 Am^{-2}. sum of three effects: double layer charging (curve 1), ϵ^* shift (curve 2), and the superpolarization effect (curve 3). According to Roiter *et al.* (18) superpolarization is not characteristic of the charge-transfer process since it can be made to disappear. The present work is in agreement with this, in that all four grades of iron exhibited decreasing superpolarization after long corrosion times. With these metals, the superpolarization at any t^* decayed to a negligible value within about 0.1 sec.

It is concluded that $\Delta\epsilon_{oc}$ obtained from half-second pulses contains no superpolarization component and is a valid measure of the desired charge-transfer controlled potential. This conclusion was tested in the following way. A pair of pre-Tafel cathodic and anodic polarization curves, corresponding to a given corrosion time t^* of the system Fe(z-r)/1M $NaHSO_4$, was analyzed by the three-point method using anodic $\Delta\epsilon_m$ data; the values of i^*, b_a, and b_c so obtained showed wide variations. When the corresponding $\Delta\epsilon_{oc}$ anodic data were substituted, the resulting values of b_a and b_c were constant within $\pm 3\%$. Similar results were found at other corrosion times, both for $NaHSO_4$ and H_2SO_4 solutions. These results show that our $\Delta\epsilon_{oc}$ measurements are in agreement with an I-ϵ relation of the form of Eq. [4], whereas the $\Delta\epsilon_m$ measurements (to which the "nonsteady-state" data in the literature correspond (4, 20) are inconsistent with Eq. [4].

Based on these results, we recommend $\Delta\epsilon_{oc}$ as the most reliable measurement of charge-transfer polarization for the iron-acid system. Steady-state potential measurements, on the other hand, cannot be readily interpreted. During steady-state measurements there occur significant and variable shifts in the reference corrosion state (in potential ϵ^* and current I^*). Such measurements violate the theoretical principle that all points on a true polarization curve, whether in the Tafel or pre-Tafel region, must correspond to a single reference corrosion state. Because of this violation no attempt was made in the present work to establish steady-state anodic polarization curves. Clearly the slope of an approximately linear steady-state Tafel region can differ appreciably from the true charge-transfer slope. Thus a steady-state measurement of b_a is unreliable as a criterion for distinguishing between proposed iron-dissolution mechanisms.

All of the results to follow were based on $\Delta\epsilon_{oc}$ measurements. All measured currents were converted to current densities by use of the geometrical electrode area.

Dependence of ϵ^*, i^*, b_a, and b_c on corrosion time.—Corrosion parameters for a typical 72 hr experiment with the system Fe(z-r)/1M $NaHSO_4$ are summarized in Fig. 4. The corrosion potential, recorded as a function of time, showed a characteristic slow rise before leveling off. The potential rise was not greatly changed

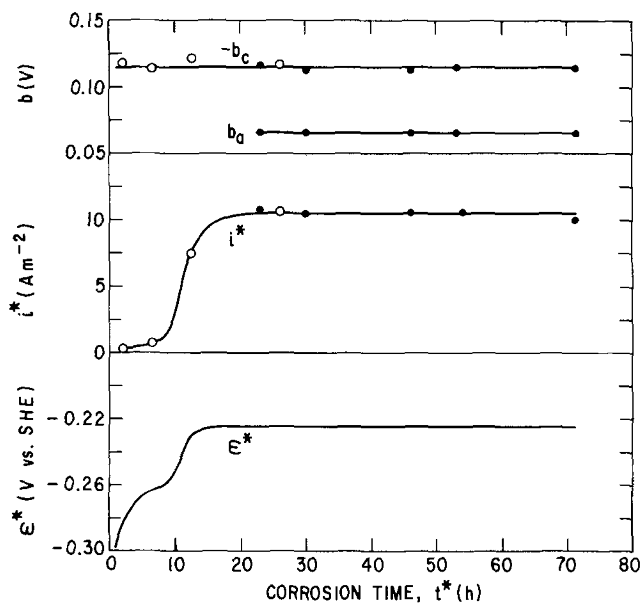

Fig. 4. Variations of corrosion potential, corrosion current, and Tafel slopes with corrosion time, Fe(z-r) in 1M $NaHSO_4$. ●, By three-point analysis; ○, from cathodic Tafel line.

by using other etching pretreatments of the electrode. Also, if the electrode were allowed to corrode until ϵ^* leveled off, and were then removed, re-etched, and replaced in the cell, ϵ^* reverted almost to its initial value and the rising portion of the ϵ^*-t^* curve was qualitatively reproduced.

Polarization curves (i-ϵ) covering the potential range $\epsilon^* \pm 0.06$V were determined periodically by application of anodic and cathodic pulses, and these pre-Tafel curves were analyzed by the three-point method to obtain i^*, b_a, and b_c. In the particular case of zone-refined iron, however, this procedure was usable only after ϵ^* leveled off. At shorter times ϵ^* shifted too rapidly: a shift of more than 3 mV during the interval required to obtain the two polarization curves led to appreciable errors in i^* and the two Tafel slopes. Fortunately it was possible in the early corrosion period to obtain linear cathodic Tafel lines, over the limited range ($\epsilon^* = 0.09$-0.14V), by applying a minimum number (four to five) of cathodic pulses. In this way b_c and i^* were evaluated. Such data, shown as open circles in Fig. 4, agreed well with data obtained by the three-point method where the two methods overlapped. During the period after ϵ^* leveled off, ϵ^* varied less than ± 0.5 mV during measurement of the two polarization curves, and the latter were readily analyzed to yield b_a as well as b_c and i^*.

Figure 4 shows that b_c remained substantially constant over the entire corrosion period. Also b_a was constant where it was evaluated, namely after ϵ^* had leveled off. Initially i^* was remarkably small, about two orders of magnitude less than the final steady current.

The other zone-refined metal, Fe(z-r, 0.5 Mn), gave curves showing all the same general trends as in Fig. 4. The Fe(0.15 Ti) metal, however, differed in showing changing Tafel slopes during the initial period of changing ϵ^* and i^* (Fig. 5). Both b_a and b_c drifted to larger (more positive or less negative) values, before becoming constant in the steady corrosion condition. Figure 5 shows that ϵ^* drifted more slowly for Fe(0.15 Ti) than it did for the zone-refined metals during the early corrosion period, so that it was possible to obtain pre-Tafel polarization curves with little hysteresis and to evaluate b_a after 5 hr of corrosion.

The steady corrosion conditions achieved by the three metals just discussed are compared kinetically in Fig. 6. Shown here are the calculated "partial" log i-ϵ relations for anodic iron dissolution and cathodic hydrogen evolution. These lines are established by the

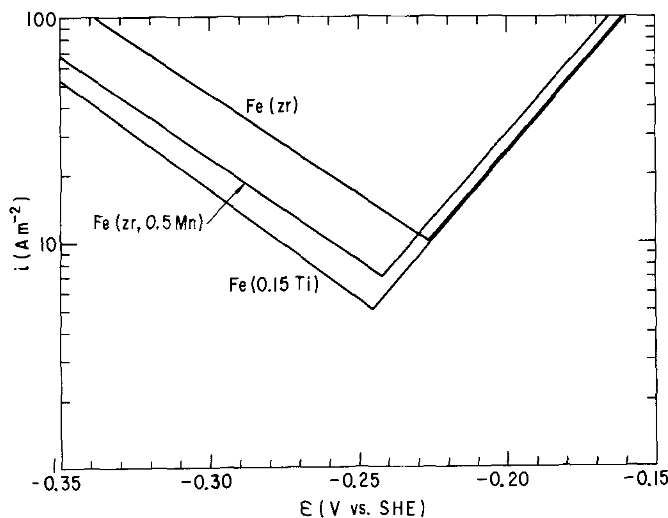

Fig. 6. Steady reaction rates of anodic iron dissolution and cathodic hydrogen evolution in 1M $NaHSO_4$ as functions of potential, $t^* > 30$ hr.

values of i^*, b_a, and b_c, determined from the measured polarization curves by the three-point analysis. The intersection of the anodic and cathodic lines gives the values of ϵ^* and i^*. The addition of manganese or titanium primarily reduced the hydrogen evolution rate at a given potential, manganese having a smaller effect than titanium (with its accompanying minor impurities). The reduction in hydrogen evolution rate is associated with a shift of ϵ^* to a less noble potential and with a reduction in corrosion rate.

A summary of all of the long-time corrosion data obtained for the four metals studied is presented in Table II. The data on zone-refined iron in the two solutions studied (pH 0.05 and 0.48) are in accord with the well-known effect that increasing acidity reduces the rate of the iron-dissolution reaction at a given potential. These data also exhibit an increase in hydrogen-evolution rate with increasing acidity, in conformity with the slow-discharge mechanism of hydrogen evolution.

Table II and Fig. 6 show that manganese or titanium additions to iron had no effect on b_a in the steady-ϵ^* region. Our measured range $b_a = 0.065$-0.069V, based on $\Delta\epsilon_{oc}$ measurements, is remarkably close to the range 0.065-0.070V obtained by Bockris, Drazic, and Despic

Table II. Mean kinetic parameters for iron corrosion in 1M $NaHSO_4$, corrosion time 30-70 hr

[a] After 70 hr corrosion, ϵ^* decreasing slowly.
[b] After 47 hr corrosion, ϵ^* decreasing slowly.

(1) from $\Delta\epsilon_m$ measurements in sulfate solutions at low pH (1-2). In these low pH solutions their steady-state values were in the range $b_a = 0.045$-0.054V, appreciably higher that the value 0.039V required by the Bockris *et al.* mechanism. Many other authors have obtained approximately $b_a = 2.303\ RT/F$ (or 0.059V) from $\Delta\epsilon_m$ measurements in various electrolytes (20). Whether our larger value 0.067 ± 0.002, as determined from $\Delta\epsilon_{oc}$ data, is significant mechanistically or whether the difference from the value 0.059V is attributable to small amounts of surface impurities cannot be settled yet (see below).

Ferrovac E exhibited a major difference from the other metals listed in Table II, in that a steady corrosion potential was not reached even after 75 hr of corrosion, although the values of i^*, b_a, and b_c all leveled off. A typical set of corrosion-time data is plotted in Fig. 7. The initial portion of the ϵ^*-t^* curve was similar to that for the other metals, but as the corrosion current approached its final value ϵ^* went through a maximum and thereafter decreased considerably. The existence of a maximum in the ϵ^*-t^* curve for annealed Ferrovac E was reported by Akiyama, Patterson, and Nobe (11) but without interpretation. The kinetic significance of this maximum is revealed upon plotting the calculated partial anodic and cathodic log i-ϵ relations as a function of corrosion time, Fig. 8. These data show that, after the maximum ϵ^* is passed, the iron-dissolution rate continues to increase whereas hydrogen evolution reaches a maximum rate (for any given potential) and then decreases continuously. Even though both the iron-dissolution and hydrogen-evolution rates are changing continuously, i^* becomes apparently constant after 40 hr of corrosion (Fig. 7).

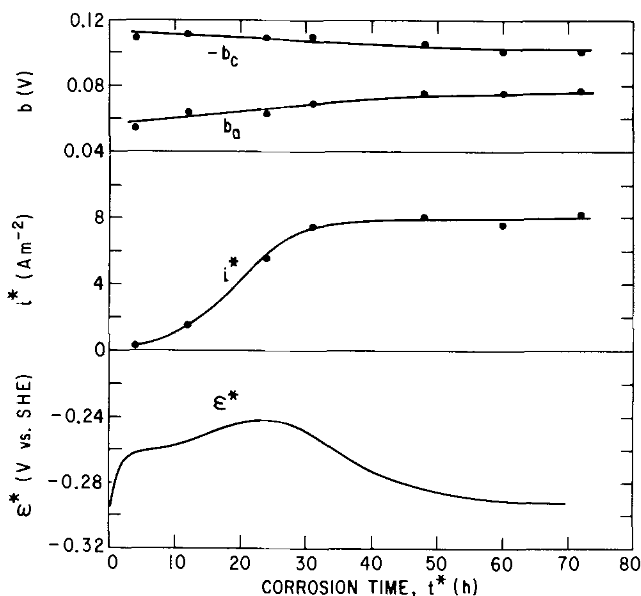

Fig. 7. Variations of corrosion potential, corrosion current, and Tafel slopes with time, Ferrovac E iron in 1M $NaHSO_4$.

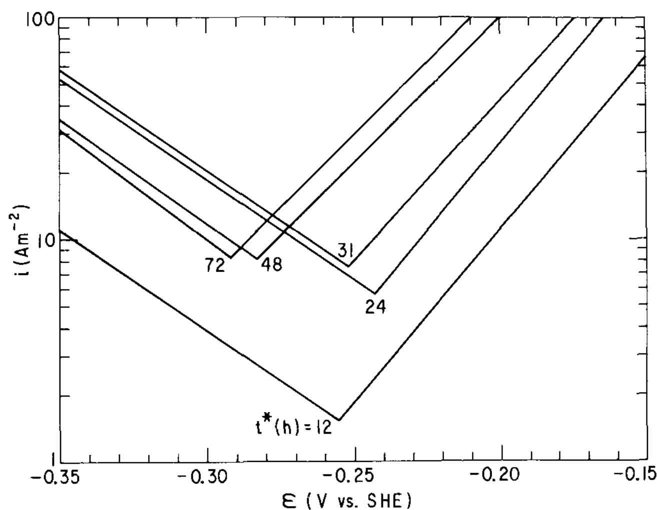

Fig. 8. Movement of the anodic and cathodic Tafel lines with corrosion time, Ferrovac E in 1M $NaHSO_4$.

A major kinetic effect of impurities in the metals studied here is a reduction in the hydrogen-evolution rate at a given potential. In Fe(0.15 Ti) and Ferrovac E the impurities also induce slow changes of Tafel slope as corrosion proceeds, causing b_a and b_c to increase with time from their initial values of approximately $b_a = 0.06$V and $b_c = -0.12$V. It is reasonable to suppose that slowly developing impurity effects arise from an enrichment of impurities on the corroding metal surface. This has been demonstrated recently by Cartledge (19) for iron containing 0.1% by weight technetium, where the corroded surface layer was shown by β-emission measurements to be highly enriched in technetium. It remains a possibility that even the two zone-refined metals could have suffered some surface-impurity enrichment by the time of the first b_a measurement (Fig. 4), and that a rise of b_a similar to that shown in Fig. 5 for Fe(0.15 Ti) could have occurred during the initial corrosion period.

Surface analysis.—Surface morphology of the corroded metals was studied by scanning electron microscopy. One typical example of the surface appearance of each of the four metals is shown in Fig. 9. In all cases crystallographic etching was observed. Some relatively flat facets were found on Fe(z-r), Fe(0.15 Ti), and Ferrovac E, but on Fe(z-r, 0.5 Mn) all crystal surfaces had the distinctive roughness seen in Fig.

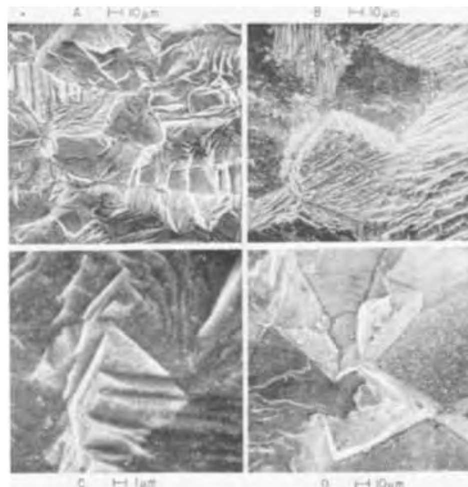

Fig. 9. Scanning electron micrographs of iron surfaces after corrosion in 1M $NaHSO_4$ for the following times: A, Fe(z-r), 50 hr; B, Fe(z-r, 0.5 Mn), 52 hr; C, Fe(0.15 Ti), 70 hr; D, Ferrovac E, 30 hr.

9B. No pitting and no preferential grain-boundary attack occurred on any of the metals.

Second-phase particles were not discernible on corroded surfaces of the two zone-refined metals, which showed no internal second phase. Also no second-phase particles were seen on corroded Ferrovac E; oxide particles present inside the metal would be expected to dissolve during the corrosion process. Second-phase particles were present on corroded Fe(0.15 Ti), as shown in Fig. 9C where they appear as irregular white specks. These were proven to be titanium-rich particles, in the scanning electron microscope, by having the electron beam stationary and focused at the center of the particle, then analyzing emitted x-rays with an energy-dispersion x-ray analyzer.

Microprobe analyses of corroded surfaces of the Fe(z-r, 0.5 Mn) metal showed a manganese content slightly lower than that of the uncorroded surface. Since the analysis was considered reliable to $\pm 5\%$ and the difference between the corroded and uncorroded surfaces was less than 5%, these results were inconclusive with respect to changes in surface manganese content. Similarly, no conclusive evidence was found for surface depletion or enrichment of other impurities on corroded zone-refined iron or Ferrovac E by analyzing long-count x-ray spectra.

Undoubtedly traces of impurity equivalent to less than a monolayer could influence the kinetic behavior of the iron surface, but such traces are not readily detectable by the x-ray method employed, which samples the surface to a depth of roughly 2000Å. More sensitive techniques will be needed, such as the radiotracer method already mentioned (19) and methods based on removing sub-monolayer amounts, analyzing either the material removed (as by mass spectrometer) or the newly created surface (as by Auger spectroscopy).

Conclusions

1. The most reliable measure of charge-transfer polarization from anodic galvanostatic transients is the total potential fall, $\Delta\epsilon_{oc}$, at the end of a short current pulse.

2. The $\Delta\epsilon_{oc}$ data yield an anodic Tafel slope of 0.067V for zone-refined iron in sulfate solutions at low pH. This is higher than the commonly observed steady-state values. The steady-state Tafel slope is subject to error from drift in the reference corrosion state, hence it is not a good indicator of the reaction mechanism. This weakens the present experimental support of each of the two popular iron-dissolution mechanisms.

3. Trace impurities in the iron can reduce cathodic hydrogen-evolution rates considerably while having little effect on anodic iron-dissolution rates.

4. Impurities can cause both the anodic and cathodic Tafel slopes to drift to more positive values as corrosion proceeds.

Dissolution Potentials and Activation Energies of InSb Single Crystals

M. E. Straumanis* and Lih-da Hu

Departments of Metallurgical and Chemical Engineering and Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

The rest (or corrosion) and dissolution potentials of InSb single crystals in HCl were determined. There is no potential difference (within error limits) between the inverse {111} faces in pure HCl. A difference of up to 44 mV and more develops as soon as the InSb electrode is anodically dissolved. The potential becomes less noble in the sequence In{111}, {100}, {110}, Sb$\{\bar{1}\bar{1}\bar{1}\}$. The Tafel relationship is observed over three decades of current density. With additions of $FeCl_3$, $FeCl_2$, $K_3Fe(CN)_6$, $K_4Fe(CN)_6$, $H_2C_4H_4O_6$ to 2*N* HCl, the anodic potentials of both inverse {111} faces are shifted to more active values; the ϵ'_H of In{111} is always nobler than that of Sb$\{\bar{1}\bar{1}\bar{1}\}$. There are indications that the various potentials observed are a function of current density within the pores of a protective layer, $Sb_4O_5Cl_2$. The apparent activation energy, *ca.* 20 kcal/mole, of the anodic dissolution reaction is nearly the same on all crystallographic planes of InSb. The rate of anodic dissolution of Sb{111} in pure 2*N* HCl is 3-7 times larger than that of the inverse face at the same potential.

In a previous publication (1) the anodic dissolution reaction of InSb single crystals in HCl was described and the cited literature can be found there. However, no potential measurements were made. The anodic potentials obtained for a InSb single crystal electrode under various conditions of corrosion or dissolution are reported here.

The construction of the electrode and the type of contact with the crystal were similar to that of GaAs (2); the potentials were measured against a normal calomel electrode using a salt bridge (~3.5*N* KCl) and a Luggin capillary. The data were reduced to the standard hydrogen scale. The measurements were performed with a precision potentiometer and the potential (ϵ')-current density, *i*, curves were obtained by potentiostatic and galvanostatic methods. Purified N_2 was introduced into the reaction vessel containing the electrodes.

The n-type, undoped single crystals were obtained from the Monsanto Company (St. Louis, Missouri) and were grown in the [111] direction by the Czochralski or the gradient-freeze technique. The impurity level was less than 1 ppm, the carrier concentration was 8×10^{15} atoms·cm^{-3}, mobility 1.7×10^5 cm^2·V^{-1}·sec^{-1}, and the resistivity 0.005 ohm·cm; 670 etch pits·cm^{-2} were developed on the {111} planes. The surface area subjected to the electrolyte was between 0.35-0.82 cm^2 for the various electrodes.

Results

Rest potentials.—The potential readings were taken as soon as possible after the electrode was chemically pre-etched with CP-4 (1). Then the next reading was made after 5 min and subsequent readings after 15 min intervals. No anodic current was applied.

The results are summarized in Fig. 1. Figure 1 shows that:

1. The ϵ_H's of the inverse {111} faces in the same concentration of HCl are approximately equal, $\Delta\epsilon'_H \sim = 10$ mV; however In{111} has a slightly more noble potential than does Sb{111}.
2. For both inverse {111} faces, the higher the normality of HCl, the less noble is the ϵ'_H.
3. Time has no particular influence on ϵ'_H; steady potentials are usually obtained after 15 min of immersion.
4. The potentials are reproducible within ±10 mV.

*Electrochemical Society Active Member.
Key words: InSb, dissolution potentials, activation energies, Tafel lines.

Significant potential changes occurred in the presence of Fe^{3+}, added as $FeCl_3$ to the HCl. The potentials of the inverse {111} faces differed by as much as ~40 mV; the In{111} faces were always more positive than the Sb$\{\bar{1}\bar{1}\bar{1}\}$. However, the behavior of the InSb electrode in the presence of Fe^{3+} employing no anodic current required further investigation.

Anodic potential-current density relationship in 2N HCl.—The anodic potential measurements were carried out as previously described (1, 2). The platinized platinum electrode serving as the cathode was coupled with the InSb electrode. During each run, the time, milliammeter and potentiometer readings were recorded. The readings were taken after 5 min at each milliammeter setting. All current densities were plotted against the measured anodic potential (SHE). The oxygen was excluded (N_2 atmosphere).

The separation of the dissolution potentials into those characteristic of the In{111} and Sb$\{\bar{1}\bar{1}\bar{1}\}$ faces occurred even at low anodic current densities. The potentials were in the vicinity of those of InSb in 2*N* HCl as shown in Fig 1. At a current density of 3×10^{-3} mA/cm^2 the difference was about 12 mV. This increased with increasing current density (Fig. 2). It is evident from Fig. 2 that:

1. The ϵ'_H of the four different faces becomes less noble in the sequence: In{111}, {100}, {110}, Sb$\{\bar{1}\bar{1}\bar{1}\}$.

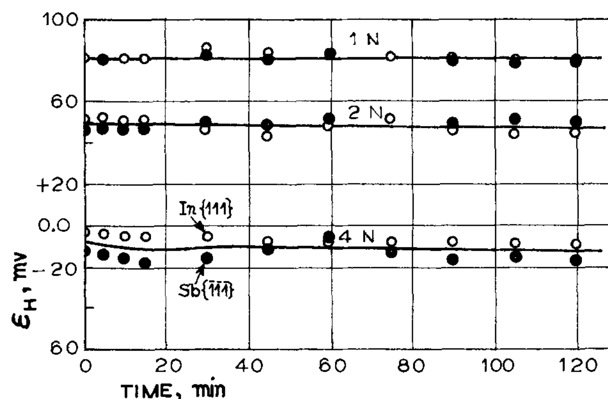

Fig. 1. Rest potentials, ϵ'_H of InSb single crystals in various concentrations of HCl (reagent grade) at 25°C. ○—In{111} and ●—Sb{111} faces.

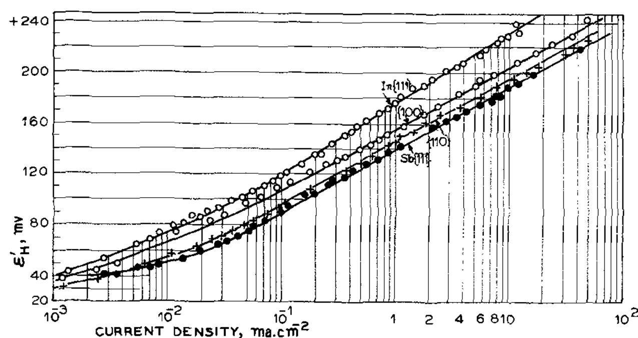

Fig. 2. Anodic dissolution potentials ϵ'_H of InSb vs. log of current density i of the single crystal planes In{111}, Sb{$\bar{1}\bar{1}\bar{1}$}, {110}, and {100} at 25°C. 2N HCl.

The potential difference between the inverse 111-faces approaches 30 mV at 3×10^{-2} mA/cm^2 and 44 mV at 10 mA/cm^2.

2. All four anodic polarization curves obey the Tafel relation over about three decades of current density (3×10^{-2} to 30 mA/cm^2).

3. Within this range of current density the latter three faces give parallel Tafel lines with a slope of ~48 mV/log i, while the first line has a slope of ~56 mV/log i. However, significant departures from these potentials occur upon addition of oxidizers or reducers to the HCl.

ϵ'_H-log i relationship in 2N HCl in the presence of Fe^{3+}.—The results of these measurements are summarized in Fig. 3, where the Tafel lines of InSb in pure 2N HCl are redrawn to show the influence of Fe^{3+}. The Tafel region occurs only between 1 and 10 mA/cm^2. Clearly, in the presence of Fe^{3+} ions, the potentials of both inverse {111} faces are shifted to more active values by approximately the same amount (~ 33 mV in 0.0004M and 37 mV in 0.002M solutions of Fe^{3+}). The slope of the Tafel line of In{111} in both solutions is 62 mV/log i and that of Sb{$\bar{1}\bar{1}\bar{1}$} is about 58 mV/log i.

Similar measurements were also performed by adding $FeCl_2$ solutions to the 2N HCl. As the solutions were prepared in air, part of the Fe^{2+} ions oxidized

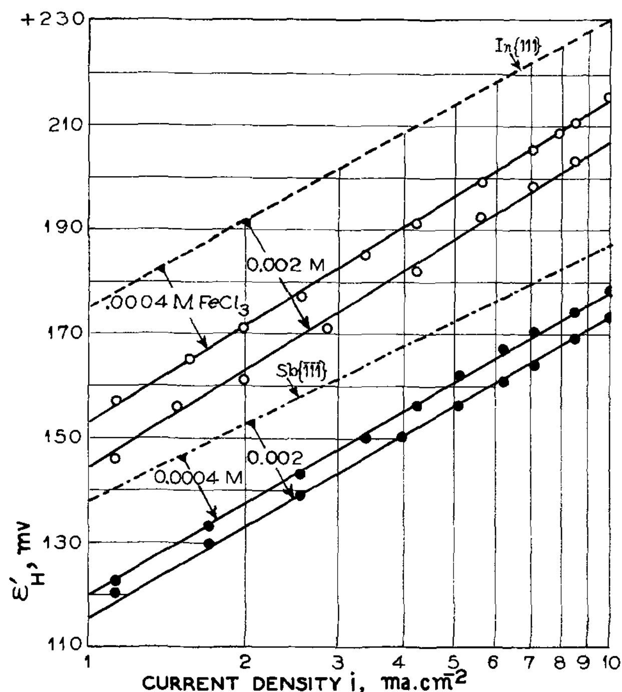

Fig. 3. ϵ'_H of the inverse {111} faces of InSb vs. log i in 2N HCl in presence of Fe^{3+} at 25°C. Dashed lines — ϵ'_H in pure 2N HCl.

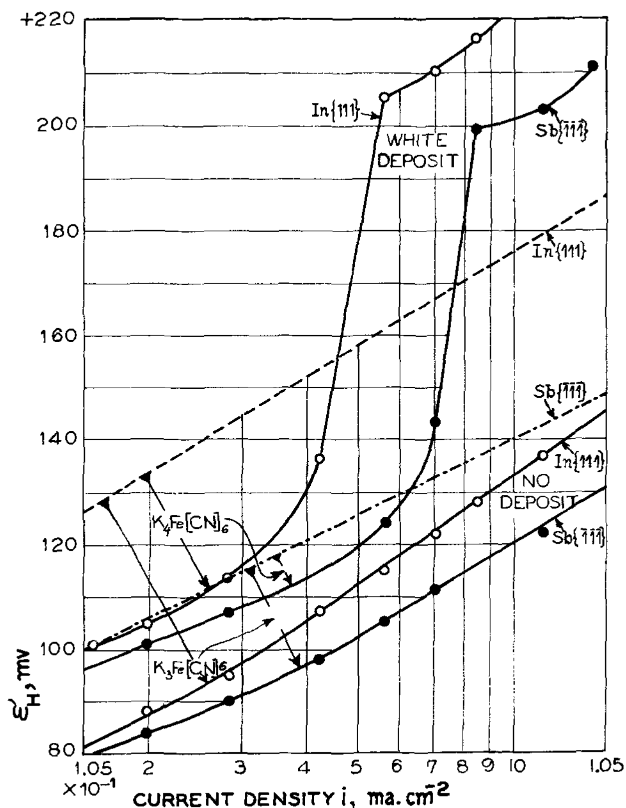

Fig. 4. ϵ'_H of the inverse {111} planes of InSb vs. log i in 2N HCl in presence of 0.00125M solutions of $K_4[Fe(CN)_6]$ and of $K_3[Fe(CN)_6]$. Dashed lines — ϵ'_H in pure 2N HCl.

to Fe^{3+} and, therefore, the results obtained resembled those with Fe^{3+}. There was a shift of potentials to more active values; however, the polarization lines were not as parallel as shown in Fig. 3.

The influence of $K_4[Fe(CN)_6]$ and of $K_3[Fe(CN)_6]$ on the anodic potential.—The ϵ'_H-log i curves in the presence of potassium ferro and ferri cyanides are shown in Fig. 4. The influence of the cyanides was observed even below 1 mA cm^{-2}. The potentials of the inverse {111} planes shifted to more active values, the action of $K_3[Fe(CN)_6]$ being stronger. No deposit was observed on the anodes when $K_3[Fe(CN)_6]$ was added. However, a white sediment appeared on both inverse faces in the presence of $K_4[Fe(CN)_6]$ at current densities above 0.4 mA/cm^2. In all the measurements the potential of the In{111} face was more positive than that of the Sb{$\bar{1}\bar{1}\bar{1}$}. Evidently the potential changes were connected with the formation and presence of deposits on the anodic surfaces. This possibility was checked by trying to remove chemically the oxide layer which is formed on Sb (of the InSb) in HNO_3.

Potentials of InSb in HNO_3 in the presence of tartaric acid.—It is known that antimony oxide dissolves in $H_2C_4H_4O_6$ yielding water-soluble, antimony-tri-tartrate. Polarization curves of the InSb{111} inverse planes are reproduced in Fig. 5. They show that, indeed, at low anodic current densities (up to 0.3 mA/cm^{-2}), the potentials of both faces coincide. A possible explanation is offered in the discussion. The Tafel relationship is nevertheless partially fulfilled.

Activation energies.—The chosen temperature of the water bath, containing the U-vessel with the InSb and Pt electrodes, was maintained at ± 0.2°C. Purified N_2 was bubbled slowly through the electrolyte (HCl). Figure 6 shows the curves obtained for the inverse {111} planes of InSb. As can be seen, the anodic dissolution potential ϵ'_H for both inverse {111} planes becomes less noble with increasing temperature and the Tafel lines exist over three decades of i. The slopes differ slightly: 55.6 mV/log i for In{111} and 47.1 for

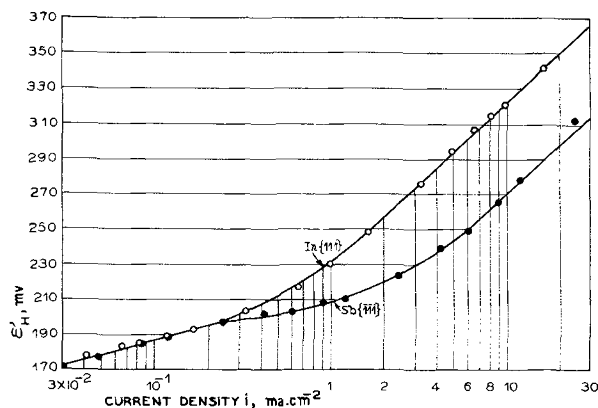

Fig. 5. ϵ'_H of the inverse {111} planes of InSb vs. log of anodic current density in 1N HNO_3-1N $H_2C_4H_4O_6$ at 25°C.

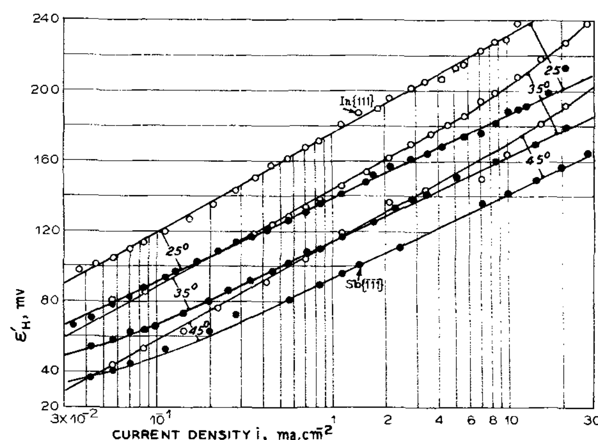

Fig. 6. ϵ'_H of In{111} and Sb{$\bar{1}\bar{1}\bar{1}$} vs. log i in 2N HCl at three temperatures. Galvanostatic measurements.

Sb{$\bar{1}\bar{1}\bar{1}$}. The In{111} faces are always nobler than the inverse by ~ 36, 27, and 20 mV at 25°, 35°, and 45°C respectively.

Current density measurements for four different crystal planes of InSb, were plotted against T^{-1} (Fig. 7).

The apparent activation energies E_a were calculated (Table I) from the slopes of the lines (Fig. 7).

Discussion

As InSb consists of two elements, it is interesting to see what the dissolution potentials of the latter are relative to that of InSb. In Fig. 8 the respective potentials are plotted *vs.* log i.

Figure 8 reveals that the dissolution potentials of the inverse {111} faces are close to that of Sb and at a current density of 1 mA/cm² there is no difference within experimental error limits. However, metallic Sb starts to passivate at about 15 mA/cm², whereas the Sb{$\bar{1}\bar{1}\bar{1}$} face remains active at higher current densities and the Tafel relationship results over nearly 3½ decades of log i. Evidently In, which passes simultaneously into solution (1), prevents the formation of a tight, adherent Sb-oxychloride protective layer on the InSb. In fact a thicker layer can be removed easily with a soft brush (1). Metallic In, which displays a

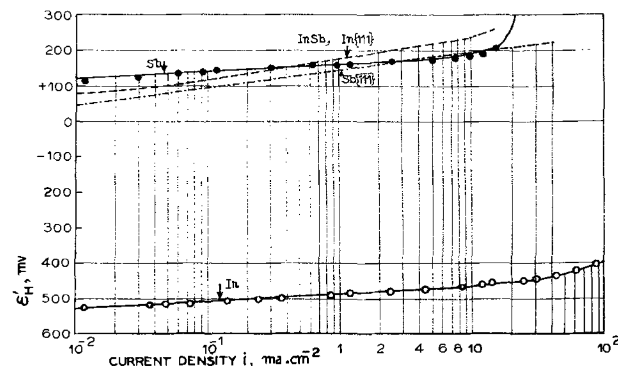

Fig. 8. ϵ'_H of metallic In, metallic Sb (both 99.999% pure) and of the inverse faces of InSb vs. log i in 2N HCl, 25°C.

very negative potential in 2N HCl (Fig. 8) loses much of its free energy by combining with Sb. Thus, the In in InSb might be in a form which is more electropositive than the Sb. At high anodic current densities part of the latter accumulates on the surface and is embedded in the oxychloride layer (anodic disintegration of Sb). This results in a lower electron number for InSb [Ref. (1), Fig. 6].

For immersion of InSb into pure 2N HCl, where the corrosion rate is very low [Ref. (1), Table I], the protective layers formed on all crystallographic faces are evidently of the same consistency and adherence. Therefore, there is little, if any, potential difference between the inverse {111} faces and the potential is strongly dependent on the pH of the solution (Fig. 1) as it is for a pure Sb electrode (3, 4).

However, as soon as an anodic current is applied, the oxychloride layer is at least partially removed from the various faces of the InSb crystal. The difference in valency of the two constituents now comes into play and this can be noticed, especially on the inverse {111} planes. The potential difference between these planes is the greatest among those investigated and the potentials become more negative in the order: In{111}, {100}, {110} and Sb{$\bar{1}\bar{1}\bar{1}$} (Fig. 2). Explanations of this difference have been offered by other authors (5, 6). GaAs in KOH behaves similarly (2) (Fig. 3).

If now at the same current density various crystallographic planes exhibit different anodic potentials (Fig. 2), it can be assumed (if InSb behaves like a metal) that this is due to the difference in the structure of the protective films. During anodic dissolution both inverse {111} planes of InSb are covered with a Sb-oxychloride film (1), but this film may be, for unknown reasons, more dense and/or more adherent to the In{111} rather than to the Sb{$\bar{1}\bar{1}\bar{1}$} plane. Moreover, it is also probable that In (within the InSb structure), due to the loss of free energy, is present in a different form, than in a metal, and now has less ability to go into solution. Both assumptions contribute to the presence of a more noble potential on the In{111} than on the Sb{$\bar{1}\bar{1}\bar{1}$} face, especially under conditions of anodic dissolution. The other planes should exhibit intermediate values. This anodic behavior, as a current density effect, requires a smaller pore size on the In{111} face which results in a higher current density within the pores and a steeper Tafel line will be obtained (Fig. 2). When the anodic current is decreased, the quality of the previous oxide film on the faces will be restored and consequently the potential difference between the inverse {111} planes will diminish (Fig. 2) and finally approach zero (Fig. 1).

Therefore, agents which partially remove the Sb-oxide film from the InSb electrode should also decrease the potential difference between the inverse planes. This is the case when InSb is dissolved in 1*N* HNO_3 containing tartaric acid (Fig. 5). At low current densities the oxide film is thin on both planes, since the newly formed Sb-oxide easily dissolves in tartaric acid. However, at current densities above 0.3 $mA \cdot cm^{-1}$ the thickness of the film increases so much that the dissolution of the film is not rapid enough and a separation of the potentials occurs. The film on the In{111} should be denser. This follows from the inclination of the Tafel lines: at low current densities—26 mV/log *i* and above 4 $mA \cdot cm^{-2} \sim 92$ mV/log *i*. Furthermore the potential of InSb in 1*N* HNO_3 is much more positive than in HCl (compare Fig. 2 and 5) caused partially by the difference in the composition and properties of the layers. Denser oxide or hydroxide films are formed in HNO_3 because of the oxidizing action of the acid.

Increasing the concentration of a nonoxidizing acid (*e.g.*, HCl) should decrease the thickness of the surface oxide layers, which results in a more negative potential, as shown in Fig. 1.

Similar to the behavior of the Sb electrode, the potential of the InSb electrode is very easily disturbed by oxidizing and reducing agents, and it is difficult to understand this disturbance. For instance (Fig. 3), minute amounts of $FeCl_3$ added to 2*N* HCl shift the potential of both inverse {111} planes to less noble values, the shift increasing with increasing concentration of the Fe^{3+} ions. Nevertheless the Tafel line relationship persists and the In{111} planes are always nobler than the inverse. Evidently Fe^{3+} ions are adsorbed by the oxychloride layer, changing its properties, increasing its pore size, which results in a lower pore current density and in a more active potential.

The action of $K_4Fe(CN)_6$ and of $K_3Fe(CN)_6$ additions is still more complicated. In both cases the potential of the anode becomes more negative relative to the dissolution potentials in pure 2*N* HCl (see Fig. 4). Again the In{111} is more noble than the inverse face.

If the InSb is anodically dissolved in a 2*N* HCl-0.00125M $K_4Fe(CN)_6$ solution, then at current densities higher than 0.4 $mA \cdot cm^{-2}$ the formation of a white collodial layer is observed on both inverse {111} planes. The layer can be removed by rinsing with water. No deposit was observed in a 2*N* HCl-0.00125M $K_3Fe(CN)_6$ solution, even at current densities above 10 $mA \cdot cm^{-2}$. According to Mellor (7) $K_4Fe(CN)_6$ forms a white precipitate with In^{3+} but $K_3Fe(CN)_6$ does not. This was confirmed experimentally. Thus the jump in the curves (Fig. 4) is explained as the onset of the precipitate formation. At about 1 $mA \cdot cm^{-2}$ the precipitate is already so dense that one can see it readily. Thus this surface layer causes a strong polarization, which does not occur for $K_3Fe(CN)_6$, because the salt formed is water soluble and the slope of the Tafel-lines above 0.6 $mA \cdot cm^{-2}$ is $\sim$ 70 mV for In{111} and 60 mV for Sb{$\bar{1}\bar{1}\bar{1}$}.

With increasing temperature the dissolution potentials become more negative (Fig. 6) partially because of thermodynamic reasons and also due to the decrease of the anodic current density within the pores (widening of the pores with increasing temperature).

Since the slopes of the Tafel lines fluctuate mostly between 40 and 60 mV/log *i*, the possibility of a one electron charge transfer as a rate-determining step is not excluded. Nevertheless, the rate of dissolution in pure 2*N* HCl of Sb{$\bar{1}\bar{1}\bar{1}$} at the same potential is 3-7 times larger than that of the inverse face, in agreement with the concept of pore width. Evidently, the effective current density (within the pores) is the same on all the faces. However, as the pores of the protective layer on Sb{$\bar{1}\bar{1}\bar{1}$} are larger, a stronger current results from this face.

The apparent activation energies (Table I) for the anodic reactions on various planes of InSb are the same within the error limits, suggesting that the reactions (1) are all the same, independently of the plane chosen for the anode. However, the E_a value of $\sim$ 20 kcal/mole is relatively high for a dissolution reaction. A similar value of 16.7 kcal/mole was also obtained for the anodic dissolution reaction of the compound GaAs in KOH (2). Much lower activation energies were found for metals simply dissolving in acids, *e.g.*, 5.3 ± 0.5 kcal for Hf dissolving in 1*N* HF or in a mixture of HF and HCl (8) and 3.8 to 4.2 kcal for Zr in 0.2*N* HF or 0.1*N* HF + 1.0*N* HCl respectively (9). However, when the oxygen content of Zr was increased up to 7% b.w., the E_a increased to 5.9 kcal. Simultaneously the rate of dissolution decreased, evidently the dissolved oxygen tightly bound by the Zr atoms hampered the reaction rate with the acid.

As InSb exhibited a much lower dissolution rate (1), a higher activation energy should be expected for this reaction, because it is chiefly the value of E_a which determines the rate (10), even of an anodic dissolution process. The activation energy of $\sim$ 20 kcal/mole was, therefore, expected. Thus a high activation energy of dissolution of InSb (and of GaAs) in comparison with that of pure metals is characteristic of the former and corresponds to its reaction sluggishness.

The Effect of Two-Dimensional Nucleation on the Rate of Electrocrystallization

Ugo Bertocci

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

The effect of random two-dimensional nucleation on current-potential curves, valid for epitaxial electrodeposition on single-crystal faces, has been examined employing a specific model for nucleation and surface step motion. Computations have been performed for the electrodeposition of silver and copper: for the first metal the results are in reasonable agreement with some experimental data concerning two-dimensional nucleation on close-packed surfaces. In the case of copper the agreement with experimental results seems to be less satisfactory. The influence of assumptions, such as the type of surface step distribution, on the rate of electrocrystallization has been examined and discussed. Computer simulations of potentiostatic transients have also been carried out, and some effects of suppressing nucleation in the vicinity of steps have been investigated.

From computer-simulated experiments on the influence of two-dimensional nucleation and step motion on the rate of crystal growth (1), formulas have been obtained which allow one to estimate the relative importance of random nucleation and step density on the growth rate. The purpose of the present paper is to apply these results to the case of electrocrystallization processes, attempting to evaluate current-potential curves for the deposition of metals on close-packed and vicinal surfaces of single-crystal electrodes.

Models and Methods of Calculation

In the epitaxial growth of a single crystal by electrocrystallization, the current density i depends on the density and velocity of the steps moving on the surface

$$i = \frac{zFh_{(hkl)}}{V_m} V \theta \quad [1]$$

where z is the number of electrons exchanged, $h_{(hkl)}$ is the height of a crystal layer in the [hkl] direction, V_m the molar volume, and V and θ the step velocity and step density. If the dependence of the current density on the overvoltage η has to be found, it is necessary to express V and θ as a function of overvoltage. The step velocity can be considered in general to depend on η and θ and an expression will be derived later (Eq. [13]). Steps on the surface can be due to misorientation with respect to a close-packed plane (the step density due to misorientation is indicated as ζ) or to the interplay between two-dimensional nucleation rate R_n and step velocity V. The formula relating these quantities is (1)

$$\theta = \sqrt[3]{\frac{2R_n}{V} + \zeta^3} \quad [2]$$

and our purpose is to obtain the dependence of R_n and V, and therefore θ, on the overvoltage.

According to nucleation theory (2), R_n is given by the product of the concentration of critical nuclei, which are formed by aggregating adatoms over the close-packed portions of the surface, the rate of addition of single adatoms to the critical nucleus, and the Zeldovich nonequilibrium factor

$$R_n = Z\, n_{cr}\, \omega \quad [3]$$

Since two-dimensional nucleation is considered here, nuclei are assumed to be cylindrical in shape, their height being one atom layer. The concentration of critical nuclei is

$$n_{cr} = NA \exp\left(-\frac{\Delta G^{\ddagger} + \Delta G_q + \Delta G_s}{kT}\right) \quad [4]$$

where N is Avogadro's number and A the concentration of unaggregated adatoms (in mol/cm^2); $\Delta G^{\ddagger}$ is the free energy for the formation of a nucleus

$$\Delta G^{\ddagger} = -\frac{\pi h_{(hkl)} \gamma^2 V_m}{\Delta\mu} \quad [5]$$

where γ is the surface energy and $\Delta\mu$ is the decrease in free energy in the crystallization process. ΔG_q is the contribution to the free energy due to the distribution of nuclei on the various sites of the substrate. The number of such sites is equal to $Nd_{(hkl)}$ where $d_{(hkl)}$ is the surface density of the close-packed layer (hkl) (in mol/cm^2).

$$\Delta G_q = \frac{kT}{A}\left[d_{(hkl)} \ln\left(\frac{d_{(hkl)} - A}{d_{(hkl)}}\right) + A \ln\left(\frac{A}{d_{(hkl)} - A}\right)\right] \quad [6]$$

Calling K the ratio $d_{(hkl)}/A$ where K is a constant greater than 1, Eq. [6] becomes

$$\Delta G_q = kT \ln\left[\frac{A}{d_{(hkl)}}\left(\frac{K-1}{K}\right)^{K-1}\right] \quad [7]$$

The free energy of separation, as defined by Lothe and Pound (3), is

$$\Delta G_s = kT \ln(\sqrt{2\pi i_{cr}}) \quad [8]$$

where i_{cr} is the number of atoms in the critical nucleus.

Key words: electrodeposition, electrochemistry, computer simulations, copper, silver.

The Zeldovich nonequilibrium factor is (4, 5)

$$Z = \left(\frac{\Delta G^{\ddagger}}{4\pi kT i^2_{cr}} \right)^{1/2} \quad [9]$$

The rate of addition ω of adatoms to the nucleus is the product of the number of adatoms per unit surface NA, the circumference of the critical nucleus $-2\pi\gamma V_m/\Delta\mu$, and the velocity of an adatom on the surface which is equal to the surface diffusion coefficient D_s divided by the length of a jump $\alpha_{(hkl)}$ between two rest positions on the (hkl) plane. Therefore

$$\omega = -\frac{2\pi\gamma V_m N A D_s}{\alpha_{(hkl)}\Delta\mu} \quad [10]$$

Combining Eq. [3]-[10], the nucleation rate is obtained

$$R_n = \sqrt{\frac{(-\Delta\mu)}{2RT}} \left(\frac{K}{K-1} \right)^{K-1} \frac{NAD_s(-\Delta\mu)}{\pi V_m \alpha_{(hkl)}\gamma} \exp\left(\frac{\pi h_{(hkl)}\gamma^2 V_m}{kT\Delta\mu} \right) \quad [11]$$

It should be noted that if $K >> 1$, $[K/(K-1)]^{K-1}$ approaches the value e.

In the following, calculations are performed only for the (100) and (111) surfaces of a fcc metal. In this case, given the atomic radius E, the molar volume $V_m = 4\sqrt{2}\, NE^3$, $h_{(100)} = \sqrt{2}\, E$, $h_{(111)} = 2\sqrt{2}/\sqrt{3}\, E$, $\alpha_{(100)} = 2E$, and $\alpha_{(111)} = 2/\sqrt{3}\, E$. The formulas employed are therefore

for (100)

$$R_n = \sqrt{\frac{(-\Delta\mu)}{RT}} \left(\frac{K}{K-1} \right)^{K-1} \frac{AD_s(-\Delta\mu)}{16\pi E^4\gamma} \exp\left(\frac{8\pi\gamma^2 E^4 N}{kT\,\Delta\mu} \right)$$

for (111)

$$R_n = \sqrt{\frac{3(-\Delta\mu)}{RT}} \left(\frac{K}{K-1} \right)^{K-1} \frac{AD_s(-\Delta\mu)}{16\pi E^4\gamma} \exp\left(\frac{16\pi\gamma^2 E^4 N}{\sqrt{3}\,kT\,\Delta\mu} \right) \quad [12]$$

The nucleation rate depends on the adatom concentration A. In order to evaluate it, a particular model describing the electrocrystallization process has to be chosen. Here the model employed assumes that the adatom concentration is always the equilibrium one in the immediate vicinity of a step (6). For the sake of simplicity it will be assumed that the electrode charge-transfer reaction involves only one electron: $M \rightleftarrows M^+ + e^-$, that is $z = 1$.

The adatom concentration as a function of the distance x from a surface step between two parallel steps which are a distance l apart is

$$A(x,l,\eta) = A_{eq}\left[\exp\left(-\frac{\mathbf{F}\eta}{RT} \right) - \left(\exp\left[-\frac{\mathbf{F}\eta}{RT} \right] - 1 \right) \frac{\cosh(\lambda[l/2 - x])}{\cosh(\lambda l/2)} \right] \quad [13]$$

where

$$\lambda = \sqrt{\frac{i_o}{\mathbf{F}D_s\,A_{eq}}} \exp\left[\frac{(1-\beta)\mathbf{F}\eta}{2RT} \right] \quad [14]$$

Here η is the overvoltage (excluding concentration polarization), i_o is the exchange current density, and β is the symmetry factor (in the computations β is taken as 0.5).

The expression $\Delta\mu$ which occurs in the formula for the nucleation rate is given by

$$\Delta\mu = RT \ln \frac{A_{eq}}{A(x,l,\eta)} \quad [15]$$

where A_{eq} is the equilibrium adatom concentration.

According to the same model, the step velocity V can also be expressed as a function of the overvoltage η and step spacing l

$$V(\eta,l) = \frac{2}{d_{(hkl)}}\sqrt{\frac{i_o D_s A_{eq}}{\mathbf{F}}} \left[\exp\left(\frac{(1-\beta)\mathbf{F}\eta}{2RT} \right) - \exp\left(-\frac{(1+\beta)\mathbf{F}\eta}{2RT} \right) \right] \tanh\left(\frac{\lambda l}{2} \right) \quad [16]$$

The average nucleation rate $\overline{R_n}(\eta,l)$ for a surface covered with parallel steps with step spacing l can be found by introducing [13] and [15] in [11] and integrating

$$\overline{R_n}(l,\eta) = \frac{1}{l}\int_o^l R_n[A(x,l,\eta)]dx \quad [17]$$

The system formed by Eq. [2], [16], and [17] can be solved, giving the rate of growth (and therefore the current density) as a function of the overvoltage η and the step density due to misorientation ζ, if the effect of random nucleation is supposed to be equivalent to an increase of step density above the value ζ producing, however, a uniform step distribution. Then all steps are supposed to be spaced at a constant distance l, and $\theta = 1/l$. Therefore

$$i = \frac{\mathbf{F}h_{(hkl)}}{V_m} V(\theta,\eta) \sqrt[3]{\frac{2\overline{R}_n(\theta,\eta)}{V(\theta,\eta)} + \zeta^3} \quad [18]$$

The computational procedure consists of calculating $A(x,l,\eta)$ from [13] at several distances from a step, employing the results for the numerical integration of [17]. Evaluation of [2] with the calculated values of $\overline{R_n}$ and V will give a new value for θ, and [18] can be solved by successive approximations.

Random nucleation, whether or not steps due to misorientation are present, obviously generates a surface where steps are not arranged in a uniform manner. This is visualized, for instance, in Fig. 1 which represents a misoriented surface on which random patches are

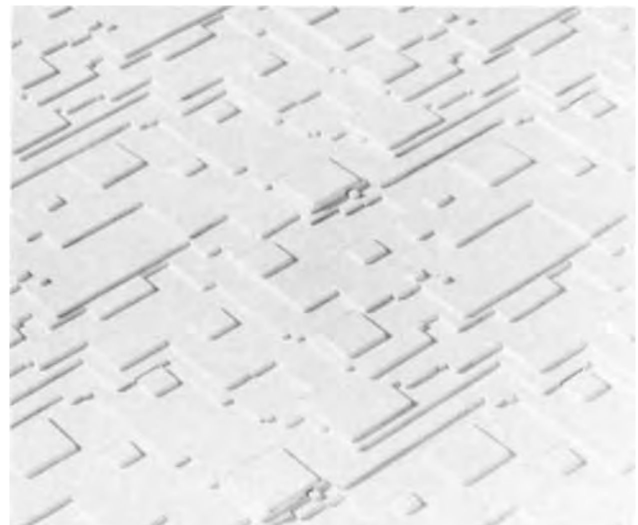

Fig. 1. Appearance of a single-crystal surface produced by computer simulation of crystal growth. Random two-dimensional nucleation superimposed to growth by step motion.

growing, as it was generated in a computer run. It is interesting, therefore, to have an idea of the influence of a nonuniform step distribution on the rate of growth. An approximate solution for such a case can be obtained in the following way: from the results obtained for a uniform distribution, if the value of $(R_n)_\infty$, the nucleation rate at infinite distance from a step, is compared with the average value $\overline{R_n}(l)$, it is found that to a good approximation

$$\overline{R_n}(l) = (R_n)_\infty \left(1 - \frac{2f(\eta)}{\lambda l}\right) \quad \text{for } l \geq \frac{2f(\eta)}{\lambda}$$

$$\overline{R_n}(l) = 0 \quad \text{for } l < \frac{2f(\eta)}{\lambda} \quad [19]$$

Equation [19] corresponds to assuming that nucleation is completely suppressed at distances less than $f(\eta)/\lambda$ from a step, elsewhere being equal to $(R_n)_\infty$. The function $f(\eta)$ represents, in units of diffusion distance $1/\lambda$, how far from a step nucleation is prevented. That a step function such as [19] describes the influence of step spacing is not surprising: the nucleation rate is greatly affected by relatively small changes in adatom concentration. Several experiments have shown the existence of the threshold value in $\Delta\mu$ below which the rate of nucleation is negligibly small. Computations carried out with many different sets of parameters have shown that the function $f(\eta)$ is very insensitive to variations of i_o, D_s, or A_{eq}, and it is independent of step distance until l is so small that the average nucleation rate for that step spacing is small with respect to $(R_n)_\infty$.

By means of the simplification afforded by [19], it is possible to obtain the expression for the average nucleation rate as a function of the average step density θ when the spacings between steps are distributed exponentially, according to the distribution function $n(l) = \theta^2 \exp(-\theta l)$

$$R_n(\theta) = (R_n)_\infty \theta^2 \int_{2f(\eta)/\lambda}^{\infty} \left[l - \frac{2f(\eta)}{\lambda} \right] \exp(-\theta l)\,dl = (R_n)_\infty \exp\left(-\frac{2f(\eta)}{\lambda}\theta \right) \quad [20]$$

The limited validity of [19] has little effect on the accuracy of [20], since areas of small step spacing contribute very little to the average nucleation rate.

The average step velocity $V(\theta)$ can also be obtained by integration of the product of [16] and the step distribution function

$$V(\theta) = \frac{V_\infty \theta}{\lambda} \left[\Psi\left(\frac{\theta}{2\lambda} + \frac{1}{2}\right) - \Psi\left(\frac{\theta}{2\lambda}\right) - \frac{\lambda}{\theta} \right] \quad [21]$$

where V_∞, the step velocity for infinite step spacing, is obtained from [16] by setting the value of the hyperbolic tangent term to 1. The function Ψ is the derivative of the logarithm of the gamma function. The computational procedure is analogous to that described above, introducing [20] and [21] in [2] and [18], instead of [16] and [17].

Potentiostatic Transients

The concepts and computational methods employed in the simulations which led to obtain formula [2] for the steady-state rate of growth are very similar to those used by Bewick, Fleischmann, and Thirsk (7) to simulate the initial potentiostatic transients. These authors found that the growth rate underwent damped oscillations, in some cases of considerable amplitude. It was interesting to see if these results could be confirmed, and to what extent the amplitude of the oscillation might depend on the intrinsic limitations of the computer model. Accordingly, initial transients were computed using two different simulated surface areas having a ratio 6.25.[1]

[1] The surfaces were represented by arrays having 32400 and 5184 places, respectively. For the details of the simulation method, see Ref. (1).

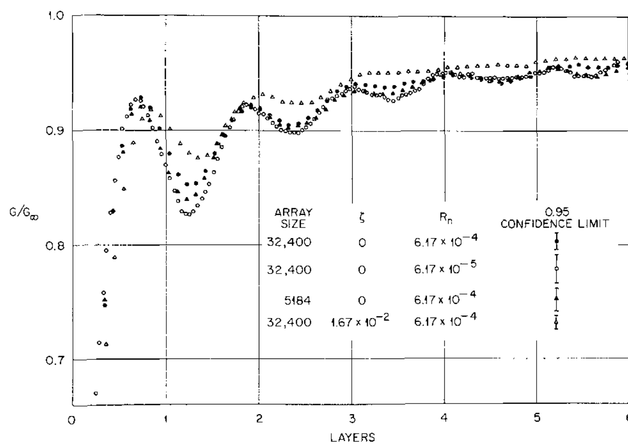

Fig. 2. Initial transient of the growth rate. Constant nucleation rate.

If the results are plotted as ratio of the growth rate over the asymptotic growth rate *vs.* the number of layers grown, the curves obtained are substantially independent of surface size as well as ratio between nucleation rate and step velocity. The results are shown in Fig. 2. It can be seen that damped oscillations are indeed produced, the maximum amplitude being about 10% of the asymptotic rate. The oscillations decrease rapidly and only four or five can be detected with some degree of certainty.

If comparison is made with experimental results for potentiostatic transients starting from a smooth surface (7), the simulated oscillations are smaller in amplitude and more rapidly damped. However, an important difference between the computer simulations and the analytical models describing electrocrystallization (such as the one employed in the preceding section) is that in the latter the nucleation probability is thought to decrease in the vicinity of a step if the supersaturation of the crystallizing species is a function of the distance from a step. In order to test if variations in the nucleation rate can be responsible for the large and persistent oscillations, a computer simulation was carried out in which nucleation was prevented close to a step, up to the third nearest neighbor place. This caused the initial oscillations to be larger and more persistent, as shown in Fig. 3.

Obviously, the simulation is but a crude approximation of the phenomena occurring on real surfaces. The extent of the surface on which nucleation is reduced because of steps depends on the value of the diffusion distance and this can conceivably be large. The computer simulations, however, show that if the nucleation rate depends on step density, large periodic oscillations of the current density during a potentiostatic transient can be generated.

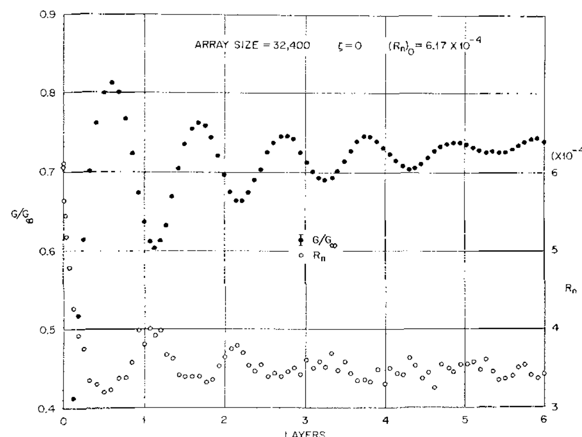

Fig. 3. Initial transient of the growth rate. Variable nucleation rate.

Results of the Computations

Computations according to the formulas given above have been carried out. Their purpose is two-fold: on one side they give examples by means of which the significance of different assumptions, such as uniform or exponential step distribution, can be assessed. On the other hand the best estimates for the parameters necessary to carry out the computations have been chosen so that comparison with experiment, whenever possible, could give some indication of the validity of the models employed here.

Calculations have been performed for copper and silver, considering a one electron over-all charge-transfer reaction. This, for Cu, would correspond to deposition from halide or ammonia solutions.

Silver.—For this metal, Budevski and co-workers (8) have derived a value for the surface energy from the time necessary to form the first nucleus as a function of the overvoltage. However, such a calculation involves the assumption that a steady-state condition is instantaneously achieved. Of the two possible reasons for a delay in the onset of steady state, the nonideal behavior of the potentiostat can be considered negligible: because of the small surface area of the electrode, of the order of $2 \cdot 10^{-4}$ cm^2, the adatom concentration can be brought to the value corresponding to overvoltages between -10 and -20 mV in times much shorter than those required to form the first nucleus. However, even when the adatom concentration is stationary, an initial transient in the nucleation rate occurs because of the finite time necessary to aggregate adatoms in clusters of various sizes up to the critical nucleus. The solution of this problem is obtained by integrating the Frenkel-Zeldovich equation (4, 9). The expression for the nucleation rate as a function of time is (10)

$$R_n(t) = R_n(\infty)\left[1 + 2F\left(\frac{t}{\tau}\right)\right] \quad [22]$$

where $R_n(\infty)$ is given by [11] and

$$F\left(\frac{t}{\tau}\right) = \sum_{i^n}^{\infty} (-1)^n \exp\left(-n^2\frac{t}{\tau}\right) = \frac{1}{2} - \sqrt{\frac{\pi\tau}{t}}$$

$$\exp\left(-\frac{\pi^2\tau}{4t}\right)\sum_{o^n}^{\infty}\exp\left(-n(n+1)\frac{\pi^2\tau}{t}\right) \quad [23]$$

The two expressions for $F(t)$ can be obtained from each other by means of Jacobi's imaginary transformation (11). The time constant τ is given by

$$\tau = -\frac{8kT}{\pi^2\omega\left(\dfrac{\partial^2\Delta G}{\partial i^2}\right)_{i=i_{cr}}} \quad [24]$$

where ω is given by [10]

and

$$\left(\frac{\partial^2\Delta G^\ddagger}{\partial i^2}\right)_{i=i_{cr}} = \frac{\Delta\mu^3}{2\pi h_{(hkl)}V_m\gamma^2} \quad [25]$$

For a (100) surface of a fcc metal therefore

$$\tau_{(100)} = \frac{16\sqrt{2}}{\pi^2}\frac{RTE^2\gamma}{\mathbf{F}^2A_{eq}D_s\eta^2}\exp\left(\frac{\mathbf{F}\eta}{RT}\right) \quad [26]$$

since $A = A_{eq}\exp(-\Delta\mu/kT)$, and $N\Delta\mu = \mathbf{F}\eta$ all over the surface when no steps are present.

The steady-state nucleation rate can be evaluated by integration of [22]

$$1 = S\int_0^t R_n(t)dt \quad [27]$$

where S is the surface area and t the time necessary for the formation of the first nucleus. The integral [27] obtained from the left-hand side expression in [23] has been reported in the literature (10). When t/τ is small, however, the right-hand side expression in [23] converges more rapidly. Integral [27] becomes

$$1 = S \cdot R_n(\infty)\tau G(t/\tau) \quad [28]$$

where

$$G\left(\frac{t}{\tau}\right) = 4\sqrt{\pi}\left\{\sum_{0}^{\infty}{}_n \exp\left[-\left(n+\frac{1}{2}\right)^2\frac{\pi^2\tau}{t}\right] - \pi^{3/2}\left(n+\frac{1}{2}\right)\mathrm{Erfc}\left[\left(n+\frac{1}{2}\right)\pi\sqrt{\frac{\tau}{t}}\right]\right\} \quad [29]$$

From [28] it can be seen that for a given overvoltage the value of $G(t/\tau)$ depends only on γ, since A_{eq} and D_s drop out of the product $R_n(\infty)\tau$. The time necessary to form the first nucleus, therefore

$$t = \tau G^{-1}\left(\frac{t}{\tau}\right) \quad [30]$$

decreases linearly with an increase of the product $A_{eq}D_s$, besides being strongly dependent on γ. Figure 4 shows a comparison between calculated values of log t *vs.* $1/\eta$ and Budevski's experimental points (8). The range of γ values which produce agreement is very small, variations being of the order of few per cent. The value of the product $A_{eq}D_s$, which gives the best fit is $2 \cdot 10^{-19}$ mol/sec, and can be increased or decreased by a factor of 3.

Another comparison between calculated and experimental values can be made: The time necessary to form a monolayer from a single nucleus at the overvoltage of 6 mV was found to be about 3.5 sec for a circular electrode of 150 μm diameter (8). Therefore, the step velocity in these conditions can be estimated as being between 20 and 50 μm/sec. The velocity of an isolated step can be obtained from [16] letting tanh $(\lambda l/2) = 1$. The velocity increases with the square root of the product $i_oA_{eq}D_s$, so involving parameters whose values have already been chosen for the best fit in the nucleation rate. If a value of $5 \cdot 10^{-18}$ A·mol/cm^2 sec is chosen for $i_oA_{eq}D_s$, a velocity of 17 μm/sec is obtained.

Bachmann and Vetter (12) have reported values of 2 and 5.4 A/cm^2 for the exchange current density of (100) Ag in 0.1 and 0.5M $AgClO_4$ solutions respectively. They also found a crystallization capacitance of the order of 300-500 μF/cm^2 corresponding to about 10^{-10} mol/cm^2 for the surface adatom concentration. As expected for a symmetry factor β close to 0.5, i_o increases approximately with the square root of the concentration in solution. Therefore, in a 6M solution

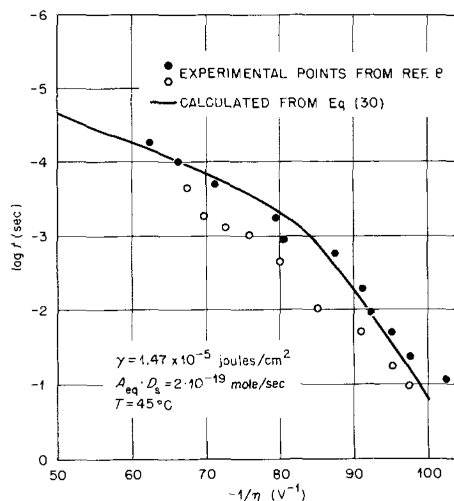

Fig. 4. Comparison between experimental and calculated values for the time necessary to form the first nucleus.

at 45°C as Budevski employed, it is not unreasonable to assume i_0 to be as high as 25 A/cm².

In order for the product $i_0 A_{eq} D_s$ to be $5 \cdot 10^{-18}$, a value of $2 \cdot 10^{-9}$ cm²/sec for D_s should be chosen. No reliable values for D_s are available in the literature, and estimates range between 10^{-7} and 10^{-10} cm²/sec. With such values, the product $A_{eq} D_s$ becomes $2 \cdot 10^{-19}$ mol/sec, which allows a good fitting of the experimental data concerning the nucleation rate.

Steady-state current density as a function of overvoltage and misorientation could be calculated also, once the various parameters have been chosen. However, in such conditions transport in solution would become the slowest process and both crystallization and charge-transfer would no longer be rate determining.

Copper.—Experimental data concerning the electrochemical behavior of Cu in monovalent copper solutions are scarce and tend to indicate that some of the assumptions used in developing the present treatment may not be applicable, chief among them the hypothesis of equilibrium at a step, particularly for (100) orientations (13). Computations therefore have been performed principally in order to show the effect of conditions such as the step distribution or to indicate broadly the limits of validity of the formulas. Nevertheless, the choice of the values of the parameters involved in the computations has been made according to the best evidence available. In this way it is hoped that when comparison with existing data is possible, some conclusions can be drawn from the degree of agreement between experimental and calculated values.

In order to obtain values for A_{eq}, which were not available in the literature, galvanostatic pulses at low current density for the system Cu/Cu^+ 0.1M, KCl 2M, HCl 1M at 23.5°C were recorded. Single crystals having (100) and (111) orientation were used as electrodes. Surface preparation and other experimental methods have been described (13, 14). Anodic and cathodic constant current pulses between 50 and 300 μA/cm² were superimposed to small bias currents between +3 and −3 μA/cm², so that the overvoltage at the beginning of the pulse could be varied about 10 mV above and below the equilibrium value. Oscilloscope sweep rates ranged between 2 and 50 msec/cm. The slopes of the voltage-time curves were measured at regular time intervals and plotted as log $(d\eta/dt)$ *vs.* time.

A detailed interpretation of the results is complicated, since in certain current density and time ranges the plots are not straight lines. However, for (111) surfaces a reliable extrapolated value $(\partial\eta/\partial t)_{t=0}$ could be obtained. Figure 5 reports the values of the electrode capacitance

$$C = \frac{i}{\left(\frac{\partial \eta}{\partial t}\right)_{t=0}} = \frac{i}{C_{dl} + \frac{\mathbf{F}^2 A}{RT}} \quad [31]$$

(i = current density) plotted as a function of the bias overvoltage. Equation [31] shows the relationship between C and the adatom concentration A (15). It was found that the capacitance tends to increase at lower electrode potentials, which can be interpreted as being due to changes in adatom concentration under the assumption that the small bias currents caused negligible charge-transfer overvoltage. Then

$$A(\eta) = A_{eq} \exp\left(-\frac{\mathbf{F}\eta}{RT}\right) \quad [32]$$

if the double layer capacitance C_{dl} is known, the equilibrium adatom concentration A_{eq} can be derived from [31] and [32]. The straight line in Fig. 5 is calculated assuming C_{dl} = 30 μF/cm² and from these data A_{eq} for (111) copper is estimated as $4 \cdot 10^{-11}$ mol/cm². For (100) surfaces the capacitance was about 30 μF/cm²,

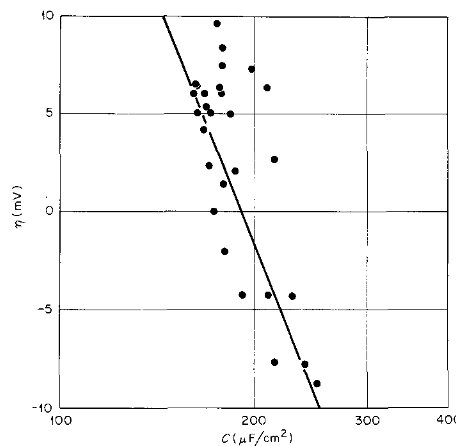

Fig. 5. Electrode capacitance vs. initial overvoltage for Cu in Cu^+ 0.1M, KCl 2M, HCl 1M.

and independent of the potential, and it can only be concluded that A_{eq} cannot be deduced from these experiments. Its upper value could be tentatively set at 10^{-12} mol/cm².

From the examination of the first milliseconds of the galvanostatic transients, as well as from steady-state polarization curves, the exchange current density can be estimated to be between 1 and 10 mA/cm² both on (111) and (100). Considering that the Cu^+ activity in these solutions is of the order of 10^{-8}M, such a value is compatible with the high i_0 for this reaction found in cupric solutions (16) where Cu^+ activity is of the order of 10^{-4}M.

In vacuum the surface energy of Cu is approximately 1.4 times that of Ag (17); accordingly, a value of $2 \cdot 10^{-5}$ j/cm² for Cu in contact with an electrolytic solution has been chosen. It should be noted, however, that other authors (18) have estimated a value more than 10 times larger.

The available information indicates that the exchange current density as well as the surface energy, should not be strongly dependent on orientation. In the case of γ, the value of which affects nucleation rate very strongly, only differences from 1 to 4% were observed for copper in vacuum (19). For the surface diffusion coefficient, however, calculations by Haruyama (20) and more recently by Wynblatt and Gjostein (21) indicate large differences between (111) and (100) surfaces, which would lead to diffusion coefficients of 10^{-5} cm²/sec for (111) and 10^{-8} cm²/sec for (100) at room temperature. An interesting point is that, according to these authors, on copper (100) vacancy migration could be more important than adatom migration, since both energy of formation and energy of migration are significantly lower for vacancies than for adatoms. Vacancy migration could effectively reduce the differences in surface diffusion coefficient between the two close-packed surfaces. The effect of considering a metal-solution interface, instead of a metal in vacuum for which the calculations are valid, is very difficult to estimate: a reduction of a factor of 10 for D_s has been suggested (18). For our purposes only the product $A_{eq} D_s$ has to be determined. According to the preceding discussion, the product could range between 10^{-17} and 10^{-19} for (111) and between 10^{-19} and 10^{-21} mol/sec for (100). These are the values used in the computations.

Figures 6 and 7 show some steady-state current-potential curves for (100) and (111). In the first case, the lower value of $A_{eq} D_s$ would give a qualitative agreement with experimental data (13) if a misorientation of 0° were taken. The actual electrodes, however, because of slight misorientation and the presence of dislocations, had at least an average step density corresponding to a misorientation of 30′ of arc. The agreement with the curve calculated for this misorientation is less satisfactory. The main cause of the discrepancy

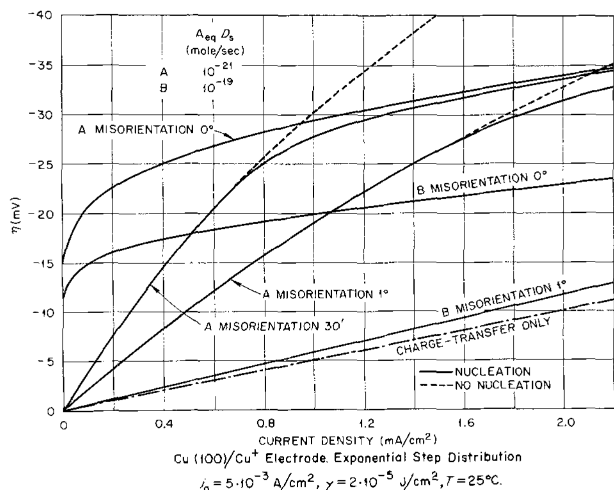

Fig. 6. Current-potential curves calculated for the Cu(100)/Cu$^+$ electrode. Exponential step distribution. $i_o = 5 \cdot 10^{-3}$ A/cm^2, $\gamma = 2 \cdot 10^{-5}$ j/cm^2, $T = 25°C$.

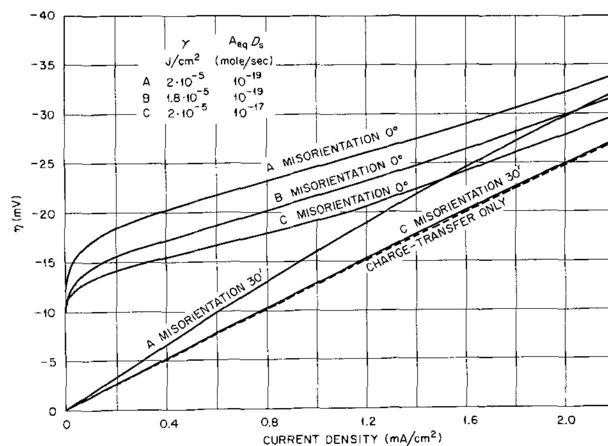

Fig. 7. Current-potential curves for the Cu(111)/Cu$^+$ electrode. Exponential step distribution. $i_o = 2 \cdot 10^{-3}$ A/cm^2, $T = 25°C$.

is probably that the assumption of equilibrium for adatoms in the immediate vicinity of a step is not satisfied for these surfaces, the motion of the steps being hindered by adsorption (22).

The curves for both (100) and (111) show that even in the presence of small misorientations the influence of the nucleation rate on current density is felt only beyond −25 mV. The range of conditions where two-dimensional nucleation is rate-determining is shown to be rather restricted.

Some calculated values are reported in Tables I and II. It can be seen that the choice of the step distribution affects step velocity and step density, the two parameters which determine the rate, in opposite ways. As nucleation rate is higher for the exponential distribution, the step density is increased and this is very pronounced at small misorientations. The average step velocity, on the contrary, is slowed down, since many of the steps are close together. The two effects tend to compensate each other, so that the current density is in many cases only slightly influenced by the distribution. In Table I, calculated for a surface 15' from (100), the radius of the critical nucleus and the number of atoms in it are also given. The numbers indicate that the assumption of a circular nucleus is probably justified for overvoltages up to −30 mV.

Table II shows the effect of step distribution on current density, step velocity, step density, and nucleation rate for surfaces near (111). Depending on how close the surface is to (111), the choice of the distribution can lead to an increase or a decrease of the current density.

Discussion

The purpose of this work was to apply nucleation theory to the case of electrocrystallization and to indicate how values accessible to measurement, such as current density, could be calculated. Since experimental values for many of the parameters involved in the calculations are not known with certainty, comparison with experiment is often difficult. However, it must be borne in mind that in electrochemistry comparisons between theoretical expectations and experimental data have sometimes not been performed for lack of a clear understanding of the way such calculations might be carried out. This work is intended to illustrate methods for this purpose.

For the calculation of nucleation rates, both pre-exponential and exponential factors have been de-

duced from the theory. In view of the continuing controversies (23) involving uncertainties of several orders of magnitude, it is encouraging that the computations are in good agreement with the best set of data existing in the electrochemical literature (8).

In order to estimate the influence of two-dimensional nucleation on current density, a formula derived from computer simulations has to be employed. This formula is admittedly empirical, but its approximate validity can be demonstrated (24), and it has been shown that the value of numerical coefficient which is the result of the averaging procedure, is rather insensitive to the details of the model (1). The same computer simulation which had been used for deducing the formula has provided here a way to explain the transient behavior of potentiostatic curves, providing an argument in favor of interpreting some electrocrystallization data as influenced by surface diffusion.

In many problems concerning electrocrystallization processes, the step velocity, and therefore the reaction rate, are evaluated for a uniform step density distribution. Although uniform step spacing can be stable for certain step-interaction functions, it has been proved that under a wide range of conditions such a distribution is unstable (25) and the assumption would be unjustified. In this paper an attempt has been made to evaluate the influence of a different step spacing distribution. It has not been shown that the exponential distribution is closer to the experimental conditions, and the ways whereby a nonuniform distribution can be attained have not been discussed. The calculations, however, have shown that the average step velocity, and therefore the current density, are sometimes strongly dependent on the distribution. The effect of releasing the constraint of uniform step spacing is in general a decrease of the current density, unless nucleation is rate determining; the current density also becomes less dependent on orientation. The last point could contribute to explaining why, in a number of cases, little dependence of current density on orientation was observed.

Electrohydrodimerization Reactions

II. Rotating Ring-Disk Electrode, Voltammetric and Coulometric Studies of Dimethyl Fumarate, Cinnamonitrile, and Fumaronitrile

V. J. Puglisi and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

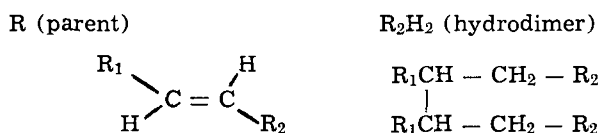
ABSTRACT

The reduction of the activated olefins dimethyl fumarate, cinnamonitrile, and fumaronitrile in tetra-n-butylammonium iodide-dimethylformamide solutions at a platinum electrode has been studied by rotating ring-disk electrode (RRDE) voltammetry, cyclic voltammetry, and coulometry. The results indicate that each compound undergoes a one-electron reduction to the anion radical which then undergoes a dimerization reaction. Rate constants for this dimerization reaction were found to be 110 (dimethyl fumarate), 880 (cinnamonitrile), and 7×10^5 (fumaronitrile) l/mole-sec. Evidence of some bulk polymerization reaction was obtained from the coulometric results.

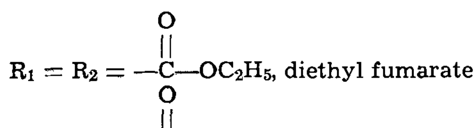
The general equation for electrohydrodimerization (or electrolytic reductive coupling) of an activated olefin, R, is shown in Eq. [1]

$$2R + 2e + 2H^+ \rightarrow R_2H_2 \qquad [1]$$

The first paper in this series (1) dealt with the determination of the mechanism of this reaction for diethyl fumarate reduction in dimethylformamide (DMF) solutions. Results of



R (parent) $\qquad$ R_2H_2 (hydrodimer)



$R_1 = R_2 = $ —C(=O)—OC_2H_5, diethyl fumarate

$R_1 = R_2 = $ —C(=O)—OCH_3, dimethyl fumarate

$R_1 = C_6H_5$, $R_2 = $ —CN, cinnamonitrile

$R_1 = R_2 = $ —CN, fumaronitrile

double potential-step chronoamperometry experiments showed that the reduction proceeded by coupling of the electrogenerated radical anions (mechanisms I)

$$R + e \rightarrow R^{\cdot -} \qquad [2]$$

$$2R^{\cdot -} \xrightarrow{k_2} R_2^{2-} \qquad [3]$$

rather than by reaction of the radical anion with parent and subsequent electron transfer (mechanism II)

$$R^{\cdot -} + R \xrightarrow{k_2'} R_2^{\cdot -} \qquad [4]$$

$$R_2^{\cdot -} + e \rightarrow R_2^{2-} \qquad [5]$$

[and variations of this mechanism (2)] or initial formation of a dianion (mechanism III)

$$R + 2e \rightarrow R^{2-} \qquad [6]$$

$$R^{2-} + R \xrightarrow{k_2''} R_2^{2-} \qquad [7]$$

We assume throughout that protonation can occur at any stage of the reaction sequence, ultimately leading to R_2H_2, but that the protonation steps are not rate determining.

Key words: reductive coupling, electrochemical dimerizations, rotating disk electrode, coulometry, cyclic voltammetry.

In this paper we extend the study of the mechanism of electrohydrodimerization to the compounds dimethyl fumarate, cinnamonitrile, and fumaronitrile, with special emphasis on the application of rotating ring-disk electrode (RRDE) techniques, which have been shown to be particularly useful in distinguishing among mechanisms I, II, and III (2). Previous studies of these compounds [(3-6) and references therein] have verified that hydrodimers are the major products of the electroreduction. Since the lifetimes of the electrogenerated intermediates for these compounds span the range of millisecond to second, these studies also provide a useful test of the application of RRDE techniques over a wide range of reaction rates.

Experimental

Reagents.—Dimethylformamide (DMF), obtained from Baker Chemical Company, was purified by the method of Faulkner and Bard (7) and was stored under He. Solvent purity was ascertained by voltammetric analysis of a DMF solution of tetrabutylammonium iodide (TBAI). Southwestern Analytical Chemical's polarographic grade TBAI was used as received. Fumaronitrile (Aldrich Chemical Company) was sublimed twice prior to use. Dimethyl fumarate, twice sublimed, and cinnamonitrile, used as received, were obtained from K. and K. Laboratories, Inc. All reagents were stored over Drierite.

Apparatus.—A Model 170 Electrochemistry System (Princeton Applied Research Corporation, Princeton, New Jersey) was employed throughout the study. A regulated power supply was used as a constant current source. The current was determined by measuring the potential developed across a 10 kohm ($\pm$ 0.025%) resistor with a digital multimeter. The electrochemical cell and dispensing vessel are shown in Fig. 1. The platinum Teflon rotating ring-disk electrode, having a disk radius (r_1) of 0.187 cm and inner (r_2) and outer (r_3) ring radii of 0.200 and 0.332 cm, respectively, was constructed by Pine Instrument Company, Grove City, Pennsylvania. The N-value for this electrode was determined from the geometry and by experimental measurements on electrochemical systems unperturbed by reactions of the disk generated species (*e.g.*, azobenzene) and was found to be 0.555 ± 0.001. The electrode was rotated using a Motomatic Model E-550 motor and controller (Electrocraft Corporation, Hopkins, Minnesota). Electrical contact to the shaft was made using two sets of silver graphalloy brush and leaf assemblies. A platinum wire spiral served as the auxiliary electrode. The reference electrode was either a saturated calomel electrode (SCE) (coulometric experiments only) or a silver wire spiral (Ag-RE). The working electrode in the coulometric experiments was

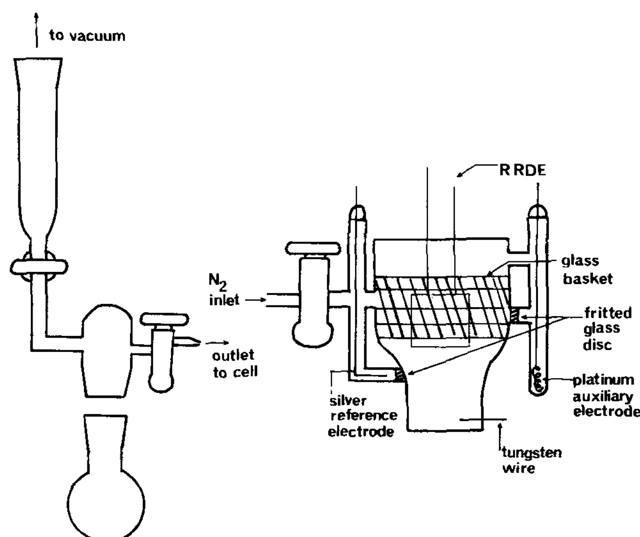

Fig. 1. Electrochemical cell and dispensing vessel

either a mercury pool or a platinum wire gauze. Cyclic voltammograms were recorded on a Tektronix, Type 564 storage oscilloscope. All experiments were carried out at 24°C. Dissolved oxygen was removed from the solution by the freeze-pump-thaw technique. The dispensing vessel was then brought to atmospheric pressure with He. The solution was transferred to the electrochemical cell, which was continually being flushed with N_2, by the introduction of positive N_2 pressure. It was convenient to fill each compartment of the electrochemical cell separately. All experiments were conducted with a continuous stream of N_2 flowing over the solution surface. Impurities in the cinnamonitrile appeared as a irreversible reduction wave at the foot of the main cinnamonitrile reduction wave. This small wave was removed by carrying out exhaustive electrolysis at a potential on the plateau of this wave. The cinnamonitrile reduction current, after electrolysis of the impurity, equaled, within experimental error, the sum of the impurity and cinnamonitrile reduction currents prior to the pre-electrolysis. Limiting disk current ($i_{d,l}$) rotation rate (ω) relationships were determined at several different potentials on the limiting current plateau. These $i_{d,l}$-values were determined both from voltammograms obtained at scan rates of 5 and 10 mV/sec and from currents obtained by stepping to potentials corresponding to the limiting current region. In all collection efficiency measurements a constant current was applied to the disk while the ring was maintained at a controlled potential. The ring was adjusted to a potential such that the ring current (i_r) was zero at the current sensitivity to be used in the measurement of i_r, when the disk current (i_d) equaled zero; this potential was always at a value where any radical anion being produced at the disk would undergo mass transfer controlled electrochemical oxidation at the ring. This procedure for measuring i_r allowed the accurate determination of even very small values of i_r, and is most useful for studying short-lived disk generated species.

Results

Dimethyl fumarate.—Rotating disk electrode (RDE) voltammograms (i_d *vs.* E_d) taken at slow scan rates (5-10 mV/sec) for millimolar solutions of dimethyl fumarate in DMF-0.1M TBAI at ω-values of 47.6-200 sec^{-1} exhibit a reduction wave with $E_{1/2} = -0.75V$ *vs.* Ag-RE followed by a dip in i_d after development of a well-developed plateau. This dip develops into a second reduction wave on addition of water (6). The discussion of all results here are limited to processes occurring at the first reduction wave. Values of the Levich constant, $i_{d,l}/\omega^{1/2}C$, for different values of ω and C are given in Table I. Although the values of the Levich

[a] The solutions were all 0.1M TBAI in DMF. The RDE radius was 0.187 cm.

constant are independent of ω, in accordance with the Levich equation [8], there is a small decrease of $i_{d,l}/\omega^{1/2}C$ with increasing concentration.

$$i_{d,l} = 0.62\, nFAD^{2/3}\nu^{-1/6}\omega^{1/2}C \qquad [8]$$

This decrease is probably caused by a small contribution from a polymerization reaction consuming parent material. This polymerization is more strongly reflected in coulometric experiments, where controlled potential reduction of millimolar solutions of dimethyl fumarate at potentials on the plateau of the first reduction wave ($-1.625V$ *vs.* SCE) yields an n_{app} value (n_{app} = number of faradays per mole of electroactive substance) of 0.62. Similar n_{app} values were found for diethyl fumarate (1).

To obtain information about the mechanism of the reaction, RRDE experiments were undertaken, and the variation of the kinetic collection efficiency, N_K, where

$$N_K = |i_r/i_d| \qquad [9]$$

i_r and i_d are the ring and disk currents, respectively, as a function of the disk current, expressed as *CONI*, at different values of ω and C was determined

$$CONI = i_d/i_{d,l} \qquad [10]$$

Typical results are shown as the points in Fig. 2. The trend of N_K with *CONI*, *i.e.*, N_K decreasing with increasing *CONI*, has been shown to be characteristic of mechanism I (given in Eq. [2] and [3]) and excludes mechanisms II (it is possible that a nuance of mechanism II [see (2) case IId, Fig. 6] could exhibit, for some values of equilibrium and rate parameters, this same trend. However, in that case N_K would vary as the square of the bulk concentration and the N_K *vs.* 1-*CONI* trends could also be different for different concentrations of parent R), and III (2), as well as first order decomposition of R^{-}. Note these other reactions of R^{-} may be occurring in parallel with the dimerization of R^{-} (Eq. [3]), but dimerization must be the predominant pathway. The experimental points

Solid lines are theoretical curves corresponding to mechanism I and (a) $XKTC = 0.16$ and (b) $XKTC = 0.25$, where $XKTC = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}C\omega^{-1}k_2$.

were fit by simulating mechanism I for different values of *XKTC*, the dimensionless simulation

$$XKTC = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}\omega^{-1}k_2C \qquad [11]$$

variable defined in Eq. [11]. For example, the line in Fig. 2 corresponds to an *XKTC* value of 0.25. Values of *XKTC* obtained by this method at different C and ω are given in Table II, along with the normalized parameter $(XKTC)(\omega)/C$. Values of k_2 were calculated from this parameter and the diffusion coefficient determined from $i_{d,l}$ and Eq. [8]; the average value of k_2 obtained from this data is $1.1 \pm 0.1 \times 10^2$ liters/mole-sec. This value can be compared to the dimerization

rate found previously for diethyl fumarate by double potential step chronoamperometry of about 34 liters/mole-sec.

Cinnamonitrile.—The rotating disk electrode voltammogram for cinnamonitrile shows a reduction wave with $E_{1/2} = -1.21V$ *vs.* Ag-RE. The limiting current for this wave conforms closely to the Levich equation for different values of both ω and C (Table I). A second reduction wave with a height about 1.5 times that of the first wave, occurs at $-1.83V$ *vs.* Ag-RE. Controlled potential coulometric analysis at the first wave shows n_{app} values of 0.96 ± 0.10 for cinnamonitrile concentrations of 1 to 11 mM. The coulometric n_{app} value near one, the existence of a second reduction wave even without the addition of water, and the lack of dependence of $i_{d,l}/\omega^{1/2}C$ on C suggest that polymerization reactions are absent during reduction of cinnamonitrile under these conditions.

RRDE experiments involving determination of N_K with *CONI* were also carried out; typical results are shown in Fig. 3. Again the behavior is characteristic of mechanism I, and best fit values of *XKTC* and k_2 are listed in Table II. The average value of k_2 for dimerization of cinnamonitrile was $8.8 \pm 0.1 \times 10^2$ liter/mole-sec. For concentrations of cinnamonitrile of 7.5 mM or higher a better fit to the experimental data was obtained by carrying out the simulation with the inclusion of some reaction of $R^{\cdot-}$ by the reaction of Eq. [4]. Simulations of this scheme, simultaneous occurrence of mechanisms I and IIa (2), assuming only $R^{\cdot-}$ was oxidized at the ring, gave the same k_2 values as found at lower concentrations and k_2' values of 0.6×10^2 liters/mole-sec.

Fumaronitrile.—RDE voltammetry of fumaronitrile exhibits a reduction wave at $E_{1/2} = -0.68V$ *vs.* Ag-RE and a dip in the limiting current where a second reduction wave is expected. Values of the Levich constant listed in Table I are quite constant with ω, but show a strong dependence on concentration. The coulometric n_{app} values for reduction of 1 to 3 mM solutions at the first reduction wave are 0.44 ± 0.02. These results suggest some polymerization of fumaronitrile occurs. The Levich constant for fumaronitrile is smaller than expected, based on the values for dimethyl fumarate and cinnamonitrile. Similar results are found by cyclic voltammetry (Table III). Although this result could be ascribed to polymerization, the constancy with ω and with time, as well as the trend with C lead to an explanation based on some fumaronitrile in a dimeric form in rapid equilibrium with monomeric form. This point will be discussed more fully in a later communication.

The anion radical of fumaronitrile is the least stable of the compounds studied here. For example, no

[a] Solutions contained 0.1M TBAI and DMF. The platinum working electrode area was 0.11 cm².

[b] i_{pc} = cathodic peak current for first reduction wave (μA), v = scan rate (V/sec), C = concentration (mM).

[c] $\tau = (E_\lambda - E^\circ)/v$, where E_λ is the switching potential, E° is the formal electrode potential, and v is the scan rate.

[d] $\log \omega = \log 2k_2C\tau + 0.034\ (a\tau - 4)$, $a = (nF/RT)v$ [see Ref. (8)].

[e] Note that Nicholson *et al.* (8) define the rate constant for reaction in Eq. [3] in terms of loss of R^-, i.e., $d[R^-]/dt = -k_{2N}[R^-]^2$, while we define k_2 in terms of formation of the dimer $d[R_2^{2-}]/dt = \frac{-1}{2} d[R^-]/dt = k_2[R^-]^2$. Therefore, $k_2 = \frac{1}{2} k_{2N}$.

reversal wave is observed in cyclic voltammograms for scans of up to 500 mV/sec (see below) and only very small ring currents are measured during generation of R^- at the disk. However, by using the technique of adjustment of E_r to a potential where $i_r = 0$ for $i_d = 0$, and then determining i_r at high current sensitivity for increasing i_d values, precise values of i_r could be determined. Typical results of N_K *vs.* *CONI* for a 0.92 mM fumaronitrile solution are given in Fig. 4; note the small N_K values. As in the case of cinnamonitrile, the trend is clearly that of mechanism I, but a best fit to the data is obtained by assuming a small contribution (*ca.* 1-2%) for mechanism IIa. A summary of results for different concentrations of fumaronitrile are shown in Table II. The somewhat larger scatter in the data probably reflects the larger deviation in determining small N_K values, as well as a greater perturbation of the measurements by the polymerization reaction. Assuming the data at the lowest concentration is the least perturbed, we can give the following estimated rate constants

$$k_2 = 7 \times 10^5 \text{ liters/mole-sec}, \quad k_2' = 10^4 \text{ liters/mole-sec.}$$

Cyclic voltammetry experiments.—Cyclic voltammetric experiments were undertaken to obtain additional evidence pertaining to the proposed mechanism and to confirm the RRDE simulations. Typical cyclic voltammograms of the three compounds are shown in Fig. 5. Cyclic voltammetric treatments of dimerization reactions like that in mechanism I have been given by

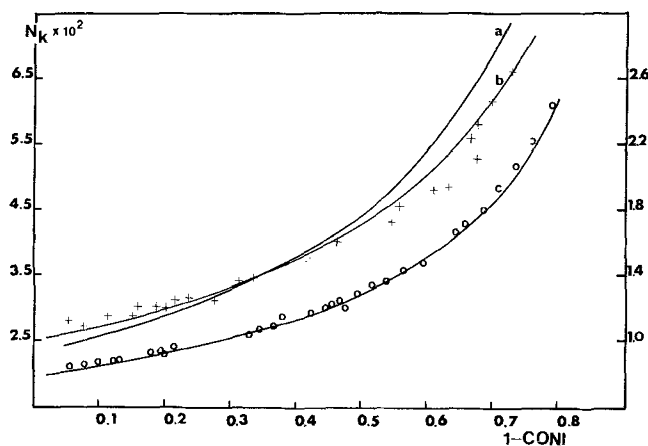

Fig. 4. Collection efficiency (N_K) *vs.* 1-*CONI* at ω = 202 radians/sec for 0.92 (o) and 1.92 (+) mM fumaronitrile solutions. Solid lines are theoretical curves corresponding to (a) mechanism I, *XKTC* = 133, (b) mechanism I, *XKTC* = 92, and mechanism IIa, *XKTC* = 1.0, considered as parallel paths, and (c) simultaneous consideration of mechanism I, *XKTC* = 50, and mechanism IIa, *XKTC* = 0.5. The right scale applies to curves a and b whereas, the left to curve c.

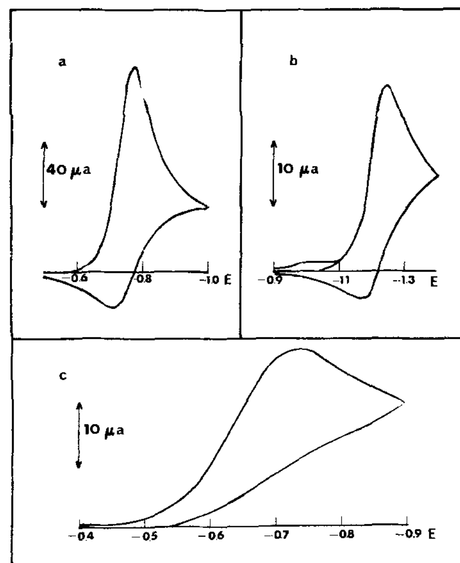

Fig. 5. Cyclic voltammograms at 100 mV/sec. of (a) 4.45 mM dimethyl fumarate, (b) 1.09 mM cinnamonitrile. Note the small impurity wave prior to the cinnamonitrile reduction wave. This wave was removed upon pre-electrolysis at — 0.98V *vs.* Ag-RE, and (c) 1.92 mM fumaronitrile solution.

both Nicholson and co-workers (8) and Saveant and co-workers (9). Second order ECE reactions, such as shown in mechanism II, have also been considered (9). Qualitatively, both mechanisms show i_{pa}/i_{pc} ratios [i_{pa} and i_{pc} are anodic (reversal) and cathodic peak currents, respectively] which increase with increasing scan rate, v. However, the mechanisms differ in the behavior of the current function $i_{pc}/v^{1/2}C$ with scan rate (1, 9). For the EC dimerization (mechanism I) $i_p/v^{1/2}C$ decreases with increasing v, while the ECE process (mechanism II) shows the opposite trend. Typical cyclic voltammetric data for the three compounds are given in Table III. The current function trend characteristic of mechanism I can be discerned in the data for cinnamonitrile and fumaronitrile, while the data for dimethyl fumarate shows this trend at faster scan rates, but is considerably more scattered. A similar trend has also been observed for diethyl fumarate (1). If one assumes that mechanism I is occurring, then the i_{pa}/i_{pc} values can be employed to calculate the dimerization rate constant, k_2, following

the procedure of Nicholson *et al.* (8). This procedure was carried out for dimethyl fumarate and cinnamonitrile in the region where i_{pa}/i_{pc} is most sensitive to variations in k_2. The i_{pa} values for fumaronitrile were too small to allow precise calculations from cyclic voltammetric data. The results and some intermediate factors used in the calculations are shown in Table III. The k_2 values obtained for dimethyl fumarate and cinnamonitrile are 1.6×10^2 and 7.9×10^2 liters/mole-sec, respectively.

Discussion

The results obtained here support the previous studies (1) and point to the major pathway in the electrohydrodimerization of these compounds as involving initial production of the anion radical followed by a coupling step. Other aspects of the mechanism, the protonation steps, the nature of the polymerization reaction, and the reactions at the later waves, which sometimes lead to secondary radicals (10), still await elucidation.

In examining the results, we see that dimethyl fumarate, which undergoes dimerization at the slowest rate of the three compounds, shows the most scatter in the k_2 value calculated from RRDE results and only fair agreement with that obtained by cyclic voltammetry. Several factors contribute to this. Because the radical ion disappearance is slow on the RRDE time scale, N_K values are close to those for an unperturbed collection efficiency, and the observed slopes are rather insensitive to small changes in *XKTC*. Moreover, the small value of k_2 necessitates use of high dimethyl fumarate concentrations, which increases the polymerization side reaction.

The RRDE results for cinnamonitrile fall into the sensitive N_K *vs.* *CONI* region for our electrode and the reaction is unperturbed by polymerization. The k_2 values determined by RRDE measurements over a wide range of C and for differing ω show good precision and agree very well with the value determined by cyclic voltammetry. This good agreement between a steady-state and transient technique also is suggestive of lack of involvement of adsorption of parent or intermediates in the reaction mechanism.

The fumaronitrile RRDE experiments were performed near the upper limit of determinable k_2 values with our RRDE. For this reaction, for concentrations of 0.4 to 4 mM, N_K values of only 0.020-0.006 (*CONI* = 1) were found. For both the cinnamonitrile and fumaronitrile reactions the data suggest some contribution from a reaction of the anion radical with parent, although in both cases this contribution was relatively small. It is interesting that even this small contribution can be noticed and accounted for in the analysis of the data, although other processes removing anion radical, such as a first order ECE reaction leading to RH_2, may also account for the small deviations from a close fit to mechanism I.

Rotating Ring-Disk Electrodes

IV. Dimerization and Second Order ECE Reactions

Vincent J. Puglisi and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Digital simulation techniques have been employed to compute the steady-state currents at the rotating ring-disk electrode (RRDE) as functions of a rate parameter exhibiting explicit dependence on concentration of parent species (A) and rotation rate and also as functions of the flux at the disk for those cases in which the disk generated product (B) undergoes a following dimerization EC reaction (2B → products) or a second order ECE reaction (B + A → C, where C may be electroactive at the disk potential) and nuances thereof. Diagnostic criteria are given for using RRDE results to distinguish among possible reaction mechanisms and working curves are provided to allow calculation of the rate constants of the homogeneous reactions.

The rotating ring-disk electrode (RRDE) has been used to study electrogenerated intermediates which react by different schemes (1). Past papers in this series (2-4) have discussed the use of digital simulation techniques to treat the currents at the disk and the ring of the RRDE and discussed methods for extracting kinetic information about the reactions of the disk-generated species. In this paper results of the digital simulation of reaction mechanisms in which the disk generated species can couple with itself (dimerization) or with the parent compound are presented. Many examples of actual electrode reactions which proceed by mechanisms such as these can be given; particular current interest centers around reductive coupling reactions of activated olefins or elec-

trohydrodimerizations [see (5-6) and references contained therein].

The following mechanisms are considered:

I. Dimerization EC (electrochemical-chemical)—Species B, which is generated at the disk electrode by

$$A + n_1e \rightarrow B \quad [1]$$

dimerizes to a nonelectroactive product

$$2B \xrightarrow{k_2} X \quad [2]$$

At the ring electrode A is regenerated from B by the reaction

$$B - n_1e \rightarrow A \quad [3]$$

II. Second order ECE.—Species B, produced at the disk as in Eq. [1], reacts with parent

$$B + A \xrightarrow{k_2} C \quad [4]$$

where C is immediately reduced at the disk

$$C + n_2e \rightarrow Z \quad [5]$$

At the ring electrode either (*a*) B alone is oxidized, as in Eq. [3], or (*b*) both B and C are oxidized. Nuances of ECE mechanism IIa (7-8) consider (*c*) the irreversible reaction represented in Eq. [4] or (*d*) the reversible reaction

$$B + A \rightleftarrows C \quad K_{Eq.} \quad [6]$$

followed by an irreversible oxidation-reduction charge transfer reaction

$$B + C \xrightarrow{k_2'} Z + A \quad [7]$$

III. Second order EC.—Species B, produced at the disk as in Eq. [1], reacts with parent to form a nonelectroactive product

$$B + A \xrightarrow{k_2} Y \quad [8]$$

Again at the ring B oxidizes to A via Eq. [3].

Note that these three mechanisms represent possible paths from A to a coupled product (X, Y, or Z). The treatment below is aimed at computing how the collection efficiency, N_K,

$$N_K = |i_r/i_d| \quad [9]$$

where i_r and i_d are the ring and disk currents, respectively, varies with concentration of parent, C, rotation rate, ω, i_d, and the rate constants of the reactions consuming B and at establishing criteria for distinguishing between these mechanisms. The application of the RRDE to the elucidation of the mechanism of electrohydrodimerization of dimethyl fumarate, cinnamonitrile, and fumaronitrile is demonstrated in the accompanying paper (9).

Digital Simulation

The general approach to the simulations and the notation to be used has been described in the previous communications (2-4). Two different types of experiments were simulated. In the first the disk was assumed to be held at a potential where the concentration of A at the disk surface was always zero and for mechanism II, the concentration of C at the disk surface was also zero. A second simulation concerned a constant current maintained at the disk, so that the flux of A (or the sum of the fluxes of A and C in mechanism II) was held constant at the disk. In both cases the boundary condition at the ring electrode was that the concentration of B was zero at the ring. In mechanism IIb, the concentration of C was also held at zero at the ring surface. Surface boundary conditions for the different experiments and mechanisms considered are given in Table I. As in previous simulations, the results are specific for the particular RRDE geometry considered. The electrode under consideration here had IR1 = 94, IR2 = 100, and IR3 = 166, where IR1, IR2, and IR3 are the number of simulation boxes necessary to represent the radius of the disk electrode, and the radii to the inner and outer edge of the ring electrode, respectively; these values yield a collection efficiency in the absence of kinetic perturbations of 0.555. Values of i_d, i_r, and N_K were calculated as functions of the dimensionless parameter *XKTC* in the controlled

$$XKTC = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}C_A{}^{\circ}\omega^{-1}k_2 \quad [10]$$

potential simulation and as functions of *XKTC* and the flux at the disk in the constant disk current simulation. Because a basic assumption of mechanism II is that species C is more easily reduced than species A, it was first necessary to establish in the constant current simulation if the total flux at the disk, as defined by the current, was greater or less than the maximum flux possible for species C. If greater, a fraction of the total current was allocated sufficient to maximize the concentration gradient of C at the disk surface

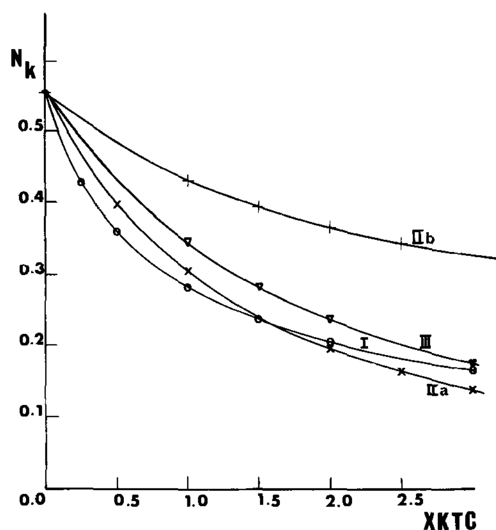

Fig. 1. Collection efficiency (N_K) vs. $XKTC$ for the EC dimerization mechanism (I), the ECE radical-parent coupling mechanisms (IIa and IIb), and the EC radical-parent coupling mechanism (III).

[FC(1,1) = 0] while the remaining current diminished the concentration of A. If less, a finite concentration of C remained at the surface and the concentration of A was not altered by the passage of current. In every instance the diffusion coefficients of species A, B, and C were assumed equal, although provision is included in the program for introducing a different value for each species.

Results

Controlled disk potential results.—The results of simulations where the disk potential is maintained on the limiting current plateau for reaction [1] and the ring maintained at a potential where [3] occurs at the mass transfer controlled rate are shown in Fig. 1. [Mechanisms IIc and IId are not shown in Fig. 1 because of N_K's dependence on two parameters (equilibrium constant and rate constant) instead of one for the mechanisms as shown but qualitatively they would show the same sort of behavior.] All curves yield a value of $N_K = N = 0.555$ as $XKTC$ approaches 0 (k_2C approaches 0, or ω approaches infinity) and all show a similar decrease of N_K with increasing $XKTC$. While these N_K-$XKTC$ curves are indicative of kinetic perturbations and could be used to determine k_2 values once the mechanism is known, they are clearly not very useful in distinguishing among the various mechanisms under consideration. Further, the dependence of the disk limiting current on $XKTC$ (Table II) is of value only in distinguishing case III from cases I and II. Case II, categorized as an ECE type, is unlike the simple ECE case in that n, the number of electrons per molecule of starting material, A, electrolyzed, equals one independent of the rotation rate. Case III, however, undergoes a change in n from $n = 1$ to $n = 2$ with increasing rotation rate and thus, exhibits a dependence of disk limiting current with varying $XKTC$ values.

Controlled disk current results.—Experiments involving disk currents at values below the limiting one are more diagnostic in deciding among the various reaction schemes under consideration here, because the relative fluxes of A and B from the disk can be varied. Simulations in this case are of N_K at different values of the relative disk current, $CONI$, where

$$CONI = i_d/i_{d,l} \qquad [11]$$

and $i_{d,l}$ is the limiting disk current, and for different values of $XKTC$. In this case a separate N_K vs. $CONI$ curve must be given for each value of $XKTC$. Results for the mechanisms under consideration here are given in Fig. 2-7. Note that for a first order decomposition

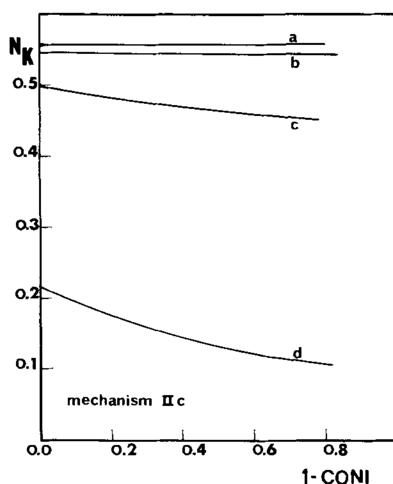

Fig. 5. Collection efficiency (N_K) vs. 1-*CONI* for mechanism IIc, *XKTC2* equal to 1000 and *XKTC1* equal to (a) 0.001, (b) 0.010, (c) 0.10, and (d) 1.0, where *XKTC1* and *XKTC2* describe the reactions represented in Eq. [4] and [7], respectively.

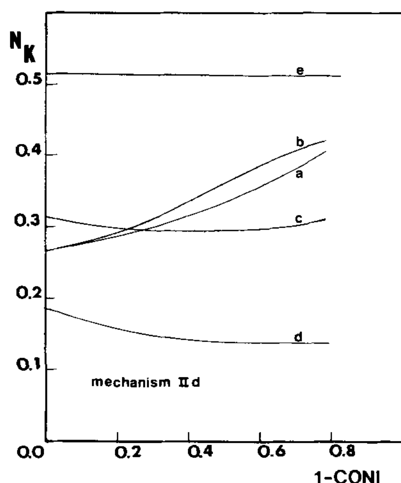

Fig. 6. Collection efficiency (N_K) vs. 1-*CONI* for mechanism IId and (a) $CK = 10^{-4}$, $XKTC = 10^5$; (b) $CK = 10^{-3}$, $XKTC = 10^4$; (c) $CK = 10^{-2}$, $XKTC = 10^3$; (d) $CK = 10^{-1}$, $XKTC = 10^2$, and (e) $CK = 10^{-3}$, $XKTC = 10^3$.

qualitatively different for cases I and IIa (or IIb, IIc, III). For mechanism I, the dimerization EC reaction, the velocity of the following reaction only depends on B concentration. Hence, as i_d becomes smaller (*CONI* approaches 0), the B concentration at the disk decreases and the kinetic perturbation of the following reaction becomes less. Hence, for case I, $N_K \rightarrow N$ as $CONI \rightarrow 0$ and N_K approaches its minimum value as $CONI \rightarrow 1$. For cases IIa, IIb, IIc, or III, which involve coupling with the parent, the rate of the following reaction is a function of both A and B concentration at the disk. Hence, as i_d approaches $i_{d,1}$ (*CONI* approaches 1) the A concentration decreases and the following reaction rate decreases. For these cases N_K approaches its maximum value at a given value of *XKTC* as $CONI \rightarrow 1$. As *CONI* approaches 0, the concentration of A is essentially constant and the reaction of B approaches pseudo-first order conditions. When product C is also electroactive at the ring electrode (mechanism IIb), the trend is the same as for mechanism IIa but the N_K values are larger because i_r is larger. Although case IId exhibits qualitatively different behavior depending on the value of the equilibrium constant for [6] and the rate constant for [7] as shown in Fig. 6, some trends are evident. For values of *CK* (*CK* = bulk concentration of A × equilibrium constant (*K*) for reaction [6]) greater than or equal to 0.10 and *XKTC* values resulting in collection efficiencies in the normal working range for the simulated RRDE ($0.02 < N_K < 0.54$), N_K approaches its maximum value as $CONI \rightarrow 1$. As $CONI \rightarrow 0$, the concentration of C is essentially constant and the reaction consuming B approaches pseudo-first order behavior. For *CK* values less than or equal to 0.001 (*e.g.*, $K = 1$ when $C = 1$ mM), the N_K variation with *CONI* is qualitatively similar to case I because the velocity of the following reaction assumes an over-all second order dependence on B concentration. Transitional behavior, exemplified by curves b, c, and e (Fig. 6), occurs at intermediate values of *CK*. Quantitatively, the behavior of case IId differs from that of case I, for all values of *CK*, because the product of the appropriate dimensionless simulation parameters for case IId (*i.e.*, *CK* and *XKTC*), which defines the velocity of the reactions consuming species B (and thus the magnitude of N_K) has a squared dependence on the bulk concentration of A, whereas for case I, the reaction velocity is described by only one dimensionless simulation rate parameter, *XKTC*.

Discussion

The results show that the RRDE should be useful in studying different mechanisms of following reactions. Since RRDE studies involving steady-state N_K measurements are relatively free from adsorption and double layer charging effects, the experimental results will be subject to fewer complications than transient methods. Digital simulation methods are capable of treating rather complex reaction schemes involving higher order chemical reactions. Variations of the mechanisms considered here, such as the simultaneous

occurrence of two of the reaction paths, can be treated by straightforward extensions of the described programs. For example, in studies of hydrodimerization reactions with the RRDE (9) it was sometimes necessary to consider the possibility of parallel reaction pathways of the intermediate radical ion (equivalent to substance B here) by both coupling and ECE mechanisms. The results in that work provide experimental confirmation of these theoretical results.

Electrochemical Reduction of Allopurinol

P. K. De and Glenn Dryhurst

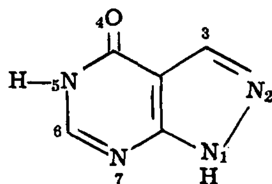
Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

Allopurinol (1H-pyrazolo [3,4-d] pyrimidin-4-ol) is electrochemically reduced at the dropping mercury electrode by way of a single polarographic wave. Above pH 2, the electrode reaction is a $2e$-$2H^+$ reduction of allopurinol to give 6,7-dihydroallopurinol as the sole product. At lower pH (*i.e.*, pH 0) the single polarographic wave involves $4e$ and is due to reduction of allopurinol to 2,3,6,7-tetrahydroallopurinol. Under the conditions of prolonged electrolysis, however, the latter product slowly decomposes to give 4-carbamido-5 aminopyrazoline (2,3). The mechanism of these reactions have been elucidated by polarography, coulometry, cyclic voltammetry at the pyrolytic graphite electrode, mass electrolysis and isolation of products. The products have been identified by u.v., *IR*, NMR, mass spectrometry, and elemental analysis.

Pyrazolo [3,4-d] pyrimidines have found considerable application in clinical biochemistry as carcinostatic agents. Allopurinol (1H-pyrazolo [3,4-d] pyrimidine 4-ol) is a well-known inhibitor of the enzyme xanthine oxidase (1), and, hence, inhibits the formation of uric acid by oxidation of purines in organisms containing this enzyme (2, 3). This property of allopurinol makes it possible to use lower doses of otherwise highly toxic 6-thiopurine in the treatment of leukemia (4). Allopurinol also substantially alters pyrimidine metabolism (5).

Because of the importance of understanding the oxidation-reduction behavior of biologically important compounds which interact with oxidation-reduction enzymes, we have begun a detailed and systematic study of the electrochemistry of the allopurines. The structure of allopurinol and the numbering employed in this paper is that used in "Chemical Astracts," and is shown below.



Experimental

Chemicals.—Allopurinol was obtained from Aldrich and was found to be chromatographically homogeneous. The other chemicals were of reagent grade. Argon (Linde) used for deoxygenating was equilibrated with water; no other purification was necessary. Buffer solutions used had an ionic strength of 0.5*M* except sulfuric and acetic acid solutions which were 1*M* in strength.

Apparatus.—The electrochemical apparatus has been described elsewhere (6-8). All potentials are referred to the SCE at 25°C. The dropping mercury electrode had normal m and t values.

Ultraviolet absorption spectra were recorded on a Perkin Elmer-Hitachi Model 124 spectrophotometer. Infrared spectra were recorded on a Beckman *IR*-8 using KBr pellets. NMR spectra were recorded on Varian Model T-60 spectrometer. Mass spectra were recorded on a Hitachi Model RMU-6E spectrometer.

Coulometry and macroscale electrolysis.—For coulometry a measured volume (usually 100 ml) of background solution was introduced into the working electrode compartment of a three compartment cell. This solution was electrolyzed at the appropriate potential until an electronic current integrator gave a constant and small count. Then a weighed amount of allopurinol was introduced into the working electrode compartment sufficient to make the solution *ca.* 1 mM. After dissolution electrolysis was recommenced at the same potential, stirring rate, and flow rate of argon. Many macroscale electrolyses were carried out in the same fashion except that solutions were *ca.* 5-6 mM in allopurinol and an integrator was not employed. Completion of the electrolysis was confirmed by disappearance of the characteristic u.v. absorption and polarographic wave of allopurinol, and by characteristic cyclic voltammetric behavior at the pyrolytic graphite electrode.

Key words: 1H-pyrazolo [3,4-d] pyrimidin-4-ol, bioelectrochemistry, 6,7-dihydroallopurinol, 2,3,6,7-tetrahydroallopurinol.

In order to reduce contamination of the products of macroscale electrolysis with KCl (from salt bridges and SCE reference electrode), a two-compartment cell was frequently employed, one compartment for the working electrode, one for a platinum gauze counter-electrode. These two compartments were separated by a fine sintered glass disk and an agar-acetic acid salt bridge. Such salt bridges were made by heating 4g of agar with 40 ml of water until a homogeneous solution was obtained. Then, 40 ml of 2*M* HOAc was added and the solution cooled to room temperature when a stable gel was formed. The reference electrode was a Beckman fiber-tip SCE inserted into the working electrode compartment.

Chromotropic acid test for formaldehyde.—Aliquots of 0.2 to 0.6 ml of electrolysis solution were transferred to 25 ml volumetric flasks and diluted to 1 ml with water. Then 1 ml chromotropic acid solution (0.6g of the disodium salt of chromotropic acid in 20 ml water added to 180 ml of concentrated H_2SO_4) was added and the volume made up with concentrated H_2SO_4. The flasks were heated for an hour on a steam bath, cooled to room temperature, and the absorbance measured at 570 nm against a water blank carried through the same procedure. A calibration curve was prepared with standard formaldehyde solution. Allopurinol itself does not respond to this test.

Estimation of formaldehyde in argon stream from electrolysis cell.—In order to decide if free formaldehyde is liberated upon electrochemical reduction of allopurinol, an electrolysis was carried out in a cell with the working electrode compartment sealed with a rubber stopper provided with inlet and outlet tubes for argon. After bubbling the argon through the electrolyzing solution it was passed sequentially through three gas bubbling towers containing distilled water, 0.1*M* sodium sulfite, and chromotropic acid reagent solution. After completion of the reduction the contents of the three towers were analyzed for formaldehyde by the chromotropic acid method (see above). The sodium sulfite solution gave a positive formaldehyde test when the electrolysis was carried out in 1*M* H_2SO_4. Using 1*M* HOAc as the supporting electrolyte solution, no formaldehyde could be detected in any of the trap solutions. In 1*M* H_2SO_4 one mole of formaldehyde was determined per mole of allopurinol reduced, approximately 10-15% in the sodium sulfite trap and 85-90% by direct application of the chromotropic acid procedure to an aliquot of the electrolysis solution. The same quantity of formaldehyde was detected for an electrolysis in 1*M* HOAc, all in the electrolysis solution.

Isolation of acetic acid reduction product.—After the completion of a mass electrolysis, the solution was freeze-dried. The resultant white solid was separated from small amounts of potassium chloride (from reference electrode and salt bridges) by extracting with absolute methanol. This, on crystallization from chloroform and methanol, formed white crystals melting at 115°-120°C which were very very soluble in water and gave a positive test for acetate (14). The *IR* and NMR spectra of this compound clearly indicated that it was an acetate salt. In order to isolate the free base, the freeze-dried white solid was dissolved in methanol and passed through a column (30 cm × 1 cm) of basic alumina. The column was eluted with methanol and five 15 ml fractions were collected. The first fraction was contaminated with some KCl and the other fractions, upon evaporation of the methanol, gave pure 6,7-dihydroallopurinol as evidenced by *IR*, NMR, and u.v. spectra, and elemental analysis. The free base is a white crystalline compound, sparingly soluble in water, having a mp of 210°C. Elemental analysis: found, C = 43.23%, H = 4.36%, N = 40.32%; theory, C = 43.47%, H = 4.35%, N = 40.58%. The yield of pure product was *ca.* 80%.

The free base could also be isolated by passing an aqueous solution of the acetic acid product through a basic ion-exchange resin (Dowex 2-X8 in OH^- form). On eluting with water, KOH (from KCl contaminating the sample) eluted first followed by the base. After evaporation of the water, the sample was dissolved in methanol and passed through a small basic alumina column. The resultant product was analytically pure.

Reduction of allopurinol, in McIlvaine buffer *p*H 2.2, gave the same product. Isolation of the product from such a buffer was carried out by first freeze-drying the product and extracting with absolute methanol, evaporating the methanol and extracting again. This methanol extract was then passed through a Florosil column and eluted with methanol. A 60% yield of 6,7-dihydroallopurinol was obtained.

Isolation of sulfuric acid reduction product.—After complete electrolysis of a 6 mM solution of allopurinol in 1*M* H_2SO_4, the solution was treated with a slight excess of saturated barium hydroxide solution. The precipitated barium sulfate was removed by filtration and then the clear solution was treated with carbon dioxide to remove excess of barium. The barium carbonate was removed by filtration and the clear solution was freeze-dried. The resultant solid obtained was separated from the KCl present and then recrystallized from chloroform and methanol. The reduction product was a canary yellow solid, mp 125°-30°C which was very soluble in water.

Thin layer chromatography.—A 2 mg/ml solution of the isolated electrolysis products and allopurinol itself, in water, were employed. Approximately 100 μl of these solutions were spotted onto thin-layer plates. The most definitive data, which is quoted below, was obtained with a silica gel support (Eastman Chromogram 6060 with fluorescent indicator) and n-propanol-water (70-30) as solvent. The reduction product isolated from acetic acid, and McIlvaine buffer *p*H 2.2, was chromatographically homogeneous and had an R_F value of 0.75 (fluorescence). Allopurinol had an R_F of 0.85. Neither allopurinol nor its reduction product formed in acetic acid gave a positive test with Ehrlich reagent (for ureido groups) on a thin layer plate. The product isolated from sulfuric acid gave a single spot (fluorescence), $R_F = 0.7$; this spot when sprayed with Ehrlich reagent gave a bright yellow color.

Results and Discussion

Polarography.—Allopurinol gives a single polarographic reduction wave in solutions between *p*H 0-8. At low *p*H, the wave is very close to background discharge, but at *p*H above *ca.* 4, it becomes well defined and easy to measure. In 1*M* H_2SO_4 (*p*H 0), and in acetate buffer *p*H 4.7, the limiting current appeared to be entirely under diffusion control as evidenced by the drop-time dependence of the wave and its temperature coefficient (2.1%/°C at *p*H 4.4). The wave rapidly decreased in height above *p*H 6 and disappears above *p*H 8.

In 1*M* H_2SO_4, the diffusion current constant ($I = i_l/Cm^{2/3}t^{1/6}$) is about 10, but decreases at higher *p*H so that between *p*H 2.3-6, it has an average value of close to 4 (Fig. 1, section A). Over this latter *p*H range, the magnitude of the diffusion current constant indicates a 2*e* polarographic process. The half-wave potential of allopurinol shifts linearly more negative with increasing *p*H (Fig. 1, section B), and is described by the equation $E_{1/2} = -1.118\text{-}0.067\ p\text{H}$.

Voltammetry at PGE.—Allopurinol shows a single reduction peak at the stationary pyrolytic graphite electrode (PGE) between *p*H 0-6. Generally the peak is so close to the onset of background discharge that, often, it merely forms an inflection; and hence, it is not possible to measure meaningful peak current values. In as far as it could be determined, the variation of peak potential at PGE is given by $E_p = -0.85\text{-}0.120\ p\text{H}$.

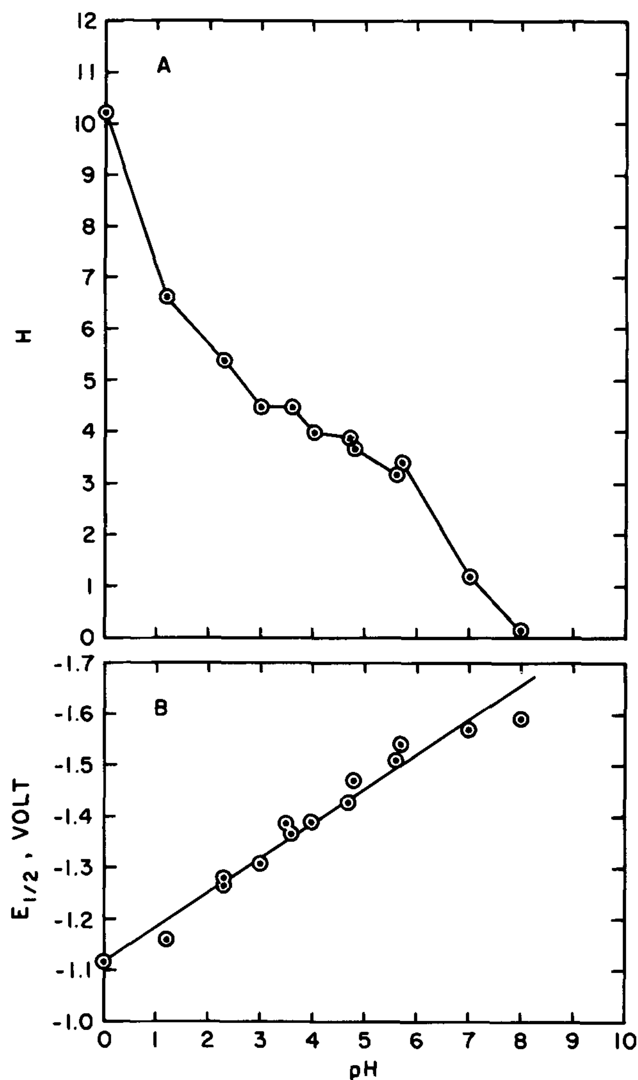


Fig. 1. A, Variation of the polarographic diffusion-current constant with pH and; B, variation of $E_{1/2}$ with pH for allopurinol.

Coulometry and macroscale electrolysis.—Because of the closeness of the voltammetric reduction peak at PGE to the background discharge, it was not possible to obtain meaningful n values at this electrode. Preliminary studies of the controlled potential electrolysis of allopurinol, at a mercury electrode in a number of background electrolytes, revealed that either allopurinol or its reduction product considerably lowers the hydrogen overpotential. Thus, owing to considerable catalytic hydrogen reduction, large apparent electron numbers were obtained when coulometry was performed at potentials corresponding to the crest of the polarographic waves. Accordingly, in order to circumvent this problem, coulometry was carried out by only partially electrolyzing at potentials on the rising portion of the wave. In 1*M* H_2SO_4, the n value was found to be 4.0 ± 0.2; whereas, in 1*M* HOAc, McIlvaine (pH 4.0) and acetate (pH 4.7), the values of n were 1.8 ± 0.1, 2.0 ± 0.2, and 2.2 ± 0.2, respectively.

Following the initial coulometry, extensive electrolysis in 1*M* H_2SO_4 and 1*M* HOAc were carried out; detailed spectra were obtained and cyclic voltammetry performed during, and at the completion of, the electrolysis. These two electrolyte systems were selected because they were representative of media in which the 4*e* and 2*e* processes occur. In addition, both H_2SO_4 and HOAc are relatively easily removed, hence, allowing product isolation.

Electrolysis in 1M HOAc.—After complete reduction of allopurinol in 1*M* HOAc, the u.v. absorption spectrum of the product (λ_{max} = 266 nm and λ_{max} = 240 nm) was quite different to that of allopurinol (λ_{max} = 250 nm). The solution gave a positive test for formaldehyde (9), one mole of reduced allopurinol giving rise quantitatively to one mole of formaldehyde. However, attempts to bubble formaldehyde out of the reduced solution were not successful indicating that a product is formed that yields formaldehyde only under the extremely acidic conditions of the chromotropic acid-formaldehyde reaction.

Cyclic voltammetry of allopurinol at the PGE showed one cathodic peak [peak I_c very close to background discharge, E_p = −1.55V to −1.60V (Fig. 2, section A)]. Once having scanned this cathodic peak, two well-defined anodic peaks were obtained, E_p = 0.40V and 0.80V (peaks I_a and II_a Fig. 2, section A). Peak II_a was always larger than peak I_a. Cyclic voltammetry of reduced allopurinol indicated that on the first scan toward negative potential at a clean electrode there were no cathodic peaks. However, on the first scan toward positive potentials, two anodic peaks were observed whose peak potentials corresponded exactly with peaks I_a and II_a (Fig. 2, section B). Peak I_a was always much smaller than peak II_a and occasionally was not observed at all. Having scanned anodic peaks I_a and II_a, a large cathodic peak at the same potential as cathodic peak I_c was observed (Fig. 2, section B).

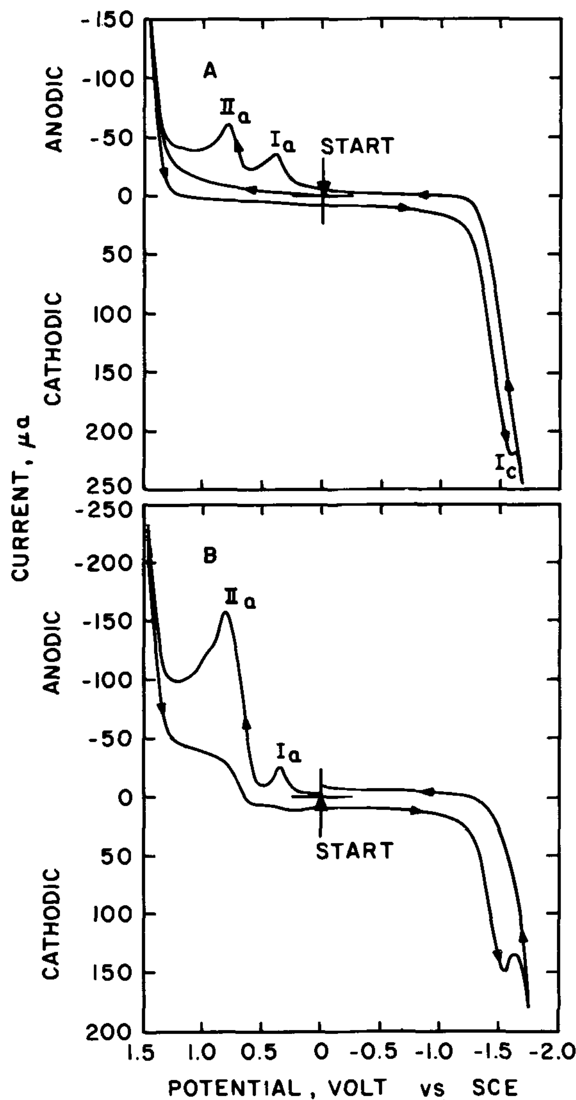

Fig. 2. A, Cyclic voltamogram of 4 mM allopurinol in 1M HOAc at PGE; scan pattern: 0.0V → 1.45V → −1.70V → 1.45V → 0.0V. B, Cyclic voltamogram at PGE of product of complete electrochemical reduction of 4 mM allopurinol at mercury in 1M HOAc. Scan pattern: 0.00V → 1.45V → −1.75V → 0.00V; scan rate: 200 mV/sec.

After completely reducing a solution of allopurinol, reverse coulometry was carried out on the product solution using a large PGE and applying a potential of 0.9V, *i.e.*, sufficient to completely oxidize the product giving rise to anodic peaks I_a and II_a. Under these conditions allopurinol was quantitatively recovered as evidenced by u.v. and polarographic analysis. An average value of 2.2*e* was obtained for reverse coulometry.

Electrolysis in 1M H_2SO_4.—The u.v. absorption spectrum of the product of reduction of allopurinol in 1*M* H_2SO_4 (λ_{max} = 245 nm and 202 nm) was somewhat different than that of allopurinol at the same pH (λ_{max} = 252 nm and 210 nm). When a fairly concentrated solution (4-8 mM) was electrolyzed, it took *ca.* 16 hr for complete removal of allopurinol (u.v. spectrum, polarography). However, often the u.v. spectrum revealed a distinct shoulder at 270 nm in addition to the peaks described earlier; the shoulder gradually disappeared with time. During and after completion of the electrolysis, formaldehyde could be detected in the solution; one mole of formaldehyde was produced for every mole of allopurinol reduced. Some formaldehyde could be bubbled out of the solution and trapped in sodium sulfite solution (see Experimental). This indicates that part of the product formed in the 4*e* reduction of allopurinol in 1*M* H_2SO_4 decomposes giving formaldehyde.

Cyclic voltammetry at the PGE of allopurinol showed no oxidation peak if the first voltage sweep was towards positive potential. However, on sweeping toward negative potentials, a single cathodic peak (peak I_c), $E_p = -1.30V$, is observed (Fig. 3, section A). Having scanned this peak, two anodic peaks are observed on the next cycle toward positive potential (peaks I_a and II_a), E_p = 0.35V and 0.75V, respectively. After complete reduction, cyclic voltammetry of the product at PGE reveals no cathodic peaks on the initial scan toward negative potential at a clean electrode. However, the first sweep toward positive potential shows three peaks at E_p = 0.34V, 0.75V, and 0.95V (Fig. 3, section B). The first two peaks correspond to peaks I_a and II_a observed on cyclic voltammetry of allopurinol. The most positive third peak will be designated as peak III_a. Further cyclic voltametric experiments on the reduced solution revealed that cathodic peak I_c could be observed if peaks I_a and II_a were first scanned.

When cyclic voltametric scans were made at various times throughout the course of a controlled potential electrolysis in 1*M* H_2SO_4, it was found that, in the early stages, anodic peaks I_a and II_a were of nearly equal height and peak III_a was absent. As the electrolysis progressed peak III_a appeared. In order to further investigate the relationship of anodic peaks I_a, II_a, and III_a to cathodic peak I_c, the solution obtained after complete reduction of allopurinol was reoxidized at a large PGE at potentials corresponding to each of the oxidation peaks. After complete removal of peaks I_a and II_a by such oxidation, only *ca.* 65% of the original allopurinol was regenerated and peak III_a remained. Further oxidation at potentials of peak III_a did not form any more allopurinol. Accordingly, the species responsible for III_a was considered to be a product of breakdown or rearrangement of the species giving rise to peak I_a.

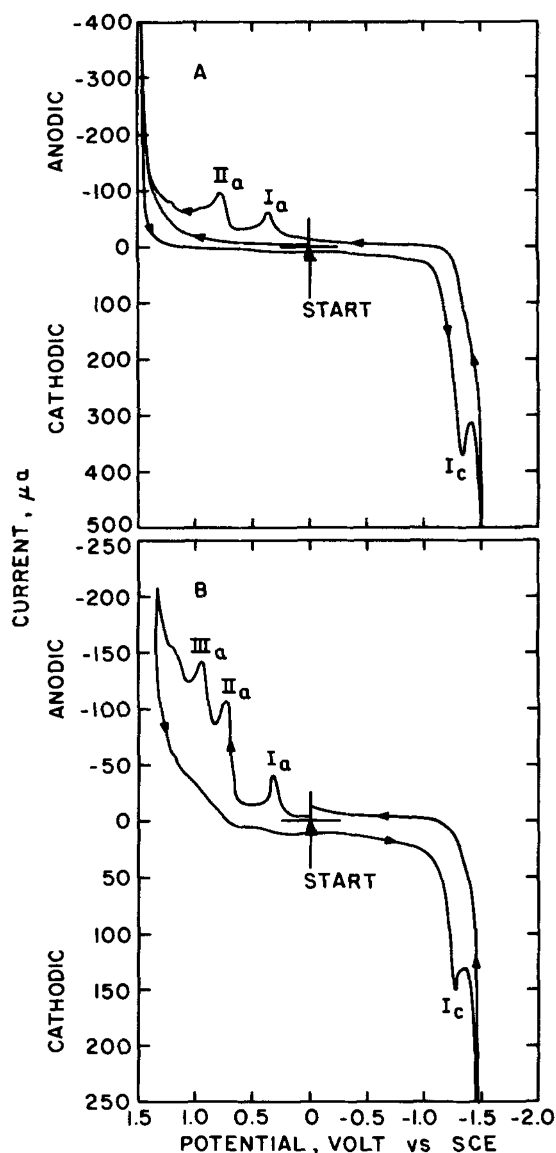

Fig. 3. A, Cyclic voltamogram of 6 mM allopurinol in 1M H_2SO_4 at PGE; scan pattern: 0.00V → 1.45V → −1.50V → 1.45V → 0.00V. B, Cyclic voltamogram at PGE of product of complete electrochemical reduction of allopurinol at mercury in 1M H_2SO_4. Scan pattern: 0.00V → 1.40V → −1.45V → 0.00V; scan rate: 200 mV/sec.

Characterization of isolated electrolysis products.—Acetic acid.—A product could be isolated by solvent extraction and column chromatography as an acetate salt or free base (see Experimental). Infrared spectra of allopurinol, the reduction product acetate salt, and the free base are shown in Fig. 4, sections A, B, and C, respectively. Thang and Delbarre (10) assigned the 1695 cm^{-1} band of allopurinol to >C=N. The inflection on this band at *ca.* 1650-1660 cm^{-1} corresponds to the amide carbonyl—C(=O)—NH— absorption. The intense band at 1580 cm^{-1} is cyclic C=C and around 3000 cm^{-1} various N—H stretches are observed. On reduction, the >C=N absorption is decreased (shoulder at *ca.* 1700 cm^{-1}) and the amide carbonyl, 1650 cm^{-1}, becomes prominent. The cyclic —C=C band remains at 1580 cm^{-1}. Two small bands at 1450 cm^{-1} and 1360 cm^{-1} in the reduction products may be attributed to >CH_2 bending. The acetate salt (Fig. 4, section B) gives a typical carboxylate band at 1405 cm^{-1} (11).

NMR spectra of allopurinol, and the acetate-free product in deuterated dimethyl sulfoxide, are shown in Fig. 5, sections A and B, respectively. This solvent was used because the compounds were not sufficiently soluble in D_2O. Allopurinol shows two singlet peaks at 7.95δ and 8.10δ. The latter is associated with the hydrogen at C_6, the former with the hydrogen at C_3 (12). These assignments are made by analogy with the NMR spectrum of hypoxanthine (6-oxypurine) in the same solvent (13). The reduction product has no NMR peak at 8.10δ; but one at 7.8δ, which is ascribed to the C_3 proton, remains. In addition, a triplet centered around 4.35δ appears (Fig. 5, section B) typical of a methylene group which must be located at C_6. For this methylene group δH_1 = 4.35 ppm and δH_2 = 4.41 ppm, JH_1H_2 = 8 Hz. The three broad peaks at 3.40δ, 6.20δ,

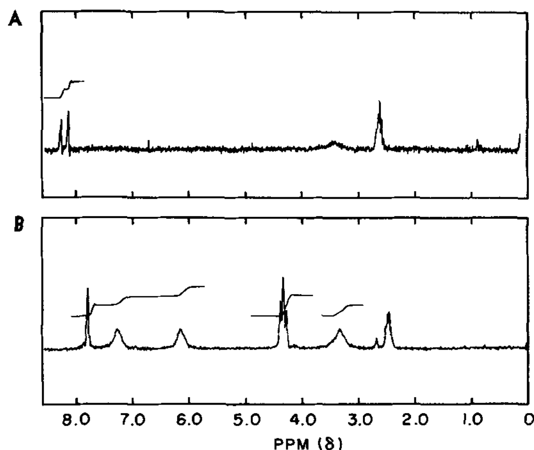

Fig. 5. 60 mHz NMR spectrum of A, allopurinol; and B, the product of electrochemical reduction of allopurinol in 1M HOAc (acetate-free base). Solvent: deutero dimethylsulfoxide.

and 7.35δ are for hydrogens associated with three N-atoms of the reduced product. Integration of the peaks centered at 7.8δ, 7.35δ, 6.20δ, 4.35δ, and 3.4δ, reveal a proton ratio of 1:1:1:2:1. In view of this evidence the compound is clearly 6,7-dihydroallopurinol.

The mass spectrum of the free base shows a molecular ion of $m/e = 138$ (Fig. 6) which is that expected for 6,7-dihydroallopurinol. The base peak ($m/e = 110$) corresponds to the primary fragment $C_4H_4N_3O^+$ by loss of $\cdot NCH_2$ ($m/e = 28$) from the molecular ion. Subsequent loss of CO and a proton results in the fragment $C_3H_3N_3^+$ ($m/e = 81$) as proposed by Chalmers *et al.* (15). A mechanism illustrating the

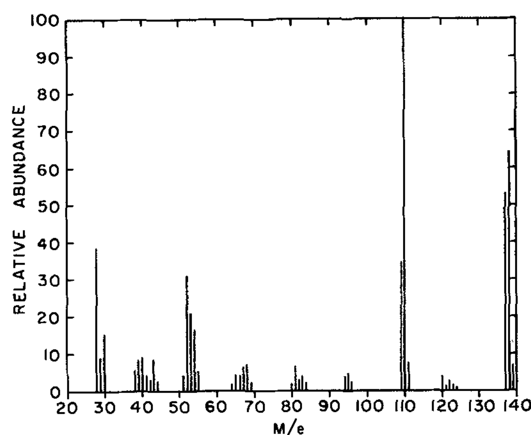

Fig. 6. Mass spectrum of the product of electrochemical reduction of allopurinol at Hg in 1M HOAc; Source temperature: *ca.* 200°C; ionizing voltage: 12 eV.

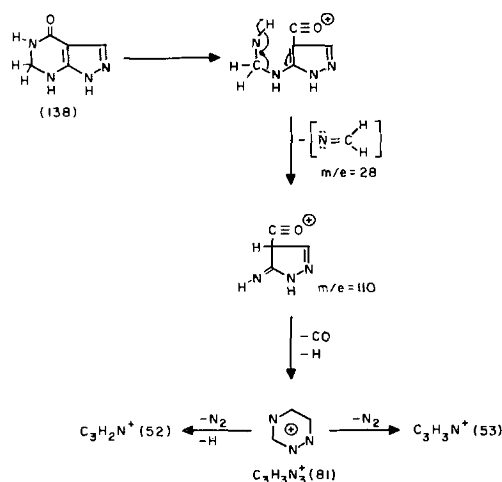

Fig. 7. Proposed mass spectroscopic fragmentation mechanism for 6,7-*dihydroallopurinol*.

probable formation of the major fragments in mass spectrometry is shown in Fig. 7.

Elemental analysis (see Experimental), *IR*, NMR, and mass spectroscopic data all support the view that the product of reduction of allopurinol at $pH > 2$ is 6,7-dihydroallopurinol.

Sulfuric acid.—Thin layer chromatography under a variety of conditions failed to indicate that more than one product was formed in sulfuric acid. Cyclic voltammetry and reverse coulometry, however, support the view that two products are formed, one which could be reoxidized to allopurinol and one which could not. Thin layer chromatography, however, did support the view that a ureido group ($-\overset{\text{O}}{\overset{\|}{\text{C}}}-NH_2$) was present because of the intense yellow spot developed with Ehrlich reagent. The two products of reduction could never be satisfactorily separated. However, the infrared spectrum of the reduction product (Fig. 4, section D) did reveal the presence of >N—H groups by broad absorption around 3200 cm^{-1}. Two very close bands at 1640 cm^{-1} and 1600 cm^{-1} are compatible with the presence of amide, carbonyl, and cyclic >C=C groupings, respectively. Also, the very pronounced peak at 1455 cm^{-1} is indicative of the presence of a methylene group (11).

Mass spectra of the sulfuric acid product show the existence of a molecular ion of $m/e = 140$. This lends support for a tetrahydroallopurinol in the reduction product.

Mechanism.—pH > 2.—The value of diffusion-current constant and coulometry support a 2*e* process

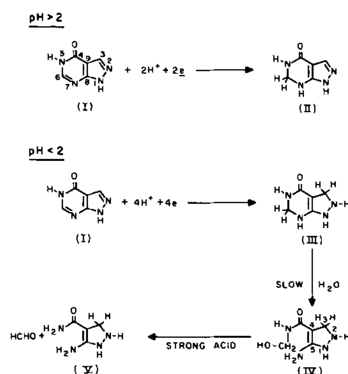

Fig. 8. Proposed scheme for the electrochemical reduction of allopurinol at mercury electrodes.

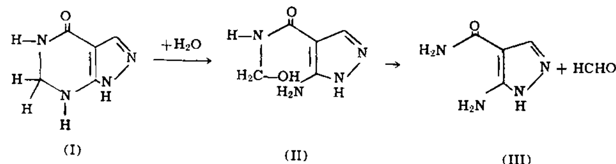
above a pH 2. *IR*, NMR, and mass spectra indicate that the product is 6,7-dihydroallopurinol. The reaction can be written as a straightforward $2e$-$2H^+$ reduction of allopurinol (I, Fig. 8) to 6,7-dihydroallopurinol (6,7-dihydro-4-hydroxy-[3,4-d] pyrimidine) (II, Fig. 8). Under cyclic voltammetric conditions at the PGE the appearance of anodic peaks I_a and II_a (Fig. 2, section A), after having scanned the cathodic peak I_c of allopurinol, suggests that at the PGE some additional electrochemical or chemical reduction of the dihydroallopurinol to tetrahydroallopurinol occurs. The latter compound gives rise to peak I_a. However, in view of the fact that peak I_a is so small, or nonexistent after coulometry of allopurinol at mercury, suggests that at the latter electrode little or no further reduction occurs. The closeness of allopurinol peak I_c to the background discharge in $1M$ HOAc at the PGE, suggests that considerable hydrogen ion reduction could accompany the electrochemical reduction; and the dihydro derivative could be partially reduced to a tetrahydro derivative by reduction with hydrogen. Similar behavior was observed at higher pH at mercury and graphite electrodes to that in $1M$ HOAc. In view of the $2e$ nature of the reduction process at high pH, the mechanism must be essentially identical to that observed in acetic acid.

The fact that the reduced form of allopurinol in $1M$ HOAc gives a positive test for formaldehyde, under the conditions of the chromotropic acid reaction, is explained by hydrolysis of 6,7-dihydroallopurinol (I, Eq. [1]) to the corresponding alcohol (II, Eq. [1]). This would yield formaldehyde and the pyrazolamine (III, Eq. [1]). This process is identical to that observed with all purines reduced at the C_2-N_3 position under similar conditions (16). In the electrolysis solution the conditions are such that the reaction (Eq. [1]) does not proceed to any extent and formaldehyde cannot be bubbled out of the solution.



[1]

The decrease in height of the allopurinol reduction wave above *ca.* pH 6, and disappearance above pH 8, is related to the fact that, at pH 8 and above, allopurinol undergoes a rapid degradation to 3-amino-4-carbamidopyrazole (17). The latter compound is not polarographically reducible.

$pH < 2$.—Below pH 2 the limiting current for polarographic reduction of allopurinol increases and at pH 0 involves $4e$. Infrared spectra indicate that both —C=N groupings have been reduced and that $>CH_2$ groups are present. Mass spectra support the view that a tetrahydroallopurinol is present. These observations support the view that at low pH allopurinol (I, Fig. 8) is reduced in a $4e - 4H^+$ process to 2,3,6,7-tetrahydroallopurinol (III, Fig. 8). This is the sole product when the electrolysis time is short as is evidenced by the fact that only two anodic peaks, peaks I_a and II_a of equal height, appear on cyclic voltammetry of the product at the PGE. Since the product isolated from acetic acid ($2e$) dissolved in $1M$ H_2SO_4 gives only peak II_a, it is clear that peak I_a is due to oxidation of 2,3,6,7-tetrahydroallopurinol to 6,7-dihydroallopurinol. Correspondingly, peak II_a is due to oxidation of the 6,7-dihydro compound to allopurinol.

After complete reduction in sulfuric acid, peak III_a appears in addition to peaks I_a and II_a. The products responsible for peaks I_a and II_a can be reoxidized back to allopurinol; but that responsible for III_a cannot. Also, the u.v. spectrum of the somewhat more concentrated solution of allopurinol (4-8 mM) shows a shoulder at 270 nm, in addition to the peaks at 245 nm and 202 nm, which are observed after electrolysis of a more dilute solution (1-2 mM). The nature of the product responsible for cyclic voltametric peak III_a and the u.v. absorption at 270 nm can be inferred from the TLC and estimation of formaldehyde. Thus, spraying the single spot observed by TLC with Ehrlich reagent gives a positive test for the ureido group (—C(=O)—NH_2). In addition, after prolonged electrolysis approximately 0.1-0.15 mole of formaldehyde/mole of allopurinol reduced can be bubbled out of the solution (the remaining 0.85-0.9 mole of formaldehyde is found in solution under the conditions of the chromotropic acid reaction). This evidence suggests that the product of $4e$ reduction, *i.e.*, 2,3,6,7-tetrahydroallopurinol (III, Fig. 8), slowly decomposes to a compound having a ureido group and formaldehyde. The fact that the product still absorbs at *ca.* 270 nm suggests the basic chromophore in the allopurinol system, —C_8=C_9—C_4=O is still present. Accordingly, it is proposed that the tetrahydroallopurinol (III, Fig. 8) slowly hydrolyzes to the 4-substituted-2,3-dihydro-5-aminopyrazole (IV, Fig. 8; note numbering change for pyrazole derivatives). This is a reaction very similar to that proposed for breakdown of tetrahydropurines (16). Compound IV (Fig. 8) appears to readily cleave in the presence of concentrated acid to give formaldehyde and 4-carboxamido-5-aminopyrazoline (2,3) (V, Fig. 8). The latter species would be expected to give a strong ureido test with Ehrlich reagent and to absorb in the u.v. region owing to the —C=C—C=O chromophore. The nature of the product of peak III_a, which is presumably due to oxidation of compound V (Fig. 8), is not known although it is certainly not allopurinol.

The Thermodynamic Properties of the Zn-Sn-Cd-Bi Liquid Quaternary Solutions

W. Ptak and Z. Moser

Polish Academy of Sciences, Institute for Metal Research, Reymonta 25, Kraków, Poland

ABSTRACT

The emf method employing concentration cells with liquid electrodes and electrolyte for the determination of zinc activity in the quaternary system Zn-Sn-Cd-Bi has been used. Experiments were conducted on seventy-five liquid alloys of different mole fractions, with zinc liquid reference electrodes, over the temperature range 714°-877°K. The results were compared with calculated data obtained using Krupkowski's formulas. The zinc isoactivity plots made for constant tin concentration show good agreement between the experimental and theoretical results. Krupkowski's formulas also enable the calculation of the activity coefficients of the remaining components of the quaternary system, namely, tin, cadmium, and bismuth.

Measurements of the electromotive force of concentration cells using liquid electrodes and liquid electrolyte has been applied successfully to the determination of the thermodynamic properties of multicomponent liquid metal solutions. This method is particularly suitable for investigating low-melting alloys where the proper electrolyte can be found easily, *e.g.*, zinc alloys. Experimental investigations on liquid zinc alloys for binary and multicomponent metal solutions (1-2) and in dilute solutions (3-6) were carried out. Research work on multicomponent solutions requires both extensive experimental data and the application of specific methods for the interpretation of the experimental results. In the investigations reported here, on the quaternary Zn-Sn-Bi-Cd solutions, Krupkowski's method (7) was applied for the calculation of activity coefficients of alloy components. The experimental data of zinc activity obtained by the emf measurements of concentration cells are compared with a_{Zn} values calculated from Krupkowski's formulas (7). For the thermodynamic analysis of multicomponent systems in Krupkowski's method, the dependences of activity coefficients of respective binary alloys are sufficient. From among the different methods applicable for the interpretation of experimental results, Krupkowski's method was chosen which, on the basis of binary data, enables the full thermodynamic description of the multicomponent system. The good agreement between the a_{Zn} values obtained from the emf measurements and the theoretical activity data from Krupkowski's formulas led to the choice of this method for the calculation of the integral molar thermodynamic functions of the liquid Zn-Sn-Cd-Bi solutions (8).

Experimental Method

For the determination of the thermodynamic properties of liquid quaternary solutions the emf method of concentration cells was chosen. This method enabled the evaluation of the partial thermodynamic functions of one component. In our case it was zinc, which also formed the reference electrode in the concentration cell

$$(-)\ Zn|ZnCl_2,\ LiCl,\ KCl|Zn\text{-}Sn\text{-}Cd\text{-}Bi\ (+) \quad [1]$$

The experimental arrangement is shown in Fig. 1. The basic element was the quartz tube which contained a large amount of molten electrolyte composed of lithium, potassium, and zinc chlorides. This quartz tube, drawn separately on Fig. 1, had a water-cooled cover. The tungsten wires in glass shields went through the cover in the center of which was the Pt-Pt-10% Rh thermocouple mounted in molten electrolyte. There was a special tube for the inlet and outlet of argon which was passed through a heated column of copper turnings and over phosphorus pentoxide to remove water and oxygen. Six tubes made of high-melting glass with orifices on the lower part were suspended from the cover. These tubes contained the liquid alloys in which the tungsten wires were submerged. When the cover with the tubes was transferred to the quartz vessel the liquid electrolyte entered the tubes containing the alloys. In this manner contact was obtained between the liquid metals and electrolyte.

The cells were operated in a high heat capacity resistance furnace which had three windings to enable the proper regulation of the temperature along the axis of the furnace. In addition, a block of heat resistant steel was placed in the furnace to maintain a constant temperature gradient in the cells. The thermocouple was connected to the temperature regulator in this block. The voltage of each winding was adjusted experimentally to maintain a uniform temperature distribution. The outer jacket of the furnace was water-cooled to keep heating conditions constant. Temperature deviation after several hours did not exceed ±1°C.

Key words: concentration cell, liquid quaternary system, zinc isoactivity plots.

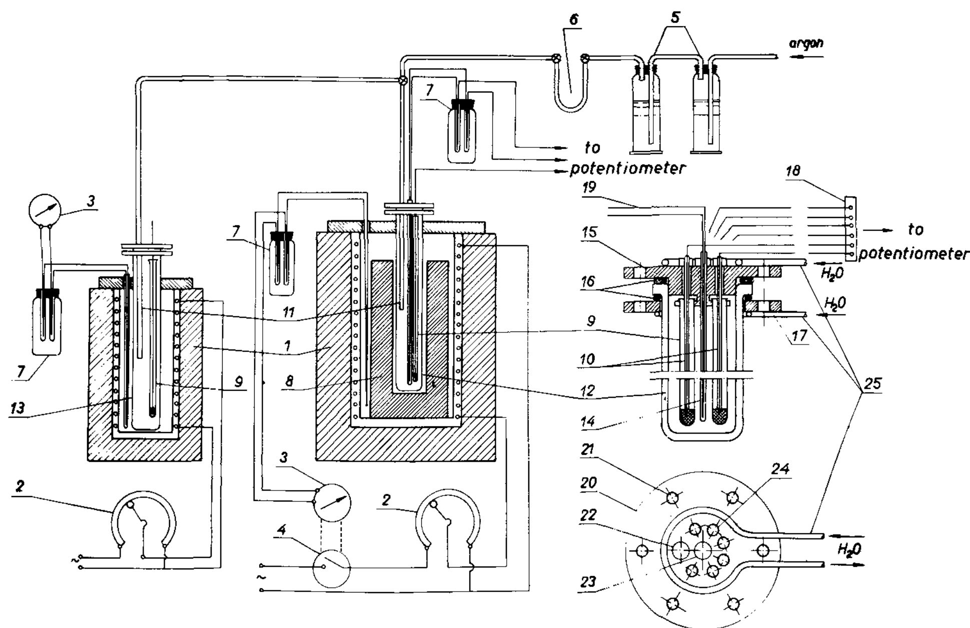

Fig. 1. Schematic diagram of the experimental arrangement for the investigation of the thermodynamic properties of liquid metal solutions: 1, resistance furnaces; 2, autotransformers; 3, galvanometers; 4, regulator of temperature; 5, gas purifier with concentrated H_2SO_4; 6, U-tube with P_2O_5; 7, thermostats; 8, steel block for thermostating; 9, supremax tubes for alloys; 10, tungsten electrodes; 11, inlet and outlet of argon; 12, measuring quartz tube; 13, tube for melting samples; 14, tube for thermocouple; 15, cover of quartz tube; 16, rubber seal; 17, bottom cover; 18, outlet of electrodes to potentiometer; 19, outlet of thermocouples to potentiometer; 20, upper view of the quartz tube cover; 21, orifices for cover screws; 22, orifice for argon inlet; 23, orifice for thermocouple; 24, orifices for tubes containing liquid metals; 25, inlet for water-cooling system.

In the second furnace shown also in Fig. 1, the alloys were heated to a molten state in argon before being put into the quartz tube. This took several seconds. The same prepared electrolyte could be used several times. With this arrangement five alloys could be measured simultaneously.

Experimental Results

The emf values of the concentration cells [1] were used for the direct calculation of activity, the activity coefficient, the partial molar heat of solution, and the partial molar entropy of zinc in the Zn-Sn-Cd-Bi quaternary solutions.

The activity and the chemical potential of zinc were calculated from the following formulas

$$\Delta\overline{G}_{Zn} = -zE\mathbf{F} \qquad [2]$$

$$\Delta\overline{G}_{Zn} = RT \ln a_{Zn} \qquad [3]$$

where $\Delta\overline{G}_{Zn}$ = change in chemical potential of zinc, a_{Zn} = activity of zinc, E = emf of cell [1] in volts, z = valence (in the case of zinc = 2), and $\mathbf{F}$ = Faraday's constant in cal/volt.

The measurements were performed for 75 alloys with different concentrations of the components. The zinc concentrations were varied from 0.1 to 0.6 in steps of 0.1 mole fractions. In a similar manner the concentrations of the other components were changed. The first column of Table I gives the concentrations of the components used in the experiments.

The next factor which was taken into account was temperature. The range of temperature was limited both by the melting point of zinc and by the pressure of such metals as zinc and cadmium. The emf values were measured at 714°, 757°, 805°, 842°, and 877°K. At the highest temperatures the cadmium vapor pressure over the pure metal is about 100 Torr, which could result in some change of composition by cadmium vaporization. This process may be decreased by a several centimeter layer of molten electrolyte. In addition, the vapor pressure of cadmium in the alloys is lower than in pure cadmium. These two factors prevented detection of the change in cadmium concentration by means of chemical analysis.

Experimental errors may result from side reactions between zinc chloride which is present in the electrolyte and the components of the alloys. Taking into account the affinity of metals to chlorine, we can find the similar position of zinc and cadmium in this series. Zinc has a higher affinity to chlorine and therefore was chosen as the reference electrode. At lower zinc concentrations, side reactions may influence the emf values and the activity of the zinc in the solution. Wagner (9) evaluated an error of 0.5% in zinc activity in the zinc-cadmium alloy when $X_{Zn} = 0.1$ and $X_{Cd} = 0.9$ at 783°K as the result of side reactions.

In our experiments this error is smaller. Side reactions have no influence on the measurements of the other components such as tin and bismuth.

The accuracy of the emf measurements of cell [1] was evaluated at ± 0.05 mV, and greater errors are possible at lower zinc concentrations. The metal used in these experiments was of minimum purity 99.99%. The composition of the electrolyte was LiCl, 57 m/o (mol per cent); KCl, 38 m/o; and $ZnCl_2$, 5 m/o.

The experimental results are given in Table I. The total emf error of the cells was 4-7%. The binary Zn-Bi system is partly immiscible in the liquid state. The obtained experimental results enabled the determination of the range of immiscibility in the liquid state in quaternary solutions (10).

The activity coefficients of zinc in quaternary solutions were calculated from the formula

$$\gamma_{Zn} = \frac{a_{Zn}}{X_{Zn}} \qquad [4]$$

where X_{Zn} = zinc concentration in mole fractions and γ_{Zn} = activity coefficient of zinc.

Comparison between Experimental and Theoretical Results

The thermodynamic properties of zinc in the ternary systems Zn-Bi-Sn, Zn-Sn-Cd, and Zn-Cd-Bi have been reported in Ref. (11), (12), and (13), respectively. These solutions form the ternary limiting values for the Zn-Sn-Cd-Bi quaternary system. For the determination of the activity coefficients and activities of metals in quaternary solutions we used Krupkowski's formu-

Table I. Concentrations of liquid Zn-Sn-Cd-Bi solutions in mole fractions and electromotive force values

las (14, 15). This author states that for the determination of the relations of activity coefficients in multicomponent systems it is sufficient to know the respective formulas for the binary systems, which for the j-k solutions have the following form

$$\ln\gamma_j = \omega_{j,k}(T)\left[(1 - X_k)^{m_{j,k}} - \frac{m_{j,k}}{m_{j,k} - 1}(1 - X_k)^{m_{j,k}-1} + \frac{1}{m_{j,k} - 1}\right] \quad [5]$$

$$\ln\gamma_k = \omega_{j,k}(T)\,(1 - X_k)^{m_{j,k}} \quad [6]$$

where γ_j and γ_k = activity coefficients of the components j and k in the binary system, X_k = concentration of the component k, $m_{j,k}$ = the asymmetry coefficient of thermodynamic functions independent of concentration and temperature, and $\omega_{j,k}(T)$ = energy coefficient dependent on temperature.

In the case of multicomponent solutions Krupkowski (14) gives the following formula for the activity coefficient of component i

$$\ln\gamma_i = \sum_{\substack{i=1 \\ j \neq k}}^{n} [\ln\gamma_i]_{j,k} \quad [7]$$

where $[\ln\gamma_i]$ = contributions introduced into the formula by respective binary systems dependent on the concentration of the components and temperature.

To determine the contributions in formula [7] it is enough to know the respective values of $m_{j,k}$ and $\omega_{j,k}(T)$ in binary systems, namely: Zn-Sn, Zn-Cd, Sn-Cd, Bi-Cd, Zn-Bi, and Sn-Bi. These values, given in Table II, were obtained from Ref. (16-20).

The bismuth-cadmium binary solutions in the liquid state were investigated by Elliott and Chipman (21). A critical review on the basis of the literature data was given by Hultgren *et al.* (22). It was shown in this

Table II. Values of functions $\omega(T)$ and m for binary solutions

System	m	$\omega(T)$	Ref.
Zn-Sn	1.10	$\frac{1081}{T} + 0.79\,(2.303 \log T - 1) - 5.61$	(16)
Zn-Cd	1.67	$\frac{392}{T}$	(17)
Zn-Bi	1.05	$\frac{687}{T} - 0.29$	(18)
Cd-Sn	1.60	$\frac{537}{T} + 0.27\,(2.303 \log T - 1) - 2.04$	(19)
Sn-Bi	1.55	$\frac{49.3}{T}$	(20)

monograph that the deviation of these solutions from ideal ones with reference to the values of the activity coefficients is smaller than 15%. Therefore, we can assume that these solutions may be treated with some approximation as the ideal ones.

The data from Table II and Krupkowski's scheme (14) enabled us to give the formulas for the activity coefficients *vs.* temperature over the whole range of concentration in quaternary solutions in the following form

$$\log\gamma_{Zn} = -\omega_{1,2}(1 - X_{Zn})^{-0.9}X_{Zn}X_{Sn} + \omega_{1,2}(1 - X_{Zn})^{-0.9}X_{Sn} - \omega_{1,3}(1 - X_{Zn})^{-0.33}X_{Zn}X_{Cd} + \omega_{1,3}(1 - X_{Zn})^{-0.33}X_{Cd} - \omega_{1,4}(1 - X_{Zn})^{-0.95}X_{Zn}X_{Bi} + \omega_{1,4}(1 - X_{Zn})^{-0.95}X_{Bi} - \omega_{2,3}(1 - X_{Cd})^{-0.4}X_{Cd}X_{Sn} - \omega_{2,4}(1 - X_{Sn})^{-0.45}X_{Sn}X_{Bi} \quad [8]$$

The equations for activity coefficients of tin, cadmium, and bismuth are summarized in the Appendix.

The respective relations of energy coefficients $\omega(T)$ are from Table II, and the numbers in the equations for the activity coefficients correspond to the different metals, namely: 1-Zn, 2-Sn, 3-Cd, and 4-Bi. The activity coefficients of zinc at 714°, 805°, and 877°K were calculated from formula [8] and the activity values of zinc were calculated from formula [4].

The activity data were used for plotting the zinc isoactivity curves. In Fig. 2-5 the zinc isoactivities at 714°K are given. The constant tin concentration was varied from $X_{Sn} = 0.1$ to $X_{Sn} = 0.4$ in steps of 0.1. In Fig. 2 and 3 the dashed regions correspond to immiscibility in the liquid state (10). In a similar manner, Fig. 6-9 illustrate the zinc activities at 805°K for the same constant tin concentrations.

The immiscibility in the liquid state exists only for $X_{Sn} = 0.1$ (Fig. 6). Finally Fig. 10-13 give the zinc

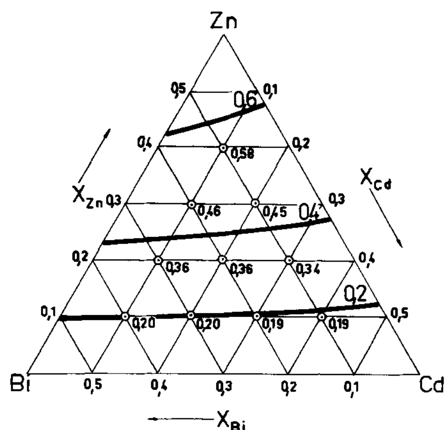

Fig. 13. Isoactivity curves of zinc, continuous lines, and the experimental values of zinc activity in a Zn-Sn-Cd-Bi system, $X_{Sn} = 0.4$ at 877°K.

isoactivities at 877°K. Figures 2-13 were plotted for zinc isoactivities $a_{Zn} = 0.2$ to 0.8 in steps of 0.2. The experimental activity values from Table I are also given on these figures.

While comparing the isoactivity curves with the experimental data we see that good agreement is obtained at 805° and 877°. Deviations in this case do not exceed 8%, while the greater deviations are observed at lower temperatures. In general we can state that the experimental data obtained in this paper are higher than those calculated from Krupkowski's method. The agreement would be better if the influence of the liquid Bi-Cd solutions showing negative deviations from Raoult's law were considered. Then the energy coefficient $\omega(T)$ appearing in formulas [5] and [6] would be negative and the component of formula [8] $-\omega_{3,4}(1 - X_{Cd})^{m_{3,4}-2}X_{Cd}X_{Bi}$ would result in the increase of the log γ_{Zn} values and in better agreement between experimental data and those calculated from Eq. [8]. The data from the literature summarized by Hultgren *et al.* (22) on the liquid Bi-Cd system allow us to consider it as ideal and not ascribe to it negative or positive deviations from Raoult's law. Such an assumption is based on γ_{Cd} values obtained from emf measurements which oscillate about unity.

Discussion

It was shown for the second time in the investigations of the liquid Zn-Sn-Cd-Bi solutions that it is possible to apply Krupkowski's method for the calculation of partial and integral thermodynamic functions of components. The first papers dealt with research on the liquid Zn-Sn-Cd-Pb system (23, 24, 25). As in the case of the results shown in this paper good agreement was obtained between the experimental data and those calculated from Krupkowski's formulas. These formulas were used for the interpretation of experimental data for liquid metal solutions over the wide range of concentrations of components. For example, the investigations on the liquid Zn-In-Pb alloys when $X_{Zn} > 0.1$ molar fraction (26), a systematic comparison between Krupkowski's (14) and Darken's (27) method was carried out and very similar results from both methods were obtained. We suppose that Krupkowski's method can be applied successfully in the case of binary, ternary, and quaternary solutions and this was verified experimentally. In the case of multicomponent systems this method is also promising.

The fundamental assumption of Krupkowski's method consists in the additivity of thermodynamic properties of multicomponent systems given by formula [7] on the basis of the properties of binary systems. When for the components j, k in solutions j, k the activity coefficients are given by formulas [5] and [6], then the respective terms of the sum [7] are the following

for i = j

$$[\log \gamma_j]_{j,k} = -\omega_{j,k}(1 - X_k)^{m_{j,k}-2}X_jX_k + \frac{\omega_{j,k}}{m_{j,k} - 1}[1 - (1 - X_k)^{m_{j,k}-1}] \quad [9]$$

for i = k

$$[\log \gamma_k]_{j,k} = -\omega_{j,k}(1 - X_k)^{m_{j,k}-2}X_jX_k + \omega_{j,k}(1 - X_k)^{m_{j,k}-2}X_j \quad [10]$$

for $i \neq k$, $i \neq j$

$$[\log \gamma_i]_{j,k} = -\omega_{j,k}(1 - X_k)^{m_{j,k}-2}X_jX_k \quad [11]$$

Equation [11] shows the influence of thermodynamic properties of j,k solutions on the activity coefficient of the remaining components i in multicomponent system. Formula [7] and others of the type [9], [10], and [11] enable the establishment of the dependence of the activity coefficient of the component in the multicomponent system. It should be added that a detailed analysis of Krupkowski's method has been given (28).

Deuterium Labeling by Electrochemical Reactions

John R. Cockrell[1] and Royce W. Murray*

Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514

ABSTRACT

The extent to which d_1-labeled isomeric anisoles and toluene result from electrolysis of the corresponding iodoaromatics in deuterium-containing solvent media has been explored. Solvent mixtures of D_2O and unlabeled acetonitrile or dimethoxyethane give products of excellent isotopic purity when lithium perchlorate serves as supporting electrolyte. Use of tetraethylammonium as supporting electrolyte cation gives appreciable percentages of unlabeled product.

The electrochemical reduction products of many classes of organic compounds contain hydrogen which was abstracted from the solvent medium during the electrochemical reaction. An example is the reduction of an aromatic halide, which generally proceeds by the reaction (1)

$$ArX + 2e + HA \rightarrow ArH + X^- + A^- \quad [1]$$

HA is the solvent, a supporting electrolyte component, or an acidic additive. If this reaction is carried out in a medium where HA is replaced by a deuterium source DA, a labeled product ArD will result. Such an experiment offers two possibilities. One is the electrosynthesis of ArD in high isotopic purity if DA acts as the exclusive donor. Failing such exclusivity, isotopic analysis of the ArH,ArD product mixture provides a quantitative assessment of the degree to which other components of the electrochemical solvent medium can serve as hydrogen donors in the electrode reaction. This report explores these two points for the aromatic halide reduction, using the isomeric (*o, m, p*) iodoanisoles and o-iodotoluene as examples.

* Electrochemical Society Active Member.
[1] Present address: Ivorydale Technical Center, Proctor and Gamble Company, Cincinnati, Ohio 45200.

Key words: deuterium, electrosynthesis, iodoanisole, isotopic labeling, supporting electrolyte.

There have been several previous publications dealing with electrochemical deuterium labeling. Throop and Tökés (2) contributed the sole electrosynthetic study, in which steroid carbonyl functions were reduced at constant current at lead electrodes in dioxane/D_2O/D_2SO_4 solvent. The labeling efficiency was high, and some polydeutero product also resulted. Webb, Mann, and Walborsky (3), seeking information on hydrogen donor sources, reduced (+)-1-bromo-1-methyl-2,2-diphenylcyclopropane in $CD_3CN/N(C_2H_5)_4Br$ to obtain 75% deuterium label on the 1-carbon. Barger and Coleman (4) examined the potential dependence of the extensive hydrogen-deuterium exchange which propane and benzene undergo at a Pt fuel cell electrode in D_2O/D_3PO_4 medium.

The choice of the deuterium-containing solvent medium is obviously crucial if a high labeling efficiency is to be sought in reaction [1]. The following considerations apply in this choice. A per-deutero solvent clearly offers assurance of high labeling efficiency; for organic solvents this entails costly reagents. If an acidic additive DA is to be used in an otherwise unlabeled solvent, a suitable level of DA acidity and concentration includes the opposing factors of sufficiently low acidity and concentration to avoid direct electrochemical discharge of deuterium, and suffi-

ciently high concentration to avoid interference from ubiquitous H_2O impurity in the solvent. In this study, we chose to employ the very weakly acidic donor D_2O in gross amounts, mixed with unlabeled acetonitrile or dimethoxyethane (DME). The choice of supporting electrolyte is shown to be equal in importance to that of the solvent.

Experimental

Chemicals.—Spectrograde and "anhydrous" acetonitrile, tetraethylammonium perchlorate (Et_4NClO_4), o-, *m*-, and *p*-iodoanisoles, o-iodotoluene, and 1,2-dimethoxyethane were obtained from Eastman, anhydrous reagent $LiClO_4$ from G. F. Smith Company, D_2O (99.9% isotopic purity) from Columbia Organic Chemicals, and CD_3DN from Bio-Rad. All were used as received. Solutions were prepared under nitrogen in a closed system to avoid external water contamination. The Et_4NClO_4 was vacuum-oven dried at 60°C for 24 hr.

Apparatus.—The electrolysis cell followed the design of Harrar and Shain (5), consisting of two concentric cylinders terminating in medium and fine frits and nested in a beaker cell containing a stirred mercury pool. The three compartments thus provided, namely, the (lower) sample compartment with pool electrode, sample solution, and reference electrode, the (middle) salt bridge compartment containing sample solution, and the (upper) auxiliary electrode compartment containing the large Pt gauze auxiliary electrode and sample solution, were closed to the atmosphere by appropriate sleeves and o-rings and were filled with solution to equal, concentric levels to minimize intercompartment mixing. The sample compartment had provision for inserting a dropping mercury electrode for polarographic assessment of appropriate electrolysis potentials and for closed system removal of product solution, and had a volume of either 50 (mainly used) or 250 ml of sample solution in contact with the mercury pool electrode. Further details of cell construction can be provided upon request.

The electrolysis potentiostat utilized either a Wenking Model 61R or a Kepco Model 120-5M operational power supply as control amplifier and conventional associated operational amplifier circuits. The electrolysis required approximately 30 min for completion.

Gas chromatographic product isolations were accomplished with a Varian Autoprep unit (3/8 in. × 20 ft Dowex-11 column) or an F & M Model 30 chromatograph (1/8 in. × 2 meter column containing 10% SE-30/chromosorb, for anisole, or 25% TCEP/chromosorb, for toluene). The chromatographically purified labeled product was analyzed for isotopic purity using a Hitachi-Perkin Elmer Model RMU-6E or an AEI Model MS-902 mass spectrometer.

Procedure.—Following polarographic assessment of appropriate control potential for preparative electrolysis, a small-scale electrolysis was conducted to provide a product solution for ultraviolet spectrophotometric comparison to the expected authentic (unlabeled) product. Then a larger scale electrolysis was conducted and the pure product isolated for mass spectrometric analysis. The electrolysis was continued until the current had decayed to background levels. In the case of iodotoluene, a spontaneous reaction (unknown products) occurred with the open-circuit mercury pool. This reaction was circumvented by applying the control potential to the working electrode in contact with supporting electrolyte solution prior to injection of the iodotoluene sample. In the case of *m*-iodanisole, the solution developed a yellow-orange color during electrolysis. A high-melting red-brown precipitate obtained during solvent stripping could not be identified. This side reaction was not apparently deleterious to the labeling reaction.

To remove the supporting electrolyte prior to the gas chromatographic product isolation, the sample and about one-half of the organic portion of the solvent, plus some D_2O, were stripped off with a 12-in. unpacked glass column. One milliliter injections were used with the Autoprep chromatograph. In the analytical-scale F & M chromatograph, several 100 μl injections of distillate were required for collection of sufficient anisole from the SE-30 column. The anisole eluted (80°C) from this column after about 30 min, following the large solvent peak, and was captured in a glass wool-packed capillary maintained at dry ice temperature. After sufficient sample (several microliters) had been collected in the capillary, it was sealed for subsequent introduction into the mass spectrometer. In the case of toluene, 500 μl injections into the TCEP column gave a toluene peak resolved from and just preceding the large solvent peak which was collected as above.

In the mass spectral isotope analysis, the labeled parent ion peak M_{d_1} was corrected for contributions from the C^{13} peak of d_0 unlabeled product and the C^{13} $(M\text{-}1)_{d_1}$ peak. The parent ion peak for unlabeled product, M_{d_0}, was corrected for the $(M\text{-}1)_{d_1}$ contribution. The per cent deuteration was calculated from these corrected peak heights as $100\ M_{d_1}/(M_{d_1} + M_{d_0})$ and is believed accurate to ±1%. No d_2-labeled products could be detected in any of the isotopic analyses.

Many of the electrolysis and analysis experiments were performed in duplicate; the per cent deuteration was found in these replicates to be reproducible to within ±1%.

Results and Discussion

The results of labeling experiments using a variety of solvent media are presented in Table I. The results of Experiments 1, 2, and 8-11 show that an excellent level of d_1 labeling efficiency can be obtained electrosynthetically. The $D_2O/DME/LiClO_4$ mixture proved in the few experiments run in this medium to be superior to the several D_2O/acetonitrile mixtures tested. These isotopic purities compare favorably with previous chemical syntheses of d_1-anisoles, where the isomeric d_1-forms have been prepared in 90% purity by Grignard conversion of bromoanisoles (6), and *p*-d_1-anisole was obtained at essentially 100% purity from catalytic D_2/Pd/charcoal reduction of *p*-bromoanisole (7). Other standard chemical methods for halide-reductive labeling, such as CH_3COOD/Zn, $LiAlD_4$, and $NaBD_4$ reductions (8) and tributyl stannane-d_1 reactions (9), appear not to have been applied to the anisoles but should provide comparable results.

While no attempt was made in these studies to isolate more than the few milligrams of product required for mass spectral analysis, a more exhaustive gas chromatographic isolation could be expected to yield at least 50 mg of pure product (corresponds to 50%

recovery from 50 ml of 0.02*M* d_1-anisole solution). Experiments 3 and 4 show that use of more concentrated sample solutions for production of larger quantities can lead to lowered isotopic purity. This is a disadvantage as compared to the chemical synthetic approaches. The electrosynthetic experiments in this study were unbuffered, and the use of appropriately labeled buffers or of pD-statting during electrolysis may increase the usable sample concentration levels.

The results of Table I also allow some conclusions as to the source(s) of hydrogen abstracted (from species other than D_2O) during the electrode reaction.

The first point which must be inspected is the level of H_2O contamination of the D_2O label source. The mole percentage of H_2O in the original D_2O is insignificant (0.1%). The H_2O level in the spectrograde acetonitrile is 100 mmole or less. This H_2O level in 60/40, 35/65, 25/75, 20/80, and 10/90 D_2O/acetonitrile mixtures corresponds to 0.33, 0.57, 0.80, 1.00, and 2.00 mole per cent H_2O (with respect to D_2O). These levels are too small to account for more than a small fraction of the total hydrogen impurity in the d_1-labeled materials prepared in these mixtures. Karl Fischer titrations of solutions of $LiClO_4$ and Et_4NClO_4 in acetonitrile showed no detectable increase in the water level from residual moisture in the dried supporting electrolytes. The results in so-called anhydrous (titration-grade) acetonitrile Experiments 13 and 14, were inferior to those in untreated spectrograde solvent, indicating the presence of a more potent hydrogen donor impurity in the former.

In the $D_2O/CH_3CN/LiClO_4$ mixtures, the acetonitrile itself, rather than impurity H_2O, must then provide the source of hydrogen impurity in the labeled product. Higher proportions of acetonitrile (Experiments 5-7 compared to 8) yield slightly more hydrogen impurity. A more definitive demonstration is provided by use of per-deutero-acetonitrile in Experiment 12 (compare to Experiment 8). The results of Wawzonek *et al.* (9) and Webb *et al.* (3) have shown, in controlled potential electrolysis experiments, that acetonitrile does undergo hydrogen loss in certain electrode reactions. It is interesting in the present results that acetonitrile can compete, albeit at a minor level, with the D_2O as a proton source.

Use of tetraethylammonium rather than lithium salts as supporting electrolyte bears the consequence of rather substantial hydrogen impurity in the labeled product (see Experiment 15). Webb, Mann, and Walborsky (3) have shown that proton abstraction from the tetraethylammonium cation occurs in the reduction of a bromocycloalkane from acetonitrile solvent. They present evidence that this proton abstraction occurs indirectly; the carbanion electrochemically derived from the alkyl halide primarily attacks the solvent, the resulting CH_2CN^- secondary base reacting with the tetraethylammonium species. This indirect pathway is not dominant in the iodoanisole reaction, however; the reactive base from iodoanisole reduction clearly attacks the tetraethylammonium cation directly and more readily than it does the acetonitrile solvent (compare Experiments 8 and 15). Indirect attack of tetraethylammonium by OD^- to yield HOD can also be ruled out, owing to the high dilution of the latter species by the D_2O, as a major source of hydrogen introduction into the anisole product. The possibility that any ion pairing effect of lithium ion distorts the comparison of Experiments 8 and 15 is likewise ruled out, by Experiment 16, which shows that the addition of $LiClO_4$ causes no change in the hydrogen impurity level observed in the presence of tetraethylammonium cation.

The above results show, in summary, that:

1. Reductive electrosynthesis of deuterium-labeled organic compounds can lead to labeled materials of very high isotopic purity in small quantities.
2. Use of isotopic labels can lead to better understanding of electrode reaction mechanisms and, in particular, to recognition of components of the solvent medium which must be controlled if one wishes to minimize sources of acidic reactivity toward electrode reaction products or intermediates.

The Bockris-Swinkels Isotherm and Low-Coverage Electrosorption of Monocarboxylic Acids on a Copper Cathode

R. S. Salter, P. Seto, and A. J. Sukava

Department of Chemistry, University of Western Ontario, London, Ontario, Canada

ABSTRACT

A theoretical analysis of equations pertaining to the electrosorption of normal monocarboxylic acids on a copper cathode indicates that, at surface coverages approaching zero, the net free energy of adsorption of the polar carboxyl group depends on the number of adsorbed water molecules displaced per molecule of adsorbing additive, while the free-energy contribution of the hydrocarbon part of the molecule is independent of this number. Accordingly, the carboxyl and hydrocarbon parts of the molecule appear to be specifically and nonspecifically adsorbed, respectively. A coverage-dependent interaction parameter or apparent free energy is inherent in the Bockris-Swinkels isotherm and is proportional to the fractional surface coverage as the coverage approaches zero, with the proportionality constant also dependent on the solvent displacement number. An equation is derived relating the solvent displacement number to other physical properties of the adsorbate. The results seem consistent with a condensation mechanism of physical adsorption.

Studies of the effects of normal monocarboxylic acids on the cathode overpotential during electrodeposition of copper from acid sulfate electrolyte have shown (1, 2) that specific adsorption free energy contributions due to the individual structural units of such additive molecules can be calculated from overpotential increment and additive concentration data. A coverage-dependent apparent free energy, assumed to be due to lateral interaction, is also calculable (2), with results similar to those obtained for the adsorption of butanoic and 2-methyl-propanoic acids on mercury (3). Theoretical considerations indicate that the lateral interaction arises primarily from dipole-dipole effects in the adsorbed phase (2).

The present paper deals with the electrosorption of monocarboxylic acids in general terms, with restriction to very low or near-zero coverages. The blocking equation (1, 2, 4) and an appropriate form of the Bockris-Swinkels isotherm (2, 5) are assumed applicable, and some pertinent and useful information is derived based on this assumption. Special attention is given to the relationship between the various free energy components and the solvent displacement number n, the number of adsorbed water molecules displaced per molecule of additive in the adsorption "reaction" (5)

$$A_{soln.} + nH_2O_{ads.} \rightarrow A_{ads.} + nH_2O_{soln.}$$

Theory

Calculation of θ, the fraction of cathode surface covered by adsorbed additive, from the overpotential increment $\Delta\eta$ caused by such additive, assumes the applicability of the blocking equation (1, 4)

$$\theta = 1 - \exp(-\Delta\eta/b) \quad [1]$$

where b is the Tafel slope. Obviously, this equation can only be applied to the so-called Tafel region where charge transfer is rate determining (6, 7), and only if the presence of adsorbed additive does not alter the charge-transfer kinetics of the cathode process, that is, only if the additive merely increases the true current density at the electrode surface.

For normal monocarboxylic acids as additives, the coverage θ can then be related to the individual adsorption free energy contributions of the various parts of the adsorbed molecule by writing the Bockris-Swinkels version of the Langmuir isotherm (5) (derived for adsorption involving solvent displacement) in the appropriate form (2)

$$\frac{\theta}{(1-\theta)^n} \cdot \frac{\{\theta + n(1-\theta)\}^{n-1}}{n^n} = \frac{C}{55.5} \exp\left[\frac{-\Delta G^\circ_P - x\Delta G^\circ_{CH_2} - g(\theta)}{RT}\right] \quad [2]$$

In Eq. [2], C is the concentration of additive, x is the number of methylene groups in the additive molecule, including the terminal methyl, and n is the solvent displacement number. ΔG°_P and $\Delta G^\circ_{CH_2}$ denote the standard free energy contributions of the polar carboxyl group and each methylene group respectively,[1] while the coverage-dependent parameter $g(\theta)$ is a Frumkin-like interaction term definable as an apparent standard free energy (8) due to lateral forces between the adsorbed molecules.

Values of $g(\theta)$ have been calculated (2) for adsorbed straight-chain monocarboxylic acids from cathode overpotential increments in accordance with Eq. [1] and [2]. The results are in reasonable agreement at low coverages with values calculated from theory, assuming only dipole-dipole interaction and neglecting dispersion effects [see Fig. 6 of Ref. (2)]. Accordingly, for these compounds, $g(\theta)$ can be treated to a first approximation as a dipole-dipole interaction energy only, provided the surface coverage is not too high.

Experiments with low concentrations of the straight-chain monocarboxylic acids from propanoic to octanoic inclusive have also shown (2) that, in the adsorption of these compounds on a copper cathode during electrodeposition under galvanostatic control, the free energy term $\Delta G^\circ_{CH_2}$ is independent of surface coverage. Therefore, since change in coverage gives rise to change in cathode potential under galvanostatic conditions, then, within the limitations of the data, $\Delta G^\circ_{CH_2}$ can be treated as independent of potential. For this reason, any potential dependence of the free energy of adsorption of short-chain normal monocarboxylic acids is considered in this paper to be incorporated in the term ΔG°_P, primarily.

Since the cathode overpotential in galvanostatic experiments is determined by the concentration and nature of any surface-active additive, as well as by the apparent current density, the temperature, and the composition of the standard electrolyte apart from the

[1] While this division of the standard free energy of adsorption into separate contributions from the carboxyl and methylene groups follows from experimental data in this instance (2), it should be noted that the same division would arise in a purely theoretical manner if Traube's rule is assumed to apply to the adsorption from solution of compounds in a homologous series such as the straight-chain monocarboxylic acids.

Key words: theory, isotherm, blocking, homologous, additives.

additive, then, assuming the adsorption of the carboxyl group to be potential dependent, the value of ΔG°_P in Eq. [2] varies with additive concentration in such experiments. By extrapolating the galvanostatic data to zero additive concentration, *i.e.*, to zero surface coverage, a limiting value of ΔG°_P is obtained which corresponds to a potentiostatic state arbitrarily determined and fixed by the experimental current density, the temperature, and the composition of the standard electrolyte. Purely mathematical equivalents of such an extrapolation can be derived by applying Eq. [1] and [2] to low surface coverages and considering the limiting case as the coverage approaches zero.

Proportionality of $\Delta\eta$ *and C at low surface coverage.*—Experiments have shown (2) that the cathode-overpotential increment caused by adsorbed monocarboxylic acid is proportional to the concentration of the additive if the surface coverage (or additive concentration) is sufficiently low. This proportionality can be shown to follow as a direct consequence of Eq. [1] and [2].

As θ approaches zero, $\Delta\eta$ and $g(\theta)$ also approach zero, and Eq. [1] and [2] become, respectively

$$\theta = \Delta\eta/b \qquad [3]$$

and

$$\theta = nKC \qquad [4]$$

where K is given by

$$K = \frac{1}{55.5} \exp\left[\frac{-\Delta G^\circ_P - x \cdot \Delta G^\circ_{CH_2}}{RT}\right] \qquad [5]$$

Obviously, for a given additive at a fixed apparent current density and temperature, K is fixed at near-zero coverages since ΔG°_P takes on its limiting zero-coverage value as determined by the arbitrary experimental conditions, and since $\Delta G^\circ_{CH_2}$, being independent of coverage (2), is assumed to be independent of potential. Equations [3] and [4] then give, in the limit

$$(\Delta\eta/C)_{C\to 0} = nbK \qquad [6]$$

showing that the initial slope of the $\Delta\eta$ *vs.* C curve is fixed for any monocarboxylic acid and for any fixed value of n.

Substituting Eq. [5] into [6], and writing the result in logarithmic form, gives

$$\ln(\Delta\eta/C)_{C\to 0} = \left[\ln\frac{nb}{55.5} - \frac{\Delta G^\circ_P}{RT}\right] - \frac{\Delta G^\circ_{CH_2}}{RT}\cdot x \qquad [7]$$

Therefore, as has been shown by experiment [see Fig. 3 of Ref. (2)], the logarithm of the initial slope varies linearly with the number of methylene groups in a normal monocarboxylic acid molecule.

Equation [7] leads to some interesting observations, assuming that Eq. [1] and [2], on which it is based, are both valid. Obviously, in the electrosorption of normal monocarboxylic acids on copper, the methylene-group contribution to the free energy, given by the slope in Eq. [7], is independent of the solvent displacement number n. On the other hand, the carboxyl-group contribution can only be found from the intercept in [7] if n is known, and consequently, it appears that adsorption of these compounds on copper from aqueous solution must occur in a manner such that adsorbed water molecules are displaced only by the carboxyl group. The free energy of adsorption of the carboxyl group, ΔG°_P, is then, presumably, a net free energy, the algebraic sum of the actual free energy of adsorption of this group and the free energy of desorption of n moles of water. It follows that a distinction can be made between the carboxyl-group and methylene-group effects as specific and nonspecific adsorption, respectively. Further, to be consistent with the significance of x in Eq. [7], the hydrocarbon chain of an adsorbed monocarboxylic acid molecule probably lies parallel to or along the copper surface, and presumably on top of undisplaced, adsorbed water molecules.

Proportionality of g(θ) and θ at low surface coverage.—Experimental data and calculations reported by different workers (2, 3, 5, 9) appear to indicate that, in any adsorption, the coverage-dependent energy parameter $g(\theta)$ becomes proportional to the surface coverage at coverages approaching zero, with the proportionality constant having some nonzero value. This proportionality follows as a consequence of the adsorption isotherm, Eq [2].

Solving Eq. [2] for $g(\theta)$, and introducing Eq. [5], gives, after rearrangement

$$g(\theta)/RT = \ln\frac{nKC}{\theta} + n\ln(1-\theta) - (n-1)\ln\left\{1 - \frac{n-1}{n}\cdot\theta\right\} \qquad [8]$$

which applies at all values of θ. Straightforward substitution of power-series expressions for the logarithms in the second and third terms in [8], followed by division through by θ and taking the limit as θ approaches zero, gives

$$\frac{1}{RT}\left[\frac{g(\theta)}{\theta}\right]_{\theta\to 0} = \left[\frac{1}{\theta}\ln\frac{nKC}{\theta}\right]_{\theta\to 0} + \frac{1}{n} - 2 \qquad [9]$$

where the first term on the right is indeterminate in view of [4]. Equation [9] permits direct calculation of the zero-coverage slope of the $g(\theta)$ *vs.* θ curve, requiring only that the indeterminate quantity be found.

For sufficiently low values of θ, and assuming the blocking theory to be valid, Eq. [6] can be applied to give, on substitution from [1]

$$nKC = -\ln(1-\theta) = \theta + \frac{\theta^2}{2} + \frac{\theta^3}{3} + \cdots$$

which applies only when surface coverage is sufficiently low to make $\Delta\eta$ proportional to C. With this substitution for nKC, the first term in [9] becomes, after further substitution of power series and simplification

$$\frac{1}{\theta}\ln\frac{nKC}{\theta} = \left(\frac{1}{2} + \frac{\theta}{3} + \frac{\theta^2}{4} + \cdots\right) - \frac{1}{2\theta}\left(\frac{\theta}{2} + \frac{\theta^2}{3} + \cdots\right)^2 + \cdots$$

which, for the zero-coverage limit, is

$$\left[\frac{1}{\theta}\ln\frac{nKC}{\theta}\right]_{\theta\to 0} = \frac{1}{2} \qquad [10]$$

Equations [9] and [10] then give the slope of the $g(\theta)$ *vs.* θ curve at coverages approaching zero as

$$\left[\frac{g(\theta)}{\theta}\right]_{\theta\to 0} = \left(\frac{1}{n} - \frac{3}{2}\right)RT \qquad [11]$$

The nonzero value of $g(\theta)$ at all nonzero values of θ as given by Eq. [11] is a characteristic inherent in the Bockris-Swinkels isotherm. It is consistent with the expected nature of any physical adsorption at near-zero coverages. To attain their lowest possible free-energy state at such coverages, molecules of adsorbate would be expected to achieve a degree of lateral interaction by locating adjacent to each other in oriented and clustered array, in a manner analogous to ordinary condensation. This condensation mechanism of adsorption would be similar to the formation of so-called coherent islands as found in the case of long-chain monocarboxylic acids at the air-solution interface (10). The adsorbed phase would not be expected to exist as randomly spaced individual and separately adsorbed molecules.

Solvent displacement number and physical properties of the adsorbate.—If localized adsorption is assumed with lateral interaction due mainly to dipole effects (2, 5), then, according to theory (5), the molal value of $g(\theta)$ can be given in terms of coverage θ and dipole interaction $U_{dip.}$ by

$$g(\theta) = \phi\,\theta N\,U_{dip.} \quad [12]$$

where N is the Avogadro number and where ϕ, a constant, depends on the manner in which the adsorbed molecules are arrayed and oriented on the surface (5). The molecular contribution to the dipole interaction is given by (5)

$$U_{dip.} = -\frac{\mu_D^2}{\epsilon r^3} \quad [13]$$

where μ_D is the dipole moment, ϵ the dielectric constant of the medium (the primary electrode layer), and r the average distance between adjacent dipoles in the adsorbed phase. Consequently, an equation can be written relating the solvent displacement number n directly to the parameters on the right in [13] by substituting [12] and [13] into [11] to give, for sufficiently low coverages

$$\left[\frac{3}{2} - \frac{1}{n}\right] kT = \frac{\phi\mu_D^2}{\epsilon_{\theta\to 0}\, r^3} \quad [14]$$

where k is the Boltzmann constant and where the zero-coverage value of ϵ is specified to conform to the requirements of Eq. [11]. [It should be noted that the dielectric constant of the primary electrode layer has been considered to vary with coverage (5, 11, 12)].

The quantities n, μ_D, ϵ, and r in Eq. [14] are not accurately known. In particular, widely different values of ϵ have been considered appropriate at zero coverage, *e.g.*, 80 (5), 15 (11), 6 (12), and 1 (13), depending on the adsorbate, the mode of adsorption, and the proximity of the dipole to the surface (13). However, assuming the validity of Eq. [14], at least as an approximation, and noting that n, ϕ, μ_D, and r are presumably determined by the fixed dimensions and structure of the adsorbate molecules, then $\epsilon_{\theta\to 0}$ is likewise also fixed and determined primarily by these molecules themselves, even at coverages approaching zero. This conclusion is consistent with the view that clustering of adsorbed molecules occurs at near-zero coverages, according to the condensation concept, as has been stated in connection with Eq. [11].

Furthermore, it is of interest to note the value of $\epsilon_{\theta\to 0}$ as calculated from reasonable estimates of the parameters in Eq. [14] for adsorbed monocarboxylic acids. If n is taken as about 2.2 [estimated from the cross-sectional area of the hydrocarbon chain relative to the projected area of the water molecule (3)], r as about 4.9Å [estimated for close-packed array from the cross-sectional dimensions of the hydrocarbon chain (5)], and μ_D as about 1.5 Debye [taken as an average for short-chain monocarboxylic acids (14)], and if localized adsorption, hexagonal array, and antiparallel orientation are assumed, *i.e.* if $\phi = 4.5$ (5), then $\epsilon_{\theta\to 0}$ for these compounds is about 2.1 at 25°C. For parallel orientation, with $\phi = 9.24$ (5), $\epsilon_{\theta\to 0}$ would be about 4.3. These values of $\epsilon_{\theta\to 0}$ may be compared with the liquid-state value of about 2.5 for pure monocarboxylic acids (15).

Condensation concept of adsorption.—The argument that the nonzero slope of the $g(\theta)$ *vs.* θ curve given by Eq. [11] is consistent with a condensation mechanism of adsorption finds support in a simple calculation based on Eq. [12] and [13], according to which the initial zero-coverage slope of the $g(\theta)$ *vs.* θ curve would be zero if the adsorption occurred by a random distribution of separate molecules.

If such a random distribution of individual adsorbate molecules is assumed, then ϵ and r in Eq. [13] would be functions of θ, the coverage. This assumption is implicit in the belief that the dielectric "constant" of the primary cathode layer varies linearly with coverage (5, 11, 12), according to which one would write for monocarboxylic acids adsorbed from aqueous solution

$$\epsilon = 6 - 3.5\,\theta$$

where the zero-coverage ϵ-value of 6 is assumed to be that of pure water in the primary cathode layer (12) and that at full coverage, taken as 2.5, is the value for pure liquid monocarboxylic acids (15). Then, since the coverage dependence of r would be given by (9, 16)

$$r = q \cdot \theta^{-1/2}$$

where q is a constant,[2] Eq. [12] and [13] would give, for separate-molecule adsorption with dipole-dipole interaction assumed predominant

$$\frac{g(\theta)}{\theta} = -\,\phi N \mu_D^2 q^{-3}\left[\frac{\theta^{3/2}}{6 - 3.5\,\theta}\right]$$

Obviously, as θ approaches zero, this would become

$$\left[\frac{g(\theta)}{\theta}\right]_{\theta\to\theta} = 0$$

in contrast to the behavior inherent in the Bockris-Swinkels isotherm as given by Eq. [11].

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

[2] This simple relation between r and θ arises from a basic statistical relationship according to which the average distance between randomly distributed and separately adsorbed molecules is given by the square root of the average over-all surface area per molecule. Since this area is inversely proportional to the coverage, the r *vs.* θ relation follows as given.

Linear Models and the Kinetics of Thermally Activated Currents and Voltages

B. Gross[1]

Escola de Engenharia de São Carlos, Departamento de Física, Avenida Dr. Carlos Botelho, 1465; São Carlos, Estado de São Paulo, Brazil

ABSTRACT

Experimental results from thermally activated measurements can be analyzed by different methods. In view of the difficulty of obtaining precise solutions of the differential equations describing the transport and trapping of charge carriers in solid dielectrics, various linearized theories have been developed. In the present paper the isothermal theory of conventional models is generalized and a nonisothermal model theory is established. Current transients generated by heating in short-circuit and voltage-transients generated by heating in open-circuit are discussed. It is found that under nonisothermal conditions the concept of equivalency of models must be severely restricted and that the assumptions of charge invariance and absence of current reversals, implicit in many existing theories, cannot be taken for granted. One concludes that the interpretation of thermal activation measurements without the knowledge of the structure of the system under consideration and the underlying physical mechanism leads to ambiguities.

The measurement of thermally stimulated currents has become an important tool for the investigation of relaxation processes in solid dielectrics (1). When the temperature of a polarized dielectric is increased, depolarization currents are generated and current peaks are observed which are indicative of the successive release of charge carriers or dipoles from fixed positions. But the quantitative interpretation of results is still open to discussion since procedures based on existing theories (2) have recently been questioned by several authors (3).

The method of thermal activation is an extension of the isothermal methods of analysis previously used in the practice of dielectric measurements. The isothermal behavior of solid dielectrics has been adequately described with the help of electrical models in which temperature appears as a time-independent parameter. It can be expected that model theory will be equally useful for the discussion of nonisothermal behavior. It is the purpose of the present paper to generalize isothermal model theories by introduction of temperature as a time-dependent variable and to study nonisothermal transitions of linear models. Results show the limitations of some of the assumptions inherent in existing theories and give a comprehensive treatment of temperature-induced electrical transients. They indicate that the measurement of thermally stimulated voltages is complementary to that of thermally stimulated currents and suggest them as a new experimental approach to the problem. The concept of equivalence of models is found to lose validity. Therefore the selection of a particular model can no longer be dictated by the convenience of mathematical description but must be determined by the physics of the relaxation system.

