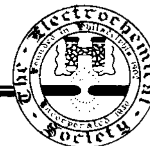
Technical Note



Cyclic Oxidation of Hastelloy X

S. K. Rhee and A. R. Spencer

Research Laboratories, Bendix Corporation, Southfield, Michigan 48076

This investigation has been conducted as a part of a program to evaluate and select high-temperature alloys which are particularly suitable for fabricating transpiration-cooled (porous) materials used in turbine blades and similar engine components.

The kinetics of cyclic oxidation of Hastelloy X in the form of sheet and wire were studied over the temperature range 760°-1200°C. The chemical composition of the alloy is listed in Table I, as provided by the manufacturer. Sheet specimens were cut to nominal dimensions of 6 × 0.5 × 0.060 in. Wire specimens were 0.005 ± 0.0005 in. in diameter. Surface contamination of specimens was removed by sonic-cleaning in hot trichloroethylene followed by acetone rinsing. After cleaning the specimens were annealed for 8 hr at 1150°C in dry hydrogen (dew point below —62°C). Wires were loosely wound around prefired mullite tubes for support during the annealing cycle. The specimens appeared clean and bright after the anneal. The sheet specimens were then polished with successively finer grades of abrasives, and were finished with 320 grit silicon carbide. A bright, smooth surface of approximately 10 μin. RMS roughness was produced. Final sonic cleaning was accomplished in hot trichloroethylene with an acetone rinse.

Sheet specimens were contained in zircon ceramic thimbles with four-point minimum contact at the corners of the specimen. Wire specimens consisted of loose bundles about 6 in. long and 1½ in. in diameter containing approximately 100 ft of 0.005 in. diameter wire which weighed about 3g. Each wire bundle was placed in a separate zircon thimble. All thimbles were fired at 1600°C and baked out at 760°C to constant weight before using. Separate specimens (a total of 9 for each temperature) were subjected to cyclic oxidation in air for times of 4, 16, 64, 100, 200, 300, 400, 500, and 600 hr at each given temperature. After each exposure cycle, a tray containing all specimens was removed from the furnace and air-cooled. One specimen was removed for evaluation and the rest returned to the furnace. Temperatures are generally ±5°.

Key words: oxidation, oxidation of superalloy, cyclic oxidation, cyclic oxidation of superalloy, oxidation of Hastelloy X.

Calibrated Chromel-Alumel thermocouples of heavy wire were placed at several locations on each tray and temperatures recorded continuously. At higher temperatures, thermocouples were replaced frequently. Specimen weight and oxidation weight gain were determined to ±0.1 mg with an analytical balance after each oxidation cycle. At high temperatures where the amount of oxide spall was large, the ceramic thimble and the specimen were weighed together before and after oxidation, and this method was found to be more reproducible than direct weighing. Further details of the experimental procedure together with the resulting data, which is analyzed herein, have been reported elsewhere (1, 2).

The weight-gain vs. oxidation time curves for the sheet specimens and for the wire specimens are shown in Fig. 1 and 2, respectively; in the case of wire specimens, the mean surface area was used for calculating the specific weight gain, based on the initial and final diameters of the metal. In all cases, initially the weight increases parabolically in a manner similar to that often found for continuous oxidation (3, 4). At higher temperatures and longer times sheet specimen behavior was observed to be erratic. In these cases, the differing spall behavior of the individual specimens explains the observed results because fresh surfaces oxidize rapidly. Also, a few points seem to show a large experimental error at lower temperatures, partly because weight gain was small.

The oxidation rate constants calculated for the sheet specimens are given in Table II, and for the wire specimens in Table III. The rate constants are plotted as an inverse function of temperature in Fig. 3. The rate constants obtained from continuous oxidation of Hastelloy X wire (5) and sheet (6) are also included in Fig. 3 for comparison. A least-squares fit to the Arrhenius plots yields an activation energy of 49.9 ± 2.6 kcal/mole for the sheet specimens and 51.6 ± 1.5 kcal/mole for the wire specimens, respectively. Taking into account the estimated experimental errors (±5%), the activation energies become 49.9 ± 5.1 kcal/mole, and 51.6 ± 4.1 kcal/mole, respectively. The activation energies are practically equal for both types of speci-

mens, indicating that the same activation process is rate-controlling for the cyclic oxidation. The parabolic rate constants for the sheet specimens used in the present work are substantially smaller than the constants found for the wire and sheet specimens in continuous, or cyclic oxidation (Fig. 3). This difference in rate constants is probably due to various factors such as surface preparation, composition, and history

Table II. Parabolic rate constants for sheet specimens

870	3.56×10^{-13}	>600
982	2.02×10^{-12}	>600
1093	1.55×10^{-11}	100
1150	3.57×10^{-11}	64

of heat-treatment. For example, according to Caplan *et al.* (7) the oxidation rate of the Fe-26% Cr-0.5% Si alloy was found to increase in the following order of surface treatment, electropolished plus etched, abraded plus etched, machined, abraded, and electropolished. They found that the weight gain after 210 min at 1100°C was 0.4 mg/cm² on the electropolished and etched surface, compared with 1.05 mg/cm² on the electropolished surface. It was suggested that the effects were due to the differences in defect concentrations in the oxide films produced by the various pretreatments. Similarly, in the case of Ni-Cr alloys, the oxidation rate was increased when the surface was grit-blasted, compared with the grit-blasted and annealed surface, and the effects of surface preparation also depended on the composition of the alloys (8). Wlodek (6) found that the rate constants varied with a small variation in the composition of Hastelloy X. According to Wood and Wright (9), the oxidation rate of Ni-Co alloys was very sensitive to the previous history of the specimen; coherent or noncoherent oxides were observed depending on the previous history.

Metallographic and x-ray analyses were performed on the oxide scales formed on the sheet specimens (10). Metallographic examinations revealed that dark spots started to form along surface scratches after 4 hr at 982°C, and almost the entire surface was covered with the dark phase and with some lighter phase after 100 hr at 982°C. The 600 hr 1093°C specimen had an adherent scale, which was light green near the substrate, while it gradually darkened near the surface, indicating either a change in the oxide Cr_2O_3 or the presence of a finely dispersed, dark second phase. The x-ray diffraction and fluorescence studies showed that the major phases of the scale were Cr_2O_3 and (Fe, Ni) $(Cr, Mn)_2O_4$ up to 1093°C, and mostly Cr_2O_3 at 1204°C.

In the case of continuous oxidation of Hastelloy X wires, the activation energy is reported to be 63.1 ± 2.3 kcal/mole, and this value was attributed to chromium ion diffusion in Cr_2O_3 (5). In the case of continuous oxidation of Hastelloy sheets, the activation energy is reported to be 60 kcal/mole for the early stage and 57 kcal/mole for the late stage (6). The low values

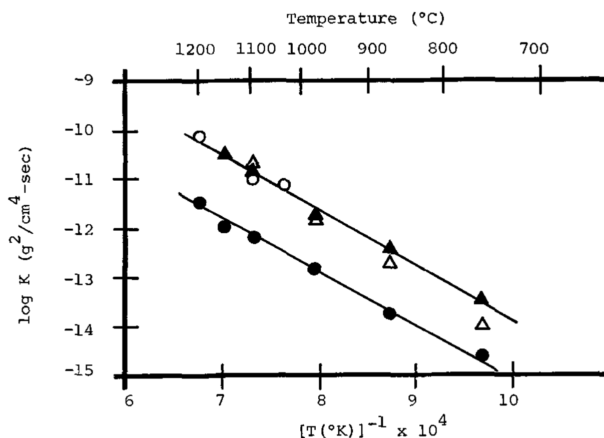

Fig. 3. Temperature dependence of parabolic rate constants for cyclic oxidation of Hastelloy X: Q = 51.6 ± 4.1 kcal/mole for wire specimens (▲) and Q = 49.9 ± 5.1 kcal/mole for sheet specimens (●). △ represents *K* values obtained from continuous oxidation of Hastelloy X wire (Ref. 5) and O from continuous oxidation of Hastelloy X sheet (Ref. 6).

determined in the present work indicate that a different mechanism is rate-controlling for the cyclic oxidation. According to Gulbransen and Andrew (11) a Ni-Cr alloy containing approximately 20% Cr exhibits two rate constants during continuous oxidation. They proposed that the early stage was due to the initial oxide NiO and the late stage due to Cr_2O_3. The activation energy for the early stage was 49,739 cal/mole, which is very near the values found in the present work. Also, an activation energy of 53.6 $\pm$ 3.8 kcal/mole was found for cyclic oxidation of TD-Ni (12). According to Iitaka *et al.* (13) the Fe-18% Cr-9% Ni alloy was found to form a very thin layer of NiO between the outer oxide layer [$(Fe, Cr)_2O_3$ plus spinel] and the alloy substrate during high-temperature oxidation. Thus, it appears that the NiO formation might be rate-controlling for the cyclic oxidation of Hastelloy X. However, this conclusion is rather tentative.

In summary, the cyclic oxidation of Hastelloy X can be described by the parabolic rate law, and the activation energy is 49.9 $\pm$ 5.1 kcal/mole for the sheet specimens and 51.6 $\pm$ 4.1 kcal/mole for the wire specimens. These values are approximately 10 kcal/mole lower than the activation energy found for continuous oxidation.

Electromotive Force Measurements on High-Temperature Sulfide Formation Cells

W. T. Thompson*[,1] and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario, Canada

ABSTRACT

Using formation cells with a sulfur vapor electrode, relative partial molar thermochemical properties are reported for the sulfide-rich region of the molten lead sulfide-lead chloride and silver sulfide-silver chloride systems. Negative deviations from Raoultian ideality observed in the former system and positive deviations in the latter are tentatively related to available molar conductance data.

Most base metal reduction practices involve some stage in which solid or liquid sulfides are reacted with oxygen. As a result metal production is attended by the evolution of large volumes of sulfur dioxide. Sulfur dioxide emission could be eliminated if it were possible to reduce the metal directly from the sulfide by a method which yields only the more easily handled elemental sulfur as a by-product.

It is known that base metal sulfides are soluble in chloride melts particularly those containing a cation common to the sulfide (1-4). Further, it has been found that such melts when dilute in sulfide (containing less than 0.1 mole fraction sulfide) are electrolytes (5, 6). As a result of such findings, one method of reducing base metal sulfide that has been proposed is fused salt electrolysis (7-9). In this process, the products of electrolysis are metal and sulfur gas.

In previous publications, the reversibility of a sulfur vapor electrode was demonstrated (10), and free energies of formation of silver and lead sulfide were determined (11). This paper reports measurements, using this electrode, of partial molar properties in the lead sulfide-lead chloride and silver sulfide-silver chloride systems. This study was intended to supplement other investigations of the physical chemistry of sulfide-chloride melts carried out in this laboratory (1-6) and in particular establish any relationships which may exist between melt structure, as inferred from the thermodynamics, and the electrical conductance behavior.

Experimental

Details of the cell

are shown in Fig. 1. The electrode compartments, as in previous work, were separated with an asbestos diaphragm. This feature, which restricts sulfur diffusion to the lead electrode, is most important if a reproducible stable emf is to be observed. The upper portion of the apparatus, showing the arrangement of the molten sulfur bath used to establish a sulfur pressure in an argon flow over the positive electrode, is identical to that shown in a previous publication (10). The molten lead used for one of the electrodes was cominco five nine grade etched with dilute nitric acid prior to melting. The lead sulfide was prepared by reacting stoichiometric quantities of the high purity lead with doubly distilled sulfur in vacuum sealed quartz cells as described previously (5, 11). The lead chloride was vacuum oven dried Fisher reagent grade. The graphite electrodes were spectroscopic grade. Since considerable glass blowing was involved in setting up each cell, the entire apparatus was evacuated for an hour or more while those portions of the apparatus enclosed by the furnace assembly were warmed to about 150°C. The salts were then fused and dried argon was slowly passed through the lead electrode compartment; at the same time, the sulfur argon mixture was admitted to the other compartment and circulated over the graphite rod thereby creating a sulfur electrode. When measurements on an electrolyte of one composition were complete, the cell was discarded and a new one constructed. Temperature measurements of the sulfur bath

and molten electrolyte were made with Chromel-Alumel thermocouples. The output of the thermocouples and the cell voltage were determined with a Leeds and Northrup K-3 potentiometer.

Results

The emf measurements, $\overline{E}$, are reported in Table I to the nearest mV. The potentials were measured on both increasing and decreasing temperature cycles and found to be reproducible over periods of up to three days. During this period, the sulfur electrode was operated at relatively low S_2 partial pressure, in the range 10^{-2} to 10^{-3} atm. The electrolyte compositions were calculated from the initial weighings.

To facilitate thermodynamic calculations on the electrolyte, the measured potentials were adjusted to the condition corresponding to S_2 gas at one atmosphere pressure.

Since the cell reaction may be written

$$Pb_{(liquid)} + \tfrac{1}{2}S_{2(gas)} \rightarrow PbS_{(solution)} \quad [1]$$

for which the Nernst expression is

$$\overline{E} - \frac{RT}{4F}\ln(P_{S_2}) = E^\circ - \frac{RT}{2F}\ln a_{PbS} \quad [2]$$

The adjusted potentials, E, are therefore given by

$$E = \overline{E} - \frac{RT}{4F}\ln(P_{S_2}) \quad [3]$$

In these equations, R is the gas constant, T is the electrolyte temperature, and F is the Faraday. P_{S_2} is the actual partial pressure of S_2 in the sulfur-argon mixture when the cell emf was determined. Since sulfur vapor in the temperature range of this investigation exists in a complex molecular state, this partial pressure is not directly available from the experimental measurements. The partial S_2 pressure may however be calculated from a knowledge of the liquid sulfur temperature and the electrolyte temperature since the equilibrium constants for sulfur vapor association

$$\nu S_2 \rightleftharpoons 2S_\nu \quad [4]$$

are known (12); these data covering the range $3 \leq \nu \leq 8$ include all the important sulfur gas molecules. The details of this rather involved calculation have been described elsewhere (10, 11). The S_2 pressures have been estimated to be accurate to about ±5% (11).

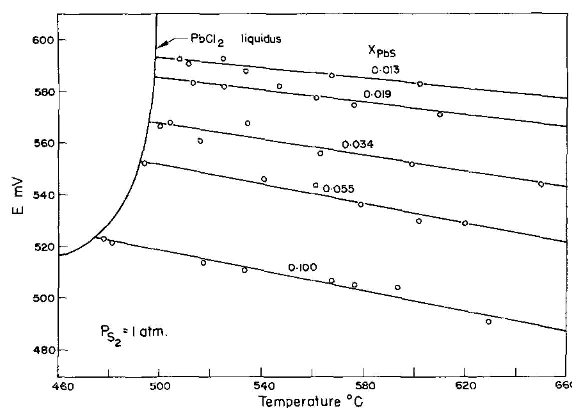

Fig. 2. EMF vs. temperature for lead sulfide formation cell

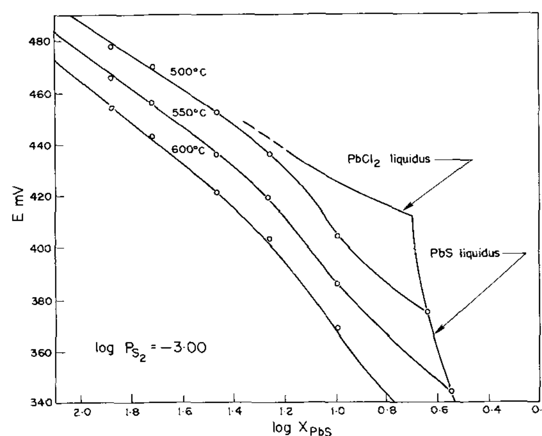

Fig. 3. Nernst plot for lead sulfide formation cell

The adjusted emf measurements are plotted against temperature for various sulfide concentrations in Fig. 2. The lead chloride liquidus that limits the lower temperature is taken from the work of Bell and Flengas (2). The upper experimental temperature limit was determined by the volatility of lead chloride. Electrolytes more concentrated than 0.1 mole fraction lead sulfide were not studied since the more concentrated melts are not truly electrolytes but conduct current to some extent electronically (6). This mode of conduction makes it difficult to interpret the cell voltages in a thermochemical manner. The equations of the least squares lines through the data points are given in Table II together with standard deviations. A Nernst plot is shown in Fig. 3. This was constructed by interpolation from Fig. 2 using the equations for the straight lines. A sulfur pressure adjustment to 10^{-3} atm S_2 was made in order to separate the isotherms. The limiting slopes of the plots correspond to 2 electrons per sulfur atom.

Measurements made with the sulfur vapor electrode on multicomponent sulfide saturated melts (11) gave the equation (mV − °K)

$$E^\circ = 867.4 - 0.4884T \quad [5]$$

for a cell reaction corresponding to the formation of pure solid lead sulfide from pure liquid lead and S_2 gas at one atmosphere pressure over the temperature range 876°-1075°K. The standard deviation for this equation

* At 600°C relative to pure solid lead sulfide.

was 4.5 mV. Equation [5] together with those in Table II, allow calculation of the partial molar enthalpy and entropy of mixing as well as the activity of the sulfides.

The partial molar enthalpy and entropy of mixing, taking pure solid sulfide as the standard state, $(\Delta\bar{H}_m)^S$ and $(\Delta\bar{S}_m)^S$ respectively, were calculated for each melt composition by applying the equations

$$(\Delta\bar{H}_m)^S = -2\mathbf{F}\frac{d((E - E^\circ)/T)}{d(1/T)} \quad [6]$$

$$(\Delta\bar{S}_m)^S = 2\mathbf{F}\frac{d(E - E^\circ)}{dT} \quad [7]$$

The activity of lead sulfide relative to pure solid at 600°C was calculated using the equation

$$a^S = \exp\left[\frac{(\Delta\bar{H}_m)^S}{RT} - \frac{(\Delta\bar{S}_m)^S}{R}\right] \quad [8]$$

All the calculated properties are listed in Table III.

For the purpose of making inferences about melt structure, it is usual to refer partial molar properties to the liquid state. Unfortunately, there is insufficient accurate thermal data on the heat of fusion and liquid heat capacity to make this change of state calculation reliable for lead sulfide particularly since its melting point is about 600°C higher than the temperature range examined experimentally for this system.

A least squares fit of the data in Table III resulted in the equations

$$(\Delta\bar{H}_m)_{PbS}{}^S = 13.761 - 5.654X^2_{PbCl_2} \quad [9]$$

$$(\Delta\bar{S}_m)_{PbS}{}^S = 12.354 - 3.952X^2_{PbCl_2} - R\ln X_{PbS} \quad [10]$$

The standard deviations for these fits were 174 cal/g mole and 0.184 gibbs/g mole respectively. The constants 13.761 and 12.354 appear in these expressions because the standard state for lead sulfide is pure solid. The constants are in fact related to the enthalpy and entropy of fusion at 600°C, but are about 35% higher than one might expect based upon a reported value for the enthalpy of fusion of 8700 ± 800 cal/g mole at the melting point of 1113°C (3, 13). Physical significance however, can only be attached to these constants if the other terms in Eq. [9] and [10] are absolutely correct. It is probably better to view the equations as empirical expressions, valid for the range $0 \leq X_{PbS} \leq 0.1$, that have a form consistent with thermodynamic requirements. In this connection, the first power term in X_{PbCl_2} does not appear in the equations in order that Raoult's law will apply as a limiting condition to the lead chloride solvent.

The partial molar properties of lead chloride were calculated at 600°C by an analytical integration of the Gibbs-Duhem equation. The expressions taking pure liquid as the standard state are

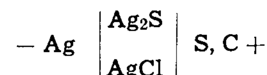
$$(\Delta\bar{H}_m)^L{}_{PbCl_2} = -5.654X^2{}_{PbS} \quad [11]$$

$$(\Delta\bar{S}_m)^L{}_{PbCl_2} = -3.952X^2{}_{PbS} - R\ln X_{PbCl_2} \quad [12]$$

The partial molar properties are depicted in Fig. 4 along with the data points listed in Table III.

Calculations for the Silver Chloride-Silver Sulfide System

In a previous paper (10), emf measurements of the cell



were reported for sulfide concentrations less than 0.12 mole fraction. Subsequent work by a modified technique (11) yielded the standard cell potential for the formation of silver sulfide. As for the lead sulfide-lead chloride system, these data make it possible to determine partial molar property data for the sulfide-rich melts. For comparison purposes, the results of these calculations are presented in this section. A plot of measured emf data appears in Fig. 5. This plot differs slightly from the one reported originally (10) in that the

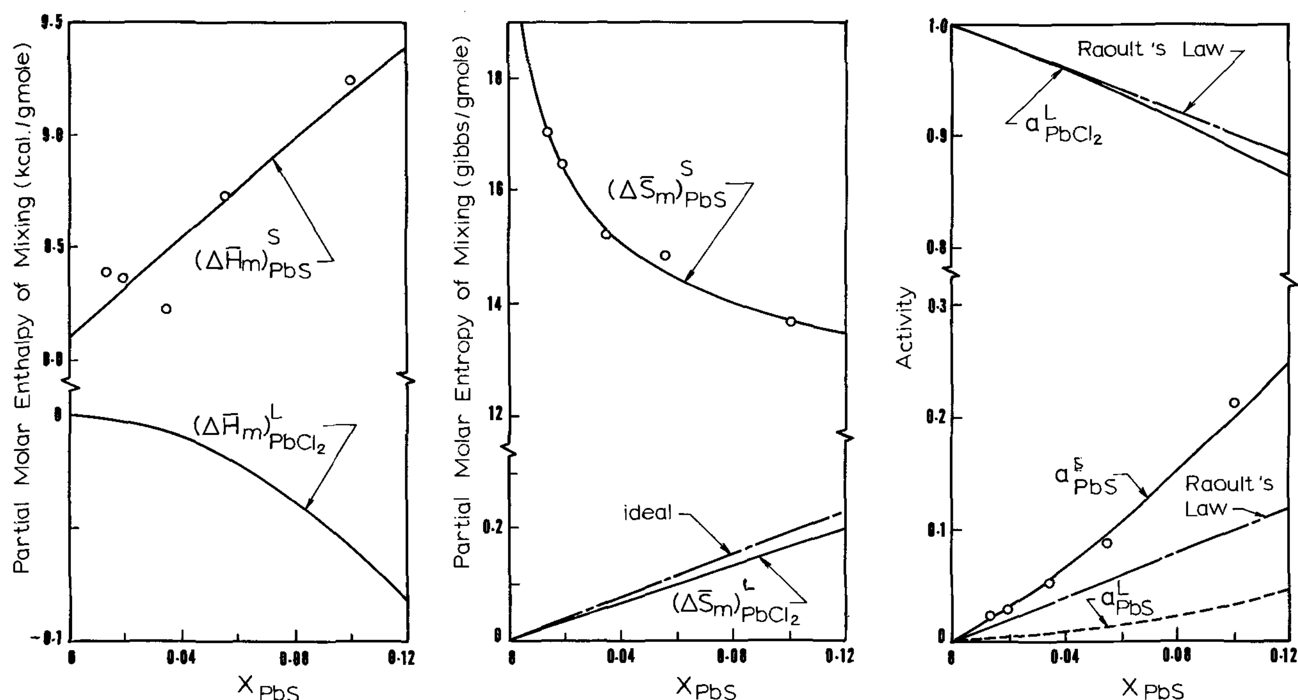


Fig. 4. Partial molar properties for sulfide-rich melts of lead sulfide and lead chloride

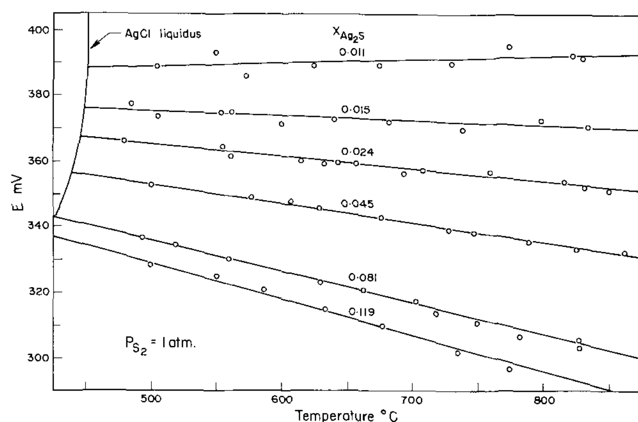

Fig. 5. EMF vs. temperature for silver sulfide formation cell

+Ag/C-thermoelectric voltage (11) was added to the measured cell potentials. In computing the magnitude of the thermoelectric voltage, the cold junction temperature was taken to be equal to that for the liquid sulfur since the silver connections from the potentiometer were located directly below the sulfur bulb. This voltage correction amounts to about 5 mV and consequently has a significant effect on the calculation of thermodynamic properties of the electrolyte. The equations of the least square lines through the data points in Fig. 5 are given in Table IV together with standard deviations.

For the cell which realized the formation of solid silver sulfide from pure solid silver and S_2 gas at one atmosphere pressure (11), the equation (mV − °K) was

$$E^\circ = 455.3 - 0.1919T \quad [13]$$

over the temperature range 773°-1071°K. The standard deviation was 3.2 mV. Partial molar property data for silver sulfide relative to solid sulfide were calculated using Eq. [6] and [7]. In the case of silver sulfide however, it is possible to refer the properties to the pure liquid sulfide since enthalpy of fusion and heat capacity data for solid and liquid sulfide are available from calorimetric work by the present authors (14). Defining the difference in heat capacity between solid and liquid silver sulfide as

$$(C_p)^L - (C_p)^S = \Delta\alpha \quad [14]$$

the partial molar enthalpy and entropy of mixing referred to pure liquid silver sulfide, $(\Delta\overline{H}_m)^L$ and $(\Delta\overline{S}_m)^S$ respectively, were calculated at 600°C for each melt composition studied by applying the equations

$$(\Delta\overline{H}_m)^L = (\Delta\overline{H}_m)^S - \Delta\alpha\,(T - T_f) - \Delta H_f \quad [15]$$

$$(\Delta\overline{S}_m)^L = (\Delta\overline{S}_m)^S - (\Delta H_f/T_f) - \Delta\alpha \ln (T/T_f) \quad [16]$$

In these equations ΔH_f is the enthalpy of fusion of silver sulfide, 1880 cal/g mole (14) at the fusion temperature, T_f, of 830°C (1). The calculated properties are listed in Table V.

In order to determine partial molar properties for silver chloride at 600°C, $(\Delta\overline{H}_m)^L$ and $(\Delta\overline{S}_m)^L$ were first fit by the method of least squares to equations in mole fraction. The following expressions were obtained

$$(\Delta\overline{H}_m)^L{}_{Ag_2S} = -14.123X^2{}_{AgCl} + 16.201X^3{}_{AgCl} \quad [17]$$

$$(\Delta\overline{S}_m)^L{}_{Ag_2S} = -14.798X^2{}_{AgCl} + 13.785X^3{}_{AgCl} - R \ln X_{Ag_2S} \quad [18]$$

The standard deviations for these equations are 164 cal/g mole and 0.255 cal/g mole respectively. By integrating the Gibbs-Duhem equation, expressions for the partial molar enthalpy and entropy of mixing for silver chloride with the pure liquid as standard state were obtained.

Table IV. Temperature-emf relationships in silver sulfide formation cells

* At 600°C relative to pure liquid silver sulfide.

$$(\Delta\overline{H}_m)^L{}_{AgCl} = -6.023 + 28.247X_{AgCl} - 38.425X^2{}_{AgCl} + 16.201X^3{}_{AgCl} \quad [19]$$

$$(\Delta\overline{S}_m)^L{}_{AgCl} = -7.905 + 29.596X_{AgCl} - 35.476X^2{}_{AgCl} + 13.785X^3{}_{AgCl} - R \ln X_{AgCl} \quad [20]$$

Equations [17]-[20] apply when $0 \leq X_{Ag_2S} \leq 0.12$.

The partial molar properties given by these equations together with the calculated activities are depicted in Fig. 6. Included in this presentation are the data points listed in Table V.

Discussion

A rough approximation of the lead sulfide activity isotherm relative to pure liquid is shown in Fig. 4. A temperature independent enthalpy of fusion of 8700 cal/g mole (13) was assumed for this calculation in the absence of more complete data referred to previously. Moderately negative departure from Raoultian ideality is indicated therefore for both lead sulfide and lead chloride, a situation generally taken to be indicative of a tendency toward weak compound formation in the melt. This inference is supported by the negative partial molar enthalpy of mixing of lead chloride and is consistent with an identified solid compound occurring at lower temperatures in this system (15). Furthermore, the partial molar entropy of mixing of lead chloride exhibits a negative departure from ideal behavior.

The thermodynamic properties in Fig. 6 indicate a general tendency toward immiscibility for silver sulfide-silver chloride melts, at least for those dilute in sulfide. This is evidenced by the positively deviating activity isotherms and positive enthalpy of mixing. It appears in Fig. 6 that the partial molar enthalpy of mixing of silver sulfide may change sign. This was found to be the case in calorimetric data reported previously (14). These results, represented in Fig. 6, indicate that cross-over takes place at 0.23 mole fraction silver sulfide compared to an estimated 0.13 resulting from the emf measurements. This change in sign of the enthalpy of mixing may be indicative of unusual structural changes occurring in melts of this system and may be consistent with the partial molar entropy of mixing of silver chloride being unexpectedly greater than the ideal value.

Figure 7 shows some of the liquidus data reported by Bell and Flengas (1). Since solid solubility is negligible, limiting liquidus slopes were obtained by application of the equation

$$\Delta T = \frac{\nu X R T_f 2}{\Delta H_f} \quad [21]$$

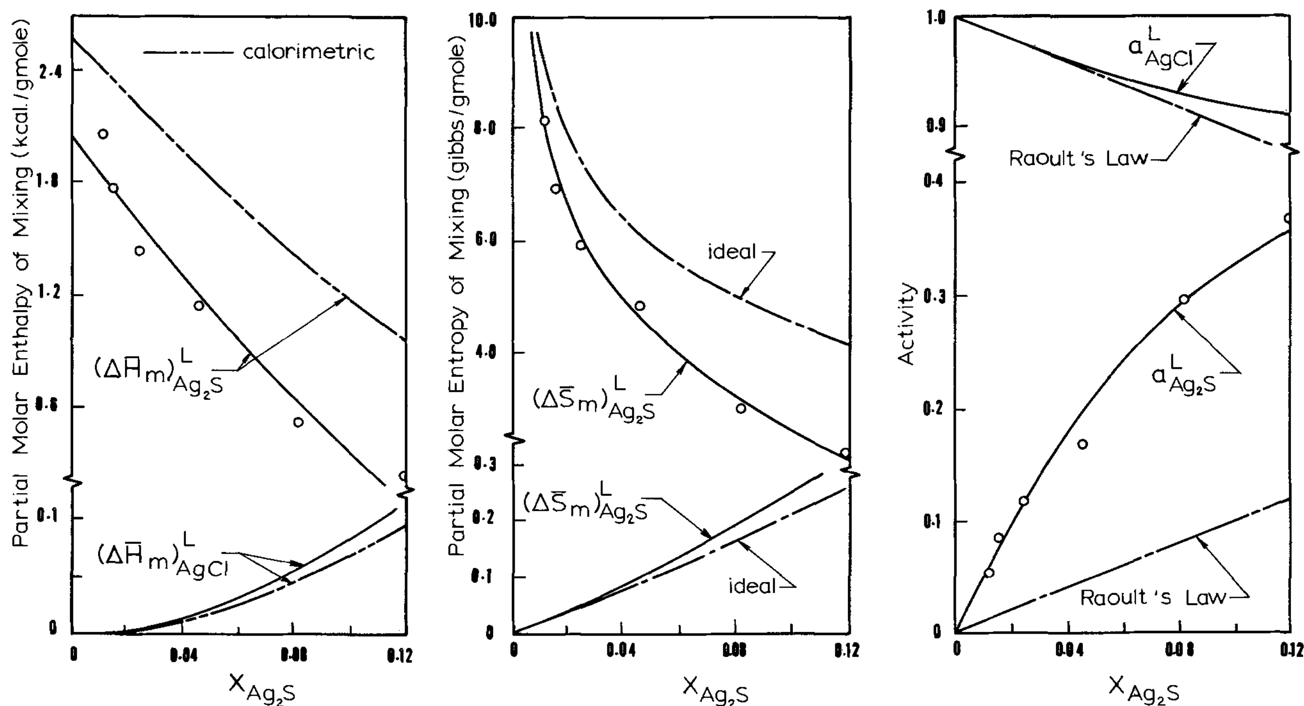

Fig. 6. Partial molar properties for sulfide-rich melts of silver sulfide and silver chloride.

In this equation ΔT is the freezing point depression, X is the mole fraction of solute, and ν is the number of moles of foreign particles contributed to the solution per mole of solute; other symbols are as previously defined. The sparse amount of data suggests that silver chloride contributes two moles of foreign particles per mole to silver sulfide-rich melts but that silver sulfide contributes only one to silver chloride-rich melts. A possible explanation requires that silver sulfide exist as a molecule-like entity in the melt in which silver atoms are linked to a sulfur. Similar references to apparently molecule-like entities have appeared for other high temperature solutions, notably molten metal-oxygen systems (16). At the present time, there is insufficient cryoscopic and heat of fusion data to show that lead chloride dissolves to yield three foreign particles in lead sulfide. On the lead chloride-rich side of the system there appears to be significant solid solubility.

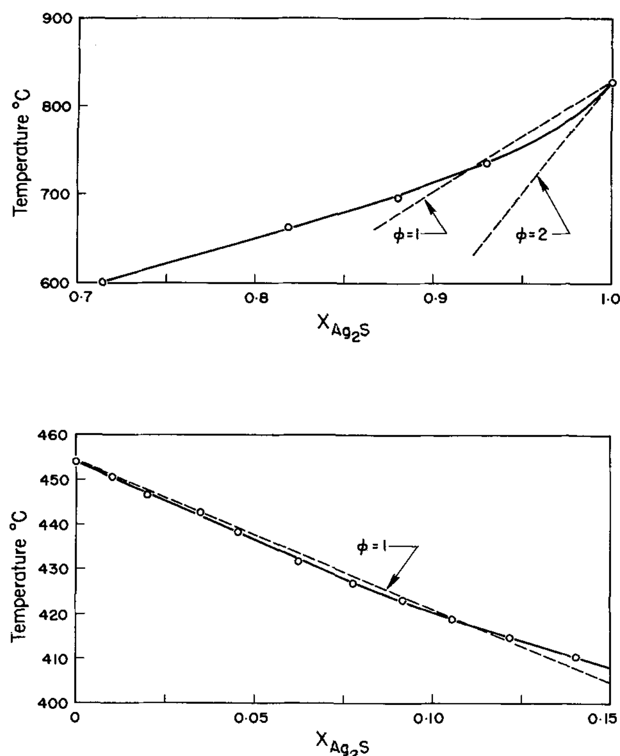

Fig. 7. The silver sulfide and silver chloride liquid

Molecule-like sulfide entities offer a convenient qualitative way of accounting for the observed conductance behavior. Measurements of Bell and Flengas (5, 6) have shown that for both melt systems molar conductance is ionic on the chloride side, decreases in magnitude as the sulfide is dissolved and then rapidly increases while changing in character to electronic. In the silver sulfide-silver chloride system, the increase occurs at about 0.15 mole fraction sulfide while in the lead sulfide-lead chloride systems it occurs near 0.25. Electronic conduction requires the existence of a continuous sulfide network in the melt similar to what must exist in the pure molten sulfide. Random mixing considerations indicate that when about one fifth or greater mole fraction sulfide exists in the melt, the probability of adjacent sulfide entities forming continuous chains is unity. At signficantly lower sulfide concentrations, it is improbable that such continuous chains exist when random mixing is assumed. The implication is that in chloride-rich melts molar conductance is totally ionic but decreases as the population of noncharge-carrying sulfide particles increase. In sulfide-rich melts molar conductance is large and virtually totally electronic as the sulfide network develops with increasing sulfide concentration to more closely resemble that for the pure molten sulfide.

The difference in the extent of the ionic range of conductance is consistent with the thermodynamic properties. In the silver sulfide-silver chloride system, the tendency exhibited toward immiscibility suggests that the proposed sulfide particles prefer being adjacent to others, in this way making it possible to establish continuity at concentrations lower than expected on a random mixing basis. The opposite situation is indicated for the negatively deviating lead sulfide-lead chloride system. Accordingly, electronic conduction is exhibited at lower sulfide concentrations in the silver system compared to the lead system.

The proposal of metal sulfide existing in these melts predominantly as molecule-like entities is not inconsistent with it being possible to set up a reversible

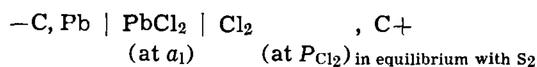
electrochemical cell with a sulfur electrode. Even in the complete absence of sulfide ions, the sulfur electrode could reach the expected sulfide-sulfur potential via the chloride ion. For example, although the standard free energy change, ΔG^o, for the reaction

$$\tfrac{1}{2}S_{2(gas,1\ atm)} + PbCl_{2(liquid)} \rightarrow PbS_{(solid)} + Cl_{2(gas,1\ atm)} \quad [22]$$

is about +35 kcal/g mole PbS, a very small chlorine partial pressure, P_{Cl_2}, exists which is closely approximated by

$$P_{Cl_2} = P_{S_2}{}^{1/2} \cdot \frac{a_1}{a_2} \cdot \exp \frac{-\Delta G^o}{RT} \quad [23]$$

In this equation, P_{S_2} is the partial S_2 pressure fixed experimentally, and a_1 and a_2 are the activities of lead chloride and lead sulfide respectively in a melt of given composition. Since the chlorine pressure is quite small, the melt composition changes insignificantly with time. It follows, however, since there is some chlorine at the positive electrode, the formation cell may be schematically represented by



$$-\text{C, Pb} \mid \underset{(\text{at } a_1)}{PbCl_2} \mid \underset{(\text{at } P_{Cl_2})\ \text{in equilibrium with } S_2}{Cl_2}, \text{C}+$$

instead of

$$-\text{C, Pb} \mid \underset{(\text{at } a_2)}{PbS} \mid \underset{(\text{at } P_{S_2})}{S_2}, \text{C}+$$

since the free energy changes for the primary reactions, respectively,

$$Pb_{(liquid)} + Cl_{2(gas,P_{Cl_2})} \rightarrow PbCl_{2(solution,a1)} \quad [24]$$

and

$$Pb_{(liquid)} + \tfrac{1}{2}S_{2(gas,P_{S_2})} \rightarrow PbS_{(solution,a2)} \quad [25]$$

are equal. The potential at the positive electrode may therefore be due to $S^{=}/S_2$ or Cl^-/Cl_2 or both with no mixed potential resulting. These arguments may be readily extended to include the trace concentrations of S_2Cl_2, known to exist at the temperatures and gas pressures under consideration. In this connection, it is noteworthy that chlorine, sulfur, and sulfane reactions have been reported at liquid sulfur electrodes by Delarue (17) and Bodewig and Plambeck (18) as a result of polarographic studies.

The foregoing concept of sulfide-chloride melts would affect the igneous electrolysis of base metal sulfide. During the passage of current, electrochemically oxidized chloride ion would have to react chemically to reestablish as equilibrium for reaction [22] as it applies to sulfide dissolved in the anolyte. This might result in a rate-limiting condition related to sulfide-chlorine diffusion and reaction if it were desired to generate predominantly sulfur at the anode during electrolysis.

Conclusions

Electromotive force measurements on sulfide formation cells in the vicinity of 600°C employing a sulfur vapor electrode were reported. These showed that melts containing up to 0.1 mole fraction lead sulfide in molten lead chloride exhibit negative deviation from Raoultian ideality. Similar measurements indicated positive deviations for the sulfide-rich region of silver sulfide-silver chloride melts. These data in conjunction with published molar conductance data suggest that the sulfide may dissolve to yield little or no free sulfide ion. Instead, molecule-like sulfide entities were postulated to exist. The consequences of this proposal were briefly explored.

A Theory for the Propagation of Stress Corrosion Cracks in Metals

David A. Vermilyea*

Corporate Research and Development, General Electric Company, Schenectady, New York 12301

ABSTRACT

A quantitative theory for the rate of propagation of stress corrosion cracks in metals is presented and discussed. The theory is based on the film rupture mechanism and is valid when phenomena at the crack tip control the propagation rate. The important parameters in the theory are the strain required to rupture the passive film, the amount of corrosion before repassivation, and the creep rate of material at the crack tip. Plausibility of the theory is demonstrated for stainless steel and for a magnesium alloy.

The objective of this paper is to present and discuss a model which makes it possible to predict the rates of propagation of stress corrosion cracks in metals in terms of experimentally accessible characteristics of the system. The theory is based upon the film rupture mechanism (1, 2) and is applicable to situations in which phenomena at the crack tip control the propagation rate. The theory accepts the generally held view that during stress corrosion cracking metal strain and corrosion are mutually stimulative. Strain accelerates corrosion by periodically causing film rupture, while, as suggested by Hart (3), corrosion accelerates strain by removing the most severely strain hardened material in the immediate vicinity of the crack tip. From the point of view of the theory, adequate information is not presently available about all of the system characteristics, especially about the details of stress and strain at the crack tip, in order to permit accurate rate predictions. Nevertheless the theory provides a conceptual framework which is amenable to further development and identifies the relevant material characteristics so that their influence on the process can be discussed from at least a semiquantitative point of view.

Theory

Model.—The model is outlined in Table I.

The metal is assumed to be homogeneous, isotropic, and uniform, and the detailed atom motions involved in creep strain, including dislocation motion, are ignored. The rate of crack propagation, $\dot{\ell}$, according to this model is

$$\dot{\ell} = \frac{L}{t_c} \quad [1]$$

Corrosion is assumed to proceed at a negligible rate when the metal is passive.

Figure 1 portrays schematically the strain rate and strain during crack propagation. Following film rupture an abrupt increase in strain rate occurs because the restraining influence of the surface film is removed. During corrosion prior to repassivation a further strain rate increase occurs as the most highly strained material near the crack tip is removed. After repassivation the strain rate decreases because of the presence of the surface film and because of strain hardening.

* Electrochemical Society Active Member.

Key words: film rupture, creep.

Table I. Model of stress corrosion cracking mechanism

Event	Time
1. Passive film ruptures	$t = t_0$
2. Metal corrodes to a depth L	$t = t_L$
3. Repassivation occurs	$t = t_L$
4. Creep strain continues	
5. Passive film ruptures at a critical strain ϵ_c	$t = t_c$

In order to predict crack propagation rates it is necessary to determine the values of L, ϵ_c, t_L, and t_c. Values for L, ϵ_c, and t_L can be obtained from transient experiments in which specimens covered with films formed in a solution chosen to simulate the crack-tip solution are strained while maintained at the crack-tip potential. If the specimen is strained slowly ϵ_c can be determined from the specimen strain at which a marked current change occurs. Values for L and t_L can be obtained from the current transient following a sudden extension of the specimen.

The film rupture time, given by $t_c - t_L$, is found from the creep strain *vs.* time behavior of the metal and the value of the critical strain. The creep behavior must be known for the material present a distance L ahead of the crack tip, that is, for the material at the

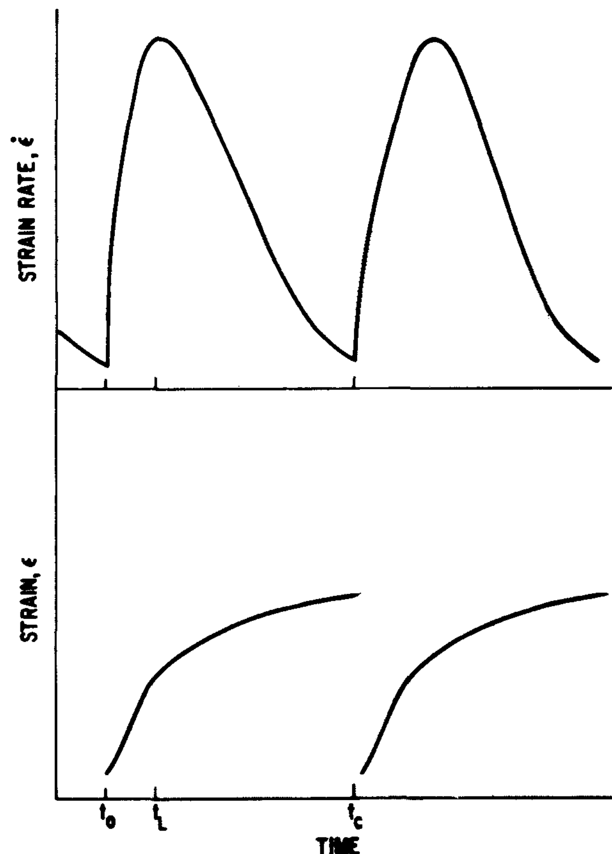

Fig. 1. Variations of crack tip strain and strain rate during stress corrosion cracking. Film rupture occurs at $t = 0$; corrosion occurs to t_L; repassivation occurs at t_L; creep continues to t_c at which film rupture occurs again and the cycle repeats.

position of the crack tip after film rupture and repassivation.

The most difficult quantity to determine is undoubtedly the film rupture time, because creep behavior, especially in response to sudden large stress transients at low temperatures, is poorly understood. In addition, the distribution of stress and strain near the crack tip in an elastic-plastic medium is not amenable to exact treatment, so that approximations must be made in determining crack tip conditions. The characteristics of stress corrosion cracks suggest that the plastic strain near crack tips is less than 0.2, for no gross deformation is visible from the microstructure, but more than 0.05, for the cracks are generally sharp and represent large stress concentrators. A reasonable assumption might be that the plastic strain near the crack tip is 15%. Transient creep measurements using material cold-worked 15% should then provide data from which the film rupture time can be estimated.

Applications of the Theory

The literature does not presently supply enough data for any system to make an adequate test of the theory. The only useful data are for the creep strain *vs.* time behavior of stainless steel in boiling magnesium chloride, and for a magnesium alloy at ambient temperature. Although the available data were not originally obtained with the objective of duplicating crack-tip conditions, they do at least give an order-of-magnitude idea about the rates involved. Values of L, ϵ_c, and t_L are also not available. The best that can be done is to demonstrate plausibility by assuming reasonable values for ϵ_c; assuming that t_L is small compared to t_c; and using the available creep data and stress corrosion crack propagation rates to calculate values for L.

The fracture strain, ϵ_c, for aluminum oxide has been reported by Cochrane and Block (4) to be $3 \cdot 10^{-4}$; by Bradhurst and Leach (5) to be $3 \cdot 10^{-3}$; by Brummer and Cocks (6) to be 10^{-3} to $5 \cdot 10^{-3}$; and by Grosskreutz (7) to be $1.5 \cdot 10^{-3}$ to $3 \cdot 10^{-3}$. These average to about $2 \cdot 10^{-3}$, and accordingly a value of $2 \cdot 10^{-3}$ for ϵ_c will be used, the assumption being made that the fracture strain would be about the same for most oxides, at least as to order of magnitude.

Brauns and Ternes (8) reported that the creep strain rate, $\dot{\epsilon}$, for an AISI 304 stainless steel at the temperature of boiling $MgCl_2$ obeyed the relationship

$$\dot{\epsilon} = kt^{-m} \quad [2]$$

in which $m \approx 1.1$ to 1.3 and k is a constant. From their data for 20 kg/mm² (28,300 psi) $k = 1.45 \cdot 10^{-3}$. From Eq. [2] by integration, taking $m = 1.2$

$$\dot{\epsilon} = \text{const} - 5kt^{-0.2} \quad [3]$$

Assuming repassivation to be complete at 1 sec, Eq. [3] gives 5 sec for the strain to reach $2 \cdot 10^{-3}$. According to Brauns and Ternes the time to crack a 0.35 cm test specimen at 20 kg/mm² and at a potential of −80 mV is 2 hr, so that the crack propagation rate is about $5 \cdot 10^{-5}$ cm/sec. From Eq. [1] $L \simeq 3 \cdot 10^{-4}$ cm. At $E = -110$ mV the failure time increased to about 200 hr, and the corresponding value of L would be $3 \cdot 10^{-6}$ cm. Brauns and Ternes also give values for the creep strain rate at 10 kg/mm² and 30 kg/mm², and also for the cracking time at those stresses. At 30 kg/mm² the creep strain rate is about a factor of 2 greater than at 20 kg/mm², and the failure time at −80 mV is about half that at 20 kg/mm². At 10 kg/mm² the creep rate is lower by a factor of 3 and the failure time longer by a factor of 5. All these data are consistent with a constant value of L at a given corrosion potential, and the values deduced for L seem reasonable.

Logan (9) gave data for the creep strain rate of magnesium alloy AZ31. An analysis similar to that above gives a value of L of 10^{-2} cm, which at first glance seems rather large. On the other hand the specimens cracked in only a few minutes, and the cracks appeared from the 10× photographs to be rather wide. The value of L of 10^{-2} cm is at least conceivable. It is also possible that the value assumed for ϵ_c is too high, or that the repassivation times are very short so that creep strain below one second is important.

Discussion

The parameters of the model.—The critical strain, ϵ_c, will depend on the nature of the film which forms and on its homogeneity, and hence in turn primarily on the alloy but also possibly on the solution composition. Film rupture probably nucleates at flaws, and hence the nature and distribution of precipitate particles in the metal will be important. If the reaction product exhibits considerable plasticity, stress corrosion cracking may be impossible.

The value of L will be influenced by the metal, the solution (a possible role for inhibitors), and especially the potential. If the potential is low enough (cathodic protection) the value of L will be too small for crack propagation. A minimum value for L can be computed as follows. It is necessary for corrosion to result in a change $\Delta\epsilon$ in the crack tip strain of at least ϵ_c. $\Delta\epsilon$ is given by

$$\Delta\epsilon = \epsilon_o - \epsilon_{(\rho+L)} \quad [4]$$

where ϵ_o is the crack tip strain and $\epsilon_{(\rho+L)}$ is the strain at the crack tip after corrosion to the depth L. Tetelman and McEvily (10) state that the plastic strain varies approximately as x^{-1}, so that

$$\epsilon_x = \frac{\rho\epsilon_o}{x} \quad [5]$$

in which ϵ_x is the strain at distance x and ρ is the radius of curvature at the crack tip. Using Eq. [5] to find $\epsilon_{(\rho+L)}$ gives

$$\Delta\epsilon = \epsilon_o \left(1 - \frac{\rho}{\rho + L}\right) \quad [6]$$

Setting $\Delta\epsilon \geqq \epsilon_c$ and solving for L gives

$$L \geqq \frac{\epsilon_c}{\epsilon_o} (\rho + L) \quad [7]$$

and a minimum value for L is given by

$$L_{\min} = \frac{\rho\epsilon_c}{\epsilon_o - \epsilon_c} \quad [8]$$

Taking $\epsilon_c = 10^{-3}$, $\epsilon_o = 10^{-1}$, $\rho = 10^{-4}$ gives $L_{\min} = 10^{-6}$ cm, while if $\epsilon_c = 10^{-3}$, $\epsilon_o = 10^{-2}$, $\rho = 10^{-3}$ the value of $L_{\min}$ is about 10^{-4} cm. Note that L may be associated with the striations often observed on stress corrosion fracture surfaces, and that the value obtained for L can be confirmed from a measurement of the spacing of such striations. A casual perusal of the literature shows striation spacings of about 0.03 to 1 μm.

The repassivation time, t_L, will be influenced by the metal, the potential, and especially by the solution composition. Aggressive species like chlorides may cause a large increase of t_L.

Following film rupture the creep rate which determines the time to cause cracking, t_c, is influenced by the stress, the metal composition, and by L. The effect of stress is particularly important and is discussed below. Metal composition determines the detailed transient creep response to a stress change. An example of an important metal composition effect is represented by the possibility of strain aging. Strain aging should play a very important role in stress corrosion cracking for two reasons. In a strain aging alloy a large value of $\Delta\sigma$ may be required to start plastic deformation, and the ensuing transient creep may be sharply curtailed so that stress corrosion cracking might not occur. The role of L in determining the creep rate arises from the fact that a large L results in larger increments of

stress and strain following crack advance, so that a large L should result in faster creep.

Roles of temperature and stress.—The temperature will influence the creep rate and the corrosion process. An increase in temperature would always be expected to increase the creep rate, and usually would increase the value of L. In special cases an increase in temperature may decrease L and decrease the rate of stress corrosion cracking. For instance, a higher temperature may increase the rate of repassivation more than it increases the rate of corrosion prior to repassivation.

The stress dependence of the creep rate can be expressed by the equation

$$\dot{\epsilon} = \text{const} \cdot \sigma^a \quad [9]$$

where a is a constant (the strain rate exponent) which, for low homologous temperatures, has values of about 5-10. A smaller dependence of the creep rate on applied stress may be expected in stress corrosion cracking, however, since an increase in applied stress will produce a proportionately smaller increase in the stress at the crack tip where plastic strain has occurred. A high-power dependence of crack propagation rate on stress can be expected when stress corrosion cracking occurs with crack tip stresses which are just above the yield stress, *i.e.*, at low applied stresses, and when the strain rate exponent is high. On the other hand there may be a value of strain rate exponent above which stress corrosion cracking does not occur at all. If the strain rate exponent is very large then the film rupture induced application of a stress increment to material just ahead of the crack tip will result in a very large creep rate. In consequence nearly all the deformation following film rupture may ensue before repassivation occurs, with the result that the total remaining creep strain is insufficient to rupture the film again. In short, not only the magnitude of the strain transient but also its detailed time-dependence determine whether the crack can progress. It should especially be noted that if the total strain transient following repassivation is less than ϵ_c stress corrosion cracking by this mechanism is impossible.

The influence of cold work, strain hardening, and grain boundaries.—Cold work should have an influence on the rate of stress corrosion cracking through its influence on the creep rate and because some grains will be left in residual tension. Small amounts of cold work may increase the dislocation density and creep rate, while large amounts of cold work may produce dislocation structures in which few free dislocations are available and in which transient creep may be very small.

The strain hardening exponent will be important in determining the distribution of stress and strain near the crack tip. If the material strain hardens relatively little, there will be a gradient of strain but little gradient of stress near the crack tip. When corrosion allows the tip to advance the same stress will therefore act on a material which is plastically strained a smaller amount and creep will occur. For materials which strain harden markedly there will be gradients of both stress and strain near the crack tip, so that after crack advance not only will the material at the new crack tip be plastically strained less than it was before crack advance but also the stress acting on that material will be greater than before the advance of the crack. Accurate predictions require more detailed knowledge of these gradients, but it may be that materials which strain harden markedly are more susceptible to stress corrosion cracking because crack advance results in faster creep than in those materials which do not strain harden much.

Grain boundaries could influence stress corrosion in several ways. First, strain is likely to be greater near the grain boundary, which may also be the site of numerous dislocation pile-ups. Second, the composition at the grain boundary may differ from the bulk composition. Third, the grain boundary may contain precipitate particles which change ϵ_c. There are therefore several reasons to expect that stress corrosion cracking should be predominantly intergranular. On the other hand, for several reasons slip at low stresses may often be easier within the bulk of the grains than near the grain boundaries. Then providing L is large enough to give an adequate crack advance per film rupture event so that the new creep rate can be large the material may be susceptible to transgranular cracking.

Silicon Nitride Coatings on Copper

Sylvain C. Audisio and Henry Leidheiser, Jr.*

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

Silicon nitride was deposited on copper substrates at room temperature by a reactive sputtering technique. The coatings, in the thickness range 500-1500Å, were amorphous, transparent, and had glass-like smoothness. They were tightly adherent to the substrate. Infrared analysis indicated the coatings were pure silicon nitride when precautions were taken to eliminate oxygen and water from the system. The coatings exhibited dielectric constants of 8-11 with a dissipation factor less than 10^{-2} at 1000 cycles/sec. The ductility approached 1% as measured on a copper substrate. The coatings reduced the charge passing across the metal/electrolyte interface when the coated samples were anodically treated in sodium hydroxide, sulfuric acid, and phosphoric acid. The coatings provided good resistance to attack of the copper surface in ammonium hydroxide and sodium hypochlorite; provided moderate protection in concentrated acids, mediocre protection in sodium thiosulfate and sodium sulfide solutions, and very little protection in concentrated nitric acid.

Silicon nitride has been known for a long time for its chemical inertness, high temperature strength, high electrical resistivity, good thermal shock resistance, and extreme hardness. It has very attractive chemical and physical properties which have encouraged its use as a coating material for microelectronic devices. Several methods (1-14) of preparing silicon nitride have been reported in the literature. The three major methods for depositing silicon nitride on high melting substrates are: (*i*) chemical vapor deposition, (*ii*) reactive sputtering, and (*iii*) rf glow discharge. The chemical vapor deposition (1-7) of silicon nitride is carried out by reacting a silicon compound such as SiH_4, $SiBr_4$ or $SiCl_4$ with nitrogen or ammonia at temperatures above 800°C. Reactive sputtering (8-11) is a technique which involves the sputtering of silicon in a nitrogen plasma. In the rf glow discharge method, the silicon nitride is deposited by reacting ammonia and SiH_4 in a radio frequency glow discharge (12-13). Several other techniques have also been used to form silicon nitride coatings, but these methods have shortcomings which do not make them suitable candidates for use with copper substrates (14).

The first method (CVD) is not attractive for use with copper alloys because the high temperature required leads to changes in the metallurgical structure and consequent changes in physical properties. Both reactive sputtering and rf glow discharge could be used to deposit silicon nitride films on copper, but reactive sputtering was chosen over radiofrequency glow discharge because of its simplicity, the ease in changing experimental variables, and because preliminary experiments indicated high quality coatings were obtained. The three important steps which govern the formation of silicon nitride coatings by reactive sputtering are: (*i*) sputtering of silicon atoms from the cathode, (*ii*) activation of the sputtered silicon atoms and interaction with nitrogen species, and (*iii*) condensation of the silicon-nitrogen compound on the anode and on the substrate (copper).

In order to attain a high rate of deposition of silicon nitride, it is important to maximize the number of silicon atoms permanently sputtered from the cathode. The number of atoms permanently sputtered from the surface is the difference between those sputtered and those which recondense on the silicon as a consequence of collision with gaseous species. Thus the gas pressure must be sufficiently high to maintain the discharge and yet low enough to reduce sufficiently the number of collisions in the gas phase. The voltage between the cathode and anode must be high enough to maintain the glow discharge yet low enough to avoid sparking. The cathode-anode distance must be optimized to maximize the rate of deposition of silicon nitride and yet avoid sparking.

Experimental Procedure

The apparatus used in this study is shown schematically in Fig. 1. After achieving a vacuum of 10^{-6} Torr, ultrapure nitrogen is flowed through the system at a pressure of 0.2-0.3 Torr. The nitrogen gas was supplied through a trap cooled by liquid nitrogen. A d-c glow discharge is maintained between a water-cooled silicon cathode and a copper anode arranged at 90° to the cathode by application of a potential of 1500-2000V. The current passed between the anode and the cathode is of the order of 3 mA/cm² under the conditions used. The copper substrate, on which the silicon nitride coatings is desired, is placed in the gas stream, in a parallel position with the silicon cathode.

Both electrodes were protected on their periphery by quartz sleeves. If this precaution was not observed, sparking occurred at the edges with rapid deterioration of the electrodes and consequent inability to maintain a good discharge without sparking. In order to obtain high quality coatings it was essential to avoid sparking

Key words: corrosion, protection, refractories, sputtering, coating.

when the voltage was first applied by gradually increasing the potential until the glow discharge was observed. The cathode-substrate spacing finally adopted was 2.5 cm.

The copper substrate in the form of a square sheet, 1.5 × 1.5 × 0.1 cm, was surfaced before each deposition either by electrolytic polishing in phosphoric acid or by metallographic polishing and washing in deionized water. No difference was observed between these two types of surfacing procedures.

All samples on which property measurements were made were prepared under the following experimental conditions: nitrogen gas pressure 0.2-0.3 Torr; cathode-substrate spacing, 2.5 cm; potential between cathode and anode 1500-2000V; current density, 3 mA/cm^2.

Experimental Results

Rate of coating growth.—The thickness of the coating was determined with an ellipsometer. A computer program was developed to calculate film thickness from readings obtained from the ellipsometer.

Typical growth rates were of the order of 15Å per min. Figure 2 shows the rate of film growth. The film growth rate increases with increase in anode-cathode potential, with increase in current density, and with decrease in anode-substrate spacing.

Composition of the coating.—Analysis of the coating was performed by infrared absorption. Highly polished silicon or germanium substrates, which are transparent to infrared radiation in the area of interest, were substituted for copper. During the early stages of the program, oxygen contamination was recognized by the fact that absorption bands characteristic of silicon dioxide were observed along with those of silicon nitride. The preparation method was then modified as follows to minimize oxygen and water contamination in the system: use of ultrapure nitrogen; pumping the system down to 10^{-6} Torr before admission of nitrogen; flushing the system with nitrogen before starting the experiment; and maintaining the system under vacuum when not in use.

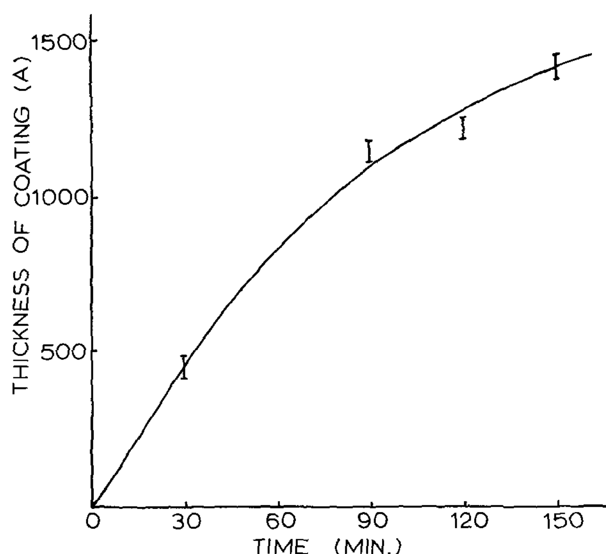

Fig. 2. Rate of growth of silicon nitride coatings under the slow-growth conditions used.

A typical infrared absorption spectrum of the silicon nitride coating is given in Fig. 3. The broad absorption band centered at 900 cm^{-1} is characteristic of silicon nitride (3, 4). The absorption band centered at 2200 cm^{-1} has been attributed to a silicon nitride triple bond and may indicate a lack of stoichiometry in the coating.

Adherence and color of the coating.—The coatings were smooth and very tightly adherent to the substrate as judged by the fact that hard rubbing with non-abrasive papers or cloths had no effect on the coating. The sample could be severely bent without macroscopic separation of the coating from the substrate. The films were smooth and mirrored the smoothness of the substrate. They imparted slight color presumably as a

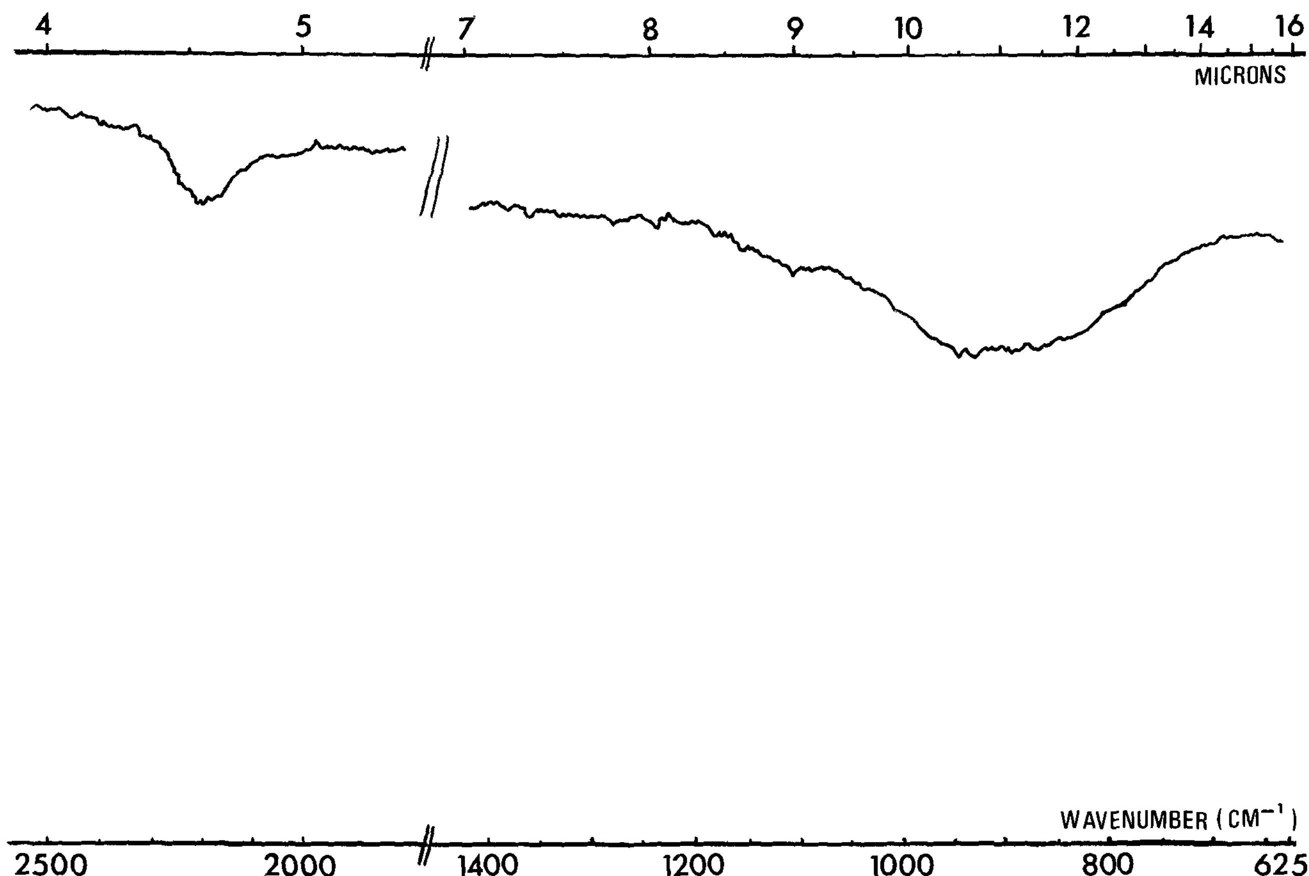

Fig. 3. Infrared absorption spectrum of silicon nitride coating formed on a germanium substrate

consequence of interference between light reflected from the silicon nitride-air interface and the copper-silicon nitride interface. Films, 200-400Å in thickness, were reddish to brown in color, and films, 1000-1500Å in thickness, were yellow to gold in color. The coating appeared transparent and structureless under the microscope and the grain boundaries of the substrate were readily visible.

Dielectric constant.—The dielectric constant of films ranging in thickness from 500-1500Å was determined at 1000 cycles/sec. There was no unique value of the dielectric constant for the amorphous silicon nitride films. It varied with the conditions under which the films were formed, and ranged from 8 to 11. It is likely that the dielectric constant is intimately associated with the structure and stoichiometry of the coating. The possible cause for the high dielectric constant of the coating is the increase in molecular and dipole polarizabilities of the amorphous structure or the presence of shallow impurity levels in the films causing higher electronic polarization. The dissipation factor at 1000 cycles/sec was less than 10^{-2}.

Behavior of coatings upon polarization.—In order to obtain information about charge motion across the copper-environment interface, potentiostatic polarization curves were determined in several electrolytes. Typical polarization curves are given in Fig. 4-6. All potentials are given with respect to a mercurous sulfate reference electrode.

Anodic polarization of the silicon nitride-coated copper in sulfuric acid (1M), phosphoric acid (1M), and sodium hydroxide electrolytes (1M) yielded polarization curves in which the current passed at equivalent anodic potentials was appreciably less than that of uncoated copper.

Prepolarization of samples in phosphoric acid caused a significant reduction in current at equivalent anodic potentials upon anodic treatment in sulfuric acid solution. Sealing of pores in the coating is the likely explanation. The localized nature of the attack of the copper upon anodic treatment as observed by the naked eye and under the microscope suggests that defects in the coating are largely responsible for charge movement through the coating.

Corrosion resistance.—The coated samples were exposed at room temperatures to a number of aqueous corrosive environments. In each case a 0.5 cm^2 section

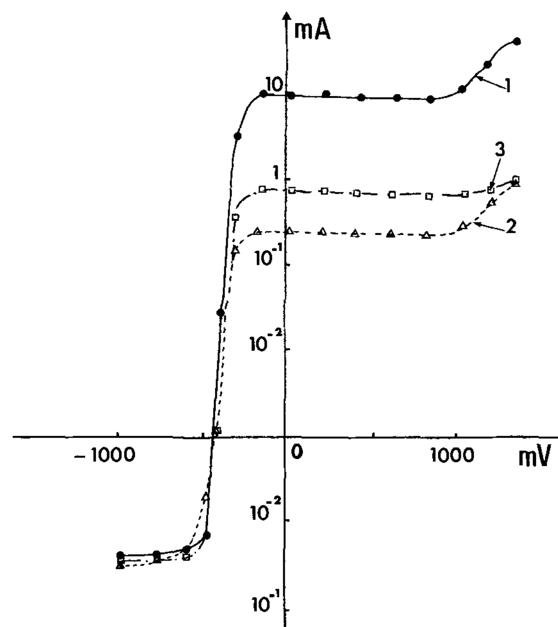

Fig. 5. Polarization curves of pure copper (curve 1) and silicon nitride-coated copper (curve 2) in 2*N* phosphoric acid. Curve 3 is a second polarization curve on the same silicon nitride-coated sample. Note that current plateau is at the same position as the highest current used in determining curve 2.

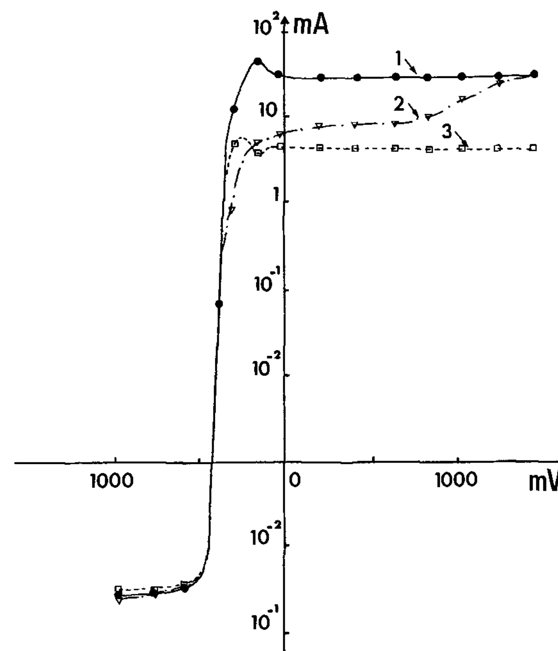

Fig. 6. Polarization curves of pure copper (curve 1) and silicon nitride coated copper in 2*N* sulfuric acid (curve 2). Curve 3 is a polarization curve after the silicon nitride-coated sample was polarized anodically in 2*N* phosphoric acid. The lower current observed with the "phosphated" copper suggests that pores in the coating were sealed.

in the center of the coated sample was isolated by masking off the remainder of the surface with a proprietary resistant lacquer. Control samples of electrolytically polished copper were attacked immediately or within a short time in the same environments. The results of these experiments are summarized in Table I.

The coated samples afforded a good resistance to corrosion in sodium hypochlorite and ammonium hydroxide solutions; moderate resistance in phosphoric and sulfuric acids; short-term protection in sodium

Fig. 7. Photomicrograph of silicon nitride-coated copper strained 1% in tension. Cracks are readily identified by interference fringes adjoining crack.

thiosulfate and sodium sulfide solutions; and little or no protection in nitric acid.

Complete protection was afforded to coated surfaces adjoining uncoated surfaces during electrolytic polishing in phosphoric acid solutions.

Mechanical properties of the coating.—Qualitative tests involving severe bending of the silicon nitride-coated samples indicated that the coating had ductility and that sharp bends did not cause the deposit to flake from the surface. Quantitative experiments were then performed by straining coated copper samples on an Instron Universal Testing Machine at a cross head speed of 0.02 in./min. Conventional tensile test specimens were coated with silicon nitride.

In order to determine the mechanical behavior of the coating, axial tensile loads were applied in successive elongation steps of 0.3%, 0.5%, 0.7%, and 1%. After each degree of elongation, the sample was examined microscopically for indication of fracture in the coating. No cracks were detected on samples strained 0.3%, 0.5%, and 0.7%. At 1% elongation, however, short cracks largely at right angles to the loading axis were detected as shown in Fig. 7. The cracks were readily identifiable by the interference fringes which occurred in areas adjoining the cracks. Presumably the coating broke from the substrate in these highly localized sites and the silicon nitride film formed an angle with the surface.

Summary and Conclusions

Amorphous films of silicon nitride have been deposited on copper substrates at room temperature by reactive sputtering. Because of the greater reactivity of silicon towards oxygen, the partial pressure of oxygen in nitrogen must be carefully controlled. No problems have been encountered with adherence of the coating to the copper or with macroscopic defects in the coating. The coatings were crack free and gross-defect free.

It does appear, however, that 1000-1500Å thick coatings were porous to electrolytes as judged from the fact that coatings passed appreciable current when subjected to an applied potential in media such as sulfuric acid, phosphoric acid, and sodium hydroxide. Nevertheless, the silicon nitride coating did reduce greatly the rate of anodic copper dissolution and did afford short-term protection in aggressive environments.

Improvements remain to be made in the direction of a decrease in the porosity through modification in the rate or method of formation, or through a post-treatment such as heat treatment.

The coatings tolerated strains less than 1% without apparent fracture.

Table I. Behavior of 1000 Å-thick silicon nitride coatings on electrolytically polished copper substrates upon exposure to corrosive environments

Environment	Behavior
Phosphoric acid, conc	First attack on the coating noted after 24 hr
Sulfuric acid, conc	First attack on the coating noted after 24 hr
Nitric acid, conc	First deterioration of the coating noted in 5 min
Nitric acid, 10%	Samples resisted attack for 3 hr
Ammonium hydroxide, conc	No observable deterioration of the coating within 24 hr
Sodium hypochlorite, conc	No observable deterioration of the coating within 24 hr
Sodium thiosulfate, 1M	First attack visible after 2 hr
Sodium sulfide, 0.1M	First attack visible after 2 hr with buckling of coating and darkening of the copper

Characterization of Platinum Electrodes in H_2-Saturated Sulfuric Acid Solution

I. Transient Conditions

Murray Rosen,* Sigmund Schuldiner,* and David R. Flinn*,[1]

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

A single cycle of anodic-cathodic constant current pulses (1-3 A/cm^2) were applied to a normal hydrogen Pt electrode. Following anodic charging to between 0.4 and 1.75V, the total faradaic and nonfaradaic cathodic charge to the H_2 evolution plateau was equal to the net anodic charge. The distribution of total faradaic charge into hydrogen and oxygen processes in each half-cycle, as based on a geometric separation of charging regions, showed that anodic charging gave a much better resolution of each of these processes. The irreversible reduction of Pt-O occurred in two separate regions of unequal charge content. The two regions represent a complex reduction of Pt-O where the O is held with different bonding energies rather than a sequence of two one electron steps. The amount of H deposited up to the negative limiting potential plateau where H_2 evolution occurred is numerically equal to the amount of H that is associated with Pt at the normal H^+/H_2 equilibrium.

There is a great deal of confusion and conflict in the literature concerning the transient amounts of anodically oxidized H and generated Pt-O and the subsequent reduction of the Pt-O and regeneration of H. Table I in the Discussion Section will review some of this literature. Differences appear to be the result of solution purity, voltage ramp and galvanostatic pulse rates, potential or current control in between transients, and pretreatment. Pursuit of the last point has resulted in data in which the state of the Pt system between cyclic pretreatment (n cycles) and the electrochemical measurement perturbation (n + 1 cycles) hardly differed, but the question as to the effect of n cycles on the electrode character was unanswered.

In the present work, a high-purity, normal hydrogen electrode (NHE) with no immediate pretreatment was subjected to a single cycle of constant high current density pulses in the order anodic, cathodic. When the potential at which the anodic pulse was switched to a cathodic pulse, E_{sw}, ranged from 0.4 to 1.75V, the total faradaic and nonfaradaic anodic charge was equal to the cathodic charge. However, the distribution of the total faradaic charge into hydrogen and oxygen processes in each half-cycle, as based on the geometric regions of the charging curves, had to be resolved.

Experimental

The high-purity, gas-tight electrochemical system and experimental conditions were the same as previously used (1-3). Two working Pt bead electrodes were used. Their true areas (2) were 0.37 and 0.42 cm^2. The temperature was 25° ± 1°C, and all measurements were made in 1M H_2SO_4 stirred with H_2 and measured *vs.* the NHE.

The circuit used is shown in Fig. 1. The Pt working electrode was polarized by an anodic, constant current pulse (1-3 A/cm^2) to various potentials between equilibrium and 1.8V. This anodic current pulse was triggered (START) by depressing the RESET button on the Hewlett-Packard 5214L Electronic Preset Counter. At the end of the preset count, which corresponded to selected potentials along the anodic charging curve, the Preset Counter (STOP) triggered the cathode pulse generator on. The latter in turn produced a TURN-OFF pulse which shut-off the anodic pulse generator. The pulse generators were EH Models 132A that were adapted here to accept turn-off pulses. Tektronix 454 and 547 oscilloscopes, the latter using a Type W plug-in, were used to display the anodic and cathodic charging curves, respectively. In order to locate the start of cathodic polarization in a photograph of the oscilloscope display, a second sequence of current pulses was applied but this time only the cathodic polarization was recorded at a 1 μsec/cm sweep rate. By extrapolating to zero time, the initial point of the cathodic charging curve and any potential at any time on the full charging curve could be determined.

In some cases, a third pulse was applied, that is, an anodic pulse was applied at some point during the cathodic polarization. For this phase of the work, the first anodic polarization was recorded on the Tektronix 454 oscilloscope. The cathodic and second anodic polarizations were recorded on a Tektronix 565 Dual-Beam (Type 3A6 plug-ins). The second anodic current pulse was provided by a third EH Pulse Generator triggered by the 565 oscilloscope's DEL'D TRIG. OUT, which was positioned along the horizontal time axis of the cathodic charging curve to correspond to the desired switching point. As before, when the second anodic pulse generator was triggered, it simultaneously provided a turn-off trigger pulse to the cathodic pulse generator. In summary, by using this arrangement, an anodic followed by cathodic followed by anodic sequence of high, constant current pulses, with switching times of about 500 nsec, were applied. By merely depressing the RESET button of the Preset Counter a sequence of events occurred that resulted in photographed oscilloscope traces of the resultant polarizations.

Except where otherwise indicated, anodic and cathodic measurements of q in μC/cm^2 were corrected for

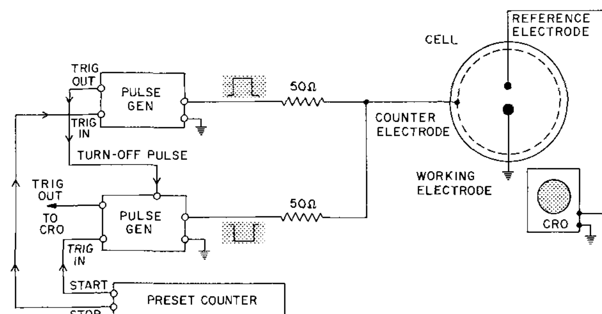

Fig. 1. Circuit for applying a constant, anodic current pulse that is terminated by a constant, cathodic current pulse at switching times less than 1 μsec. See text for explanation.

Key words: platinum, hydrogen, oxygen, adsorption, transient polarization, fast switching.

the double layer contribution following previously established procedures (1). The vertical and horizontal deflections of the scopes were periodically checked. Numerous checks of the current density and of the true areas of the bead were also made. The current from the pulse generators was determined either by measurement with a Tektronix P6042 Current Probe, positioned in the current path where the Pt working electrode was grounded or by differential measurement of the voltage drop across the individual series resistors using Type W or Type 1A5 plug-ins. Throughout the course of this work it was found that the cyclic pulsing had little effect on the true area. Variations in area measurements were random and dependent on electronic effects, that is, calibrations, etc., and how the oscilloscope traces were read. When care was taken, the true area as determined from the three pulse generators would agree with an average deviation of about ± 0.007 cm^2 ($\pm 2\%$). An average deviation of ± 0.010 cm^2 ($\pm 2.5\%$) was observed for the deviation of six average areas of which each one was determined as the average one measured from three pulse generators.

Results

Anodic-cathodic polarization.—The anodic polarization response below 1.76V for Pt bead electrodes to a high current density galvanostatic pulse results in potential-time regions representing two faradaic processes. From 0.0 to about 0.88V, hydrogen atoms which were associated with the electrode at equilibrium (NHE) are oxidized (276 $\mu C/cm^2$). Following the oxidation, a monolayer of Pt-O (420 $\mu C/cm^2$) is formed from the oxidation of water. Consequently, the reactions that occur and the resultant potential-time responses of the cathodic pulse depend on the selection of E_{sw}.

Potential *vs.* time curves for cathodic polarization following current reversal at various E_{sw} are shown in Fig. 2. From the several breaks that can be observed in the charging curves only two major potential-time regions were used for quantitative study. The first one, given the symbol "□," begins at the anodic to cathodic switching potential, E_{sw}, and includes all the charge found in the rising portion of the curve. The second region, given the symbol "⬡," begins at the end of region □ where there is a large slope change and extends all the way to the beginning of the long plateau. Since the faradaic reactions of the first anodic pulse are H oxidation followed by Pt-O formation, it is logical to expect only two faradaic reactions during the cathodic pulse, namely, Pt-O reduction followed by H formation. Consequently, the data for regions □ and ⬡ should primarily represent these two processes. The ratio of the total charge (faradaic and nonfaradaic),

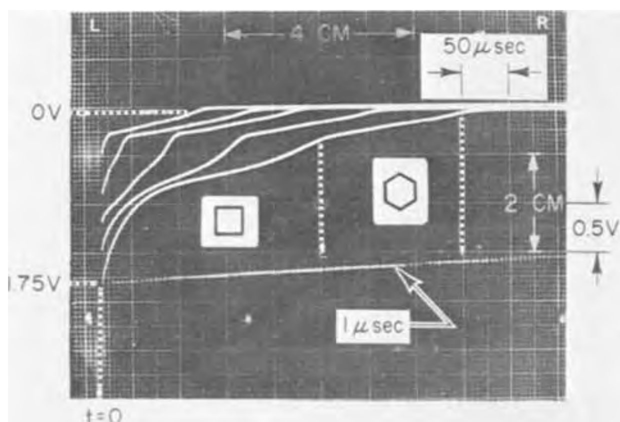

Fig. 2. Potential *vs.* time response for cathodic pulses terminating anodic pulses at E_{sw} (top to bottom) 0.38, 0.78, 1.1, 1.4, and 1.75V. (□), First reduction region; (⬡), second reduction region. Arrow (1 μsec) refers to the cathodic charging curve polarization at the rate of 1 μsec/div.

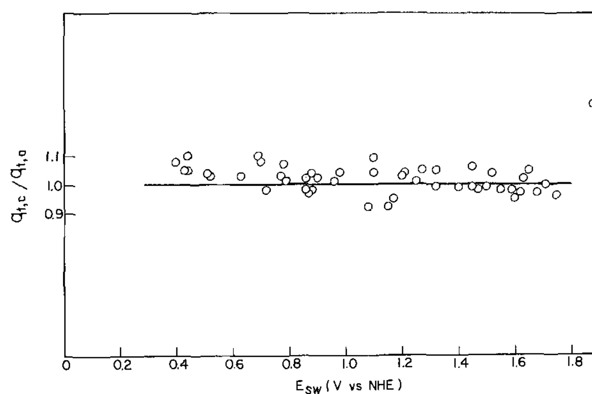

Fig. 3. The ratio as a function of E_{sw} for the total coulombs of faradaic and nonfaradaic processes of the cathodic branch divided by the total coulombs of faradaic and nonfaradaic processes of the anodic branch.

$q_{t,c}/q_{t,a}$, is plotted *vs.* E_{sw} in Fig. 3, where $q_{t,c}$ is the total cathodic charge and $q_{t,a}$ is the total anodic charge.

Hydrogen oxidation/formation.—The amount of hydrogen atoms, q_H, oxidized up to E_{sw} is shown in Fig. 4 as open circles. Beyond 0.9V the amount of q_H determined should be constant since all the H is oxidized below this potential. The mean for this q_H is 276 ± 14 $\mu C/cm^2$ where the second term is the standard deviation. The charge consumed in the ⬡ region primarily represents the formation and accumulating of atomic H. The amount of q found in region ⬡ *vs.* E_{sw} is plotted in Fig. 4 as ⬢. The mean for $q_{⬡}$ > 0.88V is 258 ± 21 $\mu C/cm^2$. The potential for the start of region ⬡ *vs.* E_{sw} is shown in the upper portion of Fig. 4. The potential for the end of the region, or the beginning of the long plateau, is about 50 to 100 mV negative.

Oxygen formation/reduction.—The amount of Pt-O formed, as determined from an anodic pulse, up to E_{sw} is shown in Fig. 5 as open circles. Symbol ■ is for the data when $0.4 \leq E_{sw} \leq 0.88V$ where no Pt-O was formed and □ is for $E_{sw} > 0.88V$ where Pt-O was formed. Although there is some scatter, the data points, □ and ⬡, could be separated over the potential range 0.9 to 1.7V by individual computer-fitted straight lines. The dashed line ($q_{⬡} = 416\ E_{sw} - 345$) is for the rapid transient formation of O, and the solid line ($q_{□} = 316\ E_{sw} - 262$) is for the total faradaic charge in region □ (both corrected for double-layer charging).

Discussion

Cathodic/anodic ratio of total charge.—Table I compiles data comparing the q_c/q_a ratios for oxygen spe-

c. First cycle.
c.* First cycle is assumed.
d. Some n^{th} cycle is assumed.

cies. Our ratio $q_{t,c}/q_{t,a}$ being one over the E_{sw} range 0.4 to 1.75V shows that when a single cycle of high intensity galvantostatic pulses is applied to a NHE, all the oxygen formed is reduced and that all the hydrogen oxidized is reformed at the negative plateau (Fig. 2), no matter how the faradaic charge is divided between hydrogen and oxygen.

Pearson and Butler in 1938 (8) applied high current density pulses to electrodes that had been previously cathodized in N_2-saturated solutions. From the shape of their anodic charging curves and the −0.6V limiting potential of the cathodic charging curves, it is apparent that their electrodes were not free of impurities. They did not determine the amount of H oxidized in the 0.4-0.8V region.

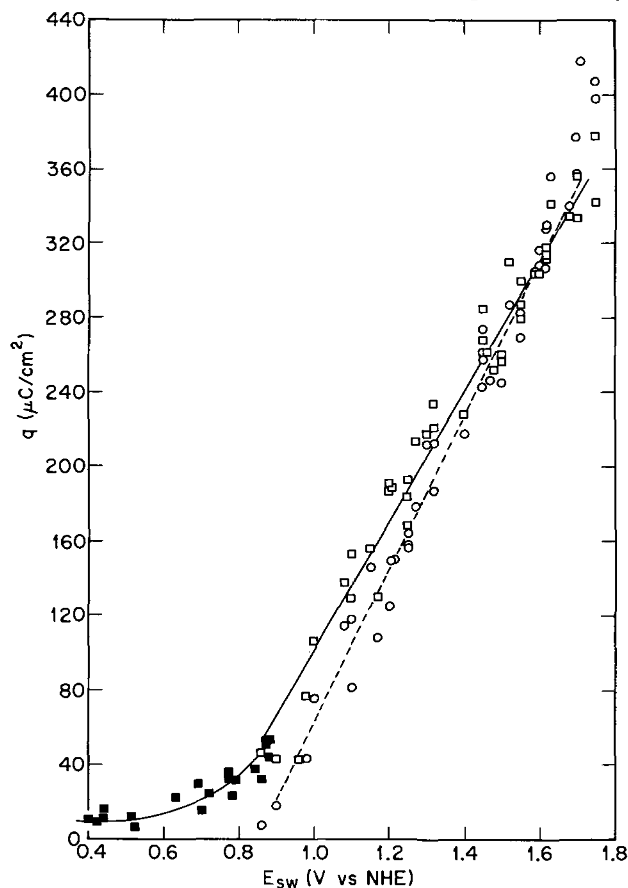

Fig. 5. Relation between faradaic charge in region □ vs. $E_{sw} \leq 0.88$V (■) and for $E_{sw} \geq 0.88$V (□). The straight lines between 0.9 and 1.7V are computed least square fits; (solid) $q_{\square} = 316\, E_{sw} - 262$, (dashed) $q_{\bigcirc} = 416\, E_{sw} - 345$. Amount of O formed by anodic charging to E_{sw} (o).

Will and Knorr (9) found equal amounts of charge for the anodic and cathodic hydrogen regions. However, their determination gave 640 μC/cm² for each q_H and q_O. They did not state if the determination was for the first or n^{th} cycle.

The charge ratios shown in Table I for just the oxygen reactions demonstrate the confusion encountered in the literature concerning this measurement. The major problems are solution purity and the fact that the measurement cycle was not the first cycle applied at an initial, well-defined condition. Indiscriminate "activation" leads to undefined conditions. A clean system does not require immediate pre-anodization. Paper II (12) of this series shows in detail how stable O and anion species, which may be generated during pretreatment, do affect the character of Pt.

The cathodic potential plateau at the end of region ○ (Fig. 2) being negative to zero V indicates that the H atoms formed during the rapid transients are not associated with Pt as would an equivalent amount of H at the NHE (1). Counting the charge back to this plateau rather than to 0.0V is logical because the plateau in effect represents a limiting condition for the transient perturbation. Making the comparison of total charge by including nonfaradaic coulombs precludes any posssible error due to area determination or double-layer correction. Even though the cathodic plateau may go to −0.1V, the additional double layer charge from 0 to −0.1V would be less than 2 μC/cm², which is well below our experimental error.

Faradaic charge distribution.—Although the faradaic charge can be adequately separated into hydrogen and oxygen regions, there is a significant amount of overlap. The q_H anodic average (Fig. 4) of 276 μC/cm² is greater than the $q_{\bigcirc}$ cathodic average of 258 μC/cm². Figure 5 shows that there is excess faradaic charge ($q_{\blacksquare}$) for $E_{sw} \leq 0.88$V and that more charge is consumed in region □ than is necessary to reduce Pt-O formed in the preceding anodic pulse. Because the anodic-cathodic charging curves are unsymmetrical, a geometric method for separating reaction regions may show significant differences in the amount of charge. To determine in a charging curve where one process ends and the next one begins, an electrochemical end point is assumed by drawing straight lines through the charging curves near the transition region. If the geometric and electrochemical end points do not coincide, then overlapping occurs.

Previous measurements (2) of anodic charging curves have shown that below E_{sw} of 0.88V (the geometric separation point between the hydrogen and oxygen regions) no oxygen intermediates are formed.

Table II. Ratio of hydrogen formed by cathodic pulse to hydrogen oxidized by second anodic pulse

Potential E_{sw}	Cathodic μC/cm², region ◯ / Anodic μC/cm² $q_{◯}/q_H$	Cathodic μC/cm², total / Anodic μC/cm² $(q_{◯}+q_{■,△})/q_H$
0.44	0.90	0.97
0.84	0.87	1.04
1.20	0.83	0.92
1.25	0.91	0.99
	0.91	0.96
1.45	0.91	0.93
	0.95	1.05
1.48	0.96	0.98
1.50	0.93	0.98
1.55	0.96	0.96
	0.89	0.94
1.60	0.95	0.95
1.70	0.99	0.99
1.75	1.03	1.03
Average	0.93 ± 0.04	0.98 ± 0.03
Std. Dev.	0.05	0.04

This means that an accurate separation of the hydrogen and oxygen regions is possible in the anodic charging curve. Hence, the excess charge shown in the cathodic charging curve results of Fig. 5 may be due to significant H^+ reduction in the □ region. Since the possibility of H^+ reduction at potentials around 0.4V is open to question other reasons for the excess charge may be possible. However, a reasonable alternate explanation has not been found and we assume that this excess charge is due to H^+ reduction

The experiments in which 1½ cycles were applied, *i.e.*, anodic, cathodic, and anodic, showed that in order to account for all the faradaic charge (see Table II, column 2) used for H oxidation in the second anodic pulse, $q_{■}$ or $q_{△}$ ($q_{△} = q_{□} - q_{○}$) had to be added to $q_{◯}$, *i.e.*, $q_{◯} + q_{■,△}$. This sum is plotted in Fig. 6 as filled-in circles. The continuous line is the same as in Fig. 4.

Table II compares both the ratio of the H formed in in the ◯ region, $q_{◯}$, and total H formed ($q_{◯} + q_{■,△}$) to the q_H measured by the second anodic pulse. Included are cases in which the cathodic pulse was terminated before the end of region ◯ to avoid the plateau. Since for the $E_{sw} = 0.44V$ value, not all of the H is oxidized by the first anodic pulse, the H not oxidized was subtracted from the q_H of the second anodic pulse. This correction was the difference between 276 μC/cm² and the amount oxidized by the first pulse, *e.g.*,

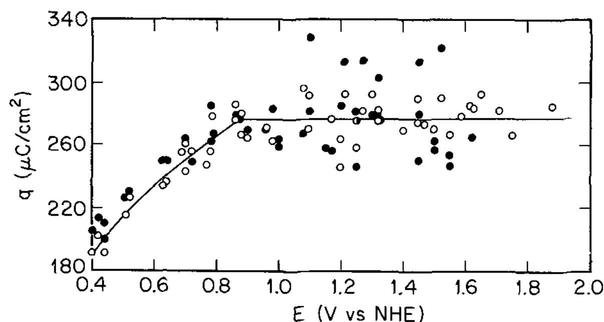

Fig. 6. Relation between amount of H oxidized by an anodic pulse up to E_{SW} (o) and the sum (•) vs. E_{SW} for the amount of faradaic charge in region ◯ plus the faradaic charge in region □ less any charge for oxygen reduction ($q_{○}$).

at $E_{sw} = 0.44V$

$$\frac{(q_{◯} + q_{□,△})}{[q_H - (276 - q_{H'})]} = \frac{(195 + 15)}{[300 - (276 - 191)]} = 0.97$$

where, $q_{H'}$ and q_H is the number of μC/cm² of H oxidized in the first and second anodic pulses, respectively.

Further evidence that part of the charge in region □ was the result of a faradaic process when Pt-O was not formed was shown by the capacitance, as measured by the slope of the charging curve prior to the beginning of region ◯. Slope determinations for the portion of the cathodic charging curves just before the beginning of region ◯ for E_{sw} equal to 0.44 and 0.77V gave capacitances of 57 and 70 μF/cm², respectively. The double layer capacitance at the beginning of region ◯ in these solutions is about 30 μF/cm² (13, 14).

This overlapping of the two reduction processes complicates a determination of Pt-O reduction in the second part of region □. Nevertheless, qualitative inspection of the charging curves (Fig. 2) shows that in the higher potential portion of region □ more charge is consumed than in the lower potential portion. For example, at E_{sw} of 1.75V, this ratio is nearly 2:1. Consequently, it is concluded that the two breaks do not simply mean consecutive one electron steps, but actually involve a complex reduction of Pt-O where the O is held with different bonding energies so that the potential *vs.* time relation does not follow the simple linear relation found during formation.

Previous work (2) has shown that the anodic oxygen region was not dependent on the initial presence of H on the electrode. It is therefore evident from the present work that anodic charging curves give a better separation of the H and O regions than are possible by the cathodic charging curves.

On the Potentiostatic Oxidation of Iron in Neutral Sulfate Solution

I. "Oxide-Free" Specimens

D. Barry Gibbs[1] and Morris Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada

ABSTRACT

The anodic oxidation of electropolished iron in deaerated sodium sulfate solution (*p*H 8.4) has been studied by a potential-step method over the range −500 to +1550 mV *vs.* SHE. The iron surfaces were prepared by cathodic reduction in a borate buffer solution immediately prior to oxidation. The anodic behavior of an "oxide-free" surface so obtained was found to be markedly different from that of a surface which had not been completely reduced.

Neutral sulfate solutions are relatively corrosive media for iron (1-3). However, studies of anodic passivation of iron in this system have been reported, notably by Freiman and Kolotyrkin (4-7), much of whose work has been concerned with two active-passive transitions, and the dependence of the transition potentials on *p*H and sulfate ion concentration.

Most work to date has been carried out using iron specimens initially carrying at least an air-formed film. In contrast, the data presented below describe the anodic behavior of iron which has been cathodically reduced in a deaerated borate buffer solution immediately before oxidation in the sulfate solution, with no intervening exposure to air. The results, which are rather different from those of Freiman and Kolotyrkin, for example, indicate that even a thin air-formed film exerts a major influence on the passivation characteristics of iron.

The present paper is intended mainly to describe the electrochemical behavior of the initially "oxide-free" iron in deaerated Na_2SO_4 solution. The effects of the air-formed film will be explored more fully in a subsequent report.

Experimental

Apparatus.—The cell was similar to that described previously (8) except that the counterelectrode consisted of two pieces of fine mesh platinum gauze surrounding the working electrode. The cell was fitted with Teflon stopcocks for solution transfer. A saturated calomel reference electrode was used; however all potentials are quoted with respect to the standard hydrogen electrode. All runs were carried out at a temperature of 25° ± 0.2°C.

A Wenking Model 61 RS fast-rise potentiostat was used for anodic oxidation, the variation of current with time being followed by a Texas Instruments Servo/Riter II chart recorder (1 or 10 mV full scale). For galvanostatic reduction, a constant-current source constructed from operational amplifiers was employed, with an E-H Research Laboratories electrometer coupled to a Leeds and Northrup Speedomax G recorder being used to monitor the potential of the working electrode.

Solutions.—Solutions were prepared from AR grade reagents and doubly distilled water. The borate buffer solution (*p*H 8.4) used for cathodic reduction was an equivolume mixture of a solution of 28.6 g/liter sodium tetraborate decahydrate and a solution of 18.5 g/liter boric acid. The *p*H of the 0.15*N* sodium sulfate solution was adjusted to 8.4 by addition of 1*N* sodium hydroxide. This *p*H was chosen for oxidation since no change of bulk *p*H from this value was observed during a run (solutions of lower initial *p*H rapidly approached a *p*H of approximately 8.4 upon application of current).

Argon was used for deaerating solutions and for providing an inert atmosphere for experiments. Commercial high-purity argon was further purified by passage through a column packed with finely dispersed copper on Kieselguhr heated to 200°C (9). The solutions were deaerated in storage vessels by bubbling argon through them for 48 hr. They could then be transferred to the cell under an argon atmosphere.

Iron electrodes.—Ferrovac E sheets 0.015 in. (0.038 cm) in thickness and 1, 2, 5, or 10 cm^2 in area (depending on the magnitude of the current) were suspended in solution by means of narrow handles. Surface preparation steps were carried out in the following sequence: (*i*) degreasing in benzene in Soxhlet extractor for several hours; (*ii*) chemical polishing for 4 min in oxalic acid-hydrogen peroxide bath; (*iii*) electropolishing for 1 min in acetic acid-perchloric acid bath (10); (*iv*) annealing in hydrogen in a system capable of ultra-high vacuum (2.5 hr at 700°C, hydrogen pressure 1-2 Torr); (*v*) re-electropolishing for 1 min just before installation in the cell. If a specimen was to be reused for a later experiment, it was again electropolished as in step (*v*).

For oxidation experiments, three types of surface were used, classified according to the initial degree of oxidation. These are designated C (complete preliminary cathodic reduction), B (incomplete preliminary reduction), and A (specimen carrying air-formed film). These will now be described more fully:

C specimens were subjected to thorough cathodic reduction in the borate solution immediately before oxidation. All reductions were carried out at a current density of 10 $\mu A/cm^2$ while passing argon over the solution (the solution was not stirred). These electrodes were distinguished by the magnitude and rate of attainment of the initial rest potential upon immersion in the sulfate solution. This potential was approximately −565 ± 5 mV *vs.* SHE and was reached very rapidly, *i.e.*, within 1-2 sec. If left on open circuit it would remain constant at this value for extended periods of time.

B specimens could be prepared either by interrupting the current before cathodic reduction was complete, or by carrying out the reduction in a borate solution which had not been sufficiently deoxygenated. In contrast to those of type C, these assumed an unsteady initial potential in sulfate of −400 to −500 mV, which decreased very slowly toward the C value. The surfaces of the B electrodes always contained a small amount of electrochemically reducible oxide which was, however, much less than the air-formed film.

An A specimen was prepared by first cathodically reducing as for type C. It was next removed from the

Key words: iron passivity, anodic oxidation, oxide films.

cell, washed with freshly redistilled water, and quickly dried by blotting lightly with Fisher lens paper. It was reinstalled in the cell just before introduction of the sulfate solution for anodic oxidation, the total time of exposure to air being exactly 15 min.

Procedure.—After obtaining the desired starting surface (see preceding section) the cell was rinsed carefully with the sulfate solution to remove all traces of borate. An argon atmosphere was maintained (except in the case of A electrodes) to prevent air oxidation of the specimens.

Upon immersion in sulfate, the initial open circuit potential was noted; the potentiostat was then immediately switched on. Each run was carried out at a single potential, this being applied in one step from the rest potential. During oxidation, argon was bubbled through the solution at a constant rate.

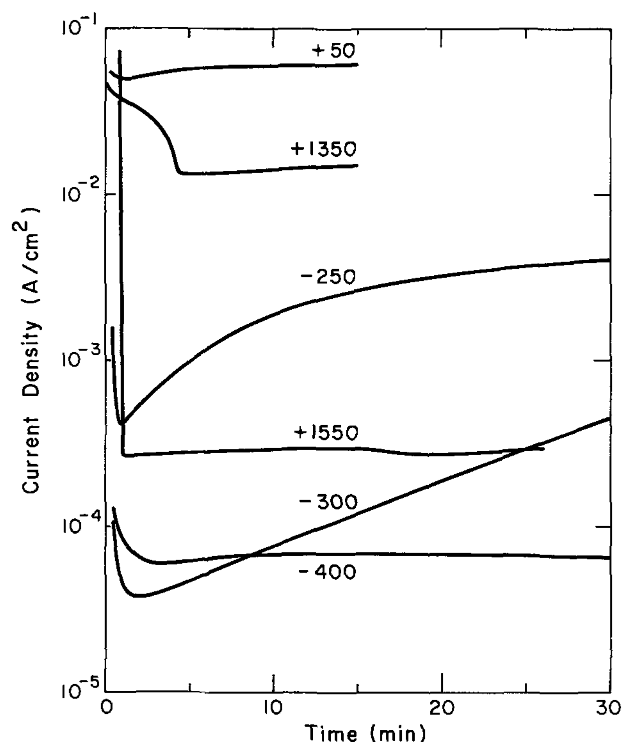
Following oxidation for the desired period, the working electrode was again cathodically reduced in the borate solution.

Results

The behavior of C electrodes will be described first. It is convenient to divide the potential range covered (−500 to +1550 mV) into three regions, based on the nature of the current-time curves. These are (*a*) the low potential region, −500 to −385 mV; (*b*) the major active region, −385 to +1450 mV; and (*c*) the region of vigorous oxygen evolution, $\lesssim$ + 1550 mV. Representative current-time curves are given in Fig. 1.

Because the cell currents did not, in general, readily attain steady values (especially at the low potentials), a "steady-state" polarization curve was not plotted. However, polarization curves could be made for fixed periods of oxidation. An over-all picture of C electrode behavior can be had from such a curve for an oxidation time of 15 minutes, shown in Fig. 2.

Region (a).—Upon application of low potentials, the current density rapidly decreased from the initial high-current peak to relatively small values, of the order of 100 $\mu A/cm^2$. The data in Fig. 2 suggest that there is an active region centered at *ca.* −450 mV, the currents, however, being fairly small. An active-passive transition is found at *ca.* −400 mV.



Fip. 1. Representative curves of current vs. time for potentiostatic oxidation of C electrodes. The numbers on the curves give the potential of oxidation in millivolts vs. SHE.

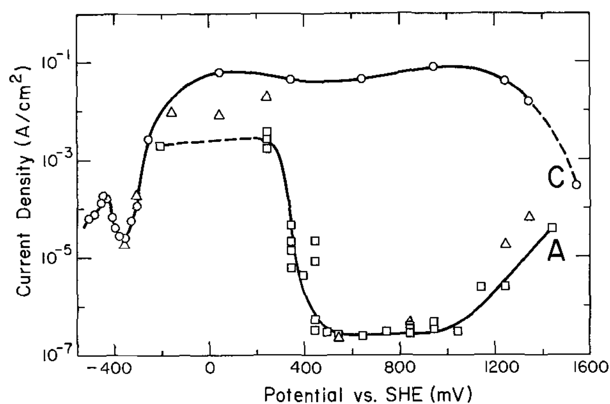


Fig. 2. Polarization curves for C and A electrodes, plotted for an oxidation time of 15 min. The points Δ are for B electrodes. Region (a) −500 to −385 mV; (b) −385 to −1450; (c) vigorous O_2 evolution > + 1550 mV.

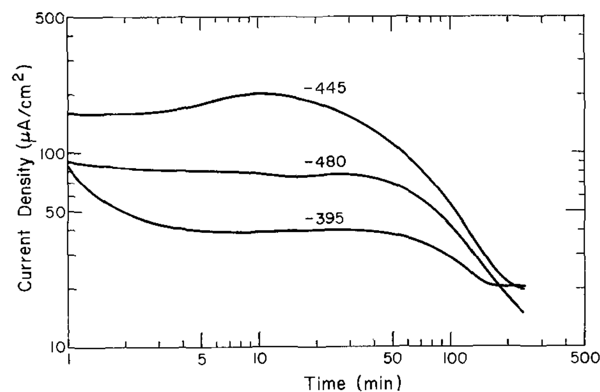

Fig. 3. Current-time curves for long-time potentiostatic oxidation of C electrodes at certain low potentials. The numbers on the curves give the potentials in millivolts vs. SHE.

Examination of the current-time curves in Fig. 3 shows that these conclusions are not valid for long periods of polarization. In this figure, the behavior at three different potentials for oxidation times of four hours are plotted. It is seen that much lower currents may eventually be reached, so that a polarization curve plotted for a prolonged period of oxidation would display no active peak around −450 mV, and no active-passive transition.

For short oxidation times (up to 30 min) at these potentials, apparent surface attack was comparatively slight; only a small number of tiny pits (diameter <0.001 mm) could be seen at low magnifications. In contrast, after several hours of oxidation the nature of the attack changed and the specimen became coated with a spongy, poorly adherent green film which could not be completely removed by cathodic reduction. The underlying surface exhibited fairly severe general etching, the degree of attack increasing with potential. Identification of the film was not attempted because of its susceptibility to air oxidation. This film was probably a ferrous hydroxy sulfate. Exposure of the specimen to air produced a very rapid color change from green to orange.

The cathodic reduction curves (potential *vs.* time) obtained after oxidation resembled in shape those of Nagayama and Cohen (11) for iron oxidized in a borate solution. However, they tended to be diffuse and poorly defined. Film thicknesses estimated from the curves were small, amounting to only a few tens of angstroms.

Transition from Region (a) to Region (b).—These two regions have been defined arbitrarily in terms of the current-time behavior. At potentials less than about −385 mV, the current always decreases monotonically following the initial transient peak. (A very broad,

superficial second peak was sometimes observed; see Fig. 3). At potentials greater than this value, on the other hand, the current reaches a minimum after a period of 1 to 5 min, and then begins to increase. By carrying out a number of runs at potentials in the range −400 to −350 mV, the potential at which the current just failed to decrease at long times could be determined fairly accurately as −385 ± 5 mV.

It is to be noted that the current minimum around −360 mV (Fig. 2) falls within the active range (b) according to this criterion. This serves to emphasize how much the shape of the polarization curve is dependent on time. At a potential of −360 mV, for example, the current density reaches a minimum of about 20 $\mu A/cm^2$ after a few minutes. Four hours later, however, it has increased to a value of a few milliamperes per square centimeter.

The change in the nature of the transition region with time is depicted in Fig. 4.

Region (b).—In this potential range, the current passes through a minimum after a few minutes and then increases, eventually levelling off at a much greater value which is dependent on potential. With increasing potential, the minimum current becomes greater, and the long-time steady-state current is reached sooner (Fig. 1).

At potentials greater than about 0 mV, the minimum is barely discernible, and the very high currents cause rapid dissolution of the specimen and formation of a thick green precipitate. The current densities given are only estimates based on unit roughness factor; they are doubtless too high because of the severe attack and roughening of the metal surface.

Such behavior is observed up to about +1250 mV. From +1250 to +1450 mV, very high currents are still observed, but the shapes of the current-time curves are different (see Fig. 1).

During oxidation at the lower potentials in this region (up to *ca.* 0 mV), the specimen became covered with a loose green film. After cathodic reduction, numerous very tiny pits (0.001 to 0.005 mm in diameter) could be seen distributed more or less uniformly over the metal surface. With increasing potential, the number of pits became greater, attack evidently proceeding by an increase in the density of pits rather than by the growth of a few pits.

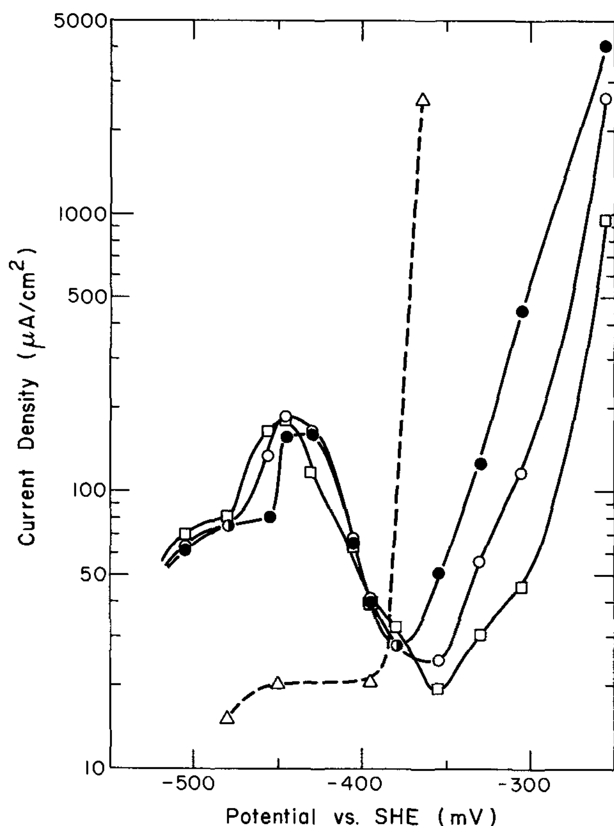

Fig. 4 Polarization curves for C electrodes at low potentials, plotted for oxidation times of □-5 min, ○-15 min, and ● 30 min. The points indicated by Δ are for an oxidation time of 240 min.

At higher potentials, the pits became numerous enough to coalesce into patches, giving the appearance of uneven general attack. The patches appeared to be free of a colored overlying film, in contrast to the remainder of the surface, which became covered with a gold-colored film. Examination by reflection high-energy electron diffraction of a specimen oxidized at +650 mV showed this film to consist of γ-FeOOH and Fe_3O_4. A satisfactory diffraction pattern could not be obtained from the "bare metal" patches.

In all cases, cathodic reduction curves obtained after oxidation consisted of two well-defined waves as for Fe oxidized in borate solution (11), the lengths of the waves depending on potential and time of oxidation. Film thicknesses estimated from these curves were relatively large; for example, for 15 min oxidation at +650 mV, the amount of charge associated with the first wave corresponded to a Fe(III) oxide film thickness of a few hundred angstroms. Some of this Fe(III) oxide was probably deposited from Fe(II) in solution by anodic deposition (8).

Region (c).—At a potential of +1550 mV, bubbles of oxygen were rapidly evolved from the electrode surface. After about one minute of polarization, the concentration of oxygen in solution reached a value sufficiently large to cause a rapid drop in current density (Fig. 1) to a few hundred microamperes per square centimeter. The presence of oxygen was emphasized by formation of a yellow precipitate in the solution, in contrast to the green precipitate observed at lower potentials.

B and A electrodes.—At potentials from −350 to −150 mV, B specimens showed qualitatively the same behavior as those of type C. In general, the initial current peak was smaller for the former type (presumably because of the film already present), and the current density increased less rapidly following the minimum. Specimens of type A could not be examined at potentials less than about −200 mV, the initial open circuit potential of an A electrode in the sulfate solution.

Around −100 mV, very marked differences became evident, not only in the magnitudes of the currents (Fig. 2), but also in the type of surface attack. The B and A specimens showed intensely localized attack, with formation of only a few large pits (up to 0.5 mm in diameter), in contrast to the much more general attack observed for C electrodes.

Both B and A electrodes exhibited a most important change for potentials in the range +550 to +1100 mV, where such attack ceases due to passivation. The active-passive transition occurs over the range +350 to +550 mV. Upon application of a potential in this passive region, the current density rapidly falls to a fraction of a microampere per square centimeter, and metal dissolution virtually stops. Even at very high potentials, the presence of an initial film greatly reduces the rate of metal attack.

Discussion

The anodic behavior of iron in a deaerated neutral sulfate solution has been shown to be strongly dependent on the initial degree of oxidation of the surface. In particular, the passive region at high potentials, extensively studied by Freiman and Kolotyrkin (4-7), is seen to be entirely absent for electrodes which have been completely cathodically reduced before oxidation. This passive region evidently exists only if an air-formed film is initially present on the surface. The present results for B electrodes indicate that even a very thin initial film, such as might result when preliminary cathodic reduction is carried out with insufficient care, is able to give rise to such a region of passivity.

On C electrodes, the anodic film formed at all potentials more positive than −385 mV is nonprotective and gradually suffers general breakdown, the rate of breakdown increasing as the potential becomes more "noble." Attack probably begins at a few discrete points but soon becomes widespread. The film is not able to repair itself and the electrode remains active. Thus the cell current, which is the resultant of components due to film formation (including any deposition of oxide from iron in solution) and metal dissolution, reaches a minimum a few minutes after the potential is applied, and then begins to increase. The sulfate ion may prevent the formation and/or repair of a protective layer by adsorption (12) at the metal surface with displacement of water molecules, by altering the interfacial potential distribution so as to favor metal dissolution, by its incorporation into the film lattice (13), or by some other mechanism.

In Region (a), it is possible that the sulfate ion plays a smaller role, so that the anodic film resembles more closely that formed at corresponding potentials in borate solution; the potentials associated with the critical passivating current and active-passive transition are similar (11).

It is concluded that C electrodes do not become satisfactorily passive at any potential. While low currents do result after long polarization times at low potentials, this is only after considerable attack of the metal surface has taken place, with formation of a thick, spongy precipitated film. The data in Fig. 4 illustrate the danger of drawing conclusions from short-term polarization measurements: thus, the active region around −450 mV "disappears" at very long times, while the apparent region of passivity around −360 mV soon gives way to rapid corrosion.

An obvious question is that of how much oxide must be present initially in order to cause a departure from C behavior at high potentials. Experiments with B electrodes, which may be thought of as intermediate between C and A, ought to allow examination of this question. Unfortunately, B electrodes do not lend themselves readily to experiment because of the nonreproducible nature of the rest potential on immersion in the sulfate solution. This potential is believed to be a sensitive measure of the amount of oxide initially present; it is, however, difficult to prepare a specimen whose immersion potential has a specified value.

The initial film on A specimens can be prepared more reproducibly, and the behavior of these electrodes, particularly in the passive region at high potentials, will be the subject of a future communication.

Anodic Film Studies on Steel in Nitrate-Based Electrolytes for Electrochemical Machining

Kao-Wen Mao,* Mitchell A. LaBoda,* and James P. Hoare*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Steady-state polarization measurements along with constant-current film stripping determinations were carried out on steel wires in solutions of $NaNO_3$, $NaClO_4$, and mixtures of $NaNO_3$ and $NaClO_4$ from which it was found that ClO_4^- ion can efficiently remove the film formed by nitrate by a potential-dependent mechanism. In a closed system employing an ECM test rig, mass balance studies showed that the film formed by NO_3^- ion is electronically conducting since most of the current is consumed in O_2 evolution instead of metal removal. With additions of ClO_4^- ion to the nitrate, the current efficiency for metal removal is increased to 100%. The character of the surface finish in the mixed electrolytes is highly dependent on the flow rate of the solution which was confirmed by the machining of fully hardened type 5160H steel bushings in a through-hole ECM machine. To account for these results, an ion exchange model for metal removal in the transpassive region is suggested.

Since Keeleric (1) announced the commercial development of an electrolytic grinding machine and Anocut Engineering Company (2) published the details of a pure electrochemical machining (ECM) device, considerable effort has been expended in developing and refining the ECM process (3, 4) to the growing commercially important machining method of today. One of the important steps in achieving such progress was the

* Electrochemical Society Active Member.

Key words: electrochemical machining, anodic films, steel anodes, metal removal, surface finish.

realization that an understanding of the electrochemical processes underlying the ECM operation is essential to further progress. From research on ECM electrolytes carried out by LaBoda and co-workers, the use of solutions of $NaClO_3$ as a superior ECM electrolyte was published (5).

It was soon realized (6-9) that the nature of the anodic films formed on the workpiece metal by contact with the given electrolyte profoundly affected the quality of the finished product. Because there is a limit to the number of single-salt electrolytes available for use in an ECM operation, interest was generated in the possible modification of the electrolyte properties by investigating the ECM behavior of mixed electrolytes.

If the film formed is too highly protective such as that formed in chromate-based electrolytes, little or no ECM takes place (9). If, however, a poorly protective film is formed such as that produced in chloride-based electrolytes, stray cutting impairs the integrity of the workpiece. By mixing electrolytes, it may be possible to form protective films on the metal surface with the most desirable properties of high metal removal rate with good control of geometry and dimensions. Nitrate-based electrolytes form protective films on iron and steel, and the ClO_4^- ion is known (9a) to be a good dissolver of films formed on iron. It is thought that electrolytes composed of mixtures of NO_3^- and ClO_4^- ions may possess the properties of a good ECM electrolyte.

It is the purpose of this report to describe the results of an investigation of the anodic corrosion of mild steel in mixtures of solutions of $NaNO_3$ and $NaClO_4$ as a function of the composition of the electrolyte and the potential. These results were compared with the actual machining of steel bushings in a through-hole, sizing-and-finishing, ECM test rig as a function of solution flow rate and applied voltage as well as electrolyte composition.

Experimental

Polarization Studies

Steady-state, anodic potentiostatic polarization curves were obtained on mild steel wire electrodes which had been abraded with fine emery cloth, degreased in benzene, washed in acetone, rinsed in distilled water, and embedded in polyethylene so that a measurable length of wire was exposed. Three such electrodes to be used as checks were sealed in one compartment of a dual Teflon cell (10), and a probe-type, saturated calomel electrode (SCE) was placed in the other compartment connected by a glass frit. To minimize the effects of mass transfer, the solutions were stirred with purified O_2 at a rate of about 200 to 300 cm^3/min. Stock solutions, 3M in $NaNO_3$ and 3M in $NaClO_4$, were made from reagent grade chemicals in triply distilled water so that all mixtures contained a total anion concentration of 3M.

When the output of the Wenking 61R potentiostat had come to a steady value, as noted on a strip recorder driven by a Keithley Model 600A electrometer, the potentiostat was removed from the circuit by a mechanical switch and a constant current cathodic stripping pulse was applied to the steel wire anode by means of a mercury-wetted relay (11). The resulting transient was displayed on a Tektronix 541 oscilloscope and recorded photographically. From a determination of the transition times (12) associated with the arrests on the transients and from the known value of the constant current applied, it was possible to determine the amount of charge, Q, associated with the film adsorbed on the steel wire surface at the potential held by the potentiostat (7). In this way, the amount of charge associated with the film could be determined for each point on the anodic polarization curve. The temperature at which these experiments were carried out was $24° \pm 1°C$.

Current Efficiency Studies

The ends of mild steel tubes were machined at constant current in the fixed-cathode, ECM test rig in the closed system described in detail elsewhere (8, 13) to carry out mass-balance and current efficiency determinations. The gases evolved in the process were passed through a series of traps designed to give quantitative analyses for H_2 and O_2 liberated (13). The chemical analyses of the electrolytes and the sludges were carried out in the Chemistry Department of Research Laboratories, General Motors Corporation. Calculations of current efficiencies for iron removal were based on the two-electron dissolution of iron to ferrous ion, and the Type 1020 steel was assumed to be 100% iron. When NO_3^- ion is present in the electrolyte, the NO_3^- ion is reduced at the cathode to form NH_3, NO_2^- ion, and NH_2OH (13) instead of the evolution of H_2. In this case, the NH_3 was absorbed in a trap containing 20% H_2SO_4 solution.

Through-Hole ECM Studies

To assess the metal removal rate and the quality of the surface finish as a function of electrolyte composition and flow rate, mild steel (Type 1020) and fully hardened steel (Type 5160H) bushings were machined in a through-hole ECM test rig described before (5). In this device, the anodic bushing is clamped in place so that the Elkonite (Cu-W) rod cathode extended about halfway into the bushing. After the electrolyte flow rate had been set at the desired value, either 1.5 or 4.5 gpm (electrolyte was pumped from the bottom of the fixture through the gap between the anode and cathode and out of the top of the cell), and the desired applied cell voltage had been set, the inside wall of the bushing was machined for 30 sec. The amount of metal removed was determined from the increase in the ID of the bushing with a bore gauge. In this way, only the desired metal removal in the high current density region is determined, and unwanted stray metal removal in the low current density region is eliminated from the measurements. The quality of the surface finish as well as the profile of the bore was obtained by means of a Proficorder.

Results

Polarization Studies

Steady-state polarization curves obtained on mild steel anodes in mixtures of $NaNO_3$ and $NaClO_4$ for the following compositions expressed in terms of per cent NO_3^- ion 100, 90, 84, 67, 50, 33, 10, and 0 are presented in Fig. 1, and the amount of charge, Q, in millicuries/apparent square inch associated with film stripped from the electrode for each point on the polarization curves is plotted in Fig. 2. A roughness factor of 10 was used in the calculation of apparent area, using the geometric dimensions of the wire anode.

As ClO_4^- ion is added to pure NO_3^- ion solutions, the current in the passive region becomes smaller, and the film thickens with ClO_4^- ion concentrations up to about 16%. Also, the transition from the passive to the transpassive regions becomes sharper. When the NO_3^- ion concentration falls below 84% NO_3^- ion, the transpassive region appears at less noble values with increasing ClO_4^- ion concentrations until a minimum potential is reached at 67% ClO_4^- ion. Afterwards, the transpassive region appears at more noble potentials again with further increases of ClO_4^- ion. It was found (Fig. 2) that for all solutions below 90% NO_3^- ion, a potential is reached where all trace of the surface film disappears. This potential is a function of the composition of the electrolyte and is in direct correlation with the potential at which the transpassive region begins as shown in Fig. 3. Here, the potential at which the transpassive region begins (circles) and the potential at which a surface film can no longer be detected (triangles) are plotted as a function of per cent ClO_4^- ion.

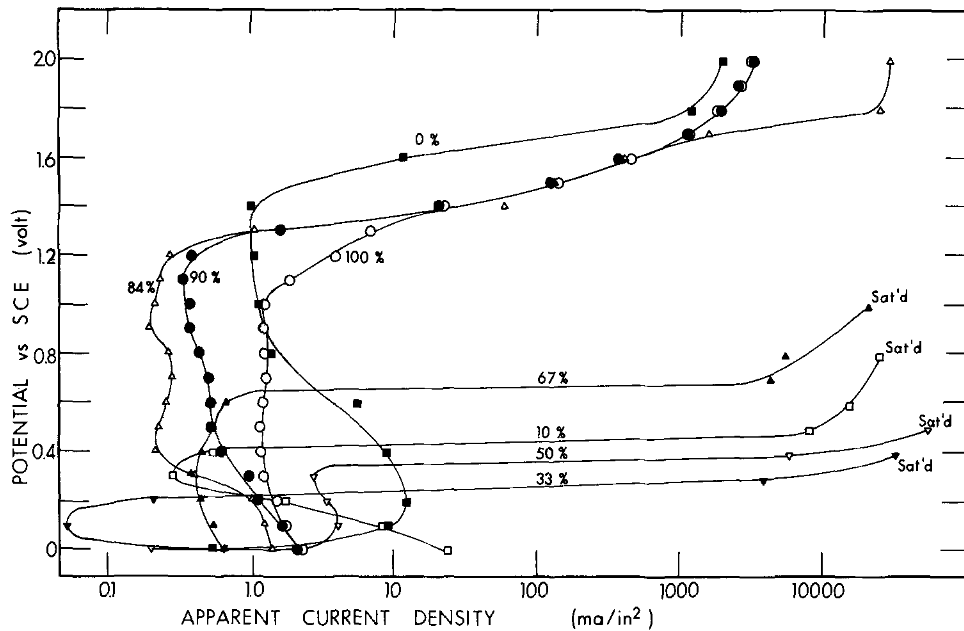

Fig. 1. Steady-state potentiostatic polarization curves obtained on mild steel wire anodes in 3M solutions of mixtures of $NaNO_3$ and $NaClO_4$. The per cent $NaNO_3$ is indicated on the respective curve. The point at which the potentiostat loses control (potential cannot be raised further, current determined by resistance of the cell) is noted by "Sat'd."

The upturning of the curves in Fig. 1 toward a limiting current at the highest current densities investigated is due to mass transfer effects since these points are stirring-dependent. For those curves where the transpassive region lies below 1000 mV such high currents are drawn that the current becomes limited by the resistance of the cell, and the potentiostat loses control. This situation is indicated on Fig. 1 by the notation "Sat'd" (saturated). This saturation current had a value of about 30 A/in.^{2}.

Consider, for example, the 67% NO_3^- ion curve in Fig. 1. When the potential was raised from 600 to 700 mV, the current shifted four orders of magnitude to the saturation value in about 100 to 200 sec, which indicated that once a threshold potential was reached it required a certain amount of time to remove the film. If, now, the potential was lowered below 400 mV, the potentiostat would regain control and the polarization curve could be retraced down to 0V.

Current Efficiency Studies

The results of the machining of mild steel tube ends in electrolytes composed of mixtures of NO_3^- and ClO_4^- ions expressed in terms of the current efficiency for metal removal as a function of electrolyte composition and applied current density are given in Table I. The appearance of the machined tube ends is shown in Fig. 4.

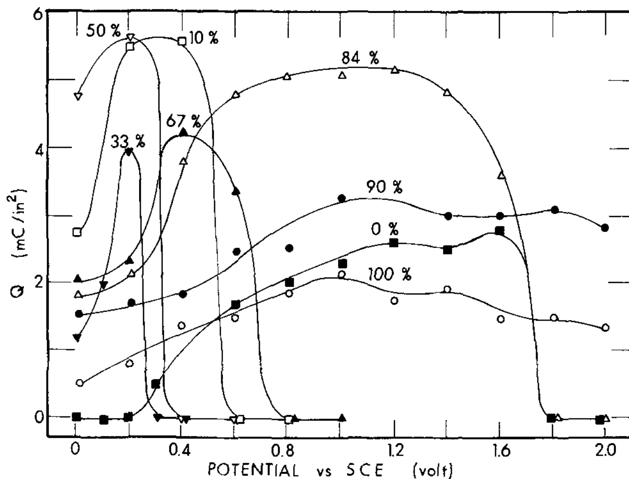

Fig. 2. The amount of charge, Q, per apparent square inch associated with the surface film present at each point of the polarization curve in Fig. 1.

The fact that the current efficiency for O_2 evolution is so large in pure $NaNO_3$ solutions gives evidence that the protective film formed on steel is electronically conducting. The actual metal removal is very low, thus accounting for the observation that in the ECM process using $NaNO_3$ electrolytes, metal removal is slower than that in NaCl or $NaClO_3$ solutions. In pure $NaClO_4$ solutions some current is used in the evolution of O_2, but in the mixtures of $NaNO_3$ and $NaClO_4$ all the anodic current is used in the metal removal process.

The formation of NH_3 at the cathode in the $NaNO_3$ electrolyte changes the pH of the electrolyte from the initial value of 6 to a final steady value of 11. In pure $NaClO_4$ solutions the final steady pH value of the ECM electrolyte is about 9, which agrees well with the pH value of a saturated solution of $Fe(OH)_2$. It may be noted that the color of the sludge in $NaClO_4$ elec-

Table I. Current efficiency for metal removal in ECM of Type 1020 steel

Composition of electrolyte	Apparent current density (A/in.²)	Current eff. for O_2 evol. (%)	Current eff. for Fe removal (%)	Iron removal (Mole)	Final pH
3M $NaClO_4$	300	6	90	0.0327	9
2.5M $NaClO_4$ + 0.5M $NaNO_3$	240	—	97	—	11
2M $NaClO_4$ + 1M $NaNO_3$	240	0	100	—	11
1.5M $NaClO_4$ + 1.5M $NaNO_3$	300	0	112*	—	11
1M $NaClO_4$ + 2M $NaNO_3$	300	0	112*	0.0406	11
0.5M $NaClO_4$ + 2.5M $NaNO_3$	300	0	106*	—	11
0.3M $NaClO_4$ + 2.7M $NaNO_3$	300	—	82	—	11
4.5M $NaNO_3$	300	56	33	0.0120	11
2M $NaNO_3$	300	85	12	0.00418	11
4.5M $NaClO_3$	300	25	79	0.0285	6
2.0M $NaClO_3$	300	38	63	0.0230	6

* During metal corrosion, severe grain boundary attack may account for apparent efficiencies greater than 100%.

trolyte, as well as in the NO_3^--ClO_4^- mixtures, is greenish black.

An interesting point in Fig. 4 is the brightening of the lip of the tube machined in the mixed electrolyte.

Through-Hole ECM Studies

After machining in the through-hole ECM device, the steel bushings were cut open. The hardened steel (Type 5160H) bushings are pictured in Fig. 5 and Proficorder tracings are displayed in Fig. 6. Since the cathode extended only about halfway into the bushing, only about one-half of the bushing is machined. The area machined is referred to as the high current density (hcd) region; beyond this area is the low current density (lcd) region.

In pure $NaNO_3$, the steel surface is relatively poor and covered with a black film. In pure $NaClO_4$, the surface in the hcd region is smooth and somewhat bright, and its quality is improved at higher potentials and lower flow rates. This observation is different from that obtained in $NaClO_3$ where the surface brightness is virtually independent of the flow rate. Another difference between the $NaClO_4$ and $NaClO_3$ solutions is found in the lcd region. Whereas pitting is found in the lcd region in $NaClO_4$, no attack in the lcd region is observed in $NaClO_3$.

The results obtained in the mixed electrolytes is very dependent on the flow rate. At high flow rates, no brightening is obtained [Fig. 5(G)]; but as the flow rate is lowered, the amount of brightening is increased [Fig. 5(H)]. In general, the best results are obtained at high applied voltage and low flow rate. There is a difference in the kind of brightening one obtains in mixed electrolytes [Fig. 5(F)] as compared with that obtained in $NaClO_3$ [Fig. 5(C)]. The surface machined in $NaClO_3$ seems to be more mirror bright. The metal removal rate in the mixed electrolytes is higher than that in other electrolytes for the same operating conditions (Tables I, II), and the black film characteristic of iron in nitrate electrolytes is found in the lcd region even though the surface in the hcd region is bright.

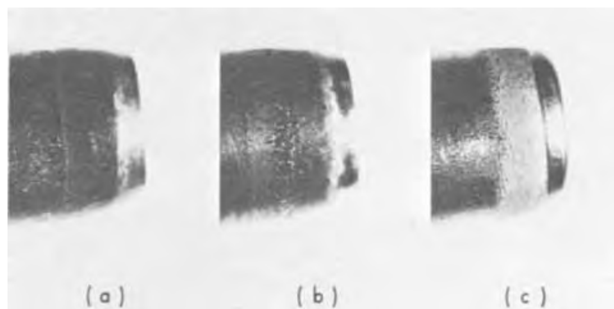

Fig. 4. Photomicrographs of mild steel tube ends which had been machined in 50% $NaNO_3$ (a), 66.7% $NaNO_3$ (b), and 100% $NaClO_3$ (4.5M) (c) at 300 A/in². Note reflectance and evenness of cut on lip of tube ends.

A summary of the through-hole cuts of the steel bushings is given in Table II. The results of both the polarization studies and the ECM studies indicate that similar behavior is obtained on both mild and fully hardened steel.

Discussion

The $NaNO_3$ Electrolyte

The steady-state polarization curve for mild steel in pure $NaNO_3$ electrolyte (open circles in Fig. 1) exhibits more of a limiting current region than a passive region, although relatively thick films are present on the surface as noted by the data (open circles in Fig. 2). Such behavior could be explained if the film were electronically conducting. In this case, the double layer would extend from the solution side of the film into the solution so that one would expect that anodic current would be consumed by the discharge of a chemical

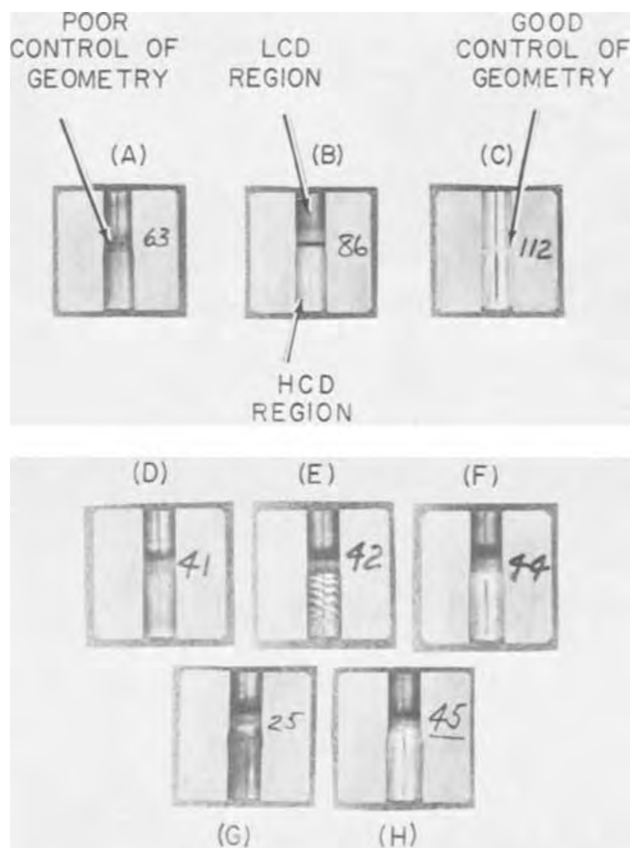

Fig. 5. Photographs of fully hardened steel bushings cut open to show quality of the metal removal operation for samples machined for 30 sec in $NaNO_3$ (A), $NaClO_4$ (B), $NaClO_3$ (C), 1M $NaClO_4$ + 2M $NaNO_3$ (D)-(G); applied cell voltage is 20V (A)-(C), 10V (D), 15V (E), 25V (F), 30V (G), (H); solution flow rate is 1.5 gpm (A)-(F) and (H), 4.5 gpm (G).

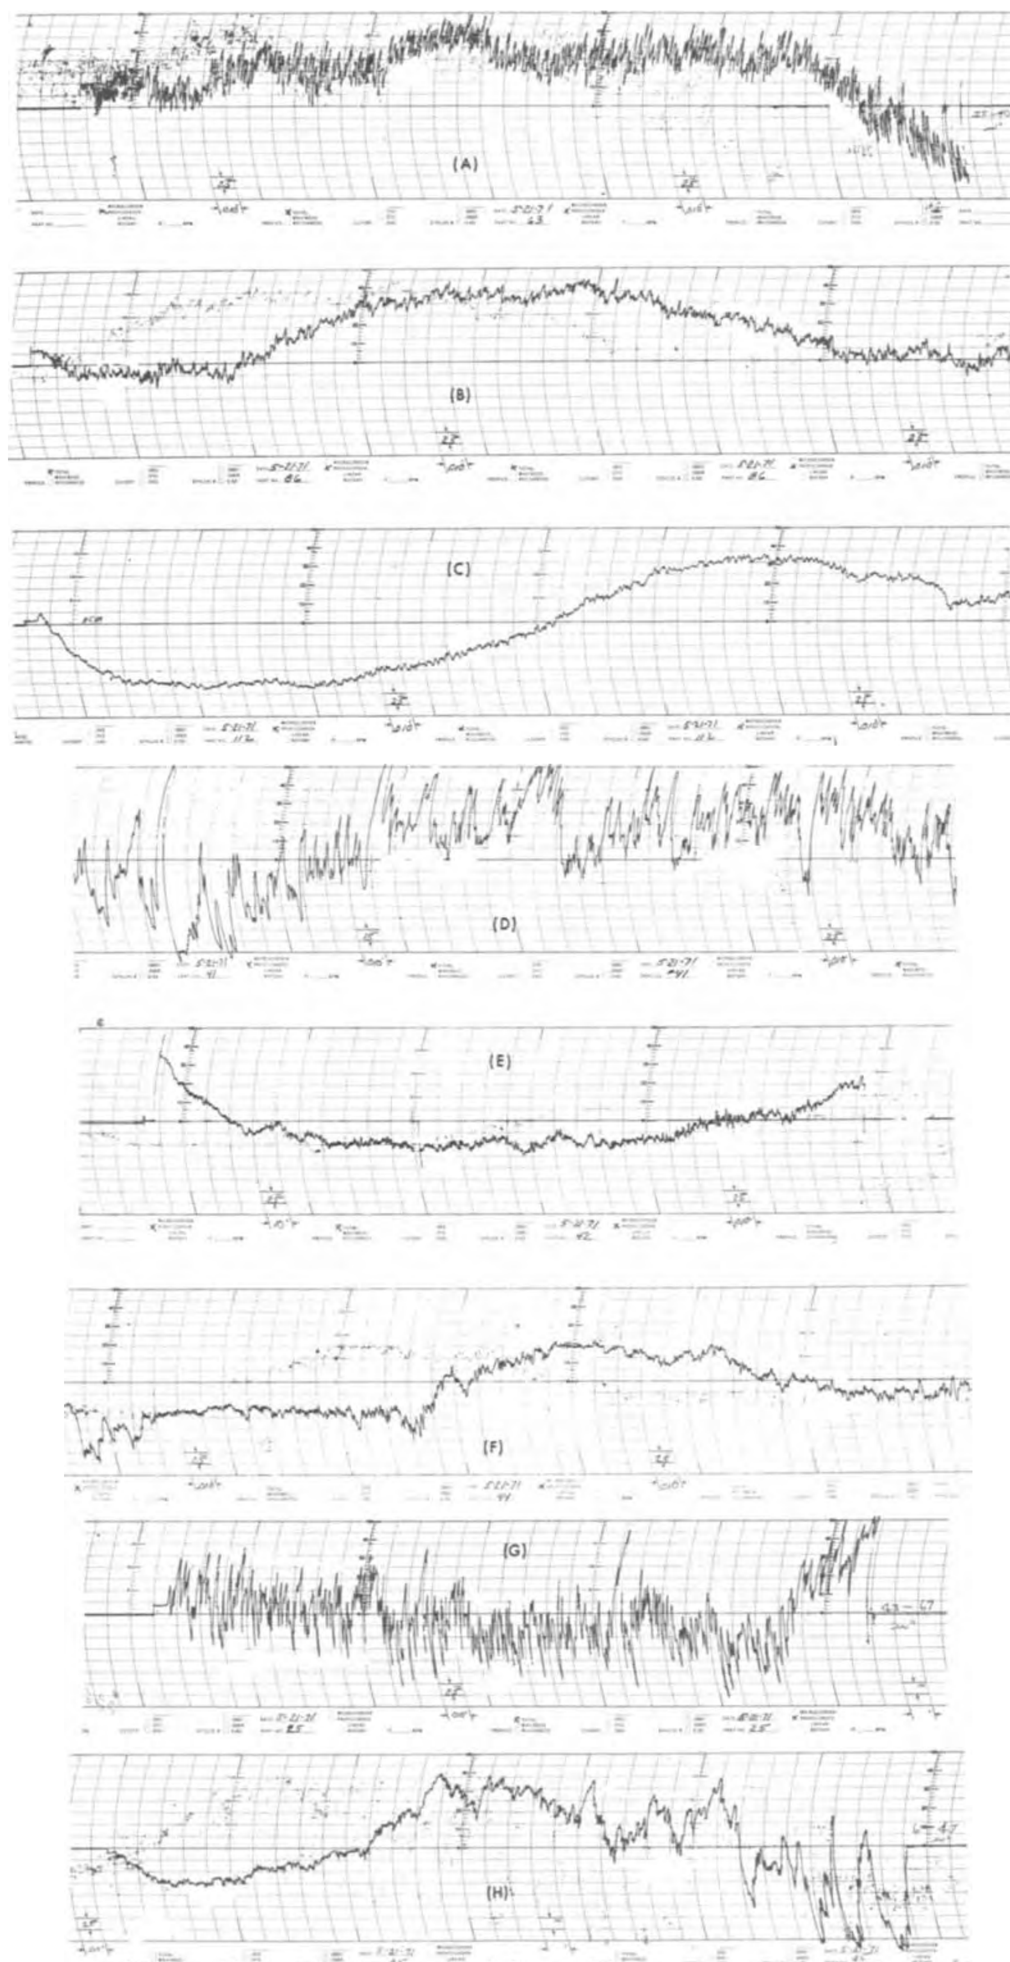

Fig. 6. Proficorder traces of the machined surface for each sample shown in Fig. 5. As one progresses up the bore as shown in Fig. 5, the trace is read from right to left, each unit being 0.01 in. On the y-axis, the scale is given in μin. The RMS value of surface roughness reported in Table II is estimated from the trace by taking 1/3 of the peak-to-peak value.

* It is to be noted that the metal removal rate in pure $NaNO_3$ electrolyte is much higher in Table II than that observed previously (13) or in the current efficiency studies (Table I) of this work. It is possible that interfering amounts of $NaClO_4$ or $NaClO_3$ were occluded in the pumping system of the through-hole machine from previous runs and were later leached out into $NaNO_3$ electrolyte producing the anomalously high metal removal rate.

entity present in solution rather than by the dissolution of the metal lattice of the anode.

This conclusion is supported by the current efficiency studies (Table I), where it is seen that nearly all the current (85%) is consumed in the evolution of oxygen with only about 12% used in metal dissolution. Additional evidence in favor of the conducting film concept is the fact that a black smut or film is always obtained on steel surfaces machined in $NaNO_3$ solutions. Such a black film is evidence for the formation of Fe_3O_4. It has been found (14) that ferrous hydroxide can be oxidized chemically by the nitrate ion, but in all cases Fe_3O_4 was the resultant product. The presence of the electronically conducting protective film on steel in $NaNO_3$ solutions accounts for the slower metal removal obtained for the machining of steel in this electrolyte as compared with NaCl or $NaClO_3$ solutions under similar conditions.

Even at the high potentials in the transpassive region (see Fig. 1 and 2), the film on steel in $NaNO_3$ solution is not greatly reduced in thickness. As noted by Hoar (15, 16), a thin compact film is required to give an electropolishing of the surface so that one does not expect a brightening of the steel surface machined in $NaNO_3$ solutions due to the presence of the thick conducting film of Fe_3O_4. The surface of the bushings machined in $NaNO_3$ [Fig. 5(A) and 6(A); Table II)] is relatively poor.

The $NaClO_4$ Electrolyte

In pure $NaClO_4$ solutions, the polarization curve for steel (filled squares in Fig. 1) has a sharp transition from the passive to the transpassive state. This property of the system, it has been suggested (6-10), is responsible for the good control of geometry and dimensions obtained in the machining of steel in such an electrolyte because the hcd region of the machined piece is associated with the transpassive region of the polarization curve and the lcd region with the passive region. It has been observed from rotating disk studies (17) that the critical current at the point where the transition from the active to the passive region takes place is a function of the stirring rate of the solution. As the stirring rate increases, the critical point is shifted to more noble potentials. Such behavior is characteristic of a salt film, the thickness of which may be reduced by increased agitation. With increasing potential, a point is reached where a more compact film is formed by precipitation of a salt from the salt film onto the metal surface followed by conversion of the salt to the more protecting oxide-type film. The relatively slow buildup of the protective film (Fig. 2) accompanied by the gradual onset of passivity (Fig. 1) is in agreement with this interpretation. Finally a potential is reached above which the film becomes unstable and can no longer be detected on the anode surface.

This behavior is different from that reported (7, 9) for steel in $NaClO_3$ solutions where a compact oxide film is formed quickly and independently of the rate of solution stirring (18). In the transpassive region some oxide film may still be detected which is believed (8) to be responsible for the brightening and good surface finishes obtained on steel with $NaClO_3$ electrolytes. Since the film formed in $NaClO_4$ is not so compact, it is expected that the quality of the surface finish obtained on steel in $NaClO_4$ will not be as good as that in $NaClO_3$. In Fig. 5 and 6 it is seen that the surfaces of the bushings machined in $NaClO_4$ [Fig. 5(B)] are not as bright as those machined in $NaClO_3$ [Fig. 5(C)] in the hcd region for a given set of conditions and there is an area of pitting in the lcd region. For high potentials and low flow rates the surface finish of the bushings machined in $NaClO_4$ approaches that in $NaClO_3$ [Fig. 6(B) and 6(C)].

Mixed $NaNO_3/NaClO_4$ Electrolytes

Consider now the data for mixed electrolytes. As $NaClO_4$ concentration is increased in the series of mixed electrolytes, the film formed on the steel surface becomes less and less electronically conducting as noted by the decreasing value of the current in the passive region for 90% and 84% NO_3^- ion solution in Fig. 1 and by the increase in the current efficiency for metal removal in Table I. For concentrations of NO_3^- less than 85%, a potential may be reached where the presence of the adsorbed film can no longer be detected (Fig. 2), and the potential is shifted to less noble values as the ClO_4^- ion concentration is increased until a minimum value is reached at about 33% NO_3^- ion. As a consequence, the transpassive region appears at less noble values in correspondence with the disappearance of the surface film as noted in Fig. 3. With further increases in the ClO_4^- ion concentration, the

potential above which surface films are not observed is shifted once more to more noble values. Current efficiencies for metal removal equal 100% (see Table I) for these solutions which is to be expected if adsorbed films are absent.

These data suggest that the metal removal rate for steel in $NaNO_3/NaClO_4$ mixtures with NO_3^- ion concentrations between 70 and 10% should be higher than in any other electrolyte studied so far for a given set of conditions. Since the transpassive region for these mixtures lies at such low potentials, good dimensional control of the machining of steel in such mixtures is not expected. These predictions were confirmed by the machining of the bushings. As observed in Fig. 5, more metal was removed (Table II), but the region of wild cutting (metal removal in the lcd region) was greater in the mixtures [Fig. 5(E) and (F)] than in $NaClO_3$ [Fig. 5(C)].

When the bushings were machined in the mixed electrolytes at high flow rates (4.5 gpm), the machined surfaces were dark [Fig. 5(G)] and relatively rough [Fig. 6(G)], but when the flow rate was lowered to 1.5 gpm, the surface became smoother [Fig. 6(H)]. At this low flow rate, the surface became brighter as the applied voltage was raised from 5 to 30V until, at this highest voltage, the surface was highly reflecting.

Brightening of the surface, then, can take place by at least two different mechanisms. In one case where a thin uniform porous oxide film is formed on the steel surface in an electrolyte such as $NaClO_3$ (8), electropolishing occurs virtually independently of the flow rate (19) and takes place by the mechanism suggested by Hoar (15, 16, 20).

In the absence of adsorbed oxide films, metal may be dissolved rapidly, forming a thick salt layer next to the metal surface. When the concentration of salt becomes high enough, a salt film may be precipitated onto the surface; and if the potential is high enough, the salt film may be converted to a thin oxide film. Under these conditions electropolishing can take place. If, however, the flow rate is high, the salt concentration in the salt layer cannot reach a value high enough to precipitate a salt film on the metal surface; and if the applied potential is too low, the thin oxide film necessary for electropolishing cannot be formed. Thus, polishing of the machined surface in the presence of salt films is highly dependent on the applied potential and the solution flow rate as observed in the machining of steel bushings in the $NaNO_3/NaClO_4$ mixed electrolytes [Fig. 5(D)-5(H)]. Because the films formed from salt layers are not as compact or protecting as those formed by a passivating electrolyte such as $NaClO_3$, pitting of the surface in the lcd region usually occurs and the dimensional control is not as good in the mixed electrolytes as in $NaClO_3$ solutions. An advantage, however, of the mixed NO_3^--based electrolytes is the ability to ECM steel at high metal removal rates with little or no evolution of H_2.

Anion Effects and the Ion-Exchange Model of Anodic Films on Iron

From these studies it becomes a matter of concern how these adsorbed anodic films become unstable and dissolve in the transpassive region. It appears that this phenomenon may be associated with the type of anion present in solution (20). For a small anion such as Cl^- ion, it may be possible for this ion to penetrate the pores of the film (21), causing a breakdown of the film particularly since the Cl^- ion easily forms soluble complexes with iron (22).

It has been pointed out (9a, 23, 24) that the ClO_4^- ion is as good as Cl^- ion, or better in some cases, as an aggressive agent for the breakdown of iron oxide films. Because the ClO_4^- ion is much larger than the Cl^- ion, it is difficult to see how such an anion can penetrate the oxide film lattice or be such an efficient agent for film dissolution.

A possible mechanism called the mechanical mechanism has been suggested by Hoar (21) to account for the ClO_4^- activity. According to this scheme, the anions are adsorbed on the surface of the oxide film; and with increasing potential, more and more anions become adsorbed. The repulsive forces between the adsorbed anions can reach a point where the film may be ruptured at weak spots caused by dislocations, inclusions, *etc.* On the new surface caused by this rupture, more anions can be adsorbed causing a further rupture of the film and exposure of the underlying metal to attack. It may be possible that the exceptional ability of the ClO_4^- ion to dissolve iron oxide films in the transpassive region may be attributed to the symmetrical, nonpolarizable nature of the ion (25, 26). Such behavior may lead to weak chemical bonding.

The only really protective film is one that is electronically conducting (24); but for anodic brightening, the adsorbed film must be a good ionic conductor. Hoar (24) reasoned that the passive films on metal anodes cannot merely be composed of the metal oxides. He speaks of a "contaminated" film in which anions and water molecules are occluded in the oxide layer. In this way the ionic conductivity of the film is increased to the extent that metal ions may pass easily through the film producing a brightening of the surface. It has been suggested (27) that the protective film formed on steel in these neutral-salt electrolytes may have properties similar to an ion exchange membrane.

With these ideas in mind and from analyses of the data obtained on steel anodes in $NaNO_3/NaClO_4$ mixed electrolytes, we conclude that the structure of these anodic films most likely takes the form of a matrix-type honeycomb in which water molecules and anions reside in the interstices. It is proposed that the material of the matrix network is composed of iron and oxygen atoms with the stoichiometry, but not necessarily the properties, of bulk iron oxide.

When Cl^- ions are present, soluble complexes are made with the iron ions so that the matrix of iron oxide units cannot be formed. This accounts for the fact that protective films are not formed on steel in NaCl electrolytes (7, 9).

In $NaNO_3$ solutions, black films of Fe_3O_4 are formed on the steel surface. Such a film is likely to be a ferrous ferrite, $Fe(FeO_2)_2$ which is a good electronic conductor (28). The matrix of the protective film is composed then of ferrous ferrite units, and the electronically conducting network is truly protective so that the current is consumed by the discharge of a chemical species in solution on the surface of the adsorbed film as observed experimentally (discharge of H_2O to O_2 evolution, Table I).

A compact film of γ-Fe_2O_3 is formed on the steel surface in solutions of chromates (29, 30), carbonates (31), phosphates (32), and chlorates (18). On the steel surface in these electrolytes, the matrix network is made up of the poorly conducting Fe_2O_3 units by the strong oxidizing power of these anions. Any current that flows in the passive region is accounted for by whatever ferrous ions can migrate through the interstices of the Fe_2O_3 network.

Once the oxide matrix is formed on the passivated steel surface by well-known methods (33, 34) of film nucleation and growth, anions may be adsorbed not only on the external but also the internal surfaces of the network by exchanging with adsorbed water. The presence of these adsorbed anions can increase the ionic conductivity of the adsorbed film (24). Although the concentration of adsorbed anions increases with potential (36), it is suggested that at high enough potentials these adsorbed anions can exchange with the oxygen ions of the iron oxide matrix. Eventually, a point is reached where so many oxide sites are replaced with anions from solution that the matrix breaks down and dissolves. It may be expected that the concentration of replaced oxide sites would be greatest at the solution side of the adsorbed film (36). This viewpoint would account for the thinning of the passivating film

observed (7) in the transpassive region for steel in chromate, nitrate, and chlorate electrolytes.

This ion-replacement model can also explain the effect of concentration of the electrolyte on the metal removal rate. Not only was it observed in this work but also in previous studies (9, 13, 37) that the metal removal rate, as well as the current efficiency, increased with increasing concentration of $NaNO_3$ or $NaClO_3$ electrolytes. With increasing concentration, more anions can be adsorbed on the surface of the film for a given potential causing the film to be thinned quicker, besides increasing its ionic conductivity. This effect, in turn, produces a lowering of the transition region of the polarization curve (37) and an increase in the rate of metal removal as well as current efficiency at the given potential.

The more difficult it is for a given anion to replace an oxide ion in the matrix of the passive film, the higher will be the potential at which the transpassive region will appear. Since the transpassive region lies at higher potentials on steel in $Na_2Cr_2O_7$ than in $NaClO_3$ solutions (7), it is concluded that chromate ions exchange with more difficulty than chlorate ions. It may be possible that the presence of dislocations or inclusions may make one part of the matrix more susceptible to anion exchange and an uneven removal of the film could take place.

In the case of solutions of $NaClO_4$, a compact film of Fe_2O_3 units is not built up on the steel surface at low anodic potentials since the ClO_4^- is a weak oxidizing agent (26). As a result, a salt film is formed, [see *e.g.* (35)], and at a high enough potential, the layer of ferrous perchlorate precipitated out on the steel surface is oxidized to a passivating oxide film similar to that formed on steel in $NaClO_3$ solutions. With further increases in potential, the adsorbed ClO_4^- ions can exchange with the oxide ions of the Fe_2O_3 matrix causing the oxide film to disintegrate. It appears that the film is completely removed when the ClO_4^- ion is the chemical species which is exchanged. Possibly because of the highly symmetrical structure of the ClO_4^- ion, the oxide matrix with substituted ClO_4^- units is more soluble than that with ClO_3^- units.

In electrolytes where both NO_3^- and ClO_4^- ions are present at a steel anode at low potentials, the NO_3^- ions can form a passivating ferrous ferrite film on the steel surface. The symmetrical ClO_4^- ions can adsorb more easily on the conducting Fe_3O_4 surface than on the poorly conducting Fe_2O_3 surface; but since ClO_4^- is in competition with NO_3^- for adsorption sites, a threshold concentration must be reached before the effect of ClO_4^- ion addition can be observed. With increasing addition of ClO_4^- ion to a $NaNO_3$ solution above about 15% ClO_4^- ion, the adsorbed ClO_4^- ions can exchange with the ferrous ferrite units of the oxide matrix at increasingly less noble potentials with the consequent dissolution of the protective film and lowering of the potential of the transpassive region to less noble values.

Further increases in ClO_4^- ion beyond the maximum lowering of the transpassive region at about 70% ClO_4^- ion impairs the electronic conductivity by contaminating the ferrous ferrite film with ClO_4^- salt films or Fe_2O_3 units and hence impairs the ability of ClO_4^- ion to adsorb on the surface of the passive film. Consequently, the transpassive region appears at more noble potentials again at very high concentrations of ClO_4^- ion. With complete destruction of the protecting films on steel in mixtures of NO_3^- and ClO_4^- ions, the very high metal removal rates observed in this work may be accounted for.

The breakup of the protective film on the steel surface in the mixed electrolyte with increasing potential can be observed in the series of photographs, Fig. 5(D)-5(F). At low applied voltage, the surface is covered with the black ferrous ferrite film in Fig. 5(D), the surface is very rough [Fig. 6(D)], and a small amount of metal is removed (see Table II). The breakup of the film is seen in Fig. 5(E) by noting the patterns of light and dark bands. Corresponding undulations of the Proficorder trace can be detected in Fig. 6(E). At high enough potentials, in Fig. 5(F), the film is removed; and at the low flow rate and high metal removal rate, a salt film produces a brightening of the surface.

Because brightening of the steel surface is caused by the salt film as described in the previous section, the process is very dependent on the electrolyte flow pattern as observed in Fig. 6(H) as well as on the flow rate [see Fig. 6(G) and 6(H)]. At the entrance to the bushing [extreme right-hand side of Fig 6(H)], the turbulence of the solution is great and the structure of the salt film is highly disorganized. This situation produces a high degree of surface roughness (47 μin., Table II). As the electrolyte progresses upward along the channel [from right to left in Fig. 6(H)], the flow pattern becomes more regular and the structure of the salt film becomes more uniform with a resulting decrease in surface roughness (6 μin., Table II) and an increase in the reflectance of the surface.

Preparation and Properties of Pyrolysis of Vanadium Oxide Films

L. A. Ryabova, I. A. Serbinov, and A. S. Darevsky

Institute of Radio Engineering & Electronics, Academy of Science, Prospect Marx, 18, Moscow K-9, U.S.S.R.

ABSTRACT

Vanadium oxide films (V_2O_3, VO_2, V_2O_5) were obtained by the pyrolysis of vanadium acetylacetonate $(C_5H_7O_2)_4V$ in controlled atmosphere. The influence of deposition parameters on the film composition is studied. It was revealed that the composition of the gas carrier is the main factor determining the film composition. Electron diffraction and electron microscopy analysis of films are carried out. Temperature dependence of resistance was studied. VO_2 films deposited on glazed ceramic and sapphire change resistance by factor 10^3 at about 340°K. V_2O_5 films had an activated conductivity.

Currently, thin films and single crystals of vanadium oxides attracted attention of investigators due to the phase transitions in VO_2 and V_2O_3. Thin films and crystals were grown by the decomposition of $VOCl_3$ in controlled atmosphere (1, 2) and by the reactive sputtering using post deposition treatment (3).

This report concerns the preparation of thin films of V_2O_3, VO_2, V_2O_5 (thickness 600-10,000Å) by the pyrolysis method and investigation of their properties.

Pyrolysis makes it possible to prepare any of these oxides by the thermal decomposition of vanadium acetylacetonate in the corresponding atmosphere. This method was chosen because of: (*i*) the simplicity of the equipment, (*ii*) the few parameters to be controlled in the process, and (*iii*) the high reproducibility of film properties.

Experimental

Acetylacetonates of 4-valent vanadium $(C_5H_7O_2)_4V$ were used as the initial substance. Films were deposited on the substrates of various materials by the thermal decomposition of vanadium acetylacetonate in vacuum and in the flow of the gas carrier by the reaction

$$(C_5H_7O_2)_4V \xrightarrow{\text{heat}} VO_x + \text{gases}$$

The composition of vanadium oxide films changed in dependence on the composition of the reaction medium.

The technique of the film preparation is the same as described in Ref. (4). In the process of film preparation in vacuum, in the absence of foreign gases, films consisting of a mixture of stoichiometric and intermediate oxides are formed. The temperature dependence of the resistivity did not have the sharp transition as did single crystals of stoichiometric VO_2 and V_2O_3. VO_2 films with the resistivity change by a factor of 10^2 at 60° were obtained by introducing oxygen (oxygen pressure 10^{-2}-10^{-1} Torr) during the pyrolysis process in vacuum. Probably there was a small amount ($\sim$1%) of intermediate oxide. The composition and properties of these films were poorly reproduced. Increasing the oxygen amount (oxygen pressure, 10 Torr) leads to the formation of dense, uniform in thickness films of V_2O_5.

Successful deposition of V_2O_3, VO_2, and V_2O_5 films was finally effected by using a carrier gas flow of nitrogen or appropriate mixtures of nitrogen and oxygen.

Experimental equipment for film preparation in the gas flow is analogous to that described in Ref. (5). It consists of a 2-zone resistance oven where the reaction quartz tube is placed (diameter 50 mm, length 1000 mm). A quartz boat with vanadium acetylacetonate is placed at a distance of 200 mm from the substrates, which are placed on the quartz holder.

Glass, glazed ceramic, KCl, sapphire, muscovite mica, and single crystal quartz were used as substrates. The structure and phase control were carried out by means of electron diffraction and electron microscopy. Data on the phase analysis are given in Table I.

Experiments showed that the film composition and their properties mostly depend on the composition of the gas carrier.

V_2O_3 films are formed when the reaction is carried out in the flow of pure nitrogen. Films are smooth, dense; the grain size is about 1000Å. Polycrystalline films are formed on glazed ceramic (Fig. 1a). In the reflection diffraction pattern of this film there are three extra lines: $d = 3.07$Å, $d = 2.82$Å, $d = 1.37$Å (Table Ia). Probably these lines are of intermediate oxide. Single crystal films are formed on mica; the "c" axis is perpendicular to substrate plane (Fig. 1b). This figure shows that separate crystallites have a characteristic for hexagonal phase of V_2O_3 angle relations between planes. On the temperature dependence of the resistance of these films deposited on glazed ceramic and mica, there is no sharp transi-

tion at 150°K characteristic for V_2O_3 single crystals. Probably it is an evidence of the existence of the impurities of intermediate oxides (composition between V_2O_3 and VO_2).

It may be possible to prepare a pure V_2O_3 phase, either by choosing corresponding composition of gas carrier or by using as the initial substance acetylacetonate of 3-valent vanadium.

The temperature dependence of the resistance of films prepared in the flow $N_2/O_2 = 10/1$ is shown in Fig. 2. This figure shows that films on glazed ceramic and sapphire have a characteristic for VO_2 phase transition, the resistance changes with a factor 10^3. Resistance of the films obtained on mica slightly depends on the temperature (Fig. 2).

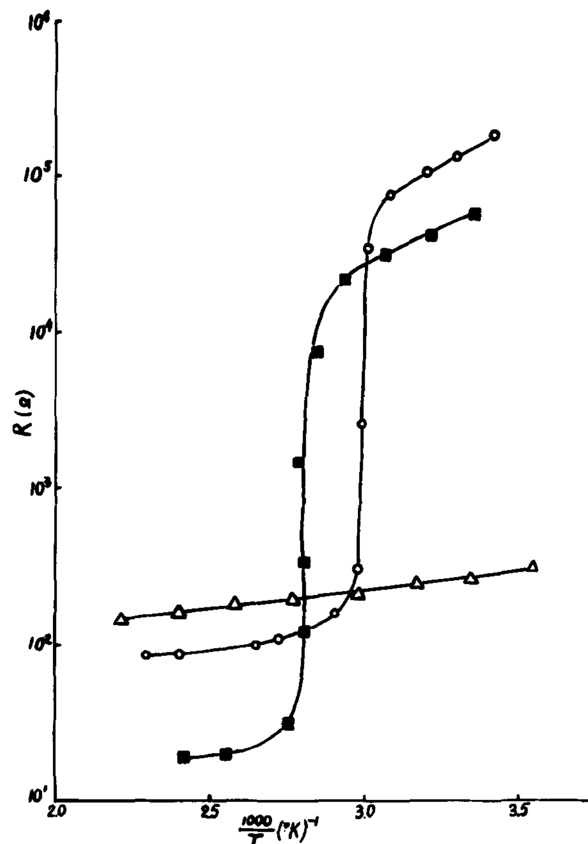

Fig. 2. Resistance vs. $1000/T(°K)^{-1}$ for VO_2 films deposited on glazed ceramics (○), sapphire (■), and mica (△).

In the process of film formation in the mixture of nitrogen and oxygen ($N_2/O_2 = 1/1$) polycrystalline textured films of V_2O_5 are formed (Table Ib). Resistance of these films in the temperature range from the room temperature to 200°C has an activated character with activation energy 0.1-0.2 eV. These films are needle-like with the "c" axis parallel to the substrate plane (Fig. 3a, b). Polycrystalline films of V_2O_5 are formed on the glazed ceramic. The grain size is about 2000Å (Fig. 3c). Highly oriented films with platelet crystallites of V_2O_5 are formed on mica (Fig. 3d, e). Data on electron diffraction analysis of polycrystalline V_2O_5 films are given in Table Ib. Optimum conditions of preparation of vanadium oxide films (dense, transparent, uniform in thickness) in the flow of gas are given in Table II.

Conclusions

Thin films of vanadium oxides (V_2O_3, VO_2, V_2O_5) are obtained by the pyrolysis method. The technique of film preparation is very simple. The composition of the gas carrier is the main factor determining the film composition.

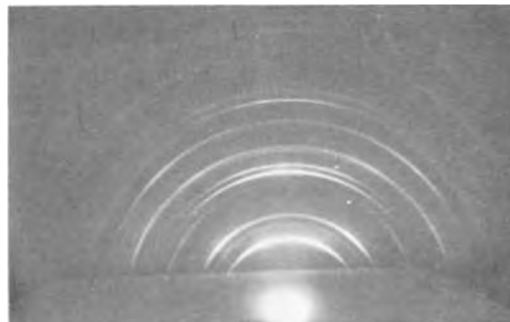

Fig. 3 (a). Reflection electron diffraction of V_2O_5 film deposited onto quartz.

Table II. Optimum conditions of the preparation of vanadium oxide films

Film composition	Composition of gas carrier N_2 flow rate ml/min	O_2 flow rate ml/min	Substrate temperature, °C
V_2O_3	500	—	420
VO_2	500	50	400
V_2O_5	500	500	340

Polycrystalline textured films are formed on unoriented substrates. Highly oriented and single crystal films are formed on oriented substrates.

The temperature dependence of the resistance of VO_2 films on glazed ceramic and sapphire have a transition by a factor 10^3. Phase transition is V_2O_3 films was not observed, probably because of nonstoichiometric composition of oxide.

Sputtered Manganese Dioxide as Counterelectrodes in Thin Film Capacitors

R. W. Landorf[1] and S. J. Licht

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Manganese dioxide films were sputtered with resistivities as low as 0.3 ohm-cm. Ta-Ta_2O_5-MnO_2-Metal (TMM) capacitors were fabricated and found to have dissipation factors of 0.008 at 1 kHz and 0.011 at 100 kHz. Leakage currents for the TMM capacitors were 10^{-9}A when measured at 75V (33% of the anodizing voltage). By chemically removing the sputtered MnO_2 from the capacitors and then replacing the counterelectrodes the effect of sputtering on the dielectric could be observed. It was found that rf + 2 kV d-c sputtering conditions increased the dielectric dissipation factor by $\leq$20% while the 3 kV d-c + rf conditions caused a 50% increase in the dielectric dissipation factor. The sputtered MnO_2 films were found to be γ-MnO_2 and showed a conduction activation energy of 0.10 eV ($\pm$0.01) for 3 kV d-c + rf and 2 kV d-c + rf indicating that similar material has been deposited under both sputtering conditions.

The use of manganese dioxide in thin film capacitors has been studied by McLean and Rosztoczy (1) and various techniques have been used to deposit the manganese dioxide films. These methods include pyrolytic spraying (1), electroless deposition (2), reactive evaporation (3), and reactive sputtering (4, 5). The results of these studies, in general, were: (*i*) MnO_2 is beneficial to thin film capacitor reliability and initial yield, (*ii*) the dissipation factor of the capacitors were an order of magnitude higher at 1 kHz than the equivalent Ta-Ta_2O_5-Metal (TM) capacitor, (*iii*) the dissipation factor became much higher at higher frequencies, and (*iv*) the resistivity of the MnO_2 was always >5 ohm-cm, if, in fact, MnO_2 was deposited.

The bulk of the work on Ta-Ta_2O_5-MnO_x-Metal (TMM) capacitors has involved only pyrolytically deposited MnO_x films of high resistivity ($\sim 10^3$ ohm-cm) and the purpose of this study was to investigate the properties of TMM capacitors with sputtered MnO_2 films. The effects of various sputtering conditions on dissipation losses in the dielectric, the effect of MnO_2 on the dissipation factor, and the effect of counterelectrode area were studied. In addition to capacitance measurements, capacitor yields, and leakage current measurements were made for comparison with TM capacitors.

Experimental

The manganese dioxide films were sputtered in a conventional, diffusion pumped vacuum system as shown in Fig. 1. The sputtering cathode was in two equal area sections so the rf supply could be operated in the push-pull mode. The rf supply was operated at 7.5 mHz for the present experiments with a constant 100W power input. The cathode-substrate separation was 6.3 cm. The cathode was 8 in. in diameter and made of electrodeposited Mn metal (99.5% Mn). Three 7050 glass slides were mounted on the substrate table for each run.

The substrates were 1 in. $\times$ 3 in. glass slides with the tantalum and the Ta_2O_5 dielectric predeposited on the slides. Details on the fabrication of the tantalum thin film capacitors are given elsewhere (6) and are only briefly mentioned here. Before sputtering the MnO_2 films, the tantalum was anodized to 170V, heat stabilized at 350°C for 1 hr, back-etched for 5 sec at 90V, and reanodized to 230V. Anodization was carried out in 0.01% citric acid at 25°C with a constant current density of 0.5 mA/cm².

Table I. Conditions investigated

Independent variables				Dependent variables		
D-C + rf	Pressure (μ)	D-C current drawn (mA)	Grid used	Substrate temp.	Deposition rate (Å/min)	ρ range (ohm-cm)
3 kV + rf	20	40-45	NO	207°C	17	0.2-5.0
2 kV + rf	20	0	NO	170°C	15	0.5-1.6
1.5 kV + rf	20	0	NO	150°C	23	0.4-0.6
3 kV + rf	20	45	+50V	140°C	4.3	>5
3 kV + rf	20	33	+5V	170°C	8.8	4.3-9.1
3 kV + rf	20	35	−25V	230°C	8.2	1.5-4.0
3 kV + rf	20	45	−100V	200°C	16	0.4-2.4

The deposition temperature was measured by a Pt-Pt 10% Rh thermocouple clamped to a glass substrate. Temperatures read in this manner were compared with temperature measurements made with a thin film Pt-Pt 10% Rh thermocouple. The thin film thermocouple measurements were found to read $\sim$30°C higher than the temperature measurements with the conventional thermocouple. The deposition temperatures reported in Table I were made with the conventional thermocouple.

Before each sputtering run the vacuum chamber was pumped to 1×10^{-6} Torr and given a mild (hot

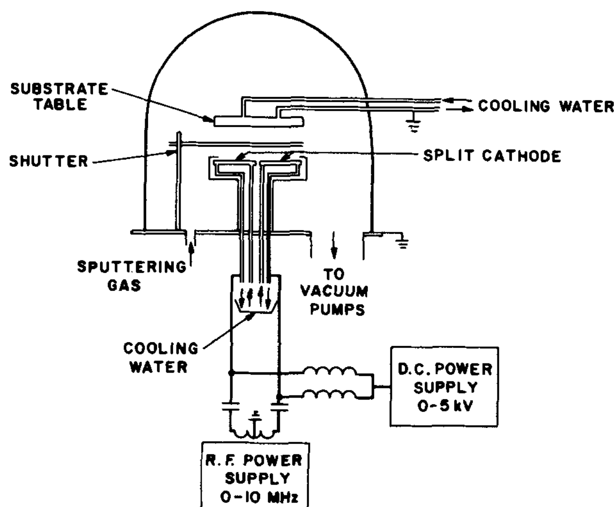

Fig. 1. Diagram of the sputtering system used in this experiment

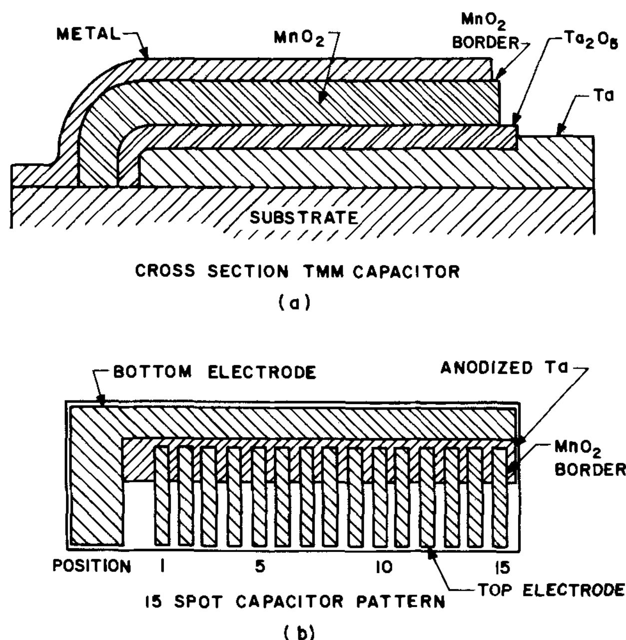

Fig. 2. (a). Shows the cross section of capacitor. (b). Shows the 15 spot capacitor pattern.

water) bake. A 15 min presputter in oxygen was completed before opening the shutter for deposition on the substrate. Manganese dioxide was then sputtered over the entire slide and nichrome-gold counterelectrodes were applied. The capacitor pattern, shown in Fig. 2b, was generated in two ways. First, evaporation of the counterelectrode through a mask was followed by photoetching and removal of the unwanted MnO_2. This technique left a 0.025 cm border of MnO_2 around the nichrome-gold counterelectrode. Second, the counterelectrode was evaporated over the entire slide and then the capacitor was defined by photoetching techniques that required the removal of nichrome-gold and MnO_2 from the unwanted areas. This method left no border around the nichrome-gold counterelectrode. Some undercutting of the counterelectrode took place with this method, but this effect was minimized by reducing the time in the etching solution.

The cross-sectional thicknesses of the capacitor, (TMM) as shown in Fig. 2a, were: Ta = 3500Å, Ta_2O_5 = 3600Å, MnO_2 can be chosen, nichrome-gold counterelectrode = 5000Å. The TM capacitors were made with the same thicknesses but without MnO_2; the TM capacitors were used as monitors throughout the experiments.

The experimental conditions for the deposition of MnO_2 films are given in Table I. The experiments which used a biasing grid had that grid placed 2.5 cm from the substrate table. Special emphasis was placed on the work at 2 kV + rf because there was some indication that these conditions were the best conditions of those studied here.

The TMM capacitors were measured for leakage current at 75V; capacitance and dissipation factor were measured from 400 Hz to 100 kHz on many capacitors. Dissipation factors and capacitance were routinely measured at 1 kHz on an automatic capacitance bridge assembly (General Radio Model 1680). The MnO_2 films were checked for carrier type, resistivity, and x-ray diffraction techniques were used to check the phase or phases of MnO_2 present (7).

To investigate the effect of sputtering on the Ta_2O_5, a number of TMM capacitors were etched in a KI-I_2 solution to remove the nichrome-gold counterelectrode. The MnO_2 could then be removed with a solution of 10 cc HNO_3, 5 cc superoxol, 85 cc water. These solutions did not attack the Ta_2O_5. The nichrome-gold counterelectrode was then evaporated on the Ta_2O_5. These capacitors are designated as TMM-M capacitors.

As a check on the effect of the etching solutions on the dissipation factor and leakage current, control TM capacitors were made after exposure to the etching solutions. No change in either leakage current or dissipation factor was found.

Results

MnO_2 films.—The MnO_2 films were sputtered on clean glass substrates for x-ray diffraction analysis. The deposits were mainly amorphous with diffuse rings indicating the presence of pyrolusite and/or γ-MnO_2. Films were sputtered in pure oxygen with rf and 2 or 3 kV d-c power (Table I).

The density of the sputtered MnO_2 was found to be 3.0 g/cc, as determined by weight difference, area, and thickness measurements. The theoretical density is 5.0 g/cm^3 (8) and 4.7 g/cm^3 has been obtained experimentally by Klose (9) on pyrolyzed samples of MnO_2. The resistivity of MnO_2 is as low as 0.0028 ohm-cm for bulk pyrolyzed samples (9). The MnO_2 films sputtered in the present experiments had apparent (measured) resistivities as low as 0.3 ohm-cm. Using the equation of Wiley and Knight (10) to correct for the porosity of the MnO_2 films, the sputtered MnO_2 films have resistivities as low as 0.2 ohm-cm. Valletta and Pluskin (5) obtained MnO_2 films of 5 ohm-cm using d-c sputtering.

The activation energy for conduction was measured for various samples with resistivities from 1 to 5 ohm-cm. Typical data are shown in Fig. 3. The change in activation energy at approximately 60°C was not found when the samples were remeasured. This nonreversible behavior of the activation energy indicates that there may be a small change in stoichiometry. The initial measured activation energy between −55°C and 60°C was found to be 0.10 eV (±0.01) for all samples and the initial activation energy measured from 65° to 125°C was 0.21 eV (±0.03). This higher activation energy was not observed when the samples were remeasured and an activation energy of 0.10 eV was found over the temperature range of from −55° to 125°C. The measured activation energy and the initial anomaly temperature were similar to those values found by Bhide and Damle (11) on both natural ores and chemically pure β-MnO_2 pellets. Wiley and Knight (10) observed a change in activation energy at 115°-140°C while

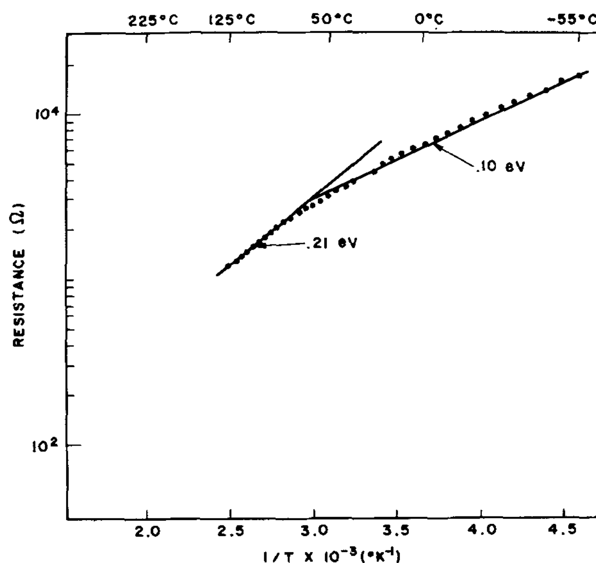

Fig. 3. Typical plot of resistivity vs. 1/T for activation energy determination.

other workers (12, 13) found no change in activation energy.

The MnO_2 films used in the TMM capacitors were always n-type and had apparent resistivities of less than 1 ohm-cm. The MnO_2 sputtered in these experiments is thought to be nonstoichiometric but not differing by more than 5% from an O/Mn ratio of 2, on the basis of the resistivity *vs.* O/Mn data of Wiley and Knight (10).

Capacitors.—Using the model of McLean (14), the measured dissipation factor was taken as

$$\tan \delta = \tan \delta' + \omega R_s C$$

where tan δ' represents the dissipation in the dielectric and R_s represents dissipation losses due to the resistance of the electrodes, MnO_2, and geometry. From the data in Fig. 4, it can be seen that the series resistance, R_s, is most important at high frequencies and can be neglected at 1 kHz. The TMM-M curve of Fig. 4 represents the same capacitors as in the TMM curve, however, the counterelectrode and the MnO_2 have been removed from the dielectric. After replacing the counterelectrode, the TMM-M curve was taken. At 1 kHz it can be seen that the tan δ' for the TMM-M has been reduced, but remains higher than the tan δ' value for the monitor capacitors. This indicates some change in the dielectric due to the sputtering process. Whether this increase in tan δ' is due to substrate heating or bombardment by energetic particles cannot be determined at this time. The series resistance for the TMM capacitors is ~17 ohms; R_s for the TMM-M is ~4 ohms and R_s for the monitor (TM) is ~3 ohms. The TMM capacitors have higher capacitance values because they have an area of 0.192 cm^2 as compared with an area of 0.132 cm^2 for the TMM-M and TM capacitors. This difference is due to the 0.025 cm border on the TMM capacitors. The capacitance density for all the capacitors is 0.052 $\mu F/cm^2$ at 1 kHz.

The data in Fig. 5 show the effect of d-c sputtering voltage on the dissipation in the dielectric; at 1 kHz the tan δ' value is lowered by a factor of 3 when sputtering is done at 2 kV d.c. Removal of the border of the 3 kV sputtered TMM capacitors shows a drop in the series resistance from ~16 to ~3 ohms. The tan δ curve of the TMM capacitors without the border is very close to the curve for the TMM capacitors with the MnO_2 removed. This drop in R_s is due to the removal of the high series resistance capacitor elements located at the edges of the MnO_2 border. Calculations show that these outer elements have a series resistance of approximately 10^5 ohms and could

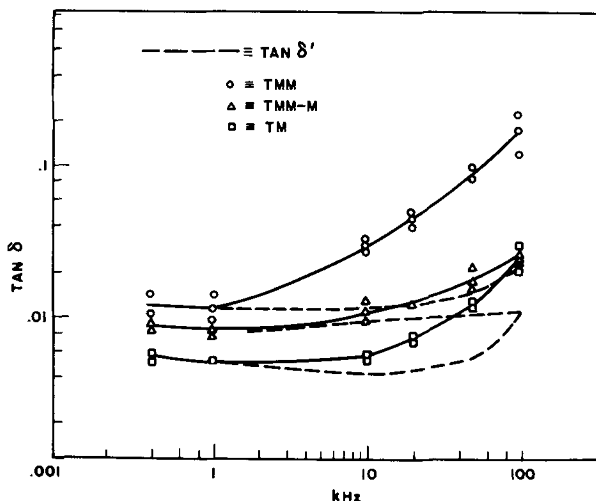

Fig. 4. Separation of the series resistance, R_s, from tan δ for TMM, TMM-M, and TM capacitors.

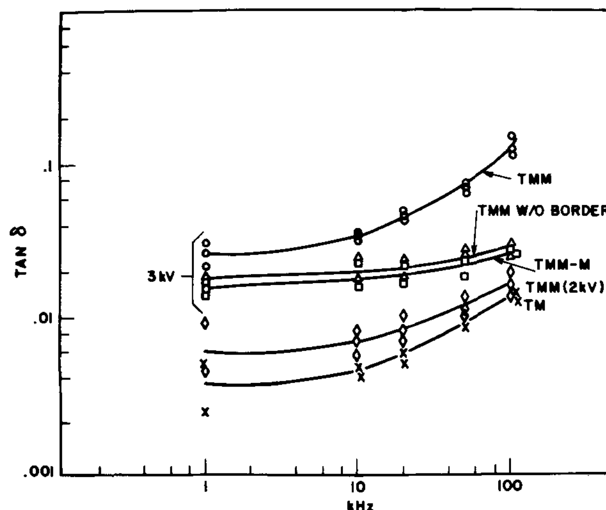

Fig. 5. Log dissipation factor *vs.* log frequency for capacitors sputtered at 3 kV + rf and 2 kV + rf. Also the effect of the MnO_2 border on dissipation factor is shown.

add several ohms to the measured series resistance of the TMM capacitors. The TM monitor capacitors and the TMM capacitors (without the MnO_2) border have similar series resistances because the MnO_2 layer between the dielectric and the metal counterelectrode only contributes about 10^{-4} ohms to R_s. The curves for the 2 kV sputtered depositions show similar results. In the case of the 2 kV depositions there is still some change in the tan δ' at 1 kHz, however, it is much less than the results at 3 kV when compared with the TM capacitors.

The effect of thickness of the MnO_2 on the dissipation factor was found to be negligible for MnO_2 films from 750 to 1800Å thick. Dissipation factors (1 kHz) and leakage currents were measured on 150 TMM capacitors with 1120 ± 80Å of sputtered MnO_2. These capacitors were fabricated without the 0.025 cm border. The dissipation factor was uniform from slide to slide to 12% and the MnO_2 thickness as measured by a Taly-Step was uniform to 7%. Variations in tan δ must be due to localized temperature gradients and/or plasma variations.

Leakage current measurements were made on these capacitors at 75V. It was found that higher leakage currents were observed in the capacitors that had high dissipation factors. The initial yield of the TMM capacitors was 96%, while the monitors had an initial yield of 100%. The initial yield is determined by the number of shorts at 60V. Leakage current measurements at 75V on the TMM capacitors showed that 91% had acceptable leakage currents; there were no additional shorts at 75V. An acceptable leakage current was taken as 1 A/F or 7×10^{-9}A for these TMM capacitors. The test condition for the monitors (TM capacitors) was 50V with a leakage current of 2 A/F to be acceptable. Under this condition, no monitors had acceptable leakage currents.

The dissipation factors for the TMM capacitors with 1120Å of MnO_2 sputtered at 2 kV d.c. were measured as a function of frequency and can be compared with the TM capacitors from the same batch. The dissipation is slightly higher than the values for the TM capacitors, but a significant decrease in tan δ is obtained over 3 kV d-c sputtered TMM capacitors.

Conclusions

It has been demonstrated that low resistivity MnO_2 can be sputtered with deposition rates of 15 Å/min and with resistivities as low as 0.3 ohm-cm; 1 ohm-cm material can be sputtered routinely and reproducibly.

It has also been shown that TMM capacitors can be fabricated with sputtered MnO_2 films that have repro-

ducible dissipation factors of 0.008 at 1 kHz and 0.011 at 100 kHz. This is a large improvement over the dissipation factors for TMM capacitors produced with chemically deposited MnO_2 (0.015 at 1 kHz and 0.06 at 100 kHz). Leakage currents for the TMM capacitors with sputtered MnO_2 were on the average 1×10^{-9} A with 7×10^{-9}A being acceptable. Deposition of MnO_2 by 3 kV d-c + rf sputtering was found to increase the dissipation factor of the dielectric (at 1 kHz) by 50% when compared with TM monitors. This increase in the dielectric dissipation factor was reduced to $\leq$20% when 2 kV d.c. + rf was used.

Solution Chemistry and Colloid Formation in the Tin Chloride Sensitizing Process

R. L. Cohen and K. W. West

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

For many years, stannous chloride solutions have been used to prepare surfaces so that they would catalyze deposition from electroless plating solutions. This paper discusses the colloid and solution chemistry of such baths, including the colloid formation, size mediation, and aging processes. The colloid is shown to be nucleated by stannic ions, and mediated by stannous ions. The investigation was carried out primarily using Mössbauer spectroscopy to characterize the materials involved.

For many years, dilute solutions of stannous chloride in HCl have been used to prepare surfaces for electroless plating. Typically, the technique used has been to dip the object to be plated in the tin solution, wash it, and then dip it into another solution containing. *e.g.*, Pd ions. This treatment can be used to prepare a wide range of materials for electroless plating by copper, nickel, gold, or other metals. A recent useful review (1) of this topic lists patents going back to 1933, and a wide range of variations on the basic approach.

Generally in the literature, the tin bath treatment is called "sensitization" and the Pd (or similar) second treatment is called "activation." The technique is believed to work (1) via the deposition of Sn^{2+} ions from the tin bath, and subsequent reduction of Pd ions by the tin

$$Sn^{2+} + Pd^{2+} \rightarrow Sn^{4+} + Pd$$

The Pd deposited in this way serves to nucleate the deposition from the electroless plating bath.

Despite the extensive practical application of the process and its variants, relatively little fundamental research into the chemical processes and surface physics at work has been reported. The importance of such research has increased recently with the demonstration that the sensitizer is photosensitive (2) and that the sensitizer could be applied to specific areas of the substrate (3); either of these approaches allows generation of controlled patterns. The application of these processes for manufacture of printed cables and wiring boards has considerably increased the possible use of the traditional technique.

Recently, a number of studies have been reported dealing with the nucleation and growth of the plated metal layer (4-6), and the morphology of the sensitizing layer. However, we have been able to find no published work studying in detail the chemical composition of the film deposited by the tin chloride bath, or on the chemistry of the bath itself. Sard (4) showed that the electron diffraction pattern of the tin coating on the sensitized substrate was identifiable as belonging to SnO_2, but was careful to point out that the material might have undergone some change in handling. Recent unpublished work (7) found an electron diffraction pattern which could be attributed to a mixture of SnO and SnO_2, but also pointed out that the high vacuum environment, heating from the electron beam, and oxidation during handling might have affected the results. Thus, further research on the chemical composition of the sensitizing layer seemed indicated. At the time we began this work (8), we could find no published research discussing the formation of the sensitized layer from the tin chloride solution, though the chemistry of such solutions has been extensively studied.

On the other hand, the morphology of the sensitized surface has been studied (4, 5) by electron microscopy, and the studies have shown that the layer produced by the tin chloride bath consists of (typically) 100Å

Key words: Mössbauer effect, tin complexes, metalization.

clumps of 25Å particles, covering ~25% of the surface area. The amount of tin deposited typically ranges from about 1-10 $\mu g/cm^2$, measured by x-ray fluorescence analysis (7, 8).

There are basically two pieces of evidence showing that the sensitizing material deposited on the substrate is present as a colloid in the bath. The first is Sard's observation (4) that the sensitized surface contains small discrete particles. The second is the fact, discussed elsewhere (9) that the Mössbauer spectrum of the layer deposited by the tin bath is distinctive and unusual, but identical with the spectrum of colloidal particles centrifuged from the solution. These facts suggest that a study of the sensitization process should begin with a study of chemical processes in the bath itself. There will be no further discussion here of the chemical makeup of the deposited layer itself.

We present here the results of recent studies of the "front end" of the sensitization process—the tin solution chemistry and the formation of the colloid. Data are presented to establish

(*i*) that the colloid is based on Sn^{4+}, but contains roughly half as much Sn^{2+},
(*ii*) the mechanism of colloid formation and size mediation,
(*iii*) the details of the solution aging.

The discussion proceeds in four parts: We first show briefly the applications of Mössbauer spectroscopy to the study of tin chemistry. Second, the experimental techniques are described. Third, we discuss the colloid formation in terms of the well-known tin solution chemistry. The model developed in this way is then confirmed with some further experiments.

Mössbauer Spectroscopy

Mössbauer spectroscopy (MS), known more formally as recoil-free nuclear gamma ray resonance spectroscopy (10), has in recent years been increasingly used for studying the chemistry and bonding of various elements, and has more recently been used for analytical determinations as well. The elements that have been the most used in chemical research have been iron and tin. A review of the use of MS in chemistry generally has been given by Herber (11); a brief discussion of the MS of tin compounds has been given by Donaldson (12), and an exhaustive survey of Sn organic compounds has been done by Zuckerman (13). The MS technique is one in which the changes in energy levels of nuclei (in this case, Sn^{119} nuclei are the resonant species) due to electronic perturbations are studied. The effects important in the work here are the presence of the 5s electrons (in stannous ions) which tend to increase the nuclear transition energy over that observed in the Sn^{4+} ions, and quadrupole interaction, which splits the absorption line into a doublet. Generally, the stannous ions have larger quadrupole splittings than the stannic, and in most of the spectra shown here the splitting of the divalent tin absorption lines is large enough to be resolved.

Experiments are performed by varying the source gamma-ray energy by small amounts (using the Doppler effect), and measuring the transmission of the sample as a function of gamma-ray energy. A "dip" in the spectrum then corresponds to resonance absorption by Sn^{119} nuclei in the absorber. The energy of the resonance absorption, and the quadrupole splitting of the Sn^{2+} peaks, are characteristics of particular ionic surroundings and can be used to identify compounds in favorable cases. Examples of spectra of some well-characterized tin compounds are shown in Fig. 1. Since the experiments were done with a source containing Sn^{4+}, nuclei of stannic ions in the absorbing materials resonantly absorb near the source emission energy, *i.e.*, near zero (Doppler shift) velocity. The isomer shift between Sn^{2+} and Sn^{4+} corresponds to about 3-4 mm/sec, so that the (quadrupole split) divalent lines are centered about this region.

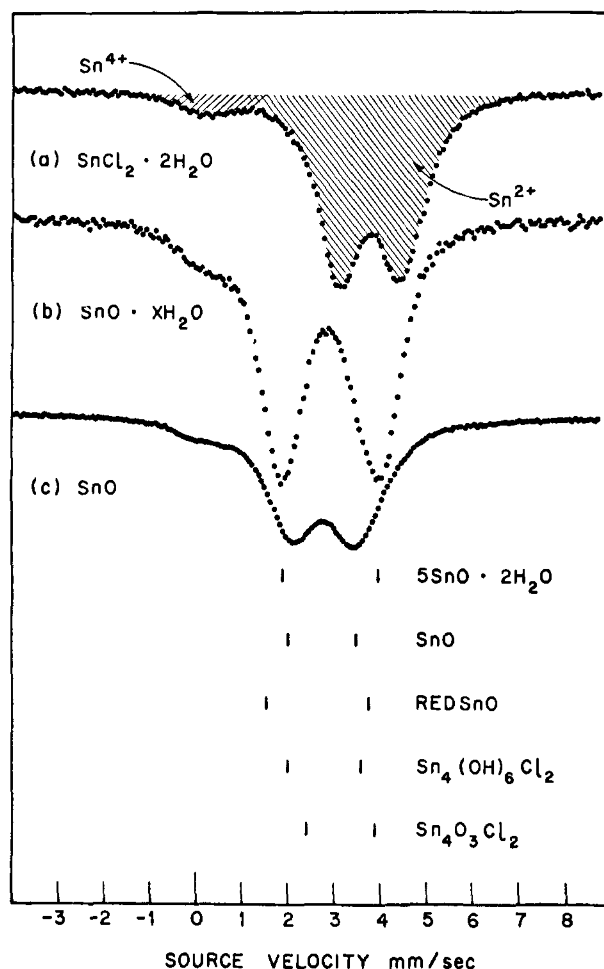

Fig 1. Observed spectra of 3 stannous compounds. The $SnCl_2 \cdot 2H_2O$ was Baker, reagent grade; the other two were made in our laboratory by standard preparative techniques. Note the existence of a line due to Sn^{4+} in all samples. Line positions reported in Ref. (14) for various well-characterized tin compounds are shown below the spectra.

Experimental

The Mössbauer spectroscopy experiments were done with standard techniques: Transmission geometry was used, with a source of ~2mCi Sn^{119m} in the form of $BaSnO_3$. Both the source and absorber were maintained at ~80°K during the measurements to increase the resonance strength. The gamma rays were detected with a sodium iodide scintillation crystal and photomultiplier. A "critical absorber" of 45μ Pd was used to separate the Sn x-rays from the desired 23.8 keV gamma rays. Standard nuclear electronics were used for counting. The data were taken with a constant-acceleration drive (15) and multichannel analyzer used in the multiscaling mode. Up-down multiscaling was used to fold the two halves of the spectrum in the analyzer, and the spectra shown were traced directly from X-Y plots produced by the analyzer. The absorber was in the Dewar vacuum, and was inserted with the Dewar precooled. Thus, the absorber was frozen (in a nitrogen gas atmosphere) to very low temperatures before being subjected to vacuum; this should have greatly reduced alteration due to dehydration. "Frozen solution" (16) samples were prepared by mixing the tin solution with 50% of its own volume of methanol, placing in a 5 mm deep polyethylene dish, covering, and quick-freezing in liquid nitrogen. Additional experiments with different amounts of methanol and with glycerol showed that a glass was being formed by this process.

Unless otherwise stated, the solutions studied here were made by dissolving reagent grade $SnCl_2 \cdot 2H_2O$

in water, and promptly adding reagent grade (37%) HCl. The concentrations used were 20g $SnCl_2 \cdot 2H_2O$/l (0.089M) and 10 ml HCl/l (0.1M). Solutions were mixed at room temperature and kept under nitrogen gas to inhibit oxidation.

Tin Chloride Solution Chemistry

The colloid and solution chemistry of the tin chlorides has been extensively studied, and we can use the existing information, in combination with our Mössbauer spectroscopy measurements, to analyze the solutions and precipitates made in this process.

We will begin with some of the basic reactions and equilibria which are important for the system:

1. The solution of divalent tin in water results in hydrolysis

$$Sn^{2+} + H_2O \rightarrow Sn(OH)^+ + H^+$$

Divalent tin ions can hydrolyze more than one molecule of water; in fact the dominant complexed species is the polynuclear $Sn_3(OH)_4{}^{2+}$ ion (17). Figure 2 shows the relative concentration of the various complexes as a function of *p*H. The results shown in Fig. 2 are for a perchloric acid medium, which was used to eliminate the effects of chloride complex formation. It can be seen that in the concentration range used in our solutions, the hydroxy complexes form a relatively small fraction of the total divalent tin.

2. Sn^{2+} ions also complex with Cl^- ions in solution; an indication of the relative population of these complexes (18) (under slightly different conditions from those existing in our solutions) is shown in Fig. 3. Other results published in Ref. (19) show that the complex formation is not very different for the tin and chloride ion concentrations used by us, except that the $SnCl_4{}^{2-}$ complex is probably not present.

The data in Fig. 2 and 3 show that as HCl is added, the fraction of chloride-complexed Sn^{2+} is increased, while the hydroxy complex is decreased. Reducing the H^+ concentration, though, (*e.g.*, by neutralizing with NH_4OH) increases the fraction of the $Sn_3(OH)_4{}^{2+}$ complex, culminating in the precipitation of some form of stannous hydroxide (or hydrous stannous oxide) typically around *p*H 1-3, depending on conditions.

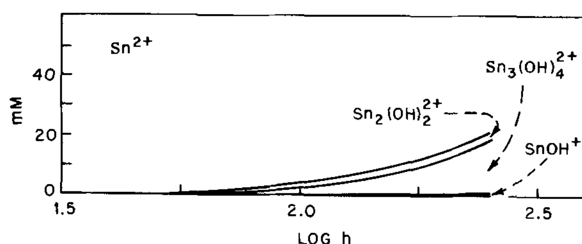

Fig. 2. Distribution of hydrolyzed complexes in solution [from Ref. (17)].

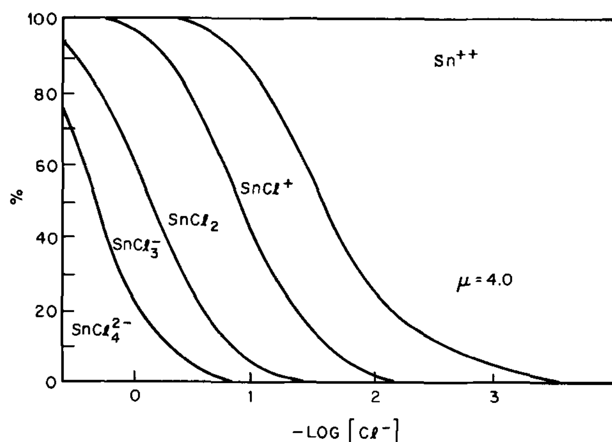

Fig. 3. Chloride complex formation by stannous ions [from Ref. (20), ion strength 4.0].

3. Though the solution preparation procedures used do not intentionally generate Sn^{4+} ions, our results show that stannic ions are present in large quantity, and seem to be important for the working of the process. There are two obvious ways for stannic ions to get into the solution initially: as an impurity in the starting $SnCl_2 \cdot 2H_2O$, and by oxidation of the stannous ions by oxygen dissolved in the bath water. The $SnCl_2 \cdot 2H_2O$ spectrum shown in Fig. 1 shows that even in the fresh reagent grade material used there, ~5% (21) of the tin ions are tetravalent, and will appear in the bath in that form. The solubility of oxygen in water is enough so that dissolved oxygen can convert an additional ~1% of the stannous ions to stannic form. This reaction proceeds rapidly, especially in the presence of light. Once the bath is made up, of course, the continued oxidation from atmospheric oxygen will contribute to the aging process.

4. No spectra attributable to dissolved mixed valence (Sn^{2+}-Sn^{4+}) complexes were observed in this work.

The solution chemistry of the stannic ion is dominated by the complete hydrolysis in aqueous solutions, with almost $4H^+$ ions being produced per Sn^{4+} ion (22). It seems to be unclear, however, despite extensive research, whether essentially all the tin ions have been complexed as $Sn(OH)_4$, or whether a distribution of species with different degrees of hydrolysis (as in the Sn^{2+} case) exists. The hydrolysis can be inhibited (23) by the presence of more than 0.5M Cl^- ions; presumably the $SnCl_6{}^{2-}$ complex becomes the dominant species in that case.

Thus, combining this information, we would expect our freshly made tin sensitizing solutions to consist of about 95% Sn^{2+} ions, mostly complexed with Cl^- ions, and 5% Sn^{4+} ions, which we will for simplicity assume to be complexed as $Sn(OH)_4$. However, this situation is not stable, because of the tendency of the hydrolyzed stannic ions to polymerize and precipitate as $Sn(OH)_4 \cdot nH_2O$. This reaction has been studied in solutions of pure $SnCl_4$ (23) and as a function of added bases and acids (24). Depending on the concentration of various ionic species, the colloid formation and subsequent precipitation can take from a few minutes to months (23, 24).

Our results, which show (Fig. 4a) that divalent tin is present in the colloidal precipitate in a *p*H and chloride ion concentration range where it should be dissolved, suggest that the colloid formed by the stannic ions also bonds stannous ions. The great relative abundance of the stannous ions (~20X Sn^{4+} concentration at the beginning of colloid formation, and increasing as the stannic ions get removed from solution by the polymerization) should encourage this process.

The sensitizing bath, then, appears to work in this way: the tin chloride solution forms a colloidal suspension which is based on the polymerization of hydrolized Sn^{4+} ions. Because of the large relative abundance of Sn^{2+} ions, they are bound in the colloid as it forms, roughly in the ratio of one Sn^{2+} per $2Sn^{4+}$ ions. (Estimated from the areas in the respective spectral regions.) When the substrate is dipped into the bath, the colloidal particles adhere to (or are adsorbed on) it, and these contain the divalent tin which later deposits the Pd from the Pd bath.

The description contains two new features, as pointed out by D'Amico *et al.* (8): First, the view that the material deposited on the substrate is present as a colloid in the bath, and second, the idea that the colloid itself is based on Sn^{4+}. Though colloidal systems involving more than one cation species have been extensively studied (25), we believe this to be the first case in which different valence states of the same element play distinct roles.

It is interesting to see how this approach can explain some of the aspects of the bath formation process. For example, sensitizing baths are often made (as we

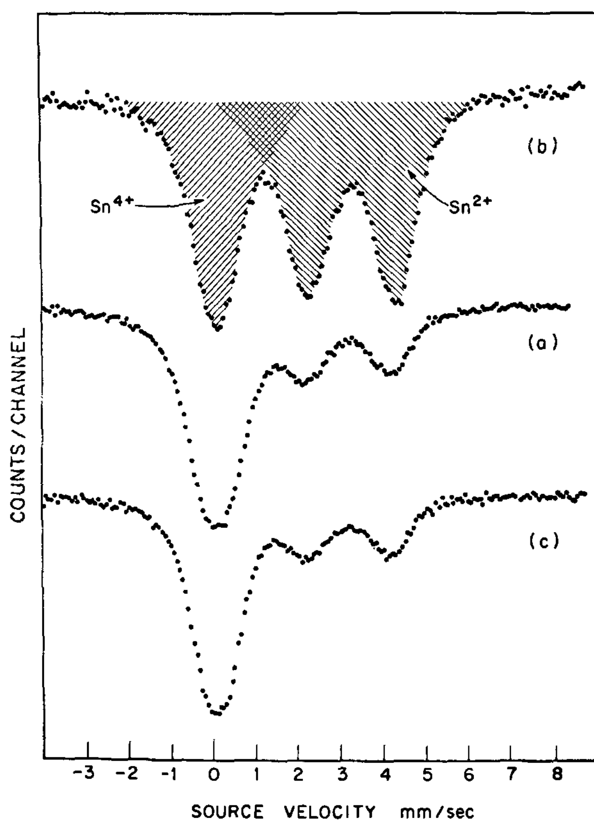

Fig. 4. Spectra of precipitates from various tin chloride baths: (a) colloid centrifuged from solution "A" as discussed in text; (b) heavy precipitate following solution of 2g $SnCl_2 \cdot 2H_2O$ in 100 ml water (no acid); (c) colloid centrifuged from solution "C." Note that the solids formed in the acidified solutions have far less divalent tin than the material shown in (b).

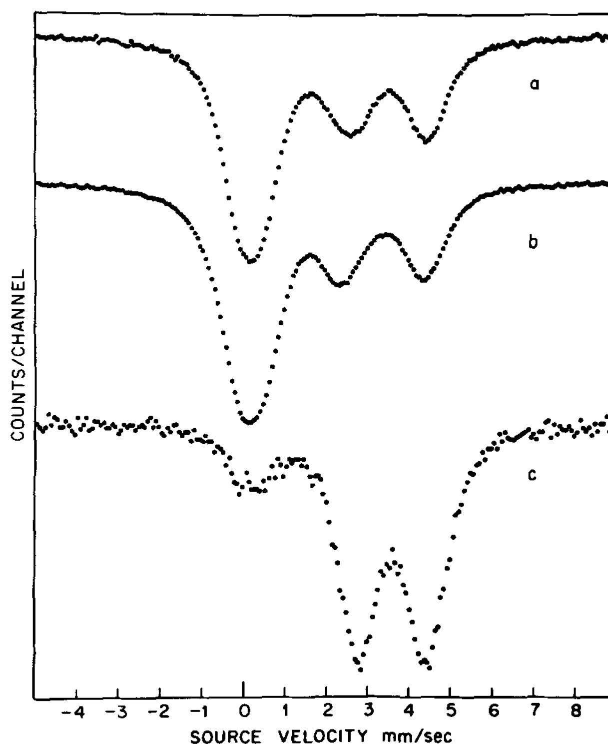

Fig. 5. Mössbauer spectrum of a frozen tin chloride bath is shown in (a). Centrifugation (100,000G for 16 hr) removes most of the colloid, the spectrum of which is shown in (b). The spectrum of the (frozen) supernatant solution is shown in (c). Note that essentially all the ions in solution are divalent. The bath was aged three days exposed to air before the separation and measurements.

describe above) by first putting the tin chloride in the water, and then adding the acid. When this procedure is followed, a heavy precipitate forms immediately, while the tin chloride is dissolving. (If left for a few minutes, the precipitate coagulates and settles.) Prompt addition of the acid "dissolves" the precipitate, leaving a slightly opalescent solution (which we call "A"). If the tin chloride is dissolved in the acid first, and then the water added, a relatively clear solution is obtained (which we call "B"). If the acid is added to the water first and then the tin chloride is added, the solution formed (C) is slightly less milky than A.

With the interpretation we have given above, plus the discussion in the references, it would appear that "A," the technique of redissolving the precipitate, is a controlled way of generating the colloid. As a step in understanding the formation process, we have studied the Mössbauer spectrum of the heavy precipitate formed in the first stage of "A," before the acid is added to redissolve it. The results are shown in Fig. 4b. Comparison with Fig. 4a shows that the divalent line positions are the same as those in the colloid, but that relatively more of the tin is divalent.

Our MS experiments have indicated that essentially all the tetravalent tin in the fresh "A" solutions is tied up in the colloid (26). Figure 5 shows (for an aged solution) that the tetravalent tin is in the colloid and the dissolved ions are essentially all divalent. Thus, the solution is mostly depleted of its Sn^{4+}, and the ratio of dissolved Sn^{4+}/Sn^{2+} must have decreased as the colloid grew. This would make the colloidal particles richer and richer in Sn^{2+} as they increased in size. Adding the acid, then, dissolves the Sn^{2+}-rich outer layers.

This picture is supported by an experiment in which we added perchloric acid (instead of HCl) to increase the H^+ concentration without increasing the Cl^- concentration. Increase in H^+ concentration is effective in dissolving precipitates of divalent tin, which are strongly pH controlled, but ineffective (23) in dissolving the hydrolyzed Sn^{4+} precipitate, which is Cl^- sensitive. Since the perchloric acid was effective in dissolving the heavy precipitate (leaving again a slightly opalescent solution), it would appear that the divalent tin is the dominant species in coagulating the mixed 2^+-4^+ colloid initially formed on dissolving the tin chloride in water. When the $SnCl_2 \cdot 2H_2O$ is dissolved in water, the colloid forms, coagulates, and settles, and the visible reactions cease. This can be explained by the fact that as the hydrolyzed stannous ions precipitate out, the solution is further hydrolyzed to maintain an appropriate fraction of OH-complexed ions in solution. Thus the H^+ ion concentration increases from ~0.02M (due to hydrolysis of the stannic ions) initially until the bath is acid enough to keep the remaining Sn^{2+} ions in solution. At this point the precipitation stops. Addition of alkali causes the precipitation of Sn^{2+} to resume, while addition of acid tends to redissolve the divalent-rich precipitate. We have determined that the precipitate formed by the addition of alkali in fact has a still higher ratio (Fig. 6) of Sn^{2+}/Sn^{4+} than that shown in Fig. 4, as would be expected.

The clear solution B, made by dissolving the tin chloride in acid first, appears to contain much smaller colloidal particles. The solution used by Sard (4) was made up in this way, and showed a deposit of particles mostly smaller than 30Å diameter, too small to have been separated by our centrifuging conditions (27). Thus the transparency of those solutions means that the colloid is only partly formed (*i.e.*, Sn^{4+} still in solution) and/or is much finer than the colloid in A. Solution C (tin chloride into acidified water) has also had the colloid forming slowly (relatively to the heavy and rapid precipitation of the first step of A). The colloid formed in C appears (see Fig. 4c) identical to that formed from the A solution. The greater transparency

of C, however, suggests that the particle size range is somewhat smaller.

This analysis of the situation, in which the coagulation and precipitation are limited by the cumulative hydrolysis of the Sn^{2+} ions, helps to explain why such a wide range of tin concentrations [solutions containing from 0.16g to 200g $SnCl_2 \cdot 2H_2O$/liter H_2O have been mentioned by Ref. (1)] has proved useful in making sensitizing baths. The HCl concentration is also not very critical, because of the relatively wide range of Cl^- concentrations over which the colloid forms, the slow solution of the colloid even in solutions containing large concentration of Cl^-, and possibly, shielding of the Sn^{4+} cores by the divalent-rich outer layer.

We now turn to the evidence that the colloid is not simply a mixture of two compounds, one stannous and the other stannic.

One of the strong indications is that the line positions of the divalent ions do not correspond to those reported for known divalent compounds in the oxychloride or hydroxide family. The picture we have presented, of tetravalent tin hydroxide particles picking up divalent tin ions from solution, makes possible an additional test. If $SnCl_2 \cdot 2H_2O$ is dissolved in water, a heavy precipitate is formed, as stated previously, and then visible reactions stop, leaving a slightly milky solution above the precipitate. According to our model and measurements, that precipitate should contain most of the stannic ions. If alkali (NaOH or NH_4OH solution) is added to the liquid, additional precipitate is formed, leaving again a slightly milky solution. This new precipitate can be removed, and the process repeated. Mössbauer spectra of the resultant solid products at various stages of this reaction are shown in Fig. 6. The spectrum of 6c can be readily identified as belonging to the hydrous oxide $5SnO \cdot 2H_2O$, and appears after the Sn^{4+} ions have been precipitated. The line positions of the Sn^{2+} ions precipitated with the Sn^{4+} ions are significantly different, and we have only found spectra with these line positions in mixed valence materials. It is important to note that except for the number of Sn^{4+} ions present, the concentrations of the various ionic species do not change greatly during the successive stages depicted in 6A, 6B, 6C. Even the *p*H remains roughly constant (~1.5) as the additional precipitate is formed. Thus, the distinctive line positions shown by the Sn^{2+} ions in the colloid appear only when Sn^{4+} ions are present in the precipitate as well.

The failure of the divalent ions alone to form a colloid in the tin chloride solution would also be expected from the complex-formation studies discussed earlier which indicate solubility of the divalent species in this range of ionic concentration. We have directly confirmed this by making up a solution of the same ion concentrations specified above, but essentially free of Sn^{4+} ions (28). Such a solution remains absolutely clear for days when stored under nitrogen gas to prevent oxidation of the Sn^{2+}. However, if this solution is then oxygenated, (by bubbling O_2 through it for 5 min) a visible opalescence appears in a day or so. This suggests again that stannic ions are necessary for colloid formation. A similar result is reported by D'Amico *et al.* (8), who also show that, in the absence of colloid formation, sensitization may occur via the precipitation of hydrous SnO during the water rinse step.

This analysis envisages the tin chloride sensitizing bath as a suspension of colloidal particles, based on Sn^{4+}, with Sn^{2+}-rich outer layers, in a bath of bare and complexed Sn^{2+} ions. With this picture in mind, it is easy to see what the "aging" process during normal use of the bath does. Exposure to atmospheric oxygen produces Sn^{4+} ions in the solution; but these are precipitated on the existing colloid particles, and also nucleate new colloidal particles. Spectra in Fig. 7 show the oxidation of an A solution with time.

The discussion above suggests that the best way to maintain the desired colloid during operation is to prevent the production of Sn^{4+} ions; a gas shield over the

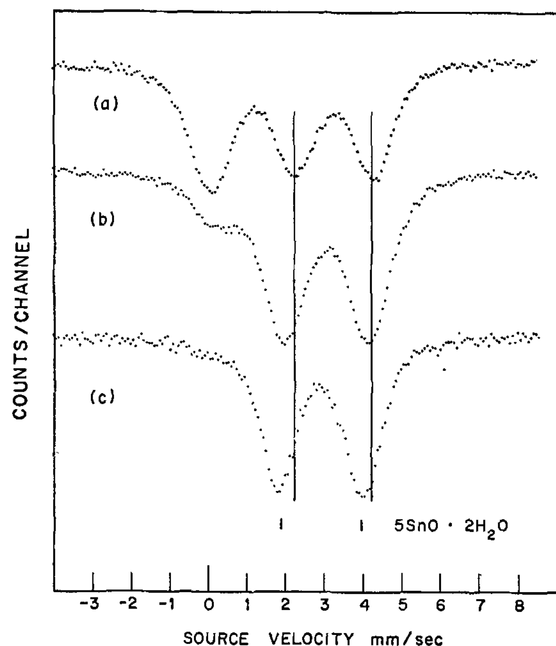

Fig. 6. (a). ppt from solution of 2g $SnCl_2 \cdot 2H_2O$ in 100 ml H_2O. (b). additional ppt obtained by adding 8 ml 1M NaOH to milky solution remaining after A ppt; (c). ppt obtained between addition of 10 ml and 16 ml NaOH. Line positions [from Ref. (14)] for $5SnO \cdot 2H_2O$ are shown.

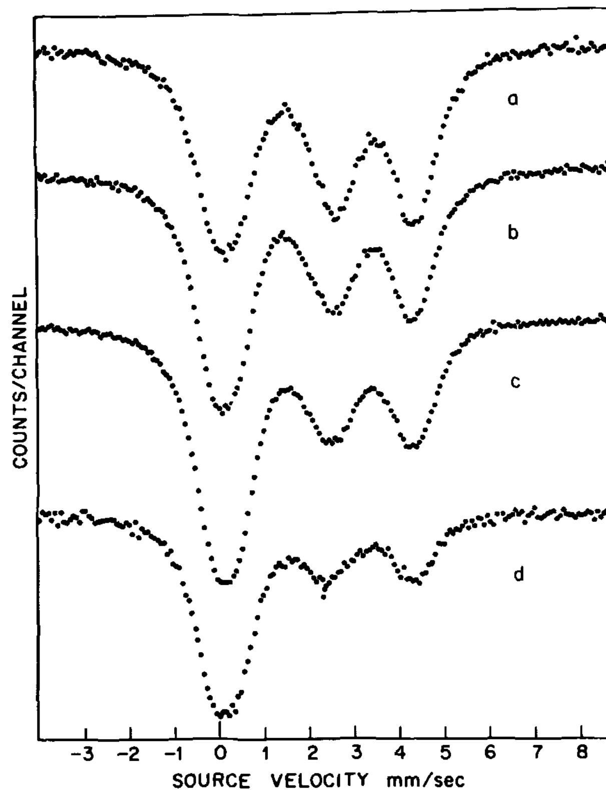

Fig. 7. Spectra of frozen solutions after exposure to air for (a) 1 day, (b) 2 days, (c) 4 days, (d) 6 days in loosely covered beaker. Note that initially, the spectrum of the divalent tin is that shown by Sn^{2+} ions in solution (compare Fig. 5c). As the stannic fraction (line near zero velocity) increases with air oxidation, it forms more colloid, and the divalent tin spectrum gradually changes to that of stannous ions in the colloid (compare Fig. 4a). This shows explicity that the stannous ions, which are initially dissolved, are incorporated into the tetravalent-based colloid as it forms.

bath to exclude atmospheric oxygen (nitrogen would be satisfactory, but CO_2 or argon would be easier to maintain) should be effective for this. It would probably be much more difficult to remove or reduce Sn^{4+} ions which have gotten into the bath by oxidation.

Although it might appear that this would lead to eventual depletion of the sensitizing colloid in the bath, a simple estimate shows that with the known coating density of 5-10 μg Sn/cm^2, bulk depletion (due to mechanical carry-out on the substrate) will severely reduce the bath volume before the colloid is exhausted.

One additional aspect of the process should be discussed here. Some of the substrate pretreatments involve an etch using NaOH just before immersion into the tin bath. Any carry over of OH^- from this bath will tend to precipitate additional Sn^{2+} on the colloid (see Fig. 6 and discussion); this could lead to changes in colloid size and copper deposition.

Conclusions

This research on the tin chloride sensitization process by Mössbauer spectroscopy has been successful in investigating the chemistry and chemical intermediates appearing at various stages. We have developed a detailed picture of the colloid formation mechanisms and size mediation reaction. This information has been used to discuss some of the possible difficulties which might arise in production applications.

Acknowledgments

We are greatly indebted to J. F. D'Amico and other members of the Western Electric (ERC) Chemical Process Technology Department for frequent discussions during the course of this work, and for making reports available to us before publication. Work on the colloids was greatly aided by the availability of the Biophysics Research Department's ultracentrifuge, and advice from T. Yamane. R. Sard provided helpful discussions on the structure of sensitized surfaces.

Manuscript submitted June 22, 1971; revised manuscript received *ca.* Nov. 19, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

21. We assume throughout that the "f value" (recoil-free fraction, related to the strength of the Mössbauer effect) is the same for both the di- and tetravalent tin ions. For the mixed-valence materials we have measured, we have verified this to $\sim \pm 20\%$ by converting all the ions to Sn^{4+}. Any change in f is not very significant for the interpretation of the data, which is based primarily on the relative proportion of divalent tin under various conditions, rather than the absolute $2+/4+$ ratio.

26. This view is based on a number of experiments with different tin solutions, centrifuging conditions, and measurements on both precipitates and supernatant liquids. Though it is impossible to remove completely the Sn^{4+} based colloid from solution by centrifuging, all our experiments suggest that few, if any, of the stannic ions are in solution.
27. If we assume that the density of the colloid particles is 2 g/cm^3, centrifuging for 2 hr at 100,000G separates particles down to 60Å diameter.

The Field-Dependence of the Dielectric Constant during the Anodic Oxidation of Tantalum, Niobium, and Tungsten

J. L. Ord,* M. A. Hopper,* and W. P. Wang**

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT

In situ ellipsometric measurements on the galvanostatic oxidation of tantalum, niobium, and tungsten show that both the refractive index and the thickness of the oxide change suddenly on changing the current applied to the film. For all three metals the thickness was found to increase linearly with the electric field, whereas both the refractive index and low frequency (1000 Hz) dielectric constant were found to decrease linearly with increasing field. The magnitudes of the changes in dielectric constant and refractive index that were detected experimentally, when compared with theoretical predictions using standard dielectric theory and the observed change in thickness, indicate that these changes are due to the variation in the density of the film with the applied field. The inclusion of the linear dependence of the dielectric constant on field into an effective field model of the ionic conduction process is shown to be a possible explanation of the curvature in the plot of ln(i) *vs.* E for the anodic oxidation process.

It has been known for quite some time that the dielectric constants of valve metal oxides vary with the electric field in the film. Guentherschultze and Betz (1) reported results on a wide variety of valve metals in 1931, and results reported recently (2, 3) show a continuing interest in this phenomenon.

The measurements of refractive index variations with field were carried out in our laboratory in the spring of 1966 to determine whether our recently completed ellipsometer (4) had sufficient sensitivity to detect small variations in the refractive index of a growing film. Also in the spring of 1966, Young and Zobel (5) reported results of experiments which found a curvature in the plot of ln(i) *vs.* E for the anodic oxidation of niobium, and they confirmed the earlier measurements (6) of this curvature on tantalum. In that paper and in the oral discussion of it at The Electrochemical Society meeting, several possible reasons for this effect were suggested.

The experiments we report in this paper were designed to determine whether the curvature could be explained using a model in which the local electric field controls the ionic conduction process. The logarithm of the current density can be linearly dependent on the local electric field and yet show a quadratic dependence on the external field if the dielectric constant varies with the field. We present results of measurements on the field-dependence of the dielectric constants of the anodic oxides of tantalum, niobium, and tungsten and test the local field model by comparing its predictions with the data of Young and Zobel for tantalum and niobium.

Experimental

The ellipsometer used to obtain the data reported in this paper was the second of two following ellipsometers built in this laboratory and has been decribed in detail elsewhere (7). This instrument differs little from the first instrument on which the initial measurements were made. Both instruments have 0.01° resolution, and the *in situ* nulling time on thin anodic oxides is typically less than 1 sec. The nulling times for the measurements reported here are somewhat longer than this because they were carried out at film thicknesses for which it is possible to distinguish between small variations in film thickness and index. Under these experimental conditions the analyzer null readings are generally in excess of 70° and the intensity of light detected by the photomultiplier is not very sensitive to angular displacement from the null position, particularly in the case of the polarizer. The increased sensitivity to thickness and index variations at large A values more than compensates for any increases in nulling times and standard deviation of the data. The light source used with the ellipsometer is a low-power helium-neon gas laser, and all refractive indexes calculated in this paper are pertinent to its wavelength 6328Å.

The initial measurements were all made using a cell with windows mounted for an angle of incidence of 75°, but the more recent results reported in this paper were all obtained at an angle of incidence of 60° using a cell made from a hollow equilateral prism. The cell has standard-taper joints for mounting the electrode holder, platinum counterelectrode, mercury-mercurous sulfate reference electrode (fitted with a 0.1N K_2SO_4 salt bridge), and gas dispersion tube. The electrolyte, 0.2N H_2SO_4, is saturated with argon, and argon is bubbled through the solution during the experiments. All experiments were performed at room temperature (23°C).

Cylindrical samples were prepared from single crystals of tantalum, niobium, and tungsten. When a sample is mounted between Teflon washers in the electrode holder, a vertical surface of approximately 1.2 cm^2 area is exposed to the solution. Optical measurements are made on a flat on one side of the cylinder. The surfaces are prepared initially by chemically polishing niobium and tantalum and by electropolishing tungsten. In all the experiments reported here, the surface treatment just prior to an experiment consisted of dissolution of the oxide film left by a previous experiment in a solution consisting of hydrofluoric acid saturated with ammonium fluoride for tantalum and niobium and in dilute sodium hydroxide for tungsten. In the case of tantalum, the process progressively etches the sample with each successive run and care must be taken to orient the optical flat parallel to a crystallographic plane that does not tend to roughen when the sample is etched. This was necessary to ensure reproducibility in the optical data which tend to be affected by surface roughness.

The electronic circuitry used with the cell consists of a set of five operational amplifiers, three of which are used to apply constant currents, constant poten-

Key words: anodic oxidation, valve metals, ellipsometry, dielectric constant.

tials, or linear potential sweeps to the cell. Of the remaining two, one is used to follow the potential and the other is used as a transresistor to monitor the current. In these experiments the galvanostat is the most critical circuit component. Measurements are made as the galvanostat is switched through a sequence of preset d-c currents, all with a superposed a-c current whose amplitude and phase are required to be independent of the d-c current. The output of the potential follower is connected to a lock-in amplifier whose internal reference potential is used to drive the a-c section of the galvanostat. Tests of the galvanostat with passive circuit components show that the a-c current is independent of the d-c current to better than the 0.1% required for these measurements. The 0.1% accuracy is imposed by the fact that when the lock-in amplifier is set 90° out of phase with the current, the a-c potential measured is inversely proportional to the equivalent series capacitance of the cell rather than the capacitance of the oxide layer. The extent to which changes in the equivalent series capacitance are due to changes in the capacitance of the oxide layer rather than its resistance depend on the frequency of the a-c current and the magnitude of the d-c currents. At a frequency of 1000 Hz, changes in the layer resistance for the range of currents used in our experiments produce changes in the equivalent series capacitance of less than 0.1%. The changes we measure in the equivalent series capacitance are typically a few per cent, and hence are mainly due to variations in the capacitance of the oxide film.

The experimental data were recorded on a digital printer, except for the output of the lock-in amplifier which was recorded on an X-Y plotter with calibrated offset. The laboratory HP2114B computer was used for the analysis of the optical data using a program written in BASIC, but it was not used for data acquisition in these experiments.

Results

The first series of experiments were carried out using samples of tantalum, the metal whose oxide turns out to be the least sensitive to field variations of the three metals studied. The ellipsometric data obtained during the anodic oxidation of tantalum at 100 μA/cm^2 are plotted in Fig. 1. In the upper portion of the figure, the polarizer null readings, P, are plotted *vs.* the analyzer null readings, A. The data points start at A and trace out the clockwise loop A-B-C-H-I-J-K, point K overlapping the initial point, A. The complete set of data points would appear as a continuous curve if plotted on the scale of Fig. 1. The points in the figure are a set of points selected from the data at approximately 5° increments. The curve passing through the points is a theoretical curve for the growth of a film of index 2.2 on a substrate of index 3.02-2.57i. In the lower part of the figure the thickness of the film determined from the theoretical curve in the upper portion of the figure is plotted *vs.* potential. The slope of this plot, 5.85 $\times$ 10^6 V/cm, gives the field in the film at a current density of 100 μA/cm^2. Its intercept gives an initial thickness of 30Å of oxide at the beginning of the experiment. When the optical data return to their starting point, the thickness of the oxide on the electrode is 1720Å.

The design of an experiment to test for a field-dependent refractive index makes use of the fact that as the layer is grown at a constant rate, the optical data points trace out the loop at a very nonuniform rate. The rate at which the segment between C and H is traced out is more than 14 times the rate at which the segment J-K is traced out. The nonuniformity can be seen in Fig. 1 by comparing the thickness intervals between the lettered points with the

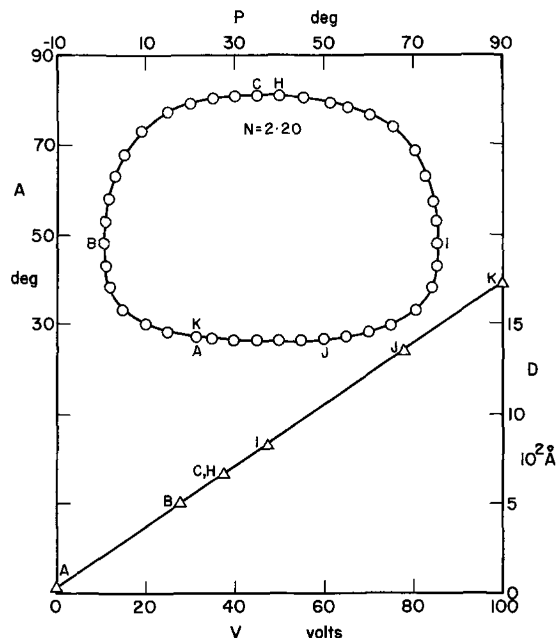

Fig. 1. Anodic oxidation of tantalum at 100 μA/cm^2 in 0.2N H_2SO_4. The optical data in the upper part of the figure start from point A and trace out the loop A-B-C-H-I-J-K as the oxide film grows. The curve fitted to the optical data is for the growth of a film of index 2.20 on a substrate of index 3.02-2.57i. The film thickness determined from this fitted curve plotted vs. potential in the lower part of the figure.

lengths of the corresponding arcs on the P-A plot in the upper part of the figure. In the region between C and H the optical data are most sensitive to slight changes in film thickness. In addition, changes in thickness give rise to changes in P with virtually no changes in A, whereas changes in index at constant thickness give changes in both P and A. Hence, if the current density is switched to another value as the layer is grown through this region, it is possible both to detect and to distinguish between small changes in film thickness and in film index.

The results of an experiment in which the current density is switched from 20 μA/cm^2 to 1 μA/cm^2, then back to 20 μA/cm^2 are plotted in Fig. 2. The optical data are depicted on a P-A plot in the upper section of the figure, and the plot of the potential *vs.* time is given in the lower section. For segments CD and GH the current density is 20 μA/cm^2 and all the optical data points are plotted; for the segment EF the current density is 1 μA/cm^2 and points are plotted at 0.1° intervals in P. In this figure the analyzer scale is expanded tenfold over the polarizer scale to show the fine structure in the data. With this expansion, the most significant feature of the optical data is the shift to higher A values as the current is lowered, and the shift back when the current is raised again. A theoretical curve for the growth of a layer of index 2.2045 is fitted to the data at 20 μA/cm^2, and a curve for a layer of index 2.2059 is fitted to the 1 μA/cm^2 data. The number of figures to which these indexes are quoted is sufficient to allow us to estimate that the difference in the indexes, 1.4 $\times$ 10^{-3}, is accurate to within about 10% although the absolute values of the indexes themselves are not significant to 4 decimal places. An important feature to note is the sign of the index change: as the field and current density increase, the refractive index decreases.

An explicit equation can be written to express the dependence of the refractive index on the steady-state field. If a range of current densities is used in the experiment, a linear dependence of the refractive index on the steady-state field is found in contrast

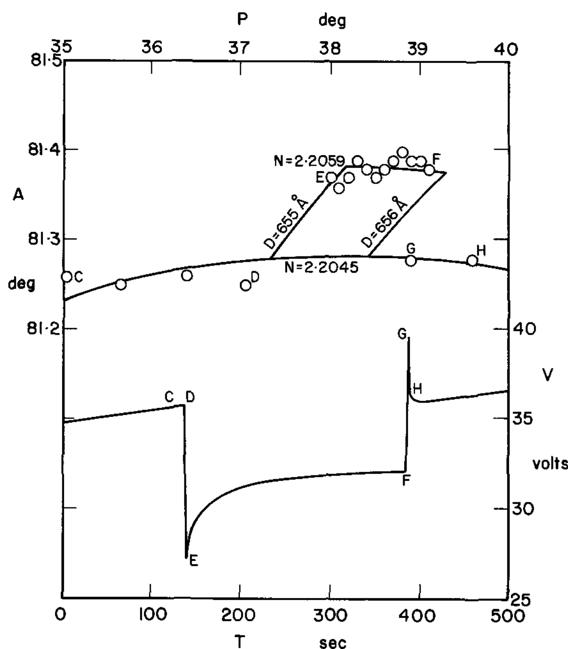

Fig. 2. Transients observed on switching the current density from 20 to 1 to 20 $\mu A/cm^2$ in the region between C and H in Fig. 1. Theoretical curves for layer growth at indexes of 2.2045 and 2.2059 and index change at thicknesses of 655 and 656Å are fitted to the optical data in the upper part of the figure. Potential is plotted vs. time in the lower part of the figure.

to the quadratic field dependence common in nonlinear optics. If an equation of the form

$$n = n_o (1 - \alpha E) \qquad [1]$$

is used to fit the data of Fig. 2, α must have a value of 0.117 Å/V. Another significant feature of the dependence of the index on the field is a lack of overshoot in the optical data during the overshoot in potential. The lack of overshoot in the optical data is an important result which turns out to hold true for all the metal oxides we have studied.

It may be possible to interpret the data plotted in Fig. 2 as resulting from some process other than a change in the layer index, perhaps from a process taking place at the oxide-electrolyte interface. That this is not the case can be demonstrated by measurements at other layer thicknesses. The simplest experiment which demonstrates that the entire layer is involved in the optical changes consists of comparing the results produced by changes in current density at points A and K in Fig. 1. The optical conditions are the same at these two points, but the layer thicknesses differ by a factor of over 50. No optical changes can be detected when the current is switched at point A, whereas significant changes are produced at point K. We do not present the results of this experiment here because in the region of points A and K the optical results do not enable changes in index to be differentiated clearly from changes in layer thickness. We choose instead to present the results of an experiment in which film growth is continued beyond the potential range plotted in Fig. 1 to return the optical conditions to what they were at points C through H in Fig. 1 and 2. Although this experiment is designed mainly to determine whether or not the thickness remains constant as the index changes, its results exhibit the larger optical shift on the second cycle of film growth expected for a process involving the whole film.