Concepts of Nonisothermal Model Theory

Assumptions.—The paper deals with the theory of linear electrical relaxation processes in solid dielectrics with a finite, discrete spectrum of activation energies. It discusses electrical transients in charged or polarized systems after the external source of electrical energy has been disconnected. Conductivity glow curves are not included. The characteristic variables are current, voltage, and temperature which might all be functions of time. Temperature shall, however, vary slowly enough to ensure no departure from spatial uniformity throughout the sample. Phase transitions and irreversible processes like aging are excluded. The activation energies are considered as temperature-independent physical constants. Physical systems are represented by linear electrical models with lumped elements composed of resistors and capacitors. Changes of temperature shall not affect the arrangement of the elements of a model but only their values. These shall be state variables. The link between physical system and model is established by means of conventional rate theory.

Isothermal and nonisothermal theories.—Conventional theory, as it has been applied to relaxation processes (4), considers current transients caused by voltage changes and voltage transients caused by current changes at different, but constant temperatures; therefore it is an isothermal theory. It leads to differential equations with constant coefficients. Thermally activated processes involve nonisothermal transitions during which system parameters are time-dependent functions. They are no longer described by differential equations with constant coefficients. The formalism must therefore be generalized. A suitable starting point is found in model theory. Thus the present nonisothermal theory uses the method of network analogs to discuss current transients caused by temperature changes at constant (*i.e.*, zero) voltage and voltage transients caused by temperature changes at constant (*i.e.*, zero) current.

Models.—Many different models have been used to discuss molecular relaxation processes (5). Here we shall discuss in detail only two representative models: the Maxwell model, given by a parallel arrangement of branches, each containing a series connection of resistor and capacitor; and the Wagner-Voigt model, given by a series arrangement of loops, each containing a parallel connection of resistor and capacitor.

State variables.—How does a given model react to a change of temperature? The model structure, *i.e.*, the particular arrangement of elements that characterizes the model, must remain the same if the model concept is to be meaningful at all under nonisothermal conditions, but the values of the elements become variables.

A priori the value P of a circuit element can depend on temperature $T(t)$, its time derivatives $dT/dt, d^2T/dt^2, \ldots$, and explicitly on time t. In this case one would have $P[T(t), dT/dt, \ldots, t]$. To develop a theory one

[1] Present address: Sternwartestrasse 55, Vienna, Austria A-1180.

Key words: electrets, thermally stimulated currents, thermally stimulated voltages, linear electrical model theory (nonisothermal).

must specify the type of functional dependence. If P depended explicitly on time, the system would undergo irreversible modifications, *e.g.*, aging. If P depended on any time derivative of temperature, it could assume different values for the same value of T and lead to "thermal hysteresis." Here we shall not consider these effects and assume that at any time P is uniquely determined by the value of T at that time. This definition makes P a state variable which is written $P[T(t)]$. A system composed of elements whose values are state parameters goes through a succession of equilibrium states during a change of temperature.

Charge invariance.—Most theories of thermally stimulated currents implicitly assume that the time integral over the short-circuit current from zero to infinity is independent of the function $T(t)$ during the discharge interval and defines the initial "charge of the system." In a preceding paper we have called this the principle of charge invariance and derived from it a theory of nonisothermal effects (6). But charge invariance is not an assumption of the present theory. Rather it will be shown that it does not always apply and is a criterion which allows one to distinguish between different models.

Current and Voltage Measurements

In electric network and model theory a parallelism exists between the treatment of short-circuit currents and open-circuit voltages. Past experience in the field of electrets, closely related to that of thermally activated relaxation processes, has shown that a combination of current (7) and voltage (8) measurements is necessary to understand nonisothermal conduction and polarization effects (9), but recent studies of thermally activated processes have relied exclusively on current measurements. Introduction of the method of voltage measurements is an important complement of current measurements. No analytical treatment is complete that does not discuss both methods on the same level.

Thermally stimulated currents.—The dielectric is charged at a high temperature, cooled to a low temperature, and short-circuited. After a suitable period of quiescence it is reheated in short-circuit. A depolarization current is observed.

Thermally stimulated discharge voltage.—The treatment is the same as before up to the moment of the short-circuit. Then, while the voltage source is removed, the dielectric remains in open-circuit. A slow low-temperature voltage decay sets in. The discharge is accelerated by reheating. In the presence of several relaxation processes with different activation energies a stepwise voltage curve should be observed (Fig. 1, part III).

Thermally stimulated return voltage curves.—The experimental conditions are the same as for the measurement of thermally stimulated currents, until the beginning of the reheating. Then, instead of leaving the system in short-circuit and measuring currents, one removes the short-circuit and measures voltages. A return voltage is observed; the voltage recovery proceeds stepwise when charge release is governed by multiple activation energies; eventually the increase of the intrinsic conductivity of the dielectric causes the voltage to drop to zero (Fig. 1, part IV).

Thermally Stimulated Currents

Maxwell model.—The differential equation.—The Maxwell model is represented in Fig. 2. The values of the resistors and capacitors are state variables, thus $R_i = R_i[T(t)]$ and $C_i = C_i[T(t)]$. Their products $R_iC_i = \tau_i[T(t)]$ are also state variables; under isothermal conditions they are the time-constants of the system. The short-circuit current J is given by the sum of the branch currents J_i, thus

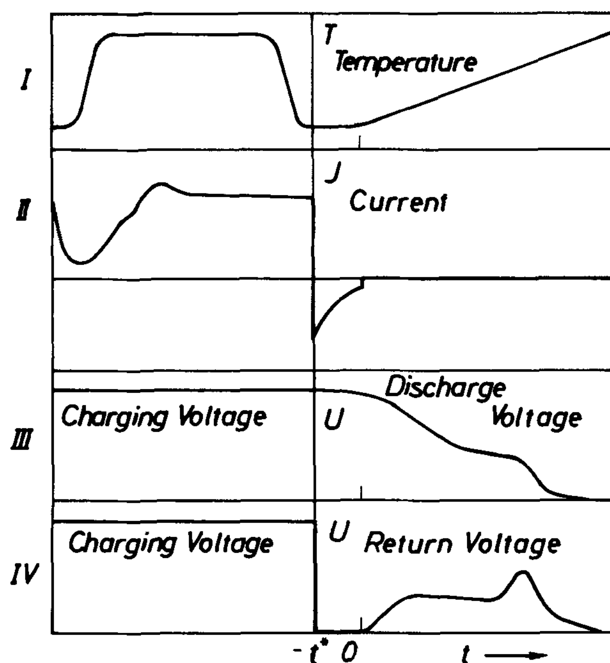

Fig. 1. Thermally activated voltages. I, Temperature; II, Current; III, Discharge voltage curve; IV, Return voltage curve. $t < -t^*$: polarization period; $-t^* < t < 0$: short-circuit; $0 < t$: open-circuit. Time scale in hours.

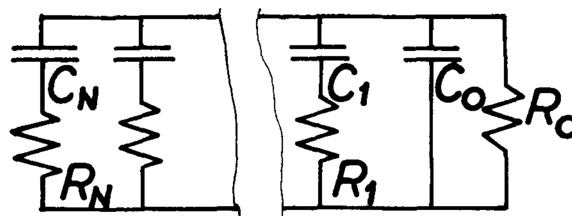

Fig. 2. Maxwell model

$$J_i(T,t) = \sum_1^N J_i(T,t) \qquad [1]$$

where N is the number of branches. The voltage across a resistor R_i is R_iJ_i and that across a capacitor C_i is $(1/C_i)\int_0^t J_i dt$. In short-circuit the sum of both voltages must be zero and therefore

$$R_iC_iJ_i + \int_0^t J_i dt = 0,\ i = 1,2,\ldots,N \qquad [2]$$

Introducing τ_i and differentiating with regard to time one has

$$dJ_i/dt + J_i(1/\tau_i + d\ln\tau_i/dt) = 0,\ i = 1,2,\ldots,N \qquad [3]$$

Let us introduce the notations

$$I_i(t_1,t_2) = \int_{t_1}^{t_2} (\tau_i[T(s)])^{-1} ds \qquad [4]$$

and

$$q_i(t_1,t_2) = q_i(0)\exp(-I_i(t_1,t_2)) \qquad [4a]$$

one obtains the solution

$$J_i(T,t) = (\tau_i[T(t)])^{-1} \cdot q_i(0,t) \qquad [5a]$$

The quantities $q_i(0) = J_i(0) \cdot \tau_i(0)$ are integration constants which depend on the initial conditions at $t = 0$.

The coefficients of J_i in the differential Eq. [3] can be written explicitly in the form $k_i = (1/\tau_i)(1 + (d\tau_i/dT)(dT/dt))$. They contain the time derivatives of the temperature and therefore are not state variables. If

the temperature is constant, $dT/dt = 0$ and $k_i = (1/\tau_i) = \text{const.}$ This gives the well-known differential equations of the isothermal theory. If one were to take these equations as the starting point and generalize them by allowing T to become a function of time, one would miss the term containing dT/dt.

Charge invariance.—By noting that

$$dq_i(t_1,t_2)/dt_2 = -q_i(t_1,t_2)/\tau_i[T(t_2)] \quad [4b]$$

one can write Eq. [5a] as

$$J_i(T,t) = -dq_i(0,t)/dt \quad [5b]$$

The current is therefore a total differential. Since T and τ_i are always finite, the value of the integral I_i in Eq. [4] becomes infinite when t_2 becomes infinite and the exponential goes to zero. Integration over time between an arbitrary time t_0 and ∞ gives therefore

$$\int_{t_0}^{\infty} J_i[T(t),t]dt = q_i(0,t_0) \quad [6]$$

The integral on the left side contains the arbitrary function $T(t)$ in the time interval $t_0 < t < \infty$, but the value of this integral, given by the expression on the right side, depends only on the values of the function $T(t)$ in the time interval $0 < t < t_0$ and on the initial conditions at $t = 0$. Therefore the value of the time integral over the current between t_0 and ∞ is independent of T in the interval. Since $J = \sum_1^N J_i$ the same conclusions apply also to the total discharge current J. Taking in particular $t_0 = 0$ one has

$$\int_0^{\infty} J[T(t),t]dt = q(0), T(t) \text{ arbitrary} \quad [7]$$

This equation represents a very particular situation. To each temperature function $T(t)$, $0 < t < \infty$, belongs a particular discharge current $J[T(t),t]$; different heating rates give different discharge currents. There is no *a priori* reason to assume that the time integral over these different currents has always the same value, but Eq. [7] shows that this indeed is the case. The depolarization charge $q(0)$ is a constant which depends only on the state of the system at $t = 0$, *i.e.*, on temperature and voltage during the interval $t < 0$ which precedes the reheating period. This property of the integral [7] allows one to introduce a single value for the depolarization charge without specifying the temperature as a function of time during the discharge.

Activation energies.—The relaxation variables τ_i can be related to the characteristic constants of the physical system with the aid of rate theory. In isothermal theory, the relaxation time is related to temperature by the equation $\tau = (1/\nu) \exp(u/kT)$. The temperature dependence of the frequency factor ν is small compared to that of the exponential factor and usually is neglected; u is an activation energy. In usual applications T is considered to be a parameter; in the present case where the system undergoes a temperature excursion, it is a time-dependent function. We generalize the rate equation by introducing T as a function of time, but suppose that within the limited temperature interval considered here the activation energies are temperature-independent constants. This assumption excludes the occurrence of phase transitions. Thus the constant relaxation times of the isothermal theory are replaced by the relaxation variables

$$\tau_i[T(t)] = (1/\nu_i) \exp(u_i/kT(t)) \quad [8a]$$

The activation temperatures are defined by

$$T_i = u_i/k \quad [8b]$$

The definition of the products R_iC_i as state variables allows one to identify them with the functions τ_i defined by Eq. [8a] and to write

$$R_iC_i = (1/\nu_i) \exp(u_i/kT(t)) \quad [8c]$$

Linear heating rate.—Inversion of the function $T(t)$ gives time as a function of temperature and allows one to introduce the latter as the independent variable. In most experiments heating rate is constant and temperature is a linear function of time, *i.e.*, $T = T_0 + \beta t$. Inversion gives

$$t = (T - T_0)/\beta \quad [9]$$

Introduction of Eq. [8a] and [9] into Eq. [4] gives the current as a function of temperature alone

$$J_i(T) = J_i(0) \exp\left(-u_i(1/kT - 1/kT_0) - (\nu_i/\beta) \int_{T_0}^{T} \exp(-u_i/kT)dT\right) \quad [10]$$

This is the equation for first order kinetics on which many authors (1) have based their analysis of thermally stimulated currents. Their treatment is therefore equivalent to the introduction of a Maxwell model (6). Implicitly it involves the validity of charge invariance as shown in Eq. [7].

Wagner-Voigt model.—Differential equation.—The Wagner-Voigt model is shown in Fig. 3a. Resistors R_i, capacitors C_i, and their products τ_i will again be state variables. The external voltage U is equal to the sum of the loop voltages U_i. In short-circuit one has $U = 0$ and therefore

$$\sum_1^N U_i(T,t) = 0 \quad [11]$$

The current through a resistor R_i is U_i/R_i and through a capacitor it is $d(C_iU_i)/dt$; the total current is therefore $d(C_iU_i)/dt + U_i/R_i$. Inspection of Fig. 3a shows that all currents have the same value and are equal to the external current J. This gives the system of equations

$$J(T,t) = U_i/R_i + U_i dC_i/dt + C_i dU_i/dt, \; i = 1,2,\ldots,N \quad [12]$$

which shows that the value of the current in each loop is the same. We shall give the analytical solution for a two-loop four-element model and subsequently discuss qualitatively the behavior of a multi-element model for very slow heating rate.

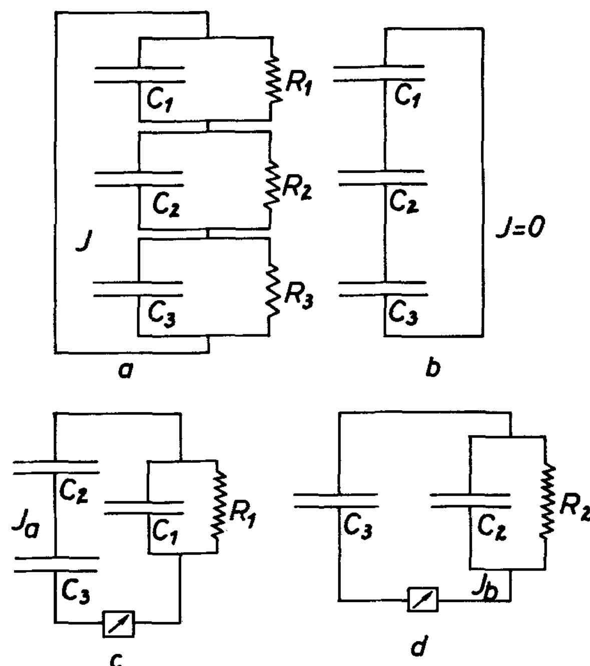

Fig. 3. Wagner-Voigt model. a, Three-loop model; b, Idealized model, low temperature; c, Idealized model, intermediate temperature; d, Idealized model, high temperature.

Analytical solution for four-element model.—With $N = 2$, Eq. [11] gives $U_1 = -U_2$ and Eq. [12] gives

$$(1/R_1 + 1/R_2)U_1 + U_1 d(C_1 + C_2)/dt + (C_1 + C_2)dU_1/dt = 0 \quad [13]$$

Introducing $1/R = 1/R_1 + 1/R_2$, $C = C_1 + C_2$, $\tau = RC$, $q(0) = U[T(0),0] \cdot C[T(0)]$, and the integral

$$I(0,t) = \int_0^t ds/\tau[T(s)] \quad [14]$$

also defining

$$q(0,t) = q(0) \exp(-I(0,t)) \quad [14a]$$

and noting that

$$q(0,t) = -\tau[T(t)] \cdot dq(0,t)/dt \quad [14b]$$

one obtains

$$U_1(T,t) = C^{-1}[T(t)] \cdot q(0,t) = -R[T(t)] \cdot dq(0,t)/dt \quad [15a]$$

and

$$dU_1(T,t)/dt = -C^{-2} \cdot (dC/dt) \cdot q(0,t) + C^{-1} \cdot dq(0,t)/dt = (C^{-2} \cdot (dC/dt) \cdot \tau + C^{-1}) \cdot dq(0,t)/dt \quad [15b]$$

Introducing Eq. [15a, b] into [12] gives the current

$$J(T,t) = -F(T,t) \cdot dq(0,t)/dt \quad [16a]$$

with

$$F(T,t) = R/R_1 - C_1/C + \tau d(C_1/C)/dt \quad [16b]$$

A comparison of these equations with the corresponding equations for the Maxwell model shows significant differences.

Nonvalidity of charge invariance.—The current given by Eq. [16a, b] is not a total differential due to the presence of the front-factor F. After partial integration one has

$$\int_0^\infty J[T(t),t]dt = -F(0) \cdot q(0) + \int_0^\infty q(0,t) \cdot (dF(T,t)/dt)dt \quad [17a]$$

The term on the right side depends on the initial conditions at $t = 0$ and on the values of the function $T(t)$ in the discharge interval $0 < t < \infty$. Each temperature function $T(t)$ gives a different value for the time integral over the depolarization current. Charge invariance does not apply and instead of Eq. [7] one has

$$\int_0^\infty J[T(t),t] \neq \text{const}, T(t) \text{ arbitrary} \quad [17b]$$

Thus the externally measured depolarization charge of an always identically charged dielectric need not always be the same. One must distinguish between the "released" charge and the "internal" charge. The first is defined as the time integral over the short-circuit discharge current; the second is represented by the amount of charge stored in the capacitors of the model. In the Maxwell model the capacitors are not shunted by resistors. During the discharge the entire "internal" charge flows through the external circuit and the integral over the external current is independent of temperature conditions during the discharge. In the Wagner-Voigt model all capacitors are shunted by resistors. During the discharge only a fraction of the "internal" charge flows through the external circuit while the rest disappears by "internal" leakage. The relation between the two fractions depends on the values of the resistors and therefore on the temperature during the discharge. This excludes the existence of a temperature invariant charge value $q(0)$.

Activation energies.—The values of the four model elements define the relaxation variables $\tau_1 = R_1C_1$ and $\tau_2 = R_2C_2$ which are linked with the activation energies u_1 and u_2 by the rate Eq. [8a-c]. But the output current does not separate into two components one containing only τ_1 and the other only τ_2 but is given by a single component containing the complex function τ and, explicitly, the values of the model elements. Formally τ can be represented by a rate equation, but the corresponding activation energy value u is not related to any elementary relaxation mechanism. Therefore if the thermally stimulated current were to be analyzed by one of the conventional methods (1, 2), one would obtain an energy value which is not one of the constants of the system; it could not readily be interpreted on a molecular basis, *e.g.*, as a trap depth.

Current reversals.—The term F in Eq. 16 can change its sign in consequence of the temperature dependence of the resistive values R_i and/or capacitive values C_i. We shall consider here only the resistive effect since the temperature dependence of the capacitive values is usually small. With $d(C_1/C)/dt = 0$, the direction of the current is determined by the sign of the term $R/R_1 - C_1/C$. We have $C_1/C < 1$ and $R/R_1 < 1$. These inequalities hold in every case. Consider a situation in which, at high T, $R_2 << R_1$, making $R/R_1 << 1$, while at low temperature, $R_2 >> R_1$, making $R/R_1 \simeq 1$. Then, as T goes from low to high a value of T can be reached at which $R/R_1 \simeq C_1/C$. Below this temperature, $R/R_1 - C_1/C$ is positive; above it, negative. Therefore the current reverses its direction. Such current reversals, which would be impossible in the case of a Maxwell model, can occur only when the temperature dependence of the R values is very different, *e.g.*, when the dielectric contains two phases with widely different physical characteristics.

Qualitative discussion of multi-element systems.—It is instructive to discuss qualitatively the behavior of a multi-element model under the assumption that (*i*) the heating rate is low and (*ii*) activation temperatures are widely spaced. The first condition might present experimental difficulties because low heating rates give low amplitudes of current peaks.

The behavior will be discussed with the aid of the three-loop model shown in Fig. 3. Loops relax one after the other at successively higher temperatures $T_1, T_2, \ldots$. The main temperature-sensitive elements will again be the resistors; the temperature dependence of the capacitors is supposed to be small. As long as the temperature is considerably below the first activation temperature T_1, all resistors are blocking, all capacitors remain charged. This is shown in Fig. 3b which is obtained from Fig. 3a by omitting R_1, R_2, R_3 (a blocking resistor is an open-circuit). When the temperature reaches the neighborhood of T_1, the first loop discharges since R_1 becomes conducting. This is shown in Fig. 3c which is obtained from Fig. 3b by adding R_1 in the appropriate place. A current transient is produced; its relaxation time which is also its approximate duration can be read from the figure and is found to be $\tau_a = R_1(C_1 + C_2C_3/(C_2 + C_3))_{T_1}$. After the temperature goes beyond T_1, the resistor R_1 becomes conducting and practically short-circuits the capacitor C_1. Eventually the temperature reaches the neighborhood of T_2 and the remaining capacitors C_2 and C_3 discharge through R_3. This is shown in Fig. 3d which is obtained from Fig. 3c by adding R_2 and deleting the discharged loop R_1,C_1 (the conducting resistor R_1 is considered equivalent to a short-circuit). The relaxation time and approximate duration of the new transient is seen to be $\tau_b = R_2(C_2 + C_3)_{T_2}$. Since $\tau_a > \tau_1(T_1)$ and $\tau_b > \tau_2(T_2)$, the "all or nothing" approximation used to describe the discharge characteristics of the loops is justified by the exponential term in the rate Eq. [8]. This equation maps a logarithmic variation of temperature into a linear variation of time. Therefore the transition

from "nonconducting" to "conducting" occurs within a small temperature interval.

The idealized models shown in Fig. 3b, 3c, and 3d terminate in single capacitors. For this reason they are charge-invariant. Indeed, if U is the capacitor voltage, the output current is $J = d(CU)/dt$. Integration gives $\int_0^\infty J\,dt = -C(0)U(0)$. Thus the time integral over the current is independent of the function $T(t)$ during the discharge and depends exclusively on the initial charge of the capacitor.

The behavior of the system is also shown in the diagram of Fig. 4. It gives temperature as a function of time for two constant heating rates. The duration of the current transients which are observed when the temperature goes through one of the values $T_1, T_2 \ldots$ is indicated on the time axis by the values $\tau_a, \tau_b, \ldots$ If the heating rate is low as in Fig. 4a, the time intervals covered by the $\tau_a, \tau_b, \ldots$ do not overlap and the output current can be resolved into independent linearly superposing components. If the heating rate is high as in Fig. 4b, the intervals on the time axis do overlap and separate treatment of transients is not justified.

Thermally Stimulated Open-Circuit Voltages

The difficulty of eliciting from current measurements the desired information in the case of a Wagner-Voigt model suggests as an alternative the resort to voltage measurements. It will now be shown that the current measurements in the case of a Maxwell system have their counterpart in voltage measurements in the case of the Wagner-Voigt model.

Wagner-Voigt model.—Differential equation.—The open-circuit is defined by the condition that the output current is zero. Introduction of $J(T,t) = 0$ into Eq. [12] gives for the loop voltages U_i the equation

$$dU_i/dt + U_i(1/\tau_i + d \ln C_i/dt) = 0, \; i = 1,2,\ldots,N \quad [18]$$

which has the solution

$$U_i(T,t) = C_i^{-1}[T(t)] \cdot q_i(0,t) \quad [19]$$

The open-circuit output voltage

$$U(T,t) = \sum_1^N U_i(T,t) \quad [20]$$

is the sum of N independent terms each of which contains only one of the variables τ_i. Therefore voltage curves in the case of the Wagner-Voigt model can be analyzed in the same way as current curves in the case of the Maxwell model. The voltages $U_i(0)$ are loop voltages at the beginning of the open-circuit. They are integration constants which depend on the initial conditions and are different for discharge and return voltage curves.

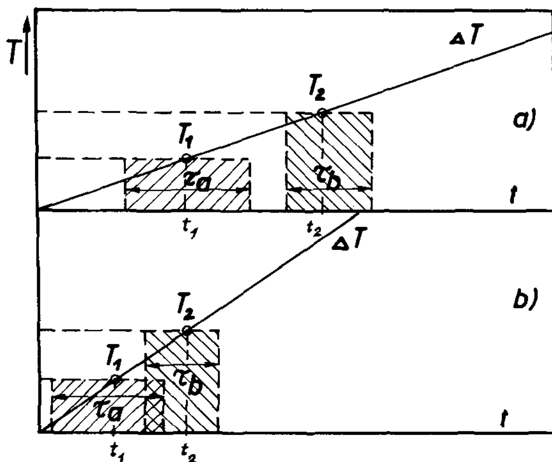

Fig. 4. Influence of heating rate, Wagner-Voigt model. a, Low heating rate; b, High heating rate.

Discharge voltage curves.—For $t = 0$, the terminal voltage is approximately equal to the charging voltage U_0 and the initial values $U_i(0)$ are approximately equal to the loop voltages at the end of the charging period. Subsequently the terminal voltage decreases stepwise from U_0 to 0, the amplitude of each step being $U_i(0)$.

Return voltage curves.—When the circuit is opened at $t = 0$ the terminal voltage is zero. This gives $\sum_i^N U_i(0) = 0$. The short-circuit removes from each capacitor the charge $U_0C(0)$ where $1/C(0) = \sum_i^N 1/C_i(0)$. Therefore, if $U_i(0_-)$ are the voltage values immediately before the short-circuit, their values afterward are given by $U_i(0)C_i(0) = U_i(0_-)C_i(0) - U_0C(0)$. (This treatment neglects the loss of charge during the low-temperature period in which the system remains in short-circuit). The loop voltages $U_i(0_-)$ immediately before the short-circuit depend on the polarization conditions. Thermal activation produces a stepwise voltage recovery shown schematically in Fig. 1, IV. A detailed discussion goes beyond the scope of the present paper and will be given elsewhere. It might be mentioned however, that isothermal voltage recovery has been discussed extensively by Gross (8).

Maxwell model.—The sum of all branch currents must be zero while the terminal voltages of all branches must be the same and equal to $U(T,t)$. Thus the short-circuit Eq. [1] and [2] must be replaced by

$$\sum_1^N J_i(T,t) = 0 \quad [21]$$

and

$$U(T,t) = R_iJ_i + (1/C_i)\int_0^t J_i\,dt = 0, \; i = 1,2,\ldots N \quad [22]$$

The analytical solution of these equations is difficult even in the case of $N = 2$. An approximate treatment for low heating rate is possible along the same lines as above. But a detailed discussion seems not warranted before experimental results on thermally stimulated voltages are known.

Discussion

The need for combined experimental techniques.—Our conclusions underline the fact that results of measurements by the method of thermal activation cannot always be taken at face value. This does not detract from the value of the method as a searching tool but suggests only that a critical review is necessary and that one should not rely on a single type of measurement, *i.e.*, currents alone or voltages alone, but try to combine both to see which is best suited in each physical situation. In addition, independent methods of analysis such as the sectioning technique (10), where feasible, might give valuable additional evidence. Assumptions such as charge invariance or the exclusion of current reversals should not be taken for granted. Their range of validity can be explored by performing measurements with different heating rates and different thermal treatment during polarization. The interpretation of peaks in curves of thermally stimulated currents or voltages depends on the particular physical model on which the analysis is based. Some knowledge about the structure of the system is necessary to obtain physically meaningful results.

Equivalence of models.—In isothermal theory it is proved that a specified physical behavior, *i.e.*, a given response function, can be represented by means of a Maxwell model or a Wagner-Voigt model; under iso-

thermal conditions these models are equivalent. The previous discussion has proved that under nonisothermal conditions the properties of these models are different. A Maxwell model is always charge-invariant, it does not admit current reversals, and its output current is always given by the superposition of independent components. None of these properties is found with a Wagner-Voigt model. Therefore these models are no longer equivalent when exposed to temperature transients. Under nonisothermal conditions the theory of equivalent models, which is one of the mainstays of the conventional theory of linear systems, loses validity. Therefore experiments involving temperature changes help to distinguish between isothermally equivalent models and thus can remove the degeneracy inherent in isothermal theory. A model that uniquely describes the behavior of a physical sytem has physical significance and a theory involving such models ceases to be formal.

Maxwell model and uniform volume polarization.—In view of the great variety of possible physical situations, one might ask how far it is meaningful to select two particular models as we have done here. We believe this is justified because these models describe correctly frequently encountered physical situations.

The Maxwell model represents a dielectric volume polarization caused by hindered dipole orientation or by the displacement of charge carriers over microscopic distances within a dielectric matrix which contains irregularly distributed traps. Orientation of dipoles and displacement of charge carriers proceeds out of phase with the applied field. The rate constants which describe the time lag are functions of temperature. The electric displacement field is $D = \epsilon E + P$ where E is the field strength, ϵ the dielectric constant, and P the "persistent" component of the polarization. In the presence of different types of dipoles or traps with different depths the polarization P is given by the sum over components P_i, *i.e.*, $P = \Sigma P_i$. The current is $J = adD/dt$ where a is the electrode area. Assuming first order kinetics one has $dP_i/dt = -P_i/\tau_i$. The short-circuit current, with $E = 0$, is therefore $J = adP_i/dt$ and the released charge is $q = aP_i(0)$. These equations describe the behavior of a Maxwell model. They were introduced at the beginning of the century by Pellat (11) and since then have been frequently rediscovered and used to describe the effects of dielectric absorption.

Wagner-Voigt model and interfacial polarization.—The Wagner-Voigt model applies to inhomogeneous dielectrics. In its simplest form it describes the behavior of a three-layer capacitor where the central layer represents the bulk of the dielectric and the two external layers represent the dielectric-electrode interfaces which have electrical properties different from those of the center section. Application of an external electric field produces what has been called interfacial polarization. When the temperature dependence of the dielectric-electrode interface is very different from that of the bulk material current reversals can occur; also the system is not charge invariant.

More complex situations exist where neither of these models is satisfactory. Release of charge carriers from traps might be described by a Maxwell model in the case of slow retrapping and by a Wagner-Voigt model in the case of fast retrapping.

Acknowledgments

The present paper is based on lectures given by the author in July and September 1970 at Centraal Laboratorium, Toegepast Natuurwetenschappelijk Ouderzoek (T.N.O.), Delft, Netherlands, and at Northern Electric Research and Development Laboratories, Ottawa, Canada. The author wishes to thank Dr. M. Perlman for reading and commenting on the manuscript, and Drs. J. van Turnhout and J. van den Eikhoff for preparation of a summary of his lectures given at T.N.O. and the Brazilian Nuclear Energy Commission for concession of a research grant.

The Anodic Behavior of Some Materials in Liquid Ammonia in Presence and Absence of Methane or Ethylene

Ashok K. Vijh*

Hydro-Quebec Institute of Research, Varennes, P. Q., Canada

ABSTRACT

Results on the anodic behavior of platinum, palladium, nickel, cobalt, graphite, lead, and sodium-tungsten bronze electrodes in liquid ammonia at −73°C in the absence and presence of either CH_4 or C_2H_4 are reported. The experiments consist of potentiostatic current-potential relationships, potentiodynamic profiles, and product analysis. The aim of these studies was to attempt anodic synthesis of CH_3NH_2 from CH_4 (or C_2H_4) and ammonia, which could not be achieved. The measurements obtained appear to have some qualitative significance, however, in relation to electrochemical behavior of materials in liquid ammonia in general and with regard to their anodic dissolution and oxidation of ammonia in particular. The characteristic features of these data are reported together with their possible qualitative significance.

Although electrosyntheses of organic compounds have been carried out for decades (1) by various investigators, a noticeable resuscitation (2-5) of interest has recently occurred in this area. It has recently (3) been suggested that a possible electrolytic conversion of low molecular weight-hydrocarbons to pure alkyl amines would perhaps offer an electrosynthetic procedure amenable to commercial exploitation. Although functionalization of low molecular weight hydrocarbons, especially paraffins is generally considered as difficult and achievable only under rather drastic conditions, by virtue of lack of reactivity of paraffins, it was regarded, nevertheless, of interest to explore the possibility by an electrochemical procedure. This problem was approached by attempting to anodize various electrocatalytic materials in liquid ammonia in the presence of an appropriate hydrocarbon. An attempt was made to explore whether it was possible to prepare alkyl amines by means of an hypothetical reaction of the type

$$CH_4 + NH_3 \rightarrow CH_3NH_2 + 2H^+ + 2e$$

Experimental Procedures

The experimental details for the work reported here are as follows.

Instruments and circuits.—The instruments employed are: Wenking potentiostat (No. 7713 68FR 0.5); Tacussel milliammeter Type MAL 284, and, in some runs, a precision resistor used in conjunction with Tacussel digital voltmeter (high input impedance) as the current measuring arrangement; Honeywell X-Y recorder, Type 550M; Tacussel function generator, Type GSTP2; General Radio decade resistor box. The potential measurements were recorded on the Tacussel digital voltmeter; vapor phase chromatograph (Victoreen, Series 400 supplied by Fischer Scientific). Conventional potentiostatic and potentiodynamic circuits were employed (6, 7).

Materials and electrodes.—All electrode materials, except the sodium-tungsten bronze, were spectroscopic grade and were in either wire or rod or plate configurations. The sodium-tungsten bronze samples were obtained from outside this laboratory and were prepared by the electrolytic method and contained an uncontrolled (up to 100 ppm) amount of platinum impurity. The sodium content of the various bronze samples was somewhat different, a fact that did not seem to influence the results to be reported here which have only a qualitative significance in any case. All electrodes (except the platinized-platinum used in the reference compartment) were mounted in heat-shrinkable Teflon tubing as described previously (8). The counterelectrodes were made of spectroscopic grade graphite rod. A hydrogen reference electrode was employed.

The electrolyte consisted of nonaqueous (probably only nominally nonaqueous since an elaborate dry box was not used although all precautions were taken to exclude moisture as far as possible) liquid ammonia containing 10% (by weight) of dry ammonium perchlorate (Fischer Certified high purity reagent). The ammonia was 99.99% and was obtained from Matheson. The He gas used in the working compartment (when CH_4 or C_2H_4 was not being bubbled) was of 99.998% purity (supplied by Matheson) and was dried by passage over suitable traps in a gas purification line. The methane used was 99% pure (supplied by Union Carbide) and the C_2H_4 employed had a purity of 98.5% and was supplied by Liquid Air.

The low temperatures were maintained by immersing the cell in a Dewar flask containing isopropyl alcohol and solid carbon dioxide mixture.

The column material for the v.p.c. was Chromosorb-P 60/80 mesh whereas the liquid phase consisted of 21% Polyethyleneimine. The carrier gas was helium. The Chromosorb-P material was intended to detect both methyl amine and dimethyl amine: the latter could, it was thought, possibly have been formed as a side product.

Cell and cleaning.—A three compartment Pyrex cell was used with the working and the counter compartments separated by a course fritted disk. The cell was provided with the usual gas inlets and outlets and all the connections to the cell from the gas lines were made by means of glass-to-glass joints. The use of grease was absolutely avoided. The cell could be closed to the atmosphere by means of appropriate stopcocks. A positive pressure of He (or CH_4 or C_2H_4 as the case may be) was always maintained inside the cell in order to minimize the possibility of diffusion of atmospheric moisture into the electrolyte solution. The cell was cleaned with chromic acid and repeatedly soaked and washed in deionized and doubly distilled water (both distillations being carried out over alkaline permanganate in Pyrex glass stills; before distillations, the deionized water was passed over suitable (proprietary) adsorbent columns designed to remove traces of organic matter) and subsequently thoroughly dried over night in an oven.

All electrodes except graphite were washed in chromic acid and subsequently soaked and washed in doubly distilled water, followed by thorough drying in an oven in a Pyrex tray. The graphite electrodes were cleaned in boiling trichloroethylene (to remove

* Electrochemical Society Active Member.
Key words: anodic behavior, liquid ammonia, methane, ethylene.

organics which are generally believed to adhere tenaciously to graphite electrodes) and dried.

Purification of gases.—The hydrogen gas for the reference compartment was "Electrolytic, Grade A" and was deoxygenated by passage over a palladium catalyst ("Deoxo") and further purified by passage through activated charcoal and activated alumina, both at liquid air temperature. Helium, methane, and ethylene were passed over molecular sieves and other traps in order to remove any moisture that may be present in them.

General experimental procedures.—The steady-state, potentiostatic current-potential relationships were obtained by stopping for 2 min at every value of electrode potential. The potentiodynamic profiles were obtained at various sweep rates.

Results and Discussion

Anodic behavior in the absence of CH_4 or C_2H_4.—Anodization of Pt, Ni, and Co in liquid ammonia led to a visible anodic dissolution which was evident from the characteristic coloration (yellow for Pt, blue for Ni, and pale greenish blue for Co) produced in the solution. In some cases, *e.g.*, on platinum, a yellow coating, probably a loosely attached precipitated corrosion product, was observed on the electrode surface. The formation of colored corrosion products in liquid ammonia on anodization of transition metals such as Pt, Ni, and Co is not entirely unexpected because of the pronounced tendency of ions of these metals to undergo coordination complex formation in liquid ammonia. The current associated with the anodization of various materials in liquid ammonia under He atmosphere must, however, be attributed only partially to anodic dissolution since part of it must arise from the anodic oxidation of ammonia itself, especially, on the more catalytic metals such as platinum. This was qualitatively confirmed by adding small amounts of water to the "nonaqueous" solution which gave rise to a noticeable decrease in current at a given potential, presumably owing to passivation of platinum and consequent decrease in the anodic dissolution current; the residual current, however, was still appreciable and is believed to have arisen from anodic oxidation of ammonia. The relative contribution of anodic dissolution and anodic oxidation of ammonia to the current at a given potential in the nonaqueous solution (under He atmosphere) was not examined, however, in any details since this aspect was not of interest in the present study. No visible signs of anodic dissolution were noted on Pd, graphite, and sodium-tungsten bronze electrodes. It may be added that the lead electrodes underwent complete disintegration as soon as the anodization in liquid ammonia was commenced. No measurements could, therefore, be made on this particular electrode material.

Anodic behavior in the presence of CH_4 or C_2H_4.—Subsequent to the investigation of the anodic behavior of various materials under He atmosphere, experiments were conducted to establish whether introduction of methane or ethylene, bubbling vigorously under atmospheric pressure, had any effect on the current-potential curves. The main observations are as follows:

1. In the presence of methane, the rate at a given potential shows some decrease on graphite, platinum, palladium, and the sodium-tungsten bronze electrodes. On cobalt and nickel, however, the rate stays unaffected.

2. In presence of ethylene, the current at a given potential shows some increase on nickel whereas on cobalt, platinum, palladium, and graphite the rate stays either unaffected or exhibits some variations only in certain regions of potential. On palladium a characteristic inhibition inflection, of the type discussed by Gilroy and Conway (9), is observed around 0.9V.

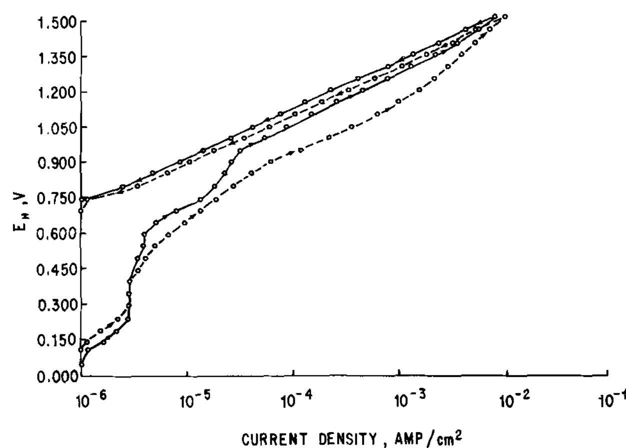

Fig. 1. Steady-state potentiostatic current-potential relationships on graphite in liquid ammonia in the absence (- - - - - -) and presence (————) of methane.

The general features of the polarization curves, from which the above qualitative observations have been deduced, may perhaps be best conveyed by considering some typical Tafel plots obtained in the absence and presence of either CH_4 or C_2H_4. In Fig. 1, the steady-state potentiostatic Tafel plots have been presented which show that anodic oxidation of ammonia (corresponding to the total current under He atmosphere in this case since no visible signs of anodic dissolution or disintegration were observed) proceeds at rather high rates on graphite and the presence of methane in the reaction chamber tends to decrease the rate. On cobalt, anodization in liquid ammonia in presence and absence of methane leads virtually to the same current-potential relationship (Fig. 2). The current observed in this case must, of course, be attributed to the oxidation of ammonia as well as the cobalt electrode itself (to form soluble complexes) as indicated earlier. On a typical case of a sodium-tungsten bronze electrode, it appears that high anodic potentials are needed to effect moderate oxidations of ammonia (dissolution of this electrode being assumed absent since no visible signs were observed to indicate otherwise) and even these oxidation rates are drastically diminished by the presence of methane in the vicinity of the electrode (Fig. 3). Rather noticeable reduction of rate in presence of methane would indicate that methane is strongly adsorbed on the electrode surface to give a species which is not easily oxidized off, even under high anodic polarizations.

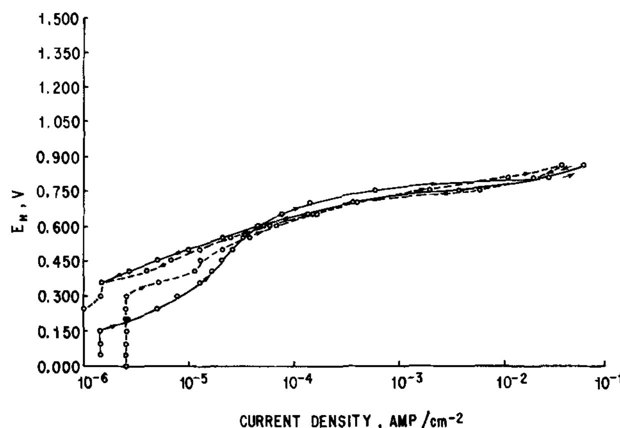

Fig. 2. Steady-state potentiostatic current-potential relationships on cobalt in liquid ammonia in the absence (- - - - - -) and presence (————) of methane.

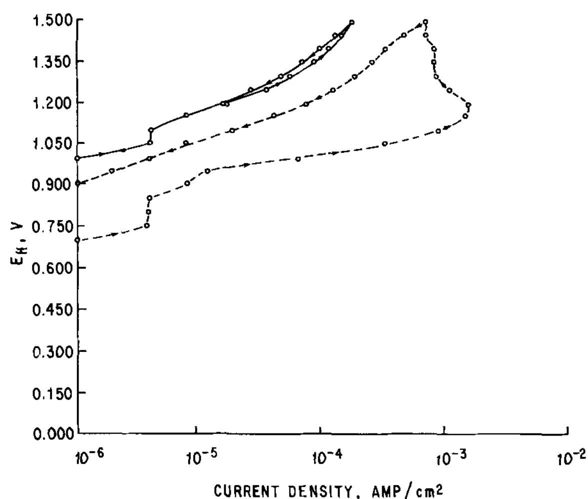

Fig. 3. Steady-state potentiostatic current-potential relationships on a sodium-tungsten bronze (containing a trace impurity of platinum) electrode in the absence (- - - - - -) and presence (————) of methane.

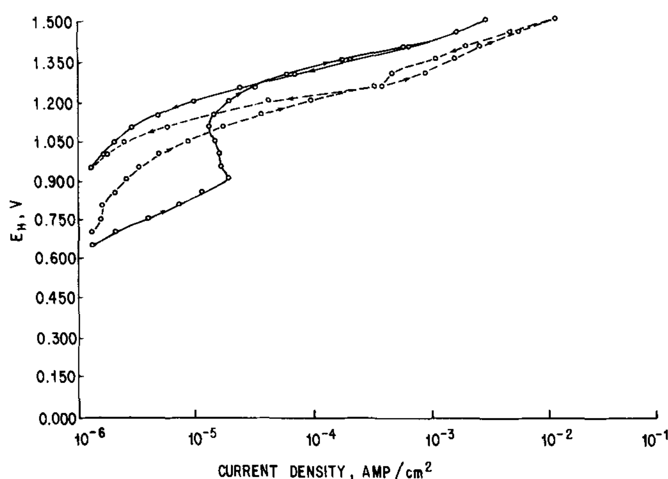

Fig. 4. A typical steady-state current-potential relationship, obtained potentiostatically, on palladium in liquid ammonia in the absence (- - - - - -) and presence (————) of ethylene.

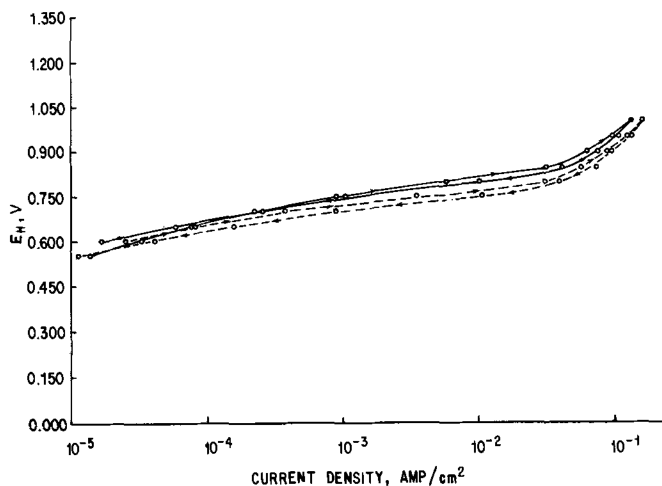

Fig. 5. A typical, potentiostatic current-potential relationship on platinum in liquid ammonia in the absence (- - - - - -) and presence (————) of ethylene.

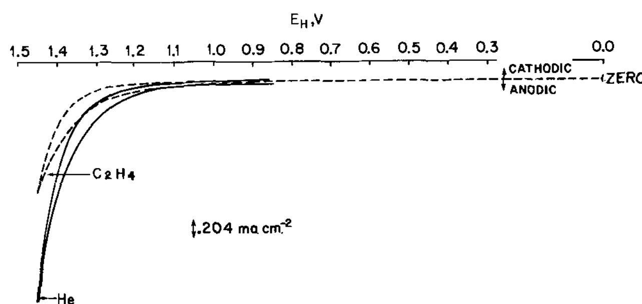

Fig. 6. Potentiodynamic current-potential relationships on palladium in liquid ammonia in the absence and presence of ethylene. The sweep rate is 48.3 mV sec^{-1}. Absence of peaks or other details may be noted.

Some characteristic cases of anodic behavior in liquid ammonia in presence of ethylene may also be considered. On palladium (Fig. 4) at low overpotentials presence of ethylene leads to an increase of rate and a characteristic inhibition inversion (9), whereas at high anodic potentials a decrease in rate is observed. This would indicate that the palladium electrode is not altogether unreactive in presence of ethylene in liquid ammonia, even though the elusive methyl amine or related side products were not indicated to be formed. Typical polarization curves representative of the anodic behavior of platinum in liquid ammonia in the presence and absence of ethylene are shown in Fig. 5. In the anodic polarization curves of nickel in liquid ammonia, rather high oxidation rates were observed at low overpotentials, both in presence and absence of ethylene, undoubtedly arising largely from the anodic dissolution of nickel.

Potentiodynamic profiles.—Extensive potentiodynamic profiles (6, 7) were obtained on various electrodes at a number of sweep rates. No peaks (either activation or diffusion controlled) or inhibition inflections could be observed. Some typical potentiodynamic profiles are shown in Fig. 6. It is clear that no significant information can be deduced from this type of profiles (Fig. 6).

General significance of the Tafel plots.—Although detailed mechanistic proposals or quantitative analyses cannot be put forward on the basis of data reported here, some general salient features of the Tafel plots may, however, be pointed out. First, a large hysteresis between the ascending and descending potentiostatic current-potential curves (Fig. 1, 3, 4) observed in some cases would indicate presence of surface films or irreversibly absorbed surface species. Second, presence of surface films on the electrode is indirectly indicated by the magnitude of Tafel slopes which in most cases (cf. Fig. 5, however) are higher than $2.3 \times 2RT/F$ which is equal to *ca.* 73 mV at the temperature of the experiments, namely, −73°C. That anomalously high Tafel slopes can often arise from the presence of solid films on the electrode surface has been discussed previously (6, 9, 10) and need not be elaborated upon here.

Acknowledgments

Behavior of Carbon Electrodes in Aqueous and Nonaqueous Systems

Richard E. Panzer*

Electrochemistry Research Section (Code 134.16), Mare Island Naval Shipyard, Vallejo, California 94592

and Philip J. Elving*

Department of Chemistry, The University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

Cyclic voltammetry was used to investigate the surface phenomena and general electrochemical behavior encountered when glassy carbon and pyrolytic graphite are used as indicator electrodes in aqueous and nonaqueous (acetic acid, acetonitrile, dimethylformamide, and pyridine) media for inorganic (ferrocyanide and ferrocene) and organic (quinone) compounds. Factors evaluated included effects of method of preparation of the graphite, different resurfacing methods including magnitude of the induced electrostatic charge and surface regularity, interplanar adsorption of electroactive solutes, presence of surfactant, acidity, and potential ranges, and potential scanning procedures used.

The limitations of the dropping mercury electrode (DME) for the electrochemical oxidation of many organic and inorganic compounds are well known. Since it cannot be used beyond a potential of about +0.4V with respect to the saturated calomel electrode (SCE), electrochemists have turned to solid electrodes. Surface adsorption effects on platinum electrodes are well documented, and, since organic compounds are so troublesome in this respect, electrochemists have searched for some material which would be more satisfactory for electrooxidation of organic compounds, with interest focusing on carbon electrodes.

The present investigation is concerned with the nature of the surface phenomena observed when carbon materials are used as indicator electrodes in voltammetric techniques, particularly in respect to the nature of the changes which occur in nonaqueous solutions. The investigation was restricted to pyrolytic graphite and glassy carbon, since these are most readily prepared and their behavior as electrodes is apparently not so heavily dependent upon the origin of and preparation from the raw materials.

Since the pyrolytic graphite electrode (PGE) or the glassy carbon electrode (GCE), and nonaqueous solvents are increasingly being combined in electrochemical studies, numerous questions require answers, *e.g.*, what are the best ways for encasing the sides of the PGE to prevent diffusion of the solution between layers, what is the effect of surface roughness, what are the optimum methods of resurfacing, what is the nature of the surface exposed by resurfacing, is the solvent as well as organic and inorganic ions adsorbed, what is the relation of chemical structure of the adsorbate and its adsorption, and what are the effects of surfactants on the electrode surface?

Consequently, the present studies are concerned with methods of encasing the electrodes, effects of resurfacing methods on the behavior of the electrode, microscopic examination of electrode surfaces, magnitude of the electrostatic charge induced by resurfacing methods, and physical variations between pyrolytic graphite from various sources and the relation of these to electrochemical behavior, as well as investigation of the interplanar adsorption of ferrocyanide in aqueous solution and of ferrocene in nonaqueous systems, the behavior of the quinone redox system with respect to electrode characteristics, the effect of a surfactant on electrode behavior in two solvent systems, and the effect of changes in acidity in aqueous and nonaqueous solutions. In all of these studies, correlation of the electrode surface character with its electrochemical behavior was emphasized. The principal electrochemical technique used was cyclic voltammetry.

* Electrochemical Society Active Member.

Key words: adsorption, cyclic voltammetry, graphite, surface phenomena.

Experimental

The cyclic voltammetry system used is based on operational amplifier units and has been described (1). The usual scan or polarization rate was 100 mV/sec. In conformity with normal voltammetric practice, cathodic (reduction) currents are shown as positive and anodic (oxidation) currents as negative. Peak heights were determined by running straight lines along the ascending and base portions of each voltammogram and using the vertical distances of the resulting points of intersection from the cathodic and anodic peaks.

Electrochemical cells.—In addition to three-compartment cells with a water jacket integral with the cell, which have been described (2), a triangular three-compartment design incorporating draincocks in the connection sections (Fig. 1), which could be immersed in a thermostat bath, was used in the aqueous investigations. The connection sections, which were attached to the compartments with O-ring joints, allowed changing the background electrolyte solution rapidly or continuously, if desired. The compartments were separated by fine frit Pyrex disks. The reference electrode was placed in one side compartment with the indicator and counterelectrodes in the center and other

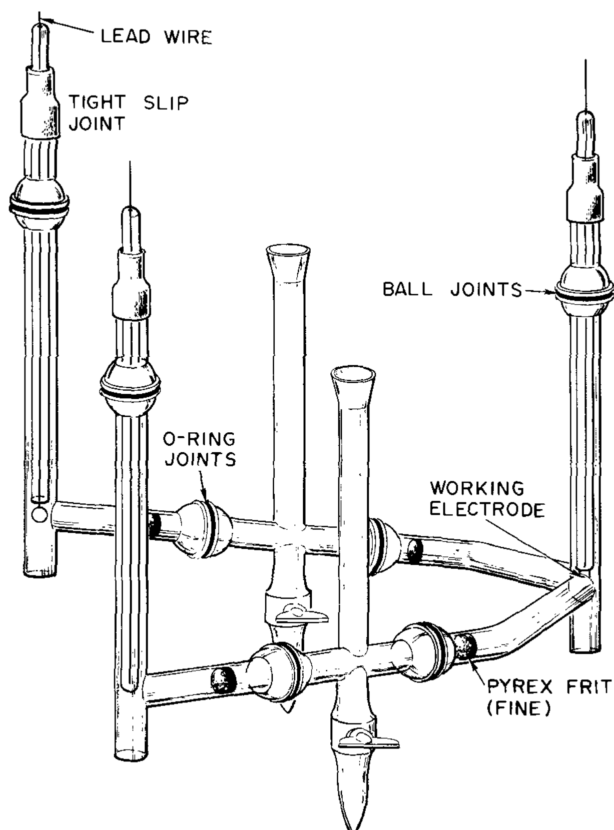

Fig. 1. Three-compartment cell with flushable bridges. For clarity, O-ring joint clamps are not shown.

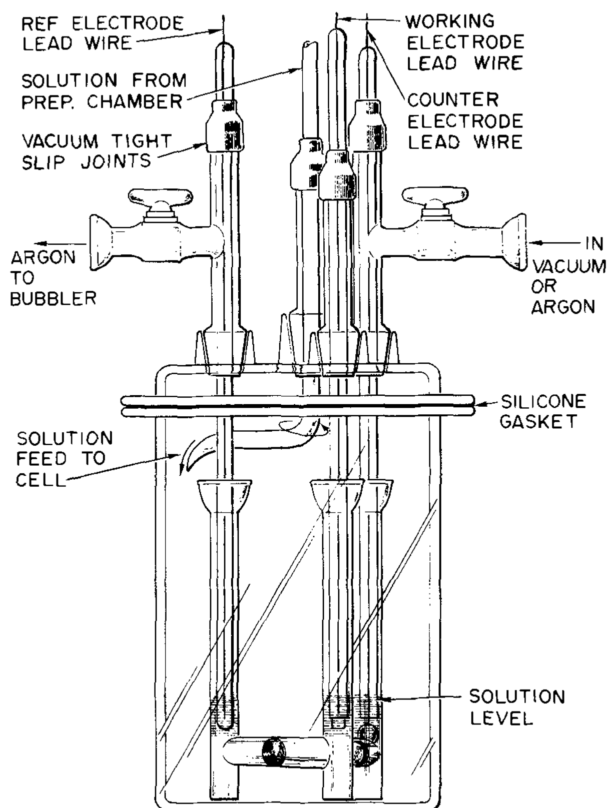

Fig. 2. Three-compartment cell in gas- and vacuum-tight jacket

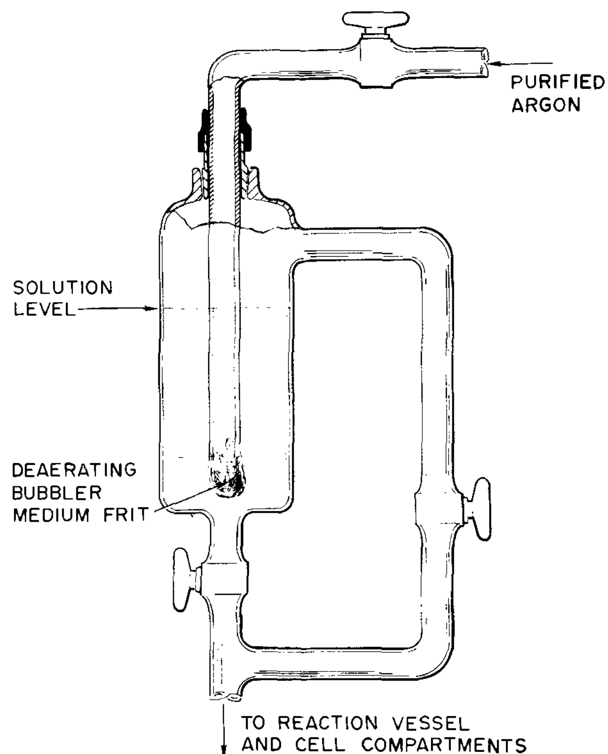

Fig. 3. Solution preparation, deaerating and feed assembly. This unit connects to the reaction vessel as shown in Fig. 2.

side compartment, adjacent to each other. A fine Pyrex glass frit with an agar-saturated KCl plug on the reference electrode side separated the reference and indicator electrode compartments.

For nonaqueous work, special three-compartment cells were designed to fit inside a 2000 ml resin reactor vessel (Pyrex No. 6947) in such a manner that the cell compartments were directly under each of the three 24/40 S.T. joints of the vessel cover (Fig. 2). Electrodes were then mounted in gas- and vacuum-tight slip joints, which allowed their immersion in the electrolyte as required. The center 34/45 joint of the cover was reduced to 24/40, into which was inserted the inlet spout for the cell solutions. A specially modified separatory funnel with a gas bypass and a 12/19 S.T. joint in its top was used for mixing the nonaqueous solutions and deoxygenating them prior to passing them into the cell compartments (Fig. 3). In this way, the background electrolyte solution for the whole cell could be deaerated with oxygen-free, dry argon gas prior to its introduction. The solution of the electroactive species was then prepared, deoxygenated, and passed into the indicator electrode compartment. At the start of a run, the electrodes were inserted into the appropriate slip joints, and the whole vessel evacuated to a pressure of about 10^{-6} atm; the vessel was then filled with argon and the evacuation-gas addition process repeated several times. Finally, the vessel was filled with argon, the deoxygenated electrolyte solutions were introduced into the cell compartments, the electrodes were dipped into their respective solutions, and a steady stream of argon was passed through the cell and vented through an oil-filled bubbler. Because of the slight back pressure caused by the bubbler, it is necessary to fasten the tapered joints with springs and to clamp the cover tightly. Since the cover could not be slid off because of the electrodes and solution feed tube dipping down into the vessel, a special gas- and vacuum-tight gasket was formed on the vessel flange with General Electric RTV 102 silicone rubber; this allowed the cover and electrodes to be lifted directly off, without sliding or sticking, when the clamp was loosened.

The vessel itself was immersed in a bath, which was placed in a fume hood and through which water at 25°C was circulated.

Graphite electrodes.—Electrode materials were pyrolytic graphite from several sources and glassy carbon from the Tokai Electrode Manufacturing Company of Tokyo. The latter material, obtained in the form of 5

mm diameter rods, was turned down to 4 mm; it is difficult to machine, since it tends to chip and fracture due to its glassy structure. The pyrolytic graphite electrodes were 4 mm diameter rods, machined from larger pieces. Material obtained from the General Electric Company (GE) appeared to have a taper structure, *i.e.*, it was thicker at one end than the other, and retained this structure when cleaved; this indicated that it was formed on a mandrel, perhaps for an exhaust nozzle. Pyrolytic graphite from High Temperature Materials Company (HTM or HT) was in the form of 0.5 in. thick plates; it was uniform in thickness, as was the pyrolytic graphite (Pyroid) from Space Age Materials Corporation (a division of the Charles Pfizer Company). Since Pyroid became available to us only late in the investigation, it was used only in dimethylformamide solutions.

Besides the taper structure mentioned, the graphite structures also varied in grain size. The GE material had large and small hemispheres (2-5 mm diameter) in a random pattern across its surface. The HTM and Pyroid graphites were more uniform in grain size, averaging 1-2 mm diameter. Such criteria are not really a prime consideration, since Coy (3) has shown that the macroscopic structure of these materials extends down into the microscopic structure. Of interest was the observation that the HTM and Pyroid graphites tended to be slightly harder, more dense, and less easily cleaved for resurfacing than the GE graphite.

The 4 mm diameter electrodes (projected area = 0.126 cm^2) were sealed into a 300 mm length of 6 mm OD Pyrex tubing, using either Epoxy-Patch, a filled epoxy material from Hysol Corporation, or melted polyethylene. The epoxy material makes a good seal and, when slightly warmed, will flow to give a smooth coating; it is impervious to the solvents used in the present work and has been used in liquid ammonia, acetone, hexamethylphosphoramide, and many other solvents with no observable deterioration. However, the epoxy was too hard to cleave when this was done to renew the electrode surface; consequently, electrodes intended for cleaving were mounted with melted polyethylene.

Reference electrodes.—Reference electrodes in the aqueous studies were saturated calomel electrodes (SCE) prepared in the usual manner.

Reference electrodes used in nonaqueous studies were all based on a silver system. Where a stable soluble silver salt could be used, the electrode was Ag/0.1*M* Ag^+ in the solvent with background (supporting) electrolyte. In some solvents, a Ag/AgCl, Cl^- (0.1*M* LiCl) half-cell was used. All of the reference half-cells were prepared in a microcracked configuration, which has been extensively used by one of the authors (4) and is adapted from Perley's controlled crack electrode (5). These high impedance electrodes require the routine use of a follower (unity-gain amplifier), since so little current can be drawn through them.

When a glass tube-crack assembly is cleaned, dried and ready for use, the reference half-cell silver system is placed in the tube to a depth of 2 cm; contact is made with a silver wire which is sealed at the open end of the tube with epoxy cement to prevent leakage or evaporation of the solution.

The potentials of the various reference half-cells used were placed on a common basis by measuring each of them against the aqueous SCE (Table I). Although such a measurement includes an unknown junction potential, the latter is probably very small in most cases; Nelson (6), who investigated this topic, makes the point that such junction potentials are not as large as commonly believed. Electrodes were prepared in batches of 5 or 6; their potentials checked against one another for stability and reproducibility to within a few millivolts, which is within the experimental error of the potential measurements.

Table I. Reference electrode potentials

Electrode system-solvent	Potential,[a] V
Ag/Ag^+ in CH_3CN	−0.016
H^+/H_2 (NHE), aq.	0.000
SCE, aq.	+0.249
Ag/AgCl,Cl^- in HOAc	+0.253
Ag/Ag^+ in pyridine	+0.304
Ag/AgCl,Cl^- in DMF	+0.754

[a] Potentials are according to the 1953 Stockholm Convention and were measured *vs.* an aqueous saturated calomel electrode (SCE) at 27.5°C and converted to read *vs.* the normal hydrogen electrode (NHE).

Chemicals.—Ferrocene was used as a standard redox material at 1 m*M* concentration, since it is readily soluble in the solvents used and produced sharp reversible voltammograms in all of the systems studied. Consequently, since the primary purpose of the present study was to characterize the electrode surfaces, complications due to the electroactive species were minimized at the outset. In addition, ferrocene had been previously characterized voltammetrically in pyridine (7), which allowed comparison to be made. The ferrocene was recrystallized several times from purified dry acetonitrile, then dried under vacuum at 50°C. Initial efforts with cobalticene were abandoned, since the compound proved to be only slightly soluble in some of the solvents to be used.

All other chemicals used were of reagent grade. The argon was dried by passage through Linde 4A molecular sieves.

Solvents.—Reagent grade solvents were dried or purified further, depending on the solvent. Pyridine, which was zone fractional crystallized (2), had very low levels of water and electroactive impurities; pyridine (reagent grade) was also used only after drying over molecular sieves. In the present investigations, there seemed to be little difference between the two solvents, since the potentials used were not in the same range as those utilized when interferences from electroactive impurities were noted (2).

Acetonitrile (Matheson Nanograde) and N,N-dimethylformamide (reagent grade) were dried over molecular sieves. Glacial acetic acid (reagent grade), freshly opened as needed, was rapidly transferred to solution mixing vessels to prevent moisture acquisition.

Electrode Surface and Resurfacing

Initial studies included microscopic examination and physical characterization of the electrode materials, and determination of the effects of resurfacing the electrodes.

Electrode resurfacing.—Pyrolytic graphite (PG) electrodes are commonly resurfaced by grinding with a rotating disk of 600 mesh SiC paper or by full layer cleavage; both are sometimes followed by vigorous rubbing on filter paper (8). Resurfacing or even machining glassy carbon (GC) generally results in fractures and chipping caused by the brittle nature of the material. Resurfacing of GC (rarely necessary) is best done by polishing with successively finer abrasives, finishing with 0.5μ alumina on Microcloth (A. Buehler Company). Giles, Harrison, and Thirsk (9) have also used the metallurgical polishing method for GC electrodes. However, Sunahara and Ishizuka (10) used "emery paper 80", which undoubtedly provided microscratches on the GC surface, not a mirror finish as is obtained by using the alumina polishing compound.

Following various treatments, the electrode surfaces were observed with 100× magnification. Cleaved PG generally had a complete new surface across the plane of the electrode, but the existence of a partial layer can allow occlusion of material under it. Use of a hand lens for inspection of the renewed PG surface provided a means of quickly checking that cleavage produced a completely fresh disk.

Microscopic examination revealed large differences in the surfaces as prepared by the different methods and, as it turned out, predicted the observed electrochemical behavior. There was no evidence that the epoxy compounds or polyethylene used to seal the carbon material to the glass tube were smeared across the electrode surface during resurfacing. Occasionally, a few particles of SiC or sealant would appear after the grinding operation; these were removed by wiping with a tissue, which also removed loose particles of carbon. However, a peculiar phenomenon was observed when these resurfaced PG electrodes were used in cyclic voltammetry. Loose carbon had initially been removed by wiping with a tissue, rinsing with acetone, pyridine or ethanol (depending on the solvent system in use), or rubbing with Whatman No. 1 filter paper. Nevertheless, after the electrode had been subjected to several charge-discharge cycles, a deposit of carbon appeared on the white epoxy rim around the PG. Occasionally, this deposit was very heavy but it was never present prior to the voltammetric cycling.

Grinding with 600 mesh SiC paper produced a flat surface on both the PGE and GCE, although the latter material is much harder. However, under 100× magnification, one could observe microfine scratches over the entire GC surface; these were found to be responsible for the very high residual currents in voltammetry. For example, electrodes treated with 600 mesh SiC paper gave a residual current of 70 μA, but, when the electrodes were lapped with 0.5μ alumina, the residual current was only about 0.5 μA.

One can visualize the effect of grinding the PG by considering the result of slicing an onion across some section of the sphere; a large number of planes (skin and onion layers) is exposed. In the case of the PG cones, the layers are quite porous, allowing large amounts of solvent to penetrate the layers. Since the macro structure is essentially duplicated in the micro structure, it is obvious why the grinding operation can lead to a greatly enlarged surface area compared to that produced by cleaving.

Charge accumulation on electrode surface.—The dust particle effect indicated that a high charge was localized on the electrodes. A Keithley Model 610B electrometer, which has a very high input impedance and indicates charge directly in coulombs, was utilized to measure the charge; its output was fed into a potential-time recorder to provide a record of the change during the experiment. For comparison with the PGE and GCE, the charge was measured for a mercury pool electrode of 7 mm^2 surface area, which was contained in a U-tube arm immersed in electrolyte solution. The solution used in these charge measurements was 0.5*M* KCl; cells were thermostated at 25°C; a Pt wire was used as counterelectrode.

The electrode to be measured was treated in the desired manner and then connected to the electrometer prior to insertion in the electrolyte solution. Changes in the charge were followed over a period of about 1500 sec (Table II). Noteworthy is the extremely high initial charge on the ground PGE; the other electrodes had a much lower initial charge which slowly increased due to the capacitance effects of the solution and effects from reaction of the electrode surface and adsorbed species. The charge on the ground GCE identified the source of the high residual current voltammetrically observed on this electrode; the microscopic (600-grain) scratches are the locale for both the charge and the residual current. The initial charge on the mercury electrode, which corresponds to 2.8 μcoulombs/cm^2 and which does not increase appreciably for several minutes, is presumably due to halide adsorption. The contribution from the grid current of the electrometer (maximum of 2×10^{-8} μcoulombs/sec) is negligible.

Open circuit potentials.—Significant variations were found in the open circuit potentials (OCP) of the various materials in 0.5*M* KCl solution (Table III). The significance of an OCP is that it indicates the sum of the preparative background effects on the electrode surface; the OCP will be a function of variations due to crystal structures, strains, and growth sites. The variation in OCP parallels that of the charge measurement (Table II).

The effect of any significant difference between PGE surfaces fabricated from the mandrel and deposition sides of the graphite can be obviated by always using the same side for the electrode surface. From a structural standpoint, one would expect the mandrel side to be only as smooth as the original substrate surface itself; the deposition side is a function of the whole pyrolysis process, including the inclusion of dirt and soot. For these reasons, the variations between the GE and HTM PG electrodes may be significant. The HTM material is produced in flat plates, while the GE material is cut from a tapered and somewhat variable density block of unknown origin (cf. Experimental section).

Behavior in Aqueous Media

Initial voltammetric investigations were conducted with an aqueous 1 m*M* $K_4Fe(CN)_6$ solution (0.5*M* KCl as supporting electrolyte) to determine the differences in behavior of the indicator electrode materials and the tendency for the electroactive species to be adsorbed in the PG layers, thus causing a memory effect due to entrapped material.

The special cell, designed so that fresh KCl solution could be run through periodically to remove diffused mercury ions from the SCE or diffused iron species, was arranged in a double, two-electrode configuration, *i.e.*, the SCE in the middle compartment and the ferrocyanide solution were one set, and the SCE and a 0.5*M* KCl solution in the third leg constituted the other set. In operation, the electrode being investigated was placed in the deoxygenated ferrocyanide solution and cycled several times until the voltammogram had reached a steady trace. The electrode was then removed, rinsed quickly but thoroughly with distilled water to remove iron species adhering to the outer surfaces, and placed in the deoxygenated KCl solution in the third compartment. Cycling was promptly repeated across the redox potential range of ferrocyanide with the recorder set at high sensitivity; any interlayer adsorbed electroactive species would then produce a current peak at +0.28V.

In all cases where the ground PGE was used, small but distinctive peaks were observed, indicating a carryover of ferrocyanide. Such peaks were not observed on the cleaved PGE, except in one case where

Table II. Charge on electrodes on insertion and after standing in aqueous 0.5*M* KCl solution

Material electrode[a]	Charge on electrode, μcoulombs Initial	After 50 sec	After 500 sec	After 1500 sec
Glassy carbon	0.5	1.0	7.8	18.5
GE PG (cleaved)	2.6	3.3	5.3	8.4
GE PG (ground)	4.6	8.0	16.5	31.0
Hg pool	0.20	0.28	0.64	2.17

Table III. Open circuit potentials of graphite electrodes in aqueous 0.5*M* KCl solution

Electrode material	Potential, V, *vs.* SCE Initial	After 1500 sec
Glassy carbon	−0.12	−0.77
GE PG (ground)[a]	+0.76	−0.29
GE PG (cleaved)	+0.25	−0.7

[a] A large positive charge also appears on the ground electrode.

a partial layer of the cleaved graphite was inadvertently left in place. As a general rule, the retention on the ground surface (and its interlayers) was ten to twenty times greater than the worst case observed with the cleaved surface. On glassy carbon, there was never any detectable carry over of iron species.

Initial current phenomena.—Of particular interest is the fact that, when an indicator electrode is connected to the recording system via a follower (unity gain) *vs.* the SCE and then immersed in the cell solution, positive potentials and anodic currents are observed, which are greatest on the ground PGE, far less on the cleaved PGE, and practically nil on GC or polished platinum electrodes.

The typical curve of Fig. 4 illustrates the high initial current on electrode immersion and the decreased cathodic peak on the first voltage scan. The cathodic peak on the initial scan is always the lowest and is an indication of the amount of ferricyanide formed on the electrode when the charged electrode is immersed in the ferrocyanide solution. No correlation appeared between the first cathodic peak height and the charge on the electrode or the time of immersion prior to initiating the sweep toward more negative potential. Thus, cathodic peak 1 in Fig. 4 is that due to the reduction of ferricyanide formed as indicated, while cathodic peak 2 is that due to the ferricyanide formed during anodic peak 1.

Effect of surfactant.—The effects of adding small quantities of a wetting agent to the aqueous ferrocyanide solution depend on the electrode material (Fig. 5). The cleaved graphite and the GC electrodes were greatly influenced by the presence of 0.002% Triton X-100; the peaks were suppressed and shifted in potential, and the voltammograms generally flattened. By contrast, the ground surface graphite electrodes were not noticeably affected; only when a 0.01% Triton level had been reached did suppression of the peak current become obvious. These observations support the suggestion that the ground PG surfaces have a very much larger effective area than either the cleaved PG or GC surfaces. The surfactant drastically suppresses electroactivity on the latter materials because it is rapidly adsorbed across a large portion of the total available electrode area.

Effect of pH.—The effect of pH on electrode behavior was studied by adjusting the pH of the ferrocyanide solution by suitable buffering (Fig. 6 and 7 present typical curves). Some effects were common, to some degree, to all electrodes and are evidently due to variation in the nature of the electroactive species caused by the pH change. The most obvious of these is the very sharp and heightened current peak at pH 1.8; the effect was extreme on the ground PGE from both sources, but was much less on the cleaved PGE. By comparison, the GCE showed a sharper peak at pH 1.8 but the variation with pH was not as extreme as on the PGE.

At higher pH, the reversibility of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple was much reduced on the cleaved PGE compared to that on the ground PGE. The values of i_p and E_p in Table IV provide a quantitative summary of the observed shifts. The shift in E_p for both cathodic and anodic processes to more negative potential with increasing pH (Table IV) results from the acid-anion equilibria involving ferrocyanic and ferricyanic acids.

Effect of electrode area.—The data on the commonly used PGE (projected area = 0.126 cm²) were compared with those on ground and cleaved PGE of 0.196 cm² area from Rosen's work (11) (Fig. 8, Table V). The sharper peaks resulting from the ground surface

	Ground	0.19	0.26	31.8	0.25	0.17	33.0

[a] Data are for 1 mM ferrocyanide in aqueous 0.5M KCl solution.

as compared to the cleaved surface are the most obvious characteristics. However, these ground surfaces could not be resurfaced as reproducibly as could the cleaved surfaces. Most of the variation in peak height is due to the much larger residual current on the ground electrode.

The peak currents do not show the expected proportionality to the electrode area. Theoretical peak currents in cyclic voltammetry for reversible systems can be calculated from the equation (12)

$$i_p = 2.72 \times 10^5 n^{3/2} A D^{1/2} C^\circ v^{1/2} \qquad [1]$$

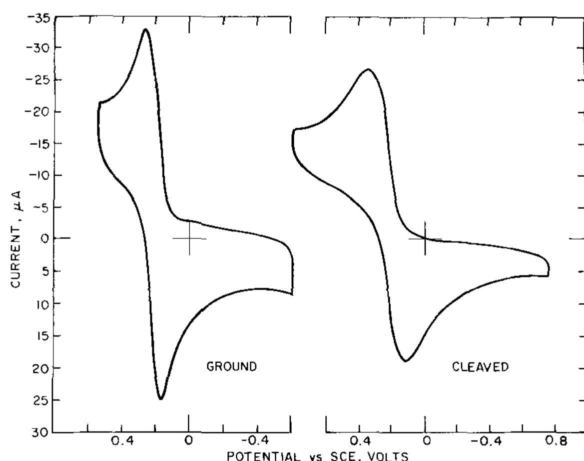

Fig. 8. Cyclic voltammograms for 1 mM $K_4Fe(CN)_6$ in 0.5M KCl aqueous solution. Pyrolytic graphite electrodes of 0.196 cm² projected area.

where i_p is the current in amperes, n the electron change, A the electrode area in cm², D the diffusion coefficient in cm²/sec and C° the concentration of the diffusing species in moles/cm³, and v the scan rate in V/sec. At v = 100 mV/sec, calculated i_p = 27.0 μA for the electrode of 0.126 cm² and 41.14 μA for A = 0.196 cm² (a value of 0.60 $\times$ 10^{-5} cm²/sec was used for D). Although the projected area was used with no allowance for surface roughness, it seems that the cleaved surface more nearly follows the expected current relationship, but the differences in cathodic and anodic E_p values are much greater on the cleaved electrode than on the ground electrode. For a reversible couple, a separation of 58 mV is expected for a one-electron change, which is about that observed on the ground electrodes in both cases. Based on the half-peak potential, $E_{p/2}$, the reversibility does not appear to vary as greatly as does that based on the E_p data.

Effects of multiple scans and initial potential direction.—The effects of multiple scans and of starting the scan in either potential direction from the zero of the SCE reference electrode were investigated and significant differences were observed.

Figure 9 shows the curves obtained on HT pyrolytic graphite and on glassy carbon. When ground PG electrodes are used, an initial high anodic peak is seen, independent of the direction of scan. If the scan is started toward positive potential, i_p is progressively less on subsequent scans and, at times, does not reach a constant level after five or six scans. On the other hand, if the scan is initially toward negative potential, although no reduction peak results from the ferrocyanide solution, the first anodic peak is high by about 2.5 μA but subsequent scans tend to superimpose; even after 25 cycles, there is often not more than 0.25 μA variation. The general effect is much less pronounced on (polished) GC electrodes; voltammograms have very sharp peaks and subsequent curves retrace the first scan. The evidence suggests that an initial cathodic scan (toward negative potential) tends to neutralize the positive surface charge on the ground electrode, thus lowering the anodic peak height on the first sweep and leading to more reproducible peak currents.

Beilby (13) has stated that, if the voltage scan is allowed to go too far positive, irreversible changes can occur on the PGE surface. Consequently, in the present

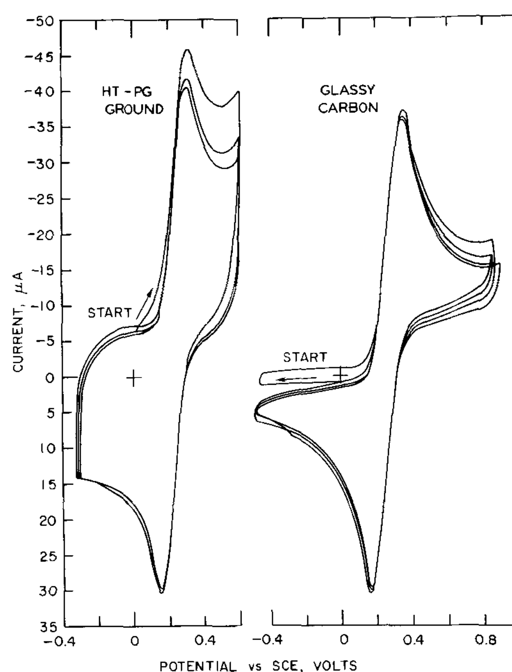

Fig. 9. Effects of repetitive scans and initial potential direction on glassy carbon and pyrolytic graphite electrodes for 1 mM $K_4Fe(CN)_6$ in 0.5M KCl aqueous solution.

study, the scan was not allowed to go more than a fraction of a volt beyond the peak potential observed on either cathodic or anodic scans. The effects of starting the scan in the cathodic direction provide additional evidence for the presence of a positively charged surface. Although the latter has been called an "oxidized surface" (14), its reduction must occur at a very low potential judging by the increased height of the ferrocyanide anodic peak. A more likely explanation, as discussed, is the presence of positive static charges induced by the grinding of the surface.

Summary.—In aqueous voltammetry under a given set of conditions, cleaved pyrolytic graphite surfaces provide a lower peak current as well as a much lower residual current. These surfaces cause the $Fe(CN)_6^{3-}$/$Fe(CN)_6^{4-}$ couple to appear less reversible, *i.e.*, the separation between the anodic and cathodic peaks is greater and the peaks themselves are more rounded. The ground PG electrodes produce sharper, more reversible peaks, but they retain electroactive species within the layers and the surface is not reproducible on resurfacing. More will subsequently be said on the latter point.

The significance of these studies in aqueous solutions is that they provide a comparison of the behavior of a well characterized electrochemical system on the various carbonaceous electrodes. From the results obtained, large differences in the performance of the electrodes might be expected when they are utilized in nonaqueous systems.

Behavior in Nonaqueous Media

Investigations in nonaqueous solutions were also designed to determine the effects of resurfacing methods on electrode behavior. Although every effort was made to eliminate water and oxygen from the solutions prior to their introduction into the electrochemical cell, "complete" elimination of these ubiquitous impurities is problematical. Even if solutions are handled in the best available inert atmosphere dry box, there remains a possibility of surface contamination due to water levels in the solvents on the order of 10^{-9} moles/cc. A situation of diminishing returns arises as the requirements of experimentation tend toward levels of oxygen and moisture which are below the presently detectable limits for these substances. A common error in nonaqueous investigations is the use of so-called spectrophotometric grade solvents without further purification. Although such solvents may have no interfering bands in a given spectrum range, they may contain quite large amounts of impurities (including water), if these materials do not absorb significantly in the given spectral range.

A recent paper (15) points out that the water levels in many purified solvents—even in some "as received" materials—do not interfere with electrochemical investigations conducted in them. On the other hand, the present work indicates that much depends on the potential range used, the stand (rest) time of the electrode in contact with solutions, and the rates of reaction of water with the solvent, solutes, or other electroactive species. It is, indeed, true, as pointed out (15), that much more than simple electrostatics is involved in solute-solvent interactions. It is important to recognize these factors; although there is obviously no such thing as a totally anhydrous nonaqueous solvent, the limits of water which can be tolerated will depend on many experimental factors.

Behavior in Pyridine

In order to determine the effects of electrode resurfacing on the redox voltammetry of an organic compound, quinone was used as the electroactive species in 0.1*M* tetraethylammonium perchlorate (TEAP) solutions in pyridine. The previously reported (2) prewave occurring at -1.72V in pyridine, which has not been sufficiently purified to remove a proton-releasing substance, did not interfere, as the potential scan was reversed just after the first reduction peak was reached, *i.e.*, at about -0.8V. The reproducibility on ground or cleaved General Electric PGE was evaluated by resurfacing the electrode a number of times and reinserting it each time in the cell system for another cyclic scan, which was started toward negative potential. The initial peaks on cleaved electrodes varied from subsequent ones by less than 0.25 μA; a series of cleaved electrode voltammograms were almost superimposable, *e.g.*, Fig. 10. However, the first sweep on the ground electrodes was often erratic; the anodic and cathodic peaks were variable in height by as much as 2.5 μA between the first and succeeding scans, and also between first scans on resurfaced electrodes. This variation amounted to 10-15%, since i_p was often around 20 μA.

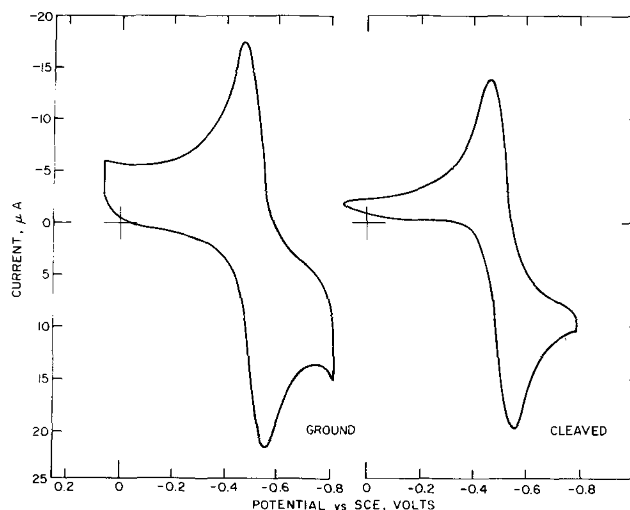

Fig. 10. Cyclic voltammograms on pyrolytic graphite electrodes of 1 m*M* quinone in pyridine (0.1*M* TEAP).

For pyridine solutions (0.1*M* $LiClO_4$) of ferrocene, the ground electrode—as in aqueous solutions—provides a very high first peak on multiple scan voltammograms; subsequent scans have a very reproducible cathodic peak, but the anodic peaks decrease with each succeeding scan. (It should be emphasized that a shift in E_p has never been observed with successive scans; variations are always in lowered i_p.)

Adding pyridinium nitrate to a solution of ferrocene in $LiClO_4$-pyridine has no noticeable effect on voltammograms taken with cleaved electrodes; curves were entirely reproducible with i_p and E_p constant for 0.5 to 10 m*M* acid (Fig. 11). Voltammograms taken with the ground PGE on pyridinium nitrate addition are not much different until about 10 m*M* is reached, at which concentration the first scan overshoot is only about 0.5 μA, compared to previously seen overshoots of 2.5-5.0 μA (Fig. 14).

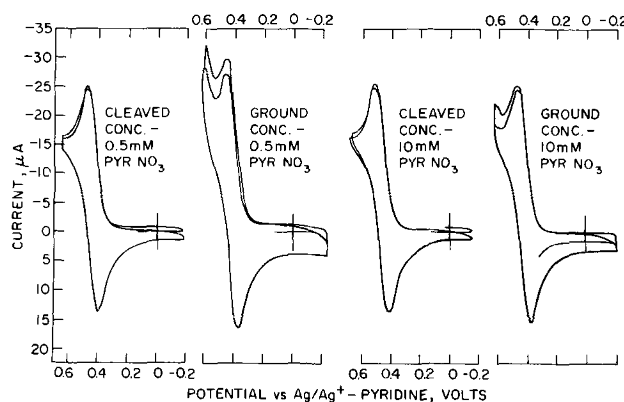

Fig. 11. Effect of added pyridinium nitrate on cyclic voltammograms on pyrolytic graphite electrodes of 1 m*M* ferrocene in pyridine (0.1*M* $LiClO_4$).

The ratio of the anodic and cathodic peak heights is approximately unity, indicating that the ferrocene/ferrocenium couple is reversible in $LiClO_4$-pyridine solutions.

Equation [1] was used to calculate i_p values for the ferrocene oxidation peak on a cleaved General Electric PGE in $LiClO_4$-pyridine solutions. At a scan rate of 50 mV/sec, the observed i_p for the ferrocene oxidation peak on a General Electric PGE in $LiClO_4$-pyridine solution, based on a series of highly reproducible voltammograms, corresponds to a diffusion coefficient of 8.34×10^{-6} cm²/sec when the projected electrode area is used in Eq. [1].

Behavior in Acetonitrile

The results for 1 m*M* ferrocene in acetonitrile solution (0.1*M* $LiClO_4$) on PG cleaved and ground electrodes are very similar to those obtained in pyridine. The ground surfaces had a very large positive charge in acetonitrile. When the electrode was first inserted in the solution, a positive potential of $E_p = +0.37$ and an anodic i_p of *ca.* 200 μA were observed. Consequently, the scan was started toward more negative potential. The scan produced a low cathodic peak since the electrode had been only briefly immersed in the solution before the scan began and there was very little time for the production of much oxidized material on the electrode surface. The scan, on being reversed toward positive potential after the first low cathodic peak, produced a very high first anodic peak, indicating that the charge phenomenon on the electrode was not completely eliminated during the initial scan towards more negative potential or that the amount of ferricinium ion produced by the inherent positive (anodic) electrode potential and charge was larger than that which was reduced on the initial scan.

Notable on all of the voltammograms on all electrode materials are the very sharp anodic and cathodic peaks, and the high degree of reversibility, *e.g.*, the ratio of the anodic and cathodic peak heights is almost exactly unity and the difference between the peak potentials is 70 mV or less. Although these characteristics hold true for all electrode surfaces, the curves on glassy carbon are much more definitive, as the electrode area is most nearly that of the projected geometrical area, 0.126 cm²; a typical run is shown in Fig. 12. The curves from the cleavage graphite surfaces are much "cleaner"

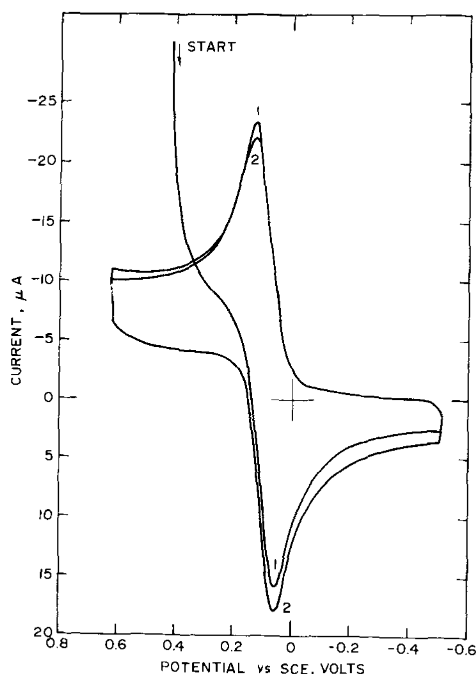

Fig. 12. Voltammograms on glassy carbon electrode of 1 mM ferrocene in acetonitrile (0.1M $LiClO_4$).

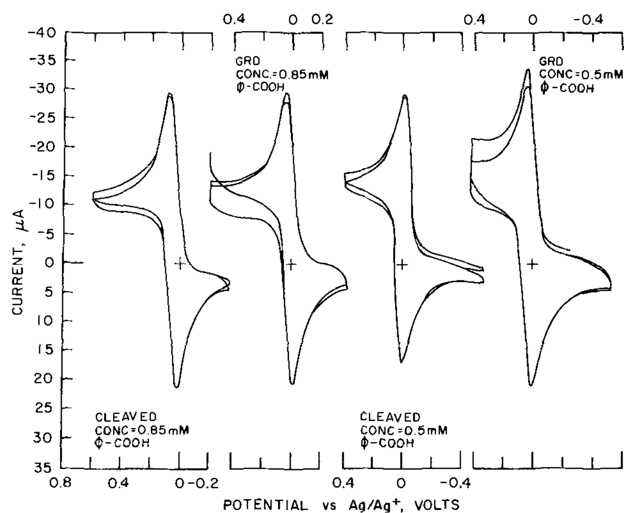

Fig. 13. Effect of added benzoic acid on cyclic voltammograms on pyrolytic graphite electrodes of 1 mM ferrocene in acetonitrile (0.1M $LiClO_4$).

than those from the ground surfaces; the peak heights for the latter are 15-20% higher, indicating the greater area of the ground surface. Using Eq. [1] and glassy carbon electrode data, the diffusion coefficient of ferrocene is calculated to be 4.26×10^{-5} cm²/sec. On the glassy carbon electrode, a plot of i_p *vs.* $v^{1/2}$ results in a straight line, indicating that the ferrocene electrode reaction is diffusion controlled.

When benzoic acid (0.5 to 1.05 m*M*) was added to ferrocene (Fig. 13), the only change seemed to be a lessening of the first scan overshoot for solutions of higher benzoic acid content. The peaks were sharper and successive traces were exactly superimposed on the first. A proton-rich environment evidently reduces the effect of the charge phenomenon on the ground and cleaved electrodes.

Behavior in Acetic Acid

In glacial acetic acid, many of the previously observed variations between the ground and cleaved PG and GC electrodes were somewhat leveled out, *e.g.*, initial overshoots on the first scan were much less, generally amounting to about 0.5 μA. Typical curves are shown in Fig. 14. Reproducibility of the ground electrodes was best in this solvent compared to the other systems utilized. For 1 m*M* ferrocene solution, i_p was 16.5 μA on the ground graphite electrode, and 16.25 μA on the cleaved electrode and on glassy carbon. If the glassy carbon surface is considered to be essentially the projected area, the closeness of the peak current values indicates that the effects of grinding are considerably lessened by the solvent.

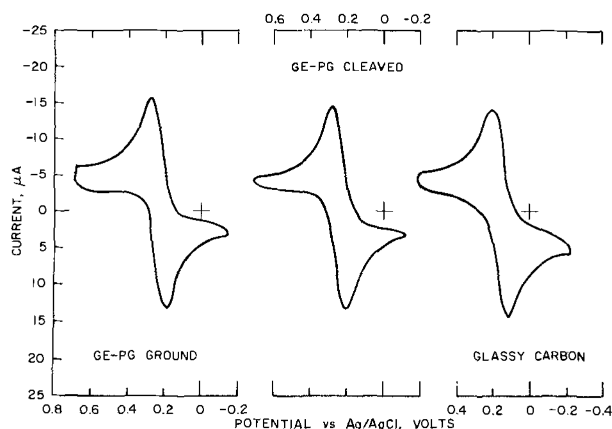

Fig. 14. Voltammograms of 1 mM ferrocene in acetic acid (0.1M $LiClO_4$).

All peak currents are much less in this solvent than in the other solvents. If the peak currents are assumed to be proportional to the square root of the diffusion coefficient (cf. Eq. [1]) and if the only change in diffusion coefficient in going from one solvent to another is that due to solvent viscosity (η), the currents would be inversely proportional to $\eta^{1/2}$ and the product $i_p \eta^{1/2}$ would be expected to be constant. The viscosities at 25° of the solvents used in the present study are acetonitrile 0.35, dimethylformamide 0.80, pyridine 0.88, water 0.89, and acetic acid 1.16 centipoise; the corresponding value of $\eta^{-1/2}$, based on water, are acetonitrile 1.60, DMF 1.04, pyridine 1.01, water 1.00, and acetic acid 0.88.

In acetonitrile, i_p values of around 30 μA are commonly observed; in acetic acid, i_p is about 16.3 μA. The ratio of 1.84 is in excellent agreement with the $\eta^{-1/2}$ ratio of 1.82.

A light blue color appeared in the ferrocene-acetic acid solution after it had stood for about 10 days. A voltammogram of this solution showed the peaks due to the ferrocene electrode reaction, but i_p was about 25% less and the potentials were about 25 mV more positive; the latter may be partially due to a shift in the reference electrode potential on standing, since the Ag/AgCl electrode does not have long term stability in HOAc.

Behavior in Dimethylformamide

On all of the electrodes (except glassy carbon) used in this solvent system (1 m*M* ferrocene; 0.1*M* $LiClO_4$), the first scan overshoot was about 1-2 μA over the average peak current, which is small compared to behavior in acetonitrile and pyridine. The Pyroid PGE, either ground or cleaved, did not provide reproducible traces on successive scans; it also tended to give a higher i_p than GE or HTM material at a given scan rate, occasionally as much as 4 μA greater. This would indicate that the Pyroid has a greater effective surface area than the others.

Generally, the ferrocene couple is less reversible in DMF than in the other solvents used, *e.g.*, i_p (anodic) was about 1.3 μA higher than i_p (cathodic) for all electrodes. Peak potential separation was 70 to 80 mV, *i.e.*, anodic $E_p = 0.84$V and cathodic E_p is 0.76 for all electrodes. These values are comparable to that of 0.88V for the ferrocene oxidation potential previously obtained in DMF ($NaClO_4$ and TEAP as supporting electrolytes) (16).

Addition of Triton X-100 caused extremely erratic behavior and poor reproducibility on successive scans. Higher surfactant concentrations eventually reduced the peak height, shifted the anodic potential in a more positive direction and the cathodic peak to a more negative direction, and caused rounding of the peaks.

The variation in performance between the three types of PGE is more obviously seen in Fig. 15. The

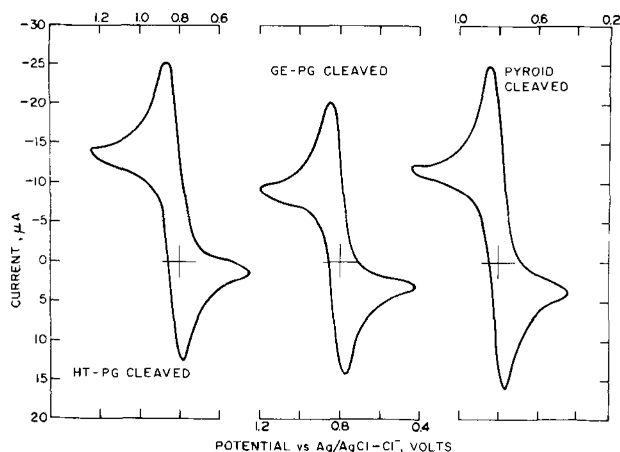

Fig. 15. Voltammograms on different types of pyrolytic graphite for 1 m*M* ferrocene in dimethylformamide (0.1*M* $LiClO_4$).

voltammograms on HTM electrodes provide clean superimposable curves with minimum residual current and sharp peaks with a very slight overshoot on the first scan and constancy on those following. Even on ground resurfaced HTM electrodes, the electrochemical behavior is better than in the other types. The General Electric material is second best and the Pyroid material is least satisfactory. Some of the variations observed are due to differences in the "cone" structure of the individual graphites, as these differences are manifested by variations in cone size, hardness, uniformity, etc. Generally, all the electrodes made from HTM material, used either in the present work or in subsequent work, have provided a much more uniform surface when they have been cleaved or ground for each resurfacing. Low power magnification shows considerable variation between various electrodes of General Electric and Pyroid material, especially in cone size and in the previously mentioned density gradients of the GE graphite. Some of the variations observed in electrode behavior are undoubtedly due to these uncontrollable physical variations in the electrode material itself.

Discussion

A thorough review of the literature (17) and unreported research results indicate that the most likely phenomena involving alteration of the surface of graphite, which would account for the variation in performance of graphite electrodes are the following:

1. Chemisorbed oxygen: This may exist by itself or may serve as an attractive site for H_2O molecules.
2. Tenaciously held water: This is of importance when the graphite is used in nonaqueous solvents.
3. Oxidation sites: Carbon-oxygen reaction sites and complexes may be localized at stress regions.
4. Carbon-oxygen surface compounds: acidic or basic organic compounds such as quinoids, quinhydrones, phenols, and carbonyls are definite possibilities, depending upon the conditions of formation. Additionally, under special conditions sulfate surface effects, hydrogen-bonded interlayer groupings, and free radicals may be involved (18, 19).
5. Mellitic acid derivatives: Pyromellitic acid-chloroquinone, pentacarboxylchlorobenzene and similar compounds could be produced under moderately oxidizing conditions (20, 21).
6. Lamellar compounds or their residues: These include bisulfates or other species, which in themselves are difficult to reduce or oxidize, and which are formed when graphite electrodes are subjected to strong oxidizing conditions.
7. Surface films: Constituting a broad field, these films encompass any of the previously listed effects, as well as some unknown effects peculiar to the dense structure of pyrolytic graphite.

Presently, no single agent of those listed appears to account for the observed phenomena on pyrolytic graphite. One distinct possibility is that exposure to air and moisture may spontaneously produce surface species. The investigator is then faced with the necessity of conducting all operations in an inert atmosphere or, at least, of handling the graphite in a sealed system or a vacuum.

Plock (22) has conducted rather extensive evaluations of the effect of *p*H and ligand changes on the usable potential ranges of glassy carbon, pyrolytic graphite, and platinum wire electrodes. Notable is the fact that the usable potential range of the GCE and PGE shift about 0.3V more negative at *p*H 8 to 11 and, with some organic materials such as diisopropylamine, the range was narrowed down significantly. There seems little correlation between Plock's results and the present results, except that the effect of the high *p*H in both cases is to restrict the range and behavior of the carbonaceous electrodes.

Concurrently with these investigations, Rosen (11) investigated certain aqueous systems, using pyrolytic graphite electrodes. Numerous questions as to the na-

ture of the PGE surface had been raised by earlier observations (14), *e.g.*, very slow changes in the activity of the surface, rather poor reproducibility under a wide variety of resurfacing, usage or storage in air, and extremely irreproducible double layer capacitance measurements.

Electrode resurfacing.—It is clear from the results of the present investigation that resurfacing a pyrolytic graphite electrode by grinding produces a nonreproducible electrode surface. The admonition of Miller and Zittel (24) that the PGE should be resurfaced not by grinding but only by cleaving and then only when absolutely necessary, is well taken. The use of ground electrodes for studies of the electrolytic oxidation of organic compounds may lead to the deposition of oxidation products which are not readily removed. Should such be the case, the material can be removed with a nitric-sulfuric acid mixture as recommended by Meites (25). Due to the strong adsorption of chromium compounds on electrode surfaces, they are not easily removed and may interfere in subsequent use of the electrode; consequently, chromate solutions should not be used to clean electrodes.

The surface of the glassy carbon electrode can be readily stripped of deposits by brief immersion in the acid mixture and normally requires little surface treatment beyond returning the applied potential to the zero point. The latter suggestion of Zittel and Miller (26) has been verified in the present study. If necessary, the glassy carbon electrode is readily repolished with 0.5μ alumina. The glassy carbon can be imbedded in an epoxy such as the Hysol material, resulting in a very sturdy electrode structure, to which connection may be made via a mercury drop on the back side.

It is instructive to relate the present results with those previously reported. The present investigations indicate that the surface charge on a PG electrode is extremely high when resurfacing is done by grinding, but much less when resurfacing is done by cleaving the c planes of the graphite to yield a new plane.

Mamantov *et al.* (27) have reported that two types of films are produced on PGE surfaces when they are subjected to chemical or electrochemical oxidation. Investigations by Kekedy, Markay, and Dragoi (28) on the pretreatment of PG electrodes established that the surfaces obtained after oxidation with nitric acid, chromic acid, or $KMnO_4$, or after reduction with ferrous ammonium sulfate could be characterized via chronopotentiometry. Using ferri/ferrocyanide and V(V)/V(IV), they found that reproducible chronopotentiograms of the former system were only obtained on untreated electrodes, whereas V(V) could only be reduced on chemically reduced or oxidized, or untreated electrodes, and not at all on cathodically reduced electrodes. The over-all electrode process for vanadium redox systems on the electrodes was irreversible, but this effect was lessened on oxidized surfaces. No explanation was given.

Rosen (11) summarizes many investigations aimed at the delineation of the electrode reactions of oxygen and hydrogen on the PGE; he calls attention to the work of Morcos (29), who showed that the reduction of oxygen to peroxyl ion proceeds much more readily on the edge planes of the PGE than on the cleaved planar surface. Grinding exposes a large number of edge planes of the truncated cones of the graphite layers. The cleaved surfaces are uniformly reproducible and provide in nonaqueous solution far better voltammograms than do the ground electrodes. The existence of the large anodic charge, shown by a high potential and peak current when the electrode is inserted into aqueous or nonaqueous solution, indicates that the anodic charge is more likely a static charge phenomenon than an oxidation. The requirement that the scan be started toward the cathodic (negative) direction in order to overcome it, indicates that, while some of the electroactive species is indeed oxidized by the charge phenomenon (first cathodic peak), some of the charge does not oxidize the Fe(II) species. This may be due to shielding of inner layers of the graphite or to some other effect arising as a consequence of the unique structure of the pyrolytic graphite.

The work of Boehm *et al.* (30) has provided a definitive view of the types of oxidized sites occurring on carbon. These include phenolic, carboxylic, lactone, and ketonic types of oxygen compounds and may include hydrogen bridging between adjacent carbon-oxygen sites on the neighboring carbon hexagons. In the present work, one can visualize what might occur when the PGE is resurfaced in air by grinding. The grinding mechanism removes carbon by breaking bonds between adjacent atoms and between planes. In the case of pyrolytic graphite with its conical structures protruding from the surface, grinding will break vastly greater numbers of adjacent carbon bonds than if the planes are merely cleaved apart. The energy of breaking these bonds is partially dissipated as heat. However, the surface area is vastly increased and, since all the surface atoms have unbalanced charges ("free valencies") in the direction away from the bulk of the carbon, the surface energy must likewise be vastly increased. Inasmuch as the grinding is conducted in the air, the combination of heat and surface energy on the carbon atoms provides an optimum environment for oxidation of the carbon by atmospheric oxygen to form the various types of C-O compounds postulated by Boehm *et al.* (30). These occur on adjacent carbon atoms on the edges of the hexagonal planes of the graphite. Depending on the sites available, there may be bridging between adjacent groups and hydrogen bonding when OH groups are present. Obviously, if the PGE cone edges are vastly increased by the grinding, these compounds should form more readily and thus interfere with the reduction of other electroactive species when used in voltammetric studies.

From the standpoint of the surface charges produced on resurfacing, we determined these to be on the order of 5-10 μcoulombs, which is equivalent to 40 to 80 $\mu C/cm^2$ of projected PGE area. Such a large positive charge on the graphite surface may lead to the adsorption of anions. When the electrode is scanned towards negative potential in pyridine, an inflection is observed which appears to be a reduction. This may actually be due to the removal of the adsorbed anions, which requires that additional negative charges (electrons) be put on the electrode and results in an inflection as observed. These negative charges are also relevant to the observed levels of open circuit potential. When the electrodes are ground in air, oxidation of the carbon atoms on the edge planes would be expected to occur to form various types of C-O groupings, depending on the -C-C-C- environment. Unfortunately, we have not yet been able to determine the effect of resurfacing the PGE in an inert, dry atmosphere and using it quickly thereafter in the dry-box atmosphere. However, such a procedure may only prove that static charges predominate or that the dry-box atmosphere with less than a part per million of water and oxygen still has too much of these species present for definitive results.

It seems likely that much of the problem of measuring double layer capacity of PGE (14) may be traceable to the charges and surface oxidation compounds produced by the grinding or cleavage of the electrodes.

A technique, which might shed further light on the nature of the surface compounds on the PGE, involves exposing a new layer of material, while the electrode is connected to the measuring circuit, to determine the "potential of zero charge" (31). If the charge on a PGE could be neutralized by several scans and the electrode then cleaved under the solution while potential and current are measured, the results may indicate the nature of the newly exposed carbon planes. Such an

operation could be conducted in a dry-box atmosphere under a highly purified nonaqueous solution.

The proposed technique for the identification of surface functional groups on active carbon by infrared reflection spectroscopy (32) may be applicable to surfaces such as pyrolytic graphite, glassy carbon, and other opaque electrode surfaces.

Acknowledgments

The authors thank the Naval Ordnance Laboratory, Corona, for the Fellowship awarded to R.E.P. under the NOLC Educational Program and the National Science Foundation for research support given to P.J.E. R.E.P. extends his gratitude to W. C. Spindler at NOLC, whose encouragement through the years is deeply appreciated.

Technical Notes

The Electrolytic Fluorination of Anthracene Derivatives

I. 9, 10-Diphenylanthracene

C. J. Ludman, E. M. McCarron, and R. F. O'Malley*

Department of Chemistry, Boston College, Chestnut Hill, Massachusetts 02167

Electrochemical acetoxylation, methoxylation, and cyanation, believed to occur by attack of the appropriate nucleophilic anion on radical cations and/or dications formed at the anode, have been reviewed (1). A similar route to fluorine derivatives of aromatic hydrocarbons seemed logical if a suitable solvent-electrolyte system were available.

Acetonitrile, with a useful anodic range of at least +3.0V *vs.* SCE (2), depending upon the anion present, was chosen as the solvent. The salt tetramethylammonium dihydrogen trifluoride $(CH_3)_4NF \cdot 2HF$ (3) was prepared and characterized. It is soluble in acetonitrile.

Knunyants and his group have used triethylammonium fluoride in acetonitrile (4) for the anodic fluorination of naphthalene, and tetraethylammonium trihydrogen tetrafluoride (5) for the anodic fluorination of naphthalene and 1-fluoronaphthalene. Earlier, Schmidt (6, 7) had described the anodic fluorination of 1,1-diphenylethylene, by electrolysis in potassium hydrogen fluoride solutions in glacial acetic acid, and silver fluoride solutions in acetonitrile, but with very low yields.

The anodic formation of cationic species from polyaromatic hydrocarbons and related compounds has been investigated extensively in a number of laboratories and is the subject of a recent lengthy review (1). The compound 9,10-diphenylanthracene DPA was chosen because of the stability of its radical cation (8, 9, 10). It has been shown to react with water (10) to form 9,10-diphenyl-9,10-dihydroxy-9,10-dihydroan-

* Electrochemical Society Active Member.
Key words: fluorination, electrolysis, polyarenes, radical-cations.

thracene. The use of $H_2F_3^-$ ion, as a nucleophile for reaction with the cationic species of DPA, is the basis of the work described here.

Experimental

Apparatus.—The controlled potential electrolysis was conducted in a cell constructed from a 500 ml Pyrex resin flask, fitted with a side arm made from a 24/40 outer joint. A medium porosity frit inserted at the juncture of the flask and a side arm separated the reference electrode compartment from the electrolysis compartment. A platinum cylindrical gauze anode (5 cm long and 1.5 cm in diameter) and a platinum foil cathode (11.25 cm^2) were suspended in the resin flask through the ground joints in the cover; no diaphragm was used to separate them. The potential of the anode *vs.* the SCE reference was controlled by an Anotrol Model 4100 research potential controller.

Before performing the electrolyses, RPE voltametric curves were obtained with a Sargent micro-platinum electrode (S-30420) rotated at 600 rpm by a Sargent synchronous motor (S-76485). A conventional Pyrex H-cell, with the electrode compartments separated by medium porosity frits, contained the acetonitrile solution of salt and organic substrate and the SCE reference electrode. The current-voltage curves were obtained on a Sargent Model XV polarograph, without solution resistance compensation.

Melting points were determined on a Mel Temp apparatus and are uncorrected. Infrared and ultraviolet spectra were recorded on Perkin-Elmer spectrophotometers, Models 137 and 202, respectively. The NMR spectra were recorded on a Varian Model HA-60 spectrometer.

Chemicals.—Matheson, Coleman, and Bell chromatoquality acetonitrile was used without further purification. Tetramethylammonium dihydrogen trifluoride was prepared as described previously (3). The 9,10-diphenylanthracene was from K & K Laboratories, Inc.

Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee. Molecular weight determinations were made by R. Sacher, U. S. Army Natick Laboratories, Natick, Massachusetts, on a Mechrolab vapor pressure osmometer, Model 301A.

Electrochemical Synthesis.—The RPE examination of DPA in 0.40M $(CH_3)_4NF \cdot 2HF$ in acetonitrile gave a value of 1.27V *vs.* SCE for its $E_{1/2}^{ox}$.

Because of the relatively low solubility of DPA in acetonitrile, it was added in portions from time to time during the electrolysis. A total of 1.00g (3.03 mmole) was added to 95 ml of 0.40M $(CH_3)_4NH_2F_3$ in acetonitrile. The current of 0.50A was observed after the addition of each portion of 9,10-diphenylanthracene and fell to 0.030A before the next addition. The electrolysis was allowed to proceed for 11 hours at which time the current had decreased to 0.015A. An atmosphere of nitrogen was maintained throughout the electrolysis.

A white precipitate formed in the vicinity of the anode. After filtration, washing with acetonitrile, and recrystallization from benzene it melted with decomposition at 229°-229.5°.

Analysis.—Calculated for $C_{26}H_{18}F_2$: C, 84.78; H, 4.90; F, 10.32. Found: C, 84.70; H, 5.30; F, 10.30. Molecular Weight: Calculated 368; Found, 391. The yield was 0.48g, 43% based on the mass of starting material. The ultraviolet spectrum had a primary absorption at λmax 219 (ϵ = 58,000) and four secondary absorptions at λmax 242 (ϵ = 221), λmax 239 (ϵ = 206), λmax 231 (ϵ = 134), and λmax 223 (ϵ = 64) were observed. A 56.4 MHzF^{19} NMR spectrum in benzene at 78° showed a single peak at 4.86 ppm upfield from 1-fluoronaphthalene.

A sample of 9,10-difluoro-9,10-diphenyl-9,10-dihydroanthracene was synthesized by the action of anhydrous HF on 9,10-dihydroxy-9,10-diphenyl-9,10-dihydroanthracene, prepared by the method of Awad, Fateen, and Zayed (11). Its properties were identical to those of the product of the electrochemical synthesis.

Efforts to fluorinate naphthalene by electrolysis in acetonitrile solutions of $(CH_3)_4NF \cdot 2HF$ failed because the anode was quickly coated.

Results and Discussion

That the fluorinated product of the electrolysis was 9,10-difluoro-9,10-diphenyl-9,10-dihydroanthracene, mp 229° (dec), was consistent with the elemental analysis, molecular weight, ultraviolet spectrum, and F^{19} NMR spectrum. A comparison of the ultraviolet spectrum with the spectrum of 9,10-diphenylanthracene showed a marked decrease in resonance. A similar decrease in resonance was shown by 9,10-dihydroxy-9,10-dihydro-9,10-diphenylanthracene. The presence of but a single peak in the F^{19} NMR spectrum supported the predicted structure, since it showed that each of the two fluorine atoms had the same environment.

The same compound was prepared by a chemical synthesis. The treatment of 9,10-dihydroxy-9,10-dihydro-9,10-diphenylanthracene with anhydrous HF gave a white solid which had the same melting point, elemental analysis, infrared spectrum, and ultraviolet spectrum. No experiment was performed which would indicate whether the *cis*- or the *trans*-form of the 9,10-difluoro compound had been formed.

The controlled potential electrolysis was conducted at a potential (1.65V *vs.* SCE) sufficiently higher than $E_{1/2}^{ox}$ of DPA (1.27 *vs.* SCE) to assure the formation of sufficient radical cations to react with the $H_2F_3^-$ anions. The potential was sufficiently lower than the decomposition potential of the solvent-electrolyte system to preclude interference from fluorine atoms formed by oxidation of the anions. Evidence that the anions are oxidized at the decomposition potential has been obtained (12).

It is not clear whether dications were formed in significant quantities to be effective in the formation of the fluorine-containing product formed. The more important mechanism involved in the anodic fluorination is probably that proceeding through two one-electron transfers, as depicted in Fig. 1.

Whether fluorinations of a wide variety of substances is possible by this method is under investigation.

Integration of Gibbs-Duhem Equation Along Phase Boundaries in Multicomponent Systems

N. A. Gokcen and E. T. Chang

Chemical Thermodynamics Section, Laboratories Operation, The Aerospace Corporation, El Segundo, California 90245

The experimental data on the partial molar property of one component may be used to calculate all the remaining partial molar properties of a multicomponent system by integrating the Gibbs-Duhem equation. The methods of integration have been presented and discussed in detail in a previous paper (1) and summarized by Pitzer and Brewer (2). These methods consist of graphical integration along a restricted path on which the system is univariant, *i.e.*, an adequate number of restrictions is imposed on the variables of state at constant temperature and pressure so that the path of integration is along one independent variable. We wish to point out in this communication that these restrictions may also be the coexistence of an adequate number of phases, and to show that it is possible to compute the numerical values of the integrand by a new method. The results are useful in checking the thermodynamic data and the compositions of coexisting phases.

The degrees of freedom or the number of independent variables for a system of p phases and c components at constant temperature and pressure is $c - p$; therefore the univariant condition prevails when $p = c - 1$. We illustrate the required mathematical treatment for $c = 3$ and $p = 2$, for which the Gibbs-Duhem relation is

$$-X'_1 d\,\overline{G}_1 = X'_2 d\,\overline{G}_2 + X'_3 d\,\overline{G}_3 \quad [1]$$

$$-X''_1 d\,\overline{G}_1 = X''_2 d\,\overline{G}_2 + X''_3 d\,\overline{G}_3 \quad [2]$$

where X_i is the mole fraction, $\overline{G}_i$, the partial molar Gibbs energy, or the chemical potential, and the primes denote the phases. The chemical potential of a component in various coexisting phases is the same; hence, we do not need primes over $\overline{G}_i$. We assume that the data on $\overline{G}_1$ exists from which we proceed to obtain $\overline{G}_2$ and $\overline{G}_3$. The algebra of determinants may be used to solve for the unknown terms $d\,\overline{G}_2$ and $d\,\overline{G}_3$ in Eq. [1] and [2]; thus

$$d\,\overline{G}_2 = -(D_{13}/D_{23})\,d\,\overline{G}_1$$

$$= [(X''_1X'_3 - X'_1X''_3)/(X'_2X''_3 - X''_2X'_3)]\,d\,\overline{G}_1 \quad [3]$$

where the determinants D_{ij} are given by

$$D_{23} = \begin{vmatrix} X'_2 & X'_3 \\ X''_2 & X''_3 \end{vmatrix} \text{ and } D_{13} = \begin{vmatrix} X'_1 & X'_3 \\ X''_1 & X''_3 \end{vmatrix} \quad [4]$$

Key words: Gibbs-Duhem, integration, multicomponent, multiphases.

The determinant D_{13} is obtained from D_{23} by substituting the coefficients of $-d\,\overline{G}_1$ in Eq. [1] and [2] in the first column of D_{23}. Likewise

$$d\,\overline{G}_3 = -(D_{21}/D_{23})\,d\,\overline{G}_1 \quad [5]$$

In general, for c components and c -1 phases, the determinant in the denominator is

$$D_{23\,\ldots\,c} = \begin{vmatrix} X'_2 & X'_3 & \cdot\ \cdot & X'_c \\ \cdot & \cdot & \cdot\ \cdot & \cdot \\ & & & \\ \cdot & \cdot & \cdot\ \cdot & \cdot \\ X_2^{(c-1)} & X_3^{(c-1)} & \cdot\ \cdot & X_c^{(c-1)} \end{vmatrix} \quad [6]$$

When $c = 2$ and $p = 1$, it is evident that the ratio of determinants in Eq. [3] becomes X'_1/X'_2 and we obtain the following well-known relationship for a binary system

$$d\,\overline{G}_2 = -(X'_1/X'_2)\,d\,\overline{G}_1 \quad [7]$$

Equation [3] may be integrated graphically by plotting D_{13}/D_{23} *vs.* $\overline{G}_1$ along the path of coexisting phases and measuring the area under the curve. The experimentally measurable property is $(\overline{G}_i - G_i^\circ)$ where G_i° is the molar Gibbs energy of pure i in a condensed state at one atmosphere, and $(\overline{G}_i - G_i^\circ)$ may be used instead of $\overline{G}_i$ in integrating Eq. [3]. This property may be obtained by measuring the emf of an appropriate cell or by determining the partial pressure of component i. Since $\overline{G}_i - G_i^\circ = RT \ln a_i$, where R is the gas constant in appropriate units, T the temperature in K, ln the natural logarithm, and a_i the activity of i, it is possible to convert Eq. [3] into the following form

$$\ln a_2 - \ln a_2\ (\text{at } X_1 = \alpha) = -\int_{X_1=\alpha}^{X_1} (D_{13}/D_{23})\,d \ln a_1 \quad [8]$$

The equation corresponding to $\ln a_3$ can readily be obtained by interchanging the subscripts 2 and 3 in Eq. [8]. We emphasize that the method by which the integrand D_{13}/D_{23} can be computed constitutes a new and convenient procedure.

We illustrate the usefulness of Eq. [8] by the published data summarized in Landolt-Börnstein (3) for the system benzene-water-ethanol, C_6H_6-H_2O-C_2H_5OH at 64.9°C, as listed in Table I. The published values of a_i were calculated (3) from $a_i = P_i/P_i^*$ where P_i is the partial pressure of i over a selected pair of coexisting liquids obtained from the measured values of total pressure and the vapor composition, and P_i^* is the

* Lower integration limit of left side in Eq. [8], same as corresponding experimental value. It is this limit and the convenience in computations that dictate numbering the components. In general, a component is labeled 1 if the experimental data for activity are available for that component.

vapor pressure over pure component i. The activity a_i of each component i is the same in each set of coexisting phases as required by thermodynamics. The data in Table I for the phase relationship are shown in Fig. 1 where the coexisting phases are indicated by the tie-lines. The path of integration for Eq. [8] is along the phase boundary curve where the system is univariant. The lower integration limits in Eq. [8] are taken as the values of a_1 and a_2 at $X_1 = \alpha = 0.819$. The last two columns in Table I contain the values of a_2 and a_3 calculated by Eq. [8]; and they are in poor agreement with the corresponding experimental values of a_2 and a_3. Significant errors could hardly be ascribed to the vapor pressure measurements, but the analytical errors in the gas, and particularly in the coexisting liquids, are largely responsible for the disagreement between the experimental and the calculated values of a_2 and a_3. This conclusion is based on the following simple analysis. The expression for $-(D_{13}/D_{23})$ in Eq. [3] and [8] is given by $(X''_1X'_3 - X'_1X''_3)/(X'_2X''_3 - X''_2X'_3)$. The numerator and the denominator in this expression contain the difference of two terms, and each term is a product of two mole fractions; therefore, small errors in the mole fractions of liquids cause large errors in D_{13}/D_{23}.

Similar calculations have also been made by using Eq. [8] and the published values (3) of a_1 for the system water-propanol-carbon tetrachloride, H_2O-C_3H_5OH-CCl_4 at 65.4°C. The results are also listed in Table I. The calculated values agree fairly well with the experimental values for this system. It is, therefore, evident that Eq. [8] provides an excellent check on the consistency of data for a_i at the phase boundaries.

Equation [8] may also be used in computing the activities in a frequently encountered system, as illustrated by Fig. 2, where the components 2 and 3 are liquids and the component 1 is a solid which dissolves limited amounts of 2 and 3. If the data are available for $\overline{G}_1 - G_1°$ the integration may be carried out as described; however, if there are no data but X_1, for the solid is greater than 0.9, it is reasonable to assume that for the solid solution Raoult's law is obeyed, *i.e.*, $a_1 = X_1$. The liquid and solid phases may be designated by (′) and (″) respectively, and the equality of $\overline{G}_1$ in both phases may be used to obtain

$$G_1°' + RT \ln a'_1 = G_1°'' + RT \ln X''_1$$

This equation may be rearranged into

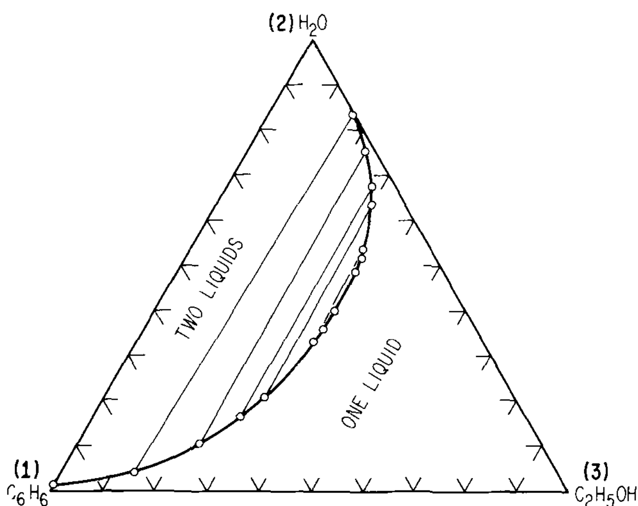

Fig. 1. Ternary system benzene-water-ethanol at 64.9°C; 1, 2, and 3 are component designations. Thin lines are tie-lines joining coexisting phases. Phase boundary curve is univariant. Data are from a summary in Landolt-Bornstein (3).

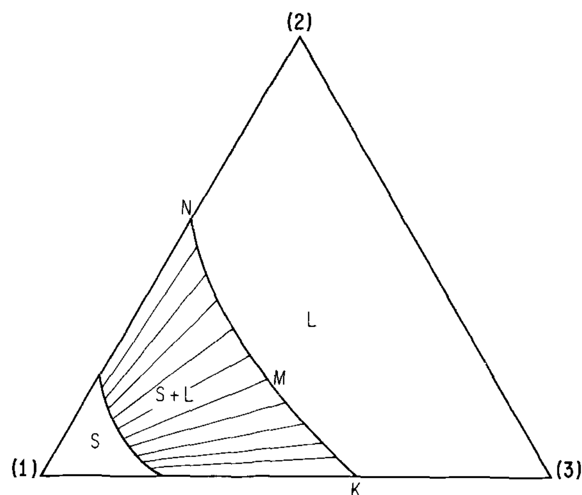

Fig. 2. Hypothetical ternary system formed by pure solid component 1, and pure liquid components 2 and 3. Solid solution is S, liquid solution, L, and thin lines are tie-lines joining coexisting solid and liquid phases. Line KMN shows composition of liquid phase in equilibrium with solid phase.

$$G_1{}^{\circ\prime} - G_1{}^{\circ\prime\prime} = -RT \ln (a'_2/X''_1) \quad [9]$$

where the left side is the standard Gibbs energy of fusion which is usually available in convenient tables for simple components (4-6); therefore, a'_1 may be calculated along the liquidus line KMN since X''_1 is also known. From the values of a_1, it is then possible to calculate the values of a'_2 by Eq. [8], and a'_3 by an equation obtained by interchanging the subscripts 2 and 3 in Eq. [8].

On the Mechanism of Low-Temperature Oxidation (23°-450°C) of Polycrystalline Nickel

M. J. Graham and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR9

ABSTRACT

The oxidation of "clean" nickel has been investigated from 24° to 450°C at oxygen pressures of 5×10^{-3} to 6×10^{-1} Torr. Ultra-high vacuum techniques made it possible to start oxidation on specimens free of oxide and surface impurities such as C, Si, and S. Oxygen uptake was measured manometrically with a capacitance gauge of submonolayer sensitivity. Initial rapid oxygen adsorption (and place exchange) on nickel was followed by slower oxidation obeying a logarithmic rate law over the thickness range 8-30Å. Growth of thicker films was in accord with a parabolic rate law, transport through the oxide occurring predominantly via easy diffusion paths. The value of 41 kcal · mole^{-1} calculated from an Arrhenius plot of the parabolic rate constants from 300° to 450°C is an approximate measure of the activation energy for growth via leakage paths. A $p^{1/6}$ dependence of the parabolic growth rate on oxygen pressure was found at 450°C.

Nickel oxidation is considered to be one of the simpler systems of study since only one oxide, NiO, is produced, and partly for this reason has been the subject of numerous investigations (1). NiO, a p-type semiconductor, grows by the outward movement of nickel cations and electrons via vacancies and holes. At high temperatures, say >1000°C, parabolic growth is generally observed. However, at moderate temperatures (around 500°C), a variety of experimental kinetics have been reported. These include parabolic (2), two stage logarithmic (3, 4), and logarithmic followed by quartic (5) rates of oxidation. It may be that differences in material purity, surface preparation, and pretreatment could account for the variation in experimental data, and the present work on well-characterized surfaces was undertaken in an attempt to resolve some of the discrepancies and, if possible, to present a simplified model for the low-temperature oxidation of nickel.

Experimental

Apparatus.—The oxidation apparatus is shown schematically in Fig. 1. It is an improved design of an earlier manometric system (6), having ultra-high vacuum capabilities (pressures $<3 \times 10^{-10}$ Torr after bakeout at 250°C) and employing a sensitive capacitance gauge to follow the pressure decrease with time during oxidation. The gauge was an M.K.S. Instruments 90H-1, held at 30°C by a temperature controller (Type 1090-1). With the exception of the quartz specimen chamber the apparatus was all metal and contained a working volume of about 1 liter. At oxidation pressures $\sim 5 \times 10^{-3}$ Torr, sub-monolayer adsorption was readily measured. During pressure measurements, the reference side of the capacitance gauge was pumped with an 8 liter · sec^{-1} ion pump. Specimen heating was by a tube furnace (hot zone variation of ±2°C) around the quartz tube.

* Electrochemical Society Active Member.

Key words: kinetics, pressure dependence, manometric apparatus.

Specimen material.—Zone-refined nickel sheet (0.02 cm thick) supplied by Materials Research Corporation was used. It was analyzed to be 99.998% nickel, containing as impurities (in ppm atomic): C, 2; O, 3; F, <0.1; Na, 0.2; Mg, 0.5; Si, 0.7; Cl, 0.2; K, 0.2; Cr, 0.6; Fe, 6; S, not detected.

Gases.—Spectroscopically standardized oxygen (<70 vpm impurities) and hydrogen (<14 vpm impurities) were used (Baker Chemical Company).

Specimen preparation.—Coupons, 0.02 by 1 cm and from 2 to 4 cm long, were degreased, chemically polished for 30 sec at 85°C in a mixture of 30% volume nitric acid, 10% sulfuric acid, 10% phosphoric acid, and 50% acetic acid, and then electropolished for 2 min at 23°C in a 4-volume sulfuric acid:3-volume water mixture at a current density ~0.5 A · cm^{-2}. Chemical polishing removed about 5 μm and electropolishing 8

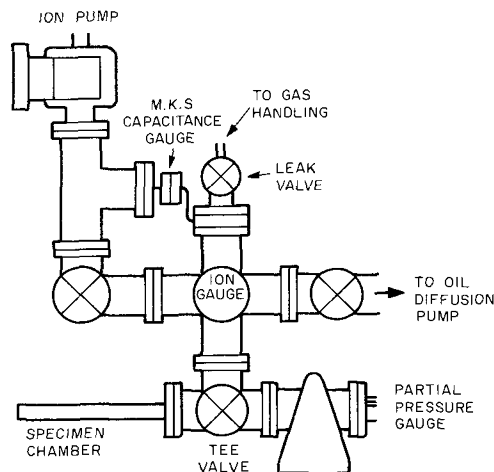

Fig. 1. Manometric oxidation system

μm of material. The specimen was then placed on a platinum support in the quartz tube of the oxidation system.

Oxidation.—After bakeout, the following procedures were carried out.

(*i*) When the system had cooled, 1 Torr oxygen was admitted for 1 hr to saturate the walls of the system; this minimized surface adsorption during a subsequent oxidation experiment.

(*ii*) To decrease the carbon impurity concentration the specimen was heated to 700°C and enough oxygen admitted to produce ~100Å of NiO. During continued annealing of the film in vacuum, CO evolved. [Gas analyzed by an A.E.1 Minimass partial pressure gauge (Fig. 1)]. In some experiments the capacitance gauge was used to follow the pressure increase in the system due to CO formation, presumably by the reaction: $C + NiO \rightarrow CO + Ni$, and corresponded after 2½ hr at 700°C to the removal of >1 ppm of C from the specimen.

(*iii*) The remaining oxide was reduced with 1 Torr hydrogen at 600°C. Gas was admitted for 5 min, pumped out, and the system refilled with fresh hydrogen.

(*iv*) Hydrogen was pumped out and the temperature set to the oxidation temperature. When thermal equilibrium was established and the pressure was $\sim 5 \times 10^{-9}$ Torr, the oxidation was performed. The "tee" valve (Fig. 1) was first closed and the initial oxygen dose size measured before oxidation of the specimen began. In this way, when the tee valve was opened the extremely rapid initial uptake by the specimen could be determined. Calibration runs without specimens at each experimental temperature measured the small uptake on the walls of the system. Oxidation pressures ranged from 5×10^{-3} to 6×10^{-1} Torr; pressures quoted are average values and during the course of oxidation were adjusted to ~25% above (by admitting more oxygen), and allowed to fall ~25% below these values.

Surface and oxide examination.—To ensure that no contamination had occurred, surfaces pretreated as above and oxidized at low temperatures were analyzed for impurities by x-ray emission techniques (7). Replicas of oxide surfaces and stripped oxide films were examined by electron microscopy.

Results

The kinetic curves for the oxidation of polycrystalline nickel (~120 μm average grain diameter) from room temperature to 450°C in 5×10^{-3} Torr oxygen are shown in Fig. 2. Uptake is expressed as μg oxygen cm^{-2}. Mean oxide thicknesses are also given and have been calculated assuming a roughness factor of 1 and an NiO density of 6.75 (1 μg oxygen cm^{-2} equivalent to 69.2Å of NiO). Uptakes are low up to 340°C and the early stages of oxidation are better observed in the expanded plot of Fig. 3. Duplicate experiments were carried out at most temperatures; the reproducibility of oxidation is indicated by the two runs at 200°C.

As seen in Fig. 3, an initial extremely rapid oxidation is followed by a transition to a period of lower oxidation rate. At room temperature an uptake of 0.15 μg oxygen cm^{-2} is approached, equivalent to a limiting oxide thickness of about 10Å. At 200°C a continuing uptake is measured and the data are found to follow a direct logarithmic law of the form, $x = A \ln t + B$, where x is the oxygen uptake (thickness) and t the oxidation time (see Fig. 4). Thin film data (up to ~30Å) at higher temperatures also follow a logarithmic law; the duration of the log dependence diminishes with temperature and at 340°C (as seen in Fig. 4) applies for only the first 2 min of oxidation. Thicker films (>30-40Å), as illustrated by data at 340° and 400°C in Fig. 5, grow in accordance with a parabolic rate law.

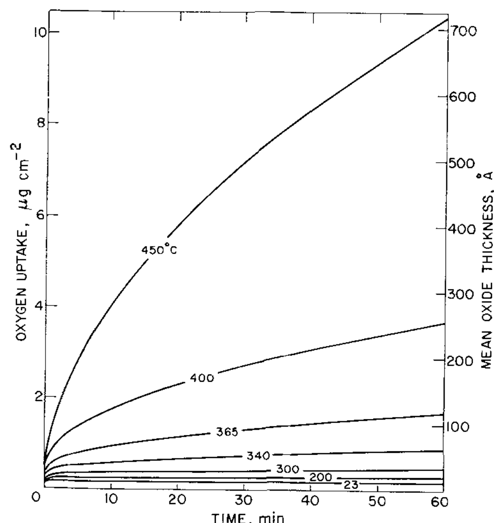

Fig. 2. Oxidation of polycrystalline nickel from 23° to 450°C in 5×10^{-3} Torr oxygen.

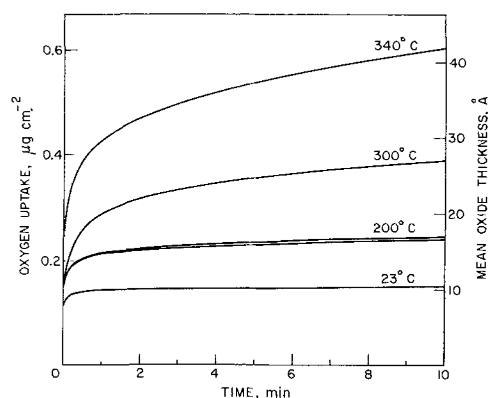

Fig. 3. Early stages of oxidation of polycrystalline nickel up to 340°C in 5×10^{-3} Torr oxygen; expansion of data in Fig. 2.

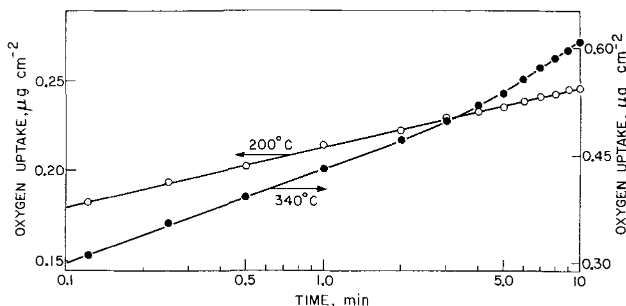

Fig. 4. Logarithmic plot of data from oxidation of a polycrystalline nickel at 200° and 340°C.

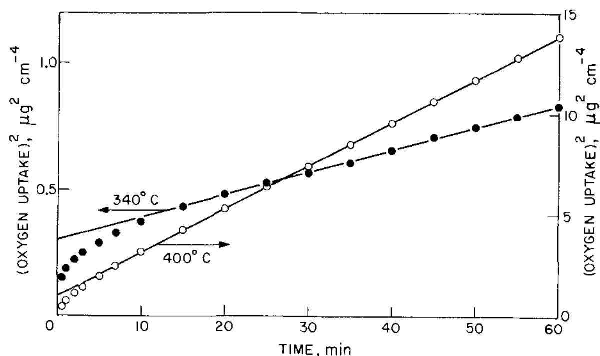

Fig. 5. Parabolic plot of data from oxidation of polycrystalline nickel at 340° and 400°C.

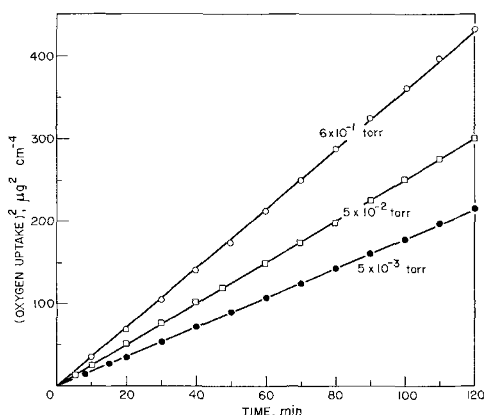

Fig. 6. Parabolic plots of data from the oxidation of polycrystalline nickel at 450°C in 5×10^{-3}, 5×10^{-2}, and 6×10^{-1} Torr oxygen.

To examine the effect of pressure on the kinetics, oxygen uptakes at 450°C were measured at three different pressures: 5×10^{-3}, 5×10^{-2}, and 6×10^{-1} Torr. In Fig. 6 the data are plotted parabolically and a good relationship is observed. Expressing the rate constant, K_p, proportional to (oxygen pressure, $p)^{1/n}$, the value of n can be obtained by plotting $\log_{10}K_p$ against $\log_{10}p$. From Fig. 7 the data fit a reciprocal slope of $n = 6$ much better than one of $n = 4$. Although only three orders of magnitude of pressure could be covered with the present gauge, a $p^{1/6}$ relationship would seem to be applicable, at least over the present range of study.

Discussion

The oxidation may be considered to proceed in three stages. Initial adsorption (and place exchange) is followed by slower oxidation obeying a logarithmic law (from oxide thicknesses 8-30Å), and if the temperature is sufficiently high for further thickening to occur, this continued growth obeys a parabolic rate law.

Initial stage.—Evaporated metal films have been used extensively for measurements of sticking coefficients (8), heats of adsorption (9, 10), and surface potentials (11, 12) of oxygen on nickel from −196° to 150°C. On nickel single crystals, electron diffraction techniques have identified sub-monolayer structures (13-16). If nickel and other metals such as Fe, Co, and Ti are exposed to oxygen at room temperature, more than a monolayer of oxygen is rapidly adsorbed with an unchanging heat of adsorption. The heats of adsorption measured are similar to heats of formation of the oxide (9), and coverage values on nickel at saturation correspond to about two to three oxygen atoms per surface metal atom (9, 10). The present data at room temperature give an instantaneous uptake

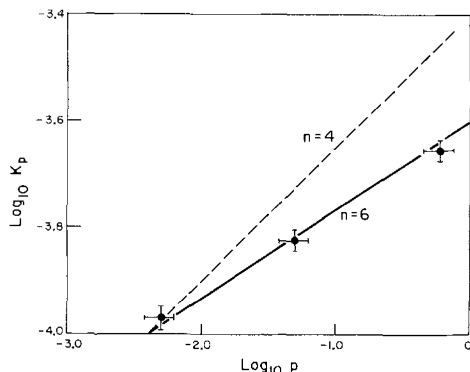

Fig. 7. Logarithm of parabolic rate constants for oxidation of polycrystalline nickel at 450°C plotted against logarithm of oxidation pressure. The bars on the data indicate the considered errors. Lines drawn have reciprocal slopes $n = 6$ and $n = 4$.

approaching a coverage value of three. It is considered that rearrangement of the initial adsorbed layer occurs by a process of rapid place exchange (17, 18), resulting in the formation of nickel oxide.

Logarithmic growth.—Continued growth on the initial oxide occurs much more slowly and the present data follow a logarithmic rate law from ~8-30Å, as illustrated by results at 200° and 340° in Fig. 4.

Previous work on nickel oxidation in this thickness range has also indicated logarithmic growth (19, 20), and many theories have been developed to account for logarithmic kinetics (21-27). Besides the difficulty in deciding whether thin film data follow a direct or indirect logarithmic law (the present results fit the former better), the absence of other information such as the pressure dependence and the effect of electric fields on thin film growth, makes it difficult to favor a particular process (either electron or ionic transport, or chemisorption at the outer oxide surface) as the rate-determining step.

Parabolic growth.—For oxide thicknesses above 30-40Å the data follow parabolic kinetics (see Fig. 5 and 6).[1] As mentioned earlier various rate laws have been previously reported for nickel oxidation at 400°-500°C including parabolic (2), two stage logarithmic (3, 4), and logarithmic followed by fourth power (5). We would consider that the variety of results arise from the development of structurally different oxides whose formation has been influenced by the nature of the starting surface. In this intermediate temperature range where grain boundary diffusion is an important factor, a change in oxide grain size with oxidation time could cause a continued decrease in the apparent parabolic rate constant (28), accounting for deviation from parabolic kinetics. The initial oxide grain size and epitaxy will depend on the nature (both chemical and physical) of the surface prior to oxidation. Impurities such as carbon and sulfur tend to segregate at the nickel surface (29, 30) and the influence of carbon and silicon on the oxide epitaxy has been reported (31). Also, the presence of a prior oxide film affects subsequent oxide morphology and growth, a point which is demonstrated in the following paper (32). The oxide-free starting surfaces in this work are considered to be clean; the experimental procedure resulted in surface impurity concentrations of sulfur, silicon, and iron below the limit of detection of the x-ray emission technique (7), which is about 5% of a monolayer. Carbon impurity levels were also usually as low, although with decreasing oxidation temperature there was an increased probability of carbon contamination due to cracking of the $<10^{-9}$ Torr background carbon monoxide.

Oxides produced on these "clean" and flat nickel surfaces were not well oriented; thinner oxides (a few hundred angstroms thick) exhibited preferred orientation, but with increasing thickness tended to become more polycrystalline. In addition, oxide grain size increased with temperature, from ~100Å at 300°-340°C to ~1000Å at 450°C. The many grain boundaries, and perhaps subgrain boundaries present in these oxide films are considered to be paths for easy nickel diffusion (33, 34), the anisotropy of oxidation in the thin-film range reflecting a varying density of these high-diffusivity paths (35). Because of structural changes of the oxide with temperature, the activation energy of 41 kcal · mole^{-1} calculated from the parabolic rate constants over the temperature range 300°-450°C (see Fig. 8) is considered to be only an approximate measure of the activation energy for growth via leakage paths.[2]

[1] Good parabolic behavior was maintained in the longest oxidation experiment performed—64 hr at 450°C (oxide thickness ~1 μm).

[2] As will be seen in the following publication, a line of slope 37 kcal·mole^{-1} may be drawn through the present data and rates of oxidation from 500° to 700°C. This value, while again probably not an accurate measure of the activation energy for growth via leakage paths because the structure of the oxide is changing with temperature, is significantly less than values ≥52 kcal·mole^{-1} representative of lattice diffusion through nickel oxide (32).

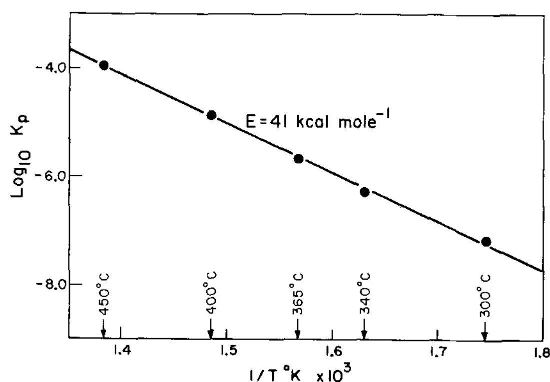

Fig. 8. Logarithm of parabolic rate constants for oxidation of polycrystalline nickel from 300° to 450°C in 5×10^{-3} Torr oxygen plotted against (absolute temperature)$^{-1}$.

Pressure dependence of parabolic growth.—The degree of ionization of nickel vacancies in NiO has been a matter for discussion (36). From electrical conductivity measurements at high temperatures (around 1000°C), both singly ionized (37-39) and doubly ionized vacancies (40-42) have been proposed as the predominant defect. The present results of the effect of oxygen pressure (5×10^{-3} to 6×10^{-1} Torr) on the oxidation rate at 450°C as seen in Fig. 7, fit a $p^{1/6}$ dependence, consistent with the formation and movement of doubly charged cation vacancies.

The Effect of Surface Preparation on the Oxidation of Nickel

M. J. Graham, G. I. Sproule, D. Caplan, and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR9

ABSTRACT

A study was made of the effect of surface preparation and pretreatment on the oxidation of zone-refined nickel from 500° to 700°C. "Clean," hydrogen-reduced surfaces, maintained essentially free of impurities such as S, Si, Fe, and C, oxidized at a faster rate than air-exposed electropolished or etched annealed nickel. At 700°C, the rapid rate, arising from a high leakage path density in the oxide, resulted in the formation of voids at the metal-oxide interface. The oxidation rate of electropolished and etched specimens was strongly dependent on substrate orientation and this anisotropy, responsible for a slower average oxidation rate, reflected varying contributions of leakage path diffusion. Very thin oxides, as on nickel orientations near (112) after electropolishing, formed primarily by lattice diffusion and the parabolic rate constant at 600°C was $\sim 10^4$ lower than for the thickest oxides. Correlation with other studies in the laboratory indicates that the activation energy for the growth of NiO on Ni is ≥ 52 kcal·mole^{-1} for lattice diffusion and approximately 37 kcal·mole^{-1} for leakage path diffusion.

A previous paper described the kinetics of oxidation from room temperature to 450°C (1) of polycrystalline nickel free of oxide and surface impurities. Oxides formed were fine grained and nickel diffusion via grain boundaries was considered to be the major transport process. Differences in kinetics and oxide structure were found on extending the work up to 700°C. The parabolic rate constant changed with time and oxide-metal separation was evident. This paper discusses these results together with the effect of different surface preparations (either sulfuric acid electropolish or nitric acid etch) on the oxidation of nickel surfaces.

Experimental

Zone-refined polycrystal and single-crystal nickel specimens were used. Analysis of the 99.998% polycrystalline sheet (0.02 cm thick) has been given previously (1). Single crystals were spark machined from rods of similar purity; contamination from cutting was eliminated by the removal of 100 μm of nickel by chemical polishing (1).

Oxidations were performed in a manometric system (1) using two distinctly different starting procedures:

(*a*) "Hot-bare" oxidations were performed on surfaces free of prior oxide; *i.e.*, the oxide film present after electropolishing in H_2SO_4 was reduced in hydrogen before admitting oxygen to the specimen at temperature. Starting surfaces were also free of impurities such as S, Si, Fe, and C. (See Ref. (1) for further details of procedure.)

(*b*) "Furnace-raised" oxidations involved heating the electropolished or etched specimen to the oxidation temperature in the presence of oxygen.

(*i*) Electropolishing was in a 4-volume H_2SO_4:3-volume H_2O mixture for 2 min at room temperature, which removed ~ 8 μm of material. Prior to electropolish, polycrystalline specimens were chemically polished for 30 sec (removing 5 μm of nickel).

(*ii*) Etching was for 30 sec in 5% HNO_3 which removed ~ 200Å of nickel. Before etching, specimens were chemically polished and then electropolished for 30 sec.

Characterization of the oxide films was carried out by reflection electron diffraction, x-ray emission analysis, transmission and scanning electron microscopy, and metallography.

Results

Hot-bare oxidation.—Oxidation of polycrystalline nickel sheet at 0.5 Torr [1] was performed at 500°, 600°, and 700°C for times up to 70 hr.

Oxygen uptake and (oxygen uptake)[2] for the first 20 hr of oxidation at 500° and 600°C are shown in Fig. 1 and 2. At both temperatures good parabolic plots are obtained. Instantaneous parabolic rate constants K_p, expressed as $2w \cdot dw/dt$ (twice the oxygen uptake times the rate of uptake) were determined and as seen in Table I also demonstrate that K_p changes little with time.

At 700°C, the oxidation showed poor reproducibility, as illustrated by the three runs shown in Fig. 3. Differences occur after the first hour of oxidation, run 1 exhibiting an abrupt change in oxidation rate. Run 2 is plotted on parabolic coordinates in Fig. 4 where it is seen that K_p for this experiment is also decreasing with time, falling from 7.6×10^{-2} mg^{2}cm^{-4}hr^{-1} at 0.1 hr to 2.3×10^{-2} mg^{2}cm^{-4}hr^{-1} at 20 hr (see also Table I).

Figure 5 shows the structure of oxide films formed at 700°C. Oxide of run 3 (Fig. 3) comprises only one

[1] Pressures quoted are average values and during oxidation were adjusted to $\sim 25\%$ above and allowed to fall to $\sim 25\%$ below these values.

* K_p calculated from slope of uptake curve, as $2w \cdot dw/dt$.

layer [see Fig. 5(a)]. Examination of oxide sections of runs 1 and 2 however revealed the presence of a double-layer oxide. In run 2 the major portion of the scale was one layer [Fig. 5(d,f)], but a few areas of duplex oxide were evident [Fig. 5(e,g)]. Oxide of run 1, which exhibited the marked reduction in oxidation rate, was duplex on all areas [Fig. 5(b)]. The duplex oxide, resulting from loss of oxide contact, comprises an inner layer bridged to the finer grained first-formed oxide. The difference in grain size is clearly evident in Fig. 5(c).

Effect of surface pretreatment on oxidation.—Comparison at 700°C of hot-bare run 2 with furnace-raised oxidation of (*i*) cold-rolled nickel, electropolished in sulfuric acid (run 4), (*ii*) annealed nickel, electropolished in sulfuric acid (run 5), and (*iii*) annealed nickel, etched in nitric acid (run 6) is shown in Fig.

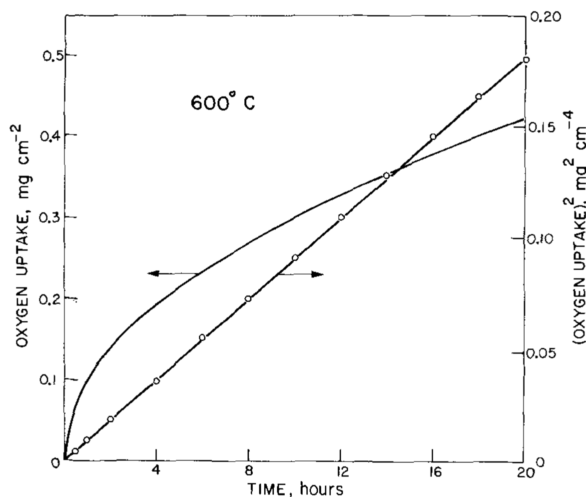

Fig. 2. Hot-bare oxidation of polycrystalline nickel at 600°C and 0.5 Torr oxygen.

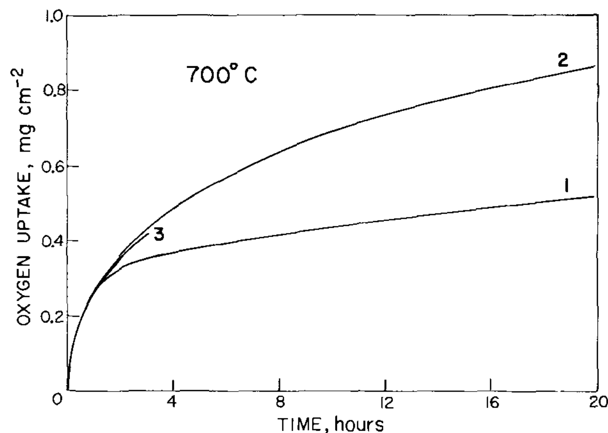

Fig. 3. Hot-bare oxidation of polycrystalline nickel at 700°C and 0.5 Torr oxygen showing nonreproducibility of oxidation.

6. The cold-rolled nickel was annealed in vacuum at 700°C after cleaning by chemical polishing and electropolishing. Run 4 oxidizes at a similar rate to hot-bare run 2, which is higher than for annealed, electropolished polycrystalline nickel and annealed, etched polycrystalline nickel surfaces.

Analysis of the kinetic data showed that for furnace-raised oxidation runs 4-6, K_p decreased with time. As seen in Table I, changes are not as marked as for hot-bare experiments, K_p falling at most by a factor of 2 over 20 hr of oxidation. Because of the relatively slow heating to 700°C (~4 min), oxidation rates at 0.1 hr are not very reliable and have been omitted from the table. The reproducibility of furnace-raised oxidations, as indicated by a repeat of run 5, was found to be about ±3% over 20 hr.

The anisotropy of oxidation at 700°C became more marked as the oxidation rate decreased for runs in Fig. 6, and two extreme cases are shown in Fig. 7. The oxide on hot-bare run 3 [Fig. 7(a,b)] is of uniform thickness over the specimen, whereas the slowest oxidizing run 6 exhibits the greatest variation in oxide thickness with substrate orientation [Fig. 7(c,d)]. The small grained structure of the thick oxides [Fig. 7(b,d)], together with the enhanced oxidation over metal grain boundaries for run 6 [Fig. 7(d)] is indicative of oxide growth via easy diffusion paths through the mismatched oxide.

The early stages of oxidation of the various pretreated surfaces were determined at 600°C. As in Fig. 8, hot-bare nickel oxidizes at the fastest rate, and electropolished polycrystalline nickel oxidizes more slowly initially than etched nickel. After a time, however, an increase in the oxidation rate of electropolished nickel is observed, resulting eventually in a cross-over of the curves; at greater oxide thicknesses etched nickel oxidizes at the slower rate, consistent with the data at 700°C. The data, of course, represent

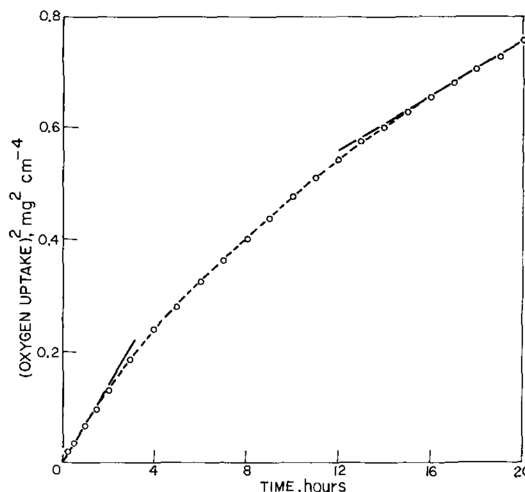

Fig. 4. Plot of (oxygen uptake)² vs. time at 700°C for data of hot-bare run 2, showing deviation from parabolic behavior.

(e) Scanning electron micrograph showing one of the few duplex oxide areas of run 2. (f), (g) Metallographic cross sections correlating with scanning electron micrographs (d) and (e) respectively, showing single-layered and double-layered oxide of run 2.

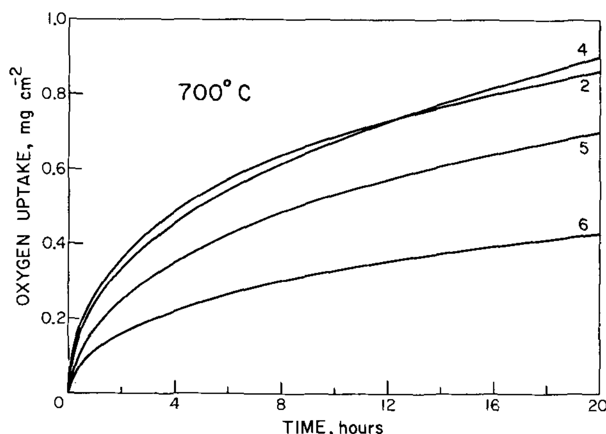

Fig. 6. Effect of pretreatment on the oxidation of polycrystalline nickel at 700°C and 0.5 Torr oxygen. Run 2, hot-bare oxidation; run 4, furnace-raised, cold-rolled, and electropolished; run 5, furnace-raised, annealed, and electropolished; run 6, furnace-raised, annealed, and etched.

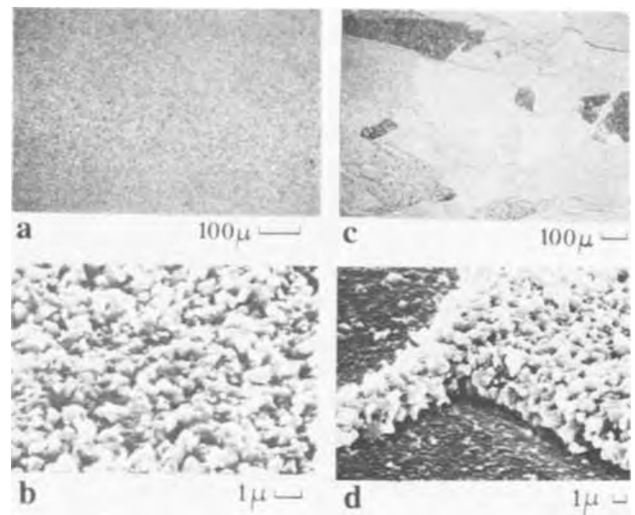

Fig. 7. Scanning electron micrographs of outer oxides formed on polycrystalline nickel at 700°C. (a) and (b), hot-bare run 3; (c) and (d), furnace-raised and etched run 6. Note marked variation in oxide thickness in run 6 (c) compared with uniform oxide of run 3 (a), and thickening of oxide over metal grain boundaries in run 6 (d).

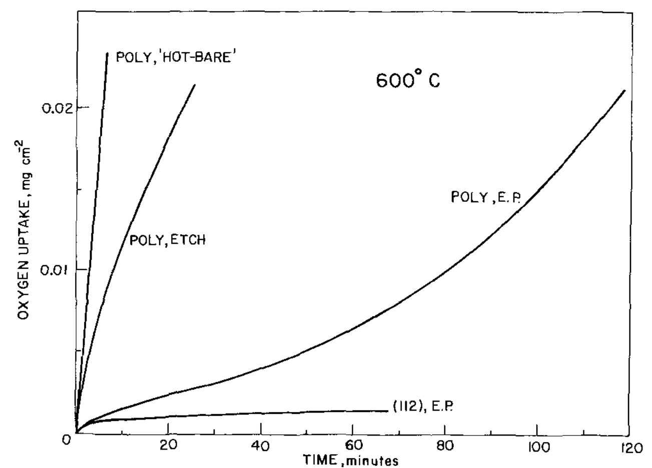

Fig. 8. Effect of surface pretreatment on the early stages of oxidation of nickel at 600°C. Hot-bare oxidation of polycrystalline nickel in 0.5 Torr oxygen; furnace-raised oxidation of etched and electropolished polycrystalline nickel in 0.1 Torr oxygen; furnace-raised oxidation of electropolished (112) nickel in 5×10^{-3} Torr oxygen.

an average oxidation rate of different nickel substrate orientations. Oxidation of a single-crystal hemisphere at 600°C illustrated the marked anisotropy of oxidation, showing that orientations close to (112) after electropolishing in H_2SO_4 oxidize at a very low rate (as low as any orientations after an HNO_3 etch). The oxidation curve for (112) electropolished nickel at 600°C is included in Fig. 8 showing that only ~100Å of oxide had formed after 1 hr; the data fit a parabolic rate law and the resulting rate constant of 1.7×10^{-6} $mg^2cm^{-4}hr^{-1}$ is about 10^4 lower than for hot-bare oxidations of polycrystalline nickel at 600°C.

Discussion

We shall first consider the hot-bare oxidations, then compare the effect of different surface pretreatments and finally correlate the data with other studies (1, 2).

Hot-bare oxidations.—At 500° and 600°C the data obey a parabolic rate law (Fig. 1 and 2), the instantaneous rate constant changing little with time (see Table I). In hot-bare oxidations, the initial oxide forms extremely rapidly and contains many mismatch boundaries which act as easy diffusion paths for nickel [*cf.* Fig. 7(b)]. At 700°C, this rapid oxidation rate leads to varying degrees of oxide separation from the metal, and hence the poor reproducibility of runs in Fig. 3. Separation was never observed at lower temperatures.

Oxide separation from the metal is due to void formation at the metal-oxide interface, probably as a result of condensation of inward moving cation vacancies. Presumably, for the first hour of oxidation at 700°C insufficient voids are nucleated to greatly reduce the oxidation rate, but when the oxide is ~2 μm thick, the combination of high vacancy flux, high oxide hot strength, and low oxidation pressure[2] leads to more complete interfacial detachment. The first-formed oxide continues to grow over unseparated areas, and where loss of contact has occurred an inner oxide layer develops on the metal, producing a duplex scale [Fig. 5(b,e)]. The hot-bare procedure (1) removed most of the carbon impurity from the metal but sufficient remains to provide CO in the void for transporting oxygen between the outer and inner oxide layers [*cf.* (4)]. The formation of pockets of CO could also contribute to the production of voids at the interface. Examination of the under surface of the duplex oxide by SEM [Fig. 5(c)] showed the first formed oxide to have a much smaller grain size than the new inner layer, and by transmission electron diffraction that the latter grains were well-oriented blocks consistent with the slow growth rate anticipated from the low oxidation potential within the void.

Effect of surface pretreatment on oxidation.—Differences in oxidation rate with surface pretreatment (Fig. 6, 8) may be explained by the formation of varying proportions of oxide high in leakage paths. High oxidation rates are observed in hot-bare run 2 and furnace-raised, cold-rolled electropolished nickel run 4 (Fig. 6), because oxide on all substrate orientations is growing by leakage path diffusion.[3] Little variation in oxide thickness is found over these specimens [*cf.* Fig. 7(a)], with the exception of some separated grains on run 2. The lower oxidation rates in furnace-raised runs with annealed nickel [runs 5, 6 in Fig. 6] demonstrate how pretreatment and the prior oxide affect the leakage path population in the oxide overgrowth. This effect is strongly dependent on the metal orientation, as illustrated by the variation in oxide thickness over the specimen [see Fig. 7(c)]. Some oxide grains are very thin, while others are as thick as those for cold-rolled metal (run 4); run 6 (etched annealed nickel) has the highest proportion of thin grains and consequently the lowest average oxidation rate. The thinnest grains are considered to grow primarily by lattice diffusion.

In all oxidations at 700°C the parabolic rate constant, K_p, decreased with time (see Table I). Explanations proposed (5) are (*i*) a continuing decrease in the effectiveness of easy diffusion paths because of growth

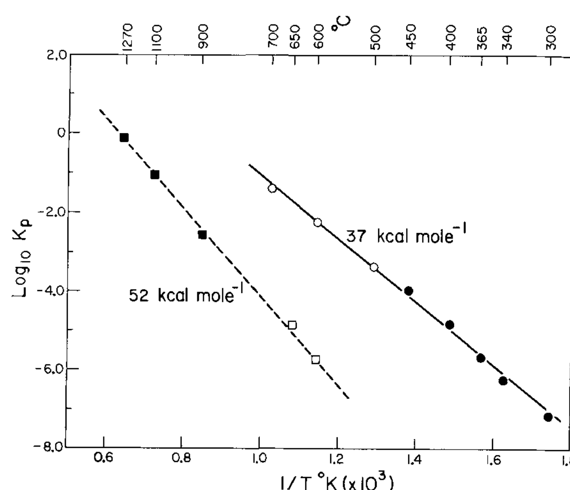

Fig. 9. Arrhenius plot for nickel oxidation from 300° to 1270°C and 5 × 10^{-3} Torr oxygen pressure. ○, This work; hot-bare oxidation rates plotted have been obtained by reducing rates of oxidation at 0.5 Torr according to a $p^{1/6}$ dependence (1). ●, Previous work (1); hot-bare oxidation rates at 5 × 10^{-3} Torr oxygen. □, This work; furnace-raised oxidation of electropolished (112) nickel at 5 × 10^{-3} Torr. ■, Caplan *et al.* (2); cold-insertion oxidation rates were obtained from thickness measurements of the thinnest oxides formed in 760 Torr oxygen, and have been reduced by a $p^{1/6}$ dependence in order to compare with data at 5 × 10^{-3} Torr oxygen.

of the small oxide grains, and (*ii*) increasing separation of oxide from the metal. This latter effect gives rise to the abrupt decrease in rate in hot-bare run 1 (Fig. 3) and is a contributing factor in hot-bare run 2. However, oxide separation was minor in runs 3-6 (not observed in runs 3, 4 and only to a small extent in runs 5, 6) and grain growth of the thicker oxide is probably the main reason for the falling K_p in these experiments.

An example of extremely slow oxidation, where the leakage path density in the oxide is approaching a minimum, is on (112) nickel after electropolish (see Fig. 8). Reflection electron diffraction showed the electropolished film (prior oxide) to be well epitaxed and the slow oxidation rate is associated with the retention of the original epitaxy during growth at 600°C. The breakaway characteristics of polycrystalline electropolished nickel in Fig. 8 indicate modification, to varying degrees, on different substrate orientations of the initial epitaxed, protective film and growth of a more polycrystalline oxide high in leakage paths. Subsequent differences in oxidation rate of electropolished or etched surfaces are explained by varying ratios of oxide growing by lattice and leakage path diffusion.

Parabolic rate constants and activation energies.—Differences in K_p approaching 10^4 between hot-bare experiments on polycrystalline nickel, and furnace-raised oxidation of (112) electropolished nickel at 600°C (see Fig. 9) show the marked increase in rate resulting from leakage path diffusion. Leakage path diffusion strongly predominates in all hot-bare oxidations and the low activation energy in Fig. 9 is consistent with this view. A single line of activation energy 37 kcal · mole^{-1} may be drawn through the present hot-bare rates of oxidation from 500° to 700°C and previous hot-bare data from 300° to 450°C (1). This value only approximates the true activation energy for growth via leakage paths because of structural changes in the oxide with temperature (*e.g.*, the degree of preferred orientation is greater at low temperatures, the oxide grain size increases with temperature, and any contributions from subgrain boundaries decreases with temperature) but it is significantly less than the 52 kcal · mole^{-1} slope drawn through other data in Fig. 9, considered to represent lattice

[2] Void formation and the effect of external gas pressure in suppressing oxide separation have been considered for the oxidation of iron (3). Oxidations were faster at 760 Torr than 10 Torr because voids formed at the Fe_3O_4-Fe interface were squashed closed by higher pressure. Similar considerations could apply for nickel oxidation, the present pressures of 0.5 Torr being insufficient to collapse interfacial voids.

[3] The increased oxidation rate of cold-worked over annealed iron (5) and nickel (2) has been considered in detail. For iron oxidation an additional factor was that extra sinks in cold-worked metal facilitated vacancy annihilation suppressing void formation at the metal-oxide interface. Interfacial voids are not generally observed on oxidizing annealed nickel (*e.g.*, runs 5, 6), and the enhanced oxidation rate of cold-rolled nickel (run 4) is primarily due to the production of an oxide high in leakage paths. However, a few thick grains on runs 5, 6 did show evidence of earlier separation as in hot-bare experiments [Fig. 5(b,e)]. Here the oxidation rate and thus the vacancy flux is at a maximum. Since no voids could be found on cold-rolled run 4 where the oxidation rate was as high, one may conclude that residual cold work in nickel has also prevented minor void formation.

diffusion. This latter line correlates present rates of oxidation of (112) electropolished nickel at 600° and 650°C with rates of formation of the thinnest oxide grains at 1270°, 1100°, and 900°C (2). In both cases, essentially single-crystal oxides are produced and the number of grain and subgrain boundaries which could act as easy diffusion paths is approaching a minimum. The low rates of oxidation are governed by bulk diffusion of nickel through the NiO lattice, the activation energy for the process being $\geqq 52$ kcal · $mole^{-1}$.

Some Properties and Electrical Instabilities in RF Sputtered Niobium Oxide Films

Mao-Chieh Chen*

Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Niobium oxide films were prepared by rf sputtering in an oxygen atmosphere and various electrical properties were investigated. Forms of ionic instability in the oxide layer were studied in relation to changes in the flatband voltage during MOS capacitance measurements. As sputtered, the films exhibited the presence of both highly mobile positive and negative ionic charges. When annealed at 800°C in a helium or an oxygen atmosphere, the films exhibited only positive ionic charge. Inclusion of a small amount of trichloroethylene in the oxygen annealing process resulted in oxide films essentially free from ionic instability.

Dielectric films deposited on semiconducting substrates serve many functions in microelectronics technology. Amorphous silicon dioxide films have been used extensively for this purpose and are still the most commonly used dielectrics. However, the diversified requirements of solid-state devices cannot be fulfilled by silicon dioxide films alone. Silicon dioxide is known to have a porous structure, a low dielectric constant, and to be permeable to ionic migration. These problems have therefore prompted the investigation of other oxide and nitride dielectrics, such as the transition-metal oxides (TiO_2, Ta_2O_5, and Nb_2O_5).

Niobium oxide (Nb_2O_5) films exhibit desirable resistivity, permittivity, and thermal stability characteristics and are attractive for use in such applications as high-resolution silicon vidicons (1, 2). The high dielectric constant permits a reduction in the area occupied by a capacitor in an integrated circuit. It is also possible to fabricate high value capacitors for uses such as decoupling (3). Dielectric constants of 41 for anodically grown amorphous Nb_2O_5 (4), and as high as 100 for the crystalline phase have been reported (5, 6). In recent years, there have been published reports of niobium oxide thin films prepared by halogen transport reactions (5) and by vapor deposition (1, 7). However, only the vapor-deposited niobium oxide has been investigated by metal-oxide-semiconductor (MOS) techniques (1, 7). A positive oxide charge below 5×10^{11} cm^{-2} for a 1000Å oxide was reported (1, 7), and a slow trapping type hysteresis was observed (1). Vapor-deposited niobium oxide and anodic niobium oxide films have been reported to be amorphous (1). Vapor-deposited niobium oxide begins to crystallize at a temperature higher than 1200°C, while the anodic oxide requires only 500°-600°C (4). In contrast to this, niobium oxides deposited by the halogen transport method tend to be polycrystalline because of the high deposition temperature. In the present case, rf sputtered (in oxygen atmosphere) niobium oxides are polycrystalline, although the substrate temperature was maintained at 150°C.

The current trend in research in this class of materials is to improve the preparation techniques and to understand the fundamental nature of materials, the parameters that influence their behavior, and the effect of associated processes. In this study, the MOS capacitance technique was employed. Along with the experimental procedure, the observed dielectric properties, oxide surface charges, and results of bias-temperature stress tests on the niobium oxide MOS structure are reported and discussed.

Experimental Technique

Polished and (111) oriented silicon wafers were used in the fabrication of the test samples. For surface charge study, epitaxial n-type wafers of 10 ohm-cm resistivity were used as substrates. On the other hand, low-resistivity (0.0014-0.0026 ohm-cm) p-type wafers were used for investigation of the dielectric properties of the sputtered niobium oxide films. Prior to oxide deposition, the silicon wafers were cleaned in a 1:1:1 solution of acetone, isopropyl alcohol, and trichloroethylene, and rinsed in ultrasonically agitated, flowing, deionized water. The niobium oxide films were then deposited by rf sputtering.

A conventional diode-type rf sputtering system was employed for this purpose. The rf generator operating at 13.56 MHz was used as the source of power which was coupled to the target electrode through a tunable MRC (Material Research Corporation) matching network to ensure matching between the coaxial trans-

* Electrochemical Society Active Member.
Key words: dielectric, instabilities in RF sputtered niobium oxide films.

mission line impedance and the sputtering system load impedance. The cathode used was a ceramic niobium pentoxide (Nb_2O_5) (nominal purity 99.99%) disk 5 in. in diameter and ¼ in. thick. It was metalized on one side and bonded to a flat water-cooled aluminum disk which formed part of the vacuum chamber wall through a system of vacuum seals and an insulating ring. A metal shield surrounded the exposed areas of the water-cooled aluminum disk at a spacing of 0.5 cm in order to prevent sputtering from this region. The substrate was set on a grounded plate which was situated about 4 cm below the cathode. Most of the depositions were performed in a pure oxygen atmosphere at pressures of 18-20 mTorr and with 0.8 W/cm^2 input power density. By proper tuning, the reflected power was kept to zero, practically, and the rate of deposition was about 30Å/min. The support plate was preheated so that nominal substrate temperatures were maintained at about 150°C throughout the entire sputtering process. The deposition was also performed in argon and argon-oxygen mixtures. It turns out that the leakage current of the MOS structure increases as the percentage of oxygen in the argon discharge decreases. In general, the niobium oxide films sputtered in a pure argon atmosphere showed such high conductance that no proper MOS behavior could be observed. It has been reported that chemical reduction of oxides was observed during rf sputtering (8, 9). As a result, the oxide conductivity arises from oxygen deficient niobium oxide. To prevent this, oxygen has to be replenished during the deposition.

Annealing treatments were carried out in two different atmospheres: in helium and in a trichloroethylene/oxygen atmosphere, both at 800°C for 2 hr. In the former case, the wafers were set in a furnace through which helium gas (1.5 liters/min) was flowing. In the latter case, a small amount of trichloroethylene (C_2HCl_3) was introduced into an oxygen gas stream before admission into the annealing furnace (10). Helium flowing at 0.05 liter/min was bubbled through a trichloroethylene solution before being mixed with the oxygen stream of 1.5 liters/min. It should be noted that no special precautions as to the cleanliness of the annealing furnace were taken.

Aluminum gate electrodes were applied to the oxide films by means of thermal evaporation and photomasking (using KMER as photoresist). Gate areas were 3.44×10^{-3} cm^2 (26 mil diameter aluminum dot). Individual devices were diced out, and die and lead bonded to TO-5 headers using ultrasonic bonders.

MOS Device Characteristics

Dielectric relaxation.—The frequency dependence of the loss tangent and capacitance, with sample temperature as the parameter, is shown in Fig. 1(a) and (b), respectively. These data were obtained in small a-c signal measurements on a film sputtered with 0.8 W/cm^2 input power density on a low-resistivity (0.0014-0.0026 ohm-cm) p-type silicon substrate and are reproducible. The oxide is about 5000Å thick and is an as-sputtered film. It can be seen that as the temperature is increased, the loss peak shifts to higher frequencies. The corresponding capacitance is roughly inversely proportional to the frequency for the aluminum-niobium oxide-silicon structure. If the logarithm of the frequency corresponding to the dielectric loss peak is plotted against reciprocal temperature (Arrhenius plot), a straight line results as in Fig. 2, implying that there is an exponential dependence of the relaxation times on temperature, $\tau = \tau_0 \exp (E/kT)$. The activation energy, E, of the dispersion process is found to be 1.135 eV. In a Cole-Cole diagram (11), shown in Fig. 3, the data points fall on an arc and thus indicate dielectric dispersion. However, two features of the diagram are to be noted. First, the data points obtained at lower frequencies (right part of the diagram) tend to deviate from the arc. This representation, together with the rising trend of loss

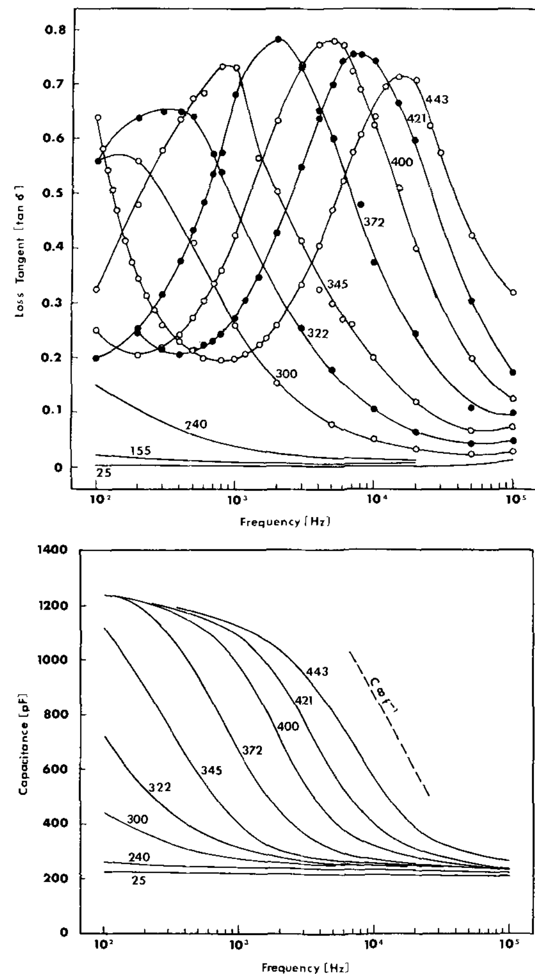

Fig. 1. Loss tangent (a) and capacity (b) behavior as a function of frequency at different temperatures. The number on each curve shows the temperature (in °C) at which each measurement was made.

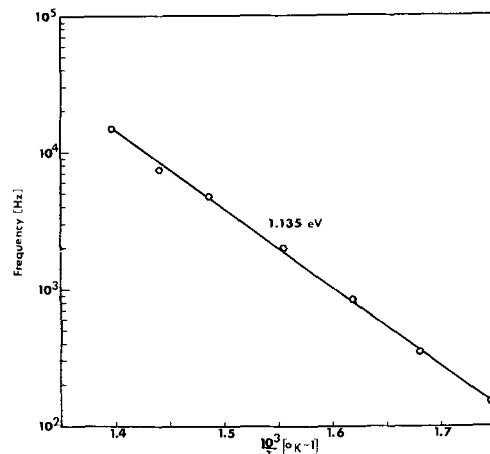

Fig. 2. Loss peak frequency as a function of reciprocal temperature (Arrhenius plot).

tangent at lower frequencies as is evident from Fig. 1, points to the existence of another well-separated dispersion region which is beyond the available frequency range. Second, the arc of the Cole-Cole diagram is displaced downward. A polydispersion with several closely distributed relaxation times (12) would explain the phenomena. It is widely accepted that the dielectric constant can be expressed, in this case, as

$$\epsilon(\omega) - \epsilon_\infty = \frac{\epsilon_0 - \epsilon_\infty}{1 + (i\omega\tau)^\beta}$$

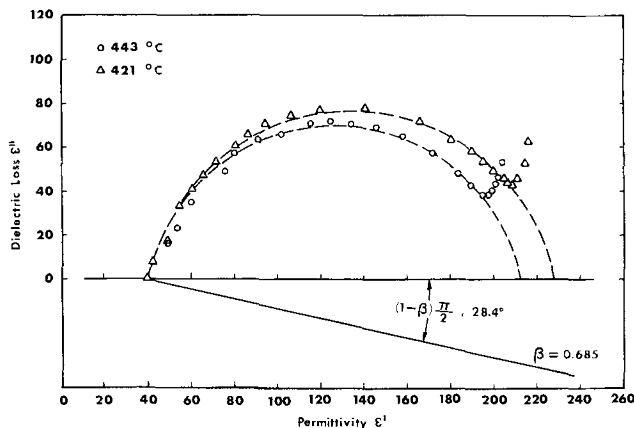

Fig. 3. Cole-Cole diagram for niobium oxide with aluminum and silicon (0.0014-0.0026 ohm-cm p-type) electrodes at 443° and 421°C.

where β represents a measure of deviation from the mono-disperse system, and its meaning is shown in Fig. 3; and ϵ_0 and ϵ_x are the values of permittivity at zero and infinite frequencies, respectively. The value of β was determined to be 0.685.

MOS capacitance and effective surface charges.— The capacitance-voltage curves of MOS structures shown in Fig. 4 are typical ones representing niobium oxide as sputtered in a pure oxygen atmosphere at power densities of 0.32, 0.80, and 1.25 W/cm^2, respectively, as well as the 800°C annealed specimens. The film thickness for the respective sample is tabulated in Table I. These curves indicate that the total surface charge, as measured from the flat-band voltage of the C-V characteristics, increases with sputtering power density. Similar observations of the deterioration of the silicon surface properties in using high power densities were also reported by Hu and Gregor (13) and Salama (14). The measured dielectric constant of the sputtered niobium oxide appears to increase with sputtering power density, ranging from 18 at a power density of 0.32 W/cm^2 to 33 at 0.8 W/cm^2 and to 58 at 1.25 W/cm^2. Low film density related to low power density has been reported (13, 14). However, densification by a factor of 3 is unlikely, and the low dielectric constant observed at low power densities may arise from compositional difference.

The typical C-V curves of C_2HCl_3/O_2, He, and O_2 annealed samples are also shown in Fig. 4. These were annealed from the samples sputtered at the power density of 0.80 W/cm^2. It is seen that these annealed samples exhibit a steeper slope in their C-V curves. This reveals, therefore, that the annealing effect has

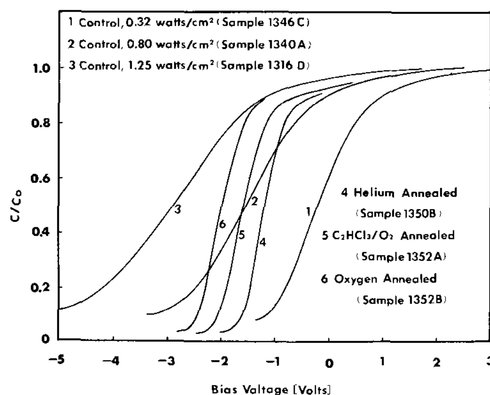

Fig. 4. Experimental MOS C-V characteristics of rf sputtered niobium oxide measured at 300°K and 1 MHz. The substrates are (111) oriented epitaxial n-type silicon wafers of 10 ohm-cm resistivity. Annealing was performed at 800°C for 2 hr from the samples sputtered at the power density of 0.80 W/cm^2.

1346D	$(8.55\text{-}10.0) \times 10^{11}$	3850	0.80	Control
1340B	$(1.02\text{-}1.18) \times 10^{12}$	3480	0.80	Annealed in C_2HCl_3/O_2
1352A	$(1.75\text{-}1.81) \times 10^{12}$	5830	0.80	Annealed in C_2HCl_3/O_2
1350B	$(1.75\text{-}1.84) \times 10^{12}$	4050	0.80	Annealed in He
1352B	$(2.77\text{-}2.82) \times 10^{12}$	5830	0.80	Annealed in O_2

reduced the fast interface states. The dielectric constants as obtained from their MOS capacitance measurements were 120, 93, and 143 for the C_2HCl_3/O_2, He, and O_2 annealed samples, respectively. The drastic increase in the dielectric constant is not understood. Values of the dielectric constant around 120 have been reported for the H-modification, polycrystalline films of Nb_2O_5 (5). Investigation of the pre- and post-annealed samples, using a scanning electron beam microscope with 15,000X and 30,000X magnification, clearly showed different patterns. The unannealed samples showed a smooth, amorphous-like surface, while the annealed samples revealed clear crystalline structure. However, x-ray diffraction pattern analysis indicated that for both samples crystalline phases are deposited, and both patterns are identical. Unfortunately, positive identification was not possible with available ASTM[1] data.

The effective oxide surface charge density for the various oxide specimens was evaluated from the flat-band voltage. The results are tabulated in Table I. These data were obtained from at least five randomly selected samples in each case. It is seen that the as-sputtered films have a larger dispersed distribution of their effective surface charge than those of the annealed films. On the other hand, the annealed films have a little higher effective surface charge density.

Ionic instabilities.—The films, as deposited and unannealed, exhibited a high degree of ionic instability even at room temperature. In order to investigate the fast ionic movement under applied bias, a 60 Hz sine wave voltage was used to sweep the device voltage, and the C-V curve was displayed on the oscilloscope. After the initial curve was obtained, the sweeping voltage was then turned off, and a d-c bias was applied to the device for a predetermined period of time. The d-c bias was then removed, and the sweeping voltage was applied to generate the C-V curve, which was displayed on the oscilloscope and a picture taken. The above process was quickly manipulated in a few seconds in order to minimize any recovery effect. Figure 5(a) and (b) are pictures showing the shifting of the C-V curves under positive and negative bias stress, respectively. The film exhibits more negative flat-band voltage after positive stress and more positive flat-band voltage after negative stress. This depicts the movements typical of ionic migration in the oxide and also clearly indicates the presence of a fairly large negative charge density in the layer (15). Similar phenomena of ionic instabilities were reported in pyrolytically deposited SiO_2 films (16). After 2 hr of stress, the rapid charge movements were further detected by short-circuiting the devices. Figure 5(c) and (d) shows the results, indicative of a highly mobile charge species. This high mobility of charge species has caused some difficulty in the recording of the C-V curves because of the disturbance of the 60 Hz sweeping voltage, particularly when the flat-band

[1] American Society for Testing and Materials, 1916 Race St., Philadelphia, Pennsylvania.

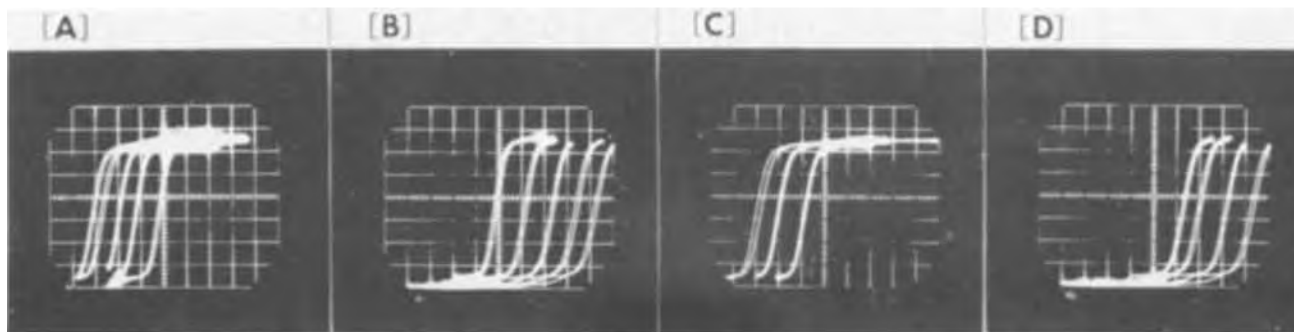

Fig. 5. Capacitance vs. voltage curves for unannealed devices showing rapid charge movement after bias at room temperature. Applied voltages are represented by the horizontal axis, 4 V/division. The numbers stated below in each case correspond to the curves from left to right in sequence in each picture. The double line in each curve results from the hysteresis. (a) +5V stress: 120, 60, 25, 9, and 0 min, respectively. (b) −5V stress: 0, 9, 25, 60, and 120 min, respectively. (c) Rapid charge movement after stress in (a): initial, 4, and 25 min. (d) Rapid charge movement after stress in (b): 120, 50, and 9 min and the initial curve.

voltage had shifted to a nearly saturated value after hours of stress. Superimposing the sweeping voltage on the d-c bias voltage, however, slows down and reduces the flat-band movement, because the positive and the negative half cycles of the sine wave do not produce the same effect during the process of bias stress.

Figure 6 depicts the dependence of the excess charges induced in the silicon ($Q_s = C_0\Delta V$) on the time of polarization at -1.5×10^5 V/cm bias as well as the time dependence of the recovery charge drift when the devices were short-circuited after hours of negative bias. It is seen that the number of the negative charges and their mobility increase with decreasing power density. It also shows that during both bias and recovery driftings, the Q_s is proportional to $t^{1/2}$ at some initial period, and then approaches a saturation value, similar to sodium ionic transport phenomena in insulating films (15). The presence of the negative ionic species is believed to be partly due to oxygen ions which are generated in oxygen glow discharges, and partly due to the drive in of energetic species of unknown origin under the influence of the anode field. When the oxide is deposited under low power density, the discharge voltage level is correspondingly low. There are more low-energy slow electrons in the plasma which favor the electron attachment process when they collide with oxygen molecules. The process in which O^- ions are formed through $O_2 + e \rightarrow O^- + O$ has been studied by Lozier (17), Hagstrum (18), Craggs *et al* (19), and Chanin *et al.* (20). The negative oxygen ions may diffuse through the plasma and be adsorbed on the substrate and the deposited oxide layer. The presence of the negative oxygen ions has been reported by Wu and Formigoni (21) and Chen (22) in low-voltage, high-pressure d-c sputtering conditions.

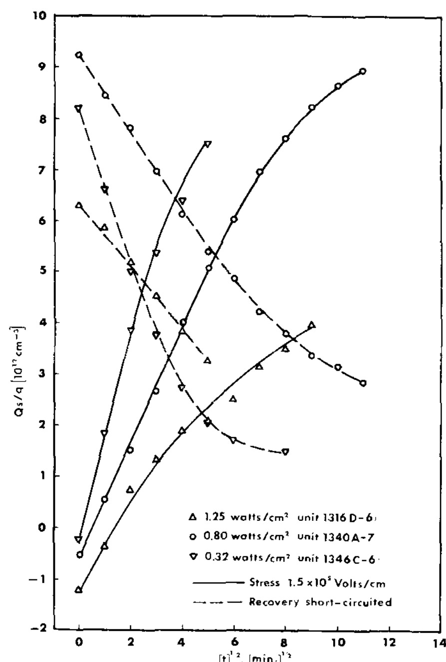

Fig. 6. Dependence of the excess charges induced in the silicon on the time of polarization at room temperature for the rf sputtered niobium oxide MOS devices under $-1.5\text{x}10^5$ V/cm stress, as well as the time dependence of the recovery charge drift when the devices were short-circuited after hours of the negative bias. Niobium oxides sputtered in three different power densities are shown.

Annealing effects.—All annealing was carried out at 800°C and shows prominent effects on the ionic instabilities. The specimens annealed in the helium and oxygen atmospheres show essentially the same characteristics: the devices are quite stable under negative bias-temperature (BT) stress, however, the positive bias stress still reveals a great amount of instability. On the other hand, the C_2HCl_3/O_2 annealed samples show a quite stable feature in response to both positive and negative BT stress.

Figure 7 shows the C-V curves of oxygen-annealed specimens under successive stressing conditions as well as the recovery movement. No practical instability was observed under negative BT stress up to 200°C. Although the stress at 300°C made the curve shift a small amount in the negative direction along the voltage axis, this is due to carrier-injection-extraction mechanism (21-28) and is not due to ionic migration. Under positive bias, rapid ionic migration still occurs at room temperature, and a test at 100°C showed a substantial increase of mobility of the ionic species.

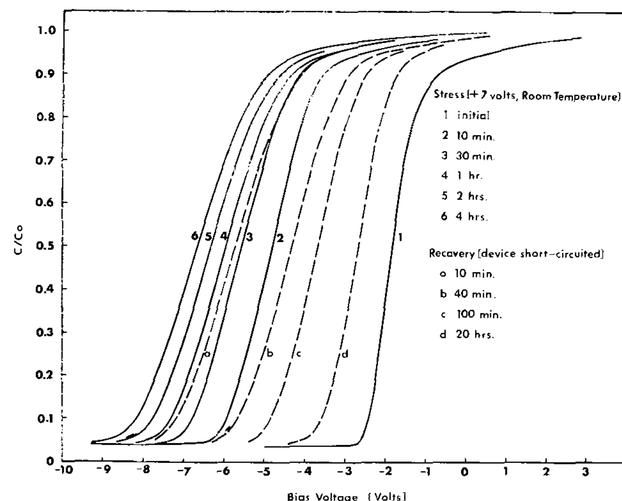

Fig. 7. MOS C-V characteristics of oxygen-annealed sample under successive positive bias at room temperature, as well as the recovery movement.

The total amount of oxide surface charges determined from the saturated flat-band voltage shift is about the same as those of the unannealed sample. From this observation, it is evident that the negative ions have essentially been eliminated through some kind of reaction at elevated temperatures. It also implies that the positive ions are distributed in a region near the metal-oxide interface. The positive ions are believed to be charged alkali ions, most likely sodium ions, which contribute to the instability under positive bias and are obviously unaffected by heat-treatment. The existence of the positively charged oxygen vacancies, produced by the reaction of aluminum with SiO_2 at the metal-oxide interface, was proposed by Thomas and Young (29). However, it is unlikely the oxygen vacancies will apply to our case, which is contrary to the assumption that oxygen inhibits vacancy formations (29). Careful examination in Fig. 7 also reveals an instability characterized by a change in slope of the C-V curve. However, it is seen mostly recovered when the C-V curve shifts back toward its original prestressed position. Hofstein (23) has reported a similar phenomenon and pointed to the generation of donor-type fast interface states as the source. However, for a clear understanding of the present reported phenomena, further investigation should be pursued.

The specimens which were annealed in C_2HCl_3/O_2 atmosphere, show the elimination of mobile ionic species in the oxide. The results of the BT test are shown in Fig. 8 which depicts the flat-band voltage *vs.* temperature with the gate stressing voltage as the parameter. The BT stress was carried out at a given bias and temperature for 30 min, and then cooled to room temperature before the C-V curves were taken. It is seen that the positive bias results in a shift of flat-band voltage in the positive direction along the voltage axis, while the negative bias results in a shifting in the negative direction. Unlike the ionic migration, prolonged short-circuit and high-temperature treatment of the devices showed only little or no recovery of the shifted C-V curves. This is a clear indication of the electron injection-extraction mechanism (21-28). This slow trapping instability was found to be thermally activated (23). The phenomena shown in Fig. 8 is, therefore, to be expected because of the decreasing slow-trapping time constant at higher temperatures, similar to those observed in the Al_2O_3 MOS structure (22). It is not known whether the slow trapping instability is present in the unannealed sample. The ionic-type instability of the corresponding unannealed sample is so large that it makes the observation of the small slow trapping instability infeasible.

The removal of the positive ionic species from the oxide by the introduction of C_2HCl_3 vapor might be expected. It is believed that the pyrolytic product, chlorine, acts as a gettering agent for sodium and other ionic contaminants during the annealing process. Presumably the chlorine reacts with the metallic ions to form volatile chlorides which are removed as a gas (10, 30). Comparison of the results obtained on

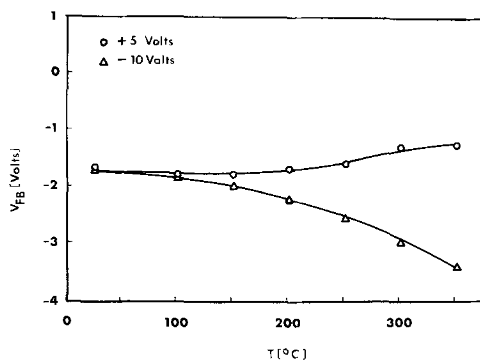

Fig. 8. Flat-band voltage *vs.* temperature with gate voltage as parameter for the C_2HCl_3/O_2 annealed samples.

thermally grown SiO_2 oxide prepared in C_2HCl_3 and CCl_4 gettering processes indicated that the chlorine is responsible for the gettering of metallic ions, while the presence of hydrogen catalyzes the gettering process as well as annealing out some fixed oxide surface charges (31). Further effort, however, is required to clarify this point.

As shown in Table I, the annealed samples show higher effective surface charge density than those of their corresponding unannealed samples. Among the annealed samples, the C_2HCl_3/O_2 annealed sample shows a little less effective surface charge density than the O_2 annealed specimen. These observations should be understandable because elimination of the negative ions in the oxide layer by annealing treatment implies the increase of the effective positive surface charges. This charge density is further reduced with the elimination of the positive ionic species through the C_2HCl_3/O_2 annealing process.

Summary and Conclusions

The niobium oxide films prepared by rf sputtering in an oxygen atmosphere are observed to be polycrystalline. The oxide films display a polydispersion of relaxation time. A drastic increase in the effective dielectric constant of the oxide films was observed after annealing treatment, but the mechanism is not known.

The unannealed films exhibited the effects of rapid charge movement at room temperature, indicative of both positive and negative ionic charges in the oxide layer. The negative charges are believed to be partly due to oxygen ions generated in oxygen glow discharges, and all of them can be eliminated by annealing treatment in helium or oxygen atmosphere. The positive charges are likely to be sodium ions which can be gettered during the oxygen annealing process by the inclusion of a small amount of trichloroethylene. Although the effective surface charge densities for the pre- and post-annealed samples do not reveal any remarkable difference, the various annealing treatments do reduce the interface states. A small amount of carrier injection-trapping polarization effect is present in the trichloroethylene-processed niobium oxide MOS structures which are essentially free from ionic instability.

Thermally Stimulated Currents and Voltages and Dielectric Properties

Martin M. Perlman

Department of Physics, Collège militaire royal de Saint-Jean, Saint-Jean, Québec, Canada

ABSTRACT

Experimental techniques for charging and observing thermally stimulated currents and voltages (TSC and TSV) in polymers and crystals are described and an outline is given of the theory of the processes. The polymers are corona charged, and trapping takes place near one surface. In an attempt to determine the microscopic nature of the traps, a study is made of a polyolefin series of ten polymers. Charge storage is shown to take place mainly along the chains themselves and through caging between neighboring molecules. In addition, the corona itself may produce changes in the polymers to create primary trapping sites. Charge storage stability is a function of electronegativity of the ions, symmetry along the chains, and packing density. The crystal work consists of a study of impurity-vacancy (I-V) dipoles in doped alkali halides, such as KCl: Sm^{++}, Eu^{++}, Yb^{++}, and Ca^{++}. The dipoles are field polarized. Analysis of the thermally stimulated dipolar peaks yields relaxation times, activation energies, and dipole concentrations. Other I-V dipole phenomena that may be studied with these techniques are described. A comparison is made between information obtainable from TSC and the more normal dielectric constant-loss tangent measurements, and we conclude that TSC is a valuable aid in the characterization of insulators. These studies also yield information on the basic electrical conduction mechanisms in insulators. The paper concludes with suggestions for further work and practical applications.

In this paper, I am advertising an experimental technique that has not been fully exploited, and am presenting some intriguing possibilities that are offered by thermally stimulated current (TSC) and voltage (TSV) measurements. The over-all purpose is to make clear the processes responsible for dipole polarization and for electron, hole, and ionic trapping in dielectrics, and to determine the parameters associated with these processes: lifetimes and activation energies for dipole polarization and escape probabilities and depths for trapping. Hopefully one may also be able to identify the microscopic nature of the dipoles and traps, and to clarify the electrical conduction mechanism in insulators.

Work on polymers and on single crystals is described, and results obtainable from TSC measurements are compared with those from the more normal dielectric constant, loss tangent, and conduction measurements. Finally, some ideas for future work in this field are presented.

Theory

In this method, a previously charged dielectric is heated at a uniform rate, and the resulting short-circuit current (or open-circuit voltage) is measured as a function of temperature (1). An electrical "spectrum" consisting of a series of peaks (or steps) is obtained.

We (2-4) recently developed a theory to account for the shape of the TSC peaks from materials charged near one surface and thermally stimulated in the absence of any external field. The result is given in Eq. [1].

$$j = A \exp \left[-E_a/kT - B \int_{T_o}^{T} \exp(-E_a/kT)\, dT \right] \quad [1]$$

Here, j is the externally measured current, T is the absolute temperature, E_a is the trap depth, and A, B, and k are constants. The temperature dependent expression in brackets is identical to that obtained by Bucci (5) for dipolar decay. Equations [2] and [3] give the values of A and B in the two cases

Near surface trapping

$$A = (n_{t_o} e\delta)^2 (\mu\tau)/(2\epsilon d\tau_o), \quad B = 2/(\beta\tau_o) \quad [2]$$

Dipolar decay

$$A = Np^2 E_C/(kT_C \tau_o), \quad B = 1/(\beta\tau_o) \quad [3]$$

Here, N and n_{t_o} are the charge concentrations, $(\mu\tau)$ the

Key words: thermally stimulated currents, nature of charge traps in polymers and dipoles in crystals, characterization of insulators.

charge mobility-free lifetime product, δ the depth of penetration of charge, τ_0 the inverse of the trap escape frequency, p the dipole moment, E_C and T_C the polarizing field and temperature, and the other quantities have their usual meaning (2-4).

Equation [1] can be written in the form of Eq. [4]

$$\ln\left[\left(\int_t^\infty j dt\right) \Big/ j\right] = \ln \tau = \ln \tau_0 + E_a/kT \quad [4]$$

Thus the parameters E_a and τ_0 may be determined from a straight line semilog plot of the remaining charge divided by the current at a particular temperature *vs.* the inverse of that temperature. Alternatively, these parameters may be determined from the low-temperature tail of Eq. [1] using

$$\ln j \doteq \ln A - E_a/kT \quad [5]$$

(The use of Eq. [1] assumes monomolecular kinetics, Eq. [5] gives the parameters independent of any assumptions as to kinetics, provided that a particular E_a has been isolated in cases where there are multi-energy levels.)

Equations [6] and [7] (6) are used to determine n_{t_0}, $\mu\tau$, and δ

$$n_{t_0} = (Q/e\delta S)(2d/\delta); \; (\mu\tau) = \epsilon(\delta/d)(\delta S/Q) \quad [6]$$

$$\delta = 2d(Q/S)/(\sigma + Q/S) \quad [7]$$

Here d, S, and ϵ are the surface area, thickness, and dielectric constant of the sample, respectively, Q is the total released charge, and σ is the externally measured charge density prior to warming.

Experimental

Thermally stimulated current spectra obtained from corona-charged Mylar and FEP Teflon have previously been published (2, 4). There are many TSC peaks and the spectra are complex. Typical thermally stimulated voltages [or net surface charge decays measured using the vibrating electrode technique (7)] obtained from corona-charged polystyrene, polypropylene, and medium- and high-density polyethylene are shown in Fig. 1. Note the TSV steps. (TSV in general shows less detail than TSC; one does not always obtain a stepwise decrease for each corresponding TSC peak.) The spectra require a cleaning technique to separate the individual peaks (or steps). Briefly, the sample is partially discharged by heating to a temperature just beyond that of the first maximum (emptying the low temperature trap), then lowered and raised again just beyond that of the second maximum, etc. Appropriate normalization and subtraction yields the isolated peaks (8).

Typical fits to a cleaned isolated peak following Eq. [1] and [4] are illustrated in Fig. 7 and 8 of Ref. (8).

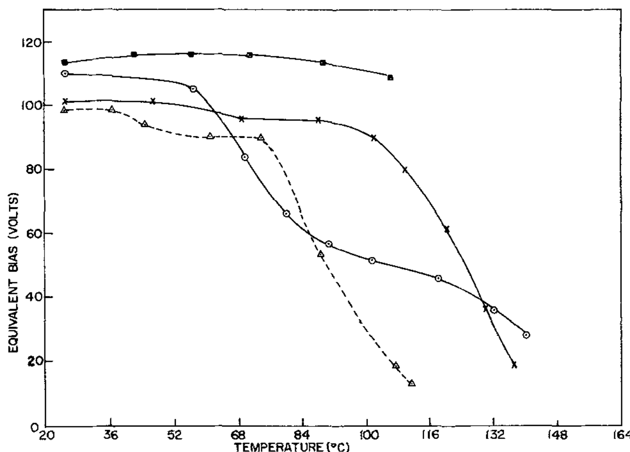

Fig. 1. Thermally stimulated charge decay. □, Polystyrene; ⊙, polypropylene; X, △, polyethylene, high and medium density.

Polytrifluorochloroethylene (PTFCE) "Aclar"	F	F	Cl	F

Polystyrenes with SO_3H end groups, also C filled (16%)
Polyethylenes with different crystallinities; branching

As a further check on the parameters obtained from the isolated peaks, a completely independent method of analysis was used. Here, the sample was heated to a series of temperatures (*e.g.*, 50, 55, 60 . . . °C) each separated by rapid cooling. The low-temperature tail of Eq. [1] is a single exponential as shown in Eq. [5]. Hence Arrhenius plots give the activation energy over the complete temperature range (8). The activation energies obtained from the plateaus in a ln E_a *vs.* T_{max} plot agree well with those determined from the overall fits to the peaks. How well this technique works depends on the number of peaks and the extent of their overlap.