Although we plotted curves of constant thickness and variable index in Fig. 2 for thicknesses of 655 and 656Å, we have as yet said nothing about variations in film thickness as the applied current density is changed. Because of problems arising from the limited following speed of the ellipsometer, it is difficult to determine whether or not a film thickness change accompanies the index changes by direct inspection of Fig. 2. The data points plotted in Fig. 2 are not simultaneous values of the polarizer and analyzer null positions, because the polarizer and analyzer are nulled sequentially, polarizer before analyzer. At high A values the time required to null the polarizer is considerably longer than that required to null the analyzer, thus complicating corrections to the data to allow for the limited following speed of the instrument. If we do attempt to make following speed corrections to the data of Fig. 2, the strongest conclusion we can reach concerning thickness changes is that the thickness changes by about the same percentage as the change in index, the direction of the change being such as to keep the optical thickness constant. Thickness changes can be detected far more readily if the experiment is performed on the second optical cycle of layer growth rather than the first.

The optical results obtained on performing current-switching experiments on a tantalum sample during the first (points A1 through E1) and second (points A2 through E2) optical cycles are plotted in Fig. 3. The current density is 20 $\mu A/cm^2$ for the segments A1-B1 and A2-B2; changing the current to 1 $\mu A/cm^2$ shifts the optical null readings to points C1 and C2 on the first and second cycles, respectively. The applied current density is then returned to 20 $\mu A/cm^2$ before significant film growth occurs, and the optical data trace out the segments D1-E1 and D2-E2. The continuous lines plotted in Fig. 3 are theoretical curves for both the growth films of constant refractive index, and the variation in index of films of constant thickness on a tantalum substrate of index 3.02-2.57i. Ideally, the second cycle data should retrace the first cycle data rather than fall on a curve of slightly different index. The offset between the two cycles gives an indication of the absolute accuracy of our index measurements. The index variation curves in the figure indicate that the P-A behavior in this region changes on the second cycle of film growth.

For the first cycle data of Fig. 3 the difference in refractive index between the data obtained at 20 and 1 $\mu A/cm^2$, 1.5×10^{-3}, is in good agreement with the data reported in Fig. 2. For the second cycle experiment the change in index, 2.2×10^{-3}, and in field are larger

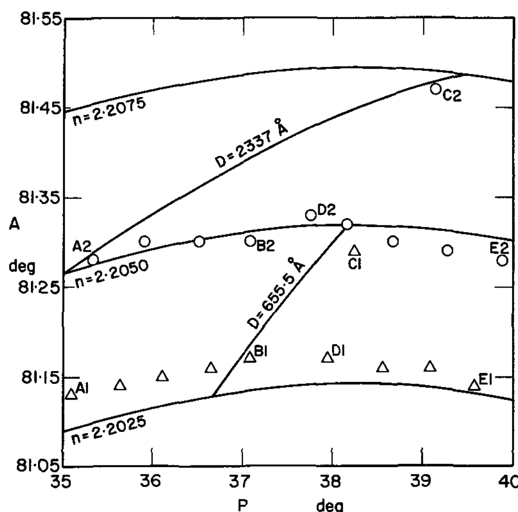

Fig. 3. Transients observed on switching the current density from 20 to 1 to 20 $\mu A/cm^2$ on the first cycle (A1-B1-C1-D1-E1) and second cycle (A2-B2-C2-D2-E2) of layer growth through the region plotted in Fig. 2. Theoretical layer growth curves for indexes of 2.2025, 2.2050, and 2.2075, and index variation curves at layer thicknesses of 655.5 and 2337Å are superimposed on the experimental data.

than in the first cycle, indicating that electronic leakage accounts for a significant fraction of the 1 $\mu A/cm^2$ current at this thickness, 2350Å, and potential, 130V. For the first cycle experiment we estimate that the fractional decrease in thickness is almost exactly equal to the fractional increase in refractive index on switching the current from 20 to 1 $\mu A/cm^2$. For the data obtained in the second cycle experiment the thickness of the film, of index 2.2050, prior to switching the current was calculated, by extrapolating along A2-B2, and checked, by extrapolating back along D2-E2, to be 2339.32Å. The point C2, obtained at 1 $\mu A/cm^2$, falls on a theoretical curve of index 2.2072, and the film thickness at this point is 2337.18Å. This experiment confirms that the fractional change in film thickness, 9.14×10^{-4}, and refractive index, 10^{-3}, are approximately equal in magnitude and opposite in sign. The fractional changes in thickness and refractive index may be related by the expression

$$\Delta d/d = -C\, \Delta n/n \qquad [2]$$

We have determined the coefficient C in Eq. [2] using data from several experiments on tantalum, and estimate that the average value we obtain, 0.872, is accurate to within 15%. All these optical experiments display two important features. First, the optical changes are due to changes in the whole film rather than in a surface layer or in the double layer in the electrolyte, and second, the thickness of the film increased linearly on application of the electric field in contrast with the prediction that the layer will undergo a compression proportional to the square of the field (8, 9).

Measurements of changes in the low-frequency dielectric constant can be made by following changes in the capacitance when the applied current density is switched to different values. It is not possible to distinguish between thickness variations and dielectric constant changes as was possible with the optical measurements, but the thickness variation can be taken as known from the optical measurements. In any event, the thickness variations detected optically for films on tantalum are small and comparable to the error estimated for the determination of the capacitance from a measurement of the a-c potential 90° out of phase with the applied a-c current. Unless simultaneous optical data are required, capacitance measurements can be made at any convenient thickness. In Fig. 4 we plot the results of an experiment in which the d-c current is switched from 200 $\mu A/cm^2$ to 1 $\mu A/cm^2$ and then back to 200 $\mu A/cm^2$ while the a-c current is held constant at 2.5 $\mu A/cm^2$ and 1000 Hz. Both the d-c potential and the a-c potential 90° out of phase with the current are plotted in the figure. The a-c potential follows the d-c potential to some extent, both showing overshoot, but the a-c potential shows less overshoot than the d-c potential even after taking into consideration the effect of the 0.3 sec time constant of the lock-in amplifier used in the experiment. An equation similar to Eq. [1] can be written to describe the dependence of the low-frequency dielectric constant, K, on the field.

$$K = K_o\,(1 - \gamma E) \qquad [3]$$

We have verified that the dielectric constant varies linearly with E, the electric field, and the constant, γ, in Eq. [3] has a value of 2.42 Å/V for the data of Fig. 4. Assuming a roughness factor of unity, we calculate the dielectric constant of the tantalum oxide layer as 24 at an applied current density of 200 $\mu A/cm^2$ in fair agreement with the previously published value of 27.6 (10). It should be noticed that the percentage change in the a-c potential on switching the current, 2.5%, exceeds by more than an order of magnitude both the anticipated 1/C error and the percentage change in film thickness. These quantities are thus small compared with changes in the dielectric constant. Considerable difficulty was encountered in attaining reproducibility in the current dependence measurements of the dielectric constant of tantalum oxide. We attribute this difficulty to factors in sample preparation over which we had inadequate control. As a result we estimate a possible error of about a factor of two in the value of γ quoted above. No difficulties were encountered in attaining reproducibility in these measurements with the other two metals.

Similar sets of measurements to those described above were carried out on niobium and tungsten, and we describe these results more briefly. Figure 5 shows the data obtained during the anodic oxidation of niobium at a current density of 100 $\mu A/cm^2$. The optical *P-A* data are shown in the upper part of the figure fitted to the growth of a film of index 2.30. The film thickness as determined from the fitted theoretical curve is plotted against potential in the lower section of the figure. Corresponding points on the two curves are designated A through N. Points K through N lie on the second cycle of the *P-A* curve, and the region between C and H is chosen for the current switching experiments plotted in Fig. 6 and 7. The same scales are used in Fig. 5 as in Fig. 1 to facilitate direct com-

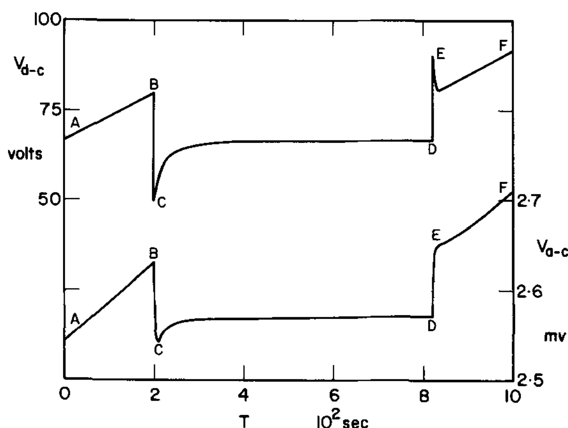

Fig. 4. Transients observed on switching the d-c current density from 200 to 1 to 200 $\mu A/cm^2$ while superimposed 1000 Hz a-c current is held constant at 2.5 $\mu A/cm^2$. The d-c potential is plotted in the upper part of the figure, and the a-c potential 90° out of phase with the current is plotted in the lower part.

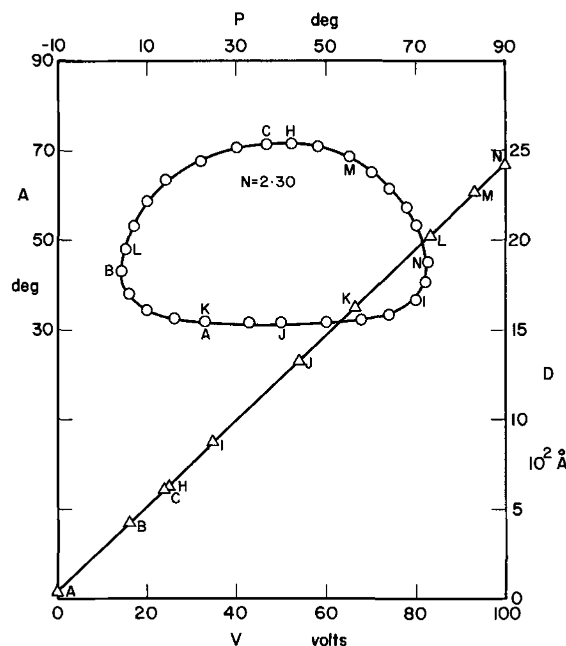

Fig. 5. Anodic oxidation of niobium at 100 $\mu A/cm^2$ in 0.2N H_2SO_4. The curve fitted to the optical data in the upper part of the figure is for the growth of a layer of index 2.30 on a substrate of index 3.03-3.61*i*. The film thickness detemined from this fitted curve is plotted vs. potential in the lower part of the figure.

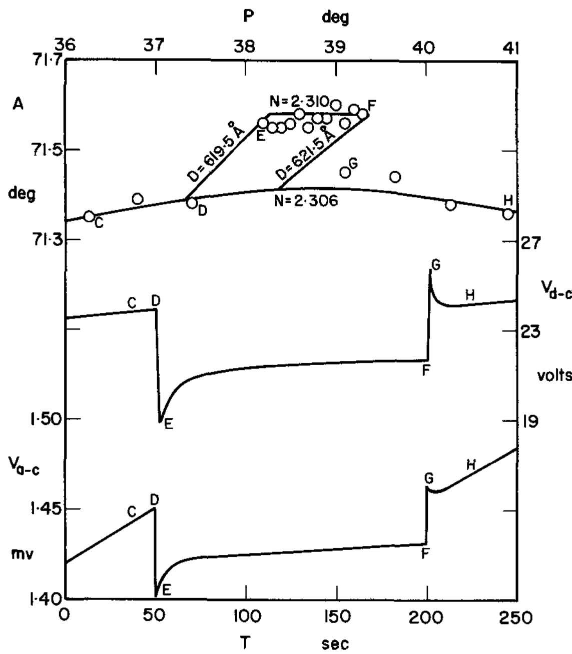

Fig. 6. Transients observed in the region between C and H in Fig. 5 when the d-c current density is switched from 30 to 3 to 30 μA/cm^2 with a superimposed 1000 Hz a-c current density of 5 μA/cm^2. The optical data, along with theoretical layer growth curves for indexes of 2.306 and 2.310 and index variation curves at thicknesses of 619.5 and 621.5Å, are plotted in the upper third of the figure, and the d-c potential and a-c potential 90° out of phase with the current are plotted vs. time in the lower part.

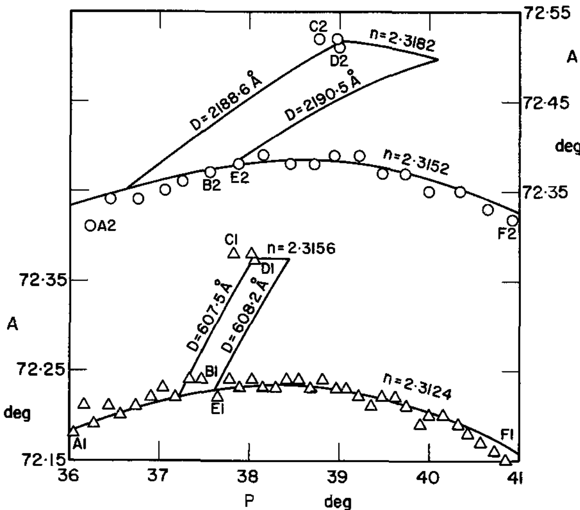

Fig. 7. Transients observed on switching the current density from 30 to 3 to 30 μA/cm^2 on the first cycle (A1-B1-C1-D1-E1-F1) and second cycle (A2-B2-C2-D2-E2-F2) of layer growth through the region plotted in Fig. 6. Offset analyzer scales are used to avoid overlap of the two sets of data. Theoretical layer growth curves for indexes of 2.3124 and 2.3156 and index variation curves at thicknesses of 607.5 and 608.2Å are fitted to the first cycle data, and layer growth curves for indexes of 2.3152 and 2.3182 and index variation curves at thicknesses of 2188.6 and 2190.5Å are fitted to the second cycle data.

parison. The electric field in the oxide, 4.16 × 10^6 V/cm, is considerably lower than that for tantalum, and the refractive index is a little higher. Generally larger refractive indexes result in the optical data falling on larger loops in the *P-A* plane, but the refractive index of the niobium substrate, 3.03-3.6*i*, differs sufficiently from that of tantalum to cause the data to fall on a smaller loop. This behavior is important in the current-switching experiments performed in the region between C and H, because the nulling time of the instrument increases markedly at large *A* values. The initial film thickness is calculated to be 30Å, the same value as for tantalum. The optical loop closes at a thickness of 1620Å at a potential of 67V.

The results of a current-switching experiment during the first optical cycle, in which the d-c current is switched from 30 μA/cm^2 (segment CD) to 3 μA/cm^2 (segment EF) and then returned to 30 μA/cm^2 (segment GH) while the a-c current is held constant at 5 μA/cm^2 and 1000 Hz, are plotted in Fig. 6. As was found for the tantalum system, the d-c and a-c potentials show overshoot, but no overshoot could be detected in the optical results. In addition, both the dielectric constant and the refractive index are linearly dependent on the electric field, decreasing with increasing field. The values of the coefficients α and γ of Eq. [1] and [3] were determined to be 0.457 and 8.61 Å/V, respectively, for the niobium system. The value of the dielectric constant at 30 μA/cm^2, assuming a roughness factor of unity, was found to be 38.5 in fairly good agreement with previous measurements (10). The change in thickness on switching the current can also be estimated from these results. On switching to the lower current the decrease in thickness observed has approximately the magnitude required to maintain constancy of the optical thickness.

Figure 7 presents the results of an experiment similar to that performed on tantalum, and summarized by Fig. 3, to determine the change in thickness that occurs upon changing the current density. In Fig. 7 the optical data for both the first and second optical cycles are presented. The experiment involves growing the oxide at 30 μA/cm^2 (segments A1-B1 and A2-B2), switching the current to 3 μA/cm^2 (segments C1-D1 and C2-D2), and returning to 30 μA/cm^2 (segments E1-F1 and E2-F2) before much layer growth can occur. This experiment confirms that the thickness of the layer decreases as the refractive index increases and that the fractional change in index is related to the fractional change in thickness by a relation of the form of Eq. [2]. the coefficient *C* having a value of 0.78 with an estimated error of 20%.

Figure 8 shows the data obtained during the anodic oxidation of tungsten at an applied current of 200 μA/cm^2. The optical data obtained in the experiment are

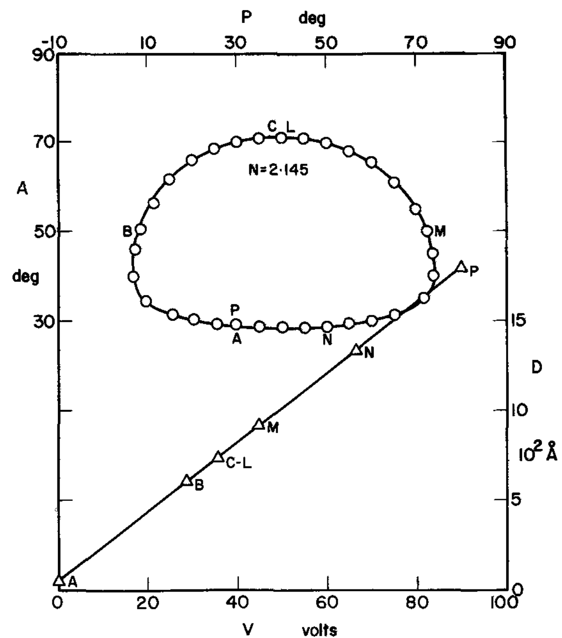

Fig. 8. Anodic oxidation of tungsten at 200 μA/cm^2 in 0.2*N* H_2SO_4. The curve fitted to the optical data in the upper part of the figure is for the growth of a layer of index 2.145 on a substrate of index 4.30-3.10*i*. The film thickness determined from this fitted curve is plotted vs. potential in the lower part of the figure.

shown in the upper portion of the figure fitted to the growth of a layer of refractive index 2.145 on a substrate of refractive index 4.3-3.1i. The film thickness, determined from the theoretical fit to the data, is plotted against potential in the lower section of the figure. From this plot the field in the film is determined to be 5.2×10^6 V/cm at an applied current of 200 μA/cm^2. Corresponding points on the two curves are designated A through P. At point P, corresponding to approximately 90V, film growth ceases presumably due to breakdown. In addition to this effect, the tungsten system exhibits other effects which complicate the interpretation of optical and electrical data.

In the initial stages of galvanostatic oxidation, before the potential increases linearly with time, the metal exhibits an active state. Typical valve metal behavior commences at 0.25V with 50Å of oxide covering the surface of the electrode. Optical results show that tungsten oxide also tends to dissolve in the electrolyte under anodic currents less than 20 μA/cm^2, although the electric field in the layer does not drop appreciably under these conditions.

We have performed current-switching experiments on this system to determine whether or not it shows the same behavior found for both tantalum and niobium. Figure 9 presents the results obtained for a current-switching experiment performed in the region between points C and L in Fig. 8. The optical data obtained are recorded in a P-A plot in the upper part of Fig. 9. During this experiment the current is switched from 100 μA/cm^2 (segment CD) to 10 μA/cm^2 (segment EF) to 30 μA/cm^2 (segment GH) to 3 μA/cm^2 (segment IJ) and returned to 100 μA/cm^2 (segment KL). In the center and lower sections of the figure, the d-c potential and the a-c potential which is 90° out of phase with an a-c current density of 4.9 μA/cm^2 at 1000 Hz are recorded. From this experiment we conclude that both the refractive index and the dielectric constant have a field dependence similar to that found for the oxides of tantalum and niobium. The values of α and γ in Eq. [1] and [3] are determined to

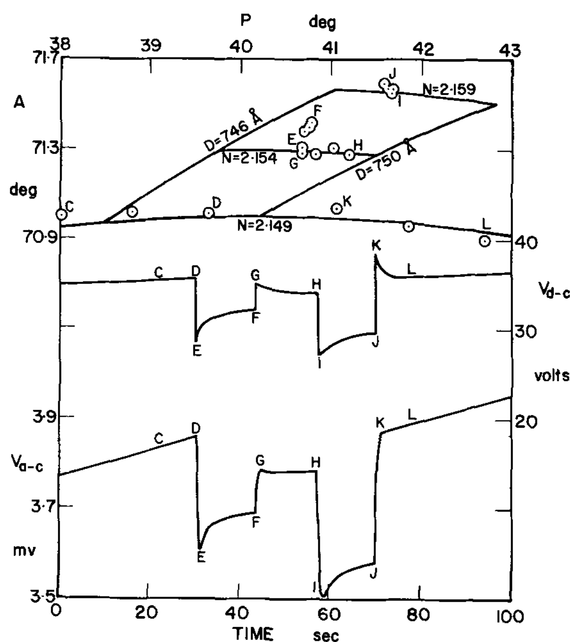

Fig. 9. Transients observed in the region between C and L in Fig. 8 when the d-c current density is switched from 100 (CD) to 10 (EF) to 30 (GH) to 3 (IJ) to 100 μA/cm^2 (KL) with a superimposed 1000 Hz a-c current density of 4.9 μA/cm^2. The optical data, along with theoretical layer growth curves for indexes of 2.149, 2.154, and 2.159, and index variation curves at thicknesses of 746 and 750Å are plotted in the upper third of the figure, and the d-c potential and a-c potential 90° out of phase with the a-c current are plotted vs. time in the lower part.

be 0.61 and 8.4 Å/V, respectively, for the tungsten system. The dielectric constant at 100 μA/cm^2 was determined, using a roughness factor of unity, to be 31.5. Measurements of thickness change accompanying changes in index are difficult to determine exactly as data on the second optical cycle cannot be obtained, but the thickness does increase as the index decreases. We estimate the coefficient C in Eq. [3] to have a value of 1.2 to within an error of 30% for this system.

Discussion

Theoretical descriptions of the ionic conduction process occurring during the anodic oxidation of valve metals have generally invoked a classical field-assisted transport model. This treatment leads to the well-known form

$$i = i_o \exp - (U/kT) \exp (qaE/kT) \quad [4]$$

for the relation between the ionic current density, i, and the electric field strength, E.

In 1960, Young (6) reported experimental results on the oxidation of tantalum, which showed that the relation between $\ln(i)$ and E was not linear and that a better fit to the data could be obtained by replacing the term qaE in Eq. [4] by $q(\alpha - \beta E)E$. This result was confirmed by the results of Young and Zobel (5) who in addition showed the necessity for including the nonlinear term in the fit of data obtained on niobium oxidation.

Our measurements were undertaken to determine whether a local field model could account for the curvature in the plot of $\ln(i)$ against E. The possibility that the local electric field rather than the external field controls the ionic conduction process in some solids has been suggested by Maurer (11), Young (6, 12), and Dignam (13, 14). In this model qaE, of Eq. [4], is replaced by $qa'E_e$, where E_e, the effective field is related to the applied field by the expression

$$E_e = E\,(K + 2)/3 \quad [5]$$

Experimentally we find that the dielectric constant varies with the field in the manner described by Eq. [3], and substituting this dependence into Eq. [5] gives

$$E_e = E\,(K_o + 2)/3 - E^2 K_o\gamma/3 \quad [6]$$

This relation has the same form as the expression used by Young and Zobel and their data could be accounted for by a local field model if

$$K_o\gamma/(K_o + 2) = \beta/\alpha \quad [7]$$

For tantalum our results give 2.23 Å/V for the left side of Eq. [7], whereas Young's results give 4.8 Å/V for the right-hand side. For niobium our results give 8.2 Å/V compared with Young and Zobel's value of 7.78 Å/V. The effective field model thus gives both the correct sign and order of magnitude of β/α for tantalum and niobium. Little work has been published on tungsten, and it is not known if the $\ln(i)$ *vs.* E plot is nonlinear. Our results indicate that there should be curvature in the tungsten system, the left-hand side of Eq. [7] having a value of 7.9 Å/V. The close agreement between the values for niobium indicates that an effective field model merits serious consideration in this case. In the case of tantalum, it is more difficult to reach a firm conclusion; although our result is too low by a factor of slightly more than two to account for all the $\ln(i)$ *vs.* E curvature, the problems we encountered with reproducibility in the data for the dependence of K on the field in this system forced us to estimate a possible error of a factor of two in our quoted γ value. Dell'Oca and Young (15) have recently shown that incorporation of electrolyte into the oxide film causes an increase in the curvature in the plot of $\ln(i)$ *vs.* E for tantalum. They suggest that some of the curvature for tantalum, even when grown in 0.2N H_2SO_4, might be due to electrolyte incorporation. We have, however,

found no optical evidence for any nonuniformity in the oxide film grown in tantalum in 0.2N H_2SO_4. Variations in the dielectric constant certainly appear to contribute to the $\ln(i)$ *vs.* E curvature for tantalum, but whether or not they are a major contributing factor, as seems to be the case for niobium, will have to be decided by further measurements.

Our ellipsometric measurements on the variation of refractive index with change in applied current, and thus in field, resulted in the detection of the important result that a change of thickness accompanies a refractive index change. We find, for all three systems studied, that the thickness change depends linearly on the field change, the thickness increasing with increasing field. All other investigations on anodic oxides have assumed that an electrostrictive effect was exhibited by these systems. Why the thickness changes should be linearly dependent on field is difficult to explain, but a knowledge of the magnitude and direction of the effect allows us to account for changes in the dielectric properties that occur on changing the field.

The change in thickness accompanying the change of field, in a current switching experiment, occurs without any charge being passed through the system; the total mass of the layer thus remains constant. Assuming that the only dimension which changes is the thickness, the fractional change in density, ρ, of the layer is related to the fractional change in thickness by the relation

$$\Delta\rho/\rho = -\Delta d/d \qquad [8]$$

For solids of the type under consideration, the Lorentz-Lorenz relation between the refractive index and density

$$(n^2-1)/(n^2+2) = A\rho \qquad [9]$$

where A is a constant, depending on the nature of the material and the wavelength of the light, should apply. Appropriate manipulation of Eq. [9] and substitution into Eq. [8] gives

$$\Delta d/d = -6\ (n^2+1-2/n^2)^{-1}\,\Delta n/n \qquad [10]$$

Comparing this equation with our empirical relation in Eq. [2], we see that the two would be identical if

$$C = 6/(n^2+1-2/n^2) \qquad [11]$$

From our optical results we can calculate the values for the right-hand side of Eq [11], and the values are 1.1, 1.0, and 1.16 for tantalum, niobium, and tungsten, respectively. Our measurements of C for the three systems are 0.872, 0.78, and 1.2, respectively, in quite reasonable agreement with the theoretically predicted values. This agreement indicates that the only contribution to the change in refractive index with field is a change in the bulk density. Our results for the change of refractive index with field are larger, by almost two orders of magnitude, than those reported by Frova and Migliorato (3) who used a field-modulated reflectance technique. They assumed that the film thickness did not change on applying a field to the electrode and that all the shift in the reflectance spectrum was due to the change in the refractive index of the film. The reflectance technique is actually sensitive to changes in optical thickness, the product nd, and as we have found that an increase in the refractive index is accompanied by a decrease in field, their results are expected to be far smaller than those we have observed.

The low-frequency dielectric constant changes may be predicted by a method similar to that described above for refractive index changes. The dielectric constant of the oxide should depend on the density through the Clausius-Mossotti relation

$$(K-1)/(K+2) = B\rho \qquad [12]$$

where B is a constant. From Eq. [12] the change in K due to a change in density would be

$$\Delta K = (K+2)(K-1)\,\Delta\rho/3\rho \qquad [13]$$

Equation [13] when combined with Eq. [8], [2], [3], and [1] yields the equality

$$\gamma/\alpha = C(K^2+K-2)/3K \qquad [14]$$

which will be true provided all the change in the dielectric constant is due to a change in the bulk density of the oxide. Our experimental values of the ratio γ/α are 20.5, 14.1, and 13.8 for tantalum, niobium, and tungsten, respectively. The values of the right-hand side of Eq. [14] for the three metals are 9.13, 13.6, and 12.5. The agreement is excellent for niobium and tungsten, but not for tantalum, perhaps due to the poor accuracy to which we determined γ for the tantalum system.

One other result obtained in this investigation, one which should be of use in the development of a more detailed and satisfactory model for the high-field ionic conduction process in anodic oxides, is the observation of overshoot in measurements of the dielectric constant at low frequencies but not at optical frequencies. The existing theories of the ionic conduction process do not give an adequate prediction of the behavior of the anodic oxide under the transient conditions that occur when the applied current, or field, is suddenly changed. The existence of overshoot in the low-frequency measurements would seem to suggest that the processes which dominate at this frequency and not at optical frequencies are intimately connected with the ionic conduction process.

Conclusion

The linear increase of thickness with increase in field we observe in ellipsometric measurements on the anodic oxides of tantalum, niobium, and tungsten results in the variation of the dielectric constant, at both high and low frequencies, with steady-state field. The variation in the dielectric constant with field, in combination with an effective field model for the ionic conduction process, can explain the existence of nonlinearity in the $\ln(i)$ *vs.* E plot observed by many other investigators for tantalum and niobium oxidation.

Acknowledgment

The authors would like to acknowledge the assistance given by Dr. J. D. Leslie in the preliminary measurements of the field-dependence of the low-frequency dielectric constant. This work was supported in part by the National Research Council of Canada under Grant No. A-1151.

Manuscript submitted Sept. 16, 1971; revised manuscript received Dec. 3, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Electrolytic Determination of Porosity in Gold Electroplates

II. Controlled-Potential Techniques

Ronald J. Morrissey*

Research Division, AMP Incorporated, Harrisburg, Pennsylvania 17105

ABSTRACT

Anodic polarization curves of gold and gold-plated copper specimens have been obtained at a sweep rate of 10 mV/min in 0.1M NH_4Cl electrolyte. The curves obtained are found to be linear over ranges of potential approaching 50 mV displacement from the free corrosion potential. From the data obtained, values of the free corrosion potential, the polarization admittance, and the leakage current are extracted and compared for each specimen. Agreement between the corrosion potential and polarization admittance values is excellent. It is shown that the polarization admittances of gold-plated copper specimens in 0.1M NH_4Cl vary with the apparent exposed area fraction of copper according to expressions derived by Stern. Agreement between the corrosion potential and leakage current values is fair, becoming poorer as the polarizing potential is displaced farther from the free corrosion potential. It is shown that at a given value of the polarizing potential, leakage currents passed by gold-plated copper specimens in 0.1M NH_4Cl vary directly with the apparent exposed copper area. Anodic current densities and minimum limits of detectability for the various techniques are discussed.

In a previous paper (1) it was shown that the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl electrolyte are related to the exposed basis metal area fractions of the specimens by means of an expression originally derived by Stern (2), and that this relationship affords a convenient and sensitive means of electroplate porosity determination. The object of the present paper is to examine two additional electrolytic techniques: linear polarization measurements and leakage current measurements, which have proven useful in electroplate porosity determinations, and to present comparisons of data obtained from corrosion potential, linear polarization, and leakage current measurements performed sequentially on the same specimens.

Linear Polarization Methods

Linear polarization methods were first applied to the determination of electroplate porosity by Clarke and Britton (3). Beginning with studies of tin-nickel platings on steel, these authors and subsequent coworkers have investigated the effects of various preplating treatments of the substrate on the porosity of electrodeposits subsequently applied (4), and have extended the use of the porosity test to a number of plating-substrate systems, including gold on copper (5, 6).

Clarke and Britton found that, in electrolytes chosen so as to corrode only those areas of substrate exposed at pores in a noncorroding metal electroplate and to do so without formation of insoluble corrosion products, the anodic polarization curves of potential *vs.* current density for electroplated specimens were linear over ranges of potential approaching 100 mV displacement from the free corrosion potential; and that the slopes of the linear plots thus obtained appeared to be directly related to the resistivity of the electrolyte and inversely related to the average porosities of the test specimens. Analyzing these data, they suggested that under these conditions, current was passed by the exposed basis metal only and was effectively controlled by the resistance of the electrolyte in the pore channels. Assuming that the change in polarization of the basis metal was negligibly small, the slope of the polarization curve for a given specimen would then be a measure of the sum of the parallel resistances of the electrolyte-filled pore channels, and the greater the value of $\Delta V/\Delta I$, the smaller would be the apparent porosity.

In this work, we consider an alternative hypothesis, namely, that the initial linear slopes of the anodic polarization curves of basis metal specimens coated with porous noble metal electrodeposits may be governed, in certain electrolytes, by the area relationships of the exposed anodic and cathodic constituents according to expressions derived by Stern (2). We do this for two reasons: first, because our own previous work has shown (1) that the Stern expressions adequately describe the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl solution. It is also felt that an approach based on the use of the Stern expressions, if applicable, represents a more general case than that treated by Clarke and Britton; and particularly avoids the perhaps questionable requirement that the polarization of the exposed basis metal remain substantially invariant as the over-all mixed potential of the plated specimen is varied over several tens of millivolts.

For the corrosion current of a binary galvanic couple controlled by activation polarization, Stern writes

$$\log I_{corr} = \frac{E_a}{\beta_a + \beta_c} + \frac{\beta_c}{\beta_a + \beta_c} \log A_c\, i_{oc} + \frac{\beta_a}{\beta_a + \beta_c} \log A_a\, i_{oa} \quad [1]$$

where E_a is the free corrosion potential of pure anodic material, measured with respect to the equilibrium potential of pure cathodic material in the same electrolyte, which is taken as zero. β_a and β_c are the anodic and cathodic Tafel constants, and i_{oa} and i_{oc} are the respective exchange current densities for the anodic and cathodic processes. A_a and A_c are the area fractions of anodic and cathodic materials in the actual couple (such that $A_a + A_c = 1$).

Following the analysis presented previously (1), we note that for a given base metal-noble metal couple in a given corrodant bath the electrochemical parameters E_a, β_a, β_c, i_{oa}, and i_{oc}, as well as the equilibrium potential of the pure cathodic material, are constants. Further, for the case of base metal specimens coated with noble metal electroplates of moderate to low porosity, $A_c >> A_a$. In this case, A_c approaches unity, and the term in ($\log A_c\, i_{oc}$) may be considered a constant. It is thus possible to rearrange expression [1], combining

* Electrochemical Society Active Member.

Key words: electroplates, porosity, porosity testing, gold, copper, galvanic cells, corrosion potential, polarization admittance, linear polarization, leakage current.

and substituting terms to yield an expression of the form

$$I_{corr} = C_1 A_a \frac{\beta_a}{\beta_a + \beta_c} \quad [2]$$

Thus, for a base metal specimen of specified total area, coated with a noble metal electroplate of moderate to low porosity, the corrosion current is found to vary as a power of the area fraction of basis metal exposed to the electrolyte.

It is now of interest to compare expression [2] with the linear polarization expression of Stern and Geary (7)

$$\frac{\Delta I}{\Delta V} = \frac{(2.3)\ I_{corr}\ (\beta_a + \beta_c)}{\beta_a \beta_c} \quad [3]$$

that relates the corrosion current of a freely corroding specimen to the slope of that linear portion of the cathodic or anodic polarization curve which is found to occur at potentials close to the free corrosion potential. The range of potential over which such linear kinetics are observed is usually small. Stern (8) estimated the expected range to be only of the order of ±10 mV from the free corrosion potential. Cases of linear polarization behavior extending over potential ranges of several times this figure are, however, well documented in practice. These and the occurrence of asymmetric behavior (in which the potential range of linear kinetic behavior is greater in one direction from the free corrosion potential than in the other) have been discussed by Barnartt (9).

Combining expressions [2] and [3] and simplifying, we obtain

$$\frac{\Delta I}{\Delta V} = C_1 C_2 A_a \frac{\beta_a}{\beta_a + \beta_c} \quad [4]$$

where the constant C_1 results from grouping the various constant terms in expression [1], and the constant C_2 is equal to $(2.3)(\beta_a + \beta_c)/\beta_a\beta_c$. According to this expression, and subject to experimental conditions as specified above, a plot of the logarithm of the linear polarization slope for a plated specimen *vs.* the logarithm of the area fraction of basis metal exposed to the electrolyte should yield a linear trace, the slope of which is in turn given by $\beta_a/(\beta_a + \beta_c)$.

Leakage Current Methods

Leakage current measurements were first applied to the determination of porosity in electrodeposits of nickel and cobalt on steel by Shome and Evans (10). Their procedure was to measure the cell current passed when the specimens were connected, in an electrolyte of 3% NaCl + 0.1% Rochelle salt, to a large copper gauze which served as an auxiliary cathode. No reference electrode was used. They reasoned that if the copper gauze were made sufficiently large, the cell current would be limited only by the rate of anodic dissolution and would thus be directly proportional to the exposed area of bare steel. This technique was subsequently extended by Ehrhardt (11) with the addition of an external power supply with which the potential between the specimen and the auxiliary cathode could be controlled. Again, no reference electrode was employed. Using an applied potential of 0.75V, Ehrhardt measured porosity values for gold-plated copper specimens in 5% H_2SO_4 electrolyte. Kamm, Willey, and co-workers (12) have employed a variation of the leakage current technique to determine the continuity of the iron-tin alloy layer in electrolytic tinplates on steel.

In their critique of leakage current methods, Clarke and Leeds (5) pointed out that the potential of the auxiliary cathode as employed in such measurements is itself a corrosion potential, subject to change from polarization by current flow or from other experimental variables. They suggested that such measurements might be improved by polarizing the specimen with respect to a reference electrode rather than with respect to the auxiliary cathode. Barnartt (13) has shown that, if the partial cathodic current can be neglected, the cell current under such conditions is approximated by

$$I = A_{anodic}\, i_{oa} \exp\,[2.3(E - E_{r,a})/\beta_a] \quad [5]$$

where E is the polarizing potential and $E_{r,a}$ is the reversible potential for the anodic process, both measured with respect to a suitable reference electrode; and A_{anodic} is the exposed basis metal area. Thus, under conditions of simple anodic dissolution of the exposed basis metal to form soluble corrosion products, and provided that the effects of concentration and resistance polarization can be kept small (*i.e.*, by restricting the investigation to fairly thin electroplates and by restricting anodic current densities to the smallest practicable values), anodic polarization of a series of plated specimens to the same potential *vs.* a suitable reference electrode should yield cell currents that in each case are proportional to the area of basis metal exposed to the test electrolyte.

Experimental

The general approach taken in this work has been to examine the anodic polarization curves of gold and gold-plated copper specimens, obtained potentiodynamically at low sweep rates (10 mV/min) in 0.1M NH_4Cl test electrolyte. The curves obtained were found to be linear over ranges of potential approaching 50 mV displacement from the free corrosion potential. The slopes of these linear plots were taken to be equal to the polarization admittance $\Delta I/\Delta V$ (14) of the various specimens. Comparisons were then drawn between the observed values of the free corrosion potential, the polarization admittance, and the leakage current (determined at several potentials with respect to a saturated calomel reference electrode) for each specimen.

A Pyrex resin kettle of 500 ml capacity served as the reaction vessel. This was equipped with a Plexiglas cap through which the electrodes could be immersed into the bath. Experiments were performed at room temperature, approximately 23°C. Solutions were made up using Analytical Reagent grade chemicals in boiled, demineralized water, the specific resistance of which was typically in the range of 200,000 ohms. The specific resistance of the 0.1M NH_4Cl solution as made up was 83 ohms.

The reference electrode employed was a Beckman No. 39170 saturated calomel electrode having a fiber junction. For convenience, this was located in the electrolyte at a distance of 3.5 cm from the test specimen, which was itself suspended in the bath by means of a 99.99% gold wire.[1] It had been shown in previous work (1, 3) that the position of the reference electrode is of negligible influence in determining the corrosion potentials of specimens coated with porous electrodeposits. Prior to each experiment, the potential of the saturated calomel electrode was checked *vs.* that of a Beckman No. 41236 silver-silver chloride electrode that was reserved as a standard. A pair of 99.99% platinum spirals, each of 9.1 cm² immersed area, served as counterelectrodes. These were located at a distance of 7 cm from each other in the bath, with the test specimen suspended midway between them.

The test specimens were small OFHC copper electrical terminals, each of 2.5 cm² gross geometric surface area. These were barrel plated in small lots with Temperex HD gold[2] to thicknesses of 50, 100, and 400 μin. (1.27, 2.54, and 10.16μ). Additionally, data were obtained using two circular gold coupons, each of 10.8 cm² geometric surface area, which had been stamped from sheet stock of 99.9% purity.[3] Cleaning and preparation of the various specimens prior to each experiment was accomplished as previously outlined (1).

[1] Obtained from the Sigmund Cohn Corporation, Mount Vernon, New York.
[2] Sel-Rex Corporation, Nutley, New Jersey.
[3] Handy and Harman, Incorporated, New York, New York.

The electrical apparatus consisted of a Wenking Model 68TS1 potentiostat, equipped with a Wenking Model MP165 motor potentiometer. Recording of the polarization curves was accomplished using a Hewlett-Packard Model 7005B X-Y recorder. Potential of the specimen with respect to the reference electrode was read using a Keithley Model 610B electrometer voltmeter, the output of which was relayed to the X-axis of the recorder. Current was read by monitoring the potential drop across a one megohm precision resistor which was inserted between the potentiostat and the twin counterelectrodes. The use of this rather large resistance served to restrict the magnitude of the cell currents obtained, as well as providing a convenient means of current measurement. The potential drop across this resistance was read using a Keithley Model 610A electrometer voltmeter, the amplified output of which was relayed to the Y-axis of the recorder.

The experimental procedure was as follows: after cleaning and preparation, the test specimen was suspended in the bath by means of a 99.99% gold wire and was allowed to attain a steady corrosion potential with respect to the reference electrode. In all cases, an equilibration time of at least 1 hr was allowed for this purpose. In this work, corrosion potential measurements have been employed as the "referee" technique, and the apparent basis metal (copper) area fractions of the test specimens have been determined from the corrosion potentials by reference to the calibration curve previously obtained (1). This is shown in Fig. 1.

When a steady corrosion potential had been attained, the potentiostat was switched into the circuit and the anodic polarization curve of the specimen was obtained at a potential sweep rate of 10 mV/min. Some representative curves obtained in this manner are shown in Fig. 2. In general, the curves obtained for the gold-plated copper specimens were found to be linear over a potential range approaching 50 mV displacement from the free corrosion potential. For the gold specimens, the linear range approached 150 mV.

A comparison of free corrosion potential and polarization admittance values for a series of gold and gold-plated copper specimens is shown in Fig. 3. The agreement in the results obtained using these two methods is felt to be excellent. Polarization admittances shown in Fig. 3 have been calculated on a gross area current density basis to compensate for the difference in geometric surface area between the gold ($A = 10.8$ cm^2) and gold-plated copper ($A = 2.5$ cm^2) specimens. The slight differences noted in corrosion potential and polarization admittance values for the two gold specimens (shown at the lower right of Fig. 3) are felt to be attributable to slight differences in their respective impurity concentrations. In both gold specimens, the major impurity was copper.

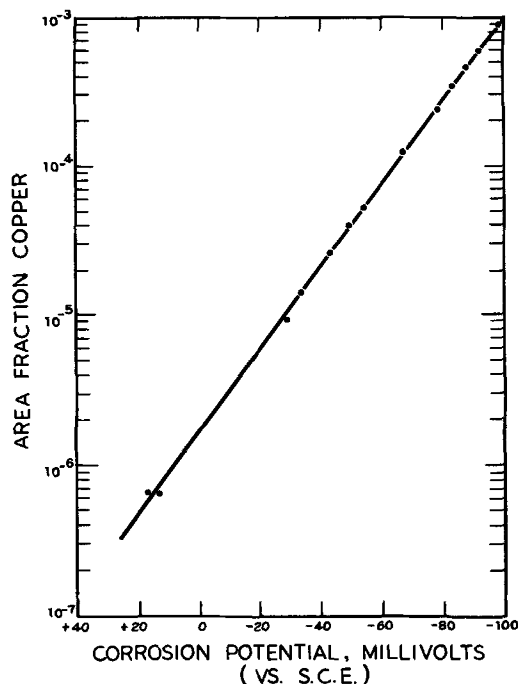

Fig. 1. Variation of corrosion potential with immersed copper area fraction.

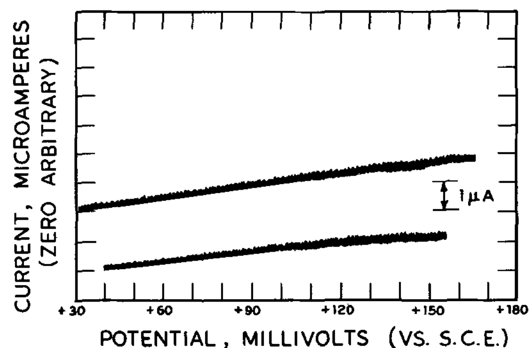

Fig. 2. Anodic polarization curves of gold-plated copper specimens in 0.1M NH_4Cl. (Deposit thickness 50 μin.)

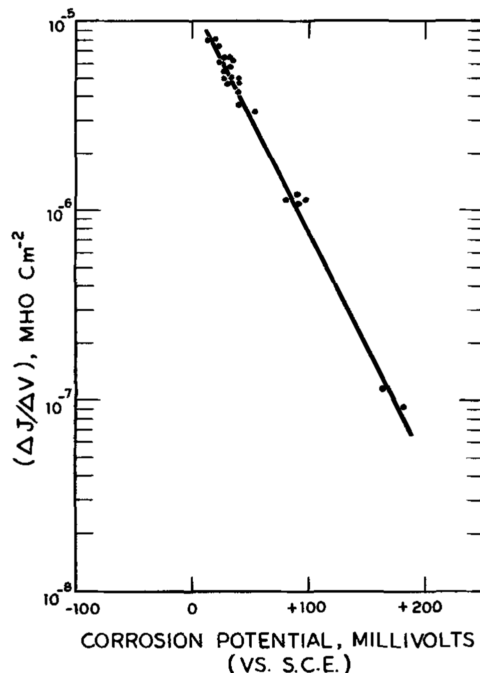

Fig. 3. Comparison of corrosion potential and polarization admittance values.

Converting the corrosion potential values for the gold-plated copper specimens to corresponding values of the apparent area fraction of exposed copper by reference to Fig. 1, it is possible to replot the polarization admittance data for these specimens in the form [$\log(\Delta I/\Delta V)$ *vs.* $\log A_a$]. Such a plot is shown in Fig. 4. Data for specimens plated with 400 μin. deposits are omitted from this figure because their apparent exposed basis metal area fractions are considerably smaller than the lower limit of calibration shown in Fig. 1. The slope of Fig. 4 is 0.384, which is in excellent agreement with the value of 0.352 calculated for ($\beta_a/\beta_a + \beta_c$) from the observed values for β_c of gold (0.0935V) and β_a of copper (0.0507V) in this electrolyte (1). This evidence is taken to indicate that, under experimental conditions as described herein, the polarization admittances of gold-plated copper specimens in 0.1M NH_4Cl electrolyte are adequately described by an expression of the form of Eq. [4].

Leakage current values were obtained in this work by reading directly from the polarization curves. A

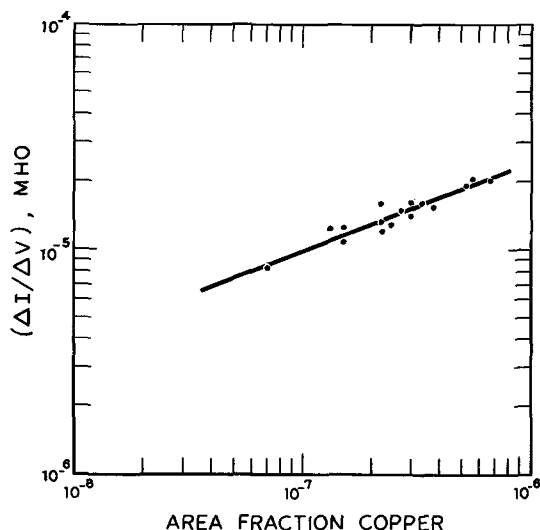

Fig. 4. Variation of polarization admittance with exposed copper area fraction.

plot of leakage currents obtained at potentials of +0.050 and +0.100V (*vs.* SCE) *vs.* the apparent areas of exposed copper for the plated specimens is shown in Fig. 5. Values of the apparent exposed area of copper for these specimens were obtained, as previously, from their corrosion potentials by reference to Fig. 1; multiplying the indicated values of the apparent area fraction by the gross geometric surface area (2.5 cm^2) of the plated specimens.

The plots shown in Fig. 5 are of unit slope, indicating that in the range considered the leakage currents obtained are directly proportional to the area of copper exposed to the electrolyte. The scatter of the experimental data, however, is observed to increase as the polarizing potential is displaced farther from the free corrosion potential; indicating that, as might be expected, the effects of various experimental artifacts become increasingly significant as the anodic current density is increased. In general, the agreement between corrosion potential and leakage current results in this work was fair.

Discussion

The employment in this work of a potential-scan technique for the determination of polarization admittance and leakage current values departs somewhat from the potential-step procedures ordinarily used. It was felt that for purposes of obtaining comparative data the scanning technique offered potentially greater reproducibility in handling numbers of specimens. The sweep rate of 10 mV/min was chosen to be sufficiently slow as to avoid double layer charging effects near the free corrosion potential, and sufficiently rapid as to avoid excessive erosion of the pore channels in obtaining the remainder of the polarization curve.

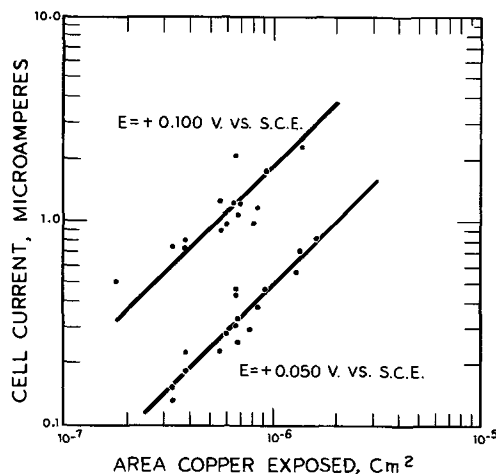

Fig. 5. Variation of leakage current with exposed copper area

We have not attempted to evaluate the effects of electrolyte *p*H, oxygenation, or cupric ion accumulation on the results of the various determinations. Previous work had shown (1) that these factors influence the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl, and presumably they would affect polarization admittance determinations as well, both by affecting the corrosion rates of the specimens and because the initial potential in such determinations is the corrosion potential. The experimental scatter observed in leakage current determinations in this work would appear to indicate that various experimental artifacts can and do exert a significant influence on such measurements, particularly at large current densities.

As was mentioned earlier, the agreement obtained between corrosion potential and polarization admittance determinations in this work was considered excellent. The evidence of Fig. 3 would indicate that either of these techniques, given a suitable means of calibration, could be extended to the lower limiting case of pure gold. This, of course, is subject in both techniques to the limitations imposed by the inability of the electrolyte to penetrate very fine or very deep pores (1, 4, 15). In the upper limit, it was shown (1) that the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl approach a plateau at values of A_a larger than about 1%, and that the method would thus fail as a porosity test in this range. It might be expected that the upper limit of applicability for polarization admittance measurements as a porosity test would be somewhat higher than this, but we have not attempted to establish such an upper limit.

The agreement obtained between corrosion potential and leakage current results was fair, becoming poorer as the polarizing potential was progressively displaced from the free corrosion potential. The major advantage of the leakage current technique is in speed of measurement, as it is not necessary when using this technique to determine the corrosion potentials of the various specimens before energizing them. This ability, however, is achieved at the cost of high anodic current densities when the specimens are energized. It can be shown from Fig. 5 that under the conditions of these experiments, polarization of gold-plated copper specimens to a potential of +0.100V *vs.* SCE produces an anodic current density of approximately 2 A/cm^2 of exposed copper. By contrast, the free corrosion current densities of the plated specimens employed in this work can be calculated from polarization admittance values to be of the order of 100-500 mA/cm^2 of exposed copper, increasing with decreasing values of A_a. A plot of free corrosion current densities for gold-plated copper specimens in 0.1M NH_4Cl solution, calculated on the basis of Fig. 4 using expression [3], is shown in Fig. 6. This illustrates a major point of difference between the corrosion potential and polarization admittance techniques, in both of which the free corrosion current density varies with A_a as shown in Fig. 6; and leakage current measurements, in which, at a given polarizing potential, anodic current density is invariant with A_a. A further difference, as was mentioned previously, is that the lower limit of detectability in porosity determinations by corrosion potential or polarization admittance measurements appears to be determined primarily by the ability of the electrolyte to penetrate very fine or very deep pores, whereas in leakage current measurements, the lower limit is also determined by the magnitude of the polarizing potential. Polarization of gold-plated copper specimens to +0.050V *vs.* SCE under the conditions of these experiments yields an anodic current density of 500 mA/cm^2 of exposed copper. At this polarizing potential, anodic currents would be passed

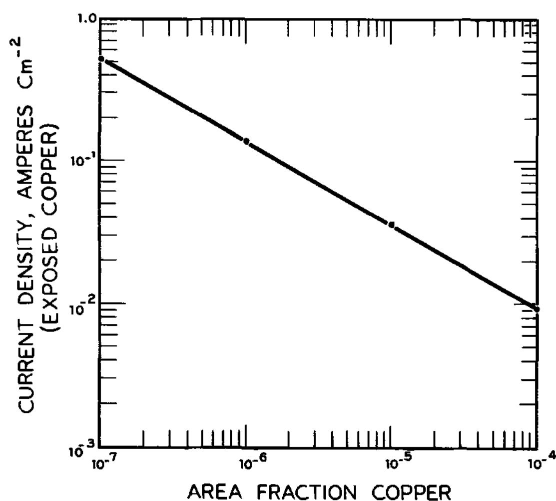

Fig. 6. Variation of free corrosion current density with exposed copper area fraction.

only by specimens having free corrosion potentials more negative than this value, thus introducing a minimum limit of detectability in A_a of approximately 10^{-7}.

In view of this work and of that previously reported (1) it now appears that, within limits at least, the results of electrolytic porosity determinations on base metal specimens coated with noble metal electroplates are expressible in terms of the electrochemical theory of galvanic couples; and that, in the case of corrosion potential measurements, it is possible to prepare calibration curves such that values of the exposed basis metal area fraction in electroplated specimens can be estimated to a reasonable approximation. Cross-calibrations of polarization admittance and of leakage current measurements with respect to corrosion potential measurements are also obtainable and are illustrated in this work. This is in contrast, particularly, to chemical porosity test methods, correlations between which are usually possible only on an empirical basis.

Organosilicon Films Formed by an RF Plasma Polymerization Process

M. J. Vasile and G. Smolinsky

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The purpose of this research was to develop a plasma polymerization process for producing polymeric films and to achieve an understanding of the chemistry involved. A technique for the production of polymer coatings from a capacitively coupled RF plasma is presented. The resulting films contain trapped free radical sites which can react with oxygen and nitric oxide. The rate of polymer formation is a complicated function of power input, total system pressure, and partial pressure of monomer. The rates of reaction differ for different monomers under identical reaction conditions. The stoichiometry and infrared spectra of the polymers indicate that considerable fragmentation and bond reorganization of the monomeric starting material occurs during the polymerization process. A mechanism is proposed to account for conversion of monomer to polymer by formation and fragmentation of ionic species in the discharge. Neutralization of the ionic fragments at the walls yields radicals which can react with adsorbed species and be cross-linked to form polymer.

There is a growing interest in coating solid surfaces with thin polymeric films by reactions resulting from electron bombardment, ultraviolet radiation, or electrical discharges in an atmosphere containing a low molecular weight organic compound. Since 1967 three reviews (1-3) have been written on this subject. It is well known that polymer can be produced on the walls and electrodes of a discharge apparatus containing a reactive gas or a mixture of inert and reactive gases. The electrical discharge may be supported by static, radio frequency, or microwave fields, or some combination of these. A polymeric film that is clear, smooth, and pin-hole free can be produced by the proper choice of discharge conditions. These films adhere well to most substrates and can be made from approximately 200Å to several microns thick. Polymers that are synthesized in electrical discharges are usually highly cross-linked, *i.e.*, they possess two or three dimensional bonding, rather than linear structures. As a result of cross-linking, the polymer films have good thermal stability and are inert to mild acids, alkalis, and most organic solvents. In this paper we describe our apparatus and experimental procedure for discharge polymerization and some of the properties of polymers formed from vinyltrimethylsilane, $CH_2{=}CHSi(CH_3)_3$ and hexamethyldisiloxane, $(CH_3)_3SiOSi(CH_3)_3$ (abbreviated VTMS and HMDS, respectively).

Experimental

A schematic representation of the discharge chamber is shown in Fig. 1. The lower electrode, E, is connected to the output of a 13.56 mHz generator through an impedance matching network. This electrode is supported 10 cm above the base plate by insulating legs, and it has provisions for water to be circulated to it from a constant temperature bath. The upper electrode, G, is supported from the top plate and is held at ground potential. The top plate contains the monomer and gas inlet tube and is supported by a glass cylinder 20 cm in diameter and 21 cm in height. The electrodes are 15 cm in diameter, and the interelectrode separation is 4 cm. All feed throughs and vacuum seals utilize Viton gaskets or Swagelok fittings.

Substrates upon which polymer is to be deposited are placed on the electrode E. The chamber is then evacuated by a 6-in. diffusion pump to a pressure of 2×10^{-6} Torr or less. The gate valve is then closed, and a throttle valve leading to a mechanical pump is opened. Argon is admitted to the chamber to the desired pressure through a variable leak valve which leads into the gas inlet tube. Gas pressure in the discharge chamber is measured to the nearest 0.01 Torr on a calibrated capacitance manometer. Monomer vapors are then introduced into the argon stream from heated reservoirs through variable leak valves. In this way, the partial pressure of each component in the discharge tube is known. The entire gas inlet is kept about 20°C warmer than the monomer reservoirs to prevent condensation. Gas flow is maintained throughout the duration of the discharge by pumping through the throttle valve.

The discharges were operated at a variety of pressures and power levels in order to investigate the effects of different reaction conditions on the produc-

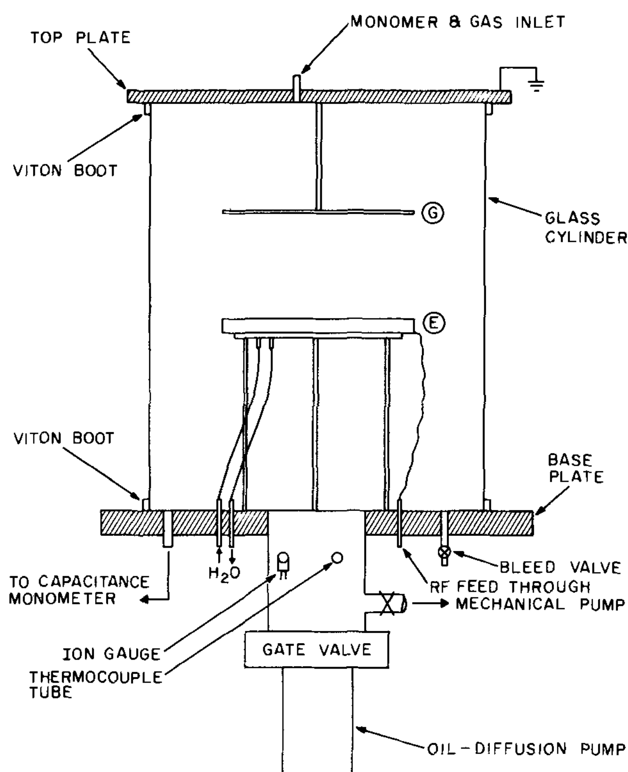

Fig. 1. Schematic representation of glow discharge reaction chamber

Key words: organosilicon films, RF plasma, polymerization.

tion of polymer films. Rate measurements were made by weighing the amount of polymer deposited on 5 × 5 cm aluminum foil substrates for a given discharge duration, power level, gas composition, and total pressure. Unless otherwise stated, polymer samples for chemical analysis, IR and ESR spectra, and differential scanning calorimetry were prepared using the same set of conditions, *viz.*, 0.4 Torr total pressure, 0.3 Torr monomer pressure, 200W input power, and 25°C electrode temperature. Infrared spectra were obtained using the attenuated total reflectance technique from polymer deposited on highly reflecting aluminum strips. Samples used for ESR measurements and elemental analysis were scraped from glass slides which had been coated with polymer.

Upon termination of the discharge the chamber was again evacuated using the diffusion pump. The discharge chamber could be back-filled with any desired gas at this point. Polymer samples that were to be heat-treated in air, vacuum, or oxygen were transferred to another apparatus that was built especially for that purpose.

Results and Discussion

Under all conditions used in this study to form polymer, a glow was visible around both electrodes, and a striated glow was observed in the interelectrode region. Polymer formation occurred in all regions of the discharge tube and under some conditions, macroscopic polymer particles were observed to form in the gas phase. The thickest deposits were on the electrodes and the walls of the chamber; deposition occurred to a lesser extent on the base plate and the top plate. In our discussion of film growth rate, we do not mean to imply a true reaction rate measurement, since all our data were obtained just on the surface of the active electrode, E, and the rate of film growth differs in different regions of the reaction chamber. However, polymer deposition on the substrate should be a function of the kinetic rate of polymerization as well as such factors as gas diffusion, mixing, and substrate temperature.

The rate of deposition of VTMS and HMDS polymers was linear with time for any particular choice of discharge conditions for reaction times up to 60 min. No tests were carried out for durations longer than 60 min. This linear growth rate is an expected result since the gas flow through the discharge tube was sufficient to maintain a constant monomer partial pressure. Furthermore, the degree of ionization in the discharge is undoubtedly low, which further insures against depletion of the monomer.

Additional information on the kinetics of the depositing polymer is obtained from the data in Fig. 2 which shows the rate of polymerization of a three-component system of VTMS, HMDS, and argon as a function of the monomer composition. The argon partial pressure was maintained at 0.1 Torr, and the total partial pressure of monomers was 0.3 Torr. The data points shown in Fig. 2 are the averages of several determinations at each composition. The scatter obtained for each of the points is principally due to the experimental difficulties encountered in maintaining the feed and power input constant. Figure 3 is a plot of the ratio of the carbon: silicon content of the films shown in Fig. 2. It is evident from Fig. 2 that HMDS films grow at approximately one-half the rate of VTMS films, while the rate of polymerization of mixtures of the two monomers is merely the sum of the individual rates. In addition the elemental composition of polymer prepared from mixtures of HMDS and VTMS (Fig. 3) is also the sum of the composition of the polymers prepared from each component. The data presented in Fig. 2 and 3 suggest that both HMDS and VTMS react independently of each other.

The rate of deposition of VTMS polymer was studied as a function of power input, total pressure, and partial pressure of the monomer. Figure 4 shows the rate as a function of power for constant total pressures of 0.3 and 0.5 Torr with equal partial pressures of argon and VTMS. In both cases, the rate increased to a plateau as the input power increased. This behavior is probably due to an increase in the electron temperature and number density with a higher power level, which in turn would enhance the rate of production of ions and radicals and hence increase the rate of polymerization. Figure 5 shows the rates obtained for VTMS polymer deposition as a function of partial pressure in

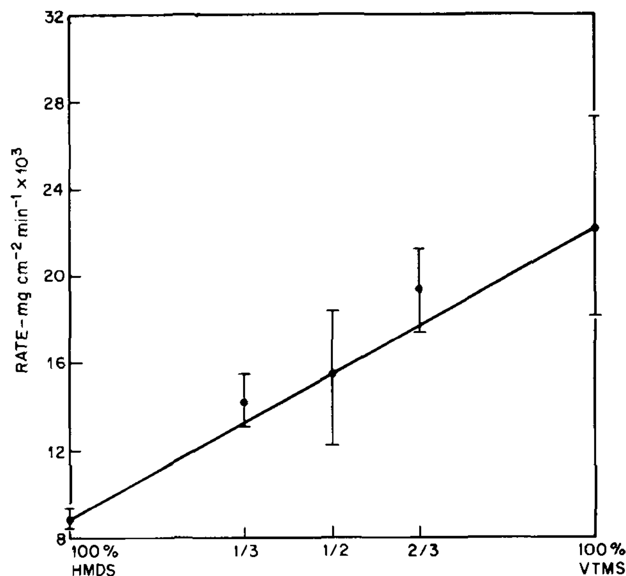

Fig. 2. Rate of polymer deposition as a function of monomer composition (VTMS and HMDS). Total partial pressure of monomers was 0.3 Torr, argon 0.1 Torr. Power 200W.

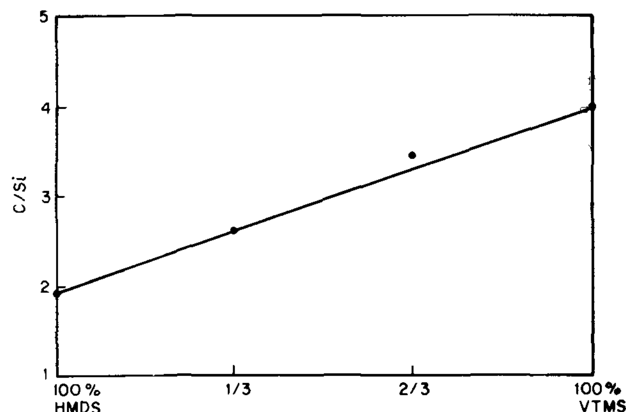

Fig. 3. Carbon to silicon ratio of polymers prepared from HMDS and VTMS.

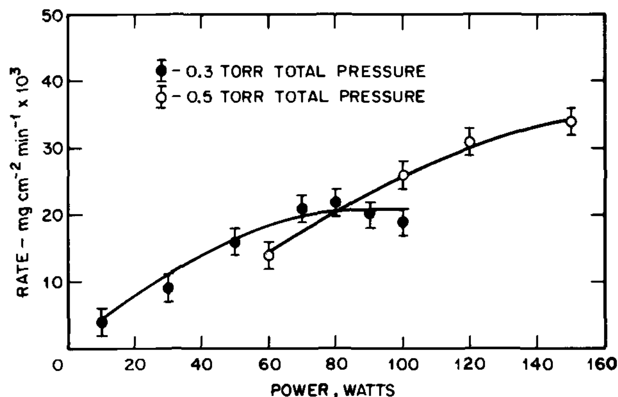

Fig. 4. Rate of VTMS polymer deposition as a function of power at constant pressure. (Equal partial pressure of argon and VTMS.)

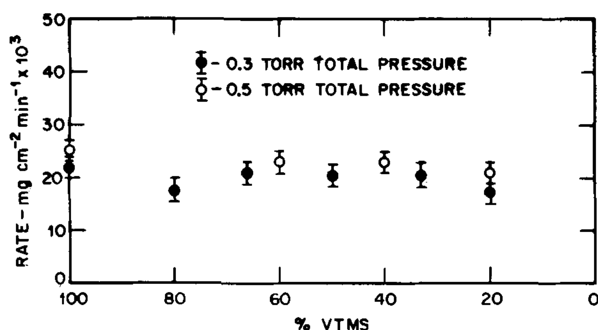

Fig. 5. Rate of polymer deposition as a function of monomer concentration in argon at constant total pressure and power (80W).

argon for constant total pressures of 0.3 and 0.5 Torr, with a constant power input of 80W. There was no significant difference in deposition rate between 100% and 20% VTMS at either total pressure. (Note that Fig. 4 shows that the rate curves obtained at 0.3 and 0.5 Torr intersect at 80W.) In addition, the data presented in Fig. 5 show that the rate of polymer deposition is controlled not simply by the concentration of monomer but perhaps by the rate at which monomer can be converted to a reactive species, since film growth remains essentially constant even though the concentration of monomer is reduced by a factor of five. Figure 6 shows the rate of polymer deposition obtained in pure VTMS at 80W as a function of pressure. At 0.1 Torr VTMS with no argon present, the rate of film growth is about 4×10^{-3} mg cm^{-2} min^{-1}, whereas at 0.1 Torr partial pressure VTMS in the argon mixtures, the rate is about five times as fast (Fig. 5). It is probable that the presence of argon helps to sustain the discharge and thus prevents the decrease in rate as the monomer pressure is decreased. The sharp drop in deposition rate between 0.5 and 0.6 Torr (Fig. 6) may be a result of having increased the frequency of inelastic collisions to the point where the electrons do not reach a temperature high enough to maintain the plasma at previous levels. It must be emphasized at this point that a precise and definitive explanation of these rate data requires diagnostics of the electron temperature and concentration while the polymerization is taking place, and such diagnostics are not conveniently performed.

Several different experiments lead to the conclusion that glow discharge polymers possess potentially reactive radical sites. Some of these sites are obviously very reactive toward oxygen since samples of VTMS polymer for which the discharge vessel was back-filled with air were found to contain 11.6 and 14.3% oxygen, while back-filling with nitric oxide reduced the oxygen content in the polymer to less than half this amount (see Tables I and II). In addition, the infrared

spectrum of a VTMS film initially exposed to air exhibited weak broad absorption at 3380 cm^{-1} (O-H) and 1720 cm^{-1} (C=O), and strong absorption at 1050 cm^{-1} (Si-O) along with the expected absorption at 2960 and 2910 cm^{-1} (CH_2 and CH_3, respectively), 2120 cm^{-1} (Si-H), and 1245 cm^{-1} (Si-CH_3). Heating the above films at 150°C for 3 hr in oxygen increased the intensities of the O-H, C=O, and Si-O bands, while the C-H and Si-H absorption essentially vanished. On the other hand, VTMS films that were initially exposed to a 3 Torr atmosphere of nitric oxide for 16 hr before exposure to air showed absorption bands at 2950 and 2900 cm^{-1} (CH_2 and CH_3), 2110 cm^{-1} (Si-H), and 1243 cm^{-1} (Si-CH_3), with virtually no absorption for O-H, C=O, and Si-O bonds. The incorporation of oxygen by glow discharge polymers on exposure to air has also been observed by Westwood (4); the amount depended on the nature of the polymer and the conditions under which it was formed.

Radical sites which were less reactive toward oxygen were detected by electron spin resonance measurements. VTMS polymer showed a broad line absorption from 6 to 13 gauss wide at $g = 2$. Heat treatment (150°C) of the polymer in air or in vacuum resulted in almost total loss of this signal. It is interesting to note that complete quenching of the free radicals and relief of conformational strain in the polymer required heating to about 150°C. Trapped free radicals in discharge produced polymers have also been observed by Schurov *et al.* (5).

Differential scanning calorimetry of VTMS and HMDS polymer indicates that the former material has a much greater concentration of potentially reactive sites than the latter, even after both polymers have been exposed to air. For example, samples of VTMS polymer produced strongly exothermic thermograms over the entire temperature range 35°-460°C, while HMDS polymer samples gave thermograms which were only slightly exothermic from 35° to 180°C and then endothermic to 460°C. After heating freshly prepared VTMS polymer at 150°C for 20 hr in vacuum, a thermogram very similar to that of HMDS was obtained. We interpret the strong exothermic behavior as due to chemical reaction, perhaps with atmospheric oxygen and/or as radical recombination.

The results of combustion analyses of VTMS and HMDS polymers are given in Tables I and II. The weight per cent of carbon, hydrogen, and silicon were determined directly; the difference between the total for these elements and 100% was assumed to be the oxygen content. The carbon to silicon atom ratio of each sample is also reported in the tables. These re-

sults demonstrate quite clearly that the elemental compositions of the polymers of HMDS and VTMS differ significantly from the compositions of the monomers. In the case of the VTMS polymer, the C/Si ratio varies from 2.7 to 4 and apparently depends on the power input and the partial pressure of argon. The VTMS monomer has a C/Si ratio of 5, so that at least one carbon atom per monomer unit must be lost when forming polymer. Similarly, HMDS polymer has a C/Si ratio of about 2, while the monomer has a C/Si ratio of 3. Tkachuk *et al.* (6) have found C/Si ratios of 1.85 and 1.59 for polymer prepared from HMDS by the action of gas discharges, as well as a dependence of this ratio on the presence of argon. Further evidence of major structural reorganization occurring in the transition from monomer to polymer is found in the infrared spectra. VTMS polymer contains Si-H bonds and lacks double bonds. HMDS polymer also contains Si-H bonds. In both cases, the monomers have no Si-H bonds.

Many workers have proposed a variety of mechanisms for the formation of glow discharge polymers. Three of these are discussed briefly to give some idea of the diversity of thinking in this area. Yasuda and Lamaze (7) studied the polymerization of styrene in an electrodeless, inductively coupled glow discharge system. They concluded that in their system polymerization is initiated (whether by a radical or ion is not mentioned) and propagates in the vapor phase until the growing polymer is too large to remain as a vapor and deposits on the wall. Westwood (8) studied the polymerization of ten conventional vinyl polymers, including styrene, in a capacitively coupled discharge. He concluded that positive ions and ionic fragments attracted to the electrode surface and walls initiate polymerization of adsorbed neutral monomer molecules. The proportion of ionic fragments to intact monomer incorporated in the polymer depended on the conditions of the reaction. Denaro *et al.* studied the polymerization of styrene (9a), styrene derivatives (9b), allyl alcohol (9c), and crotyl alcohol (9c) in a capacitively coupled discharge. These workers concluded that the reaction of radicals produced in the vapor phase was of little importance, and that the mechanism of polymerization involved competitive reactions of radicals formed on the electrodes by electron bombardment.

All the above workers have used compounds which readily polymerize by cationic and/or radical mechanisms. We have studied compounds, VTMS and HMDS, which are not suitable for polymerization by ordinary means. Experimental observations in this study which may be relevant to postulating a mechanism follow: the stoichiometry of the polymer indicates a lower carbon content and the infrared spectra show bond reorganization, both of which must occur in the transition from monomer to polymer. Potentially reactive radical sites are trapped in the polymer. Polymerization was observed in the gas phase when the input power and total pressure were high. Fragmentation of VTMS under electron impact was studied in a mass spectrometer as a function of electron energy. The parent molecular ion was found to be very unstable even at electron energies as low as 10 eV. The major ionic fragments at high or low energies had values of M/e of 85 and 59. Figure 7 shows the relative intensities of the various fragment ions for electron energies from 10 to 40 eV. The mass 85 fragment ion corresponds to a loss of the methyl radical from the parent ion, and the mass 59 fragment ion results from a loss of acetylene from the mass 85 fragment ion.

A likely mechanism of polymer formation at the walls of an RF discharge for a compound such as VTMS can now be postulated The process is initiated in the gas phase by electron impact and formation of a radical ion. Since electrons with energies in excess of 20 eV are rare in the plasma, the major fragments

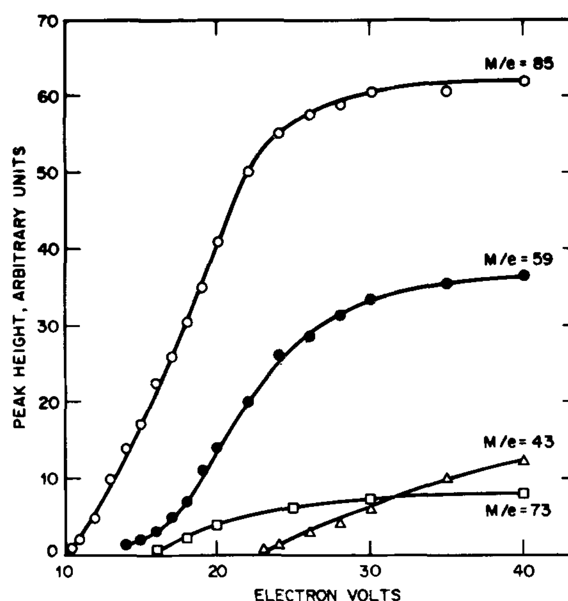

Fig. 7. Ionic fragments from VTMS on electron impact

expected due to a single electron impact on the VTMS molecule are ions of mass 85, $(C_4H_9Si)^+$, and mass 59, $(C_2H_7Si)^+$, acetylene, and methyl radicals. Ionic fragments formed near the sheath boundary are accelerated to the walls of the vessel by the plasma-to-wall potential difference. On reaching the walls, the ions recombine with electrons forming radicals. These radicals can then react with adsorbed monomer or other radical sites and become incorporated into the polymeric structure. Ionic fragments formed in the plasma at relatively long distances from the sheath boundary may react with a neutral or radical species to form higher molecular weight positive ions. If the rate of growth of this ionic chain is slow enough to allow migration to a wall, electron-ion recombination will produce a short chain radical which can then become incorporated into the polymer. If, on the other hand, the growth of the ionic chain is fast, it can continue to grow in size until it becomes large enough (*i.e.*, macroscopic) to act as a virtual wall. Radical site production in existing polymer on the walls should be a continuous process resulting from photon and ion impact. (Electrons from the plasma are retarded as they approach the walls and thus lose energy.)

Polymer production on the electrode surfaces should proceed by essentially the same mechanism, with the exception that a strong alternating electric field is present in the dark space between the plasma and the electrode surface. Electron energies are likely to be much higher in this region, resulting in increased monomer fragmentation. Charged particles of either polarity will be accelerated to the electrode on each half cycle, so the effects of high-energy electron impact must also be considered as a source of cross-linking.

This postulated mechanism is consistent with many of the observed experimental results; however, it must be emphasized that it is only one of a number of possibilities. Experiments involving the diagnostics of chemically reactive plasmas are now in progress in this laboratory and should provide more definitive data on the mechanism of polymer formation.

Calibration of Electrochemical Oxygen Meters in Sodium Using Uranium

Hugh S. Isaacs*

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

Methods using uranium to remove or getter oxygen quantitatively from sodium have been used to calibrate the potential of the meter as a function of the oxygen concentration in sodium. The oxygen meters were constructed with sodium-sodium oxide reference electrodes and ThO_2-Y_2O_3 electrolytes. The calibration methods depended on the deviation of these meters from ideal behavior. The methods involved the summation of the weight gains of uranium, *i.e.*, the weights of oxygen removed from the sodium, the derivative of the weight gains for a given potential change as a function of the number of repetitive oxygen removal steps, and the time dependence of the potential during the removal of oxygen from sodium by uranium. The behavior of a meter depended on the purity of the ThO_2-Y_2O_3 electrolyte used. High-purity electrolytes gave the theoretical dependence of potential on concentration but impure tubes showed marked deviations from theoretical behavior at low concentrations at temperatures of 500°C.

The necessity for measuring oxygen concentration in sodium used as a coolant in fast breeder nuclear reactors is related to the corrosion and mass transfer of metals in these systems. The corrosion of many metals (1) and iron-base alloys, including stainless steels (1, 2), have been found to increase with higher oxygen concentrations in sodium. Increased corrosion rates would lead to increased transfer of radioactive materials from the reactor core to the rest of the primary system, and, to minimize these effects, the concentration of oxygen should be kept as low as possible and monitored to detect any concentration changes.

Electrochemical cells using solid oxide electrolytes (3) offer a possible method for continuously monitoring oxygen concentrations in the sodium. However, the potentials developed by these cells or meters have not been reproducible (3, 4) and in some cases their response to changes in oxygen concentration have not been the same for one or more meters in the same system.

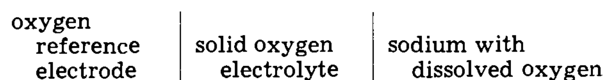
In order to study the variables which could influence the reproducibility of these meters, a rapid method for calibrating meters was required. For this study the use of small sodium containers was more desirable than the large sodium loops most frequently used for investigations of the behavior of sodium. The advantages of small containers are that impurities in the sodium, including oxygen, could be controlled more readily and rapidly than in a large nonisothermal system.

During a study of methods for removing oxygen from sodium it was found that uranium reacted rapidly with oxygen dissolved in sodium and formed uranium oxide. This oxide adhered to the uranium when the temperature was 500°C and above giving weight gains of the uranium equal to the amount of oxygen removed. The rate of reaction was also found to be proportional to the oxygen concentration and the rate was controlled by diffusion in the sodium or the mass transfer coefficient for oxygen in sodium (5). Uranium, therefore, appeared to be ideal for removing oxygen from sodium and also offered several alternative techniques for determining the relationship between the potential of the meter and the oxygen concentration in sodium. It is the purpose of this paper to describe these techniques and discuss some of the results obtained.

Theory

Electrochemistry

An electrochemical oxygen meter for monitoring oxygen in sodium is basically an electrochemical cell which may be represented by



oxygen reference electrode	solid oxygen electrolyte	sodium with dissolved oxygen

where the sodium with dissolved oxygen forms the second electrode and the potential of the cell (E) is given by the Nernst equation

$$E = E_o + \alpha \ln \frac{C_S}{C} \quad [1]$$

where $\alpha = RT/n\mathbf{F}$, E_o is the potential of the meter when the concentration of oxygen in the sodium, C, is at saturation, C_S, and R, T, and $\mathbf{F}$ are, respectively, the gas constant, the absolute temperature, and the Faraday. The solubility of sodium oxide in sodium is low (~1200 ppm) and the solution may therefore be considered as dilute. Hence Henry's law is applicable and the concentration of oxygen in solution is proportional to its activity (6). The value of E_o depends on the reference electrode used and is determined by the free energy of formation of sodium oxide from the reaction of sodium with the reference electrode; when a sodium-sodium oxide reference is used its value is theoretically zero.

Calibration Methods Using Uranium

In this section the equations that may be used for the calibration of oxygen meters using uranium are derived and their application is discussed in the following section.

Summation method.—Consider an initial potential of the oxygen meter as E_1, then this potential corresponds to an oxygen concentration C_1 and the potential increases as oxygen is removed from the sodium by reaction with uranium. When the uranium is removed from the sodium the potential will have increased to a value E_2 corresponding to a lower oxygen concentration C_2. From the weight gain of the uranium, ΔW_1, the relationship between the concentrations is

$$C_1 = C_2 + \frac{\Delta W_1}{W_{Na}} \quad [2]$$

where W_{Na} is the weight of sodium. As the measurements are related to weight changes rather than concentration changes, the weights of oxygen are considered. It is a simple matter to convert weights to concentrations when the calibration curve is obtained. If the weight of oxygen in the sodium, W, corresponds to an oxygen concentration, C, then multiplying both sides of Eq. [2] by W_{Na} gives

$$W_1 = W_2 + \Delta W \quad [3]$$

If oxygen was removed from the sodium in Z steps then

$$W_1 = W_{Z+1} + \sum_{n=1}^{Z} \Delta W_n \quad [4]$$

where W_{Z+1} is the weight of oxygen remaining in the sodium after Z gettering steps and $\Delta W_{n=Z}$ is the weight of oxygen removed by uranium for the Zth step. The corresponding weight of oxygen in the sodium before the nth gettering step is

$$W_n = W_{Z+1} + \sum_{n=n}^{Z} \Delta W_n \quad [5]$$

In the above equation the value of W_{Z+1} is unknown, but if $W_{Z+1} << W_n$ this quantity may be neglected and Eq. [5] becomes

$$W_n = \sum_{n=n}^{Z} \Delta W_n \quad [6]$$

The potential of the meter prior to each gettering is given by E_n and a plot of E_n *vs.* W_n would give the calibration curve for the meter where $W_n >> W_{Z+1}$.

This method has the advantage that the period of gettering or the resulting potential changes need not be controlled as is required in some of the methods described below. However, to overcome the restriction that the weight of oxygen remaining in the sodium must be negligible compared with the total weight of oxygen at a given potential necessitates the use of a method requiring a specific experimental procedure for each gettering.

Method using constant potential steps.—In this method a series of gettering steps are performed and n refers to a particular step as in the summation method. The weight gain for a given step is again ΔW_n. However, in this method the potential step (ΔE) for all steps must be the same (*i.e.*, $\Delta E_1 = \Delta E_n$).

The potential change for the first step is given by

$$\Delta E = \alpha \ln \frac{W_1}{W_2} \quad [7]$$

and is derived from Eq. [1]. After $n - 1$ steps the potential change is

$$(n-1)\,\Delta E = \ln \frac{W_1}{W_n} \quad [8]$$

Equation [7] with Eq. [3] can be rearranged to give

$$\Delta W_1 = W_1 \left(1 - \exp\left\{-\frac{\Delta E}{\alpha}\right\}\right) \quad [9]$$

and, in general

$$\Delta W_n = W_n \left(1 - \exp\left\{-\frac{\Delta E}{\alpha}\right\}\right) \quad [10]$$

Equations [9] and [10] indicate that the weight gain (or change in concentration) is proportional to the initial weight (or concentration) of oxygen for that gettering step on the assumption that the value of α remains constant.

Substituting Eq. [9] and [10] in [8] for the $(n - 1)$ step gives

$$(n-1)\,\Delta E = \alpha \ln \frac{\Delta W_1}{\Delta W_n} \quad [11]$$

which on differentiating gives

$$\frac{d \ln \Delta W_n}{dn} = -\frac{\Delta E}{\alpha} \quad [12]$$

Equation [11] shows that a plot of the logarithm of the weight gain as a function of the number of getterings (n) has a slope as given by Eq. [12] equal to the (constant) potential change ΔE for each gettering divided by the value of α. The slope of this curve can be measured and as ΔE is known, the value of α can be calculated.

If the value of α is constant this plot is linear, but if α changes as the oxygen concentration is reduced this is reflected in a change in slope of this plot.

Variation of potential with time during uranium gettering.— The rate of change in oxygen concentration is related to the rate at which uranium removes oxygen from sodium. When uranium is inserted into sodium the rate of change in concentration (dc/dt) is proportional to the oxygen concentration in the sodium (5), *i.e.*

$$-\frac{dc}{dt} = Ck \quad \text{or} \quad -\frac{d \ln C}{dt} = k \quad [13]$$

where k is the rate constant which is equal to the mass transfer coefficient (5). The rate of potential change is also related to the rate of change in oxygen concentration as can be seen on differentiating Eq. (1)

$$\frac{dE}{dt} = \alpha \frac{d \ln C}{dt} \quad [14]$$

Substituting Eq. [13] in Eq. [14] gives

$$\frac{dE}{dt} = \alpha k \quad [15]$$

If the value of α remains constant and the mass transfer coefficient is kept constant (by controlling the geometry of the system and the sodium velocity during uranium gettering) then the product of α and k is a constant and from Eq. [15] the potential increases linearly with time. If α decreases, the rate of change in potential also decreases.

Experimental

The oxygen meters used in this work were of similar construction to those with a copper-copper oxide reference electrode (3) except the reference electrode was replaced by sodium and sodium oxide. The thoria-yttria electrolyte tubes all containing 15% yttria by weight were about 6-8 in. long and ¼-½ in. in diameter. The tubes were leak tested and showed a leak rate of less than 10^{-10} cm^3/sec. The slip-cast tubes were obtained from Zirconium Corporation of American and the isostatically pressed tubes were obtained from General Electric Corporation. The insidious impurity in the slip-cast tubes was SiO_2 at concentrations of 100-300

Table I. Impurities in ThO_2-15 w/o Y_2O_3 tubes

Element	Slip-cast	Isostatically pressed
Si	300	<10
Fe	300	<10
Mo	10	<10
Mg	300	<1
Ni	50	<1
Mn	10	<1
Pb	5	<1
Co	5	<1
Cu	50	<1

ppm that formed a second grain boundary phase by reacting with Y_2O_3 (7). The isostatically pressed tubes had an impurity level of less than 35 ppm. Representative compositions of the two types of tubes determined spectrographically are shown in Table I. The high-purity tubes were white in color and remained white after firing in air at 700°C. The impure tubes were brown after air firing. This difference suggests that impurities in the oxide play a part in developing the brown coloration when exposed to high-oxygen activities rather than being caused by some property of the oxide solution itself (8).

Impurities present in "as-received" sodium gave reactions which tended to buffer the oxygen concentration in sodium and could act as a source or sink for oxygen (9). Distilled sodium was consequently used in these experiments. Containers of zirconium oxidized in oxygen for 3 hr at 700°C, or of stainless steel showed no difference in results. The sodium weighed 310 ± 20g and was stirred with a hermetically sealed stirrer. Stringent precautions were taken to prevent contamination of the sodium or the added sodium oxide (5) with air or water vapor. A helium cover gas at pressure above atmospheric, containing less than 10 ppm oxygen and water vapor protected the sodium from contamination by gaseous impurities.

Uranium strips were usually 5 x 1 x 0.1 cm in size. The strips were electropolished in equal volumes of ethanol and phosphoric acid at 6-12V, washed in water, and weighed to ±0.03 mg before use. After exposure to sodium the sodium adhering to the uranium was dissolved in methanol and the uranium was then washed in water and air dried prior to reweighing (5).

Results and Discussion

When oxygen is removed from the sodium the oxygen concentration decreases and the potential of the meter according to Eq. [1] increases. Figure 1 shows an example of the variation of potential with time when uranium was used to remove oxygen in a series of gettering steps. The meter was constructed with the high-purity isostatically pressed oxide tube. When uranium was inserted in the sodium the potential increased linearly with time in agreement with Eq.

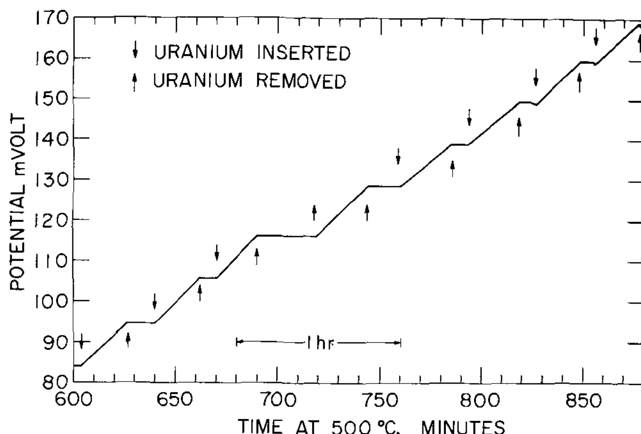

Fig. 1. Variations of potential with time during oxygen gettering with uranium for a meter with a high-purity electrolyte.

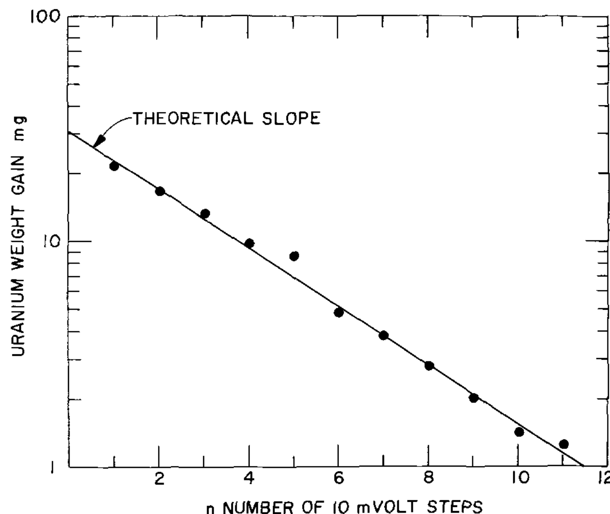

Fig. 2. Variation of uranium weight gain as a function of the number of repetitive gettering steps for a high-purity electrolyte.

[15]. Upon removing the uranium the potential no longer increased and gave the series of steps shown in Fig. 1. The weight gains of uranium tubes after each gettering shown in Fig. 1 and those obtained at higher potentials are plotted in Fig. 2 as a function of the gettering step. These results can be used to determine the calibration curve for the meter, *i.e.*, the relation between the potential and the logarithm of the oxygen concentration. The slope of this curve α can be determined from Fig. 2 as indicated by Eq. [12]. This equation can be expressed to base 10 as

$$\frac{d \log \Delta W}{dn} = \Delta E \Big/ \frac{2.3\,RT}{2F} \quad [16]$$

The theoretical slope is equal to 1/7.7 mV^{-1} at 500°C for 10 mV potential changes. The observed slope in Fig. 2 is in good agreement with the theoretical slope indicating that the value of α was in accord with the Nernst equation. An extrapolation of these results can also be used to determine the calibration curve shown in Fig. 3. The value of α determined from this curve was 79 mV/decade change in oxygen concentration which deviates by less than 3% from the theoretical value.

Three meters constructed with isostatically pressed tubes were calibrated after holding at 500°C for one

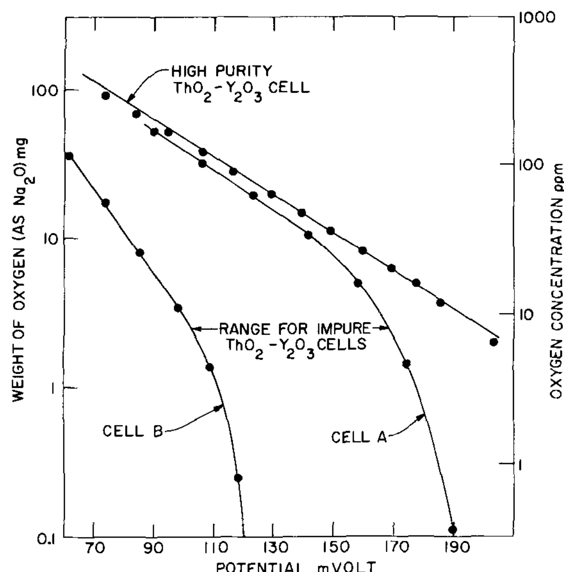

Fig. 3. Calibration curves for cells constucted with high purity and impure ThO_2-Y_2O_3 electrolytes.

day. The potential difference between the calibration curves at a given oxygen concentration varied by close to 20 mV. The curves were parallel being within 5% of the theoretical slope down to oxygen concentrations of 1 ppm. The potential of the meters, however, decreased with time but their response to changes in oxygen concentration remained the same for a period of 40 days. The decrease in potential was found to be approximately 2 mV/day when only a small excess of solid Na_2O was present in the reference electrode. Additions of Na_2O to the reference electrode after the drift had occurred increased the potential of a cell and suggested that the drift and the potential differences after one day were probably a result of the reaction between the oxide and the electrolyte at the higher oxygen activity in the reference electrode. Reactions have been observed to take place at higher temperatures and at a rate which increased oxygen concentrations in the sodium (10).

The calibration curves of 15 oxygen meters constructed with slip-cast ThO_2-Y_2O_3 tubes that were less pure than the isostatically pressed tubes, were highly variable. The results for two of the meters which represented the range of behavior of the slip-cast tubes tested at 500°C are shown in Fig. 4. This figure shows the variation of the logarithm of the weight gains for a series of gettering steps. The measurements have been normalized to effectively 10 mV steps for direct comparison between the results. Curves A and B were obtained with 17 ± 2 (for meter A) and 10 ± 2 mV steps (for meter B), respectively. Results with a high-purity isostatically pressed tube gettered to give 20 mV steps are also shown for comparison. The results using the slip-cast tubes show pronounced curvature, while those for the isostatically pressed tube are linear, and theoretical. Curve A shows that the value of α is close to but slightly greater than theoretical at weight gains above 3.5 mg. However, at lower weight gains a marked decrease was observed. This deviation is indicative of a decreased value of α with decreasing oxygen concentration. The results for meter B with the high slope indicates that the value of α was low throughout the range of oxygen concentration investigated. The value of α determined from the slope for the higher weight gains is 33 mV which is 43% of the theoretical value. This value also shows a decrease with decreased weight gains or lower oxygen concentrations.

Extrapolation of both curves A and B to weight gains below 0.1 mg indicates that very small quantities of oxygen would be removed from the sodium if the number of gettering steps were increased, or the weight of oxygen remaining in the sodium was extremely small. The amounts of oxygen in the sodium after the last getterings were therefore negligible and the calibration curves for these meters were constructed using the summation method (Eq. [6]). The calibration curves obtained by summation of the weight gains and plotting the related concentrations against the potential are also shown in Fig. 3. Above 30 ppm curve A shows a theoretical slope. At oxygen concentrations below 30 ppm for meter A and for the entire range of oxygen concentration investigated with meter B, the calibration curves show less than the theoretical value of α. This behavior was indicated by the results shown in Fig. 4.

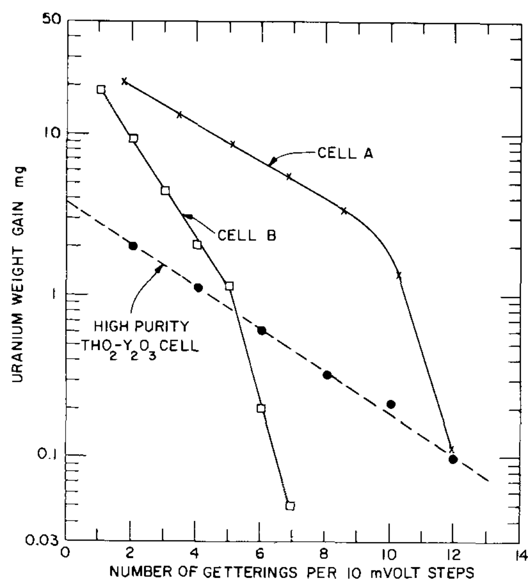

Fig. 4. Variation of uranium weight gain as a function of repetitive gettering steps for high-purity and impure ThO_2-Y_2O_3 electrolytes.

Indications of this decrease in α could also be deduced from the behavior of the rate of potential change during removal of oxygen by uranium. During gettering the rate was observed to fall continuously at the higher potentials for all slip-cast tubes tested. For example in the case of cell A the rate decreased when the potential was above 140 mV and continued to decrease at still higher potentials. It may be seen from Eq. [15] that the rate of potential change is proportional to the value of α and the observed decreased rate therefore suggested a decrease in the value of α.

Measurements of the oxygen ionic transference number have been made on thoria-yttria electrolyte of similar composition to those of the slip-cast tubes (11). These results showed that the observed decrease in α from the theoretical value could not be attributed to deviations of the transference number from unity at the oxygen activities in sodium. The observed decrease in α is probably a result of interactions of sodium with impurities present in the slip-cast tubes which also act to influence the characteristics of the electrochemical system.

Conclusion

Uranium offers a rapid and sensitive method for calibrating oxygen meters in sodium at temperatures of 500°C. The high-purity isostatically pressed ThO_2-Y_2O_3 electrolyte tubes are far superior to less pure slip-cast tubes. The former show theoretical slopes down to oxygen concentrations of 1 ppm while the slip-cast tubes are highly variable in behavior and deviate from the theoretically expected variation of potential with oxygen concentration.

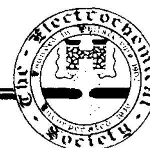
Technical Notes



D-Size Lithium Cupric Sulfide Cells

J. P. Gabano, V. Déchenaux, G. Gerbier, and J. Jammet

Societe des Accumulateurs Fixes et de Traction, Départment la Pile Leclanché, Poitiers, France

Research at SAFT on high-energy primary batteries with a lithium anode and a nonaqueous electrolyte has resulted in the design of a lithium cupric sulfide cell using an electrolyte made of a $LiClO_4$ solution in a combined solvent comprising 10% tetrahydrofuran (THF) (1) and 30% 1.2 dimethoxyethan (1.2-DME) (2). Prismatic cells of 30 A-hr capable of reaching and even exceeding 300 W-hr/kg and 400 W-hr/dm^3 have been developed in the past (3, 4) for the determination of the reliability of the system. The results indicated that this couple can be stored more than one year under normal conditions and six months at 45°C without appreciable loss of energy. On the basis of these studies D-size lithium cupric sulfide cells have been designed.

The purpose of this paper is to present the data obtained on D-size cells after optimization and to discuss their characteristics and performance in comparison with carbon-zinc and alkaline manganese dioxide cells of the same size.

Cell Design

Completely sealed D-size cells were made using cans of nickel-plated steel. The cylindrical cell has the distinguished feature of a coiled element for improving cell performance under heavy discharge rates.

The cupric sulfide used for the cathode was prepared by the thermal combination of sulfur and copper. Very pure sulfur free cupric sulfide was synthesized by this method. For the making of the cathode, cupric sulfide powder was mixed with a Teflon binder and cold-pressed onto a very thin nickel-plated steel strip of a suitable length. Then the cathode was cured at 280°C for 2 hr. This process gave a flexible electrode which could be rolled very easily. The cathode was entirely sealed in a nonwoven polypropylene bag which acted as a separator.

The lithium anode was made of a pure lithium strip with a terminal made of a tab of stainless steel soldered to one end of the strip.

The solvents used were the purest commercially available and were dried by standing one week over molecular sieves. The $LiClO_4$ solute was of the highest purity available (GF Smith Chemical Co.); it was dried at 150°C for 48 hr before use.

Key words: nonaqueous cell, organic solvents, tetrahydrofuran, 1.2 dimethoxyethan, lithium, copper sulfide.

Cells were filled with a molar solution of $LiClO_4$ in the combined solvent (THF + 1.2-DME) before sealing. Their capacity varied according to the length and the thickness of the cathode, that is to say between 11 and 14 A-hr for the cells we studied. Anode capacity was about 30% higher than cathode capacity. Moreover the amount of electrolyte was approximately 17 cm^3 per cell. The open-circuit voltage (O.C.V.) of these cells was about 2.15V and their ohmic resistance 0.3 ohm, the total weight of a single cell was about 95g, its volume 55 cm^3.

Cell Optimization

In order to achieve cell optimization, D-size cells with cathodes of different length and thickness were tested under continuous discharge through a 5 ohm load at ordinary temperature.

Table I gives the theoretical capacity of these cells according to the thickness and length of the cathode. The height was kept to a constant value of 47 mm.

Figure 1 shows the variations of the cell energy as a function of the length of the cathode, for these conditions of discharge. It can be seen that the cell energy is markedly affected by decreasing the length of the cathode below 250 mm, but remains approximately constant beyond this value.

In our further determinations, all the cells were designed with a 250 mm cathode length. This electrode gives a theoretical capacity of 13 A-hr.

Cell Discharge Characteristics

Different test loads were used in this evaluation under various conditions of continuous and intermit-

Table I. Effect of length and thickness of the cathode on theoretical cell capacity

Length of the cathode (mm)	Thickness of the cathode (mm)	Theoretical cell capacity (A-hr)
120	2.80	14.2
250	1.50	13.0
360	1.15	11.5

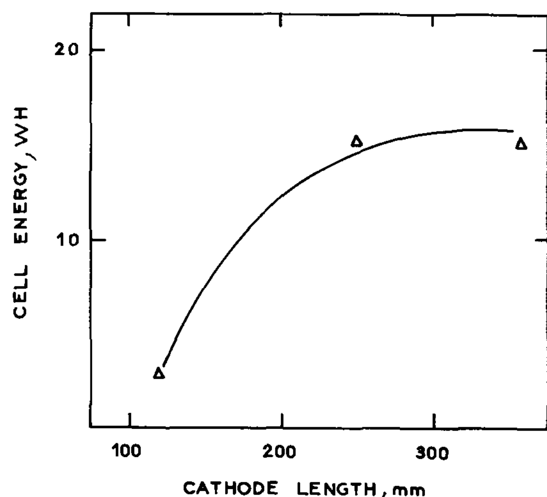


Fig. 1. Effect of cathode length on cell energy under 5 ohm continuous discharge load.

tent discharges. Regular carbon-zinc and alkaline manganese dioxide cells of the same size were discharged in the same time; however, in order to account for the difference of voltage of each system, suitable loads were selected to give the same average current drain in order to have a better comparison. All the discharges were performed to a cutoff voltage equal to 50% of the starting voltage.

Continuous Discharges

Figure 2 shows discharge characteristics of a 13 A-hr Li/CuS D-cell. It can be seen that the discharge curve has two steps corresponding to the two levels of reduction of cupric sulfide (3). However, the voltage steps become more and more diffuse when the discharge rate is increased.

Figure 3 shows the relationship between cell energy and current drain for the three systems. These results were deduced from the discharge curves of each system obtained under suitable loads. In both cases the Li/CuS cell gave better performance than the two other couples studied. Nevertheless at current drain more than 500 mA, the energy of Li/CuS cell was only slightly greater than that of the alkaline manganese dioxide system.

Intermittent Discharges

The accepted method of assessing the performance of primary D-size cells in intermittent discharge according to the various consumer applications were applied here, as is shown in the following tables.

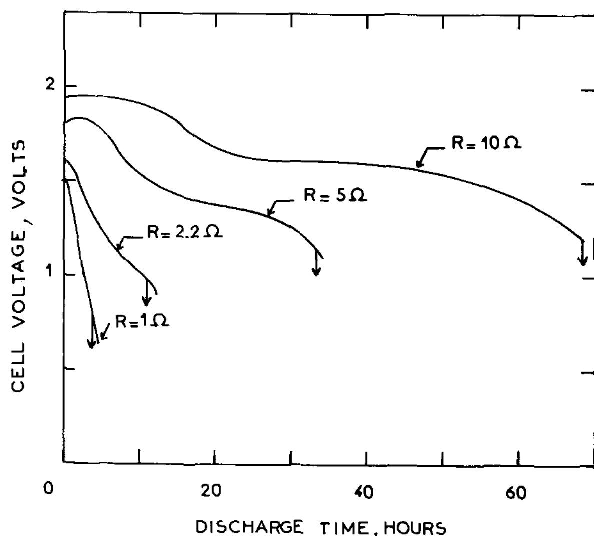

Fig. 2. Discharge characteristics of a 13 A-hr D-size Li/CuS cell as a function of various loads.

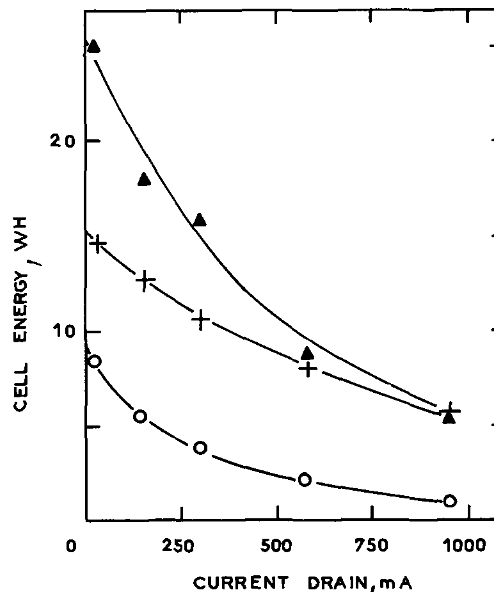

Fig. 3. Relative energy of D-size cells under continuous loads: ▲, Li/CuS cell; +, regular alkaline manganese dioxide; ○, regular carbon-zinc cell.

Table II shows the results obtained for a radio intermittent duty. It can be seen from this table that the Li/CuS cell delivered a significant amount of energy in comparison with the carbon-zinc and alkaline manganese dioxide cells and had a longer discharge duration.

Table III gives the results obtained on the cassette players/recorders intermittent duty. The discharge duration for the Li/CuS cell was approximately three times more than for the carbon-zinc cell; moreover the total cell energy was four times higher. The difference in performance with the alkaline manganese dioxide cell was, however, less pronounced.

Table IV pertains to a lighting intermittent duty. This table shows the superiority of the Li/CuS cell to the two other systems. Nevertheless, the energy difference between the carbon-zinc, alkaline manganese dioxide, and Li/CuS cell is less pronounced than in the case of radio and cassette players intermittent duty. The reason is that the carbon-zinc cell does not lose much energy on intermittent heavy drains due to its capability of recovery. The difference of performance with the alkaline manganese dioxide cell is still small, especially for discharge durations which are quite similar.

Finally, the technical performances of a battery system in a given application should be estimated from

Table II. Transistor radio intermittent duty, 30 mA, 4 hr per 24 hr day

Couple	Cell capacity (A-hr)	Cell average voltage (V)	Cell energy (W-hr)	Time of service (hr)
Carbon-zinc	6.8	1.25	8.5	225
Alkaline MnO_2/Zn	11.8	1.24	14.6	395
Li/CuS	13.0	1.8	23.4	435

Table III. Cassette players/recorders intermittent duty, 150 mA, 4 hr per 24 hr day

Couple	Cell capacity (A-hr)	Cell average voltage (V)	Cell energy (W-hr)	Time of service (hr)
Carbon-zinc	4.8	1.20	5.8	32
Alkaline MnO_2/Zn	11.2	1.15	12.9	75
Li/CuS	12.6	1.58	20.0	84

Table IV. Flashlight intermittent duty, 210 mA, 3 times for 30 min per 24 hr day

Couple	Cell capacity (A-hr)	Cell average voltage (V)	Cell energy (W-hr)	Time of service (hr)
Carbon-zinc	6.1	1.20	7.3	29
Alkaline MnO_2/Zn	12.0	1.07	12.8	57
Li/CuS	12.2	1.52	18.5	58

the volume, since available volume is usually the most critical parameter to the designer of equipment. In both applications that we have mentioned, ranging in power load from radios at the low end to flashights at the high end, we can use a stack of three Li/CuS cells instead of four conventional primariy cells for reaching approximately the same voltage. This important fact can be deduced from the values of the single-cell average voltage in Tables II, III, and IV.

Conclusions

This small test program has shown that the D-size Li/CuS cell is capable of giving useful energy within the range of rates and types of discharge applied.

A comparison with carbon zinc and alkaline manganese dioxide D-size cells has shown the superiority of the Li/CuS cell over the common primary systems in the case of consumer applications.

The best performance obtained at low drain was 25 W-hr. This corresponds to a specific volumetric energy of 470 W-hr/dm^3. This value is considerably greater than can be obtained with the HgO/Zn system, which has the best volumetric energy density (350 W-hr/dm^3) in aqueous electrolytes for the D-size cell.

Photoelectrochemical Image Conversion

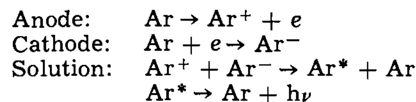
M. M. Nicholson*

Atomics International, A Division of North American Rockwell Corporation, Canoga Park, California 91304

Imaging devices that convert infrared to visible light generally involve all solid-state systems and may require high voltages to achieve the desired image intensity. This note describes an electrochemical scheme for infrared-to-visible conversion in a single cell operated by a low-voltage power supply. Efficiencies and other performance characteristics have not yet been determined, but available information on the essential processes involved supports the feasibility of the concept.

The schematic design of the electrochemical image conversion device is shown in Fig. 1, where the cell is envisioned as a thin-layer structure. The essential elements are (*a*) a semiconductor control electrode, which is responsive to infrared light, (*b*) a solution containing a supporting electrolyte and a regenerative faradaic system capable of producing electrochemiluminescence, and (*c*) a perforated or transparent counterelectrode through which the resultant image may be viewed. For discussion, it may be assumed that the semiconductor is germanium or silicon and that the solution consists of an electroactive aromatic hydrocarbon such as rubrene, dissolved in benzonitrile, with tetrabutylammonium perchlorate as the supporting electrolyte (1). The counterelectrode may be a platinum screen. The device is not limited to this type of system, although present information suggests that these materials would be appropriate for an experimental study.

It is known that many aromatic hydrocarbon systems emit light when electrolyzed at ~3V between two inert metal electrodes (2, 3). The luminescence is due primarily to the annihilation reaction between the electrolytically formed hydrocarbon cations and anions, which occurs in the solution phase when these species are brought together by diffusion. The over-all process may be represented as follows:



Anode: $Ar \rightarrow Ar^+ + e$
Cathode: $Ar + e \rightarrow Ar^-$
Solution: $Ar^+ + Ar^- \rightarrow Ar^* + Ar$
$Ar^* \rightarrow Ar + h\nu$

* Electrochemical Society Active Member.

Key words: images, semiconductors, electrochemiluminescence, hydrocarbons.

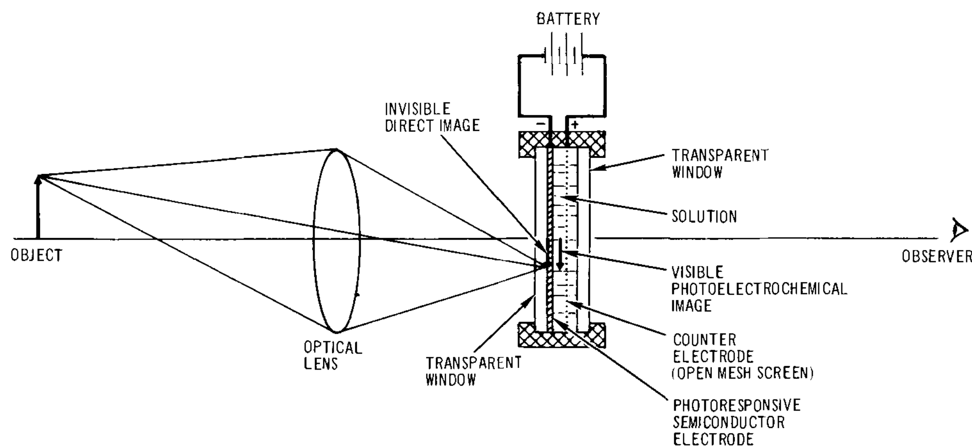


Fig. 1. Photoelectrochemical image converter.

The last two equations are consistent with an excited singlet state for the light-emitting species; detailed mechanisms are discussed elsewhere (3). For the present application it is essential to note that the net result of these reactions is the conversion of electrical energy to light, with regeneration of the hydrocarbon.

It is expected that similar reactions will occur at semiconductor electrodes. Further, if a semiconductor is chosen so that one of the faradaic processes is limited by the minority carrier concentration, the electrode will be photosensitive (4). For example, if the control electrode in Fig. 1 is p-type and the reduction of Ar requires conduction electrons, very little current will flow through the cell in the absence of light. When an infrared (or visible) image is focused on the outer surface of this electrode, a large increase in conduction electrons will occur in the areas of high light intensity. The faradaic current will then follow a corresponding pattern at the semiconductor/solution interface, and shortly thereafter, a luminescent image will appear in the solution layer, due to the anion-cation reaction. Thus, by coupling a semiconductor electrode with an electrochemiluminescent system, one may convert an infrared image to a visible image and measure a total current for the process. The sharpness of the visible image will depend on the distances traveled by carrier species in the semiconductor and solution layers. The absolute image intensity cannot be predicted at present, but luminescence from diffusion-controlled currents in $10^{-3}M$ hydrocarbon solutions is readily visible (2). Other practical details include the stability of the hydrocarbon ions and the influences of impurities.

Of interest for sensor applications is the possibility of light amplification in the cell, due to absorption of luminescence light by the semiconductor. This would, in turn, produce additional current and generate more light. Although such feedback may diminish the sharpness of a visual display, it would be advantageous in a light detection system.

Manuscript received Oct. 18, 1971.

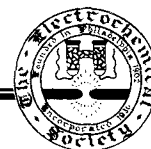
Brief Communication



The Influence of Chloride Ion on the Pitting of Aluminum

F. D. Bogar*,[1] and R. T. Foley**

Chemistry Department, The American University, Washington, D. C. 20016

Engell and Stolica (1), and later Hoar and Jacob (2), devised a technique to measure the kinetics of breakdown of passivity of iron and stainless steel by halide ions. In this technique the metal electrode is held potentiostatically in the passive range in sulfuric acid solution, a specific concentration of chloride is injected, and the induction time, τ, for a sharp rise in current is recorded. The rise in current is correlated with the breakdown of passivity and the initiation of pitting. This technique is of particular interest because the dependence of the induction time, τ, on the chloride concentration has been related to the stoichiometry of the initial metal dissolution reaction. The investigators cited above used different arguments but reached the same conclusion with respect to the significance of the chloride dependence. Further, the temperature dependence of τ can be related to the apparent energy of activation for the process, whatever the mechanism of the process might involve. In the present investigation the kinetics of pitting of aluminum and an aluminum alloy have been measured by this technique from the standpoint of achieving a better understanding of the mechanism by which chloride ion participates in the pitting process.

Experimental

The experiment was conducted in a modified H-cell in which the working compartment was separated from the counterelectrode compartment by a fine-porosity glass frit. The working compartment had a volume of 250 ml allowing the placement of a Luggin capillary and a gas dispersion tube in addition to the working electrode. An electrode holder similar to that described by Myers *et al.* (3) which exposed an electrode area of 0.637 cm^2 was used. The counterelectrode was a platinum electrode of 57 cm^2. Oxygen was removed from the solution by dispersing high purity N_2 through the electrolyte for 30 min prior to electrolysis and for an additional 30 min while the current of the polarized electrode came to a steady-state value, and for the duration of the experiment. The bubbling nitrogen excluded air and provided stirring to the system. Stirring was also provided in the cell with a magnetic stirrer. When nitrogen was bubbled through the system, the corrosion potential became more active, the major change occurring in the first 30 min. Polarization of the electrodes after 1 hr of deaeration with nitrogen produces current-potential curves with little or no difference from curves obtained from electrodes which were deaerated for 24 hr. The cell was thermostated at a preset temperature $\pm 0.1°C$ in the range of 15°-40°C.

The potential of the working electrode was regulated either with an Anotrol Model 4100 Research Potential

Controller or a Wenking Model 61 RS Potentiostat. In either case, the potential of the working electrode was measured with a Keithley Model 621 Electrometer in preference to that provided by the potentiostat circuit. The current from the output terminal of the potentiostat was recorded by a Sargent Model SRL Recorder which has a 1 sec full-scale response time.

Two aluminum alloys, Type 1199-H14 and 2024-T6, were used as electrodes. Aluminum alloy 2024 was of the nominal commercial composition. Aluminum alloy 1199-H14 was 99.99% Al and contained Si, 0.001%, Fe, 0.001%, Mg, 0.001%, and Cu, Mn, Cr, Ni, Zn, and Ti less than 0.001%. These alloys were cleaned by conventional procedures and following cleaning, were kept for 24 hr in a dessicator.

In a typical experiment, after the assembled cell had reached a preset temperature, the potential of the aluminum electrode was set at the mid-point of the passive region, usually at +0.18V with respect to the $Hg|Hg_2SO_4$ electrode. The current was allowed to reach a steady-state value and then a known volume of sodium chloride solution was injected rapidly into the cell with an all glass syringe. The mixing time for the electrolyte was estimated to be 4-5 sec as judged by the time required for uniform color to be achieved when $KMnO_4$ solutions of concentrations equal to those of the chloride solutions were injected. The time required for the current to rise was measured as τ, the induction time. Figure 1, the current plot for a 2024 alloy electrode potentiostated in H_2SO_4 at pH 3.5 represents a typical measurement.

Results and Discussion

The dependence of the induction time on chloride concentration was measured at 25°C for alloy 1199 at pH 0.0 and for alloy 2024 at pH's 0.0 and 3.5. The data for the series of experiments with alloy 2024 are plotted in Fig. 2. The plots for the other series of experiments are quite similar. The temperature dependence of the induction time was investigated over the temperature range of 15°-40°C for alloy 1199 at pH's 0.0, 3.5, and 6.08 and for alloy 2024 at pH 0.0. In these experiments chloride concentrations of 2.58×10^{-3}, 5.00×10^{-3}, and 7.75×10^{-3} molar were used. The plot for alloy 1199 in pH 0.0 H_2SO_4 in Fig. 3 is typical although at pH 6.08 (phosphate buffer) the scatter of the experimental points was greater.

Following the arguments of Engell and Stolica (1) and Hoar and Jacob (2) the reciprocal of τ is taken as a measure of the rate of the "breakdown" process. Then the slope of the line, which is plotted in Fig. 2, equals "n," wherein "n" is interpreted as the order of the reaction. From the data, the stoichiometry of the reaction of aluminum with chloride ion is not independent of the concentration of the chloride ion. Two values of n can be calculated from these data. The first corresponds to low chloride ion concentrations and is designated in Table I as n'. This stoichiometric factor was evaluated by the use of a computer which was programed to evaluate the least squares slope of the data plot. Starting from the highest chloride ion concentration, a data point at a time was dropped and the least squares slope of the data was recalculated. The program continued in this manner comparing the least squares slope until agreement was achieved to one significant figure after the decimal point. The computer was programed to print out the equation of the least squares line and to plot the data and the resultant line. The dotted line in Fig. 2 was obtained from the computer. The solid line which corresponds to high chloride ion concentrations was calculated manually as the least squares fit to the data excluded by the computer. This second value is designated in Table I as n. Also, following the Arrhenius treatment for the temperature dependence of the kinetic data, an apparent energy of activation for the process was calculated from the least squares slope of all the data; Fig. 3 is also a plot obtained from the computer. The stoichiometric factors and the energy of activation are summarized in Table I.

With the exception of the reaction at pH 6.08 the energy of activation is high, approximately 20.0 kcal/mole. Hoar and Jacobs (2) reported a value of 60 kcal/mole for the reaction associated with the breakdown of passivity of stainless steel by chloride ions. In both cases, the energy of activation is considerably higher than one associated with an adsorption process. A diffusion process such as diffusion through Al_2O_3 via lat-

Table I. Summary of kinetic data

Aluminum alloy	pH 0.00	3.50	6.08
1199	$n = 4.0$ $n' = 11.1$ $E = 22.9$ kcal	— $E = 20.7$ kcal	 $E = 12.0$ kcal
2024	$n = 3.0$ $n' = 8.8$ $E = 20.1$ kcal	 $n = 4.8$ —	 — —

tice defects would have an activation energy in the same range but the diffusion rate itself would be much too low to account for the induction times observed (4).

The value of "n" from the log τ-log c_{Cl^-} plot is interpreted as the number of chloride ions participating in the pitting process per metal atom. Engell and Stolica (1) found that their kinetics followed the third power of chloride ion concentration and postulate a sequence of the form

$$Fe^{+3} \text{ (in passive layer)} + 3Cl^- \rightarrow FeCl_3 \rightarrow Fe^{+3} \text{ (in the electrolyte)} + 3Cl^-$$

Hoar and Jacob (2) found "n" values in the range 2.5-4.5 for 18-8 stainless steel and concluded that pitting was initiated by 3-4 halide ions adsorbed around a lattice cation.

The present results indicate that n appears to be 3.0-4.8 for higher chloride ion concentrations. This is interpreted to mean that the primary reaction involves a reaction such as

$$Al + 4Cl^- \rightarrow AlCl_4^-$$

Such a complex would be transitory, would separate from the metal-oxide interface, and would essentially perform a catalytic function as previously suggested (2). For lower chloride ion concentrations, n' appears to be close to multiples of 4 (8 and 12).

These three investigations have established that the primary role of the anion in the initiation of pitting in chloride solutions in moderately concentrated solutions is chemical rather than physical in nature.

Acknowledgment

This research was supported by the Advanced Research Projects Agency of the Department of Defense and was monitored by the U. S. Naval Research Laboratory under Contract No. N 0014-68-A-0245-0001. The interest and discussion of Dr. B. F. Brown of the Naval Research Laboratory has been appreciated. The aluminum alloy 1199 was supplied by Mr. William Ailor of the Reynolds Metals Company, in Richmond, Virginia.

SSST

The Effect of Stress on the Low-Temperature Oxidation of Niobium

I. Stresses Involved in the Oxidation Process

L. J. Weirick*[,1] and W. L. Larsen

Ames Laboratory, USAEC and Department of Metallurgy, Iowa State University, Ames, Iowa 50010

ABSTRACT

Oxidation, cooling, dissolution, and annealing flexure measurements were performed on thin coupons of niobium presaturated with oxygen. Oxidation was done near 425°C in dry oxygen, dissolution in hydrofluoric acid, cooling and annealing in vacuum. From curvature measurements during each process, bending stresses were determined and correlated with oxidation rate and surface morphology. A thin-film model was applied to the bending due to niobium pentoxide formation. The resulting calculated compressive stress of about 123,000 psi agreed well with the known compressive strength of Nb_2O_5. Application of the thin-film model to an "effective" film of niobium suboxide gave compressive stresses of 125, 150, and 177 thousand psi for Nb_6O, Nb_5O, and Nb_4O, respectively, the reported formulas for NbO_x. Suboxide formation was found to cause bending during early stages of the oxidation process. An oxygen solution model did not adequately explain bending during early oxidation times for oxygen-presaturated niobium specimens. The resulting tensile stress on the substrate surface caused by oxidation was found to be significant, possibly approaching the yield stress.

The kinetics of the oxidation of niobium in the vicinity of 425°C are sufficiently well known (1, 2) that it is possible to calculate with fair precision the lifetime of a part made from niobium sheet. In the case of tubing, however, premature failure has been observed in as little as one-tenth the expected time as a result of the formation of "wedges" of Nb_2O_5 growing normal to the oxidizing surface (3, 4).

Preliminary work at this laboratory (5) established that bent specimens of sheet niobium oxidized at 425°C exhibited wedges on the concave surface. These wedges increased in number with decreasing initial radius of curvature and increasing prior cold work and were apparently unaffected by surface preparation. During oxidation, bent specimens were observed to approach straightness.

During oxidation, when one solid phase is forming upon another under isothermal conditions, elastic strains may arise as a result of any of several possible mechanisms. These sources of strain may be classified generally as those associated with (*i*) the establishment of defect or oxygen gradients, (*ii*) epitaxial effects, and (*iii*) volume changes during the reaction.

The relationship between defect gradients and stress gradients has been treated theoretically by Richmond *et al.* (6) and experimentally by Pawel *et al.* (7). Pawel *et al.* applied a flexure technique to the oxidation of niobium near 425°C and obtained data which indicated a compressive stress of about 35,000 psi existed in the surface layer of niobium metal due to oxygen solution.

Epitaxial strains have not been observed upon oxidation of niobium (7). It was originally postulated by Pilling and Bedworth (8) that the majority of oxide films should form in a state of compression since the volume of the oxide is usually greater than the metal oxidized. For the case where anion diffusion predominates and the oxide grows isotropically and adherently to the metal, or anisotropically and adherently but is not allowed to expand easily, stresses sufficient to deform and/or fracture the oxide may eventually exist. For the case where cation diffusion predominates, the oxide is formed at the oxide/oxygen phase boundary. Therefore, no restraints should act upon the newly formed oxide and it remains adherent and stress-free even for very large oxide/metal volume ratios.

Dankov and Chureav (9) derived an experimental equation for the compressive stress in a thin film of oxide as a function of bending stress as measured by flexure techniques. Pawel and Campbell (10) applied this technique to the oxidation of niobium near 425°C and obtained preliminary data which indicates that the thin-film stress would be quite high, perhaps approaching 100,000 psi.

Based upon these observations, the authors of this paper hypothesized that lateral stresses induced in the metal surface by the growth of Nb_2O_5 into a constricted volume produce a tensile strain in the underlying metal which, when exceeding the ultimate strain of the (oxygen-saturated) metal surface, produce a mechanical crack in the embrittled metal. Subsequent oxidation of the interior of the crack produces additional tensile stress and oxygen-solution embrittlement at the crack tip, resulting in a self-propagating crack. A program of research was initiated in order to test

* Electrochemical Society Active Member.

Key words: suboxide, cracks, Nb_2O_5.

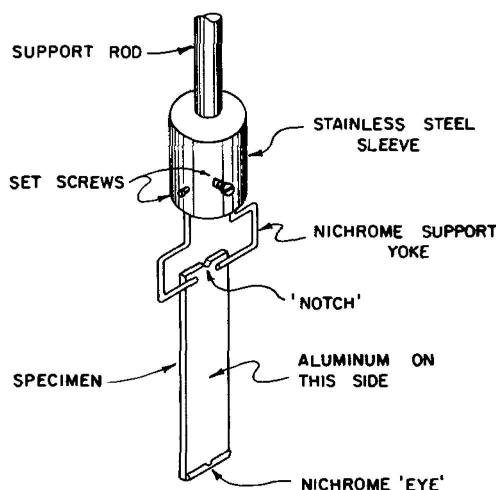

Fig. 1. Schematic drawing of flexure measurement specimen

this hypothesis and to gain further understanding of this gas-phase stress-corrosion cracking in niobium.

The present work was designed to measure that stress created in a niobium metal substrate by the formation of a thin film of oxide. By using only metal which had been previously saturated with oxygen, it was expected that the effects of concentration gradients could be eliminated and that the resultant stress would be entirely due to "Pilling-Bedworth effects." Moreover, it was felt that the results would more nearly approximate those conditions of service wherein oxygen concentrations are sufficiently low that near-saturation could occur before the formation of significant amounts of surface scale. Such conditions might be found in nuclear reactors.

Experimental Procedure

Niobium specimens[2] were cut from a 0.010 in. sheet as rectangular coupons 1 × 4.5 cm and polished on both sides with 600 grit silicon carbide paper. The polished coupons were suspended in a thermogravimetric system and oxidized to a predetermined weight gain to form a thin, adherent Nb_2O_5 layer. They were then vacuum annealed at temperatures from 500° to 1200°C for times up to 14 or 3 days respectively. This procedure gave specimens saturated with oxygen at various temperatures. The oxygen was retained upon cooling and thus the specimens had oxygen contents above the saturation value at 425°C (11, 12). These oxygen-supersaturated coupons were again polished on both sides with 600 grit silicon carbide paper and subsequently one side only was further polished with 15, 1, and 0.3μ levigated alumina. A 0.5 × 1 cm piece was cut from the end of each specimen to be vacuum-fusion analyzed for oxygen, nitrogen, and hydrogen. The coupons were first cleaned in a solution containing 50 parts lactic acid, 30 parts nitric acid, 2 parts hydrofluoric acid, and 18 parts water and then were dried with alcohol.

A support yoke of Nichrome wire was welded on the polished side of the coupon (Fig. 1). On this side at the other end, a piece of Nichrome wire was welded across the tip and a hole drilled at the middle to form a small "eye." The specimen was again cleaned in acid and alcohol and placed in a vacuum evaporator with the Nichrome wire side up. Aluminum was plated onto this side to a thickness of about 6μ. A subsequent vacuum annealing at 600°C for 24 hr formed a diffusion bond making the aluminum an excellent protective film. Specimens prepared in this manner were subsequently subjected to flexure measurements during four consecutive processes: oxidation, cooling, dissolution, and annealing.

[2] Supplied by Fansteel Metallurgical Corporation with given nominal analysis of about 99.7-8% Nb with Ta, Fe, Mo, Ti, and Zr being major metallic impurities; interstitial content determined from vacuum fusion analysis was about 650 ppm O_2, 300 ppm N_2, and 5 ppm H_2.

Oxidation.—For oxidation flexure measurements, the specimen was suspended by the Nichrome yoke in a furnace (Fig. 2). A quartz fiber, 235 mm long, was hung onto the specimen with its free end threaded through the "eye." Deflection measurements could be made by sighting through a quartz window in that part of the furnace tube extending below the furnace using a traveling microscope which was converted to an x-y cathetometer. A total deflection of about 4 cm could be measured with the accuracy of individual readings being ±0.05 mm.

The system was evacuated to a pressure less than 3×10^{-6} Torr and the temperature slowly raised to within five degrees of the desired reaction temperature. A "zero" reading was taken and dry, preheated oxygen allowed to leak into the system, raising the specimen temperature five degrees. The specimen bent as it was oxidized on the unprotected side, the aluminum being on the concave side. The quartz fiber maintained a position corresponding to the chord of the arc of the deflecting specimen and thus the end of the fiber deflected proportionately with the curvature of the specimen. A correction for elastic bending of the cantilever fiber was determined experimentally.

Following the method of Pawel *et al.* (7), these fiber deflections were converted to radii of curvature, ρ, and thus maximum bending stress, S_m, through the use of the simple flexure formula (for bending in two dimensions occurring without distortion)

$$S_m = \frac{E_m h}{2\rho} \left(\frac{1}{1 - \nu} \right) \quad [1]$$

Thus the oxidation bending stress, $S_m(\text{Ox})$, could be plotted *vs.* oxidation time.

The bending of the specimen during oxidation flexure measurements was found to be the result of a combination of growth of a very thin layer of niobium suboxide, NbO_x, just under the surface of the niobium and of a niobium pentoxide film upon the metal surface. If the flexure were due to the growth of Nb_2O_5 alone, the thin-film compressive stress within the Nb_2O_5 could be calculated using the following equation (10)

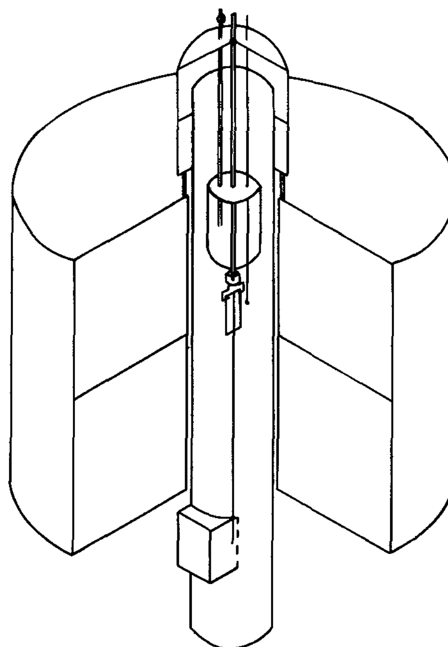

Fig. 2. Schematic drawing of flexure measurement apparatus

$$S_{1(Ox)} = \frac{1}{3} S_{m(Ox)1} \frac{h}{t_1} \quad [2]$$

Similarly, if the flexure were due to the growth of NbO_x alone

$$S_{2(Ox)} = \frac{1}{3} S_{m(Ox)2} \frac{h}{t_2} \quad [3]$$

Since weight gain measurements could not be made concurrently with flexure measurements, values of t were obtained from geometrically similar samples whose oxidation curves were previously established as being very reproducible.

Thickness was computed from weight gain measurements assuming the following:

1. Since the initial oxygen content of the specimens was higher than the oxygen solubility limit in niobium at 425°C, there should be no oxygen going into solution.
2. Since the oxide thickness on the top surface is the desired quantity, the weight of oxide on the sample edges (6.25% of the total area) must be deducted from the total.
3. The density is about 5.17 g/cc (19). Thus for Nb_2O_5

$$t_1\text{(mil)} = W_o \times 0.0593 \quad [4]$$

where W_0 is the weight gain, in milligrams, for the 1 × 4 cm sample.

4. For NbO_x, the reported formulas are Nb_6O, Nb_5O, and Nb_4O which give oxygen contents of 2.79, 3.33, and 4.13 w/o (weight per cent), respectively.
5. For NbO_x, by analogy to the data of Magneli *et al.* (20) on Ti, V, Zr, and Hf and by using data from Brauer *et al.* (21) on a tetragonal niobium suboxide (about Nb_6O), densities derived from a plot of density *vs.* oxygen/niobium ratio for Nb_6O, Nb_5O, and Nb_4O are 8.33, 8.28, and 8.20 g/cc, respectively. Thus, for Nb_5O

$$t_2\text{(mil)} = W_o \times 0.3346 \quad [5]$$

Using the densities for Nb_6O and Nb_4O gives variations of calculated film thickness of plus 18% and minus 18%, respectively, from the value for Nb_5O.

Cooling.—Following the oxidation, the system was evacuated and the furnace power shut off. Deflection readings were taken intermittently during cooling. Thus cooling bending stress, $S_{m(Cl)}$, could be plotted *vs.* temperature.

The bending of the specimen during cooling resulted from the relative difference in the thermal expansion coefficients of Nb and Nb_2O_5. Using Timoshenko's (22) equation for the cooling of a bimetallic strip and applying boundary conditions for the present Nb-Nb_2O_5 composite, the following equation was derived and subsequently verified by Bradhurst and Heuer (23)

$$1/\rho = 3n(\alpha_m - \alpha_o)\Delta T \frac{2t_1}{h^2} \quad [6]$$

Using the radius of curvature calculated from this equation, the maximum bending stress in the metal surface caused by cooling, $S_{m(Exp)}$, was calculated using Eq. [1] and compared with the cooling bending stress determined directly from deflection measurements during cooling, $S_{m(Cl)}$.

The stress in the thin film of Nb_2O_5 caused by differential thermal contraction during cooling, $S_{1(Cl)}$, is given by the application of the thin-film stress equation (10)

$$S_{1(Cl)} = \frac{1}{3} S_{m(Cl)} \frac{h}{t_1} \quad [7]$$

Oxidation and cooling flexure measurements gave bending in the same (positive) direction. After cooling a photograph was taken of the specimen profile. Measurements made on an enlargement established that the radius of the curved specimen varied less than 1% from that of an are of a circle, thus validating the assumption used in converting deflection measurements to radii of curvature. The curvature measured photographically also agreed within 3% of that calculated from oxidation and cooling fiber deflection measurements.

To separate the contributions to specimen bending from Nb_2O_5 and NbO_x growth, dissolution and annealing flexure measurements were performed.

Dissolution.—Deflections were measured during the removal of the Nb_2O_5 film by a method analogous to that described for oxidation except for the substitution of a molybdenum wire for the quartz fiber. Oxides were stripped with a 25% HF-water solution. The protective layer of aluminum is dissolved quickly with no resultant effect on sample curvature. Nb_2O_5 is dissolved easily but there is little effect of HF on Nb or NbO_2 (24).

As oxide was removed, the specimen approached straightness. The resulting loss of curvature was converted to a bending stress, $S_{m(Ds)}$, which was negative in sign, using Eq. [1].

The stress in the thin film of Nb_2O_5 removed by dissolution, is given by an application of the thin-film stress equation, Eq. [2], which relates metal surface stress to corresponding oxide film stress

$$S_{1(Ds)} = \frac{1}{3} S_{m(Ds)} \frac{h}{t_1} \quad [8]$$

Annealing.—If the curvature resulting from the oxidation process was due to the niobium pentoxide film growth alone, the removal of this film should cause the specimen to return to straightness. Since after the dissolution process the specimens still retained some curvature, a second process was apparently contributing stress during the oxidation process. This additional process is thought to be the formation of the niobium suboxide, NbO_x, near the surface of the niobium substrate. Vacuum annealing was performed in an attempt to remove this stress by removing the concentration gradient associated with the suboxide, thereby returning the specimens to straightness.

The specimen was replaced in the controlled atmosphere furnace system which was evacuated to a pressure of 2×10^{-6} Torr. The temperature was slowly raised to 300°C to outgas. When the pressure was again acceptably low, the temperature was quickly raised to 550°C and a "zero" cathetometer reading taken. Annealing for 3 days at 550°C was usually sufficient to return the specimen to straightness. Intermittent readings were taken with the cathetometer for the duration of the annealing process. The resulting loss of curvature was converted to a bending stress, $S_{m(An)}$, which was also negative in sign, by using Eq. [1].

The magnitude of the stress in the thin layer of niobium near the substrate surface due to the "removal" or redistribution of the niobium suboxide, NbO_x, is

$$S_{2(An)} = \frac{1}{3} S_{m(An)} \frac{h}{t_2} \quad [9]$$

Since the cooling stress can be accounted for entirely by the differential thermal expansion of the metal and Nb_2O_5 alone, and since dissolution appears not to affect the suboxide, it is assumed that NbO_x affects bending only during the oxidation and annealing processes. Thus, we equate the magnitudes of the NbO_x film stresses created during oxidation and removed during annealing

$$S_{2(An)} = S_{2(Ox)} \quad [10]$$

or, equating the corresponding bending stresses induced in the metal

$$\frac{1}{3} S_{m(An)} \frac{h}{t_2} = \frac{1}{3} S_{m(Ox)2} \frac{h}{t_2} \quad [11]$$

giving

$$S_{m(An)} = S_{m(Ox)2} \quad [12]$$

where $S_{m(Ox)2}$ is the oxidation bending stress due to NbO_x.

Combination of results.—The dissolution and annealing flexure measurements gave the total unbending which should then equal the total bending in the positive direction during the oxidation and cooling processes. This equality can be expressed through the summation of induced bending stresses in the metal since, by Eq. [1], these stresses are a direct function of measured curvatures

$$S_{m(Ox)} + S_{m(Cl)} = S_{m(Ds)} + S_{m(An)} \quad [13]$$

or

$$S_{m(Ox)} - S_{m(An)} = S_{m(Ds)} - S_{m(Cl)} \quad [14]$$

The deflection of the sample, and thus the stress induced in the metal, during oxidation is a result of stresses in both a suboxide layer and an Nb_2O_5 film. The stress in the Nb_2O_5 film can be separately determined as follows.

First it is noted that the stress in the Nb_2O_5 film, $S_{1(Ox)}$, is given by Eq. [2] as a function of the stress in the metal surface, S_m, which in turn is calculated from specimen curvature using Eq. [1]. The metal surface stress arising from Nb_2O_5 alone is the total induced surface stress caused by oxidation, $S_{m(Ox)}$, minus the stress induced by suboxide—the stress which is later removed by annealing. Thus, we can write

$$S_{m(Ox)1} = S_{m(Ox)} - S_{m(An)} \quad [15]$$

Substituting this value of $S_{m(Ox)1}$ into Eq. [2] yields

$$S_{1(Ox)} = \frac{1}{3}\left[S_{m(Ox)} - S_{m(An)}\right]\frac{h}{t_1} \quad [16]$$

This equation is valid if an oxide film at a given stress level will yield the same deflection when acting in conjunction with a suboxide as it will acting alone. This is the case in these experiments.

The stress in the Nb_2O_5 layer can also be computed another way. The deflection induced in the metal by differential contraction during cooling has been calculated using Eq. [6] assuming that Nb_2O_5 is the only oxide layer present. The calculated result is virtually identical to the deflection observed at the end of cooling (Fig. 7). Further, in the process of dissolution only Nb_2O_5 is attacked. Therefore, the deflections involved in cooling and dissolution can be attributed entirely to Nb_2O_5. Consequently, at the end of the oxidation process the portion of the deflection caused by stress in the Nb_2O_5 layer is equal to the difference between the total deflection removed by dissolution of the Nb_2O_5 layer and that deflection added during cooling by differential contraction of the Nb_2O_5 layer. Relating these deflections to stresses at the metal surface using Eq. [1] we have

$$S_{m(Ox)1} = S_{m(Ds)} - S_{m(Cl)} \quad [17]$$

Substituting as before into Eq. [2], we have

$$S_{1(Ox)} = \frac{1}{3}\left[S_{m(Ds)} - S_{m(Cl)}\right]\frac{h}{t_1} \quad [18]$$

Since bending deflections very nearly equal unbending deflections, the positive and negative metal stresses, S_m, also agree closely, as shown in Table I. In effect, this verifies Eq. [13] and [14]. Equations [16] and [18] thus yield equivalent values of the Nb_2O_5 stress, $S_{1(Ox)}$, since these equations differ only in that the terms in brackets are the two sides of Eq. [14]. This agreement with experiment further validates the assumptions underlying Eq. [16] that the stress in the Nb_2O_5 layer, computed from a deflection measurement, is essentially independent of the presence of a suboxide layer.

Results and Interpretation

Oxidation.—Table II lists the initial specimen conditions along with the accompanying oxidation parameters for a sampling of specimens upon which the four described flexure measurement techniques were performed. Figure 3 illustrates typical deflection-time curves for niobium specimens presaturated with oxygen and oxidized near 425°C in preheated, dry oxygen at 1 atm. The scale on the right side of this figure indicates the magnitude of oxidation bending stresses, $S_{m(Ox)}$, calculated from the deflections using Eq. [1].

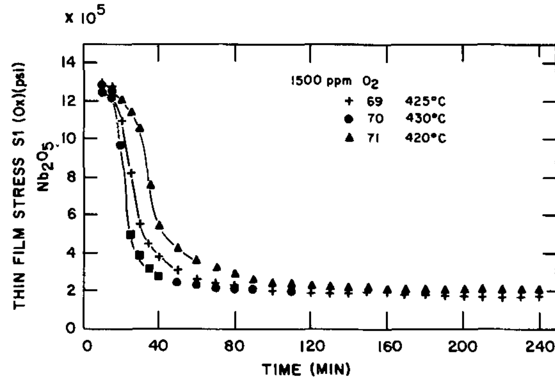

Fig. 5. Thin-film stress curves, $S_{1(Ox)}$, for niobium pentoxide on specimens 69, 70, and 71.

Figure 4 illustrates typical weight gain curves for oxygen-presaturated specimens geometrically similar to the corresponding flexure specimens. The end point of each curve is the actual measured weight gain for the complementary flexure specimen. As previously described, these curves are used to calculate the corresponding Nb_2O_5 or NbO_x film thickness for the oxidation process.

Taking data from curves such as shown in Fig. 3 and 4 and applying Eq. 2, gave plots of $S_{1(Ox)}$ (for Nb_2O_5 film only), an example of which is shown in Fig. 5. At early oxidation times when no Nb_2O_5 is observed to form, the calculated film thicknesses for the small weight gains were very small although the bending stresses were appreciable so that very high $S_{1(Ox)}$ values are obtained, around 1,000,000 psi. The $S_{1(Ox)}$ stresses drop and level off at times corresponding with the times for observed Nb_2O_5 formation and film growth.

Since published solubility limits (11, 12) may be in error, the possibility that high stresses observed at short oxidation times were due to increased oxygen solution was considered. However, calculations led to surface stresses of 90,000 psi, using Pawel's (7) equations, and surface oxygen concentrations of 8000 ppm, using Richmond's (6) equations. Both results are considered unreasonable.

Another characteristic of the early oxidation of niobium near 425°C is the formation of a niobium suboxide, designated NbO_x (1). Specimens oxidized from 10 to 20 min near 425°C were examined by x-ray diffraction. A similar occurrence to that found by previous authors (1, 25) was observed in that small peaks appear adjacent to the niobium x-ray diffraction peaks. Upon further oxidation, these extra peaks disappeared, apparently due to an overgrowth of Nb_2O_5.

Plots of $S_{2(Ox)}$ (for Nb_5O film only) are shown in Fig. 6. These stresses varied as expected for a thin film, the influence of which was important early in the oxidation and became masked when Nb_2O_5 formation was predominant. These $S_{2(Ox)}$ stresses would be 18% higher if the film analysis were made with values for Nb_4O and 18% lower for Nb_6O. Therefore, using an "effective" thin-film model[3] for NbO_x, the induced tensile stress in the substrate surface, S_m, would be at least 125, 150, or 177 thousand psi for Nb_6O, Nb_5O, or Nb_4O, respectively.

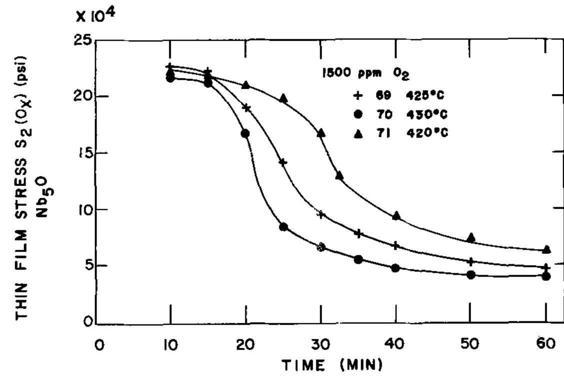

Fig. 6. Thin-film stress curves, $S_{2(Ox)}$, for niobium suboxide (Nb_5O) on specimens 69, 70, and 71.

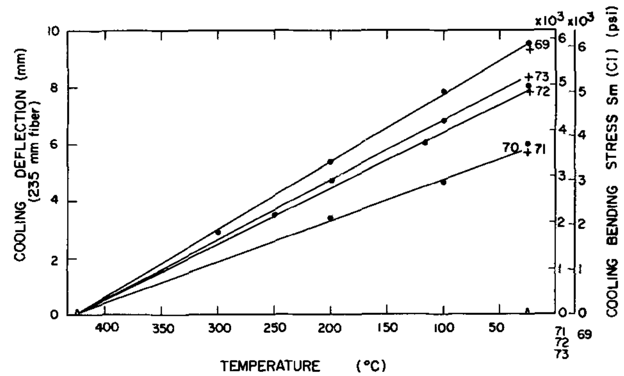

Fig. 7. Cooling deflection and bending stress curves for specimens 69, 70, 71, and 72 compared to final calculated cooling bending stress (+).

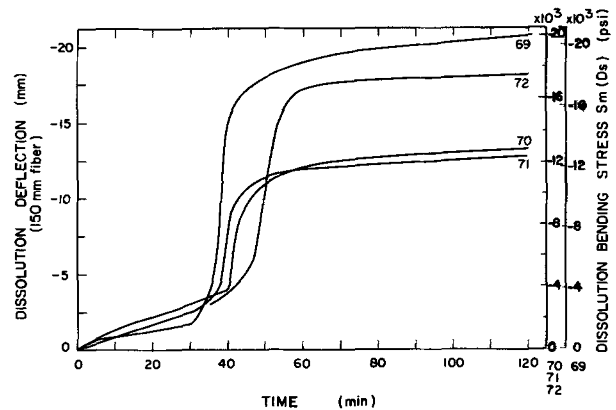

Fig. 8. Dissolution deflection and bending stress curves for specimens 69, 70, 71, and 72.

Cooling.—Typical curves of deflection and cooling bending stress, $S_{m(Cl)}$, are shown in Fig. 7 along with the theoretically calculated end point (+) for the cooling process using Eq. [6]. Thus, taking Nb and Nb_2O_5 as the controlling components and setting $n = 1/2$ gave results in good theoretical agreement with experimental observations of bending magnitude.

Dissolution.—Examples of deflection and dissolution bending stress, $S_{m(Ds)}$, curves are shown in Fig. 8. The dissolution process proceeded slowly for a time as the acid attacked the oxide/metal interface as well as the

[3] This assumes the oxide is a discrete layer of uniform thickness and composition.

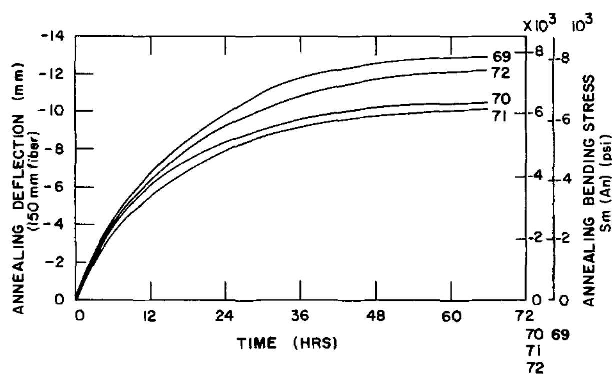

Fig. 9. Annealing deflection and bending stress curves for specimens 69, 70, 71, and 72.

oxide/solution surface. When enough oxide was dissolved at the oxide/metal interface to prevent adequate mechanical bonding of the oxide, the scale flaked off the metal substrate causing the specimen to straighten rapidly.

Annealing.—Typical deflection and annealing bending stress, $S_{m(An)}$, curves are shown in Fig. 9. The annealing procedure did remove the "additional" contribution to the cause of specimen bending, that attributed to NbO_x formation, so the specimens did return to straightness.

Although it is believed that this stress removal is associated with a diffusional process whereby oxygen concentration gradients are diminished, no precise statement of the mechanism is possible since the exact nature of the state of aggregation of oxygen at low concentrations is presently unknown. Gibala and Wert (26), using internal friction measurements, have identified oxygen clusters in niobium containing up to 2500 ppm oxygen. Van Landuyt (27) has found ordering reactions in oxygen-supersaturated niobium using electron microscopy and diffraction. Hurlen *et al.* (1) using x-ray diffraction have identified the suboxide "NbO_x" (probable formula Nb_6O) during oxidation at 425°C. Thus the actual stress reduction may involve a change in clusters or ordering or possibly the redistribution of a phase. The role of stress in promoting phase stability or in providing the driving force for change is not known. However, it was found that the "NbO_x" x-ray diffraction peak diminishes in intensity as annealing time increases. The peak does not vanish, presumably because of the presence of excess or supersaturated oxygen which results from the quenching of samples from temperatures where oxygen solubility is higher than at the test temperature.

Combination of results.—Table I summarizes the maximum bending stresses for these four processes and includes the total bending (positive) and unbending (negative) stresses with their per cent differences. This per cent difference shows that the experimental data differ by a maximum of only 2% from the theoretical Eq. [13]. Therefore, Eq. [14] holds true also to within 2%.

The last column in Table I lists the compressive stress in the thin film of Nb_2O_5, $S_{1(Ox)}$, calculated using Eq. [18]. The value for $S_{1(Ox)}$ is approximately 123,000 psi. This value compared well with the value of 117,000 psi measured by Douglass (28) as the compressive strength of Nb_2O_5 at room temperature. This agreement suggested that in this "break away" oxidation range, the individual Nb_2O_5 nuclei grow until they impinge upon one another laterally. The compressive stress increases to the ultimate compressive strength whereupon the oxide fractures or "breaks away." Since this is happening randomly over the specimen surface, the over-all compressive stress in the oxide layer approximates that of the ultimate compressive strength.

A few samples were prepared similarly to the flexure specimens but without the Nichrome wires attached. They were suspended in the thermogravimetric system and oxidized near 425°C in air for extended lengths of time. Two of these samples are shown in Fig. 10. The fact that a sample oxidized for 30 hr forms a cylinder adds support to the argument that the bending follows an arc of a circle. This resulting shape was somewhat different, but experimentally more desirable, than the spirals obtained by Pawel (10). Also, upon mounting, sectioning, and polishing these specimens, oxide wedges growing into the convex side of the niobium substrate were observed. Therefore, originally flat flexure specimens can eventually deform and form oxide wedges.

Conclusions

1. When oxygen-saturated niobium is oxidized in dry oxygen near 425°C, the oxides consist of a surface layer of Nb_2O_5 and, below it, a suboxide layer. Agreement with experiment is found when this layer is assumed to be Nb_5O.

2. The stress in the layer of Nb_2O_5 approaches a limiting value of approximately 123,000 psi, in fair agreement with the reported ultimate compressive strength.

3. Niobium pentoxide is probably nonprotective after approximately 30 min of oxidation near 425°C because its lateral growth results in compressive fracture.

4. The compressive stress in the oxide induces a tensile stress in the underlying metal which varies with time. Stresses of approximately 20,000 psi were observed after 240 min of oxidation at 425°C.

The Effect of Stress on the Low-Temperature Oxidation of Niobium

II. Oxide Wedge Formation

L. J. Weirick*,[1] and W. L. Larsen

Ames Laboratory, USAEC and Department of Metallurgy, Iowa State University, Ames, Iowa 50010

ABSTRACT

It was found that the formation of suboxide needles or plates, NbO_z, during the oxidation of niobium in the temperature range of 425°-440°C was a function of initial specimen oxygen concentration, oxidation temperature, and applied tensile stress. It was further found that when the oxygen concentration at the substrate surface had reached an equilibrium level and the suboxide plates had formed, only a small tensile stress (less than 10,000 psi on low oxygen content niobium) was needed to form microcracks in a surface of the metal associated with these suboxide needles. Upon further oxidation these microcracks formed niobium pentoxide wedges penetrating the metal causing premature failure of niobium metal sheet.

Premature failure has been observed in oxidizing niobium tubing in as little as one-tenth the expected lifetime (1, 2) as a result of the formation of "oxide wedges" growing normal to the oxidizing surface (3, 4).

Preliminary work at this laboratory (5) established that bent specimens of sheet niobium oxidized at 425° in air exhibited wedges on the concave surface whose number increased with decreasing initial radius of curvature and increasing prior cold work. These bent specimens were observed to approach straightness during the oxidation.

Based upon these observations, it was hypothesized (6) that lateral stresses induced in the metal surface by the growth of Nb_2O_5 into a constricted volume produce a tensile strain in the underlying metal which, when exceeding the ultimate strain of the (oxygen-saturated) metal surface, produce a mechanical crack in the embrittled metal. It was further hypothesized that subsequent oxidation of the interior of the crack produces additional tensile stress and oxygen-solution embrittlement at the crack tip resulting in a self-propagating crack. A program of research was initiated in order to test this hypothesis and to gain further understanding of this gas-phase stress-corrosion cracking in niobium.

Part I of this study (6) established that stresses in the Nb_2O_5 film formed at 425°C increase initially with time but after approximately 30 min, level off at approximately 123,000 psi, the apparent ultimate compressive stress of Nb_2O_5. In addition, suboxides, probably Nb_5O, were found to form near the surface of oxygen-saturated niobium, adding to the strain of the underlying metal. With the growth of the oxide film, the stress on the underlying metal increased.

Part I of this study was limited to elastic deformations (6). Quantitative stress measurements could not be made readily at stress levels high enough to cause substrate cracking or plastic deformation. It was the purpose of Part II of the research to measure the additional tensile stress needed to be applied to the surface of a metal substrate to produce cracking and resultant oxide wedges. Using a sample loaded in tension, it was possible to measure the mechanical stress equivalent to the stress which exists at the surface of a freely flexing oxidizing sheet or freely opening tube oxidizing until wedges form. Thus, useful information could be obtained for this gas-phase stress-corrosion cracking problem in niobium.

Experimental Procedure

Niobium sheet[2] of 0.020 in. thickness was cut into strips and machined to form sheet tensile specimens with a 4 cm gauge length and a 1 cm width. The surfaces were mechanically polished through 600 grit silicon carbide paper and cleaned in alcohol. The specimens were suspended in a thermogravimetric system and oxidized in air to form thin adherent layers of Nb_2O_5 of predetermined thickness. Upon subsequently vacuum homogenization annealing at various temperatures, a range of oxygen contents was obtained. Vacuum fusion analysis, checked by microhardness measurements (7, 8), gave the nominal oxygen contents obtained. Microhardness measurements across the samples indicated that the oxygen concentrations were uniform. The specimens were given a final polish with 600 grit silicon carbide paper.

In order to obtain background data on the tensile properties of niobium as a function of initial oxygen content, stress-strain measurements were made at room temperature and at 425°C in helium.

The effect of stress upon oxidation might be approached by at least four methods of testing. Stress could be constant (stress-rupture) or variable (tensile test); the oxidation state could be constant (previously oxidized) or variable (oxidizing while stressing). Since oxidation itself induces stresses in the metal, actual service conditions consist of a variable stress imposed upon continuously oxidizing metal. The combination of steady stress imposed on oxidizing metal was selected as the combination most nearly approximating service conditions and at the same time being a simple enough stress state to readily permit some form of analysis of results.

Because of the linearity of the oxidation rate in the temperature range of interest, the thickness of an oxidizing specimen diminishes linearly with time. Therefore, in order to maintain a constant applied tensile stress upon an oxidizing specimen, it was necessary to decrease the applied load proportionately with time.

The specimen was mounted in a conventional creep machine using water as the load since the quantity could be conveniently and continuously varied with time. Stress was measured by a load cell and automatically recorded. The specimen was attached by wedge grips between support rods inside a glass sleeve containing alumina chips. Air which had been previously dried using sulfuric acid was preheated by the alumina chips and then passed across the specimen.

[2] Supplied by Fansteel Metallurgical Corporation with given nominal analysis of about 99.7-8% Nb with Ta, Fe, Mo, Ti, and Zr being the metallic impurities; interstitial contents determined from vacuum fusion analysis were about 300 ppm O_2, 40 ppm N_2, and 5 ppm H_2.

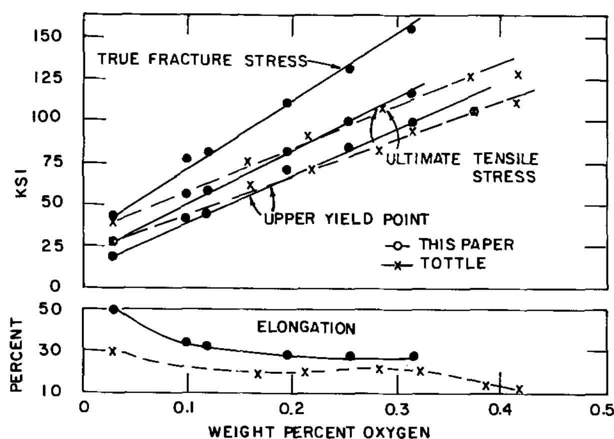

Fig 1. Upper yield point, ultimate tensile stress, true fracture stress, and elongation vs. weight per cent oxygen at 25°C.

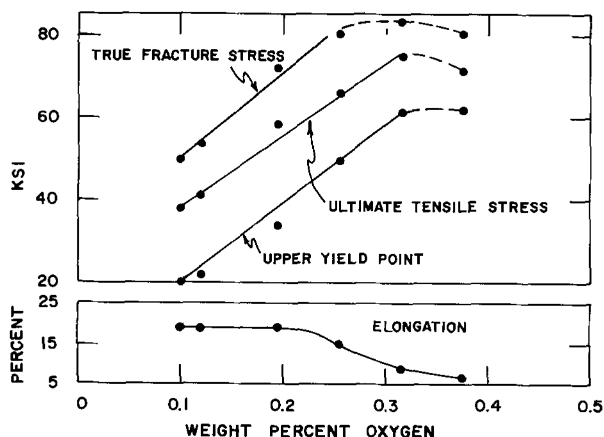

Fig. 2. Upper yield point, ultimate tensile stress, true fracture stress, and elongation vs. weight per cent oxygen at 425°C in helium.

Results

Load-elongation curves as a function of oxygen content were obtained at 25° and 425°C. Figures 1 and 2 show plots of upper yield point, ultimate tensile stress, true fracture stress, and elongation as a function of oxygen content at 25° and 425°C. The data shown in Fig. 1 show very good agreement with the data of Tottle (7). At 425°C, the true fracture stress increases linearly with oxygen content to about 0.25 weight per cent (w/o) oxygen, leveling off thereafter at approximately 80,000 psi. How oxygen is distributed in niobium at this temperature and whether saturation actually exists at oxygen contents below 0.25 w/o are questions which have never been fully answered, but it appears that if an oxygen-embrittled zone occurs at 425°C the total stress required for fracture cannot greatly exceed 80,000 psi.

In order to test the mechanics of the constant-applied-tensile-stress apparatus, a niobium specimen with an initial oxygen content of about 1000 ppm (which happened to be made from a piece of cold worked niobium sheet) was oxidized at 435°C in air while maintaining an approximate constant tensile stress of 15,000 psi. The intention was to oxidize the specimen for one week but it failed on the fifth day. Upon sectioning and mounting the specimen, numerous oxide wedges were observed. To check the validity of this result, two specimens (which were prepared as discussed from annealed sheet) were oxidized in air for 48 hr at 440° and 435°C, respectively, under a constant tensile stress of approximately 15,000 psi. Figure 3 shows an example of oxide wedges formed in the specimen oxidized at 435°C. The specimens were carefully polished and the niobium-oxide interface was observed on a metallograph at 1400X. Suboxide needles as shown in Fig. 4 were observed penetrating into the metal.

Fig. 3. Oxide wedges formed in niobium tensile specimens oxidized at 435°C in air while a constant tensile stress of approximately 15,000 psi was applied; 100X.

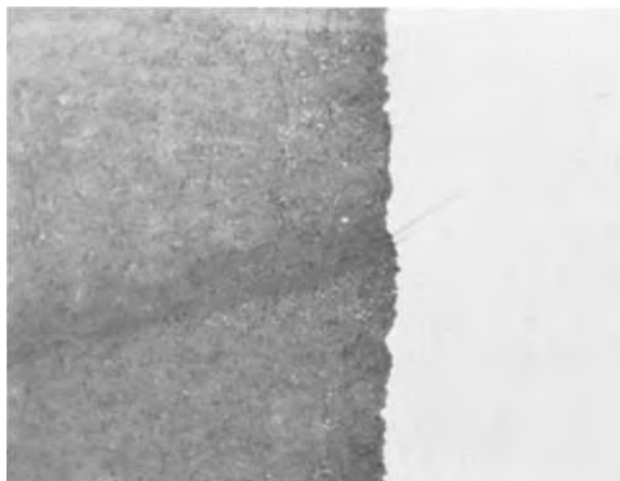

Fig. 4. Suboxide needles formed in niobium tensile specimens oxidized at 435°C in air while a constant tensile stress of approximately 15,000 psi was applied; 1400X.

Figures 5 and 6 show the microstructures of the metal-oxide interface of niobium specimens oxidized in air at 425°C for 48 hr and at 500°C for 24 hr, respectively, with no applied stress. Note the layering of the grayish niobium pentoxide upon the clear, light niobium. Also in Fig. 6 needles are observed which were not observed to occur at 430°C. These needles have been previously observed (1, 4) at oxidation temperatures from about 475° to 650°C. They were designated as a suboxide of niobium, NbO_z (1).

As shown in Fig. 4, the suboxide needles formed in the oxidized tensile specimen look very much like the needles of NbO_z as shown in Fig. 6 for the specimen oxidized at 500°C. A trail of pores and slight discoloration of the overlying niobium pentoxide were observed in both specimens. The presence of pores indicates that the needles were present during the entire oxidation process (9). The micrographic evidence strongly suggested the similarity of the suboxide needles in the two specimens.

Further observation of the suboxide needles in the specimens oxidized while being subjected to a tensile stress showed that a number of these needles had microcracks associated with them, as shown in the example in Fig. 7. Some cracks were within the needles,

Fig. 5. Microstructure of niobium-oxide interface of niobium specimen oxidized at 430°C for 48 hr; 1400X.

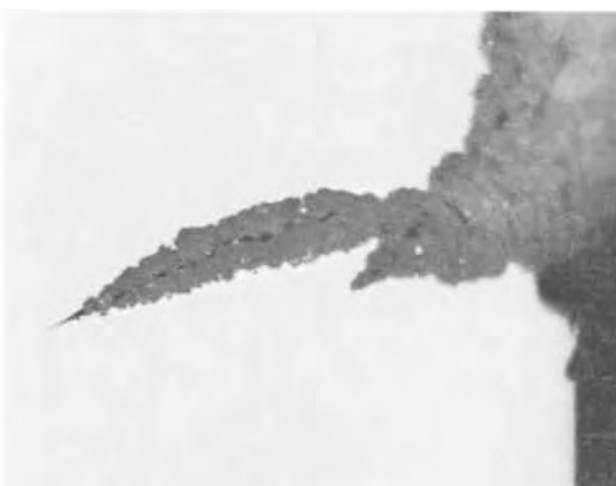

Fig. 8a. Oxide wedge in niobium tensile specimen; 1400X

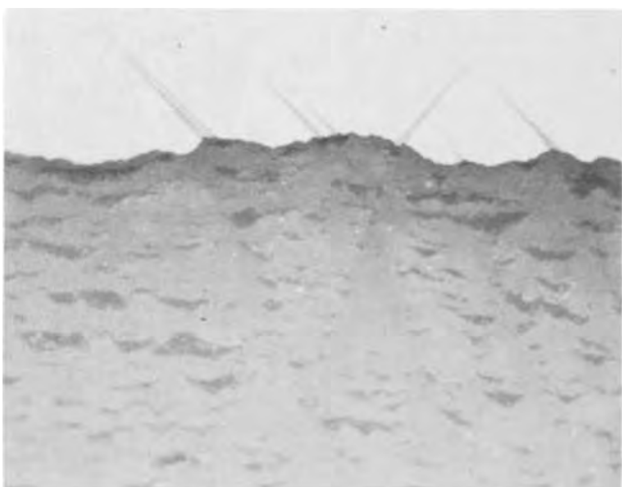

Fig. 6. Microstructure of niobium-oxide interface of niobium specimen oxidized at 500°C for 24 hr. Note the addition of NbO_z needles; 1400X.

some extended from the base of the needles, some were at the needle tip, and some occurred between a few needles. It was thus suspected that the oxide wedge formation was initiated by the microcracks associated with the niobium suboxide needles. Further evidence of this was shown by Fig. 8a and 8b. Figure 8a is a photomicrograph of a niobium pentoxide wedge in niobium at a magnification of 1400X. A point to observe is the initial direction of the oxide wedge formation before propagating more perpendicularly into the niobium. This direction was similar to that for most niobium suboxide needles indicating that the oxide wedge

may have started from a microcrack inside of a suboxide needle. Figure 8b shows an area in the niobium pentoxide layers directly adjacent to the oxide wedge shown in Fig. 8a. The trail of pores and slight oxide discoloration observed is similar to that associated with niobium suboxide needles as shown in Fig. 4. Thus there was evidence of a direct relationship between niobium suboxide needles, microcracks associated with them and niobium pentoxide wedges.

To obtain a more complete understanding of the suboxide needle and subsequent oxide wedge formation phenomena, niobium tensile specimens with different initial oxygen contents were oxidized at temperatures near 425°C while maintaining various applied constant tensile stresses. Tables I and II summarize the results for these tensile specimens. The oxidizing temperature at which most data were taken was 435°C and these data are best shown in Fig. 9. The results showed a correspondence of suboxide needle formation and oxide wedge formation with the frequency of oxide wedges increasing with the frequency of suboxide needles. Also, the frequency of suboxide needles increased and length decreased with increasing applied tensile stress for specimens with the same initial oxygen content oxidized at the same temperature for the same time (as shown in Fig. 10a and 10b).

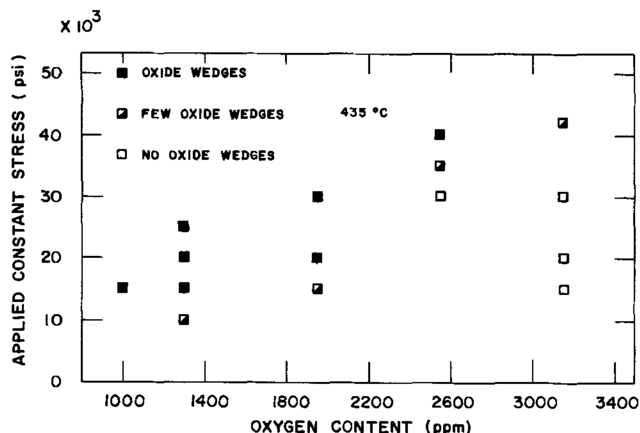

Fig. 9. Plot of applied tensile stress vs. initial oxygen content for niobium tensile specimens oxidized at 435°C in air indicating the formation of oxide wedges.

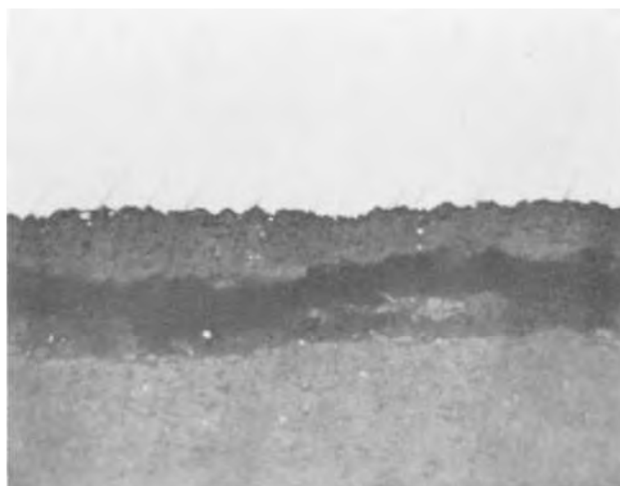

Fig. 10a. Suboxide needles formed in a niobium tensile specimen oxidized at 435°C in air while a constant tensile stress of 25,000 psi was applied; 1400X.

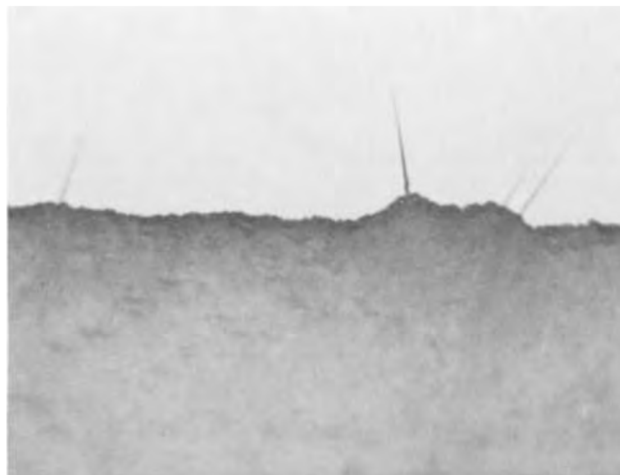

Fig. 10b. Suboxide needles formed in a niobium tensile specimen oxidized at 435°C in air while a constant tensile stress of 10,000 psi was applied; 1400X.

An important result was that there existed a critical minimum applied tensile stress required for the formation of suboxide needles and subsequent oxide wedges. This critical stress was a function of both temperature and oxygen content. At 435°C in air the critical stress was approximately 16,000 psi less than the upper yield point over the range of oxygen contents studied whereas at 430°C the critical stress was only about 5000 psi less than the upper yield point.

An additional observation was that the first tensile specimen oxidized, which was made from a cold-worked niobium sheet, showed many more oxide wedges than specimens made from the annealed sheet which were oxidized at the same temperature and had about the same initial oxygen content. This result agreed with the observation of Doyle (4) that cold working a specimen reduces the temperature required for suboxide needle formation.

Interpretation and Discussion

A detailed study of the formation of these niobium suboxide needles in niobium has not been made. Van Landuyt and Wayman (10) did perform a detailed study of the suboxide needle formation in tantalum. As outlined in their paper, the formation of tantalum suboxide, TaO_y, needles was shown to proceed in a martensitic manner. A subsequent overgrowth of another suboxide, TaO_z, then made the needles more readily visible by optical microscopy. They noted that the two-dimensional needles were actually sections of three-dimensional plates. These authors further indicated that the actual details of formation of the TaO_y plates are still largely conjectural, but certain pieces of evidence obtained shed additional light on the situation. First, the TaO_y plates did not form until a certain incubation period had passed. Second, their work established that the TaO_y plates form only near the surface. They postulated that since it appeared that during the incubation period the oxygen concentration in a surface layer is increasing, the oxygen-saturated Ta transforms to the orthorhombic suboxide plates, TaO_y, upon reaching some critical oxygen content.

Since the oxidation characteristics of niobium and tantalum are very similar, the assumption that the niobium suboxide needles are also forming in a martensitic manner would not seem unreasonable. Supporting this assumption was the observation that an incubation time was also needed in niobium to allow the surface oxygen concentration to increase. Tetragonal suboxides of niobium, NbO_x and NbO_z, corresponding to the tetragonal suboxides of tantalum, TaO_x and TaO_z, were observed, adding support to this view. Also, the information reported (11) on the indices of the plane on which these NbO_z plates lie agreed with the {100} indices observed (10) for the habit plane of TaO_z, the overgrowth phase.

However, the actual martensite phase underneath this overgrowth of TaO_z was the orthorhombic, TaO_y, with {320} habit planes. One correspondence which has not been observed is the existence of an orthorhombic niobium suboxide, NbO_y, similar to the orthorhombic tantalum suboxide, TaO_y. Since the existence of these orthorhombic suboxides is very critical to the argument favoring the mechanism of martensitic formation, a doubt exists as to the applicability of the mechanism of martensitic formation in the niobium system.

As indicated by Van Landuyt and Wayman (10), the problem is not easily analyzed because of the closeness of the {100} and {320} planes in a body-centered cubic system to one another and to the theoretical plane of maximum shear stress. Also, the overgrowth of one oxide upon another adds confusion. Therefore, because of the ambiguities of the proposed mechanism with observations, exactly which mechanism is involved in the niobium suboxide needle formation cannot be determined without further study.

The change in frequency and length of suboxide needles as a function of applied tensile stress cannot be explained unambiguously. However, a simple nucleation and growth model may be applicable. A higher applied tensile stress may increase the number of nucleation sites (possibly dislocation lines) (12) and hence the number of needles. The nucleation of a larger number of suboxide needles may cause a reduction in the stress gradient in their immediate vicinity, thus causing a reduction in the driving force for growth and a consequent reduction in length.

Regardless of the nucleation and growth or the formation mechanism of these suboxide plates, the important finding of this study was that under the proper conditions of oxygen concentration gradient, temperature, and stress these plates do form. Once they are formed, in areas where the local frequency is high, only a very small applied tensile stress (less than 10,000 psi) is needed to produce a microcrack. Once this microcrack is formed, it further oxidizes to form an oxide wedge. If the conditions of oxygen concentration gradient, temperature, and stress are not right to form suboxide plates, no microcracks or oxide wedges are observed. It appears that suboxide plates and subsequently microcracks, must occur before the oxide wedges, which are the ultimate destructive agent, can occur.

Summary

It has been shown (6) that the resulting tensile stress on a niobium metal substrate due to the formation of Nb_2O_5 may approach the yield point of the oxygen-hardened niobium surface.

No matter what the actual tensile stress is, this stress would be approximately the same for the cases of oxidizing niobium tubes, coupon specimens, flexure specimens, or sheet tensile specimens. It is the addition of an applied tensile stress either by bending (as in the case of tubes or flexure specimens) or by pulling (as in the case of tensile specimens) on the oxygen-saturated metal surface which causes the formation of suboxide needles, subsequent cracking of the metal in some localized areas where there is a high frequency of needles and a final formation of an oxide wedge.

Manuscript submitted April 23, 1971; revised manuscript received Dec. 13, 1971. This was Paper 109 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Solid-State Ionics—Solids with High Ionic Conductivity in the Systems Silver Iodide-Silver Oxyacid Salts

Takehiko Takahashi,* Shoichiro Ikeda, and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

Two kinds of high ionic conductivity solids, $Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$, have been found in the systems AgI-Ag_3PO_4, and AgI-$Ag_4P_2O_7$ at ambient temperature. $Ag_7I_4PO_4$ has a silver ion conductivity of 0.019 $(ohm \cdot cm)^{-1}$ at 25°C and an activation energy for conduction of 3.8 kcal/mole between 20° and 79°C. $Ag_{19}I_{15}P_2O_7$ has a silver ion conductivity of 0.09 $(ohm \cdot cm)^{-1}$ at 25°C and an activation energy for conduction of 3.3 kcal/mole between 20° and 147°C. The Ag/electrolyte/I_2 solid-state cells using these electrolytes showed open circuit voltages of 684 mV for $Ag_7I_4PO_4$, and 689 mV for $Ag_{19}I_{15}P_2O_7$, which agree well with the value of 687 mV calculated from $\Delta G°$ of the cell reaction. Transport number measurements using Tubandt's method showed that the transport numbers of silver ions in both new compounds are 1.00 within the experimental error. The phase diagrams of the systems AgI-Ag_3PO_4, and AgI-$Ag_4P_2O_7$ have been determined.

Recently, a new solid electrolyte group of the type MAg_4I_5, where M is K, Rb, or NH_4, was reported by Bradley and Greene (1), and independently by Owens and Argue (2), to have a high ionic conductivity of 0.27 $(ohm \cdot cm)^{-1}$ at 25°C. Many solid electrolyte batteries and electrochemical devices with MAg_4I_5, particularly with $RbAg_4I_5$, have been investigated by many authors (3-6), because of its being relatively stable to light, moisture, and handling within this group.

It was found, however, by Topol and Owens (7), and Takahashi *et al.* (8) that $RbAg_4I_5$ reacted rapidly with iodine to decompose to RbI_3 and AgI when it was maintained in an iodine atmosphere. In a Ag/$RbAg_4I_5$/I_2 cell, therefore, the internal resistance increases so fast that the cell fails its performance. Further, the decomposition of MAg_4I_5 to AgI and M_2AgI_3 was found to be promoted by moisture, when it was in contact with silver plate.

In this study, therefore, a number of investigations on some double salts with silver iodide, such as the systems silver iodide-silver oxyacid salts, have been carried out in order to find new high ionic conductivity solids which are not decomposed by iodine and moisture. Ag_3PO_4, $Ag_4P_2O_7$, $(AgPO_3)_n$, Ag_3AsO_3, Ag_3AsO_4, and $AgIO_3$ have been examined as silver oxyacid salts.

Two new high ionic conductivity solid electrolytes have been found in the systems silver iodide-silver phosphate, and silver iodide-silver pyrophosphate. The properties of both new compounds have been investigated, and the phase diagrams of these systems have been determined.

Experimental

Preparation of samples.—The following grades of starting materials were used: special grade: $AgNO_3$, KI, $Na_2HPO_4 \cdot 12H_2O$, $Na_4P_2O_7 \cdot 10H_2O$, and KIO_3; extra pure reagent: $(NaPO_3)_n$, and sodium arsenite; guaranteed reagent: $Na_2HAsO_4 \cdot 7H_2O$. All of the silver compounds were prepared by precipitation from aqueous solutions of silver nitrate with the other starting materials under safe-lights. The precipitates were washed seven or eight times with distilled water, and dried under nitrogen flow at 100°-120°C. The x-ray diffraction patterns of them were confirmed to agree with those listed in the A.S.T.M. cards.

Weighing of silver iodide and the other material was followed by mixing and grinding, and the mixture was sealed in a Pyrex tube under vacuum and heated for about 18 hr in the temperature range between 200°-400°C, according to its composition. The resulting material was ground and pressed by a hand press under 4 tons/cm^2 to form a pellet which was 13 mm in diameter and about 2 mm thick.

X-ray diffraction.—Geigerflex D-3F (Rigaku Denki Company, Ltd.) was used for x-ray diffraction analysis. A copper anode tube was operated at 15 mA and 35 kV. The shape of each specimen was a pellet as described above. A sample holder made in our laboratory was used to determine the change in structure at high temperatures.

Differential thermal analysis (D.T.A.).—A sample of 0.8g was sealed in a Vycor tube under vacuum, and α-alumina powder sealed in the same size of Vycor tube was used for the standard material. The heating rate was 3.5°C/min, controlled by a PID controller (YEW, Model EGC 5-10) and a programmer (YEW, Model PGE-12).

Conductivity measurement.—In order to reduce the contact resistance in the measurements of the conductivity change with temperature, a mixture of powdered silver and the sample was used for electrode. Namely, a mixture of 0.9g of the sample and 0.3g of 200 mesh silver powder was applied to the electrode material. The sample of 1.2g was stacked between the electrodes and pressed into a pellet of 13 mm in diameter. The electrical conductivity was measured with a 1 kHz impedance bridge (YEW, Model BV-Z-13A).

Transport number measurement.—The transport number of silver ion in both of the new high conductivity compounds was measured by Tubandt's method (9). In order to reduce an anodic polarization, an amalgamated silver plate was used for an anode material, and the change of the mass of the anode and sample-1, which directly contacted the anode, was not measured (see Fig. 1). Four specimens, 13 mm in diameter and about 1.2 mm thick, were weighed separately and stacked into a measuring cell as shown in Fig. 1. A solution of 20 w/o (weight per cent) silver nitrate was used for an electrolyte for the silver coulometer. A stabilized direct current was passed through the cells for about 4 hr at the current densities of 1.2 and 1.5 mA/cm^2 for $Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$, respectively.

Results and Discussion

AgI-Ag_3PO_4 system.—A plot of the electrical conductivity of the system AgI-Ag_3PO_4 at room tempera-

* Electrochemical Society Active Member.
Key words: silver iodide, ionic conductivity, solid-state battery.

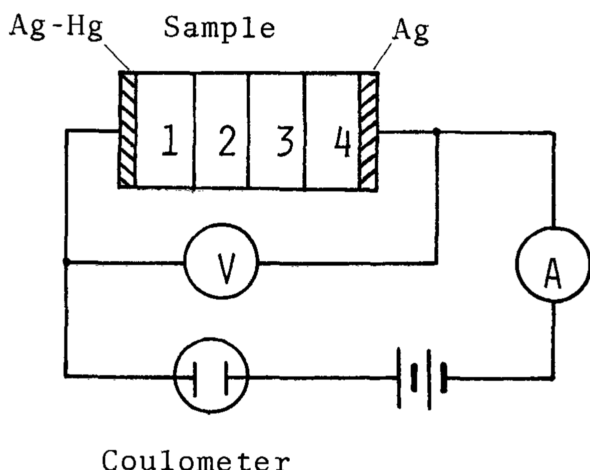

Fig. 1. Schematic diagram of the circuit of transport number measurement.

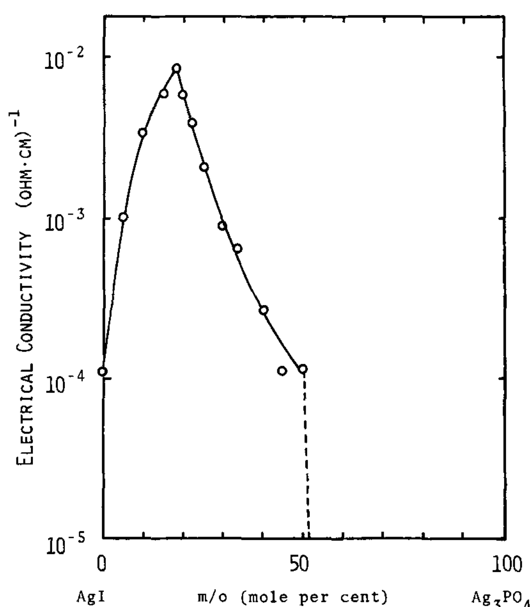

Fig. 2. Electrical conductivities in the system $AgI-Ag_3PO_4$ vs. the composition of Ag_3PO_4 at room temperature.

ture against the Ag_3PO_4 content is shown in Fig. 2, where silver plates were used for electrodes. All the samples were prepared by heating at 400°C and cooling naturally to room temperature, where the cooling rate was about 1.5°C/min. The conductivity curve suggests that two intermediate compounds may be present in this system, because the conductivity of the system showed a maximum at the composition of 20 m/o (mole per cent) and suddenly falls above 50 m/o of Ag_3PO_4.

Results of the x-ray diffraction carried out at room temperature on the samples using nickel filtered Cu-Kα radiation are listed in Table I. In the range of 0-20 m/o of Ag_3PO_4, diffraction peaks of γ phase silver iodide and Phase I appeared. Lines due to Ag_3PO_4 were observed in samples containing 60 m/o or more Ag_3PO_4, the intensity of those lines increased gradually with increasing content of Ag_3PO_4. The pattern of 20 m/o of Ag_3PO_4, Phase I, is simple to predict a new compound, which may be written as $Ag_7I_4PO_4$, and that of 50 m/o, Phase II, is also due to a single phase and is sufficiently different from those of α-, β-, and γ-AgI, Ag_3PO_4, and $Ag_7I_4PO_4$ to predict another new compound, which may be written as Ag_4IPO_4.

The electrical conductivity of $Ag_7I_4PO_4$ plotted as a function of the reciprocal of the absolute temperature is shown in Fig. 3. In the range of room temperature

Table I. Results of x-ray investigations on the system $AgI-Ag_3PO_4$ at room temperature

m/o Ag_3PO_4	Phase observed	Symmetry	Structure type	Lattice parameter (A)	Reference
0	γ-AgI	Cubic	Zinc blende	6.495	(10)
5, 10, 15	γ-AgI + Phase I				
20	Phase I	Cubic		10.6	
25, 33, 40	Phase I + Phase II				
50	Phase II	Complex pattern			
60, 67, 80, 90	Phase II + Ag_3PO_4				
100	Ag_3PO_4	Cubic		6.013	(11)

to 79°C, the conductivity increases linearly, and the activation energy for conduction is obtained from this slope to be 3.8 kcal/mole. At 25°C, the conductivity is $(1.9 \pm 0.1) \times 10^{-2}$ (ohm · cm)$^{-1}$. Above 79°C, however, the electrical conductivity decreases with increasing temperature, but it abruptly increases about 6-7 times at about 147°C, corresponding to the transition of silver iodide from β to α phase. This discontinuity was thought to be caused by the transition of the resulting silver iodide. The conductivity decreases again with temperature above this transition.

Figure 4 shows the x-ray diffraction patterns of $Ag_7I_4PO_4$ measured at various temperatures to compare with the conductivity measurements. The starting material was prepared by heating at 400°C and cooling naturally to room temperature. Each measurement was taken after the sample was kept at the desired temperature for about 20 min. At 80°C, a few small peaks different from those obtained at room temperature are seen, and at 120°C the pattern is quite different from that of $Ag_7I_4PO_4$. Above 150°C, the peaks of β-AgI were changed to those of α-AgI, suggesting that $Ag_7I_4PO_4$ was decomposed to AgI and a compound of another composition at 80°C. Both the samples which were quenched from 400°C and cooled gradually from 400°C to room temperature, the cooling rate of which was about 3-5°C/hr, showed the same x-ray diffraction patterns as those of Fig. 4.

As the x-ray diffraction pattern measured at room temperature of the sample annealed at 150°C was found to be nearly equal to that measured at 120°C, the x-ray diffraction patterns of the specimens of the other compositions annealed at 160°C for 1 or 2 hr in air were also measured at room temperature. The results of these measurements are summarized in Table II. Though in the composition range of 50 to 100 m/o of Ag_3PO_4 the patterns were quite equal to those of unannealed samples of the corresponding compositions, it was found that the x-ray diffraction patterns of the samples containing between 0-50 m/o of Ag_3PO_4 were fairly different from those measured on the unannealed samples. Namely, between 0-33 m/o of Ag_3PO_4, the peaks of $Ag_7I_4PO_4$ (Phase I) vanished, and the peaks

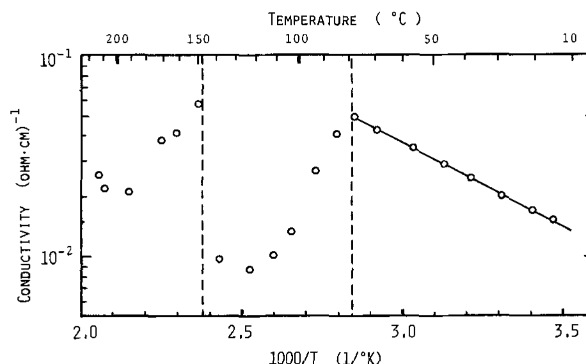

Fig. 3. Electrical conductivity of $Ag_7I_4PO_4$ vs. the reciprocal of the absolute temperature.

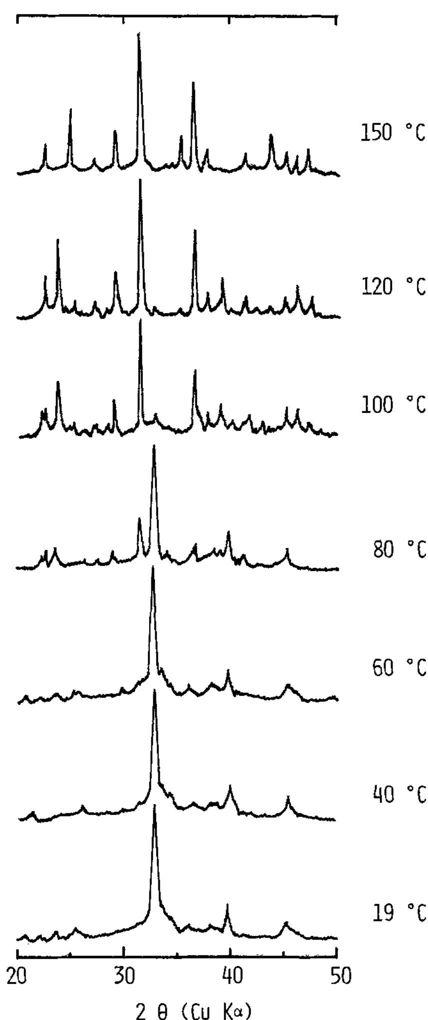

Fig. 4. X-ray diffraction patterns of $Ag_7I_4PO_4$ measured at various temperatures.

of β-AgI and 33 m/o of Ag_3PO_4 (Phase III, which may be written as $Ag_5I_2PO_4$) appeared. And between 33-50 m/o of Ag_3PO_4, the mixed patterns of Phase II and Phase III were observed.

From these results described above, it has been thought that $Ag_7I_4PO_4$ would be completely decomposed according to the reaction

$$Ag_7I_4PO_4 \rightarrow 2AgI + Ag_5I_2PO_4 \quad [1]$$

by annealing above 79°C, and the rate of the recombination reaction of the resulting materials would be fairly slow at room temperature. A mass change of the sample before and after the annealing procedure was not observed, so it was found that $Ag_7I_4PO_4$ was merely decomposed to AgI and $Ag_5I_2PO_4$, and no change of the number of oxygen atoms bonded to phosphorous atoms occurred by annealing. The sample prepared at 400°C, however, was extremely stable at room temperature, as the electrical conductivity and the x-ray diffraction pattern of it have been confirmed to be maintained constantly for at least 3 yr.

Table II. Results of x-ray investigations on the system AgI-Ag_3PO_4 annealed at 160°C

m/o Ag_3PO_4	Phase observed	Symmetry	Structure type	Lattice parameter (Å)	Reference
0	β-AgI	Hexagonal	Wurtzite	a = 4.592 c = 7.510	(12)
15, 20, 27.5	β-AgI + Phase III				
33.3	Phase III	Complex pattern

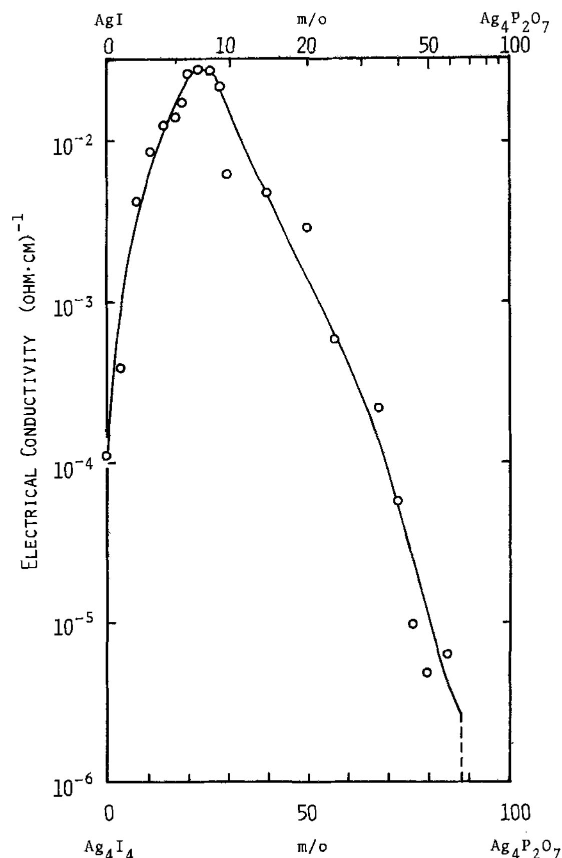

Fig. 5. Electrical conductivities in the system AgI-$Ag_4P_2O_7$ vs. the content of $Ag_4P_2O_7$ at room temperature.

The crystal structure of $Ag_7I_4PO_4$ is estimated to be a cubic structure having a lattice constant of 10.6Å from the x-ray analysis.

AgI-$Ag_4P_2O_7$ system.—Figure 5 shows the result of the electrical conductivity of the system AgI-$Ag_4P_2O_7$ at room temperature, plotted against the composition of $Ag_4P_2O_7$, where silver plates were used for electrodes. The samples containing between 0-25 m/o of $Ag_4P_2O_7$ were prepared at 200°C, and the samples containing between 30-50 m/o and between 60-90 m/o were prepared at 300° and at 400°C, respectively, where the cooling rate was about 1.5°C/min for all samples. Considering the phase diagram and the experimental results, $Ag_{19}I_{15}P_2O_7$ was mainly prepared by heating at 250°C for about 20 hr and cooling naturally to room temperature (the cooling rate was about 1.5°C/min). The conductivity curve suggests that a new compound having a high conductivity may be present in this system.

Results of the x-ray diffraction carried out at room temperature are listed in Table III. Peaks of γ-phase silver iodide were observed in samples containing less than 5 m/o of $Ag_4P_2O_7$, and new lines were observed in the samples containing about 7 and 33 m/o of $Ag_4P_2O_7$. In the sample containing more than 67 m/o, peaks of $Ag_4P_2O_7$ appeared. It could be concluded, therefore, that three new intermediate compounds are present at room temperature in this system.

From the results described above, it has been found that the new high conductivity solid containing about 7 m/o of $Ag_4P_2O_7$ is not a solid solution of AgI and $Ag_4P_2O_7$, but a new compound, so several experiments have been done in order to decide the composition of this compound. Figure 6 shows the logarithm of the conductivities of the samples of the composition rang-

Table III. Results of x-ray investigations on the system AgI-$Ag_4P_2O_7$ at room temperature

ing from 6 to 8 m/o of $Ag_4P_2O_7$ plotted against the reciprocal of the absolute temperature. The conductivity curves of 6.00 and 6.25 m/o have an abrupt change near 147°C, corresponding to the transition of silver iodide from β to α phase. In the sample containing 8.00 m/o it was found that the conductivity was decreased above 147°C. On the other hand, the conductivity curves of the sample containing 7.00 m/o showed the Arrhenius type curve in the range of the temperature investigated.

The results of D.T.A. of this system show endothermic peaks at 147°C on heating in the composition range of 0-17 m/o of $Ag_4P_2O_7$.

The x-ray diffraction patterns of the samples containing 6 and 7 m/o of $Ag_4P_2O_7$ showed a cubic structure with a lattice constant of 11.2Å, and it was assumed from the analysis of the lattice constant, specific gravity, and the ionic radii that the new compound may be written as $Ag_{19}I_{15}P_2O_7$.

Other systems.—The same procedure described in the previous section has been carried out on the systems, AgI-$(AgPO_3)_n$, AgI-Ag_3AsO_3, AgI-Ag_3AsO_4, and AgI-$AgIO_3$, and also on the systems, $AgBr$-Ag_3PO_4, and $AgCl$-Ag_3PO_4.

It was indicated by the results of the electrical conductivity measurements that no high conductivity compounds were present in these systems at room temperature. The electrical conductivities of these systems measured at room temperature were lower than that of pure silver iodide (γ phase) (14). In the AgI-Ag_3PO_4 system, exchange of silver iodide with silver bromide or silver chloride did not improve the electrical conductivity.

Properties of $Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$.—The compound $Ag_7I_4PO_4$ is an orange colored solid, and the compound $Ag_{19}I_{15}P_2O_7$ is a yellow solid at room temperature. The former was darkened by exposure to visible light in a powder state, but the latter has little

sensitivity to light. The electrical conductivities of both compounds are 0.019 ± 0.001 and 0.090 ± 0.002 (ohm · cm)$^{-1}$ at 25°C, respectively. The activation energies for conduction of both compounds are 3.8 and 3.3 kcal/mole, respectively. These values are so low for ionic compounds that they are thought to have the average structures. The compounds which are known to have the average structures are listed in Table IV.

In the experiments to find the transport numbers of these compounds, it was found that the total current passed through both cells (see Fig. 1) corresponded to the quantities of silver deposited at the cathodes, as shown in Table V, and the transport numbers of silver ion are unity within the experimental error. Figure 7 shows the results of the changes of the internal resistances of the following cells in process of time: Graphite/$Ag_7I_4PO_4$ + I_2/Graphite, Graphite/$Ag_{19}I_{15}P_2O_7$ + I_2/Graphite, and Graphite/$RbAg_4I_5$ + I_2/Graphite. A mixture of 1.3g of each sample and 0.3g

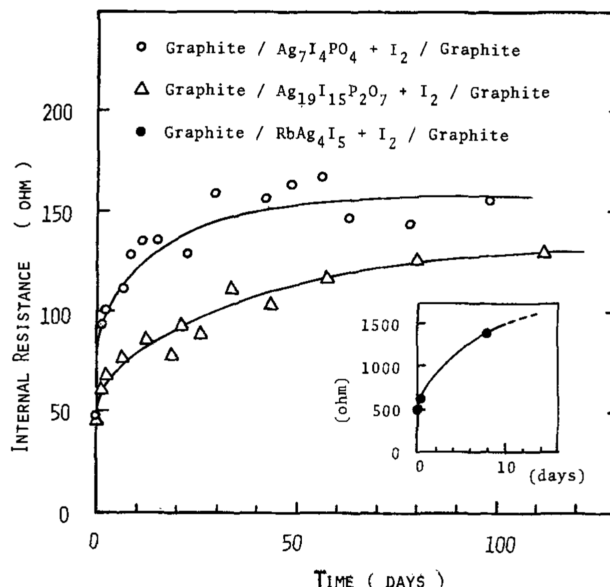

Fig. 7. The changes of the internal resistances of the cells: Graphite/$Ag_7I_4PO_4$ + I_2/Graphite, Graphite/$Ag_{19}I_{15}P_2O_7$ + I_2/Graphite, and Graphite/$RbAg_4I_5$ + I_2/Graphite.

of iodine was used, and platinum plates were used for the current collectors. In the former two cells, the resistances increased gradually with time for about a month, and then were maintained at constant values. The resistance of the last cell, however, increased about 100 times greater than those of the former two cells. This result indicates that two new compounds found in this study provide a good performance in silver-iodine solid-state batteries. The cells, Ag/ $Ag_7I_4PO_4/I_2$ + C, and Ag/$Ag_{19}I_{15}P_2O_7/I_2$ + C, showed open circuit voltages of 684 and 689 mV at 25°C, respectively. These values agree fairly well with the value, 687 mV, calculated from the change of free energy of formation of silver iodide at 25°C according to Eq. [2]

$$Ag(s) + 1/2I_2(g) = AgI(s) \qquad [2]$$

that is, the ionic transport numbers of these compounds are unity. And these results are in good agreement with the transport numbers measured by Tubandt's method.

As no other cations are present except silver ions in both compounds, the conduction in $Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$ is mainly due to the migrations of Ag^+ ions, because anions such as I^-, PO_4^{3-}, and $P_2O_7^{4-}$ ions have large ionic radii and usually do not migrate in solids at ambient temperature.

Phase diagrams of the systems AgI-Ag_3PO_4, and AgI-$Ag_4P_2O_7$.—Figures 8 and 9 show the phase diagrams of the systems AgI-Ag_3PO_4, and AgI-$Ag_4P_2O_7$, respectively, determined from the results of the measurements of electrical conductivities, x-ray diffractions, and differential thermal analysis.

In the former system, there are two intermediate compounds at room temperature at the compositions of 20 and 50 m/o of Ag_3PO_4. The high conductivity compound, $Ag_7I_4PO_4$, decomposes to AgI and a compound with 33.3 m/o of Ag_3PO_4 above 79°C. The compounds, $Ag_5I_2PO_4$ and Ag_4IPO_4 melt incongruently at 236° and 320°C, respectively. The eutectic composition is estimated to be 16 m/o of Ag_3PO_4, at 225°C. The liquidus line of the samples containing more than 67 m/o of Ag_3PO_4 was obtained by extrapolation. A

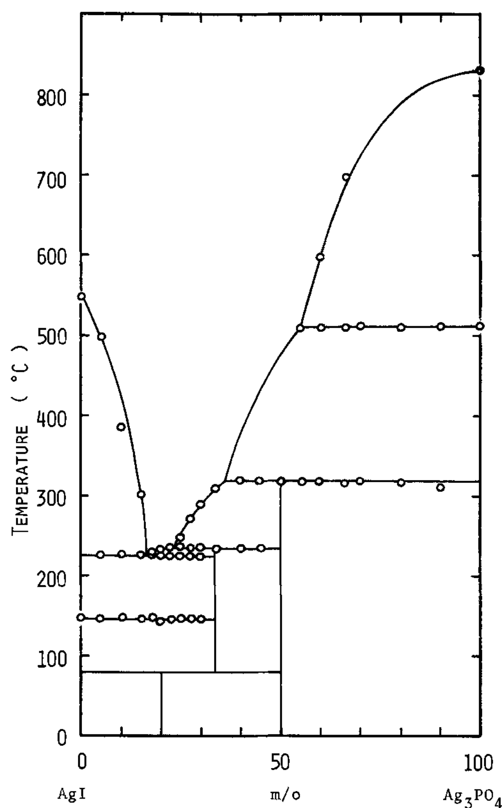

Fig. 8. Phase diagram of the system AgI-Ag_3PO_4

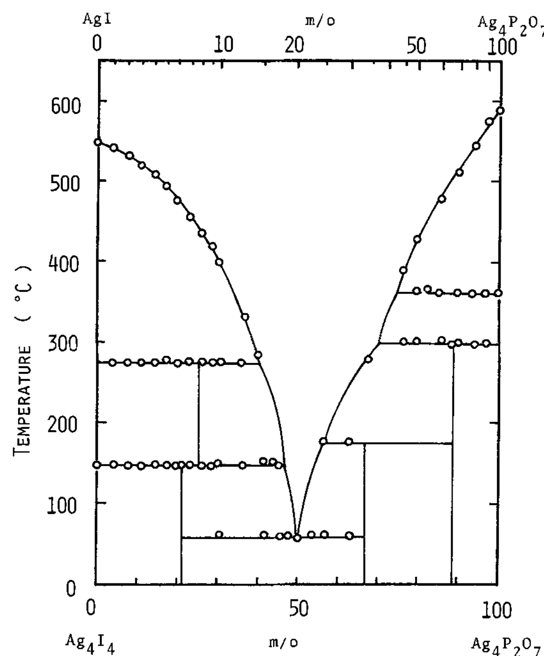

Fig. 9. Phase diagram of the system AgI-$Ag_4P_2O_7$

thermal arrest (a peak in the D.T.A. trace) at 512°C was observed for all compositions containing between 60-100 m/o of Ag_3PO_4.

In the latter system, there are three intermediate compounds at room temperature at the compositions of 6.25, 33.3, and 66.7 m/o of $Ag_4P_2O_7$. The high conductivity compound, $Ag_{19}I_{15}P_2O_7$, decomposes to AgI and $Ag_{16}I_{12}P_2O_7$, which is the compound at the composition of 7.69 m/o of $Ag_4P_2O_7$, above 147°C. $Ag_{16}I_{12}P_2O_7$ has an incongruent melting point at 274°C. $Ag_6I_2P_2O_7$ and $Ag_9IP_4O_{14}$ melt incongruently at 178° and 295°C, respectively.

When the mixture containing 6.25 m/o of $Ag_4P_2O_7$ was heated above 274°C and cooled to room temperature naturally, the x-ray diffraction peaks were mainly those of γ-phase silver iodide and those of $Ag_{19}I_{15}P_2O_7$ were absent. This result indicates that the peritectic reaction at 274°C produces the glassy product containing near the composition of 20 m/o $Ag_4P_2O_7$ and AgI, and these products may be hard to recombine to form $Ag_{16}I_{12}P_2O_7$. The electrical conductivity of the product was nearly equal to that of γ-AgI, but when the sample was annealed between 147° and 274°C, the new high conductivity compound was formed again. In the former system, however, when the mixture containing 20 m/o of Ag_3PO_4 was melted above 225°C and cooled to room temperature, the electrical conductivity was so high as to indicate the formation of $Ag_7I_4PO_4$, and the annealing procedure between 79° and 225°C gave the opposite result.

Conclusion

Though compounds in the MAg_4I_5 group have specific conductivities as high as 0.27 $(ohm \cdot cm)^{-1}$ at 25°C, they seem to be somewhat unstable to moisture, handling, and especially to an iodine atmosphere. So the search for high ionic conductivity solid electrolytes has been carried out on the new systems, silver iodide-silver oxyacid salts.

$Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$ have pure silver ion conductivities as high as 0.019 and 0.090 $(ohm \cdot cm)^{-1}$ at 25°C, and activation energies for conduction of 3.8 and 3.3 kcal/mole, respectively. Both compounds are more stable than $RbAg_4I_5$ in an iodine atmosphere. The transport numbers of silver ions in both compounds are 1.00 within the experimental error. The silver-iodine solid state batteries using these new compounds for the electrolyte materials showed open circuit voltages as high as 684 and 689 mV at 25°C, respectively, which are in good agreement with the value, 687

mV, calculated from $\Delta G°$, the free energy of formation of silver iodide(s) from silver(s) and iodine(g) at 25°C.

$Ag_7I_4PO_4$ is stable up to 79°C, and though $Ag_{19}I_{15}P_2O_7$ decomposes to AgI and $Ag_{16}I_{12}P_2O_7$ above 147°C, $Ag_{16}I_{12}P_2O_7$ has a high ionic conductivity up to 274°C in the solid state, and it is a promising material for use as a solid electrolyte for electrochemical devices.

A Very Precise Sectioning Method for Measuring Concentration Profiles in Anodic Tantalum Oxide

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Concentration profiles can be measured by removing thin uniform layers from the surface of a solid and determining the amount of the species left after the removal of each layer. The precision of such measurements depends on four factors: the thinness of the layers removed, the accuracy with which their thickness can be measured, the uniformity of the layers, and the accuracy with which the amount of the species present may be determined. The present paper describes a sectioning technique for anodic tantalum oxide, based on slow dissolution of the oxide in HF almost saturated with NH_4F. Layers as thin as 5Å have been repeatedly and reproducibly removed, and the standard error in the total thickness removed is effectively about 3Å for the purpose of profile measurements. Furthermore, the layers are removed with extreme uniformity. In effect, therefore, anodic oxide films on tantalum can be sectioned almost atom layer by atom layer.

The migration of atoms across oxide films is of great importance for the theory of metal oxidation, and of great practical significance in device technology. Study of these migrations requires that the concentration profile of the atomic species be measured before and after the migration event, and methods are therefore needed for measuring its concentration as a function of distance beneath the oxide surface. The obvious way of doing this is to section the oxide; that is, to remove thin uniform layers in succession and determine the amount of the species present in the oxide after the removal of each layer. Such a method is reported here for films of tantalum oxide formed by anodization. Since many of the species were incorporated by ion implantation, it was necessary to study the effect of ion implantation on the sectioning technique, and this is done in a separate paper (1). Other papers describe the application of the technique to the measurement of implantation profiles (2), transport numbers of metal and oxygen (3), and oxygen migration (4).

Comparison of the concentration profiles before and after the migration event yields two kinds of measurement. The relative mobility of the migrating species can be determined by measuring the change in its mean position within the oxide; that is, relative to one of the oxide surfaces. In another paper of this series (3), it is shown that it is possible to define a position in the oxide that corresponds to zero migration, and hence to calculate the absolute mobility. Second, by measuring the change, or more specifically the broadening of the concentration profile, it is possible to obtain information on the nature of the migration process itself. Experimentally, the difference between the two kinds of measurement is that the second requires a technique roughly ten times as precise as the first, and no such technique has hitherto been available. The present paper repairs this omission.

In developing a sectioning technique to this degree of precision, several factors assume an importance they do not otherwise have, and it was therefore necessary to consider them in some detail. The precision of a sectioning technique is limited by the following considerations.

(*A*) The number of experimental measurements must be sufficient to characterize the concentration profile. This means that the thickness of each layer must be considerably less than the width of the profile investigated. A method for removing layers as thin as

* Electrochemical Society Active Member.

Key words: tantalum, anodic oxidation, oxide dissolution, sectioning method, concentration profiles.

5Å is described under Sectioning Anodic Tantalum Oxide.

(*B*) The accuracy with which the mean thickness of each layer can be measured. The section on Measuring the Average Thickness of Each Layer Removed describes a spectrophotometric method for measuring anodic oxide thickness, from which the thickness of the removed layers can be obtained by difference; the standard error in these measurements is generally less than 3Å.

(*C*) The uniformity of the layers removed. Concentration profiles obtained by removing layers of irregular thickness are broader than the true profiles. The reanodization method described in the section on Uniformity of the Oxide Layers Removed shows that the effect of the irregularities is negligible for all but the very narrowest profiles.

(*D*) The accuracy with which the amount of the atomic species present in each layer can be measured. Most of the species used here were radioactive, and so their concentrations could be estimated by standard nuclear techniques; the special technique used to estimate ^{18}O is described in (4).

Once the data has been obtained, it must be analyzed to obtain the parameters of the concentration profile. Mathematical procedures for doing this, involving a computer, are described elsewhere (2-4).

Sectioning Anodic Tantalum Oxide

Preparation of Tantalum Specimens

Tantalum sheets, 99.9% pure, were obtained from Fansteel Metallurgical Corporation, and cut to shape as required. The usual specimen size was rectangular, 3.5 × 1.0 cm², cut from 0.037 cm (0.015 in.) sheet, with a 0.05 cm (0.020 in.) diameter tantalum wire spot welded on one corner to provide electrical contact. The coupons were then treated much as described by Randall, Bernard, and Wilkinson (5): 10 min each in hot Alconox and trichlorethylene to remove grease, followed by 30 min in concentrated HNO_3 to remove any copper left by the welding process. A chemical or electrochemical polish was next; either 10 sec in the usual 5:2:2 mixture of concentrated sulfuric, nitric, and hydrofluoric acids, or 10-20 min at 100 mA/cm² in a 9:1 mixture of concentrated sulfuric and hydrofluoric acids (6). Finally, the specimens were dipped for 2 min in the HF-NH_4F reagent described below to remove any film left by the polishing process. It has recently been demonstrated that this procedure is excellent for removing fluoride contaminants (7).

Anodic Oxidation

The tantalum coupons were anodized at constant current using an apparatus designed and built by Walker (8). This consisted of a Northeast Scientific Model RI-234 constant current supply, governed by an electronic control unit similar to that described by Young (6), which shut off the current automatically when the required voltage was reached. The anodizing cell was normally a stainless steel beaker, which also served as cathode, and the electrolyte was 0.1M H_2SO_4, as used by Young (9) in making the thickness calibration described later. Anodizing voltages were measured with respect to a Beckman General Purpose glass reference electrode, since absolute accuracy was not required, and the temperature of the electrolyte was maintained within 0.2° of 25°C by immersing the beaker in a water bath.

Procedure for Removing Oxide Layers

The anodic tantalum oxide was stripped in concentrated HF almost saturated with NH_4F. By varying the proportion of NH_4F, stripping rates ranging from 25 to 150 Å/min were obtained. One such solution, prepared from 200 mliters 48% HF and 80g NH_4F, stripped the oxide at the rate of 60 Å/min; by adding another 20 mliters 48% HF, the rate was increased to 140 Å/min. The uniformity of the stripping, as determined from the interference color of the remaining oxide, was excellent throughout the range quoted, but for rates faster than 150 Å/min it deteriorated. There was no evidence for any variation in the stripping rate as a function of remaining oxide thickness; the oxide dissolved as though it was completely homogeneous.

Since the time in the stripping solution was being used only as a control on the thickness removed and not as a measure of it, the stripping rate did not have to be known very accurately. No detailed study of the dependence on temperature, acidity, fluoride concentration, and oxide preparation was therefore undertaken. Qualitatively, however, it was observed that the rate increased with increasing HF concentration and with increasing temperature, and that the uniformity improved with increasing fluoride concentration. Freshly prepared solutions dissolved the oxide somewhat more rapidly; after about a week, the rate fell to an almost constant value. Similarly, freshly prepared oxides dissolved faster than aged samples, in agreement with previous observations by Vermilyea (10).

The stripping procedure was as follows. After measuring the thickness of the oxide film by the method described in the next section, the coupon was dipped into the HF-NH_4F reagent, with agitation, for the time necessary to remove the desired thickness of oxide. The coupon was then transferred rapidly to distilled water, which quenched the dissolution. After 10 sec in the first water wash and 20 sec in a second, the specimen was transferred to acetone for 15 sec, after which it was dried in a blast of cold air. Remeasurement of the oxide film thickness gave, by difference, the amount dissolved by the stripping agent.

Masking of Selected Areas

For certain experiments, it was necessary to mask portions of the specimen and then either thicken (anodize) or thin (strip) the oxide film on the remainder. The masking material had, therefore, to meet several requirements. It had to have a high resistivity to prevent current flow on anodizing, and it had to be inert to the hydrofluoric acid in the stripping reagent. It had to be readily removable, but preferably insoluble in the acetone used for washing. Furthermore, it had to make a good seal with itself so that different areas could be masked in succession. Above all, it had to cover the surface without leaving pinholes.

After various trials, it was found that the vacuum grease Apiezon N was ideal for the purpose. Tests showed that this grease could be used up to at least 200V on anodizing, and for any amount of stripping. Boundaries between masked and unmasked areas were extremely sharp, as demonstrated by the interference colors, and the colors of the masked areas remained in their original state, thus demonstrating the absence of pinholes. Furthermore, Apiezon N made an excellent seal to itself, was apparently insoluble in acetone, yet readily soluble in trichlorethylene.

By masking different areas in succession, therefore, it was possible to form the anodic film to different thicknesses on different parts of the same specimen, and either anodizing or stripping could be used to achieve this. The former was used in the uniformity of stripping tests described in the section on Uniformity of Oxide Layers Removed, while the latter was used for the consistency tests in the section on Measuring the Average Thickness of Each Layer Removed and for the study on oxygen migration described elsewhere (4).

Measuring the Average Thickness of Each Layer Removed

Spectrophotometric Method of Measuring Oxide Thickness

The mean thickness of the layers removed was obtained as the difference between the mean thickness of the oxide film before and after stripping. The prob-

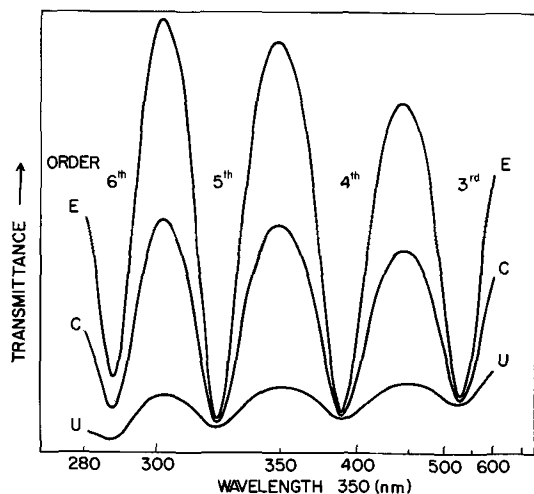

Fig. 1. Interference spectra from three tantalum specimens anodized simultaneously to show the effect of surface roughness. Anodizing conditions: 1 mA/cm² at 25°C to 172V in 0.1M H_2SO_4. Oxide thickness 2630 ± 2Å. U, unpolished; C, chemically polished; E, electrochemically polished.

lem, therefore, was one of measuring the mean oxide thickness with sufficient accuracy, and to do this, a spectrophotometric technique developed by Young (9) was employed. The specular reflectance of an anodized tantalum specimen exhibits minima at certain wavelengths (Fig. 1) due to interference between the light reflected at the oxide surface and that reflected at the oxide/metal interface. By measuring the wavelength, λ, of these minima at known orders, n, of interference, the mean thickness, h, of the oxide films could be calculated.

The conditions for interference is

$$h = \frac{(n - \frac{1}{2}) \cdot \lambda}{2\eta \cdot \cos \phi} - X \qquad [1]$$

where η is the refractive index of the oxide, ϕ the angle of refraction, and X accounts for the phase change on reflection at the oxide/metal interface. Both η and X vary significantly with the wavelength of the measuring light, and the variations are not independently known. Young (9) was, however, able to form oxides of known thickness by means of a rather complex procedure involving Faraday's law, capacity, and refractive index, and he then used these oxides to establish the variation of η and X. His interference spectra were measured at an 11° angle of incidence, so that cos ϕ was effectively unity; a polished but unanodized tantalum specimen was placed at the equivalent position in the reference beam of the Cary Model 14 spectrophotometer. Exactly the same procedure was followed here using a Beckman DK2 spectrophotometer, with a light beam of area 0.8 × 0.2 cm² incident on the sample.

As can be seen from Fig. 1, the interference minima are quite broad, and so there is a difficulty in determining the exact minimum wavelength. Excellent results, however, were obtained by means of the following procedure. With the DK2 set at the 0-10% transmittance scale to magnify changes in reflectance, the wavelengths about the minimum were manually scanned. Provided the scanning was done slowly enough, the recorder pen would give a distinct upward kick after passing through the minimum, and the wavelength at which this occurred was recorded. By scanning through the minimum in both directions, two such wavelengths were obtained, and their average was taken as the wavelength of the interference minimum. Justification for this procedure is provided by the symmetry of the interference spectra and by the extreme reproducibility, usually better than 0.2 nm, of the "kick" wavelengths.

Interference minima can be satisfactorily measured from about 280 to about 600 nm. Below 280 nm, the interference is masked by the intrinsic absorption of the oxide, while above 600 nm the intensity of the maxima are reduced so much that the minima become too broad to measure. As Young has pointed out, best results are obtained in the region from 300 to 400 nm, where the minima are most intense. The requirement for at least one minimum between 280 and 600 nm limits the method at small oxide thicknesses; the first-order minimum covers the range from 160Å at 280 nm to 520Å at 600 nm, wihle the second-order begins at 660Å with a minimum at 280 nm. Thicknesses between 520-660Å cannot therefore be measured, but above 660Å coverage is continuous. Wherever possible, therefore, experiments were performed using thicknesses greater than 660Å.

Surface Roughness and the Nature of the Thickness Measured

The thickness of a uniform film formed on a perfectly smooth flat surface is unambiguously defined, as illustrated in Fig. 2a. Real surfaces, however, are more or less rough, as illustrated schematically in Fig. 2b and 2c, and this complicates the definition. Evans (11) has suggested two measures for the film thickness on rough surfaces. The mean general intercept, MGI, is the average thickness of the film measured perpendicular to the general plane of the surface, and is equal to the film weight divided by the film density and apparent area of the metal surface. The second measure, the mean local intercept, MLI, is the average film thickness measured normal to the local metal surface; it can be calculated in the same way as the MGI, but using the real area in place of the apparent area. The real area equals the apparent area times the roughness factor, which is always greater than unity; the MGI is therefore always larger than the MLI. However, when the roughness pitch is smaller than the MGI, the definition of the MLI is no longer valid, as can be seen from Fig. 2c.

The surface roughness in a metal/anodic oxide system is very considerably influenced by the nature of the anodic oxidation. In a later section of this paper it is shown that the oxide thickness measured perpen-

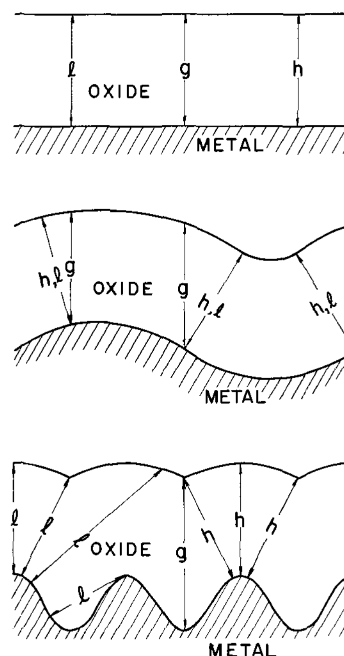

Fig. 2. Effect of surface roughness on the definition of film thickness. (a, Top) perfectly smooth flat oxide; (b, center) surface roughness of large pitch; (c, bottom) surface roughness of small pitch; g thickness averaged for mean general intercept (MGI); ℓ thickness averaged for mean local intercept (MLI); h thickness controlling the kinetics of anodization.

dicular to the local metal surface must be exceedingly uniform at all points on the specimen, and that this must be true throughout the anodization process. It follows immediately that the amount of metal consumed in forming oxide is greater at a convexity in the metal surface than at a concavity, and that the rate of consumption is proportional to the local convexity of the curvature. The formation of an anodic oxide therefore leads to a smoothing of the metal surface, the sharpest asperities being smoothed first. Lewis and Plumb have demonstrated this smoothing experimentally during the anodic oxidation of aluminum (12).

Because of the smoothing, Fig. 2c is not a reasonable picture for an anodic oxide, and so the definition of the MLI is valid. Young (9) has measured the roughness factor for chemically polished tantalum specimens that had been subsequently anodized and found that it was within 3% of unity; the MGI and the MLI are therefore almost identical.

The over-all surface roughness is therefore small, but it might still be sufficient to affect the interference minimum, and hence the measured film thickness. To test this, the following experiment was performed. Three tantalum foils, one electrochemically polished, one chemically polished, and one not polished at all were connected together by their lead wires and anodized simultaneously to 172V at approximately 1 mA/cm^2. The resulting interference spectra are shown in Fig. 1; the residual roughness obviously does have an effect on the over-all shape of the spectra. Nevertheless, the average of the kick wavelengths was the same for all three specimens, as is demonstrated later.

A simple argument suffices to explain the results of Fig. 1. Parallel light incident at a certain angle on a rough surface is reflected in various directions, depending on the local orientation of the surface at reflection. In the apparatus used here, the phototube subtended an angle of about 2° at the sample, which meant that only those portions of the surface oriented within a certain 1° range would reflect light into it. To a first approximation, the rougher the surface, the smaller the area covered by the favorable orientations, and hence the smaller the intensity of the reflected light recorded by the phototube. On a film-covered surface, therefore, the roughness will have the effect of reducing the intensity of the interference spectrum by approximately the same factor at all wavelengths. When plotted on a scale linear in transmittance, as in Fig. 1, the maxima are depressed much more than the minima, since they are reduced by a greater absolute amount. Increasing roughness therefore tends to compress the interference spectra, as is observed, and this in turn leads to an increased difference between the two kick wavelengths, which was also observed.

The surface roughness of the specimens, then, affects the precision with which the oxide thickness can be measured, since this depends on the difference between the two kick wavelengths, but it does not affect the measurement itself. It but remains to show what kind of thickness is being measured. Obviously, the light beam is sampling those portions of the surface that are favorably oriented, and on which it measures the thickness normal to the local metal surface. The result, an average of all the sampling points, is therefore an excellent approximation to the mean local intercept. Fortunately, this is just the thickness measure that is required, for the kinetics of the anodization are determined by the thickness normal to the local metal surface.

Sources of Error in the Thickness Measurements

Calibration errors.—As recreated here from the data in Young's paper (9), the thickness calibration was found to have certain inconsistencies; thus for oxide thicknesses near 1300Å, the third-order minimum at about 295 nm would regularly give thicknesses some 10Å greater than the second-order at about 430 nm. These inconsistencies may well be artifacts due to the different apparatus used, but they were unacceptable for the experiments to be performed here. The calibration was therefore revised as follows.

By means of the successive masking and stripping procedure previously described, an electropolished tantalum coupon was prepared with twelve different oxide thicknesses across its surface. The thicknesses ranged from about 2320 to about 1450Å, and all interference minima between 280 and 600 nm were measured at each thickness. The foil was then dipped in the HF-NH_4F reagent to remove approximately 650Å of oxide, so that the oxide thicknesses remaining now ranged from about 1670 to about 800Å. Again all interference minima were measured at each thickness. The cycle was repeated twice more, removing about 300 and 340Å in succession, so that the final thicknesses ranged from about 1030 to about 160Å.

This experiment tested Eq. [1] by providing: (*A*) Measurements of λ for different known n at the same h. (*B*) Measurements of λ at known n for constant differences in h.

Statement *B* rests on the assumption that the stripping proceeds uniformly all over the specimen surface; this is confirmed experimentally in the next section.

The object of the revision was to adjust the parameters η and X in [1], both of which vary with λ, in such a way as to obtain a consistent relationship between λ, n, and h. To do this, the individual oxide thicknesses were first calculated from Young's original calibration using the interference minimum closest to 350 nm. The next step was to calculate the difference in thickness between adjacent oxide areas after each stripping operation, and on the same area after successive strippings, in a manner similar to that shown in Table I. By a series of successive adjustments to the calibration, these differences were equalized as much as possible, thus meeting criterion *B* above. This largely set the calibration for the favored 300-400 nm region. Adjustments under criterion *A* were used to refine the calibration and to extend it to other wavelengths. Opportunity was taken to adjust the base of the calibration so that the oxide thicknesses for first-, second-, third-, and fourth-order interference at 350 nm were 270, 1007, 1744, and 2481Å, respectively; these figures are Young's recommended thicknesses (13) corrected for the 1 mA/cm^2 anodizing current used here (14). A final, minor, adjustment to the calibration ensured that η and X would vary smoothly with λ.

Information needed to recreate the revised calibration is given in Table II, and a test of the new calibration is presented in Table I. The test specimen was prepared and measured in the same way as that used to revise the calibration, but the oxide thicknesses were so chosen that, except for the extreme values in second order, the interference minima could always be measured in the favored 300-400 nm region, and in a single order after each stripping operation.

Table I. Thickness measurements on an oxide film with seven different thicknesses. The film was stripped three times. Thickness differences are in parentheses. Figures are in angstroms using the calibration given in Table II

Area No.	Original, measured in 5th order		After one stripping, measured in 4th order		After two strippings, measured in 3rd order		After three strippings, measured in 2nd order

Random errors in the measurement of λ.—As the oxide thickness increases, the interference minima become narrower, and so the error in the measurement of λ decreases. At the same time, $dh/d\lambda$ increases so that, as Young (13) has noted, the sensitivity of h to errors in λ remains practically constant. This has been confirmed here, using the difference between the kick wavelengths as a measure of the sharpness of the interference minima. On chemically polished specimens for wavelengths near 350 nm, these differences were about 20, 6.0, 3.5, 2.6, and 2.2 nm for the 1st to 5th orders, respectively, with a range of about 10% on either side of the values quoted; when multiplied by $dh/d\lambda$, the equivalent oxide thicknesses were 24, 24, 24, 25, and 28Å respectively. The standard error in h due to random errors in λ can therefore be represented satisfactorily by a single value, obviously much less than 25Å.

A reasonable estimate of the standard error for chemically polished samples can be obtained from the differences listed in Table I. Analysis shows that the root mean square deviation for all the differences is 2.6Å, from which it may be inferred that the standard error in each thickness measurement is $2.6/\sqrt{2}$Å or 1.8Å. Reproducibility checks on the amount of oxide removed by the stripping agent in a given time improve this figure; thus in one series of forty-seven measurements, using the same stripping solution on several samples over a period of a few weeks, the mean thickness removed in 7½ sec was 5.3 ± 2.1Å, so that the standard error in each thickness measurement was $2.1/\sqrt{2}$ or 1.5Å. In early experiments (2), therefore, the standard error was taken as 1.8Å, but this was subsequently replaced by the formula

$$\frac{2}{3} \times \left(\frac{\lambda' - \lambda''}{10}\right) \times \frac{dh}{d\lambda} \text{ Å}$$

where λ' and λ'' are the two kick wavelengths measured in nanometers, and $dh/d\lambda$ is the rate, in angstroms per nanometer, at which the oxide thickness h changes with change in the interference wavelength. Using the error formula given above, the thicknesses on the electrochemically, chemically, and nonpolished specimens of Fig. 1 were found to be $2829._3 \pm 1._7$, $2828._0 \pm 2._4$, and $2836._6 \pm 4._8$Å for the fourth order at about 390 nm, and $2833._7 \pm 1._6$, $2830._0$, $\pm 2._0$, and $2828._5 \pm 4._1$Å for the fifth order at about 320 nm; obviously, therefore, the precision decreases with increasing surface roughness. The errors quoted are standard errors, which must be doubled to obtain the 95% confidence limits; it is then apparent that the individual measurements do not differ significantly among themselves.

Absolute accuracy.—The absolute accuracy of the revised calibration depends on the accuracy with which Young's standard thicknesses are known, and these in turn depend on the refractive index of the oxide. The absolute value of the latter is not known to better than 1% (13), and so this limits the accuracy to an absolute standard error of about 0.5%. Errors of this kind and of this magnitude were not important for the experiments described in subsequent papers; the transport numbers, for example, were calculated as a ratio of thicknesses (3).

Refractive index variations.—Fluctuations in refractive index, both from sample to sample, and within the different parts of the same sample, could have an important bearing on the accuracy of the measurements. A fractional change of 0.001 from the value used in the calibration, from Eq. [1], gives rise to a fractional error of like amount in the measured oxide thickness.

Masing, Orme, and Young (14) have shown that the refractive index of the oxide varies somewhat with the temperature and current density during its formation, and that it is determined largely by conditions in the final stages of anodization. In the course of their work, they measured the refractive index several times under nominally identical conditions; analysis of these results indicates that the scatter of the individual measurements about the mean corresponds to a fractional standard deviation of 0.00144. How much of this scatter was due to real fluctuations in the refractive index is uncertain, since Masing *et al.* do not quote the precision of their measurements; the figure quoted here, therefore, is a maximum value. Errors of this kind are important for measurements involving successive anodizations of the same foil, as in the transport number measurements (3).

The term refractive index has thus far referred to the average refractive index for the whole oxide. Using ^{35}S labeled 0.1M H_2SO_4 as the electrolyte, Randall, Bernard, and Wilkinson (5) were able to show that ^{35}S was incorporated into the outer half of the oxide film at uniform concentration; assuming that the sulfur was incorporated as sulfate, their figures show that the ratio of sulfate to oxide was about 1:100 by weight or 1:600 by frequency. On stripping, therefore, the proportion of the two layers changes, and so, if the refractive indices are different, the average also changes. In the specimen of Table I, the sulfur would be uniformly distributed down to about 1600Å; no discontinuities about 1600Å are apparent in the table. Nor were any differences apparent in the stripping rates for the two layers. Films formed in dilute sulfuric acid thus appear to be effectively homogeneous, despite the variation in their composition: the optical homogeneity of such films has been confirmed ellipsometrically by Dell'Oca and Young (15).

Accuracy of the Oxide Thickness Measurements When Used for the Determination of Concentration Profiles

Random errors in the thickness measurements are important for the best squares fit computer programs described in subsequent papers (2-4). They arise from two sources; the error in measuring the wavelength of minimum interference, and the possibility of fluctuations in the average refractive index of the oxide. The total random standard error in each individual thickness measurement is given by combining these two errors in quadrature; the error is thus

$$\left[\left(\frac{2}{3} \times \frac{(\lambda' - \lambda'')}{10} \times \frac{dh}{d\lambda}\right)^2 + (0.00144 \times h)^2\right]^{1/2} \text{ angstroms}$$

where the second term represents the maximum possible error due to refractive index fluctuations.

Systematic errors in the thickness measurements can arise from four sources.

Error in refractive index. As already stated, the absolute value of the refractive index is not known to better than 1%.

Surface roughness. As previously discussed, the thicknesses of importance in the anodic Ta_2O_5/Ta system all correspond to the MLI. From the results presented in the next section, it would appear that the oxide is sectioned parallel to the underlying metal surface and so the thickness of films which have been stripped after anodizing can also be described by the MLI.