Polymers

Apparatus.—The moving polymer film (~1 mil thick) was corona charged in air, and the net surface charge density immediately monitored, using a vibrating electrode to pick up an a-c signal, and a field-canceling bias to null the received signal (2). The polymer film traversed rollers, metalized side down and grounded, 0.5 mm beneath a knife edge held at −6 kV.

The samples were coated with conducting paint electrodes. Depolarization was carried out in ovens fitted with SCR temperature programers. Heating rates were linear and typically 1°C/min. The apparatus in Fig. 2 enables simultaneous TSC and TSV measurements on two samples. The TSC is automated using a data acquisition system consisting of a multiplexer, analog-digital converter, and interface to a teletype that records current, temperature, time, and scale factor of the electrometer, and punches these values out on paper tape. The paper tape is then converted to cards, and all calculations are performed with the aid of a Control Data 3300 computer.

Results and discussion.—In an attempt to determine the nature of the charge storage traps, we studied the polyolefin series shown in Table I. In addition we used a polystyrene series with end group substitution and

carbon filled, as well as polyethylenes of different crystallinity. A complete paper on this work will be published shortly (9). The results of the TSC measurements and the constants associated with the various traps are shown in Table II. Untrapping occurs at thermal energies of the same order as required by molecular motion or phase transitions in polymer structure. The temperature maximum of some of the peaks correlate well with the known glass transition temperatures (T_g) of the polymers. The bracketed temperatures are those where molecular motion is known to take place from elastic constant measurements.

First of all we should say that the traps are not due to chemical impurities, for the same peaks have been observed in a variety of the same materials, supplied by different manufacturers, and also made from resin into film.

Charge storage in polymers can take place on three structural levels: the so-called primary, secondary, and tertiary levels. At the primary level, the traps are on the molecular chains themselves, the charge is stored at atomic sites. At the secondary level, electrons can become caged within groups of atoms in neighboring molecules and are held there due to the charge affinity of these groups. To release charge at the primary level requires individual atomic motions, while at the secondary level it is dependent on the motion of groups of atoms. At the tertiary level, charge may be stored in both crystalline and amorphous regions of the polymer, or at boundaries (1). Charge release in this case depends on main chain motion.

Table III lists the polymers in order of decreasing charge stability together with the temperature at which the externally measured charge vanishes in a thermally stimulated charge decay measurement. From this table we may conclude the following.

Charge storage stability at the primary level, *i.e.*, along the molecular chains, is determined by both the electronegativity of the ions and symmetry along the chains. In the first four polymers listed, the fluorine, hydrogen, phenyl, and methyl groups are in order of decreasing electronegativity. Since chlorine has an electronegativity between that of F and H one might expect that Aclar in which one Cl has been substituted for a Teflon F might lie between Teflon and polyethylene. Instead it lies fifth in the table. Here we feel

Table III. Charge stability

	Polymer	Symbol	Link	T ($\sigma = 0$) °C
1	Polytetrafluoroethylene	PTFE	$—CF_2—CF_2—$	230
2	Polyethylene (high density)	PE(HD)	$—CH_2—CH_2—$	145
3	Polystyrene	PS	$—CH_2—CH(\phi)—$	130
4	Polypropylene	PP	$—CH_2—CH(CH_3)—$	130
5	Aclar	AC	$—CF_2—CFCl—$	125
6	Polyethylene (medium density)	PE(MD)	$—CH_2—CH_2—$	115
7	Chlorinated polyvinyl chloride	Cl/PVCl	$—CHCl—CHCl—$	90
8	Polyvinylidene fluoride	PVF_2	$—CH_2—CF_2—$	85
9	Polyvinyl chloride	PVCl	$—CH_2—CHCl—$	55
10	Polyvinyl fluoride	PVF	$—CH_2—CHF—$	35

that the relatively large C-Cl bond (1.63Å compared with 1.06Å for C-H and 1.33Å for C-F) introduces a distortion in the symmetry along the chains that makes for poorer charge stability. The same thing happens on comparing PVCl and PE where one Cl has been substituted for an H.

Similarly substituted fluorine and chlorine polyolefins have similar electret charge stability. A single substitution of a fluorine or chlorine atom for hydrogen in PE (PVF and PVCl) produces a poor charge storer. A second substitution (PVF_2 and Cl/PVCl) produces greater storage stability. Complete substitution in the case of PTFE produces a very stable electret. Disturbing the symmetry by substitution of the trifluoromethyl group (PFEP) in PTFE and the methyl group (PP) in PE also reduces charge stability.

Charge storage stability at the secondary level, *i.e.* caging between neighboring molecules, is better the higher the packing density and the lower the branching. Teflon of highest packing density heads the table and high density (HD) PE is much better than MD which is in turn better than LD.

PS with a sulfonic end group (SO_3H) proved to be as stable as PS, and no additional traps were evident in the TSC spectra. PS and Mylar, both of which contain the phenyl group have almost identical TSC spectra. PE of high crystallinity (HC) is much more stable than PE of low crystallinity (LC). The high-temperature TSC peak at ~100°C in HC does not appear in LC. We attribute this to a loss of the charge storage site at the chain folds as the chains unfold in going from HC to LC. We made an attempt to determine the effect of charge storage at interfaces by doping PS with carbon but were unable to charge the material. The film was highly conductive and arced through under the corona.

While the above provide a fairly consistent picture of the observed phenomena, other possibilities should not be overlooked. The corona itself may produce changes in the polymer to create primary trapping sites.

All films were negatively corona charged. Negative ions are most probably trapped within some tens of monolayers at the polymer surface. The ion may combine chemically with the polymer or it may transfer an electron to the polymer. Depth of penetration measurements were made using the capacitance *vs.* frequency technique, described by Badian *et al.* (10). Estimates could also be obtained from Eq. [7]. Our experiments show that the charge penetrates to a depth of about 5% of the film thickness, assuming that the spatial distribution is uniform. Thus the "transferred" or "free" electrons can be trapped *within* the bulk, as well as at the surface.

It has been established that at least two chemical changes take place in the surface layer of a polymer exposed to a corona in air (11, 12). One is the formation of double bonds ($>C=C<$), and the other is the chemical combination of oxygen to form a carbonyl group ($>C=O$). These are present in densities as great as or greater than the charge density formed in the polymer. The double bonding (unsaturation) occurs before the reaction with oxygen (can also be O^-, O_3, etc.) (13). The electrons or ultraviolet light in

the corona can initially break the carbon-carbon bond, and supply enough energy for the H-atom rearrangement necessary in the $\gtrsim C{=}C \lesssim$ bond formation. It is then very easy, but at the surface only, to have a reaction with oxygen occur. Charge storage at the primary level might then take place on the double bond and carbonyl groups (13).

Electron trapping on molecular oxygen that has diffused in from the atmosphere is another possibility, as previously found in thermoluminescence measurements on polyethylene by Partridge (14), and more recently by Bousted (15).

The untrapping of charge may be a dual process that arises from both a lowering of trap depth with molecular motion plus thermal excitation of the charge out of the trap. Since charge release in these polymers is so intimately connected with molecular motion, it may be that some of the activation energies mentioned are not those due to charge affinity of various atoms, or groups of atoms, but rather are to be associated with molecular vibration and rotation.

Crystals

Apparatus.—We are at present also growing alkali halide crystals such as KCl by pulling from the melt using the Czochralski technique. KCl powder (mixed with dopant) sits in a porcelain crucible and is melted in a furnace. A seed is attached to a chuck which is simultaneously rotated and pulled from the melt at about ¼ in./hr. The crystals are grown in an Argon gas atmosphere, and provision is made for water cooling the various parts of the furnace. A temperature controller is used to lower the temperature slowly enough to avoid rapid surface crystallization of the melt. We have successfully grown crystals of pure KCl and KCl doped with Ca^{++}, Sm^{++}, Eu^{++}, and Yb^{++}.

A typical cryostat that enables one to charge using fields, as well as irradiate with electrons, or ultraviolet light, is shown in Fig. 3.

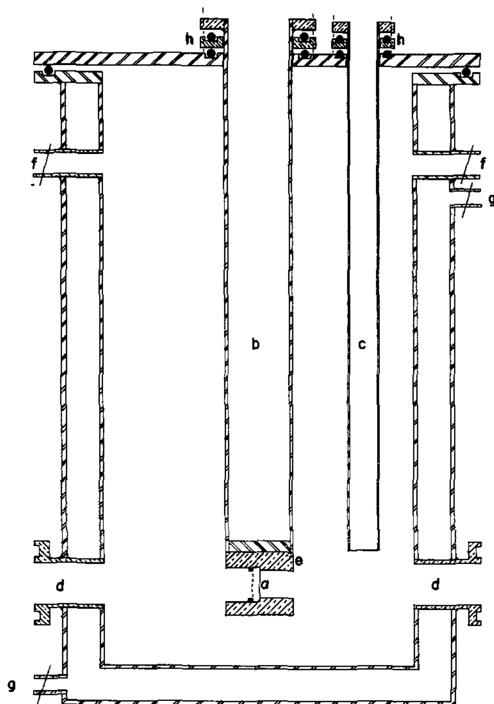

Fig. 3. Stainless steel cryostat. a, Crystal; b, liquid nitrogen and heater finger; c, liquid N_2 trap; d, ports for uv or electron irradiation; e, copper block; f, ports for vacuum or inert gas; g, ports for water; h, heat insulation.

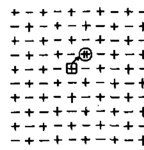

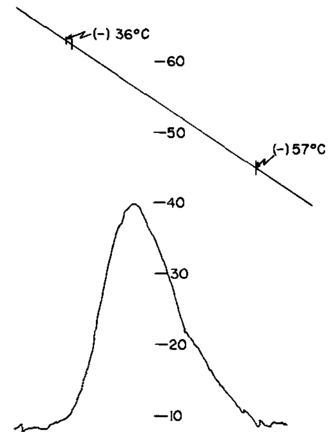

Fig. 4. Divalent impurity and associated positive ion vacancy in a fcc alkali halide. The dipole moment (arrow) is along a (100) direction. KCl: Sm^{++}; $N = 4 \times 10^{16}/cm^3$, $\beta = 6°/min$, $Ep = 11.8$ kV/cm, $T_{max} = -47°C$, $\tau_0 = 1.5 \times 10^{-14}$ sec, $E_a = 0.70$ eV.

Results and Discussion.—If during the growth of an alkali halide crystal from the melt, one dopes with doubly charged divalent ions (such as Sm^{++}), (*e.g.*, adding $SmCl_2$ to KCl) the divalent ion enters the lattice substitutionally (for K^+). To preserve charge neutrality, another positive ion must leave the lattice. The most likely place for this to occur is in the neighborhood of the impurity, thus forming a system of impurity-vacancy (I-V) dipoles, as in Fig. 4.

If one polarizes these dipoles by applying an external field to the crystal at a particular temperature, lowers the temperature with the field still applied, removes the field, and warms the crystal, one obtains a peak in the measured external current as a function of temperature. This is the so-called ITC or ionic thermal current peak (5). A typical recorder trace (KCl:Sm^{++}) is shown in Fig. 4.

Here, the polarizing field was 11.8 kV/cm, the heating rate during thermal stimulation, 6°C/min, and the temperature maximum at which the peak appeared, −47°C. Note the extremely low dipolar concentration. One can in fact detect currents a factor of 10 lower than this, *i.e.*, detect impurities to 1 part in 10^8.

Figure 5 shows overlapping Ca^{++}, and Sm^{++} I-V dipole peaks. The calcium is an unwanted impurity that is present in any inexpensive reagent powder, such as those supplied by Baker and Fisher. It is made

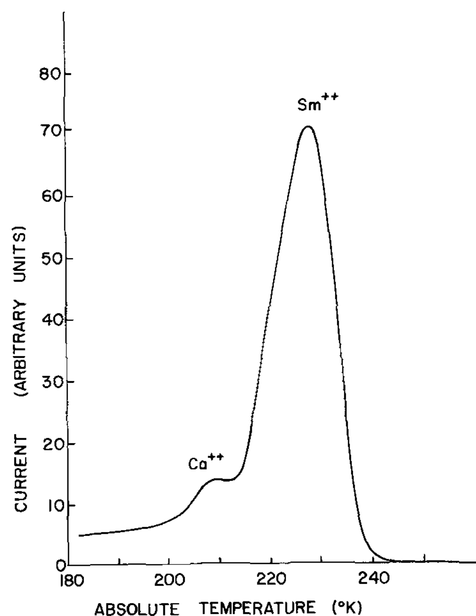

Fig. 5. Overlapping Ca^{++} and Sm^{++} I-V dipole peaks

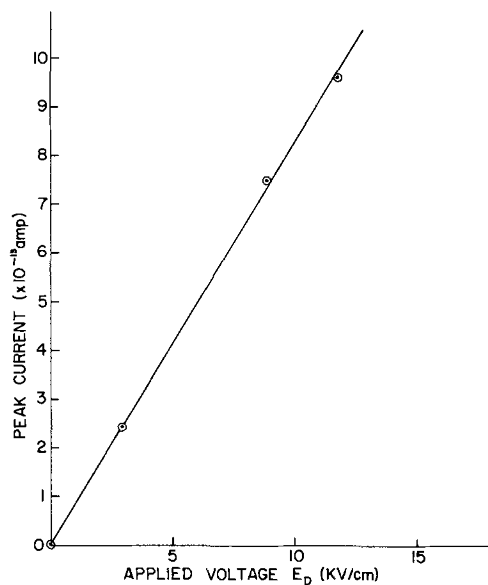

Fig. 6. Current maximum as a function of polarizing field for KCl:Sm^{++}.

negligible (relative to the Sm^{++} peak) by waiting a few days for the dipoles to aggregate (see ahead).

The theory of the dipolar peaks is summarized by Eq. [1] and [3]. Equation [3] shows that the current maximum should be a linear function of applied field if we are dealing with a dipolar phenomenon, and not, *e.g.*, space charge. Accordingly, we first measured the current maximum as a function of polarizing field. A linear relationship identified the peaks as dipolar. A typical example for KCl: Sm^{++} is given in Fig. 6.

The activation energies and the relaxation times for dipolar relaxation were determined with the aid of a computer, by the initial rise (Eq. [5]), Bucci (5) (Eq. [4]), and Cowell and Woods (2, 16) techniques and are listed in Table IV. The activation energy for KCl: Ca^{++} is a bit larger than that determined by Chiba *et al.* (17) (0.66 eV), from dielectric absorption measurements. The constants for KCl: Sm^{++}, KCl: Eu^{++}, and KCl: Yb^{++} have not been previously measured. Table IV also lists values for KCl: Be^{++}, Sr^{++}, and Cd^{++} for comparison purposes. The activation energy can be associated microscopically with one or more of the following processes: the barrier to rotation of the vacancy around the impurity, impurity-vacancy interchange, movement of the vacancy from nearest neighbor positions to next nearest neighbor, or vice versa (18).

We have a particular interest in rare-earth doped alkali halides using Sm^{++}, Eu^{++}, and Yb^{++} for it turns out that these doubly valent ions can be made singly valent by irradiation with x-rays, and that the reaction is reversible under annealing or irradiation

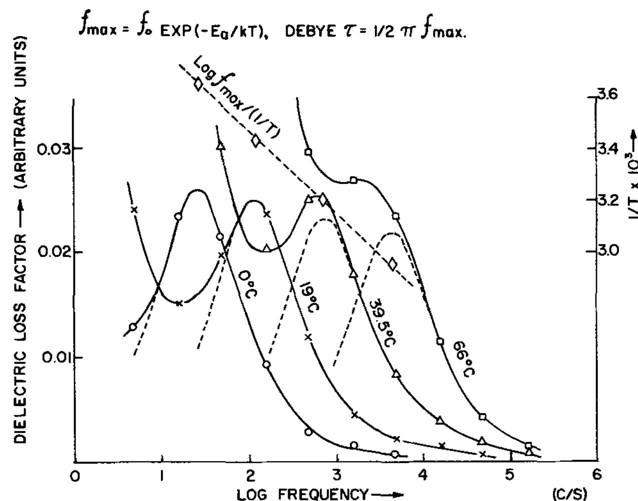

Fig. 7. Dielectric absorption at various temperatures for sodium bromide with calcium impurity.

with uv. Thus the electret can be switched on and off, with possible application to memory elements.

The thermal current method used on single crystals allows one to investigate the production, concentration, and motion of defects in solids. The I-V dipoles diffuse to form higher aggregates (often trimers) of negligible dipole moment. Qualitative aggregation rates for the various dipoles are given in Table IV. If one anneals the crystals at fixed temperatures for increasing times, and measures the decreasing released polarization charge on warming, the kinetics of the aggregation, and the activation energy for defect motion, can be determined. One can even study chemical reactions taking place in a solid matrix. If one dopes KCl, for example, with both Ca and OH, the precipitation of $Ca(OH)_2$ in the solid matrix can be followed (19), because it leads to dipole destruction that is measurable with ITC.

Since impurities can be identified with enormous sensitivity (compared with other methods of analysis such as E.P.R.), we expect that the method will eventually be used commercially for this purpose. Very little work has as yet been carried out using ITC.

TSC vs. tan δ, ε′ Measurements

For many years now, people have been characterizing insulators by measuring dielectric constant (ϵ') and loss tangent (tan δ) as a function of frequency (f) and temperature (T). A typical example is shown in Fig. 7. One usually measures tan δ *vs.* f at a series of temperatures, and then makes an Arrhenius plot of ln f max *vs.* $1/T$ from which the activation energy E_a, f_o, and the Debye relaxation time τ for a single relaxation process, may be determined. While much valuable information has been obtained, the latter suffers from two inherent disadvantages. If more than one relaxation process is present in a dielectric, this manifests

Table IV. Dipole parameters for KCl:X^{++}*

	m	r, A	T_M, °K	E, eV	τ_o, sec	R

* Legend: m = atomic weight, r = ionic radius, T_M = temperature maximum of peak, E = activation energy, τ_o = inverse of jumping probability, R = qualitative aggregation rate at room temperature, † = X^{+++}, a = this work, b = Bucci (5), c = Capelletti (24).

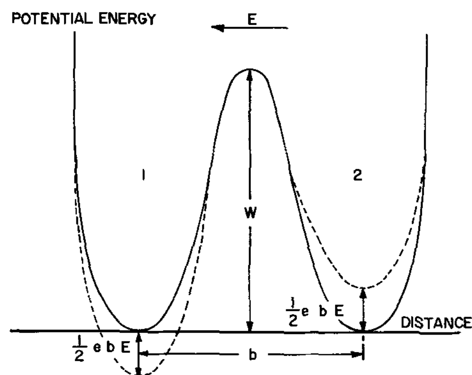

Fig. 8. Bistable model. Debye equations

$$\epsilon' = \epsilon_\infty + \frac{(\epsilon_S - \epsilon_\infty)}{1 + \omega^2\tau^2}, \epsilon'' = \frac{(\epsilon_S - \epsilon_\infty)\omega\tau}{1 + \omega^2\tau^2}, \tan\delta = \epsilon''/\epsilon'.$$

TSC gives Debye τ and Np^2/kTc. Here, $(\epsilon_S - \epsilon_\infty)/4\pi = Np^2/kTc$, ϵ_∞ from $P(O) = (\epsilon_\infty - 1)E/4\pi$. ϵ', ϵ'', $\tan\delta$ then determined.

itself as a broadening in the Debye curve ($\tan\delta$ *vs.* frequency). In addition, the dipole orientation losses usually occur on top of a background loss due to conductivity. Thus it is very difficult (usually impossible) to sort out the individual relaxation processes.

We feel that TSC measurements (without external bias) provide a better characterization of insulators than ϵ', $\tan\delta$ measurements. They produce a peak for each relaxation process, and conductivity does not interfere. If there is an overlap of a few peaks, they may be easily separated. In addition, very small dipole concentrations can be detected. ($\sim 10^2$-10^3 times more sensitive than loss measurements). This should effectively mean that we can measure very low $\tan\delta$'s, *i.e.*, those associated with bond moments and the motion of small chain segments.

Indeed ϵ' and $\tan\delta$ may be determined by combining TSC measurements with d-c response. The Debye equations together with the constants obtainable from TSC measurements are shown in Fig. 8. Also illustrated is the bistable model in which the dipole has two equivalent positions 180° apart. The application of an electric field E modifies the depth of the potential wells so that with the field the jump probability from 2 to 1 is greater than that from 1 to 2, and a net polarization results. Using this model, $(\epsilon_S - \epsilon_\infty)$ may be determined from the TSC constant Np^2/kT_c. The Debye τ is also known from TSC. ϵ_∞ may be obtained from the zero time polarization response of the dielectric to an applied step. Thus ϵ', ϵ'', and hence $\tan\delta$ are determined. Our feeling is that all of the old dielectric absorption measurements could profitably be combined with TSC to isolate the microscopic mechanisms.

In order to achieve success with the above technique, one would need a fairly ideal dielectric with a small number of relaxations. The TSC measurements must be made over a temperature range that includes all of the relaxation mechanisms. In many practical dielectrics in which there are multirelaxation processes, it may be impossible to thermally clean and separate the quasi-continuous spectra.

Electrical Conduction Mechanism in Insulators

The thermal current technique offers a key to the comprehension of the fundamental microscopic mechanisms responsible for charge storage and release, such as dipolar phenomena, electron, hole, and ionic traps, space charge, etc. It is these phenomena that govern electrical conduction in dielectrics, for example, since trap hopping is often invoked as a conduction mechanism, a knowledge of trap parameters is desirable. Thus, a study of charge storage yields valuable information about electrical conduction. An understanding of the processes responsible for electrical conduction in dielectrics is of course essential in any and all applications of insulators. Different forms of excitation, *i.e.* charging (such as corona to supply ions, electron, x-ray and ultraviolet irradiation to supply electrons and holes, d-c fields to orient dipoles) may be used on the same dielectric to characterize it electrically as much as possible.

The origin of each of the TSC peaks may be determined by performing current-voltage measurements at a series of fixed temperatures, in addition to TSC. This procedure has recently been followed by Jonscher (20) on thin film silicon oxide. There are four distinct regions of different slope in the I-V curves. An activation energy may be determined for each region from Arrhenius plots of ln I *vs.* $1/T$ at constant V. By comparing these energies with those obtained from initial rise calculations on the TSC peaks of silicon oxide, Jonscher was able to say which of the peaks were ionic, electronic, due to space charge, etc.

Using different forms of excitation and thermally stimulated currents and voltages, studies may be made of the effect on the electrical properties of plastic additives in polymers such as Polythene or PVCl, with a view toward improving the electrical characteristics of these insulators (for use in cables, condensers, breakers, etc.), or toward finding others to replace them. Discharges occurring in insulation provide copious supplies of carriers that are trapped, changing the subsequent insulation resistance and breakdown properties. This phenomenon may also be studied by the proposed methods.

The TSC spectra are unique to the insulators under study. They are fingerprints of them and are sensitive to impurities, additives, discharges, humidity, *i.e.*, to any chemical or morphological change. They provide a sensitive analytical tool that could be used to guide the production of insulators with fixed electrical properties.

We feel that TSC will eventually develop into an electrical spectroscopy and have practical application to electrical quality control.

Future Work

In conclusion, I would like to say a few words about other possible applications of TSC.

In 1967 Sinencio *et al.* (21) irradiated solution-grown orthorhombic S crystals with uv, and found that electron and hole trap filling was confined to the penetration volume of the radiation ("near surface") independent of the application of a bias during irradiation. In other words, carriers were not drawn into the bulk of the specimen by a field applied during irradiation. On the other hand if a bias were applied during subsequent thermal stimulation either carrier (depending on bias polarity) could be drawn from the "near surface" region, and separate electron and hole TSC spectra were obtained. Both electron and hole peaks occurred at $\sim$175°K. To show that these were different, growth curves (*i.e.*, peak height *vs.* filling time) studies were made on the two peaks, and indeed they exhibited different kinetic behavior. More studies of this type are needed.

Recently, Gross (22) examined a number of dielectric models which, although equivalent at constant temperature, were shown to be nonequivalent nonisothermally. He found that if the total released charge was independent of heating rate, the Maxwell model applied, and the TSC measurement was the significant one, for each cleaned peak could then be associated with a single relaxation process. If, on the other hand, the released charge varied with heating rate, the Wagner-Voigt model applied and the TSV measurement was the significant one. Figure 9 shows the TSC and TSV to be expected for the same trap depth.

The processes responsible for conduction in thin (thousand Angstrom) films (such as silicon oxide, tantalum oxide, aluminum oxide) used in integrated

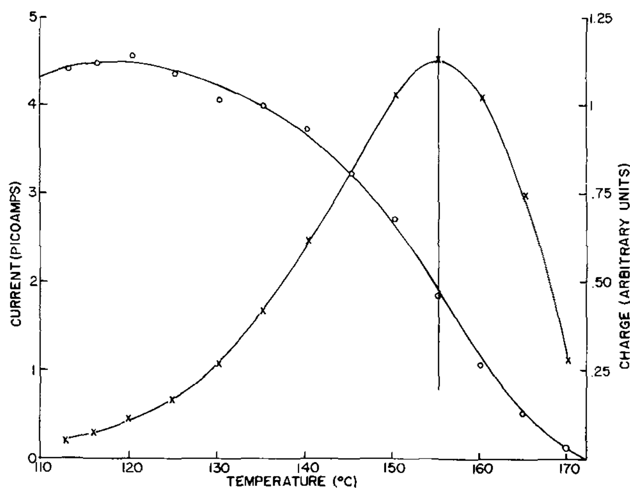

Fig. 9. Thermally stimulated current and charge decay for the same trap depth (FEP Teflon, E_a = 1.36 eV).

circuits are the same as those responsible for conduction in all dielectrics, with the possible addition of tunneling. Thus TSC studies on thin films should prove valuable. Recently, Weisberg and Schade (23) have shown how the use of a Schottky barrier can extend the use of TSC to low-resistivity semiconductors such as silicon. No work has as yet been reported on thermal currents from ferroelectrics, which should be very large.

Some practical applications of this work are the following: There has recently been a need for a high-temperature, radiation resistant plastic to use in cable wrapping. Kapton (a du Pont product) satisfies the first criterion. One measure of the second is whether it is a poor or good charge storer, a question that was easily answered by running a TSC spectrum. There are many practical applications for charge storage devices. We have developed a microphone now marketed by Sony in tape recorders and broadcast mikes, and soon to be used by Bell Canada in the microphones of all telephone handsets. There are two other uses for charged polymers in communications that represent large savings over equipment now in use, but are commercially confidential for the moment. Other possible applications are in air filters, memory elements, high-voltage and a-c generators, motors, meters, radiation dosimeters, precipitators, phono cartridges, relays, voltmeters, electrometers, explosion initiators, vibration transducers, electrostatic lenses, etc.

The Oxidation of Thin Copper Films Condensed in the Presence of Various Residual Gases

Lawrence O. Brockway and Irving M. Adler

Department of Chemistry, The University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

(100) copper films were prepared by vapor deposition in the presence of hydrogen, water, or air in the pressure range from 10^{-8} to 10^{-4} Torr. The films were annealed and oxidized under constant conditions and were examined at various stages by electron microscopy and diffraction. A reproducible decrease in the Cu_2O grain density was observed when hydrogen was the residual gas: a ten-fold increase in p_{H_2}, in the range between 3×10^{-4} to 4×10^{-6} Torr, resulted in a decrease of 6.4×10^6 grains cm^{-2}. The appearance of wide stacking faults in unannealed copper films and the occurrence of $(1\bar{2}1)$ oxide grains also was observed.

Over the past decade several studies have shown that significant variations in the physical properties of thin vapor-deposited metal films can be produced by residual gases present in the film-deposition chamber during film formation. These include observations on electrical resistivity, superconductivity, magnetization, and epitaxy (1-8). No study has appeared on the possible influence of the residual gases on the chemical behavior of vapor-deposited metal films. The present investigation looks at the influence of various gases present during condensation on the texture and oxidation behavior of thin, (100) copper films.

Experimental

Copper was condensed at a rate of about 8 Å/sec to a thickness of about 900Å on single-crystal substrates of sodium chloride held near 340°C. The principal change from previous experiments on copper in this laboratory (9) was a reduction in the residual pressure to 10^{-8} Torr. This allowed backfilling with gases whose effect on the copper film was to be tested as a function of total pressure and composition. The gases used were hydrogen, water, and air with total pressures ranging from 4×10^{-8} to 3×10^{-4} Torr. Gas compositions were determined in each case with a residual gas analyzer.

Annealing was carried out in a glass line containing a heated Vycor section with a stream of hydrogen at 1 atm and 630°C. The film was treated either (*a*) for 10 min while still on the NaCl substrate (substrate-anneal), or (*b*) for 15 min after being removed from the NaCl and mounted on a ⅛ in. diam copper support grid (grid-anneal). For the substrate-annealed films the subsequent exposure to water during the film stripping and mounting was followed by a further treatment in hydrogen (1 atm, 425°C, 10 min) in order to remove oxide formed during the grid-mounting process.

All oxidations were performed under a single set of conditions: 1.0×10^{-3} Torr of oxygen at 525°C for 5 min. Since the conditions for annealing and oxidizing were fixed, variations observed in the oxidized films were attributed to the changes in the gas pressures and compositions during the condensation of the copper.

Observations were made at various stages in the treatment of the films by transmission electron microscopy and diffraction using a Philips EM 75 and a Jeolco 6A microscope. The specimens were examined for the occurrence of stacking faults and dislocations, for the identification of the oxidation products, for the determination of the crystallographic orientation (epitaxy) of both the copper film and the cuprous oxide, and for the average size and separation (or density on the film) of the cuprous oxide grains.

Key words: films, copper, oxidation, epitaxy.

Results

The copper film crystallized in a single orientation having the (100) plane parallel to the film surface (except for an occasional area on some films with the (310) plane extended; the (310) areas amounted to much less than 1% of the total). The unannealed film showed many dislocations and twins (Fig. 1) and a pronounced thickness variation with the appearance of islands separated by narrow canals. Annealing on the substrate at 630°C reduced the thickness variations and eliminated the twins; grid-annealing at 630°C was not as effective. Substrate-annealing always produced the perpendicular network of stacking faults previously reported (9). For the first time we found wide stacking faults in unannealed films but they were very rare; the area of faulted plane was less than that in substrate-annealed films by a factor of 2×10^{-5}.

The structure and texture of the copper films before oxidation were not influenced in any detectable way by changes in the conditions of condensing the copper.

The oxidation experiments were performed on both substrate- and grid-annealed films by immediately following the exposure to hydrogen (in the reduction treatment at 425°C or the annealing treatment at 630°C) with an exposure to oxygen.

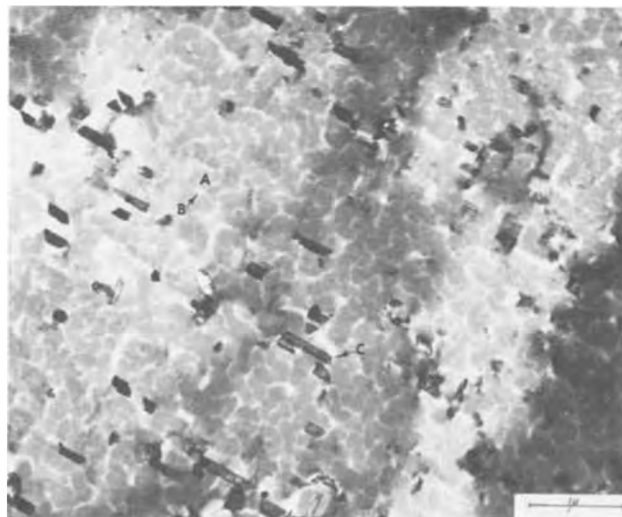

Fig. 1. Electron micrograph of unannealed copper film. The unannealed film contains islands (A) separated by narrow canals (B) and many twin lamellae (C).

Table I. Shapes and epitaxies of Cu_2O grains

Type	Epitaxy
A:	(100)Cu_2O ‖ (100)Cu [110]Cu_2O ‖ [110]Cu
A′:	(100)Cu_2O ‖ (100)Cu [110]Cu_2O ‖ [110]Cu
B:	(110)Cu_2O ‖ (100)Cu [110]Cu_2O ‖ [110]Cu
C:	(111)Cu_2O ‖ (100)Cu [110]Cu_2O ‖ [110]Cu
D:	$(1\bar{2}1)Cu_2O$ ‖ (310)Cu [111]Cu_2O ‖ $[1\bar{3}1]$Cu

Cuprous oxide grains were formed, but in none of the micrographs or diffraction patterns was there any distinction between grains formed on substrate-annealed or grid-annealed films. Five distinct shapes with four epitaxies were observed (Table I); no variations of even a few degrees in the crystallographic orientations were detected in the diffraction patterns. Three of these shapes (A, B, C,) have been observed previously. The D grains (illustrated in Fig. 2) have a $(1\bar{2}1)$ plane of the oxide parallel to the copper and occur only on the (310) areas of copper; accordingly, oxidation of (310) copper yields $(1\bar{2}1)$ cuprous oxide.

In relative abundance the B(110) and C(111) types account for about 98% of all oxide grains, with B somewhat more prevalent in most areas. The A and A′ type, both (100) orientation, make up the remainder with the A type more common. A typical micrograph is given in Fig. 3. No correlation between the occurrence of the different grain types and gas composition during condensation of the copper was observed.

The number of oxide grains appearing on an oxidized film was counted in fifteen to thirty different areas, each representing 6.9×10^{-7} cm^2 (corresponding to the field of view in the electron microscope used). The results are reported as densities in grains cm^{-2} together with the standard deviation from the mean value for the areas measured. The oxide densities observed for the four distinct gas compositions are listed in Table II.

The first four entries represent primarily water at three pressures (1.8×10^{-8}, 3.6×10^{-6}, and 1.2×10^{-5} Torr) and laboratory air (N_2 and O_2) at 3.0×10^{-5}. There is no apparent relation between pressure and oxide density; indeed, the single value of 2.5×10^7 grains cm^{-2} falls within the range of the standard deviations of all four values. Even when the partial pressures of the individual species (H_2O, N_2, O_2, CO_2) were compared with the oxide densities, no correlation appeared.

Fig. 2. Electron micrograph of $(1\bar{2}1)$ oxide grains

Fig. 3. Electron micrograph of substrate-annealed, oxidized copper film. The (100)-type (A), (110)-type (B), and (111)-type (C) grains are all present in this area of the oxidized film.

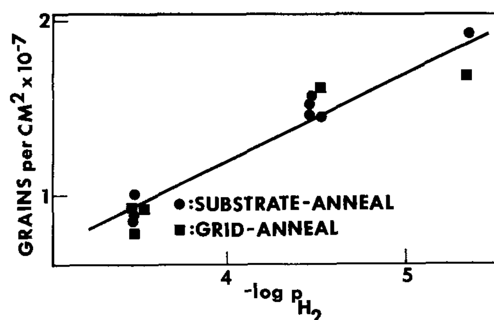

Fig. 4. Influence of hydrogen pressure on oxide density

The case of hydrogen used as a backfill is quite different. The consistency of the results at each pressure used is better; the standard deviations average to less than a sixth of those for the other gases. In addition, the oxide densities change systematically with the hydrogen pressures as shown in Fig. 4, where the individual results for thirteen oxidized films are shown. The line in the figure represents the relation

$$D\ (\text{grains cm}^{-2}) \times 10^{-7} = -0.641 \log p_{H_2} - 1.33$$

in the range of hydrogen pressure from 3×10^{-4} to 4×10^{-6} Torr. It is clear that hydrogen backfilling has a pronounced, reproducible influence on the surface density of Cu_2O grains produced on subsequent oxidation of the copper.

Discussion

The presence of hydrogen during the condensation of the copper onto the NaCl substrate has some effect whereby a tenfold increase in the pressure of hydrogen decreases the density of oxide grains subsequently formed by 6.4×10^6 cm^{-2} or about 20 to 50% in the range studied. We note that during the condensation of copper the substrate surface was bombarded with

Table II. Influence of gas composition on oxide density

Backfill	$-\log p_{avg}$	Major component	Average density (grains cm^{-2}) $\times 10^{-7}$
None	7.321	H_2O	2.55 ± 0.51
Water	5.446	H_2O	3.25 ± 0.79
Water	4.917	H_2O	2.48 ± 0.71
Air	4.523	N_2	2.15 ± 0.55
Hydrogen	5.370	H_2	1.79 ± 0.18
Hydrogen	4.519	H_2	1.55 ± 0.07
Hydrogen	3.503	H_2	0.91 ± 0.08

H_2 molecules at a rate ranging from 0.83 to 63 times the rate of arrival of copper atoms. It is easy to suppose that some of this hydrogen may be retained or trapped interstitially; however, the fact that the disturbing effect of hydrogen persists through either of the annealing treatments, where the copper is exposed to a 10^9 greater pressure of hydrogen at a higher temperature, casts doubt on interstitial trapping as the mechanism for transmitting the influence on the later oxidation. It is true that the total hydrogen bombarding the film during its condensation is 10^6 greater than the saturated concentration at 1 atm and 630°C (10), but the loss by diffusion (11) during the later heating under vacuum would produce a final equilibrium concentration of hydrogen far less than that under a pressure of 1 atm and at 630°C.

A more plausible possibility for the direct effect of hydrogen present during the condensation of copper is that the number of vacancy sites in the copper structure increases with the pressure of hydrogen. It is possible to calculate (12-14) the distortions in the copper lattice around such point defects, and we suggest that the changes in lattice energy produced by these distortions have an influence on the density of oxide nucleation sites occurring in the subsequent reaction with oxygen. The occurrence of vacancy sites in metal crystals grown in the presence of hydrogen is supported by an observation of Kokotailo (15) who found a decrease in the unit cell size of platinum crystallites grown in hydrogen as compared with those grown in air, nitrogen, or argon; he ascribed the lattice shrinkage of ¾% to vacancy sites induced by the hydrogen.

A consideration of the density of oxide nucleation sites is based on suggestions made by Benard (16). Three stages occur in the growth of oxide on metals at low oxygen pressures: (*i*) an incubation period during which the concentration of oxygen on and in the metal builds up to some critical value, (*ii*) the simultaneous appearance of isolated oxide nuclei, which then grow laterally until a continuous oxide layer is formed, and (*iii*) the thickening of the layer in a fashion which is uniform over the surface of the film. In step (*ii*), where our principal interest lies, Benard noted that the density of isolated oxide nuclei increases with the pressure of oxygen and called the area associated with one nucleus the "zone of influence," supposing that the oxygen bombarding this pressure-dependent area can contribute to only one nucleus. Observations by Brockway and Rowe (9) showed that for oxygen pressures from 10^{-1} to 10^{-3} Torr the first oxide nuclei appearing on copper at 525°C were distributed uniformly with the density in grains cm^{-2} equal to $5.5 \times 10^9 \times p_{O_2}$ (Torr). The proportionality to pressure means that the number of oxygen molecules bombarding the "zone of influence" (area per oxide nucleus) is independent of the pressure and equal to 4.0×10^{10} molecules per second.

We suggest now that the stresses in the copper due to the hydrogen-induced vacancy sites reduce the effectiveness of oxygen bombardment for oxide nucleation and that a larger number of oxygen molecules per second must be supplied for each nucleus formed. Therefore, the copper films formed in the presence of hydrogen and subsequently oxidized require a larger surface area to contribute to the formation of a single oxide nucleus and the density of oxide nuclei is reduced. Without being able to make a quantitative prediction, we note that an increase in the hydrogen pressure from 10^{-5} to 10^{-4} Torr decreases the oxide grain density by 40%; in the absence of the hydrogen effect, a 40% decrease in the oxygen pressure would have the same result.

Summary

Copper films exhibiting the (100) epitaxy were prepared by condensation onto heated, single-crystal, sodium chloride substrates. The distinguishing feature of the present work lay in backfilling the film-deposition chamber with hydrogen, water, or air in the pressure range from 10^{-8} to 10^{-4} Torr. In every case specimens of the copper films were annealed and oxidized under the same conditions used in previous investigations, and the effect of the residual gases was tested by examining the films with the techniques of electron diffraction and microscopy.

No effect of the residual gases could be detected in the epitaxy or annealing characteristics of the copper films or in the shape and epitaxy of the Cu_2O grains formed on subsequent oxidation. A pronounced reproducible effect on the surface density of Cu_2O grains was observed when hydrogen was present during the condensation of the copper. We suggest that the presence of hydrogen during the growth of the copper crystal increases the number of vacancy sites in the metal, which have an inhibiting effect on the subsequent nucleation of oxide grains.

Two other observations in this study of thin single-crystal copper were the occasional appearance of wide stacking faults in unannealed films and the formation of limited areas of copper film with the (310) epitaxy on which Cu_2O grains grew with a $(1\bar{2}1)$ epitaxy.

Optical Properties of Rare Earths in Germanate Hosts

Mohan Munasinghe[*,1]

Ceylon Institute of Scientific and Industrial Research, Colombo 7, Ceylon

ABSTRACT

The luminescence characteristics of barium magnesium germanate crystal and glass matrices doped with the rare earths Eu^{3+}, Tb^{3+}, and Nd^{3+} have been investigated. Tb^{3+} to Eu^{3+} energy transfer is indicated in the crystal but not in the glass. A partial crystal field splitting for the principal Nd^{3+} states in crystal is given. Results of the quenching of Nd^{3+} emission by iron impurity yields a value of ~14Å for the range of the neodymium-iron quenching interaction, based on a simple model. Relevant physical properties and results from a study of devitrification of the glass are used to examine the structure of the two hosts.

Rare earths are now widely used as dopants in both crystal and glass host matrices to produce fluorescence in the visible and infrared regions of the spectrum (1-3). Hence the study of the luminescence properties of these materials has become important in the search for more versatile solid-state lasers. The results of an investigation of the optical properties of the rare earths europium, terbium, and particularly neodymium in barium magnesium germanate crystal and glass hosts are presented in this paper.

Experimental Procedure

Glass samples of rare-earth doped $Ba_2MgGe_2O_7$ were prepared by melting down and stirring a stoichiometric mixture of the required composition in a platinum crucible. After mixing thoroughly at ~1300°C the mixture was rapidly cooled through the temperatures for maximum crystallite nucleation and growth rate by pouring it into a molybdenum crucible immersed in liquid nitrogen. Final cooling from ~700°C down to room temperature was carried out in a preheated oven at a slower average rate of ~1°C/min, to prevent straining and cracking of the glass. Relatively large (*i.e.*, 7 cm radius by 1 cm thickness) and strain-free pieces of clear glass could be prepared in this way. A top seeded solution method (4) was used to prepare the single crystals of doped $Ba_2MgGe_2O_7$. K^+ charge compensators were provided in all the melts. The samples were cut and polished to a standard size of approximately $5 \times 6 \times 7$ cm³.

The standard experimental setup shown in Fig. 1 was used for fluorescence and excitation studies. 1 kW mercury and xenon lamps were the chief light sources. Excitation spectra were recorded with the aid of a monochromator and suitable filters to pump in different regions of the spectrum. For emission spectra, the pumping light was passed through a 10-cm thick, saturated solution of $CuSO_4$ to attenuate wavelengths above ~5500Å. For Tb^{3+} and Eu^{3+} doped samples, an additional filter was used when necessary to cut off exciting radiation above ~4000Å.

Cary 14R and Beckman IR12 double beam spectrophotometers were used for absorption measurements in the ranges 2500-20,000Å and 1.7-5μ, respectively. Rare earth concentrations in crystalline samples were deduced from chemical analysis and absorption data. Further details of the experimental procedure may be found elsewhere (5, 6).

Results and Discussion

Tb^{3+} and Eu^{3+} data.—Figures 2 and 3 are the emission spectra of Tb^{3+} and Eu^{3+} in $Ba_2MgGe_2O_7$ crystal at 80°K. Both emission and absorption peaks of these rare earths in the crystalline host were broadened and reduced in intensity as the temperature was increased from 80° to 300°K. The main Tb^{3+} emission is seen to occur from the $^5D_3$ state, *i.e.*, <4500Å.

For a crystal sample codoped with ~1% atomic fraction[2] each of Tb^{3+} and Eu^{3+} the intensities of Tb^{3+} emission lines were found to be at least ten times weaker than the intensities of corresponding lines from a crystal doped with ~1% atomic fraction of Tb^{3+}

[2] Atomic fraction $= N_a/(N_a + N_h) \approx N_a/N_h$ when $N_h >> N_a$ and where N_a = density of rare earth activator ions and N_h = density of Ba^{+2} host matrix cation which is replaced by activator ions.

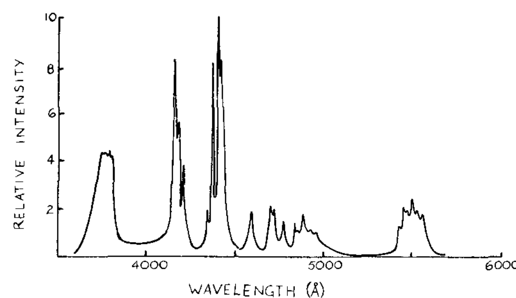

Fig. 2. Emission spectrum of Tb^{3+} in $Ba_2MgGe_2O_7$ crystal at 80°K.

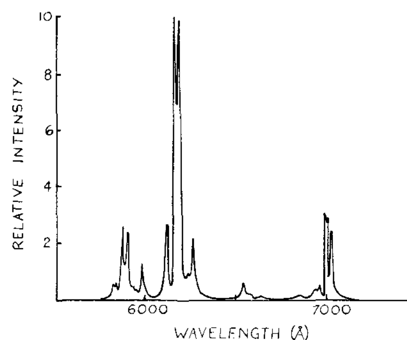

Fig. 3. Emission spectra of Eu^{3+} in $Ba_2MgGe_2O_7$ crystal at 80°K

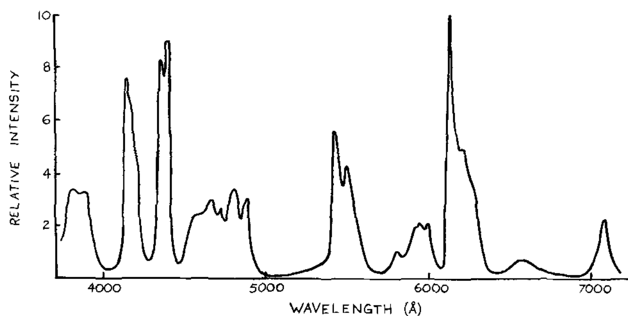

Fig. 4. Emission spectrum of $Ba_2MgGe_2O_7$:2% Tb^{3+}:2% Eu^{3+} glass at 80°K.

only. No significant enhancement of Eu^{3+} emission was observed from the doubly doped sample when compared with a crystal doped with ~1% Eu^{3+} only. Energy transfer from Tb^{3+} to Eu^{3+} may be the cause of the quenching of Tb^{3+} emission in the codoped sample (7).

No quenching of Tb^{3+} emission was seen in the equivalently doped glass host. The fluorescent spectrum of a doubly doped glass sample was found to be a superposition of the spectra in glass of the individual Eu^{3+} and Tb^{3+} activators. Temperature-insensitive inhomogeneous broadening, which is typical for rare earths in a glass matrix, can be seen for the absorption and emission spectra (Fig. 4) of barium magnesium germanate glass codoped with ~2% atomic fraction each of Tb^{3+} and Eu^{3+}. In general, broad energy bands in the spectra of the glass samples were not significantly shifted with respect to corresponding groups of lines in the crystal spectra.

Nd^{3+} data.—Absorption and fluorescent spectra of Nd^{3+} in both hosts exhibited the same general characteristics as those of the other two rare earths, *i.e.*, reduction of widths and intensification of lines with decreasing temperature for the crystal samples and inhomogeneously broadened bands, indicating variations of the crystal field at typical Nd^{3+} sites in the glass samples.

Small shifts in the positions of crystal lines occurred with changes in temperature. For a tetragonal crystal such as $Ba_2MgGe_2O_7$ the coefficients of thermal expansion along the c and a axes are different. The resultant changes in the symmetry as well as intensity of the crystal field at activator sites is likely to lead to small shifts in the energy levels as the temperature is varied. Table I gives the dependence of wavelength on temperature for a typical Nd^{3+} line. While room-temperature broadening is due to lattice phonons, the residual component of broadening at 5°K is probably caused by the presence of neighboring K^+ charge compensators at some of the activator sites. Nd^{3+} spectra in both types of host are discussed at greater length elsewhere (5).

All observed transitions in the crystal host were predominantly electric dipole in nature since the σ and axial (or δ) spectra were identical (8). Electric quadrupole transitions which are ~10^3 weaker may be ruled out. Transitions in the glass are comparable in strength to those in the crystal host. Figure 5 gives a partial

Error: ±1A for wavelength measurements.
±0.5A for halfwidth measurements.

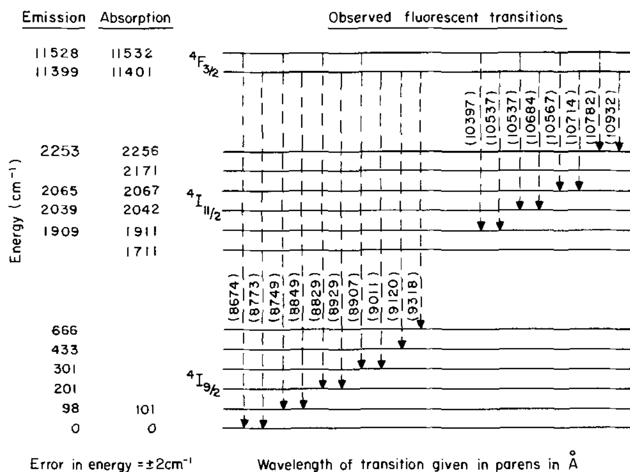

Fig. 5. Observed splittings of Nd^{3+} energy levels in $Ba_2MgGe_2O_7$ crystal at 80°K.

crystal field splitting at 80°K for the $^4F_{3/2}$, $^4I_{9/2}$, and $^4I_{11/2}$ states of Nd^{3+} in $Ba_2MgGe_2O_7$, deduced from the crystal spectra. The splitting of the $^4F_{3/2}$ state is seen to be ~130 cm^{-1} at 80°K. For variations in activator concentration up to 2% atomic fraction, shifts in these energy levels were found to be <2 cm^{-1}.

The absorption cross section for various Nd^{3+} lines was found to be independent of activator concentration. Thus Beer's law is obeyed for Nd^{3+} absorption in both types of host indicating constant oscillator strength for these transitions (9). Excitation spectra revealed that the energy absorbed directly by the matrix (*i.e.*, for excitations below the absorption edge ~2800Å) is not transferred to the activator ions (7). Concentration quenching of emission was strong in the glass but practically nonexistent in the crystal for Nd^{3+} concentrations up to 2% atomic fraction. This and other related concentration- and temperature-dependent phenomena may be attributed to two predominant types of resonant energy transfers between Nd^{3+} ions in the glass: (*a*) a Peterson-Bridenbaugh type quenching energy transfer, and (*b*) a resonant cross relaxation (2, 5, 10-12), shown in Fig. 6a and b.

Since the intensity of Nd^{3+} emission was also found to be a sensitive function of impurity iron concentration, emission from a series of glass samples doped with both neodymium and iron was studied. The iron concentration was varied while the neodymium concentration of all the samples was fixed at 0.5% atomic fraction. Earlier studies (5) showed that Nd^{3+}-Nd^{3+} interaction effects, which could complicate the analysis of the results, are negligible at these relatively low activator concentrations. Figure 7 shows the typical absorption spectrum of one such sample. The characteristic spectrum of Nd^{3+} in glass is evident, superposed over broad iron bands. The Nd^{3+} emission spectrum of this sample (and others in the series) is identical to that of the corresponding glass sample not containing iron, except for a reduction in intensity of emission due to the iron impurity. The emission per

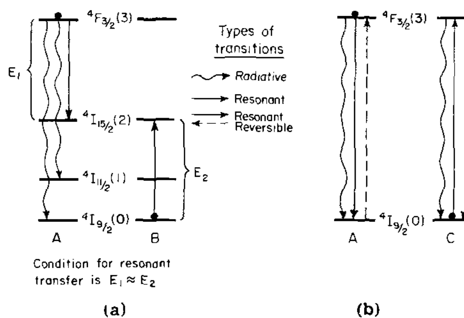

Fig. 6. Energy transfer of Nd^{3+} in $Ba_2MgGe_2O_7$ crystal

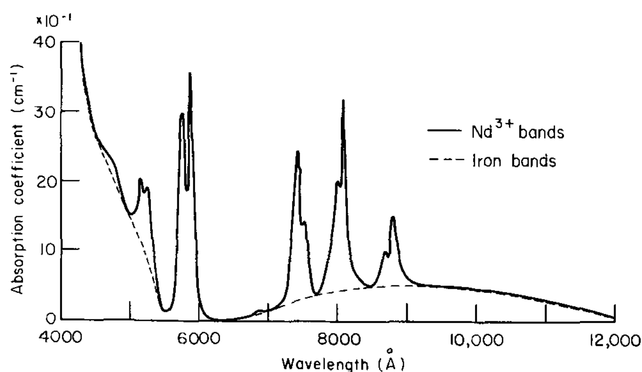

Fig. 7. Absorption spectrum of $Ba_2MgGe_2O_7$:0.5% Nd^{3+}:0.5% iron glass at 80°K.

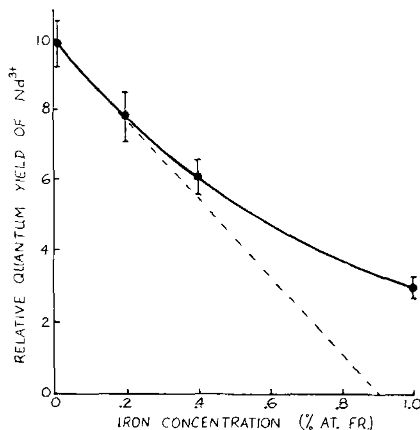

Fig. 8. Relative emission intensity per Nd^{3+} ion vs. iron concentration in $Ba_2MgGe_2O_7$ glass at 300°K.

Nd^{3+} activator is plotted as a function of iron concentration in Fig. 8. We may obtain an estimate for the range of the neodymium-iron quenching interaction from the following simple model.

We hypothesize that if an activator is located less than a critical distance R_q away from an impurity iron atom, emission from it is totally quenched. Otherwise the Nd^{3+} ion fluoresces normally. Thus each iron atom effectively poisons a spherical volume $V_q = 4\pi R_q^3/3$ around itself. The Nd^{3+} concentration is constant and we assume that both the neodymium and iron are uniformly distributed throughout the host matrix. Therefore at low concentrations, the ratio of the number of quenched Nd^{3+} ions to the total number of Nd^{3+} ions present would be equal to the total poisoned volume per unit volume of the sample. This ratio may be written as

$$r = n_i V_q$$

where n_i = number of impurity iron atoms per unit volume.

The mean intensity of emission per Nd^{3+} ion would be proportional to the number of unquenched activators. Since absorption measurements show that the energy absorbed per Nd^{3+} ion is independent of iron concentration, the mean quantum yield may be written as

$$\eta_{avg} = \eta_0(1 - n_i V_q)$$

where η_0 = the quantum yield when no iron is present.

It should be noted that we obtain a linear relationship between η_{avg} and n_i only if the iron concentration is low enough such that there is no significant overlap of the poisoned volumes of adjacent iron atoms. In fact, as n_i increased, this effect would tend to decrease the negative slope of the η_{avg} *vs.* n_i curve and flatten it out. Hence the linear relationship holds for small values of n_i only. These deductions from our model are consistent with the data shown in Fig. 8.

Now 1% atomic fraction of iron corresponds to a concentration of ~1×10^{20} atoms per cm³ of the sample. Therefore, from the intercept on the x axis made by the tangent to the linear portion of the curve (*i.e.*, at low iron concentrations) we get

$$V_q = 1/(0.9 \times 10^{20})$$

This yields the final result $R_q \approx 14Å$, where R_q is the range of the quenching interaction between neodymium and iron based on this simple model.

A study of the devitrification of barium magnesium germanate glass was attempted to provide some insight into fundamental differences between the two hosts. Some preliminary results are given below.

Several glass samples containing 4% atomic fraction of Nd^{3+} were annealed on a hot stage mounted on a polarizing microscope. Emission from the samples was monitored at various stages of the devitrification process using the apparatus of Fig. 1. Crystallites of linear dimensions up to 100μ were observed after annealing at ~850°C for about 10 min. Further growth could not be observed visually due to increasing opacity of the sample. At this stage of devitrification of the sample (*i.e.*, 10 min at ~850°C), there was no detectable change in its fluorescent spectrum. Another sample annealed at 750°C for 6 hr became completely opaque and marblelike in appearance. The emission spectrum of this sample, obtained by scattering from the surface, is shown in Fig. 9. It shows typical broad bands of Nd^{3+} emission from glass, on which are superposed some sharp lines characteristic of Nd^{3+} emission from the crystal. This implies that only certain areas of the glass have reverted to the normal $Ba_2MgGe_2O_7$ crystal structure, although the sample was opaque.

$Ba_2MgGe_2O_7$ is isomorphous with $Ca_2MgSi_2O_7$ (13, 14) (*i.e.*, it has the akermanite structure) in the crystalline state. The MgO_4 and GeO_4 tetrahedra are arranged in a sheetlike pattern parallel to the (001) plane, while BaO bonds link adjacent sheets together. A typical Ba^{2+} site in which Nd^{3+} activators are incorporated substitutionally (5) is shown in Fig. 10. The eight nearest neighbor oxygen atoms are arranged approximately in the form of an Archimedean antiprism around the cation.

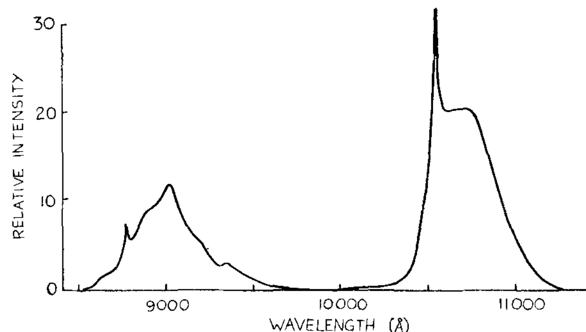

Fig. 9. Emission spectrum of partially devitrified $Ba_2MgGe_2O_7$: 4% Nd^{3+} glass at 300°K.

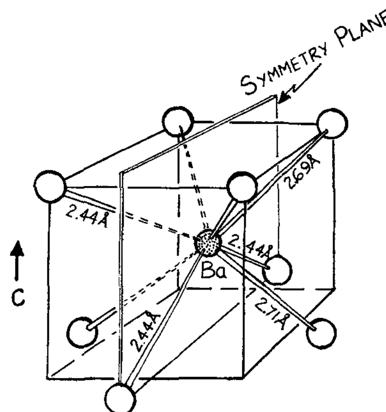

Fig. 10. Ba^{2+} antiprism site in $Ba_2MgGe_2O_7$ crystal

The densities of all crystal and glass samples were found to agree within 0.5%, indicating very little differences in the packing density. Small variations in the densities of glass samples may be attributed to the difficulty of reproducing exactly the method of preparation for each batch of samples. The density of the $Ba_2MgGe_2O_7$ crystal samples (4.737 g/cm^3) was identical to the figure calculated from the lattice parameters: a = 8.835Å, c = 5.545Å. These values were determined from x-ray measurements using oriented plates (a, c, and 110), which gave high intensity, higher order reflections (15). The values of the lattice constants and the x-ray diffraction powder pattern are similar to those reported elsewhere (14).

It was not possible to grow crystals which contained more than ~2% atomic fraction of activator concentration even though the melt itself contained much higher concentrations of activator. Thus it would not be possible for the whole of a glass sample which contained 4% atomic fraction of Nd^{3+} to devitrify into the normal $Ba_2MgGe_2O_7$ crystal structure. Furthermore since the melting point of $Ba_2MgGe_2O_7$ is ~1300°C, the fluidity of the glass is low at 750°C. The Nd^{3+} site symmetry varies in the glass, which is probably microheterogeneous (16, 17). Hence by annealing at this temperature only those localized portions of the glass which contained less than 2% atomic fraction of activator and were structurally closest to the crystal's atomic configuration could recrystallize, leaving areas of high activator concentration and high disorder relatively unchanged. This may be part of the reason for the composite spectrum observed in Fig. 9.

Summary

The advantages of the comparative study of crystal and glass hosts of identical chemical composition using rare earth fluorescence as a probe have been discussed at greater length elsewhere (5). The technique can be extended to other hosts and activators as well.

In this paper, we have used the technique to investigate differences in behavior between the crystalline and glassy states of the barium magnesium germanate host, and to study activator-activator and activator-impurity interactions. Some conclusions have been drawn regarding the structure of the two types of host. The drastic quenching effects of iron impurity on the emission intensity of neodymium has also been demonstrated.

Eu^{+2} Emission in Ternary Alkaline Earth Aluminum Fluorides

Mary V. Hoffman*

Lighting Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio 44112

ABSTRACT

The ternary systems MF_2-MF_2-AlF_3 where M = Ca, Sr, or Ba, were examined for compatibility triangles and compounds. The compounds $SrCaAlF_7$ and $BaCaAlF_7$ were found, each with three polymorphs. The β- and γ-forms in the $SrCaAlF_7$ compound could be quenched. The two low-temperature (α) forms show strong line emission at 358 to 360 nm with Eu^{+2} activation, resulting from absorption into the 5d states and emission from the $^6P_{7/2}$ levels to the $^8S_{7/2}$ ground state. The β- and γ-forms of $SrCaAlF_7$ contain a band emission and a much weaker line.

Divalent Eu activation in alkaline earth aluminum fluorides has been found to give two types of emission, the band emission normally associated with Eu^{+2} 5d to 4f transitions, and line emission from transitions within the $4f^7$ configuration. A general description of both types has been reported (1), and a more detailed

Key words: luminescence, spectra, Eu^{+2} activation, alkaline earth aluminum fluoride compounds.

description of the line emissions has also been published (2).

The binary compounds in the systems MF_2-AlF_3 (M = Ba, Sr, or Ca) have been described (1). The work on the single-crystal growth and characterization of one of these compounds, $SrAlF_5$, will be published (3). Of the three MF_2-MF_2 systems used in these ternaries, two have complete solid solution at high temperatures. In the CaF_2-BaF_2 system, this solid solution exists only above 915°C (4, 5) while for BaF_2-SrF_2, only the temperature range close to the liquidus has been reported (6). In the CaF_2-SrF_2 system, solid solution has been assumed but not verified (7).

This paper extends this work into the ternary systems MF_2-MF_2-AlF_3, and includes the compatibility triangles, the compounds and polymorphic forms, and the optical data with Eu^{+2} activation. It also includes some additional data on one binary compound in the BaF_2-AlF_3 system.

Experimental

The procedures used for the preparation, firing, and characterization of the compounds in the ternary systems and the optical measurements made were similar to those previously described (1, 2). Compositions in the ternary regions were usually formulated by combining a binary alkaline earth aluminum fluoride compound in the precipitated form and an alkaline earth fluoride, and were prepared both with and without Eu^{+2}. The use of the activation permitted comparisons of spectral distributions run at 10 Å/in. scan and 0.5Å spectral band width (SBW) to detect the presence of the several different line emitting compounds in two- and three-phase regions. In all of the systems, identification of the phases present and the validity of the joins and the triangles were verified by using identical compositions prepared by several methods and by a combination of the identification methods, x-ray diffraction, spectral measurements, and the petrographic microscope. X-ray diffraction data for the ternary compounds are given in the Appendix.

Results

Compound formation.—Compositions in MF_2-MF_2 systems were prepared by firing in HF at 800°C. In the CaF_2-BaF_2 and SrF_2-BaF_2 systems, the x-ray diffraction patterns showed only the end member fluorides. The SrF_2-BaF_2 system is probably analogous to the CaF_2-BaF_2 system in having complete solid solution below the liquidus and a lower limit of stability. This limit was not established in this work. In the SrF_2-CaF_2 system, complete solid solution was found after firings at 800°C, with the lattice parameters changing linearly with composition (Table I).

The data on transitions and melting points for most of the MF_2-AlF_3 compounds have been given (1). One compound, $Ba_9Al_2F_{24}$, has been examined in more detail by differential thermal analysis (DTA). Two heat effects were found at 770° and 820°C which are probably due to polymorphic inversions, and melting was found to occur at 915°C. Samples obtained by rapid cooling showed that the form stable above 770°C could not be quenched, but a change in the x-ray diffraction pattern was obtained on a sample which was cooled rapidly from 850°C. This pattern resembled BaF_2, but microscopic examination showed a highly

uniform anisotropic crystalline form. When $Ba_9Al_2F_{24}$ was prepared with Eu^{+2}, reflectance measurements showed weak absorption at 250 nm, but no significant emission was found from this composition with any of the heating and quenching treatments.

Ternary systems.—The compatibility triangles found for these ternary systems at 750°C are shown in Fig. 1, 2, and 3. The system CaF_2-BaF_2-AlF_3 is the least complex, and contains one ternary compound at $BaCaAlF_7$, and a limited amount of solid solution in $Ba_9Al_2F_{24}$, based on a shift in observed d spacings. The system CaF_2-SrF_2-AlF_3 also contains a single ternary compound, at $SrCaAlF_7$, with a small amount of solid solution toward Sr_2AlF_7 possible. Along the $SrAlF_5$-$CaAlF_5$ join, solid solution was found between $SrAlF_5$ and $Sr_{0.6}Ca_{0.4}AlF_5$ (1).

In the system SrF_2-BaF_2-AlF_3, two regions of solid solutions were found. One extends from $SrAlF_5$ almost completely along the join to $Sr_{0.15}Ba_{0.85}AlF_5$. The solid solution of Sr in $BaAlF_5$ is limited to less than 2 m/o (mole per cent) (1). The second solid-solution region extends from $Ba_9Al_2F_{24}$ along the join toward SrF_2 and also toward a composition of approximately $3BaF_2$:$2SrF_2$:$2AlF_3$, as evidenced by shifts in the observed d spacings. The exact region and nature of this solid solution was not investigated further.

The two ternary compounds were examined by DTA, and heat effects which are attributed to the transitions of three polymorphic forms were found in each compound (Table II).

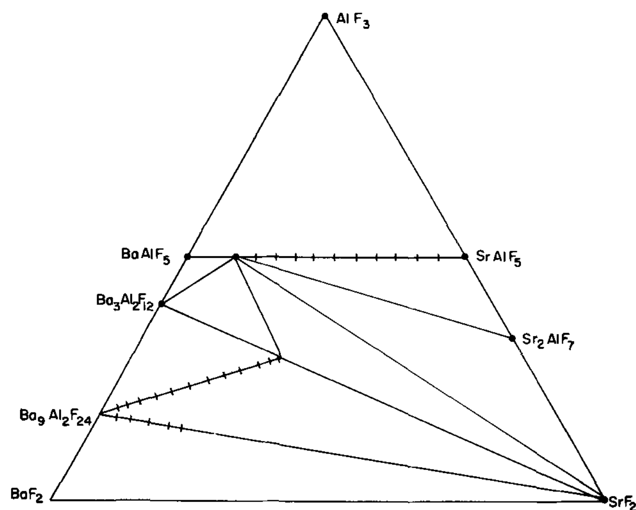

Fig. 3. Compatibility triangles in the system SrF_2-BaF_2-AlF_3 at 750°C.

In $SrCaAlF_7$, all three forms have been obtained. These were prepared by firing in the HF atmosphere, close to the melting point, for several hours, then holding in the desired stability region in flowing nitrogen. These inversions are slow to occur in both the heating and cooling direction, so that firing times of up to 16 hr were needed to completely convert the material to a pure phase. The presence of a second phase was usually caused by insufficient firing time rather than re-inversion on cooling. The quick cooling required to retain the β- and γ-phases were limited by the bulk of the tubular platinum furnace used for HF firings, which required 5-10 min to cool to below 500°C. This cooling rate was sufficient to retain the β- and γ-forms.

In the $BaCaAlF_7$ compound, only the α-form has been obtained, with no evidence of the β- or γ-form being quenched with rapid cooling. In order to obtain faster cooling than available in the HF furnace and to maintain the controlled atmosphere, samples containing Eu^{+2} were sealed in 5 mm Pt tubing under nitrogen, and quenched in water from 735° and 800°C. Optical measurements from both quenchings agreed with the emission spectra of α-$BaCaAlF_7$:Eu^{+2} and x-ray diffraction showed the α-form as the probable phase.

Quaternary solid solution.—The compositional series between $SrCaAlF_7$ and $BaCaAlF_7$ were also prepared and examined by x-ray diffraction, by DTA, and by emission spectra for possible solid solution. Samples were prepared with 0.02 Eu^{+2} from mixtures of $BaAlF_5$, $SrAlF_5$, and CaF_2. These were fired in HF above the melt point and then refired below the α-to-β inversion temperature. X-ray diffraction patterns showed neither a discernable shift in d spacings nor evidence of the presence of the end member compounds. With more than about 15 m/o substitution, the patterns showed broadened lines inconsistent with the sharp patterns obtained for the end members. DTA data obtained on these samples were not incompatible with a solid-solution series. With substitution of up to 15% Ba in $SrCaAlF_7$, the transition temperatures for the two inversions were raised and the inversions became more rapid, showing solid solution to at least this composition.

Table II. Ternary compounds

Heat effect transition	Temperature, °C $SrCaAlF_7$	$BaCaAlF_7$
$\alpha \rightarrow \beta$	487 ± 5	716 ± 4
$\beta \rightarrow \gamma$	670 ± 5	744 ± 4
Melting point	775 ± 10	816 ± 3

Luminescence.—The four structures which can be obtained in the two ternary compounds all show emission with Eu^{+2} with the two low-temperature polymorphs showing predominantly line emissions at 358-360 nm.

$BaCaAlF_7$.—The α-$BaCaAlF_7$ structure shows more intense line emission than found in any of the previously reported fluoride compounds (1). The spectra at two resolutions are shown in Fig. 4, taken at 25°C in which the single line is shown to resolve into four lines of similar intensities. When measured at 78°K, and with time resolved spectra, more than eight lines are discernable in this same wavelength region. The excitation spectra (Fig. 5) shows broad band absorption into the 5d level of Eu^{+2}. The excitation and emission mechanism follows that found for the binary fluorides, that is, excitation from the $^8S_{7/2}$ ground state to the $4f^65d$ states, followed by emission from the $^6P_{7/2}$ and $^6P_{5/2}$ levels to the $^8S_{7/2}$ ground state (2). The phosphor is also excited by cathode rays and by x-rays.

Optimum Eu^{+2} concentration was found to be between 0.001 and 0.10 of Eu^{+2}, but the matrix will accept at least 0.40 Eu^{+2}, calculated as substituting in the Ba^{+2} site, with no evidence found for the formation of a second phase by x-ray diffraction. No changes in spectra were found for much lower activator concentrations, while the high concentrations showed splitting of lines which could be resolved at 0.5 SBW at room temperature.

$SrCaAlF_7$.—The three polymorphs of $SrCaAlF_7$ show emission with Eu^{+2}, but only one is predominantly line emission. The α-form closely resembles that of $BaCaAlF_7$ at 25°C, differing in the position of the four emission lines but containing more 5d-4f emission

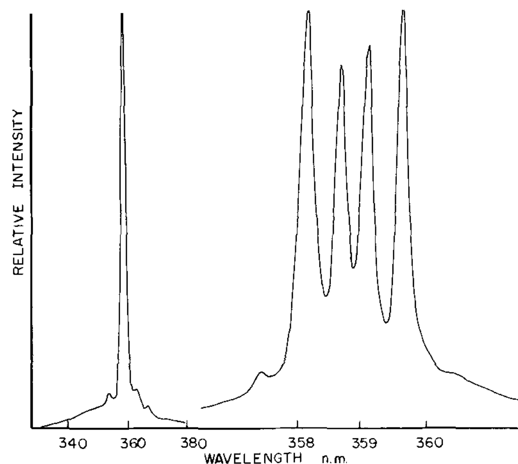

Fig. 4. Spectral distribution, α-$BaCaAlF_7$:0.02 Eu^{+2}. Left curve, 5Å SBW; right curve, 0.5Å SBW; 2537Å excitation.

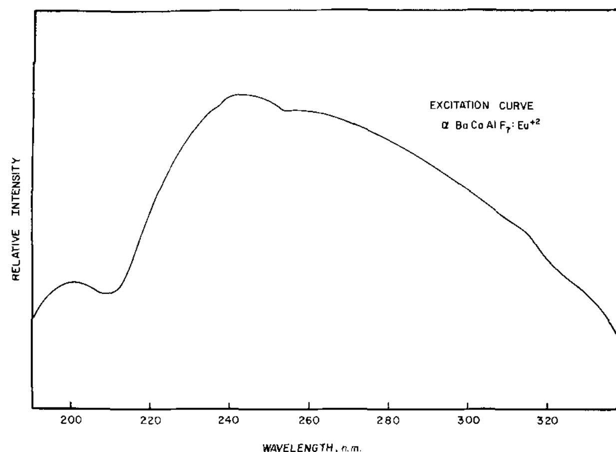

Fig. 5. Excitation curve, α-$BaCaAlF_7$:0.02 Eu^{+2}

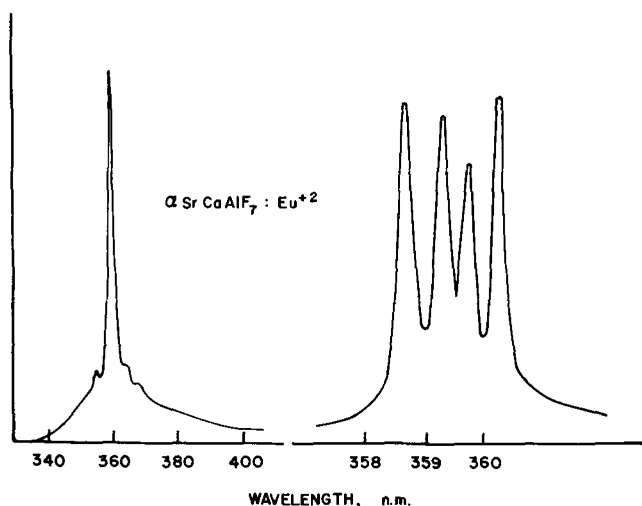

Fig. 6. Spectral distribution, α-$SrCaAlF_7$:0.02 Eu^{+2}. Left curve, 5Å SBW; right curve, 0.5Å SBW; 2537Å excitation.

(Fig. 6). At 78°K and with time resolved spectroscopy, only six lines can be resolved, with the remaining lines either too weak or overlapping too closely to be resolved.

The maximum Eu^{+2} content which could be incorporated in the α-form was 0.16 Eu^{+2} substituted for Sr^{+2}. Above this level, new x-ray diffraction lines appeared which were not attributed to either the β- or γ-forms.

The β- and γ-forms of $SrCaAlF_7$ show a mixed emission of predominantly bands peaking between 380 and 400 nm with a line positioned at 358 nm (Fig. 7 and 8). The line differs from the α-form in that little or no structure is resolved. At 78°K, the β-form shows some resolution into four shoulders, but the line of the γ-form is symmetrical.

$Ba_{1-x}Sr_xCaAlF_7$.—The similarities of the spectra of the α-forms of $BaCaAlF_7$ and $SrCaAlF_7$ are the main evidence that solid solution could exist along this compositional series, since unambiguous x-ray diffraction data could not be obtained. Samples were prepared with a final firing in the α stability range, and spectra were run on the expanded scale of 10 Å/in. over the four lines of the major emission between 355 and 360 nm. Each of the four lines was broadened, but the line position of each showed an apparent shift as shown in Fig. 9. The spectra were sufficiently narrow to permit detection of the two outside lines of the two end members if present in a mixture of the two phases. While measurements of the spectra at 25°C and without further scale expansion are insufficient to differentiate

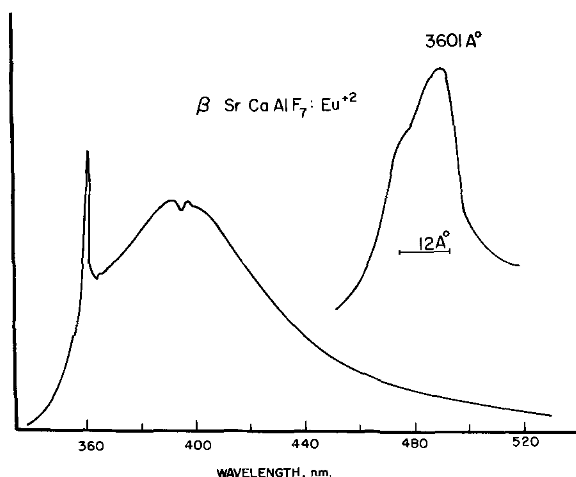

Fig. 7. Same as Fig. 6 for β-$SrCaAlF_7$:0.02 Eu^{+2}

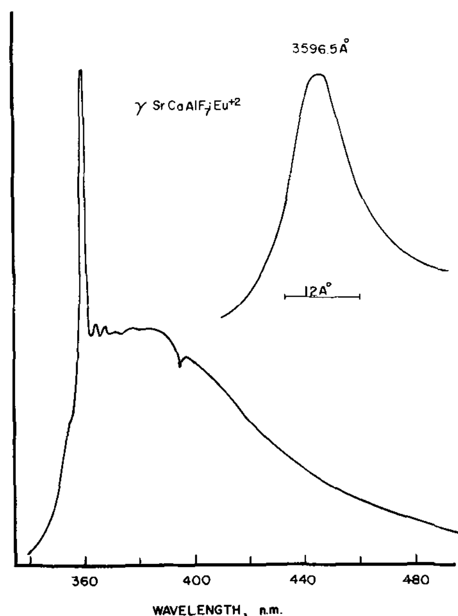

Fig. 8. Same as Fig. 6 for γ-$SrCaAlF_7$:0.02 Eu^{+2}

between a broadened, shifted emission line and a change in intensity of several overlapping lines, the absence of the strong lines of each end member would indicate that a solid solution is probable and that the line positions are affected by it.

Intensity measurements.—The relative intensities of these fluorides are shown in Table III for 2537Å excitation. These are based on the spectral distributions shown in Fig. 4, 6, 7, and 8, and compare the peak

Table III. Relative intensities, Eu^{+2} emission*

Phosphor matrix	Line	Peak height band	Wavelength, nm
α-$BaCaAlF_7$	1000		
α-$SrCaAlF_7$	420		
β-$SrCaAlF_7$	58	48	390
γ-$SrCaAlF_7$	52	25	380
$SrAlF_5$	350		
Sodium salicylate		50	415

* Measured at 5A SBW. Activator content, 0.02 Eu^{+2} per formula.

Table IV. Comparison of barium silicate: Pb and α-$BaCaAlF_7$:Eu^{+2}

Phosphor	Test condition	Relative response
Barium silicate: Pb	7 kV, 3 $\mu a/cm^2$	30.2
α-$BaCaAlF_7$:Eu^{+2}	7 kV, 3 $\mu a/cm^2$	14.3

height of the line as measured at 5Å SBW, or of the band emission taken at its peak, to sodium salicylate, which is used as an arbitrary standard at 50 units peak heat at 415 nm. The spectral distribution of $SrAlF_5$:Eu^{+2} has been similarly measured and a quantum efficiency of 65% was determined (1). The quantum efficiencies of the ternary fluorides, which contain considerably less 5d-4f emission than $SrAlF_5$:Eu^{+2}, were not measured.

Under cathode-ray excitation, α-$BaCaAlF_7$ gives the same line emission and has been compared with barium silicate:Pb, which is a band emitter with a peak at 360 nm and a width at half height of 39 nm (Table IV). The measurements compared the emission in the ultraviolet region using a Corning 7-54 filter and an EMI 9524B (S11 Type response) photomultiplier.

Summary

The ternary systems MF_2-MF_2-AlF_3 (M = Ba, Sr, Ca) contain a compound only with Ca, and, at the 1:1:1 ratio, $SrCaAlF_7$ and $BaCaAlF_7$. Each has three polymorphic forms. The α-form of each accepts Eu^{+2} and shows 4f-4f line emission at 358 to 360 nm. As with the similar compounds in the binary alkaline earth aluminum fluoride systems, the emission consists of a group of lines which can be resolved into more than eight lines and a varying amount of 5d-4f emission. The high-temperature structures, which can be quenched only in the strontium compound, contain more band emission and have a line which cannot be resolved into its structure at liquid nitrogen temperature. The phosphors are excited by cathode-ray and x-ray excitation as well as 2537Å ultraviolet. The peak height of the Eu^{+2} line in α-$BaCaAlF_7$ is the highest obtained in any compound showing this type of emission.

Acknowledgments

The author is pleased to acknowledge the help of Lynne Wichert in preparation and measurements on the samples, of Dr. R. A. Hewes and Bobbie Burts for the spectral measurements, of Jeanette Cooper and Dean McClellan for x-ray diffraction work, and of Dr. T. F. Soules for many discussions on the optical properties.

Solid-Gas Phase Equilibria and Thermodynamic Properties of Cadmium Selenide

A. Gary Sigai*[,1] and Heribert Wiedemeier

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

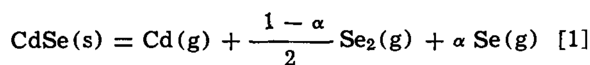
The investigation of the solid-gas phase equilibrium of CdSe revealed that at about 400°C CdSe sublimes initially by losing selenium to form nonstoichiometric $CdSe_{1-x}$, where $x \approx 0.002$; the resulting compound $CdSe_{1-x}$ sublimes congruently. Since existing thermodynamic data for CdSe are either incomplete or show significant differences, the high-temperature thermodynamic properties of CdSe were reinvestigated using the Knudsen effusion technique. With the heat capacity function for CdSe(s) ($C°_p = 12.36 + 1.45 \times 10^{-3}\,T$ eu [320°-760°K]) measured for the first time in this work and with tabulated thermochemical data, the vapor pressure measurements were evaluated in terms of the standard heat of formation [$\Delta H°_{298} = -35.7 \pm 1.0$ kcal/mole (third-law evaluation)] and the absolute entropy [$S°_{298} = 19.8 \pm 1.2$ eu (second-law evaluation)] of CdSe(s). Previous investigations are reviewed and compared with present results.

Several investigations of the mode of vaporization (1-3) and high-temperature thermodynamic properties (1, 4-8) of CdSe have been performed because of its potential use in solid-state devices and their importance for the growth of single crystals from the vapor phase. However, the precise mode of vaporization of CdSe is still uncertain and existing thermodynamic data are incomplete or show significant discrepancies. An experimentally determined heat capacity function of CdSe has not been reported prior to this work.

A knowledge of the equilibrium vapor pressure of CdSe is important since earlier investigations of CdSe (9-11) and other II-VI compounds (12) have demonstrated that these types of materials generate native point defects which are electrically active and play a substantial role in determining the electrical and optical properties of these compounds. Therefore, it is essential to define the conditions of preparation and any subsequent treatment of the specimen with respect to the equilibrium partial pressures of the components for a reliable interpretation of electrical and optical measurements.

Solid-Gas Phase Equilibria

General form of vaporization reaction.—Mass spectrometric data (1) and vaporization studies on CdSe in the presence of excess elemental Cd or Se in the gas phase (7) indicate that CdSe(g) and higher molecular weight species than Se_2(g) are negligible under present experimental conditions. Therefore, the congruent sublimation of CdSe can be described by the reaction



$$CdSe(s) = Cd(g) + \frac{1-\alpha}{2} Se_2(g) + \alpha\, Se(g) \quad [1]$$

where α is the degree of dissociation of Se_2(g). Wiedemeier and Goyette (13) have developed a calculational technique to compute α for this type of reaction from Knudsen data and the dissociation energy of the chalcogen species. With a dissociation energy for Se_2(g) of 75.7 kcal/mole (14) and with experimental data of the CdSe sublimation to be presented later, α was found to be less than 0.1% over the entire temperature range of this investigation. Therefore, monatomic cadmium and diatomic selenium are the only predominant species in the gas phase. This is in agreement with earlier mass spectrometric work (1).

Congruency of cadmium selenide sublimation.—It has usually been assumed that II-VI compounds sublime congruently according to the reaction

$$AB(s) = A(g) + \tfrac{1}{2}B_2(g) \quad [2]$$

Although early investigations (1, 4, 5) indicated the above mode of sublimation for CdSe, later studies (2, 3) suggested that the sublimation of CdSe is not completely congruent. Reisman (2) found that stoichiometric CdSe sublimes at about 400°C to form a selenium-rich gas phase and a selenium-deficient nonstoichiometric solid residue. Berkowitz and Chupka (3) conclude from mass spectrometric studies that stoichiometric CdSe does not sublime congruently. They observed that cadmium vaporizes preferentially and that the intensity ratio of Cd to Se_2 changes with time. Since a precise knowledge of the gas-phase composition is germane to the evaluation of Knudsen data and since reported results are not concordant, reinvestigation of the congruency of sublimation of CdSe was required.

For this purpose stoichiometric CdSe (as determined by wet chemical analysis and x-ray diffraction techniques described below) was prepared from high-purity elements by direct sublimation and by vapor transport (15) with iodine. The CdSe was loaded into a Knudsen cell of fused silica and heated under high vacuum ($<10^{-6}$ Torr) slowly until a weight loss was detected at about 450°C. The cell was kept at this temperature until no further weight loss occurred. X-ray analysis revealed that the condensed sublimate was elemental selenium and that the residue was CdSe. Within the limits of experimental error (±0.001Å) there was no difference in the lattice parameters of CdSe before and after the heat-treatment. From the amount of vaporized selenium the change in stoichiometry of CdSe was found to be about 0.2 m/o (mole per cent) which is below the detection limits of the x-ray diffraction technique. These results were confirmed repeatedly on both sublimed and vapor-transported material. The presence of unreacted, elemental selenium in the starting material can be safely excluded because of the method of preparation and the fact that there was no weight loss or condensate at temperatures around 250°C where elemental selenium has a measurable vapor pressure. After the preferential vaporization of selenium at around 450°C had stopped, the temperature was increased until measurable sublimation occurred again at about 600°C. X-ray diffraction patterns and lattice parameters of the starting material, residue, and sublimed material show that the selenium-deficient CdSe sublimes congruently within the limits of detectability. In addition, it should be noted that the results of this investigation presented

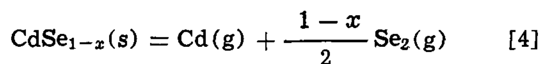
[1] Present address: RCA Laboratories, Princeton, New Jersey 08540.
Key words: equilibrium vaporization, thermodynamic properties, CdSe.

in Fig. 2 demonstrate that there is no measurable trend in the present data which would be expected for further changes in stoichiometry. Reisman *et al.* (2) reported final Cd/Se molar ratios ranging from 1.005 to 1.013 after heat-treatment of initially stoichiometric CdSe under various conditions.

The above observations indicate strongly that stoichiometric CdSe vaporizes initially according to the reaction

$$CdSe(s) = CdSe_{1-x}(s) + \frac{x}{2} Se_2(g) \quad [3]$$

and that the nonstoichiometric phase sublimes congruently according to the reaction



$$CdSe_{1-x}(s) = Cd(g) + \frac{1-x}{2} Se_2(g) \quad [4]$$

A rigorous evaluation of Knudsen data should be based on Reaction [4]. Thermochemical calculations show that the effect of the above deviation in stoichiometry on the evaluation of data according to the reaction

$$CdSe(s) = Cd(g) + ½Se_2(g) \quad [5]$$

is negligibly small. For simplicity all experimental data presented in this work are evaluated on the basis of the "stoichiometric" Reaction [5].

The significance of this particular mode of vaporization of CdSe is that Reaction [3] is not time independent; the selenium partial pressure decreases during the initial phase of the vaporization according to Reaction [3]. If stoichiometric CdSe is heated rapidly to 600°C and above, both Reactions [3] and [4] occur simultaneously. This results in erroneous partial pressures and subsequently derived thermodynamic data. This may, in part, explain some of the observed discrepancies mentioned earlier. In order to obtain reliable Knudsen data CdSe must be vacuum annealed to constant weight prior to vapor pressure measurements to establish the steady-state conditions.

For the calculation of total pressures from experimental Knudsen data the Knudsen equation modified by Pashinkin (16, 17) was used in the form

$$P_t = \frac{3m(2\pi RT)^{1/2}}{at(M_{Se_2}^{1/2} + 2M_{Cd}^{1/2})} \text{ (atm)} \quad [6]$$

where P_t is the equilibrium total pressure in atmospheres, m the weight loss in grams, T the absolute temperature, a is the effective orifice area in square centimeters, t the time in seconds, and M the molecular and atomic weight, respectively, of the effusing species.

The equilibrium constant, K_p, for Reaction [5] is given by

$$K_p = P_{Cd}P_{Se_2}^{1/2} \quad [7]$$

Since the total pressure is the sum of the partial pressures

$$P_t = P_{Cd} + P_{Se_2} \quad [8]$$

and since

$$P_{Cd} = 2P_{Se_2} \quad [9]$$

Eq. [8] and [9] can be combined with [7] to yield

$$K_p = \frac{2\sqrt{3}}{9} P_t^{3/2} \quad [10]$$

Experimental

Preparation of starting material.—Cadmium selenide was prepared by vapor transport (15) of elemental Cd (99.999%) and Se (99.999%) with iodine and by direct sublimation of stoichiometric ratios of the elements in the temperature gradient 950° → 875°C and with iodine concentrations of 1-3 mg/cm³ tube volume for the vapor transport. Wet chemical analysis by EDTA titration (18) [Cd(exp) = 58.5 ± 0.5%; Cd (theor) = 58.74%] and x-ray diffraction patterns [a_o(exp) = 4.298Å, c_o(exp) = 7.014Å; a_o(lit.) = 4.2985Å, c_o (lit.) = 7.0150Å] (19) verified that both materials were stoichiometric within the limits of experimental error and had the wurtzite structure. However, these analytical methods are not sensitive enough to detect the above discussed small deviation from stoichiometry.

Heat capacity measurements of CdSe.—For the heat capacity measurements a 300 mg sample of CdSe, prepared by direct sublimation and vacuum annealed to constant weight, was pressed into a 6 mm diameter pellet at a pressure of 13 kbar. A packing density of about 0.96 was achieved. The pellet was then hermetically sealed in an aluminum capsule with a minimum free volume and placed in the DSC cell attachment of a du Pont 900 Thermal Analyzer. During the runs the DSC cell was purged with high-purity dry nitrogen at a flow rate of 0.3 liter/min. A heating rate of 5°/min was used and high-purity alumina served as a reference material. Measurements were recorded in 5° intervals between 50° and 490°C for three separate runs and then averaged. There was no detectable reaction between the sample and the container after completion of the runs.

Knudsen effusion measurements.—The Knudsen effusion measurements on CdSe were carried out with a Cahn RH microbalance which recorded the weight loss of the sample as a function of time. The Knudsen cell was suspended by a tungsten wire and enclosed in a fused silica tube. A single-zone high-temperature Kanthal furnace with a constant temperature zone (±1°C) of about 6 cm length was maintained at the desired temperature using a West Instrument Controller. The temperature was measured with a Pt/Pt-10% Rh thermocouple in a fixed position on the outside wall of the silica tube, with the hot junction and center of the crucible at the same level. The temperature difference between the outside position and the inside of the Knudsen cell was determined under experimental conditions over the entire temperature range. The thermocouples were calibrated with an NBS secondary standard Pt/Pt-10% Rh thermocouple. The system was evacuated by means of an oil diffusion and mechanical pump. During operation the residual pressure monitored by a Veeco ionization gauge was 10^{-6} Torr or less.

The Knudsen cell made of fused silica was 25 mm in height; the maximum outside diameter was 12 mm and the maximum inside diameter 8 mm. The cell was tapered to fit conveniently into a tungsten wire basket. The effective orifice area of the cell was determined by calibration with high-purity vacuum distilled zinc under pressure conditions corresponding to the actual Knudsen measurements. The vapor pressure of zinc is well established (20). With the vapor pressure function of Barrow *et al.* (21) and experimental Knudsen data for the zinc vaporization an effective orifice area of 1.215×10^{-3} cm² was obtained.

Prior to the CdSe Knudsen measurements, the material was vacuum annealed to obtain the congruently vaporizing nonstoichiometric composition. In run No. I, about 1.5g of material prepared by chemical transport and in run No. II, about 800 mg of CdSe prepared by direct sublimation were used in these studies.

Results and Discussion

Heat capacity of CdSe.—The results of the heat capacity measurements are represented in Fig. 1. The estimated error in the heat capacity is less than 3%. The heat capacity as a function of temperature is given by the equation

$$C°_p = 12.36 + 1.45 \times 10^{-3}T \text{ (cal/deg · mole)} \quad [11]$$

for the temperature range 320°-760°K. The error involved in using only a two-term expansion is well below other errors of the measurements. The total error in using Eq. [11] between 298°K and the upper tem-

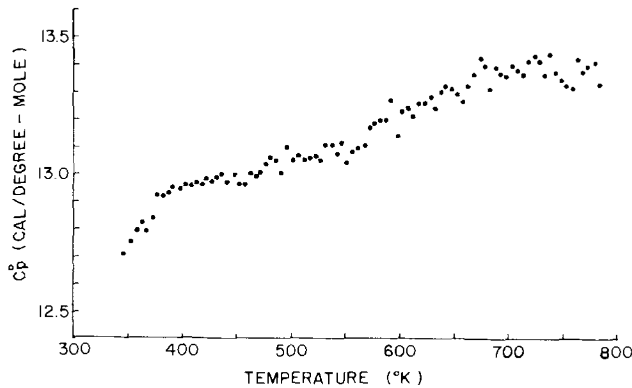


Fig. 1. Heat capacity of cadmium selenide ($CdSe_{1-x}$) as a function of temperature.

perature limit of the Knudsen studies is less than 0.3 kcal.

Knudsen effusion measurements.—The numerical results of the Knudsen measurements are listed in Tables I and II. The first two columns contain the temperature in degrees Kelvin and the weight loss in grams per hour. The errors in these quantities are less than 2° and 2×10^{-5}g, respectively. Values of the total pressure are given in the third column. Log K_p values and standard Gibbs free energies for Reaction [5] are given

in the fourth and fifth columns, respectively. The calculations were carried out on an IBM 360 computer. Based on experimental errors, the errors in P_t are less than 6%. The accuracy of $\Delta G°_T$ values is better than ±0.5 kcal/mole. The last column in Tables I and II gives values for the third-law heat of reaction, $\Delta H°_{298}$. For the third-law evaluation absolute entropies of Cd(g) (40.07 eu) and Se_2(g) (60.2 eu) from Kelley (22) and of CdSe(s) (obtained from a second-law evaluation of the data discussed below) and heat capacities of Cd(g) (4.97 eu) (23) and Se_2(g) [$8.73 + 0.32 \times 10^{-3}T - 0.34 \times 10^5 T^{-2}$ (eu)] (23), and the heat capacity of CdSe(s) measured in this work (Eq. [11]) were used. The average value of the third-law heat of reaction is $\Delta H°_{298} = 79.5 \pm 0.2$ kcal/mole. The error in this quantity is estimated at about 1 kcal/mole. The high degree of reproducibility of the individual third-law results indicates that experimental errors connected with the heat capacity, temperature measurements, and weight loss determinations are small.

The experimental data obtained in this work are shown in Fig. 2 compared to those of other investigations. The numerical results of a linear least-squares treatment of our data and of a conversion of second-law results of other investigators to 298°K are listed in Table III. For these calculations heat capacities of

Investigator	Temperature range, °K	$\Delta H°_T$, kcal/mole	$\Delta S°_T$, eu	$\Delta H°_{298}$,[a] kcal/mole	$\Delta S°_{298}$,[a] eu
Wösten (4)	1020-1170	78.7	47.7	81.9	52.8
Goldfinger (1)	870-1050	73.9	46.4	76.5	50.9
Shiozawa (7)	1070-1470	77.6	46.8	81.6	52.5
Somorjai (5)	920-1170	68.8	45.6	—	—
Korneeva (6) [corrected by Pashinkin (24)]	810-1010	75.2	45.7	77.6	50.0
Run No. I	866-1009	77.1	46.8	—	—
Run No. II	888-1035	76.2	45.2	—	—
Run No. I & II, second-law	866-1035	77.0	45.9	79.5	50.4
Run No. I & II, third-law	866-1035	—	—	79.5	—

[a] These values were derived using the $C°_p$-function of CdSe(s) determined in this work.

Cd(g) (23) and Se_2(g) (23) and the above measured $C°_p$-function of CdSe(s) were used. The values of the second-law heat and entropy of sublimation based on the combined data of runs No. I and II are 77.0 ± 0.8 kcal/mole and 45.9 ± 0.7 eu at 950°K. On being converted to 298°K, these values become 79.5 ± 1.4 kcal/mole and 50.4 ± 1.2 eu, respectively.

The data of Somorjai (5) deviate strongly in terms of vapor pressures from the results of the present and other investigations. This could be due to the use of closed systems in Somorjai's methods (5). A slight excess of an elemental component can cause serious errors in closed systems, especially at low pressures. The lower values for the heat of sublimation observed by Korneeva (6) and Goldfinger (1) could be due to a possible interference of Reaction [3]. However, in view of the sensitivity of the second-law method to experimental errors the results of Korneeva (6) [corrected by Pashinkin (24)] and of Goldfinger (1) are considered in general agreement with the present work. The same applies to the results of Wösten (4) and Shiozawa (7). The slightly larger values found by these authors (4, 7) could be explained by the increased degree of dissociation of Se_2(g) at higher temperatures which was not considered by Wösten and Shiozawa.

The heat of formation and absolute entropy of CdSe(s) obtained in this work are listed in Table IV. These values were derived from the heats and entropy of sublimation at 298°K (Table III) on the basis of Reaction [5]. The heat of formation of CdSe(s) based on the heat of sublimation of cadmium (26.75 kcal/mole) (25) and on the heat of formation of Se_2(g) (34.12 kcal/mole) (25) is $\Delta H°_{298} = -35.7 \pm 0.2$ kcal/mole. The error in this quantity is about 1 kcal/mole. The absolute entropy of CdSe(s) based on the absolute entropy of Cd(g) (40.07 eu) (22) and the absolute entropy of Se_2(g) (60.2 eu) (22) is $S°_{298} = 19.8 \pm 1.2$ eu. In Table IV are also listed the heats of formation and absolute entropies of CdSe(s) calculated from the corresponding values (Table III) of other investigations. The value of Terpilowski (8) was taken directly from the literature without further correction. Although this value (−34.6 kcal/mole) (8) is based on an estimated $C°_p$-function of CdSe(s) it is in closer agreement with the result obtained in this work than values computed from other investigations. Possible reasons for the larger deviations have been discussed above.

Summary

The original purpose of this investigation was to determine accurate vapor pressures through direct weight loss measurements employing the Knudsen effusion technique. In order to evaluate experimental data it was necessary to establish the mode of vaporization and to determine the heat capacity of cadmium selenide at elevated temperatures. Additional information was obtained through a second- and third-law evaluation of data, namely, the heat of formation and the absolute entropy of cadmium selenide.

[a] Taken directly from the literature without correcting the $C°_p$-function of CdSe(s).

A preferential loss of selenium during the initial heating of CdSe has been observed in this work, resulting in a deviation in stoichiometry. After the congruently vaporizing phase has been established, evaluation of experimental data in terms of thermochemical properties based on Reaction [4] or [5] leads to identical values within the limits of error. However, if the steady-state vaporization conditions are not established prior to actual vapor pressure measurements, erroneous partial pressures and thermochemical values are obtained. This could possibly explain the discrepancy in previously published results.

General trends and chemical considerations indicate possible inconsistencies in the heats of formation of other II-VI compounds. Similar deviations from stoichiometry on heating as observed for CdSe could occur in related systems. In order to resolve these uncertainties a precise determination of the mode of vaporization of these compounds is desirable.

Devitrification Characteristics of the Semiconductor System $(1-x)As_2Se_3 \cdot xSb_2Se_3$

N. S. Platakis and H. C. Gatos*

Department of Metallurgy and Materials Science and Department of Electrical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The devitrification kinetics in the system $(1-x)As_2Se_3 \cdot xSb_2Se_3$ were studied as a function of temperature (69°-183°C) and composition ($x = 0.1$-0.5). The activation energy of the linear growth rates of relatively large rectangular platelet-like crystals in the vitreous matrix was found to be 38 kcal/mole for $x = 0.1$ and 50 kcal/mole for $x = 0.3$, 0.4, and 0.5. Along the long dimension of the platelets the growth rate was found to be three times greater than that along the short dimension. Along this long dimension the growth rate increased about three orders of magnitude in going from $x = 0.1$ to $x = 0.5$. The number of crystals formed in the vitreous matrix per unit area increased with increasing Sb_2Se_3 content. The chemical composition of the crystals formed by devitrification was found to be different than that of the surrounding matrix. Quantitative electron microprobe analysis and scanning electron microscopy showed that the Sb content was higher in the crystals than in the surrounding matrix. Crystals grown directly from the melt (by slow cooling) were even richer in Sb than the neighboring matrix. X-ray diffraction results showed that the materials with low Sb_2Se_3 content crystallized in the system of As_2Se_3 (monoclinc) whereas materials relatively rich in Sb_2Se_3 crystallized in the Sb_2Se_3 system (orthorhombic). In alloys of intermediate composition both systems were present. In materials in which the monoclinic structure predominated the devitrification rates and the associated activation energies were found to increase with the Sb_2Se_3 content; whereas they were composition independent in materials in which the orthorhombic structure predominated.

Although the devitrification of oxide glass systems has been extensively investigated, devitrification studies on chalcogenide systems have been very limited. The rate of devitrification of bulk As_2Se_3 (1) and $As_2Se_xGe_y$ (2) has been successfully studied as a function of temperature by means of resistivity and density changes and it was found to increase with increasing temperature. As_2Se_3 films could not be devitrified, whereas Sb_2Se_3 and $As_2Se_3 \cdot Sb_2Se_3$ were readily devitrified on exposure to an electron beam. The nucleation rate was found to be temperature independent, while the growth rate was reported to increase with increasing temperature (3). Selenium is by far the most studied amorphous semiconductor not only because of its relative simplicity, but also because of its important role in xerography and electronic devices.

In recent years amorphous-crystalline transformations and the associated changes in electrical properties have received intensive attention as they are believed to be directly related to the memory switching phenomena observed in amorphous semiconductor systems. With the emerging potential of this type of phenomena the basic aspects of the vitreous state and its relationship to the crystalline state are now the subject of world-wide fundamental studies.

The present system was chosen because one of its constituents, As_2Se_3, adopts primarily the amorphous state, whereas Sb_2Se_3 is primarily a crystalline material. The tendency of their solutions to transform from the amorphous to the crystalline state increases with increasing Sb_2Se_3 content, providing a wide range of devitrification characteristics. Furthermore, these materials were found to exhibit switching and memory-switching phenomena.

Key words: chalcogenide semiconductors, amorphous semiconductors, devitrification of chalcogenide semiconductors $(1-x)As_2Se_3 \cdot xSb_2Se_3$.

Experimental

Sample preparation.—Devitrification was carried out by heating the amorphous samples at constant temperature on the stage of a microscope. The microscope's 450W xenon lamp (white light) served as the heat source. The temperature was measured with Chromel-Alumel thermocouples (25μ diameter wire) imbedded in the samples. Imbedding of the thermocouples into the samples was carried out by means of a hot stage especially designed for this purpose (Fig. 1). Vitreous material of the desired composition (prepared as described elsewhere) (4, 5) was sealed under vacuum in a quartz ampoule which then was placed into the furnace. A thermocouple was positioned into a shallow quartz vessel placed below the ampoule. While the furnace was brought to the desired temperature, the system was repeatedly evacuated and flushed with high-purity argon; then argon was allowed to flow under slightly positive pressure. The tip of the quartz tube was broken by means of a rotating blade and the molten material was cast into the quartz vessel into which the thermocouple was fixed. Fast quenching (of the order of seconds) was achieved by water-cooling the metal plate on which the quartz vessel was resting, by increasing the argon flow prior to casting, and by positioning a heat-reflecting blade between the opening of the furnace and the quartz vessel. Fast quenching was important in ensuring homogeneous vitreous samples and preventing the reaction of the thermocouple with the molten material.

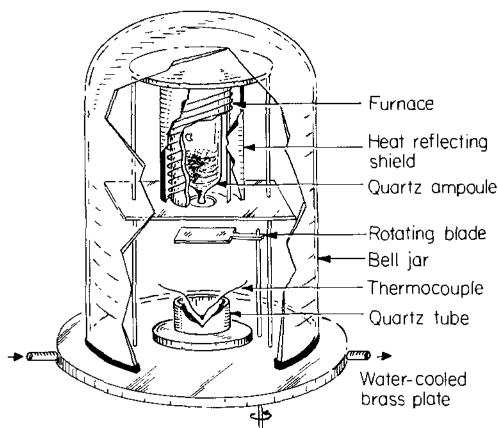

Fig. 1. Schematic diagram of the hot stage for imbedding thermocouples into the vitreous samples.

The samples were removed from the quartz vessel, mounted in plastic, and ground with a 0.25μ particle abrasive until the thermocouple junctions appeared on the surface. The samples were 12 mm in diameter and approximately 4 mm thick. Amorphous, single-phase samples with the composition $x = 0$, 0.1, 0.2, 0.3, 0.40, and 0.45 were successfully prepared as confirmed by powder x-ray diffraction, interference contrast optical microscopy, and scanning electron microscopy. Samples with $x = 0.5$ were amorphous but, toward their center, clusters of individual small crystals were present as shown in Fig. 2.

Heating procedure.—The white light beam of a microscope lamp, serving as the heat source, was focused on the desired area of the sample which was kept in an ultrapure argon atmosphere. The cross section of the impinging beam was about 0.3 mm^2. By focusing the beam on the thermocouple it was found that a constant temperature was achieved in less than 1 min; even for periods of several days the temperature remained constant within less than 0.5°C. Upon turning off the beam the sample reached room temperature in less than 1 min. Moving the sample and positioning the thermocouple in various parts of the beam's cross section led to no detectable temperature variation. The ratio of the illuminated area to the area of the thermocouple junction was about 150/1. By changing the aperture diaphragm setting any temperature in the range of 23°-190°C could be chosen. Once the desired temperature was established, areas far removed from the thermocouple were illuminated for nucleation and crystal growth observations. In this way any possible effects of the thermocouple on the stability of its adjacent sample areas were avoided. It was assumed that the temperature at any area illuminated by the beam was the same as that registered by the thermocouple when illuminated by the same beam. Heat losses through the thermocouple were considered negligible in view of its very small size. Since the rates of devitrification were very small (of the order of 10^{-5} μ/sec) it was assumed that the latent heat of crystallization caused no appreciable thermal fluctuations. The present method of heating for devitrification studies has the distinct advantage of allowing the direct observation of the devitrification process and crystal growth.

Devitrification was confined to the area illuminated (1/400 of the total sample); accordingly, several experiments could be carried out on the same sample. The self-consistency of the results as a function of temperature indicates that devitrification was heat- rather than photon-induced.

Morphology and chemical composition of the devitrified material.—The morphology of the crystals formed in the amorphous matrix was examined after several microns of the matrix material were removed by etching in an aqueous solution of KOH. The crystalline material was attacked only slightly by this solution. Scanning electron microscopy (in the secondary electron mode) was used for examining the morphology of the crystals. For studying chemical composition changes in the crystalline-amorphous matrix system an electron beam microanalyzer was used and a scanning electron microscope (in the x-ray mode) equipped with a silicon detector and a multiple-stage x-ray counter. A thin gold film was evaporated on the samples to prevent electrostatic charging and serve as a heat sink. For quantitative chemical analysis standards were used in conjunction with a computer program.

Results and Discussion

Early stage of devitrification.—The time required for the first crystal to become visible under a 570X magnification was determined as a function of temperature and composition. The results are plotted in Fig. 3 and summarized in Table I. It is seen that the (apparent) activation energy for the early stages of devitrification is approximately the same for all compositions except for that with $x = 0.1$ for which it is significantly smaller. Apparently the ease of devitrification decreases abruptly at the As_2Se_3-rich composition range. In all cases the number of crystals forming per unit

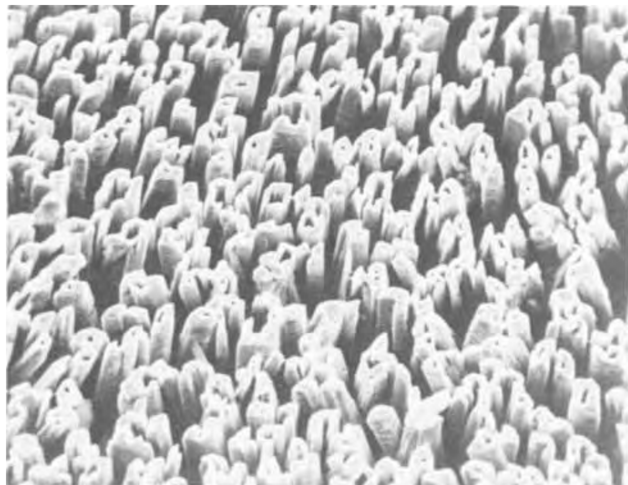

Fig. 2. Scanning electron micrograph of crystals formed while attempting to imbed the thermocouple in a sample of the composition $0.5As_2Se_3 \cdot 0.5Sb_2Se_3$. Vitreous matrix was etched with a KOH solution (370X).

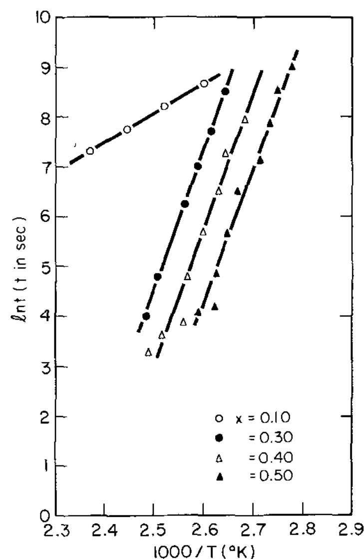

Fig. 3. Temperature dependence of the time required for the first crystal to appear during devitrification.

Table I. Activation energies (ΔH) of the early stages of devitrification. A is the pre-exponential factor

Composition	A, sec	ΔH, kcal/mole	Temperature range, °K
$0.9As_2Se_3 \cdot 0.1Sb_2Se_3$	1.5×10^{-8}	11.6	384-421
$0.7As_2Se_3 \cdot 0.3Sb_2Se_3$	0.52×10^{-29}	55.9	378-402
$0.6As_2Se_3 \cdot 0.4Sb_2Se_3$	3.6×10^{-29}	55.6	373-397
$0.5As_2Se_3 \cdot 0.5Sb_2Se_3$	1.7×10^{-29}	54.0	360-386

area was small (of the order of 10/mm^2 for materials with $x = 0.1$, and 10^4/mm^2 for the rest of the studied compositions) but under the present conditions (relatively low magnification) no observations could be made regarding the initial stages of nucleation. The time intervals presented here include the incubation period, the formation time of the nucleus, and its growth to approximately 5μ in diameter.

Crystal growth rates.—The crystal growth rates in the vitreous matrix following the initiation of crystal formation were determined as a function of temperature and composition. For the initiation of crystals an area of the sample, away from the thermocouple, was heated at 190°C with the light beam until well-defined crystallites were formed. Heating for about 3 min in the case of $x = 0.1$ and for a few seconds in the cases of $x = 0.3$-0.5 produced individual crystallites measuring approximately $10 \times 20\mu$ as shown in Fig. 4. Devitrification was arrested upon removing the light beam. No crystallites were formed outside the illuminated area. The beam was focused on the thermocouple, its intensity was adjusted to correspond to the desired temperature, and then brought to the areas where the individual crystals were earlier formed. The temperature range used was relatively narrow to avoid high growth rates which were difficult to measure. The crystal growth rates were determined by measuring the crystal dimensions before, during, and after the growth period from large magnification photographs. These photographs were taken at low beam intensity corresponding to room temperature where no crystal growth took place.

The measured growth rates along the length and width of the crystals for the composition with $x = 0.4$

are plotted as a function of temperature in Fig. 5. Their exponential dependence on temperature is shown for the same composition in Fig. 6. The activation energies and the corresponding pre-exponential factors for all compositions studied are summarized in Table II. For direct comparison, the growth rates of the various compositions were calculated for three temperatures (from the data of Table II) and are presented in Table III. Apparently, the temperature ranges employed lie below the temperature range in which the growth rates decrease with increasing temperature (6). As seen in Table II, the activation energy as well as the pre-exponential factor increase sharply in going from the composition with $x = 0.1$ to that with $x = 0.3$ and remain fairly constant for the compositions with $x = 0.3$, 0.4, and 0.5. This behavior is identical to that of the activation energy associated with the early stages of devitrification (Table I). The values of the two types of activation energies are also similar except in the material with $x = 0.1$. The relatively low

activation energy (11.6 kcal/mole) found for the early stage of devitrification of the composition $x = 0.1$ is perhaps associated with the nucleation (including incubation) rather than the growth process. It appears that at low Sb_2Se_3 concentrations the devitrification characteristics of As_2Se_3 are modified by Sb_2Se_3 whereas at the compositions with $x \geqq 0.3$, the characteristics of $(1 - x)As_2Se_3 \cdot xSb_2Se_3$ are affected only slightly, if at all, by a change in composition. Similarly, the energy gap of the composition with $x = 0.5$ is approximately the same as that for pure Sb_2Se_3 (5, 7).

Powder x-ray diffraction results showed that As_2Se_3-rich materials crystallize in the monoclinic system, the crystallographic system of As_2Se_3, while materials relatively rich in Sb_2Se_3 crystallize in the orthorhombic, the Sb_2Se_3 crystallographic system. In intermediate compositions both systems were present. The exact compositions at which the transition from the monoclinic to the mixed system and to the orthorhombic occur were not determined. However, in materials with $x = 0.2$ the monoclinic system predominated (the orthorhombic could hardly be detected), whereas in those with $x = 0.3$ both systems were equally pronounced. Materials with $x \leqq 0.1$ and $x \geqq 0.45$ crystallized in the monoclinic and orthorhombic systems, respectively. A related behavior has been reported for the system Sb_2Se_3-Sb_2Te_3 (8). These results indicate that the devitrification as well as the electrical and optical parameters in the present system are composition dependent when the monoclinic structure predominates and independent of composition when the orthorhombic structure predominates.

It is of interest to note that an activation energy of 31.2 kcal/mole has been reported (1) for the devitrification of pure As_2Se_3 which was already more than 50% devitrified. This activation energy corresponds to the growth activation energies measured in the present study and is in good agreement with the value estimated from the compositional dependence of the growth activation energy established in this study. Furthermore, the activation energy of viscous flow of pure As_2Se_3, which is believed to be relevant to the devitrification process, was found to be 37 kcal/mole (1) and is consistent with the present results.

Crystal morphology compositional changes.—The crystals formed in the vitreous matrix with $x = 0.1$ had a dendritic-like appearance and grew in blade-type shape as shown in Fig. 7. The morphology of the crystals was not temperature dependent. On the other hand, in all other compositions the shape of the crystals was found to be temperature dependent. They were rectangular single crystals (as confirmed by transmission electron diffraction patterns) and maintained their general morphology during the growth provided the growth rates were kept relatively low (Fig. 4). At higher growth rates (in the range of 120°-150°C) a number of elongated small crystals grew from the original single crystal. Figure 8 is a scanning electron microscope photograph of a crystal, the last part of which was grown at high temperatures; the surrounding vitreous matrix was etched away in an aqueous KOH solution. Near the softening temperature range of the vitreous materials, the growth rate was very fast (it could not be measured under the present experimental conditions) leading to clusters of elongated crystals as shown in Fig. 9. A similar behavior

was observed during crystallization directly from the melt by slow cooling. Figures 2 and 10 show crystals grown by cooling from 750°C to room temperature in several minutes and several hours, respectively.

The chemical composition of crystals grown during devitrification and that of the surrounding vitreous matrix were studied, employing scanning electron microscopy (in the x-ray mode). Homogeneous materials with $x = 0$, 0.1, 0.2, 0.3, 0.4, 0.45, and 0.5 were prepared and used as standards. X-ray spectra (AsK_α, SeK_α, and SbL_α lines) were taken on the samples along a line traversing along a crystal, the crystal-matrix interface, and the matrix. A computer program was used for normalizing and reducing the data.

The results obtained with crystals formed by devitrification (illumination heating) of vitreous matrices having original compositions $x = 0.1$ and 0.4 and with crystals grown directly from a melt with $x = 0.4$ by slow cooling are summarized in Fig. 11. It is seen that in all cases the crystals were richer in Sb than the surrounding vitreous matrix and that the Sb content in the crystals decreased in going from the center of the crystal toward the interface. The Sb content in the vitreous-crystal interface was lower than in the crystals and the vitreous matrix. The difference in Sb content between the crystals and the surrounding vitreous matrix is far more pronounced in the crystals grown from the melt than in crystals grown by illumination heating. It is apparent that Sb_2Se_3-rich compositions nucleate preferentially, consistent with the present results on nucleation and growth as a function of composition. Accordingly, the crystal-matrix interface is somewhat depleted in Sb_2Se_3 and enriched as As_2Se_3. Figure 12 is an electron microanalyzer scan along a sample shown in Fig. 13. It is clearly seen that the Sb content decreases and the As content increases significantly at the crystal-matrix interfaces. The higher Sb concentration and the Sb concentration gradient in the crystals are also clearly seen. Figures 14 and 15 are x-ray images obtained from the same area of a sample (similar to that shown in Fig. 13) using as signal the SbL_α (Fig. 14) and AsK_α lines (Fig. 15). The light areas in Fig. 14 correspond to the crystals and the dark areas to the vitreous matrix, clearly showing the increased Sb content in the crystals. In Fig. 15 the dark areas correspond to the crystals. Although the As segregation is not as well pronounced as the segregation of Sb (in Fig. 14) the crystals are clearly evident. Also the increased As concentration in the interface regions can be readily seen.

Fig. 14. X-ray image of an area of the specimen of Fig. 13, obtained with an electron microanalyzer using as signal the SbL_α line.

Attaching electrodes on thin samples of these materials (of the order of 30μ) or on flash evaporated films, memory switching (9) could be readily observed with switching time of the order of nanoseconds. The switching time is many orders of magnitude smaller than the time necessary to establish crystalline conduction paths through the vitreous matrix. Similarly, the resistance of the device in the "On" state is about four orders of magnitude smaller than that expected even if the entire device were in the crystalline state. These facts and the fact that appreciable compositional changes take place in the devitrified areas raise serious questions regarding the view that memory switching is directly related to reversible crystalline filament formation. A study of the memory switching characteristics as a function of composition and of the related amorphous-crystalline transformation is now in progress in our laboratory.

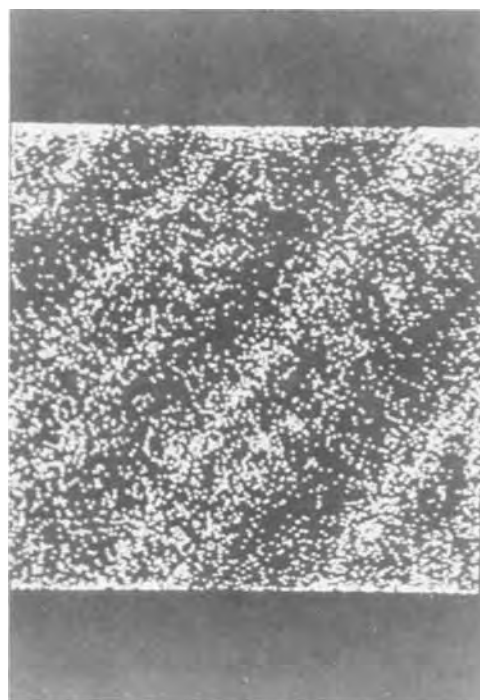

Fig. 15. X-ray image of the same area as in Fig. 14, using as signal the AsK_α line.

Summary

The activation energies of devitrification for the early stage of crystal formation and for the subsequent stage of growth were determined as a function of composition in the system $(1 - x)As_2Se_3 \cdot xSb_2Se_3$. They were found to be similar for both stages except in materials with $x = 0.1$. This difference is believed to be associated with the nucleation rather than the growth process. The dependence of the activation energies and pre-exponential factors on composition were found to be identical.

Crystals grown in As_2Se_3-rich materials had a dendritic-like appearance and grew in a blade-type shape. Their morphology was temperature independent. On the other hand, the morphology of the crystals, grown in Sb_2Se_3-rich materials was temperature dependent; in this case the crystals were rectangular single-crystal platelets at low temperatures and had dendritic-type forms at higher temperatures (120°-150°C). When devitrification took place near the softening temperature range, then, clusters of elongated single crystals were formed.

The chemical composition of the crystals was found to be different than that of the surrounding matrix. Crystals grown during devitrification were 20-100% richer in Sb than the matrix, depending on the original composition of the parent vitreous matrix.

X-ray diffraction measurements showed that low Sb_2Se_3 content alloys crystallize in the monoclinic system (that of As_2Se_3) while those with high Sb_2Se_3 content crystallize in the orthorhombic system (that of Sb_2Se_3). The transition from one system to the other is gradual, and both systems co-exist in a composition range whose exact limits were not determined. However, in alloys with $x = 0.2$ the orthorhombic system was present only in traces, while in those with $x = 0.3$, both systems were present in approximately equal amounts. Materials with $x \leq 0.1$ and $x \geq 0.4$ were crystallized exclusively in the monoclinic and orthorhombic system, respectively. The devitrification characteristics, the electrical and optical behavior of these materials are composition dependent when the monoclinic system predominates and composition independent when the orthorhombic system predominates. The devitrification rates, at least in the present sys-

tem, are far too slow when compared with the switching time of electrical switching in these materials. Accordingly, questions are raised regarding the view that amorphous-crystalline transformations are directly responsible for memory switching in these materials.

Measurements of the Absolute Radiative Efficiency of Cathodoluminescent Phosphors

V. D. Meyer

The Bayside Research Center of GTE Laboratories Incorporated, Bayside, New York 11360

ABSTRACT

The absolute efficiency of cathodoluminescent phosphors has been measured as a function of voltage and current density. The results are in good agreement with the highest values previously reported. Changes of slope in the luminance *vs.* voltage curves indicate that changes in the voltage dependence may occur at x-ray excitation potentials; these observations are related to results reported by others for x-ray excitation of scintillation crystals. The indications are that it may not be possible to assume that the intrinsic efficiency is independent of the kinetic energy of the incident electron beam unless the energy exceeds the K x-ray levels of the host.

The absolute radiative efficiency of a phosphor is the energy given off in the form of radiation[1] divided by the energy incident upon the phosphor. The absolute value of the radiative conversion efficiency of phosphors under cathode ray excitation has been measured by Bril (1), Bril and Klasens (2) (BK) and more recently by Ludwig and Kingsley (3) (LK). At high accelerating voltages (20 kV), the highest efficiency (0.25) was measured by BK for the phosphor ZnS:Ag,Al. Since they approximate their error to be 15%, the efficiency may be as low as 0.212 or as high as 0.288. Estimates of the maximum attainable efficiency calculated by several authors (4-7) when only unavoidable energy losses are accounted for range from 0.22 to 0.26 for ZnS:Ag,Al. All these estimates are based on the assumption that excitation by cathode rays leads directly to the formation of electron-hole pairs.

Measured efficiencies increase as the accelerating voltage of the exciting electron beam is increased and appear to become constant at high accelerating voltages. The increase with accelerating voltage has been interpreted (2, 3) by using Gergely's (8) formulation which accounts for surface effects. Bieringer (9) has also formulated a relationship which accounts for the so-called "dead-layer" and his predicted voltage dependence agrees with the measured change in brightness as the accelerating voltage is increased. Since surface effects may result from contamination or effects inherent to an interface, it is desirable to measure the variation with voltage using a clean surface. It would be interesting to determine if utilization of modern vacuum technology would yield higher measured efficiencies by reducing surface contamination.

The efficiency 0.08 ± 0.012 reported by Bril (1) for the National Bureau of Standards phosphor NBS 1021, $Zn_2SiO_4:Mn^{2+}$, exceeds by a significant amount the measured value, 0.047, recently reported by LK (3). This is especially significant because variations produced by different phosphor synthesis procedures and techniques are not involved in comparing these results, since investigators used phosphor from the same lot, *i.e.*, NBS 1021.

In this paper we report measurements of the absolute radiative efficiency of cathodoluminescent phosphors, using an oil-free vacuum system in order to minimize surface contamination, with special emphasis on the efficiencies of ZnS:Ag,Al and $Zn_2SiO_4:Mn^{2+}$. Other phosphors including several rare-earth activated materials have also been measured.

In the course of our measurements, we found indications of changes in efficiency at energies corresponding to electronic energy levels of the host material in the x-ray region. Due to the relative insensitivity of thermopiles and the possibility of surface charging, we found it impossible to demonstrate these changes by measuring the efficiency. In order to more carefully study the voltage dependence near x-ray levels, we have instead measured the luminosity using a sensitive photomultiplier under several experimental conditions in which the possibility of surface charging could be

Key words: luminescence, cathode-ray, sulfide, rare-earth.

[1] The term radiation used here is meant to include radiation in the visible, near ultraviolet and near infrared regions of the spectrum. It does not include x-ray or thermal radiation. Obviously the measured efficiency includes only those wavelengths which can be detected by the thermopile. In our case this would be limited by the transmission of a quartz window.

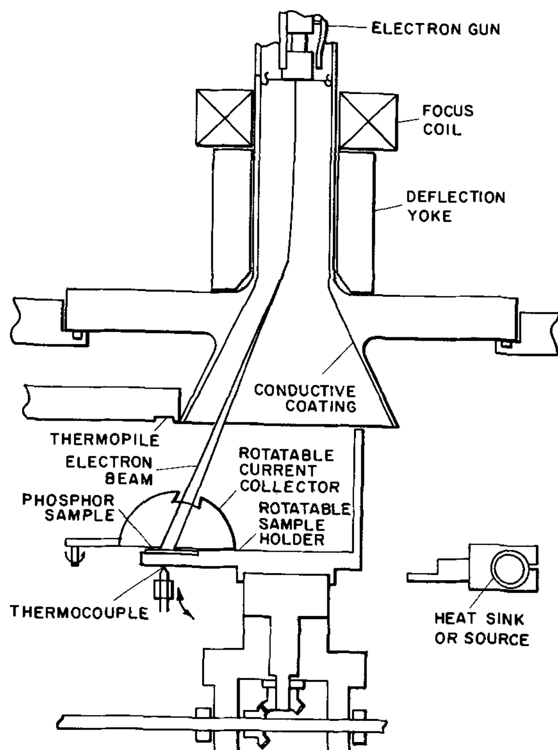

Fig. 1. Schematic diagram of apparatus. Current collector is rotated into position to measure current, and rotated out to permit measurement of emitted radiation by the thermopile. Sample holder can be rotated 180° to make contact with a heat sink or source which hangs on a hollow tube.

minimized or eliminated. These measurements are reported in the section on Voltage Dependence near X-Ray Levels.

Experimental

General description.—A schematic diagram of the apparatus is shown in Fig. 1. The electron beam generated in the electron gun is focused and scanned at normal television rate. (Field-scanning frequency of 60 Hz and frame-scanning frequency of 30 Hz.) The raster size at the screen can be varied from larger than the screen size down to spot size. The screen contains four slots for the prepared samples and by magnetic coupling the sample holder can be rotated in order to position the desired sample directly below the thermopile. The thermopile was sealed into a vacuum-tight case by the manufacturer (Charles M. Reeder Company). The quartz window of the thermopile is positioned 6.86 cm directly above the sample. Prior to sealing the thermopile into the vacuum system with a conflat flange seal, it was calibrated against a National Bureau of Standards Standard Lamp. The vacuum-pumping system consists of a VacSorb roughing pump and a Vaclon pump supplemented by a titanium sublimation pump. Pressures of 2×10^{-8} Torr are regularly obtained after overnight pumping and the pressure during operation is approximately 3×10^{-8} Torr.

A measurement of the screen current only is not a valid measure of the total beam current since secondary electrons may not be detected. To insure measurement of the total beam current, a current collector is added. This consists of a cup which, when rotated into position over the sample, forms with the screen a hemispherical enclosure with a square opening to permit the incident beam to enter.

When the sample holder is rotated 180° from the measuring position, it comes into contact with a heat sink which hangs on a hollow tube. To heat or cool the phosphor samples, a heater can be inserted into the tube, or liquid nitrogen can be poured into the tube.

Sample preparation.—Phosphor samples were prepared by settling the powder onto 1 in.^{2} aluminum

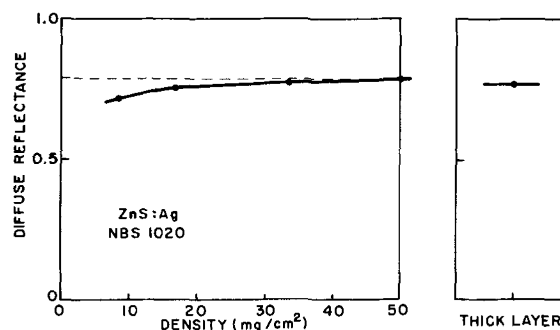

Fig. 2. Diffuse reflectance for various coating densities and for a thick layer.

plates using a silicate binder. To insure sufficient coverage of the metal slide by the phosphor powder, thick phosphor layers were prepared. However, in preparing thick layers, the possibility of the phosphor surface charging becomes more likely. Therefore, it is desirable to add just enough phosphor to obtain sufficient coverage. Our approach to this problem was to assume that diffuse reflectance from a sample with sufficient coverage should be very nearly the same as that for a thick, lightly packed powder. Figure 2 shows that diffuse reflectance for various settling weights of the phosphor ZnS:Ag (NBS 1020) and also the diffuse reflectance for the same phosphor in the form of a packed powder. We note that at a coating density of 50 mg/cm^2 the diffuse reflectance is nearly the same as that for the thick powder. This and additional evidence, given later, led us to choose 50 mg/cm^2 as the proper coating density. Since the particle sizes of the important cathodoluminescent phosphors are of the same order of magnitude, we have assumed this coating density to be sufficient for most phosphors.

Experimental procedure.—The intrinsic efficiency of a phosphor under cathode ray excitation can be expressed as follows[2]

$$\eta_i = \frac{2\pi r^2 CE}{I_o V_o (1 + R_\infty)}$$

In order to measure the intrinsic efficiency, η_i, therefore, it is necessary to know: r, the distance from the phosphor to the thermopile and C, the calibrated thermopile sensitivity in W/V cm^2; it is also necessary to measure: (*i*) E, the emf generated by the thermopile, (*ii*) I_o, the incident beam current, (*iii*) V_o, the accelerating voltage, and (*iv*) R_∞, the reflection coefficient of the phosphor sample.

With the accelerating voltage set at a measured value, a phosphor sample is rotated into position directly beneath the thermopile, and the raster size is adjusted to insure that the largest dimension (the diagonal of the raster) is less than one fifth[2] of the distance from the phosphor to the thermopile. The hemisphere current collector is rotated into position and the total current is recorded. Immediately, thereafter, the collector is rotated out and the emf generated by the thermopile is recorded. The reflection coefficient of each sample as a function of wavelength is measured using a Cary 14 Spectrometer, and the reflection coefficient at the wavelength corresponding to the peak of the emission is used to calculate the intrinsic efficiency.

Efficiency Measurements

Phosphor thickness.—Bril and Klasens (2) have shown that the intrinsic efficiency can be written as

$$\eta_i = \frac{2\eta_m(\infty)}{(1 + R_\infty)}$$

[2] In order for the inverse square relationship to be valid, and therefore the equation for intrinsic efficiency to be applicable, the distance from the source must be at least five times the maximum dimension of the source. See I.E.S. Lighting Handbook, 3rd ed., pp. 9-29, Illuminating Engineering Society, New York, N. Y. (1962).

where $\eta_m(\infty)$ is the measured efficiency uncorrected for the loss due to imperfect reflection by a very thick sample. The above equation results from assuming that the depth of penetration of the electron beam is very small compared to a thickness within which reabsorption of the emitted light becomes significant. It is further assumed that half of the light is emitted up (back toward the electron beam) and the other half is emitted downward. Of the half emitted downward, a certain fraction which depends upon the reflection coefficient is reflected back toward the detector. $R\infty$ is the reflection coefficient for an infinitely thick layer. In order for this equation to be validly applied therefore, the reflection coefficient of the phosphor sample should be equal to that of a thick powder layer of the same material.

We have measured the efficiency at various settling weights and applied corrections for the reflection coefficient of the individual samples. We call this corrected efficiency η_c

$$\eta_c = \frac{2\eta_m}{1 + R}$$

As the thickness, t, increases η_c approaches η_i, *i.e.*, $(\eta_c)_{t\rightarrow\infty} \rightarrow \eta_i$. The efficiency at various settling weights is shown in Fig. 3 together with the efficiency measured for a thick powder of the same phosphor ZnS:Ag (NBS-1020). This result agrees with our conclusion from reflectance measurements, that 50 mg/cm² is sufficient to provide not only complete coverage but enough thickness to produce a reflectance nearly the same as that for a very thick powder layer; therefore at this settling weight η_c is very nearly equal to η_i.

Beam current.—At high current densities some phosphors become "nonlinear" (saturate), and the efficiency measured at high current densities is degraded. To avoid such reduction in efficiency it is necessary to establish the current density at which such effects occur; therefore, the efficiency was measured as a function of current density for all the phosphors. Nonlinearity is most pronounced in the case of the II-VI sulfides, and Fig. 4 shows the variation with current density for ZnS:Ag (NBS 1020). Nonlinearity becomes significant at currents above approximately 0.5 μA. (This corresponds to an average current density of approximately 0.5 μA/cm² since the raster size is approximately one square centimeter.) In order to be certain that the current density was less than that at which nonlinearity becomes significant, our measurements for the true efficiency were made at 0.1 μA.

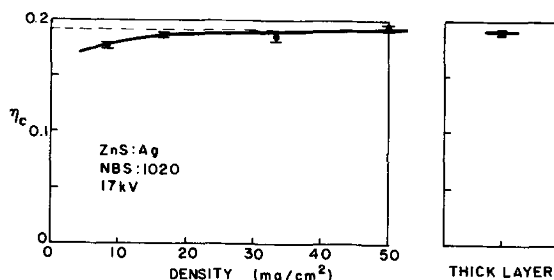

Fig. 3. Efficiency corrected for reflectance properties at various coating densities and for a thick layer.

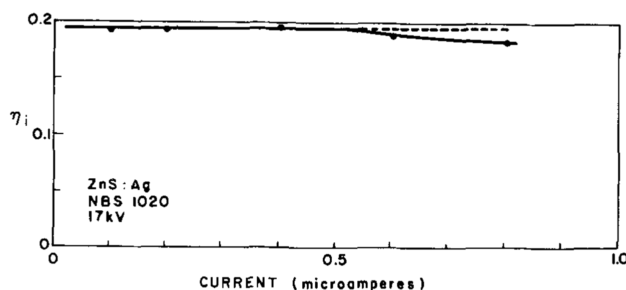

Fig. 4. Efficiency for various beam currents. The raster size is approximately one square centimeter. Nonlinearity becomes significant beyond 0.5 μA/cm².

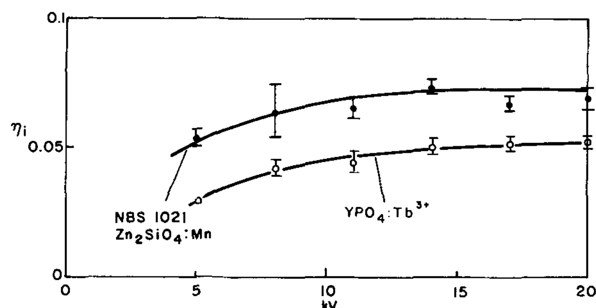

Fig. 5. Voltage dependence of intrinsic efficiency for green-emitting $Zn_2SiO_4:Mn^{2+}$ and $YPO_4:Tb^{3+}$.

Voltage dependence.—Typical efficiency measurements as a function of accelerating voltage are shown in Fig. 5. Table I shows the measured efficiencies and the voltage at which the maximum was measured for several phosphors. The phosphors have been listed according to emitted color, *i.e.*, blue first then green then red. Similar phosphors have been grouped together. The deviations listed in Table I are the deviations found for the number of measurements indicated and the average deviation over all samples at high voltage was 0.004. Mean deviations are indicated by error bars in the figure. Some of the samples show indications of surface charging at high voltages, usually at 17 to 20 kV. We have chosen to have the measurements extend from 5 to 20 kV; surface effects become pronounced below 5 kV and Bril's measurements show that the measured efficiencies do not increase appreciably beyond 20 kV for most phosphors. In some cases it is possible that the maximum efficiency has not been reached at 20 kV, and in other cases charging effects might be suspected when the apparent maximum is found at relatively low voltage.

Effect of heat treatment.—Several of the phosphor samples were heated in the vacuum system at approximately 100°C for several hours and then allowed to cool to room temperature. The results obtained with and without this heat treatment are summarized in Table II. The heating apparently reduces the charging effect and in some cases a slight but detectable increase in efficiency is observed. Figure 6 shows the case in which the largest increase occurred after the heat treatment. While our results indicate that the heating has reduced charging, it apparently has not removed surface contaminants since the efficiencies measured at low voltages (5 kV) did not increase after being heated.

Comparison with other measurements of efficiency.—The agreement among the various investigators is in

Table I. Measured efficiencies, η_i

Phosphor	η_{Max}	kV at η_{Max}	Times measured
NBS 1020 ZnS:Ag	0.204 ± 0.005	20[a]	15
$Sr_3(PO_4)_2:Eu^{2+}$	0.055 ± 0.004	14	6

[c] 5.7 m/o Eu by analysis.

general very good; however, there are a few exceptions. Table III presents a comparison of our results with efficiencies measured by others. For the phosphors NBS 1020 and 1021, our results agree with Bril's within his experimental error. The LK value of ZnS:Ag is listed separately in Table III since they apparently did not measure NBS 1020.

The measured efficiency of ZnS:Ag,Al is compared with Bril's results in Table III. Since this is not a National Bureau of Standards phosphor, we cannot be sure that the measurements were made on identical samples (phosphors vary significantly from one lot to another). In spite of this we find that our results agree with Bril's within his experimental error at high voltages. When we compared the voltage dependence of this phosphor with that reported by BK we found that our values were slightly higher at low voltages, but slightly lower at high voltages. These apparent differences in the measured voltage dependence could be the result of a reduction of surface contamination in the improved vacuum system.

One case in which there appears to be a definite disagreement is for the phosphor $Zn_2SiO_4:Mn^{2+}$, NBS 1021. Since this is a National Bureau of Standards phosphor, we can be certain that the phosphor lot used by all the investigators is identical. Any differences then can only result from differences of measurement or preparation of test samples. Our results lie between those reported by Bril and those reported by Ludwig and Kingsley; our value, however, lies within the experimental error reported by Bril, but does not agree with LK results. There are two plausible reasons for this discrepancy. The sample density, 8-14 mg/cm², used by LK was considerably less than we found necessary. For our measurements of NBS 1021 at a coating density of 33 mg/cm² we measured an efficiency of 0.062 which is already considerably less than 0.074

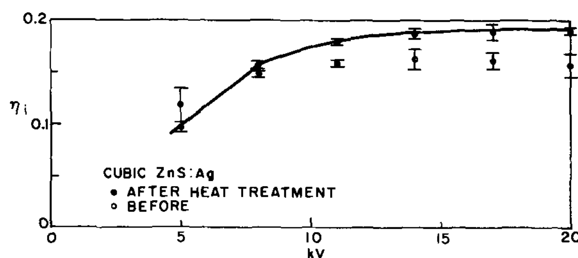

Fig. 6. Voltage dependence of intrinsic efficiency for cubic ZnS:Ag before and after being heated in vacuum.

measured at a coating density of 50 mg/cm². One might expect then that at 14 mg/cm² the measured value could be much lower. A second possible error could result in the case of this particular phosphor from using a modulation technique. LK used a lock-in amplifier at a frequency of 25 Hz. During this period (40 msec) the detector received a square wave pulse for half (20 msec) of the period so that from the end of one pulse to the beginning of another 20 msec elapsed. During that time the green emission from $Zn_2SiO_4:Mn^{2+}$ decays to approximately 10% of its brightness during excitation. Since the synchronous technique measures only the modulation there is a possibility of error for this slowly decaying phosphor.

Our measurements for Y_2O_3:Eu are somewhat higher than those of LK, but agree fairly well with Bril's value. This might result from the lighter coating density used by LK. On the other hand, for Y_2O_2S:Eu the LK value is higher than our measured value. Part of these inconsistencies may be attributed to differences in the phosphor samples or in the preparation of test samples.

Voltage Dependence near X-Ray Levels

Results

In other measurements of efficiencies we have noticed indications of changes in efficiency as the accelerating voltage increases beyond the value corresponding to x-ray levels of the host material. To more carefully study the voltage dependence, measurements have been made using a sensitive photomultiplier in place of the thermopile, and experimental conditions which minimize or eliminate charging have been used.

To eliminate charging effects, measurements of the voltage dependence of cathodoluminescence using cathode ray tubes having aluminized phosphor screens have been made. In these measurements, the luminance was measured over a wide voltage range at a constant current density. The accelerating voltage is corrected for loss in the aluminum layer by using the Thomson-Whiddington relationship and the range of electrons in aluminum films as measured by Feldman (10). The results for ZnS:Ag are shown in Fig. 7 and the K x-ray absorption edges of zinc and sulfur are indicated. There is an obvious change of slope which appears to occur near the zinc level. A similar curve for $YPO_4:Tb^{3+}$ (Fig. 7) shows no change of slope in the region of 10

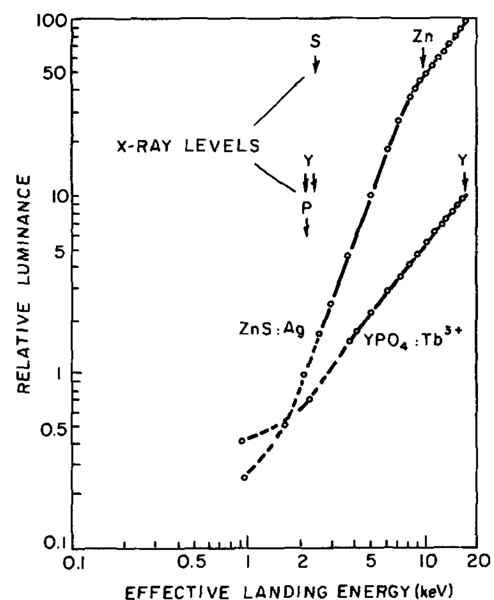

Fig. 7. Voltage dependence of luminance for ZnS:Ag and $YPO_4:Tb^{3+}$. The voltage scale is corrected for energy lost in penetrating through 2000Å of aluminum. At low voltages, the dashed curve indicates possibility of large error since correction applied to the voltage is almost as large as the measured voltage.

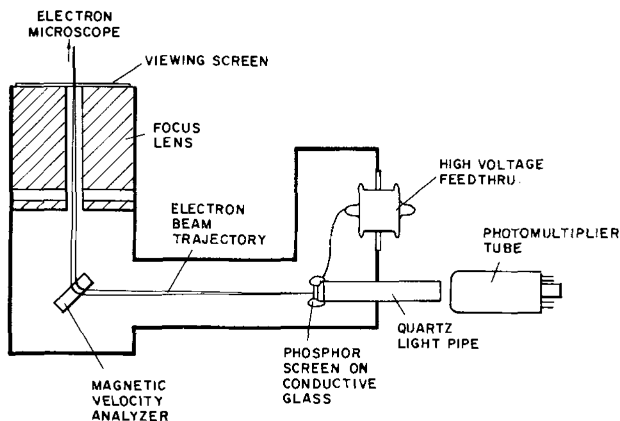

Fig. 8. Schematic representation of modification added to electron microscope.

kV. Since a correction has been applied, the voltage scale may be shifted. At low voltages the error in the corrected value of the accelerating voltage can be quite large, since the correction becomes as large as the applied potential. The curves are dashed to indicate that changes in slope suggested by points in this region are questionable.

One of the difficulties in measuring the change in brightness with accelerating voltage is the stringent requirement that the current must be maintained constant. This requires a readjustment at each accelerating voltage in the normal cathode ray tube. In order to eliminate this possible source of error, another method was used to measure the voltage dependence. In this case, an electron microscope which had been modified for other studies (11) was used (see Fig. 8). A hole was drilled in the viewing screen and a focusing lens and magnetic velocity analyzer were added. With the analyzer and focusing coil set properly the electron beam was deflected through 90° and focused onto a phosphor screen deposited on conductive glass and attached to the end of a quartz light pipe leading to a sensitive photomultiplier tube. The potential of the phosphor screen was determined by a separate highly regulated high-voltage power supply. With the electron beam current and voltage adjusted to a convenient value, the effective accelerating voltage of electrons exciting the phosphor screen (the potential difference between phosphor screen and electron source —the effective landing voltage) could be varied without changing the beam current simply by altering the potential applied to the phosphor screen. Since the phosphor screen was large (½ in. diam) compared to the focused electron beam spot (<0.005 in.) and since the photomultiplier viewed the entire screen (2 in. diam active photocathode), small changes in position on the screen or in spot size produced by changes in screen potential, even over large voltage changes, did not change the current delivered to the screen.

With a ZnS:Ag phosphor screen and the electron beam in the microscope accelerated to 7 kV, the potential of the phosphor screen was varied from 1 to 5.5 kV (*i.e.*, the effective landing voltage varied from 8 to 12.5 kV). The relative photomultiplier response over this range is shown in a log-log plot in Fig. 9, curve A. A change of slope appears to occur near the indicated Zn K ionization level. To determine if the change of slope results from a change inherent in the apparatus as a result of the voltage applied to the phosphor screen, or is due to some characteristic of the phosphor itself, the beam voltage in the microscope was reduced to 6 kV and the voltage applied to the phosphor screen was varied from 2 to 5.5 kV. The relative photomultiplier response over this range is shown in curve B of Fig. 9. The change of slope again occurs at the same effective accelerating voltage. We conclude therefore that the change of slope occurs at a characteristic voltage difference between the phosphor screen and

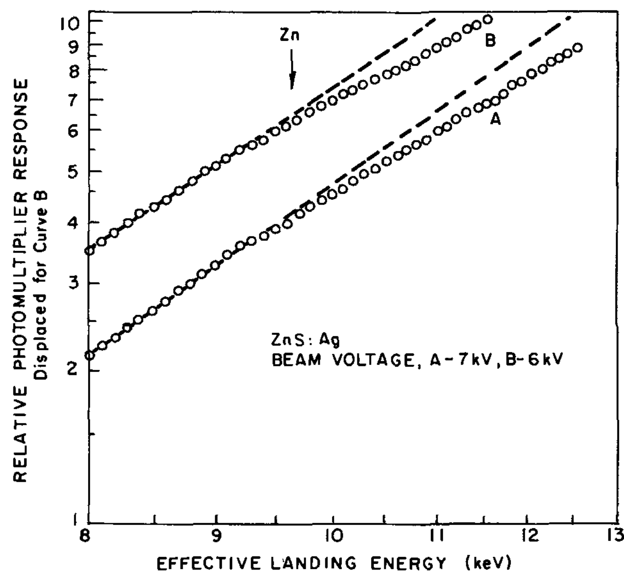

Fig. 9. Voltage dependence of luminance for ZnS:Ag. The effective accelerating voltage varied from 8 to 12.5 kV. In case A the beam voltage was 7 kV and a potential of 1-5.5 kV was applied to the phosphor screen. For case B, beam voltage = 6 kV, phosphor screen voltage = 2-5.5 kV.

the electron source (effective landing voltage) and not as a result of change in electron trajectory, focus, etc. which might result from changing the potential difference between the phosphor screen and the surrounding metal case which is at ground potential.

Similar measurements for a single crystal of $CaWO_4$ covered on the electron beam side with a thin film of aluminum are shown in Fig. 10. With the beam voltage set at 18 kV, the retarding voltage on the crystal was first increased from -1 kV to -10 kV in 500V steps and then reduced from -10 kV back to -1 kV. Thus two points appear at each effective landing potential giving an estimate of the scatter in the data. The two curves show two series of such measurements. There is a definite change of slope which appears to occur in the region of the tungsten L_1, L_2, and L_3 absorption edges. Since the aluminum film was very thin and the effective landing voltage was high, correction for energy loss in the aluminum film was small and made no detectable difference in the voltage at which the change of slope appears to occur. However, if the effective landing voltage is reduced much further the

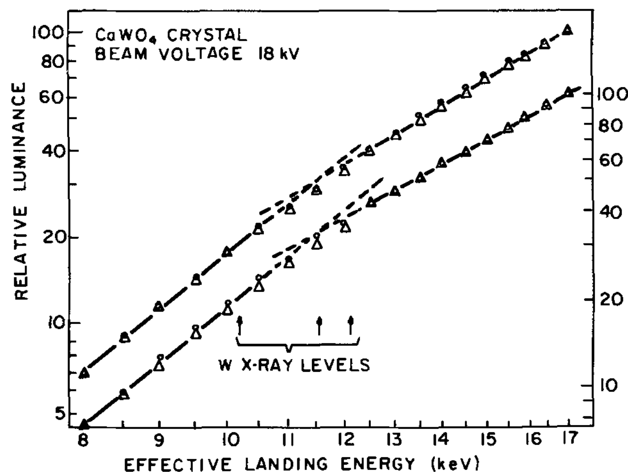

Fig. 10. Voltage dependence of luminance for $CaWO_4$ single crystal. Two series of measurements are shown. In each series the two points at each voltage are values obtained on consecutive measurements. Beam voltage = 18 kV, retarding potential of -1 to -10 kV.

correction becomes significant. Therefore, to observe lower lying x-ray absorption edges, a similar experimental arrangement was used, except that the metal film on the electron beam side of the $CaWO_4$ crystal was evaporated through a mask to provide a slot slightly larger than the beam size. That is, the metal covered the crystal except in the region where the beam landed. To minimize the possibility of surface charging the beam current was reduced to the minimum level necessary to obtain a usable signal. Visual examination of the spot showed no distortion or enlarging of the spot. With the beam voltage set at 12 kV and the retarding potential varied from −5.5 to −10 kV, the results shown in Fig. 11 were obtained. Each point in this figure is the average of three measurements and the root-mean-square deviation is indicated by the error bars. Two series of measurements are represented by the two curves, one at 500V intervals and another at finer intervals. Changes of slope are repeatedly found in the regions of the Ca and W x-ray excitation potentials. The changes can be further demonstrated by dividing the luminosity by the kinetic energy of the exciting electron beam. This quantity which is proportional to the efficiency is shown in Fig. 12. It is apparent that changes in slope occur at or near the Ca x-ray excitation potential although the change is less obvious at the W level.

Changes in slope of the brightness *vs.* accelerating voltage curve have been reported previously; however, to our knowledge, they have not been correlated with excitation potentials of x-ray levels. Brown (12) measured the brightness of willemite ($Zn_2SiO_4{:}Mn^{2+}$) at low and intermediate voltages. In his Fig. 4 he shows that the brightness varies as the second power of the accelerating voltage from 200 to 800V and then suddenly increases more rapidly. The K absorption edge for oxygen is located at approximately 500 eV. Nottingham (13) also measured the brightness of willemite as a function of accelerating voltage, but at slightly higher voltages than Brown. In his Fig. 15 Nottingham shows a plot of the logarithm of brightness *vs.* the logarithm of the accelerating voltage. There is a change of slope at approximately 1500V. The K x-ray level of silicon is located at about 1.8 keV, and zinc levels are located at 1.2, 1.05, and 1.02 keV.

The idea that the efficiency of producing luminescence is not the same from different energy levels in the x-ray region has been demonstrated by others (14-16) using photon excitation. In their Fig. 6 Aitken,

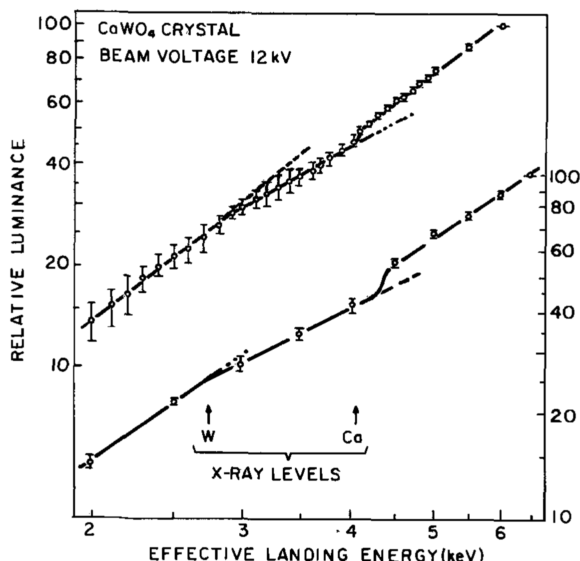

Fig. 11. Voltage dependence of luminance for $CaWO_4$ single crystal. Two series of measurements are shown. Each point is the average of three measurements and the root-mean square deviation is indicated by the error bars. Beam voltage = 12 kV, retarding potential of −5.5 to −10 kV.

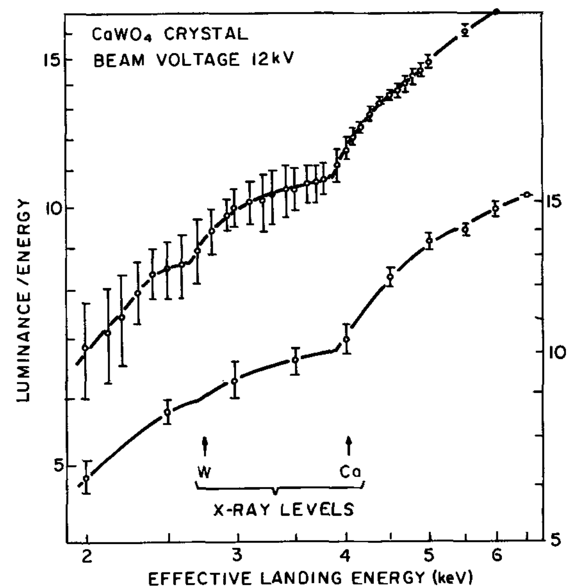

Fig. 12. Voltage dependence of luminance divided by kinetic energy for $CaWO_4$ single crystal. Conditions are the same as in Fig. 11.

et al. (14) show the response curve for single crystal CsI(Tl). Not only do these results reveal discontinuities at the iodine and cesium L- and K-shell absorption edges, but they also show that between absorption edges the response is a function of the energy. After the L-shell absorption edge (between 5 and 6 keV) there is an increase of approximately 30% in the response as the energy increases to 20 keV. It might be claimed that this is a result of a nonluminescent surface which becomes less significant as the energy is increased. However, at lower energies, the response decreases by approximately 20% as the energy increases from 4 keV to approximately 6 keV. This certainly is not a result of surface effects but must be attributed to a change in the intrinsic efficiency as the energy increases. The energy dependence of the x-ray response curves for NaI(Tl) scintillation crystals have been reported by Engelkeimer (15) and by Kaiser, Baker, McKay, and Sherman (16). They find that the response is significantly nonlinear with changes occurring at energies which correspond to iodine absorption edges. These results also show that the response is not constant until the energy is much greater than that of the absorption edge having the highest energy. In addition, Kaiser *et al.* (16) show a postulated electron response curve which shows a change of slope at the K edge of iodine (33 keV).

Discussion

The referenced studies of x-ray excitation have demonstrated that for scintillation crystals: (*i*) there is a discontinuity in the efficiency at an x-ray absorption edge, (*ii*) the intrinsic efficiency is a function of the energy, and (*iii*) postulated electron response curves are nonlinear with a change of slope occurring in the region of the voltage corresponding to an x-ray edge. The change of slope is not abrupt, but more gradual than that observed by high energy photon excitation. It should be noted in addition that the change in slope does not result solely from the discontinuity at the absorption edge; it also results from the changes in efficiency just before and after the edge. The location of the change of slope therefore may not coincide exactly with the x-ray absorption edge.

We suggest that for phosphors other than scintillation crystals, one cannot be certain that the efficiency is constant unless the accelerating voltage is much larger than the K ionization energy. We expect to find, therefore, a constant efficiency only at high accelerating voltages for materials like ZnS, Zn_2SiO_4, etc. (the K ionization energy of Zn is 9.66 keV); but at lower volt-

ages, as the accelerating voltage is increased and passes through the ionization energy of an x-ray level, we might expect to observe a small change in the measured efficiency and a change in the energy dependence. We expect to find, as in the postulated electron response curves for scintillation crystals a change of slope which is gradual rather than abrupt. Since the luminance is proportional to the efficiency multiplied by the kinetic energy of the electron beam, we expect to observe changes in slope of luminance *vs.* accelerating voltage plots at x-ray excitation potentials similar to those in Fig. 7-12.

It is not suggested that surface effects are unimportant, but the data indicate that x-ray level effects may be superimposed on the surface effect in the voltage dependence curves; therefore, it cannot be assumed that the intrinsic efficiency is constant unless the excitation energy exceeds the largest K x-ray energy of the host material.

Summary

Our measurements of efficiency show that the estimated maximum attainable efficiency has not been exceeded but has very nearly been reached for II-VI sulfides. The over-all agreement with previous measurements is generally good, and best agreement is found with the higher of previously reported values. For the NBS phosphor No. 1021, $Zn_2SiO_4:Mn^{2+}$, our results are within Bril's experimental error but do not agree with the lower value measured by Ludwig and Kingsley.

Heating the phosphor samples in vacuum prior to measurement, has reduced the charging effect at high voltages. Measurements of luminance and efficiency over a wide range of accelerating voltages together with an examination of previously reported results has led us to conclude that in some cases there may be a change in efficiency when the incident energy is increased and passes through an x-ray level of the host material. The intrinsic efficiency of a cathodoluminescent phosphor cannot therefore be assumed to be constant unless the incident energy exceeds the largest K x-ray absorption energy of the host.

Acknowledgments

It is a pleasure to acknowledge the assistance of C. Creter in making the measurements and of J. Rapp in designing the apparatus.

Comparison of Infrared and Activation Analysis Results in Determining the Oxygen and Carbon Content in Silicon

Chris Gross and Gianni Gaetano

NASA Langley Research Center, Hampton, Virginia 23365

and T. N. Tucker* and J. A. Baker

Dow Corning Corporation, Hemlock, Michigan 48626

ABSTRACT

The oxygen and carbon content of several silicon single crystals have been measured using ^3He activation techniques and are compared with values determined from infrared absorption measurements. The oxygen and carbon content of these crystals as determined from the activation analysis ranged from <0.05 to 28 ppm and <0.05 to 7 ppm, respectively. The infrared absorption measurements gave results that agreed with the activation analysis to within ~40%.

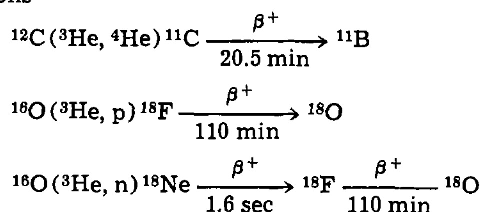
Infrared absorption spectrophotometry has been used to determine the oxygen and carbon content of monocrystalline silicon (1-3). This method is particularly attractive because it has a sensitivity in the ppba (parts per billion atomic) range and it is inexpensive, quick, and nondestructive. However, questions regarding the accuracy of this technique for measuring the total oxygen and carbon content can arise because only interstitial oxygen and substitutional carbon, with absorption bands at 1130 and 607 cm^{-1}, respectively, can be detected. Agreement between results of *IR* spectrophotometry and charged particle activation analysis for oxygen determination has been reported to vary between near identical to a factor of 2 (4-6), while an agreement within 30% has been obtained among *IR*,

* Electrochemical Society Active Member.

Key words: activation analysis, spectroscopic analysis, infrared spectroscopy, carbon impurities, oxygen impurities, silicon purity, helium 3 ions, semiconductor silicon.

mass spectroscopy, and variation in lattice parameters for carbon (3). However, chemical methods do not correlate with *IR* measurements for carbon determination in silicon. The *IR* method indicates that carbon is present in semiconductor grade silicon in concentrations in the ppma range or less, while chemical methods indicate that carbon is always present in silicon in concentration greater than 50 ppma (7-14).

Because of the importance of the *IR* absorption method and the questioning of its accuracy, we felt that a systematic comparison of this method with a sensitive and precise method, such as activation analysis, for a wide range of oxygen and carbon contents was warranted. Activation with ^{3}He ion, utilizing the reactions



$$^{12}C(^3He, ^4He)^{11}C \xrightarrow[20.5\ min]{\beta^+} {}^{11}B$$

$$^{16}O(^3He, p)^{18}F \xrightarrow[110\ min]{\beta^+} {}^{18}O$$

$$^{16}O(^3He, n)^{18}Ne \xrightarrow[1.6\ sec]{\beta^+} {}^{18}F \xrightarrow[110\ min]{\beta^+} {}^{18}O$$

was chosen because sensitivity in the ppba for both oxygen and carbon can be obtained (4-6) at relatively low energies where interferences from spallation products are negligible (15).

Experimental Procedure

Sample preparation.—Pulled-crucible and float-zoned silicon single crystals, obtained from commercial sources, and specially prepared low oxygen-carbon and carbon-doped crystals were used in this study. The commercial crystals were representative of semiconductor-grade silicon used for transistor and nuclear detector manufacturing. The low oxygen-carbon crystals were obtained by float-zone refining of ultrapure polycrystalline deposited rods. A carbon-doped crystal was prepared by vacuum-zone refining a low oxygen-carbon crystal that was painted with a mixture of acetone and spectroscopic-grade graphite (3).

The crystals were cut into cylinders 2 cm in diameter, 1 cm thickness, and polished to a surface flatness of less than 2μ for *IR* measurements. Slices 2 mm thick, adjacent to those used in activation analysis, were similarly cut and polished and were used in the *IR* carbon content determination. A 1 min etch in a semiconductor grade HF:HNO_3 mixture was given to each sample prior to activation to clean the surfaces. Reference samples of oxygen and carbon with the same dimensions as the silicon samples were prepared from high-purity quartz and carbon.

Infrared measurements.—Measurements of the 1100 cm^{-1} and 607 cm^{-1} absorption bands due to interstitial oxygen and substitutional carbon, respectively, were made at room temperature using a Beckman IR-12 double-beam grating infrared spectrophotometer. Silicon crystals containing less than 50 ppba oxygen and 200 ppba carbon (as determined by activation analysis) and of the same thickness as the unknown samples were placed in the reference beam to suppress the silicon lattice bands particularly intense in the 607 cm^{-1} carbon line region. Using this differential technique, only the differences in absorption due to the presence of impurities in the unknown samples are recorded. With 1 cm thick samples, the same as used in the activation analysis experiment, a 50 ppba detection limit at 300°K was achieved for the oxygen content determination.

For the carbon content determination, instead of using the same samples later tested by activation analysis, adjacent 2 mm thick polished silicon slices were used in the *IR* measurement. This was necessary since the strong two-phonon lattice band and reflectivity losses reduce the incident energy to about 5% of its initial value, leaving the instrument in an energy-limited condition. With extreme care, it was possible to obtain an acceptable signal-to-noise ratio with a detection limit of 200 ppba at 300°K. For both impurities, measurement accuracy was better than 2% for concentrations in the range of 1 ppma or greater.

Calibration coefficients taken from the literature (1, 2) (1.1 × 10^{17} per cm^3 for carbon and 4.5 × 10^{17} per cm^3 for oxygen) were utilized in computing the oxygen and carbon content.

Activation analysis.—Activation of the samples was performed at the ORNL Asychronous Cyclotron. Because of the difficulty of obtaining a low energy $^3He^+$ beam, an extracted 25.6 MeV $^3He^+$ beam was reduced to 16.6 MeV by the use of 27.4 mg/cm^2 of aluminum and 23.6 mg/cm^2 of silicon placed immediately in front of the sample. By removing 50μ from the sample's irradiated surfaces, the energy was further reduced to 13.9 MeV, which was chosen to give near-optimum sensitivity without producing significant interference from reactions such as Si(^{3}He, X)C^{11} and Si(^{3}He, X)^{18}F. The beam was collimated to 1 cm in diameter immediately in front of the sample holder which was water cooled and electrically insulated from ground. An electrometer was used to measure and to integrate the beam intensity.

Each of the silicon samples was irradiated at an intensity of 1 μA for 1000 sec, while the standard samples were irradiated at 0.01 μA for 10 sec. Prior to counting, 50μ of the silicon sample's irradiated surface was removed by grinding and etching to eliminate errors arising from surface contamination. Similarly, a 50μ thick slice of silicon was placed in front of the reference samples during irradiation to correct for the removal of material from the silicon samples. In addition, the ^{30}P activity produced by ^{28}Si(^{3}He, p)^{30}P of these slices was extrapolated back to the end of the irradiation time, and was used to determine whether errors were introduced in the beam-current measurements by the quartz sample, since it is an insulator. For purpose of comparison, several samples were activated twice.

A standard β^+-pair spectrometer, using two 3 × 3 in. NaI(Tl) crystals and having window widths set from 0.40 to 0.55 MeV with a coincidence resolving time of 50 nanoseconds, was used to measure the ^{11}C and ^{18}F activity. A ^{22}Na source was used to calibrate the spectrometer. Recording of the sample's activity was not started until about 40 min after irradiation to allow the 2.5 min half-life activity of ^{30}P to decay to a level where there was negligible pile-up error. The coincidence count rate was recorded by a 400 channel multiscaler with a 1 min period per channel during the first 2 hr and then with a 10 min period per channel every hour for the next 8 hr. The β^+ activities of the reference samples were counted for a period of four times their respective reaction's half-lives. The impurity concentrations were then calculated by the usual comparison method (16).

In this method, the use of reference samples of quartz and carbon, containing a known amount of the same unknown atom species that were activated in the samples, established a reference datum which eliminated most of the errors associated with the determination of reaction cross section, detector geometry, and detector efficiency (16). Assuming equal isotopic distribution of impurities in both silicon and reference samples, and neglecting the small error associated with particle removal from the beam by competing nuclear reactions, the unknown atom concentration, N_x, was calculated from the formula

$$N_x = \frac{A_x\, \phi_s\, R_s\, \bar{\sigma}_s (1 - e^{-\lambda t_s}) e^{-\mu_s d_s}}{A_s\, \phi_x\, R_x\, \bar{\sigma}_x (1 - e^{-\lambda t_x}) e^{-\mu_x d_x}} N_s \quad [1]$$

where A is the β^+ activity at the end of the irradiation period, ϕ the intensity of the ^{3}He beam, R the range of the ^{3}He ions, $\bar{\sigma}$ the average reaction cross section, λ the decay constant, t the irradiation time, μ the attenuation coefficient for annihilation radiation, d the

sample thickness, and N_s the standard sample concentration of the atoms to be measured. The x and s subscripts refer to parameters associated with the silicon and standard samples, respectively. The average radiation cross sections were calculated by numerical integration (17, 18) using values taken from the literature (19-21). Their computed values for 13.5 MeV ^{3}He ions are given in Table I along with the ranges and the attenuation coefficients.

Results and Discussion

The β^+ activities as a function of time for three silicon samples containing 22 ppma of oxygen, 4.4 ppma of carbon, and less than 20 ppba of either oxygen or carbon are shown in Fig. 1. Activity data of this type were least-square fitted (using fixed half-lives of 2.5, 20.5, and 110 min for ^{30}P, ^{11}C, and ^{18}F, respectively) to determine the activity of each component and its associated statistical error at the end of the irradiation period. Substituting these values, along with those in Table I and other measured quantities (ϕ, t, d), into Eq. [1], the amounts of oxygen and carbon present in the silicon samples were calculated and are listed in Tables II and III. The corresponding impurity concentrations obtained by the infrared absorption measurements are also listed in Tables II and III. The detectable limit of 20 ppba for the activation analysis is based on twice the one coincidence/min background and on the measured count rate of 100 coincidences/min taken 1 hr after the end of the irradiation period. This corresponds to oxygen or carbon concentration of 1 ppma.

The values listed in Table II show that infrared spectrophotometry gives oxygen concentrations that are consistently 30% lower in the case of Czochralski-grown crystals, while for the float-zone crystals, neither method detected oxygen in concentrations greater than 50 ppba. The values listed in Table III show that infrared spectrophotometry gives carbon concentrations that are consistently higher than those obtained by activation analysis.

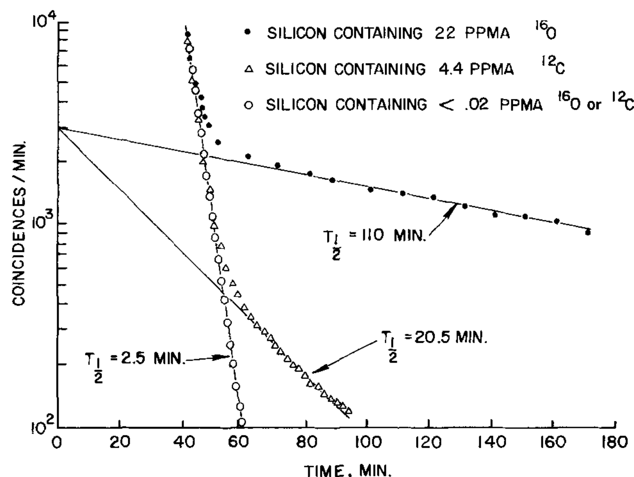

Fig. 1. Decay curves for activated silicon samples containing 22 ppma oxygen, 4.4 ppma carbon, and less than 0.02 ppma oxygen or carbon. (The 2.5 min half life is ^{30}P.)

The difference in the results of the two methods is not thought to arise from errors in activation analysis for the following reasons: (*i*) surface contamination errors were completely eliminated by the removal of 50 microns of material from the irradiated surface (4); (*ii*) interference from such reactions as Si(^{3}He, X)^{11}C, Si(^{3}He, X)^{18}F, and ^{16}O(^{3}He, 2α)^{11}C for 13.5 MeV ^{3}He ions were calculated to be negligible (15); (*iii*) the error associated with particle channeling has been shown to be insignificant (22); (*iv*) beam energy determination, etched layer thickness uncertainty, reference sample densities, and so forth were calculated to be no more than 10% for all samples; (*v*) interference arising from the possible presences of impuri-

† Carbon doped.

ties such as Al, Na, N, Be, B, F, Ne, were thought to be insignificant either because of the technology involved in the silicon crystal refining or because of their high-threshold energy values; (*vi*) the counting statistics errors associated with those samples in Tables II and III which were used for comparison purpose were found to be less than 5%; (*vii*) the total experimental error as deduced from those samples that were irradiated two times or more, has been estimated to be less than 10% for the compared values.

The difference between results from *IR* and activation analysis then can be attributed to any one or to a combination of the following possibilities: (*i*) errors in published infrared absorption coefficients, (*ii*) infrared experimental errors arising from slit width dependence on narrow absorption peaks, (*iii*) inability of the *IR* method to detect impurities present in configurations other than those possessing known absorption bands, (*iv*) nonuniform distribution of the impurity atoms throughout the crystal.

For carbon, possibility (*iii*) is not plausible, since activation analysis results were consistently lower than the corresponding *IR* values, leaving (*i*), (*ii*), and (*iv*) as probable causes for the discrepancy. For oxygen, only possibilities (*i*) and (*iii*) appear to be the probable causes of the 30% difference between *IR* and activation analysis values, since (*ii*) and (*iv*) are not plausible because of the oxygen broad adsorption peak and the fact that activation on both sides of several samples yielded the same oxygen concentration within 10%, respectively.

In view of the above, we feel that the differences between the two methods are real and that the spectrophotometric method underestimates the carbon concentration by 29 $\pm$ 15% and overestimates the oxygen concentration by 37 $\pm$ 15%.

The ranges of oxygen and carbon concentrations measured for the silicon crystals obtained from commercial sources are in general agreement with other activation analysis results (4, 5, 15, 23). However, the results obtained for the carbon content are in disagreement with chemical analysis results. The carbon content of the crystals analyzed was of the order of a few ppma or less, which is much smaller than the concentrations of 50 ppma or greater that have been measured by chemical methods. Because of the inherent reliability of the activation analysis method, it is felt that the chemical analysis techniques used to date grossly overestimate the carbon content in silicon.

Conclusions

Agreement between results obtained by infrared spectrophotometry and those obtained by the activation analysis method has been found to be consistent within ~40% in determining the oxygen and carbon impurities concentration in silicon. The carbon content of semiconductor grade silicon was found to be of the order of a few ppma, which is in disagreement with chemical analysis results.

Origin of the High Resistance Region at the Epitaxial GaAs Layer-Substrate Interface

Fumio Hasegawa

Central Research Laboratories, Nippon Electric Company, Ltd., Kawasaki, Japan

ABSTRACT

In order to find the reason for the high resistance region which appears at the interface between a vapor-grown epitaxial GaAs layer and the substrate, epitaxial layers were grown by changing the substrate temperature or arsenic pressure in the reaction system. Heat-treatment of substrates was also examined under a hydrogen atmosphere or in a flow of $GaCl/As_4/H_2$. A high resistance layer occurred even when the growth was initiated after the reaction had reached a steady state. While mere heat-treatment in hydrogen changed the surface carrier density only slightly, the heat treatment in the flow of $GaCl/As_4/H_2$ changed the region within a few microns from the surface of undoped substrates to almost semi-insulating. The experimental results seem to indicate that the high resistance region is formed on GaAs surface or at the interface if the gas etching slightly overcomes the growth in a reaction system. Results of photoresponse and photoluminescence measurements on the high resistance region are also presented.

The epitaxial growth by the $AsCl_3/Ga/H_2$ vapor transport method is the most common and useful one for GaAs epitaxy. In that method, however, the autodoping effect cannot be avoided if heavily Te- or S-doped substrates are used (1). On the other hand, when the substrate is Si- or Sn-doped, undoped, or Cr-doped semi-insulating, an anomalous high resistance region appears at the interface between the epitaxial layer and the substrate (2, 3).

The occurrence of this high resistance region is a basic problem in obtaining an epitaxial layer with a uniform doping profile and has been studied by many workers (2-10). But the problem has not entirely been solved as yet. The purpose of this paper is to clarify the origin of the occurrence of the high resistance region.

The occurrence of the high resistance region has been interpreted by either of the following two things: (*i*) formation of As vacancy or Si-As vacancy center due to arsenic deficiency at the beginning of the growth (2-7), (*ii*) impurity contamination at the interface due to improper cleaning or diffusion from the substrate (8-10). Wolfe *et al.* (2) have first found the problem in an epitaxial layer on a Si-doped substrate and attributed it to the amphoteric property of Si in GaAs. We have independently found (3, 4) the problem and attributed it to some defects formed at the interface during the initial stage of the growth. Recently, Shaw (5) has shown that when a Ga source covered with GaAs crust was heated in hydrogen, the crust dissolved in Ga and $AsCl_3$ supply of several minutes was necessary to recover the Ga source with crust. Some investigators (2, 6) have reported that the occurrence of the high resistance region could be suppressed by saturating the Ga source with arsenic or by adding excess arsenic pressure. These results seem to support the first reason. On the other hand, Blakesleee *et al.* (8) and Nakashima *et al.* (9) found the copper at the interface by the measurements of radioactive copper or photoluminescence. DiLorenzo *et al.* (10) have found Si, K, and many other impurities at the interface by a Direct Image Mass Analyzer, although its quantity (10^{21} cm^{-3}) is deemed surprisingly large. But, distribution of impurities such as copper is generally influenced by the distribution of the defect (11), and hence, existence of impurities may be related with the defect formation.

In the present work, in order to avoid the deficiency of arsenic, the growth with the Ga source covered by GaAs crust was tried. But the occurrence of the high resistance layer could not be eliminated. Furthermore, several phenomena which cannot be explained by arsenic vacancies were found. This paper will present such experimental results and give some speculations for the origin of the high resistance region. Some defects other than arsenic vacancy or Si at the As site seem to be necessary to interpret the achieved experimental results.

Key words: GaAs, vapor growth, $AsCl_3$, carrier density profile, high resistance region, deep acceptor.

Experimental

Epitaxial layers of GaAs were grown by using the $Ga/AsCl_3/H_2$ vapor transport method (1). A schematic diagram of the growth apparatus is shown in Fig. 1. It has two zones. One is the main reaction zone in which the Ga source and the substrate are placed. The other is a zone where $AsCl_3$ is decomposed to arsenic metal and where the arsenic vapor pressure of the reaction system is controlled.

The epitaxial growth procedure is the same as the one previously reported (1) unless specially mentioned. When one wants to reduce the arsenic vapor pressure in the reaction system, the sliding furnace is placed apart from the main furnace as shown in Fig. 1, and $AsCl_3$ is decomposed at 860°C before it reaches the main reaction zone. The decomposed arsenic metal deposits at the low temperature region between the main furnace and the sliding furnace. To increase the arsenic vapor pressure, the temperature of the deposited arsenic metal is raised by the sliding furnace (400° ~ 450°C). Growth rate was reduced to less than half the normal growth rate when $AsCl_3$ was decomposed at 860°C before it reaches the main reaction zone.

In order to suppress the growth on the substrate until the reaction reaches a steady state, a special substrate holder having a cover was provided. This holder is shown in Fig. 2 and will be described in detail in the following section.

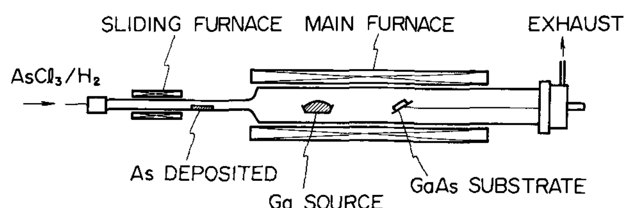

Fig. 1. Reaction system of GaAs vapor epitaxial growth. A sliding furnace is provided to decompose $AsCl_3$ before it reaches the main reaction zone.

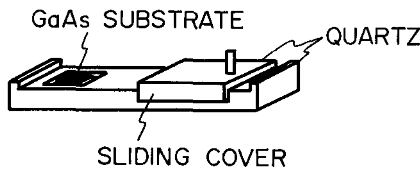

Fig. 2. A special substrate holder is provided in order to initiate growth after the reaction has reached to a steady state; the holder is made of high purity quartz.

The carrier density profiles (net donor density profiles) were measured by the differential capacitance voltage method. In some cases, a plotting apparatus was used. Measurements of photoluminescence were performed by using excitation with a 50 mW He-Ne laser, a spectrometer (Spex 1702), and a detector with an RCA 7102 photomultiplier.

Experimental Results and Discussion

Initiation of growth under steady state.—Shaw (5) has reported that, when a Ga source covered with GaAs crust was heated to the operation temperature, a portion of GaAs crust dissolved into Ga and several minutes of $AsCl_3$ supply was necessary to completely recover the Ga liquid with GaAs crust. In order to initiate substantial growth on a substrate after a Ga source is completely covered with GaAs crust and the reaction has reached a steady state, a substrate holder made of high purity quartz as shown in Fig. 2 was prepared. On the top surface of the quartz plate, a small hollow in which the substrate is put is provided. The hollow can be closed tightly with a sliding cover which can be moved by a connecting rod from the outside of the reaction tube.

The growth procedure is as follows: The substrate is placed in the hollow. The temperature of the reaction system is elevated to growth temperature while the hollow is not covered. Then, the hollow is shut and $AsCl_3/H_2$ is admitted. After the reaction has reached a steady state, the cover is removed and growth on the substrate is begun. It was verified experimentally that the growth on the substrate was negligible while the hollow was covered.

Figure 3 shows doping profiles of the epitaxial layers grown by the method mentioned above, by changing the interval from the beginning of the flow of $AsCl_3$ to the beginning of the growth on the substrate (5, 10, 15 min). The used substrates are Si-doped and are from the same ingot. No correlation between the magnitude of the high resistance region at the interface

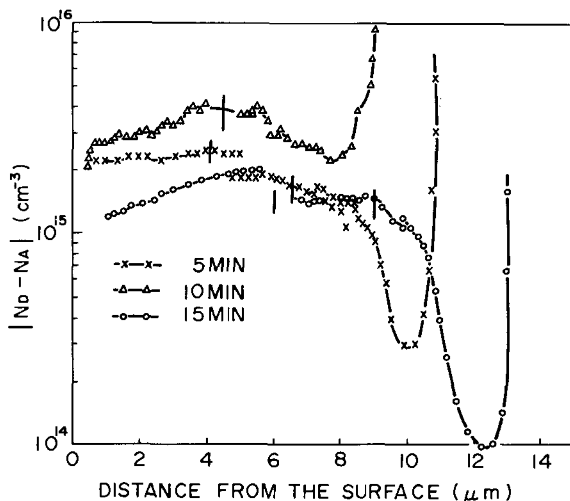

Fig. 3. Carrier density profiles of epitaxial layers grown by using the substrate holder shown in Fig. 2. The interval between the beginning of the flow of $AsCl_3/H_2$ and the beginning of the substantial growth on the substrate was changed. Substrates are heavily Si-doped.

and the interval the hollow is covered can be found in the figure. The same experiment was repeated several times, but no correlation could be found and the high resistance region could not be avoided. It has been reported (5) that the crust completely reformed in 5.3 min after $AsCl_3$ was admitted, even when the Ga source was heated for 30 min under hydrogen flow. Then, the above results seem to indicate that the high resistance region sometimes appears at the interface, even if the growth is initiated after the Ga source is completely covered with GaAs crust or the reaction has reached a steady state.

On the other hand, there is an experimental fact that the excessive pressure of arsenic can eliminate the occurrence of the high resistance region. In the next section, it will be shown that this experimental result does not necessarily imply that the deficiency of arsenic is the cause of the high resistance region.

Occurrence of a low resistance layer with excessive arsenic pressure.—Figure 4 shows the carrier density profile of an epitaxial layer grown on a Si-doped substrate by adding excessive arsenic pressure (about 3 mm Hg) from the beginning of growth as shown in the inset of Fig. 4. Instead of the high resistance region, a low resistance region is seen near the substrate in this sample as if the autodoping effect has occurred. The reason for the occurrence of this low resistance layer was thought at first to be the deficiency of Ga due to the excessive arsenic pressure (6). If this is the case, it seems that the carrier density in the whole region of the epitaxial layer shown in Fig. 4 should be greater than that of normally grown layers. But, the surface carrier density is not particularly greater than that of normally grown undoped layers.

In order to study the effect of arsenic pressure on the doping profile, the arsenic presusre of the reaction system was raised in the midst of growth. The resulting carrier density profile is shown in Fig. 5. The first half of the growth is carried out in a normal way and a high resistance layer appears near the substrate. From the mid point of the growth, the temperature of the arsenic zone was raised to 420°C, as shown in the inset of Fig. 5. A low resistance layer appeared only at the beginning of the temperature elevation of the arsenic zone, and the profile of that region resembled closely the one of the low resistance region seen in the epitaxial layer grown on a semi-insulating substrate with excessive arsenic pressure (6). This fact indicates that the appearance of the low resistance region is not peculiar to the beginning of growth, but is peculiar to the beginning of the temperature elevation of the arsenic zone. In addition, the agreement of the carrier density before and after the addition of excessive arsenic pressure seems to indicate that the

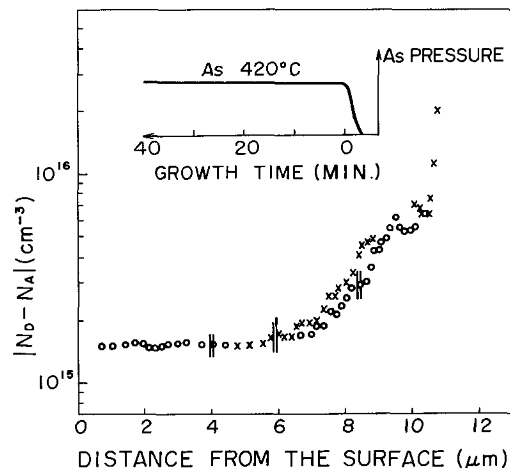

Fig. 4. Carrier density profile of the epitaxial layer grown with excessive arsenic pressure. The temperature of the arsenic zone was raised at the beginning of growth.

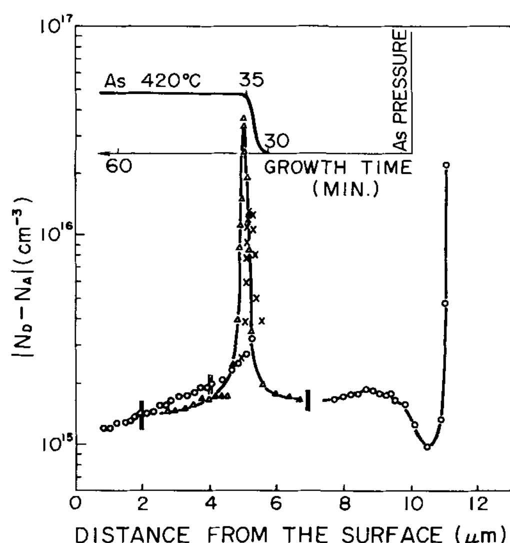

Fig. 5. Carrier density profile of the epitaxial layer grown with excessive arsenic pressure. The temperature of the arsenic zone was raised in the midst of growth as shown in the inset.

arsenic partial pressure itself does not greatly affect the carrier density of the grown layer.

If the occurrence of the high resistance region is due to the deficiency of arsenic, a high resistance region should appear even at the midst of a grown layer if the supply of arsenic is decreased. This was examined by decomposing $AsCl_3$ at 860°C with the sliding furnace shown in Fig. 1. The result is shown in Fig. 6. No high resistance region is seen at the point where the arsenic pressure of the reactor is lowered. (No high resistance region is seen even at the epitaxial layer-substrate interface in Fig. 6. This is due to the rough measurements of the interface, because the main concern is about the mid point of the epitaxial layer.) Another layer was grown also under low arsenic pressure, by decomposing $AsCl_3$ at 860°C before it reaches the main reaction zone during the growth period. The carrier density was almost the same as usual, although the growth rate was smaller than half the usual one. This fact also indicates that the carrier density is not directly controlled by the arsenic vapor pressure in the reaction system.

The occurrence of the low resistance layer shown in Fig. 5 can explain the following two facts without conflict: (*i*) Addition of excessive arsenic pressure could suppress the occurrence of the high resistance layer. (*ii*) The carrier density of the grown layer was not affected by the arsenic pressure. Disappearance of the high resistance region might be due to compensation of acceptors with the donors doped at the beginning of the heating of the arsenic zone, rather than due to the effect of the arsenic pressure.

Doping profiles obtained by changing the substrate temperature during growth.—The initiation of growth after the steady state of the reaction has been reached (or Ga source is completely covered with crust) seems to be a fascinating method to avoid the occurrence of the high resistance region. This was examined by changing the substrate temperature instead of using the special substrate holder mentioned previously. The substrate temperature was maintained at 800° or 850°C at the beginning of the growth (source temperature was 850°C). After $AsCl_3$ had flowed for 5 min, the substrate temperature was slowly lowered to 750°C. The resulting doping profiles are shown in Fig. 7 (The substrates are Si-doped). Growth rate decreased rapidly when the substrate temperature was above 800°C (5), and no growth or slight gas etching occurred at 850°C. Therefore, growth must begin after the reaction has reached a steady state (without deficiency of arsenic), when the substrate temperature is lowered from 800° or 850°C. But both of the doping profiles have a dip in the carrier density profile at the interface, in addition to a low resistance layer which is due to a higher substrate temperature than usual [carrier density increases with increase of the substrate temperature (12)]. The dip in the carrier density profile was larger when the substrate was lowered from 850° rather than from 800°C.

In order to clarify the effect of substrate temperature on the occurrence of the dip in the carrier density profile as seen in Fig. 7, the substrate temperature was changed in the mid point of the growth. The doping profiles of the grown layers are shown in Fig. 8. The substrate temperature was changed as shown in the inset of the figure (source temperature was 830°C in this case). When the substrate temperature was raised to 800°C (dotted line), only a low resistance layer was seen. But, when the substrate temperature was raised to 830°C (the same as the source temperature), a dip in carrier density profile (or a high resistance layer) appears in addition to the low resistance layer, similar to the profiles shown in Fig. 7. These facts also indicate that the occurrence of the dip in the carrier density profile as seen in Fig. 7 or Fig. 8 is due neither to the deficiency of arsenic nor to contamination with impurities.

The occurrence of the high resistance layer seen in Fig. 7 and 8 can be understood if it is presumed that the high resistance layer occurs when a substrate is heat-treated under the condition that the gas etching

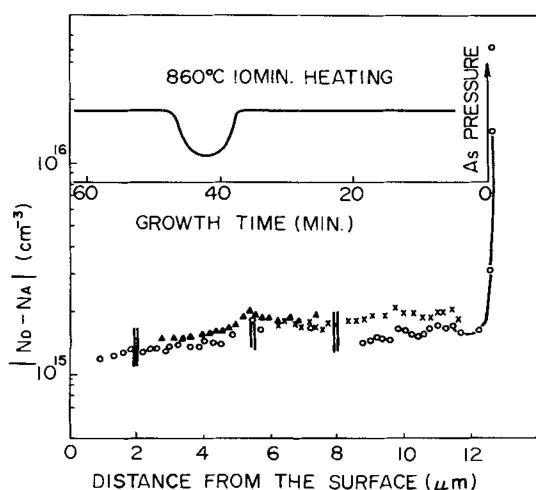

Fig. 6. Carrier density profile of the epitaxial layer which was grown by reducing the arsenic supply during growth as shown in the inset.

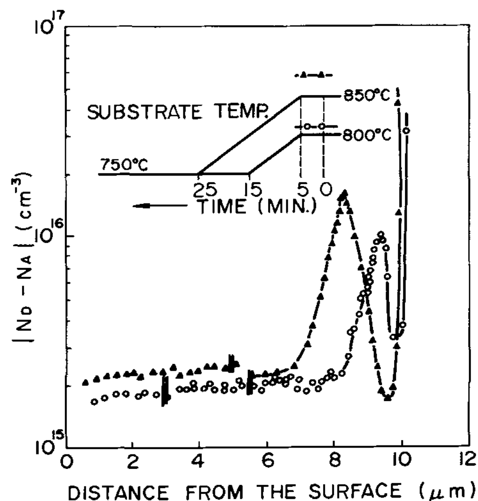

Fig. 7. Carrier density profiles of the epitaxial layers grown by changing the temperature of the substrate at the initial stage of growth as shown in the inset.

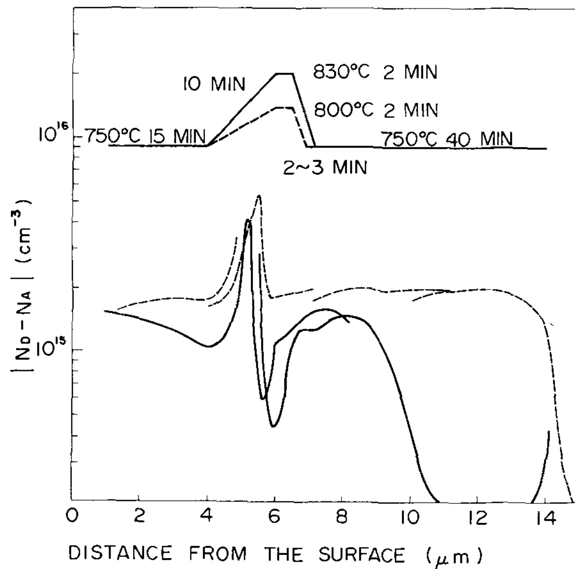

Fig. 8. Carrier density profiles of the epitaxial layers grown by changing the substrate temperature in the midst of growth as shown in the inset.

slightly overcomes the growth (this is further considered in the next section). In Fig. 8, only a low resistance layer appeared when the substrate temperature was raised to 800°C. In this case, no gas etching occurred. On the other hand, when the substrate temperature was raised to 830°C, the same as the source temperature in this case, a slight gas etching occurred and a high resistance layer would appear [the gas etching was examined by covering a portion of a substrate surface with a small quartz plate (1)]. The reason for the appearance of the high resistance layer when the substrate temperature is lowered from 800°C shown in Fig. 7 is not well understood, but a slight gas etching might occur at initial stage of reaction when arsenic is absorbed by a Ga source (5) and substantial growth is inhibited.

Change of surface carrier density by heat treatment in $GaCl/As_4/H_2$ or in H_2.—As described in the previous section, it is quite probable that the occurrence of the high resistance region is associated with slight gas etching. But no change in surface carrier density is observed when normal gas etching is performed. In order to clarify the phenomena at the state when growth balances with the gas etching, a heat treatment was carried out in a flow of $GaCl/As_4/H_2$.

Undoped bulk GaAs with a carrier density of about 1.3×10^{16} cm^{-3} was used. The sample was placed on the substrate holder in the epitaxial growth tube with a Ga source saturated with As. The sample was heat-treated in a flow of $AsCl_3/H_2$ (therefore, $GaCl/As_4/H_2$) or of only hydrogen (200 cc/min). The temperatures of the Ga source and of the substrate were 850°C. The surface carrier density profiles after the heat-treatment for 30 min in a hydrogen atmosphere are shown in Fig. 9. Sample VEF-10-4(▲) was heat-treated without the Ga source and in a just washed reaction tube. The other two samples (VEF-10-11, VEF-8-4) were heat-treated with Ga source and after several epitaxial growths. The carrier density of the former sample was clearly decreased at the surface as reported by Mũnoz *et al.* (13). But the change in the carrier density was found within only about 1.0 μm from the surface. Decrease of the surface carrier density in the other two samples is not clear. This may be due to suppression of arsenic evaporation from the surface of the sample because of the existence of the Ga source saturated with arsenic and deposited GaAs or As. These facts indicate that the surface carrier density of the substrate is not greatly changed before growth in the usual epitaxial growth procedure.

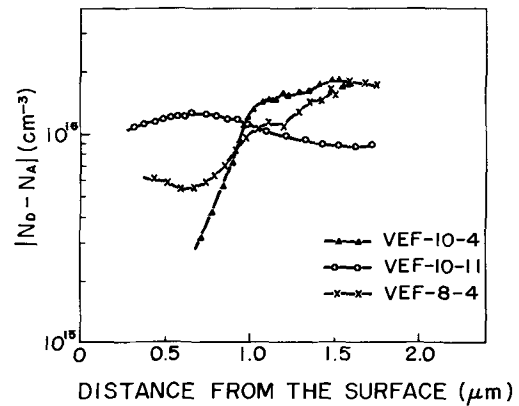

Fig. 9. Surface carrier density profiles of undoped bulk GaAs heat-treated in a hydrogen atmosphere at 850°C for 30 min. VEF-10-4, without Ga source; VEF-8-4 and VEF-10-11; with Ga source saturated with arsenic.

When the heat-treatment was performed with the flow of $AsCl_3/H_2$, the surface of the sample changed to almost semi-insulating in contrast to the case of the heat-treatment in hydrogen. The representative surface carrier density profiles are shown in Fig. 10. One (shown by ○) was heat-treated for 30 min in the flow of $GaCl/As_4/H_2$, and the other (indicated by ▲) is the one heat-treated in hydrogen for about 15 min after the same heat-treatment in the flow of $GaCl/As_4/H_2$. It was confirmed that a slight gas etching occurred during the heat-treatment and, when the etched layer was thick the surface high resistance layer was thin. Since the drastic change of the surface carrier density occurred in the atmosphere of $GaCl/As_4/H_2$ (precisely speaking, GaCl, $GaCl_3$, HCl, As_4, and H_2) and under a slight gas etching, it is reasonable to think that Ga was removed from the GaAs surface in a fairly high arsenic partial pressure and some defect, for example, such as Ga vacancy, was formed at the surface. Mũnoz *et al.* (13) also reported that, when a sufficient arsenic pressure was applied during the heat-treatment, surface carrier density was decreased due to formation of Ga vacancy.

The surface carried density of the sample VEF-8-5 (indicated by ▲) is higher than other's and the surface high resistance region is thicker. This seems to be due to evaporation or arsenic from the surface and diffusion of the defects into the substrate by the further 15 min of heat-treatment in hydrogen.

Since the surface high resistance layer was thin when the etched depth was large, the fact that there

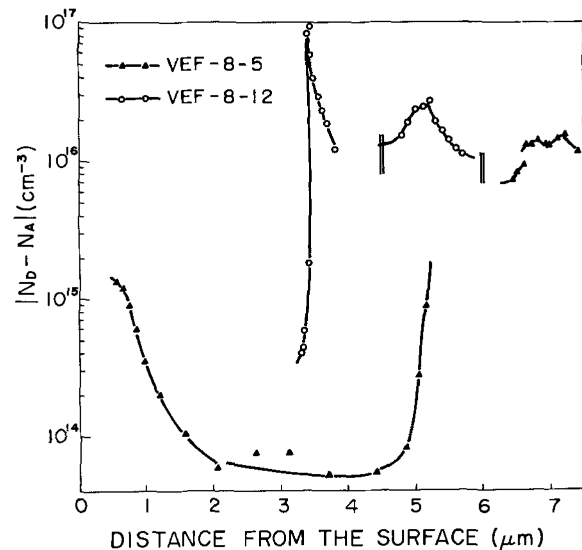

Fig. 10. Surface carrier density profiles of undoped bulk GaAs heat-treated in the flow of $GaCl/As_4/H_2$ at 850°C for 30 min.

was no formation of the surface high resistance layer by a normal gas etching must be due to the speed of gas etching being higher than the diffusion speed of the defects. But, when the reaction at the substrate is changed from gas etching to growth, the gas etching balances with the growth at some moment, and at that time, acceptors related to the defects may be induced to form a high resistance layer. In a usual growth procedure, too, a slight gas etching might occur while arsenic is absorbed in the Ga source (5) and substantial growth is inhibited. This way of thinking can explain two experimental results (4, 14, 15) which could not be explained hitherto. One is the high resistance layer found in the substrate. We have reported (4) that a high resistance layer appeared inside the substrate when a doped thin epitaxial layer was grown on an undoped substrate. The other is difference of the effect of gas etching among different investigators. When the reaction is slowly moved from gas etching to growth, the high resistance layer appears at the interface (2, 3). But Hirao *et al.* (14) and Nozaki *et al.* (15) have reported that the appearance of the high resistance layer was suppressed by a special way of gas etching. Each way differs in the transition speed from gas etching to growth. In the former way, gas etching balances with growth for a while due to a slow transition. In the latter way, the transition must be too fast for the defect to appear.

Photoresponse and photoluminescence of the surface high resistance layer.—In previous investigations (6, 16), deep energy levels of 0.5-0.6 eV above the valence band have been found in the high resistance region at the epitaxial layer substrate interface from measurements of photoresponse, capacitance, or Hall constant. Photoresponse due to similar deep centers was found in the high resistance layer at the surface as shown in Fig. 10. Such deep centers that were considered to be the cause of the high resistance layer were not observed by photoluminescence measurements.

The photoresponse measured on a reverse current of a Schottky barrier made on the surface high resistance layer is shown in Fig. 11. A broad response around 1300 mμ is observed in addition to the response of band to band transition. This result implies that many deep centers of about 0.5 eV above the valence band exist in the high resistance layer. A dotted line shows photoresponse of a Schottky barrier on an etched surface from which the high resistance layer has been removed. Extrinsic photoresponse as large as the one observed on the high resistance layer is not observed. Therefore, the extrinsic photoresponse shown by the solid line is peculiar to the surface high resistance layer, and the deep centers of about 0.5 eV above the valence band edge must be the acceptor centers induced on the surface. (These deep centers are obviously not the ones due to Si at the As site.)

The extrinsic photoresponse shown in Fig. 11 is quite similar to that of the high resistance region at the epitaxial layer-substrate interface [see Fig. 11 of Ref. (16)]. Therefore, the acceptors in the surface high resistance layer are probably the same as the acceptors in the high resistance region at the epitaxial layer-substrate interface.

Measurement of photoluminescence spectra is generally a convenient method to determine the energy level in semiconductors. Nakashima and Hirao (9) have observed a peak of 1.36 eV due to Cu_{Ga} at the grown layer-substrate interface, and they attributed the problem to the contamination of the substrate surface with copper. On the other hand, Iwasaki and Sugibuchi (7) have made the same measurement, and have found the peak of 1.40 eV peculiar to the interface, and they attributed the problem to a Si-As vacancy complex.

In order to find the acceptor levels in the surface high resistance region, photoluminescence spectra were measured in this study too. Results are shown in Fig. 12. Samples are from undoped bulk GaAs ($n \sim 1.3 \times 10^{16}$ cm^{-3}). One is as grown, another (VEF-8-6) is the one heat-treated in hydrogen at 850°C for 30 min and whose surface carrier density is little changed. Still another (VEF-8-12) is the one heat-treated in the flow of $GaCl/As_4/H_2$ and whose surface is almost semi-insulating as shown in Fig. 10. As-grown GaAs shows a peak of 1.36 eV due to the first level of Cu_{Ga} acceptors, in addition to the band edge emission. For the sample (VEF-8-6) heat-treated in hydrogen, a strong peak appears at 1.40 eV, which can be attributed to a Si-As vacancy complex. (The amplitude is scale reduced to one twentieth in this spectrum for ease of comparison with the others.) On the other hand, the sample (VEF-8-12) heat-treated in the flow of $GaCl/As_4/H_2$, shows very weak photoluminescence over the wavelength range measured.

Since the surface carrier density was only slightly decreased by heat-treatment in hydrogen, centers for the peak at 1.40 eV do not seem to be responsible for the surface high resistance layer shown in Fig. 10. From the fact that the surface high resistance layer shows only very weak photoluminescence, the acceptor centers responsible for the surface high resistance layer should be nonradiative or be too deep to be observed in the photoluminescence measurement. This result agrees with the fact that an extrinsic photoresponse appears around 1300 mμ in a reverse current of a Schottky barrier formed on the high resistance layer.