A further problem arises from the way in which the foreign atoms have been incorporated in the oxide film. If the atoms have been implanted at normal incidence using the mass separator as in (2) and (3), their concentration profiles should properly be measured perpendicular to the general plane of the metal surface; that is, using MGI measurements. The use of MLI measurements leads to the range parameters being underestimated by the roughness factor; the underestimate could, therefore, be as large as 3% (9). The problem does not arise with atoms incorporated from the electrolyte (4), for then the MLI measurements are appropriate.

Calibration errors. In view of the excellent results obtained in Table I, the systematic calibration errors in Table II must be small compared to the random errors, at least over the favored 300-400 nm region.

Spectrophotometric errors. Since the calibration of Table II is relative rather than absolute, the only errors that could be important were changes in the characteristics of Beckmann DK2. Small changes were occasionally observed after the instrument had been serviced, but these were readily compensated with the aid of standard oxide specimens.

To sum up, the absolute standard error in the oxide thickness measured by the spectrophotometric method is about 0.5% due to the uncertainty in the refractive index, while the relative error is the greater of 2Å, due to the random errors in the measurement, or 0.15%, due to fluctuations in the average refractive index.

Uniformity of the Oxide Layers Removed

Anodic oxide films on tantalum must, for the kinetic reasons given below, be extremely uniform in thickness. Any nonuniformity in the stripping, therefore, gives rise to irregularities in the thickness of the oxide film remaining on the metal surface. Such irregularities can be qualitatively characterized by a wavelength, describing their extent on the surface, and by an amplitude, which takes account of the magnitude of their deviation from the mean thickness. The spectrophotometric method of measuring thickness is rather insensitive to such irregularities because, as discussed previously, it takes an average over an area of 0.8×0.2 cm^2.

Uniformity of interference colors on stripping.—Thickness irregularities with a wavelength greater than a millimeter or so are apparent to the eye as a different interference color. Except as noted below, the interference colors observed on thinning the films by dissolution were just as uniform as those obtained on thickening by anodizing. This was confirmed by measurement of the oxide thickness at fourteen different points across a tantalum foil. As anodized, the thickness ranged from $3592._4$ to $3587._6$Å (380.8-380.4 nm in fifth order) with a mean of 3590Å. The foil was then placed in the stripping solution, with agitation, for ten successive 4-min periods, and was washed and dried in the usual fashion between each strip. Remeasurement showed that the remaining oxide thickness ranged from $1913._7$ to $1907._4$Å (375.2-374.3 nm in third order) with a mean of 1911Å, so that the amount removed was 1679 ± 2Å (standard error).

The interference colors would not remain uniform on stripping if:

(*a*) The specimens were held stationary in the stripping bath. Under these circumstances, the specimens would sometimes develop spots of different color.

(*b*) The same specimen was used repeatedly, as in the range measurements reported in (2). After anodizing and stripping the same foil half a dozen times, small irregularities became noticeable on stripping; these were probably due to the cumulative effects of field crystallization (16).

(*c*) The specimens were anodized past the breakdown voltage, at which point the character of the oxide film changes (6).

(*d*) The specimens were subjected to ion implantation at large fluence, as discussed in (1).

(*e*) The specimens were contaminated with carbonaceous polymers during ion implantation (1).

Flaws in the oxide film.—Flaws of short wavelength and large amplitude arise in the vicinity of impurities in the tantalum surface; for example, carbide particles. Vermilyea (17) has shown that these flaws are thin spots in the oxide film, and that they dissolve unusually rapidly in HF; the effect is, therefore, to punch holes through the film at these points. The area covered by these holes is, however, a very small fraction of the area sampled by the spectrophotometer, and so they are of little importance for the sectioning procedure. Another type of flaw studied by Vermilyea (16) arises from field crystallization, in which the amorphous oxide at certain places on the oxide surface is replaced by a more crystalline oxide. The latter is insoluble in HF (10) and so any radioactive species incorporated in it is retained on stripping; this has the effect of raising the background count when measuring the distribution of radioactive species in the oxide (2). Again, however, the area covered by these flaws is usually negligible, except when the same coupon is used repeatedly (2).

Effect of nonuniformity in the stripping on the measurement of profile widths.—The irregularities described so far are extreme examples arising from unusual local conditions at the tantalum surface. Of greater interest, especially for the experiments on transport number (3) and oxygen migration (4), are the small amplitude irregularities that could exist on the rest of the oxide surface, for these would affect the observed widths of the concentration profiles. Thus, if the concentration profile was normally distributed with a correct standard deviation, σ_c, the observed standard deviation, σ_o, would be given by

$$\sigma_o = (\sigma_c^2 + \sigma_h^2)^{1/2} \quad [2]$$

where σ_h is the root mean square deviation associated with the fluctuations in oxide thickness. If σ_h was a sizable fraction of σ_c, σ_o would differ significantly from σ_c; the magnitude of σ_h was therefore important. To measure σ_h, the following procedure was used.

Theory of the reanodization method for measuring the uniformity of the anodic film after stripping.—For the purpose of discussion, the equation governing anodic oxidation can be written in the simple form

$$i = D \cdot \exp(BV/h) \quad [3]$$

where i is the current density and V is the potential across the oxide film of thickness h, defined as in Fig. 2b; D and B are constants. Suppose that at a certain point in the oxide the thickness is less than h; then, from Eq. [3], the current density at that point is greater than i. If the current density is greater than normal, the oxide thickens more rapidly, and so the thickness irregularity tends to disappear as anodizing is continued. Anodic films must, therefore, be extremely uniform in thickness, a conclusion used earlier in this paper. It has also been used to advantage by Davies and co-workers in the sectioning of Al (18) and W (19).

In reanodizing a stripped oxide film at constant current, therefore, the current initially flows through the thinnest parts of the film; that is, Vermilyea's flaws. Since these cover a very small portion of the surface area, the effective current density is very high, and the applied voltage has to increase very rapidly in order to maintain the total current at its constant value. As the deeper irregularities fill up, current starts to flow through the less deep as well, so that the average current density decreases; the rate at which the applied voltage must be increased therefore decreases as well. Eventually, when all the irregularities have been filled in, the anodization proceeds in the normal fashion, with the current uniformly distributed over the whole surface and a relatively small rate of voltage increase. By monitoring the voltage as a function of time therefore, information can be obtained on the irregularities left by the stripping, and hence on the uniformity of the stripping process itself.

In practice, for reasons that become apparent later, reanodization experiments were performed on oxide films of the type illustrated in Fig. 3a. A small area A_1 of a tantalum coupon was covered with an oxide of mean (MLI) thickness h_1, and the remainder of the surface, area A_2, was covered with a larger thickness h_2. Reanodization of such a system at constant current I is governed by the following set of equations.

Anodization kinetics

$$i_1 = D \cdot \exp(BV/h_1); \quad i_2 = D \cdot \exp(BV/h_2) \quad [4a]$$

Current density

$$I = A_1 \cdot i_1 + A_2 \cdot i_2 \quad [4b]$$

Faraday's law

$$It = (A_1 \cdot \Delta h_1 + A_2 \cdot \Delta h_2) \cdot \rho \cdot \mathbf{F}/Q \quad [4c]$$

Here i_1 and i_2 are current densities in the areas A_1 and A_2, Δh_1 and Δh_2 the resulting increases in oxide thickness after an anodizing time t, ρ the density of the oxide, $\mathbf{F}$ the Faraday, and Q the equivalent weight of Ta_2O_5.

Initially, since $h_1 < h_2$, $i_1 >>> i_2$ and so the current effectively flows through the area A_1 only. Under these conditions i_1 is constant and equal to I/A_1; by [4a] and [4c] V and h_1 increase linearly with time at a rate proportional to I/A_1. As h_1 approaches the thickness h_2, however, i_2 becomes significant and hence by [4b], i_1 must decrease; h_1 and V continue to increase but at a slower rate than before, while h_2 starts to increase. At the limit, h_1 catches up to h_2 so that $i_1 = i_2 = I/(A_1 + A_2)$; V, h_1, and h_2 again increase linearly, but at a rate proportional to $I/(A_1 + A_2)$. The variations of V, h_1, and h_2 with time

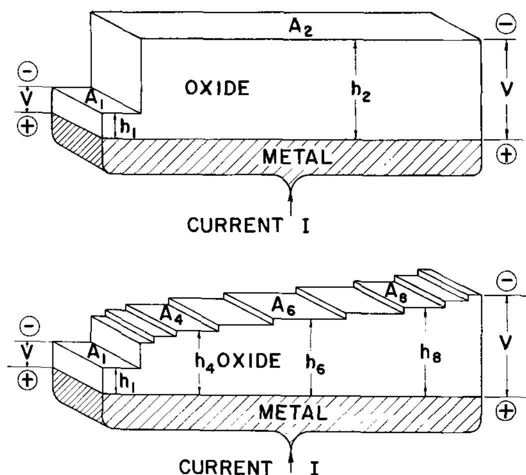

Fig. 3. Types of oxide film used in the reanodization experiments to measure the uniformity of stripping. (Type a, top) oxide of uniform thickness, (type b, bottom) simulation as per Fig. 5, to an oxide with random thickness fluctuations.

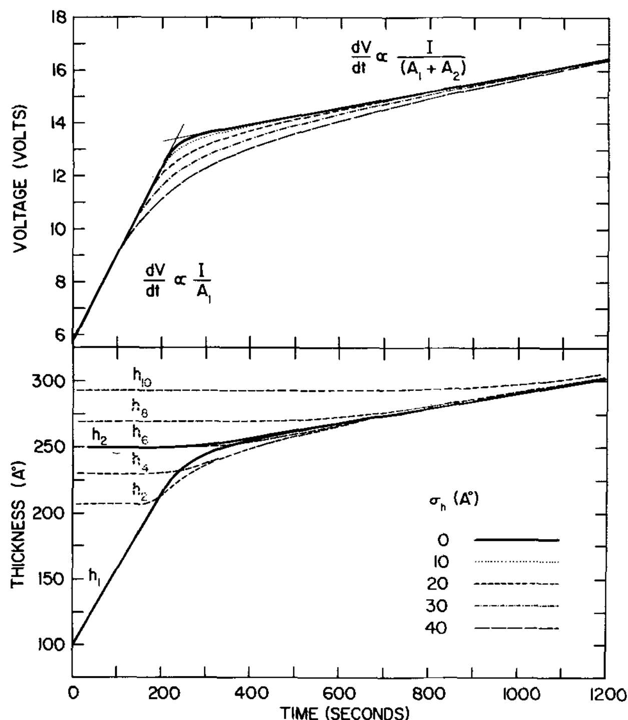

Fig. 4. Computed voltage-time and thickness-time plots for oxide films of the types depicted in Fig. 3. The heavy solid lines refer to the oxide of uniform thickness, type a of Fig. 3, and the lighter broken lines to the oxide with the random thickness fluctuations, type b of Fig. 3. Input data: $h_1 = 100Å$, $h_2(h_6) = 250Å$, initial current density $i_1 = 0.1$ mA/cm^2, final current density $i_2 = 0.01$ mA/cm^2, area $A_2 = 9 \times$ area A_1.

are illustrated by the solid lines in Fig. 4, from which it may be seen that the voltage time plot consists of two straight lines connected by a curved knee.

To compute the exact shape of the knee it is necessary to solve Eq. [4a-c] with h_1 nearly equal to h_2. This was done by means of a Runge-Kutta procedure (20), in which the variables i_1, i_2, h_1, h_2, and V were replaced by their time differentials. By integrating over successive short periods of time, values for the several variables could be computed at a series of different times. The integrations were performed on a CDC G-20 computer, with the simple form of the anodizing Eq. [3] replaced by the more precise quadratic form given by Young (12).

To find out how random fluctuations in the oxide thickness would affect the shape of the voltage-time curve, the following computations were performed. The oxide thickness on A_2 was assumed to be normally distributed about its mean h_2 with a standard deviation, σ_h, as illustrated in the top part of Fig. 5. Random fluctuations like this are equivalent to the smooth error function complement shown in the center of the figure, but the effect of this on the voltage-time plot cannot be computed by the Runge-Kutta procedure. Instead, it must be replaced by the equivalent histogram shown in the bottom of Fig. 5, and this gives an oxide film of the type shown in Fig. 3b. Time differentials for the current density and thickness of each element were derived as before, and the Runge-Kutta procedure applied. The resulting voltage-time and thickness-time plots are given in Fig. 4 for various values of σ_h.

Elimination of voltage transients from the experimental reanodization.—When an oxide film of area A and uniform thickness h is reanodized at constant current I, the current density changes almost instantly from zero to I/A. Changes in current density are associated with voltage transients (21), whose magnitude and sign are roughly proportional to the rate of change in the current density, di/dt. As the current

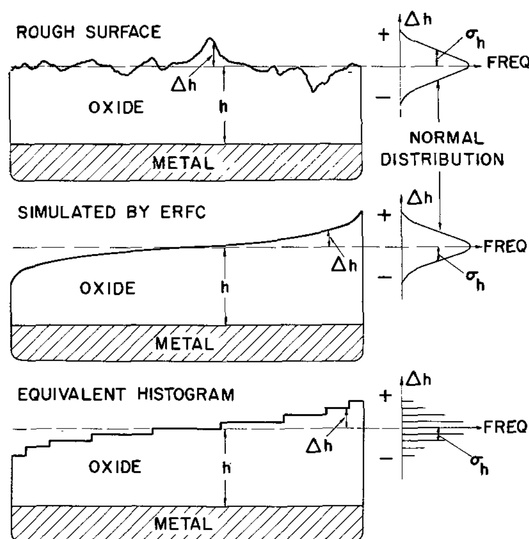

Fig. 5. Simulation of an oxide with random thickness fluctuations for the purpose of computing voltage-time plots by the Runge-Kutta procedure.

density changes from zero to I/A, di/dt is very large; within the same period, therefore the voltage V overshoots the steady-state value predicted from Eq. [3] and the values of $i(=I/A)$ and h. Adequate mathematical description of these transients is lacking, and so a satisfactory analysis of the voltage-time plots depends on their elimination.

Obviously, di/dt must be reduced as much as possible, and it was for this reason that oxide films of the type shown in Fig. 3 were used. When such an oxide is reanodized, the current density changes only as h_1 catches up to h_2, and this takes a relatively long time. The voltage transients therefore are relatively small, and only occur about the knee position. Furthermore, the current density, i_1, over the smaller area A_1 is decreasing and would normally give rise to a negative transient, or reduction in the recorded voltage; the current, i_2, over the larger area, A_2, is increasing, and so would normally give rise to a positive transient. Since the applied voltage must be the same all over the coupon surface, the outcome of the competition between the two effects is difficult to predict; experiments such as those illustrated in Fig. 6 show that there is in fact a net positive transient.

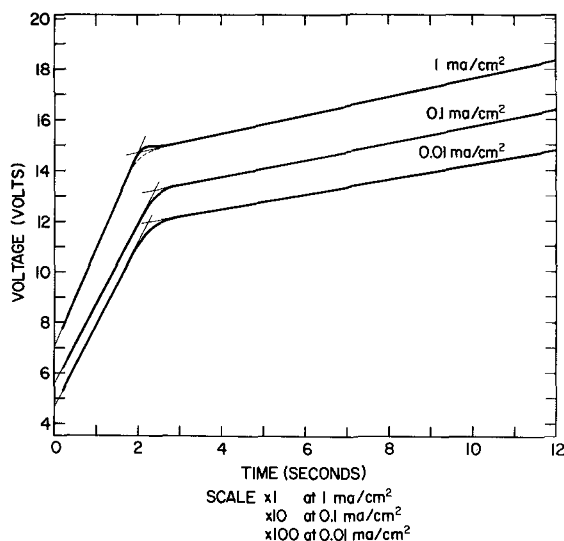

Fig. 6. Elimination of voltage transients, using oxide films of the type shown in Fig. 3a. Initial anodizations to 5.5V at 1 mA/cm², and 16V at 10 mA/cm²; reanodizations at current densities indicated. Conditions: 25°C, 0.1M H_2SO_4.

The general features of these transients are quite well known (21, 22) and so it was a relatively simple matter to minimize their effect still further. By using the lowest possible current density, 0.01 mA/cm², the time scale for the reanodization was much extended, and di/dt correspondingly reduced; this by itself effectively eliminated the transients, as shown in Fig. 6. To minimize annealing (22), initial anodizations were performed at 10 mA/cm², and the reanodizations were performed as soon as possible thereafter. The low current density on reanodization made it desirable to use thin oxides, so that the experiment would not be unduly prolonged; this was fortunate, because the sensitivity of the voltage-time relation to thickness irregularities is greatest when the irregularities are a large fraction of the mean thickness. The application of rather extreme currents, 10 and 0.01 mA/cm², to relatively thin films, 250Å, presents no problems in the analysis, for, as Young himself has shown (13), the quadratic equation gives a perfectly adequate description of the kinetics under these conditions.

Experimental reanodizations.—All anodizations and reanodizations were performed in 0.1M H_2SO_4 at 25°C, using the constant current circuit (8).

Electropolished tantalum coupons were anodized in such a way that one tenth of their total area was covered with thin oxide. The thickness h_1 was usually about 90Å, equivalent to 5.3V at 0.1 mA/cm², while h_2 was normally fixed at 200-250Å, equivalent to 11-14V at 0.01 mA/cm². The voltage was recorded using a Non-Linear Systems V91P digital voltmeter, equipped with a Hewlett-Packard Model 155 data printer. The rate of printout was a little less than 5/sec, the exact rate for each anodization being calculated by dividing the anodizing time into the total number of prints recorded. Four significant figures were obtained for each voltage printed; least squares fit analyses on the straight line portion of the voltage plots showed that the deviations were consistent with the rounding errors expected. That is, the error in 10-20V region was of the order of 0.005V.

The results illustrated in Fig. 6 were obtained to make sure that voltage transients had been eliminated by the procedure used. Suitable oxide films were prepared by anodizing the whole of an electrochemically polished tantalum coupon to 5.5V at 1 mA/cm², masking one tenth of the area with Apiezon N, and then anodizing the rest to 16V at 10 mA/cm². A voltage transient is clearly visible in the sample reanodized at 1 mA/cm², but not in those reanodized at 0.1 mA/cm² or 0.01 mA/cm². By reanodizing at 0.01 mA/cm², therefore, voltage transients were effectively absent from the system.

Analysis of the voltage-time data required a knowledge of A_1, A_2, h_1, and h_2, all of which could be calculated from the straight line sections of the V-t plot. From the slopes, dV/dt, of these sections, the current densities I/A_1 and $I/(A_1 + A_2)$ could be computed, using Eq. [4a-c]: since the total current, I, was known, A_1 and A_2 could be calculated. With the current densities known, the relation between oxide thickness and applied voltage (the angstrom/volt values) could be calculated from Eq. [4a-c], as could the rates, dh/dt, at which the oxide thickened. The thickness, h_1, was then calculated by multiplying the voltage at zero time, extrapolated from the initial straight line portion of the plot, by the appropriate angstrom/volt value. To obtain h_2, the two equations for dh/dt were solved simultaneously.

Given these values of A_1, A_2, h_1, and h_2 a voltage-time plot could be computed, as in Fig. 4, to reproduce the straight line portions of the experimental curve exactly. To reproduce the shape around the knee, σ_h had to be adjusted to the best value, and this was done by means of a least squares procedure. A suitable value of σ_h was used to compute voltages, V_{calc} (J), for a series $J = 1, 2 \ldots N$ of time t (J) about the knee. The quantity

$$\sum_{J=1}^{N} [(V_{obs}(J) - V_{calc}(J))/0.005]^2$$

was then computed, where $V_{obs}(J)$ were the observed voltages at the corresponding times, and 0.005V the standard error in each voltage measured. The best value for σ_h was then obtained by varying σ_h in units of 1Å until this sum was minimized. As a test, the 0.1 and 0.01 mA/cm^2 reanodizations in Fig. 6 were analyzed, and σ_h found to be 0 and 6Å, respectively. The expected value of σ_h was of course 0Å, since these specimens had been anodized but not stripped. In view of the insensitivity of the knee shape to very small values of σ_h, as demonstrated in Fig. 4, the agreement can be considered acceptable.

The uniformity of the stripping was tested as follows. Two tantalum coupons were anodized at 10 mA/cm^2, one to 61.45V (934Å) and the other to 121.4V (1857Å). Nine-tenths of each coupon was then masked with Apiezon N, and approximately 200Å stripped off the remainder, leaving thicknesses of 721 and 1633Å, respectively. The Apiezon was then removed, and both foils stripped in the NH_4F-HF reagent until the mean oxide thickness, h_2, on the larger area was 337 and 296Å, respectively. Accordingly, 597 and 1561Å of oxide had been stripped away, leaving a thickness, h_1, of 124 and 72Å, respectively, on the smaller area. Reanodization of these two specimens at 0.01 mA/cm^2 gave the voltage-time plots shown in Fig. 7, which are almost identical to the plots in Fig. 6. The great bulk of the oxide is therefore almost as uniform after stripping as it was after anodizing.

The voltage-time plots in Fig. 7 do differ from those in Fig. 6, however, in that the sections on either side of the knee are not quite straight. Above the knee, the slope decreases very slightly with time, but the resulting curvature is so small that it is not apparent in Fig. 7. Below the knee, however, the curvature is much more pronounced and is continuous. This indicates that a small fraction of the oxide film has been stripped to thicknesses between h_1 and h_2, which is precisely what would be expected from the behavior of Vermilyea's flaws (17) discussed previously. The curvature does, however, affect the calculations for h_1, h_2, A_1, and A_2, since these assume that the voltage-time plot is linear on either side of the knee. Tangents to either end of the curved portion have been drawn in Fig. 7 and give some idea of the uncertainty; obviously, σ_h depends on which is chosen. Using the tangents nearer the knee, represented by the solid lines in Fig. 7, σ_h was found to be 9Å for the sample anodized originally to 61.45V, and 8Å for that anodized to 121.4V.

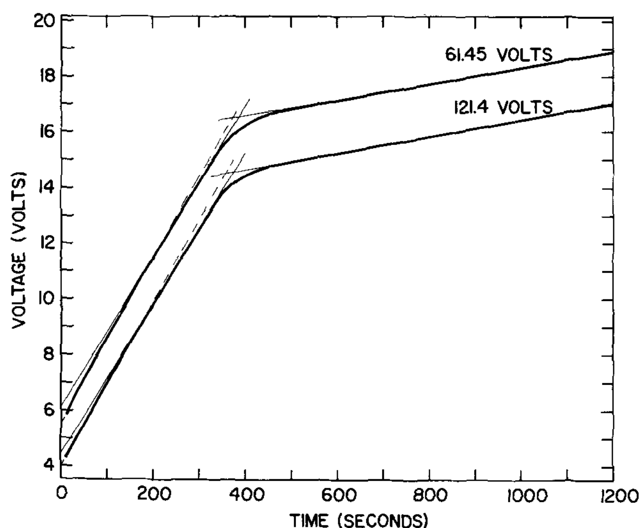

Fig. 7. Reanodization of stripped oxide films. Initial anodization at 10 mA/cm^2 to voltages indicated, followed by stripping in HF-NH_4F reagent; reanodizations at 0.01 mA/cm^2. Conditions: 25°C, 0.1M H_2SO_4.

The thickness irregularities left after stripping are therefore not normally distributed, as the difference between Fig. 4 and Fig. 7 makes clear, but they must be small. The question then arises as to whether they would be significant for the measurement of concentration profiles. Assuming that $\sigma_h = 10$Å, and that the correct standard deviation of a normally distributed profile, σ_c, is 30Å, it follows from Eq. [2] that the observed deviation would be $(30^2 + 10^2)^{1/2}$ or 32Å. Since the error in the measurement is itself of the order of 2Å (2, 3), the difference between correct and observed is definitely not significant. Observed deviations less than 30Å were obtained for low energy implantations (2), but the amount of stripping required to obtain these was so small that σ_h would probably be less than 10Å. The conclusion is, therefore, that irregularities in the stripping have no effect on the measurements of concentration profile.

Possible explanation for the uniformity of the stripping.—As is well known, most etchants act on surfaces in an irregular manner, dissolving more material from one area than another. This is particularly true of crystalline solids, where the rate of attack may vary with the crystal plane exposed (23); it can also vary substantially near imperfections such as dislocations or grain boundaries. At first sight, therefore, the extreme uniformity of the present sectioning technique seems surprising, but anodic tantalum oxide is unusual in that it is apparently both amorphous (10) and highly homogeneous. The anisotropy arising from crystal orientation is thereby eliminated, as are effects due to lattice imperfections; the small nonuniformity that remains has been attributed to impurities in the tantalum surface. The influence of the radiation damage accompanying ion implantation is discussed in another paper (1).

Nevertheless, it might seem reasonable to consider the dissolution of an amorphous solid statistically. If an average of n atomic layers be removed, the fluctuation from place to place on the surface should be proportional to a standard deviation of $\sqrt{n}$ layers. The deviations actually observed are, however, much less than this, and so some leveling process must be at work. Presumably this is related to the local curvature of the oxide surface in the same way as the smoothing action of anodic oxidation is related to the local curvature of the metal surface; that is, areas with convex curvature dissolve faster than those with concave curvature.

Conclusions

The precision of the sectioning technique is limited by the following factors.

(a) Oxide layers as thin as 5Å have been reproducibly removed. Since the minimum FWHM of the concentration profiles reported in subsequent papers (2-4) is about 10Å, the layers removed can always be made thinner than the width of the profile being investigated.

(b) The mean thickness of the oxide remaining after the removal of each layer can be measured with a relative standard error of about 2Å or 0.15% of the thickness, whichever is greater; the absolute error is about 0.5%, due to the uncertainty in the absolute value of the refractive index. The relative standard error in the mean thickness removed, which is the difference between two oxide thickness measurements, is therefore $2\sqrt{2}$Å or about 3Å.

(c) The uniformity of the layers removed is effectively perfect as far as the measurement of concentration profiles is concerned.

At a density of 8.03 g/cm^3 (24), a molecule of Ta_2O_5 occupies a cube of side 4.5Å, so that "one atom layer" would correspond to a thickness about half this. In the present experiments, therefore, anodic tantalum oxide has been sectioned two atom layers at a time; by

reducing the stripping time still further, it would be possible to section atom layer by atom layer.

Acknowledgments

It is a pleasure to acknowledge the assistance of D. Phillips, who performed many of the experimental measurements. A stimulating conversation with J. A. Davies answered the problem of measuring the uniformity of stripping, and Mrs. F. E. Lane kindly supplied the Runge-Kutta programs for the G-20 computer. B. Cox, T. A. Eastwood, and D. Marsden read the manuscript and made valuable suggestions for improvement.

Manuscript submitted July 30, 1971; revised manuscript received Dec. 2, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Internal Stresses in Multilayered Structures

P. B. Ghate and Lou H. Hall*

Semiconductor Research and Development Laboratory, Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Internal stresses in vacuum-deposited aluminum films are measured by x-ray diffraction techniques and by the Newton's rings method. The effects of annealing on the internal stresses are also determined. Aluminum films deposited at room temperature (25°C) are found to have an average stress of $(0 \pm 0.5) \times 10^9$ dynes/cm^2 prior to heat-treatment. Aluminum films deposited at 200°C are in tension with a stress of 2.6×10^9 dynes/cm^2. Films annealed at 450°C exhibit tensile stress at the same value as the films deposited at 200°C. This stress value is equivalent to a ΔT of 125°C if the stress is due to thermal considerations only. The Newton's rings method is extended to measure the changes in stresses after the processing steps required in a multilayered structure of Al/silane SiO_2/Al. The composite films are found to be in tension and the silane SiO_2 is found to have a high tensile intrinsic stress.

The desire for increased packing density in integrated circuits has resulted in the advent of medium scale and large scale integration. This technology requires a highly reliable interconnection system. Depending on the complexity of the circuits, a two or three level interconnection system is required. Some of the slice processing difficulties encountered in the development of multilevel interconnections are a consequence of the internal stresses in the multilayered composite. The use of alternate layers of aluminum/silicon dioxide/aluminum films is one of the methods used for achieving multilevel interconnections. The present investigation was undertaken to understand the nature of internal stresses in aluminum, silane silicon dioxide films, and a multilayered composite of Al/SiO_2/Al two-level structures.

The existence of internal stresses in evaporated films deposited on a substrate is well known (1, 2). Stresses in films may be calculated from a determination of either the curvature of the substrate or of the lattice distortion in the substrate or in the film. Several authors have studied stresses in thin films of aluminum (3, 4). Others (5-7) have also reported on stresses in films. In particular, Sunami *et al.* (8) and Lathlaen and Diehl (9) have reported studies on the stress in CVD silane silicon dioxide films.

The present investigation uses x-ray diffraction techniques and the Newton's rings method to determine stress in individual films and in multilayered composite films. The Newton's rings method is particularly applicable to following the changes in stress in slice form that is a consequence of sequential integrated circuit processing.

Experimental Procedures

Internal stresses in vacuum-deposited aluminum films on oxidized silicon substrates have been determined by x-ray diffraction techniques and by the Newton's rings method. Two types of aluminum films, one deposited on cold substrates Al-I, and another film deposited on hot substrates (200°C) Al-II, have been used in these experiments. The x-ray diffraction technique is employed to determine the deviations in the interplanar spacings from the known values of the strain-free material. Subsequently, stress is calculated from the lattice strain and the appropriate modulus of elasticity. In the Newton's rings method, the curva-

Key words: multilevel technology, internal stress, interconnections, thin films.

ture of the substrate on the film side is measured and the stress in the metal film is calculated from the curvature, thickness, and the appropriate modulus of elasticity of the substrate. The values of the stresses determined from the two methods have been compared. Stress changes in aluminum films due to a 450°C anneal in N_2 for 30 min have also been determined. The Newton's rings method has been extended to determine the stresses in the various layers of the multilayered composite Al/silane SiO_2/Al. The Newton's rings patterns were obtained at the following stages of fabrication: (*a*) Al, (*b*) Al/silane SiO_2, (*c*) Al/silane SiO_2/Al, and (*d*) after 450°C anneal in N_2 for 30 min. The effects of processing parameters on the internal stresses are also examined.

X-ray diffraction technique for stress measurement.—Stresses in films can be determined by measuring the changes in lattice parameters. According to Bragg's law

$$2d_{hkl} \sin \theta_{hkl} = \lambda \quad [1]$$

where d_{hkl} = interplanar spacing for the set of (hkl) planes, θ_{hkl} = Bragg angle for the hkl reflection, and λ = wavelength of X-radiation (CuK_α).

If the Al film is free of stress, then the interplanar spacing for the set of (hkl) planes corresponds to the known interplanar spacing in strain-free crystallites (reference: ASTM Data). Let d^o_{hkl} denote the interplanar spacing in strain-free crystallites. If the Al film were under tension, then the interplanar spacing d^τ_{hkl} (superscript τ denotes tension) parallel to the substrate would be smaller than d^o_{hkl}. Thus

$$d^\tau_{hkl} < d^o_{hkl} \text{ and hence } \theta^\tau_{hkl} > \theta^o_{hkl} \quad [2]$$

Similar arguments can be extended to Al films under compression

$$d^c_{hkl} > d^o_{hkl} \text{ and hence } \theta^c_{hkl} < \theta^o_{hkl} \quad [3]$$

If the deviation in the interplanar spacing d is assumed to be due to the mean isotropic strain of crystal in the film plane, then the average stress in the film is given by

$$\sigma_f = \frac{E_f}{2\nu_f} \cdot \epsilon \quad [4]$$

where ϵ = strain = $(d_o - d)/d_o$, d_o = 2.3380Å (ASTM value of d^o_{111} for aluminum), E_f = Young's modulus of aluminum = 7×10^{11} dynes/cm^2, and ν_f = Poisson's ratio for aluminum = 0.33.

Newton's rings method for stress measurements.—The average film stress can be calculated from the relationship between the stress and strain of circular substrate. It is assumed that the film strains the substrate which bends until equilibrium is reached. The adhesion of the film to the substrate is assumed to be adequately strong to suppress slippage. Since the average stress in the film is calculated from the strains in the substrate, the elastic constants and thickness of the substrate are taken into account. The following equation allows calculation of the average film stress (2)

$$\sigma_f = \frac{E_s}{6(1-\nu_s)} \frac{d_s^2}{t_f} \cdot \frac{1}{R_s} \quad [5]$$

where σ_f = average stress in the film, t_f = film thickness, E_s = Young's modulus of the substrate, ν_s = Poisson's ratio of the substrate, d_s = thickness of the substrate, and R_s = radius of curvature of the substrate.

The radius of curvature of the substrate can be determined by using the Newton's rings interference technique. The film side of the substrate is placed against an optically flat surface. The radius of curvature R_s of the substrate is determined from the radii of the Newton's rings and wavelength of light (10)

$$R_s = \frac{r_{m+p}^2 - r_m^2}{P\lambda} \quad [6]$$

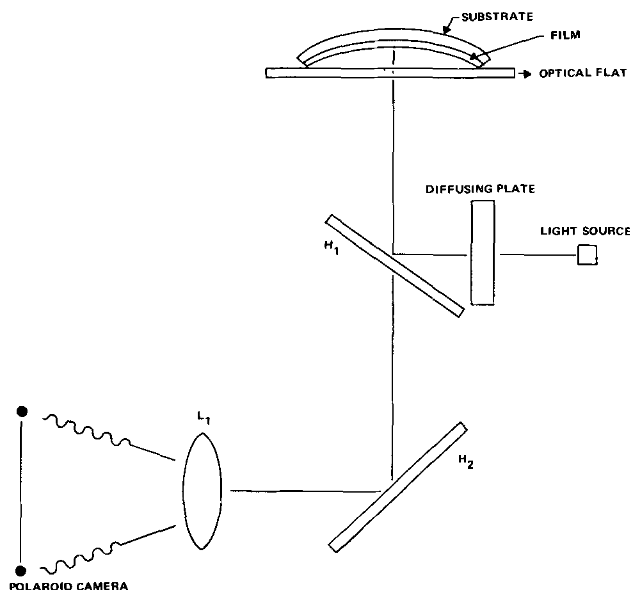

Fig. 1. Schematic of experimental setup (not to scale). L_1 lens, H_1 and H_2 are partially silvered optical flats, light source is a neon laser (λ = 6328Å).

where r_m = radius of the m'th dark ring, r_{m+p} = radius of the $(m + p)$'th dark ring, λ = wavelength of the light, and R_s = radius of curvature of the substrate.

A schematic of the experimental setup used in our experiments is shown in Fig. 1. A He-Ne laser is used to provide the monochromatic light of wavelength λ = 6328Å. The Newton's rings are photographed with a polaroid camera.

It was essential to screen the starting oxidized silicon slices for this experiment. A number of slices, whose thicknesses were close to 300 ± 10 μm, were examined to check if the slices produced acceptable Newton's rings pattern. Only those slices which produced almost circular fringe patterns were considered acceptable and were used in further experiments. In order to examine the behavior of aluminum films on plane silicon slices, *i.e.*, on slices not oxidized, a number of bare silicon slices were also chosen for further study.

The following arbitrary guidelines were used in processing the data:

1. If the center of the ring was lying closer to the edge rather than the center of the slice, then the data were discarded.

2. If the rings were circular or close to being elliptic, then the Newton's rings data were considered acceptable.

3. The average radius of curvature of the substrate (R_s) was determined from the radii of the 4th and 8th rings along the major and minor axes of the elliptic fringe pattern. The following expression was used

$$\frac{1}{R_s} = 2\lambda \left[\frac{1}{(r_8^2 - r_4^2)_x} + \frac{1}{(r_8^2 - r_4^2)_y} \right] \quad [7]$$

where λ = wavelength of the light = 6328Å, and x and y denote the directions along the major and minor axes.

Results and Discussion

The aluminum films, Al-I and Al-II, thicknesses were close to 8000Å. The metalized slice was mounted on the goniometer of a Norelco Diffractometer unit, and the x-ray diffraction pattern corresponding to the (111) reflection was scanned using the CuK_α radiation (λ = 1.5405Å). The (111) reflection from the silicon substrate served as an internal standard. The Bragg angle θ_{111} for Al was obtained from the position of the (111) diffraction peak. The diffraction traces of Al-I

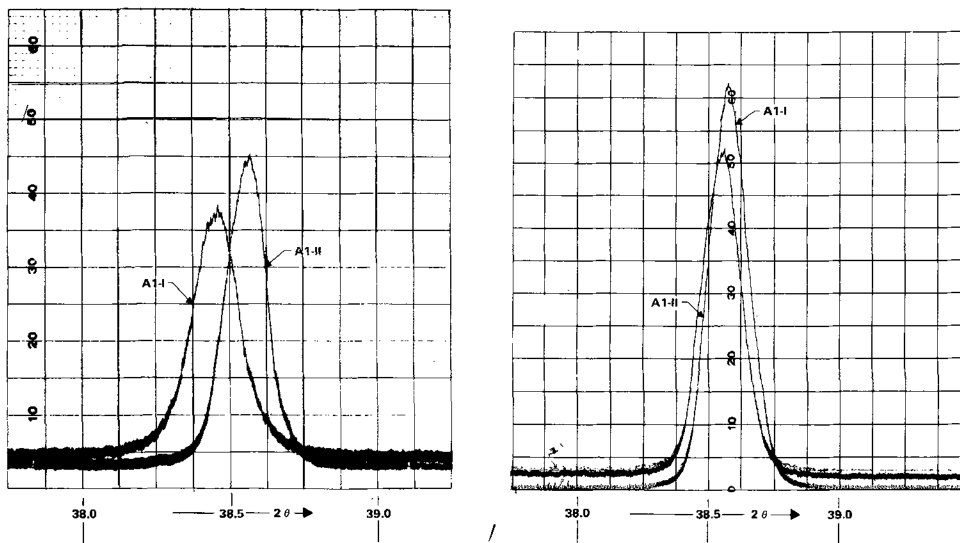

Fig. 2. X-ray diffraction traces of Al-I and Al-II films using CuK_{α} radiation. Intensity scales have been appropriately chosen to permit an easy comparison of the peak positions. a (Left), unannealed films; b (right) annealed at 450°C for 30 min in N_2.

and Al-II are shown in Fig. 2. The scan speed was (1/8) degree/minute and the chart speed was 0.5 in./min. The intensities of these peaks were so chosen that the positions of the peaks could be easily compared. The metalized slices were annealed in N_2 ambient for 30 min at 450°C. The positions of the (111) diffraction peaks of the annealed Al-I and the Al-II films were determined. The diffraction traces corresponding to the annealed films are also shown in Fig. 2. Similar diffraction traces were examined for other samples. The peak position for Al-I films before anneal was always reproducible with ± 0.02°. The peak position of Al-II films varied by ± 0.06°. For a given sample, the peak position was reproducible within ± 0.01°. After a 450°C anneal, the peak position of the (111) reflection for Al-I always shifted toward higher angles. The Bragg angles for Al-I and Al-II were almost equal. For some films, the Bragg angle θ_{111} for Al-I was greater than that for Al-II. In the last column of Table I, the average values of the stresses are summarized. These results suggest that the internal stresses in Al-I and Al-II films are almost equal after a 450°C anneal.

The average stresses in Al-I films are found to be $(0 \pm 0.5) \times 10^9$ dynes/cm² prior to any heat-treatment. Since these films are deposited at room temperature and the stress measurements are made at room temperature, the internal stresses in Al-I films can be considered as intrinsic. It appears that the intrinsic stresses in room temperature deposited Al films are small and are close to zero within the accuracy of our measurements. The stresses in Al-II films deposited at 200°C, are tensile and the average stress $= 2.6 \times 10^9$ dynes/cm².

The thermal stress component can be calculated from the known values of the coefficients of thermal expansion and moduli of elasticity for the substrate and the film (1, 2). The film is considered to be bonded perfectly to the substrate and assumed to be in zero stress at the deposition temperature. The constraints imposed by the bonding of the film to the substrate give the following strain value at the measurement temperature if the substrate temperature is constant during film deposition

Table I. Stresses in Al-I and Al-II films before and after a 450°C anneal as determined by x-ray diffraction using CuK_{α} radiation

Sample	Status of film	Average stress, $\bar{\sigma}$ (dynes/cm²)
Al-I	Before anneal	$\pm 0.5 \times 10^9$
Al-II	Before anneal	2.6×10^9
Al-I	After anneal	2.6×10^9
Al-II	After anneal	2.6×10^9

$$\epsilon = (\alpha_f - \alpha_s)(T_2 - T_1) = \Delta\alpha \cdot \Delta T \quad [8]$$

where ϵ = strain in film, α_f = coefficient of thermal expansion of film ($= 23 \times 10^{-6}$/°C for aluminum), α_s = coefficient of thermal expansion of substrate ($= 3 \times 10^{-6}$/°C for silicon), T_2 = film deposition temperature, and T_1 = temperature at which stress is measured.

The stresses are obtained by multiplying the strain value with the appropriate elastic modulus. The sign agrees with the usual convention: it is positive for tension, and negative for compression.

If it is assumed that the stress in Al-II films can be accounted for by thermal stress alone, then ΔT can be estimated from Eq. [4] and [8]. After substitution of the appropriate values, in Eq. [8] one finds that

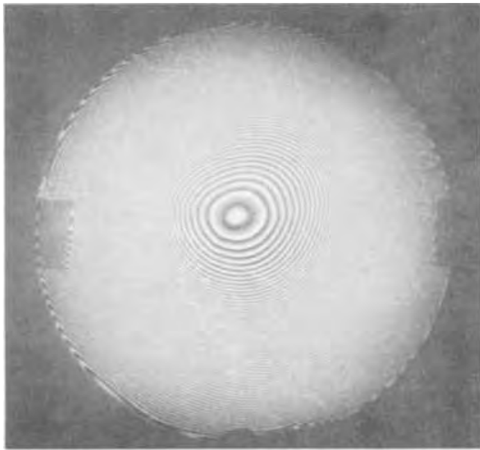
$$\Delta T = \frac{2\nu_f}{E_f} \cdot \frac{\sigma_f}{\Delta\alpha} \quad [9]$$

$$\Delta T \approx 125°C$$

Since $T_1 = 25°C$ (room temperature at which stress is measured), the apparent $T_2 \approx 150°C$. Even though this aluminum film was deposited at 200°C, the analysis of data suggests that the film has retained a thermal stress corresponding to a deposition temperature of 150°C. It appears that, as the substrates are cooled from the deposition temperature of 200°C down to room temperature, the film remains stress-free down to 150°C, and after that the thermal stress is locked in. This is ascribed to the fact that the recrystallization temperature is in the range of 150°C, and in addition the free surface of the film permits stress relief by mass migration above 150°C (4).

Figure 3 shows a Newton's rings pattern corresponding to the same slice (*e.g.*, Al-I film on oxidized silicon substrate) before and after a 30-min anneal at 450°C in N_2 ambient. The magnification of the photograph is determined from the known value of the diameter of the slice (diameter of slice = 1.5 in.). The radii of the Newton's rings as determined from the photograph are used to calculate the radius of curvature of the substrate.

The data in Table II indicate that the radius of curvature of Al-I slice decreases after a 450°C anneal. This is interpreted as clear evidence of an increase in the tensile stress in Al-I films due to 450°C annealing. The numerical values of $\Delta\sigma$ (change in stress) as determined from the Newton's rings experiments are smaller than the ones determined from the x-ray diffraction techniques. This is possibly due to the errors in the curvature determination. In the case of slices metalized at 200°C (Al-II slices), a 450°C anneal did not appreciably change the curvature and hence it is



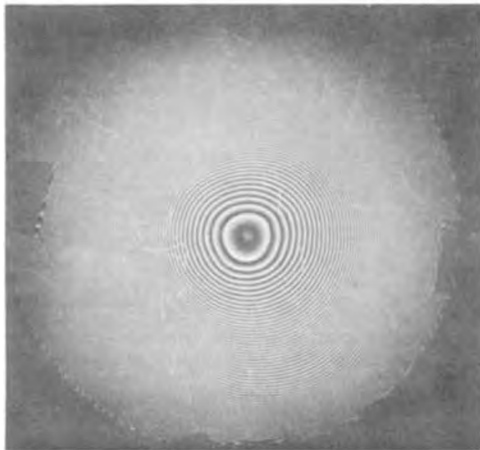


Fig. 3 Newton's rings for aluminum film Al-I on oxidized silicon substrates. a (Upper) before 450°C anneal for 30 min in N_2; b (lower), after 450°C anneal for 30 min in N_2.

considered that the stress levels in Al-II films are almost equal before and after annealing.

The absolute values of the stresses in aluminum films may be calculated from the radii of curvature listed in Table II. However, such a determination is possible only if the curvatures of the slices prior to metal depositions are known. Because the final curvature is dependent on parameters such as initial slice curvature, and bulk modulus of the substrate, the errors are propagated and stress values are good up to ± 10%. The radius of curvature of the slices used in this experiment ranged from 900 to 1200 cm. When these details are considered, the internal stresses in Al-I and Al-II films are found to be (0 to 2.5) and (1 to 3.4) × 10^9 dynes/cm^2, respectively. The stress levels determined from Newton's rings method are in fair agreement with those determined from the x-ray diffraction methods.

Stresses in multilayered structure.—Example Al/SiO_2/Al: the Newton's rings method is used to monitor the changes in slice curvature after the successive processing steps needed in the fabrication of two-level test structures. A schematic of the different layers in the test structure is shown in Fig. 4. The data on the curvature of the various slices are presented in Table III. In the same table, the values of the product of stress and thickness of the layer are also presented.

The stresses in multilayered films are discussed on a model based on the following assumptions:

1. Each layer adheres perfectly to the one next to it.
2. Each layer has a uniform thickness.
3. The material is elastic.
4. The material is isotropic.
5. Only thermal stresses need to be considered (for metal films intrinsic stresses are small).
6. Each layer is in a state of plane stress and the stress in each layer is assumed to be uniform throughout.

Consider the fabrication of Al-II/SiO_2/Al-II on oxidized silicon substrates. The aluminum film deposited at 200°C remains stress-free above 150°C and the thermal stress is locked in after the film cools below 150°C. Thus, the internal stress in Al-II is (intrinsic stresses

R_s = radius of curvature in cm
$\sigma_f t_f$ = stress × thickness in 10^4 dynes/cm

$$\sigma_f t_f = \frac{E_s}{6(1-\nu_s)} \cdot \frac{d_s^2}{R_s}$$

are approximated to zero and only the thermal stresses are considered)

$$\sigma_{Al} = E'_{Al} (\alpha_{Al} - \alpha_{Si}) \cdot \Delta T$$
$$E' = E/1 - \nu$$

We find

$$\sigma_{Al} = 2.6 \times 10^9 \text{ dynes/cm}^2$$

and

$$\sigma_{Al} t_{Al} = 20.8 \times 10^4 \text{ dynes/cm}$$

This tensile stress in the film bends the slice, and as a result the radius of curvature decreases. For slice 0-8 (see Table III), the radius of curvature has decreased to 528 cm from its initial value (approximately 1000 cm).

The substrates are heated to 350°C prior to silane SiO_2 deposition. When the substrates have equilibrated to 350°C, the metal film relaxes to a state of zero stress. As the substrate is cooled from 350°C to room temperature, the top layer of SiO_2 may cool to 150°C without any built-in thermal stress (due to the yielding of the aluminum film above 150°C). Below 150°C the composite layers assume a size equilibrium with the substrate and the deformation in SiO_2 is determined by the silicon substrate. The thermal stress in SiO_2 can be calculated as follows

$$(\sigma_{thermal})_{SiO_2} = E'_{SiO_2} (\alpha_{SiO_2} - \alpha_{Si}) \Delta T = -0.26 \times 10^9 \text{ dynes/cm}^2$$

and

$$(\sigma_{thermal})_{SiO_2} \cdot t_{SiO_2} = -2.2 \times 10^4 \text{ dynes/cm}$$

In the framework of the model, which assumes no interaction of the two films to relieve stress, $\sigma_f t_f$ is additive.

$$(\sigma t)_{Al/SiO_2} = \sigma_{Al} t_{Al} + \sigma_{SiO_2} t_{SiO_2}$$

The product σt of the composite Al/SiO_2 should decrease after the SiO_2 deposition by -2.2×10^4 dynes/cm if the internal stresses are composed of thermal stresses alone. However, Table III shows

$$\sigma_{SiO_2} t_{SiO_2} \approx 30 \times 10^4 \text{ dynes/cm}$$

and suggests large tensile stresses are present

$$\sigma = \sigma_{thermal} + \sigma_{intrinsic}$$
$$\sigma_{intrinsic} \times t_{SiO_2} \approx 32.2 \times 10^4 \text{ dynes/cm}$$
$$\sigma_{intrinsic} \approx 4 \times 10^9 \text{ dynes/cm}^2 \text{ (tensile)}$$

Thus, the intrinsic stresses in silane SiO_2 films are tensile. In another series of experiments (11), the internal stresses in silane SiO_2 films on silicon substrates were studied by use of Newton's rings method and a 5000Å SiO_2 film was found to be in tension with $\sigma \approx 1.5 \times 10^9$ dynes/cm². It was also found that on phosphorous doping of SiO_2 the films were still in tension while on boron doping the films were in compression. Aboaf (12) has observed the intrinsic stresses to be tensile for chemically vapor-deposited SiO_2 films; these SiO_2 films were prepared by the reaction of tetraethylorthosilicate whereas the films used in our experiments have been deposited by the oxidation of silane. Sunami *et al.* (8) and Lathlaen *et al.* (9) report results on stress in silane SiO_2 in agreement with ours.

The stresses after the second layer of Al-II and 450°C anneal are given in Table III. This level of metal is also in tension. The changes in σt after 450°C bake are the results of annealing of intrinsic stresses in three-layered structures and are difficult to interpret. Silane oxide films can undergo stress relief on annealing while aluminum films can undergo a stress increase. The interaction of the two make analysis of the stress difficult.

From the view point of slice processing in multilevel technology we have noted the following:

1. Aluminum films deposited on silicon substrates at temperatures of 150°C or above have the same thermal stress value ($\sim 2.6 \times 10^9$ dynes/cm²).
2. Cracks can develop in thick undoped silane oxides ($> 1\ \mu m$) because of the high intrinsic tensile stress. Doping the oxide reduces the stress in the oxide film.
3. Increasing the oxide thickness to cover the first-level metal increases the slice curvature; moreover, an increase in second-metal thickness is needed to avoid open metal at second level and this further increases the tensile stress.
4. Slice bending results in poor photoresist definition with the increased probability of stress enhanced etching.
5. Internal stresses in multilayered structures can manifest themselves in terms of oxide cracking, stress enhanced etching at steps, and open metalization.
6. Thicknesses of individual layers and the deposition parameters used in multilevel interconnections need to be optimized in order to minimize the over-all stresses.

Conclusions

X-ray diffraction techniques and the Newton's rings method have been used to examine the internal stresses in aluminum films vacuum deposited on oxidized silicon substrates at room temperature (25°C) and at 200°C. The results indicate that the room temperature aluminum film is in a state of approximately zero stress, and the 200°C aluminum film is in tension with a stress of 2.6×10^9 dynes/cm². Both of the films have a tensile stress of 2.6×10^9 dynes/cm² after 450°C anneal. The films have a thermal stress equivalent to a temperature difference of 125°C.

The Newton's rings method has been extended to understand the internal stresses in various layers of the multilayered structure $Al/SiO_2/Al$. The silane SiO_2 film is in high intrinsic tensile stress and the over-all composite is also in high tensile stress.

The results presented here are in agreement with previously reported data (3, 4, 8). The severe slice bending which results from the internal stresses of the composite multilayered structure and the hillocks formed during annealing of the aluminum (4) or during the silane oxide deposition make slice processing more difficult.

Acknowledgments

It is a pleasure to acknowledge the technical assistance of Joe Bob Leake, Naomi White, and Imogene Killen. We also wish to thank John Pankratz for helpful discussion on internal stresses in multilayered structures. Si Contamination in Open Flow Quartz Systems for the Growth of GaAs and GaP

M. E. Weiner*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Silicon contamination of III-V compounds is a potentially serious problem because of silicon's amphoteric behavior and its high affinity for oxygen. A potential source of silicon is fused quartz, which is widely used in systems for the growth of GaAs and GaP. Most open growth systems use flowing hydrogen because it is easily purified and it can remove solid gallium sesquioxide from the system. In this paper, calculations are presented for the rates of contamination of liquid gallium with silicon and of flowing H_2-HCl mixtures with volatile silicon compounds. Ideal gas behavior and local thermodynamic equilibrium are assumed. It is shown that the contact of Ga or HCl with quartz at normal growth temperatures can lead to significant silicon contamination in very dry systems. In addition, it is found that at 800°C, the pressure of water cannot be controlled below 10^{-8} atm for H_2 in contact with SiO_2 and 5×10^{-7} atm for HCl in contact with SiO_2, regardless of the initial purity of the H_2. These pressures rise appreciably with increasing temperature. In addition, models are presented for the formation of high concentrations of Si at the substrate-epitaxial interface and for the formation of SiO_2 precipitates in vapor growth systems. The former has previously been associated with the formation of "I" or insulating layers. The calculations show that HCl synthesis-type systems should give rise to much less silicon contamination than transport-type systems, and vapor growth systems using H_2O as a transporting agent give rise to nearly negligible Si contamination below 1000°C. Other possible ways to minimize silicon contamination are also discussed.

Fused quartz is a widely used material for the construction of high-temperature apparatus used for melt, solution, and vapor growth of GaAs and GaP. Although SiO_2 has a high free energy of formation (1), it cannot be considered completely inert when in contact with such reactive materials as Ga, H_2, HCl, C, and BN. Contamination of GaAs with Si during melt growth in quartz crucibles or boats has been treated fairly extensively both thermodynamically (2) and experimentally (3-6). Some evidence of Si contamination in open flow solution and vapor growth of GaAs and GaP has also been reported (6-11). Very little work on the rates of Si contamination in the latter system has been carried out. It is the purpose of this paper to examine the rates of Si contamination in open flow quartz systems in some detail under a variety of conditions and to determine how such contamination can be avoided or minimized.

General Assumptions

The following calculations of Si contamination in open flow quartz systems are for systems in which hydrogen, at atmospheric pressure, is flowing through the system at a flow rate F. The objective is to calculate the rate of contamination of Ga (of mass M_{Ga}) by Si, *i.e.*, to calculate dx_{Si}/dt where x_{Si} is the atom fraction of Si in the liquid gallium.[1] In order that the results be related to the more or less typical conditions prevalent in open tube experiments, values were chosen for F and M_{Ga}. Specifically, $M_{Ga} = 20$g and $F = 100$ cm³/min at the growth temperature (note that $F = F_{298} \cdot T(°K)/298$). It will become evident that dx_{Si}/dt is proportional to F/M_{Ga}; hence, to consider flow rates or masses of Ga other than 100 cm³/min and 20g, respectively, one need only expand or contract the time scale proportionately in the results of the Si contamination rate calculations. In these calculations, the following assumptions were made:

1. The flowing gas stream is in thermodynamic equilibrium with its immediate surroundings (*i.e.*, no forward or back diffusion of gaseous species).
2. Si is always distributed homogeneously in liquid Ga.
3. The solubility of SiO_2 in liquid Ga is neglected.
4. The pressures of elemental silicon, SiO_2, SiCl, $SiCl_2$, and $SiCl_3$ are neglected. The only volatile silicon compounds considered are SiO, SiH_3Cl, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$.
5. Any oxygen in the gas stream reacts with H_2 to form H_2O.
6. All gases obey the ideal gas law.

Specific Cases

A. Contamination of liquid Ga in an inert crucible or boat in flowing H_2.—A schematic diagram of the system under consideration is shown in Fig. 1. This situation could exist in the solution growth of GaAs and GaP.

The only volatile silicon compound to be considered in this case is SiO.

Let

$P_{SiO\ input}$ = pressure of SiO upstream from the liquid Ga

$P_{SiO\ eq}$ = pressure of SiO in equilibrium with the liquid Ga

$P_{H_2O}{}^0$ = initial pressure of water in the system (including any water from reaction between H_2 and O_2)

In general, "input" implies values upstream from the liquid Ga and "eq" implies values at the liquid Ga. Thus, since SiO resulting from the reaction of H_2 with SiO_2 is the only source for Si contamination

$$\frac{dx_{Si}}{dt} = \frac{F}{N_{Ga}RT}(P_{SiO\ input} - P_{SiO\ eq}) \qquad [1]^2$$

The following reactions are of interest in case A:

* Electrochemical Society Active Member.

Key words: silicon contamination, GaAs, GaP, compound semiconductors.

[1] The activity of liquid Ga is unity. (At the temperatures of interest, the activity of liquid gallium is not far from unity even if saturated with a III-V compound.)

[2] This equation is a differential form of the ideal gas law under the assumption that $V = O$. (V is the effective reaction volume). If ΔN moles are transferred from the gas phase to the liquid phase

$$V\Delta p = RT\Delta N$$

By differentiating, setting $V = 0$, setting $\frac{dV}{dt} = F$ and $\frac{d\Delta N}{dt} = \frac{dN}{dt} = N_{Ga}\frac{dx}{dt}$, Eq. [1] is obtained.

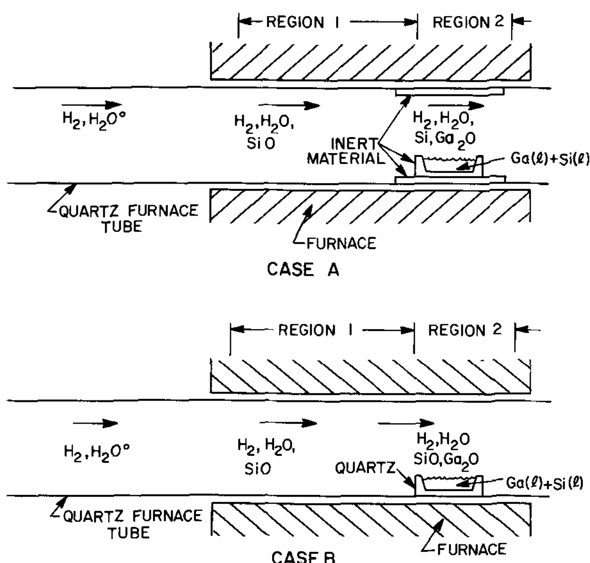

Fig. 1. Diagram of the growth systems considered in cases A and B, silicon contamination of liquid Ga. Region 1, "input" values; Region 2, "equilibrium" values.

Upstream

$$H_2(g) + SiO_2(s) \overset{K_1}{=} SiO(g) + H_2O(g) \quad [R\text{-}1]$$

At liquid gallium

$$2Ga(l) + H_2O(g) \overset{K_2}{=} Ga_2O(g) + H_2(g) \quad [R\text{-}2]$$

$$2Ga(l) + SiO(g) \overset{K_3}{=} Si(l) + Ga_2O(g) \quad [R\text{-}3]$$

Values for $P_{SiO\ input}$ and $P_{SiO\ eq}$ may be calculated from the equilibrium products of reactions [R-1], [R-2], and [R-3] and substituted into Eq. [1]. These calculations are given in Appendix I. The result is

$$\frac{dx_{Si}}{dt} = \frac{FP_{H_2O}{}^0}{2RTN_{Ga}} \left[\sqrt{1 + \frac{4K_1}{(P_{H_2O}{}^0)^2} \frac{(K_3 + K_3K_2 - K_2x_{Si})}{K_3 + K_3K_2 - K_2x_{Si}}} - 1 \right] \quad [2]$$

The activity coefficient for silicon dissolved in liquid gallium is included in K_3. An exact solution of Eq. [2] is given in Appendix I. In order to calculate K_1, K_2, and K_3, free energies of formation of $SiO_2(s)$, $SiO(g)$, and $Si(l)$ were obtained from the JANAF tables (1); the free energy of formation of $Ga_2O(g)$ was obtained from data compiled by Bass and Oliver (12), and the activity coefficient for $Si(l)$ was obtained from the Ga-Si phase diagram (13). From these data, it is easily seen that the term K_2x_{Si} in Eq. [2] is negligible if $x_{Si} < 10^{-4}$. This is equivalent to the assumption that $P_{SiO\ input} >> P_{SiO\ eq}$ and all SiO input is incorporated into the liquid gallium as dissolved silicon. Then Eq. [1] takes the form

$$\frac{dx_{Si}}{dt} = C(T) \quad \text{or} \quad x_{Si} - x_{Si}{}^0 = C(T)t \quad [3]$$

where $C(T)$ is a constant which is only a function of temperature and $x_{Si}{}^0$ is the initial concentration of Si in the Ga. Some values of $C(T)$ are given in Table I. It is easily seen that the approximation $x_{Si} < 10^{-4}$ is valid up to 10^3 or more hours.

Equation [2] also allows the calculation of a steady-state value of x_{Si}. This value occurs when $dx_{Si}/dt = 0$. Some values of x_{Si} (steady state) are also given in Table I.

B. Contamination of liquid Ga in a quartz crucible in flowing H_2.—There are now two sources of Si contamination of the liquid Ga. These are H_2 reduction of quartz (as in case A) and Ga reduction of quartz (see Fig. 1, case B). The generation of Si from the Ga reduction of quartz results from the reaction

$$4Ga(l) + SiO_2(s) = 2Ga_2O(g) + Si(l) \quad [R\text{-}4]$$

Table I. Calculated rates (C) and steady-state [x_{Si} (steady state)] values of Si contamination of Ga in an open flow quartz system with the Ga in an inert crucible or boat (case A) Assumed: local thermodynamic equilibrium, $P_{H_2} = 1$ atm, $F = 100$ cm³/min, $M_{Ga} = 20$g

T (°C)	$P_{H_2O}{}^0$ (atm)	C (atom fraction/hr)	x_{Si} (steady state)
800	10^{-8}	8.9×10^{-10}	7.6×10^{-5}
800	10^{-7}	1.2×10^{-10}	1.4×10^{-4}
800	10^{-6}	1.2×10^{-11}	1.4×10^{-6}
900	10^{-8}	2.0×10^{-8}	1.4×10^{-2}
900	10^{-7}	1.3×10^{-8}	5.9×10^{-3}
900	10^{-6}	2.1×10^{-9}	1.5×10^{-4}
1000	10^{-8}	1.8×10^{-7}	1.2×10^{-2}
1000	10^{-7}	1.7×10^{-7}	1.1×10^{-2}
1000	10^{-6}	1.0×10^{-7}	4.2×10^{-3}

Thus, for each mole of Si generated from this reaction, two moles of Ga_2O are generated. Therefore

$$\frac{dx_{Si}}{dt} = \frac{F}{RTN_{Ga}} [P_{SiO\ input} - P_{SiO\ eq} + \tfrac{1}{2}P_{Ga_2O\ gen(Ga + SiO_2)}] \quad [4]$$

As a result of the addition of the term $P_{Ga_2O\ gen(Ga+SiO_2)}$, it is helpful to use the equilibrium product of the reaction

$$Si(l) + SiO_2(s) \overset{K_4}{=} 2SiO(g) \quad [R\text{-}5]$$

Note that $K_4 = K_1K_2/K_3$. Following case A and from Appendix I

$$\frac{dx_{Si}}{dt} = \frac{F}{2RTN_{Ga}} \left[\frac{K_3K_4{}^{1/2} + K_3K_2K_4{}^{1/2}}{K_2x_{Si}{}^{1/2}} - K_4{}^{1/2}x_{Si}{}^{1/2} - P_{H_2O}{}^0 \right] \quad [5]$$

The equilibrium constant K_4 includes a value for the activity coefficient for silicon. The data required to calculate K_4 were obtained from Ref. (1) and (13). Equation [5] can be solved in closed form. However, a numerical integration by Simpson's rule is straightforward, comparable in accuracy, and much simpler. This procedure was carried out on a computer using 100 equally spaced intervals for each integration. Some results are shown in Fig. 3-5.

The steady-state values of Si activity are calculated (as in case A) by setting $dx_{Si}/dt = 0$. Some results of

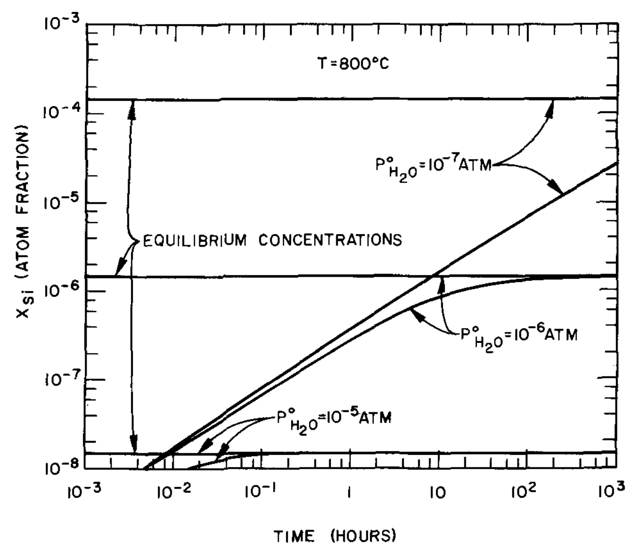

Fig. 2. Calculated rate of Si contamination of liquid Ga in an open flow quartz system with the Ga in a quartz crucible or boat (T = 800°C). Assumed: local thermodynamic equilibrium, $P_{H_2} = 1$ atm, $F = 100$ cm³/min, $M_{Ga} = 20$g.

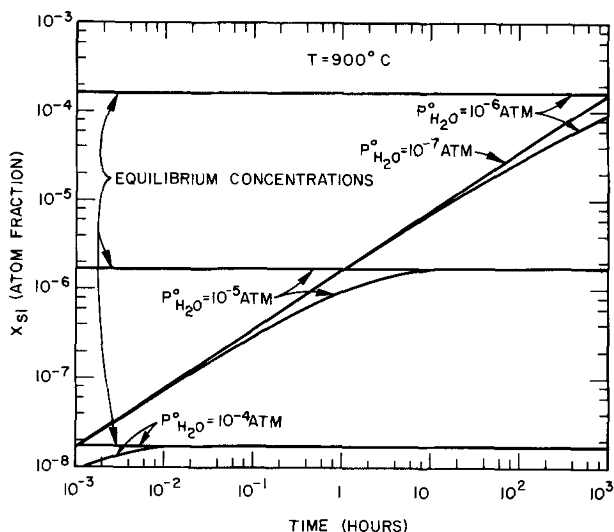

Fig. 3. Calculated rate of Si contamination of liquid Ga in an open flow quartz system with the Ga in a quartz crucible or boat ($T = 900°C$). Assumed: local thermodynamic equilibrium, $P_{H_2} = 1$ atm, $F = 100$ cm^3/min, $M_{Ga} = 20$g.

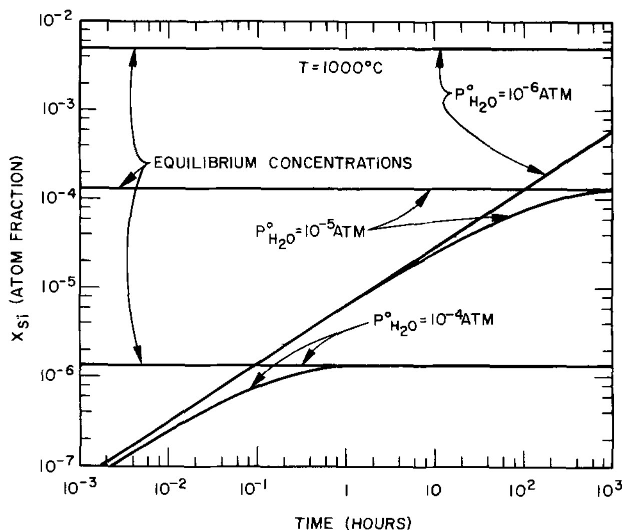

Fig. 4. Calculated rate of Si contamination of liquid Ga in an open flow quartz system with the Ga in a quartz crucible or boat ($T = 1000°C$). Assumed: local thermodynamic equilibrium, $P_{H_2} = 1$ atm, $F = 100$ cm^3/min, $M_{Ga} = 20$g.

this calculation are also shown in Fig. 2-4. Note that steady-state values of Si contamination can be approached in the range of times of interest in liquid phase growth. Note also that these steady-state values are close to those given in Table I for case A. This is because the influence of the term $P_{Ga_2O\ gen(Ga+SiO_2)}$ on Eq. [4] becomes minimal near steady state, and Eq. [4] becomes similar to Eq. [1].

C. Si contamination in an open flow quartz system in the presence of flowing H_2 and HCl.—This case is applicable to vapor growth systems. A diagram of the systems to be discussed below is given in Fig. 5. Therefore, it is of interest to calculate the quantity of volatile Si compounds in the gas stream before considering effects due to liquid gallium.

There are five volatile Si compounds to be considered. These are SiO, SiH_3Cl, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$. Unfortunately, none of the chloride species can be completely neglected over a wide range of temperatures and values of $P_{HCl}{}^O$. As above, "input" refers to values upstream of any liquid Ga and superscript "O" refers to initial values. Then

$$H_2(g) + SiO_2(s) \overset{K_1}{=} SiO(g) + H_2O(g) \quad [R\text{-}1]$$

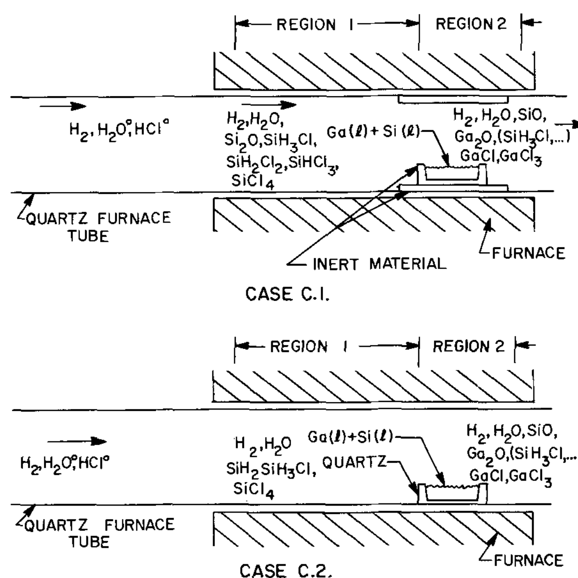

Fig. 5. Diagram of the growth systems considered in case C, silicon contamination of liquid Ga and of a gas stream containing H_2 and HCl. Region 1, "input" values; Region 2, "equilibrium" values.

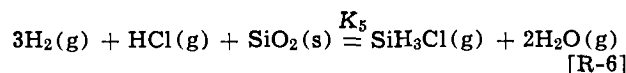
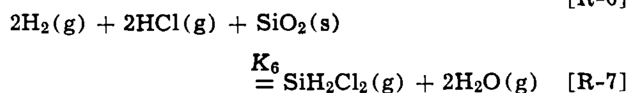
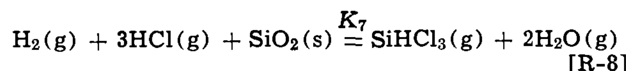


$$3H_2(g) + HCl(g) + SiO_2(s) \overset{K_5}{=} SiH_3Cl(g) + 2H_2O(g) \quad [R\text{-}6]$$



$$2H_2(g) + 2HCl(g) + SiO_2(s) \overset{K_6}{=} SiH_2Cl_2(g) + 2H_2O(g) \quad [R\text{-}7]$$



$$H_2(g) + 3HCl(g) + SiO_2(s) \overset{K_7}{=} SiHCl_3(g) + 2H_2O(g) \quad [R\text{-}8]$$

$$4HCl(g) + SiO_2(s) \overset{K_8}{=} SiCl_4(g) + 2H_2O(g) \quad [R\text{-}9]$$

In principle, the equilibrium products of these reactions allow the calculation of the total pressure of volatile silicon compounds. In practice, the calculation is greatly simplified by assuming $P_{HCl}{}^O = P_{HCl\ input}$. Actually, under normal conditions of interest, the maximum fraction of HCl lost to other compounds is about 3×10^{-3} so that this assumption is reasonable. The detailed calculation of the total pressure of volatile Si compounds is carried out in Appendix II. The equilibrium constants K_5, K_6, K_7, and K_8 were calculated from free energies of formation in the JANAF tables (1). Some results of this calculation are shown in Fig. 6.

C-1. Ga in inert crucible or boat.—In order to see how liquid Ga affects the system described in case C, it is necessary to calculate the rate of Si contamination of the liquid Ga. This will enable us to determine what happens to the gas stream after it passes over the Ga into the region of vapor growth. A diagram for case C-1 is shown in Fig. 5. Calculations for case C-1 require free energy data on the formation of GaCl and $GaCl_3$. These were calculated from thermodynamic data tabulated by Fergusson and Gabor (14), and Stull and Sinke (15). These calculations are similar to those for case A with the result

$$\frac{dx_{Si}}{dt} = C'(T) \quad \text{or} \quad x_{Si} = x_{Si}{}^o = C'(T)t \qquad [6]$$

Details of this calculation are given in Appendix III. Some values for $C'(T)$ are given in Table II. It is seen that the approximate form given by Eq. [6] is valid for times up to 10^2 hr. Since HCl would not normally be run continuously through a hot system, as might H_2, steady-state values of Si contamination would be far removed from the region of interest. A calculation of steady-state values could be carried out as in cases A and B. However, some of the approximations made

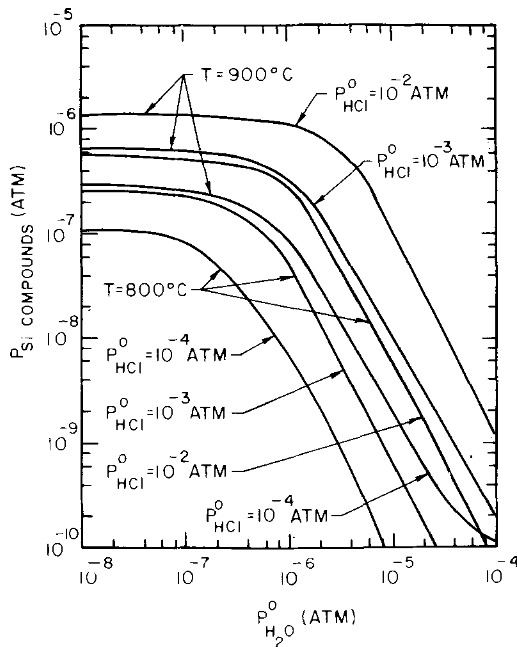


Fig. 6. Calculated total pressure of gaseous Si compounds ($P_{SiO} + P_{SiH_3Cl} + P_{SiH_2Cl_2} + P_{SiHCl_3} + P_{SiCl_4}$) in equilibrium with quartz as functions of initial pressures of H_2O and HCl. $P_{H_2} = 1$ atm.

will break down and the calculation would become very tedious. The significance of Eq. [6] is that in its range of validity, all of the Si in the gas stream is removed by the liquid Ga.

C-2. Ga in quartz crucible or boat.—Following case B (see Fig. 5)

$$\frac{dx_{Si}}{dt} = \frac{F}{RTN_{Ga}} [(P_{SiO\ input} + P_{silanes\ input} + P_{SiCl_4\ input}) - (P_{SiO\ eq} + P_{silanes\ eq} + P_{SiCl_4\ eq}) + \tfrac{1}{2} P_{Ga_2O\ gen(Ga+SiO_2)}] \quad [7]$$

From Appendix III, it is shown that Eq. [7] becomes

$$\frac{dx_{Si}}{dt} = \frac{F}{2RTN_{Ga}} \left\{ \frac{K_3K_4^{1/2}\left(1 + \frac{1}{K_2}\right)}{x_{Si}^{1/2}} - K_4^{1/2}x_{Si}^{1/2} - P_{H_2O}{}^0 - 2x_{Si}\left(\frac{P_{GaCl\ eq}}{K_9} + \frac{P_{GaCl\ eq}{}^2}{K_{10}} + \frac{P_{GaCl\ eq}{}^3}{K_{11}} + \frac{P_{GaCl\ eq}{}^4}{K_{12}}\right)\right\} \quad [8]$$

It is interesting to note that Eq. [8] is identical to Eq. [5] with the exception of the term linear in x_{Si}. Furthermore, this term is rather small except at fairly high values of x_{Si}. In general, the terms in $x_{Si}^{1/2}$ and x_{Si} are less significant than the other terms. Thus, the curves of Fig. 2-4 are, for the most part, applicable to case C-2. For this reason, no further numerical calculations were made. From a comparison of Fig. 2-4 with Table II, it is clear that the Ga reduction of quartz still provides most of the Si contamination of the liquid Ga. However, the fact that equilibrium values of x_{Si} are still approached slowly indicates that a significant fraction of the Si compounds in the gas stream is absorbed by the liquid Ga. It is easily seen that the equilibrium pressures of gaseous Si compounds above the liquid Ga are several orders of magnitude below the "input" pressures when x_{Si} is on the order of 10^{-5}. For smaller values of x_{Si}, an even greater fraction of the gaseous Si compounds is absorbed.

Table II. Calculated rates (C′) of Si contamination of Ga in an open flow quartz system with the Ga in an inert crucible or boat (case C-1)

Assumed: local thermodynamic equilibrium, $P_{H_2} = 1$ atm, $P_{HCl}{}^0 = 10^{-3}$ atm, $F = 100$ cm³/min, $M_{Ga} = 20$g

T (°C)	$P_{H_2O}{}^0$	C′ (atom fraction/hr)
800	10^{-8}	5.9×10^{-8}
800	10^{-7}	5.3×10^{-8}
800	10^{-6}	1.2×10^{-8}
800	10^{-5}	1.5×10^{-10}
900	10^{-8}	1.4×10^{-7}
900	10^{-7}	1.3×10^{-7}
900	10^{-6}	7.8×10^{-8}
900	10^{-5}	2.5×10^{-9}

Discussion

Case A.—This case is mainly of interest in open tube solution growth. From Table I, it is clear that Si contamination under the conditions of case A is of significance only at higher temperatures in very dry systems and for times on the order of days, weeks, or months, depending on the contamination level which is of concern. From Table I it is seen that the addition of water to the hydrogen stream can greatly decrease Si contamination. In very dry systems, the rate of contamination depends only slightly on $P_{H_2O}{}^0$. However, as $P_{H_2O}{}^0$ is increased, the rate of contamination drops rapidly. The reason for this is that in very dry systems, a significant fraction of the total water content is generated by the H_2 reduction of SiO_2. Thus, the effect of input H_2O is less significant than in "wetter" systems. In general, the use of an inert crucible in solution growth of GaAs and GaP should prevent serious Si contamination if small amounts of H_2O (or O_2) are added to the system, if turbulence in the flow stream is avoided (to avoid equilibration of the liquid Ga with a quartz furnace tube), and if the liquid Ga is changed after being at temperature for times on the order of 1-1000 hr, depending on specific experimental conditions and allowable contamination levels.

Case B.—This case, again, is mainly of interest in open tube solution growth. It is readily seen from Fig. 2-4 that Si contamination can arise very rapidly under the conditions of case B (*i.e.*, the liquid Ga is in a quartz crucible or boat). For example, after one hour at temperature, 1-10 ppm (atomic) of Si can contaminate the Ga, depending on specific experimental conditions. The main reason for such rapid contamination is removal of Ga_2O from the surface of the liquid Ga both by physical flow and by reaction with H_2. The addition of H_2O significantly affects steady-state values of x_{Si} (see Fig. 2-4), but has no effect on initial rates of contamination (see Fig. 2-4, and Eq. [5]). Replacing H_2 with an inert gas should lead to a significant decrease in the amount of Si contamination at any level of x_{Si}. This calculation can be performed by letting $K_2 \rightarrow \infty$ in Eq. [5]. Clearly, contact of liquid Ga with quartz is to be avoided in a system where the surface of the Ga is exposed to a flowing gas. If it is desired to use quartz as a crucible or boat, one might minimize Si contamination by growing under conditions such that a GaAs or GaP compound skin forms on the surface or by covering the surface with an inert liquid in a fashion similar to the liquid encapsulation process (12), as is done in melt growth of GaAs and GaP compounds. If the surface of the Ga is protected, the removal of Ga_2O from the surface of the Ga is minimized and the rate of Si contamination can be decreased.

There is some experimental evidence available on silicon contamination under case B conditions. Wolfstirn and Dawson (16) have measured the contamination of liquid Ga with Si from irradiated SiO_2. After 15g of liquid Ga were in a furnace at 800°C for 2½ hr under 50 cm³/min of flowing H_2 they found 3.8×10^{-7} atm fraction of Si. They measured the input pressure

of H_2O at less than 10^{-6} atm. From Fig. 3 (note that the effective time is 6 hr due to the different mass of Ga and flow rate of hydrogen), a calculated view of about 8×10^{-7} atm fraction is obtained. In view of the assumptions in these calculations and the accuracy of thermochemical data, the agreement between these two numbers is quite good.

Hicks and Greene (17) have also studied silicon contamination under case B conditions and found that the amount of contamination was somewhat less than their calculation of the steady-state value. Their information on growth conditions is not complete. However, from the case B calculations, it seems clear that they were far from steady-state conditions. Their amounts of contamination (estimated from electrical properties of solution-grown GaAs) is still less than that calculated for case B. However, the agreement between their measurements and case B calculations is much better than with their equilibrium theory.

Case C.—This case is of particular interest in vapor phase growth of GaAs and GaP. First, it is of interest to consider the pressure of volatile Si compounds resulting from the combined reactions of HCl and H_2. These are shown in Fig. 6. It can be seen that in very dry systems, it is possible to obtain ratios of Si compounds to $P_{HCl}{}^0$ of above 10^{-3}. This is undoubtedly a much higher ratio than used with dopant gases. Under almost all conditions, chloride compounds of Si provide nearly all of the pressure of gaseous Si compounds. From reactions [R-6] through [R-9], it is seen that two moles of water are generated for each mole of a silicon chloride. Thus, from Fig. 6, it can be readily seen that extreme efforts to reduce oxygen and water pressures below roughly 10^{-6} atm have very little effect on the total H_2O pressure in the system. Clearly the contact of HCl with quartz at elevated temperatures should be avoided if either Si contamination or oxygen contamination is believed to be a problem. One possible problem could be the formation of very fine precipitates of SiO_2 which must come out of the gas stream in a decreasing temperature. Such precipitates might not affect electrical properties at low fields and could be too fine to see by optical microscopy. Thus, their presence might be difficult to determine. DiLorenzo *et al.* have found Si in GaAs grown by the $AsCl_3$ transport method by use of a Direct Image Mass Analyzer (18). Unfortunately, this technique does not allow quantitative measurements of impurity concentrations. However, since the $AsCl_3$ growth technique leads to very high mobilities and low values of N_D-N_A, it is possible that part of this Si is in the form of SiO_2 precipitates. Luther has analyzed wall deposits of GaP grown in a PCl_3 transport system at 900°C for Si by a chemical transport method (6). He found about 30 ppm atomic of Si (19) presumably from the fused quartz furnace tube. Since typical N_D-N_A values were well below this value, it seems likely that part of this Si was in the form of SiO_2.

From the analysis of cases C-1 and C-2, it is seen that liquid Ga is capable of removing considerable amounts of Si from the gas stream. Furthermore, GaCl is significantly more stable than HCl so that very little HCl remains in the gas stream past the liquid Ga. Thus, further attack on the quartz prior to deposition of the GaAs or GaP should be considerably reduced. Hence, synthesis systems should have a considerable effect on reduction of Si contamination.[3] In addition, the use of an inert crucible or boat to hold the liquid Ga results in one to two orders of magnitude less Si in the gas stream than the use of a quartz crucible or boat (compare Fig. 2-4 with Table II).

In transport systems, the situation is considerably different. [The standard (As,P) Cl_3-Ga-H_2 system is really a transport system since the Ga is covered by a skin of GaAs or GaP.] First, the Ga is no longer available to remove Si from the gas stream. Second, the free energy of formation of GaAs or GaP is sufficient to prevent nearly complete conversion of HCl to GaCl, and a significant fraction of the input HCl remains in the gas stream (20-21). Thus, reactions with SiO_2 can continue to occur after the formation of GaCl. The boat or crucible material in these systems should have little effect on Si contamination.

One problem which is believed to be associated with Si contamination is the formation of "I" or insulating layers at the beginning of growth of GaAs (18). Concentrations of Si estimated at above 1 a/o (atom per cent) have been observed at the interface between the substrate and the epitaxial layer (18). Casey has suggested (22) that this layer results from the formation of a very thin layer of liquid Ga when the substrate is placed in the reactor and arsenic evaporates from it. This layer of Ga then "soaks up" silicon. It is easily seen that SiH_3Cl is the dominant equilibrium species of all of the gaseous Si compounds in case C. Thus, if we consider the equilibrium product of reaction [R-10]

$$\frac{P_{GaCl}x_{Si}}{P_{SiH_3Cl}} = K_9$$

at 800°C and let $P_{GaCl} = 10^{-3}$ atm and $P_{SiH_3Cl} = 10^{-7}$ atm, we find

$$x_{Si} = \frac{1.2 \times 10^{-7}}{10^{-3}} = 1.2 \times 10^{-4} \text{ (atom fraction)}$$

Thus, this source of the Si observed in Ref. (18) seems reasonable. It should be noted that the rate of Si contamination is inversely proportional to the mass of liquid Ga. In this case when the amount of Ga is very small, equilibrium values of x_{Si} could be reached rapidly. Once no liquid Ga is available (when arsenic is fed into the system, the Ga is converted to GaAs), the activity of Ga drops sharply and the amount of Si contamination drops, even though the gas stream composition should stay constant. The formation of liquid Ga could be avoided either by keeping the substrate below the congruent evaporation temperature until the Group V element is fed into the system (22) or by maintaining a Group V element pressure at all times in excess of that pressure at the Ga-GaAs or Ga-GaP liquidus line. Iwasaki and Sugibuchi have recently reported the elimination of high resistance layers in GaAs by initiating growth under high arsenic pressures (23). If the "I" layer problem is truly caused by Si, then the addition of H_2O or the use of a synthesis system should also help to alleviate the problem.

It is of interest to compare water vapor transport growth of GaAs and GaP with HCl transport or synthesis from the point of view of Si contamination. For this purpose, a temperature of 1000°C and $P_{H_2O}{}^0 = 10^{-3}$ atm are assumed. These conditions are typical of water vapor transport system (24). At this water pressure, we can assume that $P_{H_2O\ input} = P_{H_2O}{}^0$. Furthermore, from thermodynamic data, it is seen that the pressure of water changes only slightly after transport and before deposition. Then, from reaction [R-1]

$$P_{SiO\ input} = \frac{K_1}{P_{H_2O}{}^0} = 7.8 \times 10^{-10}\ \text{atm}$$

Thus, the total pressure of volatile Si compounds in the gas stream is about 10^3 times less than that in a dry HCl system (see Fig. 5). In addition, the equilibrium concentration of Si in liquid Ga under the above conditions is, from Eq. [4]

$$x_{Si} \approx \frac{K_3 + K_3K_2}{K_2} \frac{K_1}{(P_{H_2O}{}^0)^2} \approx 10^{-8}$$

[3] The use of the word "synthesis" in this context means that Ga and arsenic are fed into the system separately, and are not mixed until they reach the growth region. In the case considered, Ga would be transported as GaCl from the reaction of HCl and Ga, and As would be transported in the vapor as an elemental molecule (either As_2 or As_4). In contrast in a transport system, GaAs is either placed or formed upstream of the growth region, then decomposed by reaction with HCl, and reformed in the growth region.

This value is about 10^4 times less than in a dry HCl system. Thus, if "I" layer formation is truly caused by Si contamination of a very thin Ga layer on the GaAs or GaP substrate, the problem of "I" layer formation in water vapor systems should be nearly nonexistent.

Some mention has been made above of the differences between transport systems and synthesis systems. One further difference is of interest. In a transport system, it is always necessary to have the GaAs or GaP to be transported at a higher temperature than the substrate. This is because the equilibrium Ga/Cl or Ga/O ratios increase with temperature and deposition takes place only when these ratios exceed the values in equilibrium with the substrate. The free energy of formation of the GaAs or GaP is a significant factor in determining these ratios. Thus, in a synthesis system, these ratios will always be higher than in a transport system at the same temperature. Therefore, the liquid and the walls of the reactor in a synthesis system can be cooler than the substrate. Then, Si contamination will decrease and SiO_2 is less likely to precipitate out of the gas stream if the temperature of the gas stream is rising at the substrate.

Other sources of Si contamination which could be analyzed in a fashion similar to the above cases are Ga in a carbon boat or crucible in contact with quartz and Ga in a BN boat or crucible in contact with quartz. In these cases, the reactions

$$C + SiO_2 = SiO + CO$$

and

$$2BN + 2SiO_2 = 2SiO + B_2O_2 + N_2$$

could be significant. The second of these might be complicated the possible formation of Si_3N_4 and B_2O_3.

The problem of what materials can be considered inert when in contact with liquid Ga and quartz was not discussed above. It is believed that Al_2O_3 (possibly in the form of single-crystal sapphire) comes closest to being satisfactory. It has the advantages that it is highly stable, it is available in fairly high purity form, it can be shaped to some extent, and Al is isoelectronic with Ga and should not be electrically active in GaAs or GaP. Another possible inert system is a complete graphite system with no contact between graphite and quartz at elevated temperatures. Other possibilities might include coating of boats, crucibles, and/or reactors with materials such as AlN or alkaline earth fluorides.

Conclusions

It has been shown that serious Si contamination of liquid Ga in a quartz crucible or boat can occur in an open flow system under conditions used in the growth of GaAs or GaP from a Ga solution. In addition, serious Si contamination of the gas stream in HCl vapor systems can occur under typical vapor growth conditions. Furthermore, in either case, Si contamination is related to the formation of gaseous oxides, and efforts to obtain very dry systems may have little effect on oxygen contamination. It has been shown that H_2O vapor systems should not suffer from Si contamination nearly as much as HCl systems. Of course, the problem of oxygen contamination may be very severe in H_2O vapor systems. It has also been shown how large amounts of Si can pile up at the substrate-epitaxial interface in HCl systems. Such a Si rich layer is not expected in H_2O systems.

Some experimental evidence for the contamination of Ga, GaAs, and GaP with Si has been presented. Clearly more work needs to be done. Perhaps the best techniques for quantitative chemical analysis for Si in Ga, GaAs, and GaP are radio tracer methods (25) and Luther's chemical transport method (6). The former allow the best chance of an unambiguous determination of the source of Si contamination. Dean *et al.* (26) have observed evidence of optical phonons bound to neutral donors in Raman scattering experiments on GaP. This technique is expected to allow a measurement of the total number of Si donors in GaP in the range 8×10^{16} cm^{-3} to 2×10^{18} cm^{-3} (27) and could help to distinguish between total chemical Si and electrically active Si.

In summary, significant silicon contamination of GaP and GaAs from fused quartz is expected to occur rapidly under some conditions, leading to potentially serious problems. Experimental work is clearly required to determine the accuracy of the calculations described in this paper. However, the trends implied by the calculations should be valid and of use in designing open flow quartz systems and in choosing gas stream compositions.

Acknowledgments

I would like to acknowledge many enlightening hours of discussion of the problem of silicon contamination with C. D. Thurmond. My level of understanding of thermochemical problems has been greatly enhanced as a result. I would also like to thank J. V. DiLorenzo, L. R. Dawson, L. C. Luther, and B. Schwartz for informing me of many of the details of epitaxial growth systems. H. C. Casey, Jr. suggested a possible mechanism for "I" layer formation, which was discussed in this paper. I wish to acknowledge discussions of the thermodynamics of silicon contamination with A. S. Jordan, who also offered help on the use of thermodynamic data. This manuscript was critically reviewed by A. S. Jordan, B. Schwartz, and F. A. Trumbore.

Manuscript submitted July 23, 1971; revised manuscript received Dec. 4, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX I

Case A.—Calculation of $P_{SiO\ input}$

$$H_2(g) + SiO_2(s) \overset{K_1}{=} SiO(g) + H_2O(g) \qquad [R\text{-}1]$$

Thus

$$P_{H_2O\ input} = P_{H_2O}{}^0 + P_{SiO\ input}$$

Therefore

$$P_{SiO\ input}(P_{H_2O}{}^0 + P_{SiO\ input}) = K_1$$

and

$$P_{SiO\ input} = \frac{P_{H_2O}{}^0}{2}\left[\sqrt{1 + \frac{4K_1}{(P_{H_2O}{}^0)^2}} - 1\right] \qquad [A\text{-}1]$$

Derivation of Eq. [2]: The following reactions occur at the crucible or boat containing the liquid Ga

$$2Ga(l) + H_2O(g) \overset{K_2}{=} Ga_2O(g) + H_2(g) \qquad [R\text{-}2]$$

$$2Ga(l) + SiO(g) \overset{K_3}{=} Si(l) + Ga_2O(g) \qquad [R\text{-}3]$$

From conservation of oxygen (see Fig. 1)

$$P_{H_2O\ eq} + P_{Ga_2O\ eq} + P_{SiO\ eq} = P_{H_2O\ input} + P_{SiO\ input} \qquad [A\text{-}2]$$

Then, the equilibrium products of reactions [R-2] and [R-3] and Eq. [1], [A-1], and [A-2] may be solved simultaneously, yielding

$$\frac{dx_{Si}}{dt} = \frac{FP_{H_2O}{}^0}{2RTN_{Ga}}\left[\sqrt{1 + \frac{4K_1}{(P_{H_2O}{}^0)^2}}\;\frac{(K_3 + K_3K_2 - K_2x_{Si})}{K_3 + K_3K_2 + K_2x_{Si}} - 1\right] \qquad [2]$$

Solution of Eq. [2]: Since there are no explicit functions of time on the right side of Eq. [2], the solution consists simply of an integration.

Let

$$A_I = \frac{FP_{H_2O}{}^0}{2RTN_{Ga}}$$

$$B_I = \sqrt{1 + \frac{4K_1}{(P_{H_2O}{}^0)^2}}$$

$$C_I = K_3(1 + K_2)$$

$$D_I = K_2$$

$$x = x_{Si}$$

Thus, Eq. [2] becomes

$$\frac{dx}{dt} = A_I \left[B_I \frac{(C_I - D_I x)}{C_I + D_I x} - 1 \right] \qquad \text{[A-3]}$$

Then

$$\text{Let} \quad B_I C_I - C_I = E$$

$$B_I D_I + D_I = F$$

The solution to [A-3] is

$$\int_{x_0}^{x} \frac{C_I + D_I x}{E - Fx}\, dx = A_I t \qquad \text{[A-4]}$$

From integral tables

$$\frac{D_I}{F}(x - x_0) + \left(\frac{C_I}{F} + \frac{D_I}{F}\frac{E}{F}\right) \ln \left[\frac{\frac{E}{F} - x}{\frac{E}{F} - x_0} \right] = -A_I t \qquad \text{[A-5]}$$

Note that x_0 refers to x_{Si} at $t = 0$. Thus, this solution is valid *not* only for calculating the rate of silicon contamination when starting with pure Ga, but may also be used to calculate the rate of change of Si when the Ga is purposely doped with Si.

Case B.—Following case A, the term $P_{Ga_2O\ gen(Ga + SiO_2)}$ is added to the right side of Eq. [A-2] so that

$$P_{H_2O\ eq} + P_{Ga_2O\ eq} + P_{SiO\ eq} = P_{H_2O\ input} + P_{SiO\ input} + P_{Ga_2O\ gen(Ga+SiO_2)} \qquad \text{[A-6]}$$

A further equilibrium product is helpful because of the addition of the term $P_{Ga_2O\ gen(Ga+SiO_2)}$. A convenient reaction to use is

$$Si + SiO_2 \overset{K_4}{=} 2SiO \qquad \text{[R-5]}$$

Note that $K_4 = K_1K_2/K_3$. Following case A again

$$\frac{dx_{Si}}{dt} = \frac{F}{2RTN_{Ga}} \left[\frac{K_3K_4{}^{1/2} + K_3K_2K_4{}^{1/2}}{K_2 x_{Si}{}^{1/2}} - K_4{}^{1/2} x_{Si}{}^{1/2} - P_{H_2O}{}^0 \right] \qquad [5]$$

APPENDIX II

Case C.—Calculation of total pressure of volatile Si compounds.—It may be seen from reactions [R-1] and [R-6]-[R-9] that

$$P_{HCl\ input} = P_{HCl}{}^0 - P_{SiH_3Cl\ input} - 2P_{SiH_2Cl_2\ input} - 3P_{SiHCl_3\ input} - 4P_{SiCl_4\ input} \qquad \text{[A-7]}$$

and

$$P_{H_2O\ input} = P_{H_2O}{}^0 + P_{SiO\ input} + 2(P_{SiH_3Cl\ input} + P_{SiH_2Cl_2\ input} + P_{SiHCl_3\ input} + P_{SiCl_4\ input}) \qquad \text{[A-8]}$$

By substituting the equilibrium products of reactions [R-1] and [R-6] through [R-9] into Eq. [A-7] and [A-8]

$$P_{HCl\ input} = P_{HCl}{}^0 - \frac{K_5 P_{HCl\ input}}{P_{H_2O\ input}{}^2} - \frac{2K_6 P_{HCl\ input}{}^2}{P_{H_2O\ input}{}^2} - \frac{3K_7 P_{HCl\ input}{}^3}{P_{H_2O\ input}{}^2} - \frac{4K_8 P_{HCl\ input}{}^4}{P_{H_2O\ input}{}^2} \qquad \text{[A-9]}$$

and

$$P_{H_2O\ input} = P_{H_2O}{}^0 + \frac{K_1}{P_{H_2O\ input}} + \frac{2K_5 P_{HCl\ input}}{P_{H_2O\ input}{}^2} + \frac{2K_6 P_{HCl\ input}{}^2}{P_{H_2O\ input}{}^2} + \frac{2K_7 P_{HCl\ input}{}^3}{P_{H_2O\ input}{}^2} + \frac{2K_8 P_{HCl\ input}{}^4}{P_{H_2O\ input}{}^2} \qquad \text{[A-10]}$$

In principle, Eq. [A-9] and [A-10] allow the calculation of $P_{H_2O\ input}$ and $P_{HCl\ input}$. These in turn can easily be used to find the pressures of all of the gaseous Si compounds. However, an exact calculation along these lines would be very tedious and of dubious value. Great simplification will arise by assuming that $P_{HCl\ input} = P_{HCl}{}^0$. This is equivalent to assuming that only a negligibly small fraction of the HCl fed into the system is converted to Si compounds. Actually, it will be shown that the maximum fraction of HCl lost to Si compounds under the conditions assumed is only about 3×10^{-3} under the conditions of interest. Thus, the assumption that $P_{HCl\ input} = P_{HCl}{}^0$ seems valid. Once this assumption is made, Eq. [A-10] may be converted to a cubic equation in $P_{H_2O\ input}$, which is easily solved numerically. Then, the equilibrium constants K_1, K_5, K_6, K_7, and K_8 allow the calculation of the total pressure of all volatile Si compounds. (Note that each compound has only one Si atom per molecule.) Some results of this calculation are shown in Fig. 6.

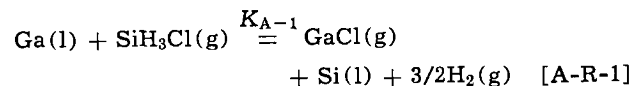
APPENDIX III

Calculations for case C-1.—Let $P_{SiH_3Cl} + P_{SiH_2Cl_2} + SiHCl_3 = P_{silanes}$. Then, following case A

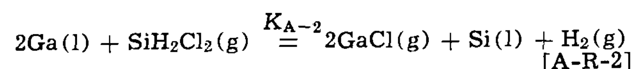
$$\frac{dx_{Si}}{dt} = \frac{F}{RTN_{Ga}} [(P_{SiO\ input} + P_{silanes\ input} + P_{SiCl_4\ input}) - (P_{SiO\ eq} + P_{silanes\ eq} + P_{SiCl_4\ eq})] \qquad \text{[A-11]}$$

The input terms were calculated in Appendix II. In order to calculate the "eq" terms (see Fig. 2), we must consider the reactions

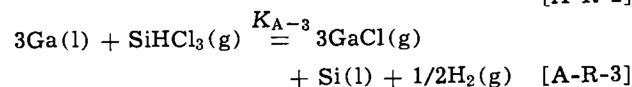
$$2Ga(l) + SiO(g) \overset{K_3}{=} Ga_2O(g) + Si(l) \qquad \text{[R-3]}$$



$$Ga(l) + SiH_3Cl(g) \overset{K_{A-1}}{=} GaCl(g) + Si(l) + 3/2H_2(g) \qquad \text{[A-R-1]}$$



$$2Ga(l) + SiH_2Cl_2(g) \overset{K_{A-2}}{=} 2GaCl(g) + Si(l) + H_2(g) \qquad \text{[A-R-2]}$$



$$3Ga(l) + SiHCl_3(g) \overset{K_{A-3}}{=} 3GaCl(g) + Si(l) + 1/2H_2(g) \qquad \text{[A-R-3]}$$

$$4Ga(l) + SiCl_4(g) \overset{K_{A-4}}{=} 4GaCl(g) + Si(l) \qquad \text{[A-R-4]}$$

and

$$2Ga(l) + H_2O(g) \overset{K_2}{=} Ga_2O(g) + H_2(g) \qquad \text{[R-2]}$$

$$Ga(l) + HCl(g) \overset{K_{A-5}}{=} GaCl(g) + 1/2H_2(g) \qquad \text{[A-R-5]}$$

$$2Ga(l) + GaCl_3(g) \overset{K_{A-6}}{=} 3GaCl(g) \qquad \text{[A-R-6]}$$

From reactions [R-3] and [A-R-1] through [A-R-4]

$$(P_{SiO\ eq} + P_{silanes\ eq} + P_{SiCl_4\ eq}) = x_{Si} \left(\frac{P_{Ga_2O\ eq}}{K_3} + \frac{P_{GaCl\ eq}}{K_{A-1}} + \frac{P_{GaCl\ eq}{}^2}{K_{A-2}} + \frac{P_{GaCl\ eq}{}^3}{K_{A-3}} + \frac{P_{GaCl\ eq}{}^4}{K_{A-4}} \right) \qquad \text{[A-12]}$$

Thus, it is necessary to calculate $P_{Ga_2O\ eq}$ and $P_{GaCl\ eq}$. Equation [A-2] is valid for this case. Thus

$$P_{\text{Ga}_2\text{O eq}} + P_{\text{H}_2\text{O eq}} + P_{\text{SiO eq}} = P_{\text{H}_2\text{O input}} + P_{\text{SiO input}} \quad [A\text{-}2]$$

Then, using the equilibrium products of reactions [R-2] and [R-3]

$$P_{\text{Ga}_2\text{O eq}}\left(1 + \frac{1}{K_2} + \frac{x_{\text{Si}}}{K_3}\right) = P_{\text{H}_2\text{O input}} + P_{\text{SiO input}}$$

The values of $P_{\text{H}_2\text{O input}}$ and $P_{\text{SiO input}}$ may be calculated from information in Appendix I. Therefore

$$P_{\text{Ga}_2\text{O eq}} = \frac{P_{\text{H}_2\text{O input}} + P_{\text{SiO input}}}{1 + \dfrac{1}{K_2} + \dfrac{x_{\text{Si}}}{K_3}} \quad [A\text{-}13]$$

Since chlorine must be conserved

$$P_{\text{GaCl eq}} + P_{\text{HCl eq}} + \frac{1}{3}P_{\text{GaCl}_3\text{ eq}} = P_{\text{HCl input}} + P_{\text{SiH}_3\text{Cl input}} - P_{\text{SiH}_3\text{Cl eq}} + \cdots \quad [A\text{-}14]$$

Then, by substituting the equilibrium products of reactions [A-R-1] through [A-R-6] into Eq. [A-14]

$$P_{\text{GaCl eq}}\left(1 + \frac{1}{K_{A-5}}\right) + \frac{1}{3}\frac{P_{\text{GaCl eq}}^3}{K_{A-6}} = P_{\text{HCl input}} + P_{\text{SiH}_3\text{Cl input}} + 2P_{\text{SiH}_2\text{Cl}_2\text{ input}} + 3P_{\text{SiHCl}_3\text{ input}} + 4P_{\text{SiCl}_4\text{ input}} - x_{\text{Si}}\left(\frac{P_{\text{GaCl eq}}}{K_{A-1}} + \frac{2P_{\text{GaCl eq}}^2}{K_{A-2}} + \frac{3P_{\text{GaCl eq}}^3}{K_{A-3}} + \frac{4P_{\text{GaCl eq}}^4}{K_{A-4}}\right) \quad [A\text{-}15]$$

The calculation of the input terms was described in Appendix II. Thus, Eq. [A-15] becomes a fourth order equation allowing, in principle, the calculation of $P_{\text{GaCl eq}}$ as a function of x_{Si}. Then, Eq. [A-11], [A-12], [A-13], and [A-15] may, in principle, be used to obtain a differential equation of the form

$$\frac{dx_{\text{Si}}}{dt} = f(x_{\text{Si}}) \quad [A\text{-}16]$$

Equation [A-16] can then be integrated numerically to obtain an equation of the form

$$x_{\text{Si}} = f(x_{\text{Si}}^0, t) \quad [A\text{-}17]$$

Thus, the formalism has been presented for an exact solution of case C-1. However, the conversion of Eq. [A-11] to [A-16] is very tedious. In practice, examination of thermodynamic data allows some reasonable approximations. The input data may be approximated in the manner previously described and shown in Fig. 6. Then, from calculations of various equilibrium constants, the following approximations were considered reasonable

$$P_{\text{GaCl eq}} \approx P_{\text{HCl input}} \approx P_{\text{HCl}}^0 \quad [A\text{-}18]$$

$$\frac{P_{\text{GaCl eq}}^2}{K_{10}} + \frac{P_{\text{GaCl eq}}^3}{K_{11}} + \frac{P_{\text{GaCl eq}}^4}{K_{12}} \approx 0 \quad [A\text{-}19]$$

$$x_{\text{Si}} << K_3\left(1 + \frac{1}{K_2}\right) \quad [A\text{-}20]$$

Equation [A-18] means that very little HCl is lost by reaction with quartz, that virtually all HCl is converted to GaCl, and that $GaCl_3$ may be neglected. Equation [A-19] states that the equilibrium pressures of SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$ in contact with liquid Ga are negligible. This is due to the fact that P_{HCl} is greatly reduced, favoring decomposition of these chlorides. Equation [A-20] means that $P_{\text{SiO}} << P_{\text{H}_2\text{O eq}} + P_{\text{Ga}_2\text{O eq}}$. This is because low values of x_{Si} favor the decomposition of SiO. Then, by using these approximations, Eq. [A-11] becomes

$$\frac{dx_{\text{Si}}}{dt} = \frac{F}{RTN_{\text{Ga}}}\left\{(P_{\text{SiO input}} + P_{\text{silanes input}} + P_{\text{SiCl}_4\text{ input}}) - x_{\text{Si}}\left[\frac{P_{\text{H}_2\text{O input}} + P_{\text{SiO input}}}{K_3 + \dfrac{K_3}{K_2}} + \frac{P_{\text{HCl}}^0}{K_9}\right]\right\} \quad [A\text{-}21]$$

It may be shown that the term $x_{\text{Si}}(\ldots)$ in Eq. [A-21] is negligible if $x_{\text{Si}} < 10^{-3}$. Equation [A-21] then takes the form

$$\frac{dx_{\text{Si}}}{dt} = C'(T) \quad \text{or} \quad x_{\text{Si}} - x_{\text{Si}}^0 = C'(T)t \quad [6]$$

Calculations for case C-2.—Equations [A-6], [A-12], and [A-15] are still valid for this case. Therefore, following cases A, B, and C-1

$$\frac{dx_{\text{Si}}}{dt} = \frac{F}{RTN_{\text{Ga}}}\left[\left(\frac{P_{\text{SiO input}}}{2} - \frac{P_{\text{H}_2\text{O input}}}{2} + P_{\text{silanes input}} + P_{\text{SiCl}_4\text{ input}}\right) - x_{\text{Si}}\left(\frac{K_4}{2[x_{\text{Si}}^{1/2}]} + \frac{P_{\text{GaCl eq}}}{K_9} + \frac{P_{\text{GaCl eq}}^2}{K_{10}} + \frac{P_{\text{GaCl eq}}^3}{K_{11}} + \frac{P_{\text{GaCl eq}}^4}{K_{12}}\right) + \frac{1}{2}\frac{K_3K_4^{1/2}}{x_{\text{Si}}^{1/2}}\left(1 + \frac{1}{K_2}\right)\right] \quad [A\text{-}22]$$

Then, using Eq. [A-8], the input terms add up to $-P_{\text{H}_2\text{O}}^0/2$. Thus, Eq. [A-22] becomes

$$\frac{dx_{\text{Si}}}{dt} = \frac{F}{2RTN_{\text{Ga}}}\left\{\frac{K_3K_4^{1/2}\left(1 + \dfrac{1}{K_2}\right)}{x_{\text{Si}}^{1/2}} - K_4^{1/2}x_{\text{Si}}^{1/2} - P_{\text{H}_2\text{O}}^0 - 2x_{\text{Si}}\left(\frac{P_{\text{GaCl eq}}}{K_9} + \frac{P_{\text{GaCl eq}}^2}{K_{10}} + \frac{P_{\text{GaCl eq}}^3}{K_{11}} + \frac{P_{\text{GaCl eq}}^4}{K_{12}}\right)\right\} \quad [8]$$

Thermodynamic Analysis of the III-V Alloy Semiconductor Phase Diagrams

II. The GaSb-GaAs System

L. M. Foster* and J. F. Woods

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A thermodynamic analysis was made of the GaSb-GaAs pseudobinary phase diagram. The solid solutions in this system exhibit strong positive deviations from ideality, as evidenced by the large excess free energy of mixing, $B^s x_1 x_2$. An excellent fit of the experimental liquidus and solidus points was obtained with $B^s/RT = 2.00$ and $B^l/RT = -0.100$. These values designate the liquid as nearly ideal and the solid as bordering on phase separation. The latter is consistent with the observation that composition homogeneity is extremely difficult to achieve in this system. The large deviation from ideality in the solid is attributed to lattice strain resulting from the large lattice mismatch between the two components.

Alloys between the Group III-Group V semiconductor compounds offer some attractive features for the design of electronic and optical devices because of the possibility of obtaining a desired forbidden energy gap by selection of the alloy system and adjustment of the composition within the system (1-3). This presupposes that there is complete miscibility throughout the solid and that no metallurgical or chemical inhomogeneities are introduced by alloying that would adversely effect device performance.

In an earlier paper (4) we presented thermodynamic arguments which suggested that under some circumstances complete homogeneity and a smooth blending of crystal properties might in fact be lacking in some of the alloys as a consequence of the large excess free energy of mixing involved in their formation. The three systems that were investigated in that study were the pseudobinary alloys, InSb-GaSb, InAs-GaAs, and InP-GaP. They constitute a homologous series where only the Group V atom changes. In each system the departure from Raoult's law of mixing is positive; that is, the excess free energy of mixing is positive, increasing from the antimonides to the arsenides to the phosphides. This is also the order of increasing lattice parameter mismatch between the two components of the alloys.

A group of alloys such as III-(As, Sb), III-(As, P), and III-(Sb, P) would constitute another homologous series, in this case with a fixed Group III atom and different pairs of Group V atoms. Unfortunately, data for both the liquidus and solidus boundaries are not yet available for all of these alloys and, in fact, there is evidence that the III-(Sb, P) systems do not form miscible solid solutions across the entire phase diagrams (5).

* Electrochemical Society Active Member.

Key words: phase diagrams, compound semiconductors, solution theory.

Recently our attention was called to unpublished data (6) for the liquidus of one of these systems (GaSb-GaAs) which, together with solidus data from the literature, permits calculation of the excess thermodynamic quantities and a comparison with the findings and conclusions of the earlier series.

Calculation procedure.—Details of the thermodynamic analysis were given in the earlier paper (4) and will not be repeated here. Briefly, the excess free energy of mixing for the liquid and solid solutions is given by $B^l x_1 x_2$ and $B^s x_1 x_2$, respectively, where x_1 and x_2 are mole fractions of components 1 and 2. The total free energy of mixing for the liquid then becomes

$$\Delta F^{M(l)} = RT(x_1 \ln x_1 + x_2 \ln x_2) + B^l x_1 x_2 \quad [1]$$

and for the solid

$$\Delta F^{M(s)} = RT(x_1 \ln x_1 + x_2 \ln x_2) + x_1 L_1 (T/T_1 - 1) + x_2 L_2 (T/T_2 - 1) + B^s x_1 x_2 \quad [2]$$

where T_1 and T_2 are the melting points and L_1 and L_2 are the latent heats of fusion for the two pure components. The parameters B are related to the activity coefficients through the relations (4)

$$\ln \gamma_1 = (B/RT) x_2^2$$
$$\ln \gamma_2 = (B/RT) x_1^2 \quad [3]$$

Reference (4) derives expressions for B^l and B^s at temperature T in terms of the liquidus and solidus compositions, x^l and x^s, taken from an experimentally determined binary phase diagram, as follows

$$B^l = \frac{RT\{(1-x^s)^2 \ln[(1-x^l)/(1-x^s)] - (x^s)^2 \ln(x^l/x^s)\}}{(x^s)^2(1-x^l)^2 - (x^l)^2(1-x^s)^2} - \frac{(1-x^s)^2 L_1 (T-T_1)/T_1 - (x^s)^2 L_2 (T-T_2)/T_2}{(x^s)^2(1-x^l)^2 - (x^l)^2(1-x^s)^2} \quad [4]$$

$$B^s = \frac{RT\{(1-x^l)^2 \ln[(1-x^s)/(1-x^l)] - (x^l)^2 \ln(x^s/x^l)\}}{(x^l)^2(1-x^s)^2 - (x^s)^2(1-x^l)^2} + \frac{(1-x^l)^2 L_1 (T-T_1)/T_1 - (x^l)^2 L_2 (T-T_2)/T_2}{(x^l)^2(1-x^s)^2 - (x^s)^2(1-x^l)^2} \quad [5]$$

Results

Kulwicki (6) obtained points on the liquidus boundary by differential thermal analysis of samples that had been equilibrated for 72 days at 695°C (Table I). These data are shown as open circles in Fig. 1. Points on the solidus boundary (filled circles) were obtained by Woolley and Smith (7) by an x-ray method, assuming that Vegard's rule applies. Equilibrium could not be achieved for compositions of lower GaAs content than those shown.[1] The dashed curves in Fig. 1 are the ideal liquidus and solidus boundaries calculated from Eq. 13 and 14 of Ref. (4), with $T_1 = 712°C$ (10), $T_2 = 1240°C$ (11), $L_1 = 15.56$ kcal/mole (10), and $L_2 = 25.18$ kcal/mole (11). The solid curves of Fig. 1 are calculated boundaries that meet certain criteria for acceptable data, as set forth in Ref. (4) and discussed in the next section.

Discussion

The GaSb-GaAs phase diagram appears to indicate strong positive deviations from ideality in the solid solution. As pointed out in Ref. (4), however, the degree to which the solid and liquid contribute separately to the gross features of the diagram cannot be guessed by cursory examination. This information can only come from actual calculation of pairs of B^s and B^l at selected temperatures, and the assignment of excess free energies therefrom. Figure 2 shows the excess free energy, Bx_1x_2, for each phase, with the B parameters calculated from Eq. [5] and [6]. It is seen that the pronounced lowering of the solidus boundary is indeed attributable to the large positive $B^s x_1 x_2$. The liquid is almost ideal, and the very small negative excess free energy could be disregarded in an approximate calculation. It is interesting, however, that the arsenide system that was studied previously [InAs-GaAs (4)] also showed small negative deviations in the liquid. This could result from a small positive excess entropy of mixing, which implies a degree of ordering in one of the pure components which is lost in mixing. This property has been suggested for arsenic melts where there is some evidence of polymeric As molecules (12).

Figure 3 gives the plot of B/RT *vs.* x for GaSb-GaAs, and similar plots for the three systems from Ref. (4) for comparison. (The relationship between B/RT and the activity coefficients is shown by Eq. [3].) It was suggested in Ref. (4) that linearity of this plot might be taken as a criterion of acceptable experimental data. Its B/RT plot for the available data is exactly linear for both the liquid and solid. Moreover, the plots are flat with $B^l/RT = -0.100$ and $B^s/RT = 2.00$, thus strengthening our earlier contention (4) that this family of binary alloys appears to be characterized by $B/RT \approx$ constant.

The significance of B/RT is illustrated in Fig. 4 (the figures are exaggerated to illustrate the effects). With

[1] Straumanis and Kim (8) showed that Vegard's law was obeyed up to 34 m/o (mole per cent) GaAs, but could not obtain equilibrated samples after annealing up to 20 days beyond 60% GaAs. Muller and Richards (9) found that Vegard's law was obeyed in one determination at 50 m/o GaAs.

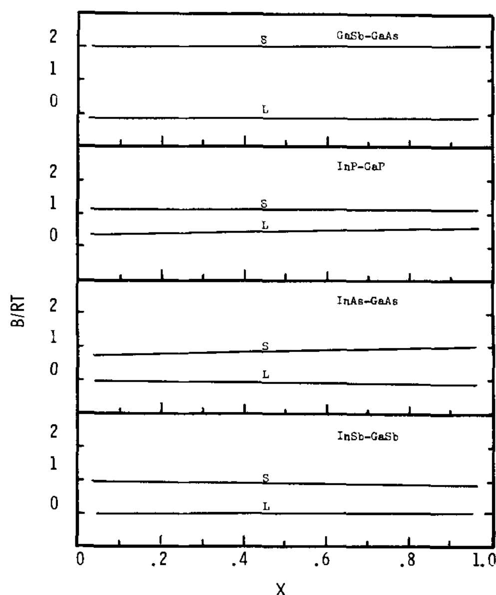

Fig. 3. B/RT vs. composition for III-V alloy systems

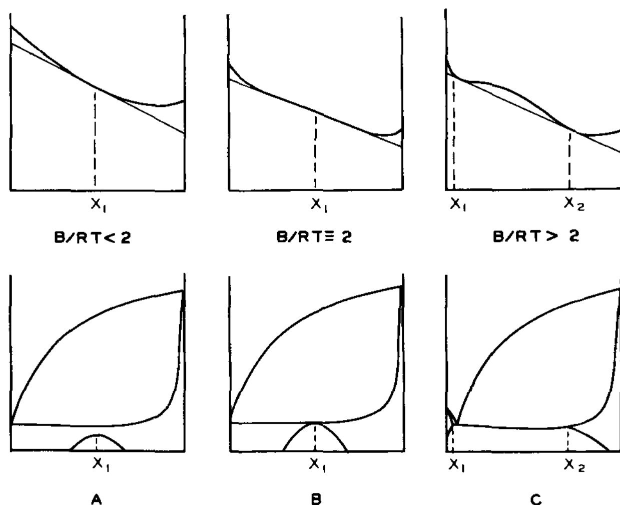

Fig. 4. Free energy of mixing of the solid and corresponding phase diagrams for cases where $B^s/RT \approx 2$.

$B^s/RT \leqq 2$, the plot of $\Delta F^{M(s)}$ vs. x is concave upward throughout its entire course and at any value of x there is a unique tangent whose slope is the change in chemical potential of component 2. A miscibility gap should appear at a critical temperature, $T_c = B^s/RT$, which will be entirely within the solid phase. This is illustrated in Fig. 4A. $B^s/RT \equiv 2$ is the upper limit of this quantity for which there is still a unique tangent to the free energy curve at any value of x and the maximum of the miscibility gap is coincident with the solidus at $x = 0.5$, as in Fig. 4B. For $B^s/RT > 2$, two inflection points appear in the $\Delta F^{M(s)}$ curve as the contribution of $B^s x_1 x_2$ in Eq. [2] becomes large in the vicinity of $x = 0.5$. There are two points of tangency where the slope is the same, corresponding to the same chemical potential at two compositions, and the solid, at equilibrium, separates into two phases, as in Fig. 4C.

The GaSb-GaAs system, with $B^s/RT = 2$, is of the type shown in Fig. 4B. The situation is very sensitive when B^s/RT is near 2, however, and values of this quantity just slightly greater or lesser would give calculated solidus and liquidus curves that would be acceptable fits to the data points, but which would predict phase separation in the solid at all temperatures on one hand, and complete miscibility just beneath the solidus on the other. (This assumes that B^s determined at a particular composition on the solidus boundary remains constant down into the solid.) For example, with $B^s/RT = 2.01$, $\Delta F^{M(s)}$ already shows two tangents corresponding to a miscibility gap of 0.12 in mole fraction (from $x = 0.44$ to $x = 0.56$) in place of the continuous solidus line; whereas, with $B^s/RT = 1.99$ the peak of the miscibility gap is at 728°C, about 6° below the solidus at $x = 0.5$. It would be extremely difficult to establish experimentally whether the solidus of the GaSb-GaAs system does indeed follow the calculated curve, shown in Fig. 1, from the melting point of GaSb to the left-most data point because of the very narrow temperature range where homogenization of samples could be accomplished in this critical region. Both Kulwicki (6) and Woolley and Smith (7) noted their inability to equilibrate solid samples in this part of the diagram.

It is particularly significant that a constant B/RT fits the available data for both phases of the GaSb-GaAs system, for this is the fourth III-V alloy system that exhibits such behavior (Fig. 3). The implications of a constant B/RT were discussed in detail in Ref. (4). Briefly, if B is not dependent on composition, $B \propto T$ and the entire excess free energy of mixing, $B^s x_1 x_2$, appears as the entropy term, $T\Delta S$, in $\Delta F^M_{ex} = \Delta H^M_{ex} - T\Delta S^M_{ex}$, leaving no excess enthalpy of mixing. This outcome is not permitted by either the regular (13) or the quasichemical (14) treatments of solutions. The implication of this finding in terms of the properties of the III-V alloys is not clear at this time [see Ref. (4)].

The severe departure from ideality in the solid of the GaSb-GaAs system is consistent with the large lattice mismatch between the pure components, according to the pattern established in Ref. (4). The mismatch in the GaSb-GaAs system of 7.52% (0.442Å) is greatest of the four systems studied thus far and, as a rule of thumb, might be considered as the maximum mismatch that can be tolerated in this class of alloys for complete miscibility near the freezing point. According to this rule, of the eighteen possible pseudobinary alloys between the nine III-V compounds of Al, Ga, and In with P, As, and Sb, three (InSb-InP, GaSb-GaP, and AlSb-AlP) should not form miscible solid solutions, and one (AlSb-AlAs) would be doubtful. Many others would be expected to undergo spinodal decomposition when held for extended periods somewhat below their freezing points.

The fact that nonideality of the solids and the lattice mismatch vary in a parallel manner in the III-V alloys studied thus far, and the fact that the liquids depart only slightly from ideality, suggest that lattice strain is the principal contributor to the excess free energy in these systems.

Acknowledgment

The authors wish to thank Dr. B. M. Kulwicki of the Texas Instruments Inc., Attleboro, Massachusetts, for calling our attention to his work on the GaSb-GaAs system and for making his unpublished data available to us.

Manuscript submitted Sept. 16, 1971; revised manuscript received ca. Dec. 5, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Contact Resistance and Contact Resistivity

H. H. Berger

IBM Laboratory, 703 Boeblingen/Württ, West Germany

ABSTRACT

This paper mainly offers guidance to the technologist who has to characterize metal-semiconductor contacts for process development and production control. To abolish confusion clear definitions are proposed for the terms contact resistance and contact resistivity. Based on these definitions, methods of determining contact resistivity are discussed, revealing the common source of error of the methods and making comparisons. New methods like the TLM method are described and included in the comparison. Results of contact resistivity measurements on Al-Si contacts over a wide range of silicon surface doping are presented.

One of the obvious measures that have been taken to obtain higher densities in monolithic circuits has been to decrease the area provided for the metal-semiconductor interconnection contacts on the circuit chips. This has put a severe burden on the technologist, who has to develop proper production processes for small area contacts of low resistance and high reliability.

For this development work and for the process control, he needs clearly defined terms to describe the practically important contact qualities, as well as proper methods to measure them.

Such terms widely used are contact resistance and contact resistivity. However, there has been a lack of common understanding of their meaning. Moreover, although a number of methods to determine contact resistivity have been offered, a clear conception of their validity and accuracy has not always been worked out.

Accordingly the purpose of this paper is to offer suitable definitions for both contact resistance and contact resistivity and then to discuss several measurement methods for contact resistivity mainly to reveal their common source of measurement error. The comparison points out that there are three new methods which offer considerable less error than conventional procedures and simultaneously are well adapted to present fabrication processes. Finally, results of such contact resistivity measurements on aluminum-silicon contacts are reported, which enlarge the relatively rare data presently available.

Definition of Contact Resistance

Experience shows that the access to a semiconductor region via a metal contact usually exhibits higher resistance than expected from an ideal contact. The additional resistance may be imagined as being a series resistor in the lead to the ideal contact. It shall be referred to as "contact resistance."

The theoretical treatment of semiconductor devices has been facilitated by this mental image. Namely, it allows the consideration of the device behavior first under the simplifying condition of ideal contacts and later adding the experimentally or theoretically derived contact resistances that provide the corrections for the actual contacts. Furthermore, it has provided a simple basis for comparing different contact-making processes.

Key words: ohmic contacts, contact resistance, contact resistivity, contact resistivity measurement, contact characterization.

The still rather vague notion of contact resistance as a series resistance describing the deviation of an actual contact from its ideal condition would be strengthened by a precise definition. But this requires first a clear conception of the ideal contact.

Practical contacts are nonideal for two basic reasons:

1. In a thin surface layer of the semiconductor beneath the contact metal the charge carrier density differs from that of the semiconductor bulk (accumulation or depletion layer) due to differences in work function of metal and semiconductor or due to surface states of the semiconductor.

2. Layers of foreign matter sometimes impede a rigorous contact of metal and semiconductor.

In contrast, an ideal contact does not exhibit any interface layers. Hence, its potential may be identified with the potential ϕ' in the contact plane of the semiconductor after extending the latter by its mirror image on that contact plane (Fig. 1).

To compare now the access via the actual contact with that via its ideal counterpart, a common reference plane P_r within the semiconductor must be identified. This plane must coincide with a plane of constant potential and must carry the total contact current. The

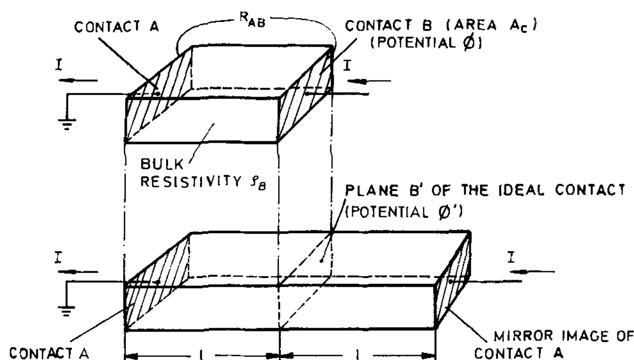

Fig. 1. Derivation of the potential ϕ' of the ideal contact (B') pertaining to the real contact (B) by mirror-imaging.

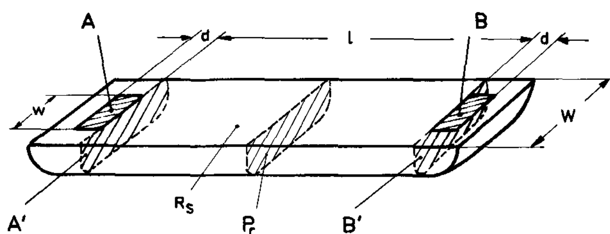

Fig. 2. Planar resistor with real contacts A and B and the most practicable locations A′ and B′ for the corresponding ideal contacts.

resistance between P_r and the actual contact is R_a, that between P_r and the ideal contact R_i. The contact resistance is then defined by the difference of these two resistances

$$R_c = R_a - R_i \quad [1]$$

Of course, for this comparison of R_a with R_i, the reference plane P_r must (practically) remain a plane of constant potential when the actual contact is replaced by its ideal counterpart. Hence, the mental image underlying the contact resistance concept fails where such a reference plane cannot be found. In such cases the contacts must be considered an integral part of the whole semiconductor device.

With the sample shown in Fig. 1, however, any plane parallel to the contacts may be taken for P_r provided that the contacts are uniform. Although no assumptions have been made in the definition of contact resistance regarding the position of the ideal contact, for the sample in Fig. 1, it is most convenient to let ideal and actual contact coincide. Taking, *e.g.*, the grounded contact A as the reference plane P_r, the contact resistance of contact B may be written according to Eq. [1] as the difference of the potential ϕ of the actual contact and the potential ϕ' of its ideal counterpart, divided by the current I

$$R_c = \frac{\phi - \phi'}{I} \quad [2]$$

With other structures it might prove advantageous to choose a plane for the ideal contact that does not coincide with that of the actual contact. This is the case with the contact on a diffused resistor[1] shown in Fig. 2. By using the planes A′ and B′ for the ideal contacts, one facilitates the calculation of R_i in Eq. [1]. Thus, with the reference plane P_r in the center of the resistor[2] one obtains for equal contacts

$$R_c = \frac{1}{2}\left(R_{AB} - R_s \cdot \frac{l}{W}\right) \quad [3]$$

where R_s is the sheet resistance of the resistor layer. Solved for R_{AB}

$$R_{AB} = R_s \cdot \frac{l}{W} + 2R_c \quad [4]$$

it corresponds to the widely used formulation in terms of an "end correction" (equivalent number of squares k of the resistor layer)

$$R_{AB} = R_s\left(\frac{l}{W} + 2k\right) \quad [5]$$

Equation [4] leads to a practicable way of measuring the so defined contact resistance of a planar resistor. Such a resistor having three equal contacts A, B, C arranged in different distances l_1 and l_2 (Fig. 3) exhibits different resistances between A and B (R_1) and B and C (R_2). The contact resistance R_c can be eliminated by applying Eq. [4] to R_1 and R_2, which results in

[1] Very likely the contact on a diffused resistor is typical also for many contacts on other planar devices (1).

[2] Obviously, the resistor has to be sufficiently long to fulfill the condition that the coincidence of P_r and a constant potential plane be maintained when either one of the contacts is replaced by its ideal counterpart.

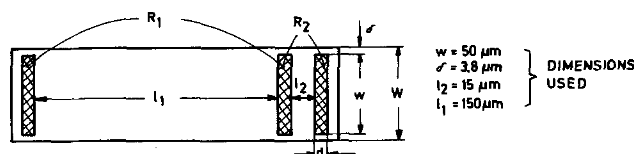

Fig. 3. Planar resistor having three contacts for contact resistance determination.

$$R_c = \frac{R_2 \cdot l_1 - R_1 \cdot l_2}{2(l_1 - l_2)} \quad [6]$$

It might appear peculiar that in this paper contact resistance has been defined in such a way as to allow a free choice of the position of the ideal contact, thus permitting the arbitrary introduction of semiconductor bulk portions into the contact resistance. Clearly, this would be a disadvantage if there were reasons to assume that coinciding ideal and actual contact planes would generally lead to a contact resistance being free of any semiconductor bulk influence and thus describing solely the metal-semiconductor interface. However, the replacement of the actual by the ideal contact alters the boundary conditions for the electric field in the semiconductor and hence changes the current distribution in the vicinity of the contact, unless it is fixed by the geometry of the sample as in Fig. 1. Obviously, a change of current distribution will introduce different bulk influence into R_a and R_i (Eq. [1]) and thus introduce bulk resistance into the contact resistance.[3] Generally attempts to split the total contact resistance into interface and bulk contribution in the form of concentrated series resistors must be rather fruitless according to the foregoing discussion. Actually, it suffices to make this separation only for infinitesimal sections of the contact. This leads to the term "contact resistivity" solely describing the metal-semiconductor interface independent of contact geometry.[4]

Contact Resistivity

Contact resistivity ρ_c can be derived formally from the contact resistance definition. Consider a tube of current streamlines in the semiconductor device carrying a portion ΔI of the total current. In the plane of the contact the tube has a cross section of ΔA_c. The tube with its portion ΔA_c of the contact may now be considered as a device with a contact, for which a contact resistance R_c can be defined according to Eq. [1]. For this purpose, the plane of the ideal contact coincides with that of the actual one. Furthermore, it is assumed that the current flow within the interface portion of the tube is directed vertically to the contact plane. Then contact resistivity is defined as

$$\rho_c\,[\text{ohm cm}^2] = \lim_{\Delta A_c \to 0} (R_c \cdot \Delta A_c) \quad [7]$$

thus taking an infinitesimal tube of streamlines.

[3] Hence, since the author believes that the expression contact resistance is worth being preserved, he had either to detach it from the described mental image underlying its usage or to refrain from the widespread association of contact resistance exclusively with the metal-semiconductor interface. The latter alternative was chosen in this paper from the outset. This choice is mainly based on the consideration that there is a sufficient reservoir of other expressions clearly referring solely to the resistance of the metal-semiconductor interface, like "transitional resistance", "interface resistance," or the geometry independent term "contact resistivity." The other choice has been tried by Ting and Chen (2). They have associated "contact resistance" solely with the metal-semiconductor interface and have used the expression "correction term" for the resistance defined by Eq. [3] ("contact resistance" in the present paper). The contact resistance contribution $R_{c_{eff}}$ to the correction term (in Ting and Chen's terminology) has been rated according to the power dissipation N in the interface layer: $R_{c_{eff}} = N \cdot I^{-2}$ (I = total current). Unfortunately, Ting and Chen have not subsequently applied this interesting concept to the semiconductor bulk resistance contributions, as these have not been rated via power dissipation. Instead, resistance calculations assuming ideal boundary conditions have been used. The error of such an approximation is probably not easy to assess. Also since $R_{c_{eff}}$ is difficult to determine, the practical value of Ting and Chen's concept appears questionable.

[4] For metal-metal contacts treated by Holm (3) contact resistivity to a large extent is comprised of an average constriction resistance, which means that a strict separation between bulk and interface is not made there because of the somewhat different nature of metal-metal contacts.

With Eq. [2] it can be written as

$$\rho_c = \lim_{\Delta A_c \to 0} \left[(\phi - \phi') \frac{\Delta A_c}{\Delta I} \right] \quad [8]$$

$$= \frac{1}{j_c} \lim_{\Delta A_c \to 0} (\phi - \phi') \quad [9]$$

where j_c stands for current density at the contact.

For a homogeneous contact having uniform current density as in Fig. 1, Eq. [7] simplifies to

$$\rho_c = R_c \cdot A_c \quad (j_c = \text{const.}) \quad [10]$$

This equation has been used to determine ρ_c via contact resistance and contact area A_c. However, it must be kept in mind, that it is valid only for contacts having uniform current distribution dictated by the sample geometry.

The assumption of vertical current flow in the interface layer is, of course, fulfilled with the sample in Fig. 1. It is also practically fulfilled even with adverse sample geometries, if the resistivity of the interface layer is much larger than that of the undisturbed semiconductor bulk. Most practical contacts indeed exhibit very thin depletion layers of very high resistivities.[5] For these, without noticeable error, the thin depletion layer may even be considered as lying outside of the semiconductor like a possible layer of foreign matter. The potential difference $\phi - \phi'$ in Eq. [9] then becomes the total voltage drop v_c across these outside layers

$$\rho_c \approx \frac{v_c}{j_c} \quad [11]$$

This is the form[6] most readily used in practical applications of ρ_c. Of course, a definite value ρ_c can only be given for contacts which are sufficiently ohmic within the range of current density under study.

Determination of Contact Resistivity

In determining contact resistivity the essential problem is to separate the metal-semiconductor interface resistance from the semiconductor bulk resistance. There are methods devised for d-c measurement and others for a-c measurement. The latter rely on the relatively large capacitance of the interface, which practically shorts its resistance at sufficiently high frequencies. Thus the interface resistance appears as the difference of a low and a high frequency resistance measured on suitable samples. Besides detrimental parasitic influences, the difficulty lies in taking small differences of large quantities.

D-C methods suffer from the latter difficulty as well; however, they are much more accurate than a-c measurements at very high frequency. In the following only d-c methods are considered.

The first three methods to be discussed (twin contact, differential, and interface probing methods) rely on samples that provide uniform current distribution so that Eq. [10] may be used. The remaining two (TLM and interface probing methods), however, utilize samples of nonuniform current distribution and thus are based on different relations for contact resistivity.[7] It is shown that in spite of these differences, the main error of all d-c methods can be commonly described by the basic equation

$$\left| \frac{\Delta \rho_c}{\rho_c} \right| \lesssim \frac{\rho_B}{\rho_c} \cdot |\Delta l|_{\text{eff}} \quad [12]$$

which considerably facilitates their comparison. In this equation, $|\Delta l|_{\text{eff}}$ is the effective error of one or more crucial length measurements which are required to separate the metal-semiconductor interface from the semiconductor bulk resistance. The accompanying electrical measurements are usually much more accurate with readily available equipment, so that they have a minor influence. The ratio of semiconductor bulk resistivity ρ_B to contact resistivity ρ_c is fixed by the nature of the contact under investigation. Thus, the relative error of the ρ_c determination for a given contact depends only on the absolute error of the crucial length measurements. According to the measurement results to be described in the section on Measurements on Al-Si Contacts, for aluminum-silicon contacts a $\rho_B/\rho_c = 0.1/\mu\text{m}$ might be used for a rough orientation. With this figure, an effective length measurement error $|\Delta l|_{\text{eff}} = 5\ \mu\text{m}$ would cause a relative ρ_c error as large as 50%! Or, to obtain less than 10% error, $|\Delta l|_{\text{eff}} < 1\ \mu\text{m}$ would be required.

Twin contact method.[8]—This measurement follows Eq. [1] and [10]. A homogeneous semiconductor body as in Fig. 1 carrying two equal contacts on opposite faces (area A_c) provides uniform current distribution so that Eq. [10] is valid. With the coinciding actual and ideal contact planes one obtains from Eq. [1]

$$R_c = \frac{1}{2} \left(R_{AB} - \rho_B \cdot \frac{l}{A_c} \right) \quad [13]$$

(compare with Fig. 1) or with Eq. [10]

$$\rho_c = \frac{1}{2} (R_{AB} \cdot A_c - \rho_B \cdot l) \quad [14]$$

The contact resistivity determined according to this equation is very sensitive to measurement errors, since usually a small difference of large terms appears. As shown in the Appendix, length measurement errors $|\Delta l|_{\text{eff}}$ have the largest influence, in agreement with Eq. [12].

When the Van der Pauw method (7) is used for ρ_B measurement, $|\Delta l|_{\text{eff}}$ in Eq. [12] becomes identical with the error $|\Delta l|$ of the probe thickness measurement. Practicable samples have a thickness of about 300 μm. $|\Delta l|$ within 5 to 10 μm can then be expected.[9] According to the foregoing discussion this is too large for an accurate ρ_c determination on typical Al-Si contacts.

Differential method.—Compared with the twin contact method this new approach improves the accuracy by more than an order of magnitude. Figure 4 shows the sample structure and the measurement principle. A direct comparison is made of contact B under investigation with the contacts A and C, having negligible interface resistance due to a highly doped layer beneath the contact metal. The areas of all three contacts are equal.

This structure reflects the definition of R_c, where a real contact (B) is compared with an ideal contact (A or C) under otherwise equal conditions. Hence, the potential difference $\phi - \phi'$ (compare with Eq. [2]) can

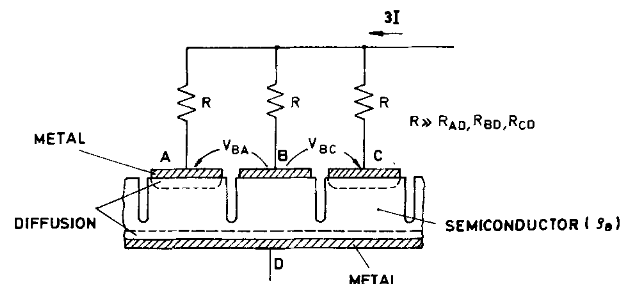

Fig. 4. Differential method for determining contact resistivity ρ_c

[5] The measurements on typical Al-Si that are presented in the section on Measurements on Al-Si Contacts indicate average resistivities of the depletion layers that are 100 to 1000 times larger than that of the semiconductor bulk.

[6] Also compare the definition of "specific contact resistance" by Chang *et al.* (4).

[7] There is another method proposed by Cox and Strack (5) that utilizes samples of nonuniform current distribution. This, however, tacitly assumes Eq. [10] to be valid in spite of a nonuniform current distribution. It appears very difficult to obtain an estimate of the error that is introduced by the contradicting assumption. Therefore, it has been excluded from the following discussion.

[8] Compare, *e.g.*, Sullivan and Eigler (6).

[9] Four-point probe measurements (8) yield about the same $|\Delta l|_{\text{eff}}$.

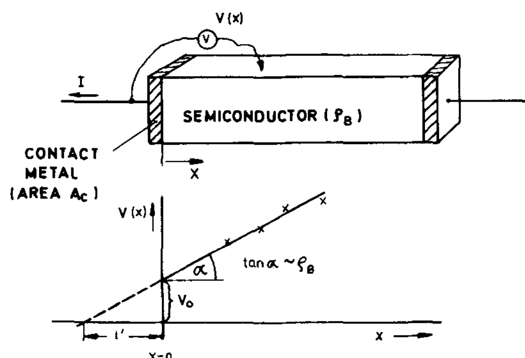

Fig. 5. Extrapolation method for determining contact resistivity ρ_c.

be directly measured as V_{BA} or V_{BC}. Usually a gradient of the sample thickness will disturb the result but can be eliminated by taking the average of V_{BA} and V_{BC}. Moreover, an error is introduced by the finite thickness x_j of the highly doped layers beneath A and C, which reduces the vertical resistance of the bulk by R_d. Hence one obtains

$$R_c = \frac{V_{BA} + V_{BC}}{2I} - R_d \quad [15]$$

For diffused layers beneath A and C, R_d can be approximated by

$$R_d \approx \rho_B \cdot \frac{x_j}{A_c} \quad [16]$$

where x_j is the junction depth obtained by the same diffusion in test wafers of equal bulk doping but opposite conduction type. Considering that Eq. [10] is valid for the sample structure, one arrives at

$$\rho_c = A_c \left(\frac{V_{BA} + V_{BC}}{2I} \right) - \rho_B \cdot x_j \quad [17]$$

Considerations similar to those explained in the Appendix for the twin contact method lead again to Eq. [12]. Of $|\Delta l|_{eff}$ the major portion here is the error in determining the thickness x_j of the highly doped layers beneath contacts A and C. Thus one obtains

$$\left| \frac{\Delta \rho_c}{\rho_c} \right| \approx \frac{\rho_B}{\rho_c} |\Delta x_j| \quad [18]$$

$|\Delta x_j|$ can be kept very small, usually about 0.2 μm, showing the main advantage of this differential method.

Extrapolation method.[10]—Figure 5 explains this method. The voltage distribution $V(x)$ is measured along the homogeneous semiconductor bulk of constant cross section using a fine probe needle. The results then allow an extrapolation to the metal-semiconductor interface ($x = 0$) thus obtaining a voltage drop V_o. This can be attributed to the contact resistance, since an ideal contact would show the voltage $V' = 0$ at this point. Hence, according to Eq. [2] the contact resistance becomes

$$R_c = \frac{\phi - \phi'}{I} = \frac{V_o}{I} \quad [19]$$

and with Eq. [10] one obtains

$$\rho_c = A_c \frac{V_o}{I} \quad [20]$$

The source of measurement error becomes obvious, when V_o is replaced by the extrapolated length l' and by the bulk resistivity ρ_B (compare with Fig. 5)

$$V_o = I \cdot \rho_B \cdot \frac{l'}{A_c} \quad [21]$$

which leads to (compare with Eq. [20])

$$\rho_c = \rho_B \cdot l' \quad [22]$$

or

$$\frac{\Delta \rho_c}{\rho_c} = \frac{\rho_B}{\rho_c} \Delta l' \quad [23]$$

This equation complies again with Eq. [12] as do the other methods. The error $\Delta l'$ is actually the uncertainty in determining the distance between contact interface and the probe needle tip. Most likely it lies in the order of 5 μm, which makes this extrapolation method only somewhat superior to the twin contact method in accuracy.

TLM method (1, 12-15).—Berger (1, 12) as well as Murrmann and Widman (13-15) have shown that contacts to planar devices like the diffused resistor in Fig. 3 can be described by their geometry, the semiconductor sheet resistance R_s beneath the contact, and the contact resistivity ρ_c, when a transmission line model (TLM) is used.

In the TLM the following important parameters have been used

characteristic contact resistance

$$Z = \frac{1}{w} \sqrt{R_s \cdot \rho_c} \quad [24]$$

attenuation constant

$$\alpha = \sqrt{\frac{R_s}{\rho_c}} \quad [25]$$

where w = contact width (compare with Fig. 2).

For sufficiently wide contacts ($w \to W$) the contact resistance according to Eq. [3] becomes (2)

$$R_c = Z \coth \alpha d \quad [26]$$

where d is the contact length (compare with Fig. 2). Thus an "electrically long" contact ($\alpha d \gtrsim 2$) exhibits a contact resistance

$$R_c \approx Z \quad (\alpha d \gtrsim 2) \quad [27]$$

Hence, from a R_c measurement[11] on an electrically long contact one can determine the contact resistivity using Eq. [24][12]

$$\rho_c = \frac{w^2 \cdot R_c^2}{R_s} \quad (\alpha d \gtrsim 2) \quad [28]$$

As is derived in the Appendix for the sample structure of Fig. 3, the relative error becomes

$$\frac{\Delta \rho_c}{\rho_c} \approx \alpha \, \Delta d \quad [29]$$

Once more, the main error is due to a length determination. To allow for easy comparison with an equation of type [12], a homogeneously doped layer having a resistivity ρ_B may be assumed instead of the diffused resistor layer. If the thickness of the resistor layer is properly chosen, a measurement error as small as

$$\frac{\Delta \rho_c}{\rho_c} \approx \frac{\rho_B}{\rho_c} \cdot 1.4 \cdot \Delta d \quad [30]$$

can be achieved (see Appendix).

Using a light microscope for measuring d, $|\Delta d|$ of less than 0.3 μm may be assumed yielding a comparative $|\Delta l|_{eff}$ (Eq. [12]) of about 0.4 μm.

[10] In its essential part the extrapolation method has been described already by Joffe (9). It has been refined by Mengali and Seiler (10). Hooper *et al.* (11) have made the first larger series of measurements on contacts to silicon using this method.

[11] Compare with Eq. [6].

[12] The method is not entirely restricted to electrically long contacts; using the diagram of Fig. 10 in Appendix 3, shorter contacts can be utilized as well.

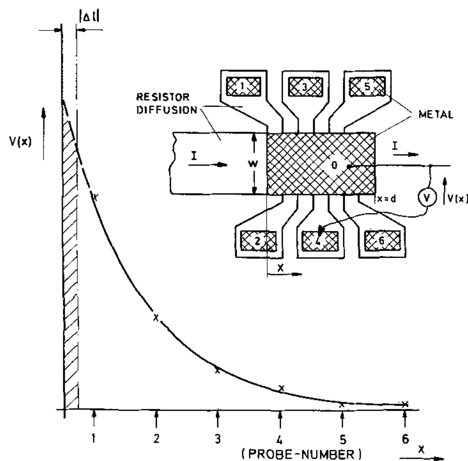

Fig. 6. Sample for the interface probing method of determining contact resistivity ρ_c after Ting and Chen (2), and typical voltage profile V(x). Effect of length measurement error $|\Delta l|$ on $\int V(x)\,dx$ is indicated.

Interface probing method.—Ting and Chen (2) have determined contact resistivities of contacts on diffused layers by probing the voltage drop across the metal-semiconductor interface. The sample structure is shown in Fig. 6.

As the TLM indicates (1, 12-15), the current density in such a contact subsides along the x-direction and accordingly so does the voltage across the metal-semiconductor interface (compare with Eq. [11]). Assuming that the vertical voltage drop in the semiconductor layer is negligible compared with the interface voltage,[13] the interface voltage profile can be probed by measuring the voltage difference between the resistor contact 0 and the contacts 1 through 6 (Fig. 6). The TLM predicts a nearly exponential voltage drop along x as the measurements by Ting and Chen have confirmed.

From this plot $V(x)$ as in Fig. 6, ρ_c can be calculated according to the following considerations

$$j(x) = \frac{V(x)}{\rho_c} \quad \text{(compare with Eq. [11])} \qquad [31]$$

$$I = W\int_0^d j(x)\,dx = \frac{W}{\rho_c}\int_0^d V(x)\,dx \qquad [32]$$

$$\rho_c = \frac{W}{I}\int_0^d V(x)\,dx \qquad [33]$$

The possible error in determining ρ_c will not be due to variations of the mutual distances of the probe fingers as these are fixed on a single mask. However, the distance of at least one probing point from the leading contact edge has to be measured, since here the alignment of two separate masks and etching tolerances are involved. The error of this length measurement Δl can be identified with the uncertainty of the position of the y-axis relative to the probing points (Fig. 6). The effect on ρ_c is then according to Eq. [33]

$$\Delta\rho_c \approx \frac{W}{I}\cdot V(o)\cdot\Delta l \qquad [34]$$

For $V(o)$, the TLM yields approximately

$$V(o) \approx \rho_c\cdot\alpha\cdot\frac{I}{W} \qquad [35]$$

The insertion of $V(o)$ into Eq. [34] yields the relative error

[13] This is also one of the basic assumptions for the TLM and is correct in most of the practical cases of at least aluminum-silicon contacts (1).

	TWIN CONTACT	EXTRAPOLATION	DIFFERENTIAL	T L M	INTERFACE PROBING
LINEARITY CHECK	NO	YES	YES	YES	YES
ERROR $\|\Delta l\|_{eff}$ [µm]	5	5	0.2	0.4	0.6
HOMOGENEITY CHECK	NO	NO	NO	YES	YES
A_C SAMPLE / A_C DEVICE	$\approx 10^4$	$\approx 10^4$	$\approx 10^4$	≈ 1	≈ 1

Fig. 7. Comparison of methods for determining contact resistivity ρ_c.

$$\frac{\Delta\rho_c}{\rho_c} \approx \alpha\cdot\Delta l \qquad [36]$$

This compares with Eq. [29] derived for the TLM method. Hence, Eq. [30] is valid also for the interface probing method, if Δd is replaced by Δl.

The determination of the distance between a probing point and the leading contact edge causing the error Δl, requires two separate measurements, namely the probing finger to contact edge distance and the finger width. The finger width has to be divided by 2, assuming that the actual probing point lies on the center line of the finger.[14] Thus in the worst case the total length measurement error is 1.5 times that of the TLM method. This results in a comparative value $|\Delta l|_{eff} \approx 0.6$ µm. Although less accurate under regular conditions, the extrapolation method appears superior to the TLM method in cases where the sheet resistance R_s of the semiconductor layer is altered beneath the contact by the contact making process. In this case it becomes intricate to determine the right value of R_s needed in the TLM method according to Eq. [28] [compare with Chang (16)], whereas the interface probing method does not require a R_s measurement at all.

Concluding comparison.—In the foregoing analysis of various d-c methods for contact resistivity determination the emphasis has been on measurement accuracy. It has been shown that Eq. [12] is indeed valid for all these methods, so that their error may be compared on the basis of the error $|\Delta l|_{eff}$ of the crucial length measurements.

However, besides accuracy a few other criteria should be considered as listed in Fig. 7. One wants to know whether the contact is indeed ohmic, which requires a linearity check. Checks for homogeneity are also important to confirm that the contact resistivity determined is meaningful and, of course, a good method uses sample dimensions that are representative for the actual device contacts. Figure 7 gives a clear cut between positive and negative answers to these criteria.[15] There only remain the TLM and the interface probing methods with all positive answers. From the other methods, the differential method is still attractive as it offers high accuracy and as it can be easily applied to lightly doped semiconductor samples.

Measurements on Al-Si Contacts

The differential and the TLM methods have been used to determine the dependence of ρ_c on semiconductor doping level for Al-Si contacts. All contacts were on <100> oriented silicon and had been sintered at

[14] For completeness it ought to be mentioned that this would be exactly true only in case of a uniform potential distribution along the finger width. The deviation of the actual probing point, from the center line, however, should be equal for all fingers (except near the contact end) due to the nearly exponential voltage drop. A corresponding correction of the position of the y-axis is principally possible from model measurements, if necessary at all.

[15] For the measurement error criterion a $|\Delta l|_{eff}$ of 1 µm was chosen as a border between "positive" and "negative" answer, corresponding to a ρ_c error of 10% if a ratio $\rho_B/\rho_c = 0.1$ µm is assumed.

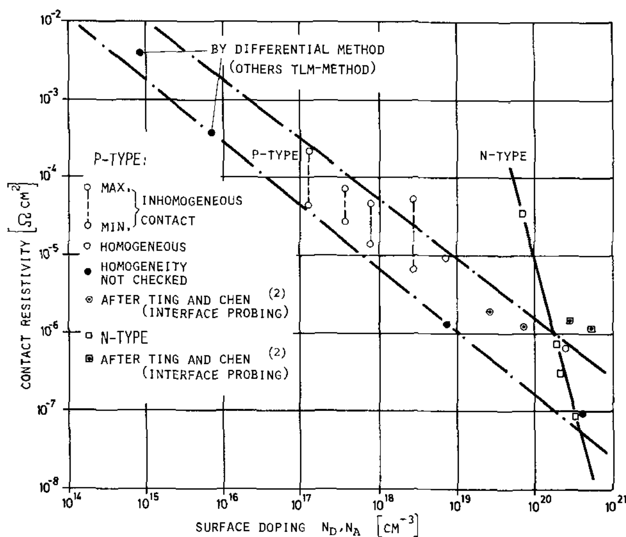

Fig. 8. Contact resistivity vs. surface doping of <100> oriented silicon for Al contacts, measured with differential or TLM method. Results by Ting and Chen (2) included for comparison (interface probing method).

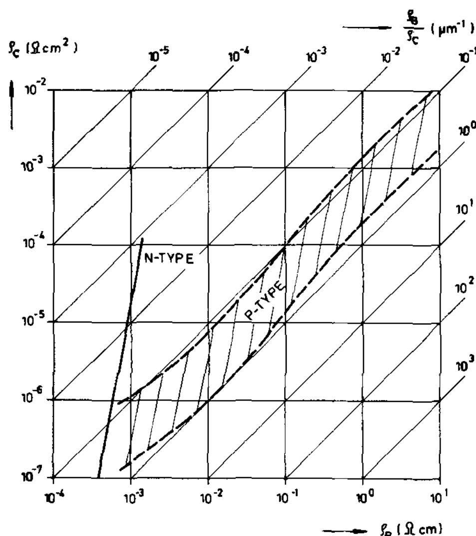

Fig. 9. Contact resistivity ρ_c vs. bulk resistivity ρ_B according to Fig. 8 for determination of measurement accuracy.

≈ 400°C for 20 min. The differential method has been most convenient for the high-ohmic p-type samples. In all other cases the TLM method has been applied using the sample structure of Fig. 3.

Figure 8 shows a plot of the results *vs.* surface doping of the silicon. Good ohmic contacts on n-type material could be achieved only above ≈ $5 \cdot 10^{19}/cm^3$. Below this doping level the contacts become at least partly Schottky diodes,[16] and a meaningful contact resistivity cannot be specified.

On p-type silicon the very wide doping range of $10^{15} \ldots 10^{21}/cm^3$ could be covered. Some of the samples, however, were inhomogeneous, with different contact resistivities at the contact edges and the center. By using different contact lengths and a supplement to the TLM method as described in Appendix 3, an upper and a lower limit for ρ_c have been determined in these cases.

The results by Ting and Chen (2) who used the interface probing method show some disagreement with the author's measurements on the highly doped n-type samples (compare with Fig. 9). However, the difference might be due to the difficulties of determining surface concentration especially in the high doping range. The author has used differential sheet resistance measurement on these n-type samples. For the p-type sample a gaussian profile has been assumed, allowing the use of Irvin's curves (17).

The measurements have demonstrated the applicability of the differential and the TLM methods. But they have pointed also to the general difficulty that inhomogeneities in the contact can appear and thus proper checks are necessary. The conditions which give rise to such inhomogeneities and their control deserves investigation, as fluctuating contact resistivities lead to uncontrolled current densities and thus are a potential reliability risk.

To get an impression on the possible effect of the length measurement on the contact resistivity errors according to Eq. [12], a diagram ρ_c *vs.* ρ_B (Fig. 9) has been derived from Fig. 8, using Irvin's curves (17) of resistivity *vs.* doping. In such a log/log-plot curves of constant ρ_B/ρ_c become straight lines, *e.g.*, for p-type silicon the error becomes almost independent of doping level; according to the range of uncertainty shown, it lies between 4 and 40%, assuming a $|\Delta l|_{eff}$ of 0.4 μm. For n-type silicon the error is a very strong function of bulk resistivity.

[16] The measurements on different contact lengths indicated that Schottky diodes with a very strong edge leakage have been obtained.

Summary

The definitions of the terms contact resistance and contact resistivity offered in this paper prevent confusion especially when dealing with contacts of nonuniform current distribution. Concurrently, the definitions are well adapted to measurement requirements.

In the discussion of different d-c methods for contact resistance determination, crucial length measurements have been revealed as a common main source of error. Considering all pertinent requirements, the TLM method, the interface probing method, and the differential method are the most promising.

Measurement results on Al-Si contacts using the differential and the TLM methods have enlarged the rare data on contact resistivities. From these results a diagram for predicting the error of contact resistance determination has been derived.

This paper can render some guidance to the technologist, how to characterize contacts during process development work and in production control. Moreover, the newer methods offered and the better appreciation of measurement accuracy might help the theorist as well in relating theoretical results with experimental data.

The author is indebted to Professors Dr. H. Beneking and Dr. D. Mlynski of the Technische Hochschule Aachen for helpful discussions. Thanks are due also to colleagues of the German IBM Laboratory for preparing measurement samples. This paper is part of a doctoral thesis approved by the Electrotechnical Faculty of the Technische Hochschule Aachen, Germany.

Manuscript submitted July 8, 1971; revised manuscript received Nov. 15, 1971. This was Paper 167 presented at the Cleveland Meeting of the Society, Oct. 3-8, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX

1. Measurement Error of the Twin Contact Method

According to Eq. [14]

$$\rho_c = \frac{1}{2} (R_{AB} \cdot A_c - \rho_B \cdot l) \qquad [A\text{-}1]$$

ρ_B is determined in a preceding measurement on the semiconductor body. No matter whether a four-point probe (8) or the Van der Pauw method (7) is used

here, ρ_B can be traced back to

$$\rho_B = R_x \cdot l^* \quad [A\text{-}2]$$

which says that both a resistance and a length measurement[17] are necessary, each with its inherent error.

Using [A-1] and [A-2] and applying the total differential, one obtains for the error of ρ_c as a function of the contributing errors

$$|\Delta\rho_c| \leq \frac{R_x \cdot l \cdot l^*}{2}\left[\frac{R_{AB} \cdot A_c}{R_x \cdot l \cdot l^*}\left(\left|\frac{\Delta R_{AB}}{R_{AB}}\right| + \left|\frac{\Delta A_c}{A_c}\right|\right) + \left|\frac{\Delta l^*}{l^*}\right| + \left|\frac{\Delta l}{l}\right| + \left|\frac{\Delta R_x}{R_x}\right|\right] \quad [A\text{-}3]$$

Dividing by ρ_c, resubstituting $R_x \cdot l^*$ by ρ_B and replacing $R_{AB} \cdot A_c/\rho_B \cdot l$ by $1 + (2\rho_c/\rho_B \cdot l)$ according to Eq. [A-1], one obtains the relative error

$$\frac{\Delta\rho_c}{\rho_c} \leq \frac{\rho_B \cdot l}{2\rho_c}\left[\left(1 + \frac{2\rho_c}{\rho_B \cdot l}\right)\left(\left|\frac{\Delta R_{AB}}{R_{AB}}\right| + \left|\frac{\Delta A_c}{A_c}\right| + \left|\frac{\Delta l^*}{l^*}\right| + \left|\frac{\Delta l}{l}\right| + \left|\frac{\Delta R_x}{R_x}\right|\right)\right] \quad [A\text{-}4]$$

The ρ_c determination is critical, since both terms on the right-hand side of Eq. [A-1] are usually large as compared to ρ_c. Hence in these critical cases the term $2\rho_c/\rho_B \cdot l$, in Eq. [A-4] may be neglected, which yields

$$\left|\frac{\Delta\rho_c}{\rho_c}\right| \lesssim \frac{\rho_B \cdot l}{2\rho_c}\left(\left|\frac{\Delta R_{AB}}{R_{AB}}\right| + \left|\frac{\Delta A_c}{A_c}\right| + \left|\frac{\Delta l^*}{l^*}\right| + \left|\frac{\Delta l}{l}\right| + \left|\frac{\Delta R_x}{R_x}\right|\right) \quad [A\text{-}5]$$

Using accurate equipment, the errors of resistor measurement can be kept much smaller than usual length measurement errors. Thus by neglecting the resistor errors, Eq. [A-5] can be written as

$$\left|\frac{\Delta\rho_c}{\rho_c}\right| \lesssim \frac{\rho_B}{\rho_c} \cdot |\Delta l|_{\text{eff}} \quad [A\text{-}6]$$

where

$$|\Delta l|_{\text{eff}} = \frac{l}{2} \cdot \left(\left|\frac{\Delta A_c}{A_c}\right| + \left|\frac{\Delta l^*}{l^*}\right| + \left|\frac{\Delta l}{l}\right|\right) \quad [A\text{-}7]$$

Assuming a sufficiently large contact area A_c, the error $\left|\frac{\Delta A_c}{A_c}\right|$ can also be neglected, so that for the Van der Pauw method with $l^* = l$, one simply obtains

$$|\Delta l|_{\text{eff}} = |\Delta l| \quad [A\text{-}8]$$

2. Measurement Error of the TLM Method

Starting with Eq. [28]

$$\rho_c = \frac{w^2 \cdot R_c^2}{R_s}$$

one obtains

$$\ln \rho_c = 2 \ln w - \ln R_s + 2 \ln R_c \quad [A\text{-}9]$$

or

$$\frac{d\rho_c}{\rho_c} = 2\frac{dw}{w} - \frac{dR_s}{R_s} + 2\frac{dR_c}{R_c} \quad [A\text{-}10]$$

Doubtlessly, the main error will be due to the error in determining R_c, because of the small differences of large numbers to be taken in Eq. [6], so that

$$\frac{\Delta\rho_c}{\rho_c} = 2\frac{\Delta R_c}{R_c} \quad [A\text{-}11]$$

It is convenient to introduce a term $y = l_1/l_2$ in Eq. [6]

$$R_c = \frac{R_2 \cdot y - R_1}{2(y-1)} \quad [A\text{-}12]$$

[17] Van der Pauw method: $l^* = l$ = thickness of the sample. Four-point probe: $l^* = s$ = distance between probe tips if $l >> s$.

The total differential then becomes

$$dR_c = \frac{\partial R_c}{\partial y} \cdot \frac{\partial y}{\partial l_1} \cdot dl_1 + \frac{\partial R_c}{\partial y} \cdot \frac{\partial y}{\partial l_2} \cdot dl_2 + \frac{\partial R_c}{\partial R_2} \cdot dR_2 + \frac{\partial R_c}{\partial R_1} \cdot dR_1 \quad [A\text{-}13]$$

From these error constituents the part due to length measurement errors will be considered first

$$\Delta R_c(\Delta l) \approx \frac{\partial R_c}{\partial y}\left(\frac{\partial y}{\partial l_1}\Delta l_1 + \frac{\partial y}{\partial l_2}\Delta l_2\right) \quad [A\text{-}14]$$

Looking at Fig. 3 one conceives that Δl_1 or Δl_2 are related to the variations Δd of contact hole lengths, as the center distances of the contact holes are fixed by the photomask. Within the small area of a diffused resistor the over- or underetching of contact holes is tracking, so that one can assume

$$\Delta l_1 = \Delta l_2 = -\Delta d \quad [A\text{-}15]$$

thus getting from Eq. [A-14]

$$\Delta R_c(\Delta l) \approx -\frac{\partial R_c}{\partial y} \cdot \Delta d\left(\frac{\partial y}{\partial l_1} + \frac{\partial y}{\partial l_2}\right) \quad [A\text{-}16]$$

Carrying out the differentiations, one obtains

$$\frac{\Delta R_c(\Delta l)}{R_c} \approx \frac{1}{R_c} \cdot \frac{R_1 - R_2}{(y-1)} \cdot \frac{\Delta d}{l_2} \quad [A\text{-}17]$$

Assuming a sufficiently long contact, so that $R_c \approx Z$ (Eq. [26] and [27] and considering Eq. [5] one can write

$$\frac{\Delta R_c(\Delta l)}{R_c} \approx \frac{R_s}{2W \cdot Z} \cdot \Delta d \quad [A\text{-}18]$$

With $w \approx W$ from Eq. [24] and [25] one recognizes this as

$$\frac{\Delta R_c(\Delta l)}{R_c} \approx \frac{\alpha}{2} \cdot \Delta d \quad [A\text{-}19]$$

The second error contribution by resistor measurement errors (Eq. [13]) can be written as

$$\Delta R_c(\Delta R) \approx \frac{\partial R_c}{\partial R_2} \cdot \frac{\Delta R_2}{R_2} \cdot R_2 + \frac{\partial R_c}{\partial R_1} \cdot \frac{\Delta R_1}{R_1} \cdot R_1 \quad [A\text{-}20]$$

A constant relative error of resistor measurement shall be assumed for simplicity

$$\left|\frac{\Delta R_2}{R_2}\right| = \left|\frac{\Delta R_1}{R_1}\right| = M \quad [A\text{-}21]$$

so that Eq. [A-20] leads to

$$\left|\frac{\Delta R_c(\Delta R)}{R_c}\right| \lesssim \frac{M}{R_c}\left(\left|\frac{\partial R_c}{\partial R_2}\right| \cdot R_2 + \left|\frac{\partial R_c}{\partial R_1}\right| \cdot R_1\right) \quad [A\text{-}22]$$

Carrying out the differentiations on Eq. [A-12] one arrives at

$$\left|\frac{\Delta R_c(\Delta R)}{R_c}\right| \lesssim M \cdot \frac{R_2 \cdot y + R_1}{R_2 \cdot y - R_1} \quad [A\text{-}23]$$

After some conversions using Eq. [3] for R_1 and R_2 and taking $R_c \approx Z$, $w \approx W$ with Eq. [24] and [25], [A-23] becomes

$$\left|\frac{\Delta R_c(\Delta R)}{R_c}\right| \lesssim M \cdot \frac{\alpha\, l_2 y + y + 1}{y - 1} \quad [A\text{-}24]$$

This error is minimized by choosing $y >> 1$

$$\left|\frac{\Delta R_c(\Delta R)}{R_c}\right| \lesssim M\,(\alpha l_2 + 1) \quad (y >> 1) \quad [A\text{-}25]$$

Now this result can be compared with the error contribution $\left|\frac{\Delta R_c(\Delta l)}{R_c}\right|$ after Eq. [A-19]. One may assume that usually $\alpha l_2 > 1$. Thus it is sufficient to compare

$M \cdot \alpha \cdot l_2$ with $\frac{1}{2}\alpha|\Delta d|$. In the sample structure according to Fig. 3, $l_2 = 15$ μm has been used, but it is possible to reduce it to ≈ 7 μm. With precision equipment $M \leq 3 \cdot 10^{-3}$ can be achieved. Using a light microscope for measuring d, $|\Delta d| \leq 3 \cdot 10^{-1}$ μm would be possible, so that $Ml_2 << \left|\frac{\Delta d}{2}\right|$ is true. This might change, if, *e.g.*, an electron scanning microscope is used for the measurement of d. So far, however, the prevailing error of ρ_c is according to Eq. [A-19] and [A-11]

$$\frac{\Delta\rho_c}{\rho_c} \approx \alpha\,\Delta d \qquad \text{[A-26]}$$

α can be related to a quotient ρ_B/ρ_c as it appears in Eq. [12] by taking a homogeneously doped resistor. According to an extended TLM (—ETLM) (1) the corresponding α becomes

$$\alpha^* = \frac{1}{\sqrt{\eta + 0.2}} \cdot \frac{1}{h} \qquad \text{[A-27]}$$

where $\eta = \frac{\rho_c}{\rho_B \cdot h}$ and h = semiconductor layer thickness.

For reasons of accuracy one requires a minimum η of 2, which also allows the term 0.2 in Eq. [A-27] to be neglected.[18] Multiplying with η/η one then obtains

$$\alpha^* = \frac{\rho_B}{\rho_c}\sqrt{\eta} \qquad \text{[A-28]}$$

Adjusting the structure for the minimum η of 2, one then obtains with Eq. [A-26]

$$\frac{\Delta\rho_c}{\rho^c} \approx \frac{\rho_B}{\rho_c} \cdot 1.4 \cdot \Delta d \qquad \text{[A-29]}$$

3. Supplement to the TLM Method

Contacts having $\alpha d \lesssim 2$ can be treated as follows: combining Eq. [24], [25], and [26] one obtains

$$\frac{R_s \cdot d}{R_c \cdot w} = \alpha d \cdot \tanh \alpha d \qquad \text{[A-30]}$$

from which via the diagram, Fig. 10, α can be determined when R_s, d, R_c, and w are known. Equation [25] then yields

$$\rho^c = \frac{R_s}{\alpha^2} \qquad \text{[A-31]}$$

There are two more possibilities of determining α required in Eq. [A-31]. A measurement according to Fig. 11 leads to a "contact end resistance" value $R_e = v_2/i_1$, which according to the TLM becomes

$$R_e = \frac{Z}{\sinh \alpha d} \qquad \text{[A-32]}$$

Thus from the quotient (compare Eq. [26])

$$\frac{R_c}{R_e} = \cosh \alpha d \qquad \text{[A-33]}$$

α can be determined.

If the contact again is electrically long ($\alpha d \gtrsim 2$), Eq. [A-32] can be approximated by

$$R_e \approx \frac{Z}{2} \cdot e^{-\alpha d} \qquad \text{[A-34]}$$

Taking two contacts with a length difference Δd = ($d_1 - d_2$) one obtains

$$\frac{R_{e2}}{R_{e1}} \approx e^{\alpha \Delta d} \qquad \text{[A-35]}$$

yielding α. This procedure offers an advantageous means of process control as the difference Δd is fixed by the photomask and is influenced only very little by the contact opening process. Thus the critical length measurement can be saved. The ρ_c results, however, are influenced much more by small contact homogeneities than when using the more averaging R_c according to Eq. [28].

[18] However, this term may not be neglected in the result ρ_c which has to be corrected by $\approx -\frac{0.2}{\eta}$ (1).

The Nature of Semiconductivity in Polycrystalline Tin Oxide

Colin A. Vincent

Department of Chemistry, University of St. Andrews, St. Andrews, Fife, Scotland

ABSTRACT

The differences in nonstoichiometric and controlled valence n-type semiconductors based on tin oxide are considered. The thermodynamic stability of tin and antimony oxides are calculated, and an assessment is made of the likely stabilities of the various forms of semiconductor.

Conducting tin oxides have been known for many years; thus Foex (1) reviewing work done up to 1943 cites investigations reported as early as 1910. However, although a number of authors have recently described methods for producing n-type semiconducting tin oxides, they have not always made clear what chemical species were responsible for producing the conductivity. Thus, for instance, Miloslavskii (2) employed pyrolytic decomposition of mixtures of SnII and SnIV chlorides at 500°-600°C to produce a semiconducting film on glass, whereas Bartholomew and Garfinkel (3) used $SnCl_2$ and Arai and co-workers (4) used $SnCl_4$. More commonly a mixture of SnIV and SbIII or FI compounds are used. It was therefore thought useful prior to attempting to prepare tin oxide semiconductors from solution to investigate the types of semiconductor which might be produced by different dopants as well as their probable stability.

Nonstoichiometric and Controlled Valence Semiconductors

Verwey (5) has described the basic difference between nonstoichiometric and controlled valence semiconductors. In the former, for every ion of deviating valency inserted into the lattice a defect such as a lattice vacancy must also be introduced; in the latter, extra ions are added so that there is no incorporation of lattice defects.

Consider a fraction δ of the SnIV sites in a SnO_2 crystal to be substituted by SbIII, by formally taking δ/2 moles of Sb_2O_3 and (1 − δ) moles of SnO_2 to give

$$Sn^{4+}_{(1-\delta)}\ Sb^{3+}_{\delta}\ O^{2-}_{(2-\delta/2)}$$

Such a system, which has correctly balanced charges of (4 − δ)+ and (4 − δ)−, if based on a cassiterite lattice has δ/2 moles of vacancies on oxide sites. These may be filled if the material is heated in an oxygen-containing atmosphere, provided that there are electrons available within it to reduce the oxygen. Here we have $Sn^{4+}_{(1-\delta)}\ Sb^{3+}_{\delta}\ O^{2-}_{(2-\delta/2)}$ reacting with δ/4 O_2 to give

$$Sn^{4+}_{(1-\delta)}\ Sb^{4+}_{\delta}\ O^{2-}_{2}$$

i.e.

$$Sn^{4+}_{(1-\delta)}\ e_{\delta}\ Sb^{5+}_{\delta}\ O^{2-}_{2}$$

where there are δ moles of electrons donated to the conduction band of the lattice. This material has no defects and is a controlled valence semiconductor. For the successful formation of such a substance it is essential that complete air oxidation of antimony to Sb_2O_5 does not occur

$$Sn^{4+}_{(1-\delta)}\ Sb^{3+}_{\delta}\ O^{2-}_{(2-\delta/2)} \xrightarrow{\delta/2\ O_2} Sn^{4+}_{(1-\delta)}\ Sb^{5+}\ O^{2-}_{(2-\delta/2)}$$

This system is an insulator.

Key words: tin oxide, semiconductivity, thermodynamic stability.

In contrast with the SnIV/SbIII system it is impossible to produce a controlled valence SnIV/SnII semiconductor. On combining δ moles of SnO with (1 − δ) moles of SnO_2 the nonstoichiometric oxide

$$Sn^{4+}_{(1-\delta)}\ Sn^{2+}_{\delta}\ O^{2-}_{(2-\delta)}$$

is formed. This is likely to be a semiconductor since the 2 moles of electrons formally assigned to the Sn^{2+} ions will be free to move to other Sn^{4+} sites. However, to form a controlled valence semiconductor an additional δ/2 moles of oxygen would be required to be incorporated with an associated transfer of 2δ moles of electrons from the SnII. Thus pure insulating SnO_2 would be formed. The stability of the nonstoichiometric tin oxide under different conditions of temperature and oxygen partial pressure will depend basically on the relative stabilities of SnO and SnO_2. A similar argument may be advanced for a system containing Sn, such as $Sn^{4+}_{(1-\delta)}\ Sn_{\delta}\ O^{2-}_{(2-2\delta)}$.

A controlled valence semiconductor may however be formed by substituting δ moles of oxide ions by chloride ions in the lattice to give

$$Sn^{4+}\ e_{\delta}\ O^{2-}_{(2-\delta)}\ Cl^{-}_{\delta}$$

Since chlorine has one less 2p orbital to fill than oxygen, for every chloride substitution a tin atom must retain an extra 5s electron which enters the conduction band of the lattice.

Thermodynamic Stability of the Oxides

The stabilities of the oxides of tin and antimony over the range of temperatures 300°-1500°K were calculated using the equation

$$\Delta G^{\circ} = \Delta H^{\circ} + aT \ln T + bT^2 + cT^{-1} + IT$$

and values for the parameters from the *U. S. Bureau of Mines Bulletin 542* (1954). Ellingham diagrams for the formation of SnO and SnO_2 and for Sb_2O_3 and Sb_2O_5 are shown in Fig. 1 and 2, respectively. From the functions illustrated the free energy changes for the reactions

$$2\ SnO + O_2 \rightarrow 2\ SnO_2$$

and

$$Sb_2O_3 + O_2 \rightarrow Sb_2O_5$$

were determined and are given in Fig. 3 together with the corresponding equilibrium constant functions in Fig. 4. It is apparent that in the presence of oxygen SnO_2 is considerably more stable than SnO over the whole temperature range investigated. On the other hand the difference in stabilities between Sb_2O_3 and Sb_2O_5 is not so great and above 1240°K the former is the more stable. In interpreting this result it is important to note that it holds for pure Sb_2O_3 with respect to Sb_2O_5 and that it is not possible to conclude that SbIII is never stable in oxygen below this temperature.

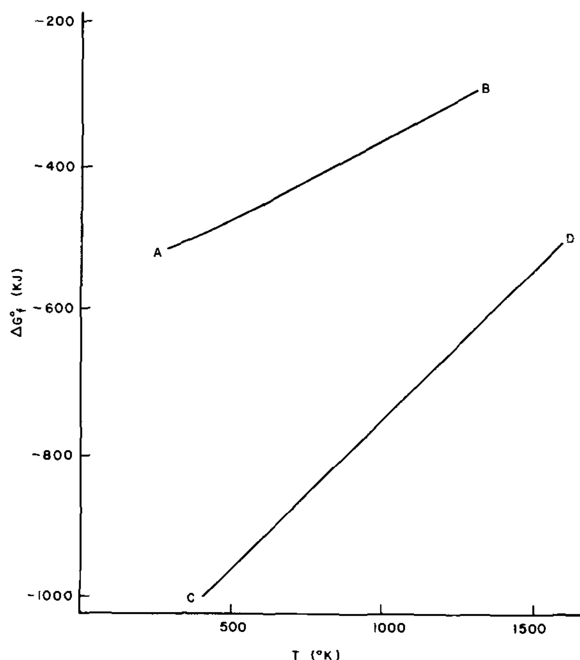

Fig. 1. AB: free energy of formation of 2SnO, CD: free energy of formation of $2SnO_2$.

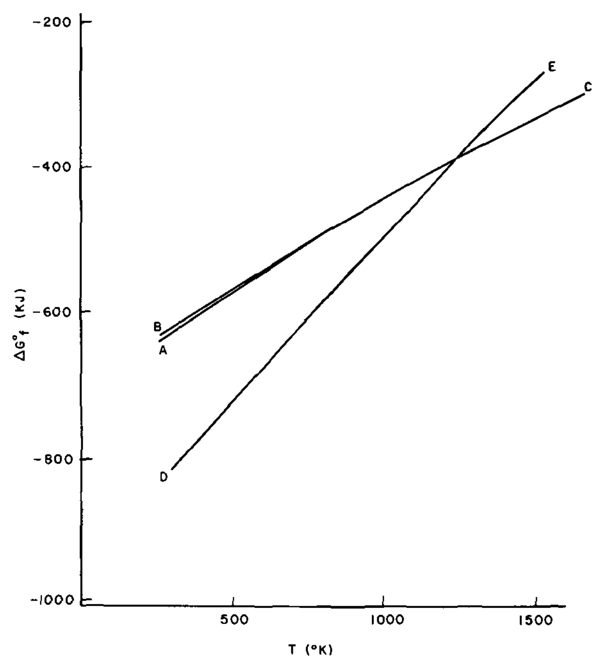

Fig. 2. AC: free energy of formation of Sb_2O_3 (cubic in solid state), BC: free energy of formation of Sb_2O_3 (orthorhombic in solid state), DE: free energy of formation of Sb_2O_5.

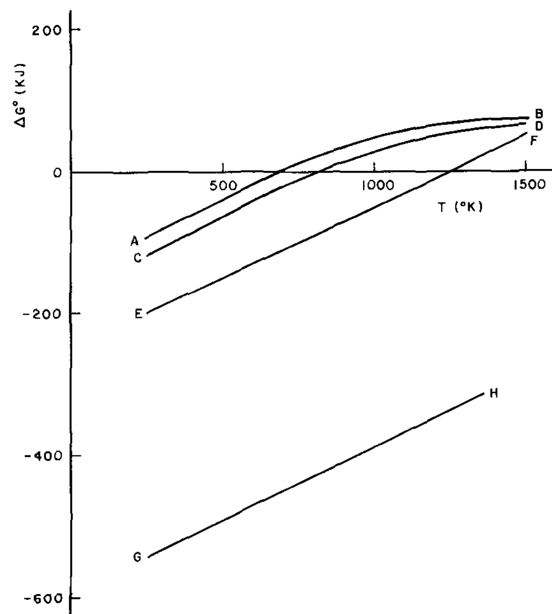

Fig. 3. AB: free energy of oxidation of Sb_2O_3'' to Sb_2O_5, CD: free energy of oxidation of Sb_2O_3' to Sb_2O_5, EF: free energy of oxidation of Sb_2O_3 to Sb_2O_5, GH: free energy of 2SnO to $2SnO_2$.

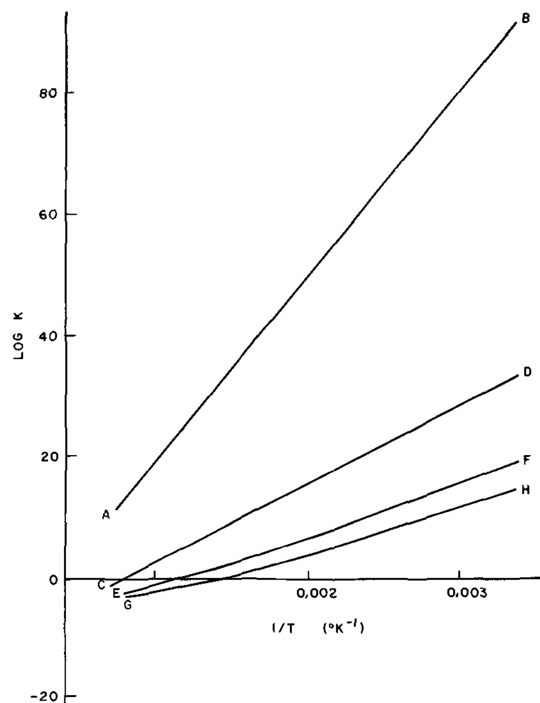

Fig. 4. AB: $2SnO + O_2 \rightarrow 2SnO_2$, CD: $Sb_2O_3 + O_2 \rightarrow 2Sb_2O_5$, EF: $Sb_2O_3' + O_2 \rightarrow Sb_2O_5$, GH: $Sb_2O_3'' + O_2 \rightarrow Sb_2O_5$.

A number of other antimony oxides are known, such as α- and β-Sb_2O_4 and Sb_6O_{13}, which contain antimony in III and V oxidation states. X-ray crystallographic studies (6) of the two Sb_2O_4 oxides have shown them to consist of units of SbV octahedrally surrounded by oxygen and SbIII having a "one-sided" fourfold coordination. The latter environment is very different from that of Sb in either orthorhombic (low temperature) or cubic Sb_2O_3.

Sb_2O_4 consists of an equal number of SbIII and SbV units and we take

$$2Sb_2O_4 \rightleftharpoons Sb_2O_3' \cdot Sb_2O_5$$

where Sb_2O_3' represents the trivalent antimony oxide in Sb_2O_4. Assuming that the pentavalent oxide in this compound is very similar to Sb_2O_5, the free energy of formation of a mole of Sb_2O_3 in the Sb_2O_4 system was estimated as

$$(\Delta G^\circ_f)_{Sb_2O_3'} = 2(\Delta G^\circ_f)_{Sb_2O_4} - (\Delta G^\circ_f)_{Sb_2O_5}$$

This function is shown as curve CD in Fig. 5. It is seen that the stability of Sb_2O_3' is so much enhanced that Sb_2O_4 is stable to oxidation at much lower temperatures than Sb_2O_3. Another well-characterized oxide, Sb_6O_{13} may be treated in a similar way as $Sb_2O_3'' \cdot 2Sb_2O_5$. ΔG°_f for 1 mole of Sb_2O_3 in Sb_6O_{13} was estimated as

$$(\Delta G^\circ_f)_{Sb_2O_3''} = (\Delta G^\circ_f)_{Sb_6O_{13}} - 2(\Delta G^\circ_f)_{Sb_2O_5}$$

and is shown in Fig. 5 as curve EF. The SbIII is seen to be further stabilized to oxidation.

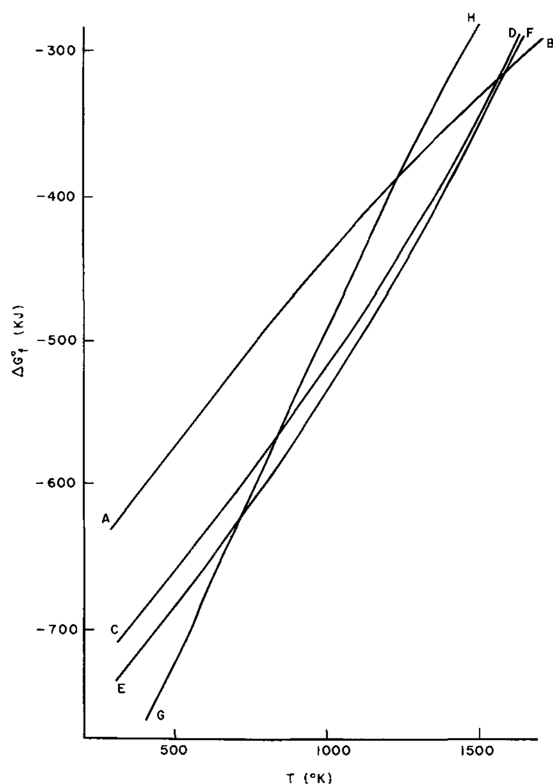

Fig. 5. AB: free energy of formation of Sb_2O_3, CD: free energy of formation of Sb_2O_3', EF: free energy of formation of Sb_2O_3'', GH: free energy of formation of Sb_2O_5.

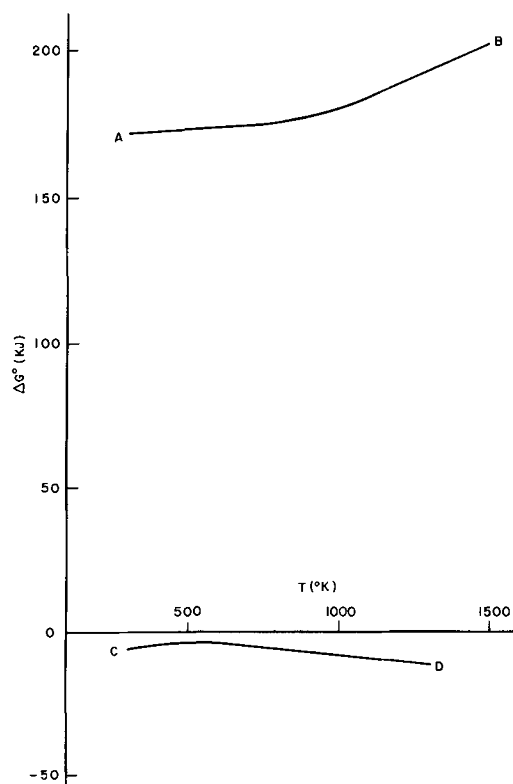

Fig. 6. AB: free energy change for 5/4 $Sb_2O_3 \rightarrow Sb + 3/4\ Sb_2O_5$, CD: free energy change for $2SnO \rightarrow Sn + SnO_2$.

Tin does not possess a similar stable group of mixed oxides. Some evidence for the existence of Sn_3O_4 has been suggested as a result of thermochemical investigations of SnO (7) and a quantity of a compound with formula Sn_5O_6 has been reported, produced by heating SnO *in vacuo* or under argon above 750°K (8). However the experiments of Niwa, Yamai, and Wada (9) suggest that such materials are composed of a mixture of SnO_2 and Sn.

So far we have considered the stability of the lower oxidization states of tin and antimony to oxidation. One must also take into account disproportionation reactions of the type

$$2SnO \rightarrow Sn + SnO_2$$

and

$$5Sb_2O_3 \rightarrow 4Sb + 3\ Sb_2O_5$$

There have been a number of reports on the stability of stannous oxide with respect to disproportionation. Platteeuw and Meyer (10) heated SnO *in vacuo* above 300°C and completely decomposed it into Sn and SnO_2. Niwa *et al.* (9) in their x-ray study found that at 550°C the decomposition was rapid and complete, but that below 500°C the kinetics were slow. On the other hand they noted that heating a mixture of Sn and SnO_2 at 400°C did not result in the production of any SnO. In Fig. 6 the standard free energy changes of the SnO and Sb_2O_3 disproportionation reactions are plotted as a function of temperature, and it is seen that solid SnO is thermodynamically unstable over the entire temperature range considered. In contrast, Sb_2O_3 is completely stable to disproportionation.

Conclusions

A number of conclusions may be drawn from the above calculations. First, since SnO is very susceptible to air oxidation nonstoichiometric semiconductors of the type $Sn^{4+}{}_{(1-\delta)}\ Sn^{2+}{}_{\delta}\ O^{2-}{}_{(2-\delta)}$ are not likely to be stable in air. Further, at high temperatures in the absence of oxygen SnO disproportionates to Sn and SnO_2. Therefore although it may be difficult but possible to make reproducible SnII/SnIV semiconductors, it is very unlikely that they will be stable in air. Several types of dopant may exist in a lattice. Nevertheless it is concluded that conducting tin oxide films formed by pyrolysis of tin (II or IV) chlorides probably owe their conductivity almost entirely to the inclusion of chloride ions in the lattice. Although the free energy change for the reaction

$$SnCl_2 + O_2 \rightarrow SnO_2 + Cl_2$$

has been calculated (3) to be −1368 kJ at 700°K, it is

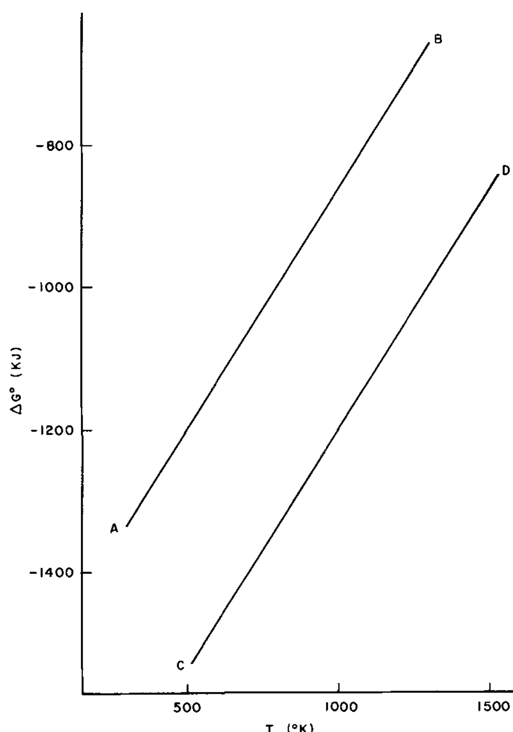

Fig. 7. AB: free energy of $2SnO + Sb_2O_5$, CD: free energy of $2SnO_2 + Sb_2O_3$.

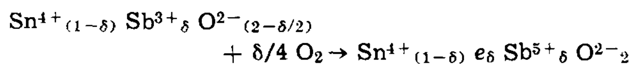
not necessary that the replacement of chloride ions by oxygen be fast. Indeed Miloslavskii noted an irreversible decrease in conductance after long baking at temperatures above 350°C, which may be due to such a slow replacement (2).

A result of the relative instability of SnO with respect to SnO_2 is that the reaction

$$2SnO_2 + Sb_2O_3 \rightarrow 2SnO + Sb_2O_5$$

is not feasible, as is seen in Fig. 7, there being a free energy increase of 335 kJ associated with the process. The equivalent redox reactions with Sb_2O_4 or Sb_6O_{13} are even less likely. This reaction must not however be confused with



$$Sn^{4+}{}_{(1-\delta)}\, Sb^{3+}{}_{\delta}\, O^{2-}{}_{(2-\delta/2)} + \delta/4\, O_2 \rightarrow Sn^{4+}{}_{(1-\delta)}\, e_{\delta}\, Sb^{5+}{}_{\delta}\, O^{2-}{}_{2}$$

the process which gives rise to the controlled valence semiconductor.

The relative stability of trivalent antimony oxide species would suggest the possibility of forming the controlled valence semiconductor rather than the complete oxidation of the antimony to Sb_2O_5.

Manuscript submitted June 20, 1971; revised manuscript received Sept. 16, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Preparation and Properties of Semiconducting Polycrystalline Tin Oxide

Colin A. Vincent and Derek G. C. Weston

Department of Chemistry, University of St. Andrews, St. Andrews, Fife, Scotland

ABSTRACT

A method is described for preparing semiconducting tin oxide by precipitation from solution. Materials subjected to heat treatment at a number of temperatures have been characterized by x-ray, spectroscopic, and conductance measurements.

There has recently been considerable interest in the electrochemical behavior of semiconducting tin oxides (1-3, *etc.*). Up until now the work has been mainly concerned with the use of thin films of this material deposited on a glass or quartz substrate. In this form electrodes have been prepared which can be used to observe electroactive species near the electrode-solution interface by internal reflectance spectroscopy in the visible region of the spectrum (2-5). Such electrodes are usually prepared by hydrolyzing a volatile tin compound, together with a suitable dopant, on a glass substrate at high temperature. A detailed method for preparing thick crystalline films in anhydrous conditions has been reported by Bartholomew and Garfinkel (6). The use of semiconductors in the form of thin films, however, has disadvantages for many applications. Further, the method of preparation makes it necessary to treat the samples at a minimum of 400°C, thus excluding investigations of the very interesting low-temperature types of semiconductor. Finally to produce exactly reproducible samples by the pyrolytic method requires considerable experimental technique. This paper describes a method of producing the semiconductors by precipitation from solution.

Verwey (7) has defined controlled valence oxidic semiconductors as oxides to whose lattices have been added a number of ions of deviating valency without the simultaneous incorporation of lattice defects, *i.e.* appropriate counterions must be included. The ions of deviating valency are substituted for the main lattice ions and thus must be of similar size and charge. Controlled valence n-type semiconductors may be prepared by substituting ions such as SbIII for the SnIV of the cassiterite lattice, or FI, or even ClI for the OII. [The conductance of SnO_2 thin films prepared by the pyrolysis of pure $SnCl_4$ is probably due entirely to residual chloride in the lattice (9, 13).] In this work we have investigated the preparation and properties of "bulk" SbIII-doped (controlled valence) and SnII-doped (nonstoichiometric) SnO_2 semiconductors.

Key words: tin oxide, semiconductivity, thermogravimetric analysis, spectroscopy.

Preparation

Antimony-doped semiconductors were prepared by the coprecipitation with ammonium hydroxide of antimony and tin hydroxides from appropriate mixtures of antimony and tin chloride solutions in HCl, followed by a washing procedure and heat treatment. SnII/SnIV semiconductors were made in a similar manner, taking particular care to exclude air from the system at all times.

Stock solutions of $SbCl_3$, $SnCl_2$, and $SnCl_4$ were prepared in HCl using "Analar" grade reagents. Volumes of these were taken to give 0.1 mole of tin oxide with a composition range of dopant of 0.1-5.0 m/o (mole per cent) for SbIII-doped samples and 1.0-5.0 m/o for SnII-doped samples. On mixing the $SnCl_4$ and dopant solutions a yellow-orange color of a solution interaction species (9, 10) was always observed. Oxygen-free nitrogen was passed through the solution to provide stirring and to prevent air oxidation of the SnII in the case of the SnIV-SnII

system. The solution was maintained at 100°C on a steam bath and 3.5% ammonia solution was added dropwise until a pH of 3.2 had been achieved. The resulting mixed hydroxide precipitate was washed alternately with NH_4NO_3 solution (to prevent peptization) and with water until the washings showed no trace of chloride ion. The precipitate was then peptized to release any further occluded chloride and recoagulated with NH_4NO_3 solution. Finally the precipitate was washed with water and filtered.

Since the presence of chloride ion was likely to seriously affect the semiconducting properties of the material, it was necessary to minimize contamination of the final product by this species. Kirkov (11, 12) favors the fast precipitation of $Sn(OH)_4$ in the cold in order to lessen the danger of occluding chloride in the precipitate. A precipitate formed in this way is, however, almost colloidal in nature, and the large surface area causes a high chloride adsorption. Since the precipitate does not settle well, it is difficult to remove the chloride-rich mother liquor right after the precipitation. With our technique, a precipitate was formed which settled well and allowed this liquor and subsequent washings to be readily decanted. The bulk of the chloride was thus removed before the precipitate was peptized and subjected to final washing. A test for chloride ion was made by refluxing approximately 1g of powdered sample of precipitate which had been dried at 45°C, in 50 ml of concentrated NaOH until it dissolved. The tin was precipitated from this solution as metastannic acid, using HNO_3, and filtered off. The resulting filtrate was tested for chloride by adding acidified 0.1M $AgNO_3$; no turbidity was found. Since it was considered very unlikely that a large proportion of any chloride ion present in the original sample would coprecipitate with the metastannic acid, it was concluded that any contamination by chloride was too low to be significant.

The yellow gel-like precipitates were dried for 48 hr at 45°C, in air for the SbIII-doped samples and under a nitrogen flow for the SnII-doped samples, to give large (0.5 cm) pieces of a transparent amber material. Samples of this material were broken up and subjected to heat treatment at temperatures from 100° to 1200°C.

Results and Discussion

Stability

It was found that all the SbIII-doped materials were completely stable and had reproducible properties throughout the composition and heat-treatment ranges investigated. On the other hand it was very difficult to prepare reproducible SnII-doped materials because (*a*) under the low oxygen partial pressures necessary to prevent oxidation there was oxygen loss from the sample and the production of variable nonstoichiometric semiconductors and (*b*) the semiconductors once prepared, especially those dried at low temperatures, varied in weight and resistivity on standing exposed to the air.

These results agree with the predictions made in the preceding study where the stability of possible semiconducting materials was considered (13).

Thermogravimetric analysis.—Samples of the clear amber material which had been held at 45°C for 48 hr were subjected to thermogravimetric analysis in a Stanton Massflow Thermobalance. In Fig. 1 the lower curve corresponds to a TGA performed at a heating rate of approximately 2°C/min up to 200°C and 4°C/min above 200°C. The points on the upper curve represent "equilibrated" weight losses occurring when samples were heated to the appropriate temperature and maintained there for periods ranging from 1 to 10 hr.

The total weight loss observed in the equilibration experiments was approximately 19%; this took place

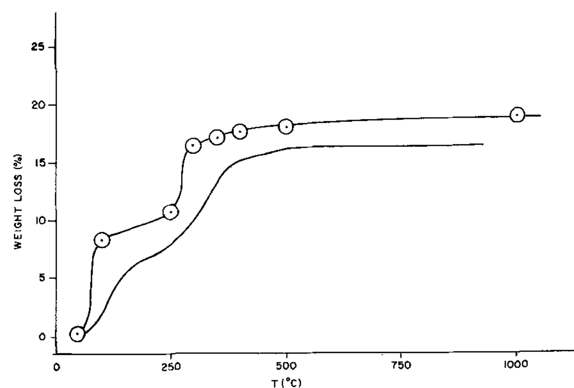

Fig. 1. Upper curve: equilibrated weight loss; lower curve: TGA scan.

in two stages, an initial loss of 8% by 100°C and a second 11% step, most of which was over by 300°C. The height of the first step varied slightly from sample to sample.

The first step corresponds to the loss of ≤ 1 mole of water per mole of SnO_2, together with small quantities of impurity such as NH_4NO_3 retained from the washing stages. Differences in the height of this step may be explained as due to a variable quantity of water being retained in the samples dried at 45°C. The 11% loss observed in both TGA and equilibration experiments agrees well with the loss of 1 mole of water per mole of SnO_2, *i.e.* with the conversion

$$SnO_3H_2 \rightarrow SnO_2 + H_2O$$

reported by Giesekke, Gutowsky, Kirkov, and Laitinen (11). (In an NMR investigation these authors showed that this compound could not be written simply as $SnO_2 \cdot H_2O$.)

In detail however, the present TGA behavior is completely different from that reported by the above authors, who found a series of four distinct dehydration steps over the temperature range 100°-700°C, corresponding to the scheme

$$SnO_3H_2 \rightarrow Sn_2O_5H_2 \rightarrow Sn_4O_9H_3 \rightarrow Sn_8O_{16}H_2 \rightarrow SnO_2$$

The absence of these additional compounds in our work is further confirmed by the x-ray results reported below.

X-ray diffraction.—X-ray diffraction measurements were carried out on powdered samples of semiconductors which had been prepared at different temperatures, using an x-ray spectrometer and Philips PW 1049 diffraction goniometer. The quantity of Sb present was too small to affect the diffraction pattern.

In all cases a cassiterite pattern was produced: this was well developed for the samples treated at the higher temperatures, but even for the 45°C samples strong broad lines were present corresponding to d-spacings of 0.335, 0.264, 0.176, and 0.149 nm. This would imply that even the glassy, highly hydrated low-temperature form contained considerable regions of SnO_2 structure. The diffraction pattern of a 500°C sample is shown in Fig. 2 as a plot of diffracted intensity against 2θ for copper K_α radiation. Peaks corresponding to d-spacings of 0.335, 0.264, 0.237, 0.176, 0.167, 0.159, 0.149, and 0.141 nm may be clearly seen,

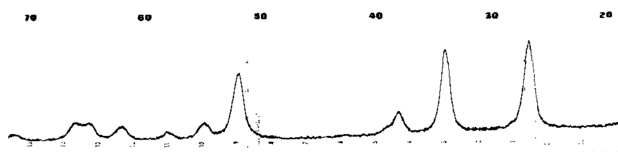

Fig. 2. Diffracted intensity of 500°C sample vs. 2θ for CuK_α radiation.

and the results are similar to those obtained for 500°C material by Niwa, Yamai, and Wada (14). Such behavior, however, contrasts markedly with the electron diffraction results of Giesekke *et al.* (11), which seem to indicate the existence of different crystalline substances formed by heating to different temperatures. For instance the d-spacings reported for their 520°C sample were 0.239, 0.199, 0.189, 0.172, 0.166, 0.156 and 0.141, 0.129 nm *etc.*, the majority of which are not to be found in cassiterite. There is even less correspondence for lower temperature samples.

The very presence of x-ray diffraction lines indicated that the semiconductors were microcrystalline in nature rather than glasses. The mean size of the microcrystals was investigated by considering the diffraction broadening of the peaks corresponding to the 110 and 101 planes. The peaks were approximately Gaussian, with half-widths in the range 0.25°-3.25°C. Measurements were first made on the peaks at 19° 9′ and 22° 20′ of an aluminum dust standard. It was assumed that the latter had such large crystals that diffraction broadening would be absent, and thus a measure of instrumental broadening was obtained. Jones' conversion curves (15, 16) were then used to determine the pure diffraction broadening of the SnO_2 peaks. The mean dimension of the microcrystals, D, was calculated using Scherrer's formula

$$D = \frac{0.9\,\lambda}{\beta_{1/2}\cos\theta}$$

where $\beta_{1/2}$ is the corrected width of the diffraction peak at half height, λ is the wavelength of the x-ray, and θ is the diffraction angle. Since the uncertainty in determining the diffraction broadening increases with increasing crystal size, D values for the high temperature samples are not very accurate. Results of the measurements (made on 1 m/o Sb semiconductors) are given in Table I.

Spectroscopy

A spectroscopic examination was carried out on equilibrated samples of 1 m/o antimony-doped tin oxides.

Visible region.—The color of the material heated to various temperatures is given in Table II.

Reflectance spectra using a freshly prepared MgO standard were obtained using a Unicam SP 300 spectrometer and are shown in Fig. 3. From these it is seen that the high-temperature specimens have a considerable absorption of energy at the red end of the spectrum, extending into the infrared. The origin of such absorption is considered below. Low-temperature samples have little absorption at long wavelengths, but

Table I. Results of measurements made on Sb semiconductors

Preparation temperature	Plane	Measured width	Corrected width	D (nm)
45°C	110	3.2° ± 0.1°	3.2°	2.5 ± 0.3
	101	3.0° ± 0.1°	3.0°

strong absorption in the violet. In pure SnO_2, optical excitation of electrons to the conductance band occurs at wave numbers greater than 30,000 cm^{-1} (17, 18), *i.e.* there is a large forbidden gap. Arai (17) has shown that the absorption edge may move to shorter wavelengths in conducting oxides if the bottom of the conduction band is occupied, so that transitions must take place from the valence band to higher levels than the ground level of the latter. In the presence of antimony, one must also consider transitions from antimony to tin levels.

In solution a SnIV/SbIII species was formed which gave rise to "interaction absorption" in the blue similar to that investigated by Whitney and Davidson in SnIV/SnII and in SbV/SbIII systems. Recently the origins of such interaction absorption have been examined by Robin and Day (19). As might be expected the highly hydrated sample (45°C) had an absorption similar to that of the SnIV/SbIII solution.

Infrared.—Spectra of 1% KBr disk samples of material dried below 300°C contained a large absorption band corresponding to water and to NH_4^+ and NO_3^- from the washing electrolyte which had not been completely removed. These bands were absent from samples dried at over 500°C, but these samples showed instead a broad transmission loss from 1000 cm^{-1} to 4000 cm^{-1} with a maximum loss near 2000 cm^{-1}. The intensity of this band increased with the temperature at which the sample had been treated.

This large drop in transmission is similar to that observed by Miloslavskii (8) in pyrolytically decomposed $SnCl_2/SnCl_4$ mixtures where a wide band in the 700-5000 cm^{-1} region centered at 1200 cm^{-1} was noted. This band was attributed to electronic transitions from the ground state of impurity centers to an excited state, such as transitions to the conduction band. Arai, Imai, and co-workers (20) also investigated pyrolytic antimony-free semiconductors. Free electrons are able to absorb energy from electromagnetic radiation only when they can interact with a crystal lattice, so that the transfer satisfies conservation both of energy and momentum. Since the absorption is a function of electron-lattice interaction frequency, it is closely connected with the conductance of the crystal. Free electron absorption or plasma oscillation increases monotonically with frequency (for a constant number of carriers and specific conductance). Although Arai *et al.* claim to have found such behavior, close examination of their results would seem to show a minimum in the transmission at about 1300 cm^{-1}. Miloslavskii (18) also went on to investigate antimony-doped films and reported a further marked decrease in the transmission above 10,000 cm^{-1}. Here the transmission did fall monotonically, *i.e.*, it was apparently due to free electron absorption.

The present results are not consistent with plasma oscillation. Rather it is suggested that the band arises

from promotion of electrons from antimony ground-state levels high in the SnO_2 forbidden band to the conduction band. The presence of the band in samples heated to 500°C and above parallels the greatly increased conductance of these samples.

Far infrared.—An absorption band in the 30-45μ region was observed for all samples, including those dried at low temperatures. This absorption corresponds to the tin-oxygen lattice vibrations reported at 33 and 39μ for SnO_2 by Ishiguro *et al.* (21). These authors point out that there is no further optical absorption at shorter wavelengths than 33μ due to lattice vibration.

We however have noticed an additional broad band in the 14-25μ region. This band is also present in natural cassiterite and in commercial SnO_2 (Fisons Ltd., reagent grade). Since this absorption was not affected by the heat-treatment of the sample nor by the presence or absence of antimony, it is not connected with the band observed by Miloslavskii (8) centered at 16.4μ and shown to be due to excitation of impurity centers. Sn-O vibrations are known in this region, for instance in tin alkoxides (22) and have been reported (23) in the region from 15.4 to 23.5μ for Sn-O-Sn vibrations in polymeric species formed from alkyl tin halides. Further, Dupuis (24) has reported tin oxide absorption bands at 16.1, 21.0, and 29.4μ.

Conductance.—D-C conductances were found of samples which had been powdered in an agate ball mill and enclosed under pressure between steel electrodes in an insulating former for the purpose of the measurement. The apparatus for this measurement will be described elsewhere (25). Resistivities of specimens of 1 m/o antimony-doped SnO_2 prepared at different temperatures and measured at room temperatures are shown in Fig. 4.

Verwey (7) has pointed out that there is a special problem in the study of the conductance of polycrystalline semiconductors, namely the existence of grain boundaries within each particle of the material, which greatly affects the impedance behavior. In the simplest cases there are layers of increased resistance due to air gaps between the grains; while in more complex situations, the chemical constitution of the surface layers may differ from the bulk of the microcrystal. Thus the d-c conductance (although completely reproducible) has only relative significance and is likely to be much lower than the "true" conductance of the material, which may only be determined at very high frequencies.

The nature of the conductance in completely dehydrated tin oxide has been investigated by a number of workers, and it is generally accepted that the position of the antimony level with respect to the conduction band is such that there is no restriction to transfer of electrons to the latter. The electrical resistance within the microcrystal is thus due entirely to electron scattering. This theory is confirmed by the findings that the temperature coefficient of conductance is relatively low and, as with metals, the conductance falls as the temperature rises. Arai (17) noted that for antimony-doped SnO_2 the conductance fell when the doping rose above 1% due to increased scattering by the impurity centers.

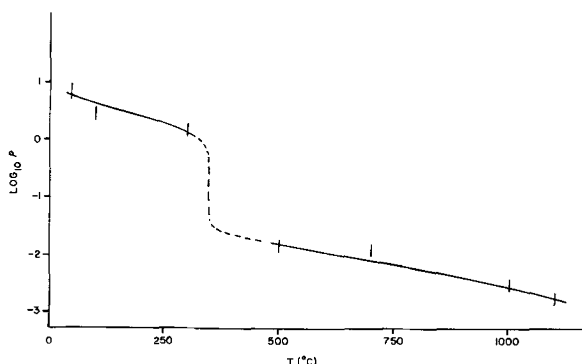

Fig. 4. Graph of $\log_{10}\rho$ measured at room temperature, against temperature of heat treatment.

From Fig. 4 it is seen that the conductance of samples having different heat treatments falls into two distinct regions. Samples equilibrated below 250°C had high specific resistances, of the order of 1-10 ohm-m, while those treated above 500°C were below 0.02 ohm-m. The sudden drop in resistance corresponds to the elimination of the majority of the water from the material, *i.e.*, to the conversion of SnO_3H_2 to SnO_2. This finding is understandable since water is not a bridging ligand and when present in large quantities tends to form an insulating system.

The slow rise in conductance in samples treated from 500° to 1200°C may be attributed to the increase in the size of the microcrystals (discussed above in the section on X-ray diffraction) and to the consequent reduction of grain boundary impedance.

Acknowledgment

We wish to thank the Department of Geology, University of St. Andrews for carrying out the x-ray diffraction measurements.

Pseudo-Brewster Angle Concentration Determination: Apparatus, Reproducibility, and Accuracy

W. A. Keenan,* C. J. Liu, and C. P. Schneider

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The angle of incidence at which the parallel component of polarized infrared reflected light attains a minimum (the pseudo-Brewster angle, or PBA) is used to determine semiconductor carrier concentrations. A PBA apparatus using a 3.391 He-Ne laser as a polarized light source is described. Experimental results for n- and p-type silicon are compared with plasma resonance and sheet resistance measurements to determine best fit of theoretical calibration curves. Results of reproducibility and correlation studies are also presented.

Optical techniques, such as infrared interference and plasma resonance for example, are very attractive for characterizing processed semiconductor material because they are in general nondestructive and contactless (1). The Brewster angle, the angle of incidence at which the parallel component of reflectivity goes to zero, has long been used to determine the index of refraction of nonabsorbing material. Semiconductors and other absorbing materials exhibit a nonzero minimum at a "pseudo-Brewster" angle which depends on the wavelength of the incident light and the optical constants of the material. Since the semiconductor optical constants are strongly dependent on the free carrier density (2), the pseudo-Brewster angle is an indication of this density.

Theory

The variation of polarized monochromatic infrared reflectivity with angle of incidence can be used to determine the carrier concentration of a semiconductor. The reflection coefficients for the parallel and perpendicular components of polarized reflectivity for an infinitely thick homogeneous material are approximately (3)

$$R_p(\theta) = \frac{(n^2 + k^2)\cos^2\theta - 2n\cos\theta + 1}{(n^2 + k^2)\cos^2\theta + 2n\cos\theta + 1} \quad [1]$$

and

$$R_s(\theta) = \frac{(n^2 + k^2) - 2n\cos\theta + \cos^2\theta}{(n^2 + k^2) + 2n\cos\theta + \cos^2\theta} \quad [2]$$

respectively, where θ = angle of incidence, n = index of refraction, and k = extinction coefficient. These approximations are accurate for $n^2 + k^2 > 1$, which is always the case for semiconductors in the infrared region of the spectrum. $R_s(\theta)$, the component of polarized reflectivity with electric vector perpendicular to the plane of incidence, increases monotonically as the angle of incidence increases from 0° to 90°. $R_p(\theta)$, the component of polarized reflectivity with electric vector parallel to the plane of incidence, exhibits a minimum at an angle θ_B

$$\theta_B = \cos^{-1}\frac{1}{(n^2 + k^2)^{1/2}} \quad [3]$$

For a nonabsorbing material where $k = 0$, substitution of Eq. [3] into [1] will yield $R_p(\theta_B) = 0$. The Brewster angle for a nonabsorbing material is defined as the angle at which the parallel component of polarized reflectivity goes to zero.

For a noninsulating or semiconducting material which has a nonzero extinction coefficient k, the minimum in the parallel component of reflectivity is not zero, but

$$R_p(\theta_B) = \frac{(n^2 + k^2)^{1/2} - n}{(n^2 + k^2)^{1/2} + n} = \frac{1 - n\cos\theta_B}{1 + n\cos\theta_B} \quad [3a]$$

The angle at which this parallel component of reflectivity attains its nonzero minimum is defined as the pseudo-Brewster angle (PBA). Figure 1 shows curves of calculated $R_p(\theta)$ and $R_s(\theta)$ for n-type silicon with an impurity concentration of $N = 1 \times 10^{19}$ cm^{-3}, a d-c resistivity of $\rho_0 = 6.9 \times 10^{-3}$ ohm-cm for a wavelength of $\lambda = 3.391$ using the free carrier infrared optical constant model of Schumann and Phillips (4), an assumed effective mass ratio $a = m^*/m = 0.26$, and an assumed relative lattice dielectric constant (no free carrier contribution) $K_L = \epsilon_L/\epsilon_0 = 11.7$. $R_p(\theta)$ appears to go to zero on the linear reflectivity scale used, but the insert showing the logarithm of $R_p(\theta)$ around θ_B shows that this minimum is indeed not equal to zero.

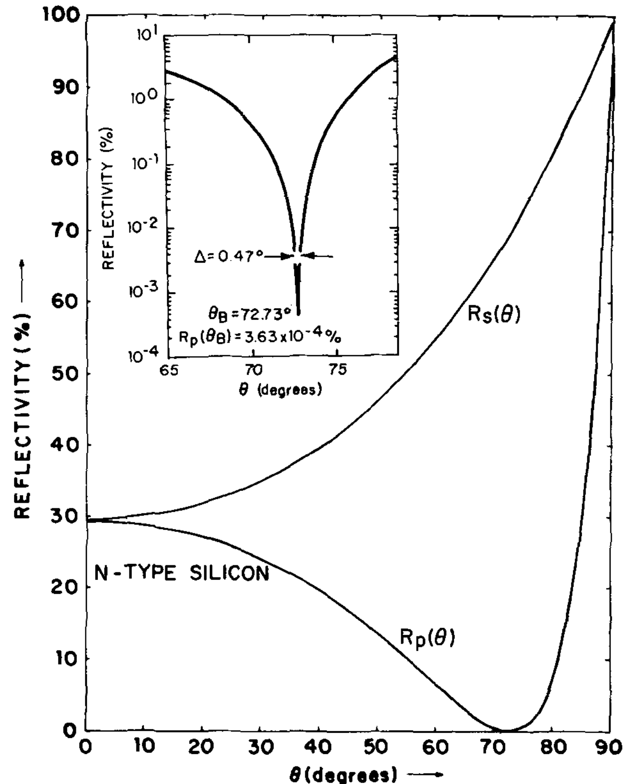

Fig. 1. Theoretically calculated $R_p(\theta)$ and $R_s(\theta)$ for n-type silicon with $N = 1 \times 10^{19}$ cm^{-3} at $\lambda = 3.391$ μm. Insert shows log $R_p(\theta)$ around θ_B.

Key words: semiconductor carrier concentration, polarized infrared light, silicon, Brewster angle, plasma resonance.

The PBA depends on n and k, the optical constants of the material. In the infrared region of the spectrum the optical constants of a semiconductor are strongly dependent on the free carrier density of the material. The above infrared optical constant theory relates n and k to the impurity concentration N and to the d-c resistivity ρ_0 of the material (4). These formulas can be schematically represented

$$\left.\begin{aligned} n &= \mathbf{F}_1\left(\frac{N}{a}, \rho_0, K_L, \lambda\right) \\ \text{and} \quad k &= \mathbf{F}_2\left(\frac{N}{a}, \rho_0, K_L, \lambda\right) \end{aligned}\right\} \quad [4]$$

where N = impurity concentration, ρ_0 = d-c resistivity, $K_L = \epsilon_L/\epsilon_0$ = relative lattice dielectric constant, $a = m^*/m$ = effective mass ratio of majority carrier, and λ = wavelength of radiation. The optical constants are thus dependent on the ratio of the impurity density divided by the effective mass ratio.

Calibration curves relating θ_B, the PBA, to N, the impurity concentration, have been calculated using the above formulas. Clearly N and ρ_0 are not independent, and for this work their relationship was assumed to be given by Irvin's (5) curves. Figure 2 shows a family of calibration curves for n-type silicon for several wavelengths with assumed values of $K_L = 11.7$ and $a = 0.26$. The strong dependence of these calibration curves on wavelength reflects the strong dependence of the optical constants n and k on wavelength. As concentration decreases, all the calibration curves approach 73.00°, the PBA for intrinsic silicon for the assumed value of $K_L = 11.7$. For values of PBA less than the intrinsic PBA, N is not a single-valued function of θ_B. For short wavelengths, the concentration range over which N is a single-valued function of θ_B is small, but θ_B is very sensitive to N for this range of concentration. As wavelength increases, the sensitivity of θ_B to N decreases but the single-valued range of N increases. This problem of N being a double-valued function of θ_B for θ_B less than the intrinsic PBA can be overcome by using two wavelengths, by observing the sharpness of the minimum around θ_B, or by monitoring $R_p(\theta_B)$ or $R_s(\theta_B)$ (6). Note that the lower limit concentration that can be detected by PBA depends only on the wavelength employed; the longer the wavelength, the lower the detectable limit of concentration. The wavelength employed in this investigation of the PBA concentration determination technique was 3.391 μm, the output of a He-Ne laser with special resonator windows. This proved to be a most convenient source of monochromatic polarized infrared light.

The PBA calibration curves for $\lambda = 3.391$ μm are shown in Fig. 3A and 3B for silicon. Figure 3A is for

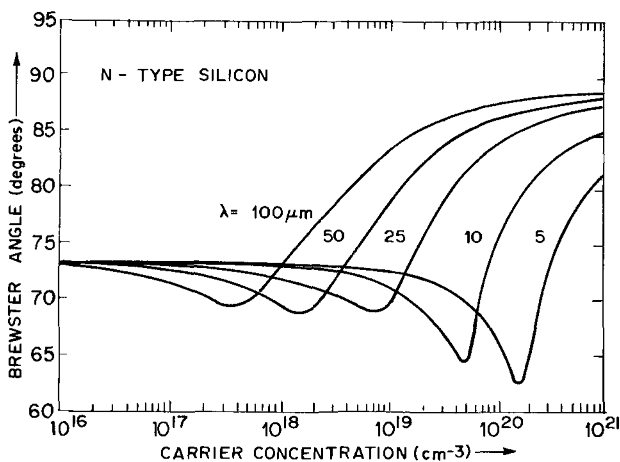

Fig. 2. Family of pseudo-Brewster angle calibration curves for n-type silicon, calculated assuming $K_L = 11.7$ and $m^*/m = 0.26$.

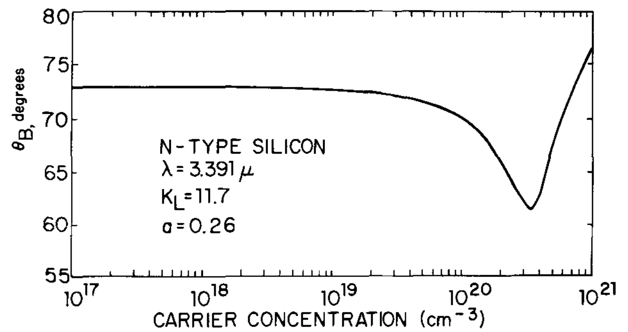

Fig. 3A. PBA calibration curves for $\lambda = 3.391$ μm for n-type silicon.

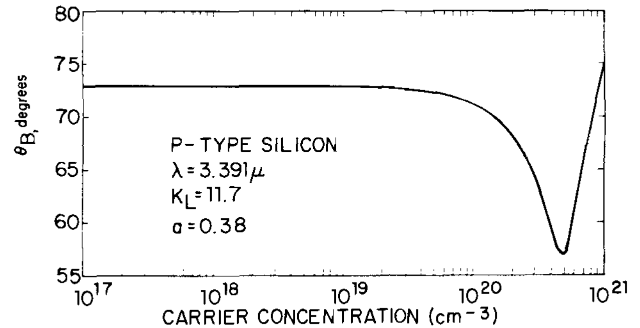

Fig. 3B. PBA calibration curves for $\lambda = 3.391$ μm for p-type silicon.

n-type silicon and an assumed value of $K_L = 11.7$ and $a = 0.26$. Figure 3B is for p-type silicon with an assumed value of $K_L = 11.7$ and $a = 0.37$. Figures 4A and B emphasize the dependence of these calibration curves on the assumed values of a and K_L. Figure 4A shows θ_B *vs.* N for n-type silicon for $K_L = 11.7$ and several assumed values of a. Since it is the ratio N/a that appears in the optical constant formulas, an increase in a is equivalent to a decrease in N and has the effect of shifting the calibration curves to higher concentration. Thus a shift in N or a horizontal shift in the calibration curve is obtained by increasing a. A shift in θ_B or a vertical shift in the calibration curve is obtained by changing K_L, the relative lattice dielectric constant. This is demonstrated in Fig. 4B, which shows a family of θ_B *vs.* N calibration curves for p-type silicon for $a = 0.38$ and several assumed values of K_L. Clearly a change in K_L will change θ_B, since as N approaches zero, k approaches zero, and

$$n = (K_L)^{1/2} \quad [5]$$

Thus, Eq. [3] above reduces to

$$\theta_B = \cos^{-1}\frac{1}{n} \quad [6]$$

$$= \cos^{-1}\frac{1}{(K_L)^{1/2}}$$

where the value of the pseudo-Brewster angle for intrinsic material depends only on the relative lattice dielectric constant.

Apparatus

The apparatus for determining carrier concentration by the pseudo-Brewster angle technique consists essentially of a source of polarized infrared light, a detector, and a means of varying the angles of incidence and reflectance so that they are kept equal. The experimental setup is shown schematically in Fig. 5. The light must be polarized with the electric vector parallel to the plane of incidence, that is the plane perpendicular to the sample surface which contains the incident (and hence also reflected) beam. The beam is

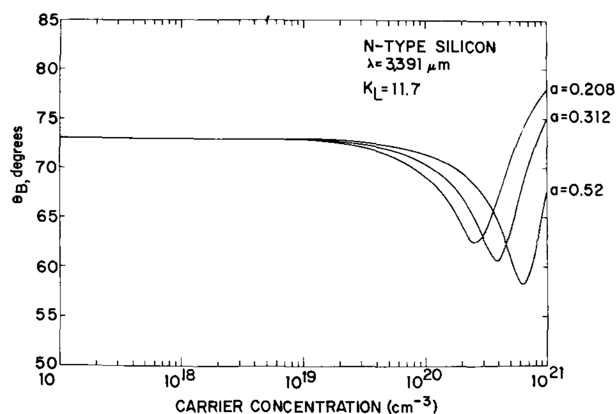

Fig. 4A. N-type silicon PBA calibration curves for $\lambda = 3.391$ μm, $K_L = 11.7$ and several assumed values of $a = m^*/m$.

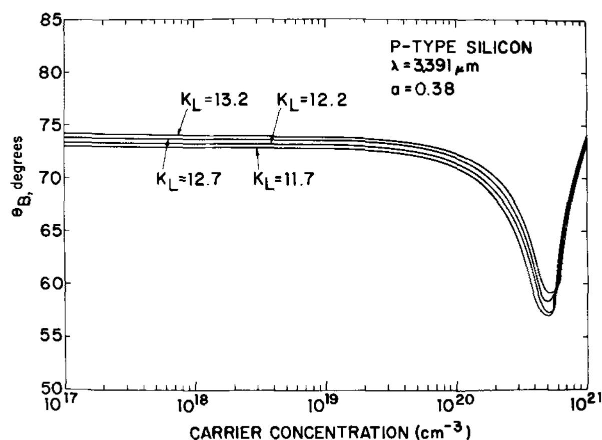

Fig. 4B. P-type silicon PBA calibration curves for $\lambda = 3.391$ μm, $a = m^*/m = 0.38$ and several assumed values of K_L.

incident on the sample surface at θ_i and reflected at θ_r to the detector which monitors the reflected light intensity as the angle of incidence and reflectance are simultaneously scanned. Figure 6 is a close-up of the laser, diffractometer, and detector system. Figure 7 shows the complete apparatus used in this work, with the X-Y recorder on top of the detector amplifier in the foreground, and the laser, diffractometer, and detector on a vibration-free table in the background.

A Spectra-Physics Model 122 He-Ne laser, adjusted to resonate at $\lambda = 3.391$ μm, was used as the polarized infrared light source. As it normally stands, this laser has its output linearly polarized with electric vector vertical to a tolerance of $\pm 5°$. At the laser exit port the beam diameter (to points where the intensity falls off to e^{-2}) is 0.4 mm. The full angle beam divergence is 1.6 milliradians. The laser was mounted on a specially designed stand with adjustments to align the optical axis of the laser with the rotational axis of the stand. This stand allowed rotation of the laser, and hence the polarization of the beam 90°, which is essential if $R_s(\theta)$, the perpendicular component of reflectivity, is to be measured as well as $R_p(\theta)$. Adjustable stops on the rotation frame allow accurate trimming of the limits of rotation, and thus the polarization.

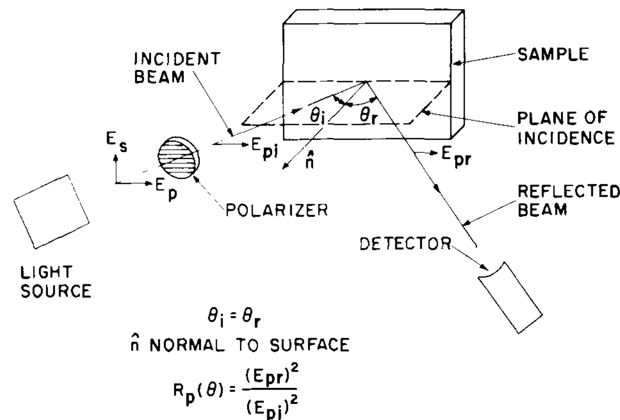

Fig. 5. Schematic of pseudo-Brewster angle apparatus

The silicon wafer mounted on the light chopper is used as a polarization filter, transmitting the light with electric vector polarized predominantly parallel to the test wafer plane of incidence. This half wafer is oriented in a plane perpendicular to the plane of incidence of the sample, and at an angle with respect to the light beam equal to its PBA. Since the PBA is the angle of incidence at which the minimum amount of parallel polarized light is reflected, it is the angle at which the maximum is transmitted for this polarization. The perpendicular polarized reflectivity is much greater at PBA, and hence its transmission is much smaller.

The Siemens diffractometer (Fig. 6) scans the angle of incidence by rotating the sample through an angle β while rotating the detector through an angle 2β, thus maintaining the angle of incidence equal to the angle of reflectance. A change in the angle of incidence as small as 0.005° can be detected with this instrument. The diffractometer is attached to the base plate of the laser-rotator stand to prevent disturbing the alignment. Much faster angular scan speeds were possible by using, instead of the diffractometer's internal drive, a variable speed motor coupled to the drive shaft of the diffractometer via a rubber hose; the hose minimized the coupling of motor vibrations into the dif-

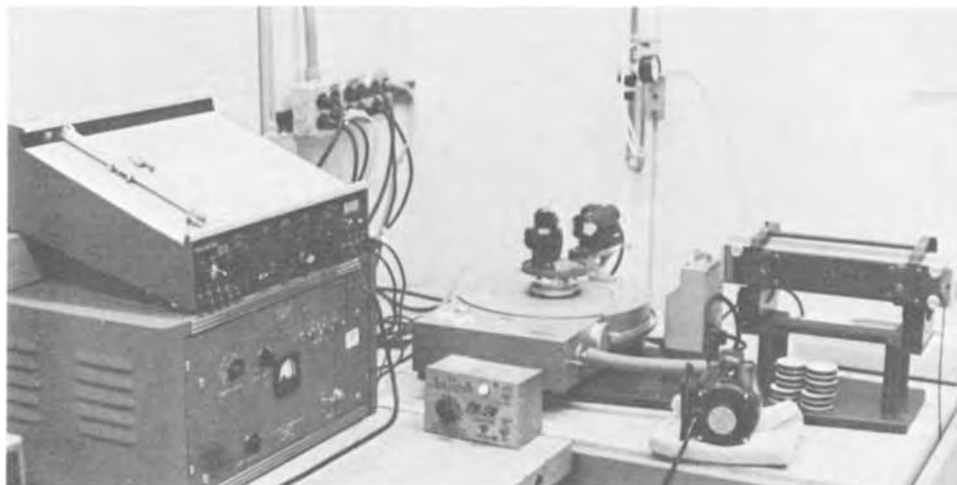

Fig. 6. PBA apparatus

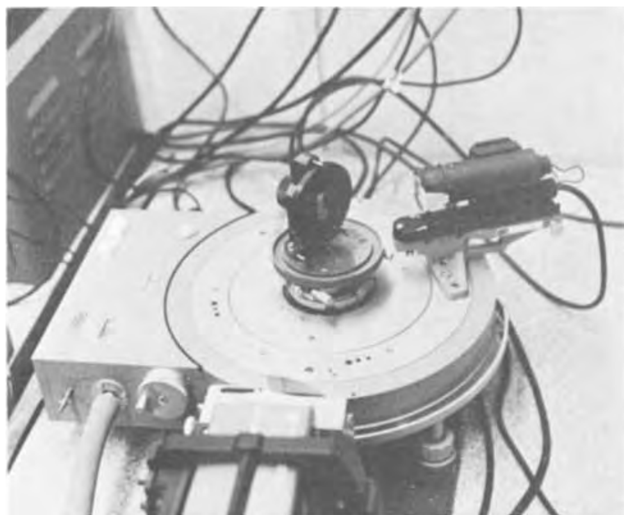

Fig. 7. Close-up of laser, diffractometer, and detector system

fractometer. Angular scan speeds of 5 to 20 degrees per minute were achieved.

An Eppley Lab Golay infrared detector was used to measure the reflected light intensity as the angle of incidence was scanned. The chopper of this detector was placed as close as possible to the output port of the laser to minimize the amount of stray chopped light reaching the detector. A silicon wafer taped to the aperture of the detector head (Fig. 6) was used to prevent visible light from reaching the detector. The Y-axis of a Hewlett-Packard Moseley Model 7000 AM X-Y recorder was used to display the output of the Golay detector, with the X-axis representing time. A capacitive discharge system in the diffractometer was used to superimpose a marker pip on the trace for every 0.5° change in the angle of incidence.

Experimental Results

Pseudo-Brewster angle measurements were made on silicon wafers doped with arsenic, boron, and phosphorus. The impurity concentrations of these bulk and diffused wafers were also measured by four-point probe and plasma resonance.

A typical detector response of reflectivity *vs.* angle of incidence is shown in Fig. 8 for a p-type silicon bulk wafer with impurity concentration $N = 2.75 \times 10^{20}$ cm^{-3} and d-c resistivity $\rho_0 = 4.52 \times 10^{-4}$ ohm-cm (plasma resonance results). The lower curve of Fig. 8 is the original scan, whereas the upper curve is that

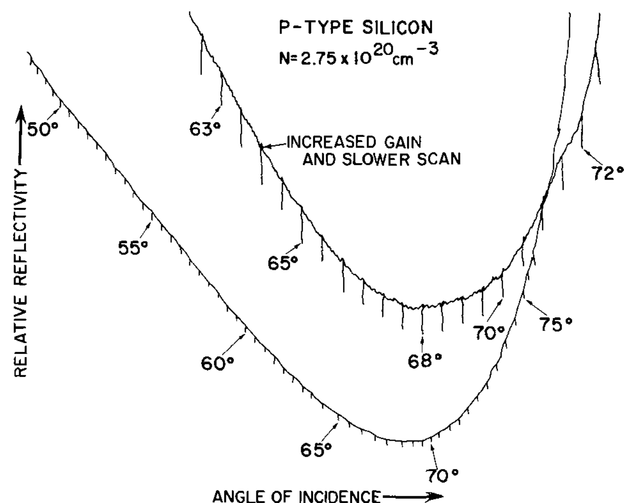

Fig. 8. Typical detector response for PBA measurement on p-type silicon bulk wafer with $N = 2.75 \times 10^{20}$ cm^{-3} at $\lambda = 3.391$ μm.

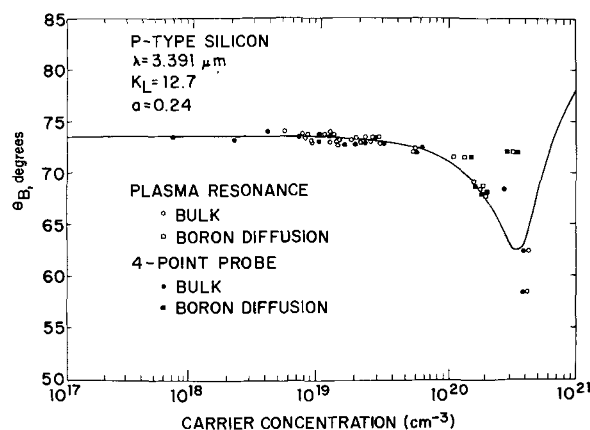

Fig. 9. Experimental results for p-type silicon samples and best fit theoretical calibration curve.

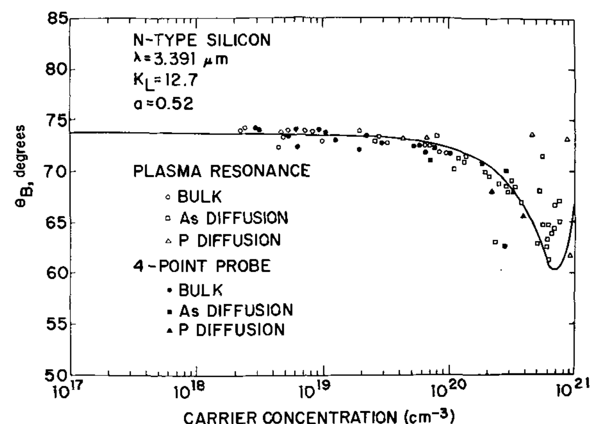

Fig. 10. Experimental results for n-type silicon wafers and best fit theoretical calibration curve.

which was recorded at increased detector gain and slower angular scan speed. Every half degree of angle of incidence is indicated by the marker pip superimposed on the trace.

The experimental results for n- and p-type silicon are shown in Fig. 9 and 10, where the experimentally determined PBA is plotted against the impurity concentration determined by either plasma resonance or four-point probe. The data points on these figures indicate the reference method of concentration determination, whether the sample is a bulk or diffused wafer (Fig. 9); and for n-type material they also indicate the dopant used, arsenic or phosphorus (Fig. 10). The data represented in these figures were used to determine the best values of the relative lattice dielectric constant K_L and the effective mass ratio a for use in calculating the theoretical calibration curves. The lower concentration data were first used to determine K_L, and then a was determined to obtain the best fit of the higher concentration data. The best fit theoretical PBA calibration curve for n-type silicon uses $K_L = 12.7$ and $a = 0.52$ (Fig. 9). The best fit theoretical PBA calibration curve for p-type silicon uses $K_L = 12.7$ and $a = 0.24$ (Fig. 10). It must be emphasized that a constant value of a was used to fit the data for each conductivity type. But since effective mass is known to vary with concentration at high impurity levels, a varying a should perhaps have been employed.

A correlation analysis was made of the measured PBA and that predicted by the theoretical calibration curves shown in Fig. 9 and 10. The correlation coefficient for all 87 n-type data points was 0.832. The correlation coefficient for all 66 p-type data points was 0.779. The confidence level, or T-value, for both are very good, as shown in Table I.

Table I. Correlation analysis

Samples	Number	Correlation coefficient	T-value
All n-type	87	0.832	13.82
N-type $\Delta\theta_B$ <3°	73	0.960	28.76
All p-type	66	0.779	9.94
P-type $\Delta\theta_B$ <4.5°	60	0.971	30.97

However, there are good reasons for disregarding some of the data points shown in Fig. 9 and 10:

Plasma resonance is known to be inaccurate on very thin diffusions (7) due to penetration of the light into the diffused layer and reflection from regions with concentration lower than the surface.

The resistivity determined by the four-point probe technique depends on accurate determination of the junction depth (7), which is extremely difficult for thin diffusions.

On wafers where both measurements were made, the plasma resonance and four-point probe concentration results differed by an average of about 30%, and in some cases by more than 100%.

Irvin's curves (5), which were used to determine the impurity concentration from the four-point probe sheet resistivity, are inaccurate at the high concentrations.

If the high concentration samples, where the measured PBA differs with the theoretical PBA by more than several degrees, are excluded from the linear regression analysis, much higher correlation coefficients are obtained. For the 73 n-type samples with $\Delta\theta_B < 3°$ the correlation coefficient is 0.96 with a confidence level, or T-value, of 28.76. For the 60 p-type samples with $\Delta\theta_B < 4.5°$, the correlation coefficient is 0.97 and the T-value is 30.97. These results indicate that the theoretical model of the PBA determination of concentration is accurate. The results are surprisingly good when it is considered that the model assumes an infinitely thick (no reflection from the back surface) and homogeneous sample (no variation of the optical constants with depth).

Table II. Reproducibility study

Sample	N-type	P-type	P-type
	$N = 3.16 \times 10^{19}$ cm^{-3}	1.01×10^{20} cm^{-3}	2.75×10^{20} cm^{-3}
Mean θ_B	73.97°	71.76°	68.47°
Range	1.0°	1.4°	1.0°
Standard deviation	0.253°	0.344°	0.348°

A reproducibility study, the results of which are shown in Table II, was made using three different wafers. Forty different PBA determinations were made for each wafer on different days. The standard deviation for all three wafers was less than 0.35° (or 0.6%) with a range of less than 1.5° (or 2%), indicating that the PBA technique is highly reproducible.

Conclusions

While the theoretical calibration curves with adjusted values of relative lattice dielectric constant and effective mass ratio agree very well with the experimental results, this agreement could perhaps be improved by introducing a variable effective mass ratio at high values of concentration.

The accuracy with which the PBA technique can determine carrier concentration for a particular semiconductor depends both on the sharpness of the reflectivity minimum (that is, the ease of determining the PBA) and also on the sensitivity of PBA to N on the calibration curve. For a given wavelength, the sharpness of the reflectivity minimum increases as concentration decreases, but the minimum is easily read at high concentration, as shown in Fig. 9.

Since the calibration curve of PBA *vs.* concentration is nonlinear and double-valued, the sensitivity of PBA to changes in N depends both on the range of concentration being investigated and the wavelength employed, as shown in Fig. 2. Once a concentration range is specified (by a particular diffusion process, for example), a wavelength can be chosen to yield the required sensitivity and accuracy. This feature of the pseudo-Brewster angle technique makes it an ideal process monitor.

Phase Transformations in Eutectic Gold-Silicon Alloys on Single-Crystal Silicon

E. Philofsky,* K. V. Ravi, J. Brooks, and E. Hall

Motorola Semiconductor, Phoenix, Arizona 85008

ABSTRACT

Phase transformations in eutectic gold-silicon alloy thin films on single-crystal silicon substrates have been studied as a function of the rate of cooling from the melt by utilizing metallography, resistivity measurements, and x-ray and electron diffraction. Cooling at rates $<10^3$ °C/sec results in the eutectic structure, which becomes finer with increased rate of cooling. The silicon is found to nucleate and grow epitaxially from the substrate silicon with different shapes and orientations depending on the orientation of the substrate. At cooling rates $>10^3$ °C/sec the eutectic transformation is suppressed, and metastable structures are obtained. Isothermal annealing studies show that the reversion of the metastable structures on heating occurs via a series of both diffusionless and diffusion-controlled transformations.

Gold-silicon alloys are commonly used in semiconductor devices for bonding silicon dice to packages. The alloy is either a eutectic preform which is sandwiched between the bare silicon and the package, or is developed by depositing gold on the silicon and alloying above the eutectic temperature (370°C). During the bonding process the alloy can be slowly furnace cooled or rapidly quenched on a cold plate or in water. Despite the extensive use of this eutectic solder, little work has been published on phase transformations in this alloy. Heath (1) has determined the eutectic composition to be 18.6 a/o (atomic per cent) silicon by metallography. The eutectic structure is composed of pure gold and silicon as there is negligible mutual solubility of the components (2). Several investigators (3-7) have reported obtaining metastable cubic phases and amorphous structures in gold-silicon alloys cooled at rates greater than 10^6 °C/sec. However, no work has been reported on the phase transformations encountered in eutectic gold-silicon alloys cooled from the melt at commercially obtainable cooling rates. The present study is intended to fill this void.

Experimental Procedure

To prepare the gold-silicon alloys, 1-5 μm layers of 99.99% gold were evaporated onto 150 μm thick single-crystal silicon wafers of (100) or (111) orientation. The wafers were etched in HF solution prior to evaporation to remove any oxide which may have formed on the surface. The gold-deposited wafers were alloyed on a graphite strip heater at 400°C as monitored by a Chromel-Alumel thermocouple. The liquid alloys on both (100) and (111) silicon substrates were cooled at various rates up to 5°C/sec by reducing the power to the strip heater. Faster cooling rates were obtained by quenching with compressed N_2 gas or in water. These cooling rates were estimated by assuming Newton's law of cooling (8).

The alloy structures obtained on the two substrate orientations at various cooling rates were examined directly using optical metallography, resistivity measurements, and x-ray diffraction. The resistivity was measured using a four-point probe. Phase identifications were confirmed using a Norelco x-ray diffractometer with CuK_α radiation. The orientation of the silicon in the alloy specimens was determined by Laue x-ray diffraction techniques.

For cooling rates higher than 10^3 °C/sec, metastable structures were obtained. To study the reversion of these structures to equilibrium gold and silicon phases, beams 3 $\times$ 0.3 cm were cut from the silicon wafers and mounted on a hot plate for aging studies conducted at fixed temperatures between 25° and 200°C. A Chromel-Alumel thermocouple pressure-mounted to the specimen monitored the temperature, which was stable to $\pm$ 2°C. Resistivity changes during aging were continuously monitored with a four-point probe accurate to $\pm$ 1.5%. X-ray diffractometer studies were also conducted on several samples at different intervals of aging.

Experimental Results and Discussion

Eutectic structures (cooling rate $<10^3$ °C/sec).—Typical microstructures obtained at various cooling rates up to 150°C/sec on (111) and (100) silicon substrates are illustrated in Fig. 1 and 2, respectively. The

structures consist of geometrically shaped pillars of silicon growing from the substrate in a matrix of gold. The pillar size and the interpillar spacing decrease as the cooling rate increases. This effect has been observed previously for a variety of eutectic morphologies (9). The shape of the silicon pillars is determined by the substrate orientation. Pillars on (111) substrates have triangular and plate-like cross sections with perimeters strongly oriented in <110>, while the morphology of pillars on (100) substrates consists of squares and rectangles with perimeters also oriented in <110>. Laue patterns show that these eutectic silicon pillars grow epitaxially from the substrate, while the gold is randomly oriented.

It can be observed by comparing microstructures for identical cooling rates in Fig. 1 and 2 that nucleation of the eutectic occurred much more rapidly on (100) silicon. Comparable interpillar spacings are obtained by cooling at 150°C/sec on (100) and 5°C/sec on (111). Because of the slow nucleation of the epitaxial eutectic, at cooling rates faster than 5°C/sec on (111) substrates sufficient undercooling can be achieved for pure gold dendrites to nucleate independently of the substrate and grow within the melt. The remaining silicon-rich liquid in these specimens still grows epitaxially with the very fine pillar size and interpillar spacing characteristic of the greater undercooling. Cooling rates faster than 150°C/sec were necessary for nucleation of gold dendrites on (100) substrates.

From these experimental observations, a model can be postulated for the solidification of the eutectic. The eutectic nucleates at the silicon substrate and grows toward the surface (in the direction of heat flow) with silicon as the primary phase. The silicon grows epitaxially with (111) sidewalls and the symmetry being governed by the substrate orientation (Fig. 3). Since the (111) sidewalls are not orthogonal to (100) or (111) substrates, the sidewalls grow at obtuse or acute angles depending on the local availability of silicon. The pure gold liquid between these silicon pillars solidifies with many nuclei in a polycrystalline array. Since the nucleation and growth of epitaxial silicon is more rapid on (100) substrates, for a given cooling rate coarser structures result on (100) than on (111) substrates.

The epitaxial growth of the gold-silicon eutectic occurs only for thin films on a silicon substrate. Bulk gold-silicon eutectic nucleated from the melt in a graphite crucible is illustrated in Fig. 4. The silicon grows as a discontinuous precipitate yielding a structure similar to that observed for Al-Si eutectic (9).

Metastable structures (cooling rate $>10^3$ *°C/sec).*— For cooling rates faster than ~1000°C/sec, the macroscopic appearance of the eutectic was silver instead of the gold color obtained at slower rates. Microscopically, the structure appears under polarized light to be composed of many small grains of a single phase with no evidence of gold or silicon. The resistivity of the silver phase is ~100 μohm-cm, two orders of magnitude higher than that for normal gold-silicon.

The x-ray peaks obtained from a diffractometer trace of this phase are listed in Table I. Luo, Klement, and Anantharaman (5) had previously studied Au-Si alloys quenched at extremely fast rates. They reported a distribution of two phases, both fcc, depending on the initial atomic per cent silicon in the alloy. Predecki, Giessen, and Grant (6) found a rapidly quenched eutectic alloy to have a bcc γ-brass structure. Columns 3-6 of Table I indicate which of the observed peaks can be assigned to silicon, gold, or the reported metastable phases. It is seen that the peaks of the γ-fcc metastable phase most closely match those found in our work. However, several other lines cannot be indexed.

To study the quenched films further, electron microscopy and diffraction were utilized. The electron diffraction patterns showed that the structure was much

Fig. 4. Optical micrograph of bulk gold-silicon eutectic alloy. Magnification X800.

more complicated than previously believed. It was impossible to index these patterns on the basis of any of the reported cubic structures (5, 6). All indications are that the structure has a lower symmetry. Aging the quenched films indicated that the reverse transformation to equilibrium gold-silicon proceeds through the formation of a faulted structure. The faulted phase is also found if the water quench is inefficient, indicating the possibility that a finite amount of the faulted phase is present in the quenched films. This fact may account for the strong intensities seen at d spacings slightly shifted from that of pure gold (10). Anantharaman (3) also reports the presence of stacking faults, as evidenced by x-ray line broadening effects, in rapidly cooled eutectic alloys of Ag-Si, Ag-Ge, Au-Si, and Au-Ge.

Aging of metastable structures.—The reversion of the metastable phase to equilibrium gold-silicon aged in both air and N_2 atmospheres was monitored by following resistance changes during isothermal annealing. X-ray diffractometer traces were also taken on several samples at various intervals of aging. There appeared to be good correlation between the fraction of metastable phase transformed as given by the fractional change in resistivity, $(\rho_i - \rho)/(\rho_i - \rho_f)$, and that obtained from measurements of x-ray peak intensity changes between the metastable and equilibrium gold peaks. Figure 5 shows the S-shaped transformation curves obtained by resistivity measurements at three temperatures.

The kinetics of the reversion to equilibrium structure over the temperature range of 25°-200°C are given in Fig. 6. The abscissa, τ, is the time for one-half the entire resistivity change to occur. It is seen that the transformation rate is affected by the annealing atmosphere, with less time required for transformation in air than in N_2 at temperatures below 150°C. The activation energy of the line drawn through the data for annealing in N_2 is 34 kcal/mole. Macroscopically, the surface of the specimens annealed in air turned a gold color immediately on annealing, before x-ray or re-

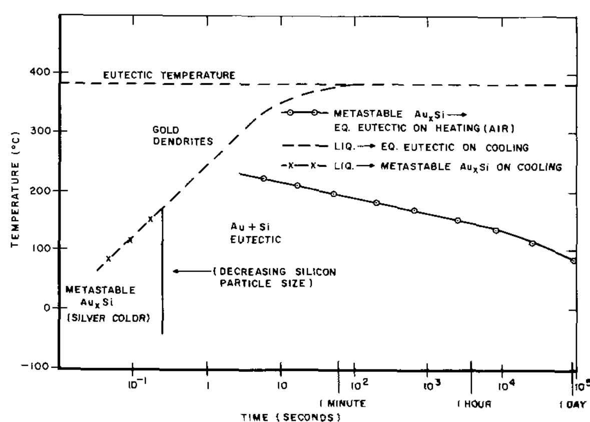

Fig. 7. Isothermal transformation diagram for gold-silicon eutectic alloy.

sistivity data showed any transformation had occurred. Analysis of the film in a Cameca ion microanalyzer showed the gold color to be caused by a surface layer <1000Å thick and composed of gold, silicon, oxygen, and nitrogen. Films annealed in N_2 remained silver-colored until the transformation was near completion. The rate data indicate this surface phenomenon in air significantly influences the transformation below 150°C.

From preliminary results obtained by transmission electron microscopy it appears that the transformation is complex, involving intermediate diffusionless steps as well as nucleation and growth. Thus, it is not surprising that the kinetics do not follow a simple Arrhenius relationship with a single activation energy. A more detailed investigation of the steps in this transformation is underway and will be discussed in a later paper.

Summary

From the observations presented in this paper it is seen that gold-silicon eutectic alloys can have a wide variety of structures depending on thermal treatment. This range of structures can perhaps best be summarized by borrowing a tool from the ferrous metallurgist viz., the isothermal transformation diagram (11). Figure 7 is an attempt at such a diagram for gold-silicon eutectic alloys. The various types of broken lines represent completed transformation (see legend in Fig. 7). The position of the various transformation curves depends on experimental conditions. For instance, the curves for freezing are shifted upward if (100) silicon is used as a substrate instead of (111). Likewise, the metastable heating transformation curve is shifted to the right below 150°C if annealing is done in N_2 instead of air. Nevertheless, the form of the diagram, regardless of substrate or atmosphere, should appear similar to that in Fig. 7.

Kinetics of Thermal Growth of Ultra-Thin Layers of SiO_2 on Silicon

I. Experiment

Y. J. van der Meulen*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The rate of formation of very thin SiO_2 films thermally grown on [111] and [100] oriented silicon wafers was studied using ellipsometry to measure oxide thickness. Film thicknesses from 10-300Å were obtained by varying oxidation time, oxidation temperature (700°-1000°C), and oxygen concentration in O_2-N_2 mixtures at 1 atm total pressure. The applicability of ellipsometry for such a study is discussed. Reproducibility of oxide films grown to thicknesses of 20-30Å was approx. ±1.0Å. Under otherwise equal conditions the oxide thickness grown differs for [100] and [111] oriented wafers. The pressure and temperature dependence of the linear rate constant, k_{lin}, show that the SiO_2 growth reaction is more complicated than was suggested earlier. In particular, a different pressure dependence for the two substrate orientations used indicates that several oxygen species participate in the rate determining steps.

Over the last decade, the increasing importance of silicon dioxide films in semiconductor technology has been evidenced by the large number of studies dealing with its thermal formation on silicon, many of which are listed in Ref. (1-3). In classifying the results, a distinction can be made between the so-called "wet" oxidation in which water vapor is the principal oxidant, and "dry" oxidation where the principal oxidizing species generally is oxygen. As the oxide film grows

* Electrochemical Society Active Member.
Key words: ellipsometry, oxygen, (linear) rate constant, pressure dependence.

thicker, both the wet and the dry process eventually follow a parabolic rate law (thickness ∝ time$^{1/2}$) of the type originally observed by Tammann (4) and theoretically treated by Wagner (5). This time dependence is a consequence of the fact that the transport of material through the thickening scale has become the slowest or rate-limiting step in the overall process. For smaller thicknesses, the oxide formation is not yet diffusion-controlled and slower surface (interface) reactions are rate-determining, resulting for SiO_2 in a linear relation between thickness and time. At intermediate thicknesses where neither the parabolic nor the linear step alone is rate-limiting, a mixed linear-parabolic equation combining them does describe the growth of SiO_2 as a function of time quite adequately over a range of conditions (1, 2).

Unfortunately, few published results are available describing the growth of SiO_2 in the thickness range between 0 and 300Å. In this interval, past work has been concerned mainly with the very slow oxidation of silicon near room temperature for thicknesses up to 25Å (6, 17); one of the few exceptions is a study by Goodman and Breece (7) of the oxide growth at 600°C for thicknesses up to ~30Å for the "dry" and ~60Å for the "wet" process. However, as the trend towards the use of thinner oxide layers continues, it is essential to further study their formation. The present article describes the thermal growth of SiO_2 films (10-300Å) on [100] and [111] oriented silicon wafers in O_2-N_2 mixtures of various oxygen concentration (1-100%) over a range of temperatures (700°-1000°C).

Experimental Procedures

In this investigation, chem-mechanically polished silicon wafers ([100] and [111] oriented, 1¼ in. diam, p-type, 2 ohm-cm) were used. They were cleaned by a standard process;[1] subjected to a clean-up oxidation in O_2 at 1050°C to form ~2000Å of SiO_2; recleaned;[1] blown dry in filtered, purified N_2 while being transferred to a quartz rack; and within 150 sec after leaving the water placed in the oxidation furnace tube which was filled with high purity N_2.

It has been reported that cleaned silicon surfaces can be temporarily protected by quenching freshly etched wafers in a saturated solution of iodine in methanol (8). The iodine can be removed by heating in N_2 (500°-550°C, atmospheric pressure) to leave a bare Si surface. We found that the index of refraction of the surface n_{Si} was not changed by such a treatment and that, on the average, oxide thicknesses were equal to those obtained without quenching in I_2. However, the scatter in the data was somewhat higher, and the method was therefore abandoned.

Oxidations were carried out in a double-walled, high purity, fused silica tube. Purified N_2 was passed through the outer jacket (2 liters/min). The water content of the effluent from the inner tube was less than 0.1 ppm. In each run, four wafers, vertically arranged on a quartz carrier, were warmed up in N_2 (15 min); oxidized at the desired oxygen partial pressure ($\bar{p}_{ox}$) in an O_2-N_2 mixture (1 atm) for the desired length of time (t_{ox}); flushed with N_2 (15 min) and finally cooled down in N_2. This procedure gave a reasonable degree of accuracy in defining smaller values of t_{ox} (the minimum value of which was 15 min), in spite of mixing between the N_2 and the O_2-N_2 mixture. Control runs were made in pure N_2.

The oxide thickness was measured by ellipsometry. Alignment of the ellipsometer was done according to standard procedure (10). The ellipticity of the polarizer was shown to be negligible (9). The adjustments necessary for the optimal alignment of the mounted sample were done as follows: The polarizer (P) and analyzer (A) were roughly adjusted to yield the minimum photo-detector response (*i.e.*, extinction); the analyzer was then rotated by 90° and the sample was adjusted until the response of the detector was at a maximum; with the sample in this position the measurements were made. This procedure gave the same results as alignment of the sample with P and the quarter-waveplate (Q) put at zero but it is much faster. All data points were measured in 2 zones with Q = 45.00°, at a wavelength λ = 5461Å and with an angle of incidence ϕ = 70.00°. Two measurements were usually made on each oxidized wafer. The data were numerically evaluated using an IBM 360/91 computer and McCrackin's program which allows one to make a number of different calculations (10).

[1] Cleaning sequence: deionized H_2O; $NH_4OH:H_2O_2:H_2O$ = 1:1:5, 65°C, ultrasonically agitated; d.i. H_2O; $HCl:H_2O_2:H_2O$ = 1:1:5, 65°C, u.a.; d.i. H_2O; $HF:H_2O$ = 1:1; d.i. H_2O.

Ellipsometric Evaluation

Proper interpretation of the ellipsometric results in terms of the complex refractive indices of the substrate ($n_s^* = n_s [1 - i \cdot \kappa_s]$) and the film ($n_F^* = n_F [1 - i \cdot \kappa_F]$), and of the film thickness (d_F), requires that a few limitations of this technique be kept in mind. A single ellipsometric measurement yields a set of two parameters (Δ, ψ), that characterize the change in polarization of the light upon reflection by the surface

$$\frac{R_p}{R_s} = \tan \psi \, e^{i\Delta} \qquad [1]$$

where R_p and R_s are the complex reflection coefficients for light polarized parallel and normal to the plane of incidence of the light beam. For transparent films, Δ and ψ are cyclic functions of the oxide thickness. From these parameters no more than two of the five unknown material parameters, defined above, can be deduced.

In order to simplify the analysis, the SiO_2 films are assumed to be completely transparent, *i.e.*, $\kappa_{SiO_2} = 0$. In addition, ellipsometry cannot be used to determine the imaginary part of the substrate index (κ_{Si}) unless the silicon has an atomically clean surface. This is because both a change in κ_{Si} and the presence of a very thin oxide film cause a shift in Δ only, which can be made to coincide to within a fraction of the experimental error (Fig. 1). Thus a value of κ_{Si} = 0.00685, obtained from optical transmission experiments (11), was used in this study. A small change in the real part of the substrate index (n_{Si}) on the other hand results almost exclusively in a shift in ψ (Fig. 2). All of this serves to reduce the number of unknown material parameters to three (n_{Si}, n_{SiO_2}, d_{SiO_2}).

Consider now the relation between these parameters and the ellipsometric data (Δ, ψ). It can be understood

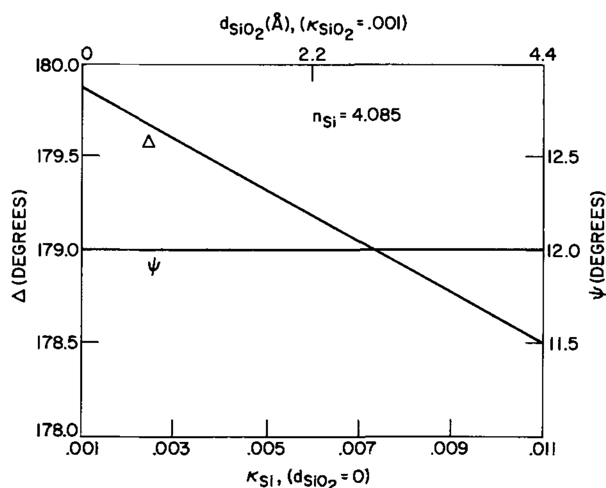

Fig. 1. The effect on (Δ,ψ) of a change in the imaginary part of the refractive index (κ_{Si}) at a constant value of the real part (n_{Si} = 4.085) for an unoxidized substrate. Also shown is the equivalency of such a variation of κ_{Si} and the presence of a thin SiO_2 film for a fixed value of κ_{Si}.

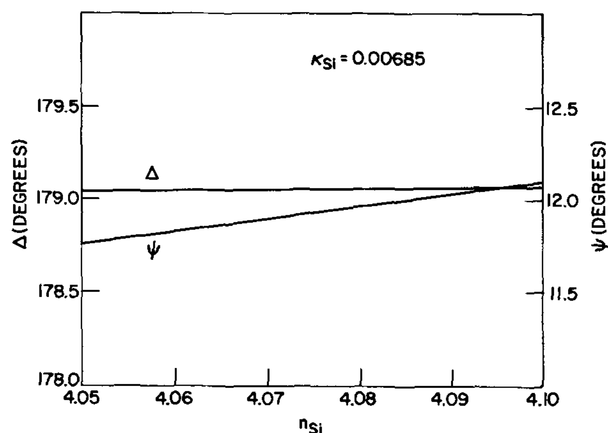

Fig. 2. The effect on (Δ,ψ) of a change in the real part of the refractive index (n_{Si}) at a constant value of the imaginary part (κ_{Si} = 0.00685). Unoxidized surface.

that as d_{SiO_2} becomes smaller, the influence of n_{Si}^* becomes dominant. Thus, for a fixed value of n_{Si}^* and small d_{SiO_2} it is not possible to determine n_{SiO_2} accurately. At the same time, some uncertainty is introduced into the determination of d_{SiO_2}. As shown in Table I(a) for $d_{SiO_2} \simeq$ 30Å, very small changes in Δ and ψ suffice to change n_{SiO_2} considerably. Taking into account the experimental errors in Δ and ψ (±0.015), the estimated accuracy in n_{SiO_2} in this thickness range is approx. ±20%. At greater oxide thickness ($d_{SiO_2} \simeq$ 500Å) the influence of a change of 1% in n_{SiO_2} already exceeds the experimental uncertainty [Table I(b)]. Determination of n_{Si}, however, is best done on surfaces covered with as thin a film as possible: Even with a small variation possible in n_{SiO_2}, the effect of a shift in n_{Si} at $d_{SiO_2} \simeq$ 30Å quickly exceeds the experimental error in ψ, whereas at $d_{SiO_2} \simeq$ 500Å the same uncertainty in n_{SiO_2} effectively prevents determination of n_{Si} (Table II).

The best procedure is thus to first compute n_{Si} from (Δ, ψ) measured on very thin films (d_{SiO_2} < 20Å) using a reasonable value of n_{SiO_2} (*e.g.*, 1.50), followed by a more precise determination of n_{SiO_2} from sets of data (Δ, ψ) taken on thicker films (d_{SiO_2} > 200Å). This calculation can be reiterated until consistent values of both n_{Si} and n_{SiO_2} are obtained. Once these values are known, one can make an accurate calculation of d_{SiO_2} for all films regardless of thickness. The tacit assumption here is that the optical constants do not depend on d_{SiO_2}. This is the case if all data in the range of observation can be evaluated using the same values of n_{Si} and n_{SiO_2}, and it was indeed found that throughout our experiments consistent results could be obtained using n_{Si} = 4.085 ± 0.003 and n_{SiO_2} = 1.47 ± 0.01. Finally, it

has been shown that, for a silicon wafer covered with SiO_2, the reflectance (R), as calculated from Δ and ψ, is constant within experimental error up to $d_{SiO_2} \simeq$ 150Å (12). This was conveniently used to check on the constancy of n_{Si} after various cleaning and oxidizing treatments.

Results and Discussion

For a given set of conditions (silicon orientation, temperature, oxygen partial pressure) an oxide thickness *vs.* oxidation time plot was always characterized by a fast initial rise followed by a (almost) linear region. The rapid initial growth process is known to have a $d_{SiO_2} \propto \log t_{ox}$ dependence at room temperature (6) and ceases to be important with increasing thickness (7). At lower temperatures ($T \leqq$ 800°C) and oxygen partial pressures ($\bar{p}_{O_2} \leqq$ 0.1 atm) the data fit quite closely to the linear relationship

$$d_{SiO_2} = k_{lin}\, t_{ox} + d_o \qquad [2]$$

where k_{lin} is a linear rate constant and d_o is a correction due to the fact that the linear region does not extrapolate back to the origin, but is preceded by the logarithmic growth. Thus we can also write

$$\frac{\partial d_{SiO_2}}{\partial t_{ox}} = k_{lin} = f\,(\bar{p}_{O_2}, T, \text{orientation}) \qquad [3]$$

At higher temperatures and pressures, the oxide thickness did not increase exactly linearly with time, and allowance had to be made for the onset of a diffusion-controlled oxidation mechanism by using a mixed linear-parabolic equation

$$\frac{d_{SiO_2}{}^2 - d_o{}^2}{k_{par}} + \frac{d_{SiO_2} - d_o}{k_{lin}} = t_{ox} \qquad [4]$$

where k_{par} is the parabolic rate constant, connected with the transport of oxidant through the oxide film.

Typical results, illustrating the large effects of silicon orientation and oxygen concentration are presented in Fig. 3 for T_{ox} = 850°C. Most of the data points represent the average value of two measurements on each of four wafers. Standard deviations are indicated for the top three curves and are smaller than 1.0Å for the lowest curve. The small standard deviations in the latter case for oxide thickness of approx. 20-35Å makes these films very suitable for use in MNOS type structures based on direct tunneling phenomena (18). The solid lines were obtained by curve fitting using Eq. [4]. Values for the parabolic rate constant were obtained from the data of Deal and Grove (1) who, with others (13), also established the proportionality of k_{par} with partial oxygen pressures albeit at higher temperatures (> 950°C) than some of the temperatures used in the

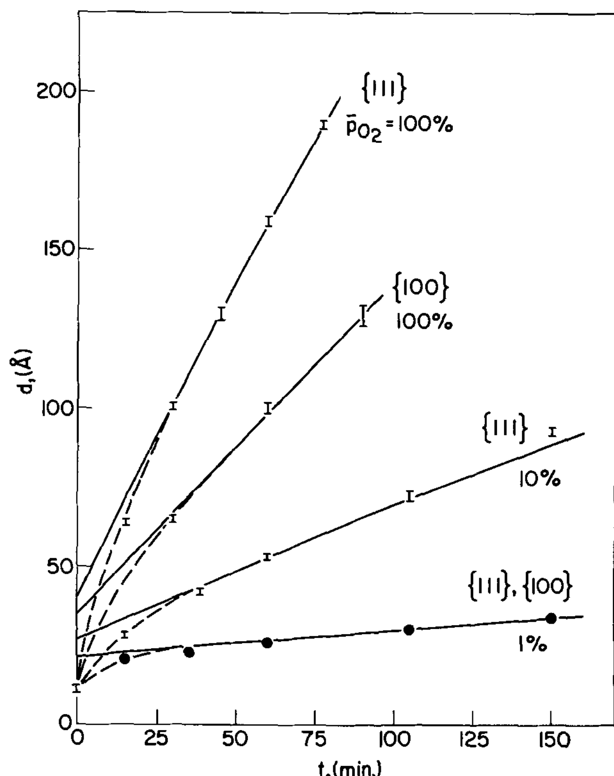

Fig. 3. Plot of oxide thickness vs. oxidation time at 850°C. Orientation and $\bar{p}_{O_2}$ have been indicated. Error bars are shown in the upper curves. Standard deviations for the lowest curve were approx. 1.0Å.

present study. At $\bar{p}_{O_2} = 1$ atm, the difference in k_{lin} between the [111] and [100] surfaces amounts to a factor two; at $\bar{p}_{O_2} = 0.01$ atm no difference could be measured between the two orientations.

Curves similar to those in Fig. 3 were measured at five different temperatures (700°, 800°, 850°, 900°, 1000°C) for [111] oriented wafers and at two temperatures (850°, 1000°C) for [100] oriented wafers. Values of the linear rate constant (k_{lin}) were obtained and are shown in Fig. 4, along with two lines having slopes of

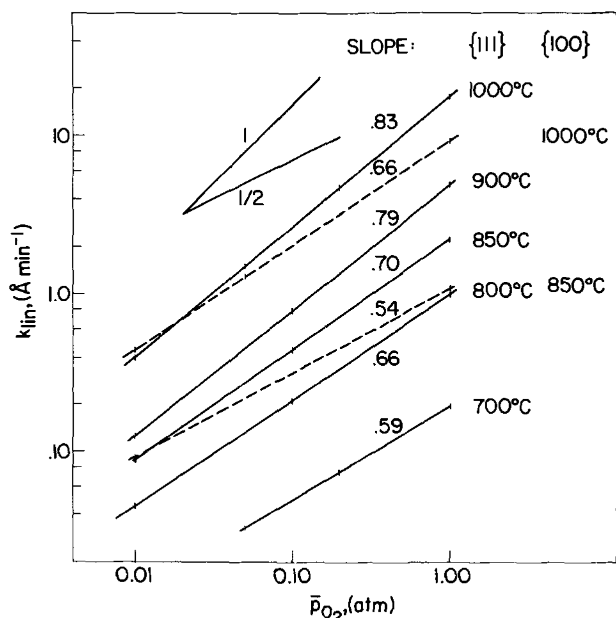

Fig. 4. Plot of log k_{lin} vs. log $\bar{p}_{O_2}$. Drawn lines: [111] wafers; dashed lines: [100] wafers. Oxygen partial pressures where measurements were taken are indicated. Shown in the upper left-hand corner are two lines with slopes 0.5 and 1.0, respectively.

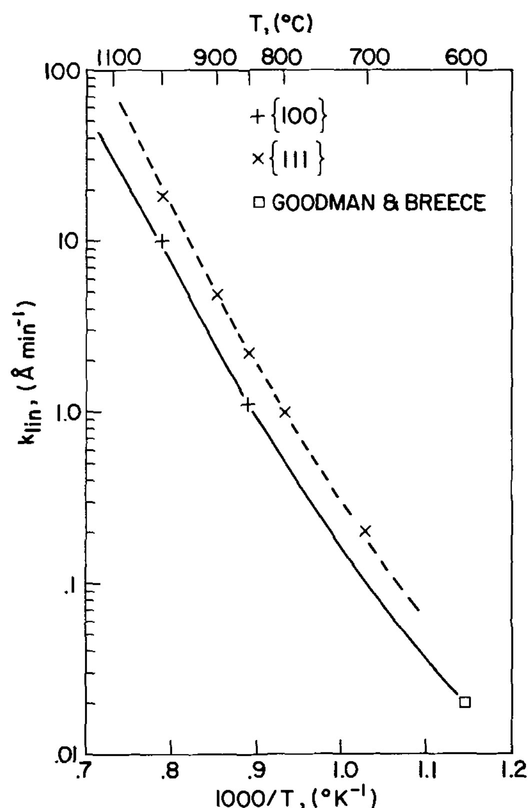

Fig. 5. Arrhenius plot of k_{lin} at $\bar{p}_{O_2}$ = 100% (1.0 atm)

½ and 1. With the possible exceptions of the [100] data at 850°C (slope : 0.54) and the [111] data at 700°C (slope : 0.59) none of the curves measured exhibit a simple pressure dependence, *i.e.*, $k_{lin} \propto \bar{p}_{O_2}{}^{y}$, where y equals either ½ or 1. Small values ($k_{lin} < 0.1$Å min^{-1}) are harder to determine accurately and accordingly the scatter in the data was somewhat larger in that range. However, it is evident from the curves in Fig. 4 obtained for the [111] oriented wafers that the slopes increase as the temperature rises from 700° to 1000°C. Although our data collected on [100] oriented wafers are more limited, they indicate a similar trend. All values obtained for k_{lin} at $\bar{p}_{O_2} = 1.0$ atm have been plotted in Fig. 5 as a function of temperature. Also shown is a point taken from recently published work (7) on the oxidation of [100] oriented wafers at 600°C. From this graph, it is clearly apparent that the data for one orientation cannot be fitted using a single activation energy (ΔE) in an Arrhenius expression

$$k_{lin} = k_{lin}{}^{\circ} \exp\left(\frac{-\Delta E}{kT}\right) \qquad [5]$$

Instead a considerably more complicated mechanism must be operative. These findings will be treated in detail in Part II of this investigation.

Consideration of both earlier published data and the present experimental results makes it possible to lay down a few ground rules that any description of the silicon oxidation mechanism should conform to. The oxide growth takes place at the silicon-silicon dioxide interface (14). Earlier work showed the oxidation in the parabolic region to be independent of wafer orientation, as indeed it must be when the process is diffusion-controlled. It was also found (1, 13) that the parabolic rate constant increases linearly with the oxidant partial pressure from 950° to 1200°C. This adherence to Henry's law thermodynamically means that molecular oxygen, perhaps as a molecule ion (14-16), must be the principal diffusing species. In this work, we measured different values of the linear rate constant at $\bar{p}_{O_2} = 1.0$ atm for wafers having a different orienta-

tion. Previously, this had only been reported for "wet" oxidation (2). This orientation dependence could simply be the result of the different atomic structure of the surface and need not imply a basically different reaction mechanism. It was also found, however, that at a given temperature the pressure dependence of k_{lin} depends on the orientation of the substrate. Thus the apparent order of the reaction is different for different orientations which means that more than one oxygen species must be involved in the rate-limiting step. In other words, the two orientations studied have different rate-limiting steps. Taken together with the fact that even for a single orientation the slope of k_{lin} *vs.* $\bar{p}_{O_2}$ changes with temperature, it means that the rate-limiting step is more complicated than was thought before and may well be comprised of various competing reactions involving different oxygen species at the $Si-SiO_2$ interface. The mathematical description to be presented in Part II will attempt to take these complexities into account.

The values calculated for k_{lin} from the experimental data at $\bar{p}_{O_2} = 1$ atm presented here—although roughly comparable—are not in complete numerical agreement with earlier values (3). This can be ascribed to the fact that the mixed linear-parabolic mechanism in prior work normally was diffusion dominated, the surface reaction giving rise to a linear correction only, whereas in the present study surface reactions are dominant. There seems to be one fundamental aspect where at first sight the discrepancy is of a more fundamental character: Deal and Grove (1) reported that k_{lin} too varies linearly with the oxygen pressure. Further examination of their data shows, however, that the observations—probably made on [111] oriented wafers—in dry oxygen were made at a single temperature (1200°C) and over a rather limited range of partial pressures ($\bar{p}_{O_2} = 190$-760 mm Hg). Thus no real discrepancy with the data presented here need exist, because the relation between k_{lin} and $\bar{p}_{O_2}$ becomes more linear with rising temperature (Fig. 4).

Summary

The thermal dry oxidation of silicon under ultraclean conditions has been studied in the region where the kinetics are predominantly linear with time and controlled by a reaction at the SiO_2 outer surface, where the incorporation of oxygen into the SiO_2 takes place, or at the SiO_2-Si interface, where the oxide growth occurs. The following findings seem to be most significant:

(*i*) For a given temperature and oxygen partial pressure the linear oxidation rate is different for [111] and [100] oriented wafers.

(*ii*) For a given temperature and orientation the pressure dependence of the linear rate constant is complicated and seems to preclude a simple reaction mechanism.

(*iii*) For a given temperature the oxygen pressure dependence of the linear rate constant is different for [111] and [100] oriented wafers.

(*iv*) For a given wafer orientation the oxygen pressure dependence of the linear rate constant varies with temperature.

The data do not seem to contradict earlier work but they definitely require a more complex reaction scheme than has been proposed for this process in the past. Possible solutions to this problem will be dicussed in Part II of this investigation.

A Survey of the Cr-Rich Area of the Cr-Si-C Phase Diagram

P. W. Pellegrini, B. C. Giessen, and J. M. Feldman

Department of Electrical Engineering and Department of Chemistry, Northeastern University, Boston, Massachusetts 02115

ABSTRACT

An investigation of the ternary phase diagram Cr-Si-C has been completed in the region Cr-Cr_3C_2-Cr_5Si_3. Phase boundaries have been established to an accuracy of ±2 a/o (atomic per cent). The extent of a ternary single-phase region of approximate stoichiometry $Cr_5Si_3C_x$ is established. Lattice parameter measurements of this phase show that all or nearly all C enters the $D8_8$-Mn_5Si_3 structure at interstitial sites, rather than substitutionally as previously reported. Finally, the possibility of SiC crystal growth from solutions of transition metal silicides is discussed.

Chromium has been considered as a solvent for the solution growth of single crystal silicon carbide, based essentially on initial phase diagram work by Griffiths and Mlavski (1) and Griffiths (2) that indicated a two-phase equilibrium Cr-SiC. Griffiths (3) subsequently corrected the earlier diagram and reported that binary Cr_3C_2 is in equilibrium with a ternary Cr-Si-C phase; this rules out a Cr-SiC pseudobinary system at least at low temperatures. A tentative Cr-Si-C ternary diagram was later given by Wolff and Das (4) which is based on the constitution of several alloys with compositions in the partial system Cr_3C_2-SiC-Cr_5Si_3-Si, supplemented by tentative tie-lines in the Cr-rich portion. They report the existence of the equilibria $Cr_{23}C_6$-Cr_3Si, Cr_7C_3-Cr_3Si, Cr_3C_2-Cr_3Si, Cr_3C_2-T (T = ternary phase), Cr_5Si_3-T, Cr_3Si_2-T, Cr_3C_2-SiC, T-SiC, CrSi-SiC, and $CrSi_2$-SiC.

We report here a reasonably detailed survey of the Cr-rich region of the Cr-Si-C isotherm at 1400°C which is shown in Fig. 1. The constitution of alloys in the Cr-Cr_3C_2-T-Cr_5Si_3 partial diagram was studied; thus, the present work is complementary to that reported in Ref. (4).

Techniques

Samples of ~ 5g weight were prepared by arc-melting in a Ti-gettered argon atmosphere from 99.999% Cr, 99.99% Si and C with < 5 ppm ash. Cr-Si and Cr-C master alloys were used to make the ternary alloys. In the preparation of the alloys in the partial system Cr_5Si_3-T-SiC-Si, SiC (99+%) was also used as a starting material. Weight losses on melting depended on the Cr content, and amounted to ~ 1 w/o (weight per cent) at 70 a/o Cr and 2 w/o at 90 a/o Cr. Considering the high vapor pressure of Cr, these losses could be taken as Cr losses; after correcting for them, the nominal compositions of the alloys were used, with a remaining uncertainty of < ± 1 a/o. No oxidation was noted. The dash-dotted line in Fig. 1 indicates the approximate limit of the compositions of alloys that could be prepared by arc-melting as described; in alloys with compositions beyond this limit large evaporation losses occurred.

The alloys were examined in the as-cast state and after annealing for 6 to 7 hr at 1400°C in He at 1 atm (< 5 ppm impurities). This period of time was found to be sufficient to produce equilibrium, as shown by the removal of nonequilibrium structures such as those due to incomplete peritectic reactions. Metallographic samples were electrolytically etched in dilute HCl; x-ray patterns of ground samples were taken on a GE-XRD6 diffractometer with filtered Cr $K\alpha$-radiation. All phases were identified by matching of the diffraction patterns with the data in the JCPDS Powder Diffraction File; phase proportions were estimated from microscopic examination of the polished, annealed samples and by comparing x-ray intensities using our own diffraction pattern matching program. Lattice parameters for T are shown in Fig. 2; they were calculated from high-angle reflections with $2\theta > 140°$ and have error limits of < 1 to 2×10^{-3}Å, as indicated in Fig. 2.

Key words: ternary phase diagram, C-Cr-Si system, SiC, solution growth, x-ray diffraction.

Results and Discussion

The Cr-Si-C system.—On the basis of these alloys, the nature of the phase equilibria in the investigated portion of the 1400°C isotherm (Fig. 1) has been established unambiguously. A more accurate location of the boundaries between the two- and three-phase fields beyond the present accuracy of ~ ±2 a/o (for boundaries given in solid lines) would have required a much larger number of alloys and was not attempted. The extent of ternary homogeneity ranges of the binary Cr-C phases was not studied but they are probably small, judging from the absence of lattice parameter changes. Cr_3Si has a limited solubility for carbon of 4 ±1.5 a/o; Cr_5Si_3 has no noticeable solubility for carbon (this may be due to the formation of the ternary phase T with the formula $Cr_5Si_3C_x$ which lowers the solubility of carbon in Cr_5Si_3).

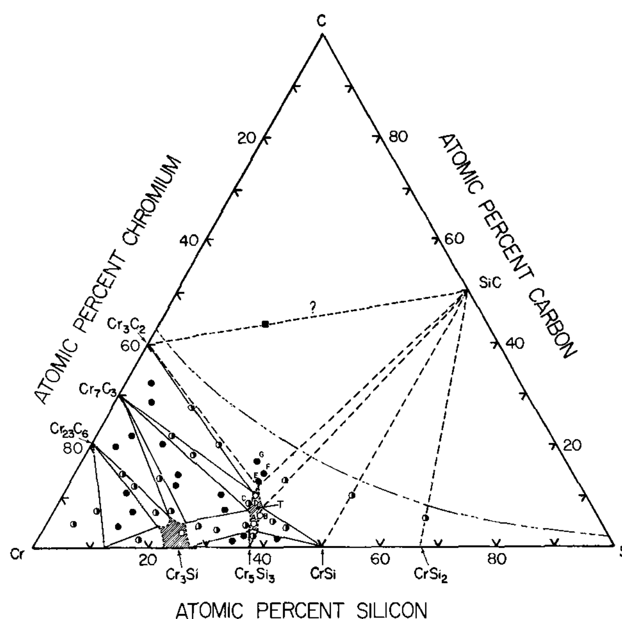

Fig. 1. Isothermal section of the ternary system Cr-Si-C at 1400°C. Binary Cr-C, Si-C, and Cr-Si phases and their compositions are taken from Ref. (5-7) respectively. ○: single phase; ◑: two-phase; ●: three phase. Dash-dotted curve indicates limit of compositions of alloys accessible by arc-melting as described in text. Alloy marked ■ was prepared by sintering a mechanical mixture of the elements, and consisted of Cr_3C_2, SiC, and T.

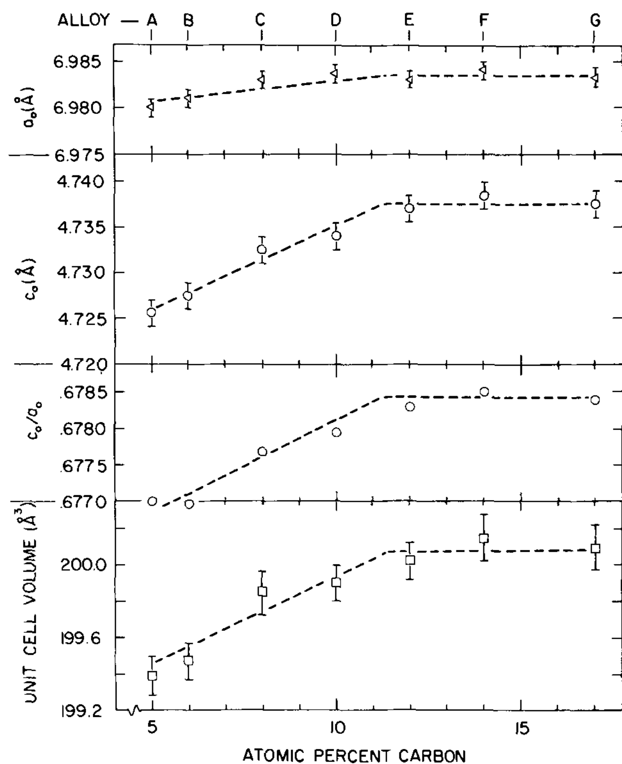

Fig. 2. Lattice parameters, axial ratios, and unit cell volumes of the ternary Cr-Si-C phase T ($Cr_5Si_3C_x$) in alloys A-G on or near the section Cr_5Si_3-C (see Fig. 1). Small departures of alloy compositions from section Cr_5Si_3-C have negligible effect on unit cell parameters due to the similar sizes of Cr and Si in $Cr_5Si_3C_x$.

The phase diagram shows clearly that combinations of silicides and carbides of Cr, such as Cr_7C_3 + Cr_3Si or Cr_3C_2 + T have lower free energies than the combination Cr + SiC. The zigzagging of the tie-lines between the silicides and carbides up to Cr_3C_2 and T, and the absence of a Cr-SiC equilibrium is possibly related qualitatively to the average valence electron concentration per atom (8) (VEC) of the silicides and carbides which changes monotonically with the C and Si contents, as shown by the following argument. It is often observed in ternary systems that two VEC-determined binary phases (such as σ-phase-related transition metal phases and noble metal Hume-Rothery phases) with a common constituent are connected by a pseudobinary solid solution range of constant VEC (8). In addition, Pfeifer *et al.* (9) noted that in the absence of a complete solid solution, tie-lines will tend to connect two phases with similar VEC's rather than two phases with a large VEC difference. As the phase diagram shows, the Cr-rich phases in the Cr-Si-C system may follow this rule.

The main changes in the present phase diagram over the tentative diagram of Ref. (4) are: (*i*) no tie-line exists between Cr_3C_2 and Cr_3Si; instead there is a tie-line between Cr_7C_3 and T (see Fig. 1); (*ii*) the region Cr_3Si-T-CrSi has been worked out; a nonexisting phase Cr_3Si_2 has been removed and replaced by Cr_5Si_3; (*iii*) missing tie-lines such as those between Cr_3Si and T or CrSi and T were established and a number of phase boundaries were refined.

The ternary phase.—Some interesting results concern the ternary phase, T. Its stoichiometry range was found to conform to the ideal formula $Cr_5Si_3C_x$, (approximate homogeneity range $Cr_{5\pm0.2}Si_{3\pm0.1}C_x$) with $0.25 < x < 1.05$. Its lattice parameters and atomic volumes (Fig. 2) show a pronounced increase with increasing x. This indicates that additional carbon does not substitute for Cr or Si, as implied by the formula $Cr_{5-x}Si_{3-y}C_{x+y}$ [Ref. (10)] but that it occupies unfilled sites of the $D8_8$-Mn_5Si_3 type structure of $Cr_5Si_3C_x$. The Mn_5Si_3 structure type provides vacant hole sites formed by the metal octahedra which are uniquely favorable for the accommodation of interstitial atoms (11). A neutron diffraction study (12) of the related Nowotny phase $Mo_{4.8}Si_3C_{0.6}$, confirmed that carbon occupies the octahedral hole positions. (In $Mo_{4.8}Si_3C_{0.6}$, the ratio Mo:Si = 1.60 causes 10% vacancies in the fourfold Mo positions, with the sixfold Mo positions being completely occupied; however, in $Cr_5Si_3C_x$ there are probably no such metal vacancies).

The present investigation provides strong support for the model (11, 12) for the C positions. Since there is one hole site per formula unit, the maximum solubility of carbon due to this position would be 11.1 a/o C (x = 1). This agrees well with the experimental value of 11.5 ± 1 a/o C (x = 1.05 ± 0.1) from metallographic observation and the discontinuities of the lattice parameters and atomic volume (Fig. 2). As in other alloy phases stabilized by interstitial atoms, additional bonding is probably provided in $Cr_5Si_3C_x$ by interaction of the s,p-states of carbon with the d-states of the transition metal (13), stabilizing the ternary phase.

Growth of SiC.—Concerning the possibility of growing SiC from Cr solutions, it can be seen in Fig. 1 that SiC is not in equilibrium with Cr at 1400°C, nor is there likely to be an equilibrium between SiC and melt at elevated temperatures in the partial system Cr-Cr_7C_3-Cr_3Si. To grow SiC from Cr-SiC melts, compositions in the partial system Cr_3C_2-T-SiC would be necessary. These would require high temperatures (1900°-2000°C) with attendant, relatively high partial pressures of Cr (~ 1-10 Torr). This makes Cr an unattractive base for equilibrium solution growth of SiC even if one were willing to operate in the requisite temperature and composition range.

Concerning other potential transition metal solvents for SiC, the following statements are possible. In accordance with the general VEC principle stated above (9), ternary Si-C-transition metal phase diagrams with transition metals between Group IVB (Ti) and Group VIII (Ni), will either have similar stable tie-lines between metal carbides and silicides as in Cr-Si-C (if the third element is an early transition metal such as Ti, V, Cr), or there will be tie-lines between the metal silicides and C (if the third element is a later transition metal such as Co and Ni). Unalloyed transition metals are, therefore, not prospective solvents for SiC; SiC growth is possible, perhaps, if one used as a solvent a relatively low melting binary or ternary intermetallic phase which is in equilibrium with SiC at all temperatures.

Spectrophotometric Determination of Photoresist Photosensitivity

I. A Theoretical Discussion of Those Photoresist Reactions Which Entail the Depletion of a Photoactive Species[1]

D. F. Ilten*

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

Many of the commonly used photoresist systems consist of two components: a polymer and a photoactive species dissolved in an organic solvent system (1, 2). During exposure, light is absorbed by the photoactive species which undergoes a chemical change promoting either a solubilization or a desolubilization reaction in the polymer. To be capable of reacting the photoactive species must, of course, according to the Grothus-Draper law (3), have an absorption band in the region of emission of the radiation source used for the exposure. As the photoactive species is depleted, its absorbance decreases also. Assuming no product arises which absorbs at the same wavelength as the photoactive species, the change in absorbance of the latter as a function of exposure can be directly determined spectrophotometrically. These facts suggest a method of monitoring the photoresist photoreaction by measuring the rate of change of the photoactive species' concentration as a function of exposure time. The theory of this method will be developed in the following sections.[2]

Discussion of Photoresist Reaction Kinetics

Assuming monochromatic radiation in all cases, the analysis is based on the following mechanism (4-8): the photoactive species, A, upon absorbing a quantum of radiation gives the excited species, A^*. This may either relax to the ground state with the emission of radiation or form one or more product species, B

$$A \overset{h\nu}{\rightleftarrows} A^* \rightarrow B \quad [1]$$

It is assumed that the rate of disappearance of A is directly proportional to the rate of the absorption of light, where the proportionality constant is the primary quantum yield, $\phi = \phi(\lambda)$. Then the rate equation for the net reaction

$$A \rightarrow B$$

may be written as

$$\frac{d(nl)}{dt} = -\phi I_a \quad [2]$$

where n = the number of moles of A/cm^3; I_a = the number of moles of quanta (Einstein) of monochromatic light absorbed per cm^2/sec; l = the optical path length, *i.e.*, the photoresist film thickness in cm, ϕ = the primary quantum yield $= \dfrac{\text{No. of molecules which react}}{\text{No. of photons absorbed}}$.

It is further assumed that the Lambert-Beer law holds for the photoactive species in the model chosen

$$I = I_0\, e^{-\epsilon' cl} \quad [3]$$

where I_0 = the incident light intensity; I = the transmitted light intensity; $\epsilon' = 2.303\epsilon$; ϵ = the molar absorptivity in liters/mole/cm; c = the molar concentration of unreacted molecules in moles/liter. Further, x = the absorbance at the measured wavelength = $\log I_0/I = \epsilon cl$, again assuming Beer's law to hold, also $x' = 2.303x$.

The absorbed light intensity is given by

$$I_a = I_0\,(1 - e^{-x'}) \quad [4]$$

Upon substitution of Eq. [4] into Eq. [2], and using the definition of x one obtains

$$\frac{dx}{dt} = -10^3\, \epsilon\phi I_0 (1 - e^{-x'}) = -a\phi(1 - e^{-x'}) \quad [5]$$

where $a = 10^3\, \epsilon I_0$ and $a' = 2.303a$

This yields

$$\int_{x'_0}^{x'} \frac{dx'}{1 - e^{-x'}} = -a'\phi \int_0^t dt \quad [6]$$

Upon integration, the expression

$$\ln\left|\frac{e^{x'_0} - 1}{e^{x'} - 1}\right| = a'\phi t \quad [7]$$

is obtained.

Finally, after cancelling the factors 2.303, the primary quantum yield can be expressed as

* Electrochemical Society Active Member.

[1] This article is Part I of a series, the second part of which is found on p. 539.

Key words: photoresist, kinetics, photochemistry, microelectronics, Süs reaction.

[2] The method would not be applicable to photoresist systems which employ an energy transfer dye which is not depleted during exposure or in cases where only a very small change in the concentration of the photoactive species is observed, *e.g.*, Kodak Photoresist (KPR).

$$\phi = \frac{1}{at} \log \left| \frac{e^{x'_0} - 1}{e^{x'} - 1} \right| \quad [8]$$

Letting $x' = x'_{0/2}$ and expanding the exponentials as a truncated power series, one obtains

$$\phi = \frac{1}{at_{1/2}} \log \left| \frac{e^{x'_0} - 1}{e^{x'_{0/2}} - 1} \right| \quad [9]$$

$$\phi \sim \frac{1}{at_{1/2}} \log 2 = \frac{0.301}{at_{1/2}} \quad [10]$$

Equation [10] is a reasonable approximation of Eq. [9] for values of $x < 1$. The half-time, $t_{1/2}$, is the exposure time necessary to reduce x to one half its initial value. More generally, ϕ may also be expressed in terms of $t_{1/n}$, where n is any arbitrary value, as

$$\phi \sim \frac{1}{at_{1/n}} \log |n| \quad [10a]$$

Determination of x as a function of time.—The values of the absorbance, x, may also be obtained as a function of time from Eq. [7].

Setting $b = e^{x_0} - 1$, Eq. [7] becomes

$$\frac{b}{e^{x'} - 1} = e^{a'\phi t} = e^{t/\tau} \text{ where } \tau = \frac{1}{a'\phi} \quad [11]$$

$$e^{x'} = 1 + be^{-a'\phi t} = 1 + be^{-t/\tau} \quad [12]$$

$$x'(t) = \ln (1 + be^{-a'\phi t}) = \ln (1 + be^{-t/\tau}) \quad [13]$$

$x'(t)$ is plotted in Fig. 1 as a function of time for various values of $a'\phi$. For small values of the variable, $a'\phi t$, Eq. [13] becomes

$$x' \sim be^{-a'\phi t} \quad [14]$$

or

$$x \sim \frac{b}{2.303} e^{-a'\phi t} \quad [14b]$$

Taking logarithms of Eq. [14b] gives

$$\log x = \log \left| \frac{b}{2.303} \right| - a\phi t \quad [15]$$

For reasonably low concentrations, the disappearance of x should approximate an exponential decay and a plot of log x *vs.* time should give a straight line. Values of $t_{1/2}$ taken from such plots of experimental data can be used to calculate the primary quantum yield, ϕ. Expression [15] also predicts a series of parallel lines for differing values of initial absorbance, x, resulting from either variations of film thickness or of the concentrations of the photoactive species.

Exposure.—Exposure is defined as the integral of the absorbed radiation over time

$$E = \int_0^t I_a \, dt \quad [16]$$

Utilizing Eq. [4], expression [16] becomes

$$E = \int_0^t I_0 (1 - e^{-x'}) dt$$

$$E = I_0 \int_0^t [1 - \exp \{-\ln (1 + be^{-a'\phi t})\}] dt$$

$$= I_0 \int_0^t \left(1 - \frac{1}{1 + be^{-a'\phi t}} \right) dt \quad [17]$$

Upon integration this yields

$$E = -I_0 \left[\frac{1}{a'\phi} \ln (1 + be^{-a'\phi t}) \right]_0^t$$

$$= \frac{I_0}{a'\phi} [\ln (1 + b) - \ln (1 + be^{-a'\phi t})] \quad [18]$$

$$= \frac{1}{a'\phi} |x'_0 - x'| \quad [19]$$

Expression [19] reduces to

$$E(t) = \frac{l}{10^3 \phi} (c_0 - c(t)) \quad [20]$$

Values for the extreme cases of zero and infinite exposure time are

$$E(0) = 0 \text{ and } E(\infty) = \frac{lc_0}{10^3 \phi}$$

Calculated values for $E(t)$ as a function of time for various values of the product, $a\phi \propto I_0\phi$, are presented in Fig. 2.

Reciprocity.—Considering Eq. [18] and expanding the logarithmic terms, assuming the variables to be $<<1$, one obtains

$$E(t) = \frac{I_0 b}{a\phi} (1 - e^{-a'\phi t}) = I_0 b\tau (1 - e^{-t/\tau}) \quad [21]$$

Expanding the exponential this becomes

$$E(t) \sim I_0 bt \text{ or } E \propto I_0 t$$

for low photoactivator concentrations and light intensities and for short exposure times. Thus, under these conditions reciprocity between exposure intensity and time appears to hold.

Conclusions

Starting from a simple kinetic model, the rate equations for the depletion of the photoactive species during the course of photochemical reactions under conditions of continuous monochromatic irradiation have been derived. An expression has been obtained for ϕ,

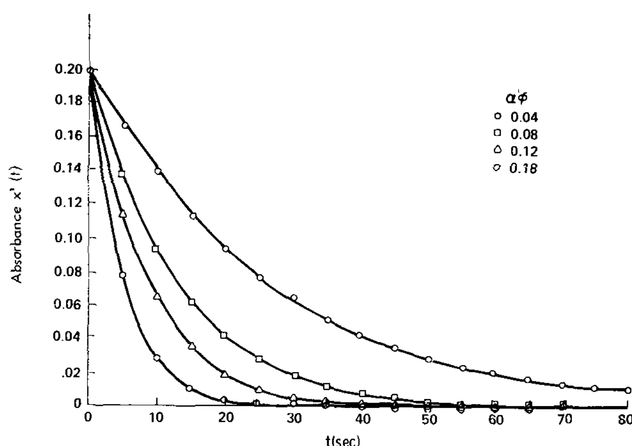

Fig. 1. Depletion of the photoactive species with constant exposure intensity.

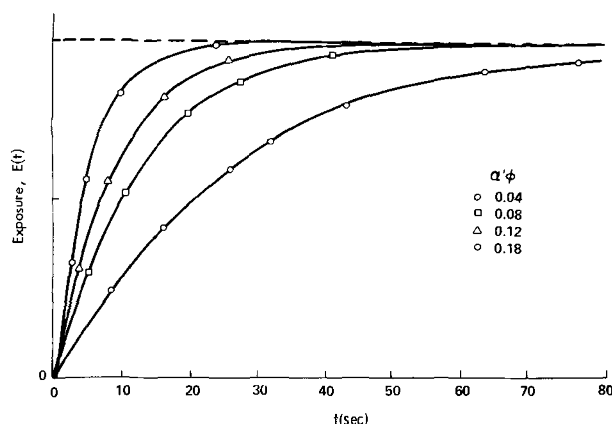

Fig. 2. Normalized exposure curves.

the primary quantum yield of the disappearance of the photoactivator, as a function of experimentally determined halftimes. For reasonably low absorbances (concentrations), *i.e.*, $x < 1$, this becomes

$$\phi \sim \frac{0.301}{a t_{1/2}}, \text{ where } a = 10^3 \epsilon I_0 \quad [23]$$

This expression also shows the inverse proportionality between $t_{1/2}$ and exposure intensity

$$t_{1/2} \sim \frac{0.301}{10^3 \epsilon \phi I_0} \quad [24]$$

Expressions are given for $x(t)$, the absorbance (which is proportional to the photoactivator concentration), and for $E(t)$, the exposure, as functions of exposure time. Again, for values of $x < 1$ and $a\phi\epsilon < 1$, the exposure relation reduces to

$$E \propto I_0 t$$

indicating that reciprocity can be expected for this rather limited condition.

Spectrophotometric Determination of Photoresist Photosensitivity

II. Comparison of the Theoretical Model with Experimental Studies on AZ-1350[1]

D. F. Ilten* and R. J. Sutton

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

Having completed a general theoretical analysis of the exposure kinetics of an idealized photoresist (1), the next step is a comparison of the results predicted with those obtained experimentally for an actual photoresist system. For this purpose the positive photoresist AZ-1350[2] was chosen. The principal reaction involved is thought to be the photochemical Süs reaction (2-5) as illustrated in Fig. 1. The diazooxide group of the photoactive species evolves nitrogen when irradiated and forms a carbene intermediate. This leads to ring contraction accompanied by the formation of a ketene. Upon hydrolysis the corresponding carboxylic acid results. It is basically the kinetics of the initial step of this reaction which will concern us here. In none of the studies was the photoresist developed, nor was the actual product of the photoreaction isolated.

Experimental

A spectrophotometric method as described in Part I was used for following the first step of the AZ-1350 exposure reaction. Both absolute and difference spectra of spin-cast films of the photoresist were taken. Typical sets of these types of spectra can be seen in Fig. 2 and 3. The difference method was found to be more satisfactory because the spectrum of the photoactive species itself and changes therein can be measured directly. The absorption of the polymer and of any reaction products is compensated for by using them as the reference in a dual beam spectrophotometer.[3] Samples were prepared as follows: two quartz wafers, 32 mm in diameter and 3.2 mm thick, were cleaned using acetone, water, and ultrasonic treatment. They were spin-

coated with AZ-1350 to give film thicknesses of ~5000Å and an initial absorbance of 0.30 after a prebake of 80°C for 30 min. One film was exposed for one-half hour using an HBO-200 hp Hg lamp.[4] Complete reaction of the photoactivator was assumed and the film was used in the reference beam of the spectrometer. The second, unexposed, film was placed in the sample beam and the spectrum was taken over the 2000-6000Å wavelength region. The wafer was exposed very briefly using a black absorbent background to prevent exposure from reflected light and the spectrum was taken once again. The process was repeated until no further change in the spectrum was observed and a family of spectra as shown in Fig. 3 had been obtained. The intensity of the exposing radiation was measured using a thermopile[5] (6). The applicability of the Lambert-Beer law was tested by casting films at a variety of spinning speeds to give a range of film thicknesses. These were measured by the Talystep (7), a stylus instrument for thickness determination. The absorbance of these samples at 4047Å was determined and the results were plotted as a function of the film thickness (Fig. 4). The linear relationship obtained indicates that the Lambert-Beer law holds, at least over the range of values investigated, and that concentrations can be determined spectrophotometrically by linear interpolation.

Results

Semilogarithmic plots of the absorbance, x, at 4047Å as a function of the exposure time, t, were made as shown in Fig. 5. A straight line resulted, in agreement with Eq. [15] of Part I (1). The exposure halftimes

for the depletion of the photoactivator were determined from these linear plots both for full spectrum exposure and for exposure using the 3650, 4047, and 4358Å Hg lines, isolated using band pass filters[6] having a bandwidth of 100Å and a maximum transmission of ~30%. By employing Eq. [9] of the kinetics section Part I (1), values of ϕ, the primary quantum yield, were obtained. The data are given in Table I. The $t_{1/2}$ values were also determined as a function of the intensity of the exposing light by using neutral density filters[7] in combination with the band pass filters. The results are presented in Table II.

Studies were conducted on films varying in thickness from 4400-10,000Å, as determined by Talystep thickness measurements. A family of straight lines was obtained, demonstrating the applicability of Eq. [15], Part I (1), over this thickness range. Also, the effects of the reflectivity of the substrate on the exposure halftimes were studied. Quartz wafers were exposed using an aluminum reflective backing and a black paper, essentially nonreflective backing. This experiment was carried out, both for full spectrum exposure and for monochromatic exposure, employing each of the three principal Hg lines in the near uv-blue region. These results are given in Table III. In all cases a reduction of exposure time of approximately one-third was found for the reflective as opposed to the nonreflective backing.

Plots of the reciprocal of the intensity as a function of $t_{1/2}$ were made also for full spectrum exposure and for monochromatic exposure using each of the 3650, 4047, and 4358Å Hg lines. Figures 6 and 7 illustrate that reasonable approximations to straight lines pass-

ing through the origin are obtained. This behavior is predicted by Eq. [24] of Part I (1) for moderately low concentrations of the photoactive species, *i.e.*, corresponding to absorbance values less than one. It might be noted that the exposure values measured were in reasonable agreement with data obtained by Htoo (8). Also, the quantum yield values of 0.2 for the diazooxide reaction agreed approximately with those obtained by Fedorov and others by measuring N_2 evolution (9, 10). These results were also confirmed by infrared spectroscopic studies carried out in this laboratory.

Conclusions

The primary quantum yield for the depletion of the AZ-1350 photoactivator has been determined to be 0.15, 0.20, and 0.14, respectively, for the 3650, 4047, and 4358Å Hg lines. The use of an aluminum reflective backing for the quartz wafers during irradiation resulted in a reduction of $t_{1/2}$ values by ~30%. This demonstrates the important role played by reflected light in photoresist exposure. A straight line was obtained when $t_{1/2}$ values were plotted against the reciprocal of intensity. Thus, $t_{1/2}I_0$ = const. when the entire spectrum of the lamp is used for exposure. That is, knowing the exposure intensity and the constant for the sample it is possible to calculate the expected $t_{1/2}$ value. Likewise, similar linear relationships exist for the exposure carried out using the three main Hg lines in the near uv-blue region. In conclusion, a measurement of $t_{1/2}$ values for a known light intensity appears to be a useful means of characterizing photoresists. By this procedure, various photoresist samples can be compared and their

On the Incorporation of Oxygen in GaP Liquid Phase Epitaxy Layers

R. H. Saul and W. H. Hackett, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Previous optical absorption studies suggest the presence of significant background concentrations of oxygen in GaP (1). According to Miyauchi *et al.* (2), residual oxygen could be comparable to the total oxygen concentration[1] in O-doped crystals. In other experiments (4), the oxygen concentration could not be correlated with the Ga_2O_3 addition to the growth solution, and changes in oxygen concentration were reported to occur during low-temperature annealing. More recently, electrically inactive oxygen, in the form of β-Ga_2O_3 precipitates, have been observed in O-doped SG (solution grown) and LPE (liquid phase epitaxy) crystals (5). The possibility of such large variations in the oxygen concentration and concomitant variation in the number of Zn-O (red) radiative centers (6) have important consequences on the reproducibility of luminescent properties. In this work, we have studied the importance of the above factors in determining the oxygen concentration in GaP LPE layers. We have also examined several aspects of dynamic oxygen incorporation which clarify earlier results on O-doping (7-9) and have determined the maximum oxygen concentration which can be incorporated via LPE growth at ~1025°C.

Experimental

Both Zn- and Zn,O-doped layers were grown on Te-doped ($N_D - N_A \simeq 8 \times 10^{17}$) SG or LEC (liquid encapsulation Czochralski) substrates using a fused quartz sealed-tube LPE system which has been described elsewhere (9). Except where indicated, layers were grown in evacuated ampoules which were cooled from 1025° to 600°C at a rate of 10°/min. For several cases, encapsulated mesa diodes were fabricated (8) and the electroluminescent quantum efficiency η of representative diodes was measured at 300°K in a calibrated integrating sphere. The electroluminescent time-decay τ_D was also measured at 300°K using pulsed current excitation and an appropriate detection system (10). Near-junction oxygen concentrations were computed (9) from high resolution doping profiles (11) of the Zn- and Zn,O-doped LPE layers. Table I summarizes some of the experimental results.

Results and Discussion

Residual Oxygen

We have previously shown (8) that at a relatively high Zn concentration of $\sim 1.3 \times 10^{18}$ atoms/cm^{-3} [0.15 mole per cent (m/o) in the LPE solution], η increases monotonically with Ga_2O_3 addition, demonstrating that substantial and controlled additions of oxygen can be incorporated by LPE, contrasting with the results recently reported for SG crystals (1, 2, 4).

The most efficient GaP red-emitting diodes have been fabricated, using additions of 0.03 m/o Zn and 0.35 m/o Ga_2O_3 to the LPE solution (8) (entry A in Table I). The addition of Ga_2O_3 results in compensation of Zn acceptors equivalent to an increase in donor concentration of 2.7×10^{17} atoms/cm^3, which has been interpreted to be entirely due to the deep O donor (9). To substantiate this interpretation, an O-doped LPE layer was grown using the same Ga_2O_3 addition. The shallow donor concentration in this layer is $N_D - N_A \simeq 4 \times 10^{16}$ which is comparable to our undoped layers. Consequently, negligible additions of shallow donor impurities accompany the Ga_2O_3 additions and the tacit assumption (9) of equivalent background levels for the Zn- and Zn,O-doped layers is reasonable. [At lower epitaxy temperatures, it has been observed that significant S incorporation can accompany additions of Ga_2O_3 (12).] The oxygen concentration for our red-emitting LPE diodes (8) is thus about a factor of ~10 higher than the background concentration of uncompensated shallow donor impurities in these LPE layers. As discussed below, this oxygen concentration is also a factor of ~10 higher than the residual oxygen concentration.

The ratio of oxygen donor concentrations in Zn and Zn,O-doped LPE layers in the present work is estimated from the measured time decay τ_D and efficiency η of the red emission and from the net acceptor concentration, using a recent analysis (13) relating τ_D to the ratio τ_n/τ_{nt} (shunt path capture lifetime/Zn-O complex capture lifetime). For both layers we used the same 0.03 m/o Zn addition, and for the Zn,O-doped layer, a 0.35 m/o Ga_2O_3 addition. If we refer to Fig. 1 of Ref. (13), assume 80% Zn ionization (7), and use the measured values of $N_A - N_D = 5.3 \times 10^{17}$ cm^{-3} and $\tau_D = 175$ nsec for the Zn-doped junction and $N_A - N_D = 4.0 \times 10^{17}$ cm^{-3} and $\tau_D = 310$ nsec for the Zn,O-doped junction we conclude τ_n/τ_{nt} increases from ~0.3 to 3.0 with the O-doping. Correspondingly, the measured (peak) electroluminescent efficiency increased from 1.5% (no Ga_2O_3 added) to 5.5% with the O-doping. Using Fig. 3 of Ref. (13) and the above values of τ_n/τ_{nt}, theoretical quantum efficiencies of ~2% and 10% are obtained for the Zn-doped and Zn,O-doped layers, respectively, in reasonable agreement with the measured values if we allow for ~60-80% light extraction and ~60-70% electron injection efficiencies. Thus assuming τ_n is constant, O-doping increases the concentration of Zn-O radiative centers by a factor of ~10. (If τ_n decreases due to impurities introduced by the Ga_2O_3, this factor will be larger.) To calculate relative O concentrations, we expect from pairing theory (14) for Zn $\sim 5 \times 10^{17}$ atoms/cm^3 and O $\lesssim 5 \times 10^{17}$ atoms/cm^3 that the (equilibrium) Zn-O complex concentration is approximately proportional to the oxygen

Table I. Near-junction oxygen concentration for LPE layers grown from an initial temperature of 1025°C

Entry	Zn (m/o)	Ga_2O_3 (m/o)	Comments	Near-junction O donor concentration (atoms/cm^3)
A	0.03	0.35	—	$2.7 \pm 0.4 \times 10^{17}$
B	0.03	0.35	Capsule backfilled	2.6×10^{17}
C	0.03	0.6	—	2.6×10^{17}
D	0.03	0.02	Capsule backfilled	2.7×10^{17}
E	0.03	0.005	Capsule backfilled	0.3×10^{17}
F	0.03	0.35	Cooling rate of 1°/min	1.4×10^{17}
G	0.03	0.6	Cooling rate of 1°/min	3.1×10^{17}

All layers were grown in evacuated ampoules using a cooling rate of 10°/min, except as indicated. Ga_2O_3 levels refer to additions to the ampoule rather than the actual growth solution concentrations. The computed O donor concentration refers to levels above the background O concentration (see text). The uncertainty in O concentration for entry A reflects the range of values obtained for 26 LPE layers. Entry A corresponds to the doping levels used to achieve 7% diode efficiencies (10).

Key words: gallium phosphide, oxygen incorporation, luminescence, liquid phase epitaxy.

[1] Hereafter, oxygen concentration is used to denote only electrically (or optically) active forms, excluding the electrically inactive oxygen which has been suggested to exist (3).

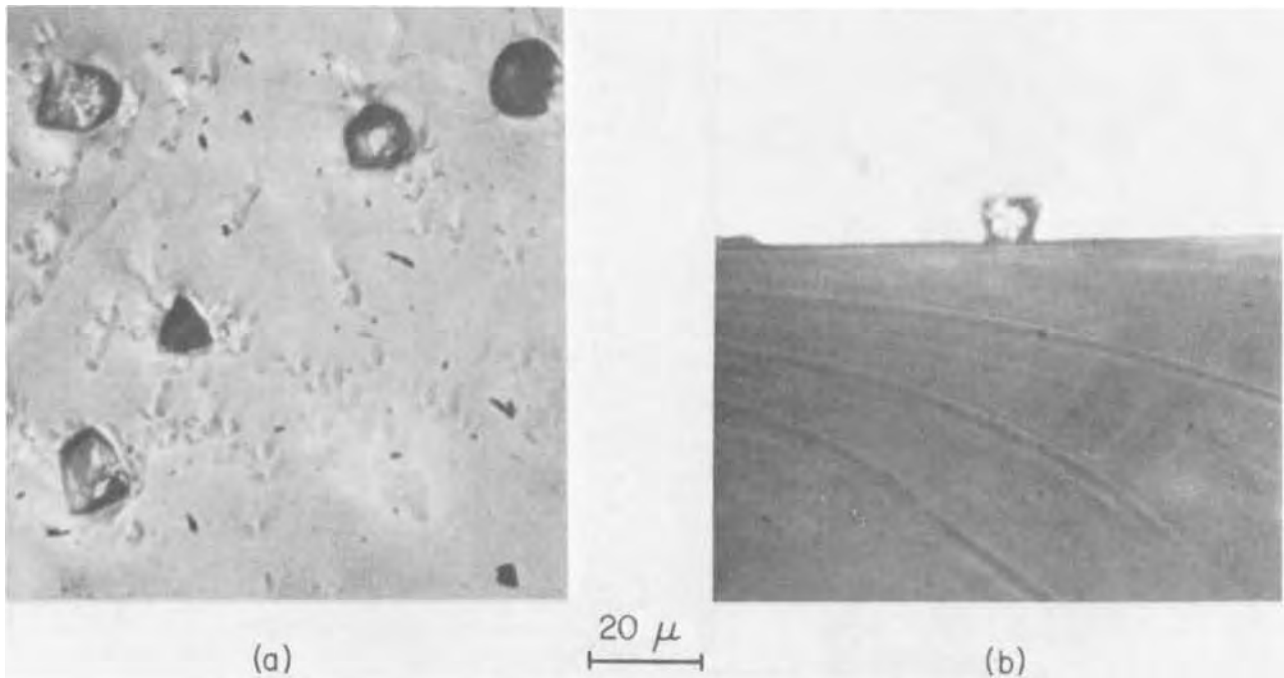

Fig. 1. (a) Granular precipitates penetrating the P{111} surface of a Zn,O-doped LPE layer, as viewed with combined incident and transmitted illumination. (b) Granular precipitate remaining after GaP matrix was removed by etching the P{111} surface, as viewed normal to the P{111} face with transmitted illumination.

concentration. Hence the oxygen concentration in the Zn,O-doped layers is expected to be at least an order of magnitude greater than for the Zn-doped layers, and the background oxygen concentration is thus $\lesssim 3 \times 10^{16}$ atoms/cm^3. This background level should not be sufficient to hamper controlled incorporation of oxygen in LPE layers, but it may be detrimental in green-emitting GaP where oxygen must be excluded from the crystal.

This background oxygen level may arise from the GaP starting material,[2] air entrapped in the Ga, or by the reaction of Ga with SiO_2 (15). We note that the substitutional oxygen concentration in SG crystals, as previously determined (7) by the degree of compensation in Zn,O-doped crystals, is only $\sim 7 \times 10^{16}$ cm^{-3} (a factor of 4 lower than for our LPE layers). Also, at the higher temperatures and slower cooling rates that are generally employed in solution growth we may expect increased oxygen incorporation from the SiO_2 growth vessel. Thus for SG crystals, unintentionally incorporated oxygen may be a substantial fraction of the total oxygen concentration as was claimed by Miyauchi (2). Variations in this background oxygen level may account for the lack of correlation between photoluminescence efficiency and O-doping reported by Dishman *et al.* (4).

Thermal Conversion of Oxygen by Annealing

Using He-3 activation, Kim (3) has determined the total oxygen concentration in SG O-doped GaP to be $\sim 2 \times 10^{19}$ cm^{-3} which is a factor of ~ 100 greater than the oxygen donor concentration determined in this work. These observations suggest that a considerable amount of oxygen can be present in electrically inactive forms, *e.g.*, interstitials, Ga_2O_3 or neutral O-complexes. In view of Kim's work, it is worthwhile to consider if thermal conversion of electrically inactive to electrically active (substitutional) O can be accomplished by low temperature annealing. On the basis of photoluminescent and absorption measurements of Zn,O-doped SG crystals, Dishman *et al.* (4) have suggested that low-temperature annealing increases the substitutional oxygen concentration. The Zn,O-doped LPE layers described in the present work were annealed for ~ 22 hr at temperatures in the range of 500°-600°C, a procedure which has been shown to increase η by a factor of ~ 3-4 (8). However, for Zn,O-doped layers the oxygen donor concentration before annealing was found to be the same as after annealing, demonstrating that thermal conversion of oxygen by low-temperature annealing is not significant for these LPE layers. This result is substantiated by reverse-bias junction capacitance measurements which indicate no change in doping levels following annealing.

Dynamic Oxygen Incorporation and Ga_2O_3 Precipitation

For several O-doped layers, optical transmission microscopy has revealed precipitates which were thought to be similar to the β-Ga_2O_3 needles previously observed by Kowalchik *et al.* (5) in O-doped GaP, SG and LPE crystals. However, careful sectioning of an O-doped layer by selective etching of the GaP matrix with hot aqua regia indicates that for these layers the precipitates are granular rather than acicular in shape and are mostly confined to the top surface of the layer. (See Fig. 1.) X-ray analysis confirmed that these precipitates are β-Ga_2O_3. The oxygen donor concentration was determined for a number of Zn,O-doped layers and found to be independent of the precipitate density. Since the precipitates are not in the vicinity of the p-n junction and contribute negligible absorption losses, they are not expected to deleteriously affect η. Indeed, re-examining our earlier (8) LPE diodes, we have found that η is independent of the presence of precipitates.

It has been previously suggested (5) that oxygen depletion of an LPE solution can occur due to the high partial pressure (~ 10 Torr) of Ga_2O over Ga saturated with oxygen at typical LPE temperatures (16). This depletion will always tend to occur in open-tube systems and can also occur in sealed-tube systems if thermal gradients exist. Measurements of the dynamic temperature profile within our growth ampoules indicate that, although the temperature along the length of the boat (containing the substrate and LPE solution) remains constant to within $\pm 3°$, the sealing plug can be

[2] The total oxygen concentration in our GaP source material is estimated to be 1.5×10^{17} atoms/cm^3, based on mass spectroscopy and He-3 activation analysis of similar material. (S. F. Nygren, Private communication.)

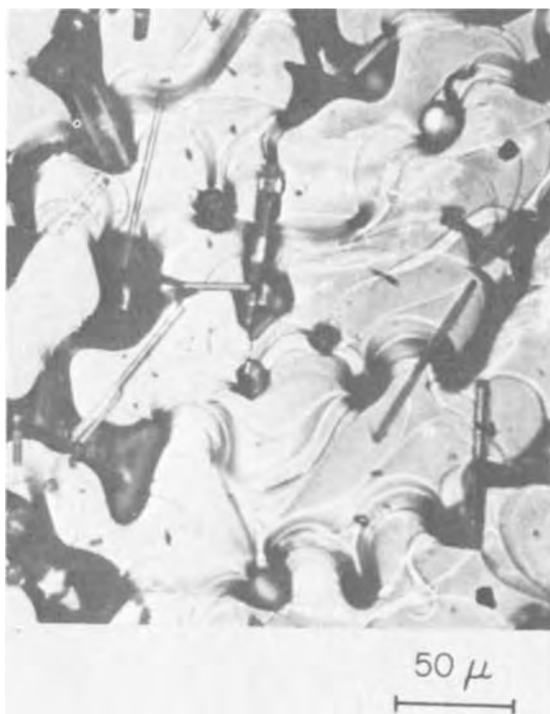

Fig. 2. Acicular precipitates on the surface of a Zn,O-doped LPE layer grown from an O saturated solution, as viewed by Nomarski interference microscopy. (See text.)

as much as 15° cooler. This temperature differential is apparently sufficient to efficiently transport oxygen (via Ga_2O pumping) since we find that reducing the mean free path, by backfilling with an inert ambient, results in a large excess of undissolved Ga_2O_3 remaining in contact with the Ga during growth. (Excess Ga_2O_3 was not observed with evacuated capsules.) In this case the LPE layers are laden with needlelike precipitates which penetrate the entire LPE layer, as observed by Kowalchik *et al.* (5). (See Fig. 2.)[3] The near junction oxygen concentration for such a layer (entry B in Table I) was found to be the same as for the LPE layers described above.

The fact that the O concentration is essentially a constant implies that either (*a*) the GaP layer is saturated with oxygen if the Ga_2O_3 precipitates within the GaP matrix during cooling of the LPE layer or (*b*) the LPE solution is nearly saturated with oxygen if the Ga_2O_3 coprecipitates with the GaP. The large size of the precipitates and lack of a common growth habit suggest that solid-solution precipitation is not occurring. Moreover, the disappearance of the precipitates when the Ga_2O_3 addition is lowered below the solubility limit of O in Ga (5), supports the contention that coprecipitation is occurring. Substantially larger Ga_2O_3 additions are thus not expected to appreciably increase the incorporated oxygen concentration, in agreement with our observation of no detectable increase in oxygen level for a 70% increase in Ga_2O_3 addition (entry C in Table I). Thus the maximum oxygen concentration which can be incorporated at 1025°C is $\sim 3 \times 10^{17}$ atoms/cm^3. This limiting value corresponds to growth from an O-saturated growth solution.[4] The effect of growth temperature on oxygen incorporation is reported elsewhere (12).

[3] For layers grown in evacuated capsules, the precipitates are confined to the surface of the LPE layer and appear to be granular; hence, the supersaturation sufficient to result in gross precipitation apparently occurs only at the lowest temperatures encountered during growth (~800°C). Extrapolating the data of Ref. (7), we estimate the solubility of oxygen in Ga to decrease by a factor of ~30 during cooling from 1000° to 800°C.

[4] We note that if the (growing) GaP solid is in equilibrium with the O-saturated liquid, *i.e.*, the chemical potential of oxygen is the same in these phases, the incorporated oxygen concentration corresponds to the maximum solid solubility.

The solubility limit of Ga_2O_3 in Ga at 1025°C has been determined to be ~0.01 m/o (7). When the Ga solution is saturated with GaP, the liquid concentration where Ga-GaP-Ga_2O_3 are in equilibrium shifts to ~0.008 m/o Ga_2O_3 (5). Since the maximum incorporated O level is thought to correspond to an O-saturated LPE solution, it follows that when Ga_2O transport is suppressed, this maximum value should be achieved with Ga_2O_3 additions of ~0.01 m/o, while for lower Ga_2O_3 additions, the oxygen concentration will be reduced. These expectations are borne out by entries D and E in Table I. O-depletion of the growth solution thus accounts for the large disparity between the low Ga_2O_3 solubility and the large Ga_2O_3 additions previously used to achieve comparable O concentrations in 7% diodes (8, 9). In this vein, it is worth noting our previous work (9) which suggested that decreasing the LPE cooling rate from 10°/min to 1°/min decreases the incorporated O level by a factor of ~2 (*cf.*, entries A and F). The reduced O level with slower cooling was probably the result of O-depletion of the Ga and serves to emphasize the dynamic nature of O incorporation. We now find that by increasing the Ga_2O_3 concentration, the limiting O concentration of $\sim 3 \times 10^{17}$ atoms/cm^3 can be attained at the slower cooling rate (see entry G). Identical results are obtained by backfilling the growth ampoules with an inert ambient.

Summary and Conclusions

The residual O concentration in GaP LPE layers grown at ~1000°C in a quartz system has been estimated to be $\sim 3 \times 10^{16}$ atoms/cm^3. This value is about a factor of 10 lower than the intentionally added O in Zn,O-doped layers and thus it should not affect the reproducibility of the red luminescence. The high radiative efficiency [η(red) = 1% for SG substrates] which can result from the residual O, may prove detrimental in green-emitting GaP.

We have found no evidence of changes in near-junction doping levels resulting from annealing in the range of 500°-600°C. The increased efficiency brought about by annealing is thus not the result of changes in electrically active O concentration.

The maximum oxygen concentration which can be incorporated by LPE at 1025°C is $\sim 3 \times 10^{17}$ atoms/cm^3; this value corresponds to an O-saturated LPE solution. For this case, β-Ga_2O_3 coprecipitates with GaP during cooling but has no effect on the electrically active O concentration. An oxygen concentration of $\sim 3 \times 10^{17}$ atoms/cm^3 can be incorporated for Ga_2O_3 additions as low as ~0.02 m/o by minimizing Ga_2O transport. When Ga_2O transport occurs, very large Ga_2O_3 additions may be required to maintain saturation of the LPE solution, and the incorporated oxygen concentration will tend to decrease with slower cooling rates.

Low-Temperature Electrostatic Silicon-to-Silicon Seals Using Sputtered Borosilicate Glass

A. D. Brooks* and R. P. Donovan*

Research Triangle Institute, Research Triangle Park, North Carolina 27709

and C. A. Hardesty

National Aeronautics and Space Administration, Langley Research Center, Hampton, Virginia 23365

The Mallory electrostatic sealing process (1, 2) is a method of anodically bonding two dissimilar materials together to form a strong, hermetic seal which involves little alteration in the shape, size, and dimensions of the members making up the joint. Previous applications have involved the sealing of a metal or semiconductor to an insulator, such as glass or ceramic. In this brief note we describe a method for sealing two silicon surfaces together by depositing a thin, borosilicate glass layer on one of the polished silicon members to be sealed. Our method for depositing the borosilicate glass layer is sputtering. Most likely the method is equally applicable with other deposition methods capable of similar control of film composition and thickness.

Experimental Technique

The surfaces of the silicon members to be sealed are polished by either mechanical, electrochemical, or high-quality chemical methods. These surfaces are cleaned and stripped of any residual oxide by immersion in concentrated hydrofluoric acid. The surfaces are then coated with sputtered borosilicate glass. We used an MRC-340 sputtering unit fitted with a 5 in. Corning 7740 ("Pyrex") borosilicate glass target. R-F sputtering was carried out in a 1% oxygen in argon atmosphere. Power levels varied between 150 and 800W. The critical property for satisfactory sealing is a minimum glass thickness of approximately 4 μm. Below this thickness the areas of satisfactory seal between the two silicon members are patchy and discontinuous. Substrate temperature during deposition was not controlled directly; the copper block upon which the silicon samples rested was either held at a temperature of about 50°C by water cooling or allowed to reach a temperature as high as 380°C when no water cooling was used. The sealing behavior of the sputtered film appeared insensitive to the deposition temperature over this span. No means of insuring good thermal contact between the silicon and the copper block was employed so that the temperature of the silicon samples themselves was most likely higher than that of the measured temperature of the copper block.

After sputtering the borosilicate glass layer, each coated silicon substrate was annealed, most often in steam, at a temperature between 500°-900°C. This steam annealing greatly improved yield during the subsequent sealing operation. The annealing temperature and ambient are not critical, but inclusion of some high-temperature heat cycle is required for satisfactory seals. Oxygen and nitrogen ambients during annealing were also used. Slightly higher yield during sealing seemed to be associated with the steam anneal.

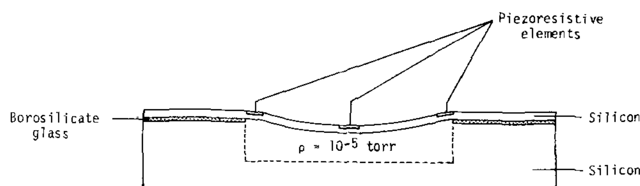
To carry out the silicon-to-silicon electrostatic seal, a second polished silicon chip is placed on top of the first silicon member which is already coated with borosilicate glass. This second silicon member is polished by the same technique used to prepare the first surface. The two members are aligned in the desired orientation and held in position by a weight which is electrically conductive so as to serve as a top electrode as well as a pressure load. The combination is then heated on a graphite strip to a temperature of 450°-550°C. After the sandwich is stabilized at temperature, a slowly increasing d-c voltage is applied across the silicon-borosilicate glass-silicon sandwich, the uncoated silicon member being positively biased with respect to the glass-coated member. The primary control during sealing is total current flow which was limited to about 0.5 mA for these samples (corresponding to a current density of approximately 1 mA/cm^2). The voltage is advanced in steps as the current decreases with time. A maximum voltage of 50V is adequate for a satisfactory seal. After reaching the maximum voltage, the sandwich is left at temperature and voltage for 5 min. The substrate heater is then shut off so that the temperature of the sandwich can decrease to near room temperature before the voltage is turned off. This completes the sealing operation.

To evaluate the hermeticity of such a seal a number of silicon-to-silicon seals were prepared in which one silicon member of the silicon-borosilicate glass-silicon sandwich had a deep cavity etched part way through it. The second silicon member was then thinned to a total thickness of 0.025-0.1 mm (1-4 mils) and the sealing operation was carried out inside a vacuum chamber at a pressure of approximately 10^{-5} Torr. Upon completing the seal and removing the unit from within the chamber, atmospheric loading on the top, thin member of the sandwich produces a visible depression in the top member above the cavity in the bottom member, as illustrated in Fig. 1.

The top member of this particular unit is a piezoresistive silicon diaphragm with twelve junction isolated resistors ion implanted into its top surface. These resistors are positioned so that some are in tension and

* Electrochemical Society Active Member.

Key words: sealing, electrostatic sealing, hermetic, housing, packaging, silicon-to-silicon seals.



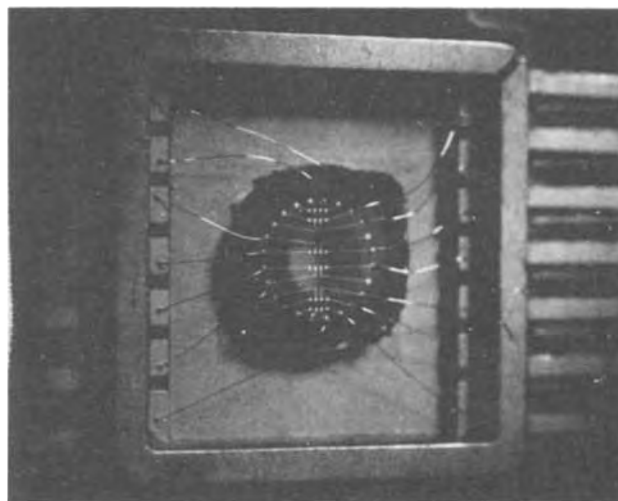


Fig. 1. Electrostatically sealed piezoresistive pressure transducer. (a, left) Sketch, (b, right) Photograph

others in compression because of the atmospheric pressure. When these resistors are externally connected in a Wheatstone bridge configuration, the output voltage of the bridge is a measure of the atmospheric pressure. The cavity diameter across which the thin silicon diaphragm is suspended is 2 mm in this illustration; the sealing area is a 1 mm ring surrounding the cavity. Reducing the ambient pressure surrounding the structure of Fig. 1b causes the dimple to disappear because the diaphragm is thereby unloaded.

Bottom views of similarly sealed units are shown in Fig. 2. The unit on the left is a silicon diaphragm electrostatically sealed to a borosilicate glass cavity. The cavity dimensions and position are clearly visible in this unit; the silicon unit on the right is identically shaped and has been sealed using the borosilicate glass methods described in this paper. These units are only one example of the application of this technique; both larger and smaller areas have been sealed. No effect associated with area has been identified. Current density during sealing has been held to $\lesssim 1$ mA/cm^2, but this current density is not optimum or anything more than an arbitrarily selected, convenient value.

An evacuated cavity such as that illustrated in Fig. 1 has been measured as essentially leak-free by helium leak-testing. Even after 63 thermal cycles between $+100°$ and $-40°$C, the unit showed no loss of dimple or measurable leak rate by helium leak-testing. To carry out the helium leak test, the unit was stored in a helium atmosphere for approximately 3 weeks at a pressure of 2×10^5 N/m^2 (2 atmospheres) of helium.

Fig. 2. Bottom view of electrostatically sealed piezoresistive pressure transducers. (a) Borosilicate glass cavity, (b) Silicon cavity.

The unit was then placed in the helium detection chamber in order to measure trace quantities of escaping helium. No traces of helium could be detected.

No other evaluation of the quality of this seal (such as tensile or shear tests) has been made; the thermal shock limits have not been determined. The value of the process is its compatibility with sealing to silicon device structures which have already been metallized with aluminum. Previous methods for housing silicon elements in silicon packages have involved higher temperature processes and have therefore required that metallization follow the sealing (3). Elimination of this restriction allows greater freedom in both device and package design.

Conclusion

A technique has been described for hermetically sealing silicon members to each other at a temperature $\lesssim 500°$C. The method involves no measurable deformation of the surfaces being sealed and hence is compatible with package designs of tight tolerance. The advantages of the all-silicon package are especially important for compensating the effect of temperature upon piezoresistive and piezojunction sensors. Since a low-pressure reference can be sealed between two members, the technique is compatible with the construction of absolute pressure transducers.

Preferential Electrochemical Etching of P^+ Silicon in an Aqueous HF-H_2SO_4 Electrolyte

C. P. Wen and K. P. Weller

RCA Laboratories, Princeton, New Jersey 08540

Electrochemical polishing and preferential etching techniques and their application to thin-film silicon device technology have been described by many workers (1-3). A major difficulty encountered has been the continued formation of thick brown films on the semiconductor surface during etching under low-current-density conditions (1). At the high bias voltages commonly employed to achieve sufficiently high current densities and insure the elimination of brown-film formation, preferential removal of a p^+ layer from a higher resistivity n layer leaves a rough surface (3) which is undesirable for device fabrication. The addition of sulfuric acid to the standard HF-H_2O solution employed by most previous workers permits a reduction of the bias to less than 0.5V yet maintains a high current density. As a result the effectiveness of the self-limiting preferential etching is increased because the higher current density eliminates the build-up of thick brown films on the p^+ silicon surface and leaves a smooth surface on the unetched higher resistivity silicon layer.

Preferential removal of p^+ silicon by the electrochemical etching process has been carried out on heavily doped substrates with epitaxially grown 5-μm-thick n-type layers ($n \cong 2 \times 10^{16}/cm^3$). The sample, with a 0.5V bias applied, is etched in a freshly mixed electrolytic solution (500 ml H_2O, 100 ml 50% HF, 100 ml 98% H_2SO_4) using a platinum cathode. Constant agitation during the etching process is required. Over 200 mA/cm^2 current density has been obtained at the 0.5V bias. Abrupt termination of the etching takes place as soon as the p-type substrate layer is completely removed and the total current then drops to less than 5% of its original value. Accompanied with the drastic drop in current is the formation of a very thin dark brown film on the exposed n-layer. This film is removed by etching the sample in a 97% HNO_3-3% HF mixture for a few seconds thereby yielding a smooth n-type silicon surface. The low bias voltage employed in this etching process reduces the possibility of hole injection from the p^+ layer into the n-layer and results in a more abrupt termination of the etching process; the increase in current density obtained by the addition of the H_2SO_4 probably provides a smoother post-etched surface condition for the n-type layer. This process has been carried out successfully under normal room illumination conditions, eliminating the complete darkness requirement mentioned by previous workers (3).

A comparison has been made of the characteristics of this three component electrolyte with the traditional aqueous HF solutions. The effect of electrolyte composition on the current density (the current density is directly proportional to etch rate) is shown in Fig. 1 for HF-H_2SO_4-H_2O, and HF-$HClO_4$-H_2O solutions. With an initial electrolyte composition of 100 ml 50% HF in 500 ml distilled water, the current density is slightly over 20 mA/cm^2 at 0.5V bias. Commercially available concentrated acids are added to the initial solution. To allow thorough mixing the current density measurements are taken 30 sec after the addition of acid. As shown in Fig. 1 the addition of sulfuric acid to the initial HF-H_2O solution is found to increase the current density and, therefore, enhance the etch rate considerably. A current density of 218 mA/cm^2 at 0.5V bias has been obtained with 100 ml of H_2SO_4 added to the initial aqueous HF electrolyte. Most important of all, the current density rises well above the critical value of $\sim$ 70 mA/cm^2. Above this critical value brown film build-up on the p^+ silicon surface does not occur (1). The change in current density caused by the addition of HF or $HClO_4$ is found to be less striking and the formation of brown film on the sample surface is observed at 0.5V bias. The brown film is removed with a quick etch in 97:3 HNO_3 (70%), HF (50%) after each data point is taken. The rise in current density in the freshly mixed HF-H_2SO_4 electrolyte is found to be caused at least partially by the 40° temperature rise in the solution when concentrated H_2SO_4 is diluted. No such change in temperature is observed when HF or $HClO_4$ is mixed with water.

The effect of temperature on the current density at 0.5V is shown in Fig. 2 for both the HF-H_2SO_4 - H_2O and HF-H_2O electrolyte of composition designated. The current density at 0.5V bias is monitored as the solutions cool by natural convection. No brown film formation has been observed on the p^+ substrate surface in the HF-H_2SO_4 - H_2O electrolyte, within the experimental temperature range (25°-66°C) while increas-

ingly rapid formation of brown film on the surface of the same sample is observed with increasing temperature when the $HF-H_2O$ solution is employed. The incorporation of H_2SO_4 into the electrolyte appears to increase the etch rate without undesirable side effects.

In summary, an $HF-H_2SO_4-H_2O$ electrolyte is found to be suitable for electrochemical preferential removal of p^+ silicon from epitaxially grown n-type layers. The introduction of H_2SO_4 to the electrolyte tends to increase the etch rate and reduce the bias requirement to less than 0.5V. This self-limiting preferential-etching process leaves a smooth surface on the unetched higher resistivity n-type layer.

Acknowledgment

The authors wish to thank H. Davis, J. Jaklik, and A. Young for their assistance in sample preparations and Y. S. Chiang for helpful suggestions and advice during the preparation of the Si epitaxial layers.

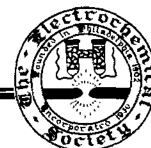
Brief Communication



A Note on Manganese-Activated Magnesium Arsenate

E. Kostiner* and P. W. Bless

Baker Laboratory of Chemistry, Cornell University, Ithaca, New York 14850

Magnesium arsenate has been reported (1) as a red-emitting phosphor activated by quadrivalent manganese having the composition $6MgO \cdot As_2O_5$. Its emission spectrum has been investigated (1, 2) and compared with manganese-activated magnesium fluorogermanate (3, 4). As part of a program investigating the structural parameters of manganese(IV)-activated phosphor systems (5-7), we have prepared single crystals of magnesium arsenate by standard flux growth techniques. This note reports the crystal growth and powder x-ray crystallographic data for this compound.

Experimental

The phosphor was prepared by standard ceramic technique. Magnesium oxide (Mallinckrodt Analytical Reagent) and arsenic pentoxide (Fisher Certified Reagent) in a 6:1 mole ratio with 1 mole per cent (m/o) manganese carbonate (Fisher Certified Reagent) added as an activator were mixed and ground under acetone. After removal of the acetone at 110°C, the mixture was fired in a platinum crucible at 1000°C in air for 1 hr, reground and fired for 16 hr at 1200°C.

A suitable high-temperature flux for the crystal growth of the arsenate was found to be a eutectic in the $PbO-As_2O_5$ system occurring at approximately 83 m/o PbO-17 m/o As_2O_5 (8). Then 33.67g of this eutectic mixture (0.150 "mole") and 7.08g of the composition $6MgO \cdot As_2O_5$ (0.015 mole) were mixed and packed into a 25 cm³ platinum crucible. The tightly covered crucible was placed in a silicon carbide resistance-heated furnace, held at 1225°C for 4 hr, cooled at a rate of 8°C/hr to 600°C, and then removed from the furnace. To protect the platinum crucible, dry oxygen was passed through the furnace. The arsenate crystals were removed from the flux by leaching with hot, very dilute hydrochloric acid and by ultrasonic cleaning in water.

* Electrochemical Society Active Member.

Key words: crystal growth, magnesium arsenate, Mn^{+4}-activated phosphors.

Results

The grown crystals were irregularly shaped with maximum dimension of about 2 mm. Occasionally, hexagonal plates up to 0.5 mm thick and 2 mm cross section were found. The experimental density (buoyant force) was 3.96(1) g/cm³.

Single-crystal precession and Weissenberg photographs indicated rhombohedral symmetry; the space group was identified as R_{3m}. The composition of magnesium arsenate was determined to be approximately

$Mg_{8.5}As_3O_{16}$ (5.67 $MgO \cdot As_2O_5$) by analytical results (Mg: calc 30.06, obs 29.6; As: calc 32.70, obs 32.7) and by a complete three-dimensional structural analysis (9). It has the same structure as the compound "$Co_8As_3O_{16}$" reported recently by Calvo (10), which is based on a twelve-layer cubic close-packed array of oxygen atoms. A detailed discussion of the structure will be presented with the completed structural analysis.

The indexed powder pattern of ground single crystals (x-ray diffractometer, Cu $K\alpha$ radiation) is given in Table I. The refined unit cell dimensions are a_o = 6.034 (2)Å, c_o = 27.67 (2)Å (hexagonal setting); a_R = 9.859 (6)Å, α = 35.64 (3)° (rhombohedral setting).

In summary, single crystals of the phosphor manganese-activated magnesium arsenate have been prepared and the indexed powder pattern has been reported. The complete three-dimensional structural analysis will be published shortly.

JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS

FEBRUARY 1972

Molecular Understanding of Electrochemical Processes by Ice Research[1]

A. von Hippel

Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Your kind invitation to give the opening lecture at this annual meeting of the Electrochemical Society greatly honored and slightly worried me. When one is exposed like a political candidate (Fig. 1), the audience expects last words of wisdom, and then the letdown comes in one way (Fig. 2) or another (Fig. 3). Fortunately, as scientists and engineers we are supposed to be experts in something, have doubts about certain developments, and ideas about others. To look at the field of electrochemistry with such doubts and ideas, however controversial they may be, I believe is the task you have set me.

[1] This is the Electrochemical Society Lecture delivered at the Cleveland, Ohio Meeting of the Society, October 4, 1971.

From turbulence to deep-freeze.—Electrochemistry was born during the French Revolution, the unexpected offspring of the frog leg experiment on this balcony in Bologna during a thunderstorm by the physician Dr. Galvani (Fig. 4). How could its youth be anything else but stormy. Not only the political but the scientific world was in violent upheaval. Cavendish had just demolished the nearly religious Aristotelian conviction held for more than 2000 years that water is one of the "four elements," by generating it from a mixture of air and "inflammable" air (alias hydrogen) with an electric spark. Actually, since nitrogen was

Fig. 1. "Pyramids rise and fall. But what our next speaker has to say will always be remembered as . . . ."

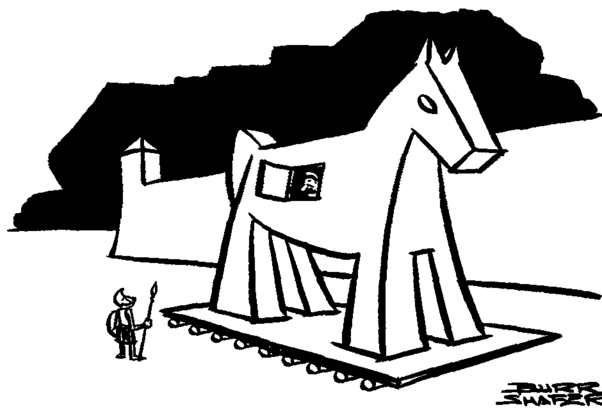

Fig. 2. "I said it's stuffy in here"

Fig. 3. "It's still in the experimental stage"

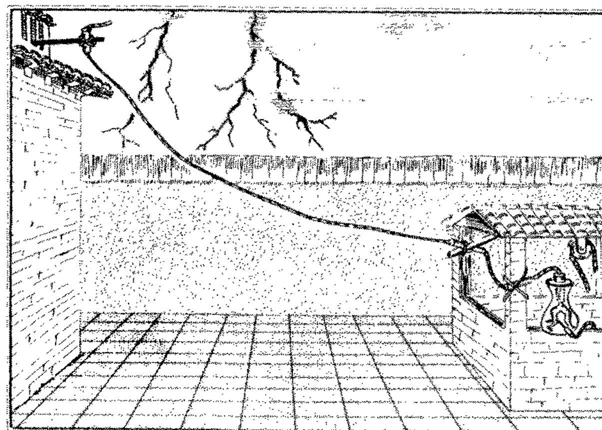

Fig. 4. Galvani and the balcony scene during the frog leg experiment (Sept. 1786)

present, the end product proved to be nitrous acid generated by an electric spark, the first certified case of automotive air pollution. This still confused Winston Churchill about one hundred years later, when he wrote from prep-school in amazement: "is it not wonderful to think that water is made of two gases, namely, hydrogen and nitrodgen." But in the meantime, Dr. Volta with his cell (Fig. 5) had opened the way to quantitative electric experimentation with low d-c voltages, and Dr. Galvani's "Animal Electricity" had fallen into disgrace. The president of the Royal Society, in presenting the Copley medal to Volta (1794), rubbed it in: "The experiments of Professor Galvani, until commented upon by Professor Volta, had too much astonished, and perhaps, in some degree perplexed many of the learned in various parts of Europe. To Professor Volta was reserved the merit of bringing his countryman's experiments to the test of sound reasoning and accurate investigation; he has explained them to Dr. Galvani himself and to the whole of Europe. . . ."

Electrochemistry, thanks to the electric cell, became proprietor of the whole field of electrolytic conduction with its science and technology of ionic systems. Its findings were of decisive help for the formulation of the periodic system. The currents of its batteries led to the discovery of electromagnetism by Oersted (1820) and, in turn, to Faraday's reverse experiment of electromagnetic induction (1831). Thus electromagnetism and electrical engineering, concerned mainly with fields, insulators, and metallic conductors, became its progenies. Electrochemistry, centered on liquid systems and ionic conductors, cast them off and chose physical chemistry, the treatment of thermodynamic and statistical equilibria, as its guide for theoretical insight.

I still had the privilege to see several of its pioneers in action. From childhood I remember Professor Nernst setting out on his impossible 120-mile trip from Göttingen to Berlin by automobile in 1905, horn-blowing and the faculty cheering and waving handkerchiefs (Fig. 6). In the dark of night, there was the auto again, broken down and pulled by two oxen, but with an undaunted Professor Nernst. He took a train to a city near Berlin, bought a new car and held his entry triumphantly at the appointed hour. Professor Tammann, his successor in Göttingen, cheered me up

Fig. 5. Alessandro Volta

Fig. 6. Professor Nernst and family setting out for Berlin.

no end when I was sitting as a young student in his lecture and thermodynamics seemed beyond my grasp: "Hü," he exclaimed, "there is 'that man' in Berlin who says he invented a Third Law of Thermodynamics; we need not to learn it." But "that man" took those laws seriously. Retiring in old age to his farms, he proclaimed: "Cattle raising is thermodynamically wrong because it heats the universe; I am growing carps"—and so he did.

As the memory drum whirls on, the sky of electrochemistry, studded with stars of the first magnitude, clouds over and a snowstorm of mathematical equations approaches, covering the landscape with semi-empirical assumptions and frozen activity coefficients. Volta's field of electrolytes seems paralyzed and Galvani is now in the ascendency with "animal electricity" an exciting center-piece of molecuar biology. What has gone wrong?

Water and ice.—Water is the basic fluid of electrochemistry and "the staff of life" for biology, but what do we really know about it? "Nearly everything that thermodynamics can measure and statistics interpret," the physical chemist is bound to answer (1). "Nearly nothing," the molecular scientist will retort "because those tools lead only to surmises." Both are right from their points of view. Physical chemistry finds itself today in the same dilemma that afflicted electrical engineering two to three decades ago. Circuit and field theory, akin to thermodynamics and statistics, could describe materials and their properties in reference to vacuum, but only the advent of "molecular science and molecular engineering" allowed us to understand them and to tailor them to order (2).

This understanding is still essentially restricted to gasses and solids. We cannot really visualize the molecular structure of water nor, in molecular detail, the happenings in aqueous solutions and on their surfaces and interfaces, because these liquids are in chameleon-like structure transitions. H_2O in the gaseous state behaves like a harmless dipole molecule with typical infrared modes of vibration and rotation and with Rydberg series of electronic excitation in the far ultraviolet (Fig. 7). In the condensed states, however, it tends to be tetrahedrally interconnected by hydrogen bonds (Fig. 8). These weak bonds of *ca.* 5 kcal/mole break about every 10^{-12} sec in thermal fluctuations at room temperature, hence the need for statistical surmises about the actual happenings behind this fluctuating structure screen. To perceive events in clear detail, we must nail the H_2O molecules into place. We have done so by shifting the emphasis from water to ice and operating with single crystals.

Several times before, our laboratory has used that roundabout approach with success in various fields to clear up tantalizing questions about the behavior of materials. Many years ago, for example, the electrical engineer tried to understand and control electric breakdown by statistical studies on materials like air, oil, paper, and glass. By choosing instead, single crystals of the alkali halides as test objects with their well-known lattice structure and wide range of ionic substitution, we could discern in detail the development of electric breakdown as a sequence of electrochemical events (Fig. 9): injection of electrons from the cathode, of copper ions from the anode, and their recombination as copper colloid; discharge of alkali ions at the cathode and dendrite growth of an alkali metal Christmas tree; electron avalanche formation leading to the drilling of a plasma path from anode toward cathode in preferential lattice direction; finally melting of the crystal when this thunderbolt hits the dendrite tree (3). From these experiments a way of understanding could be found to solids, liquids, and gases of technical importance (4). Thus, hopefully, we may learn to understand aqueous systems better by research on ice single crystals. In the time remaining, allow me to present some of the results obtained thus far.

The phase diagram of ice and its molecular interpretation.—The complexity and beauty of ice research becomes apparent when one looks at the phase diagram (Fig. 10) known, thanks to the pioneering effort of Tammann (5) and Bridgman (6) and recently completed research, especially the excellent work of Kamb (7), Whalley (8), and co-workers. Thermodynamically

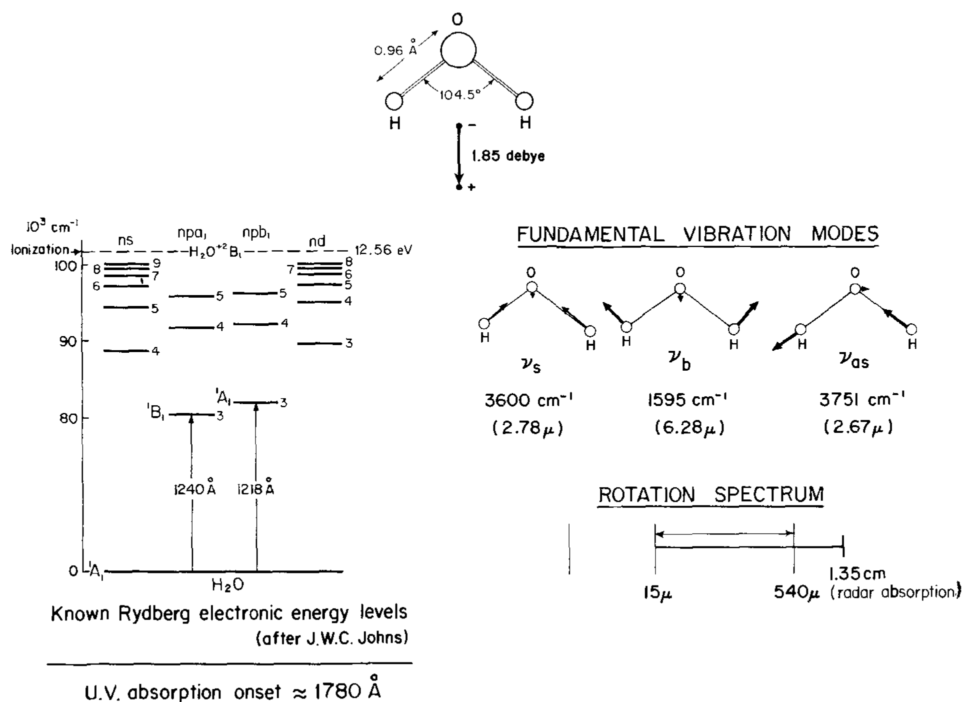

Fig. 7. The H_2O molecule and its spectrum.

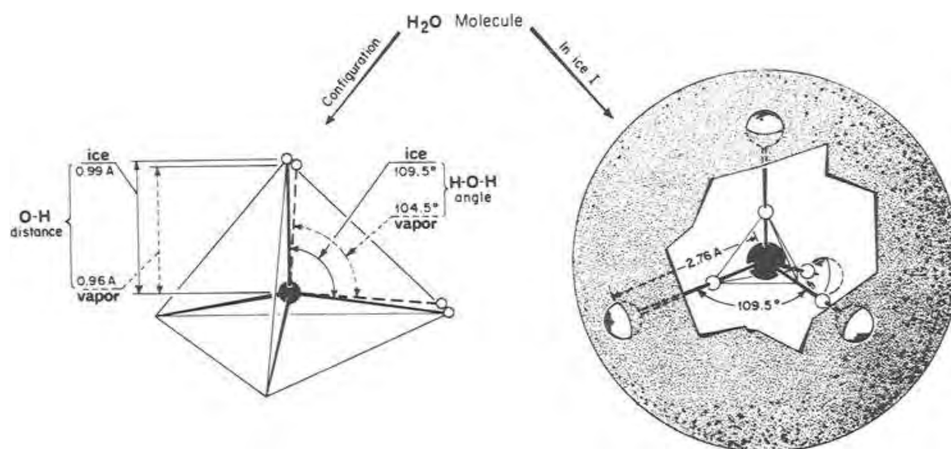

Fig. 8. The H_2O molecule in vapor and Ice I.

speaking, it is one of the most complex diagrams yet found for a simple compound. Diffraction analysis certifies that one deals with tetrahedrally bonded H_2O molecules throughout. An inquiry, how the individual water molecules must shift to produce these structures, leads to some intrinsic insight about the interaction between such molecules as function of temperature and approach distance. Let me illustrate the type of information obtainable from such a study (9).

Ice in nature crystallizes in the hexagonal wurtzite structure, puckered hexagonal chair-rings forming planes stacked in ABABAB *etc.*, sequence normal to the c axis (Fig. 11). Open hexagonal channels traverse the crystal in the axis direction and lower the density of ice by *ca.* 10% compared to that of water. Since the channels offer freely available space, they are bound to play a vital role under pressure and in accommodating addition agents.

In the Ice I → Ice II transition, the H_2O molecules remain in their puckered planes but, squeezed into the channels, tend to form diagonal bonds across them; one half of all the hexagon columns are destroyed in the bargain. The surviving ones are alternately pushed up and down; the old c axis survives as a threefold axis (Fig. 12). The Ice I → Ice III transition, in contrast, proceeds by hydrogen bond formation to second-nearest neighbors across the hexagon chair-rings in the puckered planes as well as across the hexagon boat-ring normal to these planes. All hexagon rings are destroyed and pentagon rings are formed instead. While in Ice II, all the H_2O molecules of the Ice I structure can be accommodated, in Ice III every fourth water molecule is squeezed out. These rejects may form the elusive Ice IV phase.

Focusing on oxygen positions and bond directions, one can develop systematically the structures from Ice I to Ice IX, but this is only one half of the story. The other half comes into view when one inquires about proton locations. A tetrahedral array of N water molecules has 2N O-O links, hence one proton per link, while two equivalent proton positions are offered in an ideal tetrahedral structure of six equal bond angles H-O-H $\simeq$ 109.5°. Ice I approaches this ideal situation; in consequence, the protons distribute themselves more or less at random over the competing sites as Pauling first concluded from zero-point entropy measurements (10). In the higher ice structures, however, large deviations from the tetrahedral bond angle may occur and proton ordering, preferentially seeking the smaller

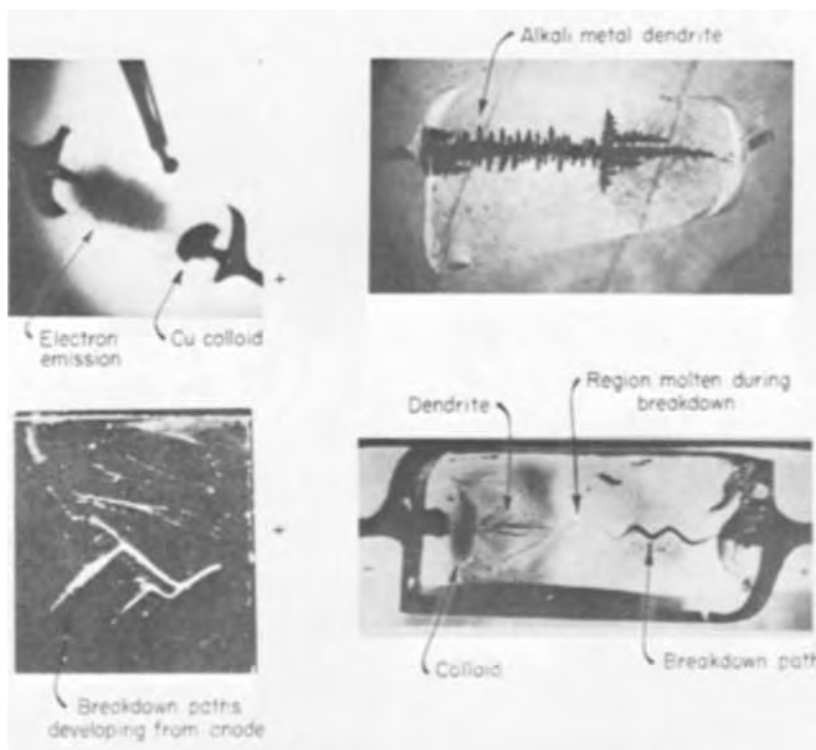

Fig. 9. Events before and during breakdown (NaCl crystal, Cu electrodes).

angles, can lower the lattice energy. Figures 13a, b show two typical situations of antiferroelectric ordering, first recognized by Whalley and co-workers (8): in the Ice I → Ice II transition, immediate proton ordering occurs and the permittivity drops to its near infrared value; the Ice I → Ice III transition offers less

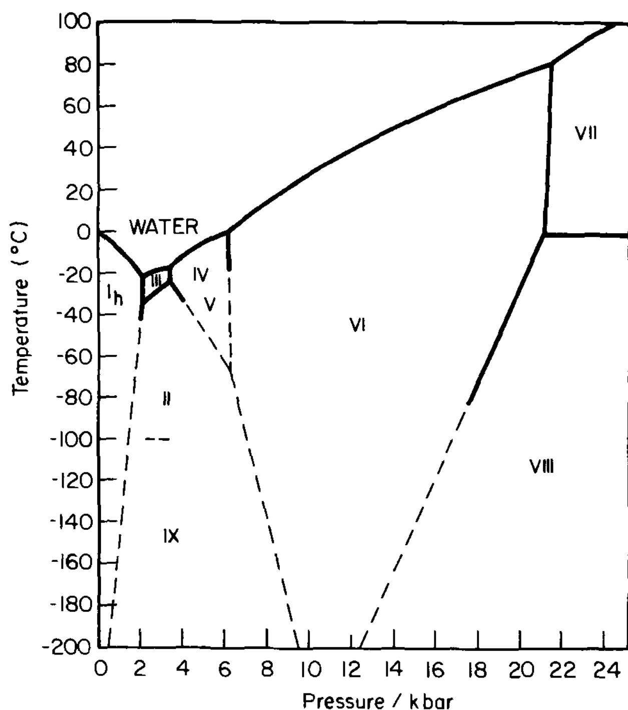

Fig. 10. Phase diagram of ice

incentive for ordering, hence the protons stay randomized until temperature decrease allows successive ordering accompanied by lattice distortion to the Ice IX phase.

Much more can be learned from the phase diagram about molecular phenomena (9), but let us hurry on to our central theme, the elucidation of electrochemical processes by ice research.

Polarization and conduction in ice—Seen from the standpoint of ideal crystal structure, the application of an electric field to ice should result in a slight charge displacement akin to its infrared dielectric constant $k_i' \simeq 3$. Instead, a big relaxation spectrum appears as in water, but is displaced by about a factor 10^7 toward lower frequencies (Fig. 14). The original explanation that ice behaves water-like but that the viscosity resisting the orientation of the H_2O molecules has increased by a factor 10^7, is obviously nonsense; the crystal lattice stays intact. Bjerrum (11) came nearer to the truth by postulating two thermal excitation processes: molecule rotation requiring the breaking of three hydrogen bonds and placing two protons on one O-O link ("D" defect), none on another "(L" defect); and proton transfer to a neighboring H_2O molecule, creating an H_3O^+ and OH^- ion. He also saw that the movement of these two types of defects by proton exchange caused proton ordering, producing polarization and antipolarization, respectively, in the affected ice lattice.

Operating with these two defect pairs, their dissociation products, proton tunneling, and extensive sets of balancing equations, subsequent investigators arrived at an impressive theory of "ice as a protonic semiconductor," the next of kin to electronic semiconductors (12).

Not convinced of the validity of these ideas, we decided to remeasure the relaxation spectrum of "pure"

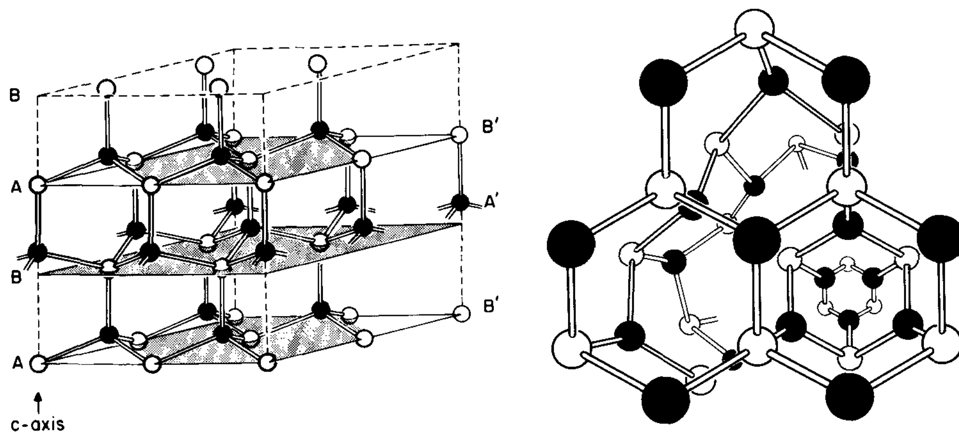

Fig. 11. Structure of Ice I_h single crystal.

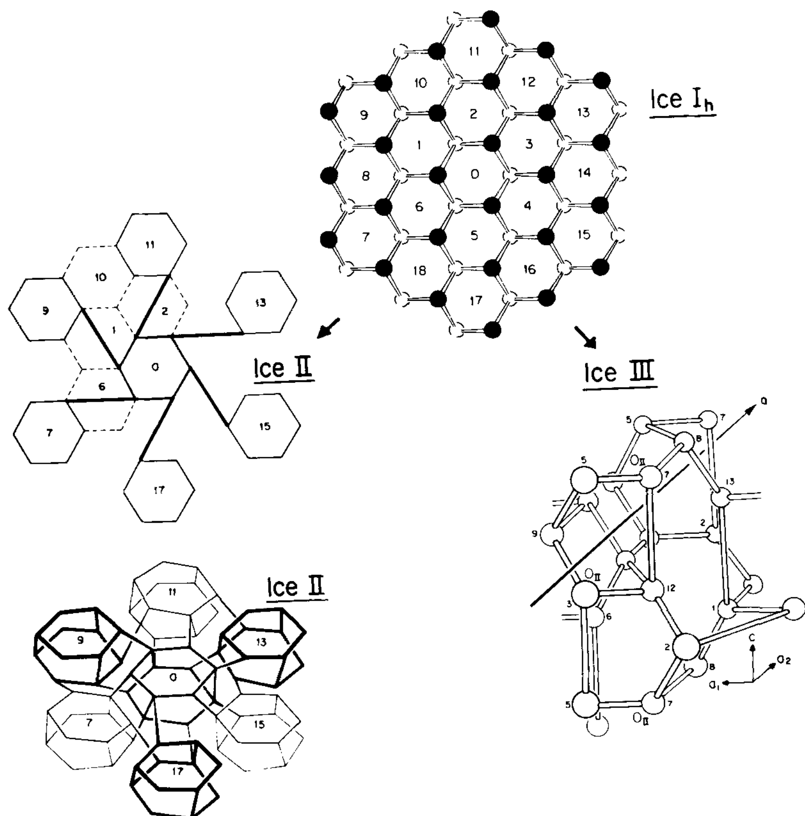

Fig. 12. Bond changes in Ice I → Ice II and Ice I → Ice III transition.

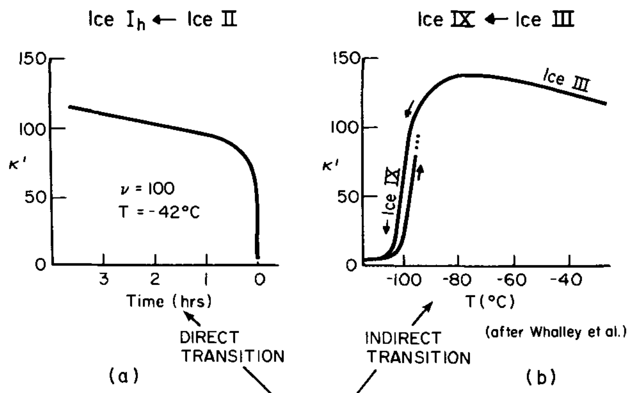
Ice I_h single crystals with improved resolving power over a wide range of frequencies (8×10^{-3} to 10^5 Hz) and temperatures ($-5°C$ to $-80°C$). And indeed, we found seven well resolved relaxation spectra (Fig. 15). Spectrum 3 is the standard volume polarization spectrum of ice previously seen; the activation energy of its time constant ($\mathcal{E}_c = 13.8$ kcal/mole) corresponds to the breaking of three hydrogen bonds as required for Bjerrum's L-, D-defect pair formation by molecule rotation. Expanding Bjerrum's concepts, we believe at present that the following molecular picture may adequately describe this polarization mechanism.



Figs. 13a,b. Antiferroelectric proton ordering in ice as observed by dielectric-constant measurements.

Creation of an L-, D-defect pair requires the thermal activation energy and proper infrared vibration to transfer a proton to an empty corner (unshared electron pair) of its H_2O tetrahedron (Fig. 16). The pair drifts apart a field-directed diffusion distance by subsequent proton exchanges until the defects are annihilated by counterdefects. These proton exchanges cause proton ordering in the ice lattice, *i.e.*, the ice matrix acts like an electric memory system in which each vanishing L-, D-defect pair inscribes a polarization dipole (Fig. 17). Each molecule of the volume will have a chance to re-enact this pair creation after a statistical waiting time τ, the relaxation time of the process. Thus τ is connected to the number N of dipole

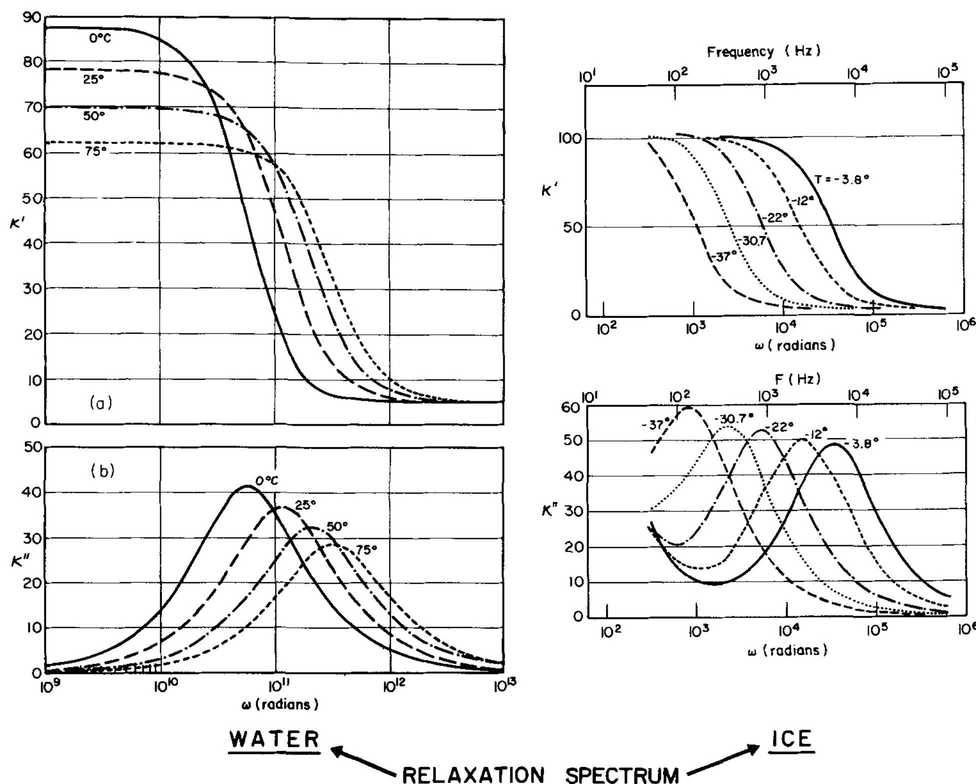


Fig. 14. Relaxation spectrum of water vs. ice.

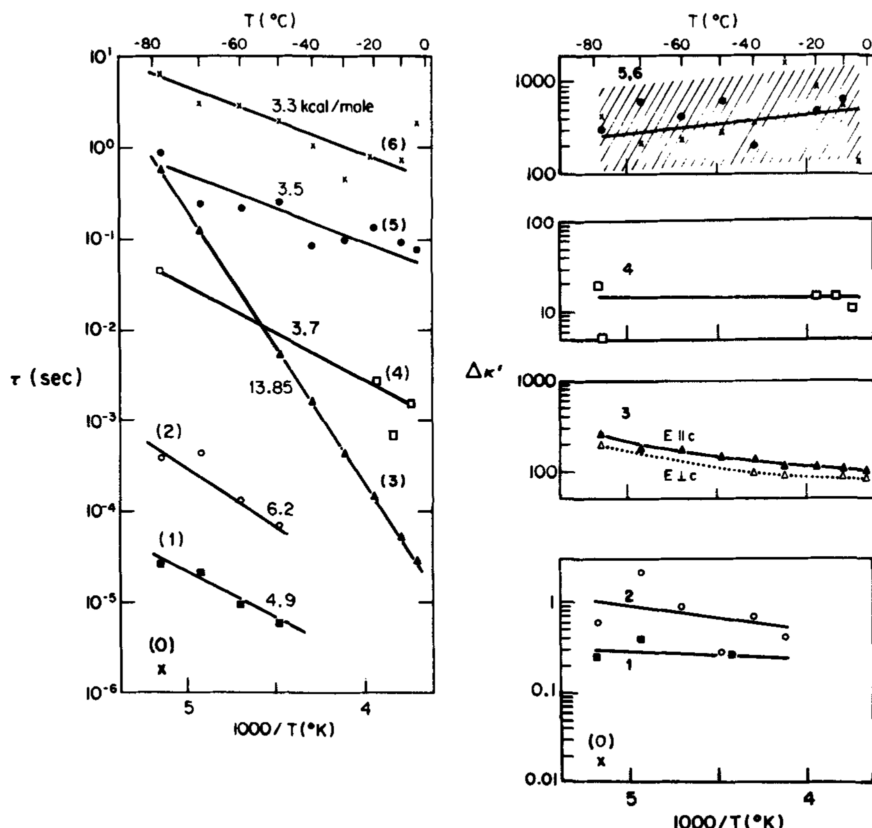

Fig. 15. Seven polarization spectra in "pure" Ice I_h single crystals.

molecules per unit volume, not, as in previous models, to the orientation of dipole moments $\vec{\mu}$.

If one applies the same reasoning to the formation of an ionic defect pair and the migration of H_3O^+ and OH^- by intermolecular proton transfer toward cathode and anode, the memory system of the ice matrix puts a stop to this process: an antipolarization arises which pumps just as much charge uphill as the ions take downhill, thus uncoupling the ions from the driving field (cf. Fig. 17). This strange situation became experimentally confirmed when we measured the transconduction of ice. Here the literature conveyed complete confusion by ascribing to the conductivity of pure ice thermal activation energies $\mathcal{E}_\sigma$ ranging from 0 to ca. 33 kcal/mole. All our measurements of polarization and conduction were made on single crystals, carefully shielded from surface effects by guarded three-terminal electrodes. Suddenly a sample cracked in its holder exposing a fresh unguarded surface (Fig.

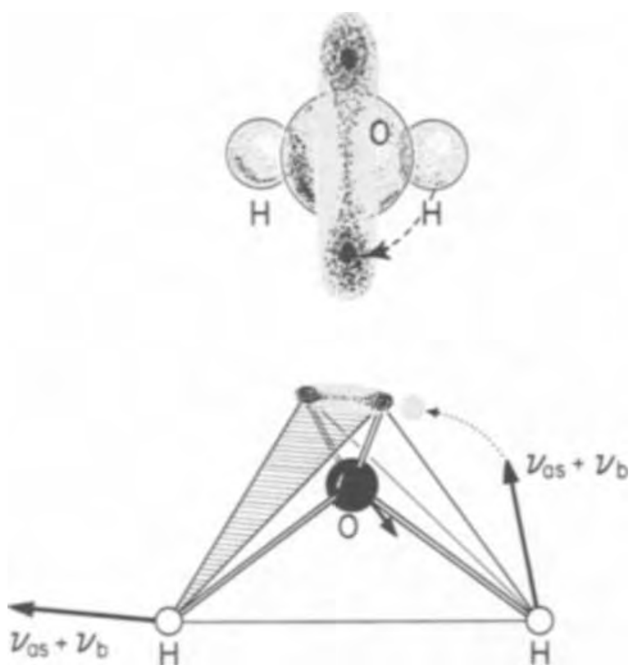

Fig. 16. L-, D-defect pair formation by intramolecular proton transfer.

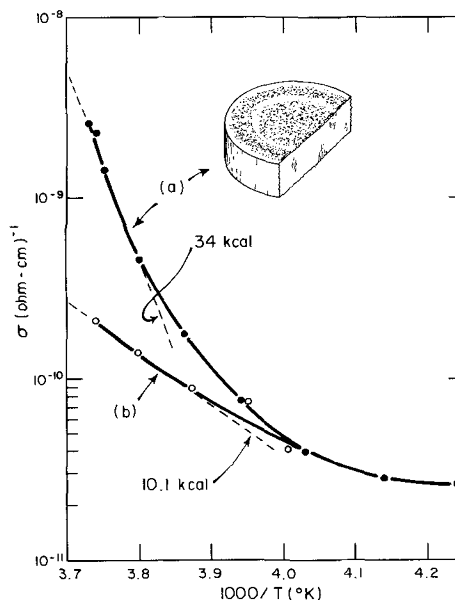

Fig. 18. Surface vs. volume conductivity of Ice I_h

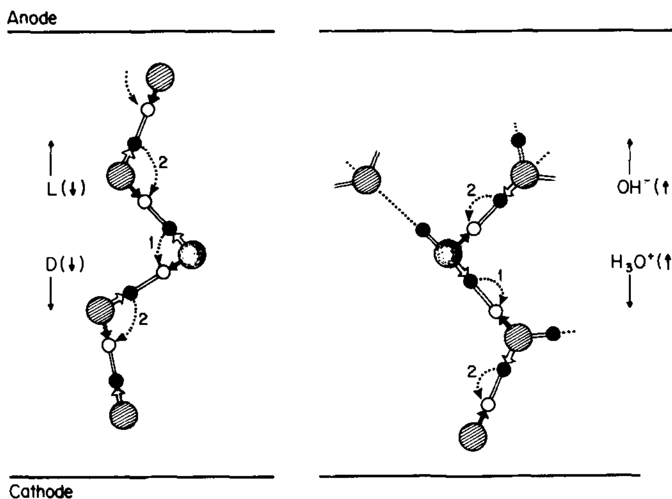
18); the conductivity jumped up by an order of magnitude and $\mathcal{E}_\sigma$ rose from about 10 to *ca.* 34 kcal/mole. Obviously, these were not simple "activation energies."

Closer inspection showed that between *ca.* 0°C and −30°C the main current in ice actually flows over its surface, where the lattice is destroyed and its antipolarization memory inactivated. Multicrystallinity has



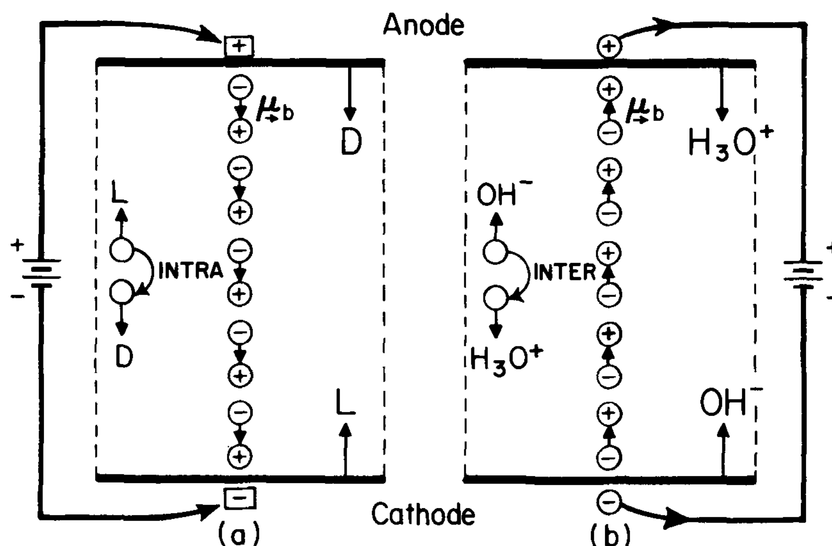


Fig. 17. Polarization by L and D defects and antipolarization by ionic defects in Ice I_h single crystals.

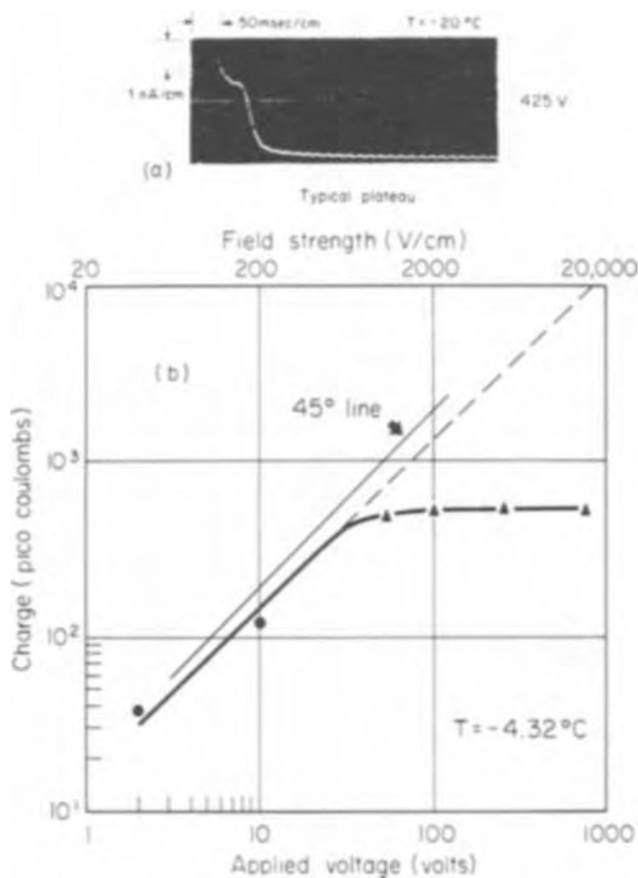

Fig. 19. Extrinsic charge-carrier removal from Ice I_h crystal by high fields.

corresponding effects by creating inner surfaces and additional polarization spectra. A small amount of extrinsic carriers is normally held loosely in an ice crystal (*e.g.*, *ca.* 3×10^{11} carriers/cm^3 in the case shown); it appears as a hump in the current-time characteristic and can be pulled out with near zero activation energy (Fig. 19). The effects of prehistory are pronounced. In short, surface conduction and space-charge effects have falsified the measurements of most previous observers, and a new picture begins to emerge about protons and their actions (13). Extensive new measurements on the interpretation of spectra $1 \rightarrow 6$, the correlation of electrical and mechanical data, and the effects of HF doping have just been completed (14), and we begin to talk with increasing confidence about "Molecular Phenomena in H_2O Systems."

Ice is not, as people previously believed, a chemically inert environment. Polishing it with alcohol, as recommended in bars around the world, creates dielectric absorption bands. Introducing fluorine softens ice crystals excessively, tempting one to offer toothpaste manufacturers a new advertising slogan: "When you sit on a glacier and brush with Crest, an ice-fall will propel you to your eternal rest."

Everywhere we find ourselves today confronted with the ecological dilemma of fitting man's activities, based on incomplete understanding, into nature's ways without ruinous results. One answer is to forego new knowledge and to plod along old pathways; the other, to seek more complete understanding and to apply it with more compassionate insight. I believe we have no choice but to go forward trusting Michelangelo's vision: "God gave a divine spark to Man" (Fig. 20).

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1971, the following graduate students received $1000 each, representing the three Summer Fellowship Awards of The Electrochemical Society:

Miss Jean Horkans, Case Western Reserve University, Cleveland, Ohio, was awarded the Edward Weston Fellowship.

Mr. Robert R. Fike, University of Massachusetts, Amherst, Mass., was designated as the recipient of the Colin Garfield Fink Fellowship.

Mr. James Webb, University of Michigan, Ann Arbor, Mich., received the James W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degree of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." It is intended to cover a period during which the recipient has no financial support for the continuance of his work.

The Edward Weston Summer Fellowship Report

A summary of Miss Horkans' report is given below.

The Electroreflectance Study of Gold

The use of optical reflection techniques in conjunction with electrochemical methods has made available a powerful additional tool for *in situ* studies of the electrode-electrolyte interface. For example, optical techniques have been used to measure the extent of adsorption of a species (1-4), to study passivation of surfaces (5), to indicate the extent of surface roughening caused by an electrochemical process (5), to follow short-lived intermediate species in solution (6, 7) to investigate the band structure and surface states of semiconductors (8-10), and to study the nature of the forces involved in adsorption (11).

In addition, the optical data obtained for gold have stimulated a discussion (12) on the mechanism of electromodulation and the importance of considering the unique electronic properties of the surface in developing a detailed understanding of the electrode-electrolyte interface. Our laboratory is currently involved in an effort to elucidate further the nature of the gold-electrolyte interface and to determine the roles played by the free electrons (those in the 6s conduction band) and by the 5d electrons at the surface. It is felt that the 5d-surface electrons and their interactions with species in the double layer are important in determining the electromodulation of gold, and that this phenomenon cannot be explained as due to modulation of the free electrons alone.

Figure 1 shows the change in relative reflectivity at

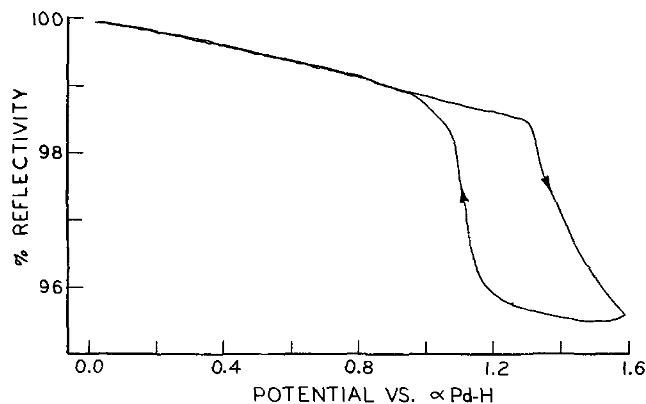

Fig. 1. The voltage dependence of the reflectivity of an evaporated gold electrode in 1*N* $HClO_4$ at 500 nm. The sweep rate is 0.1 V/sec.

500 nm of a gold electrode in 1*N* $HClO_4$ as a triangular potential sweep is applied. The formation of a layer of oxygen on gold at ~ 1.3V and its reduction at ~ 1.2V on the reverse sweep are clearly visible; but the nature of the smaller, but real changes in reflectivity occurring outside of this region is less clear. Such changes are much more obvious when a derivative reflectance technique is used, and various applications of modulated electroreflectance have been successful in studying surface films (13, 14). A variable angle specular reflection instrument with the capability of doing derivative measurements has been built in this laboratory.

The variable angle reflectance spectrometer consists of an optical cell mounted on the axis of a θ-2θ goniometer. The tungsten filament light source is mounted

ABSTRACT

Study of the cells Pt, $H_2|NaHSO_4|H_2$, Pt and Pt, $H_2|NaHSO_4||Ag_2SO_4$, $NaHSO_4|Ag$ shows that the hydrogen electrode behaves reversibly in molten sodium bisulfate. Emf's of the cell Pt, $H_2|CoSO_4(m_2)$, $NaHSO_4||CoSO_4(m_1)$, $NaHSO_4|Co$ in the range 200°-270°C have been used to calculate thermodynamic data for the reaction

$$\tfrac{1}{2}Co + NaHSO_4 \rightleftarrows \tfrac{1}{2}CoSO_4 + \tfrac{1}{2}Na_2SO_4 + \tfrac{1}{2}H_2$$

A plot of emf against log m_1/m_2 is linear, but the slope is steeper than predicted.

In previous papers (1, 2), we have shown that molten sodium bisulfate and sodium pyrosulfate are the sulfating agents in the sulfate-catalyzed roasting of sulfide ores containing cobalt and nickel. More recently, we have published data on the stability and the thermodynamics of decomposition of these compounds, and a partial phase diagram for the sodium pyrosulfate-water system, in which sodium bisulfate appears as a constituent (3, 4).

The sodium bisulfate roasting cycle includes two reactions that occur simultaneously at temperatures between the melting point of $NaHSO_4$ (187°C) and 250°C

$$2Co_3O_4 + 12NaHSO_4 \rightleftarrows 6CoSO_4 \cdot H_2O + 6Na_2SO_4 + O_2 \quad [1]$$

and

$$NaHSO_4 + Na_2SO_4 \rightleftarrows Na_3H(SO_4)_2 \quad [2]$$

so that it is difficult to obtain thermodynamic and kinetic data for the commercially significant reaction [1]. A possible approach seemed to be through the development of satisfactory nickel and cobalt electrodes in molten sodium bisulfate, and this paper describes attempts to examine the behavior of a cobalt electrode in this environment with respect to a hydrogen electrode.

The literature contains very few papers on the electrochemistry of solutions in molten bisulfates. Tajima, Soda, Mori, and Baba (5) showed that hydrogen and oxygen were obtained in a molar ratio of 2:1 when $KHSO_4$ was electrolyzed with platinum electrodes, and Shams El Din (6) studied overpotentials in the same system. Le Ber (7) briefly considered the $H_2|H^+$ system, but had some difficulty in achieving reversibility. Arvia and his co-workers appear to be the first to have considered the hydrogen electrode as the basis of an electrochemical series in a bisulfate melt (8-10). They found the electrode reaction to be reversible and determined its potential against a silver|silver sulfate reference electrode. Their attempt to establish an electrochemical series was based on corrosion potentials of a number of metals.

The only other studies of equilibrium systems involving bisulfates are those of Seward and Miller (11) on the $Hg|Hg^{2+}$ and $Ag|Ag^+$ electrodes in $NaHSO_4$ and Le Ber (7) on the $Ag|Ag^+$ electrode in $KHSO_4|NaHSO_4$ eutectic.

The decomposition of molten bisulfate to pyrosulfate poses a major problem in maintaining the purity levels of the bisulfate melts, and those used in many of the investigations quoted were likely contaminated by pyrosulfates, as well as water and sulfuric acid.

Our study of the stability of sodium bisulfate at temperatures between 100° and 400°C showed that sodium bisulfate starts to lose water at temperatures just below the melting point (187°C) to form sodium pyrosulfate. In order to effectively prevent pyrosulfate formation in our sodium bisulfate melts, we used a closed system in the present investigation.

Experimental

Preparation of materials.—Sodium bisulfate was prepared by adding stoichiometric amounts of water to sodium pyrosulfate that had been made by direct reaction between sodium sulfate and sulfur trioxide (4).

Cobalt sulfate was made by heating Fisher Certified $CoSO_4 \cdot 7H_2O$ at 400°C for 8 hr, crushing the product, and reheating for a further 8 hr (1).

Johnson, Matthey and Mallory cobalt wire and platinum foil were washed with acetone and distilled water, and oven-dried before use.

Linde hydrogen was purified by passage through a Deoxo tube, and then over copper mesh at 500°C.

Fisher Certified sodium sulfate was oven-dried at 200°C before use.

The double salt $Na_2Co(SO_4)_2$ was prepared by precipitation of its tetrahydrate from a mixed solution of the two sulfates, followed by dehydration at 400°C for 8 hr.

* Electrochemical Society Active Member.

Key words: galvanic, galvanic cells, molten, sodium bisulfate.

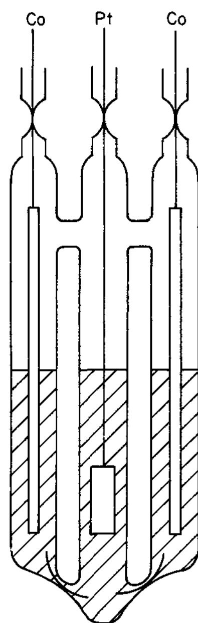

Fig. 1. Cell vessel

Apparatus and procedure: Emf's were measured with a L&N Type K2 potentiometer, using a Pye nanoammeter as a null detector. Readings were steady within 1 mV over periods of several hours.

The cell vessels were made of Pyrex glass; junctions between the half-cell containers were made with asbestos fibers (12). In such dilute solutions the activities would not differ significantly on either side of the junction, and transport should be almost exclusively by the predominating sodium and bisulfate ions. A diagram of the cell is shown in Fig. 1. The outer compartments contained cobalt electrodes and solutions of cobalt sulfate in molten sodium bisulfate. The electrodes were 1.3 mm diameter lengths of cobalt wire welded to 0.4 mm diameter support wires. A piece of bright platinum foil 1 cm^2 in cross-section was welded to 0.4 mm platinum wire to form the reference electrode in the center compartment. This arrangement permitted two series of measurements to be made simultaneously. The cells were sealed to prevent decomposition of sodium bisulfate, and their construction ensured that all three compartments were at the same pressure during the measurement.

The vessels used for the study of hydrogen electrodes were similar in that junctions were made through asbestos fibers, but some cells were designed to permit bubbling of hydrogen, while others had half cells in which the platinum electrodes were isolated completely from gaseous hydrogen. Various combinations of these half cells were used to check for zero emf between isolated and bubbling electrodes. Reversible behavior of the hydrogen electrodes was also established with respect to a silver|silver sulfate electrode.

The cells were packed in alumina powder in a Pyrex tube that fitted closely into a cylindrical brass block furnace heated by four GE 150W Type 186 H cartridge heaters. The block was insulated by layers of glass wool, firebrick, and transite. Temperatures were controlled by a Honeywell Pulse-Pyrovane unit, and cell temperatures were measured on the K2 potentiometer with a platinum-10% rhodium platinum thermocouple in conjunction with a Kaye Ice-point Reference Standard. Temperature control was within ±0.2°C.

Apparatus used for the associated differential thermal analysis and x-ray powder diffraction analysis were described in an earlier paper (2).

Results and Discussion

Differential thermal analyses on mixtures of cobalt powder and sodium bisulfate were done at a programmed temperature increase of 2°C/min between room temperature and 500°C. The sodium bisulfate fusion endotherm at 187°C was followed immediately by a large exothermic peak. X-ray powder diffraction analysis identified the products of this reaction as cobalt sulfate and sodium sulfate when the reaction was allowed to proceed at temperatures below 250°C, and the double salt $Na_2Co(SO_4)_2$ when the reaction proceeded above this temperature. Other endothermic peaks appearing at 455° and 470°C were identified as phase transitions of the system $CoSO_4$-Na_2SO_4 (13). Hydrogen was also produced by the above reaction. The suggested stoichiometry is

$$Co + 2NaHSO_4 \rightleftarrows CoSO_4 + Na_2SO_4 + H_2 \quad [3]$$

This is apparently the reaction for the galvanic cell Pt, H_2|$NaHSO_4$, $CoSO_4(m_2)$||$NaHSO_4$, $CoSO_4(m_1)$|Co. Measurement of the emf's of such a cell in which $m_1 = m_2$ should provide thermodynamic data for reaction [3], if the cobalt and hydrogen electrodes operate reversibly in a bisulfate melt.

In order to demonstrate that a reversible hydrogen electrode is formed in molten sodium bisulfate, the cells Pt, H_2|$NaHSO_4$||$NaHSO_4$|H_2, Pt and Pt, H_2|$NaHSO_4$||$NaHSO_4$, Ag_2SO_4|Ag were examined, and the results are shown in Table I.

Table I.

Pt, H_2 | $NaHSO_4$ || $NaHSO_4$ | H_2, Pt

Cells	Emf, V	Flow rate, cc/min	Temperature, °C

0.184	−0.182	215.0
0.184	−0.194	240.0
0.184	−0.200	240.3
0.184	−0.211	270.0

The potential of the platinum|hydrogen electrode is shown to be independent of the gaseous hydrogen partial pressure, implying that the melt is saturated with respect to hydrogen and that the activity of the hydrogen in the melt is constant. Arvia (9) has demonstrated that a reversible hydrogen electrode is formed in potassium bisulfate melts, and that once the platinum electrode was saturated with hydrogen from the cathodic reaction, bubbling hydrogen over its surface did not change the emf. In the present case, it would appear that the platinum surface has become saturated with hydrogen without the necessity of a prior electrolysis to saturate the surface; alternatively, mere adjustment of the potentiometer balance may have sufficed to saturate the surface.

The emf of the cell, H_2, Pt|$NaHSO_4$||$NaHSO_4$, Ag_2SO_4|Ag varies linearly with temperature and is reversible (Table I). The hydrogen electrode has also been found to be reversible with respect to a silver|silver sulfate electrode in the systems $KHSO_4$ (9), $KHSO_4$|$NaHSO_4$ eutectic (7), and NH_4HSO_4 (11). Because the potential of the hydrogen electrode does not vary with the partial pressure of hydrogen gas, melt decomposition to pyrosulfate can be prevented by using platinum immersed in the melt in a sealed system as a reversible hydrogen electrode. This also prevents contamination with atmospheric moisture; sealed vessels were therefore used in the experiments involving the cobalt electrode.

The range of molalities in which a cobalt electrode will function reversibly is restricted by the corrosion of the metal by sodium bisulfate, and by the solubility of cobalt sulfate in the melt. In experiments using the cell Pt, H_2|$CoSO_4(m_2)$, $NaHSO_4$||$CoSO_4(m_1)$, $NaHSO_4$|Co, for the determination of the thermodynamic data

Table III.

Emf of the cell H_2 | $CoSO_{4(m_2)}$, $NaHSO_4$ || $CoSO_{4(m_1)}$, $NaHSO_4$ | Co at 511.2°K. $m_1 = 0.0350m$

m_2, mole kg^{-1}	Emf, V
0.0177	−0.2668
0.0350	−0.2425
0.0530	−0.2301
0.0750	−0.2152

for reaction [3], the molalities m_1 and m_2 were set at 0.0350m. Effective inhibition of corrosion by the solute at this concentration was indicated by the absence of observable attack on the cobalt electrode during the course of an experiment. Emf's were measured at temperatures between 200° and 270°C, and were found to vary linearly with temperature. The measured emf's were constant within 1 mV for several hours. This excludes the possibility of mixed potentials due to continuing corrosion of the cobalt electrode, which would change the cobalt ion activity in the melt and alter the emf.

The measured emf's and the calculated free energies, enthalpies, and equilibrium constants for reaction [3] are shown in Table II. The entropy change for the corrosion of cobalt by molten sodium bisulfate is $\Delta S = 56.4 \pm 1.4$ eu. Using standard entropy values for aqueous solutions for a comparison

$$\Delta S = \tfrac{1}{2}S^\circ_{H_2(g)} + \tfrac{1}{2}S^\circ_{Na_2SO_4(aq)} + \tfrac{1}{2}S^\circ_{CoSO_4(aq)} - \tfrac{1}{2}S^\circ_{Co(s)} - S^\circ_{NaHSO_4(l)} \quad [4]$$

provides an entropy change of $\Delta S^\circ = 51.9$ eu at 500°K. Application of the van't Hoff isochore to the equilibrium constant data leads to an enthalpy at 500°K of $\Delta H = -34.5$ kcal · mole^{-1}, in good agreement with values calculated from the Gibbs-Helmholtz equation, providing further justification for the validity of the data.

Addition of an equivalent molar amount of sodium sulfate to the cobalt electrode vessel did not change

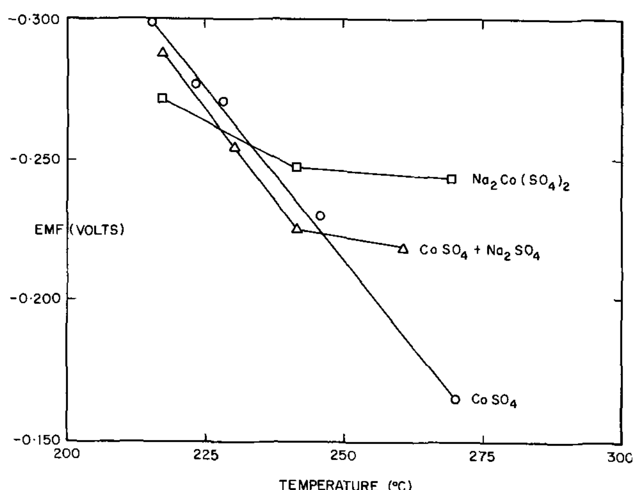

Fig. 2. Effect of addition of Na_2SO_4 and $Na_2Co(SO_4)_2$ on the emf of Pt, H_2 | $CoSO_{4(m_2)}$, $NaHSO_4$ || $CoSO_{4(m_1)}$, $NaHSO_4$ | Co.

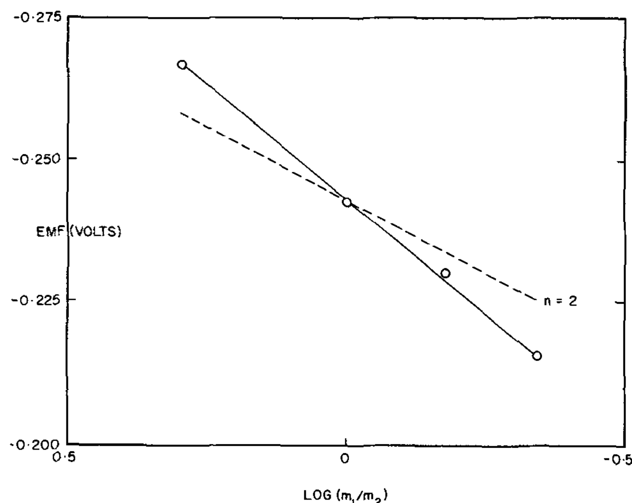

Fig. 3. Theoretical (- - - -) and observed (——) Nernst plots for Pt, H_2 | $CoSO_{4(m_2)}$, $NaHSO_4$ || $CoSO_{4(m_1)}$, $NaHSO_4$ | Co.

the slope of the emf-temperature relationship below 240°C, but the measured emf's were about 10 mV lower. Above 250°C, however, there is a marked change in slope, the new slope approximating that found when cobalt sulfate and sodium sulfate are replaced by an equal amount of the double salt $Na_2Co(SO_4)_2$. These effects are shown in Fig. 2. Seward and Miller (11) observed that the addition of sulfate ion to their cell lowered the emf, implying an increase in the activity of the silver ion. In spite of viscosity studies that indicated structural changes in the melt, they were unable to explain the increase in silver ion activity. The same effect occurs in the present work with the cobalt electrode, an increase in cobalt ion activity occurring on addition of sodium sulfate. Sodium bisulfate forms highly structured melts (14), with extensive hydrogen bonding (15), and it seems likely that the added sulfate ions would be incorporated into this structure. This would reduce association of the divalent sulfate ion with the cobalt ion, thereby increasing its activity. At higher temperatures, where the hydrogen bonding breaks down, this trend should be reversed, as is evidenced by the behavior of the cells on sulfate addition at temperatures above 250°C.

A series of experiments were done with the cell Pt, H_2|$CoSO_4(m_2)$, $NaHSO_4$||$CoSO_4(m_1)$, $NaHSO_4$|Co in which the molality m_1 was maintained at 0.0350m, and m_2 varied between 0.0177 and 0.0750m. Emf's measured at 238°C are shown in Table III; the cells usually reached equilibrium within 6-7 hr. A plot of emf against the logarithm of the ratio of the molalities is linear but the slope is about 55% steeper than that predicted by the Nernst equation (Fig. 3).

Although the Nernst slope indicates that the behavior of the cobalt ion in a bisulfate melt is complex, this effect may be qualitatively explained by reasoning similar to that used for the addition of sodium sulfate, that is, the incorporation of sulfate ion into the melt structure effectively increases the cobalt activity.

Acknowledgment

Electrode Processes in Sodium Polysulfide Melts

K. D. South, J. L. Sudworth, and J. G. Gibson

British Railways Research Department, Derby, England

ABSTRACT

Results are reported of three-electrode measurements in sodium polysulfide melts. The composition range covered was Na_2S_3-Na_2S_5 and the temperature range 300°-400°C. The electrode material used was vitreous carbon. Voltammetric, chronopotentiometric, and current interruption techniques were used to investigate cathodic and anodic processes. Evidence is produced that sulfide films are formed at the cathode and that these result in limiting currents. The lowest value of limiting current density was 28 mA · cm^{-2} obtained for Na_2S_3 at 350°C. At the anode the current appears to be limited by accumulation of liquid sulfur. The value of the limiting current density in Na_2S_5 was 100 mA · cm^{-2} at 350°C. A reaction scheme which best fits our results is suggested.

Interest in the electrochemistry of sodium polysulfides has recently been stimulated by the development of the sodium/sulfur battery (1-3), in which the overall process at the cathode is the reduction of sulfur to sulfide ions. In order to gain a further understanding of the electrode processes we decided to study the behavior of a nonporous carbon electrode in three different polysulfide melts. Vitreous carbon was deemed a suitable material for this purpose.

Following a suggestion (4) that lithium polysulfides might exhibit electronic conductivity, we decided to investigate the electronic conductivity of sodium polysulfides. Although this work is not yet complete, preliminary results indicate that the electronic contribution to the conduction in these melts is very small, and in the interpretation of our results we have assumed electronic conductivity in these melts to be negligible.

The phase diagram for the system Na_2S/S has been constructed by Pearson and Robinson (5) and revised by others (6, 7). At 350°C, if precipitation of solids is to be avoided, the sodium content of the melt must not exceed 40 atomic per cent (a/o) (Na_2S_3). Experience in our laboratory indicates that polarization of the sulfur electrode is most severe in the one-phase region (Na_2S_5-Na_2S_3). We therefore decided to study three different compositions corresponding to melts in this region, *viz.*, $Na_2S_{5.5}$ (two-phase, Na_2S_5 + sulfur), Na_2S_4, and Na_2S_3. Results in $Na_2S_{5.5}$ refer to the sulfide-rich phase (Na_2S_5).

Very little work has been reported on the electrochemistry of the alkali metal polysulfides, but recently, mass transfer effects in molten Na_2S/S mixtures were investigated by Selis (8). He used voltammetric sweeps to distinguish between the electrode behavior in the two liquids present in the two-phase region. Results in the sulfide-rich phase indicated that the current maximum was associated with an irreversible oxidation process. At cathodic potentials a current maximum followed by a current surge was observed. In a recent paper by Bodewig and Plambeck (9) concerning the S^{2-}/S^o electrode in molten LiCl-KCl, a voltammetric curve was shown for the reduction of S^o to S^{2-} at a graphite electrode. Only one current surge was evident.

In this work we have used voltammetric sweeps, current interruption experiments, and chronopotentiometry in an attempt to determine the electrode reactions.

Key words: sodium polysulfide, sulfur, vitreous carbon.

Experimental

Apparatus.—Voltammetry experiments were performed with a Wenking 61 RH Potentiostat coupled to a Wenking SMP 61 sweep unit (max rate 50 mV · sec^{-1}). A few faster cyclic voltammetric sweeps were performed with the potentiostat coupled to a Hewlett-Packard 3310A function generator. Voltammetric curves were recorded on a Bryans 26000 Series XY plotter. Chronopotentiometric experiments were carried out with the aid of a 5A max constant current unit in conjunction with a mercury-wetted relay switch. Both pieces of equipment were built in the laboratory. Chronopotentiograms were recorded on the Bryans XY plotter set in the Y/t mode. Electrode potentials were measured with a Vibron electrometer backed-off with a Pye portable potentiometer. A Techne fluidized sand bath was used to maintain the temperature at 300°-400°C. A molten salt bath would have allowed better temperature control, but was not used for safety reasons. Temperature control was by "Cal" proportional controller unit, which maintained the temperature to ±3°C.

The experimental cell is shown diagrammatically in Fig. 1. The side arm containing a porous sinter was incorporated to enable melt to be filtered *in situ* into the electrochemical compartment. Ground-glass joints were greased with Apiezon T compound.

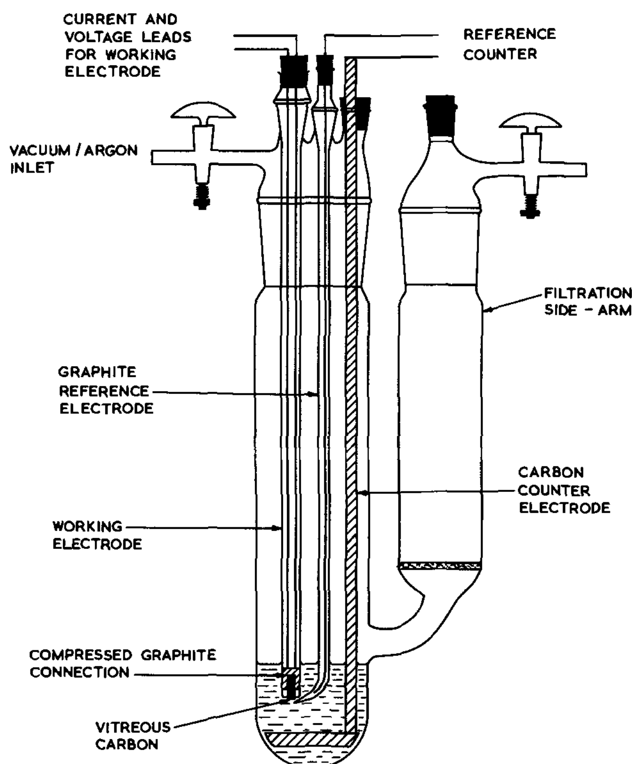

Fig. 1. Electrochemical cell assembly

Electrodes.—A conventional three-electrode assembly was used. The working electrode material, vitreous carbon, was supplied in the form of 0.32 cm diameter rod. A short length was sealed into a Pyrex tube and faced off to expose a disk of area 0.08 cm^2. The electrode was polished to 0.25μ surface finish. The sealing of vitreous carbon rod into Pyrex was carried out by the Allen Clarke Research Centre, Towcester, following several unsuccessful attempts in our laboratory to obtain a leakproof seal. The counterelectrode consisted of a large carbon disk attached to a threaded carbon rod; both pieces were spectrographic grade porous carbon. Electrode potentials were measured using a carbon/sodium polysulfide reference electrode. This electrode, which consisted of a strip of flexible graphite sheet ("Grafoil," Union Carbide Corporation) immersed in a melt of the same composition as the bulk melt, was contained in a Luggin capillary. The potential of this carbon/polysulfide reference electrode which has been shown to be reversible (10), was consequently dependent upon the composition of the melt under investigation. All electrode potentials have therefore been corrected to the carbon/Na_2S_5/S electrode, using the potential/composition relationship for the cell Na/β alumina/Na_2S_x/carbon (where $x =$ 3-5), determined independently by Gupta and Tischer (7) and Davies (10).

Melt.—Sodium polysulfide (Na_2S_3) was prepared electrochemically in a specially designed sodium/sulfur cell. Special care was taken in handling the sodium trisulfide which was removed from the preparation cell in the molten state using a large argon-purged pipette. This was allowed to cool, transferred to a glove box and removed from the pipette by breaking the glass. A dry argon atmosphere was maintained at all times in the glove box, where the trisulfide was stored until required. Higher polysulfides were obtained from the trisulfide by mutually melting with the appropriate amount of sulfur.

Procedure.—The introduction of electrolyte into the filtration side arm of the cell was done in the glove box. The electrolyte was filtered into the cell through a porosity 4 sinter under an argon atmosphere.

On completion of the filtration, rest potentials of both counter and working electrodes were measured. The cell impedance was also determined using an a-c bridge (automatic Wayne Kerr B641). These measurements were repeated at intervals of 1-2 days as a check on the condition of the cell and electrodes. Experiments were continued on any one melt for a maximum of 10 days.

Voltammetric curves were obtained at different sweep rates at both positive and negative potentials. In each case the start of the sweep corresponded to the initial rest potential of the electrode which was 2-3 mV, wrt the graphite reference electrode described previously. After each run the electrode was allowed to attain its rest potential before proceeding with further measurements.

The interruption experiments were performed by holding the electrode at a given potential with the potentiostat for 1 min, opening the circuit with a high speed switch and simultaneously recording the subsequent behavior of the electrode potential with time on an oscilloscope (Hewlett Packard 141) or an XY recorder. The rise times of the switch and the oscilloscope were less than 1 μsec.

The procedure for chronopotentiometric measurements was straightforward using the equipment already described. The same cell and electrode geometry were employed.

Results

Voltammetry.—Cathodic voltammetric curves at 350°C are shown in Fig. 2. Salient features are a current maximum followed by a sharp drop in the current, a region of limiting current and a final current surge at about -1.7 to -1.8V. The height of the current peak was proportional to the square root of the sweep rate, in accordance with the equation for peak voltammetry (11).

$$i_p = Kn^{3/2} D^{1/2} C v^{1/2} \qquad [1]$$

where i_p = peak current density; K = Randles-Sevcik constant, n = number of electrons transferred, D = diffusion coefficient, C = bulk concentration of reducible species, and v = potential sweep rate.

Values of the slope of the plot i_p *vs.* $v^{1/2}$ which was a good straight line, were $1.9 - 2.1$ A · $V^{-1/2}$ · cm^{-2} · $sec^{1/2}$ and showed no significant variation with melt composition. Peak potentials were displaced in the cathodic direction with increasing sweep rates suggesting uncompensated *IR* effects due to the large currents obtained. In successive runs at lower sweep rates, a second, more complex peak appeared on the curves (Fig. 3). The height of this peak was virtually constant below sweep rates of 16 mV · sec^{-1}.

Values of the limiting current were determined in each melt at sweep rates at which they became constant (less than 10 mV · s^{-1}). Actual values at 350°C were 28 mA · cm^{-2} in Na_2S_3; 45 mA · cm^{-2} in Na_2S_4; and 100 mA · cm^{-2} in Na_2S_5. The temperature dependence of limiting current density in Na_2S_3 is shown in Fig. 4.

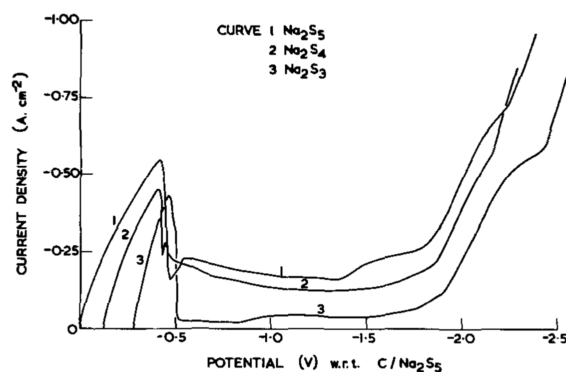

Fig. 2. Cathodic voltammetric curves for different melt compositions at 350°C. Sweep rate v, 50 mV · sec^{-1}.

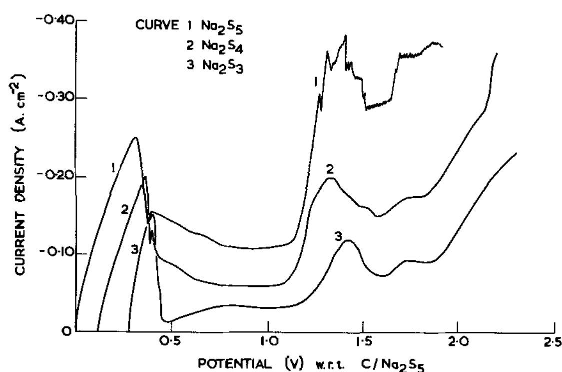

Fig. 3. Cathodic voltammetric curves for different melt compositions at 350°C showing the second current maxima. Sweep rate v, 8.33 mV · sec^{-1}.

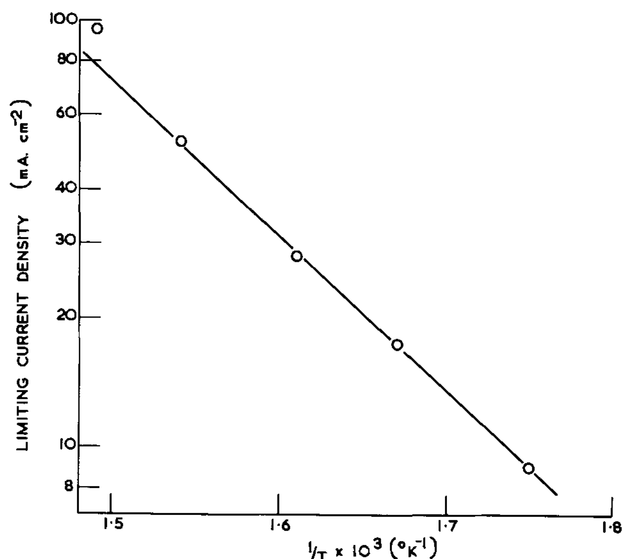

Fig. 4. Temperature dependence of the limiting current density for the composition Na_2S_3.

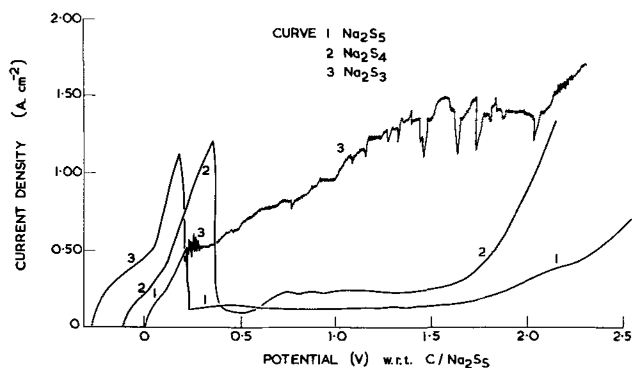

Fig. 5. Anodic voltammetric curves for different melt compositions at 350°C. Sweep rate v, 50 mV · sec^{-1}.

Results of anodic voltammetric sweeps are shown in Fig. 5. These curves were less reproducible than the corresponding cathodic ones. This was particularly so in the case of the Na_2S_3 melt composition. In this melt the curve rarely showed a current maximum. The current continued to increase up to a value corresponding to the maximum capability of the potentiostat. When a current peak was obtained in this melt as in Fig. 5, it was followed by a region of oscillating current. In the other two melt compositions the current maximum was followed by a limiting current region. The value of the limiting current in Na_2S_5 was about 100 mA · cm^{-2}. Again the height of the current density peak was proportional to the square root of the sweep rate. In Na_2S_4 the value of the slope,

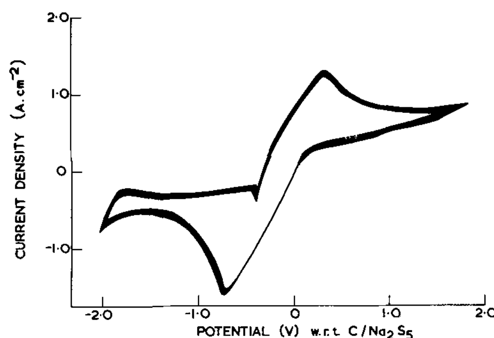

Fig. 6. Cyclic voltammetric pattern for the composition Na_2S_4 at 350°C. Sweep rate v, 0.4 V · sec^{-1}.

5.5 A · V$^{-1/2}$ · cm^{-2} · sec$^{1/2}$, was more than twice the value obtained from the cathodic results. However, in Na_2S_5 the value of slope of 0.8 A · V$^{-1/2}$ · cm^{-2} · sec$^{1/2}$ was less than half the corresponding cathodic value.

An example of a cyclic voltammogram is shown in Fig. 6. Noteworthy features are the peak separation of a 1.04V, and the greater height of the cathodic current maximum. The peak separation is very much greater than the value expected at 350°C for a reversible couple (11).

In the single sweeps the anodic current maximum was higher than the cathodic one in this composition, yet this situation is reversed in the cyclic sweep.

Interruption experiments.—These experiments were conducted in two different melts and the results for Na_2S_3 are given in Table I. Results for Na_2S_5 showed a similar trend although values of R were generally lower. Anodic experiments were not conducted above 120 mV in Na_2S_3 as the current exceeded the maximum control capability of the potentiostat. An initial sharp drop, ΔE, in the potential was noted. This was ascribed to IR drop and found to occur in less than 1 μsec. From the knowledge of I, the current flowing prior to switch off, a value for the electrode resistance, R, was obtained. Both sets of results showed an increase in the electrode resistance up to approximately -1.1V, thereafter the resistance showed a decreasing trend. Another significant feature was the sharp increase in the resistance at cathodic potentials which approximately correspond to the initial current density maxima on the voltammetric curves. Two stable potentials were evident on the cathodic decay curves, one at -340 mV and the other at about -1.9V.

Chronopotentiometry.—All measurements were made with a vitreous carbon disk electrode of geometric area 0.08 cm^2. Figure 7 shows a chronopotentiogram for Na_2S_3 together with the potential decay curve

following the opening of the circuit. The chronopotentiograms obtained in Na_2S_4 and Na_2S_5 were similar.

For cathodically impressed currents the observed transition time, τ, is proportional to the reciprocal of the current density. Results are shown in Fig. 8 and suggest that the process is controlled by diffusion in accordance with the Sand equation

$$i\tau^{1/2} = \tfrac{1}{2}\pi^{1/2}nFCD^{1/2} \quad [2]$$

where symbols have their usual significance and i is the current density.

Anodic chronopotentiograms were only recorded for Na_2S_5. The traces were again characterized by very sharp end points. The observed transition times, however, were not in accordance with the Sand equation since the plot of $\tau^{1/2}$ vs. i^{-1} was nonlinear.

Discussion

The linear dependence of both i_p and $\tau^{1/2}$ on $v^{1/2}$ and i^{-1} respectively suggests that the electroactive species are transported predominantly by a diffusion process. Simultaneous solution of the voltammetric and chronopotentiometric equations gave a value of K, the Randles-Sevcik constant, which was dependent on melt composition, *viz.*, 1.95×10^{-5} in Na_2S_3, 1.3×10^{-5} in Na_2S_4, and 1.0×10^{-5} in Na_2S_5. The theoretical value of the constant at 350°C for a reversible process is 1.88×10^{-5} (13). Experimental values are therefore in fair agreement with the theoretical value particularly in the Na_2S_3 melt where the agreement is within 5%. This suggests that under these experimental conditions effects other than those due to diffusion can be neglected. This is somewhat surprising in view of the fact that no supporting electrolyte was used.

From the shape of the cathodic voltammetric curves it is evident that several processes are occurring at the electrode. Unfortunately, lack of experimental data on the species present in sodium polysulfide melts makes interpretation of our results rather difficult. Recently, however, some data (10) on the activity of sulfur in the melts have become available. Values obtained were 0.9 in Na_2S_5, 0.2 in Na_2S_4, and 0.04 in Na_2S_3. In the light of these results we are inclined to ascribe the first current maximum in all melts to the reduction of a polysulfide ion rather than elemental sulfur. This step appears to be diffusion-controlled as indicated by the linear dependence of i_p on $v^{1/2}$. The chronopotentiometric results also confirm diffusion-control, and further imply that the diffusing species is not the same in all melts. Analysis of the current maxima over a range of sweep rates yields horizontal straight line plots of $i_E/v^{1/2}$ vs. $v^{1/2}$, (where i_E is the current density at a potential, E, less cathodic than E_p) suggesting a fast, reversible electron-transfer process. Further analysis of the current maxima indicates the occurrence of a following chemical reaction, thus the plot of $i_p/v^{1/2}$ vs. $v^{1/2}$ which should be a horizontal straight line for an uncomplicated electron-transfer step shows a positive deviation from linearity at low sweep rates in accordance with the diagnostic criteria for a chemical reaction following the initial electrochemical step (12). This is found in Na_2S_5 and Na_2S_4 melts but not in Na_2S_3 as seen in Fig. 9. We therefore conclude that this chemical step involves elemental sulfur.

The sharp drop in the current following the initial maximum could be associated with the formation of a film of Na_2S_2. The fact that this sharp drop is observed even at very low sweep rates (0.6 mV · min^{-1}) tends to support the formation of a film. The sharpness of the transitions in the chronopotentiograms are also indicative of film formation. The reduction of a higher polysulfide ion could give rise to S_2^{2-} ions which would precipitate in accordance with the phase diagram. Other S_2^{2-} ions could diffuse away into the bulk melt and recombine with sulfur to form the original polysulfide ion. This step would constitute the chemical step observed in Na_2S_5 and Na_2S_4 melts. The fact that the following chemical reaction is faster in Na_2S_5 (see Fig. 9) which is the melt having the highest sulfur activity lends support to the above explanation.

In Na_2S_5 and Na_2S_4 there is evidence of a small current peak immediately following the initial peak (Fig. 2 and 3). This could be associated with the re-

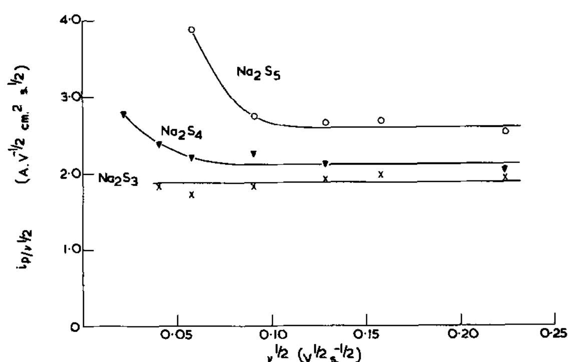

Fig. 9. Dependence of the voltammetric function $i_p/v^{1/2}$ on $v^{1/2}$ for cathodic sweeps in different melt compositions at 350°C showing the effect of a following chemical reaction at lower sweep rates [Ref. (12)].

duction of either elemental sulfur or a different polysulfide ion.

In the region of limiting current, the resistance ascribed to the film of Na_2S_2 continues to increase to a maximum at about $-1.1V$. In Na_2S_3, where the activity of sulfur is very low, we might expect a more stable film since the rate of reaction of the film with sulfur to form higher polysulfides will be much slower. This is in fact the case, as indicated by the high values of electrode resistance obtained in this melt.

The second current maximum, which is observed at about $-1.3V$, we believe to be associated with the reduction of the Na_2S_2 film to Na_2S. At this potential, however, the value of the electrode resistance began to decrease (Table I). This may be interpreted as the faster rate of dissolution of Na_2S than Na_2S_2 in the bulk melt. Alternatively, the film of Na_2S may assume some degree of electronic conductivity although there does not appear to be any independent evidence for this.

We believe the final current surge to be associated with the production of metallic sodium. This is contrary to the suggestion put forward by Selis that this surge is due to the formation of sulfide ions. Our opinion is substantiated by the agreement between the corresponding potential, about $-1.8V$, and the free energy of formation of sodium polysulfides (7). Maintaining the electrode at potentials more cathodic than $-1.9V$ resulted in a potential of about $-1.9V$ persisting for several minutes after the current had been switched off. The existence of metallic sodium at the electrode in such a reactive medium could be explained by a thin sodium ion conducting film of Na_2S protecting the metal from the melt.

The shape of the anodic current maximum suggests the occurrence of two different electrochemical steps. The first process could be the oxidation of a lower polysulfide ion to form a higher species. As the potential is increased the higher polysulfide is then itself oxidized, and the current increases until the point is reached when the electrode becomes covered by a film of liquid sulfur. The current therefore drops sharply and is subsequently limited by this film. This situation would be accentuated in melts containing sulfur at a higher activity, which was found to be the case. Conversely, the electrochemically produced sulfur could react quite rapidly with Na_2S_3 and this would explain the rarity of a limiting current in this melt.

The final current surge at around 1.8V on the voltammetric curves is difficult to explain. One explanation could be interference by the products of a cathodic process at the counterelectrode, although the high current reached renders this view somewhat doubtful.

Conclusions

At the carbon cathode the first step in the reduction of sodium polysulfide appears to be the reversible formation of a lower polysulfide species. In Na_2S_4 and Na_2S_5 melts this is followed by a chemical reaction involving sulfur. Available evidence suggests that the current becomes limited by the formation of sodium sulfide films at the electrode. At higher potentials, -1.7 to $-1.8V$, metallic sodium is formed.

At the anode the current is limited by the formation of a film of liquid sulfur and this limitation is greatest in the Na_2S_5 melt.

The Electrochemical Activity of Dispersed Platinum

ABSTRACT

A highly dispersed platinum catalyst (platinum crystallite size less than 15Å) on a conductive carbon support was prepared. These doped carbons were made into Teflon-bonded fuel cell electrodes and the platinum surface area and the dispersed platinum specific activity (*i.e.*, the activity per unit area of platinum) for oxygen electroreduction in acid electrolyte was determined. The specific activity of the dispersed platinum was found to be approximately twenty times less than that of crystalline platinum black. The lower activity of this catalyst compared with that of platinum black may be due either to the difference in the platinum crystallite sizes, or to the influence of the support on the platinum activity, or to a combination of both these factors.

To build low cost acid electrolyte fuel cells with platinum as the cathode catalyst, it is desirable to utilize Pt with the maximum activity and one method of achieving this is to use Pt with the maximum surface area. High degrees of dispersion of Pt (defined as the ratio of surface metal atoms to total number of atoms) have been prepared by supporting the platinum on a porous, conducting substrate. However a basic question which must be answered before using these supported Pt catalysts is whether the support and/or Pt crystallite size affects the platinum specific activity (*i.e.*, the activity per unit area of Pt).

Many dispersed metal catalysts supported on nonmetallic substrates have been prepared (1, 2) and in some cases the ultimate goal of an atomic dispersion of the metal has been claimed (3, 4). These dispersed metal catalysts have been used in many studies with gas reactants. The reactions have been divided into two classes: structure insensitive or facile reactions and structure sensitive or demanding reactions. Examples of the former are the dehydrogenation of cyclohexane (5), the hydrogenation of ethylene (6), and the hydrogenation of cyclopropane (7). Examples of demanding (1) reactions are propane cracking (8), the hydrogenation of benzene (9), ethane hydrogenolysis (10), and the isomerization of neopentane (11).

To relate the specific activity of metals and supported metals to the metal crystallite size, the catalyst activity free of mass transfer limitations and the catalyst area must be measured. Zeliger (12) showed that the specific activity of Pt supported on asbestos for the electroreduction of oxygen was constant for Pt crystallites in the range of 50-100Å. Bett *et al.* (13) extended this observation and showed that the specific activity of unsupported Pt for the same reaction was independent of the Pt crystallite size in the range of 100-400Å. Thus it would appear that this reaction was facile. However these observations may not be applicable to smaller Pt crystallites since the influence of the crystallite size on the specific activity of a metal is expected (1) to be much more significant for crystallites smaller than 40Å.

In the present paper we describe the preparation of a highly dispersed platinum catalyst (platinum crystallite size less than 15Å) on a conductive carbon support and the specific activity of this dispersed Pt for oxygen electroreduction. Polarization curves for oxygen reduction on Teflon-bonded diffusion electrodes prepared from these catalysts were determined in oxygen-saturated 20% H_2SO_4 solution at 70°C and the Pt area of the catalyst was measured by the electrochemical oxidation of adsorbed hydrogen and of adsorbed carbon monoxide. We have shown that the specific activity of this highly dispersed Pt for the electroreduction of oxygen is approximately twenty times less than that of crystalline Pt black.

High dispersions of Pt on nonconducting supports have been prepared either by localizing metal ions at specific sites by ion exchange prior to reduction with hydrogen (4, 14) or by using a low Pt concentration [less than 1 weight per cent (w/o)] (3, 6). The limitation of the latter method is that, at these low Pt concentrations, the minimum Pt crystallite size which can be detected by x-ray diffraction is approximately 50Å (15). Thus we prepared the highly dispersed platinum catalysts on a conducting substrate by localizing the platinum ions through exchange with ions in a commercial ion exchange resin and subsequently reducing the metal ions by resin pyrolysis in an inert atmosphere. Thus the initial stage fixes the platinum ions at specific sites while in the second stage a conducting substrate is produced and the metal ions are reduced. We have termed this material a Pt-doped carbon in order to differentiate it from the material prepared by the reduction of chloroplatinic acid adsorbed on a preformed carbon.

Experimental

Preparation of the highly dispersed platinum.—The procedure used to prepare the highly dispersed platinum was similar to that used by Pohl (16) and by Pohl and Rosen (17) in the preparation of metal-doped, semiconductor, polymer carbons.

Cation exchange resins were received in the free acid form and they were converted into the calcium form with calcium hydroxide solution. The platinum solution consisted of 3 g/liter of diamminoplatinum (II) dinitrite dissolved in a calcium hydroxide solution of pH 9. Fifty milliliters of the calcium form of the resin [measured in $Ca(OH)_2$ solution] was stirred in 500 ml of the hot platinum solution for 3 hr. The resin was doped with platinum ions in this way to ensure uniform distribution of the ions throughout the resin. The resin was decanted from the platinum solution, washed with water, dried at 110°C for 24 hr and then at 200°C for 24 hr. It was then pyrolyzed in an inert atmosphere at a temperature in the range 700°-900°C for 24 hr. The pyrolyzed material was washed thoroughly with dilute nitric acid and then water to remove the calcium salt and finally dried at 110°C in a vacuum oven.

Highly dispersed platinum was formed in the platinum-doped carbon only with weak acid cationic resins which were neutralized with calcium hydroxide solution (18). The two commercial weak acid cation exchange resins used in this work were: Amberlite IRC 50 (Rohm & Haas Company) which is based on methacrylic acid and has a particle size of 16-50 mesh and Amberlite CG50 (Rohm & Haas Company) which has a similar structure but a particle size of 200-400 mesh.

The noncombustible gases are listed in Table I and the pyrolysis time was 24 hr for all samples.

10	800	N_2	8.4

[a] These samples contained no detectable Pt crystallites.
[b] The ratio of the weight of Pt to the total weight of Pt and carbon.
[c] Sample 2 was prepared from Amberlite CG50 resin, the remainder were prepared from Amberlite IRC50 resin.

Characterization of the highly dispersed platinum.—The particle sizes of the Pt-doped carbons were in the range 0.4-12μ and it was possible to prepare Teflon-bonded diffusion electrodes from all these catalysts. Clearly it was essential to prepare reproducible electrodes and this was achieved by using the same procedure as that of Vogel and Lundquist (19). As a check on the electrode preparation technique, electrodes were also prepared from commercial Pt black (Engelhard Industries) and 5% Pt supported on graphite. The latter catalyst was prepared by the reduction of chloroplatinic acid adsorbed on graphite.

The polarization curves for oxygen reduction were determined galvanostatically in oxygen saturated 20% H_2SO_4 solution at 70°C using the floating electrode technique (20). The cell was a 500 ml round-bottom flask, and its temperature was maintained by placing in a heating mantle. The electrodes were inserted through ground glass joints in the flask. The working electrode was supported in a gold foil spring, and it was floated on the surface of the electrolyte. Current collection from the gold foil to the external circuit was made via a platinum wire. The counterelectrode was a platinum gauze on which platinum was electrodeposited. The reference electrode was a reversible hydrogen electrode which was placed in a Luggin capillary and immersed in the test electrolyte. The *IR* drop between the floating electrode and the tip of the Luggin capillary was determined using an interrupter technique. All potentials given in this paper refer to the reversible hydrogen electrode in the same electrolyte and are corrected for *IR* drop.

The available Pt area of the electrodes was measured by determining the charge due to the oxidation of adsorbed H_2 and of adsorbed CO in N_2 purged 1M H_2SO_4 solution at 30°C using the periodic triangular voltage sweep technique. These sweeps were made using an Electroscan 30 (Beckman Instrument Company).

The platinum concentrations in the doped carbons were determined by measuring the weight loss after heating in a muffle furnace at 900°C. These concentrations were checked in selected doped carbons by dissolving the platinum in aqua regia and measuring the absorbance of the stannous chloride complex (21). The size of the platinum crystallites in the Pt-doped carbons was determined from the broadening of the x-ray diffraction line from the (III) plane using a Norelco diffractometer.

Results

Preparation of highly dispersed platinum catalysts.—The minimum Pt crystallite size which can be detected depends on the Pt concentration (15). Preliminary experiments showed that 15Å or bigger Pt crystallites were detected by x-ray diffraction providing the Pt concentration was greater than 5 w/o. Thus the samples with greater than 5 w/o Pt in which Pt could not be detected by x-ray diffraction contained highly dispersed platinum. It is not known whether the Pt was monatomically dispersed or whether it existed as small crystallites but the average crystallite size was less than 15Å.

Table I lists the preparation conditions of platinum-doped carbons containing highly dispersed Pt (samples 1-10). All these samples had greater than 5 w/o Pt and Pt crystallites could not be detected by x-ray diffraction. The concentration of the highly dispersed Pt in the doped carbon could not be increased above 12.2 w/o (18) (Table I.)

In the preparation of the highly dispersed platinum it was important to ensure that all the platinum ions were ion exchanged and that no platinum salt was precipitated in the resin pores. This was achieved by doping the resin in a hot platinum solution. When the resin doping solution was at room temperature, platinum crystallites were detected in the doped carbons after pyrolysis and it was presumed that these crystallites were formed by platinum salt precipitated in the resin pores. Highly dispersed Pt was formed when either of the resins was used as the starting material and when any of the gases was used as the furnace atmosphere.

To compare the electrochemical activity of crystalline and subcrystalline platinum, three platinum-doped carbons were prepared containing platinum crystallites. These platinum crystallites were formed in the doped carbons either by precipitating platinum salt in the resin pores and pyrolyzing at 700°C (samples 12 and 13), or by doping the resin in a hot platinum solution and pyrolyzing at 900°C (Table II).

The specific resistance of several Pt-doped carbons was measured (18). The values of the materials prepared by resin pyrolysis at 700°C were approximately 0.01 ohm-cm and this is in agreement with the values determined by Pohl (16). This resistance was sufficiently low for there to be no ohmic drop in the electrode at the low experimental current densities.

Platinum surface areas.—The platinum surface areas of the doped carbons were measured by determining the charge associated with the electrochemical oxidation of adsorbed hydrogen and of adsorbed carbon monoxide. This was carried out by measuring the current/potential curve during the application of a periodic triangular potential sweep to the electrode in nitrogen-purged 1M H_2SO_4 solution at 30°C at a sweep rate of 10 mV/sec. This sweep rate was chosen since faster rates gave ill-defined oxidation peaks in the current/potential curves.

In agreement with the work of Giner *et al.* (22) we found that it was not possible to obtain reproducible values for the charge associated with the oxidation of adsorbed hydrogen (Q_H) with a floating electrode due to hydrogen evolution at potentials cathodic to approximately 0.3V. Also it was not possible to determine the charge due to the reduction of chemisorbed oxygen (Q_{PtO}) by galvanostatic stripping since there was no arrest in the potential/time curve due to chemisorbed oxygen reduction. Thus Q_H was determined on a submerged electrode.

Figures 1, 2, and 3 show the current/potential curves determined on the application of a potential sweep in the range 0.05-1.45V to electrodes prepared from sample 5, Pt black and Pt supported on graphite, respectively. Similar current/potential curves to Fig. 1 were observed with all the electrodes prepared from the Pt-

Table II. Preparation of platinum-doped carbons containing Pt crystallites

Ion exchange resin: Amberlite IRC50; pyrolysis atmosphere: N_2

Sample No.	Pyrolysis temperature (°C)	Weight % Pt	Pt crystallite diameter (Å) (from x-ray diffraction data)
11	900	9.4	55
12	700[a]	11.0	40
13	700[a]	6.7	25

[a] The Pt crystallites were formed by precipitating the Pt salt in the resin pores prior to pyrolysis.

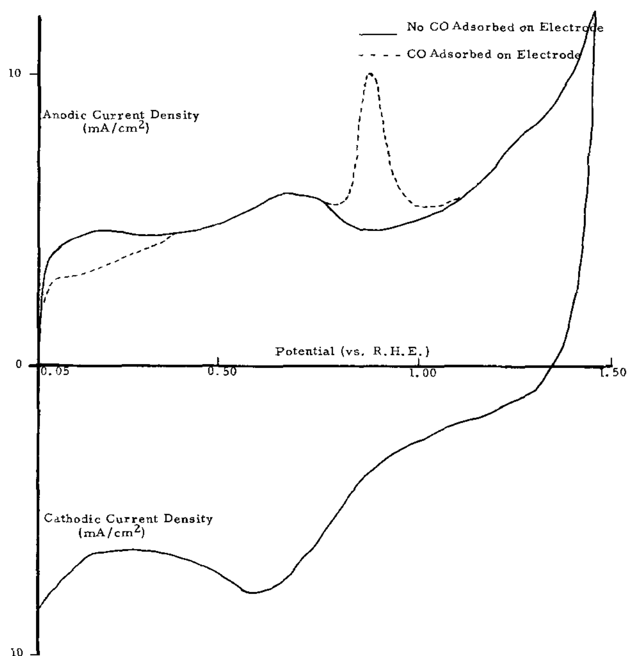

Fig. 1. Potential sweeps on electrodes prepared from sample 5. Pt loading 0.6 mg/cm^2, 1M H_2SO_4 solution at 30°C.

doped carbons containing dispersed Pt (samples 1-10) and with those containing crystalline Pt (samples 11-13).

The current/potential curves obtained with Pt black (Fig. 2) and Pt/graphite (Fig. 3) electrodes are the same as those obtained with Pt foil electrodes (23). The unusual characteristics of the current/potential curves with Pt-doped carbon (Fig. 1) were: (*i*) it had a large capacity current in the potential range of 0.05-0.40V which interfered with the measurement of Q_H on Pt, (*ii*) it had no peak due to the reduction of chemisorbed oxygen, and (*iii*) it had an anodic peak at 0.71V and a cathodic peak at 0.68V.

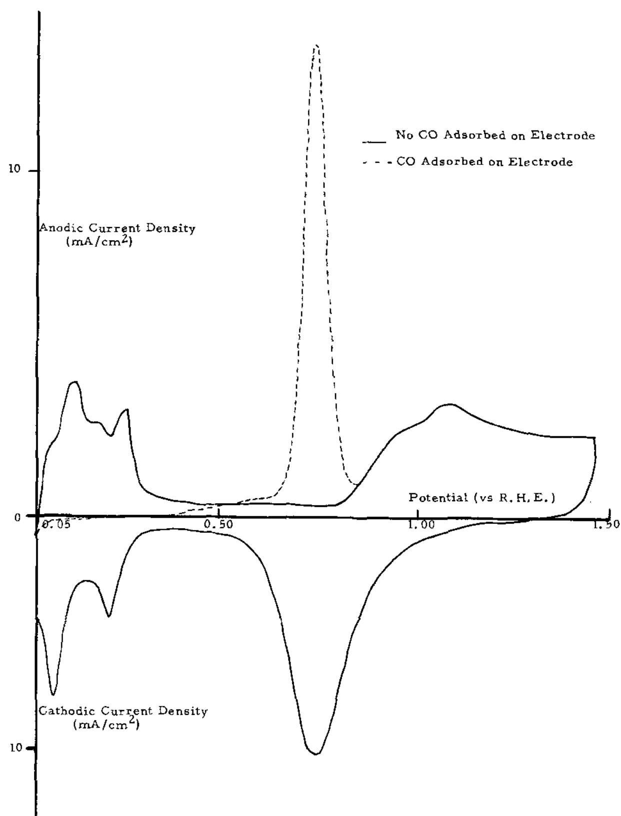

Fig. 2. Potential sweeps on Pt black electrodes. Pt loading 9.2 mg/cm^2, 1M H_2SO_4 solution at 30°C.

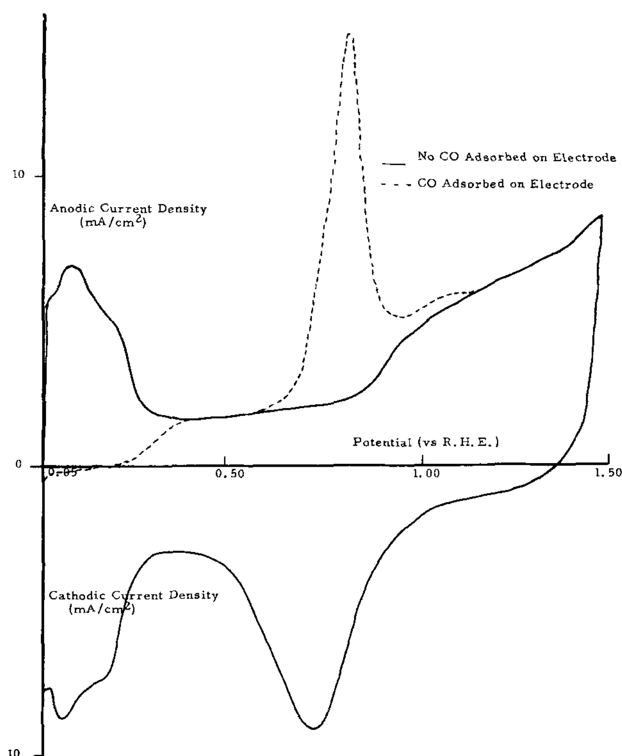

Fig. 3. Potential sweeps on 5% Pt/graphite electrode. Pt loading 0.7 mg/cm^2, 1M H_2SO_4 solution at 30°C.

Since Q_H could not be determined on the Pt-doped carbon electrodes from the potential sweeps in nitrogen-purged electrolyte, it was determined by comparing the potential sweeps with and without carbon monoxide adsorbed on the electrode surface. The same measurements were also made with the Pt black and the Pt/graphite electrodes.

Figures 1, 2, and 3 show the current/potential curves determined by the application of a potential sweep with (dashed line) and without (solid line) carbon monoxide adsorbed on electrodes prepared from sample 5 (Fig. 1), Pt black (Fig. 2), and Pt supported on graphite (Fig. 3), respectively, in N_2-purged 1M H_2SO_4 at 30°C. These measurements were made by first performing the potential sweep on the electrode in nitrogen-purged electrolyte (solid lines, Fig. 1-3). The electrolyte was then purged with CO for 1 min while the electrode was on open circuit (approximately 0.20V) and then with N_2 for 5 min to remove dissolved CO. The cyclic voltammetric sweep on the electrode was then repeated in the N_2-purged electrolyte (dashed) lines (Fig. 1-3). The difference in the shape of the two curves in the potential region 0.05-0.45V is due to the adsorption of CO on the electrode and in the potential region 0.60-0.80V it is due to the oxidation of CO. Preliminary experiments indicated that a 5 min N_2 purge was sufficient to remove all the dissolved CO from the electrolyte with minimal desorption of carbon monoxide from the electrode surface.

Figure 4 shows the potential sweeps in nitrogen-purged electrolyte on an electrode prepared from a carbon. This carbon was prepared by the pyrolysis at 700°C of the calcium form of Amberlite IRC50 ion exchange resin but similar current/potential curves were also observed with graphite electrodes. There is no peak due to the oxidation of adsorbed hydrogen or of adsorbed carbon monoxide on carbon (Fig. 4) and hence the values of Q_H and Q_{CO} calculated from Fig. 1 and 3 are due solely to reactions occurring on Pt. Also Fig. 4 indicates that the anodic and cathodic peaks at 0.71 and 0.68V, respectively, Fig. 1, are due to the oxidation and reduction of surface groups on the carbon.

Pt-doped carbons prepared by resin pyrolysis at 500° and 600°C also contained highly dispersed Pt (18).

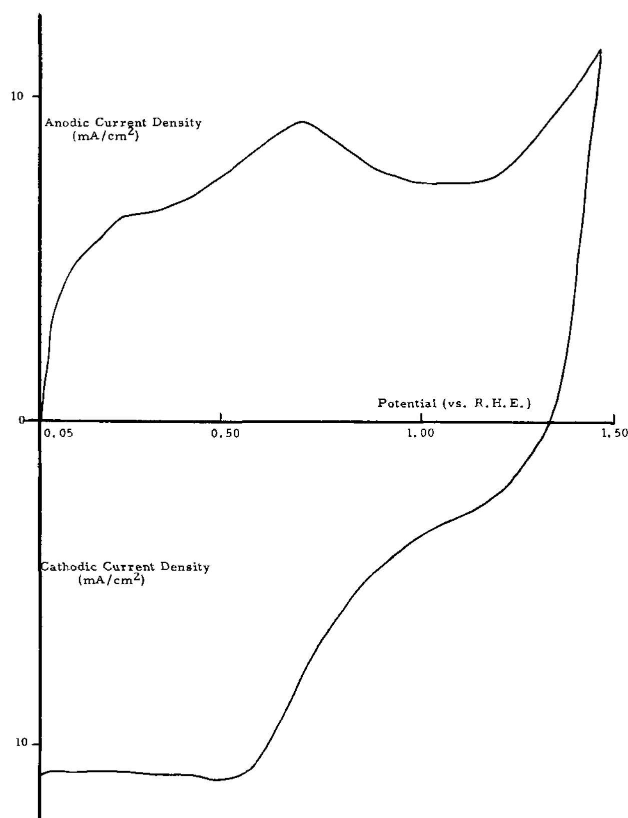

Fig. 4. Potential sweep on carbon electrode 1M H_2SO_4 solution at 30°C.

However no well-defined peaks in the current/potential curves were obtained with these materials and no further studies were made with them since it was not possible to measure their Pt areas.

For the Pt-doped carbons (samples 1-13), the ratio of Q_{CO} to Q_H was in the range 1.5-2.0 to 1. The slightly low value of Q_{CO} is probably caused by CO desorption during the N_2 purge. The values of Q_H and Q_{CO} of selected Pt-doped carbons were measured in 20% H_2SO_4 solution at 70°C as well as in 1M H_2SO_4 solution at 30°C and the same values were obtained in each of two electrolytes. With Pt black and Pt supported on graphite, the ratio of Q_H:Q_{PtO}:Q_{CO} was 1:2:2 within ±10%. Thus the oxidation of CO was a 2 electron process on dispersed and on crystalline Pt.

The values of the Pt areas (expressed as m^2/g) of the Pt-doped carbons (samples 1-13), Pt black, and Pt supported on graphite are given in Table III. They were calculated from the experimental values of Q_H and the Pt loading on the electrode by assuming that the average density of Pt atoms is 1.12×10^{15} atoms/cm^2 (3). The values of the Pt area reported in Table III are average values obtained with 3 electrodes and the Pt area of these electrodes agreed within ±10%. The area of the Pt black (Table III) agreed with other data with Engelhard Pt black (19).

The Pt areas calculated from the CO oxidation data are not included in Table III. However these values were the same as those calculated from Q_H since the ratio of Q_H:Q_{CO} was 1:2.

The calculated areas of a monatomic Pt dispersion and of a 14Å Pt crystallite are (3) 276 m^2/g and 167 m^2/g, respectively. The experimental values of the areas of highly dispersed platinum (samples 1-10) are less than the calculated values for a 14Å crystal indicating that a significant fraction of the platinum is buried inside the carbon during the resin pyrolysis and is therefore not wetted by the electrolyte.

Thus the x-ray diffraction measurements (Table I) show that there are no platinum crystallites in samples 1 through 10 greater than 14Å and the surface area data (Table III) indicates the Pt available for

[c] The average value of the specific activity of highly dispersed Pt catalysts (samples 1-10) was 0.004.

the electrochemical reaction. The "burying" of Pt makes it impossible to calculate the actual degree of dispersion of Pt.

The relatively low platinum area of sample 8 (Table III) indicates that a particularly large fraction of platinum was buried during resin pyrolysis in the N_2/CO (50% CO) furnace atmosphere. This is substantiated by the fact that calcium was detected in this sample by x-ray diffraction and it was not possible to wash it out. Hence it appears that the furnace atmosphere does influence the pyrolysis reaction but it does not measurably affect the size of the platinum crystallites (18).

Activity of highly dispersed platinum.—Figure 5 shows the steady-state polarization curves for oxygen

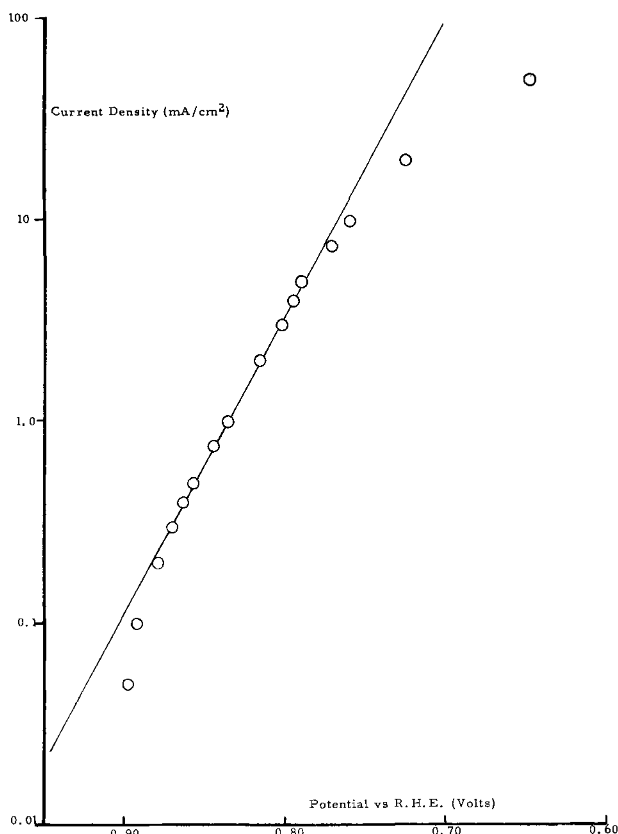

Fig. 5. Cathode performance on oxygen. Sample 4, Pt loading 0.2 mg/cm², 20% H_2SO_4 at 70°C.

reduction in oxygen-saturated 20% H_2SO_4 solution at 70°C on an electrode prepared from sample 4. The data obtained with the other electrodes followed the same general pattern and the slopes of the semilogarithmic plots were equal to 70 ± 5 mV. These plots were linear over 1½ decades of current for electrodes prepared from the platinum-doped carbons (samples 1-13) and from Pt supported on graphite and over 3 decades of current for those prepared from Pt black. Since these plots are linear over a large current density range, it is possible to obtain the activation polarization for oxygen reduction on the electrodes.

In the potential range of the oxygen reduction measurements (*i.e.,* 0.9-0.6V), there was no significant current (approximately 1 $\mu A/cm^2$) due to oxygen reduction on carbon and on the Au electrode holder and there was no current due to carbon corrosion in N_2-saturated 20% H_2SO_4 solution at 70°C. Thus the experimental polarization curves represent oxygen reduction on Pt.

The activity of Pt in Table III is expressed in two ways: (*i*) the ratio of the current at 0.9V to the weight of Pt on the electrode (mA at 0.9 V/mg of Pt) and (*ii*) the ratio of the current at 0.9V to mC for H_2 oxidation. The value of the current at 0.9V was obtained by extrapolating the semilogarithmic plot to 0.9V and hence these values of the Pt activity are free of mass transfer effects.

The first method of expressing the Pt activity (mA at 0.9 V/mg of Pt) is of practical importance since it allows the calculation of the activation polarization per unit weight of Pt. The second method (mA at 0.9 V/mC for H_2 oxidation) is used in the theoretical discussion since it is a measure of the specific activity (*i.e.,* the activity per unit Pt area) of Pt for oxygen reduction.

The average value of the specific activity of the highly dispersed Pt was 0.004 and it was apparently independent of its preparation conditions (furnace atmosphere and ion exchange resin particle size). The values of the specific activity of Pt black and of Pt supported on graphite were in excellent agreement with the value calculated from other Pt black data (19).

It can be seen from Table III that the specific activity of highly dispersed Pt is significantly lower than that of Pt-doped carbons containing crystallites, Pt black, and Pt supported on graphite. This low value was not due to an experimental artifact. Thus the high activity of Pt-doped carbons containing crystallites demonstrated that the low activity of dispersed Pt was not due to catalyst inhibition during resin pyrolysis, large carbon corrosion currents in oxygen-saturated electrolyte, and high ohmic losses between the catalyst and current collector; and the high activity of samples 11-13, Pt black and Pt supported on graphite demonstrated that it was not caused by inadequate electrode structures.

Discussion

The x-ray diffraction data indicate that a highly dispersed Pt catalyst was prepared. It was not possible from the Pt surface area data to determine whether a monatomic dispersion of Pt was prepared but the average Pt crystallite size in the samples was less than 15Å.

It was shown (24), from measurements of the rate of hydrogen chemisorption on platinized carbon from the gas phase, that hydrogen was initially adsorbed on the metal and it then migrated over the carbon surface. This process was termed hydrogen spillover (1), and it has resulted (1, 4, 24, 25) in anomalously high Pt areas for platinum suported on carbon, zeolites, and tungsten oxide.

Carbon monoxide spillover onto a support has not been reported in the literature. Thus hydrogen spillover onto the support did not occur in the present work since the ratio of $Q_H:Q_{CO}$ was 1:2. Hence the Pt areas (Table III) are not anomalously high and the specific activities of Pt (Table III) are correct values.

Table IV. Elemental analysis of Pt-doped carbons

Sample No.	Atomic per cent			
	C	H	O	Pt
4	77.4	13.9	8.4	0.4
6	65.0	22.1	12.0	0.9
7	73.0	20.5	5.8	0.5
9	77.3	15.5	6.7	0.5

The specific activity of the highly dispersed Pt for O_2 electroreduction in acid electrolyte was considerably lower than that of crystalline Pt (Table III). The specific activity of Pt foil has not been measured. However the current/potential curve in the Tafel region is the same in concentrated phosphoric and sulfuric acid solutions (19) and thus using data in H_3PO_4 (26) solution and assuming 0.21 mC/cm^2 for H_2 oxidation, the specific activity of Pt foil at 76°C is 0.02. This value is significantly lower than those of Pt black and Pt supported on graphite but greater than that of dispersed Pt.

The lower activity of the dispersed Pt catalysts may be due either to the difference in the Pt crystallite sizes, or to the influence of the support on the Pt activity, or to a combination of both these factors. It is not possible from the present data to determine which has the major influence.

The influence of Pt crystallite size on the activity of Pt arises since the coordination number of the surface atoms depends on the crystallite size. For example, Poltorak and Boronin (27) have shown that in a 14Å crystal only 33% of the surface atoms have the coordination number of atoms in an infinite, ideal face, whereas in a 50Å crystal 85% of the surface atoms have the coordination number of atoms in an infinite face. It is clear that the Pt crystallite size distribution may also affect the Pt activity.

Evidence for an interaction between Pt and the support was obtained by Nicolau, Thom, and Pobitschka (28) and by Hillenbrand and Lacksonen (29, 30). Nicolau Thom, and Pobitschka (28) found that the sample prepared by the reduction of chloroplatinic acid adsorbed on charcoal exhibited strong paramagnetic resonance absorption but that the paramagnetic resonance absorption was weaker when Pt was mixed with the charcoal. Hillenbrand and Lacksonen (29, 30) found that adsorption of Pt on carbon altered the number of unpaired electrons in the carbon and this modification depended on the pretreatment of the carbon. There are no measurements of the interaction between the metal and the support as a function of metal crystallite size but it is expected that this interaction will be greater for the smaller metal crystallites.

The catalysts prepared by the pyrolysis of an ion exchange resin at 700°C do not consist solely of Pt and carbon, and selected doped-carbons were analyzed[1] to determine the fraction of hydrogen and oxygen atoms in each support. These results are reported in Table IV.

It can be seen from Table IV that the supports contained significant fractions of hydrogen and oxygen. Comparison of the analysis results (Table IV) with the Pt specific activity data (Table III) indicates that small changes in the composition of the support does not change the activity of Pt for oxygen reduction, but this does not prove that the support is not influencing the activity of platinum. Further work aimed at larger variations in support composition is required to extend the present study.

This work demonstrates that the activity for oxygen reduction of highly dispersed Pt on a support prepared by the pyrolysis of an ion exchange resin is less than that of crystalline Pt. This may not hold true for all dispersed Pt catalysts but it may only be applicable to the Pt dispersion prepared by this particular method.

[1] Analyses were made by Schwarzkopf Microanalytical Laboratories, New York, New York.

In addition the low activity of dispersed Pt catalyst may be applicable only to the electroreduction of oxygen and the relative activity of highly dispersed and crystalline platinum will probably depend on the nature of the reactant and even of the electrolyte. For example, Poltorak and Boronin (31) using highly dispersed Pt on silica gel found that many hydrogenation, dehydrogenation, and hydrogenolysis reactions were independent of the platinum crystallite sizes. However when the same catalysts were used for reactions involving oxygen species (*e.g.*, hydrogen peroxide decomposition, methanol and ethanol oxidation, and acetaldehyde oxidation) their activity was at least one order of magnitude lower than that of Pt black. It was claimed (31) that in the latter reactions the platinum was completely covered with oxygen and consequently it lost its metallic character.

The highly dispersed Pt catalyst prepared by the pyrolysis of an ion exchange resin in which Pt ions were adsorbed is not suitable as cathode catalysts in acid fuel cells since the increase in Pt area is more than outweighed by the decrease in Pt specific activity.

Manuscript submitted Aug. 13, 1971; revised manuscript received *ca.* Jan. 7, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Hermetic Compression Seals for Alkaline Batteries

E. J. McHenry* and P. Hubbauer

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

An accelerated thermal cycle test is described which has been used to evaluate the long-term reliability of seals for nickel-cadmium batteries in Bell System use. Results of this test correlate well with life test results on long-term overcharge. Two new types of seal have been developed for use in nickel-cadmium or other alkaline batteries. The first is a simple modification of the seal developed by A. W. Ziegler for submarine cable use. It entails substitution of an injection molded nylon bushing for the machined Kel-F bushing used by Ziegler, thus eliminating a costly machining operation and greatly simplifying fabrication of the seal. The second is a design employing the same principles as the Ziegler seal but is simpler and can be made in smaller sizes than the Ziegler seal. Both designs have been subjected to accelerated thermal cycle tests and found to be superior to the seals used on commercial alkaline cells.

The maintenance-free rechargeable nickel-cadmium cell depends on a proper balance among oxygen pressure, state-of-charge of the electrodes, electrolyte content, and positive-to-negative capacity in order to function dependably. This balance can be maintained only as long as there is no material transport across the walls of the container. A leakage rate of as little as 10 std cm^3 of oxygen per month (4×10^{-6} std cm^3/sec) would result in an increase of 480 mA-hr in negative state-of-charge in one year. This represents approximately one third of the excess negative capacity in a typical D (4 A-hr) cell and would result in cell failure within three years.

Leakage is a problem which seriously limits the life of nickel-cadmium batteries in Bell System service. These batteries contain conventional commercial cells

Key words: injection molding, terminal seals.

in which economic and size limitations usually dictate the use of a seal based on a compressed plastic gasket. Aerospace cells, having no such economic limitations, have traditionally used ceramic-to-metal and glass-to-metal seals in an attempt to achieve long life. However, NASA data (1) indicate that despite their high cost, leakage occurred in 33% of the cells tested containing ceramic-to-metal seals and 53% of the cells tested containing glass-to-metal seals. In addition to the fact that glass and ceramic seals are expensive, inherently fragile, and subject to chemical degradation, previous work in the laboratory (see section on Ziegler seal) has shown better results with properly designed compression seals. Therefore, this work was directed toward improvement of the compression seal.

Experimental

Theory and accelerated testing.—The basic principle of the compression seal is shown in Fig. 1. In its simplest form the seal is composed of a plastic gasket, 1, compressed between the negative terminal, 2, and the positive terminal, 3, sealing leakage paths, A. Provided there is continuous contact between the metal and gasket surfaces and sufficient pressure is maintained on the gasket, this seal will effectively prevent leakage. When metal-to-plastic contact is not continuous or contact pressure is not maintained above a critical point, failure occurs. Failure of compression seals may be the result of any one or combination of the following:

1. Improper construction (misaligned gasket, feathered edges, burrs, etc.).
2. Poor design.
3. Chemical or thermal degradation of the gasket.
4. Thermal or mechanical fatigue of the gasket.

Chemical or thermal degradation of the gasket is normally not encountered at room temperature or below but may be serious at higher temperatures. Diffusion of gas or liquid through the gasket occurs at an appreciable rate only at high temperature or pressure. Seal failures are normally due to poor design, improper construction, or gasket fatigue, all of which result in insufficient contact pressure between the gasket and metal surfaces.

Fatigue results from pressure fluctuations inside the cell or from stress variations caused by thermal cycle of components with large differences in thermal expansion coefficients. The internal gas pressure of a sealed Ni-Cd cell varies with the state of charge and rate of overcharging. This differential may be as great as 5 atm between the end of charge and the end of discharge. In conventional cells the area of the cover acted on by the internal pressure is considerably greater than the bearing (contact) surface between the cover and the gasket. Thus the resulting stress in the gasket is of the order of 10 times the internal gas pressure. Normal operation also entails thermal cycle (daily temperature variation superimposed on a seasonal temperature cycle) which causes expansion and contraction of the seal components. Gasket materials generally have thermal expansion coefficients ten times that of metal container materials so that expansion of the gasket is restricted by the container. Heating and cooling cause a fluctuating stress on the gasket which eventually results in fatigue failure. Thus rapid, broad range thermal cycling would be expected to greatly accelerate seal failures which would result from any of the causes listed above. This test would rapidly provide comparative data on seal quality which might otherwise take months or years to accumulate.

The temperature profile that was used in our experiments is shown in Fig. 2. It consisted of cycling between −40°F and +160°F, one full cycle every 2 hr. The lag time required for the chamber to come to the set temperature was approximately 20 min on both rise and fall. Thermal cycling was continuous seven days a week with no rest period until failure of the seal. Failure was determined by applying wet multirange pH paper to the seal and observing color change after 5 min. If the paper indicated a pH of 9 or greater, the seal was considered failed. Leak checks were made every day during the first week of testing and every week thereafter.

Experimental evidence of the correlation between thermal cycle and overcharge tests is shown in Fig. 3. The upper graph is a conglomerate of leakage data on 60 commercial D cells of four manufacturers which were tested at 20°F, 32°F, and room temperature at 200 mA constant overcharge (2). The lower graph shows results of thermal cycle tests on 20 additional D cells taken from the same lots. As can be seen, there is one-to-one correspondence in relative seal quality exhibited in the two types of tests. Thus, the thermal

cycle test is established as a valid accelerated test of relative quality of compression seals.

Ziegler seal.—Among the seals developed for use with nickel-cadmium batteries for TELSTAR® (3) was a plastic compression seal designed by Ziegler (4) originally for use in submarine cable repeaters. Although the reliability of the seal design was not established in time for the TELSTAR® flights, long-term experiments carried out subsequently showed them to be superior to glass and ceramic seals as seen in Table I. More important, they show it to be capable of eliminating the leakage problem in long-term service.

A diagram of the Ziegler seal used in these experiments is shown in Fig. 4. The threaded metal barrel is first brazed into the lid of a cell. The Kel-F bushing is then screwed into the barrel and the central lead wire inserted through the bushing. Radial compression is then applied to reduce the barrel diameter from 0.250 to 0.234 in.

In order to insure continuous uniform compression of the threaded Kel-F bushing, a 0.156-32 Whitworth thread is used. The important feature of this thread is the rounded roots and crests. Normal threads with sharp roots and crests are very difficult to match by a machining operation so that a helical leakage path along the sharp root is a primary failure mode. High precision is required in machining the threads to prevent burrs which would mar the Kel-F during assembly. This construction is referred to as the standard Ziegler seal.

Injection molded Ziegler seal.—Although the Ziegler seal is very effective, the precision machining required is time-consuming and expensive. Of the possible fabrication techniques available, injection molding appeared most suitable for our design objectives of simplicity and economy. This technique is rapid, economical, and faithfully reproduces the surface characteristics of the threaded barrel. It has the added advantage of eliminating the assembly operation since the bushing is formed *in situ*.