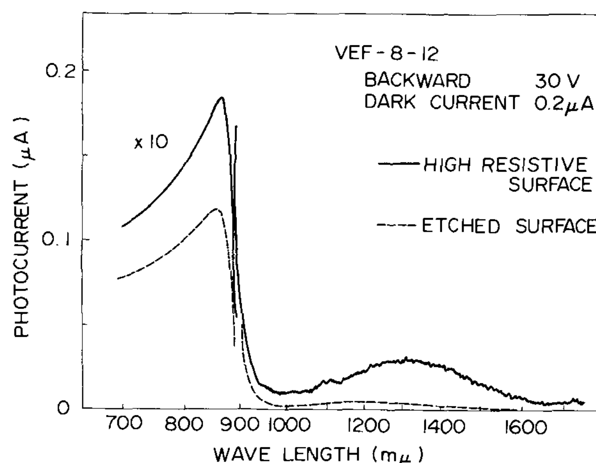

Fig. 11. Photoresponse for the reverse current of Schottky barrier diodes; solid line—Schottky barrier on the high resistive surface as shown in Fig. 10; dotted line—Schottky barrier on an etched surface.

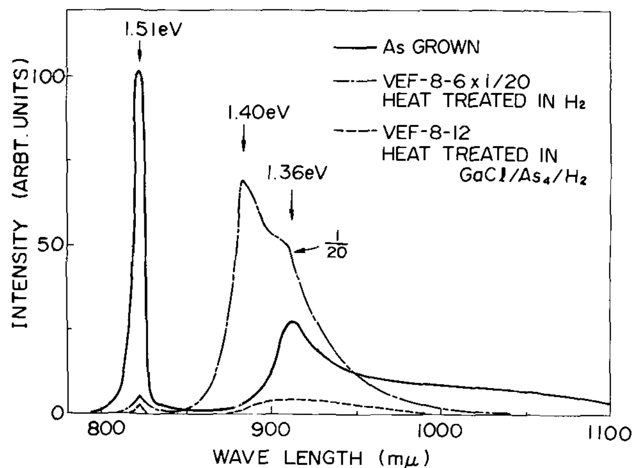

Fig. 12. Photoluminescence spectra of the surface of heat-treated GaAs. Solid line—as-grown bulk GaAs, VEF-8-12—heat-treated in a flow of $GaCl/As_4/H_2$, VEF-8-6—heat-treated in a flow of hydrogen.

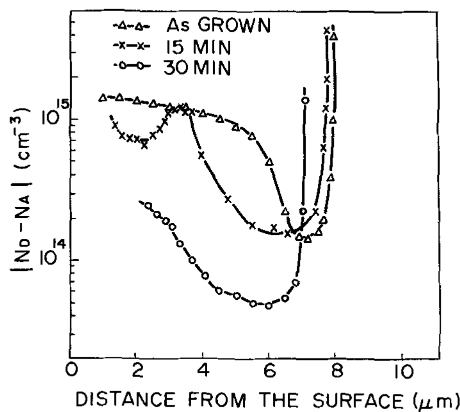

Fig. 13. Change of the high resistance region by a heat-treatment

Since the substrate is unintentionally heat-treated before growth, a photoluminescent peak of 1.40 eV may be found at the interface (7). The distribution of substitutional copper is affected by the Ga vacancy distribution (11), and hence the peak attributable to copper (9) or copper itself (8) may be found at the interface. But these seem to be not the real reason for the high resistance region from the facts shown in this study.

Change of the high resistance region by heat-treatment.—Effect of a heat-treatment on the dip in the carrier density profile was studied in order to see the diffusion of acceptors in the high resistance region. Figure 13 shows the carrier density profiles of an epitaxial layer before and after heat-treatment at 850°C for 15 min or at 850°C for 30 min. The high resistance region spreads with the heat-treatments. The diffusion constant of the acceptors was estimated to be about 10^{-11} cm^2/sec $\sim$ 10^{-10} cm^2/sec from the profiles in Fig. 13, if the profile of the diffused impurities was assumed to be a complementary error function. Mũnoz *et al.* (13) estimated the diffusion constant of the acceptors induced at the surface by a heat-treatment to be about 10^{-12} cm^2/sec for P_{As} (arsenic pressure) $\geqq$ 50 Torr and about 10^{-10} cm^2/sec for $P_{As} < 50$ Torr. These values are considered to be comparable to ours if one considers the relatively low accuracy of the measurements and the derivation. Diffusion speed of the acceptors induced at the surface by the heat treatment with $GaCl/As_4/H_2$ shown in Fig. 10 is the same order of magnitude as the one derived from Fig. 13.

Summary

Occurrence of the high resistance layer in epitaxial GaAs has been interpreted hitherto by (*i*) arsenic vacancies or Si at the As site (2-7), or by (*ii*) impurity contamination (8-10).

In the present paper, several experimental results that cannot be explained by the above two reasons were shown: (*i*) The high resistance layer appeared even when the growth was initiated after the reaction has reached a steady state. (*ii*) A high resistance layer occurred even within the grown layer when growth is slightly overcome by gas etching during the growth. (*iii*) The surface of undoped GaAs was changed to almost semi-insulating by a heat treatment in a flow of $GaCl/As_4/H_2$. (*iv*) Deep energy levels in the surface high resistance layer were about 0.5 eV above the valence band (the same as the one at the interface).

From these results, the occurrence of the high resistance layer presented here is considered to be due to formation of some defect, such as Ga vacancy, which might appear on the surface of the substrate when growth is balanced with or is slightly overcome by gas etching. This way of thinking can explain some of the phenomena that has not been explained hitherto.

Acknowledgments

The author wishes to thank S. Kikuchi for giving various facilities in the epitaxial growth, H. Iwasaki for his help in the measurement of photoluminescence, and T. Saito, Y. Seki, and K. Sekido for their stimulating discussions on this subject.

Preparation and Properties of Nonheat-Treated Single Crystal Cu_2S-CdS Heterojunctions

P. F. Lindquist[1] and R. H. Bube

Department of Materials Science, Stanford University, Stanford, California 94305

ABSTRACT

The photoelectronic properties of single-crystal Cu_2S-CdS heterojunctions have been investigated. The heterojunctions were formed on the A or B faces of conducting CdS single crystals by dipping in a cuprous chloride solution at 75°C. No separate heat-treatment was given. The cells typically had monochromatic quantum efficiencies greater than 10% in the region 0.5-0.9μ. The photoresponse is due to carrier pair generation in the Cu_2S, with transfer of electrons across the interface into the CdS. The forward current at and below room temperature is dominated by tunneling of electrons through interface states. A general band diagram of the heterojunction is discussed. Consistent differences in the behavior of A and B face samples were noted with respect to the growth kinetics of the Cu_2S, the maximum photovoltage at 300°K, the I-V characteristics, and the junction capacitance. The effect of uniaxial stress on the capacitance of A and B face samples suggests a piezoelectric mechanism.

The Cu_2S-CdS p-n heterojunction has been the subject of a considerable research effort over the past decade because of its promise as an efficient thin-film solar cell. At present, these cells typically produce 0.5V on open circuit and 20 mA/cm^2 on short circuit in sunlight, with efficiencies in the range 5-8%. The history of the development of the thin-film Cu_2S-CdS cell has been summarized by Shirland (1).

Numerous investigations have attempted to clarify the mechanism of the photoresponse of the Cu_2S-CdS junction, particularly the "extrinsic" response at wave lengths longer than the CdS band edge. Mechanisms proposed to account for this photoresponse include: a postulated p-n homojunction in the CdS with an impurity band of copper centers (2), generation of holes in the CdS at native imperfections (3, 4) or at diffused-in impurity centers (5, 6), and absorption in the Cu_2S with transfer of photoexcited electrons into the CdS (7-13). The latter process is now thought to account for the major portion of the photoresponse of relatively efficient cells.

The thin-film Cu_2S-CdS cells require a postfabrication heat-treatment to develop the maximum efficiency. This heat-treatment also gives rise to transient and secondary-light-source effects in the photoresponse which are not observed in the nonheat-treated junctions (13). These effects, also observed in heat-treated single-crystal cells, have been attributed to the trapping of holes in deep centers in the CdS depletion region near the junction (13).

This paper is concerned with the properties of Cu_2S-CdS heterojunctions fabricated from single crystals of CdS, with no heat-treatment after formation of the junction. These devices did not exhibit the transient effects mentioned above. It is shown that relatively efficient single-crystal cells can be produced without the heat-treatment step. The heterojunctions were formed on either the A or B basal plane of the CdS. While the basic properties of the cells were similar for the two orientations, certain consistent differences attributed to the polarity of the CdS structure were observed. These differences are discussed, and a model for the photovoltaic behavior of the heterojunction is described.

Experimental

Fabrication of heterojunctions.—The Cu_2S-CdS heterojunctions were formed by immersing single crystals of CdS in a saturated aqueous solution of cuprous chloride at 75°C for times ranging from 2 to 8 hr. The CdS was thereby converted to Cu_2S by a displacement reaction, the thickness of the Cu_2S increasing with time in the solution. The CdS crystals, grown by sublimation in a moving temperature gradient, had an average resistivity of 1 ohm-cm. The high conductivity was a consequence of nonstoichiometry; no intentional impurities were added.

Rectangular bars approximately 1 × 5 mm in area and 0.5-1 mm thick were cut from the CdS crystals. The large faces were normal to the c-axis within about 5° as determined by x-ray back-reflection Laue patterns. The A face [Cd, (0001)] and B face [S, (0001)] were distinguished by etching in concentrated HCl (14). These faces were mechanically polished with 0.3μ alumina on silk. Ohmic indium contacts were diffused at both ends of the crystal, on the face opposite the one subsequently dipped in the CuCl solution. The face to be dipped was either left in the as-polished condition or was etched for 2 min in a solution of $KMnO_4$ in sulfuric acid at room temperature (15).

The crystal bars to be dipped were mounted on glass slides with black wax so that only the top surface of each crystal was exposed to the solution. The solution consisted of 0.2M CuCl, 0.2M $NH_2OH \cdot HCl$ (hydroxylamine hydrochloride), and 0.5M KCl in water, to which several drops of dilute HCl were added to give an initial *p*H of about 3. The hydroxylamine hydrochloride inhibited the oxidation of the cuprous ions to the cupric state, and the KCl increased the solubility of the CuCl by promoting the formation of complex ions (16).

The barrier-forming displacement reaction was carried out in a 500 ml Pyrex crystallizing dish, sealed with an argon atmosphere over the solution to inhibit oxidation. The dish was placed in a drying oven, the temperature of which was maintained at 75° ± 1°C for the required time. The reacted crystals were then removed from the solution, demounted from the glass slides, rinsed with TCE, acetone, distilled water and methanol, dried and stored in a dessicator until ready for measurements. The samples discussed in this paper were not given a heat-treatment after formation of the junction.

Measurements.—I-V characteristics were recorded on Polaroid film using a Tektronix Type 575 transistor curve tracer. Point-by-point measurements of the dark forward and reverse characteristics over at least 5 decades of current were also made.

The spectral response of photocurrent and photovoltage was measured using a Bausch and Lomb grating monochromator with a tungsten ribbon light source. The slits were set to give a dispersion of 6.6 mμ. The

[1] Present address: Hewlett-Packard Laboratories, Palo Alto, California 94300.

Key words: photovoltaic, heterojunction, Cu_2S-CdS, capacitance, piezoelectric.

output of the monochromator was focused on the sample with a condensing lens and was incident on the junction through the CdS. The edges of the samples were masked with black wax to minimize absorption of noncollimated light. The light intensity at the sample position was measured as a function of wavelength with a Perkin-Elmer thermopile. The spectral response data were normalized to the photon flux at 600 mμ, which was 5.8×10^{14} photons/cm²-sec, with an estimated uncertainty of ± 20%.

The intensity dependence of photovoltage and photocurrent were measured using a beam of unfiltered tungsten light of integrated intensity 280 mW/cm² (hereafter referred to as intensity I_0) with a series of neutral density filters.

The short-circuit photocurrent was measured with a Keithley 149 microvoltmeter across a 1% 100 ohm resistor in series with the sample. The open-current photovoltage was measured with a Keithley 610A electrometer (input impedance of 10^{14} ohms).

Measurements of the junction capacitance as a function of bias voltage were made with a Boonton 75-D capacitance bridge with a 77-2A range extender. The operating frequency of the bridge was 1 MHz with a signal level of about 20 mV peak to peak. Bias voltage was supplied by an external source.

The temperature dependence of the dark I-V characteristics and the photoresponse in white light were measured with the samples mounted in an evacuated chamber at the end of an Air Products Cryo-Tip cooling device opearting on the Joule-Thomson principle. Photocapacitance measurements, the results of which are reported elsewhere (17), were also performed using this apparatus.

Capacitance-voltage curves were measured at room temperature for two samples under uniaxial stress. The stress was applied by means of a steel plunger which passed through two guides and rested in a copper block which contacted the crystal. The stress was parallel to the plane of the junction, in the direction of the CdS a-axis.

Results

Growth characteristics of the Cu_2S layer.—The Cu_2S layer was observed to form more rapidly on the A face of CdS than on the B face by about a factor of three. The layer thickness was measured optically using a micrometer stage and a filar eyepiece. The thickness was generally uniform over the sample area. Figure 1 shows thickness *vs.* time at the reaction temperature of 75°C for the two crystal faces. The thickness varies as t^n, with n slightly greater than unity, in both cases.

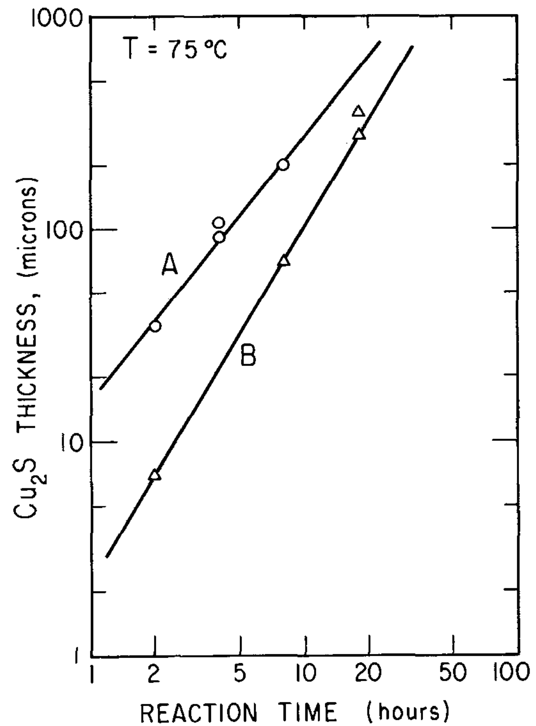

Fig. 1. Thickness of Cu_2S layer as a function of dipping time at 75°C for A and B faces of CdS.

The nearly linear time dependence suggests that the growth rate is controlled by the interface reaction rather than by diffusion through the Cu_2S layer, for which thickness proportional to the square root of time would be expected. Microscopic examination of the Cu_2S layers revealed numerous cracks perpendicular to the interface, which permitted continual passage of the cuprous ion solution to the CdS. The grown layers were confirmed to be primarily Cu_2S (chalcocite) by x-ray powder patterns.

Four-point probe measurements on a number of Cu_2S layers grown from CdS in aqueous solution gave p-type resistivities in the range 6×10^{-4} to 3×10^{-3} ohm-cm. This corresponds to a range in hole density of 10^{21} to 2×10^{20} cm^{-3}, assuming a mobiilty of 10 cm²/V-sec (18).

Diode characteristics.—Figure 2 gives Polaroid traces of the dark and light-generated I-V curves for two

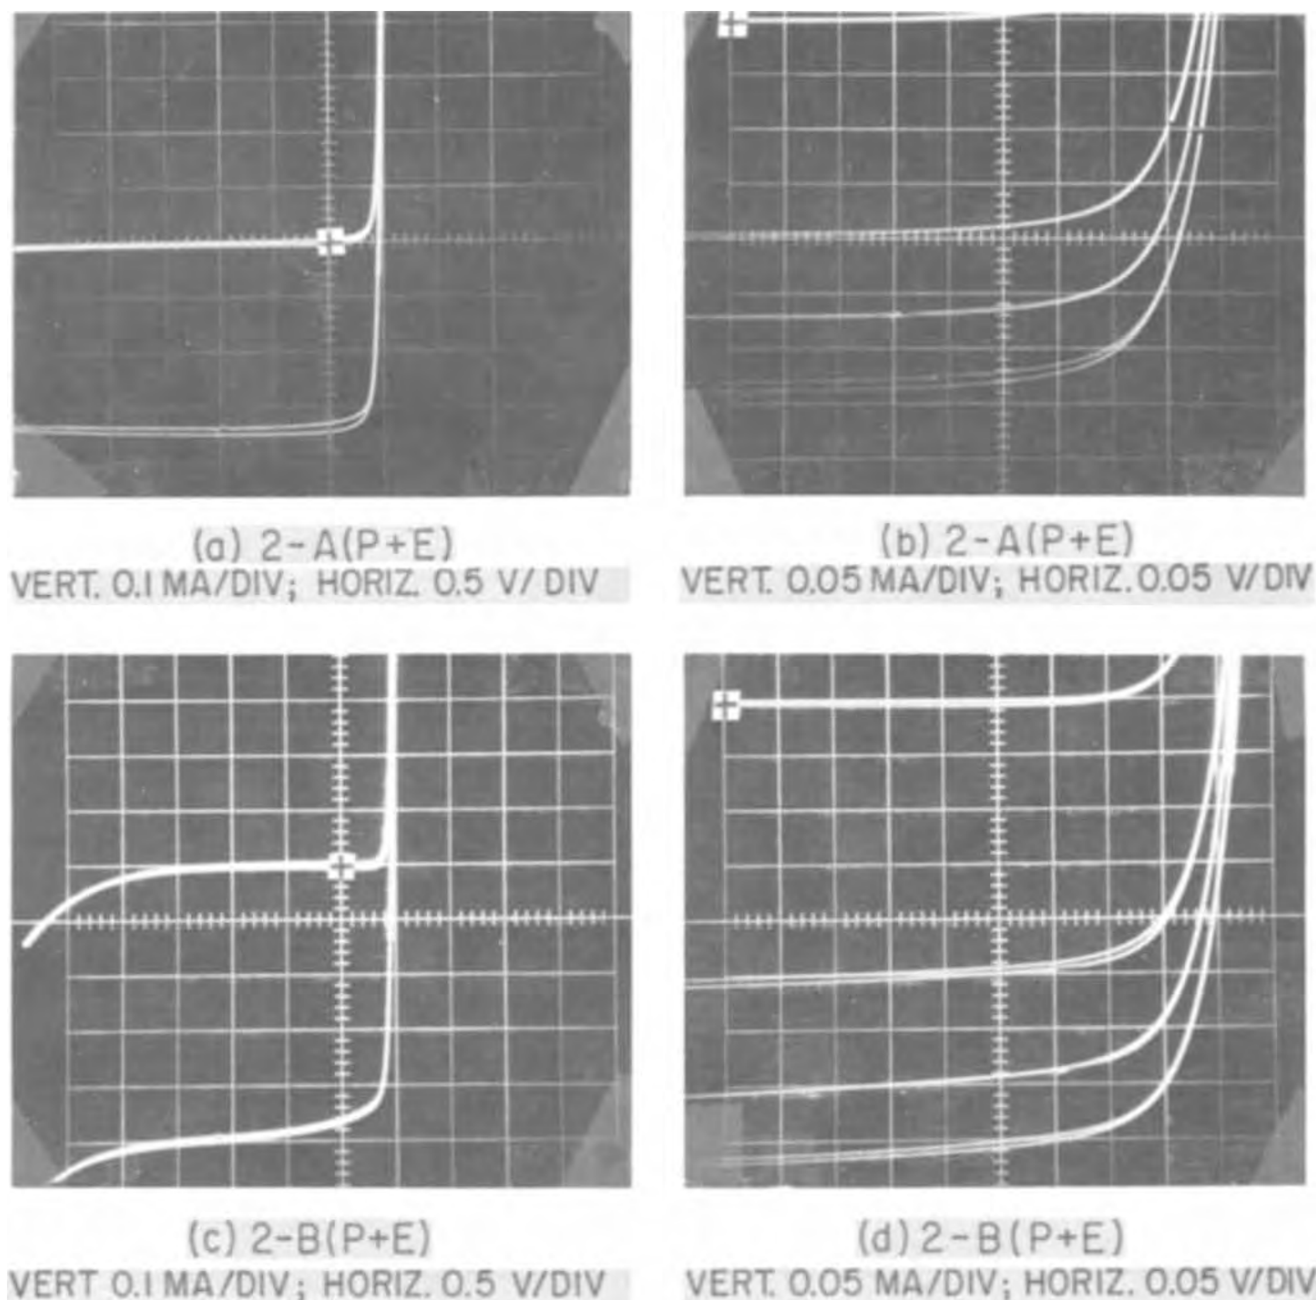

Fig. 2. Dark and light-generated I-V characteristics for samples 2-A(P+E) and 2-B(P+E)

samples. The uppermost curve in each photograph is the dark characteristic. The bottom curves are the light-generated characteristics in unfiltered tungsten light of 280 mW/cm^2 integrated intensity (I_0). The two intermediate curves in (b) and (d) are for lower intensities of white light. These characteristics are typical of those observed in a series of ten samples, 6 A-face and 4 B-face. A tabulation of data for these samples appears in Table I.

The "fill factors" of the light I-V curves (ratio of the area of the maximum power rectangle to the product $I_{sc} \times V_{oc}$) are about 70%. The open-circuit voltage of the B-face sample is somewhat greater than that of the A-face sample, and the reverse characteristic of the B-face sample is "softer." These features were generally observed for corresponding pairs of A and B-face samples (see Table I).

Photoresponse.—Figure 3 presents the spectral response of short-circuit current for two A-face samples. The curves have been normalized to a photon flux of 5.8×10^{14} cm^{-2} sec^{-1} assuming a linear dependence of photocurrent on light intensity at each wavelength. At this intensity, a current density of 10^{-5} A/cm^2 corresponds to a quantum efficiency of slightly greater than 0.1 electrons/photon. These spectral response curves show the typical relatively flat response from 0.5 to 0.9μ associated with the most efficient Cu_2S-CdS cells. The curves for the B-face samples were identical in shape to those in Fig. 3.

Figure 4 shows two spectral response curves replotted as the square root of photocurrent *vs.* photon energy. The long-wavelength edge of the response is a straight line on this plot, the slope of which changes abruptly below 1.2 eV. This behavior is similar to that of the absorption coefficient of Cu_2S, measured by Marshall and Mitra (19). The basic mechanism of the long-wavelength response of the Cu_2S-CdS heterojunction is optical absorption in the Cu_2S followed by emission of the photoexcited electrons into the CdS. The small response at energy lower than 1.2 eV is due to the phonon absorption branch of the indirect absorption coefficient of Cu_2S.

The intensity dependence of open-circuit photovoltage in white tungsten light was measured for each sample. The photovoltage decreased only slightly with decreasing intensity down to two orders of magnitude

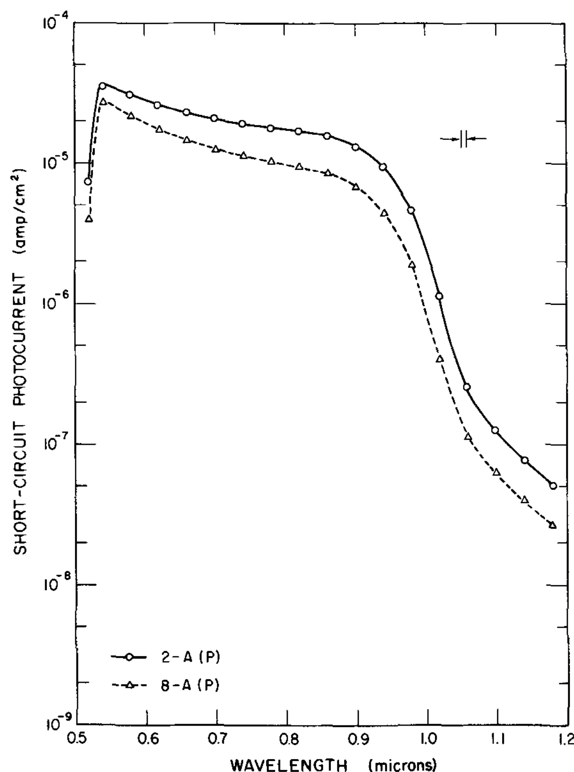

Fig. 3. Spectral response of short-circuit photocurrent for samples 2-A(P) and 8-A(P).

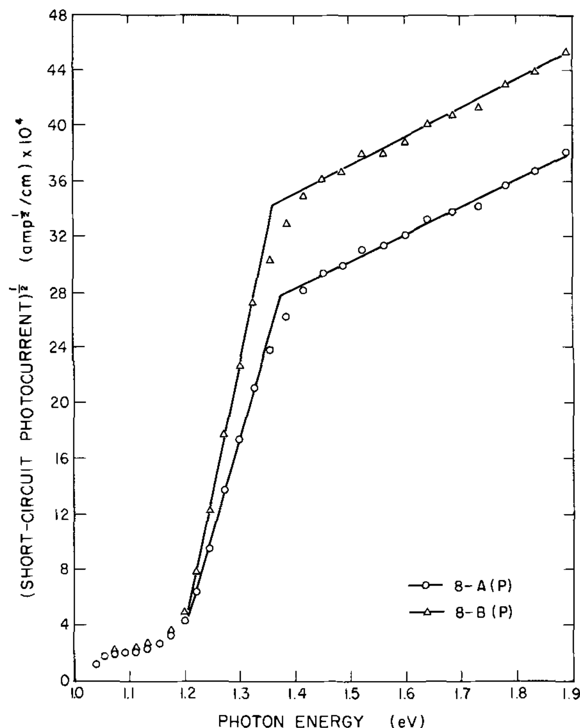

Fig. 4. Square root of short-circuit photocurrent vs. photon energy for samples 8-A(P) and 8-B(P).

below the maximum, and then dropped off more rapidly with decreasing intensity, finally becoming proportional to intensity. The same qualitative behavior was observed for all samples, both A and B face. The magnitude of the photovoltage at a fixed low intensity varied considerably from sample to sample, however, and was correlated with the crystal face and also with the surface treatment of the CdS prior to junction formation [polished (P) or polished and etched (P + E)]. This correlation is illustrated in Fig. 5, which plots the

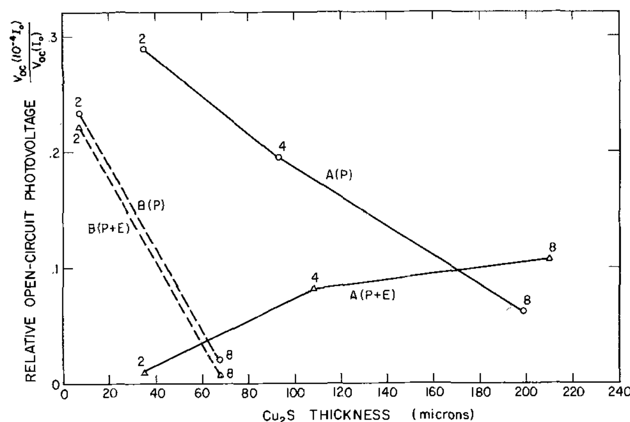

Fig. 5. Dependence of relative open-circuit photovoltage at intensity 10^{-4} I_o on thickness of Cu_2S and surface condition. (I_o = 280 mW/cm^2 white tungsten light.)

relative open-circuit voltage at intensity 10^{-4} I_o against Cu_2S thickness and surface condition. The numbers accompanying the points denote the dipping time in hours. The values of Cu_2S thickness are those appearing in Table I. For the B-face samples, the low-intensity V_{oc} drops with increasing Cu_2S thickness (dipping time), with very little difference between corresponding polished and polished + etched samples. A significant difference between the polished and etched A-face samples is observed, however. For the shortest dipping time, the polished A-face sample gives a much higher V_{oc} at low intensity than does the corresponding etched sample. The difference between polished and etched A-face samples decreases with increasing layer thickness and reverses for the 8-hr samples.

Figure 6 shows a correlation between the relative open-circuit photovoltage at low intensity and the "saturation" current density J_o (the value obtained by extrapolating the dark, forward characteristic, log J *vs.* V, to $V = 0$). The values of J_o are listed in Table I [from "low-V" column, where indicated (20)]. This

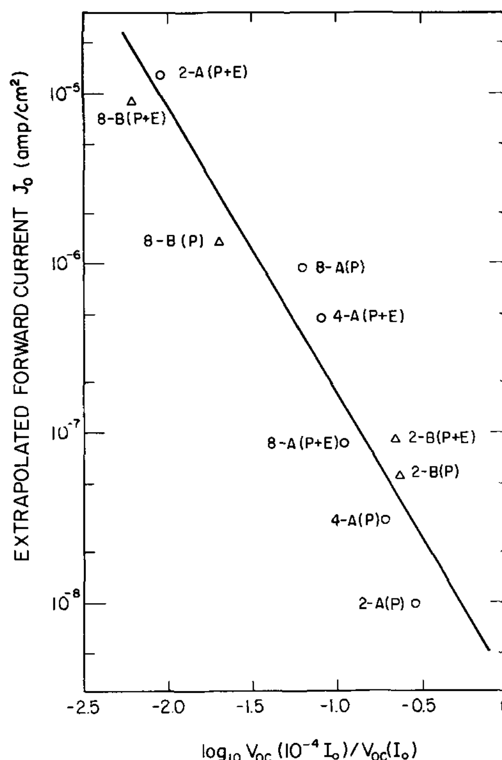

Fig. 6. Relation between low-intensity open-circuit photovoltage and dark forward current extrapolated to $V = 0$.

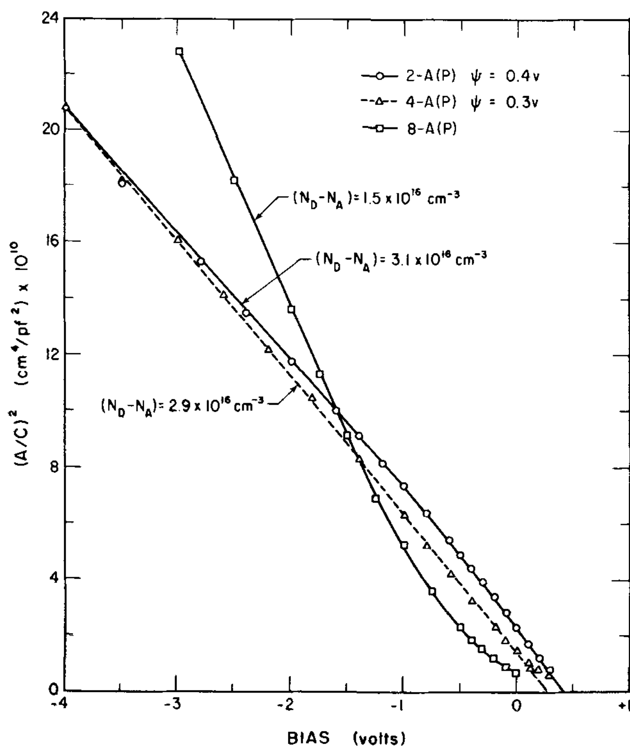

Fig. 7. $1/C^2$ vs. voltage for three A-face samples

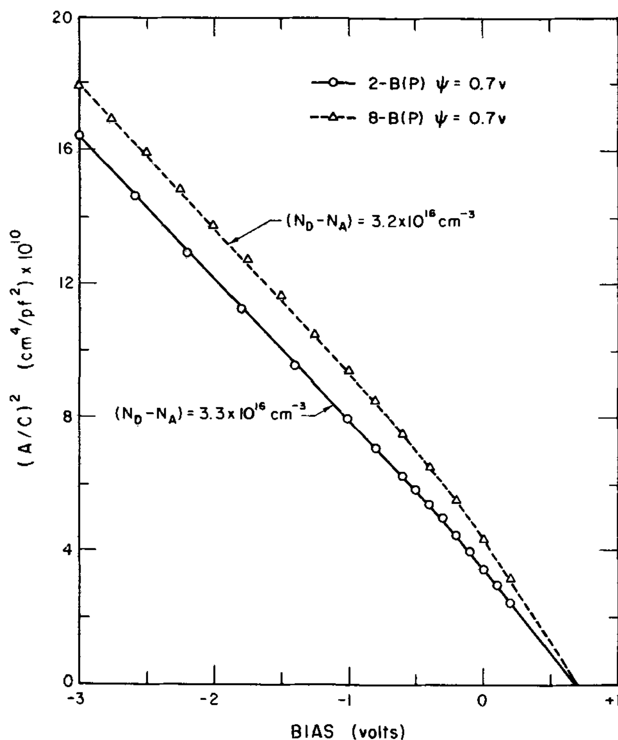

Fig. 8. $1/C^2$ vs. voltage for two B-face samples

plot indicates that a high value of V_{oc} at low intensity is associated with a low value of J_o. From Fig. 5 it may be inferred that etching the CdS surface before dipping increases the saturation (or leakage) current, J_o, of the resulting cell, and that the effect is especially pronounced for A-face samples dipped for short times. The etching had no noticeable effect on either the growth rate of the Cu_2S layer or the photocurrent response curves.

Capacitance-voltage curves.—Plots of $1/C^2$ *vs.* bias voltage at room temperature are given for three A-face and two B-face samples in Fig. 7 and 8, respectively. The values of capacitance were corrected for the effect of series resistance by the relationship

$$C = C'/\{(1 - R_sG')^2 + (R_s\omega C')^2\} \qquad [1]$$

where C' and G' are the measured values of capacitance and conductance, R_s is the series resistance, and ω is the angular frequency. Values of R_s were obtained by pulsing the forward characteristic, and are tabulated in Table I.

For the thinnest Cu_2S layers, the $1/C^2 - V$ plots were linear for both A- and B-face samples, with a slight increase in slope in the forward and low reverse bias region. The values of net donor density in the CdS, $N_D - N_A$, agreed with the measured conductivity of the initial CdS crystals. With increasing thickness of the Cu_2S, the $1/C^2 - V$ plots for A-face samples developed a pronounced upward concavity at low bias, whereas the plots for B-face samples became slightly more concave downward. Values of the capacitance per unit area at zero bias and the intercept voltage ψ from $1/C^2 - V$ data are given for each sample in Table I. For comparison, values of ψ obtained by extrapolating the series-resistance-limited forward characteristics to zero current (21) are also shown. The quantity ψ obtained by either of these techniques is a rough measure of the diffusion potential of the junction.

Temperature Dependence.—The forward I-V characteristic and the photoresponse in white light were measured between 300° and 100°K for a number of samples. Figures 9 and 10 present typical results for an A-face sample. The behavior of A- and B-face samples were qualitatively similar.

Figure 9 shows the forward I-V characteristic at various temperatures. The data fit an expression of the form

$$J(V,T) = J_o(T)e^{\alpha V} \qquad [2]$$

where α is independenct of temperature. For the case shown, the average value of α was $31.4V^{-1}$. Values of α for all the samples, based on room temperature data only, are given in Table I. The temperature-independent slope of the forward characteristic suggests a tunneling mechanism for the forward current. If the

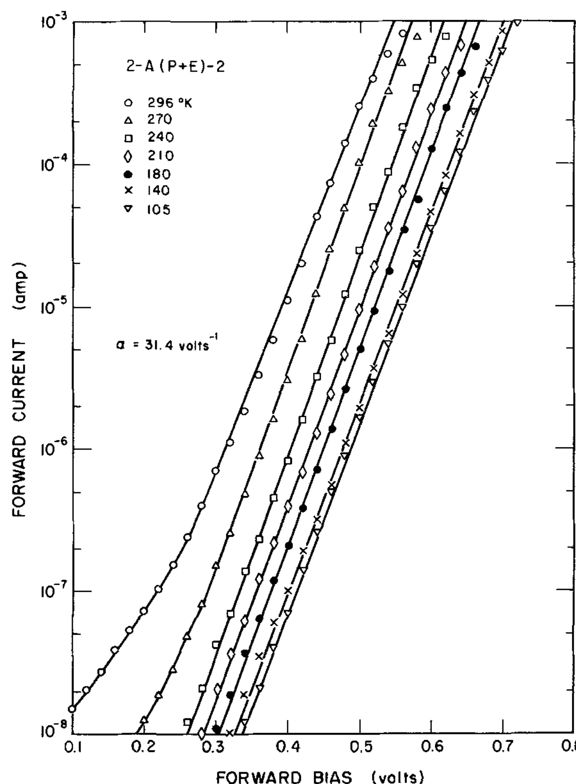

Fig. 9. Forward I-V characteristic in the dark as a function of temperature for sample 2-A(P+E)-2.

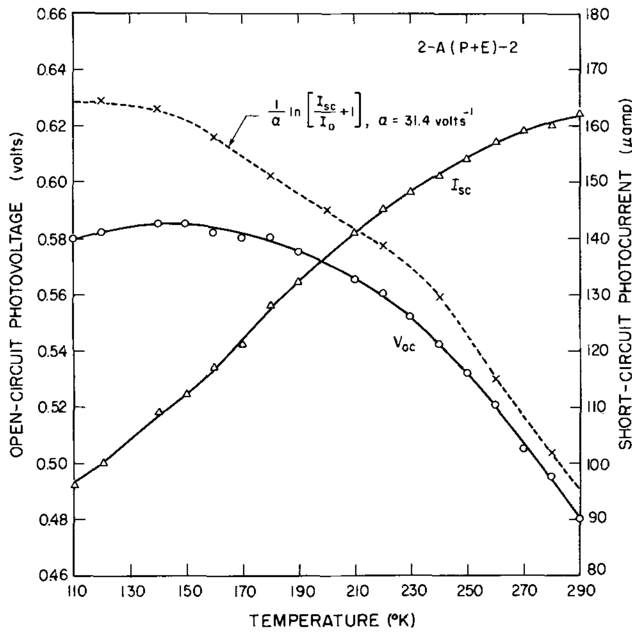

Fig. 10. Short-circuit photocurrent and open-circuit photovoltage in white tungsten light (280 mW/cm²) vs. temperature for sample 2-A(P+E)-2. Calculated curve for photovoltage is also shown.

values of current at a fixed voltage from Fig. 9 are plotted against $1/T$, it is found that near 300°K, $J_o(T)$ is apparently thermally activated with an energy of 0.26 eV. (A similar plot for the B-face samples gave an average activation energy of about 0.45 eV.) At lower temperatures $J_o(T)$ becomes increasingly independent of temperature, with no variation below about 120°K.

Figure 10 illustrates the temperature variation of the open-circuit photovoltage and short-circuit photocurrent in unfiltered tungsten light. The short-circuit current decreases by about 30% from room temperature to 100°K, approximately linearly. The open-circuit voltage increases by about 12% over the same temperature range. The increase in photovoltage is nearly linear with decreasing temperature near 300°K, but the curve bends over at lower temperatures and passes through a broad maximum at 150°K. This behavior can be understood in terms of the relationship between open-circuit voltage and short-circuit current for an idealized photovoltaic cell

$$V_{oc} = \frac{1}{\alpha} \ln \left[\frac{J_{sc}}{J_o} + 1 \right] \quad [3]$$

where α and J_o are defined by Eq. [2]. The right side of this expression is plotted in Fig. 10 (dashed line), using the experimental values of J_{sc} and J_o *vs.* T and the value of α from Fig. 9, $31.4 V^{-1}$. The dashed curve is slightly higher than the experimental V_{oc} at all temperatures but has the same general shape. The positive deviation of the calculated curve is attributed to a finite shunt resistance in the actual cell. The plot of $(1/\alpha) \ln [(J_{sc}/J_o) + 1]$ demonstrates that the "foldover" in V_{oc} with decreasing temperature is a consequence of the temperature independence of J_o at low temperature.

Effect of uniaxial stress.—The capacitance as a function of bias was measured at room temperature for two specially prepared samples, one A- and one B-face, with and without uniaxial stress applied parallel to the plane of the junction (parallel to the CdS a-axis). These samples were prepared from 5 ohm-cm CdS, with the Cu_2S layer about 10μ thick in each case. Figure 11 gives plots of $1/C^2$ *vs.* V for the A-face sample, both with stress applied (2.55 kg/mm²) and after removal of the stress. Figure 12 shows similar data for the B-face sample, with the stress in this case

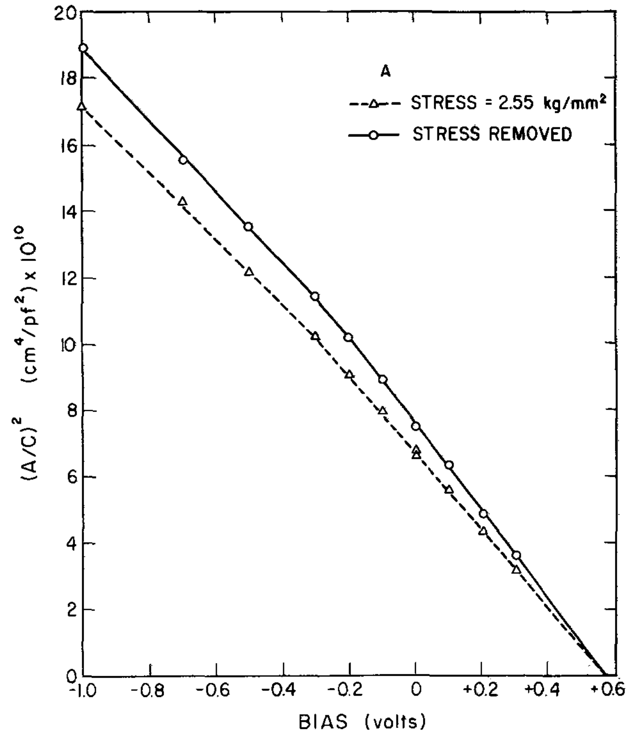

Fig. 11. Effect of uniaxial stress (2.55 kg/mm² nominal) on the $1/C^2$-V plot for an A-face sample. Capacitance values were corrected for series resistance.

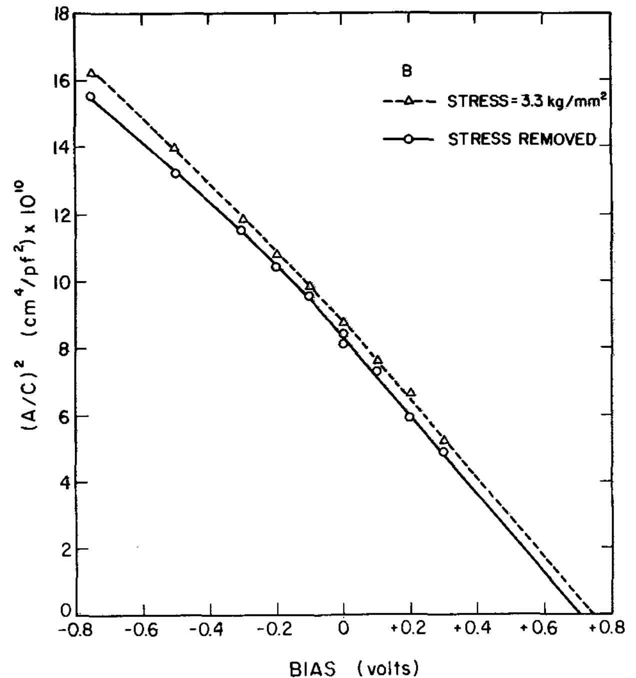

Fig. 12. Effect of uniaxial stress (3.3 kg/mm² nominal) on the $1/C^2$-V plot for a B-face sample. Capacitance values were corrected for series resistance.

equal to 3.3 kg/mm². For the A-face sample, the capacitance is increased by the applied stress for all values of bias; the opposite effect is obesrved for the B-face sample.

Discussion

Band diagram.—The general properties of the Cu_2S-CdS heterojunction can be described in terms of the energy band profile given in Fig. 13. The Cu_2S is shown as a degenerate p-type semiconductor with (indirect) band gap of 1.2 eV. The Fermi level lies roughly 0.05 eV below the valence band edge for a hole density of

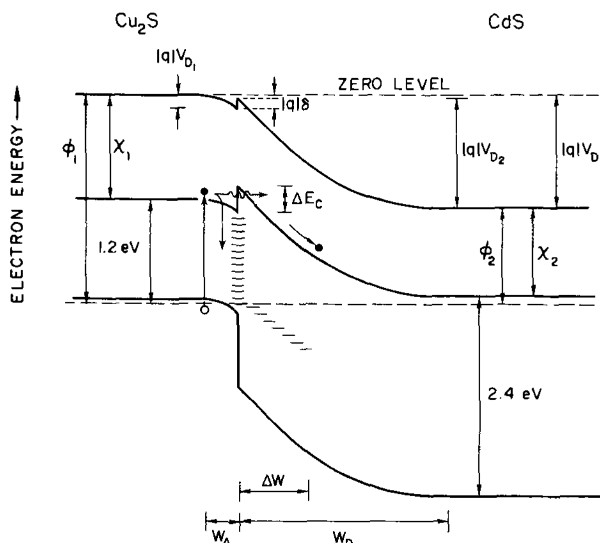

Fig. 13. Band diagram for the Cu_2S-CdS heterojunction, showing deep acceptor levels and interface states. Carriers photoexcited in the Cu_2S may cross into the CdS and contribute to the photocurrent, or may recombine through interface states.

10^{20} cm^{-3}. The CdS has a (direct) band gap of 2.4 eV. A quasi-continuum of interface states arising from the severe lattice mismatch is postulated (22).

A positive discontinuity or "spike" in the conduction band is also indicated. Such a spike may arise as a result of the difference in electron affinities of Cu_2S and CdS, and also if an electrostatic dipole of the proper sense exists at the interface. The magnitude of the spike is given by

$$\Delta E_c = \chi_1 - \chi_2 - |q|\delta \quad [4]$$

or

$$\Delta E_c = |q|(V_{D1} + V_{D2}) + (\phi_2 - \chi_2) - (\phi_1 - \chi_1) \quad [5]$$

χ is the electron affinity, δ the interface dipole (positive or negative), V_D the diffusion potential, and ϕ the work function. In this case, subscript 1 refers to Cu_2S and subscript 2 to CdS. In the case of 1 ohm-cm CdS, $(\phi_2 - \chi_2)$ is approximately 0.1 eV. With $(\phi_1 - \chi_1)$ for Cu_2S about 1.25 eV (band gap plus 0.05 eV between valence band edge and Fermi level), a total diffusion potential $(V_{D1} + V_{D2})$ greater than 1.15V is required for a positive discontinuity. This spike has been postulated as part of a model to account for the transient and secondary illumination effects observed in heat-treated cells (13), and is discussed elsewhere in relation to photocapacitance phenomena (17).

The existence or nonexistence of the conduction band spike cannot be proven from the measured values of ψ given in Table I. The general relationship between the quantity ψ, obtained by extrapolating a plot of $1/C^2$ *vs.* V from low reverse or forward bias to zero, and the total diffusion potential $V_{D1} + V_{D2}$, has been given by Donnelly and Milnes (23)

$$\psi = V_{D1} + V_{D2} - \frac{Q^2}{2q(\epsilon_1 N_1 + \epsilon_2 N_2)} \quad [6]$$

where Q is the net interface charge per unit area, N_1 and N_2 are the net impurity densities on the two sides of the junction, and ϵ_1 and ϵ_2 are the respective dielectric constants. It is reasonable to assume that the large lattice mismatch (about 5%) between oriented Cu_2S formed on the basal plane of CdS gives rise to a significant density of charged imperfections at the interface (22, 24). Thus the value of ψ may be somewhat lower than the true diffusion potential.

The values of ψ determined by the extrapolation of the series-resistance limited forward I-V characteristic to zero current are also expected to be lower than the true diffusion potential in this case, since the forward current is apparently dominated by tunneling rather than by emission over the total barrier.

Photoresponse.—The photoresponse of the junction under short-circuit conditions can be understood in terms of Fig. 13 as follows: light incident from the CdS side is absorbed in the Cu_2S, generating nonequilibrium densities of electrons and holes. The absorption coefficient of Cu_2S varies from about 10^4 cm^{-1} at 1.2 eV to about 10^5 cm^{-1} at 2.2 eV (18). The diffusion length of electrons in Cu_2S has been measured by a light microprobe technique to be in the range 1-4 $\times$ 10^{-5} cm (25). Thus most of the incident radiation which reaches the Cu_2S through the CdS is absorbed within a diffusion length in the Cu_2S. The photoexcited electrons must cross the interface into the CdS in order to contribute to the photocurrent. Some are lost due to recombination via the interface states, as indicated in Fig. 13. If a conduction band spike exists, the electrons must either tunnel through or be thermally excited over the barrier in order to enter the CdS. The absence of transient and secondary-illumination effects in efficient, nonheat-treated junctions at room temperature suggests that the spike width cannot be modulated as in the case of the heat-treated cells (13).

Deep levels in the CdS depletion layer.—A number of deep levels located about midway in the CdS band gap are also shown in Fig. 13. The existence of these levels in the nonheat-treated cells has been deduced primarily from photocapacitance data (17). The distance, ΔW, over which these deep acceptor levels are distributed in the CdS depletion region can be estimated from capacitance-voltage curves. The plots of $1/C^2$ *vs.* V for samples 2-A(P), 2-B(P), and 8-B(P), Fig. 7 and 8, show a change in slope at low reverse and forward bias. If the density of ionized donors in the CdS depletion region is assumed to have a step decrease near the interface of magnitude ΔN_D and width ΔW, then it can be shown that (26)

$$V^* = (V_{D1} + V_{D2}) + \frac{q}{2\epsilon}\left[1 - \frac{\Delta N_D}{N_A + N_D}\right]\Delta N_D(\Delta W)^2 \quad [7]$$

where V^* is the intercept voltage obtained by extrapolating the $1/C^2 - V$ plot from the linear, high reverse-bias region, and $(V_{D1} + V_{D2})$ is the total diffusion potential of the junction. (N_A in this case refers to the acceptor density on the p-type side.) If it is assumed that $(V_{D1} + V_{D2})$ is given approximately by the value of ψ obtained by extrapolation of $1/C^2$ from the low-bias region of steeper slope, and that $\Delta N_D \approx N_D$ so that ΔW is an "intrinsic" layer, then for $N_A >> N_D$ we obtain as an upper limit

$$\Delta W \approx \left[\frac{2\epsilon}{qN_D}(V^* - \psi)\right]^{1/2} \quad [8]$$

For each of the two-hour samples of Fig. 7 and 8, $V^* - \psi$ is about 0.2V. Taking $N_D = 3 \times 10^{16}$ cm^{-3} and $\epsilon = 10\epsilon_0$, where ϵ_0 is the permittivity of free space, we find $\Delta W = 860A$. For sample 8-B(P) (Fig. 11), $V^* - \psi$ is about 0.4V, giving $\Delta W = 1200A$, which is about half the depletion layer width at zero bias. The A-face samples show a rapid increase in junction capacitance with increasing Cu_2S thickness (see Table I), resulting in $1/C^2 - V$ plots which are concave upward for the two thicker samples (Fig. 7). Values of ΔW were not obtained for the thicker-layer A-face samples because of this effect. At least part of the increase in capacitance may be due to a nonplanar interface between the Cu_2S and the CdS for A-face samples which becomes more pronounced with longer reaction time. Goodman (27) has shown that this results in a voltage-dependent effective junction area which gives rise to a concave-upward $1/C^2 - V$ plot when the nominal geometrical area is assumed. The influence of

stress on the charge profile of the junction may also contribute to this effect, as discussed later.

The deep centers are most likely diffused in copper levels incorporated during formation of the Cu_2S layer. The penetration depths estimated above from capacitance data are much greater than those expected from available data for bulk diffusion of copper in CdS (28). It is therefore suggested that the motion of the copper is assisted by dislocations formed in the CdS near the advancing Cu_2S interface which accommodate the lattice mismatch. Oldham and Milnes (29) have shown that for a lattice mismatch of about 4%, the interfacial dislocations are formed in a crossed grid with spacing of the order of 200A, the thickness of the grid being less than a typical depletion layer width.

Forward current.—The temperature-independent slope of the forward I-V characteristic suggests that the forward current is due to tunneling of electrons from the CdS conduction band through the interface states to the Cu_2S valence band. The different thermal activation energies for the forward current at a fixed voltage for A- and B-face samples near 300°K indicate a possible difference in interface state density and distribution in energy in the two cases.

Uniaxial stress effect.—The results of the capacitance measurements under applied stress for the A- and B-face samples can be interpreted in terms of the piezoelectric properties of CdS. The capacitance of the A-face sample was observed to increase slightly under compressive stress applied along the a-axis, with the opposite behavior for the B-face sample. From the piezoelectric properties of the wurtzite lattice, it can be shown (30, 31) that a compressive stress applied along the a-axis gives rise to an electric field ϵ_p, directed from the A toward the B face parallel to the c-axis, with magnitude

$$\epsilon_p = \frac{P_3}{\epsilon} = \frac{d_{31}\sigma_1}{\epsilon} \quad [9]$$

where P_3 is the component of polarization charge per unit area parallel to the c-axis, d_{31} is the appropriate element of the piezoelectric tensor, σ_1 is the compressive stress applied along the a-axis, and ϵ is the dielectric constant. For CdS, $d_{31} = -5.18 \times 10^{12}$ coulombs/newton (30). This polarization field is neutralized by the mobile conduction electrons in the bulk of the crystal, but adds to or subtracts from the built-in field in the depletion region of a p-n junction formed on the B or A face of the CdS, respectively. The effect is illustrated in Fig. 14, which shows the charge density profile and electric field in the depletion layer, with and without stress, for both A and B faces. An intrinsic region of width ΔW is assumed. In the A-face case, the stress-induced field ϵ_p acts in opposition to the electric field due to the space charge on the CdS side of the junction. The electric field profile with compressive stress applied is given by the dashed line. The discontinuity in field at the Cu_2S-CdS interface implies a net positive charge on the interface states (assumed neutral in the absence of external stress). The stress narrows the depletion layer in the CdS from W_D to W_D'. From similar triangles

$$W_D' = \Delta W\left(\frac{\epsilon_p}{\epsilon_m}\right) + W_D\left(1 - \frac{\epsilon_p}{\epsilon_m}\right) \quad [10]$$

ϵ_m, the maximum field, is given by

$$\epsilon_m = \frac{qN_AW_A}{\epsilon} = \frac{qN_D(W_D - \Delta W)}{\epsilon} \quad [11]$$

for the case illustrated (differences in the dielectric constants of the two materials are ignored). Since $N_A >> N_D$ for the Cu_2S-CdS junction, the depletion layer width W_A in the Cu_2S is negligible compared to W_D, the width in the CdS. Consequently, we define the capacitance

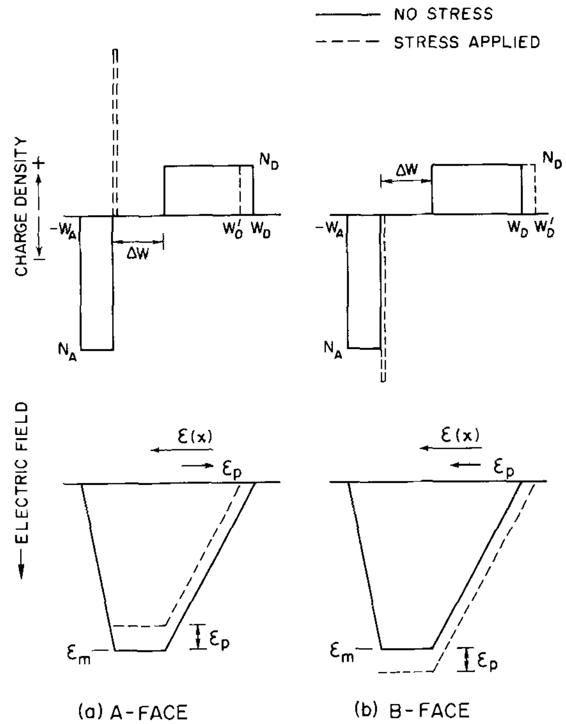

Fig. 14. Change in charge density and electric field profiles due to applied stress for A- and B-face samples.

$$C_o = \frac{\epsilon A}{W_D}, \quad C_o + \Delta C = \frac{\epsilon A}{W_D'} \quad [12]$$

The fractional change in capacitance due to applied stress, for the A-face case, is

$$\left(\frac{\Delta C}{C_o}\right)_A = \frac{W_D}{W_D'} - 1 = \left[1 - \frac{\epsilon_p}{\epsilon_m}\left(1 - \frac{\Delta W}{W_D}\right)\right]^{-1} - 1 \quad [13]$$

The increment ΔC is positive. Using Eq. [10] and [12], this can be written in the form

$$\left(\frac{\Delta C}{C_o}\right)_A = \frac{K\sigma_1}{1 - K\sigma_1} \quad [14]$$

where $K = d_{31}/qN_DW_D$ and σ_1 is the stress normal to the c-axis, negative for compression.

For the B-face case (Fig. 14b), a similar treatment gives

$$\left(\frac{\Delta C}{C_o}\right)_B = -\frac{K\sigma_1}{1 + K\sigma_1} \quad [15]$$

The capacitance increment is negative. The electric field discontinuity at the interface implies a net negative charge in the interface states.

For the two samples for which are shown in Fig. 11 and 12, the calculated values of K were $\approx 10^{-1}$. Using the values of nominal stress, Eq. [14] and [15] predict an effect larger by an order of magnitude than observed. At least part of the discrepancy may be attributed to a decrease in d_{31} due to a high density of dislocations in the CdS near the interface. Chubachi *et al.* (32) observed a decrease in d_{31} from 5.18 to 2.32 (10^{-12} coulombs/newton) as the dislocation density in CdS increased from 3×10^4 to 1.5×10^7 cm^{-2}. Additional factors may be an overestimation of the actual stress applied to the junction and an oversimplified model.

Equations [14] and [15] predict that the magnitude of the capacitance change for the A-face junction increases more rapidly with stress than that for the B-face. This is also consistent with the existence of net charge at the interface when the samples are under

stress. The dependence of capacitance on interface state charge density Q can be expressed as (23)

$$C = A(V_{D1} + V_{D2} - BQ^2)^{-1/2}\left(1 + K\frac{dQ}{dV}\right) \quad [16]$$

for zero bias, where A, B, and K depend on doping and dielectric constants and $V_{D1} + V_{D2}$ is the diffusion potential. (The above expression neglects a possible dipole.) Thus for both cases illustrated in Fig. 14 the capacitance would tend to increase under stress due to the induced interface state charge, independent of the change in capacitance resulting from widening or narrowing of the depletion layer by the polarization field (Eq. [14], [15]). In the as-formed junctions without externally applied stress, the piezoelectric effect may influence the junction capacitance through the elastic interfacial strain between the Cu_2S and CdS, and also through the stress fields associated with interfacial dislocations. For example, Table I indicates that with increasing relative thickness of the Cu_2S layer (and corresponding increase in interface stress), the zero-bias capacitance for B-face samples decreases, while that for A-face samples increases by a relatively greater amount.

Conclusions

The fabrication and properties of nonheat-treated single-crystal Cu_2S-CdS heterojunctions have been described. The major portion of the photovoltaic response arises from light absorption within a diffusion length in the Cu_2S, with transfer of the photoexcited electrons across the interface into the CdS. A large density of interface states exists due to the mismatch strain between the two materials when the Cu_2S is formed on the CdS basal planes. A density of deep acceptors comparable to the net donor density in the CdS occurs in a fraction of the CdS depletion region near the interface.

Differences between A- and B-face samples were observed with respect to Cu_2S growth rate, open-circuit photovoltage, I-V characteristics, and changes in junction capacitance under applied stress. The latter was analyzed in terms of a simple model involving the piezoelectric properties of CdS.

A High Production System for the Deposition of Silicon Nitride

V. D. Wohlheiter and R. A. Whitner

Western Electric Company, Inc., Allentown, Pennsylvania 18103

ABSTRACT

Amorphous silicon nitride is well known as a barrier to the penetration of alkali metal contaminants into junctions of semiconductor devices and as a gate dielectric for MIS devices. This paper discusses the operating characteristics of a production system for the deposition of silicon nitride by the ammonolysis of silicon tetrachloride in a hot wall furnace, and the characteristics of the resulting films.

The protective film (1700-2500Å) for bipolar devices can be deposited at a rate of 120 wafers/hr. For MIS work, where film thickness directly affects device threshold voltage, better uniformity can be achieved by modifying the wafer placement and operating procedures. The nitride films are amorphous with an index of refraction of approximately 1.95; the surface-state density is in the order of 10^{12}; and the etch rate in buffered hydrofluoric acid[1] is 11 ± 2 Å/min.

This paper describes the design of a production system for the deposition of silicon nitride and some of the characteristics of the films produced.

Amorphous silicon nitride was introduced into the manufacture of beam lead chips to act as a contamination barrier, as has been reported in the literature (1). The system was designed to meet the following specifications for the barrier film: thickness, 1750-2500Å; etch rate, 11 ± 3 Å/min in buffered HF at 23°C; sodium penetration (2), 92% removed after etching 50Å. The etch rate has been specified to fall within a normally achievable range that will allow the silicon nitride to pass the sodium penetration test; *i.e.*, when the etch rate in buffered hydrofluoric acid increases, the probability of sodium penetration increases (3). The etch rate is directly related to the amount of oxygen in the silicon nitride; and because the presence of oxygen weakens the nitride barrier to alkaline contaminants, the etch test is sufficient to provide some indication as to the quality of silicon nitride. The actual testing procedure for sodium penetration will be discussed later.

Initially, silicon nitride was deposited in either a carousel or a barrel-type epitaxial reactor. However, the need for large production numbers (greater than 50 wafers/hr) suggested that an alternate system be developed due to the high cost of reactors and the relatively long cycle time. It was decided to develop a system using a standard diffusion furnace to deposit silicon nitride. Table I compares the reactor statistics with the goals of the proposed furnace system.

Table I

	Reactor	Furnace
Cost (installed)	$50K (min)	$18K
Turn-around time	60 min	25 min
Capacity/run	25 wafers	50 wafers

These figures are based on data when the study began four years ago. A capacity ratio of 3:1 (furnace wafers to reactor wafers) and a cost ratio of 1:8 for the furnace system have been obtained.

In the initial furnace operation, the effort was directed toward producing a satisfactory nitride film. This was done using a streamlined quartz boat with the wafers lying flat. Several conclusions were drawn from this work: (*i*) the gases must be absolutely dry to meet the etch rate requirements; (*ii*) the uniformity of the film depends strongly on the geometry of the system; (*iii*) the zone of uniform deposition depends strongly on the bulk gas volume, *i.e.*, gas velocity; and (*iv*) a deposition rate of about 100 Å/min appeared optimum. To achieve volume output, it was necessary to place wafers in a stand-up position; and the next phase of development was concentrated on obtaining uniform films on at least four rows of standing wafers. The need for a high volume of nitrogen carrier flow had been suggested by previous work with boron doping systems and, in this case, solved the uniformity problem. The details of the design and operation of the system reflect the need to use and accommodate a high volume and high velocity of bulk gas.

Key words: thin films, contamination barrier, chemical vapor deposition (CVD), sodium penetration, diffusion furnace CVD, silicon integrated circuits.

[1] The etch rate of thermally grown silica in buffered hydrofluoric acid is 1000 Å/min.

Description of the System

The most recent systems consist of a standard, two-tube diffusion furnace with a quartz tube, a dry nitrogen supply, bottled ammonia, and a cooler for a flask of silicon tetrachloride. A cross-sectional view is shown in Fig. 1. The upper tube is used to preheat the bulk flow of nitrogen which reduces the heat load on the deposition furnace and, therefore, allows a longer uniform temperature zone. Other preheat schemes could also be used, such as a double walled tube. Typical operating conditions are: quartz tube size, 2⅝ × 3¼ in. (66 × 83 mm); carrier N_2, 135 liters/

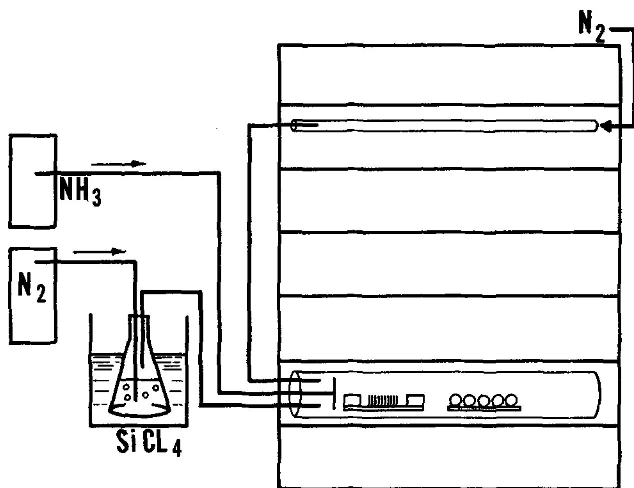

Fig. 1. Cross-sectional view of the silicon nitride deposition system.

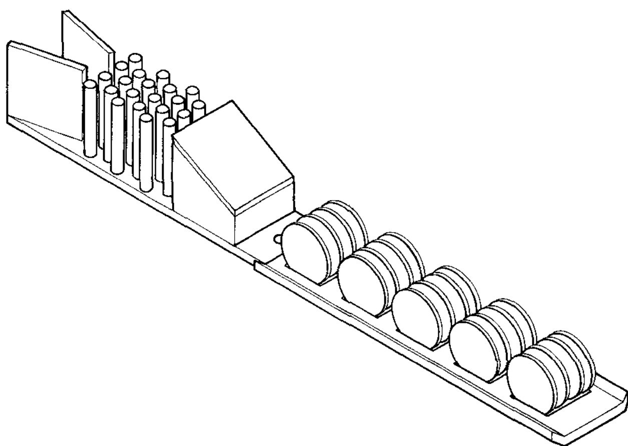

Fig. 2. The quartz gas diffuser and silicon boat containing silicon wafers.

min;[2] NH_3, 0.4 liters/min;[2] $SiCl_4$ at 10°C, 0.150 liter/min N_2 bubbled;[2] temperature, approximately 900°C.

The temperature of the silicon tetrachloride was controlled with a constant temperature bath so that the vapor pressure was constant and a specific amount was vaporized by the bubbling nitrogen. The temperature of the $SiCl_4$ cooler and the flow rate of the nitrogen through the silicon tetrachloride were experimentally determined and set to yield a deposition rate of 100 Å/min. The constant temperature baths now being used do not use water as the bath media for the silicon tetrachloride. Water can react violently if the flask were to be broken in the cooling chamber. The silicon tetrachloride utilized is an epitaxial grade while the ammonia is anhydrous and instrument grade.

During initial development the amount of moisture present in the ammonia was found to be critical. Excess oxygen and water will cause a silicon oxy-nitride to be deposited; therefore, anhydrous 99.999% pure ammonia was chosen. The silicon oxynitride can be identified by its much higher etch rate in buffered hydrofluoric acid. The flow rate of ammonia was set to provide an excess of ammonia to insure complete reaction of the silicon tetrachloride. The ratio of ammonia to silicon tetrachloride ($NH_3/SiCl_4$) used was 16.6/1. The ammonia was introduced directly into the hot zone to avoid the possibility of alternate silicon tetrachloride-ammonia reactions taking place at lower temperatures.

Figure 2 is a drawing of the baffle section and paddle design now in use. The baffle section is quartz and is used to improve deposition uniformity, both by deflecting the gas flow and by heating the reaction components. The boat which holds the wafers parallel to the gas flow is high purity silicon and was chosen because of the ease of cleaning in concentrated hydrofluoric acid, the absence of devitrification, and the accuracy achieved in machining. The silicon boat may be placed on a quartz carrier on wheels and allows automatic insertion and withdrawal from the deposition system with its attendant reproducibility.

In operation, the wafers are loaded on the silicon boat and the boat pushed into the furnace before the ammonia and silicon tetrachloride are introduced. The boat is usually preheated, and the ammonia turned on a minute or so before the silicon tetrachloride is introduced. If the reaction gases are introduced before the wafers are heated, a hazy deposit forms on the cold wafers. The ammonia is introduced first to prevent the possibility of depositing silicon from the breakdown of silicon tetrachloride. The ammonolysis of silicon tetrachloride which forms silicon nitride is a complicated series of reactions. Simply stated, it is

$$3SiCl_4 + 4NH_3 \rightarrow Si_3N_4 + 12HCl$$

The excess hydrogen chloride creates a favorable condition according to subsequent investigation by MacKenna *et al.* (4), who showed that the hydrogen chloride can act as a getter for any sodium ions present in the deposition cycle. After depositing the desired thickness, the ammonia and silicon tetrachloride are turned off and the wafers withdrawn.

Film Properties

Because the primary purpose of this film is that of a silicon nitride barrier, the thickness uniformity is not as stringent as that required for MIS work. The specifications for the barrier application are typically 2100 ± 400Å, while the thickness variation from a routine run of at least 60 wafers averages ±200Å. Usually, the deposits are uniform in any row but may vary from row to row depending upon the nitrogen flow and the wafer to wafer spacing. Rainbow effects, depicted in Fig. 3 with the edge toward the gas flow receiving a heavier deposit, are noted when the bulk nitrogen flow is too low or when the wafer to wafer spacing is too small, less than 0.214 in. Each shaded area represents a thickness variation of about 300Å; and since homogenous films of this thickness range exhibit light interference, this variation causes an apparent color difference in the various areas of the wafer. With this low flow, less than 3 ft^3/min, the last rows also tend to have thin deposits. The bulk nitrogen flow is from left to right in Fig. 3. However, if the bulk nitrogen flow is too high, the first wafer row becomes thinner than the subsequent rows due to the incomplete reaction of the silicon tetrachloride and ammonia. The amount of silicon tetrachloride influences the deposition rate; but if the gas stream is kept fairly dilute, the uniformity is not affected greatly. The baffle section and boat design also influence uniformity. The baffle section (Fig. 2) has an upper deflection plate which helps to direct the flow down towards the bottom of the wafers to help reduce the thin area above the slot mark.

The results of varying the processing parameters were investigated to properly evaluate the deposition system. The effects of changes in source bubbler rates and deposition temperatures, upon both the deposition and etch rates, were examined. In addition, a comparison of the film quality with other deposition systems was made by etching the films in buffered hydrofluoric acid and phosphoric acid. Results are presented in the following paragraphs.

To investigate the effects of varying system parameters, silicon tetrachloride was bubbled at three different rates, and each of these rates was repeated in the 850°-950°C deposition temperature range at 25°C steps. The results are shown in Fig. 4. The deposition rate showed an increase with both increased deposition temperature and bubbler rates.

As mentioned previously, the nitride film requirements are a thickness of 2100 ± 400Å and an etch rate in buffered hydrofluoric acid of 11 ± 3 Å/min. Figures 5 and 6 represent typical data for 45 runs showing a plot of average thickness and average etch

[2] Flowrates are based on data supplied by the Brookes Instrument Division of the Emerson Electric Company.

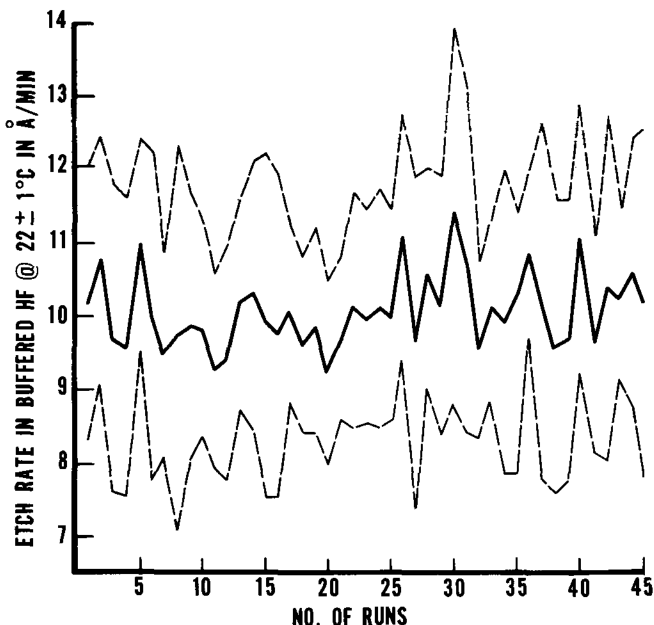

Fig. 6. Etch rate of silicon nitride in buffered hydrofluoric acid vs. deposition runs.

rate with their 2σ limits, respectively. A sample of five wafers, one from each row, was used to calculate the value. The maximum variation of average thickness between runs was less than 250Å and etch rate variation was less than 2 Å/min.

Because silicon nitride is used as a mask against buffered hydrofluoric acid, and is etched in hot phosphoric acid, the etch rate as a function of deposition temperature was measured in these etching solutions. Over the increasing deposition temperature range investigated, the etch rate in buffered hydrofluoric acid decreased slightly. This has been shown to be caused by an increase in the density of the silicon nitride (5). Figure 7 is a plot of this data. The information presented in Fig. 8 shows that the silicon nitride etch rate in boiling phosphoric acid at 180°C also decreases with increasing deposition temperature. The rates in phosphoric acid compare favorably with those reported by VanGelder and Hauser (6).

The index of refraction has been measured over a three month period and found to be in the range of 1.94-2.00. The measurements were made, with an ellipsometer at $\lambda = 5460$Å, of silicon nitride deposited upon blank silicon wafers. The density of silicon nitride

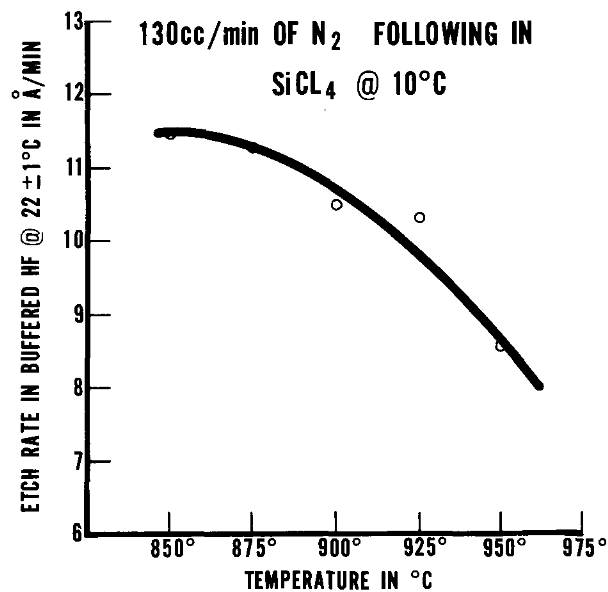

Fig. 7. Etch rate of silicon nitride in buffered hydrofluoric acid vs. deposition temperature.

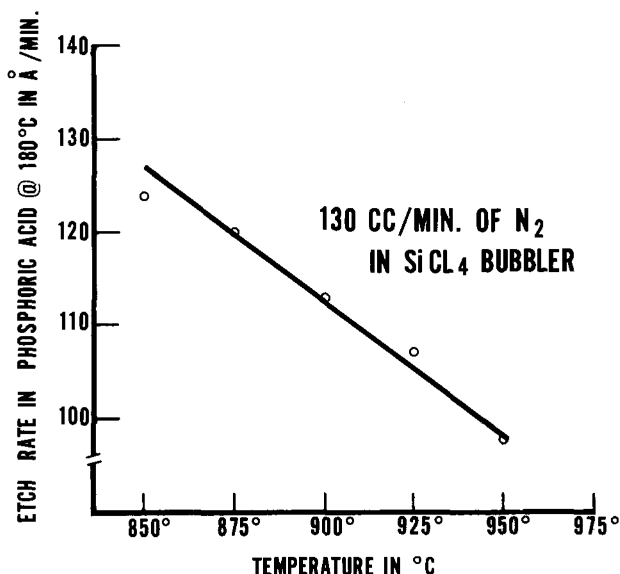

Fig. 8. Etch rate of silicon nitride in boiling phosphoric acid at 180°C vs. deposition temperature.

was determined by a weighing technique to be approximately 2.9 g/cc. Silicon nitride was deposited on polished silicon wafers which had been previously weighed. The area covered by the nitride was measured and the average thickness measured. The wafers were reweighed and the density calculated. The wafers were etched clean of silicon nitride and reweighed to verify the previous reading.

Using the deposition systems described, limited studies have been conducted on MOS properties of silicon nitride on silicon. Our results indicated the surface state density, N_{ss}, to be in the order of $10^{12}/cm^2$ and the capability to consistently deposit films in the 300Å range. This is comparable to that reported by Chu *et al.* (7) and Doo *et al.* (8). However, we have not studied charge storage effects or other properties presently considered important for gate dielectrics.

Sodium Penetration Testing

A radioactive tracer technique (3) is used to test the effectiveness of silicon nitride as a barrier to sodium penetration. Radioactive sodium in the form of sodium chloride is evaporated onto the film in a vacuum, heated to 600°C for 22 hr, and diffusion allowed to take place. Using a scintillation detector, a count of the gamma radiation from the Na^{22} is obtained for the surface and following each etch step to develop a profile. If after 50Å have been removed only 8% of the original concentration remains, it is implied that the film is a reliable barrier against sodium. The films deposited in this system consistently pass this test. A less sophisticated method of evaluating silicon nitride is by actually subjecting devices to a sodium chloride solution (10g NaCl/100 ml H_2O) during a certain baking period of 300°C for 8 hr, and then testing the semiconductor devices for high leakage currents.

Conclusion

An operating high production system for the deposition of silicon nitride using the ammonolysis of silicon tetrachloride has been described. The unit has the capability of at least 60 wafers/run.

From the data presented, it has been shown that the system has repeatability and reliability over a large number of runs with silicon nitride varying less than ±250Å within the run. The assembly costs are relatively inexpensive, and the actual operation is quite simple and reliable.

Acknowledgments

We are grateful for the technical discussions with R. E. Caffrey, V. E. Hauser, R. Berman, and E. B. Slutski of the Bell Telephone Laboratories; to Mrs. Kay Locke for performing many sodium penetration tests; and to D. H. Wyker and J. S. Pitsko for the valuable experimental assistance.

Dislocation Etch for (100) Planes in Silicon

F. Secco d' Aragona

Dow Corning Corporation, Solid State Research and Development, Hemlock, Michigan 48626

ABSTRACT

A new etch composed of a dilute aqueous solution of an alkali dichromate and hydrofluoric acid, for suitably revealing dislocations and other lattice defects in (100) planes of silicon, is reported. The etch is fast (typically 5 min), brings out both lineage (low angle grain boundaries) and slip lines, and works over a wide range of resistivities for n- and p-type material. The application of the etch is not restricted to (100) planes; dislocation etch pits are formed on all crystallographic orientations. The same etching characteristics were found with dilute aqueous solutions prepared from various chromium compounds and hydrofluoric acid.

The two etches primarily used to reveal dislocations in silicon are the Dash etch (1) and the Sirtl etch (2). The Dash etch yields deep etch pits on any surface independent of its crystallographic orientation. It has, however, the drawback of requiring long etching periods (4 to 16 hr) and is sensitive to oxygen impurity concentration.

The fast working Sirtl etch is almost exclusively used as a preferential etch for crystallographic defects in silicon but fails to produce pits on (100) planes and on planes close to (100) orientation [*e.g.*, (115)]. Mounds are formed instead, resulting in a rough surface and loss of detail. Using a modified Sirtl etch, a correlation between mounds and dislocations has been reported recently (3). However, the effectiveness of the etch is hindered due to the formation of numerous mounds of various sizes which do not appear to be related to dislocations.

In view of the previous difficulties, an effort was made to develop an improved dislocation etch for (100) planes of silicon. Such an etch should meet the following minimum requirements: (*i*) well-defined (deep) etch pits must be developed at the emergence points of all dislocations, including slip and lineage arrays; (*ii*) the etch must work for a wide range of resistivities and for n- and p-type material; (*iii*) the etch must

Key words: silicon crystals, etchants, dislocations, crystal imperfections.

work in a reasonably short time and be sensitive only to crystallographic defects (avoid surface roughness and formation of artifacts). An etch containing a dilute aqueous solution of an alkali dichromate and hydrofluoric acid was found which meets the above requirements. Moreover, the etch is isotropic in that it appears to reveal dislocations on surfaces of all orientations.

Experimental

Before etching, the silicon wafer is chemically polished. This step is important because a rough or dirty surface will automatically cause a poor etching. Any modification of the HNO_3-CH_3COOH-HF polishing mixture leading to a shiny surface can be used. A commercial polishing solution of the composition $HNO_3/CH_3COOH/HF$ (3:2:2) was used in our experiments. After 2-3 min, the polishing solution is rapidly flushed away with water. Particular care should be taken not to touch the wafer with the fingers or gloves, as this can result in subsequent anomalous etching effects. The standard dislocation etch recommended consists of one part by volume of a 0.15 molar solution of $K_2Cr_2O_7$ in distilled H_2O and two parts HF (49%). The etchant was tested on (100) wafers cut from dislocated crystals of different resistivities and type. The resistivity range was from 0.01 to 10,000 ohm-cm. P-type (doped with boron) and n-type (P, As, Sb) crystals were examined.

An etching time of 20 min is necessary to bring out dislocation pits of a size suitable for counting purposes in crystals with resistivities between 1 and 10,000 ohm-cm. Agitation strongly reduces the etching time. By using ultrasonic agitation, it can be lowered to 5 min. Ultrasonic agitation also leads to an improved surface appearance, avoiding bubble formation, and is, therefore, recommended. Lower resistivity wafers require longer etching periods of the order of 10-15 min with agitation. After a few minutes of etching, the etch changes to a brown-green color. This is due to the formation of Cr^3 cations and does not seem to affect the strength of the solution significantly.

The bulk etching rate was determined from thickness measurements at etching intervals of 10 min for dislocated and dislocation-free wafers in the resistivity range 4-300 ohm-cm, p- and n-type. Thickness measurements were made with a precision micrometer on a circular zone of approximately 8 mm diam in the center of the wafer. The wafer was held vertically and the etch temperature was kept between 25° and 30°C.

Results

A dark field view of a (100) Czochralski wafer etched 5 min is shown in Fig. 1. Perpendicular slip lines, which are dense near the periphery and less pronounced toward the center, are visible. Figure 2 shows a (100) wafer cut from a float-zoned crystal of <111> orientation. The white irregular lines, mostly radiating from the center of the wafer, are lineage or low angle grain boundaries. A closer view of the etch pits forming slip and lineage is given in Fig. 3.

In order to demonstrate that each etch pit corresponds to a dislocation, an x-ray topograph of a (100) wafer was compared to an optical image of the etch pattern of the same wafer (Fig. 4a and b). Superimposing a magnified view of the topograph to the etch pattern resulted in Fig. 4c which shows that a one-to-one correspondence between etch pits and dislocations does exist.

The effect of the etch is not restricted to (100) planes. An optical micrograph showing the shape of the dislocation pits on four different planes is given in Fig. 5. The shape of the pits varies from elliptical to circular. This indicates a basically nonpreferential character of the etch. The pits exhibit shapes no longer dictated by crystal symmetry, as in the case of the Sirtl etch, but instead they develop a pattern due to the pursuit of defects down into the crystal. When the dislocation line is perpendicular to a certain crystallographic plane, a circular pit will form as a result of the symmetrical circular strain around the dislocation. As expected, more circular pits are present on (110) planes. These are probably due to dislocations aligned in the <110> direction meeting the surface under an angle of 90°. On the other planes, the orientation of the elliptical pits is mostly random and determined by the angle the dislocation line makes with the surface. Variation in

pit shapes at dislocations in germanium, when the ratio of HF to HNO_3 is varied, was reported by Faust (4).

When dislocation-free crystals grown by the float zone method are Sirtl etched, swirls of shallow triangular pits are usually seen on (111) planes. These pits are thought to be due to vacancy clusters (5) and have been extensively described (6). Due to the nonpreferential character of the dichromate etch, the same defects cause shallow circular pits and their shape does not vary with the orientation of the silicon slice.

A typical curve for the bulk etching rate of the standard mixture is represented in Fig. 6. The etching

Fig. 5. Appearance of dislocation pits on (110), (111), (112), and (115) planes

rate is linear and equal to approximately 1.5 μ/min. No appreciable variation in etching rate exists between dislocated and dislocation-free crystals. Other lattice defects such as, for example, the hillocks of the swirl pattern (6), stacking faults, twin boundaries, etc., are also revealed by the etch.

The results reported above refer to a dilute (0.15M) aqueous solution of $K_2Cr_2O_7$ and HF. Etch pits with properties similar to those described may be formed also by using $Na_2Cr_2O_7$ as the oxidizing agent. At first it was thought that the presence of alkali ions in the recommended standard etch causes the better orientation-insensitive etching compared with the CrO_3-HF system. However, this concept was disproved when similar results were obtained substituting $(NH_4)_2Cr_2O_7$ or CrO_3 for the alkali dichromate. The main difference between the standard Sirtl etch and the etch described in this paper is a decrease in the content of Cr cations in the present etch accompanied by an increase in the acidity of the solution. These two factors together probably play the most important role in accounting for the different ecthing characteristics.

Properties of Vapor-Deposited Aluminum Arsenide

A. G. Sigai,* M. S. Abrahams, and J. Blanc

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Single crystalline epitaxial AlAs layers having donor concentrations as low as 2×10^{17} cm^{-3} and room temperature mobilities of 294 cm^2/V-sec were deposited on GaAs substrates by an open tube vapor-growth technique. The effects of various reaction liners on the purity and electrical properties of the deposited layers are considered. Optical absorption measurements show that in addition to the fundamental absorption edge at about 2.17 eV, a weaker absorption is observed at about 0.96 eV (1.3 μm) which is associated with deviations in stoichiometry. The magnitude of this peak depends on the aluminum to arsenic ratio in the gas phase. The observed bending of the epitaxial layer and measured dislocation densities in the AlAs are found to be consistent with previous models dealing with dislocation morphology and the occurrence of bending in epitaxially prepared heterojunction structures.

Because of the large energy gap of AlAs (2.17 eV) and its close lattice and thermal match with GaAs, this material is of potential interest for a variety of electro-optic devices. Alloys of AlAs and GaAs have already provided a multitude of useful devices including visible electroluminescent diodes and injection lasers. However, little is known about the properties of AlAs because its synthesis is complicated by the high reactivity of aluminum compounds at normal growth temperatures which makes high purity single-crystal growth difficult. Also, the reported hygroscopic nature (1) of this material presents difficulties in subsequent physical measurements.

Recently, the preparation of AlAs by an open tube continuous flow vapor growth system has been reported (2). In this system, aluminum is transported as a chloride by reaction of aluminum with HCl, and arsenic is provided by the thermal decomposition products of arsine. Unlike gallium and indium chlorides, the aluminum chlorides have been found to attack quartz reaction tubes. Consequently, protective liners must be used to minimize contamination during growth.

In the present work, the effects of various reaction liners on the purity and electrical properties of the deposited layers are considered. In addition, the optical and structural properties of layers employing this vapor growth technique are determined.

Vapor Growth Apparatus

The basic growth apparatus and technique have been described in detail previously (2) and, therefore, will not be described in detail here. The growth system, shown in Fig. 1, consists of a quartz tube which accommodates either an alumina or carbon liner. Within the liner, a series of alumina or carbon boats is used to contain the aluminum source metal. An alumina or carbon plug with several holes is placed at the end of the liner to provide a high velocity of gaseous aluminum chloride exiting the liner. This was found to be essential for significant epitaxial deposition, since the aluminum chloride and arsine react to form AlAs immediately at the points where the two gases begin to mix, independent of the mixing temperature or concentrations of the reacting species. Without the high gas velocity the AlAs would otherwise form at a point too close to the exit of the alumina liner to properly position a substrate.

In some experiments, a tungsten liner (not shown) is used in the deposition region, in addition to the alumina liner, plug, and boats, to further reduce the attack of the quartz by the aluminum chloride. In other experiments, all the alumina components were replaced with high purity carbon, as shown in Fig. 1, and the tungsten liner was replaced by a uniform carbon coating which was formed by the pyrolysis of electronic grade acetone at 1000°C. The GaAs substrates were supported by a carbon substrate holder on the end of a carbon-coated quartz growth rod.

The AlAs layers were deposited at 1000°C on undoped GaAs substrates oriented 3° from the {100} plane. The substrates were chemically polished in a 5:1:1 H_2SO_4:H_2O_2:H_2O solution for 1 hr followed by a 1 min polish in a 1% bromine-methanol solution just prior to growth. With nominal flow rates of 0.8 liters/min of 3% AsH_3 in H_2 and 2.3 liters/min of 1% HCl in H_2, growth rates of 1 to 2 mils/hr were realized.

The carbon components (boats, plug, and liner) were chemically cleaned and baked prior to initial use. The chemical cleaning consisted of an immersion in aqua regia for 5 hr followed by a 24 hr reflux in deionized triply-distilled water. The carbon was then fired in air at 280°C for 3 hr after which it was fired in hydrogen at 1000°C for 4 hr. Just prior to their use in the growth assembly, the carbon components were rf-heated in vacuum at 1500°C for 4 hr to remove adsorbed gases and other volatile constituents.

General Properties of Deposited Layers

The AlAs epitaxial layers were single crystalline as confirmed by the Laue back-reflection x-ray technique and were typically between 3 to 5 mils thick, although layers as thick as 15 mils have been deposited. The AlAs deposit initially appeared metallic, but on contact with air, developed uniform interference colors. After the appearance of a few fringes, very little further reaction with the atmosphere was observed. Electrical measurements on several samples (to be discussed later) stored in dry air were repeatable and reproducible several weeks later. This suggests that the reported rapid deterioration of this material (1) occurs only on the surface and that the properties of the bulk are maintained appreciably longer. The stability of the layers appeared to depend on the nature of the ambient and the crystalline quality of the deposit.

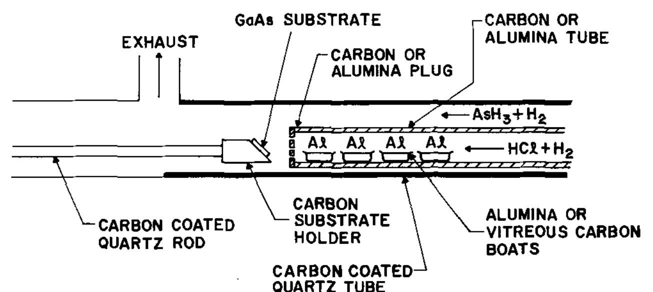

Fig. 1. Apparatus used for the vapor growth of AlAs

* Electrochemical Society Active Member.

Key words: epitaxial AlAs layers, vapor growth AlAs, optical absorption, electrical properties, dislocation structure.

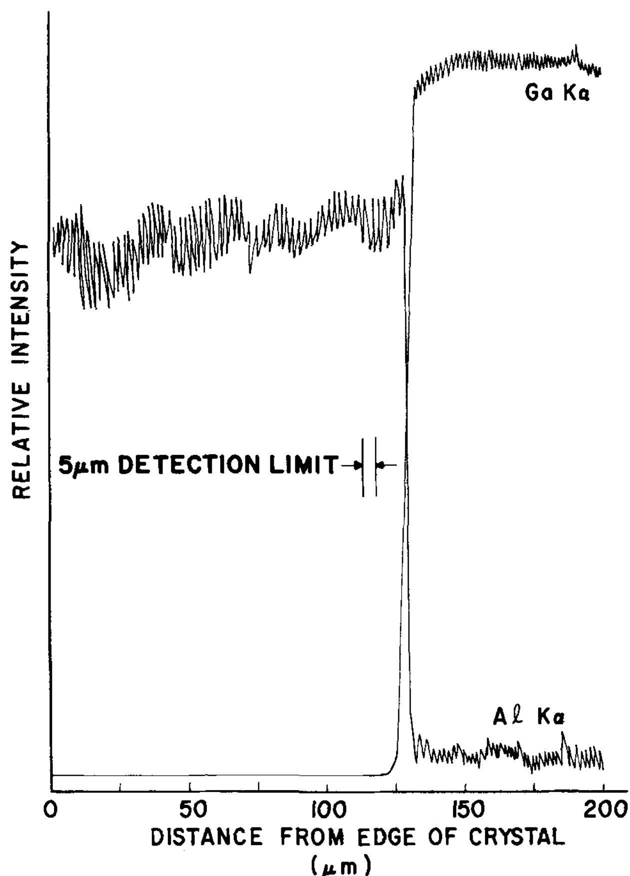

Fig. 2. The relative intensities of the Ga K_α and Al K_α wavelengths as a function of distance from the edge of the crystal along the growth direction determined on the {110} plane.

Of key importance for proper interpretation of the electrical, optical, and structural properties presented here is the extent of interaction between the AlAs and the GaAs at the epitaxy-substrate interface after several hours growth at 1000°C. Therefore, a sample was cleaved parallel to a {110} plane (*i.e.*, perpendicular to the growth direction) and examined by electron microprobe analysis. Using separate spectrometers, the relative Ga and Al concentrations were determined by monitoring the Ga and Al K_α intensities, respectively. The results were made quantitative by using polished single crystalline AlAs and GaAs as standards. The results of the analysis are presented in Fig. 2. The Ga intensity has been corrected for fluorescence of the As K_α on the AlAs side of the junction. The random variation in intensity observed for the Al K_α is believed to be due to variations in surface topography rather than in concentration, since complementary variations in the Ga K_α intensity are not observed. Clearly, the amount of interdiffusion, if it exists at all, is less than 5 μm, which is the limit of detection under the experimental conditions used.

Structural Properties

One question important for potential device fabrication is the degree of strain which may be present in an AlAs epitaxial layer which has been deposited on a GaAs substrate. For thick (> 5 mils) as-grown AlAs layers deposited on undoped substrates, the epitaxy-substrate composite is typically bowed strongly toward the GaAs substrate. Furthermore, during routine processing of relatively thin (3 mil) layers, the AlAs frequently cleaved into several pieces upon removal of the GaAs substrate. Both observations suggest the presence of large strain in these layers, which at first appears to be inconsistent with the reported (3) similarities of the room temperature lattice parameters ($a_{o\,AlAs}$ = 5.6610Å, $a_{o\,GaAs}$ = 5.6533Å) and thermal expansion coefficients ($\alpha_{AlAs} = 5.2 \times 10^{-6}$, $\alpha_{GaAs} = 6.6 \times 10^{-6}$). In fact, the excellent lattice and thermal match has been thought to play an important role in the excellent device performance of (Ga,Al)As electro-optic devices.

Both observations, however, can be explained on the basis of previous models dealing with the dislocation morphology (4) and the occurrence of bending (5) in epitaxially prepared heterojunction structures. According to these models, an orthogonal array of misfit dislocations will form at or near the heterojunction due to the difference in lattice parameter between the substrate and epitaxial layer. When the misfit dislocations bend out of the plane of growth, they give rise to inclined (4) dislocations whose density is n_I. As shown in earlier work (5), the edge components of the inclined dislocations produce a bending moment in the crystal if the extra half-planes of these dislocations are parallel to each other.

A value of $n_I = 1 \times 10^6$ cm^{-2} is calculated (4) by using the lattice parameters (3) appropriate to the growth temperature of 1000°C. Using this value for n_I, the calculated (5) radius of curvature of an isolated AlAs layer is 17 cm. This radius of curvature is in reasonable agreement with the value of 10 cm measured from a bowed layer of AlAs that had been isolated from its substrate. A similarly grown sample was examined by transmission electron microscopy; the value of n_I here was found to equal 7×10^6 cm^{-2}. Furthermore, the transmission electron micrograph of the dislocations in the AlAs layer, shown in Fig. 3, indicates that the inclined dislocations do tend to align, which is consistent with the proposed model (5). [Direct observation of the sense of bending of the inclined dislocations in III-V compounds will be published in due course (6).] Also, the layer would be expected (5) to bend toward the GaAs as observed. The difference between the calculated and measured values of n_I most likely arises from the uncertainty in the lattice parameters. The values of the lattice constant at 1000°C for AlAs and GaAs are 5.6899 ± 0.0005Å and 5.6906 ± 0.0005Å, respectively. Within the specified limits, the calculated value of n_I may vary by a factor of 4.

Further electron microscopical studies were performed on {110} cross-sectional planes which are normal to the {100} plane of growth. Examination of these specimens revealed the presence of an interfacial layer about 1 μm thick at the position of the original

Fig. 3. Transmission electron micrograph showing inclined dislocations in AlAs.

growth interface. Although the interfacial layer has not been identified, the bond strengths of the interfacial layer must be substantially different from either GaAs or AlAs. This is based on the observation that during thinning of the GaAs/AlAs interface on the {110} plane by ion bombardment for TEM studies, the etch rates of the various layers in the GaAs-interface-AlAs composite were significantly different. Practically all of the GaAs substrate was removed, clearly delineating the interface before any appreciable thinning of the interface occurred. Furthermore, a good deal of the AlAs was completely removed before the interface was thinned sufficiently for transmission of the 100 keV electron beam. It is believed that this layer has little direct effect on the bending of the composite epitaxial layer-substrate sandwich. This is because the similarity of GaAs and AlAs cause approximately equal and opposite effects at the respective interfaces. However, stacking faults with a density of 3×10^6 cm^{-2} were also present in the AlAs. The presence of faults is unexpected since the substrate surface was free of work-damage (7) and since both the substrate and epitaxial layer contained no second-phase particles (8). This high stacking fault density may well be due to the presence of the interfacial layer. It should be noted that the lattice spacing of the intermediate layer normal to the growth direction must be close to that of both AlAs and GaAs, since it would otherwise give rise to higher values of n_I than are actually observed.

The effect of strain due to differential thermal expansion was also calculated (3, 9), resulting in an expected radius of curvature of 47 cm. Any effect of the intermediate layer was neglected. This radius is clearly too large to account for the observed bending.

In view of the uncertainty in the lattice constants, the presence of a high density of stacking faults, and the presence of an interfacial layer of unknown composition, the conclusions drawn above dealing with the inclined dislocations and the radii of curvature are undoubtedly simple-minded. Nonetheless, application of this model to this system satisfactorily accounts for our observations of dislocation densities and bending.

Electrical Properties

As-grown AlAs layers.—The electrical properties of the vapor deposited AlAs were determined by standard Hall measurements on layers which were first removed from the substrate. Ohmic contacts were made by ultrasonically bonding indium and by annealing at 700°C for 5 min in a hydrogen atmosphere. Thicknesses greater than 3 to 4 mils were required to avoid cracking the layers. Table I summarizes the electrical properties of several AlAs layers which were vapor-deposited with various modifications to the growth system. Also included is the impurity analysis of each sample, determined either by mass or emission spectrographic techniques. In the first series of runs employing only the alumina boats, liner, and plug, the layers were found to be unintentionally doped n-type and show high concentrations of Si. This is to be expected based on the high reactivity of Al-compounds at high temperature and the use of a quartz reaction tube. Note also the correlation between the free electron concentration (from Hall measurements) and the concentration of Si (from mass and emission spectrographic analyses), suggesting Si as the predominant electrically active impurity. This is consistent with the observation that Si is the predominant donor impurity in many other III-V compounds prepared by similar vapor growth techniques (10).

Based on this hypothesis, a second series of runs was carried out employing an outer tungsten liner in the deposition zone to further reduce the observed attack of the quartz reaction tube. The tungsten liner was used in addition to the alumina components and liner in the source zone. Runs 3 · 23 and 3 · 24 in Table I clearly show a reduction of Si contamination by an order of magnitude with a corresponding reduction in the measured free electron concentration. Even with the tungsten liner, trace amounts of Fe, Cu, and Mg were present. These could originate from the alumina plug and boats since they contained 0.05% SiO_2, 0.1% Fe_2O_3, as well as a multitude of other trace impurities.

In a third series of experiments, efforts were made to reduce the Si contamination even further by replacing the tungsten liner with a pyrolytic carbon coating on the quartz reaction tube in the source and deposition zones and by replacing the alumina boats, plug, and liner with carbon components. The results in Table I show that the free electron concentration was reduced to 2×10^{17} cm^{-3} with reduced amounts of Fe, Cu, and Mg. However, some reaction with the carbon and quartz was observed which may have been related to pinhole cracks in the carbon coating. This may also account for the relatively high Si concentration in these samples compared to other III-V compounds grown by this technique.

In Fig. 4 the mobility of the unintentionally doped n-type vapor-deposited samples are plotted as a function of electron concentration. Although no simple curve is apparent, a general trend of increasing mobility with decreasing carrier concentration is observed. The carrier concentration of 2×10^{17} cm^{-3} and mobility value of 294 cm^2/V-sec represent the lowest concentration and highest room temperature mobility values obtained for our vapor-grown AlAs.

P-type doping.—It has been demonstrated previously (11) that Zn can be satisfactorily diffused into vapor-deposited AlAs layers to form p-n junctions which emit near bandgap radiation at room temperature. However, it is also of interest to examine the feasibility of growing p-n junctions *in situ*. Therefore, using a doping arrangement similar to that described by Tietjen (12) for GaAs and GaP, Zn vapor was introduced into the reaction tube during growth. Although a very high Zn concentration ($>10^{-3}$ atm) was obtained in the gas phase, mass spectrometric analyses of several layers revealed that only about 1 ppm Zn was incorporated into the AlAs, which is not sufficient

to overcompensate the background donor concentration. This inability to obtain p-type AlAs during growth may be related to the presumably high vapor pressure of Zn required for its incorporation into the AlAs at the growth temperature of 1000°C. For example, since the vapor pressure of Zn in the gas phase is introduced at only 10^{-3} atm compared to an equilibrium vapor pressure of Zn at the growth temperature of >1 atm, very little Zn would be expected to be incorporated. Although the activity of Zn in AlAs has not been considered, it is not expected that this would significantly alter these conclusions. These results further suggest that it may also be difficult to incorporate Zn or other volatile dopants at high-growth temperatures into other III-V compounds employing this vapor-phase growth technique.

Optical Properties

For optical absorption measurements, several vapor-deposited AlAs layers were polished flat and parallel on both sides using a chemical-mechanical polish technique with a ½% bromine-methanol solution. Layers at least 5 mils thick were required for the measurements and polishing procedure, since thinner layers inevitably cleaved as the GaAs/AlAs interface was approached. Layers polished in this manner were typically mirror smooth and transmitted orange light. However, a few minutes after exposure to the atmosphere the surface developed blue interference fringes, indicative of oxidation. To avoid appreciable oxidation, layers were stored and transported in trichloroethylene after polishing. Optical measurements were made using a Carey 14 double-beam spectrophotometer which had been thoroughly purged with high purity dry nitrogen prior to use. No apparent change in either the optical density or the general shape of the absorption curve was observed during several scans of the same sample. The absorption coefficient was calculated using the simple relation

$$\alpha = 1/t \ln (I_0/I)$$

where t is the thickness and I_0 and I are the initial and transmitted photon intensities, respectively. Although values of α obtained in this manner could be in considerable error in the region of long wavelengths due to neglecting reflection considerations, the relative values of α are quite reliable. Furthermore, values of α thus obtained were partially corrected for reflectance and other unaccounted-for absorption losses by subtracting the absorption which was present at wavelengths greater than that of the absorption edge and which remained relatively constant with wavelength. The values thus obtained were used for the subsequent evaluations.

The absorption coefficient of the AlAs layers were found to follow the relation

$$\alpha = K(h\nu - E_G)^m$$

with $m = 2$ for an indirect energy band structure. The energy gap was then determined from a plot of $\alpha^{1/2}$ *vs.* $h\nu$ with α extrapolated to zero. Analysis of several AlAs samples in this manner have yielded a value of the energy gap at room temperature of 2.17 ± 0.02 eV, which is in excellent agreement with previously published values of 2.15 eV (13) and 2.16 eV (14).

In addition to the fundamental absorption edge, Yim (13) has reported a weaker absorption peak at 1.3 μm in vapor-grown AlAs, which he suggested was associated with deviations in stoichiometry. Since this peak had never been observed in vapor-grown samples prepared in the present investigation or in AlAs grown by other techniques (14, 15), efforts were made to determine the existence of such an absorption peak. Several samples were grown using various HCl flow rates over the aluminum source and various flow rates of AsH_3 in order to change the aluminum to arsenic ratio in the gas phase. The absorption curves of these samples are presented in Fig. 5. It can clearly be seen that a peak does indeed exist at 1.3 μm and that the intensity of this peak depends on the HCl/AsH_3 flow rates, and, in turn, on the aluminum to arsenic ratio in the gas phase. This may be the reason why these deviations had not been apparent earlier in melt-grown AlAs (14) or in aluminum-rich (Ga,Al)As layers grown by liquid phase epitaxy (15). These findings demonstrate that the stoichiometry of the material can be controlled during vapor-phase growth by adjusting the Al/As ratio in the gas phase. Similar deviations in stoichiometry have been observed in other vapor-grown III-V compounds such as AlP (16), and, recently, GaAs (17) and Ga(As,P) (18). In the later works (17, 18), the deviations in stoichiometry have been found to have a profound effect on the luminescence properties of the vapor-deposited layers.

Summary and Conclusions

The epitaxial deposition of AlAs layers using the $Al/HCl/AsH_3$ vapor-phase growth technique requires many precautions to prevent serious contamination of the grown layers. After examination of several methods for reducing the attack of the quartz reaction tubes, the highest purity layers ($n = 2 \times 10^{17}$ cm^{-3} with $\mu = 294$ cm^2/V-sec) were found to be obtained in an all carbon component system. However, the residual

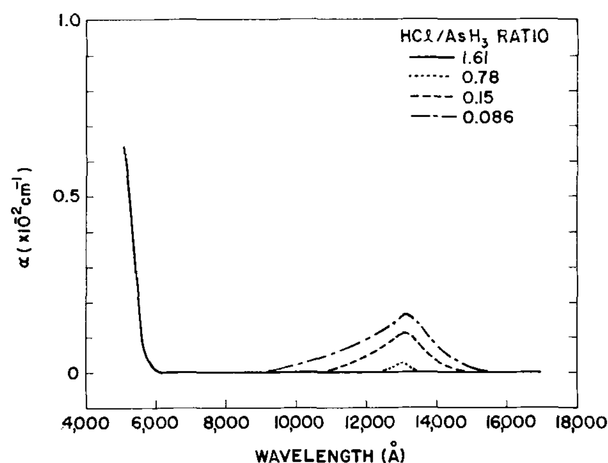

Fig. 5. The optical absorption spectra of several AlAs layers grown under various HCl/AsH_3 flow rates.

impurity content is still higher than that desired for reproducible control of the electrical properties. The electrically active impurity is thought to be silicon.

P-type layers could not be grown *in situ* by doping with Zn vapor presumably due to the high residual donor concentration and the difficulty with which the Zn is incorporated into the layer at the high growth temperature. Deviations in stoichiometry are suggested by the presence of a 1.3 μm peak in the optical absorption spectra of AlAs grown in an arsenic-rich atmosphere. However, this can easily be controlled by adjusting the Al/As ratio in the gas phase.

Despite the apparent thermal and lattice match between the AlAs epitaxial layer and the GaAs substrate, bending of the heterojunction structure occurs toward the GaAs with a radius of curvature of 10 cm. This observation can be explained on the basis of earlier models in which inclined dislocations, formed by misfit dislocations bending out of the growth plane, produce a bending moment if the extra-half planes of these dislocations are parallel to each other. The calculated inclined dislocation density, 1×10^6 cm^{-2}, is in good agreement with the measured value of 7×10^6 cm^{-2}.

An interfacial layer was found between the AlAs and GaAs. Although this layer was not identified, it is thought that it gives rise to an unexpected stacking fault density of 3×10^6 cm^{-2}.

Optical Response in the Photoselective Metal Deposition (PSMD) Imaging System

J. F. D'Amico,* F. A. Litt, and M. A. DeAngelo

Western Electric Company, Engineering Research Center, Princeton, New Jersey 08540

ABSTRACT

The optical response of a representative PSMD imaging system, stannous chloride sensitized polyimide film, was determined by exposing sensitized substrates to ultraviolet radiation and measuring the resulting decrease in catalytic activity for electroless copper deposition. This activity was determined by measuring light transmission through the deposited metal and substrate.

The imaging reaction photoresponse was measured in the 200-400 nm wavelength range. The sensitivity was found greatest at 200 nm, decreasing monotonically with wavelength. The upper limit for useful imaging in air occurred in the vicinity of 350 nm. The imaging reaction rate was also found proportional to $I^{0.7}$, where I is the incident light intensity. This intensity dependence was found over the entire range of measured wavelengths. An explanation of the system's optical behavior in terms of light-generated electron-hole pairs is offered.

A process for generating metal patterns on dielectric substrates using uv light exposure in combination with electroless (chemical) plating has been reported in a recent patent (1) and in several recent papers (2-7). This process, known as photoselective metal deposition (PSMD), combines conventional electroless plating technology with an imaging procedure added to the conventional two-step process between sensitization (immersion in aqueous $SnCl_2$) and activation (immersion in aqueous $PdCl_2$). Where exposed to the uv radiation, the sensitized substrate becomes noncatalytic in the subsequent metalization procedure. The imaging system is, thus, a positive working one since it generates a replica of the photomask.

The papers cited above contain a general description of the PSMD process and its potential capabilities and uses. In this paper we shall focus on the system's

* Electrochemical Society Active Member.

Key words: photoimaging, pattern generation, ultraviolet photo chemistry, electroless plating.

optical characteristics as they relate to the formation of images. Accordingly, we have provided a detailed description and analysis of a specific (but also representative) imaging system: hydrated stannous oxide[1] as sensitizer and, following activation with aqueous palladium chloride, deposited electroless copper. The scope of this paper is limited to effects of the incident radiation, and accordingly, all procedures relating to the substrate preparation and the image development have been arbitrarily fixed. In a future paper, we will report on the role of ambient conditions and substrate preparations in the PSMD system.

We have determined the extent of photoconversion in our system *vs.* incident light wavelength and intensity, using as a basis for analysis the degree of metalization with electroless copper under a fixed set of development parameters. In effect, we have used the imaging reaction itself as an analytical device for evaluation of the extent of reaction. This somewhat indirect procedure has been necessary because a direct quantitative analysis of the sensitizer reaction, Sn(II) → Sn(IV), is not feasible in this range using available methods.

The techniques involving image development, which will be described in detail in this paper, can be used to provide basic information related to the PSMD photoreaction. In addition, they provide the PSMD user with necessary information for the design and operation of practical imaging systems.

Method of Analysis

As previously described (6, 7), the electroless metalization process can be summarized in the following reactions

$$\mathrm{Sn(II) + Pd(II) \rightarrow Sn(IV) + Pd(O)}$$

$$\mathrm{Cu(II)} + 2e \xrightarrow{\mathrm{Pd(O)}} \mathrm{Cu(O)}$$

$$\mathrm{Cu(II)} + 2e \xrightarrow{\mathrm{Cu(O)}} \mathrm{Cu(O)}$$

where the electrons in the electroless copper reactions are provided by a reducing agent in the bath, formaldehyde in this case. The PSMD imaging step consumes Sn(II) in the exposed areas by the reaction

$$\mathrm{Sn(II)} \xrightarrow{h\nu} \mathrm{Sn(IV)} + 2e \qquad [1]$$

the electron transfer in reaction [1] being made to ambient oxygen.

The divalent tin is deposited on the substrate by immersion into a dilute solution of stannous chloride and then a water rinse. As deposited, the sensitizer appears mainly as a hydrated SnO/SnO_2 mixture, with the tetra- to divalent tin ratio (7) close to 2/1. Some aspects of the structure and chemistry of the sensitizer deposit have been studied using Mössbauer techniques and are reported in Ref. (7). The metallic palladium microdeposits generated by the Sn(II)-Pd(II) redox reaction provide catalytic sites for initiation of the electroless metal deposition (9).

On polyimide, a substrate opaque in the ultraviolet, it is not possible to monitor reaction [1] by spectrophotometry. We can, however, follow the photoconversion by taking the sensitized/exposed substrate through the remaining steps in the metalization process and measuring the optical density of the metal deposit as an indicator of the density of active sensitizer sites. While the ratio of metal atoms to active sensitizer atoms depends on the development procedures, we can use the amount of copper deposited as an index of the degree of tin oxidation by maintaining all sensitizing, washing, and plating procedures constant.

[1] The general form of the sensitizer deposit following immersion in the conventional $SnCl_2 \cdot 2H_2O$ – HCl solutions and a water rinse. For further details, see Ref. (7, 8).

While the tin conversion that corresponds, for instance, to 50% reduction in the optical density of the copper deposit is not known, we are assured that in two experiments which give the same density reduction, that the fractions of the Sn(II) consumed in each via reaction [1] are equal.

In using this method, we have selected an electroless plating time brief enough to ensure that the copper layer remains optically transparent; otherwise, changes in optical density would not be readily detectable. We shall indicate the extent of the sensitizer reaction by the ratio D/Do, where D is the optical density of the metal deposit over the exposed sensitizer and Do is that over the unexposed region.

Experimentally, we have imaged a narrow beam of monochromatic light of known intensity on a sensitized polyimide specimen for a precisely specified time; we have then developed the beam image in electroless copper and measured light transmission through the plated specimen. This method is possible because the polyimide is transparent over a portion of the visible range. In this way, we have obtained T and To, the light transmission through the copper deposits in the exposed and unexposed regions, respectively. The transmissions T and To have been defined relative to the light transmission through a blank substrate which is used to set the value of $T = 100\%$ on a microphotometer. Thus, $T = 100\%$ corresponds to the measured transmission through a polyimide film devoid of all deposits. The respective light transmissions have then been used to determine the optical density ratio D/Do, where

$$D = \log(1/T) \quad \text{and}$$

$$Do = \log(1/To)$$

At present, we are not in a position to state the exact relationship between the deposited copper optical density D (or Do) and the concentration of active tin atoms from which the deposit was initiated. It is sufficient in the present discussion that D (and Do) *vs.* light exposure merely be a sensitive single valued index of the tin oxidation. Further discussion of the use of the optical density measurements to characterize the sensitizer activity is given in Appendix A.

At each wavelength, we have fitted a smooth curve to plots of D/Do *vs.* light exposure E,[2] with light intensity I as a parameter ($E(\lambda) \equiv I(\lambda) \cdot t$, where t is exposure time). From such plots, we have determined $E_{1/2}$, where $E_{1/2} \equiv$ light energy required to reduce D/Do from 1.0 to 0.5. This energy will be used to indicate the relative reaction sensitivity at the given wavelength.

Experimental

Sensitizer-substrate system.—The PSMD process has made use of several sensitizer solutions on a variety of substrates. The solution used in the work reported here consisted of 10g $SnCl_2 \cdot 2H_2O$ and 10 ml conc HCl dissolved in one liter of deionized water. The substrate was a 2 mil polyimide film (du Pont KAPTON®).

Stannous chloride-based sensitizer solutions undergo ostensible changes in their appearance on standing in air; they become increasingly cloudy with time and eventually form a readily visible colloid mixture of stannous and stannic oxide (6-8). They also undergo color changes, going from colorless to yellow as they age. Such changes in solution properties produce changes in the sensitizer deposit (7), principally the total weight deposited and the Sn(II)/Sn(IV) ratio.

In the work reported here, we have used a sensitizer system whose properties change relatively slowly with time. In our case changes in the sensitizer properties over the duration of about 8 hr were not significant. Using solutions freshly prepared each day, we were able to ignore the time dependence and still sensitize the substrate reproducibly.

[2] The customary procedure for characterizing photographic sensitizers is to plot density *vs.* log E rather than E as we have done here.

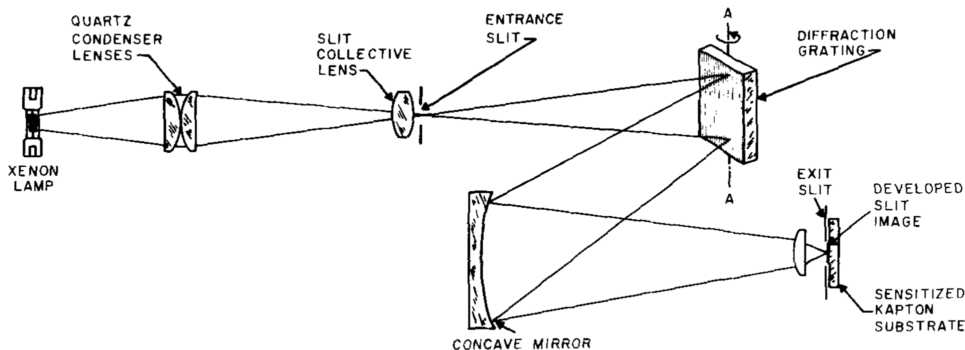

Fig. 1. Exposure system

Substrate preparation, sensitization, and development.—The polyimide substrate was cut into 1.5 in. × 3 in. specimens which were treated for 10 min in 24°C 10*N* NaOH, then rinsed an equal time in running deionized water. Specimens were then sensitized by a 3 min immersion in the sensitizer solution (no agitation), then immediately rinsed for one minute in flowing deionized water. Following a gentle drying in a jet of N_2, specimens were immediately exposed to monochromatic uv light, as described below.

Following exposure, specimens were immersed for 30 sec in a solution of 1g $PdCl_2$ and 10 ml conc HCl dissolved in 2 liters of deionized water (no agitation). Finally, after being rinsed in flowing deionized water for 30 sec, specimens were electroless[3] copper plated for 1.50 min.

Exposure system.—The sensitized specimens were exposed to uv light by means of the optical system shown schematically in Fig. 1. A 900W high pressure xenon lamp, mounted in a Christie UF Xenolite housing with uv quartz condenser lenses was used as a light source; a Bausch & Lomb high intensity monochromator with a uv-visible grating (No. 33-86-07, dispersion 7.4 nm/mm) was used to form monochromatic light images. Sensitized specimens were placed directly against the exit slit so that a contact print of the slit outline was produced. Measurement of light intensity at the slit was made by removing the specimen and placing the entrance slit of an Eppley laboratory-type linear thermopile in the same position.

The exit slit width was 2.5 mm, giving a wavelength spread of 18.5 nm across the slit image. Measurements in the wavelength range 200-400 nm were made in 25 nm intervals. For measurements above 340 nm, a glass filter was inserted into the optical train ahead of the monochromator. This filter, transparent above 320 nm but essentially opaque below 300 nm, was used to prevent any possible leakage of 180-200 nm radiation through the monochromator due to second order diffraction from the grating.

Determination of optical density.—After exposure and development of the slit image in the electroless copper solution, light transmissions T and To through exposed and unexposed regions, respectively, were measured using a Jarrell-Ash Model 21-050 recording microphotometer and optical densities of the respective regions were computed. The measuring procedure is illustrated in Fig. 2. Specimens to be measured were mounted in the microphotometer carriage between two glass plates, then scanned as indicated to obtain the recorded transmission trace.

In all measurements, the point $T = 1.0$ (*i.e.*, 100% transmission) was adjusted to correspond to the reading of the instrument through cleaned but unsensitized and undeveloped polymide substrate. The $T = 0.0$ point was adjusted for the condition where the light beam was completely blanked off.

The transmission trace in Fig. 2 is typical, a dip in transmission at the uppermost slit edge (relative to specimen orientation in the electroless bath) being observed. This dip was found to be highly reproducible for specimens which were reproducibly positioned in the electroless bath. This effect was also more pronounced at greater exposure, suggesting that it may be the result of differences in plating rates in the exposed *vs.* the unexposed regions, in conjunction with local convection in the plating cell. In view of the effects just mentioned, variations in the copper deposit produced by light intensity and/or wavelength gradients across the slit image were not significant.

To minimize variations in copper deposition, we maintained exactly reproducible procedures and plating geometry during image development. Special fixtures were used to ensure accurate specimen placement in the bath, and fresh solutions of electroless solution were prepared daily. In addition, slit images were kept small (relative to over-all specimen size) and limited to one per specimen. With these precautions, transmission measurements reproducible within the error limits of the microphotometer could be obtained.

Results

Exposures were made at nine wavelengths in the 200-400 nm interval. At each wavelength values of D/Do were plotted *vs.* exposure E with light intensity I as a parameter. Figure 3 shows representative results for light of 250 nm wavelength. In this figure, we observe the anticipated reduction in D/Do as exposure is increased. We also observe a systematic increase in the curve slope (*i.e.*, the sensitivity) as light intensity is reduced. The behavior noted in Fig. 3 for the reaction at 250 nm was found at all other wavelengths. Control experiments established that the dark reaction was not significant over the times used in the experiment, so that the changes in slope are indeed due to the light intensity variations.

Values of $E_{1/2}$ at each wavelength have been determined from plots such as those in Fig. 3. In Fig. 4 we have summarized our results by plotting $E_{1/2}$ *vs.* I with wavelength as a parameter. Each point in this figure is derived from one D/Do *vs.* E line. Representa-

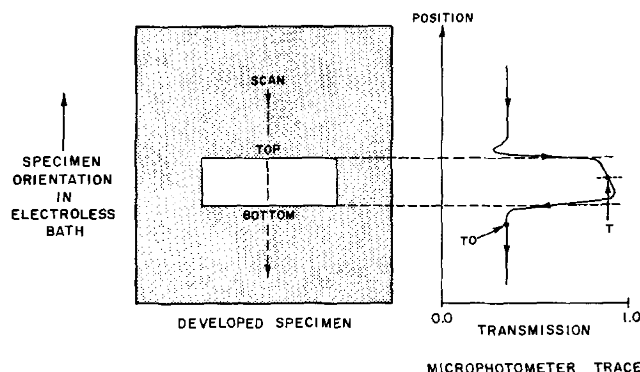

Fig. 2. Measurement of light transmission of slit images

[3] Fresh Enthone 400, prepared as recommended by the manufacturer, was used in all our experiments. All plating was done under room ambient conditions.

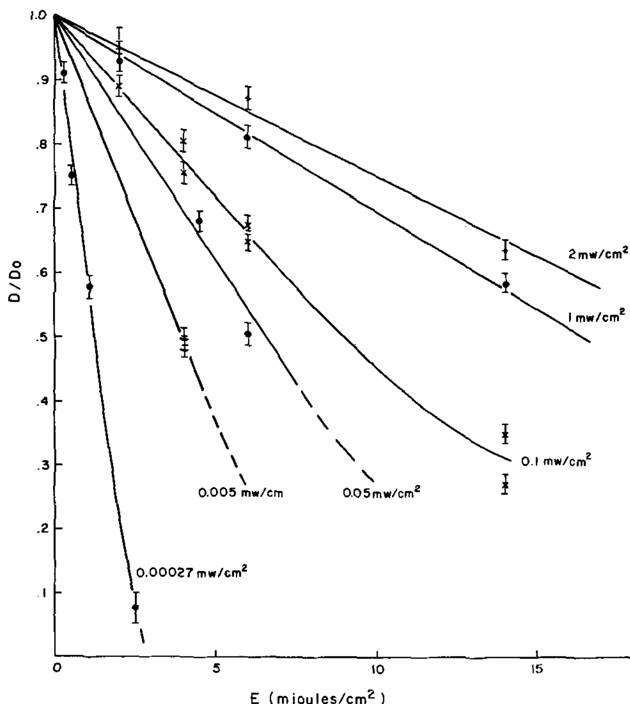

Fig. 3. Optical density vs. light exposure E at 250 nm (light intensity as a parameter).

tive average deviations for the individual determinations are also shown in both figures.

We have used a linear least squares analysis to fit our $E_{1/2} - I$ data at each wavelength. The slopes of the individual lines at each wavelength (and also their standard errors) are presented in Table I. The results in Table I suggest that, within experimental accuracy, the lines have a common slope. This hypothesis was tested by application of a multiple correlation analysis, from which a correlation coefficient of 0.9980 was obtained. Thus we conclude that the observed differences in slope are not statistically significant.

On the assumption of a common slope at all λ, we have fitted all data, Fig. 4, to a single expression re-

Table I. Slope of log $E_{1/2}$ vs. log I plots as a function of wavelength

Wavelength (nm)	$d(\log E_{1/2})/d(\log I)$
200	0.199 ± 0.043
225	0.245 ± 0.003
250	0.309 ± 0.015
275	0.275 ± 0.012
300	0.284 ± 0.025
325	0.300 ± 0.009
350	0.383 ± 0.026
375	0.349
400	0.326

lating $E_{1/2}$ to I and λ

$$\ln E_{1/2} = 0.3931 - (0.0148 \pm 0.0037)\lambda + (0.00007 \pm 0.00000)\lambda^2 + (0.3013 \pm 0.0105) \ln [1000 I] \quad [2]$$

In Eq. [2] the units for $E_{1/2}$, I, and λ are mj/cm², mW/cm², and nm, respectively. Error estimates here are standard errors from the regression analysis. From Eq. [2], the common slope $d(\ln E_{1/2})/d(\ln I)$ $(= d(\log E_{1/2})/d(\log I))$ is 0.30 ± 0.01. A typical photoresponse (or action spectrum) for the reaction, $E_{1/2}$ vs. λ, is shown in Fig. 5 at $I = 0.2$ mW/cm².

Discussion

Sensitization reaction.—Dependence on light intensity.—In Fig. 3, we note that D/Do is not a unique function of E but also depends upon I. This differs from many photographic systems which obey a "reciprocity law" with regard to light exposure (10); in these, the extent of image development depends on the product $I \cdot t$ but not on I separately.

It will be useful at this point to look more closely at Eq. [2] since this relationship sheds some light on the reaction mechanism. To interpret Eq. [2], we first postulate a rate expression for the imaging reaction, presumed to be an oxidation of a stannous tin species to the stannic form. Thus

$$\frac{d[\mathrm{Sn\ (II)}]}{dt} = -k \cdot I^m \cdot A \quad [3]$$

where A is a time-independent function of [Sn (II)] and [Sn (IV)], and t is the exposure time. Equation [3] may be integrated from initial conditions to a degree of oxidation that reduces D/Do to 0.5

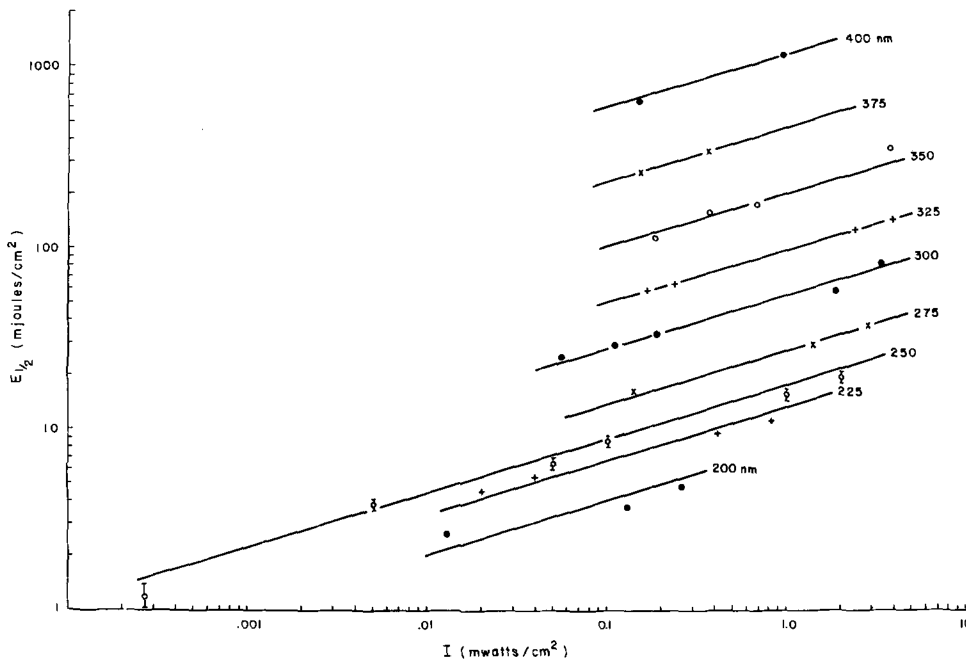

Fig. 4. $E_{1/2}$ vs. light intensity (wavelength as a parameter).

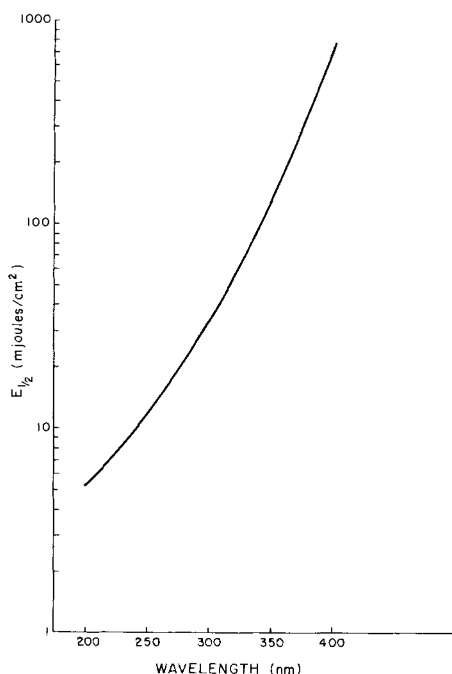

Fig. 5. $E_{1/2}$ **vs. wavelength** ($I = 0.2$ **mW/cm²**)

$$\int_{[\mathrm{Sn\ (II)}]_0}^{[\mathrm{Sn\ (II)}]_{1/2}} \frac{d[\mathrm{Sn\ (II)}]}{A} = -k \cdot I^m \int_0^{t_{1/2}} dt$$

Defining $-B$ as the integral on the left, then $B = k \cdot t_{1/2} \cdot I^m$ and is a constant characteristic only of the sensitizing and developing procedures. Recalling that $E_{1/2} = I \cdot t_{1/2}$, then

$$E_{1/2} = \frac{B}{k} \cdot I^{(1-m)}$$

The slopes in Fig. 4 are, therefore, equal to $1 - m$, with $m = 0.70$. Thus $d[\mathrm{Sn(II)}]/dt \sim I^{0.70}$, an intensity dependence similar to that observed in other solid-state photoconductors (11, 12). From elementary steady-state kinetics (13), this type of intensity dependence suggests that the reaction proceeds by a mechanism requiring the presence of a transient carrier species (for example, electrons or holes). This species would decay via a reaction step which is of higher order in this species than is the reaction step of the tin oxidation. Thus, for example, the tin oxidation step could be first order in the concentration of mobile electrons while the decay rate of these species could have a term proportional to the square of their concentration. As an example, if n denotes the concentration of mobile electrons and p the corresponding concentration of mobile holes generated as a result of incident light of intensity I, then the net rate of the electron (or hole) carrier generation can be expressed as

$$\frac{dn}{dt} = \alpha I - \beta n \cdot p = \alpha I - \beta n^2$$

since $n = p$ in an intrinsic photoconductor. If n_o denotes the equilibrium value of n (or p) for a given steady I, then $\alpha I - \beta n_o^2 = 0$ and, thus, $n_o \sim I^{0.5}$. Thus, if $d[\mathrm{Sn(II)}]/dt \sim n_o$, we would expect that $d[\mathrm{Sn(II)}]/dt \sim I^{0.5}$. An intensity dependence I^m, where $\frac{1}{2} < m < 1$, in this case suggests the presence of traps, *e.g.*, defects or impurities. These can readily modify the mean carrier lifetime and thereby shift the equilibrium carrier density n_o and p_o at any given I. The value of m obtained in any given system depends upon the number and energy distribution of the trapping levels (14).

An alternative explanation for an $I^{0.7}$ dependence is that the carriers are participating in a mixture of mono- and bimolecular processes. This dependence, however, would be observed only as transition between high and low light levels and should occur over a small range in intensity (11, 14). This appears not to be the case for our data, at least at 250 nm.

In our model for the SnO-SnO_2 sensitizer layer, we are postulating that the role of the light is to generate electron-hole pairs, one or both of which would be relatively mobile in the sensitizer layer and could either recombine (a second order process) or participate in the tin oxidation (a first order process). The light intensity dependence of the imaging reaction which we have reported above refers to a specific sensitizer/substrate system. For other systems, we might expect differences in both the over-all system response (as characterized by $E_{1/2}$) and in the light intensity dependence (as characterized by m). Experiments using alternate sensitizer and substrate systems are now in progress.

Dependence on ambient conditions.—From previous work[4] and our own experiments in progress, the ambient conditions during light exposure are known to affect the reaction rate. However, the measurements presented in this report were made under conditions of constant ambient, within the capability of local temperature and humidity controls. Room temperature was maintained at 24° ± 2°C while relative humidity was maintained in the range 40-50%. Throughout the course of experimentation, we maintained a check on the repeatability of the measurements in order to insure that ambient variations were not significant. Our data show that ambient fluctuations within the above limits did not introduce a significant source of variation in these experiments. Ambient effects outside the above ranges are being measured and will be treated in a future paper.

Photoresponse and reaction quantum efficiency.—In Fig. 5, $E_{1/2}$ is observed to increase by more than two orders of magnitude over the measured wavelength range, the minimum light energy requirement occurring at 200 nm. The light absorption spectrum for a chemically similar sensitizer on quartz (15, 16) shows the absorption greatest at 200 nm, steadily decreasing with increasing wavelength. The possibility is thus suggested that the behavior of the photoresponse is merely a reflection of the wavelength dependence of the absorption. If this were so, then the quantum efficiency of the basic reaction, *i.e.*, the amount of photo-oxidation per photon absorbed by the sensitizer, would be constant over the entire wavelength interval. We estimate however, that the quantum efficiency is not wavelength independent but decreases monotonically from a value of about 0.6 at 200 nm to about 0.06 at 400 nm for the data presented in Fig. 5. Thus, while absorption accounts for much of the action spectrum, other factors must also be contributing to the observed behavior.

Using sensitizer absorption data on quartz (16), we can make an order of magnitude estimate of the quantum efficiency Φ of the primary reaction. In this case, Φ is defined as the number of active stannous atoms converted per light photon absorbed. The absorption data is taken as approximate because of known differences in the sensitizer films due to differences in sensitizing solutions and substrates used.

In order to estimate Φ, we need estimates of: (*i*) the number of active tin atoms per unit area of the sensitizer film, (*ii*) the optical absorption of the film, and (*iii*) the number and efficiency of alternate light absorbing processes which may or may not promote the reaction. The details of our estimate of Φ are given in Appendix B. The result for $\lambda = 250$ nm is $\Phi \sim 0.5$, a value not inconsistent with the photoelectronic model proposed earlier. Quantum efficiencies for photoconduction in germanium phototransistors (12), by way of comparison, are typically 3 or 4.

PSMD energy requirements compared to other imaging processes.—For the purpose of comparison, the

[4] Most pertinent on this topic are Ref. (6, 7, 15).

light energy requirements of the PSMD process and other imaging systems are given in Table II. We have selected the energy at 254 nm to characterize PSMD since low-pressure mercury lamps (whose output is primarily at this wavelength) are the most common light sources used at the present time. In terms of our data, the energy for full image development is approximately twice the value of $E_{1/2}$.[5] We note in Table II that the PSMD system which we have discussed here has a photographic speed comparable to that of conventional photoresists.

Summary

For the sensitizer-substrate system described in this report, the imaging reaction sensitivity is greatest at 200 nm and steadily decreases with wavelength. The useful wavelength range for image generation was found to be 200 nm to about 350 nm. Reaction rate was also found proportional to light intensity to the 0.7 power. The observed light-dependent properties are consistent with a photoelectric model for the reaction, the light absorbed by the sensitizer serving to generate electrons and holes, one or both of which promote the oxidation.

Manuscript submitted Nov. 1, 1971; revised manuscript received Feb. 2, 1972.

[5] We have assumed here, for simplicity, that D/Do *vs.* E remains linear as D/Do goes to zero. This is not quite the case as seen in Fig. 3.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

APPENDIX A

Characterization of Sensitizer Activity by Optical Density Determinations

Sensitizer activity (*i.e.*, the rate at which a sensitized substrate initiates electroless metal deposition) has been characterized by measuring optical density D through the deposited copper film and substrate. The results of a representative series of microphotometer measurements of D *vs.* immersion times, in the electroless bath, are presented in Fig. A-1. The D *vs.* time plot is seen to be linear for times greater than about 45 sec.

Our value of Do, the optical density of an unexposed substrate after a total immersion time of 1.5 min, is also indicated in this figure. For $D = Do = 0.48$, the copper thickness is estimated to be on the order of 200-300Å (17).

The rate of metal deposition from an electroless bath (under reasonably constant conditions) should also be constant, once the catalytic surface has been completely covered by the depositing metal. (This rate is determined by the characteristic catalytic activity of the deposited metal itself, plus solution parameters such as temperature and ion concentrations.) In our system, complete surface coverage occurred after about 45 sec, as observed by scanning electron microscopy by G. W. Kammlott, Bell Telephone Laboratories, Murray Hill, New Jersey, and by the electron microscopy studies of R. Woods of our laboratory. For depositions of greater than 1 min duration (for the unexposed substrate), therefore, the linear D *vs.* time range also corresponds to a linear change in copper weight *vs.* time. Thus, the copper deposit after a brief initial period follows Lambert's law, D proportional to the thickness of the copper film. This is not an unexpected result.

When the sensitized specimens are exposed to uv light, their catalytic activity is reduced depending on the degree of exposure. For partial exposures, the substrates can still be metalized, but the time for complete coverage with copper is extended due to the reduced catalytic activity. This process is depicted schematically in Fig. A-2. As exposures $E_2 > E_1 > E_0 = 0$ are used, the initial growth of the electroless deposits are slowed, and the net result is that after the fixed immersion time T, the optical densities show a monotonic (though not necessarily linear) decrease *vs.* exposure.

Of course, once the surface is completely metalized with copper, then further deposition occurs at a rate which is characteristic of the bath parameters, and not the sensitizer activity. Thus the slopes are constant at long times and are independent of the light exposure.

APPENDIX B

Estimate of Quantum Efficiency for the Photo-Oxidation Reaction

The quantum efficiency for the photo-oxidation reaction will be denoted by Φ, where

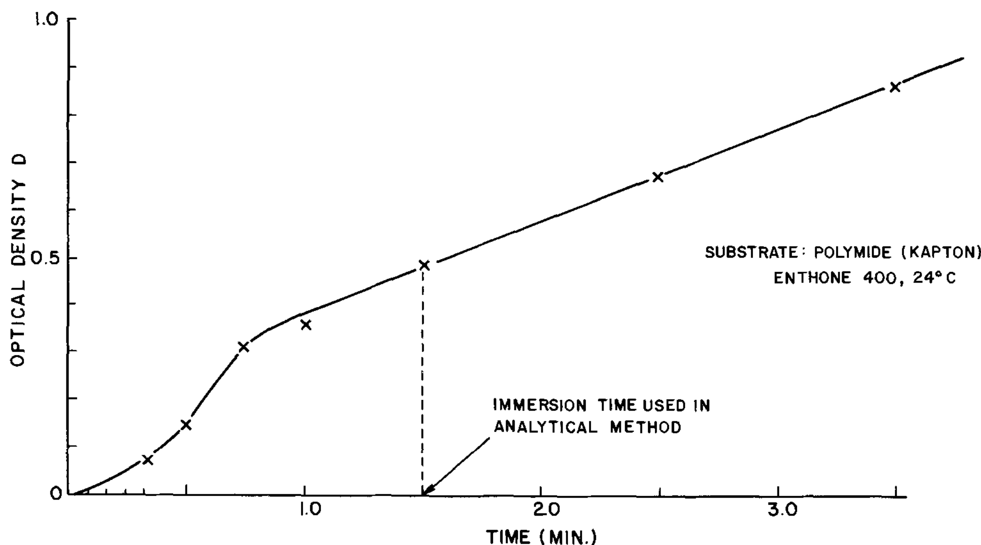

Fig. A-1. Optical density of copper deposit vs. immersion time in electroless bath.

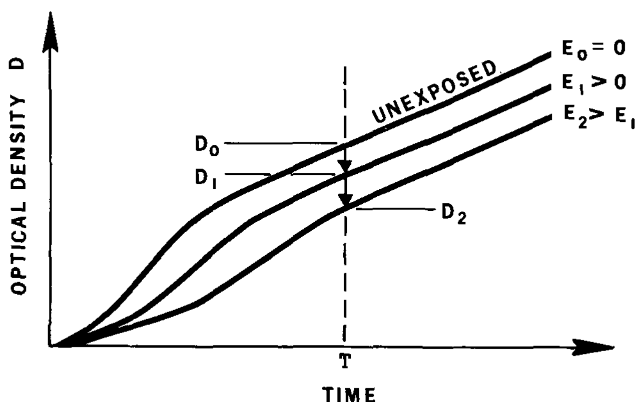

Fig. A-2. Optical density of copper deposit *vs.* immersion time in electroless bath (light exposure *E* as a parameter).

Φ = number of Sn (II) atoms reacted per photon absorbed by the sensitizer film.

The determination of Φ was carried out using a substrate of uv grade quartz which was sensitized using a solution containing 10g of $SnCl_2 \cdot 2H_2O$ and 0.8 ml conc HCl in 100 ml of deionized water [for details, see Ref. (15)]. Immediately following sensitization, the optical density *D* of the unexposed deposit was measured from 200-400 nm on a Cary 14 spectrophotometer, using the double beam mode with a duplicate quartz specimen as the blank. The specimen was then exposed to uv radiation from a low-pressure mercury lamp, then remeasured on the spectrophotometer. The exposure was sufficient for complete oxidation of the Sn(II) to Sn(IV) [a typical spectrophotometer plot *vs.* exposure is given in Ref. (6)]. A duplicate substrate was also sensitized, then dipped in aqueous $PdCl_2$ solution, followed by a water rinse. After this procedure, the remaining palladium atoms are due only to reaction with Sn(II) and can, thus, be used to determine the initial Sn(II) in the sensitizer deposit. A determination of total tin in the sensitizer was also made, both analyses by x-ray fluorescence (16).

In this case we have assumed a one-to-one correspondence between Sn(II) and the deposited Pd, and found a surface density of 1.8×10^{15} Sn(II) atoms/cm^2. We will assume that all of these are reacted when the deposit becomes noncatalytic.

The light energy required for reaction of all species is approximately $2E_{1/2}$. At 250 nm, for $I = 0.2$ mW/cm^2, $E_{1/2}$ on polyimide is $\sim$ 11 mj/cm^2. Here we are using the photoresponse (Fig. 5) and assuming the changes in substrate and in sensitizer do not appreciably alter the energy requirements of the reaction.

The fraction f of $2E_{1/2}$ absorbed by the sensitizer is $1 - 10^{-D}$, where *D* is the optical density of the sensitizer layer.

This optical density has been measured on the same quartz specimens from which the atom concentrations were determined. At 250 nm, *D* initially was 0.078. After prolonged light exposure this value had dropped to 0.042, the absorption of the completely photoconverted film. The average of these *D* values will be taken as representative of the mean light absorption, $\bar{D}$. Thus $\bar{D} = 0.060$ and $\bar{f} = 1 - 0.87 = 0.13$.

The total energy absorbed by the sensitizer in reacting the tin atoms is $2E_{1/2}\cdot\bar{f} = 2.86$ mj/cm^2 $= 2.86 \times 10^4$ ergs/cm^2.

Each photon at 250 nm has an energy $h\nu$ of 7.94×10^{-12} ergs, so that the total number of photons absorbed, $2E_{1/2} \cdot \bar{f}/h\nu$, is 3.6×10^{15}/cm^2. Therefore

$$\Phi = \frac{1.8 \times 10^{15}}{3.6 \times 10^{15}} = 0.50 \text{ at } I = 0.2 \text{ mW/cm}^2$$

If we compute the range of Φ over the light intensity values measured at 250 nm, we find Φ to vary from 4.1 at $I = 0.0002$ mW/cm^2, $E_{1/2} = 1.4$ mj/cm^2 to 0.3 at $I = 2.0$ mW/cm^2, $E_{1/2} = 23$ mj/cm^2.

Thermodynamic Properties of Solutions of Group IV Metals Dissolved in Liquid Sodium

I. Sodium-Lead and Sodium-Germanium Solutions

P. Hubberstey

and A. W. Castleman, Jr.

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

An emf cell technique was used to measure the thermodynamic properties of Pb-Na solutions at temperatures ranging from 245° to 500°C and compositions between 2.35 and 16.79 atomic per cent (a/o) Pb. The results, while in general agreement with earlier work, reveal that the deviations from ideal solution behavior cross over from negative to positive at low Pb concentrations. This property has not been previously reported for the Pb-Na system. Sodium activity measurements, which were made as a function of decreasing temperature, display a marked change in slope upon transition to a two-phase region. The resulting liquidus-line is in agreement with the published phase diagram. A study of the change in sodium activity as a function of temperature was also made for saturated solutions of Ge in Na. The results show that the solubility of Ge in Na is represented by the equation

$$\ln S_{Ge} = 2.657 - 4837/T$$

Thermodynamic properties of sodium solutions of the Group IV metals tin and lead have been reported for a wide range of intermediate solute compositions, but only limited data are available for both the dilute and concentrated regions. We employed an emf technique to measure the partial molar excess free energy of mixing and related enthalpy and entropy values for liquid sodium solutions containing less than 20 atomic per cent (a/o) solute and report the results in a two-part series. The results for solutions of lead and germanium in liquid sodium are presented in this first paper, while the second one comprises a detailed discussion of the tin-sodium system.

The thermodynamic properties of solutions of lead in liquid sodium have been investigated by three previous groups. Lantratov *et al.* (1, 2) reported data over the concentration range 10 to 95 a/o lead; the data of Hauffe and Vierk (3) extends from 6 to 66 a/o lead, whereas that of Porter and Feinleib (4) extends from 59.9 to 94.9 a/o lead. Hultgren *et al.* (5) critically reviewed the available information and concluded that the thermodynamic properties of these solutions were best represented by the data of the first group of authors; they computed their selected values accordingly. Examining the concentration ranges investigated in the earlier studies clearly shows that there is a paucity of data at the two extremes of concentration, particularly for dilute solutions. Consequently, we chose the dilute region for detailed investigation. A further impetus for studying the properties of dilute solutions was provided by our continuing interest (6-11) in the nature of solutes dissolved in liquid metals at concentrations where interactions between the solute atoms are less important than those between the solute and solvent.

No previous investigations of the thermodynamic properties of solutions of germanium in liquid sodium have been published. The Ge-Na results reported in the present paper are preliminary, but are of considerable value because they provide information on the limited solubility of germanium in liquid sodium, for which no other data are available.

Key words: solution thermodynamics, sodium-lead solutions, sodium-germanium solutions, emf.

Experimental

The cell.—The electrochemical cell used in this investigation is represented by the cell reaction

$$\text{Na}|\text{Na}^+|\text{Na (solution)} \quad [1]$$

The measured emf, E, is related to the difference in chemical potential of the sodium at the two electrodes by the equation

$$\mu_{Na} - \mu^{\circ}_{Na} = -E\mathbf{F} \quad [2]$$

where μ°_{Na} and μ_{Na} are the chemical potentials of pure sodium and sodium in the solution, respectively, and $\mathbf{F}$ is the Faraday. It is implicitly assumed that one electron is transferred during the reaction. By definition

$$\mu_{Na} = \mu^{\circ}_{Na} + RT \ln a_{Na} \quad [3]$$

where a_{Na} represents the activity of the sodium component of the solution. Hence

$$RT \ln a_{Na} = -E\mathbf{F} \quad [4]$$

Pure liquid sodium at the temperature and pressure of the cell is chosen as the standard state. Therefore, the excess partial molar free energy of sodium, $\Delta\overline{G_{Na}}^E$, is given by

$$\Delta\overline{G_{Na}}^E = RT \ln \gamma_{Na} \quad [5]$$

where γ_{Na}, the activity coefficient of the sodium in the solution, is related to its activity and mole fraction x_{Na}, by the expression

$$\gamma_{Na} = a_{Na}/x_{Na} \quad [6]$$

Hence

$$\Delta\overline{G_{Na}}^E = -(E\mathbf{F} + RT \ln x_{Na}) \quad [7]$$

Apparatus.—The electrochemical cells were constructed of Pyrex. Pyrex was chosen because it is suitable as a selective cation electrolyte for sodium transfer via cell Reaction [1]. Basically, the cell, shown in Fig. 1, consisted of two reservoirs, A and B, linked by a pressure equalizing capillary D. The inner reservoir (1.5 cm diam, 20 cm long) extended into the outer reservoir (4.5 cm diam, 2.5 cm long) to a depth of 2 cm. A loading tube C (1.5 cm diam, 10 cm long), through which the metals could be introduced, was

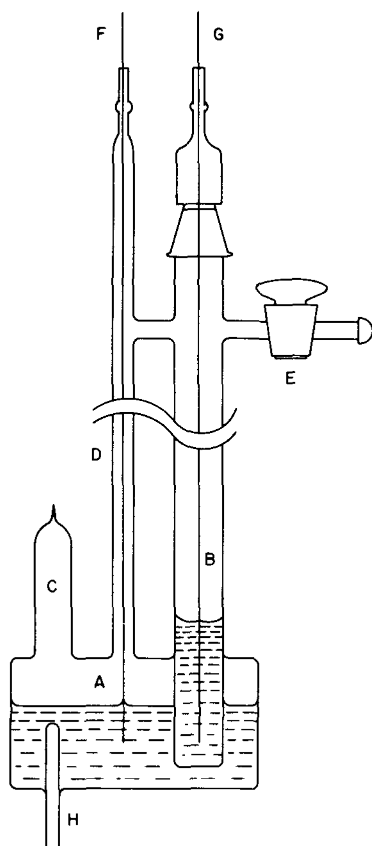

Fig. 1. The electrochemical cell. A,B—reservoirs; C—loading tube; D—equalizing capillary; E—evacuation port stopcock; F—outer reservoir electrode; G—inner reservoir electrode.

attached to the top of reservoir A. A ground joint was fitted to the top of the cell to allow access to the inner reservoir. Provision was made for evacuation of the cell through both port E, and the vacuum connection at the top of reservoir B. Stainless steel rods (ASME Type 316), known to be chemically resistant to attack towards sodium at temperatures $\geq$ 600°C (12) were used as electrodes. The outer reservoir electrode, F, was fitted through a glass-to-metal seal at the top of the capillary section; the other electrode, G, was also fitted through a glass-to-metal seal and was introduced into the cell through the ground glass connection located above reservoir B.

During operation, the cell was mounted in a 1.5 kW wire wound resistance furnace which had a maximum operating temperature of 600°C. A Honeywell Electronik 18 proportional-band controller was used for accurate temperature control, the maximum variation being $\pm$0.5° at 500°C. The temperature of the cell was measured by means of a Chromel-Alumel thermocouple inserted in the thermocouple well, H (also shown in Fig. 1). The emf resulting from Reaction [1] was measured using a Keithley 602 high impedance electrometer in conjunction with a Doric digital voltmeter.

Materials.—The sodium used in the experiments was obtained from the J. T. Baker Company and was specified to have a purity of 99.9%. In order to effect a further reduction in impurity level, the sodium was pipetted from a stock source heated to $\approx$120°C. At this temperature, the maximum concentration of dissolved nonmetals is *ca.* 10 ppm. The lead, 99.9% purity, was obtained from the General Chemical Division of the Allied Chemical Corporation. Ultrapure single crystals of germanium were prepared at Brookhaven National Laboratory and were used without further purification.

Procedure.—Prior to loading, the cell was cleaned with a concentrated solution of chromic acid, thoroughly outgassed by evacuation to a pressure of 10^{-5} mm Hg, and baked at 500°C for several hours. It was then transferred under vacuum to a special high purity vacuum glove-box chamber in which the metal additions were made. The helium atmosphere of the glove-box was continually circulated through a cryogenic purification system, the total volume of the box being replenished every 1.5 min. The concentrations of oxygen and water vapor measured in the recirculating helium stream were less than 1 and 0.1 ppm, respectively.

The solutions were prepared in the outer reservoir; their compositions being determined by weighing the individual components before addition. After introduction of the metals, the cell was evacuated to $\approx$300 Torr and the loading tube C (Fig. 1) was sealed off. The cell was then placed inside the furnace and heated overnight at $\approx$25°C above the estimated liquidus-temperature corresponding to the solution under investigation. During this time period, both the dissolution process and the aging of the cell were accomplished. Subsequently, the emf of the cell was measured at 25° intervals, up to a maximum temperature of 500°C. The temperature was then decreased from 500° to 300°C, during which period measurements were also generally taken at 25°C intervals. However, as the temperature approached the estimated liquidus-line, the measurements were recorded at 5°C intervals. The heating and cooling cycles were always repeated a second time.

Results and Discussion

The lead-sodium system.—The temperature dependence of the excess partial molar free energy of solution for sodium was investigated for solutions containing up to 16.79 a/o lead. Measurements were made over the temperature range from the respective liquidus temperature to 500°C. Representative plots of $\Delta\overline{G}_{Na}{}^{E}$ *vs.* T are shown in Fig. 2 for solutions containing 2.35, 5.08, 10.01, and 14.61 a/o lead, respectively. The experimental results were obtained during two heating and cooling cycles over a period of 48 hr. Considering the temperature cycles and their duration, as well as the very low emf produced by these cells and the concomitant expanded ordinate scale required in plotting the results, the indicated scatter of the data is quite reasonable.

Since

$$\Delta\overline{G}_{Na}{}^{E} = \Delta\overline{H}_{Na} - T\Delta\overline{S}_{Na}{}^{E} \quad [8]$$

curves of $\Delta\overline{G}_{Na}{}^{E}$ *vs.* T can be used to deduce the corresponding enthalpy, $\Delta\overline{H}_{Na}$, and excess entropy, $\Delta\overline{S}_{Na}{}^{E}$. Numerical values of $\Delta\overline{H}_{Na}$ and $\Delta\overline{S}_{Na}{}^{E}$ were computed by means of a least squares analysis. These values are plotted as a function of composition in Fig. 3. As the concentration of lead in the solution increases, the partial molar enthalpy of sodium rises to a maximum at

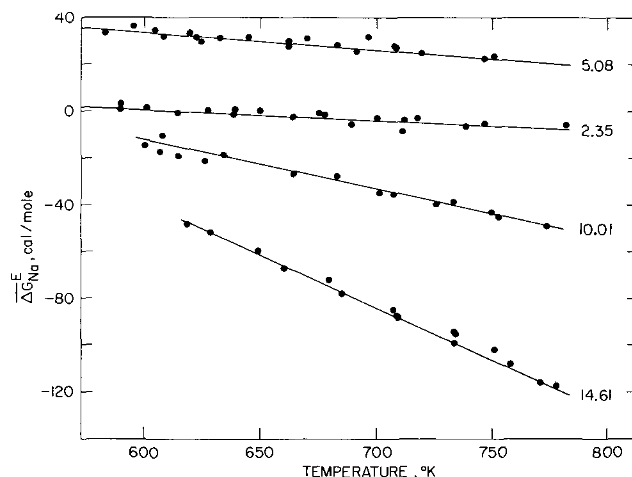

Fig. 2. Typical curves of $\Delta\overline{G}_{Na}{}^{E}$ vs. temperature derived from the emf data using Eq. [7].

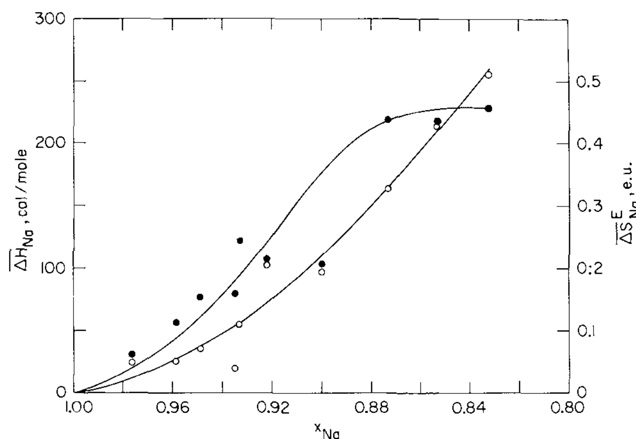

Fig. 3. Plots of the enthalpy and excess partial molar entropy of solution, for the sodium component, vs. sodium composition. The $\overline{\Delta H}_{Na}$ is represented by the closed points while the $\overline{\Delta S}_{Na}^{E}$ values are shown by open circles.

≈14 a/o lead. However, the entropy increases continually throughout the composition range investigated. These results are indicative of an initial positive deviation from ideality followed by a pronounced negative deviation thereafter. The fact that there is a positive deviation from ideality at low composition is borne out both by the sodium activity coefficients calculated from emf's measured at compositions of 2.35 and 5.08 a/o Pb, and by the sodium activity coefficients derived from the corresponding averaged enthalpy and entropy values obtained from Fig. 3. Consequently, we believe this observation to be a real property of the system.

The thermodynamic properties for the complete composition range have been tabulated by Hultgren *et al.* (5). These were based on the data of Lantratov *et al.* (1, 2) noting that the results reported by Hauffe and Vierk (3) were in approximate agreement. A comparison of the results obtained in this study with the earlier work shows generally good agreement in terms of the over-all picture, the basic difference being our observation of an initial region where the deviation from the properties of an ideal solution is positive. This positive deviation was not observed by either of the two previous investigators, undoubtedly due to their lack of substantive results over the concentration range 0 to 15 a/o lead. The lowest concentration investigated by Lantratov *et al.* (1, 2) was 10 a/o lead; Hauffe and Vierk's measurements for solutions containing 6 and 13 a/o lead were in conflict with the former result. It should also be noted that sodium solutions of thallium (3), cadmium (13), and tin (14) also exhibit initial positive deviations before crossing over to negative deviations from ideality at progressively higher solute compositions.

If, in simple terms, the behavior of the thermodynamic properties of these solutions is considered to be attributable to the two factors, size and electronic structure difference of the component metals, then it is possible to rationalize the observations. We follow the arguments of Wagner (15) who has accounted for the behavior of the partial molar enthalpy of silver solutions of tellurium in terms of the electronic structures. Thus, in the present system, the addition of sodium to a sodium-rich solution will simply involve an increase in the number of electrons in the conduction band. The corresponding contribution to the free energy term will be negligible; the dominant factor will be the size difference of the component metals which may give rise to small positive deviations from ideality. On the other hand, in more concentrated solutions, the extra electrons provided by sodium will tend to localize on the lead atoms forming loosely bound pseudo-ionic salt intermetallic compounds (Na_4Pb, NaPb, etc.). The corresponding free energy term will be strongly exoergic. This very large factor will dominate at higher

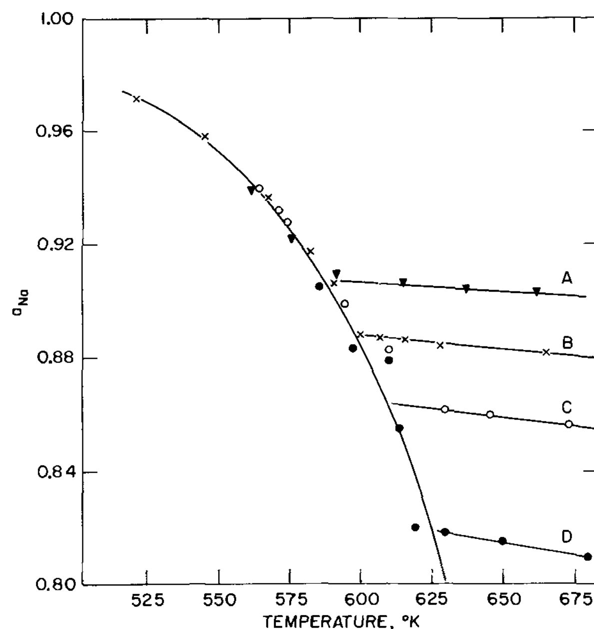

Fig. 4. Plot of the sodium activity as a function of temperature for Pb-Na solution. Curve A (triangles) was obtained with a solution having an initial lead composition of 7.79 a/o, B (crosses) 10.01 a/o, C (open circles) 12.65 a/o, and D (closed circles) 14.61 a/o.

concentrations, eventually giving rise to a negative deviation from ideality.

Additional experiments were carried out to extend the measurements of the sodium activity to temperatures low enough where the onset of a two-phase region might be observed. A plot of the temperature dependence of the sodium activity for the lead-sodium system is shown in Fig. 4. In the homogeneous liquid phase, the temperature coefficient of the activity is approximately constant. However, in the two-phase region it constantly changes because of the continued depletion of lead with decreasing temperature. The transition from the single to the two-phase region is marked by an abrupt discontinuity in the activity-temperature curve as seen in Fig. 4. Since this transition corresponds to the liquidus phase boundary, these data lead to an estimate of the liquidus-line for the sodium-lead phase diagram. As shown in Fig. 5, the results obtained by this analysis are in reasonable agreement with the phase diagram compiled by Hansen (16).

The germanium-sodium system.—The temperature dependence of the sodium activity for saturated solu-

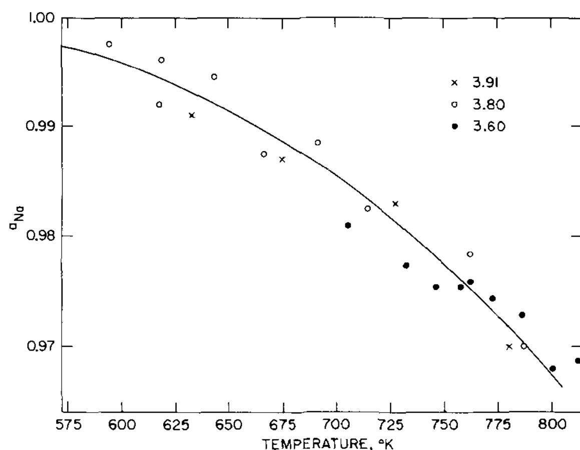

Fig. 6. Plot of the sodium activity vs. temperature for saturated solutions of Ge in Na. The experimental measurements were made with solutions of the following compositions: crosses, 3.91 a/o Ge; open-circles, 3.80 a/o Ge; closed-circles, 3.60 a/o Ge.

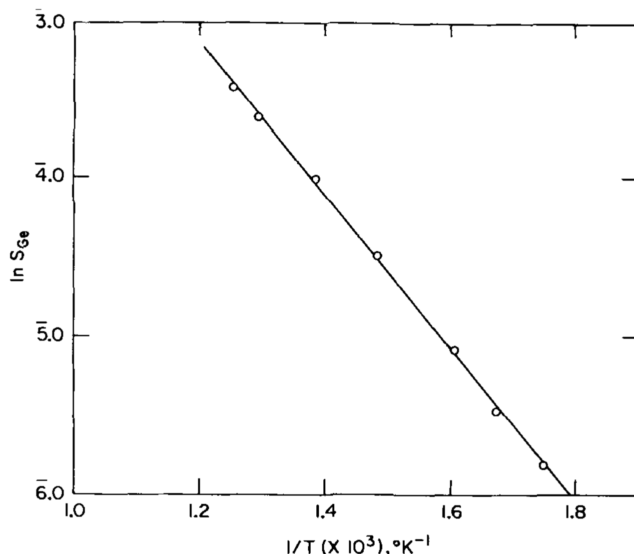

Fig. 7. Plot of ln S_{Ge} vs. reciprocal temperature. The germanium solubility is expressed in terms of mole fraction.

tions of germanium in liquid sodium is shown in Fig. 6. This curve is plotted on the basis of emf measurements made over the temperature range 300° to 550°C using cells containing 3.60, 3.80, and 3.91 a/o germanium. These Ge concentrations were found to be high enough to maintain a saturated solution even at 550°C. Other experiments were carried out with dilute solutions of germanium in liquid sodium corresponding to compositions of 1.03, 1.78, and 2.34 a/o Ge at temperatures sufficiently high for a homogeneous liquid phase to be attained (*ca.* 360°, 420°, and 470°C, respectively). Although the resulting activities could be differentiated from those obtained with saturated solutions, the accuracy of the data was insufficient to ascertain the exact temperature of the activity discontinuity corresponding to the point of complete solubility. This was due to the very small magnitudes and differences in the measured emf values.

Although the present Ge-Na results are of a preliminary nature, they are of value since they give a very good estimate of the temperature dependence of the solubility of germanium in liquid sodium. To our knowledge, there is no previous data available for this property of the Ge-Na system. Over the temperature range considered, 300° to 550°C, the mole fraction of sodium in the liquid phase does not decrease below 0.967. As a first approximation, we can take the sodium activity coefficient to be nearly unity over this relatively small composition range. This is justifiable since, for the corresponding composition range in the Pb-Na system $\gamma_{Na} \leq 1.00^5$ at 400°C and for Sn-Na solutions, $\gamma_{Na} \leq 1.00^9$ when $x_{Na} = 0.967$ (14). With the assumption of unit activity, the mole fraction of germanium in the saturated solution, S_{Ge}, can be calculated from the activity-temperature data. A plot of the resulting ln S_{Ge} *vs.* $1/T$ is a straight line as shown in Fig. 7. The equation of the line is

$$\ln S_{Ge} = 2.657 - 4.837/T \quad [9]$$

where T is the absolute temperature in degrees Kelvin.

The enthalpy, $\Delta H_{Ge}(\text{sol})$, and entropy, $\Delta S_{Ge}(\text{sol})$, of solution can be computed from the solubility data using the relationship

$$\ln S_{Ge} = -\frac{\Delta H_{Ge}(\text{sol})}{RT} + \frac{\Delta S_{Ge}(\text{sol})}{R} \quad [10]$$

where R is the molar gas constant. The calculated values of the enthalpy and entropy of solution are 9.61 kcal/mole and 5.28 eu, respectively.

ABSTRACT

Using an emf technique, the thermodynamic properties of dilute sodium solutions containing tin were measured over the temperature range 300° to 500°C. Results are reported for solution compositions ranging from 0.82 to 19.04 atomic per cent (a/o) tin, thereby, completing the requisite studies to detail the thermodynamic properties for this system over the entire range of composition. The results, in agreement with earlier findings for the Cd-, Tl-, and Pb-Na systems, show that the deviations from ideal solution behavior cross over from negative to positive at low Sn concentrations. Sodium activity measurements, which were made as a function of decreasing temperature, display a marked change in slope upon transition to a two-phase region. Appropriate measurements, made as a function of temperature for the two-phase region, give 13.07 kcal/mole for the enthalpy and 15.65 eu for the entropy of solution. The standard enthalpy and entropy of formation for the compound Na_4Sn were also determined; the values are −20.65 kcal/mole and −9.63 eu, respectively.

The thermodynamic properties of sodium solutions containing tin have been investigated by several authors. Delmarskii and Kolotin (1) have measured the excess thermodynamic functions for the sodium component over the composition range 11 to 75 a/o Sn and temperatures ranging from 723° to 923°K. The results of less comprehensive studies have been reported by Hauffe and Vierk (2) and Alabyshev *et al.* (3) in terms of the excess free energy of sodium in Na-Sn solutions. Their studies have covered the composition ranges from 5 to 73 a/o and 13 to 91 a/o tin, respectively, but each study was only made at a single temperature. Hultgren *et al.* (4) critically reviewed the data in 1963 and calculated selected values using the results of Delimarskii and Kolotin. However, at that time there was a paucity of data for both dilute and concentrated solutions, and the excess thermodynamic functions compiled for these regions were somewhat uncertain.

More recently, Yuan and Kröger (5) have reported the results of a study of concentrated tin solutions in liquid sodium thereby completing the work needed to detail the thermodynamic properties for the high concentration region. We have made an extensive investigation of the dilute concentration region below 20 a/o Sn and report the results herein.

Experimental

The cell and experimental procedure.—The electrochemical cell used in this investigation is represented by the cell reaction

Na | Na^+ | Na-Sn [1]

Pyrex has been shown to be a suitable material for selective sodium cation transfer (2, 5, 6) and it was used for the electrolyte in this study. The design of the cell, the ancillary equipment, and the experimental procedure have been described in detail in an earlier paper (6). Briefly, the procedure was as follows: After the cell was charged with the component metals, it was heated overnight at ≈25° above the estimated liquidus of the solution under investigation. This effected both the necessary aging of the cell and the complete dissolution of the tin in the liquid sodium. The emf of the cell was then measured as a function of increasing and decreasing temperature, the cycle being carried out twice.

Key words: solution thermodynamics, sodium-tin solutions, emf.

The measured emf, E, is related to the excess partial molar free energy of the sodium, $\Delta\overline{G}_{Na}{}^E$, and mole fraction of sodium in the solution, x_{Na}, by the relationship

$$\Delta\overline{G}_{Na}{}^E = -(E\mathbf{F} + RT \ln x_{Na}) \quad [2]$$

where $\mathbf{F}$ is the Faraday and T is the absolute temperature.

Materials.—The sodium used in the experiments was obtained from the J. T. Baker Company and was specified to have a purity of 99.9%. A further reduction in impurity level was effected by pipetting the sodium from a stock source heated to ≈120°C. At this temperature, the maximum concentration of dissolved nonmetals is *ca.* 10 ppm. The tin, purity 99.9%, was obtained from the General Chemical Division of the Allied Chemical Corporation and used without further purification.

Results and Discussion

The temperature dependence of the excess partial molar free energy of sodium was investigated for solutions containing up to 19.04 a/o tin. Measurements were made over the temperature range extending from the respective liquidus temperature to 500°C. Representative plots of $\Delta\overline{G}_{Na}{}^E$ *vs.* temperature are shown for tin compositions of 16.64, and 19.04 a/o in Fig. 1 and 0.82 and 10.20 a/o in Fig. 2. The experimental scatter of the data is reasonable considering the small magnitude and range of the measured emf, *i.e.*, the minimum and maximum emf values measured for the 19.04 a/o tin solution were 14.10 and 15.48 mV, respectively.

Since

$$\Delta\overline{G}_{Na}{}^E = \Delta\overline{H}_{Na} - T\Delta\overline{S}_{Na}{}^E \quad [3]$$

the corresponding enthalpy, $\Delta\overline{H}_{Na}$, and entropy, $\Delta\overline{S}_{Na}{}^E$, are readily deduced from these plots. The actual numerical values were computed using a least squares

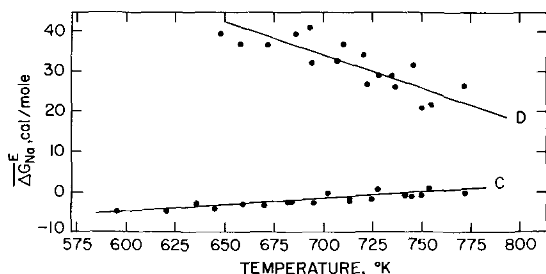

Fig. 2. Plot of partial molar excess free energy of mixing for sodium vs. temperature. C and D represent least-squares lines fitted to data obtained for solutions of composition 0.82 and 10.20 a/o, respectively.

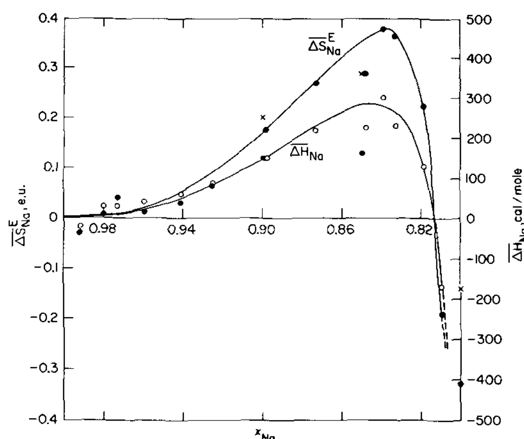

Fig. 3. Partial molar enthalpy and excess entropy of mixing plotted vs. composition [open circles, $\Delta\overline{H}_{Na}$, present results; open circles plus crosses, $\Delta\overline{H}_{Na}$, Ref. (4); closed circles, $\Delta\overline{S}_{Na}^{E}$, present results; crosses, $\Delta\overline{S}_{Na}^{E}$, Ref. (5)].

analysis. The $\Delta\overline{H}_{Na}$ and $\Delta\overline{S}_{Na}^{E}$, so obtained, are plotted as a function of composition in Fig. 3. The figure also includes data taken from the compilation of Hultgren *et al.* (4), based on the data available in 1963. It is readily seen that, in general, the present results are in good agreement with the assessments made by Hultgren *et al.*; the latter were, of course, based on rather sparse data for the regions of dilute concentration.

It can be seen from Fig. 3 that the enthalpy and entropy increase with increasing tin concentration up to *ca.* 16 a/o at which point both functions reach a maximum. A further increase in tin concentration leads to a decrease in the thermodynamic functions; they ultimately pass through zero and subsequently exhibit large negative values. These variations are indicative of an initial positive deviation from the properties of an ideal solution ($\gamma > 1$) followed by a pronounced negative deviation ($\gamma < 1$).

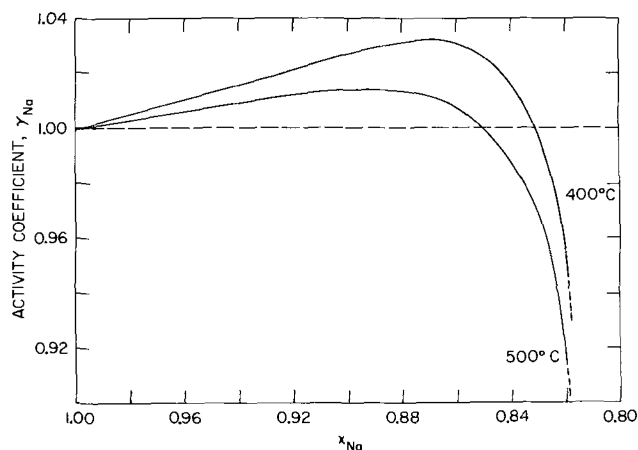

Fig. 4. Sodium component activity coefficient plotted vs. sodium composition for temperatures of 400° and 500°C. The activity coefficients, calculated from the average $\Delta\overline{H}_{Na}$ and $\Delta\overline{S}_{Na}^{E}$ values given in Fig. 3, show a crossover from values less than unity (negative deviation from ideal solution behavior) to greater than unity (positive deviations) at progressively lower tin compositions.

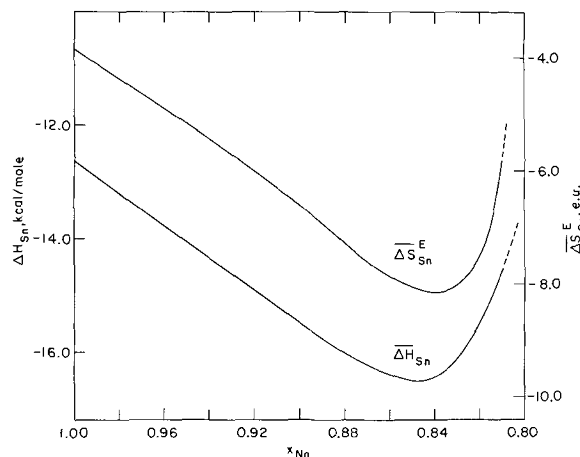

Fig. 5. Plot of the partial molar enthalpy and excess entropy of solution for the tin component.

The activity coefficient-composition isotherms at 400° and 500°C, derived from the average enthalpy and entropy functions given in Fig. 3, are shown in Fig. 4. Although the initial positive deviations are small, the trends discussed above are readily discernible. Similar observations have been reported for solutions of thallium (2), cadmium (7), and lead (6) in sodium. This type of behavior has been rationalized in terms of the size and electronic structure differences of the solute and solvent for the case of Pb-Na solutions (6) and the same arguments are applicable for the Sn-Na system as well.

As shown in Table I, the selected data of Hultgren *et al.* agree very closely with the present results. Therefore, it was deemed reasonable to select the corresponding value of $\Delta\overline{H}$ and $\Delta\overline{S}^{E}$ for the tin component and employ a Gibbs-Duhem integration to calculate the excess thermodynamic properties of tin from the properties measured for sodium. The resulting partial molar enthalpy and excess partial molar entropy of solution are plotted as a function of composition in Fig. 5. For dilute solutions, these functions decrease

Table I.

500	19.50

regularly with increasing tin concentration. As the concentration increases, both functions pass through a minimum and then increase rapidly. Since the excess thermodynamic functions of tin are approximately linearly dependent on composition below 10 a/o, it is possible to estimate its activity coefficient at infinite dilution. Values are tabulated as a function of temperature in Table II.

Experiments were also carried out to study the temperature dependence of the sodium activity of these solutions for the temperature range extending from the single- into the two-phase region. The results are shown in Fig. 6. For the region where the solution is single phase, the temperature coefficient of the activity is approximately constant. The boundary between the regions is characterized by an abrupt change in the temperature coefficient of the activity; at this point, activity commences to increase much more rapidly with decreasing temperature. The temperature dependence of the activity for the two-phase region, when correlated with the composition of the solutions, gives a good measure of the liquidus-line for the corresponding region of the phase diagram. The liquidus temperature determined in these experiments is compared in Fig. 7 with the phase diagram given by Hansen (8). The agreement between the two is excellent.

The enthalpy, $\Delta H_{Sn}(\text{sol})$, and entropy, $\Delta S_{Sn}(\text{sol})$, of tin dissolved in liquid sodium are related to the solubility of the tin, S_{Sn}, by the equation

$$\ln S_{Sn} = -\frac{\Delta H_{Sn}(\text{sol})}{RT} + \frac{\Delta S_{Sn}(\text{sol})}{R} \qquad [4]$$

where R is the molar gas constant and T, the absolute temperature. The solubility of tin in liquid sodium, calculated from the liquidus determined in the present study, is given as a function of temperature in Fig. 8. The equation of the straight line relating the solubility to temperature, is

$$\ln S_{Sn} = -\frac{6579}{T} + 7.874 \qquad [5]$$

The corresponding enthalpy and entropy of solution, which were computed by means of a least squares analysis, are 13.07 kcal/mole and 15.65 eu, respectively.

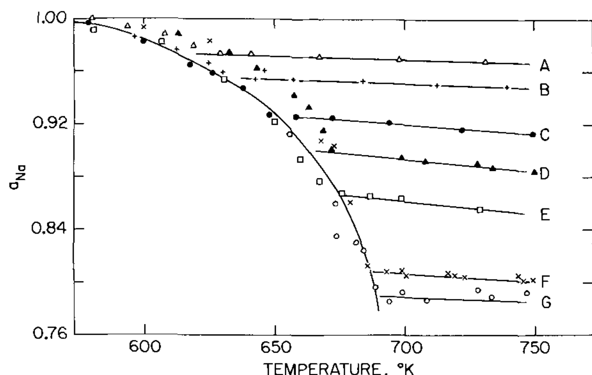

Fig. 6. Sodium activity vs. temperature showing the transition from a single-phase to a two-phase solution at progressively lower temperatures. The respective solution compositions in a/o tin are as follows: A—5.92, B—7.46, C—10.20, D—12.72, E—15.15, F—18.12, and G—19.04.

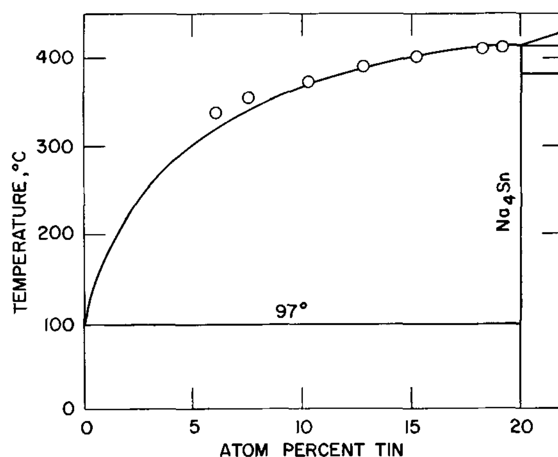

Fig. 7. Comparison of the phase diagram taken from Ref. (8) with the liquidus determined in the present study. Present results shown by the open circles.

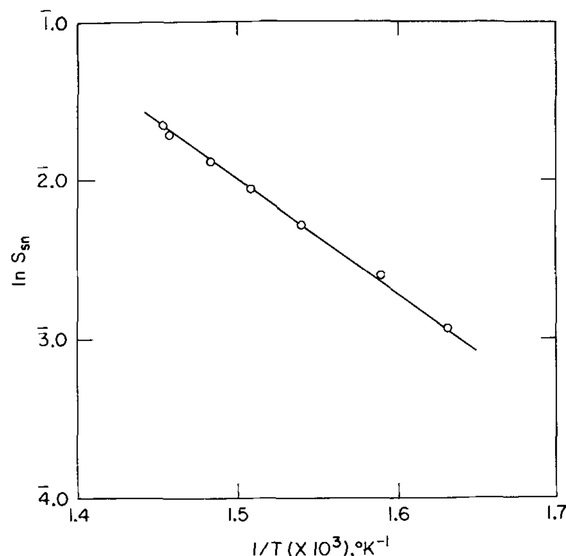

Fig. 8. Natural logarithm of the solubility of tin in sodium plotted vs. reciprocal absolute temperature.

These values are compared with those published by Lamprecht *et al.* (9) in Table III. The present results were determined over the temperature range 340°-415°C whereas those of Lamprecht *et al.* were measured for the temperature range 100°-260°C.

A consideration of the phase diagram (8) (also see Fig. 7) indicates that the compound Na_4Sn does not exhibit appreciable solid solubility. Thus the solid phase which precipitates when solutions containing up to 20 a/o tin are cooled, constitutes the pure intermetallic compound Na_4Sn. The activity of the sodium in a particular solution is measured directly at the liquidus temperature; the corresponding activity of tin can be calculated from the values of $\Delta\overline{H}_{Sn}$ and $\Delta\overline{S}_{Sn}^{E}$ compiled above.

Since the activity of the compound is unity for the chosen standard states, the free energy of formation of Na_4Sn can be calculated directly from the data and the relationships

$$4Na + Sn \overset{K_{eq}}{\rightleftarrows} Na_4Sn \qquad [6]$$

Table III.

	ΔH_{Sn} (sol) kcal/mole	ΔS_{Sn} (sol) cal/dg/mole

Thermodynamic Properties of Ternary Refractory Carbides

III. Relations between Thermodynamic Properties, Bonding, and Compressibility

M. Hoch and S. Yamauchi

Department of Materials Science and Metallurgical Engineering, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

The high-temperature thermodynamic data previously obtained on ternary carbides having the sodium-chloride structure are correlated with the bonding and mechanical properties of these carbides. The metal-metal bonding on the metal sublattice in the carbide is found to be the same as in the binary body-centered cubic metals. The variation of the carbon-carbon and metal-carbon interaction energies is interpreted to mean that the metal-carbon bonds are localized bonds. From the dependence of metal-carbon interaction energy on composition at elevated temperatures the compressibility of the carbides was calculated. The values obtained agree to within a factor of two with values derived from room temperature measurements of mechanical properties. The results show that the metal-carbon bond is responsible for the carbide properties and that the metal-metal and carbon-carbon bonds play a minor role.

In a previous paper (1), Hoch investigated the pairwise interaction energies in binary compounds having the sodium-chloride structure. As pointed out in that paper, these energies show a certain regularity. Their values for zirconium, hafnium, and niobium carbide are reproduced in Table I together with the values for uranium carbide which were derived later (2). (The nomenclature in this paper has been changed: 1 refers to zirconium, 2 to hafnium, niobium, or uranium, and 3 to carbon.)

In subsequent papers, Jun and Hoch (3) and Hoch, Hapase and Yamauchi (4) studied the activities of the components in the single phase, NaCl type structure in zirconium-niobium-carbon (3) zirconium-uranium-carbon (4), and zirconium-hafnium-carbon (4). From these data they derived the pairwise interaction energies, or their differences, between the various atoms. The present paper will attempt to interpret the thermodynamic results and will calculate the compressibility from these pairwise interaction energies.

Key words: ternary carbides, thermodynamic properties of carbides, bonding in carbides, compressibility of carbides.

Table I. Energy terms in binary carbides

Material	E_{33}, kcal/mole	$E_3 + E_{13} + E_{33}$ $(E_3 + E_{23} + E_{33})$, kcal/mole
ZrC	28 ± 3	-35.2 ± 4
HfC	15 ± 8	-47 ± 10
UC	0	-28.1 ± 1.6
NbC	15.2 ± 2.5	-28.6 ± 2.5

The paper of Jun and Hoch (3) indicated that the carbon-carbon interaction energy in the ternary zirconium-niobium-carbide, $Zr_xNb_{1-x}C_y$ varied parabolically with composition and was given by

$$E_{33} = 15.62 + 9.37x - 29.50(1 - x)x \quad \text{kcal/mole}$$

(Note that x here refers to the relative amount of Zr, and y refers to the carbon/metal ratio. Some authors use x for the latter purpose in describing monocarbides, *e.g.*, ZrC_x.)

This result, in itself, suggests that the bonding in the system is localized because a parabolic variation with composition requires that carbon atoms be "attached" to niobium and to zirconium, according to an analysis by Jun and Hoch (3).

The model used for the statistical thermodynamic derivation of the activity has been discussed earlier (11, 12) and needs only to be summarized here. The standard state for all elements is the pure, condensed element at the temperature in question. The atoms are assumed to be distributed randomly over the available sites, as in a regular solution, since the error introduced is very small. [First assuming ordered, and, later, randomly distributed atoms, Hoch *et al.* calculated only a 10% change in the pairwise interaction in the case of NbO (11)].

The grand partition function was then set up with only pairwise interaction energies, E_{ij}, neglecting the additional terms which reflect the influence of nearby atoms.

The model also neglects the small amount of Schottky defects present, and therefore is only valid when $1 - y >> \delta$, the concentration of Schottky defects.

Experimental Results and Discussion

Table II presents the metal-to-metal distances in pure elements as calculated from Darken and Gurry (5) and those in the carbides as determined during the previous investigations of this series. Those figures reveal that the metal-metal distance in the carbides is about 10% greater than the metal-metal distance in the pure bcc metals.

In addition, Table II gives the metal-metal interaction energy on the metallic sublattice as determined in three cases and also as calculated from the binary metal phase diagrams. These data show that the interaction energy on the metal sublattice in the carbide is approximately 2 kcal/mole larger than that in the bcc metal phase. This small difference of 2 kcal/mole can be attributed mostly to the transformation of the bcc structure to a fcc structure and to the expansion of the metal-metal distance. Thus, we conclude that the metal to metal bonding in the carbides is the same as in the pure metallic systems.

Another result obtained during the previous investigations (3, 4) was that the value of $[E_{13} - E_{23}]$, the difference in bonding energy between the zirconium-carbon bond and the other metal-carbon bond, was found not to be constant but to vary with composition. The equations obtained for $[E_{13} - E_{23}]$ are given in Table III. This variation suggests that localized metal to carbon bonds get compressed or expanded as the composition changes.

To explain the behavior of the carbides, it is necessary to look at a potential energy *vs.* distance diagram (Fig. 1). Since the lattice parameters of the various carbides are similar, the amount of compression or expansion of each metal-carbon bond is small, and our attention can be restricted to the bottom of the potential well. Although the carbon-carbon bond and the metal-metal bond contribute to the total cohesive energy, we assume that the metal-carbon bond is primarily responsible for the force constants (*i.e.*, shape of the potential) near the equilibrium separation. That is, the carbon-carbon and metal-metal bonds are assumed to be independent of separation for small displacements. Then, by subtracting off the (constant) energies of the other two bonds, we can write the two metal-carbon interaction energies as

$$E_{13} = \alpha_1(r - r_1)^2 + E^\circ_{13} \quad [1]$$

$$E_{23} = \alpha_2(r - r_2)^2 + E^\circ_{23} \quad [2]$$

where E°_{13} and E°_{23} are the metal-carbon interaction energies in the binary carbides, r_1 and r_2 are the metal-carbon distances in the binary carbides, r is the average metal-carbon distance in a ternary carbide (obtained from lattice parameters), and E_{13} and E_{23} are the metal-carbon interaction energies in the ternary carbide. The coefficients α_1 and α_2 are related to the compressibilities of the two carbides. As the compressibilities of the carbides are not very different at room temperature (see Table III), we assume, as a first approximation, that they are not very much different at 2500°K, and thus, set $\alpha_1 \simeq \alpha_2 \simeq \alpha$. So we finally obtain

Table II.

A. Metal-metal interaction energy $[E_{12} - \frac{1}{2}(E_{11} + E_{22})]$ in binary body-centered cubic metal alloys and on the metal sublattice in ternary carbides

System	$E_{12} - \frac{1}{2}(E_{11} + E_{22})$, kcal/mole		
	bcc metal	fcc carbide sublattice	Difference carbide-metal
Zr-Hf-C	≅0	1.86 ± 0.3	1.86 ± 0.5
Zr-U-C	4.4 ± 0.2	6.7 ± 0.6	2.30 ± 0.8
Zr-Nb-C	4.9 ± 0.3	6.5 ± 0.3	1.60 ± 0.5
		Avg:	1.92 ± 0.6

B. Metal compressibility and metal-metal distance in body-centered cubic metals and face-centered cubic sublattice in carbides

System	$P = 1/\beta$ (10^{12} dyn/cm²)	Distance in A		
		bcc metal	fcc carbide sublattice	Difference carbide-metal
Zr	0.90 (13)	3.11	3.32	0.21
Hf	1.10 (13)	3.07	3.29	0.22

U		3.00	3.52	0.52
			Avg:	0.31 ± 0.10

Table III. Dependence on composition of $[E_{13} - E_{23}]$ in ternary carbides

System	
Zr-Nb-C	$E_{13} - E_{23} = (1.08 \pm 0.11) - (16.15 \pm 0.44)x$ kcal/mole
Zr-U-C	$E_{13} - E_{23} = (8.5 \pm 0.05) - (23.6 \pm 0.2)x$ kcal/mole
Zr-Hf-C	$E_{13} - E_{23} = (9.6 \pm 0.8) - (7.8 \pm 0.2)x$ kcal/mole

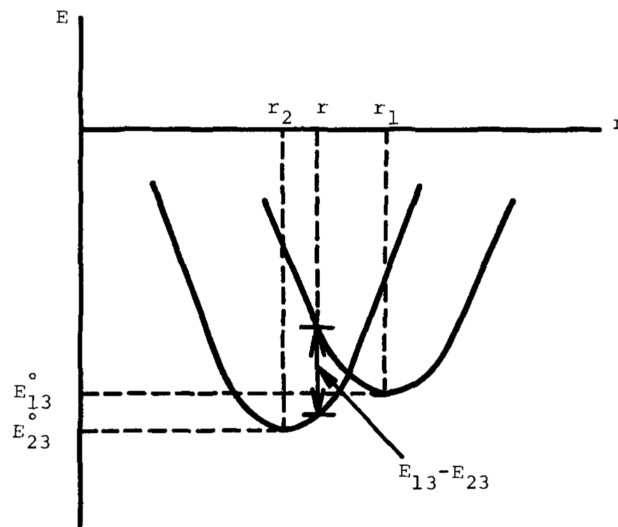

Fig. 1. Schematic potential-distance curves for two metal-carbon bonds.

$$E_{13} - E_{23} = \alpha(r_2 - r_1)[2r - (r_1 + r_2)] + E°_{13} - E°_{23}. \quad [3]$$

The lattice parameters in the ternary carbides at constant carbon content vary linearly with metal composition (3, 4)

$$r = r_2 + x(r_1 - r_2) \quad [4]$$

Combining Eq. [3] and [4], we have

$$E_{13} - E_{23} = E°_{13} - E°_{23} - 2\alpha(r_1 - r_2)^2 (x - 0.5) \quad [5]$$

This equation indicates that $[E_{13} - E_{23}]$ should be equal to $[E°_{13} - E°_{23}]$ when $x = 0.5$. These values, which were calculated from the thermodynamic data on ternary carbides in Table III and from binary data in Table I, are presented in Table IV. The agreement between the two sets of values is within a factor of two. In using the data in Table I, it was assumed that $E_3 + E_{33}$ was the same for all the carbides investigated. This term represents the energy required to take a carbon atom from its standard state (graphite), put it on the carbon sublattice, and then cause it to form a bond with another carbon atom.

The value of α, which is related to the compressibility of the carbide, can now be calculated from the variation of $[E_{13} - E_{23}]$ with composition using Eq. [5]. We can also calculate α using the method of Slater (6) to treat the cohesive energy of metals. With the choice of a Morse potential, Slater (6) obtains a relation which can be put in a form appropriate for our treatment

$$\alpha = N_0 \, c \, r_0 (9/2) P \quad [6]$$

where N_0 is Avogadro's number; r_0 is the nearest-neighbor distance; P is the bulk modulus $= 1/\beta$, where β is the compressibility; and c is a constant, such that the volume per molecule is $c\, r_0^3$ and $c = 2$ in the NaCl type structure. The results of both calculations are shown in Table V.

Looking at Table V-B, α appears to be the same within a factor of two for all the carbides used in the present investigation; thus, the earlier assumption that α_1 and $\alpha_2 = \alpha$ seems to be justified. It must be kept in mind, however, that the values of α in Table V-B were obtained from data taken at room temperature on polycrystalline materials. The values presented in Table V-A are from thermodynamic data taken at 2500°K and represent values for single crystals.

Table IV. Calculation of $E°_{13} - E°_{23}$ in ternary carbides

System	$E°_{13} - E°_{23}$, kcal/mole: Data from Table III $E_{13} - E_{23}$ at $x = 0.5$	Data from Table I $[E_3 + E_{13} + E_{33}] - [E_3 + E_{23} + E_{33}]$
Zr-Nb-C	-7.0 ± 0.5	-6.6 ± 5
Zr-U-C	-3.3 ± 0.2	-7.1 ± 4.5
Zr-Hf-C	$+5.5 \pm 0.8$	11.8 ± 10.8

Table V. Evaluation of α

A. From thermodynamic data at 2500°K

System	Slope (kcal/mole)	$(r_1 - r_2)^2$ A^2	α (10^{21} cal/cm² mole)
Zr-Nb-C	-16.1	0.0144	5.6
Zr-U-C	-23.6	0.0169	4.8
Zr-Hf-C	-7.8	0.0009	43.5

B. From the compressibility $\alpha = N_0\, c\, r_0\, (9/2)\, (1/\beta)$

System	$P = (1/\beta)$ (10^{12} dyn/cm²)	r_0 (A)	α (10^{21} cal/cm² mole)
ZrC	2.2 (9)	2.35	7.0
NbC	3.0 (10)	2.23	9.0
UC	1.4 (11)	2.48	4.7
HfC	2.42 (10)	2.32	7.5

The results derived from thermodynamic measurements and from room temperature compressibility are of the same order of magnitude. The average value of α for zirconium-carbide and niobium-carbide is 8×10^{21} cal/cm²mole and compares with the value of 5.6×10^{21} cal/cm²mole obtained from high-temperature thermodynamic measurements for Zr-Nb-C. Similarly, the average value for zirconium-carbide and uranium-carbide is 5.9×10^{21} cal/cm²mole, compared with 4.8×10^{21} cal/cm²mole obtained from high-temperature thermodynamic measurements on Zr-U-C. The value of 43.5×10^{21} cal/cm²mole for α in the Zr-Hf-C system can be disregarded because $(r_1 - r_2)^2$ is very small, giving a very uncertain value to α.

Comparison is possible with the results of Speck (7), who measured elastic constants of polycrystalline $NbC_{0.97}$ having 95% theoretical density. At room temperature, he found the compressibility was 3.05×10^{12} dyn/cm², which corresponds to $\alpha = 5.3 \times 10^{21}$ cal/cm²mole. However, his values decrease more rapidly with increasing temperature than the thermodynamic data of Table V-A would indicate.

The agreement, within a factor of two, between calculated compressibility values and experimentally measured ones shows that the assumption used here is correct: the carbon-metal bond determines the properties (such as bonding, mechanical properties, etc.) of the refractory carbides, and that the metal-metal and carbon-carbon bonds play a minor role. (The small role the metal-metal bond plays in the control of properties of carbides was already indicated as the metal-metal interaction is the same in the fcc carbide and the pure bcc metals.)

The bulk moduli of the carbides is at least, by a factor of two larger than that of the metals (Tables II and V) and thus the compressibility is lower. Such a large difference in bulk moduli can only be expected if the controlling factor is the metal-carbon bond. An enhanced metal-metal bond in the carbides (compared to the pure metals) could not account for the difference in bulk modulus.

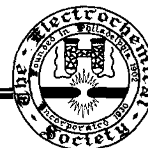
Technical Notes



A Scanning Electron Microscope Investigation of Etching Phenomena in GaP Electroluminescent Diodes

W. H. Hackett, Jr., T. E. McGahan, R. W. Dixon, and G. W. Kammlott

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Chemical etching is commonly used in semiconductor device fabrication as a convenient method for thinning, polishing, and shaping material, as well as for junction delineation (1). Moreover, the formation of complicated device structures from III-V compounds is greatly aided by the use of preferential etching. Several authors have demonstrated preferential etching for p-type material in Ge (2, 3), Si (5, 6), and GaAs (6, 7) using a variety of electrolytes which include solutions of NaOH, HF, and $HF-HNO_3$. More recently, solutions of NaOH have been similarly applied to several additional III-V semiconductor systems (8), including $GaAs_x$, $P_{1-x}InP$, $In_xGa_{1-x}P$, and $Al_xGa_{1-x}As$.

The p-type preferential etching is usually achieved under conditions in which the p region is the anode in the electrolyte. For these conditions it has been shown that the current density is generally much higher at the (p-region)-electrolyte interface (analogous to a forward-biased p-n junction) than at the (n-region)-electrolyte interface (analogous to a reverse-biased p-n junction), and is related to the participation of holes in the conduction process (9). Since the semiconductor etching rate is proportional to the current density at the semiconductor-electrolyte interface, etching is highly preferential for p-type material.

In addition, there have also been a few early reports of anodic n-type preferential etching in Ge, using solutions of NaOH, KOH, HCl, and NaCl (2, 10, 11). In this case, the n-region is the anode in the electrolyte and the p-region is either the cathode or is floating. Here electrical conduction of holes is relatively poor in the reverse direction of the p-n junction when compared to the (n-region)-electrolyte interface. This poor conduction tends to block dissolution of the p-region with respect to the n-region.

It is the purpose of this paper to describe several observations of similar n-type and p-type preferential etching in GaP, which have been made with the scanning electron microscope (SEM) during our investigations of the near-junction properties of GaP electroluminescent diodes (12, 13). For example, it has been found that a 3:1:1 solution of H_2SO_4:H_2O_2:H_2O, which is used to remove surface damage for red-emitting diodes (14), is highly preferential for p-type GaP and is electrochemically controllable under conditions in which the p-region is the anode in the electrolyte. Solutions of $HF-HNO_3$ (15) and NaOH (16) have also been found useful for p-type preferential etching in GaP. It has also been observed that, using a solution of HF:H_2O_2, the photoetching delineation of GaP p-n junctions (17) is due to preferential etching of the p-region. Finally, a complementary preferential etchant for n-type GaP is reported, in which the n-region is the anode in an electrolyte consisting of a solution of NaOCl-HCl.

Key words: electrochemistry, scanning electron microscopy, gallium phosphide.

Experimental Results and Discussion

Several properties of these etchants have been investigated on assembled GaP red-emitting diodes using the SEM. With its high resolution, large depth of field, and versatile detection system [which includes secondary emission, cathodoluminescence (CL), and specimen current (SC) modes], this instrument has been found to be ideally suited for this purpose. For example, etch steps are easily seen without cleaving the device for optical examination and direct observations of etching isotropy are possible. Detailed weight measurements are not necessary. In addition, the location of the p-n junction may be unambiguously obtained using the voltage contrast in the secondary emission, the CL, or the SC modes. For more quantitative information, such as absolute etching rates and detailed current-voltage characteristics of the respective semiconductor-electrolyte interfaces, additional care may be taken to mask electrical contacts, agitate the electrolyte, and provide uniform current densities. These precautions were not taken here and, therefore, the results are considered to be of a preliminary and semiquantitative nature.

Preferential etching of p-type GaP (3:1:1 solution H_2SO_4:H_2O_2:H_2O).—The red-emitting GaP electroluminescent diodes are diced structures which have been fabricated and assembled on Au-plated TO-18 headers. Figure 1a is a secondary emission image of such a diode, and illustrates its general appearance. The junction structure consists of an n-type Czochralski substrate, a Te-doped n-type epitaxy layer grown on the {111} P-face, and a Zn,O-doped p-type epitaxy layer grown on the n-layer (18). The two layers are approximately 25-30μ thick. Prior to assembly, appropriately doped Au contacts were evaporated and sintered onto the junction material, after which the material was slurry-cut into 0.4 mm × 0.4 mm dice. The wire bonded to the top surface of the diode in Fig. 1a is the electrical contact to the p-type epitaxy layer on the {111} P-face of the crystal.

The etching characteristics of a 3:1:1 solution of H_2SO_4:H_2O_2:H_2O were first investigated because it has been used in this laboratory to remove slurry-cutting induced surface damage from assembled diodes (14).

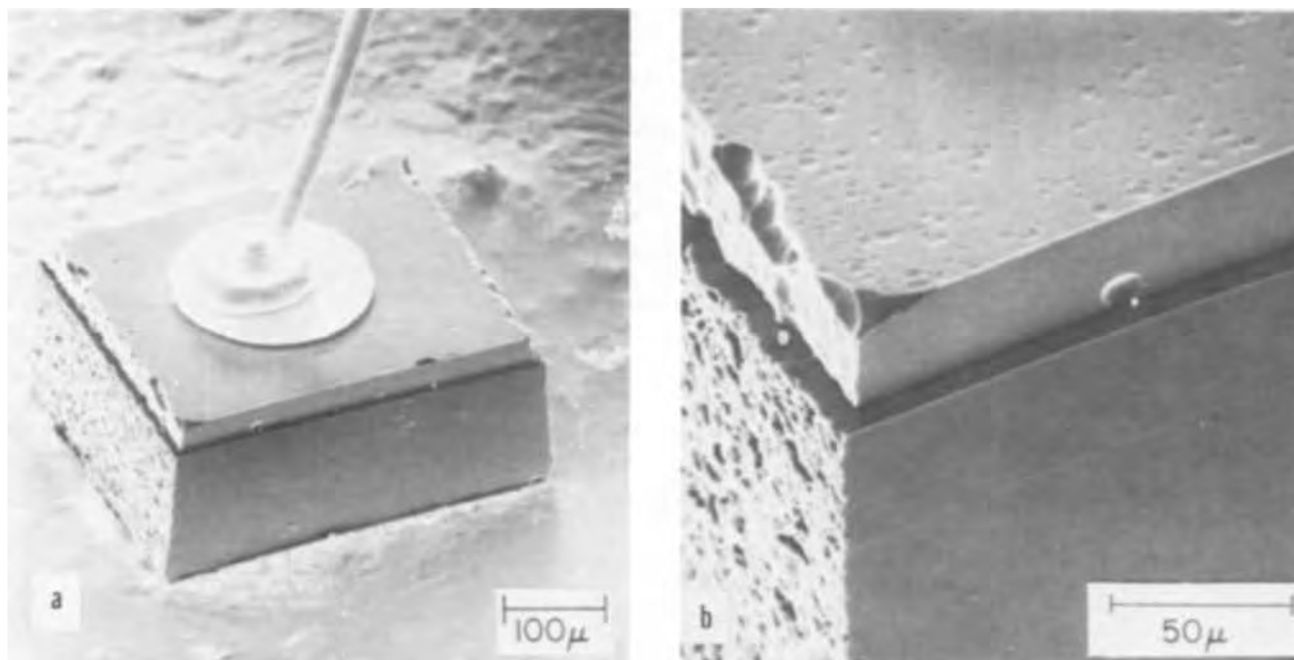


Fig. 1 a. Secondary emission image of a GaP red-emitting diode, which is a diced structure consisting of an n-type Czochralski substrate (bottom), a ~25 micron n-type epitaxy layer (center), and a ~30 micron p-type epitaxy layer (top). This diode has been etched in a 3:1:1 solution of H_2SO_4:H_2O_2:H_2O for 20 min at 60°C, with a resulting etching step at the junction, as shown. Etching is also evident near the p-contact, in addition to a faint delineation of the (n-Czochralski)-(n-epitaxy) interface. b. A magnified view of the corner of the same diode. In addition to the features described above, etch pits are clearly discernable on the top surface of the p-region.

For example, after diodes were etched in a freshly prepared solution for 5 min at 60°C, they typically exhibited a step at the p-n junction as a result of preferential etching of the p-region. Figures 1a and 1b show such a diode after 20 min of etching. In this case, the front surface of the die had been polished prior to assembly in order to provide more quantitative data. The coincidence of the etching step with the p-n junction is confirmed by the voltage-contrast at the junction, and has been independently verified using the CL mode (which determines the location of the red-emitting p-region) and the SC mode (which determines the locus of efficient beam-induced junction current) (13).

To make a quantitative estimate of the etch rate, the diode was repositioned so that both the p-n junction plane and the polished surface were parallel to the viewing direction as shown in Fig. 2. In addition, from this perspective, a comparison can be made of relative etch rates in different crystallographic directions. In this case the etching step at the junction is approximately 8.6μ wide and the etch rate is 0.42 μ/min in directions perpendicular to the <111> axis (*i.e.*, the etching step has the same width for all four slurry-

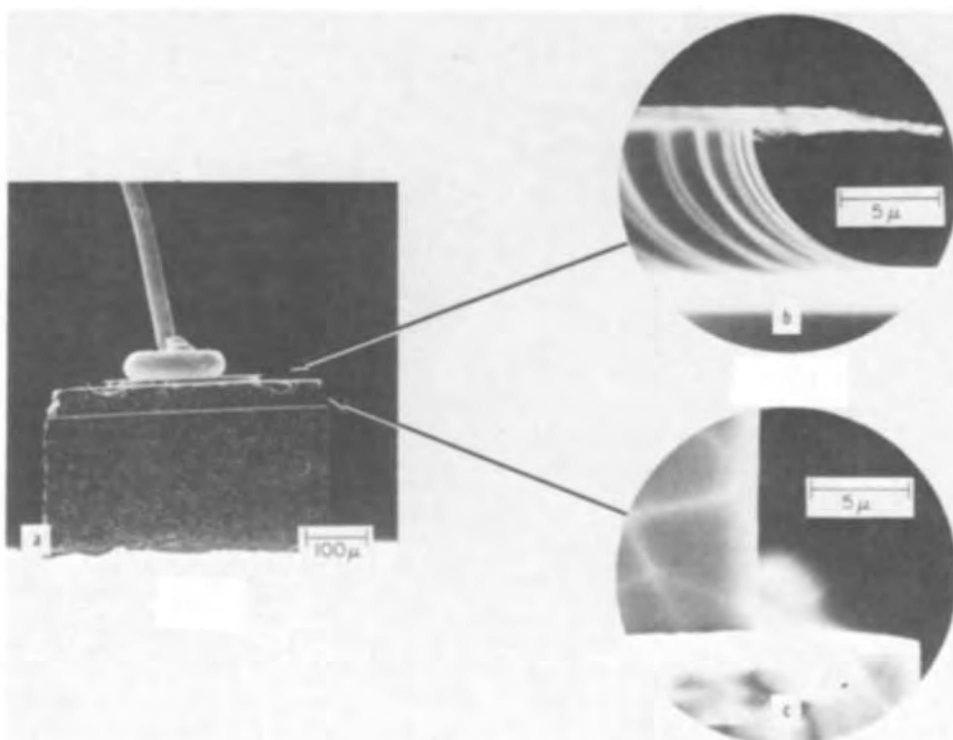

Fig. 2 a. Secondary-emission image of the same diode as in Fig. 1, but with both the junction plane and the polished surface parallel to the viewing direction for a better perspective. Here the etching step at the p-n junction and the undercutting at the p-contact are clearly defined. b. Magnified view of the material removed at the p-contact. The thin top layer is the evaporated and sintered contact, and the rest is p-type semiconductor. c. Magnified view of the etching step at the p-n junction.

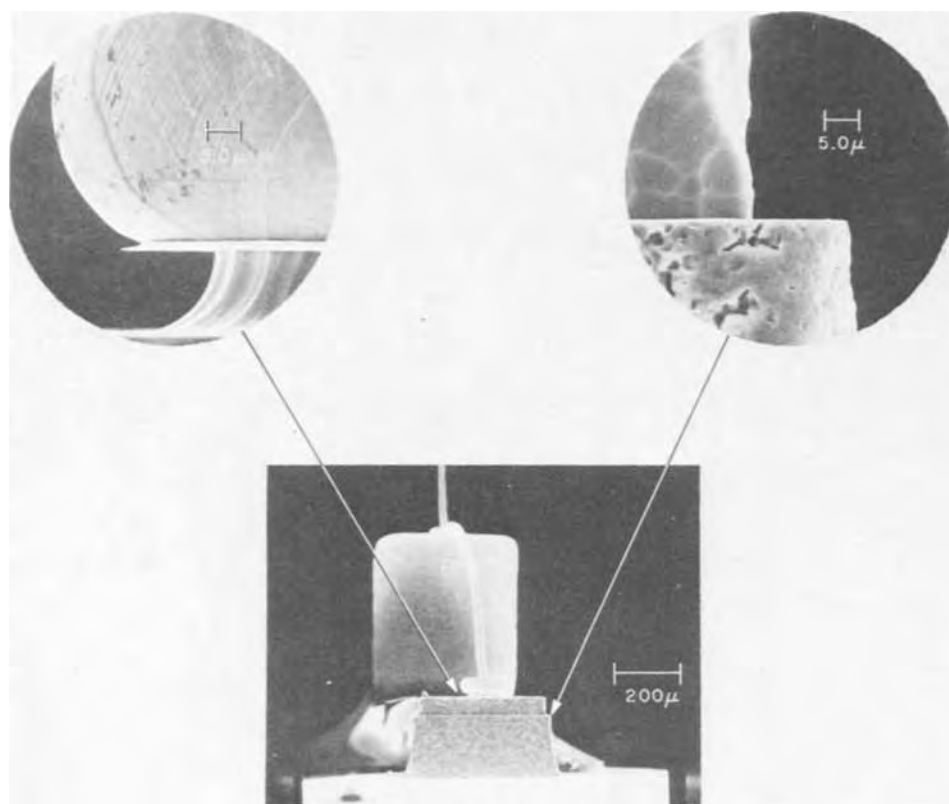

Fig. 3. Secondary emission image of a GaP red-emitting diode, which has been etched in the 3:1:1 solution under conditions in which the p-region was the anode in the electrolyte. The diode has been etched for 20 min at 60°C., using 5 mA electrode current.

cut faces). Also, as shown by the etching about the p-contact, the etching rate along the <111> axis is within 20% of this value. Thus, the etching in the p-region appears to be approximately isotropic. The taper at the step forms an angle of 6 degrees, with respect to the junction plane, which can be used to estimate the relative etching rates for the n- and p-material, viz., p-rate/n-rate $=$ cot 6° $\cong$ 9.4. These results confirm that the etching is highly preferential to p-type material.

To further define the characteristics of this etchant, an assembled diode was immersed in the electrolyte with the p-region biased positive with respect to a stainless or platinum electrode, which is similar to procedures reported previously (2-8). Typical results are shown in Fig. 3 for a diode etched for 20 min at 60°C, and for 5 mA electrode current. In this case, the preferential etching has been enhanced to the extent that the angle of the step relative to the junction plane is nearly zero. This enhanced preferential etching for p-type material is generally consistent with the respective characteristics of n- and p-type semiconductor-electrolyte interfaces (*i.e.*, a positive potential across the p-electrolyte interface conducts current easily, while a similar potential across the n-electrolyte interface results in only limited current densities) (9).

In this case, approximately 12.8μ of p-material have been removed, at an etching rate of 0.64 μ/min. From the relative magnitudes of the etching step, and the etching under the p-contact on the top surface, it is concluded that the etching is still isotropic for the p-region even though there has been no attempt made to keep the current density uniform at the semiconductor-electrolyte interface. There was also no unusual attack at the contact-GaP interface. Approximately 0.6-0.8V were required to produce the 5 mA electrode current, but no detailed current-voltage relationships were determined in this preliminary characterization.

With the present diode-electrode configuration, the current density is probably somewhat nonuniform over the p-electrolyte interface. In addition, it is likely that the etching rate is slightly inhibited by gas evolution and the formation of by-products at the semiconductor surface since no special precautions were used to promote mixing of the solution near the interface. Nonetheless, the enhanced p-type preferential etching under these anodic conditions is amply demonstrated.

For completeness, a similar diode was also immersed in the electrolyte for 20 min at 60°C, but with the p-region biased negatively with respect to the electrode. Under these conditions, the preferential etching was suppressed. No undercutting of the contact was visible, and there was no measurable etching step. Very little etching of either p- or n-type material was evident. These observations are consistent with the general current-voltage characteristics of the p-electrolyte interface and demonstrate the electrochemical control of the preferential etch.

The HF:H_2O_2 photoetch.—A solution of HF:H_2O_2 has often been used as a photoetch to delineate p-n junctions in GaP (17). In order to better understand the cause of this delineation, a slurry cut diode similar to those previously discussed was selected. One surface was polished with Linde A and then etched in hot aqua regia to remove any remaining surface damage prior to assembly. The topography at this surface near the junction plane was smooth, as expected for the assembled diode, without any etch step at the junction indicating that hot aqua regia does not selectively etch n- or p-type GaP. When this diode was subsequently photoetched for 90 sec, at 24°C in a 1:1 solution of HF:H_2O_2, a step approximately ½μ wide resulted at the p-n junction due to preferential etching of the p-region. At present, the origin of the dominant etching mechanism is not clear, although it may be simply a preferential dissolution of the p-region caused by a photoinduced voltage at the p-n junction. It is evident, however, that the junction delineation results from preferential etching of the p-region.

Preferential etching of n-type GaP.—We also report here what we believe to be the first successful attempt to preferentially etch n-type GaP. In this case the n-region was the anode in an electrolytic solution of NaOCl and HCl (which is unstable under acid conditions), and a stainless steel or platinum electrode was

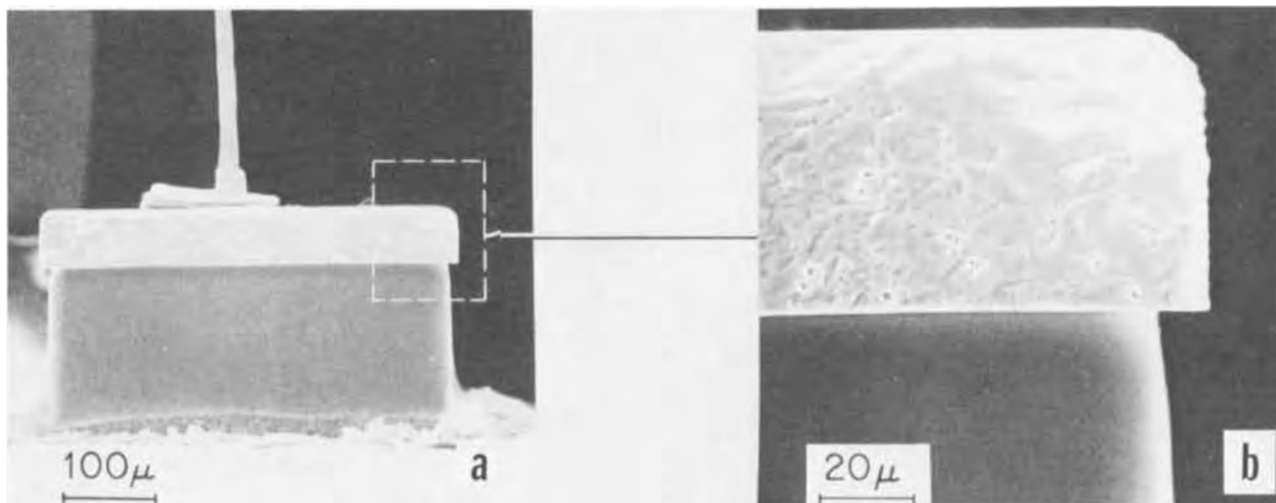

Fig. 4. Secondary emission image of a GaP red-emitting diode, which has been n-preferentially etched in an electrolyte consisting of a solution of NaOCl and HCl. In this case, the n-region was the anode in the electrolyte.

the cathode. This procedure takes advantage of the relatively poor conduction of holes in the reverse direction of the p-n junctions, and, thus, preferentially removes n-type GaP from assembled diodes while having no appreciable effect on the p-type material.

Figure 4 shows the result of electrochemically etching an assembled diode for 5 min at 24°C in an etchant consisting of a 7:1 ratio of (5.25% wt solution of NaOCl):(HCl). The electrode current was 5 mA. The abrupt step at the p-n junction is now indicative of n-type preferential etching. The fact that no detectable angle exists between the junction plane and the etching step indicates that very little or none of the p-type material has been removed. Note that somewhat more n-material has been removed near the p-n junction than further away. From this and similar observations it is believed that the etch rate is highest where the doping concentration is highest (near the junction $N_D - N_A \sim 2 \times 10^{18}$ cm^{-3}) and decreases in more lightly doped material (the bulk of the n-substrate has $N_D - N_A \sim 2 \times 10^{17}$ cm^{-3}) (18). (The preferential etching was suppressed when the applied potential was reversed.) The etch rate of this solution, nominally 2 μ/min, is considerably faster than that of 3:1:1 for p-material. Also the gold n-contact is somewhat attacked by this etch.

While no attempt has been made to optimize this etch, or to investigate its characteristics in detail, its discovery does demonstrate the feasibility of n-type preferential etching in GaP. The existence of such solutions complements the growing number of p-type preferential etchants for this material.

Summary and Conclusions

Several interesting observations of preferential etching of GaP electroluminescent diodes have been made using the SEM. Specifically, two electrochemically controllable etchants have been found, one for p-type material, and one for n-type material. Although the detailed anodic characteristics have not been determined for the respective n- and p-type semiconductor-electrolyte interfaces, one would expect, on the basis of the anodic preferential etching characteristics, that they are similar to those for Ge and Si. Also, it has been determined that a commonly used photoetch is, in fact, a preferential etch for p-type material. These and similar preferential etchants have potentially important uses in the technology of GaP light-emitting diodes, where it is desirable to economically fabricate sophisticated structures (19).

Diffusion from a Thin Layer into a Semi-Infinite Medium with Concentration Dependent Diffusion Coefficient

M. Ghezzo*

General Electric Corporate Research and Development Center, Schenectady, New York 12301

It is well known in the literature (1) that the Boltzmann transformation is the most suitable method for solving the diffusion equation with concentration dependent diffusion coefficient when the boundary conditions satisfy certain requirements. In particular, this transformation may be applied when the surface concentration of the indiffused medium is invariant with time, for example, in the predeposition process used in silicon device manufacturing (2). The Boltzmann transformation yields, in this case, a convenient formula for determining the diffusion coefficient as a function of concentration when the diffusion profile has been experimentally determined. The opposite is more difficult and, in order to compute the diffusion profile from the diffusion coefficient, an iterative method must be followed (1).

When the diffusing substance is subject to a redistribution within the indiffused medium, the Boltzmann transformation may not be applied because the surface concentration decreases with time which implies a time dependence of the concentration separate from the ratio of penetration depth to square root of diffusion time postulated by Boltzmann. A very important case of concentration redistribution in a semi-infinite medium with an impermeable boundary is represented by diffusion of impurities from a superficial thin layer of this medium into its bulk. An example is provided in silicon device processing by the so-called drive-in diffusion, which is used for adjusting the concentration profile to the device specifications after the predeposition step (2).

The purpose of this note is to show the potential inherent in the transformation approach even in the case of concentration redistribution within a semi-infinite medium, provided that the Boltzmann transformation is replaced by a suitable modification in accordance with the different boundary conditions. As the main interest of this work consists of a demonstration of the method, the mathematical treatment was kept as simple as possible, at the expense of its utility in solving actual diffusion problems, by limiting the investigation to a diffusivity dependence on the ratio of concentration to surface concentration instead of on concentration alone.

Theory

By calling Q the total amount of impurities per unity of surface in the indiffused medium, the assumption of an impermeable boundary results in the constancy of Q with time. Thus, the relationship

$$Q = \int_0^\infty N\,(x,t)\,dx \qquad [1]$$

imposes a condition on the functional dependence of the impurity concentration, $N(x,t)$; on the time, t; and the penetration depth, x. As Q must have a finite value, Eq. [1] requires that at any time

$$N(x,t) = 0 \text{ for } x \rightarrow \infty \qquad [2]$$

Besides, the initial concentration profile will be represented as a delta function

$$N(x,t) \neq 0 \text{ for } x = 0,\ t = 0 \qquad [3a]$$

* Electrochemical Society Active Member.

Key words: diffusion theory, Boltzmann's transformation, concentration dependent diffusion coefficient.

$$N(x,t) = 0 \text{ for } x > 0,\ t = 0 \qquad [3b]$$

The Boltzmann's transformation may be represented by

$$N(x,t) = G(x/\sqrt{t}) \qquad [4]$$

with G satisfying the diffusion equation and the boundary conditions.

Application of Eq. [4] to [1] shows a time dependence of Q given by

$$Q = \sqrt{t}\int_0^\infty G(x/\sqrt{t})\,d(x/\sqrt{t}) \qquad [5]$$

which contradicts the hypothesis of an impermeable boundary.

Comparison of Eq. [5] with [1] shows that the required time independence of Q is easily achieved by the following transformation

$$N(x,t) = F(x/\sqrt{t})/\sqrt{t} \qquad [6]$$

which gives for Q the value

$$Q = \int_0^\infty F(x/\sqrt{t})\,d(x/\sqrt{t}) \qquad [7]$$

Assuming that the diffusion coefficient D is concentration dependent, the diffusion equation may be written for a one-dimensional geometry (1)

$$\frac{\partial N}{\partial t} = \frac{\partial}{\partial x}\left(D(N)\,\frac{\partial N}{\partial x}\right) \qquad [8]$$

Replacing N in Eq. [8] with its expression given by Eq. [6], and performing a change of coordinates from (x,t) to (η,t), where η is defined by

$$\eta = x/\sqrt{t} \qquad [9]$$

the diffusion equation becomes

$$-\frac{1}{2t\sqrt{t}}\frac{d}{d\eta}[\eta \cdot F(\eta)] = \frac{1}{\sqrt{t}}\frac{\partial}{\partial\eta}\left[D\left(\frac{F(\eta)}{\sqrt{t}}\right)\cdot\frac{1}{t}\cdot\frac{dF(\eta)}{d\eta}\right] \qquad [10]$$

which simplifies to

$$-\frac{1}{2}\frac{d}{d\eta}[\eta \cdot F(\eta)] = \frac{\partial}{\partial\eta}\left[D\left(\frac{F(\eta)}{\sqrt{t}}\right)\cdot\frac{dF(\eta)}{d\eta}\right] \qquad [11]$$

The need for Eq. [11] to be self-consistent imposes a limitation on D which must depend on η alone for avoiding the situation in which the solution for F would depend both on $\sqrt{t}$ and η in contradiction with the assumption used in the derivation of Eq. [11].

As the surface concentration at time t, $N(o,t)$ is equal to

$$N(o,t) = F(o)/\sqrt{t} \qquad [12]$$

this specification on D is satisfied by adding the limitative hypothesis that D be a function of the ratio $N(x,t)/N(o,t)$, which is equivalent to assume $D(F(\eta)/F(o))$.

Equation [11] is immediately integrated between η and ∞, yielding the first order differential equation

$$-\frac{1}{2}\eta F(\eta) = D\left(\frac{F(\eta)}{F(o)}\right)\cdot\frac{dF(\eta)}{d\eta} \quad [13]$$

The passage from Eq. [11] to Eq. [13] is possible because

$$\lim_{\eta\to\infty}(\eta\cdot F(\eta)) = \lim_{\eta\to\infty}\left(D\left(\frac{F(\eta)}{F(o)}\right)\cdot\frac{dF(\eta)}{d\eta}\right) = 0 \quad [14]$$

as Eq. [7] requires that $F(\eta)$ be of order greater than one in $1/\eta$ in order to yield a finite Q.

Equation [13] may be integrated between $\eta = o$ and η after proceeding to a variable separation between the two members of the equation. This results in the relationship

$$\int_1^{F(\eta)/F(o)} \frac{D(\xi)\,d\xi}{\xi} = -\frac{1}{4}\eta^2 \quad [15]$$

where $\xi = F/F(o)$.

The constant, $F(o)$, can be determined from Eq. [7] after a suitable modification of this equation as shown below.

Changing the integration variable from η to ξ by means of Eq. [13], Eq. [7] becomes

$$Q = 2F(o)\int_o^1 \frac{D(\xi)\,d\xi}{\eta(\xi)} \quad [16]$$

where it was taken into account that according to Eq. [2] and [6] $\xi = 0$ and $\eta \to \infty$.

Replacement of $\eta(\xi)$ in Eq. [16] with its expression given by Eq. [15], yields this formula for $F(o)$

$$F(o) = Q \Bigg/ \int_o^1 \frac{D(\xi)\,d\xi}{\sqrt{\int_\xi^1 \frac{D(\rho)}{\rho}\,d\rho}} \quad [17]$$

where ρ is defined as ξ.

A check of the validity of the above equations is provided by computing the concentration profile for the case $D = D_o$, with D_o a constant.

Integration of Eq. [15] yields immediately

$$F(\eta) = F(o)\exp(-\eta^2/4D_o) \quad [18]$$

which is equivalent, according to Eq. [6] and [9], to

$$N(x,t) = N(o,t)\exp(-x^2/4D_ot) \quad [19]$$

Application of Eq. [17] gives the value of $F(o)$

$$F(o) = Q/\sqrt{D_o}\cdot\int_o^1 \frac{d\xi}{\sqrt{\ln(1/\xi)}} \quad [20]$$

As the definite integral in Eq. [20] is equal to $\sqrt{\pi}$ (3), Eq. [19] becomes the familiar gaussian distribution function

$$N(x,t) = \frac{Q}{\sqrt{\pi D_o t}}\exp(-x^2/4D_ot) \quad [21]$$

Example

Let us assume that

$$D(N(x,t)/N(o,t)) = D_o[1 + k(N(x,t)/N(o,t))] \quad [22]$$

which corresponds to a *linear dependence of D on the* ratio of concentration to surface concentration with slope $k \cdot D_o$, where D_o is the intrinsic diffusivity, and k a real positive number.

From Eq. [15], [12], and [6], the expression of D given by Eq. [22] yields, after integration, the formula

$$\frac{x}{2\sqrt{D_ot}} = \sqrt{k\left(1 - \frac{N(x,t)}{N(o,t)}\right) - \ln\frac{N(x,t)}{N(o,t)}} \quad [23]$$

which is the normalized version of the diffusion profile.

In Fig. 1 a plot of the profiles, corresponding to different values of k, shows that an increase in k flattens the initial part of the profile and introduces a sharper concentration drop in the profile tail. The profile for $k = 0$ is represented by the gaussian error function, while the profiles for higher values of k correspond to an enhanced diffusion. In particular, the profile for $k = 30$ was included in Fig. 1 for making the example more realistic; because in high concentration arsenic diffusions into silicon, the ratio of maximum diffusivity to intrinsic diffusivity is about 30 for a wide temperature range (950°-1150°C) according to Kennedy and Murley (4).

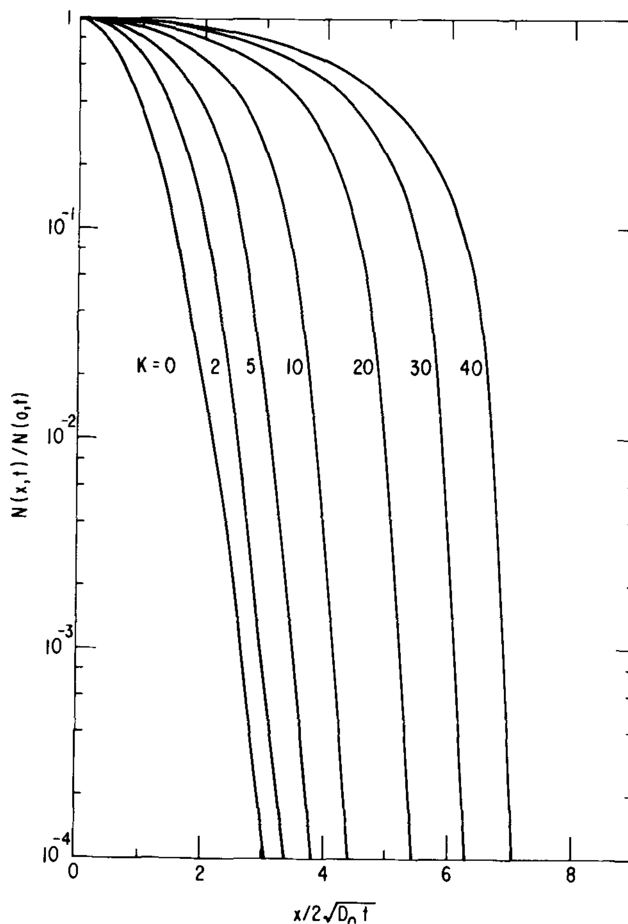

Fig. 1. Normalized diffusion profiles for a diffusion coefficient $D = D_o[1 + k(N(x,t)/N(o,t))]$ with k = 0, 2, 5, 10, 20, 30, 40, in the case of planar diffusion into a semi-infinite medium limited by an impermeable boundary. The solute is concentrated before diffusion in a very thin layer adjacent to the boundary.

The profiles of Fig. 1 are expressed in normalized form. So as to determine the actual profiles the surface concentration at time t, $N(o,t)$, must be computed through a numerical integration of Eq. [17].

Conclusion

A modified version of the Boltzmann transformation method was used for obtaining an exact solution of the diffusion equation in a semi-infinite medium, limited by a plane impermeable boundary with finite source initially close to this boundary, and with the diffusion coefficient dependent on the ratio of concentration to surface concentration. The general solution was verified for a constant diffusion coefficient by yielding the gaussian error function. Calculation of the profiles corresponding to a diffusion coefficient linearly dependent on the ratio of concentration to surface concentration was used for illustrative purposes.

Erratum

In the paper "Diffusion of ^{51}Cr in NiO Single Crystals" by M. S. Seltzer which appeared on pp. 802-805 in the May 1971 JOURNAL, Vol. 118, No. 5, in converting from natural logarithms to base 10 logarithms the diffusion coefficients were multiplied by the factor 2.303 when they should have been divided by this factor. Therefore, to get the correct diffusivities in Fig. 2 and 3, one must divide by $(2.303)^2$.

Stress Corrosion Cracking of 18% Cr Ferritic Stainless Steels

R. T. Newberg* and H. H. Uhlig*
Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Stress corrosion cracking of ferritic 18% chromium stainless steels in $MgCl_2$ solution depends on nickel content (0-8%) as well as on heat-treatment and cold work. Maximum susceptibility occurs at 2% Ni; alloyed manganese has a small effect; molybdenum can be detrimental. Rolling direction has little or no effect on failure times of ferritic 18-8, contrary to failure by hydrogen cracking, indicating different mechanisms of failure. Whether or not failure occurs depends on the relation of critical to corrosion potentials for all but the lowest nickel alloys. Hence galvanic couples can be useful or damaging. The results are not readily explained in terms of electrochemical dissolution or brittle oxide films. A mechanism is favored based on adsorption of Cl^- ions on appropriate surface imperfection sites.

The relatively good resistance or complete immunity of ferritic stainless steels, *e.g.* AISI Type 430, to stress corrosion cracking (s.c.c.) in hot aqueous chloride solutions was pointed out by Scheil *et al* (1) as early as 1943. Later tests showed that ferritic alloys containing small amounts of Ni, *e.g.* 12% Cr, 2% Ni-Fe; or 28% Cr, 5% Ni, 1.7% Mo-Fe, exposed to $MgCl_2$ boiling at 154°C either failed or showed surface cracks (2). Copson (3) presented data showing that additions of Ni to 15-26% Cr-Fe stainless steels at first increased, then decreased their susceptibility to s.c.c. in boiling 42% $MgCl_2$ resulting in maximum susceptibility between 0 and 8% Ni. Riedrich and Kohl (4) established that minimum resistance of austenitic alloys containing 16% Cr, 9% Mn appeared at about 4-5% Ni, with Mn having little effect on susceptibility, but with copper, at a given weight per cent, being more damaging than Ni.

Uhlig, White, and Lincoln (5, 6) found that a low C, low N, 18% Cr, 8% Ni stainless steel, ferritic (or martensitic) as quenched from 1050°C, was resistant to cracking in $MgCl_2$ boiling at 154°C (>250 hr) whereas a similar alloy when austenitic as quenched (containing higher C and N), failed in short times (0.2-1.4 hr). The structure rather than C and N content was responsible for the difference as was shown by the parallel observed resistance to s.c.c. of originally austenitic 18-8 alloys subsequently transformed to ferrite by cold working at liquid N_2 temperatures (5, 6). A higher Ni alloy, *e.g.*, 20% Ni stainless steel, which did not transform, became less rather than more resistant after cold rolling. Bond and Dundas (7) reported that 18% Cr-Fe ferritic stainless steels annealed at 815°C for 1 hr did not crack in $MgCl_2$ boiling at 140°C if the Ni content was below about 1% and similarly if the Cu content was below 0.5%. For resistance to s.c.c., the total Ni plus 3 × Cu content, they stated, should preferably be below 0.9%. Small alloying additions of Mo (1-5%) had no effect, but 2% Mo combined with small amounts of Ni, Cu, or Co induced susceptibility.

* Electrochemical Society Active Member.

Key words: critical potential, alloyed molybdenum, alloyed nickel, stress-sorption cracking, NaOH solutions, nitrate solutions, magnesium chloride solutions.

It is the purpose of the present investigation to extend the available information on susceptibility to s.c.c. of the ferritic 18% Cr stainless steels containing from 0 to 8% Ni. It appears particularly desirable to know more about possible mechanisms that can account for the relative resistance of some ferritic-type stainless steels (body-centered cubic) and the comparable lack of resistance of austenitic alloys (face-centered cubic) of a similar or even the same composition.

Experimental Procedure

Alloys were vacuum melted by high frequency in dense pure alumina crucibles, followed by casting in purified argon by drawing up the melt into 7 or 9 mm diameter Vycor tubing and water quenching. Ingots were homogenized in argon at 1050°C for 24 hr, then cold-rolled to strip about 0.041-in. thick. Starting materials were electrolytic iron deoxidized at 1150°C for 2 hr in dry H_2 and decarburized at 760°C for 48 hr in wet H_2. Carbonyl Ni was furnished by courtesy of the

* Numbers in parentheses were estimated from first and last split heat.

International Nickel Company and pure Cr was purchased from the Electrometallurgical Company. Molybdenum was Johnson-Matthey spectroscopic grade; Mn was electrolytic grade. Chemical analyses of the cold-rolled strip are listed in Table I. Duplicate alloys A and B of the 5 and 8% Ni, and triplicate alloys A, B, and C of the 2% Ni compositions, were prepared to furnish additional test specimens; they performed similarly for any one category of composition within the experimental variations of the tests.

Specimens measuring 1 3/4 × 3/16 × 0.041 in. (4.5 × 0.5 × 0.1 cm) were sheared from the cold-rolled strip with the long dimension in the rolling direction, unless otherwise specified. They were either tested as such (*cold-rolled* 80% reduction in thickness), or water quenched from 1050°C (*water quenched*), or heated to 1050°C and subsequently annealed at 815°C for 1 hr in argon followed by air-cooling (*annealed*). In all cases, specimen surfaces were abraded with wet No. 120C silicon carbide paper followed by No. 0 emery paper. They were then degreased, and pickled in 15 v/o (volume per cent) HNO_3-5 v/o HF at 90°C for 5 min.

Specimens were bent beyond the elastic limit to a span of 1⅝ in. (4.1 cm), transferred by means of a notched gauge to insulated holders of the test apparatus, and adjusted to a final span of 1 7/16 in. (3.7 cm), avoiding springback. They were held at constant flow stress by means of a compressed spring. When tests were conducted under constant applied potential, a Ni wire or one of the same composition alloy as the specimen was spot welded to one end of the specimen and enclosed with Teflon tubing. A saturated calomel electrode at room temperature was located in a side arm containing $MgCl_2$ solution nearest the point of maximum bending and separated from the boiling $MgCl_2$ solution by a fritted glass disk. Auxiliary electrodes of graphite were located in two arms on either side of the specimen, also separated by fritted glass disks. The test apparatus employing $MgCl_2$ solution boiling at 130°C has been depicted in a former publication (8). Because of variations in batches of $MgCl_2$ as received, all solutions were prepared from salt obtained by thorough mixing of several batches. Tests were run to a maximum of 200 hr; controlled potential runs normally ran to only 50 hr because of chemical changes in the solution resulting from electrolysis. The critical potential for a given alloy was obtained by plotting failure times *vs.* controlled potentials for 10 to 15 specimens. Typical plots of this kind were presented in an earlier publication (9).

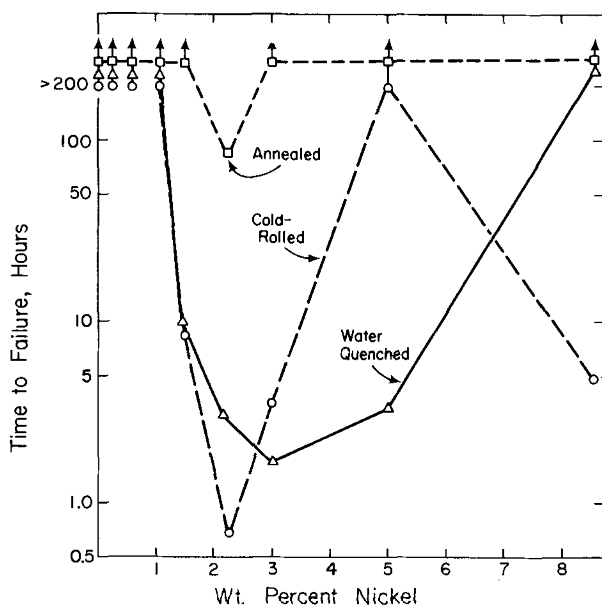

Fig. 1. Effect of alloyed nickel in 18% chromium stainless steels on stress corrosion cracking in $MgCl_2$, 130°C.

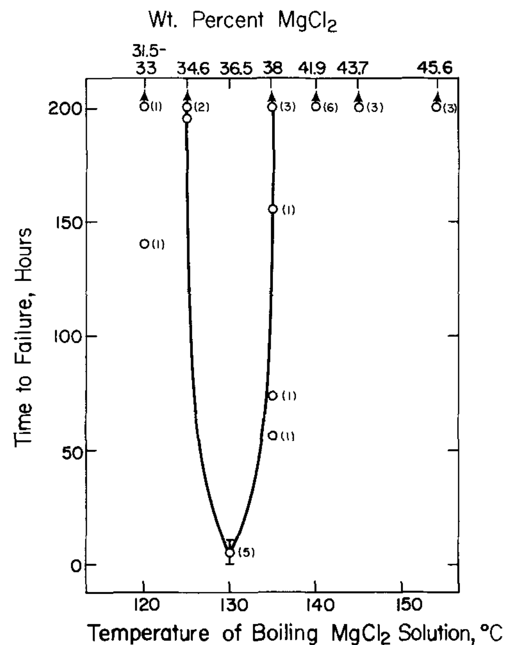

Fig. 2. Effect of $MgCl_2$ concentration on stress corrosion cracking of cold-rolled ferritic 18-8 stainless steel, boiling temperatures.

Failure Times

Cracking times of 16-18% Cr stainless steels as a function of Ni content are shown in Fig. 1. Each point represents the average of three or more tests. Most cracks followed predominantly transgranular paths, as far as could be determined, but with some evidence of partial intergranular cracking in some alloys such as the water-quenched 1.5-5% Ni compositions. No failures were observed up to 1% Ni within 200 hr, whether the alloys were cold-rolled, quenched, or annealed. At 1.5% Ni, the cold-rolled and quenched alloys failed, but the annealed alloys still resisted cracking above 200 hr. At about 2% Ni, susceptibility became maximum, and the alloy failed in short times typical of the behavior of austenitic 18-8 stainless steels. The annealed alloy remained more resistant than the quenched or cold-rolled alloy. At 5% Ni, both the annealed and cold-rolled alloys (stressed parallel to rolling direction) were resistant (>200 hr), but the quenched alloy failed. At 8% Ni, the alloy failed only in the cold-rolled condition, but this behavior turned out to be peculiar to 130°C. The same alloy, for example, as had been reported previously (5, 6) did not fail within 200 hr in $MgCl_2$ boiling at 154°C, nor did it fail at 140° or 145°C. It failed in relatively longer times at 120°, 125°, and 135°C as shown in Fig. 2. A commercial austenitic 18-8 alloy, on the other hand, cold-rolled 35% reduction in thickness, failed in shorter times the higher the temperature. Cracking times were 29, 0.3, 0.2, and 0.1 hr in $MgCl_2$ solutions boiling at 120°, 130°, 140°, and 154°C respectively (10).

The ferritic 16-18% Cr stainless steels containing less than 8% Ni failed in about the same times in $MgCl_2$ at 130° or 154°C with the exception of the quenched 5% Ni alloy which was resistant at 154°C. The Ni-free 16% Cr-Fe alloy did not fail by cracking at either temperature, but was observed to undergo pitting corrosion in long-time tests, which in the extreme caused failure by creep of the spring-loaded specimen.

It was of interest to learn whether direction of applied stress had an effect on failure times of the cold-rolled ferritic 18-8 stainless steel in $MgCl_2$ at 130° or 154°C. Five specimens at 130°C stressed parallel to the rolling direction failed in 4.9 ± 1.0 hr, whereas four specimens stressed at right angles to the rolling direction failed in 2.4 ± 0.3 hr. This difference of cracking times is not considered to be of great significance. At 154°C, cold-rolled ferritic 18-8 did not fail within at least 200 hr whether stressed parallel or at right angles

Table II. Effect of alloyed Ni, Mn, and Mo on cracking times in $MgCl_2$, 130°C

Alloy	Time to failure, hr: Water quenched from 1050°C	Cold-rolled 80% reduction in thickness	Annealed 815°C, 1 hr
16% Cr-Fe	>200 [3]*	>200 [3]*	>200 [3]
18% Cr, 1.1% Ni-Fe	>200 [3]	>200 [3]	>200 [3]
19% Cr, 1.1% Ni, 1.6% Mn-Fe	>200 [3]	>200 [3]	>200 [3]
18% Cr, 3% Ni-Fe	1.6 ± 0.5 [3]	3.6 ± 0.3 [5] (Parallel) 1.4 ± 0.4 [3] (Perpendicular)	>200 [3]
18% Cr, 3% Ni, 1.5% Mn-Fe	3.2 ± 1.4 [4]	3.1 ± 0.6 [3]	90 ± 9 [3]
18% Cr, 3% Ni, 3% Mn-Fe	3.2 ± 1.1 [4]	2.8 ± 1 [3]	33 ± 3 [3]
18% Cr, 5% Ni-Fe		>200 [3] (Parallel) 2.2 ± 0.4 [3] (Perpendicular)	
16% Cr, 2% Mo	>200 [3]	5.6 ± 4 [3]	>200 [3]
17% Cr, 2% Ni, 2% Mo-Fe	2.0 ± 0.2 [2]	2.0 ± 0.2 [3]	2.0 ± 0.4 [3]
18% Cr, 8% Ni-Fe (Ferritic)	>200 [3]	4.9 ± 1 [5] (Parallel) 2.4 ± 0.3 [3] (Perpendicular)	>200 [3]
16% Cr, 8% Ni, 2% Mo-Fe (Ferritic)	1.4 ± 0.4 [3]	73 ± 23 [3]	7 ± 2 [3]

* The number in brackets is the number of specimens tested.

to the rolling direction. By way of contrast, the same alloy stressed parallel to the rolling direction was resistant to hydrogen cracking (>200 hr) when cathodically polarized in 5% $H_2SO_4 + As_2O_3$, but failed in short time (0.1 hr) when stressed perpendicular to the rolling direction (11). This marked difference of behavior can be taken as evidence that crack nuclei and fracture paths associated with hydrogen cracking, and which are oriented by cold rolling, are not the same nuclei and fracture paths associated with stress corrosion cracking. Obviously the mechanisms of the two types of fracture are not the same.

The effect of small alloying additions of Mo or Mn to 16-18% Cr-Fe alloys was usually either inconsequential or in the direction of increasing susceptibility. Some of the relevant data are tabulated in Table II. Included are data on the effect of rolling direction on failure times of the 3, 5, and 8% Ni alloys showing that an appreciable effect is observed only with the 5% Ni alloy. Manganese tends to make the 3% Ni alloy, as annealed, more susceptible; it has no measurable effect on the 1.1% Ni alloy. The quenched and cold-rolled alloys are unaffected. Riedrich and Kohl (4) found that 9-18% Mn in quenched alloys containing 5-16% Cr were resistant to cracking in $MgCl_2$ at 154°C provided that Ni was below 1.5-2% and Cu below 0.7%. Two per cent Mo addition is not damaging (Table II), in accord with conclusions of Bond and Dundas (7), except for the cold-rolled state in which the Mo alloy fails. For the annealed alloy, molybdenum combined with 2% Ni is worse than Ni alone. The combination of 2% Mo with 8% Ni makes s.c.c. properties of the ferritic alloy worse except perhaps for the cold-rolled alloy. A few 2% Ni stainless steels were made up with additions of 0.08-0.15% Sn, or with 0.5% Zr but these elements had no marked effect on time to cracking in $MgCl_2$.

Tests in 35% NaOH + 0.1% PbO boiling at 126°C showed that both the cold-rolled 16% Cr-Fe and the cold-rolled 17% Cr, 2% Ni-Fe alloys were resistant to cracking for at least 300 hr. The former alloy showed evidence of superficial intergranular corrosion which appeared to be independent of stress. The two alloys also did not fail by s.c.c. within 200 hr in 60% $Ca(NO_3)_2$,, 3% NH_4NO_3 solution boiling at 110°C. These results confirm similar data reported earlier by Bond, Marshall, and Dundas (12).

Critical Potentials

A specific potential below which s.c.c. of 18-8 stainless steel is inhibited in boiling $MgCl_2$ or $CaCl_2$ solutions has been reported by several investigators (8, 9, 13-15). For cold-rolled commercial austenitic 18% Cr, 8% Ni alloy (35% reduction in thickness) in $MgCl_2$ boiling at 130°C, the observed value is −0.145V (SHE) (9) and for the quenched alloy it is −0.130V (16). With increasing amounts of alloyed Ni, this value becomes more noble, reaching −0.10V for a cold-rolled stainless steel containing 21% Cr, 34.8% Ni (8). Whenever the prevailing steady-state corrosion potential of the alloy (measured for the stressed or unstressed alloy) is noble to the critical potential, which is the normal situation for austenitic 18-8 immersed in boiling $MgCl_2$ solution, cracking can and does take place. But at higher Ni compositions (>26%), the corrosion potential tends to be less noble than the critical potential and hence cracking is no longer observed (maximum test period: 200 hr).

In evaluating the present ferritic alloys, the same relation of corrosion potential to critical potential describes whether or not cracking takes place. For example, although the stressed cold-rolled low-nickel alloys (<1.5%) and the 5% Ni alloy did not fail on immersion in boiling $MgCl_2$ solution, cracking was observed nevertheless whenever the alloys containing >0.2% Ni were anodically polarized above a specific critical potential. Cracking of the 0.2% Ni alloy was uncertain because of simultaneous pitting. A critical potential was also typical of the higher Ni compositions (1.5-8%) which failed spontaneously in immersion tests, but which required cathodic polarization in order to inhibit cracking. The Ni-free alloy and the annealed or quenched 0.2-1.1% Ni alloys were exceptions in that they did not crack in either immersion tests or when anodically polarized; when polarized they tended to thin and pit instead. For this reason, a critical potential for s.c.c. cannot be assigned to these particular alloys.

The corrosion and critical potentials for various cold-rolled alloys are plotted in Fig. 3. The steady-state corrosion potentials, as measured 48 hr after immersion for unstressed specimens, lie below the critical values up to and including 1.1% Ni; these alloys do not fail when unpolarized. The indicated critical potential of −0.26V for the 0.2% Ni alloy is uncertain, for reasons mentioned earlier, but neither pitting nor cracking occurs below this value of potential. Above 1.1% Ni, the corrosion potential continues to shift with increasing Ni in a noble direction,

Table IV. Effect of galvanic coupling on stress corrosion cracking of stainless steels in $MgCl_2$, 130°C

Alloy	$\phi_{crit.}$, V	Coupled to equal area of	$\phi_{corros.}$, V	Failure time, hr Uncoupled	Failure time, hr Coupled
17% Cr, 2% Ni (Cold rolled)	−0.225	16% Cr-Fe	−0.360	0.7	>200
18% Cr, 8% Ni (Cold rolled)	−0.145	17% Cr-Fe (Commercial)	−0.225	4.9	>200

but the critical potential takes a sudden drop corresponding to observed failures of the 1.5-3% Ni alloys. At 5% Ni, the corrosion potential is 10 mV active to the critical potential and hence this alloy as cold rolled and unpolarized does not fail. At 8% Ni, the corrosion potential is 10 mV noble to the critical potential and the alloy fails. However, when the latter alloy is quenched from 1050°C, the corrosion potential becomes 30 mV active to the critical potential and now the alloy does not fail. Corresponding potentials for the quenched 2-8% Ni stainless steels are given in Table III. Cold rolling of the 2 and 8% Ni alloys, it will be noted, shifts the critical potential in the active direction corresponding to greater susceptibility to s.c.c. The reverse situation, however, applies to the 5% Ni alloy. To make certain this was not an experimental accident, a second alloy of the same approximate composition (Table I) was prepared, but the critical potential of this alloy as cold rolled, −0.140V, was still noble to the observed value for the alloy as water quenched, −0.185V, in agreement with the sequence of values shown in Table III for alloy B. As is discussed later, this alloy is an exception probably because its behavior is sensitive to rolling direction.

Failure of the cold-rolled ferritic 18-8 in $MgCl_2$ at 130°C but not at 154°C is also explained by the relative potentials at either temperature. At 130°C, the corrosion potential is noble to the critical potential by 10 mV and the alloy fails (Table III), but at 154°C, the corrosion potential, −0.095V (SHE), is active to the critical potential, −0.060V, by 35 mV and the alloy does not fail. In other words, in summary, whether a susceptible stainless steel, either austenitic or ferritic in structure, fails spontaneously by s.c.c. in a given chloride environment depends on the relative order of corrosion and critical potentials.

For the few alloys that were studied, molybdenum additions to the ferritic alloys tended to shift the corrosion potential in the noble direction more so than the critical potential. However, more data are needed in order to reach any general conclusions.

Galvanic Coupling

The necessity of a corrosion potential noble to the critical potential for spontaneous s.c.c. suggested the important conclusion that galvanic coupling should in principle induce or inhibit cracking of any susceptible alloy. Two such couples are listed in Table IV. Both the cold-rolled 2 and 8% Ni alloys, which normally fail in short times, do not fail when coupled to a ferritic stainless steel which polarizes them to a potential that is active to their critical potentials. It was shown previously (8) that pure nickel coupled to stressed 18-8 austenitic stainless steel inhibits failure in $MgCl_2$ solution at 130°C because nickel with a more active corrosion potential (−0.18V) in this solution polarizes the couple to a value more active than the measured critical potential (−0.145V) of 18-8.

Discussion

Annealing at 815°C for 1 hr improves resistance to transgranular stress corrosion cracking of the ferritic stainless steels containing up to 8% Ni. This heat-treatment is also effective for improving resistance of ferritic stainless steels to intergranular corrosion (not requiring stress) and is usually recommended for this purpose. Annealing in this instance probably reduces Cr concentration gradients established in the vicinity of carbide precipitates localized at grain boundaries (17-19). Whether C (or N) in the small amounts that are normal to the present alloy series is responsible for transgranular s.c.c. is not established by the present or any previous data. Stress corrosion cracks may follow paths other than the grain boundaries where carbides tend to concentrate, suggesting that susceptibility has no obvious relation to carbides or associated Cr concentration gradients. In addition, the low solubility of C in the b.c.c. ferritic lattice argues against any important role played by C, but tests on C-free alloys are probably needed to resolve the question. The beneficial effect of annealing is likely related to reduced imperfection density, as is discussed later.

Additions of small amounts of Ni to 15-18% Cr-Fe account for alpha and gamma phases in equilibrium at both annealing and quenching temperatures as the phase diagrams of Fig. 4 show (20). A consequent two-phase structure is observed under the microscope for 2-5% Ni alloys (Fig. 5). Both phases are ferritic, consisting of the b.c.c. structure, as was proved for the present alloy series by x-ray determinations, but they differ in Cr and Ni content. The two-phase structure is not required for susceptibility to s.c.c. because a still lower 1.5% Ni composition which is single phase (as shown by microstructure) nevertheless fails when cold

rolled or quenched (Fig. 6). The resistant 8% Ni alloy is single-phase martensite as quenched.

Increased corrosion of test specimens at the base of a notch, supposedly brought about by small alloyed nickel additions, is not likely to account for initiation of cracks nor their propagation. For one thing, cold work, if it has an effect at all, usually increases the corrosion rate, but cold-worked specimens do not crack in appreciably shorter times compared to the quenched alloys except for the 8% Ni alloy. For the latter alloy, failure occurs at 130°C but not at 154°C, despite cold working. Cold working of the 5% Ni alloy actually improves resistance to s.c.c. Second, if the critical potential is the potential below which the corrosion rate is severely limited or is zero (open-circuit anode potential), it is impossible to have a corrosion cell in which the observed corrosion potential is active to such a potential. The corrosion potential for any corrosion cell must always be noble to the open-circuit anode potential. Since this expected relation is not observed for the present alloys, the critical potential must have another interpretation, as has been discussed previously (8, 9).

Fracture of a supposed oxide film rich in nickel or any other element is also an unlikely mechanism because the low-Ni alloys fail independent of time of anodic polarization during which an oxide film can form provided the polarized potential is above and not below the critical value. And the higher Ni alloys which fail spontaneously continue to fail when cathodically polarized unless the polarized potential is below the critical value. Stainless steels containing more than 45% Ni, or none, do not fail at all whether or not they are polarized. Furthermore, either cold-rolled or quenched 1.5-3% Ni alloys fail spontaneously but only the quenched and not the cold-rolled 5% Ni, and the cold-rolled but not the quenched 8% Ni alloys fail, which would require unusual oxide properties to account for such varied behavior.

It seems more likely that Ni influences the imperfection structure of the plastically deformed alloy, allowing damaging Cl^- ions to adsorb on appropriate imperfection sites located at the alloy surfaces and to reduce metal bond strength. Such adsorption favors both crack initiation and crack growth (stress sorption cracking) (21). Whether or not adsorption occurs depends not only on a favorable imperfection array, but also on a favorable electrical field; in other words, the required adsorption takes place only above but not below a well-defined critical potential. The effect of Ni on the imperfection structure of the alloy presumably increases with Ni content, but the affinity of surface imperfections for Cl^- ions diminishes with Ni content (negative free energies of formation are in the order: $CrCl_2 > FeCl_2 > NiCl_2$). Bergen (22) showed, for example, that surface migration of radioactive Cl^- ions toward the region of maximum stress (highest imperfection density) in an austenitic 18% Cr stainless steel decreases as Ni content increases from 9.9 to 33%. These two opposing tendencies probably account for maximum susceptibility of 18% Cr-Fe stainless steels to cracking in chloride solutions at 2% Ni. In other media, *e.g.*, OH^- and NO_3^- solutions, a parallel affinity of imperfection sites does not exist regardless of Ni content, and hence s.c.c. is not observed. Accordingly, annealing of the present alloys at 815°C leads to greater observed resistance to failure in $MgCl_2$ solution, probably because imperfections favorable to s.c.c. are annealed out, or their subsequent formation in the strained alloy is inhibited.

The effect of Ni on susceptibility to s.c.c. in $MgCl_2$ solution is also clearly seen in parallel properties of Ni-Fe alloys. Copson (23) showed that iron itself did not fail, but alloys containing up to 8.7% Ni did fail, and there was again no failure at the next higher Ni contents of 28 and 42%. Royuela and Staehle (24) showed similarly that stressed Ni-Fe alloys failed in $MgCl_2$ up to and including 25 a/o (atom per cent) Ni, but not at higher Ni compositions. Present data obtained in $MgCl_2$ at 130°C showed that low-carbon Ni-Fe alloys undergo s.c.c. at 4.6 and 11.9% Ni (failure time: 6 and 17 hr, respectively); they did not fail at 2.3 and 3.5% Ni (>200 hr) or at still lower Ni contents, but with some tendency toward pitting and increased general corrosion for the lowest Ni alloys. Nickel alone, therefore, and not chromium or the passivity it confers, is apparently responsible for the observed susceptibility of the ferritic Cr-Fe-Ni stainless steels. Chromium may shift the range of Ni content within which the alloys are susceptible, but cracking can occur without it. A suitable imperfection array, the alloy composition, and the make-up of the environment, in turn, determine the critical potential above which Cl^- ions can adsorb attended by crack initiation and below which they desorb without subsequent cracking. These factors may also shift the corrosion potential in relation to the critical potential and thereby influence the possibility of spontaneous cracking.

Additional cold work of the 8% Ni alloy is necessary to shift the critical potential below the corrosion po-

Table V. Critical and corrosion potentials in $MgCl_2$, 130°C of 18-8 stainless steel quenched from 1050°C

	$\phi_{crit.}$ (SHE), V	$\phi_{corros.}$ (SHE), V (48 hr)	Failure time, hr
Ferritic (18.3% Cr, 8.4% Ni, 0.001% C)	−0.100	−0.130	>200
Austenitic (18.8% Cr, 9.2% Ni, 0.06% C)	−0.130	−0.090	1.4 ± 0.1

tential, accompanied by spontaneous cracking. Any predicted effect of cold work on behavior of the 2 and 5% Ni alloys is complicated by their two-phase structure. Susceptibility of the latter compositions depends both on the relative susceptibility of each phase, and the degree to which the two phases are interspersed. If the resistance of one phase is much greater than the other because of composition differences, cold work would then increase the difficulty of crack propagation through the more susceptible phase. This situation probably accounts for the observed resistance of the cold-worked 5% Ni alloy stressed parallel to the rolling direction. When the alloy is stressed perpendicular to the rolling direction, cracks through the more susceptible phase meet fewer barriers interposed by elongated grains of the resistant phase, and hence the alloy fails (Table II). The 2 and 3% Ni alloys, on the other hand, are less affected by cold work probably because the two phases are both susceptible to s.c.c., and hence their relative dispersion by cold work has little effect on rate of crack propagation. Direction of rolling of the 3% Ni alloy is not of great consequence (Table II).

In addition to an effect of alloyed Ni, lattice structure of the alloy apparently also plays a part in the formation of favorable imperfection sites. As mentioned earlier, the corrosion potential of a quenched ferritic 18-8 is 30 mV active to its critical potential, hence the alloy does not fail. To the contrary, the corrosion potential of a quenched austenitic 18-8 is 40 mV noble to its critical potential and the alloy fails within a short time (Table V). It appears, therefore, that surface imperfections generated by straining a quenched austenitic 18-8 are better adsorption sites for damaging Cl^- ions than are comparable imperfections generated in a quenched ferritic alloy of the same approximate composition. Accordingly, the critical potential for austenitic 18-8 is 30 mV active to that for the ferritic alloy. The corrosion potential, on the other hand, which is determined by the electrochemical polarization characteristics of the corroding alloy, including effects of surface (sometimes visible) oxide films (8) is more noble for the austenitic compared to the ferritic 18-8. The effect of lattice structure on both critical and corrosion potentials explains, therefore, why ferritic 18-8 is resistant but austenitic 18-8 is susceptible to s.c.c.

Conclusions

1. Ni-free 16-18% Cr stainless steels are resistant to s.c.c. in boiling $MgCl_2$ solution (130° and 154°C), in boiling 35% NaOH + 0.1% PbO (126°C), and in boiling calcium nitrate-ammonium nitrate solution (110°C). Addition of 2% Ni makes the alloy susceptible to failure in $MgCl_2$ solution but not in the other media.

2. Maximum susceptibility to s.c.c. in $MgCl_2$, 130°C, is observed at 2% Ni. Alloys containing less than about 1% Ni are resistant whether cold rolled, annealed, or water quenched. Alloys containing >2% Ni annealed at 815°C, 1 hr, are resistant.

3. Cold-rolled ferritic 18-8 fails in $MgCl_2$ boiling at 130°C but not at 154°C. Susceptibility to s.c.c. is not dependent on rolling direction, contrary to a dependence when failure is by hydrogen cracking.

4. Whenever the prevailing corrosion potential is noble to the critical potential for s.c.c., but not otherwise, the alloys fail spontaneously. This relation applies to the behavior of galvanic couples and also accounts for the resistance of cold-rolled ferritic 18-8 in $MgCl_2$ at 154°C but not at 130°C, and to the resistance of the quenched ferritic but not of the quenched austenitic 18-8.

5. Alloyed Mn in 16-18% Cr-Fe alloys has but little effect on susceptibility; alloyed Mo can be damaging.

6. The present results are not readily explained by electrochemical dissolution of metal atoms at the base of a notch, or by rupture of oxide or passive films. They are more successfully explained by adsorption of damaging Cl^- ions on appropriate defect sites favored by alloyed Ni which reduce bond strength of strained metal atoms at a notch or incipient crack (stress sorption cracking).

The Anodic Deposition of Oxide Films on Platinum from Ferrous Sulfate Solutions

J.-L. Leibenguth[1] and Morris Cohen*

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada

ABSTRACT

A study has been made of the effect of pH and Fe^{++} ion concentration on the anodic deposition from ferrous sulfate solutions of ferric oxide type films on a platinum substrate. Examination of the deposition kinetics and film composition was made. The rate of deposition was increased by increases in pH and ferrous ion concentration. The films were mainly γ-FeOOH but also contained small amounts of water, Fe^{++}, and sulfate ions. The proportion of sulfate decreased markedly with an increase in pH. It was concluded that the film is deposited mainly by the diffusion and oxidation of a complex hydroxy ferrous ion with some contribution from a sulfate containing ion. The relationship of these films to anodically formed passive films is discussed.

It was shown in previous work that hydrated iron oxide films can be deposited on both iron (1, 2) and platinum (3) by the anodic oxidation of ferrous ion dissolved in borate solutions. The films contained quite large amounts of boron and appeared to be a mixture of hydrated iron and boron oxides. It was not possible to obtain electron diffraction patterns from the films.

In this paper the deposition of films on platinum from sulfate solution is described. The sulfate ion is not as strong a complexing agent as borate ion, and it was believed that purer and more crystalline-hydrated iron oxide films could be obtained. The effect of pH on the rate of deposition and composition of the film was also studied.

Experimental

The electrolytic cell with its accompanying storage vessels, gas deaerating and bubbling system, and electrical devices were the same as described previously (2, 3). High-purity tank argon, further purified by passage through a copper column, was used as both purging and stirring gas. The volume of the solution was 30 cc.

Platinum specimens were 1×5 cm with handles 0.2×2 cm cut from smooth sheet. Reactive metals in the platinum were removed by alternate cycles of oxidation and treatment in hot 6*N* HCl. After this the specimens were heated to 800°C and pumped to a vacuum of 10^{-8} Torr. Hydrogen (1 Torr) was then introduced and heating continued for 6 hr at 800°C. Reflection electron diffraction after this treatment gave only a few broad weak rings characteristic of smooth polycrystalline platinum. The potential of clean specimens was -640 mV *vs.* SCE on cathodic polarization at 10 μA/cm^2. Contaminated specimens exhibited much more negative potentials.

Anodic deposition.—All anodic oxidation experiments were carried out at a constant potential of $+300$ mV *vs.* SCE. The supporting electrolyte was a 0.15*N* (in SO_4^{--}) solution of $(NH_4)_2SO_4$ to which NH_3 was added to adjust the initial pH. The iron was added to the solution in the form of ferrous ammonium sulfate. Both solutions were deaerated separately before mixing in order to avoid oxidation of the ferrous ion. The cell was flushed with deaerated electrolyte to remove oxygen from the system. Current density *vs.* time was recorded and the curves integrated by planimeter to obtain coulombs. The ferrous concentration of the solution was measured before and after the experiments. Specimens were weighed before and after anodic deposition to $\pm$ 2 μg on a Mettler M5 balance.

* Electrochemical Society Active Member.

[1] Present address: Institut de Chimie, Université Louis Pasteur, Strasbourg, France.

Key words: iron oxide, passivity, anodic deposition.

Examination of the deposited films.—In order to determine the sulfate content of the film, S^{35} isotope in the form of sulfate ions was added to some of the solutions. The procedures and precautions for this measurement have been published previously (4).

The crystal structure of the oxide was examined by reflection electron diffraction and x-ray diffraction. Using a Debye Scherrer Camera and chromium Kα radiation the x-ray diffraction technique required films at least 400-500Å thick (5) to give patterns.

Some of the specimens were cathodically reduced at a current density of 10 μA/cm^2 in a borate buffer solution of pH 8.4.

A number of the film-covered specimens were heated in an oxidizing atmosphere (air or oxygen at 1 Torr) at 400°-500°C or in vacuum over a range of temperatures. In the case of the vacuum heating the evolved gases were monitored with a mass spectrometer. The specimens were examined by diffraction and chemical analysis after heating.

Many of the films were dissolved in HCl for chemical analysis. Normally, warm 1*N* HCl was used. For specimens which had been heated to 800°C hot 6*N* HCl was required for dissolution of the film. Total iron was determined by the o-phenanthroline method and ferrous iron by α-α' bipyrydyl. Blanks were run in all cases to correct for iron in the reagents.

Results

Formation of Films

Two series of deposition experiments were carried out. In the first the solutions started at the same pH but contained various concentrations of ferrous ion. Results from this type of experiment are shown in Fig. 1. In the second series the initial iron concentration was the same and the pH was varied. The shape of the log current-log time curves were similar to those shown in Fig. 1, with the initial deposition rate being greatest at the higher pH's. A plot of coulombs *vs.* time for this type of experiment is shown in Fig. 2. These curves are similar to those observed using borate solutions (3).

In all cases there is a rapid drop in current density within the first 10 sec. This decrease is considered to be due to the buildup of a continuous resistant film. The charge passed during this initial stage is of the order of 1 to 2×10^{-9} eq./cm^2. Assuming the film composition to be FeO(OH) with a density 4.3 the thickness of this initial continuous film is less than 25Å.

During the steady-growth region the slowly decreasing rate of deposition is a rather complex function of film thickness, Fe^{++} concentration in the solution, and pH of the solution during deposition. The electrolyte is a poor buffer in the pH range used in these experi-

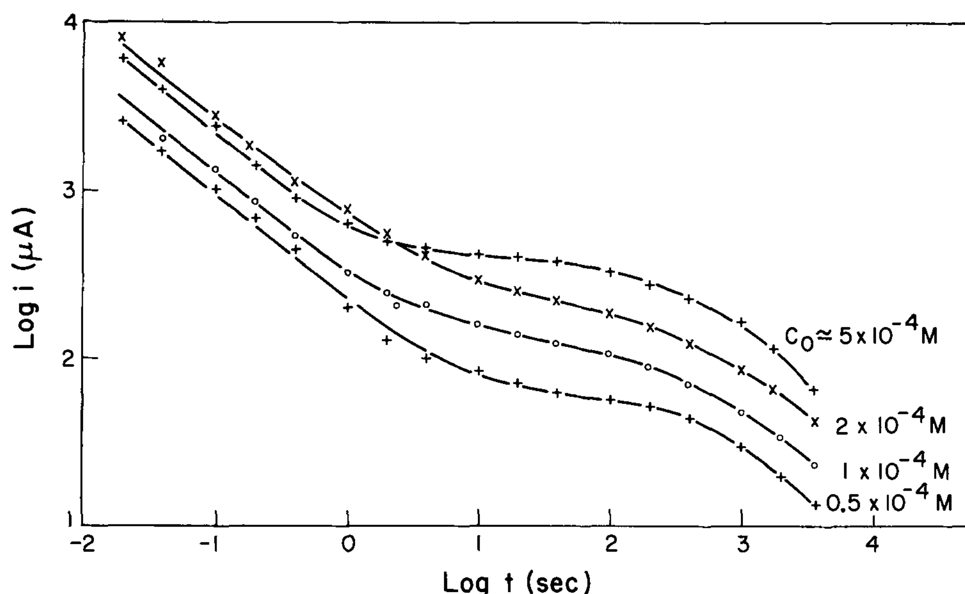

Fig. 1. Effect of initial Fe^{++} concentration on deposition current. Initial $pH \simeq 7.0$.

ments, and there is some decrease in pH during the experiment. This decrease is negligible at pH 8.0 but is 0.3 at a pH of 6.6. In general the rate of deposition increases with increases in either Fe^{++} concentration or pH.

Current efficiency for formation.—The amount of film deposited was determined by weighing the platinum specimens before and after deposition. This weight was converted to equivalents on the basis of a film composition of FeOOH (nFeOOH $= \mu g \times 1.125 \times 10^{-8}$). The amount of iron used to form the film was determined by before and after analysis of Fe^{++} in the solution. It was converted to equivalents of FeOOH, and is referred to in the tables as Qi.

These results were compared with Qe, the number of coulombs passed (also expressed as equivalents and based on the reaction $Fe^{++} \rightarrow FeOOH$ and are shown in Tables I and II for either constant initial iron concentration or constant pH. There is excellent agreement between Qi and Qe in all cases. The weights of the films are all too high if based on pure FeOOH as the composition of the deposited film. The effect of time of deposition (or thickness of deposit) is shown in Table III. Once again there is good agreement between Qi and Qe (indicating a high current efficiency for deposition) and also an overweight of films in all cases. The overweight ratio, $n_{FeOOH/Qe}$, decreases as the film thickens.

Sulfur content of films.—The amount of sulfur in the films, probably present as SO_4^{--} ion, was determined by the use of S^{35} as a tracer (4). The effect of initial pH on the amount of sulfur in the film is shown in Fig. 3. There is a marked decrease in the per cent sulfate content of the film as the pH increases. The effect of

initial Fe^{++} ion concentration is not nearly as dramatic, (Table IV). There is a small increase in per cent sulfate at the higher initial Fe^{++} ion concentrations. This may be partly related to the thickness of the film. As shown in Table V, there is a definite increase in the ratio as the film thickens. This latter increase is probably enhanced by the lowering of pH during deposition at pH 7.

Fe^{++} content of films.—Some of the deposited films were dissolved in 1*N* HCl and the resulting solutions analyzed for total iron and ferrous ion. In all cases a small amount of Fe^{++} (<5%) was found to be present in the films. The total iron found by dissolving the films is in good agreement with the total iron calculated from the current-time curves (*Qe*). Some results are shown in Table VI. The per cent of ferrous ion in the films appears to decrease as the thickness of the films increases (due to either higher initial pH or Fe^{++} ion concentration in the depositing solution).

Structure of films.—As deposited.—The films were examined by both x-ray diffraction and electron diffraction. No patterns were obtained by x-ray diffraction—which would indicate that either the films were too

thin and/or the crystal size too small to be detected by x-rays. Good patterns corresponding to γ-FeOOH were obtained with electron diffraction.

On heating.—When the specimens were heated in air or oxygen water was driven off and the γ-FeOOH was converted (at 500°C or higher) to α-Fe_2O_3. If the specimen was first heated *in vacuo* and then air or oxygen admitted a cubic oxide structure was observed by electron diffraction. Chemical analysis of the dissolved oxide showed the presence of only a small amount of Fe^{++} in the oxide. The bulk of the cubic oxide was probably γ-Fe_2O_3. Heating in vacuum gave quite variable results which were highly dependent on the pretreatment of the platinum. Unless great care was taken to purify the platinum with respect to both carbon and traces of other elements a proportion of the deposited oxide was reduced to iron and dissolved in the platinum. This reduction was mainly caused by carbon, and mass spectrometry of the gases evolved on heating showed the formation of both CO and CO_2. The dissolved iron in the platinum could be removed by heating in oxygen and then dissolving the resultant surface oxide in acid. Electron diffraction results from an "as deposited" specimen and a vacuum heated specimen are shown in Fig. 4.

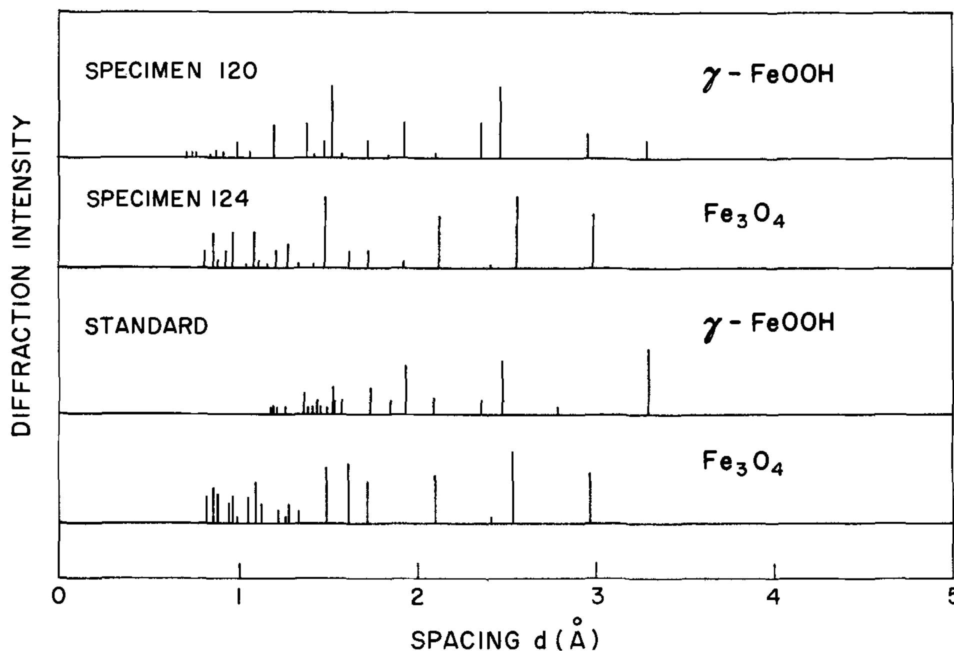

Fig. 4. Electron diffraction patterns of deposited films compared to standard patterns of Fe_3O_4 (γ-Fe_2O_3) and FeOOH. Specimen 120—as deposited. Specimen 124—heated *in vacuo* and then exposed to oxygen. Temp. < 500°C.

Cathodic Reduction

Some of the films were cathodically reduced in the deaerated borate-boric acid buffer at a constant current density of 10 $\mu A/cm^2$. The potential-time curves showed two arrests, with a rather sharp inflection point between the two. When the final steady potential of -860 mV (*vs.* SCE) was reached no further reduction of the film to ferrous iron in solution took place, although it was obvious that some film remained on the specimen. If at that stage the solution was changed, without exposure of the specimen to oxygen, the cathodic-reduction potential dropped rapidly to -860 mV with no reduction of the film. However, if the specimen was exposed to air before the second cathodic reduction step, the film was further reduced. By running a series of reductions with intermediate exposure to air it was possible to reduce the film to an equivalent thickness of about 20-30Å. Electron diffraction examination of the film after each reduction gave a pattern corresponding to γ-FeOOH, the same as that of the originally deposited film. An example of a series of cathodic reductions on one specimen, with intermediate exposure to air, is given in Fig. 5.

When a clean platinum specimen is treated cathodically at 10 $\mu A/cm^2$ in the borate buffer solution a steady potential of -640 mV is reached. The cathodic process is the evolution of hydrogen. If, however, there is iron in the solution the potential of the specimen drops to about -800 mV. The specimen becomes covered with a thin film which is soluble in HCl and corresponds to an iron oxide thickness about 20Å. This would indicate that the potential -860 mV corresponds to hydrogen evolution on deposited iron.

The estimation of the exact quantity of ferrous ion produced by cathodic reduction of these thick films is complicated by the reoxidation and deposition of some of the ferrous iron at the anode. There is also some precipitation on the walls of the vessel. Hence one analysis for reduced iron requires the dissolution of this deposited and precipitated iron in dilute HCl. Some of the ferrous ion is reduced to metallic iron at the cathode and the ease of hydrogen evolution on this iron accounts for the cessation of cathodic reduction of the remaining film. By taking these factors into consideration it has been possible to balance deposition equivalents and cathodic reduction equivalents.

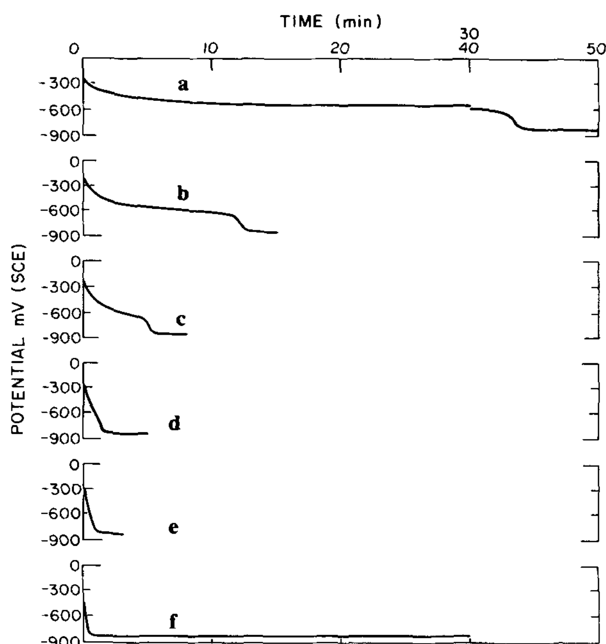

Fig. 5. Successive cathodic reduction of film with intermediate exposure to air.

Discussion

As can be seen in Fig. 1 and 2, films are deposited from the sulfate solutions with much the same current and coulomb-time characteristics as in the deposition from borate solutions. However, the films differ considerably in terms of both chemical composition and physical structure.

Composition of deposited films.—The major portion of the film has a composition corresponding to FeOOH. However all films formed under the range of conditions studied in this work contain varying small amounts of water, sulfate, and Fe^{++} ions. The per cent of water decreases as the film thickens (Table III). The per cent of sulfate decreases as the *p*H increases. At constant *p*H the per cent of sulfate is independent of thickness. At constant *p*H the per cent of Fe^{++} decreases with thickness.

Properties of deposited films.—In contrast to the "amorphous" films deposited from borate solution the films deposited from the nearly neutral sulfate solutions are mainly crystalline γ-FeOOH. They also contain small amounts of water, sulfate, and ferrous ions.

When the films are heated, they lose both water and sulfur and, depending on the conditions of heating, can be converted to either γ-Fe_2O_3 or α-Fe_2O_3. The films which were converted to γ-Fe_2O_3 contain small amounts of Fe^{++} ion, probably present in the films before heating. If the platinum supporting electrode contained carbon or other available reducing agents (due to inadequate pretreatment), the deposited films were converted on heating to Fe_3O_4 with some dissolution of iron into the platinum.

None of the deposited films could be completely cathodically reduced in a single step. Although the residual film gave the diffraction pattern of γ-FeOOH cathodic reduction to dissolved Fe^{++} in solution had ceased and the potential had dropped to -860 mV (*vs.* SCE). If the specimen were then exposed to air further cathodic reduction could take place. A cathodic potential of less than -800 mV could be obtained with platinum on which iron had been electrochemically deposited. This would indicate that the cathodic reduction of γ-FeOOH ceased when sufficient iron had been deposited from Fe^{++} in solution to either cover the γ-FeOOH and/or produce an alternate current carrying path to the underlying platinum. In any case the preferred cathodic reaction became hydrogen evolution. Exposure of the partially reduced film to air resulted in the oxidation of the finely divided deposited iron, and further reduction of the deposited oxide became possible. A more detailed study of cathodic reduction of deposited γ-FeOOH will be presented in a subsequent paper.

Mechanism of deposition.—Under all the conditions used in this study the films were deposited with approximately 100% current efficiency with respect to the nominal reaction.

$$Fe^{++}{}_{sol} \rightarrow Fe^{+++}{}_{film} + e$$

The rate of deposition at constant potential was dependent on both the hydroxyl ion (*p*H) and Fe^{++} ion concentration. The concentration of sulfate in the film decreased as the *p*H increased. These observations are all consistent with the concept that the film is formed by the direct oxidation of ferrous containing

species in the solution. Some of the possible ionic equilibria are as follows

$$Fe^{++} + OH^- \leftrightarrows (FeOH)^+ \quad [1]$$

$$(FeOH) + OH^- \rightleftarrows Fe(OH)_2 \quad [2]$$

$$Fe(OH)_2 + OH^- \rightleftarrows (HFeO_2)^- + H_2O \quad [3]$$

$$Fe^{++} + (HSO_4)^- \leftrightarrows (FeHSO_4)^+ \quad [4]$$

$$Fe^{++} + SO_4^{--} \leftrightarrows FeSO_4 \quad [5]$$

$$FeSO_4 + (OH)^- \leftrightarrows (HFeOSO_4)^- \quad [6]$$

The equilibria tend to go from [1] to [3] and [4] to [6] as the pH increases. However the hydroxyl ion complexes are more stable than the sulfate ion complexes, and one would expect that the ratio of oxidation of ferrous ion from the hydroxyl complexes to oxidation from the sulfate complex would increase as the hydroxyl ion concentration increases. This is confirmed by the results shown in Fig. 3.

The rate of oxidation will depend on the rate of arrival of the ferrous ion complex at the anode. This rate was shown to be dependent on both Fe^{++} ion and hydroxyl ion concentration, which would indicate that the major portion of the current is being carried by hydroxyl ion complexes. This also follows from the relatively small amount of sulfate in the film even at the lowest pH tested. The greater ease of migration of the less positively charged hydroxy complex in the diffusion layer probably accounts for both the rate effect of pH and the formation of FeOOH rather than Fe_2O_3.

As was the case with deposition from borate, there is a very rapid decrease in current during the deposition of the first 20-30Å of oxide. This is probably due to the relatively high resistance of the FeO(OH) film.[2]

[2] Assuming an electronic resistance of 10^{14} ohms/cm^3 for FeOOH a 30Å film would add a resistance of 30×10^6 ohms to the original low solution resistance. This would be quite sufficient to account for the large decrease in current.

It would appear that the deposition rate at constant pH is dependent on both Fe^{++} complex ion concentration and the thickness of the film.

Implications for anodic passivity.—From this and the previous work it is clear that the possibility of film formation from Fe^{++} in solution must be considered in any study of the anodic passivity of iron, particularly in nearly neutral solutions. If the initial conditions are such that corrosion of iron takes place to any significant degree before the onset of passivity some of the passive film will contain some γ-FeOOH, as well as the anhydrous oxides. It will also contain any anionic species of the solution which may be codeposited with the iron. Hence the anodic passive behavior becomes very dependent on the method of bringing the specimen into the "passive potential" region. Any sequence which allows an initial corrosion to Fe^{++} ion, such as a slow or stepwise potential rise will automatically lead to a change in the over-all composition of the passive film (and probably its thickness). The incorporation of foreign anions in the film will also have a strong modifying effect on the stability of the final film. In all cases where deposition is possible, anodic passivation will result in the formation of a film containing several chemical species.

ABSTRACT

A 1N solution of H_2SO_4 in O^{18}-enriched water was used to study the passivity of nickel by means of nuclear microanalysis. The fixation of the first monolayer of oxygen coming from the water was shown to have a decisive effect on the passive nature of the metal; however, further thickening to a maximum of five layers also influences the anodic current through an ion transfer mechanism. The oxygen loss rate of the passive layer, measured in open circuit and under polarization near steady-state conditions, was found to be equal to $\sim 10^{13}$ atoms/cm^2·sec. The current efficiency for passive film formation was calculated and found to be low. It is suggested that passive layer growth occurs at the metal-film interface.

Investigations of the passivity of metal such as nickel, iron, chromium, and their alloys, by electrochemical (1) or optical (2) methods, have displayed the role played by oxygen in the mechanism of the formation of passive layers (3) as well as in the dissolution processes (4). A certain number of models, often controversial, have been proposed on the basis of this experimental evidence (5-11). Differences among them are partly caused by a lack of quantitative experimental data on the oxygen content in passive layers, and on its behavior.

Key words: corrosion, dissolution, nuclear microanalysis, O^{18} tracing, nickel, passivation, passive film thickness, polarization, sulfuric acid.

In this work, we carried out a microanalysis of the oxygen isotopes by means of nuclear reactions [$O^{16}(d,p)O^{17*}$ and $O^{18}(p,\alpha)N^{15}$] to study the oxygen content of passive films formed on nickel in 1*N* H_2SO_4. The method of nuclear microanalysis which has been developed in our laboratory for the purpose of studying the anodic oxidation of "valve" metals (12-14) and of semiconductors (15), allows one to determine the number of O^{16} and O^{18} atoms/cm^2 present near the surface of the material with an experimental error of about 1% for coverages as low as one monolayer. Thus, the above method, which has been described in detail elsewhere (16, 17), provides a powerful means for studying passivity phenomena.

Nickel was chosen on account of experimental data available from previous investigations (1, 5, 6, 18). We undertook to study: (*i*) the relationship between the potential or current and the quantity of oxygen fixed on the metal surface (first results on this point have been presented in Ref. (19), (*ii*) the behavior of passive layers under polarization and in open circuit, and (*iii*) the current efficiency for layer formation.

Experimental

Application of O^{18} tracing.—The high sensitivity of nuclear microanalysis for the determination of minute amounts of O^{16} makes it very useful for the study of passivity films. However, the method cannot be applied directly since measurements are not performed *in situ*: the samples to be analyzed must be transferred from the passivation cell to the scattering chamber which is connected to the Van de Graaff accelerator. During transfer in the ambient atmosphere, some oxygen may be thermally fixed on the passivated samples, therefore changing the total content on the metal surface. In order to determine precisely the quantity of oxygen, attached to the metal, that originates from the solution, we resorted to the O^{18} tracing techniques described here.

All experiments were performed in a 1*N* H_2SO_4 degassed solution in ordinary water ("S_o16" solution), or in water enriched to about 10% in O^{18} ("S_o18" solution). Labeled water was purified under vacuum in order to eliminate impurities introduced during the process of enrichment. This method of purification has been described previously in Ref. (14). The isotopic composition of hydrogen in the O^{18} enriched water was normalized to natural abundance.[2]

The S_o18 solution was prepared by introducing labeled water into highly pure 95% H_2SO_4 of normal isotopic oxygen content. It was established by investigations on O^{18} labeling of oxygenated compounds that no isotopic exchange occurs at room temperature between the water and sulfate anions at acid concentrations similar to those used in the present experiments (20). This was furthermore confirmed by a control study of the labeling level of the water in S_o18 by the tantalum oxidation technique (21). The absence of exchange means that any O^{18} detected at the surface of the nickel actually comes from the water.

In order to remove air, purified dry nitrogen was passed through the solutions for at least 3 hr before immersing the specimen and during the experiment. On account of the high cost of the enriched solution, a special small-capacity cell was used, of about 12 cm^3. Since most of the experiments were performed in the passive range, the contamination of the electrolyte by nickel was kept at a minimum.

The time during which the samples to be analyzed were in actual contact with the ambient atmosphere was reduced to a minimum (~5 min). In order to avoid the exchange of oxygen between O^{18} enriched samples and the atmosphere, the samples were stored in dry oxygen at $-45°C$ between the end of the polarization and the beginning of analysis with the accelerator. Preliminary experiments showed that under such storage conditions, the oxygen exchange can be disregarded. Nevertheless, some oxygen exchange could have occurred just when oxygen from the atmosphere is fixed on the surface, when the sample is taken out from the enriched solution. Such an effect would decrease the quantities of oxygen 18 measured on the metal surface. We have based the interpretation of our results on the assumption that this effect is negligible.

[2] Normalized O^{18} enriched water produced at the Weizmann Institute, Rehovot, Israel. The natural abundance of O^{18} is 0.204%.

Preparation of samples.—Nickel plates of 99.99% purity were used. The samples were carefully degreased in acetone under ultrasonic vibration and then electrochemically polished for 10 min at room temperature, in stirred 54.5% sulfuric acid at 400 mA/cm^2. After polishing, the sample was carefully rinsed in triple-distilled water and kept under vacuum. Just before experiment, the samples were repolished for 1 min under the same conditions. The quantity of oxygen remaining on the surface varied from sample to sample, but lay within the limits $(6 \pm 1.5) \times 10^{15}$ atoms/cm^2. The effectiveness of the polishing procedure has been discussed in detail in Ref. (19).

The experiments were performed with a Tacussel potentiostat (Model PRT 2000 C) and potentials were measured with a high impedance Keithley voltmeter (Model 610 B). All potentials are expressed on the hydrogen scale. The experiments were carried out at $22° \pm 1°C$.

Experimental procedure.—The sample was left unpolarized for 5 min during which its potential stabilized at -60 mV. Then, cathodic polarization at -450 mV was applied for 5 min. As shown below, this procedure removed practically all the initial oxide. Polarization was then switched off for 5 min; the potential immediately rose to values near zero, decreased gradually, and stabilized at -100 mV. This phenomenon is presumably related to the expulsion of hydrogen which might be present near the surface of the metal. A positive potential was then applied by means of the potentiostat. On completing the process, the polarized samples were removed under polarization, and immediately plunged into triple-distilled water of natural isotopic composition. Preliminary experiments verified that this process stops dissolution of the passive layer and does not involve isotopic exchange of oxygen. After rinsing, samples were dried and stored in dry air at $-45°C$.

Nuclear measurements.—The analytical techniques for O^{16} and O^{18} determinations were routine, as quoted above, except for the following point. Adsorbed elements may be desorbed under bombardment due to ionization by the beam during the measurements. In the case of nickel, this problem arose and was avoided by continuously changing the impact point of the 0.2 μA beam, which has a diameter of 1 mm. The scanning speed was 0.2 mm/sec. Moreover, the use of three 3-cm^2 detectors, with a total solid angle of detection of 0.3 steradian, enabled us to keep the duration of bombardment short while getting sufficiently accurate results. It was observed that this procedure eliminates any detectable desorption of oxygen.

Results and Interpretations

The results of nuclear microanalysis yield the number of O^{18} atoms/cm^2 (N_O18) and the number of O^{16} atoms/cm^2 (N_O16) in the film. The number of oxygen atoms coming from the water, $\hat{N}_O18$, may be obtained by dividing $N_O{}^{18}$ by the water enrichment (ratio of O^{18} to total oxygen in the water), *i.e.*, by normalizing the results. Moreover, by subtracting $\hat{N}_O18$ from the total oxygen detected on the metal surface ($N_O16 + N_O18$) we can obtain ΔN_O16, the number of oxygen atoms coming from sources other than the water of the solution.

As conditions for preparation of sample surfaces were rigorously the same for all experiments, the roughness factor can be considered to be a constant. Like most authors, we take it to be equal to unity. This implies that the absolute values for quantities of oxygen as given below are in fact, upper limits of the true values. Nevertheless, we would point out that certain values (such as the relative rates of oxygen loss which are obtained from the slopes of curves showing oxygen loss transients) are independent of the roughness factor if the latter is constant for all samples.

O^{18} contents in passive layers formed in labeled solutions.—We have studied the quantity $\hat{N}_{O}18$ attached to the surface of nickel as a function of the potential V_{ox} in solutions of $S_{O}18$. Below the region of passivity, polarization was stopped upon stabilization of the current. In the region of passivity, polarization was switched off at potentials when the current density I dropped to 20 $\mu A/cm^2$. This value appeared to be the best compromise between the need for rapid experiments (owing to the very high cost of O^{18} solution and the need to reduce solution loss, etc.) and the desire to approach steady-state conditions. The time required to reach this final current density depends on the potential. It is, for example, 140 sec for V_{ox} = 640 mV and 750 sec for V_{ox} = 1040 mV. We preferred to predetermine the final current density rather than the duration of passivation, in order for the experimental conditions to be similar to those which give a linear relationship between film thickness and formation potential in anodic oxidation of "valve" metals. In fact, in the latter case, there exists an empirical relationship at constant temperature between I and V_{ox} (14)

$$I = A \exp B \frac{V_{ox}}{d} \quad [1]$$

where d is film thickness and A and B are constants.

The number of atoms ($\hat{N}_{O}18$) at the surface of the metal as a function of polarization potential applied to the sample is given typically in Fig. 1. It should be noted that repeated experiments at 1040 mV result in a scatter of 5% or less in the values for the O^{18} levels. The salient observations are:

1. No oxygen coming from the water was fixed at the surface of the nickel below the passive region.

2. The relationship between $\hat{N}_{O}18$ and V_{ox} is approximately linear in the passive region.

3. The maximum number of oxygen atoms ($\hat{N}_{O}18$) in the passive region is never more than $(6.3 \pm 0.4) \times 10^5$ atoms/cm², which corresponds approximately to 5 monoatomic layers of oxygen, assuming that one atom of Ni is bound to one atom of oxygen, or to 10Å of nickel oxide if a NiO structure with density 7.45 g/cm³ is assumed.

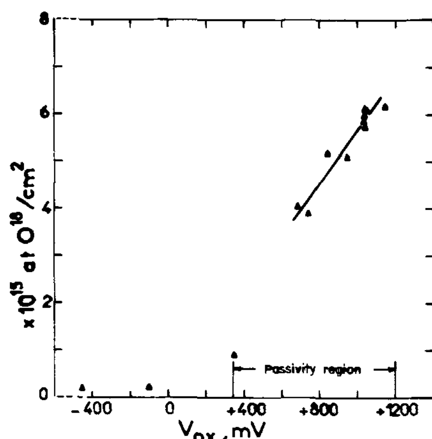

Fig. 1. Normalized O^{18} content ($\hat{N}_{O}18$) as a function of applied potential V_{ox} for samples for which polarization was stopped at a final current density I = 20 $\mu A/cm^2$ [from Ref. (19)].

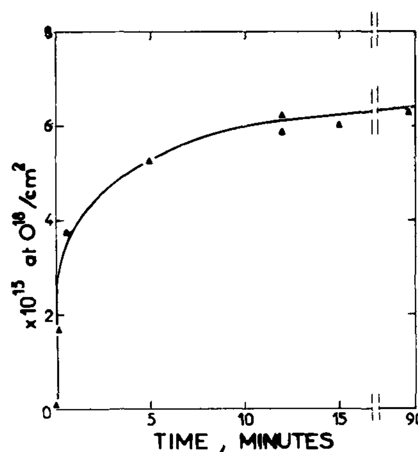

Fig. 2. $\hat{N}_{O}18$ as a function of time for V_{ox} = 1040 mV [from Ref. (19)].

In a second series of experiments, we have studied the quantity of $\hat{N}_{O}18$ attached to the surface of nickel as a function of polarization time for a constant potential V_{ox}. In Fig. 2, $\hat{N}_{O}18$ is plotted as a function of time for V_{ox} = 1040 mV. It is shown that the rate of oxygen pickup decreases rapidly with time. The formation of a first layer of $\sim 1.2 \times 10^{15}$ atoms/cm² takes place in about 10 sec. Subsequently several minutes are required to quintuplicate the quantity of oxygen and to reach a value which does not change appreciably for long polarization periods. Within the margin of error, it can be considered that at this applied potential (V_{ox} = 1040 mV), the growth of the passivation layer is negligible after a time (t_f) of 10-12 min, even though the current density, which at t_f is about 20 $\mu A/cm^2$, continues to decrease slightly for $t > t_f$ and does not actually stabilize until several hours later.

A quasi-exponential decrease of the current densities is observed during the formation of the passive films at constant potential. It was interesting to relate the number of oxygen atoms, $\hat{N}_{O}18$, attached to the metal surface (Fig. 2) to the corresponding values of the current density. We observed that the relationship between $1/\hat{N}_{O}18$ and current densities was neither linear (ohmic conduction) nor logarithmic (high-field conduction) over the whole range of current densities investigated. On the other hand a high-field conduction process may be expected to occur (1, 7, 10) in passive layers exceeding the monolayer coverage (unit-cell thickness). It might also be expected that the mechanism of ionic transport is different depending on whether the thickness of surface coverage is of the order of or less than unit cell. Our results show that the $\hat{N}_{O}18$ values exceed the equivalent of a unit-cell thickness for current densities lower than ~ 60 $\mu A/cm^2$. In this range a logarithmic law

$$1/\hat{N}_{O}18 = K \operatorname{Log} I + Ko \quad [2]$$

may be assumed. The results are illustrated in Fig. 3 for the whole range of current densities. They show indeed that Eq. [2] is followed up to current densities around 60 $\mu A/cm^2$. The much faster variation of $1/\hat{N}_{O}18$ with I above this value is discussed below.

Behavior of oxygen in the passivity layers.—Attempts were made to investigate the mechanisms of ionic transport near the steady-state conditions. The existence of a steady state was studied and discussed

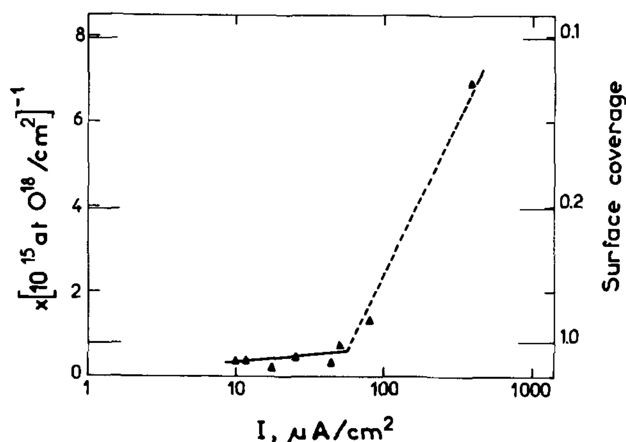

Fig. 3. Inverse of normalized O^{18} content ($1/\hat{N}_O18$) as a function of the logarithm of the current density I for V_{ox} = 1040 mV. Also shown is an ordinate depicting the surface coverage (deduced from $\hat{N}_O18$ values).

Straight lines correspond to the minimum and maximum initial slope, *i.e.* oxygen loss rate.

in a series of papers (1, 3, 6, 22-24). Two principal hypotheses have been proposed:

1. The steady state would be due to the balance between the rate of chemical dissolution of the film (rate which would be independent of the potential) and its rate of anodic formation (6, 7).

2. The growth would be stopped when the layer has a thickness sufficient to reduce the average gradient of the electrochemical potential of oxygen to such a value that the rate of inward oxygen penetration becomes negligible. This means that a quasi-stationary state is obtained when the electrochemical equilibrium of oxygen is reached (25).

Two series of experiments were carried out to study the rate of the loss of oxygen O^{18} attached to the surface of the samples, when the latter are held in the solution without polarization for various times. The samples were first polarized in S_o18 at 1040 mV with a final current density of 20 μA/cm². In the first series of experiments, the samples were held in the S_o18 solution used to prepare them, whereas for the second series, the experiments were repeated under identical conditions of film formation, but dissolution took place in an S_o16 solution.

Typical results obtained in both cases are shown in Fig. 4. The error ranges given for the curves are due to irreproducibility of the initial passive layers. The experimental points indicated by circles represent losses of O^{18} in the S_o18 solution and those indicated by squares represent the O^{18} losses in the S_o16 solution. It seems that the rate of oxygen loss is about the same for S_o16 and S_o18. This would indicate, first of all, that isotopic exchange phenomena of oxygen between the solutions and the passivity film are negligible as compared to the rate of oxygen 18 loss by dissolution. In fact, isotopic exchange should have been more rapid than dissolution for these phenomena to be distinguished in the curves of Fig. 4. By maximizing the effect of film irreproducibility, the initial rate of oxygen 18 loss v_{lo} and the corresponding errors may be estimated from the curves of Fig. 4 and is presented in Table I.

In a further series of experiments, the oxygen 18 losses under polarization were studied. Samples were initially formed down to 20 μA/cm² in S_o18 at 1040 mV and then immersed in S_o16 and kept at the same potential. After a sharp rise, the current leveled off in about 1 min to the final current value in S_o18 and continued to decrease at the same rate as in the case of an uninterrupted formation. Curve 1, in Fig. 5, shows a decrease of O^{18} in the second solution as a function of time. The value for the initial rate of oxygen 18 loss v_{lp}, which was obtained from this curve, is presented in Table I. We then performed an experiment in an inverse sequence, *i.e.*, the passivity was first induced in S_o16 under the previous conditions down to 20 μA/cm²; the samples were then immersed and polarized in S_o18. The uptake of O^{18} at the surface of nickel as a function of time is shown on curve 2 of Fig. 5. The initial rate of O^{18} uptake v_{up} is represented in Table I.

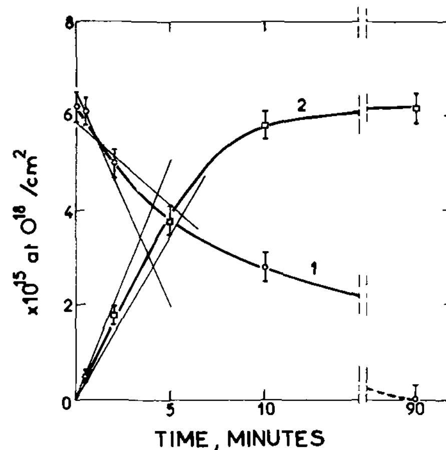

Fig. 5. $\hat{N}_O18$ loss (curve 1) or uptake (curve 2) as a function of time of polarization at 1040 mV. Curve 1: samples polarized in S_O18 at 1040 mV, then repolarized under the same conditions in S_O16 solution. Curve 2: the reverse. Straight lines correspond to the minimum and maximum values of oxygen loss and uptake.

For similar reasons as before, a large degree of error is involved in the estimation of v_{lp} and v_{up}. However, from the values in Table I, it can be deduced that the initial rates of oxygen 18 loss are the same in open circuit and under polarization, v_{lo}, v_{lp}, although it seems that v_{up} is slightly higher than v_{lp}.

Origin of oxygen coming from other sources.—The amount of oxygen in the film coming from sources other than the water (ΔN_O16) was measured for a number of cases (Eq. [3])

$$\Delta N_O16 = N_O18 + N_O16 - \hat{N}_O18 \qquad [3]$$

In principle, three sources may be assumed as possible contributors of oxygen: (*i*) the initial layer of O^{16} that remains on the metal in the solution after cathodic treatment; (*ii*) incorporation of SO_4^{-2} anions; and (*iii*) oxygen uptake from the atmosphere (oxidation or adsorption) during transfer of samples from the polarization cell to the accelerator.

Figure 6 shows ΔN_O16 as a function of potential for samples polarized in S_O18 at the final current density $I = 20\ \mu A/cm^2$. The content $\hat{N}_O18$ for these samples is also given in Fig. 6 which includes results from Fig. 1. Figure 7 shows results of ΔN_O16 obtained on samples for which losses of O^{18} in open circuit, in S_O18 and S_O16, had been studied (see Fig. 4). $\hat{N}_O18$ as a function of time is shown. It is seen from Fig. 6 and 7 that the total quantity of oxygen analyzed N_O remains practically constant ($9 \pm 1.5 \times 10^{15}$ atoms/cm²) for the quantities of $\hat{N}_O18 \geqq \sim 2 \times 10^{15}$ atoms/cm² and slightly decreases for the surfaces free of oxygen coming from the solution ($\hat{N}_O18 \approx O$). The arrows indicate the range of values of oxygen contents measured in S_O16 solution. Details of these experiments are presented in Ref. (19). It appears that, at some stage between the initial preparation of the specimen and its final analysis, any deficiency in oxygen picked up from the water is supplemented by oxygen from another source.

Since the O^{18} content was shown before to be determined only by the polarization conditions, it turns out that the additional oxygen depends on the O^{18} content and not vice versa. This would rule out the assumption that the additional oxygen originates from an initial film which remained on the film despite cathodic polarization. It is also difficult to consider a mechanism by which sulfate ions should combine more heavily with a thinner passive film.

Of the three possible sources, the most likely one seems to be the outer atmosphere during the transfer of samples.

From the above, it should follow that if indeed the outer atmosphere is contributing the extra oxygen, the total film formed in air is (3 to 5) $\times 10^{15}$ atoms/cm² thicker than the passive film.

Components of the current.—In the absence of redox systems other than the natural redox system of water in the solution studied, the current I is entirely ionic. This point, emphasized by several authors, was demonstrated for iron in $1N\ H_2SO_4$ by Franck and Weil (26). Most authors assume that the same is true for nickel. The current density I passing through the film-solution interface at any instant may hence consist of two components: I_{ox}, the part of the current which contributes to passive layer growth and I_{dis}, the dissolution current, so that

$$I = I_{ox} + I_{dis} \qquad [4a]$$

while

$$I_{dis} = I_{cat} + I_{ch} \qquad [4b]$$

as I_{dis} includes the current density I_{cat} of direct dissolution of cations and I_{ch}, which is the amount of oxide dissolved chemically, expressed in terms of the equivalent charge required to have formed it (per unit area, per unit time).

Attempts were made to deduce the components of the current from the N_O18 measurements. On the basis of the literature data (6, 18, 24, 27) and of our results (see preceding heading) we assume that the transfer of oxygen 16 ions at the passive film-solution interface due to the SO_4^{2-} fixation on the metal surface can be neglected compared to the oxygen transfer from the water (O^{18}). This assumption is reasonable (13, 24) for low current densities ($I = 20\ \mu A/cm^2$) but could be incorrect for high current densities. Details of this phenomenon will be studied in the near future, both by O^{18} tracing and by direct nuclear analysis of sulfur.

We present here the results for two ranges of values of I:

(*i*) $I = 20\ \mu A/cm^2$

The difference between v_{up} and v_{lp} should give the over-all rate of growth of the passive layer at $I = 20\ \mu A/cm^2$. However, in view of the inaccuracy in the results, it is not possible to estimate this difference. Considering the values of v_{up} and v_{lp}, it can be stated that the maximum value for over-all growth rate of the passive layer at $I = 20\ \mu A/cm^2$ is 1.3×10^{13} atoms/cm² · sec. This corresponds to a maximum value of I_{ox} equal to $4.2\ \mu A/cm^2$ (if we assume that two charges are attached to each oxygen atom), *i.e.*, a maximum value of current efficiency for passive film formation, R, of 21%. From these two observations, it may be inferred that I_{dis} lies within the limits

$$15.8\ \mu A/ \leq I_{dis} \leq 20\ \mu A/cm^2 \qquad [5]$$

The value of v_{lp} taken from Fig. 5 contains the rate of O^{18} loss by dissolution and the rate of O^{18} loss by isotopic exchange with the solution. This implies that the values of v_{lp} are in fact upper bounds of I_{ch}. This means that $I_{ch} \leq 4.8\ \mu A/cm^2$ (see Table II). It should follow that the current density of electrochemical dissolution of cations I_{cat} amounts to at least $11\ \mu A/cm^2$ or 55% of I. These data are shown in Table II.

(*ii*) $20\ \mu A/cm^2 < I < 800\ \mu A/cm^2$

The total current efficiency for the formation of passive films, from the start of polarization until $t = t_f$ (for which $I = 20\ \mu A/cm^2$) can be measured, under the assumptions indicated above, by comparing the charge passed through the circuit and N_O18 measured at t_f.

In fact [see Ref. (14)], the number of oxygen atoms per square centimeter coming from the water and fixed in the layer at time t is $N_O18(t)$

$$N_O18(t) - N_O18(o) = K \int_o^t I_{ox}(\theta)\, d\theta$$

$$= K \int_o^t R(\theta)\, I(\theta)\, d\theta \qquad [6]$$

where $R(t)$ is the current efficiency for passive film formation at any instant t

$$R(t) = \frac{I_{ox}(t)}{I(t)} \qquad [7]$$

and where the constant K is equal to 0.312×10^{19} atoms of oxygen per coulomb if we assume that the oxygen is fixed in the films in the form O^{2-}.

On the other hand, the number Q of coulombs per square centimeter

$$Q = \int_o^t I(\theta)\, d\theta \qquad [8]$$

consumed during polarization allows one to determine the current efficiency for passive film formation from the following relation, deduced from [6]

$$R = \frac{1}{K} \frac{d\hat{N}_O18}{dQ} \qquad [9]$$

Experimental measurements of this quantity can be used to determine I_{ox} by means of Eq. [7].

The very high current during the first few seconds of polarization was not recorded by the experimental system. The total current efficiency for passive film formation was therefore measured between $t = 5$ sec and $t = t_f$, using the difference between N_O18 found at these times, respectively. We obtained $R = 6 \pm 1\%$ at V = 1040 mV, which leaves 94 ± 1% for the losses. If the layer dissolution current (I_{ch}) measured at $I = 20\ \mu A/cm^2$ is assumed to be constant during the entire layer formation, it would only account for at most 10% of the total losses measured between $t = 5$ sec and t_f: this, in turn, implies that electrochemical dissolution of cations constitutes at least 84% of the losses during layer formation. These data are shown in Table II.

Table II. Components of the current deduced from N_O18 measurements for samples prepared at $V_{ox} = 1040$ mV (HE)

Near the steady-state conditions $I \approx 20\ \mu A/cm^2$	From the start of polarization (t_o = 5 sec) to the steady-state region (t_f = 12 min $\sim 800\ \mu A/cm^2 > I > 20\ \mu A/cm^2$)

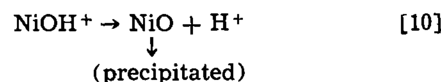
Discussion

The results obtained clearly show the existence of two different kinetic regions of fixation of oxygen coming from water. As shown in Fig. 3, fixation of the first monolayer in the region of high passivity potential (V_{ox} = 1040 mV) is accompanied by a large drop in current. Thus, to go from a surface coverage of about 10% ($1/\hat{N}_O18 \sim 8 \times 10^{-15}$ cm²/atom) to a total coverage ($1/\hat{N}_O18 \sim 0.8 \times 10^{-15}$ cm²/atom), one observes experimentally a current drop of one order of magnitude, whereas to pass from a coverage by a single monoatomic layer to a formation of approximately five monoatomic layers, the current only changes from $I \sim 60\ \mu A/cm^2$ to $I \sim 10\ \mu A/cm^2$. Moreover, Fig. 1 clearly shows that the metal is virtually stripped of oxygen coming from water after cathodic polarization and stabilization of the solution ($V_{ox} = -100$ mV), in agreement with ellipsometric observations of Sato (28), Bockris *et al.* (5), and Reddy and Rao (29).

According to the Tafel curve drawn from the results of Sato and Okamoto (18), the theoretical value of the initial current on application of V_{ox} = 1040 mV would be about $\sim 10^4$ A/cm². Therefore, for the fixation of a monoatomic layer totally covering the surface ($1/\hat{N}_O18 \sim 0.8 \times 10^{-15}$ cm²/atom and $I \sim 60\ \mu A$), there is a current drop of eight orders of magnitude if initial limitation by diffusion in the solution is not considered. This conclusion, similar to that drawn by Frankenthal (9, 10, 22) on passivation of iron and Fe-Cr alloys, suggests that the fixation of the first monoatomic layer of oxygen coming from water plays a fundamental role in the passivation process. This hypothesis is consistent with the assumption we have made above, namely, that the incorporation or electrochemical decomposition of SO_4^{2-} anions is not of great or of decisive importance in the process of passivation on the metal surface.

To explain this effect, Frankenthal supposes that for short times at high potential (that is, before fixation of the monoatomic layer with total coverage), there exists a mechanism of preferential dissolution-adsorption and a mechanism of anodic dissolution by direct activated transfer of the surface ions of the metal in the solution.

Bockris, Reddy, and Rao (5) suggested, to explain the formation of the first layer of passivation, another mechanism called dissolution-precipitation. In this model, it is assumed that when the concentration of $NiOH^+$ increases to above the saturation value, which is determined by the solubility product of NiO, precipitation of NiO occurs in the area around the surface, by the reaction



$$NiOH^+ \rightarrow \underset{\text{(precipitated)}}{\underset{\downarrow}{NiO}} + H^+ \qquad [10]$$

Frankenthal does not find this model convincing, since if the prepassive film is converted entirely into passivation film, then the former must also be of monomolecular dimensions, which is most unlikely for a precipitate. Moreover, Sato and Okamoto point out that the oxide film deposited from the solution according to Reaction [10] is expected to have a porous character; this would lead to the formation of a layer whose great thickness would be easily detectable by the present measuring method. However, this is not the case, and thus we are inclined to think that the adsorption mechanism would be more probable than the precipitation mechanism, under our experimental conditions.

The second point to be discussed concerns the behavior of passivity films in the slow kinetic region, *i.e.*, when the film thickness deduced from N_O18 measurements exceeds one monoatomic layer. The results in Fig. 1 allow us to assume the existence of a linear relationship between film thickness and potential, for a final constant current density which is close to the steady state ($I = 20\ \mu A/cm^2$). Between 640 and 1040 mV, the thickness varies from 3 to 5 monoatomic layers. The linearity between N_O18 and V_{ox} in the passive range is in agreement with the ellipsometric observations of Sato (28); under similar conditions, he observed a linear increase in passive film thickness with increasing potential.

Bockris *et al.* (5) did not observe any variation of thickness with potential in the passivity region; the thickness was reported to remain constant, to the order of 70-100Å. It should be noted that the solution used by Bockris *et al.* ($0.01N\ H_2SO_4 + 0.5M\ K_2SO_4$) was less acidic than the present $1N\ H_2SO_4$.

According to Frankenthal (9, 10, 22) the steady state would not be reached until formation of an oxide film of more than unit cell thickness, anodic dissolution and film formation proceeding by field-assisted ionic transport through the oxide. This conclusion seems to be in agreement with our results. In fact, the linear variations of $1/\hat{N}_O18$, at low current densities, with log I (Fig. 3) and of $\hat{N}_O18$ with V_{ox} (Fig. 1) can be interpreted in terms of a high-field conduction process. Moreover, the change of mechanism of oxygen fixation is observed, when the "thickness" of passive film deduced from N_O18 measurements, exceeds one unit cell.

From the above, it should follow that a high-field conduction process is most likely when the thickness of the film exceeds that of one unit cell.

The results obtained permit us to define precisely the nature of the mechanisms involved in this growth region. We shall first examine the principal mechanisms proposed in the literature (3, 6, 7, 23). In order to explain the potential-independence of the final current I_f in the passivity region under steady-state conditions, two reactions schemes have been presumed possible: (*a*) the direct transfer of Ni^{++} from the passivation layer to the solution; (*b*) a transfer by an intermediary complex of the $NiOH^+$. Transfers (*a*) and (*b*) would be independent of the electrode potential and controlled solely by the potential difference across the oxide-solution interface, which would be maintained at an equilibrium value dependent on the *p*H for the reaction $(O^{2-})_{film} + 2H^+ = H_2O$ (7). The results of Sato and Okamoto (6) suggest that the second type of transfer would be dominant. It should be noted that this transfer would produce a rate of oxygen loss $v_{fo} = 0.63 \times 10^{13}$ atoms/cm²·sec for $I_f = 2\ \mu A/cm^2$, value observed on the nickel in $1N\ H_2SO_4$ at 25°C (6). For our part, we measured, for the quasi-stationary state ($I = 20\ \mu A/cm^2$) a rate of oxygen 18 loss (v_{lp}) equal to $(1 \pm 0.5) \times 10^{13}$ atoms/cm²·sec (see Table I). We should add that v_{lp} although higher corresponds, within the margin of experimental error, to v_{fo}, if we take into consideration that v_{lp} was measured not at 2 but at 20 $\mu A/cm^2$.

As shown by our results the oxygen 18 losses are independent of potential ($v_{lo} = v_{lp}$, Table I). Thus, it is reasonable to assume that I_{ch}, deduced from O^{18} measurements (v_{lp}) is due to the same process that produces I_f. This means that I_{ch}, as well as I_f, are a result of transfer mechanism (*b*).

Vetter (7) and Sato (6) implicitly assume all of the metal dissolution to be due to mechanism (*b*). According to our findings, it appears that the equivalent current I_{ch}, due to mechanism (*b*) represents at most 24% of the total current crossing the film-solution interface at $I = 20\ \mu A/cm^2$. This leads us to consider that, in addition to reaction (b), reaction (*a*) takes place, even though the transfer mechanism of metal cations toward the interface cannot be precisely defined. It should be recalled that Novakovsky *et al.* (25) suppose transfer (*b*) to be completely blocked and dissolution to be due to transfer (*a*). Our findings imply the existence of both types of transfer for $I = 20\ \mu A/cm^2$. It is logical to assume that whenever the current decreases and tends toward a limiting value ($I_f = 2\ \mu A/cm^2$), mechanism (*a*) is blocked and dissolution of the metal occurs only by mechanism (*b*), *i.e.*, the limiting value of I_{ch} is 2 $\mu A/cm^2$.

Mobility of ionic carriers during formation of passive layers near steady-state conditions.—Another problem we attempt to elucidate was the determination of the interface at which the oxidation reaction, *i.e.*, film growth, takes place near the steady-state conditions. As shown in Fig. 2 the growth of passive layer is practically stopped when the current densities drop below 20 $\mu A/cm^2$, although the equivalent current of layer dissolution (I_{ch}) is within the range 2-4.2 $\mu A/cm^2$ (see above). From the above, it should follow that the equivalent current for new layer formation is equal to I_{ch} (dynamic equilibrium).

The existence of an electrochemical dissolution of cations (I_{cat} is at least 55% of I) provides experimental evidence for the mobility of cations. *A priori*, this could imply that growth would occur at the oxide-solution interface. If this were the case, the processes of dissolution and oxygen fixation would both occur on the external interface and the internal layer would not be in direct contact with the solution, which will imply that the increase in oxygen in Fig. 5 (v_{up}) could have occurred only by isotopic exchange and diffusion. However, as indicated by the results in Fig. 4, these phenomena are negligible in comparison with dissolution. On the basis of these results, we therefore suppose that the increase in O^{18} measured in Fig. 5 (v_{up}) is due to growth rather than to isotopic exchange phenomena. Thus, the formation of new layers can only take place at the metal-passive layer interface by migration of oxygen coming from the solution. This pattern of growth was proposed by Novakovsky (23) to explain the passivation of iron and also by Hoar and Mott (30) for porous growth of aluminum during anodic oxidation in acids. Moreover, in accordance with Novakovsky (23), one can explain the absence of passive film formation at the passive layer-solution interface, in spite of the large cation flow across this interface, by a decrease in chemical potential of the cations resulting from formation of bonds with oxygen in the oxide. The same reasoning was used to explain the presence of the current of electrochemical dissolution of cations during anodic oxidation af aluminum in aqueous solutions of ammonium citrate (14) or sulfuric acid (31).

Stability of passive layers.—As shown by the results, the passive layers are not stable and reoxidize in air. This seems to confirm our conclusions according to which the "thickness" of the passive layer in the solution is determined by the equilibrium between the rates of layer formation and dissolution. When the specimen is removed from solution, the rate of dissolution of the layer is virtually zero. On the other hand, the equilibrium thickness of passive layer formation in

the presence of adsorbed water and gaseous oxygen should be higher than in the N_2-purged H_2SO_4 due to a higher oxygen redox potential. The new equilibrium requires an increase in layer thickness, which we observed ($\Delta N_O 16$). The passive layer is not thermodynamically reversible, in agreement with Frankenthal (22). Dissolution (Fig. 4) requires about 30 min, whereas the electrode potential goes down to the initial value after ~30 sec.

Conclusions

The conclusions based essentially on the measurements of the quantities of the oxygen coming from the water (O^{18}) may be summed up as follows. The first layer of oxygen fixed on the metal surface is found to have a decisive effect on the passive nature of metal and causes the anodic current density to decrease by several orders of magnitude. When the layer thickness due to the fixation of oxygen coming from water exceeds the size of one "unit cell," the current is probably limited by "field-assisted ionic transfer phenomena." A linear relationship exists between the thickness of the layer and its formation potential, for the same final current value.

The current efficiency for passive layer formation was found to be very small. The current of cations crossing the oxide-solution interface consists of the current of direct transfer of cations, plus the current equivalent to the dissolution of oxide. The latter is equal to the current at the "steady-state condition" and to the dissolution current of the layer when it is in an open circuit.

It seems that the formation of a new layer takes place at the metal-oxide interface via migration of oxygen ions from the water. The thickness of the passive layer depends on the dynamic equilibrium between the rates of formation and of dissolution.

It was found that the passive layers are unstable and reoxidize in air, and that the rate of isotopic oxygen exchange is lower than the rate of dissolution, both in open circuit and under passivation potential. And finally, the passive layers are not thermodynamically reversible and the value of the electrode potential in an open circuit is not related to the presence of the layer.

Acknowledgments

The authors wish to thank Dr. G. Amsel for his numerous comments and suggestions during this work. They are grateful to Mr. B. Agius for enlightening discussions and for help during the experiments. The technical assistance of Mr. A. Laurent was much appreciated. This work was supported by the Centre National de la Recherche Scientifique, (RCP No. 157), the DRME, and the DGRST.

Manuscript submitted Sept. 24, 1971; revised manuscript received April 10, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Kinetics of Iron Corrosion in Concentrated Acidic Chloride Solutions

E. McCafferty*[,1] and Norman Hackerman*[,2]

Department of Chemistry, The University of Texas, Austin, Texas 78700

ABSTRACT

The kinetics of active iron dissolution at 25°C has been studied in deaerated $1N$ and $6N$ chloride solutions for hydrogen ion concentrations of 0.1-6.0N. For $1N$ chloride solutions with $[H^+] \leq 3N$, the dissolution reaction is described by anodic Tafel slope $b_a = 60$ mV and electrochemical reaction order with respect to hydrogen ion activity $z_{H^+} = -1$. These parameters are characteristic of a dissolution mechanism in which chemisorbed halide ions interact with adsorbed hydroxyl ions in a two-electron rate-determining step. For $6N$ chloride solutions, this mechanism holds only over a narrower $[H^+]$ region up to $0.24N$, in which $z_{H^+} = -1$. With increased $[H^+]$, z_{H^+} is zero; and for $[H^+]$ $2.4N$, $z_{H^+} = +2$, indicating the hydrogen ion (and no longer the hydroxyl ion) catalyzed the dissolution reaction. A positive value of z_{H^+} ensues for synergistic adsorption of hydrogen ions on the halide ion covered surface. A formal detailed dissolution mechanism is proposed, giving $z_{H^+} = +2$ and $z_{X^-} > 0$, in agreement with experiment. Alternate dissolution mechanisms including one-electron transfer schemes are discussed.

The kinetics and mechanism of iron dissolution in acids has been the subject of numerous investigations (1). Previous mechanistic studies in chloride solutions, however, have been with total chloride concentrations of $1N$ or less. Studies in this laboratory on organic corrosion inhibitors have commonly used concentrated HCl (3 to $6N$) to provide a high uninhibited dissolution rate. The purpose of the present communication is to report recent investigations on the mechanism of iron dissolution in these deaerated, concentrated acidic chloride solutions.

An important result is that with $6N$ chloride solutions at sufficiently low pH, synergistic effects between adsorbed anions and hydrogen ions in solution impose a different dissolution mechanism than is operative with more dilute chlorides. The difference in the mode of dissolution is that H^+ ions and not OH^- ions catalyze the anodic reaction, as is the case for $1N$ chloride solutions (2). Similar synergism has been recognized before between adsorbed halide ions and organic corrosion inhibitors (3-5).

The current work also bears on electrochemical processes which occur in microscopic corrosion pits growing on passive or oxide-covered iron surfaces. This application to pitting corrosion stems from the composition of local electrolyte within corrosion pit interiors. There have been many reports (6-9) that the local pH within growing pits and other "occluded corrosion cells" (10) is acidic, even when the bulk solution is neutral. An accumulation of chloride ions within the pit has been often postulated (6, 11, 12), although not yet experimentally verified. In addition, active pits are thought to be oxygen-free (7, 13). Thus the uniform dissolution of iron in deaerated concentrated acidic chlorides can serve as a scaled-up model of localized corrosion within active corrosion pits. Macroscopic models which simulate corrosion pits and other related forms of "occluded cell" corrosion have been used from the early 1940's (14) to the present (13, 15). The approach taken, however, has been the thermodynamic rather than kinetic one with emphasis on factors such as resultant pH and electrode potential, solution composition, and the like.

In order to relate the present work to previous kinetic studies, it will be helpful to briefly outline prior work which bears on the present problem. It is generally recognized that there are two main types of dissolution mechanisms for active iron, depending on the nature of the solution anion. For solutions of weakly adsorbable anions, such as sulfate or perchlorate, dissolution proceeds through the dissociation of chemisorbed water molecules at the iron surface. Surface active anions, such as halide ions, on the other hand, are believed to participate directly in the dissolution process by adsorption at the metal surface.

Two different reaction mechanisms have been proposed for the anodic dissolution of iron in acidic sulfates and perchlorates (in the absence of halides). The more generally accepted Bockris-Kelly (16, 17) mechanism is

$$Fe + H_2O \rightleftharpoons Fe \cdot H_2O_{ads} \quad [1]$$

$$Fe \cdot H_2O_{ads} \rightleftharpoons FeOH^-{}_{ads} + H^+ \quad [2]$$

$$FeOH^-{}_{ads} \rightleftharpoons FeOH_{ads} + e^- \quad [3]$$

$$FeOH_{ads} \rightarrow FeOH^+ + e^- \quad \text{(rate-determining)} \quad [4]$$

$$FeOH^+ + H^+ \rightleftharpoons Fe^{++} + H_2O \quad [5]$$

This sequence is characterized by the parameters

$$b_a = \left(\frac{\partial E}{\partial \log i_a}\right)_{a(H^+)} = \frac{2}{3} \cdot \frac{2.303\,RT}{\mathbf{F}} = 40\text{ mV} \quad [6]$$

and

$$z_{H^+} = \left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}}\right)_E = -1 \quad [7]$$

A second group of investigators (18-20) has observed $b_a = 30$ mV and $z_{H^+} = -2$.[3] In the Heusler mechanism which yields this set of parameters, Eq. [4] above is replaced by

$$FeOH_{ads} + Fe \rightleftharpoons Fe(FeOH)_{ads} \equiv \text{catalyst} \quad [8]$$

$$Fe(FeOH)_{ads} + OH^- \rightarrow FeOH^+ + FeOH_{ads} + 2e^- \quad \text{(rate-determining)} \quad [9]$$

Recent work (21, 22) has suggested that either mechanism can be followed, depending on the surface microstructure. A low density of grain boundaries and other imperfections favored the Bockris-Kelly mechanism, while a high density of imperfections yielded the Heusler mechanism.

[3] Felloni (20) observed $z_{H^+} = -1.5$ rather than -2.0 and explained the fractional order on the basis of a Freundlich adsorption isotherm.

As is well known, a salient feature of the above mechanisms is direct participation of hydroxyl ions in the dissolution process in bulk electrolytes which are acidic. The involvement of OH^- ions at the iron/acid interface was first suggested by Bonhoeffer and Heusler (23) to explain the experimental observations that at the same electrode potential, the rate of iron dissolution in acid solutions was less than that in basic solutions (24) and decreased in acid solutions with decreasing pH (25). The generation of OH^- ions in acid solutions is presumed to occur by dissociation of water molecules at the electrode surface (1, 17-27). In addition, the reaction mechanisms are directed toward production of the species $FeOH^+$, which results from the hydrolysis of ferrous salts and "is present in significant concentrations even in relatively acid media" (28).

In the presence of the chloride ion, which is more surface active than $SO_4^=$ or ClO_4^- (4, 29), there is competitive adsorption between chloride and hydroxyl ions (30). Chloride adsorption will tend to prevail at high chloride activity and low pH; and accordingly, the dissolution mechanism will be different than in the Bockris-Kelly or Heusler cases. Fisher, Lorenz, and co-workers (2, 22, 31) have observed a change from Heusler parameters to the following for pH $< 1.5 - 2$

$$b_a = \left(\frac{\partial E}{\partial \log i_a}\right)_{a(H^+),a(X^-)} = \frac{2.303\,RT}{F} = 60 \text{ mV} \quad [10]$$

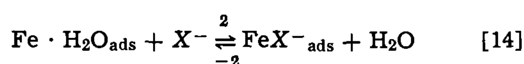
$$z_{H^+} = \left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}}\right)_{E,a(X^-)} = -1 \quad [11]$$

$$z_{X^-} = \left(\frac{\partial \log i_a}{\partial \log a_{(X^-)}}\right)_{E,a(H^+)} = -1 \quad [12]$$

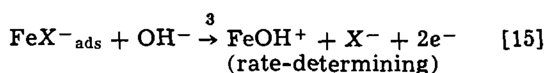
Felloni (20) reports $b_a = 60$ mV (53 to 70) and $z_{H^+} \cong -1$ (-1.09 to -0.83) for pH <2, with Bockris-Kelly parameters for pH > 2 for $1N$ chlorides. Arvia and Podesta (32) have proposed a reaction mechanism for chlorides analogous to Eq. [1]-[5], but their own data shows $b_a = 60$ mV (53 mV) for pH $= 1.78$ (33).

The following reaction sequence was first proposed by Lorenz, Yamaoka, Fisher (31) and developed in later publications (2, 22) to account for Eq. [10]-[12]

$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [13]$$



$$Fe \cdot H_2O_{ads} + X^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeX^-_{ads} + H_2O \quad [14]$$



$$FeX^-_{ads} + OH^- \overset{3}{\rightarrow} FeOH^+ + X^- + 2e^- \quad \text{(rate-determining)} \quad [15]$$

followed by Eq. [5]. Equations [13]-[15] will be referred to herein as the LYF mechanism for the sake of abbreviation. In this sequence, chemisorbed X^- ions displace adsorbed water molecules and then interact with adjacently adsorbed hydroxyls. It is necessary that the hydroxyl ion in Eq. [15] be adsorbed at a vacant site in order to give the required reaction order $z_{X^-} = -1$ (as $\theta_{X^-} \rightarrow 1$).

Other pertinent reaction mechanisms proposed in the literature will be considered after the present results have been presented. As mentioned earlier, kinetic studies have been lacking in more concentrated chloride solutions. An understanding of such systems is necessary before extension can be made to systems more complicated in composition (*e.g.*, with organic inhibitors) or in geometry (corrosion pits, crevices, or stress-corrosion cracks).

Experimental

Experimental techniques have been described previously (34). In brief, the iron electrodes were Mallinkrodt analytical grade wire (99.5% Fe, 0.01% C, 0.03% Mn, 0.001% P, $<$ 0.001% Si, 0.01% S). The wire was inserted through a close-fitting hole in a Teflon holder which fit into a standard tapered glass joint at the end of the electrode assembly. Electrical contact was made by means of mercury inside the tubing.

The wires were cut to a length of 2.0 cm to give a projected surface area of 0.227 cm^2. Before use, an electrode was degreased with spectroscopic grade pentane and then electropolished at 85 mA/cm^2 for 2 min in a 4/1 mixture of $HClO_4$:CH_3COOH. The electrode was then washed with double-distilled water and inserted into the polarization cell, which was the usual three-electrode type with provision for deaeration. Solutions were deaerated for at least 8 hr with helium passed through charcoal at $-195°C$ and then through a solution identical to that being studied to minimize vapor loss of solution in the polarization cell. Polarization measurements were made galvanostatically with a 90V battery and series of variable resistors, as described earlier (34). Steady open-circuit potentials were established in 1-8 hr, the longer times being required for the more dilute solutions. For a given applied anodic current, a steady potential was usually observed in 2-5 min.

All solutions were prepared from reagent grade chemicals and double-distilled water prepared in a Barnstead still. Polarization measurements were made in three types of solutions: (*i*) 1-6*N* HCl, (*ii*) solutions with varying pH for 1*N* constant chloride ion concentration, and (*iii*) solutions with varying pH for 6*N* constant chloride ion concentration. In the last two types of solutions, the base electrolyte was HCl with either LiCl additions to increase the chloride ion concentration, or $HClO_4$ additions to increase the acidity.

Table I. Corrosion parameters for iron in concentrated hydrochloric acid

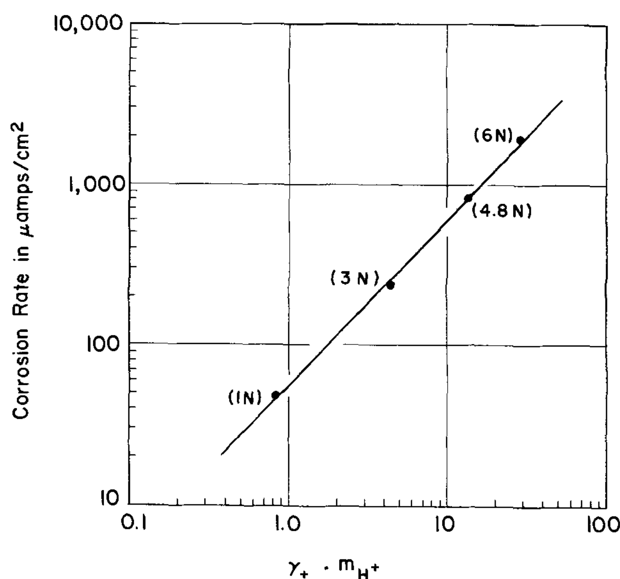

Fig. 2. Open-circuit corrosion rate of iron in hydrochloric acid as a function of hydrogen ion activity.

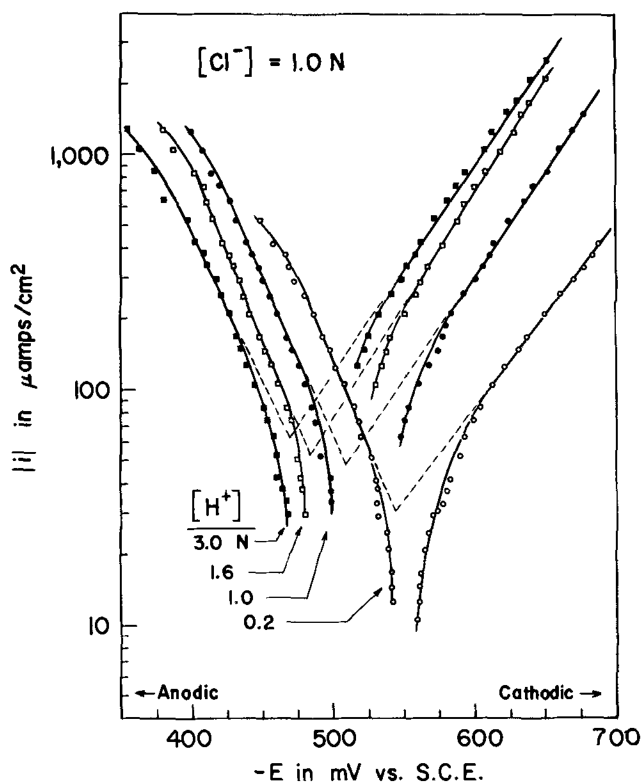

Fig. 3. Polarization curves for iron in 1*N* chloride solutions of varying acidity.

rosion rate of iron is a linear function of hydrochloric acid activity, as shown in Fig. 2. A similar linear dependence over a smaller activity range (1-8 molal) has been reported previously (35).

Activities plotted in Fig. 2 and listed in Table I are based on activity coefficients taken from Harned

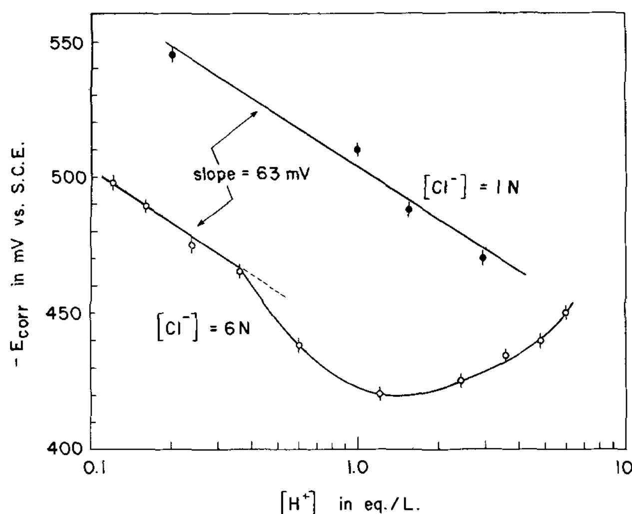

Fig. 4. Variation in the open-circuit corrosion potential with acidity for two different chloride ion concentrations.

and Owen (36). The activity of HCl a_{HCl} is given by $a_{HCl} = a_+a_- = a_\pm^2$. As usual, $a_i = \gamma_i m_i$, where γ_i is the molal activity coefficient. Definition of the mean molal activity coefficient as $\gamma_\pm^2 = \gamma_+\gamma_-$ gives $a_\pm = \gamma_\pm \cdot m_{HCl}$.

Little information on the dissolution mechanism can be inferred from Fig. 2, however, in that each of the three variables *E*, pH, and [Cl⁻] is different for each solution. Accordingly, solutions of constant chloride ion concentration were used.

1N chloride solutions.—Figure 3 shows anodic and cathodic polarization curves for iron in 1*N* chloride solutions of varying hydrogen ion concentration. The effect of decreased acidity is to shift the open-circuit corrosion potential E_{corr} to more negative potentials. The change in mixed potential with hydrogen ion concentration is: $(\partial E_{corr}/\partial pH) = -63$ mV, as shown in Fig. 4. Values of -51 mV (20) and -56 mV (37) have been reported previously.

Tafel slopes for 1*N* chloride solutions are listed in Table II. The cathodic Tafel slopes are the usual 120 $\pm$ 10 mV/decade (17). The anodic Tafel slopes are 65-70 mV/decade, in nominal agreement with the value of 60 mV, required by Eq. [10] (if $\alpha = 0.46$-0.40, rather than 0.50).

Figure 5 shows evaluation of the electrochemical reaction order with respect to the hydrogen ion. Our results gave z_{H^+} to be -0.7 rather than the theoretical value of -1.0 required by Eq. [11]. Mean molal activity coefficients $\gamma_\pm$ of HCl with and without LiCl additions were calculated from Debye-Huckel theory using the equation (38)

$$\log \gamma_\pm = \frac{-0.354}{1 + A\sqrt{2C_T}} + B(2C_1) + B'(2C_T - 2C_1) - \log(1 + 0.036\, m_T) \quad [16]$$

where C_T is the total molar concentration of the solution; C_1 the molar concentration of acid; m_T the total molality; and *A*, *B*, and *B'* are 0.747, 0.0864, and 0.0875, respectively. Activity coefficients for the HCl-$HClO_4$ mixtures were interpolated from the data of Storonkin *et al.* (39). The electrochemical reaction order z_{H^+} for the cathodic reaction was $\sim +1$, as required by the usual mechanism of hydrogen evolution (17).

2.96	1.00 HCl + 1.96 $HClO_4$	470	66	75	115	3.31	1.58	5.24

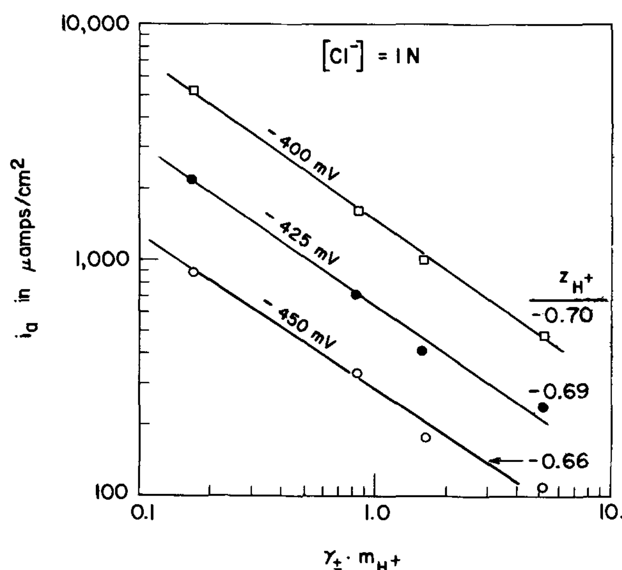

Fig. 5. Evaluation of the electrochemical reaction order $z_{H^+} = \left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}}\right)_{E,\, a(X^-)}$ **for 1N chloride solutions.**

Thus, the anodic dissolution of Mallinkrodt iron wire is adequately described by the LYF mechanism, *i.e.*, Eq. [13]-[15] for solutions 1*N* in Cl^- with H^+ concentration up to 3*N*. For hydrogen ion concentrations above 3*N*, anodic Tafel slopes of 95 ± 5 mV/decade, rather than 60 mV, were observed. In these solutions, the high concentration of ClO_4^- ions may cause a change in reaction mechanism, but this aspect will not be considered here. The effect was the same if H_2SO_4 was used instead of $HClO_4$.

6N chloride solutions.—Representative polarization curves for solutions 6*N* in chloride ion with varying acidity are shown in Fig. 6 and 7. Polarization parameters are listed in Table III. Again, the cathodic Tafel slopes are 120 ± 10 mV. As with the 1*N* chloride solutions, the anodic Tafel slopes are generally 60-75 mV

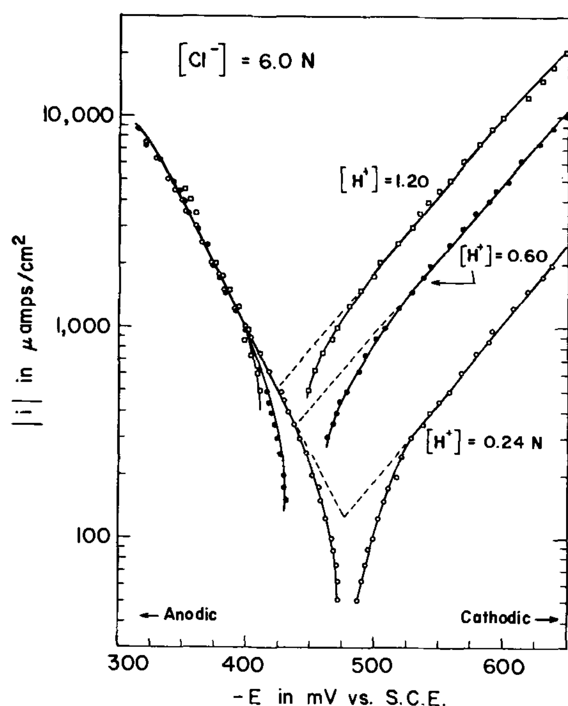

Fig. 6. Polarization curves for iron in 6N chloride solutions (for acidities where $z_{H^+} = 0$**).**

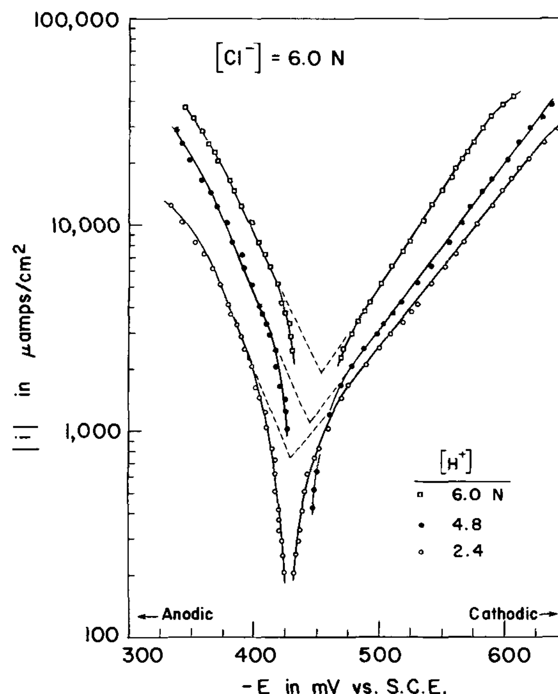

Fig. 7. Polarization curves for iron in 6N chloride solutions (for acidities where $z_{H^+} \cong +2$**).**

in accord with a 2-electron transfer (60 mV) mechanism of dissolution, if $\alpha = 0.50$ to 0.40.

Unlike the 1*N* chloride solutions, however, the corrosion potential does not shift uniformly with hydrogen ion concentration (see Fig. 4). This behavior suggests that the dissolution mechanism is not the same over the entire range of hydrogen ion concentrations shown.

This change in mechanism is evident in evaluation of z_{H^+}, as shown in Fig. 8, in which log i_a is plotted as a function of H^+ activity. Mean molal activity coefficients $\gamma_\pm$ of hydrochloric acid in HCl-LiCl mixtures were calculated from Eq. [16] and are summarized in Table III.

As seen in Fig. 8, with increased proton activity, z_{H^+} equals in turn *ca.* −1, 0, and +2 (see Table IV). These changes in z_{H^+} with proton activity indicate changes in the dissolution mechanism with increased acidity.

For the lower H^+ activities, the kinetic parameters point to the LYF mechanism of iron dissolution. The experimental value of $z_{H^+} = -0.9$ compares well with the theoretical value of −1.0, but the experimental Tafel slopes for these concentrated LiCl solutions are some 20 mV higher than the theoretical 60 mV value. However, the third kinetic parameter, the electrochemical reaction order with respect to halide ion was evaluated to be: $z_{X^-} = -1$, as required by Eq. [12]. This evaluation was based on but two data points, and is intended to show the trend rather than to be an exact value (See Table IV).

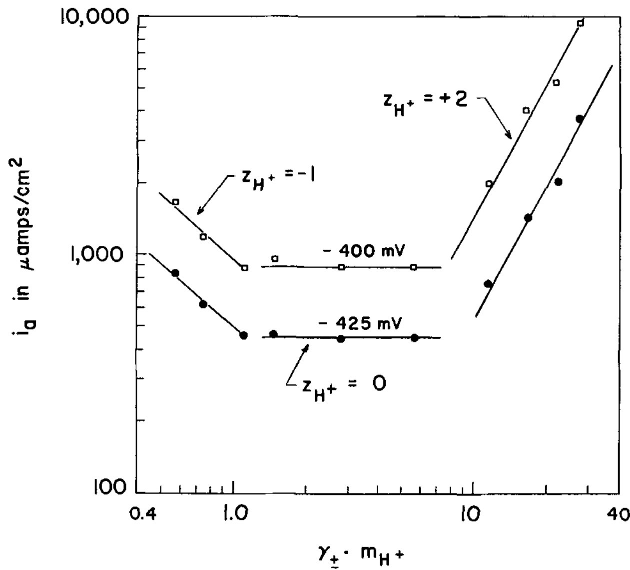

Fig. 8. Evaluation of the electrochemical reaction order $z_{H^+} = \left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}}\right)_{E, a_{(X^-)}}$ **for 6*N* chloride solutions.**

With increased proton activity, there is a region in which $z_{H^+} = 0$, *i.e.*, the anodic current density at constant electrode potential is independent of pH. At even higher proton activities, there is a synergistic effect between halide anions chemisorbed at the iron surface and hydrogen ions in solution. Hydrogen ions are electrostatically attracted toward the iron surface covered with Cl^- anions (3-5) and catalyze the dissolution reaction, as indicated by the positive value of z_{H^+}. In addition, evaluation of z_{X^-} based again on a limited amount of data gave $z_{X^-} = +0.62$ and $+0.91$ for two different electrode potentials (see Table IV).

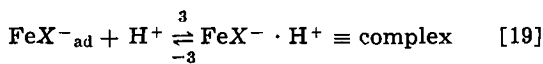
Figure 9 shows evaluation of the electrochemical reaction order for the cathodic reaction. The hydrogen evolution reaction is first order in H^+ over the entire activity range studied, in agreement with Kelly (17).

Discussion

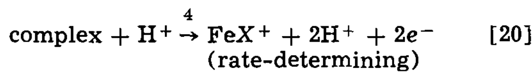
Mechanism of dissolution.—The following mechanism of dissolution is proposed to account for $z_{H^+} = +2$

$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [17]$$

$$Fe \cdot H_2O_{ads} + X^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeX^-_{ads} + H_2O \quad [18]$$



$$FeX^-_{ad} + H^+ \underset{-3}{\overset{3}{\rightleftharpoons}} FeX^- \cdot H^+ \equiv \text{complex} \quad [19]$$



$$\text{complex} + H^+ \overset{4}{\rightarrow} FeX^+ + 2H^+ + 2e^- \quad [20]$$
(rate-determining)

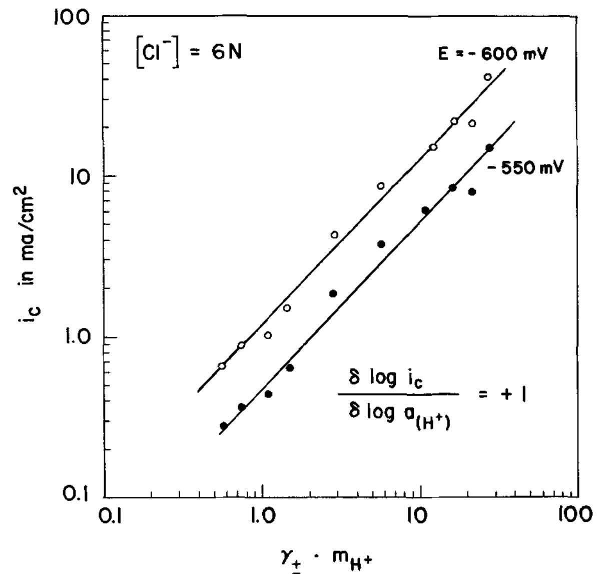

Fig. 9. Evaluation of the electrochemical reaction order $z_{H^+} = \left(\frac{\partial \log i_c}{\partial \log a_{(H^+)}}\right)_{E, a_{(X^-)}}$ **for the cathodic reaction in 6*N* chloride solutions.**

$$FeX^+ \underset{-5}{\overset{5}{\rightleftharpoons}} Fe^{++} + X^- \quad [21]$$

where FeX^+ represents a ferrous ion which is part of the metal surface but not the metal lattice.

The formal rate expression for the above sequence is derived as follows. The anodic current density is

$$\frac{i_a}{F} = 2\,\vec{k}_4\,\beta\,\theta_{complex}\,a_{(H^+)} \quad [22]$$

where

$$\vec{k}_i = k_i \exp\,(\pm \alpha n F E/RT) \quad [23]$$

with E the electrode potential, n the number of electrons transferred, α the transfer coefficient, and the plus and minus signs refer to the anodic and cathodic processes, respectively. The factor β is given by: $[FeX^- \cdot H^+] = \beta\,\theta_{complex}$, where $\theta_{complex}$ is the fractional coverage (of the anodic surface) of the complex. These notations follow Kelly (17).

This system of equations [17]-[21] is described by

$$\beta \frac{d\theta_W}{dt} = \vec{k}_1(1-\theta_T) - \vec{k}_{-1}\beta\theta_W - \vec{k}_2\beta\theta_W a_{(X^-)} + \vec{k}_{-2}\beta\theta_{X^-} \quad [24]$$

$$\beta \frac{d\theta_{X^-}}{dt} = \vec{k}_2\beta\theta_W a_{(X^-)} - \vec{k}_{-2}\beta\theta_{X^-} - \vec{k}_3\beta\theta_{X^-} a_{(H^+)} + \vec{k}_{-3}\beta\theta_{complex} \quad [25]$$

$$\beta \frac{d\theta_{complex}}{dt} = \vec{k}_3\beta\theta_{X^-} a_{(H^+)} - \vec{k}_{-3}\beta\theta_{complex} - \vec{k}_4\beta\theta_{complex} a_{(H^+)} \quad [26]$$

where θ_W and θ_{X^-} are the fractional coverages of $Fe \cdot H_2O_{ads}$ and FeX^-_{ads}, respectively; and $\theta_T = \theta_W + \theta_{X^-} + \theta_{complex} \cong 1$. In the steady-state approximation, $\beta \frac{d\theta_i}{dt} = 0$. Simultaneous solution of Eq. [24]-[26] and [22] then yields

$$\frac{i_a}{F} = 2\,k_4\,\beta^2 a_{(H^+)}^2 \frac{k_1 k_2 k_3\,a_{(X^-)}}{(k_1 + k_{-1}\beta)\,k_{-2}k_{-3} + k_1 k_2\,a_{(X^-)}\,[k_{-3} + k_3\,a_{(H^+)}]} \cdot \exp\left(\frac{FE}{RT}\right) \quad [27]$$

with $\alpha = 1/2$ and $\overline{k}_4 a_{(H^+)} << \overline{k}_{-3}$. The simultaneous equations also yield

$$\theta_{X^-} = \frac{k_1 k_2 k_{-3} a_{(X^-)}}{(k_1 + k_{-1}\beta) k_{-2} k_{-3} + k_1 k_2 a_{(X^-)} [k_{-3} + k_3 a_{(H^+)}]} \quad [28]$$

and

$$\theta_{complex} = \frac{k_1 k_2 k_3 a_{(H^+)} a_{(X^-)}}{(k_1 + k_{-1}\beta) k_{-2} k_{-3} + k_1 k_2 a_{(X^-)} [k_{-3} + k_3 a_{(H^+)}]} \quad [29]$$

If $\theta_{X^-} >> \theta_{complex}$, it follows that $k_{-3} >> k_3 a_{(H^+)}$ and Eq. [27] reduces to

$$\frac{i_a}{F} = 2\beta^2 \frac{k_4 k_3}{k_{-3}} a_{(H^+)}{}^2 \frac{k_1 k_2 a_{(X^-)}}{(k_1 + k_{-1}\beta) k_{-2} + k_1 k_2 a_{(X^-)}} \cdot \exp\left(\frac{FE}{RT}\right) \quad [30]$$

This expression yields $b_a = 60$ mV and

$$z_{H^+} = \left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}} \right)_{E, a(X^-)} = +2 \quad [31]$$

as required by experiment. Equation [30] also gives

$$z_{X^-} = \left(\frac{\partial \log i_a}{\partial \log a_{(X^-)}} \right)_{E, a(H^+)} = \frac{(k_1 + k_{-1}\beta) k_{-2}}{(k_1 + k_{-1}\beta) k_{-2} + k_1 k_2 a_{(X^-)}} \quad [32]$$

With $\theta_{X^-} >> \theta_{complex}$, θ_{X^-} is given as $k_1 k_2 a_{(X^-)} / [k_1 k_2 a_{(X^-)} + (k_1 + k_{-1}\beta) k_{-2}]$ so that $z_{X^-} = 1 - \theta_{X^-}$, and goes from 1 to 0 as θ_{X^-} goes from 0 to 1. Thus, $z_{X^-} > 0$ and not -1, as in the LYF case for more dilute halide solutions, *i.e.*, Eq. [13]-[15]. Evaluation of z_{X^-} based on a limited amount of data gave $z_{X^-} > 0$ for two different electrode potentials at $[H^+] = 3.0$ eq./liter (see Table IV).

Activity of water.—The above derivation and its application has assumed that the water activity a_W is constant. To be rigorous, the factor a_W should be included in terms k_1 and k_{-2} arising from steps [17] and [18]. In addition, the water activity would affect electrochemical reaction orders, *e.g.*

$$z_{H^+} = \left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}} \right)_{E, a(X^-), a_W} \quad [33]$$

The water activity is given by (35)

$$\ln a_W = -\frac{2m\phi}{55.1} \quad [34]$$

where ϕ is the osmotic coefficient of HCl + LiCl mixtures of total molality m. Values of ϕ for mixtures of $m = 4$ were calculated from osmotic coefficients of pure LiCl and pure HCl in water using relationships developed by Harned (40, 41). Results are given in Table V. Appropriate data were not available to make these calculations at $m = 6.8$. But Table V shows that for concentrated chlorides, the activity of water a_W is virtually constant in the system $LiCl-HCl-H_2O$. Thus, the water activity does not complicate diagnosis of the reaction mechanism.

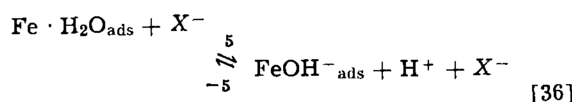
Table V. Activity of water in the system $LiCl-HCl-H_2O$ at total molality $m = 4.0$

m_{HCl}	ϕ	a_W
0	1.449	0.812
0.1	1.452	0.811
0.5	1.462	0.810
1.0	1.474	0.809
2.0	1.494	0.806
3.0	1.510	0.804
4.0	1.519	0.803

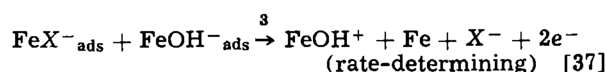
Competitive adsorption.—That different dissolution mechanisms are followed within the 6N chloride level for high and for low proton activities is due to competitive adsorption between OH^- and X^- ions. At the higher acidities, OH^- adsorption is not favored and the dissolution precursor will not be $FeOH^+$, as in the LYF mechanism. Instead, adsorption of X^- predominates, and the corrosion reaction is catalyzed by H^+ ions electrostatically attracted to the negative halide-covered surface (3-5).

This competitive adsorption can be emphasized by rewriting the LYF mechanism of corrosion, Eq. [13]-[15] as follows

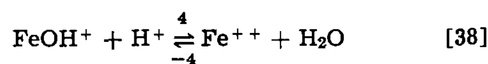
$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [35]$$



$$Fe \cdot H_2O_{ads} + X^- \begin{cases} \underset{-2}{\overset{2}{\rightleftharpoons}} FeX^-_{ads} + H_2O \\ \underset{-5}{\overset{5}{\rightleftharpoons}} FeOH^-_{ads} + H^+ + X^- \end{cases} \quad [36]$$



$$FeX^-_{ads} + FeOH^-_{ads} \overset{3}{\rightarrow} FeOH^+ + Fe + X^- + 2e^- \quad \text{(rate-determining)} \quad [37]$$



$$FeOH^+ + H^+ \underset{-4}{\overset{4}{\rightleftharpoons}} Fe^{++} + H_2O \quad [38]$$

The anodic current density is

$$\frac{i_a}{F} = 2\overline{k}_3 \beta\theta_{OH^-} \beta\theta_{X^-} \quad [39]$$

and, at equilibrium

$$\beta \frac{d\theta_W}{dt} = \overline{k}_1 (1 - \theta_T) - \overline{k}_{-1}\beta\theta_W - \overline{k}_2 \beta\theta_W a_{(X^-)} + \overline{k}_{-2}\beta\theta_{X^-} - \overline{k}_5 \beta\theta_W a_{(X^-)} + \overline{k}_{-5}\beta\theta_{OH^-} a_{(H^+)} a_{(X^-)} = 0 \quad [40]$$

$$\beta \frac{d\theta_{X^-}}{dt} = \overline{k}_2 \beta\theta_W a_{(X^-)} - \overline{k}_{-2}\beta\theta_{X^-} - \overline{k}_3 \beta\theta_{OH^-} \beta\theta_{X^-} = 0 \quad [41]$$

$$\beta \frac{d\theta_{OH^-}}{dt} = \overline{k}_5 \beta\theta_W a_{(X^-)} - \overline{k}_{-5}\beta\theta_{OH^-} a_{(H^+)} a_{(X^-)} - \overline{k}_3 \beta\theta_{OH^-} \beta\theta_{X^-} = 0 \quad [42]$$

Solution of Eq. [40]-[42] subject to $v_3 << v_{-5}$, $v_3 << v_{-2}$, and $\theta_T \cong \theta_W + \theta_{X^-}$ gives

$$\frac{i_a}{F} = 2\beta^2 \frac{k_1{}^2 k_2 k_3 k_5 k_{-2} a_{(X^-)}}{[(k_1 + k_{-1}\beta) k_{-2} + k_1 k_2 a_{(X^-)}]^2 k_{-5} a_{(H^+)}} \exp\left(\frac{FE}{RT}\right) \quad [43]$$

with $\alpha = 1/2$. Equations [43] yields $b_a = 60$ mV, $z_{H^+} = -1$, and $z_{X^-} = -1$ (as $\theta_{X^-} \rightarrow 1$), in accord with Eq. [10]-[12]. But in addition, the simultaneous Eq. [40]-[42] can also be solved for the surface coverage of hydroxyl ions $FeOH^-_{ads}$. The result

$$\theta_{OH^-} = \frac{k_1 k_5 k_{-2}}{k_{-5} a_{(H^+)} [(k_1 + k_{-1}\beta) k_{-2} + k_1 k_2 a_{(X^-)}]} \quad [44]$$

shows that the coverage of adsorbed hydroxyl ions depends upon the bulk concentrations of both bulk H^+ and X^-. For a given chloride level, θ_{OH^-} decreases with increasing acidity. The present experimental results infer that for $[X^-] = 6N$, corrosion does not pro-

ceed through $FeOH^-_{ads}$ when $[H^+] > 2.4N$. For a given acidity, θ_{OH^-} is the higher for lower chloride concentrations. At $[H^+] = 2.4N$, for example, corrosion of iron in $1N$ chlorides proceeds through $FeOH^-_{ads}$ and not FeX^+_{ads}, as in $6N$ chloride (compare Fig. 5 and 8).

Another improvement in rewriting the LYF scheme is that the sequence [35]-[38] shows clearly the origin of chemisorbed hydroxyls to be the dissociation of adsorbed water molecules. The LYF mechanism is ambiguous in this regard in that the hydroxyl ion is represented as a free solution species, *i.e.*, Eq. [15]. In fact the hydroxyl "ion" must be adsorbed at a vacant site to give $z_{X^-} = -1$ (as $\theta_{X^-} \rightarrow 1$). That is in the LYF scheme, Eq. [13]-[15], it is necessary to write

$$\frac{i_a}{F} = 2\vec{k}_3\beta\theta_{X^-}a_{(OH^-)}(1 - \theta_{X^-}) \quad [45]$$

and

$$\beta\frac{d\theta_{X^-}}{dt} = \vec{k}_2\beta\theta_W a_{(X^-)} - \overleftarrow{k}_{-2}\beta\theta_{X^-} - \vec{k}_3\beta\theta_{X^-}a_{(OH^-)}(1 - \theta_{X^-}) = 0 \quad [46]$$

with

$$\beta\frac{d\theta_W}{dt} = \vec{k}_1(1 - \theta_T) - \overleftarrow{k}_{-1}\beta\theta_W - \vec{k}_2\beta\theta_W a_{(X^-)} + \overleftarrow{k}_{-2}\beta\theta_{X^-} = 0 \quad [47]$$

When $v_3 << v_{-2}$, and $\theta_T = \theta_W + \theta_{X^-} \cong 1$, the resulting expression for i_a is similar to Eq. [43] except that $k_1k_5/k_{-5}a_{(H^+)}$ is replaced by $(k_1 + k_{-1}\beta)a_{(OH^-)}$. Both forms yield Eq. [10]-[12].

Identity relations.—Internal consistency can be checked through the following identity (17, 42) which relates several experimental variables

$$\left(\frac{\partial \log i_a}{\partial \log a_{(H^+)}}\right)_{E,a_{(X^-)}} = -\frac{\left(\frac{\partial E}{\partial \log a_{(H^+)}}\right)_{i_a,a_{(X^-)}}}{\left(\frac{\partial E}{\partial \log i_a}\right)_{a_{(H^+)},a_{(X^-)}}} \quad [48]$$

With $E = \eta + E_{corr}$

$$z_{H^+} = -\frac{1}{b_a}\left\{\left(\frac{\partial \eta}{\partial \log a_{(H^+)}}\right)_{i_a,a_{(X^-)}} + \left(\frac{\partial E_{corr}}{\partial \log a_{(H^+)}}\right)_{a_{(X^-)}}\right\} \quad [49]$$

Figure 10 shows η and E_{corr} as functions of proton activity, and Table VI evaluates the identity from the experimental data.

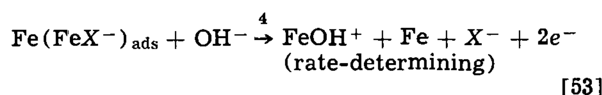
Discussion of other possible mechanisms.—The observation that hydrogen ions catalyze iron dissolution at high $[H^+]$ and $[Cl^-]$, *i.e.*, $z_{H^+} = +2$, is new. For the more familiar case of OH^- participation with $z_{H^+} = -1$, mechanisms other than LYF, *i.e.*, Eq. [13]-[15] or the modified form, Eq. [35]-[38], have been proposed and are discussed briefly below.

Lorenz (2) has suggested that an $Fe(FeX^-)_{ads}$ catalyst participates in the 60 mV mechanism at low pH similarly to the $Fe(FeOH)_{ads}$ catalyst of the Heusler mechanism. The reaction scheme is

$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [50]$$

$$Fe \cdot H_2O_{ads} + X^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeX^-_{ads} + H_2O \quad [51]$$

$$FeX^-_{ads} + Fe \underset{-3}{\overset{3}{\rightleftharpoons}} Fe(FeX^-)_{ads} \equiv \text{catalyst} \quad [52]$$



$$Fe(FeX^-)_{ads} + OH^- \overset{4}{\rightarrow} FeOH^+ + Fe + X^- + 2e^- \quad \text{(rate-determining)} \quad [53]$$

followed by Eq. [5]. If this mechanism proceeds completely analogously to the $Fe(FeOH)_{ads}$ catalyst mechanism; Eq. [8] and [9], then the OH^- in step [53] must react directly with the $Fe(FeX^-)_{ads}$ surface catalyst. The resulting rate equation which we derive is

$$\frac{i_a}{F} = 2\beta\frac{k_3k_4a_{(OH^-)}}{k_{-3}} \cdot \frac{k_1k_2a_{(X^-)}}{(k_1 + k_{-1}\beta)k_{-2} + k_1k_2a_{(X^-)}} \cdot \exp\left(\frac{FE}{RT}\right) \quad [54]$$

with $\theta_{X^-} = k_1k_2a_{(X^-)}/[(k_1 + k_{-1}\beta)k_{-2} + k_1k_2a_{(X^-)}]$. Necessary assumptions required to give Eq. [54] are $v_{-3} >> v_4$ and $\theta_T \cong \theta_W + \theta_{X^-}$. Equation [54] gives $b_a = 60$ mV and $z_{H^+} = -1$, as required, but not $z_{X^-} = -1$. As θ_{X^-} goes from 0 to 1, z_{X^-} goes from 1 to 0, and is never negative, in disagreement with the experimental data (2, 22, 31). To get $z_{X^-} = -1$, the OH^- ion in Eq. [53] must not react directly from solution with the "catalyst" $Fe(FeX^-)_{ads}$, but is required to first adsorb at the surface at vacant sites, as was the case with Eq. [15] in the LYF mechanism. The corresponding rate equation will not be detailed here, as the derivation is similar to the LYF case. With the same assumptions outlined following Eq. [54] plus $k_3 \cong k_{-3}$ the amended rate expression will give $z_{X^-} = -1$ as $\theta_{X^-} \rightarrow 1$. Now, however, the catalytic effect has been removed; and the mechanism is essentially the same as Eq. [13]-[15] except that an unnecessary additional step has been interposed between the adsorption of halide ions and their reaction with hydroxyl ions.

One possible drawback of the mechanisms proposed by Lorenz, Yamaoka, and Fisher (31) and in the present work is the two-electron transfer step. This aspect will be considered after several one-election transfer mechanisms have first been discussed.

Arvia and Podesta (32) have recently proposed a mechanism involving two successive one-electron transfers similar to the Bockris-Kelly mechanism in the absence of halide ions, *i.e.*, Eq. [1]-[5]. The Arvia and Podesta scheme is

$$Fe + X^- \rightleftharpoons FeX^-_{ads} \quad [55]$$

$$FeX^-_{ads} + H_2O \rightleftharpoons FeOH^-_{ads} + H^+ + X^- \quad [56]$$

followed by Eq. [3]-[5]. The rate expression derived by Arvia and Podesta yields $b_a = 40$ mV and $z_{X^-} = 0$. The first result is in disagreement with much evidence (including the present work) that $b_a = 60$ mV for pH

Table VI. Evaluation of Eq. [46]

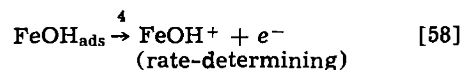
No. of runs	z_{H^+}	(A) $\left(\frac{\partial \eta}{\partial \log a_{(H^+)}}\right)_{i_a,a_{(X^-)}}$	(B) $\left(\frac{\partial E_{corr}}{\partial \log a_{(H^+)}}\right)_{a_{(X^-)}}$	(C) b_a	$z_{H^+} = -\frac{(A) + (B)}{(C)}$
3	−0.9	0 mV	+72 mV	85 mV	−0.85
4	0.0	−76 mV	+79 mV	79 mV	+0.04
4	+1.8	−43 mV	−65 mV	61 mV	1.77

Fig. 10. Evaluation of $\left(\frac{\partial E_{corr}}{\partial \log a_{(H^+)}}\right)_{a(X^-)}$ and $\left(\frac{\partial \eta}{\partial \log a_{(H^+)}}\right)_{i_a, a(X^-)}$ for 6N chlorides in the region where (a) $z_{H^+} = -1$, (b) $z_{H^+} = 0$, and (c) $z_{H^+} \cong +2$.

less than 1.5-2 (2, 20, 22, 31). As mentioned previously, Podesta and Arvia (33) themselves earlier listed $b_a \cong 60$ mV (54 mV) for pH = 1.78 and [Cl⁻] = 2M. The prediction that $z_{X^-} = 0$ is also in disagreement with experiments (20, 22, 31) and with the general observation that halide ions inhibit acid dissolution of iron (4). Thus, the above mechanism is not without drawbacks.

A recent attempt to extrude a 60 mV Tafel slope from consecutive single-electron transfer steps has been made by Asakura and Nobe (43) on the basis of Temkin adsorption. To examine their approach, it is helpful to first reconstruct the mathematics. These authors wrote the Bockris-Kelly mechanism for dissolution in alkaline solutions as

$$Fe + OH^- \underset{-0}{\overset{0}{\rightleftharpoons}} FeOH_{ads} + e^- \quad [57]$$



$$FeOH_{ads} \overset{4}{\rightarrow} FeOH^+ + e^- \text{ (rate-determining)} \quad [58]$$

$$FeOH^+ \underset{-5}{\overset{5}{\rightleftharpoons}} Fe^{++} + OH^- \quad [59]$$

The above sequence is of interest to the present work as the halide ion X^- could conceivably play the role of OH^- in Eq. [57]-[59]. Asakura and Nobe consider the species $FeOH_{ads}$ to follow Temkin rather than Langmuir adsorption. Thus

$$\frac{i_a}{F} = \overline{k}_0'(1-\theta_{OH})a_{(OH^-)}e^{-[\Delta G_1^{\ddagger} + \gamma f(\theta)RT]/RT} - \overline{k}_{-0}'\beta\theta_{OH}e^{-[\Delta G_{-1}^{\ddagger} - (1-\gamma)f(\theta)RT]/RT} + \overline{k}_4'\beta\theta_{OH}e^{-[\Delta G_3^{\ddagger} - (1-\delta)f(\theta)RT]/RT} \quad [60]$$

where $\overline{k_i}$ has the same meaning as before and is given here as $\overline{k_i'}e^{-\Delta G_i^{\neq}/RT}$, with γ, δ, and $f(\theta)$ the Temkin parameters. See Ref. (43, 44). The steady-state expression for $FeOH_{ads}$ is

$$\beta \frac{d\theta_{OH}}{dt} = \overline{k_0}(1-\theta_{OH})a_{(OH^-)}e^{-\gamma f(\theta)} - \overline{k_{-0}}\beta\theta_{OH}e^{(1-\gamma)f(\theta)} - \overline{k_3}\beta\theta_{OH}e^{(1-\delta)f(\theta)} = 0 \quad [61]$$

With $v_{-0} >> v_4$, the above expression was solved for $f(\theta)$

$$f(\theta) = \ln\left[\frac{\overline{k_0}}{\overline{k_{-0}}}a_{(OH^-)}\right] \quad [62]$$

assuming $\ln \theta_{OH}/(1-\theta_{OH})$ to be negligible at intermediate coverages compared to $f(\theta)$ (45). The current density follows as

$$\frac{i_a}{\mathbf{F}} = 2\overline{k_4}\beta\theta_{OH}\left[\frac{\overline{k_0}}{\overline{k_{-0}}}a_{(OH^-)}\right]^{(1-\gamma)} \quad [63]$$

Recall that $\overline{k_i} = k_i e^{\pm\alpha n\mathbf{F}E/RT}$. With both α and γ taken as ½, Eq. [63] gives

$$\frac{i_a}{\mathbf{F}} = 2\left(\frac{k_0}{k_{-0}}\right)^{1/2} k_4\beta\theta_{OH}a_{(OH^-)}{}^{1/2} \cdot \exp\left(\frac{\mathbf{F}E}{RT}\right) \quad [64]$$

Although this expression apparently yields $b_a = 60$ mV, it should be noted that θ_{OH} was not solved explicitly in terms of k. Moreover, the reaction sequence [57]-[59] fails to consider that the electrode surface is water-covered and that adsorption of solution anions is a replacement reaction [46]-[48]. If Eq. [57] is rewritten as

$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [65]$$

$$Fe \cdot H_2O_{ads} + OH^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeOH^-_{ads} + H_2O \quad [66]$$

$$FeOH^-_{ads} \underset{-3}{\overset{3}{\rightleftharpoons}} FeOH_{ads} + e^- \quad [67]$$

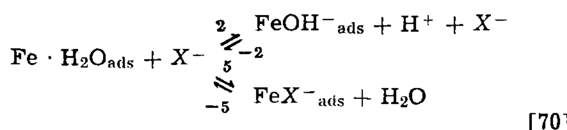
followed by Eq. [58] and [59], a different Tafel slope ensues. The result is

$$\frac{i_a}{\mathbf{F}} = 2k_4\theta_{OH}\left(\frac{k_1}{k_{-1}}\right)^{1/2} \cdot \exp\left(\frac{\mathbf{F}E}{2RT}\right) \quad [68]$$

The necessary conditions are $v_{-3} >> v_4$ and $e^{f(\theta)} >> \theta_W/(1-\theta_T)$. Solution of steady-state kinetics for Eq. [65]-[67] and [58] is similar to the Asakura-Nobe case with the addition that the Temkin parameter $f(\theta)$ vanishes from the exponential for step [67] which involves adsorbate-adsorbate interaction rather than an adsorption or desorption step. The fact that Eq. [68] yields $b_a = 120$ mV when Eq. [64] is modified only to account for the precoverage of the electrode by adsorbed water casts doubt that 60 mV Tafel slopes can be explained on the basis of Temkin adsorption in the Bockris-Kelly mechanism.

Another one-electron transfer scheme which will not explain the experimental results involves a disproportionation reaction similar to that considered by Lovrecek and Marincic (49) for cadmium dissolution. Suppose

$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [69]$$



$$Fe \cdot H_2O_{ads} + X^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeOH^-_{ads} + H^+ + X^-; \quad Fe \cdot H_2O_{ads} + X^- \underset{-5}{\overset{5}{\rightleftharpoons}} FeX^-_{ads} + H_2O \quad [70]$$

$$FeOH^- \underset{-3}{\overset{3}{\rightleftharpoons}} FeOH_{ads} + e^- \quad [71]$$

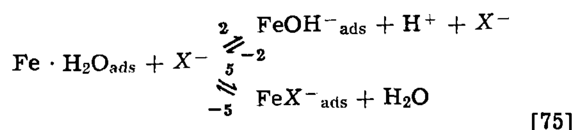
$$FeX^-_{ads} \underset{-4}{\overset{4}{\rightleftharpoons}} FeX_{ads} + e^- \quad [72]$$

$$FeOH_{ads} + FeX_{ads} \underset{-6}{\overset{6}{\rightleftharpoons}} FeOH^+ + FeX^-_{ads} \quad [73]$$

If step 6 is rate-determining, the back reaction should be discounted. With $v_{-3} >> v_6$ and $v_{-4} >> v_6$, and $\theta_T = \theta_W + \theta_{X^-}$, the resulting rate equation gives $z_{H^+} = -1$, $z_{X^-} = -1$ (as $\theta_{X^-} \rightarrow 1$), but $b_a = 30$ mV. If step 3 is rate-determining, the -3 reaction is ignored. With $v_3 << v_6$ and $v_3 << v_{-2}$ and θ_T as before, the resulting rate expression will give the correct values of z_{H^+} and z_{X^-}, but will also give $b_a = 120$ mV rather than 60 mV. If step 4 is rate-determining, similar considerations give not only $b_a = 120$ mV, but also z_{H^+} and $z_{X^-} = 0$, all of which are inconsistent with experimental data.

One mechanism with successive one-electron transfers does have some merit, however, as it can explain some but not all of the present results. This mechanism involves Eq. [1]-[3] of the Bockris-Kelly mechanism in parallel with the formation of a surface complex between $FeOH_{ads}$ and the halide ion

$$Fe + H_2O \underset{-1}{\overset{1}{\rightleftharpoons}} Fe \cdot H_2O_{ads} \quad [74]$$

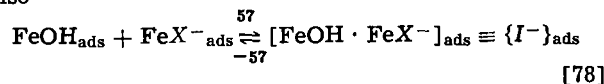


$$Fe \cdot H_2O_{ads} + X^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeOH^-_{ads} + H^+ + X^-; \quad Fe \cdot H_2O_{ads} + X^- \underset{-5}{\overset{5}{\rightleftharpoons}} FeX^-_{ads} + H_2O \quad [75]$$

$$FeOH^-_{ads} \underset{-3}{\overset{3}{\rightleftharpoons}} FeOH_{ads} + e^- \quad [76]$$

$$FeOH_{ads} \overset{4}{\rightarrow} FeOH^+ + e^- \quad [77]$$

Also



$$FeOH_{ads} + FeX^-_{ads} \underset{-57}{\overset{57}{\rightleftharpoons}} [FeOH \cdot FeX^-]_{ads} \equiv \{I^-\}_{ads} \quad [78]$$

$$\{I^-\}_{ads} \overset{58}{\rightarrow} FeOH^+ + FeX^-_{ads} + e^- \quad \text{(fast)} \quad [79]$$

This scheme is the same as that given by Kelly for the effect of the benzoate anions on iron dissolution in sulfuric acid (50). Here X^- plays the role of Bz^- in Ref. (50). The resulting rate equation is

$$\frac{i_a}{\mathbf{F}} = 2\beta\frac{k_1k_2k_3k_4}{k_{-2}k_{-3}a_{(H^+)}} \cdot \frac{k_{-5}}{k_1k_5a_{(X^-)} + k_{-5}(k_1 + k_{-1}\beta)}\exp\left(\frac{3\mathbf{F}E}{2RT}\right) + 2\beta^2k_{57}\frac{k_1k_2k_3k_{-5}}{k_{-2}k_{-3}a_{(H^+)}} \cdot \frac{k_1k_5a_{(X^-)}}{[k_1k_5a_{(X^-)} + k_{-5}(k_1 + k_{-1}\beta)]^2}\exp\left(\frac{\mathbf{F}E}{RT}\right) \quad [80]$$

with the necessary conditions being $\overline{k_{58}} >> \overline{k_{-57}}$, $v_{-3} >> v_4 + v_{58}$, and $\theta_T \cong \theta_W + \theta_{X^-}$. For details see Ref. (50). With $\theta_{X^-} = k_1k_5a_{(X^-)}/[k_1k_5a_{(X^-)} + k_{-5}(k_1 + k_{-1}\beta)]$, the first term on the right hand side of Eq. [80] can be recast as $i_{a,\theta_{X^-}=0} \cdot (1-\theta_{X^-})$, as noted by Kelly (50), so that Eq. [80] can be abbreviated as

$$i_a = i_{a,\theta_{X^-}=0}(1-\theta_{X^-}) + i_a{}^* \quad [81]$$

If $v_{58} >> v_4$, then $i_a = i_a{}^*$ and Eq. [80] yields Eq. [10]-[12]. It may be noted that if the desorption of the halide ion is the slow step ($k_{58} << k_{-57}$), the ensuing Tafel slope will revert to 40 mV.

If the electrostatic attraction of H^+ ions for FeX^-_{ads} is considered, the reaction mechanism may be modified to be Eq. [74]-[77] plus

$$FeX^-_{ads} + H^+ \rightleftharpoons FeX^- \cdot H^+ \equiv \text{complex 1} \quad [82]$$

$$FeX^- \cdot H^+ + FeOH_{ads} \rightleftharpoons [FeX^- \cdot H^+ \cdot FeOH]_{ads} \equiv \text{complex 2} \quad [83]$$

$$\text{complex 2} \rightarrow FeOH^+ + FeX^- \cdot H^+ + e^- \quad [84]$$

With $\overrightarrow{k}_{84}a_{(H^+)} >> \overleftarrow{k}_{-83}$, $\theta_T \cong \theta_W + \theta_{X^-}$, $v_{-3} >> v_4 + v_{84}$, and $v_{84} >> v_4$, the result is

$$\frac{i_a}{F} = 2\beta^2 \frac{k_{83}k_{82}}{k_{-82}} \cdot \frac{k_1k_2k_3k_{-5}}{k_{-2}k_{-3}} \cdot \frac{k_1k_5a_{(X^-)}}{[k_1k_5a_{(X^-)} + k_{-5}(k_1 + k_{-1}\beta)]^2} \cdot \exp\left(\frac{FE}{RT}\right) \quad [85]$$

which gives $b_a = 60$ mV, $z_{H^+} = 0$, and $z_{X^-} = -1$ (as $\theta_{X^-} \rightarrow 1$). The first two parameters correspond to the middle region of Fig. 8 (z_{X^-} was not determined experimentally.[4] However, this system of parallel reactions cannot be extended to explain synergistic dissolution where $z_{H^+} = +2$. To get $z_{H^+} = +2$, it is necessary that a total of three hydrogen ions participate in steps [82] and [83], *e.g.*, three H^+ ions could be electrostatically attracted to FeX^-_{ads}. This occurrence seems unlikely. It should be noted that the number j of H^+ ions (if any) participating in step [84] is unimportant as the term $\overrightarrow{k}_{84}(\beta\theta_{\text{complex 2}})a_{(H^+)}{}^j$ is recast in terms of $\overrightarrow{k}_{83}$ in the steady-state solutions of the dissolution kinetics for Eq. [74]-[77] together with [82]-[84].

Thus, at present it is difficult to interpret the total experimental results reported herein without invoking the concept of the two-electron transfer step. According to one point of view (51), the probability of two electrons tunneling simultaneously between the metal and an ion is low enough to be prohibitive. However, this question still remains open as the theoretical treatment of electron tunneling at the electrode/solution interface in the presence of "adsorbed" species is not yet well-developed. The rate constant is given by (52)

$$k = \frac{k_BT}{h} \chi_e \exp\left(\frac{-E^*}{RT}\right) \quad [86]$$

with χ_e the probability of electron tunneling. Thus, a lower probability of tunneling ($\chi_e < \chi_e{}^2$) could be coupled with a lower activation energy E^* (possibly caused by adsorbed chloride) to give a rate comparable to a higher probability coupled with a higher activation energy.

The two-electron transfer step has in fact been shown to be possible for Tl(I)-Tl(III) exchange in solution (52), and is thought possible when the reaction is catalyzed by a platinum black surface (53). Within the past year, two-electron transfer steps have been proposed for the dissolution of tungsten in NaOH (54) and for zinc in water-propanol mixtures (55). To cite another case, Timmers, Sluyters-Rehbach, and Sluyters (56) are of the opinion that Zn^+ is not a stable intermediate at the zinc amalgam electrode, which instead reacts in a two-electron step. Hampson and co-workers (57) have recently proposed that for PbO_2 in alkali, the charge transfer at low overvoltage is a two-electron transfer step.

Summary

An important feature of the present results is that iron dissolution at high $[H^+]$ and $[Cl^-]$ is promoted by hydrogen ions rather than by hydroxyls. A detailed mechanism has been proposed involving electrostatic attraction of H^+ ions to chemisorbed halide ions. Various reaction mechanisms which have appeared in the literature have been discussed and have been shown to be either inadequate or inapplicable.

[4] In a two-electron transfer scheme, $z_{H^+} = 0$ ensues for Eq. [17], [18] followed by $FeX^-_{ads} \rightarrow FeX^+ + 2e^-$ and then Eq. [21].

Kinetics of the Deposition of Inert Particles from Electrolytic Baths

N. Guglielmi*

Laboratori di Ricera Tecnologica, Ing. C. Olivetti & C. S.p.A., Ivrea, Italy

ABSTRACT

To explain the peculiarities shown by the codeposition of inert particles from electrolytic baths, a mechanism based on two successive adsorption steps is proposed. In the first step the particles are loosely adsorbed, and they are in equilibrium with the particles in suspension. In the second step the particles are irreversibly adsorbed. Making a few elementary hypotheses about the mechanism that governs the two steps it is possible to deduce a general expression relating the concentration of the embedded particles to the suspension concentration and the electrode overpotential. This relationship is verified experimentally.

The possibility of codepositing inert particles from electrolytic baths in order to obtain composite layers of a metal matrix containing finely dispersed inert particles has long been known (1, 2). In more recent years this technique has received increasing attention in view of the interesting possibilities it offers, for example, the electrodeposition of layers characterized by desirable properties like wear and abrasion resistance, the electroforming of dispersion-hardened alloys, and so on (3, 4).

Although the technique has been considerably developed from the practical point of view, the theoretical details of the deposition mechanism have not received particular attention, and are actually far from being well understood. The problem is to give a physical explanation of the deposition of the "inert" particles together with the metal ions, and to justify the influence of the principal parameters acting on the process, which have been shown to be the current density and the particle concentration in the bath. In Fig. 1 a typical example of codeposition curves is shown. The nonlinear dependence on concentration, even in very diluted suspensions, and the pronounced dependence on current density, can be noted.

Two different phenomena can be taken into account to explain the observed deposition: electrophoresis and adsorption. Both possibilities can be supported by some arguments and contradicted by others.

An electrophoretic effect could explain the observed dependence on current density, but some difficulty would arise as far as the nonlinear concentration dependence is concerned. In every case a fundamental objection must be advanced against the possibility of an electrophoretic effect in a medium of very high ionic strength such as a plating bath.

On the other hand, the striking similarity of the curves in Fig. 1 with the well known adsorption isotherms undoubtedly supports a mechanism based on an adsorption effect. But such an hypothesis is contradicted by the very low value of the coverage where the surface appears to be saturated. In addition, it can be shown that a simple adsorption mechanism cannot give a satisfactory explanation for the observed dependence on current density.

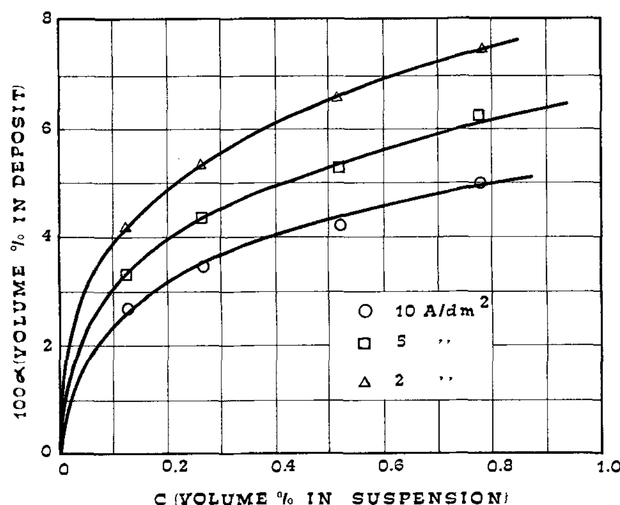

Fig. 1. Codeposition of TiO_2 particles from nickel sulfamate bath

* Electrochemical Society Active Member.

Key words: composite deposits, deposition mechanism, inert particles.

To find a solution for the above dilemma we make use of the evident complementary relationship existing between the two mechanisms just discussed and advance a hypothesis in which both are taken into account in such a way as to eliminate the contradictions.

The proposed mechanism is based on two consecutive adsorption steps. The first step is postulated to be substantially physical in character and to produce a layer of loosely adsorbed particles with a rather high coverage. The second adsorption step is thought to be field assisted, therefore substantially electrochemical in character, and produces a strong adsorption of the particles onto the electrode. The strongly adsorbed particles are then progressively submerged by the growing metal.

As to the physical meaning of the two adsorption steps, it can be inferred that in the first the inert particles are still coated by a thin layer of adsorbed ions and solvent molecules, which substantially screens the interaction between the electrode and the particles. In the second step the electrical field existing at the interface helps to uncover the particles, so producing a stronger, field-assisted adsorption. There is an evident analogy between the two postulated stages of adsorption for the particles and the adsorption of ions respectively in the outer and inner Helmholtz planes of the electrode.

It can be shown that the postulated mechanism is not affected by the above-mentioned objections, and makes it possible to justify both current density and nonlinear concentration dependence of the deposition process. In the following a quantitative treatment of the proposed model is developed and subjected to experimental verification.

Mathematical Treatment

The previously outlined model is schematically shown in Fig. 2. The steps of loose adsorption, strong adsorption, and embedding have been represented as progressing from the top to the bottom of the figure, but are obviously randomly distributed over the whole surface of the electrode. The minimum approach distance of the loosely adsorbed particles, which has molecular dimensions, has been markedly exaggerated. We define the loose adsorption coverage, σ, and the strong adsorption coverage, ϑ, respectively as

$$\sigma = S_l/S \quad \vartheta = S_s/S \qquad [1]$$

where S, S_s, S_l are the total electrode area, and respectively the area overshadowed by strongly adsorbed and partially embedded particles and by loosely adsorbed particles.

The dependence of σ on the concentration C of suspended particles can be deduced in much the same way as the classical Langmuir adsorption isotherm (5), the difference being that only a fraction $(1 - \vartheta)$ of the surface area is really available for the establishment of the equilibrium. It is easily seen that such a limitation can be taken into account by introducing a factor

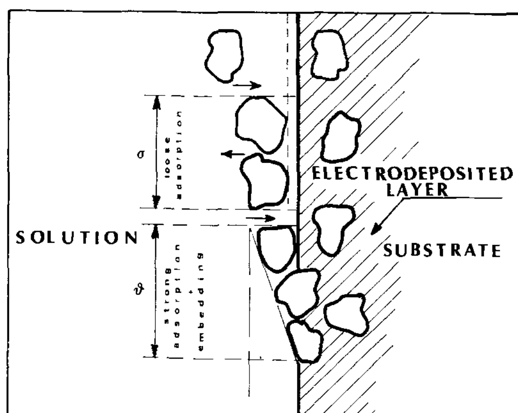

Fig. 2. Scheme of the two-step deposition process

$(1 - \vartheta)$ into the classical expression of the isotherm and therefore

$$\sigma = \frac{kC}{1 + kC}(1 - \vartheta) \qquad [2]$$

where the constant k depends essentially on the intensity of the interaction between particles and electrode.

The dependence on σ of the strong adsorption rate is obviously linear. To take into account the postulated field dependence of the process, we introduce an exponential rate factor $v_o e^{B\eta}$ where η is the overpotential related to the metal deposition process, while v_o and B are constants.

Such a factor has a strict analogy with the Tafel exponential governing the electrode processes at high overpotentials, and it is compatible with an adsorption mechanism implying a field-assisted activated state.

As to the apparently arbitrary dependence on η, which is here introduced for convenience, it can be noted that, if an exponential dependence on field intensity at the interface is accepted, every magnitude linearly related to such field intensity, and therefore also η, can be inserted in the exponential if the constants v_o and B are properly adjusted. We can therefore write for the strong adsorption rate, taking Eq. [2] into account

$$dV_p/dt = \sigma v_o e^{B\eta} = v_o e^{B\eta}(1 - \vartheta)\frac{kC}{1 + kC} \qquad [3]$$

where dV_p/dt is the volume of particles strongly adsorbed on 1 cm^2 of electrode surface per second.

The volume dV_m/dt of metal electrodeposited on 1 cm^2 of electrode surface per second can be deduced from Faraday's law

$$dV_m/dt = \frac{Wi}{n\mathbf{F}d} \qquad [4]$$

where $\mathbf{F}$ is the Faraday constant, W the atomic weight of the electrodeposited metal, d the density of the same, n the valence, and i the current density.

If the particle concentration in the deposit is expressed as volume fraction α, it is easily seen that the total volume (metal + particles) deposited on 1 cm^2 of electrode surface per second can be expressed as

$$dV/dt = \frac{dV_m}{dt(1 - \alpha)} = \frac{Wi}{n\mathbf{F}d(1 - \alpha)} \qquad [5]$$

On the other hand, the current density i is related to the overpotential by the Butler-Vomer equation (6), which at high field approximation can be written in the Tafel form

$$i = (1 - \vartheta)i_o e^{A\eta} \qquad [6]$$

where the factor $(1 - \vartheta)$ takes into account the area really available for electrodeposition. Inserting Eq. [6] in Eq. [5] we get

$$dV/dt = \frac{Wi_o e^{A\eta}(1 - \vartheta)}{n\mathbf{F}d(1 - \alpha)} \qquad [7]$$

The volume fraction α of particles in the deposit can be related, in a stationary condition, to the rates of strong adsorption dV_p/dt and total deposition dV/dt

$$\alpha = \frac{dV_p/dt}{dV/dt} \qquad [8]$$

Substituting Eq. [3] and [7] in Eq. [8] and rearranging, we arrive at a general expression, relating the volume fraction of the embedded particles to the suspension concentration and the electrode overpotential

$$\frac{\alpha}{1 - \alpha} = \frac{n\mathbf{F}dv_o}{Wi_o} \cdot e^{(B-A)\eta} \cdot \frac{kC}{1 + kC} \qquad [9]$$

This equation summarizes all the principal features of the inert particle codeposition. The depen-

dence on concentration is proportional, but not identical with the adsorption isotherm factor [2] and therefore the observed apparent saturation of the electrode at low values of ϑ can be explained by the related high values of σ. The parameters v_0 and B, related to the particles' deposition, play a symmetrical role with the parameters i_0, and A related to the metal deposition. In particular, α increases or decreases with η depending on the relative values of A and B. In the restricted case of low values of α the factor $(1 - \alpha)$ can be dropped and Eq. [9] can be rearranged in the following form

$$\frac{C}{\alpha} = \frac{Wi_0}{n\mathbf{F}dv_0} \cdot e^{(A-B)\eta} \cdot \left(\frac{1}{k} + C\right) \quad [10]$$

If the expression constituting the left-hand side is plotted against C for different values of η, it represents a sheaf of straight lines having the common intersection on the point $1/k$ of the C axis and a slope equal to the factor outside the parenthesis

$$tg\phi = \frac{Wi_0}{n\mathbf{F}dv_0} \cdot e^{(A-B)\eta} \quad [11]$$

Equation [10] should be tested by deposition experiments at constant potential; however it also has an approximate validity at constant current, as long as the factor α is small. In this approximation, $i/i_0 \simeq e^{A\eta}$ and the following substitutions can be made in order to express $tg\phi$ as a function of i

$$i_0 e^{(A-B)\eta} = i_0 e^{A\eta(1-B/A)} = i_0^{B/A} i^{(1-B/A)} \quad [12]$$

Substituting the last expression in Eq. [11] and taking the logarithms we get

$$\log tg\phi = \log \frac{Wi_0^{B/A}}{n\mathbf{F}dv_0} + (1 - B/A)\log i \quad [13]$$

which shows linear dependence of $\log tg\phi$ on $\log i$.

If we plot $tg\phi$ against i in logarithmic coordinates we obtain a straight line having a slope $(1 - B/A)$ and a value at $i = 1 (\log i = 0)$ equal to the argument of the first term appearing in the right-hand side of Eq. [13].

Experimental

The apparatus and the experimental techniques used to obtain the deposits have been described elsewhere (7). The plating solution was a normal sulfamate bath of the following composition:

Nickel sulfamate	400 g/liter
Nickel chloride	5 g/liter
Boric acid	30 g/liter
Antipit agent	0.5 g/liter
pH	4 ± 0.2
Temperature	$50°C \pm 2°C$

To this bath were added variable amounts of the following powders: (*i*) TiO_2, C. Erba S.p.A. reagent grade, mean size 1 μm, density 3.84. (*ii*) SiC, Elektroschmelzwerk GmbH, mean size 2 μm, density 3.21. All deposits were obtained at constant current. The analyses were performed by gravimetric methods.

Results and Discussion

In Fig. 3 the experimental results of Fig. 1, concerning Ni-TiO_2 deposits, are plotted according to Eq. [10]. The experimental points can be satisfactorily grouped on a sheaf of straight lines converging at a negative point on the abscissa, as required by the above-developed theory.

The common intercept on the C axis has a value -0.19, which can be equated to $-1/k$ giving 5.3 for the adsorption constant k. Such a constant is dimensionally a pure number, being the inverse of a dimensionless per cent concentration.

For particles of reasonably regular shape, the volume fraction α has nearly the same value as the surface fraction ϑ. It is therefore possible, knowing k and ϑ, to compute σ by means of Eq. [2]. In Table I the computed concentrations are listed at a fixed current density. All the values being given as percentages it is possible to compare surface and volume concentrations on a common scale. The values 100α, as noted above, are also indicative of the surface concentration of strongly adsorbed particles.

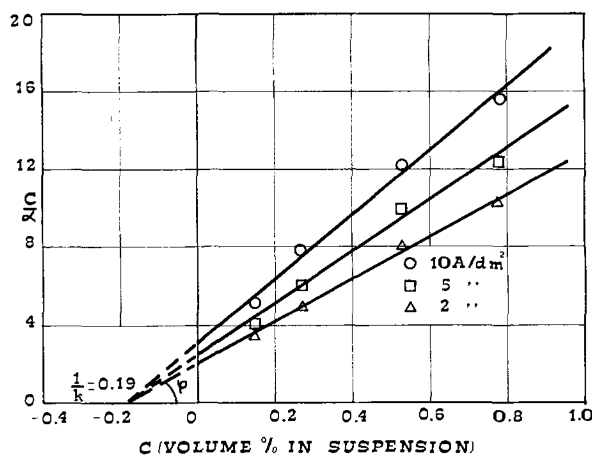

Fig. 3. Codeposition of TiO_2 particles according to Eq. [10]

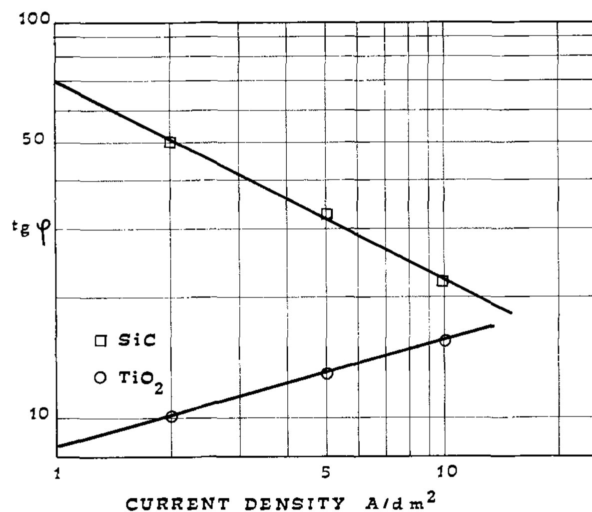

Fig. 4. Slope ($tg\phi$) dependence on current density

It can easily be seen that the concentration of loosely adsorbed particles is greater by two orders of magnitude than the concentration of suspended particles, and that also in very diluted suspensions a prevailing fraction of the electrode surface is screened, so justifying the premature saturation of the surface experimentally observed. The substantially lower concentration of strongly adsorbed particles shows that the second adsorption step is relatively slow. In Fig. 4 the logarithms of the slope $tg\phi$ of the lines in Fig. 3, are plotted against $\log i$. The values are well grouped on a straight line with a slope 0.35. Equating this value to $(1 - B/A)$ according to Eq. [13] it is possible to express B in terms of A

$$B = 0.65A \quad [14]$$

A similar analysis has been carried out on Ni-SiC

Table I. Per cent concentration of TiO_2 particles at 5 A/dm²

C (%)	100σ (%)	100α (%)
0.13	40.8	3.5
0.26	55.2	4.3
0.52	69.5	5.2
0.78	75.5	6.2

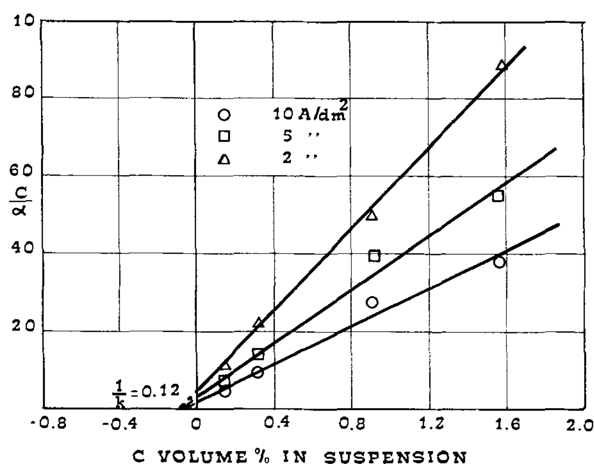

Fig. 5. Codeposition of SiC particles according to Eq. [10]

deposits on the basis of the experimental results plotted in Fig. 5 in the same way as those of Fig. 3. Also in this case the points group well on a sheaf of straight lines converging to a negative point on the C axis. The constant k is substantially higher than in the previous case, having a value 8.3. By use of such a value the surface concentration of loosely adsorbed particles can be computed, obtaining the results reported in Table II for $i = 5$ A/dm^2. The loose adsorption of SiC particles is notably greater than that of TiO_2 particles and can lead to an almost complete saturation of the surface.

Figure 4 shows the dependence of $tg\phi$ on current density for Ni-SiC deposits. The slope of the straight line is negative with a value -0.51 which gives the following expression for the constant B

$$B = 1.51A \quad [15]$$

We note that if $B > A$ there is an increase of α when current density is increased while in the case $B < A$ there is a corresponding decrease. TiO_2 and SiC particles in sulfamate baths illustrate the two cases.

The very high coverage by loosely adsorbed particles observed on the electrode points out the problem of the interference of these particles with the electrodeposition of metal ions. Since the metal layers are compact and uniformly deposited it must be concluded that the interference is not so important. It can be argued that the particles, gigantic in respect to ionic dimensions, do not block the arrival of ions to the electrode surface, in a similar way as a disconnected row of irregular big stones does not stop a stream of water. It seems probable that by means of electrode polarization measurements a better insight into this problem could be obtained.

Table II. Per cent concentration of SiC particles at 5 A/dm^2

C (%)	100σ (%)	100α (%)
0.16	55.7	1.9
0.31	70.8	2.1
0.93	86.5	2.3
1.56	90.2	2.8

Conclusions

The experimental data agree well with the proposed codeposition mechanism based on a two-step adsorption process. In this model the deposition of inert particles depends on three parameters (k, v_o, B). All these can be computed by means of the relations [10] and [13] once the constants i_o and A, obtainable by overpotential measurements in the plating solution, are known.

The strong dependence of particle codeposition on solution composition, observed by many authors, can easily be justified in the present model since the behavior of the particles depends strictly on the structure of the layer of molecules and ions adsorbed on their surface, and indirectly on the composition of the solution.

A separate determination of the three parameters k, v_o, and B at different compositions could probably give more detailed information on the effective action of the various solution components. Research in this direction is presently being carried out by our laboratory and will be the subject of a later paper.

The Role of U.V. Light in the Inhibition of Electroless Deposition

S. L. Chow, N. E. Hedgecock, M. Schlesinger, and J. Rezek

Department of Physics and Department of Engineering Materials, University of Windsor, Windsor, Ontario, Canada

ABSTRACT

Ultraviolet light has been shown to be effective in inhibiting the electroless deposition of Cu, Ni, and Co if applied after sensitization, and of Ni and Co after activation. Electron microscopic techniques are applied to investigate these phenomena. It is concluded that structural changes in the sensitizing and activating agents induced by the u.v. light are connected with the inhibition of metal deposition.

Thin metal films deposited by the electroless process have attracted the interest of a number of workers recently. This is largely so because of the considerable technical potential that this kind of film has. One of the rather interesting characteristics that these films have is the relative ease with which they can be deposited. Although quite a number of chemical systems for metal deposition have been developed (1), little is understood about the actual mechanisms which govern the physical chemistry of these systems.

We have investigated previously (2) the nucleation and growth of thin electroless Ni-P deposits. Sard has carried out (3) similar studies on electroless copper deposits. The nucleation of electroless Co-P deposits has been studied to some extent by Frieze, Sard, and Weil (4).

An important property of electroless systems is their ability to deposit metals selectively. This has been demonstrated by Sharp and co-workers (5) who desensitized portions of a surface with u.v. radiation. The same effect has been observed by other workers [see, for example, Ref. (6)]. In an effort to further elucidate the process of sensitization prior to deposition, Cohen *et al.* (6) used Mossbauer spectroscopy to study tin sensitizer deposits formed on Kapton films (du Pont polyimide). On the basis of these and other results, they have concluded that the sensitizer is present as a colloid in the sensitizing bath and is adsorbed on the substrate when it is dipped. They also suggested that the photosensitive substance contains more Sn^{+4} than Sn^{+2}. The Sn^{+2} is oxidized by exposure either to air or to the Pd activation bath. In the Pd bath the process

$$Pd^{+2} + Sn^{+2} \quad Pd^{\circ} + Sn^{+4}$$

presumably leads to the formation of a Pd layer on the substrate. This surface supposedly provides catalytic sites for deposition of the electroless metal. Ultraviolet irradiation is assumed to inhibit the metal growth by simply oxidizing the Sn^{+2} to Sn^{+4} prior to the Pd bath, hence, preventing the formation of a palladium layer.

No previous studies have been reported of the effect of u.v. irradiation on the palladium activated surface. Working with Ni and Co, we have found that u.v. light is effective in inhibiting the electroless deposition even if it is applied after activation. This, we shall show, renders the model of Cohen *et al.* (6) rather incomplete. Based on some experimental evidence, we claim that the u.v. introduces structural changes in the catalytic sites. As a result of those changes electroless deposition becomes impossible.