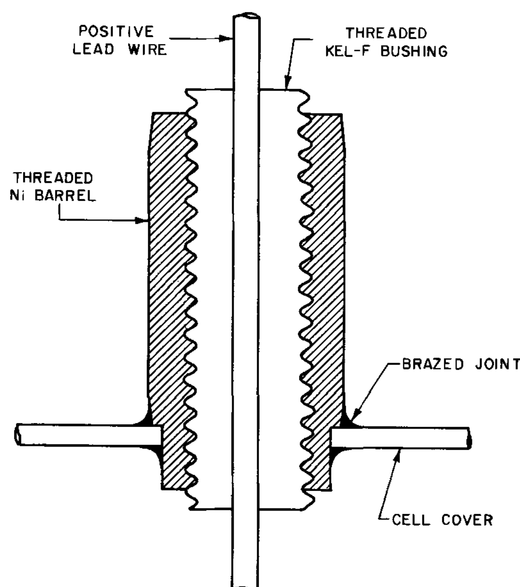

Fig. 4. Construction of Ziegler seal

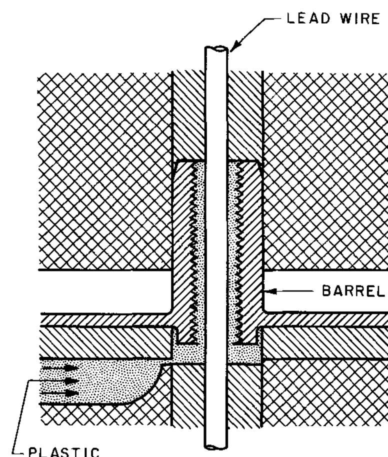

Fig. 5. Injection mold for Ziegler seal

Starting with the basic Ziegler design, a modified seal was fabricated by injection molding a nylon 6-6 bushing into a nickel barrel. The barrel was identical to the standard Ziegler barrel (shown in Fig. 4) with the exception of the thread which was cut with a standard 8-32 tap. Threaded barrels were brazed into covers made to fit a standard D cell can. The cover and lead wire were placed in a mold (Fig. 5) and plastic material was injected into the cavity to form a bushing. Molding conditions are shown in Table II. A cylindrical electrode core taken from a standard commercial D cell was then placed in a can and the cover with the injection molded seal was welded onto the can. The barrel was then crimped in the same manner as the standard Ziegler seal. At this point the cells were pressurized with 60 psig of helium and placed on a mass spectrometer leak detection device. This instrument is capable of detecting a leak rate of 2×10^{-10} std cm^3/sec or 0.0063 std cm^3/yr. No leakage was detected on any of the cells. Approximately 18 ml of electrolyte was then added to the cell through a fill tube on the bottom of the can. The cells were placed on thermal cycle at 50 mA overcharge. Results of these tests are presented in Table III.

As can be seen, these seals are equally as effective as the standard Ziegler seal. A major difference between the two types of seal is the quality of workmanship required in their fabrication. To illustrate this

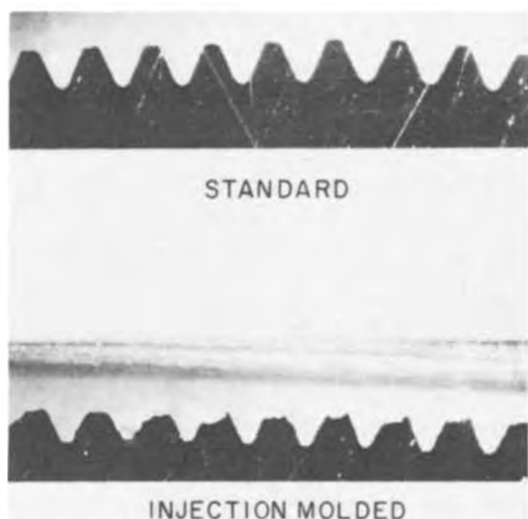

Fig. 6. Thread design for Ziegler seals

point, seals were constructed using a worn 8-32 tap to produce deliberately poor thread quality. Figure 6 shows a comparison between the threads of the standard and these injection molded seals. Both of the seals shown have withstood over 1000 thermal cycles without any indication of leakage.

Multiple crimp seal.—The proportionally large increase in over-all cell height accompanying the use of the Ziegler seal on small cylindrical cells is a major disadvantage. For this reason another design (5) operating on principles similar to that of the Ziegler seal was developed in which the seal is inverted and extends into the central void of the cylindrically wound core of the cell as shown in Fig. 7.

It consists of a metal tube containing a coaxial plastic tube and a central metal lead wire. The lead wire is normally nickel and serves as the positive terminal of the cell. The outer metal tubing is brazed into the cell cover, and the plastic tubing and wire are inserted into it. Multiple crimps compress the plastic tubing between the outer metal tubing and the central lead wire, thus effecting a seal. A 0.125 in. OD by 0.062 in. ID nickel tubing was employed in all of these seals with a 0.060 in. OD by 0.031 in. ID plastic tubing. The central wire was drawn to approximately 0.001 in. less than the plastic tubing ID. In all cases the crimping operation reduced the outside metal tubing diameter by approximately 0.017 in. Each crimp was ⅛ in. long, and the space between crimps was ⅛ in. Two groups of seals were made 2 in. long with seven crimps, and two groups were made with two crimps and a length of ⅜ in.

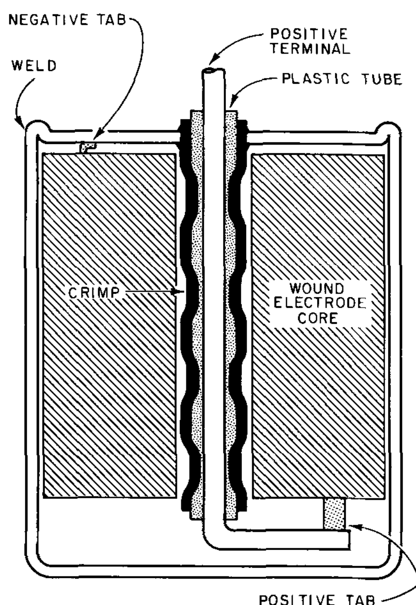

Fig. 7. Diagram of crimp seal

Injection molding was also applied to the crimp seal in order to simplify construction and avoid assembly errors. A larger tubing measuring 0.187 in. OD by 0.125 in. ID by 1 in. long was used with a 0.060 in. diameter nickel lead wire. Plastic material was injected into the annulus between the wire and the metal tubing. The tubing was crimped in four equally spaced sections of ⅛ in. length. Crimping reduced the tubing OD from 0.187 to 0.176 in. on the crimped portion.

Since this type of seal extends into the cell it is not possible to crimp after the welding operation. Therefore, adequate heat sinking is required to prevent the seal from being heated above 200°F during welding. Helium leak check and electrolyte addition were performed in the same manner described for the Ziegler seals. Thermal cycle performance of the new seals is presented in Table IV.

Discussion

Values of gas diffusion rates through plastic bodies comparable in size to the Ziegler seal have been calculated. These values are presented in Table V for ¼ in. diameter by ½ in. long bodies of nylon 6 and Kel-F and are based on diffusion rates reported in the literature (6) and a 1 atm pressure differential at room temperature. Leakage of helium through the standard and injection molded Ziegler seals as well as the crimp seal has been measured as less than 6.3×10^{-3} std cm^3/year (2×10^{-10} std cm^3/sec). This value is of the same order as the calculated gas diffusion rates shown in Table V. Thus gas diffusion is not considered to be a life-limiting factor. Accelerated thermal cycle tests indicate that fatigue failure may also be eliminated as a failure mode in a five to ten year life. All available evidence suggests that leakage is no longer a problem in any application where the Ziegler or crimp seals can be employed.

A major advantage of the new seals over the standard Ziegler or ceramic seals is the simplicity and expected economy in their fabrication techniques. Costly precision machining has been eliminated and replaced by punching, drawing, stamping, and welding operations. It is expected that relatively unskilled workers can assemble these seals quickly with very low in-

cidence of rejects. The new seals have the added advantage of flexibility in design change. That is, the seal dimensions need not be changed at all unless a gross change is made in the cell design. Thus exactly the same seal design can be used in the size range from "sub C" to D cell without any change in any dimension of the seal. It is conceivable that in small quantities of special cells it may be cheaper to use the Ziegler or crimp seal rather than the ordinary commercial seal.

All of the seals studied in this work employed a nylon insulating bushing. Ease of fabrication, prior experience with nylon in Ni-Cd cells, and physical and chemical properties were the main reasons for this choice. Other materials such as polypropylene, FEP Teflon, Kel-F, and Kynar appear to be suitable for use in these types of seals. Some of these materials were used in preliminary experiments, and results indicate that with proper control, they will be equally suitable in these designs. Further work is planned to investigate other plastic materials and to develop a seal which will withstand sterilization at 135°C for 72 hr.

Conclusions

The injection molded Ziegler seal and the multiple crimp seal perform far better on accelerated thermal cycle testing than do ordinary commercial seals and are expected to perform satisfactorily for five to ten years of normal operation. These seals are simple in construction and can be produced at a cost considerably below that for ceramic seals, which they will outperform under most conditions.

A New Water-Activated Lead-Acid Battery Concept

R. F. Amlie,* E. Y. Weissman,* C. K. Morehouse,* and N. M. Qureshi

Globe-Union, Inc., Milwaukee, Wisconsin 53201

ABSTRACT

A discussion is presented of a reserve lead-acid battery concept based on water-soluble sulfuric acid gels. The gels consist primarily of 100% sulfuric acid plus small amounts of boric and phosphoric acids. These gels exhibit excellent mechanical and thermal stability characteristics when prepared with a relatively large molar excess of boric acid with respect to phosphoric acid. The rate of water activation of a battery containing this gel is controllable, and no solid residues are left after the activation has been completed. Performance, life, and electrolyte composition aspects are covered in this discussion, with a view to defining the advantages and limitations of the system and its future possibilities.

The development of a satisfactory water-activated dry-charged lead-acid battery is of particular interest since it would fill a definite need that exists in military and possibly also commercial applications for a reserve system. A water-activated battery would have several advantages over the widely accepted acid-activated battery in that no separate acid volume is required and shipment, storage, and activation are inherently less costly, safer, and simpler. A satisfactory water-activated concept requires the internal storage of concentrated sulfuric acid (or its precursor) in a mechanically and thermally stable form which will produce sufficient sulfuric acid electrolyte in a safe yet sufficiently rapid manner upon addition of water. Other characteristics for a practical concept require that the acid concentrate occupy essentially a minimal volume, since internal free space is greatly limited in conventional batteries, and that it produce no degradation of cell components. Further, performance should be comparable to that of a conventional battery of the same external dimensions.

Various concepts for water-activated lead-acid batteries are described primarily in the patent literature and have appeared at an increasing rate in recent years following a feasibility study reported in 1965 (1). Briefly, these concepts could be described as involving the immobilization of concentrated sulfuric acid by mechanical encasement of the liquid (2-4), physical sorption (5-9), chemical reaction (10), and gelation (11-17), although this classification may not always be completely rigorous.

Stable Boron Phosphate Gels

This paper presents a water-activated lead-acid battery concept based on the use of stable "boron phosphate" gels of concentrated sulfuric acid. Gelation of concentrated sulfuric acid and oleum by the addition of essentially equimolecular amounts of boric and phosphoric acids was described by Leicester in 1948 (18). Leicester suggested that gelation is due to the formation of a boron phosphate, (BPO_4), structure which may be isomorphous with a silicic acid gel of sulfuric acid in which the silicon atoms are alternately replaced by boron and phosphorous atoms. He describes general properties of these gels including the observation that, "Equimolecular proportions of the two acids (H_3BO_3 and H_3PO_4) gave the best gels, but the quantities could be varied within wide limits (±30%) with-

* Electrochemical Society Active Member.

Key words: gelled sulfuric acid, boron phosphate gels, water-activated battery, lead-acid battery, dry-charged battery.

out seriously affecting gel formation for the 1/100 (mole ratio BPO_4/H_2SO_4) and more concentrated gels." Other properties listed included: (*a*) increased firmness with concentration, (*b*) faint to strong opalescence, (*c*) slight syneresis (separation of liquid phase due to gel contraction) with little indication of thixotropic properties, (*d*) readily broken down and dissolved by the addition of water, (*e*) good thermal stability at 100°C, and (*f*) good room temperature stability for several months. Leicester also shows that gelation time decreased rapidly with increasing water content and moderately with increased BPO_4 content.

We found these gels to be easily prepared starting with boric acid crystals, 85% orthophosphoric acid, concentrated sulfuric and oleum solutions. Since the composition of the sulfuric acid component (or H_2O/SO_3 ratio) of the mixture greatly influences gel stability, we assumed the gelation reactions shown below in order to define a calculated H_2O-SO_3 composition

$$H_3PO_4 + (1 + x)H_3BO_3 \rightarrow BPO_4 + xH_3BO_3 + 3H_2O \quad [1]$$

$$xH_3BO_3 \rightarrow xHBO_2 + xH_2O \quad [2]$$

$$H_3PO_4 + (1 + x)H_3BO_3 \rightarrow BPO_4 + xHBO_2 + (3 + x)H_2O \quad [3]$$

In addition to the water introduced in the gelation process, the 85% phosphoric acid and the concentrated sulfuric acid ingredients also introduce water into the system. This water is effectively removed by the addition of oleum (free SO_3) and the resulting H_2SO_4 and H_2O, or SO_3 contents were calculated according to the above assumptions. Laborious material balance equations involving different ingredient concentrations and gel compositions were avoided by use of a FORTRAN program in our computer facility.

In actual practice, it was found that gel preparation can be readily monitored by measuring the electrolyte solution conductivity which is very sensitive to concentration in the range of interest. Specific conductance values of liquid gelling mixtures with an acid mole ratio of $2H_3PO_4/5H_3BO_3/100H_2SO_4$ are plotted in Fig. 1 as a function of the weight per cent (w/o) H_2SO_4. The weight per cent H_2SO_4 calculated for each solution is based on the total SO_3 content, and H_2O which was both added and assumed to be derived from gelation and dehydration. Gel compositions with this 2/5/100 mole ratio exhibit excellent stabilities in the calculated H_2SO_4 concentration range from about 99 to 101%, above which SO_3 fuming becomes progressively evident. The specific conductance curve of a pure sulfuric acid solution with a minimum at 99.7 w/o H_2SO_4 (19) is also included in Fig. 1. It is evident that the minimum, as calculated for the gelling solution, exceeds that of pure H_2SO_4 by approximately 1 w/o. This would indicate that the assumed gelation reaction [3] does not provide a complete description of this complex system which may involve interaction of acid species. A systematic study of the boron phosphate-sulfuric acid system is required to clarify these results.

Gels prepared in our laboratory using Leicester's formulations did not exhibit satisfactory thermal and storage stabilities toward syneresis as deemed necessary for a water-activated battery application. The hygroscopic gels were stored in tightly capped glass bottles at temperatures up to 100°C. In agreement with Leicester, it was found that gel stability was improved by decreasing the water content and increasing the BPO_4 content, but neither the equimolar gels nor gels containing up to 30% excess of boric or phosphoric acid were sufficiently stable.

Gel stabilities were found to be greatly improved when a relatively large molar excess of boric acid relative to phosphoric acid is used (16). Table I summarizes the optimum ranges of acid mole ratios necessary to produce battery-stable gels. An approximate stability-composition domain for gels containing a 99-

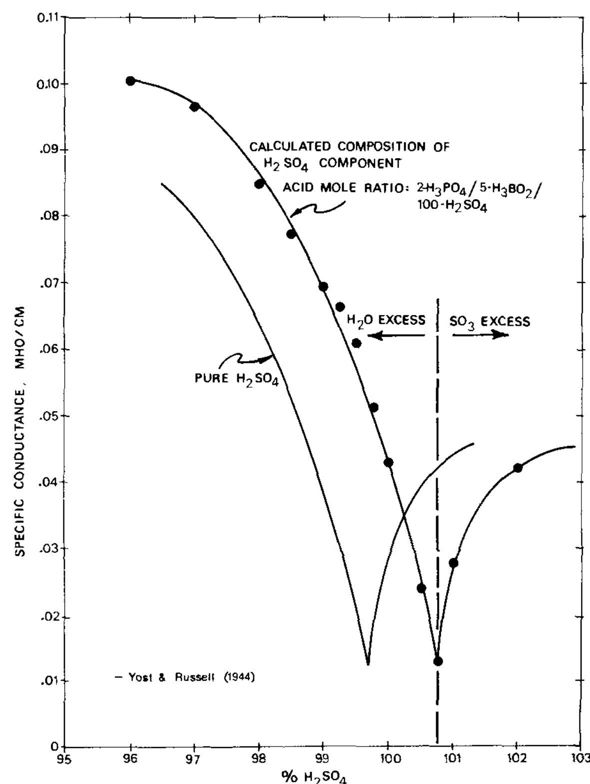

Fig. 1. Specific conductance vs. per cent H_2SO_4 at 30°C

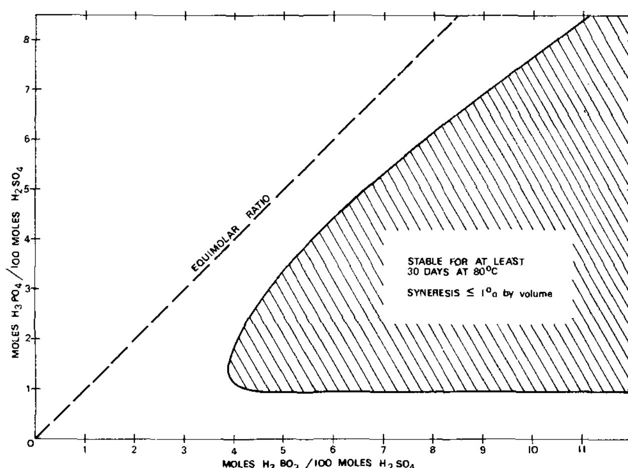

Fig. 2. Approximate stability composition domain for $H_3PO_4/H_3BO_3/H_2SO_4$ gels containing 99-100% calculated H_2SO_4.

100% calculated (aqueous) H_2SO_4 component, wherein syneresis was less than 1% by volume after 30 days' storage at 80°C, is shown in Fig. 2. Acid composition of the gels is given in moles of phosphoric and boric acid per 100 moles of calculated (100%) sulfuric acid. Stabilities of these gels were generally best in the lower portion of the composition domain where the H_3PO_4 content exceeded 1 mole per 100 moles H_2SO_4 and the maximum H_3BO_3/H_3PO_4 mole ratios were attained. The more stable gels exhibited no evidence of syneresis or breakdown after 100 days' storage at 100°C

at which time the tests were discontinued. Attempts to liquify the most stable gels at even higher temperatures produced instead a surface decomposition with gradual reduction of the gel body size.

Gel appearance varied from strongly opalescent to water-clear and was found to be dependent on the H_3PO_4/H_3BO_3 ratio, the water content, and the setting temperature. Water-clear gels generally exhibited the greatest stability and were obtained only with an excess of boric acid and minimal (or no) calculated water content. A photograph of a water-clear gel sample is shown in Fig. 3.

A particular advantage with this gel is that it can be combined rapidly with water without the hazard encountered with concentrated sulfuric acid liquid.

Having established that gels could be prepared with excellent mechanical, thermal, and storage stabilities, effort in this development was devoted to determining the effect of gel-prepared electrolytes on battery performance.

Water-Activated Battery Performance

Electrochemical phenomena arising from the use of solutions prepared from gelled acids rather than pure sulfuric acid are primarily due to the presence of orthophosphoric acid. Furthermore, our measurements and observations support Leicester's view that the addition of water (at least 10-15% by volume of gel) readily hydrolyzes the gels to the constituent acids yielding a clear solution (18).

The addition of phosphoric acid to the lead-acid battery has been rather extensively tried (20) and will not be reviewed here. Definitive conclusions have often been dependent on the materials, design, and test mode or service employed. While the earliest patents claimed such general improvements as "the elimination of harmful sulfation" (21), it is now generally accepted that phosphoric acid additions are of particular benefit in improving the cycle life of nonantimonial grid batteries (22, 23). More fundamental investigations of the reactions of phosphoric acid with the lead dioxide electrode have also been reported (23-27) and we have carried out measurements on the electroanalytical determination of Pb(IV) phosphate species in solution (28). Nevertheless, a more comprehensive understanding of the incorporation of phosphoric acid in the positive plate and the changes it produces is definitely needed.

Activation of Prototype Batteries

Initial 20-min activation performances of prototype water-activated batteries are superior to comparable commercial acid-activated batteries owing to the heat of dilution of the concentrated sulfuric acid gel. This advantage is illustrated in Fig. 4 wherein discharges are plotted for 12V-60 A-hr batteries activated and discharged according to the standard SAE ∼ 0°C (30°F)-150A discharge test specification. These batteries were assembled with production dry-charged 60 A-hr elements in polypropylene containers (and covers). The water-activated batteries contained 210 cc (388g) of gel mounted above each cell element (16). Prior to activation, the batteries and the (1.270 sp. gr.) sulfuric acid solution had been cooled to ∼ 0°C (30°F) and the water to +1°C. These water-activated batteries were designed to dissolve the gel body in about 20 min after the addition of water and the dissolution occurred with no emission of liquid from the filling ports. The 150A discharge was started 20 min after filling, at which time the average temperatures of the commercial acid-activated and water-activated batteries were 3.5° and 69.5°C, respectively.

Short and Long Term Results

Only a brief summary of available storage, cycle-life, overcharge, and field service results for one gelled electrolyte composition will be given at this time. A more detailed presentation of design and performance characteristics will be given elsewhere (29).

Standard production dry-charged 12V-60 A-hr batteries with 6% antimonial-lead grid alloy have frequently been used to compare the performance of solutions prepared from gelled acids with the standard sulfuric acid solutions. No effort was made to optimize or alter the batteries for this application. To make this extensive comparison, gel with an acid mole ratio of $2H_3PO_4/5H_3BO_3/100H_2SO_4$ was selected based on initial laboratory test results. The acid concentrations of a solution prepared from this gel are typically 9, 14, and 455g per liter of phosphoric, boric, and sulfuric acid, respectively. The solution prepared by the addition of 480g of a 2/5/100 gel containing 0.5 w/o "excess" water to 802g of water has a specific gravity of 1.282 at 21°C. The control batteries were filled with 1.270 sp. gr. sulfuric acid (460 g/liter).

The most significant available results can be summarized as follows:

1. The 60 A-hr sealed, dry-charged, SLI-type batteries with gel mounted above the plate elements continue to show satisfactory storage after more than six months in a 60°C-100% relative humidity environment.

2. Gel prepared electrolyte capacities on the 20-hr (3A) discharge at 27°C (80°F) have shown an average reduction of 6% relative to their respective controls.

3. At low temperatures (0 to −29°C) and high discharge rates (150 and 300A), the 2/5/100 gel prepared electrolyte solution has exhibited increased 5 sec voltages[1] of 3 to 6% and reduced discharge times ranging from 5 to 33% relative to the control.

4. When cycled according to the SAE cycle-life specification (30), the 60 A-hr SLI batteries with the 2/5/100 composition electrolyte have averaged only 2/3 of the control cycles. On the other hand, Edison Cycle Life Test (see Appendix) results average about 10% higher for the experimental batteries. Field test results are still inconclusive but seem to suggest a detrimental effect on life in hot climate use.

[1] Voltage measured after 5 sec of discharge at the given rate.

5. Overcharge life test comparisons for 60 A-hr batteries on the standard SAE overcharge test (30) routine have shown the same performance for the 2/5/100 acid solution and the sulfuric acid control.

6. There appears to be a structure-dependent scale effect when evaluating experimental and control batteries so much so that certain types of low-capacity batteries (not of the SLI variety) have not exhibited the above-mentioned performance differences. This aspect will be discussed at a later date.

7. Gel prepared electrolyte solutions used in batteries fabricated with nonantimonial lead alloy grids are expected to improve positive paste adherence. Fortunately, a practical phosphoric acid concentration for typical nonantimonial systems (*e.g.*, lead-acid batteries having lead-calcium grids), namely 10 g/liter of solution, corresponds to what results from the utilization of the gelled acids described in this paper.

Conclusions

The technical feasibility of a water-activated, dry-charged lead-acid battery based on stable boron phosphate-concentrated sulfuric acid gels has been demonstrated. Properly formulated gels have been developed which exhibit superior mechanical, thermal, and shelf stabilities when stored out of contact with moisture. The low-temperature activation performance of prototype SLI batteries is excellent due to the H_2SO_4 heat of dilution released. Laboratory cycle life, and field testing of SLI prototype batteries indicate that the gelled acid may reduce the performance of standard batteries in certain SLI applications, although optimization of the system to compensate for the modified electrolyte effects is possible.

Finally, while this discussion addresses itself to the SLI type of battery, it should be obvious that the water-activation principle described here is adaptable to any battery system utilizing a sulfuric acid electrolyte.

Manuscript submitted Nov. 1, 1972; revised manuscript received Dec. 20, 1971. This was presented at the Cleveland Meeting of the Society, Oct. 3-8, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

APPENDIX

Edison Cycle Life Test for Lead-Acid SLI Batteries

Temperature: 38°-43°C in air environment
Cycle time: 10 min; 1000 cycles/week
Charge — 6 min, 27 sec at 5-6A
Discharge — 10 sec at 150A } 10 min
Rest — 3 min, 23 sec
Capacity test: 150A to 7.2V (1.2 V/cell)

Specified minimums:
Capacity — > 0.5 min to 7.2V
Life — 10 weeks (10,000 cycles) for 60 A-hr battery

Effect of Chloride Ion on Iron Corrosion in NaOH Solution

Clarence M. Shepherd* and Sigmund Schuldiner*

Naval Research Laboratory, Electrochemistry Branch, Washington, D. C. 20390

ABSTRACT

Potentiostatic polarization curves for the system Fe-NaOH, in which the level of reactable impurities had been reduced to 10^{-6} ppm, showed that Fe did not corrode and that the Fe behavior was similar to Pt. Introduction of chloride ion changed the potentiostatic polarization behavior and at Cl^- concentrations ≧2 μg/cc Fe corrosion occurred. Chloride ion also caused the development of a pronounced active dissolution region in the anodic polarization curves. At 0.2 μg/cc of chloride ion, the changes in the polarization curve were small. At 2 μg/cc of chloride ion a typical pattern had developed which showed a definite corrosion region, followed by "passivity" as the potential was increased. At 2000 μg/cc of chloride ion corrosion was marked, even in the "passive" region.

The present work extends our previous (1) study of the effects of chloride ion on the potentiostatic behavior of iron in oxygen-free ($<10^{-6}$ ppm) NaOH solution. Mayne, Mentor, and Pryor (2) showed that in oxygen-free solution chloride ion concentrations from 3.5 to 35 μg/cc will cause iron to corrode, however no corrosion occurred when oxygen was present. The chloride ion concentration in our high-purity 0.2M NaOH was approximately 0.01 μg/cc so that we were able, under O_2-free conditions, to determine the effects of chloride ion at considerably lower levels than previously had been investigated.

Experimental

The electrode was a high purity Fe wire immersed in 0.2M NaOH under an atmosphere of helium at 25°C. The closed system and measuring equipment have been previously described (1, 3, 4). The 20 mm diameter Fe wire was fabricated from 3 pass electron beam zone refined iron which was reported by the supplier to contain less than 4 ppm metallic impurities. The NaOH electrolyte was prepared by dissolving high purity sodium from a glass capsule inside the closed cell (1). Final purification was by electrolysis to remove traces of heavy metals and organic material. A point on the curves shown was determined by potentiostating the Fe electrode until a constant current was reached. The potential was then increased and another steady-state current was obtained. The process was repeated until the potential was well up into the O_2 generating region after which the potential was decreased stepwise until well into the H_2 generating region. The potential was then increased stepwise back to its original value, thus completing a cycle. Repeated cycling gave essentially the same results.

Results and Discussion

The results for the highly purified system, Fe/0.2M NaOH containing about 0.01 μg/cc Cl^- (from NaCl) as an impurity, are shown in Fig. 1 where the constant value of the apparent current density is plotted against the potential measured against the normal hydrogen electrode (NHE). This curve is used as a standard for comparison with the results that were obtained when small known amounts of Cl^- were added to the pure system. No visual corrosion or changes in the Fe were observed under low power microscopy nor was Fe found in the analyzed solution.

When Cl^- is added to the system the potentiostatic polarization curve of Fig. 1 is affected. The results are shown in Fig. 2-5 for concentrations of Cl^- from 0.2 μg/cc to 2000 μg/cc. The concentration of O_2 in these systems was less than 10^{-6} ppm (4).

When the chloride ion concentration reached 2 μg/cc (Fig. 3-5), one observes a large increase in the anodic current density, particularly in the region of the loop where the potential is being increased from point C through K to L. This increase in current is accompanied by corrosion. This confirms the Mayne, Mentor, and Pryor (2) finding of iron corrosion in O_2-free solution containing 3.5 to 35 μg/cc of Cl^-. Under conditions in which no chloride has been added to the electrolyte the iron remains bright and shiny over repeated cyclings. After 2 cycles in the solution containing 2000 μg/cc of chloride ion, the iron electrode was pitted appreciably. Considerable amounts of dark brown corrosion products were observed, particularly in the

pits. These pits were not randomly distributed but tended to occur in clusters.

In Fig. 3-5 the Fe electrode is exhibiting normal passive behavior. At a potential in the neighborhood of C, a reaction is initiated involving the oxidation of iron. The current reaches a maximum at the point K, declines, and enters the passive region along line L-E. As the amount of chloride ion increases, the nature of the passive region changes as is evident by the higher current densities. The current density at 2000 μg/cc of chloride ion is several times that at low concentrations of chloride. If the reactions that take place in the system shown in Fig. 1 take place at the same rate in the systems shown in Fig. 3-5, their current density in the passive region is being masked by a reaction or reactions, whose current density is several hundred per cent higher. If this latter reaction or reactions involve the oxidation of iron, then an appreciable amount of corrosion is being experienced in the so-called "passive" region. Around point K in Fig. 5 the current densities are 100 times higher than found in Fig. 1. As the potential moves upward from E toward F (the transpassive region), the current density involved in the production of O_2 becomes so high that it completely masks out the effect of the impurities. Consequently, this portion of the potentiostatic polarization curve was not affected by change in chloride content.

As the potential was decreased the current went from anodic to cathodic at about −0.22V in the presence of 2000 μg/cc of Cl^-. When the potential was increased the current went from cathodic to anodic at about −0.61V. The difference between these two potentials, ΔE, is 0.39V. This difference in changeover potentials is characteristic of impure systems and decreases monotonically as the amount of impurity decreases, as can be seen in Fig. 6 where ΔE is plotted as a function of the chloride content of the electrolyte. As the chloride content is increased, the value of ΔE appears to be leveling off in the neighborhood of a value of 0.4V. As the chloride value is decreased ΔE approaches zero in value (1). Similar results have been observed qualitatively with other impurities.

In Fig. 3-5 it can be seen in each case that the potential at point K remains fairly constant at −0.2V, whereas the potential at point C decreases appreciably with increase in chloride content.

The maximum current, i_M, is a good measure of the extent of corrosion in the system. In Fig. 7, the current density at the potential of −0.2V has been plotted as a function of the chloride content. This is the potential that gives the maximum current density at point K in those cases where the chloride content is sufficiently high to show a corrosion loop. The relationship is

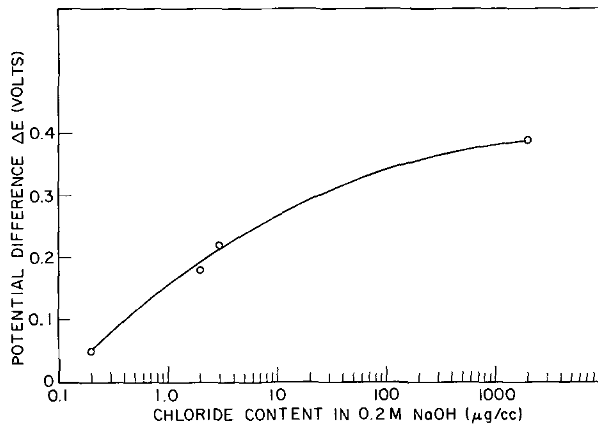

Fig. 6. The effect of Cl^- ion content on ΔE, the potential at which the current changes from anodic to cathodic minus the potential at which the current changes from cathodic to anodic.

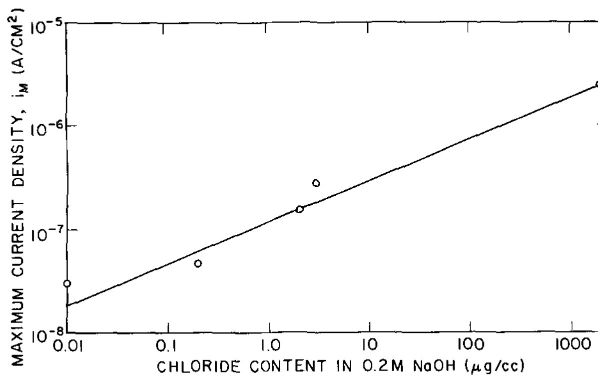

Fig. 7. The effect of Cl^- ion on the maximum corrosion current (current density measured at −0.2V).

logarithmic and can be expressed as the equation

$$i_M = 1.2 \times 10^{-7} C^{0.4}$$

where C is the concentration of chloride ion in μg/cc and i_M is the current density at −0.2V *vs.* the normal hydrogen electrode (NHE) and is measured on the increasing potential curve. In the standard system, where impurity effects have been minimized, there is no visible corrosion and the potential-current relationships, as shown in Fig. 1, are essentially straight lines, it seems quite likely that the low chloride content of approximately 0.01 μg/cc neither causes Fe corrosion nor typical passive behavior. At a level of 0.2 μg/cc of chloride ion in the electrolyte (Fig. 2), definite changes have occurred in the potentiostatic polarization curve, and at 2 μg/cc of Cl^- (Fig. 3), there is the first evidence of an active dissolution region. This indicates that a concentration of 10^{-1} to 1 μg/cc of chloride ion must be present to initiate corrosion or the steps that lead to corrosion.

The variation in results obtained using two successive cycles in a given purified electrolyte is not large, in most cases, and is much less than the variation in results obtained between separately prepared and purified electrolytes unless the chloride content is high. At 2000 μg/cc of chloride ion the iron is corroding and pitting rapidly, thus causing a rapid increase in the surface area which resulted in an increase of 50% in the current density in going from one cycle to the next. The data in Fig. 1-5, as well as each of the points plotted in Fig. 6 and 7 were obtained from separate solutions. The variation between results would probably have been much less for low chloride contents if the data had been taken on a single solution for each of the successively added increments of chloride ion.

It has been observed that a silver or a silver-silver oxide anode would under certain conditions remove Cl^- from a 15% KOH solution as AgCl on the electrode. The optimum conditions were not determined nor is it known to how low a level the Cl^- can be reduced. It does suggest the possibility that the Cl^- content of existing purified electrolytes could be lowered even more in this manner. The silver introduced into the system could be removed by electrodeposition. This technique might also be useful commercially in keeping the Cl^- content low enough to inhibit appreciably metallic corrosion in a system.

Techniques of this sort might lead the way to the possibility of efficiently removing unreactable impurities. For a given electrolyte containing a given unreactable ionic impurity, a suitable electrode material, temperature, potential, etc., might be found which would make it possible for this ion to react with the electrode and form an insoluble film which then could be removed from the system by removing the electrode.

Highly porous metallic electrodes can be prepared (5) which have surface areas so large that the formation of even a fraction of a monomolecular layer would remove relatively large amounts of a given ionic impurity. This would thus open up the possibility of removing nearly all of the impurities in an electrolyte down to levels that in many cases might approach the approximately 10^{-6} ppm that is now being obtained with reactable impurities. Under these conditions it would be possible to prepare a wide range of reagents whose impurity levels would be several orders of magnitude less than can be achieved with current techniques.

Anodic Oxidation of Ethylenediaminetetraacetic Acid on Pt in Acid Sulfate Solutions

J. W. Johnson,* H. W. Jiang, S. B. Hanna, and W. J. James*

Departments of Chemical Engineering and Chemistry and the Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

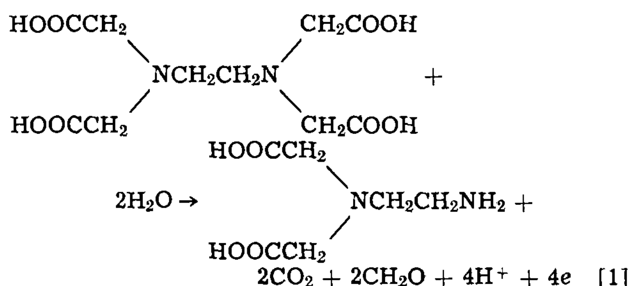
The anodic oxidation of EDTA was studied in acid sulfate solutions on platinized-Pt at 25°C. Polarization relationships were obtained for the EDTA concentration range 3.42×10^{-5} to 3.42×10^{-3}M and *p*H range 0.35 to 3.80. Numerous reaction products were identified that indicated a sequential removal of acetate groups from the EDTA, each by an initial decarboxylation followed by a reverse Schiff-type reaction, that produced formaldehyde and the corresponding amine. A reaction sequence which correlated the experimental data involved Frumkin-type adsorption of the EDTA species through an unionized acetate group followed by a rate-determining electrochemical decarboxylation.

Ethylenediaminetetraacetic acid, commonly abbreviated "EDTA," forms very stable, water-soluble complexes with many metal ions. Because of this, studies involving EDTA have dealt mainly with complex formation and associated analytical and industrial applications. A few reports have been concerned with electrochemical aspects. One, a polarographic investigation of the products of the anodic oxidation of EDTA on Pt in alkaline solutions, was made by Kopek'a (1).

* Electrochemical Society Active Member.

Key words: ethylenediaminetetraacetic acid, anodic oxidation, decarboxylation.

The over-all anodic reaction proposed was



In another, Rèishakhrit *et al.* (2) studied the oxidation of EDTA on a Pt rotating-disk anode and found increases in the limiting currents with *p*H. Shifts in the polarization curves with *p*H were attributed to shifts in the dissociation equilibrium. With carbon paste indicator electrodes, Kitagawa and Tsushima (3) reported a single anodic wave for EDTA in acidic media with $E_{p/2} = 0.93V$ (*vs.* SCE).

The presence of EDTA during electrochemical processes (*e.g.*, corrosion, metal dissolution, metal deposition, etc.) is not uncommon. Thus, it is of interest to know if EDTA itself is reactive. The purpose of this investigation was to determine if it could be oxidized on platinized platinum, and if so, to obtain information about the electrochemical reaction kinetics. The investigation included polarization measurements in acid sulfate solutions of various *p*H, the determination of reaction products and coulombic efficiency for CO_2 production, and the effect of temperature on the reaction rate.

Experimental

The electrolyses were carried out in the usual H-cell (400 ml capacity). All solutions employed analytical grade chemicals and conductivity water. Prepurified nitrogen was bubbled through the electrolyte to provide an inert atmosphere and for stirring. A constant flow rate (50 cm^3/min STP) was maintained through the anode compartment. The electrodes consisted of 52-mesh Pt gauze folded on Pt wire frames for support. They were platinized using a platinum chloride solution to which a trace of lead acetate had been added. The anode had a geometric surface area of 11.5 cm^2. It was activated in 1.0*N* H_2SO_4 before each experiment as described previously (4).

The electrolytes for the studies were H_2SO_4 + Na_2SO_4 solutions (*p*H 0.35-4.0) in which the sulfate concentration was kept constant at unit normality. The EDTA concentration was varied from 3.42×10^{-5} to 3.42×10^{-3}M. The polarization measurements were made potentiostatically. A Hg/Hg_2SO_4 (1*N* H_2SO_4) reference electrode was used in conjunction with a salt bridge of the same electrolyte as in the cell. The potentials are reported *vs.* the standard hydrogen electrode (SHE) at 25°C. Reaction products were determined by standard qualitative analyses and paper electrophoresis. All studies were carried out at 25°C except as noted.

Results

Polarization measurements.—The rest potentials, Tafel slopes, and limiting currents from the polarization studies are summarized in Table I. The rest potentials and limiting currents were affected by the N_2 bubbling rate (the rest potentials decreased and limiting currents increased with increasing bubbling rate). There was no effect on currents in the linear Tafel region. All reported data were taken with the constant N_2 bubbling rate mentioned above. Steady currents at a given potential were obtained within about 25 min and remained quite stable for hours. Individual points were reproducible within ±10%.

Semilogarithmic plots of the polarization curves are shown in Fig. 1. There are linear sections in the potential regions slightly above the rest potentials, with

slopes varying from 105 to 130 mV. The limiting current region was reached at potentials of about 0.95V (SHE). No pronounced passivation regions were found.

Two basic solutions, 3.42×10^{-2} and 1.028×10^{-1}M EDTA in 1*N* NaOH, were also investigated. The polarization curves are shown in Fig. 2. Very small limiting currents were reached at potentials immediately above the rest potentials. Visible oxygen evolution occurred at potentials above 0.78V.

Reaction products.—Qualitative analyses showed the anodic oxidation products of EDTA to be quite numerous. A positive test for CO_2 was obtained by passing the N_2 purge through a saturated $Ba(OH)_2$ solu-

tion where a white precipitate ($BaCO_3$) was formed (5). Formaldehyde was detected by determining the melting point of a yellow precipitate formed on addition of a saturated solution of 2,4-dinitrophenylhydrazine (6). Other products in the electrolyte were identified by paper electrophoresis (7), the results of which are shown schematically in Fig. 3. Quantitative measurements of CO_2 production were made galvanostatically for 3.42×10^{-3}M EDTA in $10^{-3}N$ H_2SO_4 + $0.999N$ Na_2SO_4 at potentials in the linear Tafel region. The average efficiency based on Eq. [1] was 124 ±6%.

Temperature dependence.—Arrhenius plots of current *vs.* temperature for 3.42×10^{-3}M EDTA in $10^{-3}N$ H_2SO_4 + $0.999N$ Na_2SO_4 are shown in Fig. 4 for potentials of 0.76 and 0.86V (SHE). The slopes of the two straight lines yielded activation energies of 18.4 and 17.0 kcal, respectively. These further give an effect of potential on the activation energy, $\partial E_a/\partial V$, of *ca.* −14 kcal/V which is consistent with the Tafel slopes.

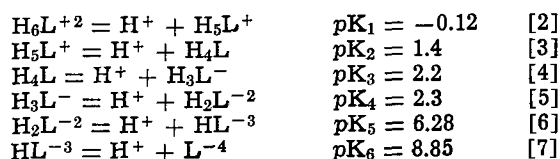
Discussion

Limiting currents.—An initial consideration of the limiting (potential-independent) currents, i_L, from the polarization curves indicated them to be of the same order of magnitude as diffusion currents. However, the expected first-order dependence between current and concentration (8) was not found when the total EDTA concentration was used. This, together with the absence of reaction prior to oxygen evolution in basic solutions, suggested that some EDTA species may be preferentially participating. It is well known that EDTA engages in various equilibria with hydrogen ions with reported species covering the complete spectrum from H_6L^{+2} to L^{-4}.[1] Constants for these equilibria have been reported and are given in Eq. [2]-[7].



$$H_6L^{+2} = H^+ + H_5L^+ \qquad pK_1 = -0.12 \qquad [2]$$
$$H_5L^+ = H^+ + H_4L \qquad pK_2 = 1.4 \qquad [3]$$
$$H_4L = H^+ + H_3L^- \qquad pK_3 = 2.2 \qquad [4]$$
$$H_3L^- = H^+ + H_2L^{-2} \qquad pK_4 = 2.3 \qquad [5]$$
$$H_2L^{-2} = H^+ + HL^{-3} \qquad pK_5 = 6.28 \qquad [6]$$
$$HL^{-3} = H^+ + L^{-4} \qquad pK_6 = 8.85 \qquad [7]$$

There is a considerable variation in the values of these constants reported by various investigators. All the values in Eq. [2]-[7] were from a single source, those reported by Anderegg (9). The concentrations of the EDTA species in all the electrolytes were calculated and are shown in Table II. The hydrogen ion activities used in the calculations were evaluated directly from the measured pH. For all other species, the activities and concentrations were assumed equal.

A comparison of the limiting currents with concentrations of the individual species (Tables I and II) shows that no single species can account for the reaction over the entire region studied. Various combinations of species were tried and the one most successful in correlating the data was the summation of the concentrations of the species H_5L^+, H_4L, H_3L^-, H_2L^{-2}, and HL^{-3}. A log-log plot of i_L *vs.* C_Σ [2] is shown in Fig. 5 with a straight line of unit slope drawn through the

points. Although there is a great deal of scatter, the trend is correct and covers the entire concentration range. A least squares analysis of the data gives a slope of 0.8 ± 0.1.

Product analyses.—The product analyses suggest that the oxidation of EDTA proceeds along at least two paths. Such a reaction scheme is shown in Fig. 6 for which all the species were identified with the exception of ED3A, 3-KP, U-KP, and S-KP. The paper-electrophoresis method used was not sensitive to the latter three, and according to Doran (7), the cyclization of ED3A to 3-KP is so extensive in acid solutions that ED3A cannot be detected. Separate studies have indicated that equilibria are reached in the other cyclization reactions (U-KP ⇄ U-EDDA, S-KP ⇄ S-EDDA, and 2-KP ⇄ EDMA) in which appreciable quantities of both species exist (10). From the product distribution, it appears that each decarboxylation step is a separate electrochemical reaction that gives a desorbed product capable of further similar reactions as long as acetate groups are available. This indicates adsorption through the carboxylate group with a Hofer-Moest-type reaction (11) occurring which involves the loss of two electrons, decarboxylation, and a reaction with water (not necessarily in that order) to form an alcohol. The two most common sequences offered to explain such reactions involve free-radical and/or carbonium ion intermediates. In both sequences, the first electron transfer is thought to form a free radical which leads to decarboxylation, *i.e.*

$$R—CH_2—COO^{\bullet} \rightarrow R—CH_2^{\bullet} + CO_2 \quad [9]$$

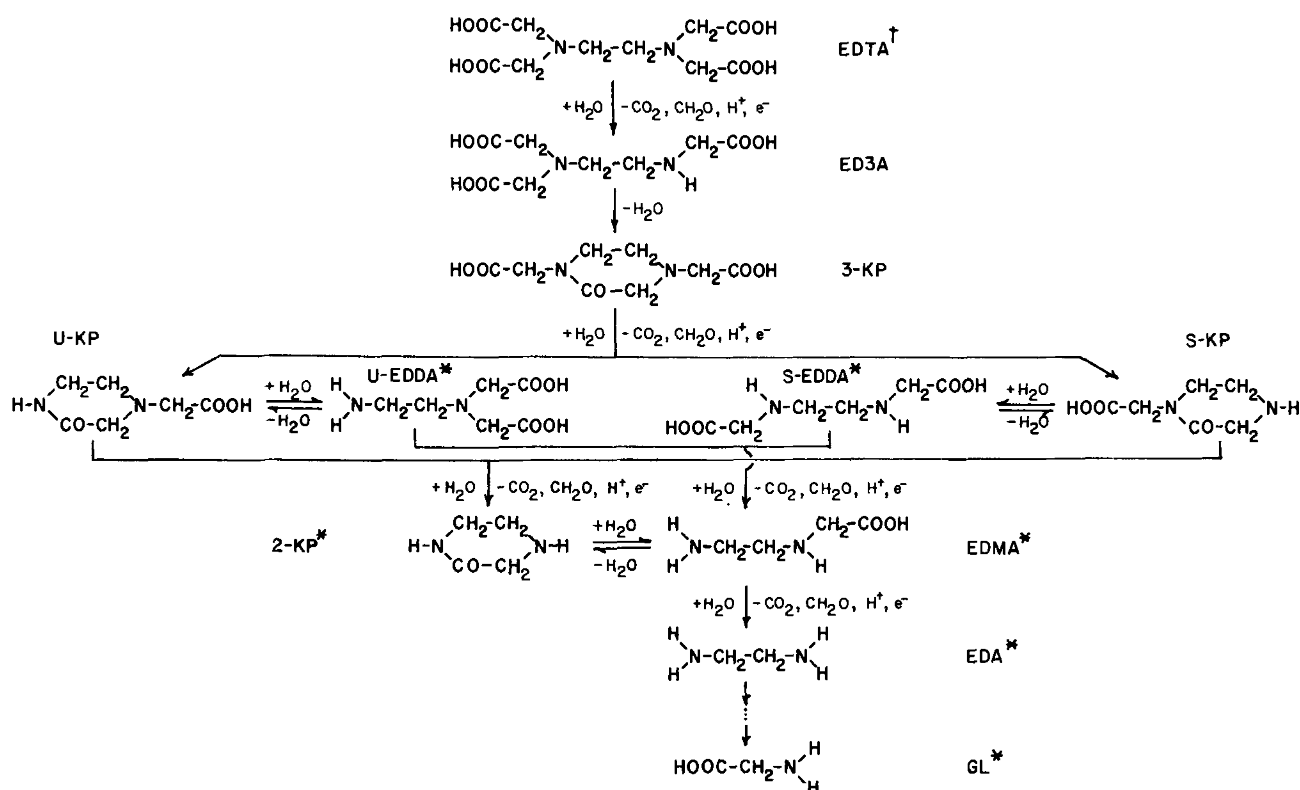

Fig. 6. Suggested reaction scheme for EDTA oxidation on Pt in acidic sulfate solutions at 25°C. †, Representative of any of the reactive species; *, species identified by paper electrophoresis, bands shown in Fig. 3.

At this point the sequences diverge with $R—CH_2\cdot$ either forming a carbonium ion by the second electron transfer or reacting to form another intermediate that may or may not involve an electron transfer. These can be represented by

$$R—CH_2\cdot \rightarrow R—CH_2^+ + e \quad [10]$$

$$R—CH_2^+ + H_2O \rightarrow R—CH_2OH + H^+ \quad [11]$$

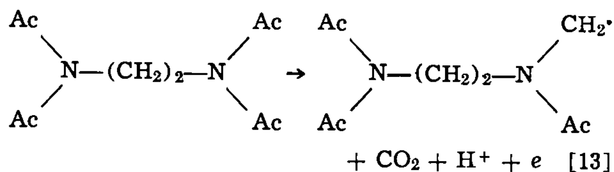
and

$$R—CH_2\cdot + H_2O \rightarrow R—CH_2OH + H\cdot \quad [12]$$

In either case with EDTA, the group $—\overset{|}{N}—CH_2OH$ is formed which is unstable and produces formaldehyde through a reverse Schiff-type reaction, leaving $—\overset{|}{N}H$ (12). A feature that might allow one to distinguish between these two possibilities is the opportunity for different coulombic efficiencies for CO_2 production. In the first case (Eq. [10] and [11]), the carbonium ion is believed to be formed by electron transfer to the anode (13) which gives 1 mole of CO_2 per 2**F** of charge as shown in Eq. [1]. (Also implied here is the continued adsorption of the reacting species until after formation of the carbonium ion.) In the second case, it is possible that the radical $R—CH_2\cdot$ may have been desorbed during decarboxylation and that Eq. [12] represents a homogeneous reaction. (This is consistent with adsorption through the carboxylate group as mentioned above.) The $H\cdot$ produced in this manner could be oxidized at the anode which would again give $1CO_2/2\mathbf{F}$, but there is also opportunity for it to participate in some homogeneous reaction which would lead to $1CO_2/\mathbf{F}$. If this latter reaction should occur, CO_2 efficiencies (based on Eq. [1]) greater than 100% would be observed. As seen above, efficiencies greater than 100% were found experimentally, thus favoring the sequence of Eq. [8], [9], and [12].

If adsorption had occurred through bonding with the nitrogen (as opposed to adsorption through the carboxylate), one would expect both the acetate groups to be removed before desorption with only U-EDDA and EDA as products as well as a $1CO_2/2\mathbf{F}$ coulombic efficiency.

Rest potentials.—According to the reaction scheme shown in Fig. 6 and discussed in the above section, the initial electrochemical reaction is between EDTA and the precursor to ED3A and involves only one electron. (The proceeding reactions will become significant only when sufficient current has passed so that appreciable quantities of the subsequent reactants are produced.) Thus, the measured rest potentials may reflect the reaction



$$(Ac)_2N—(CH_2)_2—N(Ac)_2 \rightarrow (Ac)_2N—(CH_2)_2—N(CH_2\cdot)(Ac) + CO_2 + H^+ + e \quad [13]$$

Although the CO_2 and ED3A precursor ($R\cdot$) concentrations are not known and their standard free energies of formation are not available to allow a comparison of the rest and calculated potentials, the Nernst equation will allow a test of the effect of EDTA concentration and *p*H on the potential. At 25°C, the relation for Eq. [13] is

$$E = E°_{13} - 0.0591 \log(a_{EDTA})/(a_{R\cdot})(a_{CO_2})(a_{H^+}) \quad [14]$$

Assuming $a_{R\cdot}$ and a_{CO_2} constant and $a_{EDTA} = C_\Sigma$ gives

$$E = E_{13} - 0.0591 \log(C_\Sigma/a_{H^+}) \quad [15]$$

(C_Σ is the concentration of the species as mentioned previously.) A plot of E_{rest} *vs.* $\log(C_\Sigma/a_{H^+})$ is shown in Fig. 7. The relationship is linear and has a slope of 55 mV, in good agreement with that predicted by Eq. [15].

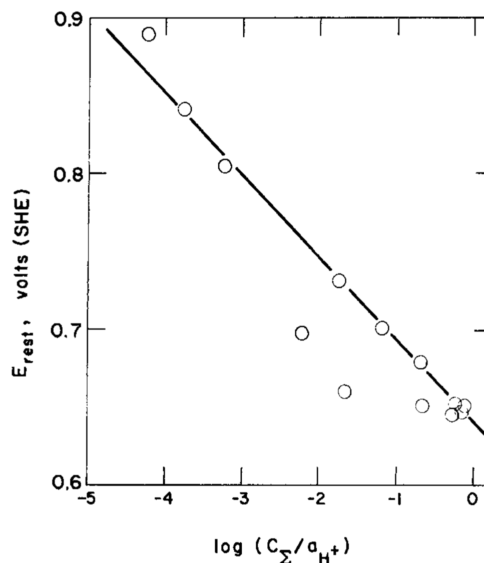


Fig. 7. Rest potentials for EDTA on Pt in acidic sulfate solutions at 25°C.

Polarization curves.—The oxidation of EDTA is seen to occur at potentials somewhat more positive than those for other organic compounds where CO_2 is produced (exclusive of Kolbe-type syntheses). For example in 1*N* H_2SO_4, ethylene (4) oxidizes in the potential region from *ca.* 0.35 to 0.75V; formic acid (14), 0.15 to 0.45V; oxalic acid (15), 0.5 to 0.8V; and maleic acid (16), 0.35 to 0.60V. Acetic acid has been reported not to be reactive (17). In the majority of these cases, adsorption of the organic species was thought to involve the formation of bonds between C and Pt atoms, and passivation was observed between the upper potential limit for the organic oxidation and that for the commencement of oxygen evolution. The passivation ordinarily occurred in the region where EDTA has been found to be oxidized. This absence of passivation with EDTA indicates a different type of adsorption bonding that can presumedly take place on an oxide-covered surface. Considering the apparent step-wise decarboxylation, the adsorption reaction thus appears to involve the carboxylate group and the electrode surface.

The Tafel slopes of *ca.* 120 mV or $2(2.3RT/\mathbf{F})$, are ones frequently encountered in electrochemical kinetic studies and normally associated with first-electron-transfer rate determining steps. The concentration and *p*H effects were unusual in that they were both fractional and approximately equal. The EDTA concentration effect (reaction order) was fairly well defined as 0.36 from the experiments in 1*N* H_2SO_4 where the *p*H was constant. It should be noted from Table I for 1*N* H_2SO_4 that the fraction of EDTA forming any of the individual species is independent of the initial EDTA concentration. Thus, the same reaction order (~0.36) would be found for any individual or combination of EDTA species. By a trial and error procedure, it was found that a *p*H effect also of 0.36 in conjunction with the concentration of EDTA species, C_Σ, best correlated the data. A log-log plot of i *vs.* $(C_\Sigma/a_{H^+})^{0.36}$ is shown in Fig. 8 for the entire EDTA concentration and *p*H region of the study. The line of unit slope drawn through the points show the data to be reasonably well correlated. This gives an empirical expression for the current as

$$i = n\mathbf{F}k\,(C_\Sigma/a_{H^+})^{0.36} \exp(\alpha \mathbf{F}V/RT) \quad [16]$$

Reaction mechanism.—From the preceding, several qualitative conclusions can be drawn about the reaction mechanism:

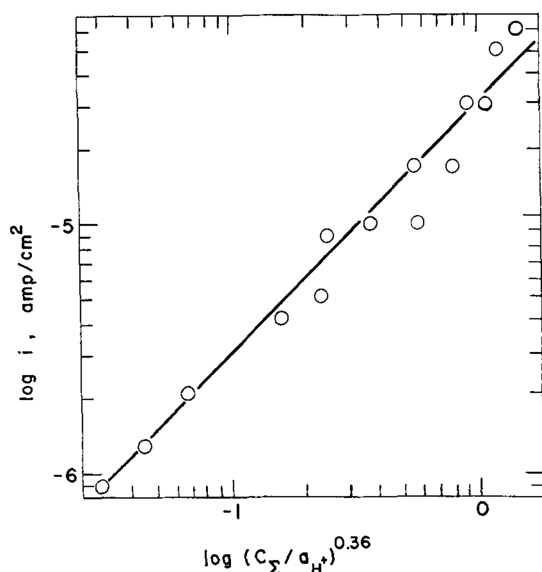

Fig. 8. Effect of concentration and pH on current for EDTA oxidation on Pt in acidic sulfate solutions at 25°C.

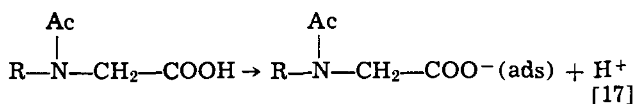
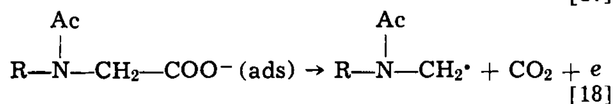
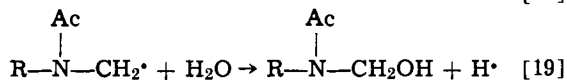
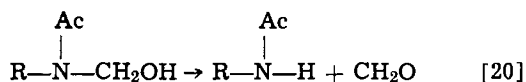
1. The rds (rate determining step) involves EDTA species or species derived therefrom since the concentration effect is positive.
2. The fractional concentration effect indicates that the EDTA species are adsorbed and that significant, although not complete, coverages are involved.
3. The positive *p*H effect indicates OH^- as a reactant or H^+ as a product during or prior to the rds. Since the OH^- concentration is very small, the latter case would be the most probable and would necessarily occur in an equilibrium step prior to the rds.
4. From the product analyses, there appears to be separate step-wise over-all reactions involving the acetate groups on EDTA, each of which yields CO_2 and CH_2O. From the rest potential and CO_2 efficiency studies, it further appears that only one electron is transferred to the faradaic circuit during the reaction that directly involves CO_2 production from the acetate group of the EDTA species.
5. From the concentration correlations for both the current and rest potentials, the *p*H effect, and the absence of reaction in basic solutions where L^{-4} is the predominant species, it appears that an un-ionized carboxyl group may be initially involved in the reaction sequence.
6. The occurrence of the reaction in a potential region where the anodic oxidation of ethylene, acetylene, etc. is passivated indicates that water discharge is not involved.

With these considerations, the initial electrochemical sequence (EDTA → ED3A, Fig. 6) can be represented as follows[3]









The atomic hydrogen produced by reaction [19] can be oxidized at the anode and contribute to the faradaic process or be removed by some nonelectrochemical reaction causing the CO_2 efficiency (based on Eq. [1]) to be increased. The ED3A thus produced can participate further in the sequence as shown in Fig. 6.

[3] Species shown in these reactions are nonadsorbed unless otherwise indicated.

The type of adsorption (*e.g.*, Langmuir, Temkin, etc.) as well as the nature and position of the rds in a reaction sequence can affect the associated kinetic parameters. For Langmuir-type adsorption, a first electron transfer rds is normally associated with the Tafel slope of 120 mV. For this case (reaction [18]), an EDTA concentration effect either close to zero or unity should be observed for conditions where this type adsorption is applicable, *i.e.*, either high or low coverages. This does not appear to be the case.

The Temkin isotherm is often assumed for intermediate coverages when lateral interactions between adsorbed species are appreciable. For EDTA with the same rds (reaction [18]), Temkin-type adsorption gives a Tafel slope of 120 mV and concentration dependences $(a_{EDTA}/a_{H^+})^{0.5}$. These concentration effects are reasonably close to the observed values although 0.5 gives a poorer correlation than the value of 0.36 illustrated in Fig. 8. The use of the Frumkin isotherm allows a better correlation, primarily due to the added adjustable parameter associated with the variation of free energy of adsorption with coverage (18). This isotherm takes into account long-range interactions between adsorbed species which may be especially applicable due to the geometry of the EDTA molecule. Its application to the present case is as follows:

From reaction [17]

$$r_{17} = k_{17}\, a_{EDTA}\, \theta_v \exp(-\beta\theta/RT) - k_{-17}\, \theta_{R^\cdot}\, a_{H^+} \exp[(f-\beta)\theta/RT] \quad [21]^4$$

Assuming quasi-equilibrium and the effect of coverage to be predominately controlled by the exponential terms gives

$$f\theta/RT = \ln(K_{17}\, a_{EDTA}/a_{H^+}) \quad [22]$$

From the rate determining step, reaction [18]

$$i = n\mathbf{F}k_{18}\, \theta_{R} \cdot \exp(\alpha \mathbf{F}V/RT) \exp(\beta\theta/RT) \quad [23]^4$$

Again assuming the exponential term to dominate the effect of coverage and substituting Eq. [22] into Eq. [23]

$$i = n\mathbf{F}k' (a_{EDTA}/a_{H^+})^{\beta/f} \exp(\alpha \mathbf{F}V/RT) \quad [24]$$

The term β/f can be made equal to 0.36 by assigning the appropriate value to the adjustable parameter f, thus making Eq. [24] correspond to the empirical rate expression, Eq. [16]. For the present case, f would equal 1.4 (assuming $\beta = 0.5$).

The Anodic Oxidation of Hydrogen on Platinized Tungsten Oxides

I. Composition of Tungsten Blue in Platinized WO_3 Hydrogen Electrocatalyst

B. S. Hobbs[1] **and A. C. C. Tseung**

Department of Chemistry, The City University, St. John Street, London ECIV 4PB, England

ABSTRACT

A synergistic effect is apparent when Pt/WO_3 catalysts are used in hydrogen electrodes. The exact mechanism of this effect depends on the composition and mode of formation of a reduced intermediate tungsten oxide. Chemical analysis and x-ray studies confirmed that this intermediate oxide consists of blue tungsten bronzes. The influence of Pt loading, platinizing technique, temperature, and *p*H on the bronze composition was investigated. The maximum reduction ($H_{0.44}WO_3$) was obtained using WO_3 impregnated with 0.8 weight per cent (w/o) Pt in acidic solution between 25° and 100°C.

When platinum is admixed with WO_3, it undergoes an apparent enhancement in its ability to catalyze the anodic oxidation of hydrogen in acid solution (1-3). WO_3 alone has no activity towards H_2-oxidation. Past workers have been unable to make definite conclusions on the origin of this effect owing to difficulties encountered in eliminating electrode structural effects from their results. Thus, the higher activity observed with WO_3 electrodes compared to other platinized substrates [*e.g.*, graphite or TaC (2, 3)] could have arisen from differences in Pt morphology or physical electrode parameters such as wetting, permeability, etc. However, an alternative explanation has been proposed in which WO_3, in physical contact with Pt, participates in the electrode reaction via formation of hydrogen tungsten bronzes (2).

Hydrogen tungsten bronzes belong to a general class of nonstoichiometric mixed oxides (4) of general formula $A_xM_yO_z$; where M is a transition metal, M_yO_z its highest binary oxide, A is some other metal or hydrogen, and x is a variable, usually $0 < x < 1$. Formation of blue hydrogen tungsten bronzes generally occurs whenever WO_3 is exposed to reducing conditions, *e.g.*, gaseous atomic hydrogen (5-10), treatment of aqueous suspensions of WO_3 with reducing agents (11-14) (*viz.* Zn/HCl, $SnCl_2$, etc.), but of special interest to this study is their appearance in mixtures of platinized WO_3 when exposed to H_2, particularly in the presence of water vapor (15, 16). According to Benson *et al.*, gaseous H_2 dissociatively chemisorbs on the Pt then migrates across the metal/oxide interface to form bronzes. The migration is considerably aided by the presence of an adsorbed water layer when an exchange mechanism operates and the WO_3 particles are rapidly reduced in depth. Bronze oxides are characteristically chemically inert, metallic conductors of electricity and the H-compounds are typical group members, except that they are sensitive towards oxidizing conditions which reconvert them to the parent oxide (13), *e.g.*, air, hydrogen peroxide, oxidizing ions such as Fe^{3+} and Ce^{4+}, and presumably anodic potentials. Thus a reaction scheme can be formulated for the H_2-electrode to include the WO_3 support, namely

$$H_{2(g)} + Pt = Pt(H_2)_{ads} = Pt2(H)_{ads} \quad [1]$$

$$Pt2(H)_{ads} = Pt + 2H^+ + 2e \quad [2]$$

(normal Pt mechanism)

$$Ptx(H)_{ads} + WO_3 = H_xWO_3 + Pt \quad [3]$$

$$H_xWO_3 = xH^+ + WO_3 + xe \quad [4]$$

(Bronze route)

By means of the bronze route the reaction zone can be extended and the Pt appears to increase its activity. No such possibility exists for graphite or TaC which can be termed "passive" catalyst supports, WO_3 being an "active" support.

Both moist Pt/WO_3 powders, and suspensions in acidic solutions, rapidly turn blue when exposed to H_2, indicating partial reduction of the oxide. However, this "tungsten blue" may consist of either, or both, of two classes of compound, namely the lower tungsten oxides (17, 18) (WO_x, where $2 < x < 3$) or hydrogen

[1] Present address: Electrical Research Association, Cleeve Road, Leatherhead, Surrey, England.

Key words: hydrogen, oxidation, platinized tungsten oxides, tungsten bronzes, tungsten blue, chemical analysis, x-ray studies, H_2 uptake, crystal structure.

bronzes. Although direct reduction of WO_3 to lower oxides by H_2 at room temperature does not occur (19), they could form by local cell action between the hydrogenated Pt surface and WO_3

$$2Pt(H)_{ads} = 2Pt + 2H^+ + 2e \quad [5]$$

$$2WO_3 + 2H^+ + 2e = W_2O_5 + H_2O \quad [6]$$

Although the reduction of WO_3 to W_2O_5 (or $WO_{2.5}$) is not thermodynamically favored at normal H_2 anode potentials [$E°$ WO_3/W_2O_5 = $-0.03V$ (20)], reduction might occur through the formation of nonstoichiometric WO_3 [$WO_{3.00\text{-}2.95}$ (18)], the stable intermediate phase $W_{20}O_{58}$ (17, 18) or solid solutions of lower oxide phases, for which no thermodynamic data could be found. Bronze formation is also possible by local cell action and again no thermodynamic data is available for such reactions

$$WO_3 + xH^+ + xe = H_xWO_3 \quad [7]$$

In any system whereby local cells are the sole means of WO_3 reduction, *e.g.*, via the lower oxides of tungsten, no net contribution to the steady state anodic current is possible since all the anodic current will be cancelled by the cathodic reducing current (reactions [6] and [7] above). The oxide will equilibrate at any given working potential and the local cells will merely provide a mechanism for electron conduction between the Pt particles and current collector.

Benson *et al.* (15, 16) have studied tungsten blue formation in a vacuum system and shown it to consist exclusively of bronzes formed by chemical reduction (reaction [3]). However, in view of the importance of the nature and mode of formation of the reduction product to the electrochemical oxidation of H_2, it is necessary to confirm this finding under conditions closer to those in a fuel electrode, *viz.* Pt/WO_3 slurries in $5N$ H_2SO_4 between ambient temperature and 80°C and 1 atm of bubbling H_2.

Experimental

Using x-ray diffraction and analytical techniques, the tungsten blue composition was determined as a function of: (*i*) platinizing method, *viz.* mechanical mixing and impregnation—this has been shown to exert considerable influence on both the rate of tungsten blue formation (15) and the electrochemical performance (2); (*ii*) Pt content; (*iii*) pH of slurry; and (*iv*) temperature.

Due to the extreme sensitivity of tungsten blue to air, all preparations and analyses were carried out in completely O_2-free conditions.

Materials.—(*i*) Impregnation of WO_3—to ensure a high, uniform and intimate dispersion of Pt on the oxide, a freeze drying technique was employed for the impregnation (21, 22): A slurry of WO_3 powder, suspended in chloroplatinic acid solution, was quickly frozen by pouring into liquid nitrogen. The water was then removed by vacuum sublimation and the Pt-salt reduced to metal in a warm H_2 stream (50°C) below its melting point (60°C). Complete decomposition was checked by weighing before and after reduction.

The Pt content was analyzed by extracting the WO_3 with warm NaOH solution and weighing the washed and dried Pt residue. This residue was also used for surface area determination by "BET nitrogen adsorption." Blank Pt black samples were measured for surface area before and after NaOH treatment to ensure that the area remained unaltered during the extraction procedure. Specific surface areas of extracted Pt residues were all around 35 m^2/g.

(*ii*) WO_3 and chloroplatinic acid—Hopkin and Williams laboratory reagent grade chemicals were used without further purification. The measured specific surface area of WO_3 was 8 m^2/g.

(*iii*) Pt-black used in mechanical mixtures—Johnson Matthey Company fuel cell grade, specific surface area 30 m^2/g.

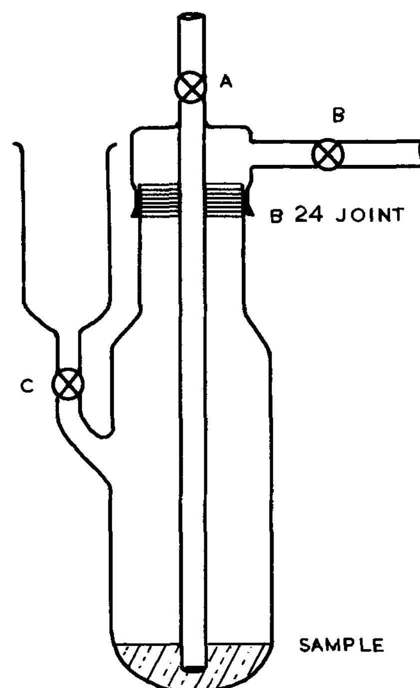

Fig. 1. Apparatus for tungsten blue analysis

(*iv*) $5N$ sulfuric acid was prepared from ANALAR grade concentrated acid and distilled/deionized water.

(*v*) White spot H_2, purified with a palladium diffuser, was used throughout.

H_2-uptake experiments.—Before carrying out the tungsten blue preparations, the time required to reach equilibrium was determined using a conventional volumetric apparatus at 1 atm pressure and ambient temperature. With impregnated powders the H_2-uptake volume reached a limiting value after about 1 hr corresponding to a tungsten blue composition of $H_{0.44}WO_3$ or $WO_{2.78}$. The time taken to reach this value is almost certainly controlled by H_2 mass transfer through the slurry. In practical fuel electrodes the conditions are designed to achieve high transfer rates and the oxide composition will change much more rapidly.

In all experiments involving tungsten blue preparation a standard H_2-contact time of 2 hr was used.

Analysis of tungsten blue.—Tungsten blue was prepared and analyzed in the apparatus shown in Fig. 1 as follows: Tap A was connected to N_2(O_2-free) and H_2 supplies. After N_2 purging, H_2 was bubbled from A through a weighed platinized WO_3 sample suspended in $5N$ H_2SO_4. The H_2 was turned off after 2 hr and a measured volume of standard potassium dichromate solution admitted through tap C. The vessel contents were heated to *ca.* 60°C, when the blue color changed to yellow indicating complete oxidation. The cooled vessel contents were transferred to a beaker and the excess dichromate back-titrated with standardized ferrous ammonium sulfate solution. The end point was determined potentiometrically using a platinized wire indicator electrode with a glass standard electrode. In all cases a small correction was made to the titre to allow for reaction with H_2 adsorbed on the Pt surface.

Preparation of tungsten blue for x-ray diffraction.—The apparatus, shown schematically in Fig. 2, is a modified version of that described by Glemser and Naumann (13). Taps A_1, A_2, and A_3 were connected to N_2 (O_2-free) and H_2 supplies. The flask contained distilled water, freed of O_2 by boiling during the passage of N_2 from A_2 and out the pressure release valve. After purging with N_2 and sealing the capillary, H_2 was bubbled through the sample suspended in H_2SO_4, from A_2 and out B_2, for 2 hr. The tungsten blue formed

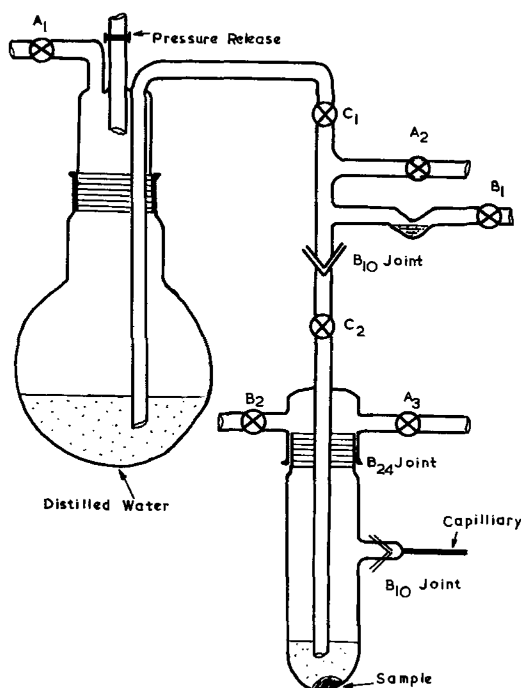

Fig. 2. Preparation of tungsten blue for x-ray examination

was washed by decantation—pressurized H_2 from A_3 forced the supernatent liquor from the settled suspension through C_2 and out B_1. Water from the flask was forced onto the sample by pressurizing at A_1. This procedure was repeated until the washings were neutral (pH 7.0). After the final wash all taps were closed and the apparatus below the B_{10} joint (between C_1 and C_2) detached and fused into a high vacuum line ($< 10^{-5}$ Torr) at the B_2 outlet. The product was dried by evacuation through B_2, then after closing B_2 and detaching from the vacuum line, a sample of powder was sealed into the capillary by lying the vessel on its side, gently vibrating the powder, then when sufficiently full, applying a spot flame to remove and seal the capillary without releasing the vacuum.

X-ray powder photographs were taken of the samples using an 11.4 cm Phillips camera, copper $K\alpha$ radiation and exposure times of 8 hr. Lattice d-spacings were calculated from the patterns to within ±0.005Å from the Bragg equation.

In order to simplify the glassblowing of the apparatus, Pyrex capillaries were used instead of the usual Lindemann glass. Diffraction photographs of WO_3 using both materials showed no differences.

Results and Discussion

Analytical results.—The analytical results are summarized in Table I. The reproducibilities of the quoted values agreed closely with the estimated limits of experimental error which were as follows: tungsten oxidation state ±0.2%, tungsten oxide composition ±0.2%, and bronze composition ±7%.

The most notable result in Table I is the considerably higher extent of reduction achieved by impregnation methods over straight mechanical mixtures. This result parallels previous findings (2, 15), and is certainly due to the higher dispersion of the Pt and intimacy of contact with the oxide.

The analytical result for a 0.8 w/o Pt impregnated powder in 5*N* H_2SO_4 agreed with the H_2-uptake value of $H_{0.44}WO_3$ or $WO_{2.78}$.

The Pt content of impregnated powders had little effect on the oxide composition above 0.8 w/o, but when reduced to 0.1 w/o a drastic fall in the degree of reduction occurred. This effect is explained in Part II dealing with the electrochemistry of the Pt/WO_3 system. The small decrease in the reduction of the 10 w/o powder could have arisen from greater uncertainties in the correction applied for H adsorbed on the Pt.

With mechanical mixtures, reduction was significantly increased by changing the Pt content from 2 to 10 w/o. Even at 10 w/o Pt however, the reduction was still only about half that achieved with 0.8 w/o impregnated powders.

As long as the solution remained acidic the extent of reduction remained independent of *p*H. In neutral solutions however, blue formation was severely restricted.

Increasing the temperature to 100°C resulted in a slight decrease in reduction of an impregnated powder.

X-ray diffraction results.—Measured d-spacings (within ±0.005Å) and relative line intensities are recorded in Table II for diffraction patterns obtained from a 2 w/o Pt/WO_3 mechanical mixture and 0.8 w/o Pt impregnation. Both patterns exhibited line broadening at high diffraction angles due to small particle size (23), but the lines were sharp enough for accurate measurements of angles corresponding to d-spacings above 1.2Å.

Comparison of the d-spacings with the A.S.T.M. index values for the possible species showed no evidence for the presence of lower tungsten oxides and interpretation could be made entirely in terms of the bronze phases, $H_{0.1}WO_3$, $H_{0.33}WO_3$, and $H_{0.5}WO_3$ (13). The Pt concentration was below the detection limits for any diffraction lines to be discernible.

The mechanically mixed powder had a complex pattern which proved difficult to index. Most lines were attributable to $H_{0.1}WO_3$ and $H_{0.33}WO_3$, or solid solutions of these phases—as evidenced by lines having intermediate values between those quoted for the separate phases. This conclusion was supported by the empirical formula $H_{0.14}WO_3$ obtained by analysis. Some

lines remained which were best interpreted as being due to unreacted WO_3, possibly in solid solution with the bronzes.

The impregnated powder had a far simpler pattern and evidently consisted of a solid solution of $H_{0.33}WO_3$ and $H_{0.5}WO_3$ (*cf.* data in Tables II and III). Using a Bunn Chart (24), the "blue" was shown to possess a tetragonal unit cell and assigned the *hkl* values given in Table II. The unit cell parameters a_o and c_o were calculated from the relationship (24)

$$d_{\text{tetragonal}} = \frac{1}{\sqrt{\dfrac{h^2 + k^2}{a_o^2} + \dfrac{l_2}{c_o^2}}}$$

using d-spacings of the 110 and 002 planes respectively. The choice of these planes gave maximum accuracy and ease of calculation. Closer spacings and secondary reflections at higher diffraction angles (*e.g.*, 220, 003, etc.) had diffuse lines due to particle size effects, and the sharp 001 lines had a high inherent error due to the finite specimen thickness (25).

The a_o and c_o values are compared with those quoted for $H_{0.5}WO_3$ and $H_{0.33}WO_3$ (13) in Table IV. Differences in a_o were too small to draw any conclusions as to the composition of the solid solution, but the c_o-axis for the tungsten blue had an intermediate value between $H_{0.5}WO_3$ and $H_{0.33}WO_3$. Assuming that as H_2 progressively enters the tetragonal $H_{0.33}WO_3$ lattice, the c_o-axis linearly decreases until the system becomes cubic at $H_{0.5}WO_3$, then an empirical formula can be calculated for the "blue" of $H_{0.42 \pm 0.06}WO_3$. This is in good agreement with the analytical result of $H_{0.44 \pm 0.03}WO_3$.

Final confirmation of the composition of the impregnated powder was obtained by reducing some plain WO_3 with zinc and hydrochloric acid to the same reduction state—previously determined by analysis of various Zn/WO_3 mixtures. This method which is definitely known to form bronzes (13, 26), produced an identical diffraction pattern.

Conclusions

Hydrogen tungsten bronzes (H_xWO_3) are formed in platinized WO_3 under the prevailing conditions in a fuel cell hydrogen electrode. The highest degree of reduction $H_{0.44}WO_3$, was obtained at 25°C using an impregnation technique for platinizing with 0.8 w/o Pt. Mechanical mixtures do not produce very intimate mixing, resulting in slower, incomplete reduction which can be improved by increasing the Pt loading. So long as the electrolyte is acidic, *p*H has no effect on the reduction.

Although bronzes are the major product when platinized WO_3 is reduced in acid slurries by H_2, it is not apparent whether they form by chemical reduction or by local cell action. Whether or not the bronzes contribute to the net anodic current of a H_2-anode will depend on which of these mechanisms predominates, as well as the relative rates of bronze formation and anodic oxidation. Part II describes work aimed at answering these questions.

The Effect of Viscous Shear on a Meniscus in an Electrochemical System

P. C. Wayner, Jr.

Fluid, Chemical, and Thermal Processes Division, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Fluid flow in the evaporating meniscus of an electrode-gas-electrolyte reacting system has been studied to examine the effect of viscous shear on the meniscus profile. The evaporating meniscus profile, the pressure derivative profile, and the curvature profile for various assumed evaporation profiles were calculated for 1*N* H_2SO_4. Due to the thinness of the meniscus profile in the interline region, large pressure gradients were needed to balance the viscous shear stress. The resulting evaporating meniscus profile was significantly different from the static profile. Depending on the evaporation rate the interline radius of curvature could be micron size for a large meniscus. Heat and mass transfer rates would also be significantly effected by these changes during an electrochemical reaction. Therefore, the effect of viscous shear should not be neglected in analyzing electrochemical processes in a "finite contact angle" meniscus.

The triple interline region of a meniscus formed on an immersed solid surface has been the subject of considerable research. In part, this derives from interest in the potentially high heat and mass transfer rates associated with a large surface area covered by a thin liquid film in the form of a myriad of menisci (porous fuel cell electrodes are of particular interest herein). The study of electrochemical processes on wetted metallic surfaces partially immersed in an electrolyte could be classified according to whether or not a thin film extends above the intrinsic meniscus. The obvious and significant characteristic of a meniscus without a thin film ["finite contact angle meniscus" (1)] is that the diffusion path length across the liquid film approaches zero at the interline. This study is particularly concerned with the outstanding work of Bockris and Cahan (1) which discusses the effect of a finite contact angle meniscus on kinetics in porous electrode systems. Conversely, various other authors (2-4) considered models and systems that included a thin film above the intrinsic meniscus. Due to the large number of experimental variables, the complete set of conditions that insure the presence of a particular type of meniscus is still questionable.

The following three of many conclusions concerning electrochemical kinetics in a meniscus presented by Bockris and Cahan (1) are of particular interest herein: (*i*) "most of the current is produced in the first 1% of the meniscus;" (*ii*) "the extreme concentration of current density into this small area can produce local heating and create a dynamic situation in the physical location of the meniscus;" and (*iii*) "the local geometry of the meniscus, particularly in the three-phase region, dominates the behavior of porous electrodes." They also state that some of the heat is readily removed by evaporation. In their analysis of this extremely complex system, the geometry of the meniscus is represented by the equation for a cylindrical surface, thereby neglecting the effect of viscous flow of the evaporating liquid on the meniscus profile. The major effect of this shear stress would be in the thinnest and most important region of the meniscus. Recently, a procedure to evaluate the effect of viscous flow on the profile has been developed (5). Although it is not the present objective to completely reanalyze the very complex transport processes occurring in an active electrochemical meniscus, the results presented below demonstrate that it is very instructive to examine the effect of viscous flow in a few selected and related cases.

* Key words: meniscus profile, capillarity, porous gas electrode, planar electrode.

Synopsis of Reference (1)

In Ref. (1) a 1*N*, H_2SO_4 meniscus was formed between two parallel optical glass flats. One glass surface of the resulting slot was coated with Pt to serve as an electrode. Optical measurements of the resulting meniscus were made through the other glass surface. Using reflectrometric techniques, the slope was determined as a function of distance from the interline at intervals of approximately 12.7μ. Interferometrically, fringes of the same kind reoccurred at film thickness differences of 2945Å. Simultaneously, the steady-state total current-potential behavior of the system was also measured for both H_2 and O_2 dissolution is the electrolyte. Within the accuracy of the experiments, the results indicated that the most stable meniscus configuration was one with a finite contact angle between 1° and 3°, and that it could be represented by the surface of a cylinder with a diameter equal to the slot width. On the basis of the experimental measurements, a detailed second-order nonlinear nonhomogeneous differential equation describing the reaction zone was derived and solved numerically. The microscopic description of the reaction zone was a strong function of the meniscus profile. The calculated relationship between the total current and potential which depended on many variables agreed well with the experimental results.

Qualitative Description of an Evaporating Meniscus

Consideration is given herein to an evaporating meniscus formed on a vertical flat plate immersed in a pool of liquid. The pressure gradient for fluid flow from the pool to the zone of evaporation results from a change in the meniscus profile (curvature). Relative to the isothermal case, the interline of the evaporating meniscus has migrated down the plate so that the profile can accommodate the increased pressure gradient needed to balance the viscous stresses of fluid flow. Assuming that the contact angle remains constant, the average curvature of the evaporating meniscus is larger than that of the isothermal meniscus and varies with heat flux. The present analysis only evaluates the effect of capillary pressure given by σ/R and does not include the additional effects of a disjoining pressure, surface tension variation, and surface viscosity. Insufficient data are presently available to include these additional factors. Therefore, bulk fluid properties and Newtonian flow are assumed applicable in the interline region. The effect of surface tension variation on thin supermeniscus electrolyte films of a uniform thickness has been analyzed by Lightfoot and Ludviksson (6). Comparable effects would be present in that portion of a finite contact angle meniscus where

the pressure gradient becomes relatively small. The principal conclusions of the present study are primarily concerned with that portion of the meniscus where the pressure gradient is relatively large and the effect of surface tension variation relatively small. A significant amount of research has been done using a fluid flow model in which the average velocity was assumed to be zero (7, 8).

Quantitative Description of the Evaporating Meniscus

Basic relations.—The following treatment parallels that developed in Ref. (5) except for the use of a different boundary condition at the meniscus base. The four fluid mechanical conditions at the boundaries of the liquid are (*i*) the base pressure of the meniscus is given by

$$P_f = P_a - \frac{\sigma_{fv}}{R} \qquad [1]$$

with $R = R_b$, the radius of curvature at the base of the meniscus; (*ii*) the fluid velocity goes to zero at the wall; (*iii*) the force balance per unit length at the interline is given by the well-known Young-Dupré equation

$$\sigma_{sv} = \sigma_{sf} + \sigma_{fv} \cos \theta_c \qquad [2]$$

and (*iv*) the following normal stress for a constant $R = R_i$ surface represents the local stress on the liquid at the interface

$$\tau_{RR} = -P_f = -P_a + \frac{\sigma_{fv}}{R} \qquad [3]$$

Some of the nomenclature for the present analysis is presented in Fig. 1 with a cross-sectional drawing of the meniscus. The local curvature, $1/R_i$, of the meniscus at location "i" is

$$K_i = \left(\frac{d\theta}{dS}\right)_i = \left[\frac{\dfrac{d^2t}{dy^2}}{\left[1+\left(\dfrac{dt}{dy}\right)^2\right]^{3/2}}\right]_i \qquad [4]$$

At equilibrium $p_g = -\rho g(Y - y)$, $K_i = \rho g(Y - y)_i/\sigma_{fv}$, and $(\partial p_g/\partial r)_i = \rho g \cos \theta_i$. With evaporation, $p_g < -\rho g(Y - y)$ as a result of the additional pressure gradient required to balance liquid acceleration and viscous shear stresses. Since the pressure in the liquid at the liquid-vapor interface is a function of the curvature, $p_g|_i = -K_i\sigma_{fv} < -\rho g(Y - y)_i$ when there is evaporation. Using Eq. [4] with the modified pressure $P = p_g + \rho g(Y - y)$

$$\left(\frac{\partial P}{\partial r}\right)_i = -\frac{\partial}{\partial r}\left[\frac{\sigma_{fv}\dfrac{d^2t}{dy^2}}{\left[1+\left(\dfrac{dt}{dy}\right)^2\right]^{3/2}} - \rho g(Y-y)\right]\Bigg|_i \qquad [5]$$

The results of Sparrow and Starr (9) for fluid flow in a wedge are now used to approximate the dependence of the local average velocity, $\bar{u}_i$, on the local pressure gradient and film geometry. Using a linearized momentum equation, they obtained Eq. [6] for the velocity in a converging plane-walled passage with the half-taper angle, θ_i. Since this result is symmetrical with respect to the mid-plane where the shear stress vanishes, Eq. [6] applies locally in the present system for small angles and thin films.

$$u(r_i, \zeta) = \frac{\bar{u}_i[\cos \lambda_i - \cos \lambda_i\zeta]}{\left[\cos \lambda_i - \dfrac{1}{\lambda_i}\sin \lambda_i\right]} \qquad [6]$$

in which $\zeta = \phi/\theta_i$, and

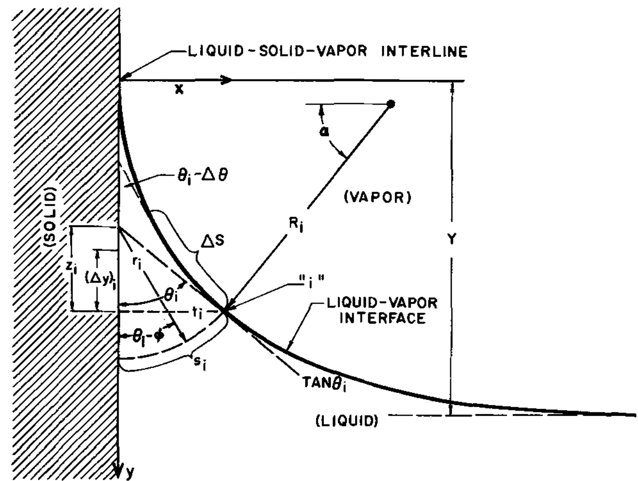

Fig. 1. Nomenclature for the analysis of an evaporating meniscus

$$\lambda_i = \left(\left|4 + \frac{\epsilon\,\mathrm{Re}_i}{2\theta_i}\right|\right)^{1/2}\theta_i \qquad [7]$$

where

$$\mathrm{Re}_i = \left(\frac{\bar{u}\,2\theta r}{\nu}\right)_i$$

In this approach the normal acceleration to the interface is assumed to have negligible effect. Their results can also be used to obtain Eq. [8] which relates the velocity to the pressure gradient.

$$u(r,\zeta) = \frac{\bar{u}\lambda^2 \cos \lambda}{4\theta^2\left(\cos \lambda - \dfrac{1}{\lambda}\sin \lambda\right)} - \frac{r^2}{4\rho\nu}\frac{\partial P}{\partial r} \qquad [8]$$

These last two equations can be combined to give

$$\bar{u}_i = \frac{z_i^2\left(\dfrac{\partial P}{\partial r}\right)_i\left(\cos \lambda_i - \dfrac{1}{\lambda_i}\sin \lambda_i\right)}{\rho\nu \cos^2 \theta_i\left[\left(\dfrac{\epsilon\mathrm{Re}}{2\theta}\right)_i \cos \lambda_i + 4\right]} \qquad [9]$$

Taking the normal force due to curvature to be the predominant interfacial effect the radial pressure gradient, $\left.\dfrac{\partial P}{\partial r}\right|_i$ is given by Eq. [5].

Numerical.—Using a finite difference technique, the above equations are sufficient to calculate the meniscus profile for a given heat flux at the vapor-liquid interface which can be assumed equal to a given per cent of the total thermal energy generated. The rest of the heat is conducted away through the solid. Assuming that all the fluid entering the initial interval, $(\Delta y)_1$, is evaporated, the average velocity of the fluid entering the initial wedge is

$$\bar{u}_1 = \left(\frac{q\Delta y}{\rho\Delta S}\right)_1 \qquad [10]$$

The initial arc length, s_1, is

$$s_1 = \frac{\theta_1(\Delta y)_1\,(\tan \theta_c + \tan \theta_1)}{2 \sin \theta_1} \qquad [11]$$

The wedge angle, θ_i, which is the inverse tangent of the slope at i is obtained from the slope and curvature at i-1 using the Euler finite difference approximation of curvature, K_i. This requires that the initial values of curvature, K_o, and contact angle, θ_c, be assumed. The change in meniscus thickness, $(\delta t)_i$, is the product of the step size and the average slope between i and i-1. Knowing the average velocity and the geometry of the wedge at i, the derivative of the pressure and curvature are obtained from Eq. [9] and [5]. The volumetric flow entering each wedge is equal to the total fluid

evaporated in the meniscus above that level. Using Euler's method the above process can now be continued until either the heat flux becomes negligible or the wedge angle equals ninety degrees. In the present case, the effect of evaporation on the meniscus profile is significant only at small angles. However, continuing the analysis until $\theta = 90°$, allows the use of the boundary condition at the base of the meniscus ($K = 1/R_b$, $\theta = 90°$) to select the initial curvature.

Evaporation in H_2SO_4 Meniscus

The above analysis is now applied to three arbitrarily selected evaporation rates, water vapor equivalent of 8, 24, and 72 W/cm^2, which are assumed to occur over the top 250Å of a 1*N*, H_2SO_4 meniscus. Although these flux profiles are not intended as a definitive description of the evaporation zone described in Ref. (1), which is beyond the scope of this work, the results based on their use significantly improve the understanding of the transport process occurring in a reacting system. Alternatively, considering the large IR drop and polarizations calculated for the finite contact angle mensicus in Ref. (1), these evaporation rates are possible in the interline region. Since we are only investigating the general effect of viscous flow, the size of the evaporation region is purposely limited. As a result of the thinness of the interline region, the effect of the same evaporation occurring further down the meniscus would be substantially less. In this model, the generated vapor could easily diffuse away under a vapor pressure gradient and condense on a surface at a lower temperature. Even with an enlarged zone of evaporation, the total power dissipation would remain small in the finite contact angle model because the upper limit on the zone is very small. In this analysis, Δy was equal to 250Å for the initial five intervals, 625Å for the next ten intervals, 1.25×10^{-4} cm for the next 380 steps, and 6×10^{-3} cm for the remaining distance. The radius of curvature at the base of the meniscus is assumed to be 0.5 mm (one half the slot width), and the fluid properties are assumed constant and evaluated at 25°C.

Results

The calculated meniscus thickness at 250Å below the interline and the meniscus heights for the assumed heat fluxes and contact angles are presented in Table I. Comparing the isothermal and evaporating cases, these results demonstrate that the meniscus interline migrates a small, though measurable distance as a result of viscous shear. There is a possible +6% error in the calculated meniscus height due to the use of only the boundary condition for curvature at the base of the meniscus instead of both the meniscus thickness and curvature. Since the approximate size and sign of the error is the same in all cases, the error in the migration distance is less than 6%. Auxiliary work (not presented herein), in which a fixed height at $\theta = 90°$ was used as a boundary condition, demonstrated that the meniscus profile in the interline region is not significantly different from the results presented herein. However, the profile at the base of the meniscus is significantly different. The average radius of curvature for the fixed height boundary value analysis is approximately 5% less. Previous work (5) demonstrated that the error due to step size is small. It is interesting to note that for the cases studied the evaporating meniscus height is not strongly affected by the initial contact angle and that the height for the larger contact angle is slightly larger. This results from the slightly larger pressure gradient (curvature change) in the initial portion of the meniscus with a zero contact angle where the film is thinner.

Comparing the film thicknesses for the various cases at a point 250Å below the interline demonstrates the following: (*i*) the film thickness of an evaporating meniscus is substantially larger than the film thickness of an isothermal meniscus with the same contact angle; (*ii*) the film thickness of an evaporating meniscus with a 0° contact angle is larger than the film thickness of an isothermal meniscus with a contact angle of 2° (however, the 0° contact angle meniscus must start smaller in the interline region); (*iii*) the film thickness for the present isothermal model and the cylindrical surface model are approximately the same; and (*iv*) an increase in the heat flux and/or the contact angle results in a larger film thickness. These substantial changes in the film thickness due to viscous shear would have a correspondingly large effect on the transport processes occurring in this region of potentially high current densities.

The liquid-vapor interfacial height and the logarithm of the reciprocal of the distance from the interline are plotted *vs.* the logarithm of the meniscus thickness in Fig. 2. The curves for the reciprocal distance from the interline start at $y = 125$Å. These curves show the substantial effect of evaporation on the meniscus profile. At a given distance from the interline (for $y > 175$Å) the evaporating meniscus with a zero contact angle for the heat fluxes analyzed is always thicker than the isothermal meniscus with a contact angle equal to 2°. Previous analysis (1) indicated that 90% of the current is produced in the region $y < 10^{-4}$-10^{-5} cm, with the largest current density in the immediate vicinity of the interline. These results were partly based on diffused interferences fringes that reoccurred every 2.9×10^{-5} cm. The interaction of these results indicates that it is theoretically possible to define an evaporating meniscus with a contact angle equal to 0° that is indistinguishable from an isothermal meniscus with a 3° contact angle

Table I. Meniscus thickness at 250Å below the interline and over-all meniscus height

Conditions	Meniscus thickness, Å, at $y = 250$Å	Meniscus height, cm
$\theta_c = 0°$ isothermal	Less than mono layer	0.0558
$\theta_c = 2°$ isothermal	8.75	0.0546
$\theta_c = 0°$ $q = 8$ W/cm^2	11.4	0.0532
$\theta_c = 0°$ $q = 24$ W/cm^2	15.1	0.0521
$\theta_c = 0°$ $q = 72$ W/cm^2	19.8	0.0507
$\theta_c = 2°$ $q = 72$ W/cm^2	20.2	0.0508
$\theta_c = 2°$ cylindrical surface	8.73	0.0483

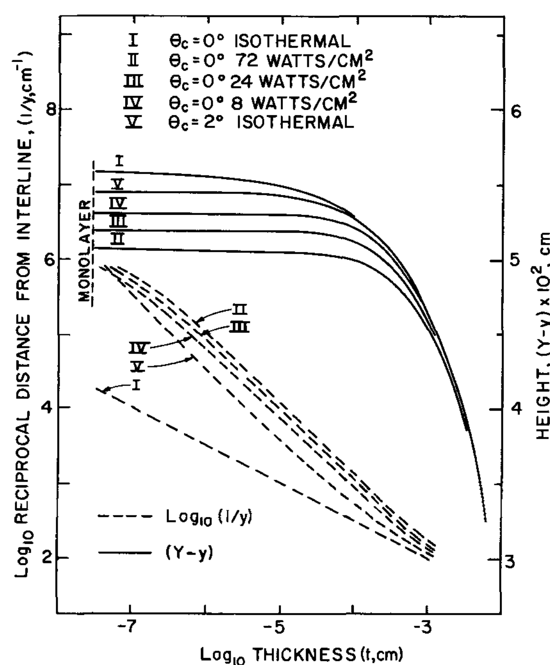

Fig. 2. Calculated meniscus profiles

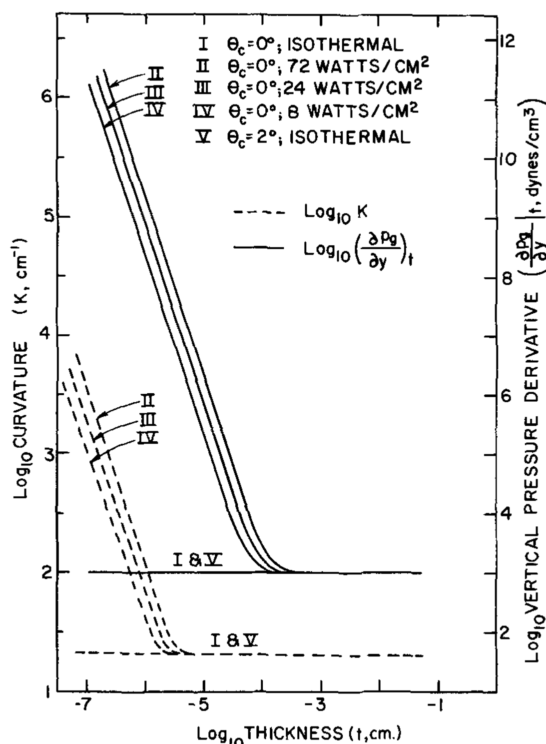

Fig. 3. Calculated vertical pressure derivative and curvature vs. the calculated meniscus thickness.

within the accuracy of the described experimental data and theoretical analysis. Considering this conclusion and the current understanding of transport processes in the critical interline region, considerable additional study of this area is needed to properly model the electrochemical reaction zone.

The logarithm of the meniscus curvature and the vertical pressure derivative are plotted *vs.* the logarithm of the film thickness for the upper portion of the meniscus in Fig. 3. These results demonstrate that there are orders-of-magnitude increases in the pressure gradient to balance the effect of viscous flow. The horizontal solid line near the bottom of the figure is the weight density of the fluid. The effect of viscous shear becomes negligible before the wedge angle is equal to 10°. The absolute value of the approximate wall shear stress can be calculated using

$$|\tau_s| = \left(\frac{\partial p_g}{\partial y}\bigg|_{x=t} - \rho g \right) t \qquad [12]$$

In this analysis the integrated product of the local wall shear stress and the area would be equal to the decrease in weight of the meniscus. These results also indicate that there are orders-of-magnitude increases in the radius of curvature near the interline. The average radius of curvature in the first interval for run No. 4 in Fig. 3 is 2.5μ *vs.* 479μ for the isothermal meniscus. Therefore, the meniscus profile in the interline region more closely resembles the meniscus found in a pore than that found on an immersed flat plate.

Discussion

Curve IV presented in Fig. 2 and 3 represents a system with an evaporative heat flux of 8 W/cm² which is assumed to occur over only the top 250Å of the meniscus. This is 30% of the average thermal energy generated in the top 250Å of the meniscus presented in Fig. 24e of Ref. (1), and a small per cent of the total heat generated. A substantial flow profile change occurs when the evaporating fluid flow results from a curvature change, which gives a plausible mechanism for the flow. This particular evaporating meniscus profile starts with a zero contact angle but resembles an isothermal meniscus with a 4° contact angle for a large portion of the main reaction region. Curve III (72 W/cm² over 250Å, 0° contact angle) corresponds closely to an isothermal curve with a 6° contact angle in a large portion of the main reaction region. If a reliable method of predicting the relative percentage of the thermal energy removed by evaporation were available, the method described herein could be used to improve the results of Bockris and Cahan. At present, these results give a good estimate of the effect of contact angle on the current *vs.* overpotential curve if the apparent contact angle is used. For example, in Fig. 17 of Ref. (1), the per cent decrease in the current at an overpotential of one volt for a change in the apparent contact angle from 1° to 4° is 26%. Additional results are presented in Ref. (10). The same change would occur if the profile change was due to fluid flow instead of the contact angle. This supports the model of an evaporative heat sink by giving a plausible mechanism for fluid flow. The large predicted increase in evaporative heat flux required to go from an apparent contact angle of 4° to 6° indicates that sufficient fluid flow is available for even the highest thermal fluxes. A similar effect could be expected to occur in porous electrodes.

In the complete system, conduction in the electrode would also remove some of the thermal energy. Therefore, it is instructive to make an order-of-magnitude calculation of the unit thermal conductance in a porous solid (k_{eff}/L) and compare it to a "mass conductance" in the pores. The unit thermal solid conductance ($L = 1\mu$) is 1400 cal/sec-cm²-K° in nickel, 100 in carbon, 31 in quartz, and 5.6 in Teflon. The conduction path in Ref. (1) was quartz with a thin surface film of sputtered Pt. The unit thermal conductance in a porous media is much lower than this and is a strong function of the manufacturing process. For example, the conductance in strongly consolidated sintered metals is an order-of-magnitude less than the solid conductance and could be a factor of 100 less in poorly sintered specimens. For unconsolidated packed material, the ratio of the two conductances could be 1000. Therefore, thermal conductance in a porous electrode is a strong function of the material, the manufacturing process, and the meniscus location (relative to the junction between two particles).

Assuming that molecular diffusion through a stagnant gas occurs in a uniform pore, the conductance of the vapor space for water can be estimated to be (in equivalent thermal units) 7 cal/cm²-sec-K° at 25°C. This is obtained using Eq. [13] with $T = 298$°K, $L = 1\mu$, $p = 1$ atm, $D_{H_2O\text{-}H_2} = 0.825$ cm²/sec, and a water vapor pressure difference corresponding to a temperature difference of 1°C

$$N_A = \frac{p\,D_{AB}}{RTL} \ln \left(1 + \frac{\Delta p_B}{p_B} \right) \qquad [13]$$

This is larger at higher temperatures since the rate of change of vapor pressure with temperature and the diffusivity increase with temperature. Like the thermal conductance, the effective mass conductance in a porous material is a function of its manufacturing process. These calculations indicate that the evaporative heat flux in porous electrodes made from carbon and Teflon is relatively large. Alternately, the solid heat conduction process is much more effective than evaporation in well-sintered metal electrodes. However, in both cases, the evaporation-condensation mechanism could cause meniscus migration but at different velocities. In addition, if vaporization occurred at a surface with a large radius of curvature and condensation occurred in a crevice with a small radius of curvature, vapor transport would be enhanced. Theoretically, once the ideal electrochemical meniscus is completely described, the porous electrode design can be optimized.

The above analysis is based on the premise that a fully developed wedge flow model can be used in the meniscus. A partial feeling for the correct velocity

distribution can be obtained from a boundary layer calculation of the distance required for the boundary layer thickness for flow over a flat plate to be equal to 1×10^{-3} cm. This is the approximate thickness of the meniscus in the region where viscous effects become negligible. A simple form of the boundary layer equation is

$$x = \frac{t^2 u_\infty}{30\nu} \qquad [14]$$

Using the interfacial velocity at $t = 1 \times 10^{-3}$ cm for u_∞, the calculated distance is negligible compared to the distance from the bottom of the plate to this point. In fact the velocity is so low and thickness so small, that the use of the simple form of the boundary layer equation is not justified. However, the large difference between these two distances definitely indicates that the accelerating velocity profile is well developed in and above this region. In addition, since the angle θ_i is still small in this region, θ-direction flow has a small effect on the meniscus profile. These two results demonstrate that the wedge flow model is a good approximation to the flow field in the upper portion of the meniscus. Since viscous effects become negligible below this region, the continued use of the model does not effect the validity of the rest of the profile.

The thermocapillary shear stress at the liquid-vapor interface is assumed to be negligible in the present analysis. This assumption is based on the results of Ref. (5) which demonstrated that the thermocapillary effect in the upper portion of the meniscus was small compared to the curvature effect. Thermocapillary flow would have an effect on the profile in the lower and less important portion of the meniscus. Further, inclusion of this effect requires *a priori* knowledge of the temperature gradient. Since this gradient is unknown, its inclusion would require an additional set of iterations which is beyond the scope of the present study.

Conclusions

Fluid flow in the evaporating meniscus of an electrode-gas-electrolyte reacting system was modeled and analyzed. The meniscus profile, the curvature profile, and pressure derivative profile were calculated for 1*N* H_2SO_4 using various assumed evaporation profiles. The results demonstrate that: (*I*) A sufficiently large capillary force was available to supply the required fluid flow for a large evaporative heat sink. (*II*) Due to the thinness of the meniscus profile in the interline region large pressure gradients were needed to balance the viscous shear stress. (*III*) The change in curvature due to viscous flow had a significant effect on the meniscus profile in the critical interline region. (*IV*) Depending on the evaporation rate, the interline radius of curvature could be micron size for a large meniscus. (*V*) This change in meniscus profile would have an equally significant effect on the transport and kinetic processes occurring. (*VI*) The effect of viscous shear on the meniscus profile should not be neglected in analyzing electrochemical processes in a finite contact angle meniscus. (*VII*) Currently used optical techniques are not sufficiently accurate to measure the meniscus profile in the critical region.

Low Current Density Microcell Diffusion Layer Thickness at Shallow Vertical Electrodes

R. N. O'Brien*

Chemistry Department, University of Victoria, Victoria, British Columbia, Canada

Use of microcell interferometry techniques which have been well reported (1-4) permit detailed analysis of the limiting effect of natural convection at vertical electrodes. A number of authors (5-9) have evolved equations to describe natural or free convection at vertical electrodes. Only that evolved by Wilke, Eisenberg, and Tobias (10) has been tested for microcells and found satisfactory (11, 12). Since the testing of this expression by conventional means, interferometric data has become available and is presented here. Microcells are for the purposes of this work defined as those with electrolyte volumes of 0.5 ml or less. Those used also had electrode area to electrolyte volume ratios of about 10^4 in contrast with conventional cells which have ratios usually in the range of 10^{-2} cm^{-1}.

The cell used was very similar to that reported in Ref. (1). The electrodes were 0.31 cm apart and were 0.191 cm thick, of high purity microcrystalline copper carefully prepared and polished to give a vertical edge to avoid shadowing. The experiments were done at room temperature (22°C).

The limitation of the extent of the diffusion layer by natural convection is shown in Fig. 1. Fig. 1(a) shows the concentration gradients for horizontal electrodes with the cathode over the anode (C/A) previously published in Ref. (3), and Fig. 1(b) shows them for shallow vertical (S/V) electrodes in the cell $Cu/CuSO_4/Cu$ at the natural pH of 4.3 of 0.05M $CuSO_4$ at a nominal 1 mA/cm^2 C. D. (0.902 mA/cm^2). For short periods of electrolysis, irregularities of the surface of horizontal electrodes, small departures from the truly horizontal position, and inequalities of electrode areas in activity have usually not produced detectable convection.

The differences between the convecting system and the nonconvecting system are that the diffusion layer constantly expands for the horizontal C/A system and is limited after about 15 sec by convection in the S/V arrangement of electrodes to about 0.025 cm. The differences under these conditions are more easily seen in Fig. 2(a) and (b) where the concentration at a given distance out from the electrode is plotted at various times. An idea of the uncertainty of the measurements is given by the scatter of points shown in Fig. 2(b) at times less than 10 sec.

Contrasting Fig. 2(b) with 2(a) convection appears to have begun at the anode first and is detectable as an undulation in the curve at 10-15 sec after electrolysis was begun. The first irregularity in the cathode side occurred farther out from the electrode at just over 20 sec and was more severe, the slope of the concentration contour actually reversing. Close to the electrode, the anode exhibited 3 anomalous changes in concentration contour until settling down at about 45

sec to a constant concentration value and a pseudo-steady state. At 0.01 cm out from the anode small changes in concentration were still occurring at 60 sec. At the cathode, stability at the electrode and at 0.01 cm from it occurred at the same time, about 50 sec, and only two major perturbations to the smooth curve occurred. Two convective vortices were set up by 50 sec with overflow and underflow between them as described previously (4).

The characteristics shown in this experiment are generally true, that is, although the number of changes of slope to the pseudo-steady state is not constant, the anode region has the most, and they begin and end there first. The initial 10 sec has a smooth concentration change form similar to that of a convectionless system and like it, gives a linear plot of ΔC *vs.* $\sqrt{t}$, but the plot does not go through the origin. Higher current densities produce noticeable convection a little sooner and have less extensive diffusion layers as shown in a recent paper by Tvarusko and Watkins (13). Ibl and Bohm (12) have found a similar instability in a redox system when similar heights and separations of electrodes were used. Optical errors calculated according to Ibl (14) are negligibly small, of the order of 1% for these concentrations and current densities.

Dielectric Breakdown in Silicon Dioxide Films on Silicon

I. Measurement and Interpretation

C. M. Osburn* and D. W. Ormond

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Depending on how one measures the dielectric breakdown strength of thermally grown SiO_2 films in the thickness range useful for MOSFET applications, different results may be obtained. These results are shown not to be an intrinsic property of the SiO_2 but rather are artifacts dependent on metallurgical contact thickness, oxide thickness, capacitor area, applied bias voltage, instrument impedance, and time constant. These parameters lead to phenomena commonly referred to as self-healing (or nonshorting) breakdowns which represent a voltage collapse followed by thermal processes that vaporize the shorting electrode metal allowing the capacitor to break down repeatedly at higher fields. Statistical distributions of breakdown fields for the initial breakdown event point to a continuum of oxide defects having different breakdown fields in contrast to prior work showing specific defect types. Measurements of the final shorting voltage (after self-healing breakdown events no longer occurred) are useful in determining the maximum dielectric strength of a defect-free film. A ramp-rate dependence of the breakdown field is observed for slow ramps, and a time instability is seen in the high-field conduction which leads to breakdown.

The dielectric strength of SiO_2 films on silicon is important to the performance of MOSFET devices. Both the initial yield and the reliability of these devices during operation can be related, at least in part, to the breakdown characteristics of the SiO_2 gate dielectric.

Dielectric breakdown in materials has been of interest for many years, particularly as related to high-voltage insulators and capacitors. More recently, growing interest in the large-scale integration of transistors and other thin-film components has shifted attention to breakdown in very thin films, and, consequently, breakdown strengths have been measured for films of many different materials. Unfortunately, only a limited amount of work has been done to relate materials and processing parameters to the breakdown characteristics in SiO_2, in order to both improve the oxide integrity as well as to determine the major breakdown mechanisms.

Several ways of describing the dielectric strength of thin insulating films have been developed and refined in recent years (1). The following three methods have received special attention: (*i*) measuring one capacitor sample having thin metal electrodes in order to allow self-healing breakdowns (2) to take place by vaporizing the metalization over the failed or weak spot in the dielectric, thereby eliminating the weak spots; (*ii*) constructing a statistical distribution of breakdown values by using a large number of test specimens (3-4); and (*iii*) determining the current-voltage characteristics of a capacitor, just prior to the breakdown event (5). Each method has certain advantages and disadvantages, and the choice is important. For instance, the first method permits the taking of a large amount of data from a single capacitor structure, but its usefulness is usually restricted to studying the so-called primary, or high-field, breakdown strength; as such, it tells little about the low-field breakdown strength which is important for device applications, and it does not reveal the effect of materials and processing parameters on the number of oxide defects. The statistical approach (*ii*) gives perhaps the best indication of when an actual MOSFET device might fail during loading, but it does not shed as much light as the former technique on the nature of the breakdown mechanism. While current-voltage measurements (*iii*) provide additional information on the breakdown mechanism, their usefulness is restricted mainly to observing primary-type breakdowns; furthermore, the measurements can be very tedious and difficult to interpret when other time-dependent components (*e.g.*, from ionic displacements) appear in the total current.

When measuring breakdown in MOS capacitors, the statistical approach is often employed because it is probably most directly related to device reliability. It has the additional advantage of being the most sensitive measure of the effect of materials and processing parameter changes. However, it will be shown that the procedure used in measuring statistical distributions does affect the results obtained and that care must be taken in interpreting data. In this paper, the results of an attempt by the authors to interrelate various materials and measuring parameters to the dielectric breakdown characteristics of thermally grown SiO_2 films are reported. The interactions of such variables as oxide thickness, metal electrode area and thickness (here, aluminum), time response, and impedance of the electrical measuring circuit, as well as testing ramp rate

* Electrochemical Society Active Member.

Key words: dielectric breakdown, silicon dioxide films, metal-oxide-semiconductor (MOS), self-healing breakdown, conduction.

and polarity, are discussed. In addition, certain implications of the current-voltage characteristics are considered since they suggest a likely breakdown mechanism.

Experimental Procedure

Metal-oxide-semiconductor capacitors were fabricated on 2 ohm-cm, p- and n-type <100>-oriented silicon wafers. The wafers were ultrasonically cleaned using NH_4OH-H_2O_2, HCl-H_2O_2, and HF solutions, while the quartz glassware was etched with HNO_3-HF; oxides from 200 to 2000Å thick were then grown in dry oxygen at 1000°C. By using all reasonable precautions to insure pure SiO_2 films, mobile Na^+ ion concentrations on the order of $5 \times 10^{10}/cm^2$ were obtained as determined by the flatband voltage shift technique (6). One hundred aluminum electrode dots were electron-gun evaporated through metal masks onto each wafer in a clean evaporation system, and the wafers were then given a 5-min anneal at 500°C in dry nitrogen.

Measurements were made with the circuit shown in Fig. 1, wherein a ramp voltage (*i.e.*, increasing linearly with time) was applied to the MOS sample. Breakdown was accompanied by a rapid voltage drop across the MOS capacitor which was sensed by a special triggering circuit that would record the breakdown voltage on a voltmeter. Often, particularly if the aluminum electrode was thin, the MOS capacitor would not short out but would recover and continue increasing in voltage as the ramp voltage increased until another breakdown event occurred. This process of recovering is the well-known phenomenon of self-healing whereby the capacitor discharges through the breakdown path and vaporizes the metalization over the path leaving a nonshorted capacitor containing a small, burned-out area. Up to several hundred of these self-healing events could take place before the sample would short permanently. The voltage at which this shorting, or final, destructive breakdown, took place was recorded on a second, peak-reading voltmeter. Thus only the initial, self-healing breakdown voltage and the final, destructive breakdown voltage were recorded and the intermediate breakdown events were ignored. When the aluminum was thick and self-healing did not occur, both breakdown values were the same. After all the capacitor specimens on a wafer were tested, histograms giving the percentage of capacitors that broke down *vs.* the voltage of breakdown for the initial and the final breakdown were constructed. From a practical point of view, only the initial breakdown distribution was important; from the point of view of understanding breakdown processes in defect-free SiO_2, the final one was important. This measuring procedure combined methods (*i*) and (*ii*) described earlier in that (*a*) statistical distributions were constructed in order to study low-field breakdown events, and (*b*) self-healing events were allowed in order to measure the intrinsic breakdown strength of SiO_2. Intermediate-field breakdown events gave no additional information since the use of statistical distributions made it possible to determine the probability of breakdown at any given field.

The voltage ramp was obtained by charging a fixed capacitor by means of a constant current generator, and its speed was varied by adjusting the current. The value of the series resistor (R_s) ranged from 10 ohms to 100 kilohms. The triggering circuit was basically the nanoampere sensing arrangement described elsewhere (7) with the input impedance reduced in order to speed the response time to under 1 μsec. The circuit would trip a relay when a 1-volt, 1-μsec pulse appeared across R_s. With a large series resistor, the time constant for recharging the MOS after a self-healing event was larger than 1 μsec so that the circuit would detect all of the self-healing events in which the capacitor voltage dropped by one volt or more; later considerations show that the chances of self-healing occurring with less than a one-volt drop are quite remote.

Results and Discussion

Measurement of statistical distributions.—When the series resistor was 100 ohms or less, the initial and final breakdown distributions were identical, and visual inspection at 100 magnifications showed that no self-healing breakdowns had occurred. For larger R_s values (>10 kilohms) self-healing breakdowns occurred which were later observed as small black specks on the aluminum electrodes under this magnification. Accordingly a 100-kilohms series resistor was used subsequently to permit self-healing so that the maximum breakdown strength of each sample could be evaluated. Figure 2 compares the initial and final breakdown distributions for a typical wafer with the metal biased negatively. It was found that the initial breakdown values were continuously distributed over the entire field range from 0 to 10 MV/cm and did not show distinct peaks in general. More careful preparation of the SiO_2 films did, however, reduce the frequency of breakdowns occurring below 2 MV/cm. The final (*i.e.*, destructive) distribution, on the other hand, consisted of distinct peaks similar to those observed earlier by Fritzsche (3) as well as by Chou and Eldridge (4). The measuring circuit of Chou and Eldridge was identical to the one used here for measuring the final breakdown voltage except that their series resistor was even larger (250 kilohms); furthermore, visual inspection did show that their samples experienced self-healing which was undetected by their slower responding (~0.1 sec) testing circuitry; hence, their data are probably more representative of the final breakdown phenomena. The presence of a low-field peak in the final breakdown distribution can be explained simply by the lack of sufficient energy stored in the MOS capacitor to promote self-healing at low fields. At low fields, breakdowns are shorting giving rise to a low-field peak while at intermediate fields breakdowns are self-healing. This behavior is explained more fully later. The occurrence of this peak in the final break-

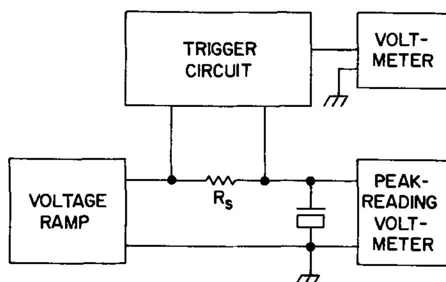

Fig. 1. Diagram of the breakdown measuring circuit

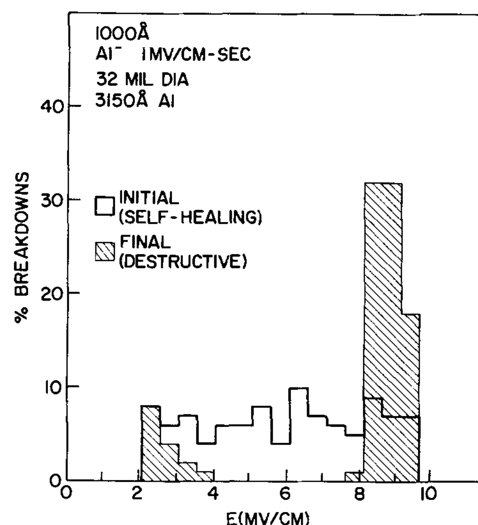

Fig. 2. Initial and final breakdown distributions

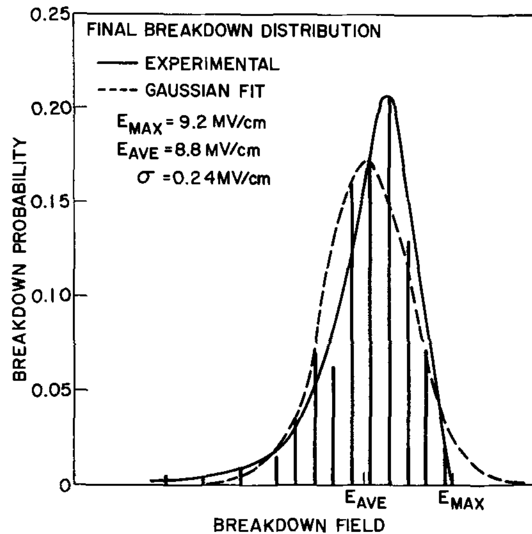

Fig. 3. Shape of typical final breakdown distribution

down distribution does not reflect any property of the SiO_2 film but is rather a consequence of measuring conditions. The wide distribution of breakdown fields across a wafer, as determined from the initial self-healing breakdown events, indicates either a distribution of weak spot sizes or several breakdown mechanisms. Both initial and final distributions were dependent on the electrode area since the frequency of low-field breakdown events increased with increasing electrode area.

A more expanded plot of a typical final breakdown distribution, as used to determine the maximum dielectric strength (see Fig. 3), shows that the high-field curve is not Gaussian but rather is skewed at low fields and has a sharp cutoff at the upper end (E_{max}). Furthermore, the peak of the experimental distribution occurs at a field that is greater than the average field. The variance of the distribution in most cases is two to five times larger than would be expected from thickness fluctuations over the wafer and must be explained in terms of other mechanisms, possibly large numbers of very small defects. The shape of the final distribution is largely independent of measuring temperature. The variance of the distribution remains about 4% of the average field down to 400Å thick films. Distributions for thinner oxides have larger standard deviations which can be attributed to the lack of self-healing.

A correlation has been observed between the initial and the final breakdown strength of a particular capacitor. Those which had a low initial, self-healing breakdown also had low final breakdown voltages; conversely high final breakdown usually followed high initial breakdown voltages. It has not been possible to determine whether the process of self-healing weakens the remainder of the film or whether both breakdowns are associated with a generally defective film. Destructive breakdown usually involves a series of propagating breakdowns in a cluster until the breakdown area is so large that insufficient energy is stored to sustain further clearing of shorted regions.

Polarity.—When the aluminum is biased negatively in p-type MOS capacitors, the silicon surface is in accumulation and the entire applied voltage appears across the oxide. When the aluminum is positive, however, the surface can be either depleted or inverted, depending on the field applied and the minority carrier generation rate. In the equilibrium case, the maximum voltage across the silicon is equal to the maximum amount of band bending allowed or about 1 volt; this is a small correction factor for samples that break down at roughly 50V or more. On the other hand, when the carrier generation rate is slow compared to the measuring ramp, deep depletion can occur, and most of the applied field can be in the silicon. Avalanching in the silicon could possibly trigger the breakdown in this case. Because of this potential difficulty, most of the measurements in this study were made with the aluminum negative; a comparison was made with the aluminum positive, however. Under room lighting and with a ramp rate of 1 MV/cm-sec, the distribution for the aluminum positive was spread out over a very large range. The maximum breakdown voltage ranged up to 150V for 1000Å films and went over 80V for 200Å films (15 and 40 MV/cm, respectively, if the entire voltage were across the oxide). This compares with maximum breakdown strengths of 92 and 25.8V for 1000 and 200Å films (9.2 and 12.9 MV/cm, respectively) with the aluminum negative. As expected, the Al(+) distribution results were very light sensitive since light increases the carrier generation rate and gives faster equilibration; strong illumination reduced the maximum breakdown voltage in a 200Å film from over 80 to 19.4V and from 150 to 89V in a 1000Å film. Comparisons of breakdown distributions measured under strong illumination with both polarities gave identical results for the most part. The maximum dielectric strength for Si(+) is about 0.4 MV/cm less than for Si(−) however. Occasionally a capacitor withstood an abnormally high voltage with depletion bias even under illumination. Subsequent examination showed that these capacitors exhibited a high leakage current through the oxide. The authors attributed the high breakdown voltage in this case to the high oxide leakage prohibiting the formation of an inversion layer in the silicon and not to superior breakdown strength. Thus care must be taken to insure that equilibrium occurs if meaningful breakdown measurements are to be made with the silicon depleted. Many measurements were made on n-type Si wafers with the aluminum biased positively. The behavior observed was the same as that with Al(−) on p-type wafers. Apparently the measuring polarity is not an important factor in itself but rather the condition of the silicon surface (*i.e.*, accumulated or depleted).

The tendency for self-healing was found to be very polarity dependent; *viz.*, self-healing breakdowns would occur for both polarities but were much less frequent when the aluminum was biased positively. For a sample to self-heal with positive aluminum, thinner aluminum, larger capacitor area, or thicker oxide was required than for Al(−). Klein (2) found that for p-type samples of 0.3 and 9 ohm-cm the resistance of the discharge path was an order of magnitude greater for Al(+) than for Al(−) so that the initial current surge through the discharge path was an order of magnitude greater for negative aluminum. It could be argued that the high-current, Al(−) breakdown could vaporize the discharge path more effectively (and, hence, self-heal) while the low-current, Al(+) breakdown could not. In an actual device, only the first breakdown event is important, of course, and is not affected by self-healing and hence is not affected by polarity.

Ramp rate.—If the breakdown mechanism in SiO_2 is thermal in nature, one would expect to find a ramp-rate dependence of the maximum breakdown strength. In this study, the ramp rate was varied from 0.05 to 10^5 MV/cm-sec with only subtle changes in breakdown strength. For Al(−) the high-field, or primary, breakdown peak was observed to shift to higher field values by about 7% when the ramp rate was increased from 0.05 to 2 MV/cm-sec, as shown in Fig. 4. No statistically significant changes in the lower field breakdowns could be discerned. Breakdown measurements on a single sample using the self-healing technique (2) showed that the breakdown strength was constant for ramp rate over 2 MV/cm-sec (see Fig. 5). These results extend the work of Fritzsche (3) who found no pulse duration effect from 8 to 400 μsec. With the silicon depleted in room light, the faster ramp in-

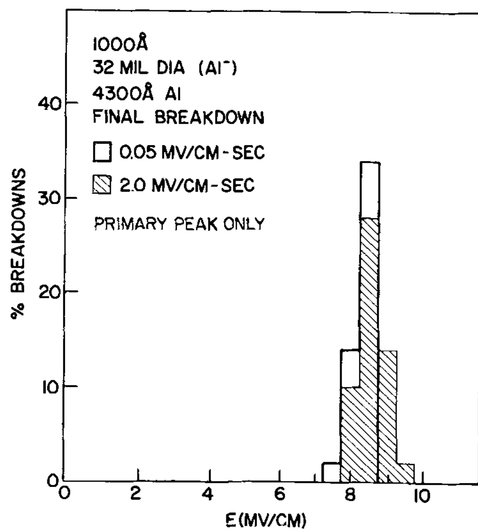

Fig. 4. Ramp-rate dependence of breakdown distributions

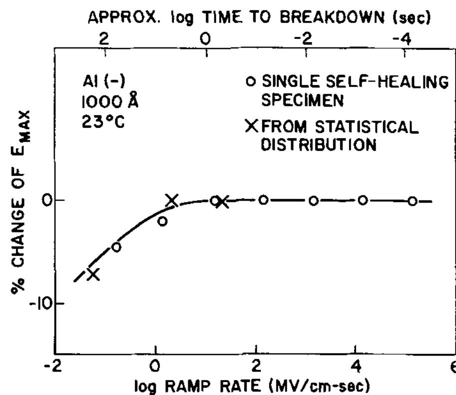

Fig. 5. Ramp-rate dependence of maximum dielectric strength

creased the low-field breakdowns but had no real discernable effect at high fields. It should be noted that even in room light, many samples withstood voltages that would create fields in the oxide greater than 10 MV/cm for over 5 min (this anomalously high voltage is divided between the oxide and the silicon and results from a low minority carrier generation rate as compared to the rate of loss of carriers through oxide conduction). Previous studies of low-frequency C-V characteristics (8, 9) also found very slow carrier generation rates.

Effect of material parameters on breakdown distributions.—Oxide thickness.—One significant finding here where the breakdown distributions were determined for various oxide thicknesses is that fewer self-healing breakdowns occur in thinner SiO_2 samples. Thus, for thin films (*e.g.*, 200Å), the initial and the final breakdown distributions are almost identical while they are quite different for much thicker SiO_2 layers. One qualitative explanation for this behavior is apparent; namely, the energy (W) stored in a capacitor of area F and oxide thickness d is

$$W \alpha F \cdot d \cdot E^2 \quad [1]$$

where E is the electric field strength applied across the oxide. For a given field and area, thinner oxide samples store proportionately less energy that can be subsequently released for volatilizing a portion of the metal, thereby resulting in a self-healing event. The implications of this observation are important when it is realized that several breakdown studies in the past have measured the final breakdown only. The final breakdown voltage in a thick film is usually much higher than the initial breakdown because the MOS capacitor can self-heal; in contrast, the final breakdown in a thinner film is identical to the initial breakdown. Hence, a determination of only the final breakdown distributions can make the apparent intrinsic breakdown strength and the apparent high-field breakdown frequency decrease with decreasing SiO_2 thickness; these observations are artifacts of the measurement and do not represent the properties of the film itself.

Aluminum thickness.—The electrode area dependence of the fraction of capacitors having final breakdown strengths within the range of the high-field, or primary, breakdown peak (*i.e.*, the high-field peak of the final breakdown distribution in Fig. 2) has been used to characterize a defect density of the oxide film. For example, Chou and Eldridge reported defect densities for several oxide thicknesses wherein the mobile Na^+ concentration was $\sim 2 \times 10^{11}/cm^2$ and the immobile sodium was not determined. Since self-healing breakdowns were present but undetected in their samples, it was necessary to determine the extent of any interaction between their measurements and results. Accordingly, the aluminum thickness was varied, and, as expected, those samples having thicker aluminum contacts showed fewer self-healing breakdowns and therefore more low-field, final shorting breakdowns; however, some self-healing events were observed with over 10,000Å of aluminum thicknesses. The electrode area dependence of the fraction of high-field breakdowns is shown in Fig. 6 for several thicknesses of aluminum; the oxide defect density, ρ, can be determined from this figure using the relation

$$-\ln P = \rho F \quad [2]$$

where F is the electrode area and P is the probability of a primary breakdown. Since ρ, as computed from final breakdown distributions, is a function of aluminum thickness (see Fig. 7), it is not a true measure of a density of defects in the oxide but is apparently a more complicated indicator of the defect density coupled with the aluminum thickness. The occurrence of undetected self-healing events can greatly distort results obtained for defect densities. The initial breakdown distribution, on the other hand, was independent of aluminum thickness to first order at least; although the wafer dependence precluded an exact comparison of wafers having different thicknesses of metal, no statistically significant difference was ever observed.

Capacitor area and defect density.—In examining the initial and final breakdown distributions, one observes a more or less definite threshold field (V_t) below which no self-healing breakdowns occur. In practice, it was found that most samples with initial breakdown above this threshold do self-heal but no samples self-heal below the threshold. This threshold voltage varied with the capacitor area, F, as

$$K = \frac{kF}{2d} (V_t^2 - V_r^2) \quad [3]$$

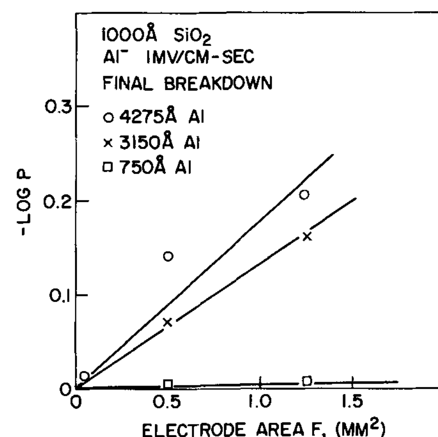

Fig. 6. Electrode area dependence of breakdown

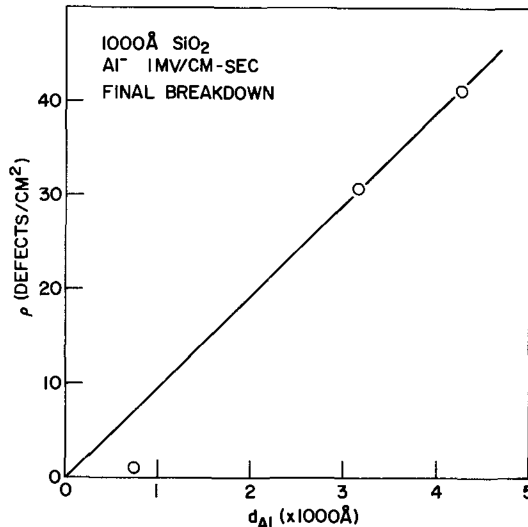

Fig. 7. Aluminum thickness dependence of breakdown

where V_r is associated with the minimum voltage remaining across the capacitor during a self-healing breakdown event; d is the thickness of the oxide having dielectric constant k; and K represents the minimum energy required to vaporize the discharge path for self-healing and is dependent on aluminum thickness. A value of V_r about 23V gave the best fit to the experimental data for the present films. By comparison, Klein (2) found that the theoretical lower limit of V_r should be 12.2V for SiO_2 films; this value is considered to be the minimum voltage needed to support a gas discharge and is composed of the aluminum work function plus the silicon ionization potential. High-speed oscilloscope traces showing the voltage across the capacitor during a self-healing breakdown event with the wafers used in this study further verified the minimum value of V_r as 22-24V; Klein found an experimental value of 16V for V_r by using oscilloscope traces.

Since the fraction of the final, secondary breakdown events varies with aluminum thickness and since the self-healing threshold voltage of the secondary breakdown varies with capacitor area, it becomes necessary to re-examine the defect density, ρ, as used first by Fritzsche and then by Chou and Eldridge. The past work has made the assumption of a single type of defect responsible for the secondary breakdown peak; this study finds the absence of a well-defined secondary peak for the initial breakdown distribution. Instead the breakdowns are distributed over a wide range of fields. The probability, $p_F(E)$, that a capacitor of area F will break down between E and $E + dE$ can be determined from the initial breakdown histograms. Typical distributions of the breakdown probability for three different capacitor diameters are given in Fig. 8. In the most general case, three regions can be discerned: (*i*) high fields (0.8 E_{max} to E_{max}) where $p_F(E)$ does not depend on the area F and can be associated with the intrinsic breakdown of the film, (*ii*) low fields (0 to 0.8 E_{max}) where $p_F(E)$ can be expressed as $F \times \rho(E)$, and $\rho(E)$ can be considered as the density of defects having breakdown E, and (*iii*) moderately high fields (0.6 E_{max} to E_{max}) where $p_F(E)$ increases with increasing area but not linearly and appears to be a transition between the intrinsic breakdown region and the defect-related breakdown region. It should be noted that the range of each region varied from one sample to another. The use of the defect densities as a function of field was a very sensitive indicator of the variability in breakdown properties of different wafers. Some wafers did show a distinct peak in the defect density at lower fields indicating a high incidence of a single type of defect in those particular wafers. Most wafers, however, showed a continuum of defect sizes or properties. As expected the probability of a defect being present increases as the defect size decreases. No significant variations in the defect densities have been observed as a function of oxide thickness beyond normal wafer to wafer differences.

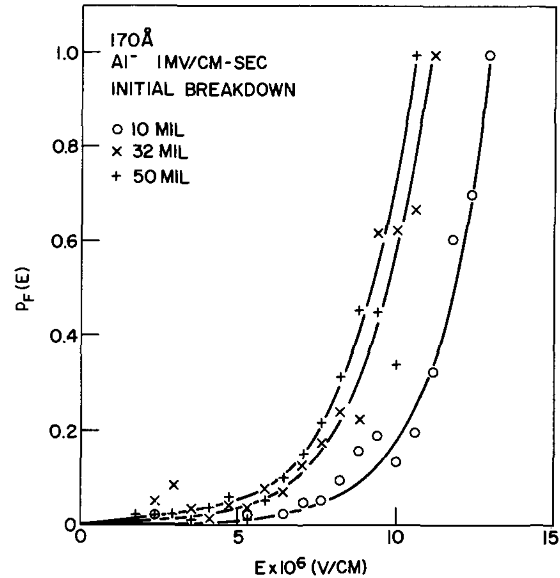

Fig. 8. Breakdown probability as a function of field

The mathematical treatment of a distributed defect density is only slightly more complicated than for the discrete defect case. In the defect-related breakdown region, if we let $P(E)$ be the probability that a capacitor of area F has a defect with breakdown less than or equal to E, then

$$P(E) = \int_0^E F\rho(\xi)\,[1 - P(\xi)]\,d\xi \qquad [4]$$

Solving gives

$$P(E) = 1 - \exp\left\{-\int_0^E F\rho(\xi)\,d\xi\right\} \qquad [5]$$

If $P'(E)$ is the probability that the capacitor has breakdown greater than E, then

$$P'(E) = \exp\left\{-\int_0^E F\rho(\xi)\,d\xi\right\} \qquad [6]$$

or

$$-\ln P'(E) = F\int_0^E \rho(\xi)\,d\xi \qquad [7]$$

which is the same as Eq. [2] with an integral replaced for a discrete density. It should be noted that the data of Fig. 8 fit Eq. [7] at all oxide thicknesses for $E = 0.8\ E_{max}$ with

$$\int_0^{0.8\,E_{max}} \rho(\xi)\,d\xi \simeq 120/\text{cm}^2 \qquad [8]$$

Measurement of current-voltage characteristics.—Figure 9 gives the steady-state I-V curves for a 1300Å oxide film at room temperature. The data were taken after the field had been applied for a few hours to drive the mobile ions to one electrode or the other. The data are quite similar to those of Lenzlinger and Snow (10) showing Fowler-Nordheim tunneling. In the present case Al(+) gives higher current at a given field than Al(−) which is opposite of their result indicating different barrier heights. There is one major difference in the results: at the high fields, particularly with Al(−), the current increases with time (½ to 10 min) from its instantaneous value to a stable, equilibrium value. This change is repeatable: if the voltage is reduced, the current decreases with time to its original value at the voltage. When the voltage is increased again, both the instantaneous current and

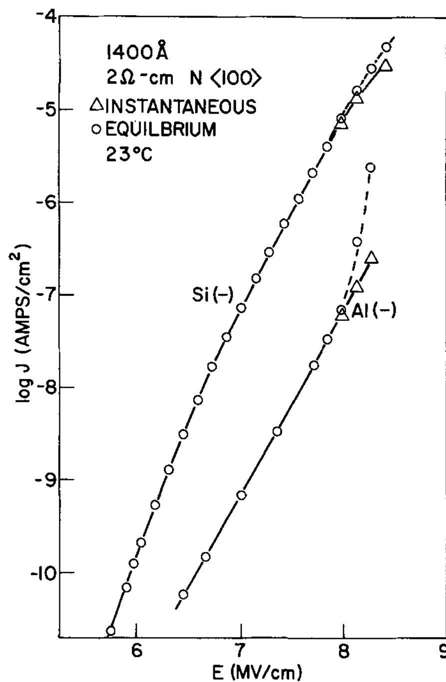

Fig. 9. Current-voltage characteristics of SiO_2

the equilibrium current are the same as they were initially. The range over which this instability could be observed was only about 4% of the entire voltage range; at any higher field the current would run away at too fast a rate to stop. Conduction measurements made on capacitor structures with a guard ring ensured that surface conduction does not affect these results. Although this instability is suggestive of joule heating in the sample, the power levels are too low to cause heating (see Appendix). Furthermore, the onset of the instability occurs at the same field for both polarities although the power levels are two to three orders of magnitude different. This field-dependent mechanism is thus more likely associated with an electronic process having a long time constant.

These steady-state I-V characteristics also shed light on the effect of breakdown measurement on the results obtained. If the breakdown voltage is defined to be the voltage at which a prescribed current flows (for example 1 μA), then the breakdown for Al(−) will always be 1 to 1.5 MV/cm higher than for Al(+). If the runaway point is defined as being the breakdown point, this polarity difference will be smaller since the instability occurs at the same field for both polarities.

Summary

The dielectric breakdown properties of thermally grown SiO_2 films show a wide variability. Depending on the measuring conditions, this variability may or may not be observed. Statistical breakdown distributions as determined from the initial breakdown event can be considerably different from distributions of final destructive breakdown when self-healing or nonshorting breakdowns occur. Initial breakdown distributions reveal a continuum of defects having different breakdown fields rather than distinct defect types while final distributions show a low-field peak which is an artifact of the measurement.

The initial breakdown distributions were largely independent of materials and measuring parameters. Metalization thickness, oxide thickness, capacitor area, and measuring circuit impedance did not affect the initial, self-healing results. Final distributions, on the other hand, were very strongly influenced by these parameters.

The differences in the two distributions are best explained in terms of the self-healing breakdown process. Only when self-healing takes place is the final distribution different from the initial. The final distribution depends on the number of self-healing breakdown events while the initial distribution is not influenced by these events. For a nonshorting breakdown to occur, sufficient energy must be stored on a capacitor to vaporize the metalization over a breakdown path. The metal thickness, oxide thickness, capacitor area, and circuit impedance are merely the parameters that affect the stored energy or the energy required for self-healing and would be expected to influence the final breakdown. It should be emphasized that the phenomena of self-healing breakdowns is not related to any fundamental property of the SiO_2 film but rather is related to the measuring parameters.

Due to the interaction of the materials and measuring parameters with the final breakdown, it is concluded that the initial distribution gives the better measure of the breakdown characteristics of the SiO_2 film itself. Furthermore, since actual devices use thicker metalization which is covered with glass, self-healing does not occur readily, and the initial breakdown is destructive and is therefore the important one. Final breakdown distributions are useful, however, for determining the maximum dielectric strength of the film and the mechanism of breakdown.

Measurements of the ramp-rate dependence of the breakdown distribution, coupled with steady-state I-V characteristics, indicate that for the aluminum-biased negatively the breakdown occurs via an electronic instability.

APPENDIX

The equation governing heating in a film per unit area on silicon with no radial heat loss is

$$J \cdot V - k \frac{dT}{dx} = dC \frac{dT}{dt}$$

where T = temperature of the film, J = current density flowing through film, V = voltage across film, k = coefficient of thermal conductivity (11) $\simeq 3 \times 10^{-3}$ cal cm^{-1} sec^{-1} °K^{-1}, C = heat capacity (11) $\simeq$ 0.4 cal/cm^2, d = thickness of film, x = vertical dimension, and t = time.

The highest observed current density from Fig. 9 was 10^{-5} A/cm^2 at about 100V, thus the first term giving the heat imput is about 2.5×10^{-4} cal/cm^2-sec. Assuming even a minimal 1°C temperature difference across the 1000Å film gives a thermal conductance loss (second term) of 3×10^2 cal/cm^2-sec or six orders larger than the heat generated. Thermal runaway seems highly unlikely under these conditions. In 5000Å films of evaporated silicon oxide Klein and Burstein (12) observe thermal runaway when the $J \cdot V$ term is about 1 cal/cm^2-sec or four orders higher than ever attained with SiO_2; in addition their thermal conductance loss should be at least one order of magnitude less than for the 1000Å films here.

Acknowledgments

The authors would like to thank Dr. J. Eldridge and Dr. N. Chou for many interesting and stimulating discussions during the course of this work and for critically reviewing the results. Dr. D. Young was consulted several times and his comments are gratefully acknowledged. They would also like to thank R. Hammer for the test probe used in breakdown measurements.

Manuscript submitted Sept. 1, 1971; revised manuscript received Dec. 10, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Dielectric Breakdown in Silicon Dioxide Films on Silicon

II. Influence of Processing and Materials

C. M. Osburn* and D. W. Ormond

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The breakdown characteristics of thermally grown SiO_2 films on Si are shown to depend on oxide thickness, substrate doping concentration, sample preparation, presence of passivating layers, and testing temperatures. The maximum breakdown strength varies as $[\text{thickness}]^{-0.21}$ below 800Å, is essentially constant from 1000 to 2000Å, and increases slightly (8%) with increasing testing temperature in the range $-196°$ to $+300°C$. The breakdown strength is only moderately affected by the dopant-type level in the starting silicon wafer: 10^{20} phosphorus atoms/cm^3 in the silicon reduced the breakdown strength in 200Å thick oxides by only 20%. The initial condition of the silicon wafer, cleaning procedure, oxidation temperature, passivation layer, and postmetalization anneal are important parameters in the control of defect-related, low-field breakdowns, while the oxidation ambient, substrate doping, oxide thickness, metalization, and measuring temperature have little or no influence on this process.

The fabrication of MOSFET devices requires the growth of SiO_2 films that will withstand moderate electric fields. Defects in the oxide that lead to dielectric breakdown reduce both the yield and the reliability of devices. For this reason, it is important to study processing and other material parameters that could lead to breakdown.

Low-field breakdown in SiO_2 films has previously been attributed to flaws or defects in the oxide or silicon by several investigators (1-5). Considerable work has been done to establish the conditions which reduce defect concentrations and thereby maximize the dielectric strength. The effects of oxide thickness (2, 3, 5-11), substrate doping (3, 4, 6), reactivity of the metal electrode (2), postmetalization annealing (2), passivating layers (2), and temperature (3, 9) have been examined, but, unfortunately, the results have not always been in agreement. For instance, it has been reported that SiO_2 breakdown strengths increase (2), decrease (3, 5-9), or are constant (10) as the oxide thickness is increased. One common problem of many past studies is that breakdown measuring conditions have not been well defined; as a consequence, defect-related breakdowns have obfuscated the results of investigations made to determine the thickness and temperature dependence of the maximum breakdown strength, and the occurrence of undetected self-healing events has distorted statistical breakdown characteristics. Consequently, earlier papers report breakdown strengths in the range 5-7 MV/cm, while later ones give values of 8-10 MV/cm. This study represents an attempt to systematically determine the effect of different processing and material variables on breakdown strengths through more carefully controlled, well-defined measurements.

Key words: dielectric breakdown, silicon dioxide films, silicon processing; MOS, silicon dioxide defects.

Experimental Procedure

Metal-oxide-semiconductor capacitors were fabricated on silicon wafers using procedures previously described (1). Both p-type and n-type substrates, having from 10^{14} to 10^{20} dopant atoms/cm^3 of phosphorus or boron, were used in growing SiO_2 films from 50 to 2000Å thick. Oxide thicknesses were measured ellipsometrically. Dry oxygen as well as oxygen saturated with water at 95°C were used as ambients, and oxidations were carried out from 900° to 1200°C. The standard processing involved dry oxidation at 1000°C of 2 ohm-cm material. Phosphosilicate glass layers were grown on some samples by depositing P_2O_5 onto SiO_2 at 800°C in an ambient of 91% N_2, 9% O_2, and a small amount (0.02-0.3%) of $POCl_3$ followed by a drive-in at 975°C. One hundred metal electrode dots were electron-gun evaporated onto each wafer through masks in a clean evaporation system, and the wafers were given a 5-min postmetalization anneal at 500°C in dry nitrogen. Aluminum, magnesium, chromium, molybdenum, gold, and platinum electrodes were added, but aluminum ones were used for most of this work. A standard metal thickness of 3000Å was used to permit self-healing breakdown events to occur (1). Statistical breakdown distributions were measured, and care was taken to measure the voltage of the first, self-healing breakdown as well as the voltage of the final destruction (1). For device applications, only the voltage of the first breakdown event is of interest since it would render a device useless; furthermore, initial breakdown distributions are used to determine the defect density as a function of breakdown field as discussed in Part I (1). The final breakdown field is important only in studying the maximum dielectric strength of a defect-free film. The measuring polarity was selected to accumulate the silicon surface thereby minimizing the voltage drop in the wafer.

Results and Discussion

Oxide thickness.—When the distribution of final breakdown voltages is measured (self-healing events ignored), the fraction of high-field breakdown events increases with increasing oxide thickness as shown in Fig. 1 [the field value of 0.8 E_{max} is used as the dividing line between low-field, defect-related breakdowns and high-field, intrinsic breakdown as discussed in the previous paper (1)]. This thickness behavior, first reported by Chou and Eldridge (2), occurs because low-field breakdown events are more likely to recover through self-healing if the oxide is thick (1). Thus for thick oxides, the breakdown events are self-healing until the intrinsic dielectric strength is attained; for thin oxides, all breakdown events are destructive. It therefore must be emphasized that the behavior in Fig. 1 is the result of a peculiarity in the measurement and cannot be related to any fundamental property of the oxide.

On the other hand, distributions of the initial breakdown voltages show a markedly different oxide thickness dependence. From the results in Fig. 2 for three different capacitor areas, it is evident that the fraction of high-field breakdowns is independent of oxide thickness, within experimental error. Even though each point represents an average of several wafers (or 400 to 1000 capacitors tested), the data show a large amount of scatter because the breakdown characteristics have a strong wafer dependency. The capacitor area dependence of the breakdown probability is consistent with films having 120 defects/cm^2. It is clear that the occurrence of high-field breakdowns does not fall off markedly, even for oxides as thin as 200Å. Films thinner than 100Å do show increased low-field failures, suggesting that nonuniformities in the Si/SiO_2 or SiO_2/Al interface regions have dimensions that are

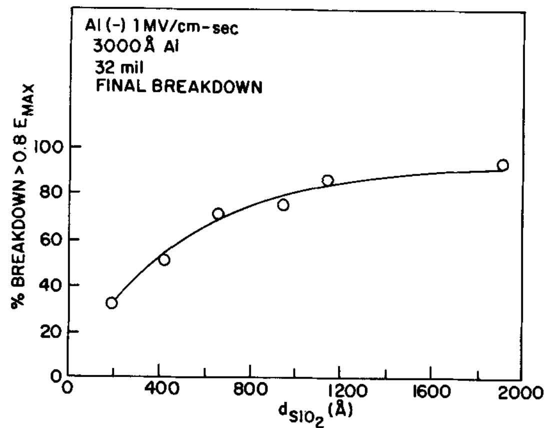

Fig. 1. Oxide thickness dependence of final breakdown distribution.

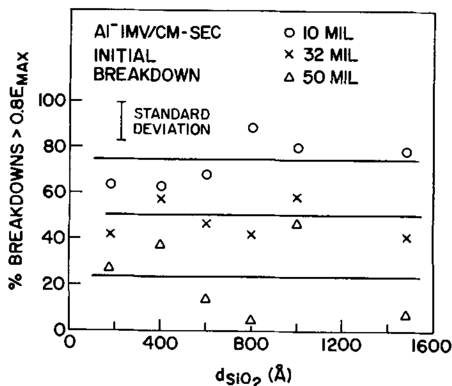

Fig. 2. Oxide thickness dependence of initial breakdown distribution for capacitors that have electrode diameters of 10, 32, and 50 mils.

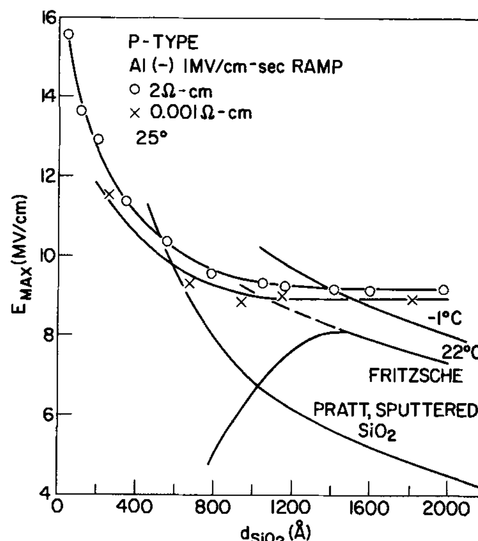

Fig. 3. Oxide thickness dependence of maximum breakdown strength.

at least a sensible fraction of ~100Å. On occasion, exceptionally defect-free ($\simeq$20 defects/cm^2) oxides were grown which did seem to show a few more defects in 200-500Å films as compared to 1000Å thick ones. The authors observed that the initial breakdown voltage distribution provides a more sensitive measure of wafer-to-wafer defect variations than does the final breakdown one. When self-healing can occur, the final breakdown distribution reflects the maximum breakdown strength of a uniform film rather than the breakdown strength of a defective area. Initial breakdown voltages give results that can be interpreted in terms of a property of the film (such as a defect density from the data in Fig. 2) while the final breakdown voltage cannot be easily related to the quality of the film.

The oxide thickness dependence of the maximum breakdown strength shows still another type of behavior (Fig. 3). The maximum dielectric strength actually increases with decreasing thickness as observed by some previous investigations (3, 5-9, 11) and as predicted by both thermal (12-13) and electronic (13-15) breakdown models. Due to the limited range of data available, it is not possible to precisely determine the relationship between E_{max} and d. With 2 ohm-cm Si and $d \gtrsim$ 1000Å, the breakdown strength is constant; however, with film less than 800Å the maximum breakdown strength varies as $d^{-0.21}$. The oxide thickness dependence is smaller for more heavily doped silicon wafers and is discussed later. This is smaller than the usual $d^{-0.50}$ dependence associated with the simplest models for electronic or avalanche breakdown but it does approximate the $d^{-0.25}$ behavior predicted by Forlani and Minnaja (15). Furthermore, O'Dwyer's (13, 16) consideration of space charge buildup due to avalanching as well as collision ionization gives breakdown strengths which do not vary with thickness as strongly as $d^{-0.50}$.

Data of Fritzsche (3) and Pratt (11) are also included in Fig. 3 for reference. Both show increasing breakdown strength with decreasing oxide thickness with the exception of Fritzsche's curve at 22°C where defects have possibly masked the intrinsic breakdown strength. Samples used in this study did not exhibit as pronounced a temperature dependence as reported by Fritzsche. In Pratt's sputtered SiO_2, $E_{max} \propto d^{-0.66}$ for films up to 10,000Å thick in contrast to the constant breakdown strength observed here above 1000Å. This thickness independence of the dielectric strength for thicker films is even more surprising in view of theoretical (13) and experimental (14, 15) evidence showing a varying dielectric strength for bulk dielectric

layers of other materials. This finding suggests that the breakdown process in thin-film structures is initiated in a small region of fixed thickness, possibly near the injecting electrode.

The data in Fig. 3 also fit reasonably well to a $E_{max}^{1/2} \propto \log (1/d)$ plot, which would indicate that the breakdown is thermal in nature. However, this alternate failure mechanism seems remote because of the low power input levels supported by the capacitor just prior to breakdown and because of the observed temperature dependence of breakdown. The high-field instability in the current-voltage characteristics prior to breakdown (1) is more likely associated with collision ionization and Fowler-Nordheim emission (16).

Substrate doping.—In the MOSFET configuration, the gate electrode extends over the diffused source and drain regions. Limited data in the literature (3, 6) (see Fig. 4) indicate that the SiO_2 breakdown strength decreases markedly as the substrate doping increases from 10^{14} to 10^{19}/cm. Extrapolation of this data, to $\sim 10^{20}$ dopant atoms/cm^3 typically used in the source and drain regions of an FET device, reveals a maximum breakdown strength in the range 3-5 MV/cm, about twice that encountered in proper device operation.

The maximum breakdown fields, obtained using 100 capacitors for each condition, are shown in Fig. 4 and 5 as a function of dopant concentration for several SiO_2 thicknesses. Clearly substrate doping has a rather small influence on dielectric strength since only a 10-20% decrease in the usual strength was observed for the extreme case of 200Å films with 10^{20} impurity atoms/cm^3. The effect was even less pronounced for thicker SiO_2 films, as summarized in Fig. 3 and 6, where the thickness dependence of the maximum breakdown field for 2 and 0.001 ohm-cm wafers with boron and phosphorus doping, respectively, are plotted. It should be noted that the behavior is roughly the same for all cases: *i.e.*, increasing breakdown strength with increasing thickness. The effect of thickness is somewhat more pronounced for the more lightly doped substrate. For thicker films (over 800Å), high substrate doping reduces the breakdown strength by a few per cent at most. The effect of doping becomes as large as 20% when the SiO_2 thickness is reduced to 200Å. This change must be considered minor, however, in light of the more pronounced SiO_2 thickness dependence which improves oxide breakdown over both heavily and lightly doped wafers. Curiously, high phosphorus concentrations have more influence than boron does. The reverse situation might have been expected since phosphorus segregates to the silicon during the SiO_2 growth while boron moves into the oxide (17-19).

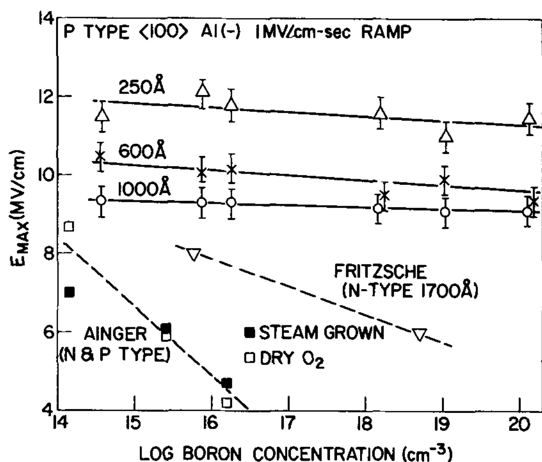

Fig. 4. Maximum breakdown strength vs. boron concentration

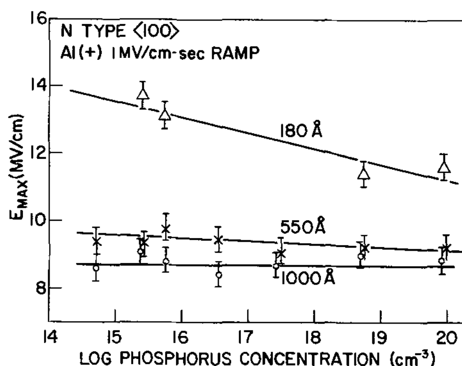

Fig. 5. Maximum breakdown strength vs. phosphorus concentration

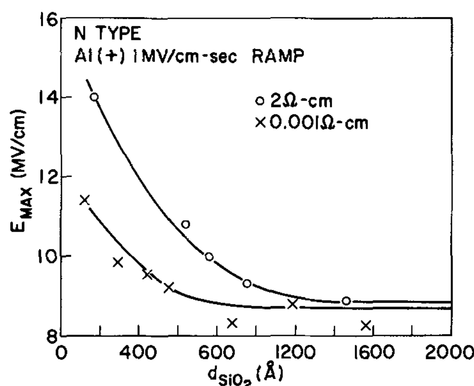

Fig. 6. Oxide thickness dependence of maximum breakdown strength with phosphorus-doped wafers.

Substrate doping had no significant effect on the statistical distribution of initial breakdown events when evaluated in terms of two statistical parameters: namely, the fractions of very low-field ($<0.2E_{max}$) and of very high-field ($>0.8E_{max}$) initial breakdown strengths. (Neither of these parameters correlated with the doping level in the silicon.) Statistical comparison did show, however, that certain wafers exhibited substantially poorer breakdown characteristics than usual. Quite possibly, surface defects associated with a given lot of wafers can be more important than dopant concentration. Although the heavily doped wafers (0.001 ohm-cm) contained spiral rings of differing color (presumably nonuniformities introduced during growth), they exhibited typical breakdown properties. For some unknown reason, the n-type samples used here were consistently poorer than the p-type ones for all doping levels. Typically there were $\sim$300 defects/cm^2 in n-type samples but only $\sim$150/cm^2 in p-type specimens, as estimated from the relationship

$$-\ln P = \rho A \quad [1]$$

where ρ is the defect density, A is the area of a capacitor dot, and P is the fraction of very high-field ($>0.8E_{max}$) breakdown events (1). The difference might be attributed to intrinsically higher defect densities for SiO_2 film grown on n-type silicon wafers or, more likely, to the use of different oxidation furnaces for n- and p-type materials.

Steady-state current-voltage measurements were taken on MOS structures fabricated from 2 ohm-cm p-type as well as on 2 and 0.001 ohm-cm n-type Si wafers. When the capacitors were biased sufficiently long for the low-field transient to decay, the resulting I-V characteristics were essentially identical. The slight differences were well within the normal wafer-to-wafer variation and are most likely explained by minor variations in SiO_2 thicknesses across the wafers. Since conduction is limited by the barrier height of the injecting electrode (20), these measurements further support the observation (21) that the barrier height does not vary with silicon doping.

It is evident that any breakdown mechanism must explain: (*i*) the effect of substrate doping increases

with decreasing oxide thickness and (*ii*) phosphorus doping has more influence with Al(+) than boron does with Al(−). The reported segregation coefficient (17-19) for phosphorus is 10 compared to 0.1-0.3 for boron. Thus the difference between dopant concentrations in the oxide and the silicon is greater for phosphorus, but the absolute dopant concentration in the oxide is greater over the boron-doped substrates. If a certain fraction of the dopant ions in the oxide were charged (*i.e.*, P^+ and B^-), the excess positive charge in the phosphorus-doped sample would enhance the electric field for the injected electrons while the negatively charged boron atoms would reduce the field. This mechanism would explain the first observation; unfortunately capacitance-voltage curves do not show any fixed charge in the oxide. In addition a charged-impurity model leading to a field enhancement would predict lower dielectric strengths for thicker films since the magnitude of the enhancement is related to the total charge in the film.

Wafer processing.—In order to determine some possible origins of defects in thermally grown SiO_2 films, specimens were prepared under various conditions including different SiO_2 growth temperatures in both O_2 and steam; the possible effects of different metal electrodes and the postmetalization anneal were also studied.

Clearly, one obvious source of oxide defects stems from surface faults (*e.g.*, scratches, pits, bumps) in the starting silicon wafer. Chou and Eldridge (2) found that an HCl vapor polish of the silicon followed by *in-situ* oxidation using rf heating resulted in far fewer defect-related breakdowns, but apparently this reduction of defects was related more to the oxidation step than to the surface etching. A strong wafer dependency of breakdown was already noted for Fig. 2 where the data are quite scattered even though the points actually represent averages over many wafers each having 100 capacitor dots. Caines and Duffy (22) have correlated the position of breakdown in pyrolytically grown Al_2O_3 with defects or contamination of the starting silicon wafer.

In order to better understand the role of the substrate in breakdown, wafers from three suppliers were cleaned, oxidized, and metalized in the same run. Large area electrodes (50 mil diameter) were used to raise the frequency of defect-related breakdowns. The resultant defect densities (computed using Eq. [1]) were 29, 16, and 27 defects/cm^2 $\pm$ 5/cm^2 for the three wafer sources; it thus appears that defects related to the silicon polishing can vary slightly from one lot of wafers to another. However, the defect densities that can be attributed to silicon defects here ($\sim$25/cm^2) are only a fraction of the defects computed from the data of Fig. 2 (*i.e.*, 120/cm^2) and from the experiments with high dopant concentrations (150-300/cm^2). Thus, much of the wafer dependency of the defect density apparently arises from processing variations such as: solvent residues left on wafers during cleaning, incomplete drying, or dirty or partially devitrified furnace tubes. For instance, wafers given a cleaning sequence of trichloroethylene, isopropyl alcohol, and HF solution had 160 defects/cm^2 while control wafers had only 50/cm^2 after cleaning with NH_4OH-H_2O_2, HCl-H_2O_2, and HF. It has been also observed on many wafers that low breakdown capacitors are spacially clustered indicating the presence of either a larger defective area or a line defect. A large defect area ($\gtrsim$ 200 mil diameter) would more likely be due to processing than to wafer defects, although line defects could be due to scratches or crystallographic steps. Scratches introduced during handling have been observed to cause clustering of low-breakdown capacitors; otherwise, microscopic examination at 500 magnifications has generally failed to detect this defective area.

Laverty and Ryan (5) have previously reported an effect of the oxidation temperature on breakdown distributions. Unfortunately, their distributions were not very similar in shape to those encountered in other studies (1-3); they represent very substandard oxide films. This effect, as found on oxide films typical of this study, is shown in Fig. 7 where the oxidation temperature has very little effect on films over 1000Å thick; for thinner films higher oxidation temperatures promote defects. The effect of oxide thickness becomes more important as oxidation temperature is increased. When grown at 900° or 1000°C, the 200Å films in this particular lot had about 15% more low-field breakdowns than 1000Å films; when grown at 1200°C, they had 45% more low-field breakdowns.

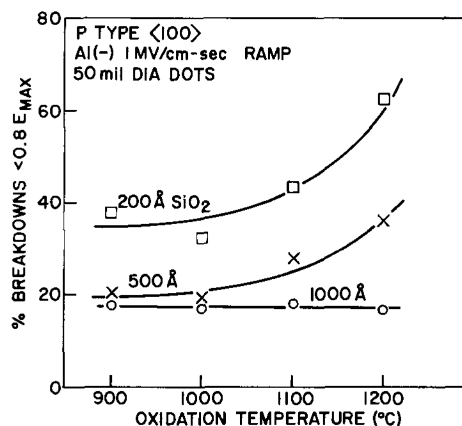

Fig. 7. Effect of oxidation temperature on breakdown distributions.

Since oxidation temperature influences breakdown, one might expect to find a correlation of breakdown characteristics with oxidation ambient. Strangely enough it does not matter whether oxidation is done in dry O_2 or in oxygen saturated with water at 95°C. No difference in defect densities could be seen in oxides from 200 to 1000Å thick grown under either condition at 1000° or 1200°C. These findings are in agreement with the more recent results of Fritzsche (3), but disagree with those of Ainger (6) and Deal (23), who reported much lower dielectric strengths for their samples. High-temperature annealing in nitrogen (15 min at 1000°C), following oxidation, increased defect densities by 50% in 1000Å films and by 400% in 200Å ones. Cleaning of the oxidation tube at 1150°C with a 6% HCl/O_2 mixture (24-25) followed by oxidation at 1150°C resulted in a 60% decrease in defect density. Other work (26) has shown that oxidation in 1% HCl/O_2 at 1000°C is likewise effective in reducing the number of defects causing dielectric breakdown. These results suggest that the improved breakdown characteristics seen with HCl vapor-polished wafers (2) may be due to the presence of HCl in the system rather than due to a better surface polish.

Several oxide films were deliberately contaminated with NaCl, during or after growth, to gain an understanding of the role contaminant ions play in defect formation and growth. Films having 10^{14} Na^+/cm^2, evaporated onto the SiO_2 prior to electroding, showed normal breakdown behavior when the aluminum electrodes were biased negatively; for Al(+) however the peak of the breakdown distribution was shifted to a lower field as seen earlier by Raider (27). Other films were grown to half their final thickness, were contaminated with 10^{14}/cm^2 sodium ions, and were then grown to the desired final thickness. These films showed 5 $\times$ 10^{12} mobile charges/cm^2. It was not determined if the remaining sodium evaporated during the final growth period or if it was left immobile in the film. Breakdown measurements with Al(−) showed no degradation while Al(+) slightly lowered the field at which the peak in the distribution occurred; nevertheless, the fraction of lower field or defect-related breakdowns did not increase due to the presence of the sodium.

The oxidation temperature and the nitrogen annealing dependence of the defect density support a model where a metal excess in the oxide favors increased numbers of defects. As the oxidation temperature increases or after a high-temperature N_2 anneal, the oxygen content of the oxide would be expected to be reduced; both conditions give high defect densities particularly for thin films. The rate of oxide growth is irrelevant as seen with the steam oxidation. Although crystallization was suspected, the data do not support this mechanism since both steam and NaCl should enhance recrystallization.

The choice of metallization material did not influence breakdown to any significant extent either. When biased negatively, magnesium, chromium, aluminum, molybdenum, gold, and platinum all gave similar breakdown distributions with a maximum breakdown strength of over 8 MV/cm. However, conduction measurements (28) show many orders of magnitude difference in current levels at a fixed field for injection from magnesium and for gold verifying the Fowler-Nordheim, barrier-height-limited conduction mechanism.

The postmetalization annealing treatment (5 min at 500°C in N_2) resulted in a slight improvement of oxide integrity by reducing the defect density from 32 defects/cm^2 to 11/cm^2 on 1000Å test films. This reduction of defects is believed to be due to the elimination of interface states, which if present, could create internal fields which would then enhance the applied field. Thus it appears feasible that at least some of the oxide defects are electrically charged clusters rather than structural or geometrical defects. Chou and Eldridge (2) report that a short anneal improves the shape of the final breakdown distribution and that a more protracted anneal at 500°C would induce structural defects which are responsible for shorts. Figure 8 extends the temperature range of that work down to 200°C. No measurable effect is observed after 800 hr at 200°C while at 300°C annealing doubles the defect density in only a few hundred hours. Even at 250°C only a minor change is observed after 900 hr. The degradation after prolonged annealing at 500°C in the work of Chou and Eldridge was related to the reactivity of the metal used for electrodes. Likewise with this lower temperature testing the onset of defect formation at 300°C correlates well with the onset of injection of aluminum into SiO_2 (29). Samples made with Pt electrodes do not show the pronounced deterioration at 300°C. The degradation in breakdown characteristics is dependent on oxide thickness as well as temperature; 200Å thick oxides show a high defect density after a few hundred hours at 250°C.

Oxide passivation.—Earlier work (2) has shown that a thin phosphosilicate glass layer was effective in reducing the low-field or so-called secondary breakdown events and hence in reducing the measured defect density. Furthermore the PSG increased the resistance of undoped and Na^+-doped wafers to extended annealing in N_2 at 500°C. The improved properties are explained by a continuous film of PSG over the underlying SiO_2 thereby filling pinholes or cracks in the film. The thickness and concentration of the passivating PSG required to eliminate defects has not been fully explored however. In this investigation PSG layers were deposited on both good (<30 defects/cm^2) and poorer (>100 defects/cm^2) films of SiO_2. The substandard films were fabricated with an organic cleaning step, and oxidation was followed by a 1 hr anneal in N_2 at 1000°C; both conditions were previously shown to increase the number of defects in the film.

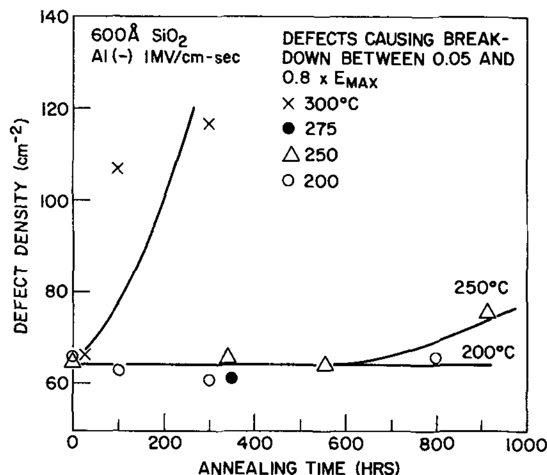

Fig. 8. Effect of extended annealing on defect densities

Table I. Effect of phosphosilicate glass layers on defects causing dielectric breakdown in SiO_2 films

PSG thickness (Å)	P_2O_5 concentration (%)	Defect density* (cm^{-2})
0 (starting oxide)	0	15
0 (30 min 975°C, N_2)	0	37
60	2.1	19
60	3.7	17
60	4.0	12
60	5.4	6
15	3	22
35	3	18
60	3	17

* ±30% as measured on 500Å SiO_2 films.

The results obtained with the good oxide are summarized in Table I. One immediately sees that the 30 min nitrogen drive-in at 975°C more than doubles the defect density; hence, it is not surprising that in many cases (when PSG thickness and concentration are low) the defect density is higher in glassed films than it is in the starting films. Nevertheless, the defect density does decrease with both increasing PSG thickness and P_2O_5 concentration in the glass. At least 60Å of 4% P_2O_5 glass is needed to obtain films that are substantially better than the starting films. Defect densities less than 5/cm^2 were never observed even with 200Å of 9% P_2O_5 glass layers. Apparently these defects (5-10/cm^2) were due to defects in the wafer and could not be eliminated with PSG. We have already shown that wafers obtained from different sources result in defect densities that vary by over 10 defects/cm^2. It should also be emphasized that the improvement in breakdown characteristics seen with thicker PSG is very substantial particularly in eliminating low-field ($<0.2E_{max}$) breakdown events. A PSG layer, 10% of the total oxide thickness, can give an 80% improvement in the breakdown strength of a capacitor. Apparently very deep pinholes or cracks in the SiO_2 layer are filled with the PSG. Since 60Å of PSG is needed to realize better films, it appears that the pinholes are of the order of 100Å in diameter.

With the poorer films ($\simeq$100 defects/cm^2), the PSG addition markedly reduced the defect density. The defect density dropped to 60/cm^2 with 60Å of 2% P_2O_5 and to 40/cm^2 with 60Å of 5% P_2O_5 glass. Although this improvement is substantial, it is not as large fractionally as the improvement seen with good starting films. It is apparent that the effectiveness of PSG in improving breakdown characteristics is closely linked to the condition of the starting oxide films.

Temperature.—The temperature dependence of the breakdown strength is expected to be very helpful in analyzing the nature of the intrinsic breakdown mechanism. Fritzsche (3) reported that the intrinsic maximum dielectric strength decreases with increasing temperature from 0° to 80°C in much the same way as amorphous quartz. Chou and Eldridge (2) found very little change in breakdown characteristics in the 25°-150°C range. Korzo (9) on the other hand reports an increasing breakdown strength up to about 25°C followed by a slight drop at 50°C; his measurements were on oxides grown by pyrolytic decomposition of

ethylates and had unusually low over-all breakdown strengths leading one to suspect defect-related breakdown.

To evaluate the effect of measuring temperature, a matrix of samples with 200, 400, 600, 800, 1000, and 1500Å SiO_2 layers were tested at −30°, +25°, 70°, 130°, and 200°C; in addition, several wafers were also measured at −196° and +300°C. Figure 9 gives some typical results showing a very slight increase ($\simeq$8%) in maximum dielectric strength on going from liquid nitrogen to 300°C. Breakdown distributions were also only slightly affected by temperature. The defect density could not be correlated with measuring temperature other than by noting that the fraction of very low-field ($\leq 0.2E_{max}$) events increased by a few per cent on going from −30° to 185°C. These results further support the conclusion that most defects are present in the MOS structures after fabrication, and, except for the lowest field breakdown, are largely unaffected by measuring temperature.

The temperature dependence of breakdown supports an electronic rather than thermal mechanism for breakdown. With thermal breakdown, models indicate that $E_{max}^{1/2}$ should decrease linearly with increasing temperature (13), a trend that is contrary to the present data. Although it will not be dealt with in detail here, it should be remarked that the analysis of the temperature dependence of electronic breakdown is by no means complete. This dependence enters into electronic models via the temperature dependence of various ionizing processes that can take place in the oxide layer and is presumed to have a small effect on E_{max}. Thus the behavior observed in Fig. 9 is consistent with most electronic breakdown models and inconsistent with the temperature dependence expected for thermal breakdown. A ramp-rate dependence of the breakdown distribution similar to that reported earlier (1) was observed over the entire temperature range giving further support to the electronic breakdown model. The observation of the ramp-rate dependence at liquid nitrogen temperatures suggests that a space charge redistribution in the oxide occurs and is due to electronic rather than ionic charges.

Summary

Many processing and material variables are important to the breakdown characteristics of thermally grown SiO_2 films. The condition of the starting silicon wafer, the wafer cleaning sequence, the oxidation temperature, the passivation layer, and the postmetalization anneal are important parameters in the control of defects that have low breakdown strengths. No single factor was ever responsible for all of the defect-related breakdowns although poor wafer cleaning would substantially decrease yield. A number of the defects can be associated with the wafer as determined by comparison of wafers from different sources; others can probably be associated with electrically charged clusters that are neutralized during the postmetalization anneal, and the rest can be attributed to defects introduced during growth. A 1200°C oxidation substantially increases the defect density in 200Å films.

Surprisingly enough, oxidation ambient (wet or dry O_2), substrate doping, oxide thickness, metalization, and temperature had little or no influence on defect-related breakdowns. High temperatures seemed to favor more low-field breakdowns although the increase was only a few per cent for a 200°C increase. Even though the maximum breakdown strength increased with decreasing oxide thickness, the number of defect-related breakdowns remained constant down to 200Å. Below that thickness the percentage of low-field failures increased. A very strong wafer dependence was observed, however, and several lots of wafers showed poorer than average characteristics for thin samples. High oxidation temperatures did aggravate the influence of the thickness dependence on breakdown distributions.

Oxide thickness, temperature, and substrate doping influenced the maximum breakdown strength. Films grown on 2 ohm-cm p-type wafers from 60-800Å followed the relationship $E_{max} \propto d^{-0.21}$; above 1000Å the dielectric strength was 9.2 MV/cm. More heavily doped wafers resulted in a less pronounced thickness dependence. The breakdown strength increased very slightly (8% over a 500°C range) with increasing temperature. This behavior points to an electronic breakdown mechanism; the observation of a high-field instability in the current voltage characteristics (1) provides experimental evidence of a space charge redistribution possibly due to internal collision ionization (13, 16). Substrate doping had only a minor (20%) effect on dielectric strength and was most noticeable for thinner films although phosphorus doping of the silicon wafers had a greater influence than boron doping.

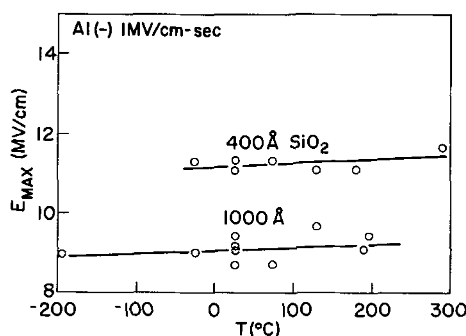

Fig. 9. Effect of measuring temperature on maximum breakdown strength.

Electrical Conduction and Dielectric Breakdown in Silicon Dioxide Films on Silicon

C. M. Osburn* and E. J. Weitzman

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Conduction through SiO_2 films, thermally grown on Si substrates, was found to take place via a Fowler-Nordheim (F-N) tunneling mechanism, after an initial transient current associated with trapping of charge, mobile ions, and space charge redistribution has died away. The temperature dependence of the steady-state F-N current decreases with increasing applied field and was found to be smaller in magnitude than previously reported. Typical post-metalization annealing treatments (*e.g.*, 5 min at 500°C in dry N_2) lowers the conductivity of the MOS capacitor structures by two to three orders of magnitude, an effect that can be attributed to the elimination of either traps or fixed charge distributed throughout the oxide. For applied fields larger than 8 MV/cm, a current instability arises which can lead to dielectric breakdown. For a wide range of different electrode materials, the onset of this instability appears to correlate well with the temperature and oxide thickness dependences of breakdown, as observed earlier (10). These findings are discussed in terms of a model which suggests that carriers can be generated and redistributed by collision ionization processes within the oxide.

Electrical conduction in SiO_2 films grown on Si substrates has been studied by several investigators (1-9) largely because of the importance of this insulator in silicon transistor technology. In particular, it is well known that metal-oxide-semiconductor FET's are operated with extremely large electric fields (*e.g.*, 1 to 2 mV/cm) so that during testing dielectric breakdown can substantially lower the performance of these devices. As part of a continuing effort to investigate the electrical integrity of thermally grown SiO_2 films (10), prebreakdown current-voltage characteristics become important for gaining insight into the major breakdown mechanisms and for relating various materials and processing parameters to the resultant intrinsic dielectric strength.

Since several authors (11-13) have recently reviewed the various conduction mechanisms taking place in thin insulating films, this topic will not be detailed here other than to remind the reader that it is essential to distinguish between bulk-limited and electrode-limited conduction processes. In general, electronic conduction, space-charge-limited conduction, nonblocked ionic conduction, and impurity conduction are bulk limited while Fowler-Nordheim (F-N) tunneling and Schottky emission are electrode limited. Since SiO_2 is such an effective insulator, measurements of conduction in Metal/SiO_2/Si capacitors are highly sensitive to preparation and purity; consequently, results vary widely from one investigator to another. Earlier studies (3-5) indicated that the process was ionic in nature due to the presence of mobile impurities. Refinements in processing of MOS capacitors reduced the impurity content (notably Na^+ ions) to the point where electronic conduction could be observed, wherein the currents were believed to be space-charge-limited modified by traps (6) or space-charge-limited with tunneling at the electrodes (7). Later, multiple conduction states were observed in both thermally grown (8) and pyrolytically deposited SiO_2 films (9), and the switching from one state to another was linked to the presence of certain impurities in the oxide. Finally, conduction through high-purity SiO_2 has been demonstrated to occur via a Fowler-Nordheim tunneling mechanism (1-2).

This paper deals with conduction through high-purity SiO_2 in MOS capacitors and its relationship to dielectric breakdown. The parameters describing F-N conduction are evaluated from experimental data, particularly the temperature and voltage dependence of the current. Finally an instability in the conduction is compared to the oxide thickness and temperature dependence of breakdown.

Experimental Procedure

Silicon wafers, 2 ohm-cm p-type as well as 2 and 0.001 ohm-cm n-type, were cleaned in solutions of NH_4OH-H_2O_2, HCl-H_2O_2, and HF and then oxidized in dry O_2 at 1000°C to form oxides from 200 to 1500A thick. An array of 100 metal electrodes, 32 mils in diameter, were electron-gun evaporated through metal masks. Aluminum, chromium, magnesium, molybdenum, gold, and platinum were deposited for this purpose since they cover a wide range of electrode work functions. The MOS samples were subsequently annealed for 5 min at 500°C in dry N_2 in order to remove radiation damage from the evaporation step (14). Capacitance-voltage tests made on electrothermally stressed capacitors indicated typical mobile ion concentrations of less than 5×10^{10} cm^{-2}.

Current-voltage characteristics were measured with a Keithley 416 picoammeter. For measurements from room temperature to 325°C, the samples were placed on a small hot stage inside a shielded box with a dry N_2 ambient. Measurements were also made in liquid nitrogen. Care was taken to ensure that external leakage was negligible. Special measuring procedures were required to obtain repeatable results because the I-V characteristics were not at first reproducible (see Fig. 1). Note that the applied field must be cycled between

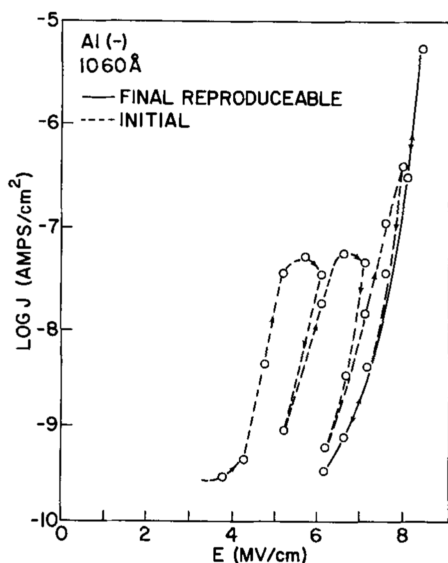

Fig. 1. Current-voltage characteristics of typical MOS capacitor showing cycling needed to achieve reproducibility.

low and high values several times before the I-V curves for increasing and decreasing fields coincide. This same degree of reproducibility could be attained by stressing the capacitor at moderately high fields ($E \simeq 7$ MV/cm) for several hours while the current decreased with time to a steady-state value. Although this behavior was similar to ionic polarization effects frequently seen in other glasses, its appearance at temperatures as low as that of liquid nitrogen pointed to an electronic rather than ionic polarization in this case. No appreciable flatband voltage shift ($< 5 \times 10^{10}$ charges/cm^2) was seen as a result of cycling or prestressing.

Using thin metalization ($<$ 3000Å) so that weak spots or flaws in the oxide would be eliminated by self-healing breakdown processes (15), it was possible to obtain on a wafer, I-V characteristics for several capacitors that were within a few per cent of one another. This high degree of reproducibility, coupled with earlier observations that the current scaled with the capacitor area (1), indicated that the measured current was distributed over the entire electrode area and not localized.

Results and Discussion

Transient conduction.—The temperature and the field dependencies of the initial current transient were studied in order to determine the origin of the decay seen here. Previous workers have reported similar transients and have attributed them to ion motion (2, 5, 17) notably sodium or protons, charge trapped or released by irradiation (18) or charge storage (4). Not surprisingly, the transient decay rate increased at higher applied voltages. The decay was not accompanied by a current transient in the opposite direction when the voltage was reduced to zero as is often seen (19) when polarization occurs. The charge levels involved in the decay, as determined by integration of current-time plots (16), were typically 10^{11}-10^{14}/cm^2 and were found to increase with increasing voltage as might be expected with trapped charge and in contrast to mobile charge. It thus appears that the transient is due to trapped charges being released at high fields. The trap depth determines the field required for release. It should be noted that a current decay is observed at a high field after steady-state conduction was attained at a lower field, giving further evidence that the transient species is released by the high field. The almost linear increase in the transient charge concentration, with applied field in one sample from 3 to 7 mV/cm, indicates that the trap density must be uniformly distributed over this energy range in that sample. The transient behavior is observed for both polarities of applied field with roughly the same amount of charge involved. Nevertheless, capacitance-voltage measurements have not been able to detect an appreciable flatband voltage shift ($>$ 0.1V) after the decay has occurred. Thus if traps are involved in the process, they must be located near the metal SiO_2 interface as concluded earlier (4). Calculations show that for these traps to account for 10^{14} transient charges/cm^2, they must be located within 0.2Å of the metal-oxide interface for less than 0.1V flatband voltage shift in a 1000Å thick film. In addition, 10^{14} charges/cm^2 in the oxide would create fields up to 50 MV/cm. It appears more reasonable to postulate a lower number of traps (*i.e.*, 10^{11}-10^{12}/cm^2); the field created by these trapped charges could then enhance the injected current. The transient would thus be due to two components: (*i*) mobile charge released from traps and (*ii*) injected electron current due to an internal space charge region.

The shape of the current decay curve shows a large variability although it is similar to an exponential curve. A single time constant τ in $I \propto I_0 e - t/\tau$ does not satisfactorily describe the data at room temperature. Instead two different time constants must be considered. Likewise the data could be represented by $I \propto \beta_1 t^{-1/2} + \beta_2 t^{-1/2}$ as might be expected with ionic motion of different species (3, 17). The time constant for the fast decay in one sample was about 15 sec at room temperature, about twice that at -200°C and half that at 75°C, making an exponentially activated process unlikely since it would have such a low activation energy ($\sim$0.01 eV). These time constants are not within the range observed for sodium or proton release from traps as reported by Hofstein (17) and probably represent electronic traps. The slow decay ($\tau \simeq 150$ sec at 23°C) is within the range described for ionic motion although its smaller contribution to the total current prohibited accurate temperature measurements. Likewise the complexity of this current decay made it impractical to get estimates of the distribution of trap energies. Occasionally with the metal biased positively, the current would increase with time for the first 50 sec and then decay. At this time the origin of this behavior is not known although the characteristics are similar to those involving space-charge-limited (SCL) transients (5, 17, 20) with a very long transit time. The lack of a steady-state current after the peak (rounded cusp for SCL transient) indicates trapping is important.

Conduction mechanism.—The conduction process is not affected by the oxide thickness in the 200-1500Å range since the applied fields required to produce given current densities are independent of thickness, in accord with the earlier results reported by Lenzlinger and Snow (1) (see Fig. 2). Furthermore, to within experimental error, the currents are independent of substrate type and dopant concentration for injection from either electrode. Figure 3 shows typical I-V characteristics for various electrode metals; the curve for injection from the bulk silicon is independent of the counterelectrode material. The spread in behavior is indeed very large. For the most part, the logarithm of the current density (J) is roughly proportional to the applied field (E), although at higher fields a deviation from this behavior is observed with Mg electrodes. In addition, for high-field injection from Al, Mo, Pt, and Si (at least), another type of instability occurs in which the current increases with time until a stable value is reached within a few minutes. Figure 4 illustrates this effect in more detail for a 1400Å-thick oxide grown on a 2 ohm-cm n-type wafer; since the same type of behavior was seen with p- and n-type substrates, it can be concluded that this particular instability is not due to minority carrier generation effects taking place in the Si depletion region. This high-field instability occurs at roughly the same field (8 MV/cm) independent of electrode

material although the current levels may be considerably different when it is observed.

Both the Fowler-Nordheim and the Schottky conduction mechanisms are highly sensitive to the barrier height at the injecting electrode, and hence to the metal as observed in Fig. 3. The distinction between Fowler-Nordheim and Schottky emission are best seen with the energy level diagram of Fig. 5a. The energy difference between the metal Fermi level and the oxide conduction band presents a barrier (ϕ) for the electrons in the electrode to enter the oxide which is triangular-shaped when an electric field is applied. Electrons can tunnel through the barrier from the metal Fermi level (Fowler-Nordheim) or can be emitted over the barrier by thermal emission (Schottky). The intermediate conduction mechanism is thermally assisted electrode tunneling whereby thermally excited electrons tunnel through the upper portion of the energy barrier. The actual barrier is not a sharp tri-

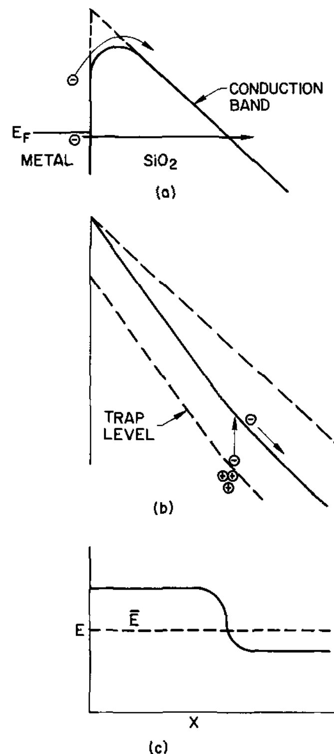

Fig. 5. Energy and field distribution near metal-silicon dioxide interface. angle but is curved and has a height less than ϕ because of image-force lowering. The image-force lowering term arises from the potential redistribution in the oxide as a result of image charge induced in the metal from charge in the oxide.

The Fowler-Nordheim tunneling current J_{FN} into a solid with a barrier height of ϕ with image-force lowering is given by (1)

$$J_{FN} = (q^3E^2m/8\pi h\phi m^*)\ [1/t^2(y)]\ [\pi CkT/\sin(\pi CkT)]$$
$$X \exp\{-[4(2m^*)^{1/2}\phi^{3/2}/3\,hqE]\ v(y)\} \quad [1]$$

where m^* is the electron effective mass in the SiO_2, E is the applied field, q, m, h, k are the electronic charge, electron mass, Planck's constant, and Boltzmann's constant, respectively, and

$$C = 2(2m^*\phi)^{1/2}\,t(y)/hqE \quad [2]$$

$$y = 1/\phi\ (q^3E/4\pi\,\epsilon_r\,\epsilon_0)^{1/2} \quad [3]$$

with ϵ_r being the relative dielectric constant of SiO_2 and ϵ_0 the permittivity of free space. The correction for image-force lowering appears in the elliptic integrals $t(y)$ and $v(y)$ and are tabulated elsewhere (21).

The Schottky current J_S is given by (13, 20)

$$J_S = (4\pi mqk^2/h^3)\ T^2 \times \exp\{-[\phi - \sqrt{E}\,(q^3/4\pi\,\epsilon_r\,\epsilon_0)^{1/2}]/kT\} \quad [4]$$

This Schottky conduction mechanism can be rejected for several reasons: (*i*) It predicts an exponentially activated temperature dependence which is not observed in Fig. 6 and 7. (*ii*) The slope $d \log J_S/d\sqrt{E}$, at room temperature gives a dielectric constant of only 0.35, well below even the optical value of 2.2. (*iii*) Temperature-field plots (13) giving regions for Fowler-Nordheim tunneling, thermally assisted tunneling, and Schottky emission show that Fowler-Nordheim conduction is expected for the conditions in this work with the possible exception of the highest temperature (~300°C) at lower fields where conduction does appear to vary exponentially with reciprocal temperature. The intermediate mechanism of thermally

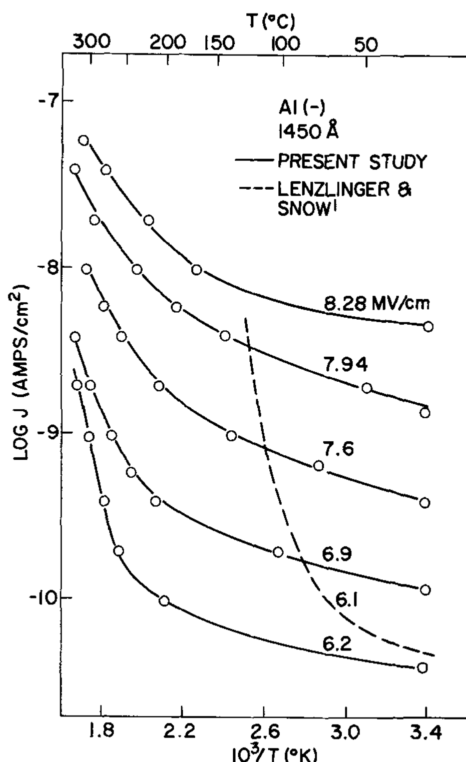

Fig. 6. Temperature dependence of conduction for electron injection from aluminum.

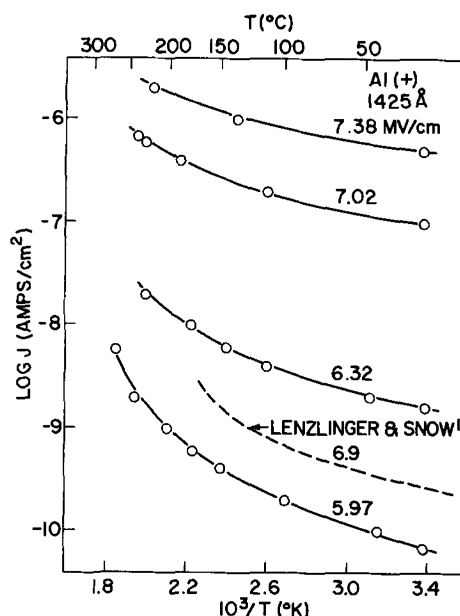

Fig. 7. Temperature dependence of conduction for electron injection from silicon.

assisted tunneling can also be ruled out since that current should vary roughly exponentially with $1/T$.

For a given field, the currents observed in this study were one-to-three orders of magnitude greater than those reported by Lenzlinger and Snow, with the exception of aluminum injection where it was two orders less (see Fig. 3). It should be noted that a layer of phosphosilicate glass (100Å, 5% P_2O_5) under the aluminum contact did not change the normally observed current. Within the limits of experimental error, the present data would fit Eq. [1]; furthermore, Lenzlinger and Snow's observation of the absolute magnitude of the current being one order of magnitude low can be explained by only a few per cent error in barrier height, effective mass, or even oxide thickness which seems very reasonable in view of their discrepancies in effective mass.

Due to the dominant exponential term in Eq. [1], it was not possible to independently determine the barrier height and the effective mass from the data but only their product. Lenzlinger and Snow used additional barrier height measurements to determine the effective mass; they found a best fit for a mass ratio of about 0.43, but this ratio varied by over 10% depending on the metal electrode, and it was not sufficient to explain their observed temperature dependence.

Table I gives the slope of the J/E^2 *vs.* $1/E$ plot for injection from various metals in column 2; column 3 gives the barrier height if one assumes $m^*/m = 0.5$ with the standard deviation for the least squares fit

Table I. Conduction and breakdown strengths for injection from various metals

Metal	$\phi^{3/2}\cdot\sqrt{\frac{m^*}{m}}\cdot v(y)$	Barrier height, eV: This study†	Barrier height, eV: Literature	Breakdown strength E_{max} (mV/cm)
Mg	1.7	1.9 [0.3]	2.4 (1) 2.25-2.5 (2)	8.3
Si (bulk)	3.6	3.1 [0.1]	3.25 (1) 3.15 (18, 22), 3.29 (23)	8.9

† Assuming $m^*/m = 0.5$.

given in brackets [the correction for image-force lowering, from $v(y)$, is about 7% using the optical dielectric constant of 2.2]. The barrier heights are within 10% of those reported (1, 18, 22-24) elsewhere for Si, Cr, Mg, and Al; the agreement for the Au barrier heights is not as good where the experimental error is large. Despite the high work function of Pt, the Pt-SiO_2 barrier was only 3.2 eV high, as determined by I-V measurements. Quite possibly this unexpectedly low value as well as differences in conduction levels between this work and that of Lenzlinger and Snow can be explained in terms of impurities at the M/SiO_2 interface altering work functions. As shown by the measured barrier heights in Table I, there is a reasonable spread in the values from one study to another.

The most obvious temperature-dependent term in the Fowler-Nordheim conduction equation is $(\pi CkT)/\sin(\pi CkT)$. By adjusting the effective electron mass, Lenzlinger and Snow could fit their data to that functional form for one given field strength but then show that such a mass adjustment is unwarranted. They subsequently calculated the temperature dependence of the barrier height that would give such results. An examination of the temperature dependence of the conduction in Fig. 6 and 7 for several different field strengths show: (*i*) the temperature dependence is smaller for higher fields; (*ii*) the Si(−) polarity condition gives a more pronounced variation with temperature than the Al(−) one; and (*iii*) at lower fields, the current at higher temperatures begins to increase very rapidly. On the basis of these observations, it seems that more than one term in Eq. [1] is temperature dependent. Although the $\pi CkT/\sin(\pi CkT)$ term does give a more pronounced temperature dependence at low fields since $C \propto 1/E$, it does not quantitatively describe the variation of temperature dependence with field. In the exponential term, m^*, ϕ, and the dielectric constant in $v(y)$ could vary with temperature; a variation in barrier height seems most likely to explain the second observation. Table I also gives the least squares slope of the conduction for a few temperatures and shows that the exponential term in Eq. [1] decreases with increasing temperature. The rapid increase in current at high temperature and low field can be accounted for by either the $\pi CkT/\sin(\pi CkT)$ term which becomes infinite at $CkT \rightarrow 1$ or by a change of conduction mechanism to one that is activated such as Schottky emission or even bulk conduction; Faradaic currents are probably too small to make any contribution at these temperatures (25). Higher temperature measurements will be necessary to resolve this conduction mechanism. Although the temperature and field dependence of the current are more complex than originally reported (1), the magnitude of the variation is smaller particularly with Al(−). This may be attributed in part to a transient species that required special precautions to insure steady-state results as discussed earlier. Often a very large temperature dependence of conduction was observed on initial thermal cycling. These data were not repeatable however, and the final reproducible data showed much less variation with temperature.

Annealing of the SiO_2 films after metalization had a very important effect as shown in Fig. 8 by markedly reducing the current resulting from a given applied field for electron injection from both the Al and the Si contacts. Additional heat treatment (5 min or more at 500°C) did not further shift the 10 min, 500°C curves by more than a few per cent. Analysis of the data reveals that the Fowler-Nordheim slopes of the unannealed specimens give barrier heights for both electrodes that are 1.5 eV lower than those of annealed specimens. It seems unlikely that this is a true barrier height lowering due to impurities or surface states at the injecting interface since the apparent barrier lowering is the same for the Si/SiO_2 interface as for the Al/SiO_2 one. Instead two alternate models are proposed. First there is a trap level 1.5 eV below the conduction band in SiO_2 that can be annealed out; electrons are injected into this level with the unannealed samples and have sufficient mobility to travel along this trap level through the sample. It should be noted that trap levels (18) 2.0 eV below the conduction band have been reported and that irradiation has changed barrier heights at Si-SiO_2 and Cr-SiO_2 interfaces (23). In the second model, unannealed charge trapped in the bulk varies the potential distribution within the oxide resulting in a nonlinear potential *vs.* distance profile thereby altering the shape of the tunneling barrier. If the trapped charge is somewhat uniformly distributed throughout the oxide, the tunneling barriers at both interfaces will be equally reduced. Flatband voltage shifts during the anneal show relatively small changes in charge ($\sim 10^{12}/cm^2$) compared to the amount of charge necessary to Schottky lower the barrier by 1.5 eV ($\approx 2 \times 10^{13}/cm^2$); nevertheless, localized charges are not detected by the flatband voltage measurement. Without additional measurements it is not possible to determine which model is more correct. Since samples metalized from a tungsten filament instead of with an electron gun did not show as large an effect of annealing, the traps or oxide charge are presumed to be induced during metalization rather than present in as-grown oxide films.

Dielectric breakdown.—The high-field current instability is of particular interest in the study of dielectric breakdown. Figure 9 shows a typical current *vs.* time plot in this region of instability. The time constant associated with this current buildup appears to decrease slightly as the applied voltage increases. This instability is observed over only a small upper field region with a width of about 5% of the applied field making it somewhat difficult to observe experimentally. As Fig. 4 shows, there is a voltage at which the steady-state I-V curve becomes vertical and results in breakdown. The instability in Fig. 9 also occurs at a comparable rate when the sample is immersed in liquid nitrogen making a thermal breakdown mechanism unlikely. Likewise, any redistribution of space charge by motion of ionic carriers seems unreasonable particularly since the low-field I-V characteristics are reproducible after the conduction has been unstable. When the field is reduced after a period of time in the unstable region, the current relaxes to its original low value at that field; the time constants for this relaxation are about the same at −196° and 23°C. Capacitance-voltage flatband measurements made immediately after the instability had occurred showed at least 0.2V shift for the M(−) instability and $\simeq$1V for the M(+) one. This C-V shift apparently indicates posi-

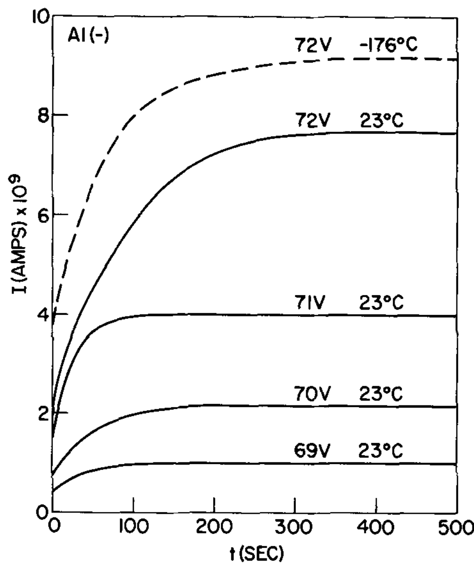

Fig. 9. Time dependence of current instability for various applied voltages.

tive charge in the oxide near the injecting electrode as a result of the high-field instability.

This onset of this instability correlates very well with the maximum breakdown strength [measured with a voltage ramp (10)] in both thickness and temperature dependence. Figure 10 shows the onset current increasing markedly with decreasing oxide thickness for films less than 800Å thick and remaining constant for thicker films. Data showing the increasing dielectric strength with decreasing thickness below 800Å are included for reference (10). The current region over which stable Fowler-Nordheim tunneling occurs is merely extended for thin oxides. The temperature dependence of the maximum breakdown strength (10) is plotted in Fig. 11 along with that of the onset of the instability. The scale is greatly expanded, and both the breakdown field and the instability field increase by a few per cent with increasing temperature. The observation that the instability occurs at a fixed field regardless of the barrier height of the injecting electrode is further substantiated by breakdown measurements included in Table I showing the maximum breakdown strength is constant to within 10% for the different metals tested.

The relative temperature and barrier height independence of the current instability are evidence that the instability is field-controlled. In this regard, it is possible to associate the instability with the onset of nondestructive avalanching in the oxide in a region, probably close to the injecting electrode. After injected electrons drift under the influence of the applied field,

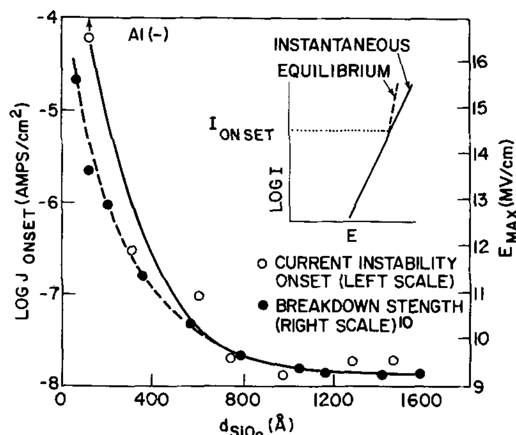

Fig. 10. Oxide thickness dependence of current instability and breakdown strength.

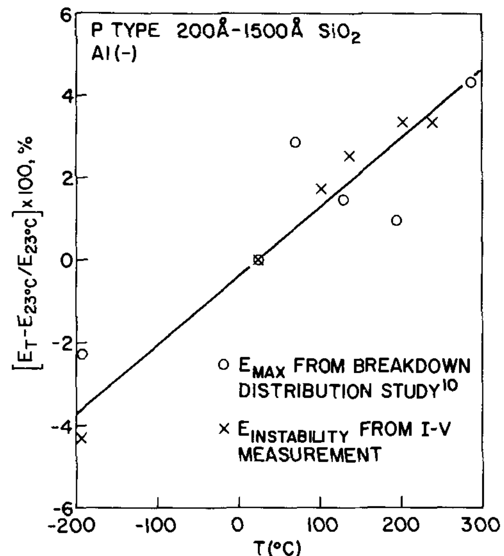

Fig. 11. Temperature dependence of current instability and breakdown strength.

additional carriers are created by collision ionization forming a space charge region which can modify the shape of the previously triangular tunneling barrier. The process is diagrammed in Fig. 5b and c, wherein, under the application of a field $\overline{E}$, injected electrons with mean free path λ gain energy $\overline{E}\lambda$; above a critical field this energy becomes enough to excite carriers from an energy level within the bandgap upon collision. The excited electrons are rapidly swept to the collecting electrode leaving positive charge a distance of λ from the injecting electrode. This charge modifies the potential and field distribution as seen in Fig. 5b and c with the effect of increasing the field in a narrow region around the injecting constant and reducing the field in the rest of the bulk. The reduced field prevents further collision ionization in the bulk that could lead to complete breakdown. Ionization at the interface continues until all the available traps are excited or until recombination and ionization rates equalize resulting in a steady-state condition after a few minutes (see Fig. 9). The current enhancement is due to the reduction in the size of the tunneling barrier (Fig. 5b); calculations with a 4 eV high barrier demonstrate over a 30% reduction in barrier area with 10^{13} charges/cm^2 (0.01 of a monolayer) located 100Å from the interface. With a 34Å mean free path (26) and an 8 MV/cm nominal field, the injected carriers should be able to excite traps 2.7 eV below the conduction band. Certainly a sophisticated treatment of the process would consider the energy distribution of traps and the variance of the mean free path. It is surprising, however, that an electronic process should have such a long time constant (*viz.*, 100-500 sec).

Recently, O'Dwyer (27-28) has made theoretical calculations of high-field conduction for a dielectric material in which collision ionization processes are taken into account. His I-V curves for both Fowler-Nordheim and Schottky cathode emission show a negative resistance instability which he associates with breakdown in very much the same way that the instability observed here can be associated with breakdown. The dielectric thickness coefficient (γ) of breakdown as computed in $E_{max} \propto d^{-\gamma}$ using his model is generally less than one half which is usually associated with electronic breakdown and one quarter which has been predicted under certain conditions (29). Samples similar to those used there (10) showed $E_{max} \propto d^{-0.21}$. This work then provides qualitative experimental support for O'Dwyer's model. More precise quantitative comparisons will need to be based on physically determined properties such as ionization coefficients and

carrier mobilities; these data, unfortunately, are not yet available.

Summary

The initial conduction in thermal SiO_2 films is seen to decrease with time. The decay can be characterized by at least two different exponential time constants. The fast decay is nearly temperature dependent while the magnitude and temperature dependence of the slow component agrees with data (17) on release of mobile ions from traps. Due to the lack of an appreciable flatband voltage change during decay, only a small component of the transient current can be attributed to mobile ion motion or polarization. A steady-state conduction is observed after several hours under high-field (7 MV/cm) stressing. The data equally well fit log J *vs.* $E^{1/2}$ and log J/E^2 *vs.* $1/E$ plots indicative of Schottky and Fowler-Nordheim emission processes, respectively. The former mechanism seems unlikely because it predicts a dielectric constant value for SiO_2 which is much less than the experimentally observed one and the temperature dependence of J is not exponentially activated, as expected. The data fit the Fowler-Nordheim conduction equation, although both the effective mass and the barrier height could not be independently computed because the results were not sufficiently accurate. However, assuming a reasonable effective mass, the calculated barrier heights give good agreement (to within 10-20%) to previously measured values.

The temperature dependence of the conduction is more complex than previously reported (1) since it was found to decrease with increasing applied field, vary with electrode material, and become exponentially activated at low fields. The results cannot be explained in terms of the usual temperature dependence of Fowler-Nordheim conduction; rather, one is forced to consider a temperature-dependent barrier height or effective mass. It is not known whether the activated region represents Schottky or bulk conduction.

The postmetalization anneal reduced the current level by up to three orders of magnitude for both polarities. The mechanism proposed involves charged defects or traps in the unannealed oxide film. It was not possible to determine if tunneling and conduction were via these trap levels rather than the oxide conduction band or if the charged defects modified the internal potential distribution so as to reduce the size of the tunneling barrier.

A high-field current instability was observed that could lead to dielectric breakdown; the onset field of this instability was about 8 MV/cm and was independent of the electrode material. Likewise maximum breakdown strengths were not significantly influenced by the choice of the electrode metal. The onset of the instability increases with decreasing oxide thickness and increasing temperature in much the same way as dielectric strength. The observation of this instability at low temperatures points to an electronic mechanism. The results qualitatively fit O'Dwyer's (27-28) model where the instability is due to collision ionization. Further calculations with this model must await additional data on ionization and drift kinetics in SiO_2.

Acknowledgments

The authors would like to express their gratitude to Dr. J. Eldridge and Dr. N. Chou for stimulating discussions and reviewing this work and to Dr. S. Raider and Dr. T. Hickmott for helpful discussions and exchange of ideas. They are also indebted to D. Ormond for the preparation of samples.

Preparation of (Y,Yb,Er)F_3 Phosphors for Green-Light Emission

Sidney G. Parker* and Rowland E. Johnson

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

A coprecipitation method has been used to prepare (Y,Yb,Er)F_3 phosphor powders for conversion of infrared to visible light. The coprecipitated material was treated in a stream of HF at 800°-900°C to dehydrate the powder and convert oxyfluorides to the fluorides. An interesting example of crystal growth occurred which gave a stable phosphor of the desired particle size. The phosphor converted up to 3% of the infrared radiation of GaAs: Si diodes to green light at 5400Å.

(Y,Yb,Er)F_3 has been used for conversion of infrared light of 9300-9600Å to green light having a wavelength of 5400Å (1). The phosphor has previously been prepared by melting the fluorides of Y, Yb, and Er together or by heating the fluorides together in a flux such as BeF_2, then leaching out the flux (1, 2). The material obtained by melting the fluorides was uniform in composition, but the particles were too large for an application which required a particle size ≤20 μm. When ground to the desired particle size, the crystals were apparently damaged, seriously reducing the phosphor conversion efficiency by 50% or more. Flux-grown material also required grinding and, in addition, was nonuniform and contained a high concentration of flux even after extensive leaching. A further disadvantage is the highly toxic nature of BeF_2. In both methods, the starting material must be the anhydrous, high-purity rare-earth fluorides.

We describe a method of coprecipitation of the rare earth fluorides, washing and filtering the precipitate, and treatment with HF at 900°C to prepare the phosphors. The phosphors are uniform, of the proper particle size and show a high conversion efficiency. The starting materials are rare earth oxides which are readily available in high purity at relatively modest price levels.

Experimental

Oxides of Y, Yb, and Er of 99.999%, 99.999% and 99.9999% purity (with respect to other rare earths) were used. Approximately 10g of the oxides in the desired mole ratio were dissolved in 25 ml of hot concentrated HCl. The clear solution was diluted with 50 ml H_2O and cooled to room temperature. To this solution in a polyethylene beaker we slowly added, while stirring vigorously, a mixture of 10 ml concentrated HF and 10 ml concentrated HNO_3. The gelatinous precipitate which formed was digested at ~70°C with constant stirring for 20-24 hr during which the precipitate became more crystalline. The supernatant liquid was decanted and the precipitate washed with 10% HF-10% HNO_3 until the wash was free of chlorides. The digestion and washing with 10% HF-HNO_3 was repeated several times. The precipitate was then rinsed with methanol, filtered, and air-dried at 110°C; it was a free-flowing powder which was probably a mixed rare earth fluoride and oxyfluoride with an unknown amount of water of hydration.

The material was heated slowly to 800°C over a period of 2 hr in a stream of He or N_2. Anhydrous HF was then mixed into the gas stream and the material was heated at 900°C for 4-8 hr. The reaction chamber was a vitreous carbon tube or an iridium tube with carbon liner; the phosphor was held in a platinum or vitreous carbon boat. The final product from this dehydration-crystal growth treatment was very stable in air and could be used as a phosphor without further processing. It is routinely stored in a desiccator or drying oven and has shown no degradation of phosphor efficiency in more than a year.

Optimum processing conditions were selected by comparing conversion efficiencies of the phosphors. We define efficiency as the ratio of green-light output to infrared power emitted by a GaAs diode; an efficiency of 3.0% was achieved with our best phosphors.

Results and Discussion

Composition and Purity

An optimum phosphor composition was $Y_{0.80}Yb_{0.19}Er_{0.01}F_3$ as determined by varying the Y/Yb and Yb/Er ratios independently. The source of the starting materials greatly influenced the efficiency of the resulting phosphor. For example, Y and Yb, reported to be 99.999% purity, from two different sources gave phosphors of 1.5 and 2.5% efficiency. Analysis of the rare-earth elements and their compounds is very difficult; although emission spectroscopy is frequently used, the complex spectra make detection of many impurities impossible. Table I shows emission spectrographic analysis of typical phosphors; in this series, only Batch 36 had a high efficiency, and it also had the highest purity.

Table II shows the results obtained by mass spectrographic analysis on phosphor material as coprecipitated and after the dehydration-crystal growth steps and indicates the large number of impurities present. The concentration of all impurities except carbon and gold was decreased by the dehydration-crystal growth in HF. The amount of oxygen in the material was rather high even after dehydration and suggests that the final product may still contain oxyfluoride. Carbon could come from the organic compounds used for extraction and purification of the rare-earth oxides or from the carbon tube and boat used during dehydration. The effects of various impurities on phosphor performance were not studied. Electron microprobe analysis showed the particles to be homogeneous within the accuracy of the instrument which was ±2%.

Coprecipitation Conditions

It was necessary to exercise control over the coprecipitation conditions to give a material easy to handle,

as established in past work (3), as well as a material which has a high conversion efficiency. Standard procedures described for gelatinous precipitates include low temperature (25°C) precipitation, dilute solutions, and slow addition of the precipitant with stirring. Phosphors prepared from concentrated solutions or at elevated temperatures gave approximately 1/20 the conversion efficiency of the best phosphors. The poor phosphors were presumably due to occlusion of impurities or water during precipitation which could not be removed in subsequent handling.

Homogeneous precipitation (4) to produce the mixed fluoride would presumably be of value here. A method has been reported by Vecht (5) which produces fluoride ion by acid hydrolysis of fluoroborate ion, $(BF_4)^-$, but we have not tested his method on this system.

Digestion and Washing

The digestion and washing conditions had a great effect on the phosphors. The best phosphors were formed by digestion for 24 hr at about 70°C with a 10% HF-10% HNO_3 solution followed by washing and additional digestion with dilute HF-HNO_3 solution. Digestion is a well-known method of obtaining particle growth and exclusion of impurities (3). Digestion of our gelatinous precipitate made it denser until it was transformed into a fine powder.

Analysis of phosphor efficiency indicated that it was necessary to use an acidic wash solution and to repeat the wash and digestion step a number of times. Digestion and washing in water alone gave phosphors with 0.1% efficiency compared with 3.0% for the best. This "water only" material could be improved to 2.5% by acid digestion and wash. Material which was digested once for only 24 hr or which was washed in water after acid digestion gave low-efficiency phosphors. Repeated digestions and washings seemed necessary to obtain breakdown of the gelatinous precipitate and to give a crystalline material containing much less water of hydration. Debye-Scherrer x-ray diffraction patterns of the material after the digestion washing in dilute acid solutions showed that the material was crystalline although the lines were rather diffuse and weak in intensity.

Dehydration—Crystal Growth

The dehydration period and temperature were also important factors in producing a good phosphor. The highest efficiency phosphors were obtained by starting a flow of N_2 or He, increasing the temperature over a period of 2 hr to 800°C and then maintaining at that temperature for 1 hr. TGA and gas chromatography showed H_2O was evolved, starting at about 500°C. After complete dehydration, anhydrous HF was added to the gas stream, the temperature raised to 900°C, and the system maintained for 4 hr. Heating at temperatures greater than 900°C gave inferior phosphors as did heating at 800°C for up to 12 hr in anhydrous HF. Bringing the temperature directly to 900°C also gave a degraded phosphor. Heating at 900°C for periods longer than 4 hr did not improve the phosphor.

Phosphors with almost identical conversion efficiencies were formed when the dehydration-crystal growth steps were carried out in either a vitreous carbon boat or a Pt boat in a vitreous carbon tube. Mass spectrographic analysis of phosphors treated in Pt boats showed 0.2-2 ppm(wt) Pt in the final product. Using an iridium tube resulted in doping the phosphor to 500 ppm with IR which reduced the conversion efficiency to 1/10 of its normal value. However, reaction of HF with Ir could be prevented by placing a carbon foil inside the Ir tube. There was little or no reaction of carbon foil or vitreous carbon if exposed to anhydrous HF. The phosphor was packed roughly into the boat; presumably these processes would occur more efficiently if the powder were spread in a thin layer or if gas flow could be directed through a bed of the powder.

As indicated in Table III, x-ray diffraction patterns on the freshly coprecipitated material which had been air dried at 110°C were diffuse, but after heating in HF the lines were sharp. This suggested that crystal growth occurred as well as dehydration. The diffraction pattern for the final product corresponded to that for the material produced by melting the anhydrous fluorides together in a dry HF ambient. Scanning electron micrographs of the phosphor at various stages confirmed that crystal growth occurred during heating in HF at 800°C and higher. Little if any crystal growth occurred by heating in the absence of HF. Figure 1(a) shows a scanning electron micrograph of the material after heating for 1 hr at 800°C in He; the appearance is identical to the unheated powder. Figure 1(b) shows the same powder after He treatment followed by treatment in HF at 800°C for 1 hr. It can be seen by comparison that the particles have increased in size by sintering together during the HF treatment. Continued heating in HF at 800°-900°C for 4 hr or more gave well-shaped crystals ≤20 μm in diameter, as shown by microscopic examination. Previous treatment also affected crystal growth. Thus, a fluoride precipitate which had been washed with H_2O, rather than the HF-HNO_3 mixture, showed very little crystal growth under the standard treatment and showed poor conversion efficiency as a phosphor.

Figure 2 shows photomicrographs of samples in index matching oil in transmitted light and crossed polarized light of material treated in HF at 900°C for 4 hr. It can be seen from the shape of the well-faceted

particles that crystal growth has occurred. There is some strain in the crystals as evidenced by the shading. It is also apparent that during sintering or crystal growth, occlusions were formed in the crystals, most likely due to the pores or holes between the small particles during agglomeration (6). Heating in HF at 800°C did not give the pores; however, the particles treated at 800°C were less efficient light converters than those treated at 900°C. It was possible that the pores acted as scattering centers and increased the conversion efficiency. Prolonged sintering in anhydrous HF at 900°C did not reduce the number or size of the pores.

We conclude that dehydration, in the absence of HF, is necessary before the fluoridation step. This latter

process converts any oxyfluoride to fluoride and induces the desired crystal growth at about 900°C. Moisture in the HF stream could degrade the phosphor by forming an excessive amount of oxyfluoride or by attacking the carbon tube or boat and dispersing carbon particles throughout the system.

Testing and Application of the Phosphor

The method for evaluating the phosphors gave a rapid relative comparison but was not optimized for maximum output. For testing, the phosphor powder was mixed with silicone oil to form a viscous slurry with about 75% phosphor by weight. The slurry was applied to a 0.072-in. diameter domed GaAs: Si diode which gave infrared of 9300-9600Å. Slurry was applied until maximum green light output was obtained. The GaAs diode was operated at 2A at a power level of 3.36W. The diode was well heat-sinked and operated for only short periods. The green-light intensity was determined with a silicon solar cell, filtered to remove the infrared. The solar cell voltage was measured across a fixed resistor and had been calibrated to give output power. The maximum conversion of diode infrared output to green light output was 3.0% which represented a brightness of ~8000 ft-L. No effort was made to obtain the maximum in light output by use of reflective surfaces, index-matching media, or a particular particle size, although some preliminary experiments indicated that the green-light output could be doubled by use of reflective coatings. The test method was reproducible to 1% and accurate to probably ±10%; it enabled phosphors to be checked for conversion efficiency in only a few minutes. The phosphor-oil slurry was readily removed so the same diode was used for all tests.

Evaluation devices were made from diode chips, 0.024 in. square. An epoxy was applied; then the phosphor powder was allowed to settle through the epoxy. After curing, the epoxy-phosphor layer was ~200 μm thick and roughly 50% phosphor. Characteristics of some devices are given in Table IV. Since the phosphor emission depends on a 2-(or more) photon absorption, there is a nonlinear relation of infrared emission to green-light emission. Again, no effort was made to optimize the brightness of these devices. These green-light emitters showed little or no degradation in light output after 6 months under constant load at 50 mA but did show 10% degradation at 100 mA load. This

* Brightness 99% after 6 months at 50 mA.
** Brightness 90% after 6 months at 100 mA.

was caused by degradation of the diode rather than the phosphor. There appeared to be no reaction of the phosphor with the epoxy. Phosphors tested periodically over the span of one year showed no decrease in conversion activity. This suggests that the lifetime of a green-light emitter would be determined by the lifetime of the GaAs diode.

Acknowledgments

We wish to acknowledge the help of Mr. Jack E. Pinnell in the preparation of the phosphors. Dr. Kent Watts provided valuable aid in measuring the efficiencies of the phosphor, and Mr. Kent Carson obtained the scanning electron micrographs.

Manuscript received Oct. 12, 1971. This was Paper 55 presented at the Washington, D. C., Meeting of the Society, May 9-13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Thermodynamic Calculations for $GaAs_{1-x}P_x$ Vapor Growth

M. Bleicher

Technische Universität, Institut für Technische Elektronik, 8 München 2, Germany

ABSTRACT

The combined transport of GaAs and GaP to form $GaAs_{1-x}P_x$ mixed crystals in an open-flow system by $AsCl_3$ and PCl_3 with two separate Ga sources has been calculated, based on simple thermochemical considerations. A new approach has been taken to determine theoretically the solid composition of the $GaAs_{1-x}P_x$ mixed crystal. The influence of the seed temperature on the solid composition has been studied as well as the influence of the total concentration of the incoming gases.

Production of $GaAs_{1-x}P_x$ mixed crystals has become very important in recent years. Two ranges of composition are especially favored: first the composition of x about 0.4 for applications in the visible, and second very low-phosphorus contents to produce GaAs heterojunction lasers (1). One of the reasons for the great interest in the $GaAs_{1-x}P_x$ mixed crystals is their relatively easy and cheap production by means of epitaxial

Key words: vapor phase deposition, thermodynamics, $GaAs_{1-x}P_x$, computer calculations.

growth from the vapor phase. A well-known system is the Ga-As-P-Cl-H open tube flow system, which uses Ga, $AsCl_3$, and PCl_3 as starting materials and hydrogen as a carrier gas.

Since the early investigations (2, 3) much work has been done on the arsenic half of this system, for example by Boucher and Hollan (4), Shaw (5), and Kirwan (6). On the phosphorus half Luther and Roccasecca (7), Seki *et al.* (8, 9), and Kirwan (6) have made a new approach experimentally as well as theoretically since the early work of Oldham (10). For the whole complex system however only experimental studies of the preparation and investigation of the crystals are known.

This paper carries out thermodynamic calculations for the complex system and highlights the influence of the substrate temperature on the composition of the epitaxial deposit.

Computer Calculations

Chemical and thermodynamical background.—Calculations are made for a system containing two separate gallium sources, which are fed by PCl_3 and $AsCl_3$, respectively. The incoming pressures p_{PCl_3} and p_{AsCl_3} are varied from 10^{-4} up to 0.1 atm.

Within the reacting tube nine different vapor species are taken into account, which are assumed to govern seven dominant chemical reactions, taking place at the usual operation temperature range between 700° and 1000°C. These reactions are listed below together with their equilibrium constants.[1]

$$Ga(l) + HCl(g) = GaCl(g) + \tfrac{1}{2}H_2(g)$$

$$K_1 = \frac{p_{GaCl}\, p_{H_2}^{1/2}}{p_{HCl}} \quad [1]$$

$$GaCl(g) + 2HCl(g) = GaCl_3(g) + H_2(g)$$

$$K_2 = \frac{p_{GaCl_3}\, p_{H_2}}{p_{GaCl}\, p_{HCl}^2} \quad [2]$$

$$GaAs(s) + HCl(g) = GaCl(g) + \tfrac{1}{4}As_4(g) + \tfrac{1}{2}H_2(g)$$

$$K_3 = \frac{p_{GaCl}\, p_{As_4}^{1/4}\, p_{H_2}^{1/2}}{p_{HCl}} \quad [3]$$

$$GaP(s) + HCl(g) = GaCl(g) + \tfrac{1}{4}P_4(g) + \tfrac{1}{2}H_2(g)$$

$$K_4 = \frac{p_{GaCl}\, p_{P_4}^{1/4}\, p_{H_2}^{1/2}}{p_{HCl}} \quad [4]$$

$$P_4(g) = 2P_2(g)$$

$$K_5 = \frac{p_{P_2}^2}{p_{P_4}} \quad [5]$$

$$As_4(g) = 2As_2(g)$$

$$K_6 = \frac{p_{As_2}^2}{p_{As_4}} \quad [6]$$

$$1/2P_2(g) + 3/2H_2(g) = PH_3(g)$$

$$K_7 = \frac{p_{PH_3}}{p_{P_2}^{1/2}\, p_{H_2}^{3/2}} \quad [7]$$

Recently it has been shown by Ban (17) that the assumption for the reactions is justified especially for the deposition process (Eq. [3] and [4]). All of the itemized vapor species, except PH_3, are commonly expected to occur in systems like the one described. But, concerning PH_3, Ban (17) stated its existence in a relative high concentration experimentally.

Combinations between phosphorus and arsenic like AsP, As_2P_2, As_3P, or AsP_3 are not taken into considera-

[1] Some further possible vapor species were estimated and found to lie several magnitudes below that of the interesting ones. Over the whole range of considered temperatures and input concentrations $p_{AsCl_3} < 10^{-7}$ atm, $p_{PCl_3} < 10^{-8}$, $p_{AsH_3} < 10^{-10}$ atm, and $p_{Cl_2} < 10^{-13}$ atm; hence these species are ignored in the analysis.

Table I. Equilibrium constants, atm units

$\log_{10} K_1 = 3.67 - 0.87 \times 10^3/T - 0.16 \ln T$
$\log_{10} K_2 = -13.95 + 9.58 \times 10^3/T + 0.92 \ln T$
$\log_{10} K_3 = 8.04 - 6.99 \times 10^3/T - 0.35 \times 10^{-3}T - 0.22 \ln T$
$\log_{10} K_4 = 6.08 - 7.255 \times 10^3/T - 0.03 \ln T$
$\log_{10} K_5 = 11.5 - 1.21 \times 10^4/T - 0.5 \ln T$
$\log_{10} K_6 = 11.5 - 1.59 \times 10^4/T - 0.43 \ln T$
$\log_{10} K_7 = -4.04 + 3.58 \times 10^3/T - 0.207 \ln T$

tion because of the lack of thermodynamical data. As soon as this information becomes available, there will be no difficulty in introducing them in the given set of reactions. The values for the reaction equilibria constants, which are related to the standard free energy change of the concerned reaction in the form $-\Delta G_i = RT \ln K_i$, are taken from a list given by Kirwan (6) for the first five equations, while the sixth is taken from Hurle and Mullin (13) and the seventh is calculated from data of the JANAF Tables (14). These values which are listed in Table I originate from a careful literature survey and have been found to be the least contradictory ones.

Arsenic-saturated source reaction equilibria.—For source temperatures of the Ga boat of about 925°C it is assumed that after some time of saturation with arsenic a thin layer of GaAs will cover the liquid gallium. Therefore the reaction equations [2], [3], and [6] must be applied. Because the pressures of six different vapor species are involved at this place, three more equations are required. The latter are denoted as equations of conservation. In general, for such problems one gets for n different vapor species always n-3 equations from the chemical reactions and three equations of conservation, from which one describes the conservation of the total pressure of the system. For an open-flow system this is expressed as

$$\Sigma p_i = 1 \text{ atm} \quad [8]$$

The remaining two equations are given in the case regarded here by conservation of chlorine

$$p_{GaCl} + 3p_{GaCl_3} + p_{HCl} = 3p_{AsCl_3} \quad [9]$$

and conservation of arsenic

$$4p_{As_4} + 2p_{As_2} = p_{AsCl_3} \quad [10]$$

where p_{AsCl_3} denotes the partial pressure of the incoming $AsCl_3$.

It must be stated at this point that due to the criterion of constant pressure a volume change is induced in the system while the reactions are taking place, because mole numbers are changing. For this reason the equations of conservation Eq. [9] and [10] should be expressed in terms of moles instead of partial pressures. Since the relative volume change for the whole system has been estimated to be smaller than 3%, this error will be ignored in the calculations. Equation [10] is only true for the source region, where no deposition can occur. The etch rate ER of the gallium source in grams per minute is expressed by

$$ER = \frac{(p_{GaCl} + p_{GaCl_3})\, g_{Ga}}{RT_o} \cdot V_o \quad [11]$$

where g_{Ga} is the atomic weight of Ga, T_o the temperature at which the reaction products are entering the tube, and V_o is the total flow rate (cubic centimeters per minute).

Phosphorus-saturated source reaction equilibria.—The same procedure described above is now applied to this source, also containing gallium. In this case, however, Luther (7) and Seki (8) have pointed out that no skin of GaP forms. For this reason Eq. [1], [2], [5], [7], [8] and in addition

$$p_{GaCl} + 3p_{GaCl_3} + p_{HCl} = 3p_{PCl_3} \quad [12]$$

and

$$4p_{P_4} + 2p_{P_2} + p_{PH_3} = p_{PCl_3} \quad [13]$$

have to be taken into account.

Deposition reaction equilibria.—In the deposition zone of the reaction tube the incoming vapor mixture is allowed to form an equilibrium phase between all its species and solid GaAs and GaP, respectively, for all temperatures considered. This assumption is only true for low flow rates as well as for a long deposition region. Here Eq. [2] to [7] must be applied and, in addition, the heat of mixing which occurs at the reaction

$$(1-x)GaAs(s) + xGaP(s) = GaAs_{1-x}P_x(s) - \Delta H_m \quad [14]$$

The heat of mixing is given by

$$\Delta H_m = \Omega x(1-x) \quad [15]$$

Huber (15) has calculated Ω to be 1 kcal/mole, *i.e.*, the maximum heat of mixing at $x = 0.5$ is 0.25 kcal/mole. The resulting modification in the equilibrium constants is negligible and therefore ignored in the following. Equation [8] and the conservation of chlorine is still valid

$$p_{GaCl} + 3p_{GaCl_3} + p_{HCl} = 3p_{AsCl_3} + 3p_{PCl_3} \quad [16]$$

The third equation of conservation states that the sum of arsenic and phosphorus atoms precipitating out of the vapor phase must be equal to that of the gallium atoms

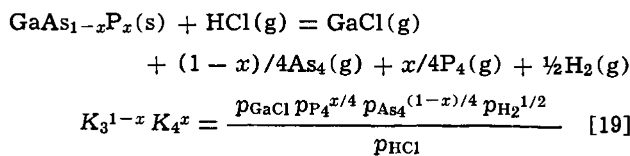
$$4p_{oAs_4} + 2p_{oAs_2} + p_{oPH_3} + 4p_{oP_4} + 2p_{oP_2} - 4p_{As_4} - 2p_{As_2} - p_{PH_3} - 4p_{P_4} - 2p_{P_2} = p_{oGaCl} + p_{oGaCl_3} - p_{GaCl} - p_{GaCl_3} \quad [17]$$

where the p_{oi}'s indicate the partial pressures coming from the source into the deposition zone of the reactor.