Experimental

Although our main interest in this work has been a study of the premetalizing stages, the complete processes for electroless deposition of nickel, copper and cobalt were used in the investigation. The chemical solutions employed for deposition of the three metals were as given in the literature (2-4). All chemicals were supplied by Fisher or Canlab, and were used without further purification.

Microscope slide glasses coated on both sides with Formvar (4g polyvinylformal in 1 liter of ethylene dichloride) were used as substrates. The Formvar was floated off the glass in distilled water.

The samples were examined with a Hitachi HU-12 electron microscope. The effect of irradiation on the microstructure of the sensitized and activated surfaces was investigated by examining samples in the microscope, removing them for irradiation, and then reexamining the same samples.

In investigating the effect of u.v. irradiation on the metal deposition, Formvar coated glass substrates were immersed in the sensitizing (or sensitizing and activating) solutions and then irradiated, on one side only, with u.v. light. The opacity of the glass prevented irradiation of the other side. Continuation of the deposition process resulted in normal deposition on the nonirradiated side, showing that any inhibition of deposition on the other side was directly due to the irradiation.

The u.v. irradiation was carried out using an Oriel 50W mercury lamp at a distance of about 5 cm from the sample.

Results

In Fig. 1 we present transmission electron micrographs of Formvar coated surfaces: a, sensitized (1 min) and rinsed (½ min); and b, sensitized (1 min), rinsed (½ min), activated (1 min), and rinsed (½ min). In accordance with Sard's observation, the product of the sensitization process appears to consist of particles of approximately 20Å diameter, agglomerated into dense clumps an order of magnitude or so larger. The clumps themselves are randomly distributed on the surface. The activated surface shows particles of about 50Å in size. This is presumably (3) a deposit of metallic palladium.

In Fig. 2, the corresponding diffraction patterns are shown. Figure 2a, for the sensitized surface, is a pattern which seems to be characteristic of SnO_2 (3). The pattern for the sensitized and activated surface is seen in Fig. 2b. It is rather difficult to attribute these diffuse patterns to any one symmetry or chemical compound. One might expect a more distinctive pattern from the activated layer since a palladium layer would be expected in accordance with Bravais' law to form with the close packed planes {111} parallel to the substrate surface. We assume that the lack of a distinctive pattern is due to the small particle size.

Figure 3 shows the effect of ultraviolet irradiation on the a, sensitized, and b, sensitized and activated

Formvar surfaces. The electron diffraction patterns obtained before (I) and after (II) 50 min of u.v. illumination are shown for each case. We have found that the u.v. treatment is effective at both stages in inhibiting the deposition of nickel and cobalt. In the case of copper, however, u.v. light is effective only after the sensitization stage. The significance of the difference in behavior between copper on the one hand and nickel and cobalt on the other is discussed below.

Figure 4 shows micrographs and corresponding diffraction patterns of Co-P films at early stages of growth. These results show clearly that the deposit is initially amorphous, and that the extent of crystallization and the size of the individual crystallites increase with deposition time. Other factors, such as the *p*H of the metalizing bath, influence the degree of crystallization and are being currently investigated by us.

Discussion

Working with electrolessly deposited copper, Cohen *et al.* (6) have found that u.v. irradiation after sensitization is sufficient to inhibit metal deposition. This they explained in terms of the oxidation of Sn^{+2} to Sn^{+4} by the u.v. light. The Sn^{+2} is essential for the formation of the metallic Pd deposit in the activation stage (see above). It is plain that this cannot be accepted as the complete explanation of the role of u.v. in inhibiting growth since, for Co or Ni, u.v. light is effective in inhibiting metal deposition even after the Pd bath.

Based on the results presented in Fig. 3, we believe that an explanation of the influence of u.v. light must also include crystalline structure changes. While more experimental work is needed before a complete model

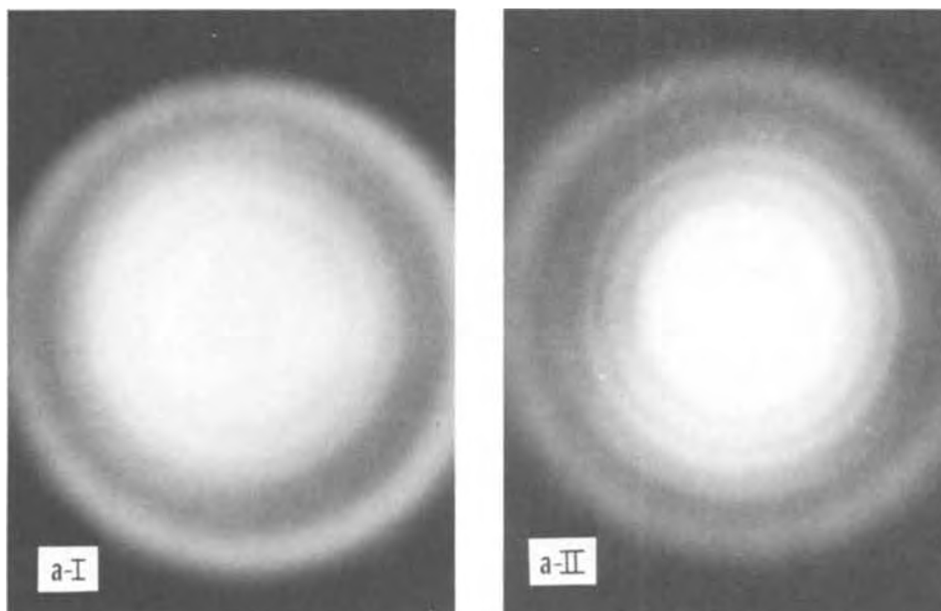

Fig. 3a—I. Electron diffraction pattern of sensitized Formvar (no u.v.); Electron beam energy 100 keV. 3a—II. Diffraction pattern for the same sample as in 3a—I after 50 min u.v. illumination.

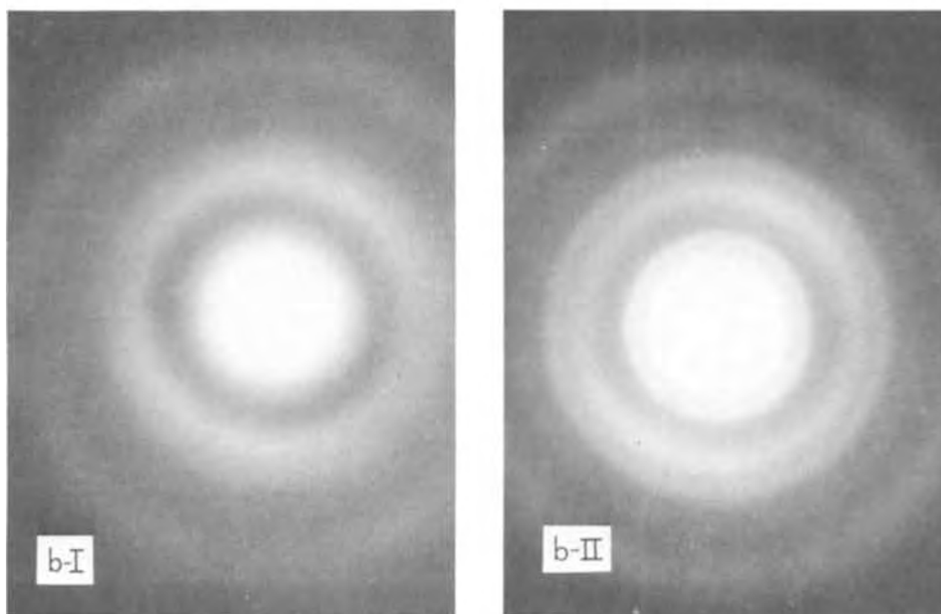

Fig. 3b—I. Electron diffraction pattern of activated Formvar (no u.v.); Electron beam energy 100 keV. 3b—II. Diffraction pattern for the same sample as in 3b—I after 50 min u.v. illumination.

can be drawn, one can argue in the following qualitative way.

The effect of irradiation on the diffraction patterns of both the sensitized and activated layers is to increase the degree of crystallization. This is a consistent trend which was observed in many samples prepared under various conditions. In the case of the sensitized layer, this may well be associated with the oxidation of a divalent tin compound to form SnO_2; but it is also clear that the degree of crystallization is also increased by the irradiation. The situation is similar for the activated layer. It is harder to envisage a chemical change in metallic palladium resulting from irradiation, although, it is tempting to suggest an oxidation to a divalent state by analogy with the oxidation of the tin compound. In any event, again a higher degree of crystallization definitely results from the irradiation.

The fact that deposition of nickel and cobalt is inhibited by irradiation of the activated layer, while copper is deposited with no discernible change in the rate of deposition, is particularly interesting. This disparity in behavior cannot be explained simply in terms of the crystal structure of the metals involved. Palladium is face-centered cubic, and it is reasonable to suppose that other metals with the same crystal structure could form epitaxially on the palladium. Both copper and nickel are face-centered cubic; cobalt is normally hexagonal close packed. Hence, on this basis one would expect cobalt rather than copper to behave differently.

The difference most probably lies in the fact that the chemistry of the nickel and cobalt deposition processes is closely related, and involves phosphorus, which is incorporated into the deposited layer. For copper, however, no hypophosphite is used in the metalizing solution, and it is known that hydrogen is incorporated into the deposited film. This difference might be the reason for an initially liquid-like structure for both Ni(2) and Co (see Fig. 4). In carrying this point somewhat further it may be speculated that, under such circumstances, an increased crystallinity in the Pd prior to metalizing might well inhibit the deposition of Ni and Co. The present state of knowledge of the detailed chemistry of the processes is inadequate to provide any further explanation.

Two-Layer Printed Wirings on Mylar Foil

A. Politycki

Siemens AG, Forschungslaboratorien München, 8000 München 80, Balanstrasse 73, West Germany

ABSTRACT

Two-layer wirings with a total thickness of only 15 μm could be prepared by chemically metalizing a 5 μm Mylar foil, electrodeposition of copper and photoetching. It was possible to produce plates of the outer dimensions 170 × 360 mm. Resistances of the metal lines (100 μm width and 5 μm thickness) were equal to within ±5% of an average value. Matrices of this sort may be used for various purposes, *e.g.*, as drive line systems for low-current plane magnetic film memories.

For the realization of plane magnetic film memories, suitable drive line systems are necessary to operate the magnetic elements. It has proved advantageous to apply flexible printed wirings in front of the memory plane. They may be produced by photoetching of commercial copper-clad polyester or polyimide foils, as was done by Bittmann *et al.* (1). In commercial copper-clad laminates, which are now available in great variety (2), the separation between the two metallic sheets amounts to more than 20 μm. The distance of the lines from the magnetic elements has a very great influence on the intensity of the necessary drive current. In order to develop a low-current planar magnetic film memory it was, therefore, necessary to have a line matrix with a very small separation of the lines on both sides of the support. It was the purpose of the present work to produce a two-layer wiring matrix with a total thickness of 15 μm.

A Mylar foil of 5 μm thickness was chosen as the substrate, which was to be chemically metalized without using adhesives. The thin metal film was to be reinforced by electrodeposited copper so that the line pattern could then be etched.

The main problem was the poor adherence of the metal to the Mylar due to the lack of chemical bonding forces on the mechanically smooth surface. Without adhesives, Mylar foils have only been coated with metal films of less than 0.3 μm thickness (3, 4).

In preparation for metalization, the specimens were dipped into a hot solution of sodium hydroxide for 5 min. By this means, a surface layer of about 1 μm thickness was dissolved and the remaining foil was roughened. It was useful to mechanically vibrate the frame during this hot dip. After activation in solutions of tin chloride and palladium chloride the Mylar was ready for metalization. Chemically deposited copper or nickel resulted in unsatisfactory adherence. Satisfactory adherence was achieved, however, when chemically deposited films of silver, which had been aged, were reinforced by copper.

Without aging, the peel strength of etched silver/copper lines was very poor, but an increase was noticed when the silver film was heated for several hours at 100°C. A second heat-treatment after the electrodeposition of copper resulted in a further small improvement. This adherence, though not very strong, proved satisfactory, since all parts of the memory matrix were to be held together by compression. Figure 1 shows a micrograph of this type of double-coated Mylar foil. The silver film, having a thickness of only 200 nm, cannot be observed, whereas the copper deposit on both sides of the insulating material is clearly visible. The separation of the two metallic planes is 4 μm. In comparison to this, the separation of the two metallic sheets of a commercial copper-clad foil ranges between 20 and 30 μm.

For reasons of corrosion resistance and soldering technique, it was preferred to have the lines coated with gold. A reversed photomask was, therefore, applied, and the noble metal was electrolytically deposited onto the unprotected areas. This was performed by applying a commercial, neutral gold bath, which operated at 75°C and had a yield of nearly 100%. The gold layer of 2 μm thickness served as an etching mask for the production of the line pattern on both sides of the foil. Etching was carried out using a solution of chromium oxide in sulfuric acid. To complete the removal of the silver, an intermediate treatment in a solution of sodium thiosulfate was used. Figure 2 shows a matrix with the outer dimensions of 160 × 200 mm. The word lines are seen on the upper side of the foil in a vertical position. They begin near the edge of the frame and extend to the opposite strip

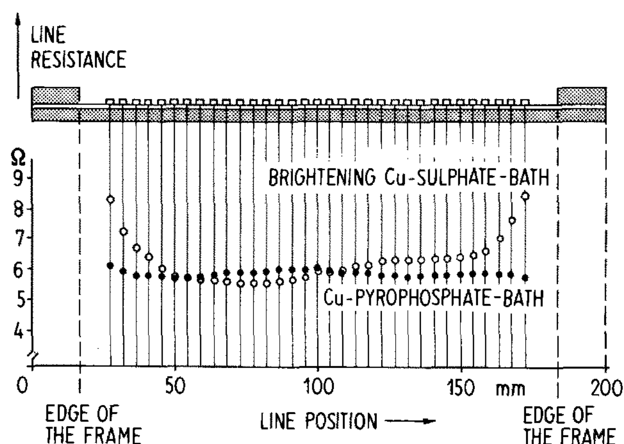

Fig. 3. Resistance of word lines as a function of the position in the matrix.

below. On the reverse side, the digit lines cover the foil in a horizontal position. It was necessary that all resistances of the lines should be equal to within ± 5% of an average value. We were, therefore, obliged to check the resistance of every line. This was performed automatically by a motor driven contact and a strip-chart recorder. Figure 3 shows typical resistance values for the x-lines of two different matrices. Over the middle of the plate, whose copper deposit was produced by a brightening $CuSO_4$ bath (open circles), the resistances were constant to within ± 0.5 ohm. Near the edge of the frame, however, the values increased considerably. It was observed that a reduced thickness of the copper deposit was the cause of the increased resistances, due to a screening effect of the frame. The throwing power of the applied brightening copper sulfate bath was not good enough. The effect did not appear, when the deposition of the metal was performed in a copper pyrophosphate electrolyte and the values shown in the other curve (filled circles), were obtained. The tolerances prescribed for the resistances of the lines were thus achieved.

Having overcome the main problems, it was possible to produce plates with the outer dimensions of 170 × 360 mm, which were needed for a memory model. The results concerning the function of this memory device have been published recently (5).

Double Layer Capacity Measurement in Dilute Solution: A New Technique

M. Babai,* N. Tshernikovski, and E. Gileadi*

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

ABSTRACT

An instrument is described that can automatically plot the capacitance-potential curve of polarizable electrodes. The instrument is suitable for operating with solid electrodes and in dilute solutions, using positive feedback for IR correction. Several illustrations of its applicability are given and its limitations discussed.

Measurement of the impedance of the ionic double layer at mercury and at solid electrodes is of major importance for the understanding of double layer structure, electrosorption, and electrode kinetics. The methods of measurement may be classified in two groups, namely, the a-c and the pulse techniques.

The a-c group includes the well-known bridge method which was developed to a high degree of accuracy by Grahame (1) and applied widely for the dropping mercury electrode. It is the most accurate method for impedance measurement. However, its time-consuming character limits its use to electrodes whose impedance is independent of time and mostly to liquid metal electrodes. Another method is the so-called a-c polarography developed by Breyer and Gutmann (2) in which a small sinusoidal signal is superimposed on a slowly varying triangular potential sweep. In modern a-c polarography a phase-sensitive unit is incorporated that yields separately the "in-phase" and the "out-of-phase" (quadrature) components of the double layer impedance. Recently, Tshernikovski and Gileadi (3) have replaced the sinusoidal by a small triangular signal. As long as the impedance measured is mainly capacitative, the response to a small triangular wave is a square wave whose amplitude is proportional to the capacity. Rectification of the resulting square wave by a proper sampling technique allows one to obtain directly the whole capacitance *vs.* potential curve, as in a-c polarography.

Pulse techniques include repetitive square wave, single pulse, and the coulostatic method. The first two have been developed by Hackerman and coworkers (4) and applied mostly to the study of double layer capacitance at solid electrodes. These two methods are usually simpler and faster than the a-c techniques, but provide results of much lower accuracy. The coulostatic method developed by Delahay, De Levie, and Giuliani (5) permits double layer measurements in very dilute solutions.

Key words: capacitance meter, double layer, solid electrode, dilute solutions.

Until recently, all methods neglected the ohmic potential drop (IR) due to the resistance in solution between the working electrode and the tip of the Luggin capillary connected to the reference electrode. This potential drop can be compensated for by adding a positive feedback loop to a conventional potentiostat. De Levie and Husovsky (6) have used this mode of IR compensation in a modern version of an a-c polarograph with phase sensitive detection, developed by them. In the present communication, an instrument similar to that of Tshernikovski and Gileadi (3), in which an IR compensation loop and a modern sampling unit have been incorporated, is described. This instrument allows quick and accurate measurements of the double layer capacity at concentrations down to 3×10^{-4}M.

Circuit Description

A small triangular signal (1-25 mV) is produced internally by a triangular wave generator shown in the upper section of Fig. 1. This signal is fed to the input of a conventional potentiostat having a positive feedback loop for IR correction (7) (operational amplifiers 1-3 in Fig. 1). Total compensation for large series resistance (very dilute solutions) is impossible because the whole circuit then tends to go into oscillations. This difficulty was also realized by De Levie and Husovsky (6) who had to use *a-posteriori* corrections when the total ionic strength in solution was below 0.01M. Figures 2b and 2c show the uncorrected and the corrected forms of the square wave, respectively, obtained with the present instrument, compared to the theoretical waveform which would be expected for a pure capacitor (Fig. 2a). Comparison of Fig. 2a and 2c shows that after a certain fraction of the period (marked by arrows) the current becomes constant and equal to that obtained for an ideal capacitor of the same magnitude. It is in this portion of the wave that one should sample the current to minimize errors due to IR drop and its incomplete compensation. The shorter the sampling time, the smaller the error due to the above effect as seen from Fig. 2c. In addition to sampling, a clamping circuit was used to isolate d-c currents, which may originate in the instrument itself or in slow Faradaic processes, from being included in the output of the sampling unit. Eliminating the d-c level of the signal by a capacitor is not suitable because the final state is established only after several cycles. The clamping circuit described below has the advantage of reaching it in the first cycle.

The switching circuit includes two FET gates, one of which is open while the other is closed. Their opening and closing is synchronized with the square wave output of the potentiostat (after IR compensation) as shown in Fig. 3. The part of the switching circuit which controls the FET gates is shown in Fig. 4. Pulses are fed to A and B (*cf.* Fig. 4) from two comparators (amplifiers 5 or 7 and 6). One of them is controlled by the square wave (Fig. 3a) and the other by the triangular wave (Fig. 3b). The gate will open when both A and B in Fig. 4 are negative (or positive for the second FET in Fig. 1). Owing to the fact that the triangular wave is anti-phase with the square wave (Fig. 3a, 3b), they must be fed to opposite inputs of the corresponding comparators. The exact moment at which the gate will be opened is determined by the adjustable d-c level at the second input of the comparators which are synchronized with the triangular wave.

Performance

Measurements on dummy cells with capacitors in the range of 0.1-5 μF in series with resistors from 10 ohms to 10 kohms indicate proper correction for the series resistance up to frequencies of 4×10^3 Hz. Phase shifts in the positive feedback loop limit the upper frequency range. There is no instrumental limitation on the lowest frequency which can be employed. This will tend to be limited by electronic noise on the one hand and by the purity of the chemical

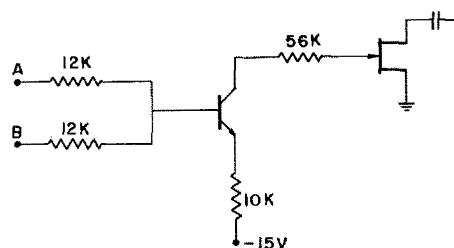

Fig. 4. Circuit controlling the FET gate

system (which determines the magnitude of the undesirable Faradaic currents) on the other hand.

The proper IR compensation is determined by viewing the square wave signal at the negative input of amplifier 4 (Fig. 1). The resistance of the potentiometer in the positive feedback loop is increased gradually, until the waveform changes from a shape such as in Fig. 2b to one resembling that in Fig. 2c. If the constant part of the square wave is longer than the sampling time (10% of the period in the present work), total compensation has been achieved. When the instrument capability is exceeded, such compensation cannot be achieved for any setting of the potentiometer, unless the frequency is decreased. Overcompensation drives the instrument into large amplitude oscillations. This should be avoided when working with solid electrodes since the surface of the electrode is likely to change in an irreversible manner.

The absolute value of the measured capacitance is obtained by calibration with a dummy cell consisting of calibrated capacitors and a variable series resistor. The dummy cell is connected directly to the working electrode terminal of the instrument and through 100-ohm resistors to the counter and reference electrode terminals. After measurement with the electrochemical cell the system is switched to the dummy cell. A capacitance similar to that of the real cell is chosen and the series resistance is changed (without changing the IR compensation) until a proper square wave is seen. The recorder reading in this position is calibrated in terms of the known value of the calibrated capacitor in the dummy cell.

The data of Grahame (8) for 0.01M NaF are compared in Fig. 5 with those obtained with the present instrument. The agreement is particularly good if it is remembered that our results were taken on a hanging mercury drop while those of Grahame are for a dropping mercury electrode. The whole *C vs. E* plot in Fig. 5 was obtained in a few minutes by applying a slow linear potential sweep from an external function generator (introduced to the summing point of amplifier 1 in Fig. 1). In Fig. 6 the comparison to Grahame's data (9) is made for a 1 mM solution of KCl at a frequency of 200 Hz. Here a dropping mercury electrode was used and the capacitance value was read off the recorder trace at a fixed time in the drop life, so that every mercury drop yielded a single point. In this dilute solution the IR compensation had to be readjusted in different ranges of potential, where there is a substantial change in capacity, to obtain best results. The agreement with Grahame's results for the same system is seen to be very good over the whole potential region. In Fig. 7 the capacitative component of the double layer impedance on a gold electrode in 0.3 and 1 mM solutions of $HClO_4$ are shown. For this purpose a gold rod was press-mounted in a Teflon plug in such

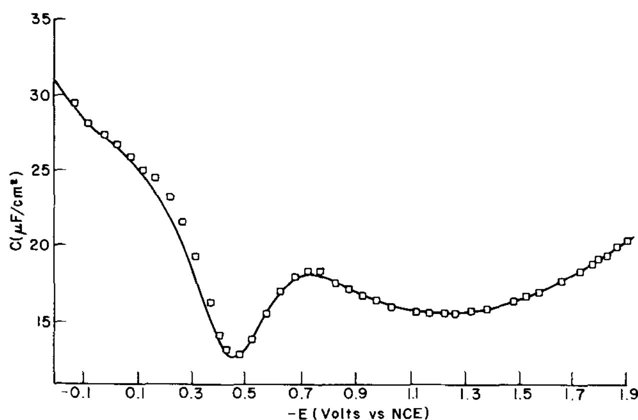

Fig. 5. Capacitance/potential plot for hanging mercury drop in 0.01*N* NaF at 25°C (solid line). Frequency 500 Hz, amplitude 12 mV. Sweep rate 20 mV/sec. Points are taken from data by Grahame (9).

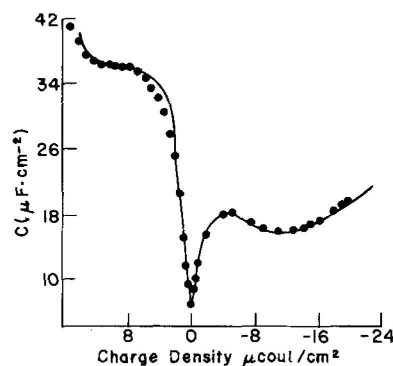

Fig. 6. Capacitance/charge plot in 10^{-3}M KCl at 25°C on a dropping mercury electrode. Frequency 200 Hz, amplitude 12 mV. Solid line taken from data by Grahame (4).

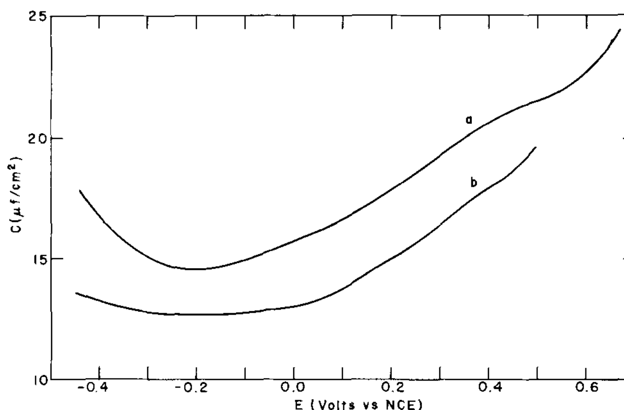

Fig. 7. Capacitance/potential plot on a gold disk electrode in (a) 10^{-3}M $HClO_4$, (b) 3×10^{-4}M $HClO_4$. Frequency 200 Hz, amplitude 12 mV. Sweep rate 3 mV/sec.

a way that the gold surface was equiplanar with the bottom face of the Teflon. Thus the electrode in contact with the solution was a gold disk of well-defined dimensions (diameter 2 mm). The electrodes were polished using aluminum oxide, particle size 0.05μ on a Slyvat cloth. Solutions were deaerated by bubbling high purity helium. The results obtained for 1 mM solution generally agree with those reported by Schmid and Hackerman (10) who employed the single current-pulse technique.

Correction for Faradaic Current

The existence of Faradaic currents due to incomplete polarizability of the (solid) electrode under the desired experimental conditions, may be considered as a parallel resistance in the equivalent circuit representation of the ionic double layer impedance. The error introduced by this factor in the measured capacity is reduced by increasing the frequency and adjusting for optimum IR compensation. The shape of the square wave at the output of the potentiostat is shown for such a case in Fig. 2d. The error resulting from the Faradaic current can be readily estimated from the shape of the signal on the oscilloscope. The true capacitance C is related to the measured capacitance C_m through the equation

$$C = C_m \frac{i_{min}}{(1 - P) i_{max} + P\, i_{min}}$$

where P is the fraction of the half-cycle during which sampling is made, i_{min} and i_{max} are the values of the current at the beginning and at the end of the half-cycle, measured on a curve such as Fig. 2d. Thus, as long as $(i_{max} - i_{min})/i_{min}$ is relatively small a good estimate of the correction required to the measured capacity due to Faradaic reaction can be obtained.

Conclusions

The instrument described herein is best suited for double layer capacity measurements at highly polarizable electrodes. Correction for a small Faradaic current is possible, but the existence of electrochemical reactions at a high rate make measurements impossible. The dependence of the capacitance on potential or time can be plotted continuously. Measurements can be extended to very dilute solutions (lowest concentration used was 3×10^{-4}M) by incorporating a positive feedback loop. Measurements in 10^{-3}M KCl solution on Hg showed excellent agreement with the best literature data obtained by the bridge technique, but the instrument may find more applications for measurements on solid electrodes, where it can follow the slow drift in the values of double layer capacity with time. It can also be conveniently used to obtain the capacitance/potential curve during cycling with a triangular wave.

The advantage of a circuit applying a triangular wave over that applying the sine wave is that the occurrence of a series resistance is easily detected by the deviation of the resulting a-c current from square wave shape. Moreover, with the sampling method described above complete compensation for the series resistance is not necessary, thus measurements at higher frequencies and/or higher solution resistances are possible. The numerical value of the capacitance is obtained directly at the recorder output of the instrument and no *a posteriori* correction need be applied.

Electrochemical Reactions with Consecutive Charge-Transfer Steps: Steady-State and Time-Dependent Behavior under Charge-Transfer and Diffusion Control

K. J. Bachmann

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Electrochemical reactions involving consecutive charge-transfer steps as expressed by the reaction schema

$$S_\nu = S_{\nu+1} + z_\nu e^- \qquad \nu = 1, 2, \ldots, n$$

are considered assuming that the only irreversible processes are charge-transfer and diffusion and that disproportionation of the intermediate reaction products does not occur. An arbitrary number of n consecutive steps is assumed where feasible, but detailed discussion is restricted to the experimentally best understood case of a two-step reaction. A general description is given of the steady-state current density-overvoltage characteristics and for the current density *vs.* time curves in potentiostatic single-pulse experiments and for the variation of overvoltage with time in galvanostatic single-pulse experiments, respectively.

In recent years much attention has been devoted to studies of multistep electrochemical reactions mainly because of the increasing interest in organic electrochemistry where the over-all electrode reaction frequently consists of a sequence of chemical and charge-transfer reaction steps. Polarographic techniques have been particularly useful for studying reactions of this type partly because of the experimental advantages connected to the DME but, also, because an advanced theoretical concept of the effect of various combinations of chemical and electrochemical reactions was earlier available for d-c polarography than for other electrochemical methods. We refer here to the well-known publications of Koutecky and Brdicka (1-3) and to the fundamental paper of Koutecky and Koryta (4) in which a general theory of polarographic kinetic currents was worked out by reducing all transport problems involving fast chemical reactions to a diffusion problem that may be solved by the usual means of a Laplace transformation or by the method of the dimensionless parameters (5). Tables of the appropriate boundary conditions and dimensionless parameters for a large variety of types and

Key words: consecutive reactions, Tafel lines, potentiostatic and galvanostatic single-pulse method.

combinations of one chemical reaction and one charge-transfer step have been provided in Ref. (4). More recently the theoretical consideration of multistep electrode reactions was extended to other experimental methods, as, for example, a-c polarography, cyclic voltammetry, controlled-potential electrolysis, chronocoulometry, chronoamperometry and voltammetry on rotating disk and ring disk electrodes. An extensive review of the literature in this field up to 1966 has been given by Bewick and Thirsk (6) but considerable progress has been made since then, especially with respect to a-c and nonsteady-state type techniques.

The theory of a-c polarography was extended by Hung and Smith (7) and McCord and Smith (8-10), respectively, to include systems with two consecutive charge-transfer steps and coupling of a first-order chemical reaction to a preceding or subsequent charge-transfer reaction. Also, McCord and Smith (11) presented a general theory of second harmonic a-c polarography for the case of homogeneous chemical reactions coupled to a single heterogeneous charge-transfer step. Sluyters and Sluyters-Rehbach (12) considered the potential dependence of the kinetic parameters that determine the admittance of an electrode solution interface where the charge-transfer reaction is combined with first-order chemical reactions including reactant adsorption and catalytic reactions.

Because of their importance in organic electrochemistry much effort was made developing the theory with respect to electrode reactions following the ECE mechanism. The d-c polarographic current-potential relation was discussed by Sobel and Smith (13) and the changes in current density and reactant concentrations with time under the conditions of controlled-potential analysis were considered by Karp and Meites (14) and Harrison and Shoesmith (15). Nicholson and Shain (16) examined the characteristics of cyclic voltammograms assuming that both charge-transfer reactions occur at the same equilibrium potential. The effect of a separation in the equilibrium potentials was later discussed by Polcyn and Shain (17). The special case of the intermediate chemical reaction being reversible was studied by Mastragostino, Nadjo, and Saveant (18) who also considered disproportionation as an alternative reaction path which may be distinguished from a reaction of the ECE type by a variation of the peak C.D. larger than proportional to the concentration. A discussion of the implication of uncompensated ohmic drop and double-layer charging in cyclic voltammetry with fast sweep rates as employed in investigations of multistep electrochemical reactions was given by Imbeaux and Saveant (19). The effect of a disproportionation reaction onto the limiting C.D. obtained on a DME and a RDE was examined by Kastening (20) and Holub (21), respectively. Koopman (22) presented a theoretical treatment of double-step chronocoulometry for ECE reactions involving a chemical surface reaction assuming a linear adsorption isotherm for the reactants. Further references on the application of the various aforementioned methods in studies of the kinetics of organic electrode reactions may be found in the excellent reviews of Adams (23) and in the book of Frumkin and Eshler (24), an English translation of which has been recently published.

Aside from their relevance to organic electrochemistry, consecutive charge-transfer processes also have been recognized as being important in many metal/metal-ion systems and metal-ion redox electrodes. Classical examples are the copper/copper(II) and the thallium(I)/thallium(III) systems for which a consecutive mechanism of the type

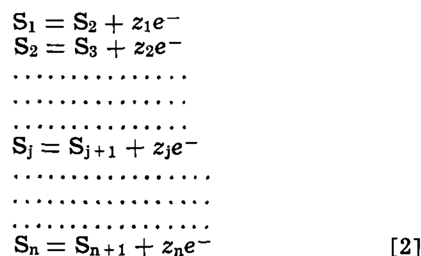
$$S_1 \rightleftharpoons S_2 + e^-$$
$$S_2 \rightleftharpoons S_3 + e^- \quad [1]$$

($S_1 = Cu, Tl^+$; $S_2 = Cu^+, Tl^{2+}$; $S_3 = Cu^{2+}, Tl^{3+}$) was proposed in the earlier literature (25, 26). While this mechanism was confirmed for the Cu/Cu^{2+} electrode by recent investigations of various authors (27, 30) the results of Vetter and Thiemke (26) for the Tl^+/Tl^{3+} electrode appear to be somewhat in question by later work of Catherino and Jordan (31), Ulstrup (32), and Jonasson and Stranks (33). Extensive investigations of Losev and co-workers (34-38) resulted in a three-step mechanism for the In/In^{3+} and the Bi/Bi^{3+} electrode reactions. These results are supported by the work of Armstrong *et al.* (34) on the anodic dissolution of indium in alkaline solutions and by studies of Lovrecek and Mekljavic (40) for the electrochemical behavior of bismuth amalgam electrodes. Recently a mechanism according to Eq. [1] was proposed by Gaiser and Heusler (41, 42) for the Zn/Zn^{2+} and the Cd/Cd^{2+} electrodes assuming strong adsorption of the intermediate monovalent ions ($S_2 = Zn_{ads.}^+$ and $Cd_{ads.}^+$, respectively) on the surface of the electrode. A two-step mechanism for the Cd/Cd^{2+} electrode was also concluded by Despic *et al.* (43) who studied the faradaic impedance of a Cd-amalgam electrode; but no adsorption effects were incorporated in their analysis.

In the author's opinion, only for the Cu/Cu^{2+} electrode sufficient experimental evidence is available for convincingly stating a consecutive charge-transfer mechanism.[1] All the other above-mentioned examples appear to be somewhat indeterminate and need further consideration, particularly since the major part of the arguments in favor of consecutive mechanisms was based on interpretations of steady-state C.D. *vs.* overvoltage curves in terms of Tafel lines, which as demonstrated below can easily lead to ambiguous results. Also, the outcome of nonsteady-state type experiments is far from being understood when adsorption of the reactants is of importance since in this case, as shown by Delahay and co-workers (49, 50), charging of the double layer cannot be approximated by an *a priori* separable capacitive current. The problems which arise in a theoretical treatment of electrochemical reactions under such conditions were recently discussed by Rangarajan (51) but multistep reactions have not yet been considered in this context. In this paper we restrict ourselves to systems for which the influences of adsorption-desorption processes can be neglected. Both the steady-state and nonsteady-state behavior of electrodes characterized by a consecutive charge-transfer mechanism are described.

Steady-State Current Density-Overvoltage Characteristics

For a general description the consecutive charge-transfer reactions are expressed by the reaction scheme



$$\begin{aligned} S_1 &= S_2 + z_1e^- \\ S_2 &= S_3 + z_2e^- \\ &\cdots\cdots \\ S_j &= S_{j+1} + z_je^- \\ &\cdots\cdots \\ S_n &= S_{n+1} + z_ne^- \end{aligned} \quad [2]$$

where the symbol S_1 stands for the most reduced substance of the electrochemical systems, S_j is an intermediate substance, and S_{n+1} is the most oxidized substance. In the following discussions all parameters related to $S_1, S_2, \ldots, S_j$, and S_n, respectively, are noted by the subscripts 1, 2, ..., j, and n, respectively (for

[1] In another paper (44) new experimental results on the Cu/Cu^{2+} electrode will be presented which support this mechanism. Note that in nonaqueous solvents the reaction $Cu \rightleftharpoons Cu^{2+} + 2e^-$ occurs in two well separated steps (45, 47) but disproportionation of the Cu^+ in aqueous solutions is assumed in Ref. (45-47). A recent investigation of Hampson and Latham (48) on the dependence of the exchange C.D. on Cu^{2+} concentration did not confirm the participation of Cu^+ in nitrate solution.

example c_1 = concentration of S_1, D_4 = diffusion constant of S_4). Also we label the current density carried by the νth charge-transfer reaction as i_ν, i.e., the current density carried by the first step as i_1, etc. In analogous fashion the exchange current densities and charge-transfer coefficients related to the νth reaction are denoted as $i_{\nu,o}$ and α_ν, respectively. If the first charge-transfer step, Eq. [1], is a redox reaction, then $z_1 = 1$. However, if it is a metal/metal-ion charge-transfer reaction, where a metal ion of charge z_1 crosses the double layer, then $z_1 \geqq 1$. In this case Reaction [2] would be a redox reaction in which the metal ion S_2 created in Reaction [1] changes its valency by 1. Since we do not consider here adsorption-desorption processes which may be associated with partial charge-transfer steps, and also, exclude purely chemical reactions, $z_\nu = 1$ for all $\nu > 1$. It is assumed that the only irreversible processes are charge-transfer and diffusion and that disproportionation of the intermediate substances S_j does not occur. The electrode surface is considered to be an infinite plane, so that diffusion takes place in direction x perpendicular to the interface. Also the assumption is made that prior to the flow of an external current the electrode is in equilibrium with respect to all charge-transfer reactions and that a large excess of supporting electrolyte is present. Anodic current densities i and overvoltage η are taken to be positive. The total current density flowing through the electrode is given by

$$i_t = \sum_{\nu=1}^{n} i_\nu \qquad [3]$$

where i_ν is the current density carried by the νth charge-transfer reaction.

By Volmer's equations i_ν is related to the concentrations of S_ν and $S_{\nu+1}$ at the interface

$$\begin{aligned} i_\nu &= i_{\nu,o} \cdot \frac{c_\nu(x=0)}{c_{\nu,o}} \cdot \exp\left(\frac{\alpha_\nu z_\nu \mathbf{F}}{RT}\eta\right) - i_{\nu,o}\frac{c_{\nu+1}(x=0)}{c_{\nu+1,o}}\exp\left(-\frac{[1-\alpha_\nu]z_\nu\mathbf{F}}{RT}\eta\right) \\ &= i_{\nu,+}\frac{c_\nu(x=0)}{c_{\nu,o}} - i_{\nu,-}\frac{c_{\nu+1}(x=0)}{c_{\nu+1,o}} \end{aligned} \qquad [4]$$

Also, by combining Fick's law with Faraday's law we get n + 1 equations relating the gradient of the concentration of the n + 1 substances S_ν to the C.D.'s of the reaction steps in which S_ν is created and used up, respectively

$$\frac{dc_\nu}{dx} = \frac{i_\nu}{z_\nu \mathbf{F} D_\nu} - \frac{i_{\nu-1}}{z_{\nu-1}\mathbf{F}D_\nu} \quad \text{at } x = 0 \qquad [5]$$

We assume that under steady-state conditions a diffusion layer of constant width δ is established and that in the bulk of the solution, i.e., at $x \geqq \delta$, the equilibrium concentrations $c_{\nu,o}$ are maintained. If no chemical reactions occur in the diffusion layer the concentration gradients may be written as

$$\frac{dc_\nu}{dx} = -\frac{c_\nu(x=0) - c_{\nu,o}}{\delta} \quad \text{at } 0 \leqq x \leqq \delta \qquad [6]$$

$$\frac{dc_\nu}{dx} = 0 \quad \text{at } x \geqq \delta \qquad [7]$$

Let

$$\frac{c_\nu}{c_{\nu,o}} = y_\nu \qquad (\nu = 1, 2, \ldots, n+1) \qquad [8]$$

and substitute [6] and [4] into [5] to get

$$a_{\nu,\nu-1}y_{\nu-1} + a_{\nu,\nu}y_\nu + a_{\nu,\nu+1}y_{\nu+1} = 1 \qquad [9]$$

where

$$a_{\nu,\nu-1} = -\frac{z_\nu}{z_{\nu-1}} \cdot \frac{i_{\nu-1,+}}{i_{\nu,l}} \qquad [10]$$

$$a_{\nu,\nu} = 1 + \frac{i_{\nu,+}}{i_{\nu,l}} + \frac{z_\nu}{z_{\nu-1}} \cdot \frac{i_{\nu-1,-}}{i_{\nu,l}} \qquad [11]$$

$$a_{\nu,\nu+1} = -\frac{i_{\nu,-}}{i_{\nu,l}} \qquad [12]$$

and $i_{o,+} = i_{o,-} = i_{n+1,+} = i_{n+1,-} = 0$. The quantity

$$i_{\nu,l} = \frac{z_\nu \mathbf{F} D_\nu c_{\nu,o}}{\delta} \qquad [13]$$

is the formal diffusion-limited C.D. for substance S_ν. In matrix notation, the set of n + 1 nonhomogeneous linear equations with n + 1 unknowns y_ν (ν = 1, 2, . . . , n + 1) defined by Eq. [9] may be represented as

$$[a]\{y\} = \{1\} \qquad [14]$$

where

$$[a] = \begin{bmatrix} a_{11}a_{12}O & \cdots & O \\ a_{21}a_{22}a_{23}O & \cdots & O \\ Oa_{32}a_{33}a_{34}O & \cdots & O \\ \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots \\ O & \cdots & a_{nn-1}a_{nn}a_{nn+1} \\ O & \cdots & a_{n+1n}a_{n+1n+1} \end{bmatrix} \qquad [15]$$

is the (n + 1) by (n + 1) coefficient matrix and $\{y\}$ and $\{1\}$ are column vectors of order (n + 1). Since the determinant of $[a]$ does not vanish, the solutions to Eq. [9] and [14] are obtained explicitly by premultiplication of Eq. [14] by the inverse coefficient matrix $[a]^{-1}$

$$\{y\} = [a]^{-1}\{1\} \qquad [16]$$

i.e., the value of x_ν is determined by the sum of the elements of the νth row of the adjoint of $[a]$ divided by det. $[a]$.

$$i_t = \sum_{\nu=1}^{n} i_\nu = \sum_{\nu=1}^{n} i_{\nu,+}y_\nu - \sum_{\nu=1}^{n} i_{\nu,-}y_{\nu+1} \qquad [17]$$

represents in conjunction with Eq. [16] the general form of the C.D.-overvoltage characteristics in case of an electrode reaction involving an arbitrary number of n consecutive charge-transfer steps under both charge-transfer and diffusion control.

For a two-step reaction Eq. [17] reduces to

$$i_t = i_1 + i_2 \qquad [18]$$

$$i_1 = \frac{i_{1,+}}{i_{1,+} + i_{1,l}} \cdot (i_{1,l} + i_{1,-} \cdot Q) - i_{1,-} \cdot Q \qquad [19]$$

$$i_2 = i_{2,+} \cdot Q - \frac{i_{2,-}}{i_{2,-} + i_{3,l}} \cdot (i_{3,l} + i_{2,+} \cdot Q) \qquad [20]$$

where

$$Q = \frac{c_2}{c_{2,o}} = \frac{1 + \dfrac{i_{1,l}}{zi_{2,l}} \cdot \dfrac{i_{1,+}}{i_{1,+} + i_{1,l}} + \dfrac{i_{3,l}}{i_{2,l}} \cdot \dfrac{i_{2,-}}{i_{2,-} + i_{3,l}}}{1 + \dfrac{i_{1,l}}{zi_{2,l}} \cdot \dfrac{i_{1,-}}{i_{1,+} + i_{1,l}} + \dfrac{i_{3,l}}{i_{2,l}} \cdot \dfrac{i_{2,+}}{i_{2,-} + i_{3,l}}} \qquad [21]$$

and

$$i_{1,l} = \frac{z\mathbf{F}D_1c_{1,o}}{\delta} \qquad [22]$$

$$i_{2,l} = \frac{\mathbf{F}D_2c_{2,o}}{\delta} \qquad [23]$$

$$i_{3,l} = \frac{\mathbf{F}D_3c_{3,o}}{\delta} \qquad [24]$$

assuming $z_1 = z$ and $z_2 = 1$.

For large anodic overvoltage the diffusion-limited C.D. $i_{1,+}$ is given by

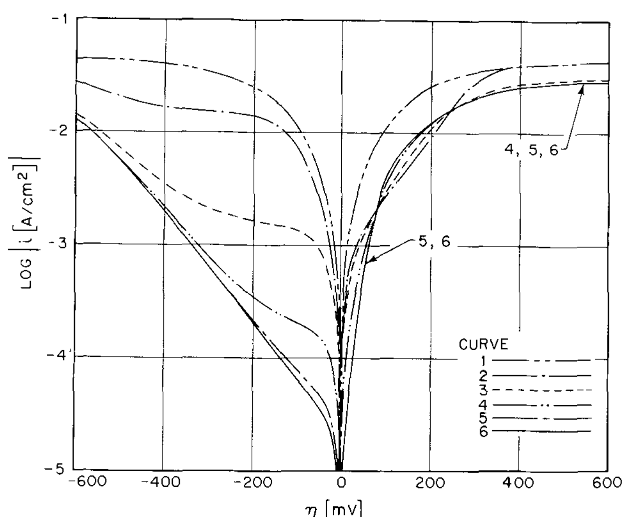


Fig. 1. Curves log | i | vs. overvoltage η, varied parameters $i_{2,o}$ and $i_{2,l}$.

Curve 1: $i_{1,o} = i_{2,o} = 10^{-3}$ A/cm²; $z = 1$; $\alpha_1 = 0.3$; $\alpha_2 = 0.7$; $D_1 = D_2 = D_3 = 1.5 \times 10^{-5}$ cm² sec⁻¹; $c_{1,o} = c_{2,o} = c_{3,o} = 10^{-5}$ mole/cm³; $i_{1,l} = i_{2,l} = i_{3,l} = 1.5 \times 10^{-2}$ A/cm².
Curve 2: as curve 1 but $i_{2,o} = 10^{-5}$ A/cm².

Curve 3: as curve 2 but $c_{2,o} = 10^{-6}$ mole⁻²/cm³; $i_{2,l} = 1.5 \times 10^{-3}$ A/cm².

Curve 4: as curve 2 but $c_{2,o} = 10^{-7}$ mole/cm³; $i_{2,l} = 1.5 \times 10^{-4}$ A/cm².

Curve 5: as curve 2 but $c_{2,o} = 10^{-8}$ mole/cm³; $i_{2,l} = 1.5 \times 10^{-5}$ A/cm².

Curve 6: as curve 2 but $c_{2,o} = 10^{-9}$ mole/cm³; $i_{2,l} = 1.5 \times 10^{-6}$ A/cm².

$$i_{1,+} = \lim_{\eta \to \infty} i_t = \frac{1}{z} \{(z+1) i_{1,l} + z i_{2,l}\} \quad [25]$$

While for large cathodic overvoltage the diffusion-limited C.D. $i_{1,-}$ is given by

$$i_{1,-} = \lim_{\eta \to \infty} i_t = -\{(z+1) i_{3,l} + z i_{2,l}\} \quad [26]$$

However, if $i_{2,o} = 0$ then $i_{+,l} = i_{1,l}$ and $i_{-,l} = -z i_{2,l}$, and if $i_{1,o} = 0$ then $i_{+,l} = i_{2,l}$ and $i_{-,l} = -i_{3,l}$, *i.e.*, the quantities $i_{1,l}$, $i_{2,l}$, $i_{3,l}$ are the diffusion-limited C.D.'s as expected if only either one of the two reactions would occur. As demonstrated in Fig. 1 only under certain special conditions the individual values of $i_{1,l}$, $i_{2,l}$, and $i_{3,l}$ may be derived from the C.D. overvoltage characteristics.

Clearly $\lim_{i_{\nu,l} \to \infty} Q = 1$ and $i_t = (i_{1,+} + i_{2,+}) - (i_{1,-} + i_{2,-})$, *i.e.*, under pure charge-transfer control the Tafel lines would be determined by both reactions and if $i_{1,o} \neq i_{2,o}$ by the reaction with the larger exchange C.D. in both the anodic and the cathodic branch. If one considers the more likely special case $i_{1,l} = i_{3,l} \to \infty$ but with $i_{2,l} \to 0$ then $Q \to (i_{1,+} + i_{2,-})/(i_{1,-} + i_{2,+})$ and Eq. [18] becomes identical with the expressions derived by Vetter (52). For $\eta >> 0$, $i_t \approx 2i_{1,+}$ while for $\eta << 0$, $i_t \approx -2i_{2,-}$, i.e., here the anodic Tafel lines depend on Reaction [1] while the cathodic Tafel lines yield the parameters of Reaction [2]. A detailed evaluation of Vetter's method of determining kinetic parameters from the steady-state C.D.-overvoltage characteristics in the Tafel regime was undertaken by Hurd (53) on the basis of digitally simulated curves. However, no rigorous treatment of the interaction of charge-transfer and diffusion was given and transport phenomena were neglected in extending Vetter's theory to an unlimited number of consecutive charge-transfer reactions.

Losev, Gorodetskii, and Molodov (54, 57) have recently published a number of papers in which the special case of a three-step reaction is discussed. Their work does not add any new information to the previously published results of Vetter (52) and Hurd (53) but, in my opinion, it is wrong in a fundamental assumption. While Vetter recognized that the steady-state continuity condition $i_\nu = i_{\nu+1}$, is satisfied only if diffusion of the intermediate substances can be neglected and Hurd restricts his extension of Vetter's work to pure charge-transfer control, Losev *et al.* state explicitly [for example in Ref. (55)] that this condition is always satisfied even at high concentrations of the intermediate products and assuming exchange of these substances with the bulk via diffusion. This is obviously not true since under such conditions the bulk solution represents an additional source or sink from which the equivalent mass flow at the interface may be balanced in steady state even if $i_\nu \neq i_{\nu+1}$.

For a demonstration of the properties of the C.D.-overvoltage characteristics in the general case of mixed diffusion and charge-transfer control for all three substances involved in a two-step reaction a family of log $|i|$ *vs.* overvoltage curves has been generated via digital simulation on the basis of Eq. [18]-[21] assuming $i_{1,o} >> i_{2,o}$ $i_{1,l} = i_{3,l} \approx 15\ i_{1,o}$ but $i_{2,l} << i_{2,o}$ and $\alpha_1 = 0.3$ and $\alpha_2 = 0.7$. If $i_{1,l}$ and $i_{2,l}$ are finite and $i_{1,o} \neq i_{2,o}$, a situation may occur where the Tafel line for the reaction with lower exchange C.D. exists but the Tafel line for the faster reaction step is masked by the over-all diffusion limited C.D. This behavior which according to Vetter and Abend [*loc. cit.*, p. 380 Ref. (26)] may be realized in the case of the Sn^{2+}/Sn^{4+} redox couple, is demonstrated by curve 6 in Fig. 1. Extrapolation of the cathodic Tafel line to $\eta = 0$ yields $2i_{2,o}$ and its slope is governed by $(1 - \alpha_2)$. A pseudo Tafel line may be considered in the anodic branch at low η yielding also $i_{2,o}$ [compare Mohilner (58)]. Although $i_{1,l}$ exceeds $i_{1,o}$ by a factor of 15, no true anodic Tafel line is observable in curve 6. Curves 5 to 2 were calculated with the same parameters as curve 6 except that $i_{2,l}$ was increased by a factor of 10 from curve to curve. For curve 5, $i_{2,l} \approx i_{2,o}$ and the slope of the cathodic "Tafel line" decreases which experimentally may not be recognized as a deviation from the true Tafel line at $i_{2,l} << i_{2,o}$. If $i_{2,l} >> i_{2,o}$ the cathodic C.D. tends to show $i_{2,l}$ as a separate step in the C.D.-overvoltage characteristic. In this case neither the parameters of Reaction [1] nor those of Reaction [2] can be derived. Even worse, curve 3 shows an "apparent Tafel line" in the anodic branch, but extrapolation of this linear section to $\eta = 0$ yields an intermediate value between $i_{2,o}$ and $i_{1,o}$. This demonstrates that interpretation of the steady-state C.D.-overvoltage characteristics on the basis of "Tafel lines" becomes an ambiguous affair if the two exchange C.D.'s differ very much and $i_{2,l}$, although much less than $i_{1,l}$ and $i_{3,l}$, has a value comparable or larger than the smallest exchange C.D.

It should be mentioned here that a more general consideration of the steady-state C.D. *vs.* overvoltage curve in the vicinity of the equilibrium potential which involves an arbitrary number of charge-transfer steps and chemical reactions in series was given by Mauser (59), subsequently extended by Riddiford (60) to include transport control and more complex coupling between the partial reactions. However, with increasing complexity of the reaction path, separation of the various consecutive steps on the basis of an interpretation of the steady-state C.D.-overvoltage characteristics becomes more and more impractical and other experimental techniques offer a better chance for successfully deriving the kinetic parameters. An especially promising approach seems to be investigations with a ring disk electrode that have been theoretically evaluated in a series of papers by Albery *et al.* (61) [compare Ref. (6) for the earlier literature]. Also, the utilization of nonsteady-state type experiments, demonstrated in the following section, may be of advantage.

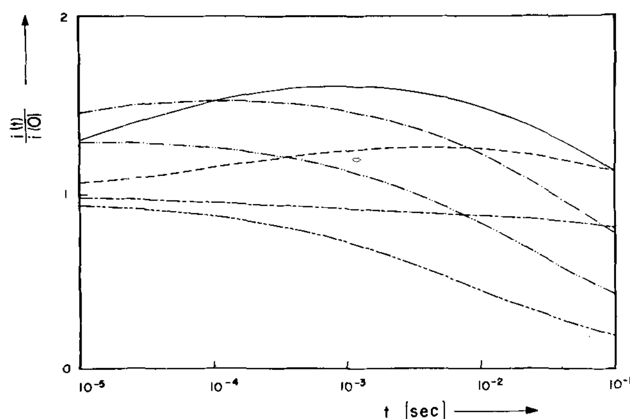

Fig. 2. Current densities $i(t)$, expressed as fractions of the initial current densities $i(o)$, as a function of time t.

Parameters: $i_{1,o} = 10^{-3}$ A/cm^2; $i_{2,o} = 10^{-5}$ A/cm^2; $\alpha_1 = 0.3$; $\alpha_2 = 0.7$; $z = 1$; $D_1 = D_2 = D_3 = 1.5 \times 10^{-5}$ cm^2/sec; $c_{1,o} = c_{3,o} = 10^{-5}$ mole/cm^3 $c_{2,o} = 10^{-8}$ mole/cm^3 (compare curve 5 Fig. 1).

Current Density vs. Time Curves in Potentiostatic Single-Pulse Experiments

Analysis of single-pulse potentiostatic transients for pure metal/metal-ion and for alloy/metal-ion electrodes under charge-transfer and diffusion control in case of an electrode reaction involving two consecutive charge-transfer steps was presented in two preceding papers (62, 63).[2] As shown, the current density *vs.* time is of the form

$$i(t) = A \cdot f(t) + B \cdot g(t) \qquad [27]$$

where $f(t)$ is a function which decreases in the time interval $[0, \infty]$ monotonically from 1 to 0, while $g(t)$ is zero at the beginning of the overvoltage pulse and at infinite time, but positive in between. A and B are constants, A being always of same sign as η. The sign of B may be the same as the sign of A if $i_{1,o} \neq i_{2,o}$ and $c_{2,o}D_2 < c_{1,o}D_1$; $c_{3,o}D_3$. In this case a characteristic delayed maximum occurs in the $i(t)$-transient at $\eta < 0$ if $i_{1,o} < i_{2,o}$ and at $\eta > 0$ if $i_{1,o} > i_{2,o}$. It turns out that these conditions, for which potentiostatic single-pulse experiments reveal a property which is specific for consecutive charge-transfer reactions and which depends quite sensitively on the values of the kinetic parameters, are identical with those for which interpretation of steady-state data is particularly difficult. For example, taking the kinetic parameters and bulk concentrations which were chosen for the calculation of curve 5 in Fig. 1, an anodic overvoltage regime 85 mV $< \eta <$ 295 mV exists for which sign A = sign B = sign η. Figure 2 shows a family of curves $i(t)/i(t = 0)$ *vs.* time t calculated with the same parameters on the basis of Eq. [27] and with the amplitude of the overvoltage pulse as varied parameter. For η = 80 mV and η = 300 mV, *i.e.*, 5 mV outside the limits of η for which sign B = sign η, the usual monotonically falling function is observed. In accordance with the properties of the C.D. *vs.* time curves discussed in Ref. (62, 63) at 100, 150, 200, and 250 mV delayed maxima appear. Note that due to limitations by convection and by the finite rise time of electronic potentiostats the electrode process can be described in terms of the model discussed in this paper only within a time range $10^{-5} \leq t \leq 1$ sec. Therefore, the delayed maximum in the $i(t)$ transient for η = 250 mV would not be recognized in an experiment.

[2] The general case of n consecutive charge-transfer reactions was considered by Koutecky (2) assuming pure diffusion control. Note that in a chronoamperometric study of the reduction of p-nitrosophenol Alberts and Shain (64) discussed the ECE case but with different b.c. as used in Ref. (62, 63) since only one substance was assumed to be present at $t = 0$ in their treatment.

Overvoltage vs. Time Curves in Galvanostatic Single-Pulse Experiments

Since experiments under galvanostatic conditions require much less involved apparatus than those performed under potentiostatic conditions the galvanostatic single-pulse method frequently has been favored in studies on the nonsteady-state behavior of electrode systems although its theoretical analysis is more complicated than the potentiostatic case. This is due to the fact that in boundary condition Eq. [5], the desired function $\eta(t)$ occurs in the exponentials and double-layer charging has to be considered.

In case of a single-step electrode reaction the function $\eta(t)$ was derived by Berzins and Delahay (15) under the assumptions that the total C.D. may be separated into capacitive C.D. i_c and faradaic C.D. i_f and that a linear relationship exists between i_f and η. These assumptions hold only approximately and require that the charge stored in the double layer due to changes in the excess of substances which attend in the charge-transfer reaction is negligible and that the overvoltage is limited to $|\eta| < 1$ mV [compare Ref. (49, 50) and Koijman *et al.* (66)]. Nevertheless, the classical formula derived by Berzins and Delahay for the overvoltage *vs.* time curve in galvanostatic single-pulse experiments has found many useful applications.

Very little is known yet on the nonsteady-state behavior under galvanostatic conditions in case of consecutive charge-transfer reactions. Plonski (67) considered the $\eta(t)$ curve in case of a reaction of the type $M \rightleftharpoons M^{z_1+} + z_1e^-$ and $M^{z_1+} \rightleftharpoons M^{z_2+} + (z_2 - z_1)e^-$ where M stands for a pure metal. However, mass transport was neglected in this treatment, which in the opinion of the author, is an unrealistic assumption unless strong adsorption of the intermediate ion and the existence of a very large concentration of the most oxidized ion in solution are assumed. In the latter case, however, other problems arise, a discussion of which is outside the scope of the present paper. We consider here the $\eta(t)$ curve for the reaction being controlled by both charge-transfer and diffusion with no restrictions on the bulk concentrations and diffusion constants of all substances involved, but do not include adsorption so that the aforementioned assumptions made in Ref. (65) may be utilized in a treatment of the two-step case.

It can be shown that under these conditions the desired expression for the overvoltage as a function of time is

$$\eta(t) = iR_D \cdot \{K_1\theta_1(t) + K_2\theta_2(t) + K_3\theta_3(t) + K_4\sqrt{t} + K_5\} \qquad [28]$$

where

$$R_D = \frac{RT}{z\mathbf{F}i_{1,o}} + \frac{RT}{\mathbf{F}i_{2,o}} \qquad [29]$$

is the charge-transfer resistance and

$$\theta_\mu = \exp\left(\frac{t}{\tau_\mu}\right) \cdot \operatorname{erfc}\sqrt{\frac{t}{\tau_\mu}}, \quad \mu = 1,2,3 \qquad [30]$$

The constants $K_1 \ldots K_5$ may be written in terms of the time constants τ_1, τ_2, τ_3, and $\tau_D = R_D \cdot C_D$

$$K_1 = \frac{\tau_1^2(\tau_D - \sqrt{\tau_2\tau_3})}{\tau_D^2(\sqrt{\tau_1} - \sqrt{\tau_2})(\sqrt{\tau_1} - \sqrt{\tau_3})} \qquad [31]$$

$$K_2 = \frac{\tau_2^2(\tau_D - \sqrt{\tau_1\tau_3})}{\tau_D^2(\sqrt{\tau_2} - \sqrt{\tau_1})(\sqrt{\tau_2} - \sqrt{\tau_3})} \qquad [32]$$

$$K_3 = \frac{\tau_3^2(\tau_D - \sqrt{\tau_1\tau_2})}{\tau_D^2(\sqrt{\tau_3} - \sqrt{\tau_1})(\sqrt{\tau_3} - \sqrt{\tau_2})} \qquad [33]$$

$$K_4 = \frac{2}{\sqrt{\pi}} \cdot \left\{ \frac{K_1}{\sqrt{\tau_1}} + \frac{K_2}{\sqrt{\tau_2}} + \frac{K_3}{\sqrt{\tau_3}} \right\} \quad [34]$$

$$K_5 = -(K_1 + K_2 + K_3) \quad [35]$$

The time constants are related to the kinetic parameters and bulk concentrations by a cubic equation

$$(\sqrt{\tau})^3 - \frac{\Delta}{\epsilon}(\sqrt{\tau})^2 + \frac{\sigma}{\epsilon}\sqrt{\tau} - \frac{1}{\epsilon} = 0 \quad [36]$$

where

$$\epsilon = \frac{\mathbf{F}}{RTC_D} \cdot i_{1,o} i_{2,o} \cdot \left\{ \frac{1}{z\mathbf{F}\sqrt{D_1}c_{1,o}} + \frac{(z+1)^2}{z\mathbf{F}\sqrt{D_2}c_{2,o}} + \frac{z}{\mathbf{F}\sqrt{D_3}c_{3,o}} \right\} \quad [37]$$

$$\Delta = \frac{i_{1,o} i_{2,o}}{z\mathbf{F}^2\sqrt{D_1 D_2 D_3}c_{1,o}c_{2,o}c_{3,o}} \cdot (c_{1,o}\sqrt{D_1} + c_{2,o}\sqrt{D_2} + c_{3,o}\sqrt{D_3}) + \frac{1}{\tau_D} \quad [38]$$

and

$$\sigma = \frac{i_{1,o}}{2\mathbf{F}\sqrt{D_1}c_{1,o}} + \frac{i_{1,o}}{2\mathbf{F}\sqrt{D_2}c_{2,o}} + \frac{i_{2,o}}{\mathbf{F}\sqrt{D_2}c_{2,o}} + \frac{i_{2,o}}{\mathbf{F}\sqrt{D_3}c_{3,o}} \quad [39]$$

Details on the derivation of Eq. [28] and its application to the interpretation of experimentally obtained $\eta(t)$-curves are discussed in another paper (44).

Summary

A general description of the steady-state C.D.-overvoltage characteristic is derived for electrochemical reactions involving an arbitrary number of consecutive charge-transfer steps as expressed by the equation

$$S_\nu = S_{\nu+1} + z_\nu e^- \quad \nu = 1, 2, \ldots, n \quad [1]$$

assuming both charge-transfer and diffusion control. A detailed discussion of the properties of plots of log $|i|$ *vs.* η is given for reactions involving two charge-transfer steps and it is demonstrated via digital simulation that interpretation of the steady-state C.D.-overvoltage characteristics in terms of Tafel lines becomes ambiguous if the exchange C.D.'s differ in magnitude and the formal diffusion-limited C.D. for the intermediate product becomes comparable or larger than the smallest exchange C.D.

As demonstrated under these conditions characteristic delayed maxima appear in the C.D. *vs.* time curve obtained in potentiostatic single-pulse experiments which, therefore, are a very useful supplement to steady-state type measurements. Also, a general expression is given for the variation of overvoltage with time in galvanostatic single-pulse experiments which is interpreted in terms of the charge-transfer resistance and of three characteristic time constants.

Acknowledgments

The author would like to thank J. H. Wernick for many helpful suggestions and for his interest in this work.

The Electrosorption of Pentane on Bright Platinum Electrodes

A. R. Blake, A. T. Kuhn,[1] and J. G. Sunderland

The Electricity Council Research Centre, Capenhurst, Chester, England

ABSTRACT

The kinetics of pentane adsorption on bright Pt electrodes were studied in 1*N* sulfuric acid at 85°C over the potential range +0.1 to +0.4V RHE. The process is shown to be activation controlled. The adsorption process is analyzed in terms of the number of electrons per site for the adsorbed species, which are separated into cathodically desorbable and nondesorbable material.

The literature devoted to the anodic adsorption and oxidation of hydrocarbons is extensive (1-14) and a variety of studies based on steady-state experimental data and nonsteady-state have been investigated. Various techniques have long been available for the measurement of coverage of adsorbed species on solid electrodes. Thus galvanostatic and potential step techniques (multipulse potentiodynamic, MPP) (8-12) terminating in a potential ramp or constant current, have been employed. Through the work of Brummer (2-6), Shropshire (7), Gilman (8-11), and Cairns (12) this concept has been advanced by linking measurements of the anodic charge with measurements of free surface area, determined under identical conditions of electrode pretreatment, adsorption potential, and time. From these two determinations may be calculated a value of *e*, the number of electrons (2-6) required to oxidize the adsorbate per platinum site. A further refinement enables the adsorbate to be characterized in terms of adsorbed species which can be cathodically desorbed (θ_{des}) and those which cannot ($\theta_{non\text{-}des}$).

Brummer *et al.* (4) studied the kinetics of hexane adsorption in 85% phosphoric acid at a temperature of 130°C using the technique of MPP followed by a constant current transient. They found that the process under these conditions was essentially diffusion controlled. This paper reports on the adsorption of pentane at lower temperatures and in dilute acid where the adsorption process might be expected to become activation controlled and the adsorbate to exist in a highly reduced state. The results confirm this and also reveal a number of interesting features which would of necessity be obscured under diffusion-controlled conditions.

Experimental

The technique of MPP has been described elsewhere (8-11), as have the methods in which this is followed by a galvanostatic charging process (3-6) (either anodic or cathodic). The generation of the potential program was achieved with a pulse generator designed in these laboratories (15), the output of which was fed into a Chemical Electronics, 1.6A potentiostat. The constant current was obtained by the use of suitable value tin oxide resistors in series with the cell to drop 90V from a stabilized d-c source to obtain the desired current. Substitution of the potential sequence for the constant current was achieved by rapid switching using a mercury-wetted relay (Elliot EB2). The relay change over from potential control to a constant current mode was achieved in 800 μsec by over-running the relay for a short time; the relay coil was activated by a pulse from the pulse generator. Potential-time transients were recorded photographically on a Tektronix 502A oscilloscope, via a type-O operational amplifier.

The three compartment cell, with a bubbling hydrogen reference electrode was housed in a separate chamber in the third compartment. Purified hydrogen was obtained by passing through a heated Pd/Ag thimble. Argon was used as a purge gas, and was Air Products prepurified grade. Further purification to remove any trace hydrocarbons was achieved by passing the gas through molecular sieve, glass spheres, and glass wool cooled to 142°K. All gas outlets were via bubble traps containing water. The cell was provided with presaturators for the hydrogen electrode and each gas purge stream.

Solutions of 1*N* H_2SO_4 were prepared by dilution of B.D.H. Aristar sulfuric acid with triply distilled water, followed by potentiostatic pre-electrolysis with a platinized platinum electrode (40 cm^2 geometric area) at 0.7V for 48 hr and 0.2V for 48 hr with gas stirring. After use the pre-electrolysis electrode was raised into the gas space above the electrolyte. The level of dissolved impurities was determined with anodic and cathodic charging curves in an argon-stirred system after 10 msec adsorption time at 0.2 and 0.3V and again after 300 sec using the potential program shown in Fig. 1A. The length of the potential arrests indicated

[1] Present address: University of Salford, Salford 5, Lancashire, England.

Key words: electrosorption, pentane.

the level of dissolved impurities, and runs showing more than 8% change of arrest time were abandoned.

Pentane was Phillips Research Grade (99.99% minimum purity) and was introduced into the anode compartment with the argon purge gas. The partial pressure of the pentane was controlled by maintaining constant temperature in a water bath (± 0.1°C) the pentane being passed into the cell via a heated tube maintained at the cell temperature before being introduced into the presaturator. A constant cell temperature was achieved by thermostating in an air oven at 85°C (± 0.2°C).

The counterelectrode was a 10 cm^2 platinized electrode. The working electrode, which was a flamed platinum wire (Johnson-Matthey) 1 cm long and 0.0254 cm^2 diameter (R.F. = 1.95) was inserted through a Teflon cap at the bottom of the cell so that it was in close proximity to the Luggin capillary. Results are expressed in terms of "real area" derived from hydrogen atom charging (2) and potentials refer to the hyrdogen electrode in the same electrolyte.

Results

Variation of charge as a function of current density.—As in all adsorption studies, it is essential to ensure that the anodic (Q_{ox}) and cathodic (Q_H) charges are determined at a current density in the region where Q_{ox} or Q_H are substantially independent of current density. This was verified as outlined below. The potential sequence of Fig. 1A was used to make these measurements, at 0.2V, for three adsorption times 20, 60, and 100 sec. For the anodic component Q_{ox} (Fig. 2A), the variation was ±15 $\mu C\ cm^{-2}$. Similar current density constancy was observed by Brummer (2, 4) for propane and hexane. A current density of 60 mA cm^{-2} was used for routine measurements.

Since it has been shown that much of the adsorbed pentane is readily desorbed at potentials below 0.1V, it is essential to ensure that the hydrogen deposition charging process is completed before cathodic desorption can occur. The constancy of charge at several cathodic current densities over the range 20-160 mA cm^{-2} is shown in Fig. 2B and is seen to vary by only ±9 $\mu C\ cm^{-2}$. A current density of 120 mA cm^{-2} was used for routine measurements.

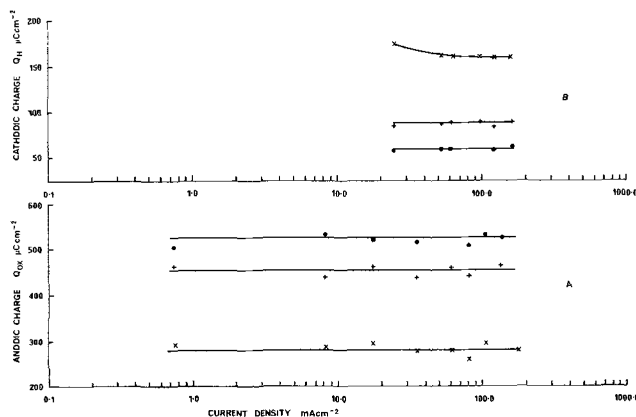

Fig. 2. Adsorption of pentane at 0.2V and 85°C. X 20 sec, + 60 sec, and ● 100 sec.

Adsorption as a function of time.—The anodic charges Q_{ox} *vs.* the adsorption time for 0.1-0.4V are plotted in Fig. 3 and 4. Potential sequence shown in Fig. 1A was again used to obtain these data. The data shown are for 85°C and a pentane partial pressure of 611 mm. Stirring had relatively little effect on the rate of adsorption; the rate remaining essentially unaffected.

Experiments on the effect of the partial pressure of pentane were also carried out; as expected the rate of adsorption was lower at the lower partial pressure. The partial pressures employed were 611 and 183 mm. At the higher partial pressure, the anodic charge corresponding to 300-sec adsorption time was approximately 25% higher than that observed at the lower partial pressure.

Similarly for the above, coverages $\theta_{H.C.}$ have been determined. $\theta_{H.C.}$ is defined by

$$\frac{Q_H^S - Q_H}{Q_H^S}$$

where Q_H^S is the number of coulombs cm^{-2} required to form a monolayer of hydrogen on the electrode, and Q_H is the charge required to fill the sites available for

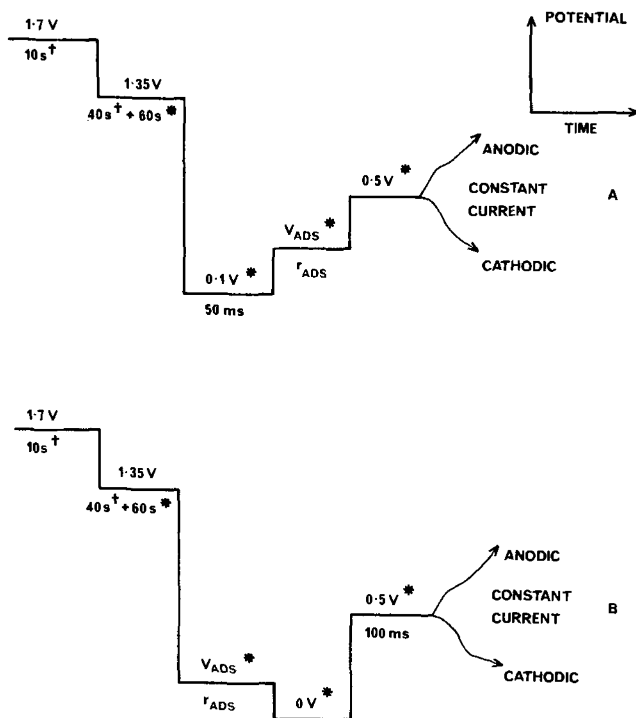

Fig. 1. Potential sequences used in galvanostatic estimations of the anodic charge and electrode coverage. + Stirred, * quiescent.

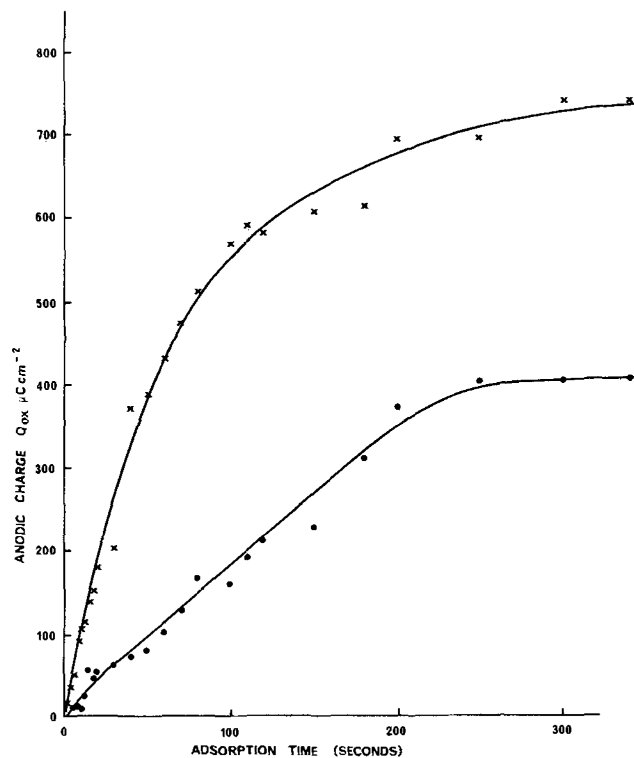

Fig. 3. Quiescent adsorption of C_5H_{12} at 85°C. ● 0.1V, X 0.2V

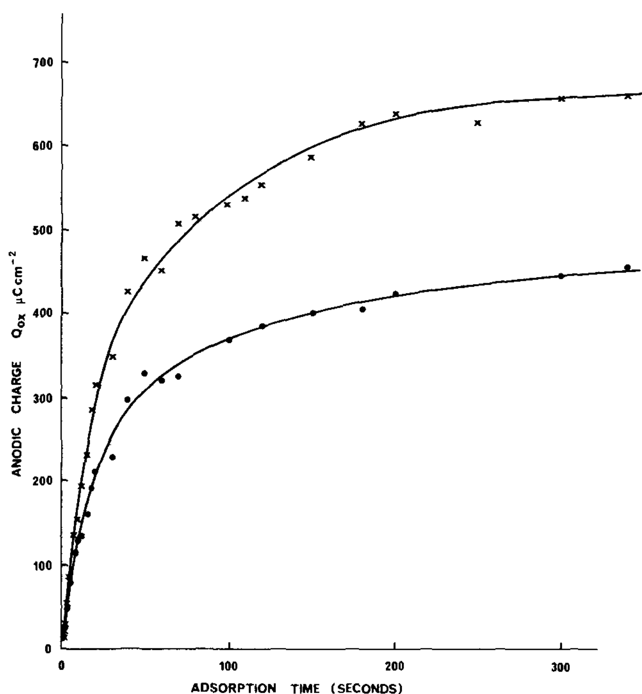

Fig. 4. Quiescent adsorption of C_5H_{12} at 85°C. X 0.3V, ● 0.4V

hydrogen adsorption in the absence and presence of pentane, respectively.

A typical plot of coverage as a function of adsorption time, for the total adsorbate θ_{TOT} and the cathodically nondesorbable $\theta_{N.D.}$ species, is shown in Fig. 5 for adsorption at 0.2V. Similar behavior was observed at 0.3 and 0.4V. However, at 0.1V, the cathodically nondesorbable species was not detected.

Variation of the anodic charge with electrode coverage.—Variation of the anodic charge Q_{ox} with electrode coverage $\theta_{H.C.}$ during the adsorption of hydrocarbon has been investigated as a function of potential. It has been separated into two components, for the cathodically desorbable species, CH-α, Fig. 6 shows this. Figure 7 shows the complementary cathodically nondesorbable species O-type. A combination of potential sequence shown in Fig. 1A and 1B was employed to determine the two adsorbed species. Sequence 1A was used to determine the charge corresponding to the total adsorbate and sequence 1B to determine that associated with cathodically nondesorbable species. Subtraction of the cathodically nondesorbable charge from the total charge was used to construct Fig. 6.

Adsorption at infinite time as a function of potential.—The adsorption isotherm, in terms of Q_{ox}, at maximum coverage as a function of potential is shown in Fig. 8.

Discussion

Kinetics of adsorption of pentane from H_2SO_4 at 85°C.—The adsorption if hexane (4) has been shown to be diffusion controlled at 130°C and it was thought that pentane, at a lower temperature and in a higher concentration, might also be expected to adsorb under diffusional control. However, although classical $\tau^{1/2}$ plots could readily be fitted to the experimental data, diffusional controlled adsorption was not thought to be the predominant process for the following reasons:

1. If diffusional controlled adsorption were operative, potential dependence on the rate would not be expected to occur.

2. Stirring should have a profound effect on the rate of adsorption. In fact, the rate remains essentially unaffected.

3. If diffusional controlled kinetics are operative, the linear region would only be expected to hold over

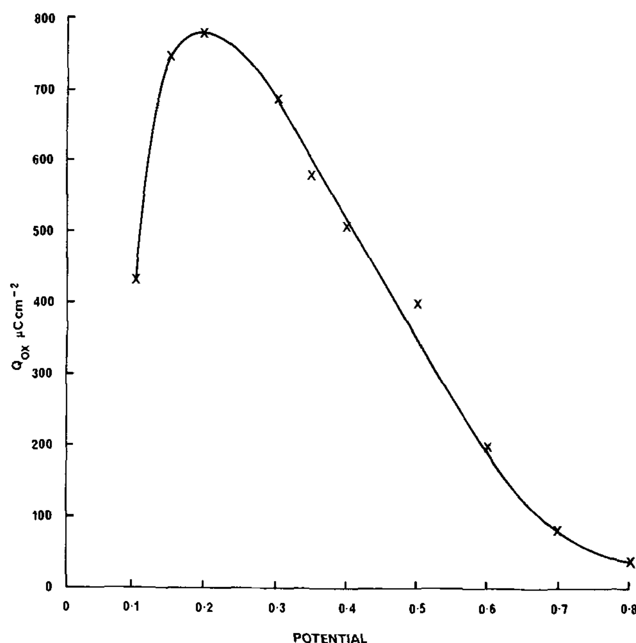

Fig. 8. Variation of the maximum anodic charge with potential

a short time, *c.f.*, Cairns (12) and Brummer (2-4) not as is observed in this case, a linear region extending up to about 70 sec.

4. The strongest evidence against diffusion-controlled adsorption is the time before adsorption becomes significant, which is referred to as the "induction period."

Confirmation that diffusion-controlled adsorption was not operative at any stage of the adsorption process was obtained by analyzing the diffusion equation for pentane diffusing to a cylindrical electrode under potentiostatic control, over the range of

$$Q_{ox} = \int_0^{\tau} (f)\, d\tau \qquad [1]$$

where Q_{ox} is the anodic charge and therefore is a measure of the number of moles of pentane adsorbed on the electrode, and τ is the adsorption time in seconds.

The solution of the diffusion equation requires a knowledge of the solubility of pentane (C_∞) under our experimental conditions. This is not available in the literature. Solubility data (17-19) for several hydrocarbons are shown in Fig. 9.

It is noted that the solubility/temperature relationship is parallel over the temperature range 25°-90°C. On this basis, the reported solubility at 25°-90°C has been extrapolated to 85°C. By this method a value of $C_\infty = 2.36 \times 10^{-7}$ moles cm^{-3} is obtained. Since adsorption in our case lay in the mid region 1-100 sec the complete solution of the diffusion equation [1] is necessary; (see Appendix). This was carried out on a Univac 1108 computer and the solution plotted in Fig. 10 together with the corresponding experimental values of Q_{ox} and τ for each potential.

It is seen that in all cases the experimental values fall well below the theoretical curve. The evidence presented above clearly shows that the adsorption rate is activation controlled. This is in accord with the findings of Gilman (8) and Flannery (14) for ethane and butane, respectively.

In view of the complex chain of reactions involved, it was not thought appropriate to analyze the data in terms of the equilibrium relationships (Langmuir or Temkin). It has, however, been analyzed in terms of a Langmuir-type relationship (20), relating the rate of adsorption to the available surface of the electrode $(1 - \theta_{H.C.})$.

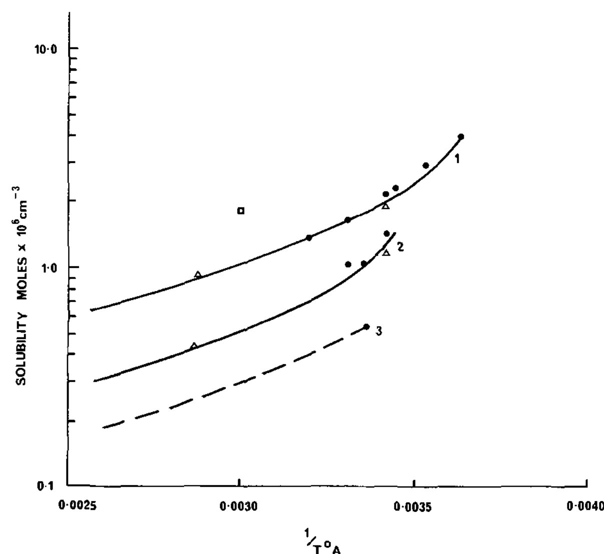

Fig. 9. Solubility of several hydrocarbons as a function of the reciprocal of the temperature. 1 Ethane. 2 butane, 3 pentane (extrapolated to 85°C). Data indicated is taken from following: ● Ref. (17, 18); Δ Ref. (19); □ Ref. (8).

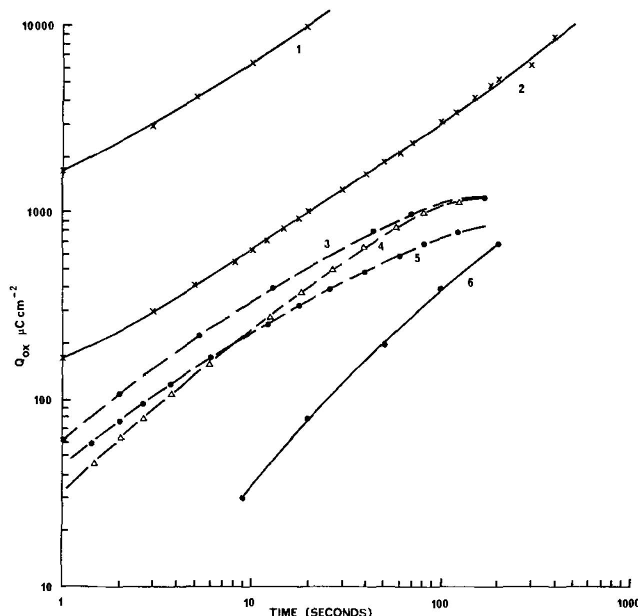

Fig. 10. Graphical solution of diffusion equation. Curves 1 and 2 relate to the theoretical relationship for the charge per unit area to the adsorption time. Curve 1: $C = 2.36 \times 10^{-7}$ moles cm^{-3}. Curve 2: $C = 1 \times 10^{-7}$ moles cm^{-3}. Curves 3-6 relate to the experimental data: 3, 0.3V; 4, 0.2V; 5, 0.4V; 6, 0.1V.

$\theta_{H.C.}$ is the electrode coverage with pentane at time τ.

Using the Langmuir relationship in terms of $\theta_{H.C.}$ the rate equation is

$$\frac{d\theta_{H.C.}^{\tau}}{d\tau} = kC(1 - \theta_{H.C.}^{\tau})^m \qquad [2]$$

where $\theta_{H.C.}$ = coverage with hydrocarbon, defined by the expression

$$\theta_{H.C.} = \frac{Q_H^{\infty\ org} - Q_H^{\tau\ org}}{Q^{\infty}_{org}} \qquad [3]$$

$Q_H^{\infty\ org}$ = hydrogen charge at infinite time: in μC cm^{-2}
$Q_H^{\tau\ org}$ = hydrogen charge at time τ: in μC cm^{-2}
m = reaction order in available surface
k and C = constants

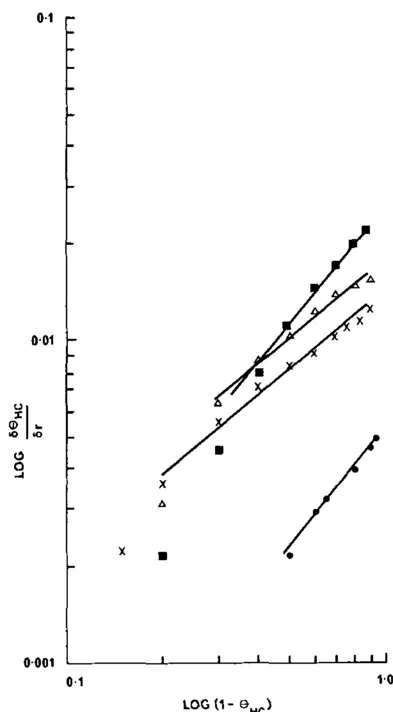

Fig. 11. Rate of electrode coverage vs. available electrode surface. ● 0.1V, X 0.2V, △ 0.3V, □ 0.4V.

Plot of log $d\theta_{H.C.}/d\tau$ against log $(1 - \theta_{H.C.})$ (Fig. 11) showed that the reaction was predominantly first order in available surface suggesting that the first step in the adsorption in terms of free surface is rate controlling.

A study of the kinetics of the formation of the cathodically nondesorbable species does not appear to have been attempted before since diffusional controlled adsorption has generally been operative. A simple attempt at analysis is presented below.

Plotting the rate of formation of the nondesorbable species $d\theta_{N.D.}/d\tau$ as a function of available electrode area $(1 - \theta_{des}) \times \theta_{des}$ results in a linear relationship at 0.3 and 0.4V. However, at 0.2V the relationship breaks down; this is probably due to the presence of significant coverage with hydrogen (21).

The result for 0.4V is plotted in Fig. 12 and indicates that the formation of O-type is first order in available surface, as well as θ_{des}; thus supporting the hypothesis that the nondesorbable species is derived from the cathodically desorbable species. The Q_{ox} *vs.* τ plots, Fig. 3 and 4, indicate a significant induction period before measurable adsorption occurs at 0.1V. This is potential dependent the longest "induction" period

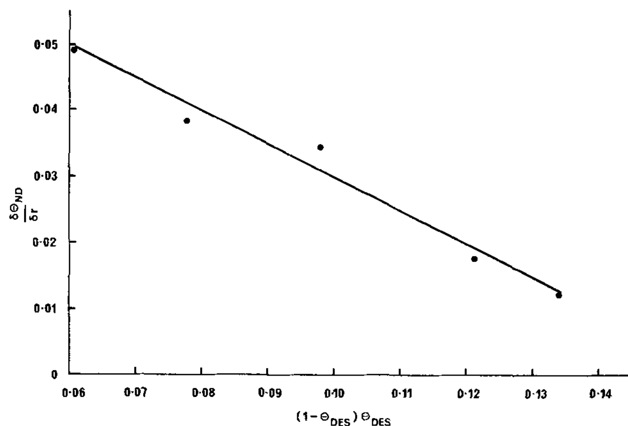

Fig. 12. Relationship between the rate of formation of nondesorbable material to available electrode area 0.4V.

being at 0.1V subsequently reducing as the potential is made more anodic. It is likely that adsorbed hydrogen plays a part in controlling the length of the "induction period." This is explained by assuming that a replacement mechanism is involved and that the replacement of hydrogen by hydrocarbon is significantly slower than the subsequent rate-controlling adsorption step. The absence of a significant induction period at 0.3 and 0.4V gives strong support to this assumption. Similarly, it was found that on lowering the temperature to 30°C the "induction period" was increased by about a factor of *ca.* 3 at 0.2V. Reducing the concentration of pentane also resulted in an increase in the "induction period" again consistent with the proposed replacement mechanism.

Adsorbed species.—Two distinct types of adsorbed species are present on the electrode, one cathodically desorbable and the other cathodically nondesorbable. This finding is similar to that of Brummer for the adsorption of propane and hexane on platinum. Brummer designated the species CH-α and O-type (and CH-β), respectively, and the same nomenclature is used here. The CH-α species has been found in our experiments to be always predominant. The CH-α species (except at 0.1V where adsorbed hydrogen results in anomalously low values) gives on oxidation an average $[e]$ value of 5.2. It is noted that at 0.3V possibly a second CH-α species is present. Although two lines have been drawn through the experimental points, the significance is questionable. On account of the high value of 5.2 "electrons per site" it is suggested that the adsorbed species is uncracked.

A simple model of pentane adsorbed on a platinum (100) face is a close-packed array (Fig. 13) would result in an $[e]$ value of 5.4, *i.e.*, 27 electrons for total oxidation to carbon dioxide and water. Considering the simplest case where hydrogen is not co-adsorbed, *e.g.*, 0.3V, it is possible to calculate the number of molecules of pentane adsorbed on 1 cm^2 of platinum. The experimental value at 0.3V for the CH-α species to 6.6×10^{14} molecules cm^{-2} compares with the expected theoretical value of 8.8×10^{14} molecules cm^{-2}. These values are felt to be in close agreement in view of the fact that screening of the available electrode surface, which is inferred from the data shown in Fig. 6, occurs, which reflects a somewhat higher theoretical value since the electrode coverage will be higher than is in fact the case. In addition, not all the surface is available for adsorption since the Pt-Pt and C-C bond lengths are not identical and therefore a lower value still would be expected for the theoretical value.

The O-type species oxidizes, yielding values of 3 and 1.5 electrons per site and are probably oxygenated species, as suggested by Brummer (3, 4, 6) and Cairns (12). The $[e]$ value decreases with increasing potential (Fig. 13) which is consistent with the formation of a more highly oxidized species at high potentials.

Conclusions

Pentane has been shown to adsorb under predominantly activation-controlled conditions and the adsorption process is first order in available electrode surface at all the potentials studied. At low potentials an induction period is observed which is thought to be connected with a hydrogen replacement stage.

The majority of the pentane is adsorbed in an uncracked state (CH-α) and is readily cathodically desorbable. The cathodically nondesorbable O-type forms only a small proportion of the adsorbate and becomes more highly oxidized with increasing potential. The formation of O-type species is shown to be first order in the available electrode surface.

APPENDIX

The mathematical relationship for relating the diffusion of hydrocarbon in an infinite region surrounding a cylindrical electrode, radius a, where the diffusion coefficient, D, and the concentration in the bulk

electrolyte, C_∞, are given is related to the current per unit area of electrode by

$$i = \frac{4n\mathbf{F}D\,C_\infty}{\pi^2 a}\int_0^\infty \frac{\exp\left(-\frac{Dt}{a^2}z^2\right)dz}{z\,(J_0^2(z) + Y_0^2(z))}$$

Carslaw and Jaeger (22) give the formula for the heat flow in the corresponding heat problem as

$$f = \frac{4KV}{\pi^2 a}\int_0^\infty \frac{\exp\left(-\frac{Kt}{a^2}z^2\right)dz}{z(J_0^2(z) + Y_0^2(z))}$$

where $z = a, u$ and $V \equiv C_\infty, X \equiv D, K \equiv n\mathbf{F}D$.

To carry out the numerical analysis of the integral given above for all times the asymptotic series (first four terms) for $0 \leq T \leq 0.3$ are employed. For $T > 0.3$ the following is integrated numerically

$$q = \frac{4n\mathbf{F}DC_\infty}{\pi^2 a}\int_0^t\int_0^\infty \frac{\exp\left(-\frac{Dt}{a^2}z^2\right)dz\cdot dt}{z(J_0^2(z) + Y_0^2(z))}$$

$$= \frac{4n\mathbf{F}C_\infty a}{\pi^2}\int_0^\infty \frac{(te^{-Tz^2})dz}{z^3 J_0^2(z) + Y_0^2(z)}$$

To carry out this integrand it is found that for $T > 0.3$, $z > 3.6$, $1 - e^{-z^2T}$ is a monotonic increasing function and equal to 0.99 to an approximation of $\pm$ 1%, and that $\frac{1}{a(J_0^2(z) + Y_0^2(z))}$ is a monotonically decreasing function and equal to 1.58 to an approximation of $\pm$1%. Consequently

$$\int_{3.6}^\infty \frac{(1 - e^{-z^2T})dz}{z^3(J_0^2(z) + Y_0^2(z))} \simeq 0.99 \times 1.58\int_{3.6}^\infty \frac{dz}{z^2}$$

$$= \frac{0.99 \times 1.58}{0.36} = 0.4345$$

Now for modified integral limits

$$0 < \alpha < \frac{0.2}{T^{1/2}},\quad \frac{1 - \exp^{-z^2T}}{z^2} \simeq \frac{(1 - \alpha^2 T)}{4}\,T$$

to within 1%, and for

$$0 < \alpha \leq 0.2 : Y_0 \simeq 0.07 + \frac{2}{\pi}J_0 \ln\,(z)$$

$$\therefore z(J_0^2(z) + Y_0^2(z)) \simeq z\,(J_0^2(z))\left(1 + \left(-0.07 + \frac{2}{\pi}\ln\,(z)\right)^2\right)$$

$$\therefore q = \frac{4n\mathbf{F}C_\infty a}{\pi^2}\left\{\frac{\left(1 - \frac{\alpha^2 T}{4}\right)T}{\left(1 - \frac{\alpha}{4}\right)}\int_0^\alpha \frac{dz}{z\left(1 + \left(-0.07 + \frac{2}{\pi}\ln\,(z)\right)^2\right)} + \int_\alpha^{3.6}\frac{(1 - e^{-z^2T})dz}{z^3(J_0^2(z) + Y_0^2(z))}\right\} + 0.4345$$

where α is a minimum at $(0.2, 0.2/T^{1/2})$. Now

$$\int_0^\alpha \frac{dz}{z\left(1 + \left(-0.07 + \frac{2}{\pi}\ln\,(z)\right)^2\right)} = \frac{\pi}{2}\left[\frac{\pi}{2} + \tan^{-1}\left(-0.07 + \frac{2}{\pi}\ln\alpha\right)\right]$$

in the range $-\pi/2$ to $\pi/2$.

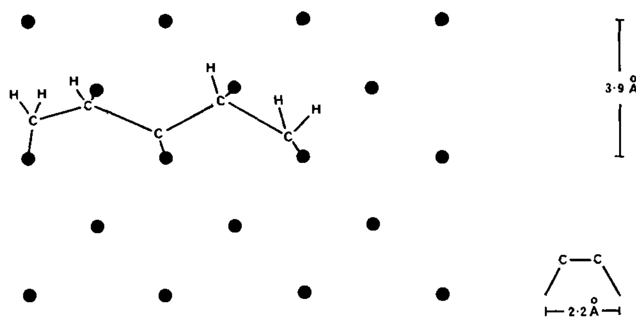

Fig. 13. Model of platinum lattice with pentane dissociatively adsorbed on the surface. ● Pt atom.

The integral between α and 3.6 was integrated numerically using the Simpsons rule procedure SIMINI given in the Univac Mathpack (23) with a relative error setting of 0.001. The integrand was evaluated (24) using

$$2 \leq z \leq 3.6\quad \frac{1}{z(J_0^2(z) + Y_0^2(z))} = 1.59$$

(better than $\pm$ 1%)

$$0 \leq z \leq 2\quad J_0(z) = 1 - 2.25\left(\frac{z}{3}\right)^2 + 1.26562\left(\frac{z}{3}\right)^4 - 0.31639\left(\frac{z}{3}\right)^6$$

$$Y_0(z) = \frac{2}{\pi}\ln\left(\frac{z}{2}\right)J_0(z) + 0.367467 + 0.605594\left(\frac{z}{3}\right)^2 - 0.743504\left(\frac{z}{3}\right)^4 + 0.253\left(\frac{z}{6}\right)^6$$

The following numerical values were then substituted into the above expressions: $D = 2.15 \times 10^{-5}$ cm^2 sec^{-1} (25); $a = 0.0127$ cm; $n = 27$. The curves shown on the graph of experimental results Fig. 13 are for $C_x = 10^{-7}$ and 2.34×10^{-7} moles cm^{-3}.

Acknowledgments

The authors wish to thank Dr. R. Hodgkins for the solution of the diffusion equation and Dr. D. Gilroy for helpful discussions.

Manuscript submitted Dec. 8, 1971; revised manuscript received April 4, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Thermodynamic and Physical Properties of Molten Sodium Polysulfides from Open-Circuit Voltage Measurements

Nirmal K. Gupta* and Ragnar P. Tischer*

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The open-circuit voltage of the cell Na/β-alumina/Na_2S_x/pyrolytic graphite has been measured as a function of temperature and sodium-polysulfide composition. From these data, differential free energy, entropy, and enthalpy values for the potential-determining reaction and the differential free energy of formation for various polysulfide compositions were calculated. The partial differential enthalpy ($\overline{H}_1$) of adding Na to the polysulfide melt is −47.6 kcal/mol independent of melt composition and temperature. The solubility of sulfur in sodium pentasulfide was determined between 280°-390°C, and the Na_2S-S phase diagram of Pearson and Robinson was revised in the Na_2S_2-S range and extended to show the Na-rich border of the miscibility gap.

So far very little has been known about the electrochemistry of the Na-S system in the molten state. With the application of β-alumina and related structures of high sodium ion conductivity, direct electrochemical investigation of this system became possible. The application in the Na-S battery makes a more detailed knowledge of the electrochemical behavior of the system highly desirable.

As a first step in a program to gather such knowledge, the open-circuit voltage of the cell Na/β-alumina/Na_2S_x melt/graphite has been measured as a function of temperature and of the composition of the melt. The data obtained in conjunction with recent DTA measurements by Oei (1) of this laboratory permit a revision to be made of the Na_2S-S phase diagram by Pearson and Robinson (2). The use of open-circuit voltage (OCV) measurements for the determination of a phase diagram has the distinct advantage that one can wait an unlimited time (at least theoretically) for equilibrium to be reached. This is quite important in a system with such strong tendency for undercooling as the Na-S system. The limits of the miscibility gap, for instance, cannot be determined by the usual method of analyzing the phases, because the two phases will not separate, at least under natural gravity, when kept at temperature for three weeks.

From the open-circuit voltages a variety of thermodynamic values can be calculated hitherto not available in literature. A search revealed only a few heats of formation for sodium polysulfides in the solid state at room temperature and in liquid ammonia (3, 4).

Theoretical Considerations

Na_2S_2-S phase diagram. Sulfur solubility in Na_2S_5.—For the purpose of determining the solubility of sulfur in Na_2S_5 as a function of temperature, two sets of data were needed. One set of data consisted of OCV measurements as a function of Na-polysulfide composition at various temperatures. The other set was obtained by measuring OCV using a Na-polysulfide melt in equilibrium with sulfur at the same temperatures. The plot of OCV *vs.* composition extrapolated to the OCV of the S-saturated melt at the same temperature yields the composition of this melt. The S-solubility in Na_2S_5 as a function of temperature forms the Na-rich boundary of the miscibility gap in the Na_2S-S phase diagram.

Liquidus line.—The liquidus line, including the melting points of the Na-polysulfides that exist as definite compounds in the solid state, and the melting points and compositions of eutectics can be determined from the OCV *vs.* temperature curves.

Thermodynamic properties.—The Gibbs free energy, enthalpy, and entropy for the three reactions involved are symbolized as follows

$$2Na + (x-1)\,Na_2S_x = xNa_2S_{x-1}\ (\overline{G}_1, \overline{H}_1, \overline{S}_1)\quad (x = 3\ldots5) \qquad [1]$$

$$S + Na_2S_{x-1} = Na_2S_x\ (\overline{G}_2, \overline{H}_2, \overline{S}_2) \qquad [2]$$

$$2Na + xS = Na_2S_x\ (G, H, S)\ (x = 2\ldots5) \qquad [3]$$

The (barred) partial molar quantities are differential energies and entropies of adding Na or S to a large excess of polysulfide melt such that the over-all polysulfide composition does not change. Subscript 1 represents Na and subscript 2 represents S.

Calculation of $\overline{G}_1$, $\overline{G}_2$ and G.—The OCV of the cell is determined by Reaction [1]. Sodium is ionized or discharged at the sodium electrode and passes through the Na-ion conducting ceramic to or from the melt.

$$Na = Na^+ + e^-$$

The sulfur electrode transfers electrons and responds to the reaction

$$(x-1)\,S_x^{=} + 2e^- = xS^{=}_{x-1}\,(x = 3\ldots5)$$

* Electrochemical Society Active Member.

Key words: free energy of formation, phase diagram.

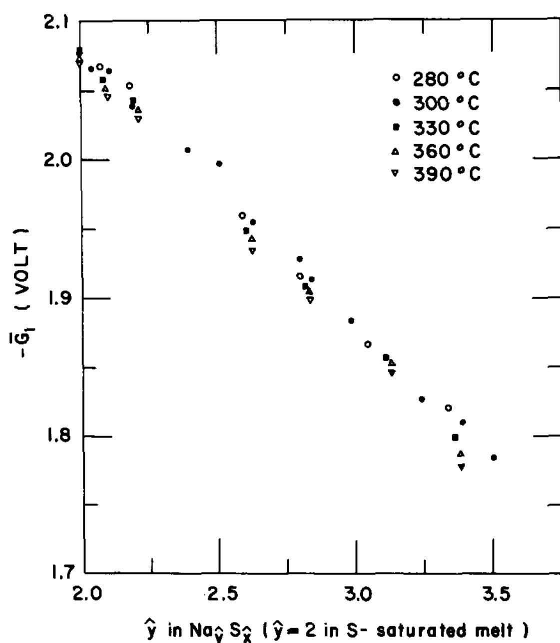

Fig. 1. $\overline{G}_1$ as a function of $\hat{y}$ at various temperatures, indicating that $d\overline{G}/d\hat{y}$ = constant.

We have here the rare case of a redox system with the oxidized and the reduced form of an atom present in one and the same ion (cp. I_3^- in aqueous solution). The OCV (difference of reversible potentials) is related to $\overline{G}_1$ by

$$-\overline{G}_1 = \mathbf{F}E$$

where $\mathbf{F}$ = Faraday constant and E = open circuit voltage.

The value of $\overline{G}_2$ is calculated from $\overline{G}_1$ by using the Gibbs-Duhem relation

$$\hat{y}\, d\overline{G}_1 + \hat{x}\, d\overline{G}_2 = 0$$

where 2 and x are the stoichiometric numbers of Na and S in Na_2S_x; $\hat{y} = 2\hat{x}/x$ with $\hat{x}$ = constant = stoichiometric number of S in Na_2S_x in equilibrium with free sulfur. $\hat{x}$ is a function of temperature.[1]

Dividing this by $d\hat{y}$ and integrating with respect to $\hat{y}$ while having $\hat{x}$ constant, we obtain

$$\int_0^{\hat{y}} \eta \frac{d\overline{G}_1}{d\eta} d\eta + \hat{x} \int_0^{\hat{y}} \frac{d\overline{G}_2}{d\eta} d\eta = c$$

A plot of $-\overline{G}_1$ *vs.* $\hat{y}$ at constant $\hat{x}$ shows that in this system at any temperature within the range of interest $d\overline{G}_1/d\hat{y}$ is also a constant (Fig. 1). Hence

$$\overline{G}_2 = -\frac{\hat{y}^2}{2\hat{x}} \frac{d\overline{G}_1}{d\hat{y}} + c$$

The value of the constant c is calculated by introducing the data for a reference polysulfide composition in which a small addition or removal of sulfur does not cause a free energy change, *i.e.*, $\overline{G}_2 \equiv 0$. Such a reference composition is given by the sodium-rich boundary of the miscibility gap, because there the melt is in equilibrium with sulfur. As we have set $x = \hat{x}$ at this composition, we have

$$c = \frac{\hat{y}^2}{2\hat{x}} \frac{d\overline{G}_1}{d\hat{y}} = \frac{2}{\hat{x}} \frac{d\overline{G}_1}{d\hat{y}}$$

since here $\hat{y} = 2$, or

$$\overline{G}_2 = \frac{1}{2\hat{x}} \frac{d\overline{G}_1}{d\hat{y}} (4 - \hat{y}^2)$$

where $2 \leq \hat{y} \leq \hat{x}$. The value of G is then calculated from the relation

$$G = 2\overline{G}_1 + x\overline{G}_2$$

It should be noted that the G-values are based on one mole of Na_2S_x whereas $\overline{G}_1$ and $\overline{G}_2$ are for one atom of Na and S, respectively.

Calculation of the entropy term.—The value of $\overline{S}_1$ can be calculated from the temperature dependence of $\overline{G}_1$, *i.e.*

$$(\partial\overline{G}_1/\partial T)_p = -\overline{S}_1$$

Calculation of $\overline{H}_1$.—Making use of the thermodynamic relation

$$\overline{G}_1 = \overline{H}_1 + T(\partial\overline{G}_1/\partial T)_p$$

substituting $-\overline{G}_1 = \mathbf{F}E$ and rearranging, we get

$$[(\partial E/\partial T)_p - E/T] = (1/T)\overline{H}_1/\mathbf{F}$$

so that a plot of $(\Delta E/\Delta T - E/T)$ *vs.* $1/T$ has a slope equal to $\overline{H}_1/\mathbf{F}$.

Experimental Procedure

Material preparation.—The Na_2S_4 obtained from Alpha-Inorganics contained traces of S and C_2H_5OH as impurities. It was purified by shaking with spectrograde CS_2 (Matheson-Coleman & Bell) at room temperature followed by vacuum drying at 70°C over P_2O_5 for one week. The purified Na_2S_4 was stored in a dry box (under helium) until used.

Na_2S was prepared from the hydrate by the conventional method (5). The high-purity sulfur (99.999%) obtained from American Smelting and Refining Corporation was used without further purification.

Na_2S_5 was synthesized by mixing Na_2S and S in the stoichiometric proportions and heating at 500°C for 1 hr in a Vycor tube sealed under vacuum. Any excess sulfur was removed by shaking Na_2S_5 with spectrograde toluene at 25°C followed by vacuum drying over P_2O_5.

The various Na_2S_x compositions were prepared by taking appropriate amounts of two of the following compounds: Na_2S, Na_2S_4, Na_2S_5, and S, and heating at 500°C for 4 hr in a Vycor tube sealed under vacuum. The melt was cooled and all the solid was transferred to the cell.

Cell construction.—Pyrolytic graphite electrode.—Pyrolytic graphite (p.g.) rods (¼ in. diam x 6 in.) obtained from Union Carbide were shaped to a pencil point as shown in Fig. 2. A high-purity titanium wire, of 0.062 in. diam and with 0-80 thread at one end, was threaded into the p.g. This assembly was enclosed in a Vycor tube and the p.g. was degassed at 900°C for 4 hr with continuous evacuation. The Vycor tube was subsequently allowed to shrink over the p.g. tip by heating. The titanium wire was sealed into the Vycor tube close to the p.g. rod by careful heating followed by slow annealing. The tip of the electrode was ground flat and polished to expose the cross section of the p.g.; and the whole assembly was immersed in distilled

[1] Stoichiometric numbers can be used conveniently for this calculation because the Gibbs-Duhem equation is homogeneous.

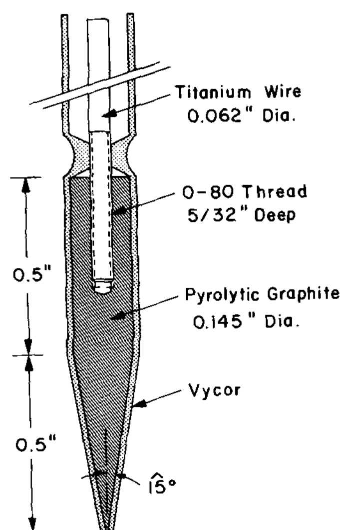

Fig. 2. Pyrolytic graphite microelectrode

water to check for leakage. After testing for 12 hr, the other end of the Vycor tube was also shrunk onto the titanium wire. A vacuum-tight Vycor-to-titanium seal was made at this end by using Torr-seal low vapor pressure resin supplied by Varian Associates. No creepage of the polysulfide melt was detected along the p.g.-Vycor interface.

The Cell.—Figure 3 shows the Pyrex cell used. Sodium (99.999% pure) was filtered through a Pyrex fritted disk and introduced into the β-alumina tube. The connecting Pyrex tube A was then sealed at B under vacuum. Electrical contact was made by using a tungsten wire sealed in Pyrex.

A calibrated Chromel-Alumel thermocouple was used to measure the temperature of the melt. The Na_2S_x was introduced into the cell in an atmosphere of dry nitrogen. The cell was then evacuated and sealed at C at room temperature to avoid changes in the composition of the melt at high temperature due to sulfur evaporation.

The cell construction was such that the polysulfides came in contact with Pyrex, Vycor, p.g., and β-alumina ceramic only.

Voltage measurements.—A Keithley 660A differential d-c voltmeter was used to measure the thermocouple emf and the open-circuit voltage between the Na-reference electrode and the $S/S^=$ electrode. The correction for thermo emf between the two electrodes was negligible (< 1 mV at all temperatures).

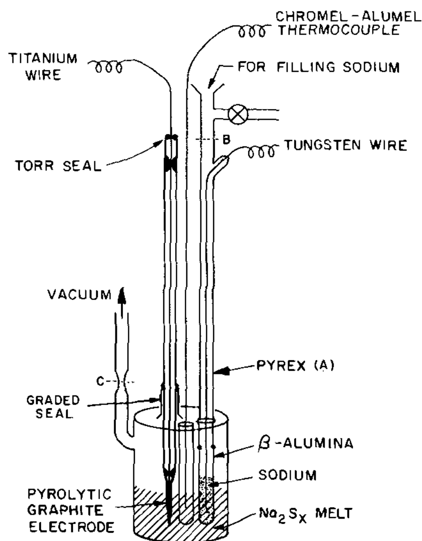

Fig. 3. Pyrex cell

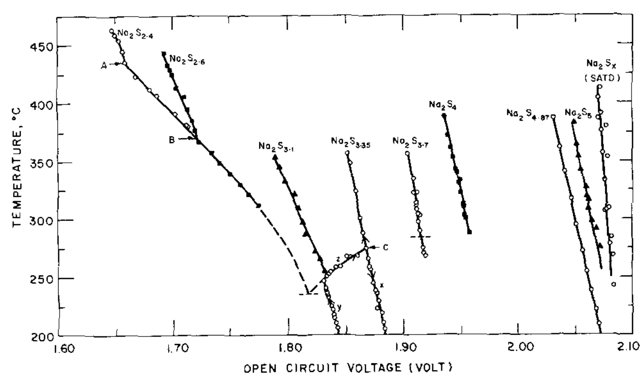

Fig. 4. Open-circuit voltage vs. temperature data

Results and Discussion

Solubility and phase diagram.—Figure 4 shows the OCV *vs.* temperature data for various polysulfide compositions studied. For all compositions, the OCV increases with decreasing temperature. In the case of the $Na_2S_{2.4}$ and $Na_2S_{2.6}$ compositions, the OCV increases until a break occurs (A and B, respectively) due to the separation of solid Na_2S_2 phase out of the melt. The curves further on coincide for both starting compositions. The shape of this curve is determined by the change in the OCV due to the changing composition of the melt with temperature, because solid Na_2S_2 phase precipitates, and by the changing temperature. The points A and B lie on the liquidus curve in the Na_2S-S phase diagram.

In melts that contain a larger amount of sulfur, *e.g.*, $Na_2S_{3.35}$ composition, no such break occurs in the cooling curve. A supercooling by as much as 100°C (stable for more than three days) has been observed in this case, before the melt solidifies. It should be noted that supercooling has been observed in all the melt compositions studied above $Na_2S_{2.6}$ composition. The supercooling tendency increases with increasing length of the sulfur chain present in the polysulfide ions. The point C corresponding to the liquidus line, in such a case, is determined by reheating the solid. A hysteresis loop (xyz) is observed as expected. The OCV decreases as the temperature is raised until the liquidus line (z) is reached. A break in the OCV *vs.* temperature curve (y) occurs and the OCV increases owing to changing composition of the melt along the liquidus line in the Na_2S-S phase diagram. At the second break (C), the heating curve leaves the liquidus line. After the solid phase has disappeared, the original cooling curve is retraced.

The composition of a eutectic that exists between Na_2S_2 and Na_2S_4 composition is also determined from the $Na_2S_{3.35}$ data. According to Pearson and Robinson (2), and Oei (1), the melting point of this eutectic is 235°C. If we extrapolate the OCV *vs.* temperature data obtained along the liquidus line (z) for $Na_2S_{3.35}$ composition to 235°C, we find that the composition of the eutectic corresponds to Na_2S_3. A second-order least square approximation was used for this extrapolation. Pearson and Robinson (2) reported a composition close to $Na_2S_{3.24}$.

Consistent results could not be obtained by this method between Na_2S_4 and Na_2S_5 because the cell was not equipped for stirring to overcome the severe undercooling in this region.

The sulfur solubility in Na_2S_5 is determined from the OCV *vs.* composition relationship at fixed temperatures taken from Fig. 4, and the OCV's of sulfur-saturated melt shown in Fig. 5. The data in Fig. 5 were obtained using polysulfide melts with excess sulfur. The curve (D) was obtained on cooling the melt. The straight line (U) was obtained on heating after allowing the Na_2S_5 to crystallize out of molten sulfur by cooling. The hysteresis loop is formed because of the

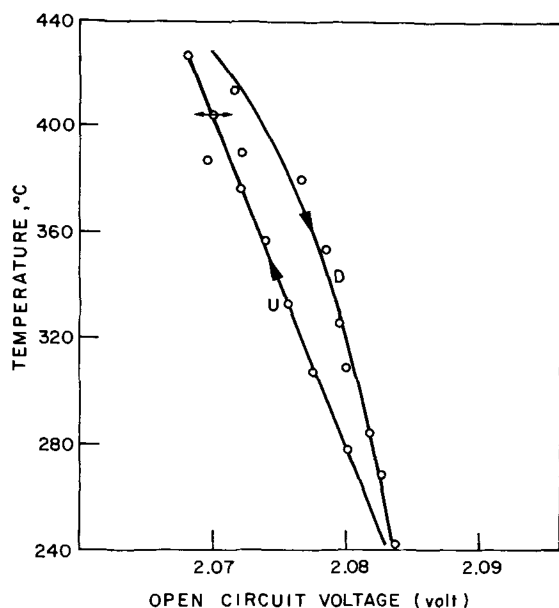

Fig. 5. OCV vs. temperature data for Na-polysulfide melt containing excess sulfur.

formation of supersaturated melt on cooling. These supersaturated melts have proved to be very stable. The OCV values at each point on the curve did not change even after waiting for 24 to 72 hr. The straight line shows the OCV of polysulfide melts in equilibrium with sulfur as a function of temperature. The composition of such melts at various temperatures is obtained by plotting the data from the straight line in Fig. 5 and the OCV *vs.* composition data obtained from Fig. 4. Such plots are shown in Fig. 6, which depicts the OCV *vs.* composition data at five different temperatures. The horizontal lines correspond to the data obtained from straight line U in Fig. 5. As explained earlier in the theoretical section, the line passing through the points of intersection forms the Na-rich boundary of the miscibility gap (Table I). The accuracy with which the S-solubility can be determined by this method is of the order of $\pm 0.02\%$ total sulfur.

The almost linear dependence of the OCV on composition does not permit any decision as to the potential-determining reaction. The range of compositions accessible in this system is so small that any logarithmic plot is linear with good approximation. But the

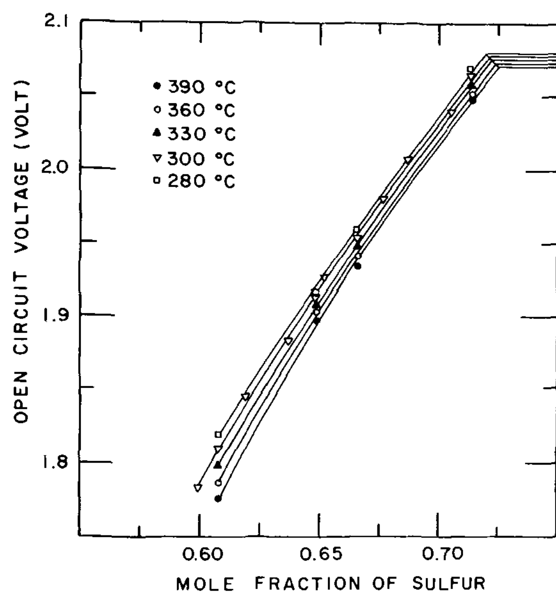

Fig. 6. OCV vs. composition at various temperatures

Table I. Sulfur-saturated melt composition at various temperatures

Temp, °C	Sulfur (wt %)
280	78.28
300	78.33
330	78.40
360	78.48
390	78.50

slope ($RT/n\mathbf{F}$) of reasonable logarithmic plots yields an n of 0.25. This suggests that the oxidized form S and the reduced form S^- in the sulfur/sulfide redox couple cannot be treated as separate entities.

Figure 7 shows the Na-S phase diagram constructed using the Na-rich boundary of the miscibility gap (line A) and the points (solid) on the liquidus line obtained from the data in Fig. 4. The open circles show the data points obtained by Oei (1) using DTA and other analytical methods. The thin line (B) shows the Na_2S-S phase diagram as published by Robinson and Pearson (2) in 1930. The S-rich boundary of the miscibility gap has not yet been determined. The miscibility gap does not close at the top because sulfur boils at 444.6°C under atmospheric pressure. Whereas the DTA data by Oei and the OCV data presented in this paper agree very well, there is a discrepancy with the diagram obtained by Pearson and Robinson (2). This may be attributed to an uncertainty in the polysulfide compositions caused by the analytical method used by Pearson and Robinson and/or the supercooling associated with polysulfide melts with a S/Na ratio $\geqq 1.3$. Pearson and Robinson obtained all their data from cooling curves. Figure 8, which is an enlarged view of a portion of the Na-S phase diagram, shows that the S-solubility limit does not pass through Na_2S_5 at its melting point. This clearly indicates that some sulfur dissolves in liquid Na_2S_5 down to solidification. No attempt was made to determine the solubility of sulfur in solid Na_2S_5. Establishment of equilibrium, being very sluggish in the melt, can be expected to be considerably more so in the solid state.

Thermodynamic properties.—Table II lists the values of $-\overline{G}_1$ and $-\overline{G}_2$ calculated from the experimental data. At any temperature, $-\overline{G}_1$ decreases with de-

creasing S content of the melt, whereas the $-\overline{G}_2$ value increases. The $\overline{G}_2$ values for the $Na_2S_{2.4}$ and $Na_2S_{2.6}$ compositions were not calculated because of difficulties in determining the composition of the S-saturated polysulfide melt (needed as a reference point) close to the boiling point of S with any accuracy.

Figure 9 shows plots of $-(\Delta E/\Delta T - E/T)$ *vs.* $1/T$. For all the compositions investigated, the relationship is linear and all the lines have practically the same negative slope. Such a constancy in the value of $\overline{H}_1$ (-47.6 ± 0.7 kcal/mole) means that the same reaction is potential determining over the entire temperature and composition range. This reaction is the addition of Na to the polysulfide melt (Eq. [1]).

Table III shows the values of the total free energy (G) for the formation of the polysulfide, and $\overline{H}_1$ and $\overline{S}_1$ for adding Na to the polysulfide melt (Eq. [1]). Since the variation of $\overline{G}_1$ with temperature for any polysulfide composition is small, the values of S, $\overline{S}_2$, H,

A Calomel Cell and the Fugacity of Hydrogen

W. R. Howell, Jr.,[1] J. H. Woodson, and H. A. Liebhafsky*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

By use of recent data for hydrogen as a real gas, it has been shown that there is no need to introduce changes in the activities of condensed phases to explain the electromotive forces measured when the partial pressure of hydrogen in a calomel cell (0.1*N* HCl as electrolyte) is increased up to 1035 atm at 25°.

In a classic investigation (1, 2) it was found at 25° that the emf, ϵ, of the cell

$$H_2(g)Pt|HCl(0.1N)|Hg_2Cl_2(s)|Hg(l)$$

increased more rapidly than required by the Nernst equation when the partial pressure p of hydrogen, varied up to 1035 atm, was used in the calculation. The departure of hydrogen from ideal behavior was of course mainly responsible, and all but 2.3 mV of the difference at 1000 atm was accounted for by using a simple equation of state for this gas in a treatment based on the volume change attending the cell reaction. The residual difference was attributed in the main to an effect of hydrogen dissolved at high pressure on the partial molal volume of hydrochloric acid. Calculations reported here, which are based on recent data (3-6), show that this assumption is no longer necessary. Extensive preliminary calculations indicated the results of Michels *et al.* (5, 6) to be best for our purposes.

Two sets of final calculations were made. In the first, the increment $\Delta\epsilon$ resulting from an increase of p above 1 atm (101325 N/m^2) was obtained for each such increase from the familiar equation

$$\Delta\epsilon = (0.029580\text{V}) \log f_p/f_1 \qquad [1]$$

which contains the fugacity quotient for the two partial pressures in question. The fugacities were obtained from

$$\ln f/p = (14.38P)/RT + (0.006671P^2)/2RT \qquad [2]$$

where P is the pressure in atmospheres for a hydrogen Pv isotherm experiment; R has the value 82.056 $cm^3 \cdot$ atm/kmol, and T is the temperature in Kelvins. The calculation assumes that P may be substituted for p, the partial pressure of hydrogen in the cell, when the two pressures are equal. This assumption is tantamount to saying that the water vapor present does not change the fugacity of hydrogen. The first virial coefficient is the value of B for 25° in Ref. (6); the second is that of $(C - B^2)/RT$ for the same temperature.

In addition, a differential calculation was needed. This is based on three thermodynamic relations

$$d \ln f = (pv/RT)\, d \ln p \qquad (v = \text{molar volume of } H_2) \qquad [3]$$

$$\epsilon^a = \epsilon^* + (RT/2\mathbf{F}) \ln f \qquad (a \text{ denotes actual gas}) \qquad [4]$$

$$\epsilon^i = \epsilon^* + (RT/2\mathbf{F}) \ln p \qquad (i \text{ denotes ideal gas}) \qquad [5]$$

which lead to

$$(\delta\epsilon)_n = \epsilon^a{}_n - \epsilon^i{}_n = (RT/2\mathbf{F})\,(\ln f_n - \ln p_n) \qquad [6]$$

or

$$(\delta\epsilon)_n = (0.029580\text{V})\,(\log f_n - \log p_n) \quad \text{at } 25°\text{C} \qquad [7]$$

as the "departure from ideality" for the n'th cell. Experimental values of $(\delta\epsilon)_n$ may be plotted against $\log p_n$ and measured slopes, $d(\delta\epsilon)/d \log p$, taken from the resulting curve. These may be compared with slopes calculated from

$$d(\delta\epsilon) = (0.029580\text{V})\,(pv/RT - 1)\, d \log p \quad (p = P) \qquad [8]$$

Equation [8] results from Eq. [3] and [7] applied to a pair of cells with partial pressures of hydrogen only slightly different. Equations [7] and [8] thus permit a direct intercomparison of two kinds of measured quantities: emf and Pv isotherms.

In Eq. [4] and [5], ϵ^* is the emf of the cell at unit fugacity of hydrogen. We have used $\epsilon^* = 0.39375$V, a value based on the first measured result of Ref. (7), Table I, corrected to 0.1*N* HCl by use of activity coefficients in Tables III and IV.

The data to this point are given in Table I.

The complexity of the calomel cell, uncovered (7) since 1924, could be responsible for the Δ's in Table I. It is gratifying to see that they show no dependence on p, and that they are smaller and opposite in sign to the 2.3 mV mentioned above.

Figure 1 shows the plot of $(\delta\epsilon)_{meas}$ *vs.* log p. Table II gives the comparison of the measured slopes from Fig. 1 with calculated values from Eq. [8] at five pressures at which isotherms were measured. The agreement is satisfactory. The fugacity of hydrogen is thus the only variable needed to explain the variation of ϵ with p in the cell under consideration. The measured emf's give no evidence of any net change in the activities of the condensed phases. In particular, they show no effect of the difference of electrolyte composition in the regions near anode and near cathode even at a hydrogen partial pressure that exceeds 1000 atm (10^8 N/m^2).

Electrochemical Studies of Zinc Tetraphenylporphin

J. G. Lanese[1] and George S. Wilson*

Department of Chemistry, University of Arizona, Tucson, Arizona 85721

ABSTRACT

The reduction of zinc (II) tetraphenylporphin (ZnTPP) in dimethylformamide (DMF) was investigated. The products of electron transfer and associated chemical reactions were studied by polarography, cyclic voltammetry, thin-layer controlled potential coulometry and spectroscopy, and epr. Reduction proceeds initially as a series of two reversible one-electron steps. After the second and subsequent steps, however, proton abstraction from the solvent medium occurs which, in turn, determines the reaction path. Characteristics of the porphyrin ring reactions are studied and compared with those of porphyrin free bases.

In recent years, there has been considerable interest in the area of porphyrin chemistry. The background and implications of these studies have been discussed in a previous paper, and a scheme for the electrochemical reduction of tetraphenylporphin (TPP) in aprotic medium (DMF) proposed (1). The present study was carried out as a continuation of the previous work (1, 2) in order to examine the effect of a central metal atom on the reactivity of the porphin ring in aprotic medium. The compound used for the

* Electrochemical Society Active Member.

Key words: zinc tetraphenylporphin, optical spectra, coulometry, cyclic voltammetry, aprotic solvent.

study was zinc tetraphenylporphin, ZnTPP. Of particular interest is the manner in which the central metal atom will influence ring reduction and associated chemical reactions without undergoing reduction itself.

The chemical reduction of ZnTPP in THF to yield the anion radical $ZnTPP^{\cdot -}$ and the chlorin, ZnTPC, has been reported by Closs and Closs (3). Seely and co-workers (4, 5) have reported the photochemical reduction of ZnTPP and zinc porphin to the respective chlorins in benzene and ethanol. The polarography of ZnTPP has been studied by Clack and Hush (6) while Felton and Linschitz (7) have reported polarography and epr spectra of electrochemical reduction products of TPP, ZnTPP, and ZnTPC in DMSO. The present study involves the detailed examination of porphyrin reactions by spectral and electrochemical methods.

Experimental

Materials.—ZnTPP was prepared from tetraphenylporphin by the method described by Adler *et al.* (8). The product was purified by column chromatography on neutral alumina eluted with benzene and recrystallized from chloroform.

The solvent, dimethylformamide (DMF), and the supporting electrolyte, tetraethyl ammonium perchlorate (TEAP), were purified as described elsewhere (2). Purification of degassing nitrogen has also been described (2).

Apparatus and methods.—Polarographic and cyclic voltammetric data were obtained using the apparatus described previously (2). A conventional hanging mercury drop electrode (HMDE) was employed. For measurements at very negative potentials, however, the electrode tip was inverted. This prevented the drop from falling off in regions of low mercury surface tension. All potential measurements were made with respect to an aqueous saturated calomel electrode (SCE) at 25° ± 0.1°C.

Near infrared and visible spectra were obtained with a Cary 14R spectrophotometer used in conjunction with a thin-layer cell of approximately 0.07 mm path length utilizing a gold minigrid electrode (2). Spectra of products produced were also obtained during the thin-layer cyclic voltammetric studies.

For thin-layer cell controlled potential coulometry, reductions and oxidations were carried out in the thin-layer cell using the polarographic apparatus and integrating the resultant current-time curve. The volume of the thin-layer cell was determined by coulometric determination of a solution of the disodium salt of anthraquinone 2,6 disulfonate of known concentration in 0.1M HCl. Current-time curves were corrected for cell edge diffusion. The current quickly decays to a small but constant value which is due to electrolysis at both ends of the cell. If this constant value is subtracted from the current-time curve, excellent agreement between known systems is obtained.

Epr spectra were generated *in situ* in the cavity of a Varian E-3 epr spectrometer in a cell similar to that described by Visco (9).

Results

Polarography and cyclic voltammetry.—The reduction of ZnTPP gives four diffusion controlled waves. A typical polarogram is shown in Fig. 1. Data for these waves are listed in Table 1. When corrected for drop time, the four wave heights are in the ratio of 1:1:1.2:1.5. No prewaves were observed. A poorly defined wave follows the second wave and will be discussed subsequently. The polarographic data for ZnTPP indicate that the first two waves are a result of one electron steps to form the anion radical ($ZnTPP^{\cdot -}$) and the dianion ($ZnTPP^{2-}$) respectively. The third and fourth waves result from irreversible, multiple electron processes. All four waves give currents which are linearly proportional to concentration over the range of about 5×10^{-5} to 1×10^{-3}M.

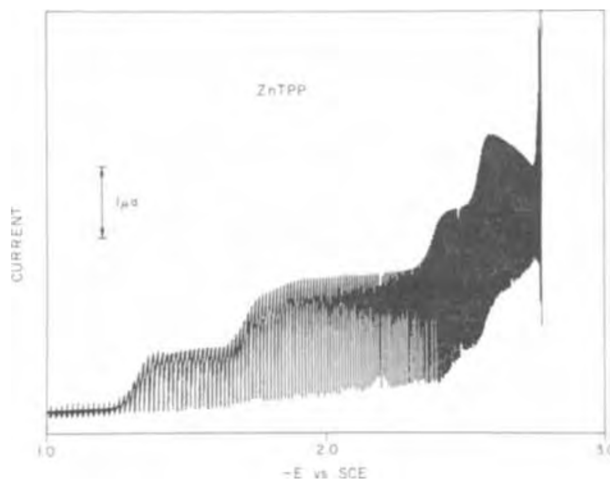

Fig. 1. Polarogram of 3.2×10^{-4}M ZnTPP in DMF, 0.1M TEAP

The effect of proton donor addition was studied by introducing water or benzoic acid into the aprotic medium. Above 1.3% (*v/v*), water and 0.03% benzoic acid, the first and second waves merged to form one long poorly defined wave somewhat lower in height than the sum of the first two waves. The small wave which initially followed the second wave became more prominent. The third and fourth waves became poorly defined as many new overlapping processes began to occur in this region.

The polarographic data are confirmed by cyclic voltammetry using the conventional polarographic cell (Fig. 2). At moderate scan rates (about 0.1 V/sec), the first two processes show cathodic and anodic peak separation indicative of a reversible one electron step (Fig. 2A). At slower scan rates, the anodic peak associated with the second step disappears and a new anodic peak appears at about −0.5V (Fig. 2B). This latter process corresponds to the oxidation of the product formed by the chemical reaction of the dianion ($ZnTPP^{2-}$).

When the potential is scanned at less than 0.1 V/sec, an additional reduction process appears at −1.9V (Fig. 2C) with cathodic and anodic peaks at −1.88 and −1.82V respectively. This process coincides in potential with the small polarographic wave noted above. When the scan is held at −1.9V, the oxidation peak (−1.82V) disappears and a small oxidation peak appears at −1.2V. The latter is in addition to the previously described peak at −0.5V. The sequence of events occurring when the electrode is polarized at −1.9V might be characterized as an ECECE mechanism. The first electrochemical step is reversible and involves the formation of the porphin dianion ($ZnTPP^{2-}$) from the anion radical. This is followed by rapid protonation to form the phlorin anion ($ZnTPPH^{-}$). Analysis of the cyclic voltammetric data yields a pseudo first order rate constant for the protonation of about 1 sec^{-1} as calculated by the method of Nicholson and Shain (10). The second electrochemical step involves the one-electron reduction of the

phlorin anion to form the phlorin dianion ($ZnTPPH^{2-}$). This assignment is verified by cathodic-anodic peak separation and by the coulometric data to be presented subsequently. The second chemical step and the electron transfer process associated with it are quite slow as described below.

The third and fourth cyclic voltammetric processes are irreversible and occur at −2.38 and −2.55V respectively. At scan rates greater than 0.008 V/sec, the third wave merges into the fourth. When the potential is scanned through all four waves, interpretation becomes complex due to the many oxidation peaks which result from large numbers of reactions of the reduction products with protons.

Thin-layer Electrochemistry.—Figures 3 and 4 show the spectra of the species formed in the thin-layer cell. Table II summarizes the spectral data between 350 and 1000 nm. When the ZnTPP is reduced at −1.35V, the anion radical $ZnTPP^{\overline{\cdot}}$ is formed (3). This product may be reversibly oxidized back to the parent compound, ZnTPP. Electrolysis at −1.75V yields a compound giving the spectrum of Fig. 3. The product

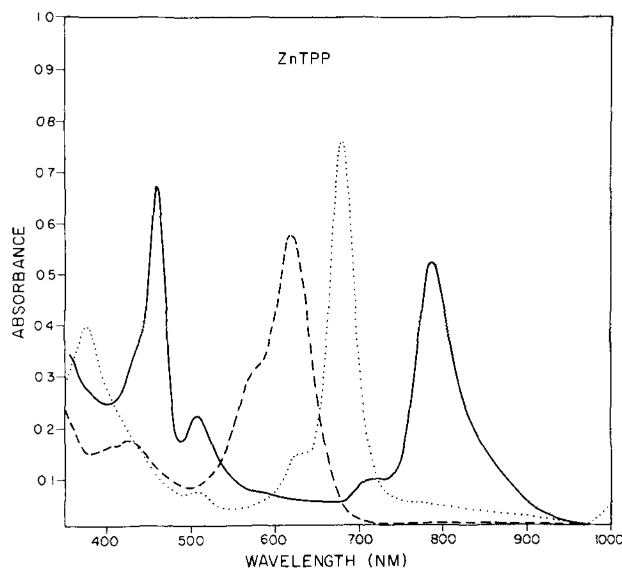

Fig. 4. Spectra of ZnTPP reduction products in DMF, 0.1M TEAP in thin layer cell. Concentration—1.5 X 10^{-3}M. $ZnTPPH^{2\overline{\cdot}}$ (———), $ZnTPPH_{(c+1)}^{(4-c-1)-}$ (- - - - -), $ZnTPPH_{(c+1-d)}^{(4-n-c-1+d)-}$ (. . . . .).

$ZnTPPH^-$ is identified from its similarity to the spectrum of Closs and Closs (3) who obtained bands at 457 and 810 nm in THF. This anion is irreversibly oxidized to the parent compound at −0.45V. At a potential of −1.90V, the phlorin anion is converted by a one-electron reversible reduction to $ZnTPPH^{2-}_{\cdot}$ as described above. The product is oxidized back to the phlorin anion at −1.8V. If the potential is held at −1.9V, the reduction product $ZnTPPH^{2-}_{\cdot}$ is converted to $ZnTPPH_{c+1}^{(4-c-1)-}$ by a one-electron process. This conversion is slow, requiring about an hour to go to completion. The conversion can be followed spectrally, and two isosbestic points are exhibited at 535 and 678 nm. These observations suggest that the rate of conversion is controlled by a slow chemical step involving a proton, isomerization, or both, and also that only two species are observed.

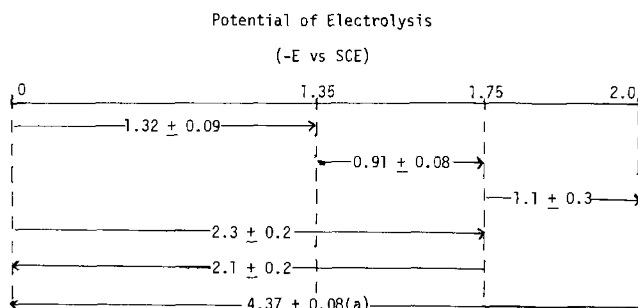

Fig. 5. Results of coulometric studies.—Number of electrons involved in oxidations and reductions by stepping between various potentials. a—Oxidation performed after holding at −2.0V for 1 hr.

The $ZnTPPH_{c+1}^{(4-c-1)-}$ is oxidized to a spectrally distinct intermediate, $ZnTPPH_{(c+1-d)}^{(4-n-c-1+d)-}$ at −1.2V, then to the phlorin anion, $ZnTPPH^-$.

Figure 5 summarizes the results of the thin-layer coulometric studies. A potential step from 0 to −1.35V results in the formation of $ZnTPP^{\cdot-}$ as confirmed spectrally. The N_{app} values are somewhat greater than the expected value of unity and this is probably due to the presence of reducible impurities in the solvent. The step from −1.35 to −1.75V converts the $ZnTPP^{\cdot-}$ to $ZnTPPH^-$. Oxidation of this product back to the parent compound at 0V confirms the assignment of oxidation state. The conversion of $ZnTPPH^-$ to $ZnTPPH^{\cdot 2-}$ (−1.75 to −2.0V) requires about 1.1 electrons/mole. Because the chemical reaction following electron transfer is slow, it is possible to obtain the coulometric data and phlorin dianion spectrum before further electron transfer can occur at the applied potential (−2.0V). If the potential is held long enough for complete reaction to occur, about 4 electrons are required to convert the resulting product ($ZnTPPH_{c+1}^{(4-c-1)-}$) back to the parent compound. This means that the conversion of the phlorin dianion to $ZnTPPH_{c+1}^{(4-c-1)-}$ must be a one-electron process. It is not known at present whether this latter step involves proton addition, but such a possibility is quite likely. In each of the controlled potential thin-layer electrolyses described above, the products were confirmed by spectral measurements. Typical electrolyses are completed in about 20 sec for an effective solution volume of approximately 20 microliters.

Typical thin-layer cyclic curves are shown in Fig. 6. Curve A shows the reversible reduction to $ZnTPP^{\cdot-}$ at −1.3V and the irreversible reduction to $ZnTPPH^-$ at −1.7V. The $ZnTPPH^-$ is oxidized back to the parent at −0.45V. The reduction at −1.85V (Fig. 6B) to $ZnTPPH^{\cdot 2-}$ is reversible as the dotted line indicates. The double peak in the −0.4 to −0.7V range is attributed to the oxidation of the phlorin anion and a presumably isoelectronic form of the phlorin anion to the parent compound ZnTPP. This latter conclusion is based on the area and potential of the oxidation peak.

EPR studies.—In situ generation of $ZnTPP^{\cdot-}$ confirms its paramagnetic character. A single line with a width between inflection points of 22 gauss is obtained. This is clearly distinguished from the spectrum obtained at −1.95V which is considerably narrower (6.4 gauss) and possesses hyperfine structure. The spectrum appears possibly consistent with that expected for a phlorin dianion (11).

Conclusions

Figure 7 shows a scheme for the reduction of ZnTPP which is consistent with the experimental observations. Acid-base reactions play an important role in determining the path of the electron transfer reactions. In this regard, the insertion of zinc(II) as a central metal atom produces some significant differences in porphyrin ring reactions. For example, the dianion of the porphin free base (TPP^{2-}) is quite stable in DMF (1) and in contrast to $ZnTPP^{2-}$ does not undergo the above-described protonation reaction to form the phlorin anion. Porphyrin electrochemical reduction has been shown to be followed by electrophilic attack on the methine bridge positions between the pyrrole rings (12). In this case, the result would be saturation of one of the bridge positions. Such a process is favored by increased electron density in the bridge position. The manner in which central metal atom substitution might influence bridge electron density is the subject of continuing study.

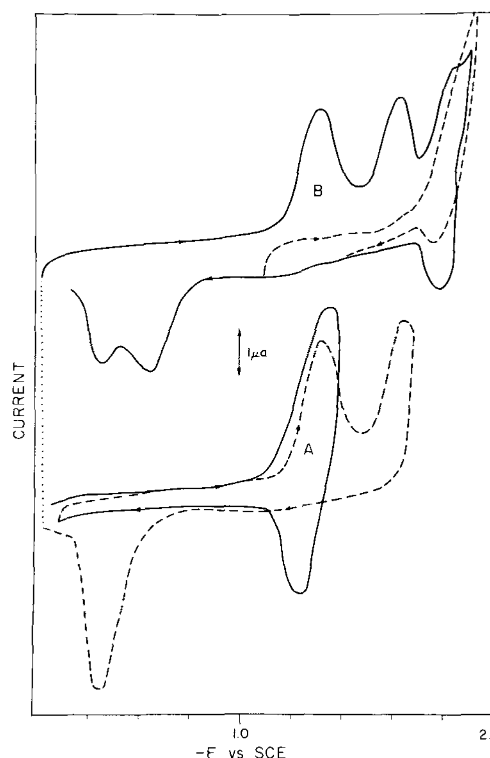

Fig. 6. Typical thin layer cyclic voltammetry. Approximately 10^{-4}M ZnTPP in DMF, 0.1M TEAP. Scan rate, 0.05 V/min.

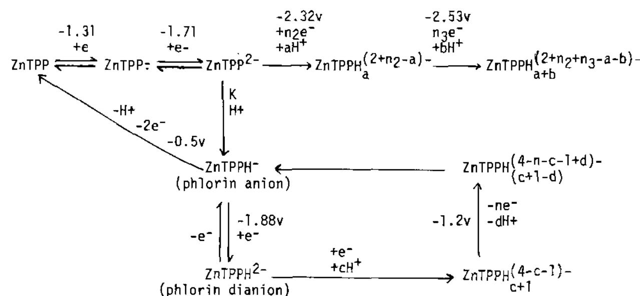

Fig. 7. Scheme for the electrochemical reduction of ZnTPP in DMF, 0.1M TEAP.

Phlorin anion oxidation to the parent porphin is similar for both $ZnTPPH^-$ and the corresponding $TPPH^-$. In neither case is there evidence of neutral radical ($ZnTPPH^{\cdot}$) formation during the oxidation. There is also no evidence of chlorin formation from the phlorin anion in this medium. $ZnTPPH^{\cdot-}$ is reduced in a one-electron reversible step to form the paramagnetic phlorin dianion. The latter species reacts slowly, probably with a proton, and a further one-electron reduction occurs at the same potential as the reduction of $ZnTPPH^-$. Some porphyrin-free base phlorin anions may well proceed by a similar mechanism, but if this

is so, the phlorin dianion is unstable, protonates rapidly, and the over-all irreversible process involves an apparent two-electron step (2).

Reduction beyond the two-electron level is complicated by the varying extent of acid-base reactions with reduced forms. It is clear on the basis of potentials that beyond the formation of the phlorin anion, the polarography-cyclic voltammetry conditions are not the same as the thin-layer experiment. This is due to the difference in time scale between the various experiments which allows varying degrees of protonation to occur.

Anodic Films and ECM Dimensional Control: A Study of Steel Electrodes in Solutions Containing Na_2SO_4 and $NaClO_4$

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The relationship between the passive film and the dimensional control of electrochemical machining (ECM) has been demonstrated experimentally with the behavior of steel electrodes in neutral Na_2SO_4 and $NaClO_4$ solutions. Potentiostatic transient measurements were first made with a mild steel rotating spherical electrode to reveal the mechanism of passivity, and the results were then compared to those obtained with rotating rods under actual ECM conditions. It is found that passivation is initiated by the formation of a salt layer resulting from supersaturation of dissolution products in the immediate vicinity of the anode. The rate of film formation is diffusion controlled, and the ECM dimensional control achieved by passivity of this kind is convection dependent. The results also indicate that this anodic film of the dissolution-precipitation type can serve only as partial protection for the metal surface during ECM.

One of the major problems associated with electrochemical machining (ECM) is that of obtaining satisfactory dimension control of a desired machining configuration. In practice, this is done by designing a proper shape for the cathode in order to give a required contour on the anode. The cathode (tool) design must rely on various process variables, *e.g.*, electrolyte properties, fluid flow effects, current and temperature distributions in the electrode gap (1-5). Among the parameters, the most important factor for achieving successful dimensional control is the choice of electrolyte. For instance, the use of NaCl solution in the ECM of steel brings about extensive stray cutting at sites located some distance from the machining surface facing the cathode, whereas under the same conditions the highly localized action of $NaClO_3$ gives excellent dimensional control (6, 7). Additions of Na_2SO_4 have been claimed to improve the ECM performance of NaCl solutions (8). Recently, $NaClO_4$ has been reported to give dimensional control similar to that obtained with $NaClO_3$ (9, 10).

* Electrochemical Society Active Member.
Key words: passivation of mild steel, rotating spherical electrode.

To explain why the use of different electrolytes results in different machining characteristics, Hoare, LaBoda, McMillan, and Wallace (11, 12) propose a film theory based on steady-state polarization measurements. According to them, to achieve good ECM dimensional control, the electrolyte used must be able to passivate the metal at certain anodic potentials. During ECM, metal is removed most heavily from the surface of the anode directly facing the cathode. This portion of the anode is called the cutting area or the high current density area where the voltage gradient across the electrode gap is high, and the dissolution is assumed to take place in the transpassive state. At places on the anode located well away from the cutting area, the distance to the cathode is large, and the IR drop in the solution lowers the metal/solution interfacial potential difference to values corresponding to the passive state. A passive film, therefore, is formed, resulting in little or no metal removal at these places.

Consequently, it is necessary to understand the nature of passivity to achieve further development of the ECM process. In a previous report (13), the mechanism of film formation was described for steel in NaCl

and $NaClO_3$ solutions. That investigation employed potentiostatic transient measurements with a rotating disk electrode (RDE). In the present work, the study has been extended to Na_2SO_4 and $NaClO_4$ solutions. Since a steel RDE would recede into the support and upset the flow characteristics during metal dissolution, a steel rotating spherical electrode (RSE) was used instead. The concept of a RSE is to replace the disk electrode on the RDE with a hemispherical head electrode. The hemispherical head merely reduces in diameter during the dissolution; this change does not alter the flow characteristics. A mathematical theory for the use of the RSE has been reported elsewhere (14).

To compare the transient results with the ECM behavior of steel in the electrolytes, experiments were also made under actual ECM conditions using a rotating steel rod, a stationary cathode, and a narrow gap space. Similar to the rotating rod experiment described by Dyke, Gurklis, and Faust (15), the method has the advantage of avoiding the complexity of pumping electrolyte at high pressures, while still providing a high rate of electrolyte flow in the electrode gap. This paper describes the results of these investigations.

Experimental

Potentiostatic transient studies.—A RSE was used for the study of anodic transients on steel in Na_2SO_4 and $NaClO_4$ electrolytes. With slight modifications, the electrode construction was similar to the one reported in an earlier mass transfer study (16). It consisted of a replaceable, mild steel hemispherical head electrode,[1] a cylindrical Teflon support, and a stainless steel holder. The head electrode was 0.317 cm in radius, and was mounted on one end of the Teflon support, 1.9 cm OD × 9 cm long. The other end of the support was attached to the stainless steel holder, which was machined to fit snugly into the spindle shaft of a high speed rotator. The electrolytic cell was an acrylic container, 15 cm ID × 15 cm high, having a platinum cathode on the bottom. The RSE was extended down from the rotator into the cell, and the spacing between the anode and the cathode was kept at 3 cm. A saturated calomel electrode immersed in a Luggin capillary tube was used as the reference electrode. To avoid disturbing the flow characteristics, the capillary tip was placed on the downstream of the electrolyte flow around the spherical electrode.

Procedures for the transient measurement were described in a previous report (13). For each run, the surface of the mild steel anode was degreased in isopropanol, cleaned in dilute HCl, and rinsed in distilled water. The clean RSE was then transferred to the cell filled with the test electrolyte, and was installed on the rotator. The electrode was further treated cathodically at −1.2V *vs.* SCE to remove any remaining trace of oxides on the surface. After the cathodic treatment, the system was permitted to rest for several minutes to allow the anode potential to return to the steady-state value at open circuit. A constant potential pulse was then applied to the anode, and the current transient was recorded on a Sanborn 296 recorder. A Magna 4700M potentiostat was used to control the anode potential.

The solutions used were 1M Na_2SO_4 and 4M $NaClO_4$; the pH of these solutions varied from 5 to 7 at room temperature. Before the start of each test, the solution was presaturated with nitrogen, and during the run, a nitrogen atmosphere was maintained by passing the gas through the cell. All the experiments were performed at a constant temperature of 24° ± 1°C.

ECM tests.—The ECM test was made with an uncoated steel rod rotating in the test electrolyte above a stationary cathode with a narrow gap space between them. Figure 1 illustrates the arrangement. The hydrodynamic condition within the electrode gap, studied by

[1] Composition of the mild steel: Fe, 98.4%; Mn, 0.98%; S, 0.29%; C, 0.10%; P, 0.06%; Si, 0.005%.

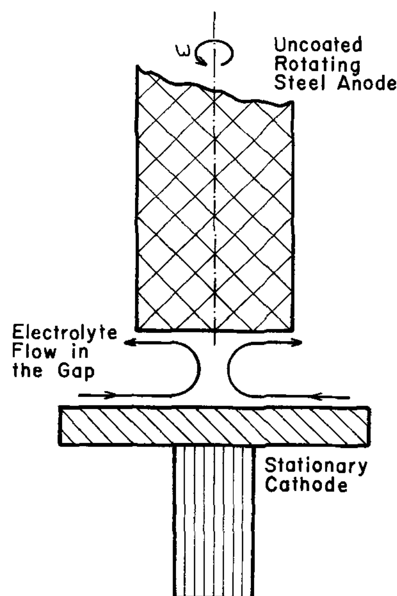

Fig. 1. Schematic diagram of ECM tests with a rotating rod

Mellor, Chapple, and Stokes (17), is characterized by flow of electrolyte into the gap near the stationary cathode and a swirling outward-flowing boundary layer on the tip of the rotating rod. Between the two there is a core flow (toward the anode) rotating with a constant angular velocity. The Reynolds number is calculated by $Re = \omega g^2/\nu$, where ω is the angular velocity of the rotating rod, g, the electrode gap; and ν, the kinematic viscosity of the electrolyte. It has been found by these investigators that the flow becomes turbulent when the Reynolds number is greater than 100.

In the present study an SAE 5160H steel rod, 0.635 cm diameter × 10 cm long, was used as the anode. It was mounted on the high speed rotator, and extended down into a 5 liter glass jar filled with the test electrolyte. The tip of the anode faced a stationary copper cathode, 1.27 cm diameter, as shown in Fig. 1. A jack was used to support the glass jar, and the anode-cathode gap space could be varied by adjusting the height of the jack. An initial gap of 0.085 cm was used for all the tests. After applying a selected angular velocity to the rotator, the tip of the steel rod was electrochemically machined at constant current for a given period of time. The current was controlled by a Magna 4700M potentiostat. Current density values were based on the cross-sectional area of unmachined rod (0.317 cm^2). The voltage drop across the cell was recorded on a Sanborn 296 recorder. No attempt was made to adjust the electrode gap space during the ECM. The rod was weighed before and after machining to determine the amount of metal removal, and the computation for current efficiency was based on ferrous ion as the dissolution product. The solutions used were: 1.5-3M $NaClO_4$, 1M Na_2SO_4, 3M $NaClO_3$, and a mixed electrolyte containing 0.5M Na_2SO_4 and 1.5M $NaClO_4$. All experiments were performed at a constant temperature of 24° ± 1°C.

Results and Discussion

Steady-state polarization curves.—Before the transient measurements, steady-state current/potential curves were first determined for the steel RSE in the test electrolyte. Figures 2 and 3 give the results of the measurements in 1M Na_2SO_4 and 4M $NaClO_4$, respectively. For comparison, a polarization curve of steel in 4M $NaClO_3$ is also plotted in Fig. 3 as the dashed line.

The current density in sodium sulfate electrolyte is given for three different anode revolution rates in Fig. 2. The data points obtained at zero (black dots) and 400 rpm (triangles) exhibit three distinct potential

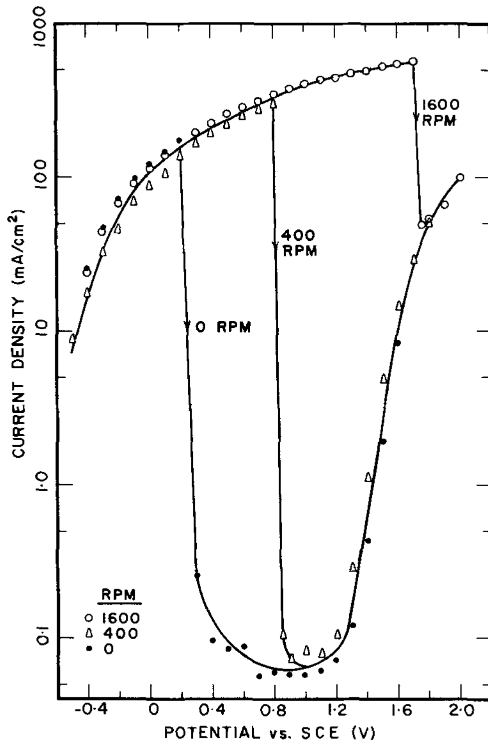

Fig. 2. Steady-state polarization curves in 1M Na_2SO_4

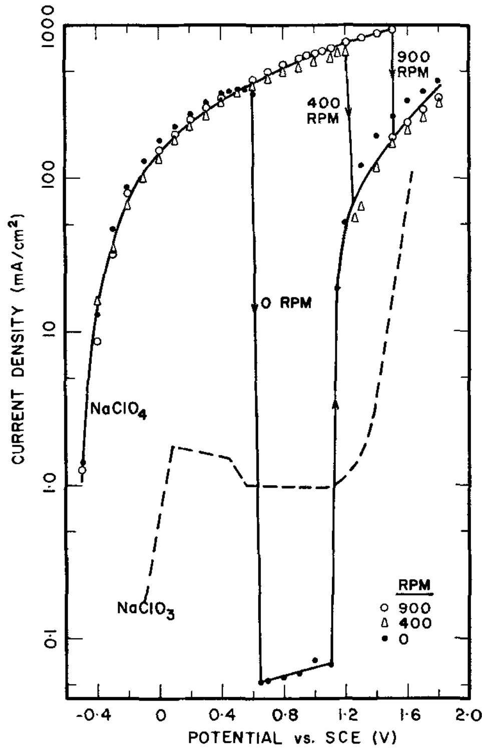

Fig. 3. Steady-state polarization curves in 4M $NaClO_4$. For comparison, a steady-state polarization curve obtained in 4M $NaClO_3$ is also plotted as the dashed line; this curve is independent of the speed of rotation.

states, *i.e.*, active dissolution, passive and transpassive regions. The current density does not seem to vary with the rotational speed; however, the critical potential at the point where the transition from the active to the passive region takes place is shifted in the noble direction as the speed of rotation increases. Consequently, the span of passive potentials diminishes with increasing speeds. At 1600 rpm, no passive region was observed, and the current density dropped directly from the active dissolution state to the transpassive state at 1.7V *vs.* SCE. Figure 3 shows that the same phenomena occur in sodium perchlorate solution, and that the effect of electrode rotation on passivity appears to be greater than was found in Na_2SO_4. The dissolution product was ferrous compounds in the form of greenish-black precipitates in the sulfate electrolyte, and black precipitates in the sodium perchlorate electrolyte.

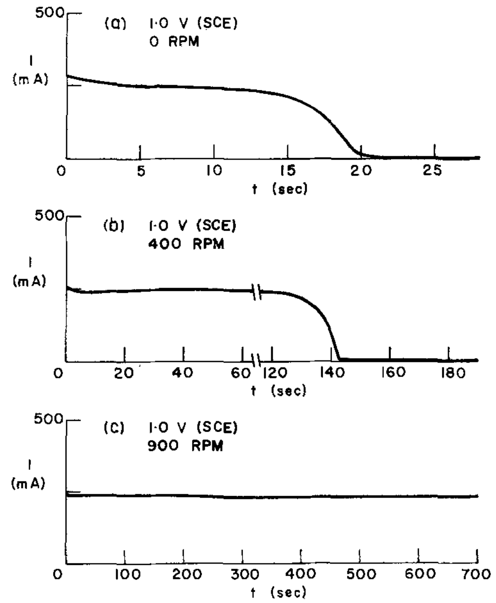

Fig. 4. Typical current transient in 1M Na_2SO_4 solution

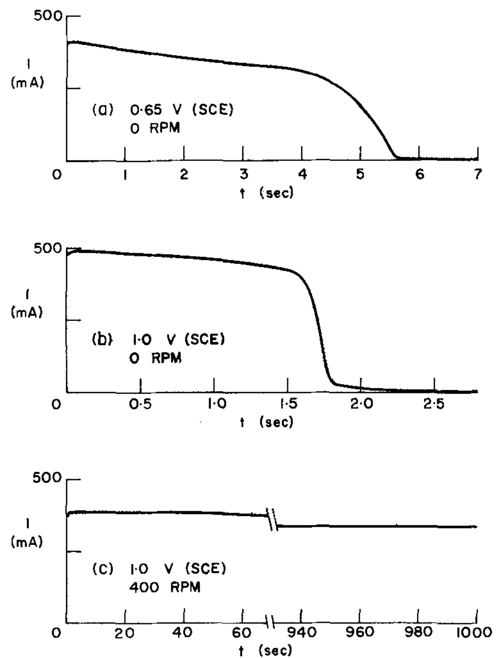

Fig. 5. Typical current transient in 4M NaClO solution

Anode transients at passive potentials.—Typical results of a potential pulse in the passive region are shown in Fig. 4 and 5 for Na_2SO_4 and $NaClO_4$, respectively. These curves are characterized by an initial constant current plateau followed by a rapid drop to the steady state. The magnitude of the plateau current, I_p, corresponds to the magnitude of the active dissolution current on the steady-state polarization curve. Evidently, the plateau current represents the iron dissolution rate prior to the passivation, and the current drop is caused by decreasing dissolution due to spreading of an anode film over the electrode surface. At a constant potential, the time required for passivation to

occur becomes longer as the rate of anode rotation increases. In Na_2SO_4, for instance, the passivation time increases from 20 sec at zero rpm to 145 sec at 400 rpm (Fig. 4a and b). At 900 rpm, no current drop occurs over a period of 700 sec after the potential pulse (Fig. 4c); the slight decrease in current observed in Fig. 4c is due to reduction of the electrode size as the iron dissolves. The effect of rotation is even greater in $NaClO_4$ solution, as shown in Fig. 5b-c, where no current drop takes place at an anode revolution rate of 400 rpm. Also at a constant rotational speed, Fig. 5a and b shows that the current transient period decreases with increasing anode potentials.

Onset of passive films.—Both the steady-state and the transient results demonstrate that the passivation of mild steel in Na_2SO_4 and $NaClO_4$ is of the dissolution-precipitation type. Transient behavior of this kind has also been found to occur during the anodic dissolution of steel in NaCl solution (13), iron in sulfuric acid (18-20), and copper in hydrochloric acid (21). For these systems the passivity is attributed to formation of a salt layer of reaction products on the anode surface. During ECM of copper in H_2SO_4 and $NaClO_3$ solutions, the work of Cooper, Landolt, Muller, and Tobias (22, 23) also reveals the presence of a salt layer on the anode.

In the present study, ferrous compounds are found to be the dissolution product. Evidently, the initial stage for the passivity of steel in Na_2SO_4 and $NaClO_4$ electrolytes involves precipitation on the metal surface of a ferrous salt. The current density during the active dissolution is high (Fig. 2 and 3), and the concentration of dissolution products in the vicinity of the anode is likely to increase to a value required for the precipitation (24, 25). The time required to attain such a concentration is represented by the duration of the initial plateaus on the transient curves. Once the precipitate starts to form on the electrode surface, it appears to impede the dissolution reaction, causing the current to drop rapidly as shown in Fig. 4 and 5 (26). The longer time for the onset of passivation observed at faster anode revolution rates implies that diffusion of reaction products away from the electrode is the rate-determining step for the film formation process. Because of a non-*in-situ* technique used presently, the composition of the salt layer is not known. However, judging from the greater convection dependence for the passivity of steel in $NaClO_4$ solution as compared to Na_2SO_4 solution, and from the higher solubility in water of $Fe(ClO_4)_2 \cdot 6H_2O$ as compared to $FeSO_4 \cdot 7H_2O$ (26.4g Fe/100 ml for the perchlorate as against 3.14g Fe/100 ml for the sulfate) (27), it is probable that the salt film is a layer of hydrated ferrous perchlorate in $NaClO_4$, and hydrated ferrous sulfate in Na_2SO_4.

Passivation of iron has been studied galvanostatically by Serra and Feliu (28) in neutral Na_2SO_4 solutions, and by Snavely and Hackerman (29) in a nearly neutral sulfate solution. Serra and Feliu measured the duration of passivating time as a function of applied current densities, and the results were in accordance with a kinetic model for the dissolution-precipitation process (24). Snavely and Hackerman's mass balance data also indicate that dissolution of iron is a necessary step to achieve passivity. These results give supporting evidence that the passivating of mild steel in concentrated Na_2SO_4 and $NaClO_4$ solutions starts with a salt layer.

The mechanism may be further confirmed by comparing the transient data with Muller's dissolution-precipitation theory (18). Under potentiostatic conditions, the current-time relation during the precipitation of reaction products is given by

$$t = C_1 + C_2 \left(-\frac{1}{I_p - I} + \frac{1}{I_p} \ln \frac{I_p - I}{I_p} \right) = C_1 + C_2 f(I) \quad [1]$$

where I_p is the constant plateau current; I, the current in the drop period; and C_1 and C_2 are constants for a given transient. Accordingly, a plot of $f(I)$ *vs.* t would be expected to be linear with a slope equal to $1/C_2$ and an intercept at $t = C_1$. The constant C_1, is therefore a measure of the passivating time, and C_2 is inversely related to the rate of current drop. Figure 6 shows a set of such plots for various potentiostatic transients in Na_2SO_4 solution at zero rpm. The same plots for the perchlorate data are given in Fig. 7. It is seen that agreement between the theory and the experimental data is reasonably good. The accompanying table in each figure lists the magnitude of the plateau currents as well as values of C_1 and C_2 computed from the transient data. These tables indicate that the higher the dissolution rate (represented by the plateau current), the less in the passivating time (C_1), and the faster is the rate of film spreading ($1/C_2$) over the electrode surface.

Results of ECM tests.—Since the dissolution-precipitation type of film formation is limited by the diffusion of reaction products away from the anode, dimensional control is expected to be convection-dependent for the

ECM of steel with electrolytes containing Na_2SO_4 and $NaClO_4$.

To test the validity of this prediction, actual ECM experiments were made with rotating steel rods. Figure 8a-d shows a set of photomicrographs of rod-ends that have been electrochemically machined for 2 min in 3M $NaClO_4$ solution at various rotational speeds. The applied current density for the tests was 15.8 A/cm^2 (102 A/in.^{2}), based on the cross-sectional area of the steel rod. The amount of metal removal in each run is indicated in the brackets; the average current efficiency based on Fe going into the solution as Fe^{++} ions was 100%. Also given in Fig. 8 are photomicrographs of an unmachined rod (Fig. 8e), and of a rod-end that has been electrochemically machined in 3M $NaClO_3$ solution (Fig. 8f). The current density for the chlorate run was also 15.8 A/cm^2; however, for the sake of comparison, the machining time was made longer in order to give approximately the same amount of metal removal. The dimensional control obtained with $NaClO_3$ is excellent; the metal removal took place only at the very end of the steel rod. For the perchlorate, it varies from fair to poor with increasing speed of rotation, and the agreement with the prediction is apparent.

Figure 8g illustrates three distinct current density regions for rod-ends electrochemically machined in $NaClO_4$ solutions. During the machining, the metal is removed most heavily from the tip of the rod opposite the stationary cathode. This region is called the cutting area (or the high current density area) as shown in the diagram. Next to the cutting area is a film-protected region, where the distance to the cathode is larger, and hence the IR drop in the solution lowers the metal/solution interfacial potential difference to the value corresponding to the passive state on the steady-state polarization curves. A protective film, therefore, is formed on the surface, resulting in only a slight amount of metal removal in the region; the mirror-like bright surface is probably caused by dissolution through the film as suggested by the mechanism of electropolishing (30). Further away from the cathode is an active dissolution region, where the IR drop is large enough to lower the interfacial potential difference to the value corresponding to the active region on the polarization curves. The groove-cut at the end of this zone is caused by the peak current density near the critical potential. In accordance with the results of the potentiostatic studies, the film-protected region diminishes in size as the speed of rotation increases (Fig. 8a-d). At 4900 rpm, the film-protected region has completely disappeared, and the cut resembles those obtained with NaCl solutions.

Figure 3 indicates that the current density for the active dissolution of mild steel in $NaClO_3$ is two orders of magnitude smaller than that in $NaClO_4$. In addition, the current density in $NaClO_3$ has about the same order of magnitude in both the active and the passive regions. Since chlorate ion is a strong oxidizing agent in the anodic process (31), iron is readily passivated due to the formation of a stable oxide film on the surface. As a consequence, the surface of the steel rod during ECM with $NaClO_3$ is well protected except at the cutting area directly facing the cathode. On the other hand, perchlorate ion is a weak oxidizing agent (32) so that the passivation must rely on the dissolution of iron to form a salt layer on the anode surface. At sufficiently high potentials, the inner portion of this salt layer in contact with the metal may be converted into a more protective oxide film as suggested by polishing of the surface in the film-protected regions (Fig. 8). Since the passivity is preceded by the high rate active dissolution, the passive film of the dissolution-precipitation type can give only partial protection to the metal surface. This limitation appears to impede the usefulness of $NaClO_4$ for the ECM of steel.

Comparison of the ECM results and the basic studies for Na_2SO_4 is not possible, for the Na_2SO_4 electrolyte did not cut steel under the ECM experimental conditions. The current efficiency for metal removal was found to be less than 10%. Apparently in the sulfate,

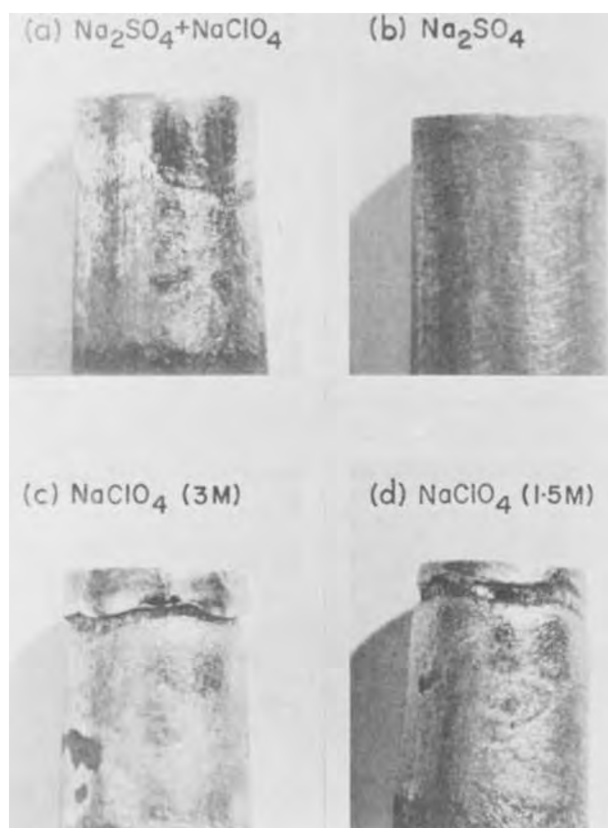

Fig. 9. Photomicrographs of steel rod-ends machined by ECM at 1000 rpm in (a) mixed Na_2SO_4 and $NaClO_4$ solution; (b) 1M Na_2SO_4; (c) 3M $NaClO_4$; (d) 1.5M $NaClO_4$.

the electrolysis of water is the favored reaction at the transpassive potentials. Therefore, the effect of passivation by sulfate ions on the ECM of steel could be studied only by mixing Na_2SO_4 with other electrolytes such as $NaClO_4$. Since the passive film formed with Na_2SO_4 is less subject to convection influence, it was thought that by adding Na_2SO_4 to the $NaClO_4$ solution, one might promote salt layer formation, and thus improve the ECM dimensional control at a given flow rate. To test the assumption, ECM experiments were carried out in an electrolyte containing 0.5M Na_2SO_4 and 1.5M $NaClO_4$. A current density of 14.5 A/cm^2 (93 A/in.^{2}) was used for the tests. In spite of the presence of sulfate ions, the current efficiency based on $Fe \rightarrow Fe^{++}$ was found to be 100%. Figure 9a is a photomicrograph of a steel rod-end that has been electrochemically machined in the mixed electrolyte for 5 min at an anode rotational speed of 1000 rpm. For comparison, photomicrographs of rod-ends obtained with 1M Na_2SO_4, 3M $NaClO_4$, and 1.5M $NaClO_4$ are also given in Fig. 9. It is seen that while Na_2SO_4 gives little cutting on the steel rod, stray cutting takes place in the active dissolution region with $NaClO_4$ solutions. Addition of Na_2SO_4 to the $NaClO_4$ electrolyte appears to widen the film-protected area, and thus improves the ECM dimensional control.

Summary

In summary, correlation between the formation of passive films and dimensional control has been demonstrated experimentally by the ECM of steel in electrolytes containing $NaClO_4$ and Na_2SO_4. It is found that the passivity of mild steel in the electrolytes originates in the formation of a salt layer resulting from supersaturation of dissolution products near the anode. The rate of film formation is diffusion-controlled, and the ECM dimensional control achieved by this kind of passivation is convection-dependent. This passive film of the dissolution-precipitation type can provide only partial protection for the metal surface during the ECM process.

Rotating Spherical Electrode: A Perturbation Theory for Schmidt Number Corrections

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Using a method of singular perturbation, the theory of the rotating spherical electrode has been extended to include the correction terms for convective diffusion at small Schmidt numbers. The resulting rate equation expressed in the form of an asymptotic series permits a good approximation of the transfer rate for Sc ≧ 1. Within this region the accuracy of the theory increases with increasing Schmidt numbers; the maximum error, occurring at Sc = 1, is less than 5%.

In a previous paper (1), a theory has been reported for laminar mass transfer on a rotating spherical electrode (RSE). The result for a hemispherical electrode can be expressed in dimensionless form as

$$\mathrm{Sh} = 0.474\ \mathrm{Re}^{1/2}\ \mathrm{Sc}^{1/3} \quad [1]$$

where Sh is the average Sherwood number, Re is the Reynolds number based on the electrode radius, and Sc is the Schmidt number. An experimental study over the range of Schmidt numbers between 920 and 37,000 (2) has shown that this expression is valid for Reynolds numbers less than 15,000. For Reynolds numbers larger than 15,000, the flow becomes turbulent, and the laminar theory is no longer valid.

Equation [1] represents only the asymptotic behavior of the transport process occurring at large Schmidt numbers. It has an inherent error on the order of $\mathrm{Sc}^{-1/3}$. At Schmidt numbers considerably less than 1000, the use of the equation would yield a great error.

This paper describes an extension of the theory to include the correction terms for convective diffusion at lower Schmidt numbers. A method of singular perturbation for large Sc is used, and the resulting differential equations are solved either analytically, or numerically on an IBM 360 digital computer. The solutions combine to give an asymptotic expansion which permits a good approximation of the rate of transfer for Sc ≧ 1.

Theoretical

Perturbation analysis.—Throughout this analysis we shall confine ourselves to a domain specified by a set of spherical polar coordinates, r, θ, and ψ. The coordinate, r, is measured radially outward from the center of the spherical electrode, θ is an angle measured from the pole of rotation, and ψ is the azimuth. It is assumed that sufficient inert electrolyte is present such that the migration flux of the diffusing ion in the electric field can be neglected. The spherical electrode has a radius, r_o, and is rotating with an angular velocity, ω, in a solution of constant properties. The boundary layer equations of fluid motion and convective diffusion have been given elsewhere (1) and are not repeated here. It has been shown that by introducing a transformation

$$\eta = \left(\frac{\omega}{\nu}\right)^{1/2} (r - r_o) \quad [2]$$

on the radial distance, r, and by expanding the concentration of the diffusing ion in a power series of θ

$$C = C_\infty + (C_o - C_\infty)\{\Phi_1(\eta) + \theta^2\Phi_3(\eta) + \theta^4\Phi_5(\eta) + \ldots\} \quad [3]$$

the equation for the convective diffusion can be transformed into the following set of ordinary differential equations

Zeroth-order equation

$$\left(-0.51023\eta^2 + \frac{1}{3}\eta^3 - 0.10265\eta^4 + \ldots\right)\frac{d\Phi_1}{d\eta} = \frac{1}{\mathrm{Sc}}\frac{d^2\Phi_1}{d\eta^2} \quad [4]$$

First-order equation

$$\left(0.52762\eta^2 - \frac{1}{2}\eta^3 + 0.20231\eta^4 + \ldots\right)\frac{d\Phi_1}{d\eta} + \left(-0.51023\eta^2 + \frac{1}{3}\eta^3 - 0.10265\eta^4 + \ldots\right)\frac{d\Phi_3}{d\eta} + 2\left(0.51023\eta - \frac{1}{2}\eta^2 + 0.20531\eta^3 + \ldots\right)\Phi_3 = \frac{1}{\mathrm{Sc}}\frac{d^2\Phi_3}{d\eta^2} \quad [5]$$

Boundary conditions

$$\text{at } \eta = 0, \quad \Phi_1 = 1, \quad \Phi_3 = 0$$
$$\text{at } \eta \to \infty, \quad \Phi_1 = \Phi_3 = 0 \quad [6]$$

The exact solutions to these differential equations are not possible. However, for electrochemical applications one always speaks of a system of large Sc (usually larger than 50). This implies that an asymptotic representation of the concentration profile may be obtained by carrying out successive perturbations of the parameter, Sc. The details of this perturbation technique have been described (3-4), and are not discussed here. Following the procedure of a singular perturbation method, we introduce a stretched coordinate

$$Z = \mathrm{Sc}^{1/3}\eta \quad [7]$$

for the diffusion domain, and assume that the dimensionless concentrations, Φ_1 and Φ_3, can be represented by the following asymptotic expansions in a power series of Sc

$$\Phi_1(Z, \mathrm{Sc}) = \phi_{11}(Z) + \mathrm{Sc}^{-1/3}\phi_{12}(Z) + \mathrm{Sc}^{-2/3}\phi_{13}(Z) + \mathrm{Sc}^{-1}\phi_{14}(Z) + \ldots \quad [8]$$

$$\Phi_3(Z, \mathrm{Sc}) = \phi_{31}(Z) + \mathrm{Sc}^{-1/3}\phi_{32}(Z) + \mathrm{Sc}^{-2/3}\phi_{33}(Z) + \mathrm{Sc}^{-1}\phi_{34}(Z) + \ldots \quad [9]$$

Substituting these expressions into Eq. [4]-[5], and equating the terms having the like powers of Sc, we have

Zeroth-order equations

* Electrochemical Society Active Member.

Key words: mass transfer, convective diffusion, limiting current.

$$\frac{d^2\phi_{11}}{dZ^2} + aZ^2\frac{d\phi_{11}}{dZ} = 0 \quad [10]$$

$$\frac{d^2\phi_{12}}{dZ^2} + aZ^2\frac{d\phi_{12}}{dZ} = \frac{1}{3}Z^3\frac{d\phi_{11}}{dZ} \quad [11]$$

$$\frac{d^2\phi_{13}}{dZ^2} + aZ^2\frac{d\phi_{13}}{dZ} = \frac{1}{3}Z^3\frac{d\phi_{12}}{dZ} - 0.10265Z^4\frac{d\phi_{11}}{dZ} \quad [12]$$

First-order equations

$$\frac{d^2\phi_{31}}{dZ^2} + aZ^2\frac{d\phi_{31}}{dZ} - 2aZ\phi_{31} = 0.52762Z^2\frac{d\phi_{11}}{dZ} \quad [13]$$

$$\frac{d^2\phi_{32}}{dZ^2} + aZ^2\frac{d\phi_{32}}{dZ} - 2aZ\phi_{32} = 0.52762Z^2\frac{d\phi_{12}}{dZ} - \frac{1}{2}Z^3\frac{d\phi_{11}}{dZ} + \frac{1}{3}Z^3\frac{d\phi_{31}}{dZ} - Z^2\phi_{31} \quad [14]$$

$$\frac{d^2\phi_{33}}{dZ^2} + aZ^2\frac{d\phi_{33}}{dZ} - 2aZ\phi_{33} = 0.52762Z^2\frac{d\phi_{13}}{dZ} - \frac{1}{2}Z^3\frac{d\phi_{12}}{dZ} + 0.20231Z^4\frac{d\phi_{11}}{dZ} + \frac{1}{3}Z^3\frac{d\phi_{32}}{dZ} - 0.10265Z^4\frac{d\phi_{31}}{dZ} - Z^2\phi_{32} + 0.41062Z^3\phi_{31} \quad [15]$$

where the convection constant, $a = 0.51023$. The new boundary conditions are

$$\begin{aligned} &\text{at} \quad Z = 0, \quad \phi_{11} = 1, \quad \phi_{12} = \phi_{13} = \phi_{3i} = 0 \\ &\text{at} \quad Z \to \infty, \quad \phi_{1i} = \phi_{3i} = 0 \end{aligned} \quad [16]$$

with the dummy index, $i = 1, 2, 3$. It should be noted that the terms of the "zeroth-" and the "first-order" equations are not referred to the parameter perturbations of Sc, but to the coordinate perturbation of θ. This arrangement is necessary in order to avoid confusion in the text.

Equation [10] and its boundary conditions represent the famous Levich problem (5) of the rotating disk electrode (RDE), and we may immediately write down the solution in the form

$$\phi_{11} = 1 - 0.62045\int_0^Z \exp\left(-\frac{a}{3}Z^3\right)dZ \quad [17]$$

Equation [13] has been solved by Chin (1); a solution that satisfies the prescribed boundary conditions can be expressed as

$$\phi_{32} = 0.12832Z\exp\left(-\frac{a}{3}Z^3\right) \quad [18]$$

Equations [17] and [18] are the first terms in the series expansions of Eq. [8] and [9], respectively. They can be termed as the basic solution for the convective diffusion at the RSE, for together they characterize an asymptotic rate of ionic transfer when Sc approaches infinity. At finite Sc, the accuracy of the theory may be improved by successively solving the rest of the differential equations for ϕ_{12}, ϕ_{13}, ϕ_{32}, and ϕ_{33}. Such attempts are described in the next two sections.

Exact solutions of ϕ_{12} and ϕ_{13}.—Equations [11] and [12] differ from Eq. [10] by only a perturbed quantity on the right-hand side. Since the equations are of the first order in $d\phi_{1i}/dZ$, the function, ϕ_{12}, may be solved analytically in terms of ϕ_{11}, and the function, ϕ_{13}, in terms of ϕ_{12} and ϕ_{11}. To solve for ϕ_{12}, we first substitute Eq. [17] into Eq. [11]

$$\frac{d^2\phi_{12}}{dZ^2} + aZ\frac{d\phi_{12}}{dZ} = -\frac{0.62045}{3}Z^3\exp\left(-\frac{a}{3}Z^3\right) \quad [11a]$$

Equations [11a] and [16] can be integrated at once to give the following solution

$$\phi_{12} = 0.62045\int_0^Z\left(0.29801 - \frac{1}{12}Z^4\right)\exp\left(-\frac{a}{3}Z^3\right)dZ \quad [19]$$

Similarly, by substituting Eq. [17] and [19] into Eq. [12], carrying out the integration and making use of the prescribed boundary conditions, we have

$$\phi_{13} = 0.62045\int_0^Z\left(0.056335 + 0.024834Z^4 + 0.020531Z^5 - \frac{1}{288}Z^8\right)\exp\left(-\frac{a}{3}Z^3\right)dZ \quad [20]$$

Now the first three terms in the asymptotic expansion of Φ_1 have been obtained; these functions are plotted in Fig. 1 on arithmetic scales. It is seen that for large Z, the second and third terms of the series are becoming increasingly important with increasing Z. All the functions become zero for $Z > 4$; this gives us a rough idea of the extent of the concentration boundary layer on the RSE. In the next section these solutions are used where required for the appropriate terms in the first-order equations.

Numerical solutions of ϕ_{32} and ϕ_{33}.—Equations [14] and [15] have been integrated numerically on an IBM 360 digital computer. A fourth-order Runge-Kutta method (6) is used. In view of the extent of the concentration boundary layer as shown in Fig. 1, the integration is carried out over the range, $0 \leq Z \leq 5$, with an increment of 0.05. The boundary value problems described in Eq. [16] are solved by a trial-and-error method. Briefly, the method consists of: (*i*) integrating Eq. [14], for example, from $Z = 0$ to $Z_\infty = 5$ with a trial value of $d\phi_{32}/dZ$ at $Z = 0$; and (*ii*) repeating the integration with a new trial value until the boundary condition at Z_∞ is satisfied. In this way Eq. [14] is first integrated, and the values of ϕ_{32} and $d\phi_{32}/dZ$ are stored in the computer for the successive

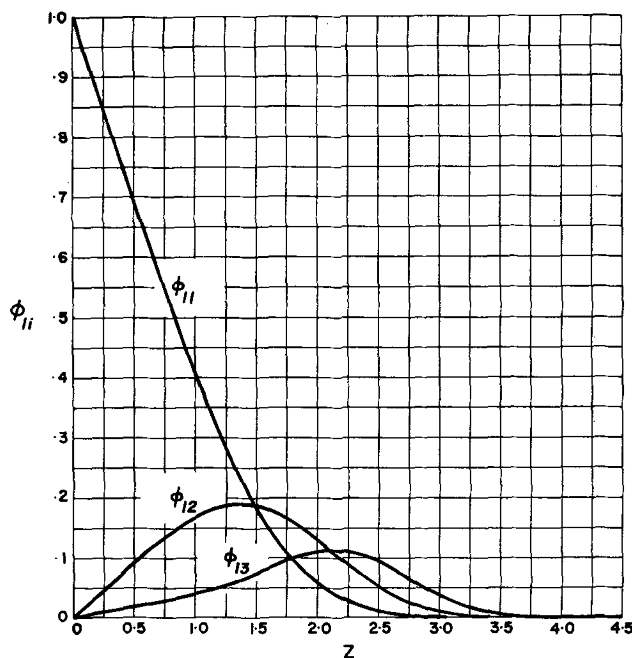

Fig. 1. Zeroth-order concentrations

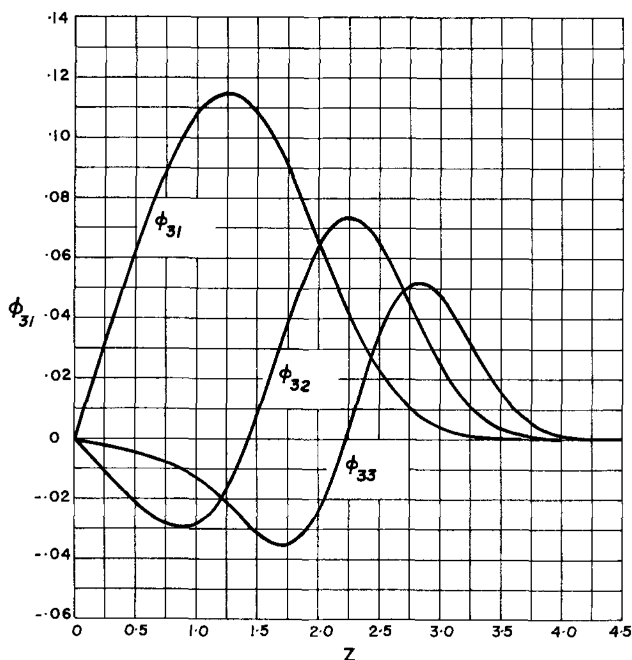

Fig. 2. First-order concentrations

integration of Eq. [15]. The results for ϕ_{32} and ϕ_{33} are expressed graphically in Fig. 2; also plotted in the figure is a curve for ϕ_{31} as calculated from Eq. [18]. The derivatives of ϕ_{32} and ϕ_{33} at $Z = 0$ are found as

$$\left[\frac{d\phi_{32}}{dZ}\right]_{Z=0} = -\,0.043437 \qquad [21]$$

$$\left[\frac{d\phi_{33}}{dZ}\right]_{Z=0} = -\,0.009456 \qquad [22]$$

Rate of transfer at the electrode.—Now we shall relate the results of the previous analysis to the rate of ionic transfer on the RSE, for this is the principal interest for electrochemical applications. The local mass flux at the electrode surface is related to the concentration gradient by

$$j = -D\left[\frac{\partial C}{\partial r}\right]_{r=r_o} = k\,(C_o - C_\infty) \qquad [23]$$

Here k is the mass transfer coefficient. The local Sherwood number, $\mathrm{Sh_{loc}}$, defined as kr_o/D, can now be evaluated from the following equation

$$\mathrm{Sh_{loc}} = \mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3}\left\{0.62045\left[1 - \frac{0.29801}{\mathrm{Sc}^{1/3}} - \frac{0.05633}{\mathrm{Sc}^{2/3}}\right] - 0.12832\theta^2\left[1 - \frac{0.33851}{\mathrm{Sc}^{1/3}} - \frac{0.07369}{\mathrm{Sc}^{2/3}}\right]\right\} \qquad [24]$$

The average Sherwood number, Sh, can be obtained by integrating $\mathrm{Sh_{loc}}$ over the spherical surface; the result is

$$\mathrm{Sh} = \left[\frac{Kr_o}{D}\right] = \mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3}\left\{0.62045\left[1 - \frac{0.29801}{\mathrm{Sc}^{1/3}} - \frac{0.05633}{\mathrm{Sc}^{2/3}}\right] - 0.12832\left[1 - \frac{0.33851}{\mathrm{Sc}^{1/3}} - \frac{0.07369}{\mathrm{Sc}^{2/3}}\right]\frac{2(\cos\theta - 1) + 2\theta\sin\theta - \theta^2\cos\theta}{1 - \cos\theta}\right\} \qquad [25]$$

Here K is the average mass transfer coefficient. Equation [25] represents the dimensionless mass transfer rate to a spherical electrode having an active surface specified by the angle θ. For a hemispherical electrode or a sphere whose entire surface is subject to the mass transfer, we have $\theta = \pi/2$, and Eq. [25] can be simplified to

$$\mathrm{Sh} = 0.47396\mathrm{Re}^{12/}\,\mathrm{Sc}^{1/3}\,(1 - 0.28549\mathrm{Sc}^{-1/3} - 0.05097\mathrm{Sc}^{-2/3}) \qquad [26]$$

The average diffusion current density, I, on the electrode is related to the average mass transfer coefficient, K, by

$$I = n\mathbf{F}K\;(C_\infty - C_o) \qquad [27]$$

Thus Eq. [26] can be rearranged in dimensional form as

$$I = 0.47396n\mathbf{F}\,(C_\infty - C_o)\,D^{2/3}\,\nu^{-1/6}\,\omega^{1/2}\left[1 - 0.28549\left(\frac{D}{\nu}\right)^{1/3} - 0.05097\left(\frac{D}{\nu}\right)^{2/3}\right] \quad (\text{for } \theta = \pi/2) \qquad [28]$$

Discussion of Results

The results presented in Fig. 1 and 2 would allow one to calculate the concentration profile on the RSE. For electrochemical applications, the rate equation expressed in the form of Eq. [25]-[28] could be used for determining diffusivity of the diffusing ion, and for electrode kinetic studies. It is seen that Eq. [26] differs from Eq. [1] by two correction terms inversely proportional to $\mathrm{Sc}^{1/3}$ and $\mathrm{Sc}^{2/3}$. The present theory would, therefore, extend the application of the RSE to electrolytes with smaller Schmidt numbers, for the inherent error is now on the order of Sc^{-1}, as compared to $\mathrm{Sc}^{-1/3}$ for Eq. [1]. The exact error is not easy to determine unless the perturbation is further carried out for the functions, θ_{14} and θ_{34}, in the asymptotic expansion of Eq. [8] and [9]. One could, however, estimate the approximate error by comparing with point-solutions given in the literature. For the case of a rotating sphere, Banks (7) has computed numerically the thermal boundary layer at Prandtl numbers equal to 0.7 and 1.0. Since the Prandtl number is equivalent to the Schmidt number used in mass transfer, we may substitute $\mathrm{Sc} = 0.7$ and 1.0 into Eq. [26], and arrive at

$$\mathrm{Sh}/\mathrm{Re}^{1/2} = 0.258 \quad \text{for } \mathrm{Sc} = 0.7$$
$$\mathrm{Sh}/\mathrm{Re}^{1/2} = 0.314 \quad \text{for } \mathrm{Sc} = 1.0 \qquad [29]$$

The comparative values given by Banks' computation are 0.25 at $\mathrm{Sc} = 0.7$, and 0.30 at $\mathrm{Sc} = 1.0$. The agreement is excellent considering that the successive perturbation is supposedly for large Schmidt numbers.

Figure 3 is a log-log plot of $\mathrm{Sh}/\mathrm{Re}^{1/2}$ *vs.* Sc for a rotating sphere or hemispherical electrode. The thick solid curve is calculated from Eq. [26]. The dashed straight line is given by Eq. [1]. Banks' results at $\mathrm{Sc} = 0.7$ and 1.0 are represented by the crosses. For comparison, the rotating disk theory (8) is also given in the figure as the thin solid curve. It is seen that the $0.474\,\mathrm{Sc}^{1/3}$ dependence given by Eq. [1] represents a limiting behavior for $\mathrm{Sc} \to \infty$. Banks' results show the magnitude of transfer rates in the neighborhood of $\mathrm{Sc} = 1.0$. Equation [26] obviously represents a curved portion that smoothly connects the two limits. Therefore, one may speak with confidence that the rate equations given by Eq. [25]-[28] are valid for $\mathrm{Sc} \geqq 1$. Since the accuracy of the asymptotic expansion is increasing with increasing Schmidt numbers, the maximum error would occur at $\mathrm{Sc} = 1$, where the deviation from Banks' numerical result is only 4.8%, an error that is permitted by most experimental techniques. If one assumes that the error is proportional to Sc^{-1} as suggested by Eq. [8] and [9], it would then be reduced to 0.5% at $\mathrm{Sc} = 10$, and 0.05% at $\mathrm{Sc} = 100$. On the

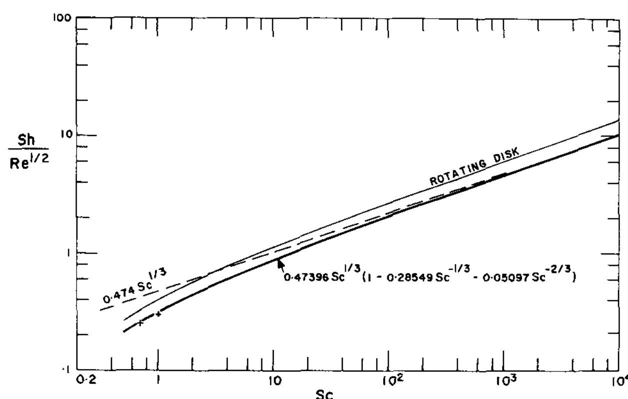

Fig. 3. $Sh/Re^{1/2}$ vs. Sc for a rotating sphere or hemispherical electrode. The thick solid curve is the result of the present analysis, Eq. [26]. The dashed straight line is calculated from Eq. [1] given by the previous theory. Banks' point-solutions at Sc = 0.7 and 1.0 are represented by the crosses. For comparison, the rotating disk theory is also given in the figure as the thin solid curve.

other hand, Eq. [1], which represents only the first term in the asymptotic expansion, can lead to an error of 3% at Sc = 1000. With the two additional correction terms, the accuracy of the theory has been greatly enhanced.

Figure 3 shows that the curve for the RDE is nearly parallel to the curve given by Eq. [26]. As discussed in the previous paper (1), the rotating disk can be treated as a special case of the RSE by merely setting $\theta = 0$. Thus, making use of Eq. [25], the present analysis gives

$$Sh_D = 0.62045\, Re^{1/2}\, Sc^{1/3}\, (1 - 0.29801\, Sc^{-1/3} - 0.05633\, Sc^{-2/3}) \quad [30]$$

where the subscript, D, signifies the transfer process occurring on the disk electrode. The Schmidt number correction on the RDE has been treated by Newman (9, 10). Using the present notation, his result can be expressed as

$$Sh_D(\text{Newman}) = \frac{0.62048\, Re^{1/2}\, Sc^{1/3}}{1 + \dfrac{0.2980}{Sc^{1/3}} + \dfrac{0.14514}{Sc^{2/3}} + 0(Sc^{-1})} \quad [31]$$

Using the binomial theorem, Eq. [31] can be expanded to

$$Sh_D(\text{Newman}) = 0.62048\, Re^{1/2}\, Sc^{1/3}\, [1 - 0.2980\, Sc^{-1/3} - 0.05634\, Sc^{-2/3} + 0(Sc^{-1})] \quad [31a]$$

Thus, Newman's expression is essentially the same as our result for the disk electrode, Eq. [30]. The difference in the fifth decimal digits can be attributed to the truncation error in the numerical computations.

Based on the above discussions, we may conclude that the rate equations expressed in the asymptotic series of Eq. [25]-[28] would give an accurate estimate of the mass transfer rate on the RSE for $Sc \geqq 1$. Within this region the accuracy of the equations increases with increasing Schmidt numbers; the maximum deviation that occurs at Sc = 1, is less than 5%.

Charging Method for Batteries, Using the Resistance-Free Voltage as Endpoint Indication

K. V. Kordesch*

Union Carbide Corporation Research Laboratory, Cleveland, Ohio 44101

The methods for charging batteries vary in many respects, depending on the type of batteries, their construction, and their application. However, all methods need to detect the fully charged state to avoid damage to the battery by overcharging.

The endpoint of charging may be determined by measuring the cell voltages, volume of gas evolved, pressure, and heat development; and by employing sensing electrodes, coulometers, or control cells.

The mode of charging can be "rapid charging," "tapered-step charging," "constant current," "constant voltage," or even "computer controlled"—depending on the type of the battery concerned and its use in a specific circuit or application.

Ni-Cd batteries and lead-acid batteries have been the most extensively investigated systems in accord with their wide range of use. Fast charging has been considered recently as essential for some users; in this method of charging, the endpoint detection has become more important from the safety standpoint. Even a short overcharge at high current can have catastrophic results.

In the case of sealed Ni-Cd batteries operating on the oxygen recombination cycle, the start of overcharge at high rates results in an increase in temperature and pressure which can be easily detected. However, their reliable use as control parameters depends on special construction of the batteries. As an example, commercially available small batteries can now be overcharged at the 1 C rate and can safely use inexpensive thermal cutoff devices like snap action switches or thermistors (1).

For other batteries which are not designed for rapid oxygen recombination, pressure sensing, or the use of auxiliary electrodes, the cell voltage is still the commonly used means of detecting the state-of-charge.

When a voltage control method is used under load conditions, the voltage drop caused by the resistive components of the cell (contacts, electrode current collector, electrolyte, etc.) influences the "terminal voltage" readings, often in an uncontrollable way. Gas evolution, concentration gradients in the electrolyte, and temperature effects are variables which are difficult to control or predict. If included in the control signal, they may cause large errors, especially under fast-charging conditions.

The Resistance-Free Measuring Principle

Several methods of determinating the ohmic resistance of an operating galvanic cell are known: the use of temperature-compensated a-c bridge circuits; interrupting the current and determining the immediate voltage rise on the oscilloscope screen; and superimposing a-c on the d-c. load are some examples of methods which can be applied to finished cells. Luggin capillaries and auxiliary reference electrodes in proper positions can, of course, be used in test cells.

* Electrochemical Society Active Member.

Key words: battery-charging method. resistance-free voltage, state-of-charge detection, fast charging.

For practical evaluation in the field, directly indicating interrupter circuits have been developed which allow reading of the electrode polarization values (on discharge) or electrode overvoltages (on charge) without incurring the voltage drop across the internal resistance ("resistance polarization") of the cell. The measurements are independent of electrode spacing and, in case reference electrodes are used, insensitive to the reference positioning.

Figure 1 is a schematic diagram showing what the term "resistance elimination" means in connection with the use of an interrupter technique.

Figure 2 shows a simple double-throw switch circuit used to demonstrate the circuit principle (2). In the right position, the battery is charged (or discharged); in the left position, the voltage is measured. Due to the "slow" speed of electrochemical (mass transport dependent) processes, the average load condition is essentially maintained while the current is interrupted for voltage measurements. Only the "fast"

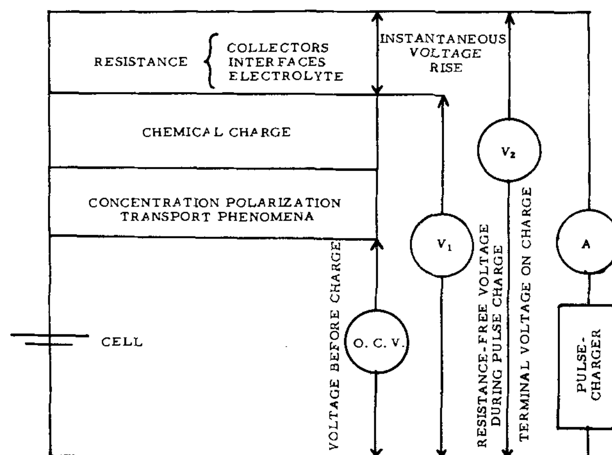

Fig. 1. Schematic diagram picturing the various types of "overvoltages" occurring in a galvanic cell during charging.

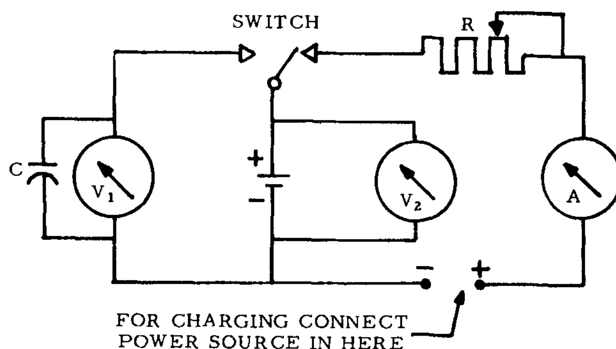

Fig. 2. Principle of a pulse current circuit for reading of the resistance-free voltage.

(electronic) voltage change across ohmic resistance components is eliminated (voltmeter 1). The battery is an excellent current integrater and the ammeter in the circuit reads the average current, as voltmeter 2 reads the average (terminal) voltage.

It should be noted that every interrupter method includes a time element of uncertain "recovery" of the voltage, depending on how the voltage was observed. Nearly instantaneous (10^{-8} sec) voltage changes can be followed with a very fast oscilloscope, while a technical interrupter circuit operated from the 60-cycle a-c line averages the potential for 1/120 sec after the interruption (unless a special bridge circuit is used; see Fig. 4).

A more practical circuit for battery charging which bypasses the need for mechanical contacts is shown in Fig. 3. Its operation is very similar to that of the circuit described in the literature in 1960 except that solid-state components are used for automatic current regulation (3).

This circuit has found wide use in the practice of battery testing; it has been incorporated in instruments designed to determine the state-of-charge of secondary batteries by combining charge and discharge tests (4, 5).

The replacement of square-wave pulses by sine-wave pulses does not change the response of the batteries; also the D'Arsonval meter movements of the voltmeter and ammeter indicate the same average value. (Note that average means ι/π with sine-wave pulses and $\iota/2$ with square-wave pulses of equal length.) Difficulties with slow reacting electrodes have been realized (6) but could be circumvented by operating at higher frequencies or by restricting the voltage sensing period to a small fraction of the off-current phase, as near to the interruption point as possible.

Figure 4 shows the oscilloscope traces of a charge pulse through a cell. The timing of the voltage sensing periods is indicated. The voltages are stored in capacitors and read on conventional high-resistance meters.

Charge Control with Resistance-Free Endpoint Sensing

There are many ways of producing the resistance-free signal and feeding it back to the charge-controlling SCR. In Fig. 3 is an example, showing an operational amplifier receiving the resistance-free voltage signal from the gating circuit—which is biased by the preset full-charge voltage—feeding it to the current controlling SCR circuit. The out of phase relationship between the secondary windings is important.

The circuit of Fig. 3 can be modified to operate a self-locking switch for complete shutdown, or may contain a bypass resistor for trickle-charge, or it could employ an additional control signal from a temperature sensor built into the battery. Increasing temperature lowers the preselection point of constant voltage charging circuits; therefore, this correction is an important one.

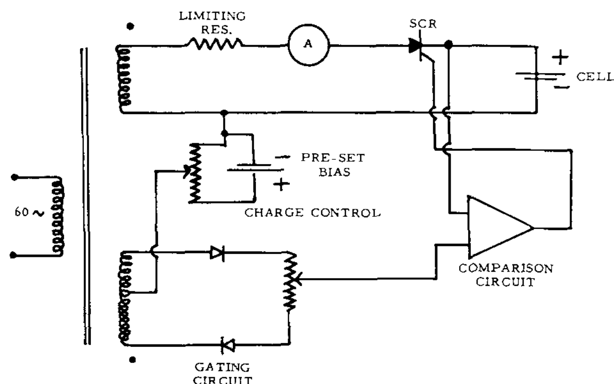

Fig. 3. Battery charger with resistance-free voltage control

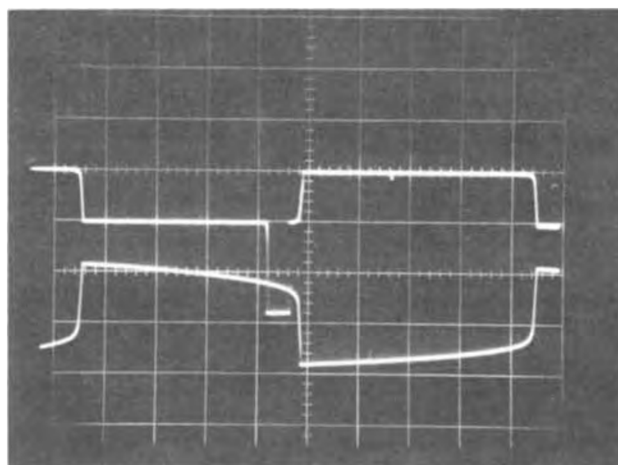

Fig. 4. Voltage-current diagram of a battery on pulse charge (60 cycles). Upper part of oscilloscope picture: Voltage trace (+ direction). Lower part: Current trace (— direction) indicating "window" in the early portion of the open-circuit period at which voltage readings are taken. The battery is in a very low state-of-charge, otherwise the curvature of the voltage curve would not be observable. (Zero line for voltage is off picture.)

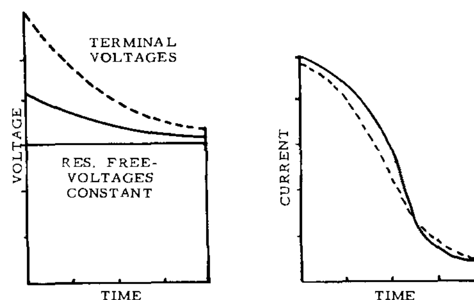
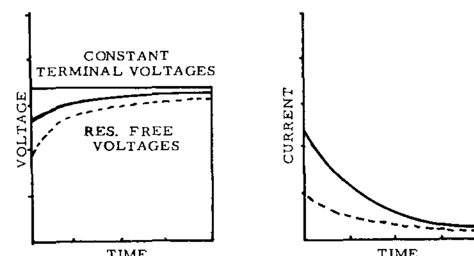
An interesting circuit achieving essentially the same effect as the circuit of Fig. 2 is described in a General Electric Company patent (7); in this case a magnetic flux-controlled reed switch acts in response to the temperature-compensated battery voltage only during the intermediate period between current pulses, thereby eliminating the voltage drop on the ohmic resistance components from the signal.

Figure 5 indicates the differences between "terminal voltage" sensing and "resistance-free voltage" sensing, if one charges batteries with different internal resistance. If the charging circuit is set to a preselected voltage, the charge acceptance changes considerably and far more charging can be accomplished in the same time period if the resistance-free voltage is kept constant instead of the terminal voltage. Differences in internal resistance of old and new cells do not affect the charge acceptance if such cells are connected in series. It also does not matter too much if



a) High Rate Charge Acceptance with Resistance-Free Constant Voltage Setting



b) Low Rate Charge Acceptance with Constant Terminal Voltage Setting

Fig. 5. Different charge acceptance of batteries with low (———) and high (- - -) internal resistance.

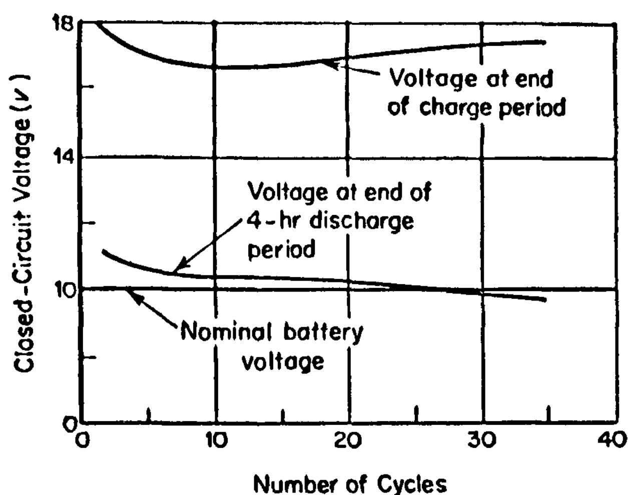


Fig. 6. Voltage characteristics of alkaline-manganese secondary battery.

the intercell connections vary somewhat. The situation becomes even more pronounced if cells are charged in parallel.

In Fig. 5, only general examples are shown. However, with all cell types the charge characteristics obtained during resistance-free charging are more reproducible and more suitable for rapid charging then are terminal voltage measurements.

Figure 6 shows the variability of the end-of-charge voltage of an alkaline MnO_2-zinc cell dependent on the number of cycles (1). The change is to a large extent due to the increase in the internal cell resistance. Considering that a higher charge current (with a higher voltage rise) may be used, the value of the resistance-free voltage determination is obvious. In the case of the battery shown in Fig. 6 the resistance-free charge voltage would be 16.5V.

Extremely high-charge currents can only be used when the batteries are properly constructed: thin plates, good current collection, narrow spacing are essential features. High-charge currents are not objectionable; in some cases (Ni-Cd) the efficiency of charging increases with the charge rate (8). The charge acceptance and gassing rates of lead-acid batteries are functions of the charge rates, and multistep charging control is more precisely controlled with resistance-free voltage sensing. Also, the detection of "voltage steps" in the charge curves, *e.g.*, as observed with mixed depolarizer cells like MnO_2-Ni oxide/zinc cells (9), is more accurate when not obscured by resistance phenomena.

Following the circuitry shown in Fig. 3, a resistance-free battery charger with an output of 12V-16A was built. The resistance-free voltage endpoint could be set with an accuracy of ± 10 mV.

This battery charger was capable of bringing a lead-acid battery of 12.5 A-hr capacity to 80% of the fully charged condition in 30 min if a resistance-free voltage setting of 2.40 is used.

D-size Ni-Cd cells could be brought up to 75% of capacity in 15 min at a voltage setting of 1.48V. Silver-zinc cells require a setting of 2.00V and could be recharged even faster.

Summary and Conclusions

These results are preliminary in nature and require more experience before the resistance-free charging method can be recommended generally. However, it is evident that this method provides an improved way of determining the endpoint of charging electrically.

Especially in view of the future need for faster recharging of many consumer batteries for portable equipment and probably also for electric vehicles, fast-pulse charging will be required. As an example, a four-passenger city car will need a 20 kWhr-capacity battery for operating over a distance of 100 to 150 miles. Recharging such a battery (of *e.g.*, 200V) in half an hour will require a 300A charging capability for each vehicle at a "power station" which must then be supplied by a high voltage line to satisfy more customers at a time.

The fact that resistance-free charging can accommodate batteries (of the same type) in various conditions and of various ages simultaneously is probably the biggest advantage.

Acknowledgments

The author is indebted to Mr. Gunars Sprogis, Electronic Engineer, at the Parma Technical Center for construction of the Resistance-Free Battery Charger mentioned in this paper and to Mr. A. Marko, Wright Air Force Development Center, Dayton, Ohio, for advice on circuitry.

Density and Electrical Conductivity of Molten LiI-LiCl-KI Eutectic

N. P. Yao*,[1]

Atomics International, A Division of North American Rockwell Corporation, Canoga Park, California 91304

A low-melting salt mixture which possesses a high electrical conductivity, a large decomposition potential, and is chemically stable, will provide a useful electrolyte medium in several areas of molten salt electrochemical technology. The eutectic mixture 59 mole per cent (m/o) LiI-8.5 m/o LiCl-32.5 m/o KI (melting point 264°C) reported by Johnson and Foster (1) is one of the lowest melting ternary alkali-halide systems known to date.

This low-melting and lithium-rich salt electrolyte is being utilized in some high temperature battery systems with a lithium anode (2, 3). It was observed that the potassium ions in this melt would not interfere with the lithium electrode reaction in these systems (4).

In this work the density and the electrical conductivity of molten LiI-LiCl-KI eutectic are reported over a temperature range of 273°-454°C.

Experimental

Chemicals.—Anhydrous, polarographic grade LiI and LiCl were supplied in 200g ampoules by Anderson Physics Laboratory, Champaign, Illinois. "Baker analyzed" KI was vacuum dried over a 2 week period at gradually increasing temperatures up to 250°C and at 13μ Hg pressure. The eutectic mixture (59 m/o LiI-8.5 m/o LiCl-32.5 m/o KI) was prepared by weight, fused, and filtered through a 25μ glass frit in an argon gas-filled dry box. The melt was colorless and clear. The melting point of the eutectic mixture from the cooling curve was 264° ± 0.5°C, in agreement with the literature value (1). "Baker analyzed" KCl, which was used in preparing the standard aqueous solution for cell constant determination, was recrystallized twice from redistilled water. The salt was dried *in vacuo* at 300°C for 120 hr. "Baker analyzed" KNO_3, which was used in the volume calibration of the pycnometer, was dried *in vacuo* at 250°C for 100 hr.

Apparatus and procedure.—The fused silica capillary cell for the conductivity measurements, containing four bright tungsten electrodes and a 1.5 mm ID capillary, was previously described by Grantham and Yosim (5). The cell used in this work had a capillary length of about 25 cm in a spiral form. The a-c conductivity determinations were made with a Leeds and Northrup No. 1666 Jones bridge which had been calibrated against secondary NBS standards. The capacitance and impedance of the cell were balanced during measurements by a variable capacitor in the bridge. The a-c signal was supplied by a Hewlett-Packard Model 200 CD audio oscillator in conjunction with a Newcomb amplifier; the signal null was detected with a General Radio Type 1231-B amplifier. The conductivity of the LiI-LiCl-KI solution was found to be frequency independent from 1 to 50 kHz. The cell constant obtained with 1 Demal standard KCl solutions (6) at 25°C was 1528.0 ± 0.6 cm^{-1} determined with two separately prepared KCl solutions. The calculated cell constant varied by less than 0.03% in the temperature range of 25°-455°C. The cell constant redetermined after the experimental run did not show any change.

After proper amount of LiI-LiCl-KI eutectic salt was added to the conductivity cell in the argon gas dry box, the cell was sealed under vacuum. Conductivity measurements were made after the cell had been heated in a furnace at approximately 270°C for a few hours. The measurements were made at increasing temperatures with periodic rechecks of the previous points. Each measurement was taken 30 min after the thermal equilibrium was attained. The data were reproducible to within 0.03%; the values reported are the average of at least three determinations. The temperature of the solution was measured with a calibrated Alumel-Chromel thermocouple in contact with the cell capillary wall in conjunction with a Leeds and Northrup Millivolt Potentiometer. A temperature difference of only 0.2°C occurred over the length of the capillary.

Density measurements were made in a fused silica pycnometer which incorporated two thermocouple wells for temperature measurements. The volume of the pycnometer was calibrated with double distilled water at 25°C and with molten KNO_3 (7) at 422°C. The average volume based on four measurements at each temperature was 18.65 cm^3 at 25°C and 18.71 cm^3 at 422°C. The volume expansion is in agreement with the calculated thermal expansion for the pycnometer of about 0.4% in the same temperature range. The pycnometer was heated in a small insulated furnace in the argon gas dry box and the maximum temperature difference in the solution was 0.5°C. The uncertainty in the individual measurement was about 0.3%; the values reported are the average of at least three determinations.

Results

The specific conductivity of molten LiI-LiCl-KI (59 m/o-8.5 m/o-32.5 m/o) eutectic over a temperature range of 273°-454°C is given in Table I. The curve shown in Fig. 1 represents the computer-fitted, least squares equation ($\sigma = 0.009$) and can be represented by

$$\kappa = -1.708 + 1.197 \times 10^{-2}t - 1.009 \times 10^{-5}t^2 \quad [1]$$

where κ is specific conductivity in $ohm^{-1}cm^{-1}$ and t is temperature in °C.

[1] Present address: Heliotek, Division of Textron Inc., P. O. Box 4158, Sylmar, California 91342.

Key words: LiI-LiCl-KI eutectic, density, electrical conductivity.

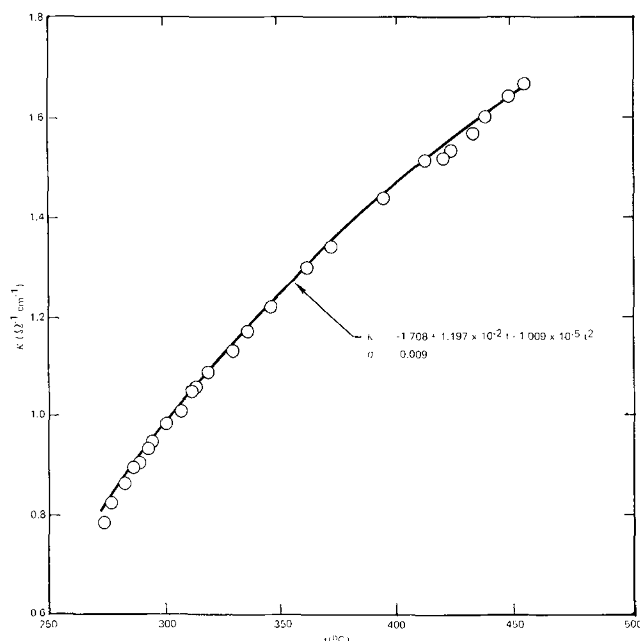

Fig. 1. Specific conductance vs. temperature for molten LiI-KI-LiCl eutectic.

Four density data, over a temperature range of 274°-437°C, are represented by a linear equation (σ = 0.007)

$$\rho = 3.214 - 7.850 \times 10^{-4} t \qquad [2]$$

Surprisingly, the density values (in g/cm^3) conform approximately (to within 0.5%) the additivity rule of molar volume although the densities of LiI, LiCl, and KI had been extrapolated from the reported values (8) at above the melting points of the salt components.

The specific conductivity-temperature relationship, Eq. [1], and the density-temperature relationship, Eq. [2], were both used in calculating equivalent conductances, Λ, the logarithms of which were examined for curvature when plotted *vs.* $1/T$(°K). The densities at the three temperatures, *i.e.*, 273.0°, 447.5°, and 454.2°C, were calculated from Eq. [2].

The curvature exhibited in the plot of specific conductance *vs.* temperature (Fig. 1) persisted in the log Λ *vs.* $1/T$(K°) plot. Therefore, the three parameter equation, Vogel-Tammann-Fulcher (VTF), successfully employed by Angell (9) for glass-forming melts has been fitted to the present data using a computer program (10). The least squares representation of the data (σ = 0.008) is

$$\ln \Lambda = A - \tfrac{1}{2} \ln T - \frac{k}{T - T_0}$$

$$= 8.652 - \tfrac{1}{2} \ln T - \frac{377}{T - 348} \qquad [3]$$

where Λ is in cm^2/ohm-equivalent and T is in degrees Kelvin. The three parameters, A, k, and T_0 (the zero mobility temperature) are respectively 8.652, 377°K, and 348°K.

The zero mobility temperature T_0 for the glass-forming $Ca(NO_3)_2$ + KNO_3 molten salt mixtures was reported (9) to vary from 237°K for pure KNO_3 to 330°K for a 45% $Ca(NO_3)_2$ mixture. The T_0 value for the LiCl + KCl eutectic was reported (9) to be 320°K. The present data are in the range of $1.6\ T_0 \leq T \leq 2.1\ T_0$ based on the value of T_0 = 348°K for the LiI-LiCl-KI eutectic. Since Eq. [3] is strictly applicable for temperature $\leq 1.7\ T_0$, the value T_0 = 348°K for the present eutectic must be considered tentative.

The Arrhenius coefficient for equivalent conductance, E_Λ, can be evaluated from the derivative of the analytic representation, Eq. [3], as follows

$$E_\Lambda = -R \frac{\delta \ln \Lambda}{\delta (1/T)} = -\tfrac{1}{2} RT + 377R \left(\frac{T}{T - 348} \right)^2 \qquad [4]$$

The E_Λ decreases with increasing temperature; from about 5.1 kcal/mol at 273°C to about 2.0 kcal/mol at 454°C.

Recovery of Chlorine from Waste Gas–Fundamentals

Fumio Hine* and Masaki Yasuda

Nagoya Institute of Technology, Nagoya 466, Japan

One to two per cent of the total production of chlorine by electrolysis, accounting for about 50,000 tons a year in Japan and about 100,000 tons in the United States, is being wasted. Chlorine should be recovered from such waste gases. Some processes, such as the absorption-desorption method with a chlorinated solvent, have developed, but comparatively few of practical application have been announced. Here a new electrochemical process with the depolarized cathode, called electrochemical recovery of chlorine, is described.

* Electrochemical Society Active Member.
Key words: chlorine recovery, chloride electrolysis, depolarized cathode, diffusion-limiting current.

Electrochemistry of the Process

The electrolytic solution consisting of HCl and $CuCl_2$ is electrolyzed with the chlorine depolarized cathode. The process resembles the Kyoto-type HCl cell investigated by the same author (1).

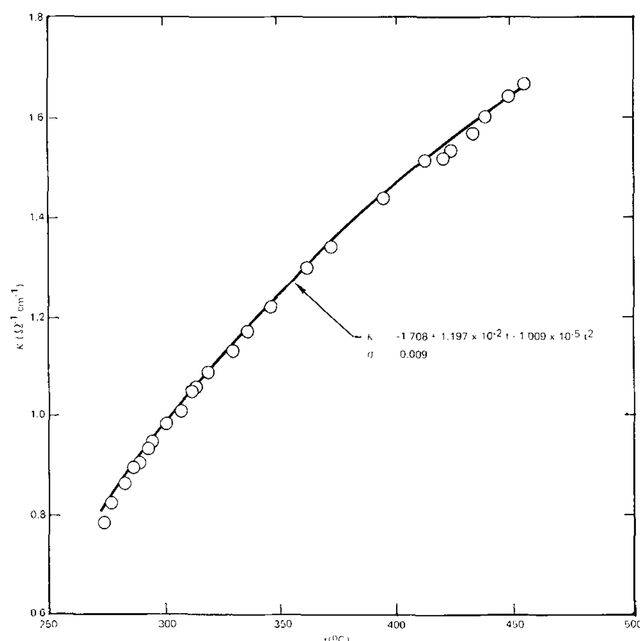

Fig. 1. Specific conductance vs. temperature for molten LiI-KI-LiCl eutectic.

Four density data, over a temperature range of 274°-437°C, are represented by a linear equation (σ = 0.007)

$$\rho = 3.214 - 7.850 \times 10^{-4}t \qquad [2]$$

Surprisingly, the density values (in g/cm^3) conform approximately (to within 0.5%) the additivity rule of molar volume although the densities of LiI, LiCl, and KI had been extrapolated from the reported values (8) at above the melting points of the salt components.

The specific conductivity-temperature relationship, Eq. [1], and the density-temperature relationship, Eq. Recovery of Chlorine from Waste Gas—Fundamentals

Fumio Hine* and Masaki Yasuda

Nagoya Institute of Technology, Nagoya 466, Japan

One to two per cent of the total production of chlorine by electrolysis, accounting for about 50,000 tons a year in Japan and about 100,000 tons in the United States, is being wasted. Chlorine should be recovered from such waste gases. Some processes, such as the absorption-desorption method with a chlorinated solvent, have developed, but comparatively few of practical application have been announced. Here a new electrochemical process with the depolarized cathode, called electrochemical recovery of chlorine, is described.

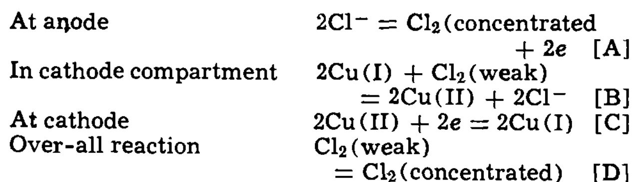
* Electrochemical Society Active Member.

Key words: chlorine recovery, chloride electrolysis, depolarized cathode, diffusion-limiting current.

Electrochemistry of the Process

The electrolytic solution consisting of HCl and $CuCl_2$ is electrolyzed with the chlorine depolarized cathode. The process resembles the Kyoto-type HCl cell investigated by the same author (1).

The anode reaction is the evolution of chlorine from Cl^- ion (reaction [A]). Waste or weak chlorine is sent to the cathode compartment, where dissolved chlorine reacts with cuprous chloride complex ions to give cupric ions (reaction [B]). Cupric ions are cathodically reduced into cuprous by reaction [C], which has been studied in detail in the previous paper (2). The over-all reaction is, thus, represented by reaction [D] as follows



At anode	$2Cl^- = Cl_2(\text{concentrated}) + 2e$	[A]
In cathode compartment	$2Cu(I) + Cl_2(\text{weak}) = 2Cu(II) + 2Cl^-$	[B]
At cathode	$2Cu(II) + 2e = 2Cu(I)$	[C]
Over-all reaction	$Cl_2(\text{weak}) = Cl_2(\text{concentrated})$	[D]

where Cu(I) and Cu(II) are the cuprous and cupric chloro complex ions, probably $CuCl_3^{2-}$ and $CuCl_3^-$, respectively (2).

The solubility of chlorine in the mixed solution consisting of HCl and $CuCl_2$ is considerably larger than that of oxygen (3), and the reaction rate of chlorine at the cathode is high in comparison with that of the dissolved oxygen. Thus the side reaction [E] would occur in parallel with reaction [C] at the working cathode

At cathode $\quad Cl_2(\text{dissolved}) + 2e = 2Cl^- \quad$ [E]

The reversible potentials for the anodic and cathodic processes [A] and [C] are close to each other when reaction [C] is coupled with reaction [B], a fast reaction, therefore, the decomposition voltage for the over-all reaction [D] is small enough, say about 0.1V or less, depending on such operating conditions as electrolyte composition and temperature. The cell voltage is estimated from the polarization data to be about 1.3V at 10 A/dm^2 and 1.7V at 20 A/dm^2. It will be discussed in detail in the future.

The anode process [A] has been discussed previously as a part of studies on the Kyoto-type HCl cell (4). Therefore, the present work will emphasize the cathodic processes represented by reactions [B], [C], and [E] at the surface of the chlorine-depolarized electrode.

Experimental Procedure

The rotating graphite disk cathode of 1 cm^2 was placed at the center of the glass cell of about 1 liter capacity. A graphite anode was inserted into the anode compartment, which was separated from the cathode compartment by a sintered glass diaphragm. The Luggin probe connected to the calomel reference electrode was located 1 mm from the center of the working cathode. The *IR* drop between the working cathode and the Luggin probe was calibrated by means of the current-interruption technique (5).

The electrolytic solution was made up with reagent grade HCl and $CuCl_2$. Since the limiting current density for the cathodic reduction of cupric ions was independent of the HCl concentration, 6*N* HCl was generally used and 3*N* HCl was also sometimes employed, while the $CuCl_2$ concentration was varied over a wide range. The temperature and the moisture of the gas mixture, consisting of chlorine and nitrogen, were brought to equilibrium with the cell liquor before measurements were made.

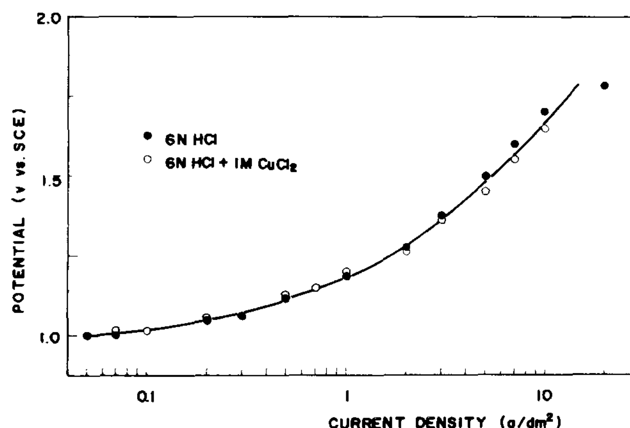


Fig. 1. Potential *vs.* current density curves of graphite anode in HCl and mixed solution of HCl + $CuCl_2$ at 40°C.

Results and Discussion

An example of the anodic polarization curves is shown in Fig. 1. It is clear that the potential is almost independent of $CuCl_2$ in the electrolyte. It disagrees somewhat with the data in the paper on the Kyoto Process (4), although it has not yet been clarified.

Figure 2 shows the polarization curves for rotating graphite cathode at 500 rpm in a 6*N* HCl under various conditions. In a deaerated solution with nitrogen (rectangular points), only the hydrogen evolution reaction takes place at less noble potential ranges. Since the rate of the cathodic reduction of dissolved oxygen is slow, an almost similar curve is obtained even in an aerated solution (triangular points).

On the other hand, the static potential is considerably noble in the solution containing chlorine (circular points). The cathodic potential tends to become more negative with increase in the current density, the lim-

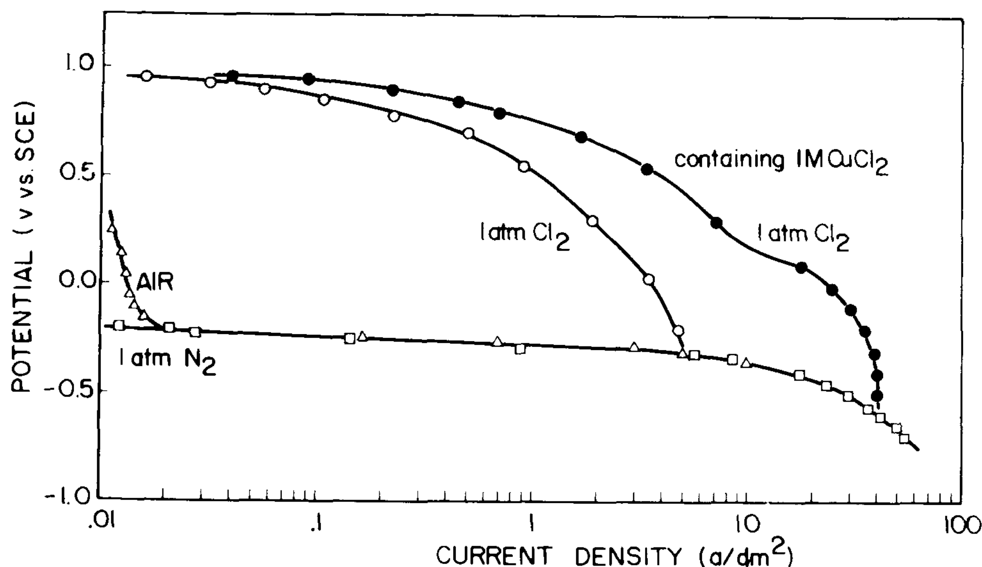

Fig. 2. Polarization curves of graphite cathode in 6*N* HCl at 40°C under various conditions (500 rpm).

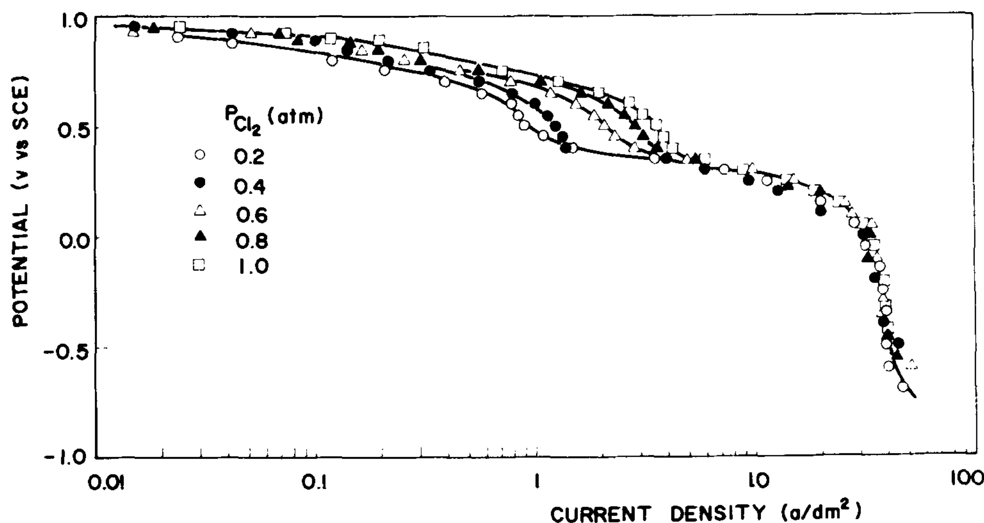

Fig. 3. Potential vs. current density curves in a mixed solution consisting of 6N HCl and 1M $CuCl_2$ at 40°C and 500 rpm.

iting current density for dissolved chlorine being relatively large.

It is interesting that two current density arrests appear in cupric chloride solution saturated with chlorine (closed points): these are, diffusion-limiting current densities for chlorine and cupric ions.

The first current density arrest in Fig. 3 varies with the chlorine partial pressure, and is proportional to the partial pressure, whereas the second is independent of it.

The two limiting current densities depend greatly on the rotational speed of the working cathode. The results obtained are summarized in Fig. 4. The dotted line is a plot of the current density and rotational speed at +450 mV *vs.* SCE, and shows that the former is independent of the $CuCl_2$ concentration. The current density in the mixed solution is smaller than in HCl solution at the same potential, probably due to the small solubility of chlorine in the mixed solution (3, 6).

At −400 mV *vs.* SCE, the current density depends on the rotational speed, as shown by the solid lines in Fig. 4. The limiting current density at this point is also proportional to the $CuCl_2$ concentration. With these results, it can be concluded that the first current density arrest is the diffusion-limiting current density for dissolved chlorine, and the second is for cupric chloride, and hence, the next equation is obtained

$$i_L = k_1(p_{Cl_2})/\overline{\omega} + k_2(a_{Cu(II)})/\overline{\omega} \quad [1]$$

where i_L = limiting current density at −400 mV *vs.* SCE; k_1 and k_2 are constants for the cathodic reduction of chlorine and cupric chloride, respectively, at −400 mV; p_{Cl_2} = partial pressure of chlorine; ω = rotational speed.

It is clear that the first term of the right hand side in Eq. [1] is much smaller than the second term from experimental data such as Fig. 5, Eq. [2] can be obtained

$$i_L = k_2(a_{Cu(II)})/\overline{\omega} \quad [2]$$

This would be the maximum current density for cell operation.

Because k_2 involves the diffusion coefficient and the viscosity of the solution, it would be a function of the operating temperature. At less noble potentials, the limiting current density increases with temperature, on the other hand, the current density at +0.5V at high temperature is smaller than at low temperature because of the difference in the solubility of chlorine. The limiting current density at −0.4V depends linearly on the operating temperature as shown in Fig. 5, thus

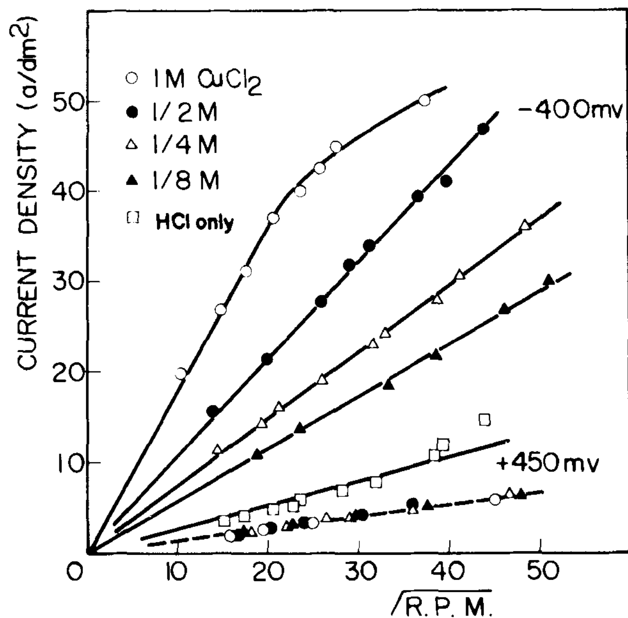

Fig. 4. Current density vs. rotating speed at constant potentials in 3N HCl containing $CuCl_2$ at 40°C. (p_{Cl_2} = 1 atm).

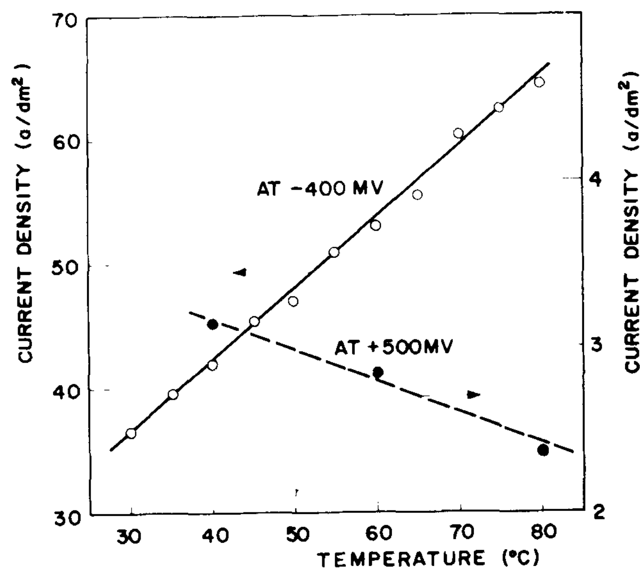

Fig. 5. Limiting current density vs. temperature in a mixed solution consisting of 6N HCl and 1M $CuCl_2$ under p_{Cl_2} = 1 atm and 500 rpm. Closed points at 500 mV represent the limiting current density of Cl_2 dissolved, whereas open points are of Cl_2 plus Cu(II) at −400 mV.

the cell should be operated at high temperature. The maximum current density might be a function of the Reynolds number as well as the operating temperature. Therefore, it should be investigated further, for development and scale-up of this process, from a chemical engineering point of view.

Conclusion

An electrochemical process for recovery of chlorine from waste gas has been developed. Fundamental studies on this process, emphasizing the cathodic reaction, have been made. Since the limiting current density for dissolved chlorine is small, the rate of the over-all cathodic process is almost controlled by the diffusion current for cupric chloride in the electrolyte. The higher the concentration and the temperature, the larger the current density obtained. The flow velocity of the electrolyte near the working cathode is also an important factor because the cathode reaction is controlled by diffusion (7).

A Time-Dependent Solvation Number for Ions in Solution

J. O'M. Bockris*,[1] and P. P. S. Saluja*,[2]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania 19104

The concept of a solvation number for ions in solution existed for many decades but was associated with difficulties arising from a lack of accepted and sufficiently sharp definition. However, a primary solvation number was defined (1) as the number of water molecules per ion which had lost their own translational freedom and exhibited those of the ion. A certain number of experimental methods (1) seem to give a quantity relatively independent of the method, while from the nature of the concordent methods one may comprehend that they might be expected to yield solvation numbers corresponding to the definition ("The solvation number of an ion is the number of water molecules which have lost their own degrees of translational freedom and have those of the ion.")

However, the concept was not clear in the absence of an expression of the model in "dynamic" terms (2). A quantitative version of this model has recently been developed (3). It is wished to present it here in a qualitative way.

The suggestion is to interpret the concept of primary solvation number in terms of the residence time of the water molecules around the ions. Upon the arrival of an ion at a given site in the solution, it acts electrostatically on the surrounding solvent molecules to orient them toward an optimal energetic position. In the limiting case of small ions of high valency (*e.g.*, Mg^{+2}), all of the first, and perhaps some of the second, shell of water molecules, will be oriented into a relatively incompressible solvent sheath around the ion. At the other extreme, with large ions and low valency (*e.g.*, I^{-}), none of the water molecules will be thus oriented and they will continue to remain in the solvent structure while the ion remains in its position before it jumps to the next site in solution.

The primary solvation number may be defined as the number of water molecules which are attached to the ion for a sufficiently long time so that they move with the ion from a given position in the solution to its next site. Thus, whether a water molecule, which is a coordination water molecule for the ion, is also a part of its solvation sheath depends[3] upon: (*i*) the time the ion waits at a given site in solution ($\tau_{ion,\ wait}$); and (*ii*) the time the water molecule takes to orient around from its position in the solvent to come into a position of minimum energy in respect to the ion ($\tau_{water,\ orient}$).

To test this model, it is necessary to have a method which distinguishes between the solvation number due to cation and anion, for most methods of determining primary solvation water molecules give rise only to the sum of these. Such a method has been recently developed (3) by combining Passynski's method for the determination of the total amount of incompressible solvent water molecules around the ion with the measurements of ionic vibration potential which measures the difference in the masses of the cation and anion. We have given (3) reasons which suggest that the two methods measure the same quantity. The compressibility method gives the sum, the other method gives the difference, of the solvation numbers of cation and anion. In Fig. 1, some of these solvation numbers are plotted as a function of ionic radius.

These concepts may be tested. If they are correct, in a plot of $\tau_{ion,\ wait}/\tau_{water,\ orient}$ against solvation number, the solvation number would tend to zero if the ratio is small; and if $\tau_{ion,\ wait}/\tau_{water,\ orient}$ is large, the solva-

[2] Present address: Cornell University, Department of Chemistry, Ithaca, New York 14850.

Key words: solvation number, coordination number, ion-wait time, water-orientation time, solvational coordination, nonsolvational coordination.

[3] The coordination water molecules which are part of the solvation sheath around an ion are defined as "solvational" coordination water (SCW) molecules. The remaining water molecules (equal to total coordination number minus SCW molecules) are defined as "nonsolvational" coordination water (NSCW) molecules in the solvational model presented here.

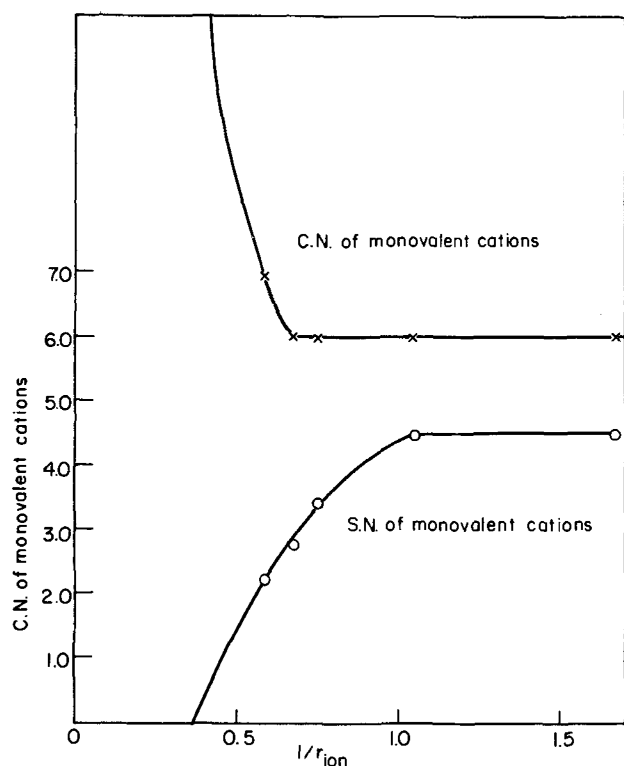

Fig. 1. S.N. and C.N. of alkali metal cations plotted as reciprocal function of cations radius.

tion number will tend to be equal to the coordination number. In Fig. 2, such a graph is shown and is seen to be consistent with the concept presented.

These ideas thrust light upon the relationship between the coordination number, as recently obtained from a systematic analysis of x-ray measurements (4), and the solvation number (see Fig. 1). These quantities are not equal, although they tend to become equal for small ions and high valency.

This work stresses the invalidity of the older concept (6) of assuming that the coordination number round an ion is always 4 or 6: it is seen that in fact a coordination number is an experimental quantity, and may vary continuously from about 4 to about 9 (4, 7) depending upon the size of the ion.

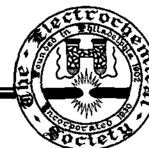
Brief Communication



Electrochemical Synthesis of Ferromagnetic Fe_3S_4

S. Yamaguchi* and T. Moori

National Institute for Researches in Inorganic Materials, 2-29-3 Hon-Komagome, Bunkyo, Tokyo, Japan

Water was bubbled with nitrogen at room temperature to remove air and was then saturated with hydrogen sulfide gas. A small amount of calcium chloride was added to augment the electrical conductivity. The concentrations of H_2S and of $CaCl_2 \cdot 2H_2O$ and the pH were 0.0145 mol/liter, 0.007 mol/liter, and 4.6, respectively.

Two sheets of iron were employed as electrodes. The size was about $0.1 \times 100 \times 100$ mm³. An electrolysis was carried out with the current density 0.6 mA/cm² at about 80°C for 7 hr. The bath was replenished occasionally with the electrolyte prescribed in order to keep its concentration constant. About 0.5g of black iron sulfide was deposited in the neighborhood of the cathode. The bath containing the deposit was aged at about 100°C for 30 min. The black sediment having experienced this hydrothermal treatment became ferromagnetic and crystalline. It was attracted sensitively to a hand magnet, and was also subjected to crystallographic analysis by electron diffraction. The diffraction pattern obtained from the specimen is shown in Fig. 1. Figure 2 is a reference pattern from pure Fe_3S_4 of spinel type (1). The result of analysis of Fig. 1 is given in Table I, which verifies that the iron sulfide produced here corresponds mainly to greigite (space group: Fd3m, spinel type, lattice constant: 9.875Å).

Selective Photoetching of Gallium Arsenide

F. Kuhn-Kuhnenfeld

Wacker-Chemitronic, Burghausen, Germany

SSST

ABSTRACT

Etching of GaAs in an oxidizing etchant under intense local illumination was found to be selective and, moreover, to be a powerful method for the characterization of this material. A flat bottom hole is etched into the illuminated surface region of n-type GaAs, whereas a mesa structure forms on p-type material. Thus, it is possible to determine the conductivity type of very small surface areas. Height and depth of those structures both decrease with increasing doping level. Striations, precipitates, and decorated dislocation lines are revealed with excellent resolution even in undoped or semi-insulating samples. By measuring photovoltages between an illuminated and a dark GaAs electrode in H_2SO_4-H_2O_2-H_2O-solution, the surface photovoltaic effect was shown to be the origin of selective photoetching.

Various techniques have been employed to characterize the homogeneity of dopant distribution in GaAs. Among these are infrared transmission (1, 2), schlieren images (3), cathodoluminescence (4, 5), photoluminescence (6), x-ray topography (7), transmission electron microscopy (8), ion analyzer (9), and etching (10-14).

Etching methods are the ones most frequently used for delineating striations and growth profiles; they are best suited for routine work because of their simplicity and their good resolution. On the other hand, etching has been considered a purely qualitative method (15), and little is known about the mechanisms involved. In dealing with pulsed anodic etching Dickhoff (13) has assumed that current density is higher at zones of higher conductivity and dissolution there proceeds faster. Winteler and Zimmerli (16) used Dickhoff's etching technique on GaAs, but did not find correlation in every case between etch figures and Schottky diode isoconcentration-lines. While distinct bright and dark striation zones are easily obtained by pulsed anodic etching of GaAs, the difference seems to be one of roughness rather than of depth. There are, of course, other striation etching techniques (14) that are clearly based on locally different etch rates; but no decisive answer has been given to the question of whether striation valleys or striation ridges coincide with regions of higher than average resistivity. An analogous problem has been solved, however, in the study of cathodoluminescence (4, 5).

Selective photoetching, as described in the present paper, is not only accessible to semi-quantitative interpretation, but is also much more sensitive than conventional etching techniques. Resolution is improved, and striations are revealed even in undoped or semi-insulating samples, regardless of surface orientation. So far, etched striations in undoped GaAs could hardly be detected at all (1, 14), whereas for semi-insulating material only the method of Plaskett and Parsons (12) was available and only on $\{\bar{2}11\}$-planes. Finally, this selective photoetching is the only method for the absolute determination of conductivity type on a microscopic scale. Selective photoetching is not just etching under illumination, which is a widely used procedure. It is essential that only part of the etched surface be intensely illuminated, a fact that was first recognized by Haisty (17). Haisty's experiments, however, were performed in dilute electrolytes, with comparatively weak illumination, so that striations could not be developed.

Etching Procedure

Polished GaAs samples[1] were mounted on a quartz disk of 2 in. diam. The disk was then put into a small petri dish filled with the etchant. Best results were obtained with a solution of 3 parts H_2SO_4, 1 part 30% H_2O_2, and 1 part H_2O at a temperature of 30°C; but a solution of 1 volume per cent (v/o) bromine in methanol was also successfully used. Due to the intense color of the etchant, however, much light is absorbed in the layer of liquid covering the sample.

The petri dish was then placed on the stage of a Zeiss Universal microscope, where the light of the illuminator (HBO 200 mercury lamp) could be projected onto a sharply confined area of the GaAs surface. The diameter of this area was adjustable between 0.5 and 5 mm by means of an iris diaphragm. The long working distance of 9 mm necessary for this type of experiment was provided by a special objective lens (Epiplan 4X POL). A heat protection filter served to make sure that IR radiation was minimized.

Short etch and exposure times of typically 5 min were sufficient for maximum resolution. It did not matter if the GaAs sample was kept in the etchant for a limited time before exposure, but it was quite important that the etching action be stopped at the same time as the illumination. This was accomplished by submerging the petri dish and its contents into a water vessel, which was kept ready next to the microscope.

An interesting feature of photoetching by means of a microscope is that one can clearly see what is going on during the exposure. Not only can striations and

Key words: compound semiconductors, striations, dislocations, selective etching, etch mechanism.

[1] Most of the GaAs samples were grown at Wacker-Chemitronic by the III-V group of B. K. Bienert.

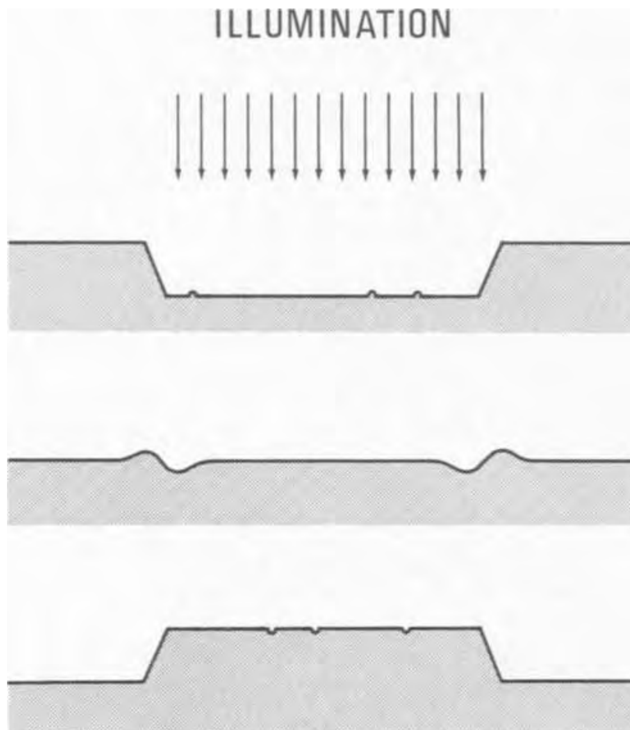

Fig. 1. Schematic diagram of photoetching effect on n-type (top), semi-insulating (middle), and p-type GaAs (bottom).

dislocations be observed while being revealed, but also occasional artifacts. It is fascinating to see some small particle move slowly across the sample surface, leaving behind an extended masking trail. A certain type of small cone is readily identified as the result of masking by tiny gas bubbles. Misinterpretation can, thus, be easily avoided.

Photoetching Results

A flat bottom hole is etched into the illuminated surface region of n-type GaAs, whereas a mesa structure forms on p-type samples (Fig. 1 and 2). The outline of such a photoetched structure is the same as that of the illuminated area, which again is an image of the diaphragm aperture (a regular dodecagon in this special case). If the diaphragm is replaced by a transparent slide, the GaAs surface may be shaped in a desired manner.

A flat bottom hole photoetched into n-type GaAs is shown in Fig. 2 (depth = 3 μm). Striations are shallow in comparison, but they still can be resolved quantitatively by the interference microscope (Fig. 3 and 4). Worm-like lines are identified as dislocations by photoetching a 111(A)-surface, where most of these lines meet at or start from etch pits.

In many cases, the vertical dimension of etched dislocation lines is smaller than 200Å, so they do not show up in the etch profile (Fig. 4). In Nomarski contrast, however, such lines with a vertical extension of no more than some 10 monolayers cannot only be discerned, but one can also safely distinguish between protruding and recessed dislocation lines by comparing their bright-dark sequence with that of known structures, *e.g.*, scratches. As a rule dislocations are elevated on n-type, and deepened on p-type GaAs; *i.e.*, they are of the opposite sign as that of the dodecagon itself. This behavior is indicated in Fig. 1. Exceptions to the rule were found in two Cr-doped samples where the chromium content was not large enough to make them semi-insulating. Although these samples were of a low resistivity n-type, dislocation lines were deepened just as in genuine semi-insulating GaAs. An explanation might be that the chromium content was used up in forming a Cottrell atmosphere around dislocations, rendering the rest of the crystal essentially undoped.

Measured widths of etched dislocation lines were found to vary between less than 1 μm up to more than 50 μm. (If exposure time is kept short, there is no danger of measuring "memories" of dissolved dislocations.) In some crystals with resistivities between 10

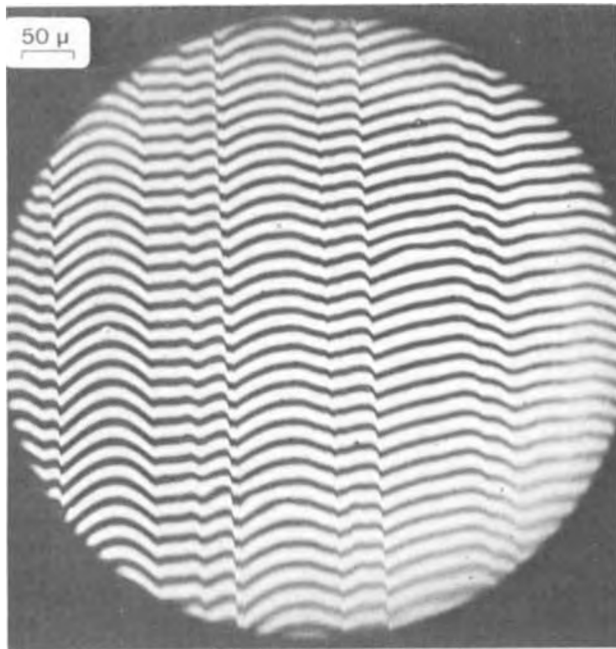

Fig. 4. Interference photomicrograph ($\lambda/2$ = 270 nm) of etch profile representing striations.

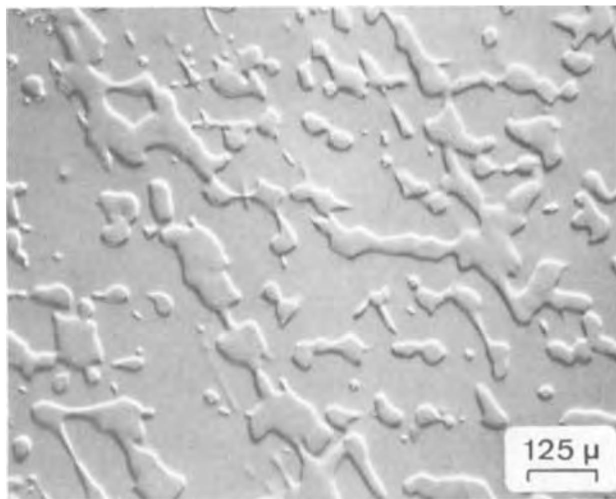

Fig. 5. Photoetched 111B-surface of undoped 200 ohm cm GaAs

and 1000 ohm-cm the width of the etched dislocation lines was comparable to their visible length (Fig. 5). Such structures might be at least one of the reasons for the rather low mobilities usually encountered in this resistivity range. In these and several other cases, dislocation cores and halos could be distinguished; details of this kind have been described earlier by Shaw and Thornton in their cathodoluminescence work (5).

In order to obtain a relation between etch rate and doping level, meticulous care had to be employed in preparing the H_2SO_4-H_2O_2-H_2O-solution, since the method of preparation and the time elapsed since preparation of the etchant were found to have considerable influence on the etching rate. (The method of preparing the etchant is not critical, as long as only qualitative information is required.) Cold sulfuric acid was added dropwise to the cooled hydrogen peroxide solution in such a way that the temperature did not rise above 25°C. Subsequently, the H_2O_2-content of the etchant was controlled by means of permanganate titration. Measured heights (+) and depths (−) of illuminated dodecagons relative to their unilluminated surroundings are listed in Table I. These photoetching rates agree well with the general impression gained

Table I. Etch differences between illuminated and dark regions of photoetched GaAs samples. Exposure time 10 min.

Sample	Type	Carriers, cm^{-3}	Mobility, $cm^2/Vsec$	Relative height 1st run μm	Relative height 2nd run μm
1	n	9×10^{17}	3400	−2.45	−2.25
2	n	2×10^{17}	3100	−4.75	−5.25
3	n	8×10^{16}	3900	−4.1	−4.1
4	p	2×10^{17}	240	+3.9	+3.3
5	p	7×10^{18}	90	+2.8	+2.6

from the results on more than 300 GaAs samples; the absolute value of the etch difference increases with the decreasing doping level as long as the carrier concentration is not lower than about 10^{17} cm^{-3}.

From Fig. 6 it can be seen that the photoetching rate is strongly dependent on the incident light intensity. Because of the considerable "chemical" etch rate of GaAs in an oxidizing etchant, low light intensities will have no noticeable influence. Illumination in these experiments was, therefore, selected for sufficient intensity so that the etch rate of n-GaAs was more than doubled by the influence of light. (Accurate measurements were restricted to the step height between the illuminated and the unilluminated area.)

Light intensity cannot, however, be increased indefinitely. If the etch rate is too fast, numerous small pyramids of random orientation suddenly form on the illuminated surface area of n-type samples after several seconds or minutes of photoetching. These pyramids look exactly like the ones observed by Yeh and Blakeslee (18) that have been identified by Kyser and Millea (19) as As_2O_3 precipitated from the supersaturated etchant. This explanation makes it clear why pyramids of this type also used to develop on samples with very fast etch rates (*e.g.*, sample 2 in Table I), or during attempts to photoetch flat bottom holes deeper than 20 μm by prolonged exposure.

Photovoltage Measurement

Photoetching in dilute electrolytes has been described by Haisty (17) as an electrochemical process being driven by surface photovoltage. By separating illuminated and unilluminated surface regions, and by measuring the open circuit voltage (and short circuit current) between them, it could be shown that this picture also applies to the present case of photoetching in an oxidizing etchant.

Photovoltage measurements were designed so as to simulate photoetching. For this reason, another part

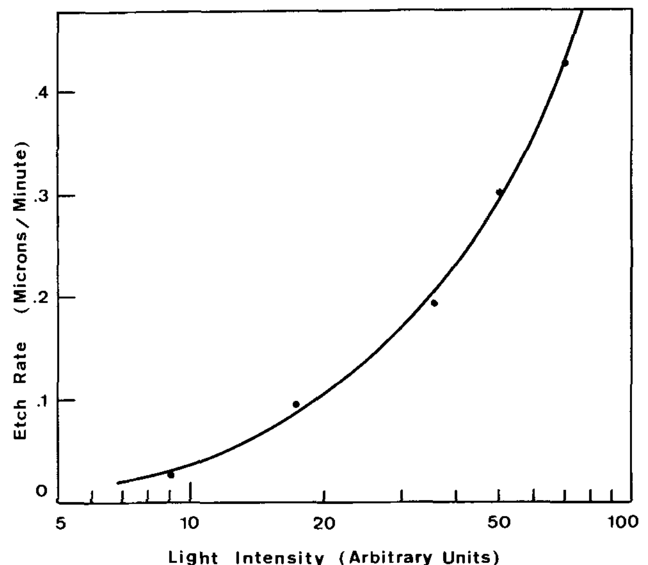

Fig. 6. Photoetching rate of Te-doped GaAs (n = 4 x 10^{17} cm^{-3}) in H_2SO_4-H_2O_2-H_2O (3:1:1) as a function of light intensity.

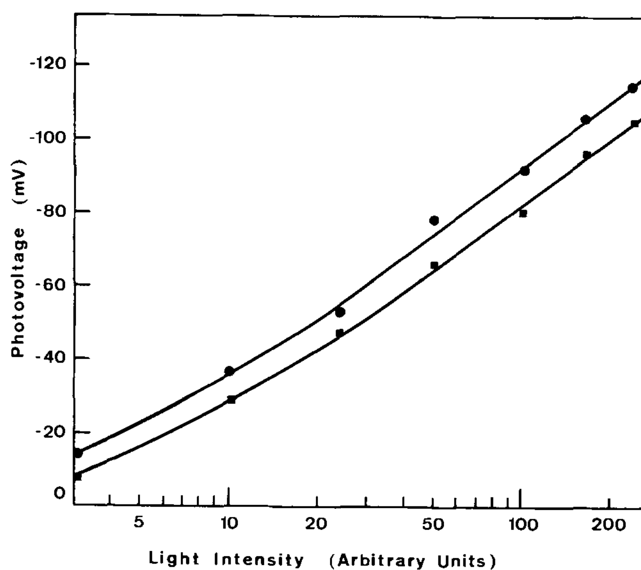

Fig. 7. Photovoltage of p-type GaAs electrodes as a function of light intensity (●, p = 2×10^{18} cm^{-3}; ■, p = 4×10^{18} cm^{-3}).

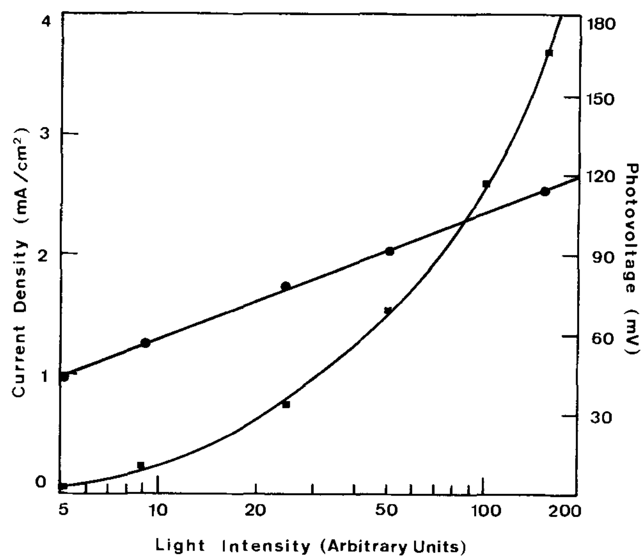

Fig. 8. Photovoltage (●) and short circuit current (■) vs. light intensity; same crystal as in Fig. 6, but different sample geometry.

of the same slice or of an adjacent slice of GaAs was chosen as the counterelectrode. This was of great advantage since galvanic elements or other related voltages turned out to be negligible as compared to the photovoltage. Large area back contacts were applied to the electrodes so that the contact resistance was less than 1 ohm. For this purpose, numerous small dots of conductive silver paint were individually formed by capacitor discharge and then connected with each other and the leads. Subsequently, both GaAs electrodes were mounted on the same quartz block with a silicone resin,[2] leaving only those surface regions exposed to the etchant that were to be illuminated later. The quartz disk was then put into a petri dish just as described above. Initially, a Solartron voltmeter ($R_i = 10^{10}$ ohms) was used for measuring photovoltages, but as the typical source resistance was less than 100 ohms, a digital multimeter was also found adequate.

Photovoltage response to light intensity changes was instantaneous, which shows that photoetching is not influenced by thermal effects. Actually, no indication of temperature increase was observed when a thermocouple was illuminated in the same way. This is consistent with a temperature increase of less than 0.1°C as calculated by rough estimate.

As a result of these measurements in H_2SO_4-H_2O_2-H_2O (3:1:1) solution, the unilluminated electrode was found to be positive in the case of n-type and negative in the case of p-type electrodes (Fig. 7). Contrary to Haisty's results (17), when he measured a large photovoltage on n-type and "essentially none" on p-type GaAs, photovoltages here were opposite in sign but comparable in value.

In the plot of photovoltage *vs.* logarithm of light intensity I, straight lines are obtained for large light intensities where the photovoltage is larger than kT/e (Fig. 7). This dependance may be described by the empirical formula for the photovoltage V_{ph}

$$V_{ph} = n \frac{kT}{e} \ln \frac{I}{I_0} \quad [1]$$

where n is a factor close to unity and I_0 an experimentally determined constant. No signs of saturation of the photovoltaic effect were observed in either n- or p-type GaAs in spite of a light intensity that presumably exceeded the one of Haisty (17) and that of Goldbach and Graff (20) by a factor of 100.

In Fig. 8, finally, photovoltage and short circuit current between two n-GaAs electrodes are plotted together *vs.* the light intensity incident on the smaller electrode. (The current curve has not been corrected for source resistance.) The short circuit current is very small at low light intensity; its increase with illumination is steep but still less than linear. A nearly linear dependence was obtained, however, when an external voltage of 0.3V or more was applied to the electrodes so that the illuminated n-GaAs electrode was positively biased.

Discussion

The photovoltage measurements described above have shown conclusively that selective photoetching in an oxidizing etchant is the result of the surface photovoltaic effect. This photovoltaic effect is based upon the separation of light-induced hole-electron pairs in the built-in electric field of the semiconductor surface.

A detailed account of the surface photovoltaic effect has been given by Goldbach and Graff (20). In their experiments on n-type GaAs, the illuminated surface was positive with respect to the bulk (the same can be concluded from the present results) and the photovoltage was a logarithmic function of light intensity similar, not only to Eq. [1], but also to the familiar formula describing the photovoltage of a silicon p-n junction (21). Goldbach and Graff have also determined the dependence of surface photovoltage on the carrier concentration; the photovoltage of n-type GaAs was found to decrease with increasing carrier concentration in a well defined way, so that surface photovoltage measurements could be used successfully for the contactless routine determination of carrier concentration (20). This dependence also provides the explanation for the etching results of Table I.

One necessary requirement for the surface photovoltaic effect is the existence of an electric field in the surface layer of the semiconductor. Depletion layers are the rule for GaAs of usual surface preparation (20), which means that the bands are bent upwards near the surface of n-type, and downwards near the surface of p-type GaAs. This original band-bending gives rise to a photovoltage of opposite sign that will eventually compensate it if the generation rate is high enough. The present photovoltage measurements in H_2SO_4-H_2O_2-H_2O have shown that such a saturation

[2] Wacker Elastosil 07.

does not occur at photovoltages up to 0.12V in either n- or p-type GaAs. This result is consistent with a large density of deep surface states, and a surface Fermi level fixed near the middle of the gap. By means of the contact potential method, Atalla (22) has obtained a surface Fermi level pinned at about 0.76 eV above the valence band. Since this result was from GaAs samples cleaved in an ultra high vacuum, a direct comparison is, of course, impossible. Still, a semiconductor surface in the process of being carried off by a chemical etchant is easily reproducible and, in this respect, not inferior to a vacuum cleaved surface.

Photovoltage measurement in an oxidizing etchant is especially straightforward as compared to the small signal measurement in the air where capacitive coupling and phase-sensitive detecting have to be used (20). While the main function of the etchant is that of a translucent contact, the etchant also determines the density and distribution of surface states. The photovoltaic and photoetching behavior of GaAs in other ambients may, indeed, be very different (17) if the surface Fermi level is fixed near one band edge or if the density of surface states is low so the bands will be flat. On the other hand, the exact position of the Fermi level will be of little influence as long as the electric field strength is sufficient to collect virtually every generated charge carrier.

If an increased generation rate (*e.g.*, illumination) leads to an increase of photovoltage, then an increased recombination rate must have the reverse effect. Lifetime and diffusion length are, therefore, to be considered primary reasons for the different photovoltages (and photoetching rates) encountered in different GaAs samples, provided that the surface recombination is not too high. Wittry and Kyser (23) have obtained a normalized surface recombination velocity (LS/D) of about 20; such a value would, indeed, drown the bulk recombination. Hilsum and Holeman (24), on the other hand, have reported a value of less than unity. In the present case of a semiconductor surface exposed to a polishing etchant, the surface recombination velocity should be especially low. The surface photovoltage is, however, not only an implicit but also a direct function of the carrier concentration; the carrier concentration has an additional direct influence as it enters into the expression for the space charge layer width. A rigorous theoretical treatment will be difficult because the optical absorption length, the diffusion length of minority carriers, and the width of the space charge layer are all of the same magnitude so that no simplification or neglect can be made. The existing theory of Goldbach and Graff (20) is, in fact, only in qualitative agreement with the experiment. The situation is somewhat more favorable with p-type GaAs where the diffusion length clearly exceeds the other two parameters.

Due to the surface photovoltaic effect, the illuminated surface area of an n-type sample is charged positively and, thus, becomes the anode of an electrochemical cell. The etching rate of this illuminated area is enhanced by anodic oxidation whereas the unilluminated area is etched more slowly than in the absence of illumination. The rate of photoetching is determined by the ion current flowing from the anode to the cathode portions of the surface (see Fig. 6 in comparison to Fig. 8).

This ion current will be sustained by the surface photovoltage but is also determined by the total series resistance of the following circuit: (*i*) the IR of the space-charge layer below the illuminated surface (this resistance will be small if the light intensity is high, otherwise the number of generated hole-electron pairs will limit the current); (*ii*) the GaAs bulk resistance; (*iii*) the resistance of the space-charge barrier below the large unilluminated surface area (this surface barrier will be biased in forward direction by the surface photovoltage); (*iv*) the resistance of the GaAs-etching solution interface; (*v*) the ohmic resistance of the etchant; (*vi*) the resistance of the interface between the etching solution and the illuminated GaAs surface.

It will require further work to clarify the exact role of each resistance in this seemingly complex sequence. In the usual case of intensely illuminated n-type GaAs, the photocurrent is mainly limited at the (unilluminated) cathode. This can be seen by alternately illuminating the larger and the smaller one of two otherwise equal n-GaAs electrodes; the photocurrent is several times greater when the smaller electrode is illuminated. Although the cathode area is important for the total photocurrent, this does not lead to qualitative changes of etched structures within the illuminated surface area. The resistance of the large unilluminated electrode can be minimized by applying an additional negative bias, *i.e.*, by reducing the cathode barrier (and, at the same time, increasing the anode barrier). This does not necessarily mean that the semiconductor space-charge layer is the sole reason for the cathodic barrier; Gerischer and Mattes (25) have been able to show that a considerable part of the voltage drop at a GaAs cathode can be across the Helmholtz double layer. In any case, a few tenths of a volt are sufficient to make the increase of the short circuit current nearly linear with illumination, as is characteristic of a p-n photodiode. This short circuit current is then essentially equivalent to the net generation rate within the illuminated surface barrier and can, therefore, not be increased beyond the saturation value even if the applied voltage is further increased.

The photovoltaic nature of photoetching makes it clear that zones of higher carrier concentration are etched as striation ridges on n-type GaAs and as striation valleys on p-type GaAs. For the case of n-type material, this conclusion disagrees with Dickhoff's model (13) but is in line with observations on other semiconductors. Vieweg-Gutberlet (26) reports that the chemical etching rate of heavily doped n-type silicon is distinctly slower than that of slightly doped samples. (According to Vieweg's technique, silicon samples are etched for several hours at ordinary room light.) A similar dependence has been recently obtained by Lichtensteiger, Witt, and Gatos (27) on InSb. They found that the "etching rate is a sensitive function of dopant concentration (it decreases with increasing Te concentration)." This may also be due to photoetching; but as comparable results of p-type semiconductors are not available, the possibility that the chemical etching attack is hampered by high dopant concentrations cannot be excluded either.

In semi-insulating GaAs, the anode and cathode are rudimentary (Fig. 1). Because of the high bulk resistivity, a sizable ion current can flow only at the contours of the illuminated area where anode and cathode sites are in immediate proximity to each other. Striations and dislocation lines within the illuminated area can still be recognized in most cases as an extremely shallow relief. The fine structure of the photoetched contour consists of a ridge and a ditch running parallel to each other. From the contour width, the sample resistivity may be roughly estimated. In semi-insulating material with n-type conductivity, the ditch will form on the illuminated side (Fig. 1). More than 20 semi-insulating samples (the conductivity type of which has been established by Hall effect measurement) were photoetched for comparison. The correct conductivity type was obtained in every single case. Apart from these, a "photoetching conductivity type" could be ascribed to a number of other semi-insulating samples where Hall effect results had been ambiguous. In semi-insulating GaAs, the Dember effect may possibly interfere with the photovoltaic effect. If this is the case, high resistivity p-type GaAs would appear to be high resistivity n-

type; no experimental evidence of this kind has been found, however.

Not the least merit of this selective photoetching is that it is a comparatively simple technique and requires little expenditure. It gives, nevertheless, a plastic and reliable picture of the homogeneity and perfection of GaAs.

Acknowledgments

The author is indebted to Professor H. J. Queisser for a critical review of the manuscript; to D. Reimann for many helpful discussions; to Miss C. Schreyer for performing the etching.

Manuscript received Feb. 3, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

A Limitation of the Pulsed Capacitance Technique of Measuring Impurity Profiles

A. R. LeBlanc, D. Dale Kleppinger, and J. P. Walsh

IBM Components Division, Essex Junction, Vermont 05452

ABSTRACT

This paper reports the results of an investigation of a limitation of the pulsed-capacitance technique for measuring impurity profiles in semiconductors (1). The limitation arises from the neglect of the majority carriers in the derivation of the previously published equation. The results, for the mathematically tractable example of a uniform profile, show that there is a minimum depth at which the technique is accurate and that this depth is a function of impurity concentration—decreasing with increasing concentration. This is a fundamental limitation of the technique as opposed to an instrumentation limitation.

A technique for determining impurity profiles in semiconductors using MOS capacitors has recently been described by Van Gelder and Nicollian (1). Their technique, based on the depletion approximation, utilizes the high-frequency capacitance of a capacitor biased in the depletion condition by short duration voltage pulses to obtain plots of $1/C^2$ *vs.* gate voltage. The slopes of these curves are expected to be proportional to the impurity concentration at the edge of the space charge layer. One simple check on the range of validity of the technique is to calculate the impurity profile of a uniformly doped substrate using the final equations of their paper. This calculation is straight forward since the capacitance of an MOS capacitor with uniform doping has a well-known, exact, closed-form solution (2).

The differential capacitance of a uniformly doped semiconductor space charge region is (2)

$$C_s = \frac{dQ_s}{d\psi_s} = \frac{\epsilon_s}{L_D} \frac{(1 - e^{-\beta\psi_s}) + \frac{n_{po}}{p_{po}} (e^{\beta\psi_s} - 1)}{\mathbf{F}\left(\beta\psi_s, \frac{n_{po}}{p_{po}}\right)} \quad [1]$$

where ϵ_s is the permittivity of silicon, β is q/KT, ψ_s is the semiconductor surface potential relative to the bulk of the semiconductor, p_{po} is the equilibrium hole concentration in the bulk of the semiconductor, n_{po} is the equilibrium electron concentration in the bulk of the semiconductor, L_D is the extrinsic Debye length in the semiconductor, and

$$\mathbf{F}\left(\beta\psi_s, \frac{n_{po}}{p_{po}}\right) = \left[e^{-\beta\psi_s} + \beta\psi_s - 1 + \frac{n_{po}}{p_{po}} (e^{\beta\psi_s} - \beta\psi_s - 1) \right]^{1/2} \equiv \mathbf{F} \quad [2]$$

Key words: pulsed MOS measurements, silicon impurity distribution, C-V measurements, impurity profile, technique limitation.

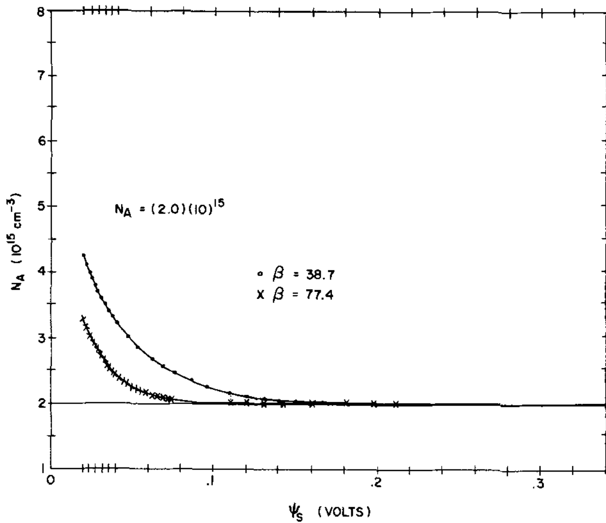

Fig. 1. The calculated impurity concentration as a function of surface potential for $\beta = 38.7$ and 77.4, and an assumed uniform concentration of 2×10^{15} cm^{-3}.

The total measured capacitance of the MOS capacitor is

$$C = \frac{C_o\, C_s}{C_o + C_s} \quad [3]$$

where C_o is the oxide capacitance.

The relationship between gate voltage and the capacitance measured in deep depletion that yields the impurity profile is given by Van Gelder and Nicollian (1) as

$$N(W) = \frac{2}{q\, \epsilon_s \frac{d}{dV}\left(\frac{1}{C^2}\right)} \quad [4]$$

which for purposes of calculation is more conveniently written as

$$N(W) = \frac{-C^3}{q\, \epsilon_s\, dC/dV} \quad [5]$$

where V is the applied voltage. The derivative in Eq. [5] is given by

$$\frac{dC}{dV} = \frac{dC}{d\psi_s}\, \frac{d\psi_s}{dV} \quad [6]$$

From Eq. [1] and [3]

$$\frac{dC}{d\psi_s} = \left(\frac{C_o}{C_s + C_o}\right)^2 \frac{\beta \epsilon_s}{L_D\, \mathbf{F}^2} \left\{ \mathbf{F}\left(e^{-\beta\psi_s} + \frac{n_{po}}{p_{po}} e^{\beta\psi_s}\right) - \frac{1}{2\mathbf{F}}\left[1 - e^{-\beta\psi_s} + \frac{n_{po}}{p_{po}}(e^{\beta\psi_s} - 1)\right]^2 \right\} \quad [7]$$

The voltage drop across the MOS capacitor is

$$V = \frac{-Q_s}{C_o} + \psi_s = \frac{\epsilon_s\, E_s}{C_o} + \psi_s \quad [8]$$

where the electric field at the silicon surface is

$$E_s = \frac{2}{\beta\, L_D}\, \mathbf{F}\left(\beta\psi_s, \frac{n_{po}}{p_{po}}\right) \quad [9]$$

Differentiating Eq. [8] yields

$$\frac{d\psi_s}{dV} = \frac{1}{1 + \frac{\epsilon_s}{L_D\, C_o\, \mathbf{F}}\left[1 - e^{-\beta\psi_s} + \frac{n_{po}}{p_{po}}(e^{\beta\psi_s} - 1)\right]} \quad [10]$$

Finally, combining Eq. [5], [6], [7], and [10] yields

$$N(W) = \frac{-C^3}{q\epsilon_s\left(\frac{C_o}{C_o + C_s}\right)^2 \frac{\beta\epsilon_s}{L_D\, \mathbf{F}^2}\; \frac{\left\{\mathbf{F}\left(e^{-\beta\psi_s} + \frac{n_{po}}{p_{po}} e^{\beta\psi_s}\right) - \frac{1}{2\mathbf{F}}\left[1 - e^{-\beta\psi_s} + \frac{n_{po}}{p_{po}}(e^{\beta\psi_s} - 1)\right]^2\right\}}{1 + \frac{\epsilon_s}{L_D\, C_o\, \mathbf{F}}\left[1 - e^{-\beta\psi_s} + \frac{n_{po}}{p_{po}}(e^{\beta\psi_s} - 1)\right]}} \quad [11]$$

Equation [11] gives the doping level as a function of surface potential. The depth of the space charge region can be approximated by using the depletion approximation to obtain

$$W = \sqrt{\frac{2\epsilon_s\, \psi_s}{q\, N_A}} \quad [12]$$

The impurity concentration as a function of surface potential is plotted in Fig. 1, 2, and 3 using Eq. [11] for doping concentrations of 2×10^{15}, 5.35×10^{15}, and 8×10^{15} cm^{-3}, respectively. In each figure curves are plotted for temperatures of 150° and 300°K. At surface potentials between 0 and 0.10V, these curves predict levels larger than the assumed uniform doping.

For surface potentials less than 0.1V, the pulsed technique for profile measurements appears to be in significant error.

Equations [11] and [12] have been combined to plot impurity concentrations as a function of depletion layer depth in Fig. 4, 5, and 6 for the same uniform doping levels and temperatures that were used in Fig. 1, 2, and 3. Again, accuracy of the technique is better for more heavily doped substrates and at lower temperatures. However, at depths shallower than 2000Å, the predictions of the technique deviate substantially from the assumed profile.

For analysis of the equations at surface potentials close to or at zero, the series approximation to the dif-

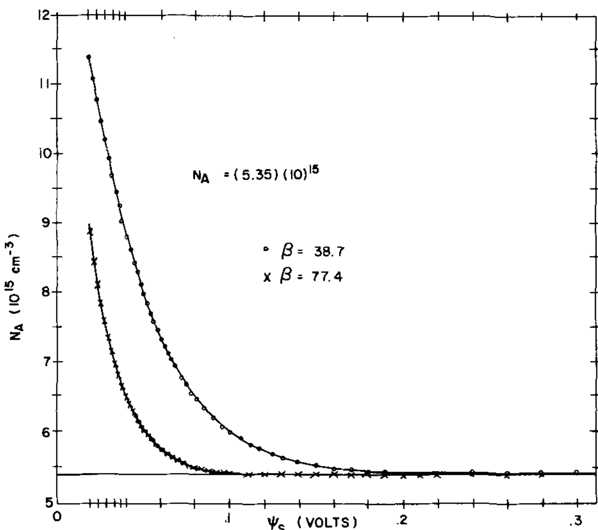

Fig. 2. The calculated impurity concentration as a function of surface potential for $\beta = 38.7$ and 77.4, and an assumed uniform concentration of 5.35×10^{15} cm^{-3}.

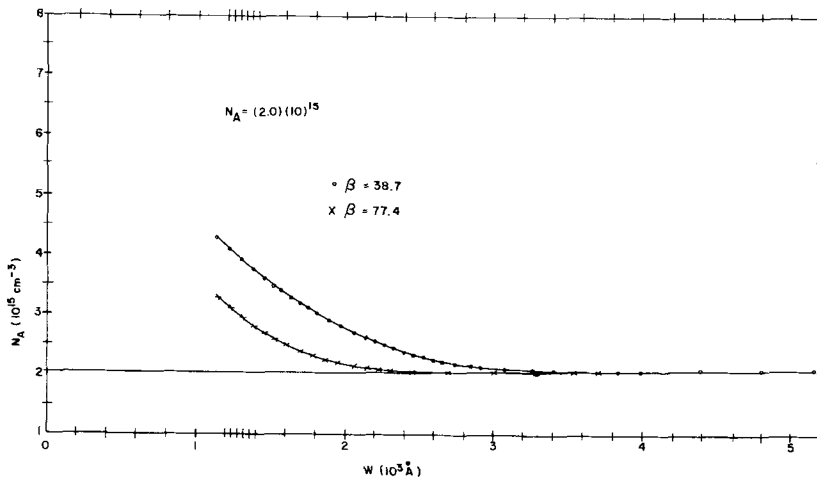

Fig. 4. The calculated impurity concentration as a function of the depletion layer depth for β = 38.7 and 77.4, and an assumed uniform concentration of 2 x 10^{15} cm^{-3}.

ferential capacitance can be utilized. This approach leads to

$$C_s = \frac{\epsilon_s}{L_D} \frac{\sum_0^\infty \frac{(\beta\psi_s)^i}{(i+1)!}\left[(-1)^{i+2} + \frac{n_{po}}{p_{po}}\right]}{\left\{\sum_0^\infty \frac{(\beta\psi_s)^i}{(i+2)!}\left[(-1)^{i+2} + \frac{n_{po}}{p_{po}}\right]\right\}^{1/2}} \quad [13]$$

where i is the summation index. At $\psi_s = 0$, this formulation reduces to

$$C_s|_{\psi_s=0} = \frac{\sqrt{2}\,\epsilon_s}{L_D}\left(1 + \frac{n_{po}}{p_{po}}\right)^{1/2} \quad [14]$$

which extends Sze's (2) equation (Eq. [21], p. 432) to the case where n_{po}/p_{po} is not negligible with respect to unity.

Equation [13] enables us to write the following expression

$$\frac{dC_s}{d\psi_s} = \frac{\epsilon_s}{L_D}\left\{\frac{\left[\sum_0^\infty i\frac{\beta^i\psi_s^i}{(i+1)!}\left((-1)^{i+2}+\frac{n_{po}}{p_{po}}\right)\right]}{\left[\sum_0^\infty \frac{\beta^i\psi_s^i}{(i+2)!}\left((-1)^{i+2}+\frac{n_{po}}{p_{po}}\right)\right]^{1/2}} - \frac{\left[\sum_0^\infty \frac{\beta^i\psi_s^i}{(i+1)!}\left((-1)^{i+2}+\frac{n_{po}}{p_{po}}\right)\right]\left[\sum_0^\infty i\frac{\beta^i\psi_s^{i-1}}{(i+2)!}\left((-1)^{i+2}+\frac{n_{po}}{p_{po}}\right)\right]}{2\left[\sum_0^\infty \frac{\beta^i\psi_s^i}{(i+2)!}\left((-1)^{i+2}+\frac{n_{po}}{p_{po}}\right)\right]^{3/2}}\right\} \quad [15]$$

which can be used in Eq. [6]. At $\psi_s = 0$, Eq. [15] reduces to

$$\left.\frac{dC_s}{d\psi_s}\right|_{\psi_s=0} = \frac{\epsilon_s}{L_D}\left\{\frac{\left(\frac{\sqrt{2}\,\beta}{3}\right)\left(-1+\frac{n_{po}}{p_{po}}\right)}{\left(1+\frac{n_{po}}{p_{po}}\right)^{1/2}}\right\} \quad [16]$$

The remaining factor in Eq. [6], $d\psi_s/dV$, can be calculated from

$$V = V_{ox} + \psi_s \quad [17]$$

and

$$dQ = C_{ox}\,dV_{ox} = C dV \quad [18]$$

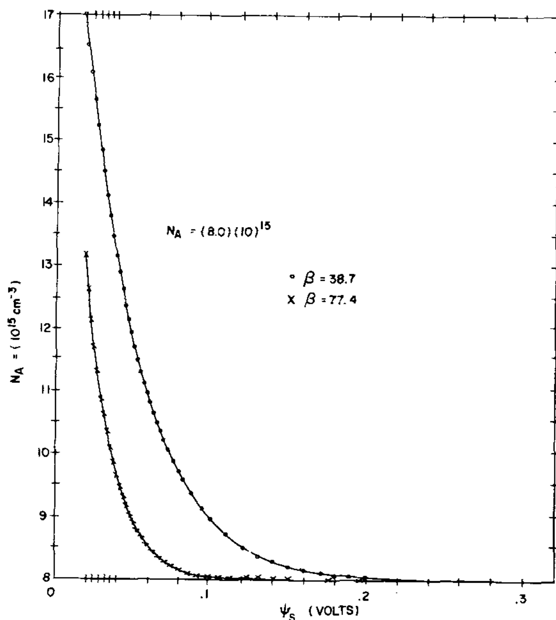

Fig. 3. The calculated impurity concentration as a function of surface potential for β = 38.7 and 77.4 and an assumed uniform concentration of 8 x 10^{15} cm^{-3}.

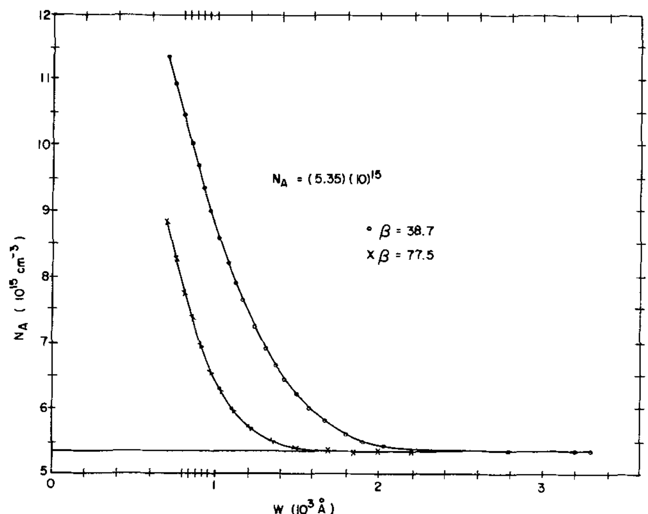

Fig. 5. The calculated impurity concentration as a function of the depletion layer depth for β = 38.7 and 77.4, and an assumed uniform concentration of 5.35 x 10^{15} cm^{-3}.

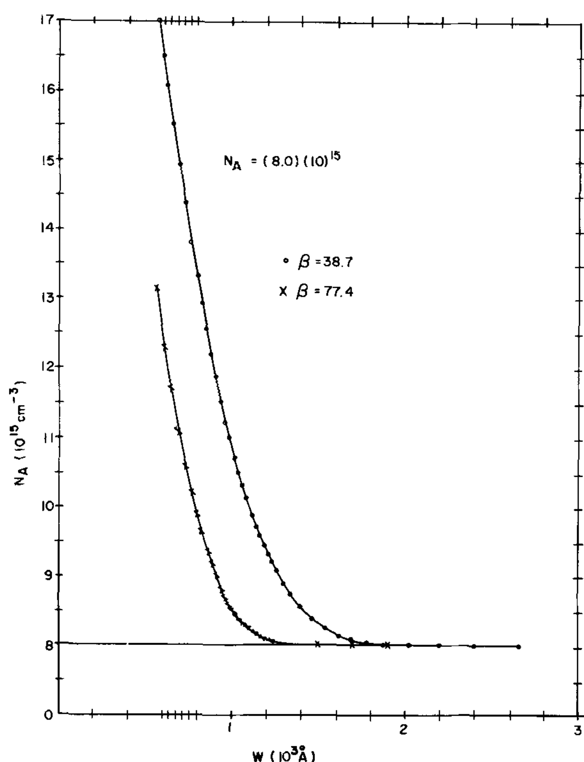

Fig. 6. The calculated impurity concentration as a function of the depletion layer depth for $\beta = 38.7$ and 77.4, and an assumed uniform concentration of 8.0×10^{15} cm^{-3}.

Thus

$$\frac{d\psi_s}{dV} = 1 - \frac{C}{C_o} = \frac{C_o}{C_o + C_s} \quad [19]$$

Equations [15] and [19] show that the factors that enter the denominator of Eq. [5] through Eq. [6] are nonzero for all ψ_s, including $\psi_s = 0$ (cf. Eq. [16]). Therefore, Eq. [5] will predict a well-behaved $N(W)$. However, using Eq. [14] and [16] to evaluate N at $\psi_s = 0$ results in

$$N(0) = 3N_A \quad [20]$$

which contradicts our assumption of uniform doping.

In summary, the technique of Van Gelder and Nicollian (1) does not properly predict the profile for small values of ψ_s since, as they acknowledge, the free carriers that they have neglected become important. They state that this occurs for $\psi_s \approx 0.05$V. Our calculations, which include the free carriers, are useful in visualizing this effect for the case of uniform doping. Figures 1, 2, and 3 show that at 0.05V the predicted profile is in error by 30-50% for the doping levels shown. [Figures 4, 5, and 6 show that the usable minimum depth decreases (improves) as the substrate doping increases. Thus, the technique is usable nearer the surfaces of more heavily doped substrates.]

Furthermore, the limitation related to interface states which Van Gelder and Nicollian point out can be mitigated by increasing the a-c measurement frequency and decreasing the amplitude of the signal. However, by using the example of uniform doping, we have shown that the contributions of the free carriers provide an underlying limitation on the minimum depth at which the impurity concentration can be usefully determined by this technique. This limitation exists even in the absence of the effects of interface states.

Vapor Deposition and Properties of Binary Arsenosilicate Glass Films

J. Wong

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The deposition characteristics of an argon-diluted SiH_4-$AsCl_3$-O_2 reaction system for the chemical vapor deposition of binary arsenosilicate glass films have been studied systematically as a function of substrate temperature and flow rates of the reactants. Film composition in the range 0 to 20 mole per cent (m/o) As_2O_3 can be controlled reproducibly at deposition rates as high as 1000Å min^{-1}. Properties such as composition uniformity, etch rate, d-c dielectric strength, and moisture resistance have been measured and their compositional dependence determined.

In an earlier communication (1) the chemical vapor deposition of binary arsenosilicate glasses in the range 0-20 mole per cent (m/o) As_2O_3 from a one-liquid source system consisting of argon-diluted mixtures of SiH_4, O_2, and $AsCl_3$ vapor has been described. Preliminary heat treatments of these binary films deposited on silicon showed that the so-far reported "glass damage" in the process of solid-to-solid state diffusion of arsenic into silicon (1-3) is strongly dependent on the composition of the arsenosilicate films; the higher the concentration of As_2O_3, the lower the temperature required to bring about the damage.

Key words: CVD, arsenic diffusion sources into silicon.

The object of the present paper is twofold: (*i*) to investigate systematically deposition characteristics such as deposition rate and chemical composition of the deposited films for the SiH_4-O_2-$AsCl_3$-Ar system as a function of substrate temperature and flow rates of

the reactant gases; and (*ii*) to determine film properties such as composition uniformity, etch rate, d-c dielectric strength, and moisture resistance, that are important in the consideration of using arsenosilicate glass films as n-type solid-state diffusion sources into silicon in the planar technology for constructing microelectronic devices and circuits.

Experimental

Materials.—One ohm-cm p-type[1] (100)-oriented silicon wafers, 2.5 cm in diameter and 0.5 cm thick were used as substrates for film deposition. These were heavily etched in a conc. HNO_3-conc. HF solution (3:1 by volume) and rinsed thoroughly in distilled water prior to deposition. The silane source used was semiconductor grade obtained from the Matheson Company as a calibrated 1% mixture in argon. Ultrapure $AsCl_3$ liquid from Alpha Inorganics was used. All other etching solutions, *e.g.*, HNO_3, HCl, HF, and NH_4F were either reagent or semiconductor grade.

Deposition apparatus.—The gas-flow system and vertical reactor used in the present study have been described elsewhere (1). The temperature of the hot stage in the vertical reactor was controlled to $\pm 5°$ at 300°C and $\pm 10°$ at 450°C during deposition. All flowmeters were calibrated with the respective gases or mixtures using two Brooks flow calibrators having capacities of 0-70 cc and 0-1000 cc. Except for the dielectric measurements, all films studied were of the order of 8000Å thick.

Furnace for heat-treatment.—A conventional horizontal diffusion furnace consisting of an electrically heated fused quartz tube having a projecting side arm for sample loading was used. Purified argon was used to purge the system at a few cc min^{-1} while not in use, and at 470 cc/min ($\sim$1 ft^3 hr^{-1}) while a sample was being heat-treated. The temperature of the constant temperature zone (1½ in. long) was controlled to within 3°C or better at 1100°C. Typical heat-treatment times were of the order of 10 min.

Growth rate and etch rate measurements.—For convenience, both the growth rate of films during deposition and the etch rate were performed by visual observation of the color of the glass film under a daylight fluorescent lamp. The color chart of Pliskin and Conrad (4) for thermally grown SiO_2 was used to evaluate the thickness of the films. The actual thickness of the arsenosilicate film may be 5% lower than the one obtained by color because of the higher refractive indices of arsenosilicate glasses ($\sim$1.55, depending on composition, compared to a value of 1.46 for thermal SiO_2). For deposition rate determinations, the color of the film and hence its thickness was recorded continuously with time during the deposition while the samples were in the reactor. The deposition rates were calculated from the slopes of these growth curves. For etch rate measurements, the initial thickness of the film was noted from deposition. The film was totally immersed into the etchant with constant agitation (by means of forceps holding the wafer) for a given period of time, then rinsed in distilled water dried with acetone. The magnitude of the slope of the dissolution curve gives the etch rate.

Because of the strong dependence of etch rate on the composition of the glass in a given etching solution, three solutions were used in order to make high As_2O_3 content glasses measurable within the time scale of the experiment. A buffered HF (BHF) solution consisting of a mixture of conc. NH_4F solution and conc. HF (10:1 by volume) was used for glasses varying from 0-6 m/o As_2O_3. A second solution consisting of a 1:10 (by volume) mixture of the above BHF solution and distilled water was used for glasses varying from 0-16 m/o As_2O_3, and a third 1:100 BHF:H_2O solution was used for glasses having concentration greater than 14 m/o As_2O_3. Overlappings of glass composition allowed the etch rates of the same glass to be compared in different solutions.

Determination of film composition.—The composition of as-deposited films were determined nondestructively from the infrared spectra by calculating the optical density ratio of the As-O band at 930 cm^{-1} and the Si-O band at 1060 cm^{-1} and using a predetermined *IR* ratio-composition calibration curve (1). A Perkin-Elmer 457 double beam spectrophotometer was used to record the *IR* spectra. Reflection loss due to the silicon substrate were compensated for in the reference beam by a silicon wafer of the same resistivity and type.

Dielectric strength.—For dielectric strength measurements glass films of about 2000Å thick and of various compositions were deposited on n-type silicon wafers. MOS capacitors were constructed and consisted of a 5000Å top layer of sputtered Mo that was delineated by standard lithographic techniques to a pattern of 0.45 mm diameter circular dots. The current-voltage characteristics of these capacitors at room temperature were measured with a Tektronix transistor curve tracer. Twenty capacitors were measured per sample. The reported strength for each sample is the arithmetic average of these 20 maximum voltages without breakdown divided by the film thickness measured ellipsometrically.

Results

Deposition rate and film composition.—Two parameters are of interest in the preparation of multicomponent films by chemical vapor deposition. These are the deposition rate and film composition. For the deposition of binary arsenosilicate glasses using the SiH_4-$AsCl_3$-O_2-Ar reaction system, the above parameters were studied systematically as a function of the substrate temperature during deposition and flow rates of the reactant and carrier gases.

In Fig. 1 the amount of As_2O_3 incorporated into the film is plotted as a function of substrate temperature at two different O_2 flow rates while the flow rates of the remaining gases were held constant. The composition is little or not affected by the O_2 flow rate (for which the molar ratio of O_2 to total SiH_4 and $AsCl_3$ was always greater than 10:1). The deposition rate, however, is strongly dependent on the O_2 flow rate as shown in Fig. 2 in which an Arrhenius-type plot of log deposition rate *vs.* reciprocal absolute temperature (of the substrate) is given.

In Fig. 3, the deposition rate is plotted as a function of the flow rate of Ar into the $AsCl_3$ liquid at substrate temperatures of 300°, 350°, and 450°C while the flow rates of the Ar carrier gas and SiH_4 were held constant. Note the lower flow rate of O_2 used at 300°C. At all three temperatures, the deposition rate increases initially with increasing $AsCl_3$ introduced into the reactor and decreases at higher Ar flow rates into $AsCl_3$. The chemical composition of the resultant film shows a similar but more systematic trend as shown in Fig. 4. The concentration of As_2O_3 in the glass increases initially with the amount of $AsCl_3$ introduced into the reactor and decreases again at high Ar flow rates into the $AsCl_3$ source. An interesting feature is that the lower the substrate temperature, the greater is the amount of As_2O_3 incorporated into the glass film. The dotted line in Fig. 4 is the film composition calculated from the molar ratio of $AsCl_3$ to SiH_4 in the reaction mixture assuming stoichiometric oxidation of both reactants.

The deposition parameters were also studied as a function of SiH_4 flow rate at 450°C and at constant flow rates of Ar, O_2, and Ar into $AsCl_3$. The deposition rate increases monotonically with SiH_4 flow rate as shown in Fig. 5a while the As_2O_3 content decreases monotonically as shown in Fig. 5b. The dotted line in

[1] For dielectric strength measurements, n-type wafers of similar resistivity and orientation were used.

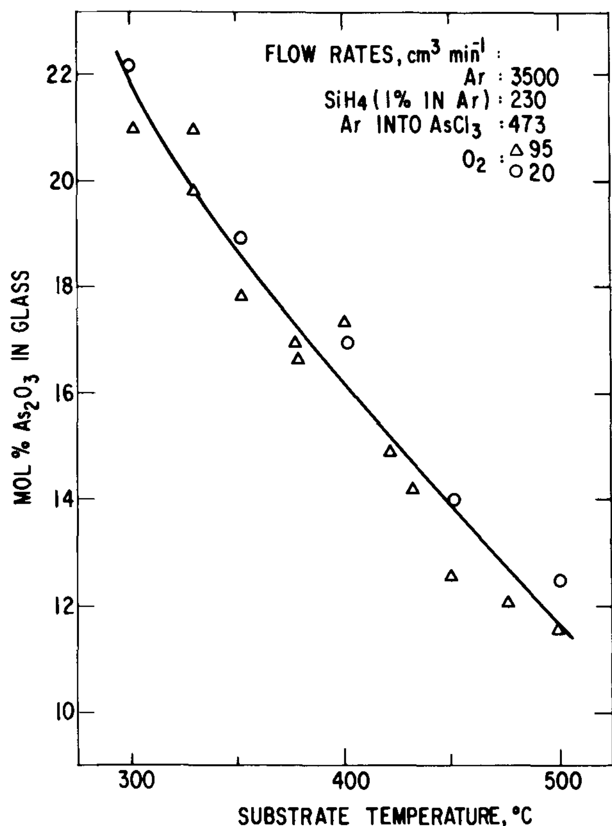

Fig. 1. Glass composition vs. substrate temperature at two given sets of flow rates of reactants.

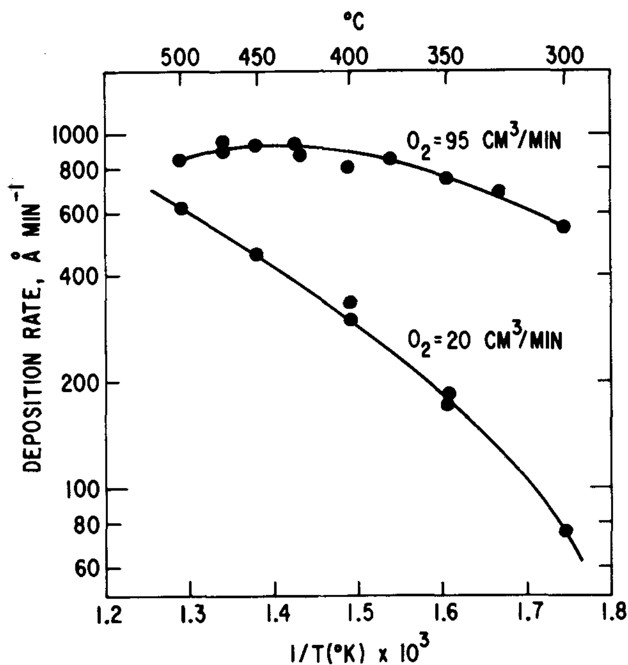

Fig. 2. Deposition rate vs. reciprocal temperature of substrate at two flow rates of O_2. All other flow rates are given in Fig. 1.

Fig. 5b represents the film composition calculated from the molar concentration of SiH_4 and $AsCl_3$ in the reaction mixture assuming stoichiometric oxidation of each component.

Etch rate.—In Fig. 6, the etch rate of as-deposited arsenosilicate films is plotted as a function of As_2O_3 content in the films in various HF solutions. In a standard buffered HF (BHF) solution glasses in the range 0-6 m/o As_2O_3 deposited at a substrate temperature of 450°C show an approximate twofold decrease in the etch rate in going from as-deposited films [curve (a), Fig. 6] to the same films after heat-treatment in Ar at 800°C for 10 min [curve (b), Fig. 6]. Of interest, too, is the dependence on the substrate temperature during deposition of the etch rate in a 1:100 (by volume) solution of BHF and water of as-deposited films. Films deposited at 300°C [curve (e), Fig. 6] have higher etch rates and a greater etch rate dependence on film composition than those deposited at 450°C [curve (f), Fig. 6].

Composition uniformity.—The composition uniformity of as-deposited films have been studied as a function of film thickness (*i.e.*, layer uniformity) as well as the position along a diameter across the film surface

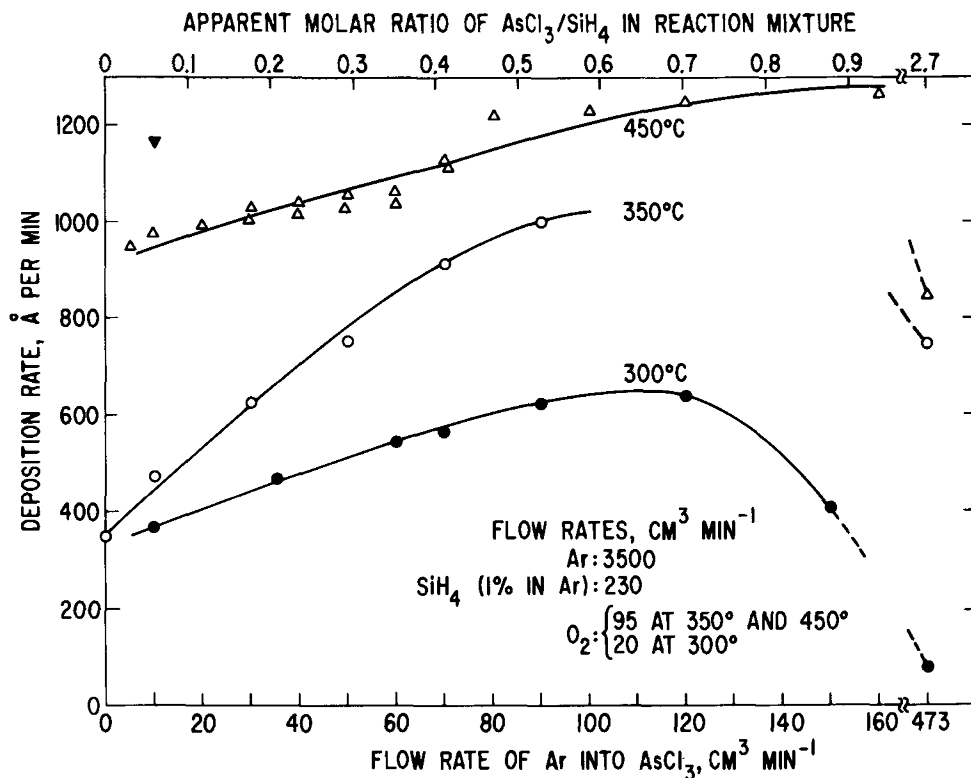

Fig. 3. Deposition rate vs. flow rate of Ar into $AsCl_3$ liquid source at various substrate temperatures, all other flow rates being held constant at a given temperature. The apparent molar ratio of $AsCl_3/SiH_4$ is calculated from the flow rates assuming saturation of $AsCl_3$ in Ar and from the known vapor pressure (10 mm Hg) (5) of $AsCl_3$ at room temperature. The ▼ point is for Ar flow rate of 1750 cc min^{-1} at 450°C, all other flow rates being invariant.

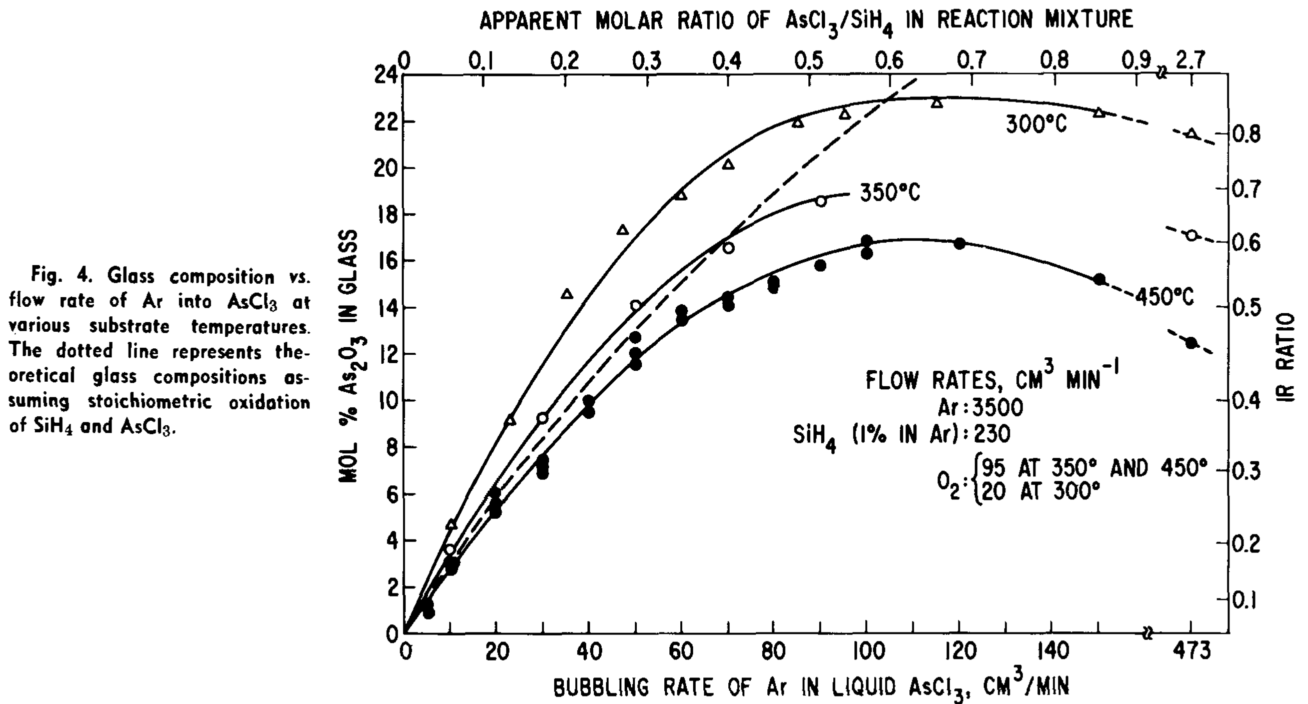

Fig. 4. Glass composition vs. flow rate of Ar into $AsCl_3$ at various substrate temperatures. The dotted line represents theoretical glass compositions assuming stoichiometric oxidation of SiH_4 and $AsCl_3$.

(*i.e.*, point uniformity). The layer uniformity was studied using the technique of *IR* spectroscopy by following the absorbance ratio of the As-O band at 930 cm^{-1} and the Si-O band at 1060 cm^{-1} as the films were etched progressively in the appropriate HF solution depending on film composition given in Fig. 6. The results are plotted in Fig. 7 as *IR* absorbance ratio for these two bands *vs.* film thickness (measured visually by color) at various over-all composition of the as-deposited films ranging from 21.5 to 1.5 m/o As_2O_3. Films with over-all compositions of 9.6-21.5% As_2O_3 were richer in As_2O_3 during the initial stage of deposition (the first 5000Å or so) as shown by the progressive increase of the *IR* ratio as the films were etched down. The possibility of a preferential etching of the SiO_2 component in the 1:100 BHF or 1:10 BHF

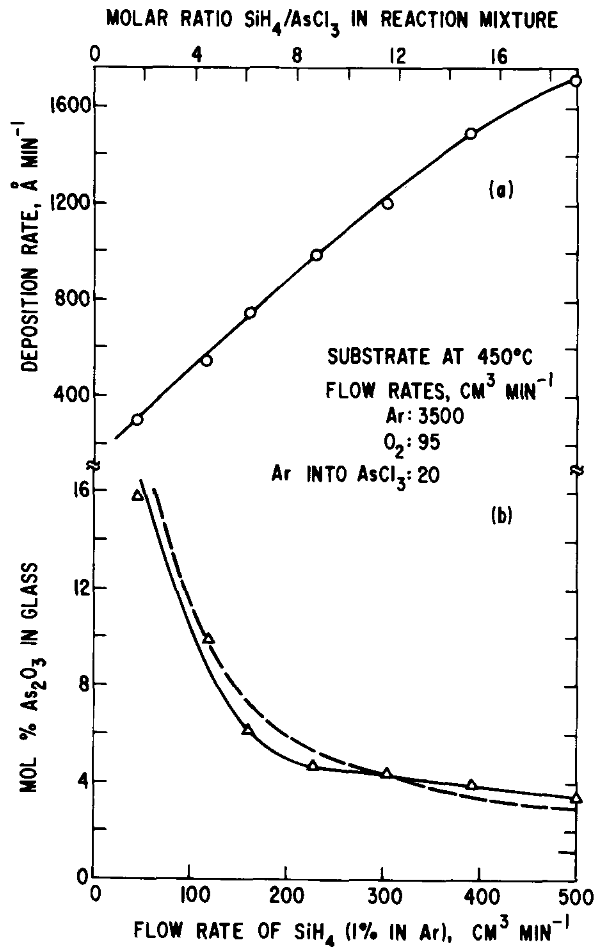

Fig. 5. (a) Deposition rate and (b) glass composition vs. flow rate of SiH_4 at 450°C. All other flow rates were held constant. The dotted line represents theoretical glass composition assuming stoichiometric oxidation of SiH_4 and $AsCl_3$.

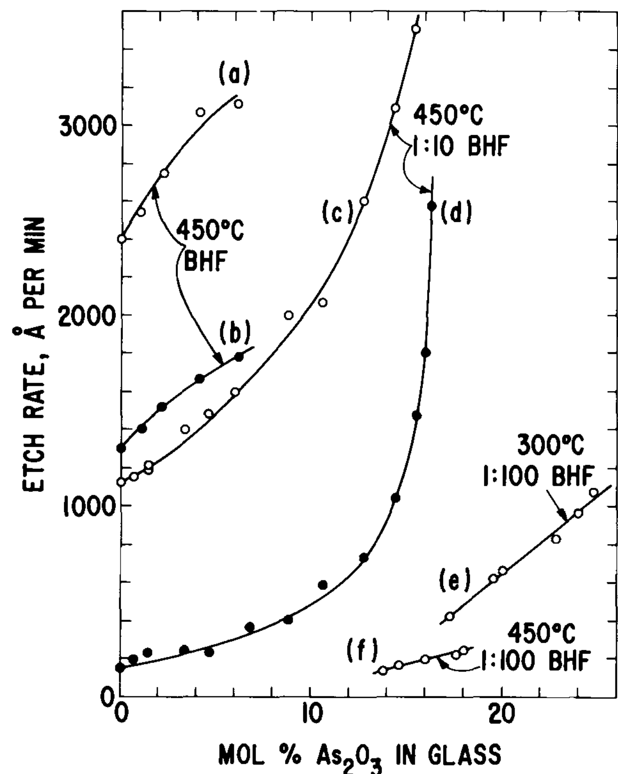

Fig. 6. Etch rate of as-deposited (open circles) and heat-treated (closed circles) arsenosilicate films vs. glass composition in various HF solutions. All heat-treatments performed at 800°C in Ar for 10 min.

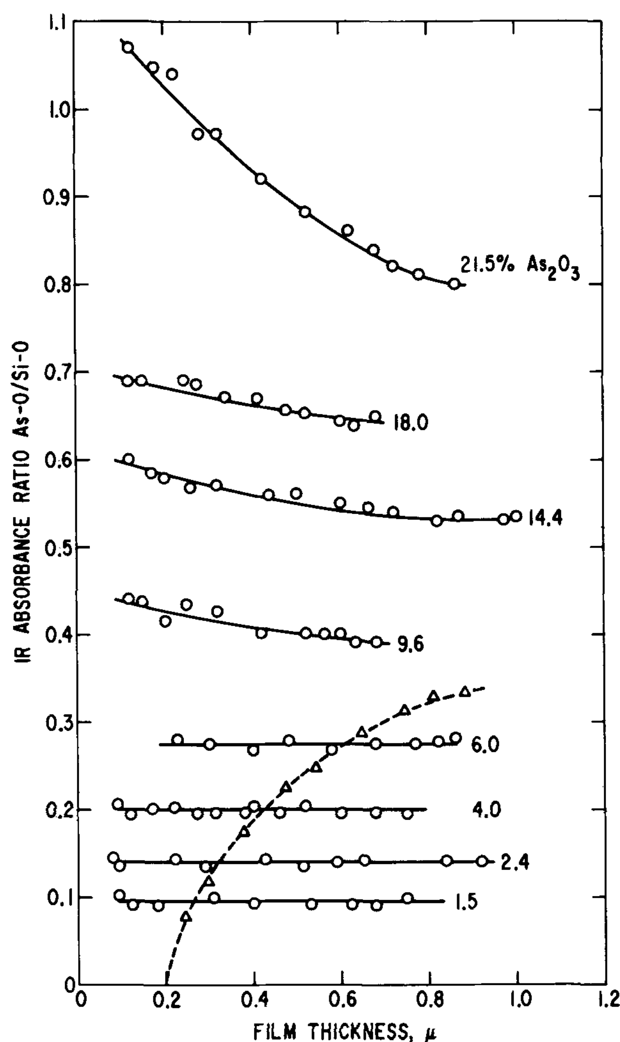

Fig. 7. Layer uniformity of as-deposited glass films at various over-all compositions determined from the *IR* ratios of the as-deposited films using a previously published calibration curve (1). The triangles are data for a binary film deposited on a layer of 2000Å SiO_2 on silicon.

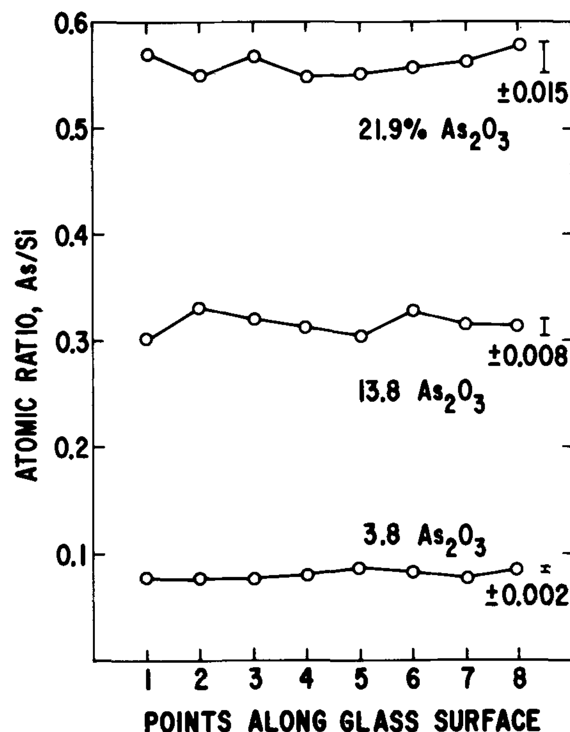

Fig. 8. Point uniformity of as-deposited glass films at various over-all composition. Analysis by x-ray microprobe. The bars denote instrumental errors.

solution can be ruled out because (*i*) if preferential etching in these dilute aqueous HF solutions were to take place, As_2O_3 and not SiO_2 would be leached out first because of the much higher solubility of As_2O_3 in H_2O, and (*ii*) in a control experiment in which a layer of pure SiO_2 (2000Å) had been deposited prior to the deposition of the binary film, the *IR* ratio dropped progressively to zero (triangles in Fig. 7), as expected, in the absence of preferential etching of the SiO_2 component, as the top binary film was etched down.

To examine composition uniformity across the glass surface, the amounts of As and Si in the glass films were analyzed by the technique of x-ray microprobe operated in the scanning mode. The x-ray beam was focused down to 1μ in diameter and the scan rate was set at 2.5 mm min^{-1}. The beam was allowed to probe the sample for 10 sec after which 8 sec were allowed for computation (by an on-line computer). Under the above scanning conditions each point in Fig. 8 represents the average composition over a length of 420μ of the sample and the separation between successive points is of the order of 320μ, the distance traversed by the x-ray beam in 8 sec during which the previous point data were being computed. Within the instrumental error, composition is quite uniform across the as-deposited films in the over-all composition range of 3.8 to 22 m/o As_2O_3.

In order to examine the composition uniformity further on a microscopic scale, the action of conc. HCl on the as-deposited binary arsenosilicate films was studied as a function of As_2O_3 content in the glass. Changes in the films were followed by infrared spectroscopy. The results are given in Table I. Films with 19 m/o As_2O_3 or more showed preferential leaching of the As_2O_3 component in a matter of minutes upon immersion in conc. HCl. An example is given in Fig. 9 for a film containing 21.5 m/o As_2O_3 as-deposited. A progressive decrease in the As-O absorbance at 930 cm^{-1} was observed after 1 min in conc. HCl at room temperature. After 20 hr the As-O intensity was markedly reduced with the simultaneous appearance of the OH band at 1625 and 3300 cm^{-1}. The film appeared optically continuous immediately after the 20 hr conc. HCl treatment, but was found to craze completely 3 months later. Control experiments indicated that pure As_2O_3 powders (crystalline) dissolve spontaneously in conc. HCl while a film of as-deposited CVD SiO_2 was not at all affected by the acid in 20 hr (Table I).

Dielectric strength.—The dielectric strength of as-deposited arsenosilicate glass films is plotted in Fig. 10 as a function of As_2O_3 content in the film and decreases monotonically with increase in As_2O_3 concentration. The strength of pure SiO_2 agrees quite well with those reported in the literature (6-8) for CVD SiO_2

Table I. Action of conc. HCl on as-deposited films containing various mole per cent As_2O_3

m/o As_2O_3 in as-deposited film	Substrate temp. during deposition	Action of conc. HCl
0 (Pure SiO_2)	450°	No action after 20 hr.
4.5	300°	No action after 21 hr.
12.5	450°	No action after 48 hr.
16.0	450°	No action after 22 hr.
19.0	350°	No action after 1 hr; As_2O_3 leached out after 65 hr, and OH bands at 1625 and 3300 cm^{-1} appeared in the *IR* spectrum.
21.5	300°	As_2O_3 leached out progressively after 1 min. More markedly after 20 hr—see Fig. 9.

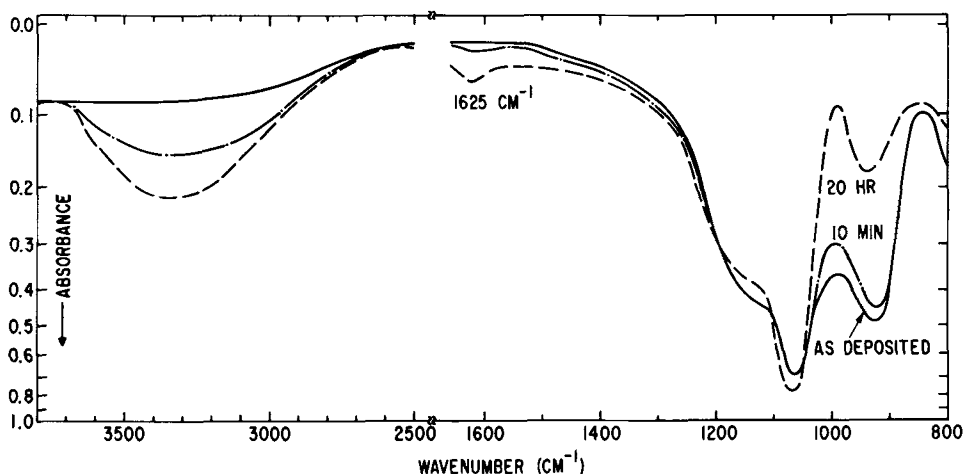

Fig. 9. Infrared spectra of a 21.5 m/o As_2O_3 glass (8000Å thick) treated for various times in conc. HCl.

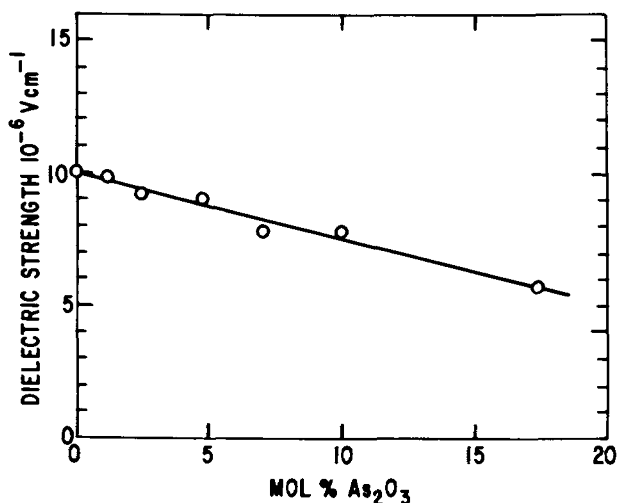

Fig. 10. Dielectric strength at room temperature of as-deposited films vs. composition.

deposited from SiH_4 and O_2 on silicon substrate at 500° and 400°C.

Moisture resistance.—In order to study water attack on the as-deposited binary glasses, films containing various amounts of As_2O_3 were exposed in controlled atmospheres of 30, 80, and 100% relative humidity at room temperature.[2] The water uptake by the films was followed by *IR* spectroscopy in the OH absorption regions at 1630 cm^{-1} and 3300 cm^{-1}, while the vibrational spectrum of the glass in the range 1400-250 cm^{-1} was used to follow any intrinsic change in the arsenosilicate structure. The results are given in Table II. Films with 8.8 m/o As_2O_3 or less suffer no moisture attack at low humidity over a period of 570 hr (see column 2 of Table II). At higher humidities (80-100%) slight water uptake in these films were detected after 100 hr or so; but the vibration bands of the arsenosilicate was not shifted at all. A film with 19 m/o As_2O_3 absorbed water even at a low humidity after 65 hr. The vibration bands of the arsenosilicate were progressively shifted (intensity as well as frequency) with increasing humidity and time. Figure 11(a) shows the progressive increase in intensity and frequency of the Si-O band at 1060 cm^{-1} and decrease in intensity of the As-O band at 930 cm^{-1} with time in a 100% relative humidity. After 2500 hr, the surface of the film appeared frosted. A micrograph of the frosted surface is shown in Fig. 12(a). A parallel, but more drastic, test of water uptake was performed in boiling distilled water. As-deposited films with 16 m/o As_2O_3 or less showed no water absorption and no change in the infrared spectrum after an hour immersion in boiling water. Films with 19 m/o As_2O_3 and up, however, showed OH absorption and spectral change in the infrared [Fig. 11(b)], and complete crazing in a matter of minutes of immersion [Fig. 12(b)]. The action of boiling water on these binary films containing various amounts of As_2O_3 is quite similar to that of conc. HCl shown in Table I.

[2] These constant humidities were generated in the closed space of a dessicator using saturated solutions of $CaCl_2 \cdot 6H_2O$, $(NH_4)_2SO_4$ (9) and distilled water respectively.

Discussion

Deposition reactions.—At low temperatures, 240°-450°C, the oxidation of silane is shown by Strater (10) to follow the reaction

$$SiH_4 + O_2 \rightarrow SiO_2 + 2H_2 \quad [1]$$

stoichiometrically. Furthermore the deposition rate of CVD SiO_2 was lowered when the same reaction mixture was diluted with hydrogen instead of an inert carrier gas such as Ar or N_2 (11). These two studies show clearly that H_2 is the gaseous reaction product in the oxidation of SiH_4 and not H_2O as was assumed earlier by Goldsmith and Kern (12), presumably on

Table II. Moisture attack on as-deposited glass films in various controlled atmospheres

m/o As_2O_3	Relative humidity 30%	80%	100%
0.8	No attack after 570 hr.	After 144 hr H_2O absorption at 1625 and 3400 cm^{-1} detected. The Si-O band at 1060 cm^{-1} and As-O band at 930 cm^{-1} were *not* shifted.	Water absorption detected after 100 hr. Spectrum of glass unaffected up to 2500 hr.
2.0	No attack after 570 hr.	After 144 hr H_2O absorption at 1625 and 3400 cm^{-1} detected. The Si-O band at 1060 cm^{-1} and As-O band at 930 cm^{-1} were *not* shifted.	Water absorption detected after 100 hr. Spectrum of glass unaffected up to 2500 hr.
4.0	No attack after 570 hr.	After 144 hr H_2O absorption at 1625 and 3400 cm^{-1} detected. The Si-O band at 1060 cm^{-1} and As-O band at 930 cm^{-1} were *not* shifted.	Water absorption detected after 100 hr. Spectrum of glass unaffected up to 2500 hr.
8.8	No attack after 570 hr.	After 144 hr H_2O absorption at 1625 and 3400 cm^{-1} detected. The Si-O band at 1060 cm^{-1} and As-O band at 930 cm^{-1} were *not* shifted.	Water absorption detected after 100 hr. Spectrum of glass unaffected up to 2500 hr.
19.0	After 65 hr H_2O absorption at 1630 and 3300 cm^{-1} detected. No change in the *IR* bands of the glass.	After 144 hr, there is progressive change in the *IR* spectum. cf. Fig. 11(a).	Progressive change in the *IR* spectrum [see Fig. 12(a)]. Glass surface became frosted [see Fig. 12(a)].

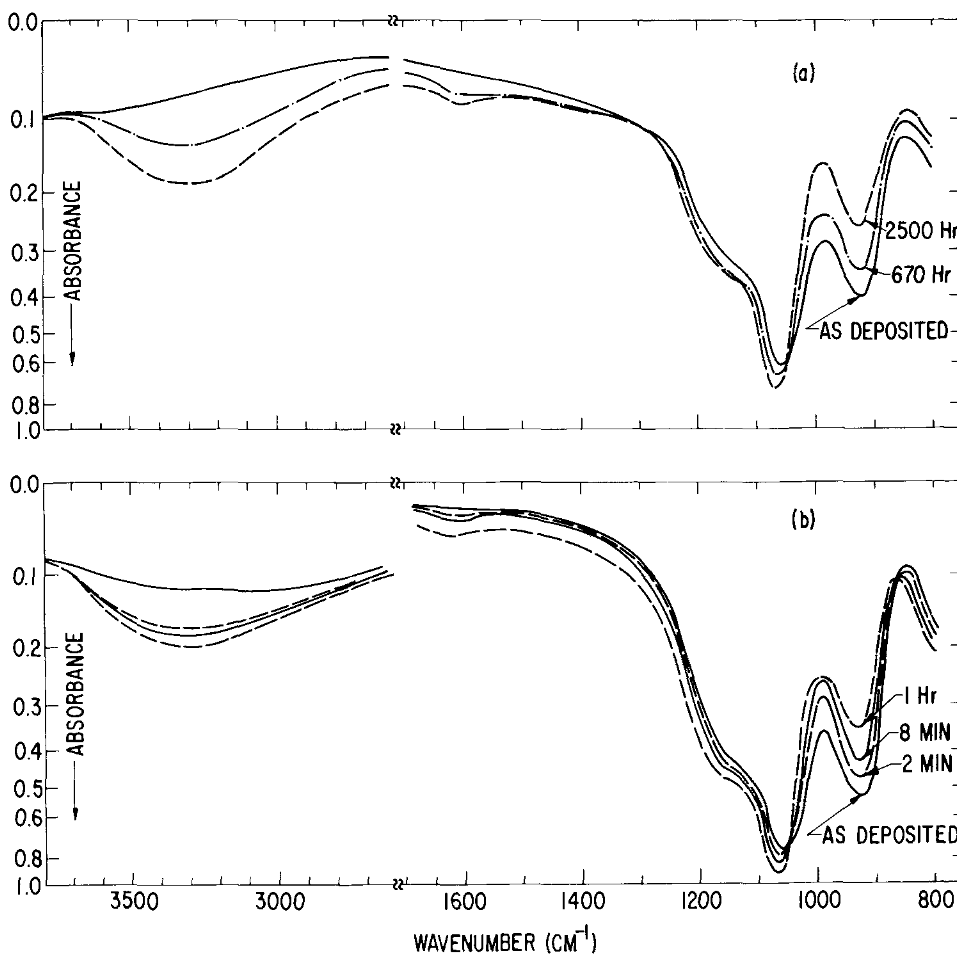

Fig. 11. Infrared spectra of a 19 m/o As_2O_3 film (8000Å thick) treated for various times in (a) 100% relative humidity (room temperature) and (b) boiling distilled water.

the basis that the free energy change for the reaction

$$SiH_4 + 2\,O_2 \rightarrow SiO_2 + 2H_2O \qquad [2]$$

has a larger negative value (−300 kcal mole^{-1}) than reaction [1] (−215 kcal mol^{-1}) (13) at the deposition temperature.

In the $(C_2H_5O)_4Si$-$AsCl_3$-O_2 system used previously for the deposition of binary arsenosilicate glasses (2, 3) the oxidation of $AsCl_3$ appeared to be initiated by the hydrolysis of $AsCl_3$ by the water produced in the thermal pyrolysis of $(C_2H_5O)_4Si$ to form $As(OH)_3$ which was then thermally decomposed to yield the trioxide. The as-deposited film, however, contained an appreciable amount of "water" as shown in the *IR* spectrum (3). In our present one-liquid source SiH_4-$AsCl_3$-O_2 system, however, hydrolysis of the $AsCl_3$ vapor is unlikely because H_2 and not H_2O is produced in the oxidation of SiH_4. The oxidation of $AsCl_3$ however may be initiated in the presence of H_2 as follows

$$4AsCl_3 + 3\,O_2 + 6H_2 \rightarrow 2As_2O_3 + 12HCl \qquad [3]$$

Hydrochloride gas was detected as a reaction product in the effluent gas. Control experiments showed that no film formation occurred when an argon-diluted mixture of $AsCl_3$ and O_2 was passed over the heated silicon substrate in the range 300°-500°C. It appears therefore that the deposition of the binary As_2O_3-SiO_2 mixture is the result of the intermediate reaction given in Eq. [1] and [3] and can be represented by an over-all stoichiometric reaction

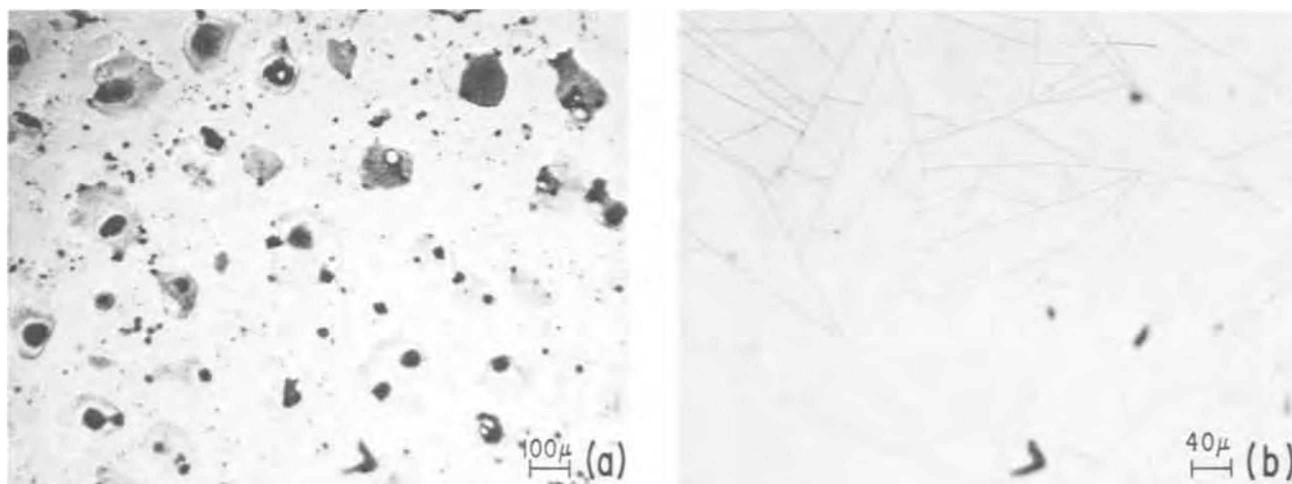

Fig. 12. Micrographs of film surface of a 19 m/o As_2O_3 film after exposing (a) 2500 hr in 100% humidity at room temperature (magnification: 69X) and (b) 1 hr in boiling distilled water (magnification: 170X).

$$3SiH_4 + 4AsCl_3 + 6\,O_2 \rightarrow 2As_2O_3 + 3SiO_2 + 12HCl \quad [4]$$

The final composition of the deposited film depends, of course, on the molar ratio of the reaction gases in the reaction mixture. However, no OH absorption was detected in the 2.7μ region of the *IR* spectrum of any of the deposited films.

Film composition.—In the presence of excess O_2, the film composition was found to be independent of the O_2 flow rate at constant flow rates of both SiH_4 and $AsCl_3$ (Fig. 1). The amount of As_2O_3 incorporated into the glass film decreases with increase in substrate temperature. This suggests a decrease in the sticking coefficient (14) of the As_2O_3 component with an increase in substrate temperature, which in turn can be rationalized in view of the short liquidus range of As_2O_3 (m.p. 313° and b.p. 460°C) and hence high vapor pressure in the range 300°-500°C of investigation (15).

The composition dependence on substrate temperature during deposition is further illustrated by the data given in Fig. 4 in which the composition of the deposited films was plotted *vs.* the Ar flow rate into the $AsCl_3$ source at substrate temperatures of 300°, 350°, and 450°C. At any given set of flow rates of reactant gases, the amount of As_2O_3 incorporated into the film decreases with increase in substrate temperature. At each temperature, however, the As_2O_3 content in glass increases with initial increase in the flow rate of Ar into $AsCl_3$ at constant flow rate of SiH_4, reaches a maximum at about 100 cc min^{-1} and decreases as the Ar carrier gas into $AsCl_3$ is further increased. This behavior, which is independent of the substrate temperature during deposition, appears to arise as a result of undersaturation of the Ar carrier gas at high flow rates into the $AsCl_3$ liquid source, and not as a result of changes in the reaction mechanism. Hence, the term "apparent molar ratio" is used for the upper horizontal scale in Fig. 4.

Under saturation conditions, the observed composition in the deposited glass follows quite closely the theoretical value (dotted line in Fig. 4) calculated from the molar ratio of $AsCl_3$ to SiH_4 in the reaction mixture, assuming stoichiometric oxidation of the reactants. A similar conformity is found between the experimental and calculated [dotted line in Fig. 5(b)] compositions for films deposited at 450°C with varying SiH_4 flow rate at constant flow rates of the remaining reactant gases. Furthermore, the oxidation rate of SiH_4 to SiO_2 is quite independent of the amount of co-deposited As_2O_3 as shown by the constancy of the *IR* absorbance of the Si-O band at 1060 cm^{-1} in a series of film deposited at 450°C and at constant time of deposition and flow rates of all reactant gases while the flow rate of Ar into the $AsCl_3$ liquid source was being varied in the saturation range (5-100 cc min^{-1}) (19).

Deposition rate.—In general, the deposition rate measured as the time rate of growth of film thickness of binary arsenosilicate films using the present one-liquid source system increases with increase flow rate of O_2 (Fig. 2), $AsCl_3$ (in the saturation range, Fig. 3) and SiH_4 (Fig. 5a) and with a decrease in the flow rate of the carrier gas (the ▼ point in Fig. 3).

In a chemical vapor deposition process, the over-all observed deposition rate is governed by both the chemical reaction rate and the rate of physical processes such as condensation-evaporation (sticking coefficient) nucleation and growth. When the reaction rate is the limiting factor, *i.e.*, chemical rate $<<$ physical rate, the deposition rate at a given temperature may be given by

$$\text{dep. rate} \sim k\,[SiH_4]^m\,[AsCl_3]^n\,[O_2]^p \quad [i]$$

where the square brackets denote concentrations of the respective reactants, k is the rate constant, and m, n, and p are positive exponents, fractional or integral. From the data in Fig. 5(a) which shows the deposition rate at 450°C as a function of SiH_4 flow rate while the flow rates of $AsCl_3$, O_2, and Ar carrier gas were held constant, a plot of log (dep. rate) *vs.* log (SiH_4 flow rate) gives a slope of 1.0 ± 0.1 which is the value of m under the above deposition conditions.

The temperature dependence of deposition rate shown in Fig. 2 at two O_2 flow rates is interesting. At both O_2 concentrations, the log (dep. rate) *vs.* reciprocal temperature plot is non-Arrenhius implying a temperature dependence of the "over-all activation energy," which is larger at low O_2 concentration.

At a given set of reactant flow rates, a reduction of the carrier gas flow rate from 3500 cc min^{-1} to 1750 cc min^{-1} gave rise to an increase of deposition rate from 990Å min^{-1} to 1180Å min^{-1}. Similar observations have been reported in the chemical vapor deposition of SiO_2 from the SiH_4-O_2-N_2 system (10) and boron from the BCl_3-H_2-He system (20). In the latter system, Gruber (20) found that the deposition rate of boron varies inversely with the square of the carrier gas partial pressure.

Film Properties

Nature of as-deposited films.—A knowledge of the basic chemical nature and compositional uniformity of vapor-deposited binary films is a very important prerequisite to the understanding of their properties such as etch rate, dielectric strength, moisture resistance, and heat-treatment characteristics. Preliminary x-ray diffraction studies showed that the binary As_2O_3-SiO_2 films are amorphous in nature (3, 21). Until recently (18) it was not clear whether vapor-deposited binary silicate glasses such as the borosilicates (16, 17) and phosphosilicates (17) are really true chemical mixtures like the bulk materials prepared by quenching homogeneous mixtures from the liquid state, or mechanical mixtures of the end components matrix-isolating one another. In a recent study, advantages have been taken of the ability of the SiH_4-B_2H_6-O_2-Ar reaction system to allow vapor deposition of binary borosilicate film from 0-100 m/o B_2O_3, whereby the vibrational spectra of these mixtures could be studied by *IR* absorption spectroscopy across the whole composition range. From an analysis of the spectral distributions of the Si-O-Si, B-O-Si, and B-O-B bonds as a function of composition and comparison with those from a simple random distribution model, Tenney and Wong (18) showed that vapor-deposited binary borosilicates are true chemical mixtures, at least in the range 0-60 m/o B_2O_3, with the formation of Si-O-B linkages, and not mechanical mixtures of B_2O_3 and SiO_2.

Although such a 3-center bond distribution analysis is not possible in the narrow composition region (0-20 m/o As_2O_3) of the As_2O_3-SiO_2 system, some indirect experimental findings are of interest. In the *IR* spectrum of pure crystalline As_2O_3 (22, 23) strong absorption bands are found at 351, 493, 815 cm^{-1} and relatively weaker bands at 914 and 1044 cm^{-1}. In the vitreous state (24), the strong band 815 cm^{-1} broadens and absorption in the 1050 cm^{-1} region is merely observable. In vapor-deposited arsenosilicate films, a distinct and relative strong band at 930 cm^{-1} appeared as shown in Fig. 9. This band has been attributed by Arai and Terunuma (3) to a red shift of the very weak band of 1044 cm^{-1} for pure As_2O_3, although from intensity consideration a blue shift of strong pure As_2O_3 band at 815 cm^{-1} is more probable. Notwithstanding the dynamical origin of this band at 930 cm^{-1}, it is worth noting that this band is not present in the pure As_2O_3 spectrum, and that its intensity varies proportionally with the amount of As_2O_3 incorporated into the glass found by chemical analysis (1). These two observations imply that As-O oscillators in the mixture are in a different chemical environment than in pure As_2O_3, and that vapor-deposited As_2O_3-SiO_2 films are not likely mechanical mixtures of the end components. The conclusion is further substantiated in the HCl etching results (Table I) which shows that no

preferential leaching of As_2O_3 occurs until the composition is exceeded by 16 m/o As_2O_3. If the mixtures were mechanical, the pure As_2O_3 component (which is very soluble in conc. HCl) would be leached out preferentially regardless of film composition.

The composition appears to be uniform from point to point across the film surface as shown in Fig. 8. Good layer compositional uniformity can be obtained only with low As_2O_3 films (Fig. 7). For the deposition of high As_2O_3-content films, there seems to be a change in the over-all reaction kinetics and/or a change in the sticking coefficient of As_2O_3 as the film grows. In light of the variation of the *IR* ratio with film thickness in high As_2O_3-content glass, it is estimated that the previously published calibration curve (1) of *IR* ratio *vs.* m/o As_2O_3 is accurate to within 2 m/o As_2O_3 in the over-all composition range of 9.6-18.0 m/o As_2O_3. Above 20 m/o As_2O_3, deviations of as much as 4 m/o As_2O_3 may be expected for films less than 5000Å thick. Films having 6.0 m/o As_2O_3 and less have very good layer uniformity as shown by the bottom four curves in Fig. 7.

Etch rate, moisture resistance, and dielectric strength. —Having gained an insight into the chemical nature and composition uniformity of the as-deposited binary films, the composition dependence of etch rate, moisture resistance, and dielectric strength can easily be rationalized in terms of the corresponding properties of the end components. The monotonic increase in etch rate in various HF solutions with increase in As_2O_3-content in these films is no doubt due to the relatively higher solubility of the pure As_2O_3 end component, which dissolves even in pure water. When heat-treated for 10 min in Ar at 800°C, the etch rate drops to a half or more of its as-deposited value, but the monotonicity with composition still persists (Fig. 6). The phenomenon is often attributed to the so-called "densification" effect (25, 26) which, in the case of CVD SiO_2, is accompanied by increases in the film density and refractive index when films deposited at low temperatures are heat-treated above the deposition temperature.

In view of the large differences in thermal and evaporation characteristics of pure As_2O_3 and SiO_2, the decrease in absorbance of the As-O band at 930 cm^{-1} upon heat-treating as-deposited arsenosilicate films (27) appears to suggest a change in composition due to evaporation loss of the As_2O_3 component. Detailed spectral and chemical analyses (27), however, show that structural change and not composition variations are responsible for the observed shifts in band frequency and maximum absorbance in the resultant heat-treated films. The decrease in film etch rate upon heat-treatment is, therefore, one of structural origin. Besides the effects of structural changes, the deposition history also affects the film etch rate. For instance, as shown in Fig. 6, films deposited at 300°C are etched at a higher rate than those deposited at 450°C in a given etching solution.

Film deterioration by moisture attack is also strongly dependent on composition as well as the relative humidity (see Table II). With increase in humidity and time of exposure, water pickup can be detected in low As_2O_3 content films as shown by the appearence of the OH bands at 3300 cm^{-1} and 1630 cm^{-1} in the *IR* spectrum (Fig. 11). The absorbed "water" is strongly held in the glass lattice and cannot be removed even when the moist films are heated to 800°C as indicated by the persistence of the OH bands in the resultant spectrum. Prolonged exposure of a high As_2O_3 film (19 m/o) in a 100% R.H. atmosphere led to drastic film deterioration indicated by a pronounced change in both the Si-O and As-O absorption [Fig. 11(a)] as well as visual frosting of the film as shown in Fig. 12(a). The moisture attack in this case must involve a conversion of the As_2O_3 component to some arsenic compounds which does not absorb in the *IR* at 930 cm^{-1}. This may be contrasted in the case of the boiling water attack in which As_2O_3 can conceivably be leached out of the film giving rise to a decrease in intensity of the As-O band at 930 cm^{-1} [Fig. 11(b)] (27).

The d-c dielectric strength for as-deposited SiO_2 from silane oxidation has been reported by various authors (6-8, 12), with values ranging from 2.5 to 12.0×10^6 V cm^{-1} under different deposition conditions, oxide thickness, and the capacitor structure. These are collected in Table III. Despite the diversity of results for the strength reported for CVD SiO_2, the systematic decrease in dielectric strength of as-deposited arsenosilicate films with increase As_2O_3 content is noteworthy (Fig. 10). The tendency of dielectric breakdown whether thermal or electrical (28) must no doubt increase with the As_2O_3 concentration in the binary film.

Conclusions

The deposition characteristics of binary arsenosilicate glass films using the present one-liquid SiH_4-$AsCl_3$-O_2-Ar system have been studied systematically as a function of reactant flow rates and substrate temperature. Film composition and deposition rates have been evaluated reproducibly under various sets of deposition variables. High deposition rates (500-1200 Å/min) at relatively lower substrate temperatures (300°-500°C) are the main advantage of the present system over the so-far reported two-liquid source systems based on $(C_2H_5O)_4Si$ and $AsCl_3$ (2, 3, 29-31). In addition, the deposited films are relatively free from water contamination, which is not a byproduct of the SiH_4 oxidation (10). Furthermore, the film composition is not restricted in a narrow region of high As_2O_3 concentration, but can be monitored at will and controllably in the range 0-20 m/o As_2O_3 or higher. This enables film properties such as composition uniformity, etch rate, dielectric strength, and moisture resistance to be studied systematically as a function of chemical composition.

Thermal Stresses in CVD Films: The Case of Binary Arsenosilicate Glasses

J. Wong

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The heat-treatment characteristics and surface morphology of binary arsenosilicate glass films vapor-deposited on silicon have been studied systematically as a function of temperature and film composition. Initial heat-treatments in Ar at 800°C and up indicated that the thermal stresses generated in the film arising from a mismatch of expansion coefficient with the silicon substrate are largely responsible for the observed film detachment from the substrate. The higher the As_2O_3 content in the glass, the lower is the temperature required to bring about the detachment. However, when the amount of As_2O_3 in the deposited film is substantially reduced [to 0.5 mole per cent (m/o) As_2O_3] film detachment can be eliminated altogether even at temperatures as high as 1100°C. Prolonged heat treatments of these low As_2O_3 films yield very uniformly diffused N^+ layers in silicon.

Binary silicate glass films are of considerable importance in recent years as solid-to-solid state diffusion sources into silicon for the formation of p-n junctions in the planar technology for fabricating microelectronic devices and circuits (1-10). The use of binary arsenosilicate glasses as n-type diffusion sources has recently been demonstrated by Lee (6) who prepared vitreous films of As_2O_3-SiO_2 on silicon from a two-liquid-source system based on $(C_2H_5O)_4Si$ and $AsCl_3$ by a CVD technique. Subsequent studies by various authors (7-10) showed that glasses prepared from this two-liquid-source system suffer severe "glass damage" when heated to the diffusion temperatures. The glass damage introduces undesirable characteristics into the resultant diffused layers and appears to offer a stumbling block to the use of arsenosilicate glasses as arsenic diffusion sources in the silicon technology.

Key words: surface morphology, film detachment.

In the present paper, advantage has been taken of the ability of the SiH_4-$AsCl_3$-O_2-Ar reaction system to allow vapor deposition of binary arsenosilicate glass films of various compositions in the range 0-20 mole per cent (m/o) As_2O_3 (11), whereby initial stages of glass damage due to heat-treatment could be followed by optical and scanning electron microscopy as a function of film composition and temperature. Furthermore, it is hoped that suitable glass compositions in this binary system can be located so that the use of arsenosilicate glasses as n-type solid-state diffusion sources into silicon may be revived in the semiconductor industry.

Experimental

Binary arsenosilicate glass films were prepared on silicon wafers by a CVD technique using argon-diluted

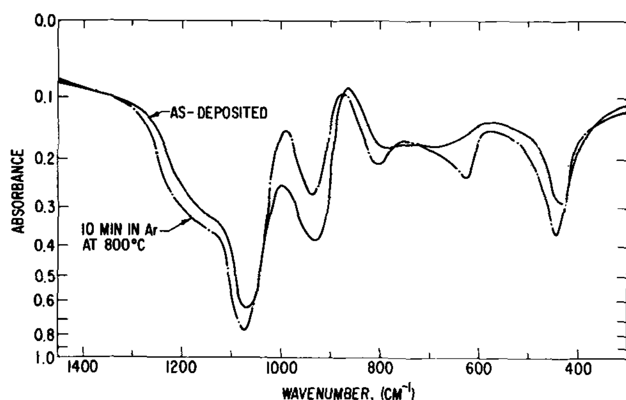

Fig. 1. *IR* spectra of a 14.4 m/o As_2O_3 film before and after heat-treatment in Ar at 800°C for 10 min. Film was deposited at 450°C.

mixtures of SiH_4-$AsCl_3$-O_2 at 450°C. Details of the deposition procedure and composition determination of as-deposited films from the infrared spectra have been reported elsewhere (11, 12). All films studied were 8000Å thick. A horizontal quartz-tube furnace was used to heat-treat the deposited films in a flowing atmosphere of argon. Typical heat-treatment times were of the order of 10 min. Surface morphology of heat-treated films was examined by the technique of scanning electron microscopy.

Results and Discussion

Changes in the film structure and surface morphology due to an initial short-time heat-treatment at temperatures above deposition temperature were followed by *IR* spectroscopy and optical microscopy respectively. When heat-treated at 800°C for 10 min in a flowing argon atmosphere, glasses having various amounts of As_2O_3 showed the following general behavior in the *IR* absorption: (*i*) a blue shift of the silica bands from 1060 cm^{-1} to 1080 cm^{-1}, 790 cm^{-1} to 800 cm^{-1}, and 430 cm^{-1}, to 450 cm^{-1}, all accompanied by an increase of band maximum absorbance; (*ii*) a blue shift of the As-O band at 930 cm^{-1} to 940 cm^{-1} accompanied by a decrease of band maximum absorbance; and (*iii*) the appearance of a well-defined band at 630 cm^{-1}. An example of these effects for a glass containing 14.4 m/o As_2O_3 is shown in Fig. 1. The systematic results are tabulated in Table I. Detailed chemical and spectral analyses of the combined Si-O and As-O bands in the region 1400-800 cm^{-1} of the infrared as a function of thermal history of CVD arsenosilicate films show that structural changes and not composition variations are responsible for the observed shifts in band frequency and maximum absorbance in the heat-treated film (13).

Films containing 20 m/o As_2O_3 and higher appear frosty when heat-treated at 800°C in Ar. Microscopic examinations showed that the frostiness was actually due to the appearance of very circular fringes arranged in a somewhat random manner over the entire film. Systematic heat-treatment at various temperatures in Ar for 10 min showed that the temperature required to bring about the appearance of these circular fringes is strongly dependent on the composition of the as-deposited film; the higher the concentration of As_2O_3 in the film, the lower the heat-treatment temperature is necessary to produce the fringes. Micrographs of these fringes are shown in Fig. 2 for various composition films heat-treated at the respective temperature to produce frostiness. With low enough As_2O_3-content (0.5 m/o As_2O_3) films, fringe formation can be avoided even when heat-treated at temperatures as high as

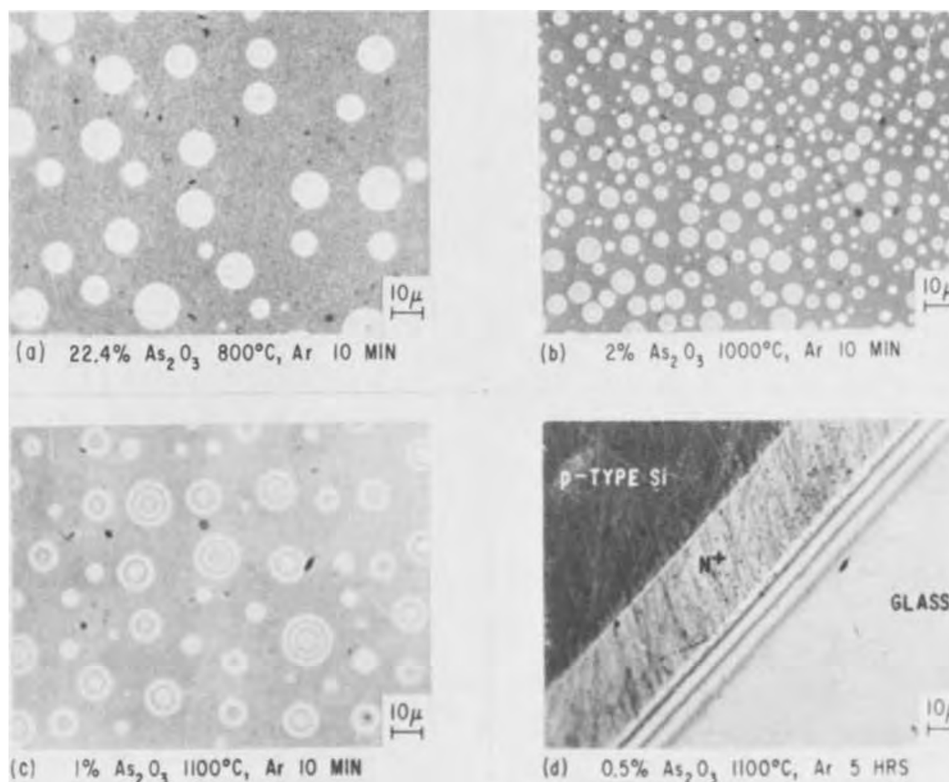

Fig. 2. Micrographs of film surfaces after heat-treatment.

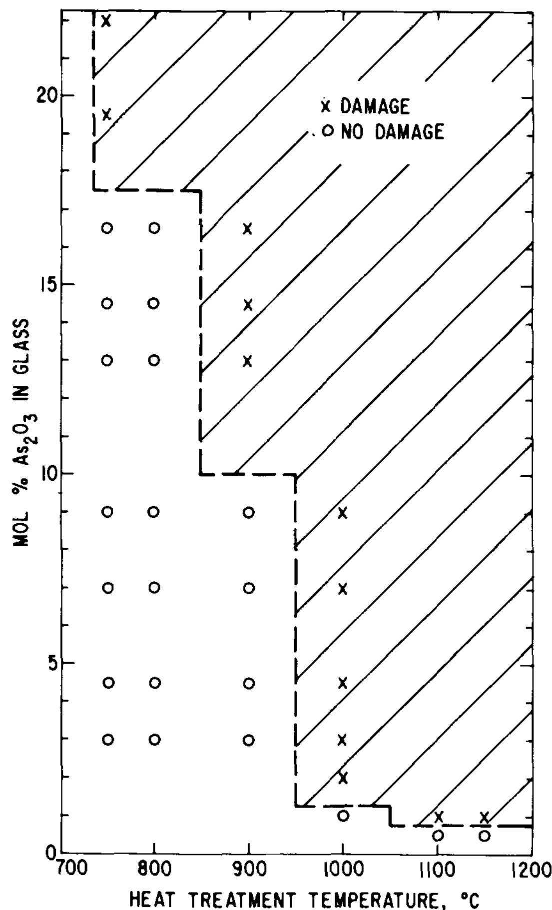

Fig. 3. Glass composition *vs.* temperature of circular fringe formation due to heat-treatment in Ar for 10 min.

1100°C for a period of 5 hr. The net result is the formation of a very uniform N^+ diffused layer (see Fig. 2d) as reported earlier (11). The boundary separating the compositions which give rise to circular fringe formation at various heat-treatment temperatures is given in Fig. 3. These circular fringes are found to be very reproducible and their appearance or otherwise at a given heat-treatment temperature can be predicted quite accurately once the chemical composition of the film is determined. Heat-treating a given composition glass in the temperature range covered by the shaded area shown in Fig. 3 will always induce fringe formation.

Optically, these very circular fringes suggest regions of optical discontinuity between the silicon substrate and the glass film. Indeed, direct observation using scanning electron microscopy reveals that these fringes are actually regions of circular convex domes (Fig. 4) of the glass film heaving off from the silicon substrate under a biaxial compressive stress.

To elucidate the mechanism of fringe formation of vapor-deposited arsenosilicate films on silicon, we examine the thermal component of the stress in the glass film, arising from the difference in the thermal expansion coefficients of the film and the substrate and follow its magnitude and sign with the deposition and heat-treatment histories. The thermal stress generated in a thin film deposited on a thick substrate is given by (14)

$$S_{th} = (\alpha_f - \alpha_s)\Delta T\, E_f \qquad [1]$$

where α_f and α_s are the average coefficients of expansion for film and substrate, ΔT is the difference in temperature of the substrate during film deposition and measurement, and E_f is the Young's modulus of the film. S_{th} is positive when the film is under a tensile stress, and negative when it is under a compressive stress.

Consider the case where $(\alpha_f - \alpha_s)$ is positive, *i.e.*, the expansion coefficient of the glass is greater than that of the silicon substrate. Assume also that the intrinsic component of the stress[1] in the deposited film is negligible compared with the thermal component at all temperatures under consideration. We examine

[1] The intrinsic stress constitutes the second component to the total stress but its origin is not well understood at present (14). Its contribution to the total stress is by no means trivial in certain cases. In our thermal cycling experiments, however, it is expected that the thermal stress plays a major role in the observed mechanical phenomenon as will be evidenced in later discussion.

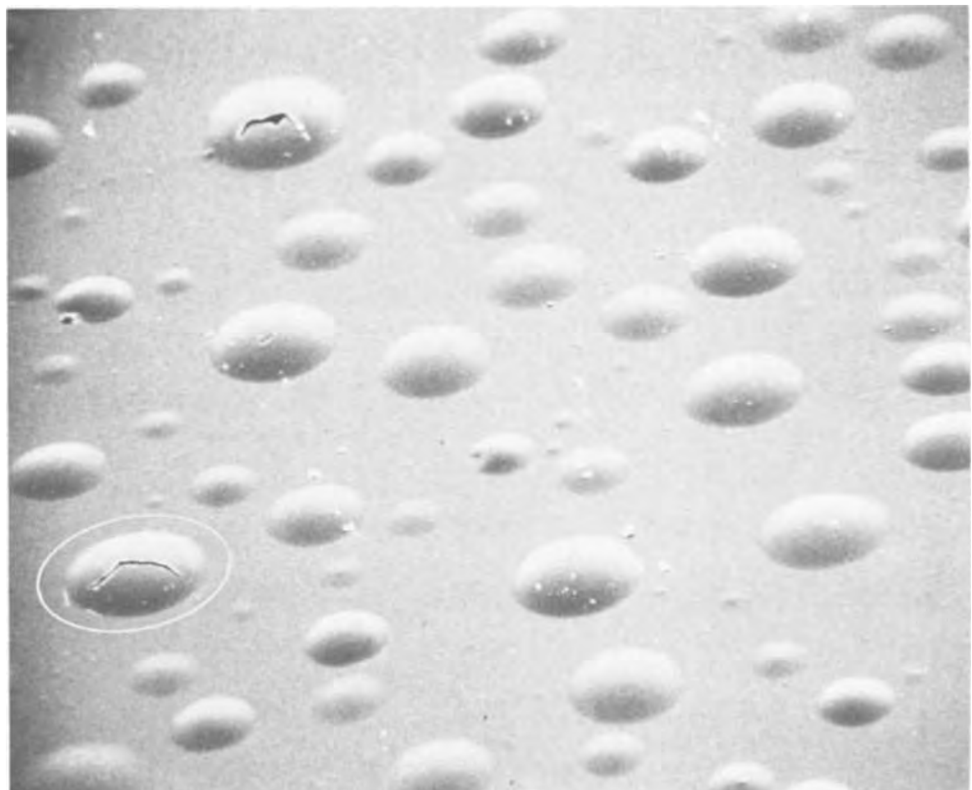

Fig. 4. Scanning electron micrograph of a 14.0 m/o As_2O_3 film after 10 min heat-treatment at 800°C in Ar. Film was deposited at 450°C. Magnification: 500X.

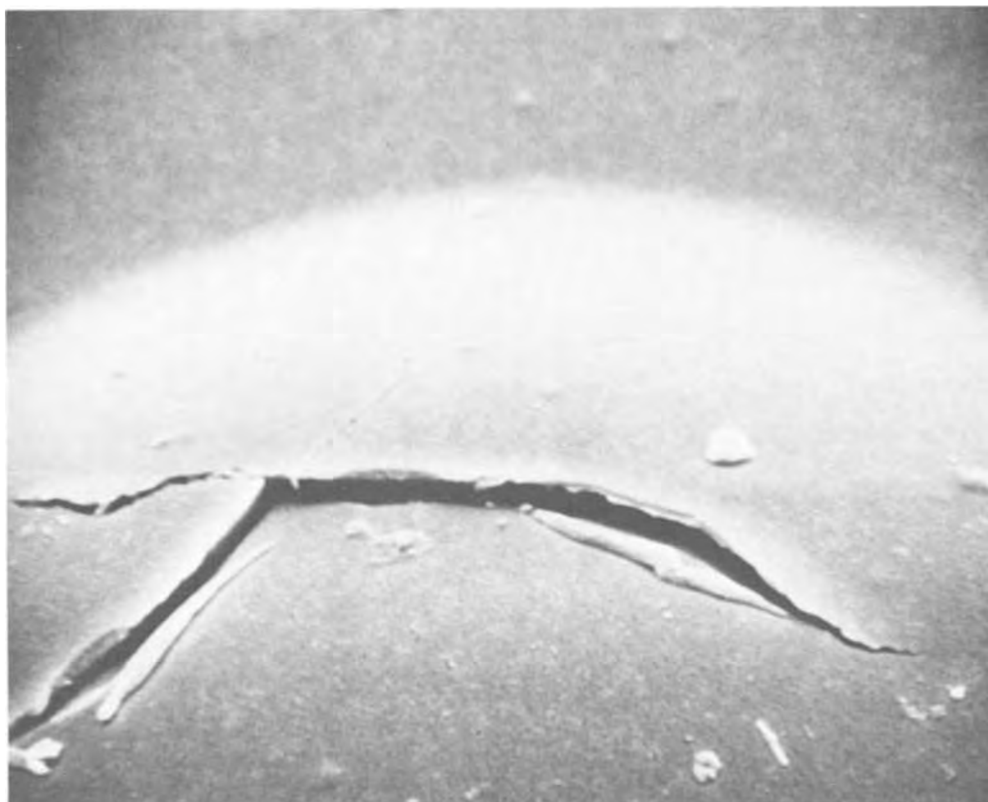

Fig. 5. Scanning electron micrograph of a cracked convex dome (circled in Fig. 4) showing relief of the biaxial compressive stress. Magnification: 500X.

the stress history of the film in the following temperature cycle. When the film is deposited at the deposition temperature, the thermal stress in the film is zero because ΔT is zero. When cooled to room temperature, the film will contract more than the substrate because of its higher expansivity, but is restrained from doing so by the substrate. A biaxial tensile stress is thus generated in the film upon cooling. Upon heat-treatment, this biaxial tensile stress is progressively reduced as the sample is heated to the deposition temperature from room temperature. At temperatures above the deposition temperature the film will expand more than the substrate, but again is restrained from doing so. In this case, S_{th} is negative because ΔT is negative, and a biaxial compressive stress is thus set up in the film. When this compressive stress is high enough, stress relief will take place to cause film buckling from the substrate as shown in Fig. 4, which in turn gives rise to the colored fringes observed under the microscope (Fig. 2).

The buckling due to a biaxial, thermal, compressional mechanism is further substantiated by a more detailed examination of the heat-treated glass surface by scanning electron microscopy at a higher magnification. In Fig. 5, a micrograph of a ruptured circular convex dome circled in Fig. 4 is further magnified 10 times. Crackings occur along two perpendicular lines, showing clearly the biaxial compressional mechanism (14). The detachment of the film from the silicon substrate as a result of the convex dome formation is shown in Fig. 6 which is a scanning electron micrograph of a diamond-scribed edge of the same sample.

In light of the present systematic study on the initial heat-treatment characteristics of vapor-deposited arsenosilicate glass films on silicon as a function of glass composition and heat-treatment temperature, the so-called "glass damage" encountered in all the early works (7-10) on high As_2O_3 concentration glass may be understood. Arai and Terunuma (9), for instance, working with 25-31 m/o As_2O_3 glasses found that heat-treatments at 1000°C and up always cause surface damage to the glass, and that the lowest temperature for damage increases with increase in deposition temperature. The latter dependence can easily be explained in terms of the thermal stress history of the film. The higher the deposition temperature, therefore, the higher the temperature of heat-treatment is required to generate a biaxial compressive stress large enough to initiate film detachment from the silicon surface, *i.e.,* in order to keep ΔT constant in Eq. [1]. Raising the temperature and/or prolonging the period of heat-treatment, will further

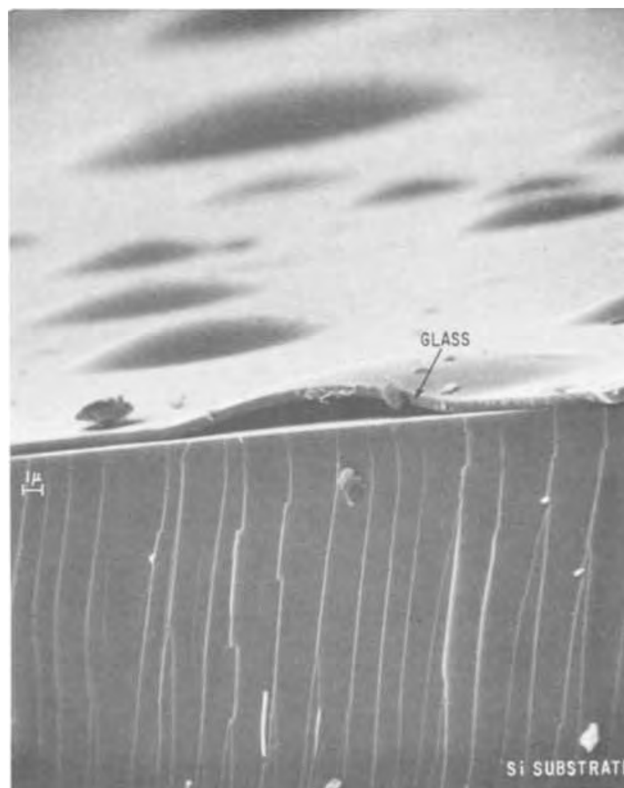

Fig. 6. Scanning electron micrograph of a diamond-scribed edge of the same film shown in Fig. 4 and 5. Magnification: 2000X.

bring about rupture of the film (Fig. 5) and even devitrification (9). The film loses its glassy appearance and acquires a dull, frosty metallic look.

Teshima and co-workers (7) found that glass damage may conceivably be reduced if a layer of 900Å SiO_2 is sandwiched between the binary glass and the Si substrate. Frosting of some kind was still observed in the glass film after heat-treatment at 1150°C.

However, as the amount of As_2O_3 is reduced in the glass film, a better expansion-coefficient match with silicon can be obtained. This automatically reduces the magnitude of the factor ($\alpha_f - \alpha_s$) in the stress expression, and thus in order to bring about the detachment under a large enough compressive stress, a higher heat-treatment temperature (*i.e.*, larger ΔT) is required. Thus a monotonic increase in the allowable heat-treatment temperature is expected with decrease in As_2O_3 content in the film and this is found experimentally as shown in Fig. 3.

Conclusion

Results on the compositional dependence in the surface morphology of CVD arsenosilicate films on silicon substrate at the initial stage of heat-treatment in Ar at various temperatures show that the thermal compressive stress generated at these elevated temperatures are largely responsible for the observed film detachment from the substrate. These observations help to give an insight into the "glass-damage" problem associated with higher As_2O_3 content films, at least during the initial stage of heat-treatment.

When the As_2O_3 content in the films is reduced substantially to about 0.5 m/o, glass damage can be eliminated altogether and prolonged heat-treatment will yield very uniformly diffused N^+ layers of As in Si. The diffusion characteristics of As from these low As_2O_3 glasses into the silicon will be given in a subsequent paper (15).

Acknowledgments

The author would like to thank Prof. J. W. Mitchell for the enlightening discussion on film properties and for his constructive comments. Thanks are due to M. Ghezzo and M. F. Ciccarelli for preliminary microscopic examinations of the heat-treated films and for the SEM analysis respectively. Encouragement by M. Garfinkel in various aspects of this work and his constructive comments on the manuscript are gratefully appreciated.

Manuscript submitted Oct. 22, 1971; revised manuscript received March 17, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

Backscattering Studies of Anodization of Aluminum Oxide and Silicon Nitride on Silicon

M. Kamoshida[1] and J. W. Mayer

California Institute of Technology, Pasadena, California 91109

ABSTRACT

Anodic oxidation of amorphous and polycrystalline aluminum oxides and amorphous silicon nitride deposited by chemical reactions on silicon were investigated by use of 2 MeV $^4He^+$ ion backscattering spectra and optical microscope examination. In anodization, the oxide layer was formed underneath the original aluminum oxide film and on the top surface of the silicon nitride layer. For a fixed current, the anodic voltage characteristics for aluminum oxide exhibited breakdown effects. After breakdown the aluminum oxide became nonuniform, and was removed at later stages of anodization, leaving a silicon oxide layer. For 700°C-grown aluminum oxide, irregular surfaces were formed after all stages of anodization while for 830°C-grown aluminum oxide, the oxide layer formed at later stages was similar in thickness and uniformity to those of anodically grown silicon oxide layers on bare silicon. The anodic voltage characteristics for silicon nitride did not exhibit breakdown. Backscattering data showed linear dependences on anodizing time of the decrease in amount of nitrogen and increase in amount of oxygen, suggesting that the nitrogen was replaced by oxygen during anodization. A similar mechanism was proposed by Schmidt and Wonsidler, and by Tripp.

Recently silicon nitride and aluminum oxide films have been investigated to fabricate high reliability devices such as beam-lead, sealed-junction devices (1), or memory devices such as MNOS memory (2) or MAS memory (3). Analysis of profiles of MeV particles backscattered from dielectric films have been also described as a nondestructive method to study films

Key words: anodization, anodization of Si, Al_2O_3 films, backscattering analysis.

of silicon oxide, silicon nitride, or multilayer structures with silicon oxide and silicon nitride (4-6). More recently, the composition of sputtered silicon nitride was determined by both nuclear reactions and backscattering techniques as a function of the nitrogen content of the reactive atmosphere (7). Backscattering techniques were also used to investigate aluminum oxide films deposited onto silicon by hydrolysis of aluminum trichloride (8-10). Films grown at temperatures of 700°C or less are amorphous and contain residual chlorine [contents of 2 atomic per cent (a/o)] uniformly distributed throughout the film. Films grown at 800°C or above are polycrystalline and contain less than 0.02 a/o of chlorine. Both films are stoichiometric in composition. Influence of heat-treatment on the film properties was also investigated (11). In oxidizing atmosphere, oxygen diffuses through aluminum oxides deposited at 700° and 830°C, and new oxides were grown underneath the original aluminum oxides. A mixture of aluminum, silicon, and oxygen was found at the interface of the aluminum oxide and thermally grown new oxide.

Anodic oxidation of silicon previously covered with aluminum oxide should be attractive for comparison with thermally oxidized specimens. Schmidt and Wonsidler (12) suggested that in the anodization of polycrystalline alpha-alumina on silicon in aqueous borate solution, growth of new oxide occurred at the oxide-silicon interface. This is in contrast with anodic oxidation of silicon nitride where the oxide layer is formed on the top surface. The data of Schmidt and Wonsidler (12), and Tripp (13) indicate that the nitrogen is replaced by oxygen.

In the present work anodic oxidation of silicon covered with aluminum oxides formed by chemical reaction, at 700°C (amorphous) and at 830°C (polycrystalline), was investigated using MeV $^4He^+$ backscattering techniques and optical microscope examination. These results were compared with backscattering data from anodically oxidized silicon nitride films.

Experimental Procedure

Aluminum oxide and silicon nitride films were deposited from the vapor state by the reaction (14) of aluminum trichloride, carbon dioxide, and hydrogen, and by the silane-ammonia reaction (15) onto the surface of silicon wafers, respectively. As previously described (8-11), before the deposition the substrate silicon wafers were mechanically-chemically mirror polished to obtain a sharp interface between the deposited insulator films and the silicon surfaces. Prior to the start of deposition, wafers were rinsed with dilute hydrofluoric acid to keep to a minimum silicon oxide on the surface. Temperatures of the silicon surfaces during deposition were 700° and 830°C for aluminum oxide, and 950°C for amorphous silicon nitride films. Substrates used were n-type, 3.5~6.5 ohm-cm Si(111) for aluminum oxide and p-type, 3~5 ohm-cm Si(100) for silicon nitride.

The detailed descriptions of the other growth parameters for both films are found in Tsujide *et al.* (16) and in Kobayashi *et al.* (17) (in our case, the reactor pressure was 1 atm), respectively. The thicknesses of 700°C- and 830°C-grown aluminum oxide and silicon nitride were 1900, 1600, and 480Å, respectively. Original film thicknesses were measured by ellipsometry.

Nonaqueous systems (18) of N-methylacetamide were used for the electrolyte to which were added 0.97 weight per cent (w/o) of KNO_3 and 1.9 w/o of deionized water. Anodizations were performed using a regulated d-c power supply capable of delivering 0-400V and 0-75 mA, and were performed under illumination following the work of Schmidt *et al.* (19). An open 40 ml Teflon beaker with a hole in the bottom (where the electrolyte anodized the sample) was used and electrical contact to the silicon wafer was made by pressing a metal (the area of which is larger than the anodic area of silicon) to the back of the silicon wafer (20). No particular precautions were taken to keep the temperature of electrolyte constant. No subsequent heat-treatment was made. Backscattering data indicated that the thickness of the 700°C-grown film (which was attacked by water) did not change if the film was immersed in the electrolyte for 30 min.

The Kellogg Laboratory 3-MV accelerator was used; typical $^4He^+$ target currents were 15~20 nA at 2 MeV incident ion energy. Particles backscattered through a laboratory angle of 168° were detected in a 25 mm^2 surface barrier detector (12 cm distance). Standard electronics, including a pulse pile-up rejection system, fed pulses to a 400-channel pulse height analyzer. Analyzer dead time was never greater than 3%. Energy resolution was about 15 keV.

Results

Relation between anodic voltage and anodizing time.—Typical characteristics of anodic voltage *vs.* anodizing time under a condition of a fixed current, 9.2 mA/cm^2, are shown in Fig. 1. Sections a, b, c, and d correspond to data obtained from the samples whose original structures were bare silicon, silicon nitride on silicon, 700°C-grown aluminum oxide on silicon, and 830°C-grown aluminum oxide on silicon, respectively. The anodic characteristic obtained from silicon nitride on silicon has a similar shape (monotonic increase) as that observed from bare silicon. In the case of silicon covered with the 700°C-grown aluminum oxide film, the characteristic curve was divided into three regions: in region 1 continuous breakdown was observed (the ratio of the peak to valley in the breakdown characteristics depended on the sample); in region 2 irregular characteristics were found; and next, monotonically stable characteristics were obtained in region 3. Many spots, whose diameters were of the order of

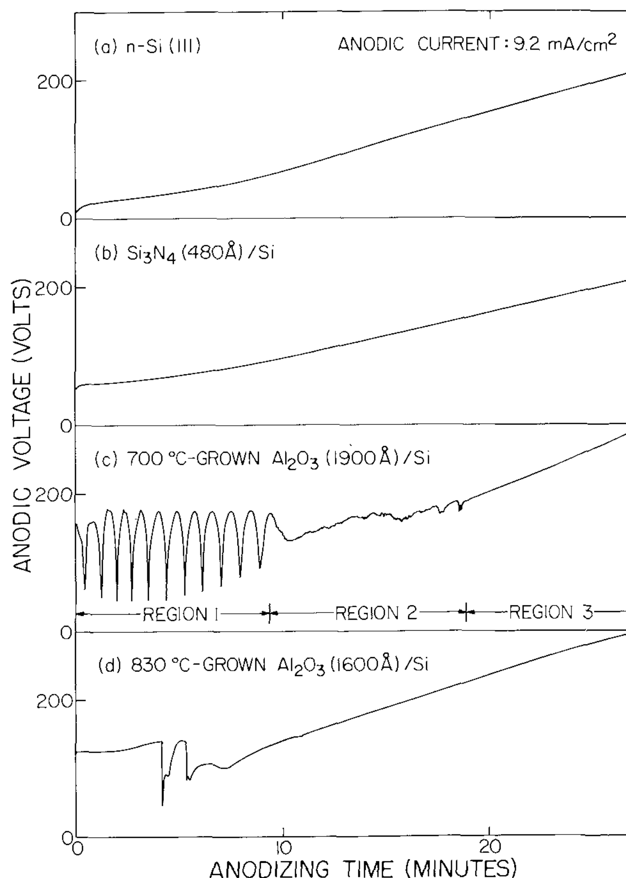

Fig. 1. Typical relations between anodic voltages and anodizing times at a fixed current of 9.2 mA/cm^2 for different samples.

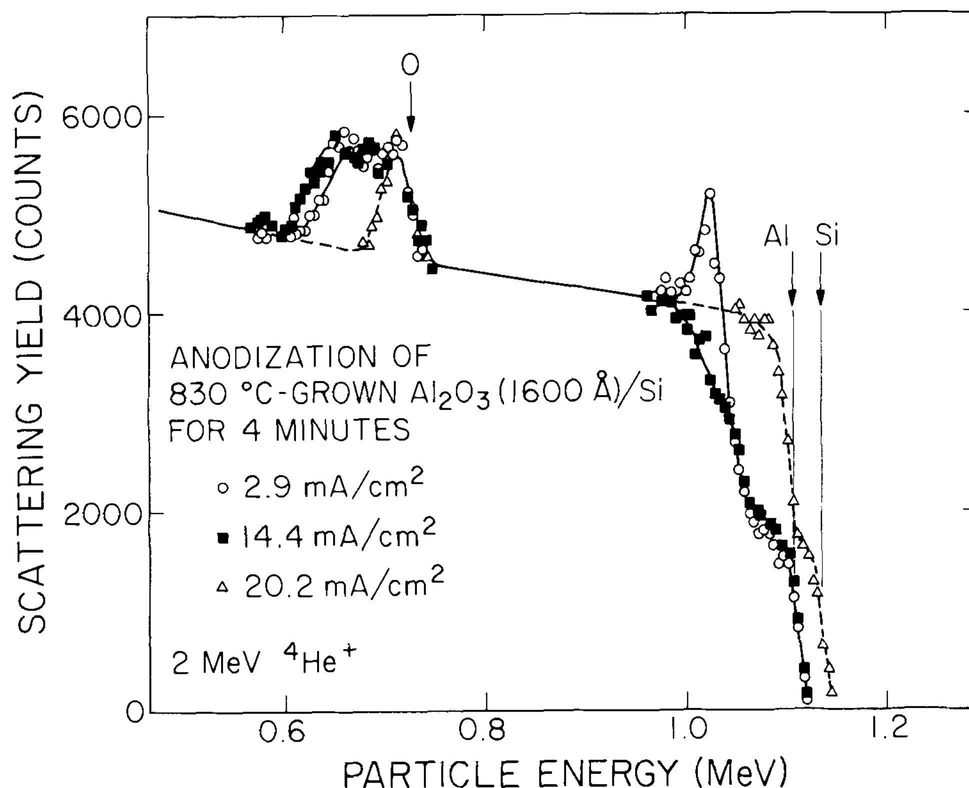

Fig. 2. Spectra of 2 MeV $^4He^+$ ions backscattered from 1600Å-thick aluminum oxide films deposited at 830°C and anodized for 4 min; inserted arrows indicate the energies of 2 MeV-$^4He^+$ ions backscattered from each element.

1 μ, were observed by optical microscopy on the surface of the aluminum oxide in region 1. After the characteristic change to region 2, the surface of the sample became nonuniform in a microscopic view. Even after the transition to the monotonic characteristic, optical microscope examination still showed surface irregularities.

Only two or three spikes (the spike shape was sharper in a thicker film) were observed in the case of 830°C-grown aluminum oxide on silicon. Before the first breakdown spike the film surface was uniform, but after the breakdown surface nonuniformity was observed. This nonuniformity did not remain (under optical microscope examination) at the stage corresponding to region 3 of 700°C-grown film, and the surface appeared like that of anodized bare silicon. Similar features of breakdown and surface nonuniformities of 700°C- and 830°C-grown films were found in the anodization over the range of current densities from 2.9 to 20.2 mA/cm². In the former case, the time between breakdown became shorter with increasing current densities and there was little change of the voltage of the top level of breakdown characteristic; in the latter case the breakdown was observed above current densities of 9 mA/cm² (up to 9 mA/cm² the characteristic change was monotonic).

Backscattering data on 830°C-grown aluminum oxide films.—Figure 2 shows spectra of particles backscattered from 1600Å-thick aluminum oxide films deposited at 830°C and anodized for 4 min at 2.9, 14.4, and 20.2 mA/cm². The spectrum (circular points) for the sample anodized at 2.9 mA/cm² [which resembled closely that for an as-grown sample (8, 10, 11)] has the following major features: (*i*) the energy of the leading edge in the region of higher energy coincides with the energy of particles scattered from aluminum at the surface; (*ii*) the step corresponds to aluminum in the aluminum oxide; (*iii*) the peak (at ~1.0 MeV) is generated by the overlap of the trailing edge of the spectrum of aluminum in aluminum oxide with the leading edge of the substrate silicon spectrum; and (*iv*) the peak at low energies (0.6 to 0.8 MeV) corresponds to oxygen in the aluminum oxide layer. After an anodization of 14.4 mA/cm² (filled square plots), the position of the leading edge of this spectrum remains unchanged but the overlap peak disappears and the width of oxygen peak increases reflecting an increase in the oxide layer thickness. Since the leading edge of aluminum spectrum does not change, the new oxide layer must be formed underneath the original aluminum oxide. After the sample was anodized at 20.2 mA/cm² (open triangle plots, corresponding to region 3 in Fig. 1c), the leading edge of the spectrum shifted to the energy corresponding to silicon at the surface and the width of oxygen peak was markedly reduced. This spectrum corresponds to that of a silicon oxide film on silicon with a thickness about 1/3 of the original aluminum oxide film thickness. This indicates that the original aluminum oxide film has been removed.

Similar results were found in anodization of 830°C-grown films on silicon at constant current (see Fig. 1d). Figure 3 shows the backscattering spectra for an as-grown film of thickness of 1600Å and samples anodized at 9.2 mA/cm² for 7 min (shortly after breakdown) and 28 min (monotonically increasing voltage). In the spectrum for the sample anodized for 7 min (filled squares) the spectrum leading edge at higher energy is at the position characteristic for aluminum, and the overlap peak has disappeared. The width of the oxygen peak exhibits a slight increase. The spectrum for the sample anodized for 28 min (open triangle points) has a leading edge corresponding to that of silicon and the width of oxygen peak decreases, *i.e.*, aluminum oxide film absent. Note that the edge of the step at 1.06 MeV (corresponding to the oxide-silicon interface) is much steeper than that of the sample anodized for 7 min. This suggests that an irregular interface is present in the sample anodized for 7 min. Visual examination also indicates the surface irregularity.

Spectra for a silicon sample with 830°C-grown film (open triangle points) and for a bare silicon sample (filled triangle points), both of which were anodized at 9.2 mA/cm² to the same final anodic voltage of 307V, are given in Fig. 4. The two spectra coincide closely indicating that two silicon oxide films are nearly identical in thickness and composition. Visual exam-

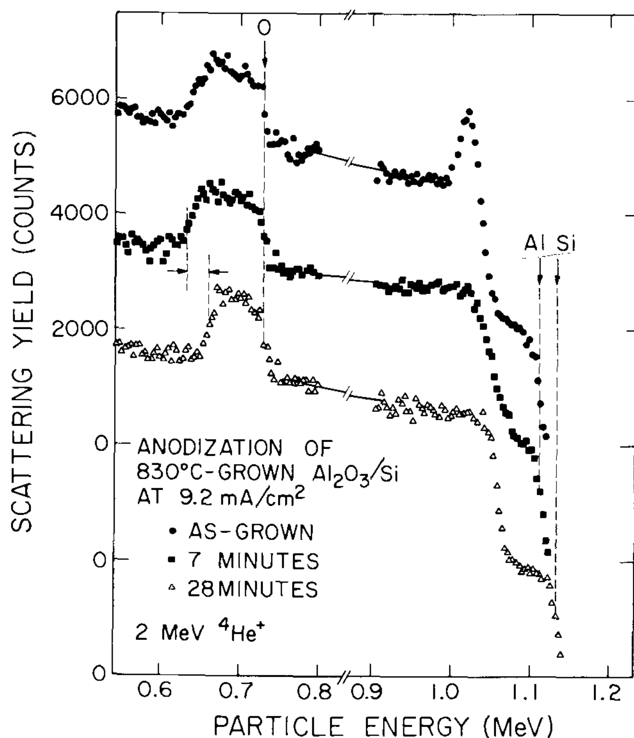

Fig. 3. Backscattering spectra obtained from anodized specimens of 1600Å-thick, polycrystalline aluminum oxide deposited at 830°C on silicon; the spectra are shifted vertically (2000 counts) for clarity.

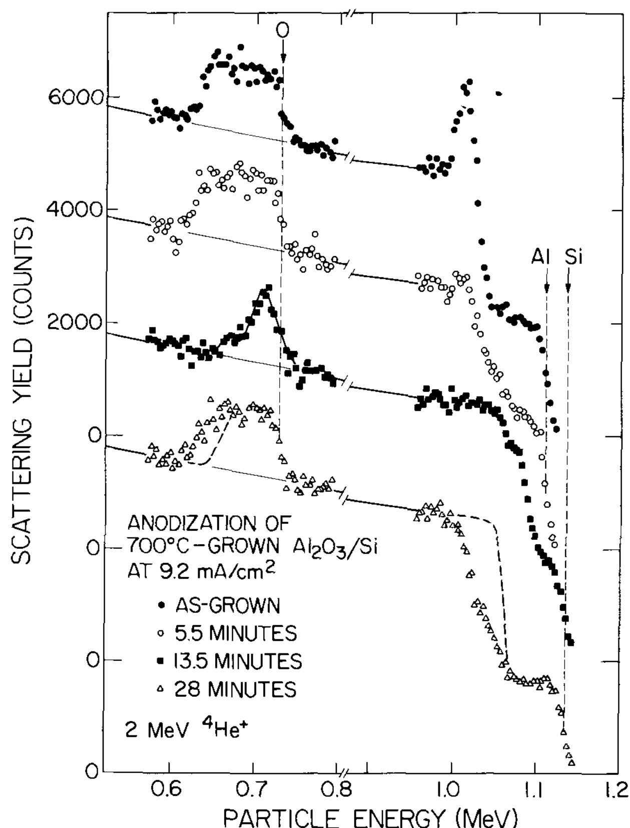

Fig. 5. Typical set of backscattering spectra indicating the anodizing time dependence obtained from 700°C-grown, 1900Å-thick amorphous aluminum oxide on silicon. Estimated silicon spectra are drawn under each oxygen spectrum with light solid curve. Dashed spectrum superposed on the data of 28 min anodization corresponds to the spectra of 29 min anodization of an 830°C-grown aluminum oxide as shown in Fig. 3. Final anodic voltages of both samples are nearly equal (~300 V).

ination indicates that both films are uniform in thickness. After anodic oxidation to the region where the voltage increases monotonically, the films are easily dissolved in hydrofluoric acid.

Backscattering data on 700°C-grown aluminum oxide films.—Figure 5 shows backscattering data of a 700°C-grown aluminum oxide of thickness of 1900Å on silicon at each anodizing stage shown in Fig. 1c, *i.e.*, after 5.5 min (region 1), 13.5 min (region 2), and 28 min (region 3) at a fixed current density of 9.2 mA/cm². In region 1 (circular points, after 5.5 min) the height of the overlap peak decreased and only small increase is noted in the width of oxygen peak.

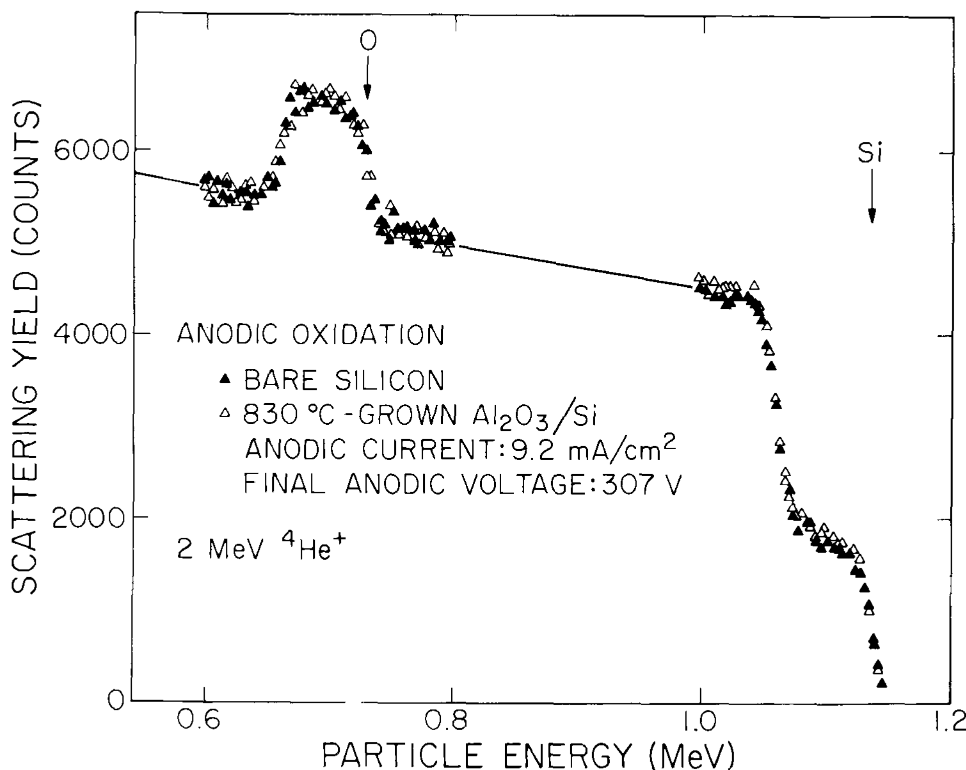

Fig. 4. Backscattering spectra (2 MeV-$^4He^+$) obtained from an 830°C-grown, 1600Å-thick aluminum oxide on silicon and bare silicon anodized under the same anodic conditions except the anodizing period; within statistics, the two spectra are identical.

After anodization for 13.5 min (filled squares, region 2 in Fig. 1c) the leading edge of the spectrum shifted to the position of silicon edge, the overlap peak disappears, and oxygen peak becomes narrower and exhibits step-like tail. This indicates that much of the aluminum oxide layer has been removed and that the remaining oxide layers are nonuniform in thickness. The slope of the leading edge suggests that some aluminum oxide is present on the predominantly silicon oxide surface. The spectrum for the sample anodized for 28 min (open triangle plots) shows an increase in the width of oxygen peak. Comparison with the spectrum (dashed line), for anodized 830°C-grown aluminum oxide film on silicon, indicates that the slope of the spectrum for the 700°C-grown film in the region around 1.07 MeV is less steep than that for 830°C-grown film. This indicates that the oxide layer is nonuniform as was also suggested by visual observation of the surfaces. Width of oxygen peak is also wider than that of 830°C-grown film on silicon anodized for 28 min.

Chlorine spectra corresponding to this sequence of anodized 700°C-grown films are of thickness of 1900Å given in Fig. 6. Anodic current density was 9.2 mA/cm^2. For the as-grown film (filled points) the amount of chlorine is about 2 a/o (8). The chlorine spectra exhibit a step in the leading edge due to the presence of the two chlorine isotopes (^{35}Cl and ^{37}Cl). Previous analysis (10) indicated that the chlorine is distributed uniformly throughout the film. After anodization for 5.5 min (circular points), the shape of the chlorine spectrum exhibits some change. Because of the nonuniform nature of the film after anodization, the shape of the chlorine spectrum varied somewhat for different positions of incidence of the analysis beam. However, one can note an increase of the tail in the spectrum in the region between 1.13 MeV and 1.16 MeV. In studies of chlorine spectra anodized for a fixed period and increased current densities, there was a decided trend towards an increase in amount of chlorine in this region towards the tail of the spectrum.

After anodization for 13.5 min (filled squares in Fig. 6) the total amount of chlorine is 10% of its value in the as-grown film. After further anodization (open triangle plots) the amount of chlorine remained at about 10% of the original value. The leading edge of residual chlorine spectrum did not exhibit an appreciable shift, and the width of the chlorine spectrum is narrower, indicating that the chlorine is confined to a region close to the surface. Under a fixed anodizing period condition with varying anodic current densities, similar features were observed.

Anodization of silicon nitride.—For comparison with aluminum oxide, the anodization of silicon nitride layers on silicon was investigated. Typical spectra of 2 MeV $^4He^+$ particles backscattered from a 480Å-thick as-grown silicon nitride film, deposited on silicon, and the sample anodized at 8.7 mA/cm^2 for 15 min (the final anodic voltage was 132V) are shown in the inset of Fig. 7 drawn by solid and dashed curves, respectively. Shapes of these spectra are similar to those described previously by Meyer *et al.* (4) with specimens of Si_3N_4/Si and $SiO_2/Si_3N_4/Si$ structures. After anodization, an oxygen signal appeared in the spectrum and the nitrogen peak was shifted and decreased.

Because of the large difference in mass between nitrogen and oxygen, the backscattering spectra near

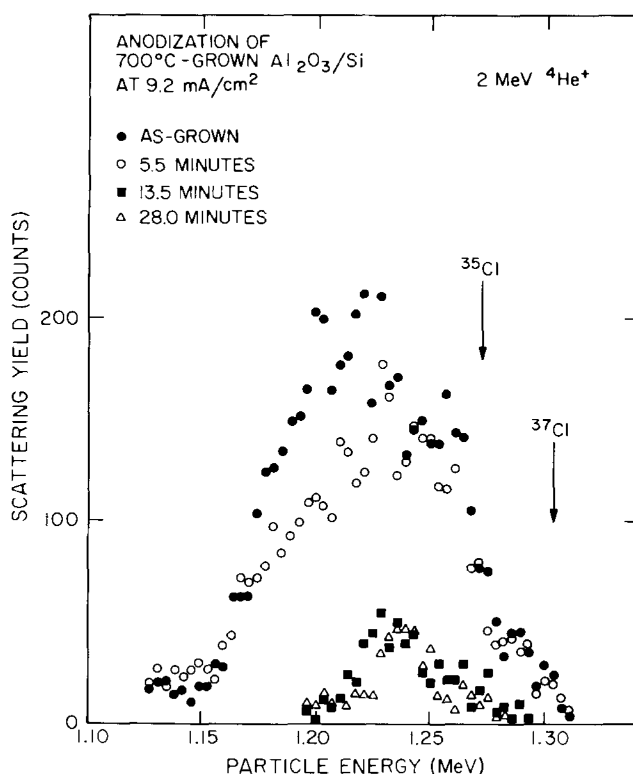

Fig. 6. Chlorine spectra corresponding to the sequence of anodized 700°C-grown aluminum oxide (1900Å). In as-grown film the amount of residual chlorine was 2 a/o. The data obtained after anodizations at 9.2 mA/cm^2 for 5.5 min, 13.5 min, and 28 min, correspond to the samples in regions 1, 2, and 3 in Fig. 1c.

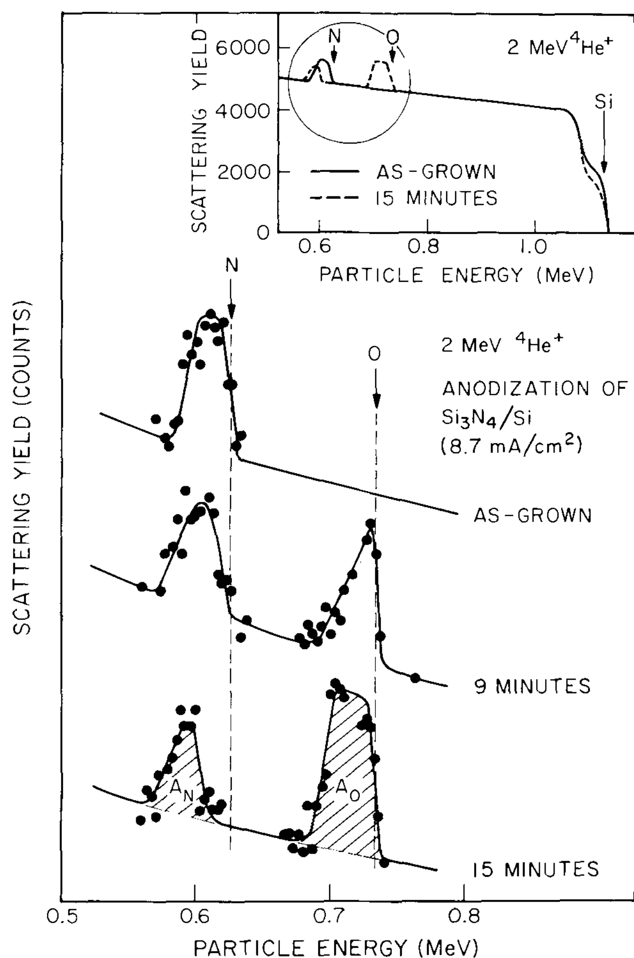

Fig. 7. Spectra of 2 MeV He$^+$ particles backscattered from anodized silicon nitride previously deposited on silicon. Inset shows the spectra obtained from an as-grown, 480Å-thick silicon nitride on silicon and the sample anodized at 8.7 mA/cm^2 for 15 min drawn by solid and dashed curves, respectively. The main body of the figure shows backscattering spectra near the energies of oxygen and nitrogen edges (the area surrounded with a circle in inset) obtained from as-grown and anodized samples. Samples are tilted through an angle of 45° with respect to the incident beam.

the energies of nitrogen and oxygen can be used to analyze the formation of the silicon oxide layer. The parts surrounded with a circle in the inset of Fig. 7 are enlarged in Fig. 7 itself, where the spectrum obtained from a 9 min-anodized specimen is also shown. The shaded areas, A_N and A_O, are the total signal from the nitrogen and oxygen, respectively. From these data the following information was obtained: (*i*) the shift to lower energy of the nitrogen edge and generation of oxygen peak indicate that the oxide layer is formed on the top of silicon nitride; and (*ii*) a replacement of nitrogen in silicon nitride with oxygen is suggested by the fact that the amount of nitrogen (A_N) decreases as the amount of oxygen (A_O) increases.

From the quantitative point of view, if the nitrogen was replaced with oxygen, the decrease in the nitrogen signal between successive anodizations (t_1 and t_2) should be linearly related to the increase in the oxygen signal or

$$\frac{A_N(t_1) - A_N(t_2)}{\sigma_N f} = K_1 \frac{A_O(t_2) - A_O(t_1)}{\sigma_O f} \quad [1]$$

where σ_N and σ_O are scattering cross sections of nitrogen and oxygen, respectively; and f is a factor determined by the target to detector geometry. The factor K_1 indicates the ratio of amounts of nitrogen to oxygen converted during anodization. If the amount of silicon in the layer remains unchanged, then $K_1 = 2/3$ since two nitrogen atoms are replaced by three oxygen atoms, and

$$\frac{A_N(t_1) - A_N(t_2)}{A_O(t_2) - A_O(t_1)} = K_1 \frac{\sigma_N}{\sigma_O} = K_2 \quad [2]$$

where the constant K_2 equals 0.49 for the σ_N/σ_O value of 0.733 in this scattering geometry. In Fig. 7 the following values are observed: $K_2 = 0.39$ and 0.48 for $t_1 = 0$ (*i.e.*, as-grown) to $t_2 = 9$ min; and $t_1 = 9$ min to $t_2 = 15$ min, respectively. These results are within the experimental error considering the problems in background subtraction and counting statistics. This suggests that the nitrogen was replaced by oxygen and agrees with the results of destructive investigations by Schmidt and Wonsidler (12) and Tripp (13).

Figure 8 shows time dependences of spectrum areas of nitrogen and oxygen. If the following relation

$$6\,O^{--} + Si_3N_4 \rightarrow 3SiO_2 + 2N_2 + 12e^-$$

is assumed (13), that there are linear relations between anodic time and variations in amounts of nitrogen and oxygen for a fixed anodic current. Then, the following equations should hold

$$\left.\begin{aligned} A_O(t) &= at \\ A_N(t) &= bt + c \end{aligned}\right\} \quad [3]$$

where a, b, and c are constant. From Eq. [2]

$$-b/a = K_2 = 0.49 \quad [4]$$

In Fig. 8, the solid line was obtained from the experimental values of oxygen spectrum areas (cross points) and the slope of the dashed line was calculated on the basis of Eq. [4]. The decrease in the nitrogen areas tended to follow the estimated dashed line. This result also suggests that the nitrogen in silicon nitride was replaced by oxygen. Some of the scatter about the dashed line could arise from differences in the original film thickness.

Anodic time dependences on anodic voltage, and on the fractional amount of remaining silicon nitride, are shown in Fig. 9. The remaining amounts of silicon nitride (filled points) were evaluated from the areas of spectra of nitrogen and oxygen as follows

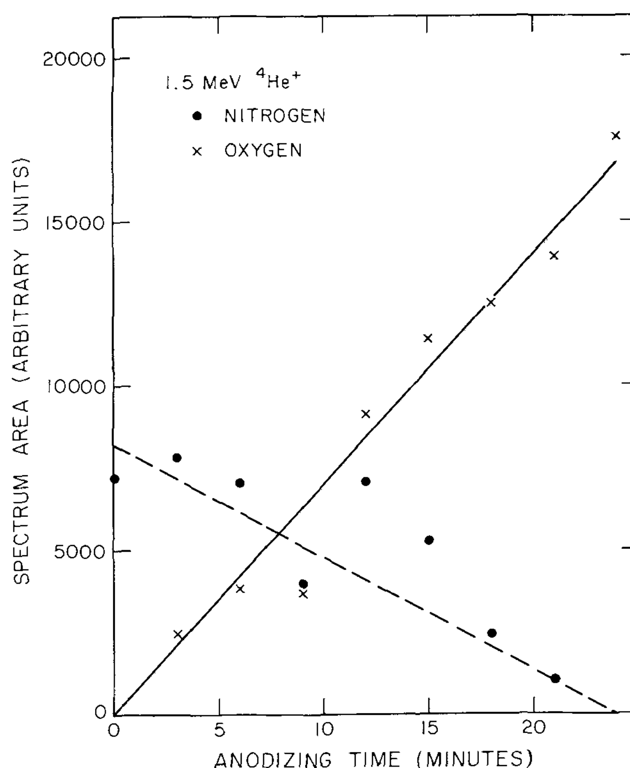

Fig. 8. Relations between anodizing times and spectrum areas of oxygen (cross points) and nitrogen (filled points) obtained by using 1.5 MeV $^4He^+$ particles. Original thickness of silicon nitride was 480Å. Solid line was fixed to experimental data and the slope of dashed line was calculated.