This new equilibrium yields the amount of GaAs and GaP depositing at the seed dependent only on the input partial pressures of $AsCl_3$ and PCl_3, the source and the substrate temperature. The concentration x of GaP in the solid is given by the rates of precipitation similar to Eq. [17]

$$x = \frac{p_{oPH_3} + 4p_{oP_4} + 2p_{oP_2} - p_{PH_3} - 4p_{P_4} - 2p_{P_2}}{p_{oGaCl} + p_{oGaCl_3} - p_{GaCl} - p_{GaCl_3}} \quad [18]$$

On the other hand it is possible to express x in terms of vapor pressures and equilibrium constants by combining Eq. [3] and [4] in the form



$$GaAs_{1-x}P_x(s) + HCl(g) = GaCl(g) + (1-x)/4As_4(g) + x/4P_4(g) + \tfrac{1}{2}H_2(g)$$

$$K_3^{1-x} K_4^x = \frac{p_{GaCl}\, p_{P_4}^{x/4}\, p_{As_4}^{(1-x)/4}\, p_{H_2}^{1/2}}{p_{HCl}} \quad [19]$$

where x becomes

$$x = \frac{\ln\left[\left(\frac{p_{HCl}}{p_{GaCl}\, p_{H_2}^{1/2}}\right)^4 \frac{K_3^4}{p_{As_4}}\right]}{\ln\left[\left(\frac{K_3}{K_4}\right)^4 \frac{p_{P_4}}{p_{As_4}}\right]} \quad [20]$$

Equation [20] serves to predict in what direction x will change as soon as equilibrium is no longer maintained.

Results

The model proposed here is based only on simple chemothermodynamical relations. No account is taken of the kinetic mechanisms which might control the growth of an epitaxial layer in reality. Also no regard has been paid to the fact that in practice total homogeneity is not achievable.

Figure 1 shows the equilibrium partial pressures of the different vapor species over the arsenic- and phosphorus-saturated gallium source at 1200°K over various input pressures of $AsCl_3$ and PCl_3, respectively. It must be noted that in contrast to the negligible arsine pressure (8, 9), phosphine by Eq. [7] has a remarkably high vapor pressure. This plot is for a single source

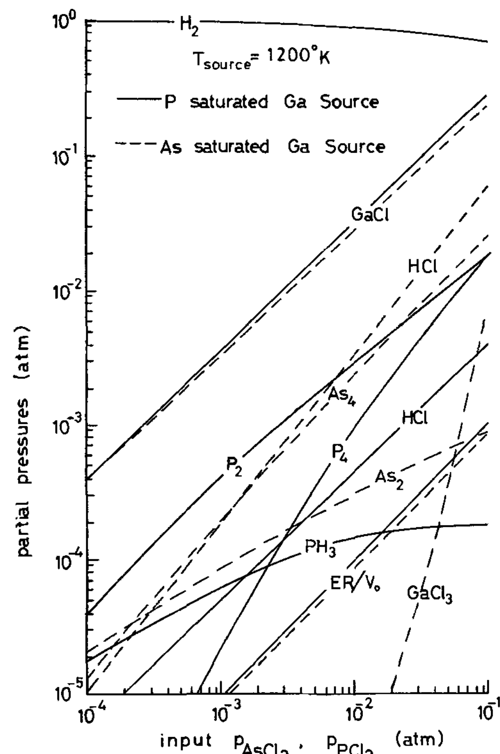


Fig. 1. Partial pressures and etch rates over a arsenic and phosphorus saturated Ga source, respectively, vs. the $AsCl_3$ and PCl_3 input partial pressures, respectively, for a constant 1200°K source temperature.

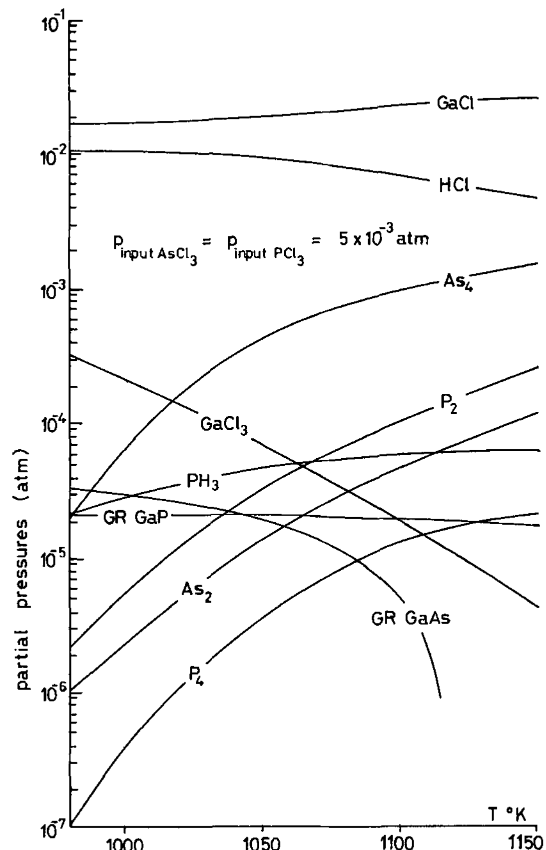

Fig. 2. Partial pressures and growth rates over a $GaAs_{1-x}P_x$ deposit vs. the deposit temperature.

temperature but above 920°C there is little influence on growth. For the Group V elements only the ratio of dimers to tetramers is varying, while their total concentration remains constant. The dominant Group III

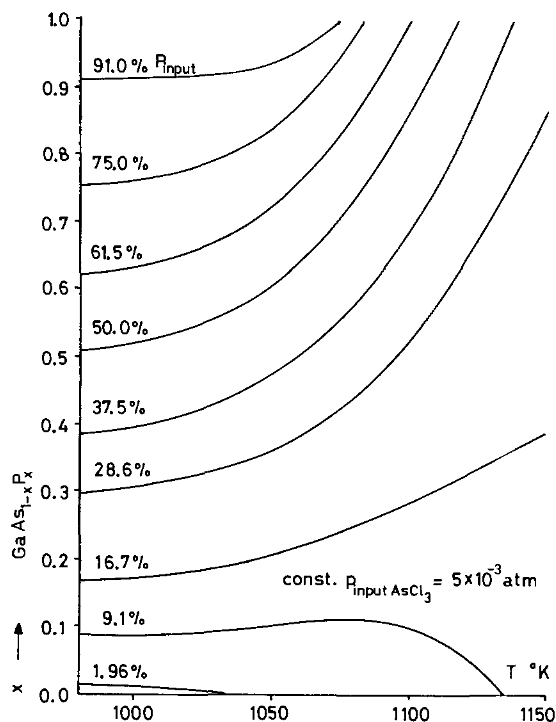

Fig. 3. $GaAs_{1-x}P_x$ deposit composition vs. the deposit temperature for several phosphorus percentages of the PCl_3 and $AsCl_3$ input gases.

element pressure, p_{GaCl}, is about constant too, because the HCl pressure lies more than one magnitude lower.

In Fig. 2 the equilibrium pressures in the deposition zone are plotted *vs.* the seed temperature for equal incoming pressures of $AsCl_3$ and PCl_3. Two things are most interesting. First again the high phosphine pressure, which dominates until about 1060°K, second the behavior of the growth rates (denoted as GR GaAs and GR GaP and weighted with their molecular weight) while the growth rate of GaP stays nearly constant, the GaAs growth rate reveals a steep slope at higher temperatures. This behavior may be explained by the temperature dependence of Eq. [3]. In any case this phenomenon causes mostly the strong variation of the GaP solid concentration *vs.* deposition temperature shown in Fig. 3. According to this figure it should be possible to grow pure GaP crystals within a vapor containing arsenic at elevated temperatures. Furthermore in this region a GaAs seed will be etched away. Figure 4 illustrates the solid composition x *vs.* the percentage of PCl_3 to $AsCl_3$ in the input gas. Once more the strong influence of the seed temperature can be seen. This is not in agreement with Finch and Mehal (11) who observed a straight relationship for temperatures between 775° and 820°C, but they used only one source, which is not comparable with the calculations done here. Stewart (16) with the AsH_3, PH_3, HCl/Ga system at ~780°C obtains a GaP solid concentration of 0.4 employing a P to As input vapor percentage of 28.6%, a point that fits exactly the calculations here. He also observed a composition variation by varying the HCl flow. This may be explained by Eq. [20], if the equilibrium over the source is not reached completely, *i.e.*, the ratio p_{HCl} to p_{GaCl} changes. Finally it can be seen from Fig. 3 and 4 that for very low-phosphorus input concentrations no GaP is forming, in fact in this range all the available phosphorus is used in forming phosphine.

The great influence of the substrate temperature on the composition of the deposit diminishes with the higher concentrations of the input gases, indicated in Fig. 5. Here the solid composition approaches exactly the same value given by the ratio of the input gas concentration.

Conclusions

Applying the $AsCl_3$, PCl_3, Ga, H_2 system for growth of $GaAs_{1-x}P_x$ mixed crystals the seed temperature influences strongly the solid composition of the crystal. This dependence becomes smaller with increasing input concentrations of the trichlorides. Within the reactor a relatively high, at any case, a nonnegligible vapor pressure of phosphine exists. Above about 920°C, variation of the source temperature has little influence on the growth conditions.

A Cross-Hatch Pattern in $GaAs_{1-x}P_x$ Epitaxially Grown on GaAs Substrate

Seigo Kishinô, Masahiko Ogirima, and Kazuhiro Kurata*

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

A cross-hatch pattern which appears on the surface of $GaAs_{1-x}P_x$ epitaxially grown on the GaAs substrate was studied by x-ray diffraction techniques. The origin of this structure was determined by x-ray diffraction topography to be a misfit dislocation array aligned along lines perpendicular to each other in the layer of graded composition. The composition profile normal to the wafer was also determined by electron microprobe analyses. Furthermore, the growth mechanism of the aligned dislocations was proposed from the fact that aligned dislocations enable a considerable reduction in the curvature of the wafer which is due to the lattice mismatch between the $GaAs_{1-x}P_x$ epitaxial layer and the GaAs substrate. The $GaAs_{1-x}P_x$ wafer having the cross-hatch pattern was determined to be high in quality from the half width of the rocking curve.

$GaAs_{1-x}P_x$ ($x \lesssim 0.4$) is one of the most promising materials currently being utilized for visible injection electroluminescence. The efficiency of emission which is in the red at room temperature is high because the bandgap is direct, and the material can be made high conductivity n- or p-type. At present, $GaAs_{1-x}P_x$ has a technological advantage over $Ga_{1-x}Al_xAs$ and GaP for display application because relatively large areas of $GaAs_{1-x}P_x$ wafer suitable for use in electroluminescent devices can be readily obtained by the vapor phase growth technique. An understanding of the role of the crystal defects in the growth mechanism is important in order to control and improve the efficiency.

The crystal defects such as dislocations and stacking faults which may be important in determining the properties of vapor phase epitaxially grown $GaAs_{1-x}P_x$ wafers have been described by a number of investigators (1-5).

This paper deals with the relationship between the cross-hatch pattern (6) and the dislocations and specifically with the origin of the dislocations and their effects on the perfection of epitaxially grown $GaAs_{1-x}P_x$ wafer.

Experimental

The $GaAs_{1-x}P_x$ crystals doped with Te were epitaxially grown on GaAs substrate in an open-tube system using Ga, PCl_3, As, and H_2 (7). Hydrogen, purified by Pd diffusion, was metered into the system through two flowmeters. One of them was connected to PCl_3 bubblers while the other controlled further dilution of the displaced PCl_3 vapors. The diluted vapors then passed over Ga feed material. The alloy composition was controlled by the temperature of arsenic source. Mechanically and chemically polished surfaces of (100) oriented seeds were used.

Typical operating conditions were: gallium temperature, 900°C; seed temperature, 810°C; PCl_3 bubbler (0°C) flow rate, 40 cc/min; dilution hydrogen flow rate, 160 cc/min; temperature gradient at the substrate, 10°C/cm; arsenic source temperature, 430°C.

To minimize strains and crystal imperfections due to lattice mismatch between $GaAs_{1-x}P_x$ and GaAs, a layer of continuously graded composition was grown before growing a thick layer of uniform composition. The layer of graded composition was grown by controlling the temperature of arsenic source in the range of 430°-530°C. The thickness of the epitaxially grown layer was usually 100 μm and the growth rate was usually 25 μm/hr. As mentioned later, the optimum thickness of the graded composition was 20-40 μm. So the temperature of arsenic source was varied from 530° to 430°C continuously for 1 hr in the initial period of epitaxial process. When the thickness of the graded composition layer was out of the range of the optimum thickness described above, the cross-hatch pattern was hardly observed.

Dislocations were observed by the Lang method, in which $AgK_{\alpha 1}$ radiation from microfocus x-ray equipment was used, with the use of two kinds of specimens. (*i*) One specimen was the epitaxially grown $GaAs_{1-x}P_x$

wafer 50-100 μm thick including the GaAs substrate, which was reduced to 100 μm thickness by mechanical polishing with 2000 mesh carborundum and chemical etching with an etch solution of $3H_2SO_4$: $1H_2O$: $1H_2O_2$. The schematic diagram of the specimen is shown in Fig. 1. (*ii*) The wafer composed of the epitaxially grown $GaAs_{1-x}P_x$ layer and the GaAs substrate was angle lapped at 5° in order to reveal dislocations in the substrate, the graded composition layer, and the constant composition layer. This specimen was also etched with a similar etch solution described above after mechanical lapping. The schematic diagram of the specimen is shown in Fig. 2(a) and (b).

The composition profiles of the phosphorus content in the $GaAs_{1-x}P_x$ layer normal to the GaAs substrate were examined by electron microprobe analyses. A particular precaution was taken to detect the variation of the phosphorus content in the graded composition layer. At the same time variation of the arsenic content was observed throughout the depth of the wafer for supporting the results.

The difference in lattice parameter between the $GaAs_{1-x}P_x$ epitaxial layer and the GaAs substrate causes a pronounced curvature in the structure. This curvature was measured by an x-ray diffraction technique (8). Prior to measurement, the thickness of the GaAs substrate was kept constant because the curvature of the wafer depends on the thickness of the substrate. In this case (400)$CuK_{\alpha 1}$ diffraction in the Bragg case was used. The x-ray beam was incident not at the $GaAs_{1-x}P_x$ epitaxial layer but at the GaAs substrate because the measured results were governed by the compositional variation when the epitaxially grown $GaAs_{1-x}P_x$ surface was used for measurement.

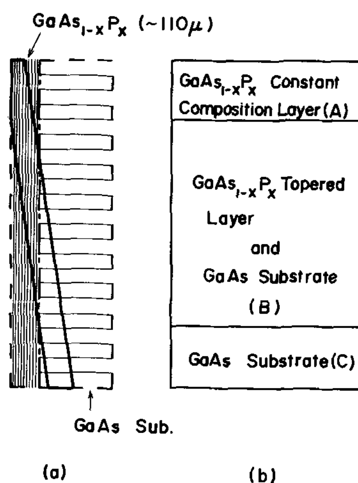

Fig. 2. The angle lapped specimen which is composed of the $GaAs_{1-x}P_x$ constant composition layer, the graded composition layer, and the GaAs substrate, respectively. (a) and (b) show the section and the plane figures, respectively.

The perfection of the epitaxially grown $GaAs_{1-x}P_x$ wafer was also examined by an x-ray diffraction technique (9) in which two different wavelengths of x-ray beams (10) were used for diffraction. X-ray radiation of two wavelengths, $CuK_{\alpha 1}$ and $CuK_{\beta 1}$, were used. With the use of this method the phosphorus content, assuming that Vegard's law of solid solutions holds for this GaAs-GaP system (11), was also examined. The perfection of the $GaAs_{1-x}P_x$ wafer was examined from the half width of the rocking curve which was the diffracted intensity *vs.* a small fraction of the incident angle $\Delta\theta$ around the Bragg angle.

The efficiency of junction luminescence was measured by silicon photocells at 10 A/cm² of diode current.

Results and Discussion

X-ray topographs were taken from the specimen whose surface revealed the cross-hatch pattern as shown in Fig. 3, and they are shown in Fig. 4(a), (b), (c), (d), and (e). The shape of the specimen in this

Fig. 3. The optical photograph of the surface which reveals the cross-hatch pattern.

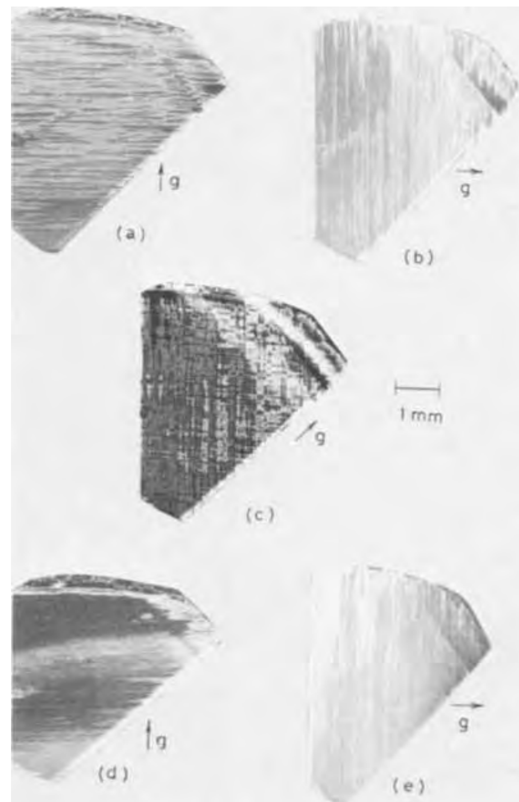

Fig. 4. X-ray topographs of the specimen 1. (a), (b), (c), (d), and (e) show topographs from (220), (2̄20), (040), (111), and (1̄1̄1) diffractions, respectively.

case is shown in Fig. 1. The type of the dislocation observed here is similar to one observed by Ewing (2), that is, dislocation networks are aligned along [011] and [01$\bar{1}$] directions with ½a[01$\bar{1}$] and ½a[011] Burger's vectors, respectively. X-ray topographs using the diffraction vectors [111] and [1$\bar{1}$1] are also reproduced in Fig. 4(d) and (e) for determining the Burger's vector more accurately. The diffraction planes used here are shown in the pole figure, Fig. 5. From these x-ray topographs and the pole figure, Burger's vector of two kinds of the dislocations aligned along lines perpendicular to each other were determined exactly to be ½a [01$\bar{1}$] and ½a [011]. The image contrast criterion (12), for [011] and [01$\bar{1}$] dislocations only, is violated in some local areas. Therefore, where contrast violations exist, dislocations may have screw component or interact each other. Detailed examinations were not established at this stage.

X-ray topographs of a similar specimen are also reproduced in Fig. 6(a) and (b), in which the shape of the specimen is shown in Fig. 2(a) and (b). From these x-ray topographs it is obvious that dislocation densities in both the GaAs substrate and the constant composition layer, are rather low, while the aligned dislocations gather in the graded composition layer of the specimen. This may be the result of the large lattice mismatch between the GaAs substrate and the $GaAs_{1-x}P_x$ layer.

An x-ray topograph was also taken from the specimen whose surface does not reveal the cross-hatch pattern as shown in Fig. 7. The shape of the specimen is similar to that shown in Fig. 1. In this case there is the irregular form in the image of dislocations because

dislocations could not align along the line. The lattice strain might be too large to be compensated by making the misfit-dislocations array in the graded composition layer because of the sudden change of the phosphorus content as discussed later.

Variation of the phosphorus contents in the growth layer were measured by electron microprobe analyses as shown in Fig. 8(a) and (b). Figures 8(a) and (b) are obtained from the specimens which reveal, respectively, the cross-hatch pattern clearly and obscurely on the surface of the epitaxial $GaAs_{1-x}P_x$ wafer. It is fairly obvious that the aligned dislocations were introduced in the graded composition layer when the epitaxial $GaAs_{1-x}P_x$ wafer has the graded composition layer of 40 μm width as shown in Fig. 8(a).

If the lattice mismatch between the $GaAs_{1-x}P_x$ epitaxial layer and the GaAs substrate causes the curvature and no dislocations are introduced to compensate the elastic strain, the curvature ρ can be obtained from the following equation (13-15)

$$\rho = \frac{6\left[t_0 \sum_{j=1}^{N} t_j\left(\frac{d_0 - d_j}{d_0}\right) + \sum_{i=1}^{N}\sum_{j>i}^{N} t_i t_j\left(\frac{d_i - d_j}{d_0}\right)\right]}{\left[\sum_{j=0}^{N} t_j\right]^3} \quad [1]$$

where t_0, $t_{i(j)}$, $d_{i(j)}$, and d_0 are the thickness of the substrate, the thickness of the $i(j)$th epitaxial layer, the lattice parameter of the $i(j)$th epitaxial layer, and the lattice parameter of the substrate, respectively. Figure 9 shows schematically the representative epitaxial layer which is composed of eight different layers. The result calculated by Eq. [1] is shown in Fig. 10 with a solid line. In this case the thickness of the substrate is 400 μm and the epitaxial layer is composed of eight layers each of 5 μm thickness but each layer has different phosphorus contents. The curvature of the wafers measured by an x-ray diffraction technique (8) are also shown in Fig. 10 in order to make correlation to the visibility of the cross-hatch pattern. Signs ○, △, and × show the wafers which reveal the cross-hatch pattern clearly, rather clearly, and obscurely, respectively. It is evident that the curvature of the wafer in which the cross-hatch pattern is visible clearly is always smaller than that of the wafer in which the cross-

hatch pattern is obscure. In this experiment a convex configuration as viewed from the GaAs side was observed. It is also to be noted that the sign of the curvature is always reverse of those observed by Saul (16). From the result that a concave configuration was observed as viewed from the GaAs side, Saul determined that the thermal mismatch was larger than the lattice mismatch between the GaP epitaxial layer and the

GaAs substrate. However, the present observed sign of the curvature supports that the stress due to lattice mismatch considerably exceeds the stress due to differential thermal contraction in the $GaAs_{1-x}P_x$-GaAs system, as Abrahams *et al.* have already reported (5).

Contrary to the result by Saul, it is reasonable to assume from our results that the wafer bends progressively during growth, if the lattice mismatch is not perfectly compensated by misfit dislocations. From the experimental results described above, a model of the formation mechanism of the misfit dislocation array in this case is proposed as shown in Fig. 11 and 12, where (a) and (b) show the plane and the section views of the wafer, respectively. Figures 11 and 12 show the model of the wafer in which the cross-hatch pattern is visible and obscure, respectively.

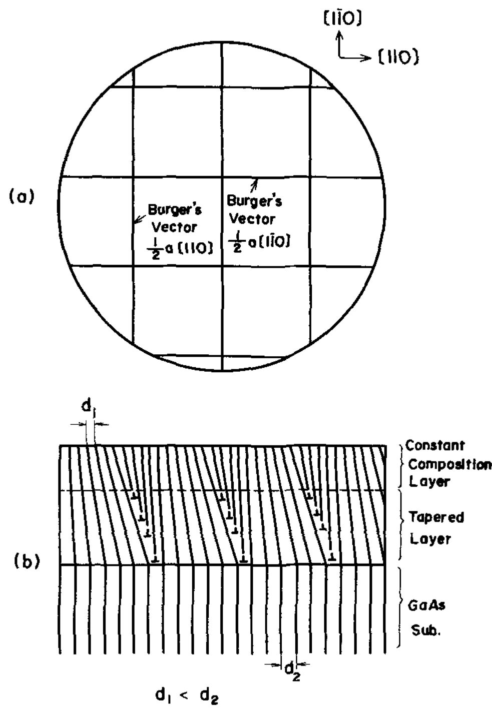

Fig. 11. The model of crystal growth in which dislocations are lined up in the graded composition layer. (a) and (b) show the plane and the section figures, respectively.

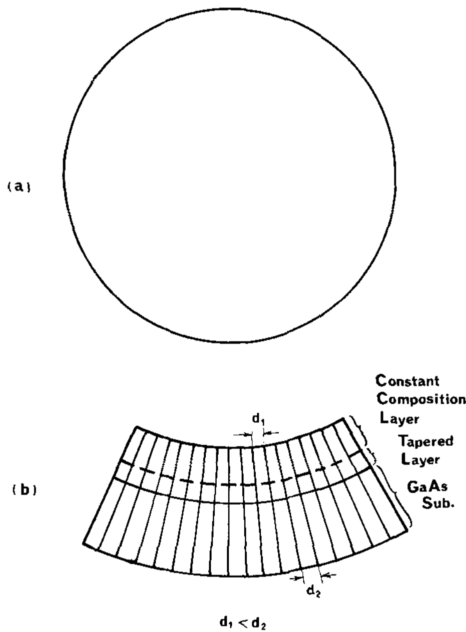

Fig. 12. The model of the crystal exhibiting curvature due to lattice mismatch between the $GaAs_{1-x}P_x$ layer and the GaAs substrate. (a) and (b) show the plane and the section figures, respectively.

When the cross-hatch pattern is visible, the aligned dislocations observed by x-ray topography may be composed of many dislocations which line up as if the small grain boundary is constructed. If the dislocations are arranged as shown in Fig. 11, the lattice mismatch at the graded composition layer can be compensated easily by the dislocations induced. The cross-hatch pattern visible on the surface, however, does not show the aligned dislocations themselves, because the aligned dislocations are existing in the graded composition layer and they are materially reduced in number on the surface as shown in Fig. 6. The cross-hatch pattern may be formed on the surface because growth rate variation of the epitaxial layer are initiated by: (*i*) the impurity concentration difference at the dislocation lines in the graded composition layer, and (*ii*) the screw components of some parts of the aligned dislocations which are visible in the x-ray topographs shown in Fig. 4.

If this model is used, it is easy to explain that the curvature of the wafer is small when the cross-hatch pattern is clearly visible. When the gradient of the phosphorus content is very sharp as shown in Fig. 8(b), the formation of the lattice strain during growth may be too large to be released by introducing the aligned dislocation array. In such a case dislocations may have a random distribution and consequently the cross-hatch pattern cannot be visible.

The phosphorus contents at the surfaces of the epitaxially grown $GaAs_{1-x}P_x$ wafers are shown in Table I with the results obtained from the energy gap data. The phosphorus contents were obtained from the lattice parameters which were measured from the differences of the two peak profiles obtained from $(511)CuK_{\alpha 1}$ and $(400)CuK_{\beta 1}$ diffractions (10, 17). The representative peak profiles are shown in Fig. 13 and 14 in which the upper and the lower profiles show $(400)CuK_{\beta 1}$, and $(511)CuK_{\alpha 1}$ diffractions, respectively. Figures 13 and 14 show the peak profiles obtained from the specimens where the cross-hatch pattern is clearly visible and obscure, respectively. This peak profile is a kind of the rocking curve, although the incident beam is not perfectly monochromatic. The

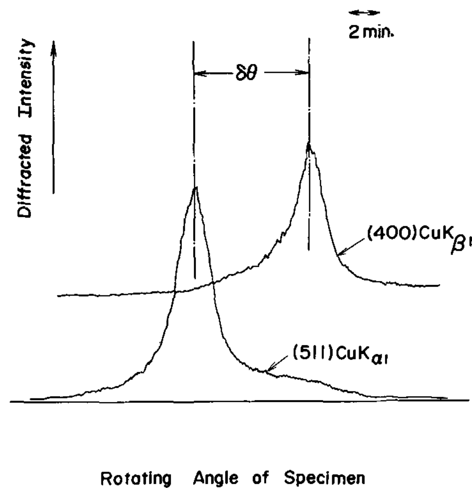

Fig. 13. Rocking curves of the $GaAs_{1-x}P_x$ wafer whose surface reveals the cross-hatch pattern clearly. In this figure $\delta\theta$ shows the lattice parameter, and the half width shows the perfection of the crystal.

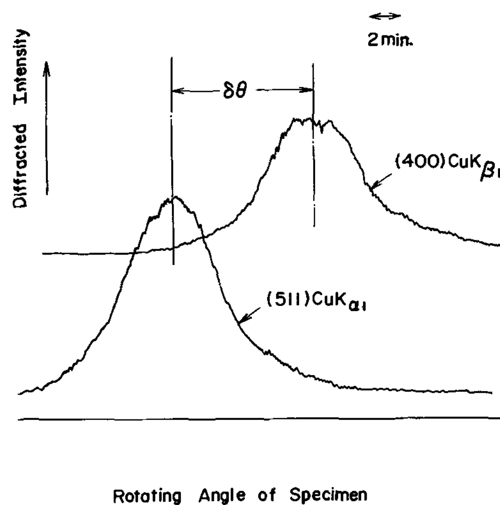

Fig. 14. Rocking curves of the $GaAs_{1-x}P_x$ wafer whose surface does not reveal the cross-hatch pattern.

perfection of the crystal, however, can be similarly estimated from the half width of the peak profile shown in Fig. 13 and 14. The half width of the peak profile of the epitaxially grown $GaAs_{1-x}P_x$ wafer, with a clearly revealed cross-hatch pattern, is comparable to that of the GaAs substrate in which dislocation density is lower than 10^4 cm^{-2}. The half width of the peak profile is broader, as shown in Fig. 14, when the wafer does not reveal the cross-hatch pattern. This high quality of the epitaxially grown $GaAs_{1-x}P_x$ wafer could be also expected from the model shown in Fig. 11 because the aligned dislocations need not be introduced at the surface.

When light emitting diodes are fabricated from the wafer which reveals the cross-hatch pattern clearly, the electroluminescent efficiency is higher by about 50% than that of the wafer with no cross-hatch pattern.

Conclusions

1. A cross-hatch pattern on the surface of $GaAs_{1-x}P_x$ layer appears when the graded composition layer of 20 ∼ 40 μm width is formed in the initial period of epitaxial process.

2. The origin of the cross-hatch pattern was determined by x-ray topography to be a misfit dislocation array aligned along lines perpendicular to each other in the graded composition layer.

3. The curvature of the $GaAs_{1-x}P_x$ wafer is small or large depending on whether the cross-hatch pattern is clear or obscure on the surface.

4. When the cross-hatch pattern is visible on the surface, the $GaAs_{1-x}P_x$ wafer is high in quality on the surface because the half width of the rocking curve is as narrow as that of the GaAs substrate.

5. These results support the proposed model with regard to the growth mechanism of the aligned dislocation array.

Acknowledgment

The authors wish to express their appreciation to Dr. H. Kusumoto for his encouragement, to Mr. Y. Taguchi for making electron microprobe analyses, and also to Messrs. Y. Ono, K. Homma, and Y. Kekoin for their helpful support. The authors gratefully acknowledge the assistance of Mr. S. Aoki in carrying out part of the experimental portion of this study.

The Equilibrium Pressure of N_2 over GaN

C. D. Thurmond* and R. A. Logan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The equilibrium pressures of N_2 over GaN and Ga are not known. Values of the heat and entropy of formation of GaN are proposed that give equilibrium N_2 pressures as a function of temperature. Experiments reported in the literature lead to consistent upper and lower bounds to the calculated curve but do not define its position very well. We report the results of three different types of experiments, using NH_3 in H_2, which tighten the bounds to the equilibrium curve: the NH_3 pressures at which GaN could be seen to form from Ga were upper limits; the pressure of NH_3 in the exiting gas stream after reaction with Ga gives a qualified upper limit; and of greatest importance, we believe, are the measurements of the NH_3 pressures generated when H_2 is passed over GaN. These latter pressures are lower limits to the equilibrium curve and are believed to lie close to it. The experimental results are in agreement with the calculated equilibrium pressures of N_2 over GaN and Ga obtained using the heat of formation of GaN based on the measurements of Hahn and Juza, and Mah and the assumption that the entropy and heat capacity of GaN are the same as those of ZnO.

The temperature and nitrogen pressure ranges over which GaN is stable are not known. It is believed that very high pressures of nitrogen are required to form GaN from Ga(l) at temperatures above 1000°C (1). At lower temperatures a skin forms on the Ga(l), presumably GaN, impeding further reaction (1). NH_3 at a pressure 1 atm reacts with Ga(l) above 1050°C (2), any reaction below this temperature also is impeded by a thin GaN film.

It has been suggested (3) that the decomposition of GaN(s) may lead to polymeric nitride molecules, $(GaN)_x$. Transport experiments offered some support for the existence of such species (4) but no evidence of polymeric nitride molecules was obtained from mass-spectrometer studies (5, 6).

It is the purpose of this paper to calculate the equilibrium pressure of N_2 over GaN and Ga as a function

* Electrochemical Society Active Member.

Key words: gallium nitride, equilibrium, decomposition pressure, heat of formation, entropy.

of temperature from a heat of formation in the literature and an estimated entropy and heat capacity of GaN. It will then be shown that this curve is consistent with previously reported experimental results which, however, do not define the position of the curve very well, and is in good agreement with our erperimental results which do define the position much more sharply.

Equilibrium Pressure Curve

The equilibrium between GaN, liquid Ga, and N_2 is described by the following reaction

$$GaN(s) = Ga(l) + \frac{1}{2} N_2(g) \quad [1]$$

The equilibrium N_2 pressure is related to the standard free energy change of reaction [1] by the expression

$$\frac{1}{2} RT\ln P_{N_2} = -\Delta G^\circ_1 \quad [2]$$

It has been assumed that GaN has a narrow nonstoichiometry range and that the solubility of GaN in Ga is negligible. The standard free energy change, in turn, is related to the free energy of formation of GaN, and the heat and entropy of formation by

$$-\Delta G^\circ_1 = \Delta G^f_{GaN} = (\Delta H^f_{GaN} - T\Delta S^f_{GaN}) \quad [3]$$

The heat of formation of GaN at 298°K given in the NBS tables (7), is −26.4 kcal. It is based on the heat of combustion of GaN measured by Hahn and Juza (2) and the heat of combustion of Ga measured by Mah (8). The entropy of formation of GaN has not been measured, but following a suggestion by Sime and Margrave (4), we have estimated the entropy of GaN by assuming it is the same as that of ZnO which is the same crystal structure (wurtzite), is isoelectronic, and is of nearly the same molecular weight. The entropy of ZnO at 298°C is 10.43 eu (9). In addition, we have assumed that the heat capacity of GaN is the same as that of ZnO (10). With the available thermodynamic information on liquid Ga (11) and on N_2 (12), the heat and entropy of formation of GaN can be obtained, from which the equilibrium N_2 pressure can be calculated.

The equilibrium N_2 pressure, estimated as described above, has been plotted in Fig. 1. At temperatures higher than 800°C, the calculated N_2 pressure is greater than 1 atm; at 1200°C, the pressure is 1000 atm, reaching 100,000 atm at about 1700°C.

Comparison with Available Experimental Data

The calculated N_2 pressures can be compared to related observations reported by a number of workers.

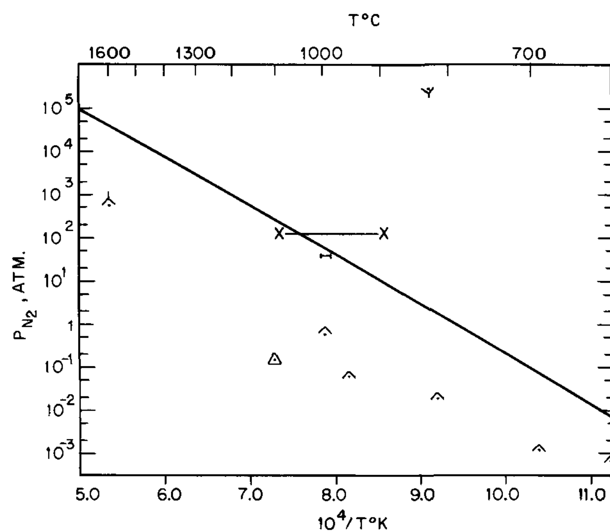

Fig. 1. Pressure of N_2 over GaN(s)-Ga(l), (log P_{N_2} vs. $10^4/T$). The solid line is calculated. Lower limits to the equilibrium curve: ⅄ MacChesney and co-workers (13), △ Juza and Hahn (2), ^ Lorenz and Binkowski (14). Upper limits to the equilibrium curve: Y Maruska and Tietjen (16), x——x Logan and co-workers (17), ⊢——⊣ Lorimor and co-workers (18).

The most direct information comes from a measurement by MacChesney and co-workers (13) who found that at 1600°C, under a pressure of about 700 atm of N_2, GaN decomposed. This observation gives a lower limit to the equilibrium curve and, as plotted in Fig. 1, is consistent with the calculated curve. Lorenz and Binkowski (14) studied the rate of decomposition of GaN over the temperature range from 600° to 1000°C. They noted the highest N_2 pressures reached at the time the rate measurements were discontinued. These pressures also represent lower limits to the equilibrium curve and are plotted in Fig. 1. The five points are consistent with the estimated curve. Juza and Hahn (15) provide one point obtained by the same method.

The three sets of measurements just cited represent all of the information found in the literature that could be used to give lower limits to the equilibrium curve. There are three reports, however, on the reaction of NH_3 with Ga that can also be used to give upper limits to the equilibrium curve.

The first of these is by Maruska and Tietjen (16) who prepared GaN by passing GaCl and NH_3 in H_2 over a sapphire substrate at 825°C and at atmospheric pressure. The fact that GaN was formed in the presence of 0.14 atm of NH_3 and 0.86 atm of H_2 permits an upper limit to the equilibrium N_2 pressure over GaN and liquid Ga to be calculated. It is equal to the N_2 pressure corresponding to equilibrium with the NH_3 and H_2 pressures used in growing the GaN layers. This equilibrium is described by the equation

$$NH_3(g) = \frac{1}{2} N_2(g) + \frac{3}{2} H_2(g) \quad [4]$$

which leads to the following expression relating the partial pressures to the equilibrium constant, K_4

$$P_{N_2}{}^{1/2} = K_4 \frac{P_{NH_3}}{P_{H_2}{}^{3/2}} \quad [5]$$

The value of K_4 obtained from the JANAF Tables (12) is about 3×10^3 at 825°C, leading to a value for the N_2 pressure of 3×10^5 atm. This point is plotted in Fig. 1 and lies far above the calculated equilibrium curve. It is, of course, consistent with this curve but does not help appreciably to define it.

Recently, two additional observations related to the reaction of NH_3 with Ga provide upper limits to the equilibrium N_2 pressure curve. Logan and co-workers (17) have added N to GaP by passing NH_3 in H_2 over liquid Ga containing dissolved phosphorus from which GaP was grown by cooling. It was found that the N concentration in GaP was proportional to the NH_3 pressure and there was an NH_3 pressure above which good crystal growth of GaP was not possible. Lorimor and co-workers (18), in applying Logan's technique to the addition of N to GaP, observed that the concentration of N saturated. That is, crystal growth could be obtained with some difficulty at higher NH_3 pressures but no further increase in N concentration was found. They observed altered crystal growth and reported that GaN was formed.

The NH_3 pressures in H_2, at which GaN was formed from Ga in the studies of N doping of GaP, were in the range of 10^{-3} atm at temperatures of approximately 1000°C. Equivalent N_2 pressure can be calculated from the conditions used and have been plotted in Fig. 1. It is seen that Logan's point straddles the calculated curve, while Lorimor's point lies slightly below the curve. The temperature range of each of these points corresponds to the range over which GaP epitaxial layers were grown.

It is concluded that the equilibrium N_2 pressure curve lies on or below the curve plotted in Fig. 1 but not lower than 1 to 2 decades below it.

We have attempted to obtain improved upper limits to the equilibrium N_2 pressures by finding the mini-

mum NH_3 pressures at which GaN can be formed from Ga. Additional information has been obtained from the NH_3 pressure leaving the tube after reaction with Ga. The discovery that high pressures of NH_3, relatively speaking, are generated by the reaction of H_2 with GaN, has led to greatly improved lower limits to the equilibrium curve.

Experimental

Most of the GaN used in these studies was grown by reacting a partial pressure of NH_3 in H_2 with Ga at 1150°C in a furnace system that was previously used (17) to grow epitaxial layers of N-doped GaP. The furnace was modified so that an easily replaceable quartz liner was used inside the main quartz furnace tube. The NH_3 pressure ranged from 10^{-3} to 5×10^{-2} atm in H_2, with gas flow rates of 70 to 280 cc/min and a tube ID of 2.1 cm. The GaN formed was in the form of small, black, irregularly shaped crystals with dimensions ranging from 75 to 500 μm. The other GaN studied was composed of smaller crystals, gray in color, grown by Zetterstrom (19) by reacting Ga with 1 atm of NH_3 at 1100°C in a similar furnace. To separate out the very small crystals formed in this growth, the batch was repeatedly rinsed with agitation and the larger crystals retained. They ranged in size from 20 to 100 μm. In all cases, the GaN was separated from the Ga growth melt by digestion in aqua regia.

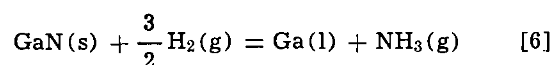
P_{NH_3} was determined by causing the NH_3-H_2 furnace exhaust gas to bubble through a 4 cm high column of HCl solution of known column and normality, and containing methyl red indicator. The normality of the HCl solution was adjusted to give a convenient titration time of 5 to 10 min so that the uncertainty (a few seconds) in the determination of the time of the indicator color change was negligible. The contribution of the indicator to the normality of the solution became significant (~10%) only at the lowest normality used ($2 \times 10^{-5}N$). Since the furnace gas flowed at constant rate rather than at constant pressure, the gas flow rate was unaffected by the small change in gas pressure due to the titration. The NH_3 dissolution into the HCl solution was complete as evidenced by doubling the column height of the HCl solution by the addition of H_2O, without changing the titration time for a given gas mixture. P_{NH_3} is determined from the gas flow rate and the titration time of the solution of known volume and normality.

The system was routinely monitored for evidence of dissociation of NH_3 in the furnace. A clear indication of dissociation was the variation of P_{NH_3} with furnace temperature. Dissociation could be made negligible by use of new quartz furnace liner which was cleaned in deionized H_2O and alcohol prior to use. No bake-out was necessary. The main quartz furnace tube caused NH_3 dissociation after continual use for one to three months. The dissociation correlated with devitrification of the tube and was rectified by replacement with a new quartz tube. It was observed that the low oxygen (and water vapor) level in the furnace ambient was essential to achieve negligible NH_3 dissociation. The pyrolytic graphite crucibles used both in the formation and dissociation studies of GaN did not cause NH_3 decomposition and the crucible weight loss during an experiment was less than 1 mg.

The NH_3 pressure from the reaction of H_2 with GaN was determined by inserting 1-13g of GaN crystals, contained in a pyrolytic graphite crucible, into the furnace, at uniform temperature and with a pure H_2 ambient. The NH_3 pressure in the exit gas was monitored continuously and increased to a constant value in about 60 min. This is about the time required to achieve a constant value of the NH_3 pressure when H_2 and NH_3 are mixed and passed through the empty tube. Typically, about 25 w/o (weight per cent) of the GaN dissociated, leaving Ga, in heating times which ranged from 16 hr at 925°C to 4 hr at 1175°C.

Results and Discussion

In the work reported here, the reaction of NH_3 with Ga has been used to give upper limits to the N_2 equilibrium pressure over GaN and Ga. The reaction H_2 with GaN has been used to give lower limits to the N_2 equilibrium pressure. Both of these reactions can be described by the following equation



$$\text{GaN(s)} + \frac{3}{2}\text{H}_2\text{(g)} = \text{Ga(l)} + \text{NH}_3\text{(g)} \quad [6]$$

The equilibrium constant relates the equilibrium pressures of NH_3 and H_2 in the equation

$$\frac{P_{NH_3}}{P_{H_2}{}^{3/2}} = K_6 \quad [7]$$

It has again been assumed that the nonstoichiometry range of GaN is small and that the solubility of GaN in Ga is negligible. The pressure ratio $P_{NH_3}/P_{H_2}{}^{3/2}$ is also given in Eq. [5] from which the following equations can be written

$$\frac{P_{NH_3}}{P_{H_2}{}^{3/2}} = K_6 = \frac{P_{N_2}{}^{1/2}}{K_4} \quad [8]$$

Since K_4 can be obtained from the JANAF Tables (12), the values of $P_{NH_3}/P_{H_2}{}^{3/2}$ can be calculated for the equilibrium N_2 pressures given in Fig. 1. They are plotted in Fig. 2 as log P_{NH_3} *vs.* $10^4/T$ and give the solid line. This is the reverse of the calculations made in the section on Comparison with Available Experimental Data to obtain upper limits to the equilibrium N_2 line from NH_3 and H_2 pressures at which GaN formed.

The minimum NH_3 pressures in H_2 at which GaN was seen to form when passed over liquid Ga, have been plotted in Fig. 2 and are upper limits to the equilibrium NH_3 pressure. Measurements made independently by Ilegems (20) are included.

An independent upper limit to the equilibrium curve is obtained from the pressure of NH_3 leaving the reaction tube. This pressure is always less than that entering. Measurements of the NH_3 pressure after NH_3 in H_2 was passed through clean empty tubes showed that negligible decomposition occurred. However, it cannot be ruled out that some decomposition of NH_3 to H_2 and N_2 occurred during the reaction with liquid

Ga. At lower NH_3 pressures where GaN is not formed, the NH_3 pressure decreased about 10% in passing through the reaction zone. We have taken this to be an estimate of the extent of dissociation of NH_3 in these experiments. The lowest observed exit pressures at several temperatures where GaN was formed are plotted in Fig. 2. These points may be too low by as much as 10%.

All of the upper limit points plotted in Fig. 2 are consistent with the calculated equilibrium line except for one point at the highest temperature which, however, agrees within the 10% estimated uncertainty.

We have found that impressively high pressures of NH_3 are generated when H_2 is passed over GaN. The measured pressures set lower limits to the equilibrium curve. The points plotted in Fig. 2 are the highest pressures measured at each temperature and are steady-state values achieved after about 1 hr of heating. They all are consistent with the estimated line and fall well within the band resulting from the 1 kcal uncertainty in the heat of formation of GaN.

The dependence of the NH_3 pressure on flow rate and sample area suggested that equilibrium was near. The observed NH_3 pressure increased ~20% as the flow rate decreased from 280 to 70 cc/min and a similar small increase was observed when the GaN area increased by a factor of 5. The GaN area was varied by changing the weight of crystals of a given mesh size. The points plotted in Fig. 2 are the highest NH_3 pressures measured at each temperature, obtained with the largest GaN area and smallest flow rate used at each temperature. It is possible, however, that equilibrium pressures were not attained because appreciable catalytic decomposition of NH_3 may have taken place in the hot tube down stream from the GaN. This possibility restrains us from accepting these as equilibrium measurements. They are, however, completely acceptable lower limits to the equilibrium curve.

On the basis of the lower and upper limiting points that we have obtained, we conclude that the equilibrium pressure of NH_3, given by the calculated line of Fig. 2, is consistent with all of the experimental information available as is true also for the pressure of N_2 given by the line of Fig. 1. The data of Lorimor *et al.* (18), plotted in Fig. 1 in terms of N_2 pressure, is plotted in Fig. 2 in terms of NH_3 pressure and provides an upper limit, with the indicated uncertainty in the NH_3 pressure. The data of Fig. 2 are summarized in Table I.

These results, then, are consistent with a heat of formation of GaN of -26.4 ± 1.0 kcal (2, 7, 8) and an entropy and heat capacity the same as those of ZnO

(9, 10). The heats of formation and free energies of formation used to calculate the curve of Fig. 1 are given in Table II.

Two criteria have been used to determine limits to equilibrium conditions: GaN must decompose or it must form. The fact that GaN may appear not to decompose under certain conditions does not give useful information since the rate of decomposition may be too slow to be observed. Similarly, Ga may appear not to react with N_2 or NH_3 and H_2 when, in fact, the reaction may be impeded by a thin surface nitride film. Conclusions can be drawn when changes occur; they cannot be drawn when changes do not occur.

We have taken advantage of two slow kinetic processes in order to closely approximate the equilibrium properties of GaN: the slow rate of decomposition of GaN to form Ga and N_2, and the slow rate of decomposition of NH_3 to N_2 and H_2. The iron-nitrogen system has been studied under somewhat related circumstances and equilibrium nitrogen pressures up to hundreds of thousands of atmospheres have been deduced from the much lower NH_3 pressures in H_2 used to control the nitrogen chemical potential (21).

Summary

The equilibrium pressure of N_2 over GaN and liquid Ga has been calculated from available thermodynamic functions with the assumption that the entropy and heat capacity of GaN are the same as those of ZnO. The calculated equilibrium pressure curve was found to be consistent with a number of reported experiments although the spread between upper and lower bounds was rather broad. NH_3 pressures in H_2, which were found to be the maximum pressures at which GaP, doped with N, could be grown (17, 18), gave equivalent nitrogen pressures in agreement with those calculated.

Three different experimental methods are reported here which were used to narrow the gap between upper and lower limits to the equilibrium pressure curve. In one method the minimum NH_3 pressure at which GaN could be seen to form on the surface of Ga was measured. Another consisted of measuring the NH_3 partial pressure in H_2 after passing over liquid Ga. Of importance is the last method, which appears to give results near equilibrium, where measurement was made of the NH_3 pressure generated by the reaction of H_2 with GaN. All measurements were consistent with the calculated equilibrium curve.

Acknowledgments

We are indebted to H. G. White for his assistance in performing these experiments. We thank M. Ilegems for helpful comments and for the experimental data used in Fig. 2 and R. B. Zetterstrom for providing the GaN crystals grown by reacting Ga with 1 atm of NH_3.

Manuscript submitted Sept. 22, 1971; revised manuscript received Dec. 27, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Kinetics of Manganeseo-Wustite Scale Formation on Iron-Manganese Alloys

P. Mayer* and W. W. Smeltzer**

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The oxidation kinetics of Fe-Mn alloys containing up to 59 w/o (weight per cent) Mn exposed to carbon dioxide-carbon monoxide atmospheres at 1000°C have been determined by a thermogravimetric technique. The experimental conditions were chosen in order that the reaction would lead to formation of a single-phase manganeseo-wustite [(Fe Mn)O] scale. The rate of parabolic oxidation decreased and the manganese content in wustite increased with increasing manganese content in the alloy. A diffusion model, which is based on equations derived by Wagner for metal diffusion through the scale under chemical activity gradients, leads to a description of the scaling kinetics, and to evaluations for the self-diffusion coefficients of iron and manganese and the nonstoichiometry as a function of the manganese content in wustite.

A major objective of this investigation was to contribute to the understanding of the oxidation mechanism of binary alloys when a single-phase superficial oxide scale is formed as the major reaction product with only a relatively small degree of oxide precipitation in an internal oxidation zone. In recent papers, Wagner (1), and Coates and Dalvi (2) have advanced methods for calculating the distribution of cations in a metal-conducting scale growing by parabolic kinetics. The Fe-Mn-O system could meet these requirements since Foster and Welch (3) have demonstrated that wustite and manganous oxide form a continuous solid solution.

In the present work, the oxidation kinetics, morphological development, and composition of the wustite scale on Fe-Mn alloys exposed to CO_2-CO atmospheres at 1000°C were investigated under conditions to insure formation of (FeMn)O scale by parabolic kinetics. These results are used in combination with diffusional and thermodynamic properties of this ternary system and the above-mentioned theoretical considerations to gain an insight into the mechanism of scale growth and the metal transport properties of the oxide solid solution.

Experimental

The alloys were prepared from electrolytic iron, 99.96 w/o (weight per cent) pure, and manganese, 99.99 w/o pure. Approximately 300g of material were placed in the melting chamber of a nonconsumable arc furnace with a tungsten electrode operating under argon. In order to prevent any long range segregation, each charge was melted, inverted, and then remelted until a total of four melting operations had been completed. It was then sealed in a quartz tube filled with argon and annealed for five days at 1000°C. The compositions of the alloys are given in Table I.

Alloy buttons were hot-rolled at 800°C to a thickness of 4 mm. The surface of each sheet was cleaned by pickling in dilute hydrochloric acid and by abrasion using 600 grit silicon carbide paper. The sheets were then cold-rolled to a thickness of approximately 2.5 mm. Test specimens, 10 × 10 × 2 mm, were prepared from these sheets by mounting plates in Bakelite and metallographically polishing all surfaces to 1μ diamond abrasive using kerosene as lubricant. After removal from the Bakelite mountings, specimens were washed with petroleum ether and stored in dried acetone.

Key words: Fe-Mn alloys, parabolic oxidation, manganeseo-wustite scale.

An Ainsworth, Type RV, continuous recording microbalance was used to determine the weight change of a specimen exposed to a reaction atmosphere. The thermogravimetric assembly has been described previously (4); the temperature of the reaction zone in the furnace was controlled to ±2°C. A specimen was lowered into the reaction atmosphere which was maintained at a flow rate of 0.6 cm/sec to prevent thermal segregation of the gases. Carbon dioxide, 99.95 v/o (volume per cent) pure, was dried by passage through columns containing magnesium perchlorate, reduced copper oxide, and activated alumina. Carbon monoxide, minimum purity of 99.6 v/o, was purified by passage through columns containing magnesium perchlorate and ascarite.

Oxidized specimens were mounted in epoxy, cold, self-setting resin, the final polishing being done with 1μ diamond abrasive and kerosene as lubricant. Chemical analyses were carried out by means of a Cameca electron-probe microanalyzer operating at 15 keV and a specimen current 50-80 nanoA. This instrument was calibrated as described previously (5). Standards for checking the calibration curves for the alloys were alloys of several known compositions. The calibration procedure for the wustite phase could be verified only for pure wustite. The Debye-Scherrer method of x-ray analysis using Co Kα radiation was used to determine oxide crystallographic structures.

Results

The dependences of the oxidation kinetics on the compositions of the exposed alloys and on the CO_2/CO ratios in the reaction atmospheres are illustrated by the parabolic plots [(oxygen weight gain/unit area)^2 *vs.* (time)] in Fig. 1 and 2. These curves, which were reproducible within ±15%, are of the same shape as those obtained for pure iron due to a relatively smaller reaction rate before onset of parabolic kinetics (6, 7). The plots in Fig. 3 illustrate that the values of the

parabolic oxidation constants decrease with increasing alloy manganese contents and carbon monoxide partial pressures.

Powder x-ray analyses of the scales demonstrated that they were composed of (FeMn)O with exception of those formed on pure iron and the alloy containing 10 w/o Mn exposed to pure carbon dioxide and a 100/10 CO_2-CO atmosphere. In these cases, the presence of magnetite was identified. The mean lattice parameter of the single-phase scales, Fig. 4, exhibited a variation linearly related to the MnO content of the oxide solid solution.

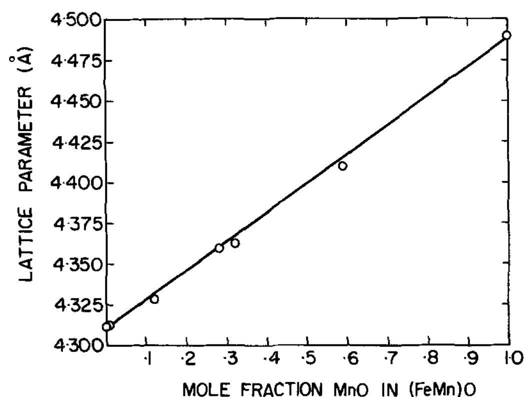

Fig. 4. Mean lattice parameter of the (FeMn)O solid solution scales.

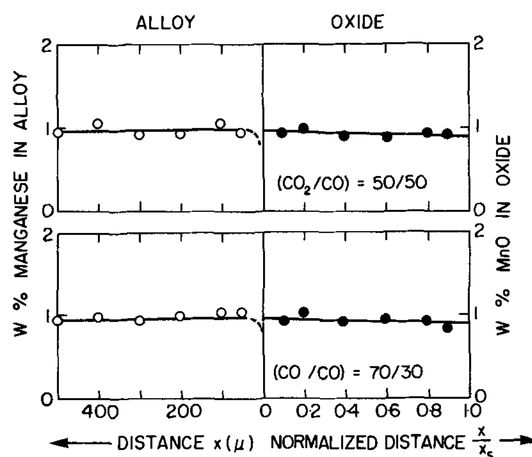

Fig. 7. Manganese concentration profiles in the metal and (FeMn)O scale of an Fe-1 w/o Mn alloy oxidized at 1000°C. The scale thickness has been standardized to $y = x/x_S$.

A scale was essentially compact and uniformly thick during its growth. There was a small degree of internal oxidation but the penetration depth of its zone was negligible compared to the thickness of the scale. These features are illustrated by the micrographs in Fig. 5 and 6. Internal oxidation for the Fe-1% Mn alloy was so small that its penetration distance could not be determined at the comparatively high magnification of 1000X. In the alloy of highest manganese content, 59 w/o Mn, the penetration depth of oxide never exceeded 10% of the scale thickness. The only oxide identified in both the scales and internal zones was (FeMn)O.

Manganese concentration profiles in the scales and alloy substrates of specimens exposed to the various atmospheres for different intervals in the regions of parabolic oxidation were determined by the electron microprobe technique. The profiles shown in Fig. 7 and 8 for the alloy specimens containing 1 and 59 w/o Mn illustrate typical distributions for the alloying element between the metal and scale. The manganese concentrations were determined to within ±0.5% of the determined values. Manganese depletion from an alloy was small, the depletion distance never extending inward more than 50μ from the alloy interface. The change of manganese concentration across a scale was small but the decrease in its concentration toward the outer surface gave rise to a linear manganese gradient. These gradients in the scales formed on the different alloys under various atmospheric conditions are recorded in Table II. Values are also tabulated for the MnO concentration at the outer scale surfaces as determined by extrapolation of the linear profiles.

Discussion

Oxidation of the alloys gave rise predominately to a scale consisting of a solid solution of the divalent oxides. An oxidation curve exhibited a region of slow reaction before onset of parabolic kinetics due to interfacial control at the scale/gas boundary. Oxidation in all atmospheres, nevertheless, proceeded at significant

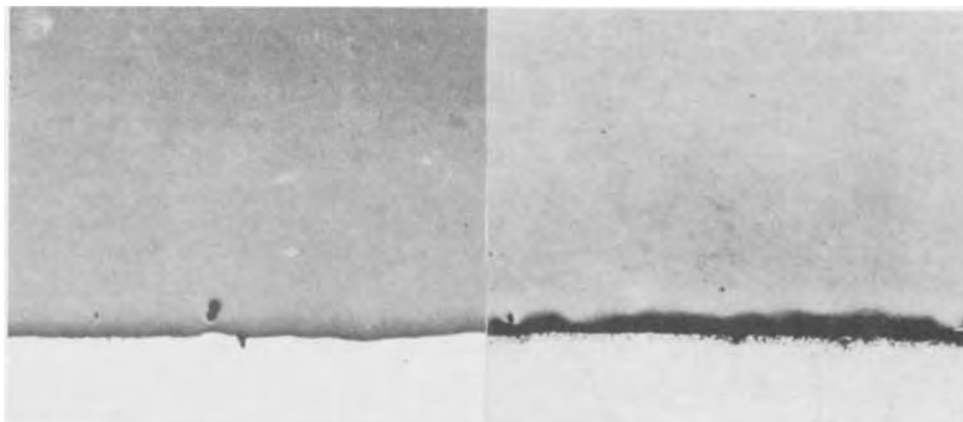

Fig. 5. The metallographic cross-sections and the interfaces between the scales formed on Fe-1 w/o Mn and Fe-12 w/o Mn alloys exposed to a 70/30 CO_2-CO atmosphere at 1000°C (X130).

Fig. 6. The metallographic cross sections and the interfaces between the scales formed on Fe-32 w/o Mn and Fe-59 w/o Mn alloys exposed to a 70/30 CO_2-CO atmosphere at 1000°C (X130).

rates because of rapid metal diffusion within the oxide layer of large nonstoichiometry. The metal ratio in the scale was only slightly different from that in the alloy inasmuch as manganese, the less noble metal, entered the scale preferentially. Further, the ratio of manganese to iron in the scale decreased with distance from the alloy interface due to manganese exhibiting a smaller mobility than iron in the oxide solid solution. The metal gradients, nevertheless, attained a steady-state value during the stages of parabolic oxidation kinetics (Fig. 7 and 8).

The occurrence of parabolic kinetics governing growth of a relatively uniform scale with steady-state gradients in the oxide solid solution and the absence of an appreciable degree of internal oxidation meet the requirements of the theoretical analysis carried out by Wagner (1) for the distribution of cations in a metal conducting scale. Accordingly, the equations that he has deduced may be utilized with the present experimental results to calculate the metal diffusion coefficients in (FeMn)O and the dependence of its nonstoichiometry on the MnO content. His formalism is used and the reader is referred to the original paper for mathematical details.

The equations for the flux of metal cations through the scale are

$$j_{Fe}(\text{eq}) = -D_{Fe}\frac{1-\xi}{V}\frac{\partial \ln a_{Fe}}{dx} \quad [1]$$

$$j_{Mn}(\text{eq}) = -D_{Mn}\frac{\xi}{V}\frac{\partial \ln a_{Mn}}{dx} \quad [2]$$

when correlation effects are disregarded. In these equations, D is a metal self-diffusion coefficient, ξ/V is the local concentration of manganese in equivalents per unit volume, and a is a local activity. Since the parabolic scaling rate is supposed to be controlled by diffusion, the above relationships yield Equation 11 from Ref. (1) for the parabolic oxidation rate constant

$$D_{Fe}(1-\xi)\left(-\frac{\partial \ln a_{FeO}}{\partial \xi}\frac{d\xi}{dy}+\frac{z_{Fe}}{z_o}\frac{d\ln a_o}{dy}\right) + D_{Mn}\xi\left(-\frac{\partial \ln a_{MnO}}{\partial \xi}\frac{d\xi}{dy}+\frac{z_{Mn}}{z_o}\frac{d\ln a_o}{dy}\right) = k \quad [3]$$

where ξ is the mole fraction of MnO in the oxide and $y = x/x_S$ is the normalized scale thickness.

The Gibbs-Duhem equation for the oxide solid solution may be expressed as

$$(1-\xi)\, d\ln a_{FeO} + \xi\, d\ln a_{MnO} = 0 \quad [4]$$

Since the (FeMn)O solid solution may be considered as nearly ideal (3)

$$\frac{d\ln a_{MnO}}{d\ln \xi} = 1 \quad [5]$$

Utilizing the equalities of the absolute valences, $z_{Fe} = z_{Mn} = z_o = 2$, we can express Eq. [3] upon substitution of [4] and [5] as

$$(1-p)\frac{d\xi}{dy} + \frac{d\ln a_o}{dy}[(1-\xi)+p\xi] = k^* \quad [6]$$

where

$$k^* = k/D_{Fe} \quad \text{and} \quad p = D_{Mn}/D_{Fe} \quad [7]$$

The metal profiles in the oxide scales which were stationary and very flat under conditions for parabolic oxidation could be approximated to a linear gradient

$$\xi = a + by \quad [8]$$

where, $a = \xi'$ is the mole fraction of MnO in the scale at its inner interface and b is the gradient across the oxide. On substitution of Eq. [7] and [8] into [6]

$$\frac{d\ln a_o}{dy} = \frac{k^* + (p-1)b}{1+(p-1)\xi} \quad [9]$$

The second equation that may be utilized in this calculation from Wagner's analysis is the algebraic expression 39 in Ref. (1) for material balance at the outer interface for manganese

$$-\left[D_{Mn}\xi\left(\frac{d\ln a_{MnO}}{d\xi}\cdot\frac{d\xi}{dy} - \frac{d\ln a_o}{dy}\right)\right]_{y=1} = \xi''k \quad [10]$$

On applying the same simplifications as in the previous case, the resulting expression is

$$k^* = p\frac{d \ln a_o}{dy} - \frac{pb}{\xi''} \quad [11]$$

Substitution of Eq [9] into [11] yields

$$k^* = \frac{pb}{(p-1)(1-\xi'')\xi''} \quad [12]$$

These equations allow one to express the cation self-diffusivities in the following forms

$$D_{Fe} = \frac{k\,\xi''\,(p-1)(1-\xi'')}{pb} \quad [13]$$

$$D_{Mn} = \frac{k\,\xi''\,(p-1)(1-\xi'')}{b} \quad [14]$$

where the parabolic rate constant k is related to the experimental rate constant k_p by the relation

$$k\left(\frac{cm^2}{sec}\right) = \frac{k_p}{2}\left(\frac{V}{16}\right)^2 \quad [15]$$

In order to carry out calculations for metal self-diffusion coefficients and oxide nonstoichiometry, certain assumptions and approximations must be made to evaluate the constant p. The manganese concentration in the scale at its outer surface for an alloy of given composition was not measurably dependent on the oxygen potential of the atmosphere over the CO_2/CO ratios examined (Table II). This result and in view of previous findings that the (FeMn)O solid solution is nearly ideal allows one to invoke the assumption by Wagner that the enrichment of a metal toward the outer surface in a scale (in this case iron) results from its larger mobility. Since there is general agreement that the transport of iron and manganese in FeO and MnO takes place by a vacancy mechanism (8, 10), we my approximate the self-diffusion coefficients to

$$D_{Mn} = D^\circ_{Mn}\frac{x_\square}{(x^\circ_\square)_{MnO}}; \quad D_{Fe} = D^\circ_{Fe}\frac{x_\square}{(x^\circ_\square)_{FeO}} \quad [16]$$

Here D° and $x^\circ_\square$ refer to the self-diffusivities and vacancy concentrations for the pure oxides, and $x_\square$ refers to the vacancy concentration in (FeMn)O. The ratio for the diffusivities in the oxide solid solution

$$\frac{D_{Mn}}{D_{Fe}} = \frac{D^\circ_{Mn}}{(x^\circ_\square)_{MnO}} \bigg/ \frac{D^\circ_{Fe}}{(x^\circ_\square)_{FeO}} \quad [17]$$

therefore essentially corresponds to the ratio of the jump frequencies for manganese and iron into an adjacent cation vacancy. Hence, the factor for manganese depletion across the scale may be regarded as corresponding to the mobility ratio of manganese to iron. That is

$$p = \frac{D_{Mn}}{D_{Fe}} = \frac{\xi''}{\xi'} \quad [18]$$

where from Eq. [8], $\xi''/\xi' = 1 + (b/a)$. A value of $p = 0.99 \pm 0.004$ is obtained using the results given in Table II.

The metal self-diffusivities are therefore related as follows

$$D_{Fe} = 1.01\,D_{Mn} \quad [19]$$

The self-diffusion coefficient of iron may now be determined by substituting the value for p and the experimental values for the oxidation parameters in Eq. [12]. These results are presented in Fig. 9. Addition of MnO to FeO decreased the diffusion rate of both cations. The values for the self-diffusion coefficient of iron in wustite for oxygen potentials corresponding to 50/50 and 70/30 CO_2-CO atmospheres may be evaluated from published results (8, 9). It is seen that the plots determined for this diffusivity in (FeMn)O under these conditions extrapolate to these limiting values.

Wustite and manganous oxide exhibit metal deficiencies associated with occurrence of cation vacancies (8, 10). The former oxide shows by far the largest range of nonstoichiometry at 1000°C and the magnitude of the self-diffusion coefficient for iron is directly proportional to nonstoichiometry (8, 9). We therefore express the dependence of the diffusivity on nonstoichiometry for the ternary oxide solid solution as

$$D_{Fe} = D^\circ_{Fe}\frac{x_\square}{(x^\circ_\square)_{FeO}} = D^\circ_{Fe}\frac{(X-1)X^\circ}{(X^\circ-1)X} \quad [20]$$

and where X° and X are the ratios of the atomic fractions of oxygen to metal in pure wustite and the ternary oxide. Consequently, we may utilize diffusion evaluations from this investigation to determine the variation of (FeMn)O nonstoichiometry with increasing manganese content.

The results of these calculations using Eq. [20] are shown in Fig. 10. A comparison is also given between the calculated values and those determined by Voetzel

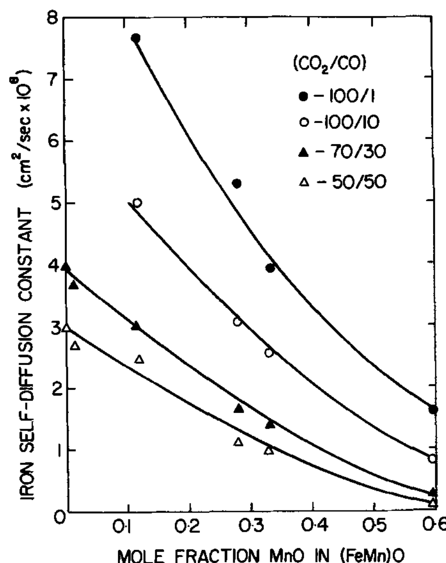

Fig. 9. Self-diffusion coefficient of iron in the (FeMn)O solid solution at 1000°C.

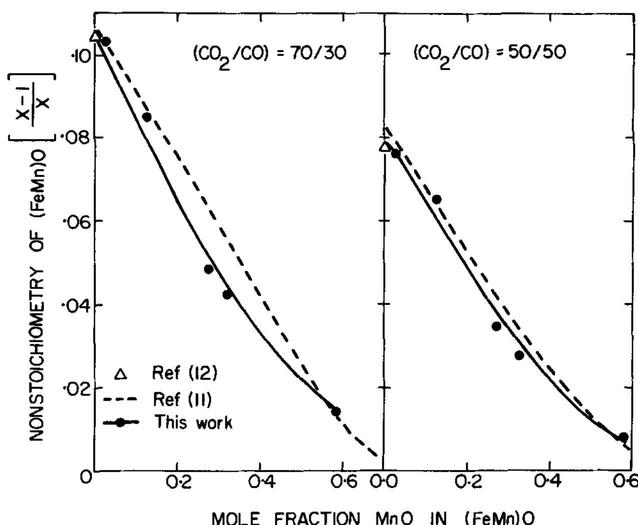

Fig. 10. Nonstoichiometry of the (FeMn)O solid solution at 1000°C. The dashed curve represents values obtained at 1100°C by Voeltzel and Manenc (11) on equilibration of (FeMn)O in atmospheres undergoing the water-gas reaction. The values for pure FeO are those determined at 1000°C by Swaroop and Wagner (12).

and Manenc (11) and Swaroop and Wagner (12). The determinations from the first investigation are those obtained at 1100°C, but the investigators report that the nonstoichiometry was practically identical within the experimental precision at 1100° and 1000°C in atmospheres of constant CO_2/CO ratio (11). A very small variation in nonstoichiometry of pure wustite only occurs over the temperature range 1000°-1100°C, the nonstoichiometry at 1000°C being 2-3% smaller than that at 1100°C for atmospheres of constant CO_2/CO ratio. Within these limitations, it can be seen from Fig. 10 that there is good agreement between values obtained in this investigation and those in the literature. This consideration offers additional substantiation to the diffusion model and analysis adopted to describe the parabolic oxidation kinetics of the Fe-Mn alloys in CO_2-CO atmospheres.

Summary

The parabolic kinetics were determined for the formation of the manganeseo-wustite scale on Fe-Mn alloys exposed to CO_2-CO atmospheres at 1000°C. The morphological development and manganese gradients in the scale and metal demonstrated that the reaction proceeded under steady-state conditions. A model based on a diffusion analysis was shown to account for this kinetic behavior. It was possible by this analysis to evaluate the self-diffusion coefficients for iron and manganese and the nonstoichiometry of wustite as a function of manganese content. All of these parameters were found to decrease with increasing amounts of manganese dissolved in the (FeMn)O solid solution.

Acknowledgments

This research was carried out under the auspices of the National Research Council of Canada. The paper is based on the thesis submitted by P. Mayer to McMaster University in partial fulfillment of the requirements for the M. Eng. degree.

Manuscript submitted Sept. 16, 1971; revised manuscript received Jan. 12, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

Electrical and Structural Properties of Metal Sulfides in Chloride Melts

The Systems Cu_2S-CuCl and FeS-$FeCl_2$

A. K. Garbee[1] and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The phase diagrams of the systems Cu_2S-CuCl and FeS-$FeCl_2$ and the densities of the liquid solutions have been measured over the permissible concentration and temperature ranges. Specific conductivities of the liquid mixtures have also been determined. The results indicate that the Cu_2S-CuCl solutions, for concentrations up to about 30 m/o (mole per cent) Cu_2S and temperatures below 1000°C, are essentially ionic conductors. Electronic conductance becomes evident for the more concentrated solutions. In the FeS-$FeCl_2$ solutions, ionic conductivity appears to be restricted to concentrations below 10 m/o FeS.

The thermodynamic calculations from the Cu_2S-CuCl phase diagram and the structural interpretation of the density measurements indicate that $(Cu_2S)_2$ dimers are present in dilute solutions. Further association occurs at higher concentrations and the formation of a continuous sulfide network appears to be related to the onset of electronic conduction. The solubility of copper metal in cuprous chloride is very low, and the conductivity of cuprous chloride, and of cuprous chloride-rich melts with cuprous sulfide, appears unaffected by the presence of copper metal. The addition of excess copper metal to molten cuprous sulfide, however, greatly increases its electrical conductivity.

Because the electrical conductivities of cuprous and ferrous sulfides are predominantly electronic in nature electrodeposition from the molten sulfides is not feasible. Electrolysis of solutions of Cu_2S in CuCl in the composition and temperature ranges of ionic behavior yielded copper metal at the cathode with high current efficiencies. Copper metal was also recovered selectively from solutions of a synthetic Cu-Fe-S matte dissolved in molten CuCl. It is also shown that FeS may be extracted from a synthetic FeS-Cu_2S matte by solvent extraction using molten CuCl at the appropriate temperatures. The extraction is attributed to an exchange reaction which converts the FeS component into the soluble ionic form of $FeCl_2$.

Previous work in this laboratory (1-4) and elsewhere (5-9) has indicated that the molten solutions of metal sulfides in their corresponding metal chlorides exhibit interesting thermodynamic and electrical properties. Within specific temperature and composition ranges such solutions, rather dilute in metal sulfide, behave like ionic conductors. As the sulfide con-

tent and the temperature are increased electronic conductivity sets in, and the concentrated solutions behave more like the electronically conducting "pure" molten metal sulfide. It is evident that in the range of ionic behavior the recovery of metals from their sulfide ores by fused salt electrolysis should be feasible. In addition to this practical aspect, the factors determining the ionic to electronic transitions as well as the thermodynamic and structural properties of such high-temperature liquid semiconductors are of theoretical interest.

The sulfide solutions investigated previously in this laboratory include Ag_2S-AgCl (1-2) and the PbS-$PbCl_2$ (3-4) binary systems. The present paper describes work on the thermodynamic and structural properties of the molten salt solutions of Cu_2S and of FeS in CuCl and $FeCl_2$, respectively. The investigation includes the determination of the liquidus curves of the binary systems Cu_2S-CuCl and FeS-$FeCl_2$, and measurements of densities and electrical conductivities in these systems. Finally, copper metal has been recovered by electrolysis of the Cu_2S-CuCl solutions and from a synthetic matte containing Cu-Fe-S dissolved in molten CuCl.

Experimental

Preparation of materials.—Anhydrous CuCl was prepared from an aqueous solution of cupric chloride by reduction with sulfurous acid. The precipitated CuCl was washed with anhydrous alcohol and was dehydrated by treatment under vacuum for several hours, followed by melting and sublimation in a stream of dry hydrogen chloride gas. Chemical analysis of the product indicated a purity of better than 99.7% by weight.

Anhydrous $FeCl_2$ was prepared from reagent-grade hydrated $FeCl_2$ dried in a vacuum oven at 110°C for several days. This partly dehydrated solid was finely ground in a dry box filled with purified argon and then was treated with dry hydrogen chloride gas at about 500°C. The chemical analysis of this product corresponded to a 99.7% $FeCl_2$ content.

Pure Cu_2S was prepared by direct reaction between stoichiometric amounts of hydrogen-reduced copper metal powder and sulfur which had been previously purified by sublimation. The reactants were charged to quartz ampoules which were then flame-sealed under vacuum. The reaction was completed by heating at about 600°C for at least three days.

The chemical analysis of the reaction product indicated a Cu_2S compound in the composition range $Cu_{1.97}S$ to $Cu_{2.00}S$. The x-ray analysis was in excellent agreement with the established diffraction patterns for Cu_2S.

Stoichiometric FeS was also prepared by reacting equivalent quantities of hydrogen-reduced iron metal powder (99.999% by weight) with sublimed sulfur in double-wall glass ampoules which were sealed under vacuum. This type of reaction cell was found necessary as, during heating, volume changes within the reacting mixtures tended to crack the inner compartment. The reaction between iron and sulfur was highly exothermic and could be initiated simply by touching the walls of the reaction site with a gas flame. When this initial violent reaction had subsided, the reaction cell was transferred to a furnace and heated to 600°C for a period of six days. The chemical analysis of the reaction product indicated an FeS composition between $FeS_{1.00}$ and $FeS_{1.01}$. X-ray analysis was in excellent agreement with the established diffraction patterns for FeS.

All other chemicals used in the course of this investigation (NaCl, KCl, and $BaCl_2$) were of reagent grade and were dried in a vacuum oven at 110°C prior to use.

Materials handling and transfer were always conducted in a dry box filled with purified argon gas, fitted with an air-lock.

Thermal stability of systems investigated.—Because of the pronounced dependence of the electrical properties of Cu_2S and FeS on stoichiometry the thermal stability of Cu_2S, FeS, and of their solutions with CuCl and $FeCl_2$, respectively, was investigated. This information was a prerequisite for designing appropriate freezing-point depression apparatus, the density measuring apparatus, and the cells for measuring the electrical conductivities. The arbitrary temperature of 750°C was selected for comparison, simply on the basis of its being about half-way between the melting points of Cu_2S and CuCl. For this measurement, about 4g of material was added to a thin-walled quartz basket which was suspended from a quartz spring thermobalance in a closed all-silica-glass system. After the entire system had been evacuated argon gas was introduced and a movable furnace kept at 750°C was raised until the part of the quartz tubing containing the basket was in the hot zone of the furnace. The observed loss of weight was then recorded as a function of time over a period of 18 hr.

Weight losses in pure Cu_2S and FeS were not detected. However, a solution containing 11 m/o (mole per cent) Cu_2S lost about 8% by weight due to vaporization of CuCl. With pure CuCl and $FeCl_2$ the weight losses due to vaporization were alarmingly high. Both samples lost about 20% by weight after 18 hr of exposure. A sample of Cu_2S of 4.642g was also studied thermogravimetrically at a temperature of 1150°C. The complete heating and holding at 1150°C for 1 hr resulted in a loss of weight of 17 mg due to sulfur evolution which is equivalent to 0.36% of the original weight. When cooled to room temperature the solidified melt had acquired star-shaped copper metal crystallites which were visible around the circumference.

Hence, at the higher temperatures in an open experimental apparatus some unavoidable desulfurization should be expected to occur. For this reason it was decided to conduct the experiments in closed systems, where possible, or otherwise to measure a given property over the shortest possible period of time which would be compatible with the establishment of equilibrium and the reproducibility of the measurement.

Experimental.—Liquidus temperatures in the Cu_2S-CuCl system were determined using a previously described technique (1, 3) and existing apparatus. Cooling rates were varied between 0.57° and 1.5°C/min. For these measurements the heart-shaped quartz cells fitted with a thermocouple well and containing about 15g of salt mixture were sealed under vacuum. Temperatures below 800°C were recorded using a 1 mV full-scale recorder and 24-gauge Chromel-Alumel thermocouples. For higher temperatures the thermocouples were platinum-13% platinum-rhodium. The sensitivity of the recorder was about 0.25°C, but the accuracy of the melting points should be taken as to the nearest degree. For chloride-rich compositions supercooling was not noticeable. However, supercooling did occur in the sulfide-rich melts and was minimized by vibrating the cells.

For the FeS-$FeCl_2$ mixtures, the steepness of the liquidus curve and the limited solubilities did not permit accurate cryoscopic measurements by this method. Only the melting point of pure $FeCl_2$ and the eutectic temperature could be detected. Hence, a decantation technique was employed. The measurements involved the equilibration at a given temperature of the sulfide-chloride mixtures placed in decantation quartz cells fitted with two side arms as described elsewhere (10).

At the beginning of a run, the cell with the salt mixture was sealed under vacuum and placed inside a graphite cylinder also containing the thermocouple wells and radiation baffles. The assembled system could be lowered into the hot zone of a cylindrical tilting furnace. The temperature along the 4-in. long graphite block was maintained constant to within +3°C. When heated to the desired temperature the liquid phase

saturated with FeS was decanted into the second side arm of the cell by tilting the entire furnace. Prior to decantation the solutions were allowed to remain for several hours at temperature to ensure equilibration. After cooling, the cell was opened and the decanted phase was analyzed by extracting the water-soluble $FeCl_2$ with distilled water. The accuracy of the method was established from separate blank experiments during which both fused samples and mechanically mixed FeS and $FeCl_2$ were used. The former method yielded consistently slightly lower FeS contents by less than 0.5%. Thus, even for the smallest sulfide composition studied, 2.34% by weight FeS, the absolute error was only 0.012%. The only significant uncertainty in this type of measurement originated from the difficulty in maintaining a temperature control over the 4-in. long decantation cell of better than $\pm 3°C$.

The densities of the molten solutions in the Cu_2S-CuCl and FeS-$FeCl_2$ systems were determined by measuring the apparent loss of weight of a density sinker dipping into a melt at given compositions and temperatures. The density sinker was made by encapsulating a tungsten rod in quartz glass. For the oxygen-free melts quartz was found to be an excellent container material. All measurements were conducted in an atmosphere of purified argon using the quartz spring thermobalance apparatus and the cathetometer described previously (1, 3).

For the present measurements the quartz spring under a load of 5g had a total extension of 65 cm, allowing the detection of weight changes of the order of ± 0.2 mg. The results were corrected for the slight increase in weight due to condensation of the salt on the quartz fiber supporting the density sinker.

The densities for pure Cu_2S could not be measured by this method because of the high viscosity and high surface tension of the melts.

Electrical conductivities in the systems Cu_2S-CuCl and FeS-$FeCl_2$ were measured as functions of melt composition and temperature, using the U-tube quartz capillary cells of 2 mm diameter described previously (2, 4). All measurements were taken under an atmosphere of oxygen-free argon gas. Cell constants varied between 500 and 900 cm^{-1}. Calibrations were made using a 1.0 demal KCl solution (11). The electrical conductivities were measured using an a-c conductivity bridge equipped with a Wagner ground and an oscilloscope detector. The bridge was operated at a frequency of 3000 Hz and resistances could be measured to within ± 0.02 ohms. All values were corrected for lead

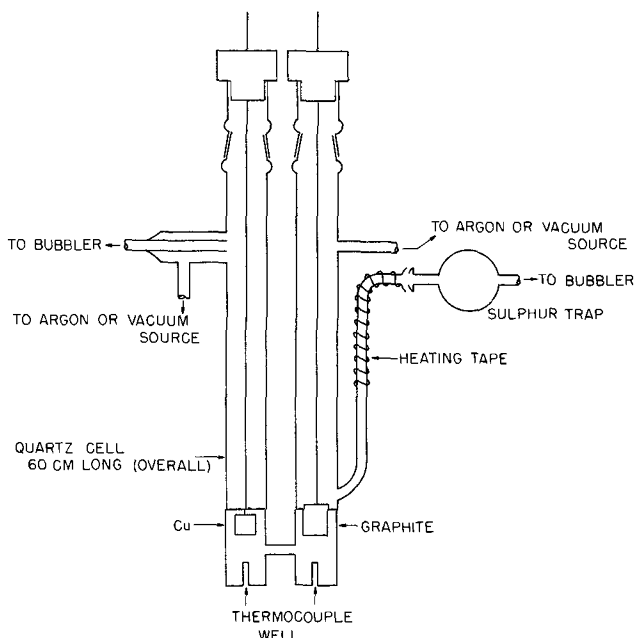

Fig. 1. Electrolysis cell

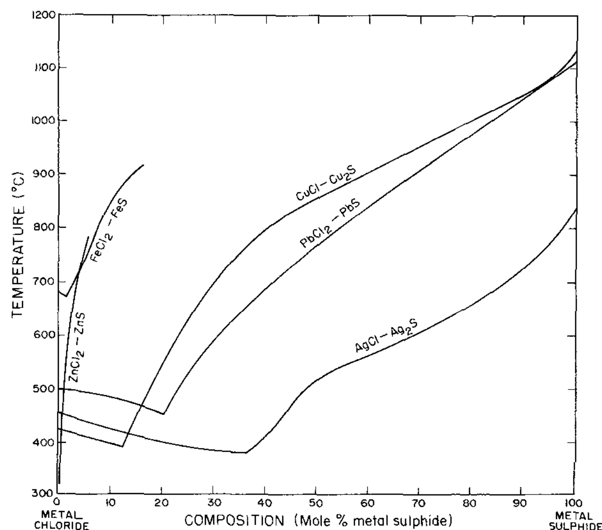

Fig. 2. Comparison between the phase diagrams of the systems: Cu_2S-CuCl, FeS-$FeCl_2$, PbS-$PbCl_2$, Ag_2S-AgCl, and ZnS-$ZnCl_2$.

and electrode resistances. For the lower temperatures the temperature control throughout the length of the cell was better than $\pm 1.5°C$, but between 1100° and 1200°C, it was only $\pm 3°C$.

Finally, the electrolysis experiments were conducted in the quartz cells shown in Fig. 1. Electrode materials were copper for the cathode and graphite for the anode. These cells were also operated under an atmosphere of purified argon.

Experimental Results

Phase diagram determination.—The liquidus curves for the system Cu_2S-CuCl and part of that for the system FeS-$FeCl_2$ are given in Fig. 2, where they are compared with those for similar systems.

The Cu_2S-CuCl system is of the simple eutectic type. The characteristic points are the melting points of CuCl and Cu_2S given as 422.9° $\pm$ 1.0°C and 1127.7° $\pm$ 2.0°C, respectively, and the eutectic temperature at 389.5° $\pm$ 1.5°C. The eutectic occurs at 12.1 m/o Cu_2S. The detailed data of the measured liquidus and eutectic temperatures are given in Table I.

Table I. Phase diagram measurements

The present data should be compared with previous measurements by Urazov and Schleide (12) and by Truthe (13). The agreement is generally poor on the Cu_2S side of the eutectic where there is a 36°C spread in the reported values for the melting point of "pure" Cu_2S. In the composition range between 70-90 m/o Cu_2S, Truthe's (13) measurements differ by about 60°C from the present results. Urazov and Schleide (12) did not report any measurements beyond 48 m/o Cu_2S.

X-ray studies on material cooled from the eutectic, on both the sulfide and the chloride-rich sides, did not show any peak shift or line broadening. Therefore, solid solubility in this system is slight, if it occurs at all.

The cooling curves for pure CuCl and for compositions rich in CuCl indicate an exothermic reaction at 406°C which should be associated with the phase transformation of CuCl (14) from α-wüstite to the β-zinc blende type structure.

Cooling curves for the system FeS-$FeCl_2$ for compositions up to 40 m/o FeS showed only one inflection at a eutectic temperature of 674°C. In nine determinations $FeCl_2$ was found to melt at 679.4° ± 0.7°C. The solubility of FeS in $FeCl_2$ is limited and was measured by the decantation technique. The results are given in Fig. 2 and in Table I.

In Fig. 2, the liquidus curves of the systems FeS-$FeCl_2$ and Cu_2S-CuCl are compared with those for Pb-$PbCl_2$ (3), Ag_2S-AgCl (1), and ZnS-$ZnCl_2$ (15).

It may be seen that at corresponding temperatures the solubility of the sulfides in the chloride melt decreases in the order: Ag_2S-PbS-Cu_2S-FeS-ZnS, which is in the same order as the cation-ionic radius, or in the approximate order of the melting points of the pure metal sulfides. Work in this laboratory (10) on the reciprocal systems, PbS-NaCl, PbS-KCl, PbS-RbCl, and PbS-CsCl has indicated solubilities of the order of only 2 to 5 m/o sulfide which increased from the NaCl-PbS to the CsCl-PbS systems. Thus, the solubility trends in common cation and in reciprocal systems are entirely different.

Cryoscopic calculations.—In order to clarify the transformation for CuCl, and also for the purpose of obtaining information regarding the nature and the activities of the ionic species present in these solutions and of their degree of dissociation, freezing point depression measurements were also made on the systems CuCl-NaCl, CuCl-KCl, and CuCl-$BaCl_2$.

From the results for the Cu_2S-rich liquidus curve, the activities of Cu_2S have been calculated using the simplified form of the van't Hoff equation

$$\ln a_{\text{solvent}} = \frac{-\Delta H_F}{R}\left[\frac{1}{T_L} - \frac{1}{T_F}\right] \qquad [1]$$

where, T_L and T_F are, respectively, the liquidus and the fusion temperature of pure Cu_2S, and ΔH_F is the heat of fusion of Cu_2S given (16) as 2600 ± 500 cal. The results of the calculations are presented in Table II and indicate positive deviations from ideality.

Activity calculations were also made for CuCl for compositions along the CuCl liquidus. For this calculation the new heat of fusion for CuCl, determined calorimetrically in this laboratory (16), was used. The calorimetric measurements have shown that the solid transformation for CuCl at 406°C is accompanied by a heat effect of 1550 ± 50 cal/mole. Fusion occurs at 422.9°C and has a heat effect of only 1800 ± 50 cal/mole. It should be noted that the solid transformation is not mentioned in compilations of thermodynamic data and the heat of fusion is reported as having such widely different values as 2430 cal/mole (17) and 3879 cal/mole (18).

For the calculation of the activities of CuCl at temperatures below the transformation temperature, the van't Hoff equation was used in the form

$$\ln \frac{a_{T_L}}{a_{T_T}} = -\frac{(\Delta H_F + \Delta H_T)}{R}\left[\frac{1}{T_L} - \frac{1}{T_T}\right] \qquad [2]$$

where, a_{T_L} and a_{T_T}, are the activities at the liquidus and the transformation temperatures, respectively. ΔH_F is the heat of fusion of (β)-CuCl, and ΔH_T is the heat for the $\alpha \rightarrow \beta$ transformation.

All activity calculations are referred to pure supercooled CuCl as the state of reference. Table II also includes the activities of CuCl in the binary systems CuCl-$BaCl_2$, CuCl-KCl, and CuCl-NaCl, calculated from the cryoscopic results. It is readily seen that in these systems the deviations from ideality are slightly negative, while in the Cu_2S-CuCl system the deviations are positive. The positive deviations from ideality in the CuCl-Cu_2S system may be considered as evidence that Cu_2S is present in the liquid solutions as associated species.

Solute association may be evaluated quantitatively by applying the limiting law to the van't Hoff relationship. For the very dilute solutions, Eq. [1] may be written as

$$\Delta T = -n\,\frac{RT_F^2}{\Delta H_F}\cdot\frac{M_{CuCl}}{1000}\cdot m \qquad [3]$$

where, ΔT, is the measured freezing point depression, m is the molality of Cu_2S, and n has the significance of the number of foreign particles produced from one molecule of solute.

Using Eq. [3], n has been calculated from the experimental ΔT values, and the calculations are summarized in Table III.

For a molten salt system with a common ion, $n = 1$ if the solute salt is totally dissociated. Inspection of the data in Table III shows that n is essentially unity for the systems NaCl-CuCl, KCl-CuCl, and CuCl-$BaCl_2$. For the system CuCl-Cu_2S, n is about 0.6, indicating that Cu_2S exists as an associated species.

If it is assumed that Cu_2S in solution is present as

* For dilute solutions

$$X_{solute} = \frac{M_{CuCl}}{1000} \cdot m$$

where, M_{CuCl} is the molecular weight and X is the mole fraction.

the dimer $(Cu_2S)_2$, the following association reaction should be expected to have occurred

$$Cu_2S \rightleftharpoons \tfrac{1}{2}(Cu_2S)_2$$

The equilibrium constant for this reaction may be written as

$$K = \frac{\frac{\alpha}{2}X}{(1-n)X} \qquad [4]$$

where, α represents the fraction of Cu_2S which forms the associated species and X is the solute mole fraction.

From a mass balance calculation it is readily shown that

$$n = 1 - \frac{\alpha}{2} \qquad [5]$$

From Eq. [4] and [5]

$$K = \frac{(1-n)X}{(2n-1)} \qquad [6]$$

Using the n values determined by cryoscopy for the dilute solutions containing up to 5 m/o Cu_2S, K is found to be practically constant for all compositions and to have the average value of $K = 1.3$.

From the α values obtained from Eq. [5] it is seen that about 80% of Cu_2S is present in the dilute solutions in the form of $(Cu_2S)_2$ dimers.

The behavior of Cu_2S in the Cu_2S-CuCl system bears close resemblance with that of PbS in the PbS-$PbCl_2$ system previously investigated (3), which also showed positive deviations from ideality. However, in the Ag_2S-AgCl (1) system the dilute solutions of Ag_2S were shown to obey Temkin's rule, thus indicating that Ag_2S could be present either as a dissociated compound or as a monomer (Ag_2S).

Similar calculations have not been performed on the FeS-$FeCl_2$ system owing to the limited solubilities observed and also because of the lack of reliable data for the heat of fusion. It is evident, however, from the low solubilities that this system should also be characterized by large positive deviations from ideality.

Density measurements.—Densities were measured as functions of composition from pure CuCl to solutions containing 69.4 m/o Cu_2S. Because of the volatilization of CuCl at high temperatures, most of the measurements with melts rich in CuCl were conducted at temperatures below 750°C.

Similar measurements for the FeS-$FeCl_2$ system could only be obtained over the narrow composition range permitted by the phase diagram. Reproducibility for all these measurements was better than ± 0.3%. The density data for each composition were fitted by

the least squares method to linear equations of the type

$$d = a + bt$$

where a and b are constants, and t is the temperature in °C. The equations for the two systems, CuS_2-CuCl and FeS-$FeCl_2$ are given in Table IV, together with the corresponding standard deviations.

Densities for pure CuCl have also been measured by Klemm (19) and are in agreement with the present results to within ± 0.5%.

From the results shown in Table IV molar volume isotherms for the Cu_2S-CuCl system were calculated at the selected temperatures of 500°, 750°, and 1000°C, and are shown in Fig. 3.

The dominant feature of the molar volume isotherms is a pronounced minimum occurring at about 30 m/o Cu_2S at 1000°C. The minimum is shifted to lower Cu_2S contents as the temperature is decreased.

The isotherm at 1000°C indicates negative deviations from apparent additivity. The approximate partial molar volumes that may be obtained from the isotherm at 1000°C by the method of tangents indicate two distinct trends. Below about 30 m/o sulfide, CuCl in solution should have about the same packing as in pure CuCl. Molten CuCl in this sense appears to be an associated liquid and to have a loosely packed structure. Cu_2S enters these solutions at a substantially decreased partial molar volume of about 25.9 cm^3/mole. For compositions containing more than 30 m/o Cu_2S the trend is reversed and CuCl appears to enter an essentially unaltered Cu_2S structure at the smaller

Parentheses indicate extrapolated values.

partial molar volume of about 27.2 cm^3/mole. The partial molar volume of Cu_2S in this range appears to be approximately the same as for pure Cu_2S.

These effects may be understood if it is considered that in concentrated solutions Cu_2S exists as a heavily associated structure of rather poor packing where CuCl can be easily accommodated. The decrease of the partial molar volume of Cu_2S for compositions below 30 m/o Cu_2S is indicative of the more efficient accommodation of the sulfide within the open CuCl structure because of dissociation of the polymeric Cu_2S to simpler species. This interpretation is in agreement with the cryoscopic calculations which indicated the presence of Cu_2S dimers in dilute solutions.

The shift with decreasing temperature of the minimum in the volume isotherms toward lower sulfide concentrations indicates the possible increase in the covalency of the melts at the lower temperatures.

The transition toward increased association at about 30 m/o Cu_2S at 1000°C roughly corresponds to the composition at which, as it will be shown shortly, significant electronic conduction appears to be setting in.

For the few compositions studied, molar volume isotherms have been calculated for the $FeS-FeCl_2$ system and are given in Fig. 4. It is seen that the molar volume decreases linearly with increasing FeS content. The initial decrease of the molar volume on addition of FeS appears to follow the same trend as with the copper system.

Electrical conductivity measurements.—Cu_2S-CuCl system.—Specific conductivities for pure molten CuCl were determined at temperatures between 450° and 970°C, and are given in Fig. 5 and in Table V.

The system has also been investigated by Grantham and Yosim (20) in the temperature range 475°-1157°C, and by Sakai (21) in temperature of 475°C to about 600°C. The present results are in excellent agreement with the former. It is of interest to note the nonlinear increase of the electrical conductivity of CuCl with temperature. At about 900°C the conductivity curve reaches a maximum and then the conductivity acquires a negative temperature coefficient. This abnormal behavior has also been detected by Grantham and Yosim (20) and has been explained as indicating increased covalency in CuCl at the high temperatures. Nevertheless, the magnitude of the conductance is typical of that encountered with ionic melts. Additional evidence for the ionic behavior of molten CuCl is provided from electrolysis experiments which have been reported to proceed with 100% current efficiency (8).

The specific conductivity of pure molten Cu_2S has also been measured in the temperature range 1130°-1195°C and is represented by the equation

$$K \text{ mho} \cdot cm^{-1} = 19.5010 + 0.1235\ (t - 1000°) \text{ in °C} \quad [7]$$

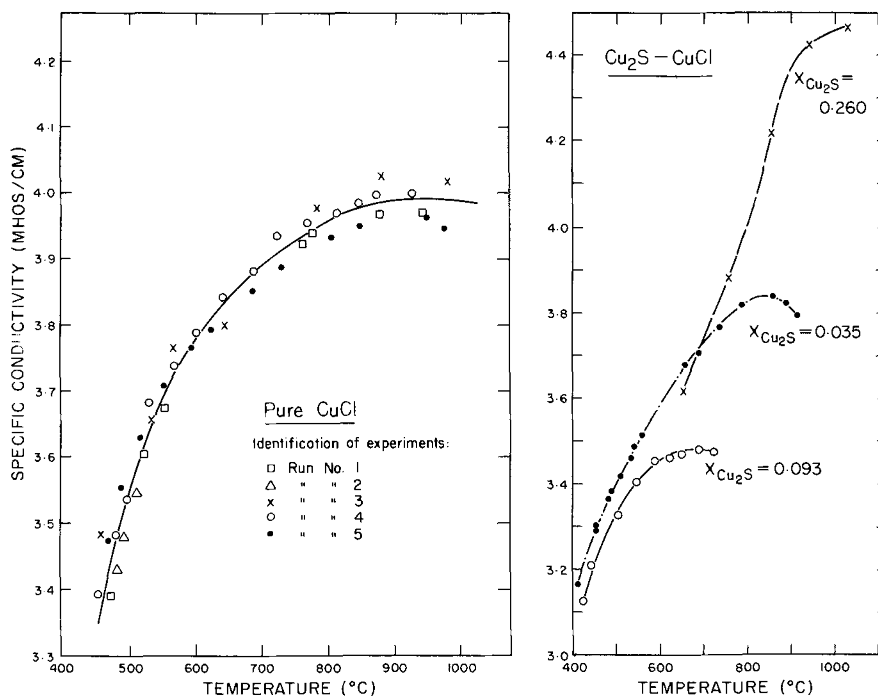

Fig. 5. Specific conductivities of pure molten CuCl and Cu_2S-CuCl melts containing 3.5, 9.3, and 26.0 m/o Cu_2S, respectively.

The standard deviation is 0.365 mho/cm. Molten Cu_2S may be described as a liquid semiconductor having conductivities which increase from 35 mho/cm at 1130°C to 44 mho/cm at 1195°C. At temperatures higher than 1200°C significant desulfurization of the molten sulfide was evident and measurements were not taken.

The specific conductivities of nonstoichiometric molten Cu_2S containing excess copper were also measured at 1150°C and the results are given in Fig. 6. For these measurements the nonstoichiometric Cu_2S was prepared by melting together in the conductivity cell known amounts of copper metal powder with stoichiometric sulfide. Clearly, the presence of excess copper causes a significant increase in the conductivity of molten Cu_2S.

The present results on "stoichiometric" Cu_2S are about 35% lower and less temperature dependent than the values reported by Yang, Pound, and Derge (8), although the Cu_2S used by the latter contained between 0.44 and 1.64% excess copper and should be expected to yield higher conductivities. Knacke and Strese (22) have also reported values for the conductivities of Cu_2S which change from 25 mho/cm at 1130°C to 97 mho/cm at 1480°C and are much lower than the present results.

The specific conductivities of the Cu_2S-CuCl solutions were also measured as functions of melt composition and temperature and the results are summarized in Table V. The specific conductance curves for melts containing 3.5, 9.3, and 26 m/o Cu_2S are also given in Fig. 5.

The conductivities for the latter were not linear functions of temperature and could not be represented by linear equations. The transition from a positive to a negative temperature coefficient which was observed with pure CuCl also characterized the Cu_2S-CuCl melts containing up to about 27 m/o Cu_2S.

The specific conductivity isotherms in the low-temperature range up to 700°C for solutions containing up to 25 m/o Cu_2S are given in Fig. 7. It is evident that the specific conductivity of the solutions decreases initially on addition of sulfide. For the isotherm at 700°C, the conductivities reach a minimum at about 10 m/o Cu_2S and then increase up to the liquidus composition. These solutions should be considered as ionic as their conductivities are still lower than the conductivities of pure CuCl at the same temperatures.

The initial decrease of the conductivity on addition of sulfide should be attributed to the lower mobility of the divalent sulfide anion and to its anchoring effect on the surrounding cations. The thermodynamic calculations have indicated the presence of associated $(Cu_2S)_2$ dimers and such nonionic groups are not expected to contribute to the ionic conductivity. The conductance minima shift toward higher sulfide concentrations at lower temperatures.

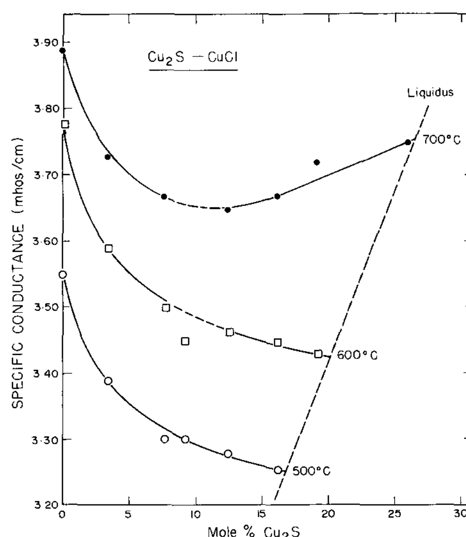

Fig. 7. Specific conductivity isotherms of dilute solutions of Cu_2S in CuCl.

The specific conductivity data at 1000°C given in Table V have been converted to molar conductivities and are presented in Fig. 8. A significant increase in the specific conductance is observed at higher temperatures when the sulfide content exceeds about 30 m/o. Thus, the molar conductivity of a solution containing 30 m/o Cu_2S is about 30% higher than that of pure CuCl. As the associated Cu_2S in solution is not expected to contribute to the conductance, as shown by the initial decrease in conductance on the addition of Cu_2S, it follows that the increase in conductance must be attributed to electronic contributions.

When the present results are compared with the measurements by Yang, Pound, and Derge (8), there is disagreement with regard to the sulfide content at which electronic conductivity sets in. At 1200°C

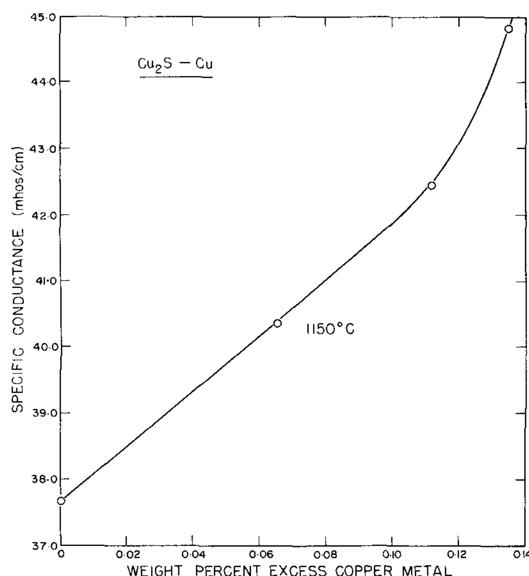

Fig. 6. Conductivities of nonstoichiometric Cu-rich cuprous sulfide at 1150°C.

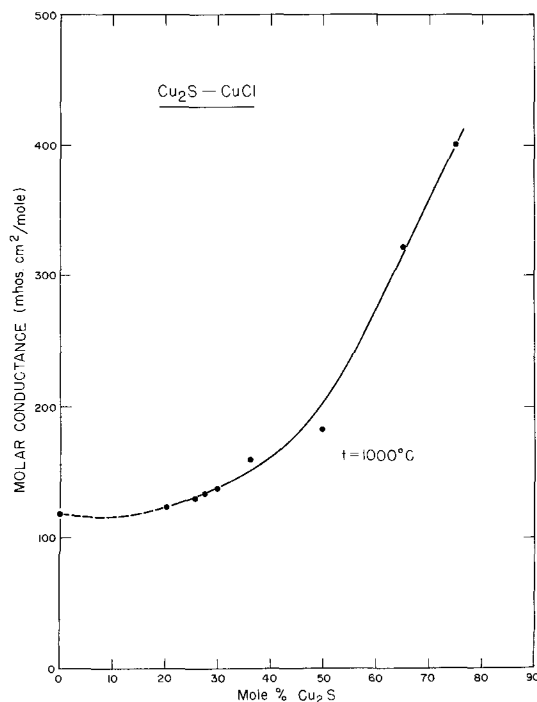

Fig. 8. Molar conductivity isotherm at 1000°C of the Cu_2S-CuCl system.

the specific conductivities measured by these authors remained almost constant at 5 mho/cm, from pure CuCl to about 50 m/o Cu_2S, and then increased to about 77 mho/cm for "pure" molten Cu_2S. Hence, melts containing up to 50 m/o Cu_2S were considered to be ionic conductors. In the present study even at 1000°C electronic conductivity sets in at about 30 m/o Cu_2S, and at 1200°C it should be expected that the onset of electronic conductance would occur at even lower Cu_2S contents.

Considering the effect of dissolved copper on the specific conductivities of the Cu_2S-CuCl melts, measurements were also obtained with conductivity cells fitted with copper electrodes immersed in melts containing pure CuCl and a Cu_2S-CuCl solution (15 m/o Cu_2S), respectively, at a temperature of 700°C. Both these solutions had previously been equilibrated with Cu metal. The resistance of these cells was monitored as a function of time. After 72 hr of operation the resistance change was only 0.5%, indicating that for all practical purposes the presence of dissolved copper in these melts, if any, does not introduce electronic contributions.

FeS-FeCl₂ system.—The specific conductivity for pure $FeCl_2$ was also measured as a function of temperature and may be expressed by the equation

$$K_{FeCl_2}\,(\text{mho}\cdot\text{cm}^{-1}) = 0.00149 + 1.889 \times 10^{-3}\, t\ (\text{in } ^\circ\text{C}) \quad [8]$$

with a standard deviation of 0.004. Other data for this system are not available in the literature.

As was the case with the density measurements with the FeS-$FeCl_2$ melts the specific conductivity measurements presented in Fig. 9 are restricted to a narrow range of compositions. The dotted lines represent extrapolated values obtained from measurements at higher temperature where the system is miscible. It is evident that in this system a conductivity minimum does not occur.

From the conductivity isotherm at 925°C it is seen that the FeS-$FeCl_2$ solutions probably remain essentially ionic up to a composition of 10 m/o FeS, and that the more rapid increase in conductance at higher concentrations could indicate possible electronic contributions.

Accuracy of results.—With regard to the accuracy and reproducibility of the results, the reproducibility of the specific conductivities for CuCl between runs was of the order of ±0.03 mho/cm, or within ±0.9%. For $FeCl_2$ the reproducibility was of the order of ±0.01 mho/cm, or better than ±0.8%. The electrical conductivity of cuprous sulfide could be reproduced within ±0.15 mho/cm, or better than ±0.4%. Reproducibilities of the conductivities of the solutions were of comparable magnitude. However, taking into account the additional factors of calibrating procedure and temperature uncertainty, the accuracy of the conductivity measurements reported herein is given with 1% confidence.

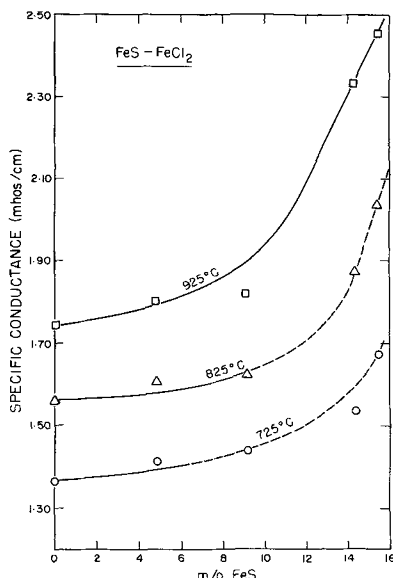

Fig. 9. Specific conductivity isotherms in the FeS-$FeCl_2$ system

Electrolysis experiments.—For the binary mixtures Cu_2S-CuCl the electrolyte contained 10 to 20 m/o Cu_2S and the temperature was varied between 450° and 600°C. Electrolysis of Cu_2S dissolved in molten CuCl, and of a synthetic Cu_2S + FeS matte dissolved in molten CuCl, produced copper metal at the cathode and sulfur gas at the anode. The choice of electrolyte composition was made so as to obtain the highest sulfide content in the ionic composition range indicated by the conductivity results. Also, it was desirable that the solutions should remain liquid at low enough temperatures. The boiling point of sulfur (444.6°C) was used as the lower temperature limit for the experiments, and therefore, the anodic reaction product was always a vapor which could be swept out of the anode compartment by the argon carrier gas.

The current efficiencies were obtained by weighing the cathodic deposits and were found to vary. Low values for the current efficiencies for small amounts of deposits could be attributed to the fragile structure of the dendritic deposits and to the resulting breakage of the dendrites while the cathodes were being removed from the melts. Continuous electrolysis produced large well-shaped copper crystals. The structure of the deposits was not uniform throughout deposition. At the initial stage of electrolysis the deposits were generally coarse and multipyramidal but further deposition led to the formation of rather large dendritic crystals having fine needle-like projections. In all 25 electrodeposition runs the measured deposition potentials were of the order of 0.3-0.5V, which values are lower than 0.63V representing the theoretical (17) decomposition potential of Cu_2S in an ideal solution.

Current efficiencies of about 80% were obtained in the low-temperature range 450°-500°C with low apparent current densities up to 15 mA/cm², and with Cu_2S concentrations not exceeding 30 m/o. An electrolyte containing 6.6 m/o Cu_2S, at a cathodic current density of 0.3 mA/cm², yielded a current efficiency of 97.3%. Apparent current densities of the order 20-40 mA/cm² usually yielded poorly defined deposits and low current efficiencies of about 50%. At 650°C, a solution containing 46.4 m/o Cu_2S yielded a small amount of spongy deposit mixed with electrolyte with practically zero current efficiency, because of the electronic conductance at such high Cu_2S concentrations.

With the ternary solutions, FeS-Cu_2S-CuCl, which are the equivalent of dissolving the synthetic matte in a CuCl solvent, electrolysis produced copper metal at the cathode and chlorine-contaminated sulfur gas at the anode. Deposition of iron metal appeared to be totally absent. This behavior should be understood in terms of the exchange reaction

$$FeS_{(S)} + 2CuCl_{(L)} \rightleftharpoons Cu_2S_{(L)} + FeCl_{2(L)} \quad [9]$$

which is thermodynamically favored and has a standard free energy of −9800 kcal/mole at 1100°C. The implications are that in the molten salt mixture of the synthetic matte Cu_2S-FeS dissolved in excess CuCl, the stable components are $FeCl_2$ and Cu_2S. Considering 1 g·mole of solution having the initial composition: X_1 g·moles CuCl, X_2 g·moles Cu_2S, and X_3 g·moles FeS, where $X_3 \leq X_1$ and X_2, the final composition after the exchange reaction has taken place is readily calculated as

$$X_{CuCl} = \frac{2X_1 - X_3}{2X_1 + 2X_2 + 3X_3}, \quad X_{Cu_2S} = \frac{2X_2 + 2X_3}{2X_1 + 2X_2 + 3X_3}$$

$$X_{FeCl_2} = \frac{2X_3}{2X_1 + 2X_2}, \text{ and } X_{FeS} = 0 \quad [10]$$

Table VI. Effect of exchange reaction on composition: FeS-$CuCl$-Cu_2S solutions

These solutions must contain an excess of $CuCl$ for the purpose of insuring complete solubility of the sulfides, and ionic type conductivities.

The approximate decomposition potentials may be calculated using Raoultian activities as

$$E_{\text{dec.}} = E^{\circ}_{AX} - \frac{RT}{ZF} \ln X_{AX} \quad [11]$$

where, E°_{AX} is the standard potential for pure liquid AX at a temperature T, and X_{AX} represents the final concentrations of a given species AX, which is calculated taking into account the exchange reaction. The standard potentials may be calculated from available free energy data for pure $CuCl$ (23), Cu_2S (17), and $FeCl_2$ (17), respectively.

The effect of the exchange reaction on the decomposition potentials of the species in solution is demonstrated by the sample calculation in Table VI. It is evident from Table VI that the Cu-S pair has the lowest decomposition potential of about 0.5-0.6V, which is in agreement with the observed decomposition voltages in all experiments. The decomposition voltage of $FeCl_2$, which is formed as the result of the exchange reaction, is greater than 1.0V and hence it should not interfere with the deposition of copper. Thus, the selective separation of copper from iron by electrolysis of a Cu-Fe-S matte dissolved in a cuprous chloride solvent is feasible.

The above conclusion appears to be more valuable than the conclusion that copper metal can be electrodeposited from the solution of Cu_2S-$CuCl$. In traditional copper extraction from sulfide ores a substantially pure Cu_2S product is only obtained after treatment of the reverberatory matte. If the matte consists essentially of Cu_2S and FeS, direct recovery of copper by molten salt electrolysis might be suggested. However, the exchange reaction (9), while it does make possible the selective electrodeposition of copper, is also consuming copper-containing solvent ($CuCl$).

Molten salt solvent extraction.—From previous work in this laboratory (10) on alkali halide-metal sulfide systems and from the present results it has been established that limited solubility is common in reciprocal chloride-sulfide mixtures. However, utilizing the exchange reaction [9], FeS may be separated from the Cu_2S present in a synthetic FeS-Cu_2S matte by a solvent extraction process involving the use of molten $CuCl$.

Exchange reaction [9] predicts that the nominal ternary system Cu_2S-FeS-$CuCl$ in the presence of excess $CuCl$, is best represented by the system Cu_2S-$CuCl$-$FeCl_2$. In the latter the solubility of iron which is now present as the ionic component $FeCl_2$ is expected to be quite high even at relatively low temperatures.

To substantiate the above possibility, quartz cells of the same type as the FeS-$FeCl_2$ decantation studies were used to sample the liquid phase representing the saturated solutions of Cu_2S and FeS in molten $CuCl$. Chemical analysis for iron and copper of the samples obtained by decantation at various temperatures indicated that the ratio of iron to copper in the molten $CuCl$ phase was greater than in the remaining solid mixture, except at the highest temperatures studied. The iron to copper ratios are summarized in Table VII. The decreasing ratio with increasing temperature is likely due to increased solubility of Cu_2S at the higher temperatures. Therefore, it is concluded that molten salt solvent extraction can separate iron from copper at appropriate temperatures. As shown, the iron-rich melt thus produced may be electrolyzed directly to yield electrolytic copper. Also, if desired, $FeCl_2$ may be separated from the sparingly soluble Cu_2S by aqueous leaching, as indicated in the experimental section.

It may be concluded that the combination of molten salt solvent extraction with electrolysis could provide the basis for a new process leading to the recovery of copper and possibly of iron from copper-iron mattes.

Discussion

When the electrical properties of the Cu_2S-$CuCl$ and the FeS-$FeCl_2$ melts are compared with the previously investigated systems Ag_2S-$AgCl$ (1, 2) and PbS-$PbCl_2$ (3, 4), there are several common characteristics which become evident. In dilute solutions of sulfide and at low temperatures the electrical conductivities in these four systems appear to be ionic. As the sulfide content and the temperature are increased electronic conductivity sets in and the solutions behave like liquid semiconductors.

In the Ag_2S-$AgCl$ (2) system, 1% electronic conduction appears at about 15 m/o Ag_2S at 750°C, and at about 25 m/o Ag_2S at 530°C. In the PbS-$PbCl_2$ system (4) electronic conduction starts at about 35 m/o PbS. In this respect the Cu_2S-$CuCl$ system behaves more like the lead than the silver systems. In addition, both pure molten PbS and pure molten Cu_2S exhibit positive temperature coefficients for conduction. The conductance of Ag_2S is relatively insensitive to temperature changes. Also, the specific conductance appears to increase for both PbS and Cu_2S on melting. There is a corresponding decrease for Ag_2S.

The more "ionic" character of the Cu_2S-$CuCl$ solutions may be related to the weaker electronic character of the "pure" molten Cu_2S. A comparison of the specific conductivities of a number of "pure" metal sulfide is given in Table VIII. It is readily seen that on the basis of the electronic conductivities, Cu_2S is a more "ionic" sulfide than either PbS, Ag_2S, or FeS.

The electrical properties of the metal sulfide-metal chloride solutions, namely, the magnitude of electronic conductivity at some common concentration of sulfide, and the sulfide composition at which electronic contributions set in, indicate similar trends. Thus, the order of increasing electronic conductance in the sulfide-chloride melts follows the sequence Cu_2S, PbS, Ag_2S, and FeS, and the order of sulfide content in the MS-MCl binary systems at which electronic conductivity sets in appears to increase in the opposite direction.

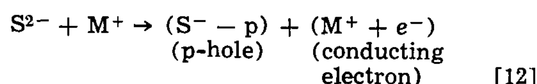
For the dilute solutions of the metal sulfides in their chlorides the thermodynamic calculations and the interpretation of the molar volumes for these systems are in substantial agreement in indicating the dissociation of the sulfides into monomeric- or dimeric-type species. These solutions appear to be ionic conductors.

The electronic conductivity in the sulfide-rich melts appears to be related to the association of the sulfide species and to the creation of a continuous sulfide network acting as a suitable path for electron transfer. This was particularly evident in the Ag_2S-AgCl and Cu_2S-CuCl melts where the abnormally high partial molar volumes of the metal sulfides for the sulfide-rich compositions indicated the presence of the associated sulfide network of rather poor packing capacity. The breakdown of the electronic conductivity on the addition of the metal chloride is at least partially due to the dissociation of the structure into monomeric or dimeric species and to their subsequent isolation by the chloride solvent. The electronic conductivity in molten metal sulfides may be understood in terms of a modified "band model."

In a perfect covalently bonded material the electrons are generally restricted in their directional bonds and cannot contribute to the conductance. The appearance of electronic conductivity requires the promotion of electrons from their valence band to a conducting energy level. At high temperatures such transitions are probable and in addition impurity-type mechanisms may arise as the result of the thermal decomposition of the sulfides which is expected to create some nonstoichiometry. Also, in polar crystals the electrons of the negative ions may be excited to a conduction band of positive ions creating positive holes which offer a convenient path for p-type semiconductivity. Electrons excited to a conduction band may contribute to the electronic conductivity by moving from one positive ion to the next.

Thus, the conductivity mechanism for monovalent molten sulfides may be described by exchange reactions of the type



$$S^{2-} + M^{+} \rightarrow \underset{\text{(p-hole)}}{(S^{-} - p)} + \underset{\text{(conducting electron)}}{(M^{+} + e^{-})} \quad [12]$$

followed by

$$(M_{*}^{+} + e^{-}) + M^{+} \rightarrow M_{*}^{+} + (M^{+} + e^{-}) \quad [13]$$

for n-type conductivity and by

$$S_{*}^{2-} + (S^{-} - p) \rightarrow (S_{*}^{-} - p) + S^{2-} \quad [14]$$

for p-type conductivity. In addition, electron trapping should not be excluded and the melts could become predominantly p- or n-type semiconductors.

The excitation of electrons from the valence band of S^{2-} species to the conductance band of the M^{+} species requires a certain energy E_g, and in an electronically conducting liquid the concept of the band model must be modified to account for the lack of long-range order. However, the degree of directional long-range order which appears to exist in these polymeric sulfides should be helpful for the purpose of understanding the conductivity path for electron transfer. In addition, collisions between polymeric chains and chain rearrangements should present instantaneous energetically favorable conditions for electron transfer from chain to chain. Apparently, the presence of the ionic component MCl in a binary system MCl-MS has the effect of decreasing the size of the polymeric M-S chains through the normal route of dissociation and the over-all energy gap for the transfer process increases with increasing MCl content until the solutions become ionic.

The measured activation energies (4) in the PbS-$PbCl_2$ system support this interpretation. The activation energy for electronic conduction which is about 8 kcal in "pure" molten PbS increases to 18, 22, 25, and 38 kcal/mole as the concentration of PbS in the binary PbS-$PbCl_2$ systems decreases to 80, −6, 45, and 40 m/o, respectively. The number of thermally activated carriers for electronic conductivity, if nonstoichiometry effects are ignored, should also be a function of temperature and increase as the temperature increases.

The addition of excess dissolved metal increases the total electronic conductivity because the added M atoms act as electron donors according to reaction [4]

$$M \rightarrow M^{+} + e^{-} \quad [16]$$

However, it should also be expected that such electrons are donated at a conduction band level and accordingly the activation energy for conduction should not be affected to any large extent. The behavior of the previously investigated Pb-PbS-$PbCl_2$ (4) ternary system supports this interpretation. For solubilities of Pb in PbS ($X = 0.45$) − $PbCl_2$ melts varying between 0.01 and 1.13 m/o Pb the activation energy for conduction remains constant at about 25 kcal/mole. This activation energy is about the same for the binary PbS-$PbCl_2$ melt containing 45 m/o PbS which do not contain any dissolved "excess" lead.

It appears, however, that the ionization reaction [16] does not proceed to completion and that only a fraction of the "excess" metal atoms present are capable of providing conducting electrons. For example, a Cu_2S-Cu melt containing 0.012 w/o (weight per cent) dissolved copper has a conductivity which is only 4 mhos/cm higher than that of pure molten Cu_2S. Similarly, in the case of the PbS-$PbCl_2$-Pb system (4) it has been calculated that if all the added metal atoms were ionized giving free electrons in the conduction band, then a concentration of 0.014 m/o excess Pb should have increased the melt conductivity by about 1000 times.

Thus, it is evident that excess metal solubility should be accounted for by both "ionized" and "nonionized" species, the latter being the most numerous. The excess metal solubility in the corresponding pure metal sulfides at comparable temperatures appears to decrease in the order Cu_2S-PbS-Ag_2S. However, the magnitude of the electronic conductivity in these liquids does not appear to be directly related to the metal solubility.

On the Transition from Internal to External Oxidation in Ternary Alloys

Howard W. Pickering*

Edgar C. Bain Laboratory, United States Steel Corporation, Research Center, Monroeville, Pennsylvania 15146

ABSTRACT

Addition of certain metals to binary A-B alloys can markedly improve oxidation resistance through formation of a dense layer of BO_ν on the surface, *e.g.*, the addition of Cr to Fe-Al alloys with the formation of a dense layer of Al_2O_3. The reason for the improved oxidation resistance is the subject of this paper. Experiments are described for the model alloy system, Ag-Zn-Al. A Ag-3 atomic per cent (a/o) Al alloy exhibits internal oxidation without formation of an Al_2O_3 layer on the surface. Upon addition of 21 or 25 a/o Zn, internal oxidation is completely suppressed and a dense, highly protective Al_2O_3 layer is formed. These data support the mechanism originally advanced by Wagner whereby Zn functions as a secondary getter for oxygen atoms. Other aspects of the results pertaining to the occurrence of exclusive internal oxidation in the alloys of low solute content and to the complex transient behavior exhibited by alloys of intermediate solute content are also discussed.

Oxidation resistant alloys for industrial use at elevated temperatures are usually ternary or multicomponent alloys rather than binary alloys. The low oxidation rate of Fe-Cr-Al alloys, for example, is well known (1-6). The good performance of these alloys results from the formation of a dense Al_2O_3 layer over the surface. The presence of Cr in the alloy in relatively large amounts is essential for the formation of this layer at feasible Al contents. Yet, Cr does not appear to enter the Al_2O_3 layer to an appreciable extent. Addition of other elements to Fe-Al alloys (in place of Cr) are in certain instances even more beneficial for the formation of an Al_2O_3 layer (7).

Wagner (8) has tentatively outlined the basic principles underlying the oxidation resistance of such alloys. In essence he suggested that one or more of the components functions as a getter for oxygen along with the component of highest affinity for oxygen. The action of the secondary getters supposedly decreases the diffusion of oxygen inward when the dissolved primary getter is depleted in the surface layers. In discussing the Cu-Zn-Al system Wagner points out that the oxygen concentration in the alloy next to the ZnO layer, determined by equilibrium between ZnO and Zn in the alloy, may be as small as 10^{-6} of that determined by the coexistence of Cu and Cu_2O, as in the case of a copper alloy containing 1 or 2 a/o Al but no Zn. Hence virtually no oxygen diffusion into the alloy is to be expected when Zn is present in rather large amounts. As a result Al atoms may diffuse to the depleted surface region without being intercepted by oxygen atoms. They may then react with oxygen and also with the Cu_2O and ZnO which are formed at the beginning of oxidation (along with nuclei of Al_2O_3) to form more Al_2O_3 by a displacement reaction.

Wagner (8) specifically explained in this manner the excellent oxidation resistance of the Fe-Cr-Al alloys as well as that of the Cu-Zn-Al alloys as reported by Dunn (9) already four decades ago. The possibility of forming a dense Al_2O_3 layer by addition to the alloy of other metals has considerable technological importance since the ternary alloys with low Al content not only give excellent oxidation resistance but at the same time exhibit good mechanical behavior—quite the contrary of their counterpart binary alloys which have poor mechanical properties as a result of the high Al contents required for the formation of a protective Al_2O_3 layer.

Pfeiffer's (5) x-ray and electron diffraction data of the oxide scales which form on Fe-20% Cr-5% Al at 1073°-1473°K in air may be an indication that the

			Ag20Zn6Al	20.2 ± 0.6 (4)	6.1 ± 0.3 (2)

Wagner mechanism operates in this system. At early stages of oxidation, corresponding to the formation of $\sim 3 \times 10^{-6}$ cm-thick scales, Al_2O_3, $FeAl_2O_4$, and Cr_2O_3 were identified, whereas at longer times ($\sim$ μm-thick scales) only Al_2O_3 could be found.

It is the purpose of the present work to obtain a more definite validation of Wagner's tentative proposal by systematically investigating the oxidation behavior of a series of binary and ternary alloys. For ease of interpretation and experimentation Ag was chosen as the principal component since it does not form a stable oxide above 460°K at one atmosphere of oxygen, and Zn and Al were chosen as the secondary getter and the protective scale former, respectively, in accord with their relative tendencies to form stable oxides. The system Ag-Zn-Al is thus a model system in which the complexities of multiphase and multilayer surface oxides are not encountered.

As a result of prior investigations on Ag-In (10,11) and other alloys (12-17), in the present study one may expect that Ag-Al and Ag-Zn alloys with low Al and Zn contents would show internal oxidation, whereas those of higher ($\gtrsim$ 15 a/o) Al and Zn contents would show external oxidation. The ternary Ag alloys of low Al and Zn contents also may show internal oxidation whereas if the Wagner hypothesis holds, ternary alloys of low Al but high Zn content should exhibit external oxidation and a low rate of oxidation through formation of an Al_2O_3 surface layer.

Experimental Procedure

Alloy samples were exposed to 1 atm of oxygen at 823°K (550°C) and in a few cases at 923°K (650°C). Except where specifically stated, data are for 823°K. The alloys, Table I, were prepared from 99.9999% Ag, 99.9999% Al, and 99.999% Zn by zone leveling in a high-purity graphite boat under an atmosphere of Pd-purified hydrogen; the Ag and Zn metals were deoxidized prior to alloying by melting under the same atmosphere. This melting procedure was found to be the best of several tried; appreciable Zn loss was encountered in the melting of the high Zn alloys but since the loss per zone leveling pass was fairly reproducible, sufficiently close estimates of the required Zn content in the initial charge could be made. The zone-leveling homogenization was determined to be satisfactory by chemical analysis. Subsequent electron microprobe examination of the specimens detected no microsegregation in the alloys. The alloys are all well within the composition range of the terminal fcc phase of the binary Ag alloys so that metallic-metallic phase transformations are not likely during oxidation. A section of each ingot was cleaned of oxide by grinding and was cold-rolled to 0.05 cm. Specimens 1.3 cm on edge were cut from the strip and a small hole drilled at one corner for suspension. The specimens were then cleaned in chloroform, rinsed in alcohol, and dried prior to a recrystallization anneal at 873°K in an evacuated silica capsule for 7.2 ksec (20 hr). Grain size of several of the alloys was measured and found to be in the range of 0.05 to 0.2 mm. Immediately prior to a run the specimen was electrolytically etched in 1N HNO_3 at 0.06 A cm^{-2} for 30 sec, as suggested by Rapp (11). This procedure gave sufficiently reproducible results in the oxidation runs. A 3-winding, vertical-(silica) tube furnace (18, 19) with a 4-cm uniform-temperature zone of ±0.2°K was used for the oxidation experiments.

Before a run a specimen was weighed by a balance precise to 0.05 mg and then suspended in the cold zone above the furnace by a silica hook and stainless steel chain. With the reaction zone at 823°K (or 923°K) and a steady upward oxygen flow of approximately 2 cm^3 sec^{-1} the specimen was lowered into the reaction zone, held there for a prescribed time, and then raised to the cold zone. After cooling the specimen was removed and weighed. Weight gain data as a function of oxidation time were obtained by oxidizing several specimens of a given alloy for different times in this manner. Each specimen was then examined by cross-section metallography and other methods. In a few experiments continuous weighings were made using another furnace of similar design and a thermobalance; this produced complete weight gain-time data with one specimen. Results were essentially the same with both weighing methods; unless otherwise stated, data in this paper were obtained by the discontinuous weighing method. Cross-section metallographic examination and electron microprobe analysis after completion of a run helped ascertain the structure and composition of the oxidation zone.

Results

The data are presented and analyzed in separate sections, first those pertaining directly to the Wagner hypothesis and subsequently two other sections, one on the Ag alloys of low solute content which undergo exclusive internal oxidation and the other on the alloys of intermediate solute content which eventually exhibit a low oxidation rate after an initial period of high oxygen uptake.

Transition in ternary alloys (Wagner hypothesis).— Weight-gain, m, and thickness, ξ, of the zone of internal oxidation, for reaction of Ag-Al and Ag-Zn specimens with oxygen at 1 atm and 823°K (550°C), are shown in Fig. 1-3. Ag3Al (Ag-3 a/o Al) was found to oxidize at a very high rate, and according to the parabolic law for the duration of the test of 61.2 ksec (17 hr) except for a relatively short initial period. This, along with other information to be presented, established that the Ag3Al alloy undergoes essentially exclusive internal oxidation, and, hence, is suitable for investigating the role of Zn additions. In contrast the rate of oxidation of Ag10Al and Ag14Al is very low (Fig. 1) as a result of the formation of a dense, protective Al_2O_3 layer. The addition of Zn by itself to Ag is not as effective as Al additions in reducing the oxidation rate (Fig. 3), *e.g.*, the Ag21Zn alloy oxidizes at a rate nearly matching that of Ag3Al.

The weight-gain at 823°K for ternary Ag-Zn-Al alloys containing 3 a/o Al and various amounts of Zn are shown in Fig. 4. Additions of 21 or 25 a/o Zn to the Ag3Al alloy are sufficient to reduce the rate of oxidation to a very low value, similar to that of the Ag14Al alloy. Actually the rate attained after an initial period is even lower than that indicated by the total weight gain of 150 μg since extrapolation of the data to zero time gives a nonzero intercept (100 to 150 μg), *i.e.*, there is an initial, though brief, higher rate

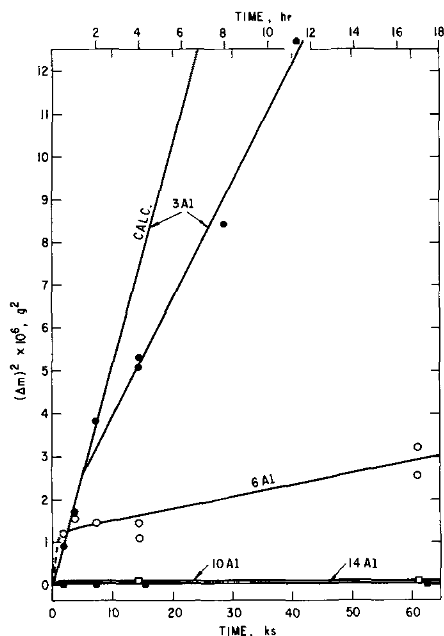

Fig. 1. Weight gain-time data for Ag3Al(●), Ag6Al(○), Ag10Al(□), and Ag14Al(■) specimens at 823°K. Calculated weight gain for exclusive internal oxidation (Eq. [7]) are given for comparison.

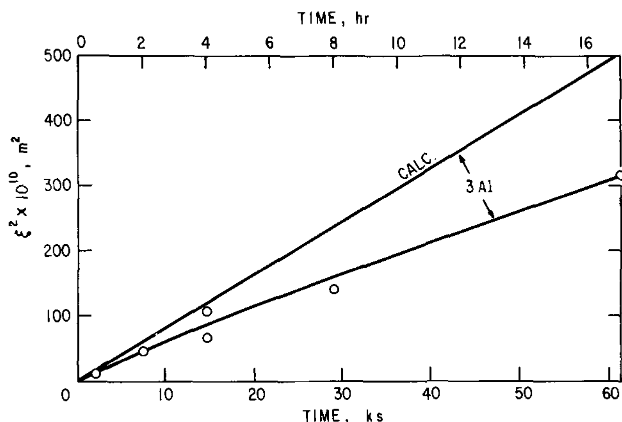

Fig. 2. Measured thickness-time data of the zone of internal oxidation on Ag3Al(●) specimens. Each point represents the mean value of 16 or more measurements on each specimen; the largest standard deviation was only 2.2 x 10^{-5} *m* for the mean value at 61.2 ksec. Calculated thicknesses (Eq. [5]) of the internal oxidation zones are given for comparison.

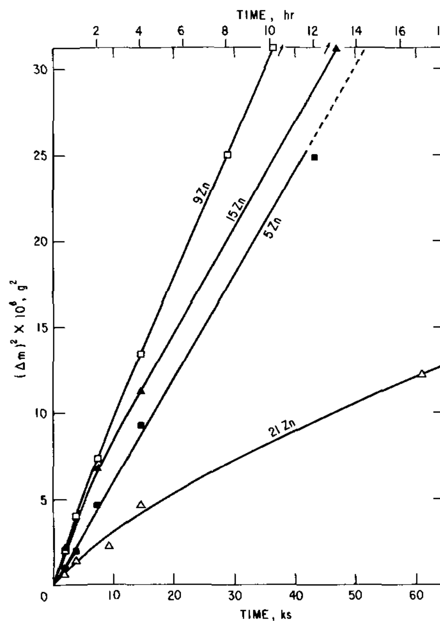

Fig. 3. Weight gain-time data for Ag5Zn(■), Ag9Zn(□), Ag15Zn(▲), and Ag21Zn(△) specimens.

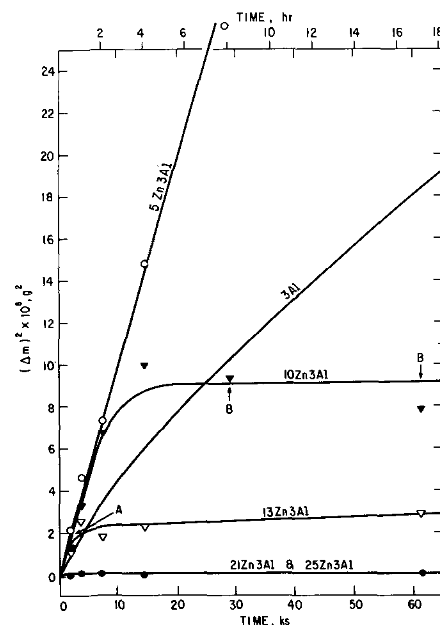

Fig. 4. Weight gain-time data for Ag5Zn3Al(○), Ag10Zn3Al(▼), Ag13Zn3Al(▽), Ag21Zn3Al(●), and Ag25Zn3Al(●) specimens. and for Ag3Al from Fig. 1.

Fig. 5. Cross-section micrograph showing a zone of internal oxidation (Z.I.O.) in a Ag3Al sample which was oxidized for 29 ksec at 823°K. Etched.

of oxidation. Similarly there was found an initial higher rate of oxidation for the binary Ag10Al and Ag14Al alloys. The exceedingly low rate of oxidation attained in the second period is essentially the same for the alloys, Ag10Al, Ag14Al, Ag21Zn3Al, and Ag25Zn3Al, in agreement with the formation of a dense, protective Al_2O_3 layer on each of the alloys.

Similar oxidation results were obtained for the ternary alloys containing 6 a/o Al and varying amounts of Zn. These data, though, are less instructive since according to Fig. 1, the Ag6Al alloy already exhibits partial formation of a protective Al_2O_3 layer.

Cross-section metallographic observations of the specimens are in agreement with the above interpretation of the kinetic data. Oxidized Ag3Al specimens show a zone of internal oxidation (Fig. 5).

In contrast the Ag10Al, Ag14Al, Ag21Zn3Al, and Ag25Zn3Al specimens form only a thin oxidized region along the surface (Fig. 6 and 7). The detailed morphology of this region is the same for all four alloys, and is more complicated than the formation merely of a dense Al_2O_3 layer at the surface. Proceeding outward from the alloy there is often a discontinuous porous layer, then a dense layer, and finally patches of a white, metallic-appearing material. A porous region appears as a cavity or gap unless precautions are taken to avoid pullout during metallographic preparation as in the middle micrograph of Fig. 6.

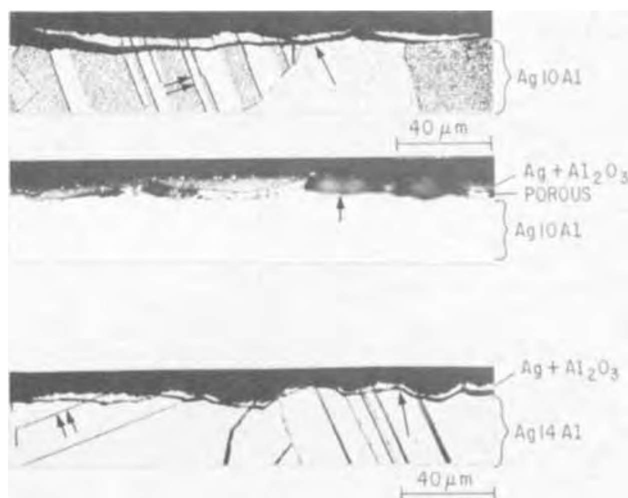

Fig. 6. Cross-section micrographs of oxidized Ag10Al and Ag14Al samples. The top and bottom micrographs are etched. ↑ indicates gap. ↑↑ indicates twin boundary.

The patches of white material were identified as Ag by electron microprobe examination. Silver was seen on the surfaces of many specimens, and particularly those containing higher amounts of solute as in Fig. 7. Wriedt and Darken (20) also observed Ag patches on the surface of internally oxidized Ag-Al alloys, and found that the amount increased with time of oxidation. They identified them by x-ray diffraction. Two sets of Ag lines were observed: one from the Ag patches on the surface and the other from an expanded and distorted Ag matrix within the internal oxidation zone.

The dense layer contains the alloy microstructure (Fig. 6 and 7), *i.e.*, grain and twin boundaries, characteristic of a zone of internal oxidation. Yet, for the ternary alloys in particular, these layers reflect light rather poorly, much as oxide layers do. Furthermore, in the case of the ternary alloys the dense layer is decidedly enriched in Zn and approximately unchanged in Al relative to the bulk alloy according to electron microprobe examination; this indicates a high volume per cent of oxide, mainly ZnO, in the layer. The Ag content in the layer on the other hand is lower than in the alloy, in agreement with the presence of Ag on the surface.

Electron microprobe examination was not made for Ag10Al and Ag14Al alloys. Presumably the dense layer has a higher ratio of Ag/Al_2O_3 than in the ternary alloys, since the (alloy) microstructure was more readily revealed by etching and the amount of Ag on the surface was less.

The occurrence of some, albeit very little, "internal" oxidation during exposure of the oxidation-resistant binary and ternary alloys to oxygen agrees with the brief, higher oxidation rate prior to the establishment of the exceedingly low oxidation rate shown for these alloys in Fig. 1 and 4. The dense Al_2O_3 layer which ultimately forms and reduces the oxidation rate to virtually nil is probably very thin and is not resolved by optical microscopy.

Discussion.—These data show that the addition of Zn to a Ag alloy containing a relatively small amount of Al results in the formation of a dense, protective Al_2O_3 layer. The beneficial effect of Zn in the formation of this layer is illustrated in Fig. 8. These data support the Wagner hypothesis (8, 21, 22) for the transition from internal to external oxidation in ternary alloys and, along with other data to be described, give some clue as to further details. On the basis of the data the transition is visualized as follows: When the surface of a Ag21Zn3Al alloy is initially bare, ZnO and Al_2O_3 are nucleated at the beginning of oxidation. The relatively large amount of Zn provides for the formation of sufficient oxide in the surface region to effectively block the diffusion of oxygen. Much of the initial silver in this region is "extruded" (20) or migrates to the surface; the latter may occur if the activity of Ag in the zone of internal oxidation is greater than unity as a result of strain. The presence of a ZnO layer ensures that the activity of oxygen in the alloy is very low, since it is determined by the coexistence of ZnO and Zn. As a result, the diffusion of oxygen into the alloy is negligible. In view of the depletion of Al in the alloy next to the surface, Al atoms migrate towards the surface without being converted to Al_2O_3 on their way. Hence, the supply of Al atoms diffusing toward the surface is sufficient for preferential reaction of the oxygen with Al. In addition, the initially formed nuclei of ZnO may be converted at least in part to Al_2O_3 by the displacement reaction

$$2Al + 3ZnO \rightarrow Al_2O_3 + 3Zn \quad [1]$$

Once a dense Al_2O_3 layer is formed between the outer Zn-rich oxide layer and the bulk alloy the oxidation rate falls to the very low value determined by transport through Al_2O_3.

Hagel (23) offers an alternative explanation of the role that a third component plays in the formation of a protective layer; it is based on the degree of protection afforded by an α-Al_2O_3 *vs.* a γ-Al_2O_3 layer. He suggests that transformation from γ-Al_2O_3 to a more protective α-Al_2O_3 layer is enhanced by the presence of certain alloying elements. This mechanism, however,

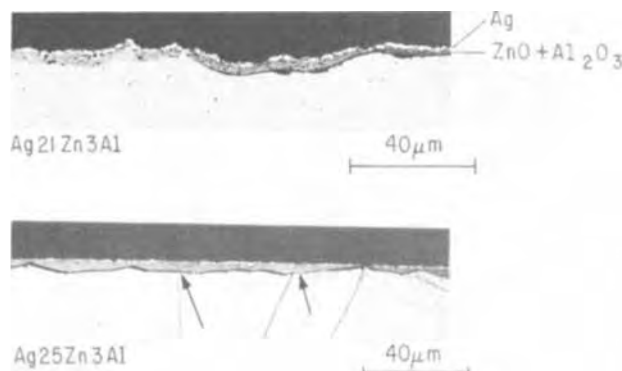

Fig. 7. Cross-section micrographs of oxidized Ag21Zn3Al and Ag25Zn3Al specimens. The bottom micrograph is etched. ↑ points to twin boundaries in the oxidized region.

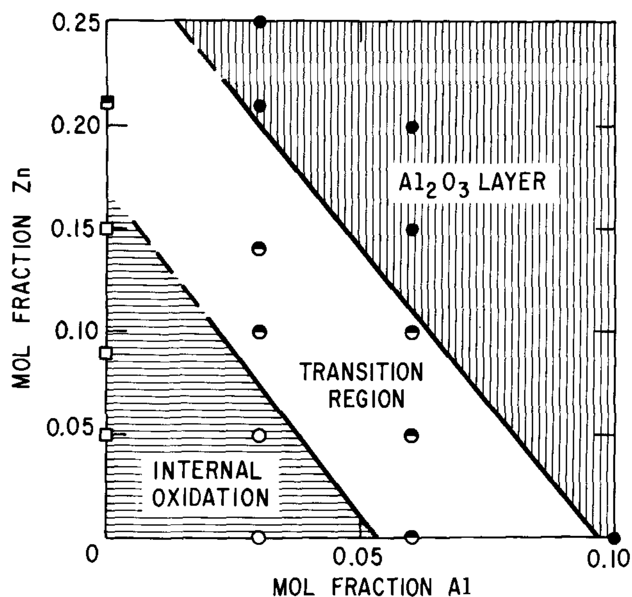

Fig. 8. Chart illustrating the beneficial effect of Zn in Ag-Zn-Al alloys for promoting the formation of a protective Al_2O_3 layer.

cannot be responsible for the transition to low oxygen uptake upon the addition of Zn to Ag-Al alloys since Ag3Al without Zn additions does not form any Al_2O_3 layer.

Hence it seems reasonable to proceed on the basis that some, and perhaps many, of the multicomponent industrial alloys rely for their superior oxidation resistance on the "gettering action" of certain components which themselves may not be a constituent of the final protective oxide layer. It follows that the basic principles advanced by Wagner (8) may be used in the development of new alloys. Certain complications, however, must be avoided. Wood (24) points out that, depending on the kinetics of growth of the solvent metal oxide and on the alloy interdiffusion coefficient, the solvent metal oxide may engulf (overgrow) the nuclei of the solute metal oxide in accord with the earlier theoretical consideration of Wagner (21) and thereby preclude the formation of a protective solute metal oxide layer. He shows for Fe-Cr-Al alloys of relatively low chromium and aluminum contents that it is possible for the iron oxides to overgrow and undercut the Cr_2O_3 and spinel nuclei. This seemingly is not a problem with the higher alloyed Fe-Cr-Al alloys where a protective layer is well known to form at low total oxygen uptake (1-6), nor with certain other oxidation-resistant, Fe-base alloys, according to recent data of Boggs (7).

Exclusive internal oxidation.—For diffusion control and fixed boundary conditions the depth, ξ, of the zone of internal oxidation is given as a parabolic function of the time, t,

$$\xi = 2\gamma (D_O t)^{1/2} \qquad [2]$$

where D_O is the diffusivity of oxygen in the two phase (solvent metal + solute oxide) zone of internal oxidation, and γ is a dimensionless parameter. Darken (25), Wagner (26), Rhines *et al.* (27), and Meijering and Druyvesteyn (28) have solved the relevant diffusion equation. For the special case that movement of the front is completely determined by diffusion of oxygen in the metal one has the conditions (26)

$$\gamma << 1 \qquad [3]$$

and

$$\gamma D_O/D_M >> 1 \qquad [4]$$

in which case Eq. [2] becomes

$$\xi \cong \left[\frac{2N_O^{(s)} D_O t}{\nu N_M^{(o)}} \right]^{1/2} \qquad [5]$$

where $N_O^{(s)}$ is the solubility of oxygen in the external interface of the solvent metal, ν is the atomic ratio of oxygen to metal in the internal oxide and $N_M^{(o)}$ is the mol fraction of the metal M in the bulk alloy. The solubility product of the internal oxide is here assumed to be negligibly small. The conditions of Eq. [3] and [4] were found to be satisfied for the alloys in the present investigation which contain low amounts of Al and Zn. For example, after internal oxidation of Ag3Al for 14.4 ksec (4 hr) the measured ξ is 8.7×10^{-3} cm (Fig. 2), and $\gamma = 0.03$ which satisfies conditions in Eq. [3] and also Eq. [4] since D_O/D_M is very large.

Modification of Eq. [5] gives a relation for the weight gain, Δm, of the specimen

$$\frac{\Delta m}{A} \cong \xi \frac{N_M^{(o)}}{V_m} \cdot \nu W_O \qquad [6]$$

where V_m is the molar volume of the alloy and W_O is the atomic weight of oxygen. Substituting Eq. [5] into Eq. [6] one has

$$\frac{\Delta m}{A} \cong \frac{W_O}{V_m} [2\nu N_M^{(o)} N_O^{(s)} D_O t]^{1/2} \qquad [7]$$

Values for $N_O^{(s)}$ and D_O in Eq. [5-7] were assumed to be the solubility and diffusivity, respectively, of pure Ag as reported by Eichenauer and Müller (29), ν was assumed to be 1.5 and 1.0 corresponding to the

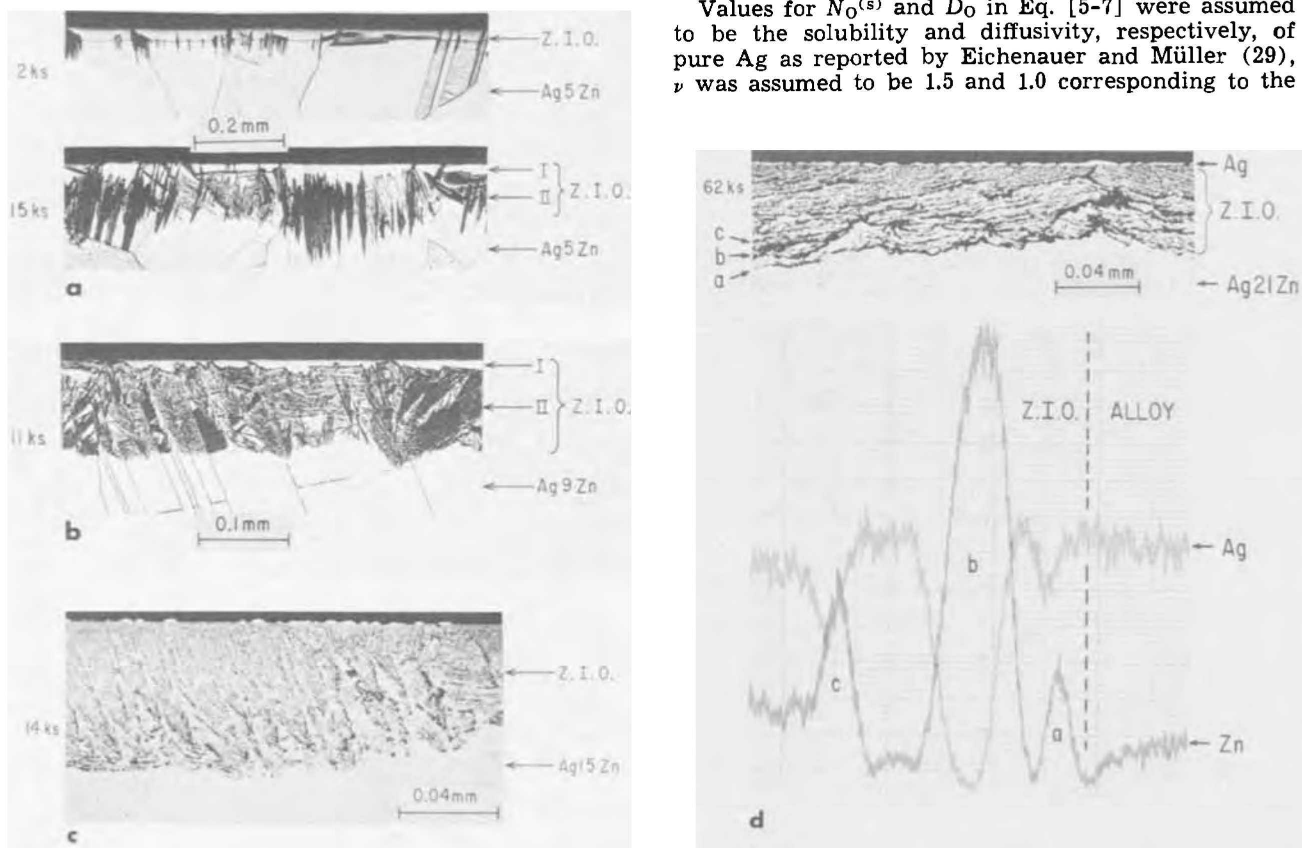

Fig. 9. Cross-section micrograph showing morphologically different zones of internal oxidation in Ag-Zn specimens, and an electron microprobe analysis which shows that the black "lines" within the zone of internal oxidation (Z.I.O.) of the Ag21Zn specimen are Zn-rich. Ag trace lags the Zn trace by 1.2 μm; probe traverse was from right to left. Specimens in (a) and (b) were etched.

formation of stoichiometric Al_2O_3 and ZnO, respectively, $V_M = 10$ cm^3 mol^{-1} and $A = 3.5$ cm^2. Data in Fig. 1-4 indicate that the alloys Ag3Al, Ag5Zn, Ag9Zn, and Ag5Zn3Al undergo exclusive internal oxidation. On the other hand definite departures occur for all other alloys, *e.g.*, the weight gain for Ag15Zn (Fig. 3) is lower than that for Ag9Zn and significantly lower than the calculated value from Eq. [7]. Still, Ag15Zn and some of the other alloys of intermediate solute content undergo appreciable internal oxidation and are discussed later in the section on transition alloys.

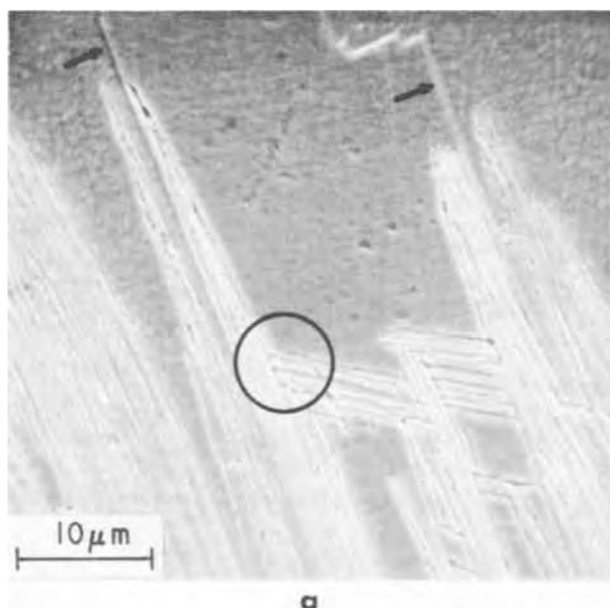
Cross-section metallographic examination shows a zone of internal oxidation for the Ag3Al (Fig. 5), Ag5Zn, Ag9Zn (Fig. 9a and 9b), and Ag5Zn3Al alloys (Fig. 10). Internal oxidation of the Ag-Zn alloys is complex. Examination of oxidized Ag5Zn specimens after polishing and etching reveals what appears as a "normal" zone of internal oxidation next to the surface and a second morphology (of internal oxidation) next to it which is comprised of acicular segments aligned mostly perpendicular to the surface (Fig. 9a). The acicular segments begin to develop after about 2 ksec oxidation as seen in the top micrograph, and to line up along twin boundaries or other planes which presumably are unresolved (micro) twin boundaries. At higher magnification the acicular segments are seen to be comprised of fine, parallel-arranged rows of material; this material may be porous as indicated by the fact that pull-out occurs during metallographic polishing. After etching, this structure is readily revealed as gaps or cavities in the scanning electron microscope (Fig. 11). The change from the normal to the acicular morphology occurs in the absence of a noticeable change in the kinetics of oxidation (Fig. 3).

Two morphologies of internal oxidation are also observed for Ag9Zn (Fig. 9b). The second morphology for Ag9Zn forms at an earlier stage and appears less acicular and less aligned perpendicular to the surface. In the higher Zn, binary alloys, on the other hand, only the second morphology, in further modified form, is observed. In the most Zn-rich alloy (Ag21Zn) the rows of material lie mainly parallel to the surface. It is shown in the next section that the formation of layers parallel to the surface is characteristic of alloys of intermediate solute content, *i.e.*, those which often exhibit a two-stage kinetic behavior, and a total oxygen uptake between that for exclusive internal oxidation and that for formation of a dense, protective oxide layer at the surface.

Electron microprobe examination of the cross-sectioned Ag3Al and Ag5Zn specimens showed that the contents of the component metals within the zones of internal oxidation were essentially the same as in the original (unoxidized) alloys. Individual internal oxide precipitates are not resolved since the area analyzed by the beam is large relative to the precipitate size. The absence of solute enrichment within the zone of internal oxidation is additional justification for the assumption that for these alloys the kinetics of the internal oxidation process are controlled by the diffusion of oxygen within the zone of internal oxidation and, hence, of the applicability of Eq. [5].

Discussion.—The internal oxidation of Ag3Al appears to be uncomplicated in comparison to that of Ag5Zn and other alloys of higher solute content. The somewhat lower-than-calculated values of ξ and Δm for Ag3Al may be the result of a slightly reduced oxygen flux as a result of incipient "blocking" by the Al_2O_3 precipitates, or the solubility of oxygen may be lower as a result of strain (30).

For the other alloys, in which the thickness of the zone of internal oxidation was irregular the "average" observed ξ for each alloy is in accord with Eq. [5] and values of $N_O^{(s)}D_O$ in the literature. However, the maximum ξ observed at only a few locations yields a significantly larger $N_O^{(s)}D_O$ product, *e.g.*, $N_O^{(s)}D_O$(max) for Ag5Zn equals 9×10^{-10} cm^2 sec^{-1} *vs.* 1.85×10^{-10} cm^2 sec^{-1} for pure Ag (29). This may be explained by significant interface diffusion or gas phase transport through pores of the acicular structure.



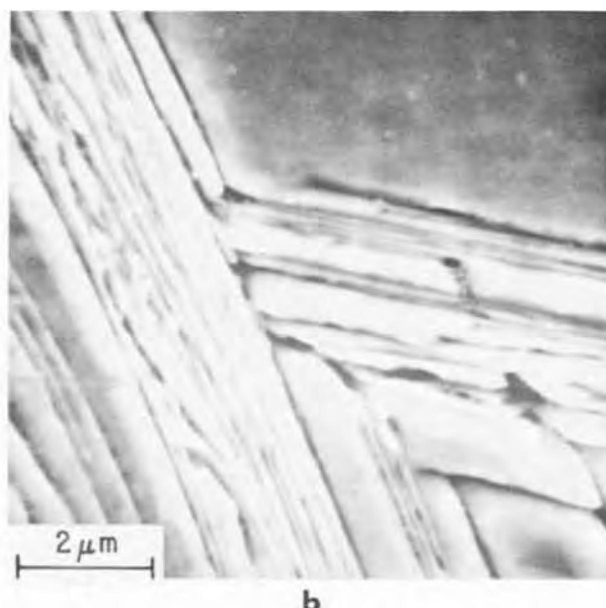


Fig. 11. Cross-section, scanning electron micrographs of an oxidized Ag5Zn specimen showing the acicular structure as gaps or cavities after pullout during mechanical polishing and subsequent etching. Micrograph in (b) is enlargement of circled region in (a). ↑ indicates twin boundary.

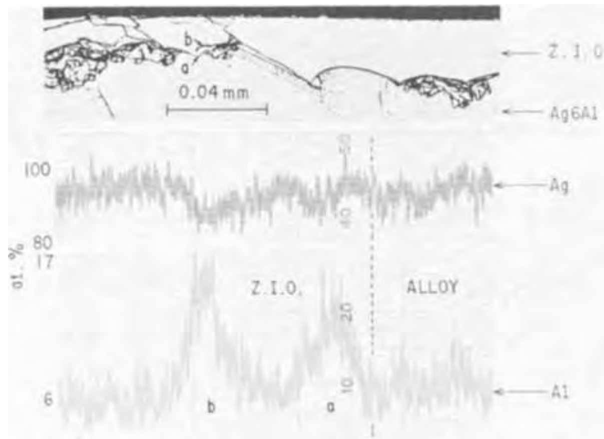

Fig. 12. Cross-section micrograph of an etched Ag6Al sample after 62 ksec of oxidation at 823°K, and an electron microprobe analysis which shows that the black "lines" in the region of the boundary between the alloy and the zone of internal oxidation (Z.I.O.) are Al-rich. Ag trace lags Al trace by 1.2 μm; probe traverse was from right to left.

Transition region in binary and ternary alloys.—Data in Fig. 1-4 show that an induction period of large oxygen uptake preceeds a falloff in the oxidation rate for the alloys of intermediate solute content, *i.e.*, Ag6Al, Ag21Zn, Ag10Zn3Al[1], and Ag13Zn3Al. In a sense, the oxidation resistant alloys, Ag10Al, Ag14Al, Ag21Zn3Al, and Ag25Zn3Al also belong in this group since they, too, exhibited an, albeit very short, induction period.

Cross-section optical metallographic examination of oxidized specimens of the Ag6Al, Ag21Zn, Ag10Zn3Al, and Ag13Zn3Al alloys always shows a zone of internal oxidation containing what appears as black, ragged lines usually aligned roughly parallel to the surface (Fig. 9d and 12). These "lines," sometimes referred to in the literature as films, have been observed in Cu-Si (12), Ag alloys (31, 32, 11), Fe-Al (33), Ni-Al (34), and other alloys. Meijering (32) found that their frequency and thickness increased with solute content and that alloys which contain them oxidize at a lower rate. Elongated shapes and alignment of internal oxide precipitates including needles, plates, and dendrites have also been observed by electron microscopy for various systems by Kahlweit and co-workers (35, 36) and others (33).

[1] Continuous weighing measurements give a weight-time curve similar to that shown and indicate that the unusually large scatter of points from the discontinuous weighing measurements for Ag10Zn3Al is not significant.

The material appearing as black lines in Fig. 9d and 12 is shown to be porous by the fact that pullout readily occurs during metallographic preparation. After appreciable pullout, gaps or cavities remain which are revealed by scanning electron microscopy (Fig. 13). Microhardness measurements show that these regions are softer than the neighboring two-phase material (Ag + oxide), in agreement with their porous structure.

Electron microprobe analysis shows that the layers even after appreciable pullout are rich in the solute metal, undoubtedly in the form of oxide (Fig. 9d and 12). The traces give average values, *i.e.*, the magnitudes of the local departures from the alloy composition are probably greater than indicated in the microprobe traces. The layers within the zone of internal oxidation for Ag10Zn3Al consist of oxides of both Al and Zn, according to electron microprobe analyses.

The top micrograph of Fig. 14 is of the Ag10Zn3Al alloy after 1.8 ksec (30 min) of oxidation and corresponds to the initial period of the high rate of oxidation (point A in Fig. 4). At these early stages of oxidation porous oxide layers are, for the most part, absent within the zone of internal oxidation. They are first observed along grain boundaries between the surface and the internal oxidation front and then along the front itself. The middle and bottom micrographs of Fig. 14 are of other specimens of the same alloy, but correspond to the later, very low rate of oxidation (point B in Fig. 4). In the bottom micrograph the specimen was etched to reveal the twin and grain boundaries. At these longer oxidation times the layers are common features within and at the front of the zone of internal oxidation, as they are after comparable oxidation times for Ag21Zn and Ag6Al (Fig. 9 and 12).

The thickness of the zone of internal oxidation varies appreciably for these alloys, in contrast to the alloys of lower solute content which do not form protective oxide layers. Some regions, usually amounting to less than 5% of the surface, are observed in cross-section to be free from internal oxidation. Presumably in these regions a protective oxide layer forms immediately upon contact of the specimen with the oxidizing environment. Such behavior has previously been observed by Rapp (11) and others.

A slight drop of the Zn content in the unoxidized portion of the Ag21Zn specimen at the internal oxidation front in Fig. 9d indicates enrichment of Zn in the zone of internal oxidation. Diffusion of solute metal and, in addition, of oxygen along grain boundaries in the alloy ahead of the internal oxidation front were

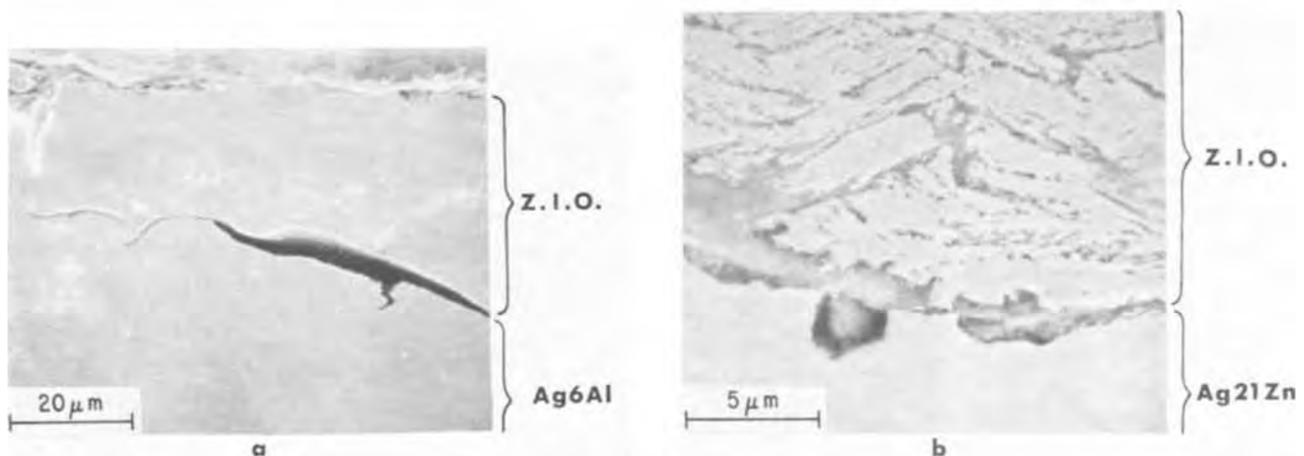

Fig. 13. Cross-section, scanning electron micrographs showing a gap(s) along the boundary between the alloy and the zone of internal oxidation (a) for an oxidized (923°K) Ag6Al specimen, mechanically polished and etched, and (b) for an oxidized Ag21Zn specimen, mechanically polished. Different phases are not distinguishable.

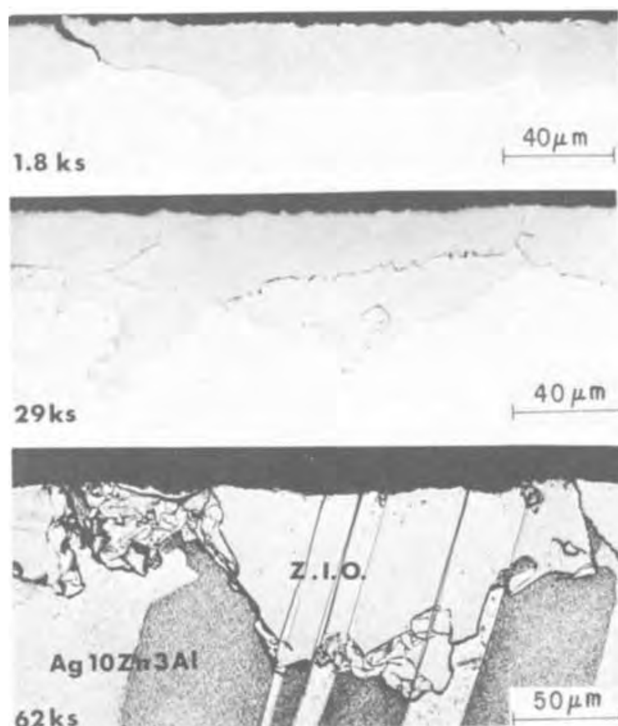

Fig. 14. Cross-section micrographs of oxidized Ag10Zn3Al specimens illustrating black "lines," identified as Al- and Zn-rich, regions, within the zone of internal oxidation. The bottom micrograph is etched.

indicated also for Ag6Al and the ternary alloys which oxidize according to the kinetics of the transition region. Subsequent deformation of these specimens revealed that grain boundaries within the nominally unoxidized portion of the specimens had become embrittled.

Discussion.—Transition from internal to external oxidation does not take place at a definite concentration in these alloys but rather over a fairly wide composition range (Fig. 8). This occurs for specimens of identical thermal and mechanical history and surface preparation. Rapp has already showed that the boundary of the transition region depends to some extent on the prior surface preparation.

The data in the present paper show further that for alloys in the transition region the attainment of a low rate of oxidation is preceded by an induction period during which the oxidation rate is much higher and a zone of internal oxidation forms. The occurrence of an induction period is not surprising in view of early considerations by Wagner (21, 22). Chattopadhyay and Wood (37) have recently emphasized the occurrence of transient behavior during initial external scale formation accompanied by internal oxidation.

The main question for binary and ternary alloys in the transition region (and seemingly general to all of the alloys which attain a low oxidation rate) is where and how a dense oxide layer of the solute metal is formed once internal oxidation has transpired. Time invariant diffusion behavior is usually assumed in analyses of oxidation processes, except initially when diffusion control would require an infinite rate. Applying the concept generally means that for a given set of experimental conditions (p_{O_2}, solute content, etc.) a single oxidation process, *e.g.*, internal oxidation, occurs for the duration of the experiment and a single rate constant is obtained. When exceptions to such behavior are observed during internal oxidation they can sometimes be traced to the initial period (prior to the establishment of diffusion control) when starting conditions allow oxidation to occur heterogeneously over the surface. One specific explanation of the transient behavior is that patches of dense oxide which form initially spread sideways and eventually impinge to give a dense oxide layer at the external surface (38). Then one has the end of inward transport of oxygen, *i.e.*, the extremely low oxidation rate which is observed after an initial period of a high rate of oxygen uptake. For this mechanism to operate it is necessary that Al can diffuse to the surface after internal oxidation begins. This would appear to be possible along segments of unoxidized alloy which extend to the surface. A surface scale is sometimes observed on the Ag6Al specimens; portions of one are barely visible in Fig. 12.

Another factor which may account for a change in the diffusion kinetics at some stage of the oxidation process is void formation during the internal oxidation process; voids may block the diffusion of an important species and thereby be a precursor to the formation of a dense Al_2O_3 layer along the boundary between the zone of internal oxidation and the alloy.

There is some reason to suspect that voids do form at temperature as part of the internal oxidation process. The easy pullout of material within the zone of internal oxidation indicates porosity which is developed either as a result of internal oxidation or of cooling after the oxidation run. Features usually associated with nonuniform contraction during cooling, however, such as matching surfaces, are not very evident.

Conclusions

Weight gain data and cross-sectional metallographic examination show that whereas a Ag3Al alloy exhibits internal oxidation without formation of a dense Al_2O_3 layer, upon addition of 21 or 25 a/o Zn internal oxidation is completely suppressed and a dense highly protective Al_2O_3 layer is formed. These data support the hypothesis advanced by Wagner (8) that Zn may be considered as a secondary getter for oxygen atoms so that virtually no oxygen atoms diffuse into the alloy and, therefore, aluminum atoms can diffuse to the surface without being intercepted by oxygen atoms. Newly arriving Al atoms may then form additional Al_2O_3 by a displacement reaction with initially formed nuclei of ZnO. Other metals such as chromium and silicon in base metal alloys containing aluminum as the least noble constituent, *e.g.*, Fe-Cr-Al, may be expected to behave similarly in the formation of a highly protective layer of Al_2O_3.

For Ag5Zn and Ag9Zn the internal oxidation process changes at a certain depth to one which is strongly influenced by the microstructure. The front of internal oxidation is irregular. At points of greater penetration the $N_O^{(s)}D_O$ product is significantly larger than that for pure Ag.

For the "transition" alloys the formation of a protective Al_2O_3 layer is preceded by an induction period during which internal oxidation occurs. Rows of aluminum oxide and/or zinc oxide form in alignment roughly parallel to the surface within the zone of internal oxidation. It is not clear though if these layer-like regions are instrumental in the eventual attainment of a lower rate of oxidation or are simply a consequence of a reduced inward flux of oxygen caused by the eventual formation of a continuous, dense Al_2O_3 layer at the surface.

Acknowledgments

It is a pleasure to acknowledge the considerable contribution of C. Wagner of the Max Planck Institut für Physikalische Chemie who outlined the experiments in this paper and made many helpful comments throughout the course of this investigation. Valuable discussions with several colleagues are also gratefully acknowledged, especially those with L. S. Darken and W. E. Boggs. Considerable assistance was provided on the oxidation experiments by H. A. Hughes, in the metallographic examinations by R. M. Lytle, P. J. Byrne, C. E. Brickner, and W. Gundaker, and on alloy preparation by B. B. Rice. The author is also grateful

to B. F. Oliver of the University of Tennessee for advice on preparation of the various alloys.

Manuscript submitted June 25, 1971; revised manuscript received ca. Oct. 5, 1971. This was Paper 116 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1972 JOURNAL.

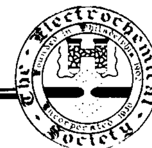
Technical Notes



Electrical Switching in Anodic Oxide Films on Zircaloy-2

N. Ramasubramanian

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

The advantage of using the Widmanstätten morphology for locating weak spots in anodic oxide films on Zircaloy-2 was reported by us (1). It was shown that the initial electrical breakdowns were centered on the α-platelet boundaries where the intermetallic precipitates and second phase impurities have segregated during cooling the alloy in vacuum from the β phase. These breakdowns were always preceded by switchings to a high conductivity state; the occurrence of one or the other was governed by the load resistance in the circuit. The results obtained on such switching phenomena are presented here.

Experimental

The details regarding material, heat treatment, surface preparation, anodization, and current-voltage measurements have been described elsewhere (1). Zircaloy-2/anodic oxide/metal sandwiches were prepared by evaporation of gold or silver contacts through masks to a thickness of 1000-1500Å (monitored by a quartz crystal). Silver counterelectrodes were also formed utilizing the Eccobond Solder 56C supplied by Emerson and Cuming Inc. and G. C. Electronics' silver paint. The Eccobond contact was cured at 70°C for 2 hr, and the paint was air-dried. The voltage sources were an Electro Pulse Inc. Model 2140A pulse generator, d.c. from dry cells and a.c. from a Variac. The series resistance was 10 kohm during switch ON operation (high to low impedance state) and varied from 3 to 1 ohm during the low to high impedance, switch OFF operation. Impedance measurements were made using a GR-1680A automatic capacitance bridge.

Electrochemical Society Active Member.
Key words: Zircaloy-2, anodic oxide, electrical switching, transition metal alloying additions.

Results

The electrical switching characteristics of the anodic oxide films on Zircaloy-2 could be classified into three types: (*a*) the most commonly observed one, associated with the delayed type of breakdown, (*b*) a nondestructive bistable switching, and (*c*) transitory switching observed in thin films, 250 to 750Å thick. Out of a total of thirty tested (as-received material), each carrying four or more diodes, all the specimens exhibited the type (*a*) and about 15% of the diodes the type (*b*) switching behavior. All the thin films tested showed the transitory switchings.

Bistable switching, type (a).—The current-voltage characteristics of the diode were traced first at 80° and 190°K; only the leakage currents were measured for potentials of both polarities up to ~60% of the anodizing voltage. Time of holding at various applied volt-

ages was varied from a few seconds to ~5 min, with no detectable change in conductivity. Similarly at room temperature a positive bias on the alloy in the same range of voltages did not produce any change in conductivity. However, when a negative potential was applied at room temperature, current bursts were observed at ~15V and holding the alloy at the voltage for a few minutes brought about a switch to the ON state. In this initial ON condition the $i \times V$ relation was ohmic, and the temperature coefficient of resistance was positive.

Considering the case of a 50V film as a typical example, −16.5V on the alloy for ½ min duration at room temperature turned the diode ON; in the ON state the resistances were 63 and 54 ohm at 300° and 80°K, respectively. A current of 100 mA (60 Hz from a Variac) turned the diode OFF. In the case of diodes carrying evaporated electrodes this initial switch OFF operation resulted in the "single-hole" type of breakdowns (1). When Eccobond solder or silver paint formed the counterelectrode, it was noticed that after the initial switching OFF operation the diode could be turned ON by a positive or a negative bias on the alloy.

A number of ON ⇄ OFF operations were carried out and the behavior was quite varied: switch ON voltages were in the range of 5 to 27V; OFF currents varied from 75 to 150 mA and the $i \times V$ relation was either ohmic or nonohmic with a positive or negative temperature coefficient of resistance, respectively.

Bistable switching, type (b).—A few of the diodes exhibited the type (*b*) switching which occurred in the temperature range of 80° to 300°K when the applied bias exceeded ±6V. As the d-c voltage across the oxide film was gradually increased, a sharp increase followed by a rapid decrease in current was observed at ~6V. More such current transients were observed when the applied voltage was increased to ~10V. Then at some stage, when lowering the applied bias, the current suddenly increased by more than two orders of magnitude at around 4V *i.e.*, a switch to the low impedance ON state. The current-voltage curves showed the following characteristics in the ON state: an initial ohmic portion, a zero temperature coefficient of resistance, a zero differential resistance region, and multiple conduction levels. Any systematic variation of the minimum voltage required for the onset of current bursts with the oxide thickness was not found.

A typical example of the conductivity changes is illustrated in Fig. 1 and 2 for a 2100Å film carrying an evaporated gold contact and tested at liquid nitrogen temperature. In the low impedance ON state a slight instability in current was observed and the $i \times V$ curves were nearly symmetrical for positive and negative bias on the alloy, curves c and d. On warming the sample to room temperature no changes in the $i \times V$ relation were noticed, and the same curves c, d were traced. From the ohmic portion of the curves a resistance of 18.5 kohm can be calculated.

Then the impedance of the diode was measured at 1 kHz, and it was found that this act had effected an ON to OFF switching. The curves shown in Fig. 2 were traced subsequently. At ~3V current transients were noticed and the diode switched ON at 3.2V, (curve a_2 in the figure). Curves a_3 and a_4 were traced in the ON state; a_4 was found to be symmetrical with a_3 until the current through the diode exceeded 90 μA, the maximum passed immediately after OFF → ON switching (curve a_3). When the current through the diode was increased beyond this maximum value, a zero differential resistance portion a_5 was traced, with the increases in applied voltage going almost entirely across the series resistor. Finally the curves a_6 and a_7 were traced. A similar type of behavior was observed when the alloy was biased negative following another impedance measurement, curves b_1 to b_7 in the figure. Switching times for OFF → ON transitions (curves a_2 and b_2 in the figure) were less than 10^{-8} sec, and attempts to trace these current-time curves were unsuccessful.

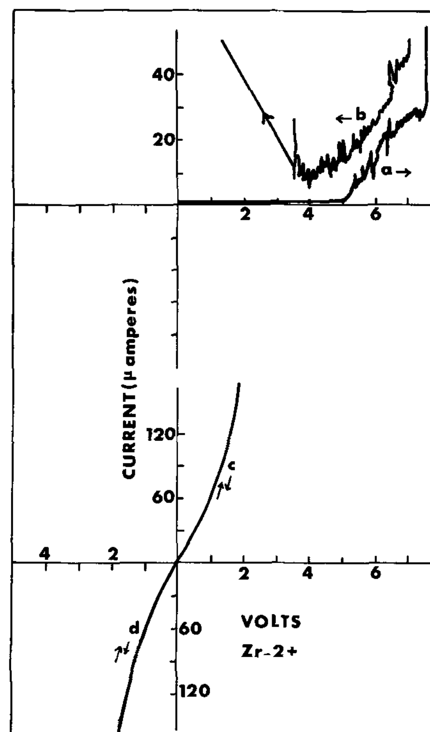


Fig. 1. Tracing of x-y recorder plots of the establishment of conductivity and switching in Zircaloy-2/2100Å anodic oxide film/gold (0.27 cm²) at 80°K.

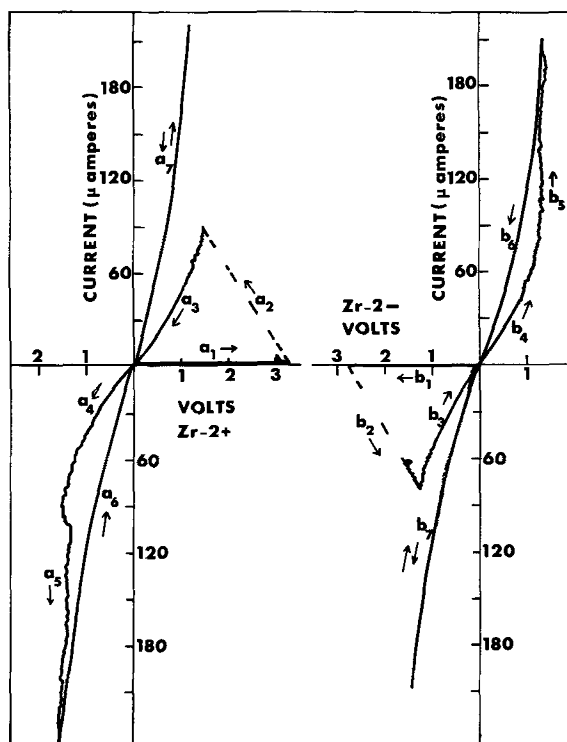

Fig. 2. Switching, zero differential resistance regions and multiple conduction levels; tracing of x-y recorder plots obtained during the tests at 80°K on the diode referred to in Fig. 1.

A number of ON ⇄ OFF operations similar to that in Fig. 2 were carried out and the $i \times V$ tracings recorded for various maximum currents through the diode in the low impedance state. Switch ON voltages were all around ±2.5V. The zero differential resistance region on both the positive and negative sides was seen to cover a current range from ~30 to >240

μA. The curves were similar in shape and symmetrical about the origin; the resistances of the ohmic portions varied from 30 to 10 kohm and the switch off currents varied from 500 to 750 μA. No surface changes were noticed on the evaporated counterelectrodes.

Transitory switchings in thin films.—A set of $i \times V$ curves, selected from those obtained at room temperature on a 25V (~700Å) film, is shown in Fig. 3. At 8.7V negative bias on the alloy the current through the diode increased abruptly, a_1 in the figure followed by a zero differential resistance portion a_2. Instability in the current flow was noticed when the diode tended to switch OFF and then ON as shown by the loop a_3, a_4 and a_5 in the $i \times V$ characteristics. When the current through the diode was decreased, slight instability was still noticed and the portion a_7 was traced which passed through the origin. In tracing a_7 the current was gradually reduced to zero, over a period of 15 sec.

Immediately after tracing a_7 the diode was found in the high-impedance state. Then a number of $i \times V$ tracings were made; in each instance the diode was highly resistive to start, was turned to the ON state at about ±1.4V and the $i \times V$ curve in the ON state passed through the origin. In the ON state, during the transitory switching, the $i \times V$ curves were almost linear and the resistance varied in the range of 5 to 8 kohm. Then the diode settled to bistable switching, and the ON state was characterized by an ohmic $i \times V$ relation and zero temperature coefficient of resistance.

Some of the diodes were tested at 80° and 190°K before the room temperature experiments. For voltages up to ~50% of the anodizing voltage, at lower temperatures only the leakage current flow was noticed. At room temperature transitory switching occurred, the easy direction for the first one to be initiated being Zircaloy-2 negative. The number of transitory operations prior to the onset of bistable mode varied among the various specimens and also on a single specimen carrying a number of diodes.

Vacuum-cooled material.—The oxide thickness varied from 1200 to 2500Å and a total of 50 diodes carrying evaporated gold electrodes were tested. All these were characterized by the type (*a*) bistable switching. The switch ON voltage did not vary with the oxide thickness and was 18 ± 2V. The initial switch OFF operation led to a few isolated single-hole breakdowns centered on the boundaries between the α platelets (1). Subsequent to this initial switch OFF operation, a second set of breakdowns were produced in some of the diodes by having a low series resistance in the circuit and by applying a negative potential of 20 ± 2V on the alloy. These breakdowns were more in number than the initial ones and their density averaged to ~$10^2/cm^2$. The diodes were highly conducting following this step; Park and Basavaiah have reported a similar type of behavior in oxide films on evaporated zirconium (2). The scanning electron micrographs of a second set of breakdowns are shown in Fig. 4. Almost all such breakdown spots were also found to be located on the α-platelet boundaries.

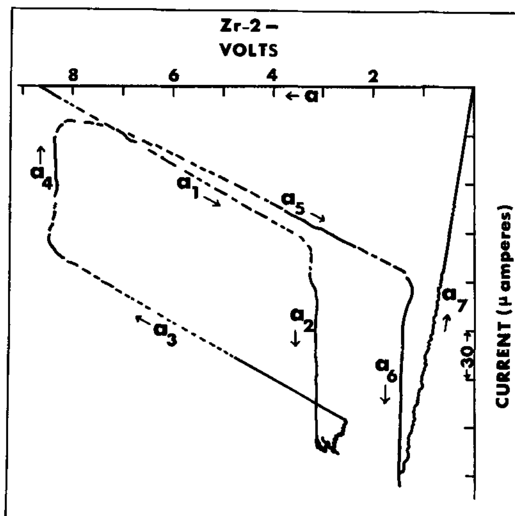

Fig. 3. Zircaloy-2/25 V anodic oxide film/silver (Eccobond, 0.12 cm^2) tested at atmospheric conditions; x-y recorder plots of the transitory switchings.

Discussion

When Zircaloy-2 is cooled in vacuum from the β phase, second phase intermetallic (Zr-Fe-Cr and Zr-Fe-Ni) particles are precipitated along the α-platelet boundaries. Second phase impurity particles (Zr and C, P, or Si present in ppm quantities) are probably the nucleation sites for the growth of the α-platelets (3). The initial and the subsequent breakdowns, in oxide films on the vacuum-cooled material, were all located on the α-platelet boundaries; the delayed type of bistable switching in these films is in the majority observed in oxide films grown on the alloy in the as-received condition. Therefore, it is reasonable to conclude that the second phase particles in the as-received alloy are the sites of such switching and the associated breakdowns.

Park and Basavaiah identified the conducting filament with the rim around the breakdown spots (2). In our experiments, however, the switch ON operation did not result in a breakdown when the series resist-

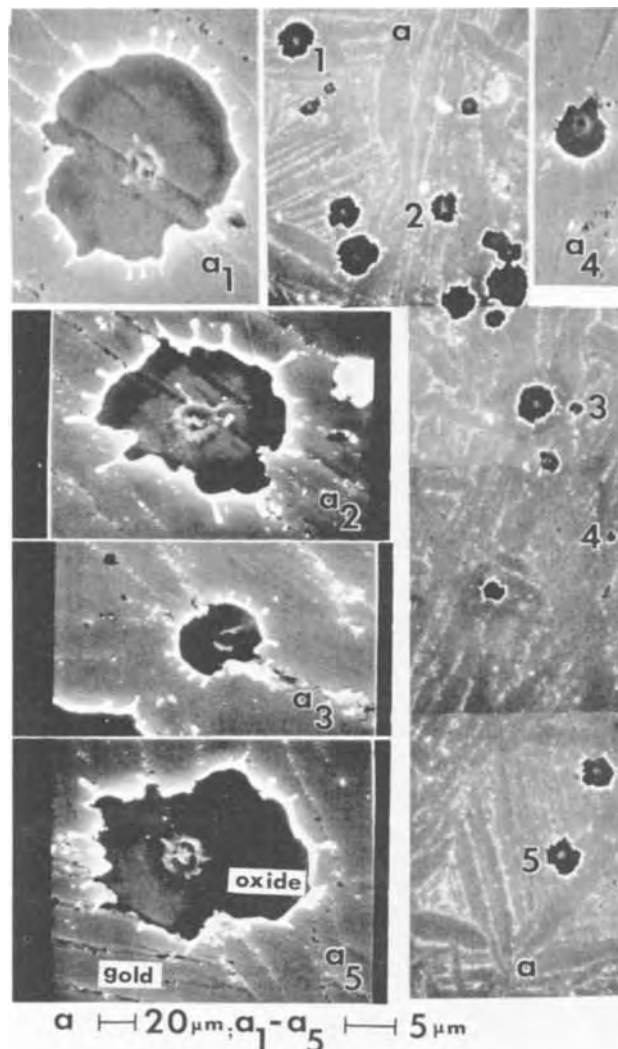

Fig. 4. Scanning electron micrographs of the second set of breakdowns in anodic oxide (2100Å thick) grown on the vacuum-cooled Zircaloy-2.

ance in the circuit was sufficiently high; also, the initial switch OFF operation resulted most often in single breakdown spots and the diode subsequently was highly resistive. Therefore, Park and Basavaiah's observation might represent an intermediate state and the current carrying filament present prior to breakdown is likely to be very different from that produced after the breakdown. The breakdown spots generally were 3 to 4 μm in diameter (*cf.* Fig. 4); however, the original current carrying filament is likely to have been much smaller in dimensions. Moreover, the oxide grown on the second phase particles has been shown to be highly heterogeneous and porous (1). Therefore, calculation of the resistivity of the filament based on the diameter of the breakdown spot and the anodic oxide (zirconia matrix) thickness would be meaningless. Though a positive temperature coefficient of resistance was found in the ON state, the nature of the filament material thus remains unknown.

At this stage, any attempt to interpret the mechanism of the initial switching would be highly speculative because the composition of the second phase particles, their behavior during wet anodization, the type of oxide grown on them, *etc.*, remain unknown. In this connection, a study of the oxide growth on the intermetallics of zirconium and iron, chromium or nickel and their electrical properties might be helpful.

Conclusions

In anodic oxide films on Zircaloy-2, the second phase particles are the sites where a majority of the bistable switchings and the associated breakdowns occur.

The Composition of $Ga_{1-x}Al_xAs$ Grown from Ga-Rich Solutions as a Function of Growth Temperature and Solution Composition

W. G. Rado, W. J. Johnson, and R. L. Crawley

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

It has been shown that efficient visible light emitting diodes can be fabricated from liquid phase epitaxially (LPE) grown layers of $Ga_{1-x}Al_xAs$ (1). The maximum direct energy gap obtainable is 1.9 eV corresponding to a composition of $x = 0.37$ (2). The work of Panish and Sumski (3) and Ilegems and Pearson (4) on the Ga-Al-As ternary system indicates that $Ga_{1-x}Al_xAs$ in the range of $0 < x < 0.37$ can be grown by LPE at or below 1000°C from solutions containing less than about 0.007 atom fraction Al. This communication presents experimental data for $Ga_{1-x}Al_xAs$ grown in the temperature range of 800°-950°C from Ga-Al-As solutions containing 0.002-0.014 atom fraction Al.

The $Ga_{1-x}Al_xAs$ was grown by LPE on (111)-Ga and As faces of single crystal GaAs substrates that were doped with Te or Se in the range of 0.5 to 2.5 $\times 10^{18}$ electron/cm^3. The growth apparatus was similar to that of Hayashi *et al.* (5) in that the solution was pushed over the substrate. Our apparatus also employed a special provision to shear the solution during its push in order to expose a fresh, unoxidized surface. The solution typically contained 4g of six nines pure Ga and the appropriate amounts of six nines pure Al and polycrystalline undoped GaAs. For each run, the saturation temperature, T_s, the temperature at which the Ga-Al solution is just saturated with the specific amount of GaAs used, was determined by using the ternary phase diagram of Ilegems and Pearson (4).

The substrates were lapped with 1 μm alumina, etched in 10 HNO_3:1 HF:5 H_2O for 10 sec, rinsed and dried before being loaded into the boat. The GaAs source material was heavily etched, rinsed, dried, and then wetted with Ga before placement in the solution.

Key words: LPE, LED, phase diagram, direct energy gap semiconductors, electron microprobe.

During loading, the solution was heated to 50°C to insure that the Al was dissolved properly. After positioning in the furnace, the system was flushed overnight with H_2 purified by Pd. The system was then heated to an equilibration temperature, T_e, either equal to T_s or exceeding T_s by about 40°C. After at least one hour at T_e, cooling at 40°C per hour was initiated. The solution was pushed over the substrate at 3°-5°C below T_s and allowed to cool to room temperature. Typical grown layers were 30 to 200 μm thick.

The x-ray emission produced from the layers by the electron beam of an ARL model EMX electron microprobe was analyzed to yield the alloy composition. Measurements were made as a function of position along the growth direction in 2-20 μm steps. The composition at the onset of growth was then obtained by interpolation to zero thickness. The error was estimated at $\pm 2\%$. The variation of the initial solid composition with atom fraction Al in the solution, $X_{Al}(l)$, and saturation temperature, T_s, is shown in Fig. 1.

Within the experimental uncertainties, the measured concentration of AlAs in the solid did not depend on substrate orientation, the physical properties of the substrate (doping level, dopant, etchpit density, etc.) or on the equilibration temperature, T_e. Examination of the metallurgical interface between the substrates and the grown layers indicated that no etchback of more than a few micrometers took place. Post-growth inspection of the solution revealed no undissolved GaAs source material. From these observations we concluded that a condition close to equilibrium existed in the solution before the initiation of growth.

In Fig. 2, our experimental values are compared to the calculations of Ilegems and Pearson (4). Our data are in moderately good agreement with the calculated

Erratum

Regarding the paper "Electroplating of Osmium" by A. J. Appleby which appeared on p. 1610 in the December 1970 JOURNAL, Vol. 117, No. 12, it has recently been brought to the author's attention that a practical aqueous bath for obtaining bright osmium electrodeposits was described by L. Greenspan [*Engelhard Ind. Tech. Bull.* **10**, 48 (1969] as the above paper was in final preparation. As stated by Mr. Greenspan: "This bath contains osmium in alkaline solution as an anionic complex formed by reacting osmium tetroxide with sulfamic acid. Using this bath at a temperature of 65°-75°C, and with current densities of 2-10 A/ft^2, deposits at a rate of about 100 μin./hr are obtained with current efficiencies of the order of 40-80%. Deposits of about 50 μin. are from lustrous to bright; those of 100 μin. and above are dull but smooth. This bath appears more suited for practical electrodeposition of osmium than the cyanide bath and is commercially available." The author is indebted to Mr. Greenspan for bringing this omission to his attention.

Removal of Surface Antimony from Antimony Lead Alloys by Sulfuric Acid-Hydrogen Peroxide Pickling

T. R. Crompton and G. Uitenbroek*

Oldham & Son Limited, Denton, Manchester, England

ABSTRACT

It has been shown that treatment of cast antimonial lead alloys with mixtures of hydrogen peroxide and sulfuric acid at 20°C dissolves surface antimony at an appreciably greater rate than occurs with sulfuric acid alone, even at elevated temperatures. Optimum hydrogen peroxide-sulfuric acid reagent compositions have been established for the maximum solution of antimony from the alloy. A correlation exists between the quantity of antimony removed by this treatment and the quantity of antimony that is subsequently released from the alloy into sulfuric acid electrolyte when it is set up as an anode against pure lead cathodes. Batteries made using positive grids which have been pickled in hydrogen peroxide-sulfuric acid mixtures, then brightened by dipping in a 10% aqueous solution of diethylene triamine have been shown to have a greater life on charge/discharge cycles than batteries made using standard unpickled grids.

Antimony is added as an alloying constituent to impart increased hardness to lead used in the manufacture of grids for lead-acid batteries. Alloy grids are much less liable to distortion during battery manufacturing operations. However, positive battery plates used in lead-acid battery manufacture, made from such castings, will, during plate formation, release a large proportion of their surface antimony, which will migrate towards the negative plate, thereby contaminating the formation electrolyte, the negative active material, and the positive active material. Similarly, in battery operation, antimony contamination of plates will occur. Both forms of antimony contamination have adverse effects on battery performance such as increases in positive plate corrosion (*i.e.*, shorter life) and in self-discharge rates; also it prevents the positive plate from reaching its true potential. For these reasons research has been undertaken to study removal of antimony from such grids.

Burbank and Simon (1) have shown the manner in which the anodic corrosion of lead and its hypoeutectic antimony alloys takes place in sulfuric acid and how such corrosion is related to the microstructure of these alloys. Pure lead and alloys containing up to 0.5% antimony corrode intergranularly (*i.e.*, grain boundary attack). At higher concentrations a combination of intergranular and interdendritic penetration occurs, but up to 6% antimony the attack remains preferentially intergranular. At higher antimony concentration (6-12%) the corrosion is more evenly distributed between intergranular attack and attack along the interdendritic network of segregated antimony. Burbank and Simon also revealed by x-ray diffraction that the surface of castings containing 6% or more antimony is richer in antimony than within the bulk of the castings, *i.e.*, an antimony-rich surface layer is present.

A search brought to light one patent, by Bosch (2), which involves a pickling treatment for removing concentrations of antimony on the surface of cast lead-antimony alloys used in lead acid battery manufacture. This process involves dipping the as-cast metal in sulfuric acid of 1.75 sp gr. This treatment it is claimed will remove antimony from a surface layer of at least 10^{-6} mm thickness of alloy.

The work described below for removing surface antimony from antimonial lead differs from that described by Bosch in that it incorporates a sulfuric acid-hydrogen peroxide reagent which has been shown to be much more effective than sulfuric acid alone in removing surface antimony from antimonial lead.

Experimental

Pickling in sulfuric acid.—Experiments were first carried out to establish the extent to which pickling in aqueous sulfuric acid dissolved antimony from 7% antimonial lead. One kilogram of metal was immersed in 2 liters of sulfuric acid of known specific gravity and maintained at a constant temperature. In the work described in this paper the lead was in the form of cast grids of the type used in the manufacture of lead acid batteries. After various time intervals portions of the acid were removed and dissolved antimony determined by a procedure which is sensitive enough to detect down to 0.2 mg antimony in a liter of test solution.

Pickling in sulfuric acid-hydrogen peroxide mixture.—A range of solutions were prepared such that the final mixtures had a known specific gravity with respect to sulfuric acid (between 1.03 and 1.60 sp gr at 20°C) and contained a known concentration of hydrogen peroxide (between 2 volume and 5 volume concentration).[1] In all cases the solutions were prepared immediately prior to use. The pickling experiments were then carried out as discussed above.

Determination of antimony in sulfuric acid-hydrogen peroxide mixtures.—Reagents.—Standard antimony so-

[1] One volume concentration H_2O_2 is that concentration (0.3g H_2O_2/liter) which upon decomposition produces 1 ml oxygen at STP per milliliter of the peroxide solution.

lution, prepared from potassium antimonyl tartrate "ANALAR" to contain 0.1 mg antimony per milliliter.

Ascorbic acid/potassium iodide reagent was prepared by dissolving 70g potassium iodide "ANALAR" and 5g ascorbic acid in deionized water and making up to 500 ml. This solution must be prepared freshly as required.

Sulfuric acid was 1.2 sp gr, aqueous.

Potassium permanganate ($1N$) aqueous, was prepared from "ANALAR" solid.

Calibration curve.—Into seven 100 ml volumetric flasks, pipette 0.0, 0.1, 0.2, 0.3, 0.5, 0.7, and 1.0 ml of standard antimony solution (*e.g.*, 0.0 to 0.1 mg Sb) then add 10 ml of 1.2 gravity sulfuric acid. Add 25 ml potassium iodide/ascorbic acid reagent to each flask then make up to 100 ml with 1.2 sp gr sulfuric acid.

Fill two 10 mm glass spectrophotometer cells, respectively with the solution which is free from antimony (control) and the solution containing 0.1 ml standard antimony solution.

Place the two cells in spectrophotometer and measure the optical density at 425 mμ of the sample solution relative to the control (antimony free) solution in the reference beam. Repeat with each of the standard antimony solutions.

Plot a curve of milligrams antimony in the original 100 ml test solution *vs.* the corresponding optical densities obtained.

Analysis of pickling solutions.—Transfer a suitable volume (maximum 10 ml) of pickling solution into a 100 ml volumetric flask. If the specific gravity of the sulfuric acid in the pickling solution is less than 1.2 then add a calculated volume of 1.6 sp gr sulfuric acid to adjust the gravity in the final mixture to 1.2. If the specific gravity of the pickling solution exceeds 1.2 then add a calculated volume of deionized water sufficient to adjust the gravity of the final mixture to 1.2. Add sufficient 1.2 sp gr sulfuric acid to make the volume up to 10 ml. To a second control 100 ml volumetric flask add 10 ml 1.2 sp gr sulfuric acid. To both solutions add dropwise from a burette, potassium permanganate solution until a faint pink color is produced which persists for 5 min, indicating complete neutralization of hydrogen peroxide. Add 25 ml potassium iodide/ascorbic acid reagent and make up to 100 ml with 1.2 sp gr sulfuric acid. Refer the optical density to the calibration curve to obtain the weight of antimony present in the original 100 ml of diluted pickling solution.

If it is found that the concentration of antimony in the original pickling solutions is too high, then this solution should be diluted by a known amount with sulfuric acid of the same specific gravity and the above analysis repeated.

Measurement of the release of antimony from alloys under electrochemical conditions.—Pickled and unpickled castings (150g) in 4.5, 7, and 10% antimonial lead were set up as anodes, against pure lead cathodes in cells containing a liter of 1.25 sp gr sulfuric acid. A 2A current was passed through the castings and the antimony content of the electrolyte determined at intervals.

Construction of test batteries.—The test batteries used in the study were Miners Caplamps batteries constructed with two cells, each containing a tubular positive plate and two negative plates and a standard separator system.

A low antimonial alloy (4.5% antimony) was used throughout; only the positive grids were pickled.

Pickling was conducted for 8 hr at 15°-20°C in a solution consisting of 4 volume strength hydrogen peroxide in 1.200 sp gr sulfuric acid. The solution was contained in a glass or polyethylene tank and the lead grids were suspended, without touching in this solution at a ratio of 1 kg of lead to 2 liters of solution.

In some experiments the grids were then rinsed in cold running water to remove acid and were then allowed to dry. Such grids had on the surface a very thin whitish layer, presumably of lead sulfate. In other experiments, pickled grids were immediately dipped in a 10% aqueous solution of diethylene triamine for a few minutes until lead sulfate had been completely removed and the metal was bright. The plates were then quickly rinsed in water and left to air dry.

Batches of batteries containing unpickled, pickled and water washed, and pickled and amine washed positive grids were then assembled by standard manufacturing methods.

The batteries were then continuously cycled according to the following schedule: charge: constant voltage charge at 4.90 to 2.45V per cell (about 15 hr); discharge: for 9 hr through a 1A calibrated bulb recording the time taken to reach 1.85V per cell. Cycling tests were discontinued when the discharge time dropped below 7 hr, *i.e.*, end of battery life.

Results

Sulfuric acid pickling.—Antimony extraction was extremely low at acid gravities of 1.2 and 1.4 even at operating temperatures up to 80°C. At 1.6 gravity and 80°C, 72 mg of antimony was dissolved from the alloy in 300 hr from 1 kilo of alloy, *i.e.*, only 0.1% of the antimony content of the original alloy (7%) was dissolved into the pickling solution. At 80°C in 1.4 gravity acid, a small amount of white precipitate was noted in the acid, presumably lead sulfate. At 80°C in 1.6 gravity acid, a small amount of a brown orange precipitate was noted in suspension in the solution and as a coating on the metal. This solid contained about 4% antimony and, presumably by its color, contained antimony sulfide. The solution itself had a deep brown discoloration. In the same experiment, a bubbler containing 10% aqueous silver nitrate solution was connected to the sealed vessel in which the pickling was carried out and it was observed that during the experiment, a black precipitate formed in the silver nitrate solution. This was presumably, silver stibnide and/or silver sulfide produced by reaction of silver ions with stibine and/or hydrogen sulfide produced during pickling. These observations fit in with the reactions known to occur between antimony and hot sulfuric acid solutions of specific gravity greater than 1.55. Decomposition products of this type were not observed in pickling experiments conducted in acid gravities below 1.4

Sulfuric acid-hydrogen peroxide pickling.—Figure 1 compares the rate of extraction of antimony from 7% antimonial lead by strong sulfuric acid at 80°C and by various acid-hydrogen peroxide mixtures at normal ambient temperatures. The dramatic increase in antimony extraction resulting upon incorporation of hydrogen peroxide is immediately evident.

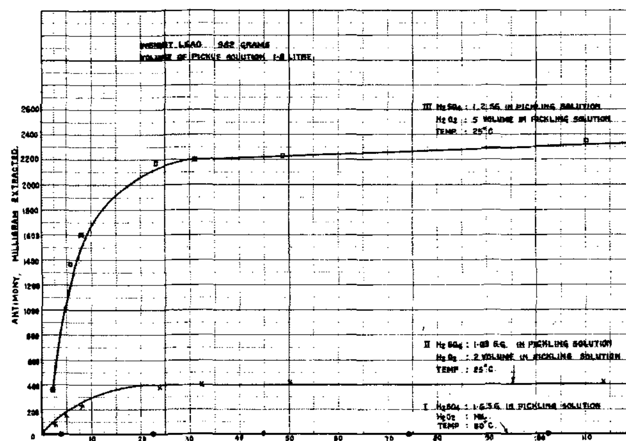

Fig. 1. Comparison of pickling rates of 7% antimonial lead in sulfuric acid and hydrogen peroxide/sulfuric acid.

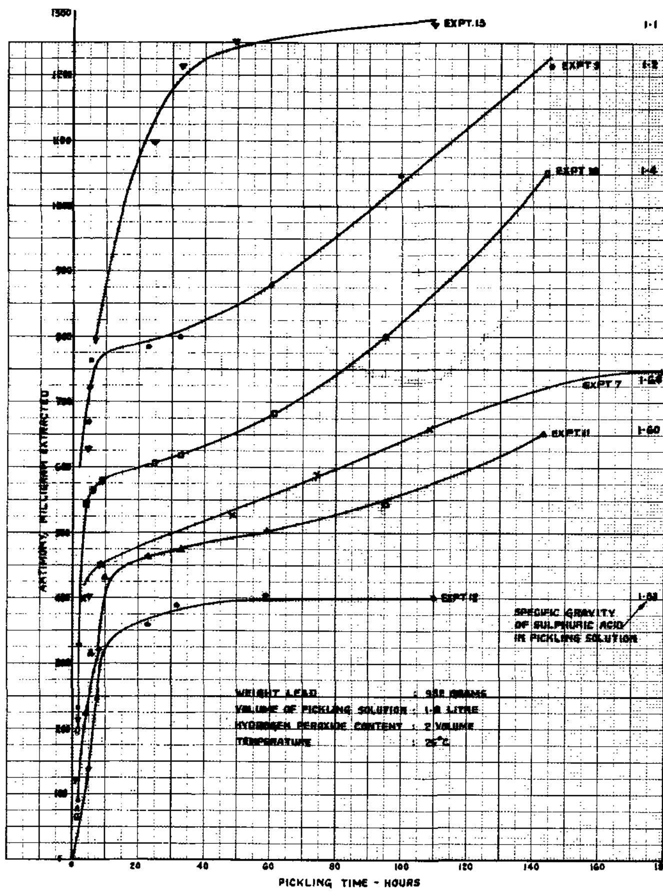

Fig. 2. Influence of sulfuric acid concentration on pickling rate of 7% antimonial lead.

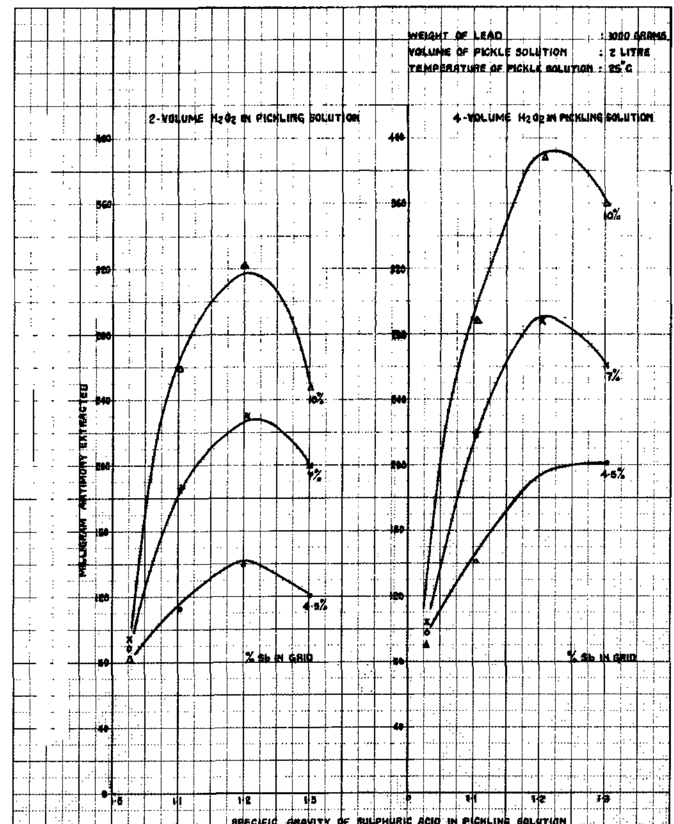

Fig. 3. Influence of acid gravity and hydrogen peroxide concentration on antimony extraction in 8 hr pickle of 4.5, 7, and 10% antimonial lead.

Increase in the concentrations of acid and peroxide leads to higher antimony extractions (compare curves II and III, Fig. 1).

Effect of sulfuric and concentration.—The curves in Fig. 2 plot the course of antimony extraction occurring from 7% antimonial lead during pickling times of up to 180 hr at 25°C in a reagent consisting of hydrogen peroxide (2 volume) and sulfuric acid (between 1.03 and 1.60 sp gr). Experimental replication is satisfactory (compare curves 7 and 11). At acid gravities of under 1.1, antimony extraction ceased after 40-50 hr, reaching 70-80% of this value in 10 hr. At acid gravities higher than 1.1 antimony extraction from the grid still continued after 180 hr with no evidence of leveling out. The highest antimony extraction recorded was obtained with 1.1 to 1.2 gravity acid. Also, at acid gravities in this range, antimony extraction following a 5 hr pickling was about half that obtained during a 140 hr pickle. After pickling, the metal became eventually gray or white colored and, at certain acid concentrations a turbidity or precipitate, presumably of lead sulfate, formed in the solution. At acid concentrations of 1.2-1.3 sp gr and pickling times up to 30 hr no insoluble matter was evident in the solution.

Effect of hydrogen peroxide concentration.—The results in Fig. 2 show that extension of the pickling time above 10-20 hr is not a very efficient method of increasing the antimony extraction rate in the case of a reagent consisting of 2 volume hydrogen peroxide and sulfuric acid in the 1.1-1.2 sp gr range. Next, a comparison was made between antimony extraction obtained for 7% antimonial lead using 2 volume and 5 volume hydrogen peroxide, both with 1.2 gravity acid at 25°C. After 10 hr the antimony extraction increased almost *pro rata* with increase of hydrogen peroxide concentration, and, in fact, the solution containing 5 volume hydrogen peroxide removed as much antimony in 5-10 hr as did the weaker reagent in 140 hr. The quantities of antimony dissolved from approximately 1 kilo of lead in a 140 hr pickle using the two and five volume hydrogen peroxide were respectively 1.3g and 2.4g. Thus, increasing the concentration of peroxide in the reagent is a more effective method of increasing antimony extraction than extension of pickling time.

Figure 3 shows the effect of sulfuric acid and hydrogen peroxide concentration on antimony extraction during an 8 hr pickle at 25°C for freshly cast lead alloys containing 4.5, 7.0, and 10% antimony. For each alloy, antimony extraction was highest at an acid gravity of 1.2 and at the higher peroxide concentration. A repeat experiment on these alloys three weeks after casting gave an identical set of curves. A plot of weight of antimony extracted during an 8 hr pickle against the antimony content of the alloy showed a linear relationship for each of the eight reagent systems quoted in Fig. 3.

Tables I and II show the effect of reagent composition and pickling time on the percentage of the original

Table I. Percentage dissolution of antimony from 7% antimonial lead (thin section 1/16 in.)

* Numerals in brackets indicate pickling time in hours, antimony extraction had reached a maximum within these times.

antimony content of the alloy which is removed by pickling. Comparison of these results show that with similar reagents the percentage of the original antimony content of the alloy which is extracted from thinner section moldings is higher than with thicker section moldings, due, presumably to the higher area to volume ratio of the former with its consequent increased surface area per unit weight of lead available for antimony dissolution. The inefficiency of pickling with strong sulfuric acid without peroxide at 80°C is clearly evident in Table I, which shows that only 0.001% of the original antimony content of the alloy has been extracted. Contrasted with this and confirming the earlier experiments, 3% antimony extraction occurs when pickling is carried out at 25°C in 1.2 gravity acid containing 5 volume peroxide. Clearly, this antimony removal must occur principally at the metal surface (or in the region near to the surface). If, with an as-cast alloy there is no enrichment of antimony at the surface above the normal level this result implies that, on the average, the pickling reagent penetrates only to a depth of between 0.001 and 3% of the average thickness of the metal. If, on the other hand, as had been postulated, antimonial lead castings have a very thin surface layer of appreciably higher antimony content than the bulk of the alloy, then the average depth of reagent penetration into the grid to produce the observed antimony extractions would be less than those quoted above.

Hydrogen peroxide decomposition.—It was observed that gas bubbles were continuously formed on the surface of grids during pickling at 25°C. The gas is produced by a gradual decomposition of hydrogen peroxide to oxygen and water and is presumably catalytically induced by lead or by impurities therein. Peroxide decomposition was monitored during pickling by analyzing timed samples by titration with standard potassium permanganate.

Figure 4, shows, for 7% antimonial grids during a 40 hr pickle, the influence of acid gravity on antimony extraction and the parallel decomposition of hydrogen peroxide. It is seen that hydrogen peroxide decomposition is highest under those conditions under which antimony extractions are highest.

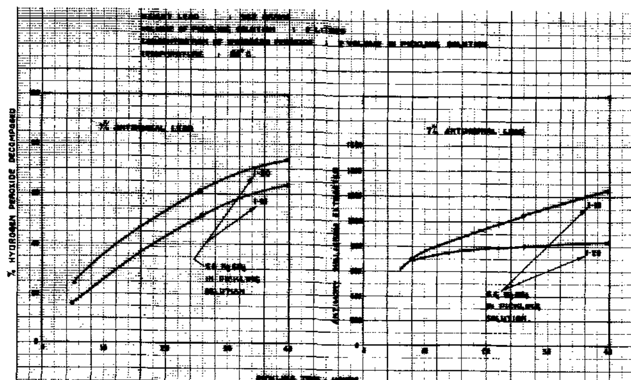

Fig. 4. Relation between pickling time, antimony extraction, and hydrogen peroxide decomposition.

Effect of pickling on subsequent release of antimony from alloys under electrochemical conditions.—Obviously, the more efficient the removal of antimony by pickling then the lower will be the equilibrium antimony content of the electrolyte in an electrolysis experiment, compared to the equilibrium antimony content obtained by electrolysis of unpickled control alloys. This procedure therefore offers a method of ascertaining the influence of chemical pickling in acid hydrogen peroxide on the subsequent rate of removal of antimony from the alloy under conditions where a current flows.

Figure 5 plots the relationship between the antimony content of the original alloy and the weight of antimony removed from 150g of three lead alloys during a 25 hr electrolysis. It is seen that less antimony is removed by electrolysis of alloys which have been previously pickled compared to the unpickled controls. The effect of chemical pickling upon subsequent antimony removal occurring upon electrolysis, is greatest

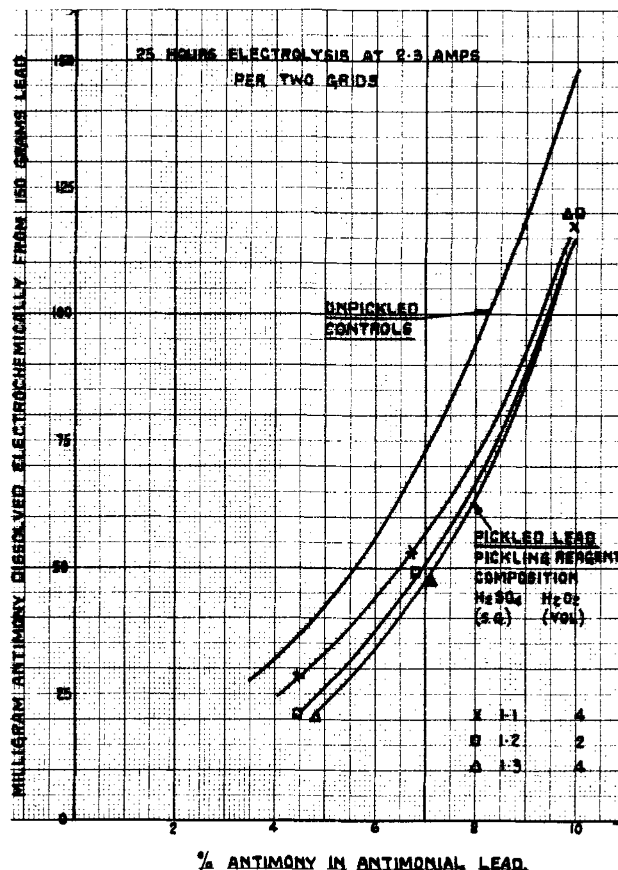

Fig. 5. Electrochemical removal of antimony from pickled and unpickled lead as a function of original antimony content of alloy.

in the case of the 4.5% antimonial alloy in which antimony removal upon electrolysis is about half the value obtained for the unpickled control. Smaller effects of pickling on antimony removal during electrolysis were noted in the case of the two higher antimonial alloys.

It was attempted to ascertain whether a relationship existed between antimony removal from the grid during chemical pickling and the amount of antimony which is subsequently removed from the grid upon electrolysis.

If, during electrolysis of an unpickled metal casting, the concentration of antimony that builds up in the electrolyte in time T is denoted by X mg Sb/g alloy and if, during the same time interval, the concentration of antimony that builds up in the electrolyte in contact with pickled alloy at the same initial antimony content is denoted by Y mg Sb/g alloy, then $(X - Y)$ is a measure of the efficiency of the chemical pickling process in removing surface antimony from the alloys. If the weight of antimony removed from the alloy during pickling is denoted by Z mg/g alloy, then it follows that for an alloy of a particular composition, an increase in the value of Z should be accompanied by a decrease in the value of Y, *i.e.*, an increase in the value of $(X - Y)$ for each of the three alloys examined. That this is so is confirmed by examination of Table III.

It follows from the previous discussion that $(X - Y)\ 100/X$ represents the percentage reduction in extractable antimony that occurs as a result of chemical pickling of alloys compared to unpickled controls in the same antimonial alloy. This quantity is a direct measure of the reduced amount of electroextraction of antimony from alloys that occurs under standard electrochemical conditions as a result of various chemical pickling treatments of the alloys. It is interesting to examine, therefore, the influence of increasing the antimony removal from alloys, *i.e.*, increasing Z during pickling (by using different pickling reagents) on $(X - Y)\ 100/X$. This is shown in Fig. 6 which plots Z against $(X - Y)\ 100/X$. It is seen that three groups of results are obtained corresponding to the 4.5, 7, and 10% antimonial alloys. At each alloy composition, as expected, an increase in antimony removal (Z) during pickling is accompanied by an increase in the percentage reduction of electroextractable antimony $(X - Y)\ 100/X$. The latter is greater in the case of the 4.5% antimonial alloy (*viz.* 40-50%) and least in the case of the 10% alloy (*viz.* about 20%).

Mining caplamp battery cycling tests.—The results in Table IV give distinct evidence that batteries made up with 4.5% antimonial lead positive grids which have been pickled and amine washed have a longer cycle life than batteries made using either unpickled grids of the same antimony content or grids which have been pickled but not amine washed.

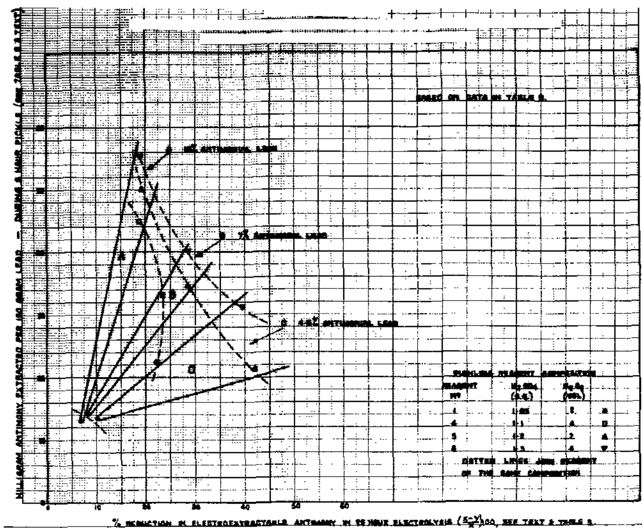

Fig. 6. Effect of efficiency of antimony removal during pickling on per cent reduction in electroextractable antimony from lead.

Discussion

Pickling of antimonial lead at ambient temperature in mixtures of hydrogen peroxide and sulfuric acid is a considerably more efficient method of stripping off the surface rich antimony layer that has been postulated to exist on these alloys than is achieved by pickling in sulfuric acid alone, even at elevated temperatures. For alloys in the composition range studied up to 10% antimony, antimony extraction is highest at a sulfuric acid concentration in the pickling solution corresponding to 1.20 ± 0.10 sp gr.

This applies at all hydrogen peroxide concentrations between the extremes of the range studied (2-5 volume strength). At any particular hydrogen peroxide concentration in the reagent, the extraction of antimony during a standard pickling time decreases as the sulfuric acid concentration is decreased below or is increased above the acid gravity of 1.20 ± 0.10. At a particular acid concentration and pickling time, antimony extraction increases with increase in hydrogen peroxide concentration. Increase of the concentration of hydrogen peroxide in the pickling solution is usually a more efficient method of antimony removal than extension of the pickling time.

Depending on various factors *viz.* reagent composition, pickling time, surface area/volume ratio of lead, antimony content of alloy, between 0.1 and 3.3% of the original total antimony content of the alloy is extracted during pickling processes (Tables I and II). Also, as indicated in Table III, the greater the amount of antimony that is removed from the surface of the lead by pickling prior to electrolysis then the smaller the amount of surface antimony that is left on the grid. This indicates that both pickling and electrolysis

remove antimony from the surface, only, of the lead. Obviously, the higher the extraction of surface antimony during pickling the less are adverse effects to be expected by antimony in subsequent battery operation. Data in Fig. 5 and 6 indicate that positive 4.5% antimonial lead grids that have been pickled for 8 hr in a 1.2-1.3 gravity sulfuric acid/2-4 volume hydrogen peroxide pickling solution would be expected under electrochemical conditions to release only approximately 50% of the amount of antimony obtained from an unpickled 4.5% antimonial alloy. The corresponding figure for pickled 10% antimonial alloy is 80% of the amount of extracted antimony that would be obtained for the unpickled alloy. Thus the beneficial effects of pickling on subsequent battery performance would be expected to be greater in the case of lower antimonial alloys.

The data in Table IV indicate that an 8 hr pickling of 4.5% antimonial positive grids in a reagent comprising sulfuric acid (1.20 sp gr) and hydrogen peroxide (4 volume) followed by amine treatment to remove surface deposits leads to an approximately 30% increase in cyclic life of the particular type of battery studied. Examination of the data in Table II shows that extension of the pickling time with this reagent to times greater than 8 hr would have removed considerably more antimony (perhaps 2-3 times as much) than was in fact removed during 8 hr. Possibly, positive grids which had been given an extended pickling time would lead to further improvements in cyclic life to that obtained in the experiments described above. Additionally, it is possible that negative grid pickling would have further beneficial effects.

It is clear that, to obtain maximum benefits from grid pickling, a careful study should first be conducted of the effect of pickling reagent composition, pickling time and other factors on antimony removal occurring during pickling for the types of plates it is intended to use in each particular type of battery.

Lead-Fluoroboric Acid Battery

G. D. McDonald,* E. Y. Weissman,* and T. S. Roemer

Globe-Union, Inc., Milwaukee, Wisconsin 53201

ABSTRACT

A reserve battery is described that can operate over a wide temperature range, including temperatures as low as −60°C at coulombic efficiencies of 16% or better. The battery is based on the system: lead/fluoroboric acid/lead dioxide and utilizes a bonded lead dioxide cathode. The system is discussed based on data such as: capacities, current-voltage relationships, and coulombic efficiencies, as a function of temperature; self-discharge characteristics; specific energy; and cost considerations.

The lead/fluoroboric acid/lead dioxide battery has typically been used for applications requiring an inexpensive reserve-type power supply capable of high discharge rates over a wide temperature range. An example of such an application is the proximity fuze battery (1, 2). The characteristics of a typical $Pb/HBF_4/PbO_2$ battery are summarized in Table I, where the listed specifications have been all exceeded to a significant degree (*e.g.*, 50 sec of 0.040A discharge, above 18V at + 60°C; 90 sec of 30 mA discharge, above 15V, at −40°C).

* Electrochemical Society Active Member.

Key words: fluoroboric acid battery, lead dioxide electrode, bonded lead dioxide electrode, lead-fluoroboric acid battery.

Fluoroboric acid is particularly well suited for such types of reserve batteries because of its wide liquidus range, good conductivity, and ready availability (used in the electroplating industry). Table II summarizes its properties as well as the over-all electrochemical reaction in which it participates. The boric acid is present in order to suppress hydrolysis in which the fluorine atoms attached to the boron are stepwise replaced by hydroxyl groups, with the other hydrolysis product being hydrofluoric acid.

An important feature of this electrochemical system is the solubility of lead fluoroborate, the reaction product formed at each electrode (approximately 380g per liter). Because of this property, dense, nonporous,

at −60°C:	0.06 ohm^{-1} cm^{-1}

and structurally stable electrodes can effectively be used with a resultant savings in required battery volume. At the same time, fluoroboric acid attacks most other metals and metal oxides to give soluble reaction products. While we have found that neither lead nor lead dioxide are attacked in the absence of oxygen, the generally corrosive nature of this electrolyte requires a careful selection of the battery materials of construction.

At the present time, lead-fluoroboric acid type batteries use bipolar electroplated electrodes consisting of nickel-plated steel shim stock with lead plated on one side and layers of α- and β-lead dioxide on the other. Capacity densities of the order of 7 A-sec per cm^2 of geometric electrode area are attainable. Attempts to increase this capacity by heavier plating have proved fruitless owing to adhesion or active material brittleness problems. The only successful attempts to increase cell capacity have resulted from increases in electrode plate area (3).

Lately, some work (4) has been carried out in the area of development of bonded lead dioxide electrodes possessing higher capacities and improved mechanical properties. The present paper summarizes results obtained along similar lines, based primarily on the use of electrode hot-pressing techniques.

Experimental

The raw materials were: commercially available lead dioxide powder (Fisher Scientific; particle size range: 90-100μ); lead sheet (99% pure, 0.52 mm thickness); and 48% fluoroboric acid (Harshaw Chemical). All materials were used without preliminary purification or processing steps. The lead dioxide particles were solvent-coated with suitable thermoplastic binders and the resulting mix was comminuted and then hot-pressed onto expanded metal (*e.g.*, nickel) current collector grids.[1] The test cells were constructed using lead sheet counterelectrodes, a "back-to-back" configuration (lead dioxide cathode sandwiched between two lead anodes), and microporous polyvinyl chloride separators.

When using 2.5 by 3.8 cm electrodes with 1.5 ml of electrolyte the cells weighed about 10g each, had a volume of 2 cm^3, and a theoretical capacity of approximately 0.5 A-hr. They were evaluated by force-discharging at constant current and recording voltage *vs.* time. Linear voltage sweeps were carried out with a Wenking Model 121 potentiostat and a Wenking SMP 66 function generator. Internal resistance measurements were based on a modification of a previously reported technique (5), using 20 μsec interruptions.

Self-discharge tests were also carried out, by maintaining a test cell at open-circuit at various temperatures for predetermined time intervals and then discharging it at the given temperature and/or at room temperature. A Conrad environmental chamber was used for all tests taking place at other than room temperature.

Results and Discussion

Figure 1 shows typical discharge curves of a fluoroboric acid test cell at various temperatures; they all exhibit well defined voltage end points and no apparent activation transients. Figure 2 exhibits the effect of discharge rate on the coulombic efficiency (*i.e.*, available capacity) of the lead dioxide electrode. For the types of electrodes evaluated there appears to be essentially no change in attainable capacity up to about 50 mA/cm^2. Higher discharge currents result in lower capacities.

It is interesting to note that 200 mA/cm^2 corresponds to approximately the 1 min rate, at which

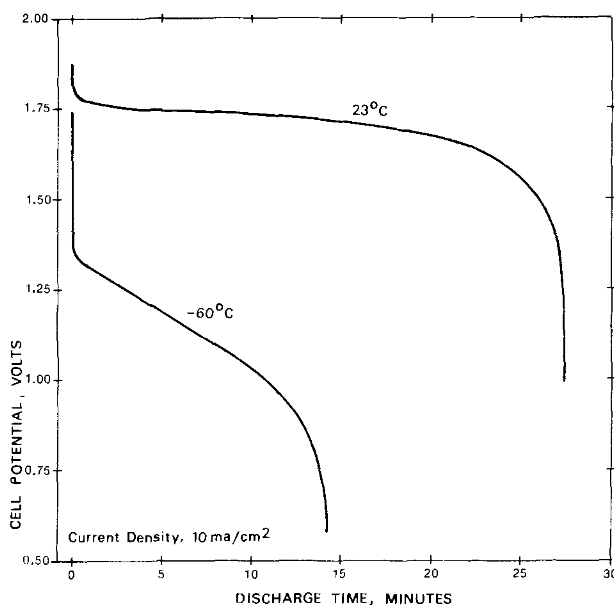

Fig. 1. Typical discharge curves for a $Pb/HBF_4/PbO_2$ test cell

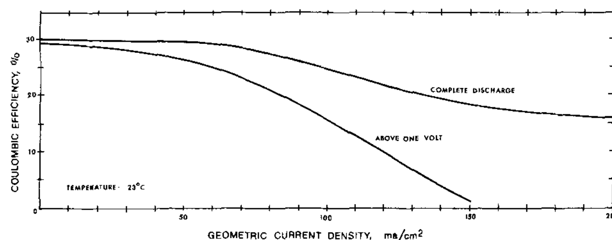

Fig. 2. Coulombic efficiency characteristics of the lead dioxide electrode in fluoroboric acid.

point the efficiency is still 16%. Furthermore, we have evidence to indicate that pulse current densities of 300 mA/cm^2 are also possible.

Figure 3 shows the effect of temperature on the coulombic efficiency of the system. At low temperatures the internal resistance accounts for the lower capacity, whereas at the higher temperatures, capacity is limited by self-discharge. Indeed, as far as this latter aspect is concerned, we note that commercially available electroplated bipolar electrodes have an activated stand capability of less than 6 min at room temperature. As opposed to that, state-of-the-art, high rate, bonded lead dioxide electrodes do not self-discharge appreciably for the first 48 hr at room temperature (Fig. 4). At a temperature of $-50°C$, corresponding to a variety of applications (*e.g.*, weather balloons), no significant self-discharge has been observed after 4 months of activated stand.

Figure 5 summarizes our findings regarding the activated stand capability of a bonded, high rate, lead dioxide electrode at the upper temperature extreme of 80°C. The capacity loss is rapid, about 1.33% per min, corresponding to complete self-discharge after 75 min. Similar studies were conducted at 40° and 60°C. The

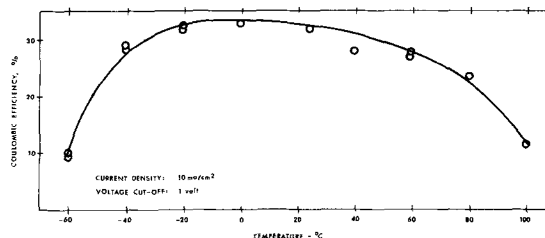

Fig. 3. Coulombic efficiency characteristics of the lead dioxide electrode in fluoroboric acid.

[1] The oxidizing characteristics of lead dioxide would seem to present a potential hazard. However, no difficulties were encountered in this work and DTA tests of the plastic-coated lead dioxide have exhibited initiation temperatures for a redox reaction which are about 30°C higher than the hot-pressing temperatures required for electrode preparation. Nevertheless, this aspect will warrant further attention prior to any development of large scale manufacturing processes.

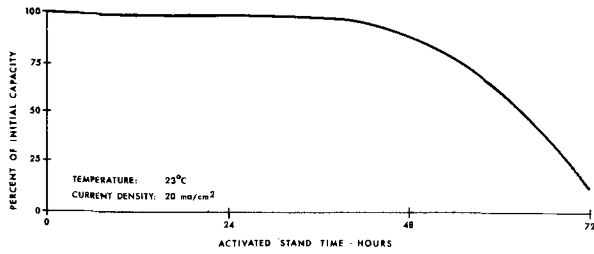

Fig. 4. Self-discharge characteristics of high rate, bonded, lead dioxide electrode in fluoroboric acid.