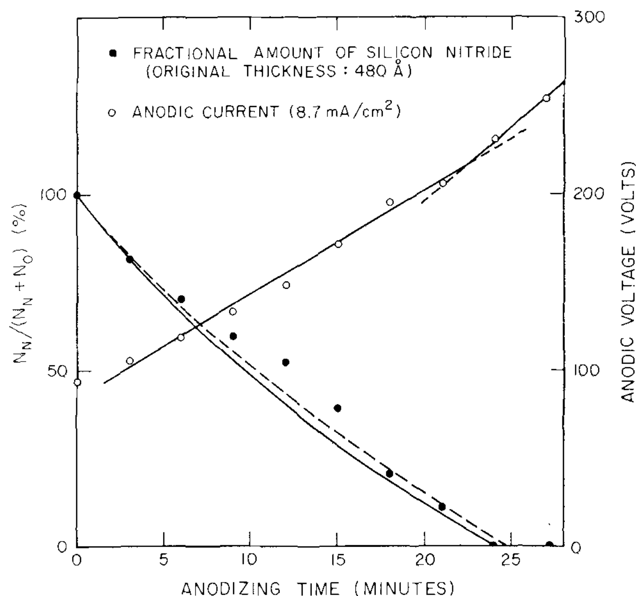

Fig. 9. Relations between anodic voltage and fractional amounts of nitrogen and oxygen in the film vs. anodization time. Solid curve was calculated from linear relations in Fig. 8, and dashed curve shows Tripp's data [Fig. 3 in Ref. (13)]. The anodic voltages were observed under a condition of fixed current of 8.7 mA/cm²; original film thickness was 480Å.

$$\frac{N_N}{N_N + N_O} = \frac{\dfrac{A_N(t)}{\sigma_N f}}{\dfrac{A_N(t)}{\sigma_N f} + \dfrac{A_O(t)}{\sigma_O f}} = \frac{1}{1 + \dfrac{A_O(t)}{A_N(t)} \cdot \dfrac{\sigma_N}{\sigma_O}} \quad [5]$$

where the values of $N_N = A_N(t)/\sigma_N f$ and $N_O = A_O(t)/\sigma_O f$ correspond to the fractional amounts of nitrogen and oxygen in the dielectric films, respectively.

If we use the linear relation of time on the fractional amounts of nitrogen and oxygen, Eq. [5] should be hyperbolic. In Fig. 9 the solid curve shows the values calculated from the linear relations in Fig. 8. The experimental data (filled points) followed such a relation. One of the reasons of deviation is the presumed different thicknesses of original films. Although the electrolyte was different than in our case, because of the similar thickness of the original silicon nitride (500Å) and the current density (7.5 mA/cm^2), Tripp's data [Fig. 3 in Ref. (13)] is also used for comparison in Fig. 9 (dashed curve). In both cases, about 500Å-thick silicon nitride changed to silicon dioxide after 24 ± 1 min. As shown in Fig. 9, the slope of the time dependence of anodic voltage changed at the time corresponding to the disappearance of the nitrogen peak.

Conclusions

The anodic oxidations of 700°C- and 830°C-deposited films of aluminum oxide on silicon have general features in common. In the initial stages of anodization, breakdown phenomena are noted. A visual examination of the surface reveals that the surfaces are irregular. Backscattering spectra show an increase in the width of oxygen peak but the leading edge of the spectrum does not shift (*i.e.*, it corresponds to the aluminum edge) indicating that a silicon oxide layer is formed underneath the original aluminum oxide film. For a longer period of anodization (or higher current densities) the width of oxygen spectrum exhibits a marked decrease, and the leading edge of the spectrum shifts to that of the silicon spectrum edge. At this stage the overlying aluminum oxide film has been removed and, for 830°C-grown films, the width of the oxygen peak and the shape of the silicon spectrum coincide with those for the bare silicon samples anodized to the same voltage. For these high temperature-grown films, once the aluminum oxide film has been removed, the growth of anodic oxide layer follows that for a bare silicon sample. This offers the possibility of a new selective etching technique of polycrystalline aluminum oxide which is similar to the technique for silicon nitride suggested by Schmidt and Wonsidler (12). The as-grown 830°C-deposited aluminum oxide films are only slightly etched by hydrofluoric acid (8), however, after the anodic oxidation the films are easily dissolved with hydrofluoric acid.

One of the major differences between the anodization of 700°C- and 830°C-deposited films is the marked irregularity of the surfaces of the low temperature films. This may follow from the large number of breakdowns observed in the initial stages of anodization for these films. Even in the region where the anodic voltage shows a monotonic increase with anodizing time, the surfaces of the low temperature films are still irregular. The leading edge of the chlorine spectra for these films are not appreciably shifted during anodization. This, again, points out that a new oxide layer is formed underneath the original aluminum oxide layer. The tail that appears in the chlorine spectrum along with the residual chlorine ($\approx 10\%$ of the original amount after anodization) might indicate that chlorine is drifted by the applied anodizing field into the underlying oxide layer. However, because of the nonuniform nature of the film after anodization, one cannot exclude the possibility that some of the original aluminum oxide has been retained.

The result of anodic oxidation of aluminum oxide films is similar to that of thermal oxidation (11) in that the new oxide layer is grown underneath the original film. However, for thermal oxidation there is a strong adherence of the aluminum oxide layer to the newly formed oxide. This might be due to the mixing of silicon and aluminum that was noted for the thermally oxidized sample. In anodized samples, the film irregularity and anodic voltage peaks might imply that the oxide growth takes place initially in localized regions where breakdown phenomena could provide easy paths for oxidation of the underlying silicon. At later stages, the removal of the aluminum oxide would lead to larger area regions.

For silicon nitride, backscattering data indicate that the oxide layer is formed on top of the nitride layer, *i.e.*, the silicon nitride films act as a substrate that is anodized, in agreement with the data of Tripp (13) and Schmidt and Wonsidler (12). The basic difference is the replacement of nitrogen by oxygen. In this respect it should be noted that it is possible (due to statistics involved in background subtraction) that some ($<10\%$) of the nitrogen remains when the anodization reaches a stage where the oxide layer just reaches the silicon. Complete disappearance of the nitrogen might occur at a later point when the substrate silicon is oxidized. Thermal oxidation of silicon nitride also proceeds by growth of the oxide layer on top of the nitride layer (21). In this case the silicon nitride masks against the diffusion of oxygen (22).

Acknowledgments

We wish to thank Nippon Electric Company, Ltd., Dr. S. Nakanuma for his encouragement, and Iida and Inoue for providing the deposited samples. We also thank R. Gorris for his preparation of equipment of anodic oxidation. This work was supported in part by Air Force Cambridge Research Laboratories and the Office of Naval Research.

The Influence of Anodic Coatings on Slip in Aluminum

P. Mehdizadeh[1] and R. J. Block

Department of Chemical Engineering and Materials Science, The University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

Aluminum single crystals were anodized and deformed in tension. Thick coatings inhibited slip of the surface except where cracking or buckling had occurred. Strengthening of the crystal depended upon the thickness but was controlled by the residual stress of the coating.

When anodized aluminum is deformed the coating accommodates deformation of the substrate primarily by cracking. The various modes of film behavior on single crystal and polycrystalline substrates have been discussed in previous papers (1-3) and have been a source of interest for some time (4-7). In the present paper the effect of the coating upon near surface slip is discussed.

Experimental

Reynolds 99.999+% aluminum was grown into single crystals by a modification of the Bridgeman technique using high purity graphite molds. Long crystals of round cross section (for tensile testing) and square cross section (to facilitate surface examination) were produced and cut into specimens of shorter length. The specimens were numbered according to a scheme which assigned the prefix R or S depending on whether the crystal was round or square and two numbers following to indicate the crystal and specimen numbers. The orientations of the crystals are shown in Fig. 1. Prior to testing the crystals were annealed, electropolished in perchloric acid-alcohol, stripped of any residual films in a chromic-phosphoric acid bath, and then anodized. The techniques were identical to those used in previous studies (1, 2).

Oxide films were formed in boric acid buffered to a pH of 5.5. The film formation current was either maintained at less than 0.2 mA/cm^2 or kept slightly above 2.0 mA/cm^2 until the required voltage was achieved. Thereafter, the voltage was maintained until the current decayed to a terminal value usually in the neighborhood of 0.01 mA/cm^2.

Previous experiments (8-10) showed that residual stresses in similar anodically formed coatings depended upon film thickness and the rate of formation. However, the literature leaves some uncertainty about the magnitude and even the sign of the residual stresses which could be expected with the electrolyte used in the present work. Experiments with pH 9-10 ammonium borate solutions (8, 10) produced 150 to 3000Å coatings which were in residual compression when the formation current density was less than 0.5 mA/cm^2, and predicted tensile stresses with current densities in excess of 1 mA/cm^2. It was also reported that the current density at which stress reversal occurred appeared to increase with decreasing solution pH. In all cases however, the residual stresses were reported to become more compressive with increasing film thickness.

Results and Discussion

After sufficient extension, anodized coatings of 1300Å and thicker always cracked at approximately 90° to the tension axis. The cracks completely encircled the specimen. The spacings between these circumferential cracks became quite uniform, rapidly reaching an equilibrium value which depended upon the coating thickness. Thinner coatings cracked along slip plane traces as well as forming a circumferential crack pattern similar to thicker films. Figure 2 shows the relationship between tensile elongation and crack density for anodic coatings of three different thicknesses formed at the low rate. The specimens used were annealed polycrystalline wires and round single crystals of comparable orientation to those of Fig. 1. Similar behavior has been reported previously by Edeleanu and Law (4) for sulfuric acid (cellular type) coatings and was predicted and analytically treated by Grosskreutz and McNeil (11) and Grosskreutz (12).

Once the limiting crack density had been reached, further extension served only to open the cracks. Figure 3 shows this behavior with a 3000Å coating on a single crystal substrate. The appearance of the sur-

Key words: anodized aluminum, residual film stress, slip lines, plastic deformation.

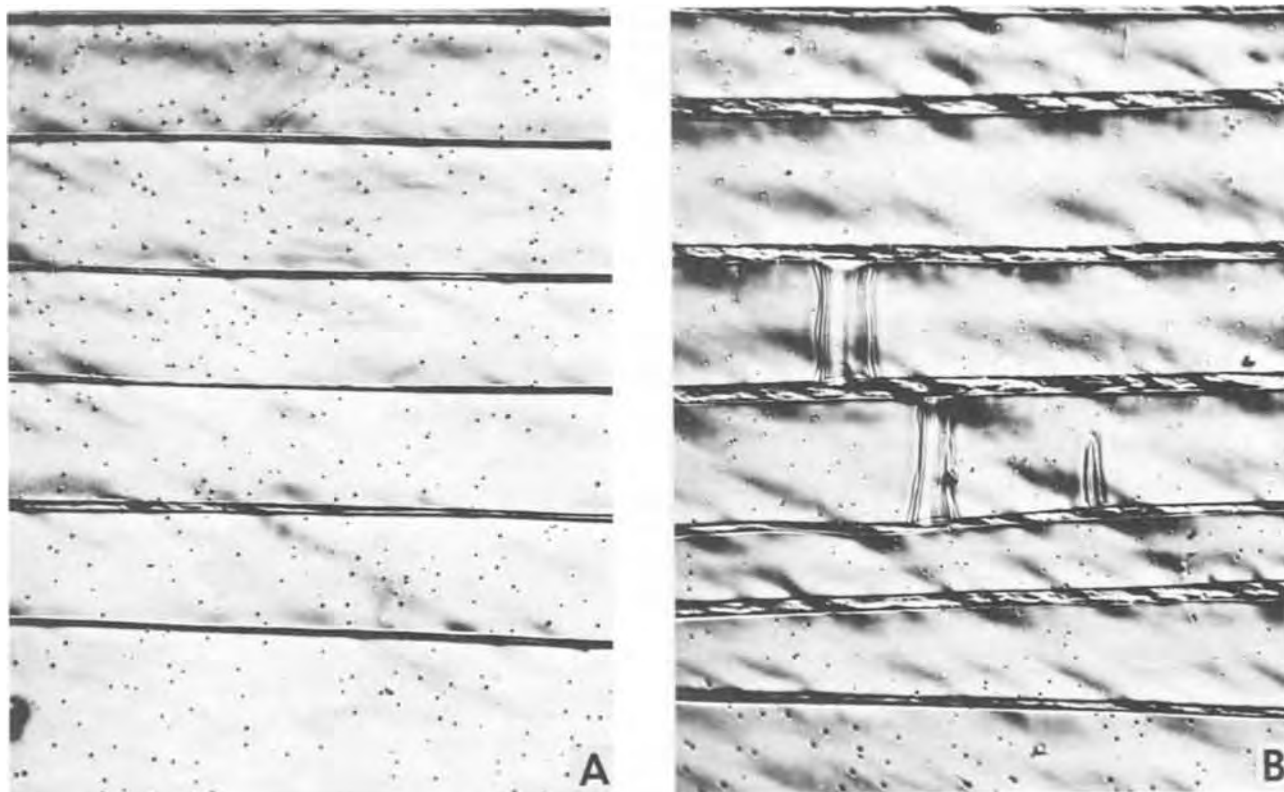

Fig. 3. Widening of transverse cracks in a 3000Å coating, face B of crystal S-4-4 is shown: a, 5.6% elongation; b, 10.5% elongation. The vertical structures in b are buckles in the coating. (X1000).

face in this figure, which is typical of a large number of specimens, may be used to illustrate several aspects of the interaction of the coating with the deformation processes in the underlying crystal.

One of the most striking features of Fig. 3 is the absence of sharp slip lines in areas where the film remained intact. The appearance of the surface immediately suggests that the coating has influenced deformation of the near surface region of the crystal suppressing or severely altering the ordinary slip processes. Cracks in the coating after 10.5% elongation are seen to be as much as 3 or 4 times larger than they were after 5.6% strain, indicating that deformation had taken place preferentially in the substrate material beneath and immediately adjacent to the cracks.

The short diagonal markings within the cracks of Fig. 3a appear to be large slip steps in the substrate crystal. Upon continued extension these were seen to enlarge further and lead out into the regions between cracks where marked undulations of the surface had developed. This deformation obviously involves the operation of a number of slip systems in a rather complex manner. The few vertical structures in Fig. 3b are the result of buckling of the coating (2) and illustrate the appearance of a coating which has become detached from the substrate.

The photomicrographs of Fig. 4 also demonstrate the ability of an anodic film to suppress slip at the coating-substrate interface. In the associated experiment, a crystal with a 3000Å coating was extended 10% and marked with two microhardness indentations (Fig. 4a). The coating was then chemically removed as evidenced by the disappearance of the interference fringes in the buckled areas. There are no sharp slip plane traces where the coating had remained intact (Fig. 4b). However, further extension by 3% produced a single set of sharp slip steps which tended to form at many of the deep slip lines within the cracks (Fig. 4c). The inclination of these slip lines corresponds to the trace of the primary slip plane in the specimen surface. Slip lines within the buckled areas have slightly different inclinations because, once film detachment occurred, the underlying surface material then deformed while the surrounding material was still constrained by the coating.

Adherent surface coatings often have been regarded as effective barriers to dislocation egress from within the crystal (13-15). Although recent work (16) has shown that this is not necessarily true for all coating-substrate combinations, in the present system thick oxide coatings on aluminum seem to have a pronounced influence upon deformation, at least at the surface. This leads one to expect a correspondingly large effect upon the mechanical properties of coated crystals. A series of tensile tests of anodized and uncoated specimens yielded the results shown in Fig. 5 and 6. The strengthening influence of the coating may be seen to depend upon both its thickness and its state of residual stress. The latter factor was shown to be of primary importance in the strengthening of copper single crystals by electroplated metal coatings (16). However, it appears that differences exist in the mechanisms through which residual stresses act to produce strengthening in these two systems. Metal coatings on copper crystals produced large effects only where cracking occurred either prior to or during deformation. Relaxation of the substrate crystal adjoining the cracks produced a layer of dislocations which impeded the motion of primary glide dislocations toward the surface. In the present case, it appears that the aluminum oxide coating itself is capable of directly inhibiting slip at the surface. Where cracks occurred, prominent primary slip lines appeared suggesting that the strengthening had been reduced in these regions.

A coating in a state of residual tension induces compressive stresses in the substrate crystal. These stresses should inhibit the motion toward the surface of dislocations having a Burgers' vector component which is normal to the surface. The absence of slip lines beneath the coating indicates that dislocations were prevented from reaching the interface. Recent experiments (17) indicated that the pH 5.5 boric acid

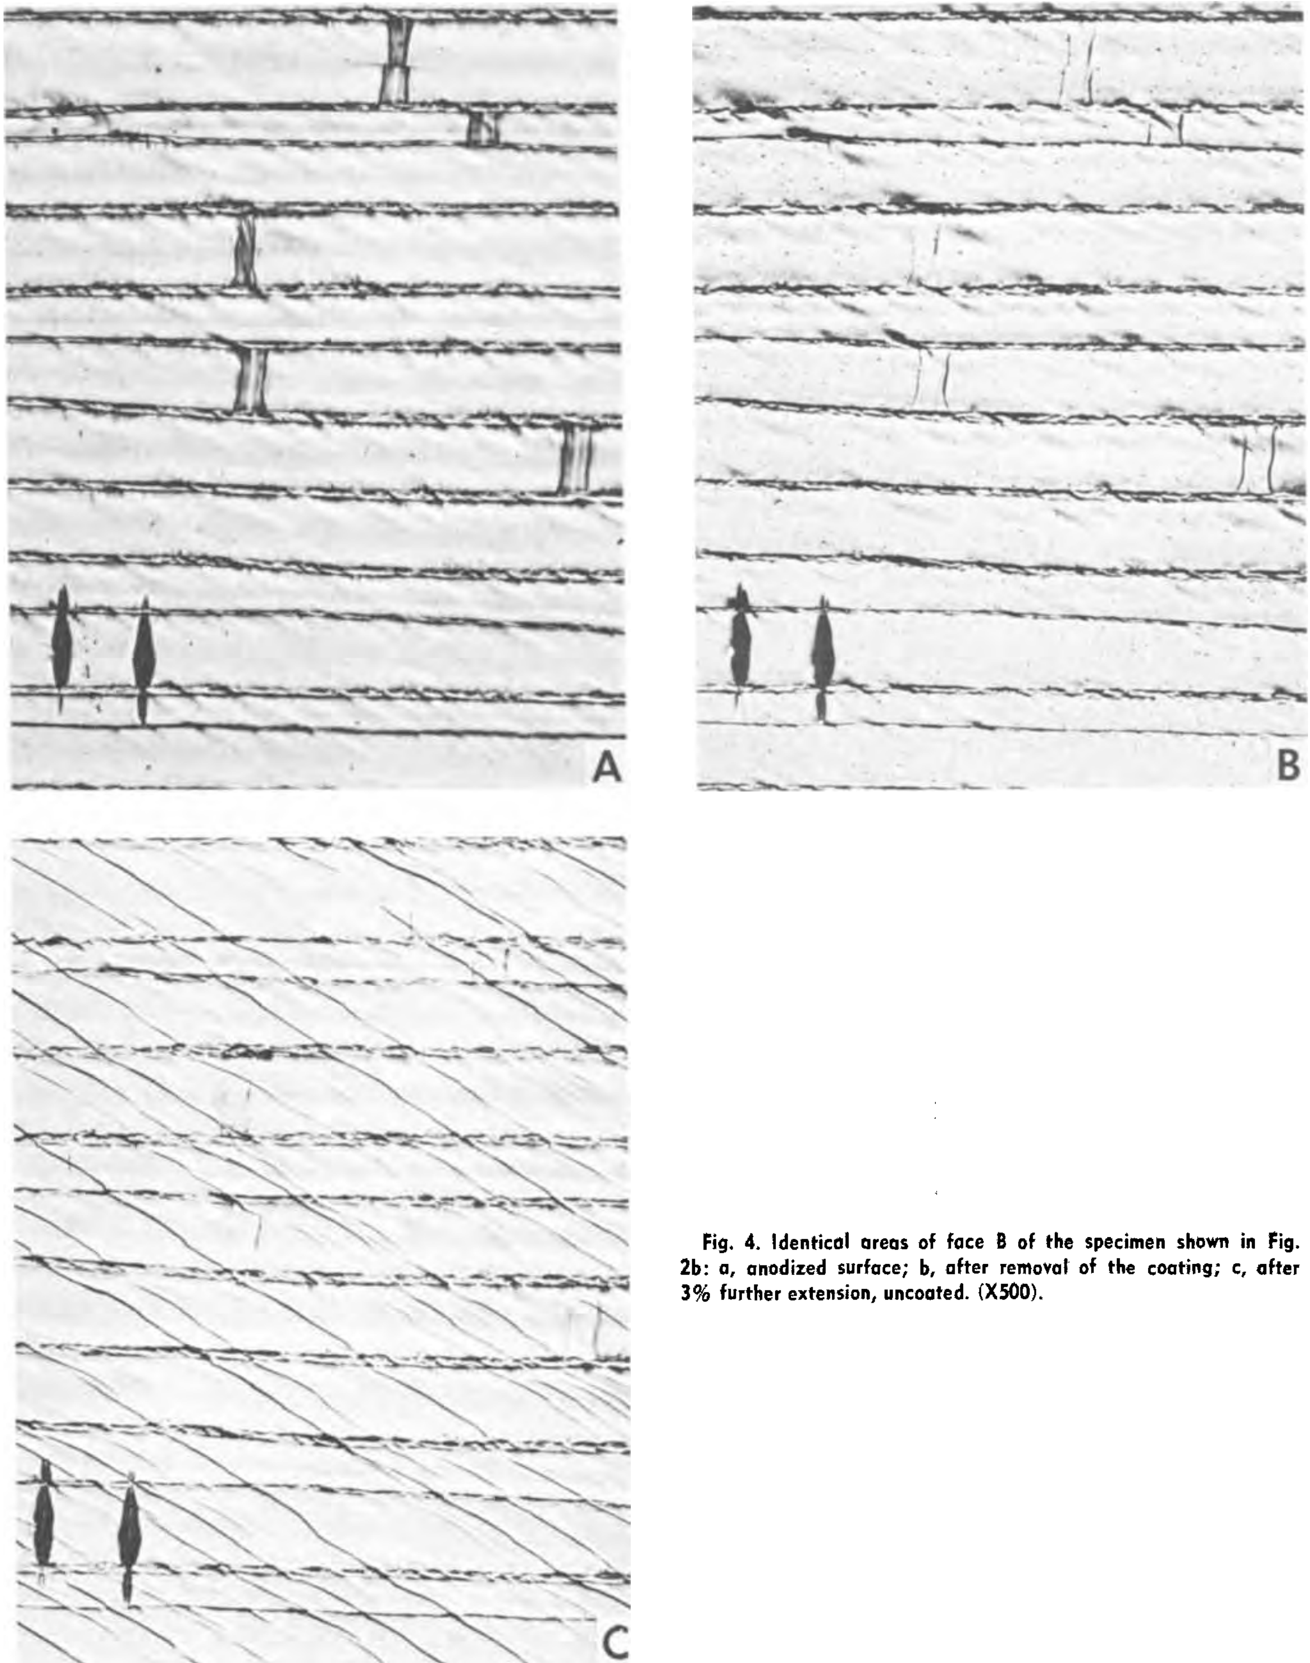

Fig. 4. Identical areas of face B of the specimen shown in Fig. 2b: a, anodized surface; b, after removal of the coating; c, after 3% further extension, uncoated. (X500).

solutions used in the present work produced coatings which were in compression even when they were formed at 2.0 mA/cm^2. The tensile stresses induced in the substrate crystal would be expected to act in the direction of coaxing dislocations toward the surface rather than repelling them. Consistent with this view the increase in strength, induced by the coatings of low residual compression (shown in Fig. 6), was much greater than with the more highly compressed film (shown in Fig. 5).

The magnitudes of the strengthening produced by anodized coatings become more impressive when one considers that the deformation of aluminum crystals should be relatively insensitive to conditions at the surface. Coatings exert their strongest influence during stage I deformation (18). Aluminum crystals with

their characteristically short, easy glide regions should not provide a system which is particularly sensitive to surface film effects. It is well known that, in aluminum, interpretation of bulk deformation behavior from the appearance of slip lines on the surface is unreliable (19-21). Slip line patterns characteristic of single slip persist long after the end of stage I, indicating that the surface and interior harden at very different rates.

The Suppression of Ionic Contamination During Silicon Nitride Deposition

E. MacKenna* and P. Kodama

Research and Development Laboratory,
Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

Electrical instabilities have been generally noted in MNOS structures incorporating SiH_4-type Si_3N_4 deposits but not in MNOS structures incorporating $SiCl_4$-type Si_3N_4 deposits. It is concluded that the $SiCl_4$ process for Si_3N_4 deposition has a built-in gettering capability for removing ionic contaminants which is not available from the SiH_4 process. It is proposed that the gettering capability arises from the presence of chloride ions. This premise was verified by purposely adding a source of chloride ions either prior to or during deposition of SiH_4-type Si_3N_4.

Many investigators (1-5) have demonstrated that thin (0.1μ) amorphous layers of silicon nitride (Si_3N_4) can be used as barriers against the diffusion of impurity ions such as sodium. Indeed, Dalton and Drobek (6) published data demonstrating the ability of Si_3N_4 layers to mask against the diffusion of sodium at temperatures as high as 600°C. Deal *et al.* (7) have also

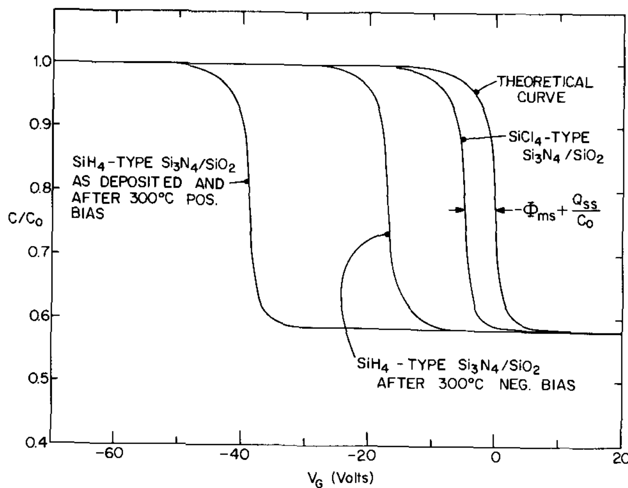

Fig. 1. Capacitance-voltage curves for a theoretical MIS capacitor, a $SiCl_4$-type Si_3N_4 MNOS capacitor, and a contaminated SiH_4-type Si_3N_4 MNOS capacitor as deposited and after 300°C stressing with -2.5×10^5 V/cm. [(111) p-type Si $C_B \simeq 1.2 \times 10^{16}$ cm^{-3}].

shown that these films act as barriers to the diffusion of hydrogen ions at temperatures as high as 550°C. Other authors (8-10) have discussed some of the advantages of MNOS as compared with MOS processing. However, because Si_3N_4 films are effective barriers to the diffusion of ionic contaminants, it is important that all sources of contamination are removed from device structures prior to Si_3N_4 deposition.

After elevated temperature processing in an oxidizing ambient, ionic contaminants such as sodium are generally located near the air-oxide interface (11). Various etching and phosphosilicate glass gettering techniques can be used to remove these sources of contamination (12). However, we have observed that the Si_3N_4 process itself can also act as a source of contamination.

During an investigation designed to study the effects of various process parameters on the electrical and physical properties of Si_3N_4 films, one anomaly was repeatedly observed. When Si_3N_4, deposited from silane and ammonia mixtures, was deposited over thermally oxidized silicon, electrical instabilities were generally noted. As shown in Fig. 1, the nature of the instability was such that it caused a negative shift (more negative turn-on voltages) to the flat-band voltages of MNOS capacitors. Application of negative fields on the order of 2.5×10^5 V/cm at 300°C caused a positive shift (less negative turn-on voltages) in the flat-band voltage. However, the flat-band voltage could not be recovered to the value corresponding to the fixed surface-state charge density (Q_{ss}/q) known to be present at the oxide-silicon interface. This fact, plus the observation that no field dependent drift of the C-V characteristics was observed, ruled out the possibility of Si_3N_4 structural polarization as being the cause of the instability.

Conductivity differences between the nitride and oxide layers, as discussed by Frohman-Bentchkowsky and Lenzlinger (13), were ruled out as being responsible for the instabilities noted because: (*i*) the capacitance-voltage curves were already shifted close to saturation in the negative voltage direction after Si_3N_4 deposition; (*ii*) application of fields on the order of $\pm 10^7$ V/cm at room temperature caused negligible shifts in the capacitance-voltage curves; (*iii*) application of fields on the order of $+5 \times 10^5$ V/cm or -2.5×10^5 V/cm at 300°C resulted in significant flat-band voltage shifts; and (*iv*) because conductivity measurements made on MNS (metal-nitride-silicon) capacitor structures indicated that the deposited Si_3N_4 was fairly nonconductive. Typically, conductivities less than 2×10^{-15} mho/cm were measured at fields of 4.5×10^6 V/cm and these values were in agreement with measurements made on silicon tetrachloride type Si_3N_4 films which did not exhibit the instability.

Trapping could also be ruled out since the observed shifts under elevated temperature positive and negative biases were opposite to those expected for hole or electron trapping in the oxide at the oxide-silicon interface, and also due to the thickness of the underlying oxide layers themselves. All evidence pointed to some type of relatively mobile ionic species as being responsible for the instabilities noted. The lack of complete recovery of the C-V characteristics under negative bias at 300°C could be accounted for by assuming that the species is mobile only in the oxide layer and could not penetrate the Si_3N_4 layer. Repeated 300°C stressing under positive and negative biases yielded the same total magnitude of C-V drift indicating that the contamination species was consistently mobile. The magnitude of the instability was completely unpredictable from run to run, or even within any one run, and could not be correlated with any of the process parameters being studied which also strongly suggested some form of ionic contamination.

Experimental

Chemically etched 1-3 ohm-cm p-type (111) Czochralski grown single-crystal silicon substrates, 1 in. in diameter, were thermally oxidized at 1200°C in dry oxygen immediately after etching and served as the primary test vehicle. The oxide thicknesses in all cases, except as noted, were 2000Å. Control wafers indicated that the conditions of oxidation yielded a fixed surface-state charge density, Q_{ss}/q, of 2×10^{11} charges cm^{-2} and a nondetectable amount of mobile ionic contamination, Q_o/q; that is, less than 4×10^{10} charges cm^{-2}.

Figure 2 shows a schematic of the deposition apparatus. The Si_3N_4 was deposited in an rf-heated horizontal system utilizing the reaction of silicon tetrachloride ($SiCl_4$) or silane (SiH_4) with ammonia (NH_3) in hydrogen or nitrogen ambients. The quartz reaction chamber has a 1¼ in. by 2¼ in. rectangular cross section and a volume of 1 liter. During the course of the investigation, total flow rates of from 3 to 6 liter/min were used. The Si_3N_4 thickness was normally 1000Å and deposited at 850°C (SiH_4 process) or 900°C ($SiCl_4$ process). The total flow rate and amounts of reacting gases were adjusted to yield deposition rates of from 100 to 150 Å/min. All deposits employed NH_3:$SiCl_4$ or SiH_4 ratios of 20:1 and 200:1, respectively; and all deposits appeared to be stoichiometric as determined by refractive index (1.99 to 2.00 at 6328Å) and etch rate measurements (3 to 5 Å/sec in 49% HF at 24°C — 0.7 to 1 Å/sec in H_3PO_4 at 153°C) and from previously conducted experiments evaluated by the technique discussed in Ref. (14).

Hydrogen and nitrogen were supplied from liquid sources through 316 stainless steel lines. The $SiCl_4$ used was supplied by Texas Instruments, Inc., and was contained in a quartz flask held at −10°C. The hydrogen carrier gas was bubbled through this flask and served to transport the $SiCl_4$ into the reaction chamber. The NH_3 used was Matheson ultra-high purity grade. Five per cent SiH_4 in nitrogen and 5% SiH_4 in hydrogen mixtures, also supplied by Matheson, were used during this investigation. Both sources of SiH_4 were analyzed for sodium by reacting the SiH_4 in a quartz combustion chamber, collecting the residue, and analyzing this using atomic absorption and flame spectrophotometric techniques (15). No evidence of sodium contamination in either source of SiH_4 was found.

As shown in Fig. 2 all gas lines, except the SiH_4 and $SiCl_4$ lines, leading to the mixing chambers were common for both types of Si_3N_4 deposits. The quartz reaction tube and susceptor support were fabricated from high purity quartz in our facilities. Care was exercised

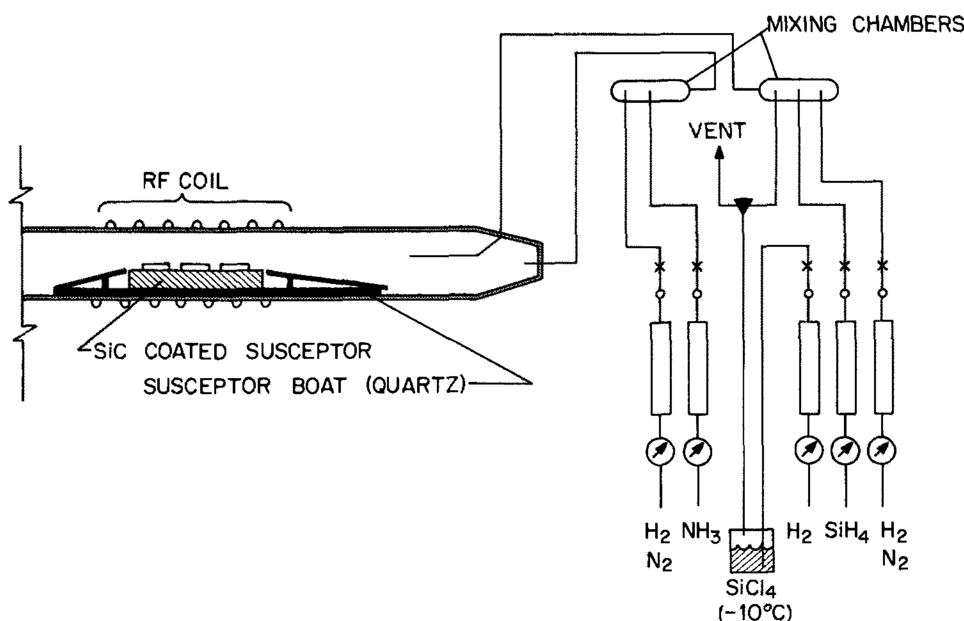

Fig. 2. Schematic of deposition apparatus used for depositing $SiCl_4$ and SiH_4-type Si_3N_4.

to eliminate any external source of contamination; nevertheless, preliminary evaluations as shown in Fig. 1 indicated that an electrical instability could be induced in the underlying oxide of MNOS device structures during the Si_3N_4 deposition process.

Electrical Measurements

Most of the electrical evaluations for this investigation employed the well known capacitance-voltage (C-V) technique (16). Early in the investigation, it was noted that if contamination was present after Si_3N_4 deposition, most of it would be located close to the oxide-silicon interface. Therefore the C-V curves were already shifted close to saturation and it was convenient to monitor the contamination levels using a gold ball probe (the gold ball serving as the capacitor field plate) immediately after deposition of the Si_3N_4 without waiting for subsequent aluminum metalization and annealing steps. For these measurements any dielectric on the backside was removed with hydrofluoric acid, and a drop of water was used to insure good backside contact between the silicon and the contact plate. The standard procedure was to monitor each run by making C-V measurements at five different locations on each wafer immediately after deposition. If no obvious C-V displacement was observed, it was necessary to metalize the structure and to stress it at elevated temperatures (300°C) with positive and negative biases applied to the field-plate to determine if any mobile contamination was present. Subsequently, all wafers were metalized and additional C-V measurements were obtained at room temperature, and after elevated temperature (300°C) bias stressing, to verify the results obtained with the gold probe. Excellent correlation between the gold probe and metallized C-V data was obtained in all cases.

In this paper, data will be expressed in terms of Q_o/q, the effective number of contamination charges per cm^2 at the oxide-silicon interface. These levels of contamination were obtained from experimental C-V curves after subtracting out the flat-band voltage component due to the metal-semiconductor work function (Φ_{ms}) and the value of the fixed surface-state charge density, Q_{ss}/q, at the oxide-silicon interface. The resulting values of ΔV (in volts), along with the effective oxide thickness ($x_{o[eff]}$) in microns, was then inserted into Eq. [1] [according to Ref. (16)] and the contamination levels computed

$$\frac{Q_o}{q}\ (\#/cm^2) = \frac{2.16 \times 10^{10}\ \Delta V\ (\text{volts})}{x_{o[eff]}\ (\text{microns})} \quad [1]$$

The constant 2.16×10^{10} includes values for the dielectric constant of the oxide layer (K_o), the permittivity of free space (ϵ_o), and appropriate scaling factors for ΔV given in volts and $x_{o[eff]}$ in microns.

Results

Silane-type Si_3N_4 deposits.—Initially, contamination levels on the order of 5×10^{11} to 10^{12} cm^{-2} were observed. However, occasionally, instability levels on the order of 10^{13} cm^{-2} were found. Experimentally, it was noted that the magnitude of the instability was considerably reduced when nitrogen was substituted for hydrogen as the carrier gas during deposition. As shown in Table I, contamination levels dropped significantly when nitrogen was employed as the carrier gas. This was very puzzling at first; however, as will be shown later, a very simple explanation is possible based on the work of Burgess and Donega (17). They studied the out-diffusion of sodium from quartz furnace tubes in various atmospheres and showed that the reaction of hydrogen with quartz resulted in a marked increase in sodium vapor pressure.

Since previous data, obtained in similar systems employing silicon tetrachloride as the source of silicon, did not show the type of electrical instability seen in the SiH_4-type deposits, it was decided to make $SiCl_4$-type Si_3N_4 deposits in the same system as had been used for the SiH_4-type deposits. No mobile ionic species were observed in MNOS capacitor structures fabricated from wafers used in these runs. Therefore, a series of consecutive Si_3N_4 deposits were made using either $SiCl_4$ or SiH_4 as the source of silicon. Table II shows typical C-V data from these runs. These data were obtained from consecutive runs without any cleaning of the deposition apparatus between runs. It

IS-308	$SiCl_4$	<0.4
IS-309	$SiCl_4$	<0.4
IS-310	$SiCl_4$	<0.4
IS-311	$SiCl_4$	<0.4

is noted that whenever $SiCl_4$ was used as the source of silicon, there was no detectable contamination in the MNOS structures subsequently fabricated on these wafers. However, whenever SiH_4 was used as the source of silicon, contamination was observed. Based on the data collected to this point, two ionic contaminants were considered as possible candidates for the contaminating species: sodium or an active species of hydrogen. Sodium was considered because of its prevalence and because of its previous history as an ionic contaminant in semiconductor processing. Hydrogen was considered based on the work of Balk (18) and Deal *et al.* (7).

In 1965, Balk proposed that adsorbed moisture at the oxide metal interface of MOS structures could react at elevated temperatures (on the order of 500°C) with aluminum or other reactive metals to form an active species of hydrogen which then migrates to the oxide-silicon interface and annihilates the fast surface-states. Recently (7) it has been shown that for MNOS structures, a SiH_4-type Si_3N_4 deposit results in lower fast surface-state densities at the oxide-silicon interface than does a $SiCl_4$-type Si_3N_4 deposit. It is speculated that a greater amount of active hydrogen is generated when the SiH_4 molecule breaks down than is available from the hydrogen carrier gas used in the $SiCl_4$-type deposits. In this study only electrical instabilities were associated with SiH_4-type deposits, and the magnitude of the instability was greater when hydrogen was used as the carrier gas than when nitrogen was used; therefore, active hydrogen was considered along with sodium as a possible candidate for the contaminating species.

Since all components except for the SiH_4 and $SiCl_4$ sources were common to both types of deposits, it was felt that either the SiH_4 had to be contributing contamination to the deposition ambient or the $SiCl_4$ process provided a chemical species capable of gettering or bonding with the contaminating species. The major chemical species present in the $SiCl_4$-type deposit, which is not present in the SiH_4-type deposit, is the chloride ion. Therefore, it was decided to add hydrogen chloride (HCl) to the SiH_4 deposition ambient to see if it would be effective in removing the source of contamination. Table III shows the results.

Since, as mentioned above, the magnitude of the instability was greater in a hydrogen ambient, for this experiment hydrogen carrier gas was employed. Run number 486 was made to obtain a rough estimate of the level of contamination associated with the SiH_4-type Si_3N_4 deposits at that time. As seen in Table III the contamination level was not as high as it had been previously, as can be seen by comparing it with data in Table I. Run number 487 was the first run wherein HCl was purposely added to the gas mixture. Only a small amount of HCl, approximately 3 cc/min, was used. From the C-V results, it is apparent that this amount of HCl was not significant enough to affect the contamination levels present. There is no explanation as to why the contamination level increased; however, based on previous history little significance need be attached to the level of contamination seen in this run.

Table III. $\frac{Q_o}{q}$ associated with SiH_4-type Si_3N_4 deposits with and without added HCl

Run	Si_3N_4 deposition ambient	$\frac{Q_o}{q}$ × (10^{-11} cm^2)
IS-486	SiH_4 in H_2	1 to 7
IS-487	SiH_4 in H_2 + 3 cc/min HCl	20 to 38
IS-488	SiH_4 in H_2 + 8 cc/min HCl	3 to 7
IS-489	SiH_4 in H_2 + 30 cc/min HCl	<0.4 (none)
IS-490	SiH_4 in H_2 + 30 cc/min HCl	<0.4
IS-491	SiH_4 in H_2	4 to 5
IS-492	SiH_4 in H_2	2 to 4
IS-493	SiH_4 in H_2 + 30 cc/min HCl	<0.4

The results from run number 488 indicate that 8 cc/min of HCl had little or no effect on the level of contamination. Therefore, in run number 489, the HCl concentration was increased until faint signs of ammonium chloride formation in the gas phase could be observed. The C-V results from this run indicated that all of the contamination had been either gettered or otherwise complexed. Therefore, the run conditions were repeated with the same results. Two additional SiH_4 in H_2-type Si_3N_4 deposits were then made in an attempt to recontaminate the furnace. As seen by the data of Table III, only a moderate amount of contamination was present; however, run number 493 again indicated that 30 cc/min of HCl was capable of gettering or complexing the ionic contamination present.

Heat-treatment with additions of HCl.—The above results demonstrated that the addition of HCl to the SiH_4 deposition ambient removed the ionic species normally seen in SiH_4-type Si_3N_4 deposits. However, the question still remained as to whether it was necessary to form ammonium chloride in order to eliminate the contaminating species. Therefore, an experiment was conducted to see if an HCl heat-treatment by itself was capable of removing the source of instability. Table IV shows C-V data obtained from this experiment. Although the amount of contamination present in the reactor during the above experiment was small, it is again seen that the added HCl was effective in removing the contamination present. The fact that contamination could be removed during a hydrogen plus HCl heat-treatment at 850°C (Table IV) indicated

Table IV. $\frac{Q_o}{q}$ associated with various types of heat-treatments and Si_3N_4 deposition ambients

Run	Heat-treatment and deposition ambient at 850°C	$\frac{Q_o}{q}$ × (10^{-11} cm^2)

IS-544	SiH_4-type Si_3N_4	1 to 5

that the ammonium chloride reaction is not necessary for removal of the contamination. Runs number 532 and 539 demonstrated that the contamination could actually be removed by introducing HCl prior to Si_3N_4 deposition. Therefore, it appears that it is not necessary to have HCl flowing during the actual Si_3N_4 deposition process to remove the source of contamination. This suggests that the contamination associated with the SiH_4-type Si_3N_4 deposits was not necessarily associated with the SiH_4 source itself, but that it was probably coming from some component of the reactor.

Sodium contaminated wafers.—Up to this time, we have conjectured that either electrically active hydrogen or sodium might be the contaminating species. The results reported above demonstrated that it is possible to use an HCl heat-treatment prior to SiH_4-type Si_3N_4 deposition and still remove the source of ionic contamination. This suggests that active hydrogen was not the cause of the instability. That is, it was possible to obtain contamination-free SiH_4-type Si_3N_4 deposits by employing the predeposition heat-treatment with HCl; and yet, active hydrogen is available when the SiH_4 molecule reacts. Of course, one could speculate that enough residual chloride ions are available during the Si_3N_4 deposition process to complex the active hydrogen; however, this possibility seems remote since typical deposition times were from 5-8 min, more than enough time to remove all traces of residual chloride. To verify that chloride ions are capable of gettering or complexing sodium ions, an additional experiment was carried out. Sample preparation for this experiment was as outlined previously, except that the wafers to be contaminated had an oxide which was 1000Å thick rather than the standard 2000Å. Each run included one purposely contaminated wafer and one uncontaminated wafer. Contamination was achieved by immersing the oxidized wafers in a solution containing 460 ppm of sodium. The contaminated wafers were then blown dry and given a 30 min heat-treatment in nitrogen at 550°C in order to diffuse the sodium close to the silicon dioxide-silicon interface. Gold probe C-V measurements were then made at five different locations on each wafer. The negative shift of the reference voltage after the heat-treatment was used to establish the minimum amount of electrically active sodium present. Table V shows typical gold probe C-V data obtained from the contaminated wafers after the 550°C heat-treatment. By referring to Table V it can be seen that, although the contamination levels were not uniform across a wafer, there were relatively large amounts of contamination in all wafers. One sodium contaminated wafer, along with an uncontaminated reference wafer, were then subjected to one of three different Si_3N_4 deposition processes.

Process I consisted of depositing 0.1μ of Si_3N_4 from SiH_4 and NH_3 in hydrogen ambient at 850°C. Process II consisted of a 10 min heat-treatment in a hydrogen plus HCl ambient at 900°C followed by a Process I Si_3N_4 deposition. Process III consisted of a 0.1μ Si_3N_4 deposit at 900°C using $SiCl_4$ plus NH_3 in a hydrogen ambient.

Table VI shows typical gold probe C-V data obtained from these wafers after Si_3N_4 deposition. From Table VI it is again seen that those runs which used either $SiCl_4$ as a source of silicon during the Si_3N_4 deposition, or those runs which had an HCl heat-treatment prior to a SiH_4-type Si_3N_4 deposition, resulted in contamination-free structures. Alternatively, for SiH_4 runs which did not have the HCl heat-treatment, considerable amounts of contamination were found in the structures after Si_3N_4 deposition. The data presented in Table VI indicate that both the $SiCl_4$-type Si_3N_4 deposition process and the HCl heat-treatment prior to SiH_4-type Si_3N_4 deposition process were capable of gettering the purposely added sodium contamination.

Table V. $\frac{Q_o}{q}$ **associated with sodium contaminated SiO_2 layers after a 30 min heat-treatment in N_2 at 550°C**

Wafer	Structure	$\frac{Q_o}{q} \times (10^{-11}\ cm^2)$
Na 1	460 ppm Na/0.1μ SiO_2/Si	25 to 130
Na 2	460 ppm Na/0.1μ SiO_2/Si	46 to 87
Na 3	460 ppm Na/0.1μ SiO_2/Si	49 to 79
Na 4	460 ppm Na/0.1μ SiO_2/Si	55 to 72
Na 5	460 ppm Na/0.1μ SiO_2/Si	46 to 70
Na 6	460 ppm Na/0.1μ SiO_2/Si	68 to 98

Table VI. $\frac{Q_o}{q}$ **associated with Si_3N_4 deposits made on sodium contaminated wafers**

Wafers	Structure	$\frac{Q_o}{q} \times (10^{-11}\ cm^2)$
640 A	0.1μ $Si_3N_4(SiH_4)$/0.2μ SiO_2/Si	24 to 27
640 B	0.1μ $Si_3N_4(SiH_4)$/Na2/0.1μ SiO_2/Si	18 to 31
641 A	0.1μ $Si_3N_4(SiH_4)$/0.2μ SiO_2/Si	14 to 21
641 B	0.1μ $Si_3N_4(SiH_4)$/Na4/0.1μ SiO_2/Si	22 to 37
642 A	0.1μ $Si_3N_4(SiCl_4)$/0.2μ SiO_2/Si	<0.4 (none)
642 B	0.1μ $Si_3N_4(SiCl_4$/Na1/0.1μ SiO_2/Si	<0.4
643 A	0.1μ $Si_3N_4(SiCl_4)$/0.2μ SiO_2/Si	<0.4
643 B	0.1μ $Si_3N_4(SiCl_4)$Na3/0.1μ SiO_2/Si	<0.4
644 A	H_2 + HCl(H.T.*) then 0.1μ Si_3N_4 (SiH_4)/0.2μ SiO_2/Si	<0.4

645 B	H_2 + HCl(H.T.) then 0.1μ Si_3N_4 (SiH_4)/Na6/0.1μ SiO_2/Si	<0.4

* Heat-treatment.

Discussion

From the experimental results obtained, it is concluded that the contaminating ionic species was sodium rather than an active species of hydrogen. However it is felt that the possibility of active hydrogen giving rise to electrical instabilities in an MNOS structure, fabricated with SiH_4-type Si_3N_4 deposits, should not be completely dismissed especially if relatively large amounts of SiH_4 are employed. Earlier experiments involving hydrogen heat-treatments on MNOS structures, employing palladium field plates, indicated that active hydrogen could give rise to electrical instabilities in MNOS structures (7).

Although sodium metal itself has a boiling point (892°C) close to the temperatures employed for Si_3N_4 deposition, it has been repeatedly verified that the ionic contamination, assumed to be sodium in all cases and known to be sodium in some, is generally located close to the oxide-silicon interface rather than at the oxide-silicon nitride or oxide-air interface after a SiH_4-type Si_3N_4 deposition or heat-treatment. Results from $SiCl_4$-type Si_3N_4 depositions, and from heat-treatments wherein HCl was added to the heat-treatment or deposition ambient, suggest that the chloride ion provides a definite gettering action in the removal or complexing of the ionic species. Two possibilities exist to explain these results: (*i*) the chloride ion reacts with sodium ions to form electrically inactive species or (*ii*) the chloride ions tend to react with the sodium ions to form a volatile sodium chloride species which is removed from the reaction chamber in the exhaust gases.

As mentioned previously, in the absence of a chloride-containing atmosphere during the Si_3N_4 deposition, most of the contamination tends to accumulate at the Si-SiO_2 interface of Si_3N_4/SiO_2/Si structures. Further, since the vapor pressure of sodium chloride at temperatures of from 850° to 900°C is only on the order of 1 mm Hg, one might therefore expect that the primary role of the chloride ion is to complex the contaminants forming electrically inactive species

rather than to form a volatile compound. Recently, Robinson and Heiman (19) have reported on a technique using HCl to getter sodium and other metal impurities in an oxidizing ambient at 1100°-1200°C. Their model assumes that HCl serves to form volatile metal chlorides. Although it is not clear which model plays the dominant role, our data seem to be in agreement with theirs indicating that chloride ions have the capability of gettering or complexing ionic contaminants from MOS structures.

It should be pointed out, however, that if there is no contamination present, stable MNOS devices can be fabricated using SiH_4-type Si_3N_4 deposits. However, if a source of contamination is present, there is no species available from the SiH_4 reaction which is capable of gettering the source of contamination. Apparently such a source of contamination existed in the quartz components of our experimental reactor which explains why, in the early stages of our investigation, larger instabilities were noted with hydrogen used as a carrier gas than with nitrogen. It is proposed that the hydrogen tends to etch the quartz releasing the source of contamination into the deposition ambient. Burgess and Donega (17) have studied the out-diffusion of sodium from a hot wall quartz furnace using atomic absorption techniques. Their work showed that the reaction of hydrogen with the hot quartz surface resulted in a marked increase in the sodium vapor pressure present in the furnace chamber. Further, their data indicated that the level of sodium contamination drops when hydrogen is replaced by a nitrogen ambient.

Conclusions

It is concluded that the $SiCl_4$ process for Si_3N_4 deposition has a built-in gettering capability for removing ionic contaminants from device structures during Si_3N_4 deposition which is not available in the SiH_4 process. It is proposed that the gettering capability arises from the presence of chloride ions. This premise was verified by purposely adding a source of chloride ions either prior to or during SiH_4-type Si_3N_4 depositions.

Acknowledgments

The authors would like to thank B. E. Deal and M. L. Barry for helpful discussions and encouragement given during the course of these investigations. We would also like to express our thanks to M. L. Barry for suggesting the HCl experiments.

Kinetics of Thermal Growth of Ultra-Thin Layers of SiO_2 on Silicon

Part II. Theory

R. Ghez and Y. J. van der Meulen*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The thermally activated growth of oxide on silicon as a function of time obeys a linear-parabolic relationship, the linear part of which stems from interface limited reactions. In Part I of this paper, it has been reported that this linear part cannot result from a single rate-limiting reaction step, because the order of the over-all reaction rate differs for different substrate orientations at a fixed temperature and varies for a given orientation as a function of temperature. A kinetic model for the reaction between silicon and oxygen at the Si-SiO_2 interface is now presented to account for the experimental data ($d_{SiO_2} \leq 300Å$, $T_{ox} = 700°\text{-}1000°C$, $\bar{p}_{O_2} = 0.01\text{-}1.0$ atm). Two parallel, competing reactions are postulated to occur. In the first of these, molecular oxygen reacts directly with silicon to form silicon dioxide and atomic oxygen; the second reaction involves the dissociation of O_2. The atomic oxygen thus formed, may either react with silicon or recombine to molecular oxygen. An analysis of the data shows that a difference in the activation energies (*i.e.*, 1.91 *vs.* 0.58 eV) associated with these competing reaction steps is responsible for the shift in their relative importance as a function of temperature.

It is generally recognized that the measurement of oxidation kinetics does not allow a unique determination of the reaction mechanism. For example, logarithmic growth (*i.e.*, the oxide thickness increases with the logarithm of time) can result from chemisorption (1), from field-assisted diffusion (2, 3), and from surface-controlled reactions (4). However, the oxidant pressure dependence of the growth rate, *i.e.*, the order of the reaction, may furnish further insight into the reaction mechanism (5).

A number of investigations of the kinetics of silicon oxidation, in dry oxygen as a function of oxidant pressure, have been made under widely varying conditions. Law (6) has observed, close to room temperature, an exponential growth rate in the 1-2 monolayer region with a square root dependence on oxygen pressure in the $10^{-4}\text{-}10^{-2}$ Torr range. At higher temperatures (850°-1200°C) and greater oxide thicknesses ($L > 350Å$), others (7-11) have observed that the kinetics are essentially of a mixed linear-parabolic type

$$\frac{L^2}{k_{par}} + \frac{L}{k_{lin}} = t$$

where k_{par} and k_{lin} are the rate constants, the first one increasing linearly with O_2 pressure. In this thickness range, the linear dependence is thought to arise from an interface reaction limited mechanism while the parabolic one is attributed to a diffusion-controlled process through the growing oxide.

Part I of this paper, by one of the present authors (12), described an ellipsometric study of the formation of thin SiO_2 layers ($L < 300Å$), on <111> and <100> oriented silicon wafers, at temperatures (T) from 700° to 1000°C and oxygen partial pressures ($\bar{p}_{O_2}$) from 0.01 to 1.0 atm. After a fast initial increase in thickness, the growth was found to be linear in time except for a slight parabolic perturbation indicating the onset of diffusion-controlled growth. The results reported in Fig. 4 of Part I have been replotted in normalized form in Fig. 1a and 1b. It can be seen that the linear rate constant depends on the oxygen partial pressure and the temperature, as well as on the silicon orientation. The pressure dependence of k_{lin} tends towards a $p^{1/2}$ behavior at lower temperatures; at higher temperatures, the trend is towards a linear pressure dependence for both orientations. The first order pressure dependence of the linear rate constant reported at 1200°C (10) is consistent with these data. Although the controversy (9, 13, 14, 15) over the ionic nature of the diffusing species remains unresolved, earlier work (10) shows that k_{par} exhibits a first order pressure dependence. Since dissociation of oxygen at the outer interface, together with the subsequent transport of the atomic species, necessarily gives rise to a non-first order pressure dependence of k_{par}, the evidence indicates that a molecular species (*e.g.*, O_2 or O_2^-) is transported across the amorphous oxide film.

Based on extensive measurements, Deal and Grove (10) proposed a kinetic scheme for the oxidation of silicon. For their model, they assume the incorporation of molecular oxygen at the gas-oxide interface followed by its transport through the oxide and direct reaction of this single oxidant species with the silicon. Consequently, the pressure dependence for all three steps should be linear. The experimental results reported in Part I of this study do not support this model since the pressure dependence of the linear rate constant was found to vary as described above. To account for this discrepancy, the present article proposes a more general kinetic treatment which incorporates two parallel, competing processes at the Si-SiO_2 interface. This scheme includes the one proposed by Deal and Grove as a special case, and it will be seen that their mechanism is valid as a limiting case at high temperatures.

Theory

Kinetic model.—Consider a growing oxide film of thickness L (Fig. 2). It is assumed that neutral molecular oxygen (O_2) is transported across the film, which implies that field and space charge effects are neglected as is ionization of the oxidant at the outer gas-oxide interface.[1] It also means that for atomic species,

[1] The existence of a fast initial mechanism is apparent in the data of Part I of this study, Fig. 3. This might be explained in terms of one of the theories previously mentioned (2-5) although there is not sufficient data to warrant such a test. It should be pointed out that the high Si-SiO_2 work function difference (≃3.2 eV) precludes any significant electron tunneling except for the very first stages of the oxidation process. The formation of charged oxygen species on the surface is, therefore, rather improbable.

Key words: Si, SiO_2, oxidation, linear rate constant, interface reactions.

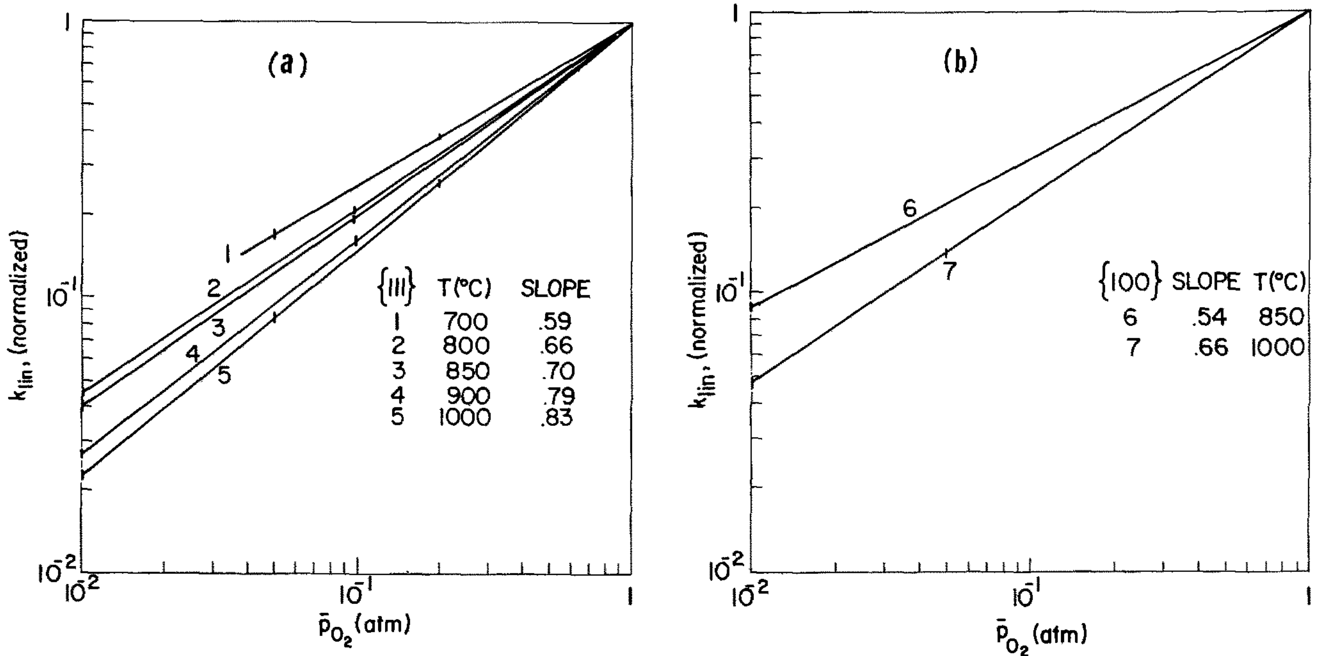

Fig. 1. Normalized plot of log k_{lin} vs. log $\overline{p_{O_2}}$: a, <111> orientation; b, <100> orientation

which are known not to contribute significantly to the oxygen transport (8, 10), the product of the effective diffusion coefficient and the concentration gradient is negligible although dissociation and association of molecular and atomic oxygen species can occur throughout the layer. The system is also thought to be in a quasi-stationary state, *i.e.*, the reactant concentrations are essentially constant during the relaxation times of the reactions involved.

The oxygen flux, F_o, across the O_2-SiO_2 interface is approximated by

$$F_o = h\,(C^* - C_o) \quad [1]$$

where h is a transfer coefficient which may include an adsorption activation energy, C_o is the actual molecular oxygen concentration in the solid at $x = 0$ (Fig. 2), and C^* is the equilibrium concentration related to the partial pressure through Henry's law

$$C^* = K\,\overline{p}_{O_2} \quad [2]$$

Under the above assumptions the flux across the oxide is derived from Fick's first law

$$F = D\,(C_o - C_L)/L \quad [3]$$

where C_L is the oxidant concentration at $x = L$, and D is the diffusion coefficient.

At the SiO_2-Si interface, the following reactions are postulated to occur

$$\text{Si—Si} + O_2 \rightarrow \text{Si—O—Si} + O \quad [R1]$$

$$\text{Si—Si} + O \rightarrow \text{Si—O—Si} \quad [R2]$$

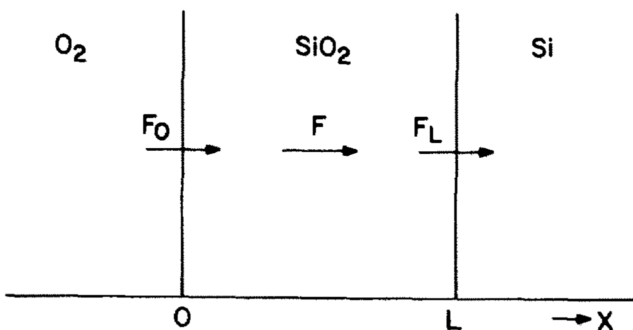

Fig. 2. Schematic representation of the $O_2|SiO_2|Si$ system

$$O_2 \rightleftarrows 2\,O \quad [R3]$$

The formulation of the first two reactions is not stoichiometric in SiO_2 but is intended merely to indicate that in reaction [R1] an oxygen molecule reacts with a Si—Si bond, whereas in reaction [R2] the attacking species is an oxygen atom.[2]

These reactions are now considered kinetically. If v_1, v_2, and v_3 are the reaction velocities of reactions [R1-R3], respectively, the time dependence of the oxygen species concentrations at the SiO_2-Si interface ($x = L$) can be expressed mathematically (16) as

$$\frac{d}{dt}[O]_L = v_1 - v_2 + 2v_3 \quad [4a]$$

$$\frac{d}{dt}[O_2]_L = F_L - v_3 - v_1 \quad [4b]$$

where F_L is the oxidant flux at $x = L$. Equation [4b] indicates that the neighborhood of the SiO_2-Si interface is an open system; thus, the quantity of available molecular oxygen depends on the flux F_L as well as on the reactions [R1] and [R3]. The assumption of quasi-stationary state implies that

$$\frac{d}{dt}[O]_L, \frac{d}{dt}[O_2]_L \cong 0 \quad [5]$$

Thus one obtains

$$v_1 - v_2 + 2v_3 = 0 \quad [6]$$

and

$$F_L = v_1 + v_3 \quad [7]$$

Mathematically, F_o and F_L given by Eq. [1] and [7] are boundary conditions for the diffusion equation of which Eq. [3] is the first integral. Thus

$$F = F_o = F_L \quad [8]$$

When C_o is eliminated from Eq. [1] and [3], one obtains

$$F = h'\,(C^* - C_L) \quad [9]$$

where the diffusion coefficient has been imbedded in the variable

[2] It is possible to formulate alternative reaction equations. The scheme chosen, however, has two advantages, i.e., different attacking oxidant species are taken into account and their reaction with the silicon is considered in terms of breaking Si-Si bonds.

$$h' = h/(1 + hL/D) \quad [10]$$

Any further reduction in the equations can only take place under the assumption of some functional relation between reaction velocities and concentrations. Because the reactions [R1-R3] are considered to be elementary steps (17), the reaction velocities must have the form

$$v_1 = k_1 [O_2]_L \quad [11a]$$

$$v_2 = k_2 [O]_L \quad [11b]$$

$$v_3 = k_3 [O_2]_L - k_{-3} [O]_L^2 \quad [11c]$$

where the subscript -3 in k_{-3} refers to the reverse reaction. The reverse reactions in Eq. [11a] and [11b] are neglected because of the large thermodynamic stability of SiO_2 relative to that of the reactants. Notice that Eq. [11a] and [11b] together represent the reaction velocity considered by Deal and Grove (10). From Eq. [6] and [11a-c], one finds that

$$2k_{-3} [O]_L^2 + k_2 [O]_L - (k_1 + 2k_3) [O_2]_L = 0 \quad [12]$$

Combining Eq. [7], [9], [11a], and [11c], and bearing in mind that $[O_2]_L \equiv C_L$, one obtains

$$F = (k_1 + k_3) C_L - k_{-3} [O]_L^2 = h' (C^* - C_L) \quad [13]$$

which yields

$$C_L = \frac{h' C^* + k_{-3} [O]_L^2}{k_1 + k_3 + h'} \quad [14]$$

Elimination of $[O_2]_L$ between Eq. [12] and [14] results in

$$(k_1 + 2h') k_{-3} [O]_L^2 + k_2 (k_1 + k_3 + h') [O]_L - h' (k_1 + 2k_3) C^* = 0 \quad [15]$$

which is a quadratic equation for $[O]_L$ in terms of the only accessible parameter C^*. Elimination of C_L between Eq. [13] and [14] yields an expression for the flux in terms of $[O]_L$; the latter concentration is the positive solution of Eq. [15]. The growth rate of the oxide film is then

$$\frac{dL}{dt} = \Omega F = \frac{\Omega h'}{k_1 + 2h'} \left\{ k_1 C^* + \frac{k_2}{2k_{-3} (k_1 + 2h')} [- k_2 (k_1 + k_3 + h') + (k_2^2 (k_1 + k_3 + h')^2 + 4(k_1 + 2h') \cdot h' k_{-3} (k_1 + 2k_3) C^*)^{1/2}] \right\} \quad [16]$$

where Ω is the volume of oxide formed per transported O_2 molecule. As is seen from Eq. [16], the order of the reaction, *i.e.*, the dependence of the growth rate on the exponent of $\overline{p}_{O_2}$ and thus of C^* (cf. Eq. [2]), lies between the limits 1/2 and 1. It will be seen later that these limiting orders can be achieved for certain ranges of the temperature dependent kinetic coefficients.

Thickness-time dependence.—In this section the rate Eq. [16] is integrated to give the dependence of the oxide film thickness on oxidation time and pressure. To simplify Eq. [16], the following dimensionless variable is introduced

$$\xi' = \frac{(k_1 + k_3 + h')}{h'} \quad [17]$$

or, using Eq. [10]

$$\xi' = 1 + \frac{k_1 + k_3}{h} \left(1 + \frac{hL}{D}\right) \quad [18]$$

Notice that ξ' is always greater than 1. If one defines four additional parameters

$$\lambda = 1 + 2 k_3/k_1 \quad [19a]$$

$$\mu = k_2^2/2k_{-3} \quad [19b]$$

$$A = 2k_1 C^*/(1 + \lambda) \quad [19c]$$

$$B = 4k_1 k_{-3} \lambda C^*/k_2^2 (1 + \lambda) \quad [19d]$$

which satisfy the relation

$$A\lambda = \mu B \quad [20]$$

Eq. [16] becomes

$$\frac{d\xi'}{dt} = \frac{k_1 (1 + \lambda)}{2D} \frac{dL}{dt} = \frac{\Omega k_1 (1 + \lambda)^3}{8D} \cdot \frac{A (\xi' + \lambda) + \mu[-\xi' + (\xi'^2 + 2B (\xi' + \lambda))^{1/2}]}{(\xi' + \lambda)^2} \quad [21]$$

Let t_o correspond to the approximate end of the fast initial oxidation when $L = L_o$ and $\xi' = \xi_o'$; if one integrates Eq. [21] from time t_o to a variable time, t, one gets

$$\frac{\Omega k_1 (1 + \lambda)^3 (t - t_o)}{8D} = \int_{\xi_o'}^{\xi'} \frac{(\xi + \lambda)^2 d\xi}{A (\xi + \lambda) + \mu[-\xi + (\xi^2 + 2B (\xi + \lambda))^{1/2}]} \quad [22]$$

The right-hand side of Eq. [22] is an Abelien integral which can be solved by standard substitutions. Alternatively, however, using Eq. [20] it is possible to reduce the integrand to

$$\frac{1}{A} \left\{ \xi + \frac{\lambda}{2\lambda - B} [((\xi + B)^2 + B (2\lambda - B))^{1/2} - (\xi + B)] \right\} \quad [23]$$

the integral of which is readily obtained from tables (18). In either case, one finally obtains

$$\frac{\Omega k_1 (1 + \lambda)^3 (t - t_o)}{8D} = \frac{1}{2A} \left\{ \xi^2 + \frac{\lambda}{2\lambda - B} (\xi + B) \cdot (R - (\xi + B)) - \lambda B \ln | R - (\xi + B)| \right\}_{\xi_o'}^{\xi'} \quad [24]$$

where R represents the radical expression in Eq. [22] and [23]. As before, Eq. [18] relates L to ξ'.

Discussion

In the preceding section, a kinetic scheme led to expressions for the oxygen flux, Eq. [16], and the oxide thickness, Eq. [24]. In this section the general pressure dependence of the growth rate is first examined. Then the conditions under which linear growth occurs are discussed and compared to the experimental data reported in Part I of this study. The various cases involving diffusion limited growth are discussed in the Appendix.

Incorporating Eq. [2] into the general rate equation, [16], one gets

$$\frac{dL}{dt} = \frac{\Omega \xi' \mu}{(2 + k_1/h')^2} \{\alpha' p - 1 + (1 + 2 \beta' p)^{1/2}\} \quad [25]$$

where

$$\alpha' = \frac{2k_{-3}k_1K}{k_2^2} \cdot \frac{2 + k_1/h'}{1 + k_1/h' + k_3/h'} \quad [26]$$

$$\beta' = \frac{2k_{-3}(2k_3 + k_1)K}{k_2^2} \cdot \frac{2 + k_1/h'}{(1 + k_1/h' + k_3/h')^2} \quad [27]$$

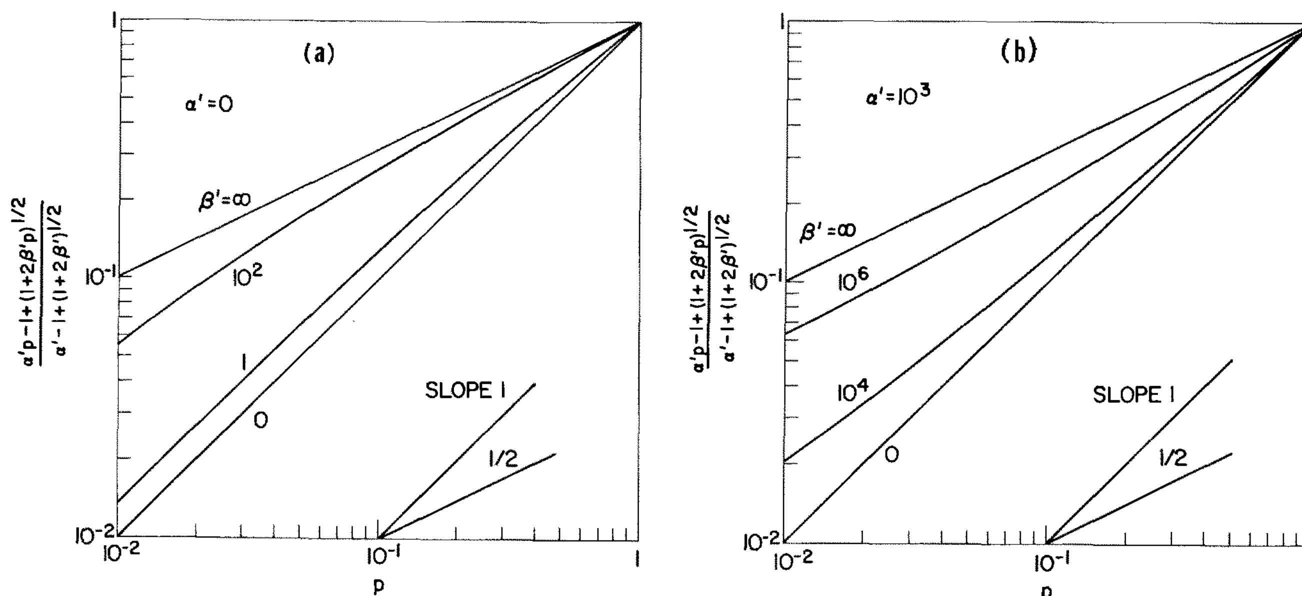

Fig. 3. Normalized plot of Eq. [25] for different values of β': a, $\alpha' = 0$; b, $\alpha' = 10^3$

Figure 3 shows normalized graphs of the growth rate *vs.* the oxygen partial pressure for various pairs of values of α' and β'. The values chosen serve to indicate the possible variation in the apparent order of the reaction and it is seen that a continuous transition between the limiting cases of half power and linear pressure dependence is possible. Moreover, the deviation from linearity in the curves between $p = 0.01$ and 1.0 atm is small and, in our case, falls outside the experimental reach. It should be noted that the coefficients h', ξ', α', and β' depend on the thickness L, making it difficult to fit Eq. [25] to the experimental results. The analysis becomes considerably more simple in the case of purely linear growth which takes place in sufficiently thin films.

Linear growth occurs when the surface (O_2-SiO_2) and the interface (SiO_2-Si) reactions are rate limiting. It is observed if, and only if, the right-hand side of Eq. [21] and [25] is independent of L. In view of Eq. [18], this condition is met if

$$\frac{hL}{D} << 1 \qquad [28]$$

for all experimentally observed values of L. In this case h' reduces to h and one may define

$$\xi = 1 + (k_1 + k_3)/h \qquad [29]$$

Defining parameters α and β, equal to α' and β' of Eq. [26] and [27], in which the primes have been dropped, the linear growth rate is

$$\frac{dL}{dt} = \frac{\Omega\xi\mu}{(2 + k_1/h)^2}\{\alpha p - 1 + (1 + 2\beta p)^{1/2}\} \qquad [30]$$

The pressure dependence of the linear rate constant is the same as that of the general rate constant, therefore, Fig. 3 also depicts Eq. [30]. The coefficients α and β are now independent of the thickness, allowing a comparison with the experimental values of the linear rate constant. Note that the expressions for α and β contain six unknown reaction rate constants, each of which follows the Arrhenius law. Comparing Fig. 3 with Fig. 1, it is already seen that the experimental results are qualitatively described by the proposed scheme.

Further analysis of Eq. [30] depends on the values of the pressure and the temperature. On the basis of the physical processes involved, several limiting cases can be distinguished:

Assume the limiting process to occur at the O_2-SiO_2 interface.—Then $\xi >> 1$ and Eq. [30] now reduces to

$$\frac{dL}{dt} = \Omega\, hC^* = \Omega\, Khp \qquad [31]$$

a result that is indeed expected and entails a linear pressure dependence. It conflicts, however, with the present experimental results and this case must, therefore, be eliminated from further consideration.

Assume the limiting process to occur at the SiO_2-Si interface.—Then $\xi \cong 1$ and Eq. [30] now reduces to

$$\frac{dL}{dt} = \frac{\Omega}{2}\left\{k_1C^* + \frac{\mu}{2}\left[-1 + \left(1 + \frac{4}{\mu}(k_1 + 2k_3)C^*\right)^{1/2}\right]\right\} \qquad [32]$$

The general form of Eq. [30] is thus maintained and the observed pressure dependence of the linear rate constant can be fully explained on the basis of reactions at this interface only.

Equation [32] allows further discussion.

Assume that the process described by reaction [R1] can be neglected.—Now Eq. [32] reduces to

$$\frac{dL}{dt} = \frac{\Omega\mu}{4}(-1 + (1 + 2\gamma p)^{1/2}) \qquad [33]$$

where

$$\gamma = \frac{8k_3k_{-3}K}{k_2{}^2} \qquad [34]$$

Equation [33] is still characterized by a mixed pressure dependence (cf. Fig. 3a).

Assume that $k_3 \cong 0$.—This simplifies Eq. [32] to

$$\frac{dL}{dt} = \frac{\Omega}{2}\left\{k_1Kp + \frac{\mu}{2}\left[-1 + \left(1 + \frac{4}{\mu}k_1Kp\right)^{1/2}\right]\right\} \qquad [35]$$

while maintaining a mixed pressure dependence. Further analysis of this case shows, however, that both for small and for large values of the parameter $\left(\frac{k_1K}{\mu}\right)$, a first order pressure dependence is obtained; and even for intermediate values of this parameter

$$\frac{dL}{dt} \propto p^x \quad [36]$$

where $0.9 \leq x \leq 1.0$. This subcase, therefore, results in a rather unsatisfactory solution.

Assume that the process described by reaction [R2] can be neglected.—Now Eq. [36] can be written as

$$\frac{dL}{dt} = \Omega F = \frac{\Omega}{2} k_1 K p \quad [37]$$

It is seen that this case is precluded on basis of the first order pressure dependence.

Assume that the processes described by reaction [R3] are negligible.—This simply reduces Eq. [32] to

$$\frac{dL}{dt} = \Omega\, k_1 C^* = \Omega\, K\, k_1 p \quad [38]$$

This is exactly the linear situation described by Deal and Grove (10) for short oxidation times; again, it does not exhibit the required pressure dependence.

Summarizing the case of linear growth, it was seen that several combinations of rate-limiting steps give rise to the observed pressure dependence of the linear rate constant. At this time it cannot be concluded unambiguously which of the steps in the proposed reaction scheme is associated with the part that is linear in pressure, as either reaction [R1] or reaction [R3] could be responsible. It is clear, however, that the part following a half power dependence stems from the reaction of atomic oxygen with silicon at the SiO_2-Si interface.

In discussing the differences found between samples of different surface orientation, we will use an approach similar to the one of Ligenza (19) who, using high pressure steam as an oxidant, observed that the oxide growth was linear in time and in steam pressure and depended strongly on the silicon orientation ($k_{(110)} > k_{(311)} > k_{(111)}$). This orientation effect was assumed to stem from the different number of bonds accessible to the oxidant per unit area. Although no experiments were reported using (100) material, it was calculated that this orientation should have the highest activation energy for oxidation, as well as the smallest surface density of available reaction sites. The approach used is valid because the rate of growth of the oxide film, *i.e.*, the silicon oxidation rate, is proportional to the number of accessible bonds per unit area at a given time. Some basic shortcomings of Ligenza's approach, which cannot be remedied easily, are that the surface planarity is thought to be ideal regardless of orientation, lattice relaxations at the oxide-semiconductor interface are not considered, and various surface defects (*e.g.*, dislocations) cannot be taken into account. A more practical objection is that the existing treatment does not take into account the fact that for the (111) orientation, in which we are interested, two different kinds of atoms can be distinguished on the basis of their position with respect to the surface. One type is connected to the underlying atoms by three bonds at an angle of 19°25′ with the surface, the other type is connected by only one bond at an angle of 90°. If this is properly accounted for one may expect an over-all reaction rate of the following form to be operative

$$\frac{1}{k} = \frac{1}{k_T} + \frac{1}{3k_B}$$

where k_T refers to the reaction rate with the three angled bonds and k_B to the reaction rate with the perpendicular bond. In (100) oriented material, on the other hand, all surface atoms are equivalent and are connected to the substrate by two covalent bonds that make an angle of 35°16′ with the surface. Thus in this case a single reaction rate can be used. The fact that our experimental results show that $k_{lin}(111) > k_{lin}(100)$ indicates that k_B is sufficiently large to preserve the sequence deduced by Ligenza. All other experimental conditions being equal, our results also show that, for oxidation on (100) oriented substrates, the order of the reaction is lower. This reflects the higher degree of steric hindrance for this direction for which direct reaction with molecular oxygen is apparently less favored than for the (111) orientation. This difference between the two orientations contrasts with the one found for the etch rates in wet ambients where the close packed (111) surface is less reactive (20).

Using the variable metric method (21), numerical values for the constants in Eq. [32] were calculated for the $\langle 111 \rangle$ orientation from the experimental data with the help of an IBM 360/91 computer. Reflecting the greater experimental precision, relatively more weight was given to data points representing higher growth rates. A minimum value of the following expression was sought

$$\sum_T \sum_P \left(\left(\left(\frac{dL}{dt} \right)_{\text{calc}} \Big/ \left(\frac{dL}{dt} \right)_{\text{meas}} \right) - 1 \right)^2 \cdot \left(\frac{dL}{dt} \right)_{\text{meas}}^{1/4}$$

This procedure gave a very satisfactory fit to the experimental points and resulted in

$$\left(\frac{dL}{dt} \right)_{\text{calc}} \Big/ \left(\frac{dL}{dt} \right)_{\text{meas}} = 1.00 \pm 0.05$$

Expressing the activation energies in electron volts, it was found that

$$\Omega\mu = 4.72 \exp(-2.07/kT) \text{ cm min}^{-1}$$

$$k_1 K/\mu = 1.75 \exp(0.16/kT) \text{ atm}^{-1}$$

$$k_3 K/\mu = 8.12 \times 10^{-6} \exp(1.49/kT) \text{ atm}^{-1}$$

The solubility of molecular oxygen in vitreous silica is approximately constant over the temperature range involved (700°-1000°C), which means that in Henry's law the exponential term containing the enthalpy of solution, $\exp(-\Delta H/RT)$, varies approximately as T at these temperatures, thus a single value of $K = 7.5 \times 10^{16}$ cm^{-3} atm^{-1} can be used (22). Estimating $\Omega = 4.44 \times 10^{-23}$ cm^3, one calculates

$$k_1 = 2.47 \times 10^6 \exp(-1.91/kT) \text{ cm min}^{-1}$$

$$k_3 = 1.15 \times 10^1 \exp(-0.58/kT) \text{ cm min}^{-1}$$

$$\mu = 1.06 \times 10^{23} \exp(-2.07/kT) \text{ cm}^{-2} \text{ min}^{-1}$$

$$\lambda = 1 + 2k_3/k_1 = 1 + 9.3 \times 10^{-6} \exp(1.33/kT)$$

$$\frac{2\lambda}{B} = 1.14 \exp(-0.16/kT) \cdot \{1 + 4.65 \times 10^{-6} \exp(1.33/kT\} p_{O_2}{}^{-1}$$

Table I shows typical values of these parameters. The activation energy of k_1 (1.91 eV) is very similar to the value reported by Deal and Grove (10) (1.99 eV).[3]

[3] Using the same procedure to fit Eq. [33] to the results yields a value of 1.89 eV for this activation energy. In this case, however, the over-all agreement between calculation and experiment is less satisfactory.

Table I. Typical values of the kinetic coefficients, k_1 and k_3, and the parameters λ and $2\lambda/B$ for $\langle 111 \rangle$ Si

T (°C)	k_1 (cm min^{-1})	k_3 (cm min^{-1})	λ	$2\lambda/B$ (atm^{-1})
700	3.21×10^{-4}	1.14×10^{-2}	72.4	6.22
800	2.68×10^{-3}	2.18×10^{-2}	17.3	1.85
900	1.56×10^{-2}	3.72×10^{-2}	5.78	0.79
1000	6.86×10^{-2}	5.84×10^{-2}	2.70	0.49

Knowledge of the equilibrium constant for reaction [R3] in the gas phase is not sufficient to calculate k_{-3} since the solubility of atomic oxygen in vitreous silica is unknown. Although k_3 has been calculated, a separate determination of either k_{-3} or k_2 is impossible, since they only occur combined in μ. It is seen that λ decreases with increasing temperature, reflecting the fact that reaction [R1] becomes dominant.

Summary

A model describing the oxidation kinetics of silicon in oxygen has been developed to account for the experimentally observed nonlinear pressure dependence of the linear rate constant. Based on earlier literature it was assumed that molecular oxygen is transported through the oxide, giving rise to a linear pressure dependence of the parabolic rate constant. The essential feature of this model is to allow for two parallel, competing reaction processes at the SiO_2-Si interface. In the first process, O_2 reacts with Si-Si bonds forming Si-O-Si and O; in the second one, O_2 dissociates prior to reaction with Si. The former process is dominant at high temperatures, the latter becomes more important at lower temperatures. A comparison with the experimental data for <111> oriented material made it possible to calculate some of the rate constants involved.

Manuscript submitted Jan. 24, 1972; revised manuscript received March 20, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1973 JOURNAL.

APPENDIX

In the general case, the growth law [24] affords a discussion of thick film growth kinetics for which diffusion effects are important. The following discussion will show that the growth kinetics remain essentially of the mixed linear-parabolic type. Inspection of Eq. [24] shows that its form depends critically on the relative magnitude of 2λ and B. This is not surprising since, in the limit $\lambda \to 1$, reaction [R1] completely dominates reaction [R3]; whereas, for $\lambda \to \infty$, the converse is true. The ratio $2\lambda/B = (k_2/k_1)^2 (k_1 + k_3)/k_{-3}C^*$ provides a more stringent condition since it depends on the ratio k_1/k_2. For example, even when $\lambda >> 1$, the process [R2-R3] will dominate over [R1] only if $k_2 > k_1$, which implies that $2\lambda/B > 1$. Table I shows that $B < 2\lambda$ holds at low temperatures, whereas, $B > 2\lambda$ is satisfied at high temperatures, the transition point occurring at roughly 865°C. The growth law [24] can now be cast into the following form

$$2\Omega C^* (k_1 + k_3)^2 (t - t_o)/D = \xi'^2 - \xi_o'^2 + \lambda B (S - S_o) \qquad [A1]$$

or in terms of the thickness L, related to ξ' by Eq. [18]

$$2\Omega D C^* (t - t_o) = L^2 - L_o^2 + 2D(1/h + 1/(k_1 + k_3))(L - L_o) + (D/(k_1 + k_3))^2 \lambda B (S - S_o) \qquad [A2]$$

where S is defined as

$$S = \begin{cases} \eta[(\eta^2 + 1)^{1/2} - \eta] - \ln[(\eta^2 + 1)^{1/2} - \eta] & \text{if } B < 2\lambda \\ \zeta[\zeta - (\zeta^2 - 1)^{1/2}] - \ln[\zeta - (\zeta^2 - 1)^{1/2}] & \text{if } B > 2\lambda \end{cases} \qquad [A3]$$

Table II. Typical values of the kinetic coefficients λB, $(k_1 + k_3)/D$, and $(k_1 + k_3)/h$ for <111> Si

T (°C)	D (cm² min⁻¹)	λB	$(k_1 + k_3)/D$ (cm⁻¹)	$(k_1 + k_3)/h$
700	0.15×10^{-7}	1680	8.04×10^5	7.06×10^{-5}
1000	3.89×10^{-7}	30	3.26×10^5	7.62×10^{-4}

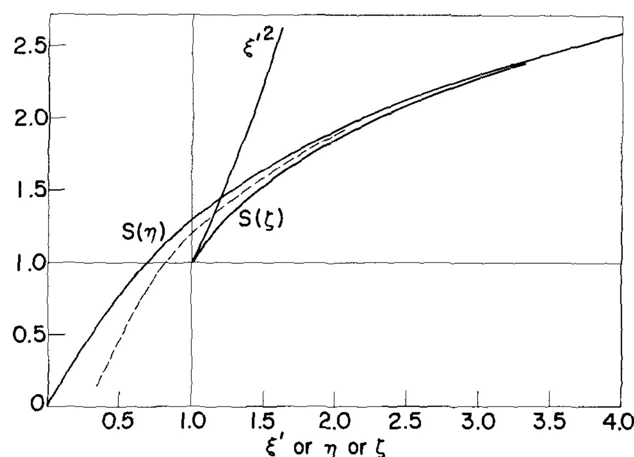

Fig. 4. Comparison of the parabolic and logarithmic terms ξ'^2 and S as given in Eq. [A1].

and is a function of the arguments

$$\begin{cases} \eta = (\xi' + B)[B(2\lambda - B)]^{-1/2} & \text{if } B < 2\lambda \\ \zeta = (\xi' + B)[B(\lambda - 2B)]^{-1/2} & \text{if } B > 2\lambda \end{cases} \qquad [A4]$$

Equation [A2] shows that the oxidation kinetics are of mixed linear-parabolic type with a correction term S which will be discussed presently. The expression S_o in Eq. [A1] and [A2] is obtained by evaluating S, given by Eq. [A3] and [A4] at $\xi' = \xi'_o$. Notice that ζ is always greater than 1 and that the logarithmic terms in S can be expressed as inverse hyperbolic functions. The relative importance of the function, S, for thick films can be seen in the following way. Using numerical values for $h (\cong 10^8 \mu/h)$ (10) and D (21), together with the results as given in Table I, an estimate of $(k_1 + k_3)/D$ and $(k_1 + k_3)/h$ can be made; the result for a "low" and a "high" temperature is given in Table II. From Eq. [18], one finds that

$$\xi'(700°C) \cong 1 + 8 \times 10^5 L \text{ cm}$$

$$\xi'(1000°C) \cong 1 + 3.3 \times 10^5 L \text{ cm}$$

and from Eq. [A4] that

$$\eta(700°C) \cong 0.46 + 0.15 \times 10^5 L \text{ cm}$$

$$\zeta(1000°C) \cong 1.54 + 0.42 \times 10^5 L \text{ cm}$$

It follows that, for $L \leq 1000Å$, ξ', η, and ζ are of the same order of magnitude. The functions ξ'^2, $S(\eta)$, and $S(\zeta)$ are plotted in Fig. 4. Although the functions S initially increase linearly with L, thus contributing to the linear growth which was discussed previously, their behavior is logarithmic for larger thicknesses. More precisely, their asymptotic behavior is

$$S \sim 0.5 + \ln(2(\eta \text{ or } \zeta)) \qquad [A5]$$

and is presented as a dashed curve in Fig. 4. Thus, except perhaps for very low temperatures when λB becomes very large, the correction term, S, is negligible in the thick film region.

Summarizing the general case, the growth kinetics described by Eq. [A2] are of mixed linear-parabolic type with a logarithmic correction for large L. The parabolic rate constant is identical to the one derived by Deal and Grove (10).

LIST OF SYMBOLS

- C_o, C_L concentrations of diffusing species at the SiO_2-O_2 and SiO_2-Si interface, respectively
- C^* equilibrium concentration of O_2 (Henry's law)
- D diffusion coefficient
- F flux of diffusing species
- L oxide thickness
- t oxidation time
- h transfer coefficient at the SiO_2-O_2 interface
- v_n reaction velocity of the n'th reaction
- k_n, k_{-n} forward and reverse rate constants for the n'th reaction
- $\underline{K}$ Henry's constant (cf. Eq. [2])
- p_{O_2}, p oxygen partial pressure

Ω volume of SiO_2 formed per transported molecule O_2

In general, a prime added to a symbol implies that diffusion effects are explicitly included.

A Quantitive Calculation of the Growth Rate of Epitaxial Silicon from $SiCl_4$ in a Barrel Reactor

E. Fujii, H. Nakamura, K. Haruna, and Y. Koga

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

A model is proposed for the epitaxial growth of silicon in a vertical reactor where the reactant gas flows parallel to silicon wafers. It is assumed that the growth rate of deposited silicon is mass-transport controlled, and the equilibrium reaction is $SiCl_4 + 2H_2 = Si + 4HCl$. The model considers the profiles of the gas velocity and the temperature of the reactant gas, and also a decrease of the concentration along the gas flow. The growth rates at various positions along the susceptor are calculated under the conditions of substrate temperatures 1100°-1300°C, wall temperatures 300°-850°C, reactant gas flow rates 40-120 liters/min, and concentrations of $SiCl_4$ to H_2 0.004-0.008 in mole ratio. The growth rate is expressed as a function of the dimensions of the reaction chamber, and susceptor and of process variables such as the concentration, the gas flow rate, and the temperature. Using the function, the sensitivity analysis of process variables to the growth rate is investigated. Good agreement between the theory and the experimental result of the growth rate is obtained.

This paper describes quantitatively the growth rate of epitaxial silicon layer in a vertical reactor using reasonable approximations to the silicon epitaxial process.

Several theoretical models have been proposed to explain the epitaxial growth rate of silicon by the hydrogen reduction of chlorosilane, either in a vertical reactor where the reactant gas is passed vertically, or in a horizontal reactor where the reactant gas is passed horizontally. These theories are mainly divided into three types: thermodynamic, boundary-layer, and parallel plate.

Steinmaier (2) and Seki *et al.* (3) treated the $SiCl_4$-H_2 and the SiI_4-H_2 systems, respectively, using the first theory. The equilibrium compositions of the component in the gas phase were calculated. A hypothetical silicon partial pressure in terms of the partial pressures of each component was related to the growth rate or the etching rate of silicon. Lever (4) made a thermodynamical calculation of the Si-H-Cl system in detail. Sedgwick (5) proposed the quasi-equilibrium model which consists of the theoretical effective concentration factor α used also by Lever and of an apparatus factor β. In general the thermodynamical analysis can provide information about the actual mechanism of a reaction system only when the process is under sufficiently low flow rate, which is required for the system to be in equilibrium.

Key words: silicon epitaxy from $SiCl_4$, epitaxy in a barrel reactor, calculation of epitaxial growth rate, controlled mass transport, chemical vapor deposition.

The second theory, the boundary-layer theory by Bradshaw (6), is applied only to vertical reaction chambers. It is assumed that there is a boundary layer of a relatively static gas adjacent to the silicon surface. The growth rate is limited by diffusion of reactants and by-products across the boundary layer. Eversteyn (7) proposed a stagnant layer model analogous to the boundary-layer theory. The stagnant layer thickness is assumed to be constant along the susceptor, but in reality the thickness of such a stagnant or boundary layer is generally not uniform but varies in the direction of gas flow. It is doubtful that the stagnant layer thickness in the case of the SiH_4 system equals that of the TiO_2 system that was used to estimate the stagnant layer thickness.

The third theory, the parallel plate theory by Shepherd (8), is applied to the horizontal reaction chamber. Two asumptions are made here: that the gas velocity profile is a fully developed parabola and that the gas temperature profile is a linear gradient along the distance normal to the gas flow.

The above theories, however, do not involve the decrease of concentration of the reactant due to the silicon deposition in the direction of the gas flow. Rundle (1) proposed the model in which the decrease of the concentration of the reactant is considered. The model is applied to the horizontal reactor by assuming that the gas velocity and the temperature are constant throughout the reaction chamber. Bradshaw (6) and Rundle (1) attempted to determine the dependence of the growth rate on the substrate temperature, on the flow rate, and on the distance along the gas flow.

In the present paper two main factors are considered: the decrease of concentration and the dimensions of a reaction chamber. A coaxial cylindrical tube is used to simulate the vertical reactor where the reactant gas flow is directed parallel to the silicon substrates. In adddition to the above-mentioned two factors the gas velocity and the temperature profiles in the reaction chamber are considered in this mode. The continuity equation in such a model is solved under various process conditions. The growth rate of silicon in the direction of gas flow and the process characteristics are calculated and compared with experimental values. Furthermore, sensitivity analysis of the process parameters and the reactor dimensions to the growth rate are discussed.

Theory

The apparatus designed to perform the growth of the deposited silicon layer by the hydrogen reduction of silicon tetrachloride is shown schematically in Fig. 1. The continuity equation for a gaseous reactant is

$$\frac{dC}{dt} = -\operatorname{div}\,(VC - D\operatorname{grad} C) \qquad [1]$$

where C is the concentration of the reactant, V is the gas velocity, and D is the diffusion coefficient of the reactant. The reaction of silicon deposition is usually carried out at the substrate temperature between 1100° and 1300°C to produce good single crystalline films. By calculating velocities from the equations by Bird (9) under the typical epitaxy condition the mean velocity component of the gas in the radial direction caused by the natural convection (5 cm/sec) is neglected comparing with that in the axial direction (50 cm/sec). The $(Gr)^{1/2}/Re$ $(=u/v)$ is applied as a parameter of critical ranges for the free, the combined, and the forced convection flows, where Gr and Re are Grashof and Reynolds numbers, respectively, and u and v show perpendicular and parallel velocity components in the axial direction, respectively. Takahashi (10) and Sugawara (11) reported that vortex or spiral flow vanishes when the range of Gr/Re^2 is less than 1-4 or 3-7, respectively. The $Gr^{1/2}/Re$ in this experiment of silicon epitaxy is 0.1 and is included in the range of vortex vanishment. The Reynolds number for the epitaxial process is not greater than 100 under typical operating conditions, therefore, the gas flow is assumed to be laminar. The velocity profile of the gas in the reactor is approximated to the following equation for an isothermal system as given by Bird (9) (Appendix I).

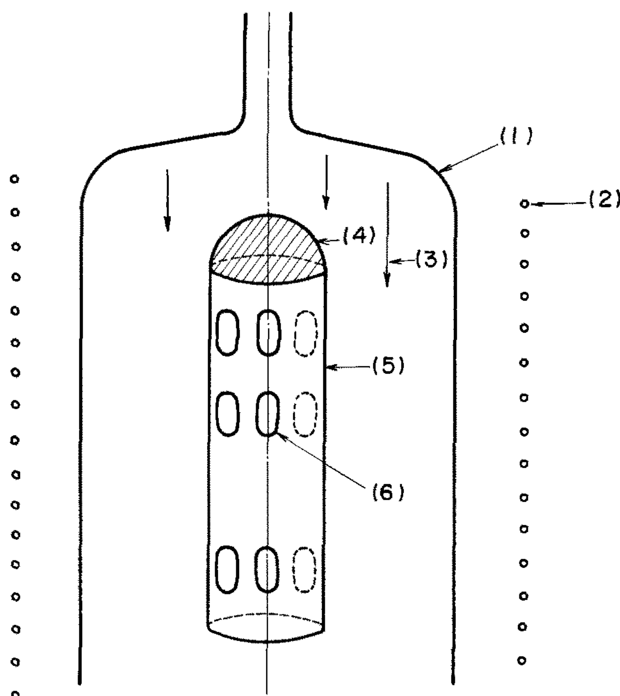

Fig. 1. Apparatus for silicon epitaxial reactor: (1) quartz tube, (2) induction coil, (3) input gas, (4) quartz cap, (5) graphite susceptor, (6) silicon substrate.

$$V_z = V(r) = \frac{2\overline{V}}{1 + \left(\frac{d_1}{d_2}\right)^2 - \frac{1-\left(\frac{d_1}{d_2}\right)^2}{\log_e\left(\frac{d_2}{d_1}\right)}} \left[1 - \left(\frac{r}{d_2}\right)^2 + \frac{1-\left(\frac{d_1}{d_2}\right)^2}{\log_e\left(\frac{d_2}{d_1}\right)} \log_e\left(\frac{r}{d_2}\right)\right] \qquad [2]$$

$V(r)$ is the gas velocity at a distance r from the center of the coaxial cylindrical tube, $\overline{V}$ is the average gas velocity, d_1 and d_2 are the inner and the outer radii, respectively.

The gas temperature profile perpendicular to the direction of the gas flow is to be determined only by thermal conduction, because the reactant gas does not absorb heat and the gas flow is laminar. Any contribution of natural convection to the heat conduction is neglected. The gas temperature in the direction of the gas flow is taken to be constant. The gas temperature profile is as follows (9)

$$T(r) = T_1 - \frac{T_1 - T_2}{\log_e\left(\frac{d_2}{d_1}\right)} \cdot \log_e\left(\frac{r}{d_1}\right) \qquad [3]$$

$T(r)$ is the gas temperature at a distance r from the center of the susceptor and T_1 and T_2 are the substrate and the reactor wall temperatures, respectively.

The diffusion coefficient in the binary system is calculated from Fujita's equation (12) which gives nearly equal value as that from Arnold's (13) or Hirschfelder's (14) equation. Fujita's equation is

$$D_{12} = \frac{0.00070 \cdot \left(\frac{1}{M_1} + \frac{1}{M_2}\right)^{1/2} \cdot T^{1.833}}{\left(\left(\frac{Tc_1}{Pc_1}\right)^{1/3} + \left(\frac{Tc_2}{Pc_2}\right)^{1/3}\right)^3} \qquad [4]$$

where subscripts 1 and 2 refer to the gaseous components 1 and 2, respectively, Tc is the critical temperature, and Pc is the critical pressure. Using Eq. [4] the diffusion coefficients of H_2-$SiCl_4$ and HCl-$SiCl_4$ are calculated to be 5.734 and 1.258 (cm^2/sec), respectively, at 1500°K and 760 Torr. The diffusion coefficient in the multicomponent gas system is calculated by Wilke's equation (15).

The over-all deposition reaction can be expressed by

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \qquad [5]$$

because the concentration of chlorosilane to hydrogen is below 0.01 in mole ratio (Appendix II). The con-

tinuity equation [1] for the steady state under the assumptions described above becomes

$$D\frac{\partial^2 C}{\partial r^2}+\left(\frac{D}{r}+\frac{\partial D}{\partial r}\right)\frac{\partial C}{\partial r}+D\frac{\partial^2 C}{\partial Z^2}-V\frac{\partial C}{\partial Z}=0 \quad [6]$$

It is assumed that the reaction is completed at the silicon surface under the mass-transfer controlled condition, and therefore the concentration of chlorosilane at this surface is zero. No decrease of the concentration at the reactor wall is assumed. The concentration gradient at the reactor wall is taken to be zero. the boundary conditions of Eq. [6] become

$$\frac{\partial C}{\partial r}=0 \quad \text{at} \quad r=d_2 \quad [7]$$

and

$$C=0 \quad \text{at} \quad r=d_1 \quad [8]$$

Equation [6] is solved using the boundary conditions, and $\partial C/\partial r$ is obtained. The flux of the reactant to the substrate $(r = d_1)$, J, is

$$J=\left(D\frac{\partial C}{\partial r}\right)\Bigg|_{r=d_1} \quad [9]$$

Expressing the growth rate G in microns per minute, the following equation can be obtained

$$G=6.00\cdot 10^5\cdot\frac{M}{\rho}\cdot\left(D\frac{\partial C}{\partial r}\right)\Bigg|_{r=d_1} \quad [10]$$

where M is the atomic weight of silicon (28.09 g/mole), and ρ is the density of silicon (2.33 g/cm^3).

Solution of continuity equation.—It is assumed that the concentration of the reactant may be expressed as

$$C(r,z)=C_r(r)\cdot C_z(Z) \quad [11]$$

where $C_r(r)$ and $C_z(Z)$ are the radial and the axial components of concentration, respectively.

Mass transport in the reactor is described by considering the three layers for the radial direction, as shown in Fig. 2. In the central region, the reactant is assumed to be carried by the gas flow caused by a pressure gradient. In the neighborhood of the reactor wall and the susceptor, the gas velocity is low because of interaction of the gas with the wall and the susceptor. In this case the reactant is carried by the diffusion resulting from the concentration gradient.

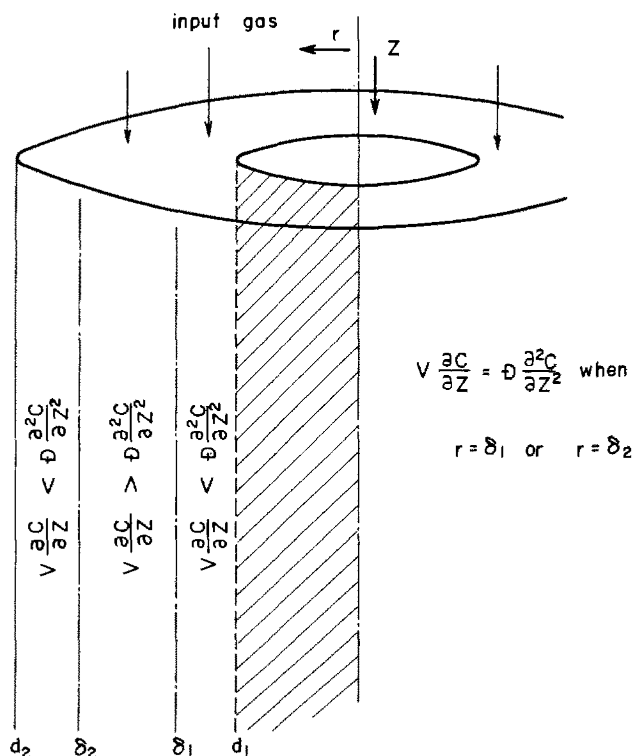

Fig. 2. Mass transport in the reactor

The three divided layers of the radial direction are now considered in turn:

(a). $\delta_1 < r < \delta_2$.—In this region the term $D\frac{\partial^2 C}{\partial Z^2}$ in Eq. [6] can be neglected in comparison with $V\frac{\partial C}{\partial Z}$ except near δ_1 and δ_2. Equation [6] with Eq. [11] gives

$$\frac{1}{C_z}\cdot\frac{\partial C_z}{\partial Z}=\frac{1}{V_z(r)\cdot C_r}\cdot\left(D\frac{\partial^2 C_r}{\partial r^2}+\left(\frac{\partial D}{\partial r}+\frac{D}{r}\right)\frac{\partial C_r}{\partial r}\right)=-\beta \quad [12]$$

$$\beta:\ \text{constant} \quad [13]$$

The following two equations are obtained from Eq. [12] and [13]

$$C_z=a\cdot e^{-\beta z} \quad a:\ \text{constant} \quad [14]$$

and

$$\frac{d^2C_r}{dr^2}+\left(\frac{1}{D}\frac{dD}{dr}+\frac{1}{r}\right)\frac{dC_r}{dr}+\frac{1}{D}\cdot\beta\cdot V_z(r)\cdot C_r=0 \quad [15]$$

(b). $\delta_2 < r < d_2$ *or* $d_1 < r < \delta_1$.—In this region the term $V_z\frac{\partial C}{\partial Z}$ can be neglected in comparison with $D\frac{\partial^2 C}{\partial Z^2}$ except near δ_1 and δ_2. Thus, Eq. [6] leads to

$$-\frac{1}{C_z}\frac{\partial^2 C_z}{\partial Z^2}=\frac{1}{C_r}\left(\frac{\partial^2 C_r}{\partial r^2}+\frac{1}{D}\left(\frac{\partial D}{\partial r}+\frac{D}{r}\right)\cdot\frac{\partial C_r}{\partial r}\right)=-\beta'^2 \quad [16]$$

$$\beta':\ \text{constant} \quad [17]$$

Equation [16] and [17] lead to

$$C_z=a'\cdot e^{-\beta' z} \quad a':\ \text{constant} \quad [18]$$

and

$$\frac{d^2C_r}{dr^2}+\left(\frac{1}{D}\frac{dD}{dr}+\frac{1}{r}\right)\frac{dC_r}{dr}+\beta'^2\cdot C_r=0 \quad [19]$$

From Eq. [14] and [18], Eq. [11] is given by

$$C=C_r\cdot e^{-kz} \quad k:\ \text{constant} \quad [20]$$

The δ_1 and δ_2 approximate the inner and the outer radii, respectively. For example

$$\delta_1=d_1+(\sim 10^{-3}\,\text{cm})$$

and

$$\delta_2=d_2-(\sim 10^{-3}\,\text{cm})$$

in the case of flow rate 100 liters/min with the above mentioned dimensions, (cf. Appendix III). The regions $\delta_2 < r < d_2$ and $d_1 < r < \delta_1$ can practically be neglected. Thus Eq. [6] and [20] are written as

$$\frac{d^2C_r}{dr^2}+\left(\frac{1}{D}\frac{dD}{dr}+\frac{1}{r}\right)\frac{dC_r}{dr}+\frac{1}{D}\cdot\beta\cdot V_z\cdot C_r=0 \quad [21]$$

$$C=C_r\cdot e^{-\beta z} \quad [22]$$

The β is not only the separation constant of the variables r and z as shown in Eq. [12], but also a parameter of the concentration decrease in the direction of gas flow from Eq. [22]. Substituting Eq. [22] in Eq. [7] and [8], the boundary conditions become

$$\frac{dC_r}{dr} = 0 \quad \text{when} \quad r = d_2 \qquad [23]$$

and

$$C_r = 0 \quad \text{when} \quad r = d_1 \qquad [24]$$

In order to solve the second order differential Eq. [21] for $Cr(r)$ $(r_1 < r < r_2)$ by the Runge-Kutta-Gill method, C_r and dC_r/dr at $r = d_1$ or $r = d_2$ must be given. A method of solving Eq. [21] is to derive C_r at $r = d_2$ and to use Eq. [23]. Equation [21] is to be solved so that the boundary condition Eq. [24] is satisfied. In this method dC_r/dr at $r = d_1$ instead of C_r at $r = d_2$ can be derived, and Eq. [21] is solved under the boundary condition Eq. [23].

Derivation of dC_r/dr at $r = d_1$.—$\overline{C_o}$ and $\overline{C_L}$ indicate the mean concentration at $z = o$ and $z = L$, respectively. Z denotes a distance from the top of the susceptor in the axial direction. The mean concentration at $z = o$ is given by

$$\overline{C_o} = \frac{\int_{d_1}^{d_2} C_o \cdot 2\pi r \cdot dr}{\int_{d_1}^{d_2} 2\pi r \cdot dr} = \frac{P \cdot C_M}{\overline{T} \cdot R \cdot (1 + C_M)} \text{ (mole/cm}^3\text{)} \qquad [25]$$

while the mean temperature in the reactor is given by

$$\overline{T} = \frac{\int_{d_1}^{d_2} T \cdot 2\pi r dr}{\int_{d_1}^{d_2} 2\pi r dr} = T_1 - \frac{d_2^2 (T_1 - T_2)}{d_2^2 - d_1^2} + \frac{T_1 - T_2}{2 \log \frac{d_2}{d_1}} \text{ (°K)} \qquad [26]$$

where R is 82.06 cm^3 atm/(deg mole), P is the pressure in the reactor, and C_M is the mole ratio of chlorosilane to hydrogen at the entrance of the reactor. From Eq. [22] and [25] the relation between $\overline{C_o}$ and $\overline{C_L}$ becomes

$$\overline{C_L} = \overline{C_o} \cdot e^{-\beta L} \qquad [27]$$

The mole numbers of the feeding gas per second is written as

$$\pi \cdot (d_2^2 - d_1^2) \cdot \overline{V} \cdot \overline{C_o} \qquad [28]$$

and that of the effluent gas per second is

$$\pi \cdot (d_2^2 - d_1^2) \cdot \overline{V} \cdot \overline{C_L} \qquad [29]$$

The reaction gas, which is passed through the feed pipe with pressure P_o, temperature T_o, and flow rate F, expands in a reactor with pressure P and mean temperature $\overline{T}$. The gas volume through the reactor per second is $1000/60 \cdot \overline{T}/T_o \cdot P_o/P \cdot F$. Thus the mean velocity of gas in the cross section is given by

$$\overline{V} = \frac{\text{gas flow per second}}{\text{cross-sectional area of the reactor tube}} = \frac{16.67 \cdot F \cdot \overline{T} \cdot P_o}{\pi \cdot (d_2^2 - d_1^2) \cdot T_o \cdot P} \qquad [30]$$

where F is the total gas flow (in l/min) at T_o (°K) and P_o (Torr), P_o and T_o are the pressure, 919 Torr and the temperature, 298°K of the reactant gas before entering into the reactor, respectively. The mole numbers of the deposited silicon between $z = o$ and $z = L$ is given by

$$\int_o^L \left(D \frac{\partial C}{\partial r} \right) \bigg|_{r=d_1} \cdot 2\pi d_1 \cdot dZ \qquad [31]$$

Equations [27] through [31], lead to

$$\frac{dC_r}{dr} \bigg|_{r=d_1} = \beta \cdot \frac{\overline{C_o} \cdot \overline{V} \cdot (d_2^2 - d_1^2)}{2d_1 \cdot D|_{r=d_1}} \qquad [32]$$

Derivation of C_r at $r = d_2$.—Experimentally in $SiCl_4$-H_2 systems the reaction gas decomposes near the silicon substrate and silicon does not deposit on the reaction wall. Therefore, it is assumed that there is no deposition on the walls of the reaction chamber. C_r is given by the ideal gas law

$$C_r = \frac{P \cdot C_M}{T_2 \cdot R \cdot (1 + C_M)} \qquad [33]$$

Given a proper initial value into the unknown parameter β, C_r and dC_r/dr becomes constant, and Eq. [21] is solved. In the case that a boundary condition is not satisfied, β is varied recursively for Eq. [21] to be satisfied. Equation [21] with boundary conditions (Eq. [24] and [32]) should be solved subjected to the boundary condition (Eq. [23]). It is difficult, however, to obtain a solution to satisfy Eq. [23] owing to the inclusion of the unknown β in Eq. [32]. Furthermore, the optimum β has not been found. In the case when Eq. [21] with the initial conditions (Eq. [23] and [33]) is solved to satisfy the boundary condition (Eq. [24]), the solution as well as the optimum β are obtained fairly easily. The wall temperature which cannot be measured exactly is involved in Eq. [33]. The sensitivity of the wall temperature to the growth rate is, however, low as will be described later. The calculation in the next paragraph is made by this method where the initial conditions at $r = d_2$ are assumed. The growth rate and β are obtained with good accuracy by dividing the radius into 100 increments.

Results and Discussion

The calculation of the growth rate based on the model.—The calculation of the growth rate based on the model is made for various diffusion coefficients in many gas systems and for various process parameters such as substrate temperature, reactor wall temperature, concentration, and gas flow rate. The apparatus dimensions used in the above calculation are as follows: the silicon carbide coated graphite susceptor is about 30 cm long and about 11 cm in diameter, and the quartz tube reactor is about 17 cm in diameter. Figure 3 shows the results of the calculations of the growth rate along the susceptor for the various gas compositions. Three kinds of reaction gas system are considered. The first system is, $SiCl_4$-H_2, where the main reactant gas is hydrogen and chlorosilane diffuses into hydrogen, the second system is, HCl-$SiCl_4$, where hydrogen is stagnant, and the third system is, H_2-HCl-$SiCl_4$, where chlorosilane diffuses into the mixture gas of hydrogen and hydrogen chloride. The

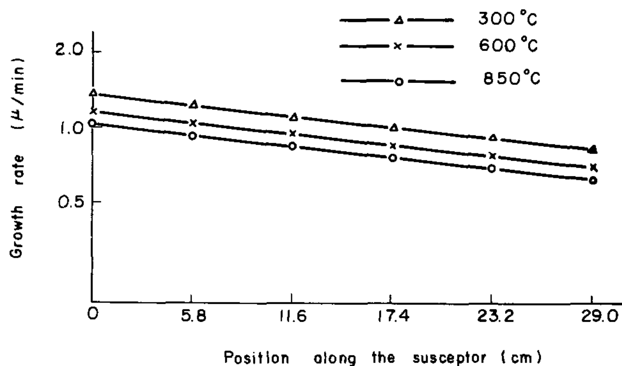

Fig. 4. Logarithm of the growth rate as a function of the wall temperature. Substrate temperature 1200°C, mole fraction 0.005, flow rate 80 liters/min (calculated).

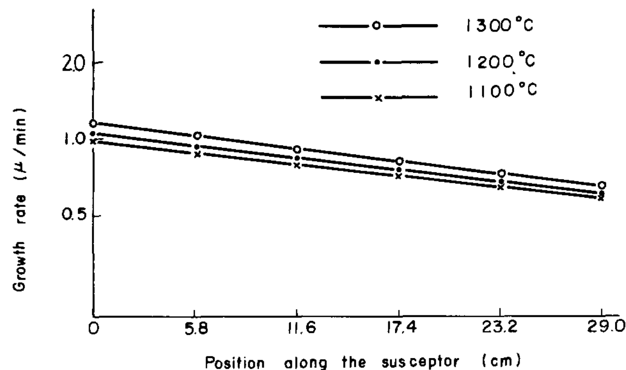

Fig. 5. Logarithm of the growth rate as a function of the substrate temperature. Wall temperature 850°C, mole fraction 0.005, flow rate 80 liters/min (calculated).

growth rate increases linearly with the diffusion coefficient. The diffusion coefficient used in the following calculations is that for the H_2-HCl-$SiCl_4$ system, which, we think, should express the epitaxial reaction better than the other gas systems, because the reaction gas consists of the one shown in Eq. [5]. Plots of the growth rate *vs.* the position along the susceptor are shown in Fig. 4 at three temperatures of the reactor wall: 300°, 600°, and 850°C. As the wall temperature increases, the growth rate decreases. This is explained by the following: as the wall temperature increases, the temperature difference between the substrate and the wall becomes smaller, hence the concentration gradient is less steep and the growth rate becomes lower.

Figure 5 indicates the calculated growth rate at the substrate temperatures, 1100°, 1200°, and 1300°C. The growth rate is slightly dependent on the substrate temperature.

The formulation of the growth rate based on the model.—The growth rate in the axial direction is formulated by calculations as a function of the dimensions of the reactor and the susceptor and the various process parameters. The following equation is obtained from Eq. [10] and [22]

$$G_{z=Z} = 6.00 \times 10^5 \frac{M}{\rho} \cdot \left(D \frac{\partial C_r}{\partial r} \right) \Big|_{r=d_1} \cdot e^{-\beta z} = G_{z=0} \cdot e^{-\beta z} \quad [34]$$

One parameter is varied leaving other parameters constant. It is calculated how $G_{z=0}$ and β are varied by changing the parameter. Thus the following equations are obtained

$$G_{z=0} = 3.004 \cdot 10^5 \cdot \left(\frac{d_2^2 - d_1^2}{d_2} \right)^{-1.020} \cdot \frac{C_M}{1 + C_M} \cdot A \cdot T_1^{1.213} \cdot T_2^{-0.38} \quad [35]$$

$$\beta = 4\pi \cdot 10^2 \cdot \left(\frac{d_2^2 - d_1^2}{d_1 \cdot d_2} \right)^{-1.043} \cdot A \cdot \frac{T_0}{P_0} \cdot T_1^{0.852} \cdot T_2^{-0.0165} \cdot \frac{1}{F} \quad [36]$$

where $G_{z=Z}$ is the growth rate at a distance Z cm from the top of the susceptor in μ/min. $G_{z=0}$ is the growth rate at the top of the susceptor in μ/min. The relation between diffusion coefficient D and A is $D = A \cdot T^{1.833}$ similar to Eq. [4]. A becomes 7.975×10^{-6} in the HCl-$SiCl_4$-H_2 system ($SiCl_4/H_2 = 0.005$). A is nearly independent of mole ratio, temperature, and pressure and is dependent on gas characteristics.

The growth rate on a tilted susceptor.—A tilted susceptor makes the gas flow rate increase due to the decrease of the cross-sectional area of a reactor. The increase of the gas flow rate is calculated at each point along the susceptor.

θ is an angle of tilting of the susceptor. The cross-sectional area at a distance Z from the top of the susceptor becomes $\pi \cdot (d_2^2 - (d_1 + Z \tan\theta)^2)$ as shown in Fig. 6.

The correction factor of the gas flow rate is written as

$$F \cdot \frac{\pi \cdot (d_2^2 - d_1^2)}{\pi \cdot (d_2^2 - (d_1 + Z \tan\theta)^2)} \quad [39]$$

The growth rate on the tilted susceptor is obtained by substituting Eq. [39] for F in Eq. [36].

Comparison of the theory and experiment.—The apparatus used to prepare epitaxial layers by the hydrogen reduction of tetrachlorosilane is shown in Fig. 1. The (111) face silicon substrate is 2 in. in diameter, approximately 200μ thick, and of low resistivity (<0.02

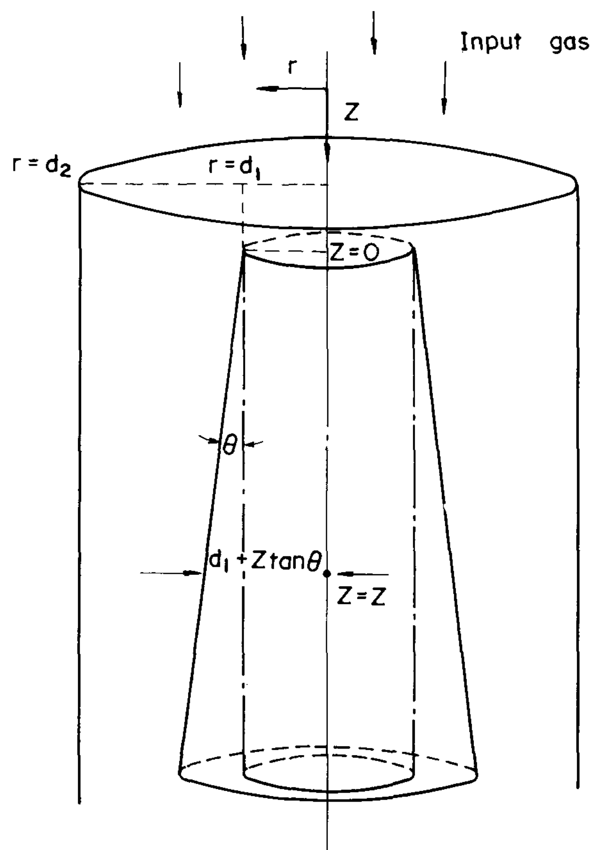

Fig. 6. Schematic view of the cross-sectional area for a horizontal reactor with the tilted susceptor.

ohm-cm). The substrate temperature has been measured with an optical pyrometer and corrected for the emissivity of the silicon. Layer thickness of about 10μ is used for the determination of the growth rate by the infrared interference method.

Silicon deposition is experimentally started at the quartz cap. But an exact growth rate on the amorphous quartz cap is not measurable. A length of the cap (6 cm) is much shorter than that of the susceptor (30 cm), therefore, the deposited quantity on the cap is small. An approximation is made that the silicon deposition is started at 6 cm in front of the top of the susceptor. The approximation expresses an experimental fact better than assuming the deposition on the cap being neglected. The following figures compare the experimental growth rate (dotted line) with the calculated (full line) under inclusion of the deposition on the cap.

Figures 7 and 8 show the growth rate at 23 cm from the quartz cap. Figure 7 gives the dependence of the growth rate on the mole ratio of $SiCl_4$ to H_2. It will be seen that the growth rate is directly proportional to the mole ratio with reasonable accuracy. The flow rate of hydrogen is varied from 60 to 150 l/min. The result is shown in Fig. 8. The growth rate increases with the flow rate, but the growth rate decreases over the flow rate 120 liters/min. This is explained by the following: in such a great flow rate the reaction [5] is in non-equilibrium and most reaction gas passes through unchanged, so that the growth rate becomes low. Figure 9 shows the growth rate in the direction of gas flow in two flow rates under constant mole ratio. As the flow rate increases, the uniformity of the thickness of the deposition layer along the susceptor becomes considerably better.

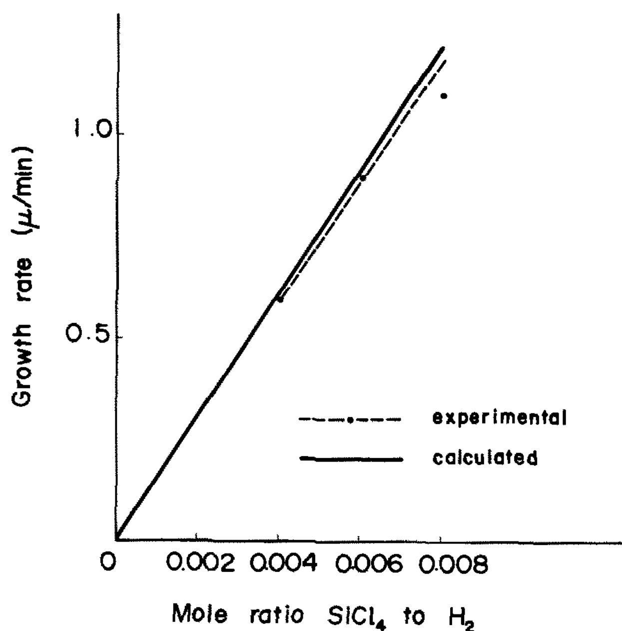

Fig. 7. The growth rates as a function of the mole ratio of $SiCl_4$ to H_2. Substrate temperature 1200°C, wall temperature 850°C, flow rate 120 liters/min.

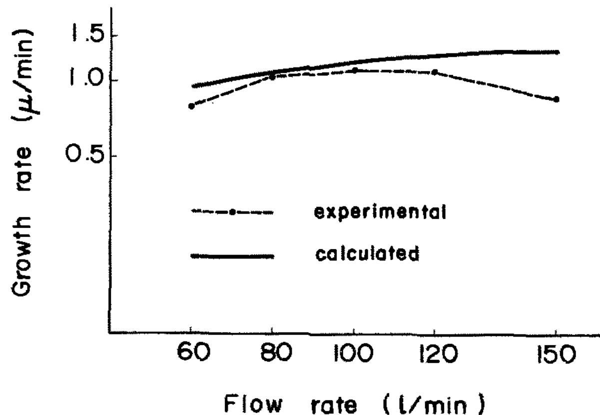

Fig. 8. The growth rates as a function of the flow rate of hydrogen. Substrate temperature 1200°C, wall temperature 850°C, mole ratio 0.008.

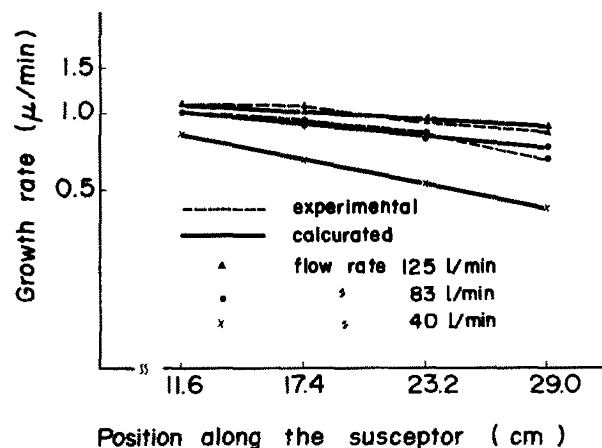

Fig. 9. The growth rates as a function of the position along the susceptor for the flow rates of 83 and 125 liters/min. Substrate temperature 1200°C, wall temperature 850°C, mole ratio 0.006.

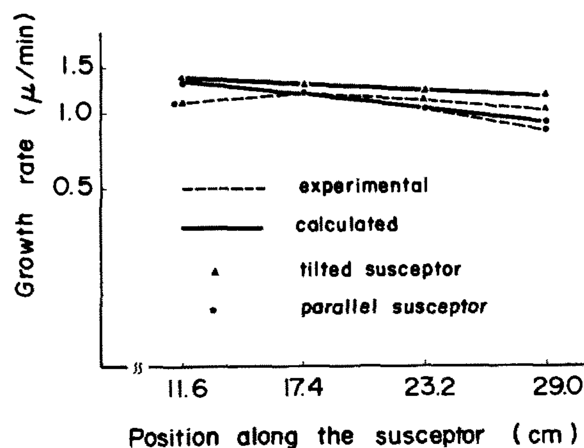

Fig. 10. The growth rates on a nontilted and a tilted susceptors as a function of the position along the susceptor. Substrate temperature 1200°C, wall temperature 850°C, flow rate 80 liters/min, mole ratio 0.008.

Figure 10 compares the uniformity of the thickness in the axial direction on a tilted susceptor with that on a nontilted susceptor. An angle of tilting of the susceptor is 3°. The growth rate at the latter half of the tilted susceptor increases by 10-20% compared with that of the nontilted susceptor. The small decrease of the growth rate near the top of the susceptor in experiment is thought to be due to the reactant gas which is not yet well heated. Comparison of the theoretical result with experimental data gives good agreement.

Sensitivity analysis.—Sensitivity analysis of the process parameters to the growth rate in silicon epitaxy will now be discussed. This analysis is made in order to obtain a constant growth rate. Influence of the growth rate by the variation of the process parameters is known from the analysis. The variation of the growth rate is calculated in such a case that the dimensions of the reactor and the susceptor and the process parameters deviate by 10% from the following conditions, $T_1 = 1200°C$, $T_2 = 850°C$, $C_M = 0.005$, $F =$ 80 liters/min.

Table I. Relative variation of the growth rate with 10% deviation of the dimensions and the process variables

Dimensions and process variables		$\Delta G/G$ ($Z = 15$)
Substrate temperature	(T_1)	9.5%
Wall temperature	(T_2)	−3.8%
Concentration (mole fraction)	(C_M)	10.1%
Flow rate	(F)	3.1%
Temperature of the feeding gas	(T_o)	−3.5%
Pressure of the feeding gas	(P_o)	3.5%
Constant term in diffusion coefficient	(A)	7.0%
Inner radius	(d_1)	7.2%
Outer radius	(d_2)	−16.7%

The following equations are applied

$$\Delta G = \left(\frac{\partial G}{\partial X}\right)\bigg|_{z=15} \cdot \Delta X \quad [37]$$

and

$$\Delta X = \frac{1}{10} X \quad [38]$$

where X is one of the process parameters and dimensions. The variation G changes with a position on the susceptor. Table I gives the result for the relative variation of the growth rate, $\Delta G/G$, at the center of the susceptor, $z = 15$ cm. According to the analysis, parameters such as T_1, C, A, d_1, and d_2 have relatively high sensitivity. The minus sign in Table I means that the growth rate decreases with the increase of the variable. A is determined by the gas components in the system. If the three components system is the case, the deviation of A is dependent on the mole fraction $SiCl_4$, H_2, and HCl, and this is within a few per cent. The fluctuation of T_1, d_1, and d_2 are experimentally controllable within 5%. The control of the concentration depends on the hydrogen quantity passed into the tetrachlorosilane and the main hydrogen quantity which is carried into the reactor directly. The concentration is also varied by the hydrogen pressure and the temperature of water to control the vaporization of tetrachlorosilane. From the sensitivity analysis the control of the concentration is found to be the most important factor in order to obtain the constant growth rate.

Conclusion

The silicon epitaxial process is performed in a coaxial cylindrical tube. The growth rate is investigated under many process conditions. The growth rate is derived as a function of the apparatus dimensions and the process variables. From the sensitivity analysis the control of the reactant concentration is the most important factor in order to produce a constant growth rate on the substrate. The change in the concentration proportionally contributes to the change in the growth rate. For the purpose of obtaining the uniformity in thickness of deposition layer on the over-all susceptor it is necessary not only to increase the gas flow rate beyond 80 liter/min but also to raise the angle of tilting of the susceptor more than 3° in the present apparatus.

Acknowledgment

The authors wish to thank Mr. K. Sugawara and Mr. H. Tochikubo for many suggestions regarding this work and to acknowledge Mr. Y. Nakazawa in acquiring the experimental data. They are particularly indebted to Mr. R. Takahashi and Dr. F. Inose for their encouragement and helpful discussions.

Manuscript submitted Feb. 10, 1971; revised manuscript received Nov. 6, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

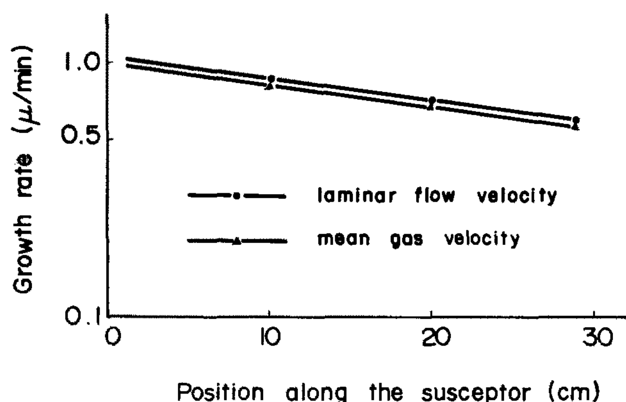

Fig. 11. Growth rates as a function of the position along the susceptor for two velocity profiles (calculated).

APPENDIX I

Velocity Profile

An equation of the velocity profile in a nonisothermal system cannot be found and the derivation of the equation is troublesome. The growth rate is calculated in the case of mean velocity and laminar flow velocity in an isothermal system as shown in Fig. 11. Hence growth rate hardly depends on the velocity profile. As a result of the calculation of the growth rate, the velocity profile has little influence on growth rate; the velocity profile in an isothermal system is used.

APPENDIX II

Mole Fraction of the Gaseous Species in $SiCl_4$-H_2 System

The gaseous species involved in the $SiCl_4$-H_2 system are assumed to be mainly $SiCl_4$, $SiHCl_3$, $SiCl_2$, SiH_2Cl_2, HCl, and H_2. The mole fraction of these gases are calculated in the same way as Lever (4) did and his equilibrium constants are used. Table II shows the mole fractions for several values of mole ratio of $SiCl_4$ to H_2 at 1500°K and 1.0 atm.

In the case of mole ratio of $SiCl_4$ to $H_2 < 0.01$, the mole fraction except H_2 and HCl is neglected.

APPENDIX III

Calculation of δ_1 and δ_2

The δ_1 and δ_2 are determined under the following conditions: flow rate of reaction gas of 100 liters/min, substrate temperature of 1200°C, wall temperature of 850°C, and susceptor length of 30 cm.

By Eversteyn (7) reactor efficiency is 35% when the mean velocity is over 50 cm/sec.

Mean concentration $\overline{C}_{z=Z}$ and $\overline{C}_{z=0}$ are as follows from Eq. [20]

$$\overline{C}_{z=Z} = \frac{\int_{d_1}^{d_2} C_r \cdot e^{-KZ} \cdot 2\pi r dr}{\int_{d_1}^{d_2} 2\pi r \cdot dr} \qquad \overline{C}_{z=0} = \frac{\int_{d_1}^{d_2} C_r \cdot 2\pi r dr}{\int_{d_1}^{d_2} 2\pi r dr}$$

Table II. Mole fractions of $SiCl_4$-H_2 system at 1500°K, 1 atom

$SiCl_4/H_2$	$SiHCl_3$	$SiCl_4$	$SiCl_2$	HCl	H_2	SiH_2Cl_2
0.003	7.068×10^{-6}	1.375×10^{-7}	1.343×10^{-4}	1.162×10^{-2}	0.9882	9.527×10^{-6}
0.005	3.084×10^{-5}	9.850×10^{-7}	3.596×10^{-4}	1.894×10^{-2}	0.9806	2.531×10^{-5}
0.007	7.961×10^{-5}	3.506×10^{-6}	6.785×10^{-4}	2.591×10^{-2}	0.9733	4.739×10^{-5}
0.010	2.114×10^{-4}	1.299×10^{-5}	1.306×10^{-3}	3.575×10^{-2}	0.9626	9.020×10^{-5}
0.020	1.234×10^{-3}	1.397×10^{-4}	4.282×10^{-3}	6.365×10^{-2}	0.9304	2.859×10^{-4}

where $\overline{C_{z=Z}}$ and $\overline{C_{z=0}}$ are the mean concentrations at z cm from the top of a susceptor and at the top of a susceptor, respectively. Consequently it leads to the following equation

$$\frac{\overline{C_{z=Z}}}{\overline{C_{z=0}}} = e^{-KZ}$$

From that this ratio is equaled to 0.35 and $Z = 30$ cm. The K becomes 3.50×10^{-2}. The following result is obtained from Eq. [20]

$$-v\frac{\partial C}{\partial Z} - D\frac{\partial^2 C}{\partial Z^2} = K \cdot C_r \cdot e^{-KZ}\ (v - DK)$$

The velocity profile is calculated from Eq. [2]. Therefore δ_1 and δ_2, that is to say, r at $-v\frac{\partial C}{\partial Z} = D\frac{\partial^2 C}{\partial^2 Z}$ lead to $\delta_1 = d_1 + 1.0 \times 10^{-3}$ cm and $\delta_2 = d_2 - 2.0 \times 10^{-3}$ cm. Accordingly the area of $d_1 < r < \delta_1$ and $\delta_2 < r < d_2$ are neglected.

Plane Defect at the Interface and Dislocations in Epitaxially Grown GaAs

Seigô Kishino and Shinya Iida

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

Lattice defects in vapor-grown GaAs on GaAs substrates were studied by an x-ray diffraction technique, *i.e.*, by using the Lang method. It was found that a plane defect was introduced at the epitaxial layer-substrate interface due to a lattice parameter difference between the epitaxial layer and the substrate. This difference depends on the impurity concentration difference between layer and substrate. Examination by x-ray topography also revealed that the plane defect was introduced for the liquid-phase epitaxy of GaAs due to an impurity concentration difference between layer and substrate. Dislocations induced in the epitaxial layer grown by the vapor phase technique were also studied by utilizing an x-ray topographic technique. Two kinds of dislocations were identified: a 30° dislocation, and a pure edge dislocation having Burger's vectors of ½ a <110>.

To study the relationship between crystal imperfections and the performance of semiconductor devices, is of present technological importance. In the growth of the GaAs crystal, epitaxially grown either by the vapor-phase or liquid-phase epitaxy technique, lattice defects such as stacking faults (1-3) and dislocations (4) are commonly observed, and they can be detrimental to the performance of the devices involved (5). Dislocations induced in the epitaxial layer have been observed by the chemical etching method (4); however, the type of dislocation has not been clarified. Damage introduced at the epitaxial layer-substrate interface was also observed (6, 7); but, here too, the origin of the defects was not clarified.

In this paper, lattice defects introducing a plane defect at the interface and dislocations in the epitaxial layer, were observed by an x-ray diffraction technique in a manner so that the origin of the defects was clarified. In the past, the Borrmann method (8) or a reflection method (9) has been used to investigate the lattice defects of III-V compound semiconductors such as GaAs, GaP, and $GaAs_{1-x}P_x$ crystals. In this report, however, the conventional Lang method has been used and the product $\mu_0 \cdot t$—where μ_0 and t are the linear absorption coefficient and the thickness of the specimen respectively—is made to be 1 unless especially noted.

Key words: gallium arsenide, epitaxial growth, dislocations, x-ray diffraction.

Experimental

Sample preparation.—Wafers were cut in the (001) orientation from horizontally boat-grown (Te-doped) GaAs crystals. The slices were lapped mechanically, and chemically etched by using an etch solution of H_2SO_4, H_2O_2, and H_2O in the ratio 3:1:1. The preparation method of the epitaxial wafers used here is described elsewhere (10). Briefly, a method that utilizes the vapor transport of GaAs with $AsCl_3$ and H_2 mixed gas in an open flow system was used. Substrate and source temperatures were kept at 770° and 870°C respectively. Hydrogen gas with a flow rate of 150 cc/min was bubbled through an $AsCl_3$ reservoir which was kept at 0°C. A growth rate of 0.6 μm/min on the (001) surface was obtained by using this method. Thicknesses of the epitaxially grown layers were about 150 μm.

Specimen 1 was made from a wafer whose surface was nearly parallel to a (001) plane as schematically shown in Fig. 1. This wafer is a Sn-doped ($n = 1 \times 10^{17}$ cm^{-3}) crystal epitaxially grown on a Te-doped ($n = 1 \times 10^{18}$ cm^{-3}) substrate. The surface of the wafer was beveled at about 5° to the epitaxially grown surface, and the total thickness of the specimen was about 45 μm. Figures 1(a) and (b) are respectively sectional and planar views of the specimen. The substrate-epitaxial layer interface is included in the middle part of the specimen as shown in Fig. 1(b).

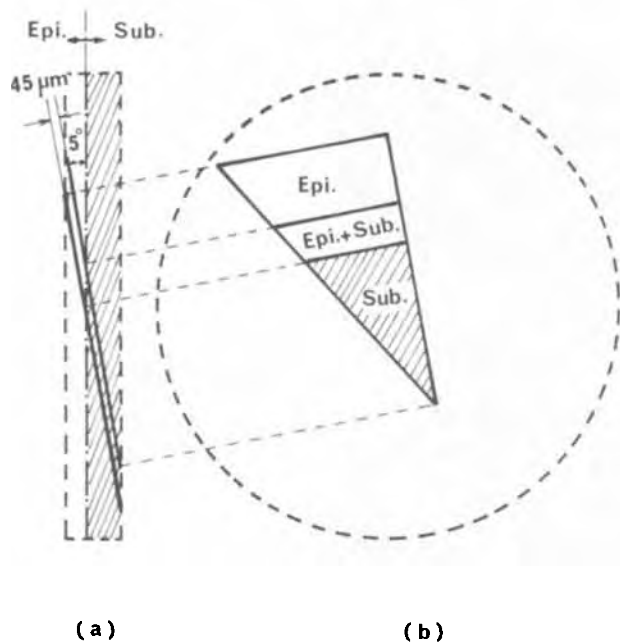

Fig. 1. Sectional (a) and planar (b) figures of specimen 1

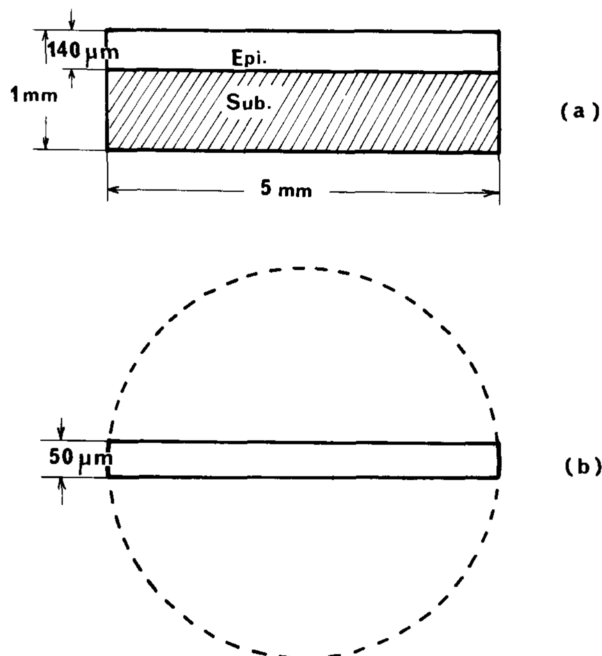

Fig. 2. Schematic diagram of method used for obtaining the section of epitaxially grown GaAs wafer. (a) Planar figure of the specimen. (b) Sectional figure of the specimen.

Specimen 2 was prepared from a Te-doped ($n = 1 \times 10^{18}$ cm^{-3}) crystal epitaxially grown on a Te-doped ($n = 1 \times 10^{16}$ cm^{-3}) substrate. The shape of the specimen is shown in Fig. 2, in which the (001) wafer was cleaved, and the specimen was thinned down to a thickness of about 50 μm, by mechanical polishing and chemical etching with the etch solution described above. Specimen 3 was made from a Te-doped ($n = 1 \times 10^{16}$ cm^{-3}) crystal epitaxially grown on a Te-doped ($n = 1 \times 10^{16}$ cm^{-3}) substrate. There is no doping concentration difference between the substrate and the epitaxial layer in this specimen. The shape of the specimen was similar to that of specimen 3.

X-ray topographs.—Standard microfocus x-ray equipment was used, operated at 50 kV and 1 mA. The images were recorded on 50 μm Ilford nuclear plates at approximately 15 hours' exposure. Representative x-ray topographs taken from specimen 1 are shown in Fig. 3(a), and (b). Figures 3(a) and (b) are x-ray topographs taken with (111) and (220) MoK$_{\alpha 1}$ diffractions. X-ray interference fringes are visible in Fig. 3(a) but invisible in Fig. 3(b), revealing that visibility of the interference fringes depends on the diffraction plane used. When diffraction planes such as (220), (040), (2$\bar{2}$0), and (400) were used, these being perpendicular to the (001) plane which is parallel to the surface of the epitaxial layer, the interference fringes were invisible. Conversely, they were visible when diffraction planes other than those described above—for example (202), (111), and (211)—were used. From these experimental results, the direction of the fault vector of the plane defect was determined to be [001].

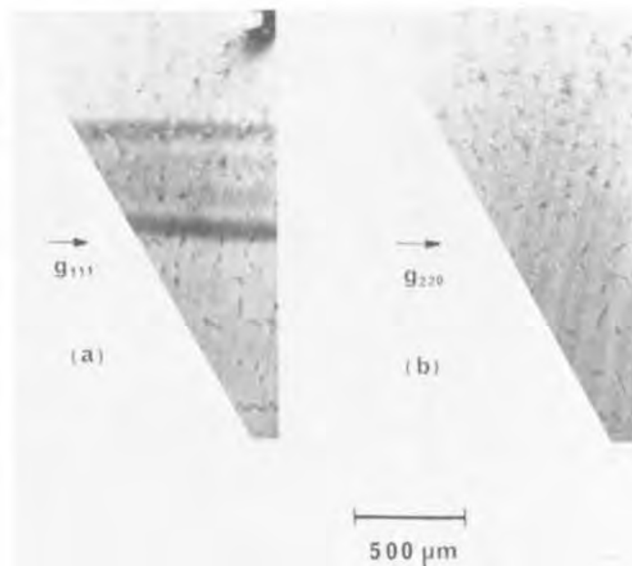

Fig. 3. X-ray topographs of specimen 1. Figures (a) and (b) are topographs with (111) MoK$_{\alpha 1}$ and (220) MoK$_{\alpha 1}$ diffractions respectively.

Specimen 2, whose surface is (220), was also examined by the x-ray diffraction technique. X-ray topographs taken from specimen 2 are shown in Fig. 4, 5, and 6. Burger's vector directions of dislocations are rather conveniently determined by the following technique (11). Use of the criterion

$$\cos \measuredangle (g\, b) = \begin{cases} 0 & \text{minimum contrast} \\ 1 & \text{maximum contrast} \end{cases} \quad [1]$$

where g is the diffraction vector and b is the fault vector, permits complete determination of the fault vector direction. From the x-ray topographs shown in Fig. 4, 5, and 6, three Burger's vector directions are determined. Those dislocations are expressed diagramatically with the signs α, β, and γ in Fig. 7. Dislocations α have a minimum contrast in Fig. 5(a) and (b) and a maximum contrast in Fig. 4(c). Dislocations β have a minimum contrast in Fig. 4(a) and a maximum contrast in Fig. 6(b). Dislocations γ have a minimum contrast in Fig. 4(b) and a maximum contrast in Fig. 6(a). Relations between the diffraction vectors and the image contrasts are summarized in Table I, including the results obtained with (202) and (022) diffractions which are not shown. Employing the results shown in Table I, Burger's vector directions of dislocations α, β, and γ are determined to be ½ a [1$\bar{1}$0], ½ a [01$\bar{1}$], and ½ a [10$\bar{1}$] respectively. The glide planes of the dislocations α, β, and γ are determined to be (110), ($\bar{1}\bar{1}$1), and ($\bar{1}$11) since images of the dislocations α, β, and γ vanished almost completely in those topographs obtained from (220), ($\bar{1}\bar{1}$1), and ($\bar{1}$11) diffraction planes respectively. From the data given by

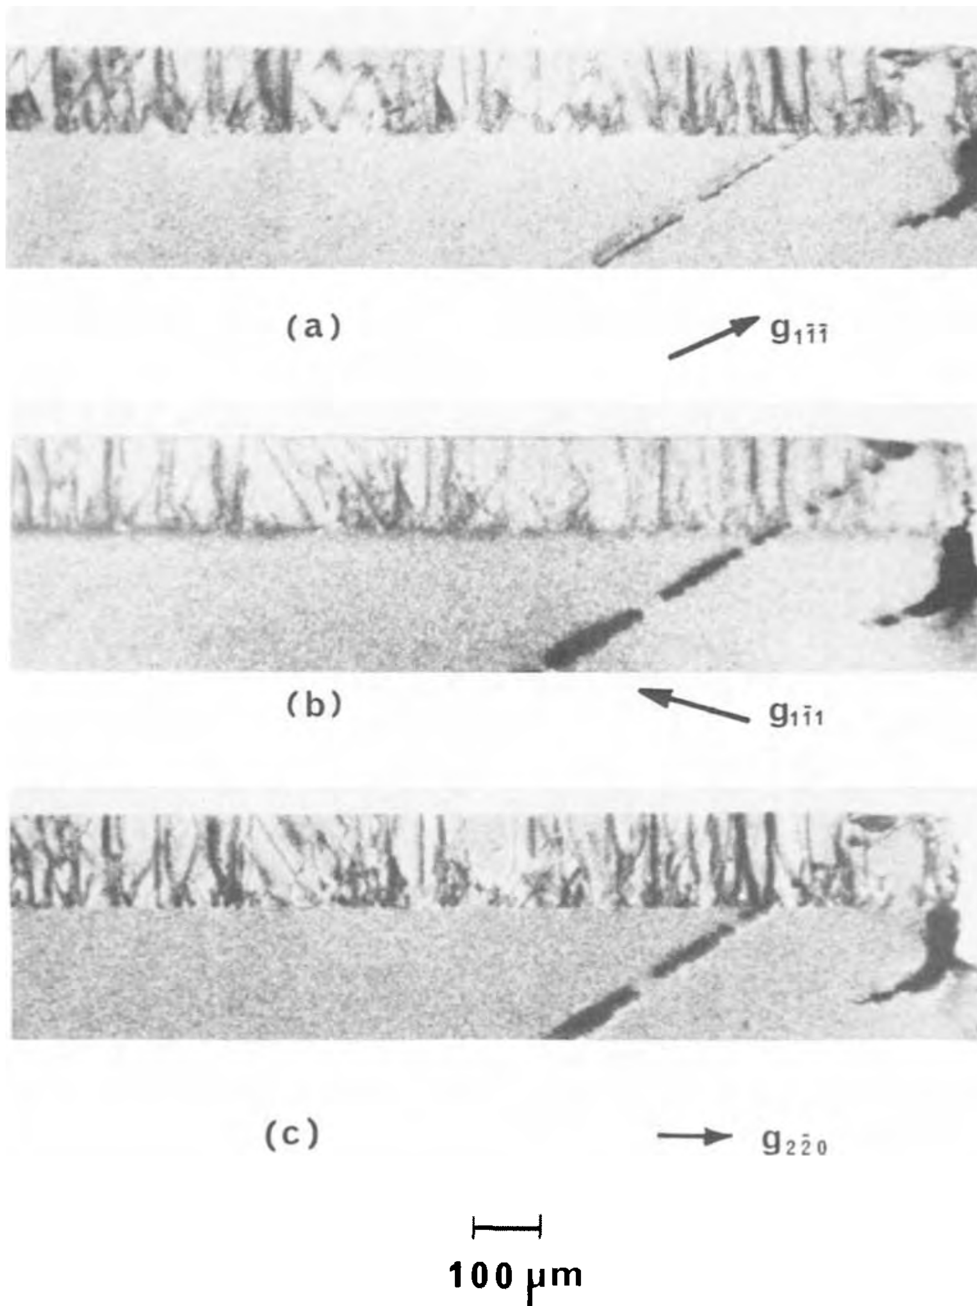

Fig. 4. X-ray topographs taken from specimen 2 (I). Figures (a), (b), and (c) are x-ray topographs with $(1\bar{1}\bar{1})$, $(1\bar{1}1)$, and $(2\bar{2}0)$ $AgK_{\alpha 1}$ diffractions respectively.

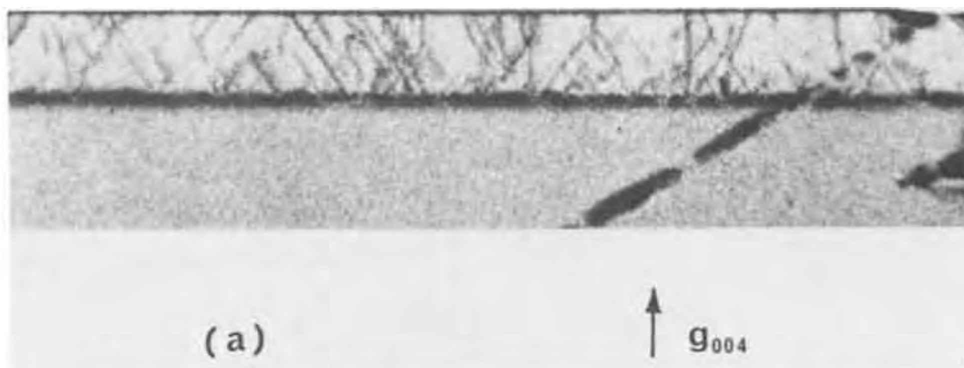
Hornstra (12) in which dislocations with ½ a <110> Burger's vector are enumerated in a diamond cubic type crystal, the three dislocations described above are determined as follows. Dislocations α are "dislocations of Type VIII," pure-edge dislocations. On the other hand, dislocations β and γ are "dislocations of Type IV," mixed-type dislocations in which the angle between the dislocation axis and Burger's vector direction is 30°, and the glide plane is {111}.

The plane defect already shown in Fig. 3 was also observed in specimen 2. Since the plane defect was laid perpendicularly to the surface of the specimen in this case, this was observed as line-shaped images at the epitaxial layer-substrate interface as shown in Fig. 5. The image assumes maximum contrast in Fig. 5(a) and (b) and minimum contrast in Fig. 4(c). The direction of the fault vector is similar to that of specimen 1. The image contrast of the plane defects shown in Fig. 4(a), 6(a), and (b), are opposite that shown in Fig. 4(b). They do not have a minimum contrast as shown in Fig. 4(c), because these images are not caused by the strain field as in the case of dislocation; rather, they are caused by a phase transition of x-ray waves.

Table I. Relation between diffraction vectors and image contrasts

Diffraction vector	Maximum contrast α	Maximum contrast β	Maximum contrast γ	Minimum contrast α	Minimum contrast β	Minimum contrast γ
$2\bar{2}0$	yes					
202						yes
$20\bar{2}$			yes			
022					yes	
$02\bar{2}$		yes				
$1\bar{1}\bar{1}$					yes	
$1\bar{1}1$						yes
113				yes		
004				yes		

The x-ray topograph taken from specimen 3 is shown in Fig. 8. Figures 8(a) and (b) are a topograph taken with (004) $AgK_{\alpha 1}$ diffraction and a corresponding optical photograph respectively. Though the diffraction plane is similar to that used in the case of Fig. 5(a), where the plane defect is observed as line-shaped images at the interface, no image contrast exists in the x-ray topograph shown in Fig. 8(a). If the plane defect is introduced due to an impurity concentration difference between layer and substrate, it is reasonable to think that the plane defect vanishes



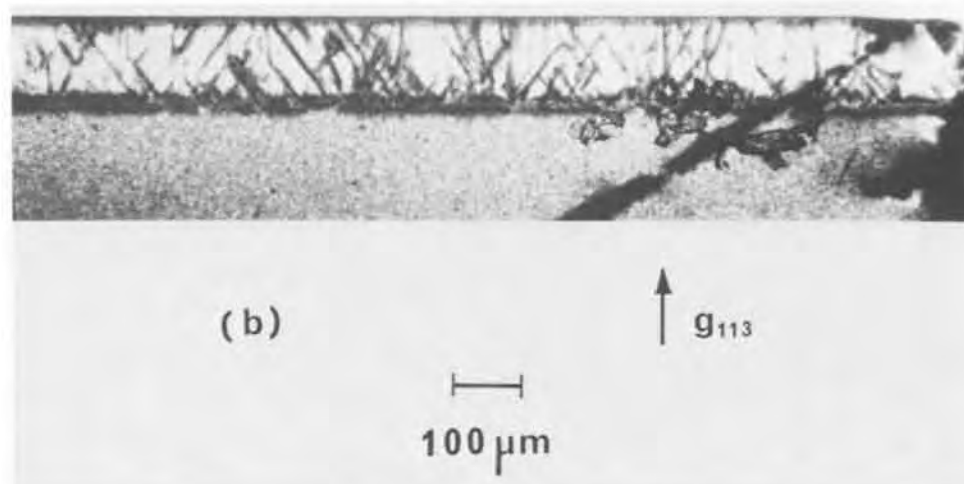


Fig. 5. X-ray topographs taken from specimen 2 (II). Figures (a) and (b) are x-ray topographs with (004) and (113) $AgK_{\alpha1}$ diffractions respectively.

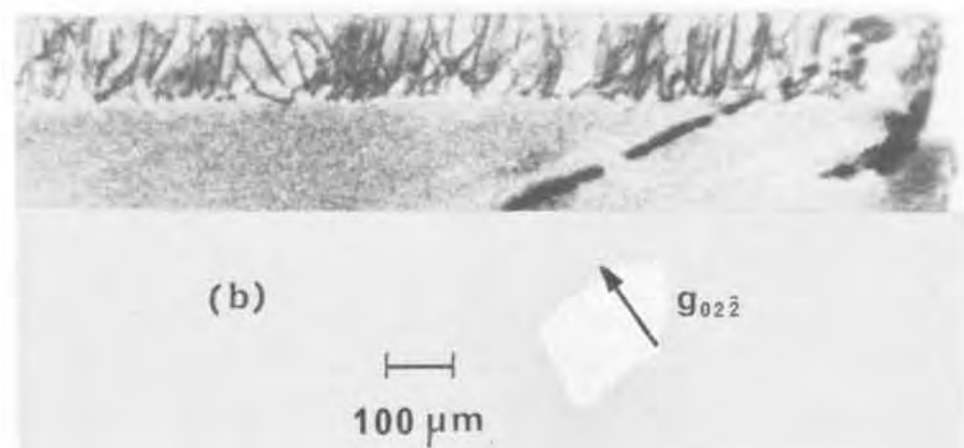

Fig. 6. X-ray topographs taken from specimen 2 (III). Figures (a) and (b) are x-ray topographs with $(20\bar{2})$ and $(02\bar{2})$ $AgK_{\alpha1}$ diffractions respectively.

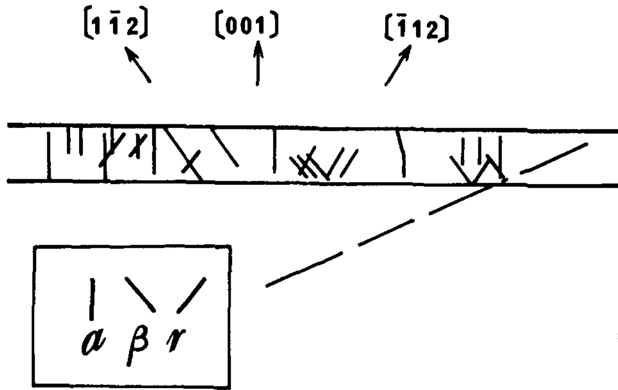

Fig. 7. Schematic diagram of dislocations observed by x-ray topographs. Signs α, β, and γ reveal dislocations in which directions of the dislocation axis are parallel to [001], [$1\bar{1}2$], and [$\bar{1}12$] respectively.

in this specimen, since specimen 3 has the same impurity concentration difference in the epitaxial layer and the substrate.

Results and Discussions

Types of dislocations induced in the epitaxial layer of GaAs single crystal differ from those of dislocations introduced in the homoepitaxy of Si (13) and the heteroepitaxy of Ge-GaAs (14), in which dislocations are introduced at the epitaxial layer-substrate interface by adding an extra half-plane to the portion with a smaller lattice parameter in order to compensate for the lattice parameter difference between them. On the other hand, such dislocations have not been observed in the homoepitaxy of GaAs.

When the impurity is doped in the GaAs crystal, the lattice parameter of the host crystal also increases (15); thus, the lattice strain at the interface must be released in the homoepitaxy of GaAs when the impurity concentration differs between layer and substrate. The lattice strain in this case was released by the plane defect at the epitaxial layer-substrate interface, and consequently dislocations of different types such as 30° or pure-edge dislocations were introduced. The formation mechanism of dislocations such as a 30° or a pure edge cannot be simply explained by strain at the interface due to the impurity difference between layer and substrate. Local strain at the interface may be released by the formation of these dislocations; however, the strain-release mechanism is not clear at present.

When a p-n junction was formed from Zn diffusion into epitaxially grown n-type {100} $GaAs_{1-x}P_x$ wafers, two types of dislocations—in which dislocation lines are parallel to <100> and <211> directions respectively—were observed from irregularity of the diffusion front (16). These dislocations may correspond to the 30° and the pure-edge type dislocations observed here. Concerning the 30° dislocations, Stringfellow (17) also observed them in $GaAs_{1-x}P_x$ crystal and offered an explanation about these dislocations in connection with the growth mechanism. The present experiment presented no explicit relation between the growth rate and the formation of 30° dislocation.

It was clarified that the plane defect was introduced at the interface when there was an impurity concentration difference between layer and substrate, as already shown. At the vapor phase epitaxy, we showed that the plane defect was not introduced at the interface if there was no impurity concentration difference between layer and substrate, as already shown in Fig. 8. This defect also may be expected in the liquid phase epitaxy of GaAs crystal, when there exists an impurity concentration difference between layer and substrate. Further studies of a sample similar to specimen 2 will be described subsequently. The sample used here has triple layers of liquid phase

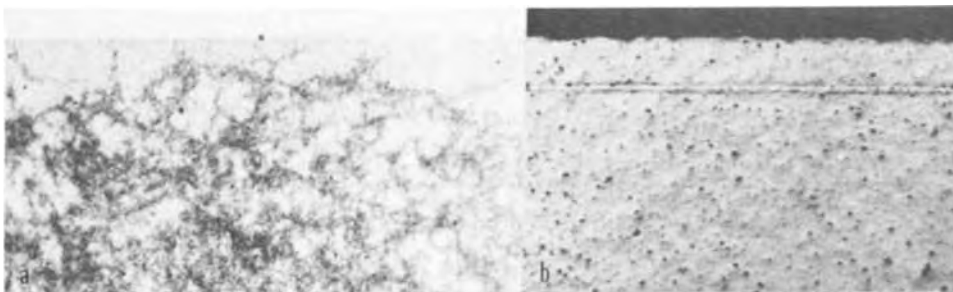

Fig. 8. X-ray topograph (a, left) and corresponding optical photograph (b, right) of specimen 3 which has no impurity concentration difference between layer and substrate.

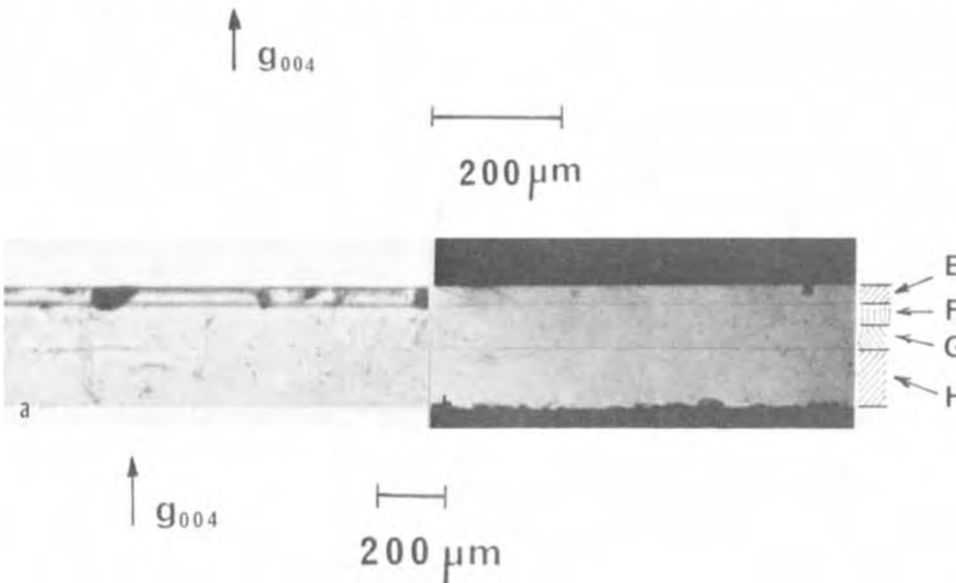

Fig. 9. X-ray topograph (a, left) and corresponding optical photograph (b, right) of sample grown by the liquid phase epitaxial technique in which the epitaxial layers are composed of triple layers E, F, and G. Impurity concentration of E, F, G, and H are 1 x 10^{19} cm^{-3}, 1 x 10^{16} cm^{-3}, 1 x 10^{16} cm^{-3}, and 5 x 10^{15} cm^{-3} respectively.

epitaxy—namely, E, F, and G. The impurity (Te) concentrations of E, F, and G are 1×10^{19} cm^{-3}, 1×10^{16} cm^{-3}, and 1×10^{16} cm^{-3} respectively; that of substrate H is 5×10^{15} cm^{-3}. The x-ray topograph and the optical photograph of this sample are reproduced in Fig. 9 (a) and (b) respectively. The x-ray topograph was taken with (004) $AgK_{\alpha 1}$ diffraction, permitting the plane defect to be observed as line-shaped images at each interface in the x-ray topograph, when the plane defects described above are introduced at each interface. It is clear that the plane defect is not introduced at the interface in the case of liquid phase epitaxy, when no lattice parameter difference exists with the preceding epitaxial layer. Further studies will be reported in the near future.

Acknowledgments

The authors wish to express their thanks to Dr. H. Kusumoto for his encouragement, to Messrs. M. Hirao, Y. Takeda, and K. Ito for their helpful support, and to Messrs. H. Sato, M. Tamura, and Y. Yoshihiro for their valuable discussions. They also express their thanks to Mr. M. Nakamura for providing GaAs wafers epitaxially grown by the liquid phase epitaxy technique.

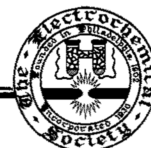
Technical Notes



Electrolytic Etching of GaN

J. I. Pankove

RCA Laboratories, Princeton, New Jersey 08540

With the advent of visible electroluminescence (1) in GaN, new developments will be forthcoming in the technology of this material. This note marks a new step in our ability to process GaN.

Heretofore, the only known etchants for GaN were molten sodium hydroxide, potassium hydroxide, or potassium pyrosulfate (2) at about 800°C. This process, done at elevated temperatures, attacks the insulating substrate (Al_2O_3) on which the GaN is grown. The hot solvent also attacks any masking material that would be used to confine the region to be etched. Hence, it is nearly impossible to control the area from which the material is to be removed by the above chemical etches. The etching of GaN films at lower temperatures was reported by Chu (3). In this case, the film was immersed in a 50% aqueous solution of NaOH at 5° to 90°C. However, when this technique was used on our single crystal layers grown by a different vapor transport method (4), no attack could be detected. It is possible that the films of Ref. (3), although dense, were somewhat porous and, therefore, more fragile than our thicker material.

We have etched GaN electrolytically in 0.1N NaOH by anodizing the crystal to which an indium contact was attached by soldering. If the crystal is immersed in a bath of NaOH, a white layer of gallium hydroxide forms which seems to block further etching. This mechanical interference was overcome by using a jet of electrolyte which flushed away any solid reaction by-

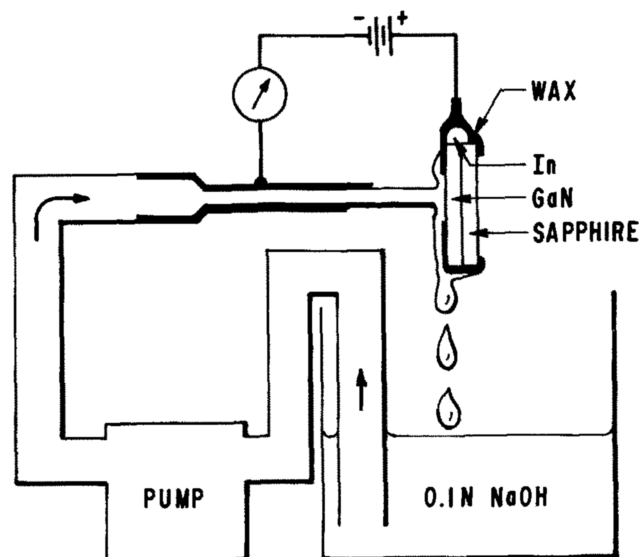


Fig. 1. Set-up for jet electrolytic etching of GaN

Key words: Jet etching, device processing, compound semiconductors, electroluminescence, surface preparation.

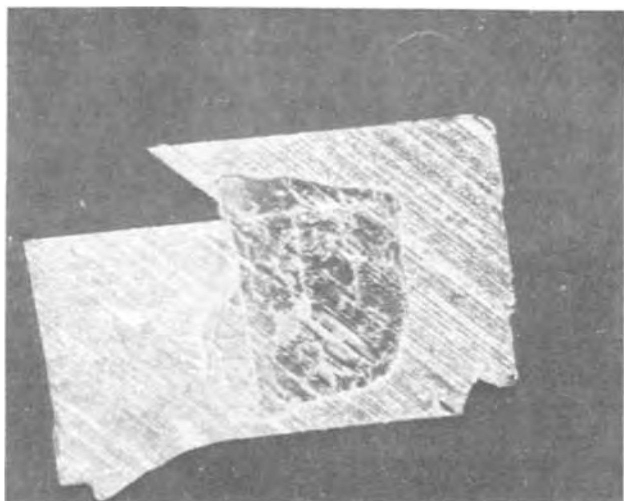

Fig. 2. Photograph of etched GaN on a sapphire substrate; the dark region is the etched unmasked portion of the crystal.

product. The experimental arrangement is shown in Fig. 1. The electrolyte is pumped through a Tygon tube to a hypodermic needle connected to the negative terminal of d-c power supply. The jet strikes the exposed region of the partially masked crystal forming the anode. The potential was adjusted to draw a current of about 2 mA. Figure 2 shows that etching proceeded as expected in the unmasked area. In this case, piceine wax was used to mask the crystal.

This electrolytic etching technique was also used to separate a layer of Zn-doped insulating GaN, grown on undoped conducting n-type GaN from the sapphire substrate. The n-type region was connected to the positive terminal of the power supply. The electrolyte jet was played on the specimen's cleaved edge which exposed the three regions: the sapphire substrate, the n-type layer, and the insulating layer. Only the conducting n-type region was dissolved, thus, freeing the insulating GaN layer. Because of the tremendous stresses generated immediately after growth by the large differential thermal expansion between GaN and the sapphire substrate, the freed insulating layer tends to break up into flakes. When the insulating GaN layer is thick (0.5 mm), larger pieces can be obtained.

Blue-green electroluminescence from the i-n transition was seen. This rather bright luminescence is observed when the applied potential is sufficiently large to permit current flow through the i-n transition in addition to the etching current along the n-type region.

The use of electrolyte etching to produce self-supporting layers of single crystal GaN may provide us with the ideal substrate for growing strain-free material, namely, a single crystal of GaN. By concentrating the current with finer electrodes, it should be possible to etch intricate patterns (5). The use of this technique for polishing surfaces or revealing dislocations has not been explored.

Acknowledgments

The author wishes to thank E. A. Miller for growing the GaN, J. E. Berkeyheiser for technical assistance, and G. S. Lozier for a valuable discussion.

The Growth of Ge-GaAs and GaP-Si Heterojunctions by Liquid Phase Epitaxy

Ferenc E. Rosztoczy* and William W. Stein*,[1]

Varian Associates, Palo Alto, California 94303

The purpose of this paper is to discuss the feasibility and practicality of growing heterojunction epitaxial layers from eutectic solutions. As practical examples for this technique, the growth of germanium-gallium arsenide and galliumphosphide-silicon heterojunctions will be described.

Eutectic epitaxy is based on the discovery that seeded single crystal layers can be obtained from eutectic liquid compositions of ternary solutions (1). Since, by definition, the liquid is in equilibrium with two solids, theoretically either of them can be used as substrates. Depending on which solid is used, one can talk about heteroepitaxy or homoepitaxy.

If the solution of a ternary system, such as A-B-C, is cooled to room temperature with a starting composition D (as seen in Fig. 1), the composition first stays constant in the liquid; then, reaching the saturation point for compound AB, AB starts to precipitate and the composition of the liquid gradually changes to E and then to F. In Fig. 1 the A-F-B line represents the eutectic valley of the system. At F the liquid is in

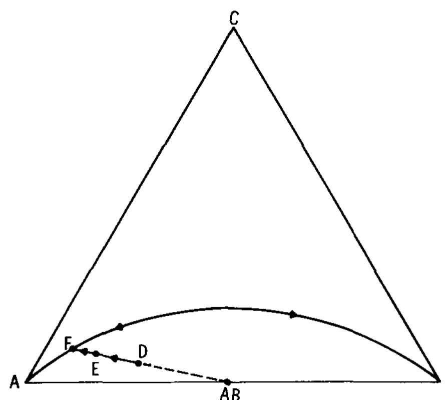

Fig. 1. A schematic ternary phase diagram (similar to the phase diagram of the Ga-As-Si system; A:Ga, B:As; C:Si).

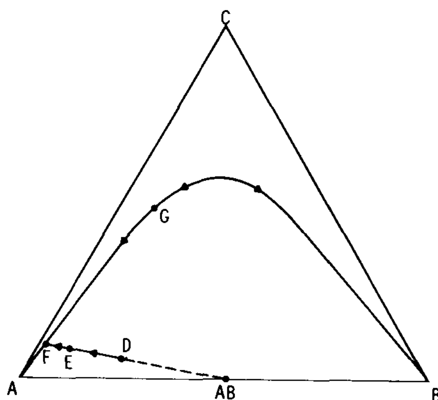

Fig. 2. A schematic ternary phase diagram (similar to the phase diagram of the Ga-As-Ge system; A:Ga; B:As; C:Ge).

equilibrium with both solids AB and C. When the liquid is further cooled, AB and C will coprecipitate and the liquid composition will vary along the eutectic line to A.

In the case of liquid-phase epitaxy, the layers of AB are grown along a line like D-E. It was assumed that on reaching F, the eutectic composition, the further growth of the single-crystal layer would virtually stop due to the coprecipitation of the other material. In the case of the Ga-As-Si system, it has been shown recently that the crystal growth did not stop but actually continued, and a Si-doped GaAs layer continued to grow while the composition of the liquid varied along the eutectic line (2).

Ge on GaAs

The Ga-As-Ge ternary system has a schematic phase diagram similar to Fig. 2 (3). When a solution with composition D was cooled to room temperature, the first grown epitaxial GaAs layer on the GaAs substrate was covered with an epitaxial layer of Ge.

Figure 3a presents the photograph of a nitric acid-stained angle lap of the wafer. The angle laps were made on a 10° block. The structure consists of n-type GaAs single crystal substrate, covered with an approximately 20 μm thick p-type epitaxial layer of GaAs, highly doped with Ge; and on the top of this is an approximately 2 μm thick p-type epitaxial layer of Ge saturated with both Ga and As at the growth temperature.

The complete uniform coverage of the GaAs growth, with a layer of epitaxial Ge from a eutectic solution that is saturated relative to both GaAs and Ge, is attributed to the phase diagram (3). While the melt is cooled from composition F to room temperature along the eutectic line (Fig. 2), the "precipitate" is more than 95% Ge. Once the GaAs surface, in contact with a melt supersaturated relative to Ge, becomes seeded with Ge, it suddenly covers the whole surface area in a very short time.

If a eutectic melt, saturated with both GaAs and Ge, is brought in contact with a single crystal GaAs substrate and cooled, then an epitaxial heterojunction, p-type Ge on n-type GaAs, can be grown. A melt was prepared by heating 0.45g Ga, 1.7g Ge, and 0.30g GaAs to 850°C. It was brought in contact with a GaAs substrate at 814°C and was cooled to 803°C at which point the melt was wiped off the wafer. For more details on the experimental procedure, see Ref. (4). Figure 3b presents the photograph of the nitric-acid stained angle lap of this wafer. There is an approximately 23 μm p-type epitaxial Ge layer on the n-type GaAs substrate. There is no epitaxial GaAs regrowth on this wafer. The Ge layer was identified by use of the electron beam microprobe. It was doped with Ga and As on the order of one atomic per cent (a/o) each.

For liquid phase epitaxy, a few per cent solubility of the source material in the solvent at the growth temperature is usually preferred. To grow epitaxial heterojunctions from eutectic solution the selection of a solvent in which the substrate crystal has a much

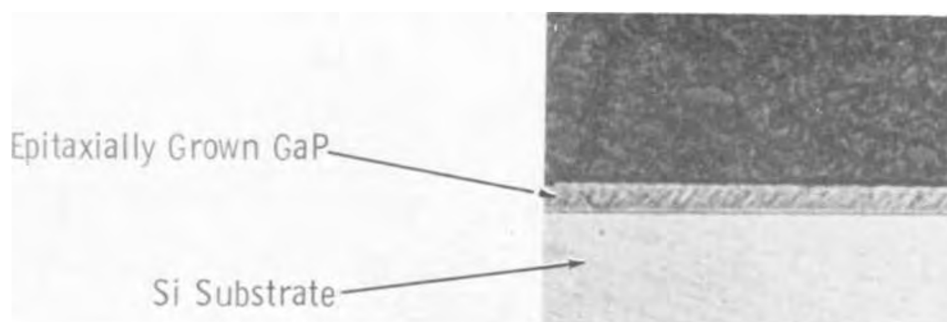

Fig. 5. Cleaved and stained cross-section of epitaxial GaP on Si substrate.

lower solubility at the growth temperature than the source material is also recommended.

GaP on Si

For device application one of the most interesting combinations is to grow epitaxial GaP on Si substrates. Using Ga as the solvent, we could not get a good epitaxial growth of GaP. We attribute the difficulty to the relatively high solubility of Si in Ga under growth conditions.

We turned our attention to quarternary systems to find the right solvent to grow GaP on Si. Based on solubility data, a number of metals appeared more favorable than Ga as a solvent. Based on thermodynamic data, lead and tin were selected. The solubility of GaP relative to the solubility of Si is relatively high in both; and the solubility of Pb and Sn in GaP crystals is relatively low.

Using a graphite boat, flowing ultra-pure dry hydrogen, and using an experimental setup similar to Nelson's design (5), a saturated solution of GaP in Pb was prepared by thoroughly mixing 13g Pb and 0.3g GaP at 950°C. After keeping the boat at 950°C for 60 min the system was quenched, subsequently saturated with Si at 950°C, and quenched again. The Si substrate was placed in the other end of the boat, the system was heated to 950°C and kept there for 30 min, then the furnace was tipped and the melt was brought in contact with the substrate. It was cooled to 800°C in 60 min and then the melt was removed from the seed. An epitaxial layer approximately 10 μm thick was grown. It was examined by x-ray and the Laue photographs proved it was epitaxial single crystal. It was identified by electron beam microprobe as GaP on Si.

The same technique and experimental setup was used to grow epitaxial layers from Sn solutions. Five grams of Sn with 0.5g of GaP were heated to 850°C to prepare a saturated solution, then it was saturated with Si. The melt was brought in contact with (111)- or (100)-oriented Si substrates at 845°C and was cooled to 650°C in 3 hr. The epitaxial layers were on the order of 10 μm thick. The epitaxial layers were identified as GaP using an infrared spectrophotometer and measuring the Reststrahlen frequency around 25 μm. As can be seen in Fig. 4, the infrared reflection spectra of the epitaxial layers (Fig. 4a) were very similar to those of pure melt-grown GaP (Fig. 4b). Figure 5 is a photograph of a cleaved and stained GaP-Si heterojunction.

The disadvantage of this technique is that the epitaxial GaP layers were degenerately doped with Si and Pb or Sn. For most device applications an additional epitaxial layer of GaP would have to be grown by a different technique.

To summarize, a new technique called eutectic epitaxy has been described. It has been used to grow GaAs-Ge and GaP-Si heterojunctions. Its potential application to grow other heterojunctions is suggested.

Acknowledgments

Helpful suggestions and discussions with R. L. Bell and G. A. Antypas are gratefully acknowledged. The aid of S. V. Szeremy in the growth of the epitaxial layers is also gratefully acknowledged.

Epitaxial Growth of Silicon from Dichlorosilane

Anders Lekholm

Microwave Institute Foundation, S-100 44 Stockholm 70, Sweden

Epitaxial silicon has found many important applications in solid-state devices. These applications may be divided into two groups: components that exploit the unique feature of epitaxy to produce layers of any desired doping on higher doped contact regions, and components that have abrupt transitions in the doping profile as an integrated part of the device.

In components where sharp steps in the impurity density distribution are required, it is necessary to minimize the Dt product of diffusion coefficient and time in the growth step. Since it is impossible to increase the growth rate above a few μm/min (and thus decrease time) in the silicon tetrachloride process, the natural solution to this problem is to decrease the growth temperature. This is also a very effective way of decreasing the Dt product because the diffusion coefficient of most impurities in silicon decreases about one order of magnitude for every 100°C decrease in temperature.

Of the different methods available for low temperature epitaxial growth of silicon, thermal decomposition of silane has attracted most interest. Growth temperatures as low as 800°C are reported (1). To obtain high growth rates special schemes, such as water-cooled reaction vessels, have to be used to avoid gas phase decomposition and fallout of polycrystalline silicon on the wafers. Improved growth techniques have resulted in growth rates of 5 μm/min at 1000°C (2). Further increase in the growth rate is possible if the hydrogen carrier gas is substituted by helium. Using this scheme, growth rates of 3 μm/min at 900°C are reported (1).

In a production system one must, however, make a choice between the simplicity of the silicon tetrachloride process and the better results (in terms of Dt product) of the more complicated silane process.

This paper presents results from epitaxial growth of silicon from dichlorosilane. It allows high growth rates at substantially lower temperatures than silicon tetrachloride. Unlike silane, dichlorosilane is relatively stable in the gas phase and problems with premature gas phase pyrolysis are small or nonexistent.

For the experiments described, an epitaxial system with vertical gas flow and a rotating rf-heated carbon susceptor was used. The susceptor diameter is 12.5 cm and is designed to carry seven 1¼ in. diam silicon wafers. The total gas flow in all runs was 27 liters/min. The system was originally designed to use silicon tetrachloride; however, no alterations were made for these dichlorosilane experiments.

The temperature of the silicon wafers was measured with an optical pyrometer or an electro-optic, *IR* detector and was corrected for emissivity and for absorption losses in the quartz of the bell jar. The gas flow rates were monitored with flowmeters calibrated for the gases used. The thicknesses of the epitaxial layers were determined from infrared interference measurements.

Great care was taken to obtain reproducible results from run to run. In order to improve the temperature measurements, the susceptor was etched clean between each experimental run and was again coated with silicon in a standardized run before the next silicon wafer was processed. At high growth rates this procedure was necessary. The silicon on the susceptor would then exhibit a large-grain polycrystalline surface and, after a few runs, the uncertainty in the temperature readings increased rapidly in an unpredictable way.

The growth rate as a function of mole concentration of dichlorosilane in hydrogen is shown in Fig. 1. The growth temperature was 1110°C. No attempts were made with higher growth rates than those shown in the graph. At growth rates above 5-7 μm/min small fluctuations in temperature or gas composition had a strong influence on the epitaxial layer quality. Above a growth rate of 10 μm/min dendritic growth occasionally occurred at a few spots on the susceptor resulting in ladder-like nests of dendrites about 100 μm long.

The temperature dependence of the growth rate is shown in Fig. 2. The growth rate is proportional to the dichlorosilane concentration for all temperatures studied, indicating a first order reaction. From the plot, an apparent activation energy of 13 kcal/mole is calculated. This value is greater than that found by other workers. Benzing *et al.* (3, 4) have reported an activation energy of 5.8 kcal/mole for this reaction. The latter value has been corroborated by Van Hoy (5).

The high value of the activation energy this author obtained, independent of the mentioned works, may be due to the different types of epitaxial systems used. In the vertical system used by the author, control of the reacting gas composition is good, while in a horizontal system as used by Benzing *et al.* (3), the gas composition gradually changes along the length of the susceptor.

For the concentrations and temperatures studied, epitaxial growth of high quality layers was achieved. The final surface finish was observed in a differential interference contrast microscope and was found to be comparable with that of the etch-polished (6, 7) substrates. Layers were grown at temperatures as low as 1000°C, but these showed a much higher concentration of stacking faults, which were probably due to the inefficiency of the hydrogen etching of silicon dioxide in this temperature range. Some layers, grown at

Key words: impurity distribution, redistribution of dopants, low temperature epitaxy.

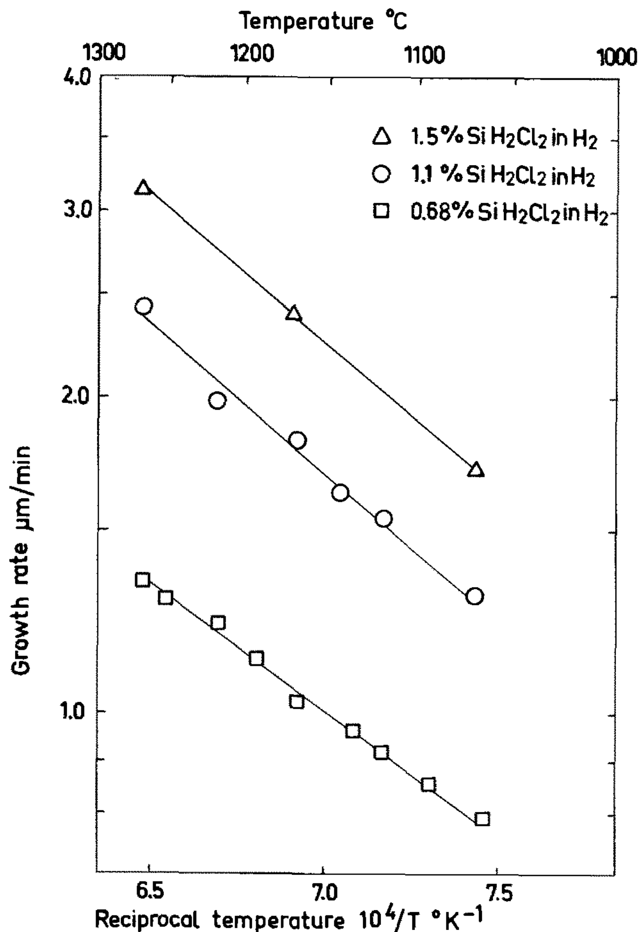

Fig. 2. Temperature dependence of the epitaxial growth for different concentrations of dichlorosilane in hydrogen.

1100°C and higher temperatures, were completely free of stacking faults (8).

The impurity density distribution at the substrate interface was determined from capacitance measurements on mesa diodes formed by diffusion and etching (9). Lightly doped layers were grown on 0.01 ohm-cm boron or antimony doped substrates. As an example, an antimony doped substrate with a 5 μm thick epitaxial layer, which was grown at 1080°C with a growth rate of 1.2 μm/min, had a step in the impurity distribution from the layer doping of $5 \cdot 10^{14}$ cm^{-3} to $1 \cdot 10^{17}$ cm^{-3} in a distance of about 0.1 μm. This result agrees well with the calculated out-diffusion from the substrate.

The similarities between epitaxy from silicon tetrachloride and dichlorosilane offers an interesting possibility to study the differences between epitaxial growth from a highly reversible reaction (silicon tetrachloride) and from an irreversible reaction (dichlorosilane). Grossman (10) and Thomas *et al.* (11, 12) have proposed that, in the reversible reaction of silicon tetrachloride and silicon in a hydrogen ambient, a thin surface layer of the silicon substrate is transferred into the gas phase and later redeposited. As a consequence of this, the impurity density distribution at the substrate-epitaxial layer interface will be more diffuse than predicted by diffusion theory.

To test this hypothesis, lightly doped layers were grown from dichlorosilane and silicon tetrachloride under identical growth conditions. Growth rates of about 3 μm/min at about 1230°C, were used in order to operate close to equilibrium in the silicon tetrachloride reaction. The back side of the substrates were sealed with a thermally grown layer of silicon dioxide to prevent the escape of impurities into the gas stream. The substrates were doped with boron or antimony to 0.01 ohm-cm. No differences in the impurity density distribution of the interfacial region was observed within the experimental error. There are two possible explanations for this result. Either the hypothesis is false, or the reaction kinetics are the same for the two growth processes. The latter assumption was tested by using other carrier gases than hydrogen in the dichlorosilane process. Experiments with nitrogen and argon as carriers showed that the growth rate at 1100°C was proportional to the dichlorosilane concentration but 30-40% lower than for dichlorosilane in hydrogen. This experiment, and the linear growth rate in Fig. 1, prove that epitaxial growth of silicon from dichlorosilane is a highly irreversible reaction. As a consequence of this, one can conclude that the interfacial region impurity distribution may be explained by diffusion theory alone as has been proposed by Grove *et al.* (13).

Acknowledgment

I wish to thank Peter Weissglas for his keen advice and many stimulating discussions.

Formation of MgO Crystals in Anodic γ-Al_2O_3 Formed on Aluminum-3% Magnesium Alloy

A. J. Brock* and M. A. Heine

Metal Research Laboratories, Olin Corporation, New Haven, Connecticut 06504

During the high temperature oxidation of Al-Mg alloys the initial protective film of amorphous γ-Al_2O_3 is degraded and a much less protective film consisting entirely of MgO, or of both MgO and amorphous γ-Al_2O_3, is formed (1). Previous workers investigating the oxidation behavior of Al-Mg alloys (2, 3) provided little information concerning the breakdown of the initial film of amorphous γ-Al_2O_3 although De Broukère (4) did consider that MgO could possibly result from the reduction of γ-Al_2O_3 by magnesium. Accordingly, the present work was conducted to study the formation of MgO in barrier-type anodic oxides formed on Al-3% Mg alloy. This follows similar studies of the formation of crystalline γ-Al_2O_3 under anodic oxide films formed on high purity aluminum (5).

The alloy composition was 3.05% Mg, 0.0006% Si, 0.0028% Fe, <0.0005% Cu, and <0.0005% Mn. The alloy, after hot and cold rolling to 0.04 cm thick sheet, was solution treated at 600°C for 8 hr followed by quenching into water. Specimens measuring 4 × 1 cm were degreased in benzene, rinsed in methanol, etched in a solution of 3% sulfuric acid and 3% chromic acid at 70°C for 20 min, rinsed in water, then methanol, and stored in a desiccator for 24 hr to allow the formation of a uniform air-formed oxide film some 20Å thick. The etching procedure results in a slightly scalloped surface which is smooth on a microscale and suitable for studying by means of electron microscopy. Specimens were then anodized in a solution of 3% ammonium tartrate at *p*H 7.0. The voltage across the cell was increased manually to 10V in such a fashion that the current surge never exceeded 5 mA/cm^2. The current was allowed to decay at this voltage for 5 min. Specimens showing a residual current density greater than 25 $\mu A/cm^2$ were rejected. Capacitance measurements revealed that the anodic oxide was 137Å thick, assuming a dielectric constant of 8.5. The unanodized portions of the specimens were cut off leaving one cut edge unanodized.

Following anodizing, the specimens were heated at 350°C for periods of 3 and 20 hr in a quartz tube through which purified argon was flowing at a rate

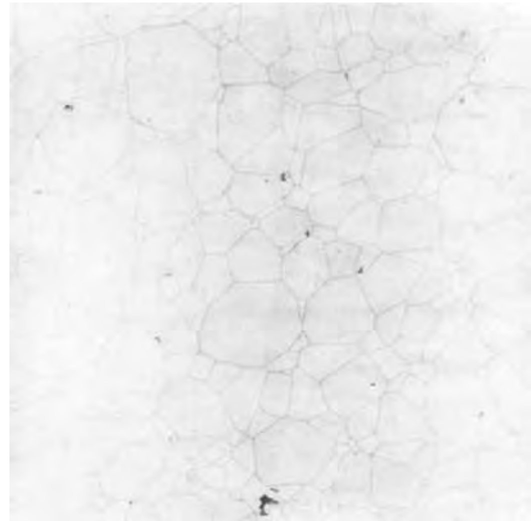

Fig. 1. Transmission electron micrograph of 10V anodic oxide film formed on aluminum-3% magnesium alloy (magnification 16,000X).

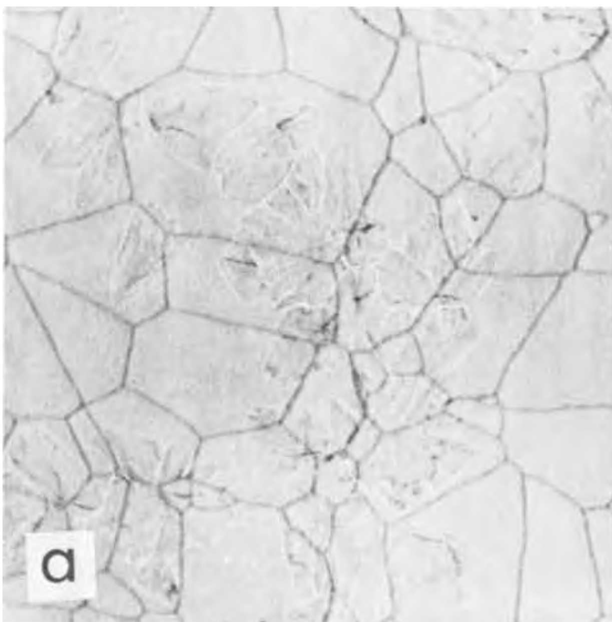

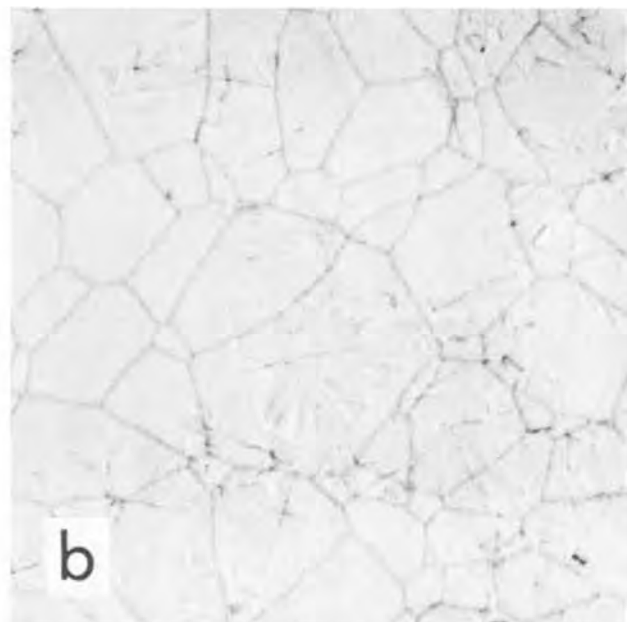

Fig. 2. Transmission electron micrographs of anodic oxide films after exposure at 350°C for 3 hr in: a, purified argon; b, oxygen at 76 Torr (magnification 45,000X).

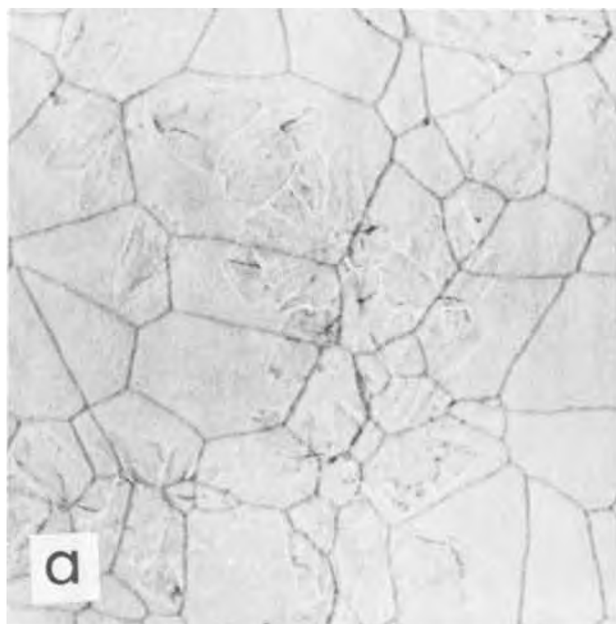
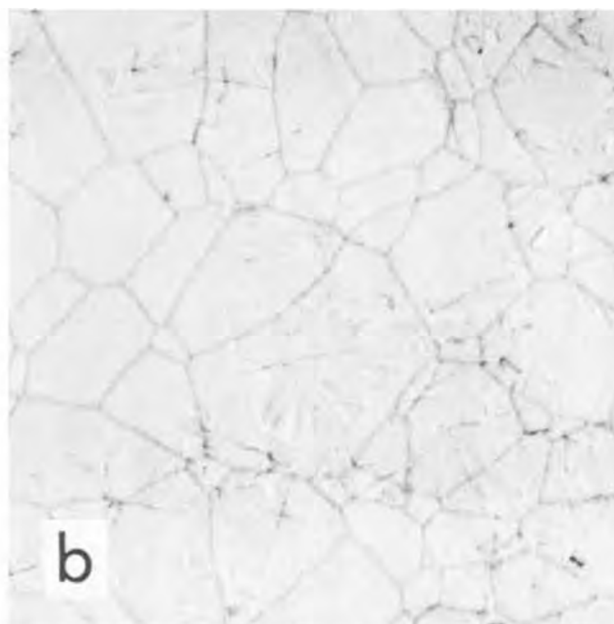
of approximately 1 liter/hr. The argon, initially 99% pure, was further purified by passing it through a column of copper turnings at 380°C and then through a dry ice-cooled cold trap. This resulted in an oxygen concentration of about 1 ppm. Other specimens were heated for 3 hr in oxygen at 76 Torr.

The various films on the aluminum-3% Mg alloy were stripped by immersion in 10% mercuric chloride in methanol and examined by transmission electron microscopy. Figure 1 shows a transmission electron micrograph of the anodic film before heating in argon. The network seen in the micrograph is characteristic of the etched surface of the alloy. Figure 2a is a transmission electron-micrograph of the anodic oxide which had been stripped from the aluminum alloy after heating for 3 hr at 350°C in argon. This micrograph depicts the presence of crystals which transmission electron diffraction experiments revealed to be MgO. Elemental aluminum was never detected in these oxides. Figure 2b is a similar electron micrograph of an anodic oxide which had been stripped from the aluminum alloy after heating for 3 hr in oxygen. The crystal frequency and coverage is similar to that observed in Fig. 2a. In both cases the contrast between the aluminum and magnesium oxides is quite poor because their electron scattering powers are virtually identical.

Figure 3a is a transmission electron micrograph of the anodic oxide stripped from the alloy after heating at 350°C for 20 hr in argon. In this case, coverage of MgO crystals is substantially complete. Weight measurements, made before and after heating the anodized specimens in argon for 20 hr, indicated a small weight loss of 3 μg from each specimen. This doubtless results from loss of magnesium through volatilization from the unanodized edge of the specimen. Gravimetric measurements made on specimens heated for 20 hr in oxygen, where crystal coverage was also complete, indicated no significant change in weight. In this case, magnesium loss from the unanodized edge would be minimized because of the formation of the thermal oxide film. From knowledge of the rate of oxidation of Al-3% Mg alloy at 350°C (1), a weight gain of 0.06 μg would be expected on the unanodized edge which is beyond the sensitivity of the microbalance.

The electron micrograph, Fig. 3b, is of a carbon-platinum replica of the oxide-gas interface of the





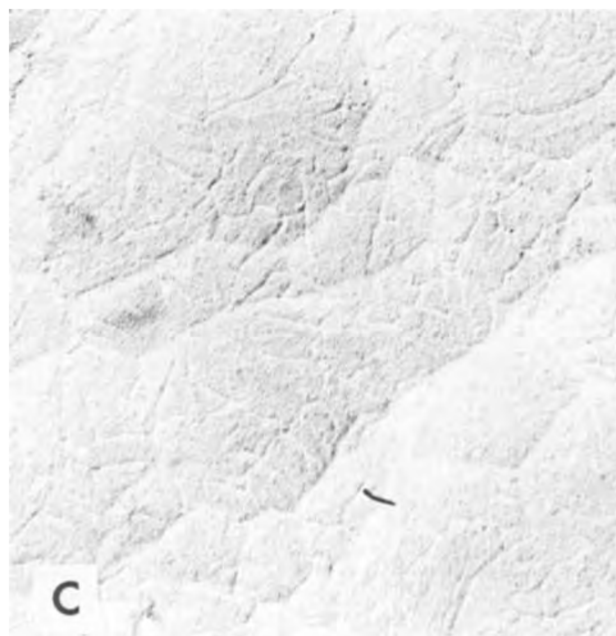


Fig. 3. Nature of the anodic oxide after exposure to argon at 350°C for 20 hr: a, transmission electron micrograph; b, positive platinum-carbon replica of oxide-gas interface; c, positive platinum-carbon replica of metal-oxide interface (magnification 45,000X).

Table I. Capacitance and resistance of anodic oxides formed on Al-3% Mg alloy before and after heating in purified argon at 350°C

Nature of film	Capacitance ($\mu F/cm^2$)	A-C resistance at 1 kHz (ohm-cm^2)
Anodized	0.548	25,200
Anodized 3 hr in argon	0.590	18,700
Anodized 20 hr in argon	0.735	10,100
Anodized 20 hr in argon 1700 min in chromate solution	1.31	2,170

anodic film after heating in argon for 20 hr. It shows details similar to those of the etched alloy surface and does not reveal the presence of MgO crystals. Figure 3c is an electron micrograph of a replica taken from the underside of a similar stripped oxide film and depicts details of the oxide-metal interface. Here the edges of the MgO crystals are clearly visible. Accordingly, Fig. 3b and 3c show that the MgO nucleates and grows at the alloy-oxide interface.

To further clarify the position of the MgO crystals, capacitance-loss measurements were made at 1 kHz on anodized specimens before and after heating in purified argon for 3 and 20 hr, and also after thinning the heated films to the maximum degree in sodium chromate solution at pH 7. This technique has been described in detail previously (6). Figure 4 shows the transmission electron micrograph of the anodic oxide heated in argon for 3 hr and after immersion in chromate solution for 1700 min after which time film thinning had ceased. Contrast between the magnesium and aluminum oxides improves as the thickness of the latter is decreased.

It is clear from Fig. 4 that thinning occurred in a uniform manner and that the underlying crystals of MgO were not attacked. Electron optical examination of a replica of the outer surface of a fully thinned film did not reveal the presence of MgO crystals; instead the surface appeared identical to that shown in Fig. 3b. The results of the capacitance loss-measurements are shown in Table I.

The anodic film formed on the Al-3% Mg alloy has a high resistance, comparable with that of a similar film formed on pure aluminum. After heating for 3 hr in argon the resistance of the film decreases due to the presence of MgO which is a lossy dielectric. The corresponding increase in capacitance results from loss of alumina by its reaction with Mg to form MgO. After heating for 20 hr in argon, at which time crystalline coverage was complete, a further decrease in resistance and in capacitance was observed. Taking a dielectric constant of 8.5 for amorphous γ-Al_2O_3, and assuming that the remaining alumina had remained unchanged while heating in argon and also that the layer of MgO does not significantly contribute to the capacitance and resistance values, the capacitance measurements indicate that 36Å of γ-Al_2O_3 were consumed. From the densities of γ-Al_2O_3 and MgO of 3.69 g/cm^2, and 3.53 g/cm^3 respectively, this corresponds to the formation of a layer of MgO crystals 38Å thick.