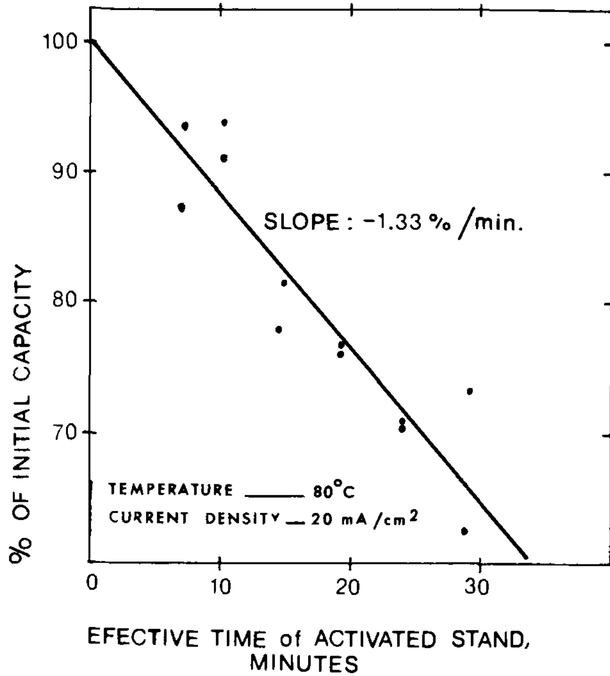

Fig. 5. Self-discharge characteristics of high rate, bonded, lead dioxide electrode in fluoroboric acid.

absolute temperature was found to be logarithmically related to the self-discharge rate with an intercept of 375 (correlation coefficient of 0.9994).

As expected, most of the loss in capacity is due to grid-active material interactions. Recent test results, based on the use of modified, low rate electrodes, not containing metallic current collector grids, have shown some promise for long activated stand lives under difficult conditions. An example in point is a 79 hr steady current discharge of 155 μA per cm² (which happens to be a discharge rate required by some applications) at 50°C, recently demonstrated in our laboratory.

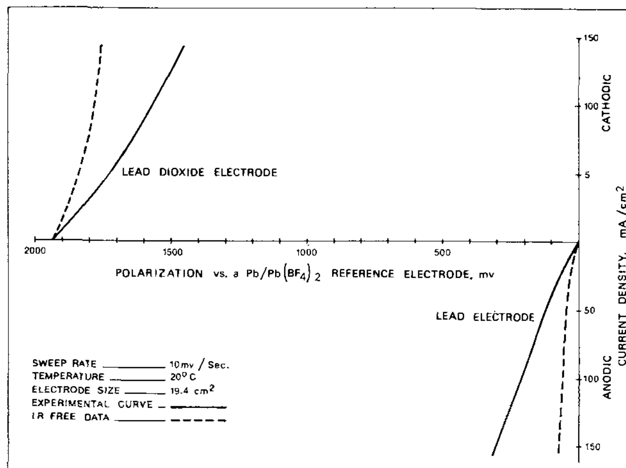

Fig. 6. Linear voltage scans for the system $Pb/HBF_4/PbO_2$

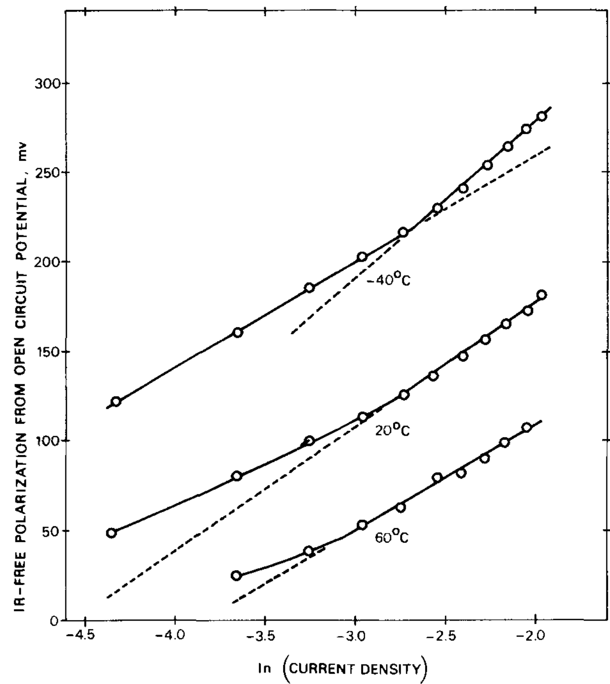

Fig. 7. Tafel plots for the lead dioxide electrode in fluoroboric acid.

A general operation aspect, noteworthy from a design standpoint, is the complete lack of gassing in this type of battery, either due to self-discharge or any other reason.

Figure 6 presents some typical linear voltage sweep data. Single electrode potentials are expressed *vs.* a

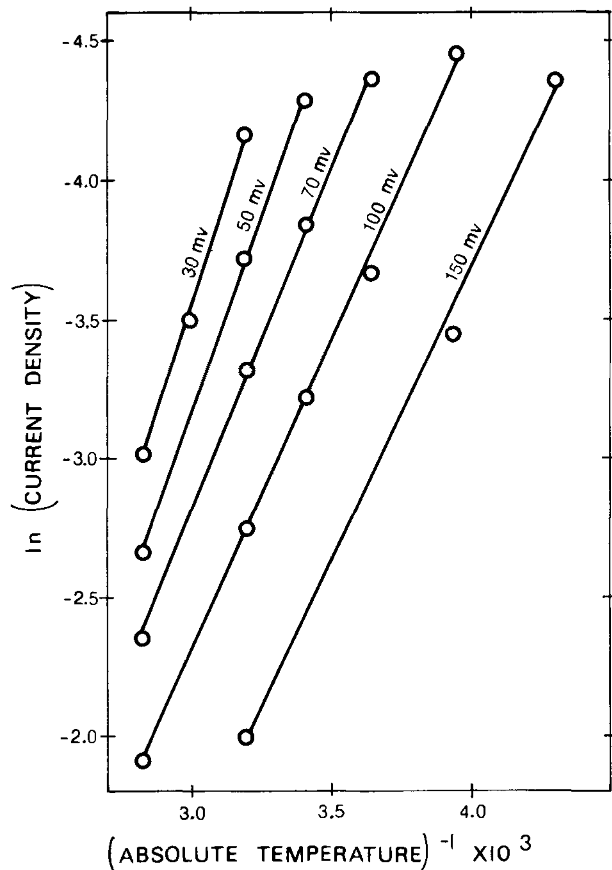

Fig. 8. Arrhenius plots for the lead dioxide electrode in fluoroboric acid.

lead-lead fluoroborate reference electrode. The scans were terminated at 3A owing to equipment limitations. Figure 7 is a Tafel plot of these data. At high temperatures essentially ideal behavior is exhibited, while at the lower temperatures, the curve is suggestive of a dissolution process (6). The Tafel slope, based on these lines, exhibits the theoretical linear temperature dependence with a slope corresponding to R/F. The calculated exchange current at 20°C is approximately 10^{-5} A/cm^2.

Figure 8 is an Arrhenius plot of the data yielding an activation energy of 1.1 kcal/gmole at 100 mV polarization for the linear portions of the curves (*i.e.*, the lower current regions). This very low value, together with the Tafel information, would indicate diffusion control of the reaction. However, an examination of Fig. 8 shows that the activation energy is dependent on electrode polarization. This suggests that chemical polarization also plays a role (7). The low activation energy, however, would seem to indicate that the electrode reaction proceeds with little impedance and that constructional parameters affecting the internal resistance of a cell will be the limiting factor for this system.

Conclusions

The improvements already demonstrated for the fluoroboric acid battery by the use of high capacity bonded lead dioxide electrodes of both the high rate (metallic current collector) and low rate variety are likely to increase the utility of this system for low specific energy (≤45 whr/kg) applications, requiring wide temperature range capabilities at low cost. One feature representing a completely new aspect of this technology is the significantly longer activated stand life demonstrated for the present state-of-the-art lead-fluoroboric acid system.

It is therefore possible that this type of reserve battery may provide sufficiently attractive design-related characteristics to be considered as an alternative to some of the costlier systems presently in use.

An Ellipsometric-Electrochemical Cell: Initial Films on Titanium in Water and Methanol Solutions

Tennyson Smith* and Florian Mansfeld*

North American Rockwell Science Center, Thousand Oaks, California 91360

ABSTRACT

An ellipsometric-electrochemical cell is described for simultaneous ellipsometric and electrochemical measurements of metal samples. The unique feature of this cell is the ability to prepare in one cavity with an appropriate etch-polishing solution surfaces which within the experimental error of ellipsometric measurements approach an atomically clean state. The reaction product and etchant are washed away in a second cavity and *in situ* measurements of changes on the surface are made in a third cavity without exposing the sample to the atmosphere. It is demonstrated that Ti surfaces, which have the same optical constants as observed after ion bombardment cleaning and annealing in an ultra high vacuum system (~10^{-10} Torr), can be prepared in the cell. Results are reported for the initial film growth on clean Ti in aqueous HF, aqueous NaCl, aqueous methanol-HCl, and anhydrous methanol-HCl solutions as a function of applied electrochemical potential.

It is well known that obtaining and studying atomically clean metal surfaces requires a means for removing surface films in an ultra high vacuum (UHV) system (*e.g.*, ion bombardment, cleaving, scraping). The UHV system must operate in the 10^{-9}-10^{-10} Torr range in order to maintain a clean surface for periods of minutes to hours. It would be desirable to study metal surfaces which approach cleanliness obtainable in a UHV system, but immersed in an electrolyte in an electrochemical cell. This can in some instances be accomplished in an ordinary electrochemical cell if the metal surface contamination can be removed electrochemically and the electrolyte does not contain surface active contamination. However, for many metals (*e.g.*, Ti) air-formed oxide films cannot be removed electrochemically.

The purpose of this paper is to report our attempts to introduce atomically clean Ti surfaces to the electrolyte of interest and observe surface reactions *in situ* via ellipsometry as well as potential and current measurements. The technique involves cleaning of the surface by a suitable process (etching, electropolishing, etc.), followed by exposing this freshly cleaned surface to the electrolyte without exposing it to another environment (such as air).

lead-lead fluoroborate reference electrode. The scans were terminated at 3A owing to equipment limitations. Figure 7 is a Tafel plot of these data. At high temperatures essentially ideal behavior is exhibited, while at the lower temperatures, the curve is suggestive of a dissolution process (6). The Tafel slope, based on these lines, exhibits the theoretical linear temperature dependence with a slope corresponding to R/F. The calculated exchange current at 20°C is approximately 10^{-5} A/cm^2.

Figure 8 is an Arrhenius plot of the data yielding an activation energy of 1.1 kcal/gmole at 100 mV polarization for the linear portions of the curves (*i.e.*, the lower current regions). This very low value, together with the Tafel information, would indicate diffusion control of the reaction. However, an examination of Fig. 8 shows that the activation energy is dependent on electrode polarization. This suggests that chemical polarization also plays a role (7). The low activation energy, however, would seem to indicate that the electrode reaction proceeds with little impedance and that constructional parameters affecting the internal resistance of a cell will be the limiting factor for this system.

Conclusions

The improvements already demonstrated for the fluoroboric acid battery by the use of high capacity bonded lead dioxide electrodes of both the high rate (metallic current collector) and low rate variety are likely to increase the utility of this system for low specific energy ($\leq$45 whr/kg) applications, requiring wide temperature range capabilities at low cost. One feature representing a completely new aspect of this technology is the significantly longer activated stand life demonstrated for the present state-of-the-art lead-fluoroboric acid system.

It is therefore possible that this type of reserve battery may provide sufficiently attractive design-related characteristics to be considered as an alternative to some of the costlier systems presently in use.

ABSTRACT

An ellipsometric-electrochemical cell is described for simultaneous ellipsometric and electrochemical measurements of metal samples. The unique feature of this cell is the ability to prepare in one cavity with an appropriate etch-polishing solution surfaces which within the experimental error of ellipsometric measurements approach an atomically clean state. The reaction product and etchant are washed away in a second cavity and *in situ* measurements of changes on the surface are made in a third cavity without exposing the sample to the atmosphere. It is demonstrated that Ti surfaces, which have the same optical constants as observed after ion bombardment cleaning and annealing in an ultra high vacuum system ($\sim 10^{-10}$ Torr), can be prepared in the cell. Results are reported for the initial film growth on clean Ti in aqueous HF, aqueous NaCl, aqueous methanol-HCl, and anhydrous methanol-HCl solutions as a function of applied electrochemical potential.

It is well known that obtaining and studying atomically clean metal surfaces requires a means for removing surface films in an ultra high vacuum (UHV) system (*e.g.*, ion bombardment, cleaving, scraping). The UHV system must operate in the 10^{-9}-10^{-10} Torr range in order to maintain a clean surface for periods of minutes to hours. It would be desirable to study metal surfaces which approach cleanliness obtainable in a UHV system, but immersed in an electrolyte in an electrochemical cell. This can in some instances be accomplished in an ordinary electrochemical cell if the metal surface contamination can be removed electrochemically and the electrolyte does not contain surface active contamination. However, for many metals (*e.g.*, Ti) air-formed oxide films cannot be removed electrochemically.

The purpose of this paper is to report our attempts to introduce atomically clean Ti surfaces to the electrolyte of interest and observe surface reactions *in situ* via ellipsometry as well as potential and current measurements. The technique involves cleaning of the surface by a suitable process (etching, electropolishing, etc.), followed by exposing this freshly cleaned surface to the electrolyte without exposing it to another environment (such as air).

Experimental Techniques

Materials.—The cell was constructed of glass reinforced Teflon, the electrolyte reservoirs were of glass, the etchant reservoir tanks were of Teflon, as were the tubes connecting the reservoirs with the cell. Consequently, the etchant (20% H_2SO_4, 20% HF, 30% HNO_3 by volume) was exposed only to Teflon, while the electrolyte was exposed only to Teflon, glass, paraffin (used for sealing), the platinum counterelectrode, and the sample.

The Ti samples were cut from Ti-75A as cylinders having a slight taper. The surface to be studied was polished to a mirror finish with 600 silicon carbide paper and etched to remove surface damage. The final polishing solution consisted of 1μ alumina in a solution of 1 part ammonium hydroxide, 1 part distilled water, and 1 part 3% hydrogen peroxide. The hydrogen peroxide was added last and was fresh.

Electrolytes.—The electrolytes were prepared from reagent grade materials and bidistilled water.

The cell.—A photograph of the assembled cell is shown in Fig. 1. Figure 2 shows a side view of the Teflon cell, which contains three cavities (A, B, and C) and a Teflon slider S that holds the metal sample. When the sample is positioned at cavity A, etchant (20% H_2SO_4, 20% HF, 30% HNO_3 by volume) can be made to flow through the cavity from its reservoir, past the sample and into the collector reservoir. After exposing the sample to the etchant for a predetermined length of time, the sample is positioned at cavity B. At cavity B the electrolyte is forced past the sample to remove etchant carried from cavity A, and is then collected in another reservoir. After thus washing the sample in cavity B for a predetermined period, it is positioned at cavity C through which the test solution is flowing for observation by ellipsometry with or without a potential applied to the specimen. The window W in Fig. 2 is used for visual inspection of the sample in cavity C. The slider S in Fig. 2 consists of a rectangular plate of Teflon S_1 bolted to a steel plate S_2. The sample is forced into a cylindrical well (slightly smaller than the large diameter of the tapered sample) with attached bolt and nut, such that the metal surface is about 0.004 in. below the surface of the Teflon slider. This is to ensure that the metal sample will not scratch the cell surface as the sample is sliding up and down and thus cause leaks between cavities. In order to prevent leakage between cavities, the slider surface must be pressed against the cell surface with considerable pressure. To accomplish this, a plate P is

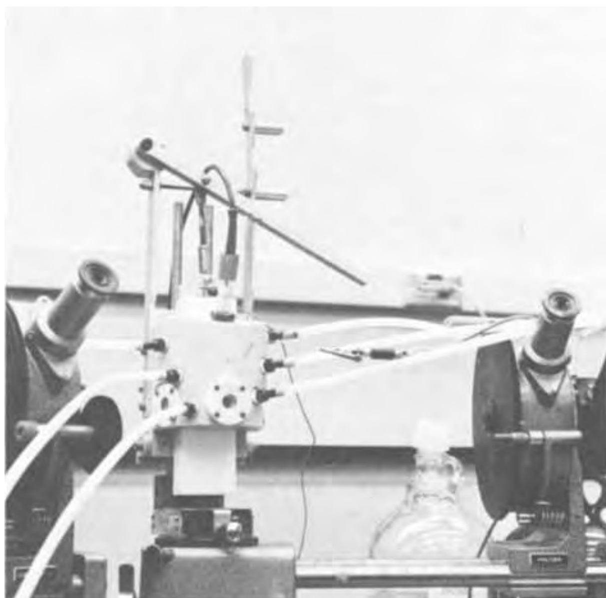

Fig. 1. Photograph of cell

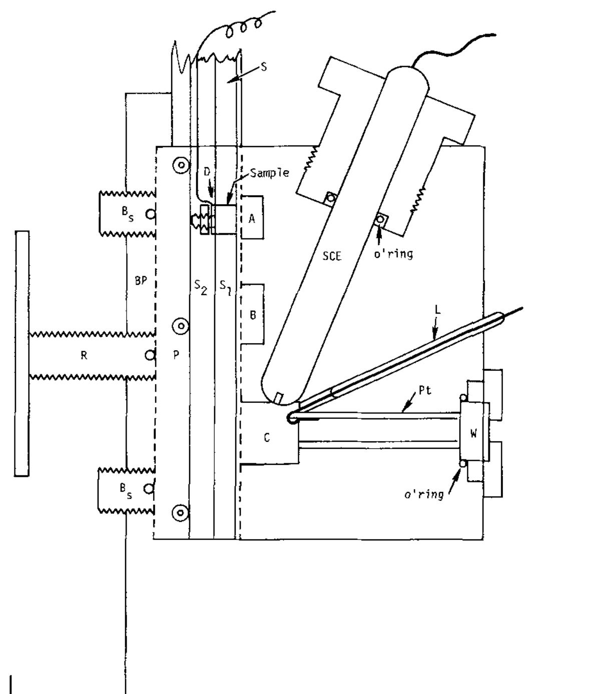

Fig. 2. Sketch of ellipsometric-electrochemical cell

spring loaded against the back plate BP, with the spring load bolts B and a wrench R. To reduce the friction between plates P and S_2, bearings are placed in plate P or S_2 to roll on. The slider is pulled up and down with a lever and can be positioned by a notched side arm such that the sample is at the center of cavity A, B, or C.

Electrodes.—The counterelectrode consists of a platinum cylinder in the channel leading to window W. This Pt counterelectrode is spot welded to a Pt wire which had been sealed into a glass tube and inserted into the cell, as shown in Fig. 2 as L. A saturated calomel reference electrode (SCE) is inserted as shown in Fig. 2. The O-rings in the windows and around the SCE were coated with paraffin before use. For electrical connections to the sample, an insulated copper wire is spot welded to a copper washer that is placed on the sample bolt under the nut as shown at D (Fig. 2). Entrance and exit channels for the etchant, washing solution, and electrolyte are placed such that the entrance to each cavity is at the bottom of the cavity and the exit at the top. This eliminates collection of gas bubbles in the cavities. The channels for the light beam are placed such that the beam has an angle of incidence of 70°.

Ellipsometry.—A good description of ellipsometry can be found in Ref. (1). The cell was constructed to be mounted on a Rudolph ellipsometer (sensitivity 0.01°). Filters were used to isolate the 5461Å light from a mercury lamp or the 6328Å light from a He-Ne laser. The polarizer and compensator were placed before the reflecting surface and the analyzer and detector after the reflecting surface. The ellipsometer parameters Δ and ψ refer to the phase shift of the normal and parallel component of the polarized light and the arctan of the amplitude ratio of these components, respectively. The polarizer angle p and analyzer angle a are related to Δ and ψ (in zone I) by $\Delta = 2p + \pi/2$ and $\psi = a$. p and a values were averaged for the four zones to minimize alignment errors (1).

To correct for the birefringence of the windows, it would be desirable to measure p and a values with and without the windows. However, since measurement with electrolyte in the cell but without windows cannot be made, it was necessary to first measure the correction due to the windows in an unstressed state, *i.e.*,

Table I. Measurements to obtain window corrections

Test condition	Zone	p	a
Windows off	1	11.52	29.63
	1	11.65	29.70
	1	11.52	29.67
	1	11.63	29.57
Average value		11.58 ± 0.06	29.64 ± 0.04
	3	10.77	30.34
	2	10.65	29.39
	4	11.50	30.70
Average of 4 zones		11.25 ± 0.41	30.02 ± 0.50
Windows, no pressure (Average 4 zones)		9.15	30.48
Correction for loose windows		2.10	−0.46
CH_3OH flowing, windows leaking (Average 4 zones)		5.08	28.93
CH_3OH flowing, leak tight (Average 4 zones)		4.37	28.02
Correction for window pressure		0.71	0.91
Correction for loose windows		2.10	−0.46
Total window correction		2.81	0.45

measurement of p and a with and without the windows but with air in the cell. The results in Table I indicate that for unstressed windows a correction of 11.25° − 9.15° = 2.10° must be made. A second correction is necessary for the stress induced in the windows when sufficient pressure is applied to prevent leakage of electrolyte from the cell. To obtain this correction, measurements of p and a were made with electrolyte in the cell and the windows held loosely in position (electrolyte leaking) and with enough pressure to prevent leakage. The results in Table I indicate this correction to be 5.08° − 4.37° = 0.71°. The total window correction is then 2.10° + 0.71° = 2.81° for p. A similar calculation yields a total correction of 0.45° for a. Measurement of p and a without windows (air in cell) show that measurements can be repeated with an average deviation of about ±0.05° (see Table I).

HF contamination.—Care must be taken to be sure that none of the HF in the etching-polishing solution is carried into the working cavity (C of Fig. 2). This can occur if scratches exist in the Teflon slider or mating cell surface, or if insufficient pressure is used between these parts. A check for such leakage was made by using distilled water in the washing and working cavities and monitoring the pH of the water leaving the working cell. To show the drastic effect of small HF contamination in the electrolyte in the working cell, a series of experiments was performed with varying concentrations of HF added to distilled H_2O as test electrolyte. The resultant changes in p and a are shown as a function of time in Fig. 3a. Tests with small additions of H_2SO_4, HCl, or HNO_3 of similar concentration gave virtually no changes in p and a readings. The effect of HF must result from the strong complexing action of the F^- ion resulting in thick films of corrosion products. Accelerated corrosion of Ti in sulfuric acid containing fluoride ions has been reported recently (7).

Since there are only two experimental ellipsometric parameters p and a and there are three unknowns, film thickness d, index of refraction n_f, and absorption coefficient κ_f, a unique solution for d, n_f, and κ_f is not possible. It becomes necessary, therefore, to interpret p and a in terms of d and n_f for reasonable ranges of κ_f. A discussion of the problems inherent in the interpretation of the ellipsometric results in terms of thickness d and film index of refraction is given in Appendix A. A computer program (2) is used to calculate solutions for d and index of refraction of the film n_f while assuming various values of the absorption coefficient κ_f (*i.e.*, κ_f = 0, 1, 2, and 3). In the case of films formed in pure water, solutions for n_f and d were not found except for $\kappa_f \rightarrow 0$. In the case of films formed in the presence of HF, solutions were found for $\kappa_f \approx 0$ and 1, but for $\kappa_f = 0$ the values of n_f were too small and d too large to be realistic. It is concluded that films formed in solutions containing HF as contamination are absorbing with $\kappa_f \sim 1$, whereas films formed in pure water are transparent with $\kappa_f \sim 0$.

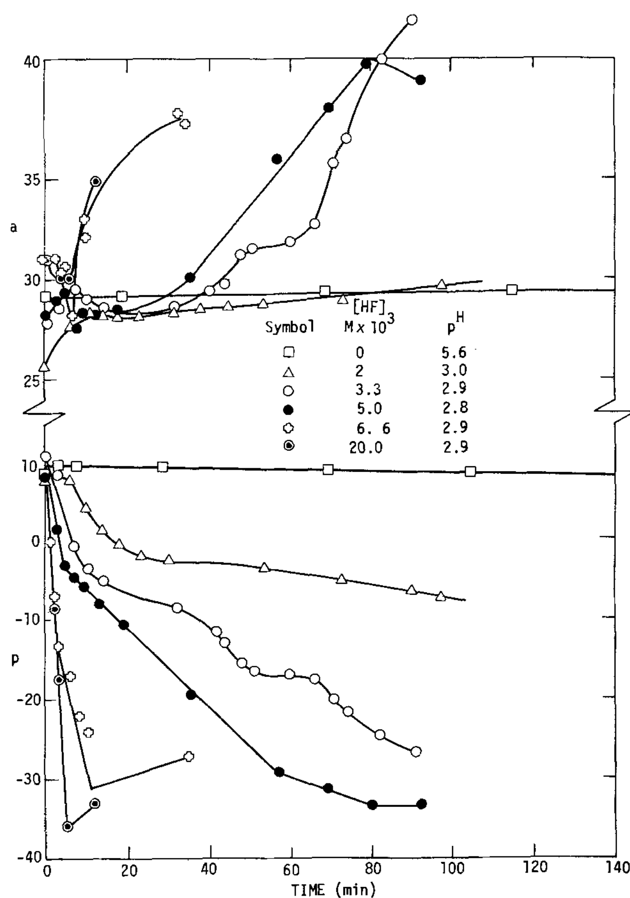

Fig. 3(a). Effect of HF contamination in distilled H_2O on ellipsometric readings (p,a).

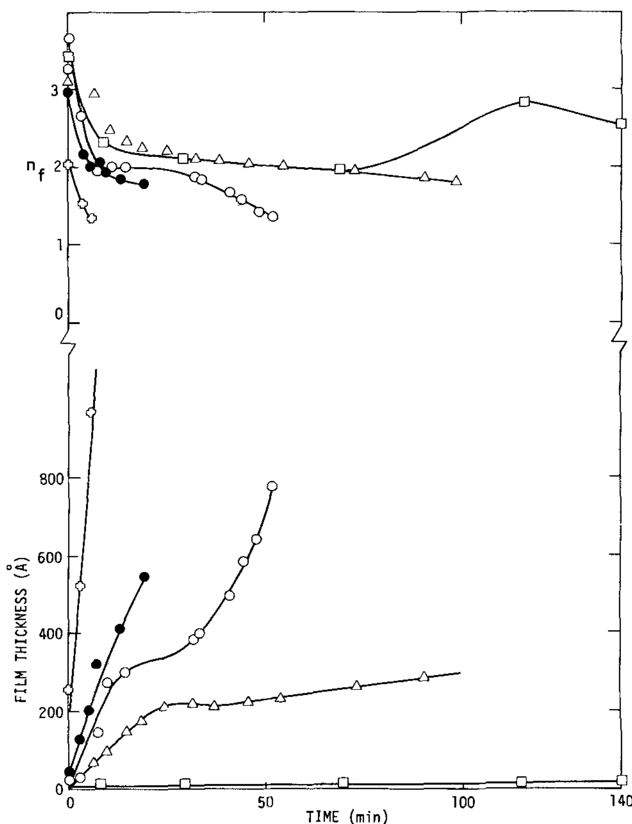

Fig. 3(b). Film thickness and index of refraction, n_f

Figure 3b shows the calculated values of film thickness d, and index of refraction n_f which corresponds to Fig. 3a, with $\kappa_f = 0$ for pure water and $\kappa_f = 1$ for HF

solutions. In distilled water, without HF addition, a film of about 14Å is formed in 100 min. The addition of HF causes very thick films to grow. The initial growth rate of these films is second order with respect to HF concentration. In every case n_f decreases and levels off as the films grow.

Experimental Results

Optical constants of cleaned surfaces.—A test of the surface cleanliness was made by comparing the optical constants obtained in the ellipsometric-electrochemical cell immediately after etching and washing, with the optical constants obtained after cleaning by ion bombardment and annealing in an ultra high vacuum (UHV) system (3). Auger spectroscopy in the UHV was used to determine the presence of contamination in the first atom layers of the Ti substrate. It was possible to prepare surfaces with less than 0.1 monolayers of Cl and S which were the only contaminants after ion bombardment and annealing at about 550°C. Zone refined polycrystalline Ti was used in the UHV system, while polycrystalline Ti-75A was used in the ellipsometric-electrochemical cell. It would be expected that the optical constants of these materials are the same. In experiments in the cell the Ti surface was cleaned by passing the etching-polishing solution[1] through cavity A for 10 sec. The specimen was then washed in cavity B for 10 sec with the test electrolyte and moved to cavity C, through which the test electrolyte was slowly flowing. The ellipsometer readings Δ and ψ were recorded as a function of time. Using the computer program (2) mentioned above the optical constants were then calculated. The initial values for various electrolytes are compared with those obtained in the UHV system in Table II. The average values of the optical constants for a freshly cleaned surface $n_s = 3.05 \pm 0.05$ and $\kappa_s = 1.20 \pm 0.06$ are close to the values obtained in the UHV system, $n_s = 3.09 \pm 0.01$ and $\kappa_s = 1.11 \pm 0.01$ for $\lambda = 5461$Å. Similar agreement is found for $\lambda = 6328$Å. This indicates that etching the Ti-75A sample in cavity A for 10 sec and washing in cavity B for 10 sec provides a surface which is approaching an atomically clean state (within the uncertainty of n_s and κ_s). The uncertainty of n_s and κ_s for experiments in the cell is about 0.05 units which corresponds to an uncertainty with respect to surface cleanliness of about 3Å effective thickness for TiO_2 as the contamination.

Electrochemical studies.—The primary purpose of the cell was to make possible simultaneous ellipsometric and electrochemical studies. Solutions used were 3.5% NaCl, CH_3OH-1N HCl "aqueous" and CH_3OH-1N HCl "anhydrous." The "aqueous" solutions were prepared by adding concentrated (37%) HCl to methanol, while the "anhydrous" solutions were prepared by saturating CH_3OH with HCl gas and then diluting with CH_3OH until the solution was 1N in HCl. For further details, see Ref. (4). These solutions were used since it had been shown earlier by potentiostatic polarization curves (4), that Ti is covered with a passive film in the aqueous solutions, but no such film can form in anhydrous solutions. Figure 4 shows a typical plot of the change in polarizer and analyzer readings as a function of time for potentiostatic anodic polarization of Ti-75A in aqueous 3.5% NaCl. The bars at the end of the curves at 1500 mV indicate the range of the scatter of the data. The data at each potential were obtained for a freshly cleaned and polished surface. Most of the curves increase rapidly with time, level off after about 100 sec, then slowly increase with time. Pitting occurred in aqueous CH_3OH-HCl solutions (4) when a potential of +200 mV was exceeded as indicated by a continuous rise of the anodic current. Within the scatter of the data p and a values were close to those measured in aqueous NaCl solutions where no pitting was observed. Figure 5 shows average values of the change in p (Fig. 5A) and a (Fig. 5b) after 100 sec as a function of the applied potential. Curve 1 in Fig. 5a is for Ti in 3.5% NaCl, curve 2 is for Ti in aqueous CH_3OH-1N HCl, and curve 3 is for Ti in anhydrous CH_3OH-1N HCl.

[1] The mixture of HF-HNO_3-H_2SO_4-H_2O removes oxide films on Ti, but also chemically polishes the surface. Effects of surface roughness on ellipsometric data are therefore not to be expected.

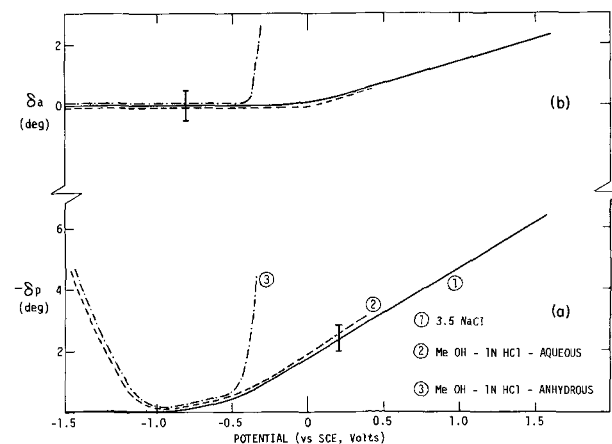

Fig. 5. Ellipsometric values after 100 sec and film thickness as a function of potential. ———— 3.5% NaCl, - - - - - - CH_3OH-1N HCl-aqueous, —′ —′ —′ CH_3OH-1N HCl-anhydrous.

The results in Fig. 5 show that the changes of the ellipsometric parameters with potential in 3.5% NaCl are essentially the same as in aqueous CH_3OH-1*N* HCl for potentials noble to the rest potential which for a freshly cleaned specimen was ~ -0.8V. However, for Ti in anhydrous CH_3OH-1*N* HCl very thick films form at potentials more positive than -0.4V. For potentials cathodic to the rest potential (< -0.8V) no film is formed in 3.5% NaCl. The films that form more negative than -0.8V in the methanol solutions are essentially the same in aqueous and anhydrous solutions.

Discussion

It has been shown (Table II) that it is possible to prepare by proper etching and washing in our ellipsometric-electrochemical cell Ti surfaces the cleanliness of which approaches cleanliness obtained in UHV after ion bombardment. The finding that it is possible to produce a clean surface in an environment like water is not contradicted by the results of Beck and co-workers (8), who showed that the anodic current on a freshly broken Ti surface in an electrolyte decreases to a very small value in a few milliseconds. While this can be called repassivation, it does not have to mean that the whole surface is being covered by an oxide film, but might result from blockage of the most active sites on the freshly broken surface by adsorbed oxygen as demonstrated by Frankenthal for passivation of Fe-Cr (9). Depending on the applied potential and the electrolyte, different films are formed; it was observed, however, that at least for the first 100 sec after the electrode was immersed in the electrolyte (cavity C) film growth was very slow at potentials close to the rest-potential. Our results in 3.5% NaCl at potentials noble to the rest-potential are similar to those obtained by Green and Sedricks (5) for Ti-7.76% Al who found a linear increase of the ellipsometric parameter Δ with potential. The film thickening at potentials active to -1.0V, reported by these authors based on some indirect evidence but not shown by ellipsometric results, was not detected in our studies.

The different behavior of Ti-75A at potentials noble to the rest-potential in anhydrous and aqueous solutions of CH_3OH-HCl can be explained based on the result obtained in a study of the effect of water on passivity and pitting of Ti (4). In aqueous CH_3OH-1*N* HCl enough water is present to produce a passive film, which is destroyed by pitting when the applied potential exceeds the critical pitting potential. Consequently, it was found in the present study that thin films grow in aqueous solutions at about 40 Å/V for the first 100 sec, when an anodic potential was applied. In anhydrous CH_3OH-1*N* HCl no passive film can be formed; thus, anodic polarization results in accelerated dissolution under charge transfer control (4). The rapid change of ellipsometric parameters in this solution is then due to accumulation of corrosion products on the surface of the test specimen.

Films formed on Ti-75A at potentials negative to the rest potential seem to be identical for aqueous and anhydrous solutions of CH_3OH-HCl. They therefore do not require water molecules for their formation. While hydride formation might take place, more experiments have to be carried out to determine the nature of these films. Potentiostatic polarization experiments in CH_3OH-HCl solutions have shown (6), that at potentials more negative than -1.2V the current continuously increases at constant potential with an ever increasing rate of gas evolution. Potentiokinetic measurements show a change in slope at this potential and a marked hysteresis when the potential is decreased to more noble potentials leading to a more noble rest-potential.

Due to the difficulties mentioned above and described in Appendix A, unique values of the complex index of refraction of the films formed and their thickness cannot be obtained. However, certain conclusions can be drawn concerning these physical parameters from the ellipsometric data in Fig. 5. In the anodic region ($\phi > -0.8$V) for films formed in NaCl or aqueous methanolic solutions (curves 1 and 2) experimental values for *p* and *a* are consistent with those calculated with a complex refractive index of $n_f \sim 2.5$ and $\kappa_f \sim 0$. These values are consistent with TiO_2 films as reported in the literature (10-13). The anodic oxide film forms at about 40 Å/V in the first 100 sec between -0.5 and 1.5V. This is estimated from the slopes of the curves in Fig. 5 between -0.5 and $+1.5$V and the slopes of the curves for $n_f = 2.5$, $\kappa_f = 0$ in Fig. A-1a. This is about twice the value reported (13, 14) for much larger potentials (0-200V).

In the cathodic region ($\phi < -0.8$V) the lack of a change in *p* and *a* indicates that films are not formed on Ti in the NaCl solutions. Very peculiar films are formed in aqueous and anhydrous methanol solutions in the cathodic region. The peculiarity lies in the fact that for these films the polarizer azimuth *p* changes dramatically but within experimental error no change in the analyzer azimuth *a* occurs. Figure A-1a of the appendix indicates that for transparent films (*i.e.*, $\kappa_f = 0$) δa remains unchanged or becomes negative only for n_f slightly greater than 1 or less. However, for these values of n_f, δp is positive. Therefore, the cathodic films formed in CH_3OH-HCl cannot be transparent (nonabsorbing). Figure A-1c and d indicate that for $\kappa_f > 2$, δa is always positive, therefore cathodic films formed in CH_3OH-HCl are limited to the range of n_f and κ_f found in Fig. A-1b and in particular to values of about $n_f \sim 1$-3, $\kappa_f \sim 1$. The large absorption coefficient $\kappa_f \sim 1$ corresponds to films of metallic character (*e.g.*, for Ti $n \approx 3$, $\kappa \approx 1$). The cathodic films formed in CH_3OH-HCl may be titanium hydride or colloidal particles of metallic Ti with some electrolyte between the particles. Further experimental data are needed to elucidate this point.

Our results also have shown that care has to be taken to avoid the presence of F^- ions which even in very small amounts leads to severe corrosion and film formation on Ti.

APPENDIX A

Since there are only two experimental ellipsometric parameters *p* and *a* and there are three unknowns, film thickness *d*, index of refraction n_f, and absorption coefficient κ_f, a unique solution for *d*, n_f, and κ_f is not possible. It becomes necessary, therefore, to interpret *p* and *a* in terms of *d* and n_f for reasonable ranges of κ_f. To aid this interpretation, values of *p* and *a* were computed for various values of *d*, n_f, and κ_f for Ti in distilled water for very thin films with $\lambda = 6328$Å and an angle of incidence of 70°. Figure A-1 shows plots of *p* and *a* *vs.* *d* for the values of n_f (first number) and κ_f (second number) reported in brackets on each curve. From Fig. A-1 and a knowledge of the range of values expected for n_f and κ_f, it is possible to anticipate the relative increase or decrease of *p* and *a* as the film

Table A-I. Comparison of optical constants of Ti and W to show the effect of surface contamination

Metal	Preparation	n	κ	Ref.
W	Ion bombard, 10^{-10} Torr, annealed	3.75	0.800	(13)
W	Heat treatment, 10^{-8} to 5×10^{-9} Torr	3.40	0.88	(15)
Ti	Ion bombard, 10^{-10} Torr, annealed	3.09	1.11	(13)
Ti	Polished in air	2.0	1.5	(16)

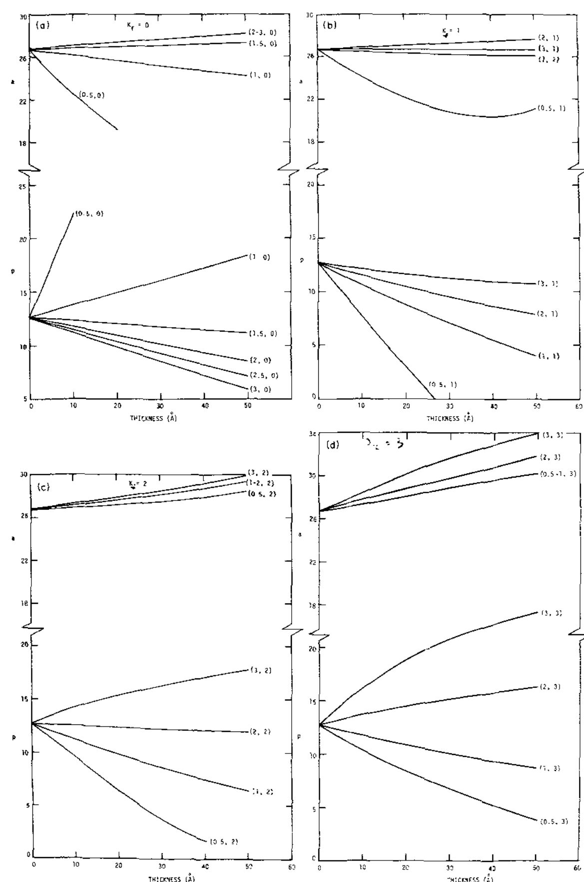

Fig. A-1. Computed values of p and a vs. film thickness d for TiO_2/Ti in water at 6328Å, for various values of the absorption coefficient of the film κ_f and refractive index of the film n_f.

grows. For example, more metallic films are expected to have lower values of n_f and higher values of κ_f. The opposite is expected for insulating films. Consequently, insulating films will always cause p to decrease and a to increase as d increases. a only decreases for very small values of n_f and κ_f, and p only increases for very small or very large values of n_f and κ_f.

It should be noted that accurate values for optical constants are difficult to obtain due to surface contamination. For example, Table A-I gives reported values for Ti and W for different preparation of the samples. Computer calculations using the exact Drude relations indicate that contamination tends to decrease n and increase κ if the ambient is gas or vacuum. Therefore, it is believed that the lower values reported for W and Ti in Table A-I resulted from surface contamination.

Contact Angle Measurements of Tin Sensitizing Solutions

N. Feldstein* and J. A. Weiner

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

A study of tin sensitizing solutions was made by contact angle measurements. Through the control of solution composition, *i.e.*, stannous and stannic concentrations, major improvements in the effectiveness of such sensitizers on hydrophobic surfaces have resulted. The incorporation of excess sodium chloride was found to further improve the performance of such sensitizing solutions. The presence of the stannic ions facilitates the adsorption of the stannous ions necessary for the reduction of palladium.

In the plating of dielectric substrates, a pretreatment of the substrate is essential in order to effectively deposit metals by the electroless plating technique. One of the more prevalent procedures in commercial use is the two-step immersion sequence of acidic stannous chloride solution followed by an acidic palladium chloride solution. In general, the first bath is referred to as the sensitizer solution while the second solution is the activator. The net result of this sequence is the formation of finely divided palladium nuclei which initiate the autocatalytic plating process (1, 2). The formation of the palladium metal nuclei is believed to be due to a redox reaction taking place between the adsorbed stannous ions on the surface and the palladium ions in the activating solution.

In spite of the wide commercial application of plated plastic parts, very little work has been reported regarding the chemistry of sensitizing and activating solutions. A review of this technology has been summarized by Goldie (3). Pearlstein (4) has observed variations in plating due to compositional changes of either the sensitizer or activator solutions. More recently, Cohen *et al.* (5, 6), investigated the solution chemistry of the tin chloride sensitizing process. This study was based upon the Mossbauer spectroscopy of

* Electrochemical Society Active Member.

Key words: sensitizer solutions, electroless plating, contact angle measurements.

tin. Their proposed model invokes a colloidal formation based on the stannic ion with stannous ions bound onto this colloid.

Although the sensitizer compositions described in the literature are most effective for a wide variety of substrates, such solutions possess a major shortcoming whenever hydrophobic substrates are employed. Based upon work in this laboratory, it has been demonstrated that the performance of conventional-type sensitizers ($SnCl_2 \cdot nHCl$ plus colloidal Sn(IV)) (5, 6) may be greatly improved for use with hydrophobic substrates. This is achieved primarily through the proper control of the stannous-stannic concentrations.

In this investigation, a study of tin sensitizing solutions was undertaken employing contact angle measurements. Such an approach was believed to be useful since adsorption of thin films can potentially alter the resulting contact angle. Such an approach may lead to a more quantitative way by which the effectiveness of sensitizers may be evaluated. A later publication (7) will propose a mechanism for the sensitization of hydrophobic and hydrophilic substrates by tin-type solutions.

Experimental Procedures

Chemicals and solutions.—All chemicals used throughout were Baker Reagent grade; the hydrochloric acid used was Mallinckrodt electronic grade. The water used was deionized and then distilled. The following solution was used throughout this investigation

Concentrate 2.6M $SnCl_2 \cdot 2H_2O$ in concentrated HCl (37%) (Final HCl is 9.4M)

Working sensitizer solutions of different compositions were made from this concentrate.

Substrate preparation.—Cover glass plates, 2 × 2 in. (E. Leitz, Inc., New York, Cat. No. 19821), which were cleaned in a mild soap solution, rinsed and spin dried, served as substrates. These substrates were coated with commercially available photoresists to form hydrophobic surfaces for testing. A positive resist, AZ-1350 (distributed by Shipley Company, Newton, Massachusetts) was spin coated onto the glass at 5000 rpm for 60 sec. To remove solvent(s) and polymerize the resist film, a baking procedure of 200°C for 3 min was employed. For a typical negative resist, KTFR (Eastman Kodak Company) was used. The resist composition was mixed in accordance with the manufacturer's specification. This resist was spin coated at 8000 rpm for 30 sec. A baking procedure of 7 min at 200°C was employed. Teflon[1] (FEP) Type A film was also used in conjunction with this study. The film thickness chosen was 20 mils. Prior to the contact angle measurements on the Teflon, a mild soap cleanup was employed.

Substrate treatment.—Two basic procedures were employed prior to the contact angle measurements. In the first procedure (procedure "a"), drops of varied sensitizer composition were placed on the photoresist surface, and the contact angle was measured. An alternate procedure was developed (procedure "b") which resulted in a greater sensitivity in the measurements. This adopted procedure consisted of

1. Immersion of substrate into various sensitizer compositions for 1.0 min.
2. Substrates were dipped (about 2 sec) in D.I. water of 1 liter volume.
3. Substrates were rinsed in D.I. water in an overflow rinse tank (volume = 1.2 liter) with a flow rate about 4 liters/min.
4. Substrates were spin dried in air.
5. Drops of D.I. water (or palladium chloride solution consisting of 1 g/liter $PdCl_2$ and 1 cc/liter concentrated HCl) were placed on the photoresist surface using a Pasteur pipette from a controlled height of 0.184 in. (See Fig. 1).
6. Contact angle was measured.

[1] Teflon (fluorocarbon film)—Trademark of E. I. du Pont de Nemours & Co.

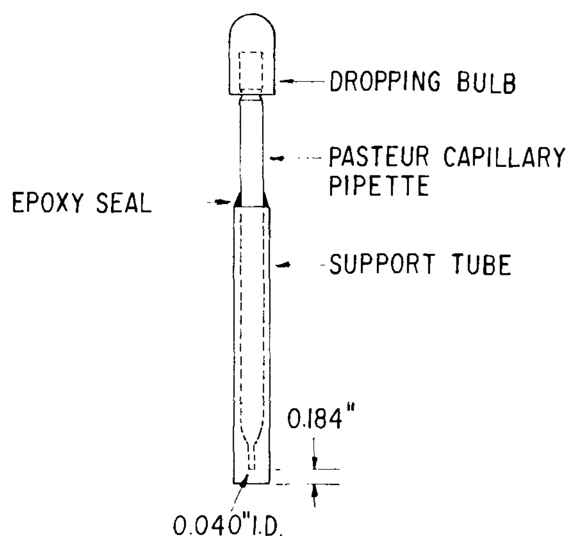

Fig. 1. Dispensing device for contact angle measurements

Contact angle measurements.—All measurements were made using a contact angle goniometer Model A-100 (Ramé-Hart, Inc., 43 Bloomfield Avenue, Mountain Lakes, New Jersey 07046). Due to the spreading effect, contact angles were measured as a function of time and extrapolated to time zero. A time interval of 10 min was chosen for convenience, however, no changes in the extrapolated values were noted in measurements greater than 10 min. Figure 2 shows the contact angle of sessile drops as employed in procedures "a" and "b," respectively. A least square calculation was used to derive the extrapolated values at zero time. All reported angles are the extrapolated values, and these values were found to be reproducible within ±2°, except for the case of Teflon, which resulted in variations of ±5°.

Surface tension measurements.—Surface tension measurements were made using a Fisher Surface Tensiometer Model 20. A 6 cm Pt-Ir ring was used for making measurements.

Results and Discussion

In the first stage of this investigation, a procedure was attempted in which the contact angle was measured by placing sensitizer drops onto the organic surface. Typical results employing this procedure showed little change upon the addition of stannic ions. Surface tension measurements of sensitizing solutions, with and without added stannic ions, resulted in variations of a few per cent. Specifically, the addition of 2.5×10^{-2}M stannic chloride to a solution composed of 0.13M $SnCl_2$ and 0.47M HCl, resulted in surface tensions ranging from 68 dynes/cm to 70 dynes/cm. These minor alterations in the surface tension of the sensitizer solutions are consistent with the minor variations of contact angle. It is concluded that a different mechanism takes place, other than surface tension modification, which accounts for the variations in the effectiveness of the present sensitizers on hydrophobic-type substrates. Therefore, this approach was not further pursued.

Examination of the contact angle following the sensitization step showed a greater degree of sensitivity in comparison to the results of procedure "a". Hence, all reported angles are based upon the modified procedure (Fig. 2, procedure "b"). In the modified procedure, it was found that results within experimental error were obtained by using drops of either water or palladium chloride solutions. For convenience, the use of water drops was adopted for most of the experimental work.

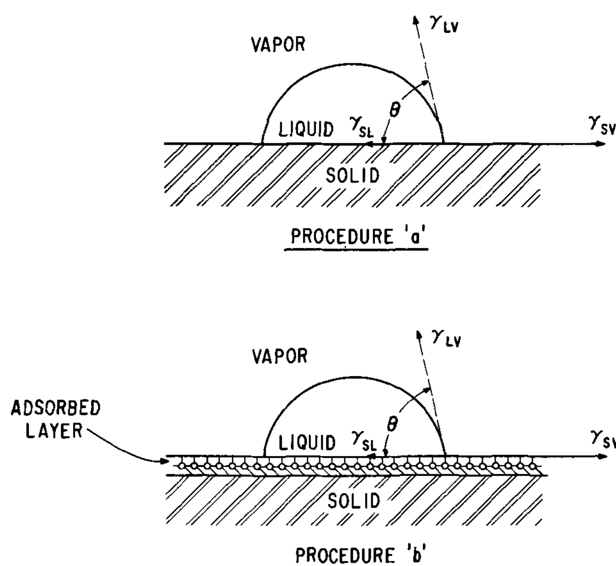

Fig. 2. Contact angle of sessile drops

In a recent study, the role of the stannic ions in conventional-type sensitizers was described. As pointed out (6), typical reagent grade stannous chloride contains approximately 5 mole per cent (m/o) stannic ions, and upon dissolution in aerated water, further oxidation yields a total of about 6 m/o of stannic ions. A model based upon the formation of colloidal stannic compound(s) has been invoked to account for the mechanism of sensitization. The stannous ions are bound onto these colloids and are presumably retained on the surface by both an adsorption- and absorption-type mechanism. Table I shows the resulting contact angle measurements of different sensitizer compositions. It is quite evident that for sensitizers 1 through 4, the contact angle is nearly the same and thus seems to be independent of composition ($SnCl_2$/nHCl ratio) as well as the manner by which the sensitizer was prepared. It should be recalled (6) that sensitizers A, B, and C were proposed as a means for controlling the colloid present in the stannous solutions. By contrast, the incorporation of the stannic chloride solution as made in this laboratory (Table I, No. 5) shows clearly the modifications associated with such combinations, further suggesting that other mechanism(s) may take place during the sensitization process which are especially important in the case of the hydrophobic-type substrates.

Figures 3 and 4 show the variations of the contact angle due to the compositional modification of the sen-

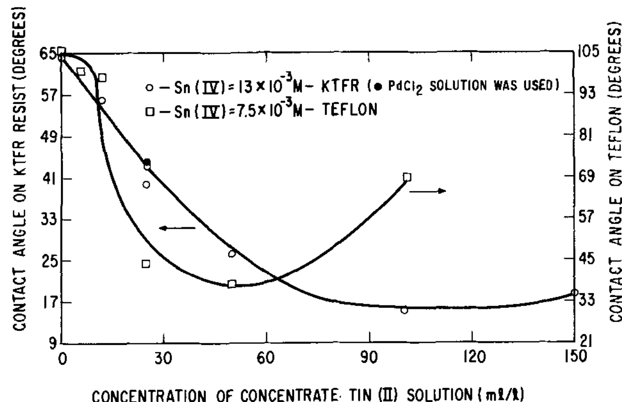

Fig. 4. Contact angle variations vs. compositional changes. Concentrate tin(II)—2.6M $SnCl_2$, 9.4M HCl.

sitizer solution. The choice of substrate materials in these figures was made because of the good reproducibility obtained in their preparation. For a constant added Sn(IV), a sharp drop in the measured contact angle takes place upon increasing the Sn^{+2}/Sn^{+4} ratio. A minimum in the contact angle is found, after which further increase in the Sn^{+2}/Sn^{+4} ratio results in an increase in the contact angle. Increasing the tin (IV) concentration results in displacing the minimum towards lower values. However, a convergence is found at the higher tin (IV) concentrations. The increasing portion of the curves with excess addition of $SnCl_2$/nHCl is due to a combination of factors: (*i*) increasing the hydrogen ion concentration tends to increase the measured contact angle and (*ii*) the large excess of stannous ions relative to the stannic ions prevents the surface adsorption of the latter ions. These factors were qualitatively tested and verified. A full account concerning the shape of these curves will be covered in a later publication.

Figure 4 shows the variations in the measured contact angle on KTFR resist and Teflon. The general trend for these cases is similar to that demonstrated in Fig. 3. Of the various materials examined, the Teflon shows the most dramatic change in contact angle with variations in the stannous/stannic ratio.

Figure 5 shows the effect(s) of added sodium chloride on the resulting contact angle. As seen from Fig. 5, the addition of this salt to a conventional-type sensitizer (0.13M $SnCl_2$ and 0.47M HCl) results in no appreciable effect on the measured contact angle. At the

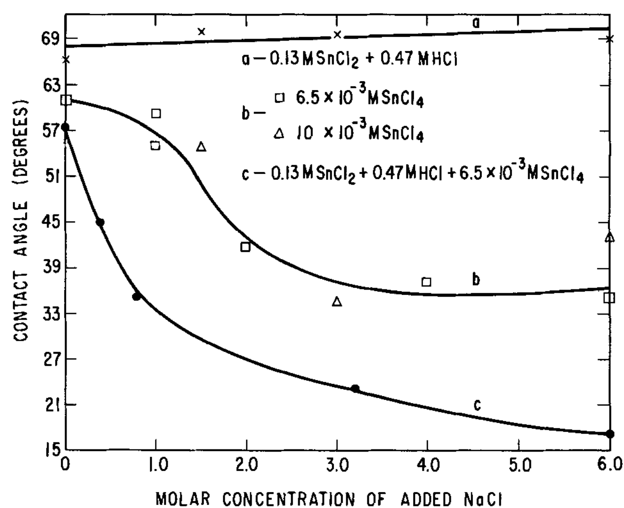

Fig. 5. Contact angle variations vs. sodium chloride concentration on AZ-1350 resist.

same time, the addition of sodium chloride to solutions containing the stannic ions alone shows a substantial decrease in the measured contact angle. Excess addition of sodium chloride to this media (6.5×10^{-3} or 1×10^{-2}M $SnCl_4$) results in a leveling effect. In curve c, the effect of added sodium chloride to a solution containing both the stannous and stannic ions is demonstrated. The concentrations of the stannous, stannic, and hydrochloric acid are the combined concentrations of those concentrations used for curves a and b. Although there is a general resemblance between curves b and c, the effect of sodium chloride is more pronounced in a system which combines the stannous and the stannic ions. These results are thus suggestive that an interaction exists whereby the degree of surface modification due to sensitization is altered to a greater extent. Substitution of bromide ion for the chloride resulted in the same general characteristics.

Table II provides a summary of the contact angle measurements resulting at each of the steps along the sensitization and activation sequence. As seen, the major surface modifications take place after the sensitization step. Once the surface is suitably "sensitized," very little change is noted at the conclusion of the activation step. In an alternative sequence, the process of sensitization and activation was divided into three distinct steps: (*i*) immersion in stannic, (*ii*) immersion in stannous, and (*iii*) immersion in palladium chloride activator solution. As seen from Table II, the major change in the contact angle is observed following the stannic immersion step with a slight change in the subsequent steps (immersion in stannous and palladium, respectively). It is interesting to note that a contact angle of 53° has resulted prior to the activation step independent of the path taken. Furthermore, upon deletion of the stannic ions, following immersion in stannous type solution, the observed contact angle is about 67°. It is thus concluded that the presence of the stannic ions provides a new mechanism (7) by which the active stannous ions are adsorbed onto the substrate. The stannic ion may be incorporated along with a conventional-type stannous sensitizer solution or used as a separate immersion step prior to conventional-type sensitization. In a subsequent publication (7), a mechanism accounting for the different modes of sensitization will be given.

Table II. Contact angle measurements during the different stages of pretreatment

Two-step sequence	Contact angle (degrees)	Three-step sequence	Contact angle (degrees)
AZ-1350 resist, as prepared	70	AZ-1350 resist as prepared	70
After sensitizaton[a]	53	After stannic[b]	59
After activation	51	After stannous[c]	53[d]
		After activation	56

[a] Sensitizer used composed of 0.13M $SnCl_2$, 7.5×10^{-3}M $SnCl_4$ and 0.47M HCl.
[b] Solution composed of 7.5×10^{-3}M $SnCl_4$ plus 1M NaCl to compensate for the chloride content present in a combined solution.
[c] Solution composed of 0.13M $SnCl_2$ and 0.47M HCl.
[d] Deletion of the stannic immersion step gives a contact angle of 67°.

Conclusion

In the plating of dielectric substrates, a pretreatment step of sensitization and activation is generally employed. Following this sequence, a catalytic layer is present which is capable of initiating electroless plating baths. In general, it is desired to have a continuous conductive metallic layer prior to an electrolytic build-up of the metallic films. There are, however, materials which do not yield a uniform metallic film. These materials are generally hydrophobic. Of the various steps prior to the electroless plating, the sensitization process controls whether the final metallic film is uniform.

In the current investigation, it has been demonstrated that contact angle measurements can quantitatively demonstrate the effectiveness of sensitizing solutions. Furthermore, controlled additions of stannic ions with or without sodium chloride provide a simple and effective way of modifying conventional sensitizers for the uniform plating of hydrophobic substrates. The role of the added stannic ions is to provide a path for the adsorption of the stannous ions. The stannous ions adsorbed on the substrate were not necessarily bound to any stannic ions in bulk solution, and, in fact, separate solutions may be used effectively, thus separating the stannous from the stannic ions.

A Study of Gold Reduction and Oxidation in Aqueous Solutions

D. M. Mac Arthur*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The electrochemical behavior of gold in alkaline cyanide, citrate, and phosphate buffered solutions has been studied using cyclic voltammetry and galvanostatic transients. Two reaction paths were observed. At low overvoltage the reaction goes through an adsorbed intermediate.

$$Au + CN^- \rightleftarrows |Au\,CN|_{ads} + e^-$$

$$|Au\,CN|_{ads} + CN^- \rightleftarrows Au(CN)_2^- \quad \text{(rate determining)}$$

At larger overvoltages a direct transfer between the gold complex in solution and the metal atom was found on reduction. The reduction reaction was the same in all the solutions but in the phosphate and citrate baths the gold did not oxidize to a soluble species.

The electrodeposition of gold on various electronic devices is in widespread practice because the metal has good corrosion resistance, electrical conductivity, and bonding properties. A complete understanding of the reaction mechanism for electrodeposition would be of considerable value to the technology of gold plating but has not been achieved. The work described here was undertaken to add to our knowledge of the reaction mechanism for gold reduction and oxidation in practical gold-plating baths.

Maja (1) has reported on the alkaline gold cyanide bath which contains an excess of free cyanide and on the basis of thermodynamics and kinetic measurements concluded that reduction from alkaline solution occurs as follows[1]

$$Au(CN)_2^- \rightarrow |Au(CN)_2^-|_{ads}$$

$$|Au(CN)_2^-|_{ads} + e^- \rightarrow Au + 2CN^-$$

He also found that the oxidation reaction is

$$Au + CN^- \rightarrow |Au\,CN|_{ads} + e^-$$

$$|Au\,CN|_{ads} + CN^- \rightarrow Au(CN)_2^-$$

Cathro and Koch (2) used potentiostatic and galvanostatic measurements on gold oxidation in alkaline cyanide electrolytes. They concluded that gold was oxidized to $|Au\,CN|_{ads}$ at potentials less than -0.6V (SCE reference) and became passive in the potential range -0.6 to -0.3V through the formation of a gold oxide or basic cyanide. A second active region was found at approximately $+0.1$V which, it was proposed, was the conversion of an adsorbed Au(I) basic cyanide to an adsorbed Au(III) basic cyanide. A third active region at $+0.4$V was found and was passivated by the formation of Au_2O_3. Thermodynamically the formation of gold oxides is expected to occur at potentials considerably more positive than -0.3V. Basic gold cyanides are not known to exist in alkaline cyanide solutions. It is difficult to accept therefore that a gold oxide or basic cyanide can form at a potential of -0.3V. It is also difficult to accept that an Au(III) salt can exist in contact with an aqueous cyanide solution since $Au(CN)_4^-$ is known to be unstable with respect to $Au(CN)_2^-$ and cyanogen in these solutions, or that steady-state currents in the range of 1-2 mA/cm^2 can be observed for the oxidation of one adsorbed species to another. We believe, therefore, that the proposed passivation mechanisms at -0.3 and $+0.1$V may be in error.

Taran and co-workers (3) have proposed that solutions with a low pH have a more easily discharged gold complex in solution and that the citrate solution, in particular, has adsorbed citrate on the gold metal surface.

These authors have proposed various reaction mechanisms. Although the solutions vary, it is difficult to accept that the reactions can be so different since the initial and final gold species are the same. In this work cyclic voltammetry and galvanostatic transient techniques are used to provide additional information on the reaction mechanisms.

Experimental

Three gold plating solutions were used in this work as follows:

Alkaline cyanide; 15.0g $KAu(CN)_2$, 55.0g KCN, 5.0g KOH per liter of solution pH 12.2

Citrate; 50.0g dibasic ammonium citrate, 20.0g $KAu(CN)_2$ per liter of solution pH 5.0.

Phosphate; 18.2g $KAu(CN)_2$; 36.4g dibasic potassium phosphate; 9.1g monobasic potassium phosphate pH 7.0.

Reagent grade chemicals were used throughout. Deionized water that had been passed through both cation and anion exchangers was used to prepare solutions.

Wire electrodes 0.025 in. in diameter and held in a gold-plated pin vise were used as working electrodes. These wires were about 1 in. in length and were immersed 0.5 in. into the solutions. It would be preferable to use an immersed electrode with defined area, but the problem of leakage around edges, particularly in cyclic potentiometry experiments led to the adoption of this technique. The counterelectrode was either a platinum- or gold-plated platinum wire. A saturated calomel reference electrode was used and all potentials are referred to this electrode. In the galvanostatic transient experiments, a gold wire reference electrode in the same solution was used, and its potential frequently checked against the calomel reference.

A standard potentiostatic circuit incorporating an X-Y recorder, potentiostat, and triangular wave function generator was used in the potential scan experiments. The galvanostatic transient experiments used a 24V battery supply for the cathodic transient with a potentiometer for current control and a Western Electric 276B mercury-wetted relay to switch the current. Another 3V battery was used to apply a small anodic current preceding the cathodic transient. Potentials were fed through a high impedance voltage follower and displayed on an oscilloscope which was triggered by the switching circuit.

Solutions (100 ml) were contained in a double-walled Pyrex flask with circulating water for tempera-

* Electrochemical Society Active Member.

Key words: electrodeposition, gold plating, cyclic voltammetry.

[1] The solutions of commercial significance in gold plating all contain gold predominately as the $Au(CN)_2^-$ complex.

ture control. The temperature was 61° ± 1°C. The flask had a machined Teflon lid. All solutions were deoxygenated by bubbling N_2 through them.

Results

Cyclic Voltammetry Experiments

The alkaline cyanide bath.—Figure 1 shows a scan of the bath using a gold wire electrode. (In this preliminary scan a 0.020 in. diameter wire was used.) Two reduction regions A and B may be observed and two oxidation regions C and F are also evident. The oxidation peaks C and F were observed as distinct peaks in all scans moving in the anodic direction, but only in the first two scans were they separate when moving in the cathodic direction. As scanning was continued, peak F disappeared and the peak in the C region became complex as shown in the figure. Peaks A and B were only observed when moving from the anodic to cathodic potentials in all scans.

The areas under peaks C and F on the anodic scan were approximately 105 and 150 millicoulombs as determined by geometric integration of the curves. The double layer charging current was about 1 μA and negligible. Oxidation of a monolayer of Au would require only about 0.05 millicoulombs (using the area of the electrode as 0.20 cm^2, assuming Au(I) was formed and taking the radius of the Au atom as 1.5Å). The peaks correspond to oxidation of 2000-3000 monolayers. This is too large to represent a thin adsorbed layer nor can it be the formation of an insoluble film since there is no corresponding large reduction peak and the peaks do not change upon continued scanning. It will be shown that peak C is an oxidation reaction that proceeds through a surface film to a soluble product and that peak F is an oxidation reaction passivated by the formation of an oxide on the electrode. The area under peak B on the other hand is approximately 1 millicoulomb, a quantity that could correspond to an adsorbed species. Peak A will be shown to correspond to reduction of $Au(CN)_2^-$ from solution.

Some of the details of the gold reaction are obscured in the standard solution because of the high free cyanide level (approximately 0.85M). Figure 2 shows a potential scan of a gold wire (0.025 in. diameter) in a solution of 0.2M KCN and 0.2M KOH. This solution is about one quarter the concentration in CN^- and twice the concentration OH^- of the standard bath. In Fig. 2 the solution does not contain $Au(CN)_2^-$ to an appreciable extent. Peak A is not present, but there is some evidence of peak B at −1.0V. It is not as large as in solutions containing relatively large amounts of $Au(CN)_2^-$, and therefore it appears to be related to the presence of $Au(CN)_2^-$ in solution. Peaks C and F are evident scanning in both directions and peak F shows further evidence of being complex. In addition a broad peak E on the side of the oxygen wave and a reduction peak D located just anodic to the oxidation peak F when scanning in the cathodic direction, are

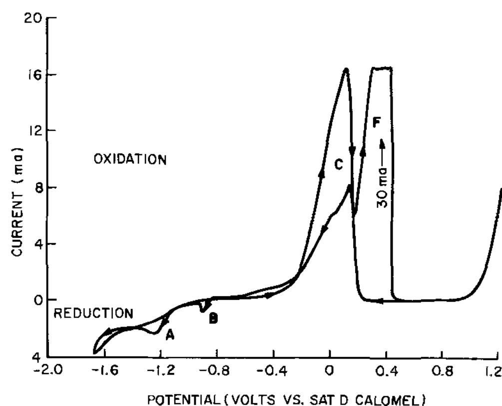

Fig. 1. Potential scan of a Au wire in the alkaline cyanide gold bath. Velocity 0.040 V/sec.

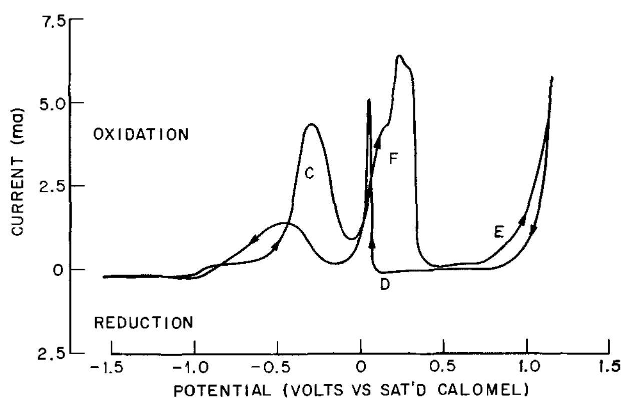

Fig. 2. Potential scan of a Au wire in 0.2M KCN and 0.2M KOH. Velocity 0.042 V/sec.

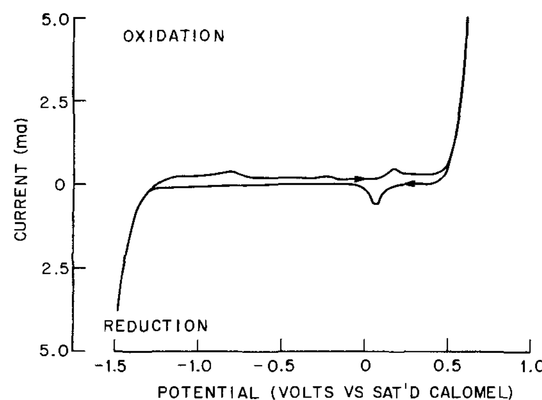

Fig. 3. Potential scan of a Au wire in 0.2M KOH

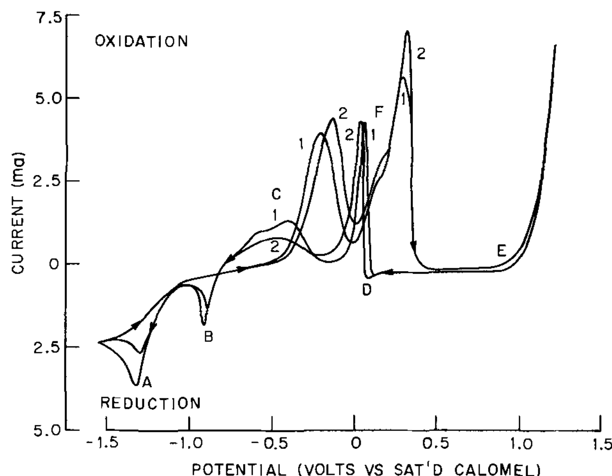

Fig. 4. Potential scans of a Au wire in 0.2M KCN 0.2M KOH and 0.035M $KAu(CN)_2$. Curve 1, 0.041 V/sec; curve 2, 0.099 V/sec.

observed. Peak D may be seen more clearly in Fig. 4. In order to identify peak D comparison may be made to Fig. 3 which is a scan of a gold wire in 0.2M KOH only. The rest potential of the Au/Au_2O_3 electrode in KOH solutions has been reported (4) as about 1.1V on the hydrogen electrode scale. For the 0.2M KOH solution this would be about 0.1V on the SCE scale. The oxidation peak and the reduction peak which are close to this value in the figure may reasonably be assigned to the formation and reduction of gold oxide. By analogy it then appears reasonable to correlate peak D in the alkaline cyanide solutions with reduction of gold oxide on the electrode. Peak E is assumed to be a thickening of the gold oxide layer which is first formed at potentials closer to 0.1V.

Figure 4 shows two scans at different velocities of the same 0.2M KCN, 0.2M KOH solution to which

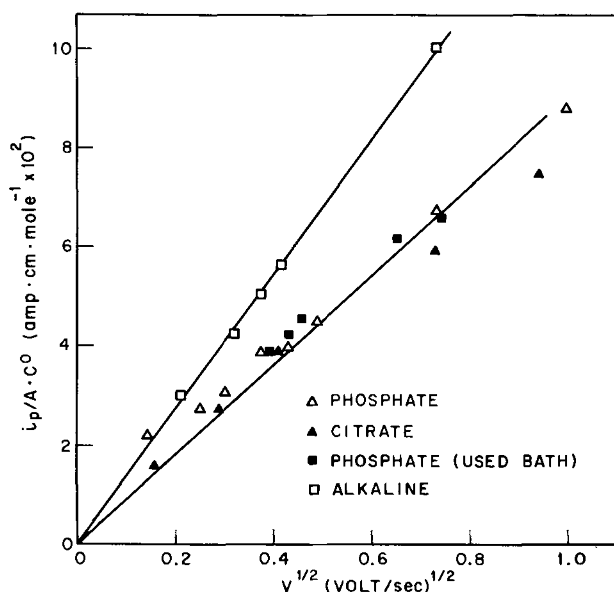

Fig. 5. Peak height as a function of the square root of the scan rate for reduction peak A.

$KAu(CN)_2$ has been added to make the $Au(CN)_2^-$ concentration 0.035M. The behavior of peaks A, B, C, and F as the scan rate is varied will now be discussed. At high scan rates the cylindrical geometry of the wire electrode may be approximated by planar geometry. This approximation is valid for rates determined by the inequality (5)

$$\frac{1}{r}\left(\frac{D}{nV}\right)^{1/2} < 0.2$$

which, for the wires used in this work requires that the scan rate be greater than 0.45 V/sec.[2] Although the effect of cylindrical geometry may be found in the shape of the recorded curves it turns out (5) that the peak height is only slightly altered, and the peak current is a linear function of the square root of the scan rate for velocities as low as 0.1 V/sec. At 61°C this function is

$$i_p = 2.57 \times 10^5 n^{3/2} A D^{1/2} C^\circ V^{1/2}$$

A plot of $i_p/A \cdot C^\circ$ as a function of $V^{1/2}$ is shown in Fig. 5 for peak A. A linear relationship was observed indicating a diffusion limited reaction which must be the reduction of the $Au(CN)_2^-$ from solution. The true area of the gold wire was estimated from the peak height *vs.* $V^{1/2}$ plot for the oxidation of $Fe(CN)_6^{-4}$ and its known diffusion coefficient in dilute chloride solution at room temperature. A roughness factor of 1.3 was determined. Using this true area of the gold wire the diffusion coefficient of $Au(CN)_2^-$ in the 0.2M KOH, 0.2M KCN solution was found to be 1.8×10^{-5} cm^2 sec^{-1} at 61°C. Literature sources (6) give the value of 1.60×10^{-5} cm^2 sec^{-1} which is satisfactory agreement.

Peak B was found to have a constant capacity of about 1 millicoulomb in the two different alkaline cyanide solutions and for the various scan rates used. This would correspond to about 15-30 molecular layers depending on how tightly packed the atoms were. The reduction reaction would appear to have two possible paths; one through an adsorbed state (peak B) and one by direct charge transfer (peak A).

The number of coulombs passed in area C increased as the scan rate decreased. This was evident not only in the cathodic to anodic scan but in the reverse direction also. In addition the current did not increase without limit when moving in the anodic direction as would be expected for a charge transfer reaction forming directly a soluble species from a metal electrode.

[2] A list of symbols used is included at the end of the paper.

These observations then are consistent with a reaction mechanism in which charge transfer forms an intermediate on the electrode and the intermediate species is solubilized in a following chemical reaction.

Cathro and Koch (2) concluded that the peak in area C was passivated by the formation of an adsorbed basic gold cyanide. The shape of the peak is not consistent with a passivation type reaction which causes an abrupt decrease in current (compare the shape of peak F and C). It is consistent with the charge transfer followed by chemical reaction mechanism in which the chemical reaction is rate limiting and the surface intermediate interferes with the charge transfer reaction.

Peak F has the characteristic shape of a passivated reaction which is depassivated upon reduction of a surface film at D. As mentioned earlier, this reduction potential corresponds to that for gold oxide which, therefore, is the passivating film. Cathro and Koch (2) observed two peaks in this area and indeed peak F does give evidence of being composed of two overlapping peaks. The number of coulombs passed in this region is much too large for the reaction to be the formation of an adsorbed layer. In addition, the observation that the number of coulombs passed does not increase with decreasing scan rate (except to a small and sometimes variable extent) suggests that the reaction is direct oxidation to a soluble species complicated by the presence of gold oxide which eventually passivates the electrode. This phenomenon has also been observed (7) for gold oxidation in acid chloride solutions and the same explanation for passivation was proposed.

The citrate bath.—Gold-plated Kovar (Fe, Ni, Co alloy) wires were used for some of the experiments in the citrate and phosphate baths. The gold was electrodeposited at about 1 mA (approximately 4 mA/cm^2) from the solution before commencing the scans. In the citrate and phosphate solutions the gold is not oxidized to a soluble species because of the absence of excess CN^- or other complexing agents and the electrocoated wires were not observed to differ from the solid gold wires.

Figure 6 shows scans at three different speeds of a gold-plated Kovar wire in the citrate bath. The peak numbering scheme used in describing the results of the alkaline bath is retained here and also for the phosphate bath to be described next. A plot of $i_p/A \cdot C^\circ$ (peak A) as a function of $V^{1/2}$ is included in Fig. 5. A linear relationship was observed but the calculated diffusion coefficient was 0.88×10^{-5} cm^2 sec^{-1} not in agreement with the literature value (6) of 1.67×10^{-5} cm^2 sec^{-1}. This lack of agreement indicates that peak A is not a simple charge transfer reaction involving reduction of a soluble species. The absence of a clearly

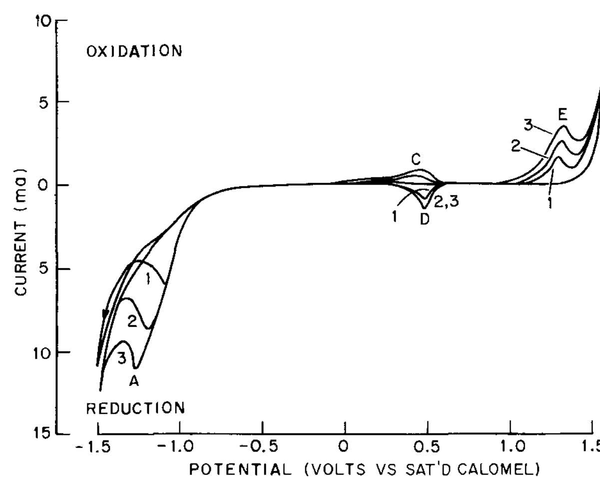

Fig. 6. Potential scans of Au plated wire in the citrate bath. Curve 1, 0.17 V/sec; curve 2, 0.52 V/sec; curve 3, 0.85 V/sec.

defined peak B which is assumed to be reduction of an adsorbed intermediate suggests that this reduction path is also occurring in the potential range of peak A resulting in the low calculated value for the diffusion coefficient. More evidence to establish that this is the case was obtained from the galvanostatic transients which will be described later.

Peak C was observed to have a capacity in the range of 0.1-0.3 millicoulombs—that expected for the formation of an insoluble surface layer. From a comparison of this figure with the preceding figures, it is concluded that this is oxidation of gold to the adsorbed intermediate observed in the alkaline bath but in this case the following chemical step to a solubilized product does not occur because of the absence of excess CN^-. Peaks D and E are reduction of gold oxide and oxidation of gold, respectively.

The phosphate bath.—Figure 7 shows scans of a gold wire in the phosphate bath. The current in peak A is plotted in Fig. 5. The calculated D is 0.88×10^{-5} cm^2 sec^{-1} the same as that for the citrate bath and not in agreement with the literature value (4) of 1.63×10^{-5} cm^2 sec^{-1}. In this bath it is also concluded that reduction through the adsorbed intermediate is occurring in the same potential range as the direct charge transfer to $Au(CN)_2^-$ although evidence for peak B may be seen on the edge of the reduction wave. Peak C was observed to have capacities ranging from 0.2 to 1.1 millicoulombs indicating that in this bath oxidation proceeds to the intermediate surface state which is not solubilized.

Galvanostatic Transient Experiments

Oxidation.—Galvanostatic transients for a gold wire during oxidation in a 0.2M KOH, 0.2M KCN, and 3.58×10^{-2}M $KAu(CN)_2$ solution were obtained in the range of 18 to 48 mA/cm^2. A potential of 0.3 to 0.45V (peak F) was observed for the oxidation followed by a sharp potential rise to oxygen evolution at potentials greater than 1V [Fig. 8(a)]. The transition time was taken as the commencement of the sharp potential rise. For the lower current densities another plateau at about 0.1V was observed with a capacity of about 1.7 millicoulombs/cm^2 before the potential plateau at 0.3-0.45V. The transition times include this plateau because the surface intermediate is later chemically dissolved. Figure 9 is a plot of $i\tau$ and $i\tau^{1/2}$ determined from these oxidation experiments as a function of current density. The linear $i\tau^{1/2}$ relationship is an indication that the predominate oxidation reaction is the formation of a soluble species. (If the reaction were predominately the formation of a surface film a linear $i\tau$ relationship would be observed.) For a metal oxidation reaction into solution the concentration of the metal ion at the surface is

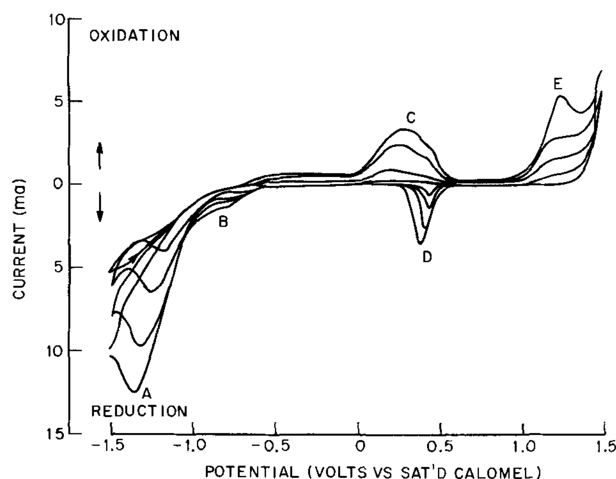

Fig. 7. Potential scans of a Au wire in the phosphate bath. Scan rates were 0.060, 0.24, 0.55, and 1.0 V/sec.

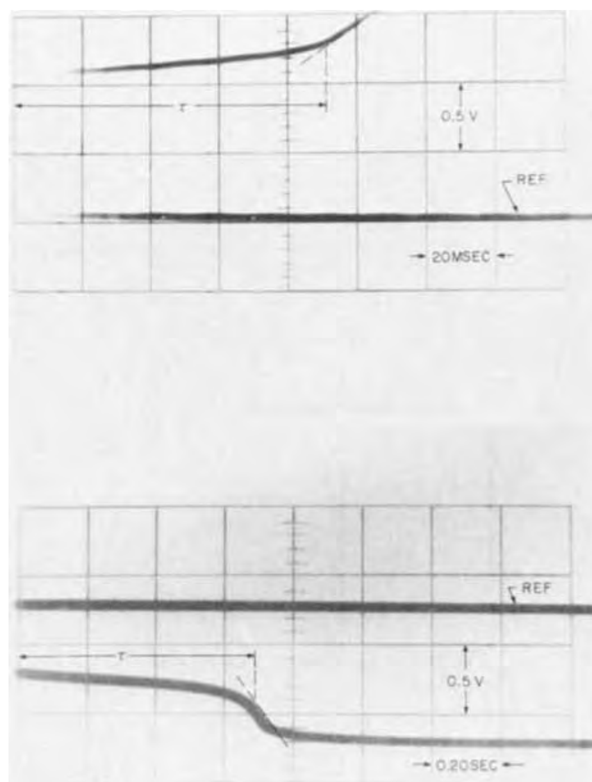

Fig. 8. (a) Upper curve, a typical potential-time transient for gold oxidation in 0.2M KOH, 0.2M KCN solution at 61°C. Current density 38 mA/cm^2. (b) Lower curve, a typical potential-time transient for gold reduction. Wire electrode, alkaline cyanide solution 0.035M in $Au(CN)_2^-$, current density 21 mA/cm^2.

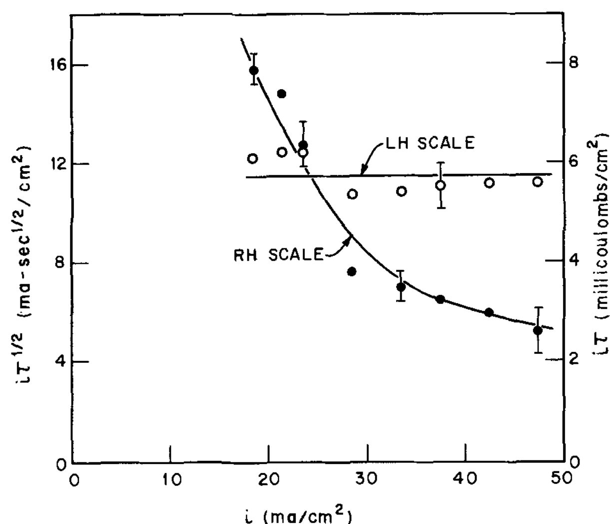

Fig. 9. Transition time curves for gold oxidation in 0.2M KOH, 0.2M KCN, and 0.2M $KAu(CN)_2$.

$$C_o = \frac{2i}{nF\,D^{1/2}}\sqrt{t/\pi}$$

If the electrode follows Nernst behavior then the potential of the electrode increases as the logarithm of the square root of time without abrupt transition. When a passivating reaction can occur, however, as it does in this case then the potential rises to the value where passivation occurs and then increases abruptly. The concentration of the metal ion when this occurs may be designated C_o^* and is given by

$$C_o^* = \frac{2i}{nF\,D^{1/2}}\sqrt{\tau/\pi}$$

Substitution of the value 11.5×10^{-3} (Fig. 9) for $i\tau^{1/2}$ into this equation gives a value of 3.5×10^{-2} mole/l for C_0*. This value is less than the saturation value for $Au(CN)_2^-$ suggesting that passivation occurs not from precipitation of gold cyanide but as a result of another reaction beginning at a potential of about 0.45V and this is the formation of gold oxide.

Reduction.—The transition time during reduction occurs when the reaction, under mass transport limited kinetics, reaches the condition that the surface concentration of the reacting species is zero. The transition time is given by

$$i\tau^{1/2} = \tfrac{1}{2}\pi^{1/2} nF C^\circ D^{1/2}$$

If the reaction is preceded by a slow chemical reaction then the $i\tau^{1/2}$ product is not constant but decreases with increasing current density. If the reaction is preceded by an adsorption step then the product $i\tau$ becomes constant at sufficiently high current densities and the $i\tau^{1/2}$ product increases. A convenient means of distinguishing these reaction mechanisms is thus available. Peters and Lingane (8) have modified transition time theory for planar electrodes to include cylindrical geometry. In the worst case considered here the correction is less than 10% for the cylindrical geometry so the unmodified theory is used throughout. A typical potential-time curve for gold reduction is given in Fig. 8(b).

The data from transition time experiments are displayed in Fig. 10. In these experiments four different solutions and three different geometries were used. Considering this, the scatter in the $i\tau^{1/2}/C^\circ$ values is not excessive. One set of data (the open circles) indicates a preceding adsorption step. These measurements were taken with the electrode "floating" without an applied potential before the imposition of the cathodic current. All the other data in the figure were obtained with an anodic current of from 50 to 200 μA applied to the electrode before switching to the cathodic current. In these latter experiments the formation of an oxide on the surface prevented adsorption of the intermediate reduced in peak B (Fig. 2). On reduction the thin oxide layer was rapidly reduced and then $Au(CN)_2^-$ was reduced from solution. The oxide layer was thin (about 1 millicoulomb/cm^2), reacted rapidly and at a potential about 0.5V anodic to the gold reduction wave so that it did not interfere in the measurements.

Experiments using the ½ in. diameter rod consistently gave transition times less than those using the ¼ in. rod, and the wire, and with less scatter. This could be the result of a better geometry. In any event examining all the data there does not appear to be any difference in the reduction mechanism from the three solutions and the diffusion coefficient of the reacting species is the same within the experimental error. This is expected to be the case since the reacting species is the same in all the solutions and the diffusion coefficient will vary only slightly with the activity of the ion in the solutions of different ionic strength. The average value from all the experiments with the exception of the "free floating" one provides a diffusion coefficient of 1.8×10^{-5} cm^2 sec^{-1}. The scatter in the data, however, place a possible error of $\pm 0.35 \times 10^{-5}$ cm^2 sec^{-1} on this value.

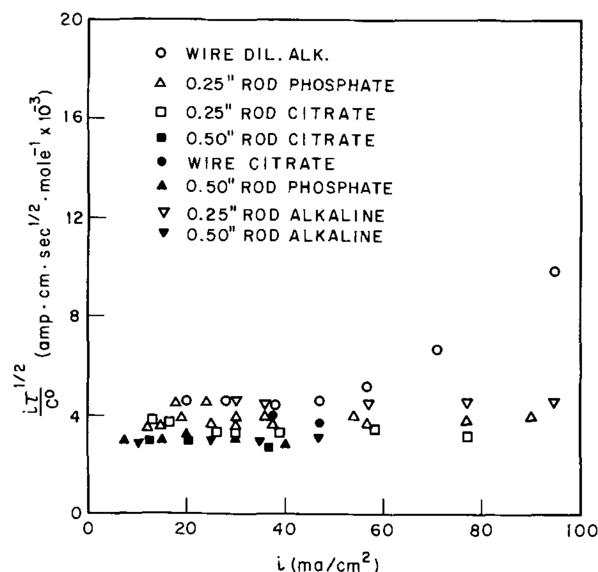

Fig. 10. Transition time plot for various Au electrodes in the citrate, phosphate, and alkaline Au plating solutions.

There is sufficient agreement between this value for D and the literature values (6) for the diffusion coefficient of $Au(CN)_2^-$ in alkaline cyanide, citrate, and phosphate solutions to conclude that $Au(CN)_2^-$ is the reacting species and that the reason for the low D values found from the cyclic voltammetry experiment was the interference of the adsorbed intermediate in the citrate and phosphate solutions.

Summary

Oxidation of gold.—The oxidation of gold in alkaline cyanide solutions is seen to be complex. It is concluded that at low overvoltages oxidation proceeds through a surface intermediate probably $|Au\,CN|_{ads}$ and that the oxidation of gold in the region −0.6 to −0.3V is limited by the dissolution of the surface intermediate. When the surface is completely covered the rate of reaction is controlled by the rate of chemical dissolution of the intermediate. In this work no true passive region was observed when the gold electrode was potentiostated at potentials less than +0.45V in the alkaline cyanide bath at temperatures higher than 40°C. The chemical dissolution reaction logically must be

$$|Au\,CN|_{ads} + CN^- \rightarrow Au(CN)_2^-$$

At higher overvoltages a complex oxidation peak (F) was observed. In agreement with Cathro and Koch (2) it is concluded that this active region is passivated by the formation of oxide on the gold surface. The capacity of the peak does not allow assignment to the oxidation of a surface film. The results indicate that in this region gold is oxidized to a soluble species. The reaction is too complex to analyze fully at this time, but two possibilities are the direct oxidation of gold to $Au(CN)_2^-$ without the formation of an intermediate and the oxidation of gold to an Au(III) complex which presumably would react with CN^- oxidizing this and being in itself reduced to $Au(CN)_2^-$.

Reduction of gold.—Two reduction paths were observed. In the alkaline cyanide bath these were evident in the cyclic voltammetry curves but in the citrate and phosphate baths they were not. One reduction path was through an adsorbed intermediate and on the basis of the oxidation results this is presumed to be $|Au\,CN|_{ads}$. The other reduction path was a direct charge transfer to the soluble $Au(CN)_2^-$. The two reduction paths may be expected to lead to electrodeposits differing in physical character.

Current Distribution at the Rotating Ring-Disk Electrode

G. Neubert, E. Gorman, R. Van Reet, and K. B. Prater*

Department of Chemistry, University of Texas at El Paso, El Paso, Texas 79968

ABSTRACT

The digital simulation method is used to calculate the current densities at both the ring and disk surfaces of a ring-disk electrode when the two surfaces are at the same potential. Simulated and experimental results show that the current density at the ring is nonuniform and measurably different from that at the disk electrode, even if the current density at the disk is assumed to be uniform. In addition, a technique is presented which allows the determination of the simulation representations of the electrode radii from experimental data.

Most treatments (1-3) of rotating disk and ring-disk electrodes have assumed that the disk is a uniformly accessible surface—that is, that the current density is uniform across the entire surface of the disk electrode. Newman (4) concluded that the current density should in fact be nonuniform at applied potentials below the limiting current. Albery and Ulstrup (5) presented results of experiments at the ring-disk electrode in which observed collection efficiencies for the Br-Br_2 system deviated from those predicted by a theory based upon the assumption of uniform accessibility. This deviation was attributed to nonuniform accessibility by the authors. Marathe and Newman (6) then pointed out that the deviation observed by Albery and Ulstrup was in the wrong direction to be attributable to nonuniform current density at the disk. It seemed to us that a more reasonable explanation for the observed deviation would be that the current efficiency at the disk was less than 100%. This has recently been confirmed by Albery and Hitchman (7). In the same chapter (7) Albery and Hitchman also present new ring-disk electrode data which are in agreement with Newman's treatment. These data and the data obtained by Marathe and Newman (6) and Bruckenstein and Miller (8) leave no doubt that under certain conditions nonuniform current density prevails at the disk electrode.

In response to the Albery and Ulstrup paper (5), Marathe and Newman (6) suggested that the ring-disk electrode could be used for a quantitative study of nonuniform current distributions by applying the same potential to the disk and ring electrodes. They suggested that observed differences in the current densities at the ring and disk electrodes would be a direct measure of the nonuniformity of the current density at the disk electrode. The purpose of this paper is to present the results of digital simulation and experimental work which show that, due to the presence of the insulating gap between the ring and disk and the different boundary condition which holds there, even if the current density were uniform at the disk, a nonuniform and measurable different current density would be observed at the ring. Only in the limit as the width of the gap approaches zero will the two current densities approach one another.

Digital Simulation

The technique for the digital simulation of the rotating ring-disk electrode has been presented previously (3). For the purposes of this study two quantities in addition to the collection efficiency (3), N, were simulated for the reversible reaction

$$A + ne \leftrightarrow B \qquad [1]$$

In order to accurately model the electrodes, it was necessary to simulate the limiting current at the ring when the disk was held at open circuit potential. This was done simply by applying the boundary condition which is used for the gap to the disk as well, and applying the usual disk boundary condition to the ring. The second simulation was that of the limiting currents and current densities at the disk and the ring when the two electrodes are shorted together and the potential is such that the limiting current is passed at the disk. In the nomenclature of Ref. (3), the boundary conditions were

$$F_A(1,1) = F_A(1,K_R) = 0.0$$
$$F_B(1,1) = F_B(1,K_R) = 1.0 \qquad [2]$$

The dimensionless disk current parameter, ZD, which is calculated by this technique is

$$ZD = i_d/(0.51)^{1/3}n\mathbf{F}A_dC^\circ{}_AD_A{}^{2/3}\omega^{1/2}\nu^{-1/6} \qquad [3]$$

where i_d is the limiting current at the disk, n is the number of electrons transferred per molecule, $\mathbf{F}$ is the Faraday, A_d is the area of the disk, $C^\circ{}_A$ is the bulk concentration of species A, D_A is the diffusion coefficient of A, ω is the rotation rate, and ν is the kinematic viscosity. Notes that ZD is proportional to the current density at the disk.

The dimensionless ring current parameter, ZR, which is calculated by this technique (3) is

$$ZR = i_r/(0.51)^{1/3}n\mathbf{F}A_dC^\circ{}_AD_A{}^{2/3}\omega^{1/2}\nu^{-1/6} \qquad [4]$$

where i_r is the limiting ring current. When ZR is multiplied by the ratio of the area of the disk to the area of the ring, A_r, a new parameter, ZRN, is generated

* Electrochemical Society Active Member.

Key words: ring-disk electrode, current distribution, uniform current density.

Table I. Dependence of current density ratio on width of gap

Width of gap[a]	CDR[b]
40	1.54
20	1.34
10	1.20
1	1.03

[a] Arbitrary units.
[b] Current density ratio—$(i_r/A_r)/(i_d/A_d)$.

which is proportional to the average ring current density.

$$ZRN = i_r/(0.51)^{1/3}n\mathbf{F}A_rC°_AD_A{}^{2/3}\omega^{1/2}\nu^{-1/6} \quad [5]$$

Note that the ratio of ZRN to ZD is the ratio of average current density at the ring to the current density at the disk when the two are shorted together. That is

$$CDR = ZRN/ZD = (i_r/A_r)/(i_d/A_d) \quad [6]$$

Thus for a given electrode, three experimentally measurable parameters were calculated (*i*) the ratio of the limiting ring current with the disk inactive to the limiting disk current, (*ii*) the collection efficiency (3), and (*iii*) the ratio of the average current density at the ring to the current density at the disk when the two electrodes are shorted.

Simulation Results

The simulated ratio of the average current density at the ring to the current density at the disk when the two electrodes are shorted together is presented in Table I for a series of electrodes differing only in the width of the gap. For these calculations, the radius of the disk was, in each case, 99.5 units, the width of the ring was 25 units, and the width of the gap was varied as shown in Table I. The current densities were calculated using the same boundary conditions at the ring and disk and assuming uniform current density at the disk.

As might be expected, the average ring current density approaches the disk current density as the thickness of the gap approaches zero. As the gap is made wider, the average current density gets larger and would be expected to approach that for a ring electrode alone.

The current density profile for each of the electrodes is presented in Fig. 1. Again the results are as might be expected with a uniform current density being approached only as the width of the gap approaches zero.

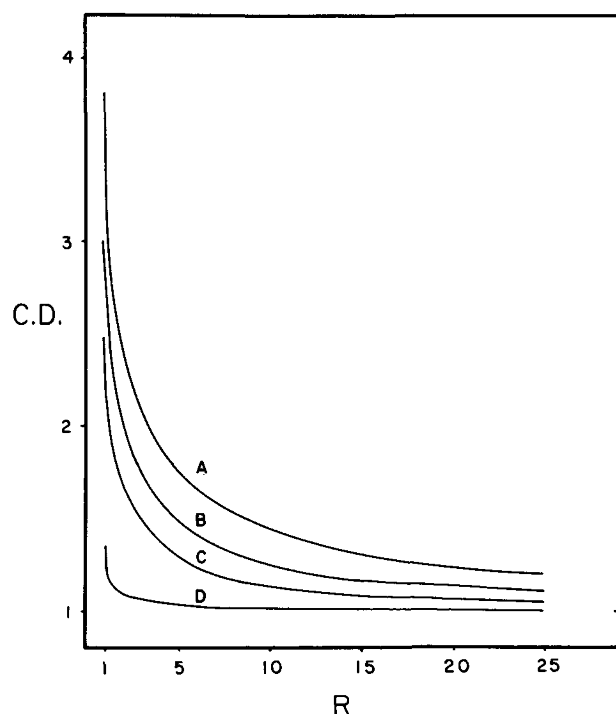

Fig. 1. Ring current density profile for electrodes in Table I. Ring and disk are shorted together. R is the distance from the inner edge of the ring. C.D. is the ring current density at each point normalized by the disk current density. The width of the gaps are: A = 40, B = 20, C = 10, D = 1.

Experimental

All chemicals were reagent grade and used without further purification. The potentiostat which was used for limiting current measurements was a Werking Model 66TS10 and the recorder was a Hewlet Packard 7004A X-Y with 17171A d-c preamp plug-ins. For collection efficiency measurements, a constant current source with a floating power supply and utilizing Analog Devices operational amplifiers was used to supply the disk current. The platinum ring-disk electrodes were obtained from Pine Instruments, Grove City, Pennsylvania, and were rotated with a Motormatic E-550 motor with feedback controller modified to operate up to 10,000 rpm which was obtained from Electro Craft, Hopkins, Minnesota. All experiments were carried out at room temperature.

Before each run, the electrodes were pretreated by rotating them in an acid dichromate solution for 60 sec, rinsing with distilled water and drying. With this procedure, limiting currents could be reproduced within ±0.5%. Measurements of the collection efficiency were made by applying a constant current to the disk electrode and determining the limiting current at the ring.

Results and Discussion

Measurements were made on two electrodes. One, electrode A, had a relatively thin gap while the other, electrode B, had a much wider gap. The collection efficiencies of these electrodes were determined for solutions which were $1 \times 10^{-3}M$ in $K_4Fe(CN)_6$ and $2M$ in KCl. The results are presented in Table II. In all runs, the current applied to the disk was less than the limiting current.

Next, the limiting disk current, i_d, limiting ring current with the disk at open circuit, i_{ro}, and the limiting current with the disk and ring shorted together, i_{rd}, were measured in succession in the same solution. This procedure was repeated at rotation rates varying from 100 to 5000 rpm.

The ratio of i_{ro} to i_d and the collection efficiency were used to determine the radius of the outer edge of the gap, r_2, and the radius of the outer edge of the ring, r_3, relative to the radius of the disk, r_1. This was done by simulating these two parameters for various values of the simulation representation of these radii, IR1, IR2, and IR3. A value of IR1 was selected and the parameters IR2 and IR3 were adjusted until the simulated values of i_{ro}/i_d and the collection efficiency were in satisfactory agreement with the experimental values. Since (3)

$$\text{IR1} - 0.5 = r_1\Delta r \quad [7]$$

and

$$\text{IR2} - 0.5 = r_2\Delta r \quad [8]$$

$$(\text{IR2} - 0.5)/(\text{IR1} - 0.5) = r_2/r_1 \quad [9]$$

Table III. Experimental and simulated collection efficiencies and limiting current ratios

	Electrode A		Electrode B	
	N	i_{ro}/i_d	N	i_{ro}/i_d
Experimental	0.566 ± 0.005	3.21 ± 0.04	0.450 ± 0.003	2.56 ± 0.03
Simulated	0.566	3.20	0.448	2.56
	IR1 = 83, IR2 = 92, IR3 = 159		IR1 = 83, IR2 = 104, IR3 = 151	

and similarly

$$(\mathrm{IR3} - 0.5)/(\mathrm{IR1} - 0.5) = r_3/r_1 \quad [10]$$

In a similar manner, it is found that the ratio of the area of the ring to the area of the disk, A_r/A_d is given by

$$A_r/A_d = [(\mathrm{IR3} - 0.5)^2 - (\mathrm{IR2} - 0.5)^2]/(\mathrm{IR1} - 0.5)^2 \quad [11]$$

Note that in order to determine r_2 and r_3 explicitly, r_1 would have to be determined independently. This is not necessary for this work. The experimental results and best fit simulation results are presented in Table III.

With satisfactory values of IR1, IR2, and IR3 determined, it was then possible to calculate the expected values of the ratio of the average current density at the ring, i_{rs}/A_r, to the current density at the disk, i_d/A_d, when the ring and disk are shorted together for each of the two electrodes for which data were available. The experimental values of i_{rs} were obtained by subtracting the measured i_d from i_{rd}, the total ring and disk current. The ratio i_{rs}/i_d when multiplied by A_d/A_r, the reciprocal of Eq. [11], yields the experimental ratio of the current densities, CDR. The agreement between the experimental and simulated current density ratios is shown in Table IV.

Conclusion

It has been shown that the current density at the ring electrode when shorted to the disk electrode is nonuniform even if the current density at the disk is uniform as it is at the limiting current. The digital simulation technique has been shown to accurately calculate the average current density at the ring when the current density at the disk is uniform. It is expected that a nonuniform current density at the disk would give rise to measurably different average current densities at the ring under these conditions and that such a technique should be valuable in measuring such nonuniformity. The digital simulation of this case is now being undertaken.

Electrode Kinetic Studies on Electro-Organic Syntheses Involving Carbonium Ions

I. Anodic Oxidation of Acetate Ions to Methyl Acetate

Ashok K. Vijh*

Hydro-Quebec Institute of Research, Varennes, P. Q., Canada

ABSTRACT

Anodic electrosynthesis of methyl acetate on graphite electrodes in aqueous acetate solutions is known to proceed via intermediate formation of carbonium ions. Kinetic-mechanistic aspects of this reaction have not been examined previously and an attempt has been made in the present investigation to elucidate these aspects by carrying out electrode kinetic studies. Potentiostatic Tafel plots, potentiodynamic profiles, anodic charging curves, open-circuit potential decay measurements, capacity-potential relationships, apparent heats of activation, and reaction order derivatives are reported for this system. On the basis of an analysis of these data, it has been suggested that initial discharge step is the rate-determining step (r.d.s.) in the over-all reaction. Possible explanation for the occurrence of a carbonium ion pathway, in preference to a radical one as observed for the Kolbe reaction, in the present case is also put forward.

An interesting aspect of modern work in synthetic organic chemistry is the elucidation of the role of radicals and radical ions in various syntheses. This problem also arises in some electro-organic syntheses in which it has been observed that radicals (1) or carbonium ions (2) can play an important role as reactive intermediates. If one considers the anodic oxidation of acetate ions in aqueous solutions on a platinum

* Electrochemical Society Active Member.

Key words: carbonium ions, electro-organic synthesis, electrode kinetics, anodic oxidation, acetate ions.

electrode, one observes that ethane and carbon dioxide are formed in the over-all reaction

$$2CH_3CO\bar{O} \rightarrow C_2H_6 + 2CO_2 + 2e \quad [1]$$

This reaction, called the Kolbe reaction, is known to proceed in several steps and is believed (1, 2) to occur by intermediate formation of radicals. When one conducts the anodic electrolysis of the aqueous acetate solutions on a graphite electrode, however, one does not obtain the usual Kolbe products but instead, methyl acetate is formed as the major product with a yield (2) of *ca.* 82%. The over-all reaction in this case is

$$2CH_3CO\bar{O} \rightarrow CH_3COOCH_3 + CO_2 + 2e \quad [2]$$

Several investigators, notably Corey and co-workers (3, 4) and Koehl (5) have presented a great deal of evidence to show that the over-all reaction in Eq. [2] involves intermediate formation of carbonium ions. In several other related anodic electrosyntheses, Ross and co-workers (2) have postulated the intermediate formation and participation of carbonium ions.

Despite a great deal of synthetic work (2-5) on electro-organic syntheses involving carbonium ions, no electrode kinetic studies seem to have been carried out. The purpose of the present series of studies is to examine the electrode kinetic features of electro-organic syntheses involving carbonium ions, on the basis of general approaches applied earlier to the Kolbe reaction (1). The aim would be to present new electrochemical evidence and an associated kinetic analysis that will seek to examine the nature of various elementary steps involved in the over-all reaction as well as the identity of the rate determining step (r.d.s.) in a likely reaction pathway. An attempt will also be made to establish the nature and role of any adsorbed reaction intermediates that might be involved in the over-all reaction. It is believed that such electrode kinetic studies will provide vital information, supplementary to the previous synthetic work (2-5), needed to formulate a kinetic-mechanistic picture of electrosyntheses involving carbonium ions. It is hoped that a somewhat better understanding of the various aspects of these electrode processes thus developed will perhaps aid in the further explorations of electro-organic syntheses involving carbonium ions.

Experimental Section

The instruments and the cell employed as well as the details on electrodes, gas purification, preparation of conductivity water, cell cleaning, etc. have been described recently (6). The general electrode kinetic approaches used in the present work were reviewed previously (1).

All electrode potentials expressed here are against a hydrogen reference electrode in the same solution. No pre-electrolysis was conducted in the present work since it was noted previously (1) that in electro-organic work pre-electrolysis tends to produce rather than remove traces of impurities.

All solutions were made from potassium acetate (Fisher, A.C.S. certified, mol. wt. 98.15), acetic acid (Fisher reagent, 99.7%), and conductivity water.

Results

Steady-state current-potential relationships.—In Fig. 1, steady-state (point-by-point) potentiostatic current-potential relationships for the anodic oxidation of acetate ions on graphite electrodes in aqueous acidic solutions have been presented. An hysteresis between the ascending and descending curves is observed which is not entirely unexpected for anodic reactions (7). A Tafel slope of *ca.* $2.3 \times 2RT/F$ is observed at higher anodic potentials, whereas Tafel lines showing higher slopes are indicated below 1.8V. Some rudimentary inhibition inflections, of the type discussed by Gilroy and Conway (8) may also be noted, around 0.5V on the ascending curve and around 1.3V on the descending curve. The change in Tafel slopes around 1.8 would indicate two parallel mechanisms (7).

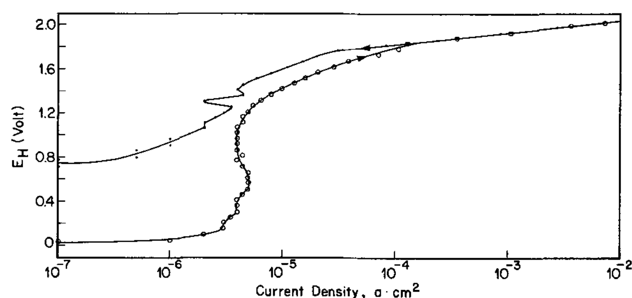

Fig. 1. Potentiostatic, steady-state (point-by-point) Tafel relationships on a graphite electrode in aqueous acetate solutions, both in the ascending and descending direction of potentials. The Tafel slope at the high anodic potentials is *ca.* $2.3 \times \frac{2RT}{F}$. Solution is 5*N* CH_3COOK + 1*N* CH_3COOH in water. Room temperature. Time of polarization at every point is 2 min.

Temperature effects on the rate.—In Fig. 2 (a) and 2 (b), effect of temperature on the ascending and descending, respectively, Tafel plots has been represented. Only the linear Tafel regions have been shown. It is seen that the potential at which the two Tafel lines with different slopes intersect depends on the temperature, *i.e.*, at higher temperature the change in the slope of the Tafel line, and the associated shift over to an alternative parallel mechanism, tends to occur at lower electrode potentials. This is not at all unexpected since temperature and potential both drive

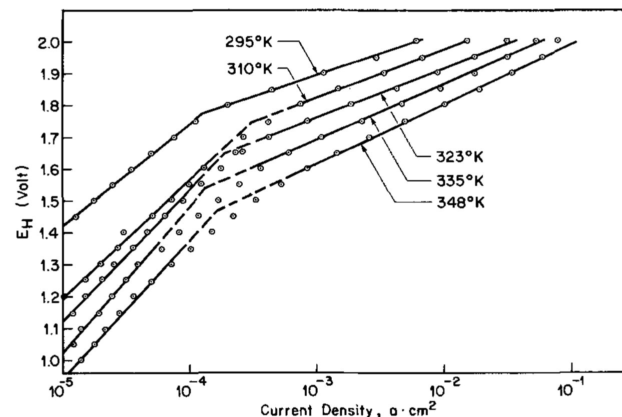

Fig. 2 (a). Tafel plots at the shown temperatures taken in the ascending direction of potentials. Graphite anode in 2*N* CH_3COOK + 1*N* CH_3COOH. Time of polarization at every potential is 2 min.

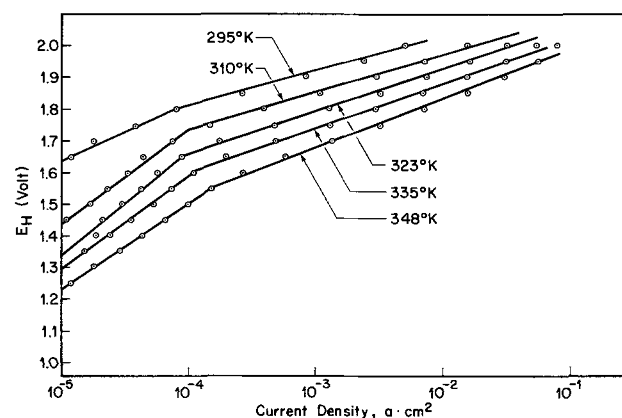

Fig. 2 (b). Same as Fig. 2 (a) but now taken in the descending direction of electrode potentials.

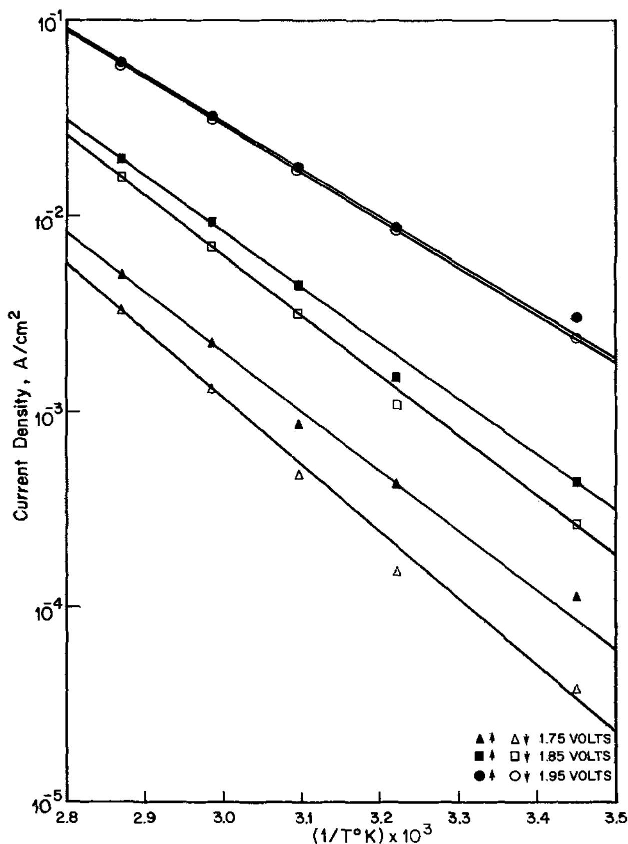

Fig. 3. The current density vs. $1/T$ (where T is the absolute temperature) plots adopted from Fig. 2 (a) and 2 (b) in order to determine the apparent heat of activation. The ΔH^* values lie between *ca.* 10 and 16.5 kcal depending on the electrode potential.

the reaction in the same direction, *i.e.*, higher rates at higher values of potential or temperature.

The electrochemical Arrhenius plots at some typical electrode potentials, as derived from Fig. 2 (a) and 2 (b) have been presented in Fig. 3. It is seen that the apparent heat of activation as given by the differential, $\left(\frac{\delta \log i}{\delta(1/T)}\right)_{\eta,\psi,...}$, lies between *ca.* 10.6 and 16.6 kcal depending on the electrode potential.

Reaction orders.—An important parameter in the modern electrode kinetic analysis is recognized to be the electrochemical reaction order (7, 9). In the present work, the potentiostatic current-potential curves were studied at various acetate concentrations, both in the ascending [Fig. 4 (a)] and the descending [Fig. 4 (b)]

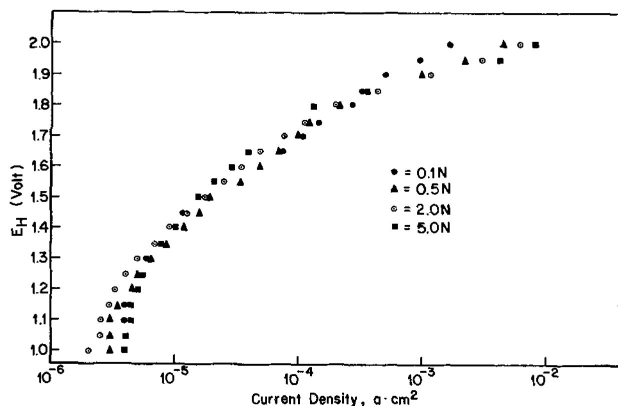

Fig. 4 (a). Tafel plots taken in the ascending direction of potentials in the following solutions: ● 0.1N CH_3COOK + 1N CH_3COOH; ▲ 0.5N CH_3COOK + 1N CH_3COOH; ⊙ 2.0N CH_3COOK + 1N CH_3COOH; ■ 5.0N CH_3COOK + 1N CH_3COOH.

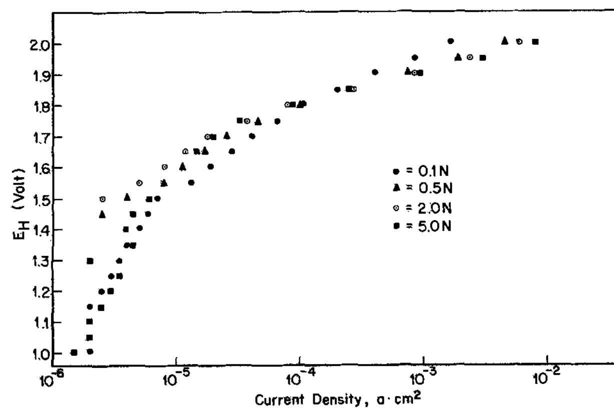

Fig. 4. (b). Same as Fig. 4 (a) but now taken in the descending direction of electrode potentials.

directions of the electrode potential. An attempt was made to deduce the reaction order derivative, $\left(\frac{\delta \log i}{\delta \log C_{CH_3COO^-}}\right)_{\eta,\psi,T,...}$, from these plots [Fig. 4 (a) and (b)] and the results are presented in Fig. 5. At lower potentials, the reaction order tends to be zero whereas at 2.0V, it is observed that

$$\left(\frac{\delta \log i}{\delta \log C_{CH_3COO^-}}\right)_{\eta,\psi,T...} \simeq 0.4$$

Potentiodynamic profiles.—No peaks were observed in the potentiodynamic profiles taken over a wide range of sweep rates. A typical potentiodynamic profile (1, 7) is shown in Fig. 6. Absence of peaks would preliminarily suggest absence of significant change in the electrode coverage in the potential range scanned as well as absence of diffusion-controlled oxidation-reduction of redox type species in the solution.

Open-circuit decays.—Open-circuit decay profiles triggered from various initial steady-state potentials show absence of any arrests. Typical results are given in Fig. 7. This would tend to confirm the conclusions deduced from the potentiodynamic profiles, namely,

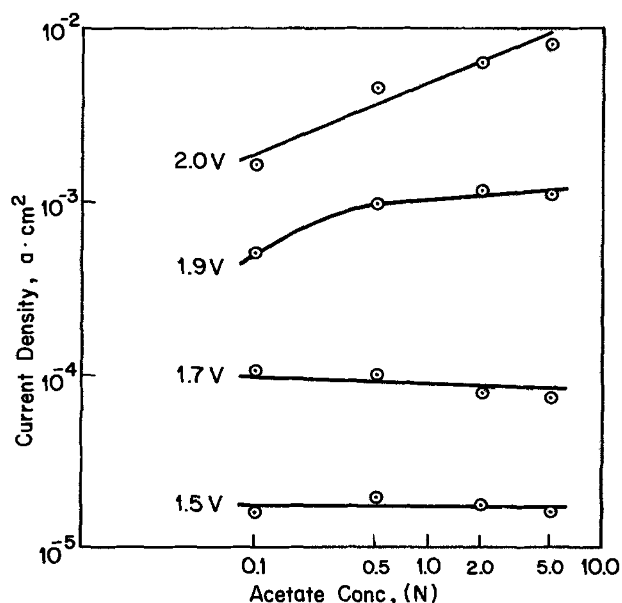

Fig. 5. Log [current density] vs. log. [acetate ion concentration] plot adopted from Fig. 4 (a). The $\left(\frac{\delta \log i}{\delta \log C}\right)$ value at 2.0V is *ca.* 0.4 whereas at lower potentials these values approach zero. Essentially similar results are obtained when one constructs this plot from Fig. 4 (b).

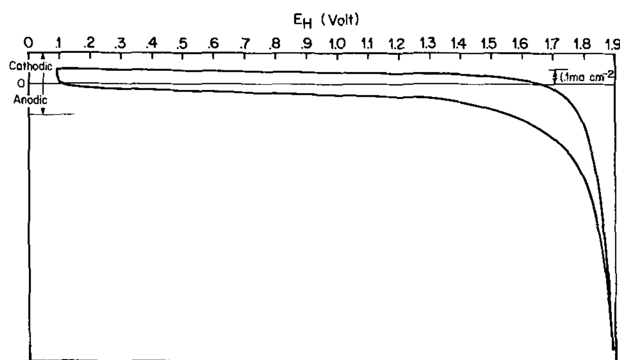

Fig. 6. A typical potentiodynamic profile on graphite in 2*N* CH_3COOK + 1*N* CH_3COOH. Sweep speed, 5 mV sec^{-1}. Absence of peaks may be noted. No peaks are observed even when one changes the sweep rate by several orders of magnitude.

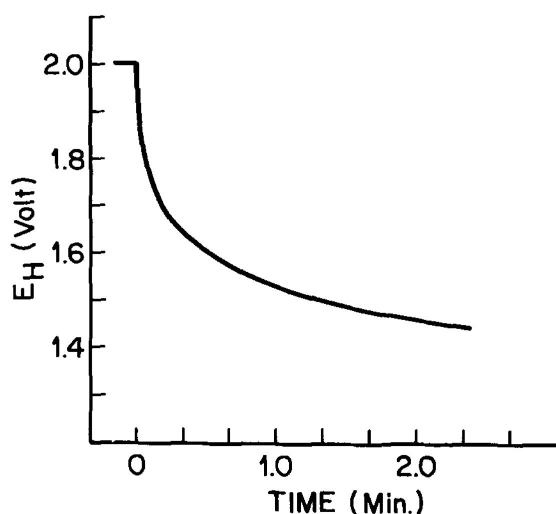

Fig. 7. A typical open-circuit potential decay profile for a graphite anode in 2*N* CH_3COOK + 1*N* CH_3COOH. Absence of arrests may be noted.

absence of significant electrode coverage by electroactive species in the steady state.

Charging curves.—In order to examine the possibility of coverage by adsorbed intermediates further, anodic charging curves were recorded at various current densities. Clear-cut arrests were again not observed although at low charging current densities, some incipient changes of slope in the charging curve were observed (Fig. 8). An electrode capacity-potential profile calculated from a typical charging curve (Fig. 8) is presented in Fig. 9 in which no clear-cut capacity maxima or minima, possibly diagnostic of changes of the electrode coverage during the transient, are observed. The maximum values of the differential capacity in this Fig. 9 would suggest the presence of some adsorption pseudocapacitance even when one takes into account the fact that the graphite electrodes have a very large ratio of real to geometric area (this ratio being unknown) and that such electrodes can uptake significant amounts of absorption (6). The values of differential capacity in Fig. 9, however, cannot perhaps be taken as a sufficient evidence for the presence of significant amounts of adsorbed intermediates in the steady state. A consideration of the peculiarities of the graphite electrode (6) as well as the evidence in Fig. 6-8 would tend to indicate rather strongly that the anodic formation of methyl acetate in the present study probably proceeds without involving significant coverage by the adsorbed intermediates during the steady-state electrolysis.

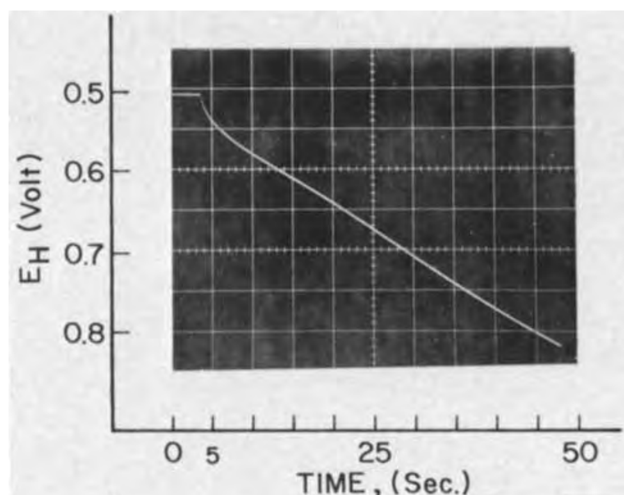

Fig. 8. An anodic charging curve (charging current density = 27.6 μA cm^{-2}) triggered from the rest potential (0.5V). Graphite in 2*N* CH_3COOK + 1*N* CH_3COOH. Although an incipient arrest is indicated, significant coverage of the electrode during steady-state electrolysis is not concluded on the basis of discussion in the text. This incipient arrest does not become more pronounced, but rather tends to disappear, when one changes the charging current density.

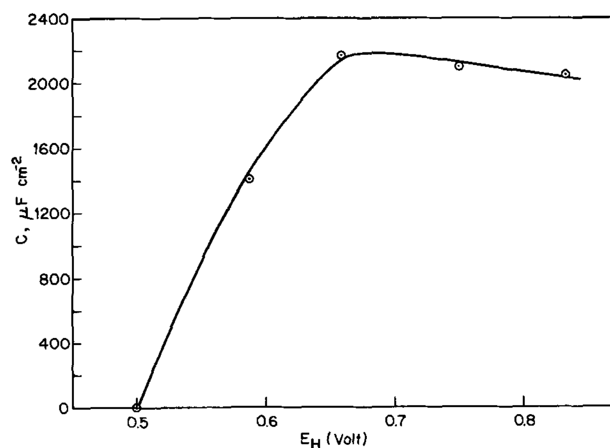

Fig. 9. A capacity-potential profile constructed from Fig. 8

Discussion

The anodic formation of methyl acetate by an over-all two-election reaction (*i.e.*, Eq. [2]), which is known to proceed via intermediate formation of carbonium ions (2-5) may be assumed to involve the following elementary steps

$$CH_3CO\bar{O} + S \rightarrow CH_3COO{-}S + e \quad [3]$$

$$CH_3COO - S \rightarrow CH_3{-}S + CO_2 \quad [4]$$

$$CH_3{-}S \rightarrow CH_3^+ + e + S \quad [5]$$

$$CH_3^+ + CH_3CO\bar{O} \rightarrow CH_3COOCH_3 \quad [6]$$

Here, *S*, denotes the graphite electrode surface on which the reaction occurs.

A value of Tafel slope equal to 2.3 × $2RT/\mathbf{F}$ and absence of a significant amount of electrode coverage in the steady state, as observed in this investigation, would indicate rather unambiguously that the initial discharge step (*i.e.*, Eq. [3]) is the likely rate-determining step (r.d.s.) in the over-all reaction (1, 7), at least above 1.8V. The rate equation for this case in concentrated solutions ($\psi \rightarrow 0$) may be written as

$$i = k\,(1 - \theta)\, C_{CH_3COO^-}\, e^{\beta\eta \mathbf{F}/RT} \quad [7]$$

Where i is the current; θ, the electrode coverage; k, a combination of constants; $C_{CH_3COO^-}$, the concentration

of acetate ions; β, the charge transfer symmetry factor; η, the anodic over potential; **F**, the Faraday; R, the gas constant; and, T, the absolute temperature. Since the coverage, θ, is observed to approach zero, one may write Eq. [7] as

$$i = k\, C_{CH_3COO^-}\, e^{\beta\eta F/RT} \quad [8]$$

$$\text{or} \quad \left(\frac{\delta\eta}{\delta \log i}\right) = 2.3 \times \frac{2RT}{F} = \text{Tafel slope}$$

The reaction order expected would be

$$\left(\frac{\delta \log i}{\delta \log C_{CH_3COO^-}}\right) = 1$$

This predicted reaction order, however, is not in agreement with the observed value ($\simeq$ 0.4 at high anodic potentials) and the source of this discrepancy is not clear, although some tentative explanations can be put forward (see below).

The heats of activation observed (Fig. 2, 3) are quite high ($>$ 10 kcal mole^{-1}), which would qualitatively tend to support the mechanism suggested here, by analogy with the case of hydrogen evolution reaction.

On the basis of reaction order evidence (Fig. 4, 5) alone, it would appear attractive to suggest that a step subsequent to the initial discharge is perhaps the r.d.s. However, other evidence such as the Tafel slopes, lack of appreciable coverage as deduced from the transient studies, and rather high heat of activation would tend to support quite strongly the mechanistic proposal put forward here, namely, initial discharge as the r.d.s.

It appears interesting to speculate here on the possible reasons for the formation of carbonium ions, and thence methyl acetate, on graphite electrodes in contrast to the occurrence of the Kolbe reaction on platinum electrodes in the electrolysis system investigated here. Since the strength of Pt—CH_3 and C—CH_3 bonds, as estimated by the Pauling equation, is nearly identical (10), the explanation would seem to lie elsewhere. It has been pointed out by Ross (10) that the graphite electrodes possess paramagnetic centers on which the methyl radicals are probably bound ultrastrongly. If this suggestion is assumed to be correct, it is easy to see that the second electron transfer from the adsorbed methyl radical, to give the carbonium ion, is more facile than the alternative path demanding desorptive coupling of the methyl radicals.

Although a clear-cut interpretation of the observed reaction orders seems difficult, a possible explanation may be mentioned. Fractional reaction orders of this magnitude would be expected if one invokes the presence of competing reactions, a situation consistent with the present case in which the efficiency of formation of methyl acetate is substantially less than 100%. This suggestion is particularly emphasized by the direction of the abrupt changes in slopes of the Tafel lines [Fig. 1, 2 (a) and 2 (b)], so characteristic of a change over to a parallel reaction or a parallel rate-determining step within the same reaction (7).

Acknowledgments

The author is grateful to Mr. R. Jacques for carrying out the experimental work. Dr. G. Bélanger is thanked for some discussions during the progress of the work. Thanks are also due to Dr. P. Lenfant for his interest and encouragement.

Surface Concentration of Molybdenum in Types 316 and 304 Stainless Steel by Auger Electron Spectroscopy

G. J. Barnes, A. W. Aldag, and R. C. Jerner

School of Chemical Engineering and Materials Science, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

Auger electron spectroscopy has been used to determine surface concentrations of Mo in Types 304 and 316 stainless steel. The technique involved was Ar^+ bombardment removal of the stainless surface with alternate monitoring of the height of the 190 eV Mo peak. Surface concentrations of 14% were observed in mill-finished Type 316 containing 1.95% bulk Mo. Surface segregation of Mo was also observed in Type 304 containing 0.45% Mo impurity.

The effect of minor Mo additions on the corrosion resistance of 18-8 Type stainless steels is well established (1) and has led to increased utilization of molybdenum-bearing (2-4% Mo) stainless steels, especially in saline environments. The role of Mo in enhancing corrosion resistance has not been established because of a lack of information about the surface composition. Indeed, due to diffusion from the bulk, concentrations in the surface phase may be quite distinct from that in the bulk. Using Auger electron spectroscopy (AES), Harris (2), Haas (3), and Sickafus (4) have shown that certain thermal treatments can be used to concentrate bulk impurities at a free surface. In the case of 3340 steel, sulfur was observed (2) to concentrate at the surface after a short time at 330°C.

In the present studies, AES has been used to determine the concentration of Mo from the surface into the bulk of Types 316 and 304 stainless steel. Surface concentration of 14% was observed in mill-finished Type 316 containing 1.95% Mo. Surface segregation was also observed in Type 304 containing 0.45% Mo impurity.

Review of Auger Spectroscopy

The technique of auger electron spectroscopy is not new (5) although its application to surface studies is relatively recent (6). The Auger electron emission process is analogous to x-ray emission from an excited atom and, in fact, the processes often occur simultaneously in a given experiment. When an inner core vacancy of an atom is neutralized by absorption of an electron from one of the outer shells either an x-ray or an Auger electron with a precise energy will be emitted from the sample (Fig. 1).

In applying AES to surface studies, the initial inner core vacancy is created by electron bombardment of the surface with 1-3 keV electrons. The secondary Auger electrons have energies typically between 0 and 1000 eV, and only those electrons coming from within a few monolayers of the surface escape with a well-defined energy (7). The Auger energy levels of many of the metals and typical surface contaminants are known and the values agree quite well with the x-ray values tabulated by Hill *et al.* (8).

The interest in Auger spectroscopy as applied to surface studies evolved from the early low energy electron diffraction (LEED) experiments of Lander (9). In analyzing the energy distribution for secondary electrons emitted by a solid surface, he attributed the small peaks to Auger transitions in the solid and suggested that the characteristic energies of these peaks could be used for qualitative surface chemical analysis. The peaks were, however, small and difficult to detect within the broad, rather uniform background distribution. Harris (6) subsequently suggested that since the background was indeed relatively uniform, detection of Auger peaks could be greatly enhanced by electronically differentiating the energy distribution. This technique brought AES into its current prominence as a valuable tool for surface studies. Subsequent refinements were made by Palmberg (10) who demonstrated that the sensitivity for atoms at the surface could be enhanced by using a grazing incidence primary beam and that the energy resolution could be improved by replacing the old 3-grid LEED optics by a 4-grid system. Palmberg also confirmed experimentally that the low energy (<200 eV) Auger electron escape depth was of the order of 4-8Å. The minimum sensitivity for surface impurities has been estimated to be a few per cent of a monolayer (11).

More recently AES experiments are being performed independent of LEED studies. In principle, since the Auger process involves inelastic collisions with the surface, a well-defined crystal geometry as required by LEED is not a prerequisite for AES. A new cylindrical mirror analyzer (12) with a coaxial electron gun provides a simple electron optics system with precise energy discrimination. This system can be adapted to most conventional ultrahigh vacuum chambers and AES experiments performed in conjunction with other types of surface studies. An example of the Auger spectra obtained from a stainless steel surface using PEI Cylindrical Analyzer is shown in Fig. 2. The various surface components are noted on the trace.

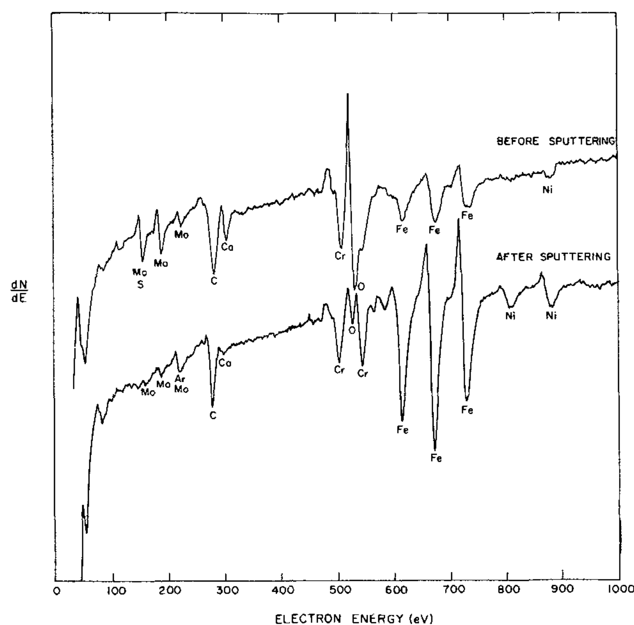

Fig. 2. (Upper) Auger electron spectrum of stainless steel before sputtering, $V_B = 2000$ eV. (Lower) Auger electron spectrum of stainless steel after sputtering, $V_B = 2000$ eV.

Experimental Procedure

Types 304 and 316 mill-finished stainless steel sheet 0.050 in. thick, was used in this investigation. Specimens were washed with detergent, rinsed in distilled water, acetone, trichloroethylene, and acetone, and then dried with a lintfree cloth. The samples were then placed in an ion and titanium sublimation-pumped vacuum chamber, which was evacuated and then baked at 250°C for 6 hr. The system was rough-pumped, oil-free, using zeolite-filled cryosorption pumps. Pressure, as indicated by a nude ionization gauge, was in the low 10^{-9} Torr range. An initial Auger spectrum was recorded and is shown in Fig. 2 (upper). This spectrum is representative of a surface cleaned in the manner described above but prior to electron or Ar^+ bombardment. The ion pump was then deactivated and Ar was admitted to a sputtering pressure of 1×10^{-4} Torr. Titanium sublimation pumps were activated during the entire sputtering sequence in order to maintain Ar purity. After sputtering for a predetermined time, usually 15 sec, the ion pump was again activated, resulting in a rapid pressure reduction into the 10^{-9} Torr range. The sample was then repositioned, by simple rotation, in front of the cylindrical mirror analyzer for Auger analysis. A spectrum was recorded next, and the sample was repositioned for additional sputtering. This sequence was repeated until the Auger spectra remained unchanged with additional sputtering. A spectrum taken after long-term sputtering is also shown in Fig. 2 (lower). It should be noted that the 190 eV Mo peak has been significantly reduced by sputtering from that in Fig. 2 (upper). The repetitive nature of several auger spectra after long sputtering times demonstrates that the procedures used to reposition the sample were reproducible, and the spectra obtained are representative of the bulk composition (13).

Results

The Auger spectrum for pure Mo is shown in Fig. 3. The major 190 eV Mo peak (14), corresponding to a $M_5N_3N_5$ (15) transition, was used to monitor the molybdenum concentration on the stainless steel surface as a function of sputter time. Assuming a unity removal coefficient (16), sputtering times were converted to atom layers removed. The resulting concentration gradients are shown in Fig. 4. As mentioned before, the values of the Mo concentration were obtained from stainless steel spectra after various sputtering times. It is also assumed that the Auger spectrum obtained after long sputtering time is representative of the bulk concentration. If the Auger peak height is taken to be directly proportional to the concentration of atoms present (17), the minimum surface concentration can be estimated. These assumptions result in a surface concentration of 14-15% and 3-4% for Types 316 and 304, respectively. The initial 190 eV peak height is undoubtedly obtained from a surface which contains a carbonaceous deposit resulting from the pretreatment and cleaning steps (18). Thus, the observed initial Mo concentration may be somewhat less than the actual values due to this overlayer.

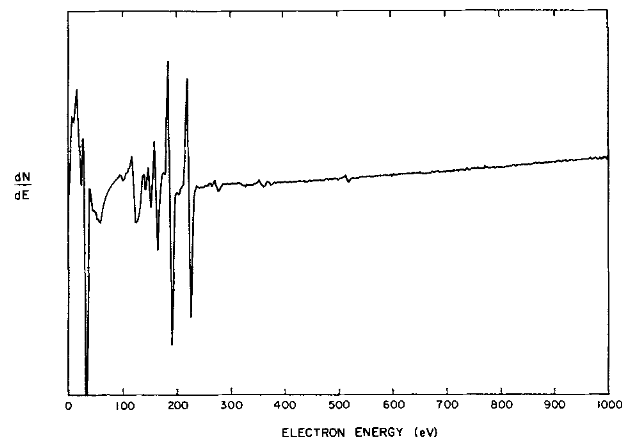

Fig. 3. Auger electron spectrum of pure molybdenum, $V_B = 2000$ eV.

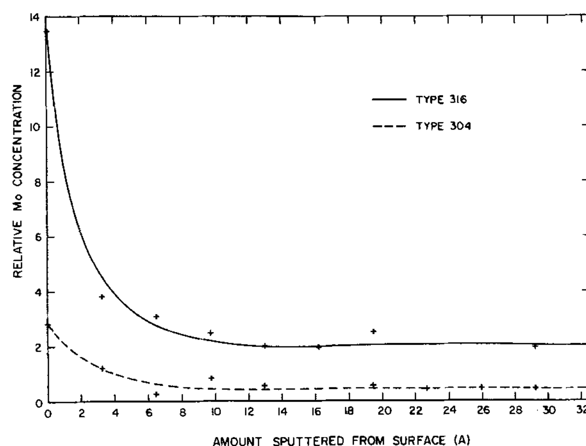

Fig. 4. Relative molybdenum concentration vs. amount of material removed in Types 304 and 316 stainless steel.

The results shown in Fig. 4 indicate that Mo concentrates at the surface of mill-processed stainless. Surface segregation is observed even in Type 304 where Mo is present as an impurity. As the surface is removed by Ar^+ bombardment, the major Mo Auger peak decreases in height to a value representative of the bulk concentration.

Conclusions

It has been found that mill processing tends to concentrate Mo at the surface of Types 304 and 316 stainless steel. This surface segregation has been brought about in some manner by mill processing. Subsequent thermal or mechanical processing would disturb this surface concentration and in all probability result in the surface concentration of Mo being dependent on treatment. Thus any property, such as corrosion resistance, that is dependent on the presence of Mo might be altered significantly. Much of the scatter observed in corrosion tests on Types 304 and 316 stainless might be attributable to differences in molybdenum surface concentrations brought about by variations in thermal-

mechanical processing as well as other metallurgical factors.

Vibration Characteristics of Crystal Slicing ID Saw Blades

S. E. Forman and W. J. Rhines

Bell Telephone Laboratories, Incorporated, Whippany, New Jersey 07981

ABSTRACT

The natural frequencies and associated mode shapes have been determined for the transverse vibration of three ID saw blades commonly used for crystal wafering. The purpose of the investigation was to determine what frequencies of excitation could excite blade natural frequencies, since excessive blade transverse motion can be a cause of severe crystal and blade damage. The fundamental frequencies for the 4 in. ID-10⅛ in. OD, the 4 in. ID-12 in. OD, and the 6 in. ID-16⅝ in. OD blades, based on a maximum cutting edge hoop stress of 130,000 psi were found to be 780, 640, and 465 Hz, respectively. Experimental measurements have confirmed that cutting edge transverse motion exists with amplitudes up to 0.001 in. but at a frequency equal to the spinning speed, which is always an order of magnitude less than the computed natural frequency.

At the present time the most widely used method of slicing cylindrical crystal ingots into thin wafers is ID sawing. Unlike the more conventional OD saw, the ID saw is extremely thin, is clamped at its outer edge, and has diamond abrasive grit on its inner edge where the cutting is performed. In order to achieve the stiffness necessary to slice crystal ingots, the clamped blade must be placed in a highly tensioned state by one of several available tensioning devices. The basic ingot-blade-wafer system characteristic of the ID sawing process is shown in Fig. 1.

The most important functions of crystal wafering are to provide wafers with flat, parallel sides and to induce a minimum of damage to each side. In order to better understand the interaction of the blade with the ingot it is useful to determine the vibration characteristics of the blade. This allows the determination of excitation frequencies needed to cause resonance of the blade and hence large transverse displacements which could severely damage one or more of the elements in the ingot-blade-wafer system.

There is a great deal of published literature concerning the vibration characteristics of rotating disks. However, in almost every case treated the disk is clamped at its center and free around its outside edge (standard OD saw geometry). Mote presents an excellent listing of many of the theoretical and experimental investigations of vibration characteristics of these disks under various environmental conditions (1). Rhines (2) has made a simplified calculation of the lowest natural frequency of an ID blade as a function of blade tension and blade dimensions. His results were obtained by Rayleigh's method using a one-term approximation for the fundamental mode shape.

In this paper, highly accurate approximations of the fundamental frequency and several higher frequencies are obtained using Lagrange's equations coupled with multiterm series approximations of the associated mode shapes. The calculations are made for the three blade sizes most widely used in the semiconductor industry. In addition, experimental measurements of actual blade transverse motion and its frequency of occurrence are presented.

Vibration Characteristics of Crystal Slicing ID Saw Blades

S. E. Forman and W. J. Rhines

Bell Telephone Laboratories, Incorporated, Whippany, New Jersey 07981

ABSTRACT

The natural frequencies and associated mode shapes have been determined for the transverse vibration of three ID saw blades commonly used for crystal wafering. The purpose of the investigation was to determine what frequencies of excitation could excite blade natural frequencies, since excessive blade transverse motion can be a cause of severe crystal and blade damage. The fundamental frequencies for the 4 in. ID-10⅛ in. OD, the 4 in. ID-12 in. OD, and the 6 in. ID-16⅝ in. OD blades, based on a maximum cutting edge hoop stress of 130,000 psi were found to be 780, 640, and 465 Hz, respectively. Experimental measurements have confirmed that cutting edge transverse motion exists with amplitudes up to 0.001 in. but at a frequency equal to the spinning speed, which is always an order of magnitude less than the computed natural frequency.

At the present time the most widely used method of slicing cylindrical crystal ingots into thin wafers is ID sawing. Unlike the more conventional OD saw, the ID saw is extremely thin, is clamped at its outer edge, and has diamond abrasive grit on its inner edge where the cutting is performed. In order to achieve the stiffness necessary to slice crystal ingots, the clamped blade must be placed in a highly tensioned state by one of several available tensioning devices. The basic ingot-blade-wafer system characteristic of the ID sawing process is shown in Fig. 1.

The most important functions of crystal wafering are to provide wafers with flat, parallel sides and to induce a minimum of damage to each side. In order to better understand the interaction of the blade with the ingot it is useful to determine the vibration characteristics of the blade. This allows the determination of excitation frequencies needed to cause resonance of the blade and hence large transverse displacements which could severely damage one or more of the elements in the ingot-blade-wafer system.

There is a great deal of published literature concerning the vibration characteristics of rotating disks. However, in almost every case treated the disk is clamped at its center and free around its outside edge (standard OD saw geometry). Mote presents an excellent listing of many of the theoretical and experimental investigations of vibration characteristics of these disks under various environmental conditions (1). Rhines (2) has made a simplified calculation of the lowest natural frequency of an ID blade as a function of blade tension and blade dimensions. His results were obtained by Rayleigh's method using a one-term approximation for the fundamental mode shape.

In this paper, highly accurate approximations of the fundamental frequency and several higher frequencies are obtained using Lagrange's equations coupled with multiterm series approximations of the associated mode shapes. The calculations are made for the three blade sizes most widely used in the semiconductor industry. In addition, experimental measurements of actual blade transverse motion and its frequency of occurrence are presented.

Table I. Dimensions and properties of blades

Blade type	Blade dimensions 2a	2b	h
1	4	10⅛	0.004
2	4	12	0.004
3	6	16⅝	0.004

Blade properties

Material: AISI 301 stainless steel
Density, ρ = 0.725 × 10^{-3} lb-sec²/in.⁴
Young's modulus, E = 27.6 × 10^6 psi
0.2% Offset yield stess: 153,000 psi

Analysis

In-plane stress state.—Physically the blade is a thin annular stainless steel plate of inner radius a, outer radius b, thickness h, density ρ, and Young's modulus E. Material properties and typical dimensions of ID blades are given in Table I. It is assumed that the stiffness given to the blade by the tensioning device is analogous to applying a uniform radial load σ_0 to the blade's outer periphery as shown in Fig. 2. At the tensioning stress levels normally used, the contribution to the blade stiffness by the bending rigidity of the blade is negligible and the blade can be treated as an annular membrane.

The in-plane state of stress in the blade is a biaxial one consisting of the radial stress σ_r and the hoop stress σ_θ. Each of these stresses is made up of contributions from tensioning and spinning. The tensioning stresses are given by the well-known formulas (3)

$$\sigma_r = \frac{\sigma_0(1 - a^2/r^2)}{1 - a^2/b^2}$$

$$\sigma_\theta = \frac{\sigma_0(1 + a^2/r^2)}{1 - a^2/b^2} \quad [1]$$

The maximum value of stress due to tensioning is the hoop stress on the cutting edge (at $r = a$), and its magnitude is

$$\sigma_{max} = \frac{2\sigma_0}{1 - \dfrac{a^2}{b^2}} \quad [2]$$

The allowable value of σ_{max} should be sufficiently below the 0.2% offset yield stress of the blade material in order to avoid large amounts of plastic deformation. Strain gauge experiments have shown (4) that for the 4 in. ID-10⅛ in. OD blade the current fully tensioned value of σ_{max} ranges from 100,000 to 130,000 psi and in what follows the value of 130,000 psi will be used for all geometries. At this tensioning stress level the contribution of spinning to the stress state is negligible for the current range of speeds used and will be ignored.

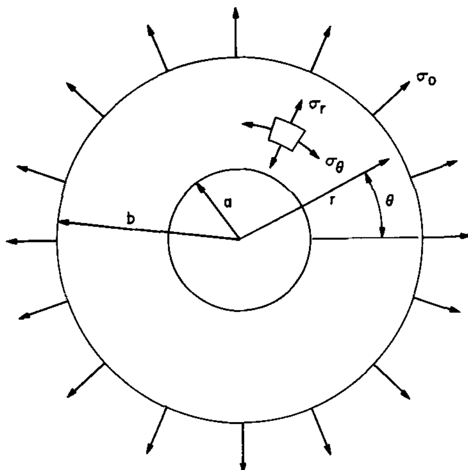

Fig. 2. Model of ID blade used for vibration analysis

Mode shapes and associated natural frequencies.—The differential equation which governs the transverse vibration of the tensioned annular membrane described previously is (5)

$$\rho W_{,tt} - \sigma_r W_{,rr} - \sigma_\theta\left(\frac{1}{r} W_{,r} + \frac{1}{r^2} W_{,\theta\theta}\right) = 0 \quad [3]$$

where W is the transverse displacement of the membrane and partial derivatives are defined using comma notation, *i.e.*, $W_{,r} = \partial W/\partial r$. The geometric boundary conditions are taken to be

$$W = 0 \text{ at } r = b$$

and

$$W = \text{finite at } r = a \quad [4]$$

Because of the form of the in-plane stresses σ_r and σ_θ given by Eq. [1] an exact solution to the previously described boundary value problem cannot be achieved and an approximate technique will be used.

The authors have found it convenient to use Lagrange's equations of motion coupled with a multiterm series representation of the transverse displacement. The displacement is assumed to be of the form

$$W(r,\theta,t) = \left[\sum_{j=1}^{J} A_j(t) \sin\frac{j\pi(b-r)}{2(b-a)}\right]\cos n\theta \quad [5]$$

where n is the number of nodal diameters, j is the number of nodal circles, and $A_j(t)$ is the set of generalized coefficients which are to be determined from Lagrange's equations of motion.

Lagrange's equations of motion for the case of free vibration are (6)

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{A}_i}\right) - \frac{\partial L}{\partial A_i} = 0 \qquad (i = 1 \ldots J) \quad [6]$$

where $\dot{A}_i = \partial A_i/\partial t$ and L is the Lagrangian $T - V$ where T is the kinetic energy and V is the potential energy of the blade. The kinetic energy is given by the formula

$$T = \frac{1}{2}\rho h \int_0^{2\pi}\int_a^b (W_{,t})^2\, r dr d\theta \quad [7]$$

and the potential energy is given by

$$V = \frac{1}{2} h \int_0^{2\pi}\int_a^b \left(\sigma_r (W_{,r})^2 + \frac{\sigma_\theta}{r^2}(W_{,\theta})^2\right) r dr d\theta \quad [8]$$

where σ_r and σ_θ are given by Eq. [1] (1).

Substituting Eq. [5], [7], and [8] into Eq. [6] and performing the indicated differentiations and integrations gives rise to the following equations of motion

$$\sum_{j=1}^{J}\Bigg[\rho h \pi \ddot{A}_j \int_a^b r \sin\frac{j\pi(b-r)}{2(b-a)} \sin\frac{i\pi(b-r)}{2(b-a)}\, dr + \frac{\sigma_0 h \pi A_j}{1 - \dfrac{a^2}{b^2}} \Bigg\{ \frac{\pi^2 ij}{4(b-a)^2} \int_a^b \left(r - \frac{a^2}{r}\right) \cos\frac{j\pi(b-r)}{2(b-a)} \cos\frac{i\pi(b-r)}{2(b-a)}\, dr + n^2 \int_a^b \left(\frac{1}{r} + \frac{a^2}{r^3}\right) \sin\frac{j\pi(b-r)}{2(b-a)} \sin\frac{i\pi(b-r)}{2(b-a)}\, dr \Bigg\}\Bigg] = 0 \qquad i = 1,2,\ldots, J \quad [9]$$

To determine the blade natural frequencies $A_i(t)$ is written in the form

$$A_i(t) = \tilde{A}_j \sin \omega t \quad [10]$$

where ω is the natural frequency of the particular mode being considered. Substituting Eq. [10] into Eq.

[9] results in an eigenvalue problem which can be written in the following matrix notation

$$[K_{ij} - \lambda M_{ij}][\tilde{A}_j] = 0 \qquad \begin{matrix} i = 1, \ldots, J \\ j = 1, \ldots, J \end{matrix} \qquad [11]$$

where

$$\lambda = \frac{\rho(b^2 - a^2)}{\sigma_0}\omega^2 \qquad [12]$$

$$M_{ij} = \int_a^b \frac{r}{b^2} \sin\frac{j\pi(b-r)}{2(b-a)} \sin\frac{i\pi(b-r)}{2(b-a)}\, dr \qquad [13]$$

$$K_{ij} = \frac{\pi^2 ij}{4(b-a)^2} \int_a^b \left(r - \frac{a^2}{r}\right) \cos\frac{j\pi(b-r)}{2(b-a)} \cos\frac{i\pi(b-r)}{2(b-a)}\, dr + n^2 \int_a^b \left(\frac{1}{r} + \frac{a^2}{r^3}\right) \sin\frac{j\pi(b-r)}{2(b-a)} \sin\frac{i\pi(b-r)}{2(b-a)}\, dr \qquad [14]$$

Equation [11] can now be solved using a straightforward eigenvalue-eigenvector computer package. The individual integrals of M_{ij} and K_{ij} are also obtained numerically by a Romberg integration computer routine (7).

For each value of n the value of J is increased (starting at $J = 2$) until less than a 1% error exists between consecutive values of λ for the cases of one to six nodal circles. When this occurs the transverse deflection of a radial cross section associated with the final value of λ is graphically compared with that associated with the previous value of λ. If there appear to be no serious deviations between the two shapes then the last value of λ is taken as the correct eigenvalue. However, if there are deviations on the order of 5% or more at any point of the cross section, J is increased until the deviations are less than 5%. It was in general found that the values of λ converged more rapidly as J increased than did the deviations between mode shapes.

Results and Discussion

The values of the eigenvalue λ associated with several different mode shapes are given in Table II. Calculations have been made for the three blade geometries of Table I. The natural frequency in cycles per second is easily attained from the value of λ by the relation

$$f = \frac{1}{2\pi}\sqrt{\frac{\sigma_{max}\lambda}{2b^2\rho}} \qquad [15]$$

where σ_{max} is given by Eq. [2].

The values of the natural frequencies and sketches showing the nodal circles and nodal diameters of the associated mode shapes are given in Fig. 3, 4, and 5 for the three blade geometries. All calculations have been

based on a maximum hoop stress of 130,000 psi. As indicated in (4), the frequencies associated with the fundamental and 2 nodal diameter-1 nodal circle modes of the 4 in. ID-10⅛ in. OD blade have been verified experimentally to within 10%.

For the particular case of the fundamental mode, the natural frequency decreases from 780 Hz for the smallest blade size (4 in. ID-10⅛ in. OD) to 465 Hz for the largest blade size (6 in. ID-16⅝ in. OD). The usual spinning speeds utilized with the three blade geometries range from 30-40 Hz for the large blade and 50-70 Hz for the other two. Thus, it appears that, for

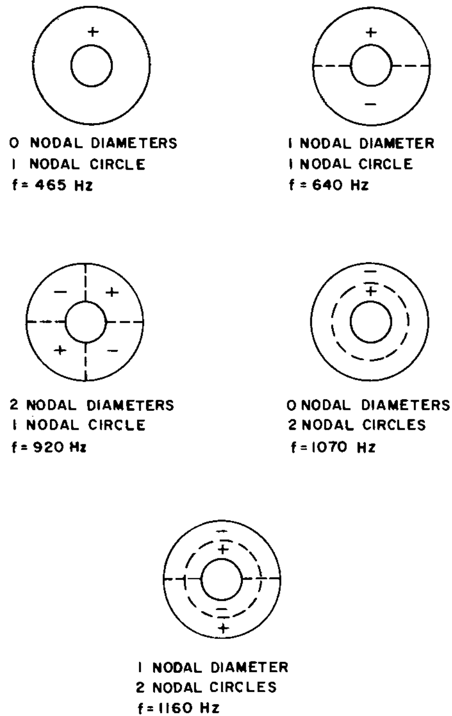

Fig. 5. Computed natural frequencies and associated mode shapes of 6 in. ID-16⅝ in. OD blade (σ_{max} = 130,000 psi).

the range of σ_{max} mentioned earlier, spindle speed is unlikely to be a source of excitation near the fundamental mode unless its magnitude is increased at least ten times.

Typical profiles of the transverse displacement of the radial cross section of a blade are presented for several mode shapes in Fig. 6-10. The number of nodal diameters is listed on each figure and the number of nodal circles is listed on each profile. In each case the displacement has been normalized with respect to the maximum value that occurs between the inner and outer radius. The curves shown are all obtained using $J = 6$ in the series representation of the displacement for the 4 in. ID-10⅛ in. OD blade.

For small numbers of nodal diameters the maximum value of transverse displacement always seems to occur at the cutting edge regardless of the number of nodal circles. This is due to the zero radial stress con-

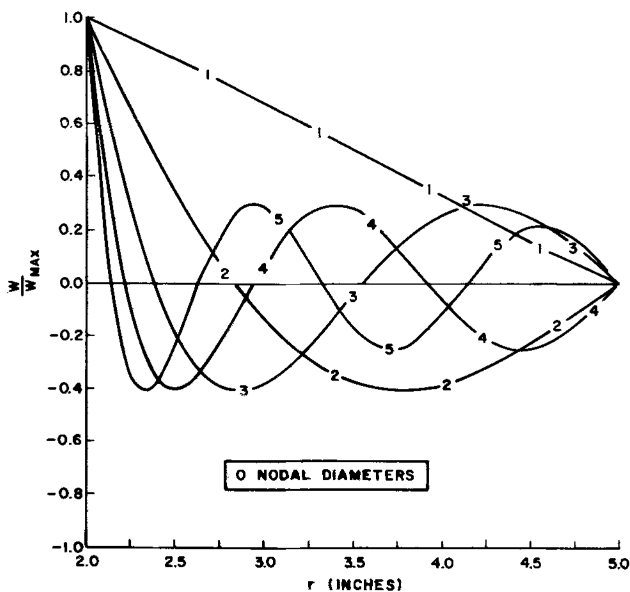

Fig. 6. Radial profiles of 4 in. ID-10⅛ in. OD blade

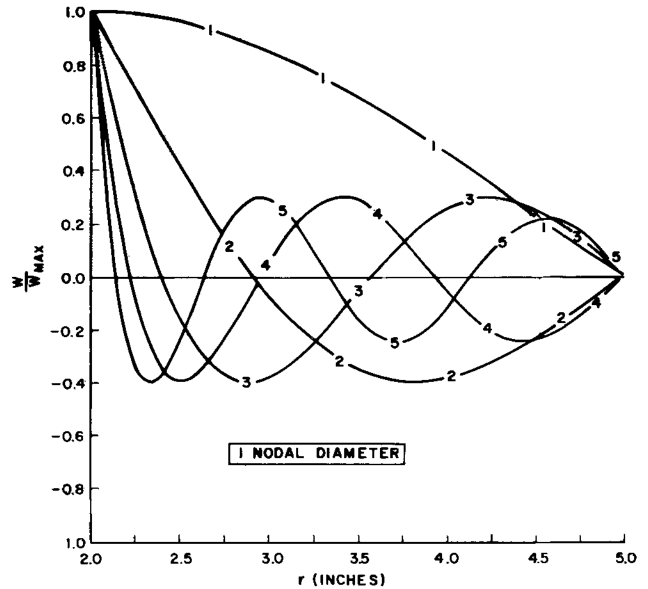

Fig. 7. Radial profiles of 4 in. ID-10⅛ in. OD blade

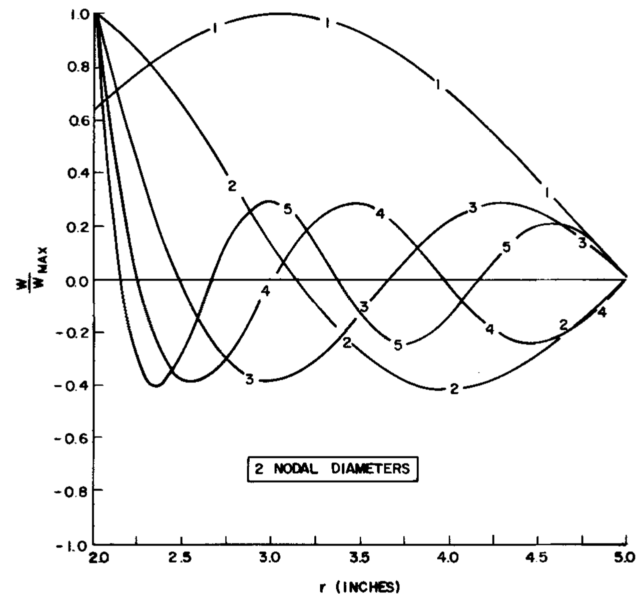

Fig. 8. Radial profiles of 4 in. ID-10⅛ in. OD blade

dition at the inner edge. However as the number of nodal diameters increases, the maximum displacements start occurring away from the cutting edge.

Experimental measurements.—In order to determine the amplitude and frequency of cutting edge transverse motion, a displacement-measuring technique described by Yakunin and Khasdan (8) was used on a current ID slicing machine. They used an "inductive differential detector with a variable air gap." As the air gap between the detector and blade changed, the amplitude and frequency of any transverse displacements from the initial position could be recorded. A device such as this, with a sensitivity that enables it to measure deflections as small as 0.1 ± 0.02 mils (1 mil = 0.001 in.) was used to make the measurements described here (4).

Hand rotation of the blade gave rise to transverse deflections of 0.6-0.7 mils. Spinning the blade without cutting (idling) gave rise to deflections ranging from 0.45 to 0.80 mils depending on the spinning speed. For both hand rotation and idling, the peak to peak displacement occurs once per blade revolution. During the cutting cycle, the transverse displacement spectrum still occurs once per revolution but the amplitude is

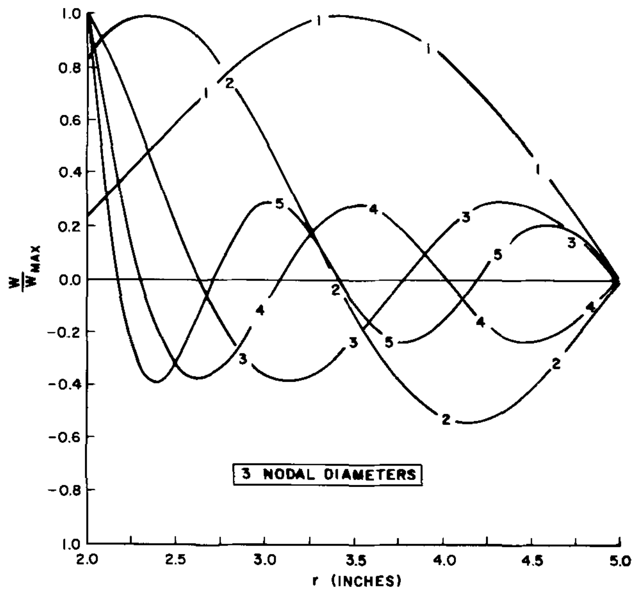

Fig. 9. Radial profiles of 4 in. ID-10⅛ in. OD blade

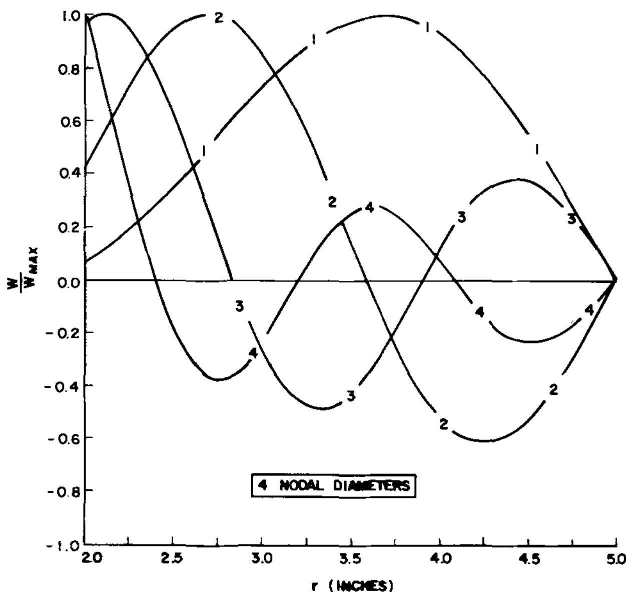

Fig. 10. Radial profiles of 4 in. ID-10⅛ in. OD blade

altered. For a given spinning speed, the amplitude of the idling deflection decreases by 50-60% during feed and by 30-40% during retraction. It is believed that this transverse motion is the cause of the periodic score marks often observed on wafers.

Conclusions

The natural frequencies and associated mode shapes have been determined for the transverse vibration of three ID saw blades widely used in the semiconductor industry. The purpose of the investigation was to determine what excitation frequencies need to exist in order to excite natural frequencies of the blade.

It was found that for all three blades the spinning speeds used are an order of magnitude less than the lowest natural frequency. Since the frequency is directly proportional to the square root of the maximum hoop stress, the range of current maximum hoop stresses (100,000-130,000 psi) would have to be reduced by two orders of magnitude in order for the natural frequency to be on the same order as the spinning speed. The frequency also decreased as a function of the blade surface area, but for the current blade sizes being used the natural frequency is always an order of magnitude greater than the spinning speed. In conclusion, experimental measurements indicate that under present operating conditions, cutting edge transverse motion occurs at a frequency equal to the spinning speed. There is no indication of any blade excitation which occurs at frequencies near the natural frequency.

Mathematics of the Electrochemical Extraction of Hydrogen from Iron

Leonard Nanis* and T. K. Govindan Namboodhiri

The School of Chemical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The transient current of hydrogen removal from iron following steady-state permeation is analyzed theoretically for two limiting conditions at the input side. For the fastest possible removal ($C = 0$ at $X = 0$ and at $X = L$), the amount extracted at the potentiostated side ($X = L$) is one third of the total present at steady-state permeation described by $C_{(X)} = C_o(1 - X/L)$. Comparison of the integrated total flux and the amount given by the integral of $C_{(X)}$ indicates possible concentration dependence of hydrogen diffusivity in iron.

The study of diffusion of hydrogen through metals has attracted much interest because of its relation to the problem of hydrogen embrittlement. The electrochemical permeation technique (1) for measurement of diffusion of hydrogen in metals has been extensively employed recently (2, 3). The mathematical basis of this method was developed by McBreen *et al.* (4). This paper presents some results and conclusions concerning permeation in Armco iron based on an extension of the theory and application of permeation technique to provide additional information regarding hydrogen entry and extraction from metals.

The permeation method.—In the electrochemical permeation method, a thin membrane of the material is cathodically charged with hydrogen on one side, while the hydrogen diffusing out at the opposite side is oxidized by maintaining anodic conditions. Mathematically, this procedure provides the boundary condition

$$C = 0, \quad X = L, \quad t \geq 0 \qquad [1]$$

The current needed to maintain the constant anodic potential is a direct measure of the rate at which hydrogen is diffusing out.

McBreen *et al.* (4) solved the diffusion equation (Fick's second law)

$$\frac{\partial^2 C}{\partial X^2} - \frac{1}{D}\frac{\partial C}{\partial t} = 0 \qquad [2]$$

applying the pertinent initial condition

$$C = C_o(1 - X/L) \qquad [3]$$

and boundary conditions to get expressions for the decay of permeation current from the steady state when the charging is stopped.

Two limiting decay transients were considered. For the fastest possible extraction, the concentration at the input side is considered to drop instantaneously to zero upon input current interruption, *i.e.*

$$C = 0, \quad X = 0, \quad t > 0 \qquad [4]$$

where time is reckoned from the instant of interruption. Slowest possible extraction through the potentiostated side Eq. [1] is based on the assumption of zero flux at the input side, *i.e.*, after current interruption, the input side ($X = 0$) becomes impermeable to hydrogen, described as

$$\frac{\partial C}{\partial X} = 0, \quad X = 0, \quad t > 0 \qquad [5]$$

Using Laplace transform methods, McBreen *et al.* (4) obtained for the slowest possible decay (Eq. [5], [1], [3], and [2]), the flux in terms of the previous steady-state value (J_x) as

$$\frac{J_\tau}{J_x} = 1 - 2\sum_{n=0}^{\infty} (-1)^n \operatorname{erfc}\frac{2n+1}{2\tau^{1/2}} \qquad [6]$$

where $\tau = Dt/L^2$, a dimensionless time parameter.

Solving Eq. [2] with Eq. [1], [3], and [4], the fastest possible extraction gives

$$\frac{J_\tau}{J_x} = 1 - 2\sum_{n=0}^{\infty} \frac{1}{\pi^{1/2}}\frac{1}{\tau^{1/2}} e^{\frac{[2n+1]^2}{4\tau}} \qquad [7]$$

It should be noted that Eq. [7] is a corrected version of a previous result (4).

The decay part of the permeation technique has been mostly neglected by previous workers. However, the decay transient is a source of additional information regarding the diffusivity and solubility of hydrogen in the membrane and of the nature of the reaction at the input metal-electrolyte interface. In particular, the time integral of flux from $X = L$ reflects the total amount of hydrogen extracted at this side and is equal to the total hydrogen in the membrane if the input side is impermeable according to Eq. [5]. The total amount at steady state ($t = 0$) is readily obtained from the product of average concentration (integral of Eq. [3]) and the volume of the permeated region of the membrane. Thus, integration of experimental decay curves of current *vs.* time should permit evaluation of the number of mols of hydrogen extracted for comparison with the prediction according to Eq. [3] using the value of C_o, which, in turn, is obtained from the steady-state permeation current density and the diffusivity derived from the build-up transient.

When the boundary conditions are such that the decay follows Eq. [7], *i.e.*, fast decay, the amount of hydrogen extracted at the potentiostated side ($X = L$) is only a fraction of the total amount in the membrane at steady-state permeation. The remaining part of the hydrogen diffuses out through the input side ($X = 0$) in order to satisfy the boundary condition given by Eq. [4]. Hence, in order to calculate the hydrogen concentration of the membrane at steady-state permeation, it is essential to have an estimate of the relative amounts of hydrogen diffusing out at both sides of the membrane ($X = 0$ and $X = L$). The following mathematical analysis was performed to get these values.

Mathematics of fast decay.—Consider a membrane of thickness L which is charged from the side $X = 0$ and potentiostated at $X = L$ in order to maintain a zero concentration of hydrogen. During charging, a hydrogen concentration C_o is maintained at $X = 0$. The steady-state concentration profile obtained by charging is described by Eq. [3]. This profile becomes the initial

* Electrochemical Society Active Member.

Key words: hydrogen dissolution in iron, hydrogen extraction, hydrogen diffusion, concentration-dependent diffusivity, permeation.

condition used together with the boundary conditions Eq. [1] and [4] to solve Eq. [2], with time measured from the instant of input current interruption. The solution sequence is to (*i*) obtain concentration of hydrogen as a function of time and position in the region $0 < X < L$; (*ii*) obtain the gradient of concentration at $X = 0$, $X = L$ to determine flux; and (*iii*) integrate each flux with respect to time over the entire range $0 < t < \infty$. Both separation of variables and Laplace transform methods were used.

Solution by the method of separation of variables.—The concentration of hydrogen within the membrane during the fast decay was obtained as

$$C = \frac{2C_o}{\pi} \sum_{n=1}^{\infty} \frac{1}{n} \sin \frac{n\pi X}{L} e^{-\frac{n^2\pi^2 Dt}{L^2}} \quad [8]$$

Differentiating Eq. [8] with respect to X gives

$$\frac{\partial C}{\partial X} = \frac{2C_o}{L} \sum_{n=1}^{\infty} \cos \frac{n\pi X}{L} e^{-\frac{n^2\pi^2 Dt}{L^2}} \quad [9]$$

Substituting $X = 0$ in Eq. [9], the gradient at the input surface is

$$\left.\frac{\partial C}{\partial X}\right|_{X=0} = \frac{2C_o}{L} \sum_{n=1}^{\infty} e^{-\frac{n^2\pi^2 Dt}{L^2}} \quad [10]$$

and for $X = L$, Eq. [9] gives the gradient as

$$\left.\frac{\partial C}{\partial X}\right|_{X=L} = \frac{2C_o}{L} \sum_{n=1}^{\infty} (-1)^n e^{-\frac{n^2\pi^2 Dt}{L^2}} \quad [11]$$

The flux F (mol cm^{-2} sec^{-1}) of material diffusing across each surface is obtained from Eq. [10] and [11] with Fick's first law as

$$F = -D \frac{\partial C}{\partial X} \quad [12]$$

The total amount per unit area, Q_E, of hydrogen diffusing out at each surface is obtained by integrating the flux, F, over the entire range of time. Hence, the amount of hydrogen evolved at $X = 0$ is

$$\left.Q_E\right|_{X=0} = \int_0^{\infty} F_{(X=0)}\, dt = \frac{-2C_oD}{L} \int_0^{\infty} \left[\sum_{n=1}^{\infty} e^{-\frac{n^2\pi^2 Dt}{L^2}} \right] dt \quad [13]$$

Integrating in Eq. [13] term by term gives a well-known convergent series as

$$\left.Q_E\right|_{X=0} = -\frac{2C_oL}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{-C_oL}{3} \quad [14]$$

In a similar fashion, Eq. [11] and [12] give

$$\left.Q_E\right|_{X=L} = \frac{-2C_oL}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} = \frac{C_oL}{6} \quad [15]$$

The sign of Q_E in Eq. [14] and [15] reflects the vectorial character of the flux with respect to the coordinate system. It is thus appropriate to consider absolute values to obtain the total amount extracted, Q_{Tot}, as

$$Q_{Tot} = |Q_E|_{X=0} + |Q_E|_{X=L} = \frac{C_oL}{2} \quad [16]$$

The amount stored in the membrane (per unit area) at steady state before current interruption ($t < 0$) is readily determined by integration of Eq. [3] as $C_oL/2$ (mol cm^{-2}), in agreement with Eq. [16]. Hence, the fraction of hydrogen diffusing out at $X = 0$ is

$$\frac{|Q_E|_{X=0}}{Q_{Tot}} = \frac{2}{3} \quad [17]$$

and the fraction diffusing out at $X = L$ is

$$\frac{|Q_E|_{X=L}}{Q_{Tot}} = \frac{1}{3} \quad [18]$$

Solution by Laplace transforms.—To check the results obtained as Eq. [17] and [18], Eq. [2], [3], [1], and [4] were solved using the method of Laplace transforms. The concentration of hydrogen within the membrane during fast decay is given by

$$C(x,t) = C_o(1 - X/L) - C_o \sum_{n=0}^{\infty} \text{erfc} \left\{ \frac{2nL + X}{2\sqrt{Dt}} \right\} + C_o \sum_{n=0}^{\infty} \text{erfc} \left\{ \frac{2L(n+1) - X}{2\sqrt{Dt}} \right\} \quad [19]$$

Differentiating Eq. [19] with respect to X, and multiplying the slopes by $-D$, the flux (Eq. [12]) at $X = 0$ is

$$\left.F\right|_{X=0} = \frac{DC_o}{L} \left[1 - \frac{1}{\sqrt{\pi\tau}} \left[\sum_{n=0}^{\infty} e^{\frac{-n^2}{\tau}} + \sum_{n=0}^{\infty} e^{\frac{-(n+1)^2}{\tau}} \right] \right] \quad [20]$$

and the flux at $X = L$ is

$$\left.F\right|_{X=L} = \frac{DC_o}{L} \left[1 - \frac{2}{\sqrt{\pi\tau}} \sum_{n=0}^{\infty} e^{\frac{-(2n+1)^2}{4\tau}} \right] \quad [21]$$

Equations [20] and [21] have to be integrated with respect to τ over the range $0 < \tau < \infty$ to get the total amounts of hydrogen diffusing out at the surfaces $X = 0$ and $X = L$, respectively. Equations [20] and [21] both become infinite for $\tau = 0$. Also, for $\tau = \infty$, the integral of Eq. [20] and [21] becomes infinite because of the term of unity. Hence, with an analytic solution of the integrals not possible, a graphical integration was performed since the summations in Eq. [20] and [21] converge rapidly for numerical evaluation. The results are in good agreement (within 2%) of the values in Eq. [17] and [18]. Equations [19], [20], and [21] are useful in preparing tables and curves for short time, since Eq. [8], [10], and [11] are very slowly convergent for $\tau < 0.05$. The $n = 0$ term of Eq. [21] is sufficient even up to $\tau \leq 0.3$ and provides a simple form.

Thus, during fast decay, only one third of the total amount of hydrogen diffuses out through the potentiostated side ($X = L$), and provides a lower bounding limit, while the upper limit $[(Q_{EX=L})/(Q_{ETot}) = 1]$ is obtained during the slow decay because of the condition imposed by Eq. [5]. Comparison of the extracted amount of hydrogen with the value predicted from the initial concentration profile (Eq. [3]) thus provides further insight as to the nature of the boundary condition existing at $X = 0$ during decay, with Eq. [4] and [5] as limits.

Experimental Results

Hydrogen permeation experiments were performed with the potentiostat circuit as essentially described by McBreen *et al.* (4). A constant current circuit was used for the cathode input side of the membrane. Build-up and decay transients were recorded for various charging current densities in 0.2*N* NaOH and 0.1*N* H_2SO_4 catholytes for annealed Armco iron at 22°C. The anolyte was always 0.2*N* NaOH.

* Numerical values for the build-up permeation-time curve may be computed by subtracting the right-hand side of Eq. [7] from unity.

By fitting the experimental build-up curves to theory (4), hydrogen diffusivity, D, and surface concentration, C_o, were evaluated. It should be noted that there is no total agreement between theory and data over the entire build-up time span. By minimizing the misfit at different time intervals, a corresponding best fitted diffusivity may be computed. The trend suggests that diffusivity increases with hydrogen concentration. This aspect will be fully explored in forthcoming publications.

In the present computations of C_o from the steady-state permeation current, the diffusivity value is that obtained by a best fit to the build-up theory for early time. This value of D may be seen to be the most appropriate choice since the hydrogen arriving at $X = L$ at the time of breakthrough has traversed a region free of hydrogen. At steady state, the flux at $X = L$ is given by Eq. [12] with, however, the implicit feature given in Eq. [1], namely that the local diffusivity (allowing for possible concentration dependence) corresponds to the zero concentration value. Based on this value of C_o and the steady-state concentration profile given by Eq. [3], the total amount of hydrogen, Q_{Tot}, held within the membrane was calculated to be

$$Q_{Tot} = \frac{1}{2} C_o V \qquad [22]$$

where V = volume of the charged section of the membrane.

An estimate of the amount of hydrogen extracted at the potentiostated side ($X = L$) was obtained by measuring the area beneath the decay current-time traces and converting to equivalents of hydrogen. This value was then compared with Q_{Tot} to obtain the ratio $|Q_E|_{X=L}/Q_{Tot}$. Table I shows the results obtained for permeation from $0.1N$ H_2SO_4. Figure 1 shows the decay transients which were compared with the two theoretical decay curves (fast, Eq. [7], and slow, Eq. [6]) to yield average D values given in columns 3 and 4 of Table I. Also indicated in this table are the D values obtained from build-up transients, based on the best fit over all time. As mentioned previously, the diffusivity at small time was used for calculating Q_{Tot} in column 5. This value is 4.0×10^{-5} cm² sec^{-1}. Comparison of the two possible decay-fitted values with the build-up D indicates clearly that the boundary condition given by Eq. [4] is most likely. The ratio $|Q_E|_{X=L}/Q_{Tot}$ in Table I varies from the theoretical limit of 0.33 for fast decay to even smaller values. Thus, the charging at 0.021 mA/cm² follows the expected behavior and also gives the best fit over-all in Fig. 1. However, charging at higher currents produces a shift of the decay curves to shorter times, indicating an increase in D, listed in Table I. The decrease in $|Q_E|_{X=L}/Q_{Tot}$ from 0.334 to 0.235 as charging current increases brings these values into a region below the lower numerical limit calculated in Eq. [18]. This negative deviation from the

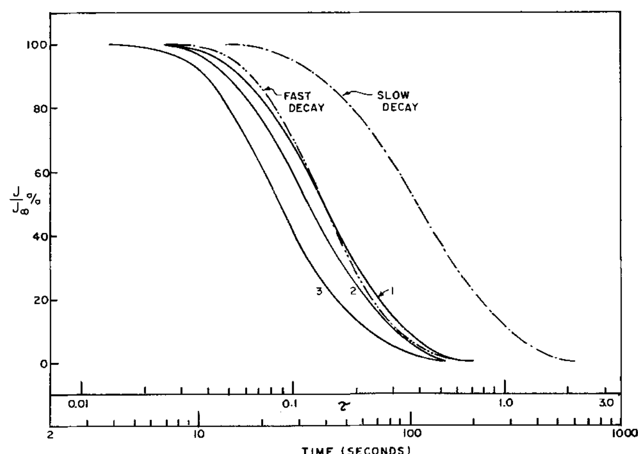

Fig. 1. Decay transients for Armco iron, $0.1N$ H_2SO_4. Catholyte, 22°C. Charging current densities (mA/cm²) are: curve 1, 0.021; curve 2, 0.194; and curve 3, 2.13.

limit based on constant diffusivity theory is in accord with a diffusivity which increases with increasing concentration. For such concentration dependence of D, the basic Eq. [2] and subsequent results are no longer applicable. Qualitatively, however, the concentrated region near $X = 0$ should provide a more rapid flux and an amount $|Q_E|_{X=0}$ greater than predicted by Eq. [14]. Thus, the flux and amount at $X = L$ will be less than that predicted in Eq. [15], causing the values for $|Q_E|_{X=L}/Q_{Tot}$ to be less than the theoretical constant D limit of 0.333.

During permeation experiments using $0.1N$ H_2SO_4 as catholyte, a cathodic protection current of 0.0215 mA/cm² was always applied to prevent corrosion of the Armco iron membrane. Permeation build-up and decays were then recorded by applying a cathodic current from a separate circuit. The response of the cathode ($X = 0$) to step current switching was sufficiently rapid so as to produce a virtually potentiostated surface when compared with the orders of magnitude greater diffusion-controlled hydrogen decay time. Thus, the boundary condition in Eq. [4] is assured.

When $0.2N$ NaOH catholyte was used, corrosion was not a severe problem, so that no cathodic protection was needed. Figure 2 shows decay transients observed for this case. Table II gives the D values and $|Q_E|_{X=L}/Q_{Tot}$ ratios obtained from these data. Best over-all fitting in Fig. 2 was found for the short time region for the 0.86 mA/cm² study. For lesser and greater cathodic input current densities, no clear pattern of shifting was observed as found for $0.1N$ H_2SO_4 (Fig. 1). In Table II, the build-up and decay determined D values

4.30	5.25	4.96	12.95	0.326

do not change appreciably with charging current, in contrast with results for 0.1N H_2SO_4 (Table I). The ratio $|Q_E|_{X=L}/Q_{Tot}$ ranges from 0.326 to 0.372, in good agreement with the lower limit of 0.333 associated with fast decay.

Discussion and Conclusions

Testing of the present decay mathematics shows unexpected lower than theoretical values for $|Q_E|_{X=L}/Q_{Tot}$ for 0.1N H_2SO_4. In combination with the shift of the build-up transients to shorter time with increased current, the data provide strong evidence for a hitherto unsuspected concentration dependence of hydrogen diffusivity in iron. The evidence suggests that D increases with increasing concentration. For 0.2N NaOH and 0.1N H_2SO_4, the fit of the decay current-time curve in comparison with the build-up curve and also the $|Q_E|_{X=L}/Q_{Tot}$ ratio values are best associated with a surface condition at $X = 0$ which corresponds to zero hydrogen concentration. From the trend of $|Q_E|_{X=L}/Q_{Tot}$ values below the constant D limit of 0.333, it is probable that, for similar charging current, the concentration of hydrogen in iron is greater in the 0.1N H_2SO_4 catholyte than in the 0.2N NaOH solution.

In testing the possibility that traps may be contributing to the nonconstant diffusivity, the phenomenological diffusivity discussed by Oriani (5) should always be less than the true lattice diffusivity. As predicted (5), the true lattice diffusivity is 3.06×10^{-5} cm² sec⁻¹ at 22°C, in good agreement with the lowest values in Tables I and II, *i.e.*, 5×10^{-5} cm² sec⁻¹. As shown, the D values increase to about 8×10^{-5} cm² sec⁻¹ with increasing current, so that trapping is an unlikely alternative to the presently suggested concentration dependence.

Standard Potentials of Ag-AgCl Electrode and Related Thermodynamic Quantities in Dimethyl Sulfoxide-Water Mixtures from 5° to 45°C

Rabindra N. Roy, William Vernon, Alfred Bothwell, and James Gibbons

Department of Chemistry, Drury College, Springfield, Missouri 65802

ABSTRACT

EMF measurements were performed at 5°, 15°, 25°, 35°, and 45°C on the cell of the type Pt|H_2 (g, 1 atm)|HCl (m), DMSO (X), H_2O (Y)|AgCl,Ag, where X = 5, 10, and 20 w/o (weight per cent) dimethyl sulfoxide (DMSO). The standard potentials were evaluated by means of a curve-fitting program. The mean molal activity coefficients of HCl have been determined for molalities from 0.001 to 0.1 mol kg⁻¹. The cell has also been used to derive (*i*) the primary medium effect on HCl, (*ii*) the relative partial molal enthalpy (L_2) of HCl, and (*iii*) the thermodynamic constants $\Delta G°$, $\Delta H°$, and $\Delta S°$ for the transfer of HCl from water to the respective solvent compositions (X = 5, 10, and 20). The standard emf has been expressed as a function of temperature. The electrostatic contribution of the Gibbs free energy of transfer has been calculated, based on Born's model, and the results have been interpreted in terms of acid-base interactions, as well as the structure-breaking processes of the solvents.

The behavior of electrolytes in dipolar, aprotic solvent-water media such as tetrahydrofuran (THF)-water (1), 1, 2 dimethoxyethane (DME)-water (2, 3) are of interest in understanding acid-base interactions, ionic solvation, and association phenomena of solution chemistry. Mixtures of dipolar aprotic solvent (DMSO) with water (4, 5), have been found to strongly accelerate the rates of many reactions involving nucleophiles or bases (6, 7). Although the chemistry of pure DMSO has been the subject of numerous investigations (8-10), no thermodynamic information for this electrolyte in DMSO-water mixtures (X = 5, 10, and 20), where X = weight per cent (w/o) of DMSO, has been reported to date. The present work is based on emf measurements on the cell, without liquid junction, Pt|H_2 (g, 1 atm)|HCl (m), DMSO (X), H_2O (Y)|AgCl,Ag at 5°,

Key words: dimethyl sulfoxide, medium effect, activity coefficient, mixed solvents standard emf, thermodynamic.

15°, 25°, 35°, and 45°C. As a prerequisite to studies of acid-base equilibria, solvent effects on rates, instability constants, solubilities, and structures of solvents, we have reported the results on (*i*) the standard emf of the cell for $X = 5$, 10, and 20, (*ii*) the activity coefficient of HCl, (*iii*) the primary medium effect, (*iv*) the relative partial molal enthalpy of HCl, and (*v*) the thermodynamic functions for the transfer of one mole of the acid from the aqueous standard state to the standard state in the mixed solvents.

Experimental

DMSO (Fisher spectroanalyzed) was used without further purification, and the label indicated the water content to be 0.02%. The solvent had a dielectric constant of 46.7 at 25°C.

An aqueous stock solution of hydrochloric acid was prepared from twice-distilled, constant-boiling acid. Analytical reagent grade acid was used to make up the constant-boiling acid. The acid was standardized by a gravimetric determination of chloride as AgCl. The average difference among replicate determinations was less than ±0.03%. The bromide content was found to be less than 0.002 m/o (mole per cent). The distilled water used in the preparation of the solutions had a conductance of $0.7\text{-}0.8 \times 10^{-6}$ $\text{ohm}^{-1}\ \text{cm}^{-1}$. The mixed solvents were prepared by weighing DMSO, water, and hydrochloric acid. All solutions were freshly prepared before each run. The acid concentration was known to within ±0.02%.

The silver-silver chloride electrodes were of the thermal electrolytic type (11) and were aged in 0.1m HCl, which was deoxygenated by bubbling hydrogen. Two days after preparation, the finished electrodes were intercompared and had bias potentials usually less than ±0.02 mV. The hydrogen electrodes were lightly coated with platinum black, according to the recommendations of Hills and Ives (12).

The purification of the hydrogen gas and other experimental details have been described previously (13).

All measurements were made with two Ag-AgCl electrodes and two hydrogen electrodes. The equilibrium was reached in about 3-4 hr after the initiation of hydrogen bubbling. The potentials of the cell were measured at 5°, 15°, 25°, 35°, and 45°C by means of a K-3 Universal Type Potentiometer which was calibrated against an Eppley standard cell. A mirror-type galvanometer with a sensitivity of ±0.02 mV per division was used. The thermostat maintained a temperature within ±0.01°C.

The emf usually was measured at 25° at the beginning, in the middle, and at the end of each run. These three readings agreed within ±0.09 mV. The average value is given in Table I. The criterion for the attainment of equilibrium was a steady reading to the nearest 0.1 mV for a period of about 1 hr. Each emf value recorded in Table I is the average of two pairs of electrodes in the same cell. Observed values of emf have been converted to a hydrogen partial pressure of 1 atm. The dielectric constant (D) of the mixed solvent at each Celsius temperature, t, was calculated from the equations

$$\log D\ (X = 5) = 1.8938 - 0.00204(t - 25°) \quad [1]$$

$$\log D\ (X = 10) = 1.8925 - 0.00204(t - 25°) \quad [2]$$

and

$$\log D\ (X = 20) = 1.8888 - 0.00204(t - 25°) \quad [3]$$

derived from the data of Tommila and Pajunen (15). The density, ρ_0, of each of these mixtures, at different temperatures, was obtained by an interpolation and extrapolation procedure from the literature (15).

DMSO has a very low vapor pressure. In order to correct the emf to a hydrogen partial pressure of 1 atm, vapor pressures of the solvent components were assumed to obey Raoult's law, and were so calculated.

[a] Accuracy of molality within 0.05%.

Results

Standard emf.—The most common method used to evaluate the standard potential involves the graphical extrapolation of some linear plot of emf of the cell against the concentration of hydrochloric acid, as in the following equations (16)

$$E^{\circ\prime} = E + 2k\ \log \mathrm{m} - 2ks_f c^{1/2}/(1 + a_0 B c^{1/2}) - 2k\ \log\ (1 + 0.002\mathrm{m}M_{xy}) = E^{\circ}_{\mathrm{m}} + f(\mathrm{m}) \quad [4]$$

where E°_{m} is the standard potential of the cell on the molal (m) scale, E is the observed electromotive force of the cell, c is the molarity of HCl, a_0 is the ion-size parameter, M_{xy} is the mean molecular weight, $k = 2.3026RT/\mathbf{F}$, and B and s_f are the Debye-Hückel constants. In this paper, we report the results of E°_{m} determined by a theoretically justified polynomial curve-fitting program, which does not require the above information such as the ion-size parameter, the Debye-Hückel constants, the densities, and the dielectric constants of the mixed solvents. It is indeed attractive to contemplate the derivation of E°_{m} without the information required in the Gronwall, LaMer, and Sandved (17) extension of the Debye-Hückel theory.

Sen, Johnson, and Roy (18) and our recent papers (19-21) have convincingly demonstrated that an equation of the form

$$E + (2RT/\mathbf{F}) \ln \mathrm{m} = E^{\circ} + A_1\mathrm{m}^{1/2} + A_2\mathrm{m} + A_3\mathrm{m}^{3/2} + \ldots \quad [5]$$

is theoretically sound and accurately expresses the standard potential.

The activity coefficient (on molal scale) can be expressed by the equation (18)

$$\ln \gamma_{\pm} = A_1'\mathrm{m}^{1/2} + A_2'\mathrm{m} + A_3'\mathrm{m}^{3/2} + \ldots \quad [6]$$

where coefficients in Eq. [5] and [6] are not arbitrary adjustable parameters. The form of Eq. [6] has been shown to be consistent with the theory (22).

Table II summarizes the values of the standard potentials on three scales, namely the molal (m), molar (c), and mole fraction (N) scales in DMSO-water

mixtures. The values of $E°_m$ are expressed as a function of t(°C) by the equations

5% DMSO

$$E°_m = 0.2179 - 7.085 \times 10^{-4}(t - 25°) - 9.782 \times 10^{-7}(t - 25°)^2 \quad [7]$$

10% DMSO

$$E°_m = 0.2147 - 6.840 \times 10^{-4}(t - 25°) + 5.807 \times 10^{-6}(t - 25°)^2 \quad [8]$$

20% DMSO

$$E°_m = 0.2119 - 6.704 \times 10^{-4}(t - 25°) + 3.300 \times 10^{-6}(t - 25°)^2 \quad [9]$$

The standard potentials on the molar and mole fraction scale, $E°_c$ and $E°_N$, respectively, have been calculated by means of the relationships

$$E°_c = E°_m + 2k \log \rho_o \quad [10]$$

and

$$E°_N = E°_m - 2k \log (1000/M_{xy}) \quad [11]$$

where ρ_o is the density of the mixed solvent at the particular temperature, and M_{xy} is the mean molecular weight of the solvent.

The mean molal activity coefficients of hydrochloric acid, ${}_s\gamma_\pm$, in DMSO-water mixtures at 25°C were computed from the equation

$$\log {}_s\gamma_\pm = [E°_m - \{E + (2RT/F) \ln m\}]/(4.6052RT/F) \quad [12]$$

using the respective values of $E°_m$ listed in Table II. The smoothed values of $\{E + (2RT/F) \ln m\}$ at rounded molalities were obtained from the constants of Eq. [5] and the values of ${}_s\gamma_\pm$ are presented in Table III.

The primary medium effect (ion-solvent interaction) is concentration-independent and measures the change in escaping tendency of HCl in the transfer from a standard state in one solvent to a standard state in another solvent. Thermodynamically, it can be represented as

$${}^wE°_m - {}^sE°_m = \lim_{m \to 0} (4.6052RT/F) \log {}^s{}_w\gamma_\pm \quad [13]$$

Table III. Mean activity coefficients (${}_s\gamma_\pm$) of hydrochloric acid in 5, 10, and 20 w/o dimethyl sulfoxide at 25°C

10	0.0263	0.0631	0.0435
20	0.0637	0.0983	0.0737

where the value of ${}^sE°_m$ is the same as $E°_m$. The superscripts w and s on $E°_m$ represent water and the mixed solvent, respectively. The subscripts w and s on $\gamma_\pm$ mean that $\gamma_\pm$ is referred to unity at infinite dilution in water and in a mixed solvent, respectively. These values are presented in Table IV.

Relative partial molal enthalpy.—The relative partial molal enthalpies of HCl for 5 w/o DMSO at five different temperatures were computed with the following equations (23)

$$L_2 = \overline{H} - \overline{H}^\infty = \overline{H} - \overline{H}° = -2RT^2\delta(\ln {}_s\gamma_\pm)/\delta T \quad [14]$$

The ($\delta \ln {}_s\gamma_\pm/\delta T$) value required by Eq. [14] was obtained from the first derivative of the least square polynomial

$$-\log {}_s\gamma_\pm = A + BT + CT^2 \quad [15]$$

where T is the thermodynamic temperature. The constants of Eq. [15] are given in Table V, together with the standard error of the calculated values of $\log {}_s\gamma_\pm$.

Combination of Eq. [14] and [15] yields

$$L_2 = (2RT^2 \ln 10)(B + 2CT) \quad [16]$$

The values of L_2 are given in Table VI.

Standard Gibbs energy, entropy, and enthalpy of transfer of HCl from water to the mixed solvent.—The standard thermodynamic functions for the transfer process (t)

HCl (in H_2O) → HCl (DMSO-water media)

in three DMSO-water mixtures were calculated from the standard emf of the cell in water (16) and in the mixed solvent together with the temperature coefficients of $E°_m$ in water and the respective mixed solvents. The Gibbs energy of transfer is defined by the equation

$$\Delta G°_{t(HCl)} = {}_s\overline{G}°_{HCl} - {}_w\overline{G}°_{HCl} = {}_s\Delta G°_{HCl(soln)} - {}_w\Delta G°_{HCl(soln)} \quad [17]$$

where $\overline{G}°_{HCl}$ represents the molar Gibbs energy in the

[a] ΔG° and ΔH° are expressed in joules mole^{-1} and ΔS° in joules K^{-1} mole^{-1}.

mixed solvent (s) and water (w), respectively. The effect of the solvent on transfer Gibbs energy has been calculated on the mole fraction scale which does not contain the change of the number of solvent molecules by different solvents; therefore, it will eliminate Gibbs energy changes due to concentration changes. The pertinent relationship for the transfer Gibbs energy is given by

$$\Delta G^\circ_t = \mathbf{F}({}^wE^\circ_N - {}^sE^\circ_N) \qquad [18]$$

The values of this quantity are given in Table VII

The transfer of charged particles, the hydrogen ion and chloride ion, from water to DMSO-water mixtures can be thought of in three stages: (*i*) desolvation of the ions in water, (*ii*) transfer of H^+ and Cl^- to the mixed solvent (s), and (*iii*) resolvation of the ions in the mixed solvent (s). The parameters that adequately describe the effect of this changing solvent composition on the transfer Gibbs energy are not yet well understood. It is convenient, however, to divide the transfer energy into two parts (24-26)

$$\Delta G^\circ_t = \Delta G^\circ_{el} + \Delta G^\circ_{chem} \qquad [19]$$

The electrostatic term, ΔG°_{el}, represents the coulombic forces between the ionic charge and the charge distributions on the solvent molecules. All other effects, including the basicity and the difference in work required to create a cavity for the ions in the two media, contribute to the second term (24, 27). The electrostatic contributions to the transfer energy has been computed from the Born equation

$$\Delta G^\circ_{el} = (Ne^2/2)(D_s^{-1} - D_w^{-1})(r_+^{-1} + r_-^{-1}) \qquad [20]$$

where D_s and D_w represent the dielectric constants of the mixed solvent and water, respectively. The radius of the "hydrogen ion" (r_+) is taken as 2.76Å (28) and that of the chloride ion (r_-) is taken as 1.81Å (29). The values of ΔG°_{chem} have been obtained by subtracting the electrostatic free energy from the total transfer quantity. Table VII summarizes the values of these quantities.

By the application of the usual thermodynamic relationship

$$\Delta S^\circ_t = -d(\Delta G^\circ_t)/dT \qquad [21]$$

to the temperature variation of E°_m, one obtains

$$\Delta S^\circ_t = \mathbf{F}[(a + 2bT - 50b - k) - (a_w + 2b_wT - 50b_w - k_w)] \qquad [22]$$

where a and b are the second and third coefficients of Eq. [7] to [9]. The values of a_w and b_w are given in the literature (16); the constant $k = (2R/\mathbf{F})\ln(1000/M_{xy})$, and k_w (a constant) is taken as 6.92×10^{-4}. The values of ΔS°_t are given in Table VII.

The values of the transfer enthalpy, shown in Table VII, were obtained from the relation

$$\Delta H^\circ_t = \Delta G^\circ_t + T\Delta S^\circ_t \qquad [23]$$

The values of the electrostatic energy, ΔG°_{el}, may be accurate, but the experimental uncertainties in the values of ΔH°_{el} and ΔS°_{el} will be greater; hence, no attempts were made to calculate these quantities. The correct evaluation of the values of ΔG°_{el} is hampered by the uncertainties of effective ionic radii and the variation of the dielectric constant with distance from the ionic surface (dielectric saturation). Nevertheless, the values of ΔG°_{el} (and hence ΔG°_{chem}) can be considered sufficiently significant to draw some general conclusions which are qualitatively correct.

Discussion

The values of the activity coefficient, Table III, for X = 5, 10, and 20 at 25°C decrease (at a given molality) with the increasing proportions of DMSO. The general pattern of this trend is similar to that found in our other investigations, such as glycerol-water (30), isopropyl alcohol-water mixtures (31). Hydrochloric acid shows the characteristic of a strong electrolyte in the experimental DMSO-water mixtures and its behavior is very similar to that in water. An error of ±0.09 mV in emf value corresponds to an error of ±0.003 in the values of ${}_s\gamma_\pm$.

An examination of Table IV shows that the escaping tendency of HCl is greater in DMSO-water mixtures than in pure water, because the primary medium effect of DMSO-water mixtures on HCl becomes greater with gradual addition of DMSO.

The total transfer Gibbs energy appears to be positive for all experimental solvent compositions in the DMSO-water system. Hydrochloric acid thus appears to be in a higher Gibbs energy state in the mixed solvent than in water. The positive values of ΔG°_{chem} also suggest that, as far as the acid-base reaction or solvation is concerned, the transfer of HCl from water to DMSO-water mixtures is not favored. In other words, water is more basic than the mixed solvent. The values of ΔG°_t are accurate to within ±24 joule mole^{-1}.

The values of ΔH°_t and ΔS°_t reflect contributions from the effects of the ions on the structure of the solvents while the values of ΔG°_t provide information in regard to acid-base theory of ion solvation. The function, ΔG°_t, is a simpler one, and may not be affected by structural factors (32-34). It may also be regarded as the resultant of the other two, and more complex. Table VII shows that the values of ΔH°_t and ΔS°_t are negative, which suggests that, on the transfer process, the net amount of order created by HCl is more in the mixed solvent than in water. Hydrochloric acid thus breaks more structure in water than in DMSO-water mixtures. This is further supported with the view (35) that all structure-forming processes, including solvation of ions are exothermic and are accompanied by a decrease in entropy.

SYMBOLS

${}^wE^\circ_N$, ${}^sE^\circ_N$	standard electrode potential in water and in a mixed solvent (mole fraction scale), volts
${}^wE^\circ_m$, ${}^sE^\circ_m$	standard electrode potential in water and in a mixed solvent (molal scale), volts
a_0	ion-size parameter, angstroms
X	w/o DMSO in a mixture with water
${}_s\gamma_\pm$	mean ionic activity coefficient of HCl (molal scale) in a mixed solvent relative to unit value at infinite dilution in a mixed solvent (subscript, s)
D_s, D_w	dielectric constant of the mixed solvent and water, respectively
M_{xy}	mean molecular weight of the solvent kg · mole^{-1}
r_+, r_-	radius of the cation (H^+) and anion (Cl^-), respectively, angstroms
L_2	relative partial molal enthalpy, cal/mole
$E^\circ, A_1, \ldots$	the constants of Eq. [5]
A, B, C	empirical constants of Eq. [15]

Diffusion Kinetics at Microelectrodes

Chris R. Ito, S. Asakura, and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The effect of the electrode size on the diffusion current of the cathodic reaction $I_3^- + 2e = 3I^-$ was investigated under transient conditions. Plane circular surfaces of platinum electrodes with diameters, d, ranging from 1.27 to 0.0127 cm were used. The diffusion current under potentiostatic conditions could be expressed as

$$i = \frac{n\mathbf{F}A\sqrt{D}C}{\sqrt{\pi}}\left(\frac{1}{\sqrt{t}} + \frac{2M\sqrt{\pi D}}{d}\right)$$

where M is an empirical parameter which is a function of d. For $d < 0.1$ cm, $M = 1$ and the diffusion mode was equivalent to semi-infinite spherical diffusion. On the other hand, for $d > 0.3$ cm, $M = 0$, and semi-infinite linear diffusion was the controlling mode. The change in the diffusion mode occurred rather abruptly at about $d = 0.2$ cm.

Diffusion kinetics at a microelectrode often plays an important role in electrochemical processes (*e.g.*, electroanalytical chemistry methods, electrodeposition, and electropolishing). It is known that the mass transfer processes at microconfigurations differ to a great extent from those at macroconfigurations. However, comparatively few fundamental studies have been reported on the subject. By dimensional analysis, Agar (1) determined that the mass transfer mode under steady-state conditions changed from convection control to diffusion control as the electrode size decreased. Ibl (2) applied boundary layer theory in his investigation of the mass transfer process at thin wire electrodes. He determined that the deviation of the diffusion current at plate electrodes increased as the diameter decreased. Jacquet (3) observed the thickness of the anodic diffusion layer during electropolishing and found that it was greater over valleys than over peaks. Beacom (4) studied the thickness of the diffusion layer over small notches by the Schlieren method. Wagner (5) examined theoretically the mass transfer process at a rough surface where the surface roughness was approximated by a sine wave.

A number of papers (6) have been published on electroanalytical studies using stationary microelectrodes. However, only a few of these studies have considered

* Electrochemical Society Active Member.

ABSTRACT

The effect of the electrode size on the diffusion current of the cathodic reaction $I_3^- + 2e = 3I^-$ was investigated under transient conditions. Plane circular surfaces of platinum electrodes with diameters, d, ranging from 1.27 to 0.0127 cm were used. The diffusion current under potentiostatic conditions could be expressed as

$$i = \frac{n\mathbf{F}A\sqrt{D}C}{\sqrt{\pi}}\left(\frac{1}{\sqrt{t}} + \frac{2M\sqrt{\pi D}}{d}\right)$$

where M is an empirical parameter which is a function of d. For $d < 0.1$ cm, $M = 1$ and the diffusion mode was equivalent to semi-infinite spherical diffusion. On the other hand, for $d > 0.3$ cm, $M = 0$, and semi-infinite linear diffusion was the controlling mode. The change in the diffusion mode occurred rather abruptly at about $d = 0.2$ cm.

Diffusion kinetics at a microelectrode often plays an important role in electrochemical processes (*e.g.*, electroanalytical chemistry methods, electrodeposition, and electropolishing). It is known that the mass transfer processes at microconfigurations differ to a great extent from those at macroconfigurations. However, comparatively few fundamental studies have been reported on the subject. By dimensional analysis, Agar (1) determined that the mass transfer mode under steady-state conditions changed from convection control to diffusion control as the electrode size decreased. Ibl (2) applied boundary layer theory in his investigation of the mass transfer process at thin wire electrodes. He determined that the deviation of the diffusion current at plate electrodes increased as the diameter decreased. Jacquet (3) observed the thickness of the anodic diffusion layer during electropolishing and found that it was greater over valleys than over peaks. Beacom (4) studied the thickness of the diffusion layer over small notches by the Schlieren method. Wagner (5) examined theoretically the mass transfer process at a rough surface where the surface roughness was approximated by a sine wave.

A number of papers (6) have been published on electroanalytical studies using stationary microelectrodes. However, only a few of these studies have considered

* Electrochemical Society Active Member.

Key words: chronoamperometry, tri-iodide, platinum.

the difference between diffusion kinetics at microelectrodes and macroelectrodes.

Under transient conditions, diffusion at planar electrodes has usually been approximated by semi-infinite linear diffusion, regardless of the electrode size. Cottrell (7), Laitinen and Kolthoff (8), and Laitinen (9) showed the constancy of the product of the current and the square root of the time under potentiostatic conditions. However, Vielstich and Delahay (10) pointed out the limitations of applying semi-infinite linear diffusion to small elecrodes. Lorenz (11) reported that surface roughness on the order of the diffusion layer thickness increased the transition time during galvanostatic polarization. Although Laitinen and Kolthoff (8) attempted to verify the applicability of semi-infinite spherical diffusion to spherically shaped microelectrodes, convection effects precluded these experimental measurements. Bard (12) surmised that the increase in the chronopotentiometric transition time constant at long transition times is due to spherical diffusion and natural convection. In order to predict more accurately the current-time behavior of finite planar electrodes during chronoamperometric experiments, Lingane (13) expanded the chronoamperometric constant as a power series in terms of the reciprocal of the radius and neglected the second and higher order terms. This expression was almost identical to that obtained for semi-infinite spherical diffusion, the former differing only slightly from the latter in the numerical value of the coefficient of the first-order term. The separate contributions of spherical diffusion and convection could not be determined from Bard's (12) and Lingane's (13) results and, therefore, their dependence on the electrode size could not be ascertained.

As shown in this brief review, only a few studies have been reported on diffusion kinetics at microelectrodes under transient conditions in spite of the importance for transient studies of electrode processes. In this work, the effect of the electrode size on the diffusion kinetics has been studied under transient conditions where the time did not exceed 1 sec. In order to exclude the complication resulting from a slow charge transfer process, a highly reversible redox reaction, $I_3^- + 2e = 3I^-$, was examined.

Experimental

The test cell was a 3 liter Pyrex kettle jar and a specially constructed cover with nine ground glass joints for the positioning of a thermometer, a gas bubbler for deaeration, an auxiliary electrode, a reference electrode, and five test electrodes.

The reference electrode was platinum wire. This wire was placed inside the Luggin capillary. The end of the capillary was placed as close as possible to the test electrode in order to minimize the ohmic potential drop within the electrolyte between the test and reference electrodes. The counterelectrode was a large platinum foil.

The test electrodes were of reference grade platinum and had a plane, circular surface with diameters ranging from 1.27 to 0.0127 cm. The electrodes of small diameter, 0.058, 0.0254, 0.0127 cm, were prepared by sealing the platinum wire in a glass tube of 0.6 cm diameter. The glass tubing was then sanded and polished so that only the cross section of the wire was exposed. For larger diameter wires of 0.206 and 0.129 cm, the platinum wire was sealed in glass tubing with Apiezon wax. The wire was held in the glass tubing and the melted wax was sucked up into the tubing. The electrode was sanded and polished as before. Mercury was used to make contact between the platinum and the copper lead wire. For the electrodes of 1.27 and 0.635 cm diameter, a circular piece of platinum foil was glued onto the polished cross section of an iron rod with conductive epoxy cement. Then, shrinkable Teflon was fitted around the electrode and only the platinum surface was exposed. A holder for these electrodes was constructed of Teflon rod. Electrical contact was made by a pressure-fitted copper wire.

The electrolyte was 1N potassium iodide containing various amounts of iodine, ranging from 0.1 to 0.001M (molar). The added iodine reacted with I^- to produce I_3^- forming the I_3^-/I^- redox couple (14, 15). Before each run, the electrolyte was deaerated with prepurified nitrogen for approximately 3 hr.

The potential was controlled and generated with a high speed potentiostat and a mercury relay. The rise time of the potential step imposed on the system was less than 10 μsec. The current was recorded with a high speed oscillograph (frequency response of 500 Hz).

Results

In this paper, the cathodic current is taken as a positive value. A decrease in current due to the diffusion of I_3^- after the imposition of a potential step was observed. Typical current variations with time are shown in Fig. 1. The current was the function of time (t), applied potential (E), and the concentration of I_3^- (C). As can be seen in Fig. 1, the current-time curve does not shift when E is negative enough. In order to examine only the diffusion process, attention was focused on this limiting current, i. The limiting current thus obtained is plotted *vs.* $1/\sqrt{t}$ in Fig. 2 and 3, for all electrode diameters at $C = 0.02M$. All plots show a linear relation in the range of 0.01-1 sec. While the plots intersect the origin, $1\sqrt{t} = 0$, $i = 0$ for large diameter electrodes, they do not for the small diameter electrodes. The following relationship was obtained

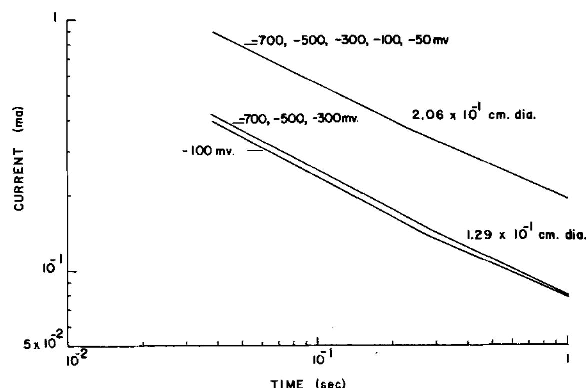

Fig. 1. Current variation with time

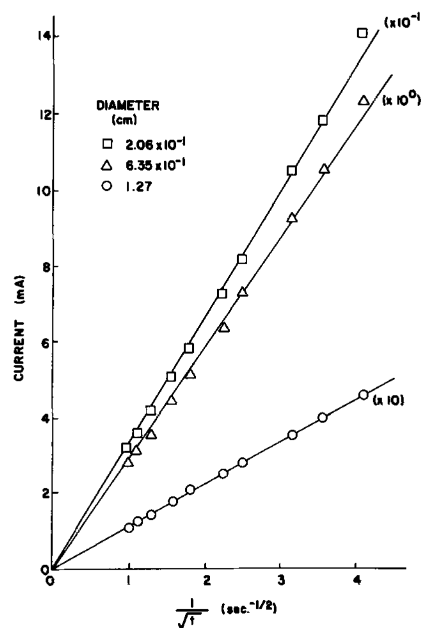

Fig. 2. Plots of current *vs.* $1/\sqrt{t}$ for relatively large electrodes

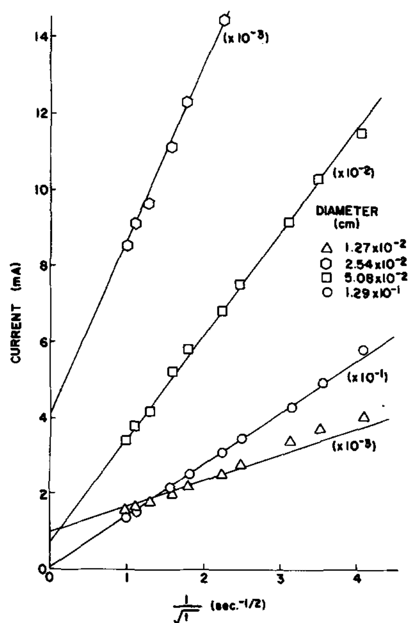

Fig. 3. Plots of current vs. $1/\sqrt{t}$ for relatively small electrodes

$$i = S(1/\sqrt{t} + f(d)) \qquad [1]$$

where S is the slope of the plot and $f(d)$ is some function of the diameter. For electrodes of large diameters, $f(d)$ is zero. The slope, S, is plotted *vs.* the electrode diameter (d) on a log-log scale in Fig. 4. A linear relation with a slope 2 was obtained, *i.e.*

$$S = k_1 d^2 \qquad [2a]$$

which can be rearranged to the form

$$S = k_1'(\pi/4)d^2 = k_1'A \qquad [2b]$$

where A is the electrode area. The dependence of k_1' on C is shown in Fig. 5. The log of S/A is linearly related to the log of C with a slope of unity. Then, S can be expressed as

$$\frac{S}{A} = k_2 C \qquad [3]$$

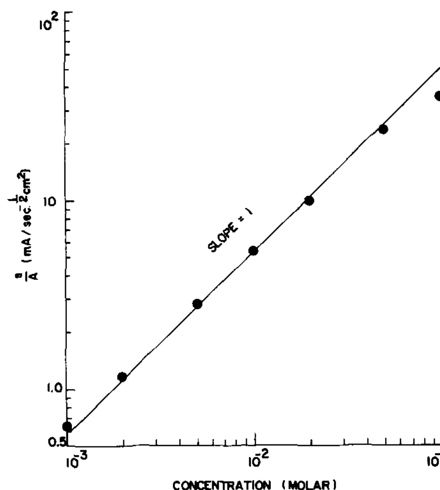

Fig. 5. Dependence of S/A on concentration

where k_2 is a constant determined experimentally (534 A-cm-sec$^{1/2}$/mole) and is independent of C and d.

The current (i) can be extrapolated to $1/\sqrt{t} = 0$ to determine $f(d)$ as seen in Fig. 3. The extrapolated current (i_x) gives the relation

$$f(d) = i_x/S \qquad [4]$$

A linear relation was obtained between i_x and d, as shown in Fig. 6, when the diameter is less than 0.129 cm, *i.e.*

$$i_x = k_3 d, \text{ for } d \leq 0.129 \text{ cm} \qquad [5]$$

where k_3 is a function of C and independent of d. To determine the dependence of k_3 on C, log (i_x/d) is plotted *vs.* log C in Fig. 7. This plot gives a linear relationship with a slope of unity. Thus, a proportionality between k_3 and C was obtained and

$$i_x = k_4 dC \qquad [6]$$

Equations [4] and [6] give

$$f(d) = k_4 dC/S, \text{ for } d \leq 0.129 \text{ cm} \qquad [7]$$

where k_4 is a constant determined experimentally (7.15 A-cm^2/mole) and is independent of d and C. Since $f(d)$ is zero for large electrode diameters, the cur-

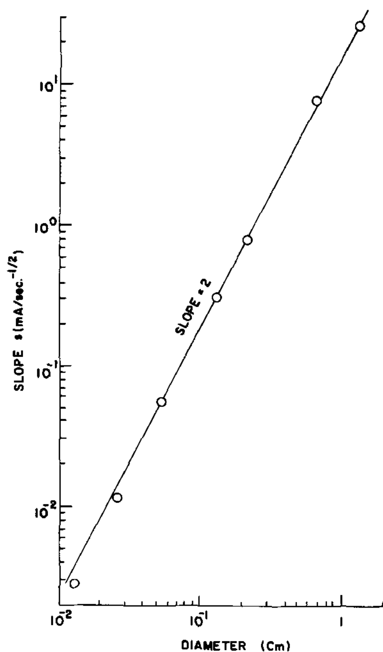

Fig. 4. Dependence of slope S on the electrode diameter

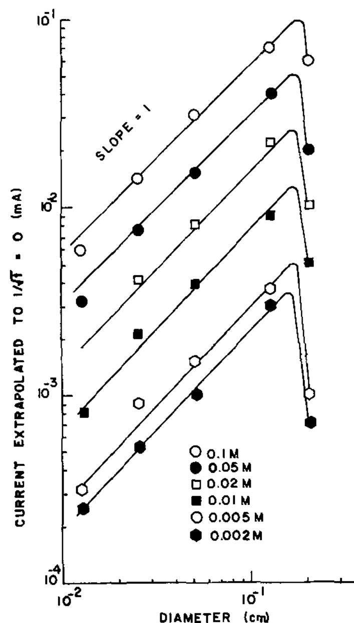

Fig. 6. Current extrapolated to $1/\sqrt{t} = 0$, i_x, vs. electrode diameter.

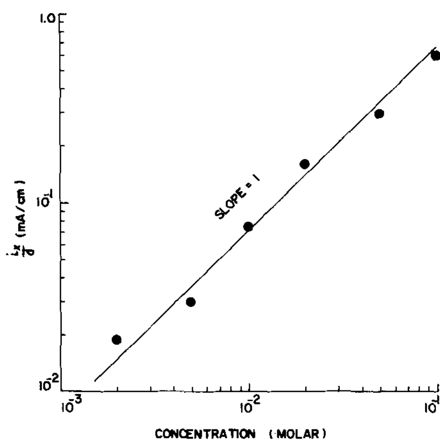

Fig. 7. Plots of i_x/d vs. concentration

rent (i) in Eq. [1] can be expressed empirically as

$$i = k_2CA\ [1/\sqrt{t} + M(k_4/k_2)(d/A)] \quad [8]$$

where M is a function of the diameter and can have values between zero and one. The dependence of M on diameter is shown in Fig. 8. It was found that M decreased rather abruptly from unity to zero as the electrode diameter increased. This abrupt decrease occurred at about the electrode diameter of 0.2 cm.

Discussion

It is known that when a circular plane electrode is large and the polarization duration is short, mass transport at the electrode is controlled by semi-infinite linear diffusion. However, when the electrode dimension is small, mass transfer is approximated by semi-infinite spherical diffusion. The limiting current for a potential step is given by Eq. [9] for semi-infinite linear diffusion and by Eq. [10] for semi-infinite spherical diffusion (16)

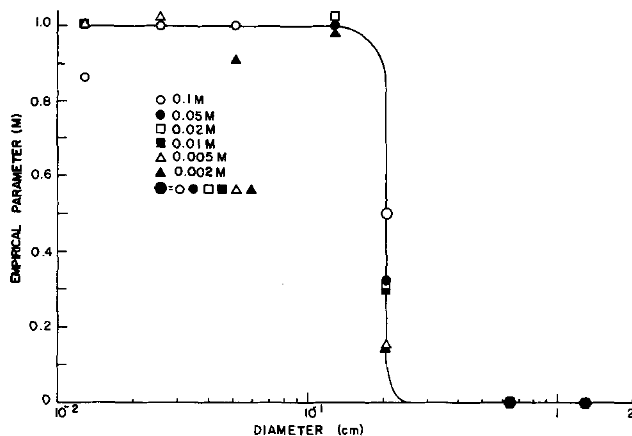

Fig. 8. Variation of the empirical parameter M with electrode diameter.

$$i_{\text{lin}} = \frac{n\mathbf{F}A\sqrt{D}C}{\sqrt{\pi}\sqrt{t}} \quad [9]$$

$$i_{\text{sph}} = \frac{n\mathbf{F}A\sqrt{D}C}{\sqrt{\pi}}\left(\frac{1}{\sqrt{t}} + \frac{2\sqrt{D\pi}}{d}\right) \quad [10]$$

where n and $\mathbf{F}$ have their usual significance and A and D are the electrode area and the diffusion coefficient of I_3^-, respectively.

The current can be expressed generally for all electrode diameters examined in this study by introducing an empirical parameter M

$$i = \frac{n\mathbf{F}A\sqrt{D}C}{\sqrt{\pi}}\left(\frac{1}{\sqrt{t}} + \frac{2M\sqrt{\pi D}}{d}\right) \quad [11]$$

In the case of $d \leq 0.1$ cm, the diffusion mode is semi-infinite spherical diffusion and $M = 1$. For $d > 0.3$ cm, $M = 0$ and semi-infinite linear diffusion is the controlling mode. The change from semi-infinite spherical to semi-infinite linear diffusion occurs around $d = 0.2$ cm. It is evident that when plane circular electrodes similar in size to those examined in this investigation are used, the change of the diffusion mode with the electrode dimensions is an important consideration.

Local Natural Convection Mass Transfer Measurements

ABSTRACT

Apparatus and experimental technique for measurements of local natural convection mass transfer on vertical and upward-facing inclined surfaces are described, and corresponding results are presented and discussed. The experiments were performed using the electrochemical technique, with Cu^{++} as the transferred ions and sulfuric acid as the supporting electrolyte. The objective of the research was to obtain highly local information. Two types of mass transfer probes were employed, the smaller of which were about ¼ mm in spanwise width, with a probe-to-probe spacing of 1/20 mm. These miniature probes were used in the measurement of spanwise mass transfer variations encountered in the laminar-turbulent transition regime on inclined surfaces. Local laminar mass transfer results and instability Rayleigh numbers for vertical and inclined plates were measured by means of a set of small circular probes. All data were collected for limiting current operation, and the requisite concentration levels of Cu^{++} ions were examined and documented. In addition, the influence of cathode-to-anode orientation was investigated, as were the edge effects associated with the lateral edges of the test surface.

Electrochemical techniques have been used by numerous investigators in recent years to study mass transfer between a surface and a liquid environment, as witnessed, for instance, by a recently published summary paper by Mizushina (1). One of the attractive features of these techniques is the capability of obtaining local mass transfer results, that is, mass transfer results for a small region of the over-all surface being studied. The present concern with local measurements is motivated by the nature of the phenomenon being investigated. It has been shown by flow visualization studies (2) that for natural convection adjacent to an inclined upward-facing surface, the breakdown of the laminar regime is marked by the presence of a secondary flow. That is, superposed on the main streamwise flow, there are alternate regions of inflow and outflow distributed more or less periodically across the horizontal span of the surface. It would be expected that such an inflow-outflow pattern would give rise to a spanwise variation of surface mass transfer. The typical spanwise dimension of the inflow-outflow cells observed in this investigation is 1 mm. Therefore, to resolve the spanwise mass transfer distribution within a cell, several local measurements must be made within a span of 1 mm. Thus, it is necessary that the mass transfer probes be very small and, also, that they be very close together.

The instrumentation and experimental technique for performing highly localized measurements of the type discussed above is described here in detail. Also, representative spanwise mass transfer distributions are presented for the laminar-to-turbulent transition regime in natural convection flow on inclined surfaces.

Quite apart from the just-mentioned spanwise distributions, another type of local measurements was made which is appropriate to either the laminar or turbulent regimes. The instrumentation and technique for this measurement is also described. Local mass transfer results are presented for laminar natural convection flow on vertical and inclined surfaces. From these results, the Rayleigh number marking the breakdown of the laminar regime is identified.

A survey of the available literature failed to disclose local electrochemical mass transfer measurements characterized by probe sizes and by probe-to-probe proximities as small as those of the present investigation. Only in connection with wall shear stress measurements, where electrodes are embedded in an inert wall, have comparably small electrodes been employed (3). Representative prior studies, where either local or quasi-local electrochemical mass transfer measurements are reported, may be found in Ref. (4-6) for natural convection flow and in Ref. (7, 8) for forced convection flow.

Key words: natural convection, inclined surface, mass transfer, limiting current.

Experimental Apparatus

An over-all schematic diagram of the experimental apparatus is pictured in Fig. 1. The electrochemical fluid, an aqueous solution of cupric sulfate and sulfuric acid, both reagent grade, was contained in a polyethylene tank (61 × 45.6 × 45.6 cm, length × width × height). The cupric ions play the role of the transferred ion and plate out on the cathode, thereby giving rise to concentration and density gradients in the fluid adjacent to the cathode. In turn, the density gradient creates a buoyancy force which causes the natural convection flow.

As seen in the figure, the main components of the apparatus included the cathode (which is the test surface), anode, reference electrode, circuitry, instrumentation, power source, and voltage control. These several components will now be described, starting with the test surface.

A front-face schematic of the test surface is shown in Fig. 2. As pictured therein, the test surface con-

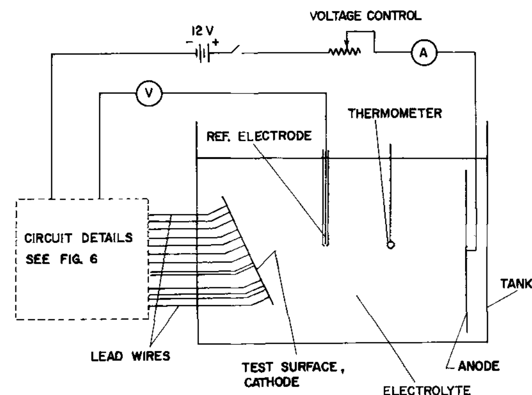

Fig. 1. Over-all schematic of the experimental apparatus

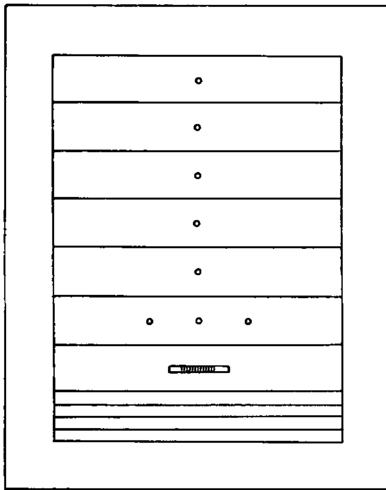

Fig. 2. Front-face view of the test surface

sisted of eleven individual segments set into an electrically passive framework. All segments were fabricated from nickel 200 and were 0.635 cm thick and 15.2 cm in spanwise width. The seven probe-bearing segments were 2.54 cm high, whereas the four uninstrumented segments, which served to vary the streamwise locations of the mass transfer probes, were 0.635 cm in height. The positions of the segments could be interchanged at will, so that their arrangement in Fig. 2 is only for illustration. The active surface had a streamwise height of 20.3 cm and a spanwise width of 15.2 cm. The width of the surrounding Teflon frame was 2.54 cm.

Six of the segments were instrumented with small circular electrodes (0.343 cm diameter) which served as local mass transfer probes for flow conditions characterized by spanwise uniformity (*i.e.*, either laminar or turbulent flow). The circular probes were situated at the centers of the respective host segments and, in one case, two supplementary probes were installed 2.54 cm to either side of the center. The installation of the circular probes is illustrated in Fig. 3, which is a schematic view of the back face of one of the host bars. The probe was electrically insulated from the host bar by a 0.0127 cm annular gap filled with epoxy. The back side of the probe and the attached end of the current-carrying lead wire were embedded in epoxy. Glyptal insulating paint was applied to the epoxy and to the entire back face of the host bar.

The seventh instrumented segment contained an ensemble of 55 very small probes whose function was to measure the spanwise mass transfer distribution in the laminar-turbulent transition regime on inclined upward-facing surfaces. The probe ensemble consisted of successive sheets of nickel 200 and of polyethylene insulation. Each probe had a spanwise dimension of 0.0254 cm, with a spacing between probes (*i.e.*, thickness of the polyethylene foil) of 0.0051 cm. In the streamwise direction, the probes were 0.318 cm in length. The end pieces of the ensemble were also of nickel 200, 0.635 cm thick, and cut in the same shape as the probes. The ensemble was held together by two nickel screws which were insulated from the probes by Teflon tubing. A photograph of the probe section is given in Fig. 4, wherein the active sensing surface is along the bottom-most edge.

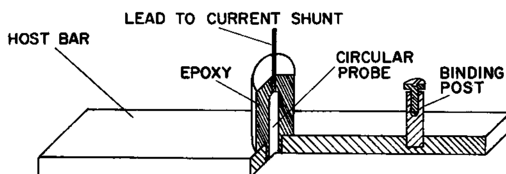

Fig. 3. Diagram showing installation of circular probes

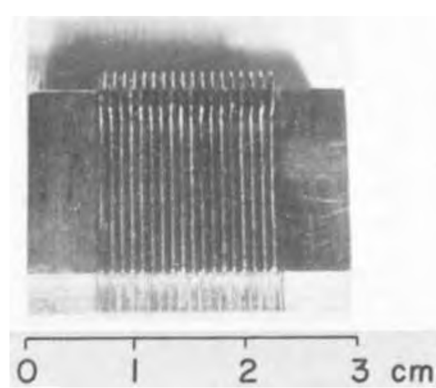

Fig. 4. Photograph of the ensemble of miniature probes

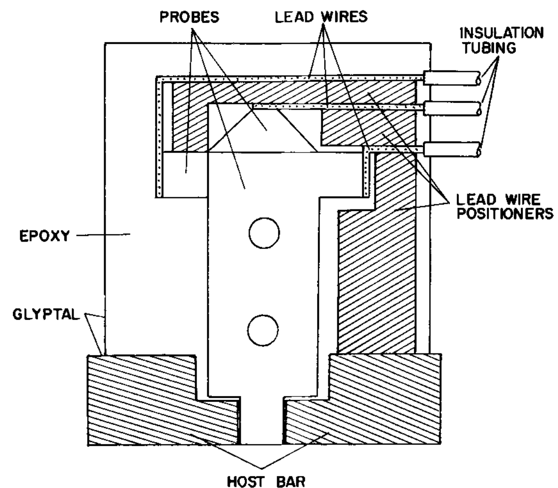

Fig. 5. Diagram showing installation of miniature probes

The assembly of the probe section and its installation in the host bar are illustrated in Fig. 5. A rectangular hole slightly larger than the face of the probe section was machined into the bar, with a clearance of about 0.02 cm being maintained. Glyptal insulating paint was poured into the gap and a coating of epoxy applied to the face of the probe section and on the hardened Glyptal filler. The hardened epoxy was carefully finished with grade 600 wet or dry Tri-M-ite paper and a fine hone, exposing the faces of all 55 probes. The probe section was held in place by a bracket mounted on the back of the host bar.

Lead wires were soldered to the probes and segregated from each other by positioners as shown in Fig. 5, the lead wires being affixed to the positioners with epoxy. The figure shows the different positions of lead wire attachment for three successive probes. The entire back side of the probe section, the positioners, and the ends of the lead wires were painted with Glyptal, embedded in epoxy, and painted again with Glyptal to ensure that no unaccounted areas were exposed to the electrolyte solution.

Each one of the eleven segments comprising the test surface was equipped with a binding post on its back face to facilitate connection to the external circuit. The posts and wire were of nickel 200. Glyptal insulating paint was applied to the binding posts, and plastic tape was wrapped around them to retard corrosion of the area of electrical contact.

The segmented test surface was housed in a Teflon frame which has already been mentioned in connection with Fig. 1. A groove was machined along the inner circumference of the frame to receive the segments, so that the exposed face of the test surface and of the frame were in the same plane. The segments themselves were carefully aligned to ensure that they presented a smooth, continuous surface to the flow, and

the alignment, once attained, was fixed by electrically isolated, thumb-tightened set screws. The Teflon frame was supported by a nickel-plated stand, which was painted with Glyptal to make it electrically and chemically neutral. The stand facilitated the positioning of the test surface at various angles of inclination. Typically, the test surface was situated about 4 cm above the floor of the tank, and its topmost edge was 15 to 20 cm beneath the surface of the electrochemical bath.

The anode was a 40-cm square copper sheet, 0.08 cm thick. For the data runs, the anode was positioned as indicated in Fig. 1. However, a number of preliminary runs were made to explore the influence of anode position on the mass transfer results, and the findings of these runs are reported in a later part of the paper.

A reference electrode was placed in the electrolyte solution to facilitate the measurement of the voltage between the fluid bulk and the test surface. The reference electrode was a 0.1 cm diameter copper wire housed in a Teflon tube. A small hole at the bottom of the tube permitted the electrolyte to contact the electrode. The reference electrode was typically positioned to the side of the test surface (about 5 cm away) and at its half-height.

External Circuitry and Instrumentation

A schematic diagram of the electric circuitry is presented in Fig. 6. A 12V automotive storage battery, supplemented by a rheostat and a trimming pot, served as the power supply. The cathode voltage was measured with a 0-1.5V, 1%, d-c Simpson panel meter. A calibrated Weston Model 901 d-c ammeter served to measure the over-all current flow through the electrolyte.

The segments which make up the cathode were tied together electrically, so that they were all of the same potential. Adjacent segments were actually in contact, but gaps are indicated in the figure in order to delineate the separate segments. A current shunt was incorporated into the circuit for each of the probes. The current shunts for the eight circular probes were 15-ohm calibrated precision resistors. For the ensemble of 55 miniature probes, 55-1%, 174-ohm calibrated precision resistors served as the current shunts.

For the steady mass transfer rates encountered under laminar flow conditions, the voltage drops across the current shunts were measured with a Leeds and Northrup K-3 potentiometer, supplemented by a low contact resistance, 24-position thermocouple selector switch. For the unsteady mass transfer rates that are characteristic of nonlaminar flows, the shunt voltage drops were read with a Dymec Digital Voltmeter. This instrument could be programmed to read repetitively the output of a single probe at preselected intervals of time. Alternatively, it could be programmed to read successively the outputs of as many as 24 probes, with the sweeping of the 24 probes being repeated as many times as desired. To accommodate the 55 probes of the ensemble to the Dymec, they were subdivided into two sets of 24 and one set of seven. About 45 sec were required to disconnect one set and to connect another.

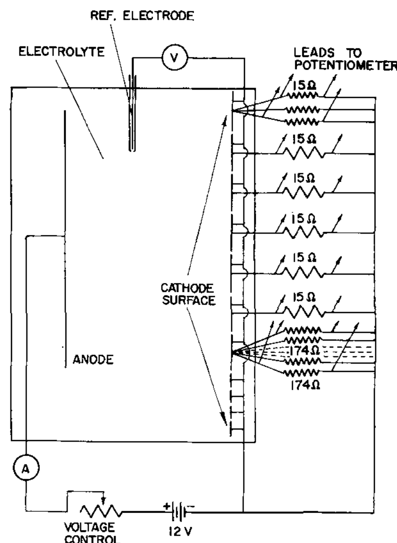

Fig. 6. Electric circuitry diagram

Experimental Technique

During the course of each data run, copper was plated out on the test surface. Removal of deposited copper and refinishing of the surface was a necessary aspect of the experimental procedure. The importance of removing the deposited copper is heightened when local mass transfer probes are used, as in the present experiments. If not removed, a build-up of deposited copper could eventually bridge over the insulation between a probe and its host bar or between adjacent probes. Such a bridging over would cause the local probe to become inoperative.

At the conclusion of each data run, the cathode and anode were water washed and carefully dried with soft paper towels, and the mass transfer probes were checked for shorts. Prior to the start of a new data run, the electrodes were painstakingly resurfaced. The resurfacing operations were performed in such a way as to ensure that the surfaces of the probes and the host bars were coplanar. First, the test surface was wiped clean of any airborne particles. Then, grade 600 wet or dry Tri-M-ite paper was used to refinish all parts of the test surface except for the ensemble of 55 miniature probes, for which a wet, very fine hone was used (to avoid shorts between adjacent probes). Immediately after the refinishing, methanol technical was freely applied to wash away small particles of copper sanding dust. Next, the epoxy insulation between the probes and their host bars was cleaned with a stiff bristle brush and methanol technical, after which all parts of the test surface were washed again with liberal amounts of methanol technical and wiped with paper gauze pads. Finally, all probes were checked to verify the absence of shorts.

The anode was also subjected to a sequence of resurfacing operations similar to those for the test surface, with grade 180 wet or dry paper being employed in the refinishing of both sides of the anode.

Prior to the initiation of the mass transfer process, the electrochemical solution was stirred to ensure uniformity of concentration and temperature, and a waiting period was allowed for the decay of motions due to stirring. No data were collected until the starting transient of the system had died away.

The data acquisition procedure for laminar and for nonlaminar conditions differed because the mass transfer rates were, respectively, steady and unsteady. Only the unsteady situation merits discussion here. The signal from any one of the circular probes was read by the Dymec Digital Voltmeter at intervals of 0.2 to 0.3 sec for a period of 3 min to determine timewise variations in the local rate of mass transfer. Alternatively, the outputs of the eight circular probes were read in succession, with the eight-probe sweep being repeated again and again. Local time averages were evaluated from instantaneous data collected from both of these measurement procedures. For the ensemble of miniature probes, the signals from the first 24 probes were read successively by the Dymec in a period of about 7 sec, and the scanning of this set of probes was repeated until about 1½ min had elapsed. Then, the second set of 24 probes was connected to the Dymec and readings were taken for 1½ min, and so forth.

The composition of the bulk solution was obtained by sampling. The concentrations of the copper ions and sulfuric acid were determined, respectively, by spectrometric and titration methods, described in Ref. (9) and (10), respectively. Vertical concentration

gradients were monitored, and data acquisition was restricted to cases where the gradient was less than 0.00007M (molar) concentration of copper ions per centimeter. No change in the mixed mean bulk concentration was detected during the course of a data run.

Limiting Current Conditions

To facilitate the evaluation of mass transfer coefficients, all final data were taken for the limiting current operating condition. This condition corresponds to a zero concentration of transferred ion (*i.e.*, copper) at the cathode, thereby eliminating the need for concentration measurements at the test surface. Limiting current operation can be identified by a plateau in a graph of cathode current *vs.* cathode voltage (measured with respect to the reference electrode).

The attainment of a limiting current plateau is favored by higher concentrations of copper ions in the fluid bulk. On the other hand, the rate at which copper plates out on the test surface is also increased with higher bulk concentrations. Such higher plating rates can lead to short circuiting of the mass transfer probes. Furthermore, high plating rates enhance the rapidity at which the surface of the plated copper may become roughened, thereby causing a change in the effective surface area (11). It is relevant, therefore, to perform the experiments at the lowest bulk copper ion concentrations which are compatible with the existence of a limiting current plateau.

Figures 7 and 8 show typical current-voltage curves. The bulk copper ion concentration ranged from 0.0066 to 0.0825M for these test conditions, while the sulfuric acid concentration was about 1.5M for all cases. It is evident that limiting current plateaus do not exist for the 0.0066 and 0.0113M concentrations. On the other hand, the curves for the 0.0375 and 0.0825M concentrations indicate limiting current operation. The absence of limiting current plateaus at low copper ion concentrations has already been noted by Fenech and Tobias (5). The cause of this behavior is not completely understood at the present.

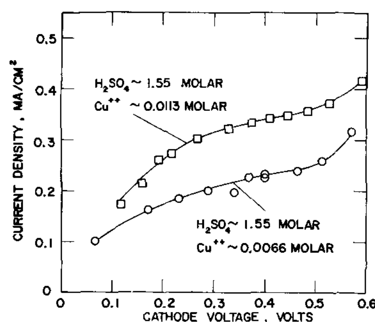

Fig. 7. Current-voltage curves at low Cu^{++} concentrations

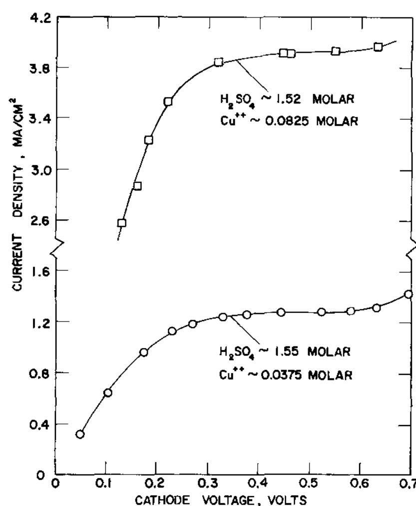

Fig. 8. Current-voltage curves showing limiting current plateaus

On the basis of Fig. 7 and 8 and of other such current-voltage curves, it was established that limiting current operation could be attained for bulk copper ion concentrations above 0.03M. To ensure that all final data actually corresponded to limiting current operation, a current voltage curve such as those of Fig. 7 and 8 was mapped out for each data run. A sequence of six or seven steps was taken to define limiting current conditions. At each step, the current was monitored with a strip chart recorder, and a steady reading was approached before advancing to the next step. The length of the data acquisition period under steady limiting-current conditions varied with the type of flow observed; for laminar flow approximately 1½ min, for turbulent flow approximately 3 min, and to monitor two sets of local spanwise readings about 4 min.

Results and Discussion

Owing to the fact that all data were taken for limiting current operation and in the presence of excess supporting electrolyte, the local mass transfer coefficient k_x can be evaluated as

$$k_x = i/n\mathbf{F}c_\infty \quad [1]$$

where i and c_∞, respectively, denote the measured values of the current density and the concentration of copper ions in the fluid bulk. The quantities n and $\mathbf{F}$ are the valence of the copper ions and the Faraday number. A dimensionless representation for k_x is provided by the Sherwood number Sh_x, which is defined as

$$Sh_x = k_x x/D \quad [2]$$

in which x is the streamwise distance along the test surface, with $x = 0$ corresponding to the leading edge of the active surface.

The other dimensionless grouping relevant to the natural convection process is the Rayleigh number. In constructing the Rayleigh number appropriate to an inclined test surface, we use the component of the body force parallel to the surface (*i.e.*, g cos θ) and indicate the presence of the inclination angle θ by the notation Ra_θ. Then, the local Rayleigh number is given by

$$Ra_{\theta,x} = [\rho g \cos\theta\,(\rho_\infty - \rho_w)x^3/\mu^2]\,Sc \quad [3]$$

where Sc denotes the Schmidt number $\mu/\rho D$, and ρ_∞ and ρ_w are the densities in the fluid bulk and at the surface. The quantities D, ρ, and μ appearing in Eq. [2] and [3] were evaluated at the average of the concentrations at the wall and in the bulk. Typically, the wall-to-bulk fluid property variations were on the order of 1%. Detailed information about the evaluation of the fluid properties is given in Ref. (12). The property evaluations were based on data given in Ref. (5) and in Ref. (19-24).

An initial set of experiments was performed to explore the effect of cathode-to-anode orientation. Another objective of this set of experiments was to examine the influence of edge effects associated with the lateral edges of the test surface. The experiments in question were performed for laminar flow conditions and with the test surface vertical. However, instead of the configuration pictured in Fig. 2, the test surface assembly was turned through 90 degrees, so that the main line of circular probes was situated along a horizontal, each probe being at the same distance from the leading edge. Five electrically active, instrumented segments were employed, each with a central circular probe, plus Plexiglas spacer bars which were used to segregate the active segments. The active segments and spacers were arranged so that, proceeding along the horizontal span of the test surface, one encounters the 2.54 cm Teflon frame, 10.16 cm of active surface, a 2.54 cm spacer, 2.54 cm of active surface, a 5.08 cm spacer, and the Teflon frame.

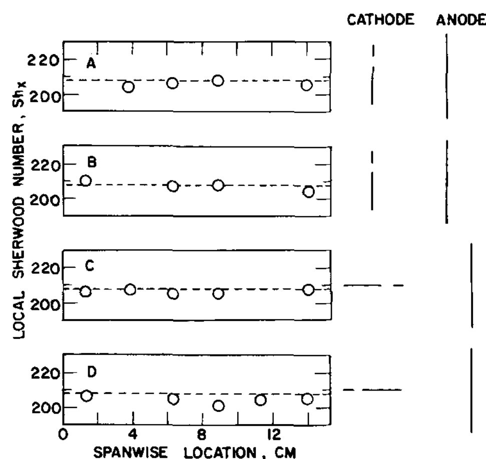

Fig. 9. Spanwise uniformity tests for laminar flow adjacent to a vertical plate.

Local Sherwood number results from four experimental runs, performed over a period of several days, are shown in Fig. 9. The dashed line appearing in each graph represents the prediction of laminar vertical plate theory corresponding to Sc = 2000 (13)

$$Sh_x/0.499\ Ra_x^{1/4} = 1 \qquad [4]$$

Adjacent to the graph for each run is a plan-view schematic indicating the positioning of the cathode and the anode. The line representing the cathode denotes the active portions of the surface, and the break in the line denotes a spacer. In runs A and B, the cathode and anode were parallel, whereas in runs C and D they were at right angles. Owing to the shorting out of a mass transfer probe, only four data points appear in the graphs for runs A and B.

Inspection of the figure indicates that the mass transfer results show no systematic variation with spanwise location, regardless of the position of the anode or of the proximity of a probe to the lateral edges of the test surface. Furthermore, the agreement of the data with laminar theory is excellent, the average deviation being about 1.6%. These findings indicate that for the conditions of the present experiments, cathode-to-anode orientation and edge effects have a negligible influence on the mass transfer results. Furthermore, the excellent agreement with theory lends confidence in the experimental technique, instrumentation, and thermophysical properties used in the data reduction.

For all subsequent experimental runs, the test surface was situated in its original configuration, and the anode was positioned parallel to the cathode and as far away as possible.

A second series of experiments was performed to determine local laminar mass transfer results for vertical and inclined surfaces and, in addition, to examine the conditions marking the breakdown of the laminar regime. The circular mass transfer probes were used in these experiments. The results are plotted in Fig. 10 with $Sh_x/0.499\ Ra_{\theta,x}^{1/4}$ on the ordinate and $Ra_{\theta,x}$ on the abscissa. The motivation for the form of the ordinate variable stems from the analytical prediction for laminar natural convection mass transfer on a vertical plate, Eq. [4], which, when generalized by replacing g with $g \cos \theta$, becomes

$$Sh_x/0.499\ Ra_{\theta,x}^{1/4} = 1 \qquad [5]$$

Equation [5] corresponds to Sc = 2000, which is the typical Schmidt number of the experiments. In view of Eq. [5] and if laminar theory is obeyed, the data, when plotted using the coordinates of Fig. 10, should fall on a horizontal line having an ordinate value of unity. A particular advantage of such a presentation is that deviations from the laminar line are readily observable, thereby facilitating the identification of the onset of laminar-turbulent transition.

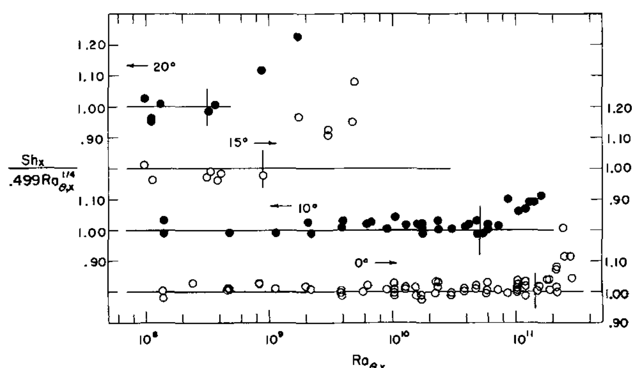

Fig. 10. Local laminar mass transfer results on vertical and inclined surfaces.

Results for surface inclination angles, relative to the vertical, of 0, 10, 15, and 20 degrees are plotted in Fig. 10. The data for each inclination angle are referred to a separate ordinate scale, as designated by the arrows. Results for inclination angles greater than 20 degrees are not shown in the figure since, for such angles, the flow at the lowermost probe was not laminar.

Inspection of Fig. 10 shows excellent agreement between the laminar data and the analytical prediction expressed by Eq. [5], adding further confidence in the experimental technique, instrumentation, and thermophysical properties. For the inclination angles of 0 and 10 degrees, the experimental results are generally within 3% of the prediction in the laminar range. At the 15 and 20 degree inclination angles, where there are fewer laminar data, the agreement is within 4%.

The present local mass transfer results for the vertical plate, when integrated over a streamwise length L, yield $\overline{Sh}_L = 0.665\ Ra_L^{1/4}$, which is in excellent agreement with the over-all measurements of Wilke, Tobias, and Eisenberg (14). On the other hand, the over-all measurements of Fouad and Ahmed (15) on vertical and inclined plates appear to lie outside the laminar regime, so that no comparisons are possible.

Next, attention may be turned to the onset of laminar-turbulent transition. One way of identifying the onset of transition is from the systematic upward departure of the data, as plotted in Fig. 10, from the horizontal lines which correspond to laminar flow. A second indication is given by the measurements of current flow. For strictly laminar conditions, the current readings were very steady. However, for Rayleigh numbers just below those at which data lift-off occurred, small fluctuations in the readings were observed. The Rayleigh numbers at which these fluctuations were first noted are indicated by short vertical lines for each angle of inclination. These Rayleigh numbers are regarded here as marking the onset of transition and are listed in Table I.

The table indicates that the transition Rayleigh number decreases with increasing angle of inclination. The drop-off is especially sharp between 10 and 20 degrees, and this might well be due to the change in the nature of the laminar instability as observed via flow visualization (16).

The transition Rayleigh numbers of Table I, which correspond to mass transfer at Sc = 2000, do not corre-

Table I. Rayleigh numbers at the onset of transition

θ (degrees)	$Ra_{\theta,x}$
0	1.5×10^{11}
10	5.0×10^{10}
15	9.1×10^{8}
20	3.5×10^{8}

late too well with those encountered in heat transfer experiments at Prandtl numbers in the range 0.7-5 (16). (The Schmidt and Prandtl numbers play analogous roles in the mass and heat transfer processes.) In particular, at inclination angles of 0 and 10 degrees, the $Ra_{\theta,x}$ of Table I are substantially higher than the available transition values from heat transfer studies. Thus, the Rayleigh number might not, in itself, be a sufficient criterion for transition, and there might be a separate dependence on the Schmidt (or Prandtl) number. This possibility has already been suggested by Fouad and Ibl (17). Also, it is quite possible that the natural disturbances in the fluid environment may be smaller in the mass transfer case than in the heat transfer case, thereby favoring a later transition in the former.

The transition Rayleigh number of Table I for the vertical plate falls in the range encountered in other electrochemical mass transfer experiments; however, as noted in Ref. (18), there is a substantial spread in the results from different investigations.

The last set of experiments to be reported here are those in which the array of miniature probes was used to measure spanwise mass transfer distributions on inclined surfaces in the laminar-turbulent transition regime. Some preliminary experiments for laminar flow adjacent to a vertical surface gave data which agreed very well with the analytical predictions. The deviations were only a few per cent, and this might well have been due to uncertainties in the visual determination of the electrically active surface area of the miniature probes.

Representative transition regime results for inclined surfaces are pictured in Fig. 11, which is for an inclination angle of 30 degrees relative to the vertical. The figure shows instantaneous spanwise mass transfer distributions. The ordinate is the current density, which is directly proportional to the mass transfer rate. The abscissa is the spanwise location, measured relative to the first probe in the ensemble. Data from probes 1 through 24 are plotted in the left-hand part of the figure, while data from probes 25 through 48 are shown in the right-hand part. To provide a clearer picture, dashed lines have been faired through the points for a given instant of time.

The instantaneous distributions presented in Fig. 11 were constructed from cross plots of the data collected from the successive sweeps of the probe ensemble. The time lapses between the successive instantaneous distributions are indicated in the figure, as is the Rayleigh number.

From the figure, it is seen that the instantaneous mass transfer rate varies in an oscillatory manner across the span of the plate. The amplitude of the variation is a substantial fraction of the spanwise average. The distance between adjacent peaks and valleys is on the order of 1 mm. Results similar to Fig. 11, but for other inclination angles, are available in Ref. (12).

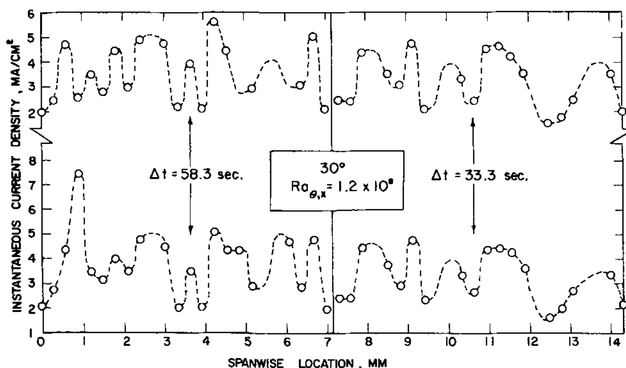

Fig. 11. Instantaneous spanwise mass transfer distributions in the laminar-turbulent transition regime.

Concluding Remarks

The miniature probes employed in the present experiments appear to have been equal to the task of resolving the spanwise variations encountered in the transition regime on inclined surfaces. The spanwise dimensions of the probes and of the insulation between the probes were the smallest that could be fabricated consistent with the avoidance of short circuits in the probe assembly prior to its use in the electrochemical solution. During the course of the experiments, the sulfuric acid in the electrochemical solution attacked the epoxy insulation, ultimately causing short circuiting of adjacent probes.

It is clear from Fig. 11 that had larger probes and/or greater probe-to-probe separation distances been employed, an accurate picture of the spanwise variations would not have been obtained.

Throwing Power Measurements during High Rate Nickel Dissolution under Active and Transpassive Conditions

Dieter Landolt*

Energy and Kinetics Department,
School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Throwing power measurements for anodic dissolution of nickel under electrochemical machining conditions were performed in a flow channel apparatus. Acidified 1M NaCl and neutral 1M $NaClO_3$ solutions were chosen as examples of a nonpassivating and a passivating electrolyte. Anode and cathode potential measurements and current efficiency determinations were used for the interpretation of measured throwing power data. Current distribution at high current densities was little affected by passivation. The lower throwing power found for the passivating $NaClO_3$ electrolyte compared to the nonpassivating NaCl electrolyte was therefore solely due to a different dependency of dissolution efficiency on current density.

Throwing power is a concept used by electroplaters to describe the ability of a bath to yield macroscopically uniform deposits. Throwing power is usually determined experimentally in a Haring Blum cell (1) by measuring the weight change of two equipotential cathodes located at different distances from a central anode. Several empirical formulas are in use for calculating a numerical value of throwing power from such measurements. The concept of throwing power can also be applied to electrochemical machining (ECM) for characterizing the degree of "overcut" or "stray cutting" occurring during a machining operation with a given electrolyte. A low value of throwing power is desirable in ECM because "overcut" can be reduced by restricting anodic dissolution to the immediate vicinity of the cathodic tool. In analogy to the electroplating situation, the experimental determination of ECM throwing power may include the measurement of the weight loss of two equipotential anodes located at different distance from a central cathode. Such measurements have recently been reported by Brook and Iqbal (2), but their data have been criticized by Chin and Wallace (3). The latter authors propose a different experimental method based on the assumption that a logarithmic relationship between weight loss ratio and length ratio exists.

It has been mentioned in the literature that better dimensional accuracy can be obtained in ECM if passivating electrolytes such as sodium chlorate are employed (4, 5), but few pertinent data have been given so far to explain this behavior. The present study was undertaken with the aim to investigate the difference in ECM throwing power between a nonpassivating and a passivating electrolyte and to relate the measured throwing power to the more fundamental parameters, current distribution and dissolution efficiency. For this purpose weight loss determinations and electrode potential measurements for anodic dissolution of nickel were carried out with well-defined cell geometry under carefully controlled experimental conditions. Acidified sodium chloride and neutral sodium chlorate solutions were chosen as examples of a nonpassivating and a passivating electrolyte, respectively. The metal-electrolyte combinations were chosen because of their technological interest and because their electrochemical behavior had been studied previously in this laboratory. Separate experiments performed on a technical ECM machine suggested that general conclusions based on the behavior of nickel in these two electrolytes ought to be applicable to the machining of steel also (6).

Experimental

Apparatus and experimental method.—In the present study it was necessary to measure dissolution rates, electrode potentials, and throwing power under identical, well-defined conditions. Because this is difficult to accomplish in a Haring Blum type cell involving the simultaneous dissolution of two anodes, it was considered more suitable to perform subsequent experiments with a single anode at varying gap width while keeping cell voltage and temperature constant. For that purpose a flow channel cell with fixed electrodes was used in which the distance between anode and cathode was given by the thickness of a Teflon spacer inserted between two PVC cell blocks. A detailed description of the cell and the apparatus which included a discontinuously driven piston pump and a 2 liter electrolyte storage flask has been given elsewhere (7). The flow channel employed was 0.317 cm wide and 0.0534, 0.140, or 0.267 cm high. The distance between fluid inlet and upper edge of the electrodes was 7 cm. At the smallest gap width of 0.0534 cm this corresponded to 77 hydraulic diameters, sufficient to establish fully developed velocity profiles at the electrodes. At larger gap width the velocity profiles at the electrodes were not fully developed, but the conclusions of the present study are not affected by this fact.

The 0.317 cm wide and 1.02 cm long electrodes were made of nickel 200 cast into a PVC holder. Before each measurement the anodes were ground to a 400 carborundum surface finish and washed with detergent. To maintain geometry, the duration of the experiments was kept short. The maximum amount of dissolved material in any experiment corresponded to an average depth of dissolution of 69×10^{-4} cm or 13% of the smallest gap width. Length ratios needed in throwing power calculations were not corrected for this small change. All experiments were conducted at a constant volume flow rate of 16.9 ml/sec. At the smallest gap width this corresponded to a linear velocity of 1000 cm/sec. Temperature in all experiments was 25.5° ± 0.5°C. Analytical grade chemicals and distilled water were used. Special care was taken to avoid the presence of chloride ion in the $NaClO_3$ solution. Tests with $AgNO_3$ indicated that the chloride ion concentration in these solutions was below the detection limit of 10^{-4} moles/liter. The apparatus did not contain any metallic parts in contact with the solution, thus eliminating possible contamination of the solution during experiments. Effects of gas evolution and electrolyte heating on measured throwing power data were eliminated by restricting the current density to values below 15 A/cm^2 (8). This current den-

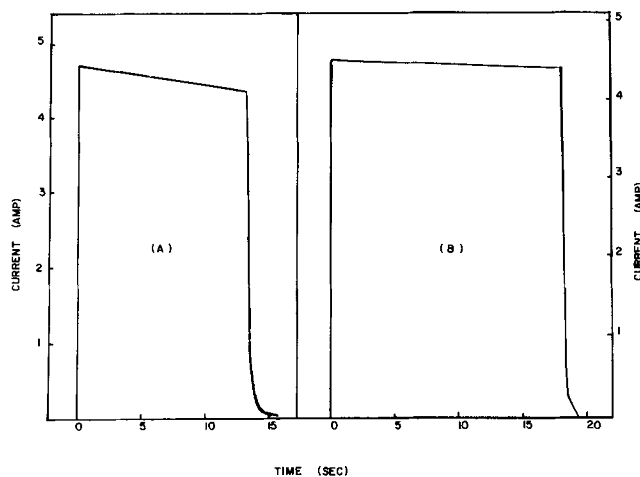

Fig. 3. Current time response to application of constant cell voltage: (A) 0.9M NaCl + 0.1M HCl, applied voltage = 9.55V; (B) 1M $NaClO_3$, applied voltage = 14.2V, electrode area 0.322 cm, gap 0.0534 cm, flow velocity 1000 cm/sec.

sity is somewhat low for practical ECM, but is significantly higher than current densities used in conventional electrolysis. The experiments were therefore expected to provide a valid insight into the factors determining throwing power in high rate metal dissolution.

Throwing power measurements.—At first current *vs.* cell voltage curves were determined by applying a constant voltage to the cell from a constant voltage/constant current power supply[1] and recording the resulting current as a function of time on a strip chart recorder.[2] The same procedure was then used for throwing power measurements, except that in addition the time of the experiment was measured with a stopwatch and the total charge passed was calculated by integration of the current trace. In all experiments the anode was ground on 400 carborundum, rinsed, and dried. It was then weighed on an analytical balance to 0.1 mg accuracy and inserted into the cell. After the experiment it was quickly removed, rinsed, dried, and reweighed.

In order to compute throwing power data from separate weight loss measurements performed at different gap width voltage, temperature and time have to be identical. In the present experiments, the amount of material dissolved at the smallest gap width had to be small to preserve geometry (see above). Keeping the experimental time the same in all experiments would therefore have resulted in even smaller amounts being dissolved at the lower currents corresponding to larger gap width. To circumvent this problem, the experiments at larger gap were run for a longer time period than at the smaller gaps. A "reduced" weight loss corresponding to the time of the shortest experiment was then computed from the measured weight loss and current data.

Current-voltage curves.—When measuring potential-current curves at high current density, voltage drops between capillary tip and measuring electrode have to be eliminated. This was accomplished here in two different ways. On one hand, a constant current was applied to the cell using the power supply mentioned above. After 2 to 3 sec, the current was interrupted by means of a mercury relay and the nonohmic potential decay was monitored on an oscilloscope with a time scale of 50 μsec/division (Fig. 1). A dynamic hydrogen reference electrode was used in these experiments. It consisted of two platinized platinum wires across which a constant current density of approximately 1 mA/cm² was applied. The potential of this electrode was periodically checked against a saturated calomel electrode.

In the second type of experiment, a constant potential was applied to the working electrode and the current was recorded as function of time. A multipurpose electrochemistry unit[3] including potentiostat, function generator, and recorder was employed. In this case anode potentials were measured *vs.* a saturated calomel reference electrode. From the measured current time traces, the over-all current potential curve was plotted as illustrated in Fig 2. At high current densities these curves exhibited a linear behavior and the effective ohmic resistance could be estimated from the slope. Using this resistance value, the IR contribution to each measured point was evaluated and subtracted from the over-all potential. Although this procedure is not accurate enough for mechanistic studies, it was sufficient for the purposes of the present investigation. All current potential measurements were performed at the smallest gap width and a temperature of 25.5° ± 0.5°C.

Results

Typical current transients measured on application of a constant cell voltage are given in Fig. 3. They exhibit a steady decrease with time which is due to the dissolution of the anode. Initial current values measured with freshly ground anodes are plotted *vs.* cell voltage in Fig. 4. Weight loss experiments were performed at the voltages indicated by the dotted line (Fig. 4). The results are summarized in Table I. Throwing power data derived from these measurements are given in the first five columns of Table II. The length ratio is obtained by dividing the larger by the smaller gap width, the weight loss ratio by dividing the "reduced" weight loss corresponding to the smaller gap by that corresponding to the larger gap.

* Based on Ni^{2+} formation.
** Weight loss computed for the time of the shortest experiment, *i.e.* 13.5 sec in sodium chloride and 18.0 sec in sodium chlorate.

Numerical values of throwing power shown in the fifth column were computed by using an empirical formula which is commonly employed in the electroplating literature

$$TP = \frac{(L - M)100}{L + M + 2} \quad [1]$$

Here L is the length ratio and M is the weight loss ratio.

For the chloride solution the calculated value of throwing power is nearly zero. This indicates that in this case the weight loss is almost inversely proportional to electrode distance (primary current distribution). In $NaClO_3$, on the other hand, negative values of throwing power are obtained. This means that here the weight loss at larger gap width is even less than predicted for primary current distribution. The throwing power data of Table II are also represented in Fig. 5 in the form of a "linear throwing index" plot. The "linear throwing index" is defined as the slope of the best straight line resulting from plotting the weight loss ratio *vs.* the length ratio. The "linear throwing index" is 1 for primary current distribution and zero for secondary current distribution. In $NaClO_3$, a throwing index larger than one is obtained, indicating again an even less uniform cutting rate than corresponding to primary current distribution.

Results of anode and cathode potential measurements in 0.9M NaCl + 0.1M HCl are given in Fig. 6 The black dots were derived from potential decay transients as illustrated by Fig. 1. All the other points were determined from measurements of the type illustrated in Fig. 2. The IR free potential values exhibit anodic Tafel behavior up to the highest current densities employed. Due to uncertainties in IR compensation, the points scatter considerably making an accurate determination of the Tafel slope difficult. The solid line indicated in Fig. 6 which reasonably well represents the data has a slope of 80 mV consistent with results of other nickel dissolution studies (9, 10). The cathodic data can be approximated by two logarithmic relationships with a slope of approximately 190 mV. The plateau separating the two cathodic Tafel regions is apparently due to a change in the mechanism of the hydrogen evolution reaction coinciding with the depletion of H^+ ions near the cathode. Conditions during weight loss experiments shown in Tables I and II corresponded to the upper cathodic Tafel region. It may be noted that potential data given here include possible concentration polarization effects since they refer to

Table II. Throwing power data

Solution	Applied voltage (V)	Length ratio	Weight loss ratio	Throwing power	Current ratio	Calculated current ratio
0.9M NaCl + 0.1M HCl	9.55	5.0	4.42	0.077	4.49	4.87

measurements taken at sufficiently long times to establish steady state with respect to mass transfer. This was done purposely because the aim of the measurements was not so much to establish detailed charge transfer kinetics, but to measure electrode potentials prevailing under conditions of throwing power determinations. From the data taken at different flow rate (Fig. 6) it appears, however, that anodically mass transfer did not substantially affect the polarization curve.[4] Potential data for 1M $NaClO_3$ are given in Fig. 7. Again Tafel behavior is observed, the anodic and cathodic slopes being approximately 150 and 240 mV, respectively. No significant effect of flow rate on measured anode potentials is observed. Compared to the data obtained in chloride solution, the anodic Tafel line is shifted to much higher potentials here. This is due to anodic passivation: nickel in acidified NaCl dissolves in the active mode, but it spontaneously passivates in neutral $NaClO_3$. The anodic current voltage curve shown, therefore, refers to transpassive behavior. Previous studies in this laboratory (9) showed that vigorous oxygen evolution occurs in the transpassive potential region.

[4] This statement holds true only within the range of measurements shown. Indeed it was observed that at a flow rate of 100 cm/sec increasing the current density above the maximum values given in Fig. 6 led to a change in the shape of the current transient and to brightening of the surface, both facts being indications of a change in dissolution mechanism.

Discussion

Numerical values of throwing power or throwing index such as given in Table II or Fig. 5 are useful for comparing different electrolytes, but they do not have much physical significance because for a given metal electrolyte combination they depend on cell dimensions and applied voltage (11, 12). In order to gain an insight into the physical parameters governing ECM throwing power, one has to consider separately current distribution and dissolution efficiency. Current distribution can be computed from a knowledge of the current-potential curve and the specific electrolyte resistance. For example, in the case of the present throwing power experiments it is possible to estimate the current ratios of Table II from measurements at a single gap width. Neglecting edge effects, the current density is given by

$$i \approx (U - \phi_t)/\rho_e l \qquad [2]$$

with ρ_e = specific electrolyte resistance and ϕ_t = sum of anode and cathode potentials, U = applied cell voltage, l = gap width. From Fig. 6 and 7, ϕ_t can be approximated for NaCl and $NaClO_3$, respectively by

$$\phi_{t(NaCl)} = 1.58 + 0.27 \log i \qquad [3]$$

and

$$\phi_{t(NaClO_3)} = 3.22 + 0.37 \log i \qquad [4]$$

The magnitude of ρ_e can be estimated from cell voltage and potential data as illustrated by Fig. 8. From Eq. [2], [3], and [4], the current density for a given cell voltage and gap width is obtained and current ratios for different gap widths can be computed. Results given in the last column of Table II show good agreement between calculated and measured current ratios. It is to be noted that in the present experiments current distribution is not affected by anodic passivation. This conclusion ought to apply in ECM whenever significant concentration polarization effects are absent and a logarithmic current-potential relationship exists.

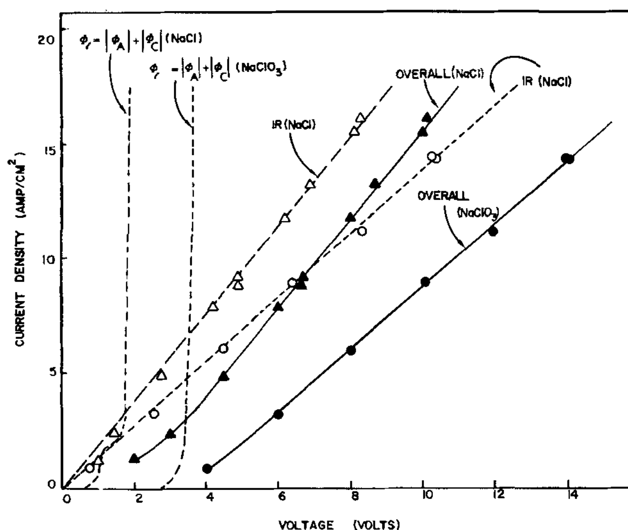

Fig. 8. Ohmic voltage drop in cell obtained by subtracting independently measured electrode potentials from cell voltage. Gap 0.0534 cm, flow velocity 1000 cm/sec; ▲ cell voltage, △ IR in 0.9M NaCl + 0.1M HCl, ● cell voltage, ○ IR in 1M $NaClO_3$, . . . sum of anode + cathode potentials (from Fig. 6 and 7).

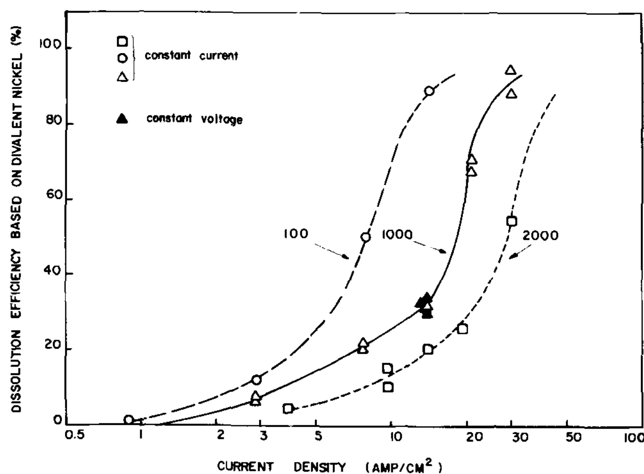

Fig. 9. Current efficiency for nickel dissolution in 1M $NaClO_3$ (based on Ni^{2+} formation) as a function of current density; gap 0.0534 cm, flow velocity 100, 1000, 2000 cm/sec.

Current distribution on the work piece is then determined by the magnitude of a dimensionless parameter (13)

$$P = \frac{b}{2.3 \rho_e l i} \quad [5]$$

where b is the anodic Tafel slope, ρ_e the specific electrolyte resistance, l a characteristic length, and i the current density. Primary current distribution is approximated for $P << 1$. Because of the high current densities employed this condition usually ought to be satisfied in ECM. For example, using the measured b and ρ_e values for NaCl and $NaClO_3$, respectively, with the gap width l as characteristic length the value of P in the present experiments varied between 0.0046 to 0.0041 for NaCl and between 0.0057 and 0.0051 in $NaClO_3$. Upon application of higher current densities, the value of P would be even smaller. It is worth noting that P does not depend on the actual anodic potential values, but only on the slope of the current voltage curve. Therefore the width of the passive potential region in a conventional potentiostatic current-voltage curve should not significantly affect current distribution under ECM conditions, contrary to some statements found in the literature (15).

The data in Table II indicate that the reason for the observed difference in throwing power between the passivating $NaClO_3$ and the nonpassivating NaCl lies in a different dependency of dissolution efficiency on current density. In the case of NaCl, the metal dissolution efficiency is constant, while in the case of $NaClO_3$ it is a strong function of current density. This is further illustrated by the data of Fig. 9, which were obtained from weight loss determinations performed at constant current density at the smallest gap width of 0.0534 cm. For comparison the weight loss data of Table I, obtained at constant voltage, are also indicated. Because of oxygen evolution, very low metal dissolution efficiencies are obtained at low current densities, but with increasing current the dissolution efficiency sharply increases. The detailed shape of the curve depends on flow rate; the higher the flow rate, the lower the dissolution efficiency at a given current density. A similar S shaped curve for dissolution efficiency of nickel in $NaClO_3$ plotted *vs.* current density has been obtained previously in this laboratory in a different experimental cell (9). The numerical values obtained in that study were somewhat different, however, and no effect of stirring was observed. This was probably because hydrodynamic conditions were not as well defined as here. A more detailed investigation of the experimental factors affecting current efficiency for nickel dissolution in the transpassive potential region will have to be made before a mechanistic interpretation of the shape of the curves shown in Fig. 9 can be given.

The present results show clearly, however, that a discussion of how passivating electrolytes affect the dimensional control in ECM cannot be based on current potential measurements alone, but it has to include the study of reaction stoichiometry. Lower values of throwing power than theoretically possible with a nonpassivating electrolyte can indeed be obtained with a passivating electrolyte provided the current efficiency for metal dissolution is an increasing function of current density. The present study, therefore, supports and puts on a firm basis ideas advanced by other workers (6, 16, 17) who recognized the importance of the metal dissolution efficiency in obtaining good dimensional control with passivating ECM electrolytes.

Technical Notes

Gallium Oxidation in Alkaline Solution

R. S. Perkins[1]

Department of Chemistry, University of Southwestern Louisiana, Lafayette, Louisiana 70501
and
Rate Processes Institute, University of Utah, Salt Lake City, Utah 84112

The electrochemistry of gallium is important not only in practical applications, but also for theoretical considerations due to its existence as either a liquid or a solid in aqueous electrode systems.

Past studies of the anodic oxidation of Ga in alkaline solutions have been limited. It is the purpose of this study to investigate in somewhat more detail, using cyclic voltammetry, the first stages of anodic oxidation of Ga in aqueous NaOH solutions.

Experimental

A three compartment Pyrex cell was used.

Carbonate free NaOH solutions were made of reagent grade materials. Solutions were made from water doubly distilled from a basic permanganate solution.

The reference, counter, and test electrodes were each in a separate cell compartment and each were in the same solution. A closed stopcock effectively separated the reference and working compartments. An open stopcock connected the counter and working compartments. A hydrogen reference electrode and a platinum counterelectrode were used. Test electrodes of several designs were used. All test electrodes were made from gallium of 99.999% purity. In some experiments the test electrode consisted of a gallium hemisphere of 0.06 cm^2 geometrical area formed in one end of a U-shaped glass tube. Another design consisted of gallium forced through a 0.051 cm diameter channel in a short length of Teflon tube. The emerging gallium formed a bead of area approximately 0.008 cm^2. In one experiment this bead was removed and the electrode was planar with an area equal to the cross sectional area of the 0.051 cm diameter channel in the Teflon.

The gallium electrode used was prepared and installed in the cell in an atmosphere of nitrogen. After fabrication, the gallium electrode was solidified. Experiments were carried out at room temperature, approximately 25°C.

Except for the reference electrode compartment, the cell was deaerated with nitrogen.

A conventional cyclic voltammetry apparatus was used with an Exact Electronics function generator and a Wenking potentiostat. The resulting curves were displayed on an X-Y recorder.

In some experiments, current-potential curves were obtained as the gallium electrode was mechanically renewed by scraping. For this work an experimental arrangement similar to that described previously (1) was used. The Teflon mounted gallium electrode was used.

Data

The data taken was in the form of potential-current plots over the potential region of hydrogen evolution to various points of anodic oxidation. Experiments in each solution were done at a number of sweep rates as will be noted in the discussion to follow. A typical curve obtained in 1M NaOH is given in Fig. 1. It is seen to consist of a region of hydrogen evolution, a region of anodic oxidation which is composed of several smaller regions defined by shoulders and changes of slope, and a small region of cathodic reduction which obviously represents much less charge than the corresponding region of anodic oxidation. The qualitative features of this curve do not change greatly when the sweep rate is altered.

Discussion

In these experiments the most striking feature of the data is the fact that with increasing anodic potential, the current increases without limit in the potential range studied, and this current is not due to oxygen evolution. Experiments were also performed in which the potential was adjusted to greater anodic values, and it was observed that although the current finally levelled out with increase of potential, no subsequent decrease was noted and oxygen evolution was never observed. It is reported that oxygen evolution in 1M KOH solutions does not occur until a potential of 10-30V *vs.* NHE is imposed on the electrode (2, 3). The absence of passivation may be explained by assuming that the product of oxidation does not form a thick film on the electrode. In view of the large amount of product formed, it must be concluded that the product of oxidation is soluble in the solution used. In this region of pH, the reaction product predicted thermodynamically is Ga_2O_3. This substance is highly soluble and forms GaO_3^{---} in basic solution (4). Dissolution of the electrode was observed visually at high current densities. Formation of a soluble product also explains the small amount of cathodic charge observed.

It is seen from Table I that over a relatively wide range of sweep rate, the size of the cathodic charge is fairly constant. This would indicate that the sub-

0.51	20.9	2.22

* Peak too small to determine area.

stance being reduced is a thin film of oxide on the electrode.

Further evidence of a thin film of oxide on the electrode is given by the scraping experiments in which it is indicated that the reaction is retarded and by exposing fresh electrode surface, additional product may be formed. In the scraping experiments, the Ga electrode was mechanically scraped with a sharpened sapphire rod rotating at 30,000 rpm. The scraping was done at various parts of both the anodic and cathodic sweeps but not in the region of hydrogen evolution. In all regions of oxidation (A1 through A4) the anodic current is increased by scraping. The scraping does not produce a smooth curve of higher current but rather a number of transients reflecting the violent scraping conditions at the electrode. The size of the transients was not reproducible although the general effect was. Most transients were larger than the prescrape current at a given voltage by a factor of between 2 and 10. In some instances, at lower current densities, scraping increased the current by as much as a factor of fifty. As well as can be determined, the current transient is not produced until the scraping drill touches the electrode. Contact with a nonrotating drill has no effect. The transient is definitely not due to stirring of bulk solution.

An idea of the thickness of the thin film can be obtained by assuming a roughness factor of one for the test electrode and further assuming that the cathodic peak is due only to reduction of the oxide film and not due at all to reduction of soluble product in solution near the electrode. With these assumptions, a value of approximately 3.4 monolayers of Ga_2O_3, as measured in terms of layers of Ga consumed, is calculated for film thickness at the time of reduction. This agrees well with film thickness obtained by constant current discharge of passivated Ga (5).

The amount of charge equal to this film thickness on the anodic sweep corresponds to the area under the curve making up the two first parts of the oxidation peak (A1 and A2). For calculating area, the anodic boundaries of A1 and A2 were taken as vertical lines drawn down to the potential axis from the current-potential curve at the points of slope changes defining A1 and A2. Experiments were done in which the sweep was reversed after A2. This reversal hardly affected the area of the cathodic peak. It appears then, that the cathodic peak is due to the reduction of an oxide film, the formation of which is represented by A1 and A2. The first part of the oxidation peak, A1, corresponds to approximately a monolayer of coverage on the electrode. It is likely that such a monolayer would alter the electrode enough to significantly change the kinetics of a reaction. Formation of such monolayers has been studied on mercury (6). The experiments done here do not allow us to state with certainty the composition of any films formed. The initial monolayer may be Ga_2O_3, or chemisorbed oxygen, or some oxide which has not been well characterized thermodynamically.

Oxidation of gallium in 1M NaOH would appear to proceed, therefore, by an initial formation of a monolayer of oxide or oxygen with subsequent thickening of this film to about three or four layers. At this point the properties of the film become such that the rate of dissolution increases and prevents further thickening.

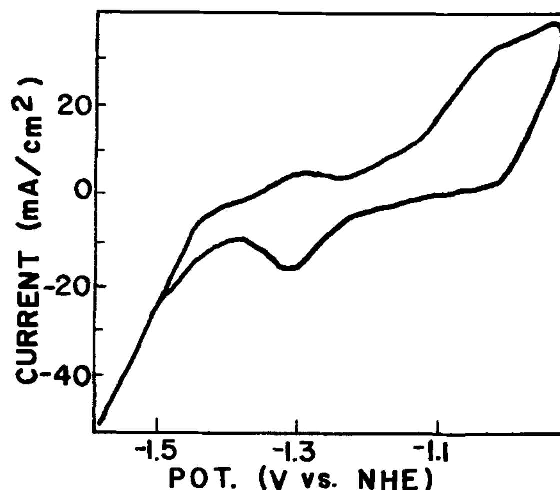

Fig. 2. Current-potential curve for planar Ga electrode in 1M NaOH. Sweep rate = 0.47 V/sec.

Further increase of potential should increase the rate of oxidation of gallium and such an increase of current is observed. As higher current densities are obtained, diffusion either through the oxide film or through the electrolyte should play a more important part in the reaction. Evidence that this is true is seen in Fig. 1 and 2. The two curves in these figures were obtained under experimental conditions which were identical except that the electrode area and shape differed. Curve 1 was obtained using a spherical electrode and curve 2 was obtained with a planar electrode. The two curves differ in that at high anodic potentials the current density obtained is higher for the spherical electrode. This is to be expected if diffusion is involved (7, 8). Evidence that the diffusion is taking place in solution is that stirring increases the anodic current as was also found by Popova and Simonova (9). The similarity of regions A1 for the two types of electrode is at variance, however, with the diffusion studies of Faizullin *et al.* (10).

Solutions of 0.1M NaOH give smaller anodic currents. Thus the limiting diffusion is that of OH^- and not of product ions.

The current-potential curve has another change of slope very near the anodic end of the potential sweep. The current increases more slowly with change of potential. This is probably not due to a change in product as the A3 and A4 segments are so similar. It is possibly due to a change in the nature of the oxide film on the electrode. Perhaps diffusion in the oxide begins to play a part in the rate of oxidation at this point but the data here are not extensive enough to study this further.

A Rapid and Complete Method to Remove Plutonium Contamination from Aluminum

P. L. Wallace, J. C. Walden, and J. W. Magana

Lawrence Radiation Laboratory, University of California, Livermore, California 94550

The Process

This process was first described in a German patent (1), and is used here to decontaminate aluminum parts of complex shapes. Its principal usage has been in decontaminating x-ray spectrographic cell holders. This contamination occurs when acid solutions of plutonium leak from standard liquid cells and attack the aluminum.

The process involves (*i*) degreasing the part in acetone, (*ii*) dipping it in a heated (90°C) bath for about 30 sec, (*iii*) rinsing the part in water, (*iv*) drying it, and, finally, (*v*) checking it for any residual contamination. All of these operations are carried out in an open front hood to prevent contamination spread.

The composition of the cleaning bath is given in Table I. It has been found important to not reuse the solution for large numbers of parts, because depletion of some components causes the reaction rate to lessen. Rinsing quickly after cleaning is mandatory, because the part will blacken rapidly otherwise. No electric current is necessary to augment the process.

Results

Parts having fixed plutonium contamination of greater than 10,000 alpha counts/min have been decontaminated to no detectable counts with the 30 sec cleaning.

Table I. Cleaning bath composition

Component	Volume (%)
Phosphoric acid	50
Nitric acid	6.5
Acetic acid	6
Sulfuric acid	25
Water	12.5

Plus 3 g/cc of crystalline nickel nitrate, $Ni(NO_3)_2 \cdot 6H_2O$.

Key words: plutonium, aluminum, decontamination.

The surface condition after cleaning is bright and somewhat shiny. However, the patent writeup indicates that a 3 min immersion would produce a mirror-like finish. While such a finish is desirable, it does entail more metal removal than is wanted to maintain the sample holder's close tolerances.

To get a feeling for the actual amount of metal removed during processing, aluminum tubes were tested as mockups for the cell holders. The weight loss for five 20g tubing sections (4 cm long by 2.0 cm ID; 2.6 cm OD) in 30 sec (bath temperature 90°C) varied from 50 to 100 mg, depending on the amount the bath was depleted by usage. The outside diameter change on these tubes was less than 0.03 mm in each case.

Conclusions

A rapid method of decontaminating aluminum parts has been found. To date, it has made every sample holder that had been grossly contaminated available for reuse.

Acknowledgment

Thanks are due to D. M. Cheney (Argonne National Laboratories, Idaho Reactor Site) who first brought this process to one author's (P. L. Wallace) attention about 1960. The adaptation for decontamination was discovered here some 10 years later.

This work was performed under the auspices of the U. S. Atomic Energy Commission.

An Electrochemical Technique for Microsectioning Silver

Nghi Q. Lam, Steven J. Rothman, and L. J. Nowicki

Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

The electrochemical technique for removing thin uniform sections from a metallic sample consists of forming an anodic oxide layer that can be either mechanically stripped or chemically dissolved without attack of the metal substrate. This method has not been applied to silver to date; the sectioning techniques that have been used have been based on the formation of dissolvable films of silver iodide or silver bromide and their dissolution in either a 1M sodium-thiosulfate solution (1) or a solution of 1.0 g/liter KCN in water (2). In our preliminary experiments, the former solvent stained the silver surface, probably due to the formation of colloidal silver on the surface (1), and the latter solvent attacked the silver substrate at an unacceptable rate. We have therefore developed an electrochemical method of removing thin sections of silver for the determination of very small diffusion coefficients. This method has also proved useful for preparing a good surface on silver diffusion samples.

Key words: anodization, silver, sectioning, stripping, surface preparation.

Experimental Methods and Results

Surface preparation.—Monocrystalline silver rods of 1.24 cm diam were grown from 99.999% purity silver by the Bridgman method and spark-cut into disks a few millimeters thick. After mechanical polishing through 0.3μ Al_2O_3, the samples were chemically polished with a solution made up of 25 ml of saturated chromic acid and 3 ml of 10% HCl (3). The chemical polishing was performed by swabbing the silver surface with a cotton-tipped applicator saturated with the solution and rinsing the sample intermittently in running water. Chemical polishing in this manner for 10 min removes a layer ~15μ thick, which was the approximate depth of the region deformed in polishing. At the end of this polishing step, the sample was washed with distilled water and then with alcohol in an ultrasonic vibrator, and dried in warm air. After chemical polishing, a few layers approximately 200Å thick were removed from the silver surface by anodizing in an electrolyte of 0.5% KOH in water (with current density = 1.0 mA/cm^2, time = 22 sec) and then dissolving the silver oxide in an aqueous solution of NH_4OH. This procedure helped remove submicroscopic irregularities from the surface. The entire surface obtained was optically flat and free of pits.

Sectioning.—Most of the anodizing experiments were made on a (100) face of a silver single crystal that had been irradiated for 3 days in a flux of 3×10^{12} thermal neutrons/cm^2-sec. The specific activity of the crystal (^{110}Ag) was measured as 5.43×10^3 cpm/μg, thus allowing a conversion from counts/min to micrograms of silver. A simple anodizing cell was used. The platinum foil cathode was cleaned with HNO_3 before use. Silver paint was used to fasten a copper wire to the back of the specimen for the electrical connection. The sample was masked with Tygon protective paint, so that only the preanodized surface was exposed to the electrolyte. The wire was also coated with Tygon. The electrolyte consisted of 5g KOH per liter of water. After anodizing, the siver oxide films, which, if thick enough, showed uniform interference colors, were dissolved in a solution of 1% (in volume) NH_4OH in water.

To determine whether this solvent attacks the silver, oxide layers of different thicknesses were formed on the irradiated silver crystal by anodizing with current densities of 0.17, 0.48, and 0.85 mA/cm^2 for 30 sec. The sample was then immersed in the NH_4OH solution, and the activity of the solution was counted as a function of time. Figure 1 shows that the NH_4OH solution dissolved the oxide and attacked the silver to an insignificant extent. About 5 sec were sufficient to remove an oxide layer 1000Å thick. Interference microscopy showed that the silver surface remained clean and flat after oxide removal.

The thickness of silver removed is plotted as a function of anodizing time in Fig. 2 for various current densities. The thickness removed in each anodizing-dissolution step was determined by counting the solvent for ^{110}Ag content and using the measured value of specific activity to convert to micrograms of silver. The sample was also weighed on a microbalance before and after removal of 40 sections; the difference between amounts of material removed, as measured by the two techniques, was about 9%, which is within the experimental error. The step height on a nonradioactive silver crystal, part of which was masked by a spot of Tygon paint, was measured on an interference microscope after anodizing and removing 40 sections under the same current and time conditions. The step height agreed, within the experimental error, with the thickness removed from the radioactive sample. The amount of material removed per anodization under identical conditions was reproducible to ± 8%. Less than 3% of the removed activity was found in the anodizing solution and on the cathode.

The same anodizing treatments on silver crystals of random orientation yielded the same anodic film

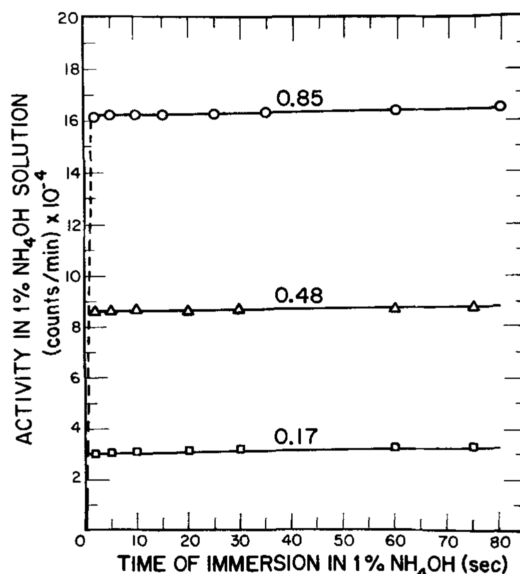

Fig. 1. Plot of ^{110}Ag activity of 1% NH_4OH solution after immersing the anodized silver sample in the solvent for various times. The different thicknesses of silver oxide were formed by anodizing for 30 sec with current densities of (□) 0.17, (△) 0.48, and (○) 0.85 mA/cm^2.

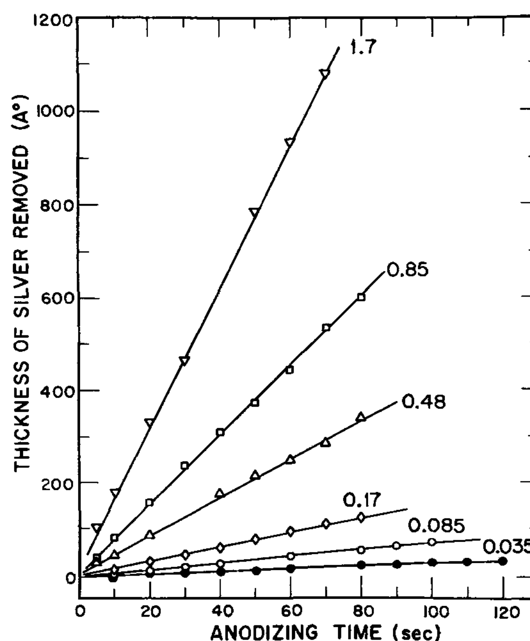

Fig. 2. Calibration of the anodizing of monocrystalline silver in an aqueous electrolyte containing 0.5% KOH. The numbers on the curves indicate the anodic current densities in units of mA/cm^2.

thickness, indicating that the rate of anodization is orientation independent, as was observed for gold (4). The thickness of the anodized layer was found to be independent of the KOH concentration in the electrolyte. The same observation was also made by Vermilyea (5) in a study of anodic oxidation of tantalum.

The thickness of silver that was anodically oxidized in 1 sec, deduced from the slopes of the curves in Fig. 2, is shown in Fig. 3 as a function of current density. An increase in current density from 0.17 mA/cm^2 to 1.7 mA/cm^2 led to a tenfold augmentation in the anodizing rate, similar to the case of anodizing gold (4). For high current densities (>4 mA/cm^2), it was better to use current pulses of ½-sec duration rather than constant current densities, because the oxygen evolution, which occurred shortly after establishing the current, could affect the uniformity and thickness of the oxide.

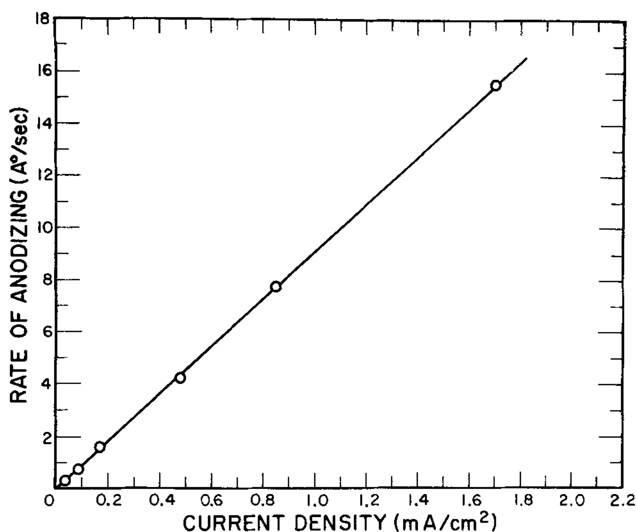

Fig. 3. Relationship between the rate of anodizing (in Å/sec) and the anodic current density (in mA/cm²). Anodizing rate = 9.1 × (current density).

Conclusions

The anodic oxidation technique can be used for removing reproducible thin sections from silver. An aqueous solution containing 1% NH_4OH appears to be the best solvent for removing the silver oxide, inasmuch as it does not attack the silver substrate and enables one to obtain a clean surface after the dissolution. A combination of chemical polishing and anodizing-dissolution techniques can be used instead of electropolishing to prepare a flat, strain-free silver surface prior to diffusion experiments.

Brief Communication

Transport in Non-Newtonian Flow

R. Greif, R. Kappesser, and I. Cornet*

Department of Mechanical Engineering, University of California, Berkeley, California 94720

Rendering a fluid non-Newtonian by the addition of a high molecular weight polymer alters the heat, mass, and momentum transport characteristics of the fluid (1-10). Electrochemists have long dealt with such non-Newtonian systems, for example, for achieving smoother and finer grained deposits in electrolytic metal deposition or in electrodeposition of rubber or related synthetic polymers from latices.

There have been several investigations that have dealt with the determination of the molecular diffusivity in non-Newtonian systems (3, 6, 7, 9, 10). These studies utilize mass flux measurements in conjunction with theoretical results for non-Newtonian systems to obtain the diffusivity. In these studies the relationship between the shear stress and the rate of strain is written in the form of a power-law, *viz.*

$$\tau_{xy} = -K\left(\frac{\partial V_x}{\partial y}\right)^n \qquad [1]$$

although more complex relations are possible. In contrast, the corresponding expression for the molecular flux of mass or heat is assumed to be a linear function of the concentration, or temperature, gradient so that

$$J = -D\frac{\partial C}{\partial z} \text{ or } q = -\lambda\frac{\partial t}{\partial z} \qquad [2]$$

* Electrochemical Society Active Member.

Key words: transport, non-Newtonian theory, molecular flux, concentration gradient.

In this study we experimentally demonstrate the validity of the assumption that J is a linear function of the concentration gradient.

In a previous investigation (10) we determined the molecular diffusivity of oxygen in aqueous 4% sodium chloride solutions which were rendered non-Newtonian by addition of various concentrations of Polyox WSR 301 (Union Carbide), a completely water soluble polymer of ethylene oxide. The system consisted of a rotating Monel disk, which was made cathodic while the anode was a platinized-titanium wire mesh cylinder. The mass flux of oxygen diffusing to the rotating disk was determined by measuring the mass transfer limiting current for the net reaction

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad [3]$$

The mass flux is dependent on the over-all oxygen concentration difference, $\Delta C_O = C_{O,\infty} - C_{O,w}$. The concentration of oxygen far from the disk, $C_{O,\infty}$, was measured by Winkler analysis while the concentration at the disk surface, $C_{O,w}$, was taken to be zero. Equating the experimental and theoretical results for the mass flux yielded the results for the diffusivity.

A critical confirmation of the experiment and analysis was readily made by comparing the value obtained for the diffusion coefficient in the absence of Polyox with the value reported in the International Critical Tables (11). The results were in excellent agreement under this Newtonian flow condition (10).

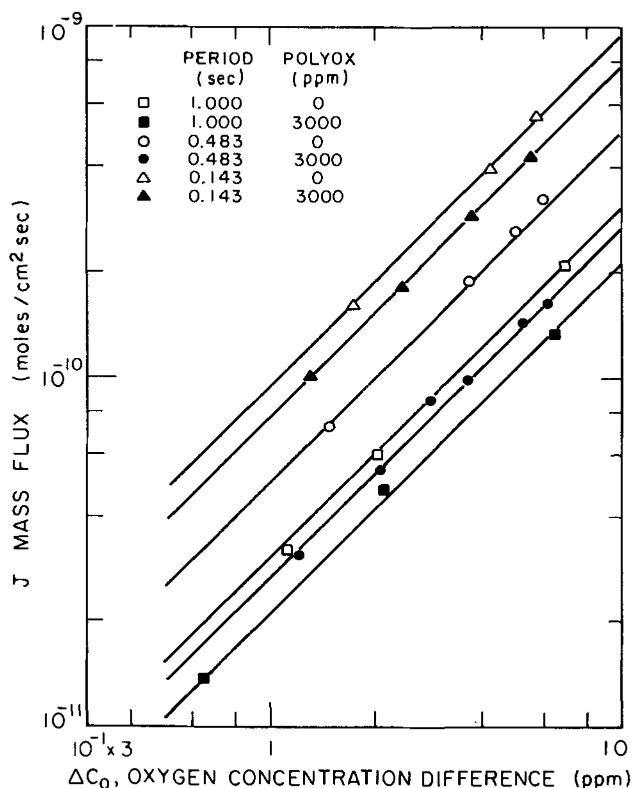

Fig. 1. Comparison of mass flux dependence on concentration gradient in Newtonian and non-Newtonian fluids.

In the analysis for the mass transport the molecular flux had been assumed to be linearly dependent on the concentration gradient (*cf.* Eq. [2]). We had thought that this assumption had been previously confirmed but apparently this is not so. Therefore, a series of tests was performed at different concentration differences, that is, for different values of $\Delta C_O = C_{O,x}$. This was achieved by first bubbling nitrogen through the solution until the desired concentration of oxygen was achieved. We note that all our previous experiments had been performed at essentially a single value of $C_{O,x}$.

The experimental results are presented in Fig. 1 in terms of the mass flux *vs.* the oxygen concentration difference. Results are shown for the Newtonian fluid (0 ppm of Polyox) and for the non-Newtonian fluid (3000 ppm of Polyox) for three periods of rotation (Reynolds number). For a linear system, the mass flux would vary linearly with the concentration difference, and this is clearly the result shown. Note that the linear slope of 1.0 is observed for all the conditions tested, thereby demonstrating the validity of Eq. [2].

Although Eq. [1] is not required, as far as the above conclusion is concerned, the values of the coefficients, K and n are of interest. For shear stress in units of dynes/cm² and rate of strain in units of sec^{-1}, $n = 1.00$, $K = 0.0094$ for 0 wppm of Polyox and $n = 0.68$, $K = 0.88$ for 3000 wppm of Polyox (temperature of 27°C). These values were obtained from measurements we performed with a Fann U-G, Model 35, rotating cylinder viscometer. Now, the theoretical result for the mass flux to a rotating disk in laminar flow divided by the concentration difference, that is, $J/\Delta C_O$, varies with rpm according to $(rpm)^{1/n+1}$ (9, 10). Thus, an independent check is afforded by comparing the value of n obtained directly from the viscometer measurement and the value of n obtained directly from the mass flux measurement. The results are in excellent agreement (10).

Lastly it should be noted that the shear rates determined from the viscometer measurements varied from 150 to 1000 (sec^{-1}) (10). In the present experiments with a 3.65 cm diam disk, the maximum shear rates may be calculated (12, 13) and the results vary from 40 to 1200 (sec^{-1}).

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 118, No. 2, 4, 9, and 10; February, April, September, and October 1971.

Investigation of the Direct Reduction of Zinc Oxide in Alkaline Electrolytes

D. Drazic and Z. Nagy (pp. 255-257, Vol. 118, No. 2)

K. Schwabe, O. Hladik, and H. Oude[1]: Drazic and Nagy have investigated the direct reduction of zinc oxide in alkaline electrolytes in the paper under discussion. From their experiments they conclude that our suggestion about the direct reduction of solid zinc oxide confirmed by our radiochemical investigations[2] and by the investigations of other authors is not true; the current efficiency of the direct reduction should be very small with respect to the reduction of the soluted zincate. We cannot agree with this opinion.

The conditions of the experiments are quite different. We have worked with a "paste electrode," that means under conditions which can be compared with a working alkaline zinc battery. The surface of the zinc oxide was very large with respect to the volume of the zincate solution. The conductivity of the zinc oxide was small compared with that of the ZnO single crystal applied by Drazic and Nagy. From the high electron conductivity of the single crystal, it is clear that it works as cathode under the conditions described by the authors, because the amount of zincate in the solution is much larger than that of ZnO in the single crystal. Up to 100 mA/cm^2, we have not observed any hydrogen evolution with our paste electrode; reducing zincate solution without solid zinc oxide already at 10 mA/cm^2 the hydrogen evolution is visible. With our paste electrode we observe H_2 evolution only if the reduction of the paste of ZnO was reduced and the formed Zn came in direct contact with the solution. The difference in the cathodic overvoltage, which the authors have found, is quite reasonable under their conditions, but not under our conditions. The structure of the zinc reduced from zincate solution is that of dendrites (Fig. 1) found also by Gerischer.[3] From ZnO-paste we receive a zinc powder without macrostructure (Fig. 2) because it is formed by destruction of the ZnO lattice. We are therefore convinced, that under our conditions, similar to that of an alkaline Zn-battery, mainly the solid ZnO is reduced because our results can only be explained by this mechanism.

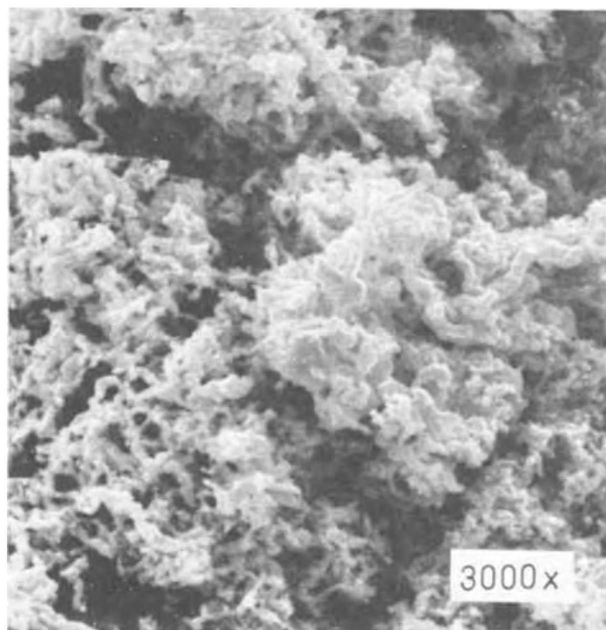

Fig. 2. Crystals electroplated from ZnO/KOH-paste (100 mA/cm^2)

D. Drazic and Z. Nagy: When referring to the paper of K. Schwabe and O. Hladik[4] we wanted to point out that the polarization curves obtained with the ZnO paste electrode in 1M and 11M hydroxide solutions can also be explained by a process other than the solid-state oxide reduction.

It is known that the polarization curves obtained with porous electrodes (ZnO paste is also a porous system) include a considerable *IR* voltage drop formed inside the pores, especially at higher current densities. The resulting linear current-voltage relation is particularly well pronounced in Fig. 5 of their paper.[5] Since no *IR* drop corrections were made, and the authors have not discussed this matter at all, we had reasons to believe (*e.g.*, if the resistance of the pores in ZnO paste was only 0.5 ohm, the *IR* drop could be as high as 500 mV at 1000 mA/cm^2) that the polarization curves obtained without *IR* drop corrections should be similar in solutions of similar conductivities, no matter what reaction was going on inside the electrode.

Further, the results of the radiotracer measurements to which the authors refer, seem very logical, but give information only about transfer processes taking place in the bulk of the solution and have nothing to do with the electrode reaction. The results would be the same whether zincate ion or a solid-state reaction path was

[3] H. Gerischer, *Surface Sci.*, 13, 265 (1969).

[4] O. Hladik and K. Schwabe, *Electrochim. Acta*, 15, 635 (1970).

[5] O. Hladik and K. Schwabe, *Electrochim. Acta*, 15, 635 (1970).

operative. Namely, if the zincate ion path was operative, it would be the zincate ions formed by dissolution of ZnO very close to the metallic zinc surface inside the pores which would be reacting, and not the zincate ions from the bulk of the solution.

The absence of hydrogen evolution from the paste electrode can also be explained by the dissolution-deposition mechanism: the zincate concentration within the pores is kept high by the continuous dissolution of the oxide.

Finally, referring to the question of morphology of zinc deposited within the porous electrode, we think that the nondendritic deposit cannot be considered as proof that zincate ions are not the reacting particles in the electrochemical step of the over-all deposition reaction. It has been shown[6] that one of the necessary preconditions for dendritic growth is diffusion control of the electrode process. This condition is not fulfilled within the pores because of ready availability of zincate through the dissolution of ZnO and, therefore, no dendrites can be expected until the zincate ions from the solution layer start taking part in deposition, *i.e.*, very close to the end of the charging process.

Hence, we still do not have any reason to believe that our conclusion about the importance of zincate ion reaction path in the charging process cannot be applied to the real situation in batteries.

The Thermodynamics and Electrode Kinetic Behavior of Nickel in Acid Solution in the Temperature Range 25° to 300°C

R. L. Cowan and R. W. Staehle (pp. 557-568, Vol. 118, No. 4)

V. Ashworth[7] and P. J. Boden[8]: The authors have shown that the data required to construct electrochemical equilibrium diagrams for any system at a temperature other than 298°K may be readily computed by means of the empirical "correspondence principle" technique due to Criss and Cobble. However, the subsequent interpretation of these diagrams is rarely so straightforward as it might appear at first even when their intrinsic limitations are fully appreciated.

In particular, it is important to recognize that the abscissa of the diagram properly refers to the negative logarithm of the hydrogen ion activity ($-\log a_{H^+}$) which for a single solution will vary to a greater or lesser extent throughout the temperature range (*i.e.*, $d \log a_{H^+}/dT \neq 0$). With the exception of solutions within a very limited range of hydrogen ion activity it is, therefore, invalid to use the solution *p*H measured at room temperature (298°K) as the reference point on the abscissa in connection with a diagram constructed for a higher or lower temperature. Fortunately it is possible to calculate the change in a_{H^+} of a solution with change in temperature and further, for a more limited number of cases, a second scale may be added to the diagram such that the use of the room temperature *p*H becomes permissible.

In the simplest case, as the temperature of an unbuffered aqueous solution is raised, chemically equivalent amounts of additional hydrogen and hydroxyl ions will be generated as a result of the increased dissociation of water. The ionic product of water, ($K_{w(T)}$), at temperature T is given by

$$K_{w(T)} = (a_{H^+(298°K)} + x)(a_{OH^-(298°K)} + x)$$

where x is the additional ion activity as a result of the temperature change from 298°K to TK. At 298°K and *p*H n

$$a_{H^+} = 10^{-n}$$

and

$$a_{OH^-} = 10^{-(14-n)}$$

thus at temperature, T

$$K_{w(T)} = (10^{-n} + x)(10^{-(14-n)} + x) \quad [1]$$

and the negative logarithm of the hydrogen ion activity becomes $-\log_{10}(10^{-n} + x)$. Clearly, with a knowledge of the value of $K_{w(T)}$, the solution of Eq. [1] will yield the corresponding value of x for any given value of n and it becomes possible to refer the negative logarithm of the hydrogen ion activity at T to the room temperature *p*H. It is this former value which should be used as a reference point when employing the diagrams derived by the authors when considering unbuffered solutions. Alternatively, as shown in Fig. 1, a second scale may be added to the abscissa which conveniently relates *p*H (at 298°K) to the a_{H^+} at temperature. Since the room temperature *p*H is more commonly measured this second scale is the more convenient to use, but its asymmetry makes it imprecise for neutral and alkaline solutions. Under these circumstances its linearization, as shown in Fig. 2, becomes desirable. The asymmetry of the new abscissa derives from its logarithmic nature; briefly, although x varies symmetrically with n, reaching a maximum in the neutral *p*H region, the introduction of small amounts of hydrogen ion by dissociation makes a greater contribution to $-\log a_{H^+}$ at high rather than low *p*H values.

When a solution has some buffer capacity, the hydrogen ion activity no longer varies as the dissociation constant of water; and, although in these circumstances the use of the second scale is incorrect, calculation of the new activity is possible. Thus an aqueous solution of a weak acid (HA) will contain H_2O, HA, H^+, A^- and OH^-, to preserve electroneutrality

$$[H^+] = [OH^-] + [A^-] \quad [2]$$

where the square brackets represent concentrations and, further, neglecting activity coefficients

$$K_w = [H^+][OH^-]$$

Thus from Eq. [2]

$$[H^+]^2 = [H^+][OH^-] + [H^+][A^-]$$

and

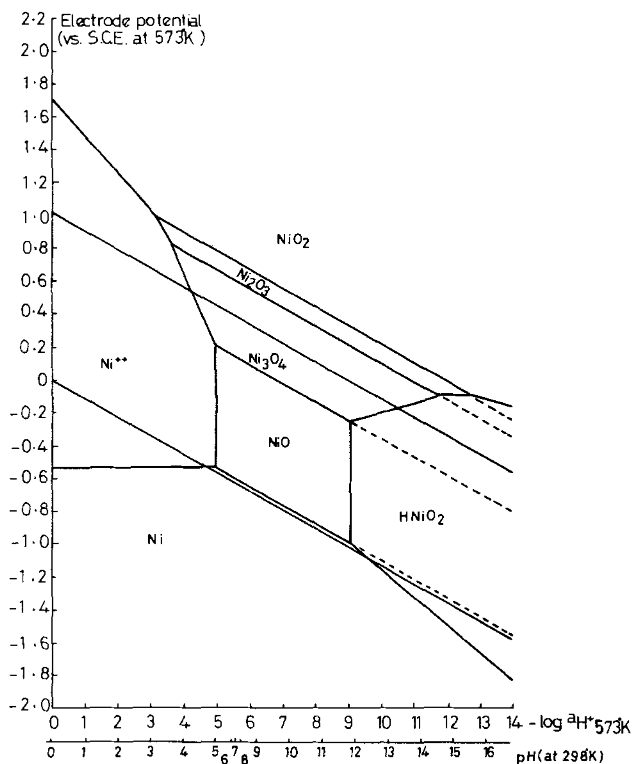

Fig. 1. Potential *p*H diagram calculated for nickel at 573°K

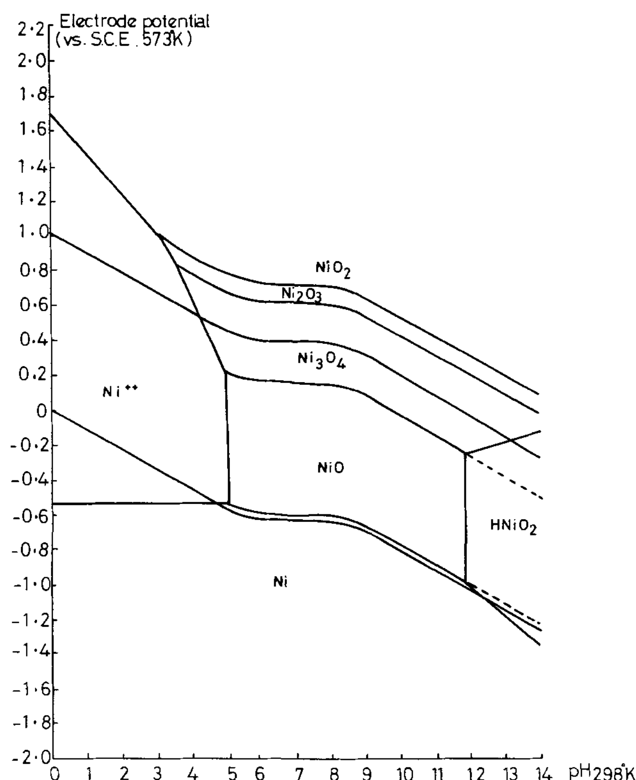

Fig. 2. Potential *pH* diagram calculated for nickel at 573°K with obscissa in *pH* units measured at 298°K.

$$2[H^+]d[H^+] = dK_w + [H^+]d[A^-] + [A^-]d[H^+]$$

or

$$d[H^+] = \frac{dK_w + [H^+]\, d[A^-]}{2[H^+] - [A^-]} \qquad [3]$$

That is, if some undissociated HA is present in the solution at 298°K, by raising the temperature the hydrogen ion activity will alter as a result of changes in both K_w and K_{HA} (the acid dissociation constant). In the special case where $[A^-]$ cannot change (unbuffered solutions of strong acids and in pure water), $d[A^-]$ becomes zero for a temperature rise and the value of $d[H^+]$ from Eq. [3] will coincide with the value of x given by Eq. [1]. The analogous equation to Eq. [3] for a solution containing a weak base (BOH) is given by

$$d[H^+] = \frac{dK_w - [H^+]d[B^+]}{2[H^+] + [B^+]}$$

To use the derived equilibrium diagrams correctly it becomes necessary to calculate the value of $d[H^+]$ and, hence, a_{H^+} for the buffered solution at the temperature in question. A buffered condition which may be overlooked occurs when the metal-water system generates a self-buffering situation which controls the a_{H^+} by means of displacement of a hydrolytic equilibrium. For example, in the Ni/H_2O system the equilibrium

$$Ni^{2+} + 2H_2O \rightleftharpoons HNiO_2^- + 3H^+$$

may become important at very high temperatures and itself represent such a self-buffered system. Although the nickel ion activity ($Ni^{++} + HNiO_2^-$) is defined, when the diagram is calculated (say at 10^{-6} kg ions/m^3), the hydrogen ion activity will depend on the dissociation constant of the weak acid Ni^{++}. Any combination of $a_{Ni^{++}}$ and $a_{HNiO_2^-}$ which satisfies the requirement

$$a_{Ni^{++}} + a_{HNiO_2^-} = 10^{-6} \text{ kg ions/m}^3$$

is permissible. Nevertheless, the use of Eq. [3] is equally applicable to such a system and requires only a recognition that all solution species must be considered in calculating the variation in hydrogen ion activity.

Returning to the original paper the authors point out that, on the basis of their electrochemical equilibrium diagrams, "the range of stability of the nickel oxy-anion $HNiO_2^-$, increases greatly with increasing temperature." Superficially this suggests that, in mildly oxidizing alkaline solution, nickel metal will be in equilibrium with NiO at 298°K; whereas, in the same solution heated, say to 573°K, the metal will be in equilibrium with the oxy-anion. That is, in the former case the material may become passive and in the latter it may corrode. In fact such a highly alkaline solution (see the authors' Fig. 2 in the paper under discussion) will be, at best, only poorly buffered; the temperature rise will increase the a_{H^+}, and as our Fig. 2 shows, the probability is that the solution will be no more aggressive at 573°K than it was at 298°K, although both predictions may be overruled by kinetic factors. The implication of this calculation is that the temperature differential of the dissociation constant of the "acid" NiO is comparable with that for the ionic product of water. As a broad generalization it can be said that the equilibrium diagrams for the Ni/H_2O system predict that an increase in temperature will lead to an over-all increase in the stability range of NiO (from pH 9-12 at 298°K to $pH_{(298°K)}$ 5-12 at 573°K), the metal being resistant, to a wider range of aqueous environments at the higher temperatures. It is interesting to speculate that had the region of stability of the oxy-anion advanced to values of $-\log a_{H^+}$ approaching 7 at the higher temperature, then a test solution based on a temperature stable buffer system of pH *ca.* 7 at room temperature might prove to be more aggressive to Ni than an unbuffered solution of similar pH (at 298°K), the additional hydrogen ions generated in the latter case shifting the metal into a passive region.

The foregoing analysis of the change of a_{H^+} with temperature broadly confirms the observations of Greeley, reported by the authors, that for a closed hydrogen saturated acid solution only small changes in a_{H^+} occur with increase in temperature. Nevertheless, that small change has a significant effect on $-\log a_{H^+}$ in weakly acid solutions ($pH > 4$ at 298°K). For example, we have calculated the activity of the hydrogen ion at various temperatures for the solutions used by the authors, assuming them to be effectively unbuffered (solutions of strong acids and the salts of strong acids and bases), with the results given in Table I.

Table I.

	Temperature (°K)						
	298	323	363	423	473	523	573
$-\log a_{H^+}$	1.30	1.30	1.30	1.30	1.30	1.30	1.30
	3.40	3.40	3.40	3.40	3.40	3.40	3.40
	6.30	6.24	6.04	5.75	5.60	5.55	5.55

The table shows that only in the case of the two most acid solutions does $-\log a_{H^+}$ remain constant. This effect interacts not only with the interpretation of the equilibrium diagrams but also with the authors correction to E_{corr}. This correction was used by the authors to allow for the thermal liquid junction potential in their system and, further, to transpose their potential measurements to the standard hydrogen scale at the test temperature. The correction is valid for the two most acid solutions but, as a result of the assumption that a_{H^+} remains constant throughout the temperature range, the authors values for E_{corr} and the arrest potentials in the least acid solution are in error by up to 86 mV [(6.30 − 5.55) × 2.3 $RT/\mathbf{F}$], that is, the potentials are not all on the "same thermodynamically meaningful scale." This does not invalidate the conclusions drawn from the potential decay experiments

Table II.

Temp, °K	E_{arrest} (V) vs. SHE(T K)	vs. SHE(298°K)	$E_{Ni/NiO}$ vs. SHE(298°K)	E_{Ni/Ni_3O_4} vs. SHE(298°K)
		pH 1.3		
295	+0.240	+0.237	+0.041	+0.231
327	+0.213	+0.239	+0.036	+0.225
		pH 3.4		
306	+0.078	+0.085	−0.089	+0.101
328	+0.048	+0.074	−0.102	+0.087
370	−0.075	−0.011	−0.126	+0.062
571	−0.205	+0.033	−0.241	−0.061
		pH 6.3		
295	−0.204	−0.207	−0.251	−0.061
327	−0.261	−0.235	−0.289	−0.100
354	−0.335	−0.286	−0.320	−0.131
381	−0.350	−0.278	−0.350	−0.163
574	−0.500	−0.259	−0.574	−0.394

since the failure to allow for changes in a_{H^+} in correcting the arrest potentials is counteracted by the same omission in the calculation of the equilibrium potentials for the oxides.

Thermal temperature coefficients of standard electrode potential may be calculated from first principles by the method due to de Bethune *et al.*[9] which uses entropy data determined at 298°K. For the Ni/NiO and Ni/Ni_3O_4 equilibria we have obtained coefficients of +0.097 and +0.062 mV/°K, respectively, using the entropy data given by Cowan and Staehle. In Table II we record the calculated thermal equilibrium potentials (*i.e.* with respect to a standard hydrogen electrode at 298°K) for these reactions at the pH levels investigated by the authors. In deriving these values no allowance has been made for changes in a_{H^+} with temperature in order that our calculations should be on the same basis as the reported results. The table also includes the values of the potential arrests obtained by the authors both as reported and also corrected to the standard hydrogen scale at 298°K (assuming $dE°/dT$ for the hydrogen electrode to be 0.871 mV/°K). The calculations appear to confirm the views of the authors that in the two most acid solutions and at the highest temperature in the least acid solution the bulk oxide, if not the passive film, is Ni_3O_4; whereas, at lower temperatures in this latter solution the bulk oxide is NiO although the near correspondence between the arrest and equilibrium potentials may well be fortuitous. While it is gratifying that the equilibrium potential calculated for elevated temperatures by two entirely independent methods give rise to the same conclusions, when compared with the present experimental data it is disappointing that these potentials do not coincide when transposed to the same reference scale. The accuracy of the method used by the authors for estimating C_p at temperature has been questioned recently[10] and it may be that the disagreement arises from this source although we have no reason to suppose that the entropy data used in our calculations is more accurate.

A serious limitation of the electrochemical equilibrium diagram has always been that it can only be as good as the data from which it is constructed. This restriction is magnified in the high temperature diagrams and a cautious approach to the interpretation of experimental data in terms of such diagrams seems appropriate.

M. Kesten[11]: In the paper under discussion, Cowan and Staehle found that the active-passive transition of the metal disappeared when the temperature of the electrolyte was raised above 90°C. For the interpretation and possible explanation of this phenomenon it is worthwhile to refer to the considerable number of

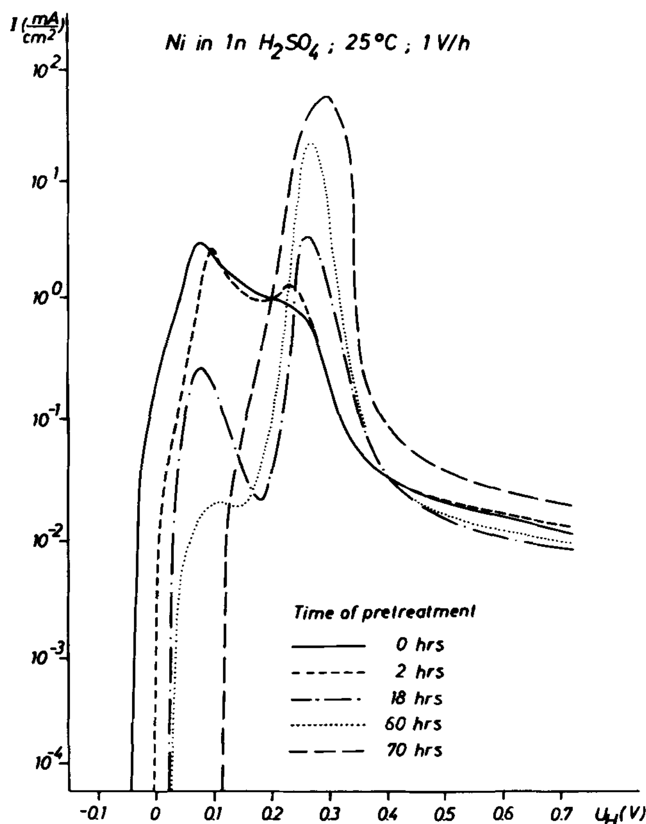

Fig. 1. Anodic polarization behavior of nickel (99.998%) in the active to noble scan mode. Before the experiment the samples have been kept in the electrolyte for different times.

recent investigations dealing with the specific influence of anions on the polarization characteristics of metals.[12-22] It has been proved in these studies that anions, which are adsorbed on the surface of the metal, are apt to participate in the dissolution mechanism. Their effectiveness on the reactions taking place at the interface depends on the bonding strength between them and the surface atoms of the metal. While weakly adsorbed ions inhibit the active metal dissolution by reducing the available free surface, strongly adsorbed ions are able to accelerate the dissolution of the metal whenever they undergo chemical reactions with the surface atoms.

This kind of behavior is not only restricted to the halide ions Cl^-, Br^- and J^-. It has been found for sulfate ions as well, although, under similar conditions these ions are adsorbed to a much smaller degree.[23] Because of the necessary activation energy, the specific adsorption of anions from the electrolyte is a matter of time and temperature. According to Dreyer and Dreyer,[24] the time to reach a maximum coverage with sulfate ions on a Zr surface is about 10^3 min at 20°C, while at 80°C this process is completed in 20 min. Besides all this, the competitive adsorption of other particles of the electrolyte (e.g., OH^- ions or chemisorbed oxygen) can also play an important

Our recent studies, about the influence of specifically adsorbed sulfate ions on the anodic behavior of nickel,[27] proved that one can get very similar results to those reported by Cowan and Staehle. But instead of increasing the temperature, the adsorption conditions for the sulfate ions were changed prior to the polarization experiment. Figure 1 shows the polarization curves obtained in 1*N* H_2SO_4 with nickel samples pretreated differently. Before the polarization was started the samples were kept in the electrolyte at the open circuit potential for different times. With increasing time of pretreatment the amount of specifically adsorbed sulfate ions increases too. At the same time, the primary nickel dissolution is lowered considerably. On the other hand, a remarkable increase in metal dissolution is observed in a potential region where untreated samples already undergo the active-passive transition. It could be demonstrated that, in this range of second activation, the nickel dissolves because of the direct participation of the sulfate ions in the dissolution process.

The described effect increases, when hydrogen is bubbled through the solution (Fig. 2). With increasing metal dissolution the so-called passivation potential is shifted to higher values. Finally, Fig. 3 shows the polarization curve of an untreated sample measured in 1*N* H_2SO_4 at 60°C. It indicates that the time for getting a sufficient coverage with sulfate ions can be minimized by increasing the test temperature.

The potential of the sudden passivation of the electrode is not reproducible. Polarization curves of that kind, reported also by Cowan and Staehle, are typical for dissolution processes proceeding with high current densities. In these cases the shape of the curve no longer reflects the true relationship between the current density and the electrode potential, because of the *IR* drop in the potential measuring system.[28] From those data alone it is not possible, therefore, to decide whether an electrode is in the active or passive condition corresponding to a certain measured potential.

On the basis of the cited literature and our own experimental results the vanishing of the active-passive transition in nickel, under the condition reported by Cowan and Staehle, is not unexpected. It is a consequence of the specific adsorption of sulfate ions favored by the temperature of the electrolyte.

Polarization Behavior of Graphite in Sodium Chloride Solutions in the Presence and Absence of Ethylene

A. Bélanger, G. Bélanger, and A. K. Vijh
(pp. 1543-1545, Vol. 118, No. 9)

N. Ibl and **P. M. Robertson**[29]: We are investigating, and have been for some time, the oxidation of olefins (mainly isobutylene) at various electrodes in H_2SO_4 and $HClO_4$ solutions, with and without the addition of mercury salts. Our results are in agreement with those of the authors. No reaction was observed at graphite anodes. Substantial oxidation takes place only at gold electrodes.[30] The oxidation on gold of lower molecular weight olefins, such as ethylene, has been the subject of a few recent papers.[31,32] On the other hand, with the system of the authors, chlorhydrin (which is an intermediate in the production of the oxide) is easily formed. We obtained, with very high current efficiency (up to 97%), ethylene and propylene chlorhydrin at graphite anodes,[33] the pH being, however, somewhat more acid than that in the experiments of Bélanger *et al.*

[33] N. Ibl and A. Selvig, *Chem. Ing. Tech.*, **42**, 180 (1970).

A. Bélanger, G. Bélanger, and A. K. Vijh: We appreciate Ibl and Robertson's comments and are gratified that their results are in agreement with ours for the comparable system. The related work on gold cited by these authors also appears of interest although clear-cut explanation of different behavior at gold and other electrodes is still an open question, notwithstanding the interpretations put forward previously.[34]

In this context, it is perhaps relevant to point out that our recent attempts[35] to carry out partial anodic oxidation of methane and ethylene in liquid ammonia, with a view to prepare alkyl amines, have not been successful even when a variety of electrode material was examined.

Energetics of Single Ion Solvation in Nonaqueous Solvents and the Effects on Electrode Kinetics

M. Salomon (pp. 1609-1614, Vol. 118, No. 10)

O. Popovych[36]: In this paper Salomon raises the known[37] valid objection to Izmailov's extrapolation methods of determining the solvation energies of single ions, but then proceeds to use what appears to be a slight modification of one of these methods. According to Salomon, Izmailov extrapolated as a function of reciprocal radius, r^{-1}, only the combinations $(\Delta G^o_M - \Delta G^o_H)$ and $-(\Delta G^o_H + \Delta G^o_X)$, obtaining nonlinear plots with potentially two different intercepts. What he fails to mention, however, is that Izmailov was aware of these difficulties and, therefore, recommended plotting the average of the above functions, $[(\Delta G^o_M - \Delta G^o_X)/2 - \Delta G^o_H]$, which in mathematical form is identical with Salomon's own Eq. [1] in the paper under discussion. This average function also gives linear plots and unique values for the intercept. The only discrepancy between Izmailov's and Salomon's approaches is that the former used average reciprocal radii of isoelectronic ions, whereas the latter interpolated his data points for hypothetical anions and cations of equal radii. Unfortunately, neither the essence of this modification, nor the rationale for its supposed superiority over Izmailov's approach are brought out for the benefit of the reader.

In my opinion, the same objections pertain to Salomon's as to Izmailov's methods. In both approaches, long extrapolations to infinite radius are made from data points representing a narrow range of small ions, mostly those of alkali metals and the halides. None of the ions in Salomon's plots are as large as 4-5Å (the point corresponding to $r^{-1} = 0.2$, in Fig. 1 of the paper being discussed, must be an extrapolation already). On the other hand, we found[38, 39] that the ΔG^o's for the tetraalkyl and tetraaryl ions with radii in the 4-5Å range are determined overwhelmingly by their non-electrostatic, or neutral components, ΔG^o (neut), which are not functions of r^{-1}. Salomon dismisses the whole question of ΔG^o (neut) too lightly, at the same time attributing, incorrectly, to Noyes[40] an endorsement of the isoelectronic inert-gas assumption for its estimation.

Salomon's rejection of the reference-electrolyte method for the estimation of solvation-energy changes for single ions is poorly founded. It is motivated mainly by the possibility of experimental errors in the determination of solubility products, rather than by any flaws in the method itself. Certainly no chemist would seriously accept the generalization that solubility products are unreliable because of possible complications due to ion pairs, crystal solvates, complexes, and micelles. Of these obstacles, only a slight degree of ion pairing was encountered in our work with the reference electrolytes, and it was easily corrected with the aid of conductance data. Thus, the above experimental difficulties are neither generally encountered nor are they fundamental to the evaluation of the reference-electrolyte method.

The only genuine criticism directed at the basic assumption of the reference-electrolyte method, is that cited from the work of Coetzee and Sharpe[41] who deduced from NMR shifts the existence of specific solvation effects even with the large reference ions. We have shown,[38] however, that the differentiating effects of the several solvent pairs in question are, at the most, of the order of experimental error in the measured solvation-energy changes for the tetraphenylarsonium and the tetraphenylphosphonium reference ions. The experimental error of the ΔpK_{sp} determinations is about 0.1 kcal/mole. To my knowledge, no extrapolation method is capable of that kind of precision.

M. Salomon: The relative merits between extrapolation and reference ion methods for obtaining individual ionic contributions to free energies and/or enthalpies is indeed a complex problem as indicated by Popovych above and elsewhere.[42] From a theoretical viewpoint there is much to be desired in either method, but there are instances in which one is to be preferred. This is true for the methanol-water systems as several inconsistencies appear in the use of solubility data (see below). In the case of careful solubility measurements, such as those reported by Cogley *et al.*[43] where oxygen and water were rigorously excluded from various propylene carbonate (PC) solutions, there is excellent agreement with those results obtained by the emf method (*e.g.*, see footnote 44). For the salts NaCl and KCl, the solubility data of Cogley *et al.* give ΔG^o_{soln} values of 10.7 and 9.5 kcal/mole^{-1}, respectively: the emf data give 10.5 and 9.4 kcal/mole^{-1}, respectively, for these salts. The split into ΔG^o_t (ion) values by the solubility method[43] and the extrapolation method[44] are gratifyingly close so that it is difficult to choose between the two.

The methanol-water systems studied by various methods[42, 45-47] are, however, not consistent as is shown in Table V of my original paper. In this table, it should be noted that for those cases[45, 47] where the sum $\Delta G^o_t(M^+) + \Delta G^o_t(X^-)$ are not equal to the observed[46] $\Delta G^o_t(MX)$, the results based on an extrapolation method[47] and a reference ion method[45] are similar. Both indicate that methanol is a weaker base than water. There is, however, contrary evidence[46, 48, 49] which indicates that methanol is the stronger base and this is suggested by negative values of $\Delta G^o_t(M^+)$ for the transfer of small cations from water to pure methanol or methanol-water mixtures.

Let us consider first, Izmailov's method of extrapolation.[47] We have shown elsewhere,[49] and in my paper, that the values of $\Delta G^o_{solv}(MX)$ used by Izmailov are in error and that this accounts for the nonlinearity of his cation plot. While it is true that Izmailov does plot the average function

$$\{(\Delta G^o_{M^+} - \Delta G^o_{X^-})/2 - \Delta G^o_{H^+}\} \ vs. \ \tfrac{1}{2}(r_{M^+}{}^{-1} + r_{X^-}{}^{-1}) \quad [1]$$

Popovych's statement above indicates that this procedure is in fact identical with mine. This is not the

case as is exemplified in my paper and in the following quote from Izmailov: "$\Delta G^o{}_{H^+} + \Delta G^o{}_{X^-}$ can be plotted as a function of $1/r$ for the corresponding halide ions and the quantity $\Delta G^o{}_{H^+} - \Delta G^o{}_{M^+}$ as a function of $1/r$ for the corresponding metal ions. Both these quantities will tend, as r increases, to one value $\Delta G^o{}_{H^+}$ .... Determination of the limit is not very reliable since it is necessary to extrapolate from distances remote from $1/r = 0$. Since, however, the two plots tend the same limit, and $\Delta G^o{}_{H^+} + \Delta G^o{}_{X^-}$ is a linear function of $1/r$, it is nevertheless possible to find that limit. This is facilitated by plotting an auxiliary line, representing the means of the sums and differences, which tends to the same limit $\Delta G^o{}_{H^+}$ ...." Thus Izmailov does not report (as Popovych suggests) average values of the intercepts for the cation and anion plots but, rather, a single one. The values of $\Delta G^o{}_{H^+}$, which I and which Franks and co-workers (*e.g.*, see footnotes 46 and 48) report, are averages of the cation and anion intercepts. The belief that not all components of the solvation energy vanish at $1/r \rightarrow 0$, which incidently was discussed and considered to be negligible by Izmailov, is the essence of the difference between our two works. The statement by Popovych, that the essence or rationale for my method is not brought out for the reader, is not well founded as considerable discussion was presented. Since my method assumes that these nonvanishing components to ΔG^o (ion) become equal for very large ions, there is then the question (which Popovych did not comment upon) of whether or not this is valid. The reference to Noyes' paper serves only to illustrate an alternate model which might invalidate my method and does not refer to any stand on the subject by this author.

The use of reference ions to calculate $\Delta G^o{}_t$ (ion) values is not rejected in my paper as discussed above. There are, however, times when the use of some reference salts should be excluded as there are instances in which some extrapolations should also be excluded. In the methanol-water systems there is no data in the literature that I could find which might indicate that such salts as tetrabutylammonium tetraphenylboride (Bu_4NBPh_4) or triisoamylbutylammonium tetraphenylboride ($TAB \cdot BPh_4$) do not exhibit specific solvent-ion or ion-ion interactions; however, there is the NMR data on similar salts studied by Coetzee and Sharp[50] which cautions one in the use of this method for the solvents under consideration here. I do not doubt that free energies based on solubility can be measured to within 0.1 kcal/mole. What I do doubt, in some cases, is the accuracy of some measurements. For example, based on the solubility of KCl in water and methanol, a value of $\Delta G^o{}_t$(KCl) was obtained[45] which is ~1 kcal/mole lower than that obtained by the emf method (*e.g.*, see footnote 46). This exceeds Popovych's stated accuracy by a factor of ten. There is also the question regarding the solubilities of the salts of the large reference ion in water and methanol[45] because of their instability in aqueous solutions, and because of the different standard states employed. Since the salts Bu_4NBPh_4 and $TAB \cdot BPh_4$ are unstable in water, an additivity method was used[45] to obtain $\Delta G^o{}_t$(salt): *e.g.*

$$\Delta G^o{}_t(TAB \cdot BPh_4) = \Delta G^o{}_t(TAB \cdot Pi) + \Delta G^o{}_t(KBPh_4) - \Delta G^o{}_t(KPi) \quad [2]$$

where Pi = picrate ion. Equation [2] is thermodynamically correct and the accuracy of the quantity on the LHS is dependent upon that of the RHS. Assuming that oxygen and water have been rigorously excluded from the methanol solutions, a problem of different standard states can arise using solubility data. For example, in methanolic $TAB \cdot Pi$ solutions, the concentration of undissociated salt (or ion-pair?) is 0.125M compared to the free ion concentration of 0.267M. Similarly, for Bu_4NPi solutions in methanol the solvated salt (or ion-pair?) concentrations is 0.359M compared to 0.514M for the free ions.[45] Two points are of interest here: first, for solutions of such high concentrations, $\gamma_\pm$ cannot be calculated from a simple Debye-Hückel equation[51,52] but rather from one of the extended relations; second, is the point that the calculation of $\Delta G^o{}_{slon}$ (salt) for the above saturated solutions (from $-2RT \ln [M_{sat}\, \gamma_\pm]$) refers to standard states of 0.125M and 0.359M of undissociated salt for $TAB \cdot Pi$ and $Bu_4N \cdot Pi$, respectively. While a constant ionic strength media is as valid a standard state, as is the zero ionic strength media, one must be consistent in employing the same standard state throughout. Since a mixing of standard states does occur in this work,[45] another source of error is introduced into the solubility data. The fact that ion-pairing has been corrected for in this work is, therefore, irrelevant to accuracy of the ΔpK_{so} results.

Finally, in answering Popovych's comments on ion-size relations, I think adequate discussion has been presented in my paper and elsewhere[46,48,49,53] where the basis of a linear $1/r$ relation is attributed to enthalpy and entropy effects. Certainly linear relations exist; or is this being questioned? If on this matter Popovych is justifying his use of reference ions of equal Stokes radii, then I can only say again that the significance of these radii is unclear. The fact that Walden's rule holds (only) for the larger ions in many solvents is misleading since it suggests a causative relationship between λ^o and η: the relevant value for η in Stokes' frictional factor $6\pi\eta r_s$ is uncertain due to electrostriction, local structure-making or breaking effects, and dielectric relaxation effects which really requires the use of local rather than bulk values of η (cf. 52, 54).

Oxidation of Beta-Phase Plutonium

J. W. Lindsay, K. Terada, and M. A. Thompson

Dow Chemical U. S. A., Rocky Flats Division, Golden, Colorado 80401

ABSTRACT

Oxidation of β-phase plutonium was studied by hot-stage x-ray diffraction, microtopography, and thermogravimetry. The oxidation process was found initially to proceed by the formation of a protective sesquioxide film. Subsequently, the protective film was destroyed by blistering and the reaction rate accelerated.

Plutonium is very susceptible to oxidation. The mechanisms involved in this oxidation are complicated by the existence of six temperature-dependent allotropic modifications of the metal and a rather complex metal-oxygen relationship (1). Of the six metallic phases, the low-temperature α-phase which is stable to 112°C, has received the most attention (2-8). Under conditions of low humidity, oxidation of the α-phase appears to follow a parabolic rate law. Sackman (4) observed a series of successive parabolic weight gain curves when the reaction was allowed to proceed for extended periods of time. This behavior was thought to arise from the continued failure and regrowth of a protective sesquioxide film.

Few in-depth investigations of the reactions of higher temperature metallic phases with oxygen have been made. Schnizlein and Fischer (9), in investigating the oxidation process above 140°C reported paralinear kinetics through the β (112°-185°C), γ (185°-310°C), and δ (310°-452°C) phases. The paralinear model involves the simultaneous production of a protective inner film and an outer porous layer. Thompson (10) observed two linear stages of oxidation in the β-phase with paralinear kinetics being followed only in the γ- and δ-phases.

Both Thompson and Schnizlein observed a reduction in the rate of oxidation of δ-phase metal at about 400°C. Thompson (10) and Vesterberg and Ekbom (11) reported an additional rate reduction occurring in the β-phase at about 160°C.

The present study was designed to investigate reaction mechanisms and kinetics associated with the oxidation of β-phase plutonium. Special attention was given to the relationship between the reaction rate, types of oxides formed, and microtopography of the resulting oxide products. Kinetic data were obtained by thermogravimetry. The types of oxides produced and the exterior oxide surface characteristics were followed by hot-stage x-ray diffraction and microscopy using conditions duplicating those in the rate studies.

Experimental Material and Procedures

Material.—Very pure electrorefined plutonium metal was used in the kinetic and mechanistic investigations. The electrorefined button was cast into an ingot and hot-rolled in the β-phase to a thickness of 0.018 in. Impurities in the resulting sheet are listed in Table I.

Key words: corrosion, alpha-Pu_2O_3, PuO_2.

Procedures.—Isothermal oxidation experiments were conducted with fresh polished samples. The samples were given a final finish with dry jeweler's rouge. The oxidation was followed thermogravimetrically on a Mettler I Thermoanalyzer enclosed in a glove box. The atmosphere used in the investigation was a 20% O_2-80% Ar mixture. Moisture was removed to less than 10 ppm by volume by passing the gas over a molecular sieve desiccant. Moisture levels were determined with a Consolidated Engineering Corporation Model 26-303 hygrometer. All runs were made at 640 Torr.

Hot-stage x-ray diffraction patterns of the initial stages of oxidation were made at various isotherms with a Picker Nuclear diffractometer fitted with a hot-stage cell. Metal samples and atmospheres were kept as closely as possible to those employed in the kinetics investigations. Hot-stage optical microscopy investigations were made using a Unitron Model HHS metallograph. Conditions were again kept as closely as possible to those employed in the thermogravimetric runs.

Results

Thermogravimetry.—Isothermal weight gain curves showing the rate of oxygen reaction with respect to time are shown in Fig. 1. The figure also shows that the over-all reaction rate increases with temperature between 120° and 175°C before decreasing to a minimum at about 190°C. Above 190°C, the rate resumes its increase with temperature. Each curve consists of two distinct stages of oxidation. This phenomenon oc-

curs throughout the β-phase. The 206°C curve was included in Fig. 1 to show that two stages of oxidation also occur in the lower temperature region of the γ-phase. The two stages are shown more clearly in the plot of the natural logarithms of the weight change with respect to the logarithms of time for the isotherm at 142°C (Fig. 2).

The initial stage of oxidation (Fig. 3), whose duration shortens with increasing temperature, conforms reasonably well to a linear rate law. Effect of temperature on the rate of oxidation during the initial stage is shown in the Arrhenius plot in Fig. 4.

The parabolic rate preceding the linear rate, reported by Schnizlein and Fischer (9) and Larson and Cash (7) was not observed in the weight gain curves. However, weight change data at the beginning of the isothermal oxidation were lost because it required several minutes for the balance to reach equilibrium after the metal was exposed to the oxidizing gas. Figure 3 shows that when the linear rate is extrapolated to the weight gain axis, the intercepts steadily increase as the temperature rises above 150°C. This suggests that the observed linear rate is not in effect during the very early stages of reaction.

Following a brief transition period, which is best seen in Fig. 2, the reaction proceeds by an accelerating rate.

Microscopy.—Microtopographic examinations were made of the oxide surface during both the initial

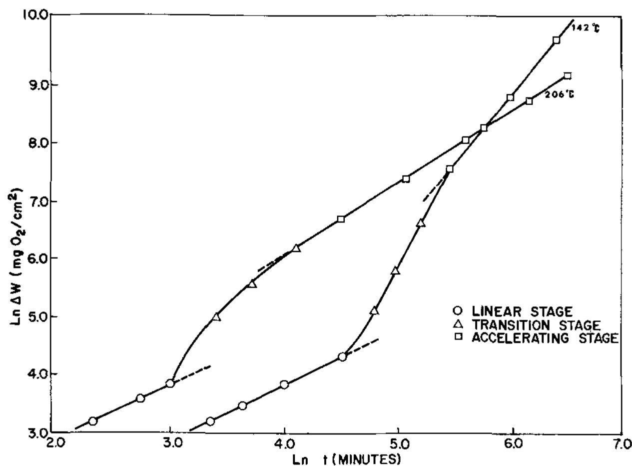

Fig. 2. Ln-Ln plot of weight gain with respect to time

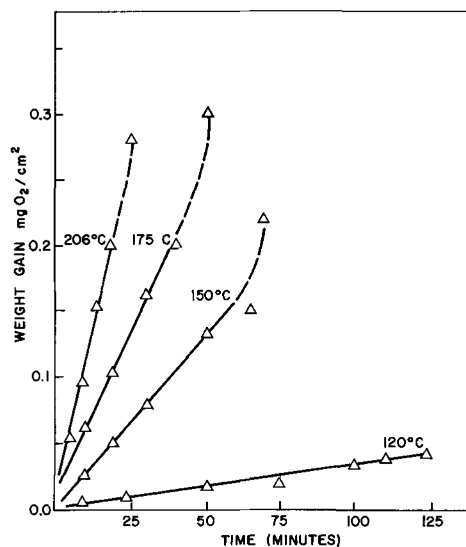

Fig. 3. Initial stage of oxidation

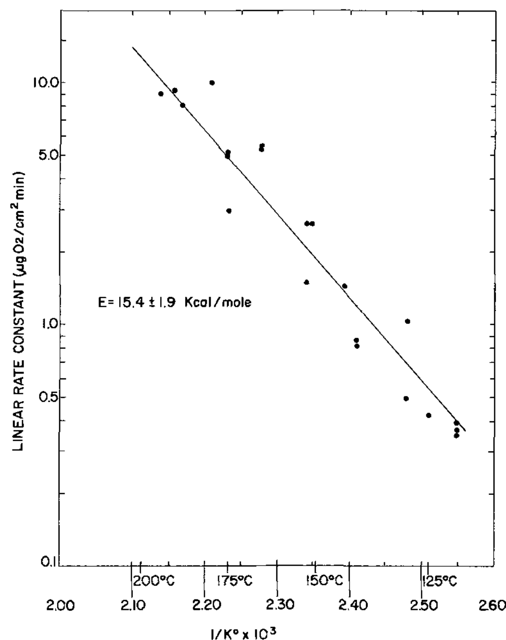

Fig. 4. Arrhenius plot of rate constants obtained from first stage of oxidation.

linear stages and the transition stages using the same conditions as those employed in the kinetic investigations. Several series of photomicrographs were taken of the surface at 750X magnification with direct and indirect illumination and at temperatures from 120° to 206°C.

During the linear stage of oxidation, an interesting pattern of oxide growth was observed. A compact, black oxide film was formed over most of the metal surface. The remaining areas consisted of dark, circular areas which formed early in the oxidation and grew larger in size and number with time. As these circular areas grew, it became apparent that they were blister-like features on the surfaces. These features eventually resulted in mounds of loose, brownish-green oxide which ultimately covered the entire surface.

Hot-stage photomicrographs taken of the oxidation process at 145°C and various time intervals are shown in Fig. 5. The photomicrographs are of representative areas of the surface and show the growth of the blister-like oxides. The light areas correspond to the compact, black oxide film, except for Fig. 5a where

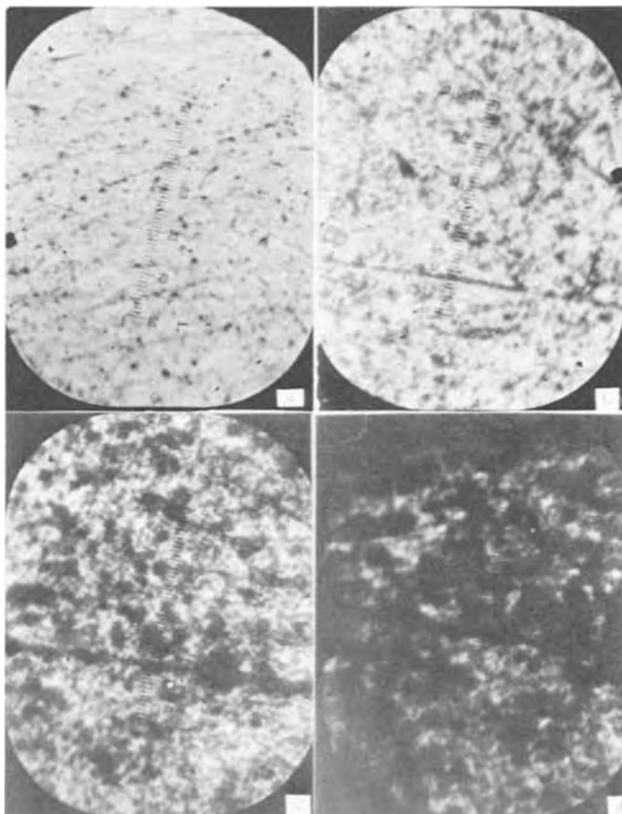

Fig. 5. Hot-stage photomicrographs (750X) of plutonium oxidation at 145°C. (a) Initial surface, (b) after 20 min, (c) after 40 min, (d) after 80 min.

the light area is the metal surface. There is no definite correlation between the spots on the initial metal surface and the dark, circular areas which develop during oxidation. Similar observations were made in other hot-stage microscopy experiments between 120° and 206°C. The rate of formation and growth of blisters increased with temperature.

X-ray diffraction.—Following several exploratory scans at each of several isotherms, it was determined that only α-Pu_2O_3 and PuO_2 were produced in the oxidation of β-phase plutonium. Progress of the formation of the two oxides was followed by scanning the α-Pu_2O_3 2θ peaks at 28.0° and 55.0°, and the PuO_2 2θ peaks at 28.1° and 56.5° (12). In addition, the strong β peak of the metal at 34.3° was periodically scanned since its presence was a good indication that loss of inner oxide layers from the diffraction scan was not due to a thicker outer film exceeding the penetration limit of the x-ray beam. Figure 6 shows the results of hot-stage x-ray diffraction and thermogravimetric experiments at 175°C. The relative areas under the 2θ peaks of 55.0° and 56.5° for α-Pu_2O_3 and PuO_2, respectively, are plotted against time to show the change in relative amounts of the oxides during a reaction. Also plotted on the same time coordinate is the thermogravimetric data of an experiment at the same temperature. The PuO_2 shown in the graph is slightly exaggerated due to a weak α-Pu_2O_3 diffraction peak at 56.4°, but it does not mask the trend.

Alpha-Pu_2O_3 was the principal oxide formed during the early stages of reaction. The decrease in the amount of the sesquioxide occurred when the rates of PuO_2 formation and weight gain began to accelerate.

Observation of only a small change in the β-metal peak height indicated that the loss of diffraction intensity of the α-Pu_2O_3 was not due to its covering by a thick layer of PuO_2. An initial decrease in PuO_2 was observed. This phenomenon is thought to be the result of the net reduction of the dioxide by the substrate metal to the sesquioxide (13). This reduction started at temperatures above 150°C. The same type of behavior described above was observed at other temperatures. The difference was only in the rates. X-ray diffraction analyses of samples removed from the thermogravimetric analyzer during the accelerated stage of oxidation were also made. Oxides readily removed from the sample surface with a camel's hair brush were analyzed separately from those that were more adherent to the metal. The loose oxide was all PuO_2. The slightly more adherent oxide was practically all PuO_2. These oxides were not as compact nor as adherent as the initially formed α-Pu_2O_3 film.

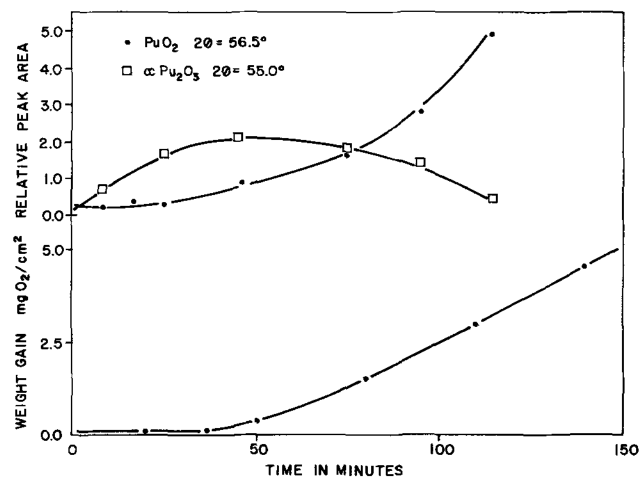

Fig. 6. Hot-stage x-ray diffraction and weight gain data for oxidation at 175°C.

Discussion

Isothermal weight gain curves obtained from the oxidation of β-phase plutonium have the general form shown in Fig. 7. The different stages of the oxidation discussed in this section are indicated in the figure.

Although experimental difficulties in this work prevented the detection of the parabolic stage (A), x-ray diffraction and TGA data point to its occurrence.

The first part of the reaction definable by TGA (stage B) conformed to a linear rate. X-ray diffraction analyses demonstrated that the compact oxide formed during the early part of this stage was principally α-Pu_2O_3. The decrease of the amount of the sesquioxide as the greenish-brown PuO_2 covered the surface was the result of the reaction

$$2\alpha\text{-}Pu_2O_3 + O_2 \rightarrow 4PuO_2$$

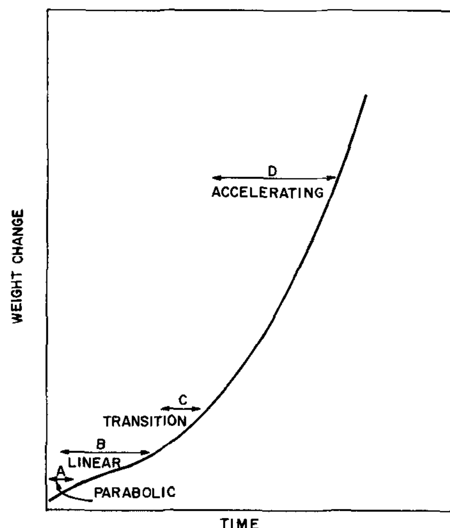

Fig. 7. Typical weight gain curve for isothermal oxidation of β-phase plutonium.

The acceleration of the oxidation rate as the sesquioxide was depleted indicated that the initial parabolic rate resulted from the formation of a protective film of α-Pu_2O_3. Microscopic examination of the α-Pu_2O_3 film surface during its formation showed localized blistering of an otherwise compact oxide film. Appearance of the blisters was observed very early in the isothermal oxidation process. The apparent linear rate was the result of a combination of the decreasing rate of oxidation due to growth of a thicker, protective sesquioxide film and an increasing rate of oxidation due to loss of areas covered by the protective film. The protective sesquioxide film was progressively replaced by less coherent and consequently less protective PuO_2.

The transition stage (C) began when the oxidation rate started to accelerate. The rate accelerated as the protective α-Pu_2O_3 was progressively depleted and replaced by nonprotective PuO_2.

During the accelerated stage (D), the oxidation reached its maximum rate. The amount of sesquioxide on the metal became undetectable by x-ray diffraction and the entire surface was covered by the greenish-brown oxide. It is interesting that the α-Pu_2O_3 did not reform under the blisters as a protective film. One possible explanation is that the conditions under which the initial oxide layer and succeeding layers were formed were quite different. The initial oxide film was formed immediately following polishing of the metal in air. During this relatively slow oxidation, the oxide formed could become the nucleus for succeeding oxide growth which could withstand higher stresses before failure. This type of oxide is contrasted to that formed where bare metal is suddenly exposed to oxygen at elevated temperatures. Support for this mechanism was obtained in a series of experiments in which metal samples were exposed to air at room temperature for 24 hr prior to oxidation. In each case, a definite delay in the accelerated oxidation rate was exhibited with high concentrations of α-Pu_2O_3 remaining for as great as four times longer.

Figure 1 shows that above 175°C, there is a minimum rate in the later stages of reaction. Thompson (10) first reported this and more recently, Vesterberg and Ekbom (11) working with moist argon, made a similar observation. However, in these earlier reports, the rate minimum was found at about 160°C, while it was observed at 190°C in this work. According to Schnizlein and Fischer (9) the accelerated rate can be eliminated by oxidation with extremely dry oxygen. One may conclude from it that the rate minimum is the result of activity of moisture on the oxide film.

Summary and Conclusions

Oxidation of β-phase plutonium metal involves several processes. Initially, there is a concurrent formation of protective α-Pu_2O_3 film and blisters in the oxide. At the beginning, the α-Pu_2O_3 grows relatively rapidly, and the blister formation and growth rate is low. With time, this is gradually reversed and eventually the entire surface is disrupted. The α-Pu_2O_3 is oxidized to PuO_2. For the period of linear reaction rate, an activation energy of 15.4 $\pm$1.9 kcal/mole was calculated.

As the protective sesquioxide is oxidized to a nonprotective PuO_2, the oxidation rate accelerates to a maximum. This maximum accelerated rate increased with temperature but began to decrease at about 175°C to minimum at 190°C.

Plutonium Oxidation in Moist Oxygen-Nitrogen Mixtures

J. L. Stakebake and L. M. Steward

Dow Chemical U. S. A., Rocky Flats Division, Golden, Colorado 80401

ABSTRACT

Plutonium oxidation studies were conducted at 90°C in dry air and moist oxygen-nitrogen mixtures using both cast and rolled plutonium. Oxidation in dry air obeyed a linear rate law with average rate constants of 0.042 and 0.050 mg/cm^2hr for the cast and rolled plutonium, respectively. Both metal samples were found to oxidize faster in the moist oxygen mixtures than in moist nitrogen. Linear oxidation rates were observed in moist oxygen-nitrogen mixtures with average rate constants of 0.68 and 0.34 mg/cm^2hr for the cast and rolled plutonium. In moist nitrogen oxidation followed a parabolic rate law with average rate constants of 3.60 and 1.11 $mg/cm^2hr^{1/2}$ for the cast and rolled samples, respectively. The reaction with water vapor observed during this investigation was greatly influenced by the purity of the metal as well as its metallurgical history. Samples of cast, electrorefined plutonium containing some microcracks reacted very rapidly, while for the relatively impure rolled material the reaction was somewhat slower. In all cases at this temperature, the reaction with water vapor was diffusion controlled and not reaction controlled as has been reported previously. The diffusing species is believed to be OH^- ions formed by the dissociative adsorption of water on plutonium dioxide.

Plutonium metal is very reactive and highly susceptible to oxidation which destroys the integrity of the metal. Two methods are known to minimize the amount of oxidation. One is by reducing the reactivity of the metal by alloying with another metal such as gallium, aluminum, or zirconium. Another is to minimize the contact of plutonium with oxidizing gases. However, taking advantage of the second method of reducing oxidation requires some understanding of the oxidation characteristics of plutonium metal. For example, plutonium oxidation is greatly enhanced by the presence of water vapor. Thompson (1) observed that an increase in water content of an oxygen atmosphere from 1.5 to 35 ppm resulted in an oxidation rate increase of about 19-38.6 $\mu g/cm^2hr$ at 85°C. Raynor and Sackman (2) found that the rate of oxidation at 90°C increased with increased humidity up to about 2% relative humidity. Above 2% relative humidity, increasing the water vapor content had little effect on the reaction. This effect was not observed above 215°C but at 190°C as little as 180 ppm H_2O caused the linear oxidation rate to accelerate an order of magnitude (3).

According to most of the earlier studies, the accelerating effect of water vapor on plutonium oxidation is more pronounced in inert gases than in air or oxygen. For example, Waber (4) stored two plutonium samples at 75°C and 50% relative humidity in helium and also air. After 26 hr, the extent of oxidation of the sample stored in helium was about 60 times greater than for the sample stored in air. Raynor and Sackman (5) have also studied the oxidation of plutonium in argon and air at 30°, 60°, and 90°C and 95% relative humidity. In all cases, the oxidation was faster in argon than in air. However, this difference was very small for unalloyed plutonium at 90°C. These early observations have led to the conclusion that it is better to store plutonium in "dry" air than in a "dry" inert gas in order to minimize corrosion. Under these conditions, the oxygen tends to inhibit the oxidation by water.

Unfortunately, storing plutonium in air presents a fire hazard since plutonium will burn in atmospheres containing more than 6% oxygen (6). Therefore, it is often preferable to store and handle plutonium in an inert atmosphere despite the increased susceptibility to oxidation. Since oxygen has been reported to inhibit water oxidation of plutonium, it is conceivable that low oxygen concentrations in an inert atmosphere would provide a significant amount of corrosion protection. However, almost no work has been done to evaluate the effect of small oxygen concentrations on the oxidation rate of plutonium by water vapor in inert gases. Tanon *et al.* (7) performed some glove box oxidation experiments using various argon-oxygen mixtures. Their results showed that the rate of oxidation of plutonium in argon-oxygen mixtures was less than in argon but greater than in pure oxygen. This was true at 50° and 70°C, but no results were reported at 90°C. The scatter of the results did not permit any definite relationship to be established between the rate of oxidation and the oxygen concentration. To be able to minimize the oxidation of plutonium in semi-inert atmospheres, this relation must be established.

Experiments discussed in this paper provide information on the oxidation behavior of plutonium in reduced oxygen atmospheres at 90°C. These experiments also provide additional information on the effects of impurities on plutonium oxidation and the nature of the plutonium-water reaction.

Experimental

Apparatus.—The experimental system used for the measurement of oxidation rates is shown in Fig. 1. The principal component is a Cahn® recording electromicrobalance. This balance has an accuracy of ±5 μg. With the vacuum system incorporated into the balance system, the working pressure can be varied from 10^{-7} to 600 Torr. A resistance furnace controlled with a power proportioning programmer was used to heat the samples. The actual temperature of the sample was measured with a thermocouple located adjacent to the

sample inside the hangdown tube. Gas mixtures were introduced into the system via a series of traps which conditioned the gas to the desired water content. Moisture levels were measured with a Panametrics® hygrometer during each run.

Samples.—Two different batches of plutonium were used for this study. One batch had been stored for about six years and was originally rolled from an electrorefined ingot. Thompson (8) used this same metal in his work and reported an average total impurity content of 870 ppm. During storage, the impurity content increased to about 3010 ppm with americium and iron being the major impurities (Table I).

Nearly all previous microbalance studies have been conducted with samples cut from rolled sheets. Recent developments, however, permitted the use of thin cast samples. The second batch of plutonium was vacuum cast from an electrorefined ingot into plates about 0.75 mm thick. Total impurities in this batch were 435 ppm (Table I).

Sample coupons were cut from bulk sheets about 0.75 mm thick so as to have a final surface area of about 0.50 cm². Each coupon was mechanically polished using 600 grit silicon carbide paper. Other techniques, such as electropolishing and a metallographic polish with 1μ diamond paste, were also tried. The mechanical polish, however, seemed to yield the most reproducible results.

Procedure.—Immediately after polishing the samples were loaded on the balance and the system evacuated. Samples which were to be oxidized in a dry atmosphere were outgassed for 2 hr at about 1×10^{-6} Torr. Those to be run in a moist atmosphere were evacuated to 1×10^{-5} Torr. After evacuation, the temperature of the sample was increased to 90°C and the system backfilled to a pressure to 500 Torr with the reacting gas. For this study, the reacting gases were mixtures of nitrogen and 0, 3, and 21 v/o (volume per cent) oxygen and also 100% oxygen. Two moisture contents, 5 and 12,000 ppm, were used during this experiment. The 12,000 ppm moisture level was generated by passing the gas through two traps containing a saturated solution of LiCl. Prepurified gases were passed through a silica gel trap to obtain the 5 ppm moisture level.

Data from the plutonium oxidation runs were processed using a digital computer curve fitting program (9) to determine the best equation for the data. In many cases, it is difficult to fit the rate data exactly to any one simple rate equation, because changes during the oxidation run are frequent. For the data from this study, the single equation which best fits the data was chosen.

Results and Discussion

Oxidation of unalloyed plutonium.—Results from this study of the oxidation of rolled and cast unalloyed plutonium are shown in Fig. 2 and 3. The pronounced effect water has on plutonium oxidation is quite evident from these runs. At 90°C oxidation was found to be faster in the moist oxygen containing atmospheres than in moist nitrogen. This observation is opposite that observed at lower temperatures where oxidation has been reported to be faster in the inert gas and any oxygen present apparently exerts an inhibiting effect on the oxidation process (5, 7).

Oxidation in dry air.—Compared to the rate observed with moisture present, plutonium oxidation in dry air was relatively slow and very reproducible. Curve A in Fig. 2 and 3 shows the results of oxidation in dry air for the rolled and the cast samples, respectively, after subtracting any inhibition time. The runs in dry air were all initially inhibited for periods up to about 200 hr. This inhibition was probably caused by the formation of a nonporous, adherent oxide film on the surface prior to the start of the experimental run. Although inhibition times for different samples varied from 32 to about 200 hr, the final oxidation rate was the same in all cases. The oxidation process in dry air followed the

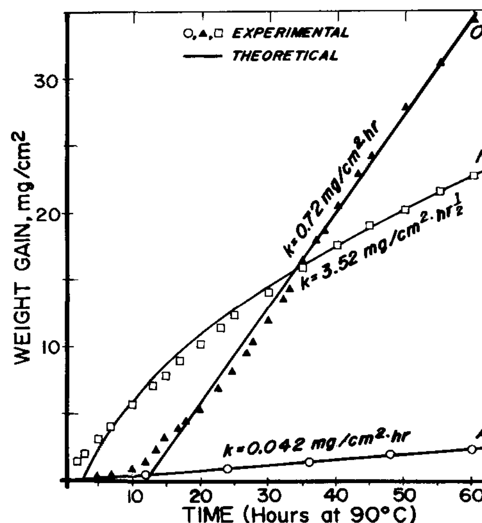

Fig. 3. Oxidation of cast electrorefined plutonium at 90°C in dry air A, moist oxygen-nitrogen mixtures O, and moist nitrogen, N.

linear rate law, $x = kt + c$. The rate constant, k, was determined to be 0.050 mg/cm^2hr for the rolled plutonium and 0.042 mg/cm^2hr for the cast plutonium.

Data from this study were compared to the results obtained earlier by Thompson (8) under the same conditions and with the same rolled metal. At 90°C, in dry air, Thompson reported a linear oxidation rate of about 0.048 mg/cm^2hr. The average rate from all runs in this study was 0.046 mg/cm^2hr. On the basis of these comparisons, it appears that storage and the accompanying increase in impurities (up to at least 3000 ppm) as well as radiation damage, has no effect on the metal oxidation rate in dry air. Furthermore, the method of metal preparation, either rolling or casting, did not influence the oxidation rate appreciably.

Linear oxidation kinetics can result from several possible rate-determining processes (10). These include: phase boundary processes involving metal/oxide or oxide/oxide interfaces; diffusion through an oxide film of constant thickness; and the adsorption of oxygen. Formation of a porous oxide, resulting in a reaction at the metal/oxide interface, is probably the most commonly used explanation for linear kinetics. However, in the present experiments the initial oxide formed was not porous as evidenced by the long inhibition times.

The observed results can be explained, however, by assuming the initial reaction with the nonporous oxide film was one which formed a porous oxide. This was a rearrangement process within the oxide structure and not further oxidation. Variations in the length of the inhibition time were due to differences in the thickness of the initial nonporous layer. After formation of the porous oxide, oxidation took place at the metal/oxide interface. Adsorption as the rate-controlling step was ruled out because the reaction rate was independent of oxygen pressure. The possible reaction at an oxide/oxide interface likewise was not considered to be the primary rate-determining step since only PuO_2 was detected by x-ray diffraction at this temperature. However, this interaction cannot be completely ruled out at this time.

Oxidation in moist oxygen-nitrogen atmospheres.—The primary objective of this study was to determine the effect of oxygen on the oxidation of plutonium by water vapor. Runs were made in moist nitrogen atmospheres containing 3 and 21% oxygen and also in 100% oxygen. In all cases, the oxidation rate was faster in the oxygen-containing atmospheres than in moist nitrogen. This is opposite all previously reported results (4, 5, 7). One possible explanation is the temperature at which these runs were carried out. The majority of the evidence for a protective oxide film has been found at room temperature and that work done at 90°C showed little difference between oxidation in moist oxygen and in moist argon (5). Furthermore, it should be noted that the experimental procedures used in earlier studies provided mostly qualitative and semiquantitative information. Because of this, a definite explanation of the effect of oxygen on plutonium oxidation by water has not been reported.

Typical results from this study are shown as curve O in Fig. 2 and 3. It is obvious from these runs that water vapor greatly accelerates the oxidation of plutonium. The protective oxide layer normally formed by oxygen during oxidation in moist atmospheres was not observed with the possible exception of the first few hours on some runs. Run O in Fig. 3 is such an example. In this case, the oxidation proceeded along the curve obtained for dry air for about 7 hr indicating water vapor was not yet taking part in the reaction. After 7 hr, the rate began increasing until the final linear rate was reached. The final linear rates obtained for the oxygen runs shown in Fig. 2 and 3 (curve O) were 0.42 and 0.72 mg/cm^2hr for the rolled and cast plutonium samples, respectively. All of the runs in oxygen-containing atmospheres followed a linear rate law with an average rate of 0.34 mg/cm^2hr for the rolled plutonium and 0.68 mg/cm^2hr for the cast metal. The difference in rates between the two metal samples is attributed to the difference in purity as well as the metallurgical history. This is consistent with the results reported by Raynor and Sackman (5).

Rate constants obtained for the rolled metal were compared with the 0.18 mg/cm^2hr rate obtained earlier by Thompson (8) using the same metal. The rate observed in this study was about twice as fast. This increased rate was probably due to differences in the moisture content for the two studies.

Effect of oxygen partial pressure on plutonium oxidation.—The relation between oxygen pressure and the plutonium oxidation rate has not been clearly established. There has been a fairly significant pressure effect reported at higher temperatures (8, 11). This ranges from a very positive effect at about 200°C (11) to an inverse effect at 400°C (8). However, the effect appears to be minimal at room temperature. Tanon *et al.* (7) reported an inverse oxygen pressure dependence for oxidation in moist atmospheres at 50° and 70°C. The exact relationship could not be defined from their data and no results were reported at temperatures greater than 70°C.

The results from this study show a very strong positive effect at low oxygen concentrations. This is evidenced by the difference between curves O and N in Fig. 2 and 3. The exact oxygen concentration required for this effect was not determined; however, it was less than 3 v/o or a partial pressure of 15 Torr. Oxygen concentrations greater than 3 v/o produced no effect on the oxidation rate at 90°C.

Oxidation in moist nitrogen atmospheres.—Typical results from the oxidation of unalloyed plutonium in moist nitrogen are shown in Fig. 2 and 3 (curve N). At 90°C plutonium oxidation by water vapor was found to be very fast and to obey a parabolic rate law, *i.e.*, $x = kt^{1/2} + c$, as shown in Fig. 4. The rate constants for the typical runs shown in Fig. 4 were 1.14 $mg/cm^2hr^{1/2}$ for the rolled metal and 3.52 $mg/cm^2hr^{1/2}$ for the cast sample. The average rate constants for all of the runs made with these two samples were 1.11 $mg/cm^2hr^{1/2}$ for the rolled plutonium and 3.60 $mg/cm^2hr^{1/2}$ for the cast plutonium.

The products from the reaction between water and plutonium were examined by x-ray diffraction and found to be PuO_2. No PuH_2 was detected although this was not totally unexpected due to the similarity in crystal structure between PuO_2 and PuH_2. The nitride, PuN, is not expected to form under 300°C and was not detected in the products. The color of the PuO_2 formed during oxidation of the rolled plutonium was yellow-green, while the oxide formed from oxidation of the cast metal was black. This difference in color may be indicative of two different mechanisms and is discussed in more detail later.

Because of the threefold difference in reaction rate for the two types of plutonium samples, the character

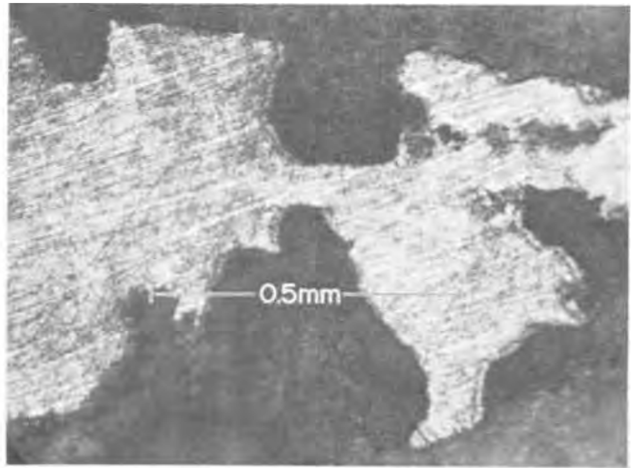

Fig. 6b. Cross section of a cast plutonium coupon following oxidation at 90°C in moist nitrogen.

of the plutonium metal was examined in detail. Photomicrographs were taken of coupons from both the rolled and cast samples after about 25% of total oxidation in moist nitrogen. Figure 5a shows the surface of the rolled coupon after all loose oxide had been removed. The water vapor appeared to be nearly uniform with the major reaction occurring on the edges. Figure 5b is a cross-sectional view of the same coupon. Again, there was no serious pitting, indicating the reaction was fairly uniform. These surfaces are indicative of an atypical water reaction with plutonium which was probably caused by the high impurity content. Photomicrographs of the cast plutonium coupon are included as Fig. 6a and 6b. The water vapor attack on this sample was catastrophic. In Fig. 6a, severe pitting is shown on the surface and in Fig. 6b the cross-sectional view shows that some of these pits nearly penetrate the coupon. This type of attack is similar to the hydrogen reaction with plutonium and is identical to that normally expected with water vapor.

Initially, the difference in impurities appeared to be the primary reason for the different types of attack on the two samples. Further comparison of these two samples, however, provided additional reasons for the difference in rates. Metallographic examinations of the two metal samples showed the cast material to contain numerous microcracks (Fig. 7). These cracks were absent in the rolled material (Fig. 8). The microcracks in the cast specimens could account for the catastrophic type attack. In this case, moisture could condense in the microcracks causing accelerated oxidation and subsequent breakaway.

The microcracks probably originate from internal stresses caused by cooling through the β-α phase transformation during casting. Since the rolled plutonium sample also was cooled from the γ-phase to the α-phase it might also be expected to contain microcracks. However, it was essentially free from any cracks. One reason for the lack of cracks may be the relatively high impurity content. It has been shown that impurities reduce the incidence of microcracking (12). Iron, particularly, serves as a stress-relieving agent by precipitation as Pu_6Fe in the grain boundaries. Thus, somewhat indirectly, impurities may be the major contributing factor in the two different oxidation rates.

Mechanism of water vapor attack.—Several mechanisms (13) have been proposed to explain the oxidation of plutonium by water vapor. Draley (14) proposed a hydride mechanism for the interaction of hydrogen with metals. In the case of plutonium, water reacts to form plutonium hydride which further reacts to form the oxide. That is

$$Pu + 2H_2O \rightarrow PuO_2 + 2H_2 \quad [1]$$

$$Pu + H_2 \rightarrow PuH_2 \quad [2]$$

$$PuH_2 + 2H_2O \rightarrow PuO_2 + 3H_2 \quad [3]$$

Waber (15) suggested that the reaction between plutonium and water vapor is under anodic control. The cathodic reaction involves the dissociation of adsorbed

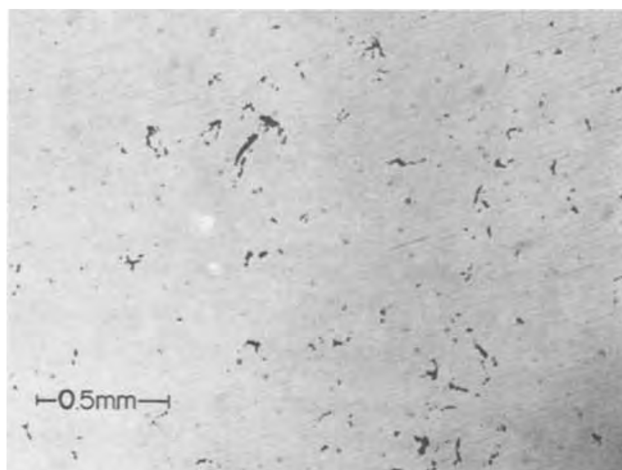

Fig. 7. Metallographic section of a cast plutonium sample

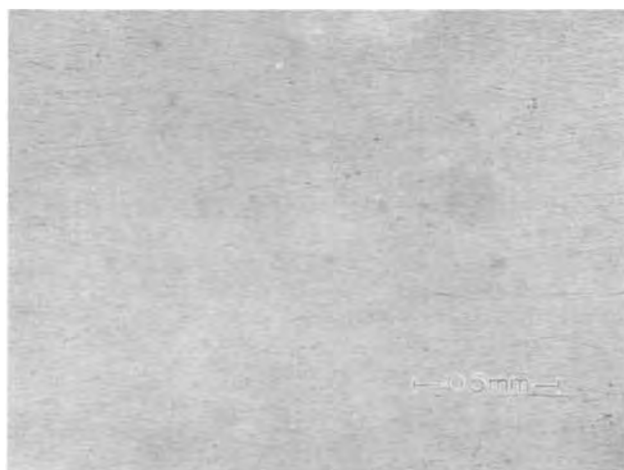

Fig. 8. Metallographic section of a rolled plutonium sample

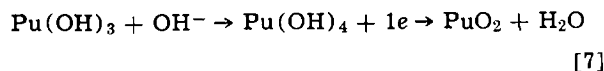
water vapor on the oxide-covered plutonium metal. Therefore

$$2H_2O \rightarrow OH^- + H_3O^+ \quad [4]$$

$$2H_3O^+ \rightarrow H_2 + 2H_2O - 2e \quad [5]$$

The anodic reaction takes place on the diffusion of OH^- anions to the metal/oxide interface and involves the reactions

$$Pu + 3OH^- \rightarrow Pu(OH)_3 + 3e \quad [6]$$



$$Pu(OH)_3 + OH^- \rightarrow Pu(OH)_4 + 1e \rightarrow PuO_2 + H_2O \quad [7]$$

which are said to be rate controlling. Hydrogen produced by dissociation of adsorbed water was thought to have only a minor effect on the over-all reaction rate. In this mechanism, it is assumed that the water produced at the metal/oxide interface in reaction [7] dissociates so that the reaction sequence [6] and [7] is again repeated. However, it is possible that water could react differently with the metal according to reactions [1]-[3] or that the hydrogen produced by the dissociation of the water could react directly with the metal thus producing some hydride.

Thompson (8) has proposed a compromise between the "hydride" and the "hydroxide" mechanisms. This hypothesis attempts to explain the importance of small amounts of moisture as well as the presence of hydride in the reaction products.

The reaction sequence is

$$Pu + 2H_2O \rightarrow PuO_2 + 2H_2 \quad [8]$$

$$Pu + H_2 \rightarrow PuH_2 \quad [9]$$

$$2PuH_2 + 6H_2O \rightarrow 2Pu(OH)_3 + 5H_2 \quad [10]$$

$$4[Pu(OH)_3] + O_2 \rightarrow 4PuO_2 + 6H_2O \quad [11]$$

with the rate-controlling step being the hydride-water reaction [10]. In the case of oxidation by water vapor in nitrogen, Eq. [11] would have to be modified to Eq. [7].

Results obtained in this study do not clearly support any of the previously proposed mechanisms. For example, the plutonium-water vapor reaction followed a parabolic rate law indicating a diffusion-controlled reaction. Previous reports, including those of Waber (15) and Thompson (8), indicated the reaction was linear and reaction controlled. The difference between these proposed mechanisms and the diffusion-controlled mechanism proposed from this work may be the temperature employed, but this has not been verified. The diffusion involved in this study was probably the diffusion of OH^- ions to the metal/oxide interface as suggested by Waber (15). This is supported by parallel studies of water adsorption on PuO_2 (16). However, in this case the diffusion was rate controlling and not the $Pu + OH^-$ reaction.

Two different plutonium dioxides appeared to be formed by reaction of the rolled and cast metal with water. Oxide resulting from oxidation of the rolled plutonium was a yellow-green while that from the cast metal was black. Black is the color which is normally observed when plutonium dioxide is formed from a hydroxide intermediate (17) or if plutonium hydride is present. Therefore, on the basis of the product formed, the reaction between the cast electrorefined plutonium and water vapor appears to follow a "hydroxide" type mechanism. Strictly on the basis of color, the reaction between the rolled plutonium and water vapor does not follow the proposed mechanism. However, color can be a function of purity and particle size so one of the mechanisms may still be applicable.

Hydrogen is a product of the plutonium-water reaction, regardless of the mechanism proposed. In these studies hydrogen has been detected in the gas phase following a reaction. Whether or not this hydrogen reacts with the plutonium is the difference between the "hydroxide" and various "hydride" mechanisms. Since hydrogen reacts so readily with plutonium, it is difficult to believe there is no hydride present. However, hydride is difficult to detect and was not found in this study. Additional work of an analytical nature is required to establish conclusively the mechanism for this reaction.

Summary and Conclusions

The oxidation of both rolled and cast unalloyed plutonium at 90°C was investigated in nitrogen-oxygen mixtures containing 12,000 ppm water vapor and also in dry air. Plutonium was found to oxidize faster in the oxygen-containing mixtures than in pure moist nitrogen. Earlier studies by other workers have shown the oxidation rates in moist air and moist argon or helium to be nearly the same or slightly faster in moist nitrogen at 90°C. It appears from this work that at about 90°C water vapor begins to exert less of an accelerating effect on the oxidation rate and oxygen assumes more of a controlling role. Because of the rapid oxidation in oxygen atmospheres at 90°C, it is apparent that there is no inhibiting effect by oxygen on the water vapor reaction. Metal purity and metallurgical history had no effect on the oxidation rate in dry air but became more important with the addition of water vapor.

The oxygen pressure dependence of this reaction became very strong at some partial pressure less than 15 Torr. The exact pressure at which this occurred was not determined. For this study there was no oxy-

gen pressure dependence observed for partial pressures between 15 and 500 Torr.

The attack by water vapor observed during this study was greatly influenced by the purity of the metal as well as its metallurgical history. Samples of cast electrorefined plutonium containing some microcracks reacted very rapidly while for the impure rolled material the reaction was somewhat slower. In all cases at this temperature, the reaction with water vapor was diffusion controlled and not reaction controlled as previously reported. The diffusing species is believed to be OH^- ions formed by the dissociation of water vapor adsorbed on the plutonium dioxide.

TiO_2 Film Properties as a Function of Processing Temperature

E. T. Fitzgibbons,*[,1] K. J. Sladek,* and W. H. Hartwig

Departments of Electrical and Chemical Engineering, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Thin film TiO_2 was produced at 150°C by chemical vapor deposition using hydrolysis of tetraisopropyl titanate. Films were amorphous as grown, but annealing in air caused crystallization, with anatase formed beginning at 350°C and rutile at 700°C. Density and index of refraction increased substantially with increasing anneal temperature, while etch susceptibility in HF and H_2SO_4 decreased. Comparison with literature data showed two groups of processes. One group yields films having properties that gradually approach those of rutile with increasing process temperature. The other group gives rutile directly at moderate temperatures. Deposition of amorphous film followed by etching and annealing is suggested as a means for pattern definition.

Thin film TiO_2 has been produced by anodization and thermal oxidation of Ti, evaporation of TiO_2, reactive sputtering of Ti, a variety of chemical vapor deposition (CVD) processes, and even by liquid deposition. The electrical, chemical, and physical properties of TiO_2 films exhibit considerable diversity, which arises from differences in stoichiometry and structure among films formed by different means. The present research began with the discovery of a unique low-temperature process for producing films of readily etchable amorphous TiO_2. Annealing procedures were found to convert these films to the anatase and rutile forms of the material. Film properties could then be determined for a range of well-controlled structures. One purpose of this investigation was to provide a comprehensive set of structure-property data which might serve to explain discrepancies in reported values of density, refractive index, and etch susceptibility. Another purpose was to develop a means for producing thin film TiO_2 for applications requiring pattern definition.

Titanium dioxide exists in two tetragonal structures, anatase and rutile, plus orthorhombic brookite. Rutile is the thermodynamically stable form at all temperatures investigated so far, but anatase and brookite retain their structures until heated to fairly high temperatures, at which they transform irreversibly to rutile. Reported temperatures for significant rates of conversion to rutile are 800°-1100°C for anatase and 700°-1300°C for brookite (1, 2). Theoretical densities of anatase and rutile are calculated to be 3.94 and 4.27 g/cm^3, respectively, using recent values of the unit cell dimensions (1). These agree reasonably well with measured values of 3.90 and 4.23 g/cm^3 (2). Average index of refraction (n) values at 0.55 μm are 2.57 for natural crystals of anatase and 2.74 for synthetic crystals of rutile (1).

While properties of bulk anatase and rutile are well established, little agreement has been reached regarding the properties of thin film TiO_2. One of the most thorough studies is due to Hass (3), who produced films both by thermal oxidation of Ti and by a CVD

Key words: thin films, chemical vapor deposition, titanium dioxide.

process. Evaporated Ti films were oxidized above 200°C and the resulting oxide was shown to be rutile by electron diffraction. The index of refraction of these films was 98-99% of that of bulk, single-crystal rutile for the whole range from 0.4 to 2.0 μm. In contrast, hydrolysis of $TiCl_4$ produced amorphous films below 280°, and anatase films above 300°C, with n values near 2.3.

Films of TiO_2 have also been produced by anodization (4, 5), reactive sputtering (6), vacuum evaporation (7), and by drying substrates which had been dipped into a titanate solution. Drying at 180°-900°C gave films with n values of 1.95-2.45 (8).

CVD processes include the $TiCl_4$-H_2O reaction near 300°C (3), at 150°C (9), and at 800°C (10). Pyrolysis of tetraisopropyl titanate (TPT) at 300°-700°C gave amorphous and anatase films exhibiting a range in density, refractive index, and etch susceptibility (11). Reaction of $TiCl_4$ with O_2 gave epitaxial rutile on some substrates above 700°C and polycrystalline rutile at lower temperatures (12). In the present work the TPT-H_2O reaction was used, as described next.

Deposition Phenomena

The CVD apparatus is illustrated in Fig. 1. The two liquid feeds are evaporated from heated flasks into metered carrier gas streams. The feed streams then issue from parallel nozzles at the ends of the delivery lines, intermingle with each other and with the room air, and are directed onto the substrate, which is heated from beneath. Film growth is controlled manually by moving the substrate around under the nozzles or by moving the nozzles. By observing the sharp interference colors, the operator can manually control the thickness uniformity of the film to within 100-200Å over a 1.25-in. diameter substrate wafer.

The best temperature range for the TPT evaporator is 75°-85°C. The water evaporator temperature is not critical and films can even be grown without using the CO_2 carrier and water source; in that case, the water vapor in the ambient air is evidently sufficient to maintain the reaction. The growth dynamics appear to be the same with and without the water vapor stream and the structural, optical, and chemical properties are also the same in both cases. The only differences were observed in the reproducibility of electrical properties, and the water vapor source was used to stabilize these.

Under typical conditions, the helium flow rate was 1 l/min, the CO_2 flow rate was ¼ l/min, the TPT and water evaporators were at 75° and 90°C, respectively, and the substrate heater was at 150°C. With these parameters, a 1.25-in. substrate could be covered with a 2000Å film in 10 min.

These conditions were chosen after making a number of observations about the film quality obtained under various deposition conditions. When the TPT evaporator was too hot (90°-100°C) a milky film having diffuse interference colors resulted. Microscopic examination revealed that the film lacked coherence,

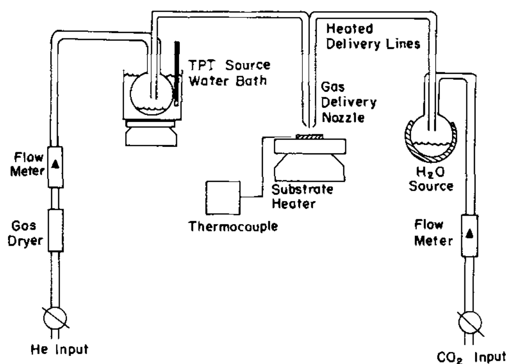

Fig. 1. Chemical vapor deposition system

but rather was made up of tiny stacked spheres. The film had an odor of alcohol or TPT and was soft enough to be smeared with a cloth. Evidently, the TPT condensed after leaving the nozzle and the resulting film was made up of small droplets of TPT which had reacted at their outer surfaces only. Similar results were obtained with the TPT evaporator at 75°C when the He carrier flow exceeded 2 l/min, when the nozzle was closer than 1 in. from the substrate, or when the substrate temperature was below 100°C. Excessive CO_2 carrier flows (> ½ l/min) caused a white powdery deposit, evidently due to premature hydrolysis of TPT, giving a powder product which rained down onto the substrate. The same effect occurred when the nozzle was held more than 3 in. from the substrate. In summary, the conditions chosen above were selected to avoid both incomplete and premature reaction which led to formation of films lacking coherence. Under the chosen conditions, the films were smooth and relatively hole free. No detail could be observed in the scanning electron microscopy at 20,000X, except for an occasional pinhole.

When film thicknesses of 4000-5000Å were reached during a normal deposition, cracks would appear and propagate over the film, reducing it to a field of small triangular pieces, each separated from the substrate with its points bending upward. This was observed with all the substrates described below at approximately the same film thickness. Several experiments with duplex films were performed. When a film was grown to several thousand angstroms and then later a new film was grown atop the previous one, fracture occurred when the sum of the two thicknesses fell into the 4000-5000Å range. However, when a film was grown and annealed above 350°C (to be described later) and then a new film was grown on the annealed one, fracture occurred when the second film reached 4000-5000Å. This behavior indicates that the film is deposited with an intrinsic tensile stress. Fracture may be associated with a failure of the film-substrate adhesive bond due to increased shear stress as the film thickens.

Films could be grown on any smooth object that could be heated. In the present work, different substrates were used for different experiments. Fused quartz was used for optical transmission measurements. Fused quartz covered with evaporated Pt and also polished Si were used as substrates in determining refractive index and thickness relationships by ellipsometry and interferometry. Soft glass microscope slides, as well as some of the other materials, were used in x-ray analysis. Before deposition, the fused quartz and the soft glass substrates were cleaned thoroughly in low residue detergent, were rinsed in deionized water, and were heated in air at 1000° and 350°C, respectively, to drive off surface contaminants. The Pt/quartz substrates were annealed in air at 1000°C to stabilize them, and no further cleaning was performed. The Si wafers had been commercially prepared using mechanical and electrochemical polishing and were used as supplied.

Annealing and Crystallization

Films produced by the CVD method described above underwent dramatic changes in physical and chemical properties during annealing. The changes in crystal structure are described here.

Crystalline phases were identified using an x-ray diffractometer with copper $K_{\alpha 1}$ radiation. Four types of samples were used. Powder samples were obtained by allowing the standard deposition process to continue for several hours until a thick white powdery deposit had built up; this was then scraped off and divided into samples for testing. The other three types of samples consisted of 3000-4000Å films grown on fused quartz, soft glass, and polished Si.

The powder in the as-grown condition showed no sign of crystallinity and was evidently amorphous. No

Table I. Crystalline phase and anneal temperature for TiO_2 on several substrates

Anneal temper-ature,[a] °C	Substrate[b]			
	Powder sample	Soft glass	Polished Si	Fused quartz
150 (as grown)	Amorphous	Amorphous	Amorphous	Amorphous
350	Amorphous + anatase	Amorphous + anatase	Amorphous + anatase	Amorphous + anatase
700	Rutile + anatase	Rutile + anatase	Rutile + anatase	Anatase
1000	Rutile	—	Rutile	Anatase

[a] All anneals carried out in air.
[b] Crystalline phases identified in all films showed no orientation.

crystallization occurred during aging at room temperature in air for one week. Annealing the powder for 10 min at 350°C resulted in the appearance of the two strongest diffraction peaks of the anatase form of TiO_2. A sample annealed at 700°C for 2 hr showed the five strongest anatase peaks and the three strongest rutile peaks. A 20-hr anneal at 1000°C completely converted the powder to rutile; many rutile peaks were observed, and no anatase peaks were detectable.

Table I summarizes the data for all four types of samples. In every case the as-grown material is amorphous, and material annealed at 350°C shows some anatase. However, the weakness of the anatase patterns suggested that only partial crystallization occurred at 350°C. This temperature can be regarded roughly, as an amorphous-anatase transition temperature. Additional anneals at 300°-400°C indicate that the transition is not sharp, but rather occurs over a range of about 50°C in which the extent of crystallization gradually progresses. The temperature, 700°C, appears similarly to be characteristic of the anatase-rutile transition. This transition appears to be less sharp and progresses over a range of about 300°C. An important exception is the films on fused quartz which persist in the anatase form, even after annealing at 1000°C. Somehow, the quartz-TiO_2 interface stabilizes the anatase structure, perhaps by preventing nucleation of rutile.

The present data are in accord with some of the literature data described earlier. The anatase-rutile transition occurs in bulk samples at 800°-1100°C (1, 2). In films produced by CVD or liquid dipping, a change from amorphous to anatase structures was found at 280°-300°C (3), and at 250°-350° (8). An anatase-rutile transition was observed at 800°C (3), and several investigators produced rutile directly at 800°C or above (10, 13). In contrast, rutile films were produced as low as 400°C from Ti oxidation (3) and from the $TiCl_4$-O_2 reaction (12).

Thickness and Index of Refraction

Changes in interference colors occurred as a result of annealing, and these indicated a change in thickness, d, and/or index of refraction, n. If a standard color chart for SiO_2 was used, the changes indicated that annealing a 150°C film at 1000°C caused an increase in d. However, measurements using an ellipsometer indicated a substantial decrease in d, accompanied by an increase in n, and indicating that a single color chart, based on fixed n, would be misleading. To obtain additional independent values of d and n, a multiple beam interferometric technique was used. Both the ellipsometer and the interferometer used the 5460Å green line of Hg.

Coated and uncoated portions of a step were used to find both d and nd with the interference method (14). The ellipsometer yields separate values of d and n (15). A cross check was provided by a color chart, which gives nd (14).

Results obtained before and after annealing at 1000°C are shown in Table II. The several methods give good agreement, and it is clear that annealing

Table II. Change in thickness and index of refraction due to annealing at 1000°C

Sample condition	Thickness, A (method)[a]	Index of refraction (method)[a]
As grown, 150°	3820(I), 3870(E)	1.98(I), 2.10(E)
Annealed, 1000°	2510(I)	2.49(I)
As grown, 150°	2400(E)	2.00(E), 1.95(C)
Annealed, 1000°	1580(E)	2.40(E), 2.47(C)
As grown, 150°	1900(E)	2.10(E), 2.06(C)
Annealed, 1000°	1220(E)	2.60(E), 2.50(C)

[a] I = interferometer; E = ellipsometer, C = color chart plus ellipsometer-determined thickness.

causes a substantial decrease in d and increase in n.

To complete these measurements, a final series of data was obtained as a function of anneal temperature. A film was deposited on Pt/quartz and data were obtained by ellipsometry, using averages of two to four measurements. Figure 2 is a plot of resulting values of thickness and index of refraction.

The thickness shrinkage of 35% is quite remarkable in magnitude. Since the film is constrained to a fixed area, any density changes are evidently exhibited only in one dimension. One might suspect that such a violent dimensional change would set up stresses which might rupture the film. However, examination of a 1000°C annealed film in the scanning electron microscope at 20,000X showed no cracks, tears, or eruptions.

It was suspected that the shrinkage might be accompanied by a mass loss, as would be expected if the as-grown material were a hydroxide or hydrate. A hydroxide, $Ti(OH)_4$, would lose 31% of its initial weight if complete dehydration occurred. Several experiments were carried out in an effort to detect a weight change on annealing. In the most sensitive experiment, a sample was weighed on a vacuum microbalance and annealed *in situ*. No weight change could be detected within the experimental uncertainty of ± 7% of the initial film weight. Although the sensitivity of this experiment was rather low, the result does rule out mass reduction as a primary cause of the volume shrinkage.

It is possible that the films are microporous and that shrinkage occurs by sintering. Swaroop (16) and Pliskin and Lehman (17) attributed densification of SiO_2 films to sintering. Sladek and Herron (18) investigated TiO_2 film growth by the TPT-H_2O reaction at 25°C, and suggested that voids are incorporated when isopropyl groups are removed from the growing film during surface reaction.

The difference between a microporous material and a "homogeneous" one of abnormally low density is only in the size of the void spaces. Our observations using the scanning electron microscope detected no pores. Qualitatively, the optical transparency and sharp interference colors of our films indicate negligible scattering by void spaces. However, both of these

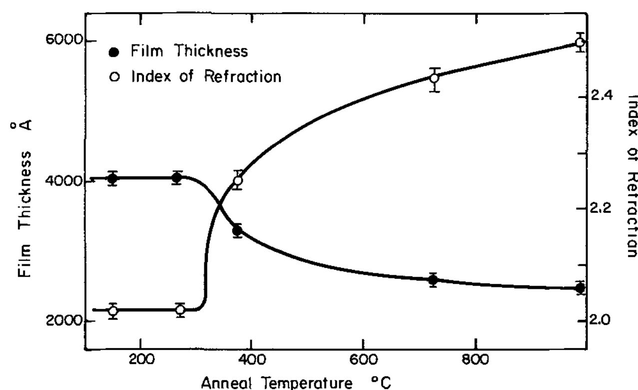

Fig. 2. Thickness and index of refraction as a function of anneal temperature. TiO_2 on Pt/quartz.

Table III. Chemical susceptibility to several etches

Anneal temperature, °C	Etch rate and behavior 0.5% HF	48% HF	100% H_2SO_4	85% H_3PO_4
150	50-75 A/sec	Very rapid	Slow at 25°C 25-40 A/sec at 50°C	Leaves residue
350	On Pt: very slow On Si: undercutting	Slow and uneven	About 15 A/sec at 50°-100°C	
700	No etching	On Pt: slow On Si: undercutting	Very slow	
1000	No etching	On Pt: slow On Si: undercutting	About 1000 A/hr at 120°C	Very slow at 120°C

observations would be insensitive to voids of size below about 200Å. We attribute the abnormally low density of the present amorphous films to voids of size somewhere in the range between atomic dimensions and about 200Å.

Susceptibility to Chemical Etch

Etch susceptibility is a prerequisite for electronic applications of TiO_2. Some past work indicates that amorphous TiO_2 is readily etched while high-temperature and hence crystalline forms are quite impervious to chemical attack. Barksdale (19) observed in 1949 that, while bulk TiO_2 is known to be slightly soluble in H_2SO_4, HF, and a few strong alkalies, material annealed near 1000°C is almost completely inert chemically.

Etchability of TiO_2 as a function of anneal temperature was determined for films grown on Si and on Pt substrates. Results are summarized in Table III. Again there is a wide, controllable gradation in properties, with the low-temperature form showing high chemical susceptibility while the 1000°C material is nearly inert. Films on Si behaved the same as those on Pt except for the 48% HF case. This etch lifted the TiO_2 off the surface of Si, evidently by dissolving a thin interfacial layer of SiO_2 and undercutting the TiO_2.

These results are in accord with data of Yokozawa *et al.* (11), who reported that their amorphous TiO_2 films etched in dilute HF at 4-60 Å/sec, while anatase films etched only slowly in concentrated HF. Feuersanger (9) reported that his films were easily etched in 10% HF; this suggests that they were amorphous, as would be expected for a 150°C process. His high index of refraction (discussed later) is then the only property that does not agree with the present results. Harbison and Taylor (10) reported an etch rate of 700 Å/min in 48% HF for material grown at 800°C. This is much higher than would be expected from our results.

Optical Absorption

An optical transmission spectrum of a 350°C annealed film is shown in Fig. 3. This was obtained by measuring the difference between the transmission of the film on fused quartz and the transmission of the fused quartz alone. We attribute the maxima and minima above 0.35 μm to interference due to multiple internal reflection, and the strong absorption peak at 0.32 μm (3.9 eV) to an electronic transition. Transmission in an amorphous TiO_2 film was also measured and similar results were obtained, except that the strong absorption peak was much broader, although still centered at 0.32 μm. In agreement with these results, Maserjian (20) found an absorption peak at 0.32 μm with a rutile film. In contrast, however, single-crystal rutile exhibits an absorption edge (21) at 0.41 μm (3.0 eV). The cause of the discrepancy between bulk single-crystal and thin film TiO_2 is not known. However, in both this work and that of Maserjian (20) the 0.32 μm peak has been established.

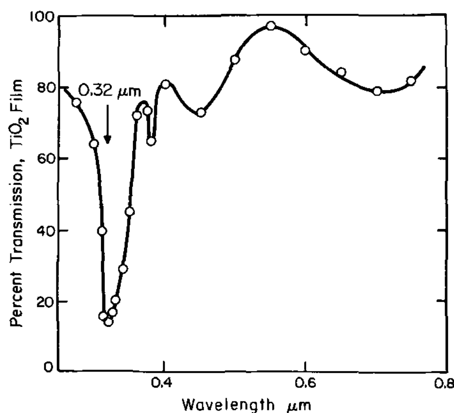

Fig. 3. Optical transmission spectrum. 2600Å film of TiO_2 annealed at 350°C.

Discussion

Present data on density and index of refraction are compared with literature values in Fig. 4. Since absolute values of density were not obtained in this work, it was necessary to choose a value for one condition, and 2.5 g/cm³ for the amorphous films was used, based on the results of Yokozawa *et al.* (11).

Results of two of the CVD studies (11, 13) and the liquid deposition (8) show good agreement with present data in both properties plotted. Results of Hass (3) on films formed by $TiCl_4$ hydrolysis and by oxidation of "TiO" (formed by exaporating Ti with O_2 present) show an increase in n with temperature similar to that observed here, although with somewhat higher values of n.

In contrast, Hass (3) obtained nearly the bulk rutile value of n with oxidized Ti, and Ghoshtagore and Noreika (12) found an even higher value with films formed from $TiCl_4 + O_2$ in the whole temperature range studied. (We have applied a small correction to their reported value of n_D to obtain a value applicable at 0.55 μm.) The fact that their n exceeds the random-orientation average for bulk rutile could have been due to preferred orientation of their films.

In summary, one group of processes produces films which show a characteristic variation in physical and

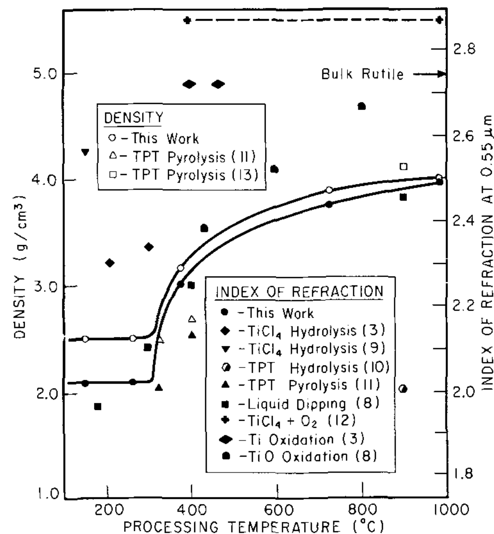

Fig. 4. Density and refractive index vs. processing temperature: a comparison with other work.

chemical properties with maximum processing temperature, whether this temperature is reached during deposition or during postdeposition anneal. These variations arise from densification and crystallization and ultimately yield material with properties approaching those of the equilibrium (rutile) bulk state. However, it is also possible to bypass these intermediate stages and obtain rutile directly at moderate temperatures.

We have found that, of the several forms produced, rutile or anatase-rutile mixtures have superior dielectric properties. The relative dielectric constant/dissipation factor at 1 kHz was about 100/0.04 for material annealed at 700°-1000°C. The sign of the surface charge of TiO_2 on Si was negative, and positive, negative and zero, values could be obtained by growing duplex TiO_2/SiO_2 films. (Details of these electrical studies will be reported later.) These properties suggest a number of applications for rutile in integrated circuit technology.

Although it is possible to produce rutile films directly, they are almost impossible to etch (Table III). In contrast, the deposition-annealing process used here could lend itself readily to the various etch steps needed for integrated circuit production. Standard photomasking techniques could be used to define a desired pattern in the as-grown film, and a later anneal would convert the material to its stable form.

The fact that the TiO_2 itself changes chemical susceptibility suggests that patterns might be defined without photoresists, if a means were found for selective conversion in desired areas. This idea has led to some further work (to be reported later) in which an electron or photon beam is used to define positive patterns in amorphous TiO_2.

In conclusion, it is possible to produce rutile films either directly or via a series of stages progressing in density, refractive index, and etch susceptibility. The present method of low-temperature deposition followed by annealing is promising for applications requiring pattern definition.

Cathodoluminescence Characteristics of Mn^{2+}-Activated Willemite (Zn_2SiO_4) Single Crystals

R. J. R. S. B. Bhalla*[1] and E. W. White

Materials Research Laboratory, Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Cathodoluminescence studies were made of Mn^{2+}-activated willemite single crystals using an electron microprobe and a simple interference-type spectrometer attachment. Use of the microprobe allows single-crystal cathodoluminescence measurements to be made on comparatively small (<0.01 mm) crystals. Green cathodoluminescence emission from Mn^{2+}-activation was found to be partially polarized. The electric vector of emission was along a direction perpendicular to the c-axis of the crystals. Examination of the emission spectra in the two perpendicular polarization directions, corresponding to the analyzer direction parallel to the c-axis, and perpendicular to the c-axis, showed a difference of about 100Å in the emission peak positions. Measurements of spectra and integrated intensity of emission were also made as a function of manganese concentration. The intensity of luminescence was maximum for Mn concentration of 2.9 w/o (weight per cent). The peak position of the Mn^{2+} band was found to shift from 5160 to 5300Å as the manganese concentration increased from just a trace to about 12 w/o. The polarized cathodoluminescence emission can be explained on the basis of crystal-field theory and symmetry arguments. These arguments lead to the conclusion that the two Zn^{2+} sites in the willemite structure, which are occupied by the Mn^{2+} ions, have effective local symmetries of C_{3v} and C_1, respectively. The emission peak shift to longer wavelengths, as the manganese concentration is increased, cannot be explained by simple crystal-field theory. A model showing emission from Mn^{2+}-Mn^{2+} pairs dominating at higher concentrations, in comparison to emission from isolated Mn^{2+} ions, is proposed to explain this shift of emission peak to longer wavelengths.

Emission spectra from oriented single crystals of impurity activated (or self-activated) phosphors can give very important clues to the site symmetry of the activator. In the past polarized emission from phosphor single crystals has been studied to determine nature and symmetry of the luminescence centers (1, 2). Thus, although the advantages of single-crystal studies were recognized for some time, such studies have been limited to very few well-known phosphors. The main reason for this is the general lack of large enough single crystals. Furthermore, almost no studies of these luminescence characteristics exist for cathode-ray excitation in single crystals. A recent communication (3) has described preliminary results for a cathodoluminescence study of oriented single crystals of Mn^{2+}-activated willemite. The main purpose of this paper is to give a detailed account of the polarized cathodoluminescence studies of Mn^{2+}-activated single crystals of willemite [Zn_2SiO_4(Mn)]. In addition, spectra and luminescence intensity, as a function of manganese concentration, are also measured on artificially doped single crystals of willemite.

Experimental

An applied Research Laboratory Model EMX electron microprobe was used for cathode-ray excitation of the willemite luminescence from sample areas as small as 5 μm diameter. The electron microprobe offers the additional advantage that the luminescence emission is observed from the surface of the sample excited by the electron beam rather than observing in transmission as is generally done in conventional cathodoluminescence apparatus. The electron beam is incident normal to the specimen surface and is coaxial with the light microscope objective. The broad band luminescence spectra were recorded using a simple light spectrometer and photomultiplier readout described by Greer and White (4). A Polaroid analyzing cap was attached to the eye piece of the probe microscope making it possible to record the luminescence emission spectra in any polarization direction. Use of this arrangement made it possible to study, individually, very small (<0.01 mm) single crystals, and micron scale inhomogeneities in larger grains with a sensitivity which is not possible with conventional cathodoluminescence apparatus.

Samples used in this study were natural willemite crystals from Franklin, New Jersey, and Tsumeb, South-West Africa. Franklin, New Jersey, specimens showed the strong green luminescence characteristic of Mn^{2+}-activated orthorhomic willemites and were found to contain 0.1-4.0% manganese in solid solution. Mn was rather uniformly distributed in the individual crystals. Other cationic impurities which have been reported in bulk chemical analyses of willemites are Fe, Mg, and Ca (5). However, probe analysis showed these impurities to be located in micron scale, highly oriented inclusions. No Fe, and only traces of Ca and Mg were detected in the willemite matrix. Absence of Fe in the willemite matrix is significant since it is known to act as a killer of luminescence in most materials. Willemite, which has only fourfold coordinated cationic sites, has a very low tolerance for Fe. In contrast to the Franklin, New Jersey, specimens, the South-West Africa willemite crystals do not luminesce green and have no detectable Mn or Fe impurities. Mn^{2+} was introduced in these crystals by solid-state diffusion at 1250°C. Selected samples were then set in Lakeside 70 and prepared as polished thin sections by grinding and polishing. Final sample surfaces were polished successively with 6, 3, 1, and ¼ μm diamond pastes and coated with a thin layer of carbon (200-400Å) by vacuum evaporation to provide a conductive path for the electrons. This method of preparation yielded grains with many different crystallographic orientations. Grains having the desired orientations for study were selected using a polarizing light microscope and marked for convenient location in the microprobe.

Experimental Results

Polarized cathodoluminescence.—Willemite belongs to the rhombohedral crystal class and as such has two principle axes (*a* and *c*). Crystals with orientations such that the c-axis was perpendicular to the surface (*a* in the plane) did not show any polarization of the green Mn^{2+} emission. However, the crystals with orientations such that the surface contained the c-axis, showed partial polarization of Mn^{2+} emission. The degree of polarization, *p*, given by $p = (I' - I'')/(I' + I'')$, where I' and I'' are maximum and minimum intensities as the analyzer is rotated around its axis, was found to be 0.25. The electric vector of the emitted radiation was along a direction perpendicular to the c-axis.

Emission spectra of Mn^{2+}-activated willemites were comparable to the commercially available willemite powders and consisted of a single broad band with peak position around 5250Å (for 1% Mn). This peak shifted toward slightly longer wavelengths as the concentration of Mn increased. The peak position as well as the degree of polarization were not found to be current density dependent. Examination of the emission spectra in the two perpendicular polarization directions corresponding to the analyzer directions parallel and perpendicular to the c-axis showed a difference of about 100Å in the peak positions. This is illustrated in Fig. 1. The peak intensities were matched by lowering the electron beam current while recording the spectrum in the maximum transmission direction. The more intense spectrum, obtained with the electric vector perpendicular to the c-axis, yielded the longer wavelength peak.

Effect of Mn^{2+} concentration on cathodoluminescence.—Measurement of the variation in the green emission spectral characteristics as a function of Mn concentration were made on South-West Africa willemite crystals into which Mn^{2+} was introduced by solid-state diffusion at 1250°C. The diffusion was carried out on small transparent prismatic crystals. Selected crystals were coated with very finely powdered $MnCO_3$ and heated to 1250°C for 12 hr in a platinum crucible. Crystals treated in this way were then mounted for probe analysis as usual. Cross sections through such crystals gave a concentration gradient of Mn. The luminescence intensity and the emission spectra along with Mn, Zn, and Si concentrations were recorded at many points along the Mn gradient. These measurements established that the Mn^{2+} is introduced in the lattice at the expense of Zn^{2+}. Figure 2 shows a plot of integrated luminescence intensity as a function of Mn concentration. This measurement was made at 20 keV and sample current of 2×10^{-8}A. The spot was about 2 μm in diameter. The intensity of luminescence is maximum for a Mn concentration of 2.9 w/o (weight per cent). This value is higher than the optimum of 1% reported

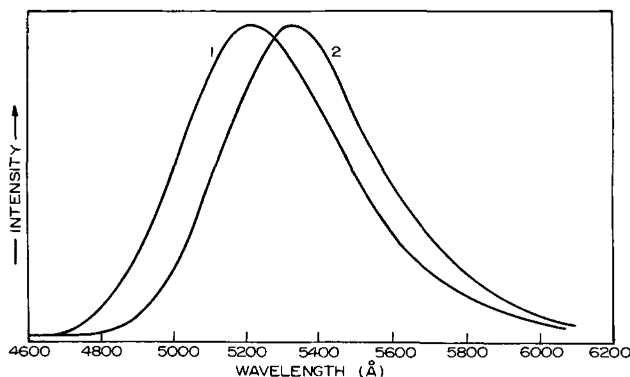

Fig. 1. Polarized cathodoluminescence spectra of Mn^{2+} in willemite. Curve 1 corresponds to the analyzer direction (electric vector) along the c-axis and curve 2 corresponds to the analyzer direction perpendicular to the c-axis. The peak intensities of the two curves are normalized to facilitate comparison of the spectra.

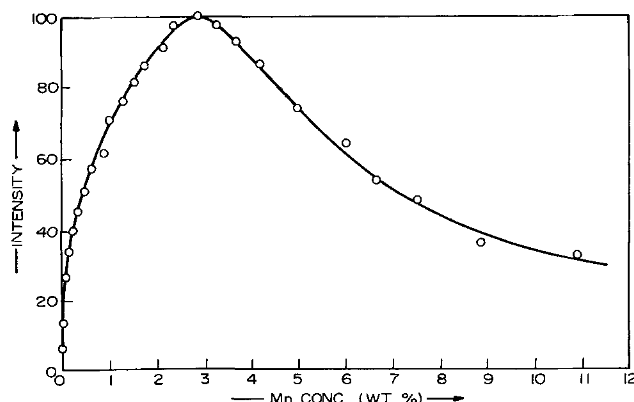

Fig. 2. Plot of integrated intensity vs. Mn concentration for a South-West Africa willemite crystal into which Mn was diffused by solid-state reaction with $MnCO_3$ at 1250°C. Measurements were made at 20 keV and a sample current of 2×10^{-8}A. The spot size was about 2 μm diameter. No correction was made for the possible change in the photomultiplier response as the emission peak shifts to slightly longer wavelengths for higher Mn concentrations.

for powder phosphors (6). It may be pointed out that the optimum concentration is dependent on the electron beam energy which is not specified in Ref. (6). It was found that, as the Mn concentration increases, the luminescence peak position shifts toward longer wavelengths. As the concentration of Mn increases from just a trace to about 12% the peak position shifts from 5160 and 5300Å. This observation compares well with similar results reported by Leverenz (6) on powder phosphors.

Discussion of Results

For an explanation of the polarization of $Zn_2SiO_4(Mn^{2+})$ luminescence, and the spectra in the two polarization directions, it is necessary to consider only the local symmetry of the activator site. The position of the Mn^{2+} energy levels involved in this luminescence emission, with respect to the position of valence and conduction bands of willemite, is not known. However, as is usual with Mn^{2+}-activated phosphors, it is fairly certain that the transition responsible for green emission of Mn^{2+}-activated willemites is localized within the 3d shell (7, 8). Although excitation by cathode-rays may be substantially through the conduction band, the final transition giving rise to the luminescence emisison takes place within the Mn^{2+} activator without any involvement of valence or conduction bands.

Mn^{2+} replaces Zn^{2+} in the crystal structure of willemite and Zn^{2+} is fourfold coordinated forming approximately a tetrahedral arrangement (9). Detailed refinement of the willemite structure has not been reported, thus the exact coordinates and distortions of the tetrahedral sites are not known. If there were no distortions in the tetrahedral Zn^{2+} sites then the symmetry of the site occupied by the activator Mn^{2+} would be T_d. The ground state of Mn^{2+}, which has $3d^5$ configuration, is ^6S with symmetry $^6A_1$. This state is changed very little in energy under the influence of a crystal field. The first excited term ^4G in the free ion gets split up into branches $^4A_1$, ^4E, $^4T_2$, and $^4T_1$ in a tetrahedral field, with $^4T_1$ level having the lowest energy. The transition responsible for Mn^{2+} emission is believed to be the one from $^4T_1 \rightarrow {}^6A_1$ (7). Group theoretical calculations show that if the symmetry of the emitting Mn^{2+} ion were perfectly tetrahedral there would be no polarization of the emitted radiation as the transitions in x, y, and z directions are equally allowed. In the crystal structure of willemite the Zn atoms, thus also the replacing Mn atoms, are reported at general positions and have a space group symmetry of C_1 (9). Under such symmetry conditions the emitting $^4T_1$ level would split up into three levels and again, according to group theory, transitions from these levels

Table I. Estimated Zn-O bond lengths of the distorted tetrahedra around Zn(1) and Zn(2) positions

Bond type	Bond length (A)
Zn(1)-O_1	1.93
Zn(1)-O_2	1.75
Zn(1)-O_3	1.88
Zn(1)-O_4	2.05
Zn(2)-O_1	1.82
Zn(2)-O_2	1.92
Zn(2)-O_3	1.94
Zn(2)-O_4	1.96

to the ground level are equally allowed in the x, y, and z directions giving no polarization. The fact that the emitted radiation is polarized leads to the conclusion (on the basis of crystal field theory arguments) that the emitting center has a local symmetry which is lower than T_d but higher than the space group symmetry C_1.

Any lowering of perfect T_d symmetery of the center would result in splitting of the triply degenerate $^4T_1$ into two or three separate levels depending on the lowered symmetry of the center. Polarization properties under the reduced symmetry conditions can be understood easily on the basis of group theoretical arguments (10), if the local symmetry of the center is known. An attempt to find out the local symmetries of Zn^{2+} ions in the willemite structure was made by calculating bond lengths and the following explanation is attempted on that basis.

The willemite structure has two different distorted tetrahedral Zn^{2+}sites [herein called Zn(1) and Zn(2) sites] where Mn^{2+} can go (9, 10). Approximate distortions in these sites were determined by using the atomic coordinates given by Bragg and Zachariasen (9). Calculations of bond lengths for the two sites are tabulated in Table I. It can be seen that the Zn(1) sites are highly distorted and do not seem to have any symmetry. Thus, taking C_1 as symmetry of this site, Mn^{2+} replacing Zn^{2+} on such sites would show no polarization. However, the Zn(2) sites have three bonds which are approximately equal, with an average bond length of 1.94Å. The fourth bond has a bond length 1.82Å which is appreciably shorter than the rest. It is very likely that this site has an effective pseudosymmetry of C_{3v}, with the threefold axis along the shorter bond. Mn^{2+} replacing Zn^{2+} on this site would have the emitting triply degenerate $^4T_1$ level split into a doubly degenerate level, ^4E, and a nondegenerate $^4A_2$ level. Strictly group theoretical arguments show that the transition $^4A_2 \rightarrow {}^6A_1$ is forbidden and the transition $^4E \rightarrow {}^6A_1$ is allowed in (x, y) direction, *i.e.*, a direction perpendicular to the shorter bond length. Since this direction makes smaller angles (~35°) with the basal plane, the electric vector in the basal plane would be of greater magnitude than the component along the c-axis. This explains the observed partial polarization of emission along a direction perpendicular to the c-axis. The energy level diagrams for the emission of Mn^{2+} at the two Zn^{2+} sites are shown in Fig. 3. At Zn(1) sites (C_1 symmetry, Fig. 3b) the $^4T_1$ level splits into three ^4A levels and these are equally allowed in x, y, and z directions, thus, contributions along the perpendicular to the c-axis are equal. The splitting is probably too small to show up in the broad band spectra. Figure 3c shows the splitting of $^4T_1$ level at Zn(2) sites (C_{3v} symmetry). Level ^4E is placed higher than $^4A_2$ in the energy level diagram since the $^4A_2$ level is connected with the shorter bond, thus, a greater crystal field. The small shift of peak to shorter wavelengths, for the spectra along the c-axis, can be explained if the peak of Mn^{2+} band for Zn(1) is at a comparatively shorter wavelength than the peak due to Mn^{2+} at Zn(2) position.

The above model explains the observed polarization satisfactorily (observed polarization, $\phi = 0.25$, in comparison to the calculated value of 0.21). However, the symmetries of the two Zn sites can be predicted with more confidence only when precise atomic coordinates for willemite structure become available. All other theoretically possible lower symmetries, which can be formulated for Zn(2) sites, do not explain the observed polarization satisfactorily.

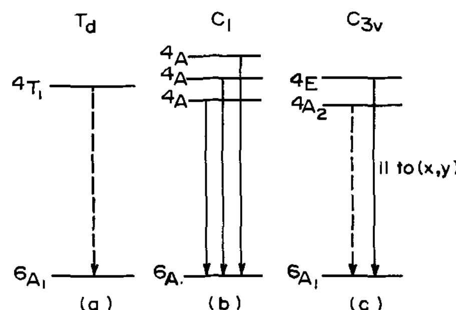

Fig. 3. Splitting of triply degenerate $^4T_1$ (G) level of Mn^{2+} ion under the influence of lowered symmetries. All the transitions are forbidden by spin symmetries, and for T_d symmetry the transition $^4T_1 \rightarrow {}^6A_1$ is also forbidden by orbital symmetry. Under C_1 symmetry all transitions are allowed but under C_{3v} symmetry only the transition $^4E \rightarrow {}^6A_1$ is allowed in (x,y) directions by the orbital symmetries.

Recently Palumbo and Brown (12) have made absorption measurements on Zn_2SiO_4:Mn powders and have seen complete splitting of the $^4T_1$ level. They did not study polarized absorption from single crystals and assignment of symmetries is not possible on the basis of their data. However, these measurements clearly show the symmetries (of one or both sites) lower than T_d. Another study of interest is that of Perkins and Sienko (11). They studied ESR spectra from Mn^{2+}-doped Zn_2SiO_4 single crystals. Their data showed the location of Mn^{2+} at two crystallographically nonequivalent zinc positions in the willemite structure. They did not elaborate on the distortions of these sites but discounted any possibility of Mn^{2+} at six coordinated sites, which would produce an associated defect also.

It may be pointed out here that the selection rules given in Fig. 3 are for electric dipole type of interactions and are allowed (or forbidden) by the symmetry of purely electronic wave functions. These rules would be somewhat relaxed by vibronic coupling, however, the intensity contributions due to vibronic coupling are usually an order of magnitude smaller than those due to purely electronic transitions.

Simple crystal-field explanation of the observed peak shift toward longer wavelengths, as the concentration of Mn^{2+} in the lattice is increased, is not possible. Increased concentration of Mn^{2+} of ionic radius 0.80Å, which replaces Zn^{2+} of ionic radius 0.74Å, causes the lattice to expand slightly (13). Thus on the basis of simple crystal field theory it would be expected that this would result in emission peak shifts toward shorter wavelengths since the field strength at the activator has been reduced (14). However, at higher concentrations it is no longer justified to consider emission from isolated Mn^{2+} ions only. With an increase in concentration, the probability that two Mn^{2+} ions would occupy immediate neighboring positions increases rapidly and the emission from these ion pairs would be expected to show up increasingly with the increase in Mn^{2+} concentration. This type of pair absorption has been found to occur in Mn^{2+} activated cubic ZnS crystals (15). An explanation of the observed shift of the green band to longer wavelengths with increasing Mn concentration can be made on the basis of pair emission concept if the model shown in Fig. 4 is considered. For simplicity, splitting of the $^4T_1$ level is ignored. The pair of two neighboring Mn^{2+} ions is shown to give rise to two levels, one of which is higher than the original $^4T_1$ level and the second level lower. A shift toward the red is expected if all the emission peak is a mixture of contributions from single ions and ion pairs. As the concentration of Mn^{2+} increases the contribution to emission intensity from ion pairs increases

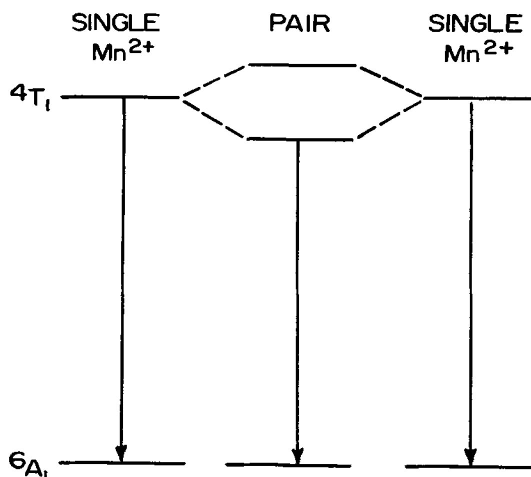

Fig. 4. Formation of ion pairs by two neighboring Mn^{2+} ions, shown for perfect T_d symmetry. The green emission peak would shift toward longer wavelengths if the emitting level for the pair is the lower level.

and the contribution from single ions decreases. This would give rise to the observed shift of emission peak wavelength.

Effect of Impurity Gas Additions on the Superconducting Critical Current of Vapor-Deposited Nb_3Sn

R. E. Enstrom,* J. J. Hanak, J. R. Appert,* and K. Strater[1]

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

The addition of various gaseous impurities into the process gases used in the chemical vapor deposition of superconducting Nb_3Sn has been found to alter the grain size of Nb_3Sn and thereby the critical current (I_c). Increasing concentrations of CO_2, CO, and N_2 cause a progressive decrease in the particle size and a concomitant increase of I_c up to three times the value found for undoped specimens. In contrast, O_2 and CH_4 increase the particle size and reduce I_c. I_c is linearly dependent on the reciprocal of the grain size, $1/D$, to values of D as small as 400Å. The present work suggests that impurities serve to control the grain size, presumably by the formation of small second-phase precipitates which interfere with the growth of Nb_3Sn grains.

One of the requirements of superconducting materials used in the construction of high-field solenoids is a high critical current, I_c. Over the years it has been found that I_c is proportional to the density of flux pinning centers, which can consist of a variety of defects such as second-phase impurities, dislocations, strain, radiation damage, etc.

In order to achieve a high, current-carrying capacity with ductile metallic alloy superconductors, such as Nb-Zr and Nb-Ti, the materials are extensively cold-worked during fabrication and are also heat-treated according to prescribed schedules. However, these conventional methods cannot be utilized with Nb_3Sn, since it is a nonductile, mechanically weak compound. In Nb_3Sn prepared by diffusion of tin into niobium, a significant increase in I_c has been achieved by the addition of small amounts (0.7%) of zirconium to the niobium (1). Zirconium presumably forms precipitates with impurities scavenged from the niobium, thereby increasing I_c. For chemically, vapor-deposited Nb_3Sn ribbon (2, 3), we reported earlier a strong dependence of I_c on the grain size (4). We have found, in turn, that the grain size can be influenced by impurities in the process gases (5). A study of the addition of various

Key words: Nb_3Sn, doping impurities, particle size, critical current, superconductivity.

gases during vapor deposition has made it possible to control and obtain reproducibly high values of I_c as is described in detail in this paper.

Experimental Procedure

The Nb_3Sn-coated ribbons were prepared by the hydrogen reduction of tin and niobium chlorides using equipment and procedures previously described (3). Briefly, Nb and Sn metal sources are reacted with Cl_2 at 900° and 800°C, respectively, and the chlorides are fed along with a H_2 carrier gas into the growth zone where the Nb_3Sn is synthesized. A continuous length of metal ribbon is passed through the growth zone and heated electrically to about 1000°C, while the growth furnace is maintained at about 700°C. This temperature profile keeps the incoming metal chlorides volatile and minimizes deposition of Nb_3Sn on the walls of the quartz growth tube. To achieve a stoichiometric ratio in the vapor-grown Nb_3Sn layer (75.0% Nb), the gas phase must have a Nb:Sn chloride ratio between 1:3 and 1:4.

Since this study focused on impurity gas additions, the process gases were purified where possible. Ultrapure hydrogen[2] with a total impurity content of less than 10 ppm was passed through a platinum catalyst and any water of reaction absorbed with $CaSO_4$. Helium was purified by passing the gas stream through Linde 5A and 13X molecular sieve held at 77°K. The hydrogen chloride gas used in the present study was not further purified. However, infrared analysis indicated no impurity bands to be present in the range 3-15 μm, the region where CO_2 and phosgene would appear if present. Infrared analysis of the Cl_2 showed it also to be quite pure.

The impurity gas additions studied included CO_2, CO, CH_4, O_2, and N_2 and these were injected either into the hydrogen or into the chlorine stream prior to entry into the growth apparatus. CO_2, CO, and CH_4 additions ranged from 0.01 to 1 v/o (volume per cent) of the total Cl_2 flow of 140 ml/min, while the O_2 and N_2 additions ranged up to 36 v/o. The equipment was equilibrated for ½ hr prior to the preparation of the 30m length of ribbon used in the superconductivity tests.

The critical current was measured on 30m lengths of ribbon, silver plated to increase electrical stability (6), and wound onto a coil form to produce a small magnet. This small magnet was, in turn, placed into another superconducting magnet, at 4.2°K, and energized so that the two magnetic fields were additive and parallel to the coil axis. The current through the small sample magnet was increased to a value which quenched superconductivity, thereby causing a large increase in voltage across a pair of potential leads; this was taken as the critical current. This procedure was repeated at background fields from 0 to 40 kG to generate a curve of I_c as a function of H. Tests at higher fields were conducted at the facilities of NASA, in Cleveland, Ohio, and at the Francis Bitter Magnet Laboratory at M.I.T. Measurements of the transition temperature, T_c, for selected samples were performed as previously described (7).

The vapor-grown layers were also examined by optical and electron microscopy. In addition, the subgrain size was determined as a function of processing using an x-ray line broadening method and procedures described earlier (4). X-ray fluorescence analyses for Nb and Sn composition on the ribbon were performed using procedures already described (3) to monitor the stoichiometry of the deposit.

Results and Discussion

Effect of doping gases on I_c.—The critical current increases by about a factor of three with the addition of CO_2 as shown in Fig. 1. Here, the undoped Nb_3Sn ribbon carries 65A at 40 kG (curve 1) and the ribbon doped with 0.25% CO_2 carries 183A (curve 6). Since the thickness of the Nb_3Sn is similar for most samples,

[2] Matheson Company, East Rutherford, New Jersey.

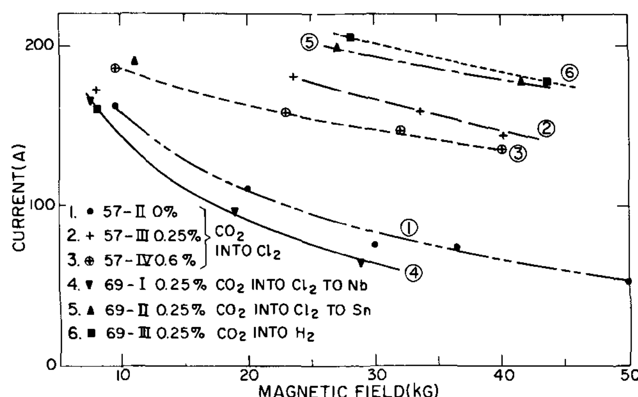

Fig. 1. Critical current as a function of total magnetic field for Nb_3Sn ribbon samples doped with CO_2.

this corresponds to current densities, J_c, of about 2.5×10^5 and 8.0×10^5 A/cm², respectively. It may also be seen that I_c is a function of the CO_2 concentration and that the optimum value is around 0.25% for injection into the Cl_2 gas stream (curves 2 and 3).

Alternative doping gas injection sites were investigated and these results also are summarized in Fig. 1. The addition of 0.25% CO_2 to the Cl_2 stream leading to the Sn metal source (curve 5) results in an I_c (H) curve nearly equivalent to that observed for injection into the H_2 port (curve 6). However, the same concentration of CO_2 injected into the Cl_2 stream leading to the Nb metal source (curve 4) results in an I_c (H) curve somewhat below that observed for undoped Nb_3Sn ribbon. This latter result probably can be explained by gettering of the CO_2 in the Cl_2 stream by the Nb metal to form NbC and Nb_xO_y so that the CO_2 is not available to the growing Nb_3Sn layer. In contrast, CO_2 does not completely react with the Sn source at the 800°C chlorination temperature and therefore is available to the Nb_3Sn being synthesized in the deposition chamber.

This hypothesis was confirmed by a thermodynamic analysis of the possible reactions of Sn with CO or CO_2, which showed that the free energy change is zero at 800°C. Thus, any reaction between CO_2 and Sn would be near equilibrium, thereby allowing a substantial portion of the CO_2 to pass through unreacted. If kinetics limited the rate of reaction, an even greater fraction of CO_2 would pass through the Sn metal zone and into the Nb_3Sn deposition chamber. If CO_2 is injected into the Cl_2 stream before it is split into portions going to the Nb source and to the Sn source, then the CO_2 is gettered from the Cl_2 exiting from the Nb chamber. Accordingly there is an apparent difference in the optimum values for the amount of CO_2 injected into the gas stream at the various locations.

This effect probably explains the dependence of the I_c (H) curve on CO concentration given in Fig. 2. In-

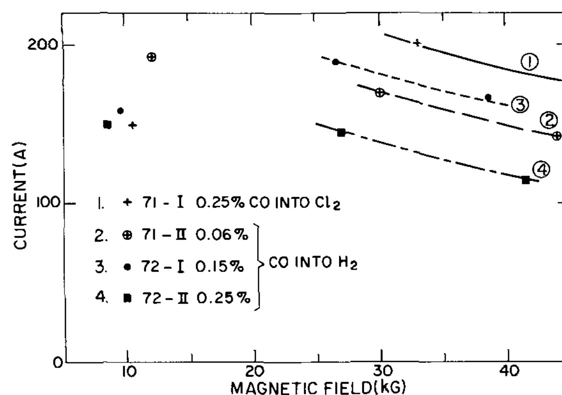

Fig. 2. Critical current as a function of total magnetic field for Nb_3Sn ribbon samples doped with CO.

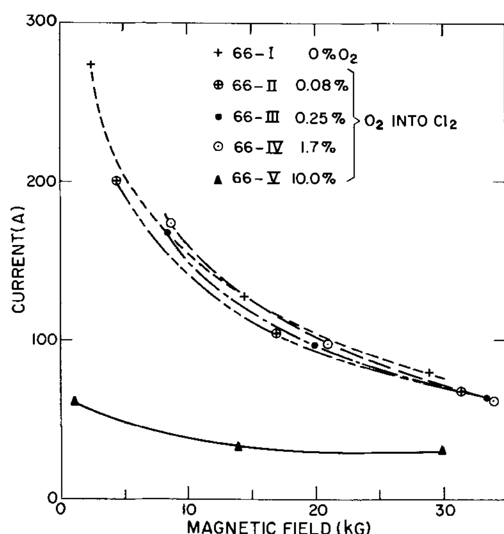

Fig. 3. Critical current as a function of total magnetic field for Nb_3Sn ribbon samples doped with O_2.

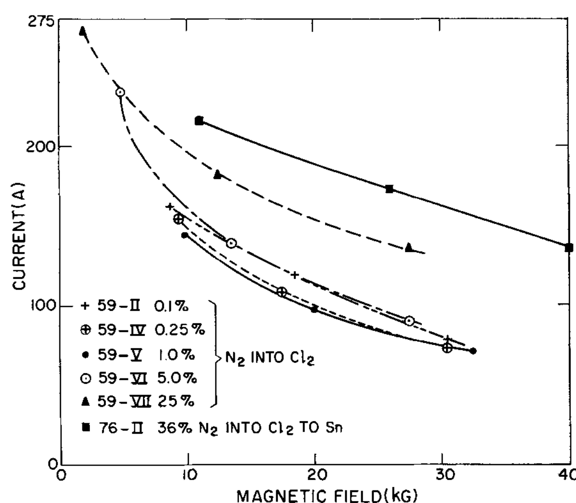

Fig. 4. Critical current as a function of total magnetic field for Nb_3Sn ribbon samples doped with N_2.

jection of the CO into the total Cl_2 stream results in a portion of the CO being gettered by the Nb metal source and the remainder, perhaps 0.18%, enters the deposition chamber. This concentration is closer to an optimum value and accordingly produces the Nb_3Sn ribbon with the highest current-carrying capability.

Thus, we have seen that both CO_2 and CO are effective in increasing I_c. In the next two series of runs, a hydrocarbon, CH_4, and O_2 were used. The results for the introduction of O_2 into the Cl_2 stream are shown in Fig. 3. Here, the undoped Nb_3Sn ribbon has the highest I_c. Increasing concentrations of O_2 result in successively lower I_c values and the value for 10% O_2, 29A at 30 kG, represents the lowest I_c observed at that magnetic field of all the various samples tested. It should be pointed out that all of the doped layers, except the 10% O_2-doped Nb_3Sn, had compositions within 1% of the correct stoichiometric ratio. The high O_2-doped sample was seriously deficient in Nb, presumably because of the formation of Nb oxides. Although these results indicate that large concentrations of O_2 should be excluded from the reactant gas stream, it is also apparent that I_c is rather insensitive to small oxygen impurity concentrations.

The results for the CH_4 doping demonstrate that CH_4 in concentrations of 0.15-0.25% is not effective in increasing the critical current. But, other results (5) show that hydrocarbon gases with a molecular weight greater than 16 (CH_4) are as effective as CO and CO_2 in increasing the I_c, presumably because they are less stable than CH_4. Therefore, since both CO and CO_2 and hydrocarbons such as ethane can successfully dope Nb_3Sn to high values of I_c, it is concluded that carbon is the principle atom responsible for the enhancement of I_c in these cases.

The next series of experiments performed with N_2 gas additions is summarized in Fig. 4. In this case, N_2 concentrations up to 36% were used to achieve values about twice as high as could be achieved with undoped Nb_3Sn. However, N_2 concentrations from 0.1 to 5% produced Nb_3Sn with I_c values not very much higher than for undoped Nb_3Sn. It should be pointed out that 99.999% pure N_2 containing less than 10 ppm hydrocarbon impurities had been used in these experiments which, when further diluted in the gas stream, should not influence I_c even at the highest flows of N_2 used. Thus, it appears that N_2 also can be used to enhance I_c. However, the use of CO_2 in conjunction with N_2 does not lead to a higher I_c than achieved with CO_2 alone, implying that the modes of enhancement are not additive.

Next, the influence of the Sn/Nb chloride ratio in the gaseous ambient was examined to determine its effect on I_c. As mentioned earlier, a Sn/Nb ratio greater than 3/1 must be used to achieve the correct stoichiometry in the vapor-grown Nb_3Sn layer; lower ratios result in Nb_3Sn with excess Nb and a lower T_c. Accordingly, ratios greater than 3/1 were examined both with and without CO_2 additions, and it was found that higher ratios produce Nb_3Sn that is up to 2.5% richer in Sn.

In Fig. 5 it is seen, in turn, that the 3 Sn/1 Nb ratio has the highest I_c (H) curve for both doped and undoped ribbons. But, CO_2 is effective in increasing the I_c at a given value of H for the three chloride ratios examined. It can be observed that the interval between the 3/1 and the 5/1 ratios is about the same for the doped and undoped series but that the 4/1 curve lies closer to the 5/1 curve for the undoped samples and closer to the 3/1 curve for the CO_2-doped Nb_3Sn. This latter result is fortunate since this allows some margin for error in the adjustment of the Sn/Nb chloride ratio while permitting a high I_c (H) relationship to be achieved.

In the standard growth process for the preparation of Nb_3Sn ribbon, the ribbon travels 15 m/hr countercurrent to the gas stream and the total flow rate of chlorine to the Nb and Sn metal sources is 140 ml/min. The effect of several variations in the process on the I_c (H) curve are given in Fig. 6 and these may be compared with both CO_2- and CO-doped as well as undoped ribbon samples. It may be seen that concurrent travel of the gas and the stainless steel substrate leads to an I_c (H) curve that is about 50% lower than when a countercurrent arrangement is used. The reason for this result is not clear.

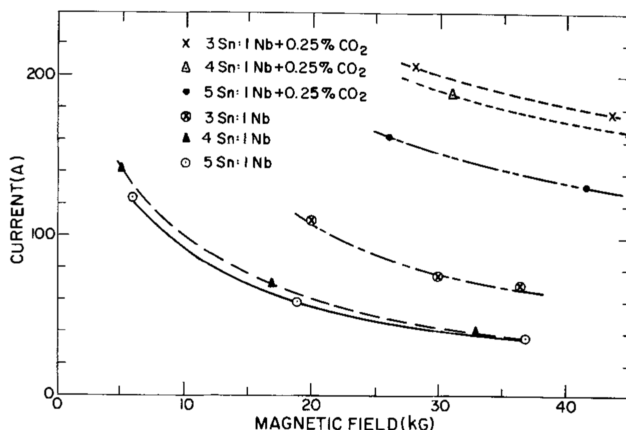

Fig. 5. Critical current as a function of total magnetic field for Nb_3Sn ribbon samples prepared with various Sn/Nb ratios in the vapor ambient.

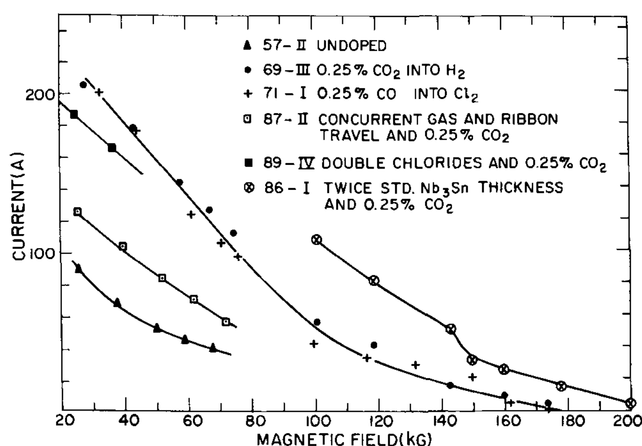

Fig. 6. Critical current as a function of total magnetic field for Nb_3Sn ribbon samples prepared under various vapor-growth conditions.

Higher partial pressures of the metal chlorides were investigated to study the effect on I_c and to increase the growth rate so that a thicker layer and thus a higher I_c could be attained for a given ribbon speed. It was found that doubling the partial pressures of the Nb and Sn chlorides by doubling the Cl_2 flow rates to the metal sources degrades the I_c (H) curve somewhat, as shown in Fig. 6. Moreover, no significant increase in deposit thickness was observed. The deposit thickness was increased to twice the normal thickness, however, by decreasing the ribbon speed from 15 to 7 m/hr. I_c was thereby doubled as shown in Fig. 6, indicating that the deposit is homogeneously doped throughout its thickness. The factor-of-two higher I_c is very important, especially for the construction of magnets above about 120 kG where the I_c is dropping rapidly. In addition, the thicker Nb_3Sn has a significantly higher critical field, H_{c2}, presumably because the extra Nb_3Sn grown onto the ribbon is further removed from the metallic substrate and therefore less contaminated by diffusion of Fe, Mo, and Ni from the substrate. The nature of the interface between the Nb_3Sn and the stainless steel will be examined in another publication (8).

Impurity doping of Nb_3Sn deposits on ribbon substrates lowers the T_c onset from 17.0°K for undoped material to 15.0°K for optimally doped material. Part of this decrease is due to elastic strain built into the ribbon, as shown by an increase of T_c to 15.9°K when the substrate is etched away with nitric acid, and part is due to a large strain in the lattice introduced by the presence of the impurities. When the substrate-free deposit is annealed at 850°C for 2 hr, the T_c increases to 17.9°K which is probably due to relief of the internal strain.

Effect of doping on grain size of Nb_3Sn.—A striking change in the appearance of the Nb_3Sn from a dull, nonreflective surface to a very bright, reflective surface occurs with the introduction of CO, CO_2, or N_2 into the gas stream. This change appeared to be associated with a reduction of the Nb_3Sn crystallite size. Accordingly, grain size measurements were made by x-ray line broadening of all specimens using techniques described in our earlier paper (4). It was found that increasing concentrations of CO_2, CO, and N_2 decrease the Nb_3Sn grain size from ~1000Å (100 nm) for an undoped sample to a minimum of ~370Å (37 nm) for the most heavily doped samples. For O_2 and CH_4 doping, a tendency toward an increase of grain size is observed. The I_c data were converted to critical current density, J_c, and to $\alpha = J_c H$ and were plotted in Fig. 7 as a function of the inverse of the grain size, $1/D$. A similar linear dependence of J_c *vs.* $1/D$ was obtained up to $1/D \approx 2.5 \times 10^5$ cm^{-1} [grain size ≈ 400Å (40 nm)] as before (4), regardless of the doping gas

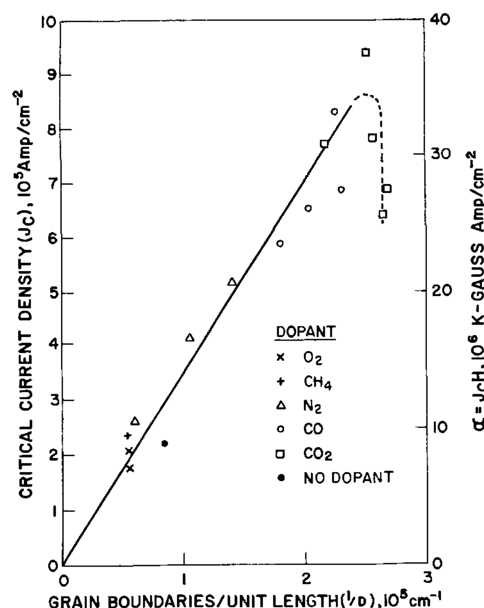

Fig. 7. Critical current density at 40 kG as a function of the reciprocal of the grain size.

used. The variable $1/D$ represents the number of pinning sites per unit distance and J_c is linearly dependent on it. The doping gas thus appears merely to provide a control over the grain size of Nb_3Sn, probably via the formation of submicroscopic precipitates such as carbides or nitrides of niobium which interfere with grain growth of Nb_3Sn.

Attempts to identify the form which the impurities take in the deposit were only partially successful. Mass spectroscopic analyses of carbon in an undoped and a CO_2-doped deposit (0.25% CO_2 in gas phase) show 50-100 ppm and 700-2400 ppm, respectively, indicating the incorporation of carbon. This amount of carbon would be sufficient to form a second phase. But, neither x-ray nor electron diffraction techniques were able to identify the presence of phases other than Nb_3Sn. However, a transmission electron micrograph of a specimen thinned by etching showed a multitude of dark spots which could be interpreted as a fine precipitate of a second phase (9).

Conclusions

The addition of various gaseous impurities into the process gases used in the chemical vapor deposition of superconducting Nb_3Sn has been found to alter the grain size of Nb_3Sn and thereby the critical current. Increasing concentrations of impurity gases including CO_2, CO, and N_2 have been found to cause a progressive decrease in the Nb_3Sn particle size and an increase in I_c. Additions of O_2 and CH_4, on the other hand, tend to increase the particle size of Nb_3Sn and lower I_c. Regarding the effectiveness of doping, CO_2 and CO have been found to be the most effective since about 0.25% impurity causes up to a threefold increase of I_c compared to undoped specimens. In contrast, 36% of N_2 impurity is required to increase I_c twofold. The process is rather insensitive to oxygen impurity as 1.7% O_2 decreases I_c only 6% and large amounts of O_2 (10%) are required to decrease I_c to less than ½ the value of undoped specimens. Since I_c scales up with deposit thickness at a given doping level, doping is a bulk effect. The increase of I_c and J_c has a similar linear dependence on the inverse of the grain size $1/D$ as reported previously (4), regardless of the type of dopant used. It appears, therefore, that the impurities serve only as a means of controlling the grain size, presumably by the formation of small, second-phase precipitates which interfere with the growth of Nb_3Sn grains.

Hydrogen Chloride and Chlorine Gettering: An Effective Technique for Improving Performance of Silicon Devices

R. S. Ronen and P. H. Robinson*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Moderate levels of lifetime killing impurities in silicon can be removed or neutralized by a high-temperature treatment in the presence of approximately 1% gaseous hydrogen chloride or chlorine in dry oxygen. Results using bulk silicon as well as thin-film silicon on sapphire (SOS) indicate a significant improvement in the effective minority carrier lifetime. Crystal quality, doping level, oxygen content of the silicon, and surface treatment are found to be important variables. The paper describes the effect of chlorine gettering on various bulk silicon and SOS devices.

It has been well documented that many high-temperature fabrication steps used in silicon device processing often result in the reduction of minority carrier lifetime (1-6), because of the redistribution of heavy metallic impurities, *e.g.*, Au and Cu, or the precipitation of such impurities on dislocations. Thus these impurities become effective recombination centers (7, 8). Heavy metal impurities were found to have states near the center of the gap (2, 5, 6, 9). Oxidation, in particular, was very detrimental to lifetime (10). Contaminants can come from a number of sources, such as the bulk and surface of the wafer or the furnace tube.

Various gettering techniques to eliminate them or prevent them from generating effective traps have been reported (3, 4, 11, 12). One has been a phosphorus glass layer in contact with the Si at elevated temperatures (4, 11). A second technique uses KCN or sintered Ni in contact with the Si to prevent impurities from in-diffusing during processing (13). Oxides such as P_2O_5, B_2O_5, and V_2O_5 have also been used, as have been chlorides (BCl_3 and PCl_5), during high-temperature diffusion for the preservation of lifetime (3, 4). Transmission electron microscopy and infrared microscopy verified the elimination of Cu precipitates from dislocations after gettering treatment (14).

Recently, bulk Si as well as thin-film Si on insulators has shown a significant increase in minority carrier lifetime after heating in a dry O_2/HCl ambient (15, 18). At 950°C, the lowest temperature used for the HCl gettering process, the diffusion constants of the lifetime killing impurities (Cu, Fe, Au) in Si range from 10^{-5} to 10^{-8} cm^2/sec. Since Cl_2 is more reactive than HCl we believe that it can more effectively improve lifetime; that is, gettering can be done at a lower temperature, and the magnitude of the improvement would be greater for the same time and temperature using Cl_2 rather than HCl. This paper describes various results obtained with Cl_2 gettering; a comparison of HCl and Cl_2 is made.

Key words: gettering, minority carrier lifetime, SOS, silicon, HCl, Cl_2.

Experimental Procedure

Gettering was carried out in a dry O_2 ambient either before device processing when films were being studied or after fabrication, just before metalization. A typical procedure consisted of the following steps:

1. Thorough cleaning of the wafer, to remove surface impurities.
2. Gettering in a mixture of 1% Cl_2 in dry O_2 at a temperature T_g of 800° to 1150°C.
3. Annealing in dry He for 15 min at T_g to remove Cl_2 from the furnace and sample and to reduce positive oxide charge (16).
4. Hydrogen annealing for 15 min at 500°C to reduce density of interface states.

The effective minority carrier lifetime was then determined by C-V and C-t measurements (17). Gettering times range from 1 to 100 hr, and the gettering temperatures were either 950° or 1050°C. The lifetime improvement was found to be dependent on the time × temperature product. When junction devices were being studied, a period of 2 hr at 950°C was used so as not to alter the diffusion profile in these devices significantly.

On several occasions, oxidation prior to the admission of HCl or Cl_2 was necessary to prevent etching and pitting of the Si. The concentration of HCl or Cl_2 was kept low (~ 0.5-1%) because severe attack of the Si was observed at higher concentrations (~ 5-10%).

Water vapor was removed from the oxygen gas by a dry ice trap. For SOS devices C-V measurements were not always effective because of series resistance. C-V measurements at d.c. and high frequency were employed with SOS devices to determine lifetime.

We tried different annealing techniques which included only inert gases such as N_2, He, Ar, H_2, as well as oxygen but no HCl or Cl_2, at various temperatures and periods. The wafers and devices showed little or no improvement, and the O_2 treatment was in fact detrimental to lifetime in most cases. These heat-treatments were carried out under conditions identical to those used for Cl_2.

Measuring Technique

The effective minority carrier lifetime was determined from the transient response of a depletion capacitance structure (17). To facilitate the measurement a mercury probe made contact with the SiO_2 in a circular pattern ($\sim$ 35 mil diam). A back contact was employed in the bulk Si measurements, and a circular contact around the dot for the SOS measurements. To minimize series resistance, particularly when measuring SOS, an interdigitated pattern was used, thus making the resistance smaller than the capacitive reactance.

Heiman (17) has shown that $\tau_{eff} = (T/2)\ (N_i/N_a)$ is an approximate solution to the recovery from deep depletion of an MOS capacitor; τ_{eff} = effective lifetime of minority carrier in depletion region, T = recovery time constant, N_i = intrinsic carrier concentration, N_a = carrier concentration of wafer under investigation. The three wave shapes shown in Fig. 1 represent recovery of an MOS capacitor with shallow surface states, with deep surface states, and with no surface states. If the transient response on the wafers is observed before and after gettering, and the response has the same shape, only one calculation of T is necessary. The second and third wave shapes were typically observed on SOS and good-quality Si, respectively.

The MOS capacitor structure used for C-t measurements is shown in Fig. 2. From the typical C-V curve shown in Fig. 3 one can calculate the doping density to within a few diffusion lengths of the surface, and effective oxide charge, and get an indication of the surface state density (19). A typical C-t curve is shown in Fig. 4. The effective minority carrier lifetime is obtained, following Heiman's method (17), without much processing; however, the results must be interpreted with care.

Comparative lifetime measurements, before and after gettering, are meaningful even though the technique assumes recombination centers at mid-gap. It was assumed that the majority carrier concentration does not change during gettering at 950°C for 2 hr. This was shown to be valid by Hall measurements, C-V curves, and 4-point probe measurements.

For very thin SOS devices (those with planar junctions such as epitaxial bipolar transistors), the C-V and pulse-capacitance measurements are difficult to make or useless; hence, other methods were used. SOS devices were evaluated by extending the logarithmic plot of the forward I-V characteristics asymptotically, determining the slope, and evaluating the zero voltage

intercept. The effective minority lifetime is then obtained, and comparison of measurements taken before and after gettering becomes meaningful. An I-V logarithmic plot exhibits a good straight line to the point where series resistance effects obscure the real junction behavior. We assume a simple junction theory of the form $I = I_0 \exp qV/nkt$ ($1 \leqq n \leqq 2$), with $n = 1$ for pure diffusion and $n = 2$ when recombination in the transition region is dominant (9). The slope of the linear part of logarithmic plot yields n directly, giving information about the relative magnitude of diffusion *vs.* recombination in the material (surface and bulk effects). The zero voltage intercept of the I-V asymptote yields a measure of the minority carrier lifetime in the depletion region of a diode. The forward diffusion current (linear part) at $V = 0$ is equated to the reverse leakage current (recombination), and the lifetime τ is calculated. This is only an approximate method, but comparison of curves before and after gettering and the absolute value of the leakage current yield very useful results. In the case of multilevel planar junctions such as SOS epitaxial bipolar transistors, high-frequency measurements of f_T *vs.* current, give the base transit time. The linear part of the curve depicting $[f_T]^{-1}$ *vs.* M is extrapolated to $M \equiv (kT/q)/I_E = 0$ (corresponding to $I_E \rightarrow \infty$, *i.e.*, zero emitter delay time) where $f_T = D/\pi w^2$ and base transit time $T_r = w^2/2D = 1/(2\pi f_T)$. Knowing T_r and D yields the base width. The low-frequency common base current gain, when very close to unity, yields the minority carrier lifetime

$$\alpha_0 \cong 1 - \frac{1}{2}\frac{w^2}{L^2} = 1 - \frac{w^2}{2Dt} = 1 - \frac{T_r}{\tau}$$

when $\beta_0 = \alpha_0/(1 - \alpha_0) >> 1$, we get $\tau = \beta_0 T_r$. The base width was also obtained by other techniques and found to be in close agreement with that obtained from UHF measurements.

Experimental Results

General observations.—1. Gettering is more effective on good-quality bulk crystals and thin-film SOS layers with scratch-free surfaces. Impurities introduced during processing can be eliminated or their effect significantly reduced by gettering.

2. In wafers exhibiting low lifetime due to oxygen contamination even below the sensitivity of mass spectrography (10^{16}/cc) improvement via gettering is marginal. The lifetime killing species is apparently bonded to the Si differently in this case, or the SiO_2 complexes introduce deep recombination centers. This was mainly observed in thin epitaxial layers grown on sapphire.

3. Using Cl_2, improvement was greater on n-type Si than on p-type material of comparable doping density. This indicates that the lifetime killing impurity may not reside near mid-gap in both types, an observation in agreement with Waldner and Sivo (4).

4. Up to a limit, the effectiveness of gettering increases with time and temperature. At gettering temperatures above 1000°C no further improvement was obtained after 30 hr.

5. If the Si is heavily contaminated with metal impurities or O_2, some impurities tend to concentrate in the SiO_2 layer formed during oxidation, thus yielding large C-V shifts. Stripping the SiO_2 and regettering still results in large C-V shifts as well as charge storage effects in the oxide; this prevents meaningful C-t measurements.

6. Gettering diode structures resulted in the reduction of reverse leakage currents by several orders of magnitude. The reverse and forward I-V characteristics were also found to improve significantly.

7. Gettering MOSFET's showed only better drain diode breakdown characteristics, with no other effect on device performance observed. Metalized MOSFET's, with Al or Cr-Au, could not be gettered at the proper temperatures.

8. Mass spectrographic analyses on bulk and thin-film SOS were below the sensitivity range needed to detect changes in the Au and Cu content before and after gettering. Analysis showed a concentration of Cl_2 in the oxide after gettering 10^3-10^4 higher than in the bulk material. This may be responsible for tying up the impurities in the oxide at the interface.

Bulk silicon.—A series of p- and n-type [100] and [111] bulk silicon wafers were obtained from Ventron and Monsanto and were gettered with Cl_2 for different periods and temperatures, as shown in Table I. The effective lifetime after high-temperature oxidation was reduced to 100-300 nsec in most wafers and to 1-2 μsec in material that had both surfaces polished and relatively free of work damage. The [111] Ventron material, least affected by gettering, had unpolished back surfaces. The [100] n-type wafers, with both surfaces chemically polished, showed the greatest improvement; less consistent results were obtained with the [111] oriented wafers. After 16 hr of gettering no

further improvement was observed in any of the wafers.

HCl gettering was studied and at 950°C was found to be slightly less effective than chlorine at the same temperature, while at high temperatures, ~ 1100°C, HCl was more effective by a factor of 2-5. Typical lifetimes were 1 μsec for an n-type Cl_2-gettered silicon wafer, as compared with 4 μsec for the HCl gettered one, with $T_g = 1150$°C.

Cooling the bulk silicon wafers and the SOS films at 100°C/min in He or quenching them in He produced no significant difference in the results.

Results on thin-film silicon on sapphire.—The minority carrier lifetime of thin-film SOS layers as grown is typically 1-2 nsec. After high-temperature processing it is usually reduced to 0.1 nsec or less. The lifetime was found to increase to 4 nsec in 2-μm-thick p-type layers after gettering in Cl_2 at 950°C for 2 hr. Increasing the gettering temperature to 1050°C increased the lifetime to the 10-40 nsec range. The n-type films showed a slight improvement over these p-type results, *i.e.*, 20-50 nsec. The C-V measurements on these layers had high series-resistance contacts; to overcome this problem interdigitated geometries were used. Films ≥ 2 μm with doping densities > 10^{16} were needed, since, with higher resistivity Si, the maximum depletion width can be equal to or greater than the film thickness, rendering deep-depletion measurements invalid. Typical C-V and C-t wave forms are shown in Fig. 5.

Silicon-on-sapphire epitaxial bipolar transistors.—Mesa-type epitaxial SOS bipolar transistors were gettered using either HCl or Cl_2 at 950°C for 2 hr just prior to the metalization step. Interdiffusion effects are insignificant, and measurements of the base width before and after gettering showed no change in thickness. The effect of this treatment on device performance, however, was quite dramatic. Figure 6 shows the transistor characteristics of a typical device before gettering, Fig. 7 after gettering. Low-frequency gain, β, increased by a factor of 2-10 after this treatment, and many devices with $\beta \approx 20$ were obtained (Fig. 8). A few devices with $\beta = 60$ were obtained. These most probably had very thin base regions and, hence, should make very good high-frequency transistors. A large reduction in the leakage current of emitter-base and base-collector diodes, along with an increase in the breakdown voltage, was observed. This is shown in the I-V characteristics of Fig. 9, before and after gettering. Note the different current scales on the two parts. The linear part of the forward I-V characteristics, $I = \exp$ (qv/nkt), exhibited $\eta < 1.4$ as compared with $\eta > 1.6$ before gettering. This result is indicative of a change in the recombination mechanism in the space charge region of the diodes (see Fig. 10).

Another measurement, that of $[f_t]^{-1}$ *vs.* $[I_E]^{-1}$, showed that the base transit time and the minority carrier lifetime in the base region had increased to 325 and 16 nsec, from values less than 2 and 0.1 nsec, respectively. This is shown in Fig. 11. Effective minority carrier lifetimes in SOS devices and films measured by the three different methods agree rather well.

The gettering process has significantly improved the SOS bipolar transistor.

Conclusions

A small amount of gaseous HCl or Cl_2 introduced during oxidation in dry oxygen significantly reduced recombination rate in both bulk Si and SOS films and devices. The mechanism whereby the lifetime is increased is still open to speculation. One possibility is the formation of volatile metallic impurity chlorides. Other mechanisms, such as Cl_2 diffusing into the Si and somehow tying up heavy or light ions, thereby neutralizing them or reducing their effectiveness as recombination centers, are also possible, as is some cleaning of the furnace. The gettering mechanism appears

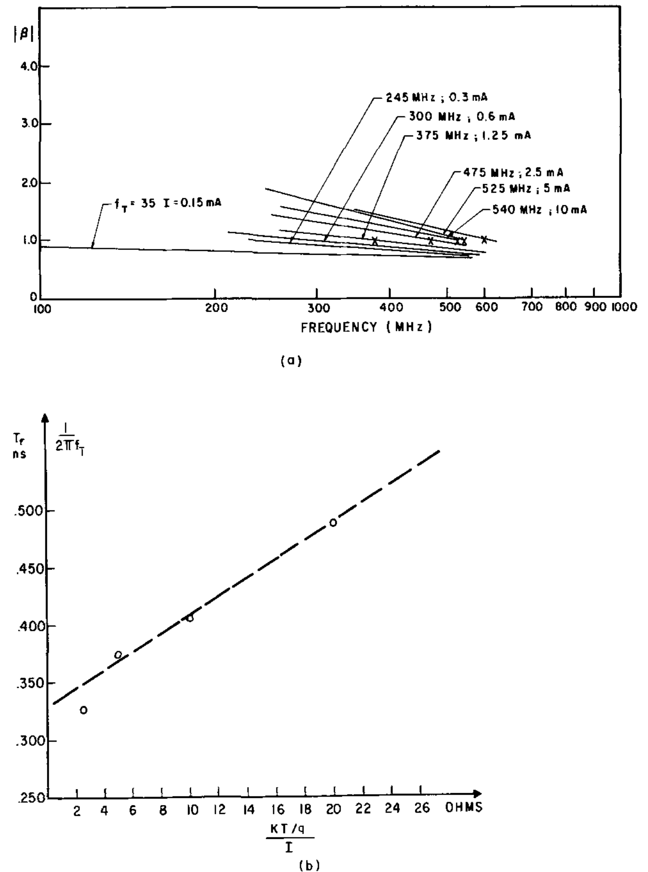

Fig. 11. High frequency behavior of SOS bipolar. (a) β vs. frequency; (b) $[f_T]^{-1}$ vs. $[I_E]^{-1}$.

to be related to the O_2 content of the starting material.

Low-temperature Cl_2 is somewhat more effective than HCl, and improvements in the electrical characteristics of both diodes and bipolar transistors fabricated in SOS resulted from the gettering treatment. Because of the increase in the minority carrier lifetime due to Cl_2 and HCl gettering, bipolar transistors with average current gains of 20 have been produced.

ABSTRACT

Thin films of cadmium oxide (CdO) and indium oxide/tin oxide (In_2O_3/SnO_2) were reactively sputtered from their respective metal or alloy targets. CdO films combine sheet resistances of less than 100 ohms/square with optical transmission greater than 45% for wavelengths greater than 5000Å, and make ohmic contacts with high-resistivity CdS films. Indium oxide/tin oxide films show optical transmission greater than 45% for wavelengths greater than 4000Å and sheet resistances of 100 to 200 ohms/square. Indium oxide/tin oxide also makes useful contacts to CdS films, but reduces the resistivity of the CdS films. A band diagram is proposed which qualitatively explains the ohmic nature of the contacts between two wide bandgap materials.

Recent interest in optoelectronic devices has led to the development of electrode materials which are transparent to light. One application of such materials is the use of transparent electrodes in a ferroelectric/photoconductor storage device (1, 2). Another application is in high-sensitivity photodetectors. There, maximum photocurrents (3, 4) are obtained when the photoconductor is sandwiched between the electrodes and the radiation is incident in the direction of the applied field, and when the thickness of the photoconductor equals the absorption length.

To be useful in high-sensitivity photodevices, the transparent electrode should have sheet resistances no larger than a few hundred ohms/square and maximum possible optical transmission. Also, the transparent electrode must make ohmic contact with the photoconductors.

In the past, thin metal films (*e.g.*, gold, indium), have been used as the transparent electrodes. However, they have the disadvantage of lower transparency for reasonable values of sheet resistance. Some attempts have been made to use metal oxides (*e.g.*, cadmium oxide and indium oxide) as transparent electrodes to photoconductors.

Only limited information about the basic properties of cadmium oxide is available. This is due to the unavailability of large single crystals (5). However, several papers have appeared during the past few years on studies of powdered material, sintered blocks, compressed tablets, or sputtered films (6). Some basic properties are given in the International Tables of Constants and Numerical Data (7). The effects of doping CdO by In and Cu and the effect of reduced oxygen in the reactively sputtered films have been studied by Lakshmanan (8). Electrical transport properties in single-crystal In_2O_3 have been discussed by Weiher (9). From high-temperature conductivity measurements, Weiher deduced the bandgap of indium oxide to be 3.1 eV, close to the value of 3.5 eV reported by Rupprecht (10). Recently, Fraser and Cook (11) reported some measurements on films of indium oxide/tin oxide sputtered from oxide targets.

Key words: transparent electrodes, cadmium oxide films, indium oxide/tin oxide films, cadmium sulfide films, reactive sputtering.

The first use of In_2O_3/SnO_2 as a transparent electrical contact with a photoconductor (CdS) was reported by Shivonen and Boyd (12). They used 82% indium/18% tin alloy sputtered in oxygen to give a transparent contact on a CdS crystal. Their films were about 200Å thick, had a resistance of 100 to 150 ohms/square, and showed very good transmittance characteristics, *i.e.*, $> 80\%$ for $\lambda > 5000$Å. Williams (13) used thin films of In_2O_3 as transparent contacts to ZnS crystals. He also prepared In_2O_3/SnO_2 films by sputtering indium/tin alloy (4:1) in oxygen. However, he found that films so deposited had a high concentration of free metal and were opaque. These films had to be further heated in air at 300°-400°C to obtain transparency. The V-I curve measurements by Williams (13) indicated that the In_2O_3/SnO_2 films made ohmic contacts to ZnS crystals.

Our paper deals with the properties of CdO and In_2O_3/SnO_2 films deposited by reactive sputtering. Deposition conditions, such as the gas, the pressure, and the substrate temperature, are varied. Optical and electrical properties of these films are studied as a function of the deposition conditions. The quality of the contact to high resistivity ($> 10^7$ ohm-cm) thin polycrystalline films of CdS is investigated. Substrate and post-heat-treatment temperatures are kept below approximately 350°C to avoid diffusion of Cd or In from the oxide films into CdS.

Deposition of the CdO and In_2O_3/SnO_2

Two kinds of transparent electrodes were deposited by reactive sputtering of two metal targets: cadmium (14) and 82 In/18 Sn (12, 13).

The sputtering system was a diode-type MRC[1] Model SM8500 sputtering module mounted on a Norton-NRC[2] diffusion-pumped vacuum system Model 3116.
